Supersaturated Zincate Solutions

W. Van Doorne and T. P. Dirkse*

Department of Chemistry, Calvin College, Grand Rapids, Michigan 49506

ABSTRACT

A study of supersaturated zincate solutions is made using light scattering and nuclear magnetic resonance techniques. The results indicate strongly that the excess zinc is present as a solute species rather than in a colloidal form. The solute species appears to be the same as that in solutions of ZnO in aqueous KOH, viz., $Zn(OH)_4^{2-}$. There is no strong evidence to indicate the presence of other solute species.

When metallic zinc is treated anodically in aqueous KOH the surface often becomes dark in color and, if the treatment is continued long enough, a white solid precipitates from the solution. Both the white solid and the dark film on the metal are zinc oxide. Thus, the end product of the anodic treatment appears to be ZnO. However, ZnO is soluble in aqueous KOH. For some time it was believed that the solution from which the white solid precipitated was a saturated solution of ZnO in KOH. But further investigation (1) disproved this assumption. Instead, it was shown that the dissolved Zn(II) content of the electrolyte decreased and after about a year approached that of a saturated solution of ZnO. Meanwhile, a white solid continued to precipitate from the solution.

This phenomenon has been known for some 20 years and it is of significance for batteries containing a metallic zinc electrode and an aqueous KOH electrolyte. However, very little work has been done with these so-called "supersaturated" zincate solutions (szs).

A variety of evidence suggests that in a saturated solution of ZnO in aqueous KOH the dissolved Zn(II) species is primarily $Zn(OH)_4^{2-}$ (2-4). Very little work has been done to determine the nature of the dissolved Zn(II) species in the szs. Dirkse (1) measured the emf of a zinc electrode in various szs and interpreted the results as indicating that $Zn(OH)_4^{2-}$ is also the predominant species in szs. However, this suggestion has been called into question. It has been suggested, *e.g.*, that the excess Zn(II) in the szs is in a colloidal form and there is evidence to support this, *e.g.*, the slow precipitation of the excess Zn(II) as ZnO. Hampson *et al.* (5) on the basis of emf measurements concluded that the excess Zn(II) in szs is electrochemically inactive. A Raman spectra investigation (6) showed that the Zn(II) species in saturated solutions of ZnO in aqueous KOH is a tetrahedral zinc-hydroxy arrangement. With anodic treatment of zinc in a 40% KOH solution saturated with ZnO the dissolved Zn(II) content increased about 70%, but the area under a band typical of $Zn(OH)_4^{2-}$ increased only about 12% and no new bands were observed. The conclusion is that about 1/6 of the excess Zn(II) is converted to $Zn(OH)_4^{2-}$. The nature of the remaining 5/6 was not determined.

In the early work with szs, it was observed (1) that the specific conductance of the solution decreased with increasing excess Zn(II). This may have been due to increased viscosity of the solutions and/or to replacement of OH^- ions by the zinc-hydroxy species.

In summary, on the basis of the work done to date it is not possible to describe precisely the nature of the excess Zn(II) in the szs. The work reported here was carried out in an attempt to gather more information about these szs solutions. Two techniques were used: (*i*) light scattering, and (*ii*) nuclear magnetic resonance (NMR). The light scattering technique may give information as to whether or not the Zn(II) in the szs is in a colloidal form. The NMR technique provides information about the environment of the protons in the solutions. This environment is averaged over all possible proton locations (*i.e.*, in water, hydroxide ions, and Zn species). Because of rapid exchange of protons among these locations the NMR technique cannot distinguish between the various proton-containing species.

The initial investigation of the ZnO-aqueous KOH system by NMR techniques was reported by Newman and Blomgren (4). Their investigation covered a series of KOH concentrations ranging from 3.89 to 13.62 molal and ZnO concentrations nearly up to the saturation point for each of the KOH solutions. The analysis of Newman and Blomgren shows that the formulation $Zn(OH)_4^{2-}$, as the primary Zn(II) species, is consistent with the chemical shift values. The present work employs a similar technique but extends the range of ZnO concentrations into those of the szs.

Experimental

The light scattering results were obtained by the use of a Coleman Universal spectrophotometer with a nephelometric attachment. The NMR spectra were obtained using a Jeolco MH60 spectrometer, operating at 60 MHz. Water was used as the external reference. After allowing time for obtaining temperature equilibrium in the sample, each spectrum was scanned five consecutive times.

Three stock solutions of KOH were prepared using reagent grade KOH. Saturated solutions of ZnO were made by dissolving the maximum of reagent grade

* Electrochemical Society Active Member.

Key words: supersaturated zincate solutions, light scattering, nuclear magnetic resonance.

ZnO in each of the KOH solutions, followed by filtration through a Pyrex frit. Unsaturated solutions of varying ZnO concentrations were prepared by mixing appropriate amounts of pure KOH solution and the KOH solutions saturated with ZnO. A supersaturated Zn(II) solution was made by anodic oxidation of metallic zinc in a saturated ZnO solution. Solutions with varying degrees of supersaturation were made by mixing the saturated and supersaturated solutions in varying ratios. All zinc analyses were made by titration with EDTA.

Results and Discussion

Light scattering.—A saturated solution of ZnO in 2.8*M* KOH [0.13*M* in Zn(II)] was used as a reference and to set the galvanometer to 0. Next a szs solution [2.8*M* KOH + 0.35*M* Zn(II)] was placed in the same cuvette and the galvanometer then read 3%. This is within the experimental uncertainty associated with making these measurements. In a second run a saturated solution of ZnO [10.2*M* KOH + 1.12*M* Zn(II)] was placed in the cuvette and the galvanometer set to read 0. When a szs [10.2*M* KOH + 1.5*M* Zn(II)] was placed in the same cuvette the galvanometer read 0%. Thus, in both these cases the szs showed no or negligible increased light scattering compared to the saturated ZnO solutions. These results indicate the absence of colloidal material. It has been argued that the light scattering results are dependent on the refractive indices of the substances involved and that in these cases the refractive indices are such that even though there is colloidal material present no light scattering is observed. It has been observed under magnification that a pronounced refractive index change occurred around the zinc electrodes during discharge, *i.e.*, during anodic treatment (6, p. 34). This argument has been used often when solutions of ZnO in aqueous KOH are said to be optically clear. However, the fact that NMR results also support the absence of colloidal material (see below), seems to make it reasonable to state that the szs solutions contain no appreciable amounts of colloidal material.

Nuclear Magnetic Resonance.—All spectra showed a single peak for the external reference and a sharp, single, downfield peak for the KOH-ZnO solution. A typical scan is shown on Fig. 1.

The five chemical shifts relative to water were measured for each sample and averaged to give the uncorrected chemical shift, δ. The standard deviation was 0.4 Hz for a typical set of five values.

Since an external reference was used, bulk susceptibility corrections were made using the equation given by Pople, Schneider, and Bernstein (7)

$$\delta = [(H - H_r)/H_r] + (2\pi/3)(\chi_{v,r} - \chi_v) \quad [1]$$

χ_{v1} and χ_v refer to the volume magnetic susceptibilities of reference and sample. χ values were obtained from the table given by Selwood (8) and it was assumed that the additivity law

$$\chi_v = \phi_1\chi_1 + \phi_2\chi_2 + \cdots + \phi_n\chi_n \quad [2]$$

was obeyed. (ϕ represents the volume fraction of each component.)

The change in the chemical shift, δ, from that of the pure KOH solution, caused by the addition of ZnO, is defined as Δδ.

As is shown in Fig. 2, Δδ increases with increasing Zn concentrations, and the slope of the lines increases with increasing KOH concentrations. The linearity of these plots, as has been observed by Newman and Blomgren (4), is consistent with the existence of a single Zn-containing species. Evidence from other authors suggests that this species is the tetra-coordinated ion $Zn(OH)_4^{2-}$ (2, 3).

Figure 3 gives a plot of Δδ *vs.* the increasing mole ratio of KOH to ZnO. In a similar graph, Newman and Blomgren found possible discontinuities in the two curves of lowest KOH concentrations (2.89 and 4.83*M*).

These discontinuities were tentatively attributed to second coordination sphere effects. Although our curve for the lowest KOH concentration (2.9*M*) also shows an increase at a mole ratio of about 11, we feel that this must be viewed with caution since the increase is less than twice the standard deviation of the δ-values, and may be due to normal statistical scatter.

In Fig. 2, 3, and 4 the dotted vertical line indicates the limit of normal solubility of ZnO in each of the KOH solutions. Neither Fig. 2 nor Fig. 3 shows a statistically significant discontinuity or change of slope on passing from the unsaturated into the supersaturated region. The absence of such a discontinuity is consistent with the view that in both the unsaturated and supersaturated regions only one type of Zn complex exists, namely $Zn(OH)_4^{2-}$.

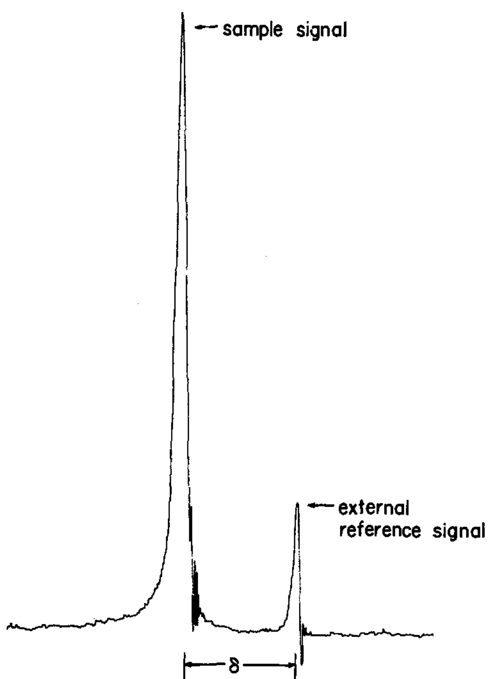

Fig. 1. Typical nuclear magnetic resonance scan

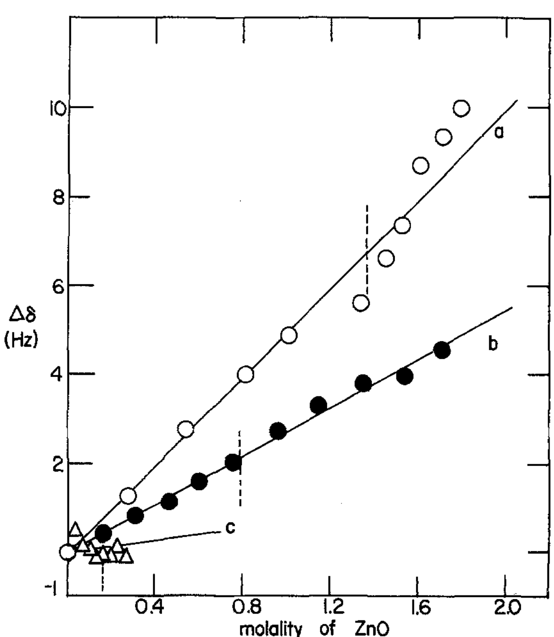

Fig. 2. Change in chemical shift with added ZnO at different base strengths: a, 12.2M KOH; b, 7.3M KOH; c, 2.9M KOH.

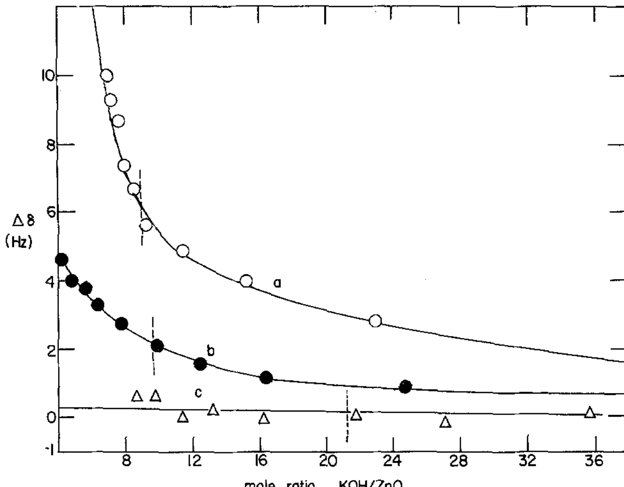

Fig. 3. Change of chemical shift with increasing mole ratio of KOH to ZnO at different base strengths: a, 12.2M KOH; b, 7.3M KOH; c, 2.9M KOH.

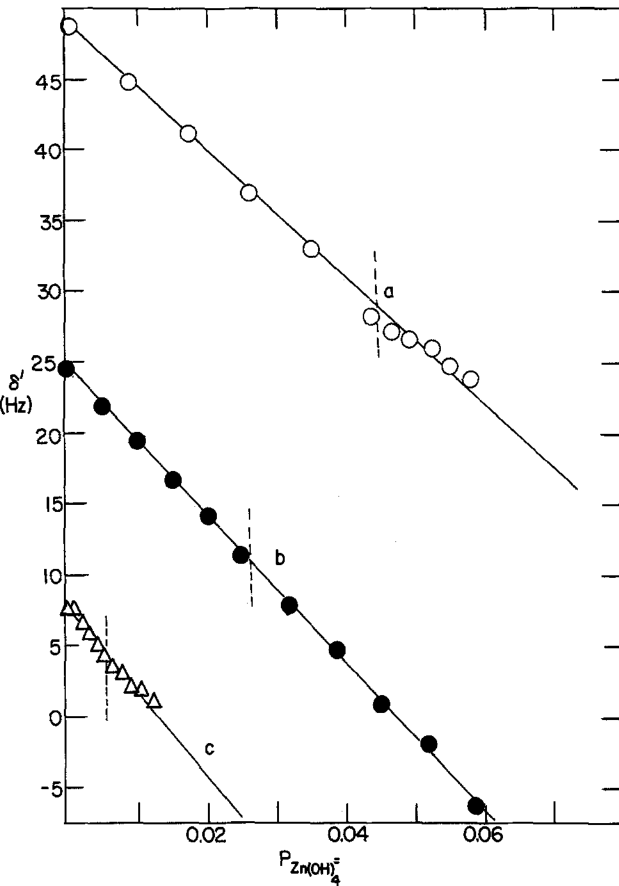

Fig. 4. Plot of δ' with increasing proton fraction of $Zn(OH)_4^{2-}$ at different base strengths: a, 12.2M KOH; b, 7.3M KOH; c, 2.9M KOH.

The total chemical shift with respect to the reference signal may be expressed by the equation

$$\delta = P_{OH^-}\,\delta^\circ_{OH^-} + P_{Zn(OH)_4^{2-}}\,\delta^\circ_{Zn(OH)_4^{2-}} \quad [3]$$

in which the following definitions apply

δ = chemical shift corrected for bulk susceptibility

P_{OH^-} = proton fraction of OH^- in solution

$$= (M_{KOH} - 2M_{ZnO})/(M_{KOH} + 2 \times 55.51) \quad [4]$$

$P_{Zn(OH)_4^{2-}}$ = proton fraction of $Zn(OH)_4^{2-}$ in solution

$$P_{Zn(OH)_4^{2-}} = 4M_{ZnO}/M_{KOH} + 2 \times 55.51) \quad [5]$$

$\delta^\circ_{OH^-}$ = ratio of change of chemical shift with change in mole fraction of OH^- at infinite dilution

$\delta^\circ_{Zn(OH)_4^{2-}}$ = ratio of change of chemical shift with change in proton fraction of $Zn(OH)_4^{2-}$

The above definitions are identical to those used by Newman and Blomgren (4).

The value for $\delta^\circ_{OH^-}$ found by Newman and Blomgren is 20.0 ppm or 1200 Hz.

This value was found by measuring the chemical shift, δ, *vs.* the proton fraction of OH^- ion and measuring the slope of the curve at zero concentration.

Both our values and those of Newman and Blomgren (4) show positive deviations from linearity which the latter authors have attributed to ion-pairing between the K^+ and OH^- ions. The magnitude of this deviation should depend on the concentration of KOH and, since water solutions are strongly hydrogen-bonded, the deviation should also be temperature dependent (7, p. 400).

The differences in the deviation from linearity (Fig. 5) for identical KOH concentrations may be attributed to different spectrometer probe temperatures.

Newman and Blomgren do not report a temperature value. Ambient probe temperature in our instrument is 40° ± 2°C. In any case, the value of the slope of the curve extrapolated to zero concentration corroborates the value of 20.0 ppm for $\delta^\circ_{OH^-}$.

From the value of $\delta^\circ_{OH^-}$ and the known KOH concentration the value of δ' may be calculated for each solution.

$$\delta' = P_{Zn(OH)_4^{2-}}\,\delta^\circ_{Zn(OH)_4^{2-}} = \delta - P_{OH^-}\,\delta^\circ_{OH^-} \quad [6]$$

A plot of δ' *vs.* $P_{Zn(OH)_4^{2-}}$ will then give as its slope, the value of $\delta^\circ_{Zn(OH)_4^{2-}}$ (Fig. 4).

The following values were found:

Molality of KOH	$\delta^\circ_{Zn(OH)_4^{2-}}$, ppm
2.9	−9.60
7.3	−8.60
12.2	−7.32

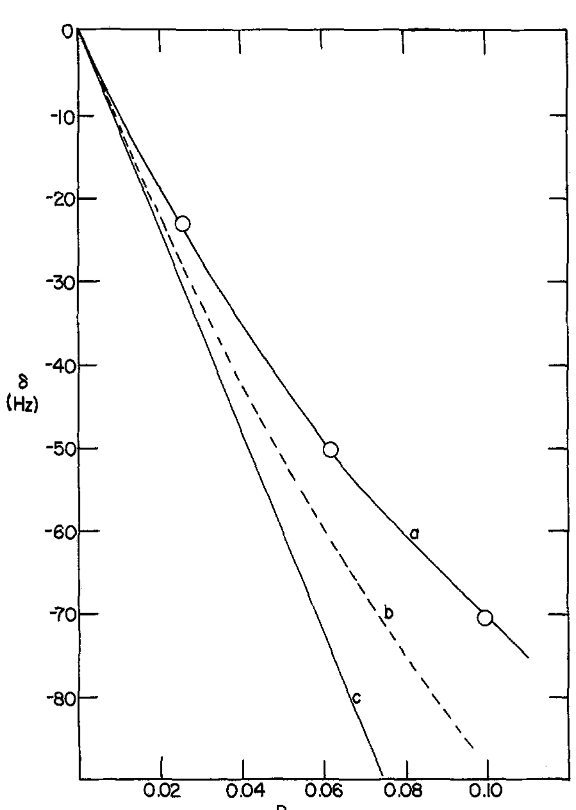

Fig. 5. Plot of proton resonance shift, δ, with increasing proton fraction of base: a, our values; b, approximate experimental values of Newman and Blomgren (4); c, slope of curves at P_{KOH} = 0. Used as values of δ°_{KOH}.

In view of the small magnitude of the effect being measured and the uncertainty in the temperature, these values compare well with those found by Newman and Blomgren (4) which ranged from −6.44 to −6.04 ppm. Although our values are slightly higher, the change in $\delta_{Zn(OH)_4^{2-}}$ with changing KOH concentrations is similar, though somewhat more pronounced.

In calculating the data in Fig. 4, it was assumed that $\delta^o_{OH^-}$ has a constant value of 20.0 ppm. The error introduced by the deviations from this value (see Fig. 5) causes the nonzero intercepts of the curves in Fig. 4, but should not affect the slopes appreciably.

The plots of δ' *vs.* $P_{Zn(OH)_4^{2-}}$ do not show a significant deviation from linearity on passing from the unsaturated to the supersaturated region. In view of this, no difference in the zinc-containing species existing in those two regions is indicated. Should a second, different, zinc species exist in the supersaturated region, a change in slope might be expected.

If, for example, the excess zinc (above the normal limit of solubility) existed as simple Zn^{++} ions, the slope of the curves in Fig. 4 should approach zero in the supersaturated region. The species which cannot be eliminated by those arguments are other complexes of zinc containing 4 protons, namely, $Zn(H_2O)_2^{++}$ and $Zn(OH)_2(H_2O)$. The existence of these, however, is placed in doubt by the work of Fordyce and Baum (3).

Finally, the linearity of the plots in Fig. 4, and the lack of signal broadening in the spectra eliminate the possibility that the excess zinc exists as a colloid or suspended solid.

The Sealed Nickel-Hydrogen Secondary Cell

Jose Giner*[,1]

Tyco Laboratories, Waltham, Massachusetts 02154

and James D. Dunlop*

COMSAT Laboratories, Clarksburg, Maryland 20734

ABSTRACT

A recently developed sealed nickel-hydrogen cell offers considerable promise to develop lightweight, long-life, rechargeable batteries. The most apparent advantages of this cell are its higher energy and power density as compared with other rechargeable systems including nickel-cadmium, lead-acid, and silver-zinc cells and the regenerative H_2-O_2 fuel cell. The energy density for lightweight 50 A-hr cells shown is 28 W-hr/lb. The cell enjoys a unique overdischarge protection mechanism which allows for long cycle life at high depth of discharge. Experimental data are presented to define the characteristics of the cell. Over 5000 high rate cycles have been completed on small 1.5 A-hr cells with good voltage performance. A 50 A-hr cell has completed to date over 800 cycles discharge to 70% of measured capacity in 1.2 hr.

A recently developed sealed nickel-hydrogen cell (1) offers considerable promise for the development of light, long-life, rechargeable batteries. This system competes favorably in many applications with such rechargeable systems as the lead-acid and nickel-cadmium (Ni-Cd) cells and with systems in the developmental stage, such as the regenerative H_2-O_2 fuel cells and Cd-O_2 cells. The most apparent advantages of the cell are its attractive energy and power densities for both charge and discharge. In addition, it shows high reliability, long cycle life, storage life which is insensitive to the state of charge, considerable overcharge protection, and a unique overdischarge protection mechanism which makes it eminently suited for connecting cells in series. It also promises attractive low-temperature performance. The specific application of this system to synchronous satellite operation has already been discussed (2). In the following the characteristics of the cell are defined, based on experimental measurements, and the lightweight 66 W-hr (50 A-hr) cell design.

Description of the System

In its construction the nickel-hydrogen cell resembles the Ni-Cd cell, except that the cadmium electrode is replaced by a catalyst electrode capable of oxidiz-

* Electrochemical Society Active Member.
[1] Present address: Giner, Inc., 144 Moody Street, Waltham, Massachusetts 02154.

Key words: batteries, rechargeable batteries, nickel-hydrogen batteries, aerospace batteries.

ing hydrogen gas on discharge and evolving it on charge at low polarizations. Figure 1 is a schematic representation which shows the basic electrode arrangement for the cell. In this arrangement, the positive plates, the separators, and the electrolyte are identical to those used in the Ni-Cd cell, while the hydrogen electrode structure consists of Teflon-bonded platinum supported within a thin, fine mesh, Ni screen. A gas diffusion mesh Teflon screen is placed on the back side of each hydrogen electrode to facilitate hydrogen diffusion to the platinum electrode. The total electrode-electrolyte separator stack is surrounded by an atmosphere of hydrogen under pressure.

Under normal discharge conditions, the reaction on the positive electrode is

$$NiOOH + H_2O + e^- \rightarrow Ni(OH)_2 + OH^- \quad [1]$$

and, at the negative electrode

$$\tfrac{1}{2} H_2 + OH^- \rightarrow H_2O + e^- \quad [2]$$

which results in the over-all cell reaction

$$NiOOH + \tfrac{1}{2} H_2 \rightarrow Ni(OH)_2 \quad [3]$$

During charge, the reverse reactions occur. From reaction [3], it can be concluded that there is no water production or consumption during operation other than that caused by differences in the amount of water of crystallization in the different nickel hydroxides. As shown by Eq. [1] and [2], there are local water concentration changes at each electrode.

On overcharge, when most of the bivalent nickel oxide has been oxidized, oxygen is evolved according to the reaction

$$2OH^- \rightarrow H_2O + \tfrac{1}{2} O_2 + 2e^- \quad [4]$$

This oxygen reacts immediately at the abundant catalytic surface with an equivalent amount of the hydrogen (which is being produced at equivalent stoichiometric rates) according to

$$H_2 + \tfrac{1}{2} O_2 \rightarrow H_2O$$

or is reduced at the negative electrode according to the reverse of reaction [4]. The $Ni-H_2$ cell is intrinsically positive electrode limited on charge because of the practically unlimited supply of water for the charging reaction at the negative electrode.

Cell reversal protection can be achieved by introducing a hydrogen precharge (*i.e.*, an amount of hydrogen gas) in the cell while it is in the discharged state. Under these conditions, the cell becomes positive electrode limited on discharge. When all the trivalent nickel hydroxide has been reduced in the discharge part of the cycle and further current is passed, hydrogen is evolved on the nickel electrode surface (since it is extremely difficult to reduce nickel hydroxide to pure nickel under these conditions). The evolved hydrogen is compensated for by an equivalent amount of hydrogen which is oxidized at the hydrogen electrode.

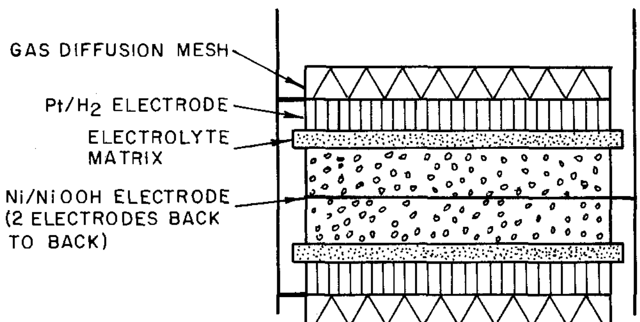

Fig. 1. $Ni-H_2$ cell configuration

Experimental Results

All experimental data presented were obtained using demountable heavy-walled pressure vessels. Two types of experimental cells were fabricated, a single 1.5 A-hr $Ni-H_2$ electrode cell, and multielectrode 5, 15, 25, and 50 A-hr cells. All of these cells used sintered nickel hydroxide positive electrodes, polypropylene separators, and Teflon-bonded platinum black negative electrodes, with a 30% KOH solution as electrolyte.

Single nickel hydroxide electrode cells (Fig. 1) were used to characterize electrochemical performance for cycle life, overcharge protection, temperature performance, and electrolyte management. Multielectrode cells (Fig. 2) were used to determine the effects of connecting a number of electrodes in parallel. In all cases the hydrogen gas was contained within the pressure vessel.

Parametric Data

The multielectrode cells were used to characterize the $Ni-H_2$ cell behavior in terms of temperature, pressure, and voltage with cycling. The cover of the heavy-walled container had an inlet tube to allow for hydrogen precharge filling and for pressure monitoring via a pressure transducer. The electrical feedthroughs were Ziegler-type plastic compression seals (3). A thermocouple was located in the cavity of the hydrogen electrode at the center of the electrode stack to determine the temperature under operating conditions. The thermocouple was encapsulated in polysulfone to avoid corrosion.

Conventional aerospace sintered nickel electrodes used in these cells were chemically impregnated and had a thickness of 0.76 mm and a measured flooded capacity of 0.12 A-hr/g. Two of these electrodes were used back to back to construct one positive electrode.

The hydrogen electrodes used in most cells were constructed from platinum black, bonded with Teflon, and pressed onto a thin nickel screen. Some of the electrodes had a porous Teflon backing on the gas side. A few cells used hydrogen electrodes consisting of a lightly platinized, graphite felt material (Energy Research Corporation proprietary electrode).

Pressure and voltage characteristics on cycling.—The pressure and voltage *vs.* time over a charge and discharge cycle are presented in Fig. 3. On charge at the C/1 rate.[2] the pressure increases linearly as hydrogen is evolved. The voltage rise at end of charge is

[2] The C/*t* rate is the rate in amperes for charging or discharging a cell, defined as the cell capacity in ampere-hours divided by the time, *t*, in hours (in this case, 1 hr).

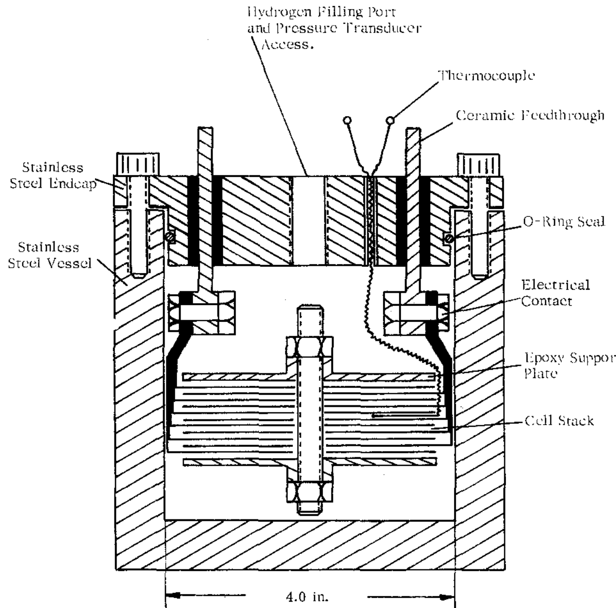

Fig. 2. Nickel/hydrogen test cell with 9.9 cm diam plates

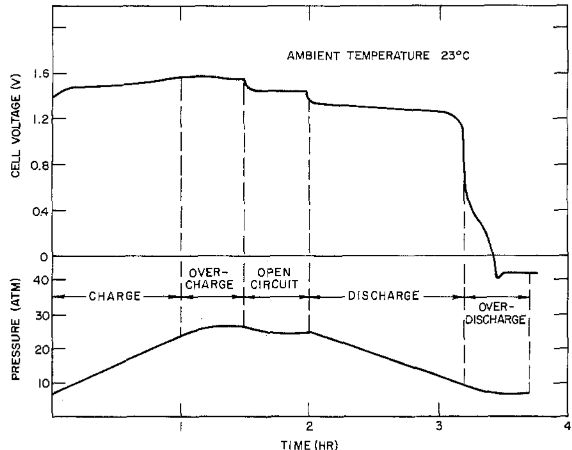

Fig. 3. $Ni\text{-}H_2$ cell pressure and cell voltage characteristics

caused by the onset of oxygen evolution at the nickel electrode. A slight voltage decrease observed during overcharge after O_2 evolution occurs is attributed to a temperature rise caused by O_2 and H_2 recombination. The pressure levels off and becomes constant. The partial pressure of oxygen measured during overcharge is less than 1% of the total cell pressure.

On discharge at the C/1 rate, the pressure decreases linearly as hydrogen is consumed. The voltage on discharge is characteristic of the nickel hydroxide electrode. A second plateau observed below 1V may be attributed either to reduction of chemisorbed oxygen on the positive electrode or to reduction of higher valent nickel. The cell voltage on discharge is not appreciably affected by the partial pressure of hydrogen at these temperatures and discharge rates.

During reversal on overdischarge of the positive electrode, the cell voltage reverses polarity and becomes slightly negative while the pressure levels off. This capability for continuous overdischarging of the cell with no adverse effects or pressure buildup is a unique feature of this cell.

Temperature characteristics.—Temperature data presented in Fig. 4 are for the thermocouple located in the center of the cell stack. On charge at a C/10 rate, the cell is slightly endothermic, and the cell temperature is practically constant. All of the power delivered to the cell on overcharge is dissipated as heat. Oxygen is evolved at the positive electrode, while hydrogen is evolved at the negative electrode in equivalent Faradaic rates. This oxygen and hydrogen react to form water (see Eq. [4] and [5]), causing the temperature to rise.

On discharge at the C/2 rate, part of the electrochemical energy is dissipated as heat, primarily because of polarization at the positive electrode which results in a temperature rise. A very high transient temperature rise occurs at the end of discharge because of the high polarization at the positive electrode.

During reversal at the C/2 rate, the temperature decreases and stabilizes to a value lower than that observed on discharge. Hydrogen is generated at the positive electrode and consumed at the negative electrode with low polarization.

In general the thermal and temperature characteristics of the $Ni\text{-}H_2$ cell are very similar to those of the Ni-Cd cell with the exception of behavior on reversal.

Temperature effects on capacity.—The voltage *vs.* time discharge characteristics with temperature as a parameter are shown in Fig. 5. The cell has been overcharged by 60% at the C/10 rate and then discharged completely to 0V. From 0° to −10°C there is a significant loss in capacity and also above 40°C a significant loss is observed. As with an Ni-Cd system, the desirable temperature range of operation is from 0° to approximately 25°C. However, the $Ni\text{-}H_2$ cell does not have the low temperature limitation of the Ni-Cd cell attributed to the poor charge acceptance of the cadmium electrode.

Self-discharge.—The self-discharge characteristics for the $Ni\text{-}H_2$ cells standing on open circuit are shown in Fig. 6. Starting with a fully charged cell, the self-discharge can be directly related to a loss of hydrogen pressure. As shown in Fig. 6, the self-discharge, similar to that of a Ni-Cd cell, occurs in a diminishing exponential fashion; after one day of standing on open circuit, the cell retains approximately 80% of its full capacity. This self-discharge is attributable either to

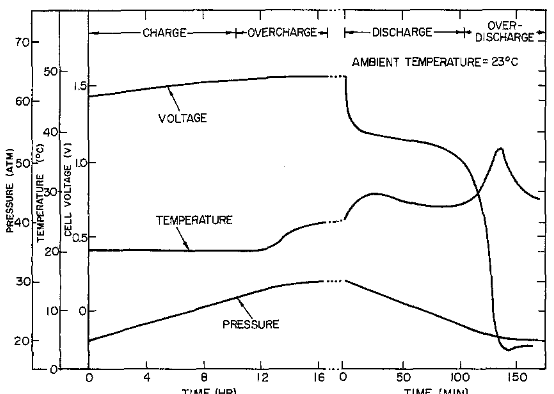

Fig. 4. $Ni\text{-}H_2$ cell temperature characteristics

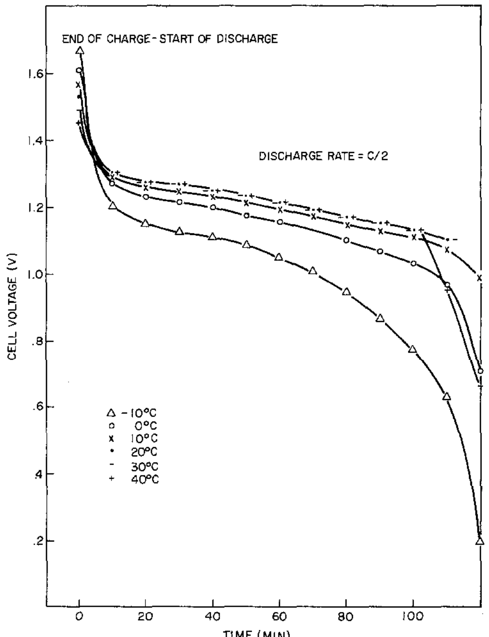

Fig. 5. Temperature effects on capacity

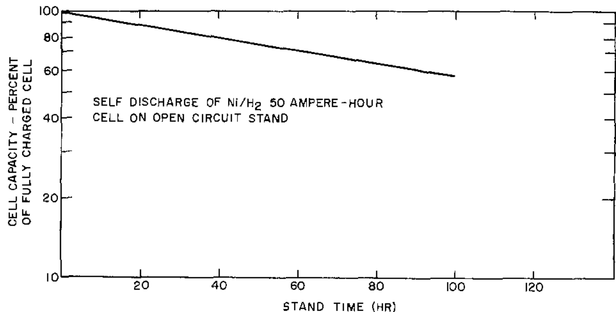

Fig. 6. Self-discharge characteristics

the direct reduction of Ni^{+3} to Ni^{+2} or to the reduction of chemisorbed oxygen on the nickel electrode.

Effects of charge and discharge rates.—Both the nickel hydroxide and the hydrogen electrodes are capable of high-rate charge and discharge. Figure 7 shows the cell voltage *vs.* the charge rate (up to the 5C rate) as a function of the state of charge of the positive electrode at room temperature. Figure 8 shows the cell voltage *vs.* the discharge rate (up to the 5C rate) as a function of the state of discharge.

Figure 9 shows the effect of the charge rate on charge acceptance. The charge acceptance was determined by charging the cell at different rates to return 5 A-hr of capacity to the cell and then discharging it at the C/1.2 rate to 1V. Maximum charge efficiency is achieved at the C/1 charge rate.

The effects of the rate of discharge on measured cell capacity after the cell is charged at the C rate to 33% overcharge are shown in Fig. 10. The capacity obtained on discharge at the 5C rate is only 10% less than that obtained at the C rate. Thus, in addition to providing a high energy density (approximately 66 W-hr/kg), the $Ni\text{-}H_2$ system has an excellent power density capability (over 300 W/kg).

Cyclic Life Data

The nickel hydroxide electrode and the Teflon-bonded H_2 electrode are the two most stable electrodes developed for sealed secondary cells to date. Since the sealed $Ni\text{-}H_2$ cell is a recent development, the major failure mechanisms must still be determined. Data are presented for cyclic test results to date.

High-rate cycle test.—The purpose of this test is to evaluate different combinations of commercially available electrodes and separator materials in terms of cyclic life performance. Data are presented for five cells with electrode and separator materials identified in Table I. These cells are subjected to a 1 hr cycle test consisting of discharge for 26 min at a C/1.5 rate which corresponds to 28.6% depth of discharge (DOD) and charge for 34 min at a C/1.5 rate corresponding to 30% overcharge.

High-rate cycle test results.—Cell S/N 123 has completed over 5000 cycles to date. (Figure 11 shows the end-of-charge and end-of-discharge voltages for this cell.) The other cells have failed at 3000, 1674, 1068, and 468 cycles. The cells are considered to have failed when the discharge voltage drops below 1V.

Cell S/N 122 failed after 3000 cycles. The measured impedance of this cell increased from 70 mohm at the start of the test to over 200 mohm at failure. The increase in impedance results from a loss of electrolyte from the separator. Examination of the separator after failure revealed that the polypropylene had dried out and would not absorb electrolyte. Examination of the positive electrodes showed that they were still structurally sound, but that the thickness had changed from 0.76 to 1.16-1.30 mm.

This cell was rebuilt by using the same positive electrodes, but with a Hercules polypropylene separator and ERC Teflon-backed hydrogen electrodes. It has now completed 2000 additional cycles.

Cell S/N 115 failed after 1674 cycles. The hydrogen electrode in this cell did not have Teflon backing. The measured impedance increased from 70 mohm at the start of the test to 620 mohm at failure. Examination of the separator after failure again revealed that the polypropylene had dried out and would not absorb electrolyte. Examination of these positive electrodes showed

130	SAFT double electrodes back to back Each electrode 0.76 mm thick	Nylon	ERC platinum and PTFE on nickel screen, Teflon backing
131	SAFT double electrodes back to back Each electrode 0.76 mm thick	Potassium titanate	ERC platinum and PTFE on nickel screen, Teflon backing
132	SAFT double electrodes back to back Each electrode 0.76 mm thick	Potassium titanate	ERC platinum and PTFE on nickel screen, Teflon backing
136	SAFT double electrodes back to back Each electrode 0.76 mm thick	Nylon	ERC platinum and PTFE on nickel screen, Teflon backing

that they also were still structurally sound, but that the thickness had changed from 0.76 to 1.16-1.30 mm.

Cells S/N 126 and 127 failed after 468 and 1068 cycles, respectively. These cells had the ERC graphite hydrogen electrodes without Teflon backing. Both failed because of loss of electrolyte, resulting in high impedance. These cells were rebuilt, S/N 126 with an ERC hydrogen electrode without Teflon backing and S/N 127 with an ERC hydrogen electrode with Teflon backing, using the same positive electrodes. These rebuilt cells have now completed over 3000 additional cycles and are still running (see Fig. 12).

Two new cells, cells S/N 128 and S/N 129, were built to evaluate the Pellon polypropylene separator material. The electrode and separator materials are identified in Table I.

Cell S/N 128 failed after 1488 cycles, again because of high impedance. The Pellon polypropylene was dried out and would not readily absorb electrolyte. This cell was rebuilt by changing the separator to Pellon nylon 2505. A significant improvement in voltage performance has been observed with the nylon separator (see Fig. 13).

Conclusions of the high-rate cycle test.—The thin graphite hydrogen electrodes and also the electrodes on nickel screen without Teflon backing have limited cycle lifetimes because of electrolyte entrainment, resulting in a loss of electrolyte from the separator. In addition, the polypropylene separators, both Hercules and Pellon, with wetting agents are becoming hydrophobic with cycling. Because of the problems with the polypropylene separator additives, cyclic tests have been initiated to investigate nylon and potassium titanate separator materials (see Table II). The cells are subjected to a 3 hr cycle test consisting of discharge for 72 min at a C/1.5 rate to 85% DOD and charge for 1.8 hr at a C/1.96 rate to 15% overcharge. They are being cycled at a very deep DOD (85% of the measured capacity). To date they have completed 500 cycles demonstrating good voltage performance (see Fig. 14).

Cycle test data for the 50A-hr cell.—This cell electrode stack is similar in construction to the lightweight

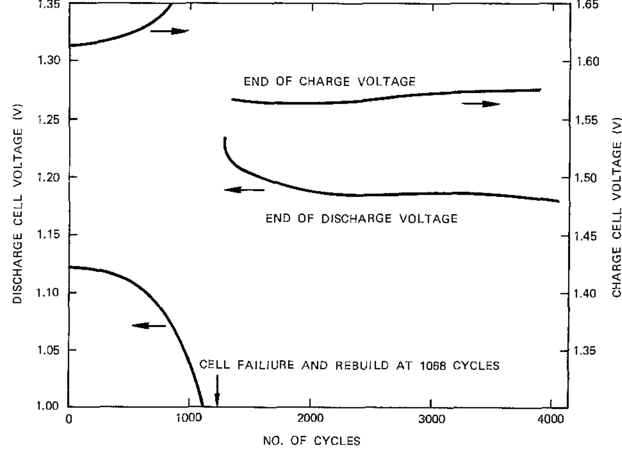

Fig. 12. Cyclic life performance of cell S/N 127

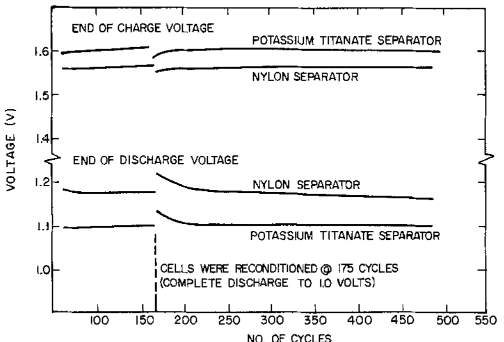

Fig. 14. Cyclic life performance of KT and nylon separator

prototype cells being fabricated. It has a 22 multi-electrode plate stack with the positive and negative electrodes connected in parallel. The hydrogen electrodes are Teflon-backed platinum and PTFE on nickel screen. SAFT aerospace positive electrodes, each 0.76 mm thick, are used back to back with the Hercules polypropylene separator.

Over 1000 cycles have been completed, demonstrating the ampere-hour turnover necessary to meet a 7 yr synchronous satellite mission (Fig. 15). A second 50 A-hr cell has now completed over 200 cycles on test. A positive SAFT nickel electrode has been manufactured specifically for this $Ni-H_2$ cell. Each nickel electrode is 0.96 mm thick; again they are used back to back to make one positive electrode, and all edges are coined. The cell has nylon separators.

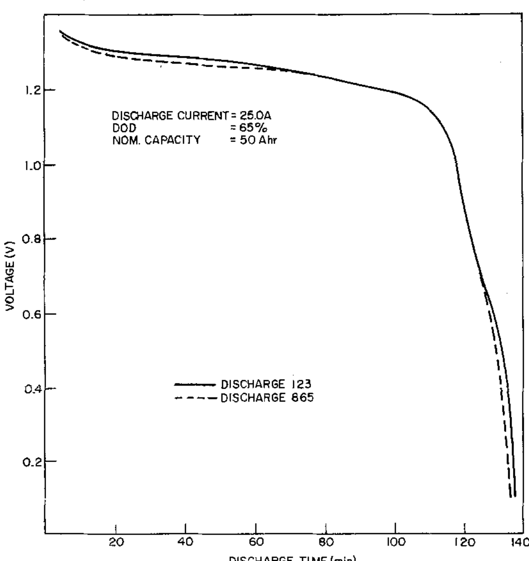

Fig. 15. Cyclic performance of the 50 A-hr cell

Lightweight Cell Design

For synchronous satellite applications, the cell design has been optimized for maximum energy density, subject to the practical restrictions discussed below.

A computer study has as the main variables cell capacity, capacity per unit area of the positive plates, cell diameter, and operating range of the cell pressure. The cell configuration for this study is a cylindrical single cell with the hydrogen contained within the pressure vessel. To characterize the electrode stack, state-of-the-art commercially available hydrogen electrodes, separators, gas diffusion screens, etc., are assumed. Inconel 625 is assumed to be the material used for the pressure vessel.

A practical cell design has been selected on the basis of the following criteria. The cell is sized to provide 66 W-hr (52 A-hr) of energy. The corresponding energy density for a cell of this capacity is 62-64 W-hr/kg (Fig. 16). Increasing the cell capacity does not significantly improve the energy density; however, if the cell capacity is reduced, there is a drop in energy density.

The cell capacity per unit area of the positive plates does have a significant effect on energy density (see Fig. 17). The practical limitations are the plate thickness that can be achieved in commercial production of the nickel plaque and the utilization of active material for thicker plates. For these reasons positive plates are used back to back in the fabrication of the multielectrode cells.

Once the cell capacity is selected, the number of electrodes is dependent on the cell diameter selected. For the 66 W-hr cell the effect of the cell diameter and the current density on the energy density and the number of electrodes in the stack is shown in Fig. 18.

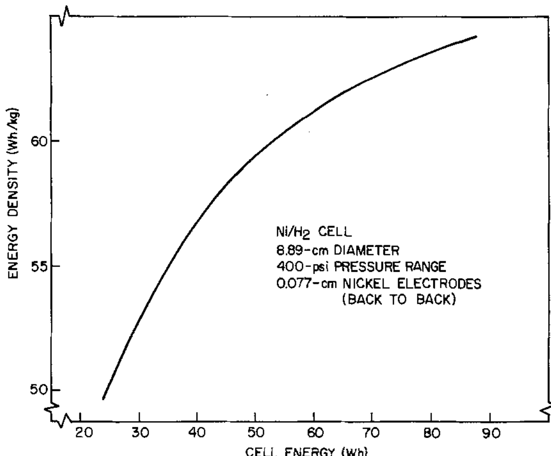

Fig. 16. $Ni-H_2$ cell, energy density vs. energy

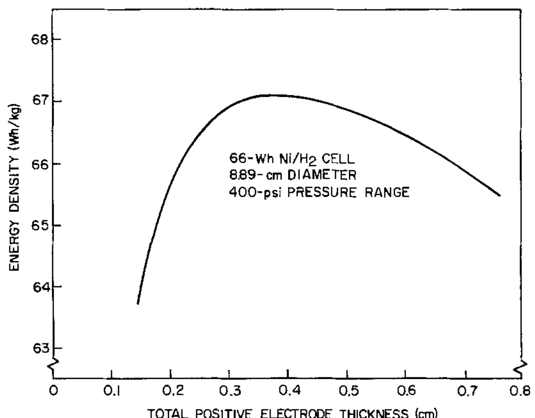

Fig. 17. $Ni-H_2$ cell, energy density vs. positive electrode thickness

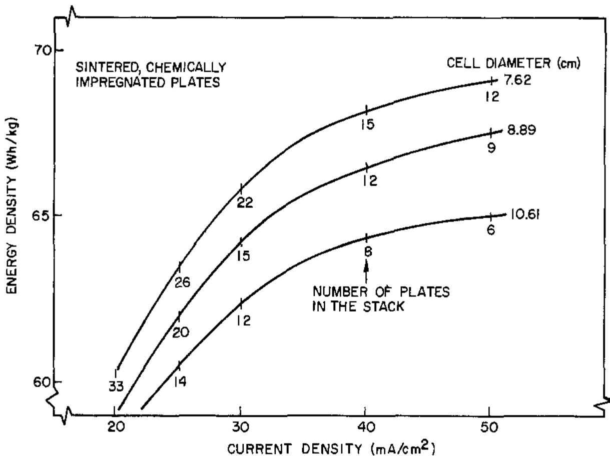

Fig. 18. Ni-H_2 cell, energy density *vs.* current density

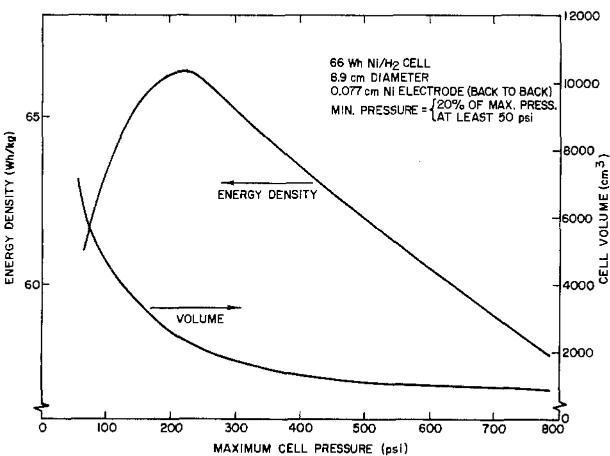

Fig. 19. Ni-H_2 cell, energy density *vs.* cell pressure

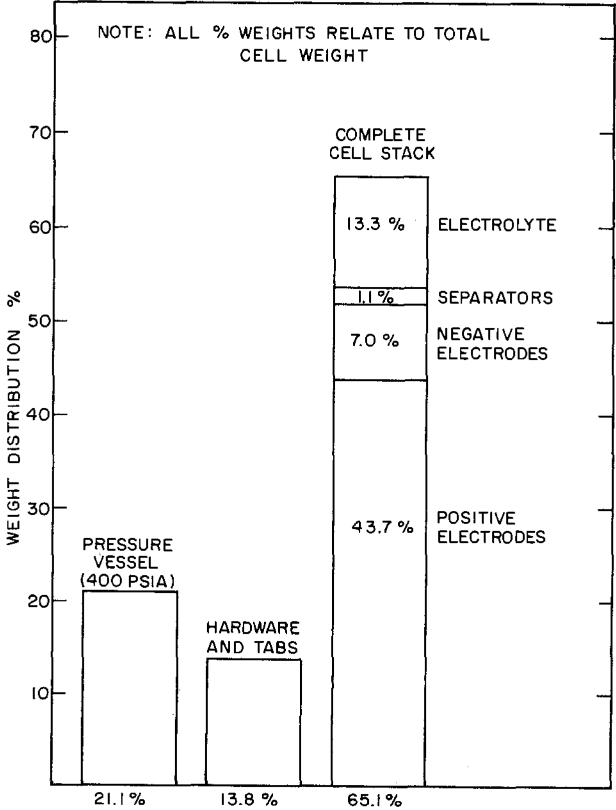

Fig. 20. Ni-H_2 cell, weight distribution

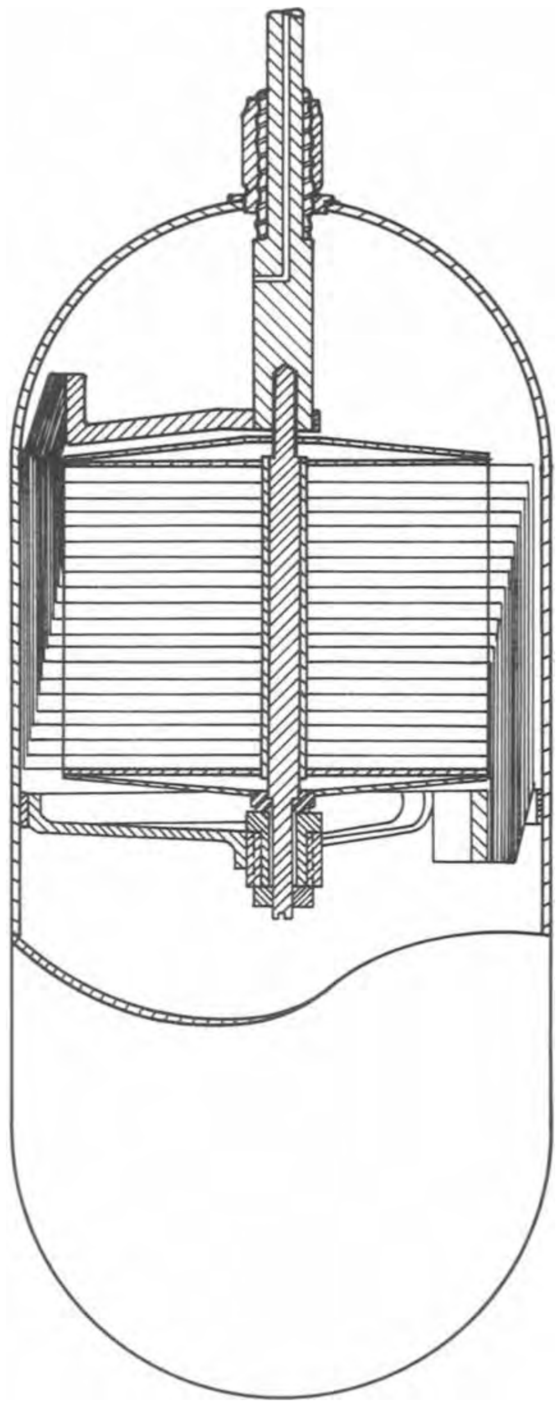

Fig. 21. Lightweight Ni-H_2 cell design

A diameter of 8.89 cm has been selected. At a current density of 25 mA/cm^2, the number of electrodes in the stack is 20. Decreasing the diameter makes it possible to achieve somewhat higher energy densities at the expense of an increased number of electrodes in the cell stack. The present design is a compromise between energy density and reliability.

The energy density and cell volume as functions of the maximum cell pressure are shown in Fig. 19 for an initial hydrogen pressure of 100 psi. A maximum pressure of 27 atm has been selected. Again, this is a trade off between maximum energy density and cell volume.

Figure 20 shows the weight breakdown for the 66 W-hr cell design. It should be noted that the weight of the nickel hydroxide electrodes is 44% of the total weight.

Lightweight Ni-H_2 cells are now being fabricated to the design shown in Fig. 21. Characteristics of the

sintered nickel electrodes are as follows:

thickness:	0.76 mm each, 0.152 mm back to back
density:	3.25 g/cm^3
capacity:	0.12 A-hr/g (measured, flooded)
utilization:	96% (measured in electrode stack)
current density:	25 mA/cm^2 (for 1.2-hr discharge)

This cell is designed to provide 66 W-hr at an energy density of 62-64 W-hr/kg.

The cylindrical pressure vessel is 8.89 cm in diameter by 19.9 cm high. The insulated feedthrough is a Ziegler plastic seal.

Conclusions

Experimental data presented from laboratory investigations demonstrate the capability of the Ni-H_2 system to meet the 7-10 year cyclic life requirements for a synchronous satellite application. In addition, the Ni-H_2 system has demonstrated performance characteristics superior to those of the Ni-Cd system in terms of higher overcharge capability, overdischarge capability, better low-temperature operation, and higher power density.

Lightweight cells have been designed and are now being fabricated. These cells are expected to demonstrate three to four times the usable energy density of Ni-Cd cells. For an INTELSAT V (2 kW) satellite, this represents a potential weight reduction of 200-300 lb for the battery system.

ABSTRACT

A study was made of the electrochemical behavior of the active iron electrode in acidic ethanol-water media. The pA (pH in pure water solvent) and potential dependence of the iron dissolution and hydrogen evolution reactions were determined. The results of this investigation served to resolve the role of water in the iron dissolution mechanism. Basic to the proposed mechanism was the validity of an "absolute acidity scale" for EtOH-HOH solutions.

A study has been made of the electrochemical behavior of the active iron electrode in acidic ethanol-water media. The purpose of the investigation was to test the applicability of an "absolute acidity scale" postulated for ethanol-water (1), and in the application of the "acidity scale," to determine the kinetic order with respect to water and protons in the corrosion mechanism.

It has been shown by Kelly (2) and Bockris (3) that the steady-state anodic dissolution of zone-refined iron in aqueous acid sulfate solutions is characterized by a Tafel slope of 2/3(2.303 $RT/\mathbf{F}$), *i.e.*, 40 mV/decade of current, and first order dependency on the hydroxyl ion activity. The results were interpreted in terms of the following mechanism

$$Fe + H_2O \rightleftarrows Fe(H_2O)_{ad} \quad [1]$$

$$Fe(H_2O)_{ad} \rightleftarrows Fe(OH^-)_{ad} + H^+ \quad [2]$$

$$Fe(OH^-)_{ad} \rightleftarrows Fe(OH)_{ad} + e \quad [3]$$

$$Fe(OH)_{ad} \rightarrow (FeOH)^+ + e \text{ (rate determining)} \quad [4]$$

$$(FeOH)^+ + H^+ \rightleftarrows Fe^{+2} + H_2O \quad [5]$$

These equations take formal account of the simultaneous coverage of the surface by adsorbed water molecules, hydroxyl ions, and the surface intermediate $Fe(OH)_{ad}$, and lead to the kinetic expression

$$i_+ = 2\mathbf{F}k_4^w(k_3^w k_2^w/a_{(H^+)}k_{-3}^w k_{-2}^w)\,\theta_1 \exp(3\mathbf{F}E/2RT) \quad [6]$$

where $\theta_1 = (k_1^w a_w/(k_1^w a_w + k_{-1}^w)$ is the fraction of the total possible adsorption sites occupied by $Fe(H_2O)_{ad}$, a_w is the activity of water, and the k_i^w are the rate constants with infinitely dilute water solvent as the reference state. Since the infinitely dilute water solvent is the reference state for all solvent compositions including pure alcohol, the superscript "w" will be omitted in subsequent rate expressions.

In a subsequent paper, Kelly (4) reported on the results obtained for the iron dissolution and hydrogen evolution reactions on zone-refined iron in hydrogen-saturated sodium benzoate solutions (referred to as the inhibited system). The mechanism proposed for the iron dissolution reaction in the inhibited system involved the formation of an electrochemically active surface intermediate from the adsorbed anion, $(FeB_z^-)_{ad}$. and $(FeOH)_{ad}$. Then by analogy with the inhibited system, an alternate mechanism for the non-inhibited system was proposed. If to the reactions

Key words: absolute acidity, electrochemical kinetics, corrosion, iron, ethanol-water.

represented by Eq. [1]-[3] are added the reactions represented by Eq. [7] and [8]

$$(FeOH)_{ad} + Fe(HOH)_{ad} = [(FeOH) \cdot Fe(HOH)]_{ad} \equiv (I)_{ad} \quad [7]$$

$$(I)_{ad} \rightarrow (FeOH)^{+} + Fe(HOH)_{ad} + e\,(rds) \quad [8]$$

where [8] is now the rate determining step, Eq. [6] becomes

$$i_{+} = 2FK_8k_7k_3k_2/[k_{-7}k_{-3}k_{-2}(a_{H^+})]\ \theta_1^2 \exp(3FE/2RT) \quad [9]$$

The steady-state current is now second order with respect to θ_1, but remains unchanged with respect to pH and potential. In pure water $\theta_1 \sim 1$ and the effect of water on the anodic dissolution cannot be determined. The addition of ethanol to the aqueous acidic sulfate solution may provide a test for the alternate mechanisms as represented by Eq. [6] and [9]. However, changing the solvent system from HOH to EtOH-HOH introduces alternate reaction paths via other intermediates, *e.g.*, $(FeOEt)_{ad}$ and $Fe(EtOH)_{ad}$, and also introduces a junction potential into the measured cell potential when the measurements are made with respect to the aqueous calomel reference electrode. In order to compare the rates at constant potential and with respect to the same reference state (infinitely dilute water solvent), the measurements must be made with respect to an aqueous reference electrode. Here, the saturated aqueous calomel electrode was chosen as the reference electrode. Since the aqueous calomel electrode is in a constant environment (saturated aqueous KCl), its potential is constant and independent of changes in the solution composition on the other side of the liquid junction. The term potential is used here as a contraction for potential difference, *i.e.*, a Galvani potential difference, ${}^{M}\Delta^{S_1}\phi \equiv \phi_M - \phi_{S_1}$, between some point in the metal phase and some point S_1 in the solution phase. Although the absolute value of this potential cannot be determined, changes in this potential are obtained when the measurements are made with respect to some unchanging reference electrode. Here, however, the measured cell potential difference, E^s_{cell}, includes a liquid junction potential difference as well as the Galvani potential differences at the metal/solution interfaces, *i.e.*

$$(\phi_M - \phi_{Hg_2Cl_2/Hg} \equiv E^s_{cell} = (\phi_M - \phi_{S_1}) + (\phi_{S_1} - \phi_{S_2}) + (\phi_{S_2} - \phi_{Hg_2Cl_2/Hg})$$

where $(\phi_M - \phi_{S_1}) \equiv E^s_M$ is the Galvani potential difference for the metal electrode, (Fe or Pt), $(\phi_{S_1} - \phi_{S_2}) \equiv - E^s_L$ the liquid junction potential difference between EtOH-HOH solvent and saturated aqueous KCl, and $(\phi_2 - \phi_{Hg_2Cl_2/Hg}) \equiv - E_{SCE}$ is the Galvani potential difference for the reference electrode. Therefore, $E^s_{Fe,Pt} = E^s_{cell} + E^s_L + E_{SCE}$, and changes in the Galvani potential for iron or platinum are obtained when the cell potential E^s_{cell} is measured and the junction potentials E^s_L are known.

Junction Potentials

In solvents other than water it is useful to distinguish between two acidity measuring functions, pA and pH (5), defined as follows

$$pA = -\log a_{+} = -\log c_{H^+}\, y^s_{H^+}\, f_{H^+} \quad [10]$$

$$pH = -\log a_{H^+} = -\log c_{H^+}\, y^s_{H^+} \quad [11]$$

where $y^s_{H^+}$ is the conventional molar lyonium ion activity coefficient in solvent S, and f_{H^+} is the "degenerate activity coefficient" for the transfer of proton from infinite dilution in solvent S to infinite dilution in H_2O (the reference state). The parameter f_{H^+} is also referred to as the "primary medium effect" term (6, 7). The pA function measures the actual proton activity, a_+, of the given solution, whereas pH measures the molar lyonium ion activity referred to the extremely dilute solution in the given solvent. Therefore, to correlate the rates of iron dissolution with respect to proton activity using the infinitely dilute water solvent, w, as the reference state, the pA of the solution must be measured. The pA can be obtained from a measurement of the emf of the Pt/H_2 electrode in the EtOH-HOH solvent with respect to the saturated aqueous calomel electrode, SCE

$$Pt\text{-}H_2\ (1\ atm)/Soln.\ (X)\ in\ EtOH\text{-}HOH/E^s_L/KCl\ (sat.\ aq.)\ Hg_2Cl_2\text{-}Hg \quad [1']$$

where

$$pA = -\log a_{+} = -\log c_{H^+}\, y^s_{H^+}\, f_{H^+} = -E^s_{Pt}/0.06 \quad [12]$$

where $E^s_{Pt} = E^s_{cell(Pt)} + E_{SCE} + E^s_L$. Again, however, for measurements in each solvent system S, the liquid junction potential E^s_L must be known, and this is known if values for f_{H^+} in each solvent can be determined. Grunwald (1, 8) and co-workers Gutbezahl and Berkowetz have determined the thermodynamic dissociation constants, (pK^s), of weak uncharged acids HA (acetic acid type) and cation acids HA^+ (ammonium type) in ethanol-water solvents. An extrathermodynamic relationship, the activity postulate (9), was used to obtain values for the "degenerate" activity coefficient of the hydrogen ions, f_{H^+}. From a knowledge of f_{H^+} it was then possible to calculate the junction potentials in cells like (1'). Rearranging Eq. [12], the liquid junction potential

$$E^s_L = 0.06 \log (c_{H^+}\, y^s_{H^+}\, f_{H^+}) - (E_{cell(Pt)} + E_{SCE}) \quad [13]$$

where for dilute solutions, $y^s_{H^+}$ can be estimated from the Debye-Huckel limiting law, all other quantities on the right-hand side of Eq. [13] are known or measurable, and E^s_L may be calculated (1). Values of E^s_L as a function of EtOH-HOH composition are shown in Fig. 1. The measurements reported here are for a solution containing $0.5M$ H_2SO_4, which is not dilute, but is constant for all solvents S. The assumption is made that the liquid junction potential is approximately independent of acid concentration to $0.5M$ acid. This assumption could lead to errors of about 0.1 pA units (5).

Aleksandrov and Izmailov (10, 11) obtained values for the "degenerate" activity coefficient of the hydrogen ion, f_{H^+}, which were not too greatly different from those of Grunwald and Gutbezahl. However, more recently, Popovych and Dill (12, 13) have obtained values which were greatly different. Liquid junction potentials calculated from these values were not only different in magnitude but also in sign. It will be shown later that these values are not consistent with the present study.

With this background and the values for E^s_L in Fig. 1, the analysis of the anodic dissolution of iron can be attempted. The experimental system can be represented as

$$(Pt\ or\ Fe) - H_2\ (1\ atm)/0.50M\ H_2SO_4\ in\ EtOH\text{-}HOH//E'^s_L//0.50M\ H_2SO_4\ in\ HOH//E^w_L//KCl\ (sat.\ aq.)\ HgCl\text{-}Hg \quad [2']$$

where $E'^s_L + E^w_L = E^s_L$ and

$$E^s_{Fe} = E^s_{cell(Fe)} + E_{SCE} + E^s_L$$
$$E^s_{Pt} = E^s_{cell(Pt)} + E_{SCE} + E^s_L \quad [14]$$

where $E_{cell(Fe\ or\ Pt)}$ is the experimental measured potential *vs.* the saturated aqueous calomel electrode. The calomel electrode becomes inoperable in solutions of

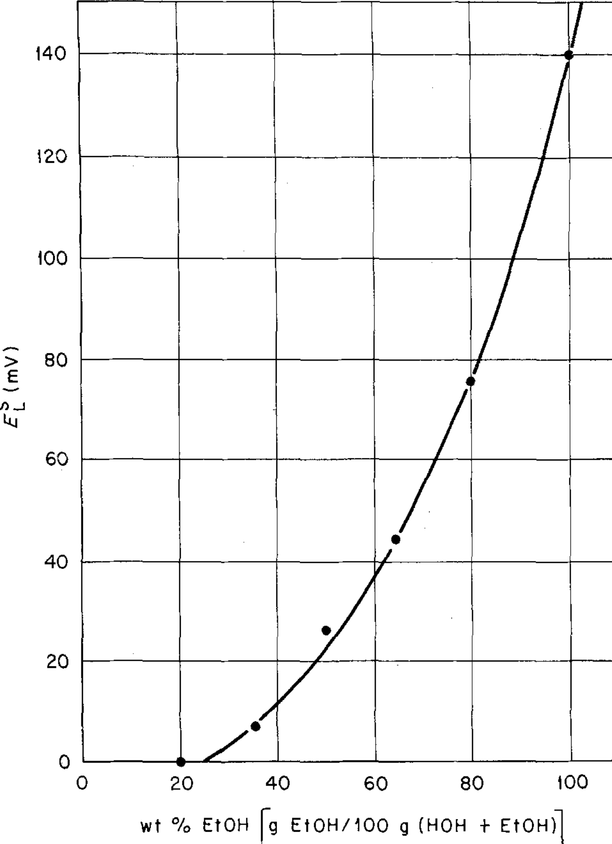

Fig. 1. Liquid junction potentials, $E^s{}_L$, between soln X in EtOH-HOH solvent and saturated aqueous KCl as a function of weight per cent EtOH in EtOH-HOH solvent.

high ethanol content due to plugging of the asbestos wick with KCl precipitation. According to [2′] a solution 0.5M H_2SO_4 in water was interposed between the calomel electrode and the ethanol-water solution. The liquid junction potential $E^s{}_L$ now becomes the sum of the two junctions $E'^s{}_L$ and $E^w{}_L$. Several measurements in cells like [1′] and [2′] showed that $E^s{}_L \sim E'^s{}_L + E^w{}_L$ within about 5 mV. An additional iron electrode was included in the cell for the polarization measurements. The liquid junction potential $E^w{}_L$ was constant and probably less than 5 mV (14).

Experimental

The high purity zone-refined iron[1] electrodes used in this investigation were cut from ¼ in. rod stock and were ¼ in. to ⅜ in. long. The electrodes were mounted in conventional Teflon electrode holders (15). The entire cell assembly was made from Pyrex glass and Teflon. The apparatus was designed so that the addition and removal of solution could be accomplished without opening the apparatus to the atmosphere. The test electrode compartment was a flat bottom cylinder made from a 55/50 TS ground glass joint. The ground surface was carefully removed by fire polishing. A glass jacket was provided for circulating water, so that the solution temperature could be maintained at 30.00° ± 0.03°C. The cap to the test electrode compartment was machined from Teflon and had seven convenience ports. The ports were ¼ in. Teflon Swagelock fittings which were epoxied into holes drilled through the Teflon cap. One port provided for the delivery of H_2 saturated 0.5M H_2SO_4 in water. A glass tube passed from the bottom of the test electrode compartment (cell) through the walls of the water jacket, to a Teflon Nupro plastic valve,[2] diaphragm stem model. This tube and valve arrangement provided for solution sample removal for the electrometric Karl Fischer water analysis,[3] and also for solution drainage, so that in conjunction with the solvent delivery facilities, varying EtOH-HOH compositions could be obtained. Ultrapure H_2 gas was provided by a Matheson generator. The H_2 gas passed successively through a presaturator containing 0.5M H_2SO_4 in absolute EtOH, a reservoir containing the 0.5M H_2SO_4 in absolute EtOH which is to be delivered to the electrochemical cell, the electrochemical cell, a reservoir containing the 0.5M H_2SO_4 in water, finally exiting to the atmosphere through a bubbler-trap which prevented back diffusion of atmospheric oxygen into the aqueous acid reservoir. Other ports in the test cell cap provided for the Fe test electrode, an Fe polarizing electrode for pA determinations, H_2 gas exit, and a Haber-Luggin capillary probe. Another glass tube for H_2 gas inlet passed through the wall of the water jacket near the top of the test cell and extended down to the bottom of the cell. An external saturated aqueous calomel electrode was used as a reference electrode in conjunction with the Haber-Luggin capillary probe. Flexible Teflon "spaghetti" tubing (⅛ in. or ¼ in.) was used for convenient connections. A Teflon-coated bar magnet was used for stirring in the test cell.

The absolute ethanol and reagent grade sulfuric acid were used without further purification. The water was triply distilled. The iron electrodes were etched in 50/50 H_2SO_4-water, rinsed in distilled water and ethanol, dried, then vacuum annealed at 800°C for 12 hr at 10^{-7} Torr, and slow cooled. The annealed electrodes were again etched in 50/50 H_2SO_4-water, rinsed in distilled water and ethanol, and transferred to the cell. In a typical experiment the iron electrodes were first exposed to the aqueous acid environment from one to several days, during which the solution was frequently replaced with fresh solution. As with Kelly (2), a well-behaved system exhibited no polarization hysteresis phenomenon, and this fact was used as the basic criterion by which the suitability of the system for investigation was determined. The solution was then drained and the 0.5M H_2SO_4 in absolute ethanol was delivered to the cell. Again, the above criterion was used for suitability for investigation. Usually, when no polarization hysteresis was observed in the aqueous environment, none was observed in the absolute ethanol environment. The absolute ethanol solvent composition was increased in water content by partial drainage of the cell and addition of the aqueous acid. When the "hysteresis" criterion was met in the aqueous and absolute ethanol environment, the solvent composition could be varied at will with increasing or decreasing water content, and no polarization hysteresis was observed at any intermediate solvent composition. Sometimes, polarization data on a given electrode were accumulated over a period of one week's time.

The polarizing currents were furnished by using the Research Model Anotrol Potentiostat in the galvanostatic mode. The currents were measured by recording the voltage drop across precision resistors in the polarizing circuit. The potentials were measured with a 610B Keithley Electrometer and recorded with a 10 mV Brown recorder.

Results

The anodic polarization data in the acidic ethanol-water environments are shown in Fig. 2. Here the total net dissolution current is plotted as a function of $E^s{}_{\text{cell(Fe)}}$ (*i.e.*, the potential of the iron electrode *vs.* the saturated aqueous calomel electrode). The Tafel slope $(dE/d \log i) = 2/3(2.3\ RT/\mathbf{F})$, and is independent of solvent composition. This implies that in each solvent S, a mechanism similar to that in pure water prevails. The alphabetical listing reveals the sequence in which

[1] Prepared and analyzed by Materials Research Corporation.

[3] The authors wish to express their appreciation to Dr. Richard Raridon of the ORNL Chemistry Division for the electrometric Karl Fischer water analysis.

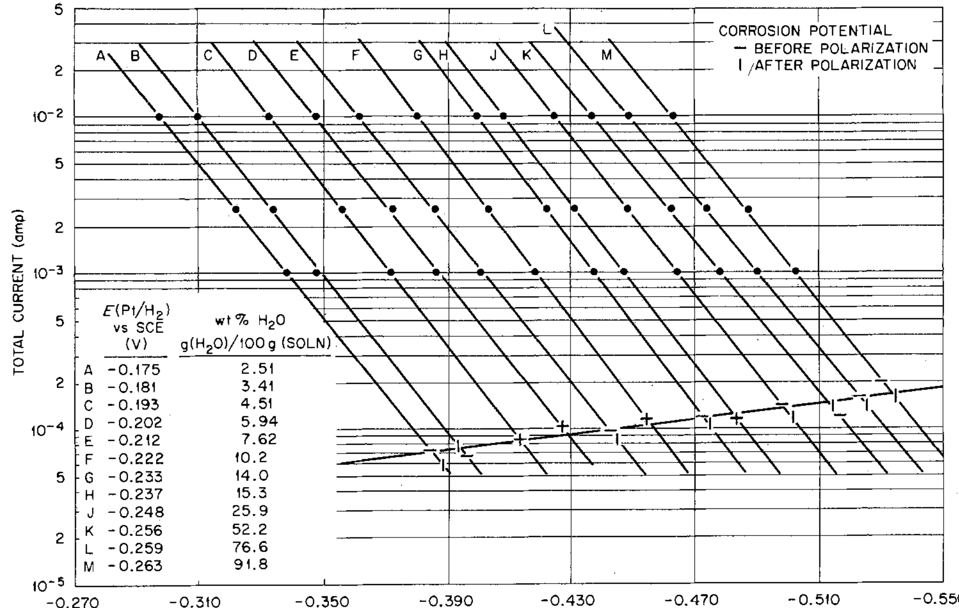

Fig. 2. Anodic polarization of iron in H_2-saturated 0.50M H_2SO_4 in various EtOH-HOH solvents, T = 30°C, electrode area 0.97 cm^2.

the polarizations were made, starting generally with the least aqueous environment. The polarization in pure water was indistinguishable from the polarization in 91.8% water shown in Fig. 2. The pure water result was repeated numerous times, and was in excellent agreement with the results reported by Eichkorn, Lorenz, Albert, and Fischer (16) for zone-refined iron. Also included in Fig. 2 are the weight per cent H_2O (as $g[H_2O]/100g$ [soln]), the potentials of the Pt-H_2 electrode *vs.* SCE and the corrosion potentials before polarization (horizontal slash) and after polarization (vertical slash). In Fig. 1 the liquid junction potentials between the acidic ethanol-water solution and the saturated aqueous KCl solution are plotted as a function of weight per cent H_2O in EtOH-H_2O solvent, where the weight per cent H_2O was calculated on the basis of $g(H_2O)/100g$ (EtOH + HOH). The weight per cent reported in Fig. 2 is calculated on the basis of g(HOH)/100g (EtOH + HOH + H_2SO_4). Consequently to obtain values for the liquid junction potentials from Fig. 1, the Karl-Fischer determinations of the water content in Fig. 2 are corrected to weight per cent (HOH)/100g (EtOH + HOH). For this calculation it was assumed that the density of the solution was the same as the density of the pure EtOH-HOH solvent at the Karl Fischer estimated water content. With these values for $E^s{}_L$, the results in Fig. 2 are replotted. Here, in Fig. 3, the polarizations are reported as current density (amperes/square centimeter) *vs.* the absolute potential of the iron electrode, $E^s{}_{Fe}$, *i.e.*, the potential of the iron electrode in solvent S *vs.* the standard hydrogen electrode in water, $(SHE)^w$. Also included in Fig. 3 are the potentials of the Pt/H_2 electrode *vs.* the $(SHE)^w$. At this point, it is probably worthwhile to emphasize that the measurement of the pA of the solutions, which is identically pH in pure water solvent, is defined according to Eq. [10]-[12]. The validity of such measurements is a test of the extra-thermodynamic postulates used for the estimation of the "degenerate" activity coefficients f_{H^+}, as a function of solvent composition. Such an application of the pA scale to inorganic reaction kinetics (in our case the corrosion of iron) has not heretofore been demonstrated. Unfortunately, the introduction of the measured pA values into the rate expression (to be derived for the EtOH-HOH solvent) does not provide

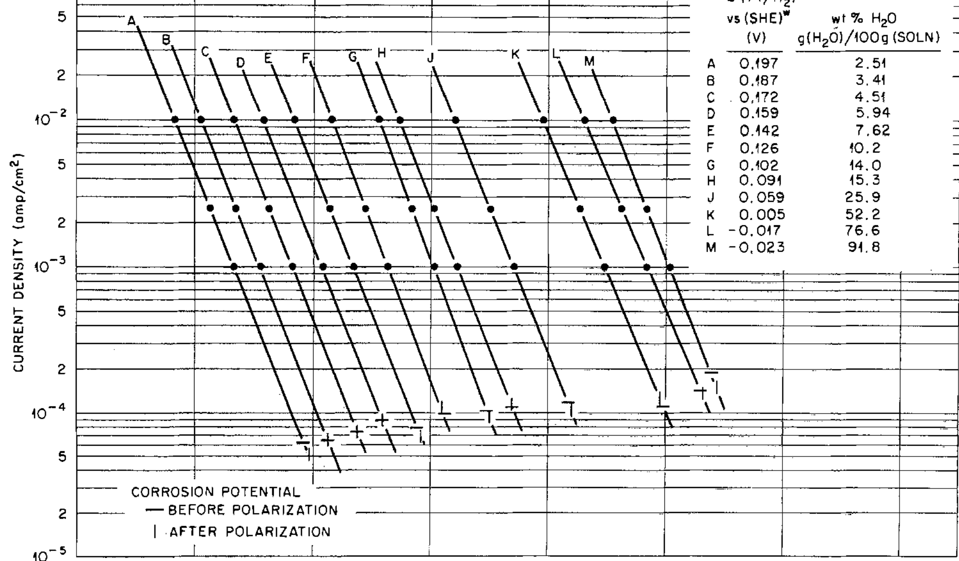

Fig. 3. Anodic polarization of iron in H_2-saturated 0.50M H_2SO_4 in various EtOH-HOH solvents, T = 30°C, electrode area 0.97 cm^2.

a direct test. In changing the solvent from pure water to EtOH-HOH, the activity of the water as well as the pA is changed, and some assumption must probably be made relating to the water activity, and presumably also to the activity of ethanol. It should be emphasized that the absolute potentials reported in Fig. 3 are based on the junction potentials provided by Grunwald and Gutbezahl. An interpretation of the results using the junction potentials provided by Popovych and Dill (12, 13) will be considered later.

The derivation of the rate expression for EtOH-HOH solvent follows very closely the mechanism proposed by Kelly (4) for the inhibited system. It is postulated that in pure EtOH the dissolution of iron proceeds by a mechanism similar to that in pure water, and in mixed solvents a simultaneous dissolution occurs by both water and alcohol, *i.e.*, $i_+ = i_w + i_a$, where i_+ is the total net anodic dissolution current, and i_w and i_a are the currents due to water and alcohol, respectively. Equations [16]-[27] give a formal description of the mechanism proposed

$$Fe + HOH \overset{1}{=} Fe(HOH)_{ad} \quad [16]$$

$$Fe(HOH)_{ad} \overset{2}{=} (FeOH^-)_{ad} + H^+ \quad [17]$$

$$(FeOH^-)_{ad} \overset{3}{=} (FeOH)_{ad} + e \quad [18]$$

$$(FeOH)_{ad} + Fe(HOH)_{ad} \overset{4}{=} [(FeOH)\cdot(Fe(HOH)]_{ad} \equiv (I)_w \quad [19]$$

$$(I)_w \overset{5}{\rightarrow} (FeOH^+) + Fe(HOH)_{ad} + e \quad \text{rds} \quad [20]$$

$$(FeOH^+) + H^+ \overset{6}{=} Fe^{++} + HOH \quad [21]$$

and simultaneously

$$Fe + EtOH \overset{7}{=} Fe(EtOH)_{ad} \quad [22]$$

$$Fe(EtOH)_{ad} \overset{8}{=} (FeOEt^-)_{ad} + H^+ \quad [23]$$

$$(FeOET^-)_{ad} \overset{9}{=} (FeOEt)_{ad} + e \quad [24]$$

$$(FeOET)_{ad} + Fe(EtOH)_{ad} \overset{10}{=} [(FeOEt)\cdot Fe(EtOH)]_{ad} \equiv (I)_a \quad [25]$$

$$(I)_a \overset{11}{\rightarrow} (FeOEt^+) + e \quad \text{rds} \quad [26]$$

$$(FeOEt^+) + H^+ \overset{12}{=} Fe^{++} + EtOH \quad [27]$$

These equations take account of the simultaneous coverage by the several intermediates, where $[Fe(HOH)_{ad}] = \beta\theta_1$, $[(FeOH^-)_{ad}] = \beta\theta_2$, $[(FeOH)_{ad}] = \beta\theta_3$, $[(I)_w] = \beta\theta_I$, $[Fe(EtOH)_{ad}] = \beta\theta_4$, $[(FeOEt^-)_{ad}] = \beta\theta_5$, $[(FeOEt)_{ad}] = \beta\theta_6$, $[(I)_a] = \beta\theta_a$, and $a_+ = c_{H^+}y^s{}_{H^+}f_{H^+}$, where θ_i is the fraction of the total possible adsorption sites occupied by $[i]$, and the surface concentrations $(\beta\theta_i)$, are expressed in moles/square centimeter, with β a proportionality constant, $y^s{}_i$ the conventional molar activity coefficient in solvent S, and f_i the "degenerate" activity coefficient. The reference state for f_i is the infinitely dilute aqueous solvent for all solvent compositions including pure ethanol. A kinetic description of this mechanism in the steady state is given by Eq. [28]-[37]

$$\frac{i_w}{\mathbf{F}} = \vec{k}_3[\beta\theta_2] - \overleftarrow{k}_{-3}[\beta\theta_3] + \vec{k}_5[\beta\theta_{Iw}] \quad [28]$$

$$\beta\left(\frac{\partial\theta_{Iw}}{dt}\right)_{ss} = 0 = \vec{k}_4[\beta\theta_3][\beta\theta_1] - \overleftarrow{k}_{-4}[\beta\theta_{Iw}] - \vec{k}_5[\beta\theta_{Iw}] \quad [29]$$

$$\beta\left(\frac{\partial\theta_3}{\partial t}\right)_{ss} = 0 = \vec{k}_3[\beta\theta_2] - \overleftarrow{k}_{-3}[\beta\theta_3] - \vec{k}_4[\beta\theta_3][\beta\theta_1] + \overleftarrow{k}_4[\beta\theta_{Iw}] \quad [30]$$

$$\beta\left(\frac{\partial\theta_2}{\partial t}\right)_{ss} = 0 = \vec{k}_2[\beta\theta_1] - \overleftarrow{k}_{-2}[\beta\theta_2][a_+] - \vec{k}_3[\beta\theta_2] + \overleftarrow{k}_{-3}[\beta\theta_3] \quad [31]$$

$$\beta\left(\frac{\partial\theta_1}{\partial t}\right)_{ss} = 0 = \vec{k}_1[a_w][(1-\theta_T)] - \overleftarrow{k}_{-1}[\beta\theta_1] + \vec{k}_2[\beta\theta_1] - \overleftarrow{k}_{-2}[\beta\theta_2][a_+] - \vec{k}_4[\beta\theta_3][\beta\theta_1] + \overleftarrow{k}_{-4}[\beta\theta_{Iw}] \quad [32]$$

and similarly for dissolution by ethanol

$$\frac{i_a}{\mathbf{F}} = \vec{k}_9\,[\beta\theta_5] - \vec{k}_{11}\,[\beta\theta_{Ia}] \quad [33]$$

$$\beta\left(\frac{\partial\theta_{Ia}}{\partial t}\right)_{ss} = 0 = \vec{k}_{10}[\beta\theta_6][\beta\theta_4] - \overleftarrow{k}_{-10}[\beta\theta_{Ia}] - \vec{k}_{11}[\beta\theta_{Ia}] \quad [34]$$

$$\beta\left(\frac{\partial\theta_6}{\partial t}\right)_{ss} = 0 = \vec{k}_9[\beta\theta_5] - \overleftarrow{k}_{-9}[\beta\theta_6] - \vec{k}_{10}[\beta\theta_6][\beta\theta_4] + \overleftarrow{k}_{-10}[\beta\theta_{Ia}] \quad [35]$$

$$\beta\left(\frac{\partial\theta_5}{\partial t}\right)_{ss} = 0 = \vec{k}_8[\beta\theta_4] - \overleftarrow{k}_{-8}[\beta\theta_5][a_+] - \vec{k}_9[\beta\theta_5] + \overleftarrow{k}_{-9}[\beta\theta_6] \quad [36]$$

$$\beta\left(\frac{\partial\theta_4}{\partial t}\right)_{ss} = 0 = \vec{k}_7[a_a][(1-\theta_T)] - \overleftarrow{k}_{-7}[\beta\theta_4] - \vec{k}_8[\beta\theta_4][\beta\theta_6] + \overleftarrow{k}_{-8}[\beta\theta_5][a_+] - \vec{k}_{10}[\beta\theta_4][\beta\theta_6] + \overleftarrow{k}_{-10}[\beta\theta_{Ia}] \quad [37]$$

Here, a_w, a_a are the activities of water and alcohol, respectively, in the mixed solvent and a_+ is the "absolute activity" of the proton (*vide* Eq. [12]). The k's are again the electrochemical rate constants referred to the extremely dilute aqueous solvent as the reference state. Equations [28]-[37] reduce to the steady-state solution

$$\frac{i_+}{\mathbf{F}} = \frac{i_w}{\mathbf{F}} + \frac{i_a}{\mathbf{F}} = \frac{k_5}{[a_+]}\left(\frac{k_4}{k_{-4}}\frac{k_3}{k_{-3}}\frac{k_2}{k_{-2}}(\theta_1)^2 \exp\frac{3\mathbf{F}E^s{}_{Fe}}{2RT}\right] + \frac{k_{11}}{[a_+]}\left[\frac{k_{10}}{k_{-10}}\frac{k_9}{k_{-9}}\frac{k_8}{k_{-8}}(\theta_4)^2\exp\frac{3\mathbf{F}E^s{}_{Fe}}{2RT}\right] \quad [38]$$

where $\theta_1 = \dfrac{1}{1+\dfrac{k_{-1}k_7a_a}{k_1k_{-7}a_w}}$ and $\theta_4 = \dfrac{1}{1+\dfrac{k_1k_{-7}a_w}{k_{-1}k_7a_a}}$.

Equation [38] assumes that the surface coverage is mostly adsorbed water and alcohol; $\theta_1 + \theta_4 \sim \theta_T$ and $\theta_T \sim 1$. In the detailed derivation of Eq. [38], $(\theta_1 + \theta_4) \sim 1$ implies $k_{-1}\,k_{-7} << k_{-1}\,k_7\,a_a + k_1\,k_7\,a_w$, and $k_{-1}\,k_{-7} \sim 0$. It is now further assumed that over the range of solvent composition studied $i_w >> i_a$, leading to Eq. [39]

$$i_+ = \frac{k}{[a_+]}\left[\frac{1}{1+\lambda'\dfrac{a_a}{a_w}}\right]^2 \exp\frac{3\mathbf{F}E^s{}_{Fe}}{2RT} \quad [39]$$

where $k = \mathbf{F}\left(k_5\dfrac{k_4}{k_{-4}}\dfrac{k_3}{k_{-3}}\dfrac{k_2}{k_{-2}}\right)$ and $\lambda' = \dfrac{k_{-1}k_7}{k_1k_{-7}}$.

It is assumed that the activity ratio $a_a/a_w = N_a/N_w$ where N_a and N_w are the mole fractions of alcohol and water, respectively. Further, it can be shown that $N_a/N_w = 18/46$ [weight per cent (EtOH)/ weight per cent (HOH)] which leads to Eq. [40]

$$i_+{}^s = \frac{k}{[a_+]} \left[\frac{1}{1 + \lambda \dfrac{\text{w/o(EtOH)}}{\text{w/o(HOH)}}} \right]^2 \exp \frac{3FE^s{}_{Fe}}{2RT} \quad [40]$$

The value for k in Eq. [40] was obtained from the results in pure water where $\dfrac{\text{w/o EtOH}}{\text{w/o HOH}} = 0$, and knowing k, the value for λ was a grand average value calculated from all data for solvent compositions ranging from *ca.* 10-50 w/o (HOH). In logarithmic form Eq. [40] becomes

$$\log(i_+{}^s) = 3.1833 - E^s{}_{Pt}/0.06 + E^s{}_{Fe}/0.04 + 2\log\left[\frac{1}{1 + 1.4R}\right] \quad [41]$$

where R = w/o (EtOH)/w/o (HOH), $-\log(a_+) = -E^s{}_{Pt}/0.06$, $\log k = 3.1833$ and $\lambda = 1.4$. It should be recalled that the "absolute" acidity, $pA = -\log(a_+) = -E^s{}_{Pt}/0.06$. A plot of the experimental anodic current densities, $(i_+{}^s)$, at constant potential $E^s{}_{Fe} = -0.222\bar{v}$ *vs.* (SHE)^w, as a function of solvent composition, for the results reported in Fig. 3, is presented in Fig. 4. The calculated values in Fig. 4 were obtained from Eq. [41]. Also included in Fig. 4 are the results from another iron electrode of larger surface area. A better fit of the data would be obtained if λ was recalculated for each electrode. The value for λ is not expected to be the same for different electrodes since it is a ratio of rate constants. The experimental current densities reported in Fig. 4 were obtained analytically as follows. In pure water at $E^s{}_{Fe} = -0.222\bar{v}$, the current density is 10^{-2} A/cm^2, for which $\log(i_+{}^s) = -2.0$. Therefore, it follows from Fig. 3 that

$$\log(i_+{}^s)_{E^s{}_{Fe}} = -2.0 \frac{(E^s{}_{Fe})_{i_+} - (-0.222)}{0.040} \quad [42]$$

where $(i_+{}^s)_{E^s{}_{Fe}}$ is the anodic current density at solvent composition S and constant potential $E^s{}_{Fe} = -0.222\bar{v}$ *vs.* (SHE)^w, $(E^s{}_{Fe})_{i_+}$ is the potential of the iron electrode *vs.* (SHE)^w at $(i_+{}^s) = 10^{-2}$ A/cm^2 and solvent composition S, and 0.040 is the anodic Tafel slope, $\partial(E^s{}_{Fe})/\partial(\log i_+)_{s,a_+}$, at constant solvent composition S and proton activity, a_+.

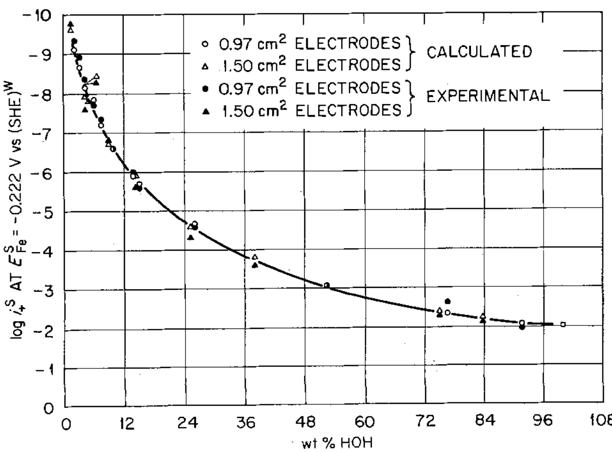

Fig. 4. Anodic current density for iron in H_2-saturated 0.50M H_2SO_4-EtOH-HOH as a function of weight per cent (HOH) at fixed potential, $E^s{}_{Fe} = -0.222\bar{v}$ *vs.* (SHE)^w at 30°C.

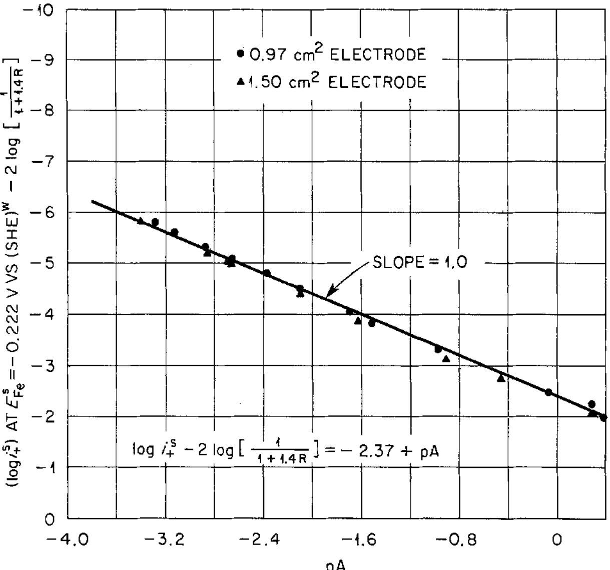

Fig. 5. The anodic current density for iron in H_2-saturated 0.50M H_2SO_4-EtOH-HOH as a function of pA at fixed potential, $E^s{}_{Fe} = -0.222\bar{v}$ *vs.* (SHE)^w at 30°C.

The calculated values for the anodic current density at constant $E^s{}_{Fe} = -0.222v$ are again presented in Fig. 5. The results are corrected for the solvent dependence, $2\log\left(\dfrac{1}{1 + \lambda R}\right)$, and plotted as a function of $pA = -E^s{}_{Pt}/0.06$. According to Eq. [41]

$$\left(\partial\left[\log(i_+{}^s)_{E_{Fe}} - 2\log\left(\frac{1}{1 + \lambda R}\right)\right] \Big/ \partial pA\right) = 1$$

if the reaction is first order in the reciprocal of the proton activity. The theoretical solid line drawn with unit slope provides an excellent fit to the data. Similarly, according to Eq. [41], after accounting for the coverage factor, and at constant anodic current density, the electrode potential should be a linear function of pA. The proportionality constant should be equal to -0.040 V/pA if the dissolution reaction is first order in the reciprocal of the proton activity. The electrode potential at constant anodic current density of 10^{-2} A/cm^2 is plotted as a function of pA in Fig. 6. The straight line drawn with a slope of -0.042 V/pA fits the data, further confirming the first order dependence and the coverage factor term.

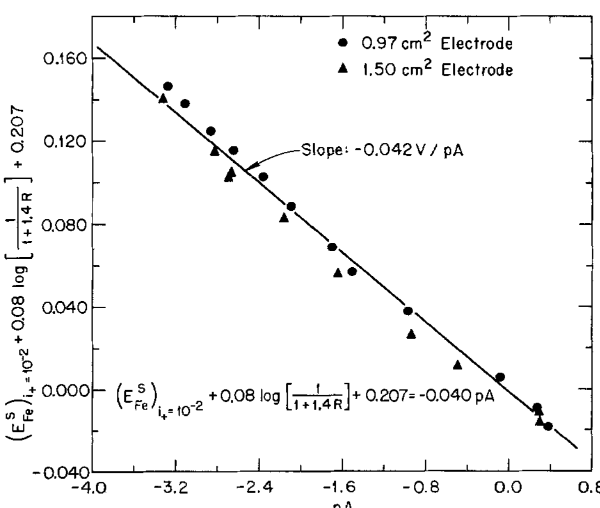

Fig. 6. The variation of the iron electrode potential in H_2-saturated 0.50M H_2SO_4-EtOH-HOH as a function of pA, at a constant anodic current density of 1 × 10^{-2} A/cm^2, at 30°C.

The cathodic evolution of H_2 as a function of solvent has been investigated here to only a limited extent. The polarizations which have been made covered the range of solvent composition from pure water to about 98 w/o (EtOH), and have shown Tafel slopes, $(\partial E^s_{Fe}/\partial \log i_-)_{s,a+}$, of 109-119 mV [approximately 2.3 (2 $RT/\mathbf{F}$)]. Since the results containing EtOH are similar to that which is observed in pure water solvent, it was postulated that the cathodic current was first order with respect to protons and that discharge occurred at both the adsorbed water sites, $Fe(H_2O)_{ads} \equiv \theta_1$, and at the adsorbed alcohol sites, $Fe(EtOH)_{ads} \equiv \theta_4$. A kinetic description of this mechanism is given by Eq. [43]

$$-\frac{(i_-{}^s)}{\mathbf{F}} = k_w a_+ \theta_1 \exp\frac{-\mathbf{F}E^s{}_{Fe}}{2RT} + k_a a_+ \theta_4 \exp\frac{-\mathbf{F}E^s{}_{Fe}}{2RT} \quad [43]$$

where recalling the anodic dissolution mechanism

$$\theta_1 = \frac{1}{1+\lambda R} \text{ and } \theta_4 = \frac{\lambda R}{1+\lambda R}$$

in the steady state. Again it is assumed that the rate via the aqueous mechanism is much greater than via the alcohol mechanism, and

$$-i_-{}^s = k_w a_+ \left(\frac{1}{1+\lambda R}\right) \exp\frac{-\mathbf{F}E^s{}_{Fe}}{2RT} \quad [44]$$

From Eq. [39] and [44] the corrosion potential and corrosion current as a function of pA and θ_1 may be obtained. It is recalled that at the corrosion potential, $E^s{}_{Fe(corr)}$, $i_-{}^s = i_+{}^s = i^s{}_{(corr)}$, and therefore

$$\log i^s{}_{(corr)} - 5/4 \log\left(\frac{1}{1+1.4R}\right) + 3.562 = -1/2\, pA \quad [45]$$

$$E^s{}_{Fe(corr)} + 0.03 \log\left(\frac{1}{1+1.4R}\right) + 0.270 = -0.06\, pA \quad [46]$$

The constants in Eq. [45] and [46] were obtained from the results in pure water where $R = 0$, $E^s{}_{Fe(corr)} = -0.292\bar{v}$ *vs.* (SHE)^w, $i^s{}_{(corr)} = 1.8 \times 10^{-4}$ A/cm^2, and $E_s{}^{Pt} = -0.022\bar{v}$ *vs.* (SHE)^w. Figure 7 shows the corrosion current, $\log i^s{}_{(corr)}$, (corrected for coverage), as a function of pA, and the theoretical line with slope $-1/2$ provides a satisfactory fit to the data. Similarly, the corrosion potential, $E^s{}_{Fe(corr)}$, (corrected for coverage) as a function of pA is shown in Fig. 8 and again the theoretical line with slope -0.060 provides an excellent fit to the data, *i.e.*, $\partial(E^s{}_{Fe(corr)} + 0.03 \log \theta_1)/\partial pA = -2.303\, RT/\mathbf{F}$.

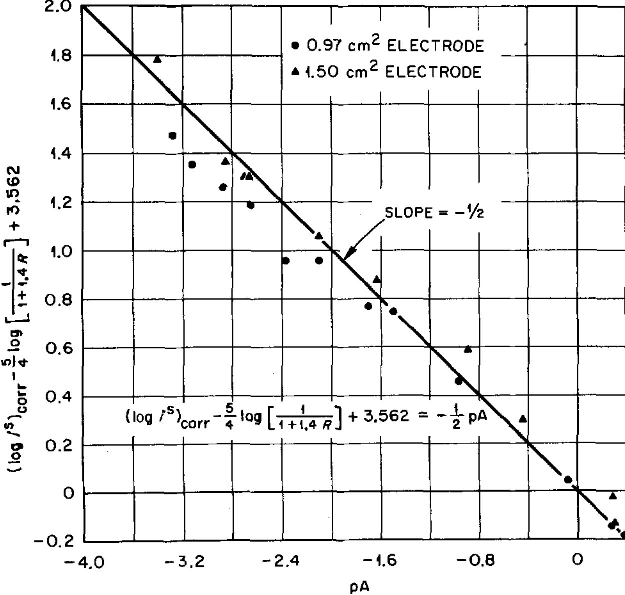

Fig. 7. The corrosion current for iron in H_2-saturated 0.50M H_2SO_4 EtOH-HOH as a function of pA at 30°C.

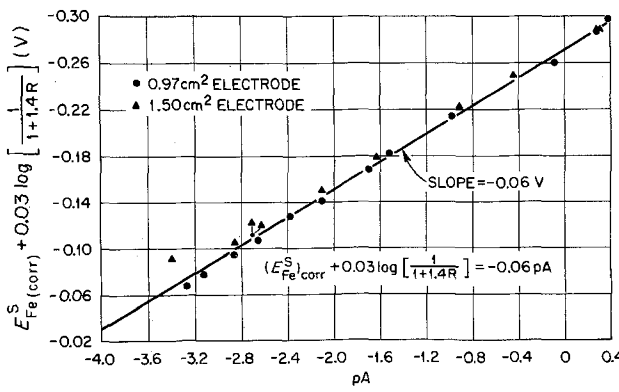

Fig. 8. The corrosion potential for iron in H_2-saturated 0.50M H_2SO_4-EtOH-HOH as a function of pA at 30°C.

Equation [46] can be written in terms of the experimentally measured cell potentials for Fe and Pt. In this form it is seen that the corrosion potential is independent of the liquid junction potential $E^s{}_L$

$$E^s{}_{(cell\ Fe)corr} = -0.270 + E^s{}_{(cell)Pt} - 0.03 \log\left[\frac{1}{1+\lambda R}\right] \quad [47]$$

The value $\lambda = 1.4$ (obtained from Eq. [40]) does indeed give good agreement between the calculated and the observed corrosion potentials. Using Eq. [47] a better value would be $\lambda = 1.8$. Alternatively, with this value of λ (say, gotten now from Eq. [47], Eq. [41] and [45] are better satisfied using Grunwald's (1) or Aleksandrov's and Izmailov's (10, 11) set of junction potentials rather than Popovych's (12, 13).

Accepting this value for λ from Eq. [47], a set of liquid junction potentials can be generated from Eq. [41]. Proton activities calculated using these experimentally determined junction potentials are compared with those estimated using the junction potentials of Grunwald and Gutbezahl (1), Aleksandrov and Izmailov (10, 11), and Popovych and Dill (13). A plot of these proton activities as a function of R is shown in Fig. 9. In this form, it is seen that the proton activities of Popovych and Dill are unacceptable.

Summary

Values for the junction potentials (1) between acidic EtOH-HOH solutions and saturated aqueous KCl were used to interpret the electrochemical polarization behavior of the active iron electrode in acidic EtOH-HOH solutions. The junction potentials were obtained from a correlation of the pK^s of organic acids in EtOH-HOH solvents. The correlation was based on the validity of the "activity postulate" of Grunwald and co-workers (1, 8).

The mechanism suggested by Kelly (4) for iron dissolution in hydrogen saturated sodium benzoate solutions (referred to as the inhibited system) was accepted with a few additional assumptions: the surface coverage was mostly adsorbed water (Fe · $(H_2O)_{ad}$) and alcohol (Fe · $(EtOH)_{ad}$), *i.e.*. $\theta_1 + \theta_4 \sim 1$; there was a simultaneous dissolution by EtOH and HOH, with the dissolution rate by water much greater than by alcohol; and finally it was assumed that the ratio of the activity of alcohol to water was proportional to the weight per cent ratio. Thus, in a competition for active sites on the electrode surface, alcohol acts as a "relative" inhibitor. The decision to test this mechanism to the corrosion data was based primarily on the observation that the anodic Tafel slope, $(\partial E/\partial \log i_+)_{s,a+} = 2/3$ (2.303 $RT/\mathbf{F}$), and was unchanged for all solvent compositions. Thus a mechanism (2, 3)

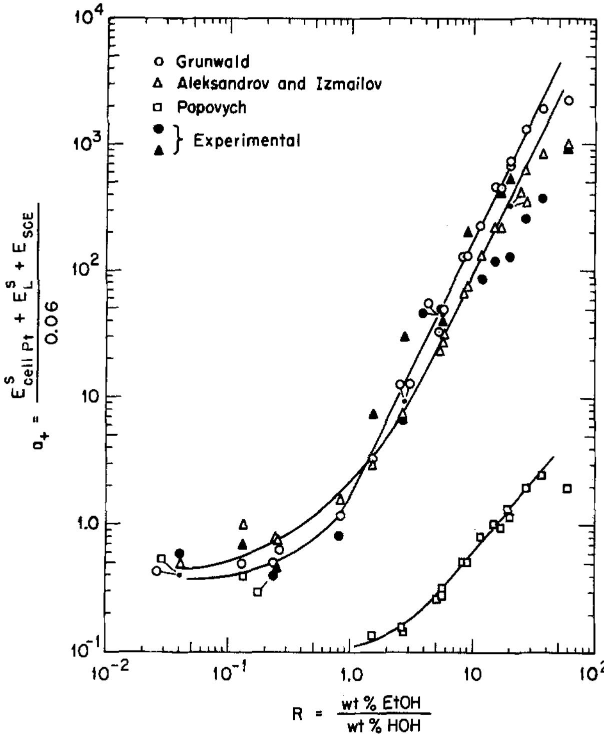

Fig. 9. The variation of proton activities, a_+, as a function of R = w/o EtOH/w/o HOH; proton activities calculated using several sets of liquid junction potentials, $E^s{}_L$.

similar to that accepted for dissolution in water solvent was suggested. The further choice of the mechanism suggested by Kelly (4) for the inhibited system was based primarily on the better fit to the results for the anodic polarization with a second order dependency on coverage.

The cathodic polarizations gave a Tafel slope $(\partial E/\partial \log i_-)_{s,a+} \sim 2\ (2.303\ RT/\mathbf{F})$, and was unchanged for all solvent compositions. On the basis of this observation, and to explain the observed variation of corrosion potential and corrosion current with solvent, it was postulated that the cathodic partial current was first order in both coverage, θ_1, and the activity of the protons, a_+.

Alternatively, accepting the corrosion mechanism, an "experimental" set of liquid junction potentials was generated. The proton activities, (a_+), calculated using these junction potentials were in much better agreement with those estimated using the values of $E^s{}_L$ from Grunwald and Gutbezahl (1) or Aleksandrov and Izmailov (10, 11) than with the proton activities calculated using the junction potentials proposed by Popovych (12) and Popovych and Dill (13).

Accelerated Life Testing of Lead-Acid Industrial Motive Power Cells

N. J. Maskalick*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Depth of positive grid corrosion is a regular and precise indicator of cell degradation during life testing of the subject lead-acid cells. Average corrosion depth at constant temperature is directly proportional to (time on cycle test)$^{0.67}$ for Pb-5% Sb positive grids. The temperature dependence of the logarithm of the corrosion rate constant is employed to predict a room-temperature corrosion function. Lifetime at room temperature is then estimated to a predefined average depth of corrosion corresponding to actual failure in normal service. This test is capable of high precision predictions of cell lifetime in a period of 4-6 months, compared to 3-4 years in conventional testing.

The time required to test lead-acid cells is greatly shortened at high temperatures as was demonstrated by Willihnganz (1) in his work with cells on float service. He observed that the logarithm of the constant potential lifetime of lead-acid cells with lead-calcium positive grids increases linearly with the reciprocal absolute temperature, and that over-all positive plate growth can be plotted as a regular function of time on test. Cannone *et al.* (2) identified this functional dependence as parabolic for cells with pure lead, or lead-calcium positive grids, and as linear, for cells with lead-antimony positive grids. They extended and corroborated Willihnganz' work by demonstrating that the logarithm of the constant term in their derived positive plate growth functions is a linear function of the reciprocal absolute test temperature. They consequently specified a value of this constant for room temperature float service by log-linear extrapolation of high temperature results.

Cell life, and positive plate growth, in all of these prior experiments, must be considered to be directly related to over-all positive plate corrosion current and time. In the case of a constant voltage test, which was chosen to relate to the usage mode of cells in float service, over-all corrosion current does not remain constant but increases with surface roughness and decreases with the buildup of barrier (passivating) layers. This progress of corrosion with time (or the positive plate growth *vs.* time) is described by experimentally determined degradation functions employing a single temperature-dependent constant.

A test relating to the positive corrosion and lifetime expectancy of cells in cyclic charge-discharge service must differ from constant voltage operation as a matter of definition. The over-all positive grid corrosion in such cells varies with time in an even more complex manner.

This present work is a study of the temperature dependence of corrosion of lead-antimony alloy positive grids in cells in deep cycle service. As an investigation involved with direct and indirect measurements of corrosion depth as a function of time and temperature, it is designed to employ a testing cycle consisting of a constant-current, constant ampere-hour discharge, and a tapered-current, constant ampere-hour charge. This test routine, essentially a constant-coulombs per cycle (coulostatic) test, was chosen instead of a constant voltage schedule to reflect more faithfully the usage pattern of motive power cells.

The purpose of this paper is to describe experiments monitoring, directly and indirectly, the time and temperature dependence of the corrosion of lead-5% antimony positive grids in specific industrial motive power cells on this fixed charge-discharge cycle routine. The test specifications employed (maximum temperature, depth of discharge, extent of overcharge) are selected from a prior unpublished study of stress parameter combinations by the author. These parameter levels are one of many possible compatible sets reflecting different types of service. One objective of the subject experiments was to produce a near maximum in cell degradation rate leading to failure comparable to field service and room-temperature bench testing. These accelerated test results are further applied to predict charge-discharge cycle lifetime for cells operating at room temperature.

Experimental

Charge-discharge cycling was conducted on a uniform group of 48 series-connected 5-plate industrial motive power cells equally divided among constant-temperature baths held at 60.0°, 70.2°, and 82.2°C. A 4 hr constant current discharge was set at 72 A-hr (90% of nominal capacity at the 6 hr rate). A 4 hr taper charge for all cells at 101 A-hr (140% of amount withdrawn) completed the cycle. The initial charging current was 101A, tapering logarithmically to 1A at 4 hr. Continuous cycling was carried out 5 days per week. All cells were given an equalizing charge of 2.0A throughout each weekend.

The test cells employed 1.280 sp gr H_2SO_4. Positive grids consisted of an alloy containing 4.83% Sb, 0.40% Sn, 0.075% As, and 0.055% Cu. These grids were approximately 14.8 cm wide, 25.2 cm high, and 0.62 cm thick at the outside frame as cast. Cured positive paste content of these grids was maintained at 1.41 $\pm$ 0.01 lb average deviation by avoiding both overpasting and underpasting. All positive plates were wrapped horizontally with Fiberglas yarn followed by Fiberglas mat; finally with a perforated PVC outer envelope. Such plates normally fail due to grid corrosion and disintegration rather than via active material loss or degradation. Cell capacities at room temperature (6 hr rate = 13.3A) were determined at 50-100 cycle intervals. Three cells were removed from each constant temperature bath at 50-100 cycle intervals for measurement of antimony content in the active material, over-all grid growth, and grid corrosion depth. Antimony content of both the positive and negative active material was determined by atomic absorption spectrophotometry. Samples for these analyses were obtained by removing active material from the entire plate, blending with a mortar and pestle, washing with water, then oven-drying to constant weight.

The dimension chosen to describe grid growth was the change in width of the positive grid at one-half of

* Electrochemical Society Active Member.

Key words: anodic, statistics, batteries, corrosion, oxidation.

plate height. Mean depth of corrosion of the positive grid was estimated from direct micrometer measurements of residual grid thickness along the outside frame of the chemically cleaned grid. Oxide film removal was accomplished with an aqueous stripping solution of 12% KOH containing 10g hydrazine sulfate per liter.

The estimated mean value of residual grid thickness was subtracted from the estimated mean thickness value (0.614 cm) of formed grids from cells in the same production run, but with no accelerated life test charge-discharge cycles. The precision of the resulting estimated mean depth of corrosion for the test grids was specified by employing tabulated values of the t statistic (3)

$$\text{precision} = \pm\, t_{\nu,0.025} \sqrt{\frac{s^2}{n}}$$

where ν = degrees of freedom ($n - 1$), $t_{\nu,0.025}$ = tabulated values for 95% confidence limits, s^2 = estimate of the variance of the data

$$\sum_n (y_i - \bar{y})^2/(n-1),$$

n = total number of observations in a sample, and y = observed values for corrosion depth.

The t statistic was similarly employed to determine precision of the curve describing the slope (E/R) of the plot of ln k *vs.* 1/°K, where R is the gas constant, and E is expressed as an activation energy. Over-all precision for the prediction of room temperature lifetime was related to the precision with which E could be specified. Details of the calculations are given in the Appendix.

Results

Periodic capacity data.—Cell capacities at room temperature (6 hr rate = 13.3A), taken at intervals during cycle life, were distributed over a range which revealed only a general trend toward capacity decay (Fig. 1a). Both positive and negative limitations were observed, as determined by individual electrode measurements *vs.* a Hg/Hg_2SO_4 standard electrode. Treatment of the data to obtain 95% confidence level estimates of the mean cell capacity resulted in improvement in precision of the capacity decay curve. but not enough to allow characterization leading to a lifetime prediction (Fig. 1b). These data did show, however, a general trend toward more rapid capacity decay with increasing test temperature. End-of-life capacity limitation was due to disintegration of the positive plate grid, leading to abrupt failure. For the 60.0°C cells this occurred beyond 216 days on test; it was not included on the curves of Fig. 1 due to the much lower confidence levels with which mean capacity values could be estimated for cells near end of life.

Periodic plate expansion data.—The positive plate expansion displayed a similar trend, with most highly expanded plates found in the highest temperature test bath. However, the results (Fig. 2) were mixed, precluding interpretation to yield any lifetime prediction.

Antimony migration.—The corrosion of the lead-antimony positive grid, accompanied by subsequent migration of soluble antimony-containing species, can be accurately monitored by direct periodic analysis of antimony pickup in the active material under ideal circumstances. Figure 3 demonstrates that test conditions are less than ideal, however, yielding antimony pickup curves showing such irregularities as concentration crossovers between discrete test temperatures and concentration maxima at approximately half-cycle life. No quantitative interpretation of these data was possible in terms of the experimental goal: prediction of room temperature cycle life. Qualitative interpretation is included in the Discussion section.

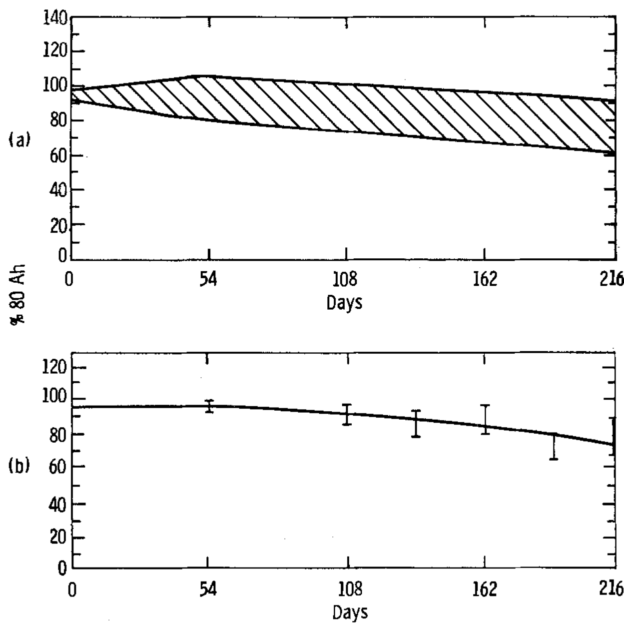

Fig. 1. Cell capacity *vs.* days on test at 60.0°C, room temperature capacity, 13.3A (nominal 6-hr rate).

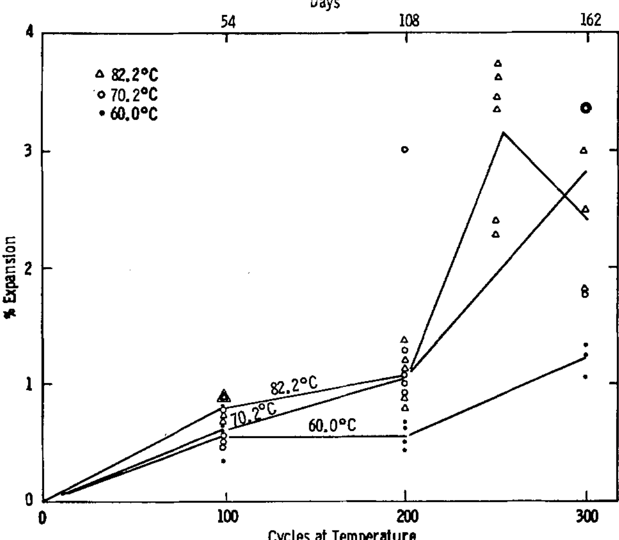

Fig. 2. Positive plate expansion during accelerated testing

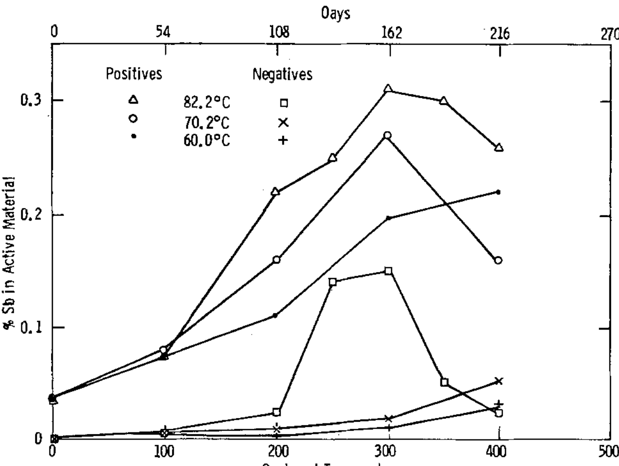

Fig. 3. Antimony absorption in PbO_2 (positive) and sponge Pb (negative).

Corrosion depth.—Residual grid thicknesses, after removal of corrosion layers, yielded estimates of mean corrosion depth. Initial measurements, involving a total of four measurements along the grid frame (Fig. 4), were insufficient to describe a precise corrosion depth *vs.* time curve. The average of 14 measurement points per grid improved precision of the estimated mean to ± 0.001 cm at a 95% confidence level. These estimates of the mean corrosion depth were plotted as points for purposes of curve fitting (Fig. 5).

The function corresponding to these curves was of the type

$$\text{Corrosion depth} = kt^x$$

where t = time on test (days) and, k = a temperature-dependent constant, with a sensitive response to temperature change such that log k is a linearly decreasing function of the reciprocal test temperature in degrees Kelvin. The best fitting value of the temperature-independent constant x, as determined by least squares approximation, is $x = 0.67$. Figure 6 illustrates this result and also specifies the k values corresponding to each test temperature, using $x = 0.67$.

The log-linear extrapolation of these k values (Fig. 7; Appendix D) leads to an estimate of 4.42×10^{-4} cm days$^{-0.67}$ for k at 25°C. The 95% confidence interval for this estimate would span from $k = 4.30 \times 10^{-4}$ to $k = 4.52 \times 10^{-4}$ cm days$^{-0.67}$.

A solution was obtained for estimated time at room temperature to corrode to a target depth of 0.035 cm for the charge-discharge cycle routine employed (Fig. 8; Appendix D). The target corrosion depth was estimated from corrosion measurements of similar plates bench-tested at room temperature according to interim federal specification W-B-00133B (GSA-FSS), performance test No. 2. In this test, and in field service, lifetime end-point is characterized by disintegration of the positive grid, the life-limiting component of the lead-acid cell on normal duty. In the accelerated test, the positive grid fails in the same manner. The extent of positive grid disintegration and the microscopic and crystallographic structure of the PbO_2 corrosion layers are equivalent to those which are found in cells cycled on long-term bench tests and cells in field service.

The assumption was made that casting quality for the room temperature, reference grids was substan-

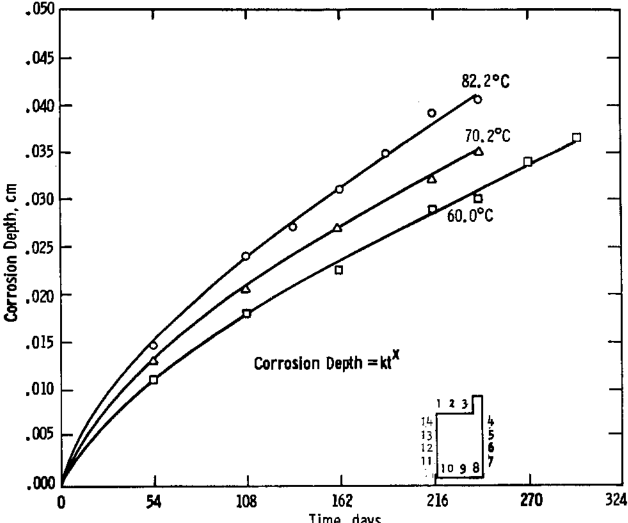

Fig. 5. Depth of grid corrosion vs. days on test. Minimum 14 points per grid.

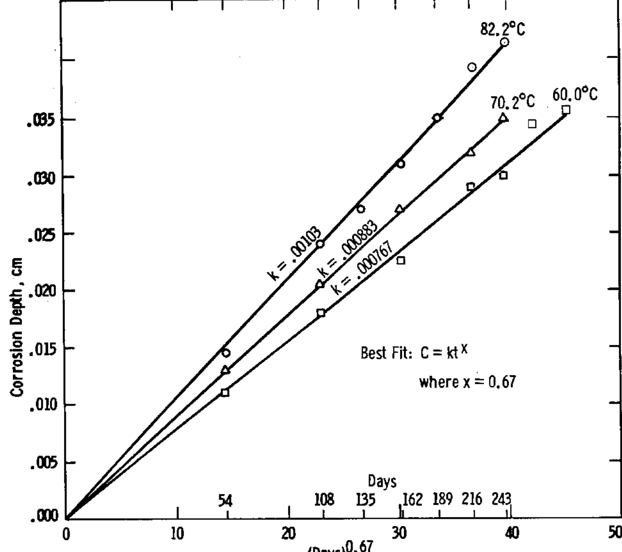

Fig. 6. Best fitting curve set at $C = kt^{0.67}$

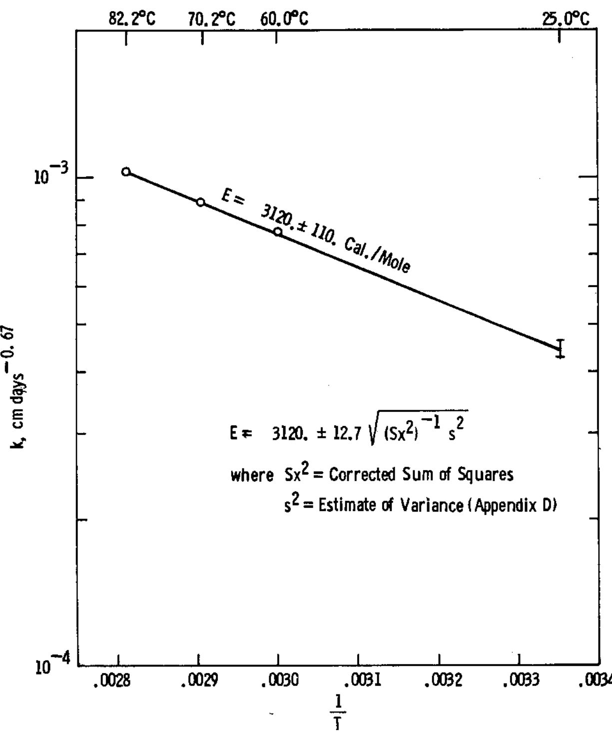

Fig. 7. Log-linear extrapolation of k

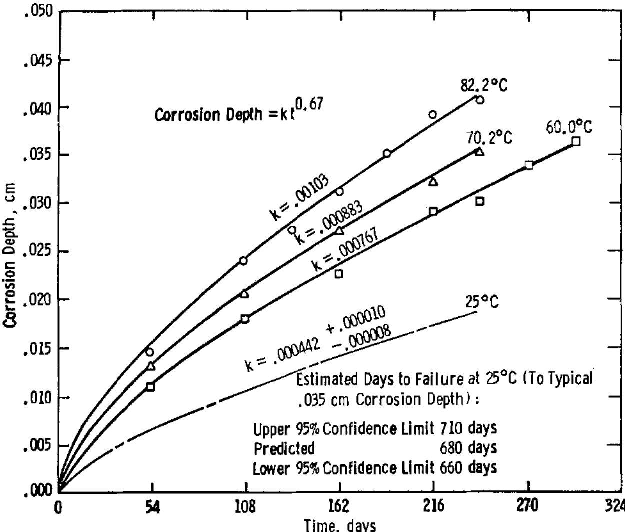

Fig. 8. Depth of corrosion vs. days on test

tially the same as for the group of positive castings employed in this accelerated test. This 0.035 cm depth of corrosion should, however, be viewed as a flexible target in a finalized life test, subject to changes reflecting casting quality, grid geometry, grid composition, etc. For this accelerated test, assuming practical equivalence with the reference grids, calculation yields a predicted lifetime of 680 days +4%, −3%. Converting to number of charge-discharge cycles, the corresponding 95% confidence statement is 1260 cycles +4%, −3%.

Discussion

Cell capacity vs. life.—During the test, some cells failed for reasons unrelated to the test objectives (shorts, loss of contact from lugs to posts, etc.). Also, progressive degradation evidence, specifically positive and negative plate voltages, did not consistently show that the positives were always failing preferentially. In cases of abrupt failure, such cells were removed, repaired, and returned to test if possible; if not, then removed permanently and disassembled to record temperature-dependent control parameter data (plate expansion, antimony migration, grid corrosion). In cases of gradual failure, lowest capacity cells were permanently removed and examined similarly at the programmed 50-100 cycle intervals. Although ultimate cell failure was due to sudden positive limitation, the capacity decline shown in Fig. 1 embodies substantial contributions from causes such as negative limitation, sediment and moss shorting, etc. Therefore, capacity curves, as taken on this test, are viewed as indicators of general cell performance, and not specific for the positive plate.

In all cases, however, the test was unaffected by these extraneous effects due to its inherent design, which called for exclusive monitoring of critical positive plate temperature-dependent control parameters. Thus, even if a cell had been abruptly removed for post failure, the critical data, *e.g.*, grid corrosion, could be taken and employed as valid for that particular point in cycle life. Therefore, the progress of, *e.g.*, grid corrosion during cycle life should be viewed as data collected on a partially selective, partially random basis.

Since the grids and plates were constructed as uniformly as possible, these data are considered to be representative of positive plate degradation for the entire group. Further, positive plate degradation is identified as the life-limiting mechanism in the lead-acid cell in deep discharge service. Consequently, the measured control parameters, particularly depth of corrosion, are viewed as related to critical normal service degradation, while cell capacity data is confused by extraneous and less significant failure modes. These extraneous modes, though extremely temperature sensitive in themselves, do not affect the temperature dependence of corrosion of the positive grid.

Plate expansion vs. life.—Prior work in the literature had indicated that simple plate growth could be correlated with plate lifetime. Lander (4) cycled strips of Pb-6% Sb and Pb-4.5% Sn about typical positive plate potentials twice a day in 30% H_2SO_4 at 49°C. He measured regular increases in strip length with testing time, reporting up to 3% elongation. Cannone *et al.* (2), working with cells for telephone service in an elevated temperature range of 60°-93°C, showed that pure lead grids on constant potential charge expanded regularly in width in a parabolic fashion and that lead-antimony grids expanded along a linear curve.

The behavior of our lead-antimony grids was analogous to these two prior studies. However, because of the tendency of our grids to corrode completely through along fault lines, then to spring open abruptly, no smooth growth curve could be measured. If grid castings showing more regular growth are tested, direct nondestructive growth measurements could provide a lifetime prediction test with a minimum of test samples. An analysis of precision would be required, however, to establish the merit of this approach relative to the depth of corrosion approach.

Antimony migration vs. life.—Corrosion of lead-antimony positive grids in the lead-acid storage cell produces either PbO_2 or $PbSO_4$, depending on state of charge. Both are essentially insoluble, and remain in place in the positive plate. The antimony component of the grid alloy is quite soluble in H_2SO_4, forming the anions $Sb(SO_4)_2^-$, $SbOSO_4^-$, and $Sb_3O_9^{3-}$, as proposed by Dawson *et al.* (5, 6). Adsorption of antimony on active material crystal surfaces is believed to occur, affecting crystalline growth habit on charge and discharge. Such adsorption is also viewed as the reason why antimony content of the positive active material increases so markedly with increased grid corrosion.

Anionic transfer to the sponge lead negative plate, and subsequent adsorption there leads to a lesser concentration buildup in the negative active material, compared with the positive, PbO_2 electrode. The well-known "poisoning" effect of Sb in the negative electrode is shown here to be associated with antimony accumulations well below antimony levels present in the positive plate. While positive plate voltages indicated that performance was virtually independent of antimony level, negatives showed decreasing voltages early in cycle life. Concentrations of antimony in the electrolyte itself are negligible, so that almost all antimony, though considered to be soluble, is associated with the solid phases of both electrodes.

If total antimony pickup in the active material can be determined, then, by direct analysis of the active material, a measure of grid corrosion would result. The irregularities found in the test are interpreted as being primarily due to inhomogeneous antimony levels in the cast grid alloy. Antimony-rich phases are known to be discrete entities in cast Pb-Sb alloys, existing in regions between the predominant, lower antimony grains. This work indicates, however, that a further change in composition occurs as corrosion strips away the outer surfaces of the cast grid, with significantly lower antimony concentrations found at levels approximately 0.025-0.030 cm below the surface. The peaks in the curves of antimony concentration *vs.* time on cycle life (Fig. 3) correspond to such a view.

In addition to these radial concentration gradients in the grid bar cross section and the concentration segregation inherent in the two-phase Pb-Sb alloy structure, a third effect is known to exist: the evolution of stibine gas, SbH_3, from the negative electrode while the cell is in the charge mode, could reduce the estimate of grid corrosion depending on the efficiency

of stibine synthesis. This effect, in combination with the radial concentration model, accounts for negative curve slopes beyond 300 cycles.

Corrosion depth vs. life.—Test precision.—As the data of Fig. 5-8 demonstrate, the precision of this accelerated life test is considerably better than typical precision in lifetime prediction currently achieved in standard, long-time industrial testing ($\sim \pm 20\%$ at 95% confidence level). It is possible to identify the factors chiefly affecting precision from the derived corrosion function

$$C = \text{mean depth of corrosion} = k_{25^\circ C} t^x$$

when C is a targeted value, and being defined, does not limit precision. X, once derived, is employed as a constant which does not affect precision, only accuracy. This simplifying assumption is justified in the same way as other work, *e.g.*, when ideally linear ($x = 1$) or ideally parabolic ($x = 2$) functions are assumed to describe phenomena. Therefore, only $k_{25^\circ C}$ has inherent limitations of precision when solving for t.

Examination of Eq. [A-9], Appendix D, shows that, if the temperatures are fixed, and precisely measured ($\pm$ 0.05°C) within the span of temperatures available in the test, then the estimate of the variance of the quantity $R \ln k$ (where $R = 1.9872$, the gas constant) and the degrees of freedom in the t statistic are the two factors influencing precision. In this three-temperature experiment (three degrees of freedom), two degrees of freedom are used up, due to the fact that, in solving for the least squares log-linear extrapolation of k, two unknowns, the slope E and the intercept $R \ln A$ are involved. Since this leaves only one degree of freedom to define the t statistic, the corresponding tabulated t statistic for 95% confidence limits is 12.7. Inspection of the t statistic tables shows that, for a four-temperature experiment, the term before the square root sign in the precision expression [A-9], is reduced to 4.3 since the t statistic can then be based on two degrees of freedom. For better precision, then, data should be grouped into four temperature groups. For industrial testing, which may involve only two temperatures, the cells should be grouped into equal samples of duplicate temperatures to yield at least four temperature groups, provided the variance of $R \ln k$ does not increase too rapidly.

The estimate of the variance of experimental values of $R \ln k$ with respect to the corresponding least squares values, $R \ln \hat{k}$

$$\frac{1}{n-2} \sum (R \ln k - R \ln \hat{k})^2$$

also decreases significantly as n, the total number of temperature groups, is increased from 3 to 4 or more. The difference term within the summation: (*i*) decreases with increasing accuracy in temperature measurement, (*ii*) decreases with increasing precision in temperature measurement, (*iii*) decreases with increasing uniformity of replication in the entire lot of positive plates employed in the test cell group, and (*iv*) decreases with increasing uniformity of replication of cell cycling parameters, *e.g.*, A-hr discharge, A-hr charge, shape of charge curve.

If means can be found to avoid rapid negative sulfation, and thereby extend the temperature range of this test, precision can be further improved.

The corrected sum of squares in Eq. [A-9]

$$\sum \left(\frac{1}{T}\right)^2 - \frac{1}{n}\left(\sum \frac{1}{T}\right)^2$$

increases with increasing temperature range. Since this term is a denominator, it therefore increases the precision as the range of temperature increases.

The question arises: Why not collect the experimental corrosion depth data at a single temperature, preferably at room temperature, and simply extrapolate the experimental room temperature curve to a targeted depth of corrosion? The answer is that this elevated temperature test magnifies the form of the corrosion function so that it can be identified and precisely specified at room temperature. Any room temperature experiment must be carried out nearly to end-of-life to achieve the same precision. Experience and analysis show that curves derived from direct room temperature measurements over the shorter period of time involved in this accelerated test lack the precision needed for satisfactory lifetime prediction. This is because, while the precision of the measurement data is constant, the actual values of corrosion depth decrease exponentially with decreasing absolute temperature.

Consequently, as an example, direct room temperature corrosion curves of differing grid alloys would be practically indistinguishable from each other; perhaps also even from a straight line over the first 200-300 charge-discharge cycles. Such room temperature curves are readily and precisely characterized with respect to k and x by extrapolation of high temperature experiments, thus revealing critical differences in calculated, room temperature, lifetime estimates.

It is appropriate to ask whether the predicted, room temperature, corrosion function has been experimentally demonstrated out to a point in cycle life where meaningful precision can be obtained. To make such a comparison it is assumed that the room temperature control cells will ultimately demonstrate the 0.035 cm mean depth of corrosion exhibited by the high temperature test groups and by prior bench testing of similar production cells. Three five-plate cells from the original test group, which were cycled at room temperature, obey the calculated corrosion function to within 0.001 cm at an estimated one-half cycle life to date, thus providing reasonable agreement of theory with experiment.

Testing time.—If subsequent test results on other types of cells and materials show that corrosion functions repeatedly turn out to be of the form

$$C = kt^x$$

then the taking of samples for corrosion depth measurements need not be conducted all along the curve, but merely at one point, sufficiently far along to permit acceptable precision in lifetime prediction. Given a test closely controlled as outlined above, with a group of cells all constituting faithful replicas of each other, excellent precision should be obtainable in 4-6 months testing time. However, any experiment with a different form of corrosion function would necessarily involve a full complement of cells being periodically extracted from test and measured to describe the exact form of the corrosion function until such time as actual failure occurs.

Number of specimens.—Five-plate cell variability is significant enough to require four or five such cells in each of four temperature groups for tests involving extraction from test and measurement at a single point in life ($c = kt^x$ assumed). As an alternative, the equivalent number of positive plates in fewer cells with more plates would serve the same purpose.

Asymmetrical upper and lower bounds in predicted life.—Adapting Eq. [A-8], Appendix D, to solve for k

$$\ln k = \frac{E\left(\frac{1}{T}\right) + R \ln A}{R}$$

it is evident that the upper and lower bounds obtained in the least squares estimate of E, at 95% confidence limits, yield a corresponding upper and lower bound expressed in $\ln k$; not k itself. As a consequence, translation of these derived limits, which are symmetrical

about ln k, results in asymmetrical limits about k itself.

The significance of this lies simply in the Arrhenius model which was originally assumed (Eq. [A-5], Appendix D)

$$k = A \exp\left(\frac{b}{T}\right)$$

where it can be seen that any symmetrical uncertainties in either temperature or Rb ("activation energy") result in logarithmically related uncertainties in k.

As a practical application of this, it can be pointed out, for example, that temperature overestimation is more damaging to accuracy than temperature underestimation. Conceptually, the range of values of predicted life may be visualized as a probability distribution skewed to the right with the mode located to the left of the predicted value of lifetime.

"Activation energy," E.—The slope in Fig. 7 is characterized as an activation energy to conform to established practice and to provide a preliminary criterion for the identification of the type of rate control which prevails. It should be noted that true charge transfer activation energies generally lie in a range above 5000 cal/mole. At 3120 cal/mole, it is difficult to distinguish from the case of diffusion limitation. However, it is evident that the over-all effect of cyclic operation of the positive plate of these lead-acid storage cells is to bring about progressive anodization of the lead alloy current collector with the corrosion depth curve tending toward a diffusion-limited value (Fig. 8). E, then, may alternatively be viewed as related to a characteristic concentration overpotential.

Conclusions

High temperature charge-discharge cycle testing of lead-acid cells can yield a prediction of room temperature cycle life in as quickly as 4 months. The logarithm of cell lifetime decreases linearly with the absolute temperature.

Measurement of positive grid corrosion depth as a function of temperature yields a corrosion function characterized by one temperature-dependent constant. The value of this constant at room temperature is specified by a log-linear extrapolation. An experimental design employing 16 five-plate 80 A-hr cells at each of three different temperatures permits a +4%, −3% precision in lifetime prediction at a 95% confidence level.

This technique of elevated-temperature corrosion function analysis permits charge-discharge cycle life prediction capability of unprecedented precision and speed.

APPENDIX

A. Estimation of Mean Depth of Corrosion

Grid corrosion depth during cycle life was estimated by subtracting the average residual grid thickness

$$\bar{y} = \frac{1}{n}\sum_{i}^{n} y_i \quad \text{[A-1]}$$

from the average initial grid thickness ($\bar{y}_o$) after formation and initial capacity determination, then dividing by two. The mean value estimate of corrosion depth obtained in this way was characterized with respect to precision at a 95% confidence level by employing tabulated values of the t statistic (3) in the following expression

$$\frac{\bar{y}_o - \bar{y}}{2} \text{ estimates } \eta = \text{mean value} \pm t_{\nu,0.025}\sqrt{\frac{s^2}{n}}$$

where $t_{\nu,0.025}$ = tabulated values for 95% confidence limits, ν = degrees of freedom $(n - 1)$, n = total number of observations in a sample of grids, s^2 = estimate of the variance of the data

$$\frac{1}{n-1}\sum_{i}^{n}(y_i - \bar{y})^2,$$

and y = observed values for corrosion depth.

The number of observations, n, was increased until the 95% confidence level precision of the estimate of the mean value of corrosion depth approached 0.001 cm, comparing with the precision of the micrometer (0.0005 cm). To do this, up to 30 individual residual thickness measurements were made per grid.

B. Estimation of Power of t in Corrosion Depth Function

It was observed that the estimated mean grid corrosion depth obeyed a time and temperature-dependent function of the form

$$C = \text{corrosion depth (cm)} = kt^x \quad \text{[A-2]}$$

where k = a temperature-dependent constant, t = time (days), and x = a constant, with no apparent temperature dependence.

Taking logarithms

$$\log C = \log k + x \log t$$

In a least squares analysis of the data (7), x is given by

$$x = \frac{\Sigma \log t \log C - \frac{1}{n}(\Sigma \log t)(\Sigma \log C)}{\Sigma(\log t)^2 - \frac{1}{n}(\Sigma \log t)^2} \quad \text{[A-3]}$$

where n = the number of t data points.

The best fitting value of x was taken as the average x over all three temperatures employed in the test

$$X_{82.2°C} = 0.694$$
$$X_{70.2°C} = 0.635$$
$$X_{60.0°C} = 0.693$$
$$\bar{X} = 0.67$$

For purposes of precision analysis, this value, approximately 2/3, was considered to be a temperature-independent, constant exponent not affecting precision. A similar assumption is commonly employed in many curves which are arbitrarily fitted to strictly linear or quadratic models.

C. Estimation of "k" in Corrosion Depth Function

The constant k was then specified for each temperature by solving

$$\log k = \overline{\log C} - 0.67\,\overline{\log t} \quad \text{[A-4]}$$

The results yielded three corrosion functions

82.2°C: C = corrosion depth (cm) = $0.00103\ t^{0.67}$
70.2°C: C = corrosion depth (cm) = $0.000883\ t^{0.67}$
60.0°C: C = corrosion depth (cm) = $0.000767\ t^{0.67}$

The adequacy of the model to represent the data is demonstrated by Fig. 6.

D. Determination of Precision of the Log-Linear Extrapolation of "k"

The decrease of k with respect to temperature conformed to an expression of the type

$$k = A \exp\left(\frac{b}{T}\right) \quad \text{[A-5]}$$

where T = absolute temperature (°K) and A, b = constants.

The best fitting value of b was expressed as an activation energy, E cal/mol, by multiplying by the gas constant, R = 1.9872 cal °K^{-1} mole^{-1}.

Taking logarithms

$$R \ln k = R \ln A + E\left(\frac{1}{T}\right) \quad \text{[A-6]}$$

Least squares analysis leads to the following expression

$$E = \frac{\left(\sum \frac{R \ln k}{T}\right) - \frac{1}{n}\left(\sum \frac{1}{T}\right)\left(\sum R \ln k\right)}{\sum \left(\frac{1}{T}\right)^2 - \frac{1}{n}\left(\sum \frac{1}{T}\right)^2} \quad \text{[A-7]}$$

where n = 3 for this case involving three temperatures. ln A is obtained by straightforward substitution of average experimental data points, ($\overline{\ }$), in [A-6]

$$\ln A = \frac{R \overline{\ln k} - E \overline{\left(\frac{1}{T}\right)}}{R} \quad \text{[A-8]}$$

permitting subsequent estimation of k at room temperature from [A-5].

The precision of the derived value of E is: 95% confidence level precision =

$$\pm t_{\nu,0.025} \sqrt{\frac{\Sigma (y - \hat{y})^2}{\left[\sum \left(\frac{1}{T}\right)^2 - \frac{1}{n}\left(\sum \frac{1}{T}\right)^2\right]} \frac{1}{n-2}} \quad \text{[A-9]}$$

where y = experimental value of R ln k, y' = least squares predicted value of R ln k, $\Sigma (y - \hat{y})^2$ = estimate of variance, and

$$\sum \left(\frac{1}{T}\right)^2 - \frac{1}{n}\left(\sum \frac{1}{T}\right)^2 = \text{corrected sum of squares.}$$

The maximum and minimum E values yield corresponding maximum and minimum predicted room temperature k values, from [A-5] and [A-8], in this case at a 95% confidence level.

E. Determination of the Precision of Room Temperature Lifetime Prediction

Maximum and minimum k values at room temperature are employed in [A-2], assuming 0.035 cm depth of corrosion, corresponding to field service and bench failure; solving for t. These room temperature, cycle lifetimes, therefore, represent the span of predicted values generated by 95% confidence level data.

The Existence of Multiple Steady States during Differential Aeration Corrosion

Richard Alkire* and George Nicolaides**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A method of calculation has been developed for predicting the multiple steady-state current distributions which may exist along a metal surface undergoing localized attack by differential aeration corrosion. The calculational method is capable of finding all such multiple steady-state solutions. A compilation of those regions of parameter space within which highly localized attack is likely has been carried out for the model system.

Owing to differential aeration the local rate of corrosion along a metal surface may be highly nonuniform, especially if the metal exhibits passivity. The problem of determining the location and the local rate of corrosion attack corresponds to elucidating the details of the current flow between the anodic and cathodic regions which occur simultaneously on the metal surface. That is, one needs to know the current distribution. Whereas electrochemical current distribution problems originated in attempts to predict the over-all current-voltage behavior of electrolysis cells, such studies have also been conducted on corrosion-like configurations of fixed anode/cathode geometry as briefly reviewed in Ref. (1). More recently, current distribution calculations have been conducted on corroding systems wherein multiple electrochemical reactions occur on localized net anodic and cathodic areas, which coexist on adjacent regions of a single conductive surface. For simple configurations, such "bipolar" current density distributions may be computed once the system parameters have been specified (*i.e.*, properties such as electrolyte conductivity, oxygen availability, electrode reaction kinetics, system geometry, etc.). Corrosion of rotating disks (2, 3) has been shown to occur with nonuniform rates wherein one portion of the disk is passive while another portion corrodes actively. The study of aeration corrosion under barrier films of variable thickness (1, 4, 5) has shown that more than one steady-state

* Electrochemical Society Active Member.
** Electrochemical Society Student Member.
Key words: corrosion, differential aeration, current distribution, mathematical model, bipolar electrode.

current distribution may be expected to exist for a single set of system parameters; some of these multiple steady-state corrosion distributions suggest the possibility of highly localized corrosion. However, the numerical methods employed in the foregoing studies were not well suited for determining how many such multiple solutions exist. Therefore the following investigation has been conducted with two goals in mind. First, a different computation method has been employed which is capable, for a given set of system parameters, of finding all possible steady-state current distributions. Second, a compilation has been carried out of all regions of parameter space within which highly localized corrosion may be anticipated for the model system under study. The results therefore contribute toward design of corrosion systems so as to avoid altogether those potentially hazardous situations where localized attack is likely.

Derivation of Model

The corrosion system to be investigated, shown in Fig. 1, is identical to that studied by other methods in Ref. (1). Readers may examine that reference for more extensive introductory remarks than are provided here. The metal is covered by an electrolyte-moistened barrier of locally variable thickness. Oxygen diffuses through the barrier layer to the metal surface, which corrodes. Both oxidation and reduction reactions occur everywhere along the corroding surface. In many cases, however, the local oxidation rate may exceed the local reduction rate, thus creating a local net anodic region. Similarly, local net cathodic regions may also arise. Electrical current flows in the barrier layer between the net anodic and the net cathodic regions which coexist along the metal surface. The buildup of corrosion products has not yet occurred to an appreciable extent. The simple situation shown in Fig. 1 has been modeled by a differential equation (1) subject to the following restrictions: (*i*) the corroding system is confined by two insulating planes as shown in Fig. 1; (*ii*) the potential within the corroding metal is uniform owing to the high conductivity of the metal phase; (*iii*) current flows in the barrier layer parallel to the corroding surface; (*iv*) oxygen diffuses through the barrier layer along paths which are perpendicular to the metal surface; (*v*) the barrier thickness varies with position in an exponential manner; and (*vi*) the concentration of ionic species is uniform.

Subject to these restrictions, the model system is assembled from Ohm's law (for flow of electrical current along the barrier layer), Fick's law (for diffusion of oxygen through the layer), a Tafel rate expression (for the oxygen reduction kinetics), and an active-passive rate expression (for the metal undergoing corrosive attack). Before proceeding it is suggested that interested readers review details concerning the derivation of the model as provided in Ref. (1). The equation of conservation of charge which models the system is

$$\frac{d^2\Phi}{dX^2} - (1 + \tanh X)\frac{d\Phi}{dX} = \frac{\xi}{(1 - \tanh X)}\left\{\left[\frac{1-\beta}{e^{\frac{(\Phi-\Phi_R)^2}{\sigma}}} + \beta\right] - \left[\frac{\zeta e^{-\alpha\Phi}}{\zeta\Gamma e^{-X}e^{-\alpha\Phi} + 1}\right]\right\} \quad [1]$$

with boundary conditions

$$\frac{d\Phi}{dX} = 0 \text{ at } X = -\lambda \quad [2]$$

$$\frac{d\Phi}{dX} = 0 \text{ at } X = +\lambda \quad [3]$$

where the dimensionless variables are

$$X = \frac{x}{l}$$

$$\Phi = (V - \Phi_s)\frac{\mathbf{F}}{RT}$$

$$C = \frac{c}{c^o}$$

$$\sigma = \left(\frac{\mathbf{F}}{RT}\right)^2 s$$

$$\Phi_R = \frac{V_R\mathbf{F}}{RT} \quad [4]$$

and the dimensionless system parameters are

$$\Gamma = \frac{a\delta_m}{4\mathbf{F}Dc^o}$$

$$\xi = \frac{\mathbf{F}l^2a}{RT\kappa\delta_R}$$

$$\zeta = \frac{k}{a} \quad [5]$$

The notation employed in the equation, boundary conditions, variables, and parameters, is the same as in Ref. (1) and is listed at the end of the text. Reading from left to right, the terms in Eq. [1] indicate that the electrical current flowing along the barrier layer suffers ohmic resistance (second derivative term) which varies locally with the film thickness (first derivative term). The bracketed term on the right side of Eq. [1] is the net local reaction rate, *i.e.*, the local rate at which current flows into or out of the barrier layer. The local net reaction rate may be anodic or cathodic, depending on which partial reaction proceeds at the greater rate. For conditions of uniform corrosion, the right side of Eq. [1] would have the value of zero everywhere along the surface. On physical grounds, Eq. [1] therefore indicates that current flows into the barrier in the net anodic regions, flows along the moist layer while experiencing ohmic

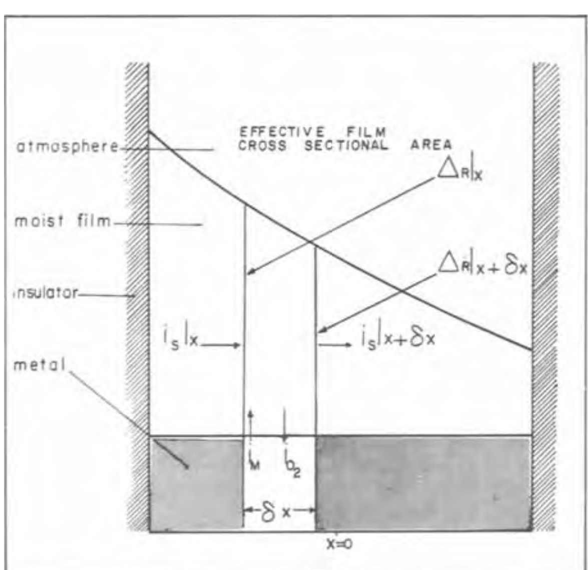

Fig. 1. System configuration for differential aeration corrosion study.

resistance and cross-sectional strictions, and flows out of the barrier into the net cathodic regions.

A detailed discussion of the physical significance of the dimensionless parameters has been given in Ref. (1). In brief, the parameter Γ is related to the ease with which oxygen diffuses to the corroding surface. Small values of Γ correspond to rapid diffusion of oxygen so that the concentration along the metal surface would be essentially uniform, near the saturated value; large values of Γ correspond to slow diffusion rates. The parameter ξ characterizes the resistivity of the barrier layer and takes on small values when the barrier layer is highly conductive. The parameter λ is a measure of the difference in oxygen availability between one end of the surface and the other end; large values of λ correspond to large differential aeration and thereby enhance tendencies toward localized corrosion. Once again, the reader is urged to consult Ref. (1) for a more complete discussion of the model.

Method of Solution

Equation [1], along with its boundary conditions, was solved numerically with use of IBM 1800 and IBM 360 digital computers. The boundary value system was transformed to an initial-value system by introducing a guessed condition at one end and adjusting this condition until the required relation was satisfied at the other end (6). That is, Eq. [1] was re-cast into a pair of first-order differential equations. Integration of an initial-value problem was then carried out such that the boundary condition at the far end of the spatial interval was satisfied by inspection. The method proceeds by writing

$$\frac{d\Phi}{dX} = Y \qquad [6]$$

hence Eq. [1] becomes

$$\frac{dY}{dX} - (1 + \tanh X)Y = \frac{\xi}{(1 - \tanh X)} \left\{ \left[\frac{1-\beta}{e^{\frac{(\Phi - \Phi_R)^2}{\sigma}}} + \beta \right] - \left[\frac{\xi e^{-\alpha\Phi}}{\xi\Gamma e^{-X} e^{-\alpha\Phi} + 1} \right] \right\} \qquad [7]$$

For initial conditions at $X = -\lambda$, Eq. [2] provides

$$Y = 0 \qquad [8]$$

For the second initial condition at $X = -\lambda$, guess

$$\Phi = A \qquad [9]$$

where A is a constant, which must be chosen with care. Equations [6] and [7] thus constitute two first-order equations having the unknown functions $\Phi(X)$ and $Y(X)$. The solution of this set, along with its initial conditions, is identical to the solution of Eq. [1], along with its boundary conditions, provided that the constant A is chosen such that

$$\frac{d\Phi}{dX} = 0 \text{ at } X = +\lambda \qquad [3]$$

The procedure for integration therefore consisted of arbitrarily choosing a value for the constant A, and then integrating Eq. [6] and [7] by means of Runge-Kutta fourth-order formulas (7). Every value of A which satisfies Eq. [3] corresponds to a different steady-state current distribution.

As a check against numerical errors, integration was also carried out beginning at the opposite end of the spatial interval, *i.e.*, beginning at $X = +\lambda$ and proceeding to $X = -\lambda$. Identical solutions were found for the current distribution regardless of direction of integration. In addition, the iterative method of solution employed in Ref. (1) was always found to converge upon any desired solution provided that a reasonable trial distribution was provided. That is, three methods of calculation provided identical numerical results.

The advantage of the "shooting" method of calculation described here is that all multiple solutions may be found for a given set of parameter values. In clear contrast, the iterative method used previously (1) had the disadvantage that one could not know how many solutions existed, except by finding them. That is, one could not determine whether a certain solution actually disappeared in some region of parameter space or whether it merely became difficult to converge upon.

Results and Discussion

Calculations have been conducted in order to clarify the nature of the multiple steady-state current distributions predicted by the model system. In addition, a compilation has been carried out in order to indicate those regions of parameter space in which at least one steady-state current distribution indicates the likelihood of highly localized corrosion. Because the model is somewhat preliminary in nature, and because it has been investigated primarily as an intuitive aid, an exhaustive compilation has not been attempted. Parameter values which were not varied in the investigation are $\alpha = 0.5$, $\beta = 0.01$, and $\sigma = 0.15$. Except where otherwise stated, the parameter ξ has the value 0.5.

It is important to make a clear distinction between the number of algebraic roots of the right side of Eq. [1], and the number of solutions to the differential equation. Although up to three algebraic roots may be found on the right side, such information bears no direct relation to the number of solutions which the differential equation may exhibit. Analyses of even simple distribution equations have demonstrated that an infinite number of solutions may be found (8, 9). In a similar manner, steady-state, nonisothermal behavior of porous, spherical, catalyst pellets has been shown to have an infinite number of multiple steady-state conditions (10). Therefore one should not go under the expectation that a maximum of only three solutions are to be expected of Eq. [1].

In certain regions of parameter space, several classes of independent solutions of Eq. [1]-[3] have been found. For one set of system parameters, for example, Fig. 2 illustrates that for many values of A [*i.e.*, the abscissa, $\Phi(-\lambda)$], the derivative at the far boundary [*i.e.*, the ordinate, $d\Phi/dX$ $(+\lambda)$] takes on values which may be nonzero. The model equations, however, are satisfied only for those situations for which the curve in Fig. 2 intersects the zero axis; each intersection point corresponds to a different steady-state current distribution. For the parameters used in Fig. 2, it is seen that thirteen multiple steady-state solutions are found. Some of the intersections are labeled (A, B, C, etc.) so that the solutions associated with them can be referred to in subsequent discussion.

It seems clear that all such solutions to the differential equation need not necessarily correspond to an observable steady-state condition of a physical system, even if that system is generally compatible with the approximations of the model. There are several reasons for which a mathematical solution may be regarded as physically unrealizable. First, a solution of the equation might predict a state of the system which is physically unstable to random disturbances. Although a stability analysis has not been conducted in this preliminary study, it should be mentioned that when multiple solutions exist as indicated in Fig. 2, it is frequently expected that the unstable solutions correspond to every other (*i.e.*, alternate) intersection. Second, a solution may be improbable in the sense that the sequence of events necessary for the attainment of the steady state may be difficult to achieve. An informal discussion of the possible transient conditions

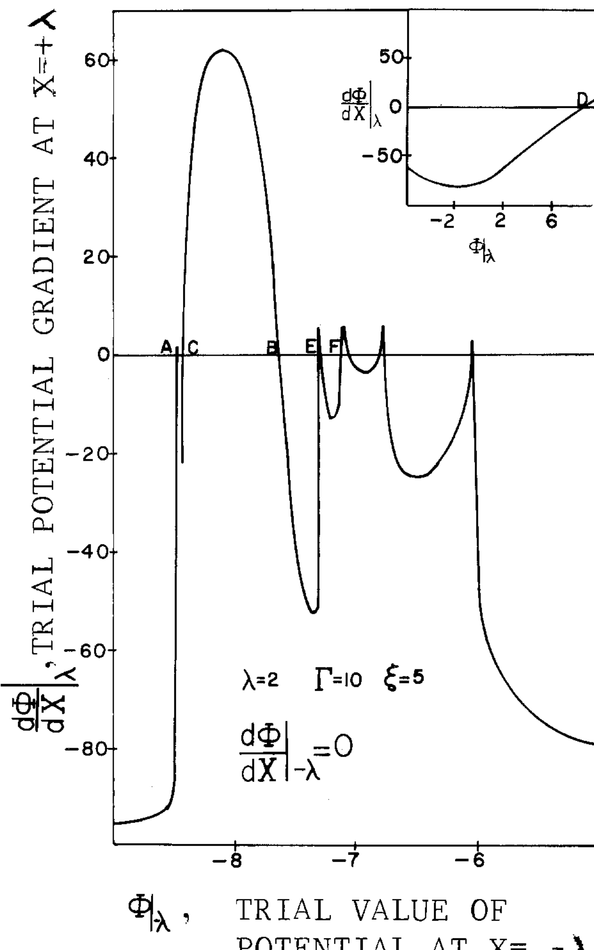

Fig. 2. Display of the existence of multiple solutions obtained by integrating Eq. [1] with a single set of system parameters. An independent solution exists at each intersection of the curve with the line.

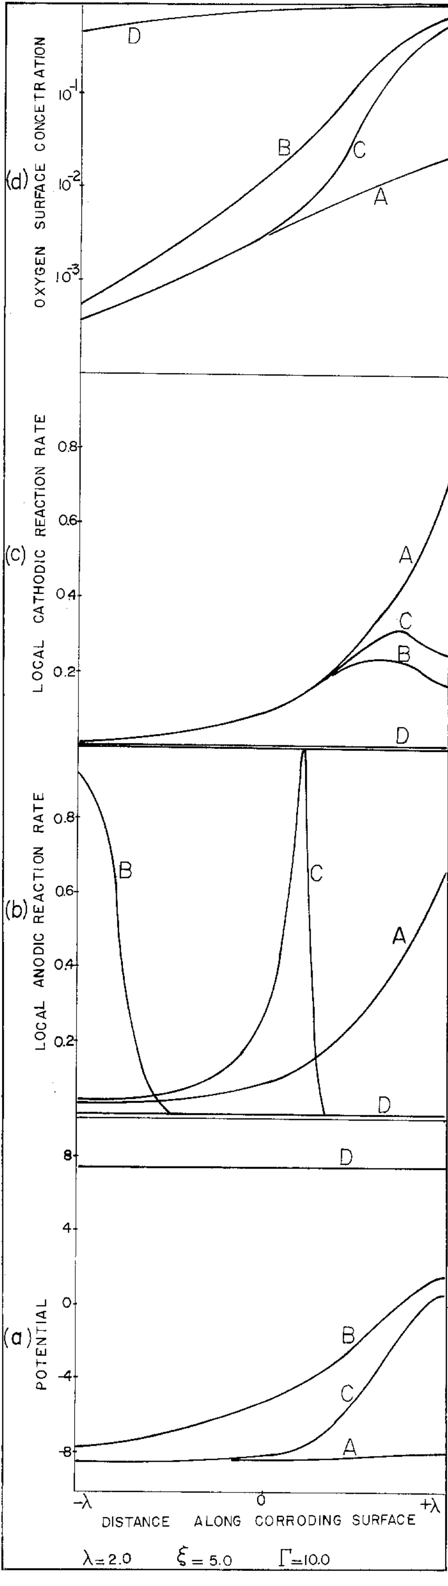

Fig. 3. Several distributions satisfying Eq. [1] were found for a single set of parameters. The curves labeled A, B, etc., comprise families of distributions which correspond to intersections A, B, etc., in Fig. 2. The distributions shown are: (a) potential of the metal relative to the solution, (b) anodic dissolution rate, (c) cathodic reduction rate, (d) oxygen concentration at the surface.

that may lead to the various steady-state solutions is given below. Finally, a solution would be unrealistic if it depends strongly on one particularly weak approximation of the model. Such unrealistic solutions would be incompatible with data from a physical system, or with predictions of a more rigorous model.

The potential, current, and concentration distributions corresponding to the intersections A, B, C, and D of Fig. 2 are shown in Fig. 3. Figure 3 also corresponds to Fig. 3 of Ref. (1), and detailed discussion of the curves is contained therein. For Solution A, the metal is in the active potential range everywhere so that the local dissolution rate increases with decreasing layer thickness. Solution D represents a fully passive situation at a very positive potential. Solutions B and C exhibit intermediate behavior where one portion of the surface is passive while the rest is reactive. Solution B lies entirely on the decreasing branch of the anodic polarization curve whereas Solution C varies all the way from mildly reactive potentials to the passive potential region. One additional solution, denoted A′, has general characteristics similar to the four solutions in Fig. 3 Solution A′ is found at an intersection located between A and C in Fig. 2 (not drawn in for want of space) and yields distributions whose nature is in every respect intermediate between distributions corresponding to A and C. That is, the anodic rate distribution for A′ usually includes a local maximum although the potential distribution has a smaller range than C.

The physical significance of the aforementioned five solutions will now be examined. The potential and anodic rate distributions of Solution A resemble closely the differential aeration corrosion of a nonpassivating metal. Since range of potential is restricted to the active branch of the polarization curve, assumptions made in the model with regard to the passivating behavior of the metal have no influence. Therefore Solution A can be regarded as a stable and realistic situation which might be encountered in a physical system. For Solution D, the potential distribution is sufficiently removed from the active region that kinetic details

regarding active/passive transitions are inconsequential. The physical reasonableness of Solution D is clear, and fully passivated metal surfaces are commonly encountered.

If we assume that solutions corresponding to alternate intersections in Fig. 2 are unstable, then since A and D are clearly stable, A' and B will be unstable while C will be stable. Solution C is especially interesting since it indicates the likelihood of highly localized corrosion at intermediate positions under the barrier layer. Solution B appears to be unstable, perhaps because the potential distribution lies entirely on the decreasing branch of the polarization curve, a region of negative charge-transfer resistance. Because the nature of Solution B depends strongly on the negative-resistance region of the passivation curve, these solutions may be regarded as unrealistic (in the narrow sense defined above) insofar as they depend strongly on a rather weak aspect of the model. It therefore seems unlikely that Solution B would be observed in actual physical systems.

It is useful to postulate in an informal manner the transient conditions which might lead to the various steady-state solutions encountered thus far. For example, if the electrolyte is saturated with oxygen prior to formation of the barrier layer, the entire surface will passivate and the steady-state condition captured by the system would be expected to be Solution D. On the other hand, if the electrolyte is deaerated so that oxygen diffusion proceeds with great difficulty, then the steady-state condition may be attained before any part of the surface undergoes passivation, as in Solution A. For intermediate initial oxygen concentrations in the electrolyte, the oxygen might passivate a part of the metal surface at the thin side of the layer before a steady state is achieved. Then Solutions C, B, or A' might be exhibited, although the foregoing discussion has cast some doubt upon the attainment of B and A'.

We will now proceed to examine the remaining solutions encountered between B and D in Fig. 2. The number of such intersections was found to vary considerably with changes in the parameter values. In addition, these solutions are quite different from any solutions reported so far. Two such solutions, denoted E and F in Fig. 2, have been chosen for display. Figure 4(a) shows that the potential distributions for E and F exhibit maxima and minima, in clear contrast to Solution A' which is also shown. As a consequence, anodic dissolution rate distributions, shown in Fig. 4(b), are highly nonuniform and indicate that localized attack may proceed at more than one location along the surface. Solution E has two strong anodic rate maxima, while F has two strong maxima and one weakly anodic region at $X = -\lambda$. The cathodic reaction rate distributions, shown in Fig. 4(c), are similar for all three solutions. By comparing Fig. 4(b) and 4(c), it is realized that Solutions E and F indicate that several anodic regions exist along the corroding metal, each separated by a cathodic region. The oxygen concentration distribution for each solution is shown in Fig. 4(d). For all cases, the oxygen concentration tends to be highest at $X = +\lambda$, where the barrier layer is thinnest, and lowest at $X = -\lambda$, where the thick barrier impedes oxygen diffusion. The remaining six solutions indicated in Fig. 2 exhibit behavior similar to E and F, but have not been illustrated since they do not appear to contribute additional information.

In accord with the informal rule that alternate intersections in Fig. 2 correspond to stable solutions, one may conclude tentatively that Solutions E and F are stable. On the other hand, one may inquire as to what transient events would be required to arrive at the steady states given by E or F. It seems reasonable that highly novel start-up conditions would be required in order to capture Solutions E or F, and their likelihood of existence may be regarded as highly improbable in comparison with Solutions A, C, or D.

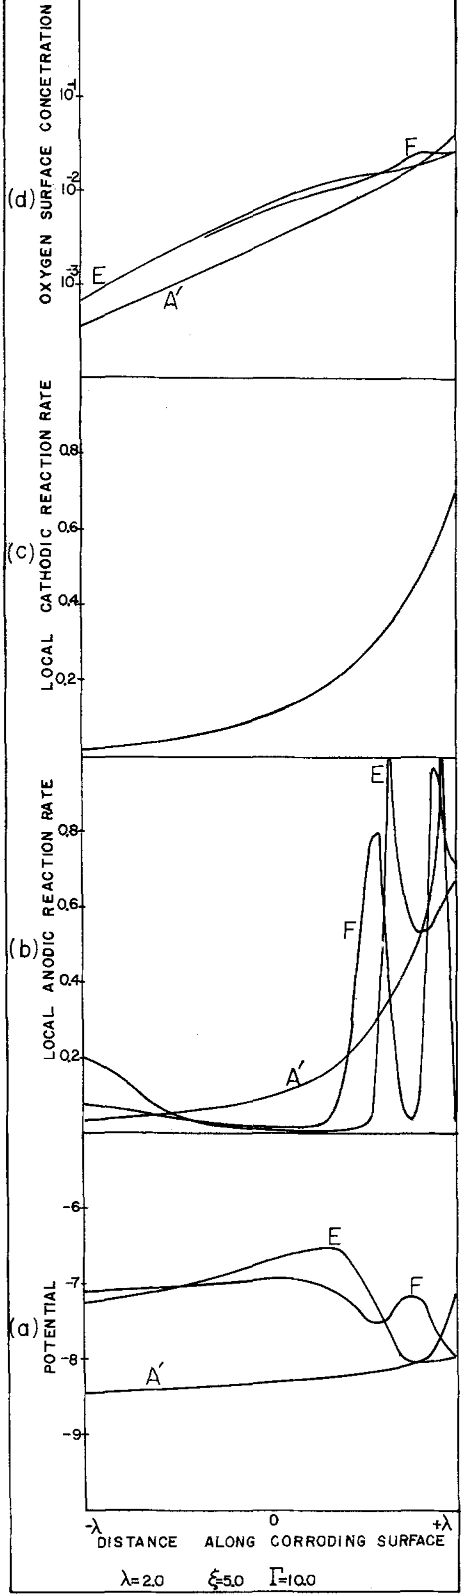

Fig. 4. Several distributions satisfying Eq. [1] were found for a single set of parameters. The curves labeled A', E, and F correspond to the solutions indicated in the text and in Fig. 2. The distributions shown are: (a) potential of the metal relative to the solution, (b) anodic dissolution rate, (c) cathodic reduction rate, (d) oxygen concentration at the surface.

As the system parameters are changed, the curve given in Fig. 2 moves up and down and also changes shape. As a consequence, points of intersection which correspond to different classes of solutions (A, B, C, etc.) may pass out of existence. For example, as parameter Γ is decreased, Solution A eventually merges with

A' and both disappear. As Γ is further decreased, Solutions B and C merge and disappear simultaneously. Such behavior also supports the contention that Solutions A' and B are unstable whereas A and C are stable.

The foregoing discussion has been directed at evaluating the mathematical model and computational method as well as gaining an understanding of a somewhat complex phenomenon. In what follows, the model is employed to indicate the regions of parameter space over which solutions with an unacceptable maximum local corrosion rate exist. In principle, the approach promises to be of value to corrosion engineers since the physical conditions corresponding to unacceptable regions may thereby be avoided through proper design.

Parameter values were compiled for which Solutions A and C indicated localized corrosion. In Fig. 5, the region between any of the two matching coded lines corresponds to the region where Solution C exists. For example, when $\lambda = 3$ and $\xi = 0.1$, localized corrosion by steady-state Solution C would be expected over the range $3 < \Gamma < 20$; outside of this range of Γ, Solution C is not found. The influence of parameter λ on the existence of C is also shown in Fig. 5. A large value of λ corresponds to a large differential aeration and thereby enhances tendencies toward localized corrosion. The region of existence of C is therefore markedly increased by an increase in λ.

The region of existence of Solution C is also influenced by the value of the parameter ζ which is the ratio of the cathodic rate constant to the maximum anodic current density at the "tip" of the passivation hump. Figure 6 illustrates, for $\lambda = 2$, the influence of parameter ζ. An increase in ζ corresponds to an increase in oxygen reactivity so that the surface concentration of oxygen would thereby be decreased. As a consequence, the range of Γ over which C exists is shifted to larger values in order to increase the extent of differential aeration, which is the sole driving force for localized corrosion in this system.

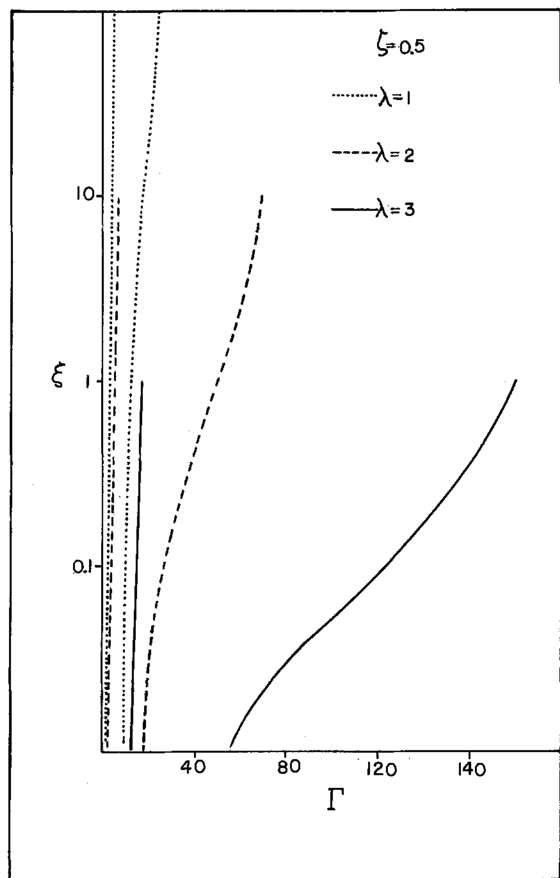

Fig. 6. Effect of differential aeration (parameter λ) on regions of parameters space where Solution A indicates highly localized attack.

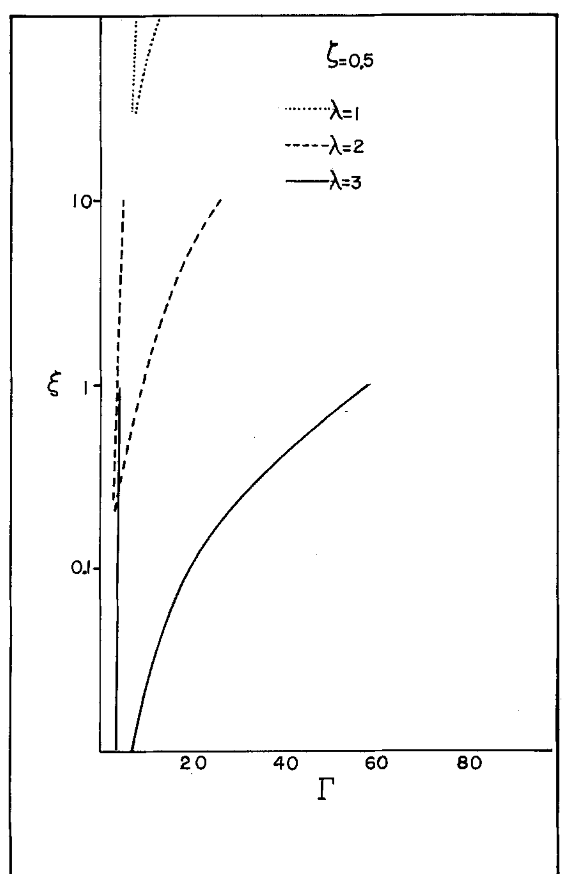

Fig. 5. Effect of differential aeration (parameter λ) on the existence of Solution C. The ξ-Γ region between any two matched coded lines is the region wherein Solution C exists.

Comparison of the influence of parameters λ and ζ as shown in Fig. 5 and 7 indicates clearly that approximations regarding the geometric form of the barrier layer have a far more drastic effect than approximations regarding the reaction kinetics which are applied to the model. Therefore applications of the results of this study to systems of different geometry would appear to risk introducing significant errors.

Solution A corresponds to the situation where the metal corrodes in the active region everywhere so that the local anodic dissolution rate increases steadily with decreasing barrier layer thickness (1). Although no passivation occurs, highly nonuniform dissolution may nevertheless occur. The regions shown between the matching coded lines in Fig. 6 correspond to situations where the maximum dissolution rate exceeds the value $0.1a$. It may be seen that the geometric parameter λ has a strong influence on the region of localized corrosion, similar to that shown in Fig. 5. On the other hand, the influence of the kinetic parameter ζ is essentially negligible and has not been displayed.

The existence of Solutions A' and B has always been found to lie within the range of existence of A and C as given by Fig. 5-7. The range of parameter space over which the remaining multiple solutions exist (excluding the passive solution, D) have not been compiled. In some cases, multipolar solutions having characteristics similar to E and F have been found which lie outside the envelopes of existence for Solutions A and C provided by Fig. 5, 6, and 7. On the other hand, arguments have already been presented regarding the improbability of attainment of steady states corresponding to the E- and F-type solutions which exhibit multipolar behavior. That is, the regions of parameter space indicated by Fig. 5-7 include all likely regions wherein highly localized corrosion rates have been found in the model system under

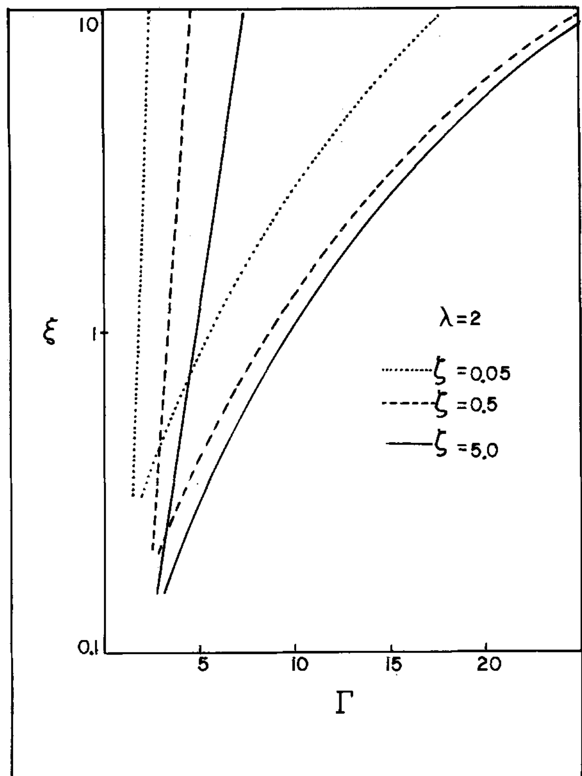

Fig. 7. Effect of the kinetic parameter ζ on regions of parameters space wherein Solution C exists.

study. Corrosion systems designed so as to lie outside these regions may therefore be expected to be unsusceptible to localized attack.

Conclusions

By determining the current distribution along a corroding surface, it has been possible to elucidate conditions under which highly localized corrosion is likely to occur in a simple model of differential aeration corrosion. Because the theoretical model is relatively straightforward, and because the underlying assumptions are relatively flexible, it is reasonable to expect that the foregoing transport phenomena approach may be extended to more complex situations of differential aeration corrosion as well as to other types of corrosion phenomena. The transport phenomena approach provides a route to predictive capabilities which has heretofore been lacking in corrosion design.

Owing to the active-passive behavior of the corroding metal incorporated in the model, multiple steady-state current distributions may exist for a single set of system parameters. The method of calculation employed above is capable of finding all of the multiple steady-state solutions. The method can therefore be used to seek out parameter regions where corroding systems would be susceptible to localized corrosion. The calculational method does not clarify the stability of the various multiple solutions in a rigorous manner but, by informal convention, suggests that Solutions A, C, and D are stable. Further, the method does not indicate which steady-state conditions would be attained following transient response from any given initial conditions; physical arguments, however, suggest that Solutions A , C, and D are most likely to be captured.

Several of the steady-state solutions exhibit multipolar behavior with up to three anodic and three cathodic regions distributed along the corroding surface. Current distributions of this type are not known to have been predicted in any previous investigation. However, the likelihood of observing such steady-state distributions in actual systems seems to be low in view of the unusual start-up conditions which would probably be required for their capture.

By developing dimensionless groups of system parameters, by investigating the response of the model to those parameters, and by developing a calculation method for finding all possible multiple solutions, the investigation provides a powerful intuitive grasp on the differential aeration corrosion phenomenon.

Magnetic Properties of Anodic Oxide Coatings on Aluminum Containing Electrodeposited Co and Co-Ni

Satoshi Kawai

The Pilot Pen Company, Limited, Hiratsuka Works, Kanagawa, Japan

and Ryuzo Ueda

Department of Applied Physics, Waseda University, Tokyo, Japan

ABSTRACT

Cobalt and Co-Ni alloy were electrodeposited into the micropores of various kinds of anodic oxide films on aluminum. Fine granular metals precipitated on the barrier layer and formed columnar structures. Although the films of cobalt or nickel showed remarkable magnetic anisotropies perpendicular to the surface, the alloy films which consisted of approximately 50% cobalt showed a strong anisotropy along the horizontal direction. Coercive forces ranged from about 500 to about 1100 oe and the density of residual magnetization rose above 1000 gauss. The films may have applications in magnetic memories and recording devices.

When the surface of aluminum is anodized in some electrolytes, a film with micropores characteristic of the electrolytic conditions is formed (12). Asada (3) found that unsealed oxide coatings show peculiar colors when immersed in metal salt solutions after application of a.c. One of the authors (4) in a previous study observed that metallic nickel and nickel oxide were precipitated in the micropores when nickel sulfate was used as the electrolyte.

As cobalt has a larger saturation magnetization than nickel, deposits of cobalt and cobalt alloy are of particular interest for applications in magnetic devices. Zetner (5) reported that electrodeposited cobalt layers have a coercive force of 150-500 oe and a residual magnetization of 4000-8000 gauss, and that the coercive force could be increased to as high as 800 oe by the use of a.c. + d.c. during deposition. Morral (6) found that the magnetic properties of electrodeposited cobalt layers depend on bath temperature, current density, concentration of cobalt salt, ratio of a.c./d.c., and time of electrolysis.

Electrodeposited layers of Co-Ni alloy have a coercive force of 200-300 oe with remanence as high as 4000-8000 gauss. Zetner studied the relationship between the magnetic properties of Co-Ni alloy and electrolytic conditions and found that as pH varied from acid to neutral, the retentivity decreased, whereas the coercivity increased by about 50%. Furthermore, he indicated that a maximum coercivity and an excellent squareness ratio were obtained at about a 60% cobalt content in the deposited layer.

Endicott *et al.* (7) studied hardness and tensile strength of Co-Ni alloy deposits obtained from sulfamic acid baths under various conditions and found that the structure of the deposit affects the physical properties. In contrast to a columnar structure of the layers of pure cobalt and nickel, deposited layers of Co-Ni alloy have a lamellar structure with approximately 50% cobalt content, resulting in improved mechanical properties.

According to the phase diagram for Co-Ni alloys, the structures are β-phase at room temperature for a cobalt content of less than about 70%, and α-phase for the rest. Aotani (8) noted in his study of the structure of Co-Ni electrodeposits, using x-ray diffraction analysis, that the deposit obtained from an electrolyte solution of pH 1.2 showed fcc structure whereas those obtained from a bath of pH 6.3 included hcp at about 70% cobalt content.

Key words: anodizing, magnetic thin film, coercive force, remanence.

Experimental Procedures

Specimens were prepared by the following three methods, and the treatment conditions were as shown in Table I:

(*i*) Rolled aluminum sheets (99.99% in purity, 0.5 × 500 × 1000 mm^3 in size) were anodized in sulfuric acid, oxalic acid, chromic acid, phosphoric acid, sodium bisulfate, and sodium hydroxide [Table I (a)]. These oxide films were electrodeposited with cobalt in the sulfate solution [Table I (c)].

(*ii*) The oxide films made in sulfuric acid bath under various conditions [Table I (b)] were electrodeposited with cobalt in the sulfate solution [Table I (c)].

(*iii*) The anodic films formed in the sulfuric acid bath [Table I (d)] were electrodeposited with Co-Ni alloy for various ratios of cobalt and nickel in these sulfate solutions [Table I (e)].

Anodizing was carried out, with sufficient air stirring, either with a carbon plate as a counterelectrode for the oxalic acid and sodium hydroxide baths, or with a lead plate for the other electrolytes. When 15V

a.c. was applied, about 5 A/dm^2 passed for a short time; after 5-10 sec a stationary current of about 1A/dm^2 was observed. The color of the oxide coating was brown at first, becoming black finally. After sealing, the specimens were wiped using a cotton cloth.

Specimens anodized in sulfuric and phosphoric acids were embedded in epoxy resin and sectioned to about 700Å using an ultrathin-film cutter. These sliced sections were then observed under an electron microscope.

For x-ray diffraction analysis, specimens anodized in sulfuric acid and electrodeposited with cobalt and Co-Ni alloy were immersed in 3% mercuric chloride solution and allowed to stand at room temperature for about 3 hr to strip the oxide. The stripped oxide films were washed, dried, and pulverized in an agar mortar.

The composition of the alloy deposited in the oxide films anodized in the sulfuric acid bath was determined by spectroscopic analysis. Specimens of 20 × 20 mm^2 were immersed in 5% sodium hydroxide solution at 30°C and the oxide films were stripped. The filtrate was boiled after adding hydrochloric acid, and the cobalt and nickel contents were determined using an atomic absorption spectrometer.

M-H hysteresis curves of the magnetic films were recorded with a vibrating magnetometer. A sample was vibrated along a direction vertical to the surface of the film; this made the measurement 50-500 times more sensitive than the usual automatic magnetometers. A schematic diagram of the apparatus is given in Fig. 1. Specimens in the form of a disk, 6 mm diameter were in sets of four on a quartz holder. The hysteresis loops along the horizontal and vertical direction were recorded to compare the magnetic anisotropies shown in Fig. 2.

Experimental Results

Figures 3 and 4 show electron micrographs of ultrathin sections of cobalt-deposited films anodized in sulfuric and phosphoric acids, respectively. The oxide film formed in sulfuric acid separated from the surface of the aluminum by a barrier layer. In the outer oxide film, columnar micropores about 100Å in diameter, about 400Å in distance from each other, and perpendicular to the surface were observed. These micropores were filled with fine granular deposits. In the phosphoric acid film, pillar-shaped deposits about 500Å in diameter were arranged nearly perpendicular to the surface at about 1000Å intervals.

From x-ray diffractometer analysis of the cobalt deposits, the structure was assigned as hcp α-Co (a = 2.507Å, c = 4.070Å) by reference to ASTM x-ray card 5-0727. In the case of Co-Ni alloy depositions, as the cobalt content decreased, the fcc crystal gradually appeared and the hcp structure disappeared. Figure 5 depicts the relationship between the calculated lattice constants and the cobalt content in the deposits.

The amount of cobalt and nickel deposited into the oxide film formed in the sulfuric acid bath is shown in Fig. 6.

The M-H hysteresis curves of the oxide films formed in various electrolytes and electrodeposited with the cobalt are shown in Fig. 7 (a)-(f). In these experiments, correction for the demagnetizing field of the quartz holder was made in advance.

With sulfuric acid, oxalic acid, and sodium bisulfate baths the cobalt-deposit layers showed strong magnetic anisotropies along the vertical direction with good squareness ratios but rather weak anisotropies along the horizontal direction. With chromic acid and sodium hydroxide baths, the anisotropies along the vertical direction were decreased. While with the phosphoric acid bath, this property along the horizontal direction was increased.

Fig. 4. Electron micrograph of ultrathin section film anodized in phosphoric acid and electrodeposited with cobalt. (a) Aluminum oxide film, (b) barrier layer, (c) aluminum.

Coercive forces indicated are characteristic of each electrolyte. The values for the films anodized in sulfuric and oxalic acid baths were greater than 1000 oe, while low values of about 500 oe were obtained with the phosphoric acid bath.

In Fig. 8 coercivities of the films anodized in the sulfuric acid bath are given as a function of the anodizing time. The effects in various electrolytic conditions were also measured. Coercive forces along the horizontal direction varied little, while the vertical components increased with increasing electrolyte concentration and decreasing current density. However, these vertical coercive forces were reduced with anodizing time and converged to a definite value.

Similarly, the relation between the strength of the residual magnetizations and the anodizing time was measured. The strength along the horizontal direction increased with the anodizing time, this increase being more pronounced as the electrolyte concentration and current density increased. After calculating the film thickness using an empirical formula, the relationship between the residual induction and the film thickness was as shown in Fig. 9. Residual magnetization increased with film thickness, but approached a saturation value. A larger magnetization value was obtained for an electrolyte of 30% concentration than with one of 15%.

In general, the density of remanence, B, can be expressed as

$$B = 4\pi M/V$$

where M indicates the strength of remanence (emu) and V designates the volume of the magnetic film (cgs). Then, $0.01M$ for a disk 6 mm in diameter having a 10 μm film thickness gives a magnetic density of about 440 gauss, and $0.025M$ is calculated to be more than 1000 gauss.

From some typical hysteresis curves for Co-Ni alloy deposits in films anodized in the sulfuric acid bath, the relation between the cobalt contents in the deposit layers to the coercivities and retentivities are shown in Fig. 10 and 11, respectively.

The coercive forces along the vertical direction varied from about 750 oe at 100% nickel content to about 1100 oe at 100% cobalt content. On the other hand, the coercivities along the horizontal direction rapidly increased from a value of 300 oe for 100% nickel content to a maximum of about 1100 oe for

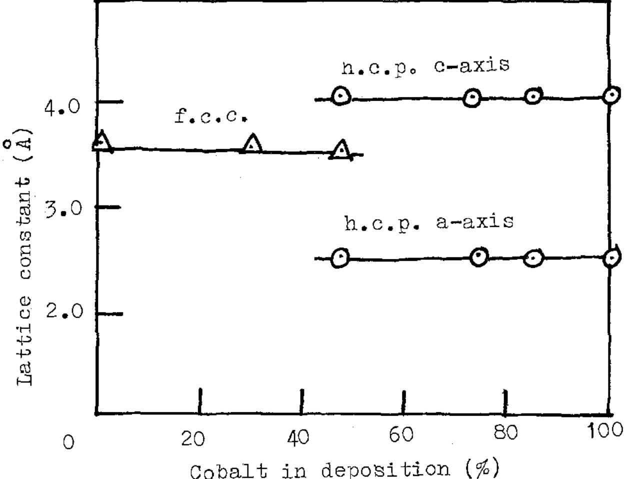

Fig. 5. Lattice constants of Co-Ni deposition onto anodic oxide films.

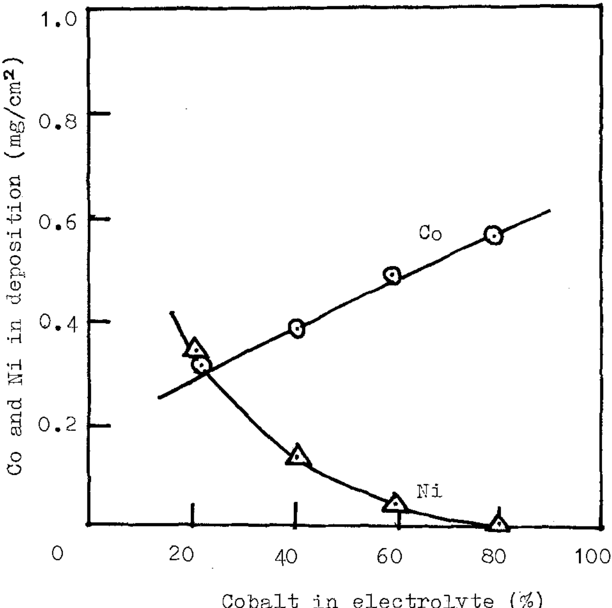

Fig. 6. Cobalt and nickel content between electrolyte and deposition.

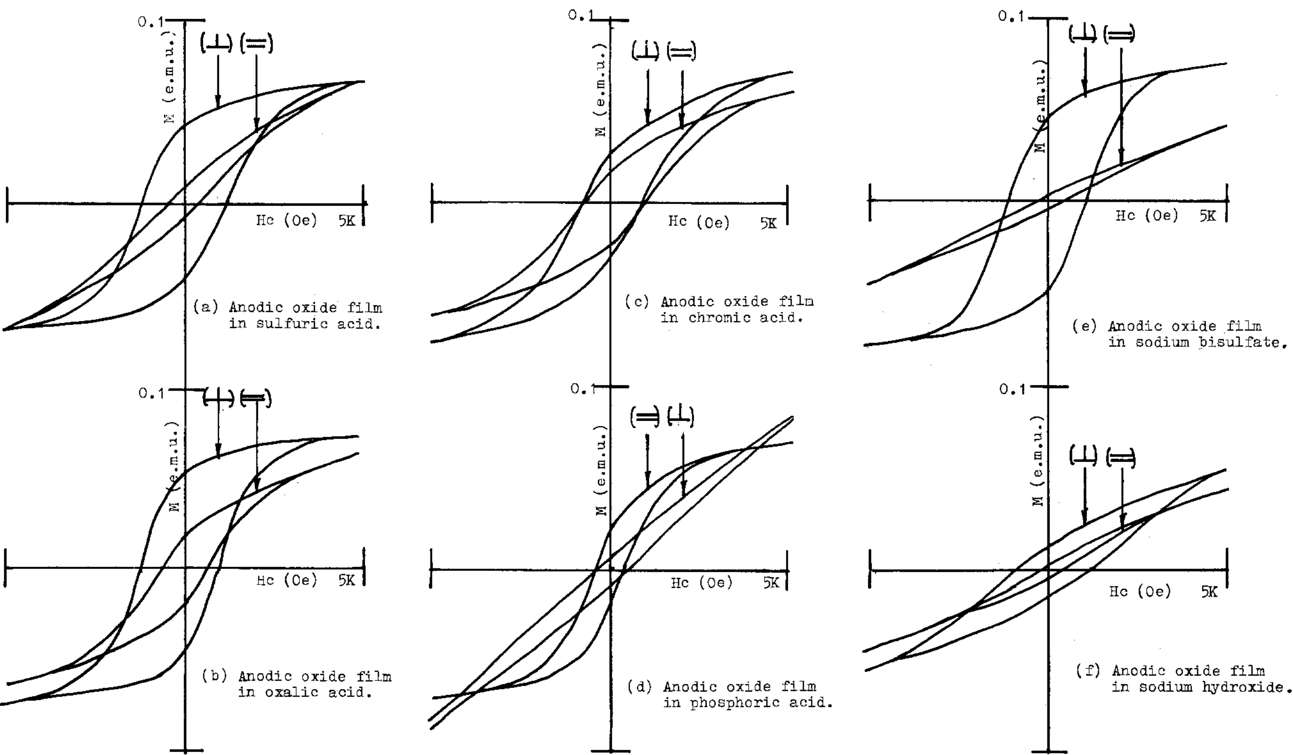

Fig. 7 (a)-(f). M-H hysteresis curves of oxide films anodized in various kinds of electrolytes and electrodeposited with cobalt

50% cobalt content, followed by a slight decrease to about 600 oe for 100% cobalt. The remanence strength along the vertical and horizontal directions showed a trend similar to that of the coercive forces, indicating a maximum value along the horizontal direction at about 50% cobalt content. The fact that the vertical and the horizontal magnetic properties reversed at around 50% content is considered to be an indication of some change in the structure of the deposited metal.

Magnetic Properties of Cobalt Deposits

The crystal orientation of the deposits has an influence on magnetic anisotropy. For α-Co with hcp structure, the axis of easiest magnetization has been measured to lie along the c-axis (9). Endicott and Knapp (7) demonstrated that electrolytic deposits obtained from cobalt salt solution show a columnar structure. Morral (6) indicated that the axis of easiest magnetization of cobalt obtained from an electrolyte near neutral pH was vertical to the surface. Thus, with the columnar structure, magnetic anisotropy along the vertical direction may be attributed to crystal growth in a direction which is parallel to the c-axis. From these facts, cobalt crystals deposited in the micropores of anodic oxide films may be presumed to have similar structures.

Assuming a film thickness of 1 μm, the ratio of the length to the diameter of the micropore will be 100:1. A needlelike structure of the metal deposit would result forming long unit magnetic domains. The magnetic anisotropy of the cobalt deposit may result not

only from the orientation of the cobalt crystal particles but also by the effect of particle shape.

Anodic oxide films obtained from the chromic acid bath are reported to form zigzag micropores, which occurrence reduces the uniformity of deposition, resulting in a weaker magnetic anisotropy along the vertical direction than that obtained from the sulfuric acid bath. Magnetic films anodized in a sodium bisulfate bath are said to have properties similar to those in sulfuric acid, hence the identical hysteresis loop. Little is known about the film obtained from sodium hydroxide baths. Although the oxide film shows good adsorption of dyestuff, this indicates relatively large micropores in the film. From the magnetic properties of this film, the presence of an irregular pore structure similar to the chromic acid bath case can be expected.

The coercive forces of the films did not show any marked variation with electrolytic conditions, although the trend was observed that coercivities increased with concentration of the sulfuric solutions and decreasing current densities. According to Keller *et al.* (1), decreasing electrode potential has the effect of decreasing the cell diameter, and it may be accepted that variations in temperature and concentration of electrolyte influence the electrode potential. From these considerations, the diameter of micropores in this case should be reduced to a certain extent. The shorter the electrolysis time, the higher the coercivity obtained. This might be due to a greater uniformity of the micropore structure for thinner films.

The remanence strength became larger with increasing film thickness and electrolyte concentration. However, it reached a saturation value probably due to a definite amount of cobalt deposition in the micropores under the given operating conditions. On the other hand, the density of magnetization was smaller than the values obtained from the usual electrodeposition, and it is considered that there is some limitation of the amount of the density because the porosity of micropores is estimated to be about 10% of the whole volume of the oxide film.

Magnetic Properties of Co-Ni Alloy Deposits

An x-ray diffraction analysis of the Co-Ni alloy deposits revealed the presence of α-Co for the film having a cobalt content greater than about 50% and a fcc structure for the lower concentration. The magnetic anisotropy of these deposits rotated by 90° from the direction vertical to the horizontal at about 50% cobalt content.

The crystal orientation of metal grain in the films was not experimentally determined in this study, but the orientation of the metal deposit in the micropores should determine the magnetic anisotropy of the film. In the lamellar structure, as the direction of the crystal growth is parallel to the surface and the c-axis is easiest magnetization, the magnetic anisotropy of the oxide film develops to the horizontal direction of the surface, and this is regarded as crystal anisotropy.

The anodic oxide coatings deposited with magnetic metals provide not only a powerful means for study of the film structures, but also have potential applications for high bit density memories and recordings.

Electrodeposition along the Air-Solution Interface

I. Experimental Investigation

R. A. DiIorio,[1] W. J. Newby,[2] and A. J. Sukava*

Chemistry Department, University of Western Ontario, London, Ontario, Canada

ABSTRACT

In the electrolysis of an acidified copper sulfate solution with a copper wire cathode located vertically along the axis of a cylindrical copper anode, addition of a small amount of norvaline to the solution causes a disklike deposit of copper to grow outwardly from the cathode and along the air-solution interface. Experiments show that this phenomenon is due mainly to a solid reaction product arising from air oxidation of the norvaline along the line of contact between the copper anode, air, and solution. This solid, presumably present in a highly subdivided state, migrates by surface diffusion from the anode to the cathode along the air-liquid interface, giving rise to nucleation sites that lead to the interfacial cathode growth. The mechanism is thought to involve a conductive surface film containing copper powder as a conducting medium. The rate of disk formation depends on the concentration of the norvaline, the area of anode surface along the air-solution interface, the acidity of the solution, the partial pressure of oxygen above the solution, and the rate of current flow. It does not depend very markedly on the concentration of the copper sulfate.

The results of preliminary experiments on the growth of a copper electrodeposit along the air-solution interface, caused by small concentrations of norvaline in the acid sulfate electrolyte, have been described in a previous publication (1). This unusual phenomenon was first noticed in this laboratory in the course of a study of excess deposit weights caused by various additives. It occurs when the acidified copper sulfate solution containing the norvaline is electrolyzed with a wire cathode positioned vertically along the axis of a cylindrical copper anode. The interfacial deposit consists of a disk-shaped growth of copper extending outwardly from the cathode along the liquid surface. The disk is sometimes radially asymmetric as a result of noncoincidence of the cathode position and the anode axis, with growth favored in the direction of greatest current flux.

As reported (1), the formation of the interfacial disk is always accompanied by a change in color of the copper sulfate solution to a blue-green, and by formation of a finely divided, black, suspended solid that settles on standing after electrolysis is stopped. Separation of the anolyte and catholyte by means of a porous thimble surrounding the wire cathode (Whatman cellulose extraction thimble as indicated by a- - -a in Fig. 1) prevents formation of the disk. Moreover, both the color change and the formation of black solid occur only in the electrode compartment outside the thimble, whether the outer cylindrical electrode is made the anode or the cathode. Obviously, these two effects are interdependent and not markedly affected by the electrode potential. They occur primarily at the electrode with the greater surface area.

Experiments showed that prior oxidation of the dissolved norvaline by air or oxygen in the presence of a copper surface (presumably as catalyst) is a primary requisite in giving rise to the interfacial disk. The color change and black solid are a result of this oxidation, and electrolysis of a solution containing these oxidation products produces the interfacial disk whether or not oxygen is excluded. If a freshly prepared norvaline-containing electrolyte is deaerated with nitrogen and then electrolyzed under a nitrogen atmosphere, none of these effects occur.

Key words: interfacial disk, anode effects, norvaline, copper powder, conductive film.

A more detailed study has now been made of this form of interfacial electrodeposition. The results of various experiments, some still preliminary in nature, are presented and discussed in this report.

Experimental Technique

The simple apparatus used in this study is illustrated in Fig. 1. The glass cell, fitted with a ground-glass cap as shown, had a total volume of about 100 mliters. A copper wire cathode, about 1 mm in diameter, was positioned approximately along the axis of a cylindrical copper anode with an inside diameter of about 3 cm. The cathode was immersed to a depth of about 4.9 cm when the cell contained 50 mliters of solution. An appropriate opening in the cell cap held the cathode in place and another opening provided access for the anode lead. Two other openings (not shown) provided for electrolysis under an atmosphere of nitrogen or oxygen as required.

Most of the anodes were made from ordinary commercial copper tubing. These anodes, as well as the wire cathodes, were heated to redness prior to use to destroy any possible organic contaminants that might have been present. They were then etched in nitric acid and washed and rinsed with distilled water. However, some of the anodes were prepared by electrodeposition of "pure" copper on cylindrical platinum gauze substrates, *i.e.*, using platinum electrodes and a copper sulfate electrolyte previously purified by passing through a column of activated charcoal. These anodes were not preheated since no organic additives were used in their formation.

The standard solution used in the disk-growth experiments contained 0.5M copper sulfate and 1.0M sulfuric acid, both reagent grade. The organic additives were also reagent grade, as obtained commercially. These were added without further purification to the freshly prepared standard electrolyte to give the desired concentration. The water used in the solutions was distilled twice with all-glass apparatus. It had a specific conductance of about 6×10^{-6} ohm^{-1}-cm^{-1}.

All experiments were carried out at a constant applied current, using a Harrison regulated power supply, Model 6201-A. In most of the experiments, several cells containing different concentrations of organic additive were connected in series so that the same amount of charge flow occurred in each. The cell assembly was immersed to the solution level in a temperature-regulated bath maintained at 25° ± 0.05°C.

Results and Discussion

Figure 2 shows photographs of a typical cathode deposit obtained after prolonged electrolysis in the presence of a small amount of norvaline. The disklike deposit grew along the air-solution interface, during a given period of electrolysis and at a given current flow, to an extent dependent on the norvaline concentration. Typical data are shown in Fig. 3. At a constant current flow of about 45 mA, the optimum norvaline concentration was about 2.5×10^{-2} molar.[3] Experiments with freshly prepared solutions always showed that the disk growth did not begin until after several hours of initial electrolysis. Furthermore, the results were qualitatively the same whether the anodes were made from "impure" commercial copper tubing or whether they were made by prior electrolysis of a "purified" copper sulfate electrolyte with deposition on cylindrical platinum substrates. The indication here is that possible minor impurities in the anode metal are of no apparent consequence in the disk growth process. The cathode and anode current efficiencies were about 100 and 83%, respectively.

Besides formation of the surface disk, the following additional effects were observed:

1. The initial blue color of the copper sulfate solution changed to a blue-green with about 24 hr of electrolysis.

2. A small amount of finely divided black solid was found dispersed and suspended in the solution.

3. Finely divided copper powder was sometimes found at the bottom of the electrolysis cell, confirming Ibl's observation (2) that such powder forms at the cathode during electrolysis.

Inhibition of disk growth.—The decreased diameter of the copper disk with norvaline concentrations greater than 2.5×10^{-2}M (see Fig. 3) is probably due to some kind of inhibiting effect caused by the excess norvaline. This suggestion is based on the observation that the same effect was obtained by adding other structurally related organic compounds to the solution. For example, if the norvaline concentration was kept constant at 2.5×10^{-2}M, and if either N-acetyl norvaline or glycine was added, the effect was to decrease the disk growth. N-acetyl norvaline was found to cause a greater decrease in disk growth than glycine at the same concentration, indicating presumably that a large additional molecule has a greater inhibiting effect than a small one.

Disk growth and rate of current flow.—Figure 4 shows the effect of the rate of current flow on the size of the disk. In these experiments, the time of electrolysis was adjusted so that the same total charge passed through the solution in every case, with the initial concentration of norvaline being fixed at the optimum 2.5×10^{-2}M. The maximum rate of disk growth occurred under these conditions when the current, kept constant throughout, was about 60 mA.

Disk growth and convective flow.—In the cell shown in Fig. 1, the presence of the cellulose thimble a- - -a

[3] In one experiment, a paper-thin layer of copper metal formed across the surface of the solution, causing a direct short between cathode and anode. Attempts to reproduce this extreme form of interfacial deposition were not successful, indicating that the conditions for maximum rate of disk growth are probably rather critical.

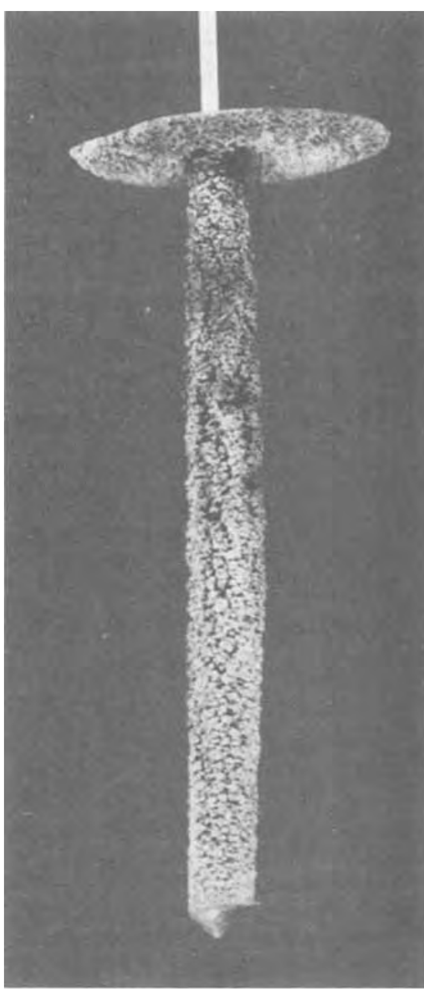

Fig. 2b. Copper cathode with interfacial disk. Bottom view

can be expected to eliminate or at least substantially reduce the normal convective flow, which is upward

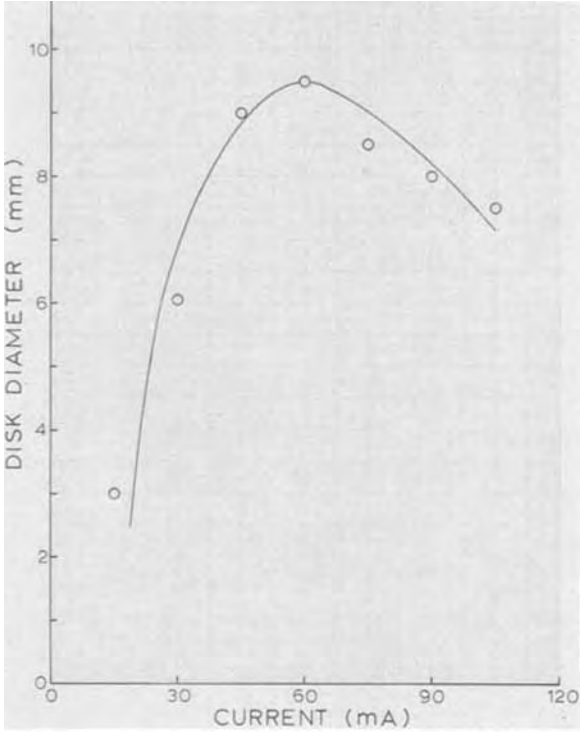

Fig. 4. Disk diameter vs. current. Norvaline concentration, 2.5 × 10^{-2}M; charge flow, 5200 coulombs; temperature, 25°C.

at the cathode and downward at the anode. Since this thimble prevents formation of the interfacial disk (1), experiments were designed to examine the role that convection might possibly play in the disk-growth mechanism. In some of these experiments, shortened, fully immersed thimbles were used such that they surrounded only the bottom 1-3 cm of the cathode. In others, pieces of cellulose cut from the thimbles were immersed in the solution in such a manner that they did not interfere with the convection stream. In every case, with the amount of cellulose being in excess of about 18 cm^2 of the thimble material, it was found that formation of the air-solution interfacial disk did not occur. Apparently the cellulose interferes with the disk-growth process by removing some soluble or colloidal active agent, possibly by adsorption.

Further evidence to support this view was obtained from experiments in which horizontal barriers were used to reduce or eliminate the normal convection (see b- - -b in Fig. 1). As was noted previously (1), formation of the interfacial disk is not prevented by a thin sheet of nonporous Parafilm (a waxy waterproof material obtained from the Fisher Scientific Company) attached to the cathode and located horizontally just below the solution line. However, similar horizontal barriers consisting of cellulose sheet (cut from Whatman extraction thimbles) do prevent the disk formation. Accordingly, since the convection stream cannot be affected very differently by these similar horizontal barriers, whether Parafilm or cellulose, then adsorption of a disk-growth agent by the cellulose is indicated. The convection stream as such is not an important factor in the disk-growth mechanism, except perhaps as an aid in keeping the disk-growth agent in suspension along the liquid surface.

Outgrowth at the bottom end of the cathode.—In the experiments with shortened cellulose thimbles, outgrowths sometimes appeared at the bottom end of the cathode and along the inner surface of the thimble (see Fig. 5). Evidence was found showing the presence of copper powder inside these fully immersed thimbles, indicating that decreased local turbulence due to reduced convection might be a factor in causing the powder to settle to the bottom. No copper powder

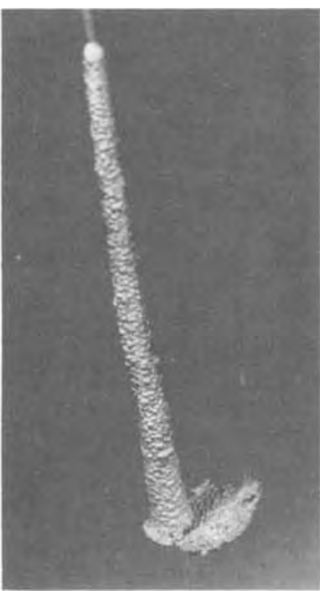

Fig. 5. Cathode growth with short, fully immersed, cellulose thimble, showing effect of settled solid and copper powder. Diameter of bottom outgrowth, 1.3 cm.

was found in any of the full-length thimbles that surrounded the cathode completely, and no such bottom-end growths occurred. Therefore, it seems evident and reasonable that copper powder is a factor in giving rise to the nucleation sites and conducting medium for the bottom outgrowth, if norvaline is present in the solution. It is also evident that a second factor required for the cathode outgrowths, whether at the bottom of a shortened thimble or at the air-solution interface, arises from an oxidation (1) of the norvaline at the anode.[4] This is indicated by the behavior of the full-length cellulose thimble apparently acting as a barrier against the transport of some active powder-forming and outgrowth-producing agent to the cathode. Moreover, the anode reaction product is probably particulate in form, against which the cellulose can act as an effective and adsorptive screen. More conclusive evidence to support this view follows.

Role of the air-solution interface.—Since the cathode outgrowth along the air-solution interface is caused by effects arising initially at the anode, and since the convection stream is not the means of transport of the active agent to the cathode, experiments were done to test the possibility of transport of particulate material from anode to cathode by a diffusion mechanism operating along the liquid surface. A vertical Parafilm cylinder was used as a surface barrier (see c---c in Fig. 1). Because this cylinder, about 1.5 cm in diameter, extended into the solution to a depth of less than a millimeter, it did not interfere with the normal convection in the cell. It isolated the cathode only along the air-solution interface, and it prevented formation of the interfacial disk. Apart from this there was no other observable effect. The color change to blue-green and the formation of black solid occurred as before.

Obviously, transport of some kind of particulate material occurs along the surface of the solution, from anode to cathode, when norvaline is present during the electrolysis. It seems reasonable that this material is involved in the formation of a conductive film along the air-solution interface such that deposit nucleation can occur, and it is suggested that the interfacial conductivity probably arises from the presence in this film of metallic copper in a highly subdivided state. Copper powder can be expected to form along the upper part of the cathode, as observed by Ibl (2), and to accumulate in the adjacent air-solution interface.

Material responsible for disk growth.—It was of interest to try to determine whether the color-change effects as well as the solid formed at the anode might be directly involved in the disk formation. Experiments with the cellulose thimbles and the Parafilm surface barriers, as already described, indicate that the material responsible is particulate in form.

It was found that if the suspended solid was removed from the electrolyzed solution by filtration through a fine sintered-glass funnel, and if the blue-green filtrate was then deaerated and electrolyzed under nitrogen, no disk formation occurred. Clearly, the disk-growth process requires the presence of the solid. (It was also found that if such a filtrate is electrolyzed in the presence of air, disk growth occurs after a few hours of such further electrolysis together with formation of more solid.) Other experiments then showed that if the solid obtained by filtering an electrolyzed norvaline solution is added to standard electrolyte containing no norvaline, and if this solution is deaerated and electrolyzed in the absence of oxygen, the interfacial disk is obtained and in a shorter period of time. The same result is obtained if the solid is first produced without electrolysis, that is, by sufficiently prolonged contact of the norvaline-containing electrolyte with air and a copper surface. (Copper turnings were used in these experiments.) Obviously, the dispersed solid is the only factor responsible for the disk growth, to the extent that the anode effects are concerned. The soluble color-affecting reaction products are not directly involved, indicating that the possible presence of dissolved copper-norvaline complexes is not important.

Particulate nature of the disk-forming agent.—A further indication that the material involved in the disk-growth mechanism is particulate in form came about in a different manner. An acid copper sulfate-norvaline solution was first electrolyzed for about 48 hr, during which the air-solution interfacial disk was formed. The electrolysis was then stopped and the system was left undisturbed for about 6 hr. After this period, during which the black solid settled to the bottom of the cell, the circuit was closed again for another 48 hr of electrolysis. The disk at the air-solution interface increased in size, but a second and larger disk now formed at the bottom along the glass-solution interface. A similar result was obtained if the solution was stirred by means of a steady stream of air flowing upward along the anode from a small capillary introduced into the cell. The effect was to decrease considerably the rate of disk formation at the air-solution interface, though not completely, and to cause a relatively rapid disk growth at the bottom end of the cathode (see Fig. 6). Obviously, the air stream causes coagulation and settling of the otherwise suspended solid to form a conducting medium along the bottom of the cell. [It should be noted at this point that a corresponding effect occurs in the disk growth along the upper surface of horizontal Parafilm sheets attached to the cathode at various depths, as observed previously (1), presumably because the solid then settles on these sheets during electrolysis due to reduced convection.]

Role of the anode.—Since the solid formed by air oxidation of norvaline is a primary cause of the disk growth at the cathode, and since this solid originates at the anode, experiments were done to examine the role of the anode in the oxidation mechanism. Variation in the area of anode surface in contact with the solution had no effect on the rate of growth of the interfacial disk, indicating that the oxidation of the norvaline does not occur on the immersed surface of the anode. Experiments were then done with a completely immersed anode, using a shortened copper cylinder such that the upper rim was immersed just below the

[4] Whatever the detailed nature of the anode reaction, the effects are not stereospecific with respect to the norvaline. Experiments with the D and L forms alone gave the same results as the DL-norvaline routinely employed.

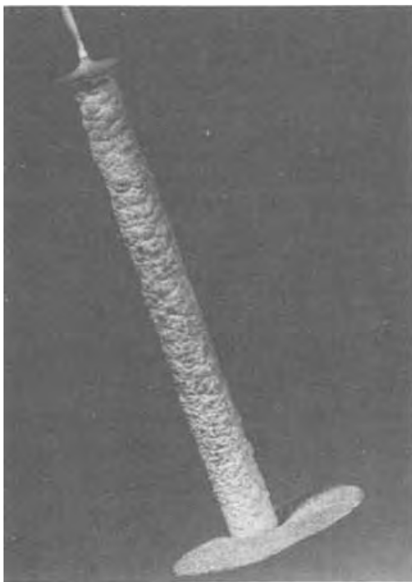

Fig. 6. Copper cathode with small interfacial disk, showing bottom outgrowth due to coagulation of solid by air flow past the anode. Diameter of bottom outgrowth, 1.9 cm.

solution line. No disk formation occurred and no color change or formation of black solid took place. Clearly, the air oxidation of norvaline at the anode occurs only along the line of contact between copper surface, air, and solution.

Dispersed solid and the oxidation reaction.—The results of preliminary and incomplete experiments indicate that a thorough study is required to examine the mechanism of air oxidation of norvaline at a copper surface, including in particular a detailed analysis of the solid and other possible products of the reaction. Roughly quantitative analyses showed that the composition of the solid material, which contains copper, varies from sample to sample. The solid is insoluble in ordinary organic solvents, indicating possibly a polymeric character. It is soluble in concentrated inorganic acids and, apart from a residue identified as copper powder, it dissolves also in dilute aqueous bases. (This evidence of copper powder in the dispersed solid reinforces our suggestion, or assumption, that conductivity of the interfacial film is probably due to metallic copper.) The base-soluble portion undergoes a nonreversible hydrolysis since a regenerated solid obtained on acidification no longer has the same organic composition as the original material. Nor does this regenerated solid have the disk-forming ability, presumably in part because it does not contain copper powder. However, analyses showed that about 30% by weight of the regenerated solid is copper, indicating that at least part of the copper in the original solid is present in combined or complexed form. This copper content, considerably greater than the amount found in the original material, about 5.5%, suggests strongly that the original solid is a mixture rather than a pure compound, with the combined copper presumably complexed in at least one component. Further study of the solid oxidation product was not attempted.

Formation of NH_3 and CO_2.—Takajama *et al.* (3) have reported that amino acids undergo electrodecomposition to yield an aldehyde of one carbon less together with evolution of NH_3 and CO_2. The oxidation of norvaline by air or oxygen in our experiments cannot be regarded as an electrodecomposition, since it occurs even in the absence of electrolysis, but it was nevertheless observed that NH_3 and CO_2 were produced, with the NH_3 appearing as ammonium ion in the acid solution. The results of various experiments are presented here primarily as observations, without attempt at interpretation.

Analyses were done to determine the NH_3 and CO_2 produced as air, and then pure oxygen, was passed slowly through the cell and over the norvaline-containing solution. The NH_3 was determined after electrolysis by a standard Kjeldahl method, and the CO_2 was found by passing the gas stream during electrolysis through a solution of $Ba(OH)_2$.

The rates of formation of NH_3 and CO_2, with a given amount of norvaline present, were found to depend on the partial pressure of oxygen above the interface as shown in Fig. 7, the amount of each gas formed being approximately linear with time. It was also found that the rates of formation of NH_3 and CO_2 do not depend on the concentration of $CuSO_4$, but that they do depend very markedly on the concentration of acid as shown in Fig. 8. Obviously, the rate of growth of the interfacial disk is correspondingly dependent on the acidity of the solution, and this in fact was observed. The maximum disk growth occurred with 2.5×10^{-2}M norvaline when the H_2SO_4 concentration was about 1.0M. It was found as well that the production of NH_3 and CO_2 does not depend on the current, which is consistent with the observation that formation of the black solid occurs with equal facility in the absence of electrolysis. The reaction requires only an acidified norvaline solution, a copper surface, and air or oxygen at the interface.

It is interesting to note in Fig. 7 that the formation of NH_3 and CO_2 in our experiments does not take place in a one-to-one ratio, as would be the case if Takajama's observation regarding formation of an aldehyde were applicable to our system (3). Our data show that NH_3 and CO_2 are produced in a mole ratio of about four to one when norvaline in acid solution is oxidized by air or oxygen on a copper surface.

Experiments with other compounds.—Numerous experiments were done to see whether compounds other than norvaline are similarly capable of causing formation of the interfacial disk. Compounds structurally

and constitutionally related to norvaline were chosen. These were: norleucine, leucine, valine, α-aminobutyric acid, β-aminobutyric acid, α-aminooctanoic acid, and N-acetyl norvaline. The concentration of the additive, the acidity of the solution, and the time of electrolysis were all varied, but no condition was found such that disk formation occurred. Qualitative and quantitative tests showed that NH_3 was formed to a greater or lesser degree with all of these compounds, and a change in color of the solution was observed with some of them, particularly with norleucine and with α-aminooctanoic acid. However, unlike norvaline, none of them showed any formation of dispersed solid in observable amount. Obviously, the functional groups are not the only requirement for the formation of the solid and the interfacial disk. The length of the carbon chain appears to be a critical factor in the process.

Summary and Conclusions

1. In the electrolysis of an acid copper sulfate solution with a wire cathode surrounded by a cylindrical copper anode, addition of a small amount of norvaline causes a disk-shaped outgrowth to form on the cathode and along the air-solution interface.
2. The primary cause of this interfacial outgrowth is a solid oxidation product arising from reaction of the dissolved norvaline with air or oxygen at a copper surface, in this case the anode. Dissolved reaction products are not involved.
3. During the electrolysis, oxidation of the norvaline occurs only along the line of contact between copper anode, air, and solution.
4. Transport of the solid oxidation product from anode to cathode takes place by surface diffusion along the air-solution interface.
5. Cathode outgrowths can be produced along the bottom of the electrolysis cell by causing the otherwise suspended solid to settle.
6. Evidence of copper powder at the bottom of the cell in some experiments, and evidence of a copper-powder residue left on dissolving the solid reaction product in dilute bases, indicates that formation of the interfacial cathode outgrowths probably involves copper powder as a conducting medium.
7. In a group of eight structurally related amino acids, all examined under similar electrolytic conditions, only norvaline produced the interfacial cathode outgrowths.

Electrodeposition along the Air-Solution Interface

II. Metallographic Study

J. M. Trenouth,[1] R. A. Dilorio,[2] and A. J. Sukava*

Department of Chemistry, University of Western Ontario, London, Ontario, Canada

ABSTRACT

A metallographic examination was made of a cathode deposit formed along the air-solution interface of an acid copper sulfate electrolyte containing a small amount of norvaline. The photomicrographs indicate initial nucleation at the interface, presumably along a preexisting conductive film, followed by growth of the deposit downward toward the solution. No evidence was found of growth cones extending radially and horizontally from the cathode and along the interface.

The preceding paper (1) describes the results of some experiments on the mechanism by which a small amount of norvaline added to an acid copper sulfate electrolyte causes the cathode deposit to grow preferentially along the air-solution interface when electrolysis occurs with a wire cathode and a cylindrical copper anode. It is speculatively suggested that this particular form of electrodeposition occurs as a consequence of a conductive film formed along the surface of the solution. This film is thought to contain copper powder formed at the cathode, thus giving rise to initial deposit nucleation at or near the cathode but along the liquid surface.

The details of the growth habit of the interfacial disk are not revealed by the chemical investigation described in Part I (1). Moreover, it is not clear whether the assumed conductive film can be regarded as a preexisting condition followed by the observed downward thickening of the interfacial deposit, due to nucleation only along its lower face, or whether a preferred horizontal growth occurs outwardly and radially from the cathode, along the air-solution interface, prior to the downward growth. To attempt a further elucidation of the mechanism, a brief metallographic examination of the interfacial deposit was carried out as part of the investigation. For this purpose, photomicrographs of deposit cross sections were produced and examined by one of us (J.M.T.) at the Structures and Materials Laboratory, National Aeronautical Establishment, National Research Council, Ottawa. The results are reported in this paper.

Specimen Preparation

Typical cathode deposits with the interfacial outgrowth were prepared as described in Part I (1). Various cross sections were then made for metallographic study, using standard techniques. Referring to Fig. 1a and b, longitudinal sections were made of the wire cathode and deposit in the region at the solution line and at the bottom end. A transverse section, made approximately midway, is represented in Fig. 1c. For the specimen examined, the interfacial disk-shaped deposit was detached readily from the electrode intact, enabling a separate cross section to be made of it as indicated in Fig. 2.

After sectioning, all specimens were coated with electroless nickel plating to preserve specimen edges and to prevent their rounding during subsequent grinding and polishing. All specimens were etched after polishing with either of the solutions A or B (Table I).

Results and Discussion

Normal deposit.—The longitudinal and transverse sections of the electrode in Fig. 1, photographed under plane polarized light, show the wire with the copper deposit as it is normally formed. A variation in the structure of the deposit from the original substrate to the outer surface is evident, the deposit near the substrate having a columnar or conelike structure of the field-oriented type and that near the outer surface having an unoriented-dispersion type of structure. The crystallinity of the outermost deposit in this specimen is also considerably coarser than that near the original wire. These structural variations are presumably the result of a combination of factors including the gradu-

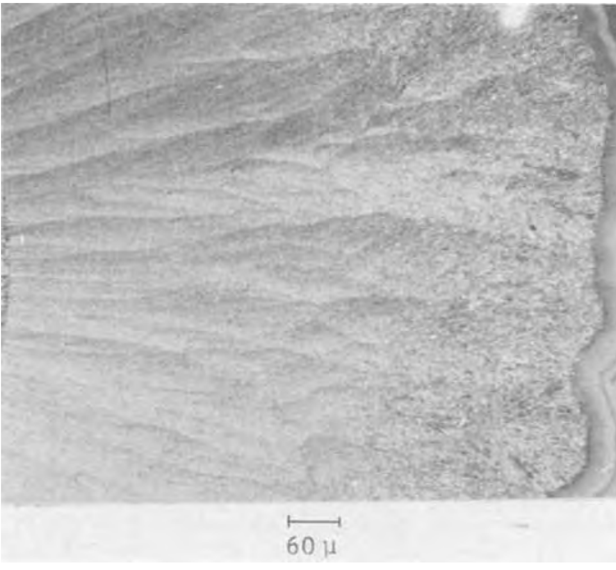

Fig. 1c. Transverse cross section of cathode deposit midway between solution line and bottom end. Part of the cathode wire substrate is visible on the left.

ally decreasing current density with increasing cathode area under constant current flow [see Part I (1)] and the presence of adsorbed components of the solution affecting the growth habit. These features were not always observed, however. In another specimen, the oriented columnar structure extended all the way to the outer surface, but only along the upper part of the cathode. The lower region showed a transition to the unoriented structure similar to Fig. 1. Examination showed that the oriented and unoriented internal structures are associated with relatively smooth and rough external surfaces, respectively.

The columnar structure evident in the longitudinal view in Fig. 1b is of particular interest in that it shows a discontinuity in direction of the growth cones at the bottom end of the electrode. The longitudinal section at the solution line where the interfacial disk was originally attached (Fig. 1a) showed only the horizontal columnar feature.

The conelike structure noted in all the sections of the deposit appears to be identical with that of vapor-deposited silicon carbide (2) and pyrolytic graphite (3, 4). The growth cones are all of the continuously nucleated type shown schematically in Fig. 12 of Ref. (3) and as an actual deposit in Fig. 2B of Ref. (2). In the case of pyrolytic graphite, such continuous nucleation has been attributed to relatively large agglomerations of carbon being deposited with much finer particles (3). However, unlike the vapor deposits, the growth cones at the bottom end of the copper electrode shown in Fig. 1b are parallel with the axis of the electrode rather than perpendicular to the surface of deposition, and in place of continuous radiation of deposit around the corners at the electrode tip, there is an abrupt change from horizontal to vertical growth. If the direction of growth of the cones in the electrodeposit follows current flow lines as indicated by the deposit in Fig. 1c and that along the axis of the electrode in Fig. 1a and b, then the deposit at the electrode tip implies a discontinuous pattern of current flow lines at the corners of the tip.

Deposit at the air-solution interface.—In several instances, the interfacial disk-shaped deposit was only loosely held to the wire cathode, as was evident in its easy detachment enabling it to be lifted off along the wire. This suggests a primarily mechanical contact between the disk and the electrode rather than the presence of actual chemical bonds of the normal metallic type, as might be expected if the disk growth occurs and originates from a preexisting conductive surface film. On the other hand, it might be possible, although it appears less likely, that a thin or brittle interfacial deposit actually bonded to the wire at the meniscus could also result in the observed easy detachment of the disk.

The cross section of the interfacial disk shown in Fig. 2 reveals a columnar or conelike structure in all regions. This is just visible in the low-power micrograph of Fig. 2a taken in ordinary illumination but more clearly revealed when examined in polarized light and under greater magnification as shown in Fig. 2b and c. An enlarged view of one of the wings is shown under ordinary illumination in Fig. 2d, slightly defocused to bring out the obvious laminar pattern in the deposit. The similarity of the structure of this copper deposit with those of silicon carbide (2) and pyrolytic graphite (3, 4) is apparent not only with respect to the growth cones perpendicular to the substrate surface but also with respect to the laminar pattern. The heavy line running midway through the deposit in Fig. 2d was probably caused by a current interruption leading to a discontinuity in the deposition process.

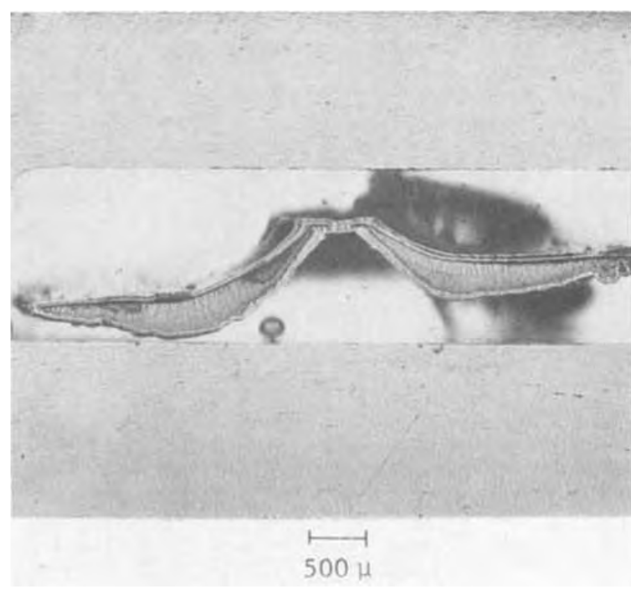

Fig. 2a. Vertical cross section of interfacial disk

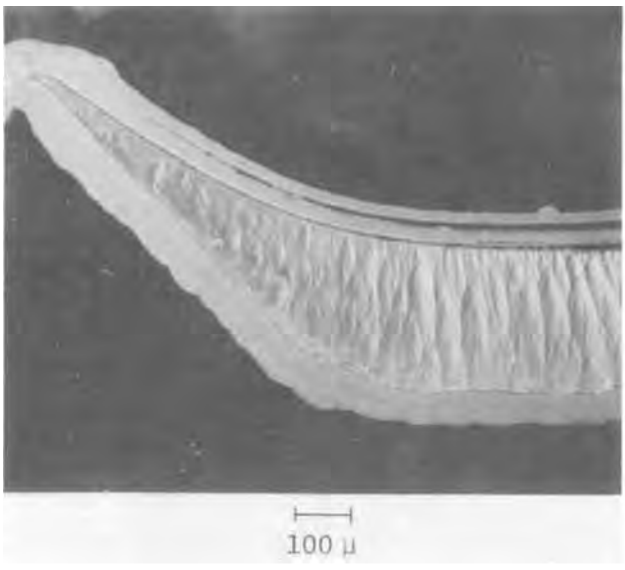

Fig. 2b. Vertical cross section of one wing of the interfacial disk under polarized light.

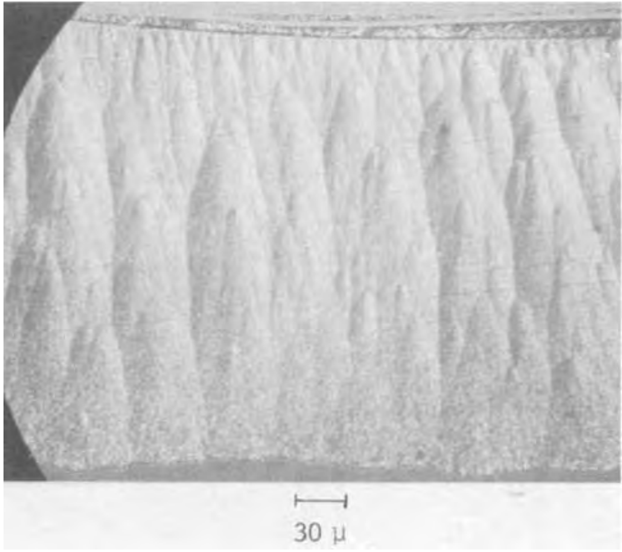

Fig. 2c. Vertical cross section of interfacial disk. Enlarged view under polarized light, showing columnar structure.

The orientation of the growth cones in the interfacial disk shown in Fig. 2 indicates that nucleation occurred at the surface of the electrolyte, along the air-solution interface. Growth perpendicular to this interface took place at all times, even within the meniscus. There is no evidence in the photomicrographs to indicate nucleation at the surface of the wire electrode with growth radiating out along the air-solution interface and perpendicular to the electrode axis. In fact, examination of Fig. 1a shows that the normal horizontal growth cones on the electrode just below the meniscus are prevented from continued growth by the downward-growing interfacial disk. Furthermore, the photomicrograph of the bottom end of the cathode in Fig. 1b seems to indicate that growth cones normally develop in a fixed orientation determined by the manner in which the growth begins, and that this orientation continues with the new cones as the deposit grows in a lateral direction. Presumably, the growth pattern of the interfacial disk is no exception.

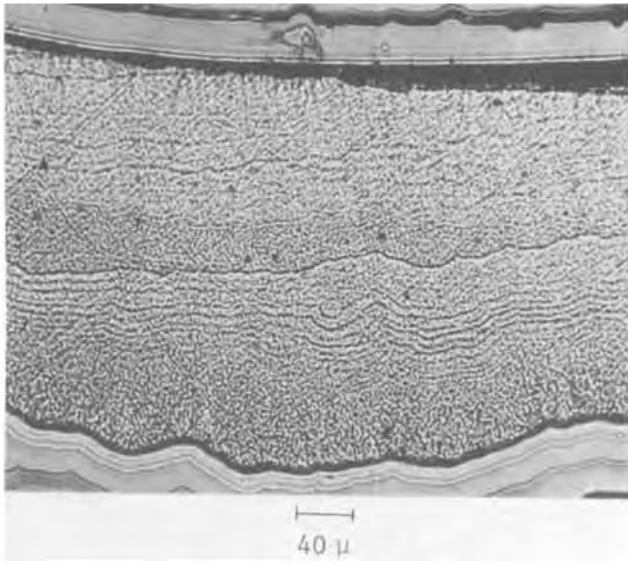

Fig. 2d. Vertical cross section of interfacial disk under ordinary illumination, showing laminar pattern.

Summary and Conclusions

1. Metallographic examination of cross sections of copper deposits formed at the cathode and along the air-solution interface, and caused by small amounts of norvaline in the acid copper sulfate electrolyte, shows growth cones extending downward from the interface into the solution.

2. The downward orientation of the growth cones, with no evidence of horizontal growth cones at the air-solution interface near the cathode, supports the view that deposit nucleation occurs at the liquid surface and that a conductive surface film is probably present as a preexisting condition for the nucleation.

3. The assumed conductivity of the interfacial film is considered to arise from the presence of copper powder formed at the cathode, in conjunction with reaction products arising from oxidation of the norvaline at the copper anode (1).

4. The disk-shaped deposit was sometimes easily detached from the cathode by lifting off along the wire, indicating mainly a mechanical contact with no particular metallic bond between the disk and the cathode wire. This is consistent with downward growth of the disk from a preexisting conductive surface film.

Electrode Kinetic Studies on Electro-organic Syntheses Involving Carbonium Ions

II. Anodic Oxidation of Acetate Ions in Presence of Dimethylformamide

G. Bélanger,* C. Lamarre,* and A. K. Vijh*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

The anodic oxidation of acetate ions in (nominally nonaqueous) glacial acetic acid and in glacial acetic acid-dimethylformamide solutions has been examined on platinum at various temperatures between 25° and 75°C. Potentiostatic and potentiodynamic techniques were used in conjunction with reaction product analysis by infrared and NMR. The real heat of activation at the reversible potential for the Kolbe reaction in glacial acetic acid is 53 kcal $mole^{-1}$. Also, acetate ions can undergo oxidation at low potentials (*e.g.*, 0.45V *vs.* RHE) when the reaction is carried out at a high temperature (*ca.* 75°C). The oxidation of DMF is indicated around 1.1-1.5V at temperature above 55°C, both in potentiostatic and potentiodynamic profiles. The product analysis shows that oxidation of DMF also occurs at high potentials (*e.g.*, 2.37V) in parallel to the Kolbe reaction. The product of DMF oxidation at this potential is N-acetoxymethyl N′-methylformamide; the coulombic efficiency for the formation of this product at 2.37V is about 5%.

In the first report (1) in this series of publications, anodic oxidation of acetate ions to methyl acetate, on a graphite electrode, was examined from an electrode kinetic point of view. The purpose of the present work was to investigate some aspects of the anodic oxidation of acetate ions in acetic acid in the presence of dimethylformamide (DMF) on a smooth platinum electrode. This has already been examined from a synthetic point of view by Ross (2) who suggests that the following reactions can occur

$$H{-}C({=}O){-}N(CH_3)_2 \xrightarrow{\text{anode}} H{-}C({=}O){-}N^{+}(CH_3)_2 + e \quad [1]$$

$$H{-}C({=}O){-}N^{+}(CH_3)_2 \xrightarrow{\text{anode}} H{-}C({=}O){-}N(\overset{+}{C}H_2)(CH_3) + H^{+} + e \quad [2]$$

$$H{-}C({=}O){-}N(\overset{+}{C}H_2)(CH_3) + CH_3COO^{-} \xrightarrow{\text{solution}} H{-}C({=}O){-}N(CH_3){-}CH_2{-}O{-}C({=}O){-}CH_3 \quad [3]$$

Product

Recently, Ross *et al.* (3) have also reported some current potential studies, both steady-state and cyclic voltammetric, on the above system. The present work explores these electrode kinetic aspects in somewhat more detail, especially with regard to the effect of temperature on the reaction. In order to obtain this information, it was necessary also to investigate the temperature effects on the oxidation of the acetate ions themselves, which has been examined previously only quite briefly (4).

Experimental

All experimental details except the following have been described recently (1).

Smooth platinum wires, sealed into Pyrex in open flame with subsequent thorough cleaning were used as the working electrodes. The platinum wire was 99.999% pure and was supplied by the Engelhard Industries Ltd. The DMF was Baker analyzed reagent.

The steady-state current-potential relationships were recorded by the automatic procedure described previously (5). All potential values refer to the hydrogen electrode in the same solution and are designated by the symbol, E_H.

Although the usual precautions to eliminate moisture from the acetate/acetic acid solutions were taken, the solutions must be presumed to contain traces of water since the experiments were not conducted in a controlled-atmosphere chamber.

For the analysis of reaction products, a large smooth platinum foil (10 cm^2) was used for the galvanostatic electrolysis of a 1M DMF plus 1M potassium acetate in glacial acetic acid solutions. The current density used was 1.5 mA/cm^2 and the electrolysis was carried out for 5 days at 78°-79°C. The product was isolated and identified from its infrared and nuclear magnetic resonance (NMR) spectra by comparing with a known product synthesized chemically by the acetylation of N-hydroxymethyl N′-methylformamide, prepared as described previously (6).

Results and Discussion

Temperature effects in the anodic oxidation of acetate ions.—In Fig. 1, potentiostatic, steady-state current-potential curves for the anodic oxidation of 1M CH_3COOK in acetic acid at smooth platinum are presented for various temperatures. Although steady-state polarization curves were conducted at several temperatures for the determination of ΔH^* values (Fig. 2), the various Tafel plots shown in Fig. 1 and 4 depict only a few representative temperatures in order to avoid cluttering. These curves were corrected graphically for the iR drop. At the higher anodic potentials, there is little hysteresis between the ascending and descending curves. From these corrected current-

potential relationships, a Tafel correlation can be observed for at least two decades. In Table I, we present the experimental values of Tafel slopes and the transfer coefficient β for various temperatures. The latter is constant within the experimental error. The b values

* $\beta = 2.303RT/b\mathbf{F}$.

for the ascending potential steps are greater than $2RT/\mathbf{F}$. This high value of the Tafel parameter has also been observed for the Kolbe reaction (7) at low temperatures (25°C) and was accounted for by a barrier-layer film mechanism (7).

The apparent heat of activation ΔH^* can be evaluated from the log current density *vs.* $1/T$ relationships for a given potential as illustrated in Fig. 2. The slopes as obtained from a least square deviation treatment of the data give value of 11-12 kcal mole^{-1} for the ΔH^*. This heat of activation does not, of course, refer to the value at the reversible potential for the over-all reaction of acetate oxidation

$$2CH_3COO^- \rightarrow C_2H_6 + 2CO_2 + 2e \quad [4]$$

The apparent heat of activation at a given potential, ΔH^*, is related to the apparent heat of activation for the reaction at the reversible potential, ΔH^*_r, by the equation

$$\Delta H^*_r = \Delta H^* + \beta\eta\mathbf{F} \quad [5]$$

where η is the value of the overpotential at which the ΔH^* value has been determined. The reversible potential for the acetate oxidation (*i.e.*, Eq. [4]) in glacial acetic acid is -1.05V (with reference to the reversible hydrogen electrode) (7). If the anodic oxidation of acetate, and hence the determination of ΔH^* is done at 2.5V (*vs.* RHE), as in Fig. 2, the value of the overpotential, η, becomes 3.55V for this case. By using this value of η and the experimental values of ΔH^* (at 2.5V) and β in Eq. [5], one obtains the value of $\Delta H^*_r \simeq 47$ kcal mole^{-1}. This is the value of the heat of activation which is relevant to the process in reaction [4] since it refers to the reversible potential. Alternatively, one could have obtained the same value by determining the exchange current density, i_o, values at various temperatures and then plotting log i_o *vs.* $1/T$; however, extremely long extrapolations needed to obtain i_o values for the present case would make the values thus determined meaningless. The only approximation involved in our determination of ΔH^*_r value, as outlined above, is that the value of β is constant at various temperatures studied. Although the values of β in Table I are not exactly constant, they do not show a systematic variation with temperature and hence must be attributed to a normal scatter of experimental data within a fairly narrow range from which a mean constant value of β may be deduced, as in our calculation.

It is interesting to point out that from the value of the apparent heat of activation at the reversible potential, ΔH^*_r, one can estimate the real heat of activation, ΔH^*_R, for the Kolbe reaction in nonaqueous medium, *i.e.*, for the reaction in Eq. [4]. This real heat of activation is given as (10)

$$\Delta H^*_R = \Delta H^*_r + \beta\,\Delta H^\circ$$

where ΔH° is the heat of the Kolbe reaction (Eq. [4]). This latter thermodynamic quantity has to be estimated from the heats of formation of $CH_3COO^-_{solvated}$, $C_2H_{6_{gas}}$, and $CO_{2_{gas}}$. The last two quantities are available in standard handbooks. The value of the heat of formation of acetate ion in acetic acid has to be approximated to its value in aqueous solution which is -116.84 kcal mole^{-1} (11). The validity of this approximation can be based on the near equality of free energy of formation of acetic acid in aqueous solution and its value in glacial acetic acid (7): the difference between these values is less than 4 kcal mole^{-1}. Since the heat of formation of the proton is defined as zero, one feels that the approximation for the ΔH° is sound. The ΔH° so obtained is equal to 13 kcal mole^{-1} with an uncertainty of ± 5 kcal mole^{-1} arising from the above assumption. Using the experimentally determined β(0.45), the real heat of activation at the reversible potential, ΔH^*_R is estimated at 53 kcal mole^{-1} with an estimated error of ± 3 kcal mole^{-1}.

It should be pointed out that the extremely high (53 kcal $mole^{-1}$) value of ΔH^*_R for the Kolbe reaction (*i.e.*, Eq. [4]) is consistent with other features of this reaction (7, 8) such as: very low exchange current densities, extremely high overpotentials needed to obtain a given rate of reaction, filming of the electrode and hence increase in the reaction resistance during the course of the reaction. No previous data, it is believed, are available for comparing the magnitude of our ΔH^*_R values.

An interesting temperature effect arises in the potentiodynamic profiles (Fig. 3). At a comparable sweep rate, the potentiodynamic profile at 75°C shows an additional anodic peak around 0.45V, which is not observed in the experiments carried out at a much lower temperature (24°C).

The appearance of the new anodic peak indicates that at high temperatures, a noticeable surface reaction between the surface oxides and the adsorbed organic (or its intermediates) occurs giving rise to the new anodic peak at 0.45V. This peak is similar to the one observed in the electrooxidation to CO_2 of other organic fuels, *e.g.*, $HCOO^-$ (9). This assignment of the peak would be consistent with the fact that at high temperatures, complete oxidation of the acetate ions to CO_2 does indeed occur at potentials below *ca.* 0.7V (4).

It has been observed that the peak at 0.45V appears only at low sweep rates (*e.g.*, 50 mV sec^{-1}) whereas it tends to disappear at higher sweep speeds (*e.g.*, 343 mV sec^{-1}). This would suggest that at faster sweep rates, the surface reaction between the oxide and the adsorbed organic does not have sufficiently long opportunity to pass enough charge needed to give rise to a pronounced anodic current peak.

Temperature effects in the anodic oxidation of acetate ions and DMF.—In the potentiostatic, steady-state current-potential curves (Fig. 4) obtained at various temperatures, it is observed that at potentials above 2.1V (*i.e.*, at which the Kolbe reaction commences), there is little difference in the behavior in the presence or absence (Fig. 1) of DMF. At lower potentials, however, at temperature above *ca.* 55°C, new features appear which are presumably associated with the oxidation of DMF. The oxidation of DMF between 1.1 to 2.0V approximately, at 55°C and above, is suggested by the new current inhibition regions appearing in Fig. 4. This type of inhibition inflections are not uncommon for electro-organic oxidations and have been discussed previously by Bagotskii (12), Conway and Gilroy (13), and others (14). The ΔH^* values for the DMF oxidation cannot be determined because of the absence of well-defined Tafel lines, at several temperatures, pertaining to the DMF oxidation (*i.e.*, at potential below 2.0V). The ΔH^* values deduced from the Tafel lines (above 2.1V) in Fig. 4 are comparable to those obtaned from Fig. 1 suggesting thereby that at high anodic potentials oxidation of the acetate is the predominant reaction even in the presence of DMF.

There are some pronounced effects of temperature on the potentiodynamic profiles obtained in solutions containing DMF (Fig. 5). At 25°C there is virtually no difference between this solution containing DMF and the profile obtained for potassium acetate in acetic acid. At 75°C, one clearly observes detailed structure in the profile, including the anodic peak around 0.5V. The

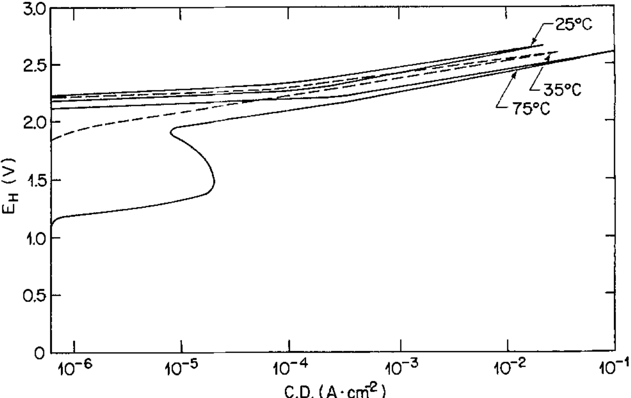

Fig. 4. Same as in Fig. 1 but now the solution made 1M in DMF

		Avg: 0.38 ± 0.01		Avg: 0.45 ± 0.06

peak at 1.35V is perhaps associated with the oxidation of DMF and the one at 0.55V may be attributed to the oxidation of acetate and of a product of the DMF oxidation.

This last hypothesis is confirmed by the fact that the peak at 0.5V increases in magnitude as the number of scans increases, and, as a function of time as shown in Fig. 6. This time effect is more pronounced in the presence of DMF than in the acetate-acetic acid solution. The increase in the anodic current at 0.5V, 1.3V, and higher potentials is concomitant with the diminution in the size of the oxide reduction peak at 0.85V; this oxide peak presumably originates from the presence of traces of water in the solution. The nature of the oxidized species at 0.5V cannot be ascertained but it could be an oxidation current of a byproduct of the DMF oxidation. The increase in current with time could indicate an accumulation of this byproduct in the solution. As the temperature is decreased to 25°C, after several potentiodynamic scanning experiments at 75°C, the peak at 0.5V is still observed which would confirm the suggestion of byproduct accumulation. Such evidence for the formation of this byproduct was not observed in the absence of DMF. For the acetate-acetic acid solution containing no DMF, the profiles at 25°C were identical in fresh solutions and in solutions in which experiments had already been conducted at 75°C.

The Tafel parameters determined from the upper (above 2.0V) part of the steady-state polarization curves are shown in Table II. The Tafel slopes are somewhat larger than those in the absence of DMF. In the potential range in which the reaction products can be practicably determined (*i.e.*, the Tafel region), the Kolbe reaction proceeds with the simultaneous oxidation of DMF that could perhaps influence the Tafel slopes (see below).

The product isolated from the reaction solution after the galvanostatic electrolysis, was identified as N-acetoxymethyl N'-methylformamide

$$\mathrm{H{-}C({=}O){-}N(CH_3){-}CH_2O{-}C({=}O){-}CH_3}$$

The refractive index, the infrared spectrum (2), and the NMR spectrum were identical with those for the same product synthesized by the acetylation of N-hydroxymethyl-N' methylformamide. The coulombic efficiency, assuming a two-electron process was found to be 5.2%. The main reaction at the potential of electrolysis (2.37V) is the Kolbe reaction. This confirms the results obtained by Ross *et al.* (3) where similar results were obtained at 25°C.

It may be added that in the anodic or cathodic charging curves triggered from the rest potentials (around 1.0V), in solutions containing DMF, no arrests were observed. This would indicate an absence of electroactive (*i.e.*, which can be deposited on, or stripped off from, the electrode in a transient) adsorbed species. Similarly, no arrests or inflections were observed in the fast (time of decay less than 1 sec) open-circuit potential decay profiles taken from various anodic potentials. In the slow (time of decay of the order of 1 min) open-circuit decay profiles, an "arrest" characteristic of the presence of a "depolarizer" was, however, observed in solutions with or without DMF. The "depolarization" effect must be associated with the relatively slow adsorption (or desorption) of intermediates (*e.g.*, traces of CH_3OH) that might be produced in an electro-oxidation such as the present one. It is obvious that open-circuit profiles such as these cannot be subjected to a meaningful analysis and are hence not shown here.

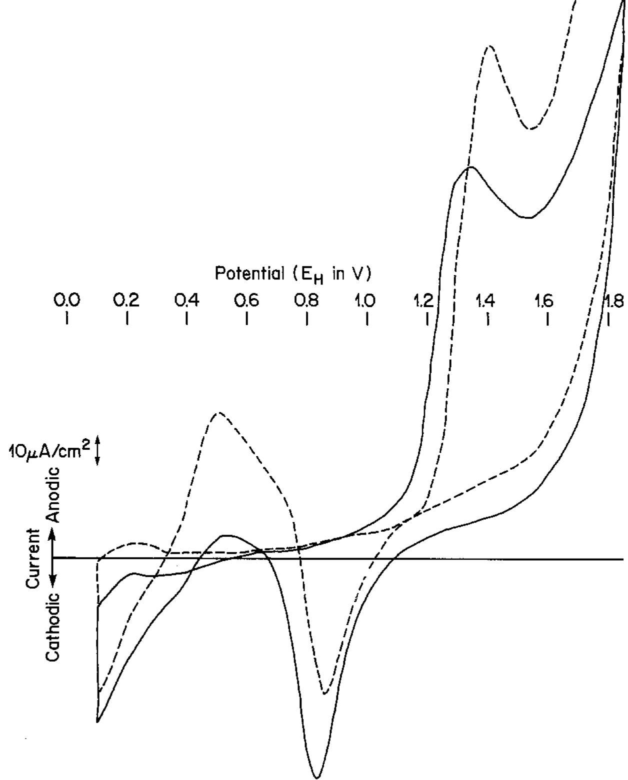

Fig. 6. Time effect for a 1M DMF and 1M CH_3COOK in CH_3COOH (T = 75°C; sweep rate = 50 mV sec^{-1}). Curve B, (dashed profile), 5 single sweeps after curve A (solid profile) and 1 hr interval between these two curves.

Conclusions

1. The apparent and the estimated real heats of activation (at the reversible potential) for the Kolbe reaction in acetate-glacial acetic acid solutions are 47 and 53 kcal $mole^{-1}$, respectively.

2. At temperatures above 55°C, the acetate ions tend to undergo anodic oxidation at potentials as low as 0.45V (RHE).

3. In the steady-state polarization curves of acetate-acetic acid-DMF solutions at smooth platinum, DMF undergoes oxidation between 1.1 and 1.5V at high temperatures (*e.g.*. 75°C). This behavior is also confirmed in the potentiodynamic profiles.

4. From the product analyses (which had to be carried out at high potentials in order to obtain reasonably high rates)at 2.37V, it is indicated that the oxidation of DMF proceeds parallel to the Kolbe reaction with a coulombic efficiency of the former equal to about 5%.

Acknowledgments

Thanks are due to Mr. Réal Jacques for his skillful contributions to the experimental manipulations, Mr. Yves Giguère for infrared analyses, Dr. Yvon Pépin, Chemistry Department, Université du Québec, at Montreal, for NMR analysis, and Mr. A. Bélanger for helpful discussions.

On the Electrochemical Nucleation of Silver on Different Crystal Orientations of Graphite

Ikram Morcos*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

An attempt was made to determine experimentally the nucleation overpotential of silver on high-pressure, stress-annealed pyrolytic graphite as a function of crystal orientation, surface oxidation state, and solution composition using both galvanostatic and potentiostatic pseudo-steady-state current-potential relationships. Silver deposits on the edge orientation from silver perchlorate with a nucleation overpotential of about 30 mV but does not adhere to cleavage orientation at the conditions of the study. The deposition of silver takes place on both cleavage and edge orientations from silver cyanide solution and is accompanied with a nucleation overpotential of about 200 and 250 mV, respectively.

A knowledge of the magnitude of nucleation overpotentials of metals on graphite and carbon substrates is useful for both fundamental and applied aspects of electrodeposition. In spite of the progress made in understanding the kinetics of electronucleation (1-5), there is a lack of reliable data on the values of nucleation overpotentials of metals on graphite. Available information (1) appears to have been obtained under poorly defined experimental conditions and on carbon substrates with poorly defined surface structure and oxidation state. The present availability of high-pressure, stress-annealed pyrolytic graphite with well-oriented structure similar to that of single crystal material permits a more reliable determination of nucleation overpotentials. The results recently reported (7-8) on the electrochemical nucleation of mercury on the latter type of graphite are strongly in conflict with both theoretically predicted (6) and experimentally determined values on carbon samples used in previous work (9).

In the present work an attempt has been made to obtain some reliable values for the nucleation overpotential of silver on well-oriented (ZYH type) pyrolytic graphite. The effect of crystal orientation, surface oxide films, and solution composition has also been explored using both galvanostatic and potentiostatic pseudo-steady-state current-potential scanning methods. The effect of solution composition was explored by performing the study in solutions containing either simple salt (silver perchlorate in perchloric acid) or complex salt (0.19*N* silver cyanide). Possible variations in the oxidation state of the graphite surface were examined by obtaining cathodic voltammograms in oxygen-free perchloric acid solutions.

Experimental Procedure

Galvanostatically controlled current-potential relationships were obtained by applying the circuit diagram shown in Fig. 1. A Tacussel function generator was used as a source of scanning voltage with a linear scanning rate of 1 $\mu A/sec^{-1}$. A Wenking potentiostat (Type 68FR 0.5) was used to convert the scanning

voltage into the applied galvanostatic current by connecting it (10) in the manner shown in Fig. 1. A Honeywell X-Y recorder was used to record the potential as a function of the current. Potentiostatically controlled current-potential relationships were obtained by connecting the potentiostat in the more conventional manner. The same potentiostatic method was applied to produce the cathodic voltammograms in perchloric acid solutions. All potentiostatic experiments were performed at a scan rate of 0.2 V/min^{-1}.

The electrochemical cell consisted of two compartments, one for the reference electrode and the other for both the working and counterelectrode. As a reference electrode a silver wire was used in silver perchlorate solution and a saturated calomel in both perchloric acid and silver cyanide solutions. The former reference electrode exhibited a potential of 0.666V (NHE). In solutions containing silver ions two silver plates were used as a counterelectrode. In voltammetric experiments in perchloric acid the counterelectrode was a spectroscopic graphite rod to avoid contamination of the solution with silver ions. The rotating disk was applied throughout the work at a speed of 1600 rpm. Electrodes of both cleavage and edge orientations were machined and fitted to the Teflon coated steel shaft of the rotating disk assembly as described elsewhere (11). Solutions were prepared from AR quality salts and water triply distilled twice from a permanganate solution. All experiments were carried out in helium saturated solutions.

Results and Discussion

The electrodeposition of a metal on a foreign substrate with which it does not form mixed crystals involves the formation of a new phase, which, therefore, requires an energy of nucleation. The latter is provided by a nucleation overpotential which is necessary to bring the concentration in the double layer (12) to a certain supersaturation value.

Nucleation overpotential is experimentally well defined in galvanostatically controlled current-potential relationships. When the current is slowly increased, the overpotential with respect to a reference of the same metal in the test solution, will first increase rapidly at a low current density until the first layer of metal nuclei is deposited on the inert substrate. A further increase in the current density will cause a decrease in the overpotential as the deposition of the metal takes place on the same metallic surface and therefore results in a well-defined maximum. If, as in many cases, the reduction of the metal ion on the same metal substrate occurs reversibly, the increase in current density following the formation of the first layer of metal nuclei, in the absence of concentration polarization, will take place at an almost constant potential. Nucleation overpotential can then be defined as the difference between the maximum potential and that corresponding to the reduction of the metal ion at constant potential.

Figure 2 shows galvanostatically controlled current-overpotential relationships for the reduction of Ag^+ ion from helium-saturated silver perchlorate solution (0.05N silver perchlorate in 1N perchloric acid) on both cleavage and edge graphite orientations. No electrode pretreatment was applied after exposing the new surface. Both plots of Fig. 2 show well-defined maxima at overpotentials of −52 and −46 mV for cleavage and edge graphites, respectively. In the case of edge graphite the increase in current following the maximum occurs at a constant potential. The difference of 14 mV between that constant potential and the reversible reference is a slight activation polarization because of the high current density caused by the small true area of formed silver nuclei. Such is not the case with cleavage graphite where it is observed that the potential shows a linear increase with the increase in current. Figure 2 then clearly indicates that the nucleation and deposition of silver from a silver perchlorate solution occurs only on edge but not on

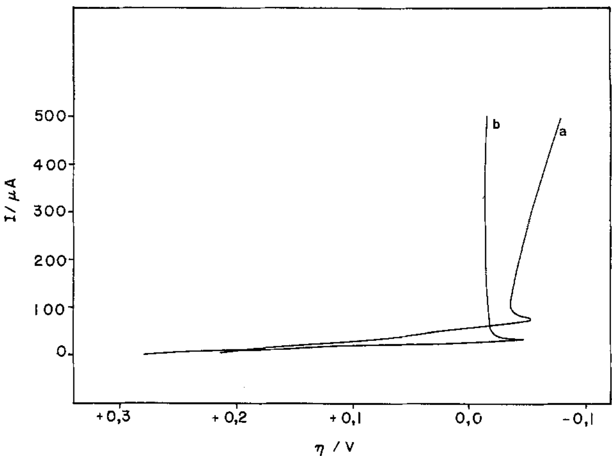

Fig. 2. Galvanostatic current-overpotential relationships for the reduction of Ag^+ ion from silver perchlorate on both cleavage and edge orientation of high-pressure, stress-annealed pyrolytic graphite. a, Cleavage graphite; b, edge graphite.

cleavage graphite. The appearance of the maximum in the case of cleavage graphite indicates that nucleation actually starts to take place on the surface, but, because of the lack of sufficient adhesion forces between the graphite surface and the formed nuclei, the process of nucleation is discontinued, the formed nuclei are removed, and the further reduction of silver ions continues to take place on the graphite surface. On the basis of the previously stated definition, nucleation overpotential, according to Fig. 2, is 32 mV in the case of edge graphite and 16 mV at the initial stage of nucleation in the case of cleavage graphite. These values are considerably smaller than a value of 100 mV reported in Ref. (1).

The observed difference in the activity of cleavage and edge orientations toward nucleation is consistent with the known differences in the chemical and electrocatalytic activity of both surfaces. Studies on the electroreduction of oxygen (11) on both surfaces have shown that edge graphite is much more electrocatalytically active than cleavage graphite. Furthermore the determination of cleavage graphite's surface tension (about 35 dynes/cm) (13) and the electrocapillary data obtained on the cleavage surface/electrolyte interface (14) indicates that ionic adsorption is strongly inhibited on that surface from aqueous solutions. The chemical and electrochemical inertness of cleavage orientation results from the lack of any unsatisfied valencies or polar surface structures. The atoms at the cleavage surface have satisfied valencies and are symmetrically arranged in rings parallel to the surface which are separated from successive carbon layers by only weak van der Waals forces. On the other hand, the edge orientation exposes different organic functional groups which can exist in different oxidation states.

Figure 2 indicates that the open-circuit potential of graphite in silver perchlorate solution is strongly shifted to more anodic values as compared with the corresponding reversible Ag/Ag^+ couple. The observed potential is probably a mixed one which consists of both the Ag/Ag^+ couple and the potential established between the surface organic functional groups and the hydrogen ions of the solution. Although only a very small number of these groups exists on the cleavage surface at sites of crystal defects, they can still have a similar effect on the open-circuit potential. Because these organic functional groups may exist in different oxidation states, it may be suggested that the maxima of Fig. 2 result from the reduction of a surface oxide rather than from the nucleation of silver on graphite.

The reduction of graphite's surface oxide can be identified with the appearance of peaks in cathodic voltammograms obtained in inert solutions. In two different studies (15-16), carried out on ordinary

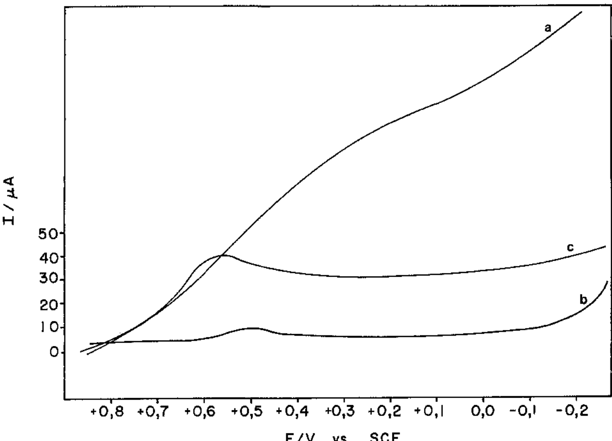

Fig. 3. Cathodic voltammograms on both cleavage and edge graphites in 1N $HClO_4$. a, Cleavage graphite; b, edge graphite without pretreatment; c, edge graphite pretreatment in conc. HNO_3.

pyrolytic graphite in 1M H_2SO_4, it was reported that the oxide film formed by either chemical or electrochemical treatment is reduced at 0.5V (*vs.* SCE). The latter value is considerably more anodic than the potentials at which the maxima of Fig. 2 occur, and accordingly these maxima result from nucleation and not from the reduction of surface oxides. However, in order to confirm this latter conclusion it was considered necessary to obtain the cathodic voltammograms on the same graphite samples used in the present study and in perchloric acid rather than in sulfuric acid. Figure 3 shows the result of such experiments and it is seen that a small peak appears only in the case of edge graphite at 0.5V (*vs.* SCE). The absence of organic functional groups on cleavage graphite explains the absence of a well-defined peak in its voltammogram. The relatively large current observed on cleavage graphite probably results from charging of the double layer. When edge graphite is pretreated in concentrated nitric acid the peak becomes more prominent but still takes place at approximately the same potential. As a further confirmation, the galvanostatic current potential relationships for the reduction of Ag^+ ion were obtained on both graphite orientations which were pretreated in concentrated nitric acid. Figure 4 shows that the section of the plots which is related to nucleation for both types of graphite is almost the same as that shown in Fig. 2. From this it is concluded that even when an oxide film is deliberately formed before the study of electrochemical nucleation, reduction occurs at a potential more anodic than that corresponding to nucleation. The higher currents observed in Fig. 4 as compared to Fig. 2 at potentials more positive than that corresponding to nucleation are probably due to surface oxide reduction. Pretreatment in concentrated nitric acid oxidizes the cleavage surface and exposes the organic functional groups. Such formation and subsequent reduction of the organic functional groups on cleavage surface has probably resulted in the observed shift of the maximum overpotential into more negative potentials (compare Fig. 2a with Fig. 4a). It is probable that the reduction of such film activates the surface towards nucleation.

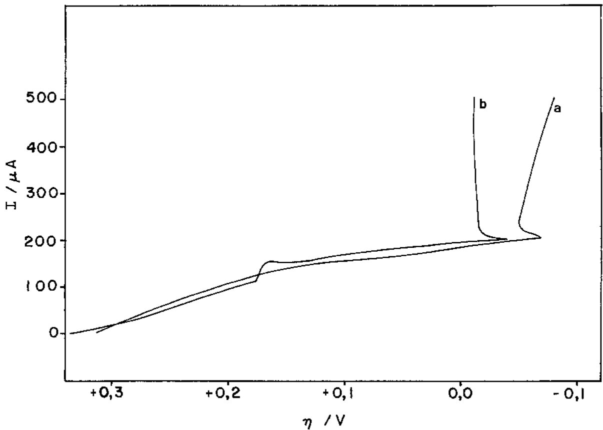

Fig. 4. Galvanostatic current-overpotential relationships for the reduction of Ag^+ ion from silver perchlorate on both cleavage and edge graphites which have been pretreated in conc. HNO_3. a, Cleavage graphite; b, edge graphite.

Figure 5 shows that nucleation overpotential of silver under potentiostatic conditions on both cleavage and edge graphite at the initial stage of deposition is 30 mV. This value is approximately the same as that determined by galvanostatic experiments on edge graphite. With the increase in current, the latter value shows only a slight increase because of the activation overpotential caused by the small true area but soon reaches a constant value. One observes, however, from Fig. 5 that this initial nucleation overvoltage in the case of cleavage graphite shows a linear increase with the increase in current for the reasons already mentioned in discussing the galvanostatic experiments.

The study of electrochemical nucleation on foreign substrates (particularly on an organic substrate such as graphite) is important in applied aspects of electrodeposition. This is because the important property of adhesion can be related to the magnitude of nucleation overpotential. It is known that conditions which favor microcrystalline deposits also favor the formation of new nuclei and better adhesion properties (17). The higher the nucleation overpotential the smaller is the grain size and therefore the stronger will be the adhesion between the deposited metal and the foreign substrate.

Such correlations between nucleation overpotential, adhesion, and grain size explain the common use of complex salts in industrial electrodeposition. Silver, for example, is deposited from alkaline silver cyanide solution. The much higher stability constant (5.6×10^{18}) of silver cyanide $[Ag(CN)_2]^-$ results in a much less concentration of silver ions. Consequently a higher magnitude of nucleation overpotential is required to break the strong bonding forces and bring the ionic concentration into the required supersaturation value. Figure 6 compares the galvanostatic current-potential plots for the reduction of silver cyanide on both cleavage and edge orientations. The nucleation overpotential is well defined and is 0.2 and 0.25V on cleavage and edge, respectively. It is obvious that the silver nuclei under these conditions can adhere to the inert cleavage surface. The accompanying overvoltage provides the silver atoms with the required energy to form the metal-graphite bonding.

Photoeffects at Polycrystalline Tin Oxide Electrodes

Hasuck Kim and H. A. Laitinen*

School of Chemical Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

The electrochemical behavior of thin-film polycrystalline tin oxide electrodes under subbandgap energy photoexcitation has been investigated. Photocurrents were dependent on the intensity of the light, wavelength, and the applied potential. The photocurrent spectrum showed a sharp decrease near the bandgap energy. This photocurrent is due to the oxidation of water in the electrolyte by holes at the permitted energy levels in the bandgap region. These energy states are formed by the presence of impurities, which are largely halides remaining from the preparation steps, grain boundaries, and adsorbed foreign molecules. A superficial hydrogen bonding interaction between oxide layers of SnO_2 and water molecules is proposed for the hydrated surface of tin oxide.

Long after the first photovoltaic effect was noticed by Becquerel, many investigators observed photocurrents at various electrode materials; such as mercury (1-3), elemental germanium (4), CdS (5), ZnO (6, 7), GaP (8), GaAs (9), and CuO (10). In all the semiconductor studies, single crystals were used. It was found that the bandgap energy illumination produced electron hole pairs which participated in the electrochemical process, *i.e.*, electrons for the cathodic photocurrent in p-type electrodes, and holes for the anodic reaction in n-type materials. It was also found that the extra currents were due to the electrochemical decomposition of the electrode material under illumination.

* Electrochemical Society Active Member.

Key words: semiconductor, thin-film electrode, transparent electrode, photocurrent, tin oxide electrode.

One of the advantages of the use of a semiconductor electrode in the study of electrochemical reactions is the fact that the charge transfer processes occur only via the energy bands. Therefore, in the presence of organic dye in the electrolyte, charge transfer processes involving the excited states can be studied by observing dye sensitized photocurrents (11).

A semiconducting thin film of tin oxide on glass or quartz has shown some distinctive advantages over metals as an electrode in electrochemical investigations. Nearly metallic conductivity, optical transparency, high oxygen overvoltage, low background current, absence of any electrochemically active oxide layer, chemical durability, and excellent mechanical stability of the film made it possible to study many special electrochemical applications. Detailed applica-

tion of polycrystalline tin oxide material as an electrode can be found in Ref. (12).

Even though there are many applications and advantages in the use of tin oxide electrode, little attention has been paid to the nature and to the physical properties of the surface. Accordingly, this study of photoexcitation with radiation of energy less than the bandgap energy is one of a series (13, 14) to characterize the electrode surface.

Experimental

Reagents.—Chemicals used in this study were reagent grade and were used without further purification except where specifically noted. Stannic chloride, stannic bromide, hydrobromic acid, and tetrabutyltin were purified by vacuum distillation. Rhodamine B was recrystallized from ethanol. Solutions were made using laboratory distilled water which had been distilled twice.

Preparation of tin oxide electrodes.—The procedure in Mochel's patent (15) was generally followed. In addition to stannic chloride-hydrochloric acid, a stannic bromide-hydrobromic acid mixture was also used. The coating of tin oxide was obtained by blowing the spray mixture onto a hot quartz or glass substrate using a conventional all-glass atomizer. Each spray lasted for about 5 sec followed by a 3 min waiting period to prevent excessive cooling of the hot substrate. After each spray, the substrate was rotated clockwise by 90° to get a uniform thickness over the surface. The surface of the tin oxide film was then polished with Gamma polishing alumina[1] and Selvyt polishing cloth.[1] The commercial tin oxide coated glass (IRR) was used as substrate instead in the case of double coated electrodes. More details about the coating, polishing, and the cleaning, are given in Ref. (16).

The thickness of the coating was determined by measuring interference fringes (17) obtained by scanning the spectral region from 250-700 nm.

Construction of electrolyte cell.—The cell used for the photoexcitation studies on tin oxide is shown in Fig. 1. Its design was similar to that reported earlier (13), but it had a side flange and a side conical end as shown. The end of this side branch was polished flat. The electrical contact to the semiconductor electrode surface was made by a flat, highly polished copper "O" ring tightened firmly onto the electrode by three 4/40 machine screws and a Plexiglas support. A Teflon washer which provided both a tight seal between the cell and the electrode and defined the area of the electrode was placed tightly inside the metal "O" ring. To insure a good seal it was necessary to polish the Teflon washer on a plate of ground Lucite until a completely smooth surface was obtained. The area of the electrode was 0.124 cm^2.

Photocurrent and photovoltage measurements.—The experimental setup is shown in Fig. 2. A saturated potassium chloride calomel electrode (SCE) with a porous Vycor junction was used as a reference electrode. A Luggin capillary filled with saturated potassium nitrate solution was placed between the reference Vycor junction and near the working electrode.

Under a constant applied potential, the SnO_2 electrode in contact with electrolyte was illuminated from the backside for a while; then the light path was interrupted manually with a metal sheet for the photocurrent measurement. The net change of current or voltage after it reached a steady-state value was taken as the photocurrent or photovoltage. The light source was a 100W xenon arc lamp with a Bausch and Lomb High Intensity Grating Monochromator (33-86-25-02).

Since the light intensity of the lamp was not uniform throughout the spectral region, the photocurrent was normalized to unit light intensity after the absolute intensity at each wavelength had been measured using a Hewlett-Packard Model 8334A Radiant Flux Detector with a Model 8330A Radiant Flux Meter.

Adsorption of rhodamine B.—C-14 labeled rhodamine B was prepared by condensation between m-diethylaminophenol and C-14-phthalic anhydride (18). A double coated tin oxide electrode was prepared by the same procedure as the electrodes used in the photoexcitation experiments. The electrode was first placed in a known concentration of labeled dye in 1*M* KNO_3 solution for a given time with or without applied potential, then was taken out. The electrode was washed thoroughly with distilled water using a wash bottle. Absolute ethanol (35 drops) was used to dissolve any adsorbed rhodamine B molecules from the electrode surface. Fifteen milliliters of scintillation liquid was then added to a counting vial in which 35 drops of ethanol had already been collected. Disintegration rates were counted using 2003 Packard Tri-Carb Liquid Scintillation Spectrometer seven times for 10 min each to achieve the desired S/N ratio.

Results and Discussion

Photocurrent measurements.—An increase of anodic residual current was observed by illumination with photoenergies which are less than the energy gap between the conduction and valence bands. The profile of photocurrent was dependent upon wavelength and applied potential. It decayed to a steady value after a sharp increase. Since the time constant of the electrode/electrolyte system was found to be 0.17-0.18 sec, while the photocurrent-time curve provided 0.3-1 sec, a simple charging-discharging of the double layer capacitance cannot be the total rate-determining process. It was also found that the photocurrent was directly related to the intensity of the light.

In order to find the most suitable surface for this study several different types of tin oxide material were examined. Since minority carriers, as mentioned before, play an important role in the photocurrent process (6), use of a poorly conductive electrode material is

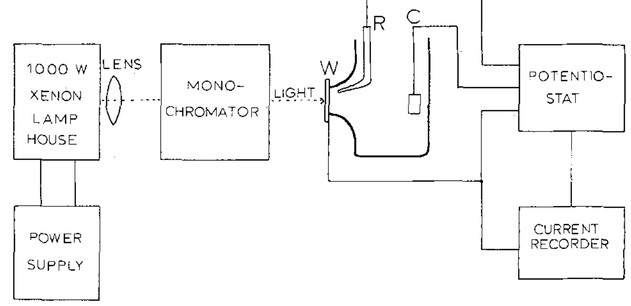

Fig. 2. Block diagram of experimental setup. W, Working electrode; R, reference electrode; C, counterelectrode.

desired. The source and nature of conductivity of "undoped" tin oxide film has been studied (16). Although the main source of conductivity is attributable to halides remaining after hydrolysis, the nonstoichiometry of tin oxide also contributes appreciably. A poorly conductive electrode can give a higher value of the ratio of the excess holes produced by photoenergy to major carrier concentration than a highly conductive electrode under the same light intensity. It also offers an electrode material with fewer impurities to cause additional complexities. But a large *IR* drop has to be considered when a highly resistive electrode is used. In order to eliminate this *IR* drop, a double coating technique was developed. The second layer of a highly resistive tin oxide film was obtained by use of nondoped stannic bromide on a commerical antimony-doped tin oxide surface. The thickness of the second layer was determined indirectly by measuring the thickness of another film obtained simultaneously on Pyrex substrate and was found to be about 0.4 μm. It is quite possible that antimony in the first layer may diffuse to some extent into the second layer during the preparation step. This electrode, however, behaves like a highly resistive one at the electrode-electrolyte interface yet has a high conductivity to facilitate passage of electricity.

The double coated electrode prepared from stannic bromide, which has the most resistive surface among the electrodes, does give a higher photocurrent and a sharper slope than any other electrode. The sharper slope indicates a clear band separation, *i.e.*, fewer impurities or energy states present between bands in the crystal structure. Therefore, double coated electrodes prepared with stannic bromide were used throughout this investigation.

Figure 3 shows a series of photocurrent spectra at different applied potentials obtained in 1*M* KNO_3. The shapes of the spectra are similar. With an ideal tin oxide single crystal, the photocurrent would be noticeable only with bandgap energy illumination, corresponding to the energy at which electrons in the valance band would be promoted to the conduction band, leaving holes behind. No electron hole pairs would be produced by illumination of energies less than the bandgap energy.

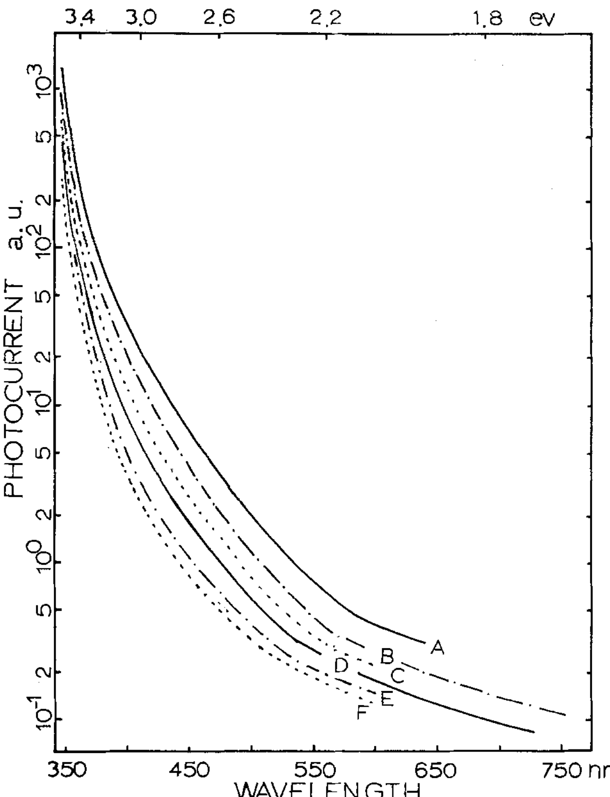

Fig. 3. Photocurrent spectra in 1*M* KNO_3. $|\Delta\lambda| = 10$ nm. Double coated electrode with $SnBr_4$. a.u., Arbitrary units; A, at 1.3V vs. SCE; B, 1.1V; C, 0.9V; D, 0.7V; E, 0.5V; F, 0.4V.

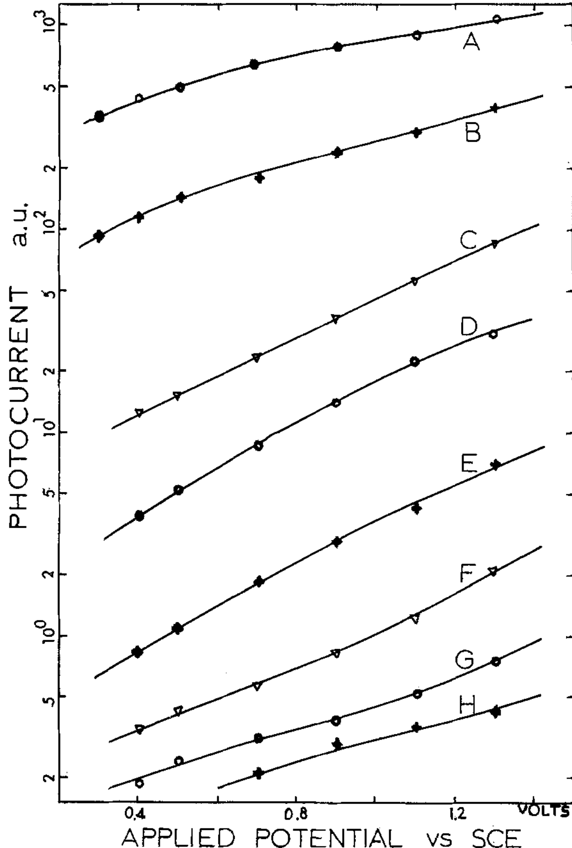

Fig. 4. Effect of applied potential on photocurrent in 1*M* KNO_3 A, 350 nm; B, 360 nm; C, 380 nm; D, 400 nm; E, 450 nm; F, 500 nm; G, 550 nm; H, 600 nm.

However, as shown in Fig. 3, the polycrystalline tin oxide electrode shows an appreciable photocurrent in wavelengths longer than 335 nm which corresponds to the bandgap energy of 3.7 eV. Therefore, there must be a number of energy states between bands. It is known that physical imperfections of a crystal, chemical impurities, grain boundaries (19), adsorbed foreign molecules, and surface states can introduce discrete energy levels into the forbidden gap much as donor and acceptor ions do in the case of a doped semiconductor.

We know there are "unintentionally added" bromides in the tin oxide electrode (16) which can be easily ionized at room temperature. These ionized donors introduce energy levels which are distributed according to Fermi-Dirac statistics. Therefore, the observed photocurrent near 350 nm decreases sharply.

As Fig. 4 shows, there is no saturation phenomenon as observed in single crystals of ZnO (6), SnO_2 (20), and CdS (1) with bandgap energy illumination in which the photocurrent is determined only by the diffusion rate of holes to the surface. In a polycrystalline material, holes produced by photoenergy could be recombined through the adjacent energy states before they reach the surface to participate in electrochemical processes.

The potential dependence of the charge transfer rate could be another reason for polycrystalline tin oxide electrodes not having a saturation phenomenon. The tunneling probability of an electron into the bulk of the electrode is governed by the shape of the energy barrier (14) and thickness of the space charge layer, which in turn primarily depends upon the density of charge carriers in the bulk and on the applied potential, since applying a different potential to a semiconductor electrode results only in a variation of the electrical potential difference in the space charge layer

without a major change in the Helmholtz double layer structure (21). Figure 5 reveals schematically the effect of applied potential on the potential energy diagram of semiconducting tin oxide. The tunneling probability or electron transfer coefficient would be much higher at the higher anodic potential than at a low anodic potential.

A change of the *p*H of the electrolyte, on the other hand, is believed to influence the Helmholtz layer, flatband potential, and surface hydroxyl groups. These changes occur at or near the electrode-electrolyte interface while the applied potential or electrode material can change the internal properties of the electrode.

HNO_3 and KOH were used to adjust *p*H values in order to eliminate any possible specific adsorption of buffer systems on the electrode surface. As shown in Fig. 6, a steady increase of the photocurrent in the range of *p*H from 3 to 10 can be explained by a continuous change of the flatband potential at a rate of 60 mV/*p*H unit (20).

A simple shift of the flatband potential by 60 mV/*p*H unit, however, cannot explain large changes of the photocurrent below *p*H = 3 and above *p*H = 10. In addition to the shift of the flatband potential, change of the charge transfer rate seems to take place due to the protonation and the formation of surface hydroxyl groups, respectively (see below). Even though this experiment had been done at a fixed applied potential, the shape of the potential energy curve, and thereby the space charge layer thickness, can be changed drastically by such surface changes.

Sensitized photocurrent.—In the presence of rhodamine B, an additional anodic photocurrent was observed and the photocurrent spectra were very similar to the absorption spectra of the dye as shown in Fig. 7. A similar phenomenon using various semiconducting electrodes has been observed (11, 22). The dye is electrochemically inactive in the dark in the region of the applied potentials. This additional photocurrent can be interpreted as a considerable increase of the number of carriers in the electronic energy states due to the adsorption of the dye molecules (23). A maximum conductivity has been observed in the course of photoconductivity measurements on ZnO single crystal (24) in the presence of adsorbed organic dye under absorption band illumination. Since the photocurrent is directly proportional to the rate of formation of carriers, there is a maximum population of carriers in the energy state corresponding to the absorption band of the dye.

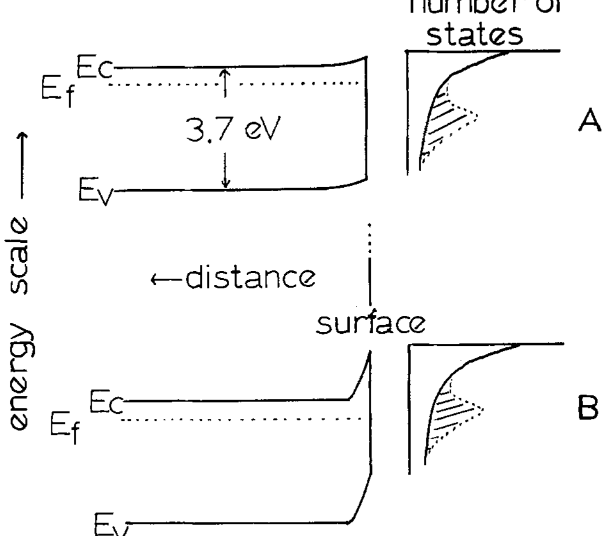

Fig. 5. Potential energy diagram of SnO_2 at the interface. A, Low anodic potential; B, high anodic potential; E_c, conduction band; E_f, Fermi energy level; E_v, valence band. Shaded areas are the energy states due to the presence of adsorption.

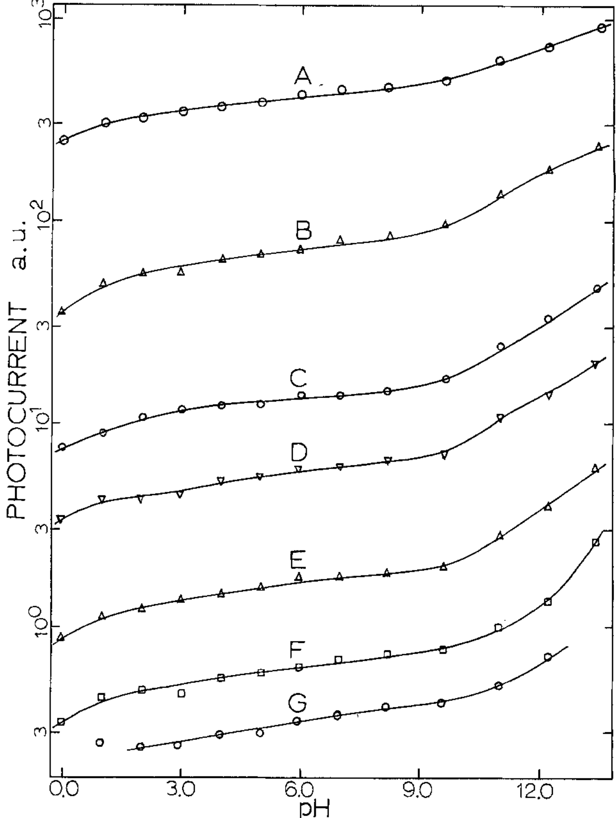

Fig. 6. Effect of *p*H on photocurrent at 0.7V vs. SCE. A, 360 nm; B, 380 nm; C, 400 nm; D, 450 nm; E, 500 nm; F, 550 nm; G, 610 nm.

The effect of applied potential on the sensitized photocurrent was very similar to the effect of applied potential on the photocurrent shown in Fig. 4. Again, no saturation was observed.

The sigmoid shape in Fig. 8 reveals a typical adsorption isotherm, and further evidence for the adsorption of rhodamine B at the tin oxide electrode surface has been provided by the radioactive carbon-14 labeling technique. The specific activity of C-14-rhodamine B was determined by relating the spectrophotometrically determined concentration to the counting rate.

The theoretical amount of a monolayer coverage was calculated, assuming 18Å as the diameter of rhodamine B molecule, to correspond to 3.93×10^{13} molecules/cm^2 or 6.53×10^{-11} mole/cm^2.

It was noticed that up to 99.5% of the adsorbed dye can be dissolved from the surface into ethanol in three successive washings, but water washings did not disturb the adsorbed dye. Adsorption of the dye appears to be very rapid because 4.2×10^{-11} moles/cm^2 (about two-thirds of theoretical monolayer coverage) of dye was observed after only 1 sec of immersion in $1.46 \times 10^{-4}M$ solution. Values between 5.8 and 6.9×10^{-11} moles/cm^2 were obtained after 2 and 10 min of immersion with or without polarization at applied potentials of 1.21 and −1.0V *vs.* SCE. About a monolayer coverage (5.9×10^{-11} moles/cm^2) was also observed in the following way. The electrode was dipped into a $4.53 \times 10^{-6}M$ dye solution for 5 min, then it was taken out very slowly. There was no washing with water. This was done on the basis that the tin oxide was not easily wettable and that uniformly distributed solution layer 1 μm thick contained an amount of dye corresponding to less than 1% of a monolayer coverage. Actually there was only a little wetted area and the solution was efficiently taken away by an absorbing paper towel.

Photovoltage measurements.—A shift of rest potential by the bandgap energy illumination is due to the generation of excess hole electron pairs. The separation of photogenerated charge carriers of the different

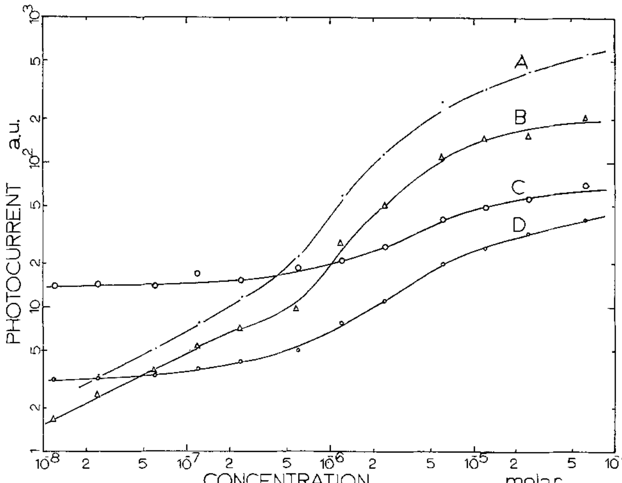

Fig. 8. Effect of rhodamine B concentration on sensitized photocurrent at 0.7V *vs.* SCE. A, At 550 nm; B, at 500 nm; C, at 400 nm; D, at 450 nm.

mobilities can also produce a photopotential (25). Both responses are known to be instantaneous because they are caused only by a nonequilibrium charge distribution.

When photoenergies of less than the energy gap were introduced on SnO_2, a long rise and decay time was observed in an open circuit as shown in Fig. 9. The measured photovoltage depends very much on the previous history of the electrode and does not give reproducible values.

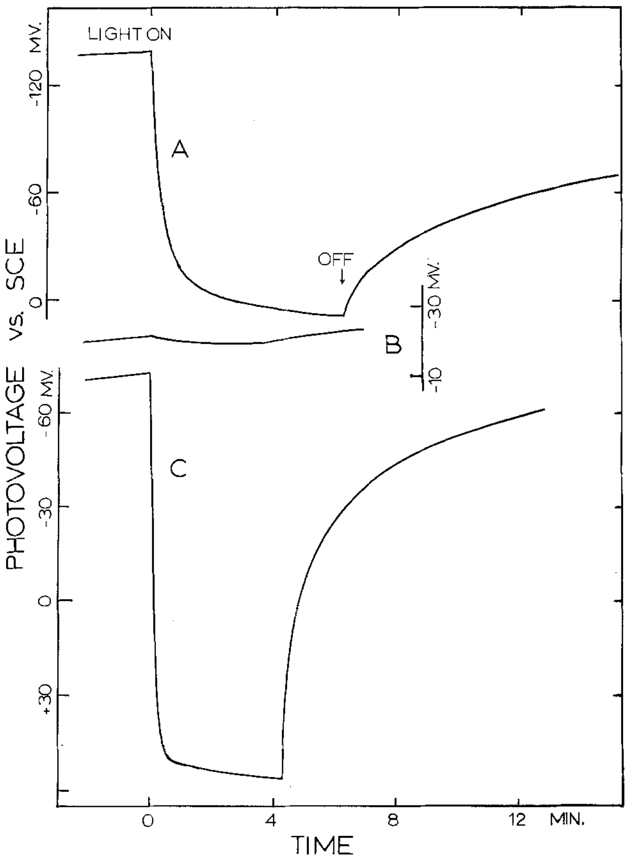

Fig. 9. Time dependence of photovoltage. A, 1M KNO_3 with 350 nm; B, 1M KNO_3 with 550 nm; C, $1.217 \times 10^{-5}M$ rhodamine B in 1M KNO_3.

The slow response of photovoltage due to chemical process at the electrode surface was discussed in Ref. (6). In the open circuit measurement, there is no net current flow between the electrode and the electrolyte interface. But we already know that holes in the case of an n-type semiconductor are responsible for the anodic photocurrent. Therefore, electrons have to be consumed by means of a cathodic reaction at the reference electrode at the same rate as holes in the anodic reaction in order to get a quasi-steady-state response. The slow photovoltage response, therefore, is limited by the charge transfer rate at the electrode surface. It cannot simply be due to a *p*H change in solution, because the quantities of electricity are entirely inadequate for such changes at steady states. Moreover, the photovoltage was found to be insensitive to stirring.

The photovoltage spectrum which was obtained by measuring the photovoltages at each wavelength was very similar to the photocurrent spectrum. In the presence of rhodamine B, the photovoltage spectrum revealed a big hump corresponding to the absorption band around 550 nm. Therefore, the photovoltage measurement can also be used to determine the position of energy levels and the relative number of states in the surface level just as the photocurrent measurement can.

Surface hydroxyl groups.—The presence of hydroxyl groups on natural crystals of Bolivian cassiterite SnO_2 was first determined by infrared absorption near 3.07 μm (26). The electrochemical behavior of the tin oxide which had been immersed in 1*M* KNO_3 for 3 days after photoexcitation work is shown in Fig. 10, curve B. The cyclic voltammogram shows not only high background and photocurrent but also a decrease in oxygen overvoltage by as much as 0.5V. Polishing the electrode with alumina made only a small change; however, heating at 90°C for 3 hr (curve C) did improve its behavior. After further heating at 115°C for 24 hr (curve D), the electrode showed about the same volt-

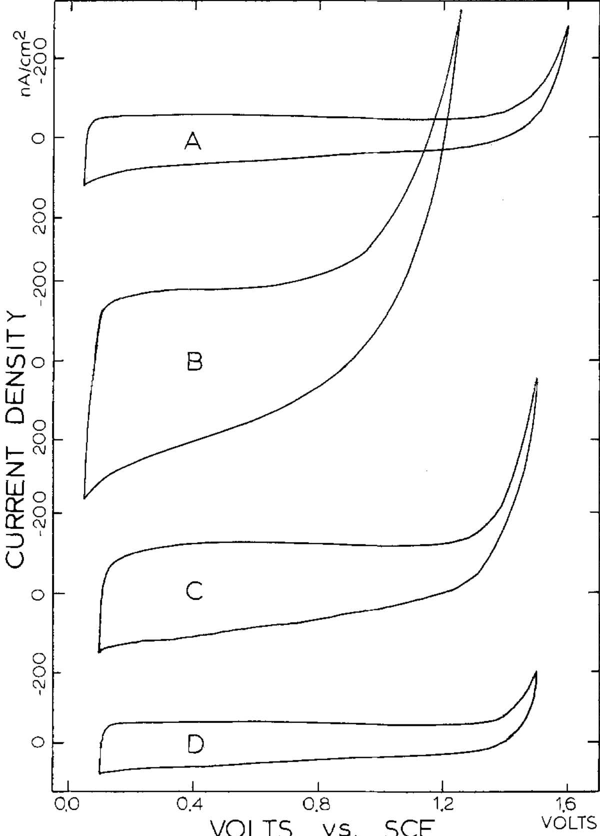

Fig. 10. Cyclic voltammograms of tin oxide electrode. Sweep rate = 20 mV/sec. A, Newly prepared electrode; B, 3 days old in 1M KNO_3 after photoexcitation work; C, dried at 90°C for 3 hr; D, dried at 115°C for 24 hr.

ammogram as shown by a newly prepared electrode. It is interesting that the wetting of the electrode surface is noticed even after polishing with alumina but not after heat-treatment. A new electrode is not wettable. Compared to the surface hydroxyl groups on silica or alumina which required much higher temperature and vacuum drying for complete removal, it seems very unlikely that such a gentle heat-treatment dehydrates a Sn-OH bond. A superficial hydrogen bonding interaction between oxide layers of SnO_2 and water molecules instead is proposed for the aging in the electrolyte. Presumably such an interaction is preserved under wet polishing conditions.

Proposed mechanism.—To determine whether the anodic decomposition of water or of the cassiterite lattice is energetically favorable we may compare the free energy changes of the reaction

$$2H_2O(l) + 4h^+ (\text{holes}) \rightarrow 4H^+aq + O_2 \; 113.38 \text{ kcal} \quad [1]$$

obtained from $\Delta G°(H_2O) = -56.69$ kcal//mole, and

$$SnO_2(s) + 4h^+ + 4H_2O \rightarrow SnO_2 \cdot 2H_2O(s) + 4H^+aq + O_2 \; 123.46 \text{ kcal} \quad [2]$$

obtained from $\Delta G°(SnO_2(s)) = -124.2$ kcal mole, $\Delta G°(SnO_2 \cdot 2H_2O(s)) = -227.5$ kcal/mole, and $\Delta G°(H_2O)$ of reaction [2] requires more energy than reaction [1] by 10.08 kcal. Therefore, the decomposition of water is energetically favored. A prolonged experiment did not show any sign of decomposition of the electrode surface. The oxidation of water by photogenerated holes at TiO_2 electrodes also has been proposed (27).

Finally, the following scheme for the anodic photoprocess at the tin oxide polycrystalline electrode is proposed

$(ES) + h\nu \rightarrow (ES)^+ + e^-$ (conduction band)

$(ES)^+ \rightarrow (ES) + h^+$ (intermediate band)

e^- (conduction band) $\rightarrow$ move to interior

$H_2O(l) + 2h^+$ (intermediate band) $\rightarrow 1/2\, O_2 + 2H^+$

where (ES) represents the surface energy states due to the presence of impurities, defects, grain boundaries, and adsorbed molecules.

Light-Deflection Errors in the Interferometry of Electrochemical Mass Transfer Boundary Layers

F. R. McLarnon,* R. H. Muller,* and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The effect of light deflection on interferograms of electrochemical mass transfer boundary layers can result in substantial errors if interferograms are interpreted in the conventional way. Corrections in boundary layer thickness, interfacial concentration, and interfacial concentration gradient for the convection-free electrodeposition of Cu from aqueous $CuSO_4$ have been calculated to provide estimates for a wide range of experimental conditions.

Concentration profiles of single solutes in electrolytes near working electrodes can, in principle, be quantitatively observed by interferometric techniques. Such observations are useful in the study of transport processes and in the analysis of different measures designed to provide uniform accessibility and increased reaction rates at electrodes. Some of the advantages of interferometry compared to other means of observing boundary layers and local transport rates are: high resolution for concentration changes (typically 10^{-5}M) and, the possibility of continuous observation without disturbance (*e.g.*, of flow), not restricted to conditions of limiting current.

In the conventional interpretation of interferograms, local changes in the phase depicted by the interferogram are taken as a direct measure of local refractive index variations in the object. Such an interpretation is often not valid because it assumes that light travels along a straight line through the specimen. Refractive index variations normal to the propagation direction of the light beam produce a deflection of the beam (refraction, Schlieren effect) that results in two types of distortions in the interferogram: (*i*) Geometrical distortion due to displacement of the beam normal to its propagation direction. This effect falsifies conventional interpretation of distance on the interferogram and causes displacement of the apparent electrode/electrolyte interface. (*ii*) Phase distortion due to increased geometrical path length and passage of the beam through regions of varying refractive index. Quantitative concentration profiles, therefore, often cannot be derived by the conventional interpretation of interferograms.

Figure 1 schematically shows the trajectories of two light rays traversing a cathodic concentration boundary layer. Ray ABC is only slightly deflected and stays within the boundary layer over its path AB because it propagates near the edge of the boundary layer where the refractive index gradient is small. Ray DEF, which enters the electrolyte where the refractive index gradient is high, is deflected so much that it leaves the boundary layer at the intersection with line GH (and then travels along a straight line) before leaving the electrolyte at point E. A deflected ray will contribute to the interferogram only if it passes through the aperture of the objective lens. For instance, if ray DEF were to be deflected at any higher angle, it would not pass through the objective lens and, therefore, would not contribute to the interferogram. The corresponding part of the boundary layer would then not be visible on the interferogram.

Details of computational techniques, that have been developed to account for the effect of light deflection on interferograms of one-dimensional boundary layers, have been described elsewhere (1, 2). Suffice it to say that for any concentration profile, the shapes of (double beam) interference fringes can now be calculated taking into account effects of light deflection. It has been found that distortions in the interferogram depend strongly on the position of the plane of focus of the imaging objective lens. Although for each concentration profile a plane of focus can be found (3) for which the location of the electrode surface is not distorted on the interferogram, it is preferable to use a more easily defined plane of focus at a fixed location and accept the resulting displacement of the electrode shadow. For the observation of cathodic boundary layers (to be considered here) we recommend (2) focusing on the inside of the cell wall on the light-entrance side of the cell, where suitable targets can be inscribed. (For anodic boundary layers, it would be preferable to focus on the inside of the cell wall on the light-exit side.)

It is the purpose of this paper to present calculations of light-deflection errors for the interferometric observation of boundary layers so that investigators may estimate errors to be expected under a wide range of experimental conditions.

Light-Deflection Errors

Figure 2 shows the experimental interferogram of a concentration boundary layer formed by constant-current electrolysis. Superimposed are the theoretical concentration profile, AE, derived by use of the Sand (4) equation, and an interference fringe, BF, computed from the concentration profile by taking light-deflection effects into account.

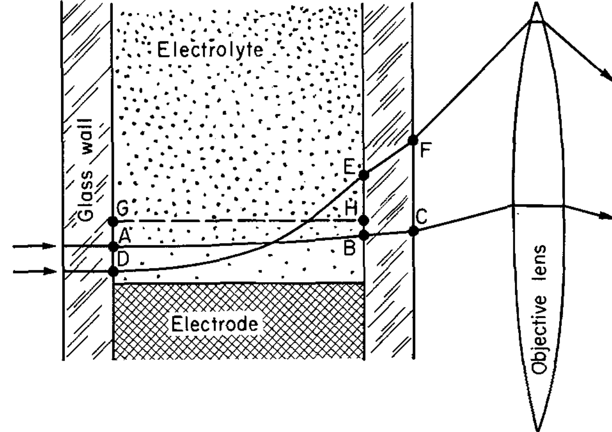

Fig. 1. Schematic of light ray trajectories in a cathodic concentration boundary layer: refractive index increases in the direction away fom the electrode surface. ABC, trajectory of a ray that remains inside the boundary layer. DEF, trajectory of a ray that is deflected out of the boundary layer. GH, edge of the boundary layer.

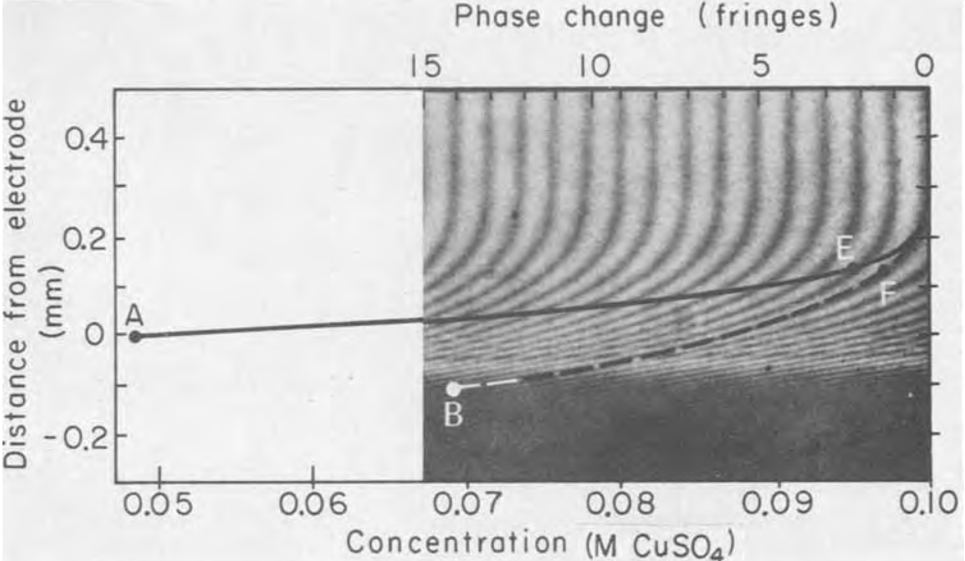

Fig. 2. Experimental interferogram of a concentration boundary layer during galvanostatic deposition of copper on a 10 mm wide electrode. $i = 10.0$ mA/cm², $C_b = 0.1M$ $CuSO_4$, and $t = 10.0$ sec. —— Theoretical concentration profile AE corresponding to experimental conditions (calculated from Eq. [13]). ----- Computed interference fringe BF corresponding to theoretical concentration profile. A, true interfacial concentration and position. B, apparent interfacial concentration and position. E, true (90%) boundary layer edge (position where $\theta = 0.9$). F, apparent boundary layer edge.

The ordinate on Fig. 2 denotes distance from the true (undistorted) image of the electrode surface. Local changes in the phase of transmitted light, visible as displacements of originally straight interference fringes, have been related to local concentration changes, as shown on the abscissa. The relationship has been based on the conventional interpretation of interferograms that assumes straight-line light propagation. Thus, local changes in phase have been linearly related to changes in concentration (or refractive index) at the corresponding point in the image.

If the interferogram was free of light-deflection effects, the interference fringes would follow the theoretical concentration profile AE. The figure illustrates that the apparent location B of the interface on the interferogram has receded from its original position A, identified by $y = 0$. Also, the apparent concentration change over the boundary layer is smaller than the true change.

Conventional interpretation of the interferogram in Fig. 2 would therefore lead to a boundary layer thickness that is too large. If we define the extent of the boundary layer as the region containing 90% of the concentration variation, the error e_t in boundary layer thickness can be defined in terms of the ordinates of the points shown in Fig. 2 as

$$e_t = (y_F - y_B) - (y_E - y_A)$$

Similarly, the apparent interfacial concentration is too high and the error can be formulated as a difference of abscissas

$$e_c = C_B - C_A$$

The interfacial concentration (refractive index) gradient is too low. The error can be represented by the difference in slope of the two curves at the interface

$$e_g = \frac{dC}{dy}\bigg|_B - \frac{dC}{dy}\bigg|_A$$

In addition to the above absolute errors in the interferometry of boundary layers, it is often desirable to estimate the relative errors. Such relative errors in boundary layer thickness, interfacial concentration, and interfacial concentration gradient, as shown in Fig. 8-13, are defined here as

$$\epsilon_t = \frac{e_t}{y_E}$$

$$\epsilon_c = \frac{e_c}{C_b - C_A}$$

$$\epsilon_g = \frac{e_g}{\dfrac{dC}{dy}\bigg|_A}$$

Convection-Free Boundary Layers

Diffusion boundary layers free of convection effects offer a useful model for optical investigation since the concentration profiles are easily derived, and experimental results can serve to test the optical calculations. Convection-free transport conditions are common in electrochemical studies, and results can be used as a basis for convective transport studies.

The convectionless electrodeposition of a metal cation from a stagnant layer of an aqueous binary salt electrolyte is described by the time-dependent diffusion equation in one dimension[1]

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial y^2} \qquad [1]$$

The current density is related to the interfacial concentration gradient by

$$i = \frac{z\mathbf{F}D}{1 - t_+}\frac{\partial C}{\partial y}\bigg|_{y=0} \qquad [2]$$

For potentiostatic electrodeposition, the boundary conditions are

$$C = C_s \text{ at } y = 0,\ t > 0 \qquad [3]$$

$$C = C_b \text{ at } t = 0, \text{ all } y \qquad [4]$$

$$C = C_b \text{ as } y \rightarrow \infty \qquad [5]$$

The solution, first obtained by Cottrell (5), is

$$\theta = \text{erf } \zeta \qquad [6]$$

$$i = \frac{z\mathbf{F}(\Delta C)}{1 - t_+}\sqrt{\frac{D}{\pi t}} \qquad [7]$$

where erf ζ is the error function of dimensionless distance

$$\zeta = \frac{y}{2\sqrt{Dt}} \qquad [8]$$

$\Delta C = C_b - C_s$ and the dimensionless concentration

$$\theta = \frac{C - C_s}{\Delta C} \qquad [9]$$

For galvanostatic electrodeposition, the boundary conditions to Eq [1] are

$$\frac{\partial C}{\partial y} = \text{constant at } y = 0,\ t > 0 \qquad [10]$$

[1] Concentration-independent diffusivity will be assumed. Solutions for variable diffusivity can also be obtained, although not in a convenient closed form.

$$C = C_b \text{ at } t = 0, \text{ all } y \quad [11]$$

$$C = C_b \text{ as } y \to \infty \quad [12]$$

The solution, first obtained by Sand (4), is

$$\theta = 1 + \sqrt{\pi}\,\zeta(1 - \text{erf}\,\zeta) - e^{-\zeta^2} \quad [13]$$

$$\Delta C = \frac{2i(1 - t_+)}{z\mathbf{F}} \sqrt{\frac{t}{\pi D}} \quad [14]$$

Concentration profiles for use in the light-deflection analysis, with electrodeposition of Cu from aqueous $CuSO_4$ serving as a model, have been calculated. Equations [6] and [7] and Eq. [13] and [14] have been used in this computation. The interfacial concentration has been set $C_s = 0$, and the values of the bulk concentration were $C_b = 0.01$, 0.10, and 0.20M $CuSO_4$ ($\Delta C = 0.01$, 0.10, or 0.20). For constant potential calculations, time t is varied to give different concentration profiles and interfacial mass flux rates. For constant current calculations, various current densities are used (substituting Eq. [2] into Eq. [10]) to give different concentration profiles and interfacial mass flux rates. (Note that specification of i and ΔC fixes t through Eq. [14].) A diffusion coefficient (6) $D = 6 \times 10^{-6}$ cm²/sec and Cu^{++} transference number (7) $t_+ = 0.36$ (typical values for 0.1M $CuSO_4$ at 25°C) are used in all calculations. Representative concentration profiles employed in the optical analysis are shown in Fig. 3 and 4.

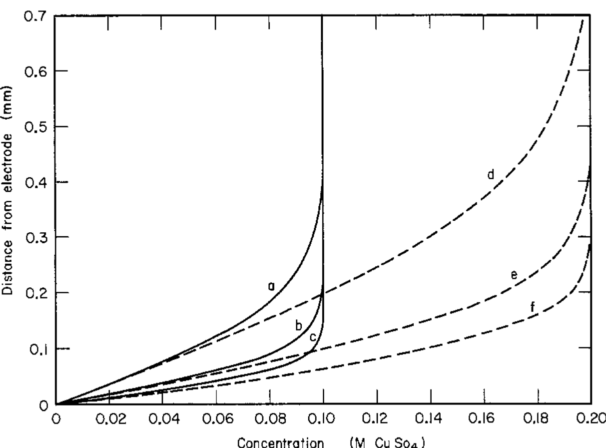

Fig. 3. Concentration profiles for potentiostatic conditions. —— $\Delta C = 0.1M$ $CuSO_4$; - - - - - $\Delta C = 0.2M$ $CuSO_4$; a, i = 10.0 mA/cm², t = 17.5 sec; b, i = 20.0, t = 4.4 sec; c, i = 30.0, t = 1.9 sec; d, i = 10.0, t = 70.0 sec; e, i = 20.0, t = 17.5 sec; f, i = 30.0, t = 7.8 sec.

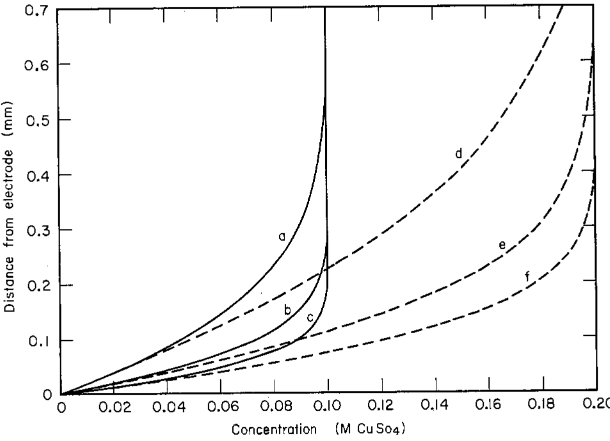

Fig. 4. Concentration profiles for galvanostatic conditions. ΔC and i designation as in Fig. 3. a, t = 43.2 sec; b, t = 10.8 sec; c, t = 4.8 sec; d, t = 172.7 sec; e, t = 43.2 sec; f, t = 19.2 sec.

Error Calculations

Cell dimensions and optical constants must be specified in order to compute interferograms from concentration profiles. The electrode, which is assumed here to fully occupy the space between the glass sidewalls, was assigned widths of 1.0, 2.5, 5.0, 10.0, and 20.0 mm. In order to model our experimental cell, the glass sidewalls were assumed to be 12.7 mm wide with a refractive index of 1.5231. However, refraction in the glass sidewalls has a negligible effect on light-deflection errors (3). Light of 632.8 nm wavelength is assumed incident parallel to the planar electrode surface and perpendicular to the glass sidewalls. The plane of focus is chosen as the plane where light enters the electrolyte. Electrolyte refractive index was experimentally found to be a linear function of $CuSO_4$ concentration at 632.8 nm wavelength and 25°C

$$n = 1.3311 + 0.029C \quad [15]$$

Interferograms similar to the dashed line in Fig. 2 are now calculated from concentration profiles using the above-mentioned computational technique (1).

Absolute errors in boundary layer thickness, interfacial concentration, and interfacial concentration gradient are shown in Fig. 5, 6, and 7, respectively, for a 10 mm wide electrode. Current density (interfacial refractive-index gradient) was chosen as abscissa because it is an easily measured variable. Note that a positive error means that the value of a variable on the interferogram is larger than the true value.

Relative errors in boundary layer thickness, interfacial concentration, and interfacial concentration gradient are shown in Fig. 8-13. Figures 8-10 also demonstrate the dependence of errors on concentration difference ΔC. The effect of electrode width is illustrated in Fig. 11-13.

Discussion

Figures 5-7 show that for a 10 mm wide electrode, the light-deflection errors depend strongly on current density and concentration difference ΔC and only weakly on the specific boundary condition (potentio-

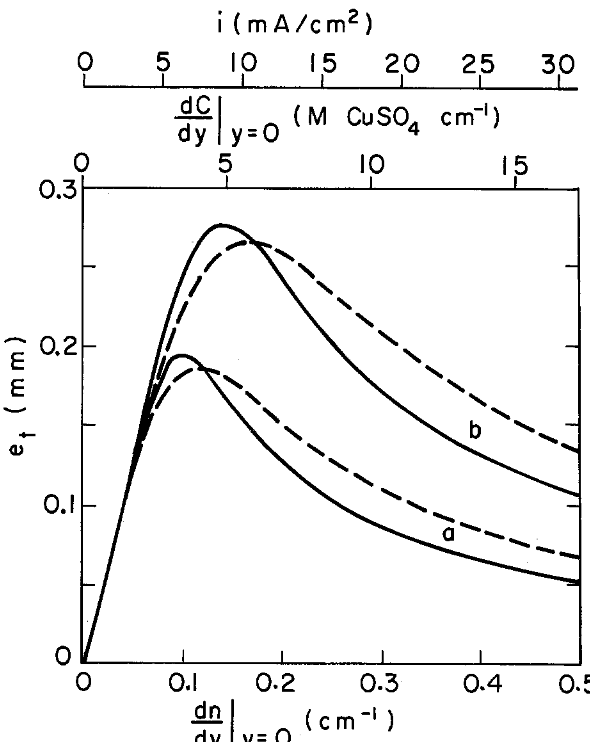

Fig. 5. Absolute error in boundary layer thickness. Electrode width = 10.0 mm. —— potentiostatic boundary condition; - - - - - - galvanostatic boundary condition; a, ΔC = 0.01M $CuSO_4$; b, ΔC = 0.10M $CuSO_4$; c, ΔC = 0.20M $CuSO_4$.

static or galvanostatic). For current densities in the order of 1 mA/cm², the errors are independent of ΔC and boundary condition. The weak dependence on boundary condition can be ascribed to the similarity between the respective concentration profiles; compare Fig. 3 and 4. Above about 2 mA/cm² for ΔC = 0.01M $CuSO_4$, about 7 mA/cm² for ΔC = 0.1M, and about 10 mA/cm² for ΔC = 0.2M, the light rays entering the boundary layer at the electrode surface are

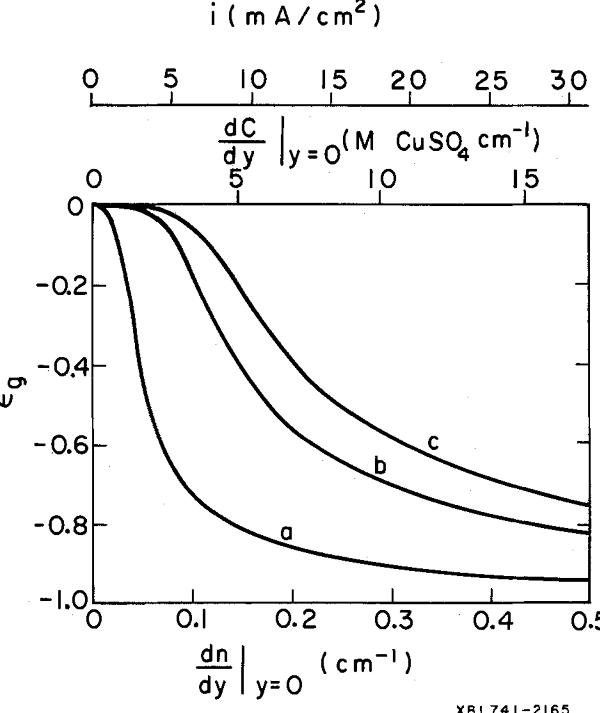

Fig. 10. Relative error in interfacial concentration gradient for various concentration differences. Designations as in Fig. 8.

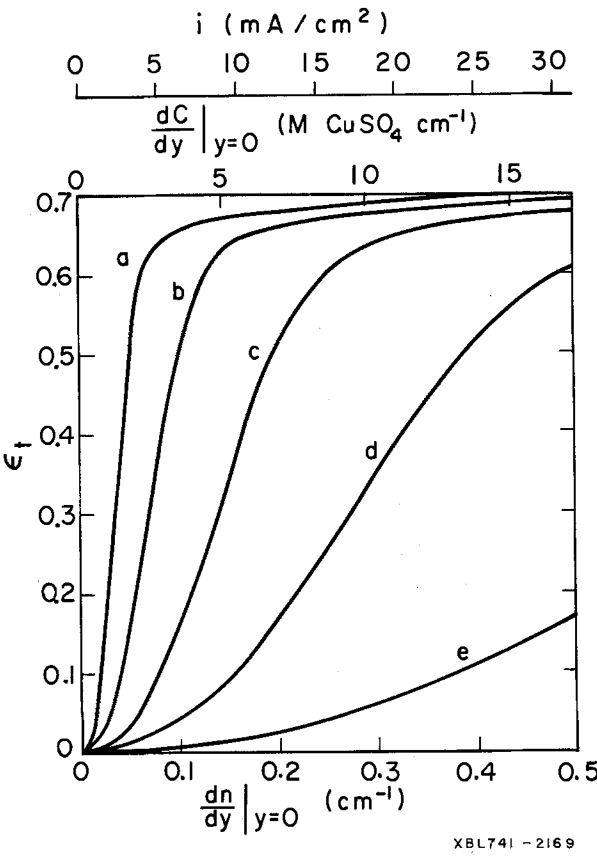

Fig. 11. Relative error in boundary layer thickness for different electrode widths. $\Delta C = 0.1M\ CuSO_4$, potentiostatic boundary condition. a, electrode width = 20.0 mm; b, 10.0 mm; c, 5.0 mm; d, 2.5 mm; e, 1.0 mm.

deflected so much that they leave the boundary layer before they leave the electrolyte (as ray DEF in Fig. 1). This effect causes an error extremum in the curves of Fig. 5 and 6 and a knee in the curves of Fig. 7. The abrupt changes in the character of the error curves are due to the straight paths traversed by the deflected

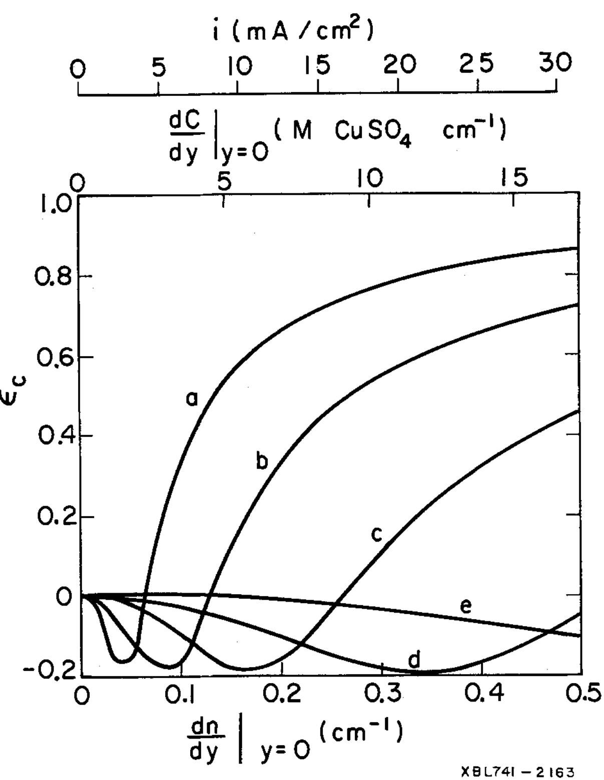

Fig. 12. Relative error in interfacial concentration for different electrode widths. Designations as in Fig. 11.

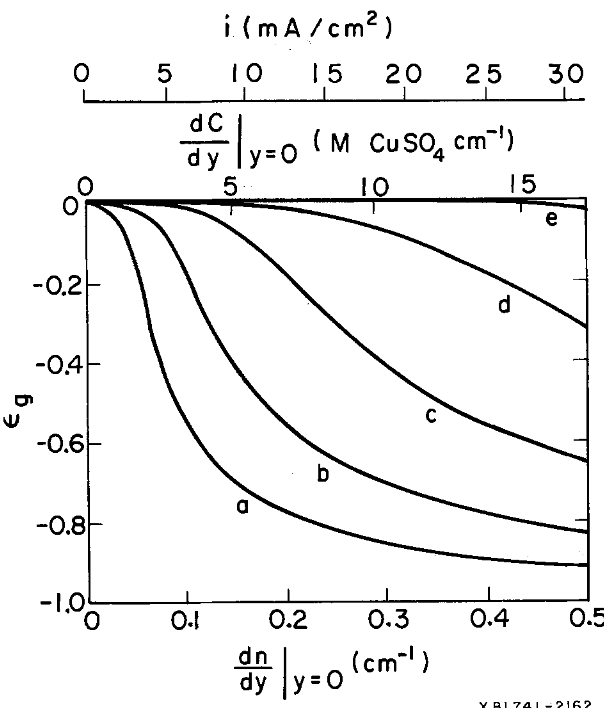

Fig. 13. Relative error in interfacial concentration gradient for different electrode widths. Designations as in Fig. 11.

rays once they leave the boundary layer; at lower current densities the rays are continuously changing direction within the boundary layer. (Fig. 2 illustrates an interferogram in which rays entering the cell near the electrode surface are deflected out of the boundary layer.) As infinite current density is approached, the error in boundary layer thickness approaches zero, the error in interfacial concentration approaches ΔC, and the error in interfacial concentration gradient approaches negative infinity.

The trend toward apparent negative concentrations (*i.e.*, on the interferogram) seen in Fig. 6, 9, and 12 is a result of the choice of focal plane position. For focus in the center of the cell, for instance, no such negative errors would occur.

Figures 8-10 show that, contrary to what one might expect, relative errors are generally smaller for larger concentration difference ΔC. However, for large concentration differences, interferogram interpretation can be impeded by crowding of the fringes near the interface.

Figures 11-13 show that similar to absolute errors derived analytically for constant concentration gradients of unlimited extent (3), relative errors strongly diminish with decreasing cell width, but are negligible only for electrodes thinner than a few millimeters.

Figures 5-13 can be used to estimate light-deflection errors in experimental interferograms if all deflected portions of the test beam are accepted by the objective lens. The maximum angle ϕ_{max} of light deflection within a boundary layer is given by (2, 3)

$$\tan \phi_{max} = \sqrt{\left(\frac{n_b}{n_s}\right)^2 - 1} \qquad [16]$$

and the maximum angle of deflected light emanating from the specimen cell can be calculated by substituting numerical values of refractive index (*e.g.*, Eq. [15] into Eq. [16]) and accounting for refraction in the glass sidewall. For example, the objective lens aperture must accept illumination at angles up to 1.59° for $\Delta C = 0.01M\ CuSO_4$, up to 4.65° for $\Delta C = 0.10M$, and up to 7.14° for $\Delta C = 0.20M$.

Conclusions

Light-deflection effects in the interferometry of electrochemical mass transfer boundary layers can lead to serious errors in the derivation of concentration profiles unless appropriate corrections in the interpretation of interferograms are employed. The magnitude of errors encountered may be estimated from the data presented in Fig. 5-13, but the accurate interpretation of interferograms with significant light-deflection effects requires individual optical analysis (2). Light-deflection errors are small (<10%) for small current densities (below 2.5 mA/cm^2 for a 1 cm wide electrode) or narrow electrodes (less than 2.5 mm for up to 10 mA/cm^2).

Electrochemical Behavior of Rotating Iron Disks

Effect of Fe(III)

R. F. Tobias* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The electrochemical behavior of iron in deaerated H_2SO_4 containing ferric ions has been investigated with rotating disk electrodes. The rest potential and corrosion current of iron in $1N$ H_2SO_4 were not affected by variation in the angular velocity. On the other hand, the rest potential, E_m, and corrosion current of iron in $1N$ H_2SO_4 containing ferric ions varied with the ferric ion concentration, C, and the angular velocity of the iron disk, ω. E_m followed the relation

$$E_m = \text{constant} + 0.040 \log C + 0.020 \log \omega, \text{ volts}$$

The corrosion current of iron increased in the presence of ferric ions and was controlled by the diffusion of ferric ions. Diffusion coefficients of ferric and ferrous ions were determined: $D_{Fe(III)} = 5.2 \pm 0.3 \times 10^{-6}$ and $D_{Fe(II)} = 6.5 \pm 0.4 \times 10^{-6}$ cm^2/sec.

Metallic corrosion which is controlled by the diffusion of an electroreducible species in the solution can be studied conveniently with the rotating disk electrode technique. Previously, Makrides (1) examined the electrochemical behavior of rotating iron cylinders in H_2SO_4-$Fe_2(SO_4)_3$ solutions. He developed relationships between the rest potential (corrosion potential) and the ferric iron concentration and the rotation rate. In addition, he constructed anodic polarization curves from the rest potential-limiting diffusion current (ferric ion reduction) data, which was in good agreement with the experimental anodic polarization curve.

In this study the rotating disk electrode has been utilized to investigate the electrochemical behavior of iron in H_2SO_4. The polarization and open-circuit characteristics of rotating iron disks in H_2SO_4 containing ferric sulfate at various rotation rates have been determined. In addition, the diffusion coefficients of ferric and ferrous ions have been determined from the limiting diffusion current densities for ferric and ferrous ion reduction, respectively. In contrast to the turbulent flow conditions in Makrides' studies with rotating cylinders (1), the rotating disk experiments were conducted within the laminar flow regime.

Experimental

The test electrodes were prepared from Ferrovac E iron rod stock which was turned down on a lathe to a diameter of either 1.25 or 0.65 cm. The rod was cut into 0.64 cm lengths with an Al_2O_3 abrasive cutoff wheel using water as a cutting lubricant. A Teflon sleeve was pressure-fitted about the cylindrical part of the electrode so that only the lower cross-sectional surface was exposed to the electrolyte. The outer diameter of the Teflon sleeve was 1.73 cm.

Before the test electrodes were mounted in the electrode assembly they were hand-polished with waterproof Al_2O_3 paper. Grit 240 was used initially to smooth out the rough surface. followed by 600 grit. After the polishing procedure the electrodes had a mirrorlike finish. The electrodes were then rinsed in water, wiped dry, placed in a Soxhlet column, and degreased with hot benzene for 4 hr. The degreased electrodes were annealed for 1 hr at 650°C and slowly cooled to room temperature under vacuum (pressure $<10^{-4}$ mm Hg). The finished electrodes were then stored in a desiccator until used.

The cell consisted of three parts: a separate compartment for the auxiliary electrode, the Pyrex jar, and the Teflon top. The Pyrex jar contained a ground glass joint, through which small amounts of a concentrated solution of $Fe_2(SO_4)_3$ or $FeSO_4$ were added to the solution from a precision burette equipped with a greaseless Teflon stopcock. The Teflon cell top had entry ports which provided space for the test electrode assembly, a Luggin capillary, a thermometer, a bubbler, and an entry to pass N_2 gas through the bottom and above the solution. The volume of electrolyte used was 1200 ml.

Analytical reagent grade chemicals and doubly distilled water were used to prepare the solutions. For the electrochemical studies of iron in the absence and presence of ferric sulfate, $1N$ H_2SO_4 was used for the supporting electrolyte. The ferric ion concentration was varied from 1.26 to 25.2 mM.[1] To determine limiting diffusion current densities for the reduction of ferrous ions, 0.5M sodium sulfate was used for the supporting electrolyte with the pH adjusted to 3.0 by addition of an appropriate amount of H_2SO_4. The ferrous ion concentration was varied from 5.03 to 13.2 mM. After the electrolyte was placed in the cell, deaeration was accomplishd by passing prepurified N_2 through the solution for at least 8 hr. All experiments were conducted at room temperature, 23° ± 1°C. All potentials are given with respect to a saturated calomel reference electrode (SCE).

The kinematic viscosity of the supporting electrolytes was measured with a Cannon-Ubbelohde semimicro viscometer. For $1N$ H_2SO_4, the kinematic viscosity was 0.973×10^{-2} cm^2/sec, while for the 0.5M sodium sulfate the kinematic viscosity was 1.088×10^{-2} cm^2/sec.

An Exact function generator Type 255 was used to drive a Wenking potentiostat for the potential sweep experiments. The potential-current data were recorded on a semilogarithmic scale by use of a Moseley Model 7561A logarithmic converter connected to a Moseley Model 7035AX-Y recorder.

The test sample was mounted in the electrode assembly. The iron electrode was washed with distilled water and then activated in $5N$ H_2SO_4 for 10 min. After activation, the sample was washed thoroughly with distilled water and then immersed in the cell solution. Then, cathodic potential sweeps were applied to the rotating disk electrode. In the preliminary experimental tests, sweep rates of 1, 10, and 100 mV/sec were investigated. Since the results of the two slower sweep rates were in good agreement, 10 mV/sec was selected for the experiments. After the hydrogen evolution reaction was determined by the first sweep, a known amount of ferric or ferrous sulfate was added to the cell from the burette. After the angular velocity

[1] Milligram ion.

was set to a specific value, the steady-state rest potential was recorded. Then, electroreduction experiments at one concentration were performed over the entire range of angular velocities selected before the concentration was increased to a new value.

A schematic diagram of the apparatus and the complete set of the experimental data are given elsewhere (2).

Results and Discussion

Fe-1N H_2SO_4 system.—In deaerated 1N H_2SO_4 solutions the steady-state rest potential (corrosion potential) of iron is -498 ± 8 mV and is not a function of the rotational velocity. The corrosion potential of iron is in reasonable agreement with Kelly (3) and with iron exhibiting Makrides' type i behavior (1) which exhibited an increase in corrosion potential with time from -550 mV to about a steady-state value of -515 mV.

The Tafel slope for hydrogen evolution, b_c, is 116 ± 8 mV/decade and is in good agreement with the values obtained by others (3-5). Makrides (1), on the other hand, reported lower values of the Tafel slope for the HER. The anodic Tafel slope, b_a, of 41 mV was also in good agreement with other workers (3, 4). Makrides (1), on the other hand, obtained values of about 60 mV for his type i electrodes.

The corrosion current, $I_{m,o}$, determined by extrapolation of the anodic and cathodic Tafel lines to the corrosion potential is 1.8×10^{-4} and 1.6×10^{-4} A/cm², respectively. $I_{m,o}$ can also be determined from the slope of the polarization, ϵ, *vs.* current density, I, plot in the region $\epsilon = 0$ as shown in Eq. [1].

$$I_{m,o} = \frac{b_a b_c}{2.303(b_a + b_c)} \left(\frac{dI}{d\epsilon}\right)_{\epsilon=0} \quad [1]$$

Equation [1], which was derived by Stern (6), is the basis of the polarization resistance method for the determination of the corrosion current. The $I_{m,o}$ value calculated from the polarization resistance plot for iron in 1N H_2SO_4 is 1.2×10^{-4} A/cm². The corrosion currents obtained in this study are in good agreement with those reported by Kelly (3) and Greene (7). Makrides (1) reports that the corrosion current obtained for his type i iron was 4.1×10^{-4} A/cm² by extrapolation of the cathodic Tafel line and the polarization resistance method and 5.6×10^{-4} A/cm² by extrapolation of the anodic Tafel line.

The electrochemical parameters of iron in 1N H_2SO_4 are summarized in Table I. These results are based on experiments with at least eight different electrodes.

Limiting diffusion currents for Fe(III) and Fe(II) reduction.—Typical cathodic polarization behavior of iron in 1N H_2SO_4 containing ferric ions at angular velocities varying from 625-4225 rpm is shown in Fig. 1. For this system at sufficiently large cathodic polarization the total cathodic current, I_c, consisted of the partial currents for the hydrogen evolution, I_H, and ferric ion reduction, $I_{Fe(III)}$, reactions. Makrides' results (1) indicate that the rate of ferric ion reduction on iron in acidic solutions is diffusion controlled. Thus

$$I_c = I_H + I_{Fe(III)} = I_H + I_L \quad [2]$$

where I_L is the limiting diffusion current.

Figure 2 represents a graphical description of the system. The cathodic polarization curves are given for four different situations: first, in the absence of ferric ions; second, with ferric ion concentration, C_1, and rotational velocity, ω_1; third, concentration. C_1, and angular velocity, ω_2; fourth, concentration C_2, and angular velocity, ω_1. For the case shown, $C_2 > C_1$ and $\omega_2 > \omega_1$. If the hydrogen evolution reaction is subtracted from the total cathodic current, the limiting diffusion current for the reduction of ferric ions is obtained. The square and triangle points shown in Fig. 2 represent cathodic polarization data constructed from the iron dissolution and the HER Tafel lines and the limiting diffusion currents for the reduction of ferric ions. The circle points represent cathodic polarization data constructed from the iron dissolution and the HER Tafel lines.

Table I. Electrochemical parameters of iron in 1N H_2SO_4

Rest potential (E_m)	-498 ± 8 mV (*vs.* SCE)
Corrosion current ($I_{m,o}$) (polarization resistance)	$1.2 \pm 0.3 \times 10^{-4}$ A/cm²
Corrosion current ($I_{m,o}$) (anodic Tafel line extrapolation)	$1.8 \pm 0.3 \times 10^{-4}$ A/cm²
Corrosion current ($I_{m,o}$) (cathodic Tafel line extrapolation)	$1.6 \pm 0.4 \times 10^{-4}$ A/cm²
Anodic Tafel slope (b_a)	41 ± 3 mV/decade
Cathodic Tafel slope (b_a)	116 ± 8 mV/decade
Initial differential capacitance	42 ± 2 μf/cm²

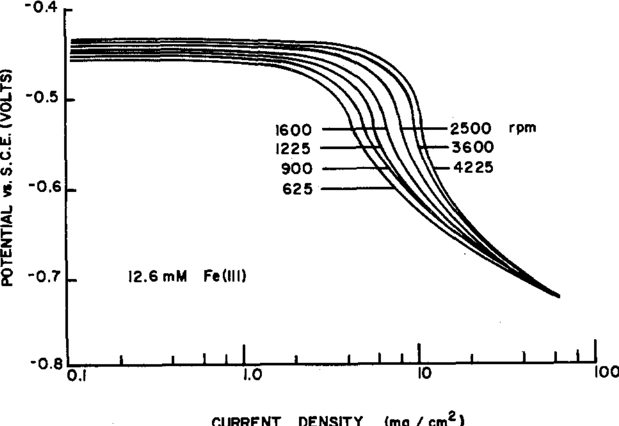

Fig. 1. Cathodic polarization of iron in 1N H_2SO_4 containing ferric ions.

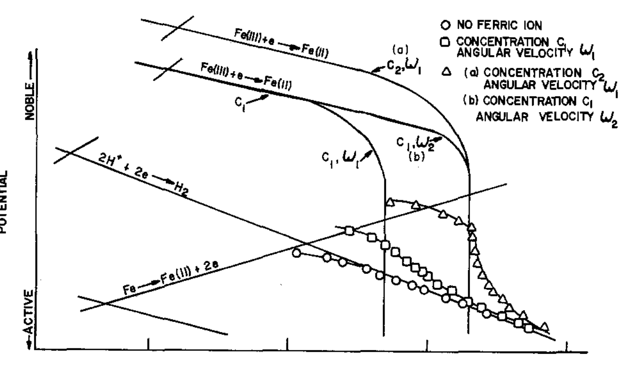

Fig. 2. Cathodic polarization of iron in absence and presence of ferric ions. Points represent calculated cathodic polarization data.

Figure 3 shows some typical results of the limiting current density for the reduction of ferric ions. These limiting currents were obtained in the following manner. First, before ferric ions were added to the sulfuric acid solution, the rate of hydrogen evolution on iron in 1N H_2SO_4 was determined. Then, with Eq. [2], the limiting diffusion currents for the reduction of ferric ions were obtained by subtracting the rate of the HER from the total measured current density obtained from the cathodic polarization curves of iron in solutions containing ferric ions as shown in Fig. 1.

The limiting current densities for the reduction of ferric ions *vs.* the square root of angular velocity are plotted in Fig. 4. A linear relationship is obtained in accord with the Levich equation for the limiting current density at a rotating disk electrode

$$i_L = 0.62\, nFD^{2/3}\nu^{-1/6}\omega^{1/2}C \quad [3]$$

where the letters have their usual meaning.

Cathodic polarization measurements of iron in Na_2SO_4 (pH = 3) were conducted at various angular velocities in the absence (Fig. 5) and in the presence (Fig. 6) of ferrous ions. The observed limiting diffusion currents in Fig. 6 are the sum of the limiting dif-

fusion currents for hydrogen ion and ferrous ion reduction. The limiting diffusion currents for ferrous ion reduction are readily determined by subtracting the I_L for hydrogen ion reduction (Fig. 5) from the total diffusion current (Fig. 6). Figures 7 and 8 show the limiting diffusion current for the reduction of ferrous ions *vs.* the square root of the angular velocity and the concentration of the ferrous ions, respectively. In both plots Levich behavior is obtained.

Fe-1N H_2SO_4-$Fe_2(SO_4)_3$ system.—The rest potential behavior of iron in the presence of ferric ions showed a marked dependence on both the concentration of ferric ions and the angular velocity of the iron disk. The data presented in Fig. 9 show the dependence of the rest potential on the concentration of the ferric ions over the range of angular velocities, 625-4225 rpm. ΔE_0 is defined as the rest potential of iron in the presence of ferric ions and at an angular velocity, ω, rela-

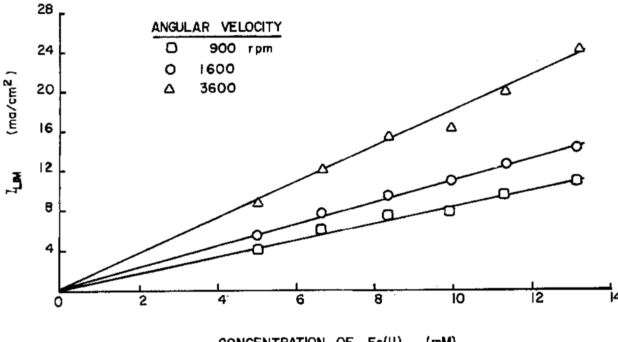

Fig. 8. I_L vs. concentration of Fe(II) for ferrous ion reduction

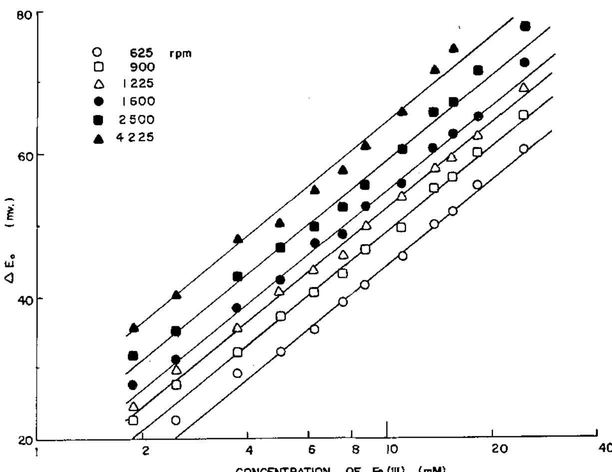

Fig. 9. ΔE_o vs. concentration of Fe(III)

tive to the rest potential of iron in the absence of ferric ions.

For iron in an acidic media containing only reducible species, H^+ and H_2O, the corrosion current $I_{m,o}$, is

$$I_{m,o} = I_a = I_c \quad [4]$$

where I_a is the partial anodic process corresponding to iron dissolution and I_c is the partial cathodic process corresponding to the reduction of hydrogen ions.

For activation-controlled iron dissolution and HER, the total measured current for iron in H_2SO_4 can be represented by

$$I = I_{m,o}\left[\exp\left(\frac{\alpha_a n_a \mathbf{F}\epsilon}{RT}\right) - \exp\left(\frac{-(1-\alpha_c)n_c\mathbf{F}\epsilon}{RT}\right)\right] \quad [5]$$

where the electrode kinetic parameters have their usual meaning. The first term on the right-hand side of Eq. [5] represents the rate of anodic dissolution of iron and the last term represents the rate of hydrogen evolution. The anodic dissolution term can be rearranged to obtain the Tafel equation

$$\epsilon_a = A + b_a \log I_a \quad [6]$$

If another easily reducible species is introduced into the solution (*e.g.*, Fe^{+3}), the total cathodic current would consist of the sum of the rate of hydrogen evolution and the rate of reduction of the added oxidized species, *i.e.*

$$I_c = I_H + I_{ox} \quad [7]$$

When ferric ions are added to the iron-sulfuric acid system, the rate of ferric ion reduction is diffusion controlled as mentioned above. For this situation, $I_{ox} = I_L$, and the cathodic current can be expressed by Eq. [2]. For the conditions studied in this work

$$I_L >> I_H \quad [8]$$

Thus

$$I_c \simeq I_L \quad [9]$$

and at the rest potential, E_m

$$I_m = I_a = I_L \quad [10]$$

where I_m is the corrosion current of iron in H_2SO_4 containing ferric ions. Since the limiting diffusion current is independent of potential, the rest potential, E_m, is determined by the intersection of the anodic polarization curve and I_L.

The rate of iron dissolution in the absence of ferric ions at the rest potential, $E_{m,o}$, can be expressed as

$$I_{m,o} = I_a = i_{o,a}\left[\exp\frac{\alpha_a n_a \mathbf{F}}{RT}(E_{m,o} - E^e{}_a)\right] \quad [11]$$

where $E^e{}_a$ is the equilibrium potential of the Fe/Fe^{+2} reaction.

When ferric ions are added to the solution, the corrosion current can be expressed as

$$I_m = I_L = I_a = i_{o,a}\exp\left[\frac{\alpha_a n_a \mathbf{F}}{RT}(E_m - E^e{}_a)\right] \quad [12]$$

where E_m is the rest potential of iron in the presence of ferric ions. The quantity, $(E_m - E^e{}_a)$, can be rearranged to

$$E_m - E^e{}_a = (E_m - E_{m,o}) + (E_{m,o} - E^e{}_a) = \Delta E_o + (E_{m,o} - E^e{}_a) \quad [13]$$

where ΔE_o is defined as the change in the rest potential with the addition of ferric ions to the H_2SO_4 solution. Equations [11] and [13] can be used to express Eq. [12] in the following form

$$I_m = I_L = I_{m,o}\exp\left[\frac{\alpha_a n_a \mathbf{F}}{RT}\Delta E_o\right] \quad [14]$$

or rearrange Eq. [14]

$$\Delta E_o = a' + b_a \log I_L \quad [15]$$

ΔE_o can be expressed as a function of both the ferric ion concentration and the angular velocity by utilizing the Levich equation for I_L, Eq. [3]. Then, Eq. [15] becomes

$$\Delta E_o = a + b_a \log C_{Fe(III)} + \frac{b_a}{2}\log\omega \quad [16]$$

Thus, ΔE_o is shown to be a linear function of the logarithm of the ferric ion concentration with proportionality constant equal to the anodic Tafel slope obtained from anodic polarization experiments. The continuous lines in Fig. 9 have slopes of 40 mV/decade. Thus, the experimental data are consistent with Eq. [16], since a value of 41 mV for b_a was determined directly from anodic polarization measurements.

Figure 10 shows a plot of ΔE_o *vs.* log ω at constant ferric ion concentration. The experimental data fit the continuous lines well. The slopes of these lines are 20 mV/ decade which is consistent with the ½ b_a slopes predicted by Eq. [16].

Figure 2 indicates that a plot of ΔE_o *vs.* I_L should give the anodic polarization curve for anodic dissolution of iron in H_2SO_4. The effect of ferric ions on iron dissolution should be evident by comparing the anodic polarization curves obtained from the ΔE_o *vs.* I_L plots and curves obtained by direct anodic polarization. Figure 11 provides such a comparison. The data points obtained by the two methods are in reasonable agreement indicating that the anodic polarization of iron in H_2SO_4 is not affected appreciably by the addition of ferric ions. These results are in accord with those obtained by Makrides (1) who showed that ferric ions had no specific effect on the anodic polarization of rotating cylindrical iron electrodes.

Since the corrosion rate is controlled by the limiting diffusion current for ferric ion reduction when ferric ions are introduced into the $Fe-H_2SO_4$ system, the cathodic Tafel slope is infinity ($b_c = \infty$). Then, Eq. [1]

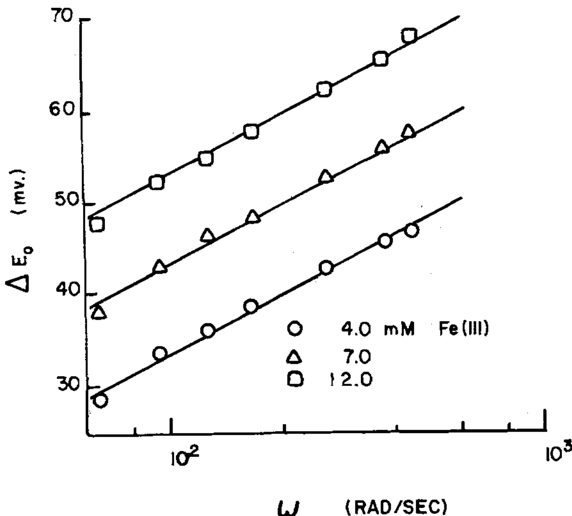

Fig. 10. ΔE_0 vs. log ω plot

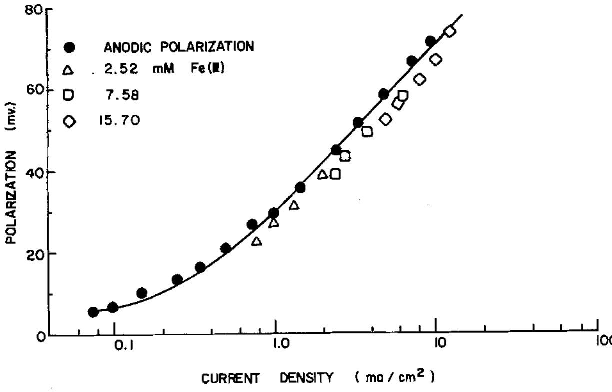

Fig. 11. Anodic dissolution of iron. Closed points represent anodic polarization data. Open points represent rest potential vs. I_L plots at various concentrations of Fe(III).

becomes

$$I_m = I_L = \frac{b_a}{2.303}\left(\frac{dI}{d\epsilon}\right)_{\epsilon=0} \quad [17]$$

Figure 12 shows typical linear plots of ϵ vs. I for small values of ϵ at a constant concentration of ferric ions. The corrosion current of iron at various angular velocities can be calculated from Eq. [17] and the slopes of these lines. Table II compares the corrosion

currents obtained by the polarization resistance method and by the cathodic polarization method. In general, the corrosion currents obtained by cathodic polarization are larger than the corrosion currents obtained by the polarization resistance method. However, for the lower ferric ion concentrations the corrosion currents of iron determined by the two methods are in good agreement.

Diffusion coefficients of Fe(III) and Fe(II).—Diffusion coefficients of electroactive species can be readily determined from limiting diffusion current plots of rotating disk electrode experiments. The diffusion coefficients of ferric and ferrous ions were determined from the I_L vs. $\sqrt{\omega}$ and concentration plots as in Fig. 4, 7, and 8. These values are presented in Table III. For comparison, diffusion coefficients reported by several other workers (8-10) are also given in Table III.

ABSTRACT

A method is presented for evaluating double-layer charging of porous electrodes. The maximum in the curve of $i\sqrt{t}$ *vs.* $\sqrt{t}$ lends itself readily to experimental evaluation. Values of the double-layer capacity determined for the Pb and PbO_2 electrodes in sulfuric acid are in agreement with those reported in the literature.

A number of models have been developed for analyzing the behavior of porous electrodes, and various degrees of complexity have been taken into account. The transient charging of the double-layer capacity (1-5) is of interest first of all because it provides a comparison between experimental and theoretical results. The transient charging can also be used to advantage to measure the capacity per unit volume of the electrode. A measurement of the double-layer capacity reflects most directly the active surface area coherently connected electrically and therefore accessible for electrochemical consumption. Such results should be useful for the characterization of battery electrodes and may be especially valuable since the electrode is not destroyed and indeed need not be removed from the cell in which it is cycled.

Transient measurement of the double-layer capacity of porous electrodes, as opposed to integration of the current passed following a potential step, has the advantage of emphasizing the charging current relative to the faradaic current, which interferes with the measurement. Furthermore, the resistance-capacity time constant will be large for an electrode with a large surface area, and the transient measurement will then reduce the experiment time substantially.

Johnson and Newman (4) have shown that the current response of a porous electrode to a step change in the potential yields, under certain circumstances, a nearly constant value of $i\sqrt{t}$, the product of the current density and the square root of time. A plot of $i\sqrt{t}$ *vs.* $\sqrt{t}$ yields a curve with a plateau. The curve is below this plateau value at short times because the ohmic resistance of the system prevents an infinite current density. At long times the curve again drops below the plateau value because the total capacity of the electrode begins to become saturated. The plateau value on a graph of this type is directly related to aC, the product of the specific interfacial area of the electrode and the double-layer capacity per unit area, and is independent of the thickness of the electrode. In this manner, Johnson and Newman inferred a value of aC = 83.5 farads/cm^3 for their porous carbon electrode.

However, most battery electrodes (for example, Pb and PbO_2 electrodes in sulfuric acid) are so thin that the ohmic limitation at short times overlaps with the approach to saturation at long times, and the plateau on the plot of $i\sqrt{t}$ *vs.* $\sqrt{t}$ is reduced to a maximum whose magnitude now depends on the electrode thickness or an equivalent parameter. This maximum still deserves the focus of our attention in a simple method for inferring the double-layer capacity aC from the measured transient current response. The earlier part of the curve is governed by the ohmic resistance, not the capacity, and the latter part is subject to interference from faradaic reactions. (This difference between thick porous carbon electrodes and thin battery electrodes can be visualized graphically by referring below to Fig. 2, where basically $i\sqrt{t}$ is plotted against $\sqrt{t}$, although dimensionless variables are used. The parameter λ is inversely proportional to the electrode thickness, if the matrix conductivity is very high.)

Analysis

Figure 1 is a diagram of the equivalent circuit of the system. R_2 represents the resistance of the solution in the pores of the electrode; R_1 that of the electrode matrix. C is the double-layer capacity between the electrode matrix and the pore solution. R_s corresponds to the resistance in the solution between the porous electrode and the reference electrode while R_L

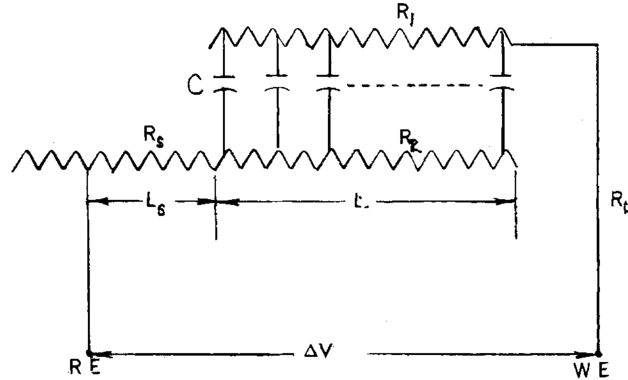

Fig. 1. Equivalent circuit of a porous electrode. The right side of the resistors represents a plane of symmetry in the center of the electrode.

* Electrochemical Society Active Member.
Key words: double-layer capacity, porous electrodes, lead-acid battery.

corresponds to the resistance in the leads and the current collector. For this system, Johnson and Newman (4) have related the Laplace transform of the current response to the Laplace transform of the applied potential. We make the following re-interpretation of their Eq. [20] (4) by including the resistance of the leads and that between the porous electrode and the reference electrode

$$R = \frac{L_s}{\kappa_s} + \frac{L}{\sigma + \kappa} + R_L \quad [1]$$

where L_s is the distance between the reference electrode and the porous electrode (κ_s being the conductivity of the medium between the two), L is the half thickness of a porous electrode with a counterelectrode opposite each face, σ is the effective conductivity of the matrix of the porous electrode, and κ is the effective conductivity of the pore solution. The terms in Eq. [1] have units of ohm-cm^2; consequently, R_L is the lead resistance multiplied by twice the apparent cross-sectional area of a porous electrode with a counterelectrode opposite each face.

Thus, R is the effective resistance of the composite system and is subject to direct experimental determination as we shall discuss briefly. At zero time, the current cannot be infinite; it is limited by the effective resistance of the system

$$i|_{t=0} = \Delta V/R \quad [2]$$

where $i|_{t=0}$ is the peak current density at time zero and ΔV the applied potential step between the reference and working electrodes. Thus, R can be directly obtained from the initial current surge measured on an oscilloscope.

Let us consider the case of a highly conducting matrix, $\sigma >> \kappa$ (for Pb and PbO_2 electrodes, $\sigma \approx 10^2$ and $\kappa \approx 0.1$ mho/cm). Posey and Morozumi (1) were the first to treat extensively double-layer charging of porous electrodes of finite thickness. They used a straight pore model and a highly conducting matrix. In an example involving the resistance between the working and reference electrodes, they inverted the Laplace transforms which are applicable to the system discussed in this paper. After some rearrangement the solution is

$$\frac{i\sqrt{\pi T}}{\Delta V}\frac{L}{\kappa} = 2\sqrt{\pi T}\sum_{n=1}^{\infty}\frac{\exp(-TX_n^2)}{1+\lambda+\lambda^2X_n^2} \quad [3]$$

where

$$T = \frac{t}{aCL}\frac{\kappa}{L} \text{ and } \lambda = \frac{R\kappa}{L} \quad [4]$$

aC is the double-layer capacity per unit volume of the electrode, and X_n is the positive root of cotangent $X_n = \lambda X_n$ [tabulated by Abramowitz and Stegun (6)]. In this result, no attempt has been made to account for faradaic reaction or concentration variations in the pore solution.

Since in our interpretation of the charging current we seek to emphasize the maximum in the curve of $i\sqrt{t}$ *vs.* $\sqrt{t}$, we plot in Fig. 2 the left side of Eq. [3] against $\sqrt{T}$. For $\lambda = 0$ the ordinate is a constant for short times. This corresponds to the plateau value discussed earlier, where

$$i\sqrt{t} = \Delta V\sqrt{aC\kappa/\pi} \quad [5]$$

At longer times, the value of $i\sqrt{t}$ begins to decrease as the charging wave penetrates to the center of the electrode. For $\lambda = 0$ the ohmic limitation at short times is not seen on this scale.

As the effective resistance in the circuit is increased ($\lambda > 0$), the instantaneous charging current is reduced, and the ordinate is initially zero. Providing the effective resistance is small enough, the ordinate may rise to the plateau predicted for $\lambda = 0$ after an initial transient period. As λ increases further, the value of the plateau (or maximum of the ordinate) decreases.

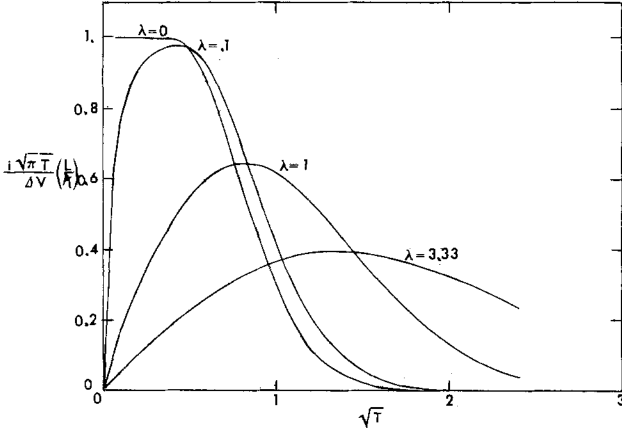

Fig. 2. Effect of the resistance-thickness parameter λ on the double-layer charging of a porous electrode.

The lower initial charging currents postpone the time at which the electrode capacity begins to become saturated and the value of $i\sqrt{t}$ begins to decrease. Consequently, the time at which the plateau or maximum occurs increases with increasing λ. This maximum readily lends itself to experimental determination.

For interpretation of the charging current we need only the coordinates of the maxima shown in Fig. 2. This information is summarized in Fig. 3 by plotting against $1/\lambda$ the following three quantities: the ratio of the coordinates of the maximum (this quantity being independent of the value of the double-layer capacity), $1/T_{max}$ (the time at which the maximum occurs, and a dimensionless value of $i\sqrt{t}$ at the maximum.

Interpretation and Evaluation of Charging Curves

Utilization of the information contained in Fig. 3 requires prior knowledge of the effective conductivity, κ, of the solution contained in the porous electrode. De la Rue and Tobias (7) found that the effective conductivity of a dispersion of glass beads in electrolytes can be represented by

$$\kappa = \kappa_0 p^{1.5} \quad [6]$$

where κ_0 is the conductivity and p is the volume fraction of the continuous phase. The effective conductivity of a solution contained in a porous medium can be estimated with this equation by using the porosity for p. Alternatively, the conductivity can be measured directly. Romanova and Selitskii (8) have employed the porous electrode as an inert separator. The ohmic potential drop through the electrode is then equal to $i2L/\kappa$. The value of κ needs to be re-estimated or redetermined if the electrode structure changes sig-

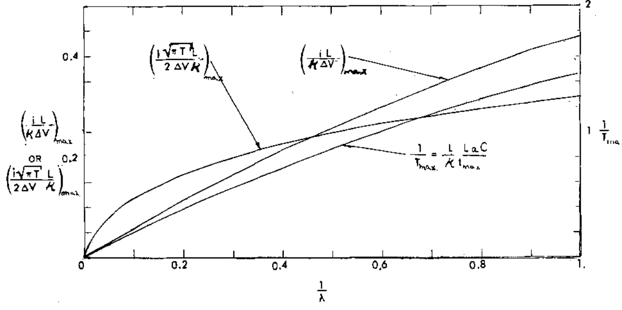

Fig. 3. Dependence of the coordinates of the maximum on the resistance-thickness parameter λ. Maximum refers to the maximum when $i\sqrt{t}$ is plotted against $\sqrt{t}$ for the double-layer charging of a porous electrode with a step change in the applied potential.

nificantly on repeated cycling. However, it is possible to determine κ by replotting the information in Fig. 3. Multiplying the ordinate of Fig. 3, $\left(\frac{i}{\Delta V}\frac{L}{\kappa}\right)_{max}$, by λ, we obtain $i_{max}/i|_{t=0}$ (where i_{max} refers to the value of the current density at the maximum in Fig. 2) which is plotted *vs.* $1/\lambda$ in Fig. 4. An oscilloscope trace of the current response to a voltage step will yield $i|_{t=0}$ directly, and a plot of $i\sqrt{t}$ *vs.* $\sqrt{t}$ will give i_{max}. The ratio of these two numbers will then yield a value of λ (which contains κ) as shown in Fig. 4. The measured value of the double-layer capacity is relatively insensitive to the value of κ when the resistance-thickness parameter λ is large.

An interesting sidelight of the results shown in Fig. 4 is that the value of κ determined in this manner can then be used to estimate the porosity of the electrode through the use of Eq. [6]. In this manner one may determine *in situ* the porosity of an electrode and follow its change through extended cycling tests.

The procedure used to extract the double-layer capacity per unit volume of electrode from the current response to a potential step can be stated as follows: (*i*) An oscilloscope trace of the current response of a porous electrode to a voltage step is obtained. (*ii*) The value of the current at time zero, $i|_{t=0}$, is recorded and a plot of $i\sqrt{t}$ *vs.* $\sqrt{t}$ is made. The coordinates of the plateau or maximum of the resulting curve are recorded and yield i_{max} and t_{max}. (*iii*) If information is available concerning κ, one then uses the left-hand ordinate of Fig. 3 to obtain $1/\lambda$ which in turn is used to obtain T_{max}, from the right-hand ordinate of Fig. 3. Using the definition of T_{max} and the experimentally determined t_{max}, one can calculate aC, the double-layer capacity per unit volume of electrode. (*iv*) If no information is available concerning κ, one first calculates $i_{max}/i|_{t=0}$ and then obtains λ from the ordinate of Fig. 4. The value of aC can then be obtained as mentioned in (*iii*).

This value of aC is regarded to be a measure of the electrochemically accessible surface area of a macrohomogeneous porous electrode. A further division of the aC product requires either specific knowledge about the total interfacial surface area of the electrode

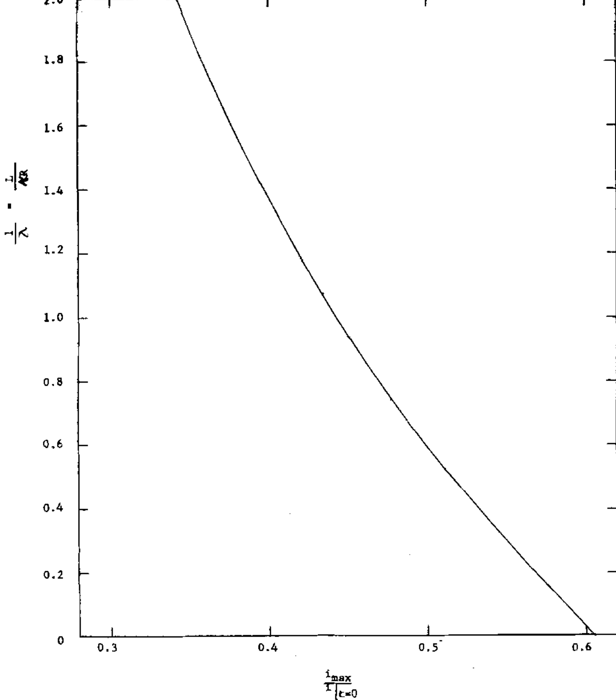

Fig. 4. Determination of the resistance-thickness parameter λ for a given set of i_{max} and $i|_{t=0}$.

or a measurement of C on a flat surface. An approximate value of a can be obtained from a BET surface area determination and then a value of C calculated. This type of calculation should only be considered qualitative due to the uncertainty of the type of microstructure existing at any given site in a porous electrode. Also the measured BET surface area does not distinguish between electrochemically active and inactive areas. One may also question whether alterations in the specific surface area might not occur during the preparation of the electrode for the BET measurement.

Errors in Double-Layer Measurements

Geometric surface area.—A real porous electrode (*e.g.*, a Pb or PbO_2 plate in the lead-acid battery) usually includes a grid support structure which, for practical purposes, does not contribute to the electrochemical capacity of the electrode but may occupy a significant portion of the electrode volume and geometric surface area. For many porous electrodes the active material is held in the grid support in the form of rectangular pellets, and it is the geometric area of these pellets which should be used in calculating the current density to be used in the treatment of the double-layer data. As grid support structures become more complicated, the specific area correction becomes more difficult leading to errors in the interpretation of the double-layer charging curves.

Electrode response time.—Most potentiostats have characteristic rise times of 1-10 μsec; however, it is the electrical analog of the electrochemical system in question which usually is the limiting factor in determining the rise time for the system as a whole. Real porous electrodes contain specific surface areas of the order of 10^4 cm^2/cm^3 and thus unavoidably present a large RC time constant. When the rise time of the potentiostat becomes significant compared to 0.1 t_{max}, one can expect errors to occur in the evaluation of the charging curves and the subsequent determination of aC. (We have examined the effect of the nonzero rise time of the potentiostat-electrode system by inverting the governing Laplace transform for an applied potential with an exponential approach to a constant value. While this is awkward for routine analysis of charging curves, it does provide an inexpensive alternative to the development of sophisticated electronics.)

Changes in electrode porosity.—For porous electrodes which undergo significant gassing, the effective conductivity of the solution within the electrode, κ, may change as a function of time (8). Also, the effective porosity of the electrode matrix may be altered by extended cycling. Therefore, it may be necessary to determine κ prior to performing a double-layer measurement.

Symmetry of the electrode.—Due to the manner in which real porous electrodes are fabricated (*e.g.*, the Pb and PbO_2 electrodes), there may exist a lack of symmetry about the center line of the electrode. Therefore, one should measure the double-layer capacity with the reference electrode at several locations and on both sides of the porous electrode in question to determine what uncertainty is associated with the measurement.

Faradaic reactions.—The electrode has been assumed to be ideally polarizable. Small departures from this requirement will result in a charging current which does not decay to zero. In a plot of $i\sqrt{t}$ *vs.* $\sqrt{t}$ the departure from a theoretical curve increases with time because the charging current is decreasing while the faradaic current is increasing. If the displacement is minor at large times, the effect on the coordinates of the maximum can safely be ignored. For battery electrodes which are selected to be highly reversible, one should minimize faradaic reactions by polarizing a fully charged electrode in the direction of further charge. (Actually, fully charged Pb and PbO_2 plates

can be polarized in the discharge direction because of the slow nucleation of $PbSO_4$.)

Experimental

The electrodes investigated in this study were positive and negative plates manufactured for use in automobile batteries. These electrodes contained grids of a lead alloy (6% antimony) as current collectors (Fig. 5). Sensing leads were attached to the top of the grid opposite the electrode tab. The solution employed was 4.5M sulfuric acid. The physical parameters for each type of electrode are given in Table I. The total current, I, is divided by the geometric electrode area to obtain the current density, i. L is half of the electrode thickness given in Table I.

The cell (a polypropylene case, filled with 4.5M H_2SO_4) used for these measurements contained the electrode in question located symmetrically between two counterelectrodes. A $Hg/HgSO_4$ reference electrode was used for both the Pb and PbO_2 electrodes. A small capillary from the reference electrode compartment was positioned adjacent to each electrode.

Controlled potential measurements were made with a Wenking Model 6BTS1 potentiostat which was programmed with a Hewlett-Packard 3300A Function Generator. An input voltage divider was required for reproducible 1-4 mV square wave signals. The current response was recorded with a Tektronix 564 storage oscilloscope and/or a recorder fitted with a function converter which would automatically plot $i\sqrt{t}$ *vs.* $\sqrt{t}$.

The PbO_2 and Pb electrodes were held at 1.17 and −0.972V *vs.* a $Hg/HgSO_4$ reference electrode, respectively, for 12 hr after they had been electrochemically cycled. This time was provided to accommodate surface modifications which have been reported to occur within the first few hours after cycling (9-12). All double-layer measurements were performed at the above-mentioned potentials.

Table I. Physical parameters of the PbO_2 and Pb electrodes

Electrode	BET surface area[1] (10^4 cm^2/cm^3)	Porosity[1]	Electrode thickness (cm)	Geometric electrode area[2] (cm^2)
PbO_2	20.5	0.56	0.2	241
Pb	2.5	0.63	0.15	241

Results and Discussion

Figure 6 shows a typical current response of a PbO_2 electrode to a voltage step and a subsequent display of $i\sqrt{t}$ *vs.* $\sqrt{t}$. Similar curves are obtained for the Pb electrode, only the time scale is two orders of magnitude smaller. The accuracy associated with the determination of aC for a given electrode is strongly dependent on the shape of the maximum in the $i\sqrt{t}$ *vs.* $\sqrt{t}$ curve, a broad maximum implying a larger error. We therefore sought to make λ as small as possible by minimizing the effective resistance in the system (*i.e.*, reference electrode placed as close to the working electrode as possible, separate sensing leads). The magnitude of ΔV was selected more for its convenience (as long as faradaic currents and the potential dependence of the double-layer capacity were small) since the value of T_{max} is independent of the value of ΔV. The effective conductivity of the solution inside the porous electrode was determined using Fig. 4.

Entrapped gases were observed to increase the effective resistance of the electrode which prolonged the charging period. As a consequence, both electrodes were placed in a vacuum chamber and degassed before the measurements were performed. Since the PbO_2 electrode is continually gassing, there will always be some entrapped gases which are unavoidably included in the measurement. One might then consider the real value of aC to be higher than that found experimentally.

Since the electrodes being examined are commercial plates, there exists a certain degree of nonuniformity over the electrodes. The extent to which the position of the reference electrode reflects these nonuniformities was observed by determining aC at three locations on each electrode. As shown in Table II, the position of the reference electrode does reflect somewhat the nonuniformities of the electrodes; also, within the potential difference applied to each electrode, the double-layer capacity appears to be a constant. However, the difference between these values is of the same order of magnitude as the error associated with the double-layer measurement (~5%). One may conclude that the assumption of a macrohomogeneous electrode is valid within experimental error.

Using the information contained in Tables I and II, the double-layer capacity per unit area for the PbO_2 and Pb electrodes is 143 and 10 μfarads/cm^2, respec-

Table II. Double-layer capacity as a function of reference electrode position and applied potential

	Reference electrode position			Applied potential, mV		
	1	2	3	2	3	4
Electrode	aC (farads/cm^3)	aC (farads/cm^3)	aC (farads/cm^3)	aC (farads/cm^3)	aC (farads/cm^3)	aC (farads/cm^3)
PbO_2	30.2	28.4	29.2	30.2	30.4	30.7
Pb	0.254	0.238	0.248	0.252	0.246	0.250

Position 2, First quadrant, left side of electrode.
Position 3, Second quadrant, right side of electrode.

tively. These values are in agreement with those reported in the literature (9-14) for electrochemically deposited PbO_2 and Pb on flat surfaces. However, it is realized that BET areas are a measure of the entire area available for gas adsorption and not the electrochemically active area. Therefore, the true double-layer capacity per unit area is higher than that calculated using areas determined by gas adsorption. The high observed value for PbO_2 may be due, in part, to a pseudocapacity. The term double-layer capacity has been used to mean interfacial capacity in a macroscopic sense and would include any capacity associated with the adsorption of charged species at the solution-matrix interface. It would exclude faradaic reactions which can be carried out in a steady state.

Conclusions

An interpretation of potentiostatic double-layer charging of porous electrodes has been presented. The emphasis on the maximum in the $i\sqrt{t}$ *vs.* $\sqrt{t}$ curve results in experimental curves which lend themselves readily to the evaluation of the double-layer capacitance, and it is this quantity which directly reflects the active electrochemical connected area. It has been demonstrated that the values for the double-layer capacity determined on commercial-size battery electrodes are in agreement with that determined on small, flat experimental electrodes. This result is encouraging since one wishes to apply fundamental techniques in the study of large electrodes. We may also note that this procedure was used on two electrodes whose aC values differed by two orders of magnitude.

One application of this type of measurement will be in the determination of changes occurring in the active electrochemical surface area with cycling. Also, the effects of additives which alter surface morphology may be detected by their effect on the double-layer capacity.

The possibility of determining the effective conductivity of the solution inside the porous electrode, and thereby inferring something about the electrode porosity, may require carefully designed experiments.

Technical Notes

Unified Approach to Cell EMF Calculations

David Gray*

Math/Science Division, Golden West College, Huntington Beach, California 92647

General Discussion

In calculating the emf of an electrochemical cell composed of two half-cell reactions, the usual procedure is to take the algebraic sum or difference (depending on convention) of the electrode potentials of the half-cells. In mathematical terms, this is expressed as

$$E_{\text{cell}} = E_{\text{ox}} \pm E_{\text{r}} \quad [1]$$

where E is the reversible or Nernst potential and the subscripts ox and r stand for oxidation and reduction half-cell, respectively. It will be shown in this paper that, while Eq. [1] is correct for most cases, it is not the general equation for cell emf calculations.

The only thermodynamic formula that will be necessary for this discussion is the well-known equation at constant temperature and pressure

$$\Delta G = -n\mathbf{F}E \quad [2]$$

where ΔG is the change in the Gibbs free energy, n is the change in the number of electrons, and $\mathbf{F}$ is the Faraday.

In general, if we consider two half-cell reactions, such as

$$A^{n_1} = n_{\text{ox}}e + A^{n_1+n_{\text{ox}}} \qquad \Delta G_{\text{ox}} = -n_{\text{ox}}\mathbf{F}E_{\text{ox}} \quad [3]$$

$$B^{n_2+n_r} + n_{\text{r}}e = B^{n_2} \qquad \Delta G_{\text{r}} = -n_{\text{r}}\mathbf{F}E_{\text{r}} \quad [4]$$

they may be combined to form a cell by the following procedure

$$n_{\text{r}}(A^{n_1} = n_{\text{ox}}e + A^{n_1+n_{\text{ox}}}) \qquad n_{\text{r}}\Delta G_{\text{ox}} = -n_{\text{r}}n_{\text{ox}}\mathbf{F}E_{\text{ox}} \quad [5]$$

$$n_{\text{ox}}(B^{n_2+n_r} + n_{\text{r}}e = B^{n_2}) \qquad n_{\text{ox}}\Delta G_{\text{r}} = -n_{\text{ox}}n_{\text{r}}\mathbf{F}E_{\text{r}} \quad [6]$$

$$n_{\text{r}}A^{n_1} + n_{\text{ox}}B^{n_2+n_r} = n_{\text{r}}A^{n_1+n_{\text{ox}}} + n_{\text{ox}}B^{n_2} \qquad \Delta G_{\text{cell}} = -n_{\text{cell}}\mathbf{F}E_{\text{cell}} \quad [7]$$

From thermodynamics, we can write that

$$\Delta G_{\text{cell}} = n_{\text{r}}\Delta G_{\text{ox}} + n_{\text{ox}}\Delta G_{\text{r}} \quad [8]$$

so that, from Eq. [2]

$$E_{\text{cell}} = \frac{n_{\text{r}}n_{\text{ox}}E_{\text{ox}} + n_{\text{ox}}n_{\text{r}}E_{\text{r}}}{n_{\text{cell}}} \quad [9]$$

Note that n_{cell} is the net cell electron change. It is obvious that

$$n_{\text{r}}n_{\text{ox}} = n_{\text{ox}}n_{\text{r}} \quad [10]$$

is true for all cases of cell formation. Thus, Eq. [9] may be written as

$$E_{\text{cell}} = \frac{n_{\text{r}}n_{\text{ox}}}{n_{\text{cell}}}(E_{\text{ox}} + E_{\text{r}}) \quad [11]$$

For cell calculations (case I, $A \neq B$) other than disproportionation reactions

$$n_{\text{cell}} = n_{\text{r}}n_{\text{ox}} \quad [12]$$

will be true, and Eq. [11] will reduce to Eq. [1].

Now, in disproportionation systems ($A = B$) there are two cases which will result in Eq. [12] and, therefore, Eq. [1] not being valid. If we set (case II)

$$n_1 = n_2 \quad [13]$$

$$n_{\text{r}} \neq n_{\text{ox}} \quad [14]$$

then we can rewrite Eq. [5], [6], and [7] as

$$n_{\text{r}}(A^{n_1} = n_{\text{ox}}e + A^{n_1+n_{\text{ox}}}) \qquad n_{\text{r}}\Delta G_{\text{ox}} = -n_{\text{r}}n_{\text{ox}}\mathbf{F}E_{\text{ox}} \quad [15]$$

$$n_{\text{ox}}(A^{n_1+n_r} + n_{\text{r}}e = A^{n_1}) \qquad n_{\text{ox}}\Delta G_{\text{r}} = -n_{\text{ox}}n_{\text{r}}\mathbf{F}E_{\text{r}} \quad [16]$$

$$n_{\text{ox}}A^{n_1+n_r} = n_{\text{r}}A^{n_1+n_{\text{ox}}} + (n_{\text{ox}} - n_{\text{r}})A^{n_1} \qquad (n_{\text{ox}} > n_{\text{r}}) \quad [17a]$$

or $\Delta G_{\text{cell}} = -n_{\text{cell}}\mathbf{F}E_{\text{cell}}$

$$(n_{\text{r}} - n_{\text{ox}})A^{n_1} + n_{\text{ox}}A^{n_1+n_r} = n_{\text{r}}A^{n_1+n_{\text{ox}}} \qquad (n_{\text{r}} > n_{\text{ox}}) \quad [17b]$$

It is obvious that for this particular case there exists no general relationship between n_{cell} and $n_{\text{r}}n_{\text{ox}}$.

Or if we set (case III)

$$n_1 + n_{\text{ox}} = n_2 + n_{\text{r}} \quad [18]$$

$$n_{\text{r}} \neq n_{\text{ox}} \quad [14]$$

then we can rewrite Eq. [5], [6], and [7] as

$$n_{\text{r}}(A^{n_1} = n_{\text{ox}}e + A^{n_1+n_{\text{ox}}}) \qquad n_{\text{r}}\Delta G_{\text{ox}} = -n_{\text{r}}n_{\text{ox}}\mathbf{F}E_{\text{ox}} \quad [19]$$

$$n_{\text{ox}}(A^{n_1+n_{\text{ox}}} + n_{\text{r}}e = A^{n_2}) \qquad n_{\text{ox}}\Delta G_{\text{r}} = -n_{\text{ox}}n_{\text{r}}\mathbf{F}E_{\text{r}} \quad [20]$$

$$n_{\text{r}}A^{n_1} + (n_{\text{ox}} - n_{\text{r}})A^{n_1+n_{\text{ox}}} = n_{\text{ox}}A^{n_2} \qquad (n_{\text{ox}} > n_{\text{r}}) \quad [21a]$$

or $\Delta G_{\text{cell}} = -n_{\text{cell}}\mathbf{F}E_{\text{cell}}$

$$n_{\text{r}}A^{n_1} = (n_{\text{r}} - n_{\text{ox}})A^{n_1+n_{\text{ox}}} + n_{\text{ox}}A^{n_2} \qquad (n_{\text{r}} > n_{\text{ox}}) \quad [21b]$$

Once again, it is obvious that for this case there exists no general relationship between n_{cell} and $n_{\text{r}}n_{\text{ox}}$.

* Electrochemical Society Active Member.

Key words: cells, emf, potential.

Further, it should be noted that in cases II and III Eq. [1] will result in erroneous cell potentials (see examples). Thus, these generalized examples demonstrate that Eq. [11] and not [1] is the general equation for cell emf calculations. It is essential to remember

path 1
$$2(Cu^+ = e + Cu^{++})$$
$$Cu^{++} + 2e = Cu$$
$$\overline{2Cu^+ = Cu + Cu^{++}}$$

path 2
$$Cu^+ = e + Cu^{++}$$
$$Cu^+ + e = Cu$$
$$\overline{2Cu^+ = Cu + Cu^{++}}$$

path 3
$$Cu = 2e + Cu^{++}$$
$$2(Cu^+ + e = Cu)$$
$$\overline{2Cu^+ = Cu + Cu^{++}}$$

that addition of half-cell reactions, even to obtain a complete cell, means addition of ΔG or nE, but not of E alone (1). But as case I illustrates, most cell combinations are such that Eq. [12] can be used. For other disproportionation systems (*i.e.*, $n_r = n_{ox}$), Eq. [12] and Eq. [1] will be valid.

For completeness, the method of combining half-cell reactions to form a new half-cell reaction will be included in this discussion. If we consider the following half-cell reactions

$$A^n = A^{n+n_1} + n_1e \qquad \Delta G_1 = -n_1\mathbf{F}E_1 \qquad [22]$$

$$A^{n+n_1} = A^{n+n_1+n_2} + n_2e \qquad \Delta G_2 = -n_2\mathbf{F}E_2 \qquad [23]$$

$$A^n = A^{n+n_1+n_2} + (n_1 + n_2)e \qquad \Delta G_{12} = -(n_1 + n_2)\mathbf{F}E_{12} \qquad [24]$$

and since

$$\Delta G_{12} = \Delta G_1 + \Delta G_2 \qquad [25]$$

we can write

$$E_{12} = \frac{n_1E_1 + n_2E_2}{n_1 + n_2} \qquad [26]$$

Specific Example

There are numerous examples which can be given to show that Eq. [1] is not always valid. Here one example will be assumed to be sufficient to show the general validity of Eq. [11].

If we take the following three half-cells (example 1) and their respective half-cell standard potentials (2)

$$Cu^{++} + 2e = Cu \qquad E^\circ_r = 0.337V \qquad [27]$$

$$Cu^+ + e = Cu \qquad E^\circ_r = 0.521V \qquad [28]$$

$$Cu^{++} + e = Cu^+ \qquad E^\circ_r = 0.153V \qquad [29]$$

we can form the cell

$$2Cu^+ = Cu + Cu^{++} \qquad E^\circ_{cell} = -\frac{\Delta G}{n\mathbf{F}} = 0.368 \qquad [30]$$

by three different paths:

$$E^\circ_{path\ 1} = \frac{2(-0.153) + 2(0.337)}{1} = 0.368V$$

(case III)

$$E^\circ_{path\ 2} = \frac{(-0.153) + 0.521}{1} = 0.368V$$

$$E^\circ_{path\ 3} = \frac{2(-0.337) + 2(0.521)}{1} = 0.368V$$

(case II)

If we had calculated these values by Eq. [1], E°_{cell} would have been 0.184V for paths 1 and 3, and 0.368V for path 2. This, in effect, would make E°_{cell} dependent on path, which it obviously is not. The important thing to note in this example is that n_{cell} has a definite and specific value which is determined by the over-all cell reaction and not by the half-cell reactions which make up the cell. In this example $n_{cell} = 1$ for all three paths

This example has been considered by Laitinen (3). However, he maintains the general validity of Eq. [1], which has been disproved in this discussion. Laitinen's book has been cited here because it is the only major textbook which discusses this problem at length.

One can now see that general use of Eq. [1] can make certain disproportionation systems path dependent, while Eq. [11] preserves the path independence of all cell emf calculations.

Relating Structural Variables of Porous Electrodes

T. Katan* and H. F. Bauman*

Materials and Structures, Lockheed Palo Alto Research Laboratory, Palo Alto, California 94304

The continued development of principles for electrode design [*e.g.*, Ref. (1-3)] and the improvement of fabrication methods [*e.g.*, Ref. (4-6)] must ultimately involve some specification of porous electrode structure. Yet, porous structures tend to elude physical description and relation of their electrochemically important (1-3) and geometrically derived variables such as specific surface area and porosity (7). Frequently, these variables are suspected to have mutual dependence, but it is not clear how a change in one variable will affect another.

It is our purpose here to show how the structural variables of battery and fuel cell electrodes can be specified and related by adapting a filamentary analog for porous structures. We also present practical values of these structural variables for typical electrodes.

The filamentary analog has been previously used by Everett and others in the study of adsorption processes (8). More complex models have been developed in other technical fields (9-13), but none of these appear to yield practical information of geometrical value so directly from a set of elementary equations.

Theoretical

In this approach a porous electrode is represented by a series of filaments, extending from one face of the mass to the other, which are assigned shapes and positions closely resembling the solid portions of an actual electrode. The filaments are assumed to have their ends situated at the centers of oppositely aligned unit squares in the electrode's facial planes and to individually occupy only the volumes contained between the squares. The unit squares have a side dimension x and comprise the grids of two matching Cartesian coordinate systems. As shown in Fig. 1, the pore parameter,[1] r, is defined as the radius of an imaginary pore with a circular cross-sectional fitting between, and touching only at the ends of, any four adjacent, parallel filaments, each with an over-all solid radius, R, and tortuosity factor, τ. For shapes consisting of regular particles, each particle is assigned a volume, v, area, a, and length, L, along the filament through the electrode of thickness t and fractional void volume θ.

From the Pythagorean theorem, R and r are related with the side of the unit square, and, considering a single filament, an expression is written for the solid volume fraction $(1 - \theta)$. These two equations are then used together with the definition of specific surface area, A, *i.e.*, the area of the particles per unit volume of electrode, to obtain a set of two equations relating $r, R, \tau, \theta, A, a, v$, and L

$$\frac{\tau}{(1-\theta)} = \frac{(R+r)^2}{v/2L} \qquad [1]$$

$$A = \frac{a(1-\theta)}{v} \qquad [2]$$

A third equation resulting from Eq. [1] and [2] also is useful

$$A = \frac{a\tau}{2(R+r)^2 L} \qquad [3]$$

For some structures, it is more accurate to treat the filaments as pores; the forms of the equations are then unchanged but the meanings of the symbols become reversed. For such filamentary pores the dimensionless group $\tau/(1 - \theta)$ of Eq. [1] is directly related to the so-called effective diffusion coefficient (14). Unless otherwise noted, filaments will be considered in analyses as the solid portion of the structure.

The equations can be generalized if it is understood that $v = k_1R^2L$ and $a = k_2RL$ for a given particle shape, where k_1 and k_2 are the applicable constants. Substitution into Eq. [1]-[3] yields, respectively, three corresponding equations relating the variables r, R, τ, θ, and A

$$\frac{\tau}{(1-\theta)} = \frac{2}{k_1}\left(\frac{r}{R} + 1\right)^2 \qquad [4]$$

$$A = \frac{k_2}{k_1}\frac{(1-\theta)}{R} \qquad [5]$$

$$A = \frac{k_2}{2}\frac{R\tau}{(R+r)^2} \qquad [6]$$

The constants k_1 and k_2 are altered only by a constant factor when particle shape is changed but are unchanged for all sizes of a given particle shape.

Results and Discussion

The set of three general equations suggests a natural division of structural variables into those which may be classified as either general, r, R, θ, τ, and A, or particulate, v, a, and L, and also suggests the use of certain groups of general variables, namely, $(R + r)$, r/R, $R/(R + r)^2$, and $(1 - \theta)$ which have practical significance. The variables $(R + r)$ and r/R are monotonically dependent on the defined pore parameter and hence, for typical τ and $(1 - \theta)$, on the effective pore radius for constant R; $(R + r)$ and R/r are similarly dependent on filament (solid) size for constant r; and $(1 - \theta)$ is the fractional solid volume. With the use of the general variables, the over-all effect on structure of suggested changes in design or fabrication becomes evident by considering, first, the relation of the general variables, and, second, the influence of particulate variables on the relation of the general variables.

General structural variables.—It is advantageous to examine plots of the general variables in some detail because the same dependences are found for all structures which can be represented by the filamentary analog. We may plot either R/r or $(r + R)$ *vs.* $(1 - \theta)$ for various τ from Eq. [1] or [4], A *vs.* R for various θ from Eq. [5], and A *vs.* τ for various $R/(R + r)^2$

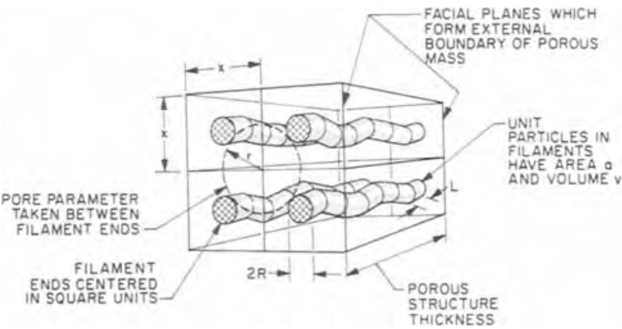

Fig. 1. Four volumetric units of electrode matrix with filaments showing effective dimensions.

* Electrochemical Society Active Member.

Key words: porous electrodes, porous structures, electrode design, batteries.

[1] The pore parameter, r, is also useful because it is essentially equivalent to an "effective" pore radius excepting when τ and $1 - \theta$ become large *i.e.*, when the average filament spacing at the interior differs appreciably from the assigned spacing of the ends.

from Eq. [6]. As a guide, we select Fig. 2 through 4 for electrodes constructed of uniform spheres, bonded together, where the filamentary analog is taken to consist of rows of touching spheres. Here, $v = 4/3\pi R^3 = k_1R^2L$, $a = 4\pi R^2 = k_2RL$, and $L = 2R$, hence $k_1 = 2/3\pi$ and $k_2 = 2\pi$ in Eq. [4]-[6].

Particulate structural variables.—From Eq. [2] and [3], it can be seen that for a given set of general variables, A is increased linearly with increases in a/v or a/L. In fabrication this increase is usually accomplished by increasing surface roughness or by using filamentary particles having micropores. Ultimately, such increases in particle area become of limited practical use because of the onset of transport process limitations within the micropores (15). From Eq. [1] we see that the ratio v/L has the same influence as τ in shifting the curves of Fig. 2. The relation of particulate to general variables of porous structures is thus evident by Eq. [1]-[3]; the form of the relations of general variables always holds while these relations are changed by a proportionality constant with changes in the particulate variables as indicated above.

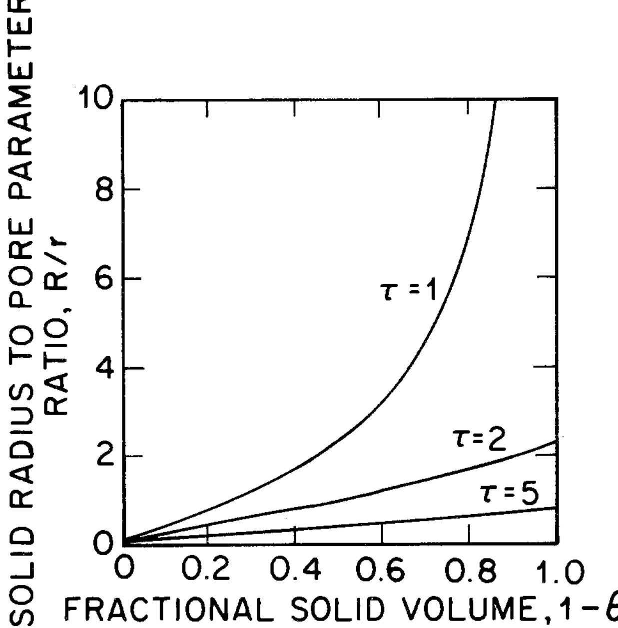

Fig. 2. Variation in ratio of effective solid radius to pore parameter for changes in fractional solid volume.

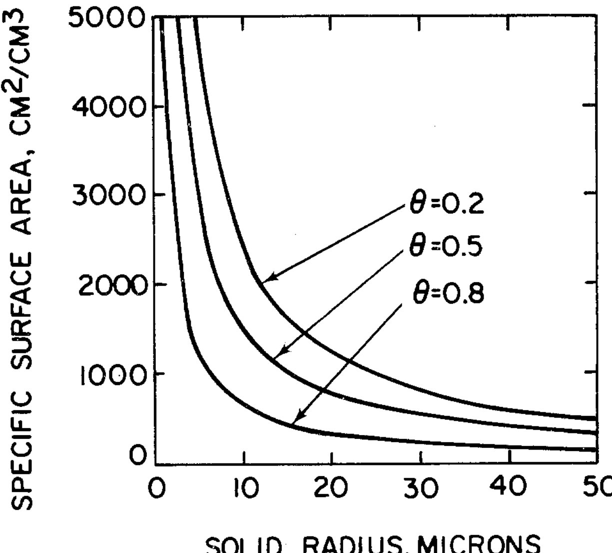

Fig. 3. Variation in specific surface area for changes in filament radius.

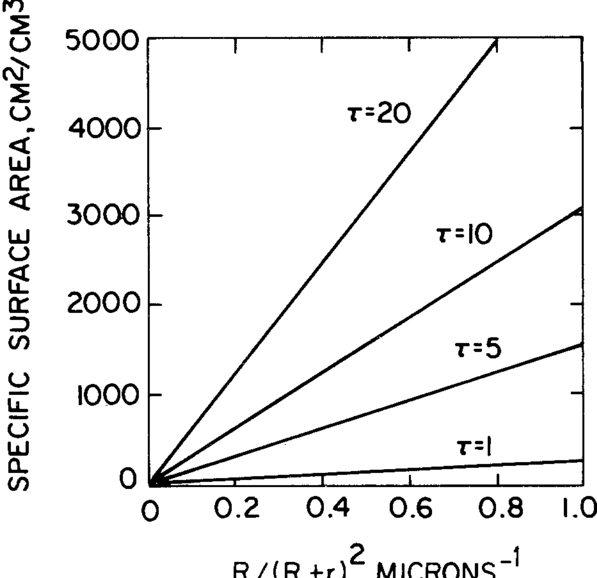

Fig. 4. Variation in specific surface area for changes in $R/(R + r)^2$.

Some applications.—Accuracy of the given equations is best for those structures whose void or solid portions are simply shaped or for those which closely resemble a filamentary network. For example, accurate relations should be obtained with many known practical structures which are structurally ordered, such as stacks of woven wire meshes or screens, bundles of parallel, uniform metal fibers (16), compacted short lengths of uniform metal fibers,[2] structures of sieved, bonded particles (5), metallized paper fiber structures (17), or uniform sphere beds (18). The latter three structures have been reported as experimental fuel cell and battery electrodes.

The filamentary analog for electrode structures should be selected so that the best correspondence in the representation is made, *i.e.*, so that variables can be easily assigned. For example, with stacks of plain square weave screens, the wires in one direction could be taken as the principal filaments while wires perpendicular to these filaments should be considered as segments with specified area, divided and attached to the principal filaments at regular intervals. With more complex structures, it is useful to consider the porous mass to be divided into smaller, identical volume elements, equivalent to x^2t volumes, taken so that each volume element contains essentially the same geometrical configuration of filaments throughout the mass. In practice, we have found that some accuracy is retained with this method even with typical electrodes.

We have summarized in Table I the structural variables of four typical, more complex, electrode structures, giving the representations selected for the filamentary analog. For the given structures, r and R were determined by averaging several values measured from photomicrographs of polished metallographic cross sections taken with an optical microscope of the porous masses after impregnation with epoxy under vacuum, *e.g.*, see Fig. 5a. Circles were fitted between the assumed filaments at a large number of randomly selected locations to obtain the average radius, r. Thickness of the assumed filaments, $2R$, was measured perpendicular to the filament direction, also at several randomly selected locations, as indicated in Fig. 5a. Photographs of a calibrated scale at the same magnification were used to ascertain distance.

Scanning electron microscopy, as shown in Fig. 5b, helped in selection of assumed filament shapes and direction. In Fig. 5b, the solid portions are visualized as approaching an ordered shape of interconnected

cylindrical filaments. For all of the complex structures, enough order could be detected to allow application of the filamentary analog method. Porosities were calculated from the measure weights of predetermined volumes of the specimens free of any supporting screen material and from the known densities of the void-free substances.

After the selection of a filamentary analog shape, A is calculated by Eq. [2], using the measured θ and R, and τ is calculated from Eq. [1] using the measured θ, R, and r. The average deviation in determined R and r values was less than $\pm$ 6%.

In Table II values are given of specific surface areas for the electrode materials determined by the filamentary analog representation (Table I), by the BET method (19), and by a stereometric method (20). The area of the specimen of silver spheres was too low to yield accurate analysis by the BET method to better than $\pm$ 50%. The stereometric analysis with the spheres also failed to yield accurate analysis because of the inability of the used method of scanning to distinguish touching spheres from single spheres. On the other hand, for those cases where BET and stereometric methods are accurate, agreement with the filamentary analog values is to within $\pm$ 15%, which thus appears to be the limit of accuracy of the filament method for complex shapes. With simple shapes, accuracy is limited only by the accuracy in measurements of R and r as applied to Eq. [4]-[6].

Summary and Conclusions

A filamentary analog of a porous mass is mathematically developed to show how structural variables can be mutually related and act as a guide in evaluations of porous electrodes. Specific surface area, porosity, solid tortuosity, solid radius, and a pore parameter are related, and the influence of changes in solid filamentary particle volume, length, and area on these relations is shown. Accuracy of the filament method in estimating specific surface area was found to be within $\pm$ 15% for complex electrode structures.

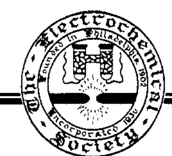
Brief Communication



The Kinetics of Nickel Passivation

Adolf Pigeaud*

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

Passive surface conditions may be produced on metals and alloys by electrochemical polarization in the anodic region. The passive condition occurs as the result of a series of surface reactions which culminate in the deposition of a highly protective film. Such films usually consist of several very thin oxide phases parallel to, and in intimate contact with, the surface. Potentiostatic experiments are often performed to study the formation of these layers on sample metal electrodes in an electrochemical cell. Current is measured while potential is generally varied according to a controlled schedule of specified values. Unfortunately, this controlled variation in most potentiostatic experiments is selected without adequate regard for the reaction kinetics of the individual film formation processes. This is evident because the normal procedure usually is to vary the applied potential in stepwise fashion or to increase it monotonically during polarization even though individual reactions obviously still have not yet run their course.

In a recent study of pure Ni-polarization in 15N sulfuric acid, very fast and very slow current changes were investigated while potential across the total cell was maintained at a constant value throughout each experimental run. Oxide layers left on the surface from previous experiments were removed before each new run by a kind of electropolishing technique in which vigorous oxygen evolution is enforced for about ½ min. The sample is then allowed to come to its equilibrium rest potential in a fresh quantity of solution. A new run begins the moment a particular desired potential is applied across the total cell (*i.e.*, from counterelectrode to working electrode without reference to any solution potential). Current data were obtained by means of two types of recorders: a light-beam oscillograph for the very fast initial changes and an $X(\log t) = Y$ recorder for the medium and very slow, long term changes. The current variable also extended over a wide range of values from about 100 $\mu A/cm^2$ to over 1000 mA/cm^2. Hence "instantaneous" log converted values of current were the actually recorded variables for obtaining high frequency, wide band response. A large number of such isopotential experiments were run and in each case current behavior was followed for a considerable length of time, from 10 msec after startup to at least 17 min (1000 sec). Thus an enormous body of data was accumulated which proved too large and cumbersome to be handled by ordinary means of curve comparison. A powerful new method of analysis, using 3D-computer graphics, was then applied and a very revealing picture of the kinetics of nickel passivation resulted. Figure 1 illustrates this total kinetic

* Electrochemical Society Active Member.

Key words: polarization, kinetics, nickel, passivity.

Fig. 1. Complete electrokinetic response in current-time-potential space of pure nickel polarized in 15*N* sulfuric acid

behavior as a complex surface in current-time-potential space. The surface was generated by manually converting the (*I*-*t*) analog data of each isopotential curve into digital form (*e.g.*, some 2304 points were read) and these were then plotted as a three-dimensional perspective view from the side of the orthogonal current-potential plane. One should note that the (*I*-*E*) curves so obtained can never be directly generated in a real experiment since potential, of course, cannot be increased from 0 to 2400 mV in zero time.

To our knowledge this method of obtaining the complete "electrokinetic" response of a system while it polarizes is unique. The data were obtained both by a greatly improved instrumental method and a somewhat different operating procedure. Analysis of these data, in the form of a complex current-time-potential surface, moreover has proven powerful indeed. Originally the minima and maxima in the isopotential curves seemed to bear little relationship to known equilibria or to familiar reaction processes. After plotting in three dimensions, however, the extremes and inflections in these curves can be recognized as part of a larger system of ridges, saddle points, and valleys which have real meaning in terms of the various reactions that are likely to occur on the surface. Thus it has been possible, with the help of other visual and analytical evidence obtained during the experimental part of this program, to identify most of these features as being due to the formation on the surface of a number of colloidal hydroxides (1) and multiphase oxide layers.

Additional support for these conclusions came when it was realized that these data, which are basically kinetic in nature, can also be used to supply evidence of the momentary existence of thermodynamic equilibria during polarization. Namely when the saddle points and valleys of the complex surface are projected onto the (*E*-*t*) base plane of Fig. 1 a kind of pseudo-Pourbaix diagram results which is illustrated in Fig. 2. This projection of the diffuse features of the complex surface in a different dimension suddenly allows one to fit rather precise straight-line boundaries to what were seemingly only vaguely defined regions of electrochemical stability. Single and dual phase layers which previously could only be inferred have also been added to this diagram which, it must be emphasized, shows stability with respect to a "time" frame of reference. When Fig. 2 is compared to a partial ver-

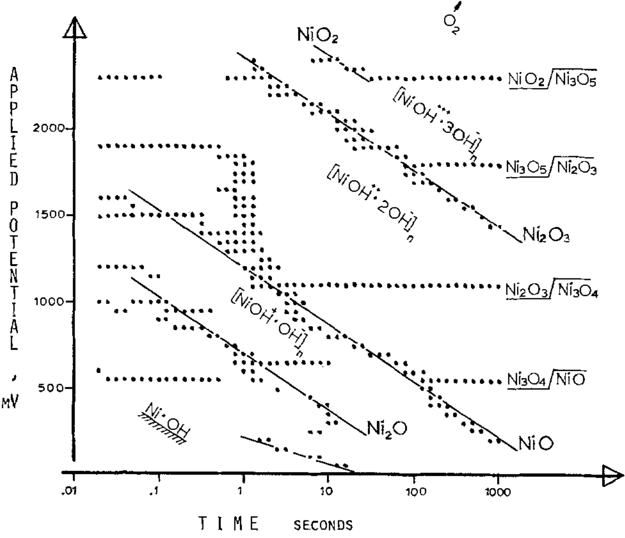


Fig. 2. Pseudo-Pourbaix diagram obtained directly from nickel polarization data.

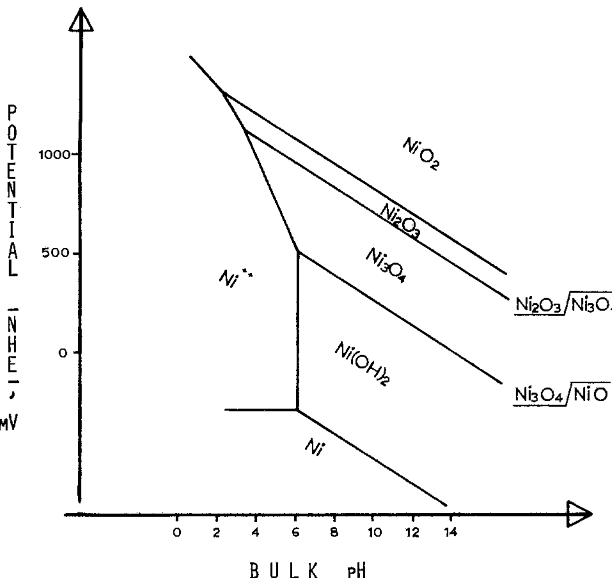

Fig. 3. Partial Pourbaix diagram of Ni-H_2O system

sion of the Pourbaix diagram for nickel, such as is shown in Fig. 3, the remarkable similarity between these two modes of expressing thermodynamic equilibria becomes apparent. In fact the almost 1:1 analogy between the phase boundaries in these two diagrams suggests that a simple inverse relationship must exist between polarization time and H^+-ion concentration in the immediate vicinity of the polarizing metal surface (*e.g.*, as compared to the bulk concentration). Such a relationship is not difficult to justify on theoretical grounds if one can assume a polarization model in which proton removal from the interface occurs at a constant electrophoretic rate of migration due to a constant electric field.

This means that a Pourbaix diagram, such as shown in Fig. 3 which is actually a composite of free energy data obtained from many different sources, can now be obtained all at once by means of a single experimental procedure and also with respect to a more realistic time frame of reference. Furthermore, when completely developed, this procedure holds the promise of being able to yield detailed information on the various spinellike phases and multilayer combinations which may occur in protective films (*e.g.*, on alloys) formed in real environments (*e.g.*, in aqueous or organic solutions containing other cationic and anionic species).

Conclusion

An improved polarization and data analysis technique applicable to most metal/electrolyte systems has been developed which shows considerable promise as a new tool for the direct, time-dependent characterization of anodically deposited films.

Acknowledgment

The author wishes to thank Professor Clair M. Hulley, the developer of the generalized computer program, and Mr. Bob Hsieh for their assistance in running his data program on the IBM-1130 computer slaved to the Calcomp-718 curve plotter of the Electrical Engineering Department at the University of Cincinnati. The present communication will be followed by a more detailed theoretical and experimental paper on a new theory of metal/electrolyte polarization after the author has submitted it to the faculty of his Department in partial fulfillment of the requirements for the Ph.D. degree (1974).

Solid-State Ionics: High-Conductivity Solid Copper Ion Conductors: N,N'-Dialkyl (or Dihydro)-Triethylenediamine Dihalide-Copper(I) Halide Double Salts

Takehiko Takahashi* and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

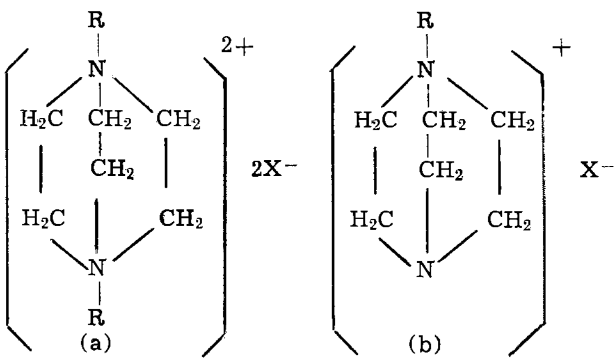
New solid electrolytes with high copper ion conductivity at ambient temperature have been found in the system N,N'-dialkyl (or dihydro)-triethylenediamine dihalide-copper(I) halide in the composition range of 94-80 mole per cent (m/o) copper(I) halide. For example, the solid-state reaction product between copper(I) bromide 94 m/o and N,N'-dimethyl-triethylenediamine dibromide 6 m/o exhibited the conductivity of 0.035 $(ohm\text{-}cm)^{-1}$ at 20°C, which was essentially ionic. X-ray diffraction investigations indicated that these new solid electrolytes are unique and not the mixtures of their constituents.

During the past decade, the electrical properties of high-conductivity solid electrolytes and their applications to electrochemical devices have been described by many authors (1). However, the high-conductivity materials reported previously have been mainly the silver ion or alkali ion conductors. Recently, promising results have been found by Takahashi, Yamamoto, and Ikeda (2), that N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide double salts exhibited high copper ion conductivities of 4×10^{-4} to 1.7×10^{-2} $(ohm\text{-}cm)^{-1}$ at 20°C and their electronic conductivities were less than 10^{-10} $(ohm\text{-}cm)^{-1}$ at 100°C. Further investigations on copper ion conductors in our laboratory have revealed that the N,N'-dialkyl (or dihydro)-triethylenediamine dihalide-copper(I) halide double salts have the ionic conductivities of 2×10^{-3} to 4×10^{-2} $(ohm\text{-}cm)^{-1}$ at 20° C.

Experimental

N,N'-dialkyl (or dihydro)-triethylenediamine dihalides, $C_6H_{12}N_2 2RX$ (R = H, CH_3, C_2H_5, X = Cl, Br, I), were prepared by mixing the ethanol solution of triethylenediamine (1,4-diazabicyclo 2,2,2 octane), $C_6H_{12}N_2$, and alkyl halides or hydrohalogenic acids. Triethylenediamine and alkyl halides used were manufactured by Tokyo Chemical Industry Company, and they were used without further purification. For example, to a solution containing 5g (0.045 mole) of triethylenediamine in 50 mliters of ethanol were slowly added 21g of a 50% methyl bromide (0.11 mole) solution in ethanol and the mixture was allowed to stand overnight at room temperature. After being filtered, the precipitate was dried in vacuo on P_2O_5. By this method, five kinds of N,N'-dialkyl (or dihydro)-triethylenediamine dihalides, $C_6H_{12}N_2 2HCl$, $C_6H_{12}N_2 2HBr$, $C_6H_{12}N_2 2C_2H_5Br$, $C_6H_{12}N_2 2HI$, and $C_6H_{12}N_2 2CH_3I$ were prepared. For the preparation of all these precipitates, the mole ratio of alkyl halides (or hydro halogenic acids) to triethylenediamine was made larger than the stoichiometric ratio (2:1 mole ratio). N,N'-dimethyl-triethylenediamine dichloride was prepared as follows: triethylenediamine (25.5g) was added to a 7.3% ethanol solution of methyl chloride (422g). After standing for two days, methyl chloride gas was blown into the solution. The mixture was allowed to stand for seven days at room temperature, and after being filtered, the precipitate was dried in vacuo on P_2O_5. The crystals obtained were recrystallized from ethanol.

Triethylenediamine has two nitrogen atoms in a molecule, and the following two types of quarternary alkyl triethylenediamine halide (a) and (b) may exist



where R is H, CH_3, or C_2H_5, and X is halogen. In this study, as the quarternary alkyl triethylenediamine halides were obtained using an excess amount of alkyl halide or hydrohalogenic acid, the chemical formulas of the obtained compounds were type (a) which are certificated by the analytical data shown in Table I. The analytical data agree well with the values calculated from the molecular form of $C_6H_{12}N_2 2RX$. The decomposition temperature of these compounds are

also shown in the table. Copper(I) halides were purified by recrystallizing in the corresponding hydrohalogenic acid.

The materials used for the conductivity and x-ray experiments were prepared by combining CuX with $C_6H_{12}N_22RX$. The appropriate quantities of both compounds were mixed with a small amount of ethanol and dried completely at about 80°C before being pressed to form a pellet under a pressure of 4000 kg/cm^2, and then heated in a sealed evacuated Pyrex vessel for 17 hr. The reactions were carried out below the decomposition temperatures of the corresponding $C_6H_{12}N_22RX$ shown in Table I, that is, at 160°C for the CuCl-$C_6H_{12}N_22HCl$ system, at 170°C for the CuI-$C_6H_{12}N_22CH_3I$ system, and at 190°C for the other systems. The resulting materials did not melt at these reaction temperatures, except for the $C_6H_{12}N_22HCl$-CuCl system.

The electrical conductivity was measured by using a cell, Cu, sample/sample/Cu, sample. The sample of about 0.8g was stacked between the mixture of powdered copper (325 mesh) and the sample (2:1 weight ratio), and pressed into a pellet of 13 mm diameter under a pressure of 4000 kg/cm^2. The pressed samples with copper electrodes were annealed for several hours at 100°-200°C, corresponding to the kind of sample, in oxygen-free nitrogen gas flow before being slowly cooled to room temperature in an oven. This treatment provides for removal of the excess halogen in the sample, thus avoiding a deficit of copper which will give hole conduction in addition to ionic (3). The resistance of the conductivity cell was measured by means of the Ando Denki conductance bridge using 1000 Hz. The frequency dependence of resistance was not observed for all samples investigated.

The method for determining the electronic conductivity was described previously in some detail (2). It was determined from the relation of the current density and the cell voltage for the cell, Cu/sample/graphite, upon passing a direct current.

The transport number of copper ion was measured by Tubandt's method. In order to reduce the electrode polarization, a mixture of powdered copper and the sample was used for the electrode, and the weight changes of the electrode and the sample of the cell of the type

$$\text{Cu, sample/sample/sample/Cu, sample} \quad [I]$$

were measured.

The x-ray diffraction patterns of the powdered samples were obtained at room temperature using conventional techniques with CuKα radiation.

Differential thermal analysis (DTA) was carried out for the sample which was sealed in a Vycor tube under vacuum. The heating rate was 3.5°/min. The decomposition temperature of samples was measured by thermogravimetric analysis (TGA), the heating rate of which was 3.3°C/min.

Results and Discussion

Electrical conductivity.—The effect of composition on the conductivity at room temperature was determined for the systems $C_6H_{12}N_22HCl$-CuCl, $C_6H_{12}N_22CH_3Cl$-CuCl, $C_6H_{12}N_22HBr$-CuBr, $C_6H_{12}N_22CH_3Br$-CuBr, $C_6H_{12}N_22C_2H_5Br$-CuBr, $C_6H_{12}N_22HI$-CuI, and $C_6H_{12}N_22CH_3I$. Of these systems, the conductivity of the thermal reaction products of the $C_6H_{12}N_22HI$-CuI system was comparable to or less than that of CuI. The other systems showed conductivities of 10^{-4}-10^{-2} (ohm-cm)$^{-1}$ at room temperature in the composition range of 95-80 mole per cent (m/o) CuX. Figure 1 shows the electrical conductivities of the systems studied at 20°C as a function of the mole per cent of copper(I) halide. These curves show that the conductivity has a maximum at a certain content of copper(I) halide and decreases rapidly with decreasing the content of copper(I) halide. The maximum values of conductivity were obtained at 85 m/o CuCl for the system $C_6H_{12}N_22HCl$-CuCl, at 80 m/o CuCl for $C_6H_{12}N_22CH_3Cl$-CuCl, at 87.5 m/o CuBr for $C_6H_{12}N_22HBr$-CuBr, at 94 m/o CuBr for $C_6H_{12}N_22CH_3Br$-CuBr, at 85 m/o CuBr for $C_6H_{12}N_22C_2H_5Br$-CuBr, and at 85 m/o CuI for $C_6H_{12}N_22CH_3I$-CuI. The highest conductivity of 4.9×10^{-2} (ohm-cm)$^{-1}$ at 20°C was found in the system $C_6H_{12}N_22HBr$-CuBr at 87.5 m/o CuBr. This value of conductivity is about three times larger than that reported in our previous paper (2), in which the conductivity of 1.7×10^{-2} (ohm-cm)$^{-1}$ at 20°C was obtained in the system N-methyl-hexamethylenetetramine bromide-copper(I) bromide at 87.5 m/o CuBr. Further, the conductivity value is comparable to that of silver ion conductors which are obtained by combining silver iodide with organic ammonium iodides (4-6).

From the above results, it is recognized that in the systems $C_6H_{12}N_22RBr$-CuBr, the conductivity decreases successively with R being H, CH_3, or C_2H_5. This result suggests that the symmetry of organic ammonium halide may play a role to give the high conductivity compound. Triethylenediamine is known as a bicyclic cage compound, the stereo structure of which shows somewhat spherical symmetry, and the symmetry of the quarternary alkyl triethylenediamine ion gets worse with increasing the volume of R from H to C_2H_5.

The temperature dependence of the electrical conductivities was determined for the samples in the

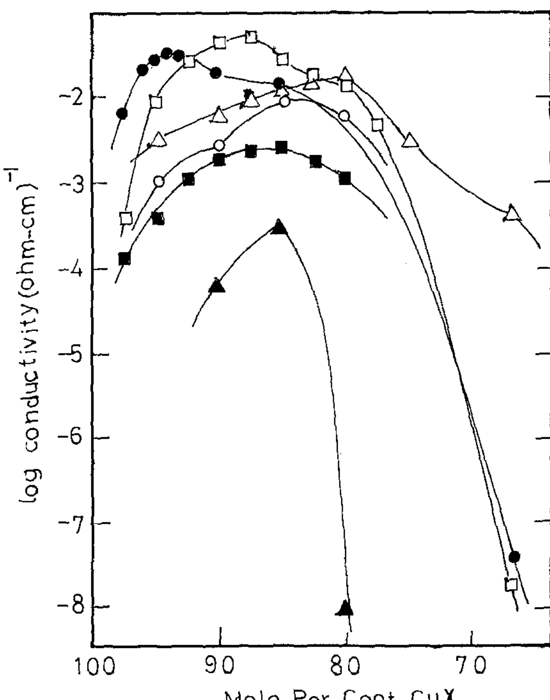

Fig. 1. Composition dependence of the electrical conductivity of the binary solid electrolyte systems $C_6H_{12}N_22HCl$-CuCl (○), $C_6H_{12}N_22CH_3Cl$-CuCl (△), $C_6H_{12}N_22HBr$-CuBr (□), $C_6H_{12}N_22CH_3Br$-CuBr (●), $C_6H_{12}N_22C_2H_5Br$-CuBr (▲), and $C_6H_{12}N_22CH_3I$-CuI (■) at 20°C.

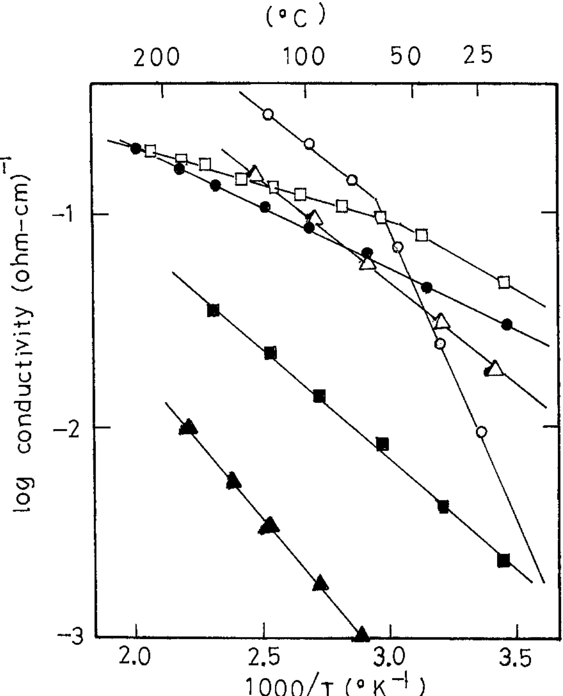

Fig. 2. Temperature dependence of the electrical conductivity of $17CuCl \cdot 3C_6H_{12}N_22HCl$ (○), $4CuCl \cdot C_6H_{12}N_22CH_3Cl$ (△), $7CuBr \cdot C_6H_{12}N_22HBr$ (□), $47CuBr \cdot 3C_6H_{12}N_22CH_3Br$ (●), $17CuBr \cdot 3C_6H_{12}N_22C_2H_5Br$ (▲), and $17CuI \cdot 3C_6H_{12}N_22CH_3I$ (■).

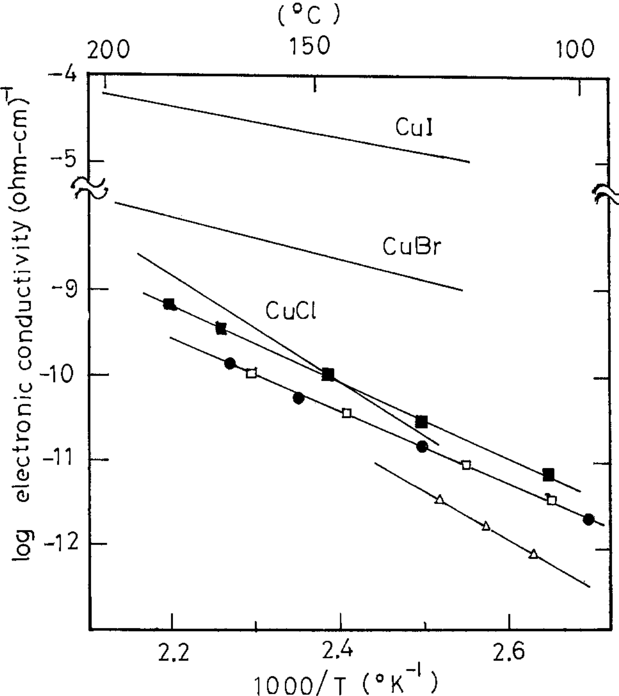

Fig. 3. Temperature dependence of the electronic conductivity of copper(I) halides, $4CuCl \cdot C_6H_{12}N_22CH_3Cl$ (△), $7CuBr \cdot C_6H_{12}N_22HBr$ (□), $47CuBr \cdot 3C_6H_{12}N_22CH_3Br$ (●), and $17CuI \cdot 3C_6H_{12}N_22CH_3I$ (■).

$C_6H_{12}N_22RX$-CuX system. The results of several temperature cycles are shown in Fig. 2. The log conductivity *vs.* the reciprocal of the absolute temperature curves for $4CuCl \cdot C_6H_{12}N_22CH_3Cl$, 47 $CuBr \cdot 3C_6H_{12}N_22CH_3Br$, 17 $CuBr \cdot 3C_6H_{12}N_22C_2H_5Br$, and 17 $CuI \cdot 3C_6H_{12}N_22CH_3I$ indicate that no phase transition occurs in the range of the temperature investigated. The activation energies calculated from these curves are 4.2 kcal/mole for $4CuCl \cdot C_6H_{12}N_22CH_3Cl$, 2.7 kcal/mole for 47 $CuBr \cdot 3C_6H_{12}N_22CH_3Br$, 5.6 kcal/mole for $17CuBr \cdot 3C_6H_{12}N_22C_2H_5Br$, and 4.8 kcal/mole for $17CuI \cdot 3C_6H_{12}N_22CH_3I$. The results for $17CuCl \cdot 3C_6H_{12}N_22HCl$ and $7CuBr \cdot C_6H_{12}N_22HBr$ exhibit an increasing activation energy at low temperature, which suggests that phase transitions occur near 65°C for $17CuCl \cdot 3C_6H_{12}N_22HCl$ and 50°C for $7CuBr \cdot C_6H_{12}N_22HBr$. However, $7CuBr \cdot C_6H_{12}N_22HBr$ is conductive at room temperature and has a low activation energy of 3.3 kcal/mole at 20°C. On the other hand, $17CuCl \cdot 3C_6H_{12}N_22HCl$ has a high activation energy of 13.5 kcal/mole at 20°C, and it indicates that the conductive phase transfers to a nonconductive phase below 65°C.

Electronic conductivity.—Though stoichiometric copper(I) halides exhibit ionic conduction predominantly, the existence of excess halogen or oxygen which corresponds to a deficit of copper causes hole conduction (3). Therefore, it is important to measure the electronic conductivity of the solid electrolyte containing copper(I) halides. The electronic conductivity of the $C_6H_{12}N_22RX$-CuX system was measured by Wagner's polarization method. The current *vs.* cell voltage curves for the cell, Cu/sample/graphite, showed a quasi-exponential increase of current in the temperature range of 100°-200°C for all samples investigated. Therefore, according to Wagner's theory, the hole conduction may be assumed to be dominant under this experimental condition. The electronic conductivities were calculated with the help of this theory. The temperature dependence of the electronic conductivity of $4CuCl \cdot C_6H_{12}N_22CH_3Cl$, $7CuBr \cdot C_6H_{12}N_22HBr$, $47CuBr \cdot 3C_6H_{12}N_22CH_3Br$, and $17CuI \cdot 3C_6H_{12}N_22CH_3I$ is shown in Fig. 3, compared to those of the copper(I) halides. The electronic conductivities of these new high conductivity materials are smaller than those of the corresponding copper(I) halides. At room temperature, the electronic conductivities of these materials were too small to measure with this method. Thus, it is concluded that the conduction in these new compounds is essentially ionic in nature.

Transport number measurements.—The ionic transport number in 47 $CuBr \cdot 3C_6H_{12}N_22CH_3Br$ was determined with the help of Tubandt's method. In order to reduce the electrode polarization, the measurement was carried out at 100°C. The direct current at the current density of 500 $\mu A/cm^2$ was passed through cell [I] over 21 hr. The total charge passed through the cell corresponded to the quantity of copper deposited at the cathode and dissolved at the anode; that is, the efficiencies of 102% at the anode and 100.5% at the cathode were obtained. This result indicates that the transport number of copper(I) ion is unity within the experimental error.

TGA and DTA.—The decomposition temperatures of these new, high copper ion conductivity materials were measured with the help of TGA, and the results are shown in Table II. All samples, except $17CuCl \cdot 3C_6H_{12}N_22HCl$, are stable up to 200°C. The N,N'-dialkyl (or hydro)-triethylenediamine dihalide-copper(I) halide double salts are thermally more stable than the previously reported N-alkyl (or hydro)-hexamethylenetetramine-copper(I) halide double salts, which decomposed below 150°C.

Table II. Thermal data for N,N'-dialkyl(or dihydro)-triethylenediamine dihalide-copper(I) halide double salts

Compound	Decomposition temperature, °C	Melting point, °C
$17CuCl \cdot 3C_6H_{12}N_22HCl$	120	112
$4CuCl \cdot C_6H_{12}N_22CH_3Cl$	222	199
$7CuBr \cdot C_6H_{12}N_22HBr$	206	300
$47CuBr \cdot 3C_6H_{12}N_22CH_3Br$	223	314
$17CuBr \cdot 3C_6H_{12}N_22C_2H_5Br$	234	196
$17CuI \cdot 3C_6H_{12}N_22CH_3I$	210	295

Further, DTA was carried out for these samples sealed in a Vycor tube. Each sample presented an endothermic peak which may be due to the melting of the sample. The melting points are also shown in Table II.

X-ray diffraction analysis.—The x-ray diffraction patterns were obtained at room temperature for the samples containing 95-50 m/o copper (I) halide in the system $C_6H_{12}N_2 2RX$-CuX. In the systems $C_6H_{12}N_2 2HCl$-CuCl and $C_6H_{12}N_2 2CH_3Cl$-CuCl, the samples containing 90 and 85 m/o CuCl showed the mixed patterns of CuCl and a new compound. Samples containing 80 m/o CuCl gave a pattern for a new single phase. In the $C_6H_{12}N_2 2HBr$-CuBr system, the high-conductivity solid containing nearly 87.5 m/o CuBr gave a single-phase pattern. Another two intermediate compounds were found at the composition of 66.7 and 50 m/o CuBr, which were poor conductors. In the $C_6H_{12}N_2 2CH_3Br$-CuBr system, the sample containing 94 m/o CuBr, which exhibits the highest conductivity in this system, did not give a single-phase pattern but gave the patterns of two phases corresponding to a new compound and CuBr. However, a single-phase pattern was observed at the composition of 90 m/o CuBr, 66.7 m/o CuBr, and 50 m/o CuBr. In the $C_6H_{12}N_2 2HI$-CuI system, only the peaks due to the starting materials were observed in the composition range of 90-50 m/o CuI. In the $C_6H_{12}N_2 2CH_3I$-CuI system, three intermediate compounds were found at the composition of 85 m/o CuI, 66.7 m/o CuI, and 50 m/o CuI. The compound containing 85 m/o CuI is a high conductive solid electrolyte and the other compounds are poor conductors.

It was found from the x-ray investigation that the highest conductivity material in each system did not always give a single-phase pattern. This may be due to the fact that the conductivity measurement is not precise enough to determine the exact formula of the compounds (4). However, it is concluded that the high-conductivity materials found in the $C_6H_{12}N_2 2RX$-CuX systems are new compounds and not the mixtures of their constituents. The x-ray diffraction patterns of the new compounds were too complex to determine their crystal structures.

Conclusion

The high, copper ion conductivity and the low electronic conductivity were found in the N,N'-dialkyl (or dihydro)-triethylenediamine-dihalide-copper(I) halide double salts. The values of the conductivity are comparable to that of the previously reported quaternary ammonium iodide-silver iodide compounds.

Interface States and Fixed Charge as a Function of Small Changes in Orientation of (111) Silicon Wafers

Sigurd Wagner

Bell Laboratories, Holmdel, New Jersey 07733

and Edward I. Povilonis

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The orientation of a silicon substrate for integrated circuits frequently deviates from its nominal value. In this study the densities of the interface states (N_{SS}) and of the fixed charge (Q_{FC}) were determined as a function of small changes of the orientation. Metal-silicon dioxide-silicon capacitors were made on eleven silicon wafers oriented from -25 to $+173$ min of arc off the [111] direction toward the [011] direction. N_{SS} and Q_{FC} were derived from the high frequency and quasi-static capacitance-voltage characteristics. Both are independent of the orientation over the range examined with $N_{SS} = (4.4 \pm 1.3) \times 10^{10}$ cm^{-2} V^{-1}, and $Q_{FC} = +(6.7 \pm 1.2) \times 10^{10}$ cm^{-2}.

Two types of electronic states, the interface states (N_{SS}) and the fixed charge (Q_{FC}) are located at the interface between silicon and silicon dioxide. The interface states exchange charge with the bulk of the semiconductor. Their equilibrium population depends on the position of the Fermi level at the interface. The fixed charge states do not alter their population when the Fermi level scans the bandgap. Because of their contribution to the threshold voltage the densities of both types of states are important characteristics of insulated gate field effect devices.

One question about N_{SS} and Q_{FC} is whether they vary when the orientation of the silicon wafer deviates slightly from its nominal value. Silicon wafers for MOS integrated circuits may deviate by as much as one degree of arc from their nominal orientation (1).

Key words: interface, orientation, silicon.

Substrates for epitaxy are intentionally oriented off low index orientations by angles of the order of one degree (1). This is done to obtain epitaxial layers of good quality free of pyramidal growth. It is known that the "offset" in orientation is retained at the surface of the epitaxial layer. Another case where the effect of a small change in orientation is of interest is found in experiments on the effects of strain on the interface characteristics (2). Neither the existing theories about the origin of these states nor the published experiments on their orientation dependence answer the question.

No theory relates N_{SS} or Q_{FC} directly to the orientation of the interface. N_{SS} has been associated with unpaired localized electrons which could result from incomplete oxidation (3) or which may exist at misfit dislocations in the interface (4). N_{SS} has also been ascribed to lateral fluctuations of the interface potential due to charges distributed in the silicon dioxide (5), and to impurity atoms located at the interface (6, 7). Q_{FC} is believed to result from charges attached to incompletely oxidized silicon on the oxide side of the interface (8), or to strained regions at the interface (9). The fixed charge may be identical with charge in interface states located outside of the bandgap where net charging or discharging cannot take place.

One important aspect of both types of states is the dependence of their density on the crystallographic orientation of the SiO_2/Si interface. Maxima of N_{SS} [Ref. (10)] and of Q_{FC} [Ref. (8, 9, 11)] exist in the vicinity of {111} interfaces, and minima near {110} and {100}. Qualitatively these extrema can be correlated with the density of atoms in the first layer of a free surface of silicon. The existing data cannot be used for conclusions about the dependence of N_{SS} and Q_{FC} on small (~1°) changes in orientation. First, the densities of N_{SS} and Q_{FC} obtained in the previous studies (9, 10) are about five and ten times, respectively, higher than the lowest obtainable values. Second, in the published studies the spacing between experimental points ranges from 5 to 30 degrees of arc, and therefore does not offer sufficient resolution. We have measured N_{SS} and Q_{FC} of eleven samples oriented between −25 and +173 min of arc off the [111] direction toward the [011] direction, *i.e.*, with the "zone axis" parallel to $[01\bar{1}]$. The (111) interface was selected to obtain comparatively large values of N_{SS} and Q_{FC} and concurrent low relative experimental errors. However, we did employ processing procedures to minimize these densities to the lowest values which can be attained for this orientation.

Experimental

One float zone grown [111] oriented 1¼ in. diameter p-type boron-doped ingot with a nominal resistivity of 0.46-0.55 ohm-cm was sawed into oriented wafers with successively increasing tilt off [111]. After a chemical etch and a Syton polish the orientation of the 14 mils (0.35 mm) thick wafers was determined by x-ray goniometry. After cleaning by a sequence of organic solvents, aqueous detergent solutions, acidic and oxidizing solutions, and by scrubbing, the wafers were prepared for oxidation by rinsing in deionized water and in dilute HF. All eleven wafers were then immediately brought into the very clean oxidation furnace. This furnace is made up of a double-walled, fused quartz tube within a silicon carbide liner. Gases enter the furnace through the inner quartz tube and flow back out through the annulus between the inner and the outer tube. All wafers were oxidized simultaneously for 100 min at 1000°C in a pure oxygen flux of 30 cm sec^{-1}, and subsequently annealed *in situ* in pure nitrogen at a flux of 30 cm sec^{-1} for 30 min at 1000°C. After rapid cooling to room temperature, the SiO_2 film was etched to 0.0925 μm in $HF:H_2O$ = 1:15. Then high purity aluminum was evaporated from a sodium-free tungsten coil onto the wafers. A 30 mil (0.076 cm) diameter dot and guard ring pattern was etched into the aluminum by standard photolithographic techniques. After a cleaning procedure, the back sides were aluminized, and the samples were annealed for 30 min at 400°C in pure hydrogen with a flux of 20 cm sec^{-1}.

The experimental setup used for the high frequency (1 MHz) and quasi-static (0.048 $Vsec^{-1}$) capacitance-voltage measurements is similar to that described by Lopez (12). The mobile charge in the SiO_2 was determined by the triangular voltage sweep technique (13) at 300°C with 0.048 $Vsec^{-1}$. In all measurements the guard ring was held at the voltage of the field plate.

The high frequency and quasi-static C-V curves were first evaluated for the doping profile, correcting for surface states (14)

$$N_A(x) = \left[\frac{2}{q\kappa_s\epsilon_0}\right]\left[\frac{1 - C_Q/C_{ox}}{1 - C_H/C_{ox}}\right]\left[\frac{d(1/C_H)^2}{dV}\right]^{-1}$$

where $N_A(x)$ is the net concentration of acceptors as a function of the distance x from the SiO_2/Si interface; q is the electronic charge, κ_s the relative dielectric constant of silicon, ϵ_0 is the permittivity of free space; C_Q, C_H, and C_{ox} are the quasi-static, the high frequency, and the maximum (oxide) capacitance, respectively; V is the voltage. For the numerical evaluation, points were taken off the C-V curves at 0.1V intervals.

The normalized flatband capacitance C_{FB}/C_{ox} was then calculated using the dopant concentration measured at $x = 0.1$ μm, N_A (0.1)

$$\frac{C_{FB}}{C_{ox}} = \left[1 + \left[\frac{\kappa_{ox}^2\epsilon_0 kT}{\kappa_s q^2}\right]^{1/2}\left[\frac{1}{t_{ox}N_A(0.1)^{1/2}}\right]\right]^{-1}$$

where κ_{ox} is the relative dielectric constant of SiO_2, k is the Boltzmann constant, T the absolute temperature, and t_{ox} the thickness of SiO_2.

The density of fixed charge, Q_{FC}, was determined from the difference between the ideal (ϕ_{MS}) and measured flatband voltage (V_{FB})

$$Q_{FC} = C_{ox}(\phi_{MS} - V_{FB})$$

(C_{ox} is the capacitance of the unit area of the SiO_2 layer.) It should be noted that this is a net charge made up of all ionized donor and acceptor states at the interface regardless of their location within or without the bandgap.

The density of interface states N_{SS} as a function of the interface potential ψ_S was derived from the difference between the quasi-static and the high frequency capacitance (15)

$$N_{SS}(\psi_S) = \frac{C_{ox}}{q}\left[\left[\frac{C_{ox}}{C_Q} - 1\right]^{-1} - \left[\frac{C_{ox}}{C_{HF}} - 1\right]^{-1}\right]$$

ψ_S was calculated by integration of the quasi-static capacitance with respect to applied voltage (16). The flatband voltage was taken as the lower limit

$$\psi_S(V) = \int_{V_{FB}}^{V}\left[1 - \frac{C_Q}{C_{ox}}\right]dV$$

Results

The mobile ionic charge in the SiO_2 films was uniformly low and ranged from 2 to 3 × 10^{10} cm^{-2}. It was too small to be determined by the bias-temperature stress technique which showed only the non-ionic "slow trapping" instability. A typical acceptor concentration *vs.* depth is shown in Fig. 1. The 5% accuracy limits (14) are denoted by $3L_B$ and $2L_B\sqrt{u_B}$. L_B is the extrinsic Debye length and u_B is the bulk Fermi potential in units of kT/q. N_A drops from the bulk toward the interface as a consequence of the depletion of boron during the oxidation. N_A at $x = 0.1$ μm is plotted against the orientation of the interface in Fig. 3c. This plot corresponds roughly to one of N_A *vs.* the position

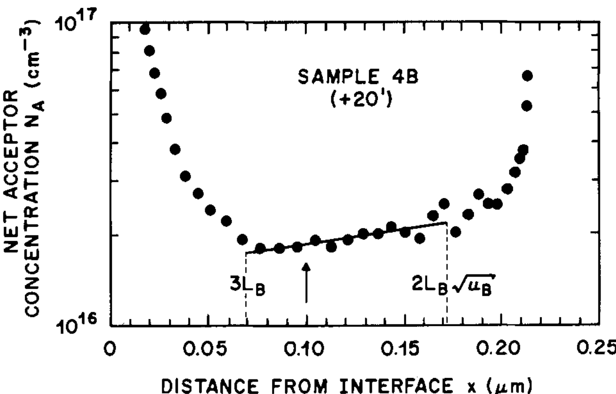

Fig. 1. Typical concentration profile of acceptors vs. distance from the SiO_2/Si interface. $3L_B$ and $2L_B\sqrt{u_B}$ denote the 5% error limits. The high values of N_A at $x < 3L_B$ and $x > 2L_B\sqrt{u_B}$ are artifacts of the capacitance-voltage technique.

in the original silicon ingot. $N_A(x = 0.1)$ is virtually constant at $(1.97 \pm 0.14) \times 10^{16}\ cm^{-3}$.

Figure 2 shows a typical plot of the density of interface states vs. interface potential. The average of N_{SS} within ±0.20V of the midgap potential is used to construct the plot of N_{SS} vs. the angle Φ, Fig. 3a. A least squares treatment of N_{SS} vs. Φ gives

$$N_{SS} = 4.60 \times 10^{10} - 0.0032 \times 10^{10} \times \Phi(\text{min}) \pm 1.31 \times 10^{10}\ cm^{-2}\ V^{-1}$$

The standard deviation corresponds to an uncertainty in the determination of $(C_Q - C_{HF})/C_{ox}$, at midgap potential, of $\pm 5 \times 10^{-3}$. An uncertainty of this order is usually encountered as a consequence of errors in the normalization of C_Q to C_{HF} in accumulation. Therefore we consider N_{SS} as constant within the experimental error

$$N_{SS} = (4.4 \pm 1.3) \times 10^{10}\ cm^{-2}V^{-1}$$

A least squares treatment of Q_{FC} vs. Φ (Fig. 3b) results in

$$Q_{FC} = 6.66 \times 10^{10} + 0.0002 \times 10^{10} \times \Phi(\text{min}) \pm 1.20 \times 10^{10}\ cm^{-2}$$

Here the standard deviation corresponds to an uncertainty of 0.06V in the determination of the flatband voltage. Q_{FC} is thus virtually constant at $Q_{FC} = (6.7 \pm 1.2) \times 10^{10}\ cm^{-2}$.

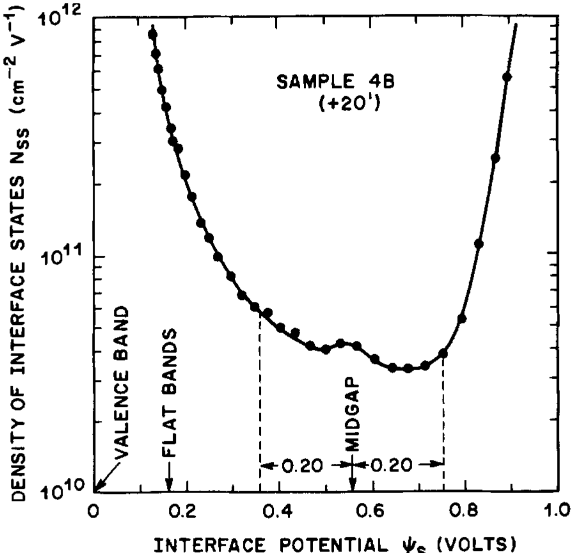

Fig. 2. Typical profile of the density of interface states vs. the interface potential. The average density within 0.20V of the midgap potential was used for further evaluation.

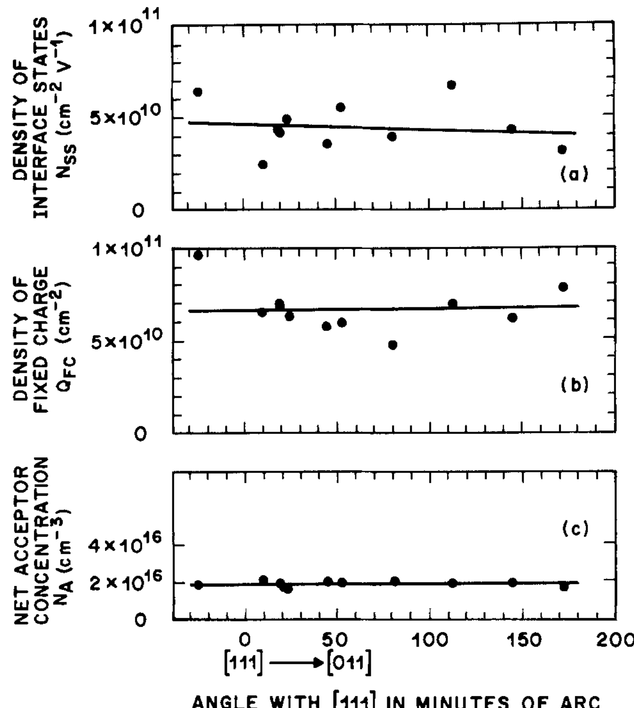

Fig. 3. (a) Density of interface states, (b) density of fixed charge, (c) acceptor concentration, all as a function of orientation.

Conclusion

The SiO_2/Si interfaces of eleven wafers, oriented within about 3° of the [111] direction, were characterized. These orientations are typical for device material. The densities of the interface states and of the fixed charge were constant with $N_{SS} = (4.4 \pm 1.3) \times 10^{10}\ cm^{-2}\ V^{-1}$ and $Q_{FC} = +(6.7 \pm 1.2) \times 10^{10}\ cm^{-2}$.

Improved Dielectric Reliability of SiO_2 Films with Polycrystalline Silicon Electrodes

C. M. Osburn* and E. Bassous*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Time dependent dielectric breakdown of SiO_2 films in MOS structures is shown to be strongly dependent on the electrode material used. Polycrystalline silicon electrodes give substantially longer times to failure than do aluminum electrodes. The improvement is 3-4 decades at 300°C; and, because of the larger activation energy for wearout with poly-Si (2.4 eV) compared to Al (1.4 eV), the relative advantage would be 8-16 decades at room temperature. Although time to breakdown is a strong function of SiO_2 thickness when the electrode is Al, it is nearly independent of thickness for structures having poly-Si electrodes.

Increasing reliability requirements for MOSFET devices makes it desirable to optimize the selections of dielectric and electrode materials as well as processing conditions used to fabricate the gate region. Device failure due to gate oxide dielectric breakdown has been reported (1) as one failure mode. Because of its importance to over-all device reliability, several recent studies (2-9) have focused on the causes of time-dependent, dielectric degradation and breakdown in SiO_2 films. The electrode metal has been shown (6, 9) to be an important factor in determining the rate of dielectric deterioration.

MOS capacitor structures having polycrystalline silicon electrodes have previously been shown to exhibit (6) a more substantial resistance to dielectric degradation at high temperature than those utilizing reactive metals like Al or Mo. However, the earlier work only considered degradation during various post-metallization annealing treatments when no bias was applied; this study specifically extends that work to determine the influence of an electric field on wearout. Data are presented to show a thousandfold improvement of SiO_2 dielectric reliability due to breakdown, as a result of using positively biased poly-Si electrodes rather than aluminum. As such, it is the most reliable MOS system reported in studies to date, including those utilizing SiO_2 films grown in HCl-O_2 ambients (7). When stressed negatively, the poly-Si was only slightly more reliable than aluminum.

Experimental

The metal-oxide-semiconductor capacitors used here were fabricated on both n- and p-type silicon wafers (2 ohm-cm); oxide films were grown in oxygen at 1000°C. To avoid electrical shorts originating at the electrode perimeter due to definition of the electrodes using chemical etching processes, a thick, supporting oxide layer was first grown; 25 mil diameter holes were opened photolithographically; and the desired thin (200-700Å) oxide film was grown. The electrodes were fabricated by: chemical vapor depositing (CVD) 3000Å of poly-Si at 650°C using a mixture of SiH_4 and N_2; doping the poly-Si surface by reaction with $POCl_3$ vapor at high temperature; and, diffusing the phosphorus throughout the electrode at 1000°C using alternate dry-wet-dry oxygen ambients. Capacitance measurements were used to determine the optimal doping parameters: a high capacitance value indicated inadequately doped poly-Si while the appearance of a high flatband voltage signaled that the phosphorus had been driven too far into the oxide.

Two different dielectric breakdown measurements were made: voltage ramp breakdown (10) and accelerated bias-temperature breakdown (6). With the former technique, many (typically 200) MOS capacitors on a wafer are stressed with a voltage ramp and the breakdown voltages (or fields) are recorded. In the second measurement, capacitors are stressed at constant electric field at elevated temperature (100°-400°C) and the times at which capacitor breakdown occurs are recorded: the largest value (t_{max}) has been shown (6) to be a good measure of the wearout time of an initially defect-free SiO_2 film.

Results and Discussion

Measurements of the breakdown voltages of MOS structures, having either poly-silicon or aluminum electrodes, by the ramping technique yielded statistically equivalent values: histograms of breakdown voltages were the same for both materials. Before reproducible silicon deposition and phosphorus-doping procedures were established, both abnormally high and low breakdown voltages were often observed using poly-Si structures. The high voltages were attributed to inadequate homogenization of the dopant in the electrode with attendant loss of voltage in this material due to the appearance of a depletion region. The low voltage values were probably caused by the large number of process steps involved and the subsequent higher chance of contamination, mask misalignment, and thermal stressing. Measurements on boron-doped poly-Si electrodes (11) also revealed carrier depletion unless the electrode homogenization was done at sufficiently high temperatures. Once the fabrication process was well controlled, it was repeatedly verified that ramp breakdown voltage values are the same for both contact electrodes. The high temperatures required to fabricate poly-Si electrodes does not degrade oxide quality once a reproducible Si deposition and doping procedure has been established.

During accelerated testing, however, the electrodes were found to play an important role. Compare the results for poly-Si and Al in Fig. 1, for stressing at 5 and 6 MV/cm at 300°C. The 300Å SiO_2 capacitors having poly-Si electrodes lasted 3 to 4 decades longer than the others. The wearout times (t_{max}) for the positive electrode bias case confirms that the ten-thousandfold improvement occurs over a wide range of applied electric fields (see Fig. 2). The maximum time to failure decreases almost exponentially with applied field; this dependence can be contrasted to a Peek s law behavior ($E \propto t^{-1/4}$) which was observed in other MOS samples (3, 4) which were intentionally contaminated with large amounts of mobile sodium. In contrast with the electrode biased negatively, t_{max} for poly-Si is only a factor of three larger than that for Al. For both polarities, the conduction current increases (often by several decades) prior to breakdown as shown earlier

(6). The only difference between samples having poly-Si electrodes and those with Al is the time at which the current increases. The fact that with negative electrode bias Al and poly-Si have nearly equal wearout times, further shows that the wearout time depends on the anode material.

By plotting log t_{max} *vs.* temperature^{-1}, it was determined that the wearout times in both aluminum and poly-Si structures had a thermal activation energy of 1.4 eV for negative bias. With positive electrode bias, activation energies of 2.4 eV were observed with the poly-Si electrodes and 1.4 eV for aluminum (6) (see Fig. 3). The activation energy with poly-Si was so high that most of the points in Fig. 3 had to be extrapolated from plots of t_{max} *vs.* E at each temperature. In the absence of alternate wearout mechanisms, the activation energies coupled with the data of Fig. 2 would predict that poly-Si devices should last 10^8-10^{16} times longer than Al ones at 25°C.

Other processing conditions were then varied in order to further enhance the dielectric reliability. For example, improved reliability has been previously demonstrated (7) for aluminum-electroded structures when the SiO_2 was exposed to hydrogen at high temperatures. During standard processing of poly-Si structures here, hydrogen is present at two stages: (*i*) during CVD deposition of Si at 650°C, and (*ii*) during the phosphorus drive-in done in steam at 1000°C. An alternate phosphorus drive-in process, using dry oxygen alone, was tested and did not give significantly different breakdown characteristics than samples receiving the dry-wet-dry sequence. Formation of the SiO_2 in a 3% HCl/97% O_2 ambient was found to further enhance the dielectric integrity of poly-Si structures. The statistical occurrence of low field breakdown events (<0.8 MV/cm) in HCl oxides was less than half that for standard oxides. The wearout time improvement attributable to the HCl oxidation step was only apparent at moderate (~6 MV/cm) to low applied fields and could not be extensively studied because of the prohibitively long times to failure. At the higher fields, no substantial difference was noted for the two types of oxides.

Limiting failure times were measured as a function of oxide thickness (from 100-1500Å) and are com-

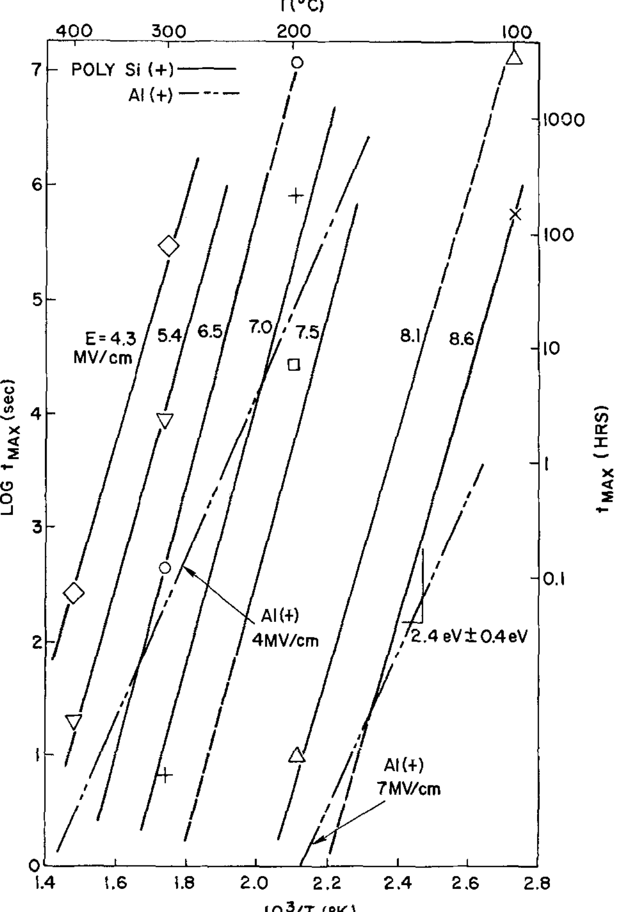

Fig. 3. Temperature dependence of wearout with positively biased poly-Si electrodes. The dashed lines go to points extrapolated from t_{max} *vs.* E plots at constant temperature.

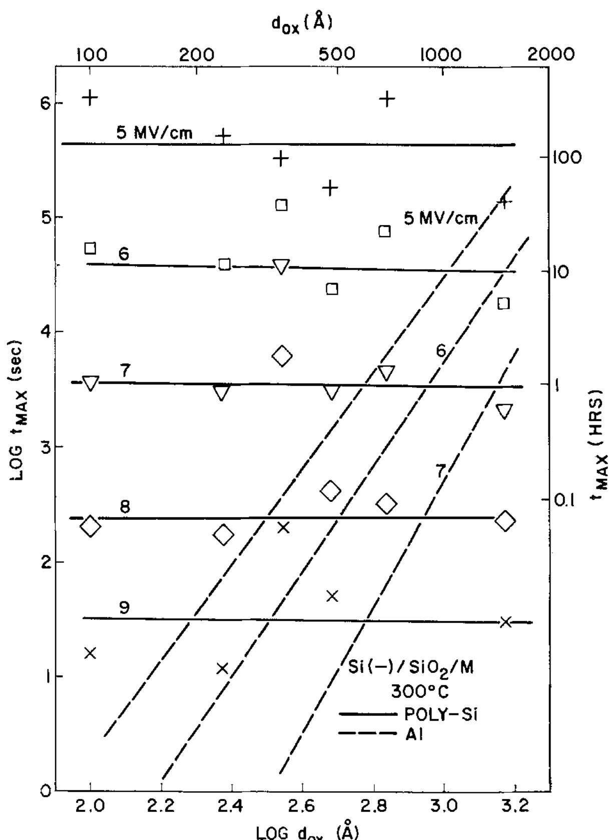

Fig. 4. Maximum time to failure as a function of oxide thickness for poly-Si electrodes biased positively at 300°C for different applied fields. The dotted lines represent the Al electrode data of Osburn and Chou (6).

pared to those using Al electrodes in Fig. 4. For some, as yet, unknown reason the scatter in the poly-Si results was greater than that for aluminum; nevertheless, it is apparent that wearout in poly-Si structures is nearly independent of oxide thickness. Thus poly-Si gates have three reliability advantages over aluminum: (*i*) under accelerated conditions, they are substantially longer lived, (*ii*) the activation energy for wearout is higher and hence they are comparatively more reliable at lower operating temperatures, and (*iii*) they are comparatively more reliable as the thickness of the dielectric is reduced.

Experiments were conducted to determine the source of the improved reliability of poly-Si devices. In one test, poly-Si was deposited on an oxide, doped and then stripped off with ethylene diamine-pyrocatechol solution (12); aluminum electrode dots were evaporated onto the oxide, and the wearout properties were characterized (see Fig. 5.) Even though the electrode was aluminum, the maximum time to failure was 2-20 times longer than with standard samples. Clearly, the silicon deposition and/or doping processes yield a longer lasting SiO_2 layer, regardless of electrode material. Nevertheless, for the positive bias case, the oxide improvement is only a small fraction of that seen with poly-Si electrodes; with a negative bias, on the other hand, the oxide improvement alone is often greater than the net improvement with poly-Si. Both electron microprobe and oxide etch rate measurements were made after doped silicon electrodes were stripped from SiO_2; phosphorus or a phosphosilicate glass (PSG) layer was not observed although neither technique is well-suited to detect a thin (10-20Å), dilute (1-3%) phosphorus-containing layer. In several instances, large flatband voltages (−1.5V) and hysteresis in *C-V* curves were observed. This might be attributed to phosphorus in the oxide (13, 14) as a result of overdoping the poly-Si. Dielectric wearout measure-

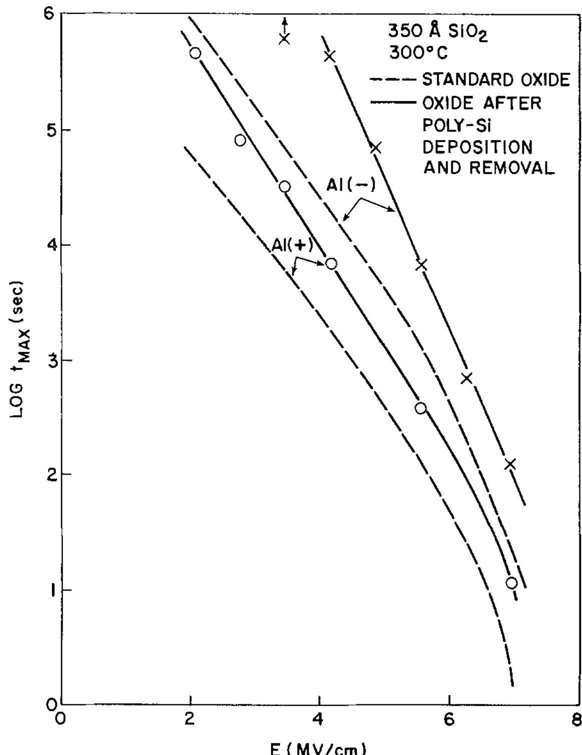

Fig. 5. Maximum time to failure as a function of applied field at 300°C for Al electrodes on standard oxides and on oxides from which doped poly-Si had been removed.

ments on SiO_2 films having different PSG layers suggest that a 50-100Å layer of 3-4% P_2O_5 would be required to give the oxide improvement that is seen after poly-Si removal.

Although several models can be proposed to account for the superior properties of poly-Si electrodes, they must all be considered speculative at this time. Poly-Si is much less reactive with SiO_2 than Al: poly-Si on SiO_2 has been shown (6) to withstand high temperature annealing better than Al on SiO_2; and aluminum injection and diffusion into SiO_2 were seen at relatively low temperature (15). Hydrogen introduced during silicon deposition or dopant drive-in contributes to the oxide integrity. A thin PSG layer or phosphorus-rich layer could also increase wearout time. Each individual model has serious drawbacks and a more complete knowledge of the mechanism of dielectric deterioration is needed to fully understand the source of the improvement seen here. Nevertheless, poly-Si electrodes can be used to fabricate MOS structures that have superior dielectric reliability.

Curie Points of Electrodeposited Nickel Films

M. Ya. Popereka

Graduate School of Applied Science, The Hebrew University of Jerusalem, Israel

ABSTRACT

An abnormally low Curie temperature was observed in nickel films up to 50 μm thick, which were electrodeposited from sulfate solutions containing saccharin. In several cases this abnormal Curie point was 100° or more below that of pyrometallurgical bulk nickel. The phenomenon is explained by the formation of solid solutions of sulfur and carbon in nickel, saccharin being the main source of the sulfur and carbon.

It has been shown (1-5) that in very thin nickel films the Curie temperature is lower than it is in bulk samples of that metal (in the latter $\theta_K \cong 354°C$). According to Neugebauer (4), this phenomenon is observed only up to thicknesses of 27Å, but Goureaux and Colombani (5) observed it in films as thick as 1000Å. The lowering of the Curie temperature in such thin films has been explained by the "thin film" state theories (7-9). Films of a thickness over 10^3Å are considered theoretically as bulk samples; also, measurements have shown that the Curie points in such films do not differ from those measured in bulk samples (6).

This paper describes nickel films of thicknesses up to ~50 μm possessing abnormally low Curie temperatures. This property is not connected with the thin film state, since the films are too thick, but is, as is shown later, connected with the technology used for preparation of the films.

Experimental

Nickel films were electrolytically deposited from a solution of composition (in grams/liter): $NiSO_4 \cdot 7H_2O$, 294; H_3BO_3, 30; and Rochelle salt, 25. Saccharin was added to the solution (1 g/liter unless otherwise indicated). Except in specified cases, the electrodeposition current density was 2 A/dm², the temperature of the solution 22°C, and pH 2.3. Polished copper rods of 2.2 mm diameter served as substrates.

The Curie points were measured by three methods. The first involved measurement of the dependence on temperature of the electric resistance by means of the automatically recording bridge-circuit. The second method was determination of the temperature at which the maximum differential magnetic permeability became zero (as observed by differential hysteresis loops displayed on the screen of an oscilloscope). The third method was based on the drop in value of the initial permeability near the Curie point; the initial permeability was measured using a device the main features of which are described in Ref. (11). In all cases, the rate of heating of the oven containing the sample was 5 deg/min and was held strictly constant. The temperature of the sample was, in all cases, controlled by a Chromel-Alumel thermocouple, graduated according to the melting points of gallium (99.999%), lead and tin (both 99.99%). The results obtained by the three methods (of which the third was the most reliable and accurate) are shown in Fig. 1-3. No measurement exceeded the margin of errors indicated.

Key words: ferromagnetic properties, magnetic films, incorporation of organic substances, solid solutions.

Results

As can be seen from the graphs, the Curie point in the films studied was, in a number of cases, lower than that in pyrometallurgical nickel (control measurements of the Curie point on the latter are represented by the dashed line in Fig. 2). In some cases, the Curie point dropped to 240°-250°C, *i.e.*, to more than 100° below the "normal" value. Increasing the electrodeposition current density (Fig. 1) elevated the Curie temperature somewhat, bringing it nearer to its normal value. A similar effect could be obtained by superimposing a magnetic field along the substrate axis (Fig. 2) during the deposition of the film, and also by

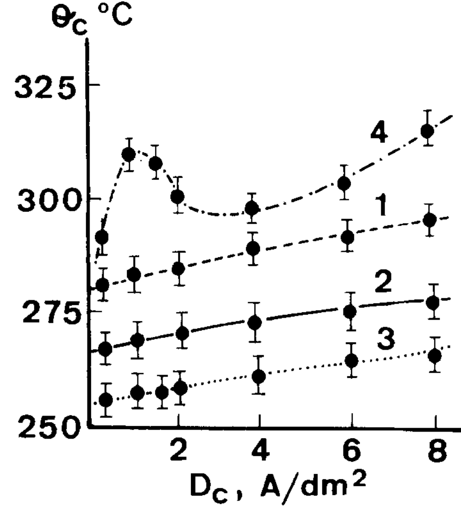

Fig. 1. Dependence of the Curie temperature of nickel films on the cathode current density. Curves 1, 2, 3: films deposited without the superposition of a magnetic field; curve 4: in field 975 Oe parallel to the substrate axis. The saccharin concentration in the solution (grams/liter) is: curve 1, 0.1; curve 2, 0.5; curves 3 and 4, 1.0. Film thickness, 10 ± 0.2μ.

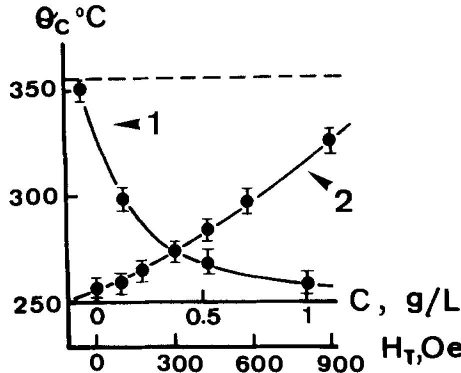

Fig. 2. Dependence of the Curie temperature of nickel films on the saccharin concentration in the solution (curve 1) and on the intensity of the technological magnetic field (curve 2). For curve 1, $H_T = 0$; for curve 2, $c = 1$ g/liter. The film thickness is $10 \pm 0.2\mu$.

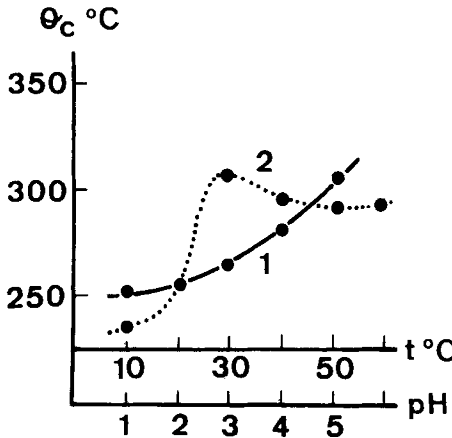

Fig. 3. Dependence of Curie temperatures of nickel film on the solution temperatures (curve 1) and on pH of the solution (curve 2). For curve 1, pH = 2.3; for curve 2, t = 22°. The film thickness is $10 \pm 0.2\mu$.

raising the solution temperature (Fig. 3). On the other hand, an increase in the concentration of saccharin in the plating solution (Fig. 2) moved the Curie point away from that of a pyrometallurgical nickel. In the absence of saccharin, the Curie point of the nickel film electrodeposited from a sulfate bath was ~352°C, *i.e.*, differing little from the value measured on a sample of pyrometallurgical nickel, of ~354°C. The Curie point of a nickel film deposited from a solution containing $NiCl_2 \cdot 6H_2O$, 150 g/liter and H_3BO_3, 30 g/liter, but containing no organic compounds, coincided with that of the sample of pyrometallurgical origin.

The results shown on the graphs can be supplemented by the following data. In the range of thicknesses from ~2 to ~50 μm, no substantial dependence has been discovered between the Curie points of the films and their thickness. The annealing of the films at 100°C (in a vacuum of $\sim 10^{-5}$ Torr for 3 hr) changed the Curie point very little (for example, for films deposited at 2 A/dm^2 in the presence of 1 g/liter saccharin, the change is from ~260° to ~265°C), but an identical annealing at 500°C increased the Curie temperature to as great as 354°C, *i.e.*, to the normal value.

Discussion

The Curie temperature is a magnitude which is structure-sensitive only to a small degree. Factors such as difference in internal stresses, in concentration of defects, in grain size, etc., cannot account for such a large range of measured Curie points. The results described above enable us to assume that the anomalously low values of the Curie temperatures observed are due to the codeposition of an alien material with the nickel, the main source of which is saccharin.

The assumption that the cause of the observed anomaly is the formation of a solid solution of the cathode hydrogen in the nickel (12) is contrary to the observed facts. Indeed, as shown in Ref. (13), with an increase in the saccharin concentration in the solution, the occlusion of hydrogen in the nickel film decreases; at the same time, the Curie point decreases from its normal value (Fig. 2, curve 1). Moreover, the nickel deposited from a chloride solution contains an amount of hydrogen approximately equal to that deposited from a sulfate solution, but in the first, the Curie point does not differ from its normal value, while in the second, it does. Thus, it is not hydrogen but other impurities that are responsible for the lowering of the Curie point.

As shown in Ref. (14) and (15), nickel films electrodeposited in the presence of a series of organic compounds, including saccharin, contain carbon (up to 0.2% by weight) and sulfur, the sulfur content generally exceeding that of the carbon. Formation of solid solutions of the elements in the nickel could be the cause of the observed phenomena.

It has been found in Ref. (16) that the Curie point of the solid solution of carbon in nickel decreases linearly with the increase in carbon content by ~30°/atom per cent (~0.2% by weight). Hence, the presence of carbon in the films studied can account for a large part of the drop in the Curie point.

We have not found any mention of the influence of sulfur on the Curie point of nickel in the literature. It can be expected that the influence of sulfur is qualitatively identical to that of other nonferromagnetic elements [they all lower the Curie point of nickel by different degrees (4)]. Hence, we can ascribe the observed phenomenon to the joint effect of sulfur and carbon.

The above explanation falls in with the facts. With an increase in current density, the amount of sulfur and carbon in the film decreases (15), since metal grows at a higher speed while sulfur and carbon are being included into the growing layers of the metal at a constant speed. At the same time, the Curie point approaches its normal value (Fig. 1). Increasing the concentration of saccharin causes the amount of sulfur and carbon in the film to increase (15), and the Curie point is lowered from that of pure nickel (Fig. 2). The same correlation is observed for the other dependencies.

Some differences between the Curie points of films deposited without saccharin from a sulfate bath and those of pure nickel are probably due, as well, to the fact that a definite amount of sulfur from the sulfate, or carbon from the Rochelle salt, is incorporated into the film. Indeed, when the film is deposited from a chloride solution containing no sulfur or organic additives, it has a normal Curie point.

Annealing at a sufficiently high temperature (in our case ~500°C) must lead to the disintegration of the solid solutions of sulfur and carbon in the nickel, hence the Curie acquires a normal value.

If the suggested explanation is correct, the conclusion may be drawn from curve 1, Fig. 2 that the superposition of a magnetic field during deposition of the film leads to a substantial decrease in the amount of alien material in the film.

Acknowledgment

The author wishes to express his gratitude to N. Suponyev and A. Ivanov who took an active part in the described experiments, and to Dr. I. Fried for her invaluable help in the preparation of the manuscript.

Manuscript received March 15, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Wavelength Dependence of PVA-Phosphor-Dot Photohardening

P. B. Branin and W. H. Fonger

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Dichromate-sensitized PVA coatings were exposed through 23V dot-aperture masks and several different absorption filters in order to study the dependence of dot growth and adherence upon exposure wavelength. For clear-resist coatings exposed under weak-absorption conditions, the hardening spectrum was proportional to the dichromate absorption spectrum. For coatings containing phosphor, the hardening spectrum was fairly flat and insensitive to the dichromate absorption spectrum; this different spectrum resulted because scattering increased the pathlengths of exposure light and led to strong-absorption conditions. With regard to phosphor-dot adherence, except at wavelengths below 350 mμ where phosphor bandgap absorption was strong, adherence was insensitive to the exposure wavelength, that is, to dichromate strong or weak absorption.

The photohardening of dichromate-sensitized polyvinyl alcohol (PVA) coatings, both with and without phosphor, was studied as a function of exposure wavelength. See Kosar (1) for a general review of dichromated colloids. Dichromate absorption spectra are shown in Fig. 1. These spectra were taken for $(NH_4)_2Cr_2O_7$-PVA aqueous solutions but are similar to $K_2Cr_2O_7$ solution spectra reported by Kortüm (2) and Davies and Prue (3). The spectra show strong, broad, u.v. absorption bands peaking near 270 and 370 mμ plus a weak, blue-green absorption tail extending to 530 mμ. For acid solutions which emphasize $Cr_2O_7^{-2}$ over CrO_4^{-2} ions, the u.v. bands are displaced to slightly shorter wavelength, the resolution between the bands is reduced, and the blue-green absorption tail is larger relatively.

O'Brien (4) and Koana (5) have reported photohardening rates of some dichromated colloids to be proportional to the rates at which photons are absorbed in dichromate ions, and this behavior is indicated for the PVA coatings studied here. However, this behavior does not make the hardening spectrum unique. Effective hardening spectra for coatings with and without phosphor were found to be different. The differences had to do with absorption conditions. For weak absorption, the hardening spectrum is proportional to the dichromate absorption spectrum; for strong absorption, it is flat and insensitive to the dichromate absorption spectrum.

Experimental

The phosphor used in these studies was $Zn_{0.92}Cd_{0.08}S$:Cu green phosphor (Z-910D). Slurries for the phosphor coatings were prepared by ball-milling a stock of phosphor, PVA, and water from which final coating formulations were made by adding PVA, water, $(NH_4)_2Cr_2O_7$ sensitizer (1:10 relative to PVA), an acrylic resin, and a surfactant. For clear-resist coatings, the phosphor was eliminated and the water content adjusted, but the ratios of the remaining constituents were maintained the same.

The coatings were applied to 23V television faceplates using a stationary single-head slurry machine in a conventional rotating-tilting and final-spinout mode. Coating weight and uniformity were controlled by adjusting spinout speed and duration.

Key words: phosphor-dot screening, photochemistry, PVA-hardening spectrum.

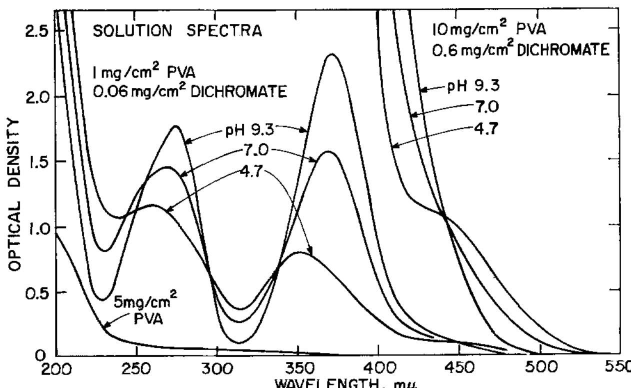

Fig. 1. Absorption spectra of $(NH_4)_2Cr_2O_7$-PVA aqueous solutions. The pH was adjusted with NH_4OH. These spectra were taken with a Cary Model 14 spectrophotometer.

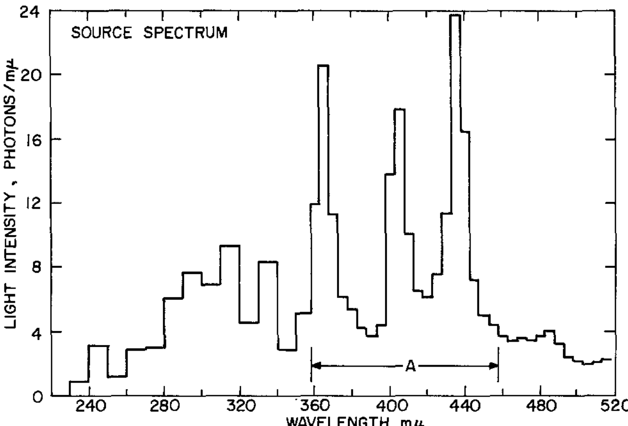

Fig. 2. Spectrum of the BH6-1 Hg capillary lamps used for the dot exposures. This spectrum contains strong Hg lines at 365, 404, and 436 mμ plus an underlying continuum. Normalization was made such that the 100 mμ interval labeled A contains 1000 photons.

The coatings were exposed in a single-position lighthouse equipped with a BH6-1 Hg capillary lamp and 100 mil quartz collimator. The spectrum of this source is shown in Fig. 2. The spectrum above 360 mμ was measured with a calibrated spectrometer. The spectrum below 360 mμ was adapted from vendor data (6) but was also roughly verified using some u.v. filters and the quantum counter liumogen (7). The coatings were exposed through a 23V dot-aperture mask plus several 2 × 2 in. absorption filters positioned below the mask as illustrated in Fig. 3. Exposures were made with the lighthouse lens package removed to provide high enough light intensity to offset low transmissions of the filters, to avoid center-to-edge variations in the spectrum caused by the lens coating, and to preserve the source spectrum down to 230 mμ.

The transmissions of the absorption filters are shown in Fig. 4. Apart from a $NiSO_4$-solution cell used in the short u.v. region (240-350 mμ), the filters were Corning glass color filters of the 3, 7, and 0 series. The 3-series filters divide up the blue-green region of the spectrum. The remaining filters involved 7-series filters and divide up the u.v. region. The transmission of the 23V panel glass is also shown because it was an added filter for some exposures made through the panel.

After exposure, the dot patterns were developed on a rotating head in a water spray at 104°F and 17 psi for 30 sec.

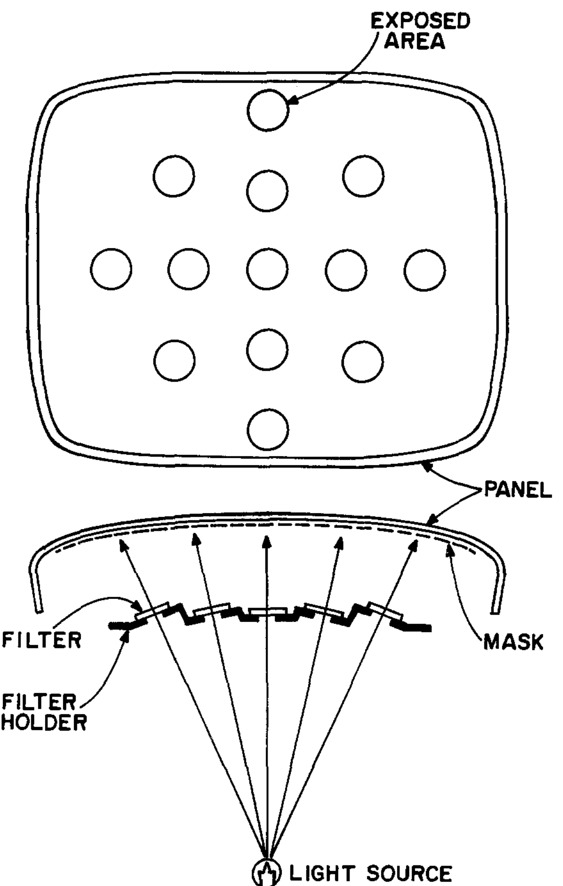

Fig. 3. Lighthouse arrangement used to make thirteen filtered exposures on 23V panels. The spacing between the mask and panel was 0.60 in.

Dot Growth with Exposure Time

The observed growth of dot diameters with exposure time is shown in Fig. 5 for 4.5 mg/cm² phosphor coat-

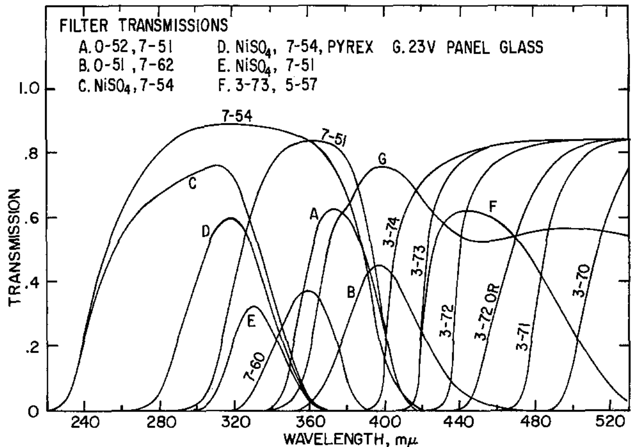

Fig. 4. Transmissions of the $NiSO_4$ and Corning filters used for filtered dot exposures; 3-72 OR was a particularly orange 3-72 filter.

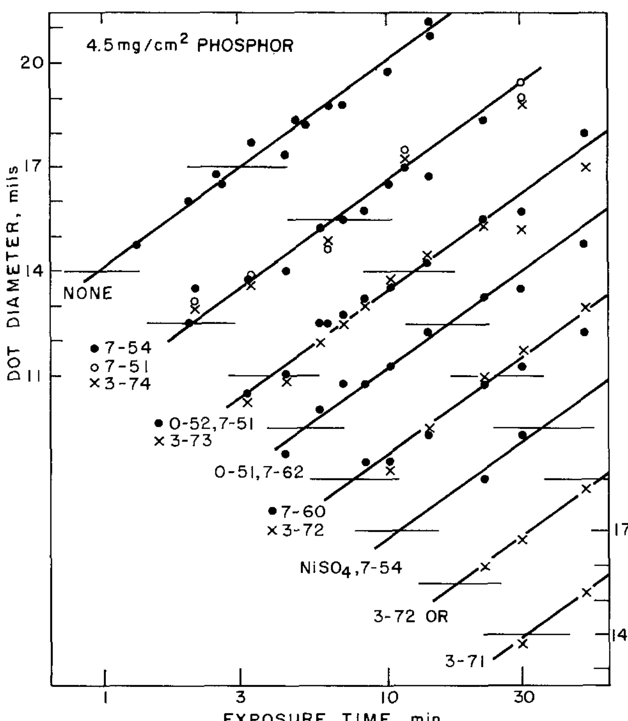

Fig. 5. Observed dot diameters vs. exposure time for 4.5 mg/cm² phosphor coatings exposed through various absorption filters. For the various sets of data, the two short horizontal lines mark the levels of 14- and 17-mil dot diameters. Exposure times have been corrected to constant light intensity.

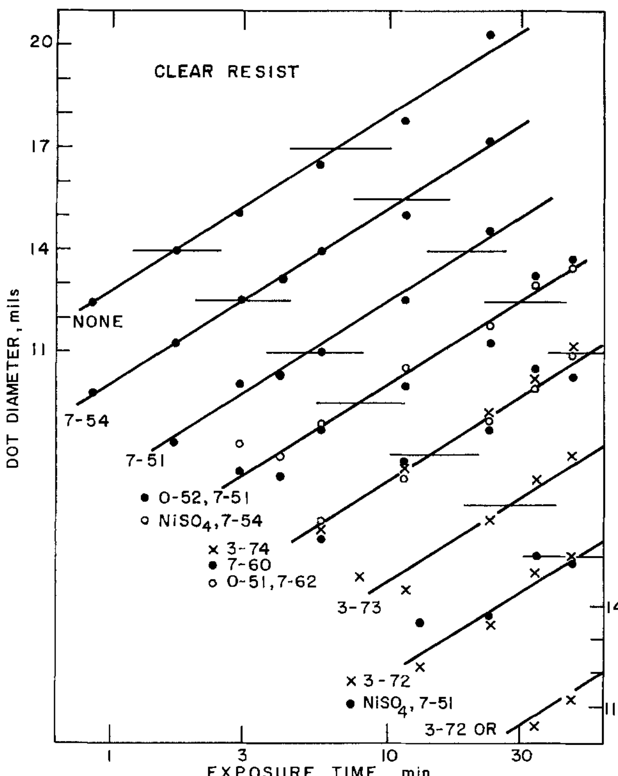

Fig. 6. Observed dot diameters vs. exposure time for clear-resist coatings.

ings. Exposures in the blue-green region through 3-series filters are shown by crosses and in the u.v. region through 7-series filters by dots. To avoid overlapping of data points, the ordinate scale is offset for the various sets of data, and the short horizontal lines show the 14-mil and 17-mil diameter levels. Dot diameters measured at the various filter positions (see Fig. 3) were corrected to center-panel values empirically. For the 23V panel mask used, 14 mils was the image size of center-panel mask holes projected from a point source, and 17 mils was the diameter of tangent tricolor dots.

For all exposures, dot diameter growth was approximately proportional to the log of the exposure time. Assuming that a fixed exposure level is needed for threshold photohardening, this behavior indicates that light intensity in the penumbra region decreased radially approximately exponentially. The slope of the D *vs.* log t lines shown in Fig. 5 corresponds to a radial $1/e$ distance of 1.30 mils.

Similar dot growth data for clear-resist coatings without phosphor are shown in Fig. 6.

Exposure times for the various filters were in different proportions for the phosphor and clear-resist coatings. That is, the hardening spectra for these coatings were different. Relative to exposure times in the near-u.v. region (most 7-series filters) as a base, the phosphor coatings required longer exposure times in the short-u.v. region with the $NiSO_4$, 7-54 filter and the 7-54 filter and shorter exposure times in the blue-green region (3-series filters). For example, exposure times for the short-u.v. $NiSO_4$, 7-54, near-u.v. 7-60, and blue-green 3-73 filters were in that order for phosphor coatings but were in the reverse order for clear-resist coatings.

Since the slopes of the D *vs.* log t lines are fairly close in all cases, we will characterize hardening rates simply by the exposure times required to produce dots of a particular size, namely, 14 mils. These exposure times, T_{CR}, and $T_{4.5}$, and their ratios, $T_{CR}/T_{4.5}$, are listed in Table I. The ratios $T_{CR}/T_{4.5}$ are ≈ 6 in the blue-green region, ≈ 2 in the near-u.v. region, and ≈ 0.7 in the short-u.v. region where light is strongly absorbed in the phosphor bandgap.

The exposure times in Table I have been compared with simple, limiting hardening rates. Following behaviors reported for some other dichromated colloids (4, 5), we assume that, following absorption in dichromate ions at wavelength λ, the quantum efficiency for hardening $\eta(\lambda)$ is insensitive to λ. Hardening rates H_i are then proportional to the rates at which photons are absorbed in dichromate ions

$$H_i \propto \int d\lambda L(\lambda) t_i(\lambda) a(\lambda)$$

where $L(\lambda)$ is the source spectrum in photons per unit wavelength (Fig. 2), $t_i(\lambda)$ is the transmission of filter i (Fig. 4), and $a(\lambda)$ is the fraction of incident light absorbed in dichromate ions. For weak absorption $a(\lambda) << 1$, $a(\lambda)$ is proportional to the dichromate absorption constant $k(\lambda)$. For strong absorption $a(\lambda) \approx 1$, $a(\lambda)$ is insensitive to λ and can be omitted from the integrals.

The clear-resist dot exposures were made under weak-absorption conditions. Layer transmissions were ≈ 0.70 at the dichromate 370 mμ absorption peak. Thus, in the table, the clear-resist exposure times T_{CR} have been compared with the weak-absorption hardening rates $\int d\lambda L(\lambda) t_i(\lambda) k(\lambda)$. The products $T_{CR} \int d\lambda L t_i k$ decrease somewhat from shorter to longer wavelengths (from top to bottom in the table) but are relatively constant compared to the strong wavelength variation of the dichromate absorption constant $k(\lambda)$. Thus, the quantum efficiency $\eta(\lambda)$ was relatively constant, and the clear-resist hardening spectrum was approximately the dichromate absorption spectrum $k(\lambda)$.

In the integrals, $k(\lambda)$ was taken proportional to the dried-layer absorption spectrum shown in Fig. 7. This spectrum was taken for fresh, dried, clear-resist coatings deposited on 23V panels (transmission measurements possible down to 360 mμ) and on 2 × 2 in. quartz slides. The resist had the same component ratios as the resist used in the clear-resist dot exposures, but the water content was reduced to give thicker coatings with absorption increased sixfold, as convenient for absorption measurements. The dried-

Table I. Observed exposure times T_{CR} and $T_{4.5}$ to make 14-mil dots for clear-resist and 4.5 mg/cm² phosphor coatings exposed through various absorption filters. These times are compared with weak- and strong-absorption hardening rates $\int d\lambda\ Lt_ik$ and $\int d\lambda\ Lt_i$, respectively. The source spectrum $L(\lambda)$ and the dichromate absorption spectrum $k(\lambda)$ are expressed in the arbitrary units used in Fig. 2 and 7, respectively.

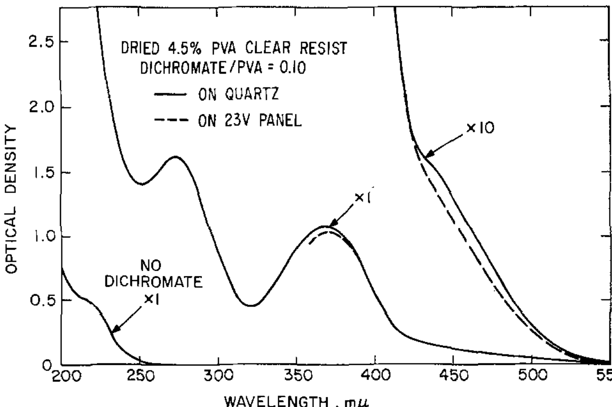

Fig. 7. Absorption spectra of dried, clear-resist coatings on a 23V panel and a 2 × 2 in. quartz slide. Substrate absorption has been subtracted out. Without dichromate sensitizer, absorption was negligible down to 250 mμ. For the thinner clear-resist coatings used in the dot exposures, the optical densities were 1/6 times the values in this figure.

layer spectrum is similar to the dichromate solution spectra shown in Fig. 1 but is not identical to any one of these spectra. The position of the 370 mμ peak is typical of the neutral solution, but the relative size of the blue-green absorption tail is typical of the acid solution.

The phosphor exposure times $T_{4.5}$ in the table have been compared with the strong-absorption hardening rates $\int d\lambda L(\lambda) t_i(\lambda)$.[1] For the phosphor exposures, light scattering increased light pathlengths in the coatings and thereby enhanced absorption and hardening. In addition, dichromate absorption competed with phosphor absorption. For $\lambda < 350$ mμ (strong phosphor bandgap absorption), hardening was inefficient, and the product $T_{4.5}\int d\lambda L t_i$ was larger ($NiSO_4$, 7-54 filter). For $\lambda > 350$ mμ (phosphor Cu-impurity absorption), the products $T_{4.5}\int d\lambda L t_i$ were smaller and increased somewhat from shorter to longer wavelengths. Nevertheless, at these wavelengths, these products were relatively constant compared to the strong wavelength variation of the dichromate absorption constant, and the hardening spectrum of the phosphor coatings can be described as fairly constant and insensitive to the dichromate absorption constant.

For 4.5 mg/cm² phosphor coatings, one-half of the hardening capacity of BH6 light is contained in wavelengths above 400 mμ, that is, in the region of dichromate weak, blue-green absorption. This result is evident from Fig. 5 where the hardening rates using the 7-54 and 3-74 filters were the same. The 7-54 and 3-74 filters are low-pass and high-pass filters, respectively, about the wavelength point 400 mμ. See the filter profiles in Fig. 4.

Dot-growth curves similar to those shown in Fig. 5 and 6 were also obtained for 2 mg/cm² phosphor layers and for 4.5 mg/cm² phosphor layers exposed through the panel glass. In the latter cases, the penumbra shape at panel center was maintained as in normal exposures by using the same source-to-mask distance and the same effective mask-to-coating distance.[2] After correction for the panel-glass transmission at the exposure wavelength, these exposure times were the same as for 4.5 mg/cm² phosphor coatings exposed in the normal way. That is, exposure times were the same for exposures from either side. For the 2 mg/cm² phosphor coatings, the wavelength dependence of the hardening rate was intermediate between the two wavelength dependences described above for clear-resist and 4.5 mg/cm² phosphor coatings.

[1] For exposures with 3-series filters, the integrals $\int d\lambda\ L t_i$ were arbitrarily terminated at 518 mμ near the end of dichromate absorption. For a different termination point, these integrals would be somewhat different.

[2] For exposures through the panel, the light source and filters were maintained as in Fig. 3, and the coated panel was inverted. A formed mask cut from its frame was attached to the bottom (convex) side of the panel via standoffs of length q_2 = 0.30 in. The effective mask-to-coating distance was then $q_{eff.} = q_1/n_1 + q_2$, where q_1 was the thickness of the panel glass and n_1 its index of refraction.

Dot Adherence

Except for exposures in the short-u.v. region ($\lambda <$ 350 mμ) where phosphor bandgap absorption was strong and adherence poor, dot adherence was insensitive to exposure wavelength. Exposure with any filter above 350 mμ always led to adherence failure at exposures corresponding to 11-11½ mils dot diameter for clear-resist coatings, to 12-12½ and 15-16 mils for 2 and 4.5 mg/cm² phosphor coatings, respectively, and to 12-12½ mils for 4.5 mg/cm² phosphor coatings exposed through the panel.

The better phosphor-dot adherence for 2 mg/cm² coatings and for 4.5 mg/cm² coatings exposed through the panel is qualitatively explained by obvious gradings of exposure light intensity across the coatings. However, the insensitivity of dot adherence to dichromate strong 370 mμ or weak blue-green absorption seems surprising. We believe that, for the phosphor layers, gradings of light intensity across the layers were determined primarily by the scattering paths of the light and only secondarily by light absorption. In this way, the adherence could become insensitive to the dichromate absorption constant.

Conclusions

Relative to the photohardening rate in the dichromate strong 370 mμ absorption region, hardening in the dichromate weak blue-green absorption region was three times greater for 4.5 mg/cm² phosphor coatings than for clear-resist coatings. For the clear-resist coatings, exposures approximated weak-absorption conditions, and the hardening spectrum was proportional to the dichromate absorption spectrum. For the 4.5 mg/cm² phosphor coatings, exposures more nearly approximated strong-absorption conditions, and the hardening spectrum was fairly flat and insensitive to the dichromate absorption spectrum. For 4.5 mg/cm² phosphor coatings, one-half of the hardening capacity of BH6 light resides in blue-green wavelengths above 400 mμ. Except at wavelengths below 350 mμ where phosphor bandgap absorption was strong, phosphor-dot adherence was insensitive to exposure wavelength, that is, to dichromate strong or weak absorption.

Luminescence Properties of Thiogallate Phosphors

III. Red and White Emitting Phosphors for Flying Spot Scanner Applications

T. E. Peters

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

ABSTRACT

Ions with the ns^2 electronic configuration were investigated as activators in the $SrGa_2S_4$ host lattice. Phosphors activated with Sn^{2+} or Pb^{2+} were found to cathodoluminesce in the red spectral region and exhibit relative efficiencies (η_{cr} Rel.) of 1.1 and 4.6%, respectively. The Pb^{2+} phosphor has a short fluorescent decay time ($I_o/100 \sim 10^{-6}$ sec) and was found suitable for use as the red screen component in a flying spot scanner tube (FSST) employed as the transducer in color video playback. Coactivation of $SrGa_2S_4$ by Ce^{3+} and Pb^{2+} was found to result in a white-emitting phosphor that exhibits lower noise in FSST screens than is usually found when phosphor blends are employed.

The cathodoluminescence emission and decay properties of the Ce^{3+} activated alkaline earth thiogallates were reported earlier (1) with particular emphasis on factors governing the use of these materials in flying spot cathode-ray tubes. Phosphors activated with ions possessing the ns^2 electronic configuration (Tl^{1+}, Sn^{2+}, Pb^{2+}, Sb^{3+}, Bi^{3+}) are also of interest for use in this type of device because their fluorescence lifetime should be very short. As a consequence, these ions were also evaluated as activators in the $SrGa_2S_4$ host lattice, and this paper describes the cathodoluminescence emission and decay characteristics of the Pb^{2+} and Sn^{2+} activated, and Ce^{3+}-Pb^{2+} coactivated $SrGa_2S_4$ phosphors and discusses their application in flying spot scanner tubes (FSST) designed for use in color video playback systems.

Experimental

Phosphor preparation.—The phosphors described herein were synthesized according to the general formulas

$$Sr_{1-x}M_xGa_2S_4 (M = Tl^{1+}, Sn^{2+}, Pb^{2+})$$

$$Sr_{1-2x}M_xNa_xGa_2S_4 (M = Sb^{3+}, Bi^{3+})$$

$$Sr_{1-(2x+y)}Ce_xNa_xPb_yGa_2S_4$$

by reacting mixtures of the previously prepared, high purity sulfides at 900°-950°C in a stream of H_2S. The activators were generally introduced at sufficiently high concentration to assure stoichiometry, and lower doping levels were achieved by dry dilution. Monovalent sodium was added as Na_2SO_4, usually in excess of the stoichiometric amount, to serve as a mineralizer and provide charge compensation for the trivalent activators. Any sodium not incorporated in the $SrGa_2S_4$ host lattice was subsequently removed from the phosphor by washing with demineralized water. The Pb^{2+} and Sn^{2+} activated phosphors did not require valence compensation; consequently, the Na_2SO_4 was usually omitted and the higher reaction temperature was employed. In the case of Tl^{1+}, charge compensation was allowed to occur through a vacancy mechanism.

Measurements.—Standard analytical techniques were employed to monitor the purity and stoichiometry of the sulfide reagents and finished phosphors. X-ray powder diffraction was used to ascertain formation of the $SrGa_2S_4$ compound.

Emission spectra were recorded in terms of relative energy, and the relative cathode-ray efficiency values (η_{cr} Rel.) were obtained by comparing the integrated area under the spectral energy distribution curves to that of selected thiogallate and NBS-1021 phosphors of known absolute efficiency.

Cathodoluminescence brightness levels of $SrGa_2S_4$:Pb were measured under conditions simulating those found in a color video playback system employing flying spot scanners (3). Phosphor-coated conducting glass slides were placed in a demountable CRT and excited with a 25 kV-100 μA electron beam which was scanned at the normal TV rate over a 5.7 cm × 7.6 cm raster. The emission was detected by a Gamma photometer equipped with a Wratten No. 25 filter.

Cathodoluminescence decay times were measured by pulsing a 20 kV electron beam of a 12.7 cm diameter FSST at a rate of 60 Hz with a pulse duration of 100 nsec. The fluorescence was detected by a photomultiplier tube equipped with a Wratten No. 25 or 47B filter and displayed on an oscilloscope. Screen noise measurements were obtained by monitoring the change in emission intensity of the flying spot of light as it was scanned across the screen of a 12.7 cm FSST.

Results and Discussion

Of the ns^2 ions evaluated as activators only Sn^{2+} and Pb^{2+} produced visible emission at room temperature. The cathodoluminescence emission and decay characteristics of these materials are given in Table I, together with similar data for $Y_3Al_5O_{12}$:Ce(YAG:Ce) (2). The latter material is a fast decay phosphor that has been advanced as a replacement for the ZnO:Zn(P-24) screen in a version of the FSST employed as a playback transducer for color television. The radiant efficiency under cathode-ray excitation (η_{cr} Rel.) of the $SrGa_2S_4$:Pb(2 atom per cent [a/o]) is slightly higher than that of YAG:Ce while the $SrGa_2S_4$:Sn(1 a/o) phosphor has a lower efficiency.

The decay time (β) given in the last column of Table I is the time required for the fluorescence to decrease to $I_o/100$. This value has been found to be more significant for FSST phosphor evaluation than the fluorescence lifetime, τ-(decay to I_o/e), because it includes even the low level, long persistence components of the decay. The fluorescence intensity *vs.* time curve for the $SrGa_2S_4$:Sn phosphor exhibits a power law dependence ($I_o \propto t^{-n}$), and its decay time is longer than that of the other phosphors which have essentially exponential decay curves (Fig. 1). The per-

sistence of the $SrGa_2S_4$:Sn phosphor is long enough to eliminate it as a candidate for use in FSST screens; however, the decay of the Pb^{2+} activated phosphor is of a magnitude which would permit its use in systems employing electronic compensation (3).

The data in Table II shows that the decay time of $SrGa_2S_4$:Pb can be reduced slightly by concentration quenching. Although the reduction is slight, the effect appears to be real, with phosphors containing 8-10 a/o Pb consistently having decay times of 1 μsec and those with lower Pb^{2+} concentrations having longer decay times. The reduction in decay attributed to concentration quenching is accompanied by a reduction in emission intensity (Table II) and a shift of λ_{max} to lower energy.

Transition metal quenching, which produced a dramatic reduction in the decay time of the Ce^{3+} fluorescence in $SrGa_2S_4$:Ce, Na (1), is seen (Table II) to exert little influence on the fluorescence decay time of Pb^{2+} in the same host compound. This result is in agreement with that of other workers (4) who have shown that transition metal quenching does not alter the persistence of a phosphor whose fluorescence decays exponentially.

The efficiency and spectral energy distribution of the $SrGa_2S_4$:Pb phosphor make it particularly attractive for use in FSST's for color TV playback. This is shown in Fig. 2 which depicts the spectral energy distribution curves for YAG:Ce and $SrGa_2S_4$:Pb together with a spectral sensitivity curve (shaded) for a simulated red detector of a video playback system. The detector sensitivity curve was generated from a convolution of the transmission curve for a Kodak No. 25 Wratten filter and the S-4 response curve of an RCA 931A phototube. The convoluted data was then normalized by setting the optimum detector output at 100. It is evident that the $SrGa_2S_4$:Pb emission is better matched to the detector's response than is the emission of YAG:Ce. This is important because most phototubes are relatively insensitive in the red spectral region and, as a consequence, the photocurrent generated by the red detector must be amplified to a much greater extent than that of the corresponding green and blue detectors.

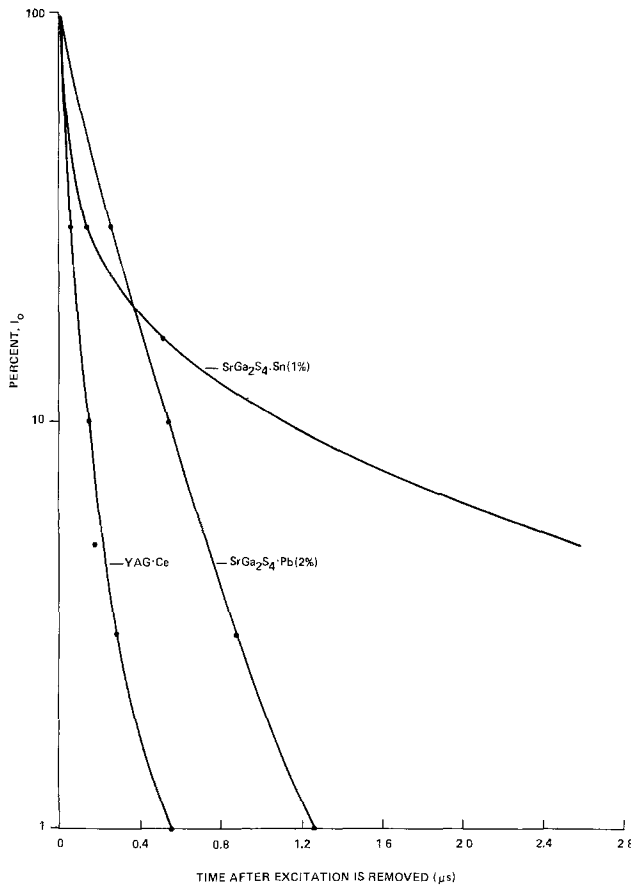

Fig. 1. Decay of fluorescence of red emitting phosphors

For color video playback applications, FSST's that exhibit a uniform emission in the visible region of the spectrum are desirable. This effect can be achieved by blending the $SrGa_2S_4$:Pb wtih a blue-emitting phosphor such as $SrGa_2S_4$:Ce,Na (1), or by activating the $SrGa_2S_4$ host compound with both Ce^{3+} and Pb^{2+}. The spectral energy distribution of the emission of FSST's prepared with the blended and single component thiogallate screens are compared to that of a commercial FSST (3) in Fig. 3. The tubes containing the thiogallate phosphors are seen to have a fairly uniform emission over the entire visible spectrum, while the commercial tube is deficient in the blue-green and red spectral regions.

The emission spectrum of the blended phosphor screen [Fig. 3(a)] can be altered to some extent by changing the ratio of its blue-to red-emitting components. Similar modifications in the spectral distribution of the single component screen [Fig. 3(b)] are best affected by altering the Ce^{3+} and/or Pb^{2+} concentration of the phosphor. This is illustrated in Fig. 4, where the trichromatic coefficients and blue (~450 nm)/red (~605 nm) peak intensity ratios (B/R) are given for $SrGa_2S_4$:Ce,Pb,Na phosphors activated with 4 or 8 a/o Pb and 0.03-0.5 a/o Ce. For materials with spectral distributions similar to that in Fig. 3(b) (viz., B/R $\cong$ 1, $x \cong 0.35$, $y \cong 0.33$), the [Ce^{3+}] should be in the vicinity of 0.1 a/o. When [Ce^{3+}] increases much beyond this value, the blue emission band begins to dominate the fluorescence spectrum.

FSST's having the spectral distributions shown in Fig. 3 were evaluated in a color video playback system, and relevant data is reported in Table III. The data show the response of all three of the playback system's photodetectors to be significantly greater for the FSST's employing thiogallate screens. The fluorescence decay times for the thiogallate screens are somewhat longer than those exhibited by the blended phosphor screen of the commercial tube, but the longer decay times did not result in a noticeable deterioration in the televised picture. Screen noise for the blended thiogallate phosphor screen is equivalent to that of the $Ca_2Al_2SiO_7$:Ce-$Y_3Al_5O_{12}$:Ce screen, but the single component thiogallate screen is noticeably better in this respect.

Summary

Ions with the ns^2 electronic configuration were evaluated as activators in the $SrGa_2S_4$ host lattice. Under cathode-ray excitation, phosphors activated with Sn^{2+} or Pb^{2+} were found to fluoresce in the red spectral region with relative efficiencies (η_{cr} Rel.) of 1.1 and 4.6%, respectively. The Pb^{2+} activated phosphor was found to have a short fluorescence decay time

($I_0/100 \sim 10^{-6}$ sec) and was judged suitable for use as the red screen component in a FSST employed as a playback transducer for color television.

For color video playback applications, FSST's that exhibit a uniform emission in the visible region of the spectrum are desirable. This was achieved by blending the $SrGa_2S_4$:Pb phosphor with a blue emitting $SrGa_2S_4$:Ce,Na or by activating the $SrGa_2S_4$ host compound with both Ce^{3+} and Pb^{2+}.

FSST's with screens containing the blended or single component thiogallate screens were found to elicit a substantially higher output from a playback system's photodetectors than a commercial tube with a screen composed of a $Ca_2Al_2SiO_7$:Ce-$Y_3Al_5O_{12}$:Ce phosphor blend. The single component thiogallate screen also exhibited lower screen noise than those of the thiogallate blend or the commercial phosphor mixture.

Rare Earth Doped Vitroceramics: New, Efficient, Blue and Green Emitting Materials for Infrared Up-Conversion

F. Auzel, D. Pecile, and D. Morin

Centre National d'Etudes des Télécommunications, 92220 Bagneux, France

ABSTRACT

New, efficient, vitroceramic hosts for rare earth luminescence are discussed. Their applications to infrared up-conversion are emphasized. Optimized compositions lead to an efficiency nearly twice as high as commercially available LaF_3:Yb:Er. As for infrared to blue efficiency, these vitroceramics are among the best compounds obtained so far. The easy preparation in air atmosphere is described. The excitation spectra have the advantage of being broader than usual for up-conversion phosphors. Kinetic studies present some puzzling behavior with respect to sample geometry; *e.g.*, the rise time increases fourfold with sample thickness between 0.1 and 4.5 mm. Segregation of rare earths in the microcrystalline phase rather than in the glassy one is clearly shown which explains the high efficiencies.

Although the up-conversion processes by energy transfer between Yb^{3+} and Tm^{3+} or Er^{3+} were first discovered in a glass matrix (1), all the hosts reported to date are pure crystalline compounds (1-3). The main reason is that the fluorescence of rare earth ions is generally less efficient in a glass. Yet Auzel has shown that in the case of Er^{3+}, the fluorescence emission at 0.54μ is strongly enhanced with respect to glass inside the devitrified glass matrix (4); one then deals with a vitroceramic since large amounts of microcrystals are embedded in an amorphous structure.

The preparation, preliminary results about the structure, as well as up-conversion properties, of such vitroceramics are discussed. The general formula of these new materials is (Ln_2O_3, Yb_2O_3, PbF_2, M_nO_m) doped with oxides of erbium, thulium, holmium, or terbium with Ln = Y, La, Gd, or Lu and M being one of the following glass forming elements B, Si, P, Ge, or Te. According to the doping ion choice, either sequential or cooperative sensitization may be obtained.

Key words: glass ceramics, up-conversion, rare earths, infrared, energy transfer.

Several glasses of different forming elements have been examined, but emphasis is given to the following example: (Yb_2O_3, PbF_2, GeO_2) doped either with Er_2O_3 or Tm_2O_3.

From an efficiency point of view, such ceramics can be favorably compared with crystalline hosts. Furthermore, their shorter time response and their easy preparation make them particularly suitable for pulsed GaAs:Si diode excitation for LED applications. The fact that such materials can be cast, cut, and polished just as glasses may be also a further advantage over crystalline phosphors when large displays are considered.

On the other hand, several fundamental interesting aspects are shown. These matrices contain a large amount of oxygen, yet their green emission yield is as high as those obtained from the best oxygen-free YF_3 hosts. This fact is in contrast with what has been generally found in crystalline hosts (3). The trapping effect and radiative energy transfer between Yb^{3+} ions before nonradiative energy transfers take place, as recently evidenced (5), are particularly strong.

Experimental

Vitroceramics composition and preparation.—The vitroceramics are obtained by simply mixing together one or several of the following glass-forming oxides SiO_2, GeO_2, B_2O_3, P_2O_5, TeO_2 with lead fluoride and high purity rare earth oxides (99.999%). The mixture, contained in a platinum crucible with a cover, is heated and melted inside a muffle furnace at 1000°C for about 1 hr. The sample is then obtained by pouring the melt, in air, into a graphite mold of the desired form, the mold is maintained at about 300°-400°C for 4 hr for annealing purposes. A white compound with a glassy aspect is finally obtained.

The compositions (GeO_2-PbF_2):Yb, Er and (GeO_2-PbF_2):Yb, Tm are mainly discussed in this paper. These compositions have been optimized for infrared up-conversion under CW excitation. Under pulsed excitation, the optimization may be somewhat different since time constants vary with composition differently from efficiencies.

Spectroscopy and optical measurements.—Absorption and fluorescence spectra as well as excitation spectra are obtained with a Cary 17 spectrophotometer. The spectrometer has been modified, when used for fluorescence and excitation, by laboratory-made attachments. Only one beam is used with external excitation for fluorescence, and with internal excitation for excitation spectra.

The vitroceramic samples are either optically polished plates of 50μ thickness or powders obtained by crushing the ceramics in a mortar and sieving to various sizes.

Efficiency comparison with other phosphors and fluorescence spectra are performed on powdered samples, whereas excitation spectra and absorption spectra are obtained from plate samples which are then compared with phosphor samples in forms of platelets of 80 mg/cm^2 sizes. This size is the optimum for relative up-conversion efficiency for an excitation through the phosphor samples. The details of the efficiency measurements have already been reported elsewhere (6).

Time constants are measured using a Texas Instruments TIXLI6 infrared emitting diode pulsed at 2A peak current with a 40 Hz repetition rate, the pulse width being usually 10 msec. The visible signal is collected from the same side as excitation, filtered by KG3, BG18 Shott glasses, detected by a photomultiplier, and fed directly to a storage oscilloscope.

The scanning electron microscope analysis has been obtained with a Cameca MEB 07 microscope to which has been added a cathodoluminescence attachment (7).

Results and Discussion

Comparative results for up-conversion efficiencies.—Several types of vitroceramics with different glass-forming elements have been prepared each having the same molar composition: M_nO_m = 27.18%; PbF_2 = 67.57%; Yb_2O_3 = 4.85%; Er_2O_3 = 0.39%. The relative efficiency is given in Table I. Except for B_2O_3 and TeO_2, about the same results are obtained for the other glass-forming oxides: P_2O_5, SiO_2, and GeO_2.

Table I. Relative infrared green conversion efficiency for different glass-forming elements in vitroceramics of the general formula (not optimized):

M_nO_m = 27.18%; PbF_2 = 67.57%; Yb_2O_3 = 4.85%; Er_2O_3 = 0.39%; (molar per cent)

Composition: M_nO_m	Efficiency relative to YF_3:Yb:Er (= 100))
B_2O_3	10
TeO_2	30
P_2O_5	70
SiO_2	65
GeO_2	70

The compositions involving GeO_2 and SiO_2 were more thoroughly investigated. The relative ratios of GeO_2 and PbF_2 were systematically varied between 5 and 36% by weight leading to the results presented in Fig. 1, where the optimum $GeO_2/PbF_2 + GeO_2$ ratio is around 20%.

Optimization of Yb_2O_3, Er_2O_3, or Tm_2O_3 in the GeO_2-PbF_2 matrix are presented in Fig. 2 and 3 for the blue and green emissions, respectively. The optimum rare earth concentrations for blue are 25% Yb_2O_3 and 0.062% Tm_2O_3; the best ones for green are 10% Yb_2O_3 and 2% Er_2O_3 (weight per cent).

In Tables II and III, comparisons are made between our best vitroceramics obtained so far, with RE fluoride phosphors. Comparison is made between powdered samples of the same particle size (about 50μ). But it should be noted that reducing vitroceramics to powder of 50μ grain size decreases their efficiency by 75% with respect to the uncrushed ceramics or crushed ceramics with grains longer than 200μ. This effect of reduction of efficiency for powdered ceramics is not yet fully understood. It does not appear to be a lack of refractive index matching but seems closely linked to the effect of photon trapping as is shown below.

Comparisons are made under CW as well as pulsed excitation by using a figure of merit defined (8) as

$$M = \eta_n(\tfrac{1}{2}\pi\tau_1)$$

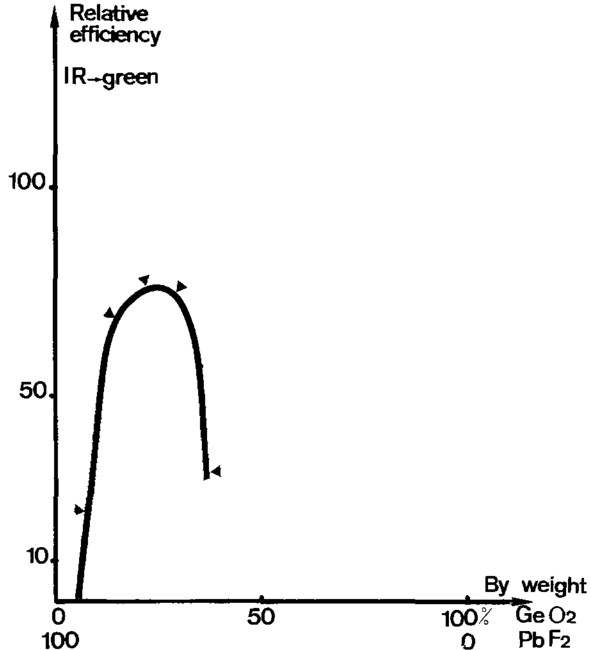

Fig. 1. Relative efficiency for infrared → green conversion vs. $GeO_2/(PbF_2)$ ratio.

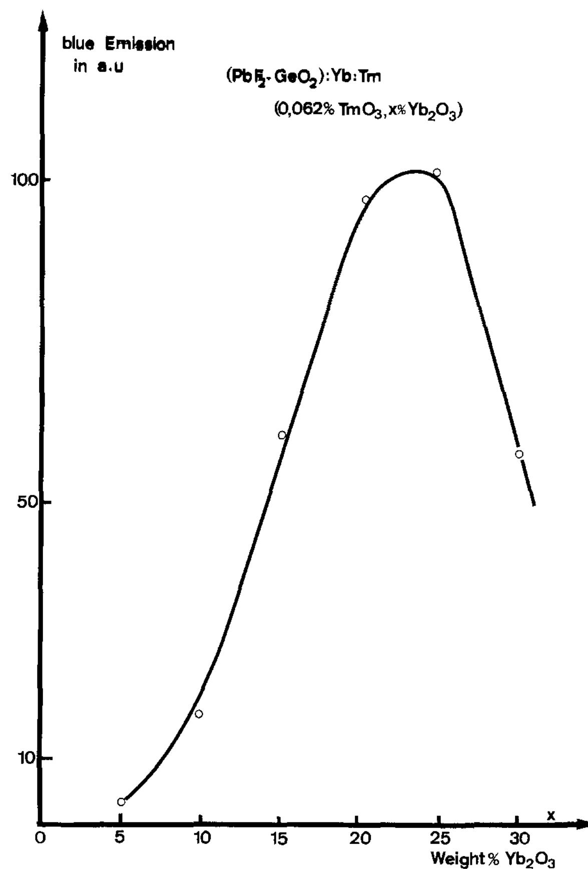

Fig. 2. Relative blue conversion efficiency vs. Yb^{3+} concentration for a $(PbF_2\text{-}GeO_2)$:Yb:Tm vitroceramic doped with 0.062% Tm_2O_3.

where η_n is the efficiency as defined by the emitted power per square centimeter when 1 mW power per cm^2 at 0.97μ is falling on the sample; τ is the rise time of the emission as measured on the powder on the same side as excitation.

It is necessary to define the frame work of the time constant measurements for excitation and emission since the infrared photon trapping effect (5) due to $Yb^{3+}(^2F_{5/2} \rightarrow {}^2F_{7/2}) \Longrightarrow Yb^{3+}(^2F_{7/2} \rightarrow {}^2F_{5/2})$ radiative transfer is particularly strong in this type of matrix. For example Fig. 4 presents the rise and fall times for the $GeO_2\text{-}PbF_2$ optimized-type vitroceramic; the measurements are made through samples of various thicknesses. A fourfold increase in rise time is found for thicknesses varying between 0.1 and 4.5 mm, and an increase of 3.4 times in decay time is found for the same thickness range. For larger thicknesses a time constant saturation takes place. This increase is due to the Yb^{3+} lifetime increase by resonance since the relation (9) τ_2 = Yb/2 is found constant for any thickness: at 0.1 mm we have τ_{Yb} = 1.6 msec or $\tau_{Yb}/2$ = 0.8 msec and τ_2 is found to be 0.9 msec; at 4.5 mm τ_{Yb} = 7 msec or $\tau_{Yb}/2$ = 3.5 msec and τ_2 is found to be 3.4 msec. This effect has to be taken into account if one wishes to calculate transfer efficiencies from lifetime measurements.

This explains the reduction in efficiency when the vitroceramics are reduced to a powder. This hypothesis is based on the fact that τ_{Yb} is found to be lower for two samples of given thickness joined together, than for one of double thickness even if the two samples are bound by an index matching medium. In the same way, the efficiency cannot be restored for a powder using such a medium. If a space limited excitation is produced using a diaphragm, light emission of a ceramic wafer is obtained at a distance of about several millimeters from the diaphragm. This is the same average distance through which energy can migrate radiatively as indicated from lifetime curves in Fig. 4.

Fig. 5. Comparative excitation spectra for YF_3:Yb:Er, $NaYF_4$:Yb:Er, and (GeO_2, PbF_2, Yb_2O_3):Er normalized to have same maximum.

These results, in our view, indicate that the radiative transfer of Yb^{3+} energy is a necessary link for the efficiency of the up-conversion process and that the structure of the material plays a determinant role in that transfer. But we feel more work is necessary to assess these hypotheses. For LED applications, the optimum sample thickness was found to be around 300μ.

Comparative spectral results.—In order to compare the vitroceramics with classical up-conversion phosphors, excitation spectra are given in Fig. 5. The GeO_2-PbF_2 vitroceramic spectrum extends as far as the $NaYF_4$ one at longer wavelengths and somewhat farther than the YF_3 one at shorter wavelengths. Therefore excitation is possible with a GaAs laser at 0.9μ or a YAG:Nd laser at 1.06μ. As far as line width is concerned the general aspects of the excitation spectra are different; the vitroceramic shows fewer and broader lines. For instance, in Fig. 6, for the strongest line, the width is 20Å as compared to 6Å for YF_3:Yb:Er. Using the same excitation and detection conditions, the spectral peak intensity is stronger for YF_3, which confirms the direct results of Table I. Similar results are presented in Fig. 7 for the blue emission. Approximately the same line width is found but the over-all splitting is stronger in ceramics.

The line widths of vitroceramics are much smaller than that usually found for the same emission in glass, 20Å against 200Å for a germanate glass. On the other hand the up-conversion efficiency is more than two orders of magnitude better than in a germanate glass (8). These two facts imply that the rare earths concentrate in the crystal phase rather than in the glass phase during the precipitation process; this segregation effect is evidenced below by the scanning electron microscope study. The Yb^{3+} concentration in the microcrystals is then higher than the one given by the bulk formula. This enhances the trapping effect found in these materials.

Another point of interest is the high efficiency and the high green/red emission ratio for hosts with such high oxygen concentration. The green/red energetic ratio for the vitroceramic is about 7 while for our best YF_3, this ratio is 10, yet it is well known that the presence of oxygen in fluorides usually gives a lower green/red ratio and lower green efficiency (4). One hypothesis is that during the microcrystal precipitation process most of the oxygen of the melt is concentrated in the glassy phase rather than in the crystalline one; most of the oxygen present is necessary for the glassy phase to exist. Also as is well known, PbF_2 may act as a

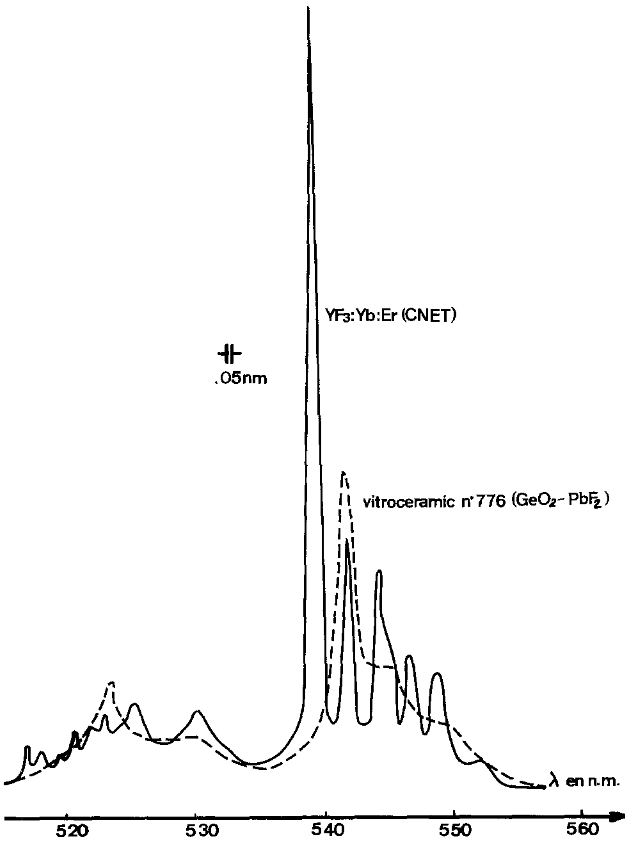

Fig. 6. Comparative green emission spectra of YF_3:Yb:Er (CNET) and (GeO_2, PbF_2, Yb_2O_3):Er vitroceramics.

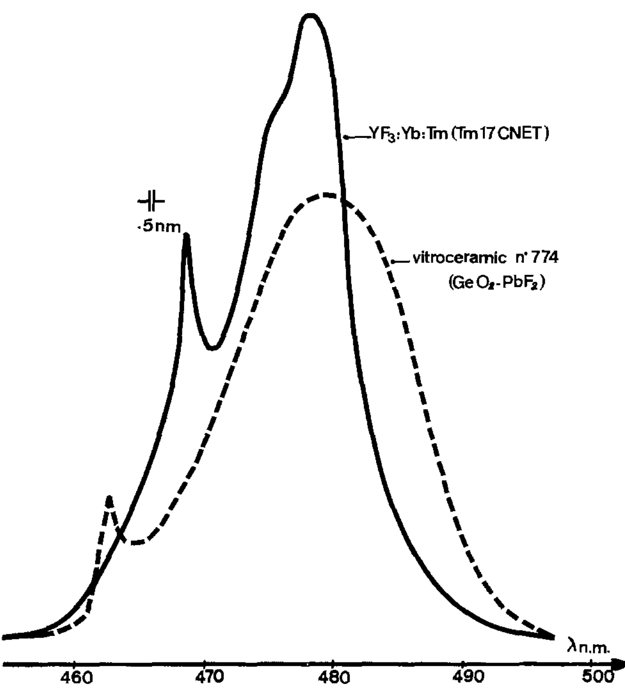

Fig. 7. Comparative blue emission spectra of Yb_3:Yb:Tm (CNET) and (GeO_2, PbF_2, Yb_2O_3):Er vitroceramics.

scavenger for oxygen; this effect can also play a role to eliminate oxygen from the microcrystals. Yet this oxygen segregation hypothesis is not necessary if one considers a homogeneous distribution of constituents since the calculated Debye cutoff frequency is then 320 cm^{-1}, which according to Matsubara (10) predicts a green emission.

Relationship between spectroscopic results and microstructure.—The hypothesis that the rare earths (Yb, Er, or Tm) concentrate mainly in the microcrystal phase and germanium only in the glassy phase has been confirmed by the scanning electron microscope. Figure 8a presents the microcrystals (white) inside the glassy phase (dark) as obtained by back scattering of electrons. Figure 8b gives the same picture obtained by x-ray fluorescence of germanium (white) which shows that Ge is the main constituent of the glassy phase; on the other hand, when looking at x-ray fluorescence of ytterbium one obtains Fig. 8c which shows that Yb is essentially in the microcrystalline phase. The same results are obtained for the cathodoluminescence of erbium at 0.65μ as shown in Fig. 8d. When analyzing for lead by x-ray fluorescence, Fig. 8e is obtained which indicates that Pb is uniformly distributed.

Hence the glassy phase is probably a lead germanate whereas the microcrystalline phase (which is found to be homogeneous as shown on Fig. 9 by electron absorption) could be a fluoride of lead, ytterbium, and erbium. Attempts at producing good up-conversion efficiency by direct preparation of PbF_2-YbF_3:Er microcrystals lead to an output of only 2% of the best vitroceramics sample. The role played by the microstructure may be an explanation. Figure 10 shows a cathodoluminescence picture of the 0.65μ Er^{3+} emission at a lower magnification than the previous one. A long distance order ($\simeq 200\mu$) is found for the microcrystalline structure; such long order cannot be obtained by a direct preparation of lead-ytterbium fluoride.

On the other hand, the decrease in up-conversion efficiency observed when crushing the ceramics into grains smaller than 200μ can be explained by the long distance order which is then destroyed and if one assumes that the radiative energy transfer migrates preferably along the microcrystal in the same way as in light-pipes, the behavior of these vitroceramics could be understood.

Conclusions

We have presented here a new class of efficient materials for infrared up-conversion which has the advantages of easy preparation and good efficiencies. However their puzzling behavior requires more experiments for a clearer understanding.

In the vitroceramics described. we have clearly demonstrated by up-conversion results as well as x-ray fluorescence and cathodoluminescence scanning microscopy that rare earth ions concentrate mainly in the precipitated microcrystals, which accounts for the high up-conversion efficiency.

Recently glass ceramics of quite different compositions have been demonstrated as replacements for glass laser materials (11, 12). But their lower fluorescence efficiency (12) and their broader emission line width (11) with respect to the glass of the same bulk composition is an indication that rare earth ions stay mainly in the glassy phase. The new high efficiency vitroceramics presented here with the rare earth segregation in the microcrystals, should be a better prospect for glass ceramic laser materials than the previous ones, provided the microcrystal size could be reduced.

For display applications, the fact that such vitroceramics can be cast, polished, and cut as glass, could lead to new ways to couple these solid phosphors to infrared sources. Seven segment displays, using the vitroceramics as a substrate coupled with discrete diodes can be encompassed. Another advantage over powder phosphors is that multidielectric coatings (8) can be used easily with a glass substrate to capture the infrared radiation.

Poly(Vinylferrocene)—Conversion to an Oxidized Iron System Suitable for Use as a Semitransparent Hard Photomask

L. F. Thompson

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A novel technique for the production of iron oxide films from a polymer precursor is described. Films of poly(vinylferrocene) (PVFc) can be converted to iron oxide films in either a 200W oxygen plasma at room temperature or thermally in oxygen at 380°C. The thermal decomposition appears to be more suitable for routine use, and process parameters for this technique have been optimized. The thermal conversion has been studied using infrared, visible, and u.v. spectroscopy and a decomposition reaction proposed. The iron oxide films prepared from PVFc have chemical and physical properties similar to the iron oxide films prepared using the iron pentacarbonyl process. Films prepared from PVFc are presently being evaluated for use as semitransparent photolithographic masks.

The use of iron oxide for the fabrication of hard, semitransparent masks for use in the manufacture of integrated circuits is gaining rapid acceptance (1). Although the film material is primarily Fe_2O_3, the exact structure is far more complicated than a pure Fe_2O_3 system. Iron oxide was chosen from a large group of transition metal oxides and mixed oxides as having the best combination of chemical and physical properties required for use as a transparent mask material (2). The relevant properties are given by Peters *et al.* (3) as: (*i*) $<1\%$ transmission in the 360-400 nm spectral region; (*ii*) $>30\%$ transmission at the sodium D line (589 nm); (*iii*) an etching rate compatible with conventional photolithographic processes and materials; (*iv*) in addition, the physical integrity of the film (hardness, abrasion resistance, etc.) must be sufficient to sustain the abuses of routine handling.

Three techniques are presently available for the deposition of thin films of iron oxide. The first is a chemical vapor deposition scheme using $Fe(CO)_5$ developed by MacChesney *et al.* (4). Iron pentacarbonyl is thermally decomposed at temperatures in the 130°-200°C range in an oxidizing atmosphere ($CO_2 + O_2$) on glass substrates. Films prepared by this technique have excellent mask properties, and this is presently the technique of choice for mask film manufacture. The only substantial disadvantage of the procedure is using a poisonous compound, $Fe(CO)_5$. A second deposition technique involving sputtering has been devised by Sinclair *et al.* (2, 3) for depositing Fe_2O_3 films. The sputtering techniques used were conventional with the exception that it was found necessary to introduce $CO_2 + O_2$ as a discharge gas in order to increase the solubility of the deposited Fe_2O_3 films to an acceptable level for etching. The exact role that CO_2 plays is not clear, but it appears likely that the presence of iron carbonate in films leads to increased solubility (3). The sputtering technique produces films which meet all mask requirements with the only disadvantage being that the process is slow and requires expensive vacuum equipment. The third general procedure, one similar to the process described in this paper, involves the decomposition of an organometallic compound in an oxidizing atmosphere resulting in the deposition of a metal oxide film. Reid and Cukor (5) suggested that organo-iron compounds could be thermally decomposed in O_2 to Fe_2O_3. Shelby and Cukor (6) decomposed nickel tetradecanoate and iron dodecanoate to Fe-Ni alloys at 500°C in a H_2 ambient. These films were subsequently used as x-ray standards and could be deposited with good reproducibility.

Key words: iron oxide, photomasks, semitransparent masks, photolithography.

This paper describes a method for the deposition of an oxidized iron film using a high molecular weight, organometallic polymer as a precursor. This technique offers the advantage of being able to deposit uniform films of sufficient thickness to yield a useful mask material in one application. However, two or more thinner films may be applied if necessary to reduce defect densities.

Poly(vinylferrocene) (PVFc) has been synthesized by a number of workers (7-9). It has been shown that PVFc can be converted to Fe_2O_3 in an oxygen plasma and subsequently to Fe° capable of serving as a catalytic tract for selective electroless deposition of Cu, Au, and Ni (10). The disadvantage of plasma conversion lies in the time required to convert a 400 nm film to Fe_2O_3. In preliminary studies it was found that in O_2 at 400°C, PVFc could be thermally converted in <30 min to an oxidized iron film possessing useful mask properties.

It should be noted that exact chemical composition of these films is difficult to ascertain. They are complex mixtures of Fe_2O_3, Fe_3O_4, $Fe(CO_3)_2$, and other inorganic iron compounds. Since any attempt to produce larger samples of material for subsequent analysis would significantly alter the physics and chemistry of the thin-film system and possibly yield a different conversion process and material, the exact structure remains undetermined.

The reaction scheme is shown in Fig. 1. The object of this study was to evaluate the oxidation of PVFc.

$$-\!\!(CH_2-CH)_n\!\!- \text{ (ferrocenyl-substituted)} \xrightarrow[400^\circ C]{O_2} Fe_xO_y + CO_2 + H_2O$$

Fig. 1. Reaction scheme of the thermal oxidation of PVFc to Fe_2O_3.

Experimental

PVFc deposition.—The PVFc used in this work was prepared by free radical bulk polymerization of vinyl ferrocene at 80°C (7, 8). The monomer, vinyl ferrocene, was purchased from Research Organics, Incorporated (ROC/FIC) and purified by vacuum sublimation (mp 50°-50.5°C). Azobisisobutyronitrile (AIBN) was used as a catalyst and was purified by recrystallization from methanol (mp 102°-103°C with slow decomposition). Vinyl ferrocene and 0.08% AIBN (by weight) were sealed in a glass tube under N_2. The vinyl ferrocene was melted and AIBN allowed to dissolve in it. The sealed tube was placed in a bath at 80° ± 0.5°C, and the polymerization was allowed to continue for 72 hr. The mixture solidified after about 12 hr. The tube was cooled in ice water, broken open, and the polymer dissolved in chlorobenzene. The PVFc was precipitated in cold methanol, recovered by filtration, and dried in a vacuum at 80°C for 24 hr. The polymer was dissolved in chlorobenzene (6-7% solids) and filtered to remove particulates by multiple passes through a 0.2μ sintered silver filter prior to use. The substrates were spin coated with PVFc using standard photoresist techniques (11). All substrates used in this study were 1 in. diameter by ⅛ in. thick quartz disks which facilitated direct quantitative visible and ultraviolet (u.v.) absorption studies.

The visible-ultraviolet absorption spectra for Fe_2O_3 suitable for use as a photomask is well established (2) and is shown in Fig. 2 (dashed curve). The spectrum from 300 to 700 nm obtained with a Cary Model 14 spectrophotometer was used to follow the conversion of PVFc to Fe_2O_3.

Infrared studies were carried out using attenuated total reflection (ATR) with a Perkin-Elmer Model 631 spectrophotometer. The samples were coated on 5 mil aluminum foil and mounted against a KRS-5 plate for ATR studies. Spectrum assignments were made with the aid of known spectra.

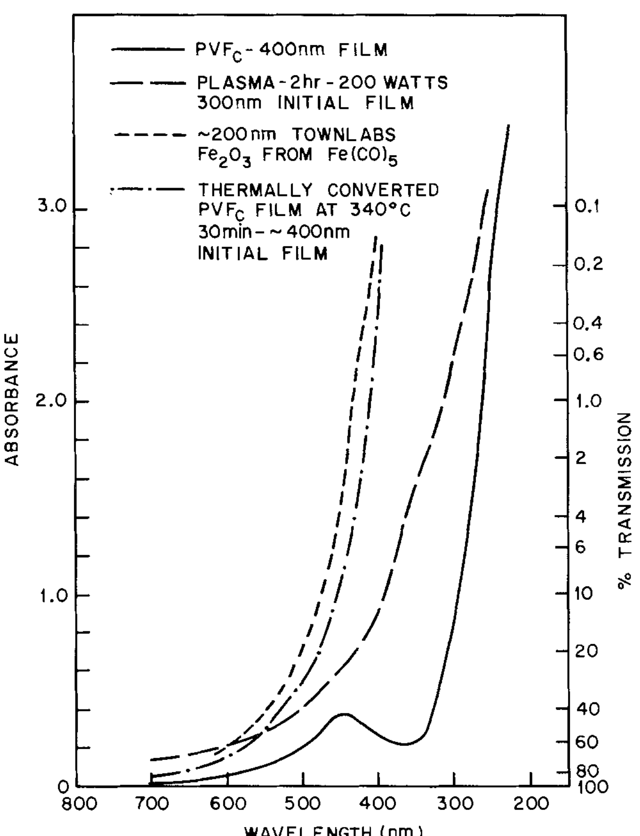

Fig. 2. 700-200 nm absorption spectra for PVFc and oxidized iron films.

Plasma conversion.—A 200W, 4 MHz radio frequency plasma was used to study plasma conversion of PVFc to Fe_2O_3. The degree of conversion was followed using visible u.v. spectroscopy to determine changes in absorption in the 360-400 nm region of interest. Although this does not yield precise information regarding structural changes, it does measure the primary parameter of interest for a semitransparent mask material.

Thermal conversion.—Thermal conversions were carried out in a 2 in. diameter tube furnace regulated to ±10°C with an O_2 flow rate maintained at ≈5 liters/min^{-1}. Infrared analysis and ultraviolet visible spectroscopy were then used to study the thermal conversion of PVFc.

Results and Discussion

The free-radical bulk polymerization of vinyl ferrocene as described yielded about 70% polymer in the 72 hr reaction time. The molecular weight of the polymer as determined by dilute solution viscosity was found to be ~80,000. Several separate batches of polymer were prepared with good reproducibility, although molecular weight varied by as much as ±20%. The yield never varied by more than 10%. A detailed study of the reaction parameter is presently underway. The polymer yielded uniform, defect-free films from a chlorobenzene solution.

Plasma oxidation.—It was found that in a 200W oxygen plasma, PVFc oxidized to an iron compound with a visible u.v. spectrum similar to that of Fe_2O_3 films prepared by the $Fe(CO)_5$ process. For complete conversion 3 hr or more were required. Figure 2 illustrates the spectrum of a 300 nm PVFc film which was oxidized in a plasma to an inorganic iron film. It is noted that the absorption is not adequate for mask purposes in the 300-400 nm region; however, if 400 nm of polymer is used, the absorption increases to an adequate level. This thickness can be achieved either by a single 400 nm coating or two sequential 200 nm coatings. The double coating technique has the advantage of reducing defects in the film at the expense of additional processing steps and time.

Plasma exposure time as a function of absorption (and per cent transmission) is shown in Fig. 3 at wavelengths of 600, 500, 400, and 350 nm. Note that the absorption in the 350 and 400 nm region increases rapidly as the oxidation proceeds, while in the 500 and 600 nm region absorption remains relatively unaffected. The plasma oxidation is complete after 3 hr. A slight decrease in absorption is noted after long exposures, probably due to sputter removal of material from the oxidized material. The oxidized films were soluble in cold 6-8M HCl and etched at about 1 μmin^{-1} after

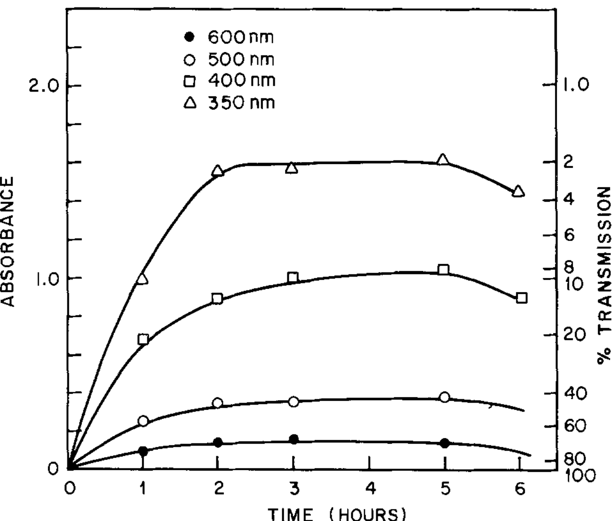

Fig. 3. Absorption as a function of time for the plasma conversion of PVFc with a 200W O_2 plasma.

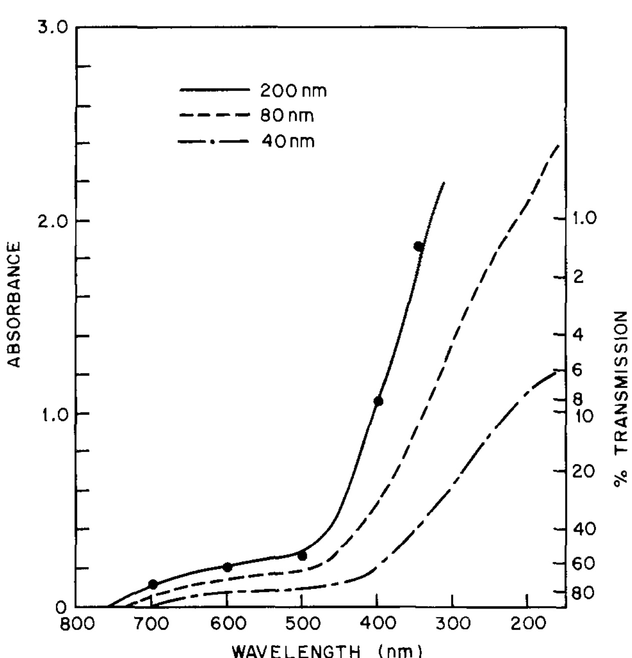

Fig. 4. 200-700 nm absorption spectra for the thermal conversion at 280°C of PVFc of three thicknesses.

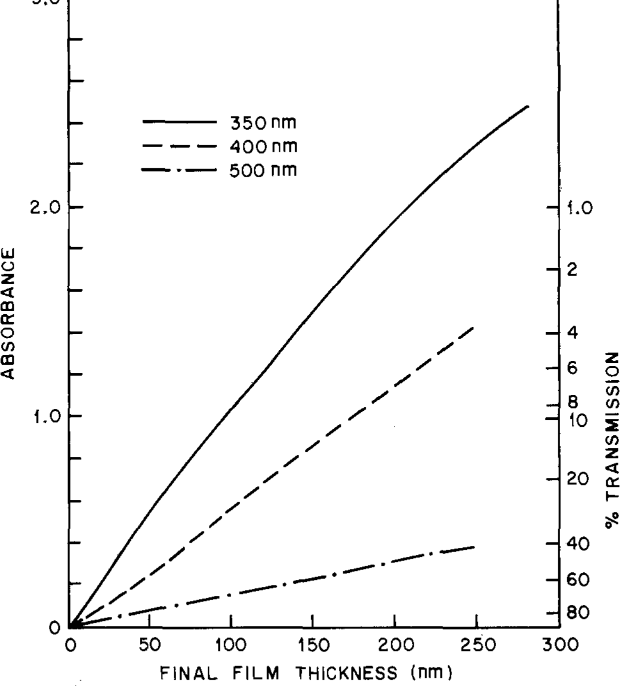

Fig. 6. Absorption as a function of thickness for PVFc films oxidized at 300°C for 30 min.

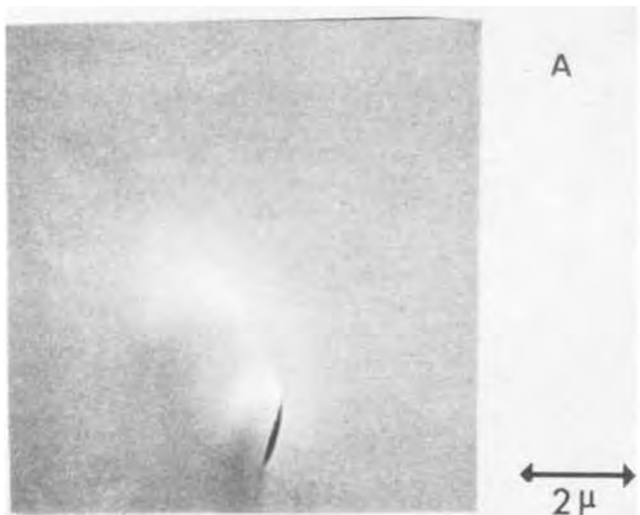
complete plasma conversion. They became insoluble after a 450°C heat-treatment, although there were no noticeable absorption changes. Scanning electron microscopy (SEM) studies revealed no defects in the oxidized films that were not attributable to particulate inclusions in the precursor polymer film.

Thermal conversion.—It was found that thermal oxidation treatments at 400°C for 20-30 min in an oxygen atmosphere was sufficient to convert PVFc to a stable oxidized iron material. The optimum oxygen flow for the furnace used was ~5 liters/min^{-1}. However, flow rates are expected to be system dependent, they are not a critical parameter. Again the energy absorption in the visible u.v. region was used to optimize the conversion process since this is the primary property of concern in mask materials. Figure 4 shows the absorption spectra for three final film thicknesses. It should be noted that the thermal conversion is accompanied by a 50-60% decrease in film thickness.[1] It was found that to minimize the detrimental effects of film shrinkage, a programmed baking schedule was necessary. Figure 5A is a (SEM) micrograph of a 200 nm film which was baked in a preheated 400°C furnace. The broken areas shown were common on films treated in this way. However, when the baking schedule was started at room temperature and increased at ~10°C/min^{-1} rates, this catastrophic crazing effect was eliminated, and uniform films were then obtained (Fig. 5B).

[1] The thickness referred to in this study is final film thickness unless otherwise stated.

It was found that ~200 nm of final film was necessary to give the desired absorption properties using thermal conversion. Figure 6 shows absorption as a function of film thickness for three wavelengths: 350, 400, and 500 nm. This film was converted with a 400° ± 10°C, 30 min baking schedule in which the temperature was increased from 22° to 400°C at ~10°C/min^{-1} and then held at 400° ± 10°C for 30 min. The 200 nm final film thickness was achieved by converting a single coating of PVFc of an initial thickness of ~470 nm. As before, there are advantages in using two thin (~240 nm) coatings each followed by a bake, since the defect density will be less and the film should be more homogeneous throughout its thickness.

Both scratch resistance and adhesion were qualitatively compared to films deposited from $Fe(CO)_5$. The adhesion (as per "scotch tape" test and epoxy pull



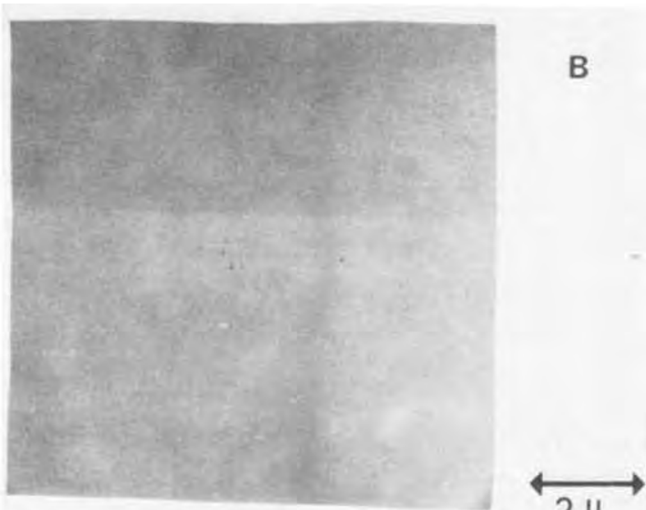


Fig. 5. SEM of thermally converted oxidized iron films

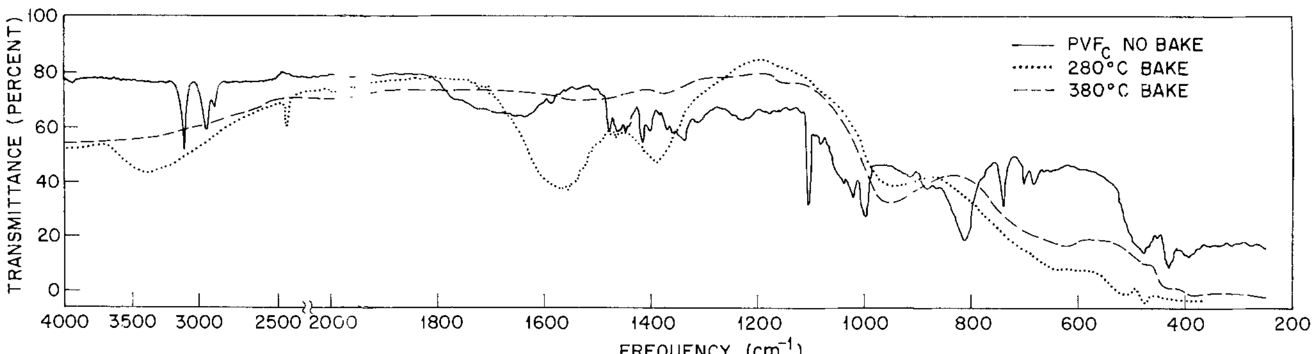

Fig. 7. Infrared spectra of a 400 nm polyvinylferrocene film baked at two temperatures, 200° and 400°C, for 30 min each

test) was in no case worse than the standard sample and exceeded that of the carbonyl film in most samples. The scratch resistance was comparable to the carbonyl standard. Precise defect density measurements are presently underway.

The conversion of PVFc to oxidized iron compounds involves considerable chemical changes in the film. Attenuated total reflectance (ATR) infrared spectroscopy was used to study the thermal oxidation of PVFc. A possible reaction spectra scheme is given in Fig. 1. Figure 7 shows three ATR spectra obtained using a 400 nm PVFc film. The spectrum of the film prior to baking is identical to those reported (8) for pure PVFc. The 250°C bake was sufficient to eliminate the general hydrocarbon structure of the original film. The C-H stretching bands in the 3225-2777 cm^{-1} region are probably the most sensitive and have completely disappeared. A broad peak centered about 3333 cm^{-1} is suggestive of bonded water, one of the decomposition products from the thermal oxidation of PVFc. The associated band at 1612 cm^{-1} also is suggestive of water. A large band at 1390 cm^{-1} has been assigned to the iron carbonate structure. The remainder of the spectrum is characteristic of Fe_2O_3. After baking at 370°C for 30 min all traces of water and iron carbonate have disappeared and normal Fe_2O_3 spectrum remains. It should be noted that carbonate free material is still soluble in dilute HCl.

If these materials are fired above 450°C, the solubility in cold acids decreases until it becomes essentially zero. This has generally been attributed to crystallization of the iron oxide. It was found that the addition of 3% $SnCl_2$ to the 6M HCl increased the dissolution rate; however, this failed to facilitate solubility of normally insoluble material.

It should be emphasized that although results of the present investigation are internally self-consistent for this system, they deviate from results reported on other iron oxide systems (2, 3). It is likely that in none of the three investigations was pure Fe_2O_3 being studied, and it is likely that complex mixtures of several iron compounds and possibly residual cyclic carbon skeletons were involved. Since in all of the studies it was the final properties, such as u.v. visible absorption, defect density, and solubility (etch rate), which were of primary consideration, it is not surprising that details of the fundamental chemistry have remained obscure. Care should be exercised in comparing the films made by the three techniques: $Fe(CO)_5$, sputtered, and the polymer precursor system.

Conclusions

1. Poly(vinylferrocene) can be converted to an oxidized iron compound with properties similar to the films presently used to make semitransparent masks.
2. The PVFc may be oxidized with a 200W rf, oxygen plasma in 3 hr yielding a film with good mask properties. The disadvantages of this procedure are the long times and expensive equipment necessary.
3. PVFc may alternatively be thermally converted in 30 min to a suitable mask material in an O_2 ambient at 400°C.
4. Infrared analyses indicates that conversion below ~280°C yields a product which contains appreciable amounts of carbonate and water.
5. Baking above 400°C removes all traces of CO_3^{++} and H_2O; however, if 400°C is not exceeded, the films remain soluble in cold acids.
6. Scratch resistance and adhesion appear to be similar to the iron oxide films prepared by the pentacarbonyl process.

Optical Characterization of GaAs Layers Grown on Ge Substrates

Hiroyuki Kasano and Sigeyuki Hosoki

Central Research Laboratory, Hitachi Limited, Kokubunji, Tokyo, Japan

ABSTRACT

The structural quality of GaAs layers grown on Ge substrates has been optically characterized as a function of the distance d from GaAs-Ge interface along the growth axis, supported by electrical measurement and also by x-ray measurement. It is found that the degradation of the structural quality due to interface alloying and autodoping of Ge can be detected in the grown layers only within $\sim 3\mu$ from the interface, where the concentration of Ge involved would exceed 1×10^{17} atoms/cm^3. However, the degradation caused by misfit dislocations extends as far as 80μ from the interface, in spite of the fact that the dislocation density decreases exponentially with increasing d. These misfit dislocations introduce quite effective nonradiative recombination centers in GaAs, which quench the luminescence intensity, L, in a form of $L = A \log (1 \times 10^6/N)$, where N is the density of these nonradiative recombination centers and A is a constant. If the GaAs layers are contaminated with Cu during the growth process, it is found that L is reduced in such a way that the constant A in the above equation is decreased.

In the commercial production of epitaxial layers of III-V compound semiconductors, such as GaAs and $GaAs_{1-x}P_x$, it is profitable to use Ge wafers as substrates. This is because Ge is superior to GaAs in wafer area and also in cost. However, heteroepitaxial growth of III-V compounds on Ge substrates causes degradation of the structural quality of the grown layers at the interface. This problem has been investigated in detail in the case of a GaAs-Ge system. The degradation includes misfit dislocations (1), interface alloying (2), autodoping of Ge (3), and the cross diffusions of Ge, Ga, and As (4). The structural quality of these GaAs layers has also been characterized by measurements on electron mobility (5) and the width of an x-ray rocking curve (6), but optical characterization has not yet been reported. Since crystal imperfections in GaAs crystals, such as dislocations (7) and precipitates (8), form deep levels and act as nonradiative recombination centers, structural quality can be studied by photoluminescence (PL) or cathodoluminescence (CL). Some works (5, 6) suggested that structural quality of these GaAs layers was rather improved in the bulk region of the epitaxial layer, more than 10μ from the heterojunction. It seems obvious that some portion of these improvements was due to an accommodation of the misfit by dislocation lines (9). However, little experimental work has been done to clarify the layer thickness dependence of the structural quality, which is an important factor for the practical use of Ge substrates.

The purposes of this study are: (*i*) to measure the distribution of crystal imperfections in these GaAs layers along the growth axis, (*ii*) to examine the influence of Ge involved in the GaAs epitaxial layers on the electrical and optical properties of the layers, and (*iii*) to examine the influence of other residual impurities on the optical properties of these GaAs layers. In order to achieve these purposes, the luminescence properties were observed at $\sim 80°$K under constant excitation level as a function of the distance, d, from Ge substrates. This conventional optical characterization, supported by x-ray topography, leads to the conclusion that degradation of structural quality due to misfit dislocations and residual impurity Cu (10) are important for the bulk properties of these GaAs layers. The concentration of Ge involved is estimated to be less than 1×10^{17} atoms/cm^3 except for the interface region, which is different from the case of $GaAs_{1-x}P_x$ layers (11).

Key words: misfit dislocations, cathodoluminescence, degradation of luminescence, nonradiative recombination, GaAs.

Experimental

GaAs was epitaxially grown on a (311) surface of a Ge substrate in the growth apparatus reported elsewhere (12) by using a $GaAs\text{-}AsCl_3\text{-}H_2$ system. The substrate, Ge, was doped with arsenic ($\rho = 3 \sim 5 \times 10^{-3}$ ohm-cm). The front face of the substrate was polished to a mirror surface and chemically etched with a solution of $1HF{:}1H_2O_2{:}1H_2SO_4$ prior to use, whereas the back and side faces of the substrate were coated with a Si polycrytalline film (11). Unintentionally doped GaAs crystals ($n = 1 \sim 3 \times 10^{17}$ cm^{-3}) and Te-doped ones ($n = 1 \times 10^{18}$ cm^{-3}) were used as source materials for the epitaxy. The source and substrate temperatures adopted empirically were in the range of 750° $\sim$ 950°C and 680° $\sim$ 720°C, respectively. Pd-diffused hydrogen and 7-nines pure $AsCl_3$ were used. The partial pressure of $AsCl_3$ was $0.5 \sim 3 \times 10^{-3}$ atm. GaAs layers, with a thickness of $20 \sim 180\mu$, were grown for 2-8 hr. All the grown layers had mirror-smooth surfaces except when the surface of the substrate was contaminated.

The doping profile in the grown layers was measured electrically along the growth axis, using both the point-contact breakdown (PCB) method and the d-c Van der Pauw technique (13) at a magnetic field of 4500 gauss. The measurement of PCB voltages, V_B, was carried out on a one-degree angle-lapped surface of the sample. The relation between the carrier concentration and V_B was calibrated beforehand by the C-V measurement on Schottky barriers formed on the as-grown surface. The PCB method is excellent for obtaining the profile of the carrier concentration near the interface. Electron mobility, as well as carrier concentration in the bulk region of GaAs layers was measured against the distance, d, from the interface by the d-c. Van der Pauw technique. Prior to the Van der Pauw measurement, both the Ge substrate and the GaAs layer of $\sim 10\mu$ in thickness adjacent to the interface were removed by lapping. Indium alloys were used as ohmic contacts. In these cases, electrical measurement and chemical etching of the GaAs layer for only the as-grown surface side were alternatively repeated on the same sample. Fluctuation of layer thickness by etching was controlled within 10μ.

Photoluminescence (PL) was measured at 80°K to examine the optical influence of Ge on GaAs layers, using the Hg 3650Å line as an excitation source and a

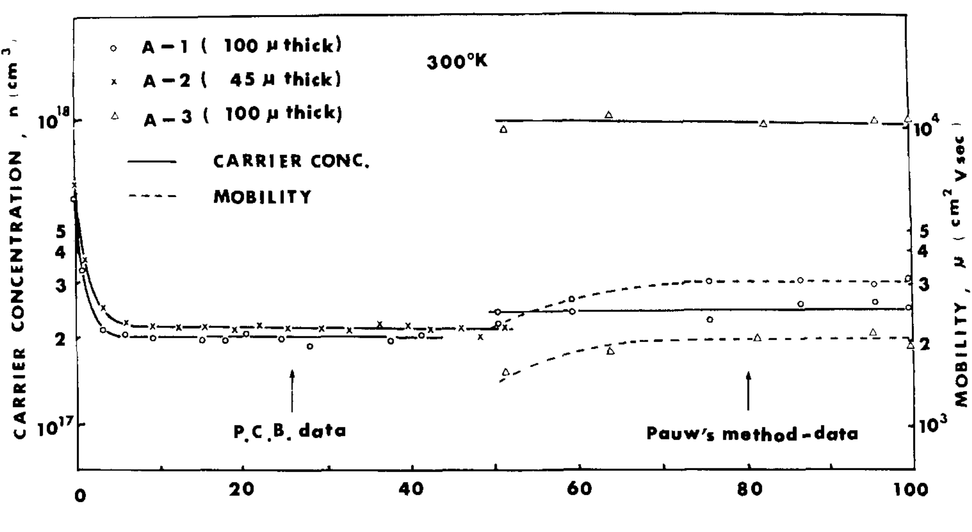

Fig. 1. Electrical properties of GaAs layers grown on Ge substrate, measured as a function of distance from the GaAs-Ge interface, *d*, at 300°K. The influence of Ge incorporated into GaAs layers is only observed in a region within ~3μ from the interface. The concentration of Ge involved is of the order of magnitude of 10^{16} atoms/cm^3 or less beyond the interface region. The gradual decrease in mobility with decreasing *d* is caused by the crystal imperfections due to lattice mismatch.

33-86-40 Type spectrometer (Bausch and Lomb) coupled with a 7102 photomultiplier (Hamamatsu TV) as a detector. The excitation level of PL was kept constant for all samples. Since the PL intensity was observed to decrease drastically with reduction of the layer thickness, the intensity variation against *d* was further investigated using cathodoluminescence (CL) at 77°K. Operating conditions of CL were: accelerating voltage 30 kV, primary beam current 10^{-7}A, and beam spot diameter $1 \sim 3\mu$ for all samples. These conditions result in a quite high excitation level of luminescence, which is higher than that of the above-mentioned PL by several orders of magnitude. In this case, an EPU-2A Type spectrometer (Hitachi) coupled with a 7102 Type photomultipler (Hamamatsu TV) was used as a detector. A step-etching technique was applied to each sample to vary *d*.

The dislocation density in GaAs layers, *N*, was measured against *d* by a transmission x-ray topograph using an Ag target. Prior to the measurement, the Ge substrates were removed by lapping, and GaAs layers with the desired thickness were obtained by using mechanical polishing and chemical etching. Samples with a different doping level and a different thickness were examined. Precipitates were observed in the GaAs layers near the interface using a transmission electron microscope. In this case, a hot H_2O_2 solution (5) was used as an etchant of the Ge substrate. After the Ge substrate was removed, the GaAs layer was carefully etched with a solution of $4H_2SO_4$: $1H_2O_2$: $1H_2O$ from only the as-grown surface side, in order to obtain the thin layer with a thickness of about 1000Å at the peripheral. These thin layers were bombarded with a 100 kV electron beam under a vacuum of 10^{-5} Torr.

In order to ascertain the origin of the acceptor-like residual impurities, a Cu-diffused GaAs sample was also prepared.

Results and Discussion

Influence of Ge incorporated into GaAs layers by autodoping process.—In this section, the influence of Ge incorporated into GaAs layers by the autodoping process is discussed.

Profiles of the carrier concentration, as well as those of mobility, were electrically measured and are shown in Fig. 1 as a function of *d*. The GaAs source crystals used for the epitaxial growth were an undoped one ($n = 2 \times 10^{17}$cm^{-3}, $\mu = 3000$ cm^2/V·sec) for samples A-1 and A-2, and a Te-doped one ($n = 1 \times 10^{18}$cm^{-3}, $\mu = 2000$ cm^2/V·sec) for sample A-3. It is found from Fig. 1 that the carrier concentrations in these layers are kept constant along the growth axis and are consistent with those in the GaAs source, except for the regions within $2 \sim 3\mu$ from the interface, where they are significantly high. These high carrier concentrations are believed to be caused by Ge incorporated by the autodoping process, because the samples examined in this section were carefully prepared in an atmosphere kept as clean as possible to minimize the influence of residual impurities. This is supported by the following results obtained using a transmission electron microscope. A high density ($10^5 \sim 10^6$ cm^{-2}) of precipitates with a diameter of ~1μ in the interface region was observed, and a typical example is shown in Fig. 2. Stacking faults were also observed to originate from some precipitates. However, no precipitate could be detected in layers a few microns apart from the interface. These results suggest that the Ga-Ge-As alloy (2) was partially produced only in regions within $2 \sim 3\mu$ from the interface as a result of relatively heavy incorporation of Ge by the autodoping process. The profiles of the carrier con-

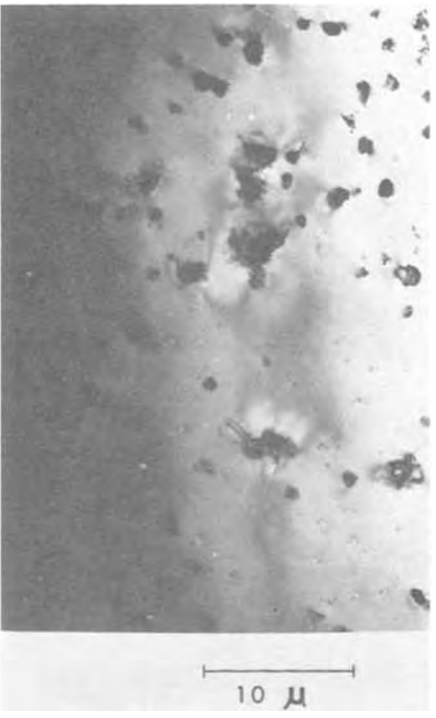

Fig. 2. A micrograph of the GaAs layer within $1 \sim 2\mu$ from the interface, obtained by using a transmission electron microscope. A high density ($10^5 \sim 10^6$ cm^{-2}) of precipitates probably due to alloying are shown to exist. Prior to measurements, the Ge substrate was completely removed from the GaAs layer by chemical etching with hot H_2O_2 solution (5).

centration in Fig. 1 suggest that the Ge concentration in the GaAs layers is of the order of magnitude of 10^{16} atoms/cm^3 or less except for the interface region, and that the impurity doping from the source materials is kept constant during the whole growth process.

The relatively low concentration of Ge in the bulk region of the GaAs layers was ascertained by the following thermodynamical consideration for the vapor etching process of Ge substrates and also by the results of photoluminescence measurement.

At the substrate temperatures adopted in this experiment, 680° ~ 720°C, the predominant reaction between Ge and HCl is expressed as (14)

$$Ge + 3HCl \rightleftarrows GeHCl_3 + H_2 \quad [1]$$

with the equilibrium constant, K_{P1}, which was given by Miller *et al.* (14) as a function of temperature. In this case, the partial pressure of $GeHCl_3$ can be expressed by

$$P_{GeHCl_3} = \frac{1}{3}\left\{ P_{HCl(GaAs)} - \left[\frac{P_{HCl(GaAs)}}{6K_{P1}} + \frac{\sqrt{\frac{P^2_{HCl(GaAs)}}{K^2_{P1}} + \frac{4}{81K^3_{P1}}}}{6}\right]^{1/3} + \left[-\frac{P_{HCl(GaAs)}}{6K_{P1}} + \frac{\sqrt{\frac{P^2_{HCl(GaAs)}}{K^2_{P1}} + \frac{4}{81K^3_{P1}}}}{6}\right]^{1/3}\right\} \quad [2]$$

where $P_{HCl(GaAs)}$ is the equilibrium partial pressure of HCl over the GaAs source and equals $3P_{AsCl_3}/(1 + \sqrt[4]{K_P/P_{As_4}})$. The equilibrium constant of the $GaAs\text{-}AsCl_3\text{-}H_2$ system, K_P, has been calculated (11). By inserting the values of the growth parameters (the source temperature, the substrate temperature, and the partial pressure of $AsCl_3$) adopted in this experiment into the above equations, we get $P_{GeHCl_3} \lesssim 1 \times 10^{-6}$ atm. This value corresponds to a Ge concentration of 3×10^{18} atoms/cm^3 in GaAs if the back-deposition rate of Ge is assumed to be 50%. Once the front face of the Ge substrate is covered with a GaAs layer, P_{GeHCl_3} may immediately drop by a few orders of magnitude. The net weight loss of Ge was measured after the grown layer was removed by chemical etching. None of the Ge was lost during the chemical etching process. The amount of the weight loss due to vapor etching was 0.05 ± 0.02 mg after a 5 hr run for a sample with an exposed surface area of 4 cm^2. This value is reasonable when compared with the calculated result, *i.e.*, the vapor etching of the Ge substrate with $AsCl_3$ is not so serious that the resultant incorporation of Ge will be reduced to less than 10^{17} atoms/cm^3 in the bulk region of GaAs more than a few microns apart from the interface.

Photoluminescence spectra from the epitaxial layers are shown in Fig. 3. The data of a Ge-free sample (sample B) is included for comparison. Sample B was grown on a GaAs substrate in a different growth apparatus using a Ga source. There exist broad and intense low energy emission bands in addition to the near-gap emission band in every sample. The origin of these low energy bands is not well understood but is considered to be complexes associated with vacancies, such as a Ga vacancy-donor complex (15), because they appear in any bulk GaAs crystal containing various kinds of donors. Emission peaks due to Ge in n-GaAs are known to locate at 8380Å for the first acceptor level (16, 17), 8890Å for the second acceptor level (18), and ~ 10,100Å for the donor level (16) at 77°K. Kressel *et al.* (18) reported

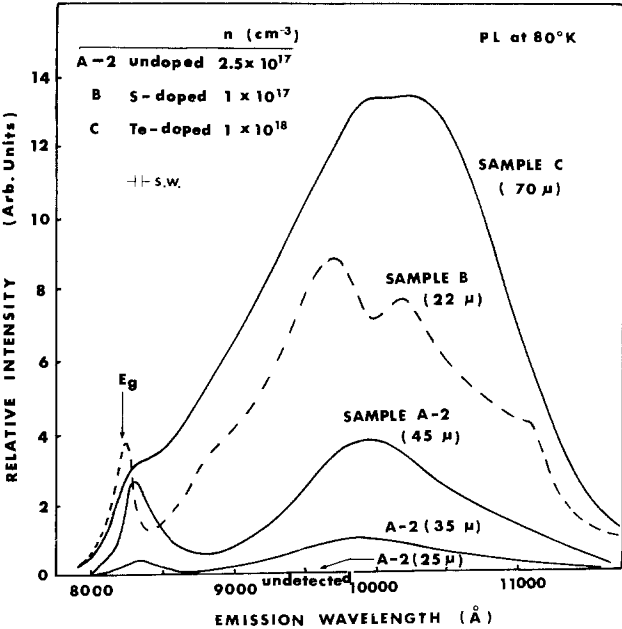

Fig. 3. Photoluminescence spectra at 80°K under constant excitation level. Samples A-2 and C were grown on Ge substrates, whereas sample B was grown on a GaAs substrate using a $Ga\text{-}AsCl_3\text{-}H_2$ system. The decrease of luminescence intensity is found in the case of A-2 as the layer thickness is reduced.

that the emission bands due to Ge could be detected in the PL spectra of GaAs if the Ge concentration exceeded 1×10^{17} atoms/cm^3. However, none of them is observed in the PL spectra on the present samples. So, there is no evidence that samples A-2 and C are doped with Ge, although they are doped more heavily than sample B.

It is found in Fig. 1 that the electron mobility of the GaAs layers grown on the Ge substrates decreases gradually as d is reduced to less than 70μ, though the carrier concentration is invariant in this region. It is also found in Fig. 3 that luminescence intensity of sample A-2 decreases drastically with reducing d, whereas the spectrum is unchanged. The other samples grown on Ge substrates also showed similar results. Therefore, it is believed that these reductions in mobility and luminescence intensity were caused by the inhomogeneous distribution of crystal imperfections, and not by that of impurities. This problem is discussed in detail in the next section.

Influence of misfit dislocations.—In addition to the autodoping of Ge and interface alloying, lattice mismatch at the GaAs-Ge interface also causes the degradation of the structural quality of the GaAs layers. In this experiment, the distribution of dislocations was investigated as a function of d, using a transmission x-ray topograph. Topographs were taken at different thicknesses of the GaAs layers as they were lapped and chemically etched from only their substrate sides. The result is shown in Fig. 4. It is found in Fig. 4 that the dislocation density, N, increases exponentially with decreasing d, which is similar to the case of GaP layers grown on GaAs substrates (19). Such a high density of dislocations and their exponential distribution could not be observed in GaAs layers grown on GaAs substrates. The value of N at the interface, 1×10^6 cm^{-2}, obtained from Fig. 4 by extrapolation is consistent with that reported by Holloway *et al.* (1), 2×10^6 cm^{-2}, for the sample grown at 750°C. As was suggested by Meieran (20), these dislocations are considered to have originated from the lattice constant mismatch between Ge and GaAs. These misfit dislocations, as is shown in Fig. 3, act as quite effective nonradiative recombination centers. On the other hand, the dislocations introduced by a four-point bending are less active recom-

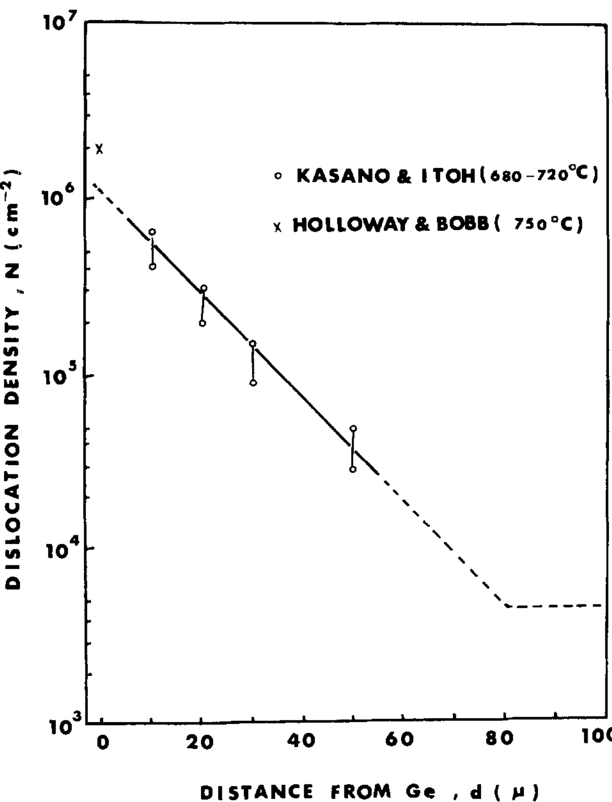

Fig. 4. Dislocation density of GaAs layers grown on Ge substrates, measured by using an x-ray topograph technique as a function of d. The dotted line is estimated from the result of the CL data shown in Fig. 5.

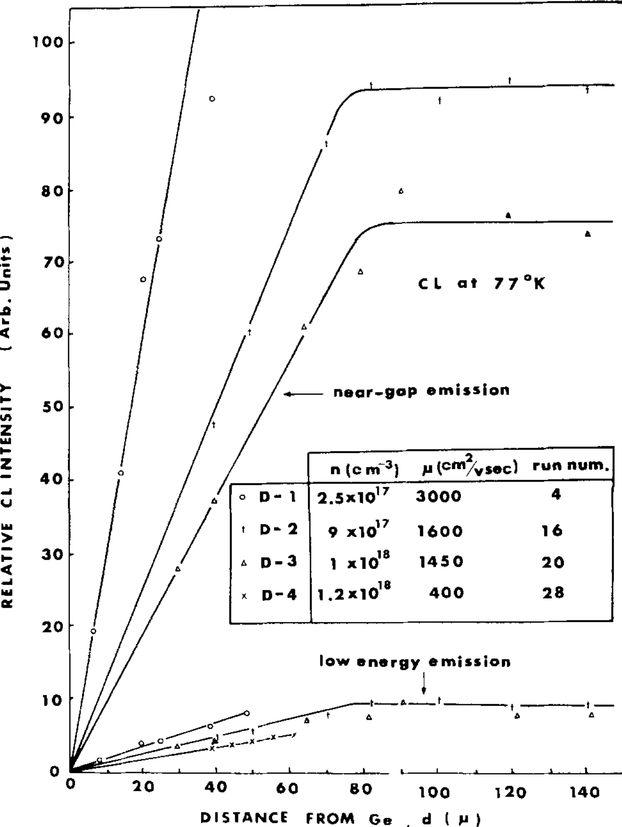

Fig. 5. Intensity variation of the cathodoluminescence from the GaAs layers grown on Ge substrates, measured as a function of d at 77°K. There are only two emission bands in the CL spectra, one of which is the near-gap emission with stronger intensity and the other is the low energy subband peaked at 9200Å with weaker intensity.

bination centers; Esquivel *et al.* (21) showed in the CL measurement for GaAs that only half of the initial intensity was quenched when high 10^6 cm^{-2} dislocations were introduced by bending. The decreasing rate of intensity is smaller than that observed in Fig. 3 by an order of magnitude. These differences in the decreasing rate may be caused by the impurity effect for dislocations; *i.e.*, grown-in dislocations associated with impurities act as effective nonradiative recombination centers (7, 22), whereas dislocations without impurity association do not do so (22). Therefore, a predominant part of the misfit dislocations in this experiment is considered to be associated with impurities, Ge, and other residual impurities.

In order to clarify the dependence of luminescence intensity, L, on the misfit-dislocation density, cathodoluminescence was measured at 77°K (23) as a function of d on several samples with different doping levels. The observed CL spectra consisted of only two emission bands as are shown in Fig. 6. They were the near-gap emission band peaked at 8230 ~ 8290Å and the lower energy subband peaked at ~ 9200Å. The intensity of both the bands varied with d as was shown in Fig. 5, though the spectra were unchanged as in the case of the above-mentioned PL. Figure 5 shows that L is nearly constant in a region of $d \gtrsim 80\mu$, but it decreases linearly with decreasing d in a region of $d < 80\mu$ in any sample and in any emission band. At the interface ($d = 0$), L converges to zero. As the excitation level increased, L generally increased until saturation occurred, whereas L at the interface remained zero. From Fig. 4 and 5, L is given as a function of N by

$$L = L_s \log\left(\frac{N_o}{N}\right) / \log\left(\frac{N_o}{N_s}\right)$$

$$= A \log\left(\frac{N_o}{N}\right), \quad (N_s \leqq N \leqq N_o) \quad [3]$$

where L_s is the saturated intensity at ~ 80μ, N_o is the density corresponding to $L = 0$, N_s is the density which gives L_s, and A is $L_s/\log(N_o/N_s)$. In this case, $N_o = 1 \times 10^6$ cm^{-2}, and $N_s \simeq 5 \times 10^3$ cm^{-2}. The excited pairs which are within a diffusion length, l, of the edge of the recombination center with the effective radius, r, will be drawn to this center, where they recombine nonradiatively via the continuum of states (24). It is noteworthy that the decrease of L is proportional to log N, and not to N in the empirical Eq. [3]. The logarithmic dependence of L on N may be caused by the decrease of l as N increases. It has been established (25) that the lifetime of minority carriers, τ, in plastically deformed pure Ge is proportional to $1/N$. If l is simply defined as $\sqrt{D\tau}$, and the decrease of L is assumed to be proportional to l^2N, the decrease of L becomes independent of N in pure Ge as suggested in the case of dislocations without impurity association in $GaAs_{1-x}P_x$ (22). However, the N dependence of τ becomes a more complicated form in the case where the dislocations are associated with impurities (25). The $D\tau$ is in this case proportional to $(1/N) \ln N$ based on Eq [3], though the mechanism is not clarified. The intensity saturation at $d \simeq 80\mu$ in Fig. 5 is probably caused by the "background" crystal imperfections, whose density is determined by the growth conditions. The dislocation density corresponding to this intensity saturation is estimated to be ~ 5×10^3 cm^{-2} from Fig. 4. The results of Fig. 1, 3, and 5 indicate that the profile of misfit dislocations is explicitly obtained by measuring luminescence intensity under the constant excitation conditions along the growth axis. This results from the fact that the intentionally doped and/or unintentionally doped impurities are uniformly distributed except for the interface region.

As briefly mentioned above, the constant A in Eq. [3] can drastically vary from sample to sample. A

typical case is shown in Fig. 5. The D-series samples in Fig. 5 were grown using the same lot of $AsCl_3$ but a small amount of leakage existed in the gas line of the growth apparatus between the Pd diffuser and the $AsCl_3$ reservoir. By comparing the electrical properties of the D-series samples included in Fig. 5, it is found that the constant A becomes smaller in the sample with lower electron mobility, and that electron mobility becomes lower with the run number for the same lot of $AsCl_3$. It was also observed that the emission bandwidth became broader for the samples with a smaller value of A. Sample D-4 is the extreme case, were no near-gap emission band but only the broad and weak subband peaked at ~ 9200Å was observed. This sample showed n-type conduction with the carrier concentration of 1.2×10^{18} cm^{-3}, but mobility was only 400 cm^2/V·sec. The growth conditions of D-4 were similar to those of other D-series samples except that the Pd diffuser was broken. The degradation of luminescence due to the decrease of A is obviously different from the degradation due to the misfit dislocations mentioned above. Both the bandwidth broadening and the relative increase of intensity of the low energy subband happen in this case. Hence, the origin of the decrease of A is deduced to be the contamination that occurred during the growth process. It should be emphasized that these contaminants also act as the origin of the low-energy subband. The details are discussed in the next section.

Influence of Cu on cathodoluminescence properties.—The CL properties of GaAs containing Cu are dealt with in this section, being correlated with the results obtained in the above section.

In the previous section, we have pointed out that the reduction of L due to the decrease of A is caused by contamination. The low electron mobility and the bandwidth broadening of the D-series samples suggest that the contaminants increase the compensation ratio of GaAs. It means that the contaminants act as acceptors in GaAs. We observed in this CL measurement at 77°K that the low energy subband was located at ~9800Å in Si-doped GaAs crystals and that luminescence intensity was not quenched in oxygen-doped semi-insulating GaAs crystals. They indicate that neither silicon nor oxygen is the contaminant in the present case. The peak position of the subband in this case, ~9200Å (1.35eV) at 77°K, is consistent with that of Cu-doped GaAs crystals, reported by Alferov *et al.* (26) using a photoluminescence technique. Hence, we can speculate the contaminant to be Cu, which can be easily introduced into III-V compounds during the growth process and degrades the radiative efficiency (27).

In order to make sure of this assignment, a Cu-diffused GaAs sample was prepared, and the CL properties of this sample were measured. A Te-doped GaAs wafer ($n = 1 \times 10^{18}$ cm^{-3}) with a mirror-smooth surface (sample E) was dipped into a Cu_2SO_4 solution for 1 min and sealed in a quartz ampule at 1×10^{-5} Torr. The diffusion was carried out at 960°C for 20 min. Then, sample E was angle-lapped at 5° and its CL properties were measured as a function of the distance from the front surface along the wafer thickness, d. Figure 6 shows the CL spectra of samples D-2 and E (before and after Cu diffusion, respectively) near the front surface of the wafer. In sample E, the intensity of the near-gap band, L_G, became very weak and the relative intensity of the low energy subband against L_G,L_{Cu}/L_G, increased as a result of Cu diffusion. This result supports the above assignment that the degradation of luminescence with reduction of A was caused by Cu contamination. The reduction of luminescence intensity, as well as the enhancement of the relative intensity of the 1.35 eV band, was also reported for Cu-doped GaAs samples (28). As was predicted by Batavin *et al.* (28), the concentration of Cu involved can be estimated by measuring L_{Cu}/L_G. Figure 7 shows the variations of L_G and L_{Cu}/L_G along the wafer thickness in the sample E before and after Cu diffusion. The values of L_G and L_{Cu}/L_G are constant with d before Cu diffusion and it indicates a uniform distribution of unintentionally doped Cu impurity in the sample E. After Cu diffusion, both of them vary with d. It is found that the concentration of Cu dips near the center of depth, $d \simeq 450\mu$ as a result of Cu diffusion from both sides of the wafer surface. It is noticeable that the anomalous diffusion coefficient of Cu in GaAs (29) resulted in a rather high concentration of Cu even at the center of depth.

Next, the excitation current (I_B) dependence of L_G and L_{Cu} was observed. Figure 8 shows the I_B dependence of the CL intensities, L_G and L_{Cu}, of a GaAs layer near the front face of the Cu-diffused sample E. It is found that L_G is proportional to I_B^2, whereas L_{Cu} is proportional to I_B. Rao-Sahib *et al.* (30) reported that CL intensity in p-GaAs was proportional to I_B^m ($1 \leq m \leq 2$) under the constant accelerating voltage, where $m = 1$ for low current region and $m > 1$ for high current region. A linear dependence of L on I_B was also observed by Casey *et al.* (31) in the Zn-O doped GaP, which was measured using an unfocused beam. These current dependences are reasonably ex-

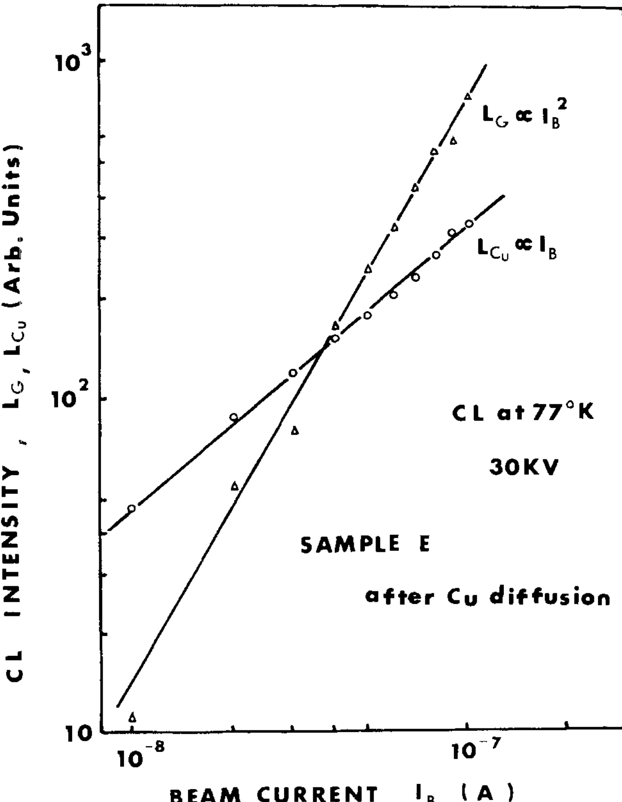

Fig 8. Beam current dependence of the two emission bands at 77°K, measured under the constant accelerating voltage of 30 kV.

plained as follows. The density of free hole-free electron pairs, N_{pair}, created by electron beam excitation is given by (24)

$$N_{pair} = K \left(\frac{I_B}{S}\right)\left(\frac{E_P}{E_0}\right) F(\gamma, d) \quad [4]$$

where E_P/E_0 is the number of pairs created per incident electron, S the excited area, γ the back-scattering rate of the incident electron, d the effective penetration depth of the incident electron, and K the constant. Though F is given as the complicated form (32) because of the nonuniform distribution of carrier generation with depth, it is considered that γ, d, and also F are kept nearly constant if the material, the accelerating voltage, and the flatness of the beam-incident plane are kept constant. As is well known, the radiative recombination rate of free electron-hole pairs under a constant excitation condition is given by the following equations

$$R_{exc} = \frac{np}{n^2_i} = \frac{(n_0 + \Delta n)(p_0 + \Delta p)}{n^2_i} R \quad [5]$$

where R is the radiative recombination rate at thermal equilibrium which was derived by van Roosbroeck and Shockley (33), n_i the intrinsic carrier concentration, $\Delta n(\Delta p)$ a deviation of electron (hole) concentration from a thermal equilibrium value of $n_0(p_0)$ caused by the excitation, or N_{pair}. Since p_0 is much greater than n_0 in uncompensated p-type materials or vice versa in n-type ones, the following relation is approximately derived for p-GaAs from Eq. [4] and [5] under a constant accelerating voltage

$$R_{exc} \propto \Delta n(p_0 + \Delta p) \propto p_0 I_B + \alpha I_B^2 \quad [6]$$

where α is the constant. Equation [6] indicates that R_{exc} is proportional to I_B at low excitation levels where $p_0 >> \Delta p$, whereas R_{exc} proportional to I_B^2 at high excitation levels or in a lightly doped p-type material where $\Delta p >> p_0$ holds. This is the case of Rao-Sahib *et al.*

If GaAs is highly compensated, which is the case of sample E, a relation $p_0 \simeq n_0$ holds and

$$R_{exc} \simeq \frac{(p_0 + \Delta p)^2}{p^2_0} R = \left(1 + \frac{\Delta p}{p_0}\right)^2 R \quad [7]$$

At the excitation levels used in this experiment, $\Delta p >> p_0$ holds in sample E. Hence, R_{exc} is proportional to I_B^2 in the case of near-gap emission, namely $L_G \propto I_B^2$.

The 1.35 eV subband was reported (26) to be due to the recombination between a free electron and a hole bound to the first acceptor level of Cu. In this case, the radiative recombination rate would be limited by the concentration of Cu in the first acceptor state, N^A_{Cu}, because of p, $n >> N^A_{Cu}$, namely, the recombination rate is proportional to the product of $n \cdot N^A_{Cu}$. Hence, a relation $L_{Cu} \propto N_{pair} \propto I_B$ is obtained if $\Delta p >> p_0$, which is the case shown in Fig. 8.

Summary

In this work the structural quality of the GaAs layers grown on the Ge substrates has been investigated as a function of distance from the GaAs-Ge interface, by measuring the photo- and cathodoluminescence properties at 77°K, as well as electrical properties at 300°K. The measurements using an x-ray topography and a transmission electron microscope were also carried out. At the interface, the structural quality of these GaAs layers was heavily degraded by misfit dislocations, interface alloying, and also by autodoping of Ge from the substrate, though the backside faces of the substrate were coated with a Si polycrystalline film during the epitaxy. It is found that the influences of interface alloying and also autodoping of Ge on the electrical and optical properties of these GaAs layers are substantially neutralized in the regions more than a few microns apart from the interface. However, it is also found that structural quality of these GaAs layers less than ~80μ in thickness is affected by the misfit dislocations, though the dislocation density decreases exponentially with d. These misfit dislocations introduce quite effective nonradiative recombination centers in GaAs. It is noteworthy that luminescence intensity, L, is reduced by these nonradiative recombination centers according to the following experimental equation

$$L = A \log(N_o/N) + L_{min}$$

where N is the density of these centers and $N \leq N_o$. In the case of the GaAs-Ge system, $N_o \simeq 1 \times 10^6$ cm^{-2} $L_{min} = 0$. Hence, by measuring the variation of L under the constant excitation conditions, the distribution of these centers can be easily estimated. The other factor which drastically reduces L is the residual impurities, especially Cu incorporated into GaAs during the growth process. The reduction of L due to Cu is found to occur as the decrease of A in the above equation. The distribution of Cu was estimated by measuring the distribution of the relative intensity of the 1.35 eV subband against the near-gap emission band, L_{Cu}/L_G, under the constant excitation conditions at 77°K. The dependence of the intensities of these two bands on the excitation level was also examined.

Acknowledgments

The authors are grateful to M. Tamura for his measurements using a transmission electron microscope, to Dr. S. Kishino for measurements using an x-ray topograph technique, to A. Doi for photoluminescence measurements, to S. Fukuhara for his technical assistance for cathodoluminescence measurements, and to K. Itoh for providing a part of the data of misfit-dislocation density. They would also like to thank Dr. J. Umeda, K. Kurata, and S. Tanimizu for their stimulating discussions and advice. They also wish to voice their appreciation of the support and encouragement given by Dr. H. Okano during the course of this experiment.

Manuscript submitted March 15, 1974; revised manuscript received July 29, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Hitachi, Limited.

Chemisorption Reactions on High Index ZnS Surfaces

W. R. Bottoms and D. B. Lidow

Princeton University, Princeton, New Jersey 08540

ABSTRACT

An attempt is made to determine the relative strength of interaction with an ambient for ZnS surfaces which differ only in the crystallographic perfection of the surface. Chemisorption reactions for a (110) crystal and a stepped high index ZnS surface with oxygen and carbon monoxide were monitored with low energy electron diffraction (LEED) and Auger electron spectroscopy (AES). The correlation of the dissociation and chemisorption activity with the disorder on these ZnS surfaces exhibits the importance of active sites in surface chemical reaction.

Various investigators have suggested that there exist certain "active sites" which are responsible for the chemical activity of catalysts (1). These "active sites" have generally been attributed to lattice defects and/or the topographic structure of a catalyst surface (2). Experimental investigations undertaken to determine the role of surface irregularities in the catalytic activity support an important role for surface imperfections in the chemical activity of these surfaces (2-4). In the present investigation an attempt is made to determine the relative strength of interactions with an ambient for ZnS crystal surfaces which differ only in the crystallographic perfection of the surface.

A (110) surface and a stepped high index face were prepared from a single ZnS crystal to insure identical bulk properties. Two independent experiments were performed upon these crystal faces to characterize the chemical activity of the edge states present upon the high index face using the nonreconstructed (110) surface as a control. In the first experiment, the two crystal faces were introduced separately into a 4-grid LEED-Auger device with a base pressure of 2×10^{-10} Torr. The surface composition and surface symmetries were then monitored with low energy electron diffraction (LEED) and Auger electron spectroscopy (AES). After cleaning the surfaces by argon ion bombardment and annealing, the crystal faces were subjected to various oxygen containing atmospheres and the chemical interaction was observed with LEED and AES. The second experiment exposed the same crystals, both faces mounted simultaneously in the system, to carbon dioxide containing atmospheres and similar LEED and AES observations were made. The results support the dominance of active sites in surface based chemical reactions.

Sample Preparation

The (110) surface, prepared by cleaving in air, exhibited a diffraction pattern upon room temperature pumpdown before any in vacuum processing. Auger spectra taken on these crystals before processing indicated the presence of oxygen, carbon, and chlorine in that order of abundance in addition to sulfur and zinc. These surface contaminants resulted in a poorly developed diffraction pattern and a sequence of annealing steps was undertaken to determine the desorption temperature for chemisorbed gases. The quality of the diffraction pattern showed no significant change until 580°C at which time there was a relatively abrupt change to a well-developed diffraction pattern. The development of the LEED pattern with annealing, illustrated in Fig. 1, indicates a relatively low binding energy for chemisorbed gases on the cleaved (110) surface of ZnS. Auger spectra taken after this high vacuum annealing confirm that the surface is relatively clean since no elements other than zinc, sulfur, and small amounts of carbon were detected. This carbon was almost completely removed by the argon ion bombardment and annealing sequence indicated in Table I before the dosing experiments.

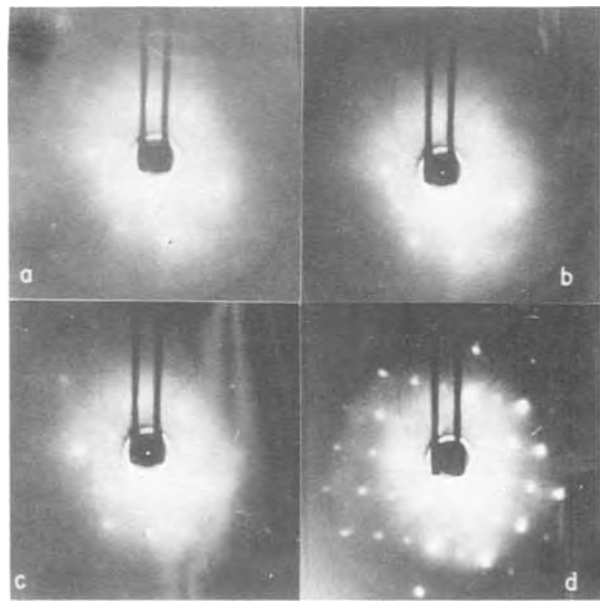

Fig. 1. Diffraction pattern of a (110) ZnS surface after cleaving in air, (a) no vacuum annealing, (b) 200°C for 10 min, (c) 500°C for 20 min, (d) 580°C for 10 min.

Numerous experimentors have founnd that a high index crystal surface will, if given sufficient energy to initiate mass transfer, reorder itself into a surface of low index steps. These stepped or terraced surfaces have been observed by LEED for copper, germanium, gallium arsenide, uranium dioxide, and platinum (6). In the present study, a ZnS crystal was cut at a low angle to the (110) and chemically polished to provide such a stepped surface. This surface did not exhibit a diffraction pattern upon its first introduction into the vacuum system, and the argon ion bombardment

and annealing steps listed in Table I were necessary to obtain a diffraction pattern and a clean Auger spectrum. The LEED pattern observed on this surface (Fig. 2) was not characteristic of any major crystal plane, and there was evidence of small scale faceting. Streaking in the pattern due to an ordered array of steps is minimal, indicating the steps in the surface were not ordered over large areas (7). Auger spectra confirmed that this surface, after the in vacuum processing, was essentially atomically clean.

Experimental Results

The high index face, after in vacuum cleaning, was subjected to oxygen dosings ranging from 1×10^{-4} Torr-sec to 20 min at 1 atm. Auger data obtained after these oxygen exposures indicated substantial changes in the carbon concentration. The relative magnitude of the carbon Auger signal increased after each oxygen exposure with no indication of saturation as illustrated by Fig. 3. The source of this carbon is attributed to the high CO partial pressure (on the order of 20%) observed in this VacIon pumped system in the presence of oxygen. In addition to the increase in the carbon signal amplitude, there was a broadening of the peak. This broadening is attributed to chemical shifts due to the distribution of bonding configurations for the carbon atoms contributing to the spectra. Subsequent annealing caused the carbon Auger peak to decrease in width, indicating that the carbon remaining on the surface was predominantly in one valence state. The relative amplitude of carbon *vs.* oxygen Auger peaks increases with gas exposure indicating that the carbon on this surface is partially dissociated from the oxygen and the oxygen partially desorbed. This was also supported by the annealing behavior since the net result of the oxygen exposure on this surface after annealing was to increase rather than decrease the relative abundance of surface carbon.

Identical experiments were conducted on the cleaved (110) ZnS surface as a control. The entire ion cleaning, oxygen exposure, and annealing sequences were repeated as in the high index surface dosing experiment. It has been demonstrated (4, 5) that surfaces of some II-VI compound semiconductors can be rendered virtually inert to chemisorption by careful processing to remove surface imperfections. The ZnS (110) surface followed this pattern in the LEED, and AES data gave little evidence for chemisorption of CO or O_2 on the cleaved surface after that surface had been cleaned and ordered by the ion bombardment and annealing sequence in Table I. An increase in the carbon Auger signal was observed. However, the changes were reversible with annealing and the slight buildup observed was found to saturate after dosings of 10^{-2} Torr-sec of oxygen. Both the slight carbon amplitude change and saturation in the Auger signal upon oxygen exposure indicates that a low density of chemisorption sites were present upon the (110) face. These sites can be attributed to imperfections left in the surface by cleaving.

The high index face was introduced into the vacuum system for CO_2 exposures, mounted on the same sample holder with the low index crystal. Concentrations of carbon found upon the surface were removed by argon bombardment and gentle annealing to produce LEED patterns similar to that of Fig. 1d. Auger spectra confirmed a clean surface. After dosings in steps from 10^{-4} Torr-sec to 45 min at 1 atm of carbon dioxide, the high index face exhibited considerably higher carbon concentration than was observed on the (110) face. The carbon peak increase was not accompanied by an increase in the oxygen peak indicating dissociation as in the oxygen dosings. As before, this additional carbon was not loosely bound to the surface since upon annealing no decrease in the carbon Auger signal was observed (Table II). These results directly contrasted those obtained from the low index face. The CO_2 that adsorbed upon the (110) surface during the dosings was found to be loosely bound and both the oxygen and carbon Auger signals virtually disappeared during subsequent gentle annealing. Little ele-

mental carbon was present since the carbon to oxygen peak ratio remained relatively constant throughout the dosings, indicating adsorption of a carbon-oxygen compound without surface dissociation.

Summary

The exposure to oxygen with a high partial pressure of carbon monoxide showed that chemisorption on the stepped surface was much faster than on the (110) surface. In addition, the stepped surface showed evidence of dissociation of the carbon monoxide which was never observed for the (110) face. Similar results were observed for carbon dioxide exposure in that a strong chemisorption and evidence of dissociation at the surface was observed for the stepped high index surface and not for the (110). This increased chemical activity can be explained in terms of active sites associated with edge states on the surface. The edges and corners present on the high index surface provide sites where the number of nearest neighbor and next nearest neighbor atoms is greater than on the clean and ordered low index surface. This results in an increase of the effective binding energy for chemisorption at certain "active sites." The correlation of the dissociation and chemisorption activity with the order of these ZnS surfaces exhibits the importance of "active site" in surface chemical reactions on II-VI compounds.

Doping Profiles by MOSFET Deep Depletion *C(V)*

D. M. Brown,* R. J. Connery, and P. V. Gray

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Deep depletion MOS $C(V)$ curves obtained by reverse biasing the junctions of MOSFET's are analyzed to produce $N(X)$ doping profiles. Analytical techniques and possible errors are discussed together with experimental results obtained from samples on bulk, ion-implanted, and epitaxial Si wafers. Experimental results are compared with spreading resistance measurements. The simplicity of the method makes it suitable for rapid impurity profile research and process control applications.

Measurements of impurity profiles utilizing reverse biased capacitance $C(V)$ measurements of diffused junction and Schottky barrier diodes have been described previously by many authors. Little use, however, has been made of MOS devices to provide doping profiles even though, as discussed by Nicollian *et al.* (1), information on the profile can be obtained closer to the surface by this method than by any other. The reasons for this, we believe, are based on a belief that the measurement techniques and required apparatus are complicated and there has been considerable concern about interface state errors in MOS doping profile determinations. Some of the techniques utilized in the past for Si profiling using MOS structures are discussed briefly below.

Because of minority carrier surface inversion, deep depletion is not easily obtainable using MOS capacitors at room temperature, and so specialized equipment and techniques have been required. Short pulses are usually used to measure the capacitance because the lifetime is usually too short to maintain the depleted state long enough to make a static measurement. Van Gelder and Nicollian (2) have used the pulsed high frequency technique to examine redistribution of impurities during thermal oxidation of Si. Slow voltage ramps can be applied to deplete the surface if the minority carrier lifetime is sufficiently long. Long lifetimes resulting in low minority carrier generation rates can be obtained by cooling the samples to 78°K and this has been utilized advantageously in the past. In fact, the analytical studies presented here indicate that accurate profile information can be obtained closer to the interface for low impurity concentrations by cooling the samples to 78°K. This has also been pointed out by Le Blanc *et al.* (3). A graphical analysis of low temperature (78°K) MOS deep depletion $C(V)$ curves was used by Brown *et al.* (4) to detect B compensation in n-type Si. This method has also been more recently used by Adda and Clemens (5). A high frequency second harmonic technique has been described as a method of obtaining profiles with minimal interface state errors (1). Also, since the second harmonic technique directly measures the slope of the $1/C^2$ *vs.* V curve used to determine N, one can use slower ramp voltages without introducing errors caused by minority carrier depletion "fill up." That is to say, only the second harmonic signal and total capacitance information are required to obtain $N(X)$. Deep depletion information at large X may still require rather long lifetimes, however, if slow voltage ramps are used. This is also true of the technique utilized by Brews where the maximum depletion width was that occurring for minority carrier inversion at thermal equilibrium (6).

Method and Purpose

MOS deep depletion caused by minority carrier removal using an adjacent reversed biased diode in MOS

* Electrochemical Society Active Member.

Key words: $N(X)$, MOS deep depletion, impurity profiles.

gate controlled diodes has been discussed by Grove and Fitzgerald (7). The purpose of this paper is to examine in detail the technique and possible errors and limitations of using deeply depleted MOS devices for impurity profiles.

This method has the advantage of the fact that static measurements can be made for a wide range of temperatures because the minority carrier depletion state is maintained as long as the depletion potential "well" produced by the reverse voltage, V_R, applied to the drain is "deeper" than that which can be produced by the gate bias. However, if the diode "well" potential, V_R, is "shallower," minority carriers will fill the gate bias well up to the bottom of the diode well. The maximum attainable depletion distance in this instance is therefore determined by the diode bias and for a uniform doping profile is given by (7)

$$X_{V_R} \cong (2\epsilon_0 K_S V_R/qN)^{1/2} \qquad [1]$$

Resultant $N(X)$ profiles for gate voltages which could produce "deeper" depletion wells than the adjacent diode well will therefore be incorrect. The surface potential produced by the MOS gate voltage on uniformly doped samples can be found from Eq. [5] below. For lightly doped samples ($N \leq 4 \times 10^{15}/cm^3$) and gate oxides about 1000Å thick the deep depletion surface potentials are only a few volts less than the applied gate voltages.

Within the limitations discussed above, and subsequently within this paper, the impurity profile $N(X)$ can be obtained by using the familiar equations (2)

$$N = 2 \Bigg/ \left(q\epsilon_0 K_s \frac{d}{dV}\left(\frac{1}{C^2}\right)\right) \qquad [2]$$

with X being obtained from

$$C_S = C_o C/(C_o - C) = \left(\frac{\epsilon_0 K_s}{X}\right) A \qquad [3]$$

$$C_o = (\epsilon_0 K_{ox}/X_{ox}) A \qquad [4]$$

where C is the measured capacitance, C_s the semiconductor space charge capacitance, C_o the oxide capacitance, X the depletion distance into the silicon, X_{ox} the oxide thickness, K_s and K_{ox} the dielectric constants of silicon and silicon dioxide, respectively, ϵ_0 the free space permittivity, and A the metal gate area. N is determined by finding ΔV and $\Delta(1/C^2)$ from the $C(V)$ data using a series of point-to-point evaluations. C_o is the measured majority carrier surface accumulation capacity. Combining C_o with the measurement of C in Eq. [3] gives X.

Errors in $N(X)$ caused by interface state densities of 1×10^{12} cm^{-2} have been examined previously (1, 6). Errors caused by interface states decrease for increasing measurement frequencies. However, for H_2 annealed samples, interface state densities are $\leq 10^{10}$/cm^2 and in these instances MOS profile measurements are valid for frequencies $\geq 10^6$ Hz.

Analytical Study

Figures 1 through 4 represent analytical studies of the $N(X)$ analysis using computer simulated $C(V)$ sample data. This was done in order to test the data processing program and to examine the validity of the system under a wide variety of circumstances; theoretical "data" were calculated using equations given in the Appendix of Ref. (8). In all cases, a model using uniform phosphorous doping was assumed.

The salient feature of all these curves is the rapid rise in apparent $N(X)$ caused by majority carrier accumulation leading to the eventual flattening of the $C(V)$ curve as C_o is approached. This basic limitation of the MOS analysis is caused by the fact that the method is sensitive only to the rate of change of C *vs.* V and as such cannot determine the sign or nature of the space charge. This limitation, called the extrinsic Debye length limit, has been previously discussed in

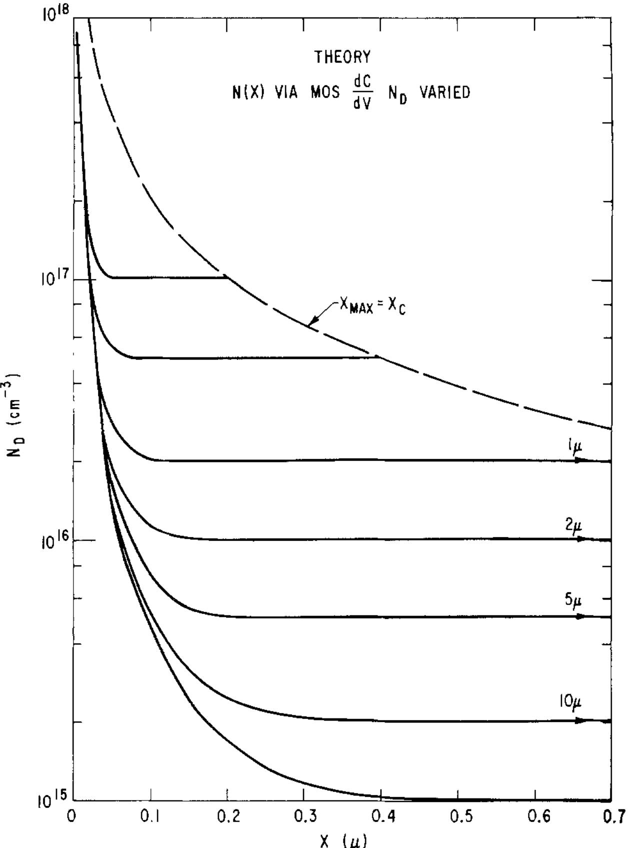

Fig. 1. Analytical $N(X)$ for uniform profiles for various donor concentrations. $X = X_c$ curve is limited by critical breakdown field $E_c = 3 \times 10^5$ V/cm.

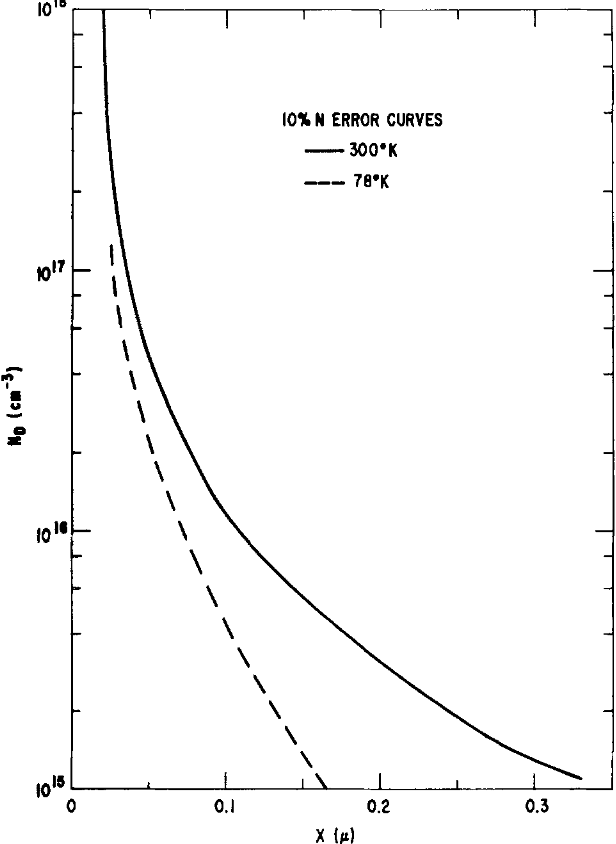

Fig. 2. 10% N error line blocking off valid analytical region to right of error line.

Ref. (1) and (3). Experimental errors caused by fixed value stray capacitances and errors in C_o are also con-

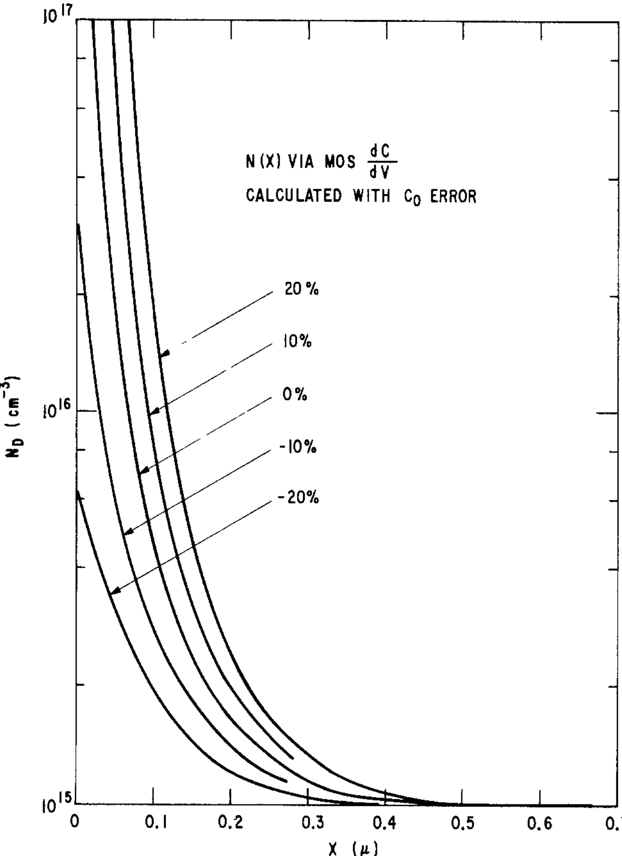

Fig. 3. *N(X)* lines showing effects of errors in oxide capacitance C_o.

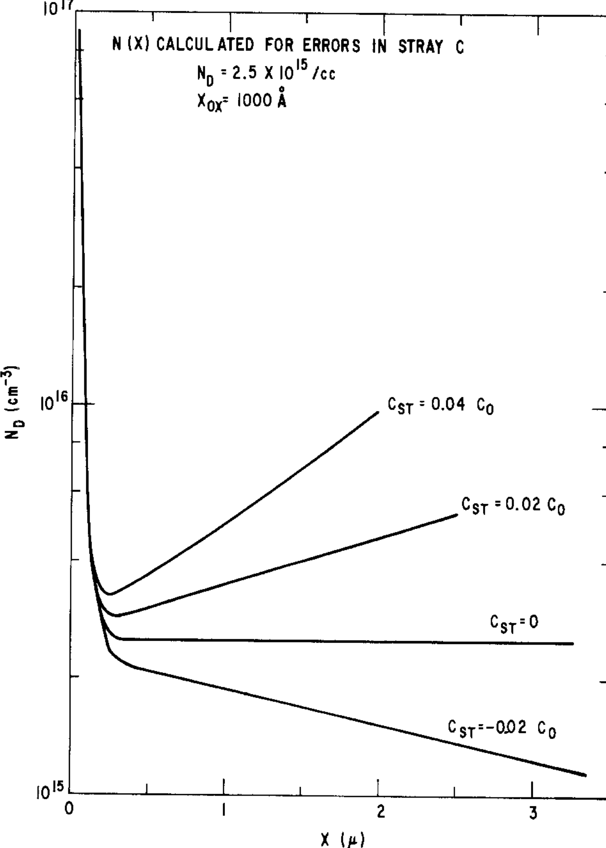

Fig. 4. *N(X)* lines showing effects of errors in estimated stray capacitance, C_{ST}.

sidered below. Stray capacitances are all fixed value capacitances in parallel with the MOS gate caused by any cable capacitances and MOS chip capacitances which are not part of the active thin oxide gate region.

The $C(V)$ equations for MOS structures on uniformly doped n-type Si from accumulation through deep depletion (no minority carrier inversion) are given by

$$V(U_S) = (kT/q)(U_S - U_B) - Q_S/C_o + \phi_{MS} \quad [5]$$

$$C_S(U_S) = \frac{q}{E_S}[A_cT^{3/2}\mathbf{F}_{1/2}(U_S - E_g) - N_D(1 + 2\exp(U_S + E_D - E_G))^{-1}] \quad [6]$$

where the surface field E_S is given by

$$E_S^2 = \frac{8\pi}{\epsilon_0 K_s} kT\left[A_cT^{3/2}\{\mathbf{F}_{3/2}(U_S - E_G) - \mathbf{F}_{3/2}(U_B - E_G)\} + N_D \ln\left|\frac{2 + \exp(E_G - E_D - U_S)}{2 + \exp(E_G - E_D - U_B)}\right|\right] \quad [7]$$

These equations have been described in detail previously (8). U_S is the surface potential in kT units. The $N(X)$ analysis on these analytical $C(V)$ curves was carried out by the computer using Eq. [2] and [3].

The limitations caused by the surface accumulation of electrons can be estimated from Fig. 1 where the results for seven different uniform densities from 10^{15} to $10^{17}/\text{cm}^3$ are given. Clearly the method is valid only for depleted surfaces and since the depletion width depends on N_D, the region of validity can be blocked off with an error curve. A 10% N_D error curve generated by picking points at approximate X values where the measured $N(X)$ would be 10% above the flat profile concentration is shown in Fig. 2. $N(X)$ data to the right of this line have an accuracy better than 10%. Figure 2 shows that accurate profile information can be obtained closer to the surface of lightly doped samples by cooling the samples to 78°K.

Errors in C_o can occur if, for instance, the gate is diode protected and C_o has to be estimated from the shape of the experimental $C(V)$ curve near $V = 0$. In this instance, C was set as $C = (C_o \pm\% \ C_o)C_S/((C_o \pm\% \ C_o) + C_S)$ and the analytical curves, Fig. 3, show that the errors in C_o have to be relatively large to produce noticeable effects for small X. Errors in C_o shift X values but do not change N because knowledge of N is independent of oxide thickness as seen in Eq. [2].

The errors introduced by unknown stray capacitances, however, are surprisingly large and have a large influence when the sample is in deep depletion and the total C is small. In this case, the error curves were calculated at a fixed donor density of $2.5 \times 10^{15}/\text{cm}^3$ assuming

$$C = \left(\frac{C_oC_S}{C_o + C_S}\right) \pm C_{ST}$$

where the positive and negative signs in front of the stray capacitance, C_{ST}, represent an over- and underestimation of the stray capacitance, respectively. Experimentally the stray must be subtracted to obtain an errorless $N(X)$ analysis as represented by the curve labeled $C_{ST} = 0$ in Fig. 4. Small percentage errors in any assumed stray can cause considerable errors in $N(X)$ profiles as indicated. The best way to check on the estimated stray is to experimentally determine $N(X)$ for bulk samples where the profile is known to be flat. Once this is done, samples with unknown profiles can be measured using the same FET device geometry.

Experimental Techniques

Test samples.—P-channel MOSFET structures with minimum size source and drain diffusions were fabricated using the p-channel Mo gate (RMOS) technique described previously (9) using phosphorous doped 4

ohm-cm bulk Si or approximately 2 ohm-cm epitaxial Si on (111) surfaces. Field oxides, 1.4μ thick, were grown in steam, and gate oxides, 1000Å thick, were grown in dry oxygen. The processing sequence will not be described in detail. H_2 annealing using 10% H_2 in N_2 for 1 hr at 500°C was carried out near the end of the process to reduce the fast interface state density to $<10^{10}/cm^2$. Ti-Au was evaporated on the backside of the wafers to ensure a low resistance contact. Arsenic ion implants at dose levels of approximately $1 \times 10^{12}/cm^2$ using implant energies of 300 keV were included in some samples at a processing stage between gate oxidation and Mo gate deposition. Ion implanted Al gate MOSFET's with large area diffused source and drain junctions have also been successfully studied.

All the planar junctions of the devices studied here were about 1μ deep with resultant reverse breakdowns of about −30V.

The junctions of the MOSFET device were connected to a large negative voltage (approximately −30V) and gate capacitance data *vs.* gate voltage were obtained by applying a slow ramp voltage to the gate in conjunction with the a-c measurement frequency. This arrangement transforms the MOSFET into a surface depletion MOS gate controlled diode structure and the $C(V)$ curves are accordingly those of a deep depletion MOS structure.

Method I ($f = 1$ *MHz*).—$C(V)$ data were obtained using a Boonton Electronics Model 71A capacitance meter which operates at a frequency of 1 MHz. These data were logged using two digital voltmeters connected to an online data logging computer terminal. $N(X)$ was obtained using the dC^{-2}/dV equations and plotted on site using an X-Y recorder and digital point plotter. The experimental data were obtained using a simple probe station, and all equipmental stray capacitance was balanced out with the gate probe lifted. Any stray capacitance was, therefore, limited to that present in the chip caused by landing pads and Al runs over thick (approximately 1.4μ) field oxide.

All the results shown in Fig. 5-8 were obtained in this manner.

Method II ($f > 1$ *MHz*).—In order to verify the assumption that any small residual number of fast interface states in properly annealed samples does not introduce errors for a 1 MHz measurement frequency, a digital capacitance bridge capable of utilizing measurement frequencies $\geqq 1$ MHz was constructed. Because of the higher frequencies, the profiling was done utilizing packaged devices in order to eliminate lead inductance and ground loop effects. Careful measurements of stray capacitances contributed by the package, instrument probes, and test jig were carried out using empty packages. This stray capacitance was subtracted from each capacitance measurement through the use of an appropriate computer program which subsequently reduced the corrected $C(V)$ data to $N(X)$ data. Measurements at 1 and 10 MHz produced identical $N(X)$ profiles. Residual numbers of fast interface states are therefore deemed to be insignificant for 1 MHz profile measurements of properly annealed samples.

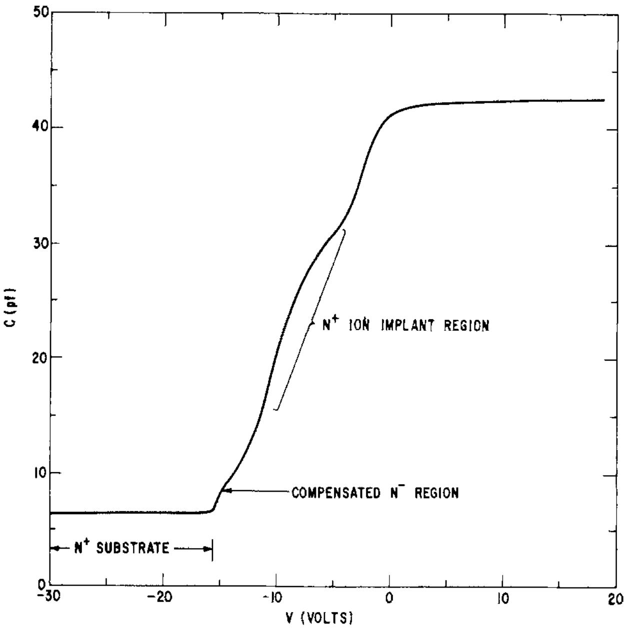

Fig. 5. Illustrative deep depletion $C(V)$ curve

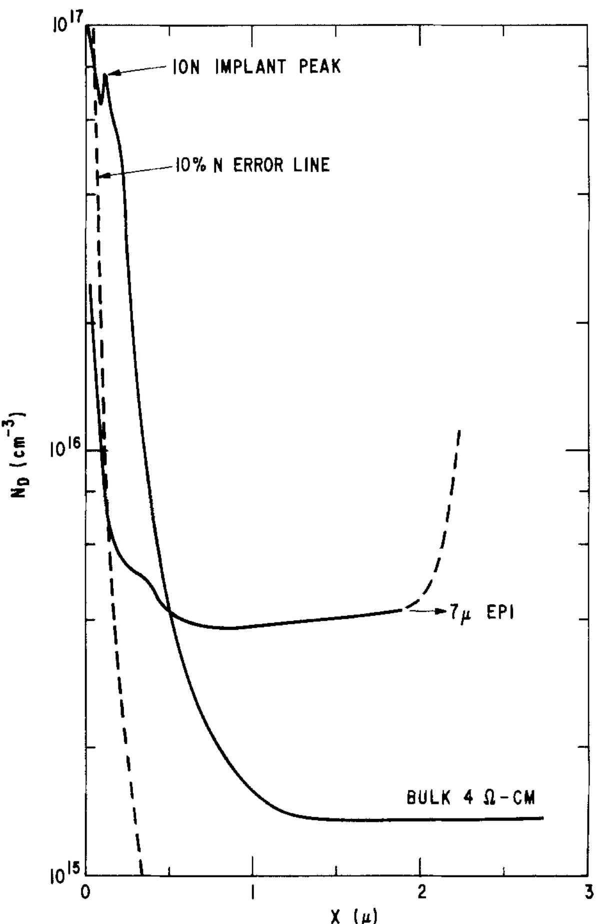

Fig. 6. $N(X)$ for bulk 4 ohm-cm ion implanted sample and $N(X)$ for lower resistivity epitaxial sample with ion implant. The sudden upward swing in the curve at large X is an indication of incomplete minority carrier removal occurring whenever the diode reverse bias is too small.

Device geometry.—Except for the expected parasitic effects discussed previously, device geometry did not appear to be a major factor. These effects were especially severe for the small Al gate FET's ($A = 6 \times 10^{-4}$ cm²) which therefore required a stray capacitance subtraction as discussed in Method II above. Ideally the areas should be large ($A > 10^{-3}$ cm²) and the junction gate overlap small. This was true of the self-aligned Mo gate structures ($A = 1.2 \times 10^{-3}$ cm²) whose diffused junction regions were furthermore limited to a very small fraction of the gate's periphery.

Experimental Results

Some illustrative features of a specific ion implanted device constructed on a thin (approximately 2μ) epitaxial layer are illustrated in Fig. 5. Several features are significantly different from the usual exponentially shaped depletion curve: the ion implant region is observed as a rather large bulge at moderate voltages and the presence of the N^+ substrate is observed at

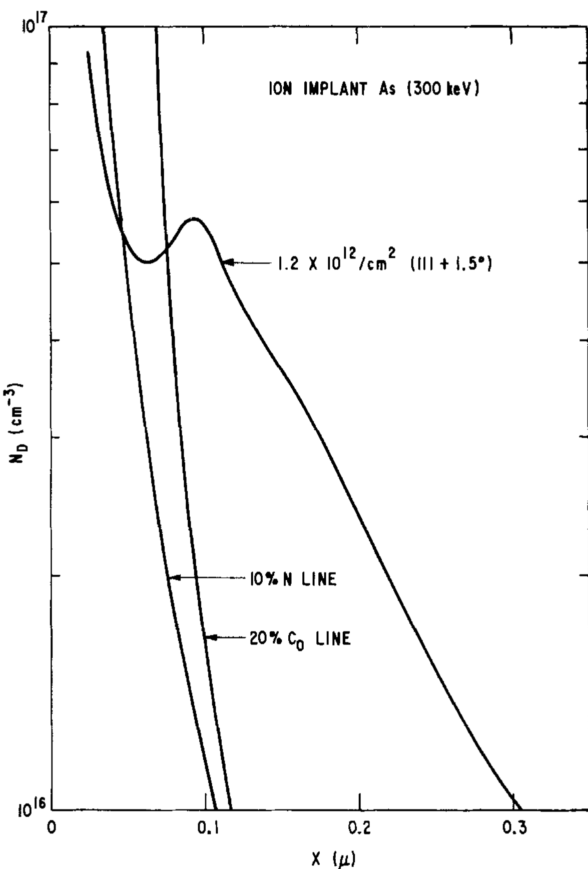

Fig. 7. As ion implant profile detail showing As ion implant peak and long tail.

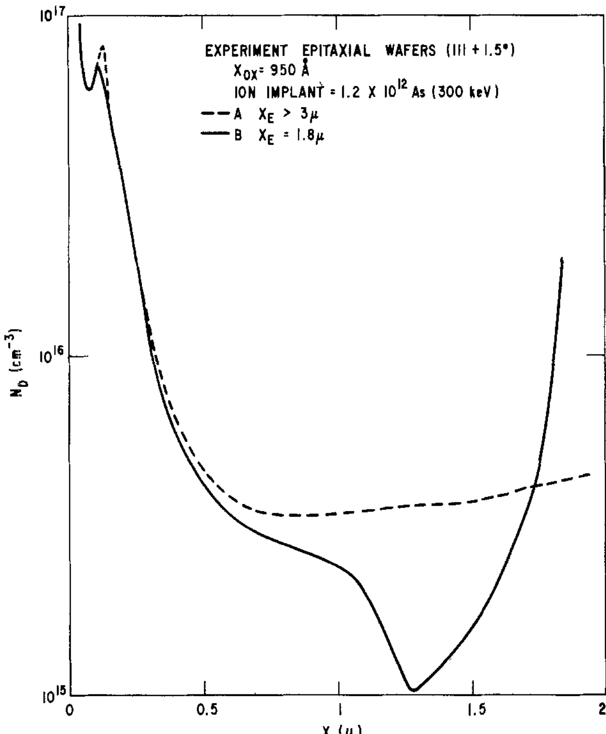

Fig. 8. $N(X)$ profiles for epitaxial layer samples. Profile B is for a complex sample whose $C(V)$ curve is given in Fig. 5. Profile shows ion implant peak, spurious high resistivity region at substrate interface, and epitaxial layer thickness. X_E means epitaxial layer thickness.

the highest voltages by the region where capacitance is independent of voltage. This particular sample contained a high resistivity region at the interface between the epitaxial layer and the N^+ substrate.

As indicated previously, the stray capacitance for the masks must be estimated with considerable accuracy and should be checked using samples where the profile and resistivity are known to be flat. A $N_D(X)$ profile of a 4 ohm-cm bulk sample is shown in Fig. 6. The measured donor concentration of $1.35 \times 10^{15}/\text{cm}^3$ for $1.5 \leq x \leq 3\mu$ is within 10% of the bulk carrier concentration obtained from four-point probe measurements. The fact that this sample received a shallow As ion implant is unimportant for the calibration check of stray capacitance errors since these errors are maximum at large depletion distances.

The data for the lower resistivity epitaxial sample in Fig. 6 indicate an important feature of this profiling technique. As discussed earlier, data taken when the surface field produced by the gate voltage approaches and exceeds that produced by the diode bias give anomalous results because the surface is not then completely depleted. This feature is observed in a flattening out of the $C(V)$ curve at high gate voltages which produces the apparent rapid increase in $N(X)$. In some cases like this it was found that the maximum depth of accurate profiling was limited by the reverse breakdown voltage of the diode rather than by the critical field condition shown in Fig. 1. Nevertheless, this sample shows the phosphorous surface pileup produced by the field and gate oxidation sequences as indicated by the data for $x \leq 0.5\mu$.

Figure 7 shows a more detailed As ion implant profile on a slightly off axis (111) surface. The concentration peak correlates well with the curves given by Gibbons (10) for an implant energy of 300 keV. The long As tail or shoulder is also apparent and has been described by others using the incremental sheet resistance technique or neutron activation analysis (11). The simplicity of our technique makes possible rapid analysis of such effects and provides useful information even though accurate analysis for very small X is limited by the N error line. It is also interesting to note that the As dose shown here is one order of magnitude less than the lowest dose in Ref. (11).

Figures 8 and 9 correlate the information obtained from our profiling technique and spreading resistance profiles of the same samples.[1] The electrical measurements on sample A indicate a nearly flat profile beyond the ion implant tail to a depth $> 2\mu$ as verified by spreading resistance profiling. Sample B whose $C(V)$ curve is shown in Fig. 5 indicates an anomalous dip in donor concentration between 0.5 and 1.5μ. This was verified by the spreading resistance profile of this sample as shown in Fig. 9. It is interesting to note that before processing, the spreading resistance data on both these epitaxial layers indicated a flat profile. The anomalous dip for sample B was caused by boron acceptor level compensation produced by an outdiffusion of boron from the 0.01 ohm-cm Sb doped substrate during high temperature processing. Higher than normal B concentrations in these substrates were verified by the substrate crystal vendor. This identical B compensation phenomenon in n-type epitaxial layers grown on n-type substrates has been studied analytically by Langer and Goldstein (12). The information presented in Fig. 8 and 9 appears to represent the first published experimental observation of this effect.

Sample A of Fig. 8 shows a slight upward tilt of a supposedly flat profile. As indicated in Fig. 4 this usually is an indication of unaccounted for stray capacitances which adversely affect the shape of the curve for large depletion distances, because the depletion capacitances are becoming increasingly small for these samples. Larger samples or slight adjustments in the stray estimates using Method II are required for high accuracy in this region. This was carried out as shown in Fig. 10 and was compared with the spreading resistance profile data of this wafer. The spreading re-

[1] All spreading resistance profiles were obtained using the Automatic Spreading Resistance Probe Model ASR-100 manufactured by Solid State Measurements Incorporated.

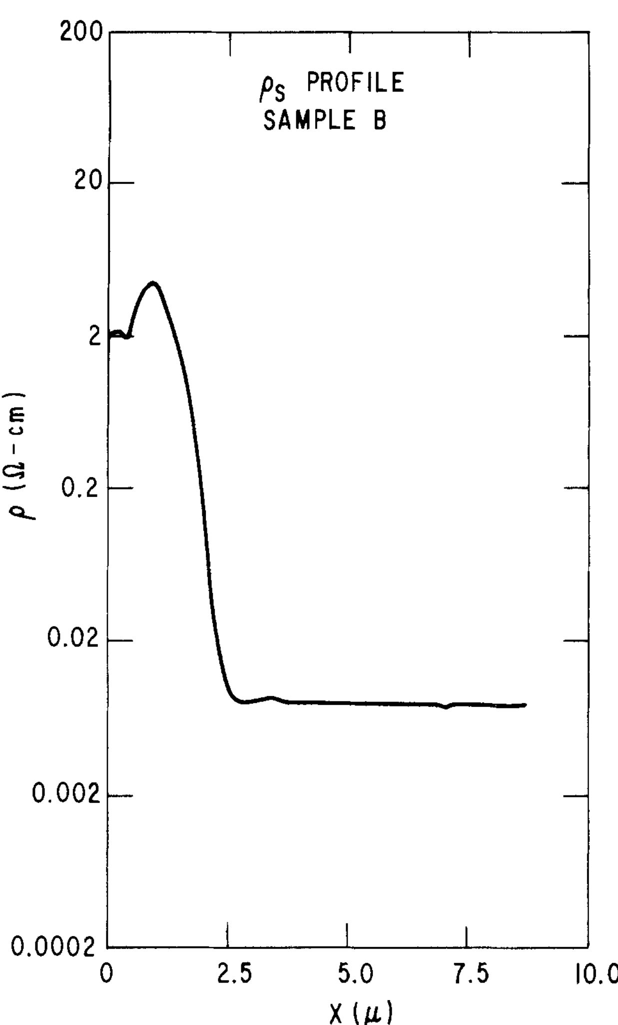

Fig. 9. Spreading resistance profile of sample verifying $N(X)$ results in Fig. 8 on sample B.

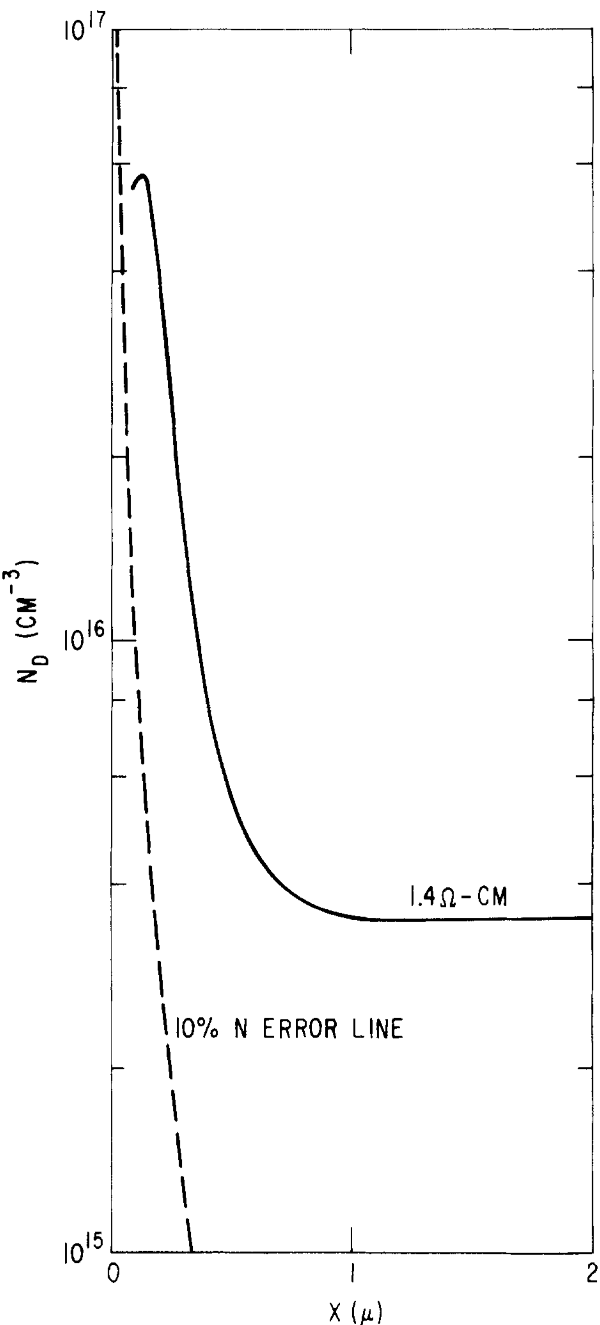

Fig. 10. Profile of sample using Method II in which small corrections for unknown stray were carried out.

sistance data indicated a uniform epitaxial base concentration of $\leq 2.5 \times 10^{15}/cm^3$ ($\rho \geq 2$ ohm-cm) whereas the $N(X)$ profile in Fig. 10 indicates a base concentration of $3.5 \times 10^{15}/cm^3$ corresponding to a resistivity of 1.4 ohm-cm. The calibration of the automatic spreading resistance probe was subsequently found to be in error (13).

Discussion and Summary

An impurity profiling technique using minority carrier depleted MOS samples has been examined analytically and experimentally.

Minority carrier removal was accomplished by reverse biasing adjacent junction diodes. The resultant deep depletion $C(V)$ curves are easily analyzed to give $N(X)$. One advantage of the method is that simple $C(V)$ equipment employing slow voltage ramps can be used, since the deeply depleted state is maintained as long as the diode potential is larger than the surface potential produced by the MOS gate bias. This feature makes static measurements of the semiconductor space charge capacitance possible over a wide range of temperatures, since sample lifetime and minority carrier generation rates are unimportant.

Furthermore, it has been shown, as expected, that fast interface state errors are unimportant at measurement frequencies of 1-10 MHz in properly annealed samples, because no dispersive effects were observed over this range of frequencies.

The extrinsic Debye length limitation caused by majority carrier accumulation is shown by error plots as a function of concentration and temperature giving the minimum depth at which the technique is accurate. Profiling errors caused by stray capacitance effects and errors in the MOS oxide capacitance have been detailed.

Experimental profiles obtained on different types of samples with ion implanted surfaces and using bulk and epitaxial wafers on compensated substrates have been presented showing the easy usefulness of the technique. The limitation in maximum depth caused by an insufficiently large drain bias, which results in minority carrier inversion at large gate voltages, has been pointed out. Some of the experimental results have been critically compared with spreading resistance profile measurements. The spreading resistance measurement is well suited to deeper profiles at even heavier impurity concentrations, whereas the major strength of this MOS profiling technique is its ability to measure profiles at shallower depths. The two methods, therefore, are good complements to one another especially when they have overlapping ranges of validity.

It is obvious that the MOS profiling technique presented here can be widely used for the study of diffusion phenomena, epitaxial layers, and ion implant pro-

files. Furthermore, it is a useful method to use for the measurement and control of the impurity profiles called for by certain types of MOS charge transfer devices.

Electron-Beam Evaporated Al_2O_3 on Si

Philip C. Munro[1] and H. W. Thompson, Jr.

Purdue University, West Lafayette, Indiana 47907

ABSTRACT

Al_2O_3 is electron-beam evaporated onto n- and p-type silicon in an ion-pumped, high-vacuum environment. Fabrication parameters of substrate temperature, evaporation rate, and O_2 partial pressure are varied for optimization. The deposited films are annealed in several gas/temperature environment combinations for varying times. The resulting MOS structures are evaluated and an optimum process schedule is obtained. The deposited Al_2O_3 films have a relative dielectric constant of 8.0, a refractive index of 1.61, and breakdown field strengths exceeding 3×10^6 V/cm. Deposition rates of 100-500 Å/min onto substrates at 100°-200°C in an O_2 ambient of 2×10^{-5} Torr, followed by a 5-20 min anneal in N_2 at 550°C yield optimum insulator/interface characteristics. MOS devices so fabricated have surface-state densities in low 10^{11} states/cm^2-eV range, hysteresis in the C-V characteristic of 0.1-0.2V, and flatband voltages in the range of ±1V.

Thin films of Al_2O_3 are being investigated for use with Si and other semiconductors in device and surface passivation applications. When compared to SiO_2, Al_2O_3 has several advantages: (*i*) it has a higher density and therefore gives better hermetic sealing; (*ii*) it has shown superior radiation resistance (1, 2); (*iii*) its dielectric constant is twice that of SiO_2; (*iv*) it has shown better resistance to ion motion; and (*v*) p-type semiconductor surfaces (positive flatband voltage) have been obtained.

Films of Al_2O_3 have been deposited by pyrolysis (3, 4), plasma anodization (2, 5), RF sputtering (6, 7), and reactive sputtering (8, 9). Although several reports of vacuum-evaporated Al_2O_3 on Si have been published (10-14), no attempt to optimize the evaporation process or postdeposition anneals has been reported. It has been suggested that an added O_2 ambient during evaporation of Al_2O_3 improves the stoichiometry of the resulting films (13). This work provides data from Al-Al_2O_3-Si samples fabricated by E-beam evaporation of Al_2O_3 in an O_2 ambient onto Si substrates from which such an optimization can be made. High frequency capacitance-voltage (CV) and quasistatic current-voltage (IV) data are used to obtain insulator and insulator-semiconductor interface electrical characteristics including surface-state density, N_{ss}, flatband voltage, V_{FB}, and hysteresis.

[1] Present address: Youngstown State University, Youngstown, Ohio 44500.

Key words: Al_2O_3, E-beam, MOS devices, oxide anneal, vacuum evaporation.

Sample Fabrication

Substrate preparation.—Ten to fifteen ohm-centimeters (111) p- and n-type Si were used. Substrates were ultrasonically rinsed in trichloroethylene, acetone, methyl alcohol, and DI water. After cleaning in hot sulfuric and nitric acids, they were rinsed in dilute hydrofluoric acid. [Further details of sample fabrication and testing are given elsewhere (16).]

Square chips, 200 mils on a side, were coated for evaporation process optimization; whole wafers were coated for anneal optimization.

Al_2O_3 deposition.—The 99.998% pure Al_2O_3 tablets used for vacuum evaporation were obtained from Electronic Space Products, Incorporated. They were 10 mm in diameter and 7 mm thick and were contained in a water-cooled copper hearth during evaporation. Electron-beam spot sizes of about 5 mm were used during evaporations. O_2 was injected into the vacuum system at the base of a 5½ in. high by 2¾ in. diameter stainless steel chimney which was used to confine the evap-

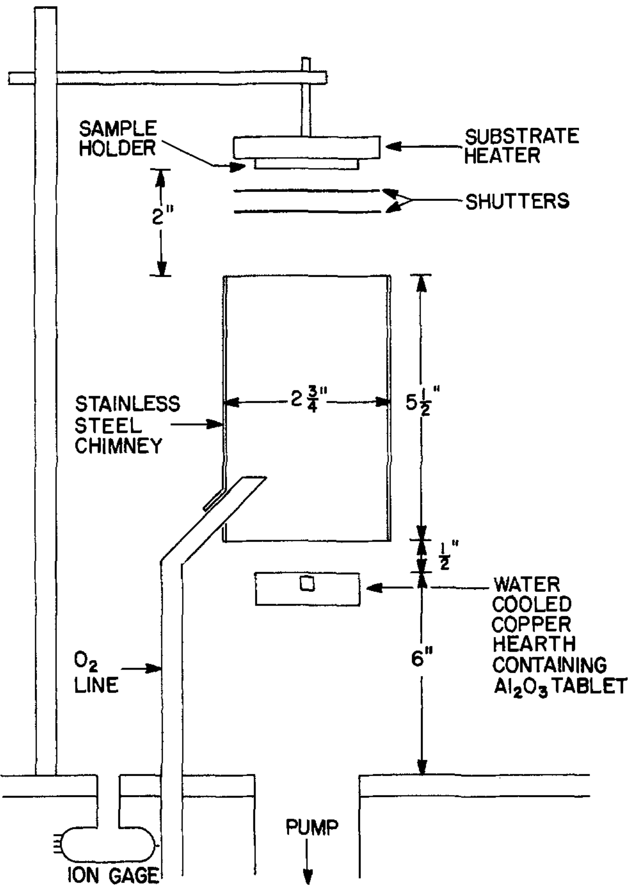

Fig. 1. Schematic layout of evaporation system

orant. System pressure was monitored at the base plate using an ion gauge. Figure 1 gives a diagram of the system showing relative placement of the substrate and the ion gauge.

The evaporations were carried out in a vac-ion system which included titanium sublimation onto a liquid-nitrogen cooled surface. Roughing was accomplished with an oil-free mechanical pump followed by sorption pumping. A 90° deflection electron gun was used to heat and evaporate the Al_2O_3. An automatic pressure controller, driven by the ion gauge unit, controlled the O_2 leak into the system. The source of O_2 was J. T. Baker Zero-Gas oxygen with a stated hydrocarbon content of less than 0.5 ppm. No attempt was made to dry or otherwise further purify the O_2 gas.

The parameters which may affect the nature of the deposited Al_2O_3 films are substrate temperature, source-to-substrate distance, deposition rate, E-beam accelerating voltage, and system pressure. Two of these parameters were fixed while the other three were purposely varied.

The E-beam accelerating voltage was held essentially constant near 5.5 kV except for minor changes needed to obtain the required E-gun power variation. Source-to-substrate distance was set at 8 in. At this distance, deposition rates as low as 100-150 Å/min were possible.

The three deposition parameters varied were (*i*) system pressure, which was varied upward from the attainable base pressure to a maximum of 2×10^{-5} Torr with the controlled O_2 leak; (*ii*) substrate temperature, which was varied upward from room temperature with a resistive heater; and (*iii*) deposition rate, which was varied by changing the E-beam power.

The optimum deposition parameters were used to obtain Al_2O_3-coated wafers for the study of postdeposition anneals. The significant anneal parameters are temperature, time, and ambient gas. Temperatures up to 800°C, times up to several hours, and N_2, O_2, and H_2 ambient gases were tested.

For the evaporation process study four pairs of n- and p-type Si chips were prepared simultaneously and then coated during a single vacuum system cycle. Each pair was coated separately by appropriately positioning two shutters.

For the anneal study, single wafers were coated and then scribed and broken into individual chips which were given different anneals.

Postdeposition processing.—Ohmic contacts consisted of plated electroless Ni for the n-type Si chips and evaporated Al for the p-type Si chips. The chips used for the evaporation optimization study were annealed for 5 min at 580°C in N_2. This anneal also produced the Al-Si alloy necessary for the p-type Si ohmic contacts. After annealing, circular aluminum gate electrodes about 7 mils in diameter were evaporated through Cu-Be dot masks onto the Al_2O_3 film in a small diffusion pumped vacuum system. The samples were not annealed after the gate electrode deposition.

CV Measurements for Process Optimizations

The numerous high-frequency CV measurements required to evaluate the results were obtained with a semiautomatic measurement system which included a Boonton 71A Capacitance Meter, a triangular-wave generator (15), and an XY recorder. Where greater accuracy was required for detailed surface-state analyses, or where higher signal frequencies were desired, point-by-point measurements were obtained with a Boonton 33A Admittance Bridge. Semiautomatic sweep-voltage amplitudes were 8-10V peak-to-peak and the CV curves were recorded beginning at accumulation bias with typical sweep rates of 100-200 mV/sec. Three or more different gate electrodes were probed on each chip. A typical CV curve is shown in Fig. 2.

CV slope was measured graphically at flatband capacitance and was normalized with respect to accumulation capacitance (approximately equal to C_i). This normalization removed the effects of differences in electrode areas and small differences in insulator thicknesses. The normalized slope is expressed algebraically as $1/C_i \cdot dC_g/dV_g$. If one writes $C = C_g/C_i$ then the relation between CV slope and surface-state density in states/cm²-eV at flatband bias can be seen to be (17)

$$N_{ss} = \frac{C_i}{Aq} \left(\frac{q}{3kT} \frac{(1-C)C}{\partial C/\partial V_g} - \frac{1}{1-C} \right) \Bigg|_{C_g = C_{FB}}$$

V_{FB} is the gate voltage at flatband capacitance and was measured on the more negative leg of a complete

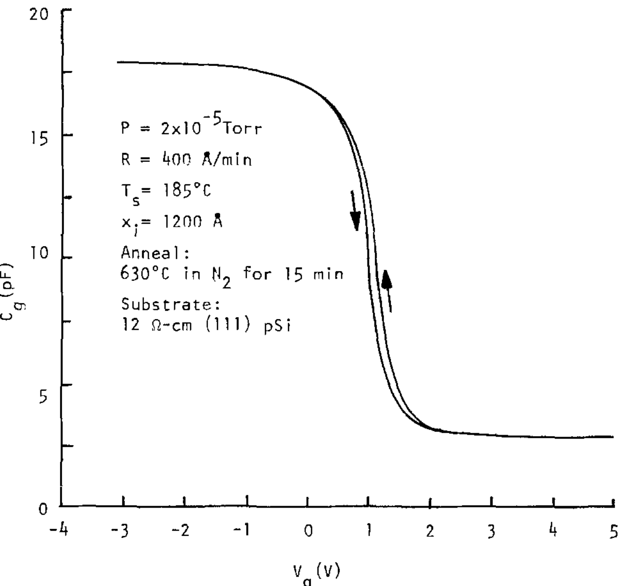

Fig. 2. A typical 1 MHz CV curve obtained with the semiautomatic measurement system.

CV curve for both n- and p-type Si samples. The ideal values of $V_{FB} = \frac{1}{q} \phi_{ms}$ are $-0.05V$ for the n-type Si and $-0.65V$ for the p-type Si samples. These values are calculated using an electron affinity of 4.0 eV for Si, work function of 4.2 eV for Al, and the appropriate fermi level positions for the Si used.

Hysteresis is the voltage difference between the two legs of a complete CV curve and was measured at flatband capacitance.

Insulator Characteristics

The appearance of the deposited Al_2O_3 films was clear and of a color appropriate to the film thickness and refractive index. Only very slight nonuniformities in color were ever detected across a sample surface, and then only on large wafers with films of at least 3000Å thickness.

No cracking or peeling occurred on any of the samples fabricated, even for film thicknesses to 6000Å. The Al_2O_3 films showed no tendency to flake or peel away from the Si either before or after postdeposition anneals. Coated wafers of Si could be scribed on the coated surface with a diamond scribe and then broken into chips with no damage to the Al_2O_3 layer away from the scribe line. It was also observed that individual MIS capacitors which were destroyed by exceeding their breakdown field strengths had only local damage and no propagation of insulator damage away from the particular capacitor in question. Insulator breakdown field strength exceeded 3×10^6 V/cm.

Several Si samples with 3000Å depositions of Al_2O_3 were evaluated by ellipsometry (courtesy of Delco Electronics). From these measurements, the refractive index of the evaporated Al_2O_3 was found to be 1.61. Si samples with 3000Å films of Al_2O_3 were also used to obtain approximate values of the relative dielectric constant, k_i. Values of $k_i \approx 8.0$ were obtained. Similar values were obtained on several samples, some with no postdeposition anneals and others with a 15 min, 560°C anneal in N_2. A somewhat higher value of $k_i \approx 8.5$ was obtained on another sample which had an additional anneal at 800°C in N_2. These results for k_i parallel a similar and more detailed study of refractive index made by Woulbourn (18) on evaporated Al_2O_3.

Results

Deposition parameter variations.—The results of bell jar pressure variations are presented in Fig. 3. For these samples, the directions of hystereses were consistent with an Al_2O_3-Si interface trapping mechanism. The hysteresis was clockwise for n-type Si chips and counterclockwise for p-type Si chips. In addition to the data of Fig. 3, it was also noted that flatband voltage, V_{FB}, and CV hysteresis were more dependent on sweep voltage amplitude and rate for samples fabricated at the lower O_2 partial pressures. In fact, for Al_2O_3 deposited with zero O_2 leak, the hysteresis was about equal to the peak-to-peak sweep voltage, and the CV curves were very distorted. The dependence of V_{FB} and hysteresis on sweep rate and amplitude decreased considerably as the O_2 partial pressure during Al_2O_3 deposition increased.

Though results obtained at one value of a variable, such as O_2 pressure, generally differed from the results at another value of that variable, data for the best samples, fabricated under optimum conditions, were remarkably consistent. In almost all cases, C-V data from sample-to-sample within a group varied by less than 0.1V. Similarly, on samples fabricated using the optimum procedures hysteresis and flatband voltage show virtually no dependence on sweep voltage magnitude or rate.

Figure 4 presents deposition rate data. The directions of hystereses were again consistent with charge trapping at the Al_2O_3-Si interface.

Figure 5 presents substrate temperature data. It was noted that Al_2O_3 deposited on 25°C chips showed more leakage and lower breakdown field strengths than those deposited at 100°C and higher. Except for the p-type Si chip coated at 25°C, directions of hystereses were consistent with charge trapping at the Al_2O_3-Si interface.

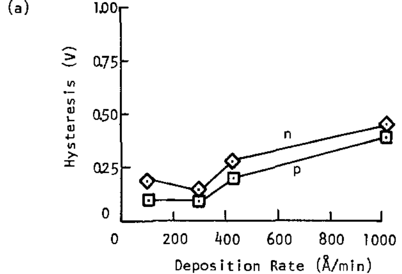

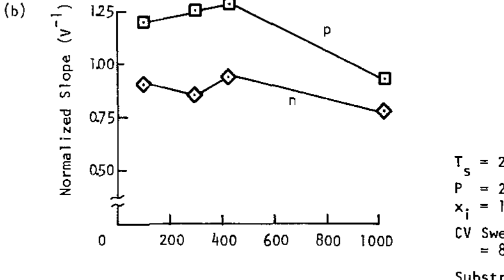

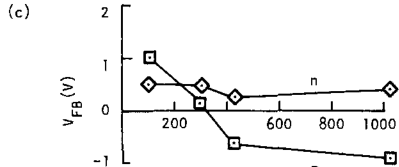

Fig. 4. CV results vs. the deposition rate during Al_2O_3 deposition on n- and p-type Si.

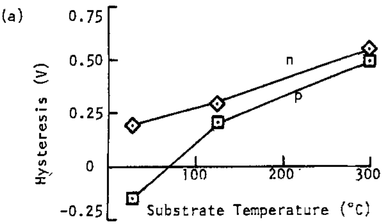

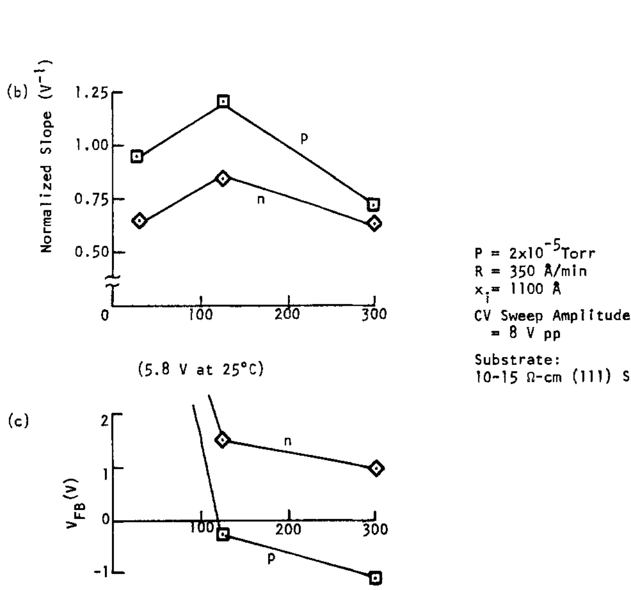

Fig. 5. CV results vs. the substrate temperature during Al_2O_3 deposition on n- and p-type Si.

Postdeposition anneal variations.—Different postdeposition anneals were tested on chips obtained from an Al_2O_3-coated wafer. Several control chips were given no anneal whatever in order to establish the zero-time point in the anneal data. Most of the chips were annealed in N_2 for different times and at temperatures which are shown on the graphs of the resulting data (Fig. 6-8). They were processed in groups of four chips each. The chips within a given group were annealed at the same temperature but for different lengths of time.

Two chips were annealed in H_2, and two in O_2, at 550°C, and the results of those anneals are also shown in the figures. Each H_2 anneal time includes 30 sec N_2 flushes at the beginning and end of the anneal.

Surface-state density.—Figure 9 shows surface-state density, N_{ss}, *vs.* energy measured from the center of the semiconductor bandgap for the sample whose semiautomatic 1 MHz CV curve is shown in Fig. 2. N_{ss}, as shown, was obtained from quasistatic IV measurements (19). An analysis of point-by-point high frequency CV measurements gave very similar results and is not shown here.

Discussion

The most favorable deposition and anneal parameters are chosen primarily to obtain minimum hysteresis, maximum normalized slope, and small or process controllable flatband voltage. In addition, deposition system constraints are considered, and observations of insulator leakage and breakdown influence the choice in some cases.

CV hysteresis is not always reported or denied in the literature, but it is a common occurrence where an insulating film is deposited, in contrast to those which are thermally grown (20). The mechanism of charge trapping and its relation to CV hysteresis has been discussed in the literature (21) and in particular for Al_2O_3 on Si (22, 23). Since the magnitude of hysteresis is an indication of trap density in the insulator (and of charge transport into and out of those traps), minimum hysteresis would be expected to coincide with the most favorable MIS conditions. It was also observed experimentally that smaller hysteresis coincided with a more stable surface potential to gate voltage relationship as the maximum sweep voltage magnitude was varied.

Deposition parameters.—Figure 3 shows the results of using different O_2 partial pressures during Al_2O_3 deposition. From these graphs and other similar experiments (24), it is evident that the higher values of bell jar pressure obtained with the controlled O_2 leak produce the most favorable CV results. Both hysteresis and slope have their best values at the highest bell jar pressure of 2×10^{-5} Torr, and the values of $|V_{FB}|$ are less than 1V at that pressure. Bell jar pressure was limited to 2×10^{-5} Torr due to increased difficulties when using an E-gun and a vac-ion system at much higher pressures. It should also be noted that the results in Fig. 3, and of previous experiments (24), show a similarity at the two higher pressures of 1 and 2×10^{-5} Torr, and therefore the improvement appears to saturate.

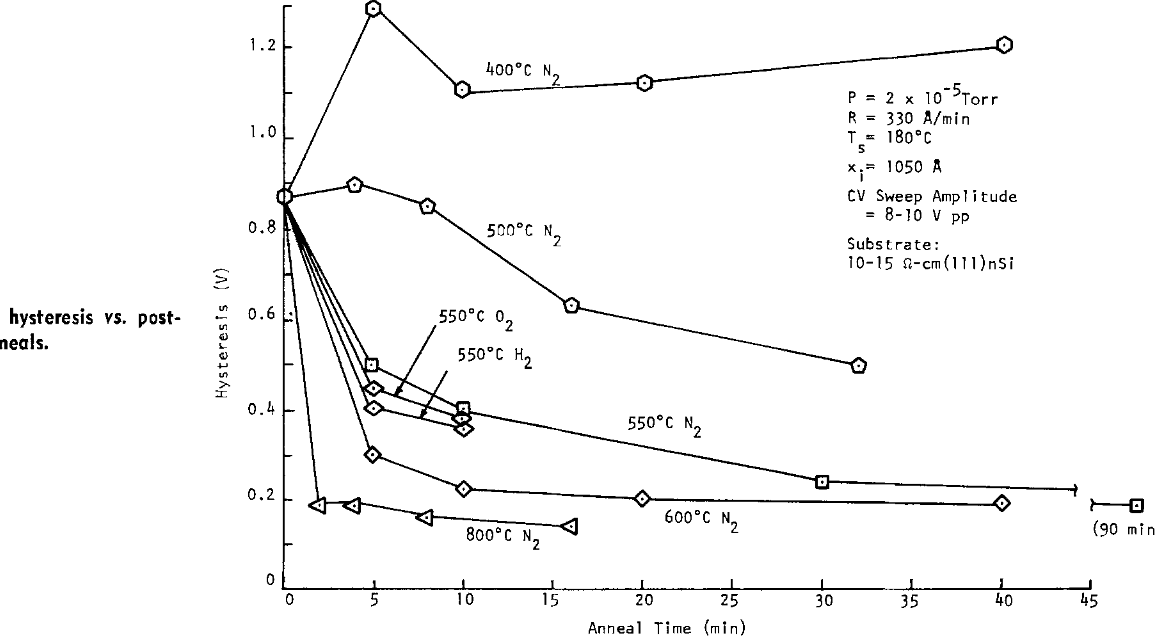

Fig. 6. CV hysteresis vs. postdeposition anneals.

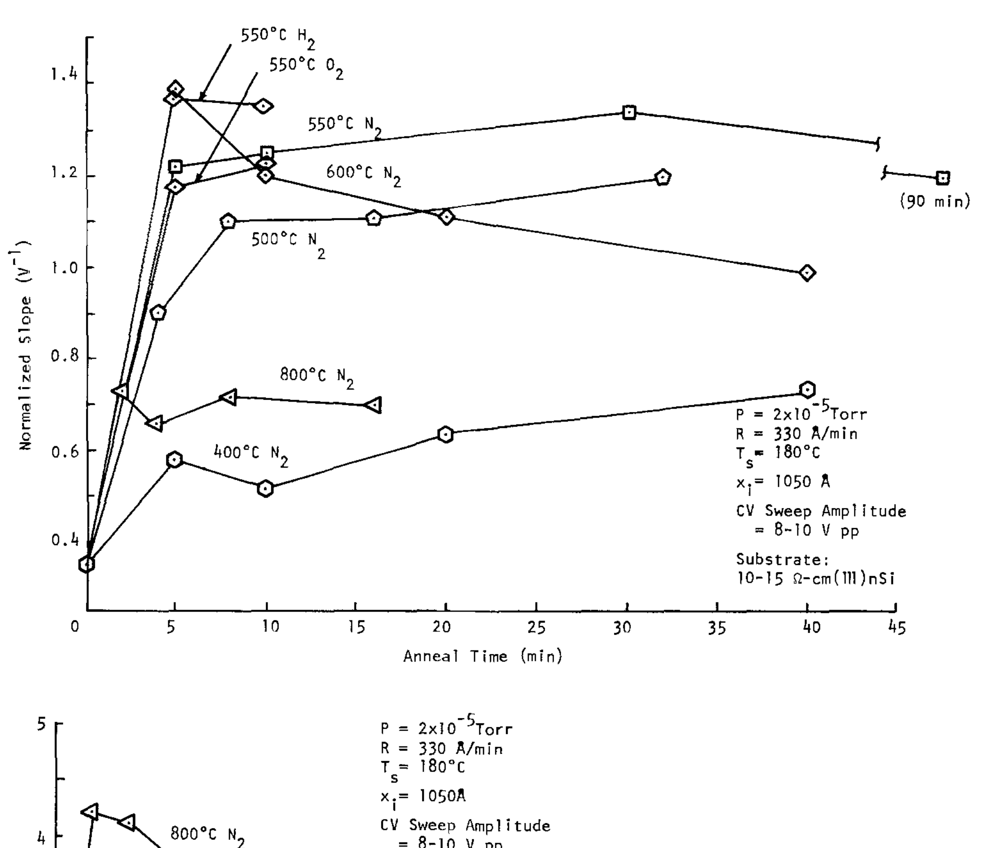

Fig. 7. CV normalized slope vs. postdeposition anneals.

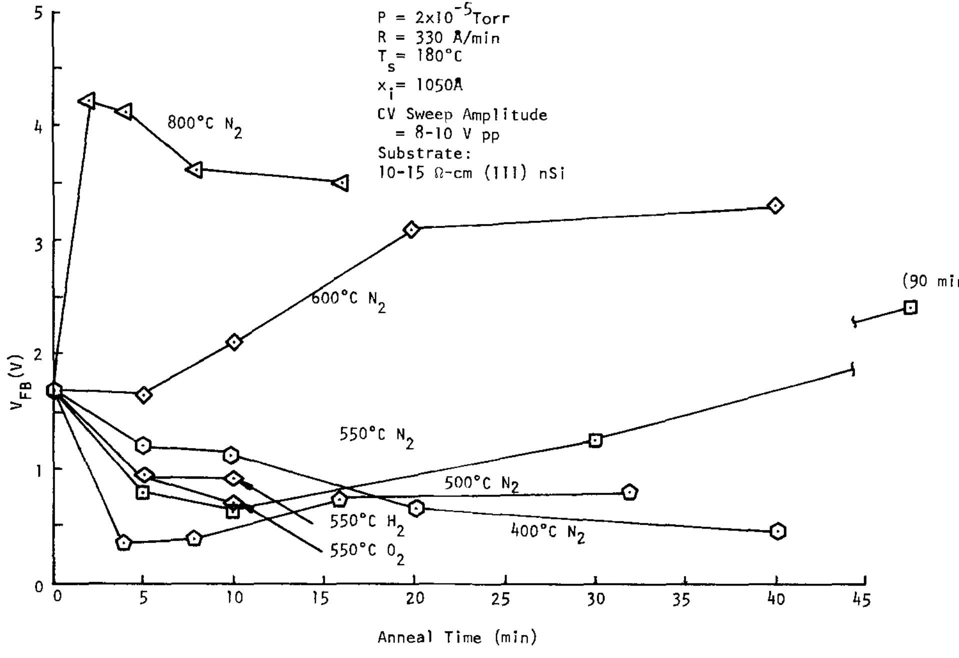

Fig. 8. CV flatband voltage vs. postdeposition anneals.

Figure 4 shows the results for different deposition rates and indicates that lower deposition rates give better results. Hysteresis of 0.1-0.2V is attainable and, more importantly, is smallest at the lower deposition rates. Normalized slope is also at its preferred higher values at the lower rates. $|V_{FB}|$ is less than 1V at all of the deposition rates tested. Deposition rate is constrained at its lower values by the total time required to obtain a given film thickness. Because of this and the favorable results obtained at both of the two lowest rates tested, it is concluded that the preferred deposition rate is in the range of 300 ± 200 Å/min.

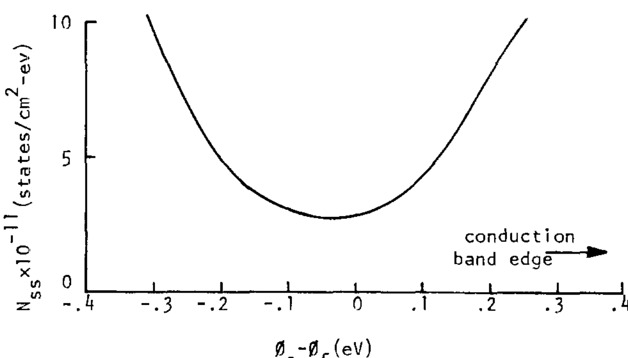

Fig. 9. Surface-state density vs. semiconductor bandgap energy measured from the center of the bandgap for the same sample whose 1 MHz CV curve is shown in Fig. 2.

Figure 5 gives results for different substrate temperatures. The increased leakage and much lower breakdown field strengths noted at 25°C may explain the "reverse" hysteresis obtained on the p-type Si chip. Such a reverse hysteresis could be due to charge injection from the metal gate, insulator polarization, or charge motion in the insulator. It is concluded that a substrate temperature in the range of 100°-200°C gives the best over-all results. CV slope is high, hysteresis low, and $|V_{FB}|$ is also low in that temperature range.

Summarizing these conclusions, the most favorable results with evaporated Al_2O_3 on Si are obtained by using an O_2 leak to hold the bell jar pressure near 2 ×

10^{-5} Torr, a deposition rate of about 300 Å/min, and a substrate temperature near 150°C.

In addition to the conclusions drawn from each of the three Fig. 3-5, comparisons can also be made among the figures. These comparisons bring together the results of samples which did not have common predeposition, deposition, or postdeposition processings, in contrast to a set of samples whose results are given within each of the three figures. This comparison reveals excellent consistency in almost every case. Best values of hysteresis are in the 0.1-0.2V range with the p-type Si chips having slightly smaller hysteresis than the n-type Si chips. Best values of normalized slope are near 1.2/V for p-type Si chips and 0.9/V for n-type Si chips. Values of V_{FB} are near the range of -1 to $+1$V for chips which had the preferred deposition parameters. Furthermore, V_{FB} for p-type Si chips is more negative than for n-type Si chips (only Fig. 4c contains an exception), which is the proper tendency for the work function differences involved. However, the value of the difference is somewhat higher than the 0.6V work function difference expected for the doping levels used.

Postdeposition anneals.—Several researchers (18, 25-27) have suggested that amorphous Al_2O_3 transforms to polycrystalline Al_2O_3 at processing temperatures above 700°C. The decrease in slope and the increase in V_{FB} seen in Fig. 7 and 8, respectively, for anneals at 600° and 800°C may be related to such a transformation. The hysteresis, as shown in Fig. 6, continues to decrease as temperature is raised. This effect, too, is consistent with previous studies of Al_2O_3 reported in the literature. Hysteresis is apparently not affected by the amorphous-to-polycrystalline transformation.

From an examination of these figures, the optimum anneal appears to be 550°C for 5-20 min. In agreement with this research, Iwauchi and Tanaka (28) reported a favorable range of anneal temperatures (500°-600°C) above which surface-state densities increase. This may indicate a similarity between their O_2-sputtered films and the present E-beam evaporated films. H_2 may offer some improvement over N_2 or O_2, but the effect of the anneal appears to be due primarily to temperature and time, and not to the gas used. This suggests that evaporated Al_2O_3 may offer a good hermetic seal for semiconductor surfaces.

Summary and Conclusion

Al_2O_3 films produced by E-beam evaporation as described in this work have a relative dielectric constant of about 8.0, a refractive index of 1.61, and breakdown field strengths exceeding 3×10^6 V/cm. The Al_2O_3 films are clear, hard, and adherent. Coated samples can be scribed and broken with no propagation of damage in the Al_2O_3 coating. Optimum interface and insulator results require Al_2O_3 evaporation in an O_2 ambient with bell jar pressure near 2×10^{-5} Torr, a substrate temperature of 100°-200°C, and deposition rates below 500 Å/min. A postdeposition anneal of 5-20 min in N_2 at 550°C is also required. Such evaporations onto Si give interface-state densities in the low 10^{11} states/cm^2-eV over the middle third of the Si energy bandgap, C-V hysteresis of 0.1-0.2V, and flatband voltages in the range of -1-$+1$V.

It is concluded that Al_2O_3 deposited by E-beam evaporation as described is comparable to and therefore competitive with Al_2O_3 films produced by other methods such as pyrolysis or sputtering. Furthermore, vacuum deposition of Al_2O_3 is truly a low temperature process (100°-200°C, or in general any temperature) compared to pyrolytic depositions (400°C and up). The absence of gaseous ambients (except O_2) during vacuum depositions should result in purer Al_2O_3 films. The lack of excited plasmas near the sample and in the deposition system (*cf.* the case of sputtering) provides a cleaner environment for the deposition and minimizes the possibility of semiconductor surface damage.

Four-Point Probe Measurements on N-Type Silicon with Mercury Probes

P. J. Severin and H. Bulle

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

With an instrument consisting of four mercury probes, simple, rapid, and nondestructive four-point probe measurements can be done on freshly etched n-type silicon samples. Measurements on bulk material and on thin layers with a conventional and with a mercury four-point probe are compared. The ratio of two current-voltage configurations is used as a figure of merit of the instruments. The precision is found to be about 2% and the systematic deviation from theory, which is supposed to be satisfied by a conventional four-point probe, amounts to about 8% for thin layers and much less on bulk material. A number of aspects which may affect the performance are discussed. Because the instrument has no penetrating probes it is particularly useful for very thin heterotype epitaxial layers and for shallow, ion implanted samples. Experiments have also been done on polycrystalline silicon, metallic glass, and conductive plastic layers.

It is generally felt that the economy of semiconductor device processing improves with increasing slice diameter, particularly for larger devices. However, this requires the pertinent slice properties to be uniform and deficient slices to be rejected at the earliest stage. These considerations form the basis for an ever increasing effort in material properties evaluation and characterization. In order to avoid losing material, thus adding to the cost, and to ensure measuring at the relevant spot, it is highly desirable for the methods to be nondestructive. They should also be rapid and simple in application. The purpose of this paper is to show how the peculiar properties of mercury on n-type Si can be used most efficiently for evaluation purposes with the four-point probe method. In this sense the present paper is a continuation of an earlier one on capacitance-voltage measurements (1), where it was stated also that a mercury contact is ohmic to well-cleaned, n-type Si. It will be followed by a paper on spreading resistance measurements, also with mercury probes (2).

The use and experimental results of mercury four-point probe measurements on bulk and thin layers of n-type Si are described below. The sources of error and the limits of applicability of the theory are also discussed. Practical conclusions are drawn and the perspectives for the mercury four-point probe are illustrated with more advanced results.

Mercury Four-Point Probe Measurements

A mercury probe with a single channel used for capacitance-voltage measurements has been described earlier (1). The mercury four-point probe (Hg-fpp) consists of four such holes and channels of identical construction at identical center-to-center distances $s = 3000$ μm. Details of the instrument are shown in Fig. 1. With the interchangeable lid (C, Fig. 1) various contact diameters can be used; the experiments described have been done with contact diameter $2A = 1020$ μm. The embodiment shown is one of the many possibilities. The four platinum wires (B, Fig. 1) should penetrate far enough into the channels to reduce contact resistance and should not be short circuited by mercury in the reservoir (D, Fig. 1). The channels are filled as follows. When the channels have been closed by a sample, the block is tilted and air pressure is applied. The surface of the Perspex block should not be too well polished so that air can escape and mercury can contact the sample. Thereupon the block is put into the horizontal position again. After removing the air pressure enough mercury remains in the channels because they have been made slightly sloping. Now the instrument is ready to be used for four-point probe measurements.

Key words: four-point probe, sheet resistance, silicon, mercury, epitaxy, polycrystalline, conductive layer, ion implanted layer.

To make an ohmic contact of mercury to silicon the surface should be carefully prepared. It should be freshly etched in HF, rinsed in deionized water, spin-dried, and subsequently left, until immediately before it is measured, top-side down closing a bottle filled with HF. As strictly speaking an ohmic contact is not required for fpp measurements, the storage stage can sometimes be skipped. The complete procedure is essential for mercury probe spreading resistance measurements (3), which will be discussed at length in a subsequent paper (2).

In the expression for the fpp resistance of a sample of resistivity ρ, thickness $d >> s$, and infinite in lateral extent, the distance s figures with $R_{2314} = V_{23}/i_{14}$

$$R_{2314} = \frac{\rho}{2\pi s} \qquad [1]$$

Hence the resistance R^{H}_{2314} measured with a Hg-fpp should be proportional to the resistance R^{D}_{2314} measured with any other, *e.g.*, a Dumas fpp, with proportionality constant s_D/s_H. In Fig. 2 these two four-point probe resistance values are compared, and it is clear that this ratio does not depend on ρ over four decades of resistivity between 10^{-3} and 10 cm n-type

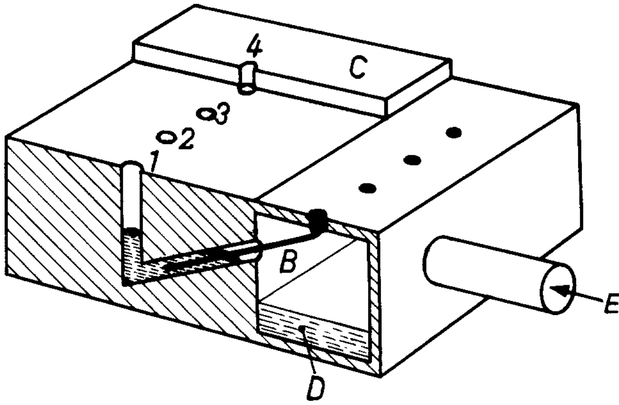

Fig. 1. The mercury four-point probe embodiment, shown schematically, cut through channel 1. Pressure is applied through E; the contact to the mercury is made with platinum wire B. Different contact diameters can be used with interchangeable cover C, shown cut through contact 4.

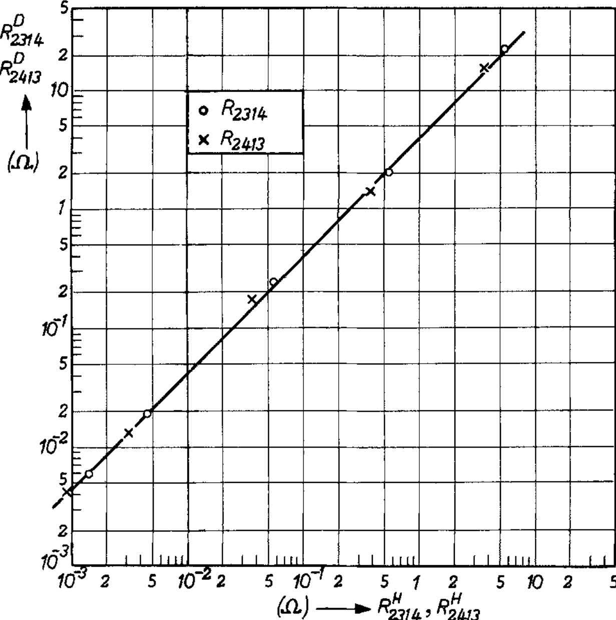

Fig. 2. The resistances R_{2314}(○) and R_{2413}(×) as measured with the mercury four-point probe plotted vs. the same parameters measured with a Dumas four-point probe, labeled H and D, respectively. The bulk sample data are given in Table I.

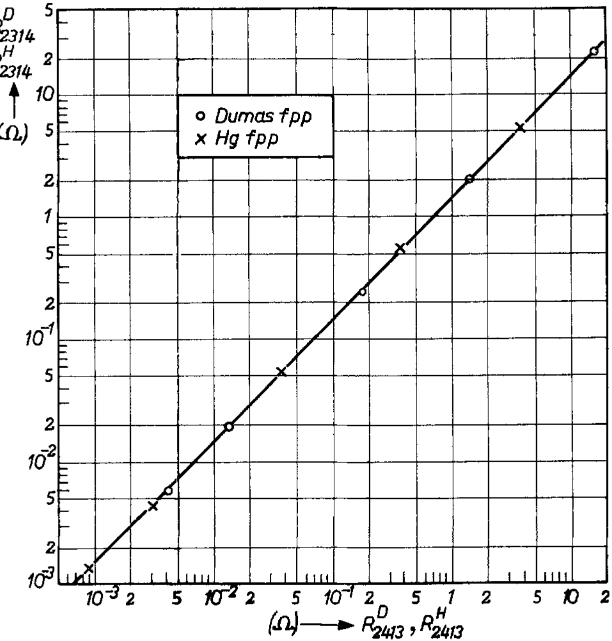

Fig. 3. The resistances R_{2314}, as measured with the mercury (×) four-point probe and with a Dumas (○) four-point probe, plotted vs. R_{2413} measured in the same way for the same samples as used in Fig. 2.

Si. As it has been explained elsewhere (4), two independent four-point probe measurements can be done by changing the probe order, the other one being for instance

$$R_{2413} = \frac{\rho}{2\pi s} 1.500 \qquad [2]$$

This resistance has also been plotted in Fig. 2 for both probes because they should have the same proportionality constant and the measurement points should be on the same line. The ratio s_D/s_H has been calculated and it is found that for both sets the ratios are equal: 0.235 ± 0.022 for R_{2314} and 0.236 ± 0.020 for R_{2413}. This error is rather large, but, as shown in Table I, the two ratios correspond more closely by an order of magnitude on the same slice. It should be borne in mind that the slices are nonuniform and that the two probes measure at different spots and integrate over widely different surface areas. This difference is typical for each slice.

Because the ratio of the two independent four-point probe resistances depends on resistivity only to second order, it mainly characterizes the instrument. In Fig. 3 these two four-point probe resistance values are compared and plotted for both instruments. The ratio R_{2314}/R_{2413} should be equal to 1.500 for both types of fpp. Calculation of this ratio for all data points yields 1.461 ± 0.026 for the Hg- and 1.464 ± 0.034 for the Dumas-fpp. The departures from the average values are found to be statistically distributed over all samples, independent of resistivity. Hence the errors may be attributed to irreproducibilities in the performance of the instruments.

The fpp resistance of a thin layer of resistivity ρ, thickness $d << s$, and infinite in lateral extent

$$R_{2314} = \frac{\rho}{2\pi d} \ln 4 \qquad [3]$$

is, to a first order, independent of the dimensions of the fpp. Hence the resistance as measured with a Dumas- and a Hg-fpp should be the same. In Fig. 4 the four-point probe resistances as measured with a Dumas- and a Hg-fpp are compared and are shown to be the same over four decades of substrate resistivities between 10^{-3} and 10 ohm-cm n-type Si. The ratio R_{2314}/R_{2413} has been measured twice with the two types of fpp on substrate slices. Typical results for a number of resistivities are presented in Table II. It is found that the reproducibility for both types of fpp is about equal; the two sets of data for both probes yield the same values which can be combined to 1.244 ± 0.015 for the Dumas- and 1.170 ± 0.029 for the Hg-fpp. The precision as measured on thin layers agrees closely

7	1.164	1.164	1.248	1.270
10	1.176	1.182	1.270	1.243

with the precision obtained on bulk material for both probes.

The value of the ratio R_{2314}/R_{2413} has been introduced as a figure of merit of the instrument. The fpp resistance is directly affected both by nonuniformities in the sample and deficiencies of the instrument. The ratio is independent of the resistivity and the error in determining the ratio is due to the instrument deficiencies only. Because the two fpp resistances are about equally sensitive to the mainly mechanical irreproducibilities, the percentage of error of the ratio is about twice the percentage of error of the two fpp resistances.

The reproducibility of the Hg-fpp is excellent: removing and reapplying the Hg contact without displacing the slice produces identical readings, and when replacing it as well as possible on the same spot the error is within 1%. With the Dumas-fpp the reproducibility is about the same. The data presented in Fig. 2-4 are typically measured data and do not represent averages. Though, as will be shown below, the contact diameter, A, does not occur in the four-point probe formula, it is interesting to know its reproducibility. It turns out that A as measured under a microscope by pressing the mercury against a glass slide depends weakly on the applied pressure. At a controlled excess pressure of 150 Torr the diameter is reproducibly found to be 1020 μm. Work has been done with contacts 500 μm across, and smaller diameters down to 200 μm have been tried successfully.

From the measured data presented in the preceding section, referring to different spots on the same slice and on slices with different resistivities, it can be concluded that fpp measurements can be done with a precision of about 1% with the Dumas- and of about 2% with the Hg-fpp. There is no consistent indication of any influence of the resistivity of the sample.

Sources of Measurement Errors

The fpp method is probably the most familiar method in semiconductor evaluation. Generally, it is assumed that within the measurement precision the measured data are accurate with respect to the reference level set by the model and the ensuing theory. However, the data presented above show discrepancies with the theory worth discussing in greater detail.

In the model by which the mode of operation of an fpp is described, identical, nondamaging, circular contacts of diameter $2A$ are assumed, which can be neglected with respect to the identical probe center-to-center distances, s. The dependence of voltage, V, on distance, r, from the center of the current-carrying contact on a thin slice is given by

$$V_o - V(r) = \frac{\rho i}{2\pi d} \ln \frac{r}{A} \qquad [4]$$

where V_o is the potential of the contact, and on bulk material by

$$V = \frac{\rho i}{2\pi A} \arcsin \frac{A}{r} \approx \frac{\rho i}{2\pi r} \qquad [5]$$

Equation [4] is evidently valid only for $r \geq A$ and the resistance R_m under the probe on a thin layer has been discussed (5) showing a complicated dependence on the contact resistance R_c and the sheet resistance R_s. Strictly speaking, this is valid only for a layer which is thin with respect to the probe diameter, whereas for fpp measurements the thickness is referred to the probe distance. In case $A < d$ in the direct vicinity of the probe, the potential drops according to Eq [5]. Because this is not of great importance with $r >> A$, Eq [4] may be considered applicable from $r = A$ onwards. Allowing for the different probe center-to-center distances, s_{ij}, Eq. [3] and related resistances should read

$$R_{2314} = \frac{\rho}{2\pi d} \ln \frac{s_{13}s_{24}}{s_{12}s_{34}}$$

$$R_{2413} = \frac{\rho}{2\pi d} \ln \frac{s_{14}s_{23}}{s_{12}s_{34}}$$

$$R_{3412} = \frac{\rho}{2\pi d} \ln \frac{s_{13}s_{24}}{s_{14}s_{23}} \qquad [6]$$

These equations have been derived, as usual, by adding the potential differences of the two probes due to currents flowing through each probe to infinity in opposite directions. This is not permitted when the potential is probed near the current source. For the mercury probe this could limit the applicability of Eq. [6].

It can easily be seen from Eq. [6] that whatever the probe contact diameters are, the three essentially different resistances on a uniform sample are always related by

$$R_{2314} = R_{2413} + R_{3412} \qquad [7]$$

and that there is one independent ratio which, when all s are equal yields

$$\frac{R_{2314}}{R_{2413}} = 1.2619 \qquad [8]$$

For bulk material the expressions corresponding to Eq. [6] are

$$R_{2314} = \frac{\rho}{2\pi} \left(\frac{1}{s_{13}} - \frac{1}{s_{12}} + \frac{1}{s_{24}} - \frac{1}{s_{34}} \right)$$

$$R_{2413} = \frac{\rho}{2\pi} \left(\frac{1}{s_{14}} - \frac{1}{s_{12}} + \frac{1}{s_{23}} - \frac{1}{s_{34}} \right)$$

$$R_{3412} = \frac{\rho}{2\pi} \left(\frac{1}{s_{13}} - \frac{1}{s_{14}} + \frac{1}{s_{24}} - \frac{1}{s_{23}} \right) \qquad [9]$$

Equation [7] holds under all conditions and the ratio given in Eq. [8] equals 1.500. In real life with a mechanical fpp all values of s are never equal.

In the above considerations it has been assumed that the voltage probes reflect the potential directly below the center of the contact, *i.e.*, they act as point contacts. It is worth considering under what conditions this simplification holds, particularly as the mercury probe contacts are 1000 μm across with $s = 3000$ μm. Any current drawn by the voltage probes can be neglected because voltmeters of 100 megohms input resistance are used. So the potential of the voltage probe is such that over the contact cross-section as much current flows into as out of the mercury. If the probe diameter is small with respect to the distance, this potential can be assumed to be the potential below the center of the probe. This would apply exactly when the sample has a rectangular shape and contacts take the form of strips; it could be easily calculated with the contacts on concentric circles, but an analysis for on-line circular contacts is virtually impossible. As long as no more detailed

theory is available, the voltage probes will be considered as point contacts.

This effect arises whatever the nature or magnitude of the resistance of the probe sample contact. A second effect is due to the finite value of the specific contact resistance R_c (ohm-cm²) or its voltage dependence. Because current flows through the contact, the same sample draws more current with a low contact resistance probe than with a high contact resistance probe; in other words the sample appears as lower resistivity material. A similar relation has been analyzed earlier for square and circular contacts used as spreading resistance probes (5). Because the main current then flows through these contacts, the theory cannot be directly applied, but the condition for negligible bypass, apart from a numerical factor of order unity, is roughly given by $R_s << R_c/A^2$ for thin layers and by $\rho << R_c/A$ for bulk samples. From mercury probe spreading resistance measurements on substrate material, to be reported in a subsequent paper (2), is follows that R_c is so low that these conditions are not met. Because, roughly, $R_c \sim \rho$, this applies equally over the resistivity range. When R_c is not very high and depends nonlinearly on ρ, the contacts may bypass the current through the sample to a different degree for various resistivity materials. A further complication may originate from a nonohmic characteristic of the voltage probe contact. When so high a potential is applied that the voltage drop over the diameter of a nonohmic contact in the material exceeds 25 mV, then the contact assumes a potential such that most of the contact draws reverse current. Moreover, the fpp resistance, as measured, turns out then to depend on the current. However, the current has, unless stated otherwise, been kept so low that the measured voltage is well below 25 mV, as advocated earlier (4).

In summary, the assumptions made in the theory are not completely met, firstly because current and probe contacts are not far enough apart to allow separation of the two current sources, secondly because the fairly large contact may partly short circuit the sample, and thirdly because R_c may depend on ρ and on the local voltage.

Discussion of Measurement Errors

From the data obtained from the experiments discussed above, conclusions could be drawn as to the precision of fpp measurements. The reproducibility on the same slices and on samples of different resistivity was tested particularly by using the ratio which depends on the uniformity of the slice to second order only. The data were arranged so as to be theoretically independent of any nonstatistically distributed influence. As the ratios did not show the expected values the theory was more carefully considered and some refinements were mentioned above. In this section the measurements related to these errors with respect to the true or theoretical value are discussed and some practical conclusions are drawn.

By way of example in Table III, the distances, s_{ij}, and probe radii, A_i, as measured under the microscope from a probes print of a Dumas-fpp are presented. From these data the ratio R_{2314}/R_{2413} is found to be 1.254 for thin layers and 1.486 for bulk material. When the two resistances are measured on two slices of widely different resistivity (10^{-2} and 10 ohm-cm n-type Si) and at two current levels, the results presented in Table IV are obtained. The ratios depend slightly on the resistivity and on the current. In actual practice the ratio is calculated regularly in this way and compared to the experimental value.

Table III. The probe center-to-center distances s_{ij} and probe radii A_i in micrometers as a practical example for a Dumas-fpp

$s_{12} = 629.2$	$s_{13} = 1259.0$	$A_1 = 19.2$	$A_3 = 25.0$
$s_{23} = 643.7$	$s_{24} = 1287.0$	$A_2 = 19.7$	$A_4 = 22.2$
$s_{34} = 653.4$	$s_{14} = 1907.8$		

Table IV. The ratios R_{2314}/R_{2413} for Hg- and Dumas-fpp on thin layers

	$\rho = 10^{-2}$ ohm-cm (10 mA)	$\rho = 10$ ohm-cm (22 μA)	$\rho = 10$ ohm-cm (220 μA)
$\left(\frac{R_{2314}}{R_{2413}}\right)^D$	1.246	1.270	1.243
$\left(\frac{R_{2314}}{R_{2413}}\right)^H$	1.195	1.176	1.182

Disagreement is always less than 2% of either sign, so systematic bias error, which affects the accuracy, is not found. Therefore, the true value which is the reference with respect to which the accuracy is to be discussed, can be considered to be given in the theory above and as measured with a Dumas-fpp.

The Hg-fpp with identical probe center-to-center distance, s, satisfies the ideal conditions, and the ratio R_{2314}/R_{2413} for thin layers should be equal to 1.2619, which exceeds the experimental values given in Tables II and IV by about 8%. It is not clear to what extent this bias error (it has always been found to have the same sign) is due to R_{2314} or to R_{2413}. It is worth noting that in R_{2413} the potential difference V_{24} caused by current through probe 3 is always zero due to symmetry, whatever theoretical assumption is made. Supposing now that this bias error has the same influence on the voltage difference between two probes for each current probe, the value of R_{2314} as measured with a Hg-fpp should be increased by 12% to reach the true value measured with Dumas-fpp. From Fig. 4 it can be seen that this semiquantitative conclusion is substantiated by experiments.

The ratio s_D/s_H as measured on bulk samples hardly exceeds the theoretical value with $s_D = 630$ μm and $S_H = 3000$ μm. The dependence on resistivity shown equally in $(R^H/R^D)_{2314}$ and $(R^H/R^D)_{2413}$ suggests some physical influence of the large area probes as discussed in the preceding section. It turns out to be an advantage of the ratio R_{2314}/R_{2413} that this resistivity-dependent effect also disappears. The experimental values of the ratio disagree with theory for both types of probe by equal amounts, not large enough with respect to the precision to be of any significance.

It would be worth investigating the influence of the ratio A/s on fpp measurements. In this paper it has been shown that the quite extreme ratio 1/6 produces results which can be interpreted in the same way and with the same amount of caution as conventional fpp measurements.

In conclusion a number of more advanced applications of the Hg-fpp are mentioned. The Hg-fpp is extremely useful for the assessment of very thin epitaxially grown heterotype silicon layers or shallow ion implanted samples, where conventional pointed probes cause substrate short circuit or even penetrate. It is found possible to measure silicon polycrystalline layers between 1000 and 2000Å thick with resistivities between 0.06 and 2 ohm-cm. These layers are increasingly used as diffusion sources, vertical resistors, and MOS gate electrodes. Layers of Au Rd-oxide about 200Å thick have been measured to yield a resistivity of about 1.6 mohm-cm. A reliable assessment of conductive plastic has also been made.

Manuscript submitted Jan. 22, 1974; revised manuscript received July 3, 1974. This was Paper 75 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Philips Research Laboratories.

Spreading Resistance Measurements on N-Type Silicon Using Mercury Probes

P. J. Severin and H. Bulle

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

With an instrument consisting of four mercury probes spreading resistance has been measured on n-type silicon bulk samples and thin layers without leaving any damage. With bulk samples the spreading resistance measured in a three-probe arrangement is found to be proportional to the resistivity without any indication of resistivity dependence of the proportionality constant between 10^{-3} and 10 ohm-cm. From repeated measurements it is concluded that the precision depends on the mechanical finish of the contact edge and can be as good as 3%. Upon comparison with the resistivity as measured with a conventional four-point probe, the mercury probe spreading resistance is found to be accurate within that error. The resistivity measured represents the average over about 1 mm^3, so that the resolving power of this instrument is intermediate between the resolving powers of conventional four-point and spreading resistance probes.

With thin layers a theory is used, in which the Hg-Si contact resistance is incorporated which is found to be almost proportional to the resistivity over the same four decades. It turns out to be small compared to the bulk spreading resistance, thus confirming the experiments on bulk material. Considering the cylinder resistance of an epitaxial n on n^+ layer as an extra contribution to the contact resistance, with a mercury four-point probe and spreading resistance measurement the product ρd can be found.

A mercury probe has been applied successfully for capacitance-voltage measurements on n- and p-type silicon and various other semiconductors (1). The procedure which should be followed to prepare a silicon surface so that the contact to mercury is ohmic has been described earlier (2, 3). An instrument consisting of four mercury probes has been used for four-point probe measurements on n-type silicon and the attainable precision and accuracy have been discussed at length (3). It is the purpose of this paper to show how with mercury probes in a three-point probe arrangement spreading resistance measurements may be carried out.

This study is a continuation of Ref. (3) in the sense that the same mercury four-point probe accessory and the same bulk and substrate samples are used. Because a spreading resistance measurement is more exacting than a four-point probe measurement, the sample preparation should be more carefully executed.

The next section is devoted to the results on bulk samples. The results on thin layers, for which 230 μm thick substrates for epitaxy have been used, are also presented in this paper. The theory needed to find the resistivity ρ and the contact resistance R_c from the measured data is recapitulated in the Appendix. In another section of this paper, a new method is outlined by which the product ρd for the top layer of thickness d of an n on n^+ epitaxial structure can be determined. In the final section the use of the same mercury four-point probe accessory for four different purposes is summarized.

This paper will be followed by a fourth paper on rapid and simple pulsed MIS capacitance lifetime measurements with the same accessory.

Key words: silicon, epitaxial layer, thickness, resistivity, contact resistance, mercury, spreading resistance, four-point probe resistance.

It is worth stressing that this paper deals with n-type silicon only. Though the contact resistance of mercury to p-type silicon may be reduced by the use of suitable etches, it is not yet small enough for spreading resistance measurements.

Mercury Spreading Resistance Measurements on Bulk Samples

In a few years' time the spreading resistance technique has become an accepted and widely used tool in semiconductor evaluation. However, the theoretical value of the spreading resistance on a semi-infinite sample of resistivity with a probe of contact radius A

$$R_s = \frac{\rho}{4A} \qquad [1]$$

is rarely found.

With hard metal probes, as discussed by Mazur and Dickey (4) and Keenan *et al.* (5), a contact resistance R_c is always found which generally is incorporated into the expression for spreading resistance as

$$R_s = k(\rho)\,\frac{\rho}{4A} \qquad [2]$$

The factor $k(\rho) = 1 + 4A\ R_c/\rho$ is experimentally determined and Eq. [2] can be used only after calibration because $k(\rho)$ depends also on the particular probe properties.

One of the present authors (6) solved the same problem in a slightly different manner by using a softer steel probe. Then the contact can be described by a series spreading resistance due to a number, n, of microcontacts with average contact radius, a, acting in parallel as

$$R_s = \frac{\rho}{4A} + \frac{\rho}{4na} \qquad [3]$$

It has been verified that R_s over four decades of resistivity is proportional to ρ. The magnitudes of the contributions of macro- and microcontacts are of the same order, which has an important bearing on the resolving power. In both approaches the precision and reproducibility of k and na are key conditions, the latter being the more relaxed one because only geometry is involved rather than ρ-dependent contact physics.

The main advantage of the spreading resistance method is the unparalleled resolving power, the information sampling depth being about equal to A which amounts to a few microns. Apart from the arguments given above an important drawback is that it is a destructive method. Furthermore, sophisticated vibration-free equipment is needed. In the experiments presented in this paper $A = 500$ μm, but it could easily be made 5 times smaller. The ensuing drop in resolving power is compensated by the fact that it is nondestructive, and that it can be done by simply switching the probe order after a mercury four-point probe measurement. Effectively, it offers a tool with resolving power intermediate between a metal spreading resistance probe and a four-point probe.

The same five bulk samples as used in the preceding paper (3) have been measured with mercury probes and the spreading resistance R_{2113} is plotted *vs.* the four-point probe resistance R_{2314} in Fig. 1. In the three-point probe arrangement chosen with center voltage-probe each of the four probes can be used as the common probe. No systematic difference turned out to exist. The spread arises from inhomogeneity of the sample and irreproducibility of the contacting process.

Working out the potential difference, V_{12}, measured due to current flow through probes 1 and 3, with the dependence on horizontal distance, r, from the probe center as

$$V(r) = \frac{\rho i}{2\pi A} \arcsin \frac{A}{r} \approx \frac{\rho i}{2\pi r} \quad [4]$$

it is found that

$$R_{2314} = \frac{\rho}{2\pi s}$$

and that

$$R_{2113} = \frac{\rho}{4A}\left(1 - \frac{A}{\pi s}\right) \quad [5]$$

With probe center-to-center distance $s = 3$ mm and $A = 0.5$ mm the term $A/\pi s$ equals 0.053 and the line in Fig. 1 is drawn so that $R_{2113}/R_{2314} = \pi s/2A = 9.42$.

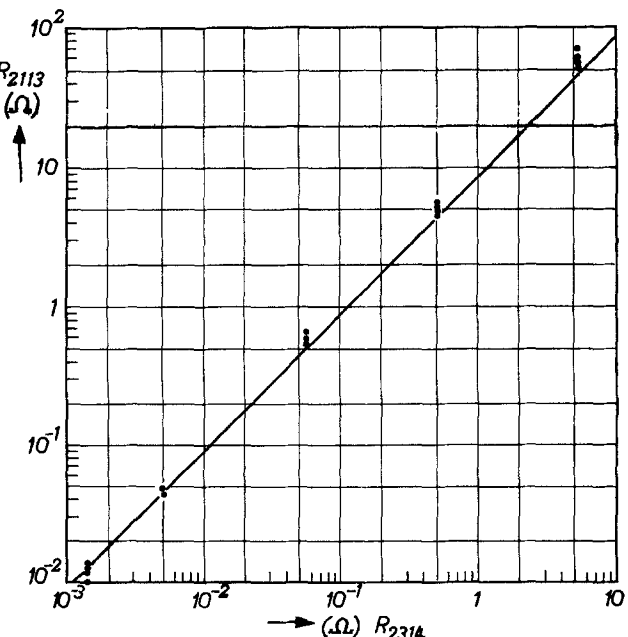

Fig. 1. The spreading resistance R_{2113} plotted *vs.* the four-point probe resistance R_{2314}, both measured with mercury probes, on bulk samples. The solid line represents $R_s = \rho/4A$, where 1 ohm corresponds to $\rho = 0.2$ ohm-cm.

It has been tacitly assumed above that any contact resistance is negligible. With specific contact resistance R_c' (ohm-cm^2), Eq. [2] should in fact be written as

$$R_s = \frac{\rho}{4A} + \frac{R_c'}{\pi A^2} \quad [2a]$$

Anticipating the results of the next section where R_c' is determined, it can be verified that for $R_{2314} = 5.3$ and 1.4×10^{-3} ohms the corrections to R_{2113} would be 5 and 2×10^{-3} ohms, respectively, hence negligible on the logarithmic scale. Therefore, the spread of the measurement points cannot be due to differences in contact resistance.

In the experimental embodiment it turns out that the series resistance due to platinum lead, the platinum-mercury transition resistance, and the mercury channel resistance cannot be neglected for low resistivity specimens. The accurate value for each of the four channel series resistances, R_{ai}, can be determined with a platinum-coated, very low resistance specimen. The resistance R_{a1} which amounts to 65 $\pm$ 2 mohms, should be considered as a series resistance in the external circuit. It is evident from Fig. 1 that it seriously adds to the error for the low resistivity specimens.

It has been found that with removing and reapplying the mercury probes the measurement does not reproduce very well. Therefore, in order to test the reproducibility, the slice was removed, prepared again, and positioned at the same spot. The results of six measurements repeated in this way are presented in Fig. 2 for each of the four probes. It was found that the averages for each of the four probes are different by a few per cent and that each of these averages is subject to an error ranging from $\pm$ 3.1% for probe 1 to $\pm$ 9.1% for probe 2. From this experiment and further experience it should be concluded that repeated etching with HF does not affect the results. The performance of the probes probably depends on the quality of the mechanical finish of the hole and particularly on the absence of burrs at the contact edge. Upon averaging the 24 results of all four probes a value of 5.17 ohms is found with an error of $\pm$7%. With a Dumas four-point probe the area of measurement has been tested for nonuniformity, and it was found that measuring with a precision better than 1%, the resistivity ρ varied around the average value $\rho = 1.08$ ohm-cm by $\pm$ 4.4%. This value corresponds with Eq. [5] where a mercury probe measured $R_{2113} = 5.13$ ohms, hence well within the experimental error of the best probe.

In this way it has been proved that with a mercury probe it is possible to carry out spreading resistance measurements with a precision and accuracy of better than 3%.

Of course the value of the contact diameter $2A$ should be reproducible and precisely known: it is measured with a microscope by pressing the mercury against a glass slide. It has turned out that with increasing pressure the contact diameter first increases until the diameter of the hole has been reached then remains constant over a certain pressure range and finally increases again with increasing mercury pressure due to mercury penetrating between the Perspex and the sample. At a controlled pressure of 150 Torr the diameter is found to be reproducible and equal to the hole diameter within 1%. With a narrower channel the diameter of the contact increases with pressure over a longer range up to the hole diameter so that spreading resistance, contact resistance, and capacitance-voltage can be measured with the surface area as a continuous variable over about a factor of two.

Mercury Spreading Resistance Measurements on Thin Samples

The same measurement as described in the preceding section has been carried out on 230 μm thick substrate slices as used for epitaxy. A spreading resistance cor-

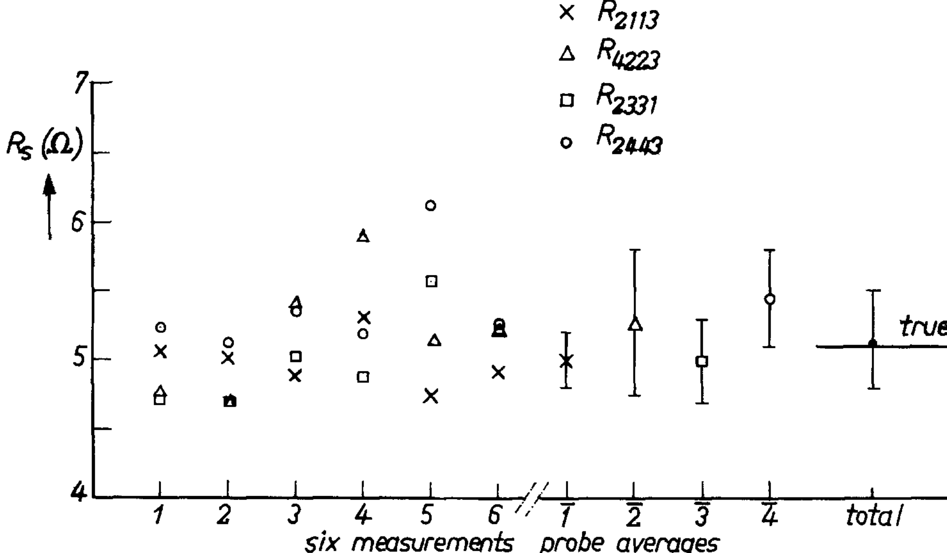

Fig. 2. The spreading resistance measurement on the same position on a 1.08 ohm-cm n-type Si bulk sample repeated 6 times. Each time data for four different common probes are obtained. The four averages and the total average are given separately; the true value ρ = 1.08 ohm-cm yields with Eq. [5] R_{2113} = 5.13 ohms, indicated by the horizontal bar.

rection formula for a thin layer on an insulating substrate based on a transmission-line model has been derived (7) and compared (10) to other models earlier. As recapitulated in the Appendix, the spreading resistance of the common probe (probe 1), with current probe (probe 4) and voltage probe (probe 2) is given by

$$R_{2114} = R_m + \frac{\rho}{2\pi d} \ln \frac{3s}{2A} \quad [6a]$$

with a four-point probe resistance

$$R_{2314} = \frac{\rho}{2\pi d} \ln 4 \quad [6b]$$

The resistance R_m is defined for a thin layer, $d << A$, as the difference between the contact potential V_o and the potential $V(A)$ at $r = A$ in the thin layer, divided by the current i_o. It is found to be equal to

$$R_m = \frac{\rho}{2\pi d} \mathbf{F}(z) \quad [7]$$

with $\mathbf{F}(z)$ plotted in Fig. 3, R_c' specific contact resistance in ohm-cm², $R_c = R_c'/\pi A^2$ and

$$z^2 = \frac{\rho A^2}{R_c' d} = \frac{\rho}{\pi d R_c} \quad [8]$$

For $s/A = 6$ the logarithmic factor in Eq. [6a] equals 2.197 and Eq. [6] and [7] can be recast into a form more suitable for calculation

$$\mathbf{F}(z) = \frac{R_{2114}}{R_{2314}} 1.386 - 2.197 \quad [9a]$$

and

$$R_c = \frac{R_{2314}}{z^2} 1.443 \quad [9b]$$

The resistance R_m is plotted *vs.* R_{2314} in Fig. 4 and found to be almost proportional to ρ from 10 to 10^{-3} ohm-cm. This suggests, from Eq. [7], that z must be independent of ρ, hence that $R_c = R_c'/\pi A^2$ is proportional to ρ, as also shown qualitatively in Fig. 4.

It has been neglected in Eq. [9a] that in fact R_{2114} includes a term which refers to the local resistivity at probe 1 and a term which refers to the average value ρ between probes 1 and 4. The latter is represented adequately by the resistance R_{2314}.

In order to get the feel of the precision and accuracy involved let us consider a measurement of an 0.03 ohm-cm slice. We then find R_{2114} = 4614 mohms, R_{2314} = 2702 mohms, so that R_m = 330 mohms, $\mathbf{F}(z)$ = 0.169, z = 6.45, hence R_c = 93.6 mohms. It is clear that with these values of $\mathbf{F}(z)$ and $\ln(3A/2s)$, the measurement conditions are very unfavorable: in order to find precise R_m within 10%, the values of R_{2114} and R_{2314} should be known within 1%. Because z hardly depends on ρ, this example is typical for the experiments described in this section. Because in this range $z >> 1$, Eq. [9a] and [9b] can be simplified by the relation $\mathbf{F}(z) = 1/z$.

As it is clear from Eq. [9a] and [9b], the measurement result is the contact resistance R_c. Usually quite some processing is involved in making an ohmic metal semiconductor contact, and R_c', though not very reproducible, is considered as a figure of merit of the process. As long as R_c is small with respect to the bulk resistance of the device concerned, this is an unimportant aspect. However, the instrument described and the spreading resistance method are intended to serve evaluation purposes, *viz.*, to measure the resistivity locally. From Eq. [9a] and [9b] it can be seen that $R_c(\rho)$ is finally the discriminating parameter which turns out not to be sufficiently precise and reproducible to yield ρ.

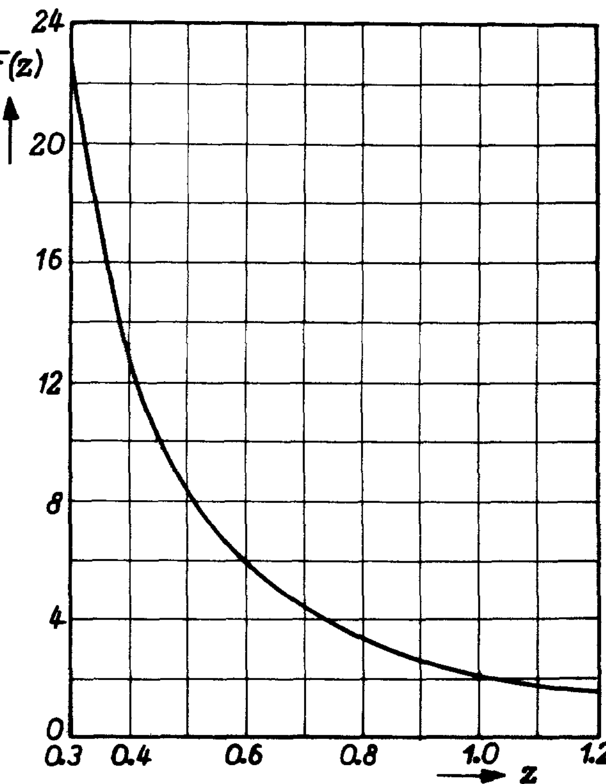

Fig. 3. The function F(z) as used in Eq. [7] and defined in Eq. [A-8]

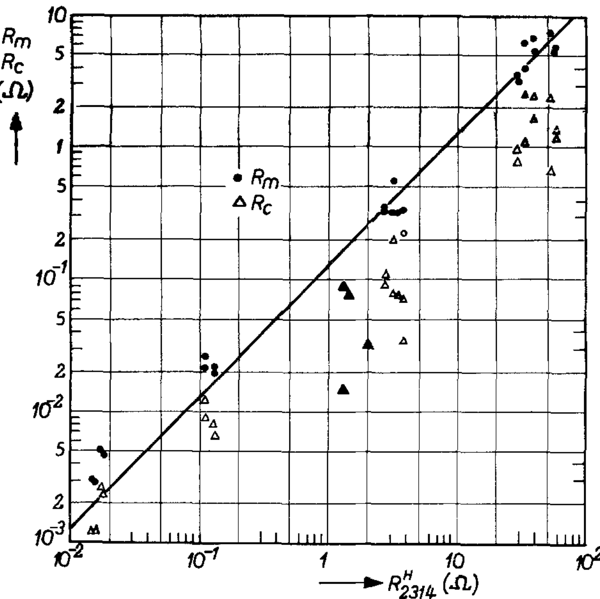

Fig. 4. The spreading resistance R_m (●) and the ensuing contact resistance $R_c = R_c'/\pi A^2$ (△) on chem-mechanically polished silicon substrate slices vs. the Hg fpp resistance R_{2314}. For a 230 μm thick slice, 9.59 ohms corresponds to 1 ohm-cm; thickness variations $\pm$ 5% are irrelevant on this scale. The contact resistance R_c (▲) on epitaxial layers agrees with R_c measured on substrate material within the measurement error.

Spreading Resistance Measurement of an N on N$^+$ Silicon Epitaxial Structure

The spreading resistance measurement discussed above can also easily be applied to measure the cylinder resistance R_y of an n-type silicon epitaxial layer on an n$^+$ substrate

$$R_y = \frac{\rho d}{\pi A^2} \quad [10]$$

For a fpp measurement such a structure can be considered as being a single isolated n$^+$ layer; with a 10 μm thick, 1 ohm-cm n layer on a 250 μm thick, 10^{-2} ohm-cm n$^+$ substrate the sheet resistances are $\rho_e/d_e = 10^3$ ohms and $\rho_s/d_s = 0.4$ ohms, respectively. The thin resistance layer is of interest only for the spreading resistance probe because the real contact resistance R_c in series with the cylinder resistance R_y can be considered as an effective contact resistance R_{ce} in the sense as defined in the preceding section

$$R_{ce} = R_c + R_y \quad [11]$$

In using this formalism with R_m the contact radius, A, should be much larger than the layer thickness, d. This eliminates the use, without additional and doubtful correction, of the steel probes with $A = 10$ μm, applied for conventional spreading resistance measurements (6, 7). For the above example, $R_y = 127$ mohms which, with the value $R_c \approx 60$ mohms to be found experimentally according to Fig. 4, should yield $R_{ce} \approx 200$ mohms.

It should be emphasized for this application of Eq. [9a] and [9b], that R_{2314} refers to the n$^+$ substrate, that R_m is influenced by both the epitaxial layer R_{ce} and the substrate ρ/d, and that R_y refers to the epitaxial layer only. The meaning of the various parameters introduced is illustrated in Fig. 5.

It turns out that for conventional epitaxial structures the function $\mathbf{F}(z)$ is near unity. Then $\mathbf{F}(z)$ can be approximated for $z < 1.2$ within 1% and for $1.5 < z < 2$ within less than 4%, by

$$\mathbf{F}(z) = \frac{2}{z^2} + 0.25 \quad [12]$$

whence Eq. [9a] and [9b] can be written as

$$R_{ce} = R_{2114} - 1.77\, R_{2314} \quad [9c]$$

Physically this means that due to the epitaxial layer cylinder resistance the contact is dominated by the contact resistance R_{ce}, whereas the substrate sheet resistance is so small that there is a horizontal equipotential surface under the probe.

In order to show simply the feasibility of this technique, R_{ce} was first determined from the measured values R_{2314} and R_{2114} for a number of $SiCl_4$-grown n on n$^+$ structures. Thereupon the resistivity ρ was determined using Sze's and Irvin's curves (8); from the CV measured (1) dope concentration at a fixed depth of 4 μm, and with the IMI measured (9) thickness d, the value of R_y was calculated. It turned out then that R_y exceeded R_{ce} so that R_c was negative. Then a few structures were selected which were low doped and thin enough to be probed by the CV method (1) over the full depth of the epitaxial layer and the integral

$$R_y = \frac{1}{\pi A^2} \int_0^d \rho(x)\, dx \quad [13]$$

was determined. It was found that the IMI measured d includes a part of the transition layer which does not contribute at all to the cylinder resistance, and also that particularly for $SiCl_4$ grown slices, the dope concentration varies strongly with depth. Figures 6a and 6b show some typical profiles. Taking into account this real, reduced value of R_y a positive contribution due to contact resistance R_c was found. Some experimental data on the contact resistance of epitaxial layers measured in this way are presented in Table I and in Fig. 4. It is clear that the method can be used for evaluation purposes as described in the preceding section only when it is surely known that the dope atom concentration does not change with depth. This is the one restriction which hampers the use of the spreading resistance method for the evaluation of epitaxial layers, both with metal and mercury probes.

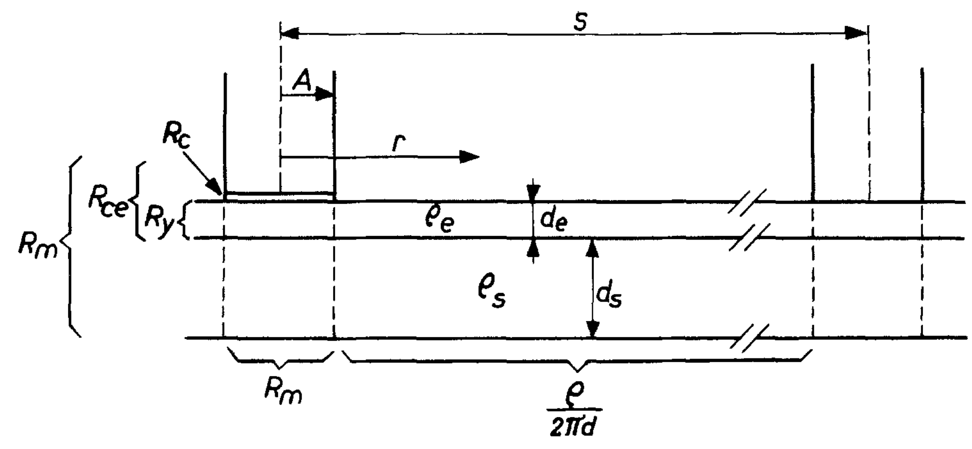

Fig. 5. The various parameters introduced for the measurement of the cylinder resistance on an n on n$^+$ structure presented schematically.

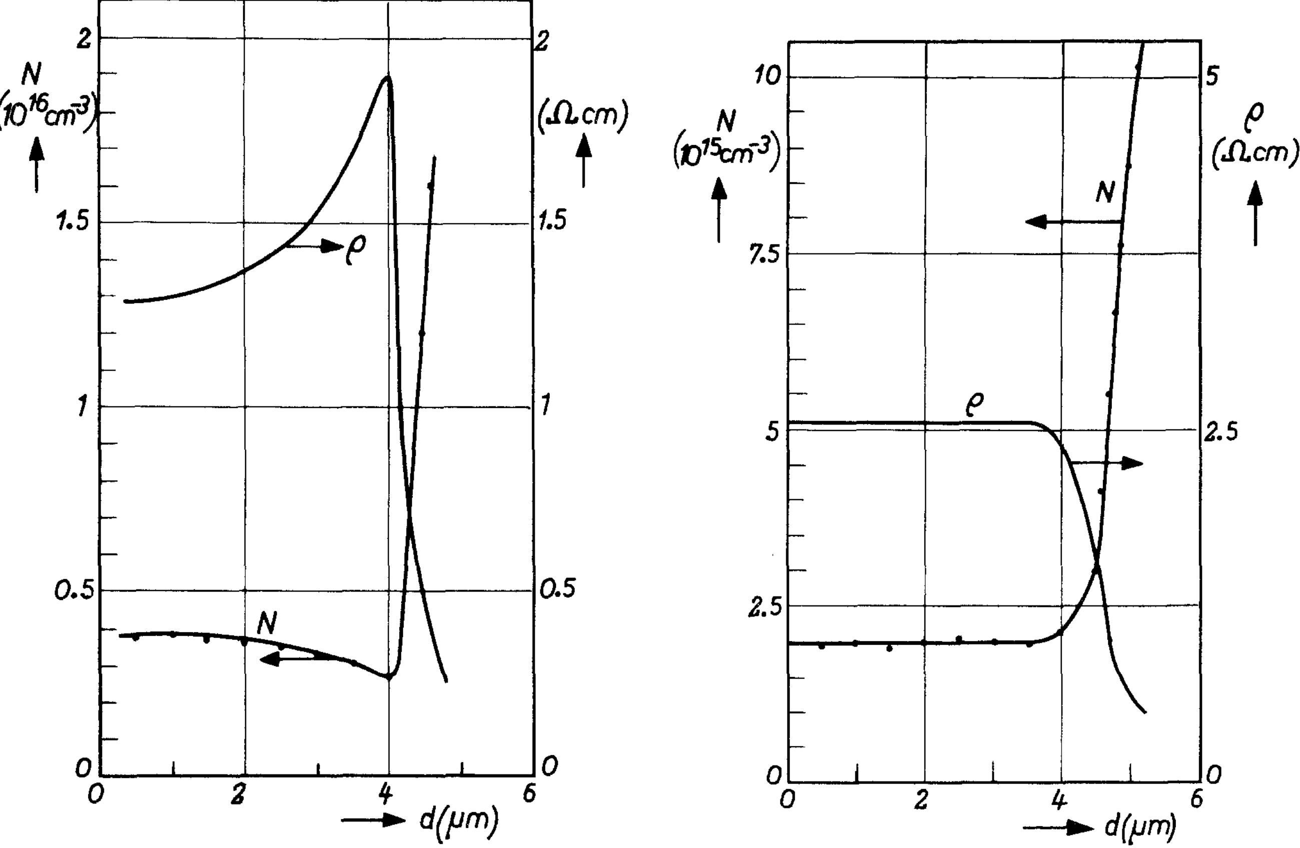

Fig. 6. The dope concentration N and ensuing resistivity ρ as a function of depth below the surface of an epitaxial n on n^+ structure. a, left: E2490-3, $SiCl_4$-grown; b, right: Ril 1345, SiH_4-grown. The IMI measured appropriately corrected thickness for a, left, 5.79 μm; and b, right, 5.96 μm.

Summary and Conclusions

An instrument with four identical mercury probes can be used most efficiently for at least four kinds of measurements. First with one probe connected to a high frequency capacitance bridge, immediate, precise, and accurate capacitance-voltage measurements can be done on substrates and epitaxial layers. An n-type silicon specimen should be slightly oxidized; p-type silicon can be measured without special preparations (1). For routine measurements the bridge can be an automated instrument of which several types are commercially available. Agreement of fpp with CV measurement data, converted with Sze's and Irvin's curves (8) to resistivity, has been obtained for substrates to within a few per cent.

Second, a freshly etched n-type silicon sample can be fpp measured with this instrument without leaving any damage. Agreement with conventional fpp instruments is within a few per cent (3).

Third, a structure prepared as above can be spreading resistance measured with this instrument, and on bulk samples the resistivity agrees within a few per cent with the four-point probe data. The resolving power of about 1 mm makes the mercury spreading resistance probe an interesting instrument, where the fpp would be too coarse and the conventional spreading resistance would be too fine. In addition it leaves no damage. The spreading resistance measured on layers of thickness $d \lesssim A$ should be corrected. A theory is used which integrates the effects of the contact resistance, R_c, into the final expression for the spreading resistance (7, 10). The parameters ρ/d and R_c are found in this way. When, as with conventional spreading resistance probe measurements, d has been obtained otherwise, the local value of ρ is found.

For an epitaxial n on n^+ structure tested in this way, the contact resistance consists of the cylinder resistance proportional to ρd and the real contact resistance in series.

It would be highly desirable to increase the precision of the method so that the contact resistance may be known from calibration, if necessary dependent on the surface preparation, in order to use the method for the determination of ρd of epitaxial layers.

Fourth, with the mercury probe a MIS diode can be made and pulse measured in order to evaluate simply and immediately the dope concentration directly below the surface and the bulk lifetime and surface recombination velocity. This will be the subject of a future paper.

APPENDIX

A current i_o enters a circular contact of radius A at potential V_o on a thin layer of infinite extent, of thickness $d << A$ and resistivity ρ, shown in Fig. 5. The current i_o leaves the structure through a contact at infinity at zero potential. The potential drops with r according to

$$\frac{\partial V(r)}{\partial r} = -\frac{\rho}{2\pi d}\frac{1}{r} \quad \text{for} \quad r \leq A \qquad \text{[A-1]}$$

and the current $i(r)$ which passes through a cylinder increases below the contact as

$$\frac{\partial i(r)}{\partial r} = 2\pi r J(r) \qquad \text{[A-2]}$$

because of the local voltage drop over the specific resistance R_c' given by

$$R_c' J(r) = V_o - V(r) \qquad \text{[A-3]}$$

Writing $R_s = \rho/d$ and $\Lambda^2 = R_c'/R_s$, Eq. [A-1]-[A-3] can be combined to yield the differential equation

$$\frac{\partial^2 V}{\partial r^2} + \frac{1}{r}\frac{\partial V}{\partial r} - \frac{V - V_o}{\Lambda^2} = 0 \qquad \text{[A-4]}$$

with solution in terms of the modified Bessel function of the first kind

$$V - V_o = aI_o\left(\frac{r}{\Lambda}\right) \qquad \text{[A-5]}$$

and hence

$$i = -\frac{2\pi d}{\rho}\frac{ra}{\Lambda}I_1\left(\frac{r}{\Lambda}\right) \qquad \text{[A-6]}$$

From the boundary condition $i = i_o$ at $r = A$ follows that with $z = A/\Lambda$ the potential drop over R_c at $z = 0$ equals

$$a = -\frac{\rho i_o}{2\pi d}\frac{1}{zI_1(z)} \qquad \text{[A-7]}$$

and that the resistance R_m measured between the contact and a point very near $r = A$ given by

$$R_m = \frac{\rho}{2\pi d}\frac{I_o(z)}{zI_1(z)} = \frac{\rho}{2\pi d}\mathbf{F}(z) \qquad \text{[A-8]}$$

The solution for $r > A$, where $J(r) = 0$ and $i = i_o$, follows from Eq. [A-1] as

$$V - V_o = \frac{\rho i_o}{2\pi d}\ln\frac{r_1}{r} \qquad \text{[A-9]}$$

The solutions of Eq. [A-5] and [A-9] should be matched; it can easily be verified that

$$V_o - V = \frac{\rho i_o}{2\pi d}\left(\mathbf{F}(z) - \ln\frac{r}{A}\right) \qquad \text{[A-10]}$$

In this way both the potential and its derivative, proportional to the current, are matched at $r = A$. A discrepancy which cannot be overcome is due to the fact that at $r = A$ the current density is maximum under the contact but vanishes at $r > A$. No doubt the approximation of J only perpendicular to the contact does not hold at the edge $r = A$, which affects the applicability of the theory less if $A >> d$. The equation actually used in the measurement arrangement can be obtained from Eq. [A-10] by superposition of the two potential systems: current i_o enters through probe 1 and leaves at infinity and current i_o enters at infinity and leaves through probe 4. The ensuing logarithmic potential drop has experimentally been found to exist precisely.

Oxygen Ion Conduction of the Fluorite-Type $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = Lanthanoid Element)

Tetsuichi Kudo and Hidehito Obayashi

Central Research Laboratory, Hitachi, Limited, Higashi-koigakubo, Kokubunji, Tokyo, 185, Japan

ABSTRACT

The compounds $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = lanthanoid element) have been synthesized and the emf and resistivity measurements have been carried out between 400° and 1000°C. It is found that charge carriers of conduction in these compounds are oxygen ions above 600°C; the oxygen transference number being above 0.95 for all measured compounds. The resistivity value for $Ce_{0.77}Gd_{0.23}O_{1.885}$ is 15 ohm-cm at 750°C which compares with that of calcia stabilized zirconia at 1000°C. It is found that the dependence of the resistivity on temperature is described by

$$\rho = (\rho_o)_L \exp(\Delta E_L/kT) + (\rho_o)_H \exp(\Delta E_H/kT)$$

for most of the compounds, where the (ρ_o)'s and ΔE's are empirically determined parameters. The activation energies of conduction are determined by the compounds' lattice constant so long as the dopant concentration is held constant. The activation energies increase as the dopant concentration x increases and ΔE_L and ΔE_H coincide at $x \geqq 0.4$.

There have thus far been numerous studies on the ZrO_2 family oxygen ion conductive solid electrolytes (1-3). However, it seems that systems other than the ZrO_2 family have attracted less interest and that a systematic approach is lacking. Several compounds having oxygen ionic conduction have been reported by Singman (4), Mazelsky (5), and Iwahara (6). These solid electrolytes, however, exhibit poorer char-

Key words: ionic conductor, solid electrolyte, cerium/lanthanoid oxide, solid solution.

acteristics both in resistivity and transference number compared with the ZrO_2 family.

Etsell and Flengas (7) published an excellent review on CeO_2-base solid electrolytes as well as ZrO_2-, ThO_2-base and other solid electrolytes.

The CeO_2 family oxygen ion conductive solid electrolytes have been widely and systematically synthesized and their properties investigated in this paper. The compounds are represented in a general formula $Ce_{1-x}Ln_xO_{2-x/2}$ where Ln stands for the trivalent lanthanoid element ranging from Y, La, to Yb.

Experimental

Sample preparation.—The oxides CeO_2 (99.99% up, Shinetsu Kagaku K.K.) and Ln_2O_3 (99.9% up, Shinetsu Kagaku K.K.) were precisely weighed and mixed in an agar mortar. The mixture was pressed softly (0.5 t/cm^2) in a die and placed in an alumina boat. It was heated to 1300°C and kept at this temperature for 8 hr. The presintered sample did not show any foreign peaks other than fluorite-type compound $Ce_{1-x}Ln_xO_{2-x/2}$ in an x-ray diffraction pattern. The sample was then ground in an agar mortar to −325 mesh. When needed, 3 mole per cent (m/o) magnesium was added as $Mg(NO_3)_2$. As a binder 1 weight per cent (w/o) methyl cellulose was added and ground again to −40 to −60 mesh. The powder was pressed in a die at 3 t/cm^2, then placed in a Pt-40% Rh basket and sintered at 1800° ± 20°C for 2-3 hr in air. The sintered samples showed a porosity of less than 4% in all cases.

Oxygen ion transference number measurement.—The average oxygen ion transference number $\bar{t}_{O^{-2}}$ is given by

$$\bar{t}_{O^{-2}} = \frac{E}{\frac{RT}{4F} \ln (p''_{O_2}/p'_{O_2})} \quad [1]$$

where symbol E stands for the observed emf of the cell

$$O_2(p'_{O_2}), \text{ Pt/Solid Electrolyte/Pt}, O_2(p''_{O_2}) \quad [2]$$

In the experiments reported here, $p''_{O_2} = 1$ atm and $p'_{O_2} = 0.21$ atm.

For measurement of emf, a vertical type gas flow apparatus was made, whose schematic profile is shown in Fig. 1. A 20 mm diameter and 1-2 mm thick disk sample was sandwiched between silver packings to which ceramic tubes were attached. The silver packings ensure the gas tightness of the cell at elevated temperatures. The gas tightness was further ensured by a spring placed at the upper end of the ceramic tube. A rotary pump vacuum test was carried out before each run to test for gas tightness. An inner gas guide pipe was placed in both the upper and lower rooms so that both electrodes were exposed to fresh gas throughout each run. Oxygen gas was introduced into the upper room and air was introduced into the lower room.

Income gas flow rates were between 50 and 100 ml/min, and the gas was not preheated. Calculated linear flow rates for these conditions were around 0.5-1.0 cm/sec assuring that the gas is well heated to the equilibrium temperature of the furnace. The temperature of the sample was measured by a Pt-(Pt-Rh13) thermocouple and a cooling effect of incoming gas was proved to be negligibly small in the employed experimental conditions.

Resistivity measurement.—The electrical contacts were made using platinum paste electrodes to both sides of a disk sample. An a-c impedance bridge method was employed usually. An RC701 (Matsushita Electric) type frequency generator was used, and the bridge was an BV-Z-1 (Yokogawa Electric) type direct reading impedance bridge. The frequency used was 1 kHz. In the a-c measurements, the resistance of the platinum lead wire was compensated. In some

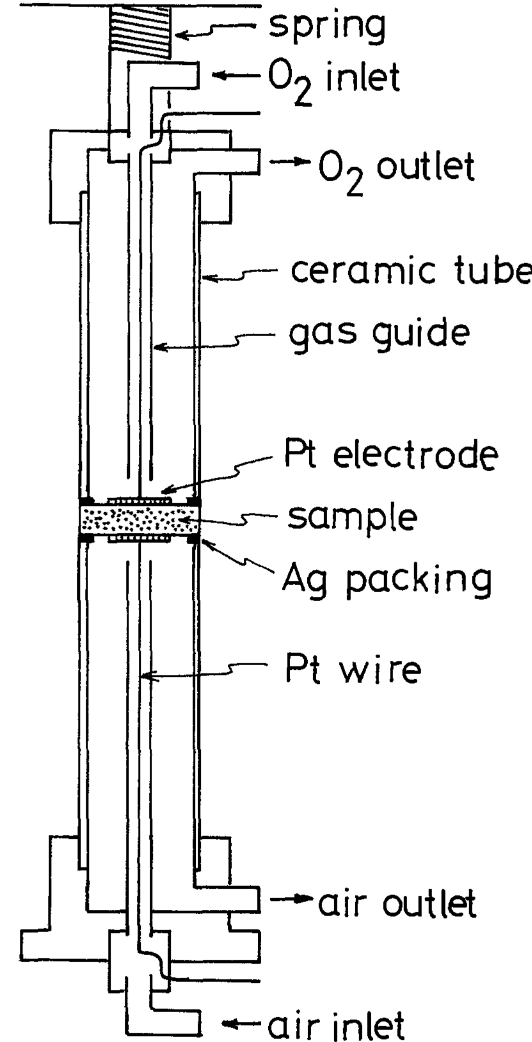

Fig. 1. Schematic drawing of emf measurement cell. The cell is placed in a vertical type furnace and the temperature is controlled within ±2°C. EMF was measured by a potentiometer.

cases, d-c four-probe method was employed. In the d-c measurements, 30 × 10 × 5 mm rod samples were used. Two platinum wires (0.3 mmφ) which work as the potential drop measurement probes were spanned on a flat and smooth alumina plate. The current flowing porous platinum paint electrodes were attached to far ends of the rod sample. This rod was placed on that plate and on the sample was another alumina plate on which a 100g platinum rod was placed. This rod was used to ensure the contacts between the sample and the spanned platinum probes. The potential drop between two probes during the constant current flow was measured by a potentiometric Hitachi QPD54 recorder. At the initial stage of this work, platinum wire probes were placed in 0.3 mm wide and 0.3 mm deep ditches surrounding the sample separated by 10 mm. However, it was assured that the above method gives the same result, therefore, we have changed to the easier method.

The uniformity of the temperature in the furnace was increased by covering a quartz tube with 1 mm thick nickel tube. At the same time, one end of the nickel tube was grounded so as to eliminate electric noises from the external field.

X-ray diffraction.—Usually, Cu K_α or Fe K_α radiation were used. The scanning speed was 2θ/min = 1°/min. For the determination of lattice constants, diffractions from (620) and (533) planes were used when Cu K_α was employed while (422) and (511) planes were used when Fe K_α was employed. For some samples, high temperature x-ray diffraction measurements

were carried out at temperatures between room temperature and 1000°C.

DTA measurement.—DTA measurements were carried out using a Type M8006 macro DTA and a Type M8076 micro DTA apparatus (Rigaku-denki K.K.). Sample weights were 1.7-1.9g for macro and 10-50 mg for micro DTA measurements, respectively. The differential thermocouple used was Pt-(Pt-Rh13)-Pt thermocouple and one junction attached to reference (α-Al_2O_3) worked as temperature detecting thermocouple. Measurements were carried out between room temperature and 800°C and the speed of temperature rise was fixed to 20°C/min throughout all the measurements.

Result and Discussion

Crystal structure.—The compound CeO_2 has a fluorite-type cubic crystal structure. When trivalent lanthanoid ions Ln (Ln = Y, La, to Yb) replace the Ce ion sites of the fluorite lattice, the modified formula is generally expressed as

$$Ce^{+4}{}_{1-x}Ln^{+3}{}_xO^{-2}{}_{2-x/2}(V_{O^{-2}})_{x/2} \quad [3]$$

where $V_{O^{-2}}$ stands for the oxygen ion vacancy generated to compensate charges in the crystal.

The CeO_2-Ln_2O_3 system has a wide solid solution region of fluorite-type lattice and the compounds $Ce_{1-x}Ln_xO_{2-x/2}$ show the pure fluorite lattice pattern up to *ca.* $x = 0.5$. The lattice constants of $Ce_{1-x}Ln_xO_{2-x/2}$ ($x = 0.3$) are summarized in Table I. This table also contains several three component compounds, where the sum of the substituting components is $x = 0.3$. As seen from this table, the lattice constants decrease as the ionic radii of the substituting ions become smaller. When the system contains two kinds of substituting ions, the lattice constants fall into the intermediate values of two respective single-substituting ion cases. Thus it appeared that the lattice constant additivity rule holds in the system $Ce_{1-x}Ln_xO_{2-x/2}$.

Figure 2 shows the lattice constant change when the amount of Gd substitution was changed. Magnesia, like Ln_2O_3, dissolves into the lattice to form a solid solution. This was proven by the fact that the lattice constants of MgO-free compounds were larger than those of MgO-added compounds and the fact that there were no x-ray diffraction peaks comprising MgO. The saturation of lattice constant at $x \geqq 0.4$ does not necessarily mean that the solubility limit exists at $x = 0.4$. Bevan, Barker, and Martin (8) interpreted that this saturation is due to the Gd^{3+} ions and oxygen vacancies' strong interaction and that point defects are complexed. A similar phenomenon was observed by Brauer and Gradiger (9), and they also observed a

[a] Scandium does not form fluorite lattice with cerium.
[b] Notations like 1Sm-4Ho mean the atomic ratio of Ln, thus, the exact formula for 1Sm-4Ho is $Ce_{0.7}Sm_{0.06}Ho_{0.24}O_{1.85}$.
[c] Lattice constant values are valid to the final digits.
[d] Activation energies and (ρ_o)'s are valid within ±0.5 of the final digits.

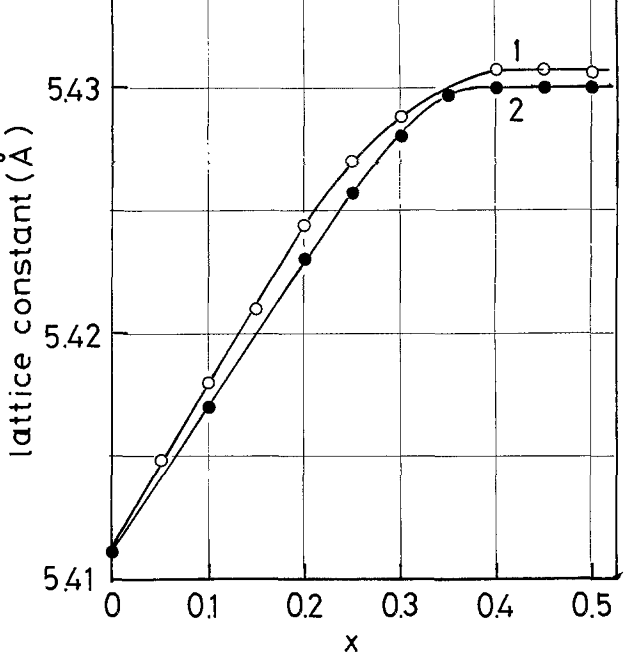

Fig. 2. Lattice constant change of $Ce_{1-x}Gd_xO_{2-x/2}$ as Gd content is changed. Curves 1 and 2 represent data for MgO free and 3% MgO added samples, respectively.

sharp decrease of lattice constant at $x \geqq 0.5$. As the fluorite lattice and the c-type Gd_2O_3 give quite similar x-ray diffraction patterns, it is difficult to determine the solubility limit precisely by this method. In our measurements, diffraction lines caused by the existence of superlattice in the compounds which could appear for c-type oxide, were not observed up to $x = 0.5$. Above this value, weak lines from superlattices were observed. Thus, it is reasonable to conclude that the system CeO_2-Gd_2O_3 keeps the fluorite lattice up to $x = 0.5$.

Figure 3 shows the lattice constant increase of the compounds $Ce_{1-x}Gd_xO_{2-x/2}$ as the temperature is raised. The change of the lattice constant is almost linear regardless of composition, in the temperature range between room temperature and 1000°C. The average linear expansion coefficient of these compounds as calculated from Fig. 3 is $\beta = 12.6 \times 10^{-6}$ $°C^{-1}$ for the three compounds measured. The compounds $Ce_{1-x}Gd_xO_{2-x/2}$ do not have any transitions

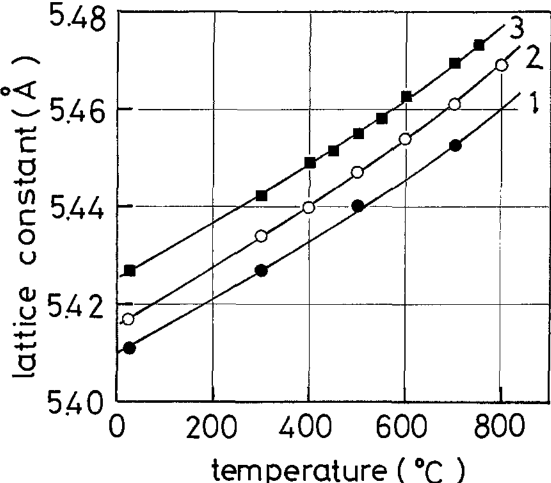

Fig. 3. Thermal expansion of lattice constants for $Ce_{1-x}Gd_xO_{2-x/2}$. Curves 1, 2, and 3 are for x = 0, 0.1, and 0.2. The average linear thermal expansion coefficient for these compounds are 12.6×10^{-6} $°C^{-1}$.

observable by x-ray diffraction in this temperature range.

Oxygen ion transference number.—The charge carrier of the conduction is considered to be O^{-2} ion. In this section, results of oxygen ion transference number measurements are presented.

Figure 4 is the change of oxygen ion transference number as the temperature is changed. The emf measurement cell setup was expressed in Eq. [2].

At temperatures lower than 400°C, the resistivity is so high that it prohibits the emf measurements. The emf value deviated from the theoretical one at temperatures below 600°-700°C for all samples. The reasons were considered to be as follows. The porous platinum paste electrode does not function as a reversible oxygen electrode at lower temperatures, suggesting a reaction polarization becomes critical at these temperatures. In this sense, Fig. 4 does not show the correct transference numbers for these samples at temperatures below 600°-700°C. Silver electrodes would have been better at lower temperatures as reversible oxygen electrodes. Above these temperatures, however, all the investigated compounds showed stable and reproducible emf values. The transference number for $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = Sm and Dy) saturates at 0.95-0.96, whereas the other compounds containing Nd, Gd, and Er gave unity as their transference number. The reason of deviation of transference number from unity in the cases of the compounds containing Sm and Dy is not known yet, however, the porosities of the two samples were measured to be a little larger than the other samples suggesting there existed some open pores in these samples.

From these data and in view of the analogy of crystal structure with ZrO_2, it was concluded that the charge carrier of conduction in Ce_{1-x}-$Ln_xO_{2-x/2}$ in air is the oxygen ion.

Resistivity measurement.—Figures 5 and 6 show the relation between log resistivity and the reciprocal temperature for the compounds $Ce_{0.7}Ln_{0.3}O_{1.85}$ (Ln = Y, La, Eu, Sm, Gd, Dy, Ho, Er, and Yb). All plots show the two differing slope lines. Around the intersection of two lines, however, data deviated from linear lines toward the high resistivity side. The resistivity values of these compounds are very small (1/10 to 1/1000) compared with those listed by Etsell and Flengas (7). However, the resistivity measurements by a-c and d-c methods gave good agreement and they are quite reproducible as shown by the plots in Fig. 5 and 6, it is believed that our data represent true resistivities for these compounds.

Figure 7 shows the resistivity isotherms against lattice constant. In these plots, resistivity values ρ were

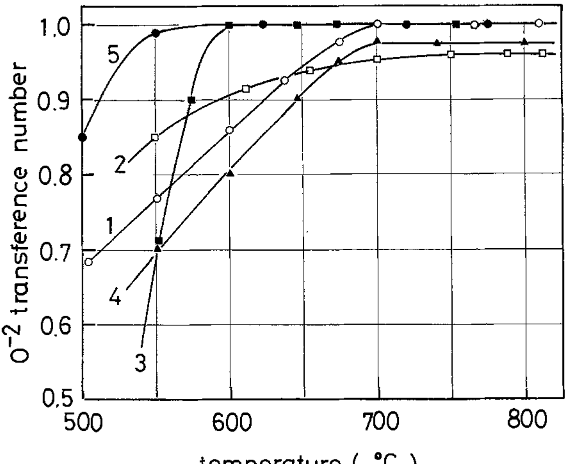

Fig. 4. Oxygen ion transference number of the compounds $Ce_{1-x}Ln_xO_{2-x/2}$ (x = 0.3). Curves 1-5 are for Ln = Nd, Sm, Gd, Dy, and Er.

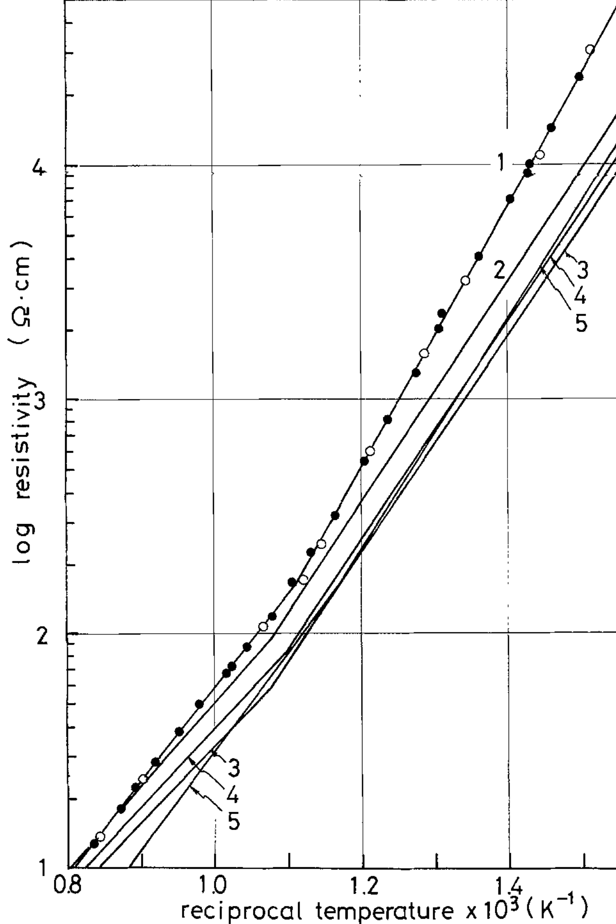

Fig. 5. Arrhenius plot of resistivity for the compounds $Ce_{1-x}Ln_xO_{2-x/2}$ (x = 0.3). Lines 1-5 are for Ln = Y, La, Nd, Sm, and Er. Filled circles are for rising temperature, and open circles are for lowering temperature measurements.

corrected in consideration of samples' porosity according to Juretschuke's formula (10)

$$\rho = \frac{1-\epsilon}{1+\frac{\epsilon}{2}}\rho_{obs} \qquad [4]$$

where symbol ϵ stands for the porosity of samples. Each isotherm has its minimum resistivity value at a certain lattice constant. This provides a guideline for the minimization of the resistivity at various temperatures. For example, in order to get a low resistivity solid electrolyte at 800°C, it would be advisable to investigate the compositions whose lattice constants range from 5.43 to 5.44Å. The fact that there exists a minimum resistivity value in the resistivity and lattice constant plot suggests the existence of a certain compensation rule between pre-exponential term ρ_0 and the activation energy ΔE in the Arrhenius-type formula.

The resistivity change of the compounds $Ce_{1-x}Gd_xO_{2-x/2}$ *vs.* temperature is shown in Fig. 8. At temperatures lower than 350°C, some samples showed small ΔE of conduction which suggested the onset of an electronic conduction; however, the data were lacking in reproducibility.

In the temperature range where the oxygen ionic conduction is predominant, the plot of resistivity *vs.* the reciprocal temperature could well be approximated by two linear lines. Similar results were obtained by Bauerle and Hrizo (11) for $(ZrO_2)_{0.90}(Y_2O_3)_{0.10}$. They proposed two hypotheses which yield such a temperature dependence; one being the vacancy trapping by yttrium ions, and the other, the grain boundary effect.

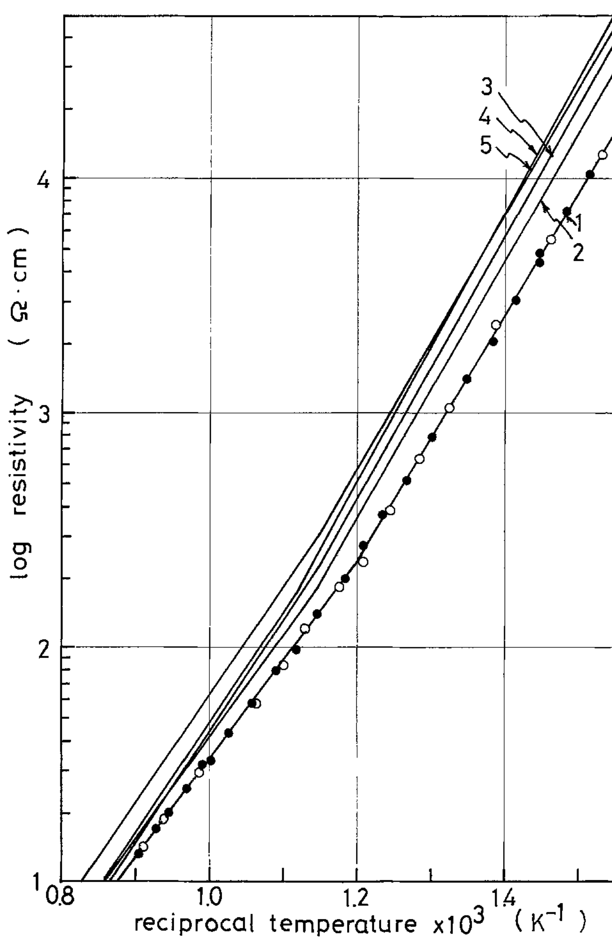

Fig. 6. Arrhenius plot of resistivity for the compounds $Ce_{1-x}Ln_xO_{2-x/2}$ ($x = 0.3$). Lines 1-5 are for Ln = Gd, Dy, Ho, Er, and Yb. Filled circles are for rising temperature, and open circles are for lowering temperature measurements.

These hypotheses are open to discussion, however, if the log ρ *vs.* T^{-1} relation was approximated by the two linear lines, it means that we assumed two Arrhenius-type formulas

$$\rho = (\rho_o)_L \exp(\Delta E_L/kT) \quad \text{lower temp region}$$
$$\rho = (\rho_o)_H \exp(\Delta E_H/kT) \quad \text{higher temp region} \qquad [5]$$

Then the temperature range could appropriately be divided into two regions, the boundary being the intersection point of the Arrhenius plot. The calculated (ρ_o)'s and ΔE's are listed in Table I. The lower temperature region has a larger activation energy and the higher temperature region has a lower activation energy. The activation energy of CeO_2-15% La_2O_3 as given by other workers are 14.7 (12) or 21.0 (4) kcal/mol (0.64 or 0.91 eV). Our results of activation energy for Ln doped compounds fall in the range of 0.77-0.93 eV for high temperature region conduction. Thus, data by Croatto and Mayer (12) seem to be too small. The calculated activation energies of conduction were interpreted in terms of lattice constant. The result is shown in Fig. 9.

The lattice constant a_o of $Ce_{0.7}Ln_{0.3}O_{1.85}$ changes in the range from 5.38Å (Ln = Yb) to 5.50Å (Ln = La). The activation energies of conduction ΔE_L and ΔE_H pass the maximum values at $a_o = 5.39$Å, then they decrease as the lattice constant becomes larger. In the range where $a_o \geqq 5.45$Å, both activation energies ΔE_L and ΔE_H seem to be determined not by the kind of lanthanoid elements but by the value of lattice constant.

If the dopant concentration x is varied, the above discussion no longer holds. Figure 10 shows the activation energy change when the dopant concentration x is varied for the compounds $Ce_{1-x}Gd_xO_{2-x/2}$ ($0 \leqq x \leqq 0.5$). As seen from this figure, the activation energy remains comparably constant in the range $x \leqq 0.2$. The values increase rapidly as x is increased in the range where $0.3 \leqq x \leqq 0.4$. The sharp increase of activation energies in this range is paralleled by the saturation range of lattice constants. We suggested that interaction between vacancy-vacancy and vacancy-doped ion begins to start. Here, again this sharp increase could be attributed to this effect reducing the mobility of oxygen ion vacancies. Above $x = 0.4$, the activation energies of lower and higher temperature regions coincide and the value increases gradually as x is increased. Heyne (13) argues that in stabilized ZrO_2, the conductivity increase cannot be interpreted by the simple concept of a conductivity proportional to the vacancy concentration. In CeO_2 base compounds, however, this concept can explain the increase of conductivity at least in the range $x \leqq 0.2$.

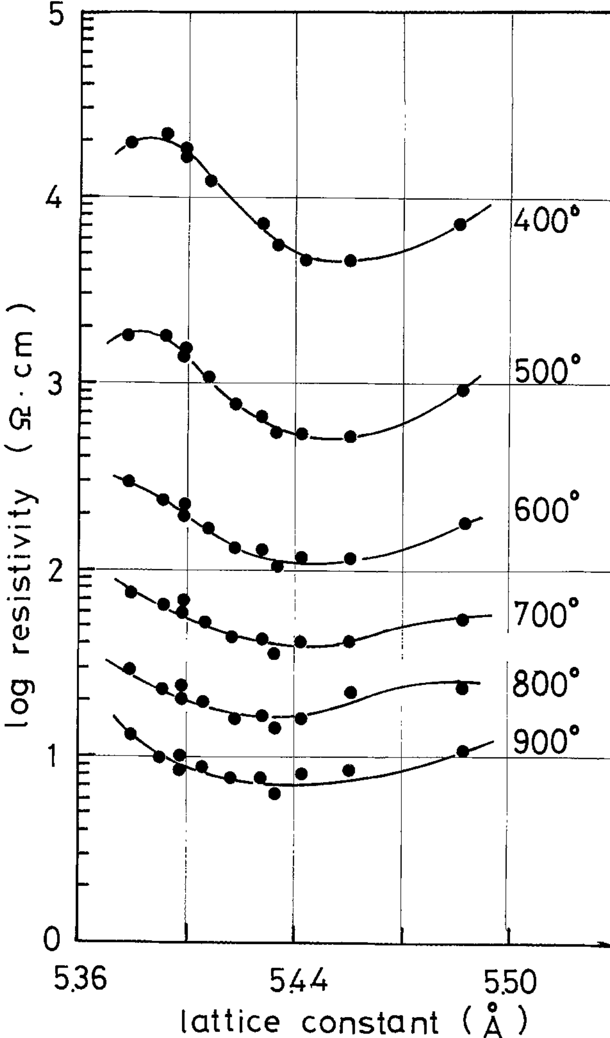

Fig. 7. Resistivity isotherms as summarized *vs.* lattice constant for the compounds $Ce_{1-x}Ln_xO_{2-x/2}$ ($x = 0.3$).

As mentioned before, the cause of the existence of two activation energies of O^{-2} conduction is not known at present, however, it was observed by DTA measurements that the base line of the DTA curve deviates to the endothermic side at temperatures near 500°C for the compounds $Ce_{1-x}Gd_xO_{2-x/2}$ ($0 \leqq x \leqq 0.5$) suggesting an increase of the specific heat of the compounds. This increase does not necessarily mean the existence of transition in the crystal lattice as x-ray measurement revealed no pattern change between lower and higher temperatures. However, it seems likely that some higher order transition other than lattice type change occurs around 500°C and that this is the reason for the existence of kinks in the Arrhenius plots of

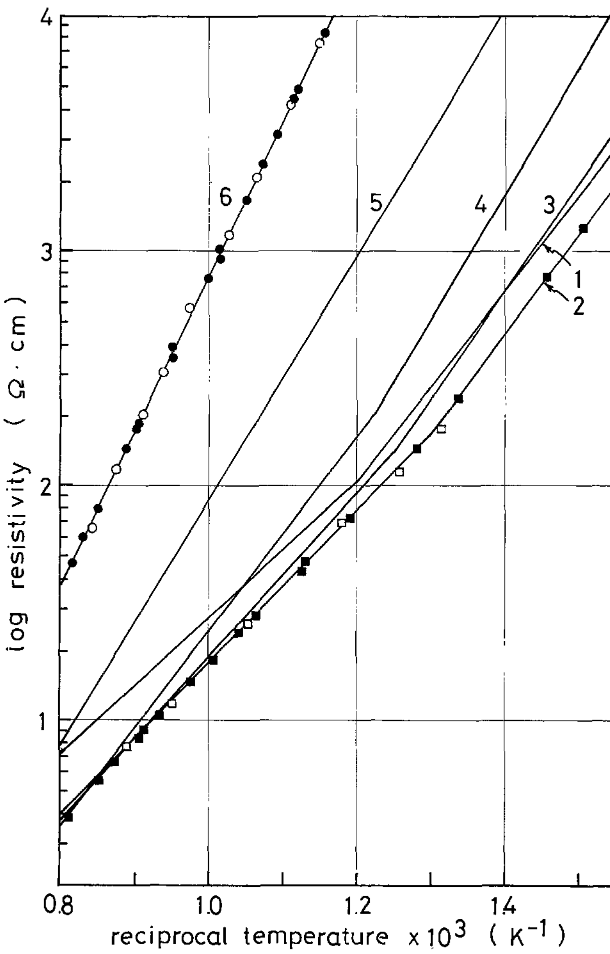

Fig. 8. Arrhenius plot of resistivity for the compounds $Ce_{1-x}Gd_xO_{2-x/2}$. Lines 1-6 are for x = 0.1, 0.2, 0.25, 0.3, 0.4, and 0.5. Filled plots are for rising temperature, and open plots are for lowering temperature measurements.

resistivity. Further study is underway and the results will be published elsewhere.

Conclusion

The CeO_2 base fluorite-type solid solution $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = lanthanoid element) can be characterized as a family of good conductive oxygen ion solid electrolytes. The following are the conclusions derived from this study.

1. The transference number of the oxygen ion as measured by an emf cell method using the oxygen concentration cell is greater than 0.95 at temperatures

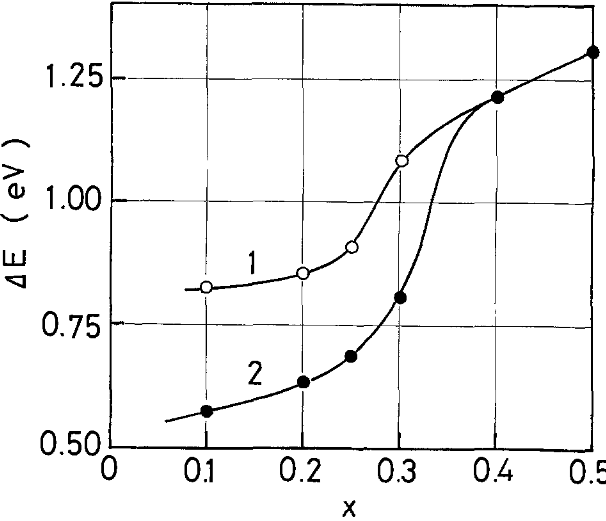

Fig. 10. Activation energy of oxygen ion conduction for the compounds $Ce_{1-x}Gd_xO_{2-x/2}$. Curves 1 and 2 are for low and high temperature regions. Above x = 0.4, both activation energies coincide.

above 600°C for $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = Nd, Sm, Gd, Dy, and Er).

2. The compounds $Ce_{1-x}Ln_xO_{2-x/2}$ (x – 0.5; Ln = Y, La, Nd, Sm, Eu, Ho, Er, and Yb) are single phase fluorite-type solid solutions. The compounds containing Sc do not form a solid solution in the same range.

3. The Arrhenius type plot of resistivity is well approximated by two linear lines in the temperature range $T \geqq 400°C$. At lower temperatures electronic conduction is observed in some compounds. The resistivity of $Ce_{1-x}Ge_xO_{2-x/2}$ (x = 0.23) at 750°C is 15 ohm-cm which rivals the value of calcia stabilized zirconia at 1000°C. The slope of the Arrhenius plot gives the activation energy of oxygen ion conduction, the value of which is determined by the dimension of the crystal lattice so long as dopant concentration x is kept constant. For x = 0.3, ΔE's pass the maximum values at a_0 = 5.39Å.

Charge Storage and Stoichiometry in Electron Beam Evaporated Alumina

Konrad M. Eisele

Institut fuer Angewandte Festkoerperphysik, Freiburg, Germany

ABSTRACT

Alumina films have been evaporated by means of an electron beam onto metal electrodes on ceramic substrates. A metal-oxide-metal structure has been subjected to an electric field and the resulting charge storage measured by recording the short circuit current. The charge storage has been related to the stoichiometry of the alumina film which in turn has been influenced by the beam power or by postdeposition treatment. The effect of electric field and temperature on the charge stored has been studied.

In a recent publication (1) aluminum oxide films have been examined for their ability to act as a barrier against alkali ion migration. This property makes such films useful as a passivation layer for integrated circuits. In these applications a low temperature process to generate the Al_2O_3 film is desirable. For this reason electron beam evaporation was considered.

It is known that this method yields Al_2O_3 films which are nonstoichiometric to various degrees. Hoffman and Leibowitz (2) showed that the stoichiometry can be regulated by controlling the potential of the substrate in such a way that secondary or reflected primary electrons coming from the hearth cannot build up charge which repels arriving oxygen ions. Whenever oxygen atoms emanate from Al_2O_3 under electron bombardment, part of these will be pumped away by the vacuum system and necessarily a certain lack of stoichiometry must result.

To study the electrical properties, especially charge storage as related to the stoichiometry of the oxide, we manufactured Al-Al_2O_3-Al sandwiches by means of an electron gun.

The Metal-Alumina-Metal Capacitor

The active area of the device (Fig. 1) was 0.185 cm^2, and the oxide thickness varied between 4,200 and 28,000Å resulting in capacities from 150 to 24 pf/mm^2. The substrate was glazed ceramic. The structure was obtained by evaporating through nickel masks; no etching was employed. Four different metals were used as electrodes. The deposition rates of the aluminum oxide varied from 10 to 400 Å/min. The power of the electron beam determined the deposition rate but also the decomposition of the source material.

In view of Ref. (2) the quantity of stray electrons responsible for charge buildup increases with the power of the primary beam. In our arrangement the masking device as well as the bottom electrode was grounded, so that secondary or reflected primary electrons moved between points of equal potential, *i.e.*, between the grounded hearth and the substrate.

At a power level of about 320W (4 kV, 80 mA) a blue glow appeared over the source material. The pressure in the vacuum system, usually in the low 10^{-6} Torr range, increased at this point indicating the liberation of oxygen from the aluminum oxide. With greater beam power the resulting Al_2O_3 film became increasingly darker in color. In addition the source material turned dark indicating loss of oxygen.

The influence of the electron beam acceleration voltage on the film composition was established by electron microprobe analysis and then correlated with the charge storage measurements. The index of refraction was derived from ellipsometer readings as being 1.762 compared to 1.765 for the bulk material and was the same for all samples. Electron diffraction analysis revealed no crystallinity. The electrical measurements could not distinguish between films deposited at various substrate temperatures in the range from 670° to 77°K. The best films were able to withstand fields as high as 5×10^6 V/cm.

Comparative measurements will be presented of two samples designated D_2 and D_4 representing the typical properties obtained with low and high beam power, respectively. For plate D_2 the evaporation of the Al_2O_3 was performed with low beam voltage (2.9 kV; 125 mA) and correspondingly low deposition rate (110 Å/min). The film was clear, of very low conductivity, and exhibited low charge storage. In contrast D_4 was deposited with high beam voltage (8 kV, 170 mA) at a rate of 410 Å/min which resulted in a dark film with a relatively high conductivity and charge storage. Between these extremes, various degrees of oxygen deficiency were produced.

Charge Storage in the Aluminum Oxide

Trap states have been encountered in various experiments with insulating films. They can store charge to change the space charge distribution in the insulator (3). Because the number of free electrons in an insulator is very small, a relatively small number of electrons getting trapped will suffice to change the charge distribution markedly.

One can assume that at a given temperature an equilibrium situation is established whereby a certain number of the traps are charged. If the metal-oxide-metal sandwich is now connected to a battery (Fig. 2), electrons will fill traps at the negative electrode and will leave them at the positive electrode. After the sample is disconnected the charge distribution is no longer in equilibrium. If the two metal electrodes are then

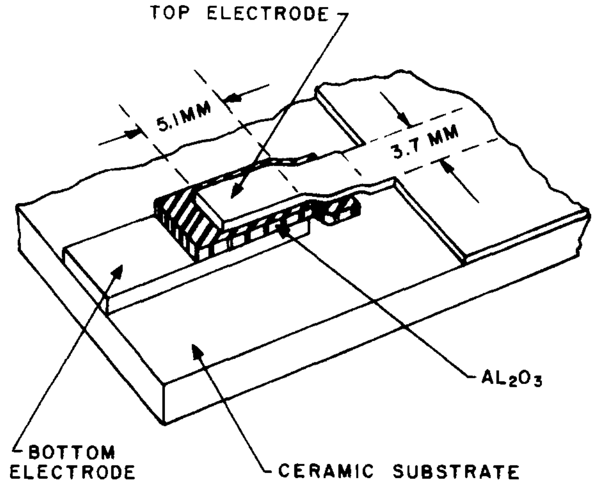

Fig. 1. Sample structure

Key words: Al_2O_3 films, stoichiometry, charge storage.

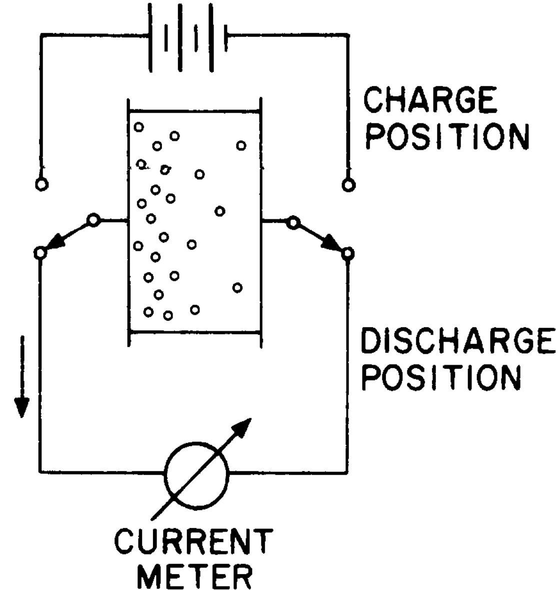

Fig. 2. Principle of charge storage measurement

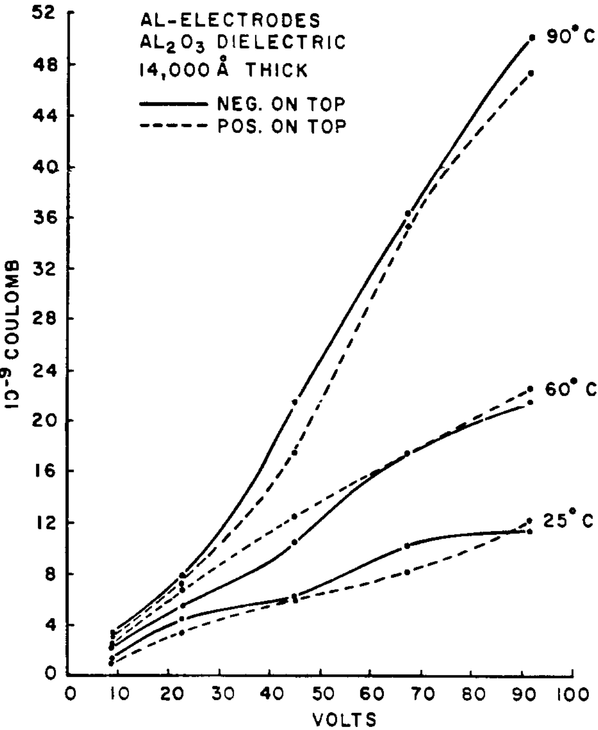

Fig. 3. Charge stored in dependence on voltage and temperature

shorted by an external conducting loop the electrons will flow in such a way as to restore equilibrium. This current was measured to investigate the number and the behavior of the trap states.

It is necessary to note that if the trapped charge was uniformly distributed in the oxide, no current would be measured in the outside loop. For this reason it is not entirely obvious that the measured current is proportional to the charge stored.

The following observation induced us to use this current as a representative quantity for investigating the alumina film. The stored charge increased measurably with the time the capacitor was connected to the voltage source but only during the first 30 min and stayed constant thereafter. Charging times of several hours did not equalize the charge distribution which would have resulted in a reduced or vanishing discharge current. There was also no saturation observed with increasing fields. In several attempts the voltage was increased to produce fields of 6×10^6 V/cm until breakdown occurred without the measured charge leveling off. In films that had low leakage up to high voltages, the increase of charge storage with voltage was close to linear. An example is presented in Fig. 3.

There have been cases (4) reported in which the charge distribution was opposite to the situation described here. But the reproducibility and the consistency with which we found the electron-injecting electrode always next to the volume of higher charge storage lead us to accept the current as a measure of the number of chargeable traps present.

For comparative measurements the voltage applied was 48V, the charging time was chosen to be 1 hr and so was the discharge time over which the current was integrated to determine the charge stored, although the discharge continued for several hours more. The contribution of the capacitive discharge to the recorded charge was not measurable because the RC product of the circuit was always $< 10^{-3}$ sec, too small to appear on the graph.

Four methods are available to influence the oxygen content of the film: (*i*) to evaporate at various oxygen pressures, (*ii*) to use different acceleration voltages on the electron beam, (*iii*) to control the substrate potential, and (*iv*) to heat the film in an oxidizing atmosphere. Table I lists the results of an experiment on three plates each with several capacitors. The film subjected to the most intensive oxidation process showed the least charge storage. Even more conclusive evidence is obtained when the same film is successively subjected to various degrees of oxidation. To this end the charge storage of a device was measured before and after heating to 350°C in air for 6 hr. The average charge storage changed from 1440.8 to 165 nC. This change in storage capability supports the argument that the traps are associated with missing oxygen atoms.

To exclude the possibility of the heat-treatment alone reducing the traps, a plate was prepared on which the film was measured after manufacture, then fired at 380°C for 7 hr in dry hydrogen, and finally fired at 380°C for 7 hr in oxygen. The results for two samples are listed in Table II. No appreciable change was observed after the hydrogen firing, but the oxygen firing did reduce the trap density.

The dependence of the charge storage on temperature is shown in Fig. 3, which is typical of the many graphs plotted. When the dielectric is heated it stores considerably more charge than when cold. Conversely, when the film is cooled to liquid nitrogen temperature, charging or discharging of traps stops immediately. Discharge will continue after warm-up at the rate obtained prior to immersing the plate in the coolant. While

Fired in O_2 380°C, 7 hr	270 266

the substrate is at liquid nitrogen temperature, no charge can be stored.

In many samples the charge storage was not symmetric with respect to polarity even though both electrodes were of the same material. Almost invariably the larger amount was stored when the negative electrode was on top, that is, near the oxide that had been deposited last. The source material has been subjected to electron bombardment for a longer time and consequently was more oxygen depleted.

Critical comparisons between various metal electrodes have to be made on the same slide. To this end a slide was prepared on which the bottom electrodes were all aluminum and only the top electrodes differed. They were of gold, copper, aluminum, and indium. The results are listed in Table III. Gold achieved the largest storage and aluminum the least. This was also evident from a slide (Table IV) in which the top and bottom electrode were of the same metal. Unfortunately the barrier heights of these metals against Al_2O_3 published by Hurst and Ruppel (5) do not explain the variation in charge storage. More recent measurements of the Al-Al_2O_3-Al work function (6, 7), differ substantially from those of Hurst and Ruppel. For thermally oxidized aluminum Gundlach (6) measured 1.6-1.8 eV; for an aluminum electrode evaporated onto the oxide he measured values larger than 2.3 eV. Antula (8) also reports that the barrier in question depends on the process by which the Al_2O_3 film was made. This adds more complexity to the problem but may provide the key to the differences in conductivity of the various samples.

Under the assumption of the traps being distributed in the bandgap, Lindmayer (8) derived a 1/time dependence of the discharge current. Although we did find a 1/time dependence (Fig. 4) for some of the samples, a $1/t^m$ with $m = 0.35 \ldots 0.44$ was frequently found.

D-C Measurements

As mentioned earlier, the insulating films of the plates D_2 and D_4 were produced with low and high beam voltage, respectively. Correspondingly their charge storage differed widely. D_2 stored 45 nC and D_4 350 nC. These plates were chosen for the I-V measurements. A process considered relevant for the transport of electrons in the Al_2O_3 film is the Poole-Frenkel effect. The electrons tunnel into trap states from which they escape again by field-enhanced thermal excitation to be trapped again further down the field. This process repeats until the opposite metal electrode is reached. Following Mead's analysis (10) log I is plotted *vs.* $v^{1/2}$

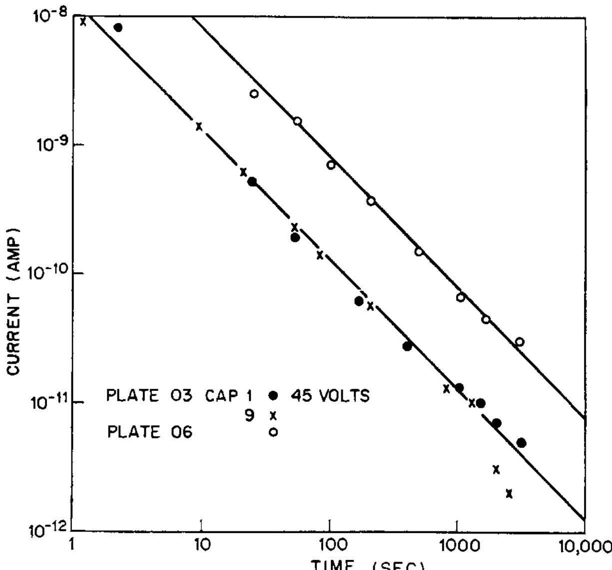

Fig. 4. Discharge current vs. time

in Fig. 5. The dashed line represents the slope obtained from the equation for space charge limited current using the static dielectric constant of $\epsilon = 8$. The corresponding current density is

$$J_1 = C_1 E \exp\{(\beta v^{1/2} - q\phi)/kT\} \quad [1]$$

with

$$\beta = \sqrt{q^3/\pi \epsilon \epsilon_0 d} \quad [2]$$

where C_1 is a constant, E the electric field, v the voltage, ϕ the depth of the trap potential well, q the electronic charge, and d the thickness of the film. If the current is controlled by the metal-insulator barrier rather than the bulk of the dielectric, the slope is half of the value in Eq. [2]. This is entered in Fig. 5 as a

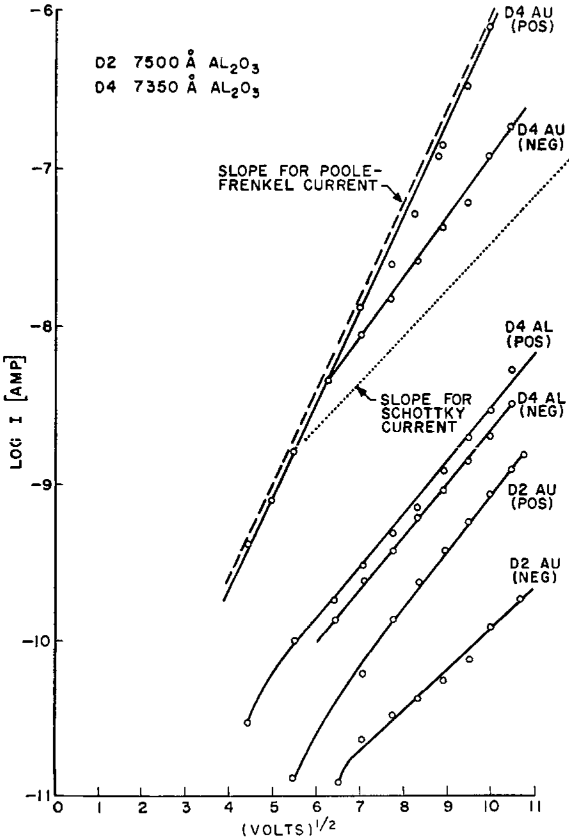

Fig. 5. Current-voltage characteristics

dotted line. For high fields the logarithm of the current followed a straight line. The current depended on the electrode material, the polarity, and it showed differences for oxides obtained under various conditions. Usually a dependence of current on polarity suggests an electrode-controlled transport mechanism. In the case presented here a sensitivity to polarity may be caused by differences in the oxide deposited at the beginning and the end of the evaporation as mentioned previously. The vertical position of the current-voltage curve is governed by the potential barrier ϕ and the density of the trap sites. The latter depends on the oxygen deficiency as derived from charge storage measurements. The slope of the straight section of the plot is controlled only by the dielectric constant and the thickness of the film. The question arises as to which dielectric constant should be used (11). The bulk dielectric constant of highly crystalline Al_2O_3 is as high as 13 from d-c to microwave frequencies and 3.1 at optical frequencies. The dielectric constants of these films were measured to be between 7.3 and 9.8, a difference too small to explain the differing slopes of the I-V characteristic in Fig. 5.

The current transport by means of trap states is temperature dependent as required by Eq. [1]. From charge storage measurements we recall that at some temperature below 0°C the movement in and out of traps was unmeasurable. Therefore, if we measure the dependence of the current on temperature we should find a corresponding behavior. This is indeed borne out by measurements plotted in Fig. 6. Below 260°K the current is independent of temperature as seen with sample D_6 which was typical of those measured over the available temperature range. Above 400°K the current rises steeply. The slopes of the straight portions of the current rise in Fig. 6 can be used to calculate the activation energy of the traps. To this end we write Eq. [1] as follows

$$\ln J = \ln C + \ln E - \frac{1}{T}\left(\frac{\beta v^{1/2}}{k} - \frac{q\phi}{k}\right)$$

where the term in brackets represents the slope of the

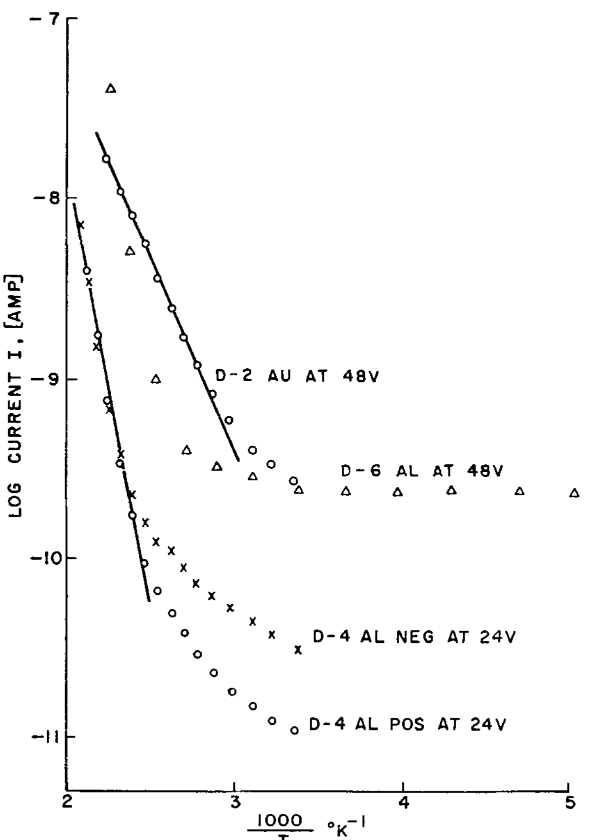

Fig. 6. Dependence of current on temperature

straight portion of the curve (D4) and the remaining terms the current for $1/T = 0$. Both numbers are obtained from the graph and yield $\phi = 1.08$V and $C = 3.67 \cdot 10^{-4}$ A V^{-1} cm^{-1}.

On the other hand we can write Eq. [1] as

$$\ln\left(\frac{J}{E}\right) = \ln C - \frac{q\phi}{kT} + \frac{\beta}{kT} \cdot v^{1/2}$$

and obtain from $\ln(J/E)$ for $V = 0$ again a value for ϕ by using the constant C calculated above. Sample D4 on Fig. 5 follows most closely the characteristics of a Poole-Frenkel mechanism and was chosen for the calculation. The trap depth found from this measurement was $\phi = 1.13$V. The agreement with the ϕ from the thermal analysis is sufficiently good to permit the Poole-Frenkel conduction to be assumed relevant for the current transport in this alumina film.

At low temperatures thermal excitation cannot be part of the electron transport through the film. A process that depends only on the field is more appropriate. Electrons are tunneling from traps into other traps further down the field and eventually into the conduction band. The current is given by (13)

$$I_2 = C_2\, E/E_o \exp(-E_o/E)$$

where E_o is a function of the energy level of the trap site and the effective electron mass. At liquid nitrogen temperatures the current depended linearly on the voltage and only above 10^6 V/cm did the current rise faster than ohmic.

Electron Microprobe Analysis

For this examination alumina films 0.30 μm thick were deposited with a beam current of 50 mA and the voltage set at various values between 3 and 7 kV. The material was Al_2O_3 pressed into pellets with a specified purity of 99.9%. The beam energy of the microprobe was 4 keV. The depth of the analyzed region was 0.17 μm, the x-ray emergence angle 41°, and the density of the film 3.15 g/cm³. The peak-to-background ratios were for

	Typically	Best
Al	630/1	1026/1
O	38/1	80/1
Si	724/1	1682/1

the minimum detectability limits were for

	Typically	Best
Al	150 ppM	115 ppM
O	3000 ppM	1317 ppM
Si	160 ppM	90 ppM

In Fig. 7 the aluminum content in atomic per cent based on 12 analyses per point and the deposition rate is plotted *vs.* the beam power. The dashed line represents stoichiometric proportions allowing for an impurity of 0.14 atomic per cent (a/o) of silicon which was found in the average in all samples. An increase in aluminum content for the high beam power is apparent. This corroborates the conclusion that high beam power during evaporation of Al_2O_3 results in oxygen deficiency of the film; hence, its dark appearance and the large effect which annealing these films in oxygen had on the charge storage.

For the samples obtained with 4 and 5 kV beam voltage the microprobe has indicated less aluminum than would be expected for stoichiometric proportions. We cannot offer a simple explanation, but one could argue in the following manner: the dashed line in Fig. 7 would be at 40 a/o if the Al_2O_3 were absolutely pure. Because of the detected silicon content, the line has dropped to 39.86. If there were other impurities not detected by the microprobe, the line would run even lower and then fall close to the measured points of aluminum. For very low evaporation rates (3 kV beam voltage) the source material turned dark slowly, but

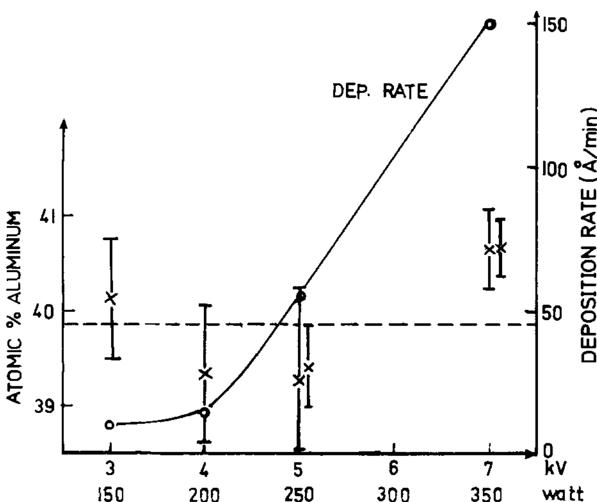

Fig. 7. The composition of the film and deposition rate for varying beam power.

because of the long times involved it became sufficiently oxygen depleted to result in poor films.

Summary

Aluminum oxide films deposited by an electron beam are aluminum rich; the degree of enrichment increasing the higher the beam power. The charge storage in the oxide is very sensitive to the degree of stoichiometry achieved. The charge storage capacity can be used to qualitatively grade the films and to study changes on postdeposition treatments. The d-c conductivity increases with decreasing oxygen content. For low conductivity, the oxide should be evaporated with a moderate beam power unless the method of Hoffman and Leibowitz is used. However, it is evident that even if electrons are prevented from striking and charging up the substrate, oxygen will still be lost through the pumping system and so not be available for complete stoichiometry of the oxide. Postdeposition heating in oxygen or air reduces both the charge storage capability and the conductivity as is expected from the trapping model used to interpret these experiments. There is a dependence on polarity due to the loss of oxygen from the source material during the whole evaporation time. This means that the source material becomes increasingly aluminum rich during the deposition process. These particular properties may become of importance if electron gun evaporated Al_2O_3 finds application in the manufacture of integrated circuits. It would also be a means of obtaining electrets (14).

Acknowledgment

I gratefully wish to express my appreciation for the careful electron microprobe analysis of Mr. D. R. Wonsidler and the constructive criticism of Prof. N. Klein.

Technical Notes

Synthesis of Rare Earth Oxysulfide Phosphors

Douglas W. Ormond*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

and Ephraim Banks*

Department of Chemistry, Polytechnic Institute of New York, Brooklyn New York 11201

The rare earth oxysulfide phosphors have been of great interest recently due to their widespread applications in color television and in lighting (1, 2). Also these phosphor systems lend themselves easily to theoretical studies regarding luminescent mechanisms (3-5).

Though much information has been published about the synthesis of these compounds, a great deal has been deleted. This report describes the development of a clearly defined and reproducible method of synthesis of rare earth oxysulfides and phosphors derived from

* Electrochemical Society Active Member.
Key words: luminescence, phosphors, yttrium oxysulfide, lutetium oxysulfide, gadolinium oxysulfide, lanthanum oxysulfide.

them. The method involves the reaction of the sesquioxide with carefully controlled N_2:H_2O:H_2S gas mixtures at temperatures near 1200°C.

There are numerous routes that will yield rare earth oxysulfides. Some of them are as follows: (*i*) partial hydrolysis of the sesquisulfide (6); (*ii*) reaction between oxide and hydrogen sulfide (7, 8); (*iii*) direct union of oxide and sesquisulfide (9); (*iv*) reaction of oxide with thioacetamide (10); (*v*) reduction of sulfates with carbon monoxide or hydrogen (11, 12); (*vi*) reduction of sulfates with an inert atmosphere which contained a small amount of hydrogen and hydrogen sulfide (8); and (*vii*) solid-state reaction utilizing a flux (13).

At the time of this investigation we were required to choose the proper synthesis route that would insure phosphors of the highest chemical purity, the reason being the ultrahigh resolution spectroscopy that was being performed on the final product by Sovers and Yoshioka (14, 15). With ultrahigh purity of the final product as the guiding factor, it was felt that the direct reaction between the rare earth (RE) oxides and hydrogen sulfide gas would be the best approach.

Eastman and Brewer (16, 17) have published many papers regarding RE oxysulfide preparation using dry H_2S firings. Hayes and Brown (8) used a similar approach. We started our investigation trying to reproduce these early works. One problem cropped up again and again. The problem was that the RE oxide would either be underfired (excess oxide left) or overfired (higher sulfide, discoloration present). Temperature, concentration of H_2S, moisture present, starting materials, and firing time were all too critical under the conditions stated in the literature; but by varying the concentration of H_2S and also the amount of H_2O present, we were able to control the reaction significantly. The water vapor kept the reaction from going too far and forming higher sulfides. In addition, the concentration of H_2S needed to be controlled. This was accomplished by mixing the H_2S with an inert gas, namely nitrogen.

Experimental Procedure

In order to insure dispersion of the activator in a homogeneous manner, the 99.999% pure rare earth oxides were dissolved in a minimum amount of nitric acid and then precipitated as the oxalates by slowly adding a 100% excess oxalic acid solution to the nitrate solution. The dried oxalates were then ignited to the oxides by firing in air at approximately 1000°C for 2 hr. Tb- and Pr-containing oxides can be refired in dry H_2 to insure that the activator is in the +3 state.

A large variation of firing conditions was tried. Experimentation with a "dry" N_2:H_2S type of arrangement quickly proved that the synthesis parameters involved, such as N_2:H_2S ratio, firing temperature, firing time, and amount of charge in the firing vessel, were too critical. This procedure was usually too long and drawn out. It involved a series of firings to achieve the desired end product, Ln_2O_2S. Samples would usually be underfired (excess Ln_2O_3) or overfired (discoloration indicating higher sulfides).

In the former case, the remedy involved repeated "dry" N_2:H_2S firings, while in the latter case, a wet N_2 firing yielding Ln_2O_3, was prerequisite to subsequent "dry" N_2:H_2S firings. Though the rare earths are often supposed to behave chemically in the same manner, La_2O_3 was exceptionally sensitive to overreacting to form some sort of higher sulfide. Y_2O_3, Gd_2O_3, and Lu_2O_3 were not found to be as sensitive in this regard.

To be able to control the oxysulfide synthesis more precisely several "wet" H_2S firings were tried. Water was introduced into the system by bubbling H_2S through a heated flask of water. The temperature of the water was held constant by means of a hot plate. Through temperature control, one is able to regulate the amount of water vapor being mixed with the H_2S, utilizing the temperature dependence of the vapor pressure of water. Indeed, water was found to be effective in controlling the process.

Through a series of trial and error type experiments, close to optimum synthesis parameters were established for the general series of Ln_2O_2S phosphor systems, namely for La_2O_2S, Y_2O_2S, Gd_2O_2S, and Lu_2O_2S phosphors. During this final process, more water was added to the system, to extend the firing time of the reactions, thus allowing for better recrystallization to take place as indicated in Fig. 1. Also an even lower H_2S concentration was used since one experiment showed an increasing trend in brightness with lower H_2S concentration. The optimum conditions finally established for the general synthesis of Ln_2O_2S type phosphors are the following: nitrogen flow, 147.0 cm^3/min; H_2S flow, 35.0 cm^3/min; water temperature, 95° ± 2°C; firing temperature, 1150° ± 10°C; firing time, 1.5 hr; firing charge, approximately 2g; firing vessel, small 2 × 3/8 in. quartz boat.

Results and Discussion

The criteria used to arrive at the most suitable synthesis conditions were twofold: one being the x-ray diffraction data and the other being the phosphor's luminescent properties.

X-ray powder diffraction patterns were taken of each sample (18). These patterns were obtained utilizing Cu Kα radiation and scanning down at a rate of 1°/min from 60 to 20°. It must be noted that one may be easily misled in judging a sample's composition by x-ray diffraction alone. X-ray diffraction, as an analytical tool, is only good above about 5%, this figure becoming even larger in some cases, depending on the atomic scattering ability and crystallinity of the material (19, 20). It is, therefore, a common experience to obtain a powder pattern of a material which appears to be a single phase yet does in fact contain a second phase. Therefore, a second criterion was used to assess the variation in synthesis parameters, namely, the luminescent properties.

Both relative brightness of the photoluminescence and spectroscopic data were taken to evaluate the phosphors. Spectroscopic data showed that when the synthesis parameters were close to ideal the photoluminescence was completely due to Ln_2O_2S:RE with no trace of Ln_2O_3:RE fluorescence. The relative brightness of the photoluminescence was also recorded in order to peak the synthesis parameters toward producing an efficient phosphor. A Photovolt photomultiplier detection system was used to record the intensity of the total light output. Excitation was produced by a low

B. Gas composition variations: with 50°C H_2O temperature, ½ hr firing time at 1150°C

$H_2S:N_2$ ratio	Body color	Relative brightness	X-ray analysis	Per cent weight gain	Per cent sulfur	Emission spectrum
1:9	White	85.2		6.38	11.9	
1:4	White	85.0	100% Y_2O_2S	7.33	13.7	100% Y_2O_2S
3:7	Tan	81.2		6.77	12.6	

C. Gas composition variations: with 95°C H_2O temperature, 1½ hr firing time at 1150°C

$H_2S:N_2$ ratio	Body color	Relative brightness	X-ray analysis	Per cent weight gain	Per cent sulfur	Emission spectrum
1:9	White	93.7		6.71	12.5	
1:4	White	100.0	100% Y_2O_2S	7.10	13.3	100% Y_2O_2S
3:7	White	95.0		7.30	13.6	

pressure mercury vapor germicidal lamp. An ultraviolet filter, Corning No. 7-54, was used to allow only u.v. to pass through to the sample. A Wratten neutral density filter No. 0.5, was used to cut down on the light intensity to the detector.

The weight increases in going from oxide to oxysulfide were recorded for each sample to study possible correlations between relative brightness and nonstoichiometric oxysulfide. In addition, gravimetric analyses for sulfur and rare earth content were performed with the oxygen content taken as the difference between 100% and the sum of the rare earth and sulfur present. Table I shows representative data used to optimize processing parameters. Theoretically, in converting Y_2O_3 to Y_2O_2S, a net weight gain of 7.11% is expected. Overreaction produces a higher weight gain due to the formation of a higher sulfide, Y_2S_3, as indicated by gravimetric analysis. Underreaction yields a mixture of Y_2O_3 and Y_2O_2S thus producing a lower net weight gain with reduced sulfur content. It can be seen from Table I that the optimal brighness results from a phosphor which is close to stoichiometric in composition.

Phosphors prepared by the aforementioned method had the following properties. The x-ray powder diffraction patterns obtained essentially agree with those found by Haynes and Brown (8). Low resolution spectroscopy showed that the photoluminescence was 100% that of Ln_2O_2S:RE. No trace of Ln_2O_3:RE fluorescence was observed, although higher resolution spectroscopy, perhaps, would detect this type of photoluminescence in trace amounts. Also, no significant shifts in emission lines were detected in the Ln_2O_2S:RE samples. Firing conditions seemed to affect only the relative intensity of the patterns and in no way affected the wavelength. The intensity of the emission spectra followed the same trend as that of the over-all relative brightness measurements in that all peaks seem to increase or decrease in the same relative proportion to each other.

Summary

Through a series of trial and error type experiments, close to optimum synthesis parameters were established for the general series of Ln_2O_2S phosphor system, namely for La_2O_2S, Y_2O_2S, Gd_2O_2S, and Lu_2O_2S phosphors. Starting at first with a dry H_2S ambient, then switching to a moist H_2S ambient, and then finally succeeding with a moist H_2S-nitrogen ambient, a successive chain of events led to the development of a clearly defined and reproducible method of synthesis of rare earth oxysulfides and the phosphors derived from them. The criteria used to arrive at the most suitable synthesis conditions were twofold: one being the x-ray diffraction data and the other being the phosphor's luminescent properties. A gas-solid reaction was chosen to be the one most free of interfering foreign ions since careful theoretical work on the emission spectra was to be performed on the synthesized phosphors. The final method of synthesis involves the reaction of the rare earth sesquioxide with a carefully controlled $N_2:H_2O:H_2S$ gas mixture at a firing temperature of 1150°C using approximately 2g of material placed in a small quartz boat.

Deposition Rate and Phosphorus Concentration of Phosphosilicate Glass Films in Relation to $O_2/SiH_4 + PH_3$ Mole Fraction

Miyoko Shibata and Katsuro Sugawara*

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

Phosphosilicate glass (PSG) films have been widely used in the passivation (1, 2), solid-to-solid diffusion (3, 4), insulation for multilevel interconnections (1), and protection of aluminum electrodes (1) in the field of semiconductor devices. In spite of these applications, few reports (5-10) have been published which systematically investigate the deposition rate and phosphorus concentration by changing the deposition parameters over a wide range. In this note, the dependence of O_2 to SiH_4+PH_3 mole fraction on the deposition rate and phosphorus concentration during PSG film formation is reported.

A planetary-type CVD reactor (11) was used in this experiment. The bell jar was approximately 40 cm in diameter and 20 cm high. Clean silicon mirror-polished wafers, Czochralski-grown, boron-doped and (100)-oriented with resistivity of 30 ohm-cm, were placed on planetary rotation gears, then the bell jar was fixed and heating was effected. After reaching set temperatures of 300°, 350°, 400°, and 450°C, reaction was carried out by introducing SiH_4 (56 cm^3/min), PH_3 (4 cm^3/min), and O_2 (90-2000 cm^3/min). The carrier gas was N_2, and the total flow rate of 20 liters/min was maintained constant during deposition. The reaction time was set to obtain a PSG film of 3000-4000Å thickness. Thickness was measured by a "Talystep." The phosphorus concentration was determined by the sheet resistance after a predetermined diffusion in accordance with a calibration curve of sheet resistance and phosphorus concentration previously prepared by activation analysis. To determine the reacted SiH_4 concentration through the reactor system, the unreacted SiH_4 concentration of the vent gas was measured under the experimental conditions. A Hitachi EPI-S2 infrared spectrometer was used for this purpose. Absorption spectra were taken in the ranges of 2200 cm^{-1} and 900 cm^{-1} (8); the peak of 930 cm^{-1} was selected to avoid interference with the CO_2 peak near 2200 cm^{-1}. The transmittance through a 10 cm gas cell at the peak of 930 cm^{-1} shows the reacted SiH_4 concentration.

As shown in Fig. 1, the deposition rate of PSG films exhibited a tendency of increase-maximum-decrease when the O_2 flow rate increased at the constant flow rate of SiH_4 and PH_3. Mole fractions at these maximum ranges are approximately 3 at 300°C, 4-6 at 350°C, 8-12 at 400°C, and 14-22 at 450°C. The higher the temperatures of the deposition were, the larger the mole fractions and the wider the maximum range became. The phosphorus concentration rapidly increased with an increase of the O_2 flow rate, displaying a constant value at the maximum plateau range of the deposition rate, and then gradually increasing at the larger O_2 flow rate. The phosphorus concentration of the silicon wafers on which the PSG films were deposited, was determined after 30 min diffusion at 1100°C in dry nitrogen, using the calibration curve. Dependence of the oxygen mole fraction on the PSG film deposition is similar to that on CVD SiO_2 film formation (5-6, 9-10). At low O_2/SiH_4+PH_3 ratio, increase in the deposition rate was found as the temperature decreased. This fact may be explained by smaller reaction rate in the hot zone; the increased deposition rate at lower temperature was brought as the result of difference between total reaction and reaction in the hot zone. The above-mentioned tendency was confirmed by the result of film thickness monitoring by a laser system (12).

Dependence of the oxygen mole fraction was also investigated in the case of various PH_3 flow rates. The oxygen flow rates were selected from 180 to 2000 cm^3/

* Electrochemical Society Active Member.

Key words: PSG film, SiH_4-PH_3-O_2 reaction, infrared gas measurement, retarding reaction.

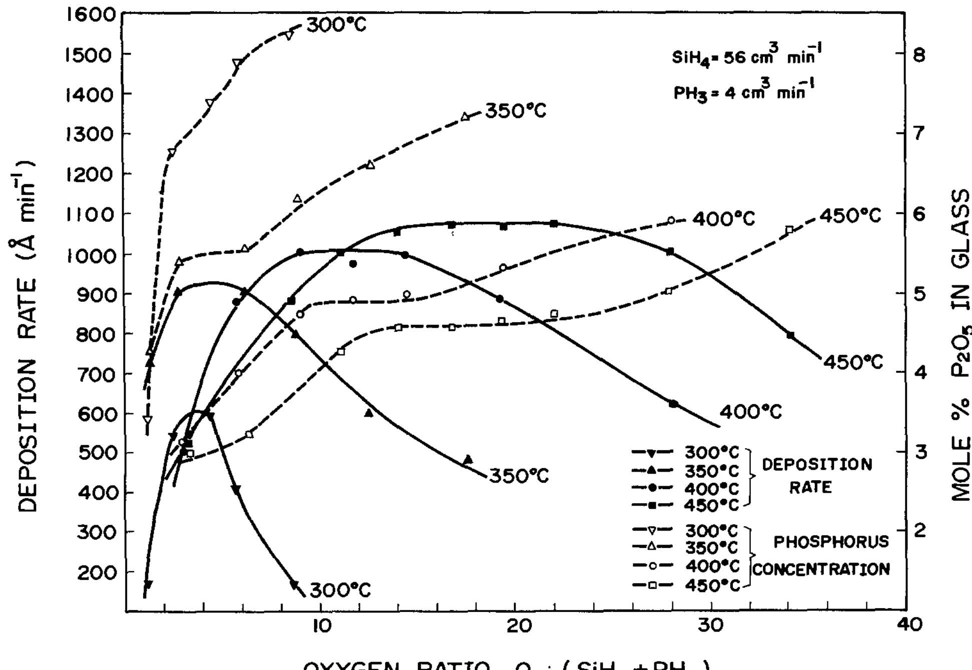

Fig. 1. O_2:(SiH_4 + PH_3) mole fraction vs. deposition rate and phosphorus concentration of PSG films.

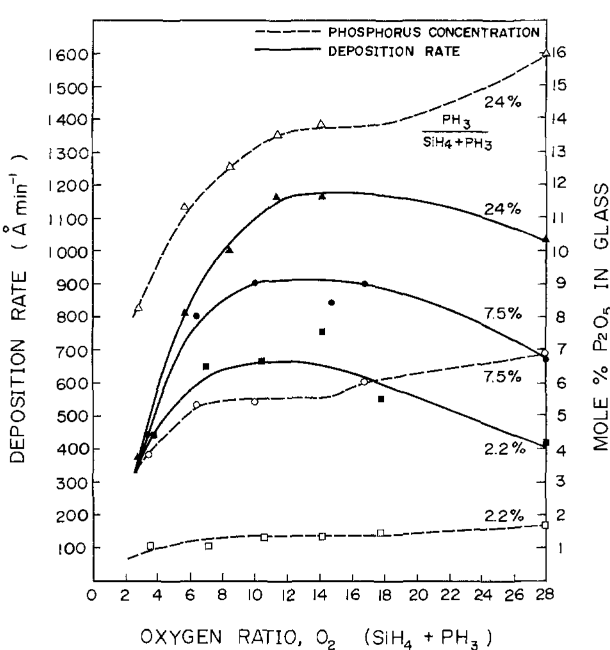

Fig. 2. Dependence of O_2:(SiH_4 + PH_3) mole fraction on the deposition rate and phosphorus concentration of PSG films in various PH_3 flow rates. Deposition temperature: 400°C.

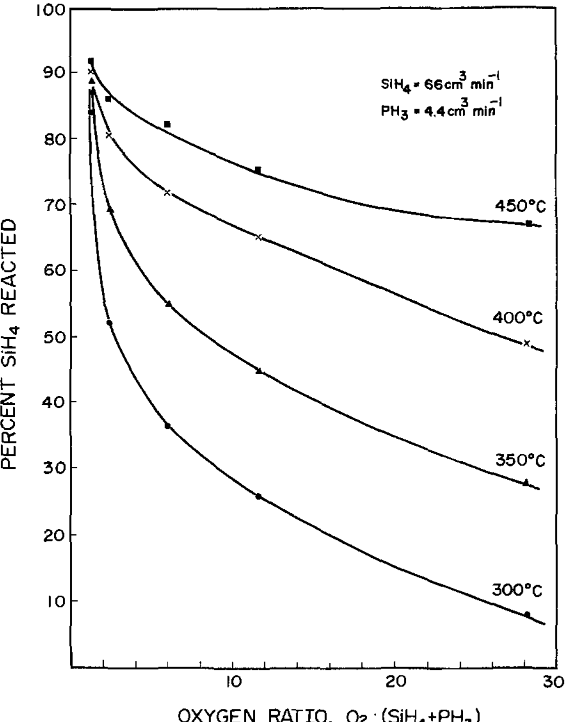

Fig. 3. O_2:(SiH_4 + PH_3) mole fraction vs. per cent SiH_4 reaction in the over-all reactor, measured by infrared absorption.

min at 1.8, 6.5, and 18.3 mole per cent (m/o) PH_3. Deposition was carried out at 400°C. Figure 2 shows that both deposition rate and phosphorus concentration became plateau at approximately constant value, 8-12 of O_2/SiH_4+PH_3.

The reacted per cent SiH_4 measured by the infrared absorption were plotted at various oxygen flow rates and deposition temperatures in Fig. 3. SiH_4-O_2 reaction was retarded as the oxygen flow rates increased. This retardation was remarkably noticeable when the film was deposited at the lower temperature. This result shows the same tendency as that of the undoped SiO_2 film formation (8).

The deposition rate and phosphorus concentration of PSG films formed by the SiH_4-PH_3-O_2 system was investigated in the temperature range of 300°-450°C by reaction with the O_2/SiH_4+PH_3 mole fraction and the deposition temperature. The deposition rate showed a tendency of increase-maximum-decrease with increasing O_2 flow rates. This maximum plateau range became larger and wider with increasing deposition temperature. The phosphorus concentration was kept constant at this range.

Acknowledgment

The authors express their sincere gratitude to Mr. S. Nishida and Mr. H. Mishimagi for the most helpful discussions. Appreciation is also due to Dr. N. Nagasima and Miss H. Suzuki for the activation analysis of phosphorus in PSG films, and to Miss Y. Tsukamoto for assistance in the experimental work.

Deposition Rate and Phosphorus Concentration of Phosphosilicate Glass Films in Relation to $PH_3/SiH_4 + PH_3$ Mole Fraction

Miyoko Shibata, Takeo Yoshimi, and Katsuro Sugawara*

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

Phosphosilicate glass films (PSG films) have been widely used for the fabrication of semiconductor devices, such as stabilization of electric characteristics, insulation of multilayer interconnection, and protection of aluminum electrodes. In spite of these wide uses, few papers have reported the detailed relation of wide range deposition parameters to the deposition rate and the phosphorus concentration (1-5). The authors reported that the deposition rate and the phosphorus concentration of the PSG films showed little variation when the films were formed under the proper mole fraction O_2/SiH_4+PH_3, being dependent on the deposition temperature (5). In this range of O_2/SiH_4+PH_3, the dependence of PH_3 flow rate on the deposition rate and the phosphorus concentration is reported.

The same CVD reactor used in the previous paper (5) was of planetary type (6). In this reactor, silicon mirror-polished wafers [(100) oriented and boron doped with resistivity of 30 ohm-cm] were charged, and the PSG films 3000-4000Å in thickness were deposited on the wafers by SiH_4-PH_3-O_2 reaction at the temperatures of 350°, 400°, and 450°C. Flow rates were: N_2, 20 liters/min; SiH_4, 56 cm^3/min; O_2, plateau range of the small, variable deposition rate and phosphorus concentration and being fixed at the temperatures, *e.g.*, at 350°C, $O_2/SiH_4+PH_3 = 5$, at 400°C, $O_2/SiH_4+PH_3 = 12$, at 450°C, $O_2/SiH_4+PH_3 = 18$; PH_3, 0.7-14 cm^3/min. The thickness of the PSG films was measured by a "Talystep." The phosphorus concentration was determined by the sheet resistance in the previously prepared calibration curve between the phosphorus concentration by the activation analysis and the sheet resistance after the diffusion. To measure total amount of the reacted SiH_4 concentration with O_2 in the reactor, infrared gas absorption through a 10 cm gas cell was carried out, as reported in the previous paper (5). The reacted mole percentage of SiH_4 was detected by the transmittance of the cell, fixed at the absorption peak, 930 cm^{-1} of SiH_4, using Hitachi EPI-S2.

Figure 1 shows the deposition rates of the PSG films under various PH_3 flow rates at the O_2/SiH_4+PH_3 in the plateau range of the deposition rate. With increasing PH_3 flow rate, the deposition rate at 350°C shows a tendency of decrease-minimum-increase. After raising the deposition temperature in this experimental condition, the deposition rate became larger and showed the same tendency observed at 350°C. This was confirmed by the monitoring experiment using a 6328Å He-Ne laser system (7).

Figure 2 is the relation of PH_3/SiH_4+PH_3 mole fraction to the phosphorus concentration in the PSG films, represented as $P_2O_5/SiO_2+P_2O_5$ at the same experimental condition. With the increasing of the deposition temperature, P_2O_5 concentration in the PSG films decreased at the same PH_3/SiH_4+PH_3 flow ratio. The similar result of decreasing dopant materials in films was obtained in the cases of P, As, and Sb doping for silicon epitaxial layers (8-9) and in AsH_3 and PH_3 doping for polycrystalline silicon films (10). In this temperature range PH_3 was almost completely reacted, while SiH_4 tended to increase the reaction rate with O_2 at the higher temperature as can be seen in Fig. 1 and in the infrared absorption in the previous paper (5). Therefore, the phosphorus concentration was diluted as a consequence of the increased SiH_4 reaction.

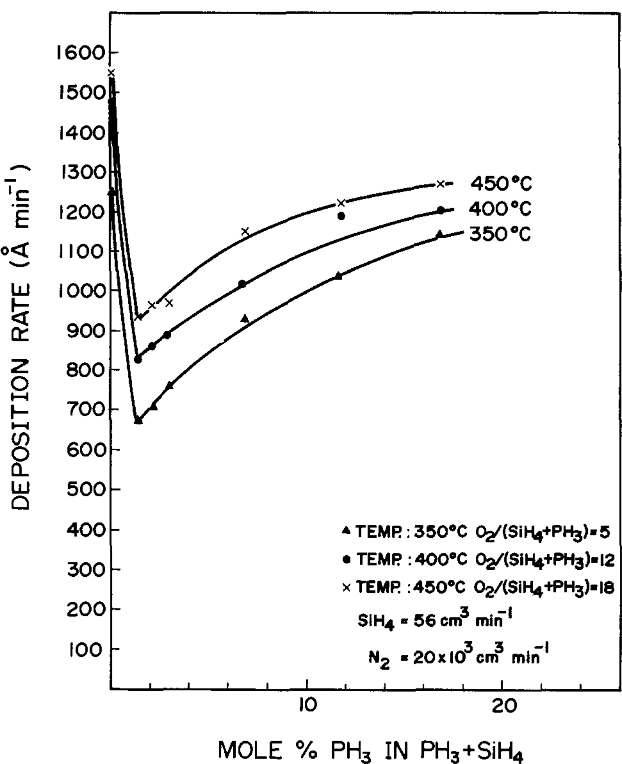

Fig. 1. Deposition rates of the PSG films vs. m/o PH_3 in $SiH_4 + PH_3$ in the plateau range of the deposition rate determined in terms of $O_2/SiH_4 + PH_3$ mole fraction.

When the reaction was effected under various PH_3 flow rates at the deposition temperature of 400°C, the result of the reacted percentage SiH_4 measured by the infrared absorption method is shown in Fig. 3, in which the O_2 flow rate is indicated as a parameter. The reacted SiH_4 concentration became suppressed independently of O_2 flow rates when PH_3 was added up to 2-3 mole per cent (m/o). With further increasing of PH_3 flow rates, the reacted SiH_4 increased. This tendency was dominant at larger O_2 flow rates.

When the PSG films were formed by the SiH_4-PH_3-O_2 reaction, it was previously reported that there existed O_2/SiH_4+PH_3 mole fraction, with little variation in the deposition rate and in the phosphorus concentration, and fixed at the deposition temperature. At this plateau range, the deposition rate showed the tendency of decrease-minimum-increase with increasing PH_3 flow rates. This tendency of the deposition rate was maintained in all reaction temperatures of this experiment.

Acknowledgment

The authors express their sincere gratitude to Mr. S. Nishida for his encouragement and helpful discussions, and to Miss Y. Tsukamoto for her assistance in the experimental work.

Electrochemical Behavior of the Perovskite-Type $Nd_{1-x}Sr_xCoO_3$ in an Aqueous Alkaline Solution

Tetsuichi Kudo, Hidehito Obayashi, and Tetsuo Gejo

Central Research Laboratory, Hitachi Limited, Higashi-koigakubo, Kokubunji, Tokyo, 185, Japan

ABSTRACT

The compounds $Nd_{1-x}Sr_xCoO_3$, which show high electrical conductivity, are electrochemically reduced in an aqueous alkaline solution to give rise to the oxygen deficient state $Nd_{1-x}Sr_xCoO_{3-\delta}$. The electrochemical redox reactions are reversible in the range $0 \leq \delta \leq x/2$. The electrode potentials of $Nd_{1-x}Sr_xCoO_{3-\delta}$ in a KOH solution have been measured as a function of δ. From these data and the measurements of potential change in the cathodic processes under constant current density, the oxygen ion diffusion constants have been calculated on the basis of a linear diffusion model of oxygen ions in the crystal, which was theoretically derived. The calculated diffusion constants at 25°C are 1.4×10^{-11} and 7.6×10^{-14} cm²/sec for $x = 0.2$ and $x = 0.5$, respectively. These values are very large as compared with ordinary oxides.

The compounds $Nd_{1-x}Sr_xCoO_3$ with the perovskite-type structure exhibit high electrical conductivity even at room temperature, and their specific conductivity is in the order of 10^0-10^4 ohm^{-1} cm^{-1} (1, 2). According to Heikes *et al.* (3), the large electrical conductivity is due to the delocalization of electrons among Co^{+3}-O^{-2}-Co^{+4} network by the super exchange effect. Recently, these compound are taken notice of as electrode materials (4), especially as oxygen (or air) electrodes in an aqueous alkaline solution (5, 6).

It was suggested by the present authors' work (2) that these lanthanoid cobalt oxides with perovskite structure are ionic-electronic mixed conductors with large oxygen ion diffusivity compared with ordinary oxides and also with the electronic conductivity far greater than the ionic conductivity. From this point of view, the electrochemical behavior of $Nd_{1-x}Sr_xCoO_3$ in an aqueous KOH solution has been studied.

It is reasonable to consider that the oxygen ions in the crystal with perovskite structure are usually mobile, because many oxygen ion conductors with this structure have been reported (7, 8). The direct measurement of the oxygen ion diffusion constant is, however, almost impossible for the compounds with high electronic conductivity: The oxygen concentration cell method or the Wagner cell (9) method are proved inapplicable. Therefore, a new method to make use of the measurement of the potential change of the compound $Nd_{1-x}Sr_xCoO_3$ under the cathodic process was employed.

The diffusion constant can be calculated from the potential change by using a linear diffusion model of the compound, which was derived from a theoretical consideration.

Theory

The electrode potential of $Nd_{1-x}Sr_xCoO_3$.—The valence setup of the compound $Nd_{1-x}Sr_xCoO_3$ is expressed as

$$Nd^{+3}{}_{1-x}Sr^{+2}{}_xCo^{+3}{}_{1-x}Co^{+4}{}_xO_3 \quad [1]$$

While this compound undergoes reduction, some of the oxygen ions are taken away from the crystal lattice and the valence set up becomes

$$Nd^{+3}{}_{1-x}Sr^{+2}{}_xCo^{+3}{}_{1-x+2\delta}Co^{+4}{}_{x-2\delta}O_{3-\delta}(V_{O^{-2}})_\delta \quad [2]$$

where $V_{O^{-2}}$ represents the oxygen ion vacancies and δ is a measure of the nonstoichiometry of the compound. Since the perovskite structure cannot be maintained if δ exceeds $x/2$, the discussion in the present paper is confined within the range $0 \leq \delta \leq x/2$.

When the compound is electrochemically reduced in an aqueous alkaline solution, the over-all reaction is

$$O^{-2}\text{ (lattice)} + H_2O + 2e^- = 2\,OH^- + V_{O^{-2}} \quad [3]$$

If the cathodic current of which integral is Q coulombs flows through 1g of the oxide concerned, the loss of oxygens ($\Delta\delta$) in this cathodic process is represented as

$$\Delta\delta = M \cdot \frac{Q}{2\mathbf{F}} \quad [4]$$

where M represents the gram formula weight of $Nd_{1-x}Sr_xCoO_3$ and $\mathbf{F}$ represents the Faraday constant.

During this process, the concentration gradient of $V_{O^{-2}}$ (or δ) in the crystal occurs, as schematically shown in Fig. 1. When the electric current is turned off, the relaxation of the concentration gradient formed by the current integral of Q coulombs sets in and continues until δ becomes uniform throughout the crystalline particles. If we consider the initial δ is zero, the value of δ in this relaxation state is $M \cdot (Q/2\mathbf{F})$.

The electrode potential of the compound $Nd_{1-x}Sr_xCoO_{3-\delta}$ regarding the electrochemical reaction represented by Eq. [3] can be written as

$$E = E^\circ - \frac{RT}{2\mathbf{F}} \ln \frac{a^2_{OH^-}}{a_{H_2O}} + \frac{\Delta F(\delta)}{2\mathbf{F}} \quad [5]$$

The symbol E° is the standard potential of an oxygen

Key words: perovskite-type oxides, electrode potential, diffusion constant, mixed conductor.

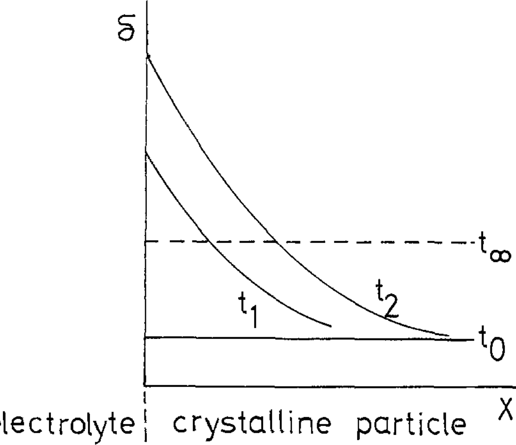

Fig. 1. Schematic diagram of the concentration gradient of oxygen ion vacancies formed in a particle of $Nd_{1-x}Sr_xCoO_3$. t_0 (initial level) $<$ t_1 (under current passage) $<$ t_2 (at which current turned off) $\rightarrow$ t_∞ (relaxation level).

electrode in basic solution (+0.401V *vs.* SHE), and $\Delta F(\delta)$ is the partial molar free energy change of the reaction

$$\frac{1}{2} O_2 + 2e = O^{-2} \text{ (lattice)} \quad [6]$$

for the composition of the oxide $Nd_{1-x}Sr_xCoO_{3-\delta}$. The symbol E is, accordingly a function of δ in general, and its value *vs.* Hg/HgO reference electrode can be represented as[1]

$$E(\delta) = 0.303 + \frac{1}{2\mathbf{F}} \Delta F(\delta) \quad [7]$$

One can, therefore, determine the electrode potential as a function of δ by setting the relaxation level of δ (Fig. 1) at an appropriate value corresponding to the integral current Q as far as either the oxygen evolution from the crystal lattice or the dissolution into the lattice is negligible during the relaxation process. It was ascertained by TGA and DTA that these losses were negligible under the conditions that the temperature was lower than 150°C, the oxygen ambient to the electrodes was far less than 1 atm, and δ did not lie in the neighborhood of the critical value $x/2$.

Oxygen ion diffusion constant.—Let us consider a flat plate of thickness L. The electronic conductive material such as platinum net is attached to one side of the sample plate and molded with an oxygen free resin, the other side is directly contacted to an aqueous alkaline solution. When a cathodic current is applied to the plate, the oxygen ions at the surface of the sample are converted into OH^- ions according to Eq. [3] and a concentration gradient of oxygen ions across the plate is built up as shown in Fig. 2.

The diffusion equations associated with ion-electron mixed conductors have been derived by Hebb (10) and other workers (11, 12). Applying a similar treatment to the model of the present paper, one can obtain as a diffusion equation

$$\frac{\partial C_V}{\partial t} = \frac{\partial}{\partial X}\left(D\left(\frac{\partial C_V}{\partial X} - \frac{2eI}{kT}\frac{C_V}{\sigma_h}\right)\right) \quad [8]$$

Notations in Eq. [8] are: C_V, concentration of oxygen ion vacancies (cm^{-3}); D, diffusion constant of oxygen ion vacancies (cm^2/sec); σ_h, specific electronic conductivity ($ohm^{-1} \cdot cm^{-1}$); I, current density (A/cm^2); e, charge of electrons (1.60×10^{-19} coulomb; k, the Boltzmann constant (1.38×10^{-23} coulomb · volt/deg); and T, absolute temperature, respectively. In the course of derivation of Eq. [8], the assumption that the σ_h is

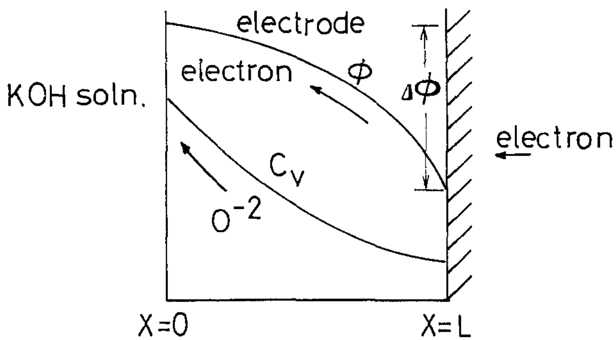

Fig. 2. Schematic diagram of a plain sheet $Nd_{1-x}Sr_xCoO_3$ electrode under a cathodic process. Arrows indicate the direction of electron and oxygen ion movements.

far greater than that of oxygen ions and the Townsend-Einstein relation were employed to eliminate the unobservable parameters. Equation [8] might be solved if the initial and the boundary conditions are given. These conditions under the constant current density process are

$$C_V(t = 0, x) = C_V^* \text{ (= constant)} \quad [9]$$

$$\left(\frac{\partial C_V}{\partial X}\right)_{X=0} = -\frac{I}{2eD} \quad [10]$$

$$\left(\frac{\partial C_V}{\partial X}\right)_{X=L} = 0 \quad [11]$$

The theoretical potential of the electrode at time t [$E_{\text{theo}}(t)$] is given by

$$E_{\text{theo}}(t) = E(C_V(t, x = 0)) - \Phi(t) \quad [12]$$

The first term of the right-hand side in this equation is the redox potential corresponding to C_V at the surface of the electrode, which is defined by Eq. [7]. The relation between C_V and δ in Eq. [7] is represented by

$$C_V = \frac{\delta}{v_c} \quad [13]$$

where v_c is the unit cell volume (cm^3) of the compound $Nd_{1-x}Sr_xCoO_{3-\delta}$. The symbol $\Phi(t)$ is the potential change across the electrode which is shown in Fig. 2. These terms might be calculated from the solution of Eq. [8] as a function of the parameter D. It is consequently possible to determine the diffusion constant of oxygen ions, if we can find out the value of the parameter D which gives such potential variation that agrees with the observed one.

As Eq. [8] cannot be rigorously solved, we will hereafter treat the problem on the basis of the following approximations. Confining the problem in the case that the current density I is so small as to hold the relation

$$\frac{\partial C_V}{\partial X} >> \frac{2eI}{kT} \cdot \frac{C_V}{\sigma_h} \quad [14]$$

and assuming the diffusion constant D is independent of C_V, Eq. [8] may be reduced to an ordinary form of the diffusion equation

$$\frac{\partial C_V}{\partial t} = D\frac{\partial^2 C_V}{\partial X^2} \quad [15]$$

Macey (13) gave the solution of this equation under the initial and boundary conditions substantially identical to the present case. Inserting Eq. [9], [10], and [11] into Macey's solution, $C_V(t, X)$ is expressed as

[1] The standard potential for Hg/HgO couple is 0.098V. Thus, when alkaline concentration around the $Nd_{1-x}Sr_xCoO_{3-\delta}$ electrode and the reference electrode is same, Eq. [7] is directly derived from Eq. [5].

$$C_V(t, X) = C_V^* + \frac{I}{e}\sqrt{\frac{t}{D}}\left[\chi_1\left(\frac{X}{2\sqrt{Dt}}\right) + \chi_1\left(\frac{2L - X}{2\sqrt{Dt}}\right) + \chi_1\left(\frac{2L + X}{2\sqrt{Dt}}\right) + \chi_1\left(\frac{4L - X}{2\sqrt{Dt}}\right) + \chi_1\left(\frac{4L + X}{2\sqrt{Dt}}\right) + \ldots\ldots\right] \quad [16]$$

where the function χ_1 is defined by

$$\chi_1(x) = \int_x^\infty \left(\frac{2}{\sqrt{\pi}}\int_y^\infty e^{-\xi^2}d\xi\right)dy \quad [17]$$

The numerical value of χ_1 ranges from 0.564 at $X = 0$ to 0.0008 at $X = 2.2$. Thus the series in Eq. [16] is highly convergent, and assuming $L/\sqrt{Dt} >> 1$, Eq. [16] can be reduced to

$$C_V(t, 0) = C_V^* + \frac{I\chi_1(0)}{e}\sqrt{\frac{t}{D}} \quad [18]$$

or using Eq. [13]

$$\delta_O(t) - \delta_O(t = 0) = 0.564\frac{v_c I}{e}\sqrt{\frac{t}{D}} \quad [18']$$

Since $\Phi(t)$ in Eq. [12] can be neglected as far as Eq. [14] holds, the electrode potential may be considered as a sole function of the surface vacancy concentration $C_V(t, x = 0)$ or $\delta_O(t)$). It is therefore possible to estimate $\delta_O(t)$ by measuring the electrode potential change with time and then the diffusion constant of oxygen ion D can be calculated by Eq. [18'].

Experimental

Measurement of the electrode potential of $Nd_{1-x}Sr_x$-CoO_3.—The compounds $Nd_{1-x}Sr_xCoO_3$ were obtained by sintering a homogeneous mixture of the component metal acetates at 900°C in air for 4 hr. The BET specific surface area of the powder oxides was about 5 m^2/g. A half gram of specimen powder was weighed precisely to which 0.025g acetylene black and 0.025g of flaky graphite were added. The mixture was mixed in an agar mortar. Several drops of a 30 weight per cent (w/o) KOH solution were added to the powder mixture. The flaky graphite improves the affinity of the powder to the electrolyte. The specimen was charged into an acryl case shown in Fig. 3, and pressed from both sides, at which the platinum net current collectors were placed. Nitrogen gas was bubbled so as to make dissolved oxygen concentration be very small. The holder was soaked in a 30% KOH solution for 5 hr to make the contact between the sample and the electrolyte complete. Temperature of the solution was kept at 25° ± 1°C.

To make the oxidation of the sample perfect, *i.e.*, δ be zero, 1 mA of an anodic current was passed for 10 hr. Then 1 mA of a cathodic current was passed for a certain period. During this process the sample changes its composition from $Nd_{1-x}Sr_xCoO_3$ to $Nd_{1-x}Sr_xCoO_{3-\delta}$, according to Eq. [4]. The current density at the surface of oxide particles is calculated as 4×10^{-2} $\mu A/cm^2$; the current efficiency in this cathodic process can be considered to be almost 100%.

After the current is turned off, the cell potential rises gradually and saturates at a constant level regarded as the electrode potential of $Nd_{1-x}Sr_xCoO_{3-\delta}$. It took several hours to reach the saturation (or relaxation) level after the current was turned off. The potential was measured *vs.* Hg/HgO reference electrode by using a digital voltmeter of the input impedance greater than 10 megohms. A similar step was repeated to obtain the electrode potential as a function of δ; δ can be changed by varying the current passing period.

Measurement of oxygen ion diffusion constant.—Disk preparation.—To the powder of the compounds Nd_{1-x}-Sr_xCoO_3 prepared by the same method as in the above section, methyl cellulose (1% aqueous solution) was added as a binder and it was pressed in a die of 15 mmϕ at the hydrostatic pressure of 700 kg/cm^2 to give a 2 mm thick disk. This disk was placed in an alumina die of 20 mmϕ; environment of the disk was filled with stabilized zirconia powder to prevent the disk from reacting with alumina. The die was put in a vertical type platinum resistance furnace and hot pressed under 350 kg/cm^2 at 1200°C for 3 hr. The obtained sample was lapped by several steps and polished finally by diamond paste. The surface area of the sample was considered to be the same as the geometrical one.

Measurement of oxygen ion diffusion constant.—The platinum net was attached to the one side of the disk sample as a current collector and was molded with an epoxy resin, the other side being exposed to a 30% aqueous KOH solution. A "H" type cell was used in this measurement as is shown in Fig. 4. The use of "H" type cell and bubble of nitrogen gas in both rooms of the cell protect the sample from the influence of oxygen. The potential change under the constant current cathodic process was measured *vs.* Hg/HgO reference electrode. The counterelectrode was

platinum net, and the cell temperature was kept within 25° ± 1°C.

Results and Discussion

Electrode potential of $Nd_{1-x}Sr_xCoO_3$.—The potential of the $Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$) after 5 hr soaking in an electrolyte is +90-100 mV *vs.* Hg/HgO. The potential becomes +510 mV after about 30 min of 1 mA anodic current passage. This value was considered to be the oxygen-evolving potential of the cell. The fact that about 30 min were needed to reach this potential may mean that the sample was already in a partially reduced state when it had been prepared. After passing an anodic current for 10 hr to make δ be essentially zero, the direction of the current was reversed. The profile of the potential decrease is shown in Fig. 5.

If all the cathodic current were due to the reaction

$$O^{2-} \text{ (lattice)} + 2Co^{+4} + H_2O + 2e \rightarrow V_{O2-} + 2Co^{3+} + 2\,OH^- \quad [19]$$

the potential would reach the hydrogen evolving potential (about −800 mV case of this cell) at the time when $2\delta/x = 1$ (*i.e.,* 11.2 hr). However, the potential did not reach the hydrogen evolving potential even when $2\delta/x$ exceeded unity. Under the 1 mA of cathodic current, the hydrogen evolving potential was obtained when 120% of the theoretical capacity available from $Nd_{1-x}Sr_xCoO_3$ were discharged. The discrepancy between calculated and observed capacity of the cell increases with a decrease in the cathodic current. The reason may be that the residual dissolved oxygen in the electrolyte fills the oxygen ion vacancies generated through the cathodic process when the reduction of the oxide exceeds a certain critical level. This suggests that $Nd_{1-x}Sr_xCoO_{3-\delta}$ works as an oxygen electrode if sufficient amount of oxygen exists.

After 13 hr of cathodic process, the direction of the current was again reversed. The potential change in the anodic process is also shown in Fig. 5. In this process, the potential reached the level of oxygen evolution after 10 hr which being 90% of the theoretical value. The disagreement arose partly from the residual Co^{+4} and mainly from the situation that the surface of the particles reached the composition corresponding to the oxygen evolution potential (*i.e.,* $\delta = 0$) faster than the inner part. The experimental results above reveal the reversibility of δ in the compound $Nd_{1-x}Sr_xCoO_3$ during the redox process.

The relation between the electrode potential and δ is shown in Fig. 6. The potential becomes nobler as Co^{+4} concentration increases; the value for $x = 0.5$

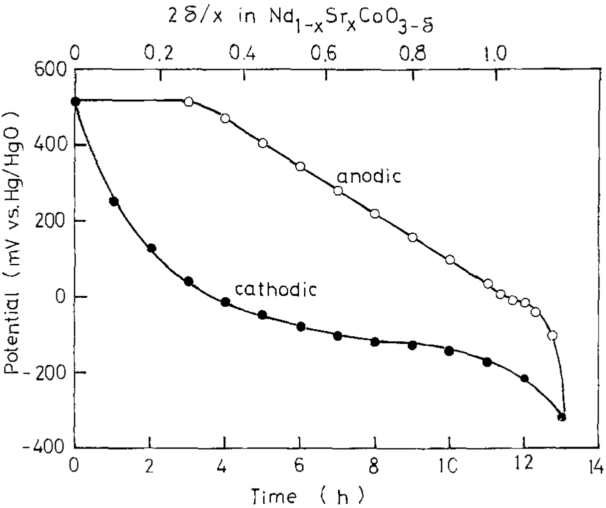

Fig. 5. Potential variation with time under the electrochemical redox processes in 30% KOH solution [$Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$)]. The current employed was 1 mA for 0.5g of the sample.

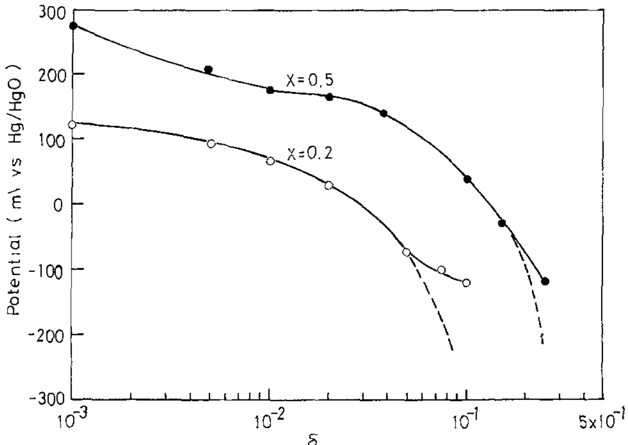

Fig. 6. The electrode potential as a function of δ in $Nd_{1-x}Sr_xCoO_{3-\delta}$.

is higher by 100-200 mV in the whole range of δ than the value for $x = 0.2$. Since the relation between the electrode potential $E(\delta)$ determined here as a function of and the partial free energy change of oxidation of $Nd_{1-x}Sr_xCoO_{3-\delta}$ holds as Eq. [7], the oxygen partial pressure in an equilibrium with this composition is expressed as

$$P_{O_2} = \exp\left[\frac{4\mathbf{F}}{RT}(E(\delta) - 0.301)\right] \text{(atm)} \quad [20]$$

The equilibrium P_{O_2} obtained from TGA data was in a fair agreement with that calculated by Eq. [20].

Diffusion constant.—In the preceding discussion, the polarizations at the electrode/electrolyte interface, (the main portion of which may be the polarization arising from the activation process of the reaction of Eq. [3]) and the ohmic polarization were not taken into account. It is needed for the validity of the discussion that these polarizations be negligibly small. The check has been done by changing the pulse current in the range from 6 to 60 μA/cm² and observing the potential buildup process at the $Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$) electrode by an oscilloscope. No significant profiles indicating the buildup of potential were found in the time constant range shorter than 2 sec. Time constants for ohmic polarization are in general very small as in the order of several microseconds and those for reaction polarization are of the several microseconds order. These results show that both polarizations are negligible in the range of current density employed in the present experiments.

The potential variations with time in the cathodic process were plotted in Fig. 7, for the samples $Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$ and 0.5). The sample $x = 0.2$

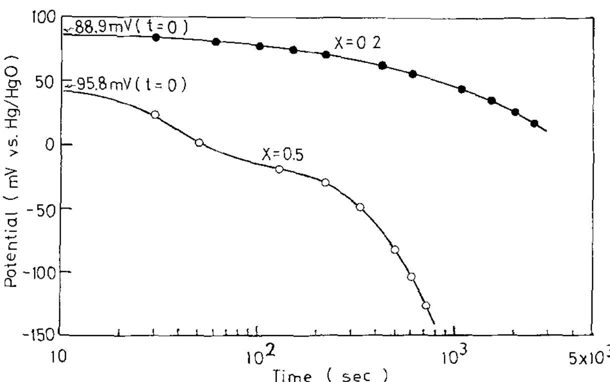

Fig. 7. The potential variations with time for the disk electrodes of $Nd_{1-x}Sr_xCoO_3$ under the constant current cathodic processes. The current densities for $x = 0.2$ and $x = 0.5$ are 6.0 and 9.8 μA/cm², respectively.

annealed from 800°C at which the platinum current collector had been attached showed the open-circuit potential of +88.9 mV, indicating δ in the electrode be 6.0×10^{-3} (cf. Fig. 6). It is reasonable to consider that the distribution of δ in the sample electrode was uniform since it was in the state which had been formed by a slow annealing from a higher temperature. The value of δ (6.0×10^{-3}) was considered to be appropriate (to start the experiment) because it was sufficiently small compared with the critical value (0.1 in this case). If the initial value of δ is as large as the critical value ($x/2$), the time range of measurement is restricted to a short period because δ cannot exceed $x/2$, and moreover the error of the diffusion constant to be calculated increases because the δ-E relation becomes inaccurate in the neighborhood of $x/2$ as shown in Fig. 5. According to this consideration, the cathodic current passage was started without any pretreatment for the sample $x = 0.2$. The current density was kept at 6.0 $\mu A/cm^2$.

The sample $x = 0.5$, on the other hand, showed the open-circuit potential of +49.9 mV which corresponded to the δ value of 9.7×10^{-2}. This value lying near the tail of the curve in Fig. 6 ($x = 0.5$), the preliminary anodic current passage (20 $\mu A/cm^2$, 2 hr) was carried out to reduce δ in the sample. When the anodic current was turned off, the potential started to decay and saturated at 95.8 mV. This indicates that the pretreatment formed a substantially uniform distribution of δ, of which the value was considered to be 6.6×10^{-2}. The cathodic current passage was started from this state with the current density 9.8 $\mu A/cm^2$.

From the x-ray diffraction, the volumes of single molecular nearly cubic unit cell of $Nd_{1-x}Sr_xCoO_3$ were given as 55.0×10^{-24} for $x = 0.2$ and 55.5×10^{-24} cm^3 for $x = 0.5$, respectively. Thus Eq. [18′] for $x = 0.2$ and $x = 0.5$ can now be expressed as

$$\delta_O(t) - 6.0 \times 10^{-3} = \frac{1.16 \times 10^{-9}}{\sqrt{D}} \cdot \sqrt{t}$$

and [21]

$$\delta_O(t) - 6.6 \times 10^{-2} = \frac{1.91 \times 10^{-9}}{\sqrt{D}} \cdot \sqrt{t}$$

respectively. It follows that the plot of $[\delta_O(t) - \delta_O(t = 0)]$ *vs.* $\sqrt{t}$ gives a straight line passing the origin and that the diffusion constant D can easily be calculated from the slope of the given straight line. Figure 8 shows these plots for $x = 0.2$ and 0.5.

The obtained diffusion constants of oxygen ions in $Nd_{1-x}Sr_xCoO_3$ are

$$D = (1.4 \pm 0.1) \times 10^{-11}\ cm^2/sec\ (x = 0.2)$$

and

$$D = (7.6 \pm 0.7) \times 10^{-14}\ cm^2/sec\ (x = 0.5)$$

at 25°C.[2] These values are presumably very large compared with ordinary oxides, while the direct comparison is impossible because the diffusion constant of oxygen ions in oxides at a low temperature has not been reported until now. However, the extrapolation

[2] These values are derived from regression analysis of Fig. 8.

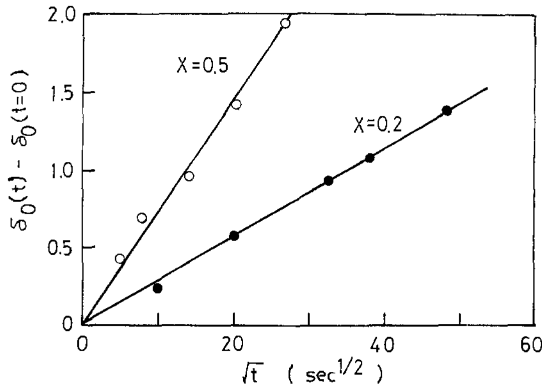

Fig. 8. The changes of δ at the surface of the electrode $[\delta_O(t) - \delta_O(t = 0)]$ as plotted against square root of t. The plots for $x = 0.2$ and 0.5 are multiplied by 10^2 and 10 in the figure, respectively. Thus, for example, $[\delta_O(t) - \delta_O(t = 0)]$ at $\sqrt{t} = 20$ sec$^{1/2}$ should read 0.6×10^{-2} and 1.4×10^{-1}, respectively. The slopes give the oxygen ion diffusion constants (see text).

from the high temperature data (14) indicates, for an example, the oxygen ion diffusion constant in Y_2O_3 would be 10^{-19} cm^2/sec at 25°C. The diffusion constant in ZrO_2-CaO solid solution (15) can also be estimated to be in the order of 10^{-22} cm^2/sec at 25°C while this solid solution is well known as a good oxygen ion conductor at a high temperature and its D at 1000°C is 10^{-7} cm^2/sec.

Surface-Catalyzed Anodes for Hydrazine Fuel Cells

II. Lifetime Studies of Heat-Treated Nickel Boride Catalyzed Anodes

Stuart G. Meibuhr* and Robert F. Paluch

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The potential-time relationship of nickel boride catalyzed anodes for the electrochemical oxidation of hydrazine is different from that relationship for similarly catalyzed hydrogen anodes. The potential of freshly catalyzed, nickel boride hydrazine anodes exhibits a decay with time. Chemical, electrochemical, and microscopic analyses related the rate of boron loss from the anode to the rate of decay of the anodic potential. By subjecting the anode to a mild heat-treatment, considerable improvement in the life was achieved. Results are presented and a mechanism proposed to explain the data.

During work at these Laboratories, the potential of nickel boride (Ni_2B) catalyzed anodes for hydrazine fuel cells initially showed a decay with operating time. The decay occurred because the Ni_2B catalyst was being mechanically removed from the substrate by the evolved N_2 gas. Black catalyst particles were found in the electrolyte. This problem was overcome by depositing the catalyst on a Mond Ni substrate (1).

Later, when the anodes were operated at 0.2 A/cm^2 for times exceeding 8 hr, the resistance-free, anode-reference (A-R) potential (using a Hg/HgO reference electrode) showed another decay. On the average, this decay (to the arbitrary cutoff potential of -0.95V) occurred in about 60 hr of operating time, corresponding to about 220 hr of activation time (abbreviated as 60/220). The best times were 80/300 hr. This decay was not accompanied by the mechanical dislodgement of the catalyst particles.

This paper discusses the cause of this second potential decay, several ways to inhibit that decay, and the mechanism of catalyst failure causing that decay.

Experimental

Two types of experiments were performed. The first involved electrochemical lifetime studies with catalyzed anodes and the other involved measuring the surface area and determining the stoichiometry of nickel boride powders that had been subjected to various treatments.

Anode preparation.—Experimental details regarding the electroformation of the ribbed Ni substrates, the deposition of Mond 255 Ni powder, and its subsequent catalyzation with Ni_2B have been given before (1). The codeposition of the Mond Ni powder with electroplated Ni was performed at the optimum conditions as detailed previously (1), the maximum number of coulombs used was 1200 and stirring of the bath was limited to the first 10% of the total codeposition time.

Heat-treating of the freshly catalyzed anodes was performed in a tube furnace (ID = 70 mm, heated length = 0.44m, total tube volume = 0.00225 m^3) modified to operate over a temperature range from about 20° to about 300°C and to accept a flowing gas—dried air, air humidified at different temperatures, Ar, or Ar containing 6% H_2. Anodes were also heat-treated under reduced pressure (about 100 Pa) in this same tube furnace.

The heat-treatment was performed in three sequential steps of flushing, heating, and finally cooling.

1. After the electrodes were positioned inside, the tube was flushed for 1 hr with Ar at 1.5 liters/min to remove the air.
2. After the first step was completed, the heating was begun. When the temperature reached the desired value, the inert-gas flow was stopped and the flow of the desired gas was started, again at 1.5 liters/min for 1 hr.
3. After the appropriate heating step, the inert gas flow was again begun and the furnace was cooled. The anodes were exposed to the air only at room temperature.

Steps 1 and 3 were eliminated during the heat-treatment in air. When anodes were heat-treated under reduced pressure, step 1 consisted of 1 hr of pumping, step 2 consisted of heating while still maintaining the pumping, and finally, step 3 consisted of cooling under the reduced atmosphere.

Test procedure.—The catalyzed, heat-treated anodes (48 cm^2 active area) were prepared and tested in duplicate. They were operated against a Ni-plated, perforated steel sheet in the cell shown in Fig. 1, at a constant current density of 0.2 A/cm^2. The electrolyte (5.7M [33%] KOH containing 1M [3.2%] N_2H_4) flow rate was about 16 times stoichiometric for this current

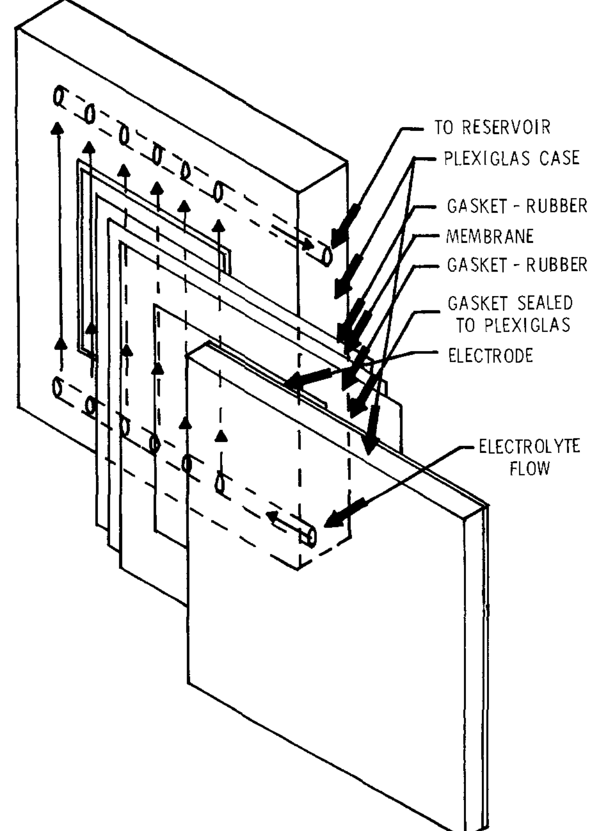

Fig. 1. Schematic diagram of test cell

* Electrochemical Society Active Member.

Key words: nickel-boride, hydrazine, anodes, fuel cells.

density; the electrolyte temperature was 31° ± 1°C. *IR*-free polarization data were taken regularly using a Kordesch-Marko (2) bridge. The 5.7M KOH electrolyte was prepared by diluting 45% KOH-mercury-cell-liquor with deionized water. In all cases, the anode potentials were measured against the Hg/HgO reference electrode.

Scanning electron micrographs were made at low magnification of the Ni_2B surface before and after the electrochemical test. Chemical analyses of the KOH half-cell electrolyte were performed for the presence of boron at the conclusion of several electrochemical tests.

Preparation of nickel boride powder.—The nickel boride powder was prepared by chemical precipitation; a 5% solution of nickel acetate was added slowly to a stirred, 10% solution of $NaBH_4$. An excess of $NaBH_4$ was used. The precipitate was washed well, filtered, and air dried for several days. This powder (about 1g) was spread thinly in a quartz boat that was then positioned in the tube furnace for the appropriate heat-treatment. The heating steps were the same as before.

Surface area determination.—All surface area determinations were made on the Numinco "Orr Surface-Area Pore-Volume Analyzer," Model MIC 103. The recommended procedure (3) was altered so that during the initial evacuation of the sample, no external heat was applied to accelerate the degassing. Thus, no heat was applied to the nickel boride powder samples except during the previous heat-treatment process. The surface area values were computer calculated from a simplified version of the program provided by the equipment manufacturer (3).

Soaking the powder in KOH.—After the surface area was determined (after the desired heat-treatment of step 2), a known weight of powder was soaked in 50 ml of hot (82°C) 33% KOH for 8 and finally for 64 hr at room temperature. The KOH was retained in a plastic beaker to eliminate any boron contamination from borosilicate glass beakers. This procedure was designed to simulate conditions existing during the electrochemical cell testing. These KOH solutions were subsequently analyzed for boron. The powders were washed to remove KOH and finally air dried for several days. The surface area was redetermined.

Differential thermal analysis (DTA).—All DTA data were obtained using a controlled atmosphere DTA system that permitted analyses to be performed at pressures from about 0.13 to about 2×10^5 Pa.

Results and Discussion

Freshly catalyzed anodes.—Freshly catalyzed Ni_2B anodes exhibited a time dependence in the anode potential as depicted in Fig. 2. The arbitrary cutoff potential was −0.95V; the anode life is indicated in terms of two numbers—the first number designates the number of hours the anode has operated at 0.2 A/cm^2, whereas the second number designates the total number of hours the anode has remained in contact with the KOH (activation time), which includes both the load time and the time at open circuit. The total activation time was about four times longer than the operating time. The potential decayed to the arbitrary cutoff value within 60 hr of operating time on the average, corresponding to an activation time of 220 hr.

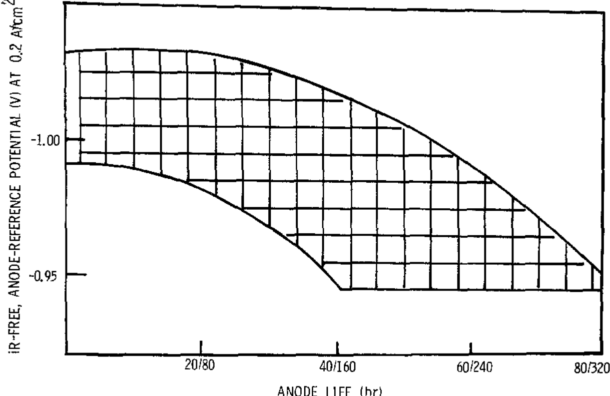

Fig. 2. Anode life (in hours) to an arbitrary cutoff potential of —0.95V (at 0.2 A/cm^2).

Figure 3 shows a representative sampling of the SEM micrographs taken of the Ni_2B surface before and after the electrochemical life test. The photomicrographs in the right column are of the freshly catalyzed Ni_2B surface, whereas those in the left column are of the Ni_2B surface after the life test. Figures 3G and 3H are side views of the electrodes and show the Ni sheet, the Mond particles, and the Ni_2B catalyst. Clearly, the photos in the left column show that there is a loss of material from the catalyst surface; the Ni_2B surface has become less dense, and the structure is more open than that depicted in the right column of photomicrographs. Since no black particles were evident in the KOH electrolyte during the electrochemical test, the shedding problem discussed before (1) was not the cause of the material loss. It appeared that the loss was by dissolution into the KOH.

To identify what was dissolving from the electrode, the KOH electrolyte was analyzed for boron and nickel at the end of the life test. No Ni was detected in the

Item	Anode No.	Boron (μg/ml)	Comments	Time operating/contact (hr/hr)	Rate of boron loss (μg/hr)
1	Blank	<0.1	33% KOH	—	—
2	227	3.6	Anode soaked in KOH for 8 days	—/196	0.018
3	212	4.0	Std anode, 2 kA/m²	56/225	0.018
4	279	5.5	Std anode, 4 kA/m²	58/230	0.019
5	—	5.9	Std anode, 2 kA/m²	78/300	0.020
6	274	0.3	Heat-treated air, 93°C, 1 hr	20/64	0.005
7	274	1.5	Heat-treated air, 93°C, 1 hr	126/509	0.003
8	275	3.8	Heat-treated, 147°C, 1 hr	56/219	0.017

electrolyte. In Table I, items 1-5, which are results for freshly catalyzed anodes, demonstrate that boron was indeed being removed from the anode (item 3). The rate of boron lost (micrograms per hour of activation time) was independent of the operating current density or operating time. The same loss rate (about 0.018 μg/hr) occurred regardless of how the anode was operated: (*i*) only at open circuit, item 2; (*ii*) at 0.2 A/cm^2, items 3 and 5; (*iii*) at 0.4 A/cm^2, item 4. These results demonstrated that the boron loss was by a chemical dissolution mechanism. The rate of boron loss was closely associated with the rate of decay in the electrochemical potential of the anode during life testing.

A material balance on boron was made, understanding that (*i*) the catalyst formula was Ni_2B, (*ii*) there were 3 mg/cm^2 Ni_2B on the 48 cm^2 anode, (*iii*) the total electrolyte volume was 300 ml. The calculation showed that only about 5-15% of the boron initially on the anode was dissolved into the electrolyte. Consequently, it may be that the boron is lost only at the surface leaving behind an inactive surface for hydrazine oxidation.

Electron probe analysis failed to identify the presence of boron on the anode either before or after the life test. X-ray analysis showed no crystalline pattern for the nickel boride.

The surface area changes in nickel boride powder caused by the contact of the powder with hot KOH is presented in Table II as items 1 and 2. These samples are duplicate batches of powder, neither of which were heat-treated. Column 1 gives the initial surface area of the powder, column 2 tabulates the ratio of the surface area before heat-treatment to the surface area after a specified heat-treatment, column 3 presents the surface area of the specified powder after the KOH contact, column 4 lists the ratio of the surface area before the contact to the surface area after the contact, column 5 gives the absolute boron content of the KOH after contact with the powder, and finally column 6 presents the normalized value of the amount of boron lost per gram of powder. These data show that contacting the powder with KOH causes the surface area to increase about 2¼ times. This increase in the surface

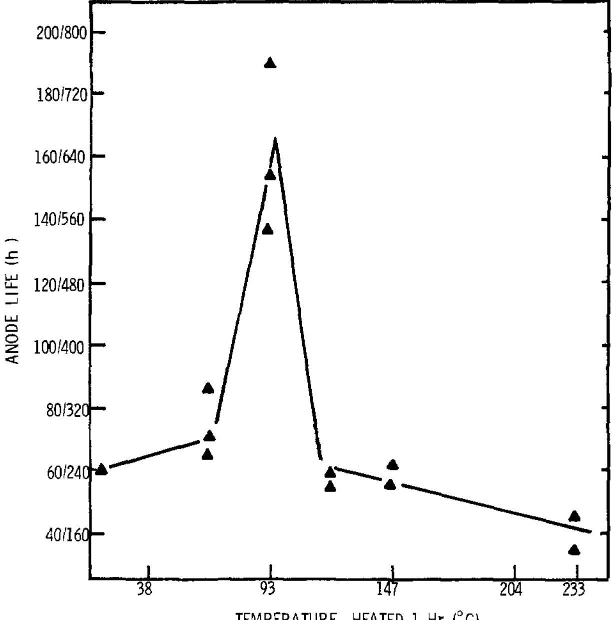

Fig. 4. Lifetime variation of heat-treated Ni_2B anodes using flowing, dry air.

area is consistent with what was seen in the SEM's of Fig. 3. The data of column 5 and 6 (Table II) agree with the data of Table I, items 2-5, that boron is leached out of the nickel boride material.

Anodes heat-treated in dry air.—Preliminary results showed that the operating lifetime of a Ni_2B catalyzed anode was significantly lengthened from 60 hr (60/220) to 160 hr (160/640) by a simple heat-treatment in air. The effect of different heat-treatment temperatures, to 233°C, on the life is displayed in Fig. 4. Despite some scatter in the data, it is clear that the optimum temperature for heat-treating Ni_2B catalyzed anodes in dry air is 93°C. The polarization curves are presented in Fig. 5 for the best performing heat-treated anode. The anodic polarization, curve A, remained unchanged for operating times exceeding 50 hr. At the 100 operating-hr time, the potential had fallen to that drawn as curve B. At the 180 operating-hr level, the potential had dropped to that given in curve C. This anode was in contact with the electrolyte for more than 700 hr.

The chemical analyses of the KOH electrolyte in contact with some of the heat-treated anodes are listed in Table I as items 6-8. These data show that the heat-treated anodes lose boron less rapidly than the non-heat-treated anodes. The rate of boron loss for anodes treated at 93°C was only 25% that for nontreated anodes. The boron loss rate for anodes treated at 147°C corresponded closely to that for nontreated anodes. These data support the hypothesis that the cause of the decay in the anodic potential during hydrazine oxidation of Ni_2B-catalyzed anodes is the loss of boron from the catalyst.

Table II. Nickel boride powder data

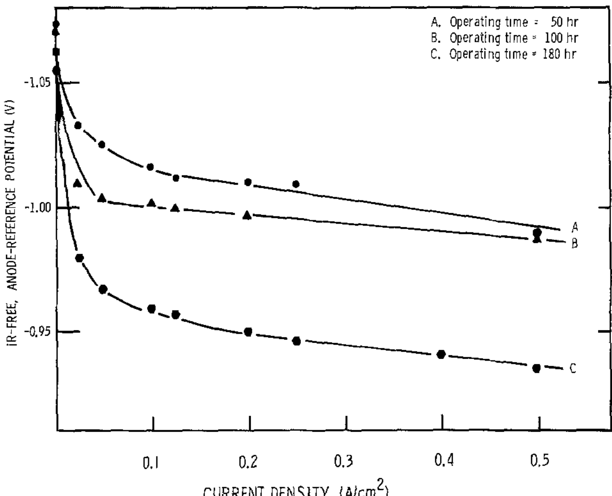

Fig. 5. Variation of the voltage vs. current density curve with time for a dry air, heat-treated, Ni_2B anode (No. 311).

In Fig. 6 are displayed the SEM micrographs showing the effect of temperature on the surface structure of the nickel boride. Parts A-C of Fig. 6 are micrographs of the nonheat-treated surface at three different magnifications; parts D-F are the micrographs of the nickel boride heat-treated at 93°C for 1 hr; and parts G-I are micrographs of the nickel boride treated at 233°C for 1 hr. The micrographs show that the nickel boride surface loses material when it is heated in dry air. This is most evident in the micrographs at low magnification in the left column.

At a heat-treating temperature of 233°C, considerably more material was lost than at 93°C. This loss must be considered excessive because the lifetime of the resultant anodes was well below that achieved for anodes treated at 93°C (see Fig. 4).

It is necessary to have a continuous flow of air over the anodes. In one experiment at 93°C in the tube furnace, no air was supplied to the system. Both ends of the furnace were open, however, so that air could diffuse through the tube. These two anodes had a very short operating life of about 20 hr (20/65) and had a poor initial operating anode-reference potential of about −0.97V.

The length of time that anodes are heat-treated is another important parameter. Table III presents the lifetime results for anodes treated at 93°C in flowing air for four different lengths of time. The data showed that (*i*) the 1 hr time yielded anodes with the best life, and (*ii*) the 16 hr time caused serious shortening in the life. The micrographs of Fig. 7 show surface changes that occurred in Ni_2B that was heated in flowing air at 93°C for times from 5 min to 2 hr. After heat-treatment for 2 hr (Fig. 7F), breaks in the Ni_2B surface have become evident, which are absent from the sample that was heat-treated for only 1 hr (Fig. 7E). It is evident that the optimum heat-treating conditions in dry air necessary to maximize the anode life are 93°C for 1 hr. Several possibilities exist to explain this improvement:

1. Some of the boron is removed during the heat-treatment yielding a stoichiometry that is more resistant to the KOH leaching of boron.

Table III. Effect of heat-treatment time

Heat-treatment time at 93°C (hr)	Operating time (> −0.95V)/ contact time
0	26/74
½	43/175
1	160/600
4	50/198
16	12/28

2. Surface oxides could form, which in turn make the surface more resistant to the KOH leaching of boron.

3. Some type of structural change occurs during the heat-treatment. With the present data, it is not possible to identify the mechanism involved in this heat-treatment stabilization of nickel boride catalyzed anodes for hydrazine oxidation.

Anodes heat-treated in a reducing atmosphere.—Heat-treating anodes in a reducing (6% H_2 in Ar) atmosphere has yielded anodes with an improvement of one to two orders of magnitude in lifetime. Figure 8 presents the lifetime data of three differently processed nickel boride catalyzed anodes. Curve A represent the average time decay of freshly catalyzed anodes (0.32 mV/hr decay rate). Curve B represents the average time decay of anodes treated in dry air at the optimum condition of 93°C for 1 hr (0.12 mV/hr decay rate). Curves C and C′ represent the time decay for two anodes treated in the reducing atmosphere at 93°C for 1 hr (0.014 mV/hr decay rate). Thus the time decay for dilute H_2 treated anodes (to the cutoff voltage of −0.95V) is about one to two orders of magnitude less than for the untreated anodes.

The effect of different heat-treating temperatures (for 1 hr in the dilute H_2) on the life (defined similarly as for the air-treated anodes) is presented in Fig. 9. The circles represent data for anodes treated exactly as indicated by steps 1-3. The triangles correspond to data for anodes that were cooled in the same dilute H_2 gas that was used for heat-treating (used the same gas in steps 2 and 3); and the squares represent data for two anodes treated and cooled in 100% H_2.

In Fig. 10 is plotted the effect of different heat-treating times (in 6% H_2 at 93°C) on the life of nickel boride anodes. The data from Fig. 9 and 10 show that the longest lived anodes were produced when the time in the flowing 6% H_2 stream was limited to 1 hr at a temperature of 93°C. The best life was also achieved when the cooling cycle was performed in Ar gas.

Anodes were also heat-treated under reduced pressure (100 Pa) at 93°C for 1 hr. The average lifetime of these anodes (before the cutoff potential was reached) was about 180/650 hr. This value is practically the same as that achieved by heat-treating anodes in air and considerably below the value achieved by heat-treating in a reducing atmosphere. The SEM micrographs of vacuum, heat-treated anodes appeared similar to the micrographs for air, heat-treated anodes. Anodes that were heat-treated in an inert atmosphere (100% Ar) at 93°C for 1 hr had a lifetime of about 300/1500 hr.

Several experiments were performed with nickel boride powders that were heat-treated in the reducing atmosphere at different temperatures. The data is presented in Table II, items 3-7. The value of the surface area measured after the heat-treatment was compared to the value measured before the treatment; the resultant ratios (column 2) are plotted in Fig. 11 as closed triangles. The open circles represent data from Jasinski (4); these powders were treated in vacuum for times varying from 2.5 to 17 hr. The closed circle represents data of Lindholm (5) for a nickel boride powder that was heat-treated in 100% H_2 for 1 hr. Although there is some scatter in the data, they do demonstrate that the surface area of nickel boride powders decrease with increased heating temperatures. Thus, the improved electrochemical performance evidenced for the H_2-treated anodes cannot be ascribed to changes in surface area.

The surface area of freshly precipitated nickel boride powders that were soaked in KOH increased about 2¼ times (relative to their surface area before the immersion); see Table II, column 4, items 1 and 2. For powders that were heat-treated in 6% H_2, this test caused the surface area to increase linearly with increasing temperature of heat-treatment (Fig. 12).

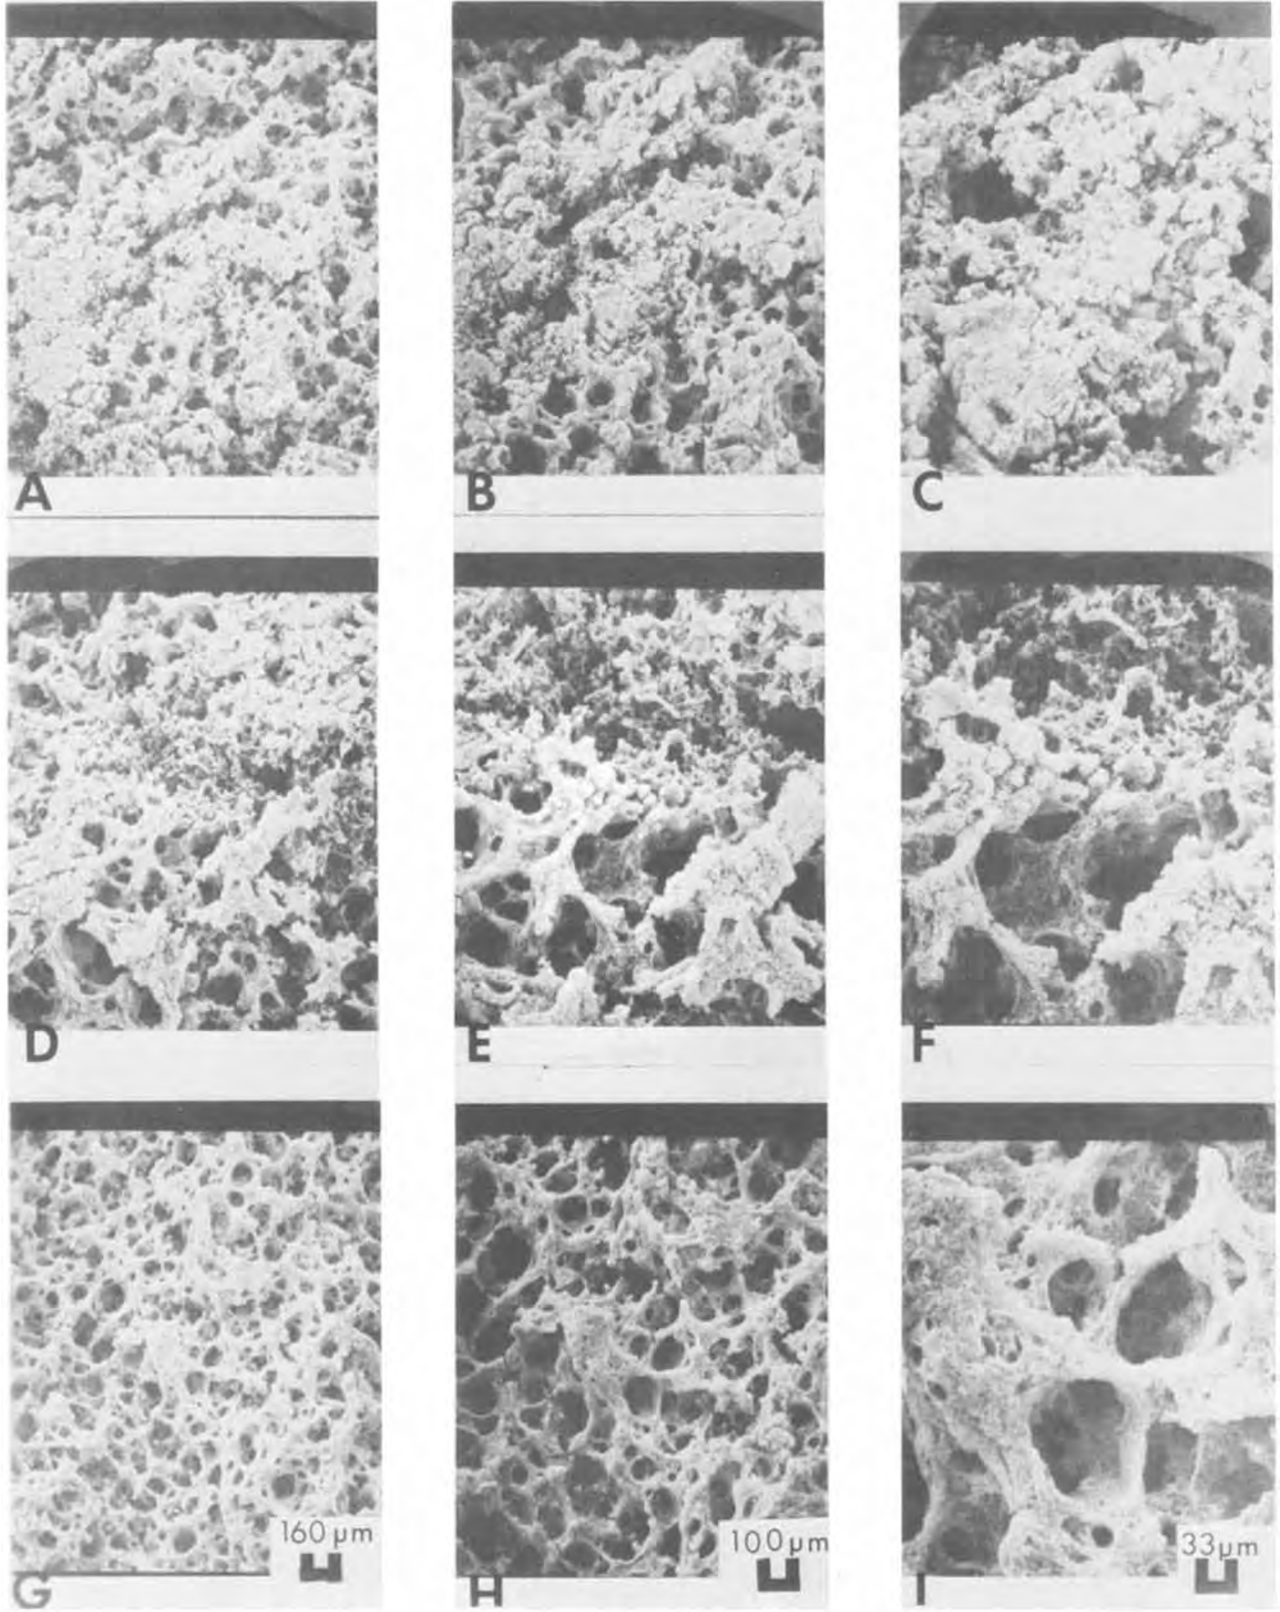

Fig. 6. Effect of temperature on Ni_2B catalyst. A, B, C, nonheat-treated; D, E, F, heated at 93°C for 1 hr; G, H, I, heated at 233°C for 1 hr. A, D, G, magnification, 60X; B, E, H, magnification, 100X; C, F, I, magnification, 300X.

Several reasons for the sudden decrease in the ratio for the powder heated at 300°C include (*i*) at 300°C there may occur sufficient physical changes such as sintering which leaves a surface that is more resistant to the subsequent chemical attack by the KOH; or (*ii*) sufficient chemical changes occur such as boron loss which leaves a surface that is more resistant to the subsequent chemical attack by the KOH.

The boron content of the KOH used in the immersion tests is listed in column 5 of Table II, and a normalized value (to unit weight) is listed in column 6. The normalized boron loss is at its lowest value for the powder that was heat-treated in 6% H_2 for 1 hr at 93°C, the same conditions that have produced the longest lived nickel boride catalyzed hydrazine anode.

Analysis of a freshly precipitated powder for both nickel and boron showed the stoichiometry to be Ni_2B in agreement with the literature (5-7). Heat-treating the freshly precipitated powder in 6% H_2 at 93°C for 1 hr, caused the stoichiometry to become $Ni_2B_{0.67}$.

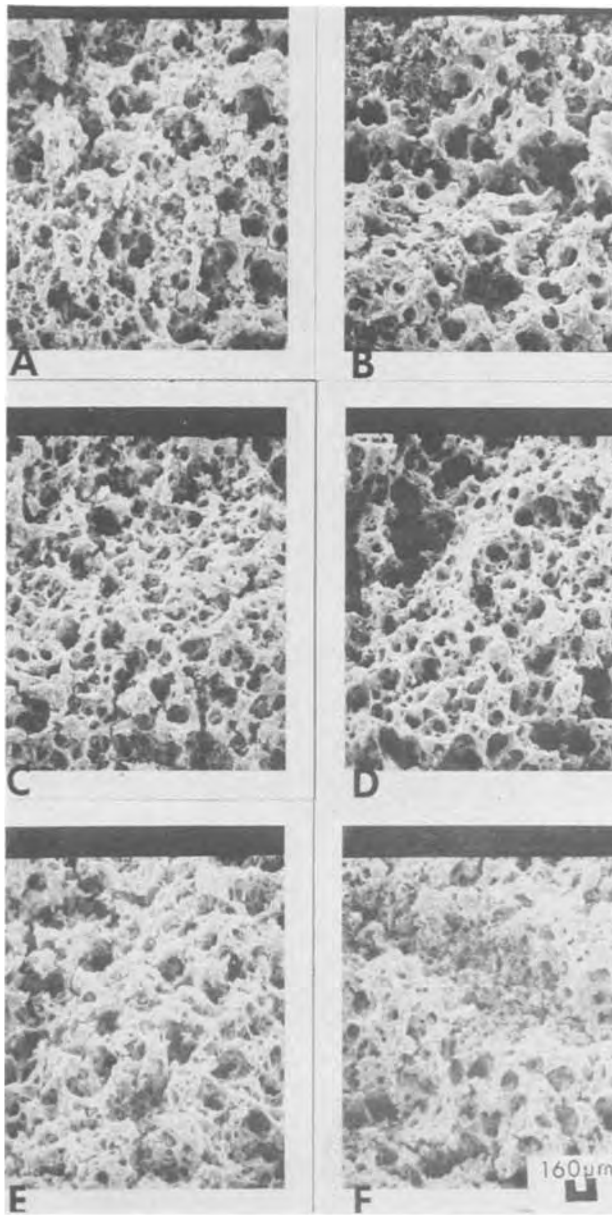

Fig. 7. The effect of heat-treatment time (in dry air) on the structure of Ni_2B at constant temperature (93°C). Magnification, 60X. A, $\Delta t = 0$ min; B, $\Delta t = 5$ min; C, $\Delta t = 10$ min; D, $\Delta t = 30$ min; E, $\Delta t = 60$ min; F, $\Delta t = 120$ min.

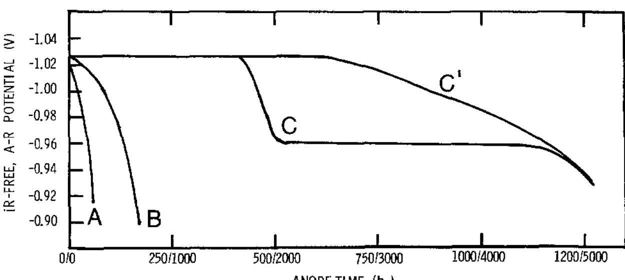

Fig. 8. Lifetimes of Ni_2B-catalyzed anodes. A, nontreated; B, heat-treated in flowing air at 93°C for 1 hr; C and C′, heat-treated in flowing 6% H_2 at 93°C for 1 hr.

Differential thermal analysis was performed on nickel boride powder before and after different heat-treatments (in 6% H_2 in Ar atmosphere). Three DTA curves (run in 6% H_2 in Ar) are presented in Fig. 13. Curve A corresponds to the nonheat-treated material; five peaks were observed, occurring at 64°C (a), 120°C (b), 345-350°C (c), 430°C (d), and 525°C (e). Curve B

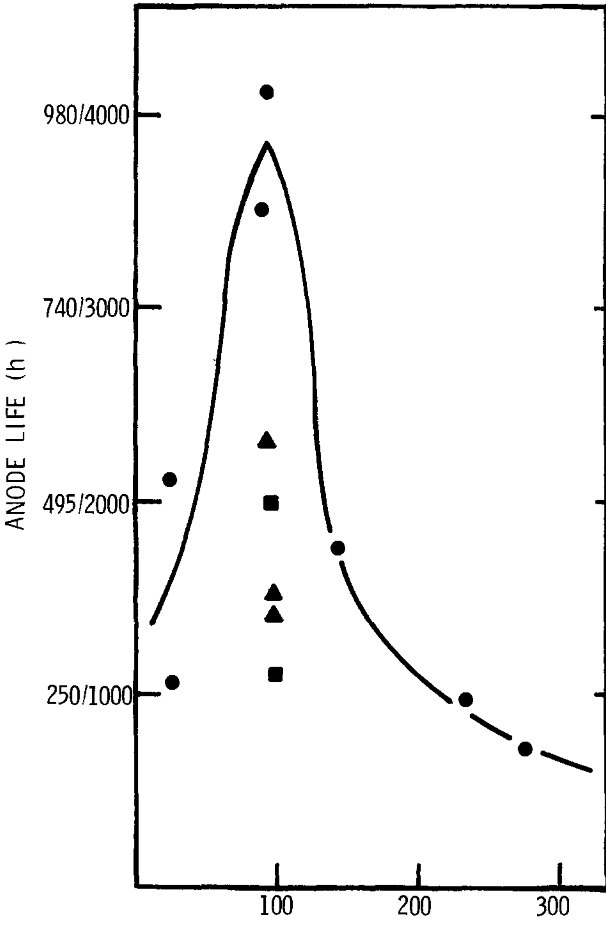

Fig. 9. Lifetime variation of heat-treated Ni_2B anodes in flowing H_2 as a function of heating temperature for a heating time of 1 hr. ●, Steps 1-3 followed; ▲, cooled in 6% H_2; ■, heated and cooled in 100% H_2.

corresponds to a material that was heat-treated in 6% H_2 in Ar at 93°C for 1 hr. Two changes occurred in the DTA curve, peak (a) was eliminated and the ratio of heights of peaks (c) and (d) was reversed. Heat-treating the nickel boride to a higher temperature of 260°C for 1 hr in the 6% H_2 in Ar produced a material having the DTA curve represented by curve C. These curves imply that the Ni/B stoichiometry was altered by the specific heat-treatment. Analogous results were obtained when the nickel boride powder was heat-treated at 93°C for different times. Nonreproducible results occurred when an inert gas (N_2 or Ar) was used to blanket the sample during the DTA run.

Nickel boride powder was scrapped off anodes that had been under electrochemical testing for 450 and 2200 hr, and then DTA analysis was performed. The results are shown in Fig. 14; curve A corresponds to the catalyst material after 450 hr in contact with KOH and curve B, after 2200 hr. No characteristic nickel boride peaks were obtained with the latter material. It is obvious that contact with KOH altered the Ni/B stoichiometry of the catalyst. The elimination of peaks (c) and (d) (curve B) after 2200 hr contact with KOH occurred at about the same time that the iR-free anode-reference potential started to drop from its original value (curves C and C′ of Fig. 8). It appears the two phenomena are related.

The chemical analysis of the nickel boride powders before and after a 6% H_2 heat-treatment and the SEM micrographs of heat-treated anodes showed that the heat-treatment process removed boron from the catalyst; and the KOH leaching of boron was retarded from the H_2 heat-treated nickel boride. Just as there were several possible explanations for the improved anode life by heat-treating in air, so are there several

possible explanations for the 1-2 order of magnitude improvement in anode life caused by heat-treating in 6% H_2. These include: (*i*) during the H_2 heat-treatment process, some of the boron is removed (perhaps by reaction with the H_2 to form volatile boron hydrides) leaving a Ni/B catalyst stoichiometry that is more resistant to attack by KOH and therefore capable of sustaining a current load at low overvoltage for prolonged times; (*ii*) during the heat-treatment process, surface oxides are removed by reduction with the H_2 followed by some sintering of the catalyst thereby rendering the catalyst more resistant to attack by KOH and therefore capable of sustaining a current load at

low overvoltage for prolonged times; (*iii*) during the heat-treatment process the surface could anneal (relieve stress).

Since the rate of potential decay of all the H_2-treated nickel boride catalyzed anodes was associated with the rate of boron loss from that catalyst, it appears that the first explanation is the most likely.

Hydrogen Overpotential on Zinc Alloys in Alkaline Solution

T. S. Lee*[,1]

Union Carbide Corporation, Battery Products Division, Parma Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

Hydrogen overpotential on uniformly prepared Zn alloys of Hg, Pb, and Cd in 9*N* KOH solution are measured. The effect of small amounts of iron evenly distributed in the sample on the overpotential of Zn-Hg and Zn-Pb alloys are also observed. Exchange current densities (I_0) and transfer coefficients (α) for the hydrogen evolution process on these surfaces are obtained.

Due to increased interest in using zinc electrodes in alkaline battery systems in the last decade, the behavior of zinc electrodes in alkaline media has been studied more in the past decade than ever before. Data on hydrogen overpotential on zinc in alkaline solution, which has both theoretical and practical interest, have appeared in the literature (1, 2). The data on zinc containing small amounts of impurities in alkaline media also have been published (3, 4). However, except for very sketchy reports (5), hydrogen overpotentials on uniformly prepared zinc alloys in concentrated alkaline solutions have not yet been reported. The present paper reports the measurement of hydrogen overpotentials on carefully prepared zinc alloys of Zn-Hg, Zn-Cd, Zn-Pb, Zn-Mn as well as Zn-Pb-Fe and Zn-Hg-Pb in 9*N* KOH solution at room temperature. It is believed that these will serve not only as scientific information but will also provide factual background for those who wish to use them to interpret zinc corrosion phenomena in alkaline systems (6).

Experimental

The cell used for the measurements is a modified H-type cell equipped as a closed system under a hydrogen atmosphere. It is made from epoxy-lined "Pyrex" so that the inner walls are highly alkaline-resistant. The details of the cell, the lining technique and tests for resistance to concentrated alkaline solution were reported previously (2).

The samples are prepared by alloying the high-purity zinc (99.999+%) with other pure metals. The purity of the other metals are as follows: mercury 99.996+%, lead 99.999+%, cadmium 99.999+%, manganese 99.99+%, and iron 99.99+%. The details of making these alloys were reported elsewhere (4). In short, the alloys are prepared under inert atmosphere with great care to assure their uniformity and, simultanously to avoid the introduction of any foreign materials. The final alloys are subjected to metallographic examinations and electron-microprobe analyses to determine their exact purity and uniformity.

The working electrodes are prepared from those alloys by cutting a piece from the center of the final casts.[2] The exposed area of this piece is about 1 cm^2; the remainder is electrically insulated with the same epoxy used to line the cell. The electrode surface is prepared and treated by following the same procedure described before (2).

The counterelectrode is made from pure nickel and its area is about 8-10 times that of the working electrode in order to minimize the introduction of peroxide in the cell. The reference is a Hg/HgO electrode in contact with the same KOH solution as that in the cell. The concentration of the KOH is 9*N*.

The constant current is supplied by a Harrison Laboratories' Model 855C power supply through a variable power resistor in series. The potentials are measured by a Keithley Model 630 potentiometric electrometer, which has a minimum input resistance of 10^{13} ohm. All measurements are carried out at room temperature which is controlled at 25° ± 1°C. Measurements are carried out from the high current density to the low current density region and back again; this process is then repeated.

At each current density, the steady potential is obtained in a few minutes. Once the steady potential is reached, the electrode will stay at the same potential as long as ½ hr without any change. The data presented here are the average values of four runs. The deviation of each run from the average value is only a

few millivolts; there is no hysteresis in any of the runs. After the measurement, the electrodes are washed, dried, and examined under a microscope. The surface does not appear to have changed from its original appearance.

Results and Discussion

Hydrogen evolution on a zinc surface under imposed electric potential in alkaline solution is known to have the over-all reaction: $2H_2O + 2e = H_2 + 2\,OH^-$. The rate-determining step in this reaction is electron transfer. The transfer coefficient $\alpha = 1/2$, and the hydrogen overpotential (η) for the reaction as shown previously (2) is

$$\eta = \text{const} + \frac{RT}{\mathbf{F}} \ln A_{H_2O}A_{OH^-} - \frac{2RT}{\mathbf{F}} \ln I$$

where A denotes the activity, I is the current density, and the other symbols have their usual meaning. At constant temperature and definite KOH concentration, the above equation reduces to the Tafel equation $\eta = a + b \log I$, where a and b are constants.

In the experiments, the hydrogen overpotentials are obtained by subtracting the reversible hydrogen potential from the measured potential. The reversible hydrogen potential in 9*N* KOH at 25°C, as both measured and calculated before (2), is −0.938V against a Hg/HgO electrode.

The hydrogen overpotentials of alloys of Zn-Hg, Zn-Cd, Zn-Pb, and Zn-Mn in 9*N* KOH are shown in Fig. 1-4, respectively, as a function of log current densities. In Fig. 1, one can see that all the mercury alloys have a higher hydrogen overpotential than that of pure zinc. The numerical value of the overpotential of Zn-2% Hg is higher than that of pure zinc and the Tafel slope is about the same as that of zinc. As the mercury content increases to 4 and 8%, the numerical

values of hydrogen overpotential increase by more than 100 mV in the low current density region, while in the high current density region, the increase is not that much. This is due to the result of Tafel slope decrease as the mercury content in the sample increases. From the figure it looks as if the hydrogen overpotential data for the 4% Hg alloys are not much different from those for the 8% Hg alloys. However, by careful examination, one can see that the slope of the overpotential for the 8% Hg alloy is slightly smaller than that for the 4% Hg alloy. This may account for the slightly better corrosion protection of a zinc electrode with 8% Hg than that with 4% Hg in an alkaline electrolyte. This is schematically illustrated in Fig. 6. The anodic reaction of $Zn/ZnO_2^{=}$ in alkaline solution is represented by curve a, which will not vary under

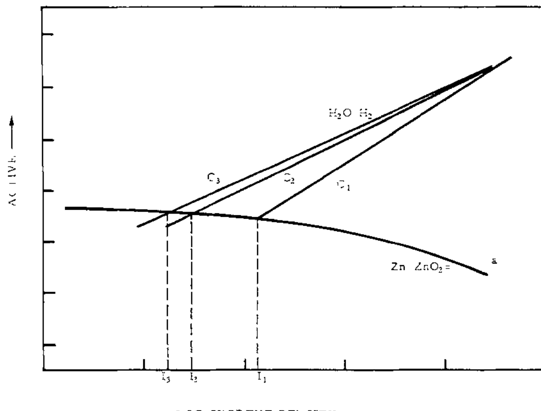

Fig. 6. Corrosion currents of zinc in alkaline solution with different slopes of H_2O/H_2 reaction.

the specific condition. The cathodic reaction of H_2O/H_2 is represented by the family of curves c_1, c_2, and c_3. Curve c_1 represents the reduction of water on zinc surface. Curve c_2 is that of the cathodic reaction on the Zn-Hg surface and that of c_3 is the reaction on the Zn-Hg surface with a higher mercury content on the sample than that of c_2. All the three curves intercept the curve of the anodic reaction $Zn/ZnO_2^=$ at I_1, I_2, and I_3, respectively. The numerical value of I_1, I_2, and I_3 are known as the corrosion currents of the respective surfaces in the KOH solution. The smallest numerical value of the three corrosion currents is I_3. This is obtained as a result of the lowest slope of the water reduction on the metal surface. The experimental data shows that the higher the mercury content in the zinc alloy the lower the slope of the cathodic water reduction reaction. In Fig. 6 curve c_3 represents the cathodic reduction of water on the zinc surface containing the largest amount of mercury and shows the lowest corrosion current (I_3) of all curves.

Figure 2 shows the hydrogen overpotential plots for the cadmium alloys. As shown previously by (4), a small amount of Cd (0.05%) in Zn does not change the overpotential one way or the other. As the cadmium content increases to 4 and 8% in the alloys, the Tafel slope changes to that of cadmium. The hydrogen overpotential on Cd is reproduced in the figure for comparison. It appears that the cadmium alloy in the alkaline system behaves like cadmium but at a higher numerical value than that of pure cadmium. It is interesting to point out that the transfer coefficients (α) derived from the Zn-Cd alloys containing 4-8% cadmium are the same as those obtained from cadmium in 6*N* NaOH solution by Zhouldev and Stender (7) ($\alpha = 0.37$) and are not much different from those obtained in 1*N* HCl by Hickling and Salt (8) ($\alpha \simeq 0.3$). The increase of the slope for the Zn-Cd alloy is the result of the cadmium component in the alloy. This might be due to a stronger adsorption of cations in the solution on the alloy surface than on pure zinc. The hydrogen overpotentials on lead alloys are plotted in Fig. 3. The slope of the overpotential on Zn-0.2% Pb is about the same as that of pure zinc; even the numerical value in the low current density region is larger than that in the high current density region, the overpotential on Zn-0.8% Pb is uniformly higher than that of zinc. As the lead content increases to higher

Table I. Electrochemical parameters for hydrogen evolution reaction on various Zn alloys surface in 9*N* KOH

Surface	Slope	α	I_0 (A/cm²)
Zn	0.124	0.48	1.5×10^{-9}
Zn-2% Hg	0.116	0.51	2.7×10^{-10}
Zn-4% Hg	0.098	0.60	8×10^{-11}
Zn-8% Hg	0.086	0.69	6×10^{-12}
Zn-4% Cd	0.158	0.37	7×10^{-8}
Zn-8% Cd	0.154	0.37	1.5×10^{-8}
Zn-0.2% Pb	0.137	0.43	2×10^{-9}
Zn-0.8% Pb	0.134	0.44	1.3×10^{-9}
Zn-2% Pb	0.172	0.34	6.2×10^{-8}
Zn-0.05% Mn	0.138	0.43	5.1×10^{-8}
Zn-0.5% Mn	0.140	0.42	7.5×10^{-8}
Zn-2% Hg-0.2% Pb	0.125	0.48	6×10^{-10}
Zn-0.8% Pb-0.05% Fe	0.125	0.48	9×10^{-10}

percentages, as in Zn-2.0% Pb, the slope of the overpotential increases. This will cause the exchange current as well as the corrosion current to become larger than that of zinc which is less desirable than a lower percentage of lead with respect to corrosion protection. Figure 4 shows the plots for manganese alloys. It is evident that manganese in the alloy lowers the overpotential. The higher the content of manganese in the alloy, the lower is the numerical value of the overpotential. In Fig. 5, the interaction of one element with the other on the overpotential of the zinc alloy is shown. The 0.05% Fe introduced into zinc causes the overpotential decrease in the low current density region (curve 4). Where 0.8% Pb is added, however, the effect of iron is canceled (curve 2). The overpotential of the alloy Zn-0.8% Pb-0.05% Fe is uniformly higher than that of zinc. In other words, the effect of lead could mask the effect of iron. Curve 1 in Fig. 5 is the overpotential plot for Zn-2% Hg-0.2% Pb, which has a higher numerical value than either that of Zn-2% Hg or Zn-0.2% Pb.

The electrochemical parameters of the hydrogen evolution process are shown in Table I. Both the transfer coefficient (α) and exchange current (I_0) are derived from the Tafel plots.

Stress Corrosion Cracking of 4140 High Strength Steel in Aqueous Solutions

Aziz Asphahani* and H. H. Uhlig**

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The critical hardness value of 4140 steel is determined above which stress corrosion cracking (SCC) in boiling distilled water initiates within short times. Also the critical applied potentials are measured immediately below which SCC does not initiate. Cold work and various galvanic couples are evaluated. A reasonable mechanism of cracking is discussed.

The stress corrosion cracking (SCC) behavior of many high strength, low alloy steels stressed to 75% of their yield strength and exposed to a marine atmosphere was described by Phelps (1, 2). Most steels with yield strengths below 180 ksi (125 kg/mm^2) were resistant for at least 1000 days, some were resistant for this exposure period up to 210 ksi (148 kg/mm^2), but all failed within days or months above this strength level. Yamamoto and Fujita (3) described a similar upper critical strength level for observed SCC of low alloy steels in water equal to 155-170 ksi (110-120 kg/mm^2) yield strength, based on service data and laboratory tests. Although they reported that composition of a low alloy steel can also be a factor, their observed times to failure showed that strength level is the more important parameter determining susceptibility. They also showed that times to failure in water are appreciably shorter at elevated than at room temperatures; moreover, time to failure in 0.3% NaCl is a function of applied potential, as had been shown earlier for 12% Cr, 1% Mo, 0.3% V stainless steel in 3% NaCl by Phelps and Loginow (4) and for a 12% Ni maraging steel in sea water by Kirk, Covert, and May (5). Peterson *et al.* (6) using notched tensile bar specimens reported the potential range within which failure of H-11 steel [225 ksi yield strength (YS)] is inhibited for at least 160 hr in sea water.

Baker and Singleterry (7), using U bend specimens of 4340 steel having a Rockwell hardness of R_c 51, confirmed shorter failure times in various aqueous solutions at above room temperature, and reported a marked *p*H and anion effect. Fujita and Yamada (8) and Okada (9) recently described the SCC behavior of various high strength steels in aqueous media, again emphasizing a critical yield stress range above which, but not below, susceptibility is observed; they also discussed metallurgical factors, mechanisms, and various protective measures. Gilchrist and Narayan (10) reported failures of stressed, high strength 0.83% C steel wires anodically or cathodically polarized; furthermore they showed that cold drawn wires were not immune and that cracks proceeded by either "active path" or by hydrogen cracking. Yamaoka and Wranglen (11) earlier reported failures of stressed, high strength 0.4% C low alloy steel whether anodically or cathodically polarized in water. Johnson and Wilner (12) employing precracked specimens of H-11 low alloy steel (230 ksi YS) showed that a given upper stress intensity factor insufficient to cause crack growth in dry argon was nevertheless adequate to cause crack growth in moist argon corresponding to as little as 0.1% relative humidity (r.h.). The rate of crack growth increased with partial pressure of H_2O up to 60% r.h., above which the rate leveled off.

Key words: low alloy steels, critical potentials, decarburization, stress-sorption cracking, cold work, galvanic couples.

It is the purpose of the present investigation: (*i*) to explore the critical potential range within which failures by SCC do not initiate, and the effect in this respect of some environmental factors and cold work, and (*ii*) to interpret presently known facts in terms of possible mechanisms.

Experimental

The present A.I.S.I. Type 4140 steel (0.43% C, 0.91% Cr, 0.23% Mo, 0.90% Mn, 0.32% Si, 0.024% S, 0.01% P, 0.15% Ni) in the form of ⅜ in. rod was made available by courtesy of Inland Steel Company. After rolling to 41 mil (1.0 mm) thick strip, specimens were sheared to the dimensions: 1 3/4 × 3/16 in. (4.5 × 0.5 cm), abraded, degreased, and pickled in 5 volume per cent (v/o) HNO_3 at 80°C for 3 min. They were then bent beyond the elastic limit to the form of a C having a span of 1 7/16 in. (3.7 cm). Bent specimens were held between porcelain insulators by remote spring loading, being subject, therefore, to constant flow stress up to the time a crack initiated. Total failure time was recorded by an electric clock. The assembly was submerged in boiling distilled water or in boiling aqueous salt solution contained in a flask fitted with a condenser. Boiling temperatures were preferred over lower temperatures because of corresponding shorter times to failure. For conditions of controlled potential, the flask was fitted with a glass frit-separated side arm which was located near the position of maximum bending of the test specimen and contained a saturated calomel reference electrode. Two auxiliary Pt electrodes 3 × 1 in. (7.6 × 2.5 cm) were placed at opposite sides of the specimen within the cell. To make electrical contact, an iron wire enclosed by closely fitting Teflon tubing was spot welded to one end of the specimen. A Wenking potentiostat controlled the applied potential throughout a test run. A sketch of the cell but with auxiliary electrodes outside the cell appeared in a previous publication (13).

The present test as applied to high strength steels is a measure primarily of conditions leading to crack initiation rather than crack growth. Although many arguments have been presented in favor of using precracked specimens and measuring crack growth, there are also valid arguments in favor of using smooth test specimens. A smooth test specimen stressed beyond the elastic limit has the advantage of conforming closely to conditions typical of practical structures which through surface scoring or assembly procedures are stressed locally beyond the elastic limit. Furthermore only a smooth specimen makes it possible to evaluate precise environmental conditions affecting failure, as well as the true operating potential range within which cracks are not initiated. By way of contrast in tests employing a precracked specimen, both electrolyte *p*H and composition within a deep fissure can vary greatly with time (14), and the

true potential at the apex of a deep crack is largely unknown.

It should also be pointed out that values of stress intensity K_{ISCC} below which cracks supposedly do not grow in a damaging environment are of doubtful value to most practical situations, including those involving high strength metals. Brown (15) referring to crack growth in precracked specimens of high strength steels exposed to sea water has stated that there does not appear to be a clear-cut threshold strength below which SCC does not occur. This conclusion is in contrast to that applying to the use of smooth specimens where a critical yield strength for SCC in water or moist air has been reported by more than one investigator, and which, moreover, correlates closely with field tests and with broad practical experience. In addition, as Peterson *et al.* (6) show, at high stress levels (such as are presently applied) the observed crack growth rate of high strength 4340 steel in sea water at room temperature can be as high as ¼ in. (0.6 cm)/min. Under these conditions, it is obviously more useful to study factors that prevent crack initiation, and it is these conditions with which the present paper is concerned.

Results

Effect of hardness.—Since high strength steels exposed to water are found to be subject to SCC only when they are heat-treated above a specific yield strength range (which can be interpreted in terms of hardness), it was important to determine whether the present laboratory test correlates with practical experience and with field tests. The 4140 steel specimens water quenched from 850°C attained high hardness and strength (R_c 53), but these on bending failed mechanically. Lower hardness values were obtained by tempering at 350°C or higher temperatures. Furnace-cooled specimens (in purified argon) were least hard, measuring about R_c 10. Tests in boiling distilled water showed that stressed water-quenched and tempered specimens (R_c 47) failed within the short time of 2 hr or less, but that furnace-cooled specimens did not fail within the maximum test period arbitrarily set at 200 hr. Averaged data (2 to 3 specimens) of Fig. 1 show that the critical hardness below which failure times are >200 hr is about R_c 42. This value corresponds to a yield strength of 185 ksi (130 kg/mm^2) which is close to the room temperature critical range established by Phelps through long time marine atmosphere tests (1, 2). The steep fall off of failure time with hardness confirms a critical range of hardness values above which SCC occurs. The lower level of hardness or yield strength corresponding to absence of SCC or very long expected life in a moist atmosphere can at best be estimated from broad practical experience; corrosion fatigue data of Lee and Uhlig (16) also contribute relevant information. They found no effect of moisture in air on the fatigue life of 4140 steel below the interpolated value of R_c 32-35 corresponding to a yield strength of 145-151 ksi (102-106 kg/mm^2). This lower critical range is reasonably close to that reported by Yamamoto and Fujita (3) and by Okada (9).

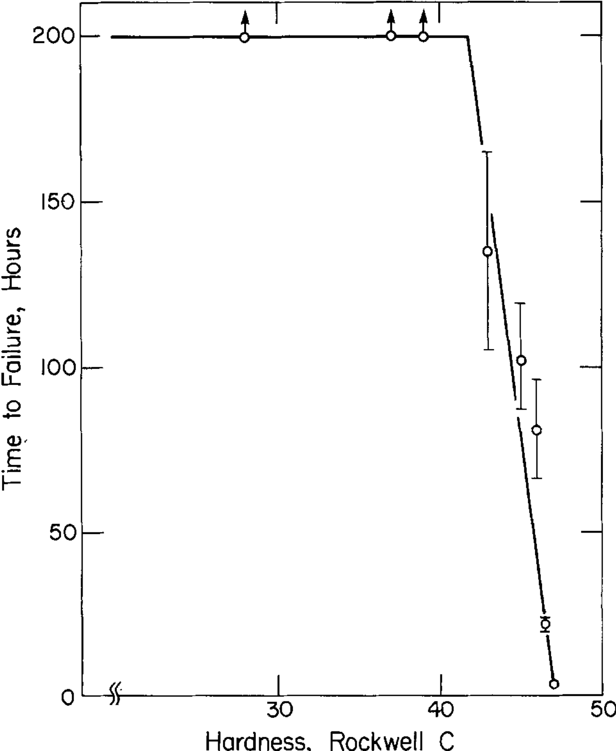

Fig. 1. Effect of hardness of 4140 steel on stress corrosion cracking in boiling distilled water.

A laboratory-prepared, relatively pure 1% Ni, 0.3% C steel tested in boiling distilled water had a critical hardness value of R_c 40 for >200 hr life; the corresponding value for a laboratory-prepared pure 1% Cr, 0.3% C steel was R_c 42. These values parallel that for 4140 steel and confirm that strength rather than composition is the important factor determining susceptibility of a steel to SCC in water.

The present accelerated test, therefore, provides a measure of susceptibility of low alloy steels to SCC in water and aqueous salt solutions. Average failure times of 4140 steel heat-treated to R_c 46 (205 ksi YS) and exposed to boiling 3% NaCl (57 hr) and to boiling 3% Na_2SO_4 (60 hr) are somewhat shorter than failure times in boiling water (81 hr), but the difference is not considered to be especially significant. The salt solutions have good electrical conductivity and were used to obtain values of the critical potential immediately below which otherwise susceptible steels do not undergo SCC failure at boiling temperatures for at least 200 hr, and probably for much longer times.

Effect of cold work and decarburization.—The effect of cold work was studied by cold-rolling steel previously water quenched from 850°C and tempered 1½ hr at 420°C having a final hardness value for the cold-rolled material varying from R_c 43 for 25% reduction to R_c 46.5 for 60% reduction. It was feasible to cold-reduce steel so tempered to not more than 60% reduction of thickness. Cold-rolling was generally but not always beneficial. Specimens cold-rolled 60% reduction of thickness consistently did not fail in boiling distilled H_2O or in boiling 3% NaCl for the maximum test period. Failures, however, were observed in boiling 3% Na_2SO_4 within an average of 93 hr (4 specimens). Data are plotted in Fig. 2. The reason for the difference in behavior between NaCl and Na_2SO_4 test solutions was clarified by critical potential measurements to be described later.

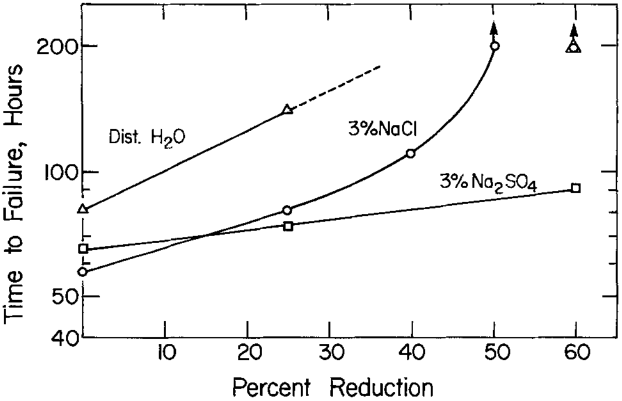

Fig. 2. Effect of cold-rolling parallel to long specimen direction of 4140 steel, R_c 43-46.5, on stress corrosion cracking in boiling aqueous solutions.

* Numbers in parentheses indicate number of specimen tested.
** Also no failure in boiling 3% NaCl and boiling 3% Na_2SO_4.

In a program to ascertain whether generation of hydrogen by the water-steel reaction may be the cause of cracking, as is thought to be the case by some investigators, specimens were prepared with a soft surface about 1-4 mils (0.03-0.1 mm) thick obtained by decarburization, allowing the core to remain at a hardness value above R_c 42 needed for susceptibility. The soft surface continues to react with water to form hydrogen, but would not supposedly initiate a crack. Such a surface was found to prevent failure, as is shown by data of Table I. These results confirm the observations of previous investigators (3, 17) who reported beneficial effects of a decarburized surface layer on SCC of high strength steels. The results of Table I also show that cathodically charging hydrogen onto decarburized specimens results in hydrogen cracking despite a soft surface. Two series of specimens failed by hydrogen cracking at room and at boiling temperature. A third series although failing at room temperature did not fail within 200 hr at boiling temperature, which may be explained by too little hydrogen entering the steel (better catalytic surface for $2H \rightarrow H_2$) at the higher temperature.

Along the same lines, if residual interstitial hydrogen in the steel were the cause of cracking, it should be possible to remove such gas by heating the specimen before applying stress. Three specimens immersed unstressed in boiling water for 25 hr, then stressed, failed within an average of 85 hr. Three additional specimens immersed unstressed for 100 hr failed within an average of 79 hr. Heating 3 specimens unstressed in air for 100 hr, then stressing and immersing in boiling water resulted in an average failure time of 86 hr. In absence of preimmersion in boiling water or previous heat-treatment in air at 100°C, the average failure time was 81 hr. All these times to failure are within the experimental variations of the test. They show that residual hydrogen in the steel, or hydrogen produced by the steel-water reaction, or heat-treatment at 100°C, are not apt to be important factors entering the cause of failure.

Critical potentials.—The importance of the critical potential relates to the decisive role it plays in determining whether or not SCC will initiate. Only a few millivolts either way accounts for initiation of damage or its absence. The significance of the critical potential in this regard was previously emphasized by data from this laboratory on SCC of austenitic (13, 18) and ferritic (19) stainless steels, and of mild steels (20) in nitrates and alkalies. For high strength steels, a similar well-defined critical potential is observed. However, because of the sensitivity of these materials to hydrogen cracking, a potential range usually beginning some tenths of a volt active to the critical potential can again lead to rapid failure. This gives rise to a potential interval within which protection is observed, as was shown by earlier data of Kirk *et al.* (5) for a maraging steel in sea water and by data of Peterson *et al.* (6) for 4340 steel in sea water. The effect of applied potential on time to failure in boiling 3% Na_2SO_4 of 4140 steel water quenched from 780°C, tempered 20 min at 420°C, R_c 46, is shown in Fig. 3. The critical potential, referring to a life of >200 hr, appears at −0.658V, SCE, or −0.416V, SHE (neglecting liquid junction and thermal gradient potentials). The corrosion potential in this solution measured at the time of failure is equal to −0.63V, SCE, or −0.39V, SHE, which is noble to the critical value, accounting for spontaneous cracking in absence of an applied potential. The corresponding critical potential in boiling 3% NaCl (Fig. 4) is equal to −0.640V, SCE, or −0.398V, SHE, and a more noble corrosion potential equal to −0.61V SCE, or −0.37V, SHE, again accounts for spon-

W.Q. 780°C, temp'd. 420°C, 20 min, R_c 46	−0.416	−0.398	−0.388	−0.368	0.030	0.030	60 (3)	57 (2)*
W.Q., temp'd., cold-rolled 60%, parallel long spec. dimension, R_c 46.5	−0.398	−0.372	−0.393	−0.383	0.005	−0.010	93 (4)	>200 (2)

* Numbers in parentheses indicate number of specimens tested.

taneous failure. The critical potential was usually reproducible to ±3 mV whereas the corrosion potential drifted with time and hence was reported only to the nearest 10 mV.

Critical potential data for steel cold-rolled 60% reduction parallel to the long specimen dimension show that the critical potential becomes more noble and the corrosion potential more active through cold-rolling, but that the corrosion potential is just noble to the critical potential in 3% Na_2SO_4 accounting for spontaneous cracking (Table II). This situation is opposite to that in 3% NaCl for which the corrosion potential remains active to the critical potential, accounting for resistance to failure.

These results demonstrate the sensitivity of failures by SCC to both critical potential and prevailing corrosion potential. This sensitivity is also shown by the inhibiting effects of alkalis and of orthophosphates. A shift of corrosion potential and critical potential accounts for lack of failure in boiling 3% NaCl at *p*H 11 and 12. Data are plotted in Fig. 5; *p*H values refer to room temperature. Because of inevitable drift of corrosion potentials with time, the cross-over of critical and corrosion potentials shown at about *p*H 9.3 may on the average occur within the *p*H range 9-10.

The inhibition of SCC by addition of 1% NaH_2PO_4 to boiling 3% NaCl adjusted to *p*H 6.4 is also accounted for by shift of potentials. In presence of phosphate the critical potential is moved 140 mV in the noble direction to −0.258V, SHE, and the corresponding corrosion potential is shifted 30 mV in the active direction to −0.40V, SHE. No failure occurs within the maximum test period of at least 200 hr.

Galvanic couples.—The importance of the critical potential to the observed SCC of high strength steels

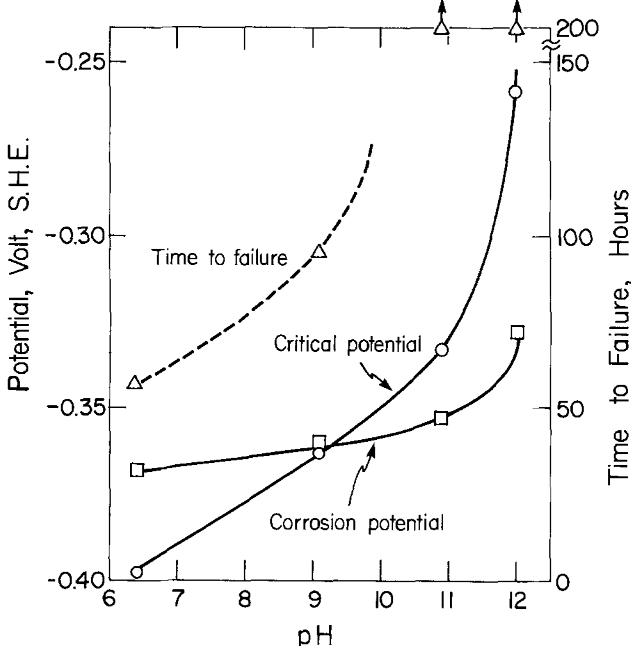

Fig. 5. Effect of *p*H of boiling 3% NaCl on critical and corrosion potentials, and on time to failure of 4140 steel, R_c 46.

leads to the prediction that coupling a steel to a more active metal of sufficient area to polarize the steel just active to its critical potential should be beneficial. At the same time, the potential must not be shifted into the still more active region where hydrogen cracking occurs. The latter form of damage is diminished at 100°C compared to room temperature because of less tendency for hydrogen to enter a cathodically polarized steel at above-room temperatures, but hydrogen cracking under some conditions can nevertheless occur at boiling temperatures, as our several tests showed. Results of galvanic couple tests in boiling 3% NaCl are summarized in Table III.

Discussion

The present laboratory results confirm that initiation of failure by SCC of low alloy carbon steels in water is sensitive largely to yield strength or hardness, and that failure times are much shorter at 100°C than at room temperature. A thin decarburized surface effectively protects a harder core (>R_c 40) against SCC damage, but not against hydrogen cracking induced by cathodic polarization. It is also confirmed that cold-rolling can be beneficial, as is well known in the application of cold-drawn steel cables to bridge construction. A high *p*H aqueous environment (*p*H 11 or 12) at boiling temperature for which the corrosion potential tends to remain active (lack of passivity) is also beneficial. The latter observations on cold-rolling and *p*H are presently explained in terms of shifts of the critical potential for SCC and of the corrosion potential. Whenever the corrosion potential or applied potential falls active to the critical value, SCC does not initiate; in the reverse order failure is observed.

Properly chosen galvanic couples of adequate area can therefore be beneficial as data of Table III show. Phelps and Loginow (4) in their atmospheric tests found that Zn-rich paints and Al coatings are protective to high strength steels. On the other hand, Yamamoto and Fujita (3) found that couples of high strength steel with Mg or Zn in aerated water at room temperature were detrimental, but that couples with Cd, Sn, Pb, Mo, Al, and Cu were without effect. Peterson *et al.* (6) reported that Zn coupled to an 18% Ni maraging steel in sea water was detrimental, but that Cd was beneficial. The reported detrimental effect of Mg or Zn is probably a result of hydrogen cracking, an effect which is less likely with Cd because its corrosion potential is less active than either that of Zn or Mg, but active enough to polarize steel below its

critical potential. The successful use of Cd coatings on high strength steel aircraft landing structures is a practical illustration of a beneficial galvanic couple.

As the applied (cathodic polarization) or corrosion potential becomes increasingly active with respect to the critical potential higher rates of hydrogen discharge eventually cause hydrogen cracking, as has been demonstrated previously by many investigators (5, 6), and which has led to the opinion by some that all failures of high strength steels are caused by hydrogen. This opinion, however, although supported by some reported values of the activation energy for cracking similar to that for diffusion of hydrogen in iron, is not consistent with most of the facts. For example, our measurements show that hydrogen cracking occurs in equal or longer times at elevated compared to room temperature. Stressed, high strength, 4140 steel specimens cathodically polarized in 3% Na_2SO_4 saturated with As_2O_3 failed within minutes either at room temperature or at boiling temperature. These results are contrasted with SCC of specimens exposed to water or 3% Na_2SO_4 without polarization, failures of which occurred in <200 hr only at elevated temperatures. This fact plus the existence of a critical potential below which (active to) SCC is not observed conflict with any mechanism of cracking dependent upon hydrogen.

Anodic polarization, on the other hand, which in neutral or alkaline solutions understandably inhibits hydrogen discharge at a steel surface can nevertheless also cause hydrogen cracking. The surface accumulation of acid anodic corrosion products, *e.g.*, $FeCl_2$ or $FeSO_4$, in sufficient amount generates hydrogen at the steel surface by local action. It is this factor that probably accounts for shorter times to failure in NaCl or Na_2SO_4 at potentials somewhat noble to the critical potential and at correspondingly increased anodic current densities, as shown in Fig. 3 and 4. Hydrogen cracking of the present high strength steel occurs in typically shorter times than does SCC. Hydrogen as the cause of cracking was also established for a cold-rolled ferritic 18-8 stainless steel stressed perpendicular to the rolling direction when anodically polarized in neutral NaCl solution, or when immersed unpolarized in saturated $FeCl_2$ ($pH = 1$) at room temperature (21). In this connection, Barth *et al.* (22) observed hydrogen permeation of an alloy steel anodically polarized in NaCl solution, as did Wilde (23) in similar measurements on a 12% Cr stainless steel. In both instances pits formed within which an anolyte of low *p*H could accumulate. It is likely that failure of an anodically polarized high strength steel reported by Yamoaka and Wranglen (11) occurred by hydrogen cracking for similar reasons.

Hence the evidence of critical potential data is that hydrogen is not the likely cause of failure by SCC when 4140 steel is exposed to boiling water or to neutral aqueous solutions, but that it enters the mechanism of failure under conditions of pronounced cathodic or anodic polarization. The presence in the environment of cathodic poisons for the reaction $2H(ads) \rightarrow H_2$ consisting of, *e.g.*, H_2S or As_2O_3, can serve to drive more hydrogen into the steel and hence extend the range of conditions under which hydrogen cracking occurs, but even in this situation, SCC can apparently occur independent of interstitial hydrogen.

There is additional evidence that SCC of 4140 and similar steels does not occur via a hydrogen cracking mechanism. They include the following observations over and above the evidence of temperature effects and the critical potential mentioned heretofore.

1. Cold work can considerably improve resistance of a carbon steel to SCC in water, but cold work does not similarly improve resistance to hydrogen cracking. The opinion is expressed, in fact, that cold work is detrimental to hydrogen cracking (24, 25). Obviously failures due to hydrogen cracking and those due to SCC do not have the same cause.

2. Failures by SCC in simple immersion tests occur as readily in distilled water as in dilute saline solutions. Although in saline media, acid anodic corrosion products can form within the confines of a notch or fissure, and in turn the acid environment in contact with steel can form damaging hydrogen, this is not an equally possible situation in distilled water. In water, the lowest possible *p*H within a notch is 7; it could also be higher corresponding to the *p*H of saturated $Fe(OH)_2$ equal to 9.5, but in neither of these environments is hydrogen generated to any appreciable extent.

3. A thin decarburized surface prevents SCC despite conditions that allow the $Fe\text{-}H_2O$ reaction forming hydrogen to continue.

4. Inhibitors effective in preventing uniform corrosion are not always effective in preventing SCC. Furthermore, Baker and Singleterry (7) report that ammonium acetate, *p*H 6-7, added to 10% NaCl inhibited SCC of 4340 steel despite continuing visible corrosion.

5. Cold-rolled Type 301 stainless steel, which is transformed to ferrite by cold work, is resistant to SCC in atmospheric tests (1, 2). A low rate of reaction with water is not the reason, because corrosion-resistant martensitic or precipitation-hardening stainless steels fail readily in moist atmospheres above the same approximate critical yield strength range as do carbon steels. Severe cold work, as in the case of 4140 steel, is probably the important factor accounting for the observed resistance of Type 301 to SCC.

6. Failure by SCC occurs in moist air, including air of less than 50% relative humidity in which rusting is not observed over many years of exposure (26). Any hydrogen generated by exposure of steel to atmospheres of this kind is inconsequential.

The latter observation in moist air, plus the rapid cracking in distilled water in absence of an electrolyte, the important parameter of the critical potential below which SCC does not occur although uniform corrosion is not suppressed, and the beneficial effect of cold work despite an increased corrosion rate of cold-worked steel in low *p*H solutions are some of the evidence that "active path" cracking by electrochemical dissolution is also not a likely mechanism. Instead, reduction of metal bond strength by an adsorbate (stress-sorption cracking) is a third and probably the best possibility.

The likely adsorbate is the water molecule itself, since water alone can cause cracking of high strength carbon steels, martensitic and precipitation-hardening stainless steels, high strength aluminum and magnesium alloys (which are not susceptible to hydrogen cracking when cathodically polarized), high strength titanium alloys, and glass. This possibility is supported by adsorption-isotherm shaped curves reported by Johnson and Wilner (12) for crack growth rates of high strength steel as a function of the relative humidity of argon. It is also supported by the inhibiting effect of alkaline solutions, adsorbed H_2O presumably being displaced by OH^- ions which shift the critical potential in the noble direction. Phosphate ions may similarly displace water by interposing an adsorbed phosphate ion layer.

The critical potential according to the mechanism of stress-sorption cracking is interpreted as that value above which, but not below, damaging water molecules can adsorb in sufficient amount on appropriate surface defect sites at which cracks nucleate. Sites suitable for adsorption are generated only at high stress levels common to high strength steels; at lower yield strength levels, *i.e.*, less than about 170 ksi, adsorbed H_2O no longer reduces bond strength sufficiently to initiate a crack although some adsorbed anions, *e.g.*, NO_3^-, can still do so causing SCC at strength levels common to mild steels. Initiation of cracks in 4140 steel by SCC occurs more readily at 100°C than at room temperature probably because formation of appropriate defect sites is favored at the

higher temperature. A similar situation exists for 18-8 stainless steel exposed to NaCl or $MgCl_2$ solutions, stress corrosion cracking being observed only at elevated temperatures.

The present facts lead to the conclusion, therefore, that at least two mechanisms enter observed failures by cracking of high strength steels. The one is hydrogen cracking, which occurs under circumstances that favor entrance of interstitial hydrogen into the steel, as occurs in acid pickling baths or electroplating operations or by interaction of steel with acid anodic corrosion products. The other is SCC in water and near-neutral or alkaline aqueous solutions which operates only at potentials noble to a critical value. The critical potential in turn is influenced by composition of the environment as well as by cold work of the steel. Failure times are not very sensitive to low alloy steel composition. The environment in addition to its influence on the corrosion potential apparently affects the extent to which H_2O adsorbs on a steel surface. The structure of steel and applied stress influence the nature and density of surface imperfection sites on which H_2O when adsorbed reduces metal atom bond strength sufficiently to nucleate a crack.

Summary

1. An accelerated test in boiling water or aqueous salt solutions employing a constantly stressed smooth specimen is well suited to measuring critical hardness, cold work, environmental factors, and the effect of applied potential on SCC of high strength steels.

2. The critical hardness value of 4140 steel, of 1% Ni, 0.3% C steel, and of 1% Cr, 0.3% C steel above which failure times by SCC in boiling water are short is in the range R_c 40-42 corresponding to a yield strength of 170-185 ksi (120-130 kg/mm^2). This range lies close to that established by other investigators through laboratory tests, atmospheric service tests, and practical experience.

3. A thin decarburized soft surface over a core of hardness $>R_c$ 40 effectively prevents initiation of SCC.

4. The critical potential of 4140 steel, R_c 46, immediately below which SCC does not initiate within at least 200 hr in boiling aqueous salt solutions is -0.40 to -0.42V, SHE.

5. Cold-working improves resistance to SCC in distilled water. Whether it is similarly beneficial in aqueous salt solutions depends on whether the critical potential is consistently noble to the prevailing corrosion potential.

6. Alkaline additions and orthophosphate additions to salt solutions inhibit against SCC by shifting potentials such that the critical potential remains noble to the corrosion potential.

7. Hydrogen cracking can occur with steel anodically or cathodically polarized at sufficiently high current densities in neutral aqueous NaCl or Na_2SO_4 solutions at boiling temperatures.

8. The over-all evidence suggests that in absence of polarization SCC occurs in distilled water or in neutral salt solutions independent of a hydrogen cracking mechanism.

A Study of Transient Corrosion in the Iron-Caustic System by Use of a Drop Weight Apparatus

R. B. Diegle*,[1] and D. A. Vermilyea*

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

ABSTRACT

Repassivation current transients in the Fe-caustic system were measured after straining potentiostatically polarized electrodes with a drop weight apparatus, which could produce strains of about 5% in 1 msec. Peak current densities varied from 0.3 to 3.8 A/cm^2 depending on electrode potential, electrolyte concentration, and temperature, and initial film coverage was complete in less than 1 or 2 msec. The amount of corrosion accompanying passive film formation was not very sensitive to the above-mentioned electrochemical variables, and it ranged from 1×10^{-3} to 5×10^{-3} coulombs/cm^2. Repassivation was facilitated by additions to the test electrolyte of the anodic dissolution product $HFeO_2^-$. The total corrosion up to 1 sec following straining was a strong function of potential, electrolyte concentration, and temperature, as was the quasi steady-state current density. The depth of corrosion 1 sec after straining ranged from twenty to several hundred angstrom units. The relevance of these results to several mechanistic models of caustic cracking is discussed.

The study of corrosion transients in alloy-corrodent systems exhibiting stress corrosion cracking (SCC) is of great importance in understanding the mechanism(s) of cracking. For instance, it has been proposed that susceptibility to SCC is in part determined by the amount of corrosion occurring after fracture of a protective passive film at the crack tip, and before repassivation occurs (1-4). Comparison of the effects of such pertinent electrochemical variables as electrode potential and electrolyte concentration on the kinetics of transient corrosion and on the rate of crack propagation during SCC should provide insight into this film rupture mechanism. Indeed, in a broader sense results can hopefully help determine the applicability to caustic SCC (CSCC) of the several types of models based on anodic dissolution, such as those involving periodic film rupture and intermittent crack advance (1-4), and others supporting uniform crack advance by corrosion at a continuously active crack tip (5, 6).

Although repassivation phenomena have been intensely investigated, relatively few studies have been made in systems which exhibit SCC. Recent exceptions are the studies of Beck (7), and Ambrose and Kruger (8, 9). Beck measured the repassivation rate of Ti in HCl electrolytes after specimen fracture, and he observed peak current densities of several amperes per square centimeter and initiation of repassivation in milliseconds due to monolayer oxide film formation. Ambrose and Kruger, using an abrasion technique called triboellipsometry (8), studied the repassivation of mild steel in NO_3^- and NO_2^- solutions (8), and of Ti in NO_3^- and Cl^- electrolytes (9). Again, large current transients resulted and repassivation began within several milliseconds after the cessation of abrasion.

This work is part of a continuing study designed to determine the validity of the film rupture theory of SCC as recently formulated (1, 2). The Fe-caustic system was chosen as a model for investigation of this theory because of the relative simplicity of electrode reactions which occur. Specific objectives were to determine the effects of such pertinent electrochemical variables as electrode potential, electrolyte concentration and temperature, and concentration of dihypoferrite ion, $HFeO_2^-$, on the transient corrosion rate, and time required for initial film formation. A unique drop weight apparatus was used to strain potentiostated Fe wire electrodes in NaOH electrolytes, and the ensuing repassivation current transients were monitored with oscilloscopes. Appropriate current-potential curves were generated so that comparison could be made between transient and relatively steady-state corrosion kinetics. Transient corrosion results are qualitatively similar to those of Beck and Ambrose and Kruger and strongly support an anodic dissolution mechanism of CSCC.

Experimental

Material.—Electrolytic grade 99.94% pure Fe was vacuum melted and cast into tapered ingots about 5 by 5 by 15 cm. These were hot forged in Ar to rod 0.25 cm diameter, which was then cold drawn with intermediate annealing to 0.127 cm diameter wire. Some wire containing 12% residual cold work was used in this condition; the rest was heated for about 24 hr in moist hydrogen. This heat-treatment not only served to anneal the wire, but it also decarburized it to a carbon level which minimized strain aging during subsequent elevated temperature straining experiments.

Current-potential curves.—The electrochemical cell used for polarization studies, Fig. 1, was constructed entirely of polytetrafluoroethylene to prevent attack by the concentrated caustic electrolytes. The thermistor and Nichrome windings permitted accurate temperature control, which was monitored with an iron-constantan thermocouple cemented inside a tube extending into the electrolyte and connected to a potentiometer. The Luggin probe, positioned to within 1 or 2 mm of the electrode, was connected to a 10% NaOH solution by plastic tubing containing a nylon wick. Potentials were measured *vs.* a room temperature saturated calomel electrode (SCE) connected to this solution by a second capillary, as shown.

Potentiodynamic potential sweeps were performed using a solid-state linear voltage-time function generator and a Wenking 68 TS1 potentiostat. Current in the counterelectrode circuit and electrode potential *vs.* the SCE were simultaneously measured with Keithley electrometers and recorded on a two channel L&N recorder. In one instance a potential stepping technique was used, with steps varied between 20 and 50 mV and current readings taken after 5 min at each potential.

In practice a 13 cm length of wire was acid etched for 2 min and electropolished 15 min in a room tem-

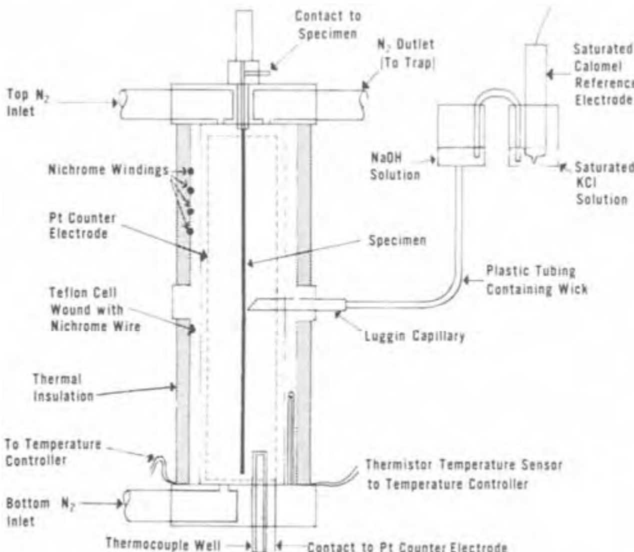

Fig. 1. Schematic cross section of cell used to study the polarization behavior of Fe in NaOH electrolytes.

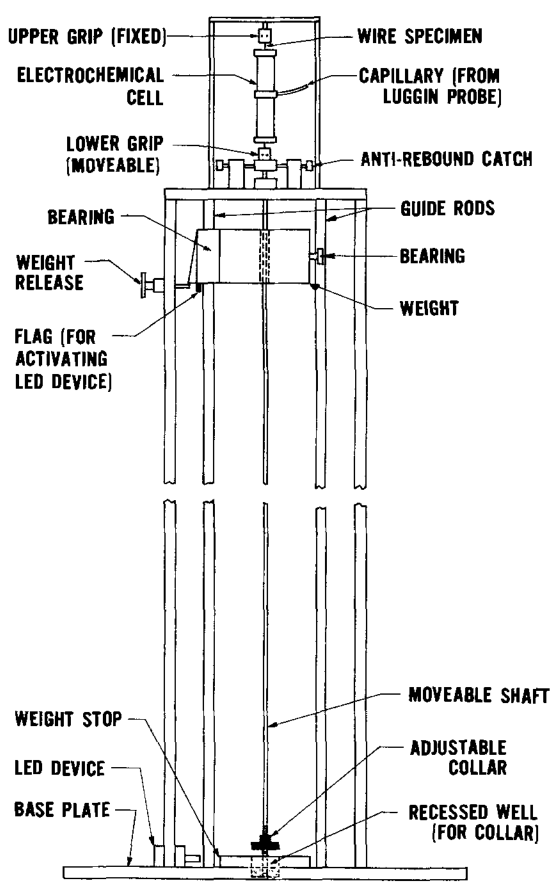

Fig. 2. Schematic drawing of the drop weight apparatus used to study repassivation behavior.

perature mixture of 1300 mliters glacial acetic acid, 108 mliters 71% perchloric acid, and 41 mliters water at a current density of about 40 mA/cm^2. The cell was filled with electrolyte, which throughout this study was prepared from analytical reagent grade, carbonate-free NaOH and distilled water, after which the thoroughly rinsed wire was inserted. The electrolyte was heated to temperature and deaerated by bubbling ultrapure nitrogen through the lower inlet. When the open-circuit potential had reached the quite reproducible value characteristic of the electrolyte-temperature combination employed, the nitrogen flow was adjusted across the surface of the electrolyte. Next a potential sweep was begun from the rest potential and continued until the beginning of oxygen evolution; in most cases the sweep direction was reversed and the potential was returned to the initial value. Sweep rates of 0.6, 1.8, and 4.1 V/hr were used.

Certain current-potential curves were performed in electrolyte containing additions of the anodic dissolution product, dihypoferrite ion or $HFeO_2^-$. In these runs the electrolyte was previously charged with $HFeO_2^-$ by dissolution of a dummy, high purity Fe electrode at -0.8V (SHE) until the desired number of coulombs of Fe had reacted, after which the wire electrode was quickly substituted and the potential sweep begun from the steady-state rest potential. The final concentration of Fe in the electrolyte was determined by volumetric analysis using EDTA and a standardized copper solution.

Repassivation transients.—The drop weight apparatus (DWA) used to generate unfilmed electrode surface is shown in Fig. 2. A 13.6 kg (30 lb) weight was allowed to free-fall a distance of 137 cm and strike a collar threaded onto a 0.635 cm diameter steel shaft. The impact drove the collar-shaft-lower grip assembly downward through a preset distance of 0.635 cm in 1 msec, thereby creating 5% strain in the electrode at a strain rate of about 57 sec^{-1}. The shaft and lower grip were prevented from rebounding after full travel by two spring-loaded anti-rebound catches, which locked the lower grip into its lowest position after the initial displacement. The electrochemical cell used to surround the wire specimen was similar to that shown in Fig. 1 except that the electrode extended through both ends to permit insertion into the grips.

In practice a wire was etched in acid, rinsed, and lightly scribed with gauge marks defining that portion of the electrode submerged in the electrolyte after insertion into the cell. The cell containing the electrode and electrolyte was mounted in position in the DWA, the lower grip having been previously elevated from its fully extended position by 0.635 cm. Anti-rebound catches were engaged, the electrolyte was heated to temperature, and deaeration, if desired, was performed. When the rest potential was established the wire was polarized to the straining potential with a Wenking Model 66TS3 potentiostat (rise time of about 30 μsec). After a reasonably steady-state current had developed, the weight was dropped and the wire suddenly strained.

Current transients were recorded photographically from two oscilloscopes which measured the voltage drop across a 10 ohm precision resistor in the counter-electrode circuit. The oscilloscope sweeps were adjusted to monitor short (0-10 msec) and long (0-0.5 sec) current-time behavior. The sweeps were automatically triggered approximately 1 msec before the start of straining by interruption of a light emitting diode (LED) device with an opaque flag mounted on the weight. The total elongation which had occurred within the electrolyte was determined after each experiment by measuring the new gauge mark separation on the electrode.

Two points of interest should be made relative to this technique. As stated, full elongation of the electrode was accomplished in about 1 msec, which is sufficiently fast to permit study of the rapid transient corrosion kinetics characteristic of the Fe-caustic system. Second, auxiliary experiments showed that the velocity of the weight during its last 0.635 cm of travel was barely perturbed by the presence or absence of wire between the grips, indicating that the strain rate was essentially constant during the straining process.

Results

Current-potential curves.—It was desired to study current-potential behavior under relatively steady-state conditions for two reasons. First, such information permitted comparison of transient corrosion rates with more time-independent corrosion behavior. Sec-

ond, it provided a means for estimating the valence change of Fe during oxidation in NaOH as a function of potential.

The effects of NaOH concentration, temperature, and electrode potential agreed well with trends reported by earlier workers (10-12), and for this reason the polarization curves are not reported. Essentially, increasing electrolyte concentration and temperature accelerated the corrosion rate; this was especially true in the potential range in which CSCC occurs, namely, that encompassing the active and active-passive transition potentials. For example, at a susceptible potential of −0.7V (SHE) and a sweep rate of 0.6 V/hr, a 30-fold increase in current density resulted from changing the NaOH concentration from 20 to 50% at 85°C. An analogous 10-fold increase was observed in 35% NaOH due to raising the temperature from 50° to 105°C.

The influence of the anodic dissolution product on current-potential behavior is illustrated in Fig. 3. This product, assumed to be $HFeO_2^-$ from reference to potential-*p*H diagrams constructed for elevated temperatures (13-15), suppressed anodic dissolution. In fact, the region of active corrosion was completely eliminated by adding 11.6×10^{-3} mole/liter of iron as $HFeO_2^-$. In general the potential at which the minimum passive current occurred was moved in the negative direction, and the potential range over which passivity was observed was extended by several hundred millivolts. The passive current density increased with increasing concentration of $HFeO_2^-$ although the total effect was less than a factor of two. The additions also reduced current densities in the postpassive potential range, but again the effect was not large.

As expected, potential sweeps with 12% cold-worked Fe electrodes resulted in corrosion behavior almost identical to that of annealed Fe.

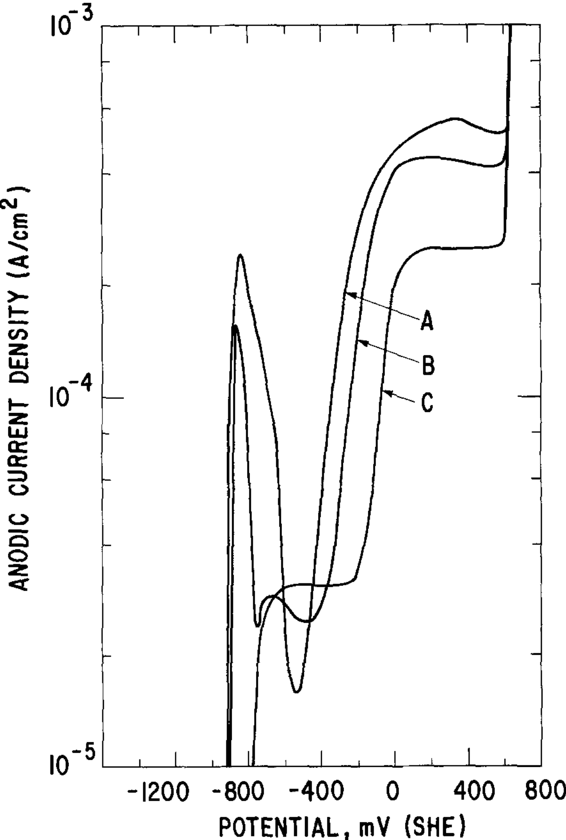

Fig. 3. Polarization behavior of Fe in 35% NaOH at 85°C containing three concentrations of Fe as dihypoferrite ion. (Curves were generated by a potential stepping technique.) Potentials were not corrected for thermal and liquid junction errors. Curve A, none; curve B, $3.1 \cdot 10^{-3}$ mole/liter iron; curve C, $11.6 \cdot 10^{-3}$ mole/liter iron.

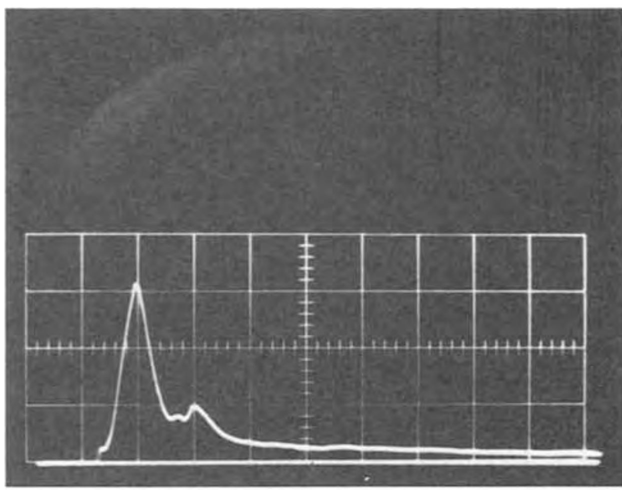
Repassivation transients.—The current values obtained from each oscillograph were converted to current density by dividing by the area change ΔA created during straining

$$\Delta A = 2\pi r(\Delta l) \quad [1]$$

where r is the wire radius after straining and Δl is the electrode elongation which occurred within the electrolyte. This equation is based on negligible ductility of the passive film, yet the assumption of perfect adherence requires that a small amount of film deformation occur. A representative pair of repassivation current transients obtained with the DWA are shown in Fig. 4. The peak anodic current density was 3.5 A/cm², and throughout the runs it ranged from about 0.3 to 3.8 A/cm² with higher values favored by positive potentials, concentrated electrolyte, and high test temperature. Initial film formation at the straining potential of 0V (SHE) occurred in less than about 1 msec, as seen by the rapid decrease in anodic current coincident with cessation of straining. The smaller peak observed 1.9 msec after the start of current rise, Fig. 4a, is thought to be caused by a slight flexure of the steel shaft and electrode at the instant the weight rebounded after impact. Transient corrosion rate was potential-dependent, as seen by comparing Fig. 4a with Fig. 5. The transient in Fig. 5, which was obtained at the rest potential of −0.916V (SHE), is much broader than that obtained at 0V (SHE) and the rate of current decay is less. This type of current-time dependence is expected if the time required for initial film formation exceeds the straining time.



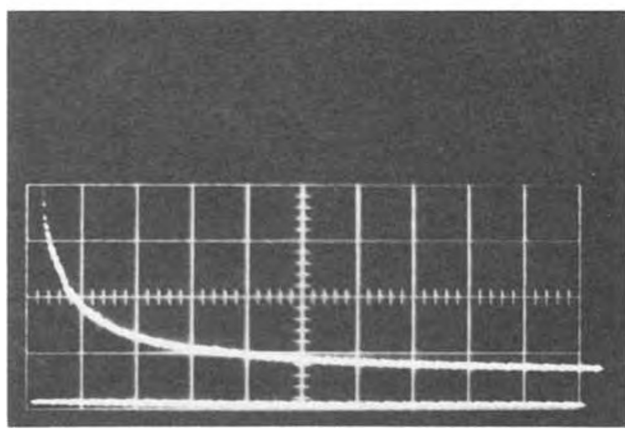


Fig. 4. Oscilloscopic anodic current transients obtained by straining in 35% NaOH at 85°C at a potential of 0V (SHE). (a) One vertical division equals 0.2A, one horizontal division equals 1 msec; (b) one vertical division equals 0.005A, one horizontal division equals 50 msec.

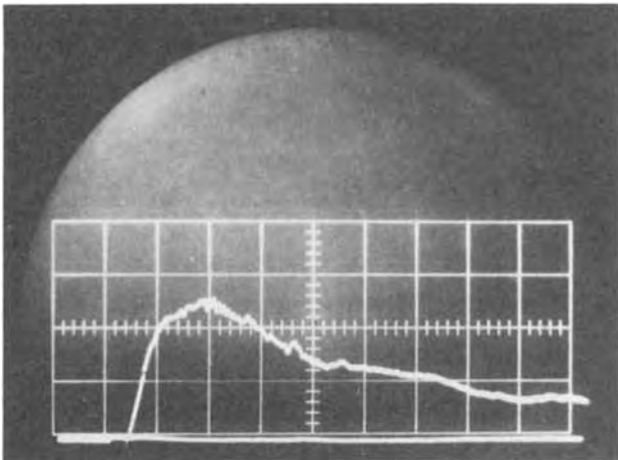

Fig. 5. Oscilloscopic anodic current transient obtained by straining in 35% NaOH at 85°C at the rest potential, −0.916V (SHE). One vertical division equals 0.02A, one horizontal division equals 1 msec.

Since one purpose of this work was to learn more about the nature of CSCC by studying transient corrosion behavior, data are presented as depth of corrosion *vs.* time curves. This manner of presentation is obviously more directly related to the kinetics of crack advance than, for example, illustration of current density-time relationships. Reduction of the current-time data was performed with the following assumptions: (*i*) no competing reactions occurred on the Fe electrode during repassivation that were comparable in rate to the repassivation process; that is, integration of the anodic current resulted in an accurate measure of the amount of Fe reacted; and (*ii*) exfoliation of the passive film did not occur during straining, an assumption which permitted calculation of the exposed area from elongation as shown in Eq. [1]. The first assumption is reasonable since the only other expected electrode reaction of any importance besides oxidation of Fe is reduction of O_2 in the electrolyte to OH^- according to the reaction

$$\frac{1}{4} O_2 + \frac{1}{2} H_2O + e^- = OH^- \qquad [2]$$

Simple theoretical calculations and preliminary experiments with deaerated and nondeaerated electrolytes confirmed that O_2 reduction decreased the measured charge transfer by a negligible amount, even in electrolytes which were not deaerated. Exfoliation was not expected due to the extremely thin nature of passive films grown for short times on Fe in NaOH solutions.

A functional relationship between current density and time after straining was obtained by noting that a plot of logarithm of current density *vs.* logarithm of time was linear for times greater than about 8 msec, Fig. 6. This relation was of the form

$$i = Kt^{-c} \qquad [3]$$

in which K and c are constants. It is identical to that observed by Nagayama and Cohen for Fe passivated in a buffered borate electrolyte (16), except that in their work c was 1 and in this study c was always less than 1. The charge-time dependence was obtained by integrating Eq. [3] with respect to time to give

$$Q(t) = \frac{K}{1-c}\,[t^{1-c}]^{t}_{\tau_o} \qquad [4]$$

in which τ_o is the shortest time at which Eq. [3] was obeyed; in this work it was taken as 8 msec, since a rather good fit to the data was obtained after about 8 msec had elapsed. The depth of corrosion as a function of time, $L(t)$, is thus given by the equation

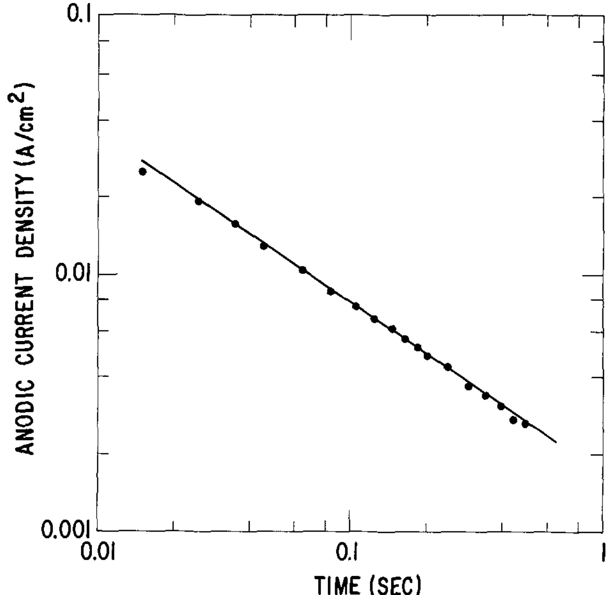

Fig. 6. Anodic current density as a function of time after straining in 35% NaOH at 50°C at a potential of −0.500V (SHE).

$$L(t) = \frac{M}{n\mathbf{F}d}\left\{Q_o + \frac{K}{1-c}\,[t^{1-c}]^{t}_{\tau_o}\right\} \qquad [5]$$

in which M, n, and d are the molecular weight (55.85), valence change, and density (7.87 g/cm^3) of Fe, respectively, and $\mathbf{F}$ is the Faraday (96,500 coulombs). Q_o, the charge transferred during the first 8 msec of repassivation, was determined by gravimetric integration of the 0-10 msec current transient to 8 msec from the start of straining. (Charge transfer from the double layer due to net reduction in electrode area after straining can be readily shown to be an insignificant fraction of the total charge passed, even that passed during the initial 10 msec.) The approach used to approximate the valence change n is explained in the Appendix.

Typical values of K, c, n, Q_o, and the peak current density i_p observed during repassivation are presented in Table I. Note that over the range of potentials investigated the charge accumulated in the first 8 msec of repassivation varied by only a factor of about 4. Also, the constant c was considerably less than 1 in every instance.

The representative set of curves shown in Fig. 7, calculated from Eq. [5] and displayed to 1 sec after film rupture, illustrates the marked influence of potential on corrosion rate. [One second was chosen as the time to which total corrosion would be displayed because it is a reasonable interval between postulated film rupture events (1, 2).] For example, after 1 sec corrosion had proceeded to only about 27Å at the passive potential of −0.5V (SHE), yet at the active potential of −0.8V (SHE) it had progressed to 80Å. Note

Table I. Characteristic repassivation parameters obtained in 35% NaOH electrolyte at 85°C at various straining potentials

Straining potential (V *vs.* SHE)	K (A-sec/cm × 10^{-3})	c	n	Q_o (coulombs/cm^2 × 10^{-3})	i_p (A/cm^2)

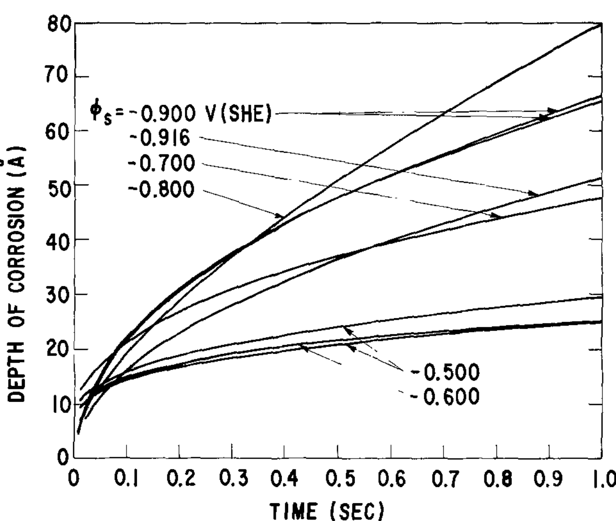

Fig. 7. Depth of corrosion as a function of time after straining and straining potential in 35% NaOH at 85°C. Potentials encompass the range in which CSCC occurs.

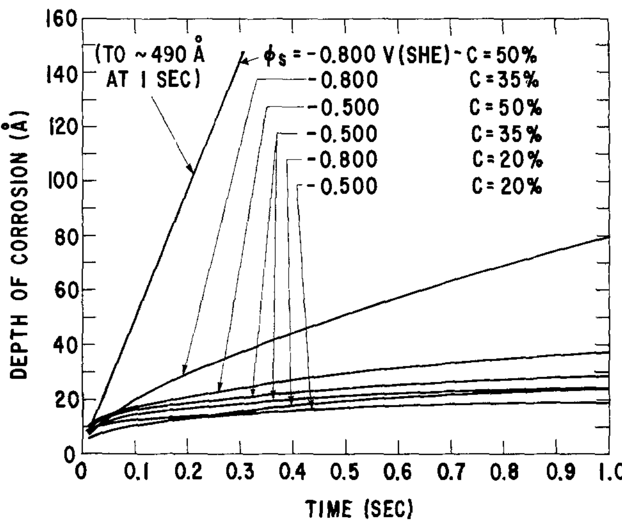

Fig. 9. Depth of corrosion as a function of time after straining for three concentrations of NaOH at 85°C. The potential −0.500V (SHE) corresponds to passive polarization behavior, while −0.800V (SHE) corresponds to active dissolution.

the appreciable corrosion rate at the rest potential, −0.916V (SHE).

Of particular interest is the rate of current decay at potentials in the postpassive region. CSCC of mild steel does not occur over most of this potential range, yet potentiodynamic polarization data suggested that transient corrosion rates at sufficiently positive potentials may exceed those in the CSCC potential range. This is indeed the case, as seen by comparing Fig. 8, in which a series of corrosion-time curves obtained at postpassive potentials is presented, with Fig. 7. The depth of corrosion extrapolated to 1 sec at potentials of +0.1V (SHE) and greater equals or exceeds that measured at −0.8V (SHE). Also interesting is the observation that the transient corrosion rate is faster at potentials above about −0.1V (SHE) than at −0.7V (SHE), which is near the potential of greatest susceptibility for CSCC in this electrolyte (12, 17, 18).

The effect of electrolyte concentration on repassivation behavior is very potential dependent, as shown in Fig. 9. Changing the NaOH concentration from 20 to 50% increased the amount of corrosion after 1 sec from 19 to only 30Å at −0.5V (SHE), but it jumped from about 23Å to about 490Å (not shown) at −0.8V (SHE), a remarkable effect.

An analogous correlation of potential with the effect of temperature is illustrated in Fig. 10. Again, at the passive potential of −0.5V (SHE) raising the temperature from 50° to 85°C increased the depth of corrosion

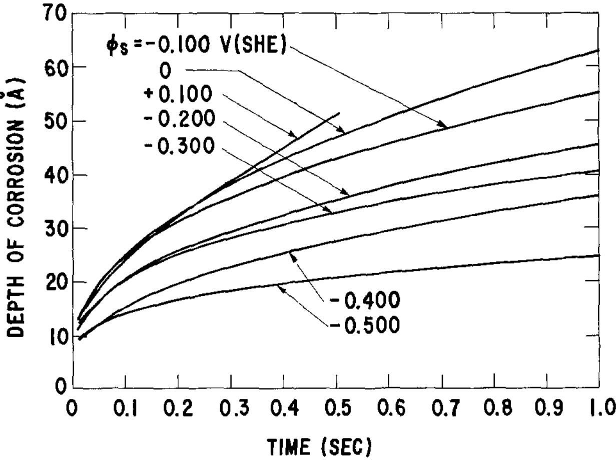

Fig. 8. Depth of corrosion as a function of time after straining and straining potential in 35% NaOH at 85°C. Potentials encompass the postpassive region of polarization behavior.

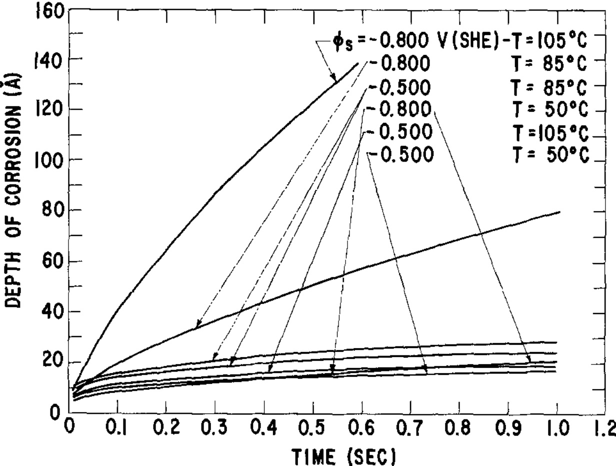

Fig. 10. Depth of corrosion as a function of time after straining in 35% NaOH at three temperatures. The potential −0.500V (SHE) corresponds to passive polarization behavior, while −0.800V (SHE) corresponds to active dissolution.

from 17Å to about 27Å; a further temperature rise to 105°C produced no further measurable increase. However, at −0.8V (SHE) the corrosion at 1 sec went from 20Å at 50°C to 203Å at 105°C.

The last effect of interest is the role of dihypoferrite ion in influencing repassivation. Figure 11 illustrates depth of corrosion-time curves calculated from data obtained in 35% NaOH at 85°C with and without prior addition of $HFeO_2^-$. (Somewhat different concentrations of $HFeO_2^-$ were added from one run to another because of nonreproducibility in the anodic dissolution technique used to charge the electrolytes.) The potential dependence of the transient corrosion rate was qualitatively similar to that observed under more steady-state conditions; however, the addition of about 3.5×10^{-3} to 5.5×10^{-3} mole/liter of Fe as $HFeO_2^-$ drastically reduced anodic dissolution at −0.8V (SHE) and below. The large current peaks occurring between about 0 and 3 msec still resulted, however, and the charge Q_0 was generally reduced by less than a factor of 2. The potential causing the most rapid corrosion rate was shifted from near the anodic peak potential of −0.8V (SHE) to about −0.7V (SHE), a potential which is within the passive region of the appropriate polarization curves in Fig. 3. This shift could be significant, since as previously stated the potential producing the fastest CSCC in 35% NaOH electrolyte is near −0.7V (SHE).

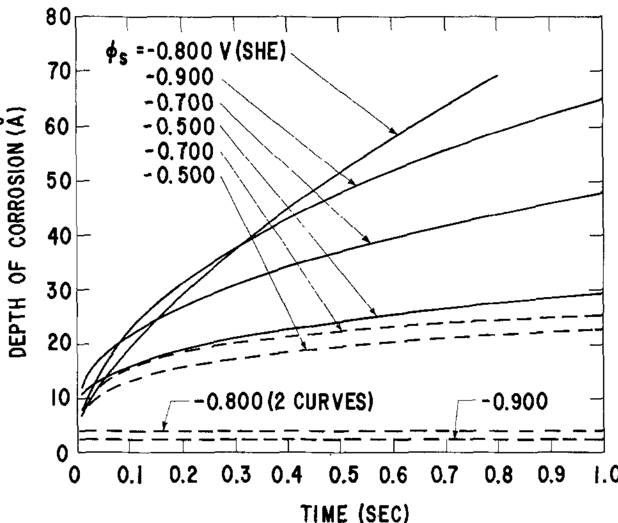

Fig. 11. Depth of corrosion as a function of time after straining and straining potential in 35% NaOH at 85°C with and without prior addition of iron as dihypoferrite ion. Solid curves, no iron added before straining; dashed curves, $3.4 \cdot 10^{-3}$ to $5.4 \cdot 10^{-3}$ mole/liter iron added before straining.

The presence of 12% residual cold work was found to have no detectable effect on the transient corrosion of Fe. Greater degrees of cold work were not investigated with the DWA since the electrodes fractured at very small strains.

Discussion

Current-potential curves.—As stated earlier in the paper, these curves were produced to enable comparison of the effects of environmental variables on transient *vs.* steady-state corrosion rates. The general shape of the current-potential curves of Fe in high *p*H electrolytes has been considered in detail elsewhere (10, 11, 19-26); therefore the curves obtained in this work are discussed only as they pertain to repassivation kinetics. Of some interest, however, is the effect of $HFeO_2^-$ on polarization behavior, since it certainly exists in undetermined concentrations in crevices during CSCC. The effect of this ion was to suppress active dissolution and facilitate passivation, which supports the postulated mechanism of passivation as being one of precipitation of some type of film, perhaps $Fe(OH)_2$ (19), when its solubility product near the electrode surface is exceeded during active corrosion. The rise in passive current density with increasing ion concentration possibly results from oxidation of divalent iron in solution to the trivalent state at higher potentials. Extension of the passive potential range to higher values and reduction of the current densities in the postpassive range may be due to a reduced rate of dissolution of the γ-Fe_2O_3 formed at these potentials due to the presence of $HFeO_2^-$.

Repassivation transients.—The internal reproducibility of this rapid straining technique was about ±5Å after 1 sec of elapsed time. The absolute accuracy is certainly less, perhaps no better than 25%, due to uncertainties in electrode roughness factor and valence change of iron during oxidation, and because of the inaccuracy inherent with oscilloscopic measurements. Another factor of possible importance was hydrodynamics, although its influence was not investigated in this study. Since the method of data presentation requires accurate knowledge of the bare metal area produced by the DWA, supplementary film fracture experiments were conducted using the technique of Bubar and Vermilyea (27) to characterize passive film ductility. The fracture strains observed were of the order of 10^{-4}, indicating negligible film ductility and the validity of Eq. [1]. On the basis of internal reproducibility and the trends shown in Table I, it is concluded that the DWA technique is sufficiently sensitive to study the effect on repassivation behavior of electrochemical parameters of major influence.

The most significant observations regarding the transient corrosion of Fe in caustic electrolytes is that the beginning of repassivation is quite rapid and is preceded by very little corrosion. Although anodic current densities reached a maximum of 3.8 A/cm^2, Table I, they usually decreased to only a fraction of these peak values within about 3 msec. (These peak current densities were of course influenced by the strain rate applied by the DWA.) Immediate current decay after the end of straining at potentials about 0.05V more positive than the rest potential indicates the extremely rapid formation of a film which was very effective in reducing the subsequent corrosion rate. It is not known just how much film formed during this initial transient current flow for various reasons. For instance the identity and material properties of the film, including density and lattice parameter, were not determined, nor was the ratio of Fe going into solution to that forming film. However, an approximate calculation can be made as follows. If it is assumed that the initial film is Fe_3O_4 of density 5 g/cm^3 and lattice parameter 8.4Å (17), then one monolayer would require 1.4×10^{-3} coulombs of Fe to react if it all went into film formation. Admittedly a rough estimate, this value compares favorably with the Q_o's listed in Table I for repassivation at potentials in the active region. It is therefore proposed that initial current decay involves the rapid formation of one or two monolayers of a film of unknown identity, and that further corrosion consists of simultaneous film growth and dissolution.

Modeling the repassivation process.—To provide further understanding of the nature of initiation of repassivation in the Fe-caustic system, the repassivation process was modeled in the following way. In order to avoid the implied infinite current at zero time, Eq. [3] was modified to

$$i = K(\tau + t)^{-c} \qquad [6]$$

in which τ is an adjustable parameter which ensures a finite current density at the instant of film fracture. It is proposed that during straining incremental film-free regions are continuously produced on the electrode surface, and that the total current I flowing after creation of an amount α of total exposed area can be obtained by integrating Eq. [6] to give

$$I = K \int_0^{\alpha} (\tau + t)^{-c} dA, \quad t \lesseqgtr \tau_1 \qquad [7]$$

in which τ_1, the time at which straining is completed, is about 1 msec. Equation [7] can be transformed to

$$I = KdA/dt \int_0^{t} (\tau + t)^{-c} dt \qquad [8]$$

The rate of creation of unfilmed area, dA/dt, can be removed from under the integral because the strain rate is constant and the film is quite brittle. The integrated equation is

$$I = \frac{KdA/dt}{1 - c} [(\tau + t)^{1-c}]_0^t, \quad t \lesseqgtr \tau_1 \qquad [9]$$

After straining has been completed, these small areas are still contributing current but no new ones are being created; therefore, the integration is performed from time $t - \tau_1$

$$I = \frac{KdA/dt}{1 - c} [(\tau + t)^{1-c}]^t_{t-\tau_1}, \quad t > \tau_1 \qquad [10]$$

Note that dA/dt is still included as a mathematical device, even though straining ceased at time τ_1.

To illustrate the application of this model, data consisting of current-time combinations were taken from

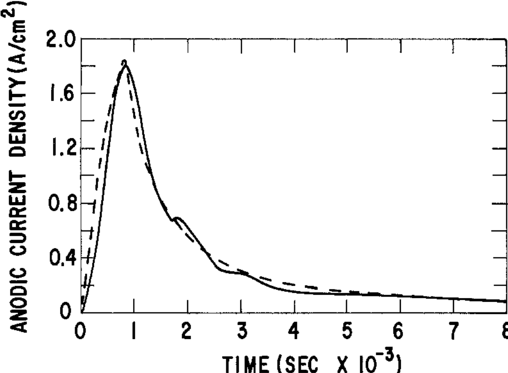

Fig. 12. Fit of Eq. [9] and [10] after dividing by ΔA (dashed curve), to experimental anodic current transient (solid curve) obtained in 35% NaOH at 85°C at a straining potential of −0.600V (SHE).

a typical 10 msec transient and introduced into a curve-fitting computer program (28). A least squares fit produced the results shown in Fig. 12, converted to current density by dividing by the total area exposed ΔA. The good fit indicates that the model chosen provides a reasonably accurate picture of the straining process. The values of K and c giving good agreement, 3.21×10^{-5} A-sec/cm^2 and 1.62, are seen to differ substantially from the experimental values applicable at longer times and listed in the fifth column in Table I. This variation is substantiated by the lack of fit (not shown) between theory and experiment beyond 10 msec and is presumably caused by rapidly occurring changes in film properties which are not understood. The reduction in c could in part be due to the onset of film dissolution after several milliseconds, thus reducing the net rate of film thickening.

Relevance to CSCC mechanisms.—The repassivation transient data provide strong support for an anodic dissolution mechanism of CSCC for several reasons. Most significantly, the influence of potential, temperature, and NaOH concentration on transient corrosion kinetics are in good qualitative agreement with their effects on crack propagation rate. For example, it has been previously demonstrated that CSCC is accelerated by increasing the caustic concentration and electrolyte temperature [results reviewed in Ref. (19)], and in this work the transient corrosion rate was strongly accelerated in the same manner in the susceptible potential range. The influence of potential on transient corrosion is interesting, since below the passive potential the dependences of transient corrosion and CSCC rates on potential are very similar. Although the potential favoring the most rapid transient corrosion corresponds approximately to that at the active peak of the quasi steady-state polarization diagram, whereas that causing the fastest CSCC is in the more positive active-passive transition region, the effect of dihypoferrite ion is to shift the potential producing the most rapid transient corrosion to slightly higher values. In the postpassive potential region, however, the transient corrosion rate again increases (Fig. 8) in accord with polarization behavior, although CSCC is not observed in mild steels at these more positive values. [CSCC does occur at about −0.4 to −0.1V (SHE) in temper-embrittled low alloy steels, Ref. (29-31).] Lack of susceptibility at postpassive potentials perhaps arises from the absence of a proper balance between active and passive corrosion rates, although an alternative explanation is suggested by the film rupture theory of Vermilyea (1). This is that the γ-Fe_2O_3 film present in this higher potential region may be more ductile than Fe_3O_4 film formed in the susceptible potential range, thereby promoting film thinning rather than fracture. Results from recent experiments indicate that indeed γ-Fe_2O_3 formed at high potentials in NaOH electrolyte is more ductile than Fe_3O_4 produced at lower potentials.

These results are also helpful in a general evaluation of proposed mechanisms of CSCC. For example, if CSCC were caused by the stress-sorption mechanism of Uhlig (32), only about 1 msec would exist after film fracture for adsorption to occur before the electrode became film covered again. (That passivity is indeed caused by a discrete film and not an adsorbed layer of oxygen atoms is supported by the t^{-c} current density dependence at essentially the start of repassivation, a dependence which is often observed for film growth phenomena.) Assuming that an unfilmed ledge of metal at least 1 atom wide, or about 3Å, must continuously exist at a slip step at the crack tip to permit adsorption of OH^- ions, the minimum rate of crack propagation would be equal to about 3×10^{-8} cm/10^{-3} sec or about 3×10^{-5} cm/sec. However, CSCC has been observed to proceed at rates of 10^{-7} cm/sec and less.

It has also been postulated that SCC proceeds due to active dissolution at an unfilmed crack tip, the crack sides remaining passive (5, 6). More recently Hoar and Jones extended this proposed mechanism to include CSCC (33). It is not likely that the crack tip can remain bare during CSCC, since active corrosion in 35% NaOH at 85°C at the susceptible potential of −0.7V (SHE) proceeds at the relatively large current density of about 1 A/cm^2, as shown in Table I. (Presumably higher strain rates with the DWA would produce even larger values.) A corrosion rate of 1 A/cm^2 corresponds to an electrochemical crack propagation rate of 3.7×10^{-5} cm/sec (for Fe = Fe^{++}), which again is considerably greater than many rates observed experimentally. Further discussion of the implication of this work to the results of Hoar and Jones will be presented in a future paper.

The data lend support to some type of film rupture mechanism of cracking, both because of the strong tendency for the electrode to remain film covered and because of the observed potential, temperature, and concentration dependences of the transient corrosion rate. For example, the depth of corrosion 1 sec after film rupture ranged from only about 20Å to several hundred angstroms as a result of appropriate changes in electrode potential and NaOH concentration. Although these distances are very small relative to the size of the plastic zone ahead of the crack tip, they nevertheless may be sufficiently large to cause enough plastic strain in the substrate after repassivation to produce successive film fracture as proposed by Vermilyea (1, 2). To further evaluate the applicability of this model data are needed describing the nature of the plastic strain gradient directly ahead of the crack tip during CSCC, as well as the fracture strain of the passive film.

Summary

Repassivation in the Fe-caustic system is characterized by peak anodic current densities on the order of 1 A/cm^2 following film fracture, with initiation of repassivation in milliseconds due to the formation of one or two monolayers of an unidentified reaction product film. The presence of 12% cold work in Fe did not affect repassivation kinetics, but the anodic dissolution product $HFeO_2^-$ reduced the corrosion current flowing under both steady-state and transient corrosion conditions. In 35% NaOH transient corrosion was inhibited most markedly at potentials below those in the active-passive transition region of the steady-state polarization curve. The amount of corrosion occurring during the first 8 msec after film fracture, which was comprised mainly of that resulting from the large 3-5 msec current transient, ranged only between $1 \cdot 10^{-3}$ and $5 \cdot 10^{-3}$ coulombs/cm^2 for all conditions investigated. Corrosion accompanying the early stages of repassivation was therefore relatively insensitive to electrochemical variables. The total corrosion occurring at longer times, however, was

strongly influenced by these variables in a manner qualitatively similar to crack propagation rate during CSCC. This parallel behavior of corrosion and cracking kinetics was interpreted as supporting an anodic dissolution model of cracking. The strong tendency for repassivation suggests that, for the most part, the crack tip is covered by a passive film during crack propagation and that crack advance is the result of oxidation of Fe to form both film and soluble $HFeO_2^-$. The nature of the corrosion transients in the potential range promoting CSCC lend support to a film rupture theory (1-4), but the large transients occurring at postpassive potentials currently represent an anomaly. Recent results of work designed to measure the fracture strains and to compare the relative ductilities of Fe_3O_4 and γ-Fe_2O_3, and which will be reported in a future paper, will hopefully further the mechanistic understanding of CSCC.

APPENDIX

Method of Estimating the Valence Change of Iron as a Function of Potential During Repassivation

The technique used to estimate the valence change n is illustrated in Fig. A-1. The potential range encompassing anodic current flow was divided into three regions based on the known behavior of Fe in high pH electrolytes. Region I is bounded by the rest potential and a potential midway between the active peak and passive potentials, ϕ_1 and ϕ_2, respectively. A valence of 2 is assigned to Fe reacting in this range because of the stability of $HFeO_2^-$ ion and the probable existence of a prepassive film of, perhaps, $Fe(OH)_2$ (19). Regarding Region II, it has been shown that at a potential between ϕ_1 and ϕ_2, Fe_3O_4 is stable but that γ-Fe_2O_3 is favored at higher potentials. This transition accounts for the increase in current flow at postpassive potentials and is presumably complete near the onset of the current plateau preceding oxygen evolution. An approximate valence for Region II would thus be between 2.67 and 3, except that some film dissolution is occurring. Therefore, an estimated average valence of 2.5 is assigned to Region II. A valence of 3 is ascribed to Region III due to the stability of γ-Fe_2O_3. This technique for estimating valence is self-consistent and not greatly in error, since the change of valence over the entire potential range investigated was only from 2 to 3.

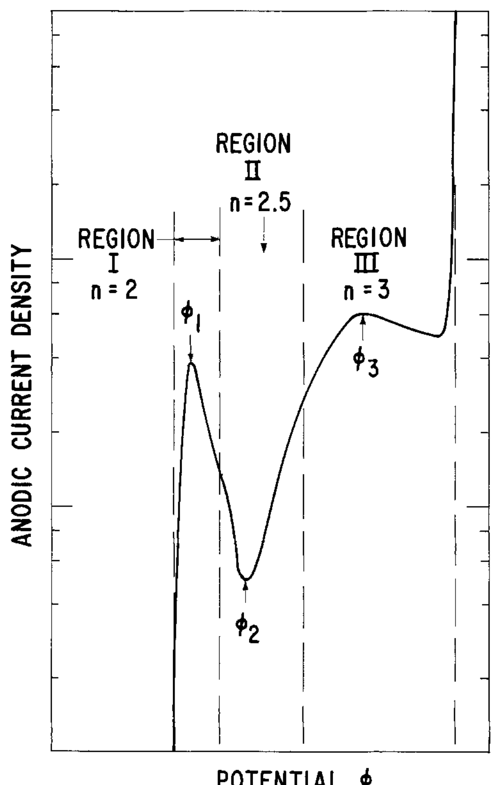

Fig. A-1. Schematic polarization curve showing the regions into which the experimental curves were divided and the valence assigned to each region.

The Na_2SO_4-Induced Corrosion Properties of Ni-Base Superalloy Phases

Glauco Romeo*,[1] and Douglas W. McKee

Research and Development Center, General Electric Company, Schenectady, New York 12301

ABSTRACT

The separate phases present in a Ni-base superalloy may offer different resistance to hot corrosion attack. Ni-Cr, Ni-Al, and Ni-Cr-Al alloys of composition corresponding, respectively, to the nominal γ matrix, the γ' phase, and a system of both these two phases, were coated with Na_2SO_4 and exposed to oxygen or H_2S-H_2 gas mixtures in the temperature range 850°-900°C. The corrosive attack was monitored with a recording microbalance. The results indicate that the degree and mechanism of corrosion of the above phases is markedly influenced by the nature of the environment and the composition of the oxide scales formed at the alloy surface. In general, the γ' phase appears to be a weak link in the over-all hot corrosion process.

The accelerated oxidation-sulfidation attack of nickel-base superalloys in the presence of sodium sulfate deposits is generally known as hot corrosion (1-6) and has been the subject of considerable investigation in the past two decades. The mechanism of hot corrosion has not yet been entirely clarified, and probably a generalized explanation for this type of phenomenon cannot be expected due to the variety of alloy compositions and environmental situations that can lead to similar corrosion morphologies. However, in the light of the available observations it is reasonable to assume that hot corrosion occurs by the combined action of (*i*) sulfur which diffuses rapidly into the alloy to produce a front of internally precipitated chromium sulfide particles that leaves the alloy matrix depleted in chromium, thus reducing its oxidation resistance (7, 8); and (*ii*) the Na_2SO_4 condensate which fluxes the normally protective oxides such as Al_2O_3 and Cr_2O_3. The stoichiometry of the salt layer can be modified by the presence of some elements in the alloy such as molybdenum, vanadium, etc., thereby enhancing the oxide fluxing effect (3). If the sulfur potential at the scale-salt melt interface is raised by the onset of reducing conditions, the rate of corrosion can become catastrophic. In this case it is likely that sulfur diffusing into the alloy is the predominant factor of alloy degradation, particularly when its activity exceeds the equilibrium value for the formation of nickel sulfide which may be liquid at temperature (9, 10).

Although the bulk chemistry of the alloy and the role of the separate elemental components in causing accelerated attack has been thoroughly investigated (3, 4), scant attention has been paid so far to the possible correlation between alloy microstructure and corrosion rate. A recent note by Billingham *et al.* (11) points to this gap in the hot corrosion literature, suggesting that different heat-treatments of γ-γ' superalloys, by modifying the elemental partitioning between the different alloy phases, may result in satisfactory mechanical properties but may impair the surface stability of the alloy with respect to hot corrosion.

A nickel-base superalloy segregates into three or more phases (12). Of these the most important are (*i*) the fcc γ-matrix, a solid solution rich in nickel and chromium and containing lesser amounts of other elements such as aluminum, titanium, etc.; (*ii*) an ordered intermetallic compound called γ', primarily responsible for the high temperature strength of the alloy. This phase has the nominal composition of Ni_3Al, but it can be alloyed with other elements such as iron and titanium, and hence is more accurately denoted as $(Ni,Fe)_3(Al,Ti)$. Further, the chemical activity of the elements in the phase will be dependent on the composition of that phase. Finally, (*iii*) the other type of phase present in significant quantities in modern Ni-base superalloys are the carbides, which may exist in several forms, such as MC, M_7C_3, $M_{23}C_6$, etc., where M is the reactive metal in the carbide.

A priori, there is no reason to believe that these different phases, namely, the γ matrix, the γ' strengthener, and the carbides, will respond to a corrosive environment in the same way. Indeed, because of the wide spectrum of compositional difference between phases, it would be expected that they would respond quite differently in a hot corrosion environment. Because both sulfur diffusivity and ability to form a certain type of protective oxide (13) may vary considerably for the different phases present in a superalloy, it appeared useful to undertake a study in the temperature range 850°-1000°C of the hot corrosion behavior of some of the major phases present in a nickel-base superalloy, each phase being investigated separately in order to determine whether any of them could be a "weak link" in the alloy with respect to its hot corrosion resistance.

This paper reports part of the results of this study, with special emphasis on the behavior of the nominal γ and γ' phases in various environments that simulate oxidizing and reducing conditions.

Experimental

Specimen preparation and experimental techniques.—Alloys of composition [weight per cent (w/o)] Ni-35 Cr, Ni-20 Cr, Ni-13.3 Al, and Ni-10.4 Cr-13.5 Al were prepared by induction melting. The first two alloys simulate the chromium-enriched composition of the γ matrix, austenitic in a typical superalloy, the third alloy corresponds to the nominal γ' composition Ni_3Al, and the last alloy to a multiphase Ni-Cr-Al system containing both γ and γ' phases. The alloys were given

Table I. Alloy preparation and treatment

Alloy composition (w/o)	Ingot preparation	Mechanical and thermal treatments
Ni-35 Cr	Melted, solidified, remelted and cast in Ar	Specimens annealed in vacuum for 3 hr at 1000°C
Ni-20 Cr	Melted and cast in Ar	Ingot forged to 0.575 in. thickness at 1100°-1175°C and rolled to 0.080 in. at 1100°C
Ni-10.4 Cr-13.5 Al	Ni-Cr melted in Ar at 1/3 atm, solidified and remelted in vacuum. Al added in Ar at 1 atm. Final casting in Ar	Used as cast
Ni-13 Al	Ni melted in Ar at 1/3 atm, solidified and remelted in vacuum. Al added in Ar at 1 atm. Final casting in Ar.	Ingots were heated to 1000°C and slices were hot cut

convenient heat and mechanical working treatments, according to their homogeneity and brittleness.

Table I shows a schematic of the alloy preparation and treatments. Due to the different ductility of the various alloys, test specimens for thermogravimetric analysis (TGA) were prepared by mechanical or electrical discharge machining of rectangular coupons approximately 15 $\times$ 5 $\times$ 1 mm in size from rolled sheets or slices of the as-cast ingots. A suspension hole was drilled in each coupon. The specimens were wet ground through 600 grit silicon carbide papers and cleaned with acetone and methanol prior to each run. The surface area was computed by measuring the dimensions with a micrometer. The specimens were coated with a layer of sodium sulfate by spray deposition and drying with an infrared lamp. Most specimens were annealed for 4-6 hr in oxygen prior to coating them with sodium sulfate. This preoxidation treatment was intended to simulate the real condition of metal surfaces in gas turbines during salt deposition. It also provided a better adherence of the salt deposit to the oxide layer than to the bare metal.

The extent of the corrosive attack was monitored by means of a thermogravimetric apparatus (TGA). This consisted essentially of a recording microbalance, a reaction vessel for metal specimens, a temperature controlled furnace, and a set of flow meters to prepare gas mixtures. The microbalance was a Cahn RG Automatic Electrobalance with a capacity range of 1-2.5g and a sensitivity of 1 μg. The balance was coupled with a digital data acquisition system, by means of which the voltage output of the balance could be punched directly on paper tape together with a time scale at preset time intervals. The tape was then processed automatically by a computer and the data could be displayed terminally as weight-gain *vs.* time plots. This greatly facilitated data collecting and analysis, especially for long term experiments. A more detailed description of the TGA can be found in a previous publication (14).

After most runs, samples of the corrosion products were submitted for x-ray diffraction analysis, and the specimens were mounted and cross-sectioned metallographically for examination of the corrosion scales with the light microscope. In some cases microprobe scanning of the cross sections was also carried out.

Choice of environmental parameters.—It is not feasible to define a single model environment for hot corrosion, because accelerated attack can occur in a great variety of situations. However, three types of environments were selected during the course of this study:

1. Sodium sulfate coatings exposed to H_2S-H_2 gas mixtures to simulate strong reducing conditions and high sulfur potentials.
2. Sodium sulfate coatings exposed to oxygen to simulate oxidizing conditions.
3. Gaseous atmospheres as described in types 1 and 2, but in the absence of sodium sulfate coatings.

Most experiments were carried out isothermally at 900°C. This temperature was selected as representative of an upper limit in current gas turbine operations and was sufficiently high for the sodium sulfate coatings to be present as a liquid film on the metal surface. The experiments were carried out with gases flowing at atmospheric pressure and flow rates of $\sim$300 cm^3/min corresponding to a linear velocity in the reaction cell of 0.5-1 cm/sec.

Crucible experiments with excess sodium sulfate.—A series of crucible experiments was also carried out with a range of Ni-Al (0-30 w/o Al) and Ni-Cr (0-20 w/o Cr) alloys, coupons of which were immersed in an excess (1g) of powdered sodium sulfate and heated in flowing air at 900°C. The resulting weight changes of these samples were measured in the Chevenard thermobalance described previously (6) as a function of the Al and Cr content of the alloy. The nominal and actual compositions of the alloy coupons used in these experiments are listed in Table II.

Results

Gamma matrix (nominal composition).—Two binary systems were used that simulated the fcc continuous matrix of Ni-base superalloys: Ni-35 w/o Cr and Ni-20 w/o Cr. Both of these systems belong to the range of existence of the γ phase at high temperature, according to the binary phase diagram (15), and correspond to an upper and medium value of chromium in solid solution with nickel.

Reducing conditions.—When Ni-35 Cr was exposed at 850°C to a 10% H_2S-H_2 gas mixture, the weight gain curve followed a pseudoparabolic trend, reaching a value of 58 mg/cm^2 after only 2½ hr. However, the reaction was not of a gas-solid type throughout the run because of the initial formation of a liquid nickel sulfide phase. Figure 1 shows a cross section of the specimen at the end of this experiment. The duplex scale consists of an external layer of Ni_3S_2, which was molten at the temperature of the experiment, separated from the alloy by an inner layer of chromium sulfide. Grain boundaries in this inner layer offered a preferential path for the penetration of liquid nickel sulfide stringers (16), as evident in the micrograph. X-ray diffraction analysis indicated the composition of the chromium sulfide layer to be mainly Cr_3S_4 with traces of Cr_2S_3. The stoichiometry of chromium sulfide can vary in the range CrS to Cr_2S_3 with the sulfur pressure (17). The composition Cr_3S_4 in particular can exist in a remarkably wide range of sulfur pressures (18).

X-ray analysis of the oxide scale grown at 900°C in oxygen at atmospheric pressure on a Ni-35 Cr alloy showed its composition to be predominantly Cr_2O_3, with a few weak extraneous lines attributable to NiO and possibly a spinel. A test was then run to check whether this scale could provide a barrier to the formation of liquid nickel sulfide and consequent accelerated attack. Two specimens of Ni-35 Cr were preoxidized but only one of them was coated with $\sim$2 mg/cm^2 of sodium sulfate. Both specimens were then treated with a 10% H_2S-H_2 mixture at 850°C. After a

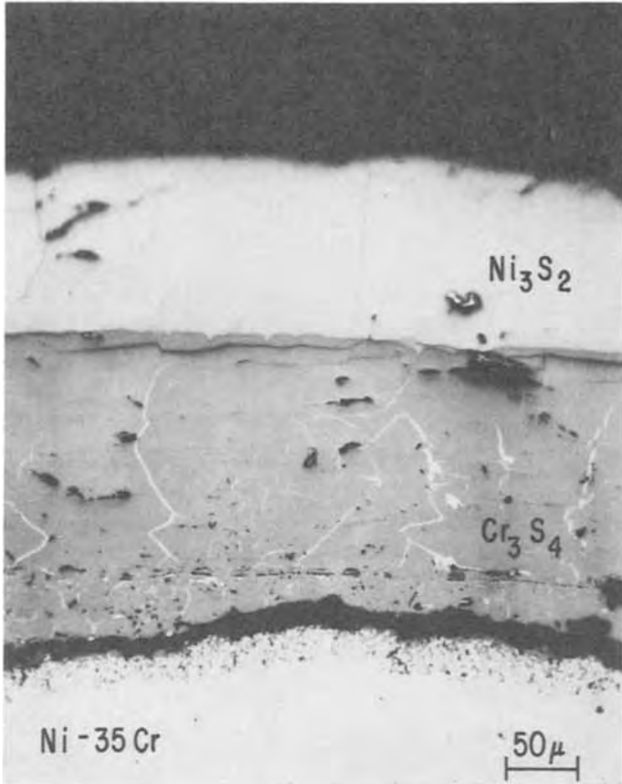

Fig. 1. Ni-35 Cr alloy treated at 850°C with a 10% H_2S-H_2 gas mixture for 2½ hr. The scale consists of an outer layer of nickel sulfide which was molten at temperature, and an inner layer of chromium sulfide.

brief induction period fast formation of liquid nickel sulfide resulted in both cases. The oxide layer did not offer significant protection against gaseous sulfidation and the sodium sulfate deposited onto the oxide did not accelerate substantially a situation which led to catastrophic attack.

Figure 2 shows an example of liquid sulfide formation over preoxidized salt-free Ni-35 Cr, where the liquid has dripped by gravity to the bottom of the specimen. Figure 3 shows the weight-gain curves for Ni-35 Cr specimens that were given different pretreatments and were subsequently exposed to a 10% H_2S-H_2 gas mixture.[2] While the extent of corrosion in Fig. 3 is of a comparable magnitude in the three cases after equal times, a larger induction period before the onset of fast sulfidation can be noticed for the specimen preoxidized and not coated with sodium sulfate. Most probably in this case a longer time was required for sulfur to diffuse through Cr_2O_3, whereas in the other two cases either Cr_2O_3 did not have time to reach a finite thickness or it was dissolved by a liquid film of Na_2SO_4-Na_2S mixture with which the specimen was coated. It should also be noted that hydrogen present in the H_2S-H_2 mixture readily reduces Na_2SO_4 to Na_2S at high temperature. Similar experiments have shown the same tendency for the Ni-20 Cr alloy to form liquid nickel sulfate when exposed to H_2S-H_2 atmospheres.

Oxidizing conditions.—A study was carried out on the effect of oxidizing conditions and cyclic oxidizing-reducing conditions on the nominal γ matrix composition, using oxygen at 1 atm throughout the run or alternating the main oxidation process with short periods of exposure to hydrogen. It is important to point out that in these conditions weight gain curves provide only an

[2] Here and in other kinetic plots no attempt will be made to interpret the curves in conformance to any quantitative rate law, because in most cases the corrosion scales lack entirely the uniformity and compactness which is required for such an analysis to be meaningful. However, the weight gain curves visualize the extent of the attack during the experiments and identify major changes in reaction mechanisms.

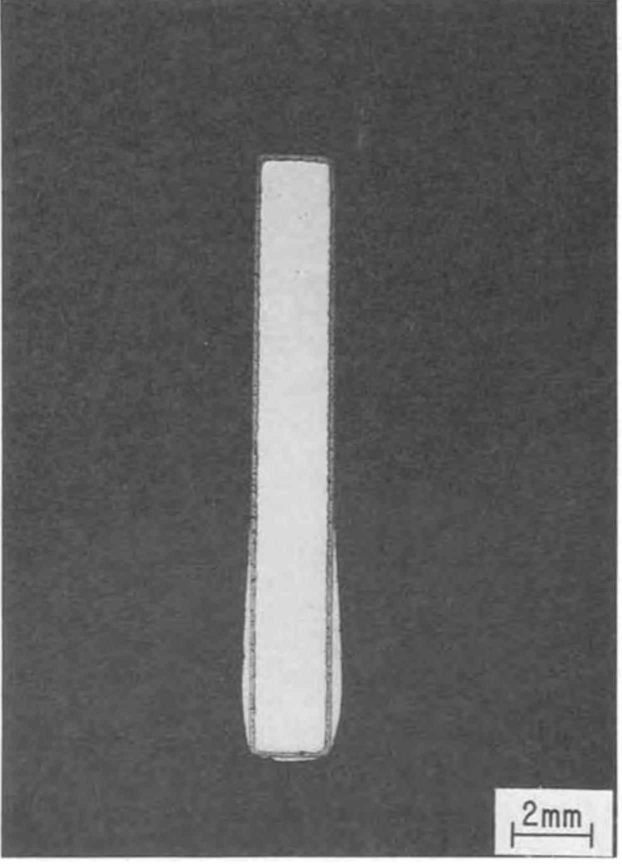

Fig. 2. Ni-35 Cr alloy preoxidized and subsequently sulfidized with a 10% H_2S-H_2 gas mixture at 850°C. Liquid nickel sulfide has dripped to the bottom of the specimen which was held vertically in the furnace.

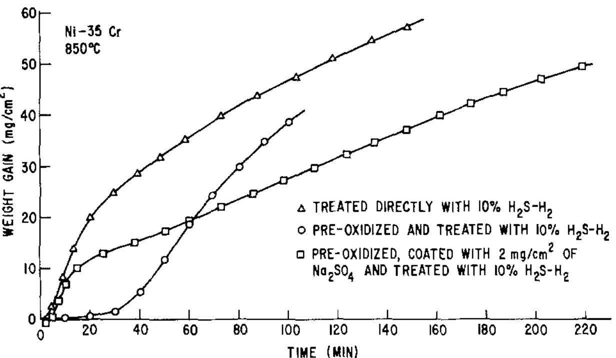

Fig. 3. Weight gain curves for a Ni-35 Cr alloy exposed at 850°C to a 10% H_2S-H_2 gas mixture after different pretreatments.

approximate indication of the extent of corrosion, since weight losses due to evaporation or reduction of sodium sulfate from the surface may be superimposed on weight gains due to formation of oxide and sulfide scales. Evaporation can be neglected, however, when reducing conditions with formation of liquid corrosion products result in a much faster rate of attack. In any case, metallographic measurements of metal recession can provide additional information on the depth of attack.

Ni-20 Cr preoxidized and coated with 10 mg/cm² of sodium sulfate was exposed to oxygen at 900°C for about 6 days. Figure 4 shows that within the first day the specimen gained less than 1 mg/cm², after which the weight loss due to evaporation of the sodium sulfate was greater than the weight gain due to oxidation. Relatively little weight gain has been reported by Goebel *et al.* (3) for a Ni-30 Cr alloy oxidized at 1000°C, and by Hardt *et al.* (19) for a Ni-20 Cr alloy oxidized at 905°C. However, in Goebel's case the alloy

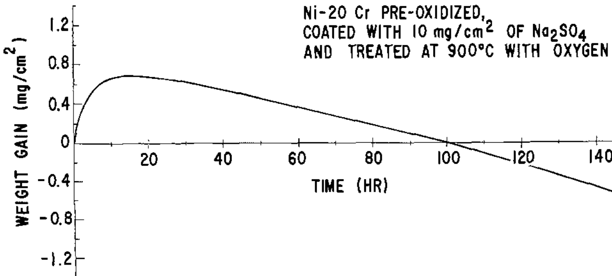

Fig. 4. Weight gain curve for a Ni-20 Cr alloy preoxidized, coated with 10 mg/cm^2 of Na_2SO_4, and exposed to oxygen at 900°C. The weight loss of the specimen can be attributed mainly to evaporation of sodium sulfate.

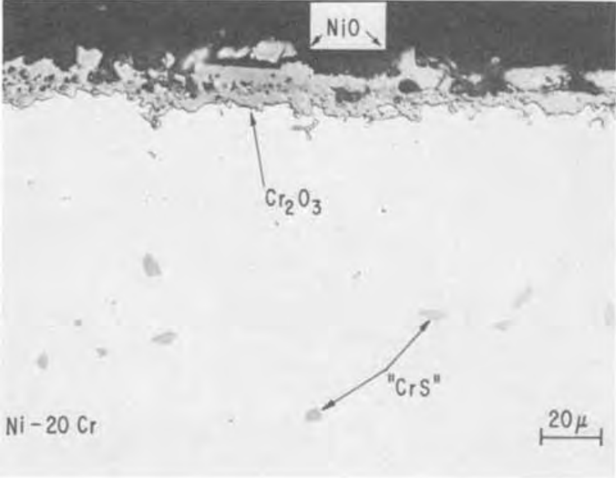

Fig. 5. Duplex oxide scale formed on a Ni-20 Cr alloy preoxidized, coated with 10 mg/cm^2 of Na_2SO_4, and exposed to oxygen at 900°C for about 6 days. Some particles of chromium sulfide have precipitated within the alloy.

was coated with only 0.5 mg/cm^2 of sodium sulfate, and in Hardt's case with 1-3 mg/cm^2 of sodium sulfate. A much larger amount of salt in our case did not seem to alter significantly the corrosion rate, indicating that dissolution or penetration kinetics are limiting, rather than solubility effects. The same is true for a temperature increase of 100°C (from 900° to 1000°C).

At the end of the run the residual sodium sulfate exhibited a bright yellow color and the presence of sodium chromate was confirmed by x-ray analysis. Light microscopy revealed a fairly compact external scale and internally precipitated particles of chromium sulfide (Fig. 5). X-ray mapping (Fig. 6) and diffraction analysis showed the upper portion of the scale to consist of NiO and the lower portion of Cr_2O_3. The formation of sodium chromate, observed also by other authors, indicates reaction between sodium sulfate and initially present Cr_2O_3 layers. However, a considerable degree of protection for the alloy substrate is still provided by the scale, which appears to react only slightly with the sodium sulfate coating. It can be concluded that, by and large, the γ matrix presents a considerable resistance to hot corrosion due to sodium sulfate deposits, in purely oxidizing conditions.

The resistance of Ni-Cr alloys to corrosion by Na_2SO_4 under oxidizing conditions is also confirmed by the results of crucible tests carried out with a series of Ni-Cr specimens, immersed in excess salt in air at 900°C. As shown by the dashed curve of Fig. 7, in which the initial weight gain rate is plotted against alloy composition, the addition of chromium to nickel results in a steady decrease in corrosion rate with increasing chromium content, becoming very small at the nominal γ matrix composition of Ni-20 Cr. This behavior is in marked contrast to that of the Ni-Al alloy series, whose corrosion behavior is shown by the solid curve of Fig. 7 and is discussed further below.

Cyclic conditions.—The effect of cyclic oxidizing and reducing conditions was evaluated with Ni-20 Cr and Ni-35 Cr alloys by treating specimens alternatively with oxygen and hydrogen, to determine whether short term reduction stages would create conditions favorable to accelerated attack. The conditions used in these experiments were similar to those employed by Simons *et al.* (29). Figure 8 shows a weight gain curve for a specimen of Ni-20 Cr preoxidized, coated with 6 mg/cm^2 of sodium sulfate, and exposed at 900°C first to oxygen, then to hydrogen, and finally again to oxygen. During the reduction period the rapid weight loss of the specimen is due to the reactions: $Na_2SO_4 + 4H_2 \rightarrow Na_2S + 4H_2O$ and $Na_2S + 2H_2O \rightarrow 2NaOH + H_2S$. The presence of H_2S in the exhaust gases was confirmed with lead acetate paper strips.

The final oxidation stage resulted in an initial rapid weight gain, which most probably corresponds to reoxidation of the residual Na_2S, followed by a steady state of very low weight gain during which a protective oxide layer is formed again and the corrosion proceeds very slowly. This behavior shows that the γ matrix offers the same resistance to hot corrosion both during continuous oxidation and when exposed to temporary reducing conditions, if the sulfur pressure at the gas-scale interface is not sufficient for the formation of liquid nickel sulfide. Indeed the morphology of

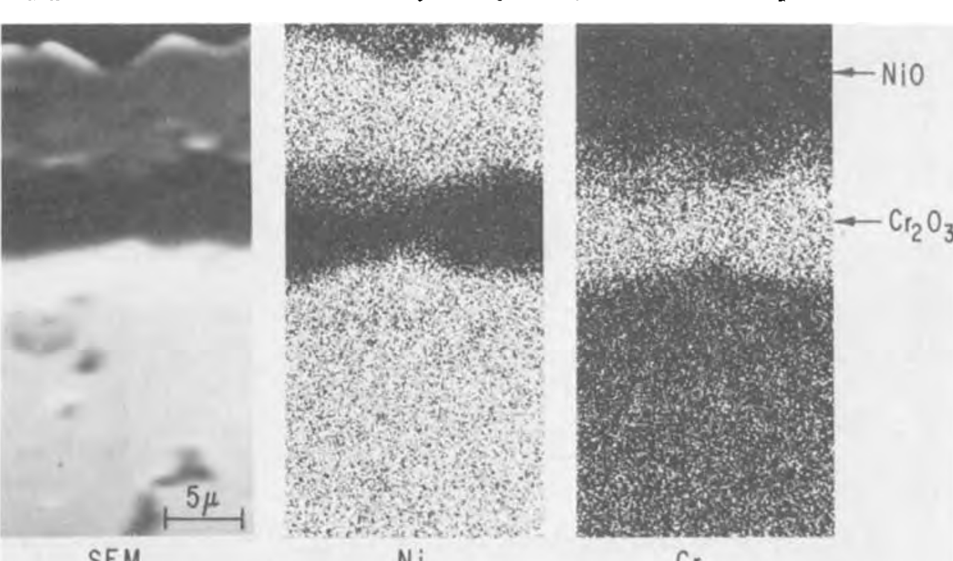

Fig. 6. Characteristic x-ray distribution for the duplex oxide scale formed on a Ni-20 Cr alloy preoxidized, coated with sodium sulfate, and exposed to oxygen at 900°C.

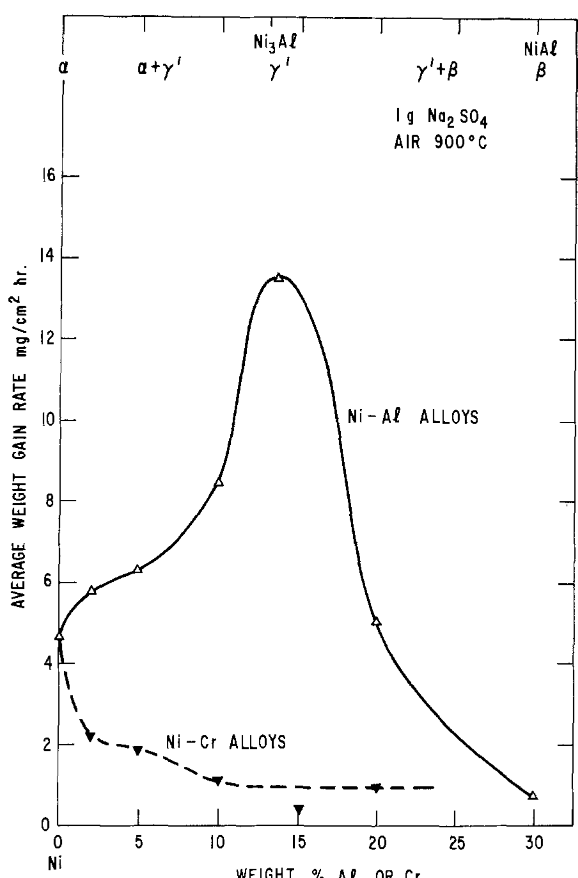

Fig. 7. Results of thermogravimetric tests carried out on Ni-Cr and Ni-Al alloys exposed to sodium sulfate in air, at 900°C.

the corrosion product is very similar in both cases with the sequence of base alloy, chromium sulfide, nickel-rich matrix, and nickel and chromium oxides indicated by the microprobe trace in Fig. 9. The Ni-35 Cr alloy showed a very similar behavior. It will be pointed out in a later section that alternate oxidizing-reducing conditions applied to a sodium sulfate coated two-phase ternary Ni-Cr-Al alloy seem to have induced accelerated attack after such a temporary re-

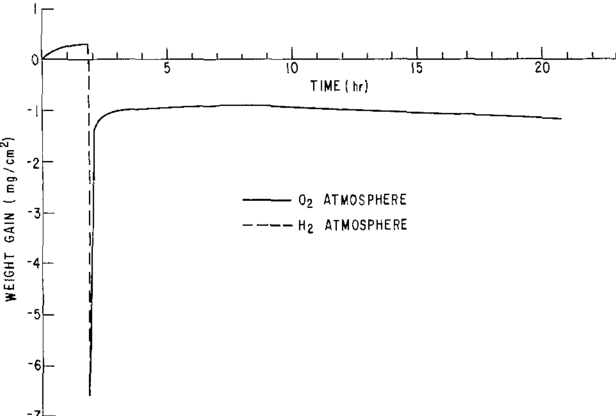

Fig. 8. Weight gain curve for a Ni-20 Cr alloy preoxidized, coated with 12 mg/cm^2 of Na_2SO_4, and exposed alternatively to oxidizing and reducing atmospheres at 900°C.

duction stage as that applied to the gamma phase above, most probably because hot corrosion is favored at areas of γ' phase.

Gamma prime (nominal composition).—Reducing conditions.—A specimen (a) of Ni_3Al was treated directly at 900°C with a 10% H_2S-H_2 gas mixture. After about 13 hr the weight gain amounted to only 2.5 mg/cm^2. X-ray analysis of the corrosion product indicated presence of Ni_3S_2 and some Al_2O_3. The latter compound probably formed because of oxygen impurity in the gas stream, and was responsible for the resistance of the specimen to sulfidation.

Another specimen (b) of Ni_3Al, preoxidized and coated with 9 mg/cm^2 of sodium sulfate, was treated with the 10% H_2S-H_2 mixture at 900°C. In this case the weight gain reached in 3½ hr, 11 mg/cm^2, indicating a marked acceleration of the corrosion process due most probably to removal from the metal surface of protective Al_2O_3 layers by the molten sodium sulfate. Figure 10 shows the weight gain curves for specimens (a) and (b). Figure 11 shows a portion of the scale formed on specimen (b). Microprobe scanning across this scale (Fig. 12) indicated an outer portion of nickel sulfide (Ni_3S_2) without any aluminum and an inner portion in which aluminum is present together with nickel sulfide. Once again the high cor-

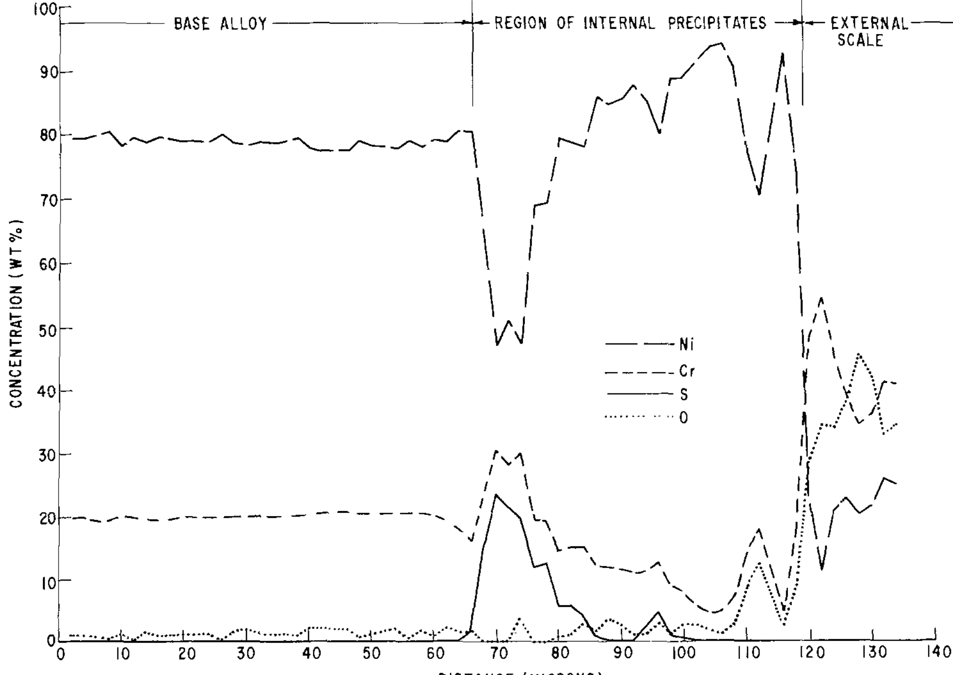

Fig. 9. Distribution profile of elements for a Ni-20 Cr alloy preoxidized, coated with sodium sulfate, and exposed alternatively to oxidizing and reducing conditions.

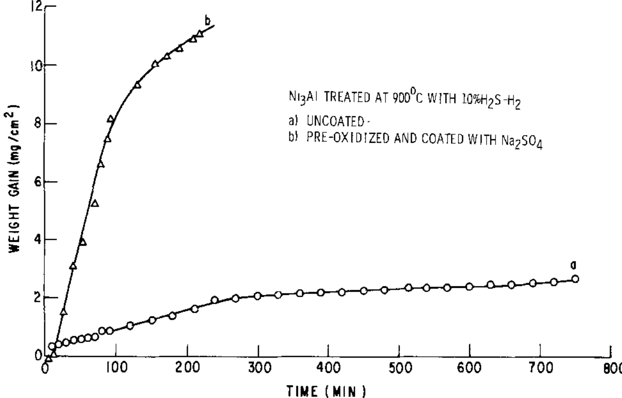

Fig. 10. Weight gain curves for a Ni-13 Al alloy treated with a 10% H_2S-H_2 gas mixture at 900°C: (a) uncoated specimen; (b) specimen preoxidized and coated with 9 mg/cm² of Na_2SO_4.

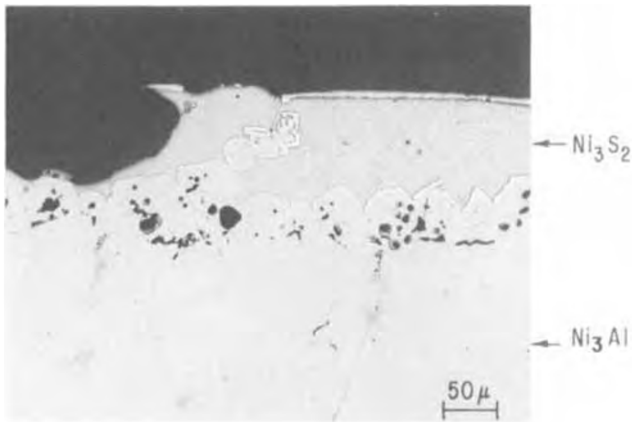

Fig. 11. Scale formed on a Ni-13 Al alloy preoxidized, coated with 9 mg/cm² of Na_2SO_4, and treated with a 10% H_2S-H_2 gas mixture at 900°C. The portion labeled as Ni_3S_2 was probably molten at reaction temperature.

rosion rate of the γ' phase coated with sodium sulfate and exposed to H_2S-H_2 mixtures can be explained by the initial formation of liquid nickel sulfide, which subsequently reacts with aluminum to form aluminum sulfide. Formation of liquid nickel sulfide has indeed been observed with the hot-stage microscope on Ni_3Al specimens coated with sodium sulfate and exposed to sulfur-bearing atmospheres in reducing conditions. However, a comparison of the weight gain curves in Fig. 3 and Fig. 10 shows that the tendency to form liquid nickel sulfides when exposed to H_2S-H_2 atmospheres is much more pronounced with Ni-Cr systems than with Ni-Al systems.

The effect of reducing atmospheres on sodium sulfate deposited onto a γ' substrate was also studied in conditions of low sulfur potential in the gas phase. A specimen of Ni_3Al (c) was preoxidized, coated with 17 mg/cm² of Na_2SO_4, and exposed at 900°C to hydrogen. Reduction of the salt to Na_2S took place within an hour, after which no weight change was noticed. At the end of the run the specimen was rinsed with hot water and the insoluble portion of the washings treated with aqua regia. A residue (most probably Al_2O_3) remained insoluble after this treatment. Chemical analysis of the soluble portion showed a higher content of Al with respect to Ni (Al/Ni $\simeq$ 12). Again this would indicate a tendency for the aluminum oxide to dissolve in the Na_2SO_4-Na_2S layer. Figure 13-1 is a cross section of specimen (c) and shows that the corrosive attack is characterized by a front of internally precipitated particles. Most of these particles were removed by polishing, leaving behind a porous section. Figure 13-2 is a high magnification scanning electron micrograph of the porous area in Fig. 13-1. An electron beam was focused on a particle (point A) and in the alloy matrix (point B). The locally excited x-ray radiations were collected and analyzed by a solid-state detector. The corresponding spectrum is shown in Fig. 13-3, indicating that sulfur is present in particle A together with nickel and aluminum. Unfortunately oxygen cannot be identified directly by the solid-state detector and further analysis would be necessary to ascertain the nature of the internal precipitate. However, it is worth noticing that even though chromium is not present in the Ni_3Al phase. the presence of a sulfur-containing internal precipitate (a feature characteristic of hot corrosion) can still be detected.

Oxidizing conditions.—When a specimen of Ni_3Al (d) was preoxidized, coated with 5.5 mg/cm² of sodium sulfate, and treated at 900°C with oxygen, rapid

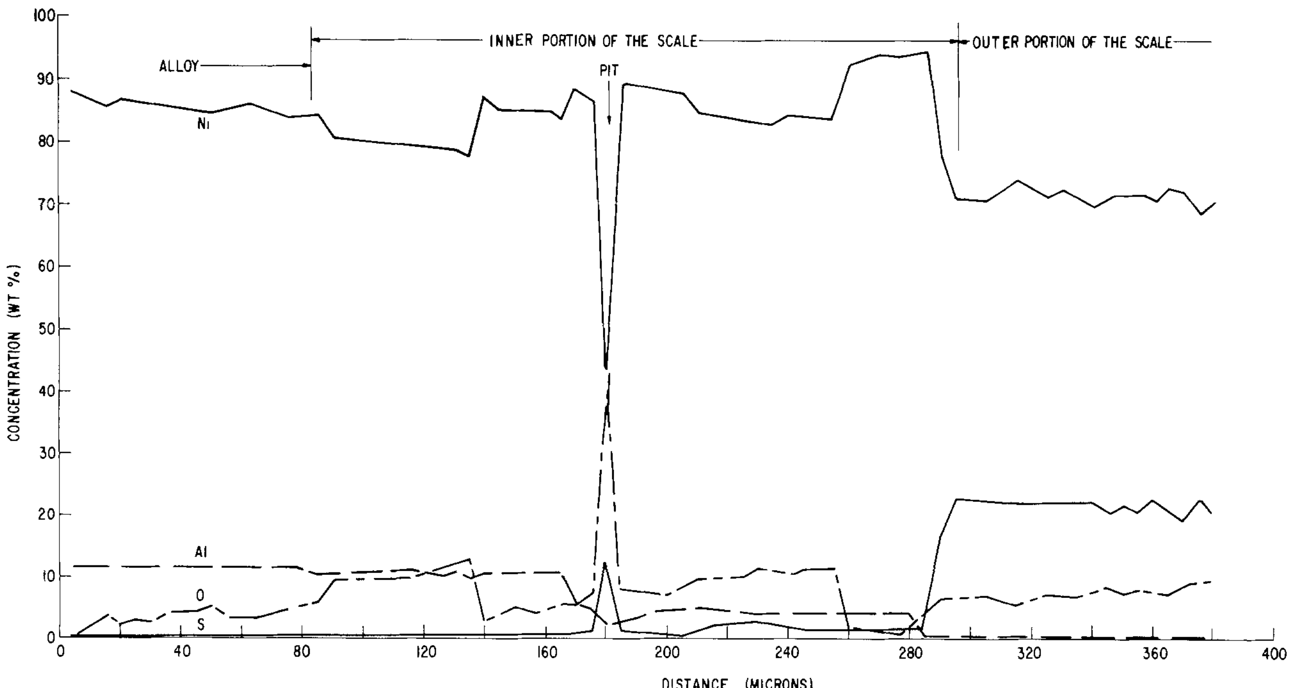

Fig. 12. Distribution profile of elements for a Ni-13 Al alloy preoxidized, coated with sodium sulfate, and treated with a 10% H_2S-H_2 gas mixture at 900°C.

Fig. 13-1. Cross section of Ni-13 Al alloy preoxidized, coated with 17 mg/cm^2 of Na_2SO_4, and treated with hydrogen at 900°C for 4 hrs. 2. SEM micrograph of porous area shown in top micrograph. 3. X-ray spectrum of particle A shown in middle micrograph.

weight gain was observed in the first few minutes, followed by a continuous decrease in the reaction rate. The same experiment was repeated on a specimen which had not been preoxidized but had been coated with 11 mg/cm^2 of sodium sulfate (e). Similar results were obtained in this case and also with a specimen which was preoxidized and coated with 17 mg/cm^2 of sodium sulfate (f). Figure 14 shows the weight-gain curves for specimens d, e, and f.

The extent of the initial rapid attack appears to be roughly dependent on the amount of salt deposit. The presence of a preexisting oxide did not affect significantly the corrosion process. In all the three cases after about 10 hr the corrosion rate dropped to a negligible value. This behavior can be explained assuming that molten sodium sulfate acts initially as a flux for thin, protective oxide layers (mainly Al_2O_3). At a later stage the growth of thicker scales that offer partial protection to the metal substrate can take place.

Figure 15 shows the somewhat porous scale grown on specimen (e). X-ray analysis identified the presence of NiO as the predominant phase, plus a small amount of α-Al_2O_3. Microprobe scanning of the scale (Fig. 16) showed some evidence of sulfides, possibly of aluminum, at the metal-scale interface, while the scale profile appears to consist essentially of Ni and and Al oxides. The growth of dark NiO crystals on the specimen surface has been frequently observed in the course of our experiments with Ni-base alloy coated with sodium sulfate and exposed to oxygen. Conceiv-

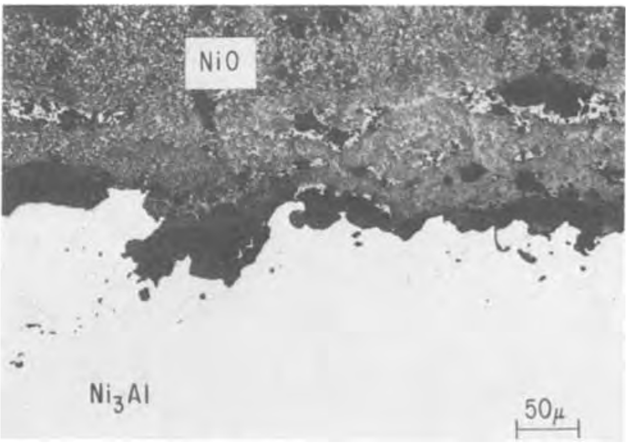

Fig. 15. Cross section of Ni-13 Al alloy coated with 11 mg/cm^2 of Na_2SO_4 and treated with oxygen at 900°C for 18 hr. A small amount of α-Al_2O_3 was detected in the main NiO porous scale.

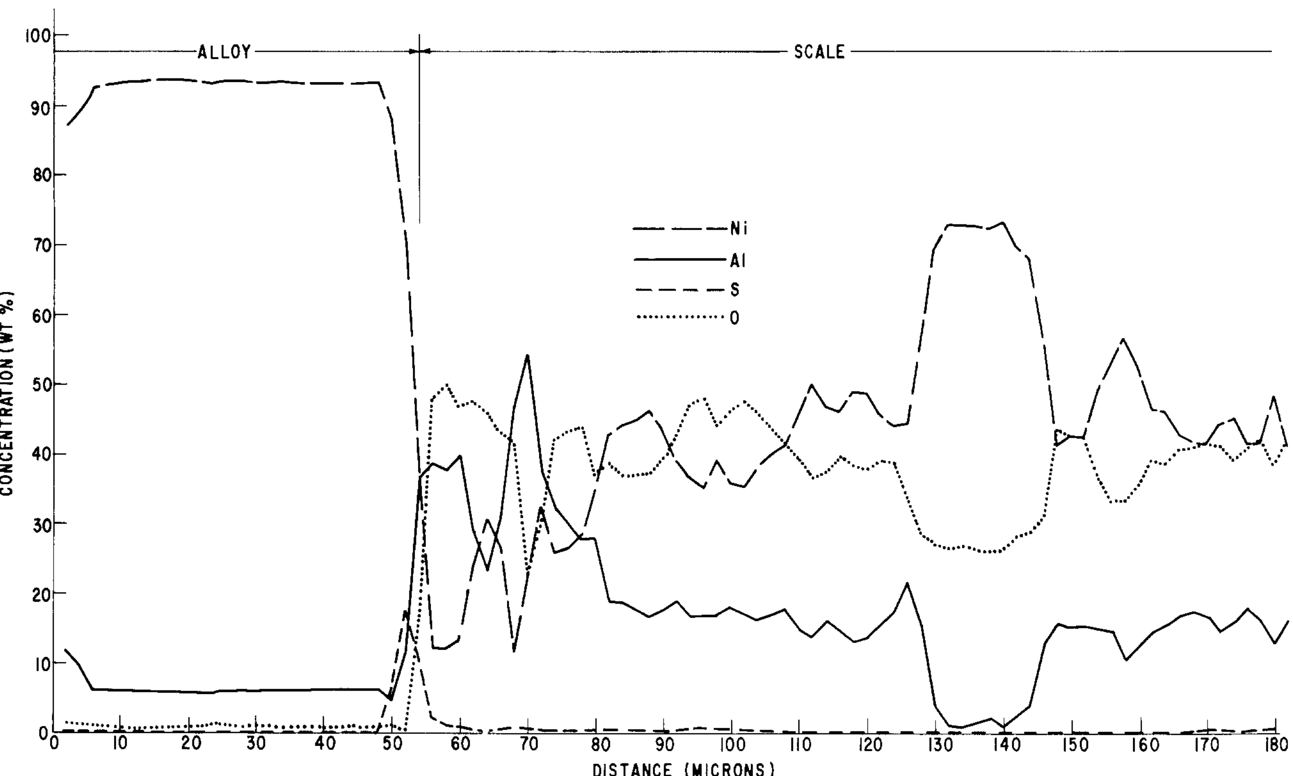

Fig. 16. Distribution profile of elements for a Ni-13 Al alloy coated with sodium sulfate and treated with oxygen at 900°C

ably the growth of thick and fairly coherent layers of NiO separates progressively the sodium sulfate film from the metal and results in a continuous slowdown of the corrosion rate for the Ni_3Al phase. This is also favored by the saturation of the salt film with corrosion products, which renders it less active in fluxing out the oxide scale.

The results of crucible experiments with a series of Ni-Al alloys exposed to excess molten Na_2SO_4 in an oxidizing atmosphere are summarized in Fig. 7. The solid curve shows the average initial corrosion rate (weight gain/cm^2 hr) at 900°C as a function of aluminum content of the alloy. On addition of Al to Ni, the corrosion rate under oxidizing conditions accelerates rapidly as the proportion of the γ' phase increases and becomes catastrophic at the nominal γ' composition, Ni_3Al. This alloy was reduced to a porous gray mass after exposure to excess Na_2SO_4 for a period of only 2 hr in air. Further additions of aluminum resulted in a decrease in corrosion rate as the proportion of the Ni-Al phase increased. The Ni-Al β phase itself (Ni-30 w/o Al) was remarkably resistant to attack and gained only 1 mg/cm^2 during a period of 4 hr in contact with the molten salt.

A multiphase Ni-Cr-Al system.—Studies of the behavior of a multiphase system were carried out on a Ni-10.4 Cr-13.5 Al (w/o). Taylor and Floyd (20) have shown that at temperatures approaching 1000°C this alloy composition can consist of up to four phases, namely the bcc solid solution of nickel in chromium (α), the fcc solid solution of chromium in nickel (γ), the ordered bcc NiAl phase (β), and the ordered fcc Ni_3Al phase (γ').

Reducing conditions.—A specimen of Ni-10.4 Cr-13.5 Al (a) treated at 850°C directly with a 10% H_2S-H_2 mixture reacted initially slowly, but after about 6 hr a breakaway took place in the weight gain curve and sulfidation proceeded at a linear rate for the rest of the run. X-ray analysis of the corrosion product indicated the presence mainly of Ni_3S_2, a mixed sulfide of chromium and aluminum,[3] and a trace of α-Al_2O_3. The same scale composition was found in another specimen (b) coated with 1.3 mg/cm^2 of sodium sulfate and exposed at 850°C to the H_2S-H_2 mixture. Preoxidation of the alloy followed by isothermal treatment at 850°C with the H_2S-H_2 mixture resulted in a surprisingly low rate of attack (c). On the other hand, the same alloy preoxidized and coated with 2 mg/cm^2 of sodium sulfate after an initial treatment with oxygen underwent little corrosion, but was deeply attacked when subsequently exposed in isothermal conditions to the H_2S-H_2 mixture (d). The weight gain curves corresponding to these four experiments are summarized in Fig. 17.

A comparison between curve (a) and earlier data on corresponding untreated Ni-Cr alloys under sulfidation conditions (Fig. 3) indicates that addition of Al slows down remarkably the sulfidation rate of the γ matrix under reducing conditions. This is probably

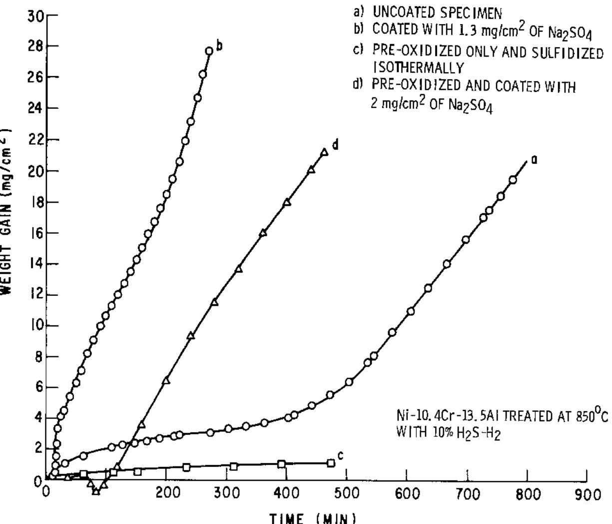

Fig. 17. Weight gain curves for a Ni-10.4 Cr-13.5 Al alloy exposed to a 10% H_2S-H_2 gas mixture at 850°C after the following pretreatments: (a) specimen untreated, (b) specimen coated with 1.3 mg/cm^2 of sodium sulfate, (c) specimen preoxidized, (d) specimen preoxidized and coated with 2 mg/cm^2 of sodium sulfate.

[3] The compound Cr_2AlS_4 has a spinel structure ($a_o \simeq 9.9$A) and is referenced in Donnay (21).

due to the initial formation of oxides and sulfides of aluminum and chromium. Subsequent depletion of the alloy in these elements favors the formation of Ni_3S_2 and the reaction becomes much faster. Curve (c) in Fig. 17 shows the effect of a preexisting layer of oxide in reducing the initial sulfidation rate in the absence of destructive salt deposits. When instead sodium sulfate films remove protective oxides, the sulfidation process proceeds catastrophically, as exemplified by curves b and d in Fig. 17. The effect of sodium sulfate deposits is shown dramatically in Fig. 18, where the top and bottom micrographs correspond to the cross section of specimens (c) and (d), respectively. In the case of specimen (d) the presence of sodium sulfate has favored the growth of a much thicker scale of complicated morphology. Large polygonal particles of chromium sulfide are embedded in a scale of nickel and aluminum sulfide. The Ni_3S_2 was probably molten at reaction temperature, and chromium sulfide segregated from it, as suggested by Seybolt (8), according to the reaction

$$x/2Ni_3S_{2(liquid)} + Cr_{(in\ solution)} \rightarrow CrS_x + 3/2xNi_{(in\ solution)}$$

Oxidizing conditions.—A specimen of Ni-10.4 Cr-13.5 Al alloy was preoxidized, coated with 10 mg/cm^2 of sodium sulfate, and exposed to oxygen at 900°C. The specimen gained comparatively little weight for about three days, after which accelerated attack took place suddenly, as shown by curve a in Fig. 19. The experiment was repeated, and in the second case onset of accelerated attack occurred after 12 hr (curve b in Fig. 19). The sudden breakaway in the weight gain curves can again be related to the nature of the oxide scales preformed on the specimens and their rate of dissolution or penetration by the sodium sulfate melt. X-ray diffraction analysis indicated that the oxide scale formed in the absence of sodium sulfate deposits was a mixture of spinels of composition $NiAl_2O_4$ and $NiCr_2O_4$. Differences in the thickness of the oxide layer due to small differences in surface preparation of the

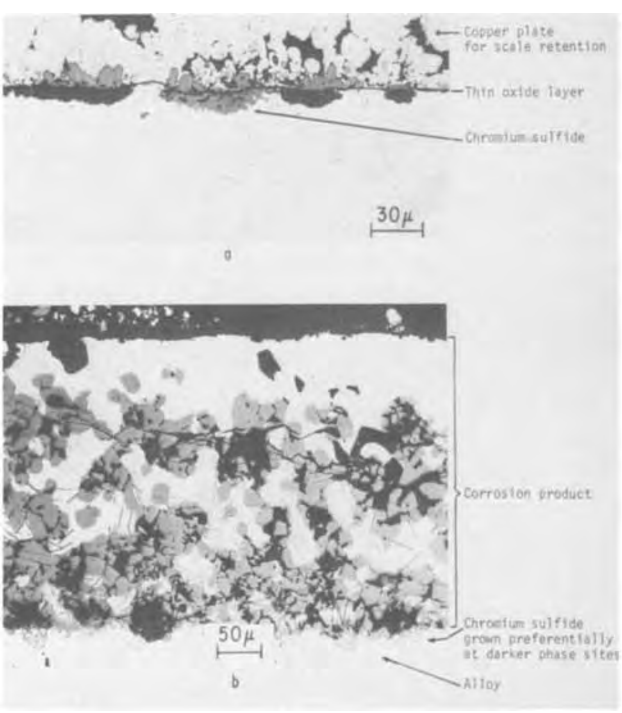

Fig. 18. Ni-10.4 Cr-13.5 Al alloy treated with a 10% H_2S-H_2 gas mixture at 850°C for 8 hr. (a) The specimen was preoxidized but not coated with sodium sulfate. A copper plate was used for retaining the relatively thin chromium sulfide layer. (b) Coating a preoxidized specimen with sodium sulfate produced deep attack and a complex morphology.

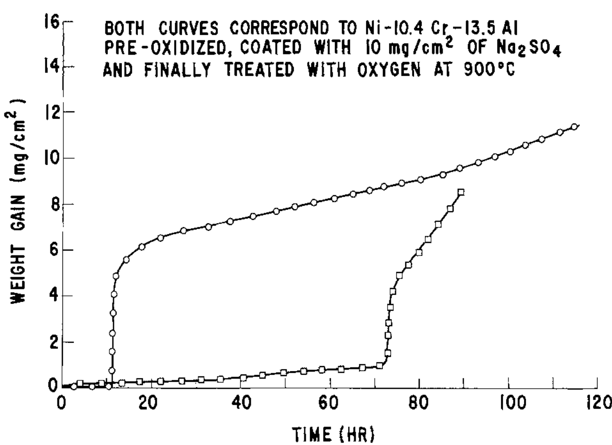

Fig. 19. Weight gain curves for two specimens of a Ni-10.4 Cr-13.5 Al alloy preoxidized, coated with 10 mg/cm^2 of Na_2SO_4, and treated with oxygen at 900°C. An incubation period of varying length has preceded in both cases accelerated attack.

specimens may be responsible for the variation in the length of the incubation period prior to accelerated attack.

Figure 20 shows a Nomarski interference light micrograph of one of the specimens at the end of the run. The external scale was identified by x-ray diffraction as consisting of NiO and $NiAl_2O_4$. As mentioned in the next section, internal precipitates of chromium sulfide can be noticed in the alloy surface layer, preferentially localized at the darker areas.

Cyclic conditions.—The effect of alternating oxidizing and reducing conditions was tested on the Ni-10.4 Cr-13.5 Al alloy by exposing to the sequence O_2-H_2-O_2 at 800°C a specimen preoxidized and coated with 5 mg/cm^2 of sodium sulfate. Figure 21 shows the corresponding changes in the weight gain curve. The weight loss due to the reduction of sodium sulfate by hydrogen is followed by an oxidation stage accelerated with respect to the initial one. The same experiment was repeated at 900°C and a similar weight gain curve was obtained. Figure 22 shows a cross section of the latter specimen. Again it can be noticed how the attack propagates preferentially at the darker γ' areas in the alloy, as mentioned in the previous section. Most probably, even at 800°C, a molten Na_2SO_4-Na_2S film dissolved protective Al_2O_3 layers favoring sulfur penetration particularly at sites of higher grain boundary density. Subsequent oxidation resulted in the growth at a higher rate of a porous NiO scale. The microprobe trace in Fig. 23 shows that the external scale consists essentially of Ni and Cr oxides in its inner portion, while Al_2O_3, which presumably formed at the very beginning of the run, also can be detected in its outer

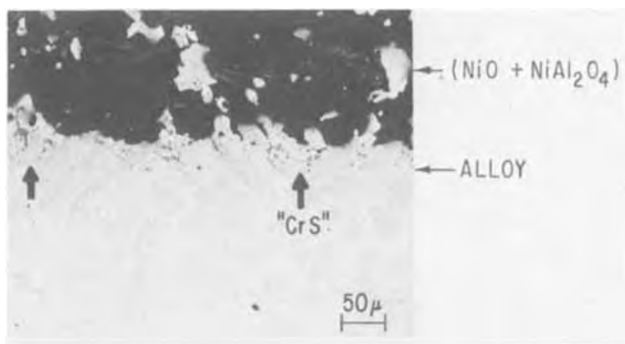

Fig. 20. Ni-10.4 Cr-13.5 Al alloy preoxidized, coated with 10 mg/cm^2 of Na_2SO_4, and treated with oxygen at 900°C for about 4 days. A thick and porous scale consisting of NiO and $NiAl_2O_4$ has grown externally. The arrows indicate internal precipitates of chromium sulfide, localized preferentially at the darker phase within the alloy.

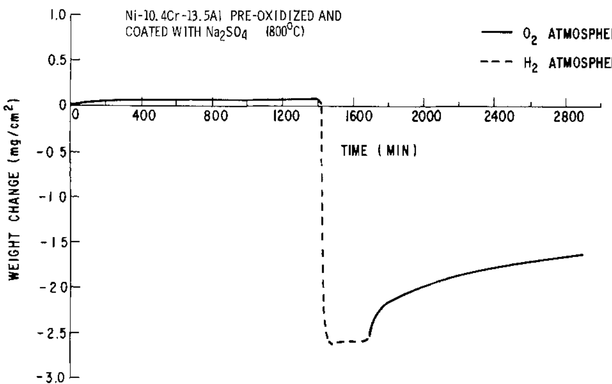

Fig. 21. Weight gain curve for a Ni-10.4 Cr-13.5 Al alloy preoxidized, coated with 5 mg/cm² of Na_2SO_4, and exposed alternatively to oxidizing and reducing atmospheres at 900°C.

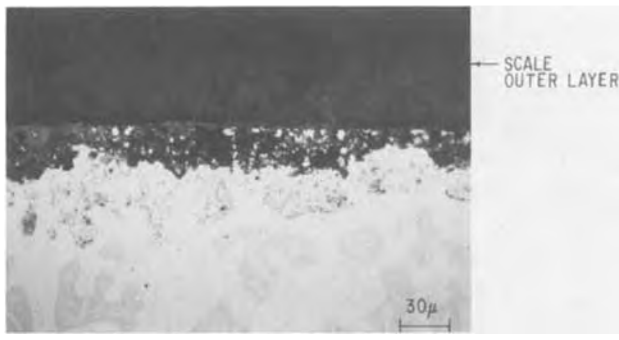

Fig. 22. Ni-10.4 Cr-13.5 Al alloy preoxidized, coated with 5 mg/cm² of Na_2SO_4, and treated at 900°C with the gas sequence O_2-H_2-O_2 for a total of 48 hr. Preferential attack can be noticed at the darker areas in the alloy.

portion. It may be noted that attack localized at the darker areas in the alloy was also observed when a specimen of Ni-10.4 Cr-13.5 Al coated with 16 mg/cm² of sodium sulfate was treated at ~870°C with a 10% CH_4-bal. N_2 mixture (Fig. 24). In this case, however, methane instead of hydrogen acted as a reducing agent for sodium sulfate.

A comparison between the weight gain curve in Fig. 8 and Fig. 21 suggests that acceleration of the corrosion rate due to transient reducing conditions is more likely to occur when a multiphase system rather than a homogeneous γ matrix-type alloy is exposed to hot corrosion environments. A high density of preferential paths for the inward diffusion of sulfur appears to favor the formation of internal precipitates and consequent weakening of the alloy surface layer.

Discussion

In order to compare the behavior of the alloy phases that have been the object of this study, the discussion is divided into two sections pertaining, respectively, to the effect of reducing and oxidizing environments.

Reducing environments.—Reducing conditions, no matter whether the reducing agent is hydrogen, carbon, or partially uncombusted hydrocarbons (6), primarily result in increased sulfur potential at the metal-salt melt interface. Seen from a different standpoint, an increase in sulfur potential can occur when the composition of the salt melt is modified by the addition of elements such as molybdenum, tungsten, or vanadium (3). However, the magnitude of the effect can be different. While in the latter case fluxing of protective oxides is deemed responsible for catastrophic attack, the presence of reducing agents can both reduce oxide scales (22, 23) and by raising significantly the sulfur potential provide additional driving force for the diffusion of sulfur into the metal. If the activity of nickel in the alloy is sufficient to form continuously nickel sulfide, this will be in the molten state,[4] thus further enhancing diffusion processes and fluxing of solid oxides such as NiO and Cr_2O_3.

In the course of this study the γ matrix phase showed a tendency to form liquid nickel sulfide whenever exposed to H_2S-H_2 atmospheres, regardless of the presence of a sodium sulfate deposit on the surface of the specimens. Furthermore, the existence of a pregrown layer of Cr_2O_3 did not prevent the formation

[4] The temperature of the eutectic nickel-nickel sulfide is 645°C.

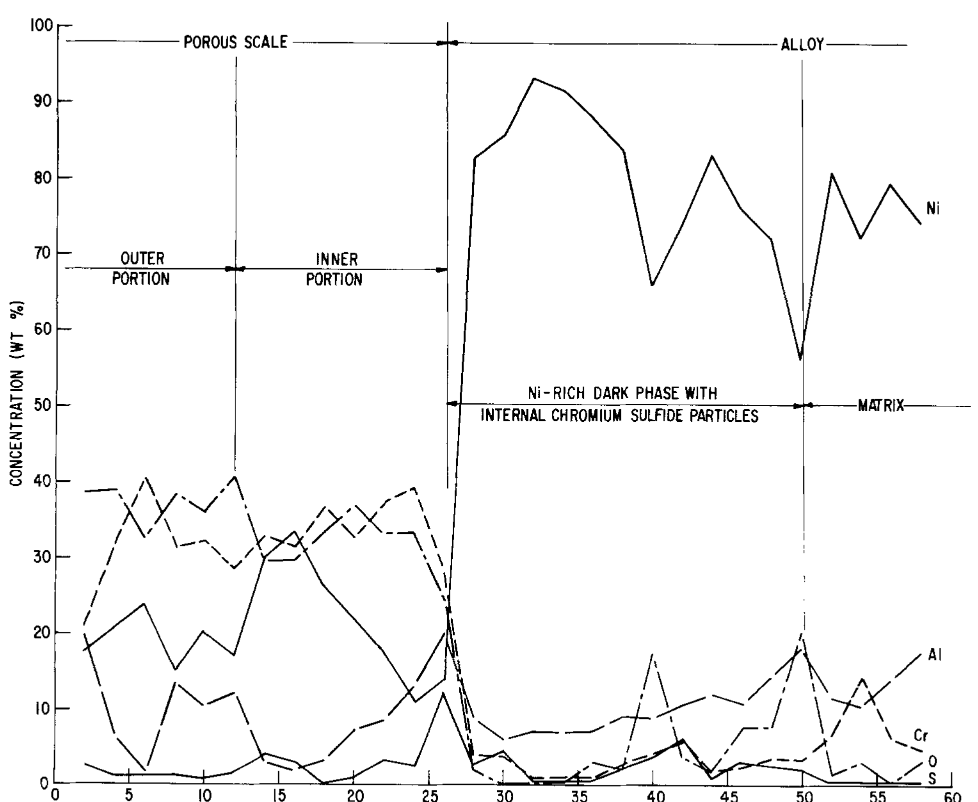

Fig. 23. Distribution profile of elements for a Ni-10.4 Cr-13.5 Al alloy preoxidized, coated with sodium sulfate, and exposed alternatively to oxidizing and reducing atmospheres.

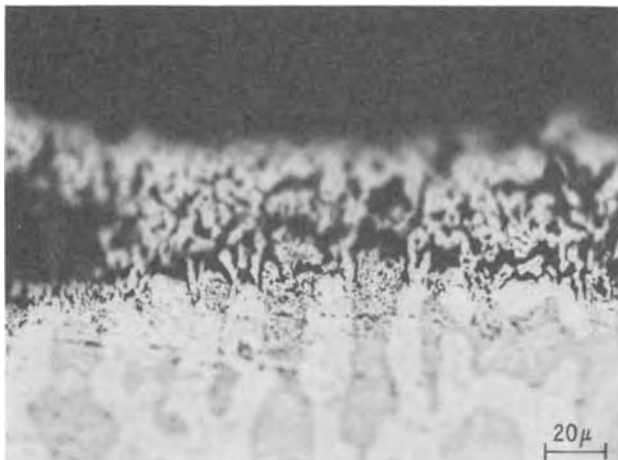

Fig. 24. Ni-10.4 Cr-13.5 Al alloy coated with 16 mg/cm² of Na_2SO_4 and treated with a 10% CH_4-N_2 gas mixture at 870°C for 3 hr. Localized attack can be noticed at the darker areas in the alloy.

of liquid nickel sulfide, but only increased the amount of time necessary for sulfur to diffuse through the chromium oxide barrier and reach the metal (24). Thus it appears that in a situation leading to local high sulfur potential the formation of liquid nickel sulfide is responsible for the catastrophic failure of the γ matrix phase.

The results obtained in analogous conditions with specimens of nominal γ' composition exposed to H_2S-H_2 atmospheres show again the same tendency to form liquid nickel sulfide as the γ matrix, although to a lesser extent, as can be seen by comparing Fig. 3 and 10. Apparently, alloying the nickel with aluminum instead of chromium reduces the formation of liquid nickel sulfide. Since the activity of nickel in the γ matrix and the γ' phase are comparable (25, 26), we have not been able to find an explanation for this effect in thermodynamic terms.

It should be stressed that the extent of the corrosive attack for both γ matrix and γ' phases considered separately, bears a direct relationship to the magnitude of the sulfur potential continuously present at the metal-salt melt interface. The cyclic oxidation-reduction treatment of the γ matrix, in which the only sulfur available was that present in the limited sodium sulfate coating, did not lead to a significant acceleration of the reaction during the reduction and the subsequent oxidation stages. Of course, the presence of hydrogen sulfide in the gas phase in equilibrium with the salt melt would have resulted in a higher rate of attack during the reduction stage, by replenishing in the melt any sulfur consumed by the alloy.

When the γ matrix and the γ' phase are coexisting, as in the case of the Ni-10.4 Cr-13.5 Al alloy, the composition of the two phases can be different from the nominal composition, because to a limited extent aluminum can dissolve in the γ matrix and chromium in the γ' phase. Localized attack at γ' areas, characterized by the formation of internal chromium sulfide particles especially at higher sulfur potentials (Fig. 18, 22, and 24) can be due to segregation of chromium within the γ' areas, which by originating a higher grain boundary density would favor the inward diffusion of sulfur by a short-circuit mechanism. However, a detailed explanation of an alloy structure effect on hot corrosion would require systematic experiments, in particular on the $\gamma + \gamma'$ system at different γ/γ' volume ratios.

Oxidizing environments.—At very low sulfur potential, such as that present in stoichiometric sodium sulfate exposed to oxygen, the hot corrosion behavior of the γ matrix and the γ' phases is remarkably different. While the former appears to be extremely corrosion resistant, the latter undergoes rapid attack in the initial stage of the reaction, followed by a progressive slowdown in corrosion rate. This behavior can be ascribed to a varying capability of the sodium sulfate melt to dissolve different oxides. From a thermodynamic standpoint, the composition of the gaseous atmosphere can influence the equilibria

$$Na_2SO_{4(l)} + \tfrac{1}{2}Cr_2O_{3(s)} + \tfrac{1}{4}O_{2(g)} \rightleftharpoons Na_2CrO_{4(l)} + SO_{2(g)} \quad [1]$$

$$Na_2SO_{4(l)} + Al_2O_{3(s)} \rightleftharpoons 2NaAlO_{2(l)} + SO_{2(g)} + \tfrac{1}{2}O_{2(g)} \quad [2]$$

since the corresponding equilibrium constants at a given temperature would be

$$K_{(1)} = P_{SO_2}/P_{O_2}^{1/4} \text{ and } K_{(2)} = P_{SO_2} \times P_{O_2}^{1/2}$$

making the simplifying assumption that all condensed phases are at unit activity. Moreover, the rate of dissolution in the sodium sulfate melt may be different for Cr_2O_3 and Al_2O_3. In the case of the Ni-20 Cr alloy (γ matrix) formation of some sodium chromate took place during exposure to oxygen, as indicated by the presence of yellow deposits on the specimen at the end of the run. In this case reaction [1] was displaced toward the right by the absence of SO_2 in the gas phase. However, the rate of formation of new Cr_2O_3 was higher than its rate of dissolution in the molten salt, as shown by the presence of a continuous inner layer of Cr_2O_3 in the scale at the end of the run. In this case the outer layer of NiO may have also provided additional protection to the alloy. A similar composition for the oxide scale on Ni-Cr alloys has been reported by Giggins and Pettit (27).

In the case of the Ni-13 Al alloy (γ' phase) the porous oxide scale after oxidation in the presence of sodium sulfate deposits was identified as consisting mainly of NiO with traces of α-Al_2O_3. Pettit has reported that the oxidation product of a Ni-17 Al alloy at 1100°C in 0.1 atm oxygen consisted of a discontinuous layer of α-Al_2O_3 at the base of the scale, which consisted of NiO, $NiAl_2O_4$, and α-Al_2O_3 (28). Dissolution of the discontinuous Al_2O_3 layer in the melt would progressively deplete the alloy surface layer of aluminum, favoring the growth of a porous scale of NiO, which would eventually separate the salt film from the metal. In addition, saturation of the salt with corrosion products would decrease its effectiveness as a flux, thus slowing down the corrosion rate. It is conceivable that the initial phase of rapid attack would persist for a longer time, were a larger amount of sodium sulfate available for the dissolution of the oxide scale. The results of crucible tests shown in Fig. 7, in which Ni-Al coupons were immersed in excess molten sodium sulfate exposed to air, show that the γ' phase can indeed undergo total dissolution in the salt melt. By contrast the resistance of Ni-Cr alloys to this type of attack generally increases with increasing Cr content.

In the case of the Ni-10.4 Cr-13.5 Al alloy, in which the prevailing phases are γ matrix and γ', the oxide scale formed at 900°C prior to exposure to sodium sulfate and oxygen was identified as a mixture of spinels $NiAl_2O_4$ and $NiCr_2O_4$. According to Giggins and Pettit (13) this ternary system at 1000°C should consist of only an external layer of Al_2O_3. Again, the rate of dissolution of the oxide scale in the salt melt can be the factor retarding accelerated attack of the alloy. In this case however, after fluxing of the oxide, the alloy microstructure may have favored inward diffusion of sulfur, thus making the alloy more susceptible to attack than the binary Ni-20 Cr alloy. This point of view is confirmed by the results of the experiments in which specimens were subjected alternatively to oxidizing and reducing conditions. In the case of the Ni-20 Cr alloy during the reduction stage the structure of the scale was not damaged extensively and could offer

protection against the increase in sulfur potential. The weight gain during the subsequent oxidation stage was then similar to the initial one. In the case of the Ni-10.4 Cr-13.5 Al alloy, the oxide scale was damaged by progressive dissolution in the salt melt during the initial oxidation stage. During the subsequent reduction stage diffusion of sulfur into the alloy was favored by the increase in sulfur potential. Sulfur diffusion may have also been enhanced by the microstructure of the alloy, if a higher density of grain boundaries was available at areas of γ' composition.

Conclusions

1. The hot corrosion resistance of an alloy is dependent on its chemistry and multiphase morphology, and the nature of the corrosive environment, in a very complex way, so that a generalized model for hot corrosion behavior is not yet possible.

2. The γ matrix phase is prone to catastrophic failure in severe hot corrosion environments characterized by high sulfur potentials. However, at low sulfur potentials such as those prevailing in a gas turbine environment, the γ matrix offers excellent corrosion resistance.

3. The γ' phase is susceptible to accelerated salt-induced hot corrosion under both reducing and oxidizing conditions. However, the comparison of weight gain data also shows that the γ' phase is much less resistant than the γ matrix to hot corrosion, under oxidizing conditions, and can be considered a weak link in the over-all corrosion process of a commercial Ni-base alloy.

4. Studies of (*i*) the rate of dissolution of Cr_2O_3 Al_2O_3, and spinel-type oxides in sodium sulfate melts, and (*ii*) alloy microstructure effects on the rate of sulfidation would significantly contribute to a better understanding of hot corrosion phenomena.

Electrochemical Reduction of Cr(III) in Molten LiCl-KCl Eutectic

Samuel C. Levy* and Frederick W. Reinhardt

Sandia Laboratories, Albuquerque, New Mexcio 87115

ABSTRACT

The reduction of chromium(III) was studied in LiCl-KCl eutectic at 500°C by means of cyclic voltammetry. It has been shown to proceed via a two-step process to the metal. The intermediate Cr(II) species reacts with the solvent anions to form an insoluble compound, $CrCl_2$. The pseudo first-order rate constant for the chemical step is 0.028 ± 0.008 sec^{-1}, while the heterogeneous rate constant for the charge transfer is 3.4 ± 0.5 × 10^{-2} cm sec^{-1}. The diffusion coefficient of Cr^{+3} was determined to be 0.5 ± 0.1 × 10^{-5} cm^2/sec at 500°C. No adsorption of any species present in solution was found to occur on the vitreous carbon working electrode.

The lithium chloride-potassium chloride eutectic is one of the most commonly used electrolytes for thermal batteries (1). Thermal batteries developed at Sandia Laboratories principally use this electrolyte and a cathode (depolarizer) of calcium chromate (2). Although there has been much speculation as to the cathode mechanism, very little is known about this complex reduction. In order to gain an insight into the reactions occurring during the discharge of thermal batteries, we have begun a study of the electrochemical behavior of chromium in molten salts. This paper describes the results obtained with the compound $CrCl_3$ in LiCl-KCl at 500°C.

Experimental

The technique of cyclic voltammetry was used for this investigation. Voltammetric scans were made with a Tacussel Model PIT 20-2X potentiostat coupled to a Tacussel Model GSTP-2 function generator. The current voltage curves were recorded on a Moseley Model 7000 AM X-Y recorder.

The cell was fabricated from a 70-mm ID quartz 102/75 ball joint sealed on one end. The lid was made from the other half of the ball joint and had openings to accommodate three electrodes, a thermocouple, a gas bubbling tube, a gas inlet, and a tube for adding samples to the melt, which also served as the gas outlet.

A three-electrode circuit was used. The counterelectrode was a rod of Union Carbide spectroscopic grade graphite with one end immersed in the melt. The Ag/AgCl couple was chosen for the reference electrode because of its stability at elevated temperatures (3, 4). The reference electrode was prepared by placing 0.1*M* AgCl in LiCl-KCl solution in a Pyrex tube sealed at one end. A silver wire was then inserted through a hole in a cork placed into the other end. Use of Pyrex, which becomes conductive at elevated temperatures, as a container and electrolyte junction prevents contamination of the solution and results in an electrode that can be used many times.

Problems were encountered in fabricating the vitreous (glassy) carbon working electrode. All attempts to seal the rods in borosilicate glass resulted in a thin void between the glass and vitreous carbon. Use of these electrodes for cyclic voltammetric scans resulted in baselines having an appreciable slope, making it virtually impossible to analyze the waves. Finally, Beckwith Carbon Corporation, when contacted, suggested that a thin film of silicon deposited on the vitreous carbon would produce a welded bond with borosilicate glass.

Electrodes were fabricated from ⅛ in. diam rods which were centerless ground to a 0.120 in. diam circular cross section (area = 0.0729 cm^2). One inch lengths were coated with a thin film (0.0005-0.005 in.) of silicon by decomposing silane on the carbon rod which was resistance heated (Fig. 1). A half-inch length of borosilicate glass (GSC-4) was then sealed to the coated rod by heating to the softening point. The end of the vitreous carbon rod protruding from the glass seal was force-fitted into a hole drilled into the end of a graphite rod. A Pyrex tube was then slipped over the graphite rod and sealed to the GSC-4 glass (5). A portion of the graphite rod was left extending as electrical contact. The vitreous carbon was ground flush with the glass and polished to a mirror finish (Fig. 2).

The electrolyte was prepared from Fisher certified reagent lithium chloride and potassium chloride. It was further purified by using a technique developed in this laboratory which is a combination of several techniques reported in the literature (6-8). Initially, the eutectic was heated under a hydrogen chloride atmosphere to 400°C. Hydrogen chloride was then bubbled through the melt for 24 hr. The temperature was then raised to 600°C and chlorine gas bubbled through the melt for 48 hr. Next, the temperature was lowered to 400°C and argon bubbled through the melt for 16 hr.

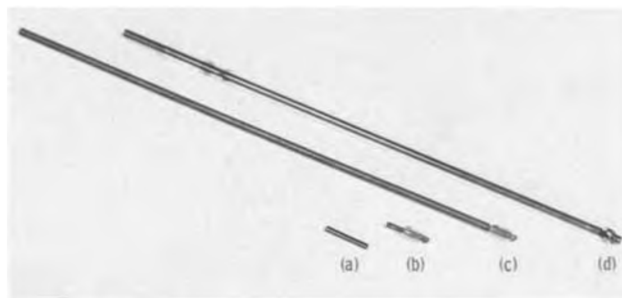

Fig. 2. Fabrication of vitreous carbon working electrode. (a) Vitreous carbon rod, (b) GSC-4 glass sealed to silicon-coated rod, (c) vitreous carbon inserted into hole in end of graphite rod, (d) completed electrode.

Finally, the electrolyte was cooled under an argon atmosphere and transferred to an argon-filled glove box.

Diamond Alkali Company anhydrous chromic chloride $CrCl_3$ was used without further purification.

The cell was assembled in an argon-filled glove box and then placed in a Hoskins furnace, Model FD104. Argon was continuously passed through the cell, and its temperature was maintained at 500°C with a Honeywell Versatronik SCR Trigger Temperature Controller, Model R7161J.

Results

Two reversible waves were obtained when scanning the LiCl-KCl-$CrCl_3$ system. They occurred at approximately +0.2 and −0.9V *vs.* the Ag/0.1*M* AgCl reference electrode (Fig. 3 and 4). These potentials correspond to the reduction of Cr(III) to Cr(II) and of Cr(II) to Cr(0) (9). Each wave was studied individually at three concentrations of $CrCl_3$ (19.55, 32.29, and 40.55 mM) over a range of scan rates from approximately 0.008 to 0.8 V/sec.

+0.2V peak.—For a reduction in which both the reactant and product are soluble, several relationships have been derived between the peak potential E_p (potential at maximum current), the half-peak potential $E_{p/2}$ (potential at one-half maximum current), the half-wave potential $E_{1/2}$ (occurs at a point 85.17% up wave), and n (the number of electrons involved in the

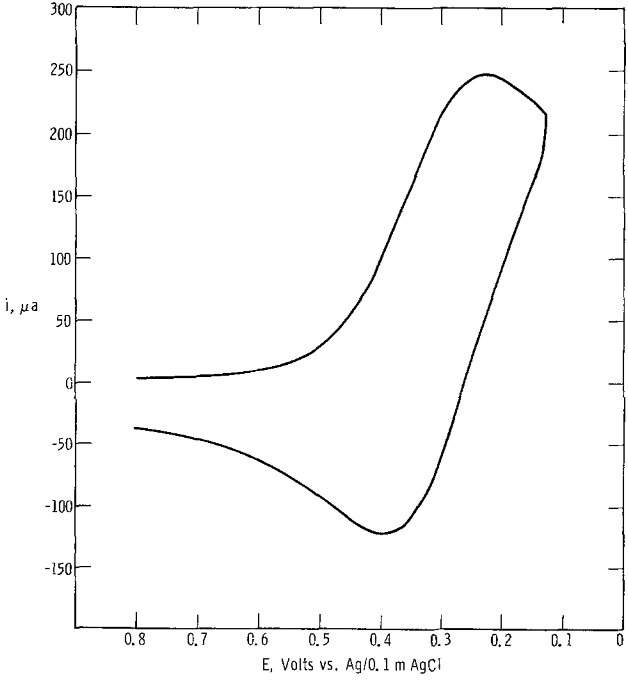

Fig. 3. Voltammogram for the reduction of Cr(III) to Cr(II). 19.55 mM $CrCl_3$, 0.1678 V/sec, 500°C.

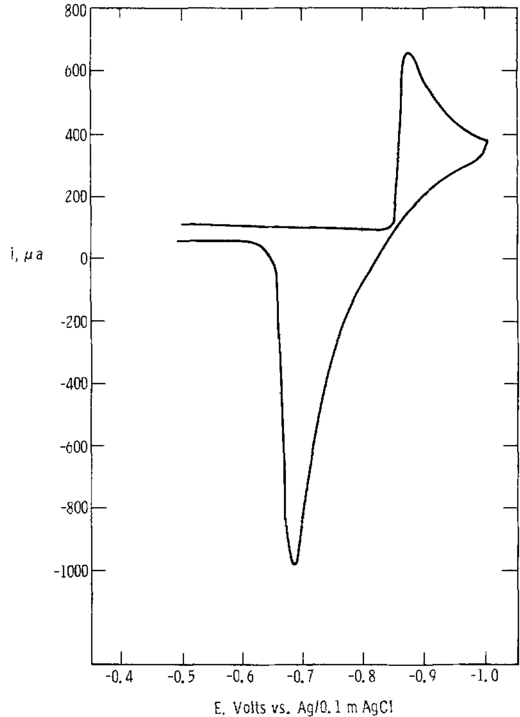

Fig. 4. Voltammogram for the reduction of Cr(II) to Cr(0). 19.55 mM $CrCl_3$, 0.0708 V/sec, 500°C.

charge transfer reaction) (10). They include the following

$$E_p = E_{1/2} - 1.109\, RT/n\mathbf{F} \quad [1]$$

$$E_{p/2} = E_{1/2} + 1.09\, RT/n\mathbf{F} \quad [2]$$

The value of n for this peak was calculated by both of the expressions at each sweep speed and concentration studied, using the values of E_p, $E_{p/2}$, and $E_{1/2}$ obtained from the individual current-voltage curves. The results are summarized in Table I.

We therefore conclude that one electron is transferred during this peak and that it represents the reduction of Cr(III) to Cr(II).

Plots of peak current i_p *vs.* the square root of the voltage scan rate were linear at each concentration, indicating diffusion control for this process (11). A typical plot is shown in Fig. 5.

The diffusion coefficient of Cr^{+3} in LiCl-KCl at 500°C was calculated by use of the expression (12)

$$x = 1.67 \times 10^5 n^{3/2} A D^{1/2} C \quad [3]$$

In Eq. [3], n is the number of electrons transferred, A is the area of the electrode, D is the diffusion coefficient, C is the concentration, and x is the intercept at $v^{1/2} = 0$ of a plot of $i_p/v^{1/2}$ *vs.* $v^{1/2}$, i_p being the peak current and v the sweep speed in volts per second. Plots of $i_p/v^{1/2}$ *vs.* $v^{1/2}$ were made for each concentration studied and the intercepts determined by the method of least squares. Results are given in Table II.

To determine if the Cr^{+3} or Cr^{+2} species were adsorbed on the vitreous carbon electrode, plots of $i_p/v^{1/2}$ *vs.* v were constructed at each concentration. Since these graphs did not show a rapid increase with increasing scan rate, it was concluded that neither species was adsorbed (13).

The diagnostic criteria of Nicholson and Shain (10) were used to determine the mechanism of the reaction $Cr^{+3} + e^- \rightleftharpoons Cr^{+2}$. First, the ratio of anodic to cathodic peak height i_a/i_c was calculated for each scan, using the empirical expression developed by Nicholson (14)

$$\frac{i_a}{i_c} = \frac{(i_a)_o}{(i_c)_o} + \frac{0.485\ (i_{sp})_o}{(i_c)_o} + 0.086 \quad [4]$$

where $(i_a)_o$ and $(i_c)_o$ are the anodic and cathodic peak currents measured with respect to the zero current axis, and $(i_{sp})_o$ is the cathodic current at the switching potential (*i.e.*, the potential at which the voltage scan is reversed) measured with respect to the zero current axis. The values of i_a/i_c were plotted *vs.* sweep speed (Fig. 6). An increase in this ratio with increasing sweep speed, leveling off at a value of 1.0, indicates the reversible charge transfer is followed by an irreversible chemical reaction. This behavior is caused by a difference in rates for the two reactions, the charge

transfer being faster. At the slower sweep speeds, the reduced species, Cr^{+2} has time to react chemically before the scan is reversed and it can be reoxidized to Cr^{+3}. At faster speeds, all of the material is reoxidized before enough time has elapsed to allow the chemical reaction to proceed.

One possible irreversible chemical reaction which could occur in this system is the precipitation of $CrCl_2$. To investigate this possibility, a saturated solution of $CrCl_2$ in LiCl-KCl was prepared at 500°C by adding excess solid to the melt and stirring for several hours by bubbling argon through the solution. It was then filtered through a fine glass frit at 500°C and the filtrate analyzed by atomic adsorption spectroscopy. A solubility of only 40 ppm (0.004%) was found. This indicates that the precipitation of $CrCl_2$ is very likely the irreversible chemical reaction that follows the reversible charge transfer.

A rate constant for the precipitation of $CrCl_2$ was calculated. Pseudo first-order kinetics were assumed since the Cr^{+2} is reacting with solvent anions. The rate constant k was determined for each scan from theoretical data giving the ratio of peak currents i_a/i_c as a function of $k\tau$, as calculated by Nicholson and Shain (10), where τ is defined as the time in seconds to go from the half-wave potential $E_{1/2}$ to the switching potential. Results are listed in Table III.

For waves having an anodic-to-cathodic peak current ratio of one, it is possible to calculate the hetero-

geneous rate constant k_h for the charge transfer reaction, if the peak potential separation varies with the sweep speed. For the reaction $Cr^{+3} + e^- \rightleftharpoons Cr^{+2}$, a ratio of one was obtained for sweep speeds >0.1 V/sec (Fig. 6) and k_h was determined at these sweep speeds by the technique of Nicolson (15), using the following expression

$$\Psi = \gamma^{\alpha} k_h / \sqrt{\pi a D} \quad [5]$$

where α is the charge transfer coefficient, γ is the ratio of diffusion coefficients for the oxidized and reduced species [except for the unusual case of very large differences between D_o and D_R the quantity γ^{α} is very near unity, regardless of α (15)], $a = n\mathbf{F}v/RT$, D is the diffusion coefficient of the oxidized species, and Ψ is dependent on the separation of the anodic and cathodic peak potentials for waves in which there is no competing chemical reactions (ratio of anodic to cathodic peak heights = 1). Data are given for the determination of Ψ from ΔE_p at 25°C.

Using the value of Ψ obtained from Nicholson's data corrected for temperature, and assuming $\gamma^{\alpha} = 1$, the heterogeneous rate constant was determined from each wave having $i_a/i_c = 1$. Results are given in Table IV. Use of this technique for the Cr^{+3}-Cr^{+2} system is discussed in a later section.

−0.9V peak.—For a reaction resulting in the deposition of a metal, several relationships between the number of electrons involved and voltage, current, and concentration have been derived (16, 17). These relationships, listed below, have been used to calculate the number of electrons transferred during the reaction represented by this peak

$$E_p - E_{p/2} = -0.7725\, RT/n\mathbf{F} \quad [6]$$

$$E_{p/2} = E^{\circ} + RT/n\mathbf{F} \ln fC - \frac{0.0815\, RT}{n\mathbf{F}} \quad [7]$$

$$\log(i_p - i) = \frac{2.2\, n\mathbf{F}}{RT} E + \text{Constant} \quad [8]$$

Table V. Average value of n* for −0.9V peak

Concentration (mM)	Eq. [6]	Eq. [8]
19.55	2.37	2.30
32.29	2.15	2.35
40.55	2.17	2.11

Volts/sec	Eq. [7]
0.007	2.02
0.036	1.91
0.071	2.25

* n average $= 2.18 \pm 0.15$.

where f is the activity coefficient and all the other symbols have their standard meanings. To use Eq. [7], a plot of $E_{p/2}$ *vs.* log concentration is required for each sweep speed. A straight line is obtained with a slope of $2.303\, RT/n\mathbf{F}$. Equation [8] assumes a constant activity of unity for the deposited metal, and was shown by Mamantov *et al.* (17) to be linear over the range of $0.7\, i_p < i < 0.9\, i_p$. This occurs because there is no metal present at the start of the wave. The activity is much smaller than unity and increases until the electrode is completely coated with the metal, resulting in the nonlinearity during the early portion of the wave (18). Values of n were calculated by each of the above methods. Slopes for Eq. [7] and [8] were calculated by the method of least squares. Results are given in Table V.

Thus, we conclude that $n = 2$, and this peak represents the reaction $Cr^{+2} + 2e^- \rightleftharpoons Cr^{o}$.

Plots of $i_p/v^{1/2}$ *vs.* v indicated that none of the species involved in this reaction are adsorbed on the vitreous carbon working electrode.

The mechanism of this reduction was studied by applying the diagnostic criteria of Nicolson and Shain (10). A plot of peak current divided by the square root of the voltage scan rate *vs.* voltage scan rate was relatively unchanged over the range of scan rates studied (Fig. 7), indicating a simple charge transfer with no coupled chemical reactions.

Discussion

Although the reaction $Cr^{+3} + e^- \rightleftharpoons Cr^{+2}$ appears to be completely reversible, as evidenced by the current-voltage curves obeying Eq. [1] and [2], it has in fact been shown to exhibit kinetic behavior. This can be

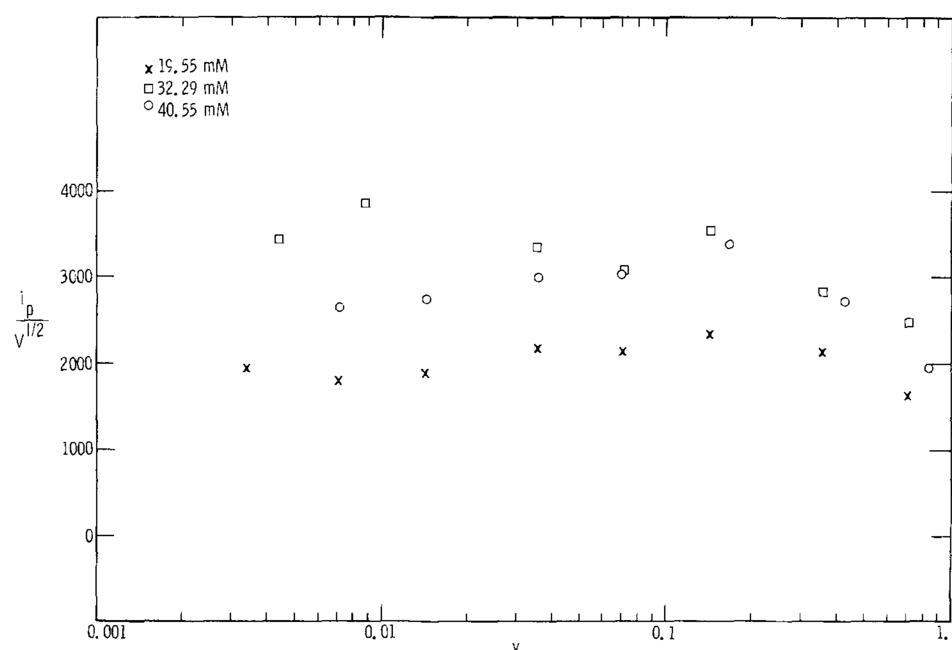

Fig. 7. Ratio of cathodic peak current to square root of sweep speed vs. sweep speed, Cr(II) to Cr(0) wave.

seen by the variation in peak potential separation with sweep speed. The heterogeneous rate constant calculated for this charge transfer reaction is fast enough that the deviation from reversibility is small. Thus, Eq. [1] and [2] are a close approximation for this system.

Conclusion

Chromium(III) is reduced to Cr(0) in LiCl-KCl eutectic at 500°C via a two-step process which is represented by the following scheme

$$Cr^{+3} + e^- \overset{\text{fast}}{\rightleftharpoons} Cr^{+2} \quad [I]$$

$$Cr^{+2} + 2Cl^- \overset{\text{slow}}{\rightarrow} CrCl_2 \quad [II\text{-}A]$$

$$Cr^{+2} + 2e^- \overset{\text{fast}}{\rightleftharpoons} Cr^o \quad [II\text{-}B]$$

If the potential is varied slowly enough, an appreciable portion of the Cr^{+2} will react with chloride ion via reaction [II-A]. Rapid changing of the potential, or maintaining the potential at a value negative to that required for reaction [II-B] will result in virtually all the Cr^{+3} being reduced to the metal, since this reaction is kinetically faster than the chemical one.

High Temperature Loss of Silica from Zircon and Refractory Silicates

R. A. Gardner[1]

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

and R. C. Buchanan

IBM System Products Division, Kingston, New York 12401

ABSTRACT

Refractory silicates such as zircon, mullite, forsterite, etc. and silica are known to lose SiO_2 at high temperature and some, such as zircon, may undergo partial decomposition. This study examines some of the thermodynamic and kinetic factors which govern silicate stabilities. Sintering studies and weight loss determinations were used to determine the effects of temperature and ambient on the loss of SiO_2 from zircon. Results indicate the loss of SiO_2 as volatile SiO from zircon by a surface rate controlling mechanism. The major factors influencing this loss were found to be the oxygen partial pressure, temperature, and to some extent the particle size or surface area of the sample. Activation energies determined for the reaction of hydrogen with zircon were 82 kcal/mole for reaction with 99.999+% H_2 containing 2 ppm H_2O and 121 kcal/mole for reaction with H_2 with a dew point of 24°C.

The importance of the loss of silica from solid silica and refractory silicates is evidenced by the number of investigations on this subject.[2] Silica can be lost from the surface of silica-containing materials by a number of mechanisms including direct volatilization of SiO_2 or reduction to form volatile silicon monoxide, SiO. The loss by direct volatilization involves, at least partially, the dissociation of silica according to a reaction such as

$$SiO_2\text{ (solid)} = SiO\text{ (gas)} + x\,O\text{ (gas)} + \tfrac{1}{2}(1-x)\,O_2\text{ (gas)}$$

where x is the degree of dissociation of oxygen. Porter, Chupka, and Inghram (2) reported that the partial pressure of SiO over silica at 1900°K, for example, was 3.4×10^{-5} atm while the pressure of SiO_2 was only 1.0×10^{-7} atm. Under reducing conditions, the formation of SiO is even more dominant. A variety of reducing agents are capable of promoting the formation of SiO from silica or silicate materials. The most important of these are hydrogen, carbon, carbon monoxide, and silicon.

This study examines some of the thermodynamic and kinetic factors which govern silicate stabilities and loss of silica, particularly in reducing ambients. The kinetics and thermodynamics are discussed with emphasis on silica and zircon, $ZrO_2 \cdot SiO_2$.

Zircon Stability

The results of a number of investigations of the thermal stability of zircon are inconsistent in many cases. In a study of the phase relations in the ZrO_2-SiO_2 system, Zhirnova (3) determined the melting point of zircon to be 2430°C. The melting temperature, however, did not correspond to equilibrium conditions and had to be reached at a very high heating rate so that the decomposition at lower temperatures was not appreciable. Zhirnova did observe considerable decomposition at 1800°C. Zircon, however, does not have a true melting point; the compound melts by dissociation to its constituent oxides, zirconia and silica.

Striking differences exist in the literature as to the temperature of the onset of the dissociation. Dissociation temperatures as low as 1450°C and as high as 2000°C have been reported by Barlett (4) and by Matignon (5), respectively. Phase studies by Geller and Yavorsky (6) and by Geller and Lang (7) indicated dissociation at the incongruent melting temperature of 1775°C. The impurity content of the zircon samples can affect the dissociation temperature, as reported by Stott and Hilliard (8) who found that samples of 91.2% and 99.5% purity had dissociation temperatures of 1650°C and 1750°C, respectively. The addition of magnesia, MgO, to zircon can cause complete dissociation at 1240°C (9) with the formation of magnesium silicate and zirconium oxide.

The most detailed study of the thermal dissociation of zircon is that by Curtis and Sowman (10). In this study, the authors determined by x-ray diffraction the amount of dissociation present in zircon samples that had been heated for 2 hr at temperatures from 1540° to 1980°C in air and then quenched. The same procedure was followed for samples heated for 8 to 10 hr at temperatures of 1540°, 1650°, and 1760°C. They concluded that zircon begins to dissociate at approximately 1540°C, that the rate of dissociation increases rapidly as the temperature is increased to 1760°C, and that dissociation is complete after 6 hr at 1760°C.

Curtis and Sowman also concluded that the ZrO_2 and SiO_2 formed when zircon is dissociated at high temperatures, will recombine to again form zircon if some provision is made to prevent the loss of SiO_2 and if sufficient time is allowed during cooling. The maximum rate of reassociation occurred in the temperature range 1425°-1540°C. A similar result was obtained by Barlett (4) who found that zircon which had been completely dissociated reacted to form zircon again when heated for 3½ hr at 1450°C.

Chemical Reactivity of Silicates and Zircon

Most of the studies of the stability of zircon have been carried out in the presence of oxidizing atmospheres, under which condition zircon will decompose at temperatures above 1540°C according to the following reaction

$$ZrSiO_4 \underset{}{\overset{1540°C}{\rightleftharpoons}} xZrO_2 + xSiO_2 + (1-x)ZrSiO_4 \quad [1]$$

A thermodynamic study of the formation of zircon from the oxides has been carried out by Matwejew and Agarkow (11). Extrapolation of their experimental data indicates that $\Delta G° = 0$ at 1800°K (~1530°C), which is in good agreement with the ob-

[1] Present address: IBM General Products Division, San Jose, California 95193.

Key words: zircon, kinetics, silica, silicate, reduction.

[2] See, for example, the review by Toropov and Barzakovskii in Ref. (1).

servations of Curtis and Sowman. One can also estimate the dissociation temperature using the Gibbs-Helmholtz equation.

Using values of the enthalpies and entropies from thermodynamic tables (12, 13), the equation becomes

$$\Delta G^\circ = 15{,}360 - 8.48T \ (1750^\circ\text{-}1850^\circ\text{K})$$

so that

$$T = 1811^\circ\text{K when } \Delta G^\circ = 0$$

Silica can be lost from the surface of pure silica, zircon or any refractory silicate by one or a combination of the following reactions:

1. Vaporization

$$SiO_2(s,l) = SiO_2(g)$$

2. Silicon reduction

$$\tfrac{1}{2}\, SiO_2(s) + \tfrac{1}{2}\, Si(s) = SiO(g)$$

3. Carbon or carbon monoxide reduction

$$SiO_2(s) + C(s) = SiO(g) + CO(g)$$
$$SiO_2(s) + CO(g) = SiO(g) + CO_2(g)$$

4. Hydrogen reduction

$$SiO_2(s) + H_2(g) = SiO(g) + H_2O(g)$$

For the vaporization reaction the equilibrium vapor pressure is given by

$$\log P_{SiO_2} = -\Delta G^\circ/RT$$

where

$$\Delta G^\circ = 127{,}200 - 36.0T^{(1)}$$

In cases where SiO_2 is part of a combined condensed phase, as in $ZrO_2 \cdot SiO_2$, then

$$P_{SiO_2}(ZrO_2 \cdot SiO_2) = a_{SiO_2} \cdot P_{SiO_2}(SiO_2,s,l)$$

a_{SiO_2} represents the activity of SiO_2 in the condensed phase.

The basic equation for reduction of silica by gaseous species such as hydrogen or carbon monoxide is

$$SiO_2(S) = SiO(g) + \tfrac{1}{2}\, O_2(g)$$

For this reaction

$$\log P_{SiO} = -\frac{\Delta G^\circ}{RT} - 0.5 \log P_{O_2}$$

and in a condensed phase, such as zircon

$$P_{SiO}(ZrO_2 \cdot SiO_2) = a_{SiO_2} \cdot P_{SiO}(SiO_2)$$

The partial pressure of the silicon monoxide thus depends on the activity of the silica in the condensed phase and on the oxygen partial pressure. Convenient methods for controlling the oxygen partial pressure are by controlling the ratios of hydrogen to water vapor and of carbon monoxide to carbon dioxide according to the equilibria

$$H_2O = H_2 + \tfrac{1}{2}\, O_2$$

and

$$CO_2 = CO + \tfrac{1}{2}\, O_2$$

Figure 1 presents a thermochemical diagram for the Si-O system at 1800°K according to the method described by Kellog (14) and by Gulbransen and Jansson (15). These diagrams are constructed such that the stability of condensed phases and the equilibrium pressures of the gaseous species can be read directly. The ordinates give the partial vapor pressures of the different gaseous species on a logarithmic scale. The dew points of particular H_2/H_2O combinations are shown on the lower abscissa. The vertical line in the diagram separates the liquid and solid phases. The diagram clearly shows the effect of changes in the partial pressure of oxygen on the partial pressures of the SiO and SiO_2 phases.

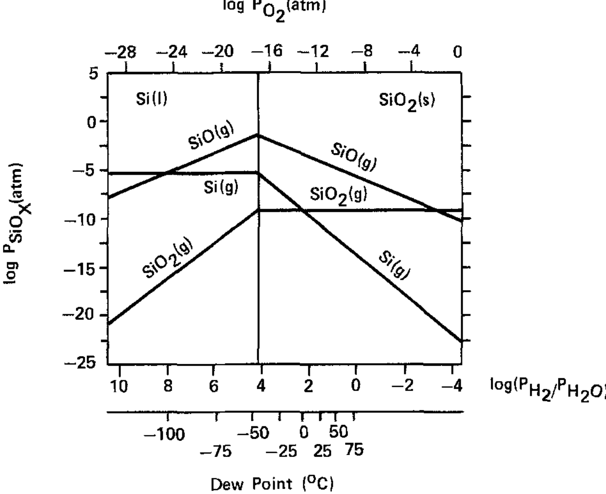

Fig. 1. Thermochemical diagram for the Si-O system at 1800°K

The reduction of SiO_2 by silicon has been extensively studied (16-22). Indeed, much of the thermodynamic data regarding reactions involving silicon monoxide has come from studies of this reaction. The evolution of SiO resulting from the reduction of SiO_2 by silicon is even more pronounced than reduction by hydrogen vapor as shown in Fig. 2 (after Toropov and Barzakovskii). This indicates that under conditions of reduction with hydrogen, the formation of SiO is more favorable than formation of Si.

Humphrey *et al.* (22) studied the reduction of SiO_2 by carbon with the results shown in Fig. 3a. It is seen that carbon is an extremely good reducing agent especially above about 1400°C. Meyer (23) also found carbon to be an aggressive reducing agent; some of his results are shown in Fig. 3b. In the cases studied by Meyer and others (24, 25) it appears that the reduction of SiO_2 occurs whether or not the SiO_2 is present in the free state or in a chemically bound state, as in zircon or mullite, $3Al_2O_3 \cdot 2SiO_2$.

Kinetics of Silica Reduction

The rate of silica loss in reducing atmospheres has been studied by Schwerdtfeger (26), Crowley (27, 28) and more recently, by Gardner (29). Schwerdtfeger and Crowley determined the rate of silica loss by weighing fused quartz spheres and silica containing samples, respectively, before and after heat-treatment in reducing atmospheres, and they concluded that the rate of reduction in hydrogen is controlled by convective diffusion or mass-transfer from the reacting surface. This conclusion was based on the dependence of the rate of weight loss on hydrogen flow rates. The

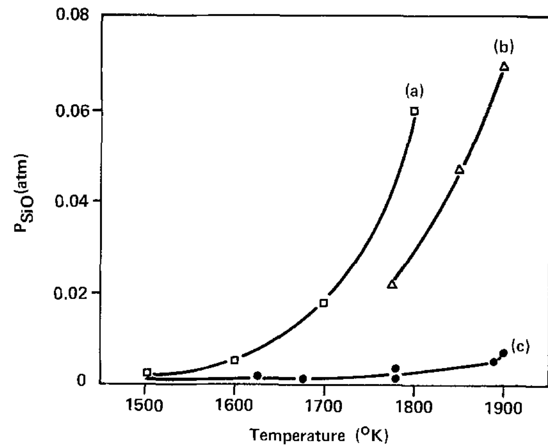

Fig. 2. Partial pressure of SiO as a function of temperature for (a) SiO_2 + Si and (b) and (c) $SiO_2 + H_2$ according to the data of various authors (see Toropov and Barzakovskii).

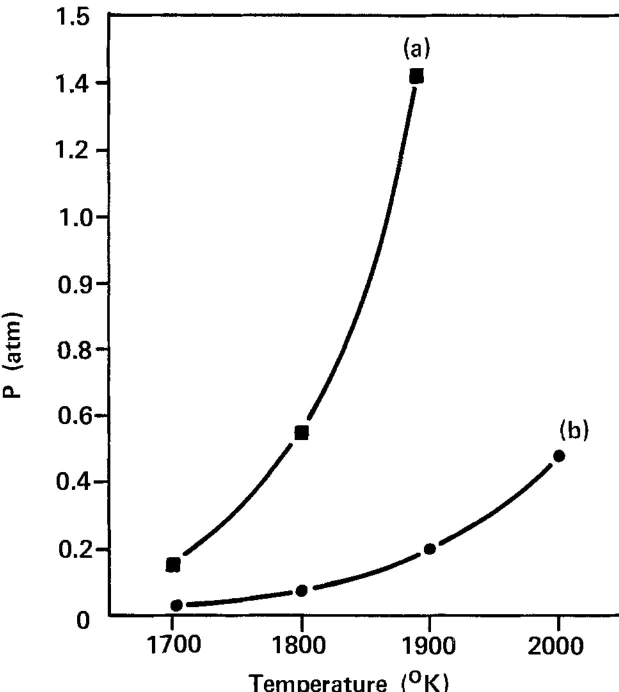

Fig. 3a. Partial pressure of (a) CO and (b) SiO as a function of temperature for decomposition of SiO_2 by Si and C. (a) PSiO for the reaction ½ SiO_2(s) + ½ Si(l) → SiO(g); (b) P_{CO} for the reaction SiO_2 + C (graphite) → SiO(g) + CO(g) with the condition that PSiO is fixed by the reaction ½ SiO_2(s) + ½ Si(l) → SiO(g). [According to data of Humphrey (22)].

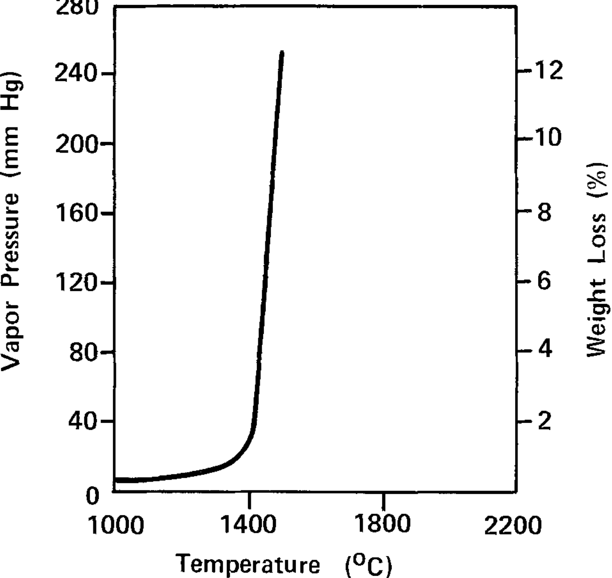

Fig. 3b. Vapor pressure of a mixture of graphite with quartz as a function of temperature [after Meyer (23)].

agreement between the theoretical and experimental rates, however, was not exact. Gardner has shown using a high temperature thermalgravimetric procedure that the rate of silica reduction in hydrogen closely obeys equations deduced on the basis of a reaction interface contracting inward from the sample surface. The velocity of the moving interface was found to depend primarily on temperature and the water vapor content of the ambient gas. The surface area of the reacting sample was also shown to be a factor in determining the rate of reduction.

Energy considerations have shown that for silicates in general there will be a significant driving force for reduction of SiO_2 to SiO and that the partial pressure of the silicon monoxide depends on several factors; the most important of these factors are temperature, the activity of the SiO_2, and the partial pressure of oxygen (dew point in H_2/H_2O gas mixtures). Kinetic factors include temperature, oxygen partial pressure, surface area and, to some extent, the atmosphere flow rate.

Experimental

Kinetic studies were carried out using a high-temperature thermal gravimetric apparatus that has been described in detail elsewhere (29, 31). The apparatus used was a graphite-element furnace containing a high-purity aluminum oxide muffle and was capable of operating at temperatures up to 1700°C. A Cahn Model RG electrobalance was mounted above the furnace. The sample was contained in a molybdenum basket and suspended in the hot zone using a molybdenum wire. The system was purged before use with argon. Hydrogen with a purity of 99.999+% and containing 2 ppm water vapor, as determined with a Beckman Trace Moisture Analyzer, was used as the reaction gas. The hydrogen flow rate was maintained at 1 cfh for experiments using water-saturated hydrogen (wet hydrogen) and at 4-5 cfh for experiments in nonsaturated hydrogen (dry hydrogen). The low flow rate in wet hydrogen was used to ensure that the gas was saturated with water vapor. The dew point of the reaction gas was checked at the entrance to the furnace using a dew point hygrometer. The dew point in all the wet hydrogen experiments was 24°C. The range of the hygrometer was not broad enough to permit measurement of the dew point of the dry hydrogen.

The electrobalance used for the dynamic weight determinations was calibrated before each kinetic run with the empty sample basket and hangdown wire attached. The system was purged first with argon for 5-10 min and then with hydrogen for a minimum of 30 min prior to turning on power to the furnace. During the heating portion of the cycle, the gas was passed through a water bubbler at room temperature to saturate the gas. This was done to minimize the reduction of the zircon before the isothermal reaction temperature was reached. The furnace reached the preselected reaction temperature in approximately 40 min during which time the extent of reaction was generally less than 0.02% depending on the desired reaction temperature. Dry hydrogen was admitted when the desired temperature was reached and the reaction was allowed to proceed isothermally. Zero time was taken as the point when conditions become isothermal.

The zircon powder used for the kinetic studies was Zircopax from the TAM Division of National Lead Company. This powder has a mean particle size of 1.3 μm. Sample sizes were 100 ± 10 mg.

The samples used to evaluate the effects of hydrogen on the sintering of zircon had particle sizes of <1, 1.5, and 6 μm. These samples were from M&T Chemicals, Incorporated. The samples were prepared for sintering by mixing with solvents and a plasticized organic resin and then casting into 0.007 in. thick sheets by a conventional doctor-blade process. Ten sheets were laminated together and sintering samples were punched from the laminated stocks. The densities of the unfired samples were generally 2.35-2.45 g/cm³. The samples were then sintered for 3 hr at maximum temperature (see Fig. 9 and 10) in a molybdenum-element, elevator-hearth type furnace with a hydrogen ambient. The dew point of the hydrogen was maintained at approximately 25°C.

The sintered samples were polished by conventional methods and optical micrographs were prepared. Samples were also examined by x-ray diffraction using Cu k_α radiation; surface and bulk compositions were determined.

Ultraviolet spectroscopic analysis results for the zircon powders used are shown in Table I. Although no kinetic experiments were carried out with the M&T zircon powders, kinetic results would not be expected to be qualitatively different from those obtained with the TAM zircon powder.

Treatment of Kinetic Data

Kinetic data were treated according to the method described by Hancock and Sharp (30). The method involves preparation of plots of $\ln[-\ln(1-\alpha)]$ *vs.* ln time (where α is the fraction reacted at time t) in order to determine the mechanism of the reaction. The slopes of such plots are diagnostic of the mechanisms of reactions which obey a number of solid-state kinetic equations. Determination of the slope, m, of $\ln[-\ln(1-\alpha)]$ *vs.* ln time leads to identification of a function $f(\alpha) = kt$. When the function was identified which best fit the kinetic data, plots of $f(\alpha)$ *vs.* time were prepared and the rate constants, k, were determined from the slopes.

The fraction reacted, α, was determined by monitoring the weight of the reacting sample on a strip chart recorder running at a constant speed and comparing the weight at time t to the initial weight. The fraction reacted was calculated for zircon on the basis of the initial silica content and not on the total weight of zircon initially present.

Results and Discussion

Figures 4 and 5 present kinetic data in the form of $\ln[-\ln(1-\alpha)]$ *vs.* ln time (hereafter referred to as "mechanism curves") for zircon samples reacted in "dry" hydrogen (*i.e.*, pure hydrogen with no added water vapor) and "wet" hydrogen with a dew point of 24°C. The average slope for samples reacted in dry hydrogen is 1.18. This value is between the values of 1.07 or 1.11 and 1.24 expected for equations based on interface controlled reactions and zero order reactions, respectively. An interesting feature of the curves in Fig. 4 is that after the reaction reaches approximately 60% completion, the slopes of the curves begin to increase. The increase in slope is likely due to a contribution to the reaction mechanism of nuclei growth and interference phenomena during the later stages of the reaction.

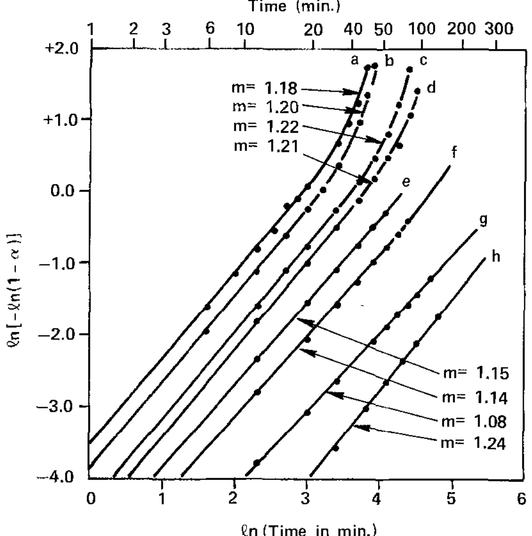

Fig. 4. Plots of $\ln[-\ln(1-\alpha)]$ vs. ln time for zircon powder reacted in dry hydrogen. a, 1625°C; b, 1598°C; c, 1578°C; d, 1552°C; e, 1520°C; f, 1490°C; g, 1405°C; h, 136°C.

Figure 5 shows that slopes of mechanism curves for samples in wet hydrogen are considerably less than for samples reacted in dry hydrogen. The average value of 0.88 falls between the values of 1.07 or 1.11 expected for interface controlled reaction and 0.5-0.6 for diffusion controlled reactions. This probably indicates at least a partial dependence on diffusion phenomena. The reaction is primarily controlled by the movement of a reacting interface but it is possible that the reacting species may have to diffuse through a hydrated surface layer.

Previous studies of the kinetics of reduction of pure silica in hydrogen have shown that the reaction of SiO_2 with hydrogen closely obeys equations for the movement of a reacting interface. On the basis of the similarity of the reaction of hydrogen with pure silica, zircon, and other refractory silicates, the equation chosen to describe the kinetics of zircon reduction is the equation for phase-boundary controlled reactions.

For a sphere of radius r which reacts from the surface inward and where the reaction is controlled by the movement of the reaction interface at a constant velocity μ, the reaction can be described by

$$R_3(\alpha) = [1 - (1-\alpha)^{1/3}] = (\mu/r)t$$

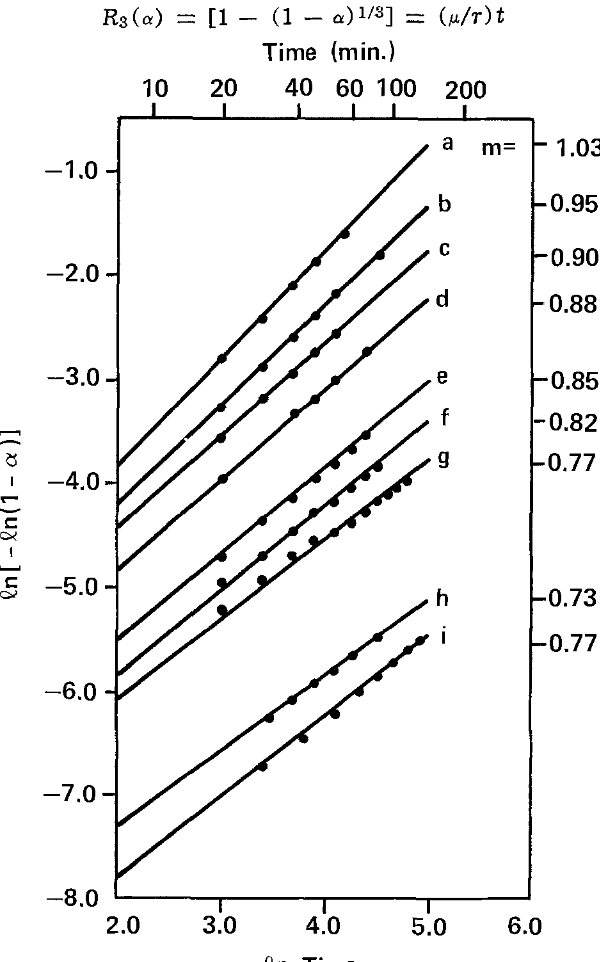

Fig. 5. Plots of $\ln[-\ln(1-\alpha)]$ vs. ln time for zircon powder reacted in wet hydrogen (dew point = 24°C). a, 1625°C; b, 1598°C; c, 1578°C; d, 1552°C; e, 1520°C; f, 1490°C; g, 1445°C; h, 1405°C; i, 1360°C.

Plots of $R_3(\alpha)$ *vs.* time will be linear with a slope of (μ/r) if this equation effectively describes a particular reaction. Figures 6 and 7 present plots of $R_3(\alpha)$ *vs.* time for zircon samples reacted in dry and wet hydrogen, respectively. As can be seen from the figures, the plots are linear when the fraction reacted is less than approximately 0.60. This indicates fairly good agreement with the theoretical equation. The nonlinearity as the reaction proceeds toward near completion is likely due to the effect of nuclei growth and interference.

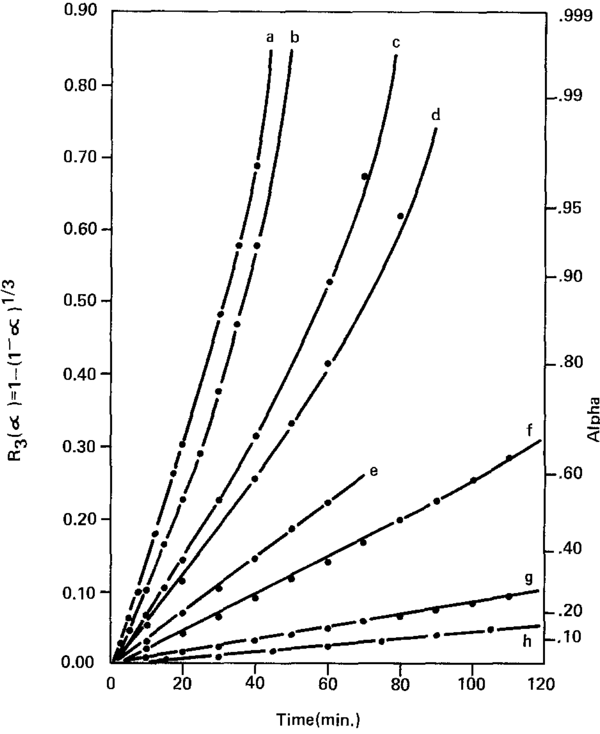

Fig. 6. R_3 (α) *vs.* time for zircon powder reacted in dry hydrogen a, 1625°C; b, 1598°C; c, 1578°C; d, 1552°C; e, 1520°C; f, 1490°C; g, 1405°C; h, 1360°C.

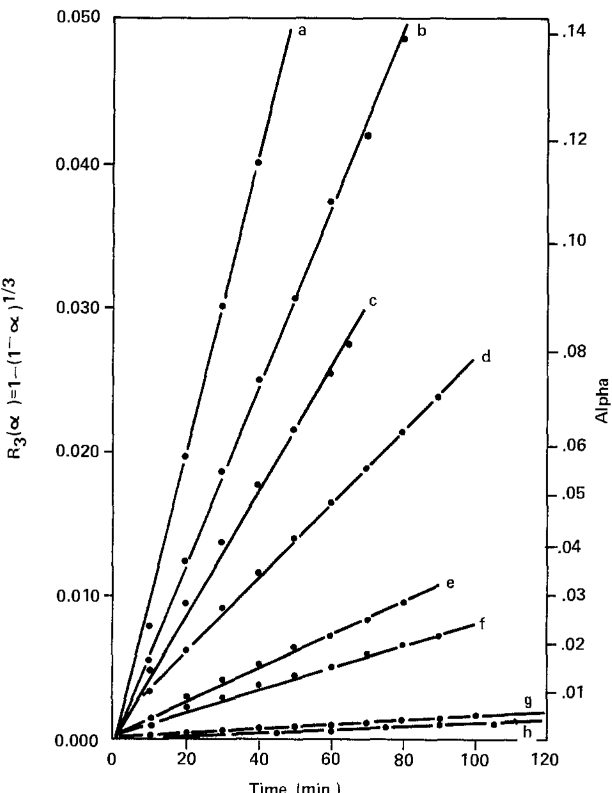

Fig. 7. R_3 (α) *vs.* time for zircon powder reacted in wet hydrogen (dew point = 24°C). a, 1625°C; b, 1598°C; c, 1578°C; d, 1552°C; e, 1520°C; f, 1490°C; g, 1405°C; h, 1360°C.

Arrhenius plots of the reaction rates *vs.* temperature are shown in Fig. 8, for zircon samples reacted in pure (dry) hydrogen and hydrogen saturated with water vapor. The activation energies are 82 and 121 kcal/mole for dry and wet hydrogen, respectively. The figure shows that the activation energies are constant throughout the temperature range studied (1360°-1630°C). The fact that zircon decomposes at about 1500°-1530°C to yield ZrO_2 and SiO_2 does not change the activation energy of the reaction of hydrogen with the silica. This indicates that the greatest energy barrier for the reaction is the energy required to break the silicon-oxygen bonds.

A previous study (28) has shown that the activation energies for the reduction of pure silica by dry and wet hydrogen were 85 and 135 kcal/mole, respectively. The observed value of 82 kcal/mole for reduction of silica in zircon is essentially the same as that for the reduction of pure silica. The lower observed value of 121 kcal/mole for reduction of zircon by wet hydrogen compared to the value of 135 kcal/mole for reduction of pure silica is probably due to the slightly lower affinity of the zircon surface for water compared to that of the pure silica surface.

The rates of reaction are slightly higher for the zircon powder studied than those observed for crystalline quartz. The rate of reduction of zircon in dry

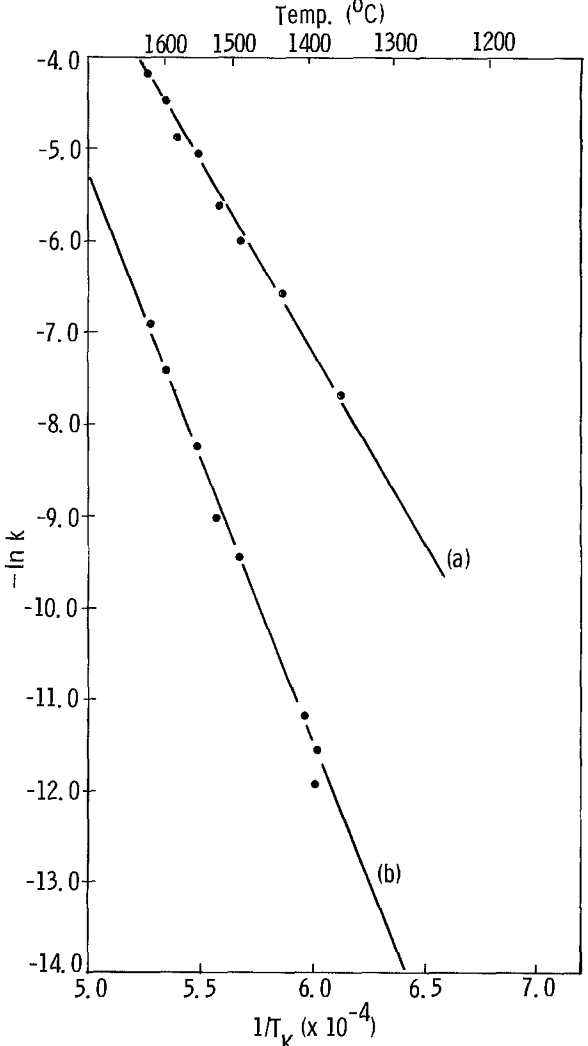

Fig. 8. Arrhenius diagram for calculation of activation energy. (a) Samples reacted in dry hydrogen; (b) samples reacted in wet hydrogen (dew point = 24°C).

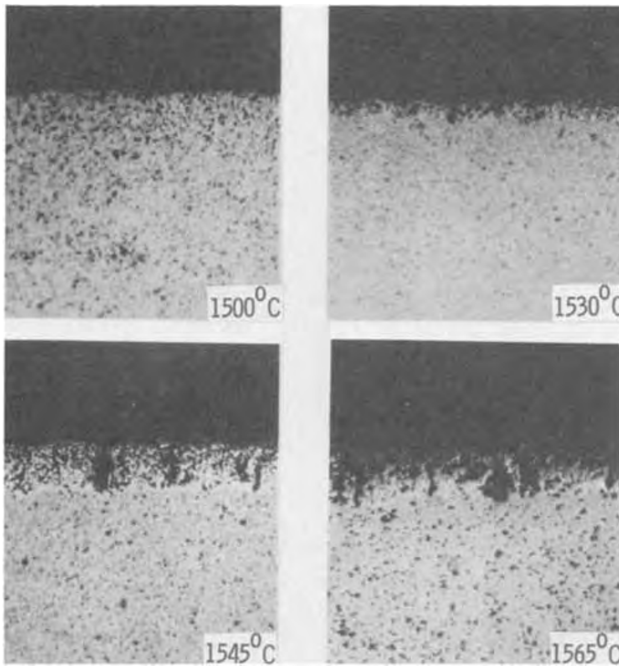

Fig. 9. Effect of hydrogen sintering temperature on surface decomposition for 1.5 μm zircon powder.

hydrogen at 1360°C, for example, is 4.62×10^{-4} min^{-1} while the observed rate for crystalline quartz powder was 3.63×10^{-4} min^{-1} (28). This relatively small difference in rate (in light of changes of several orders of magnitude with temperature) is most likely due to the difference in the surface areas of the powder samples.[3]

The previous discussion has been directed at elucidation of the reaction mechanism on a submicroscopic scale. Figure 9, however, presents photographs of zircon samples sintered in wet hydrogen (dew point $\cong$ 25°C) at various temperatures and these photographs show a reaction interface even on the microscopic scale. X-ray diffraction of the zircon samples shows the presence of monoclinic ZrO_2 on the surface of the samples when the sintering temperature is 1530°C or above. The ZrO_2 surface appears white in the photomicrographs of Fig. 9. The micrographs indicate that the zirconia surface is very porous. The actual reaction interface can be distinguished as the boundary between the white porous surface and the bulk of the sample.

Figure 10 shows the effect of particle size on the sintering of zircon and on hydrogen reduction. The samples were all sintered at 1545°C for 3 hr and the extent of the reduction is similar in each case. The ZrO_2 surface is clearly evident in the sample prepared from 0.5 μm zircon powder. In this case the ZrO_2 is fairly dense compared to the other samples except for some very large pores. Samples prepared from the 6.0 μm powder showed a zirconium dioxide surface as well as some internal ZrO_2. The hydrogen gas apparently is able to easily diffuse through the porous zircon sample.

A practical result of these studies is the recognition of the fact that, in order to effectively sinter zircon in reducing atmospheres, the particle size of the zircon powder should be chosen to permit sintering at or below approximately 1500°C. Otherwise, considerable reduction can take place and prevent further sintering.

[3] The quartz powder used in that study was −325 mesh with a surface area of 1.3 m²/g.

Conclusion

The rate of loss of silica from zircon surfaces by reduction in hydrogen has been shown to closely obey a function of α based on a model of a reaction interface contracting inward from the surface of the sample. The model, however, does not hold for the complete reaction. The reaction mechanism begins to change when approximately 60% of the available silica has been removed; above 60% reaction nuclei growth and interference phenomena become important. There is a difference in the reaction path when hydrogen containing water vapor is used as the ambient. This is evidenced by a change in the activation energy for reduction from 82 kcal/mole in dry hydrogen to 121 kcal/mole for reduction in hydrogen with a dew point of 24°C. This difference is likely due to adsorption of water on the zircon surface.

Electrohydrodimerization Reactions

IV. A Study of the Effect of Alkali Metal Ions on the Hydrodimerization of Several 1,2-Diactivated Olefins in DMF Solutions by Chronoamperometry and Chronocoulometry

Mark J. Hazelrigg, Jr. and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The reduction of the activated olefins: dialkyl fumarates (alkyl = methyl, ethyl, butyl), ethyl cinnamate and cinnamonitrile in tetra-n-butylammonium iodide-dimethylformamide solutions in the absence and presence of Li^+, Na^+, and K^+ was studied by double potential step chronocoulometric and chronoamperometric techniques, cyclic voltammetry, and controlled potential coulometry. The results in the absence of alkali metal ions confirmed the previous mechanism involving formation of the radical anion, $R^{\cdot-}$, followed by dimerization; no evidence of appreciable adsorption of the parent olefin or $R^{\cdot-}$ was found. The addition of alkali metal ion (M^+) greatly increased the rate of the dimerization reaction and a mechanism based on formation of the ion pair, $M^+R^{\cdot-}$, followed by reaction of $M^+R^{\cdot-}$ with $R^{\cdot-}$ or coupling of two $M^+R^{\cdot-}$ species is proposed based on an analysis of the kinetic data. The addition of Li^+ also decreased the extent of polymer formation during bulk electrolysis experiments.

The mechanism of electrohydrodimerizations (1) (Eq. [1]) of activated olefins and related substances has been the subject of numerous investigations

$$2R + 2H^+ + 2e \rightarrow R_2H_2 \qquad [1]$$

in recent years. The mechanism which has emerged, based on chronoamperometric (2), rotating ring-disk electrode (3, 4), electron spin resonance (ESR) spectroscopic (5), linear scan voltammetric (6, 7), chronopotentiometric (8), and a-c polarographic (9) studies, is one in which the predominant pathway for many compounds (*e.g.*, dialkyl fumarates, cinnamonitrile, α,β-unsaturated ketones) is an initial one-electron transfer at an electrode followed by dimerization of the electrogenerated radical ions (Eq. [2] and [3]), followed by protonation

$$R + e \rightarrow R^{\cdot-} \qquad [2]$$

$$2R^{\cdot-} \xrightarrow{k_2} R_2^{2-} \qquad [3]$$

* Electrochemical Society Active Member.

Key words: reductive coupling, electrolytic dimerizations, voltammetry, coulometry, ion pair formation.

Previous studies of electrohydrodimerizations of activated olefins have shown a strong effect on the electrochemical behavior on addition of alkali metal ions. Baizer (1, 10) for example, showed that the product ratios and reaction paths in reductive coupling depend upon the cation of the supporting electrolyte. Previous studies from this laboratory on the reduction of diethyl fumarate in N,N-dimethylformamide (DMF) solutions (2) showed that the addition of $LiClO_4 \cdot 3H_2O$ in millimolar concentrations to DMF solutions containing 0.44M tetra-n-butylammonium iodide (TBAI) caused the controlled potential coulometric n_{app}-value (where n_{app} is the number of faradays consumed per mole of electroactive species) to increase from 0.6 to 1.0, indicating an increase in the extent of formation of hydrodimer and a decrease in polymer formation. The addition of these small amounts of $LiClO_4$ also was found to increase the rate of the dimerization of the radical ions, although a quantitative study of this was not undertaken.

The alkali metal ion effect is most probably attributable to ion-pair formation between the alkali metal ion and the olefin radical anion. Ion-pair formation of

radical anions of organic compounds with metal ions in aprotic solvents has been of interest and has been studied using ESR and absorption spectroscopy (11), and polarography (12-15). Most of the previous electrochemical studies have been concerned with anions of aromatic quinones, nitrocompounds or carbonyl compounds. Very little work has been done with ion-pairs involving olefin anions. Ion-pairing affects the electrochemical reduction of organic compounds in different ways depending upon the electrochemical and chemical reactivity of the ion-pair. For the Nernstian reduction of neutral compounds which form stable radical anions, ion-pair formation causes a positive shift in $E_{1/2}$ or E_{pc}; this shift in the reduction potential can be used to determine the ion-pair formation constant, K, (Eq. [4]) where ΔE is

$$\Delta E = (RT/n\mathbf{F})\ln(1 + K[M^+]) \quad [4]$$

the shift in reduction potential, $[M^+]$ is the metal ion concentration, and K is the ion-pair formation constant. For example, Peover and Davis (12) found an ion-pair formation constant for the Li^+-anthrasemiquinone ion-pair in 0.1M TEAP-DMF of 39 liters/mole using this method.

Ion-pair formation has also been shown to affect the rate of reactions following the electron transfer step. For example, Philp, Layloff, and Adams (16) found that Li^+ changes the electrochemical reduction pathway of benzil. In the absence of Li^+, benzil is reduced in DMF solutions in 2 one-electron steps, while in the presence of Li^+, it is reduced in an over-all single two-electron step. They proposed that a Li^+-benzil$^-$ ion-pair is formed which immediately undergoes a second electron transfer at potentials of the original first wave. Lasia (17) recently reported the effect of alkali metal ions on the rate of dimerization of phthalic aldehyde radical anion in DMF solutions using cyclic voltammetric techniques. He showed that the rate of disappearance of the radical anion increased by several orders of magnitude in the presence of alkali metal ion, with tthe rate of disappearance following the order $Li^+ > Na^+ > K^+$.

The work described in this paper was undertaken to investigate the role of the alkali metal ion in the dimerization reaction of activated olefin radical anions and to ascertain if the reaction mechanism in the presence of these metal ions was the same as in their absence. A second purpose of this investigation, since information about the kinetics of the over-all process was to be obtained by chronocoulometric techniques, was to see if any adsorption of parent species or intermediates takes place. The previous investigations all assumed in their data treatment the absence of adsorption and the occurrence of the dimerization reaction away from the electrode surface. Although the fit of the experimental data to theoretical models not involving adsorption was very good, we felt that chronocoulometric techniques utilizing digital data acquisition (18, 19) would be a more sensitive probe of adsorption. We have recently shown using chronocoulometry (20), that neither 9,10-diphenylanthracene nor its radical anion are appreciably adsorbed in DMF solutions at a platinum electrode.

The substances investigated in this study were all activated olefins with the structure shown below

$$R_1(H)C{=}C(H)R_2$$

Dimethyl Fumarate:

$R_1 = R_2 = -C(=O)-O-CH_3$ (DMeF)

Diethyl Fumarate:

$R_1 = R_2 = -C(=O)-O-CH_2-CH_3$ (DEF)

Dibutyl Fumarate:

$R_1 = R_2 = -C(=O)-O-CH_2-CH_2-CH_2-CH_3$ (DBF)

Ethyl Cinnamate:

$R_1 = -C_6H_5$; $R_2 = -C(=O)-O-CH_2-CH_3$ (EC)

Cinnamonitrile:

$R_1 = -C_6H_5$; $R_2 = -CN$ (CN)

Fumaronitrile:

$R_1 = R_2 = -CN$ (FN)

Double potential step chronoamperometric and chronocoulometric data were fit to theoretical models produced by digital simulation techniques (2), to obtain rate constants of the reactions following electron transfer.

Experimental

The general experimental techniques were the same as those reported previously (2); a detailed description is available (21).

Materials.—The solvent, dimethylformamide (DMF) (reagent grade, J. T. Baker Chemical Company) was purified by first storing over Linde Type 4A molecular sieves for 48 hr to remove the water, then storing over anhydrous cupric sulfate for 48 hr to complex dimethylamine. The solvent was then distilled from a small amount of molecular sieves and cupric sulfate using a 100 cm glass bead packed distillation column under a nitrogen atmosphere of 15 Torr using a reflux ratio of one. The middle 50% of the distillate was retained. This was stored under a helium atmosphere and used within three weeks of purification.

The supporting electrolyte, tetra-n-butylammonium iodide (TBAI) (polarographic grade, Southwestern Analytical Chemical Company, Austin, Texas) was vacuum dried and stored in a desiccator until use. Diethyl fumarate (DEF), cinnamonitrile (CN) (K. and K. Laboratories, Incorporated), and dibutyl fumarate (DBF) (Aldrich Chemical Company) were used as received. Dimethyl fumarate (K. and K. Laboratories, Incorporated) and fumaronitrile (FM) (Aldrich Chemical Company) were sublimed twice before use. Ethyl cinnamate (EC) (Aldrich Chemical Company) was vacuum distilled twice before use. Lithium perchlorate, lithium iodide, sodium iodide, and potassium iodide (reagent grade, J. T. Baker Chemical Company) were vacuum dried before use.

Apparatus.—The electrochemical cell used in the voltammetric studies was constructed from vacuum glassware and had a 25 ml capacity and contained a freeze-pump-thaw chamber and working, auxiliary, and reference electrode compartments. The auxiliary and reference electrode compartments were isolated from the working compartment by medium porosity glass frits. The cell contained four electrodes: a silver wire reference electrode, a platinum disk micro-electrode (0.013 cm^2) for chronocoulometry, chronoamperometry, and cyclic voltammetry, a platinum gauze macro-electrode for preelectrolysis, and a platinum coil auxiliary electrode. A second cell, similar to the cell described above, was used for controlled potential electrolysis. This cell had a 50 ml capacity and an intermediate chamber between the working and auxiliary compartments to prevent contamination of the working electrode compartment by diffusion of products produced at the auxiliary electrode during bulk controlled potential electrolysis. The working electrode

in the coulometric experiments was a platinum wire gauze (2 cm by 10 cm).

The silver wire reference electrode in TBAI-DMF solutions was reproducible (less than 10 mV deviation) and was stable for more than 24 hr (less than 5 mV drift). Its use avoided the water and KCl contamination that sometimes results from an aqueous SCE and also showed a smaller amount of a-c pickup than cells in which a conventional SCE was employed.

Cyclic voltammetry and controlled potential coulometry experiments were performed with a PAR Model 170 Electrochemistry System (Princeton Applied Research Corporation, Princeton, N.J.). Positive feedback resistance compensation was employed. Double potential step chronoamperometry and chronocoulometry experiments were performed with a multipurpose instrument constructed from solid-state operational amplifiers previously described (22-24), and also employed positive feedback resistance compensation (25). The potential step was applied to the summing point of the potentiostat by a Wavetek Model 114 Function Generator. The length of the potential step was measured with a Beckman Berkley Model 7370 Universal Eput and Timer. Initial and final potentials for the potential steps were measured with a Fairchild Model 7050 Digital Voltmeter to an accuracy of ± 1 mV.

Data for the potential step experiments were taken using a PDP-12A computer system (Digital Equipment Corporation, Maynard, Massachusetts) and generally followed previously described digital data acquisition techniques [see (21, 23, 24, 26-29) and references therein]. Data sampling by the computer was synchronized to the potential step by amplifying the potential step and using it to trigger the real-time clock of the computer. The real-time clock in turn initiated data sampling at a rate determined by the computer program. The PDP-12A data acquisition program allowed sampling of 50 data points on the forward pulse and 50 points on the reverse one. These could be displayed, subjected to an internal least squares routine in studies of adsorption, listed, or printed as $i(2t_f)/i(t_f)$ or $Q(2t_f)/Q(t_f)$ where t_f is the forward pulse length, $i(t_f)$ and $Q(t_f)$ are the current and accumulated coulombs at t_f, respectively, and $i(2t_f)$ and $Q(2t_f)$ are these values at time $2t_f$.

Typical experimental procedure.—The platinum disk electrode was polished with AB ALPHA polishing alumina (Buehler Limited, Evanston, Illinois) before each experiment. The cell was assembled and pumped down on a vacuum line (10^{-5} Torr) for 1-2 hr. The supporting electrolyte was vacuum-dried in a transfer vessel. DMF was then vacuum transferred to the transfer vessel containing the supporting electrolyte to give a volume of 25 or 50 ml. After the supporting electrolyte dissolved, the solution was subjected to three freeze-pump-thaw cycles to remove any traces of oxygen. The solution was then vacuum-transferred to the electrochemical cell, brought to atmospheric pressure with high purity helium (99.995% Matheson Gas Products, La Porte, Texas), and allowed to equilibrate for 1 hr.

Liquid olefins and concentrated solutions of alkali metal ions were then added to the electrochemical cell as needed through a septum cap with the aid of syringes. Solid olefins were generally added with the supporting electrolyte in the transfer vessel. Concentrated alkali metal ion solutions were prepared in a vacuum vessel in a manner similar to that of the supporting electrolyte solution, except, that the DMF was freeze-pump-thawed several times both before and after the addition of the metal iodides. This was done to prevent the possibility of air oxidation of iodide to iodine in the presence of metal ions such as lithium.

Results

Theoretical models.—The method of obtaining kinetic and mechanistic information from the double potential step experiments generally followed that described previously (2). Briefly, digital simulations (30) of the current (i) and coulombs (Q) flowing during a potential step to the limiting current plateau of the first reduction wave (production of $R^{\cdot-}$, Eq. [2]) and of i and Q during a reverse step back to the foot of the wave (oxidation of $R^{\cdot-}$) were carried out, for different values of the rate constant of the dimerization reaction, Eq. [3]. For completeness, other possible reaction sequences leading from $R^{\cdot-}$ to hydrodimer were also considered; these are shown in Table I. Simulations employing 1000 iterations were used and tables of the normalized current and coulombs as functions of the dimensionless parameter k_2t_fC were generated. These were then used to generate tables of $i(2t_f)/i(t_f)$ and $Q(2t_f)/Q(t_f)$ as functions of k_2t_fC. To fit the experimental data to the models, it is convenient to normalize these current and coulomb ratios and to represent these ratios as functions of a particular time when these ratios attain a certain value. The normalized ratios were obtained, as previously (2), *i.e.*

$$R_I = [i(2t_f)/i(t_f)]/0.2928 \qquad [5]$$

$$R_Q = \frac{[Q(2t_f)/Q(t_f)] - 0.414}{0.586} \qquad [6]$$

so that R_I is 1 and R_Q is 0 in the absence of kinetic complications ($k_2 = 0$), with R_I decreasing to 0 and R_Q increasing to 1 for very large values of k_2t_fC. In our previous work (2) we picked as the time reference point that value of k_2t_fC where $R_I = 0.5$, calling this point $t_{1/2}$ and using plots of R_I and R_Q *vs.* $t_{1/2}$ to determine the mechanism and the rate constant. Because we make greater use of the R_Q curves in the present work, we found it more convenient (and somewhat more diagnostic since the curves for the different possible mechanisms were more spread apart) to use as a reference point that where $R_Q = 0.4$; this value of k_2t_fC is designated as $T_{Q.4}$. A plot of R_I and R_Q *vs.* $T_{Q.4}$ is shown in Fig. 1 and, as an aid for others desiring to

[a] Mechanism 1. Second order dimerization [Mechanism V in (2)]

At E_1: $R + e \rightarrow R^{\cdot-}$ $\quad 2R^{\cdot-} \xrightarrow{k_2} R_2^{2-}$
At E_2: $R^{\cdot-} \rightarrow R + e$

Mechanism 2. Second order EC [Mechanism III in (2)]

At E_1: $R + 2e \rightarrow R^{2-}$ $\quad R^{2-} + R \xrightarrow{k_2} R_2^{2-}$
At E_2: $R^{2-} \rightarrow R + 2e$

Mechanism 3. Second order ECE [Mechanism IV in (2)]

At E_1: $R + e \rightarrow R^{\cdot-}$ $\quad R^{\cdot-} + R \xrightarrow{k_2} R_2^{\cdot-}$
At E_2: $R^{\cdot-} \rightarrow R + e$

Mechanism 4. Second order ECE [Mechanism IVA in (2)]

As Mechanism 3, except:
At E_2: $R^{\cdot-} \rightarrow R + e$
$R_2^{\cdot-} \rightarrow$ products $+ e$

Rate constants for each mechanism can be calculated by the following equations: Mechanism 1, $k_2 = 0.755/T_{Q.4}C$; Mechanism 2, $k_2 = 1.92/T_{Q.4}C$; Mechanism 3, $k_2 = 1.45/T_{Q.4}C$; Mechanism 4, $k_2 = 3.86/T_{Q.4}C$.

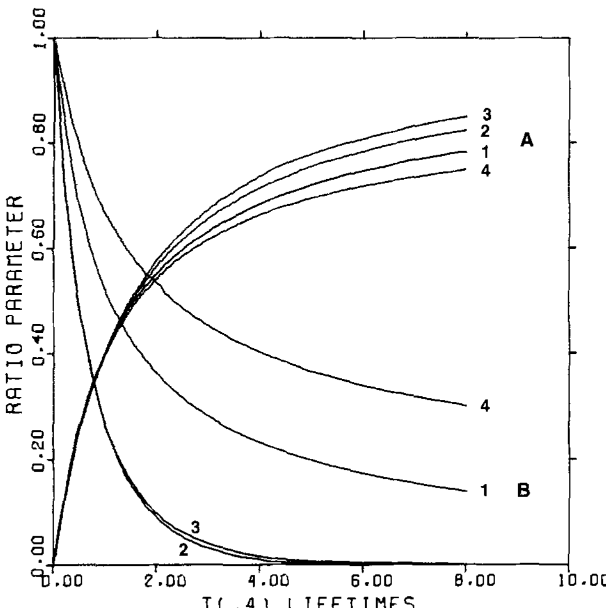

Fig. 1. Variation of the normalized coulomb (A) and current (B) ratio parameters as a function of $T_{Q,4}$ lifetimes for the different mechanisms considered.

use this procedure, the data is tabulated in Table I. In use the experimental R_I and R_Q values are plotted against t_f, and the time axis then recalibrated in terms of $T_{Q,4}$ values. The fit of the experimental curve to the different model curves reveals the best mechanism, and the $T_{Q,4}$ value for that mechanism, knowing t_f and C, yields k_2 (Table I).

Models in the presence of alkali metal ions.—The results show (see below) that the hydrodimerization mechanism involves coupling of the radical anions (Mechanism 1) even in the presence of alkali metal ions. The involvement of alkali metal ion could proceed by ion pair formation, followed by reaction of ion pair with free radical anion

$$R^{\cdot-} + M^+R^{\cdot-} \xrightarrow{k_{21}} \text{dimer} \quad [7]$$

or by coupling of two ion pairs

$$2\,M^+R^{\cdot-} \xrightarrow{k_{22}} \text{dimer} \quad [8]$$

If one assumes that these are the rate-determining steps, *i.e.*, that ion pair formation and dissociation are so rapid, that reaction [9] can be considered at equilibrium

$$M^+ + R^{\cdot-} \rightleftarrows M^+R^{\cdot-} \quad [9]$$

the over-all reaction velocity for the two paths can be obtained by combining the equilibrium constant expression for [9] (Eq. [10])

$$K = [M^+R^{\cdot-}]/[M^+][R^{\cdot-}] \quad [10]$$

with the rate expressions for [7] and [8]

$$v_7 = k_{21}[R^{\cdot-}][M^+R^{\cdot-}] \quad [11]$$

$$v_8 = k_{22}[M^+R^{\cdot-}]^2 \quad [12]$$

Taking the analytical concentration of radical anion as $C_{R^{\cdot-}}$ (Eq. [13]), the concentration of ion pair

$$C_{R^{\cdot-}} = [R^{\cdot-}] + [M^+R^{\cdot-}] \quad [13]$$

is given by Eq. [14]

$$[M^+R^{\cdot-}] = \frac{K[M^+]}{1 + K[M^+]} C_{R^{\cdot-}} \quad [14]$$

and that of the free radical ion by Eq. [15]

$$[R^{\cdot-}] = C_{R^{\cdot-}}/(1 + K[M^+]) \quad [15]$$

Using these expressions in Eq. [11] and [12] yield

$$v_7 = \frac{k_{21}K[M^+]}{(1 + K[M^+])^2} C_{R^{\cdot-}}^2 \quad [16]$$

$$v_8 = \frac{k_{22}K^2[M^+]^2}{(1 + K[M^+])^2} C_{R^{\cdot-}}^2 \quad [17]$$

Both mechanisms show an over-all second order dependence on total radical anion concentration. The dependence on free metal ion concentration, in the limit $K[M^+] << 1$ (where Eq. [18] and [19] apply) is first order

$$v_7 = k_{21}K[M^+]\, C_{R^{\cdot-}}^2 \quad [18]$$

$$v_8 = k_{22}K^2[M^+]^2\, C_{R^{\cdot-}}^2 \quad [19]$$

for the reaction in [7] and second order for that in [8]. The general over-all equation for the reaction rate under conditions where free radical ion coupling, and the ion-pair coupling reactions can all occur simultaneously is given by

$$v_{\text{over-all}} = \frac{k_2 + k_{21}K[M^+] + k_{22}K^2[M^+]^2}{(1 + K[M^+])^2} C_{R^{\cdot-}}^2 \quad [20]$$

Electrochemical results in absence of alkali metal ions.—Cyclic voltammetric data for the different activated olefins are given in Table II. All compounds show behavior typical of a one-electron transfer followed by a following chemical reaction. In all cases the voltammograms become more reversible in appearance (*e.g.*, show larger i_{pa}/i_{pc}-values) when either the scan rate is increased or the olefin concentration is decreased. In general the results for DEF and CN confirm those in earlier papers (2-3). Controlled potential coulometric reduction of these compounds was carried out at potentials beyond the first reduction peak; typical results are given in Table III. For the fumarates all show n_{app}-values smaller than one, with n_{app}-values smaller at higher (10 mM) concentrations than at lower (2.0 mM) ones. This has been attributed to a slow polymerization reaction initiated by the radical anions. For both EC and CN the n_{app}-values are much closer to one, suggesting considerably less polymerization occurs with these species.

[a] 0.20M TBAI-DMF at Pt cathode.

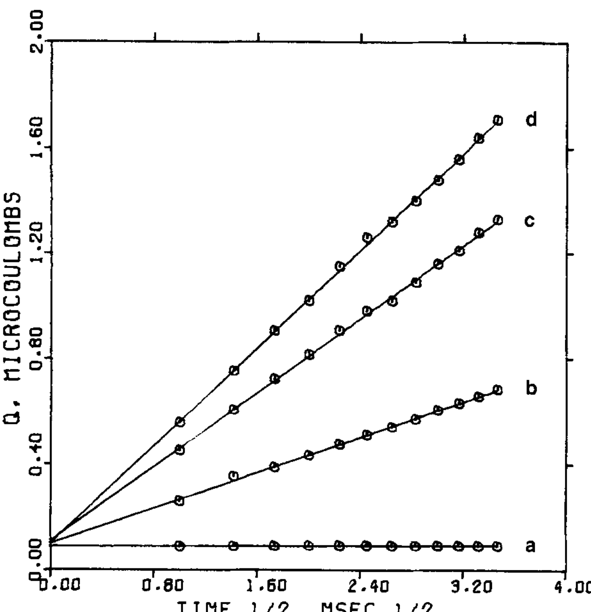

Fig. 2. Chronocoulometric data (Q vs. $t^{1/2}$) for dibutyl fumarate. The potential was stepped from −0.200 to −1.000V vs. AgR.E. and the solution was 0.2M TBAI in DMF containing (a) 0, (b) 1.49, (c) 3.20, (d) 4.11 mM DBF.

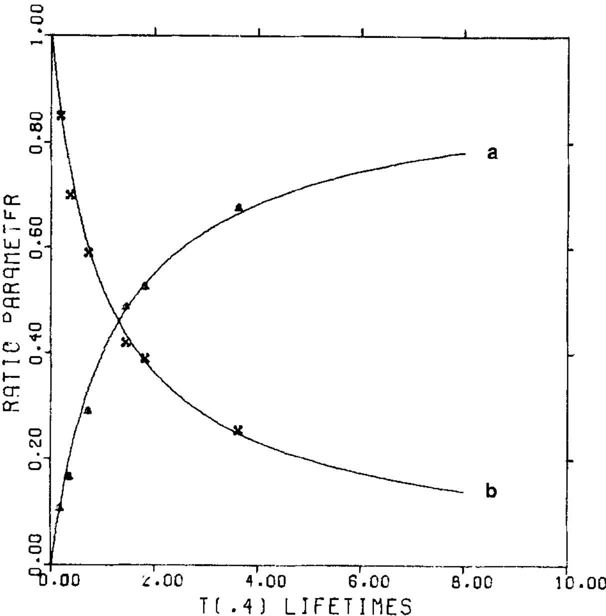

Fig. 3. Variation of the normalized coulomb (a) and current (b) ratio parameters as a function of $T_{Q.4}$ lifetimes for the reduction of 20.4 mM dibutyl fumarate in 0.20M TBAI-DMF solution. The points are experimental data and the lines are the simulation results for Mechanism 1 (radical anion dimerization).

Potential step chronocoulometry from the foot of the wave to the mass transfer limiting region in all cases produced linear Q *vs.* $t^{1/2}$ plots. Typical results are shown in Fig. 2; complete data are in Ref. (21). The intercepts and slopes for all of the compounds at several concentrations are given in Table IV. Analysis of the chronocoulometric data by the equation (18-20)

$$Q = Q_{dl} + n\mathbf{F}A\Gamma + 2n\mathbf{F}AC(D_o t/\pi)^{1/2} \quad [21]$$

shows that the intercept at $C = 0$ is the same as at higher concentrations of electroactive species, within ±0.01 μC. The maximum amount of adsorbed electroactive species is thus about 0.77 μC/cm² or 8×10^{-12} mole/cm²; this corresponds to a maximum electrode coverage of 2-3%. The slopes are proportional to C in all cases. The linearity of the Q *vs.* $t^{1/2}$ plots also indicates that polymerization is not important during

the duration of the chronocoulometric experiment, since any appreciable extent of polymerization would consume parent species and lead to a nonlinear plot.

Mechanistic information was obtained by double potential step chronocoulometry and chronoamperometry, using the variation of $Q(2t_f)/Q(t_f)$ and $i(2t_f)/i(t_f)$ with the duration of the potential step, t_f, to obtain the ratio parameters R_Q and R_I and the $T_{Q.4}$-value. These experimental R_Q and R_I *vs.* $T_{Q.4}$ curves were compared to the theoretical ones (Fig. 1) to establish the mechanism and determine the rate constant. Typical experimental data for DBF compared to theoretical curves for Mechanism 1 are shown in Fig. 3. The experimental values for the other compounds show essentially an equally good fit to Mechanism 1; complete data and curves are available (21). The experimental rate constants obtained for the dimerization from this data are listed in Table V. For those that have been determined before (DEF, DMeF, CN) (2-5), the results here are in good agreement with previously reported values.

Electrochemical results in the presence of alkali metal ions.—Addition of alkali metal salts causes the cyclic voltammograms for the reduction of the olefins to change—E_{pc} shifts slightly in a positive direction and i_{pa}/i_{pc} is decreased; typical results are shown in Fig. 4. The positive shift in E_{pc} is in the order $Li^+ > Na^+ > K^+$, and can be attributed to ion pair formation of the radical anion with the metal ion and an increased rate of the following dimerization reaction. The current functions $i_{pc}/v^{1/2}C$ were similar to those without alkali metal ions and they decreased slightly with increasing scan rate. The anodic peak current, i_{pa}, was much smaller with alkali metal ions present, indicating a much faster following chemical reaction. For a given scan rate and metal ion concentration, the voltammograms showed larger i_{pa}/i_{pc} ratios when the olefin concentration was decreased, indicating a higher order following chemical reaction. For a given cyclic voltammetric scan rate, concentration of olefin, and concentration of metal ion, i_{pa}/i_{pc} increased in the order $Li^+ < Na^+ < K^+$. Thus the rate of the dimerization reaction is in the order $Li^+ > Na^+ > K^+ >$ no added alkali metal ion.

Controlled potential coulometry experiments were performed on solutions of dimethyl fumarate, diethyl fumarate, dibutyl fumarate, ethyl cinnamate, cinna-

monitrile, and fumaronitrile in 0.20*M* TBAI-DMF with Li^+, Na^+, and K^+ ions added. Olefin concentrations ranged from 2.0 to 15.0 mM, while alkali metal ion (M^+) to olefin ratios up to ten to one were used. Typical n_{app}-values for solutions with 10 mM olefin and various $[M^+]/[\text{olefin}]$ ratios are shown in Table VI.

Experiments involving DBF, DEF, and DMeF with Li^+ added to the solution gave an n_{app} of 1.00 ± 0.03 when the $[Li^+]/[\text{olefin}]$ ratio was greater than four. The n_{app} decreased to the value obtained in the absence of alkali metal ion when the $[Li^+]/[\text{olefin}]$ ratio decreased. Experiments using LiI, $LiClO_4$, and $LiClO_4 \cdot 3H_2O$ as the source of Li^+ all gave essentially the same n_{app} values. The electrolysis times of the anhydrous solutions containing alkali metal ions were 10-25% longer than the same solutions lacking M^+ under the same electrolysis conditions. Solutions with

[a] All solutions were 10.0 mM in olefin in 0.20*M* TBAI-DMF solution.

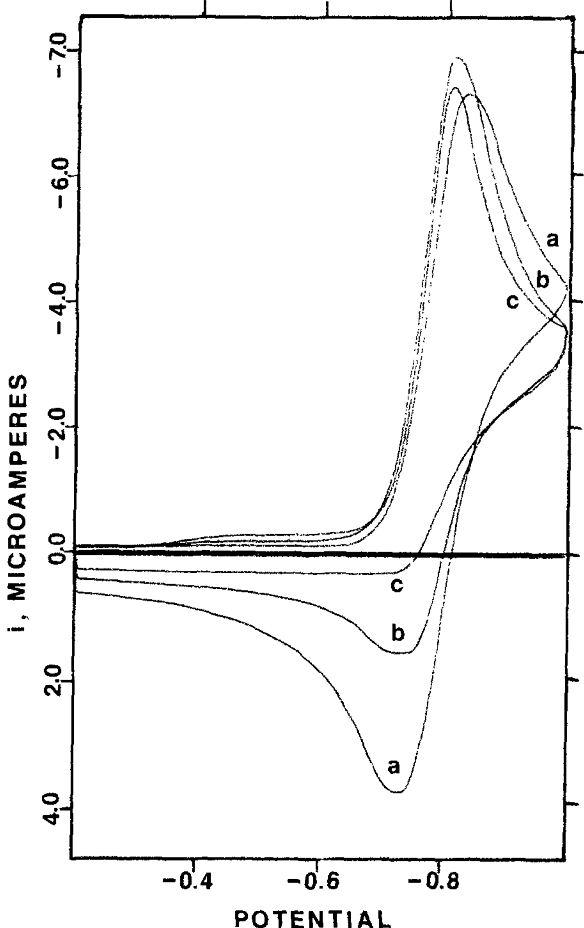

Fig. 4. Effect of Na^+ on the cyclic voltammetry of diethyl fumarate. The scan rate was 100 mV/sec and the DMF solution contained 0.20*M* TBAI, 1.49 mM DEF, and (a) 0, (b), 1.00 mM, (c) 12.0 mM NaI.

n_{app}-values close to one were colorless after the electrolysis, while solutions with n_{app}-values less than one had a yellow-brown color. During electrolysis with Li^+ present, a continuous formation of small bubbles was observed on the working electrode; the amount of these bubbles increased with increasing Li^+ concentration and were much more prevalent in the anhydrous solutions.

The n_{app}-values for the reduction of DMeF, DEF, and DBF were essentially unaffected by addition of Na^+ or K^+, even with $[Na^+]$ or $[K^+]$ to [olefin] ratios of 10/1 (film formation with DBF – K^+ solutions prevented an exhaustive electrolysis). Solutions containing Na^+ and K^+ were also characterized by a yellow-brown color after the electrolysis. The electrolysis times for solutions containing Na^+ and K^+ were three to five times longer than for solutions which did not contain alkali metal ions. We believe that a film of alkali metal hydroxide is formed during the electrolysis which partially blocks the electrode surface. This arises because the small hydrogen ion concentration that is present in solution is depleted in the vicinity of the electrode surface by the hydrodimerization reaction. When a small amount of water (0.1 ml per 50 ml DMF) was added as a weak proton source, the electrolysis times were reduced approximately 20%; however, they were still longer than the electrolysis times for solutions where no alkali metal ions were present. The water did not affect the n_{app}-values, but it did substantially increase the background current after electrolysis.

An NMR analysis was carried out on the electrolysis products for the reduction of DEF with Li^+ ($[Li^+]/[DEF]$) = 4.0 and K^+ ($[K^+]/[DEF]$ = 6.0) present. The NMR analysis could not be performed directly

on the electrolysis solution since the NMR spectra of the DMF and TBAI completely obscured the spectra of the electrolysis products. It was therefore necessary to extract the electrolysis products into methylene chloride, evaporate the methylene chloride and then obtain the NMR spectrum in carbon tetrachloride. The NMR of the electrolysis products were compared with those of pure samples of the hydrodimer (generously provided by Dr. M. Baizer of Monsanto, St. Louis, Missouri), diethyl succinate, and diethyl fumarate after they had undergone the same extraction process as the electrolysis products. The NMR spectrum of the Li^+ DEF electrolysis product was very similar to that of the pure hydrodimer, (1,2,3,4-tetraethyl butane tetracarboxylate); the electrolysis products, showed a small peak from unelectrolyzed DEF remaining in solution, and peaks from DMF carried over in the extraction. No singlet peak was observed at 7.50 τ, indicating that no dihydro product (diethyl succinate), was formed during the electrolysis. The NMR of the K^+-DEF electrolysis products gave spectra similar to that of the hydrodimer; however, each of the major peaks were split indicating several similar, but different, electrolysis products (*e.g.*, hydrodimer and polymer). When the K^+-DEF electrolysis products were vacuum distilled at 120°C, the distillate was a clear liquid (giving a hydrodimer NMR spectrum) while a brown tar remained in the distillation pot. The NMR spectrum of the brown tar exhibited the same number of peaks as the hydrodimer with slightly different chemical shifts. The NMR and n_{app} data indicate, in agreement with our previous results (2), that the polymerization reaction is eliminated and the hydrodimer becomes the only major electrolysis product upon addition of lithium ion, while, both sodium and potassium ions have no effect on the distribution of the final electrolysis products.

Electrolysis experiments were also carried out with fumaronitrile ($E_{pc} = -0.72$V *vs.* AgR.E.) to see if alkali metal ions affected its reduction products in a manner similar to that for the fumarates. The n_{app} in the absence of alkali metal ions was found to be approximately 0.40, which indicates that a polymerization reaction involving parent molecules occurs. In this case the addition of Li^+, Na^+, or K^+ had no effect on the n_{app}-value. The electrolyses of cinnamonitrile and ethyl cinnamate were obscured by electrode filming and the electrochemical reduction of the metal ions to metal.

The experimental results for potential step chronocoulometry are summarized in Table VII; typical $Q - t^{1/2}$ curves in the absence and presence of LiI and DBF are shown in Fig. 5. The addition of alkali metal iodide causes the intercept to increase above that characteristic of the 0.2*M* TBAI-DMF solution. If we assume that there is no specific adsorption of cation at the initial potential (0.00V), then this increase can be attributed to rapid adsorption of the alkali metal ion at −1.00V requiring additional (negative) charge to compensate for these adsorbed positive ions. Under these conditions the relative extent of adsorption of alkali metal ion follows the order $K^+ > Na^+ > Li^+$.[1] The intercepts with the olefins present were essentially the same as those in their absence, indicating no appreciable adsorption of DBF and DEF.

Chronocoulometric Q *vs.* θ plots for the reverse potential step, while slightly perturbed by the hydrodimerization reaction, gave intercepts close to the value (±0.04 μC) obtained for the forward step both in the absence and presence of DBF and DEF for all three alkali metal ions. This indicates that neither the radical anions produced nor any metal ion-radical anion ion-pair formed is appreciably adsorbed on the electrode surface.

[1] Another interpretation of the results, suggested by a reviewer, is adsorption of alkali metal ion at the initial potential which leads, through cooperative adsorption, to even greater adsorption of I^- and an initial increase in positive charge on the electrode.

[a] Solutions were 0.20*M* TBAI in DMF. E_i = 0.000V and E_f = −1.000V *vs.* AgR.E.
[b] Electrode filming occurred in DBF-KI solutions under these conditions.

Information about the reaction mechanism in the presence of alkali metal ions was again obtained by double potential step chronocoulometry and chronoamperometry, using the experimental R_Q, R_I, and $T_{Q,4}$-values to test theoretical models and obtain rate constants. Even in the presence of alkali metal ions, the results for reduction of DEF and DBF show the best fit with Mechanism 1 (dimerization of radical anions); typical experimental results are shown in Fig. 6. The over-all rate constants, k_{obs}, for the dimerizations as calculated from these results for different olefin and alkali metal ion concentrations are given in Table VIII. The reaction order with respect to alkali metal ion concentration was first estimated

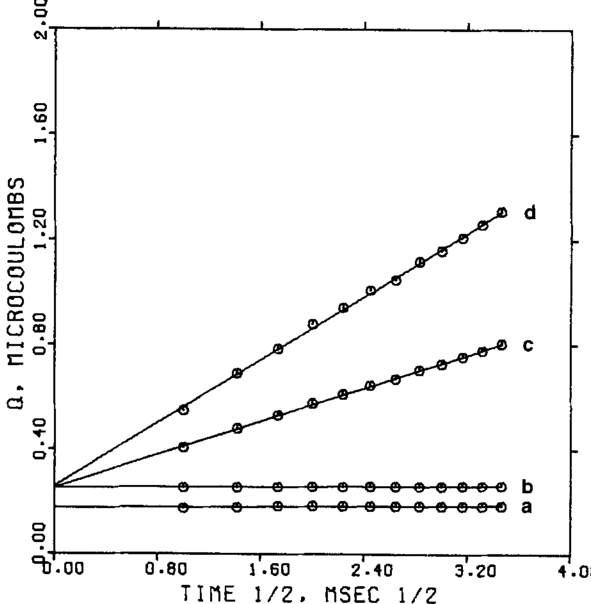

Fig. 5. Chronocoulometric data (Q vs. $t^{1/2}$) for dibutyl fumarate. The potential was stepped from 0.00 to −1.000V vs. AgR.E. and the DMF solution contained 0.20*M* TBAI and (a) 0 DBF, 0 LiI; (b) 0 DBF, 1.00 mM LiI; (c) 1.69 mM DBF, 1.00 mM LiI; (d) 3.40 mM DBF, 7.90 mM LiI.

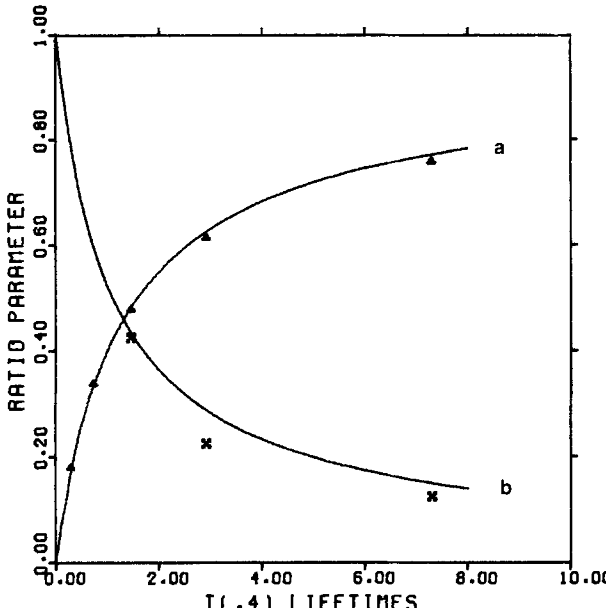

Fig. 6. Variation of the normalized coulomb (a) and current (b) ratio parameters as a function of $T_{Q.4}$ lifetimes for the reduction of 0.95 mM diethyl fumarate with 3.81 mM LiI in 0.20M TBAI-DMF solution. [a] All solutions contained 0.2M TBAI in DMF.

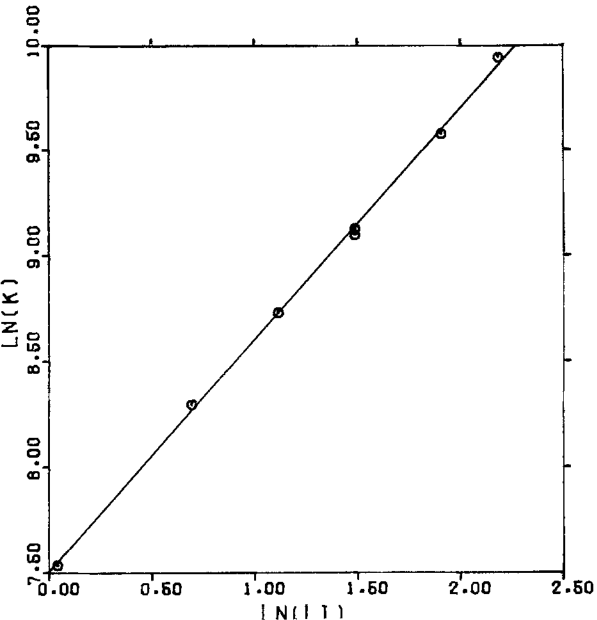

Fig. 7. Variation of ln k_{obs} with ln $[Li^+]$ for the electroreduction of diethyl fumarate in 0.20M TBAI-DMF.

0.85 ± 0.03. At ratios of M^+ to olefin less than 0.8, a larger deviation from first order dependence on M^+ was observed, because of the contribution to the over-all rate by the direct dimerization of the radical ions. Since the reactions were close to first order, the reaction mechanism most closely followed Eq. [7] and the appropriate kinetic expression is [16] or [18]. Thus the over-all rate constant, k_{obs}, is approximately $k_{21}K[M^+]$; the values of $k_{obs}/[M^+] \simeq k_{21}K$ given in Table VIII are fairly constant, as expected. The ion-pair formation constant for $DEF^{\cdot -}$ with Li^+, Na^+, and K^+ cations was estimated by the cyclic voltammetric potential shifts on the DEF reduction wave with the addition of alkali metal ions. The observed potential shifts are a result of both ion-pairing and the increased dimerization rate. The potential shift due to the hydrodimerization reaction can be estimated by using the theory of cyclic voltammetry in the presence of a dimerization reaction (6, 31) and the rate constant calculated by chronocoulometry. Once this has been calculated, the shift due to ion-pairing can be extracted, and the ion-pair formation constant is then estimated using Eq. [4]. For example, for a solution containing 1.49 mM DEF and 8.00 mM Na^+ a peak potential shift (compared to a solution in the absence of Li^+) of 14 mV is observed. Of this, using the measured k_{obs} value of 5.8×10^3 M^{-1} sec^{-1}, 11 mV can be attributed to the following dimerization reaction. The residual 3 mV then yields an ion-pair formation constant K of about 6 M^{-1}. This procedure gives K-values of 29, 6, and 2 for ion-pairs of $DEF^{\cdot -}$ with Li^+, Na^+, and K^+, respectively. These values seem to be generally in line with previously determined values of association constants in DMF; for example Peover and Davies (12) report a K of about 39 M^{-1} for p-benzoquinone anion and Li^+ while Lasia and Kalinowski (15) report K's of 120 and 41 for ion pairs of Li^+ with fluorenone and indantrione radical anions, respectively. Using these K-values, a somewhat more detailed analysis of the kinetic data can be made. From the over-all rate expression for the reaction, Eq. [20], we find a k_{obs} given by Eq. [22]

$$k_{obs} = (k_2 + k_{21}K[M^+] + k_{22}K^2[M^+]^2/(1 + K[M^+]^2) \quad [22]$$

Taking $K[M^+] = x$, this expression can be rearranged to

$$k_{obs}(1 + x)^2 - k_2 = k_{21}x + k_{22}x^2 \quad [23]$$

A plot of the left-hand side of [23] against x allows

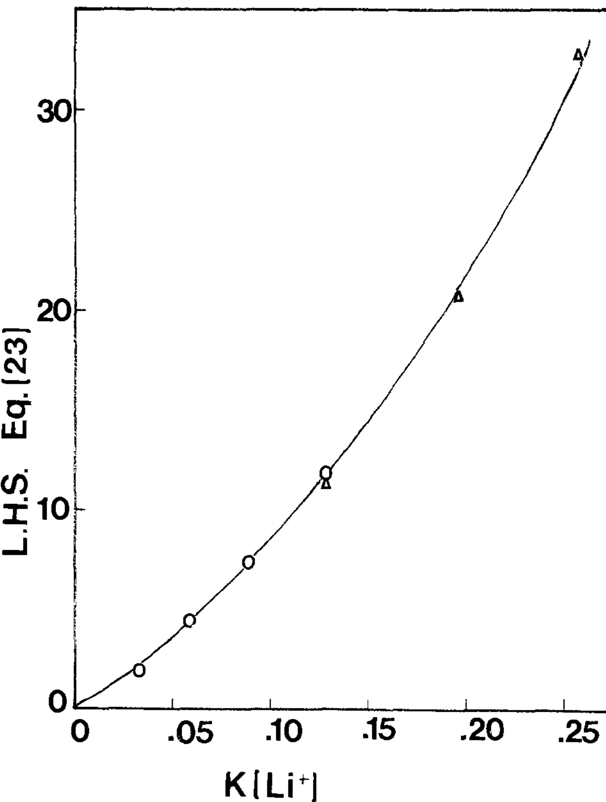

Fig. 8. Variation of lefthand side of Eq. [23] (equal to $k_{obs}(1 + K[Li^+])^2 - k_2$) against $K[Li^+]$ with the data for the electroreduction of diethyl fumarate in 0.20M TBAI-DMF. The points are the experimental results at (○) 1.13 mM DEF and (△) 2.01 mM DEF and the line the calculated result with the rate constants listed in Table IX.

one to estimate the k_{21} and k_{22}-values; a typical plot for DEF-LiI is shown in Fig. 8. The values of k_{21} and k_{22} estimated by this procedure are given in Table IX. (A similar calculation for DBF, assuming the K-values for $DBF^{\cdot-}$ are the same as $DEF^{\cdot-}$ yields 3.2×10^4 and 5.7×10^4 M^{-1} sec^{-1} for k_{21} with LiI and NaI, respectively). Extension of rate measurements to higher M^+ concentrations to obtain more reliable values for k_{22} were limited by the reaction becoming too fast to measure by our techniques for Li^+, and the appearance of electrode filming in the case of Na^+ and K^+.

We have assumed in this treatment negligible association of the metal ions with supporting electrolyte (I^-) ion. This appears to be in agreement with previous measurements on alkali metal ion iodides and perchlorates in DMF (12, 32). Several experiments were also performed using $LiNO_3$ or KNO_3 (instead of the iodides) in the 0.2M TBAI-DMF solvent on the electroreduction of DEF. While the second-order dependence in DEF and primarily first-order dependence in metal ion was still observed, the $k_{obs}/[M^+]$ values obtained (6.6×10^6 and 1.1×10^6 M^{-1} sec^{-1} for $LiNO_3$ and $NaNO_3$, respectively) were about twice those of the iodide salts. The reasons for these differences, which are well outside the experimental error limits of the measurements, are not clear, but suggest that impurities (e.g., water of hydration), adventitiously added with alkali metal ion salt, may have an effect on the reaction rate.

Discussion

The results generally show that reductive coupling of 1,2-diactivated olefins involve dimerization of radical anions both in the absence and presence of alkali metal ions. Adsorption of the parent olefins or the radical ions does not appear to be an important step in the reaction sequence. The linearity of the $Q - t^{1/2}$ plots suggests that the polymerization reactions which are of importance on the controlled potential coulometric time scale, do not interfere with the short time voltammetric measurements. In agreement with the previous results (2) we have found that addition of Li^+ decreases the extent of polymerization on bulk electrolysis. The mode by which this occurs has not been established, however two possibilities appear reasonable. If the dimer dianion, R_2^{2-}, is ion-paired with Li^+, it may be less reactive towards R and so show less polymerization. If this were the case, however, it is difficult to understand why Na^+ and K^+ have such a small effect on the coulometric results. A second possibility is that Li^+ increases the rate of protonation of R_2^{2-}. Li^+ is known to be quite acidic and hence coordinates strongly with traces of water in the DMF. This coordinated water will be a better proton donor than uncoordinated water and may be brought to close proximity to the dimer dianion by the ion-paired Li^+. Na^+ and K^+ should show this effect to a much more limited extent. The increased acidity of water in the presence of Li^+ apparently does not cause appreciable protonation of the radical anion itself, since no evidence of the 2e reduction products was found. Additional evidence of the higher proton availability in the presence of Li^+ are the small bubbles observed during coulometry when Li^+ is present. These probably are caused by a small amount of H^+-reduction at the electrode, concurrent with olefin reduction, forming some hydrogen gas bubbles. Electrode filming in the presence of the alkali metal ions, especially at higher concentrations can be attributed to the formation of insoluble hydroxides upon hydrolysis (*i.e.*, deprotonation) of the aquated ions. Similar hydrolysis of metal ions and filming have been observed in nonaqueous solvents (33, 34).

The study also provides some new information on the dependence of radical anion dimerization rate on structure. For the dialkyl fumarates, the dimerization rate constant and diffusion coefficients decrease in the order Me > Et > n-Bu. Apparently, the bulkier the alkyl group, the slower is the movement through solution and the more hindered the dimerization reaction. The rate of dimerization of ethyl cinnamate (EC) radical anions (140 M^{-1} sec^{-1}), compared to that for DEF (44 M^{-1} sec^{-1}) may at first appear anomalously large, since EC can be considered to have a structure between DEF (2 $-CO_2$ Et groups) and stilbene (2 phenyl groups), whose $R^{\cdot-}$ dimerization rate is very slow. However, consideration of the resonance structures of the radical anions of the two compounds suggests that while DEF has several structures where electron density is not on the ethylenic carbon, *e.g.*, structure

Grypa and Maloy (35) recently also found a rate of disappearance of electrogenerated EC radical anion higher than that for DEF; their interpretation of the results differs from that given here, however.

The major conclusion of this study is that alkali metal ions increase the dimerization rate of radical anions by ion pair formation, thereby decreasing the electrostatic repulsion in the coupling of the bare anions. The reaction is predominantly first order in metal ion at low Li^+ and Na^+ and all K^+ concentrations, leading to a mechanism involving reaction of free radical anion with ion pair. At higher Li^+ and Na^+ concentrations coupling of two ion pairs becomes significant. Considering the results for DEF (Table IX) where fairly similar k_{21}-values are observed for the different alkali metal ions, we can speculate that the rate of the ion pair-radical anion reaction is roughly independent of metal ion and the different over-all rates observed depend upon different ion pair association constants. After this work was completed a note by Ryan and Evans (36) appeared in which the effect of Na^+ on DEF hydrodimerization in DMSO was investigated. Although the free anion dimerization rate in that solvent was much larger than that found in DMF, their values for k_{21} and k_{22} were remarkably close to those found in this study.

Effects of Procarbazine on Ti(IV) Reduction at the DME

John P. McCue* and John H. Kennedy**

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

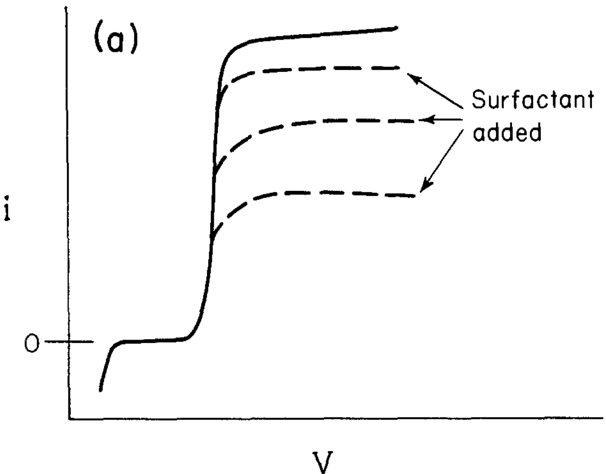
Procarbazine, an anti-Hodgkin's disease drug, adsorbs on the dropping mercury electrode and causes the reduction of titanium(IV) to occur at more negative potentials. Only one wave due to titanium was observed even when the ratio of procarbazine to titanium was considerably less than one. These observations are interpreted as the formation of a titanium-procarbazine complex at the electrode surface which is then reduced.

In 1968 Carrol and Tullis (1) reported observations of titanium in leucocytes of peripheral blood and lymph nodes. McCue (2) confirmed these observations for peripheral blood and further showed them to be specific for the white cells of Hodgkin's and leukemia subjects. In the process of studying the chemical interactions between Ti(IV) and certain antineoplastic drugs, we found that procarbazine, an anti-Hodgkin's disease drug, was adsorbed on the dme and that upon addition of small amounts of procarbazine to Ti(IV) solutions the polarographic reduction wave of titanium was shifted to more negative potentials with an increase in reversibility for this electrochemical process. We now report a mechanistic interpretation of these and related observations.

In the past, the influence of surface active agents on reduction of metal ions at the dme have mainly been interpreted as kinetic effects (3). By setting up a "barrier" to the metal ion at the Hg surface the surfactant kinetically hinders or prevents the metal ion from undergoing reduction. A larger activation energy for reduction at the covered surface results, with little or no effect on the relative energies of the oxidized and reduced forms of the couple.

In terms of wave shapes and responses the effects of surfactants can be divided into two cases. The first case occurs when the metal ion is reversibly reduced in the absence of surfactant. The kinetic effect of addition of surface active agent to such metal ions is shown in Fig. 1a, and the theoretical explanation for this effect is schematically given in Fig. 2a. In this case $\Delta G^{\ddagger}_{rev}$ is small compared to $\Delta(\Delta G^{\ddagger}_{rev})$ so that for working potentials less than that required to activate path 2 only path 1 is electrochemically active. The net effect of surfactant is to decrease the available surface area at which the reduction can occur, and this results in a decrease in i_d for the polarographic wave (Fig. 1a). At any potential large enough to activate both paths, path 1 will be $e^{+\Delta(\Delta G^{\ddagger}_{rev})/nFV}$ times more electrochemically active than path 2; therefore when $\Delta G^{\ddagger}_{rev} << \Delta(\Delta G^{\ddagger}_{rev})$ the effect of path 2 is negligible, and no shift in $E_{1/2}$ is observed since the reaction occurs predominantly on the free surface. When the entire dme surface is covered with surfactant, only path 2 exists and the electrochemical process becomes slower and thus irreversible. If $\Delta(\Delta G^{\ddagger}_{rev}) < 3\Delta G^{\ddagger}_{rev}$ at ambient conditions, path 2 becomes significant and a small broadening or tilting of the polarographic wave occurs.

The second case occurs when the metal ion is irreversibly reduced in the absence of a surfactant. For this case $\Delta G^{\ddagger}_{irrev}$ is so large that the electrochemical reaction at the free surface is slow; when surfactant is added $\Delta(\Delta G^{\ddagger}_{irrev})$ is small (Fig. 2b). Thus, the electrochemical reaction at the covered surface (path 2) is not negligible relative to the free surface (path 1). At applied potentials less than that required to activate path 2, the electrochemically active surface area is reduced similar to the reversible case. But unlike the reversible case, increasing the applied voltage significantly activates path 2. Since this path is more irreversible (*i.e.*, greater activation energy) than path 1, the resultant polarographic wave is more irreversible (*i.e.*, becomes broader as shown in Fig. 1b). These two



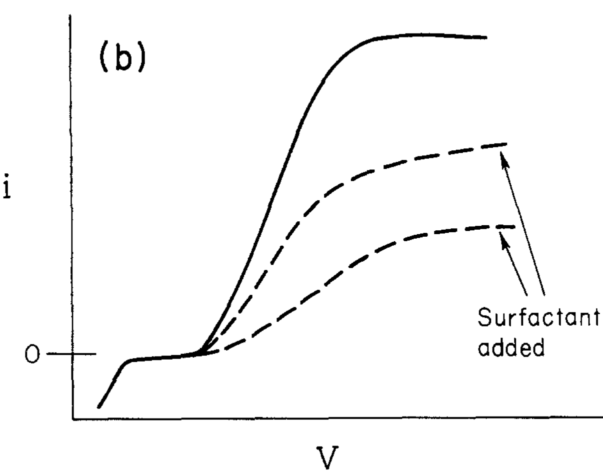


Fig. 1. Effect of surfactant on reduction of metal ion. (a) Reversible case and (b) irreversible case.

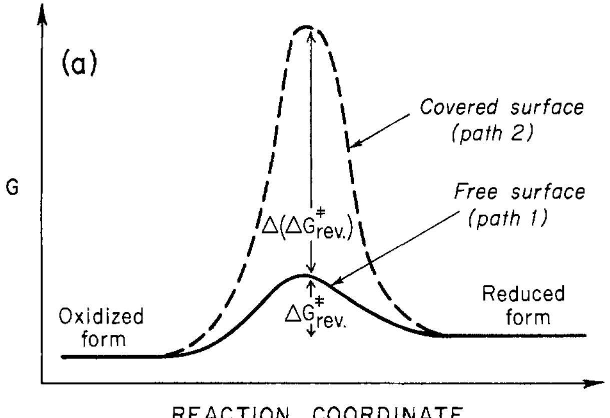

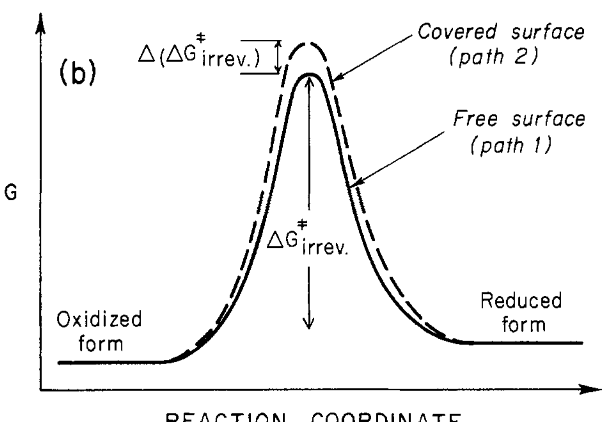

Fig. 2. Effect of surfactant on activation energy. (a) Reversible reduction in the presence of a surfactant and (b) irreversible reduction in the presence of a surfactant.

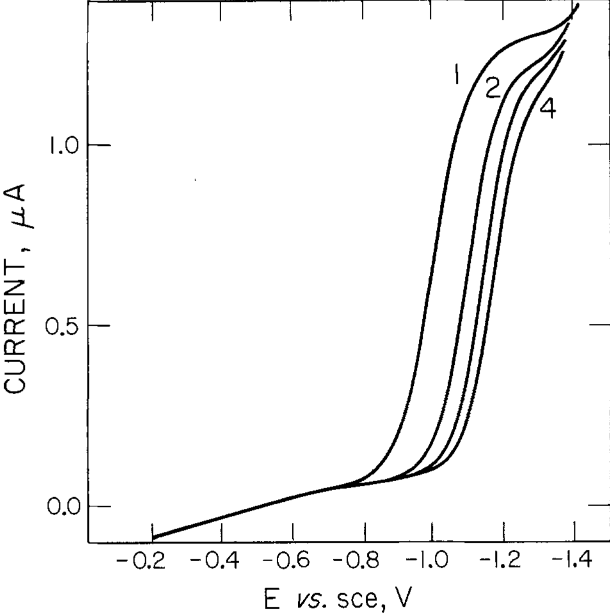

Fig. 3. Polarographic wave for 1, 20 ml of 0.6 mM Ti(IV) in 0.2M NaCl; 2, with addition of 0.5 ml of 2 mM procarbazine solution; 3, with addition of 1.0 ml of 2 mM procarbazine solution; and 4, with addition of 2.0 ml of 2 mM procarbazine solution. Drop time 1 sec and scan rate 5 mV/sec.

cases have been well documented (4-10), and their interpretation as kinetic effects are supported by theoretical calculations (11).

In contrast with the above observations, addition of the surface active agent procarbazine (at concentrations less than the metal ion) to Ti(IV) solutions causes a shift of the metal polarographic reduction wave to more negative potentials accompanied by an increase in the reversibility of the reduction process. Such behavior is identical to that seen (12) when a tenfold excess of complexing agent is added to a metallic depolarizer being monitored at the dme. Thus polarography of Ti(IV)-procarbazine mixtures displays features common to both surface active phenomena and metal ion complexation phenomena. These common features suggest that procarbazine below millimole concentration is adsorbed on the dme surface, the adsorption gives rise to a large procarbazine concentration at the surface, and that Ti(IV) at the surface reacts with this surface-concentrated procarbazine to produce a Ti(IV)-procarbazine complex for which reduction is more reversible than the Ti(IV) species in bulk solution. For such a process to occur certain critical conditions must be met, an investigation of these conditions is presented here.

Experimental

Stock aqueous solutions of Ti(IV) were prepared by adding 99.5% $TiCl_4$ (Matheson, Coleman and Bell) to concentrated HCl (Baker Analytical Grade) and diluting with deionized water. These solutions could then be diluted without hydrolysis if added to deionized water. When other chemicals were required in the titanium solutions they had to be added after dilution.

Procarbazine was supplied both as drug (Matulane®) and pure form by Roche Laboratories. Aqueous stock solutions were made by dissolving either source in deionized water with addition of HCl to *p*H 3.

Solutions were made basic by addition of NaOH or solid $NaHCO_3$ (Mallinckrodt-AR grade). *p*H was measured using a Beckman glass electrode No. 40498, and control during the polarographic experiments was accomplished by adjustment with HCl or NaOH initially and verification after the experiments. Buffer systems were not used because they would act as ligands for titanium and complicate the system further.

Polarography was accomplished with a "PAR-174 Polarographic Analyzer" equipped with a Houston Instruments "Omnigraphic-2000" X-Y recorder and a two electrode "H" cell with sce reference. Visible and u.v. spectroscopy was carried out with a Cary 14 Spectrometer.

Results and Discussion

When aliquots of 2 mM procarbazine solution were added to a 0.6 mM Ti(IV) solution, 0.2M in NaCl at *p*H 2, being monitored at the dme, Fig. 3 resulted. This behavior of the Ti(IV) polarographic wave was similar to the behavior of Cd^{+2}, Cu^{+2}, and Sn^{+2} ions in solution when a many-fold excess of complexing agent was added (13-15). However, for curve 3 in Fig. 3 for example the procarbazine-Ti(IV) molar ratio was 1:6, far below that normally required for a complexing agent to produce the observed $E_{1/2}$ shift of -0.095V. Accompanying the $E_{1/2}$ shifts were small reductions in i_d (Table I). Although this suppression of i_d indicated that procarbazine was probably adsorbed at the dme,

Table I. Decrease in diffusion current and $E_{1/2}$ shift for 0.6 mM Ti(IV) upon addition of procarbazine

Procarbazine, mM	i_d,[a] μA	$\Delta E_{1/2}$, V
0	0.85	0
0.01	0.82	−0.010
0.10	0.81	−0.095
0.20	0.80	−0.130

[a] Corrected for dilution.

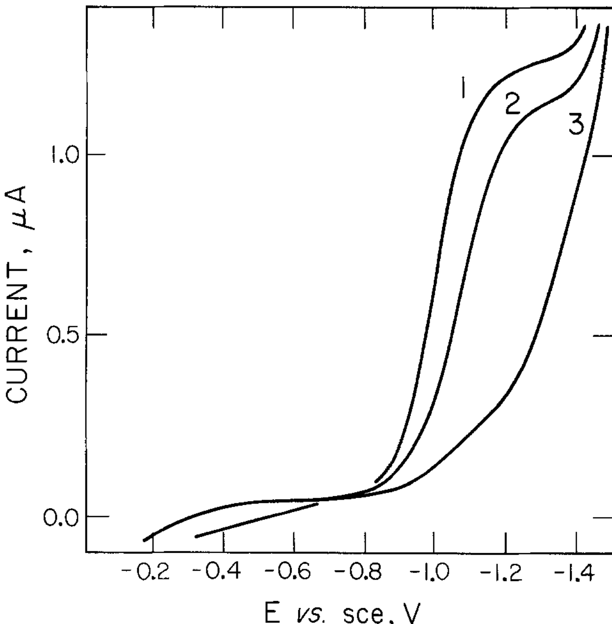

Fig. 4. Polarographic wave for 1, 20 ml of 0.6 mM Ti(IV) in 0.2M NaCl; 2, with addition of 0.5 ml of 2 mM Triton X-100 solution; and 3, with addition of 2.0 ml of 2 mM Triton X-100 solution. Drop time 1 sec and scan rate 5 mV/sec.

the change in slope for the Ti(IV) polarographic wave did not resemble that expected for a kinetically shifted wave (Fig. 4). When $E - E_{1/2}$ for the Ti-procarbazine system was plotted against $\log(i_d - i)/i$ the slope was 122.5 mV in the absence of procarbazine and 87.5 mV in the presence of procarbazine (0.1 mM procarbazine: 0.6 mM Ti(IV)). Thus, addition of procarbazine made the reduction of Ti(IV) appear more reversible, in contrast to the behavior expected for a kinetic phenomenon.

The above behavior can be explained by invoking a mechanism where (*i*) procarbazine adsorbs on the dme, (*ii*) Ti(IV) approaches the electrode and experiences a large procarbazine concentration with which it reacts to form a Ti(IV)-procarbazine complex, and (*iii*) this complex is reduced in a more reversible manner than the Ti(IV) in bulk solution.

The requirements made by this mechanism are:

1. The bulk [Ti(IV)] does not deplete the solution of free procarbazine.
2. The surface of the dme has reached maximum coverage with procarbazine by the time the depolarizer current is sampled.
3. The [procarbazine] at maximum coverage is sufficient to displace ligands from Ti(IV).
4. Ti(IV) forms a complex with procarbazine which is reduced more reversibly at the dme.

The first requirement can be met as a result of the observation that for ligand exchange reactions such as

$$ML_1 + L_2 \underset{\text{excess } L_1}{\overset{\text{excess } L_2}{\rightleftharpoons}} ML_2 + L_1$$

the equilibrium favors complex formation with the ligand which is in excess, provided the stability constants are comparable. For the system described in this paper (*i.e.*, procarbazine/Ti = 1/6) both the $[Cl^-]$ and $[H_2O]$ exceed procarbazine by at least 10^3 in bulk solution. Thus one could expect procarbazine to be primarily in its free form. This was experimentally confirmed by monitoring the u.v. spectrum of procarbazine as Ti(IV) was added. When Ti(IV) was added to a 0.2 mM solution of procarbazine a shoulder developed at 260 nm on the free procarbazine peak at 233 nm indicative of some complex formation, but the peak height at 233 nm decreased only slightly. Thus, it was found that even for tenfold excess of Ti(IV), procarbazine was predominantly in the free form.

Table II. Effect of procarbazine on the zinc polarographic wave

Metal ion	Concentration, mM	Procarbazine, mM	i_d,[a] μA
$ZnCl_4(H_2O)_2^{2-}$	0.2	0.	1.04
		0.01	1.02
		0.10	0.97
		0.20	0.96

[a] Corrected for dilution.

The second requirement involves adsorption of procarbazine on the dme. It also requires that the adsorption be fast enough so that the process is complete before the depolarizer current is sampled (*i.e.*, less than 1 sec).

Suppression of i_d for Ti(IV) reduction upon addition of procarbazine could indicate that procarbazine was being adsorbed on the dme However, if adsorption did occur, addition of procarbazine to other metal ion solutions should also show suppression of i_d. Thus, the behavior of Zn(II) upon addition of procarbazine was examined at the dme.

In the case of Zn(II), addition of procarbazine caused small decreases in i_d (see Table II) with a slight tilting of the polarographic wave (Fig. 5). In addition, the usual maximum observed for this solution disappeared upon addition of procarbazine to 0.01 mM. Such maximum supression, reduction of i_d, and tilting of the polarographic wave are characteristic of adsorption by a surfactant. Thus, these results indicate that procarbazine was adsorbed on the dme.

With regard to the requirement that the adsorption be complete before the depolarizer current is sampled, Delahay and Trachtenberg (16) have experimentally shown that coverage is essentially complete within 1 sec for the surface active agents cyclohexanol, *n*-amyl alcohol and thymol, which was the time at which current was sampled in this study.

For the requirement that the procarbazine concentration at the surface be significantly larger than in the bulk solution, an order of magnitude calculation clearly shows that the concentration of adsorbed procarbazine at the electrode surface is significantly higher than the bulk concentration.

The quantity of surfactant adsorbed per cm^2 at time t before adsorption is complete at the dme is given

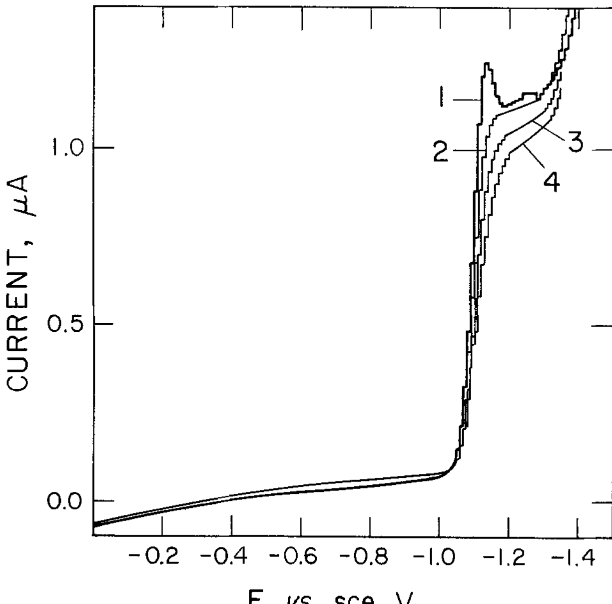

Fig. 5. Polarographic wave for 1, 20 ml of 0.2 mM $ZnCl_2$ in 10 mM HCl; 2, with addition of 0.1 ml of 2 mM procarbazine; 3, with addition of 1.0 ml of 2 mM procarbazine; and 4, with addition of 2.0 ml of 2 mM procarbazine. Drop time 1 sec and scan rate 5 mV/sec.

by (17)

$$\Gamma = 7.36 \times 10^{-4} [S] \sqrt{D_s} \sqrt{t}$$

If we assume that

$$D_s = 10^{-5} \text{ cm}^2/\text{sec}$$
$$[S] = 0.1 \text{ mM procarbazine}$$
$$t = 1 \text{ sec}$$

then

$$\Gamma = 2.3 \times 10^{-7} \text{ mmoles/cm}^2$$

If the double layer at the dme is assumed 1000Å then the concentration of surfactant within the electrolyte layer around the electrode will be

$$[S_{\text{adsorbed}}] = 2.3 \times 10^{-7}/10^{-5} \text{ mmoles/cm}^3 = 23 \text{ mM}$$

Thus the concentration of procarbazine at the surface is > 100 times that of the bulk solution, and ~ 30 times that of Ti(IV). Although this concentration gradient between bulk solution and the double layer is consistent with our model for the behavior of the Ti(IV) polarographic wave in the presence of small amounts of procarbazine, it does not establish that the procarbazine concentration at the electrode surface was large enough to form a Ti-procarbazine complex in the presence of Cl^- and H_2O. Therefore, it was necessary to examine chemically if a Ti-procarbazine complex formed in 10 mM procarbazine solutions. This was done by examining the stability of Ti(IV) against precipitation as TiO_2 in procarbazine solutions as the solution *p*H was increased. Ti(IV) will essentially precipitate completely as TiO_2 from aqueous solutions at or above *p*H 6 if no complexing agent is present to prevent attack on the metal by OH^-. If an excess of complexing agent such as phosphate or citrate is present it will prevent such precipitation.

When Ti(IV) was mixed with procarbazine in a 13:1 procarbazine:Ti mM ratio at *p*H 2, no precipitation of TiO_2 was observed as the *p*H was increased to 12 by addition of NaOH. Similar experiments in which 0.02g $NaHCO_3$/ml of solution was used to increase the *p*H to 8.5 gave similar results. (When larger amounts of $NaHCO_3$ were used to increase the *p*H Ti(IV) precipitated quantitatively as the carbonate species.)

When the procarbazine to Ti(IV) ratio was 2:1 similar results to the above were observed for both addition of NaOH and $NaHCO_3$, but when the ratio was 1:1 partial precipitation of Ti(IV) occurred from the procarbazine solutions. These results clearly indicate that the procarbazine concentration at the dme surface in a solution of 0.1 mM bulk concentration is sufficient to form a Ti(IV)-procarbazine complex.

One further experiment exemplifies the role which procarbazine plays at the dme. It was observed that H^+ ion reduction at *p*H 2 in the presence of procarbazine produced a "spike" shaped polarographic wave characteristic of strong adsorption of H^+ at the electrode. When Ti(IV) was added in tenfold excess to the procarbazine solution the H^+ reduction wave returned to a normal shape. Thus the presence of excess Ti(IV) eliminated the adsorption of H^+ caused by procarbazine, indicating that a reaction between the metal and procarbazine occurred at the electrode surface.

Finally, it was necessary to show that the new waves observed when procarbazine was added to Ti(IV) solutions were due to a Ti-procarbazine complex. This was shown to be the case by following the behavior of these waves when the known Ti(IV) complexing agent H_3PO_4 was added to the Ti(IV)-procarbazine solutions. Since H_3PO_4 forms a strong complex with Ti(IV) which can be observed at the dme, incremental addition of H_3PO_4 to a Ti-procarbazine solution should increase the wave height of the known (18) Ti-phosphoric acid wave stepwise at the expense of the Ti-procarbazine wave height.

When 20 ml of 0.4 mM Ti(IV) solution, 0.257M in NaCl at *p*H 2, was mixed with 5 ml of 2 mM procarbazine solution the Ti(IV) reduction shifted from −0.990 to −1.130V *vs.* SCE, then upon addition of H_3PO_4 a new wave appeared near −0.4V with loss of wave height at −1.130V. When the H_3PO_4 concentration reached 1M, the wave at −1.130V disappeared with the appearance of a Ti-phosphoric acid complex wave at −0.420V (Fig. 6). These results showed that the wave which appeared upon addition of procarbazine to Ti(IV) solutions was due to a Ti-procarbazine complex.

The above mechanism also predicts the proper quantitative response of $E_{1/2}$ to addition of procarbazine. The general equation for the effect of a complexing agent on $E_{1/2}$ of an irreversible reduction of metallic depolarizer is given by (19)

$$E_{1/2}{}^c = E_{1/2}{}^s + \frac{RT}{\alpha n\mathbf{F}} [\ln 0.886\, k_e{}^o \sqrt{t/D} - \ln(k_x k_{x-1} \ldots k_{i+1}) - \ln[L]^{x-j}]$$

where the usual assumption has been made that only a ligand unsaturated metal species is electrochemically active, and this species is in equilibrium with all other metal-ligand species at the electrode surface. The half-wave potential of the complex, ML_x, is more negative than that of the free ion since the ion must first be liberated from the complex before it undergoes reduction. This requires energy and is reflected in a more negative $E_{1/2}$. From the above equation it is seen that a plot of $E_{1/2}$ against $\ln[L]$ will allow $x - j$ to be determined.

If L is adsorbed on the dme surface in linear proportion with addition of L to the bulk solution, then $[L] = a[L_o]$ where $[L_o]$ is the concentration of ligand in bulk solution, $[L]$ is the concentration at the surface, and a is a proportionality constant greater than one. Substituting these relationships into the above equation gives

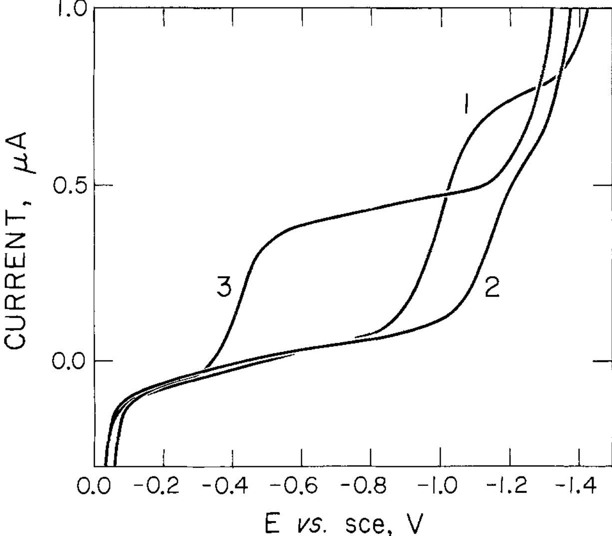

Fig. 6. Polarographic wave for 1, 0.4 mM Ti(IV) in 0.257M NaCl; 2, with addition of 5 ml of 2 mM procarbazine; and 3, with addition of 1 ml of 18M H_3PO_4. Drop time 1 sec and scan rate 5 mV/sec.

Fig. 7. Possible molecular configuration derived from to scale three dimensional models for a 1:1 Ti(IV)-procarbazine complex.

$$E_{1/2}{}^{c} = E_{1/2}{}^{s} + \frac{RT}{\alpha n\mathbf{F}} [\ln 0.086\, k_e{}^{o} \sqrt{t/D} - \ln K - (x - j)\ln a - (x - j)\ln[L_o]]$$

In using this equation it has been assumed that a steady-state condition was reached between the bulk metal ion concentration and the concentration of the complex ML_x in the double layer at the time the depolarizer current was sampled.

A plot of $E_{1/2}{}^{c} - E_{1/2}{}^{s}$ against $-\log[L_o]$ gives a slope of $2.3\, RT/n\mathbf{F}\ (x - j/\alpha)$. Such a plot constructed for the addition of small amounts of procarbazine to Ti(IV) solutions resulted in a slope of 91.66 mV and $x - j/\alpha = 1.554$. If $x - j = 1$, then $\alpha = 0.6436$, and our model is consistent with the observed shift in $E_{1/2}$; any other integer value of $x - j$ would lead to unrealistic values of α.

Thus we have found the experimental evidence to be consistent with our model for polarography of Ti(IV) in the presence of procarbazine. The adsorption of procarbazine on the dme allows its concentration to build up to at least 10 mM in the double layer, this double layer concentration is then sufficient to displace H_2O or Cl^- from the Ti(IV) species diffusing in from the bulk solution, and the new Ti-procarbazine complex formed in the double layer is the one involved in the electrochemical process at the dme. The nature of the electrochemical process itself, however, is not known. We are in the process of determining whether Ti(IV) dislodges procarbazine from the Hg surface or whether Ti(IV) is itself attached to the Hg surface through a procarbazine bridge. This latter case is possible because there are two coordination sites on procarbazine. The fact that this molecule has more than one coordination site of different chemical nature allows for both titanium complexation as well as adsorption. Finally, it should be pointed out that in the past most investigators have not looked at low levels of ligand concentrations and thus this effect may not be as rare as it appears.

Acknowledgment

We thank Roche Laboratories for supplying procarbazine samples.

Manuscript submitted July 8, 1974; revised manuscript received Oct. 18, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

LIST OF SYMBOLS

- a adsorption coefficient, has values greater than 1.
- α transfer coefficient, has values between 0 and 1.
- E potential in volts
- $E_{1/2}{}^{c}$ half-wave potential for complex metal ion.
- $E_{1/2}{}^{s}$ half-wave potential for simple metal ion.
- $\mathbf{F}$ the Faraday
- G free energy
- $G^{\ddagger}$ free energy of activation
- D diffusion coefficient of metal ion
- D_s diffusion coefficient of surfactant
- i current in μA
- j the number of ligands, L, coordinated to the electrochemically active metal species at the Hg surface
- k_n the stepwise equilibrium constants for formation of each complex ML_n in solution
- $k_e{}^{o}$ rate constant for the electron transfer process
- K over-all formation constant for ML_n
- $[L]$ concentration of ligand
- R gas constant
- $[S]$ concentration of surfactant
- t time in sec
- T temperature °K
- X maximum number of ligands, L, coordinated to the metal species as it approaches the Hg surface
- Γ quantity of surfactant adsorbed at time t per cm^2 of the Hg drop surface

An Analysis of the Impedance of Polycrystalline Beta-Alumina

R. W. Powers* and S. P. Mitoff

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

A procedure is described in this paper for distinguishing in the measured electrical properties of polycrystalline β-alumina, the separate contributions of the grain boundaries and of the crystal, *i.e.*, the grain interiors. This separation is brought about through the use of a model for these properties. Certain quantitative consequences of the model are developed and compared with experimental results. For most sintered β-alumina ceramic, the electrical properties are determined more by the characteristics of the grain boundaries than by those of the interior of the grains.

Polycrystalline β-alumina is used in electrochemical devices to circumvent the deleterious high anisotropy in the electrical and mechanical properties of single crystals. Use of the polycrystalline ceramic does require, however, consideration of the effects of grain boundaries. A procedure is described here for distinguishing in the measured electrical properties of the ceramic, the separate contributions of the grain boundaries and of the crystal, *i.e.*, the interior of the grains. This separation is brought about through the use of a model for the electrical properties of β-alumina. Certain quantitative consequences of this model are developed and compared with experimental results.

Previous Work

The conductivity both of β-alumina single crystals and of polycrystalline ceramic has already received very considerable attention (1-15). Weber and Kummer reported that β-alumina exhibits high ionic conductivity, but no electronic conductivity (1). The ionic conductivity is due to the high mobility of sodium ions in planes perpendicular to the c-axis of the hexagonal structure. However, there is no conductivity parallel to the c-axis. They reported single-crystal specific resistivity values of 30 and 3.5 ohm-cm at room temperature and 300°C, respectively. Comparable values for polycrystalline ceramic prepared from single-crystal material was 250 and 18 ohm-cm. They attributed the difference to interface resistivity between the crystals of the polycrystalline material. The activation energy associated with the resistivity of single crystals was given as 3.8 kcal/mole (2).

Imai and Harata, on observing that the activation energy associated with conduction in sintered β-alumina was considerably larger than for single crystals, concluded that the conductivity of ceramic is governed by grain boundary conduction (4).

Jones and Miles found that the Arrhenius plot curved significantly below 200°C (5). Another activated process with a higher activation energy controlled the conductivity at lower temperatures. These authors speculated that this process was grain boundary contact resistance.

Whittingham and Huggins measured the conductivity of a single crystal from −150°C to 820°C (8). They found plots of log σT to be linear in $1/T$ over this entire temperature interval. The conductivity was found to be 72 ohm-cm at 25°C. The activation energy was 3.79 kcal/mole. They reported the conductivity to be sensitive to the presence of moisture below 50°C.

Imai and Harata reported that the a-c conductivity of polycrystalline β-alumina increases with frequency but becomes independent of frequency above 5 MHz at room temperature (12). However, Fally and associates found no frequency dependence up to 10^5 Hz at 300°C (14). Kennedy and Sammells found the conductivity to vary linearly with the square root of frequency at least up to 10 kHz on measurements with polycrystalline material at room temperature (13).

The Model

Grain boundaries in β-alumina can be viewed as almost a different material with resistive and dielectric properties distinct from those of the interior of the grains. Ionic charge is considered to pass successively through the grain interiors and the grain boundaries. These ideas are embodied in a model consisting of two resistors in series, each shunted by a capacitor (16). This particular representation is really appropriate only when evidence is present that the grain boundary resistivity is very large with respect to the crystal resistivity. When this situation occurs, one may consider the limiting case in which grains are in series with grain boundaries and parallel connections can be neglected. For the purpose of this study, it is convenient, but not necessary, to ignore the contribution of the capacitor shunting the crystal interior, which represents the crystal dielectric constant. Changes of impedance resulting from this capacitance will occur at frequencies higher than those studied here. Therefore, the simplified model, to be considered in detail below, is shown in Fig. 1.

If a specimen whose electrical properties can be so described is placed in series with a standard resistor and the combination energized with the output of a sine wave generator, the parameters characterizing the model can be determined from the variation of the observed impedance and phase angle with frequency. Certain relationships between these observable quantities can be used to determine the degree to which the electrical properties of β-alumina can be so modeled. The variation of the impedance with frequency for such a specimen is given by the expression

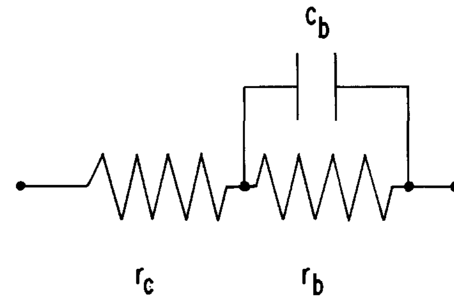

Fig. 1. Simplified model for the electrical properties of polycrystalline β-alumina.

* Electrochemical Society Active Member.

Key words: beta-alumina, solid electrolyte, electrical properties, grain boundary resistivity.

$$z = (r_c + r_b)\left[\frac{1 + \left(\frac{r_c}{r_c + r_b}\right)^2 (r_bC_b2\pi f)^2}{1 + (r_bC_b2\pi f)^2}\right]^{1/2} \quad [1]$$

where z is the measured impedance, f is the frequency, and the parameters r_c, r_b, and C_b are, respectively, the specific resistivity of grain interiors, the specific resistivity of the grain boundaries, and the specific capacity of the grain boundaries as shown in Fig. 1. This variation is shown in Fig. 2. There are two limiting levels of impedance, a low frequency one equal to $r_c + r_b$ and a high frequency one equal to r_c. Furthermore, at both very low and very high frequencies, the current through the specimen and the voltage developed across it are in phase. At intermediate frequencies, the current leads the voltage. This lead is maximum at that frequency corresponding to an inflection point on a plot of log z *vs.* log f. This crossover frequency, analogous to the loss peak in dielectric relaxation measurements and indicated as f_c in Fig. 2, is that at which the impedance is the geometric mean of the low and high frequency limiting impedances, *i.e.*, $z_c = \{r_c(r_c + r_b)\}^{1/2}$. The capacitance, C_b, can be obtained from this frequency, along with values for the limiting impedances, by means of the expression

$$C_b = \frac{1}{2\pi f_c r_b}\left[\frac{r_c + r_b}{r_c}\right]^{1/2} \quad [2]$$

Some other expressions are also useful in making detailed comparison with experiment. For example, the variation of the phase angle with frequency is

$$\tan\theta = \frac{r_bC_b2\pi f}{1 + (r_c/r_b)\{1 + (r_bC_b2\pi f)^2\}} \quad [3]$$

The maximum phase shift is

$$\tan\theta_{max} = \frac{r_b}{2\{r_c(r_c + r_b)\}^{1/2}} \quad [4]$$

Experimental Techniques

Impedance data to be presented were obtained on β-alumina tubes about 1 cm in diameter and usually 7.5-10 cm in length. While a detailed description of the specimen fabrication procedure has recently been given, it will be outlined here (17). The starting material was a powder, indicated as XB-2 β-alumina by the manufacturer, the Aluminum Company of America. Into this powder, various additives such as yttria, magnesia, or zirconia were incorporated. Yttria was added by way of yttrium oxalate powder, magnesia via basic magnesium carbonate powder, and zirconia by wear of the grinding media used to reduce the particle size. After tumble mixing, the powder was calcined at 1400°C to decompose the oxalate and carbonate additives and to dry the powder. The calcined powder was then suspended in amyl alcohol. The particle size was reduced either by ball or vibratory milling using either α-alumina or zirconia grinding media. The powder was formed in the shape of closed-end tubes using electrophoretic deposition. After removal from the forming electrodes, the green tubes were sintered in air at temperatures between 1700° and 1825°C.

Data are given in this paper on material of two different compositions. One contained 1 weight per cent (w/o) magnesia, 0.5 w/o yttria, and 1 w/o zirconia. The other differed only in the omission of yttria. Additives were incorporated mainly for the purpose of aiding densification during sintering. The composition of the as-received XB-2 powder is approximately 1.40 $Na_2O \cdot 11\ Al_2O_3$, *i.e.*, it contains a 40% excess of sodium oxide over that of the theoretical composition, $Na_2O \cdot 11\ Al_2O_3$. According to Roth and Mitoff, this composition is that of the sodium-rich boundary of the single-phase field at 1725°C (18). Some sodium oxide is always lost during sintering. However, it is most unlikely that the composition dropped below 1.35 $Na_2O \cdot 11\ Al_2O_3$ for the specimens on which data are given. This composition is well within the single-phase field.

The specimens were essentially without a preferred orientation. No phase other than hexagonal two-block β-alumina was evident from x-ray diffraction.

Impedance measurements were carried out using special jigs in which four 0.010 in. platinum rhodium wires were positioned circumferentially about the specimen at fixed distances along it. A photograph of one jig used at room temperature and below appears in Fig. 3. The 1/2 in. diameter Teflon polymer rods shown above and below the specimen were used to position the contact wires. To improve contact, the wires were wetted with very small quantities of a propylene carbonate solution, 0.6M in both NaI and iodine. For use at higher temperatures, the contact positioning rods were constructed of lava, and platinum bands were cathode sputtered circumferentially about the specimen to which contact was made with platinum wires. One junction of a thermocouple was placed inside the specimen tube in order to sense the temperature. For measurements at or below room temperature the resistivity jig was placed inside a 2 5/8 in. ID tubular brass housing which was placed in turn inside a controlled temperature Missimers environmental chamber. Measurements above room temperature were carried out in a simple wire-wound furnace.

The test circuit used for impedance measurements is shown in Fig. 4. The outer or current contacts were attached to a sine wave generator, the output amplitude and frequency of which could be varied, and to a multidecade resistance box, which served as a standard resistance. The voltage waveforms developed across the inner or voltage contacts to the specimen and across the resistance box were displayed on a dual beam oscilloscope. The impedance at some given

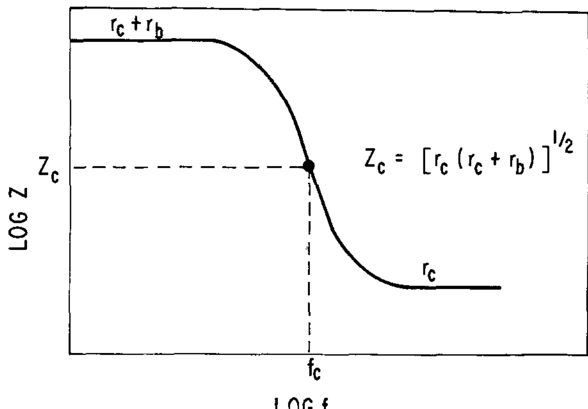

Fig. 2. Variation of impedance with frequency for simplified model.

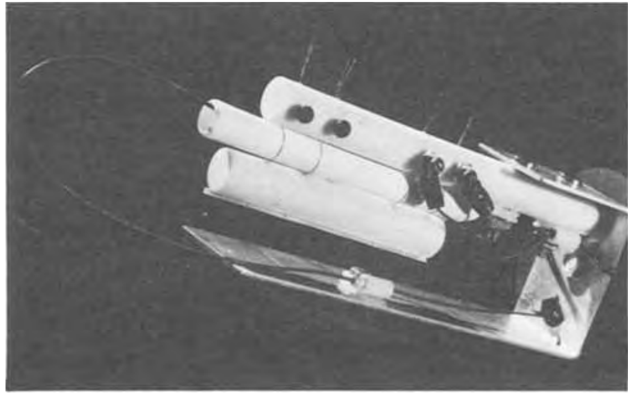

Fig. 3. Jig used for electrical measurements on β-alumina tubes

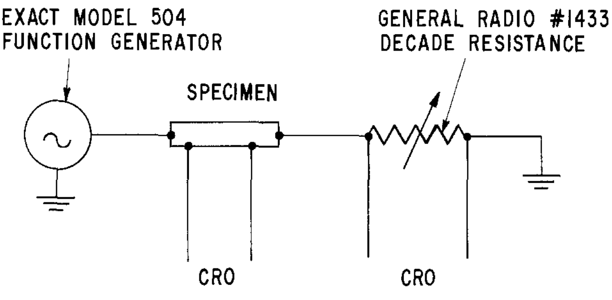

Fig. 4. Four point arrangement for measuring components of electrolyte impedance.

frequency was readily determined by adjusting the setting of the resistance box so that the amplitude of the voltage developed across it equaled that across the voltage contacts to the specimen. The phase lag was obtained from the horizontal displacement of the two waveforms in comparison with the displacement corresponding to one period.

This simple test arrangement was validated by carrying out measurements at frequencies ranging from 10 to 300,000 Hz on a simulated specimen constructed from high quality resistors and a capacitor. The measured impedances agreed with those calculated from the known values of the circuit elements using Eq. [1] to within 1.5% at all frequencies except at 30,000 Hz. Here a 3.5% discrepancy was encountered. Moreover, the value of C_b obtained with Eq. [2] differed from the true value by less than 5%.

The criterion for the suitability of contact to a specimen was that the phase angle at 10 Hz between the current through the specimen and the voltage between the two interior contact wires be no greater than one degree. It could usually be met except for two circumstances. The first arose when highly resistive surface layers formed on the specimen from exposure to the atmosphere. The second developed if the specimen was porous, causing absorption of the contact fluid and its removal from the contact wires. The problem was seldom encountered if the specimen density exceeded 3.15 g/cm^3 and was nearly always present in specimens with densities less than 3.00 g/cm^3.

The impedance values reported in this paper were found to be independent of the current level within approximately a per cent. For assurance on this point, it was routine to vary the current over a factor of about ten at each test temperature for every specimen. And on a few specimens, it was varied a thousandfold. Indium amalgams were used to make electrical contact in preliminary work. The impedance values observed were the same, within experimental error, as those using a propylene carbonate solution of sodium iodide and iodine. Further, the data obtained using only platinum contacts were not distinguishable at room temperature and above from those using the propylene carbonate contact solution. These facts indicate that the impedance values presented were not compromised by polarization effects at the electrodes.

Measurements with the test arrangement described above are limited to frequencies somewhat less than a megahertz. This limitation is mainly due to the shunt capacitance of the multidecade resistance box serving as the reference resistor. Such capacitance causes the so-called a-c resistance to be less than the d-c value at higher frequencies. A simple criterion was developed to determine if the impedance measurements were compromised from this effect. It is based on the fact that the ratio of a-c to d-c resistance depends very sensitively on the frequency and setting of the resistance box. At higher frequencies after adjusting the reference resistance so that the voltage amplitude across the box equals that across the voltage contacts to the specimen, the setting is reduced to one-half this value. If the amplitude is reduced correspondingly to one-half that across the specimen, the impedance measurement is considered valid. On the other hand, the extent to which the half-setting amplitude exceeds one-half that across the specimen provides an indication of the extent to which the measurement is compromised.

Experimental Results and Discussion

Plots of the logarithm of the specific impedance *vs.* the logarithm of the frequency are shown in Fig. 5 for five yttria-containing specimens which differed in the manner in which particle size reduction was carried out on the starting β-alumina powders. Ball milling was carried out using either α-alumina or zirconia grinding media for different lengths of time. The measurements were all carried out at room temperature. Below 100 Hz, the impedance does not vary with frequency. There is considerable variation, over a factor of 8, in the low frequency limiting value from one specimen to another. In contrast the impedance values for the different specimens almost converge around 10^5 Hz and only range from 110-140 ohm-cm at this frequency. They appear to be approaching another plateau. Using a more precise method for treating impedance data described below, a value of 84 ohm-cm was obtained for this plateau at 25°C on two different β-alumina samples containing yttria. Since the high frequency plateau is associated with the resistivity of grain interiors, it should be compared with the resistivity of single crystals. Room temperature values of 30-72 ohm-cm have been reported on single crystals without additives. It might be expected that r_c values should be slightly larger than that for single crystals in easy conducting directions because the grains in the ceramic are randomly oriented with conducting paths somewhat longer as a consequence.

If values of the low frequency impedance plateau are to be associated mainly with the grain boundary resistance, then there should exist a good correlation between this value and the number of grain boundaries per unit length intersecting a line in the direction of the electric field. Ideally, a direct proportionality would be anticipated. However, because of the extreme tendency in β-alumina for a few grains to grow to very large size at higher sintering temperatures or longer sintering times, there is a problem with uniformity of current distribution. A direct proportionality consequently would be somewhat fortuitous. An illustration of this grain size variation is presented in Fig. 6 with a 500× photomicrograph of specimen 5P1-2. This correlation between grain boundary resistivity and the number of grain boundary intersections is presented in Table I for a series of four specimens all containing yttria. The grain size was altered by sintering at different temperatures. The number of grain boundary intersections per centim-

eter length was determined by counting the intersections of grain boundaries with random lines on either 250 or 500× micrographs. Since the crystal resistance makes only a small contribution to the low frequency limiting value of the impedance, a value of r_c of 84 ohm-cm determined on specimens 5P1-1 and 5P1-2, was used for all four specimens. The correlation is sufficiently good to give some confidence in the association of the value of the low frequency plateau with $r_c + r_b$.

The observation of some previous authors that plots of the logarithm of the product, temperature times conductivity, *vs.* reciprocal temperature are sometimes nonlinear can now be readily understood. The crystal resistance has a temperature coefficient differing considerably from that for the grain boundaries. Plots of log z *vs.* log f for specimen 5P1-1 at several temperatures ranging from −13° to 320°C are presented in Fig. 7. Similar plots obtained on a specimen of somewhat smaller grain size, 5P1-2, are shown in Fig. 8. From these data, values of r_c and r_b were determined over a range of temperatures. Since there still was a small variation in the impedance with frequency at low frequencies, an effect which increases with decreasing temperature, values of $r_c + r_b$ were obtained by linear extrapolation of plots of z *vs.* f to $f \rightarrow 0$. Similarly, values of r_c were obtained by linear extrapolation of plots of z *vs.* $1/f$ at high frequencies to $1/f \rightarrow 0$. The quantities $\sigma_c T$ and $\sigma_b T$ are presented on Arrhenius type plots in Fig. 9, where $\sigma_c = 1/r_c$, $\sigma_b = 1/r_b$, and T is the absolute temperature. The activation energy for conduction through the grain

5P1-3	2.2	2.75	0.80
5P1-5	6.9	3.5	1.97

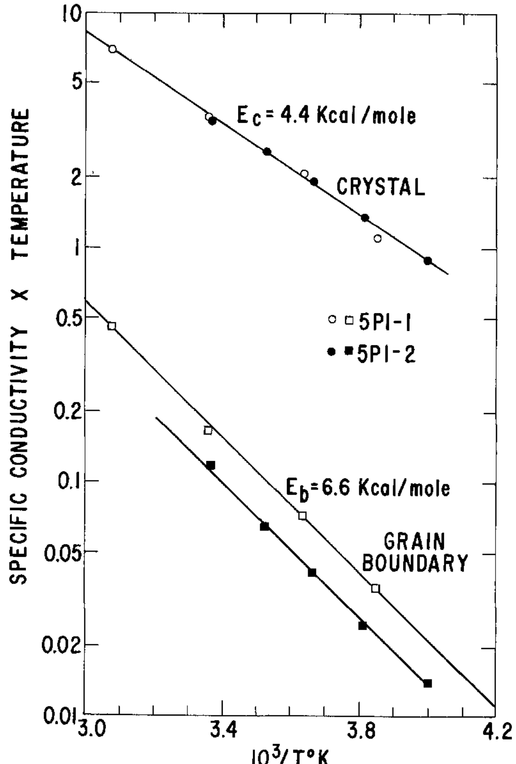

Fig. 9. Arrhenius plots for components of resistivity

interiors was nearly the same for both specimens and amounted to 4.4 kcal/mole. That for the grain boundaries on the other hand, amounted to 6.6 kcal/mole for both specimens. There can be considerable varia-

tion, however, in the measured activation energy for the grain boundary resistance from one specimen to another. A value as low as 5.1 kcal has been observed. This fact, perhaps, accounts for the considerably larger curvature on some plots of log σ_{total} T *vs.* $1/T$ reported previously than that observed by the present authors (5, 12). Here σ_{total} is the reciprocal of $r_b + r_c$.

There are still other grain boundary properties in addition to resistivity and its activation energy in which large variations are observed from one specimen to another. As shown in Fig. 10, the cross-over frequency is much larger at room temperature for specimen 6F10-2 than for the specimens on which data were presented above. The previous specimens contained 0.5 w/o yttria while this additive was absent from 6F10-2. Even at the highest frequencies, at which measurements would be made using the technique described in this paper, the impedance was only a little less than the low frequency limiting value. This fact, of course, implies a much smaller C_b value than for the other specimens. Measurements could not be extended above 300,000 Hz for reasons discussed above. Consequently, r_c values could not be measured on yttria-free specimens.

From Eq. [2], the cross-over frequency f_c is given by the expression

$$f_c = \frac{1}{2\pi C_b}\left[\frac{1+\dfrac{r_c}{r_b}}{r_b r_c}\right]^{1/2}$$

It must shift to higher frequencies with increasing temperature because both r_c and r_b decrease with temperature. In contrast to the resistive parameters in the simplified model, the grain boundary capacitance varies hardly at all with temperature. On specimen 5P1-1 the parameter C_b was 0.020, 0.0213, 0.021, and 0.021 microfarads/cm at temperatures of −13.2°, 1.8°, 24.5°, and 52.0°C, respectively. On 5P1-2, this quantity was 0.0121, 0.0124, 0.0123, 0.0121, and 0.0126 microfarads/cm at temperatures of −22.9°, −10.9°, −0.2°, 10.4°, and 23.0°C, respectively. The temperature shift of f_c, indicated by vertical bars on the individual curves, is very evident in both Fig. 7 and 8 and imposes a practical limit on the temperature range over which r_c values can be obtained using the present experimental technique.

Some clarifications need to be made with regard to the units in which impedance measurements as well as the parameters r_c, r_b, and C_b, are expressed. The impedance of a specimen at a given frequency is obtained from a setting of the reference resistance box as described above. In analogy to the specific resistivity, the specific impedance is obtained simply from the product of this impedance and the ratio of effective cross-sectional area to distance between the voltage contacts. Similarly, the parameter r_c, the specific resistivity of the grain interiors, presents no difficulties. However, the parameter r_b, although expressed in the units of specific resistivity, does not refer to a centimeter cube of grain boundary material. Rather it can be considered as the resistance of whatever grain boundaries are present in a specimen of 1 cm^2 cross section with the voltage drop measured over a 1 cm length. If r_c and r_b are expressed in units of ohm-centimeter, then from Eq. [2] the grain boundary capacitance must have units of farads/centimeter. It is possible, however, to get an order of magnitude estimate of the true grain boundary specific resistivity, ρ_b, from elementary considerations. Thus

$$r_b C_b = \left(\rho_b \frac{l}{A}\right)\left(\epsilon\epsilon_0 \frac{A'}{l'}\right)$$

where A is the effective cross-sectional area of the grain boundary normal to the electric field; l is the sum of the grain boundary thicknesses in the field direction; ϵ is the grain boundary dielectric constant; ϵ_0 is the permittivity of free space, $8.85 \cdot 10^{-14}$ farad/cm; A' is the effective area of grain boundary capacitor "plates"; and l' is the total thickness of such plates. If $A = A'$ and $l = l'$, then

$$r_b C_b = \rho_b \epsilon_0 \epsilon$$

Using values for r_b and C_b obtained on specimen 5P1-2 at room temperature and estimating ϵ to be about 5, one gets

$$\rho_b = 7.10^7 \text{ ohm-cm}$$

This value is roughly 10^5 times larger than r_c. The magnitude of this factor for β-alumina is the underlying reason for the subject given consideration in this paper and constitutes the basis for the simplified model as discussed above.

The most serious discrepancy between experimental data and predictions based on the simplified model is that the measured frequency interval between the low and high frequency impedance plateaus is larger than calculated. This fact is illustrated in Fig. 11 for specimen 5P1-1 at 52°C. This finding implies that the electrical properties of the grain boundaries cannot be described by a single set of r_b, C_b values, a result supported by measurements of the phase angle, also presented in Fig. 11. If the resistivity and dielectric constant of all grain boundaries are not identical, a satisfactory description requires a series of resistors, each shunted with its separate capacitor. At sufficiently low frequencies, the impedance of such a modified model would equal the sum of the individual grain boundary resistances plus that for the crystal as with the simplified model. The heterogeneity in the electrical properties of grain boundaries perhaps should not be too surprising because the various boundaries are oriented randomly with respect to the electric field and compositional variations from boundary to

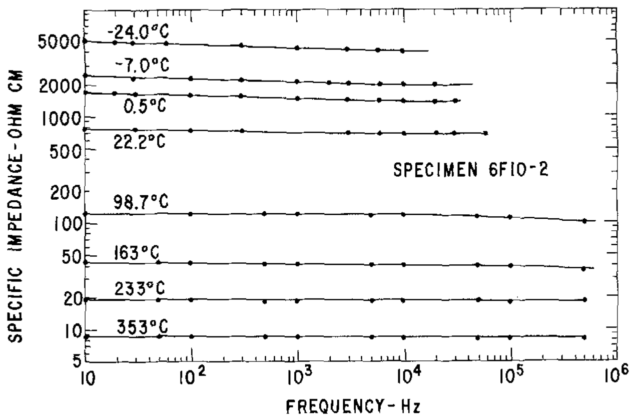

Fig. 10. Specific impedance vs. frequency curves for specimen 6F10-2.

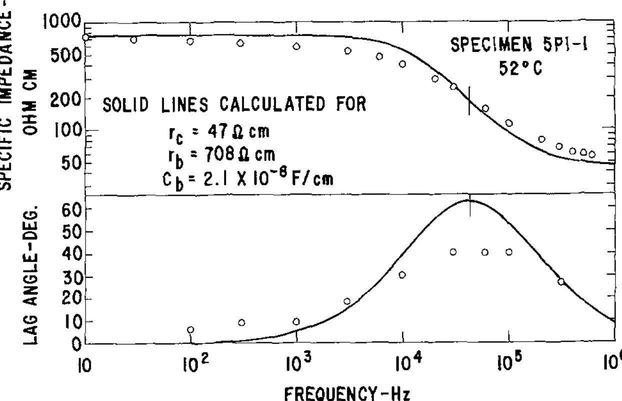

Fig. 11. Impedance and phase angle vs. frequency curves showing deviations from behavior of simplified model.

boundary are likely, due to the presence of impurities and additives.

The simplified model of the electrical properties of β-alumina ceramic shown on Fig. 1 is really that of a voltage divider for d.c. Consequently, when β-alumina is used in an electrochemical device, a large fraction of the applied voltage appears across the grain boundaries. This fraction does decrease, however, with increasing temperature. Assuming a typical β-alumina ceramic thickness of 1 mm, 10^3 grain boundaries per centimeter, a grain boundary thickness of 10^{-7} cm, and an applied voltage of 1V, all appearing across the grain boundaries, the electric field would be 10^5 V/cm. This value is sufficiently large for concern about the rapid decomposition of unstable substances which might be present in a boundary in contact with an electronic conductor. Such substances might be either additives or impurities. The cracking of β-alumina ceramic arising from sodium deposition into fine cracks may conceivably bear some association with the high fields present across grain boundaries.

Principal Conclusions

The simplified model of the electrical properties of β-alumina ceramic shown in Fig. 1 is a good first approximation but needs modification to take account of the heterogeneity of grain boundaries

The model helps place in perspective a number of findings of previous authors.

For most sintered β-alumina ceramic, the electrical properties are determined more by the characteristics of the grain boundaries than by those of the interior of the grains. Consequently, much of the voltage drop during current flow appears across the grain boundaries, giving rise there to very large electric fields.

Thermodynamic Studies of Dilute Zinc Solutions in the Zn-Sn-Cd-Pb System at High Lead Concentrations

Z. Moser*,[1] and W. Zakulski

Institute for Metal Research, Polish Academy of Sciences, Kraków, Reymonta 25, Poland

ABSTRACT

The activity coefficients of zinc were measured in the concentration range $0.03 < X_{Zn} < 0.1$ at temperatures in the range 714°-877°K for lead-rich alloys in the quaternary system Zn-Sn-Cd-Pb with tin and cadmium mole fractions limited to $0.01 < X_{Sn} < 0.1$ and $0.01 < X_{Cd} < 0.1$. Measurements were of emf of concentration cells. Experimental values of $\ln \gamma_{Zn}$ were compared with values obtained from the Krupkowski formalism and from the Wagner formalism. In the latter instance two sets of values were generated, one set considering first-order interactions only and the other set considering both first- and second-order interactions. The comparisons show that the experimental data are reasonably described by both the Krupkowski approach and the Wagner approach with first-order interactions only. However, less satisfactory accord is obtained after inclusion of second-order interactions in the Wagner equations. The present results show that in the quaternary system strong negative self-interaction parameters, $\epsilon^{Zn}{}_{Zn}$ which lead to marked positive deviations from Raoult's law in the Zn-Pb binary system also lead to negative zinc-cadmium and zinc-tin interaction parameters in the quaternary system. This is in accord with earlier results on ternary systems.

Determination of thermodynamic properties of dilute multicomponent systems is of interest from an industrial point of view but is also of fundamental interest in defining the predictability of solute-solute interaction parameters on the basis of a solute-solvent reference interaction. In this study the reference can be taken as a binary solution showing only strong positive deviations from ideal behavior. In a previous investigation (1) it was shown that in the case of ternary solutions where one binary pair exhibits extensive deviation from Raoult's law, the deviation influences in a predictable manner the thermodynamic properties of the ternary system. Zinc and lead form liquid solutions with strong deviations from Raoult's law. It has been experimentally demonstrated that negative values for interaction parameters $\epsilon^{Me}{}_{Zn}$ occur in ternary Zn-Me-Pb solutions where Me = Bi, Sb, Cd, Sn, and In. In all these Zn-Me binary systems a much smaller departure from ideality is observed than in the Zn-Pb system, and the original properties of Zn-Pb solutions are a decisive factor in the determination of the sign of the ternary interaction parameters $\epsilon^{Me}{}_{Zn}$.

The main purposes of the present investigation were to find whether or not the strong negative self-interaction parameter, $\epsilon^{Zn}{}_{Zn} < 0$ in the Zn-Pb binary system is also decisive in quaternary solutions, to determine the influence of tin and cadmium additions on zinc activity, and finally to test Krupkowski's (2) and Wagner's (3) formalisms with experimental data. In Krupkowski's formalism the thermodynamic functions of a multicomponent system are evaluated from the activity coefficients of the constituent binary systems. Wagner's series expansion which represents the logarithm of the zinc activity coefficient as a sum of interaction parameters is simplified in the present system since the relation of $\ln \gamma_{Zn}$ *vs.* concentration of tin or cadmium in lead was found to be linear. The Wagner treatment may be applied with the assumption of first-order interactions only (model I) or with the assumption of both first- and second-order interactions (model II). It may be noted that Gluck and Pehlke (4, 5) have studied bismuth-rich ternary, quaternary, quinary, hexadic, and septenary solutions with dilute zinc concentrations and have shown that in these systems the inclusion of second-order interactions is useful in predicting the activity coefficient of zinc.

Experimental Procedure

Zinc activities were determined by emf measurements on concentration cells of the type

$$Zn(l)\,|ZnCl_2 \text{ in LiCl,KCl (eutectic) (l)}|\,\text{Zn-Sn-Cd-Pb(l)}$$

Experimental details have been discussed in preceding papers (6, 7). Measurements were made with zinc mole fractions of $X_{Zn} = 0.03$, 0.05, 0.07, and 0.1 and tin and cadmium mole fractions varying between 0.01 and 0.1 in the temperature range 714°-877°K For any given concentration, the experimental emf *vs.* temperature was found to be adequately described by a linear relationship, and the experimental data were fitted to such a relationship by the method of least squares. The resulting parameters with standard deviations are listed in Table I. Values from these linear relationships were taken at arbitrarily selected temperatures of 714°, 805°, and 877°K and were converted to activity coefficients through the relation

$$\gamma_{Zn} = 1/X_{Zn} e^{-nEF/RT} \quad [1]$$

where γ_{Zn} and X_{Zn} are, respectively, the activity coefficient and mole fraction of zinc, n is the valence, **F** is Faraday's constant with a selected value of 23.066 cal per volt per gram equivalent, E is the emf in volts, T is the temperature in Kelvin, and R is the gas constant. The experimental data are summarized in Table I. The uncertainties in the experimental emf's *vs.* temperature reflect uncertainties between 1 and 5% in $\ln \gamma_{Zn}$ at any given temperature at the 95% confidence level.

Interpretation of the Results by Krupkowski's Formalism

Values of $\ln \gamma_{Zn}$ from Eq. [1] are plotted in Fig. 1 through 4 as $\ln \gamma_{Zn}$ *vs.* X_{Sn} ($X_{Zn} = X_{Cd}$ = const) and in Fig. 5 through 8 as $\ln \gamma_{Zn}$ *vs.* X_{Cd} ($X_{Zn} = X_{Sn}$ = const). The ternary end points in Fig. 1 through 4 at $X_{Sn} = 0$ and in Fig. 5 through 8 at $X_{Cd} = 0$ are from previous papers on Zn-Cd-Pb (8) and Zn-Sn-Pb (9) systems, respectively. It can be seen from the extrapolations that the present data are in good accord with earlier data. In Fig. 1 through 8 the thin continuous line corresponds to $\ln \gamma_{Zn}$ values obtained by means of Krupkowski's formalism. According to Krupkowski's

† $S(\bar{y})$ = standard deviation of the electromotive force.

method (2) the activity coefficients in binary systems take the form

$$\ln \gamma_j = \omega_{jk}(T)\left[(1 - X_k)^{m_{jk}} - \frac{m_{jk}}{m_{jk} - 1}(1 - X_k)^{m_{jk}-1} + \frac{1}{m_{jk} - 1}\right] \quad [2]$$

$$\ln \gamma_k = \omega_{jk}(T)(1 - X_k)^{m_{jk}} \quad [3]$$

where γ_j, γ_k are activity coefficients of components j and k, $\omega_{jk}(T)$ is the function dependent on temperature, m_{jk} is the asymmetry coefficient independent of concentration, X_k is the concentration of the component k in molar fraction. Equation [2] is derived from Gibbs-Duhem equation ($X_k d \ln \gamma_k + X_j d \ln \gamma_j = 0$) assuming that Eq. [3] applied for component k. Values of $\omega(T)$ and m were obtained from experimental data for the constituent binary systems and are summarized in Table II. Using these data, following the notation i = Zn, j_1 = Sn, j_2 = Cd, k = Pb(solvent) and the procedure given in the Appendix the relation for $\ln \gamma_{Zn}$ in quaternary system is as follows

$$\begin{aligned}\ln \gamma_i = &-\omega_{ij_1}[(1 - X_i)^{m_{ij_1}-2}X_iX_{j_1} - (1 - X_i)^{m_{ij_1}-2}X_{j_1}] \\ &- \omega_{ij_2}[(1 - X_i)^{m_{ij_2}-2}X_iX_{j_2} - (1 - X_i)^{m_{ij_2}-2}X_{j_2}] \\ &- \omega_{ik}[(1 - X_i)^{m_{ik}-2}X_iX_k - (1 - X_i)^{m_{ik}-2}X_k] \\ &- \omega_{j_1j_2}(1 - X_{j_2})^{m_{j_1j_2}-2}X_{j_1}X_{j_2} \\ &- \omega_{j_1k}(1 - X_k)^{m_{j_1k}-2}X_{j_1}X_k - \omega_{j_2k}(1 - X_{j_2})^{m_{j_2k}-2}X_{j_2}X_k\end{aligned} \quad [4]$$

The details of this procedure are also given in the paper (6) on the Zn-Sn-Cd-Bi system. Values of $\ln \gamma_{Zn}$ from Eq. [4] are compared with experimental values in Table III as well as in Fig. 1 through 8. From these comparisons it may be seen that the Krupkowski's formalism provides a quite reasonable approximation to the experimental data. The highest deviations from the experimental data occur at 714°K and at concentrations $X_{Zn} = X_{Sn} = 0.1$ and $X_{Zn} = X_{Cd} = 0.1$. These deviations result from the influence of immiscibility which occurs at these concentrations in the ternary systems Zn-Sn-Pb and Zn-Cd-Pb, respectively.

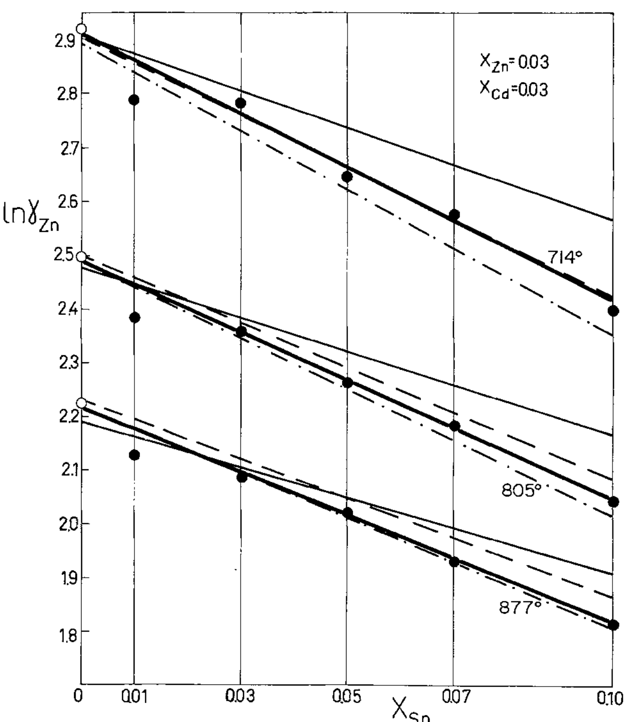

Fig. 1. $\ln \gamma_{Zn}$ vs. X_{Sn} dependence in Zn-Sn-Cd-Pb liquid solutions at 714°, 805°, and 877°K when X_{Zn} = 0.03, X_{Cd} = 0.03. ——●—— This study, ○ Ref. (8), ———— calculated from Krupkowski's Eq. [4], — — — — calculated from model I Wagner's Eq. [8], —·—·—·— calculated from model II Wagner's Eq. [7].

Interaction Models

Following Wagner's suggestion (3) ln γ_i may be expanded in Taylor series for the quaternary system in the following form

$$\ln \gamma_i = \ln \gamma_i^o + \left[X_i \left(\frac{\partial \ln \gamma_i}{\partial X_i} \right) + X_{j_1} \left(\frac{\partial \ln \gamma_i}{\partial X_{j_1}} \right) + X_{j_2} \left(\frac{\partial \ln \gamma_i}{\partial X_{j_2}} \right) \right] + \left[\frac{1}{2} X_i^2 \left(\frac{\partial^2 \ln \gamma_i}{\partial X_i^2} \right) + \frac{1}{2} X_{j_1}^2 \left(\frac{\partial^2 \ln \gamma_i}{\partial X_{j_1}^2} \right) + \frac{1}{2} X_{j_2}^2 \left(\frac{\partial^2 \ln \gamma_i}{\partial X_{j_2}^2} \right) + X_i X_{j_1} \left(\frac{\partial^2 \ln \gamma_i}{\partial X_i \partial X_{j_1}} \right) + X_i X_{j_2} \left(\frac{\partial^2 \ln \gamma_i}{\partial X_i \partial X_{j_2}} \right) + X_{j_1} X_{j_2} \left(\frac{\partial^2 \ln \gamma_i}{\partial X_{j_1} \partial X_{j_2}} \right) \right] \quad [5]$$

Equation [5] includes terms for both first- and second-order interactions. The notation is the same as used by Gluck and Pehlke (5) who were concerned with solute interactions of zinc in dilute solutions with molten bismuth. The first-order terms in Eq. [5] are

$\left(\frac{\partial \ln \gamma_i}{\partial X_i} \right) = \epsilon_i^i$ self-interaction parameter in the system i-k(solvent)

$\left(\frac{\partial \ln \gamma_i}{\partial X_{j_1}} \right) = \epsilon_i^{j_1}$ ternary-interaction parameter in the system i-j_1-k

$\left(\frac{\partial \ln \gamma_i}{\partial X_{j_2}} \right) = \epsilon_i^{j_2}$ ternary-interaction parameter in the system i-j_2-k

and the second-order terms are

$\left(\frac{\partial^2 \ln \gamma_i}{\partial X_i^2} \right) = \epsilon_i^{ii}$ second-order interaction parameter in the system i-k

$\left(\frac{\partial^2 \ln \gamma_i}{\partial X^2_{j_1}} \right) = \epsilon_i^{j_1 j_1}$ second-order direct ternary interaction parameter in the system i-j_1-k

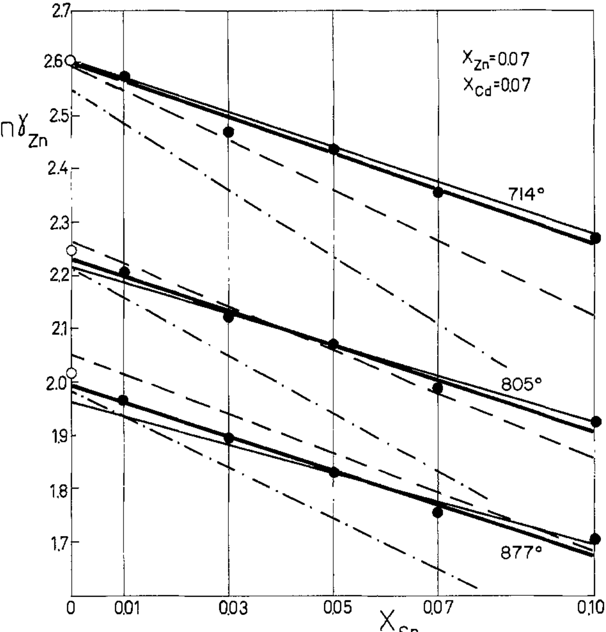

Fig. 3. ln γ_{Zn} vs. X_{Sn} dependence in Zn-Sn-Cd-Pb liquid solutions at 714°, 805°, and 877°K when X_{Zn} = 0.07, X_{Cd} = 0.07. —●— This study, ○ Ref. (8), ——— calculated from Krupkowski's Eq. [4], – – – – calculated from model I Wagner's Eq. [8], —·—·—·— calculated from model II Wagner's Eq. [7].

[4], — — — — calculated from model I Wagner's Eq. [8], —·—·—·— calculated from model II Wagner's Eq. [7].

$$\ln \gamma_i = \ln \gamma_i^o + \left[X_i \epsilon_i^i + \frac{1}{2} X_i^2 \epsilon_i^{ii} \right] + [X_{j_1} \epsilon_i^{j_1} + X_{j_2} \epsilon_i^{j_2}]$$

$$+ \left[\frac{1}{2} X_{j_1}^2 \epsilon_i^{j_1 j_1} + \frac{1}{2} X_{j_2}^2 \epsilon_i^{j_2 j_2} + X_i X_{j_1} \epsilon_i^{j_1 i} + X_i X_{j_2} \epsilon_i^{j_2 i} \right]$$

$$+ [X_{j_1} X_{j_2} \epsilon_i^{j_1 j_2}] \quad [6]$$

Table II. Values of the function $\omega(T)$ and m for binary alloys

System	m	$\omega(T)$	Ref.
Zn-Sn	1.10	$\left[\frac{2489}{T} + 1.824 (\ln T - 1) - 12.929\right]$	(10)
Zn-Cd	1.76	$\left(\frac{979}{T} - 0.051\right)$	(11)
Zn-Pb	1.53	$\left(\frac{3000}{T} - 1.059\right)$	(1)
Sn-Cd	1.92	$\left(\frac{967}{T} - 0.661\right)$	(12)
Sn-Pb	1.04	$\left(\frac{479}{T} + 0.345\right)$	*
Cd-Pb	1.73	$\left(\frac{1220}{T} - 0.368\right)$	(14)

* Calculated from Ref. (13).

It is clear from Eq. [6] that only the term in the last bracket requires data from the quaternary system. In addition a linear dependence of $\ln \gamma_i$ *vs.* X_{j_1} and X_{j_2} when X_i = const occurs in ternary solutions and results in $\epsilon_i^{j_1j_1} = 0$ and $\epsilon_i^{j_2j_2} = 0$. Similarly, in binary Zn-Pb system the linearity of $\ln \gamma_i$ *vs.* X_i makes $\epsilon_i^{ii} = 0$. After deletion of these terms the following form of Eq. [6] is obtained

$$\ln \gamma_i = \ln \gamma_i^o + X_i\epsilon_i^i + X_{j_1}\epsilon_i^{j_1} + X_{j_2}\epsilon_i^{j_2} + X_iX_{j_1}\epsilon_i^{j_1 i} + X_iX_{j_2}\epsilon_i^{j_2 i} + X_{j_1}X_{j_2}\epsilon_i^{j_1 j_2} \quad [7]$$

Dealy and Pehlke (15) used a similar equation for multicomponent alloys based on the Zn-Bi system of preponderant bismuth concentration, but in that system Henry's law is obeyed and therefore $\epsilon_{Zn}^{Zn} = 0$. A further difference in their paper was that they did not evaluate the term $\epsilon_i^{j_1j_2}$. In the present paper the value of $\epsilon_i^{j_1j_2}$ was determined, and also the behavior of the Zn-Pb system requires that $\epsilon_{Zn}^{Zn} \neq 0$.

Equation [7] with inclusion of both first- and second order interaction parameter represents what was referred to in the beginning of this paper as Wagner's model II. Neglect of second-order interaction terms shortens Eq. [7] to

$$\ln \gamma_i = \ln \gamma_i^o + X_i\epsilon_i^i + X_{j_1}\epsilon_i^{j_1} + X_{j_2}\epsilon_i^{j_2} \quad [8]$$

which represents what was referred to as Wagner's model I.

The values of respective interaction parameters are given in Table IV. Results from calculations carried out with models I and II are included in Table III and are also plotted in Fig. 1 through 8 with the dotted line corresponding to model I and the dash-dot line to model II, respectively. Values of the ternary interaction parameters ϵ_{Zn}^{Cd} were deduced (8) from the plots of $(\ln \gamma_{Zn})_{X_{Zn}=0}$ *vs.* X_{Cd}. Therefore the values of parameters ϵ_{Zn}^{CdZn} were obtained on the basis of the data given by Pehlke, Okajima, and Moore (17) as the limiting slopes of the plots

$$\left(\frac{\partial \ln \gamma_{Zn}}{\partial X_{Cd}}\right)_{\substack{X_{Cd}=0 \\ X_{Zn}=\text{const}}} \quad vs.\ X_{Zn}$$

at temperatures 723°, 823°, and 923°K; this plot shows a linear dependence from $X_{Zn} = 0$ to $X_{Zn} = 0.0375$. The temperatures differ slightly from those of the present paper, but any error which is introduced from this difference should be minor.

The plots in Fig. 1 through 8 show that model I gives better agreement with experimental data than does model II. Model II exhibits satisfactory agreement only at concentrations $X_{Zn} = X_{Sn} = 0.03$ and $X_{Zn} = X_{Cd} = 0.03$. Generally, the better fitting of the experimental data takes place at higher temperatures and at lower zinc concentrations.

Conclusions

This investigation of the lead-rich Zn-Sn-Cd-Pb system at temperatures 714°-877°K has shown that at fixed concentration the relation of emf *vs.* temperature is of linear character. Linear relationships were also observed in plots of $\ln \gamma_{Zn}$ *vs.* X_{Sn} and $\ln \gamma_{Zn}$ *vs.* X_{Cd} when $X_{Zn} = X_{Cd}$ = const, respectively.

With Krupkowski's formalism the values of activity coefficients of zinc were calculated and show gen-

** Calculated from Ref. (17).

erally good agreement with the experimental data. Also good agreement was obtained with Wagner's model I. Model II including interactions of second order seems applicable only for alloys with $X_{Zn} = 0.03$. The highest deviations (of order of about 30% in ln γ_{Zn}) with respect to experimental data appear at temperatures near 714°K and at concentrations near $X_{Zn} = X_{Sn} = 0.10$ and $X_{Zn} = X_{Cd} = 0.10$; these high deviations are believed to result from the proximity to immiscibility range in the Zn-Pb system.

Investigation also indicates that the much stronger deviation from Raoult's law in the Zn-Pb system as compared with the Zn-Cd, Zn-Sn, Cd-Pb, Pb-Sn, and Cd-Sn binary systems plays a dominant role in determining the sign of interaction parameters in the quaternary Zn-Sn-Cd-Pb system. This result for the quaternary system is consistent with earlier observations (8, 9) on Zn-Cd-Pb and Zn-Sn-Pb ternary systems where the strong negative self-interaction parameter, $\epsilon_{Zn}^{Zn} < 0$, in the Zn-Pb binary system gives rise to negative interaction parameters, $\epsilon_{Zn}^{Cd} < 0$ and $\epsilon_{Zn}^{Sn} < 0$, in the respective ternary systems.

APPENDIX

In multicomponent systems the main assumption of Krupkowski's method (18) consists in the additivity of thermodynamic properties of the binary systems. His assumption is that the logarithm of an activity coefficient on an arbitrarily chosen component i of a solution may be represented by the sum

$$\ln \gamma_i = \sum_{\substack{j,k=1 \\ j\neq k}}^{n} [\ln \gamma_i]_{j,k} \quad \text{[A-1]}$$

where $[\ln \gamma_i]_{j,k}$ is the contribution which corresponds to j-k binary system

Accordingly Krupkowski obtains as solutions of the Gibbs-Duhem equation

$$\sum_{i=1}^{n} X_i d \ln \gamma_i = 0 \quad \text{[A-2]}$$

the following

for $i \neq k$, $i \neq j$

$$[\ln \gamma_i]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k \quad \text{[A-3]}$$

for $i = j$

$$[\ln \gamma_j]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k + \frac{\omega_{jk}}{m_{jk} - 1}[1 - (1 - X_k)^{m_{jk}-1}] \quad \text{[A-4]}$$

for $i = k$

$$[\ln \gamma_k]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k + \omega_{jk}(1 - X_k)^{m_{jk}-2} X_j \quad \text{[A-5]}$$

Equation [A-3] shows the influence of thermodynamic properties of j-k binary solutions on the activity coefficient of the remaining component i in a multicomponent system. This equation is dependent on i only in the concentration term $(1 - X_k)$. The parameters ω and m are derived from binaries which do not include component i.

For a particular multicomponent system the components are enumerated as follows: i = Zn, j_1 = Sn, j_2 = Cd, and k = Pb; then for each binary system of the quaternary solutions there will be four relations according to Eq. [A-3]-[A-5]. For instance in the case of Zn-Sn system we have

$$[\ln \gamma_{Zn}]_{Zn\text{-}Sn} = -\omega_{ZnSn}[(1 - X_{Zn})^{m_{ZnSn}-2} X_{Zn} X_{Sn} - (1 - X_{Zn})^{m_{ZnSn}-2} X_{Sn}] \quad \text{[A-6]}$$

$$[\ln \gamma_{Sn}]_{Zn\text{-}Sn} = -\omega_{ZnSn}\left\{(1 - X_{Zn})^{m_{ZnSn}-2} - \frac{1}{m_{ZnSn} - 1}[1 - (1 - X_{Zn})^{m_{ZnSn}-1}]\right\} \quad \text{[A-7]}$$

$$[\ln \gamma_{Cd}]_{Zn\text{-}Sn} = -\omega_{ZnSn}(1 - X_{Zn})^{m_{ZnSn}-2} X_{Zn} X_{Sn} \quad \text{[A-8]}$$

$$[\ln \gamma_{Pb}]_{Zn\text{-}Sn} = -\omega_{ZnSn}(1 - X_{Zn})^{m_{ZnSn}-2} X_{Zn} X_{Sn} \quad \text{[A-9]}$$

Finally Eq. [4] is obtained as a sum

$$\ln \gamma_{Zn} = [\ln \gamma_{Zn}]_{ZnSn} + [\ln \gamma_{Zn}]_{ZnCd} + [\ln \gamma_{Zn}]_{ZnPb} + [\ln \gamma_{Zn}]_{CdPb} + [\ln \gamma_{Zn}]_{PbSn} + [\ln \gamma_{Zn}]_{CdSn} \quad \text{[A-10]}$$

In Eq. [A-10] the first term is equal to Eq. [A-6] and the three last terms equal $-\omega_{CdPb}(1 - X_{Cd})^{m_{CdPb}-2} X_{Cd} X_{Pb}$, $-\omega_{PbSn}(1 - X_{Pb})^{m_{PbSn}-2} X_{Sn} X_{Pb}$, and $-\omega_{CdSn}(1 - X_{Cd})^{m_{CdSn}-2} X_{Sn} X_{Pb}$, respectively. The parameters ω_{jk} and m_{jk} are determined from data for the respective j, k binaries and consequently reflect the influence of the binaries Cd-Pb, Pb-Sn, and Cd-Sn on the properties of the quaternary Pb-Sn-Cd-Zn alloys. The concentration terms $(1 - X_{Cd})$ and $(1 - X_{Pb})$ in the last three terms represent concentrations in the quaternary system.

Electrochemical Reduction of Lithium Metavanadate in Lithium Chloride-Potassium Chloride Eutectic

R. B. Chessmore and H. A. Laitinen[*,1]

Department of Chemistry, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

Two reduction steps were observed in the electrochemical reduction of $LiVO_3$ in molten LiCl-KCl eutectic. The first reduction step produces an insoluble product which undergoes a chemical reaction with $LiVO_3$ to form insoluble LiV_2O_5 and Li_3VO_4. The second reduction step produces insoluble $LiVO_2$ and Li_3VO_4. $LiVO_2$ undergoes a number of chemical reactions with $LiVO_3$ to produce a mixture of solid compounds, one of which is LiV_2O_4. VO_2 was found to react with $LiVO_3$ to produce LiV_2O_5. The addition of oxide ion to the eutectic containing insoluble VO_2 resulted in the disproportionation of VO_2 to produce either Li_3VO_4 and V_2O_3 or Li_3VO_4 and $LiVO_2$, depending on the oxide concentration.

The chemistry and electrochemistry of vanadium in molten salt systems has been partially studied by several groups. Van Norman and Osteryoung (1) found that metavanadate in a LiCl-KCl eutectic melt reacted with an excess of Na_2CO_3 to form orthovanadate as determined from the evolution of CO_2. Molina (2) has described the absorption spectra of V(II), V(III), VO^{+2}, VO_3^-, and V_2O_5, and gave a detailed discussion of the effect of adding oxide ion to either a V_2O_5 or VO^{+2} solution in LiCl-KCl eutectic melt. The standard potentials of V(II)/V(O) and V(III)/V(II) in a LiCl-KCl eutectic melt have been determined (3). Laitinen and Rhodes (4) studied the electrochemistry of V_2O_5 in LiCl-KCl eutectic melt and found that vanadium pentoxide was reduced to a mixture of a lithium-vanadium bronze and lithium vanadates. Shams El Din *et al.* (5) potentiometrically titrated metavanadate dissolved in molten LiCl-KCl, using Na_2O_2 as the titrant and an $O_2/O^{=}/Pt$ indicator electrode. The neutralization occurred in one step, forming orthovanadate in the melt. The electrochemistry of vanadyl ion in LiCl-KCl eutectic has been studied by Scrosati and Laitinen (6). These workers found that VO^{+2} is reduced in a one electron step to soluble VO^+, followed by a fast chemical reaction to produce insoluble V_2O_3 and soluble V(III).

In this study, chronopotentiometry, controlled potential electrolysis, chronopotentiometry with current reversal, and cyclic sweep voltammetry were used to investigate the electrochemical reduction of $LiVO_3$ in LiCl-KCl eutectic at 450°C.

Experimental

Reagents.—Anhydrous $LiVO_3$ and Li_3VO_4 were prepared by drying the research grade products (Lithium Corporation of America) at 150°C under vacuum for 24 hr. V_2O_3 and VO_2 were prepared according to the method given by Brauer (7). A method similar to that described by Holtzberg *et al.* (8) was used to prepare $K_4V_2O_7$. LiV_2O_5 was prepared by heating equal molar quantities of $LiVO_3$ and VO_2 in a quartz tube at 610°C under an argon atmosphere for 24 hr and then at 650°C for an additional 24 hr. $LiVO_2$ was prepared by heating equal molar quantities of V_2O_3 and Li_2CO_3 in a platinum crucible to 600°C in a flow of hydrogen for 10 hr, then to 750°C for an additional 12 hr.

Chemicals other than those mentioned were reagent grade and were used without additional purification other than drying where required.

Molten salt procedures. The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Incorporated, Champaign, Illinois, where it was prepared and purified by the method outlined by Laitinen *et al.* (9). The molten salt furnace and glassware associated with the molten salt apparatus have been previously described (10, 11). The procedures employed for cleaning glassware and handling the molten eutectic have been described in detail (11).

Electrochemical measurements.—A Pt(II)/Pt reference electrode was utilized in this work; its properties and construction have been described (12). Unless otherwise stated, all potentials are given with reference to a Pt(II) (1*M*)/Pt electrode. A carbon electrode was used as a counterelectrode. The electrodes were constructed and cleaned according to the procedure outlined by Propp (13). Both the platinum disk electrodes used in the chronopotentiometric and cyclic sweep studies and the platinum flag electrodes were constructed by spot welding 2.5 cm of 26 gauge platinum wire to a platinum foil (3 cm^2). The electrode holders have been described by Propp (13). The construction of platinum disk electrodes have been described (11). A 2.5 cm length of 36 or 41 gauge platinum wire was spot welded onto the disks so they could be attached and detached from the electrode holder.

An indicator electrode whose construction has been described (11) was made from a 2.5 cm length of 3 mm diameter glassy carbon and was used in the amperometric titration of vanadium.

Steady-state voltammetric measurements were made with a Heath EUA19-2 Polarography Module combined with a Heath EUW-19A operational amplifier system stabilized by a Heath EUA-19-4 chopper stabilizer. A

Key words: molten salts, cathodic processes, vanadium oxides.

Sargent recorder (Model S-82150) was used to record the current-voltage curves. A triangular sweep generator built by the Electronic Service Laboratory at the University of Illinois, in conjunction with a Wenking Potentiostat (Model 61RS) was used in the linear sweep studies. The Wenking potentiostat was also used for the constant potential electrolysis in preparative work. The constant current source employed for the chronopotentiometric studies has previously been described (13). A Tektronix 502A oscilloscope and a Tektronix C-12 camera were used to record the chronopotentiometric potential-time curves and the linear sweep current-voltage curves. A Sargent Model IV Coulometric Current Source was used for the generation of the Pt(II)/Pt reference electrode.

Analytical procedures.—In the preparative portion of this investigation, a number of routine analyses were performed to establish the composition of the electrode deposits. The deposits were washed with deaerated water, dried, and dissolved in H_2SO_4. A detailed procedure is given elsewhere (11).

Vanadium, as V(V) and/or V(IV), was quantitatively determined by an amperometric titration with Fe(II), utilizing a method similar to one developed by Rulfs *et al.* (14). Vanadium as V(IV) and/or V(III) was quantitatively determined by adding an excess of V(V) and amperometrically titrating with Fe(II). Lithium and potassium were determined by flame photometry. Chloride was determined by null point potentiometry as described by Malmstadt and Winefordner (15). The apparatus and detailed procedures for the various analyses are described elsewhere (11).

Results and Discussion

Chemistry of $LiVO_3$, Li_3VO_4, and $K_4V_2O_7$.—There exists some confusion in the literature concerning anionic species of vanadium oxides and their solubility in LiCl-KCl eutectic (4). A brief study was, therefore, made to determine the solubility of lithium orthovanadate and potassium pyrovanadate in LiCl-KCl eutectic at 450°C.

Five mg of Li_3VO_4 was added to 12 ml of LiCl-KCl eutectic melt at 450°C. The melt solution was filtered after it had been stirred for 2 hr to allow equilibration. Analysis of the collected precipitate showed that only about 4% by weight of the Li_3VO_4 had dissolved. Taking into account the error in determining the volume of the compartment (approximately 5%), an upper limit of about 0.3 m*M* can be placed on the solubility of Li_3VO_4 in LiCl-KCl eutectic melt at 450°C. Ten mg of $K_4V_2O_7$ was added to 4.5 ml of LiCl-KCl eutectic melt. Part of the solid appeared to dissolve, and the melt solution took on a yellow color. The x-ray powder pattern of the precipitate matched the x-ray powder pattern of commercially obtained Li_3VO_4. The results of the chemical analysis showed that about one-half of the total vanadium, on a mole basis, had dissolved in the LiCl-KCl eutectic melt. These results show that pyrovanadate is not stable in LiCl-KCl eutectic at 450°C, but decomposes to form soluble VO_3^- and a solid precipitate of Li_3VO_4.

Voltammetry of $LiVO_3$.—Representative current-voltage curves of $LiVO_3$ dissolved in the eutectic are shown in Fig. 1. The reproducibility of these curves was poor because of the formation of insoluble products that caused the surface area of the electrode to change rapidly. Only general conclusions can be made concerning the process taking place. There appears to be a series of ill-defined reduction waves occurring before the maximum limiting current is reached at approximately −1.2V. A current-voltage curve in the positive direction (curve 2), after completion of a forward run, shows that there are several anodic processes. This indicates that there are several insoluble products formed during the negative scan and that these products can be oxidized during the positive scan. It may be possible that a single insoluble reduc-

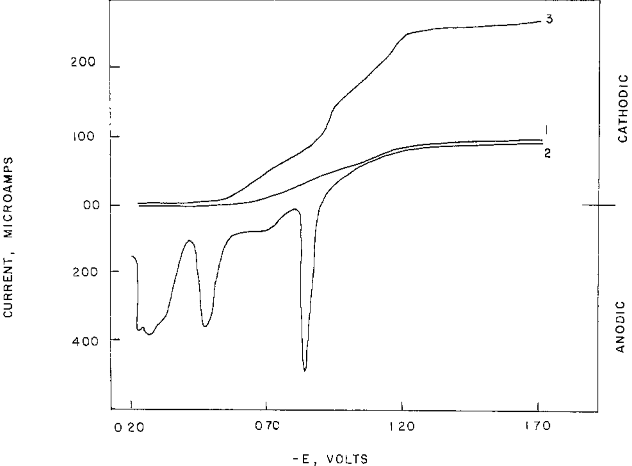

Fig. 1. Steady-state voltammogram of $LiVO_3$. Sweep rate 0.1 V/min. Curve 1, 7.25 × 10^{-3}M $LiVO_3$; curve 2, reverse of curve 1; curve 3, 2.37 × 10^{-2} $LiVO_3$.

tion product undergoes oxidation via charge transfer and/or coupled chemical reactions to form other insoluble products which are further oxidized. The insoluble product(s) found during the negative scan are probably conductive since the current does not reach a limiting value and then decay as the applied potential becomes more negative.

Characterization of electrode deposits.—Samples of electrode deposits were prepared by constant potential electrolysis. No attempt was made to do an exhaustive electrolysis since stirring the melt solution caused part of the deposits to break away from the electrode surface. The deposits were analyzed for V, Li, K, and Cl by employing the methods previously described.

The x-ray powder pattern data of the deposit obtained at a potential corresponding to the first ill-defined wave, −0.620V, of curve 3 (Fig. 1), matched the γ phase LiV_2O_5 obtained by Galy and Hardy (17) and Hardy *et al.* (18). An x-ray diffraction powder pattern of a deposit that had been washed sparingly with deaerated water matched that of LiV_2O_5, except that diffraction lines of Li_3VO_4 were also present. The oxide ion released in the reduction of metavanadate to LiV_2O_5 precipitates VO_3^- as insoluble Li_3VO_4. Table I summarizes the composition of three samples of deposits prepared under the previously given conditions. If the microequivalents of V(V), V(IV), and Li are mathematically converted to an equivalent weight of the metal oxide, as shown in Table IA, the sample weight can be completely accounted for in terms of Li_2O, V_2O_5, and V_2O_4.

The x-ray powder pattern data for a completely washed deposit obtained at −1.32V matched the pattern for $LiVO_2$ obtained by Rüdorff and Becker (19). An x-ray powder pattern obtained for an electrode deposit that had been sparingly washed was identical to that of $LiVO_2$, except that Li_3VO_4 diffraction lines were also present. The reduction of $LiVO_3$ occurring at −1.32V releases oxide ion which precipitates VO_3^-

18.21	0.272	18.24	1.659	18.21	1.510

B. Sample wt mg	Total mg found	% wt found	Empirical formula
4.382	4.353	99.34	$Li_{1.01}V_{2.00}O_{5.01}$
3.210	3.188	99.31	$Li_{0.99}V_{2.00}O_{5.00}$
3.455	3.441	99.59	$Li_{1.00}V_{2.00}O_{5.00}$

Table II. Typical analysis of deposit obtained at −1.32V

A.	μmoles Li^+	mg Li_2O	millimoles V^{+3}	mg V_2O_3
	19.15	0.286	19.59	1.468
	12.48	0.186	12.27	0.920
	25.55	0.382	25.38	1.902
B.	**Sample mg**	**mg found**	**% wt found**	**Empirical formula**
	1.765	1.754	99.38	$Li_{0.98}V_{1.00}O_{1.99}$
	1.113	1.106	99.37	$Li_{1.01}V_{1.00}O_{2.01}$
	2.300	2.284	99.30	$Li_{1.01}V_{1.00}O_{2.00}$

as Li_3VO_4. Table II summarizes the composition of three samples of the deposit obtained at −1.32V. The sample weight can be completely accounted for if the microequivalents of each metal are mathematically converted to an equivalent weight of metal oxide, as shown in Table IIA. This suggests that the oxidation occurring at −0.83V (Fig. 1, curve 2) is the oxidation of $LiVO_2$.

The steady-state voltammograms suggested that one or more intermediate reduction product exists between LiV_2O_5 and $LiVO_2$. Deposits obtained at a potential corresponding to −0.950V were bright green in color. The x-ray powder patterns of the sparingly washed deposit and the completely washed deposit were compared. The two patterns were identical except that the pattern of the sparingly washed deposit contained Li_3VO_4 diffraction lines. Table III shows the x-ray powder pattern data for a completely washed deposit obtained at −0.950V. A search of the literature did not reveal any x-ray powder patterns of vanadium compounds that matched that obtained for the deposit. A careful examination of the deposit under a microscope showed that the deposit was a mixture of solid products in the form of bright green, red, granular black, and needle-like blue-black crystals. Analysis of the deposits obtained at −0.950V showed the deposit to contain V(V) V(IV), Li, K, and Cl. Attempts to use the analysis data to determine the various compounds that might be present in the deposit were futile. Only qualitative results could be obtained. The micromoles of Cl found were always less than either the micromoles of Li or K. This shows that even if the melt components were incorporated into the deposit, one or more of the compounds in the deposit actually contains Li and/or K. The micromoles of V(V) was always much less than the micromoles of V(IV), suggesting that the mixed deposit contains a very small amount of V(V) and relatively large amounts of V(IV), or that V(III) is also present in the deposit with the

microequivalents of V(V) being slightly larger than the microequivalents of V(III).

The x-ray powder pattern of the deposit obtained at −0.800V was similar to that previously given for the deposit obtained at −0.950V, except diffraction lines that could be attributed to LiV_2O_5 were also found to be present. A similar experiment was repeated at −1.03V. The x-ray powder pattern of the deposit obtained at this potential was similar to that of the deposit obtained at −0.950V, except that diffraction lines of $LiVO_2$ were also found to be present. The appearance of the LiV_2O_5 and $LiVO_2$ lines in the powder patterns and the results of the chemical analysis show that the reduction of $LiVO_3$ in the potential range of −0.70 to −1.20V produces a mixture of insoluble products on the electrode surface. Presumably, most or all of these products can be reoxidized electrochemically, as evidenced by the steady-state voltammograms.

Chemistry of the reduction products of $LiVO_3$.—The results of the preceding section suggest that there may be a series of chemical reactions involving the solid reduction products, $O^=$ and VO_3^-. Furthermore, since VO_2 is known to be insoluble in LiCl-KCl (2, 6), it was expected that the reduction of $LiVO_3$ would produce insoluble VO_2. For these reasons, a study of the chemistry of LiV_2O_5, VO_2, and $LiVO_2$ in a melt solution containing either $LiVO_3$ or oxide ion was performed to reach a better understanding of the reduction of $LiVO_3$.

A sample of LiV_2O_5 was placed in two compartments, one containing only LiCl-KCl eutectic, the other containing excess $LiVO_3$ in addition to the eutectic. The x-ray powder pattern and chemical analysis showed that both solids were LiV_2O_5. From the experiments, it was concluded that LiV_2O_5 is stable in LiCl-KCl eutectic melt and in melt solution containing $LiVO_3$.

At potentials intermediate to the formation of LiV_2O_5 and $LiVO_2$, a mixture of insoluble compounds is formed. It was suspected that this mixture would contain mostly V(IV). No evidence as to the presence of VO_2, which is known to be insoluble in LiCl-KCl, was found in the mixture of insoluble products. This suggested that VO_2 may react with VO_3 in the melt and/or insoluble compounds containing an $O^=$/V(IV) ratio greater than 2 may exist. Vanadyl compounds such as $VOCl_2$ and $VOSO_4$ are known to be soluble in LiCl-KCl eutectic and to slowly decompose to form insoluble VO_2 and soluble V(III) (6).

A sample of VO_2 was added to the melt. An x-ray powder pattern and analysis of the solid confirmed the results of Molina (2) and Scrosati (6) that VO_2 is stable and insoluble in LiCl-KCl eutectic melt at 450°C.

Similarly, 0.262 mM VO_2 was added to 0.444 mM $LiVO_3$ dissolved in about 4.5 ml of eutectic melt. There was an immediate reaction indicated by the yellow color of the melt solution decreasing in intensity and the black granular VO_2 changing to a blue-black needle-shaped solid. The x-ray pattern and chemical analysis of the solid showed it to be LiV_2O_5. This result suggested that LiV_2O_5 may not be the first reduction product of VO_3^-, but rather the result of a chemical reaction between the first reduction product and VO_3^-. Since VO_2 reacts with VO_3^- to form LiV_2O_5, soluble or insoluble V(IV) compounds containing an $O^=$/V(IV) ratio greater than 2 would also be expected to undergo a chemical reaction with VO_3^-.

It was thought that $(Li,K)_2VO_3$ might exist in LiCl-KCl eutectic melt at 450°C. Molina (2) has shown that the addition of $O^=$ to a melt solution containing vanadyl ion precipitates VO_2. This author found that further addition of oxide ion did not visually dissolve VO_2. Results in this laboratory do not confirm the last observation. Equal moles of Li_2CO_3 and VO_2 were added to the eutectic. A reaction occurred as evidenced by the evolution of CO_2. An x-ray powder pattern of the remaining solid showed only diffraction lines of

Li_3VO_4 and V_2O_3. The analysis of the solid product, after Li_3VO_4 had been removed by washing, showed that the solid contained only V(III)and a small amount of Li. The sample weight could be completely accounted for in terms of a mixture of V_2O_3 and $LiVO_2$. Inspection of the compartment showed the Pyrex glass of the compartment was badly etched from the carbonate. Li_2CO_3 and VO_2 in a mole ratio of Li_2CO_3/VO_2 equal to about 4, to offset the reaction of carbonate with the compartment walls, was added to the eutectic. An x-ray powder pattern of the resulting solid showed only $LiVO_2$ and Li_3VO_4 lines. Analysis of the solid after removal of Li_3VO_4 showed it to be $LiVO_2$.

A number of conclusions can be reached from the preceding experiments. First, VO_2 is not stable in the presence of $O^=$, but disproportionates to form either V_2O_3 and Li_3VO_4 or $LiVO_2$ and Li_3VO_4, depending on the concentration of oxide ion. Secondly, if the compound $(Li,K)_2VO_3$ is the first reduction product of $LiVO_3$, it would not be stable but would disproportionate to form insoluble $LiVO_2$ and Li_3VO_4; or, depending on time and concentration of VO_3^-, react with VO_3^- to form LiV_2O_5 and Li_3VO_4.

If VO_3^- and $LiVO_2$ reacted in a mole ratio of one-to-one without the release of oxide, the product of the reaction would be $(Li,K)_2V_2O_5$. Equal moles of $LiVO_2$ and $LiVO_3$ were added to the eutectic melt. A definite reaction occurred as evidenced by the appearance of a green solid. An x-ray powder pattern of the sparingly washed solid showed diffraction lines of Li_3VO_4. This suggested that oxide ion is released in the reaction. Table IV shows the x-ray powder pattern of the completely washed solid. As can be seen, many of the diffraction lines that were present in the deposit obtained at −0.950V are also present in this x-ray powder pattern. The asterrated lines matched the x-ray powder pattern of LiV_2O_4 given by Rueter and Jackowsky (20). These data suggested that possibly one of the products of the reaction between VO_3^- and $LiVO_2$ in LiCl-KCl eutectic is LiV_2O_4. A definite conclusion cannot be made owing to the presence of a mixture of compounds, some of which may have diffraction lines in common with LiV_2O_4. Attempts to use the analysis data to determine the compounds in the solid proved futile.

A mole ratio of $LiVO_3/LiVO_2$ equal to 1.5 was added to the eutectic. The *d* spacings obtained from the x-ray powder pattern of the resulting solid were similar to those in Table IV, except the asterrated *d* spacings were less intense and diffraction lines of LiV_2O_5 were found to be present.

Chronopotentiometry.—A typical chronopotentiogram of $LiVO_3$ dissolved in LiCl-KCl eutectic melt is shown in Fig. 2A. Figures 2B and 2C show the effect of reversing the current along different portions of the cathodic wave.

Figure 2A shows there is only one reduction wave with a "linear" portion in the initial part of the wave.

Fig. 2. (A) Typical chronopotentiogram of $LiVO_3$ [$LiVO_3$] = 4.66 mM, C.D., 0.880 mA/cm². (B, C) Typical chronopotentiograms of $LiVO_3$ with current reversal. [$LiVO_3$] = 4.66 mM, equal forward and reverse C.D. of 0.880 mA/cm².

Figures 2B and 2C show that if the current is reversed at a forward time that is still within the "linear" portion of the wave, only one reverse wave occurs at about −0.69V. If the current is reversed after the "linear" portion, there is a new oxidation wave occurring at about −0.86V and the wave that was seen at about −0.69V has become somewhat diffuse and shifted to a slightly less negative potential. The potential of about −0.86V is in good agreement with the observed oxidation potential of $LiVO_2$ seen in the steady-state voltammograms. The diffuse nature of the oxidation wave at the more positive potential could originate from a number of chemical complications previously mentioned.

A series of experiments was performed to verify that the oxidation occurring at about −0.86V was the oxidation of $LiVO_2$. A melt solution containing 1 mg of VO_3^- was exhaustively electrolyzed by applying −1.32V. The x-ray powder pattern of the deposit matched that of $LiVO_2$.

After exhaustively electrolyzing, a constant anodic current was applied, and the potential of the test electrode monitored with an x-y recorder. Two, and sometimes three, oxidation waves were seen occurring around −0.85, −0.50, and −0.41V. The ratios of the stripping transition times were not very reproducible and the oxidation at −0.41V was sometimes absent, and when it did occur, it was always much shorter than the other two waves. There was no solid remain-

ing on the electrode after the stripping had been completed.

The experiment was repeated but the stripping electrolysis was stopped when the transition time of the oxidation occurring at −0.86V was reached. An x-ray powder pattern of the black solid matched that of LiV_2O_4 (20).

From the results of these experiments, certain conclusions can be reached. The anodic process occurring at −0.86V is the oxidation of $LiVO_2$ to LiV_2O_4. The oxidation at −0.50V is the oxidation of LiV_2O_4. In the absence of VO_3^- and $O^=$, the oxidation product of LiV_2O_4 would presumably be VO_2. The short transition time of the wave at −0.41V, compared to the transition times of the other two waves suggests that if the wave occurring at −0.41V corresponds to the oxidation of VO_2, then either all the VO_2 produced from the oxidation of LiV_2O_4 is not on the electrode surface or that the oxidation of VO_2 does not produce all V(V). It should be pointed out that the stripping conditions in this experiment are different than those under normal chronopotentiometric conditions in that there was no VO_3^- or $O^=$ present when the stripping was performed and that no cathodic electrolysis at less negative potentials had occurred before the deposition of $LiVO_2$.

Returning to the chronopotentiometric experiment, the "linear" region exhibited some unusual properties with respect to the total transition time and the oxidation of $LiVO_2$. The total number of coulombs passed in the "linear" region varied randomly between 500 and 600 microcoulombs/cm^2. If the total number of coulombs necessary to reach the total transition time was less than about 500 microcoulombs/cm^2, the total transition time was comprised entirely of the "linear" region. Current reversal under these conditions produced only one oxidation wave at about −0.69V. The oxidation wave of $LiVO_2$ was found to occur only after the forward number of coulombs had exceeded that amount needed to produce the "linear" region. After the "linear" region, the time at which the oxidation wave of $LiVO_2$ occurred depended upon the potential of the indicator electrode. If the potential of the indicator electrode was more positive than about −0.8V, no oxidation wave of $LiVO_2$ was seen. The reduction of VO_3^- to $LiVO_2$ appears to be related to the process occurring within the "linear" region and dependent upon the potential of the indicator electrode after the "linear" region. For an n value of 1, 200-500 microcoulombs/cm^2 of charge is normally required to form a monolayer coverage of the electrode. The amount of charge depends upon the unit cell parameters and the number of molecules of the reduced species per unit cell. The relationship between the "linear" region and the reduction of VO_3^- to $LiVO_2$ suggests that the platinum electrode has to be covered with a less reduced species than $LiVO_2$ before VO_3^- can be reduced to $LiVO_2$.

By employing equal cathodic and anodic current densities, a number of current-reversals were performed along the total reduction wave. The ratio of the total reverse transition time, τ_R, to the forward electrolysis time, T_F, was about 0.87, regardless of the number of oxidation waves seen when the current was reversed. Once the oxidation wave of $LiVO_2$ was seen, the ratio of the transition times of the more positive diffuse oxidation wave to that of $LiVO_2$ decreased as the forward electrolysis time was increased. A limiting value for this ratio was never reached, even when the current was reversed at the forward transition time. The only conclusion that can be made is that most of the reduction products of VO_3^-, either from electrochemical reduction or chemical reduction/oxidation, are at the electrode surface and can be electrochemically oxidized.

At higher concentrations, lower current densities and short T_F, the ratio τ_R/T_F appeared to be somewhat smaller than 0.87. The oxidation wave still occurred at about −0.69V. The ratio, however, approached 0.87 at larger T_F. Normally, the ratio had reached 0.87 before the oxidation wave of $LiVO_2$ was seen. This slight decrease in the ratio τ_R/T_F at short T_F suggested that VO_3^- might be removing the first reduction product from the electrode surface. In order to verify this supposition, a relatively large concentration of VO_3^- ($17.08 \times 10^{-3}M$) and a low current density (4.4×10^{-4} A/cm^2) were used. The ratio of τ_R/T_F varied from 0.3 to 0.63 for T_F ranging from 0.25 to 1.6 sec. The potential of the oxidation wave remained at about −0.69V. Smaller current densities caused the ratio τ_R/T_F to become even smaller. A similar effect was observed when the current density was kept constant and the concentration of VO_3^- was increased. The decrease of τ_R/T_F, when a relatively large concentration of VO_3^- exists at the electrode surface, shows that the first reduction product is not stable in the presence of VO_3^-. The first reduction product under normal chronopotentiometric conditions, therefore cannot be LiV_2O_5. LiV_2O_5 was shown previously to be stable in the presence of VO_3^-. The simplest first reduction step that can be written is

$$VO_3^- + e^- + 2(K,Li)^+ = (Li,K)_2VO_3$$

Depending on time and VO_3^- concentration, this product would either disproportionate to $LiVO_2$ and Li_3VO_4 or react with VO_3^- to form LiV_2O_5 and Li_3VO_4.

The Sand equation was tested by running duplicates of 5-7 C.D. at 5 different VO_3^- concentrations ranging from 1.78 to $17.09 \times 10^{-3}M$. It should be mentioned that these data were obtained in such a way that, in some cases, the total transition time was comprised entirely of the "linear" region and in other cases, the "linear" region was a small part of the total forward transition time. The Sand equation was found to be obeyed after correcting for residual impurities in the melt. The value of $I_o\tau^{1/2}/C$ was 0.234 ± 0.002 mA-sec$^{1/2}$ cm/mole, which gives a value of 0.76×10^{-5} eq^{2}mole^{-2}cm^{2}sec^{-1} for n^2D. Even though VO_3^- is not entirely reduced to $LiVO_2$, the Sand equation is obeyed. This suggests the following type of mechanism may be occurring for the reduction of VO_3^-. VO_3^- is first reduced in a one electron step to form, on the electrode surface, a product which is not further reduced. VO_3^- is then, depending upon the surface coverage of the electrode and the potential, reduced in a 2-electron step to $LiVO_2$. The oxide ion released would react with VO_3^- to form Li_3VO_4. If this reaction were very rapid compared to the time of measurement, an apparent n value of 1 would be obtained. If the over-all apparent n value is 1, then D is found to be 0.76×10^{-5} cm^2/sec. This estimate of D is rendered uncertain because it is not known whether oxide ion is released in the first reduction, nor are the rates of the reactions between VO_3^- and $O^=$ and between VO_3^- and its own reduction products known. These reactions, if appreciable in extent, could lead to an apparent n less than 1, and an erroneously high value for D. Regardless of the chemical complications, however, $I_o\tau^{1/2}$ is a linear function of concentration.

Attempts were made to analyze the potential-time curves. The plots of log $(\tau^{1/2} - T^{1/2})$ and log $(\tau^{1/2} - T)/T^{1/2}$ *vs.* potential gave meaningless results, a behavior which was not surprising in view of the complex nature of the reduction of VO_3^-.

Cyclic sweep voltammetry.—Figures 3A-C, 4A-C, and 5A-B show typical cyclic sweep voltammograms of VO_3^- as the sweep rate is increased from 0.1 V/sec to 30 V/sec. There were no additional cathodic or anodic peaks in Fig. 3A when the switching potential occurred at more negative values. Figure 3A resembles the steady-state voltammograms in that several ill-defined waves are present on the negative scan and a number of stripping peaks appear in the positive scan. The potential of −0.865V for the oxidation peak is in good agreement with that assigned to the

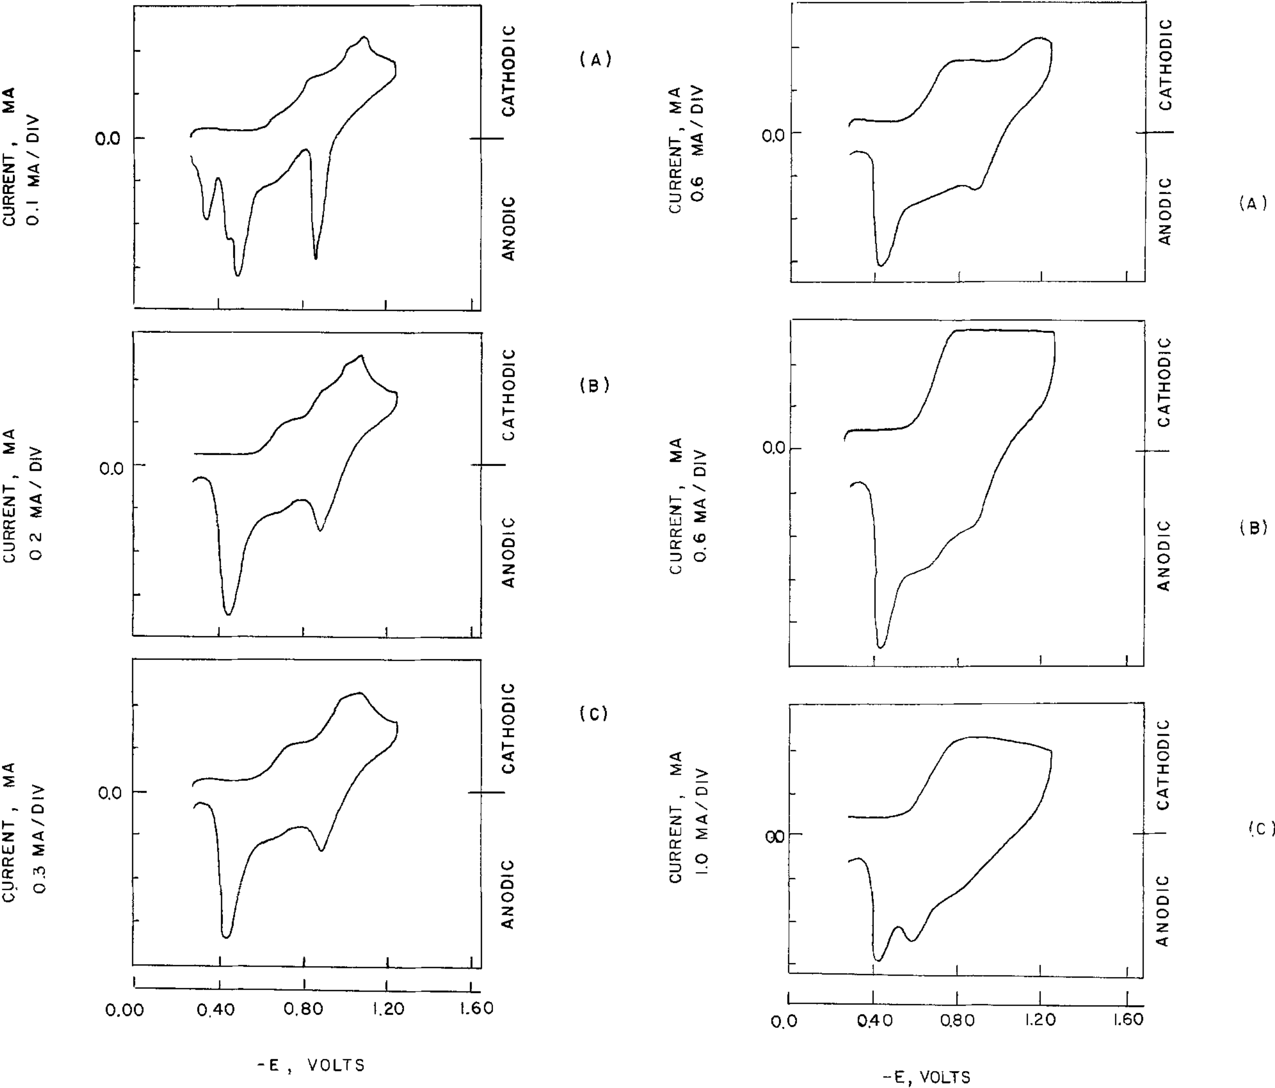

Fig. 3. Typical cyclic sweep voltammograms of $LiVO_3$ [$LiVO_3$] = 9.88 mM, switching potential = −1.25V, electrode area = 0.147 cm^2. (A), Sweep rate 0.1 V/sec; (B), sweep rate 0.5 V/sec; (C), sweep rate 1.0 V/sec.

Fig. 4. Typical cyclic sweep voltammograms of $LiVO_3$ [$LiVO_3$] = 9.88 mM, switching potential = −1.25V, electrode area = 0.141 cm^2. (A), Sweep rate 5.0 V/sec; (B), sweep rate 10.0 V/sec; (C), sweep rate 15.0 V/sec.

oxidation of $LiVO_2$. As the sweep rate was increased (Fig. 3B-C), a number of effects could be seen. First, the reduction process became somewhat better defined in that only two apparent overlapping reductions were seen at about −0.77 and −1.05V. Second, on the negative scan, many of the stripping peaks had disappeared, indicating that several of the chemical reactions between VO_3^-, $O^=$, and the reduction products were no longer occurring. The stripping peak due to the oxidation of $LiVO_2$ was still seen at −0.89V. The peak at −0.45V agreed fairly well with that expected from chronopotentiometry for the oxidation of LiV_2O_4. The shoulder occurring at about −0.67V appears to be due to the oxidation of the first reduction product observed in chronopotentiometry. As the sweep rate was further increased (Fig. 4A-C, 5A-B), the current due to the reduction occurring at about −0.77V increased with respect to the current for the reduction occurring at about −1.05V. Both peak potentials appeared to shift to more negative values. At 30 V/sec, only one broad reduction peak was seen at about −0.90V. There was also a dramatic change in the oxidation processes. The $LiVO_2$ oxidation peak and the LiV_2O_4 peak decreased and finally disappeared as the sweep rate was increased. Accompanying the disappearance of these two oxidation peaks was the appearance of an oxidation peak in the potential region of −0.60V. At 30 V/sec, only this one oxidation peak was seen. Changing the switching potential to a more negative value resulted in the reappearance of the $LiVO_2$ and LiV_2O_4 oxidation peaks. No other reduction peak was seen.

The same trends were observed when smaller or larger concentrations were used. At smaller concentrations, the appearance of the one reduction and one oxidation peaks occurred at lower sweep rates while at larger concentrations, larger sweep rates were required. The sweep rate and concentration range were severely limited because of the interference of the reduction of impurities in the melt, charging current, and chemical reactions.

Plots of potential *vs.* log $(i_p - i)$ and log $(i_p - i)/i$ for the single reduction peak occurring at higher sweep rates produced curved lines. Either the process is kinetically controlled or the activity of the deposit is not constant. At the first appearance of only one reduction and oxidation peak, the number of coulombs passed in the reduction process was found to be between 400 and 500 microcoulombs/cm^2, regardless of the concentration of VO_3^-. This value is in good agreement with the number of coulombs contained in the "linear" region of the chronopotentiograms. The number of coulombs passed in reaching the peak potential was found to be about 130 microcoulombs/cm^2, corresponding to about 0.6 monolayer of VO_2. The value 400-500 microcoulombs/cm^2 is, therefore, somewhat high for monolayer coverage, suggesting that the deposit grew in lumps or clusters, so that a larger number of coulombs would need to be passed

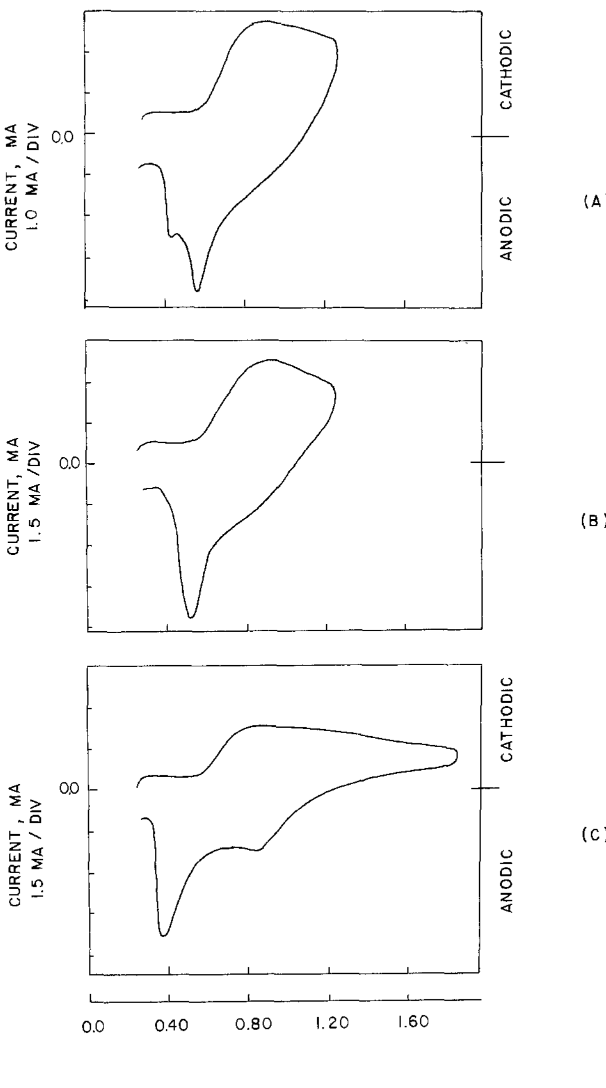

Fig. 5. Typical cyclic sweep voltammograms of $LiVO_3$ [$LiVO_3$] = 9.88 mM, electrode area = 0.147 cm^2. (A), Sweep rate 20.00 V/sec, switching potential —1.25V; (B), sweep rate 30.0 V/sec, switching potential —1.25V; (C), sweep rate 15.0 V/sec, switching potential —1.85V.

before the electrode surface was completely covered. The relationship between the appearance of the electrochemical oxidation of $LiVO_2$ and the value 400-500 microcoulombs/cm^2 suggests, as it did in the chonopotentiometric study, that VO_3^- is reduced to $LiVO_2$ only after the electrode surface has been covered with a less reduced product. If the surface had not been covered before the concentration of VO_3^- is zero at the electrode surface, no peak due to reduction of VO_3^- to $LiVO_2$ would be seen, regardless of the potential. However, if the surface was covered with the less reduced product the reduction would proceed once the reduction potential at which VO_3^- is reduced to $LiVO_2$ has been reached and its effect would be seen in the oxidation cycle by the appearance of the oxidation peak of $LiVO_2$ (−0.86V). At slower sweep rates, the electrode is covered with the less reduced species earlier in the scan and thus, a reduction peak of VO_3^- to $LiVO_2$ is seen. As the sweep rate is decreased further, a number of chemical reactions between VO_3^- and its reduction products start to occur.

The peak current increased as the sweep rate increased. Plots of peak current *vs.* the square root of sweep rate were scattered. The difference between the peak and half-peak potential for the single reduction wave was found to be on the order of 200 mV, as compared with 48 mV expected for a one electron, reversible deposition of a solid product at 450°C. White and Lawson (21, 22) have shown that submonolayer deposition has the effect of broadening the reduction peak, and thus leads to large differences between the peak and half-peak potential. The severe limitations on the sweep rate and concentration prohibited quantitative measurement of $E_{p/2}$ as a function of concentration.

Transport Behavior and Raman Spectra of Electrolytes in Methyl Formate and Propylene Carbonate

H. V. Venkatasetty*

Honeywell Corporate Research Center, Bloomington, Minnesota 55420

ABSTRACT

The conductances of $LiClO_4$, $LiBF_4$, and $LiAsF_6$ in methyl formate and $LiAsF_6$ in propylene carbonate have been measured from dilute solution to very high concentration. Anomalous conductance behavior has been observed for the concentrated solutions of these salts in methyl formate. From conductance data, equivalent conductance at infinite dilution, ion-pair dissociation constant, and information on the formation of triple ions and more complex aggregates are obtained. The detectability of water in methyl formate and the effect of water on solvent spectrum are studied by Raman spectra. In concentrated solutions, ion-ion and ion-solvent interactions have been studied by Raman spectra.

Nonaqueous solvent systems are unique in that they provide a wide spectrum of macroscopic properties like the dielectric constant, wide liquid range, viscosity, and dipole moment. They also have specific microscopic properties like solvent molecular shape, solvent size, and different functional groups attached to them which can influence the behavior of solutes (1). The versatility of the nonaqueous electrolytes not only has led to new technologies but also to rapid advances in general theory of conductance (2). Recently different nonaqueous electrolyte systems, both organic and inorganic types, are being explored and some are being used with varying amounts of success with lithium anode and different kinds of cathode materials as high-energy density power sources (3-5). The mass transport properties of these electrolytes and electrolyte solution-electrode interactions can limit the efficiency and performance of the battery. It has been shown by Keller (6) in lithium-cupric fluoride battery with 1M $LiClO_4$ in propylene carbonate that the severe performance limitations encountered in regard to discharge rates can be attributed to mass transport limitations in the electrolytes.

Since more concentrated solutions of electrolytes ($\sim$1M) are used in batteries wherever possible to minimize *IR* drop and most of the solvents have low dielectric constants, it is necessary to consider the formation of ion-pairs in these solvents even at low concentrations ($\sim 10^{-4}$M), and the formation of triple ions and more complex aggregates at higher concentrations. These complex equilibria can limit ionic transport processes particularly at low temperatures and thus affect battery operation. Unpublished results in the author's laboratory on the discharge characteristics of cells containing these electrolyte solutions have shown them to be potentially promising for high-energy density battery applications. The present studies were undertaken to determine the conductance behavior of $LiClO_4$, $LiBF_4$, and $LiAsF_6$ in methyl formate and $LiAsF_6$ in propylene carbonate over a wide concentration range and to obtain the Raman spectra for concentrated solutions of $LiClO_4$, $LiBF_4$, and $LiAsF_6$ in methyl formate which show anomalous conductance behavior. From conductance measurements such information as equivalent conductance at infinite dilution (Λ_o), ion-pair dissociation constant (K_d), and information on the formation of triple ions and more complex aggregates at higher concentration can be obtained. From Raman spectra information on the effect of water on solvent structure and ion-solvent and ion-ion interactions in more concentrated solutions can be obtained.

Key words: methyl formate, propylene carbonate, electrolyte solutions, conductance, Raman spectra.

Experimental

Methyl formate dried over Na_2CO_3 and distilled from P_2O_5 was used. It contained not more than 150 ppm of water as determined by gas chromatographic method and Karl Fischer titration. Propylene carbonate treated with CaO and distilled under vacuum contained no more than 120 ppm of water. The relative humidity of the dry room was about 4% and the dry box used in the author's laboratory with silica gel and with positive pressure of dry nitrogen showed a relative humidity of about 3% inside the box. Therefore all solutions were made in the dry room with precautions taken to eliminate any moisture contamination. The electrolytes $LiClO_4$, $LiBF_4$, and $LiAsF_6$ were the highest purity available ($LiBF_4$ and $LiAsF_6$ from Foote Mineral Company) and dried under vacuum at about 150°C for several hours and used without further purification. The electrolytes were assumed to be anhydrous and no moisture content was determined. Jones and Bollinger type conductance cells with bright platinum disk electrodes with cell constants varying from 0.2416 to 10.00 were used. All conductance measurements were made at 25° ± 0.05°C with the conventional techniques to measure resistance with a General Radio bridge. Raman spectra were recorded with a Jarrell-Ash laser-Raman spectrometer (Model 25-300) having both He-Ne (6328Å) and Ar ion (4880Å) lasers (55 and 125 mW, respectively) as excitation sources. Pyrex glass Raman tubes (0.7 mm OD and 10 cm long) with optical flats as windows were filled with the solvent and solutions under dry conditions and sealed. The spectra were run two to three times to establish band positions. The region 2800-3900 cm^{-1} was examined for water frequencies.

Results and Discussion

AsF_6^- of $LiAsF_6$ is a noninterfering anion with low polarizability and spherical symmetry (7). Therefore, it should be interesting to compare its Raman spectrum and the conductance of $LiAsF_6$ in methyl formate with those of $LiClO_4$ and $LiBF_4$.

The conductance measurements were made on $LiAsF_6$ in methyl formate covering a concentration range of 2M to 5×10^{-4}M, and in the case of $LiClO_4$ and $LiBF_4$ from 1.2 to 8×10^{-4}M and for $LiAsF_6$ in propylene carbonate from 1.2 to 2×10^{-4}M. Plots of equivalent conductance (Λ) *vs.* log concentration for $LiClO_4$ and $LiBF_4$ in methyl formate are shown in

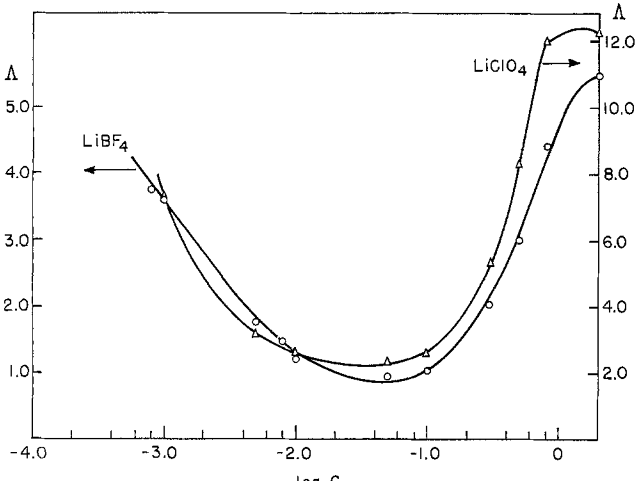

Fig. 1. Equivalent conductance *vs.* log concentration of $LiClO_4$ and $LiBF_4$ in methyl formate.

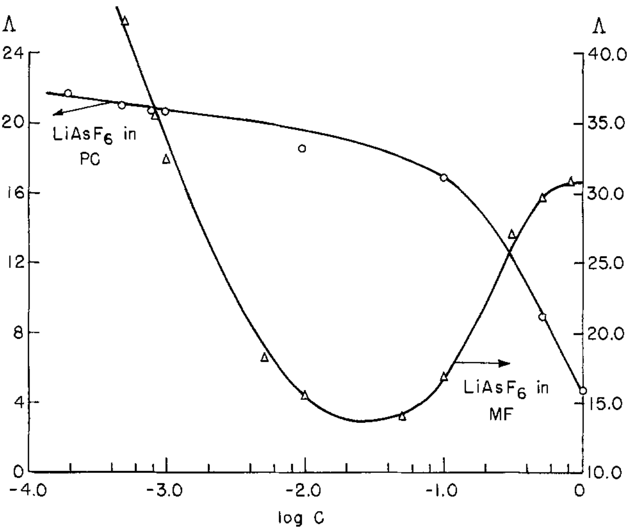

Fig. 2. Equivalent conductance *vs.* log concentration of $LiAsF_6$ in methyl formate and in propylene carbonate.

Fig. 1. Similar plots for $LiAsF_6$ in methyl formate and in propylene carbonate are shown in Fig. 2. It is interesting to note that $LiAsF_6$ as the most conducting salt shows a fairly high equivalent conductance at high dilution ($\Lambda = 42.4$ cm^2 ohm^{-1} equiv.$^{-1}$ at 5×10^{-4}M) and unusually high conductance at high concentration ($\Lambda = 21.2$ cm^2 ohm^{-1} equiv.$^{-1}$ at 2M) and the minimum in conductance appears at about 0.05M ($\Lambda = 14.1$). In the case of $LiClO_4$ at high dilution, the measured equivalent conductance is much lower ($\Lambda = 7.3$ at 10×10^{-4}M) whereas the equivalent conductance at high concentration is fairly high ($\Lambda = 12.4$ at 1.2M) and the minimum occurs at around 0.05M ($\Lambda = 2.3$). With $LiBF_4$ the conductances are lower over the entire concentration range indicating lower mobility ($\Lambda = 3.74$ at 8×10^{-4}M and $\Lambda = 5.46$ at 1.2M) with the minimum occurring around 0.05M ($\Lambda = 0.95$) as shown in Table I. In the case of $LiAsF_6$ in propylene carbonate, equivalent conductance decreases gradually with increasing concentration as expected for a solvent with high dielectric constant of 64.4 (1).

The plots of equivalent conductance *vs.* concentration shown in Fig. 1 and 2 and those of Λ *vs.* $\sqrt{c}$ for all the three electrolytes in methyl formate and $LiAsF_6$ in propylene carbonate for more dilute solutions shown in Fig. 3, indicate that all these electrolytes behave as weak electrolytes with the formation of ion-pairs, triple ions, and more complex aggregates. For such solutions, the information on the limiting equivalent

conductance (Λ_o) and the dissociation constant (K_d) for the ion-pairs is important for understanding the ion-solvent and ion-ion interactions. The conductance data in the dilute region of the solution are expected to follow the Ostwald dilution law and the law of mass action. Approximating the activity coefficient of each ionic species unity as a limiting case, an equation of the form similar to that of Fuoss-Shedlovsky (8), except the function $S(z)$, can be conveniently applied. The equation is of the form

$$\frac{1}{\Lambda} = \frac{1}{\Lambda_o} + \frac{C\Lambda}{K_d(\Lambda_o)^2}$$

where Λ_o is the limiting equivalent conductance and K_d is the dissociation constant. Plots of $1/\Lambda$ as a func-

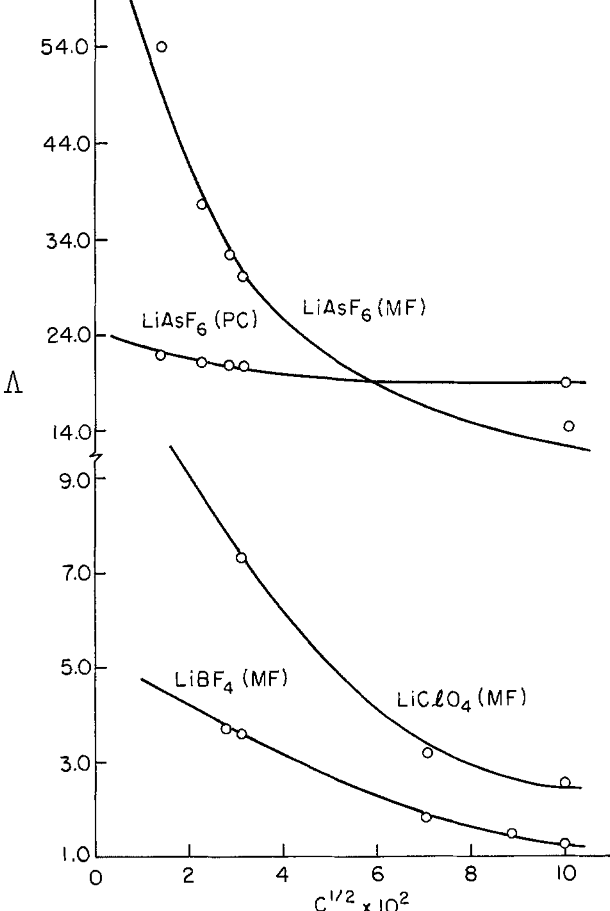

Fig. 3. Equivalent conductance *vs.* $\sqrt{c}$ of concentration of $LiAsF_6$, $LiClO_4$, and $LiBF_4$ in methyl formate and $LiAsF_6$ in propylene carbonate.

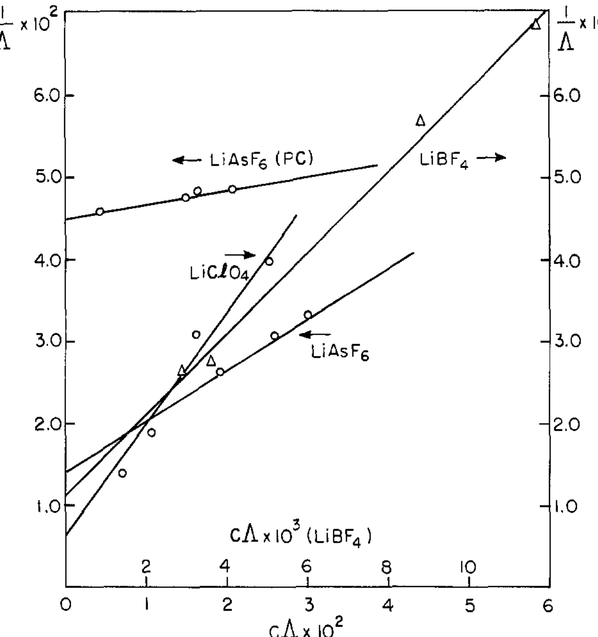

Fig. 4. $1/\Lambda$ vs. $C\Lambda$ plots of $LiAsF_6$, $LiClO_4$, and $LiBF_4$ in methyl formate and of $LiAsF_6$ in propylene carbonate.

tion of $C\Lambda$ for all the electrolytes in the two solvents gave straight lines as shown in Fig. 4. From the intercepts and the slopes, the limiting equivalent conductance(s) and dissociation constant(s) were obtained, respectively. These values are shown in Table I.

The Λ_o value for $LiAsF_6$ in methyl formate is 71.5 and K_d 3.13 $\times$ 10^{-4} whereas in propylene carbonate Λ_o is 22.2 and K_d is 11.8 $\times$ 10^{-3}. The higher value of Λ_o can be attributed to the noninteracting nature of AsF_6^- ion and lower viscosity of methyl formate (1). Likewise the smaller value of Λ_o in propylene carbonate can be attributed to higher viscosity and the higher value of K_d to the higher dielectric constant of propylene carbonate (1). In water at 25°C, the Λ_o value for $LiAsF_6$ is 94.87 and is completely dissociated as expected (7). The lower values of Λ_o for $LiClO_4$ (16.6) and $LiBF_4$ (9.1) shown in Table I can be attributed to considerable ion-solvent interactions in these systems. The K_d values are consistent with such interactions. When log Λ *vs.* log C plots are made for all these electrolytes the slope predicted for ion-pair formation, namely, $-\frac{1}{2}$ (9), is found for all the salts with minima occurring at 0.05M in methyl formate and shifting to a higher concentration in propylene carbonate, as shown in Table I.

The formation of triple ions and ion quadrupoles with increasing concentration of ionic salts in solvents of low dielectric constant has been treated theoretically by Fuoss and Kraus (9, 10). The increase in conductance with concentration after the minimum has been shown to be due to the formation of triple ions by coulombic interaction between the ion-pair and the ionic species. The equation describing this equilibrium is given by

$$\Lambda = \sqrt{\frac{K}{c}}\,\Lambda_o + \frac{\sqrt{Kc}}{k}\,\Lambda_{o3}$$

where K and k are the equilibrium constants for ion-pair and triple ion formation and Λ_o and Λ_{o3} have their usual significance (9, 10). Graphs of $\Lambda c^{1/2}$ *vs.* C in all these systems give straight lines indicating that such interactions do predominate.

The unusually high conductances observed for concentrated solutions of these salts in methyl formate can be explained partly due to large anions with low surface charge density and partly due to hydrolysis. Methyl formate solvent with a dielectric constant of 8.4 (1) has been found to show a dielectric constant of 27.4 $\pm$ 6.0 in 1.1M $LiAsF_6$ solution (11). The very low values of conductances and Λ_o (9.1) observed for $LiBF_4$ in methyl formate are probably due to the dissociation of BF_4^- ion to BF_3 and F^- and the limited solubility of LiF (3 $\times$ 10^{-5}M) in methyl formate (6).

Vibrational spectroscopy has been extensively used in molten salts and concentrated solutions of electrolytes in water to study ionic interactions. Unfortunately, very little such data are available on nonaqueous electrolytes of interest to battery technology. Janz and co-workers have used laser Raman spectroscopy to study ion-ion and ion-solvent interactions in concentrated solutions of silver nitrate in acetonitrile (12-14). Laser Raman spectroscopy has been used here to study the ion-ion and ion-solvent interactions in concentrated solutions of $LiAsF_6$, $LiClO_4$, and $LiBF_4$ in methyl formate which show anomalous conductance behavior.

Since the presence of water even in small quantity in the solvent ($\geqq$ 100 ppm) is detrimental to the stability and performance of a battery, it was decided to study the effect of water on the structure of the solvent. It was found that water in the solvent could be detected using Raman spectroscopy by the presence of a strong broad band appearing at a frequency of 3565 cm^{-1} due to symmetrical vibration (15) as shown in Fig. 5. Further, the presence of water can be detected only when the water content is larger than 1% by weight. In order to compare the spectra of solvent samples with different amounts of water in them, the height of the solvent CH_3-symmetrical stretching peak appearing at a frequency of 2840 cm^{-1}, which does not change with water content, was used as an internal standard and compared to the height of the water peak at 3565 cm^{-1}. Therefore, when the ratio of the height of the water peak to the height of the standard solvent peak *vs.* weight per cent by water is plotted, the value of the ratio increases until a water content of 8.4% by weight is reached above which the value of this ratio remains constant as shown in Fig. 6. At higher concentration of water (11.67% by weight) on careful observation, a second layer below the methyl formate phase is seen. It is possible that this layer is already formed at smaller water concentrations. When these layers were separated and the spectra taken, it is found that the spectrum of the methyl formate phase

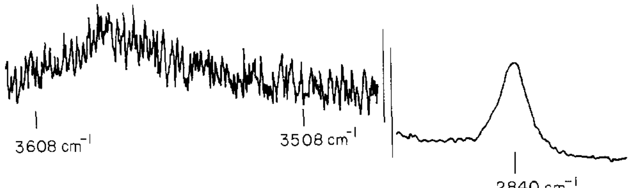

Fig. 5. Prominent water and methyl formate bands from Raman spectrum.

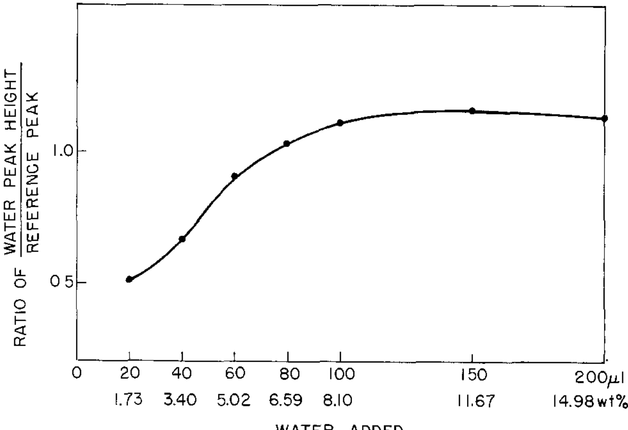

Fig. 6. Plot of the ratio of water peak height to the reference peak *vs.* the weight per cent water added.

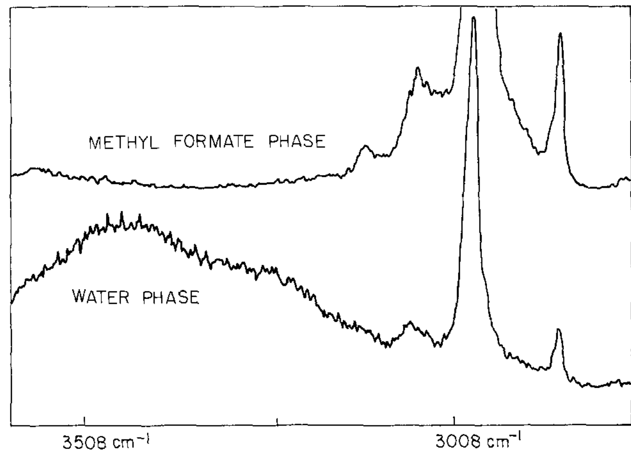

Fig. 7. Raman spectra of the methyl formate phase and the water phase.

is identical to the pure solvent whereas the spectrum of the water phase shows both the vibrations of the methyl formate and of the water modes. The carbonyl stretching band of methyl formate appearing at 1717 cm^{-1} in the pure solvent has shifted to lower frequency and the intense water peak has shifted from 3565 to 3444 cm^{-1} as shown in Fig. 7. These spectral changes can be interpreted in terms of interactions between the water molecules and the methyl formate molecules. The conclusion that can be drawn from this study is that a small quantity of water is soluble in methyl formate and it is possible that by strong interaction the carbonyl group of the solvent molecules induces a few bridges with the water molecules. Thus, it is possible that most of the soluble water in methyl formate is decoupled water and in the water phase most of the water is lattice water.

The Raman spectra of 2M $LiAsF_6$ in methyl formate have been obtained. The anion AsF_6^- with octahedral symmetry should give three Raman active fundamental vibrations (15). Three Raman frequencies are observed for solid related compounds (16). $LiSbF_6$ shows ν_1 at 668 cm^{-1}, ν_2 (double degenerate) at 558 cm^{-1}, and ν_5 at 294 cm^{-1}, whereas $CsAsF_6$ shows ν_1 at 685 cm^{-1}, ν_2 at 576 cm^{-1}, and ν_5 at 372 cm^{-1} (16) as shown in Table II. In the case of $LiAsF_6$-methyl formate solution only two Raman frequencies are obtained ν_1 at 678 cm^{-1} and ν_5 at 344 cm^{-1} as shown in Table II where the degenerate mode ν_2 has been lifted. The lifting of the degenerate mode ν_2 can be attributed to interactions of the AsF_6^- ion with the solvent as well as the cation. Similar observations have been made by Janz and co-workers on acetonitrile-silver nitrate solutions (14) and aqueous lithium chlorate solutions (17) which have been interpreted in terms of ion-ion and ion-solvent interactions.

An unperturbed perchlorate ion (ClO_4^-) with tetrahedral symmetry shows four Raman active vibrational modes; symmetric vibration, ν_1, a doubly degenerate deformation, ν_2, a triply degenerate vibration, ν_3, and a triply degenerate deformation, ν_4 (15). The Raman spectrum of lithium perchlorate-methyl formate solution (1.2M) shows the expected four bands: ν_1 at 941 cm^{-1}, ν_2 at 457 cm^{-1}, ν_3 at 1125 cm^{-1}, and ν_4 at 632 cm^{-1} as shown in Table III. These frequencies when compared to those of molten lithium perchlorate (18) and solid lithium perchlorate (18) as shown in Table III show a shift to lower values indicating considerable ion-solvent interactions in methyl formate solution. The Raman spectrum of an aqueous solution of lithium perchlorate (19) shows that all four frequencies appear at lower values compared to those of lithium perchlorate-methyl formate solution as shown in Table III indicating that the ion-solvent interactions are stronger in the aqueous system as anticipated. The tetrafluoroborate ion BF_4^- with tetrahedral symmetry should show four Raman lines appearing in the frequency range of about 1000-350 cm^{-1} (20). However, $LiBF_4$-methyl formate solution (1.2M) shows a band at 2130 cm^{-1}. It is possible that BF_4^- dissociates to BF_3 and F^- and BF_3 complexes with methyl formate while LiF with low solubility precipitates (6).

Technical Note

Polarization of Mild Steel in Mixed $NaNO_3/NaClO_4$ Electrolytes

Der-Tau Chin[*,1]

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

This communication describes an experimental measurement with a rotating mild steel[1] hemispherical electrode to see if there were convection effects on the steady-state polarization in mixed $NaNO_3/NaClO_4$ electrolytes. Details of the experimental measurement have been reported elsewhere (1). The results are shown in Fig. 1 (represented by the symbols ○, △, ●, etc.) for three electrolyte compositions at various rotational speeds. Nitrogen-saturated 4M (total anion strength) electrolytes at a constant temperature of 22° ± 2°C were used for the tests; the *p*H of these electrolytes was maintained between 6 and 8 during the experimental runs. For comparison, steady-state polarization curves previously reported (1, 2) for the rotating mild steel hemispherical electrode in 4M $NaNO_3$ and 4M $NaClO_4$ are also plotted in the figure as the thick and the thin curves, respectively.

Figure 1 shows a difference between the present results and those reported previously by Hoare *et al.* (3, 4) for stationary mild steel beads in mixed $NaNO_3/NaClO_4$ electrolytes. These authors have found that

* Electrochemical Society Active Member.
[1] Present address: Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676.
Key words: electrochemical machining, passivation, transpassive dissolution, rotating hemispherical electrode.
[1] Composition of mild steel other than iron: Mn, 0.98%; S, 0.29%; C, 0.1%; P, 0.06%; Si, 0.005%.

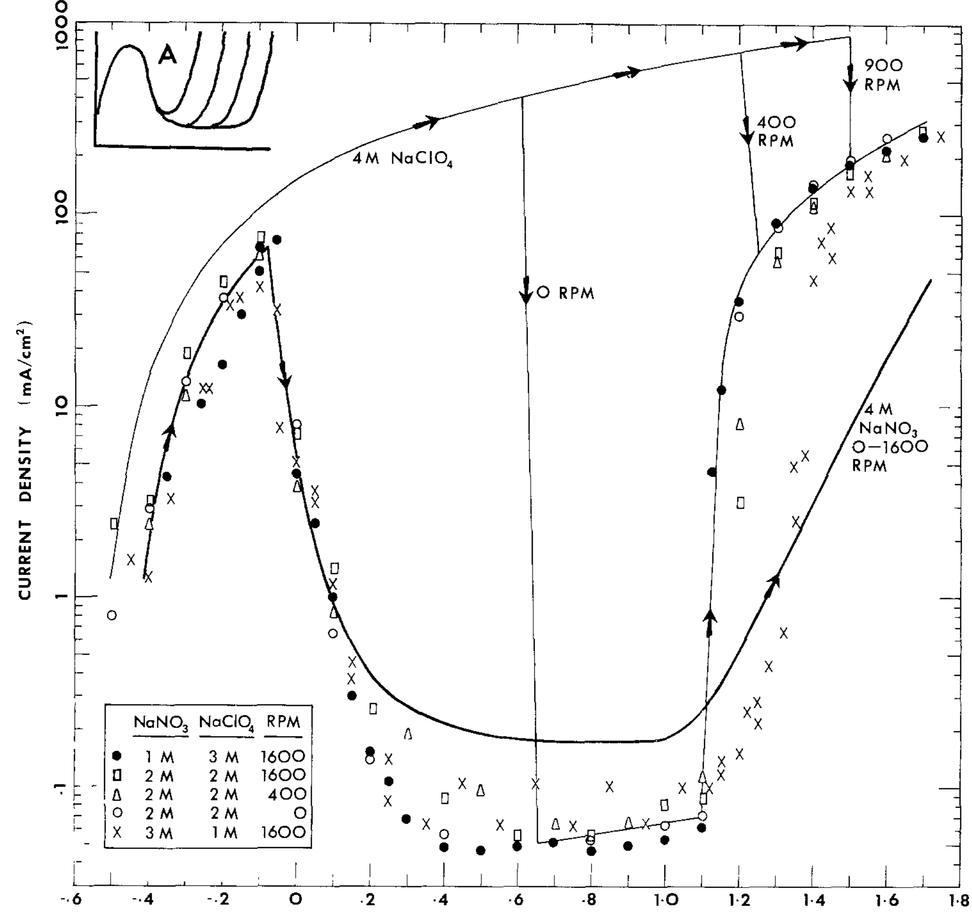

Fig. 1. Steady-state polarization of a rotating mild steel hemispherical electrode in mixed $NaNO_3/NaClO_4$ electrolytes. The data were taken at a constant temperature of 22° ± 2°C. For comparison, the results by Hoare *et al.* (3, 4) are sketched in inset A, in which the passive/transpassive transitional potential is a function of electrolyte composition.

the potential at which transition from the passive to the transpassive state began was a function of electrolyte composition (Fig. 1A). The transpassive potential began at less noble values with increasing concentration of perchlorate ions until a minimum potential of 0.3 V/SCE was reached at 67% perchlorate in a total 3M mixed $NaNO_3/NaClO_4$ electrolyte. The transpassive region then started at more noble potentials with further increase in perchlorate concentration.

In this study, the variation with the electrolyte composition is not as obvious. For all the compositions tested (ranging from 0% to 100% perchlorate), the transpassive region invariably starts at a potential of 1.1 V/SCE. The slope of the polarization curves at the very beginning of the transpassive region seems to vary with the composition. The curve for 4M $NaNO_3$ has the smallest slope, whereas the curve for 4M $NaClO_4$ has the sharpest transition from the passive to the transpassive states. The data for the mixed electrolytes exhibit a logical trend in that the slope of the transition falls between the two limits and increases with increasing perchlorate concentrations. Four other additional features can also be observed in the figure:

1. The electrode rotation had no effect on the polarization in the mixed electrolyte. The same is also true for the nitrate solution. For perchlorate, the active/passive transition potential occurs at more noble values with increasing rotational speed.

2. For potentials less than 0.2 V/SCE, the data for the mixed electrolytes fall exactly on the curve for 4M $NaNO_3$. It seems that in this low potential region, only nitrate ions participate in the anodic processes; perchlorate serves only as the supporting electrolyte. There is no doubt that the passivation in the mixed electrolytes is initiated by nitrate ions.

3. In the passive region (from 0.2 to 1.1 V/SCE), the current density for the mixed electrolytes falls below that for $NaNO_3$, and agrees with that for $NaClO_4$. Apparently, in this region, the anode starts to adsorb perchlorate ions, which in turn reduce the passive current density to the level specified by the $NaClO_4$ curve. The nature of the protective film in the mixed electrolytes probably resembles that in the perchlorate solutions.

4. In the transpassive region (potentials greater than 1.1 V/SCE), the shape of the polarization curves for the mixed electrolytes closely resembles that of $NaClO_4$ rather than $NaNO_3$ even though the initial slopes are a function of electrolyte composition. For potentials greater than 1.5 V/SCE, the data points for all the mixed electrolytes seem to converge to a single curve represented by the polarization behavior in 4M $NaClO_4$. It has been reported in previous studies (5, 6) that during the early transpassive state (below the potential where the current density at the anode is less than 5000 mA/cm^2), mild steel in nitrate solutions is covered with an electronically conductive oxide film, and the current is consumed solely in the oxygen evolution reaction at the oxide/electrolyte interface. Addition of perchlorate ion to nitrate solutions seems to greatly reduce the critical potential at which the oxide film begins to break apart and the underlying metal matrix starts to dissolve transpassively into the electrolyte.

In the present study, nitrogen-saturated 4M mixed electrolytes were used for the measurements, whereas Hoare *et al.* used oxygen-stirred 3M solutions. The solubility of O_2 in water at 25°C is 0.039 g/liter, or 0.0012M (7). It is questionable that the presence of this small amount of O_2 could reduce the onset of transpassive potential by up to 800 mV. The differences might be caused by variations in the composition of mild steels or the experimental methods used in the polarization measurements.

It is not known at the present time why the results of this study differ so much from those previously reported. The differences are of considerable importance to those working in this field. Hence, subtle, as yet unknown, factors can influence the results significantly —a fact which should be brought to the attention of future workers studying the fundamental nature of electrochemical machining.

Brief Communication

Adsorption Isotherm of Iodide Ions on Copper Single Crystal Planes in Sulfuric Acid

S. M. Mayanna

Department of Chemistry, Central College, Bangalore University, Bangalore-1, India

Halide ions are both stimulators and inhibitors of corrosion of metals (1). Inhibitive anions are known to adsorb preferentially at metal/solution interfaces that are positive to the zero charge potential of the metal (2). Hackerman (3) has proposed an adsorption theory of corrosion inhibition in which adsorption is general in character and higher order of inhibitor efficiencies favor those inhibitors which exhibit chemisorption (4). An iodide ion can show strong interaction on the metal surface because of its high polarizability (5). Copper is an industrially important metal next to iron and the study of inhibition of acid corrosion of copper is a subject with tremendous technological significance. In view of the importance of specific adsorption to practical systems of corrosion, an attempt has been made to know the nature of interaction of iodide ions on copper single crystal planes during acid corrosion. The Langmuir adsorption isotherm has been applied to the adsorption of iodide ions on copper single crystal planes in 0.1*N* sulfuric acid, and heats of adsorption have been evaluated.

Solutions were prepared from freshly distilled and pre-electrolyzed AR sulfuric acid and recrystallized AR potassium iodide using triple distilled water; 99.999% copper (110), (100), and (111) planes with dislocation density of the order $10^6/cm^2$ were mechanically polished on 4/0 emery paper using ethyl alcohol as lubricant and then electropolished in 1:1 orthophosphoric acid (6) at a cell potential of 1.2V for 30 min. The dissolution was carried out in aerated 0.1*N* sulfuric acid with the desired amount of potassium iodide. The potentials of copper single crystal planes were recorded against a Hg/Hg_2SO_4 reference electrode using VTVM. The detailed experimental procedure has been given in a previous communication (7). Copper (110), (100), and (111) planes were dissolved in aerated unstirred 0.1*N* sulfuric acid containing various concentrations of iodide ions at different temperatures, and dissolution rates ($mg/cm^2/hr$) were evaluated. Iodide ions had significant effect on the dissolution rates of the crystal planes when its concentration was in between 10^{-6} and 10^{-4}M. The surface coverages (θ) of iodide ions on the crystal planes at different temperatures were evaluated from the dissolution rates using the equation (8)

$$\theta = 1 - P/P_o \quad [1]$$

where P and P_o were the dissolution rates with and without iodide ions, respectively. The surface coverage increased on increasing the concentration of iodide ions up to 10^{-4}M. The additional increase of iodide ions above 10^{-4}M did not increase the surface coverage further. Table I shows the effect of iodide ions on the surface coverage up to 10^{-4}M at 30°C. The values of C/θ were plotted against C (C being the concentration of iodide ions in the bulk of the solution) for various

Key words: surface coverage, inhibitors, adsorption isotherm, heat of adsorption.

Table I. Surface coverage of iodide ions on copper single crystal planes in sulfuric acid at 30°C

Sulfuric acid pH	Concentration of I- ions (M)	θ (110)	θ (100)	θ (111)
1.0	1×10^{-6}	0.37	0.05	0.26
	5×10^{-6}	0.41	0.11	0.30
	1×10^{-5}	0.56	0.30	0.41
	5×10^{-5}	0.75	0.55	0.50
	1×10^{-4}	0.90	0.74	0.58

crystal planes at different temperatures. Figure 1 shows the variation of C/θ with C for all the crystal planes at 30°C. Heats of adsorption of iodide ions on copper (110), (100), and (111) planes were calculated (9) and these values were found to be 11.8, 13, and 15.2 kcal/mole, respectively.

The mechanism of the dissolution reaction of copper in acidic solution according to Bockris *et al.* (10) is as follows

$$Cu \rightarrow Cu^+ + e \quad [2]$$

$$Cu^+ \xrightarrow[\text{rds}]{} Cu^{++} + e \quad [3]$$

The experimental data obtained recently (11) from our laboratory for copper single crystal planes in sulfuric acid with and without the presence of iodide ions are consistent with the above mechanism indicating that the second electron removal is the rate determining step. In the presence of iodide ions, the rate of the

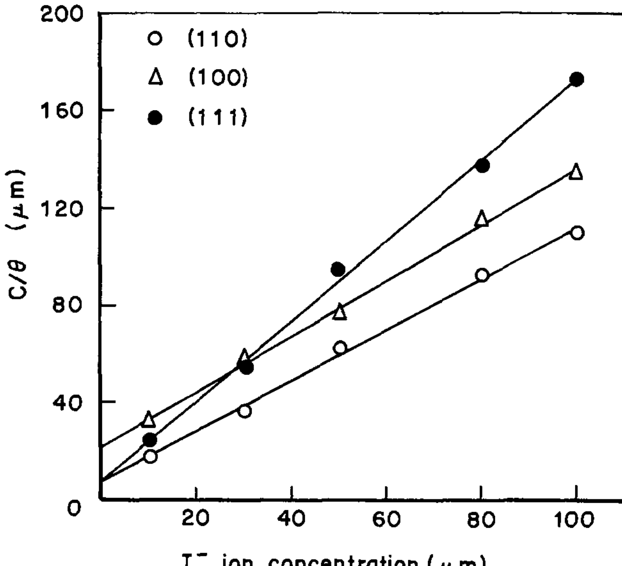

Fig. 1. Langmuir adsorption isotherm for adsorption of iodide ions on copper single crystal planes in sulfuric acid at 30°C.

dissolution reaction is decreased. However, the anodic Tafel slopes for copper single crystal planes in the absence and presence of iodide ions are the same. This indicates that the mechanism of the dissolution reaction on uninhibited and inhibited copper single crystal planes in sulfuric acid is the same.

The corrosion potential on ϕ scale (12) indicates the positive charge on the surface of the crystal plane and inhibition of acid corrosion by the adsorption of iodide ions at the reaction sites on the surface of the crystal plane. The dissolution rate of a metal depends on the number of available free reaction sites on the surface (13). If the above fact is valid, and assuming no interaction between the adsorbed ions (14) (at low values of θ), then the apparent dissolution rate of the inhibited copper single crystal plane is proportional to the number of reaction sites not covered by iodide ions. A correlation between θ and C can be achieved with the Langmuir adsorption isotherm

$$\theta = KC/1 + KC \quad [4]$$

Rearranging Eq. [4]

$$C/\theta = 1/K + C \quad [5]$$

Figure 1 is a plot of Eq. [5] and shows that the Langmuir adsorption isotherm correlates the experimental data. The values of heats of adsorption indicate that the iodide ion is strongly adsorbed on the copper single crystal planes. This is in agreement with the experimentally observed higher order of inhibitor efficiency of the iodide ions which is an important feature of chemisorption (15).

Acknowledgments

The work carried out was inspired by the late Professor T. H. V. Setty. The author wishes to express his gratitude to Professor M. Shadaksharaswamy, Head of the Department of Chemistry, Bangalore University, Bangalore, India, for his encouragement.

The Direct Radiometric Study of Electrosorption of Tritium Labeled Compounds

Adsorption of Methanol on Gold Electrodes

Andrzej Wieckowski

Chemistry Department, University of Warsaw, Warsaw, Poland

"The main drawback (of radiometric methods) would seem to be the demand for electrodes of very large area. This restriction limits precision, limits the variety of metals which can be studied, and as yet does not allow measurements on smooth metals (to which most other methods have been applied)." This opinion of Perkins and Andersen (1) seems still to be valid in spite of the fact that some new methods have been elaborated since 1969 (2-4). As a way for improvement of the methods used for the study of adsorption of organic compounds, an application of tritium atoms as a labeling agent rather than ^{14}C may be suggested. However, owing to its low energy (E_{max} = 18.6 keV), the β^- tritium radiation is strongly absorbed in adsorbent material which causes serious experimental problems. The working electrode must be prepared from a very thin layer of metals and use of a window counter (5) seems, in practice, to be impossible. This low penetrability of tritium radiation brings about, at the same time, the effective elimination of background counting (6). It should be noted that the presence of the background counting in the study of ^{14}C or ^{35}S labeled compounds has limited the range of applicability of radiometric methods.

Key words: electroadsorption, tritium labeled compounds, methanol, glass scintillator.

Knowing the half thickness of ^3H radiation [$l_{1/2}$ = 0.28 mg·cm^{-2}, (7)] we may estimate the maximum thickness of the layer of a metallic film which may be used for the adsorption study. For the case of Au or Pt electrodes, the practical thickness of the layer cannot be greater than *ca.* 2000Å. This value can be compared with the thickness of metallic films of OTE (optical transparent electrodes) described by von Benken and Kuwana (8) equal to *ca.* 100Å.

We have overcome the experimental difficulties by the use of a glass scintillator disk (NE 901, Nuclear Enterprises Limited) as a radiation detector. The metallic films were prepared by the vapor deposition of metals directly onto the scintillator surface. The tritium radiation transparent electrodes thus obtained will further be called TRTE.

Experimental

The sketch of the apparatus used, which is similar to the schemes previously reported (3, 4), is given in Fig. 1. Since Au was found to be poorly adherent to the scintillator surface, an oxide undercoating was first deposited. Lead dioxide produced the greatest improvement in film properties which is in agreement with von Benken and Kuwana's results (8). The thickness of PbO_2 was estimated to be about 100Å and the thickness of Au, about 1100Å. Gold films were mechanically stable, with the coating being removed only when hydrogen or oxygen were evolved or by immersion in concentrated acidic solutions. It was observed that after an exposure of the glass scintillators to daylight or white electric light, the strong excitation of the scintillator material occurred. It took several hours or more of keeping the scintillators in the dark to cool down their luminescence radiation. As a remedy, the annealing of the TRTE electrodes in an oven at 250°C was used. One hour of the annealing was quite enough to reduce the luminescence radiation to an acceptable level (*ca.* 20 counts per second). Moreover, it also improved the mechanical adherence of Au films (8). Further operations, which followed the annealing, were carried out using red electric light exclusively. During experiments, the electrochemical cell, the glass scintillator (TRTE), as well as the photomultiplier (Fig. 1), were placed in a lightproof box and all further operations were carried out outside the box.

Aqueous Na_2SO_4 (0.1M) solutions, used as a supporting electrolyte, were prepared from A.R. grade salt, recrystallized before use, and from threefold distilled water (the second distillation being made from alkaline permanganate solutions). The supporting electrolyte, before use, was preelectrolyzed on platinum electrodes of high geometric area (*ca.* 30 cm^2) for several hours. A 1.35V cell, connected directly between the two electrodes, was used as a polarizing source (9). The inert gas passed through the preelectrolysis cell to purge volatile impurities from the solution, additionally stirred mechanically. The stream of the inert gas served also as a blanket to exclude any contact of the solution with the atmosphere. Purified and deoxygenated (< 0.1 ppm of O_2) argon was used as the inert gas.

Tritium labeled methanol (methyl- ^3H) manufactured by "Amersham" (specific activity, 125 mCi·$mmole^{-1}$) and ^{14}C labeled methanol produced by "I.B.J.-Swierk" (5 mCi·$mmole^{-1}$) were isotopically diluted to 10 mCi·$mmole^{-1}$ and 0.50 mCi·$mmole^{-1}$, respectively. A.R. grade methanol, purified further by the use of the method given in Ref. (10) was employed as a diluting agent. Since ^3H-methanol was labeled in methyl group, the exchange of ^3H with ^1H_2O could not be taken into account (11).

The remaining details concerning the experimental procedure were similar to those recently described for the case of the study of ^{14}C labeled compounds (4). The electrode potentials are referred to the hydrogen electrode in the same solution as the working (TRTE) electrode. At the beginning of every experiment, the alternate anodic-cathodic pulsing was imposed on the working electrode for several minutes to clean the Au surface. The electrode potential was controlled with a potentiostat (Radelkis, OH-404) and a valve voltmeter (Radelkis, OP-205) set. A conventional radiometric unit, equipped with a power supply, an amplifier, a scaler, and a printer ("Polon") was employed. The photomultiplier was cooled down to 2°C to reduce its thermal background.

All experiments were carried out at ambient temperature 25° ± 2°C. The bulk concentration of methanol was constant and equal to 10^{-2} M.

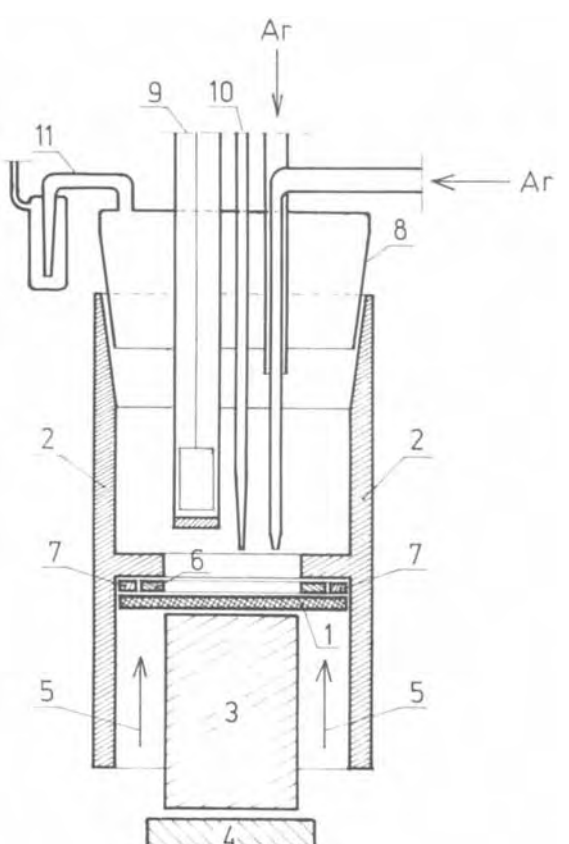

Fig. 1. Sketch of radioelectrochemical cell. 1, TRTE (tritium radiation transparent electrode); 2, Teflon frame; 3, light pipe; 4, photomultiplier (EMI-9514 S); 5, tightening; 6, Teflon gasket; 7, rubber gasket; 8, Kel-F sealed glass (Pyrex) ground joint; 9, counterelectrode (closed by fritted disk); 10, reference hydrogen electrode (Luggin capillary); 11, bubbler; Ar, inlets of argon.

Results and Discussion

At first, the linearity of the radiometric unit was checked and the results are given in Fig. 2. Tritium labeled water (specific activity, 0.2 mCi·$mmole^{-1}$), added to the radioelectrochemical cell, was used as a calibrating agent. It may be seen that the linear dependence of the counting rates (N) on the specific activity of solution was obtained in the investigated range of c.p.s. (counts per second).

The dependence of the counting rates on time for adsorption and desorption of ^3H labeled methanol is given in Fig. 3. As the minimum of adsorption was

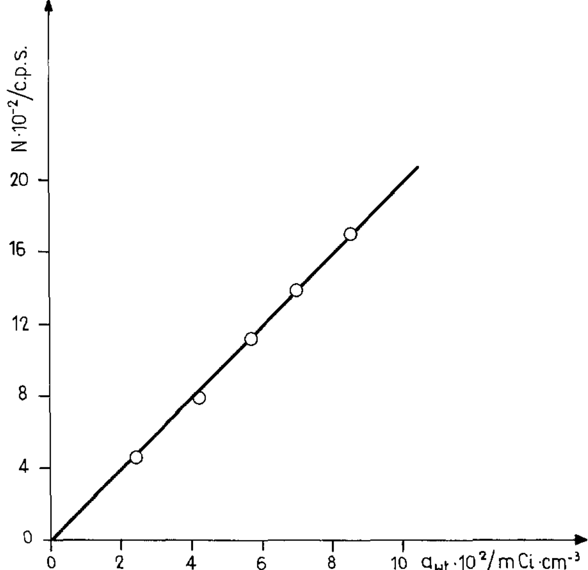

Fig. 2. The dependence of counting rates, *N*(counts per second) on the specific activity (mCi · cm^{-3}) of tritium labeled water (the check of linearity).

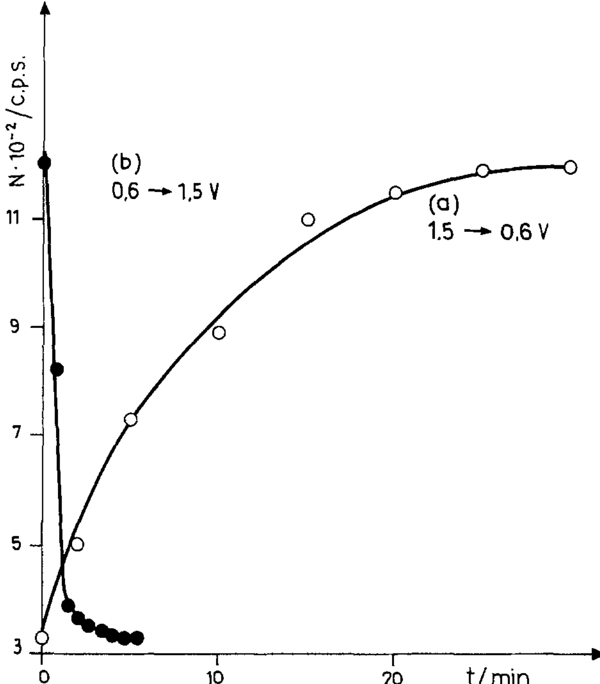

Fig. 3. The experiments with ^{3}H. The dependence of N (counts per second) on time for: (a) adsorption of methanol after potential step from 1.5 to 0.6V; (b) desorption of methanol (0.6 to 1.5V). The background of solution, $N_{soln.}$ = 325 counts/sec.

found in the potential range: 1.3-1.7V, the electrode potential E = 1.5V was chosen as a starting point. Slow adsorption at E = 0.6V (Fig. 3a) and fast desorption (Fig. 3b) after the potential step from 0.6 to 1.5V may be seen in this figure.

In order to demonstrate the difference in using ^{3}H and ^{14}C as labeling agents some experiments with ^{14}C labeled methanol were also carried out. The results are given in Fig. 4. The curve "a" in this figure corresponds to the adsorption of ^{14}C labeled CH_3OH on the Au-glass scintillator electrode. The increase in counting rates was not observed within the experimental error. Adsorption of ^{14}C labeled methanol on a platinized electrode of a roughness factor R = 50 at E = 0.4V is demonstrated in curve "b" of Fig. 4 (12). It should be noted that in both experiments with $^{14}CH_3OH$ the counting efficiency was kept practically the same.

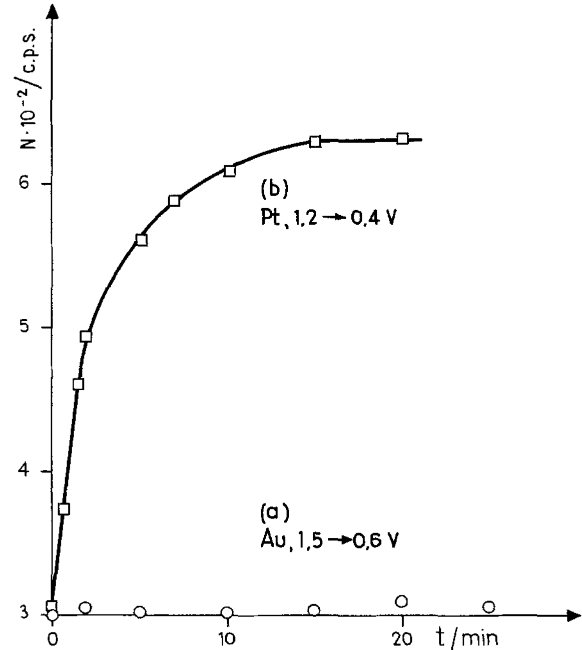

Fig. 4. The experiments with ^{14}C. (a) N (counts per second) vs. t plot for methanol adsorbed on the Au-TRTE after the potential step from 1.5 to 0.6V. (b) N (counts per second) vs. t plot for methanol adsorbed on platinized electrode of R = 50, after the step 1.2-0.4V. N_{soln} = 300 counts/sec.

The difference in the runs "a" and "b" in Fig. 4 can illustrate the importance of the roughness factor in radioelectrochemical investigations provided that the values of surface concentration of methanol intermediates adsorbed on Au and Pt electrodes are similar, which is a reasonable assumption. The difference in the plots "a" in Fig. 3 and "a" in Fig. 4 is considered as an evidence for the great improvement in the radiotracer method brought about by the use of ^{3}H instead of ^{14}C isotope in the study of the adsorption phenomena. This statement is enhanced by the fact that a very high increase in counts per second was observed for adsorption of ^{3}H labeled methanol contrary to the lack of the increase due to adsorption of $^{14}CH_3OH$. In the latter case, the radiometric method is unsuitable for the adsorption study. It must be stressed that besides the difference in the isotopic composition, the experimental conditions were in both cases exactly the same.

The main drawback of the tritium radiochemical method is its restriction to interactions of organic species with solid electrodes not involving the C-T breakage. It can be mentioned that such a process was observed during adsorption of methanol on smooth Pt electrodes (13).

For their good light output (28% of anthracene) and inert properties the glass scintillators can also fruitfully be used as detectors in the adsorption study of ^{14}C or ^{35}S labeled compounds on the electrodes of high R. Platinum adheres well to the scintillator surface, and the platinized electrodes can easily be obtained.

Further studies of electrosorption of tritium labeled compounds on the solid electrodes are in progress, and the results will be given soon.

Acknowledgments

The author is sincerely grateful to Professor J. Sobkowski for the encouragement of this work and for many valuable discussions. The help of Miss A. Jablonska in carrying out the measurements is greatly appreciated.

Doped Ceria as a Solid Oxide Electrolyte

H. L. Tuller[1] and A. S. Nowick

Henry Krumb School of Mines, Columbia University, New York, New York 10027

ABSTRACT

Ceria (CeO_2) doped with divalent or trivalent cations is a mixed conductor; conduction occurs predominantly by the motion of oxygen vacancies or by electrons, depending on the departure from stoichiometry. In order to establish the electrolytic domain (T *vs.* p_{O_2}) at which $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ behaves primarily as an ionic conductor with transference number $t_i \geqq 0.99$, a careful study was made of the conductivity, σ, as a function of temperature and oxygen partial pressure, covering the p_{O_2} range of 10^0-10^{-22} atm in small steps. From these data the electrolytic domain was determined; it extends to about 10^{-13} atm at 600°C. When compared to calcia-stabilized zirconia (CSZ), doped ceria shows a higher conductivity, lower activation energy (0.76 eV) for anion vacancy migration, and absence of polarization effects to lower temperatures. These results indicate that doped ceria may be an attractive candidate for fuel cells and other applications at temperatures below those at which CSZ is useful.

There has been much interest in oxide materials which can serve as solid oxide-ion electrolytes for applications in oxygen concentration cells and in fuel cells (1, 2). The criteria to be met include: (*i*) a high anionic (*i.e.*, O^{2-} ion) mobility, and (*ii*) negligible electronic conductivity. Item (*ii*) is equivalent to the statement that the ionic transference number t_i must be close to unity, although the maximum acceptable value of $1 - t_i$ depends on the specific application. Relatively few oxides meet both of the above criteria. The two materials most often used as solid oxide electrolytes are ZrO_2 and ThO_2, doped with divalent or trivalent cation impurities so as to introduce oxygen vacancies for charge compensation.

Ceria, CeO_2, has the same (fluorite) structure as thoria and (doped) zirconia, but is different in that pure CeO_2 undergoes large departures from stoichiometry at elevated temperatures in a reducing atmosphere, with accompanying electronic conductivity (3). Although doped CeO_2 is often mentioned as showing predominantly ionic behavior (2, 4), the exact extent of the ionic *vs.* electronic contributions has not been well established. Generally, the tendency has been to regard it as unsuitable as an electrolyte material because of its electronic component. Nevertheless, Takahashi *et al.* (5, 2) have made t_i measurements of CeO_2 doped with La_2O_3, using galvanic cell measurements, and have even tried this material in a fuel cell. The values for t_i that they obtain, however, generally fall in the range from 0.6 to 0.9, indicating a substantial electronic contribution.

In the present paper, it is intended to investigate the ionic transference number and electrolytic domain of doped CeO_2. The term "electrolytic domain" refers here to the range of p_{O_2} and temperature at which t_i is greater than 0.99. The information will be obtained not through direct galvanic cell (emf) measurements, since these are deemed to be insufficiently precise to obtain t_i values close to 1.0, but rather through measurement of conductivity, σ, as a function of p_{O_2}. Although such measurements have been performed earlier by Blumenthal *et al.* (6), one cannot obtain the type of quantitative information desired for present purposes from those measurements, primarily because of the existence of large gaps in the p_{O_2} range covered.

In the present work, with special care, it was possible to cover the entire range from $p_{O_2} = 1$-10^{-22} atm in sufficiently close steps to obtain the electrolytic domain with reasonable precision for the case of $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$. In addition, some of the parameters which characterize ionic migration in CeO_2 are obtained. Finally, some experiments on polarization effects are reported.

Theory

Ionic conductivity.—It will be assumed that the only defect giving rise to ionic conductivity in CeO_2 is the doubly ionized oxygen vacancy, $V_o^{\cdot\cdot}$ [in the Kröger-Vink (7) notation]. If the concentration of these vacancies is denoted by n_v, we may write, for the ionic conductivity σ_i, the expression

$$\sigma_i = n_v q \mu_i \qquad [1]$$

where $q = 2e$ is the (positive) charge on the vacancy and μ_i is its mobility, given by (8)

$$\mu_i = \frac{\nu a^2 q}{4kT} \exp(-\Delta G_i/kT) \qquad [2]$$

Here ΔG_i is the free energy of activation for ionic motion, expressible in terms of an enthalpy of activation ΔH_i and entropy of activation ΔS_i by

$$\Delta G_i = \Delta H_i - T\Delta S_i \qquad [3]$$

ν is a frequency factor and a is the lattice parameter of the cubic unit cell. ($a/2$ is the nearest neighbor oxygen spacing and, therefore, the jump distance of a vacancy.) Thus, in the semiempirical equation

[1] Present address: Physics Department, The Technion, Haifa, Israel.

Key words: ionic conductivity, cerium dioxide, solid electrolyte, point defects.

$$\sigma_i = \frac{C_i}{T} \exp(-E_i/kT) \quad [4]$$

the parameters E_i and C_i are given by

$$E_i = \Delta H_i \quad [5]$$

and

$$C_i = (\nu a^2 e^2/k) n_v \exp(\Delta S_i/k) \quad [6]$$

assuming that n_v is not temperature dependent.

The "activation energy" E_i is obtained in the usual way from a plot of log $\sigma_i T$ *vs.* $1/T$. It should be noted that if instead, one plots log σ_i *vs.* $1/T$, a straight line will usually be obtained within experimental error, but its slope gives an apparent activation energy E_a given by

$$E_a = -\frac{d \ln \sigma_i}{d(1/kT)} = E_i - k\overline{T} \quad [7]$$

where $\overline{T}$ is the average temperature over the range of the measurements.

Two factors determine n_v, viz., charge compensation and nonstoichiometry. To produce vacancies by means of charge compensation we may dope with an aliovalent cation, *e.g.*, CaO or Y_2O_3. In this way we obtain one $V_o^{\cdot\cdot}$ for every molecule of dopant, since the Ca^{2+} and Y^{3+} ions enter the CeO_2 lattice as Ca''_{Ce} and Y'_{Ce}, respectively. Therefore

$$n_v = [Ca''_{Ce}] + \frac{1}{2}[Y'_{Ce}] \equiv n_M \quad [8]$$

that is, the quantity n_M defined here is the total effective dopant concentration. (It is defined so as to allow both Ca and Y to be present simultaneously; actually only one will be present in significant concentration at a time.) On the basis of Eq. [8] and [1], we expect that $\sigma_i \propto n_M$ and also, from Eq. [2]-[5], that E_i is independent of both n_M and the type of aliovalent dopant. Actually, this statement is only valid at low concentrations. In fact. for ceria, σ_i *vs.* n_M is linear up to a value of n_M corresponding to less than 4% oxygen vacancies, and then it shows a broad maximum as a function of dopant concentration (2, 6). In the case of $ThO_2:Y_2O_3$ the departure apparently takes place even earlier (9). Such results mean that defect interactions become important at high concentrations. In the case of ZrO_2:CaO, for example, it is well known that ordering effects take place (10). In the range where interactions are appreciable, the semiempirical relation [4] still holds, but the simple interpretations of E_i and C_i given by Eq. [5] and [6] no longer apply.

When vacancies are produced by departures from stoichiometry, one also obtains electronic defects which give rise to an electronic contribution to the conductivity, σ_e.

Nonstoichiometry and electronic conductivity.—The reaction which leads to nonstoichiometry is[2]

$$O_o = V_o^{\cdot\cdot} + 2e' + \frac{1}{2} O_2(g) \quad [9]$$

The electronic defect e' may be regarded as equivalent to the presence of a Ce^{3+} ion, or in defect notation, Ce'_{Ce}. The mass action equation which follows from the reaction [9] is, at low defect concentrations

$$n_v n_e^2 p_{O_2}^{1/2} = K_1(T) = K_{10} \exp(-\Delta H_1/kT) \quad [10]$$

in which n_e is the electron concentration, p_{O_2} the oxygen partial pressure, and ΔH_1 the enthalpy change of the reaction. In doped samples, we will be interested in the range where nonstoichiometry is small, specifically, $n_e << n_M$. Under these conditions $n_v \simeq n_M$ and so from Eq. [10]

$$n_e = [K_1(T)/n_M]^{1/2} p_{O_2}^{-1/4} \quad [11]$$

[2] For large departures from stoichiometry, singly ionized vacancies can also be produced (11), but this complication can be ignored for the purposes of this paper.

In spite of the fact that $n_e << n_v$, however, the electronic conductivity

$$\sigma_e = n_e e \mu_e \quad [12]$$

can become appreciable because $\mu_e >> \mu_i$. Since electrons migrate by a hopping mechanism (11), μ_e is given by

$$\mu_e = (b/T)\exp(-E_e/kT) \quad [13]$$

where E_e is a small activation energy. From Eq. [11] and [12], $\sigma_e \propto p_{O_2}^{-1/4}$. The total conductivity

$$\sigma \equiv \sigma_i + \sigma_e \quad [14]$$

is then clearly made up of a p_{O_2}-independent part, σ_i, and a part, σ_e, which is proportional to $p_{O_2}^{-1/4}$. This pressure dependence provides a convenient way to separate σ_i from σ_e and thereby to obtain the ionic transference number

$$t_i = \sigma_i/\sigma \quad [15]$$

The electrolytic domain.—The electrolytic domain is defined as the region, in a plot of log p_{O_2} *vs.* $1/T$ in which t_i is greater than some selected value (often 0.99) (12). Substituting [4] and [10] through [13] into Eq. [14] and [15], we obtain

$$\ln p_{O_2} = 4 \ln \left\{ \frac{t_i b e K_{10}^{1/2}}{C_i(1-t_i) n_M^{1/2}} \right\} - 4\left(\frac{\Delta H_1}{2} + E_e - E_i \right) \frac{1}{kT} \quad [16]$$

which shows that a plot of ln p_{O_2} *vs.* $1/T$ for a given t_i value gives a straight line whose negative slope is $(4/k)(\frac{1}{2}\Delta H_1 + E_e - E_i)$ and whose intercept depends on t_i and on the dopant concentration.

The straight line given by Eq. [16] separates the p_{O_2}-$1/T$ space into two regions, the region above the line being the domain for which t_i is greater than the selected value. From the intercept formula it is clear that, for t_i close to 1.0, the line shifts upward by close to 4 decades for every decade in $(1 - t_i)$; for example, in going from $t_i = 0.90$ to 0.99, the shift is 4.17 decades in p_{O_2}.

Experimental Methods

The specimens used in this study were fabricated from nominally pure CeO_2 powder (99.9% pure with respect to other rare earths). Analysis shows an aliovalent impurity content in the range 150-200 ppmw. Samples doped with Y_2O_3 or CaO were prepared by mechanically mixing appropriate amounts of Y_2O_3 or $CaCO_3$ powders with the CeO_2. Cylindrical samples (¾ in. diam × 0.1 in. high) of the mixed powders were prepared by pressing in a steel die at 40,000 psi. The pressed specimens, covered by additional loose powder to minimize contamination and loss of dopant, were placed in high purity alumina holders and heated slowly to 1500°C in an argon atmosphere. They were held at this temperature for 12-14 hr. The densities of the samples so obtained were greater than 80% of theoretical density.

After samples were cut to size (12 × 5 × 5 mm³) electrodes were prepared using platinum paste (Englehard No. 6082) which was fired in air at 800°C to burn off the organic binder. Such electrodes are known (13) to be porous enough to allow the sample to come to equilibrium (with respect to oxygen) with the surrounding gas phase.

Measurements were carried out inside a quartz tube suspended inside a Kanthal-wound resistance furnace. Electric feedthroughs were mounted in a stainless steel cap from which four (15 mil) platinum leads ran to the specimen through insulating alumina tubes. Fine platinum wires (5 mil) were wrapped around the sample at both ends and at 1/3 and 2/3 of the length. The sample was then suspended by spot welding the sample leads to the heavier platinum wires contained in the alumina tubes. For improved contact, the area of contact between sample and wires was also coated

with several layers of platinum paste. A standard four-probe d-c technique was used to measure the conductivity. A fixed current was passed through the sample and the potential drop across the two center leads was measured with a Keithley Model 640 vibrating capacitor electrometer (input impedance of 10^{16} ohms). In addition, a-c measurements at 1592 Hz (10^4 rad/sec) were made with a Wayne-Kerr Model B221A universal bridge; results obtained by the two methods were essentially identical.

The sample temperature was measured by means of a Pt-Pt + 10% Rh thermocouple placed close to it, while the furnace was controlled to within ±1°C by another thermocouple placed close to the furnace windings.

Atmosphere control, ranging over 22 orders of magnitude in oxygen partial pressure, p_{O_2}, was achieved as follows. For the range $p_{O_2} = 1\text{-}10^{-4}$ atm O_2-Ar mixtures were used, and for the range $10^{-4}\text{-}10^{-22}$ atm CO-CO_2 mixtures were used. The value of p_{O_2} of a CO-CO_2 mixture with known ratio CO/CO_2 can be calculated at any temperature using the well-known free energy values for the CO-CO_2 reaction (14). Fixed ratios of CO/CO_2 premixed and analyzed, were purchased from the Matheson Gas Company, but these mixtures were limited to CO/CO_2 ratios between 10^3 and 10^{-3}. The value for p_{O_2} for CO/CO_2 = 10^{-3} is $\sim10^{-12}$ atm, at 800°C. Thus, a gap of approximately 8 decades in p_{O_2} exists between the lowest available O_2/Ar ratio and the least reducing CO/CO_2. Since critical data fall within this gap, we have closed it by setting up a system for: (*a*) mixing the premixed CO/CO_2 = 10^{-3} gas with pure CO_2 under controlled relative flow rates, and (*b*) monitoring the p_{O_2} level by means of a calcia-stabilized zirconia cell located in the hot zone close to the sample under study. The same technique was also used to span the gap between other premixed pairs of CO-CO_2 mixtures. In this way, it became possible to obtain p_{O_2} values from 1 to 10^{-22} atm in intervals as close as desired. Further details will be described in a later publication (11).

Results

Data for the variation of conductivity with temperature at p_{O_2} = 1 atm is shown in Fig. 1 for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ and $(CeO_2)_{0.9}(CaO)_{0.1}$. Good straight lines are obtained in the log σT *vs.* 1/T plot for the range between 400° and 1000°C. In anticipation of the fact that the conductivity is almost entirely ionic in this range, the results for E_i and C_i (of Eq. [4]) are listed in Table I. Also shown, for comparison, in Fig. 1 are data (15) for calcia-stabilized zirconia

Table I. Values of activation energy E_i and pre-exponential constant C_i for two compositions

CeO_2 doped with	E_i (eV)*	C_i (ohm-cm)$^{-1}$ °K
5% Y_2O_3	0.76	$1.9_5 \times 10^5$
10% CaO	0.91	$5.2_5 \times 10^5$

* Uncertainty, ±0.015 eV.

(CSZ), the conductivity of which is at least a decade lower than for the two doped ceria samples in the range $T < 900$°C, and which has an activation energy $E_i = 1.3$ eV.

Figure 2 shows isothermal measurements on a 5% Y_2O_3 sample as a function of p_{O_2} in the range from 635° to 1150°C. For each isotherm the p_{O_2} range was covered in close enough intervals to obtain the range in which σ was independent of p_{O_2} as well as to observe the manner in which it increases with decreasing p_{O_2}. The constant σ region shrinks with increasing temperature and has practically disappeared by 1150°C. In accordance with Eq. [11], the increase of σ with decreasing p_{O_2} indicates the appearance of nonstoichiometric carriers. The nonstoichiometric component, *i.e.*, the difference between the total σ and the p_{O_2}-independent value, is shown as dashed lines in Fig. 2. Although there is some scatter, the slope of ¼, predicted by Eq. [11], fits the data in all cases. A similar ¼ power law has been found by Neuimin *et al.* (16) for CeO_2:La_2O_3 and is also obtainable from the data given by Blumenthal *et al.* (6) for CeO_2:CaO, so that the relation may be regarded as well established. It is therefore reasonable to regard the p_{O_2}-independent conductivity as σ_i and the p_{O_2}-dependent part as σ_e.[3]

On this basis, one may obtain t_i as a function of log p_{O_2} directly from the data of Fig. 2 as the ratio σ_i/σ where σ_i is the p_{O_2}-independent value. Such a plot is given in Fig. 3. The figure shows that t_i remains close to unity over a larger range of p_{O_2}, the lower the temperature.

In order to establish the electrolytic domain, we must be able to determine the p_{O_2} and T values at which a given t_i is obtained. For good precision it is convenient to select t_i = ½. For each temperature, the value of p_{O_2} at which t_i = ½, *i.e.*, $\sigma_e = \sigma_i$, was ob-

[3] This is not quite true when the p_{O_2}-dependent part is much greater than the p_{O_2}-independent part, since nonstoichiometry introduces vacancies as well as electrons (Eq. [9]). Since $\mu_e/\mu_i \sim 20$ (11) in the temperature and composition range of interest, t_i will be ~0.05 even when all of the conductivity is due to nonstoichiometry.

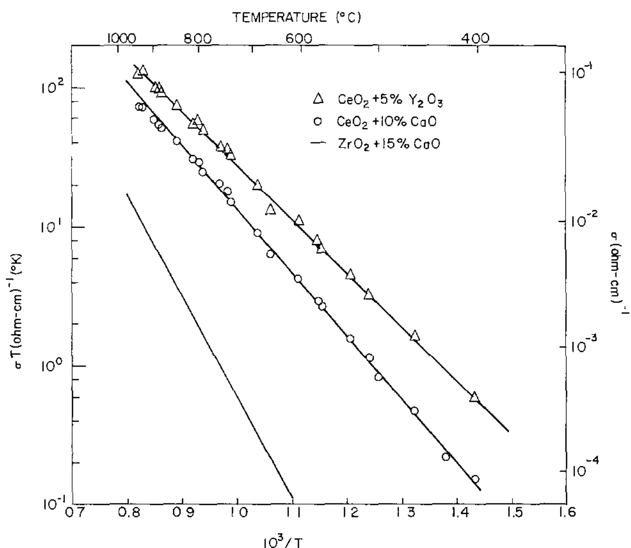

Fig. 1. Variation of conductivity with reciprocal absolute temperature for CeO_2 doped with 5% Y_2O_3 and with 10% CaO at 1 atm of oxygen, and comparison with data for calcia-stabilized zirconia.

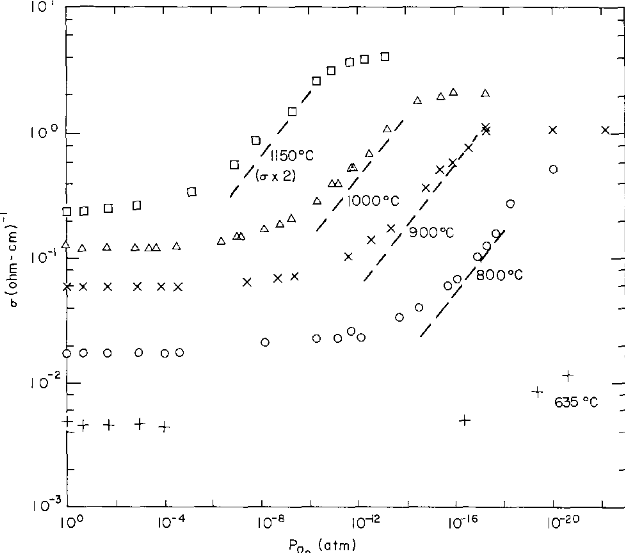

Fig. 2. Electrical conductivity as a function of p_{O_2} for a sample of $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ at five different temperatures. The dashed lines indicate the electronic component of the conductivity, σ_e.

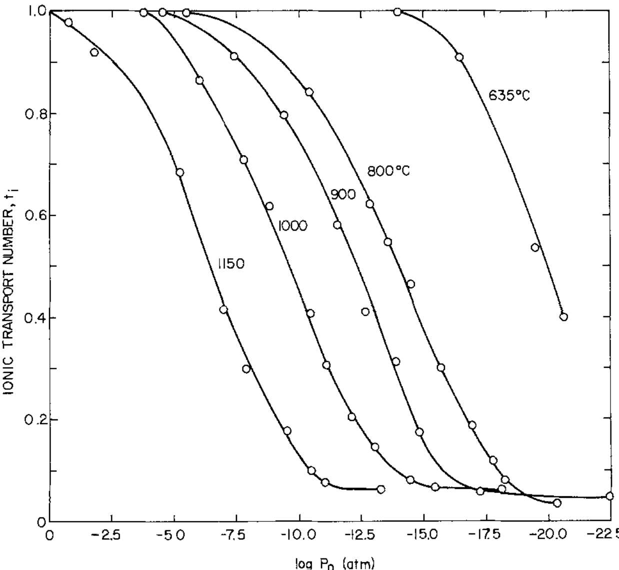

Fig. 3. The ionic transference number, t_i, as a function of p_{O_2}, as derived from Fig. 2 for various temperatures.

tained from Fig. 3. When plotted as log p_{O_2} *vs.* $1/T$ the results fall on a straight line, as shown in Fig. 4 and predicted from Eq. [16]. The same procedure was also followed for the case of $t_i = 0.9$. Although the data so obtained from Fig. 3 are less precise than that for the case of $t_i = 0.5$, the results shown in Fig. 4 strongly indicate that the the domain line for $t_i = 0.9$ is parallel to that for $t_i = 0.5$, as expected from Eq. [16]. Also, while Eq. [16] predicts a shift in intercept of 3.8 decades in p_{O_2} between these two t_i values, the actual shift obtained is 4.0. It thus appears that the predictions of Eq. [16] are well confirmed. It therefore seems reasonable to use this equation to extrapolate beyond the range at which t_i can be directly estimated. In particular, the predicted domain line for $t_i = 0.99$ is shown as the uppermost line in Fig. 4. The region above this line is then the electrolytic domain for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$. It should be noted that, although this region is small at high temperatures, it increases rapidly with decreasing temperatures, reaching values as low as $p_{O_2} \sim 10^{-21}$ atm at 450°C.

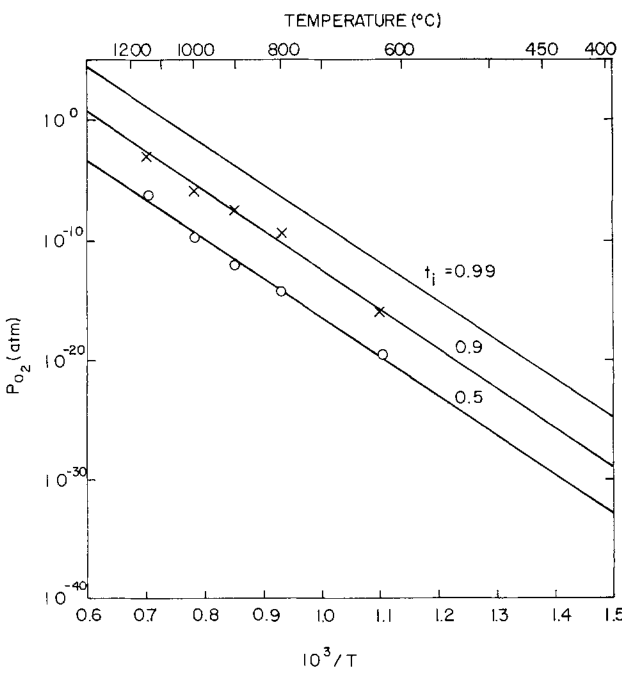

Fig. 4. Curves of p_{O_2} vs. T^{-1} at fixed values of t_i for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$. The upper curve, obtained by extrapolation, marks the boundary of the electrolytic domain ($t_i \geqq 0.99$).

In Fig. 2, the points at $p_{O_2} = 1$ atm do not agree exactly with the data as a function of temperature shown in Fig. 1. It is believed that some of the discrepancies are due to the drastic expansions and contractions of the sample which occurred during the successive cycles of reduction and oxidation which were carried out. (Other samples have even shown evidence of cracking after such repeated cycling.) It is therefore believed that the temperature dependence of σ at a given p_{O_2} as obtained from Fig. 2 is not nearly as reliable as are the relative values of σ *vs.* p_{O_2} at each given temperature.

Aside from the question of the magnitude of t_i, the other factor that limits the utility of a material as a solid electrolyte is the onset of polarization. This factor usually sets the low temperature limit of usefulness of a given electrolyte. In order to determine at which level of current density significant polarization sets in, the voltage across a $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ sample was measured as a function of time when current was applied in steps. Figure 5 shows the results of some of these measurements at 635°C, first when the current is increased in steps of 1 mA and then in steps of 10 mA. The results show no evidence of polarization up to $I \sim 4$ mA (current density $\sim$20 mA/cm²). On the other hand, at 10 mA, polarization is apparent. Such polarization behavior suggests the onset of ion blocking. Often the behavior is dependent on the type of electrodes used (17). In the present work, only the platinum paste electrodes (described in the Experimental Methods section) were used.

Discussion

Ionic mobility parameters.—Values of the activation energy E_i and pre-exponential constant C_i for the two doped materials studied are given in Table I. The 10% CaO specimen clearly falls in the range where interaction effects are important, as indicated by its composition being at about the value at which a maximum occurs in the plot of σ *vs.* n_M (6). Since E_i increases in the interaction range (10) it is not surprising that E_i for $(CeO_2)_{0.9}(CaO)_{0.1}$ is substantially higher than for

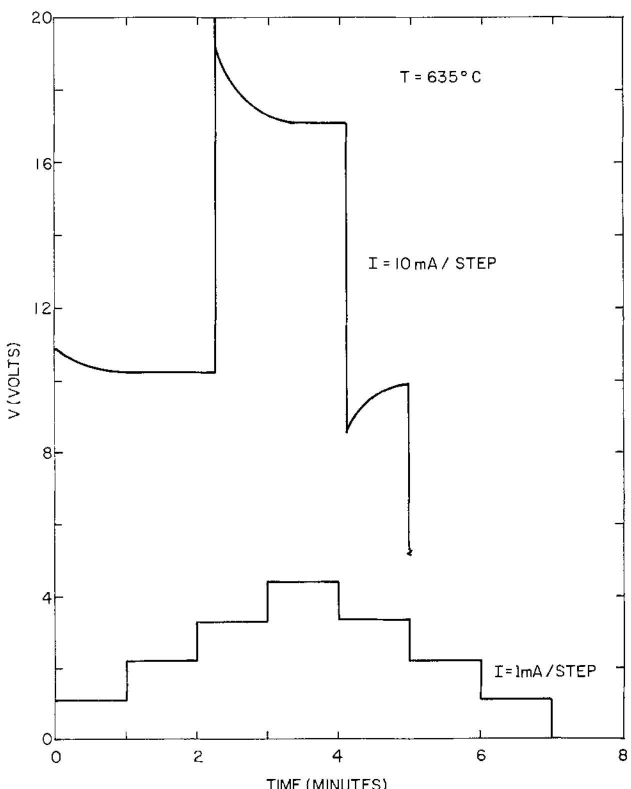

Fig. 5. The d-c potential across a sample of $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ at 635°C as a function of time, when the current is applied and removed in steps of 1 or 10 mA.

$(CeO_2)_{0.95}(Y_2O_3)_{0.05}$. The latter composition may still fall in the range where interaction effects are small, and it is therefore interesting to compare it to results at still lower concentrations. Data for 1 and 2% CaO are available from Blumenthal *et al.* (6), although the range of temperature covered is smaller, and therefore the precision poorer, than that in the present work. In addition, the activation energies that they reported were obtained from plots of log σ *vs.* $1/T$ instead of log σT *vs.* $1/T$, so that the additional correction given by Eq. [7] is required. In this way their "best value" is found to be 0.72 eV. This agrees with the present result of 0.76 eV to within experimental error.[4] Accordingly, we may conclude that (*i*) interaction effects are relatively small in the 5% Y_2O_3 specimen,[5] and (*ii*) the activation energy for migration of $V_o^{\cdot\cdot}$ in CeO_2 is close to 0.76 eV. This value is lower than the activation energy of about 0.85 eV obtained by Steele and Floyd (19) for oxygen self-diffusion in Y_2O_3-doped ceria, as well as the value of 0.86 eV obtained by Lay and Whitmore (20) for dielectric relaxation in CeO_2:CaO. (The latter represents the activation energy for migration of a vacancy which is associated with a Ca''_{Ce}.)

Inserting the value of C_i for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$ into Eq. [6], we obtain for the effective frequency factor ν' (defined so as to include the activation entropy term)

$$\nu' = \nu \exp(\Delta S_i/k) = 1.4 \times 10^{13} \text{ sec}^{-1}$$

From this result, and the expectation that the attempt frequency ν falls in the mid 10^{12} range, we may conclude that the entropy of activation is positive but not very large ($\Delta S_i/k \sim 0.7$-1.8).

Electrolytic domain and polarization.—In Fig. 4, it was demonstrated that the present method of separating σ_i and σ_e through measurement of σ *vs.* p_{O_2} can be used successfully to obtain the electrolytic domain. Equation [16] shows that the slope of the lines in Fig. 4 gives the energy $\frac{1}{2}\Delta H_1 + E_e - E_i$. The experimental value obtained is 1.61 eV. Using the values $E_i = 0.76$ eV from the present work, and $E_e = 0.3$ eV from Neuimin *et al.* (16),[6] we obtain $\Delta H_1 = 4.2$ eV for the energy of the reaction [9] (see Eq. [10]). The value for the same reaction energy ΔH_1 obtained in pure CeO_2 (11) is 4.7 eV, thus indicating that ΔH_1 may have decreased slightly with doping.

As remarked earlier, the domain of primarily electrolytic conduction ($t_i \geqq 0.99$) for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$, though small near 800°C broadens rapidly with decreasing temperature. While the widely used calcia-stabilized zirconia (CSZ) has a wider range of electrolytic behavior at elevated temperatures (12) [*e.g.*, down to $p_{O_2} = 10^{-15}$ atm at 1000°C, as against only 10^{-2} for $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$], it is well known (17) that its usefulness is limited by the onset of appreciable polarization below 800°-1000°C, as well as its low conductivity at these temperatures. Such factors limit the applicability of CSZ as a solid oxide electrolyte in a fuel cell to temperatures above 1000°C, and in an oxygen cell to temperatures above 800°C. The material $(CeO_2)_{0.95}(Y_2O_3)_{0.05}$, on the other hand, has a conductivity about 10 times larger than CSZ at 900°C (see Fig. 1) and, because of its smaller activation energy, this factor increases to nearly 100 at 600°C. Accordingly, the question of whether doped CeO_2 can be useful as a solid oxide electrolyte, by comparison to CSZ, then centers on whether polarization for CeO_2 is absent to lower temperatures. The results of Fig. 5 provide evidence that this is indeed the case, showing that at 635°C polarization is completely negligible to current densities of 20 mA/cm² and higher. Similar results were obtained for CeO_2:La_2O_3 by Takahashi *et al.* (5), who also found significant polarization for CSZ already at 800°C for current densities less than 1 mA/cm².

Takahashi *et al.* also carried out preliminary measurements using CeO_2:La_2O_3 as an electrolyte in a fuel cell at 1000°C and obtained a maximum output of 0.17W. They concluded that the output was limited by the low value of t_i at that temperature. However, now that the electrolytic domain is established, it is clear that fuel cells utilizing doped ceria as the electrolyte are more likely to be successful at lower temperatures, when operating with fuels which generate oxygen partial pressures within the allowable domain.

[4] For both the 1 and 2% CaO specimens, the plot of Blumenthal *et al.* could indeed have been drawn slightly steeper.

[5] Further evidence in support of this statement comes from comparing T *vs.* p_{O_2} plots at constant t_i from the present work with data from reference 6 (18).

[6] A similar value for E_e was also obtained by the present authors for pure CeO_2 (11).

Anodic Dissolution of N-Type Gallium Arsenide under Illumination

Akio Yamamoto and Soichi Yano

Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation, Tokai, Ibaraki, Japan

ABSTRACT

An experimental study has been made of the anodic dissolution of n-type GaAs under illumination. In the dark, the dissolution potential depended on the carrier concentration and the surface orientation of the sample. By illuminating the surface of the sample, the dissolution potential became less noble and its dependence on carrier concentration and surface orientation became small with increasing light intensity. Samples were electropolished under the condition that the surface orientation dependence of the dissolution potential was scarcely observed. In electroetching under illumination, flat-bottomed holes were obtained and the etched depth was controlled with an accuracy better than 0.1 μm. Under illumination, a damaged surface exhibited less dissolution than that of an undamaged surface. With the introduction of surface damage to selected regions of the substrates by nitrogen-ion bombardment, selective etching without the use of protective masks has been carried out.

The recent development of GaAs electronic devices demands new technologies of integrated circuits. For etching and shaping operations in integrated circuit technology, it becomes desirable to apply electrochemical processing.

Several authors (1-4) have discussed the anodic behavior; Nuese and Gannon (5) have described selective etching of GaAs. Anodic dissolution of n-type GaAs has not been widely studied as compared with p-type GaAs.

It is well-known that electropolishing of n-type semiconductors requires supplying extra holes. Gerischer (6) has described electrochemical behavior of n-type semiconductors under illumination. Harvey (3) has shown a surface profile of an n-type GaAs electrode following anodic dissolution under illumination. Regarding electropolishing or electroetching, however, few discussions have been made of anodic dissolution of n-type GaAs. The present paper discusses anodic dissolution and electroetching of n-type GaAs under illumination.

The experimental work was done in two parts. First, the measurements of *I-V* characteristics were performed carefully to obtain the dependence of carrier concentration and crystal orientation on dissolution rate. The second part was done to research the general features of electroetching and as the result of that to obtain the effects of defects and damage on dissolution rate.

Experimental

The apparatus used for the study of anodic dissolution of n-type GaAs under illumination is schematically illustrated in Fig. 1. The anodic current was pulsed at a frequency of 5 Hz and with a 10% duty ratio. Measurements of potential were made of the GaAs electrodes against a saturated calomel electrode.

GaAs samples were illuminated with monochromatic light with a wavelength of 0.8 μm in the measurements of *I-V* characteristics. For the study of electroetching, an incandescent lamp was used for illumination. The light intensity at the sample surface was calibrated in degrees by a silicon photocell positioned in place of the sample without an electrolyte. One degree in arbitrary unit corresponded to 10 $\mu W/cm^2$.

For the electrolyte, a solution composed of $2.5(10)^{-2}$ mol/liter NaOH and $1.0(10)^{-3}$ mol/liter EDTA was employed. The chemicals used were all of reagent grade. The electrolyte was kept at 25° ± 1°C, and dry N_2 gas was slowly bubbled during experiments.

The GaAs wafers were cut from single-crystal rod grown by the horizontal Bridgeman method, and were mechanically lapped with a SiC slurry and then polished with fine abrasive alumina (0.3 μm particle size). After being degreased and rinsed with deionized water, they were chemically polished in a solution composed of $3H_2SO_4$ (conc), 1 H_2O_2 (30%), and 1 H_2O. The respective surface planes were adjusted within ±0.5° of the desired orientation.

The following treatments were made for the samples used for the measurements of *I-V* characteristics. To ensure good electrical contacts, indium containing gold (10 weight per cent) was evaporated to one side of the wafers at room temperature and then annealed in H_2 at 350°C for 15 min. The other side of the wafers was polished again in the above-mentioned solution before measurements.

The wafers had carrier concentrations in the range from 10^{16} to 10^{18} cm^{-3}, and had either <100>, Ga<111>, or As<111> orientations.

Samples were fixed by a sample holder illustrated in Fig. 2. The wafer was cemented with an adhesive wax to the Teflon electrode holder and coated with paraffin. The exposed area of the GaAs surface was between 0.002 and 0.010 cm^2. The electrodes were connected to the outer circuit by using an electrically conducting lubricant.

Results and Discussion

First, measurements of the *I-V* characteristics of n-type GaAs are described and discussed. Second, the etching behavior of n-type GaAs illuminated with incandescent light is described. Finally, the observed effects of surface damage on the anodic dissolution of n-type GaAs under illumination are shown.

I-V characteristics of n-type GaAs electrodes.—The GaAs electrode potential was measured as a function of current density on <100>-oriented samples with carrier concentrations of $5.3(10)^{16}$ cm^{-3} (undoped) and $2.2(10)^{18}$ cm^{-3} (Te doped). For comparison, the same measurements were carried out on <100>-oriented Zn-doped p-type samples with carrier concentrations of $7.0(10)^{17}$ cm^{-3} and $1.7(10)^{19}$ cm^{-3}.

When a pulsed current of 5 Hz and 10% duty ratio was employed, the potential became thoroughly stable and highly reproducible. At curent densities between 10^{-2} and 1 mA/cm^2, no film formation and no gas evolution were observed on the surface.

The results are summarized in Fig. 3. The n-type samples showed current saturation. The p-type samples were readily dissolved and large currents were drawn at few volts. One can see in Fig. 3 that a dissolution rate ratio of p-type GaAs to n-type GaAs is the order of more than 10^2 at a potential of about zero volt. This presents the possibility of selective removal of only p-type from p-n structures (7).

The carrier concentration dependence of *I-V* curves for p-type samples were hardly observed. On the other hand, the *I-V* curves for n-type electrodes remarkably depended on carrier concentration. In the dark, the n-type sample of $5.3(10)^{16}$ cm^{-3} exhibited nobler dissolution potential, *i.e.*, lower dissolution rate than that of $2.2(10)^{18}$ cm^{-3}. We can not explain the fact, as in the case of heavily doped n-type Ge (8) or Si (9), that the n-type sample with higher carrier concentration is more reactive in anodic dissolution than that with the lower doping by taking account of only their hole concentration in the bulk. Since n-type GaAs of 10^{16}-10^{18} cm^{-3} has few holes in the bulk, the diffusion from the bulk cannot be a sufficient source of holes. Consequently, holes involved in the dissolution process in the dark were probably generated in the space-charge region of the semiconductor (10).

For p-type samples, there was no difference between the *I-V* curves in the dark and those under illumination. For current densities below about 2 mA/cm^2, the Tafel relation held and the slope was about 96 mV/decade.

Illumination caused an increase in the saturation current density of the *I-V* curves for n-type samples. The saturation current density was proportional to the incident light intensity. Above the saturation current density, the potentials under illumination were closely similar to that in the dark. Since the shift of dissolution potential to a less noble value by illumination was larger for the sample of $5.3(10)^{16}$ cm^{-3} than for the sample of $2.2(10)^{18}$ cm^{-3}, the dissolution potential of the former was less noble than that of the latter above a certain value of light intensity. Figure 4 shows plots of dissolution potential at constant current density *vs.* light intensity. The dissolution potential of the sample of $5.3(10)^{16}$ cm^{-3} was drastically shifted toward a less noble value in the low region of light intensity. The linear relationship between the potential and the logarithm of light intensity (6) held for the sample of $5.3(10)^{16}$ cm^{-3} only in the higher region of light intensity, while this relationship held for the sample of $2.2(10)^{18}$ cm^{-3} over the whole range of light intensity we examined. Thus, the behavior of the samples in anodic dissolution depended remarkably on the carrier concentration in the low region of the light intensity. The differences in dissolution potential between both samples became smaller with increasing light intensity. Therefore, the carrier concentration dependence is considered to disappear when the dissolution process of the samples is controlled fully by holes generated

by incident light. This leads to the conclusion that it is possible to electroetch uniformly n-type GaAs samples containing different dopant concentrations by illuminating the surface strongly.

Figure 5 shows the surface orientation dependence of the I-V curves. The samples employed had carrier concentration of 2.2(10)^{18} cm^{-3} and (100), Ga(111), and As(111) planes. In the dark, appreciable differences in dissolution potential existed. The order of magnitude of dissolution potential was Ga(111) > (100) > As(111). By illuminating the surface, the dissolution potential became less noble and the differences among the three planes decreased with increasing light intensity. Under strong illumination, the dissolution potential of the three planes was almost identical at low current densities. These results indicate that the dependence of the dissolution rate on the surface orientation becomes smaller with increasing dissolution rate by illumination.

For p-type GaAs electrodes, the dependence of dissolution potential on the surface orientation was explained by the extent of surface coverage of the $Ga(OH)_3$ which showed little solubility in alkaline solution (4). The fact that the dissolution rate of n-type GaAs can be increased by illumination shows that the dissolution reaction of n-type GaAs is limited by the supply of holes. Therefore, it is unsuccessful for n-type GaAs to explain the surface orientation dependence of the dissolution rate by taking account of coverage of the $Ga(OH)_3$ layer on the surface. It is suggestive that its dependence is due to the difference in the habit of crystal planes.

No appreciable changes were observed on the surface after the short times needed for measurement of the I-V curves. Appreciable changes occurred, however, when anodic dissolution was carried out for more than 1 hr. Figure 6 shows the etch patterns on (100) planes of n-type GaAs resulting from anodic dissolution in various conditions. In the dark, etch pits parallel to the <110> direction appeared over the whole range of current densities employed [Fig. 6(a) and (c)]. Under strong illumination, the etch pits were similarly produced at high current density [Fig. 6(b)], but not produced at low current density [Fig. 6(d)]. From the results shown in Fig. 5 and 6, one can see that the formation of the etch pits depends on the differences in dissolution potential among three planes; that is, no pits were produced and samples were electropolished under the condition that the differences in dissolution potential among the three planes were small. Even under strong illumination, the pits were pro-

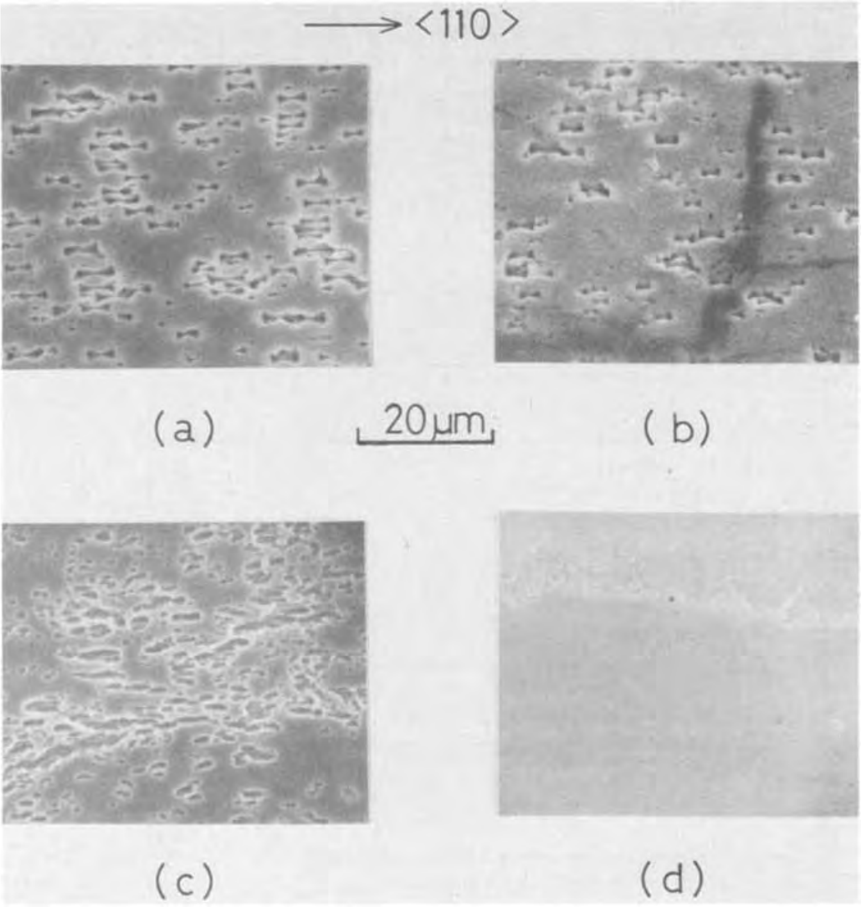

Fig. 6. SEM photographs of surfaces of n-type GaAs with (100) plane after anodic dissolution at various conditions. (a) J = 2.0 mA/cm^2, in the dark; (b) J = 2.0 mA/cm^2, I_L = 30.6; (c) J = 3.1(10)$^{-2}$ mA/cm^2, in the dark; (d) J = 3.1(10)$^{-2}$ mA/cm^2, I_L = 30.6.

duced only when differences in dissolution potential existed.

When anodic dissolution was further carried out on the surface as shown in Fig. 6(a), there was little remaining of the original plane and other planes appeared as shown in Fig. 7. The planes that remained after extensive etching were those that exhibited the smallest dissolution rate. Since their identification was hard to achieve, it was not clear whether these planes were the Ga(111) planes or other planes of high index (3).

As described, the effects of illumination were not always observed on the anodic dissolution of n-type GaAs. The light intensity and the current density are very important parameters for the study of the effects of illumination on the anodic dissolution of semiconductors.

Electroetching of n-type GaAs.—As described in the previous section, the n-type GaAs was electropolished by illuminating the surface. As those experiments were performed at relatively low current densities, etch rates were fairly small. It is desirable to obtain etch rates of, at least, 1 μm/hr. To find a practical range of electroetching, anodic dissolution of n-type GaAs was studied at current densities in the range of 1-20 mA/cm^2. In order to obtain the dissolution potential in the range -0.5 to -1.0V *vs.* SCE, samples were illuminated with incandescent light of intensities in the range $3(10)^3$-10^4 (arbitrary unit, see in Experimental section). Under these experimental conditions, no film formation and no gas evolution were observed on the surface.

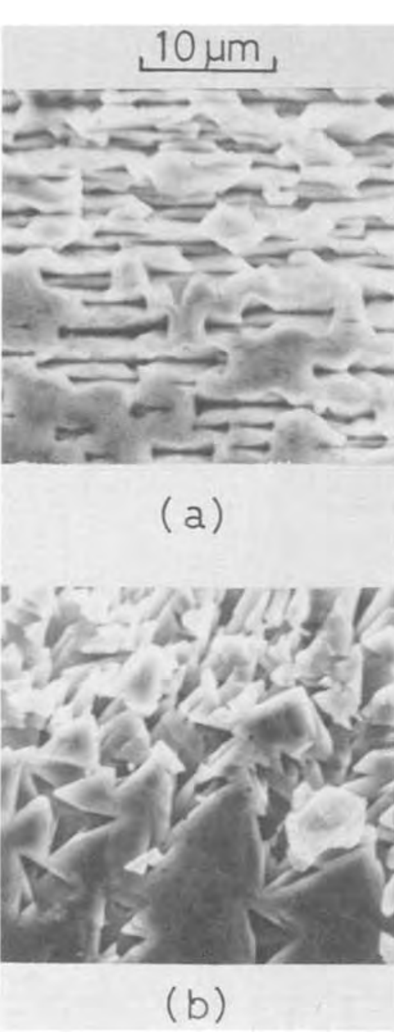

Fig. 7. Etch patterns after anodic dissolution prolonged on (a) (100) plane, and (b) As(111) plane.

A surface roughness and an etched depth were measured by Dektak (an instrument for mechanical measurement of roughness and waviness, manufactured by Sloan Corporation[1]).

Surface profiles of the samples with (100) planes after anodic dissolution are shown in Fig. 8. Current densities were roughly divided into three regions. The terms region I, region II, and region III will from now on be used to refer to the three regions, low, intermediate, and high current densities, respectively. At low current densities (region I), the surfaces were roughly etched, that is, there existed unetched areas [Fig. 8(a)]. At high current densities (region III), deep etch pits were produced [Fig. 8(c)]. Between region I and region III (region II), the surfaces were etched uniformly [Fig. 8(b)]. Figure 9 shows SEM photographs of the surfaces shown in Fig. 8. As seen in Fig. 9(a), anodic dissolution revealed a multitude of defect structures in region I. The unetched areas corresponded to the portions that involved defects. When a linear scratch mark was made mechanically on the chemically polished surface, the dissolution scarcely proceeded on the damaged part, as shown in Fig. 10. These observations suggest that the presence of defects or damage leads to a decrease in reactivity of the surface under illumination. No defect structures were observed in regions II and III. The sensitivity for the defects decreased with increasing current density. With increasing light intensity, regions II and III shifted to higher current densities and consequently region I became wide. These are summarized in Fig. 11. From the above results, we concluded that the defects became more sensitive to selective etching with increasing light intensity. The effects of defects or damage on anodic dissolution are discussed in detail in the next section.

The etch pits produced in region III were different in shape and distribution from the pits observed in the measurements of the *I-V* characteristics. The pits produced in region III were caused by the local breakdown of the surface voltage barrier, as in the case of n-type Si (11). These results suggest that the surface orientation dependence of the dissolution rate was sufficiently small in these experimental conditions. The lack of uniformity in etched depth was due to the inhomogeneity of the crystals employed.

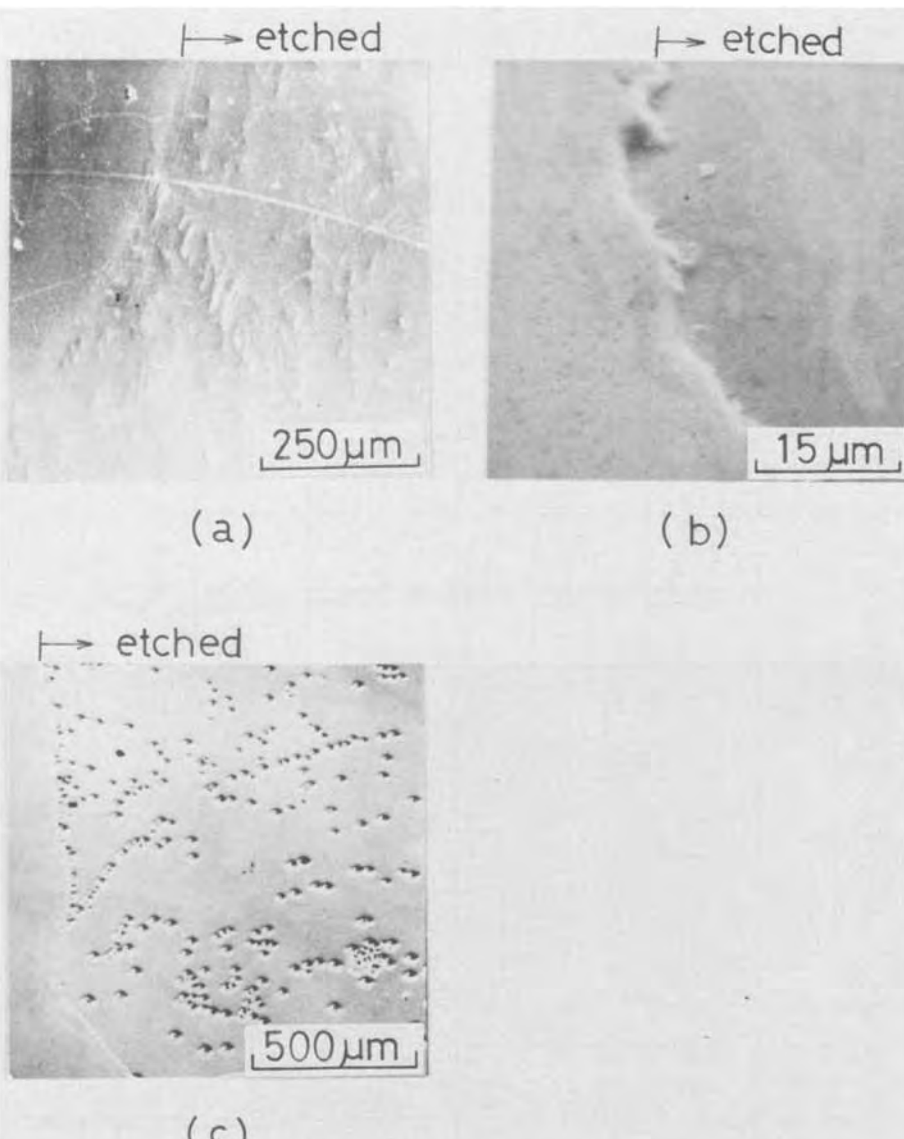

Fig. 9. SEM photographs of the surfaces shown in Fig. 8.

Samples were etched more deeply near the mask edge than at the center of the holes in regions II and III (see Fig. 8). Shaw (12) observed such an "edge effect" in the chemical selective etching of GaAs substrates and suggested that the edge effect was caused by the surface diffusion of etchant molecules along the mask. In the present investigation, the above edge effect was not influenced by stirring the electrolyte. When black wax (for example picene wax) which shielded the incident light was employed as a mask instead of paraffin, the edge effect was scarcely observed as shown in Fig. 12. In this case, the surface diffusion of etchant molecules had no effects on the edge effect, but the diffusion of holes generated by the incident light through the layer of paraffin did.

Under the experimental conditions in region II, an etched depth as a function of integrated current was measured on the samples with (100) and Ga(111) planes. The results are summarized in Fig. 13. The experimental plots were in good agreement with the theoretical data calculated by assuming that the current efficiency was 100% and the electron number was 6 (3). Figure 13 shows that etched depths can be controlled with accuracy better than 0.1 μm.

Behavior of damaged surfaces and selective removals without using protective masks.—As described in the previous section, the presence of defects or damage led to a decrease in dissolution rate of the surface under illumination. To clarify the behavior of damaged surface, anodic dissolution was studied on samples having various pretreatments.

Figure 14 shows the *I-V* curves of n-type GaAs samples polished chemically, polished mechanically, and bombarded with nitrogen-ions at room temperature. In the dark, the surfaces damaged by mechanical polishing or N-ion bombardment exhibited less noble dissolution potentials than that of the undamaged surface. This fact indicates that the presence of damage leads to an increase in reactivity of the surface atoms in the dark (11, 13). By illuminating the surface, the dissolution potential of the undamaged surfaces were shifted to more active values. The shift of the potential increased with increasing light intensity. The dissolution potential of damaged surfaces, however, was scarcely changed by illumination. Consequently under strong illumination, the undamaged surfaces were more reactive than the damaged surfaces. The difference in dissolution rate between the damaged surface and the undamaged one increased with increasing light intensity. This result explains the fact, shown in Fig. 11, that the defects became more sensitive with increasing light intensity.

The dissolution potential under illumination at a constant current density as a function of distance from the surface for various pretreatments is shown in Fig. 15. No change in dissolution potential was observed when the original surface was chemically polished. In the case of the samples treated with mechanical polishing and N-ion bombardment, however, the potential was extremely noble at the surface and became less noble with distance from the surface. The dissolution potential of the samples with various pretreatments

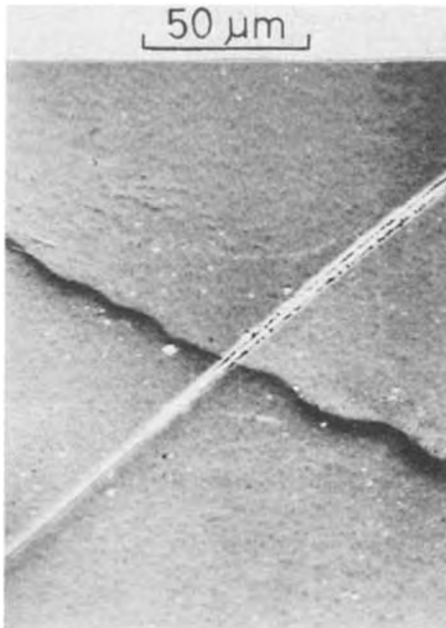

Fig. 10. Linear scratch mark made mechanically on the chemically polished surface.

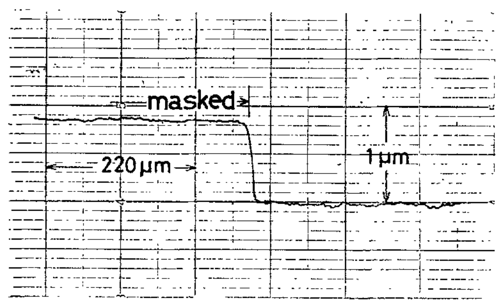

Fig. 12. Etched step obtained by employing picene wax as a protective mask.

almost coincided with the value of the chemically polished sample at a distance longer than about 0.5 μm from the surface.

The fact that the effects of illumination on the damaged surface were scarcely observed indicates that there existed few holes generated by the light. Further, this means either that the damaged surfaces had little incident light or that excess holes generated by the incident light recombined almost immediately. The former is less probable because a remarkable difference in reflection coefficient of light was not observed between the damaged surface and the undamaged one (13). Therefore we may conclude that, although holes

were generated, they recombined swiftly through many defects. Further discussion of this matter should be given on the basis of a better understanding of the actual nature of the damaged surface layer.

Selective removal of n-type GaAs substrates without using protective masks was attempted. The substrates were bombarded in selected areas with approximately 10^{15} atoms/cm^2 20 keV nitrogen ions at room temperature. Figure 16(a) and (b) show surface profiles of the samples following anodic dissolution in the dark and under illumination, respectively. In the dark, the area bombarded with N-ions was etched more deeply. As expected from the results shown in Fig. 14, on the other hand, the unbombarded area was selectively removed under illumination. As the thickness of the damaged layer was a function of the applied voltage for ions (14), the step depth produced in the dark was determined by the applied voltage for ions. Therefore, once the damaged layer had been removed the surface became very rough and the dissolution proceeded on the unbombarded area as shown in Fig. 16(a). Under illumination, the removal proceeded uniformly and the step depth was controlled with little dependence of the thickness of damaged layer because the damaged layer acted as the protective mask. It is evident that the selective removal under illumination was more selective by about ten times than that in the dark. This is readily expected from the results shown in Fig. 14.

An attempt was made to anodically etch semi-insulating GaAs (Cr-doped, 10^6 ohm-cm). Etching behavior of the above samples was similar to that of n-type GaAs except that the enhancement of etch rate near the mask edge was more remarkable. Figure 17 shows the selective removal under illumination on a Cr-doped GaAs substrate bombarded with N-ions selectively.

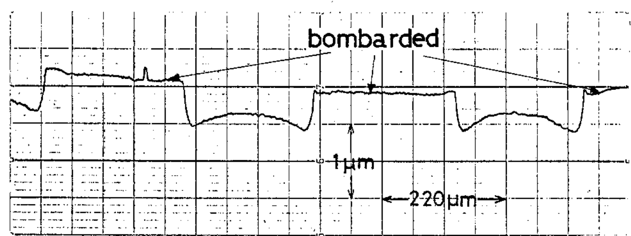

Fig. 17. A selective removal made on Cr-doped GaAs substrate

As described above, by the electroetching under illumination (without using protective masks) various etch patterns have been produced on the GaAs substrates to which surface damage was selectively introduced. This technique is powerful for the fabrication of semiconductor devices with ion bombardments or ion implantations.

Summary

Anodic dissolution of n-type GaAs under illumination was experimentally studied.

Samples in the dark exhibited different dissolution rates depending on the carrier concentration and on the surface orientation. One of the samples with higher doping levels exhibited a larger dissolution rate. The Ga(111) plane showed smallest dissolution rate among the (100), Ga(111), and As(111) planes. Etch pits parallel to the <110> direction were produced on (100) planes in the dark. When the surface was illuminated, the saturation current density increased in proportion to the incident light intensity. Below the saturation current density, the dissolution rate of the samples increased and the dependence of dissolution rate on the carrier concentration and on the surface orientation became small with increasing light intensity. Under the condition that the differences in dissolution rate were scarcely observed among the (100), Ga(111), and As(111) planes, no pits were produced and samples were electropolished. Above the saturation current density, the dissolution rate was hardly changed from the value in the dark by illumination and the etch pits similar to that observed in the dark were produced even under strong illumination.

In the electroetching under illumination, three different etched profiles were obtained at current densities in the range 1-20 mA/cm^2. At low current densities, a multitude of defect structures were observed. At high current densities, deep etch pits caused by the local breakdown of the surface voltage barrier were observed. Samples were etched uniformly by employing suitable light intensity and current density. The sensitivity for defects in anodic dissolution increased with decreasing current density and with increasing light intensity. The current density required to etch the surface uniformly was a function of the light intensity. Etched depths were controlled with accuracy better than 0.1 μm.

Damaged surfaces dissolved faster than undamaged surfaces in the dark. Under illumination, undamaged surfaces dissolved faster than damaged surfaces because of the small change in the dissolution rate of damaged surfaces by illumination. By utilizing the difference in dissolution rate between an area damaged by N-ion bombardment and an undamaged area, various etch patterns were produced without using protective masks. This method was applicable to semi-insulating GaAs.

Steady-State Anodic Leakage Current in Barrier-Type Aluminum Oxide Films

Peter G. Anderson and Owen F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

When aluminum is polarized potentiostatically in a barrier-forming electrolyte, such as aqueous ammonium tartrate, the current passed diminishes steadily to a low value commonly termed the leakage current. This value is not stable, but increases gradually, attaining a constant value after many hours. The dependence of this steady-state current on potential has been studied for aluminum electrodes in 1M aqueous ammonium tartrate at pH 7 and test temperatures of 30°, 50°, and 70°C. In the overpotential range of approximately 50-80V, current is independent of overpotential, while exponential dependence of the anodic current on overpotential is seen at lower overpotentials, with a significant reverse contribution below approximately 20V. The values of both forward and reverse exponential coefficients are extremely anomalous in comparison to normal Tafel slopes. Above approximately 80V, current increases rapidly with potential until breakdown occurs.

During the potentiostatic formation of barrier-type anodic oxide films on "valve" metals the anodic current is seen to decrease monotonically to a minimum value, commonly termed the "leakage current." For aluminum anodized in an electrolyte conducive to barrier film formation, such as neutral aqueous ammonium tartrate, this minimum is reached in a matter of minutes. However, this leakage current is not stable, but gradually increases, attaining a stable value only after many hours. A similar effect is seen if the value of the applied potential is reduced after the leakage current has stabilized. There is then a marked reduction in the anodic current, with a new minimum value being observed after a period of several minutes. Again, however, this value is not stable, but increases at an accelerating rate with a higher, apparently stable value being attained after many hours. This is apparently a distinct phenomenon from that observed by several previous investigators (1-8), in which a transient current response is seen following an abrupt change in applied potential or an interruption in the application of an anodic potential. Such transients have durations of the order of minutes, two to three orders of magnitude shorter than the time required for establishment of a stable leakage current, and have been attributed to a relaxation process involving the conducting ions in the oxide (9, 10).

Research on valve metal electrodes has been extensively reviewed (9-17); therefore, it is necessary only to refer to those aspects of previous work that directly pertain to the establishment of a stable leakage current through the anodic oxides formed on such electrodes. Much earlier work was stimulated by the rectifying properties of valve metal electrodes. Van Geel (18, 19) and Taylor and Haring (20) attributed this behavior to the occurrence of a p-n junction within the anodic oxide, while Saski proposed a p-i-n junction (21). The latter observation is somewhat supported by the results of Heine and Pryor (22), who, in studying anodic aluminum oxide, found an n-type region adjacent to the metal, a p-type region near the electrolyte, and a less-defective oxide in the intermediate region. Dewald (23), on the basis of their rectifying and photovoltaic characteristics, has treated anodic films on valve metals as semiconducting electrodes. On the other hand Vijh (24) has indicated that there may be many cases that are not amenable to this treatment, citing a variety of possible occurrences at the oxide-electrolyte interface that may lead to masking of the high bandgap of the oxide. In such cases Tafel behavior would be seen, but with an anomalous slope. Smith (25) regarded current to be limited by the rate of carrier injection at the oxide-electrolyte interface, anodic polarization causing electron injection by oxygen evolution and cathodic polarization causing hole injection by hydrogen evolution. Although the difference in behavior of these carriers would explain rectification, Smith (26) later attributed rectification to the presence of structural defects such electrolyte-filled pores formed during anodizing. Vermilyea (27) and Young (12) have espoused a similar view in attributing rectification to "weak spots" in the oxide film. Inherent in this thought is the view that the oxide is essentially nonconducting, and that significant current is passed only at structural defects.

In the cases cited above the current passed by a valve metal electrode has been, sometimes tacitly, assumed to be electronic, an obvious assumption in view of the high mobility of electronic defects and the commonly held belief that an anodic film reaches terminal thickness coincident with attaining the leakage current, thereby obviating the need for considering ionic current. It is not clear, however, that this assumption is valid. For example, Hunter and Towner

* Electrochemical Society Active Member.

Key words: electronic current, polarization, transients.

(28) observed growth of a porous oxide during prolonged anodizing of aluminum in aqueous ammonium tartrate subsequent to the formation of a barrier oxide layer of terminal thickness. Under the conditions of their experiment the porous film grew at a constant rate of 175 Å-hr^{-1} and the leakage current remained at a constant value of 15 μA-cm^{-2}. Using a density of 3.0 g-cm^{-3} for the porous film (29), 56% of the leakage current was necessary to account for the porous oxide growth and, therefore, was necessarily ionic. Plumb (30) evaluated the coulometric efficiency of barrier layer formation on aluminum and found that only a portion of the leakage current could be accounted for by electronic flow, measured as oxygen evolution. Smith (31) obtained results similar to those of Hunter and Towner but, in addition, measured the dissolution of aluminum in the anodizing electrolyte. He found that, for anodizing times up to 90 min, ionic flow, evaluated as the aluminum found as oxide plus that in solution, was equal to the cell current, *i.e.*, that there was no indication of a significant electronic contribution to the leakage current.

It is apparent that the distinction commonly made between formation of "barrier" layers and of "porous" layers on valve metal electrodes is one of degree and not of kind, a view expressed explicitly by others (14, 16, 32). Thus for prolonged anodizing of valve metals in an electrolyte conducive to barrier layer formation it is necessary to consider those processes which contribute to the current passed during the formation of a porous film (16). These include as ionic processes both the steady-state growth of a porous oxide film and the steady-state dissolution and the reformation of the barrier oxide film. The distinction between these processes may be somewhat arbitrary and both may involve both anionic and cationic transport (9). Electronic processes may involve any of several possible electrode reactions resulting in injection of electrons or holes at the oxide-electrolyte interface; electronic processes at the metal-oxide interface are energetically unlikely to be rate limiting (25).

Experimental

Specimens were prepared from 99.999% pure aluminum rod (Leico Industries, Incorporated). Small cylinders were finish-machined, axially drilled and tapped for mounting, and mechanically polished. Residual stresses were relieved by heating in argon to 345°C and furnace cooling. Each cylinder, on use, was incorporated into a specimen assembly as described by Greene (33). The assemblies were subsequently cleaned by immersion in an aqueous solution containing 3% nitric acid and 80% phosphoric acid for 15 min, followed by an ultrasonic rinse in double-distilled water (34).

Anodizing and polarization studies were conducted in 1M solutions of reagent grade ammonium tartrate in double-distilled water, adjusted to *p*H 7 by titration with a dilute ammonium hydroxide solution. These solutions were stored under nitrogen to hinder carbon dioxide absorption, and were discarded periodically during the experiments.

The test cell was that described by Greene (33), employing the aluminum specimen as working electrode, two platinum counterelectrodes, and a saturated calomel reference electrode. The latter employed a salt bridge with a Luggin-Habler probe adjacent to the working electrode. The cell was continuously purged with nitrogen through a fritted glass inlet tube, and the entire apparatus was contained in a constant temperature bath. Potentials of less than 10V were applied with a Wenking potentiostat, Model 68TS3, with the potential of the working electrode measured relative to the reference electrode; potentials greater than 10V were applied with a constant voltage d-c power supply, Raytheon Model QHD 100-2 or Hewlett-Packard Model 6299A, and were measured relative to the counterelectrodes. The applied potential and the anodic current were measured with electrometers, Keithley Models 602 and 615.

All specimens were initially anodized at 1 mA-cm^{-2} in the 1M tartrate solution at the test temperature, 30°, 50°, or 70°C, until a specimen potential of 30V was reached (22). The potential was then held constant until a stable leakage current obtained, a condition defined by zero observable variation in current over a period of time. The total duration of this initial anodizing was several hours. On reaching a constant leakage current, the specimen potential was reduced to −1V SCE, at which the specimen was slightly anodic, and held until the current reached a stable value, recorded as characteristic of that potential. The specimen potential was then increased (made more anodic) in a series of potential steps; during each step the specimen potential was held constant until the stable leakage current at that potential was established. When imminent anodic breakdown became apparent the procedure was reversed and the specimen potential was reduced in sequential steps, with the stable leakage current again being recorded.

Results

The overpotential of an electrode is defined by Young (35) as the difference between two values of the electrode potential measured relative to the electrolyte: that when the electrode reaction is proceeding at a finite rate under given conditions minus that when the electrode is at equilibrium under the same conditions. The former, v_{exp}, is the experimentally measured electrode potential relative to the reference electrode; the latter, v_o, is the value of the electrode potential when zero current is flowing in the external circuit, obtained by extrapolation or by computation on the basis of thermodynamic equilibrium (26, 35, 36). Extrapolation did not provide reliable values of v_o due to the paucity of data taken at very low current values and to lack of *a priori* knowledge of the form of the current-voltage characteristic. Hence v_o was calculated according to the afore-cited procedure, using the data of Kubachewski *et al.* (37), and taking into account the temperature, *p*H, and, for values of $v_{exp} \leq 10$V, the calomel reference electrode. The equilibrium condition was computed for the reaction between aluminum and water to produce Al_2O_3 and gaseous hydrogen. To some extent this is an arbitrary choice justified by a lack of detailed knowledge of the interfacial reaction kinetics; however, the correction to the measured potentials is modest and probably not very sensitive to the reaction selected. Values of v_o are listed in Table I. Except as noted, the data herein are reported in terms of anodic overpotential, $v = v_{exp} - v_o$. Current values are reported as current density, the specimen area being determined from its geometry.

A series of current *vs.* time curves is shown in Fig. 1, representing the change in current following a reduction of the specimen potential from the initial formation potential to a new value. Initially a large reduction in current is seen, involving several orders of magnitude in a time span of less than 1 hr. Subsequent to this initial drop the current increases nearly exponentially with time until a new, stable value is reached. The magnitude of the initial decrease and the rate of recovery are dependent on the value of the overpotential, as seen in Fig. 1, and were also observed to be sensitive to the exact manner in which the reduction in overpotential was accomplished. With respect to the latter observation the behavior shown in

Table I. Calculated values of v_o

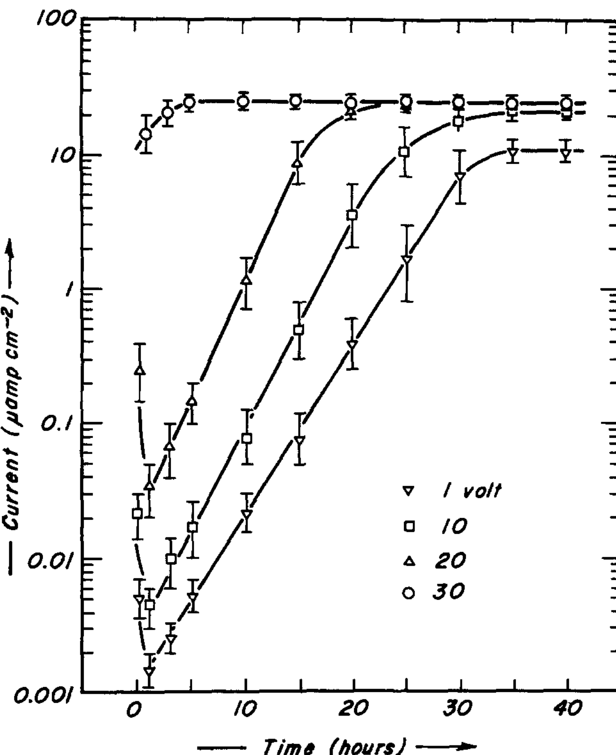

Fig. 1. Average current *vs.* time for aluminum electrodes anodized at 30V in 1M ammonium tartrate (30°C, pH 7), then reduced to stated potential at $t = 0$.

Fig. 1 may be regarded as "typical." The steady-state current did not appear to be thus affected.

Figure 2 shows the current-voltage characteristics for three specimens at 30°C, each obtained as described in the preceding section. The curves have been separated for clarity; although there is some variation between specimens and a suggestion of hysteresis, scatter

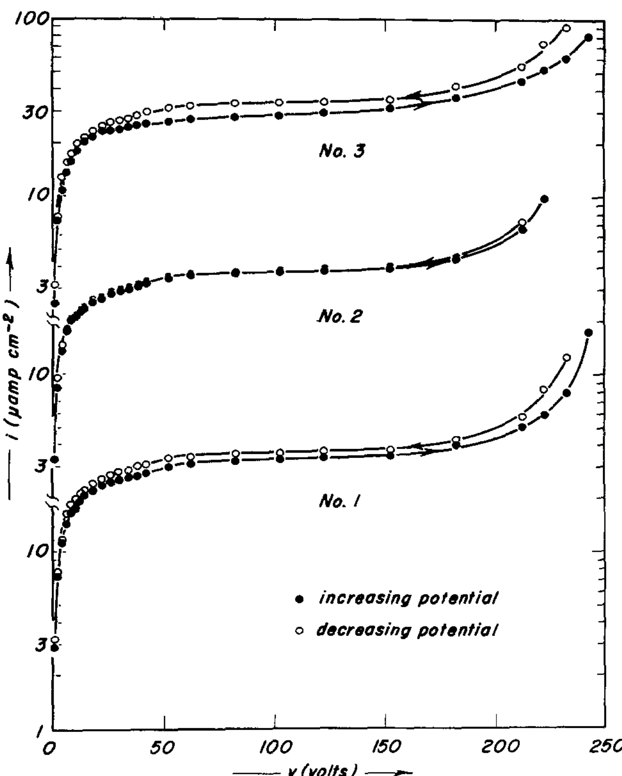

Fig. 2. Stable current *vs.* anodic overpotential for three different aluminum specimens anodized in 1M ammonium tartrate (pH 7) at 30°C, showing curves both for increasing potential and decreasing potential.

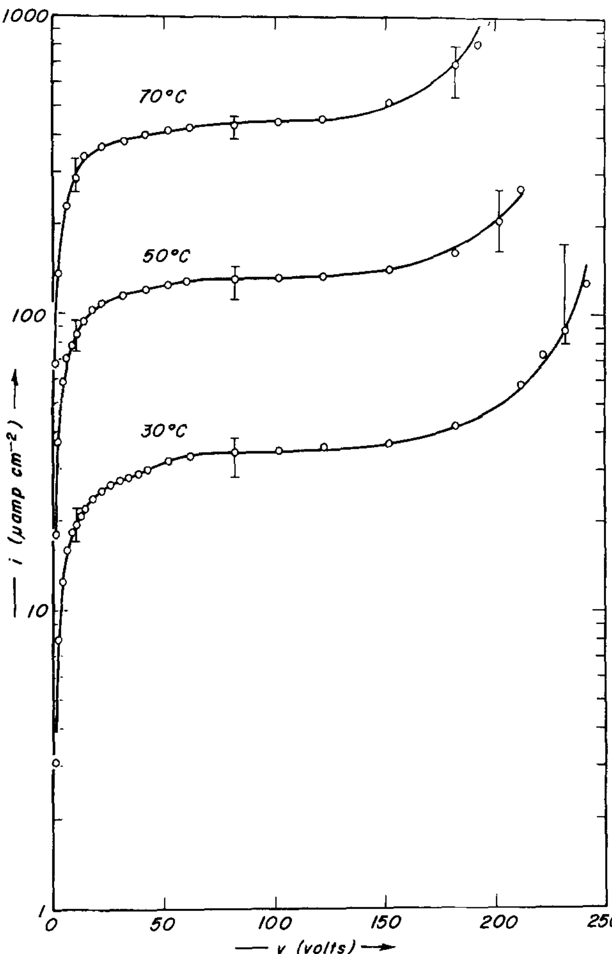

Fig. 3. Average stable current *vs.* anodic overpotential for aluminum anodized in 1M ammonium tartrate (pH 7). Error bars typical.

from a given curve is slight. Averaged values of the stable current in the tartrate environment are shown in Fig. 3 as a function of the overpotential for the three experimental temperatures. Typical error bars are shown for selected potentials representing, again, variation between specimens rather than uncertainty in a given measurement. Experimental variation is of the order of ± 13% at low overpotentials, ± 10% in the middle potential range, and increases to ±30% only in the region just preceding breakdown.

In the region of (relatively) low overpotentials, $0 \leq v \leq 50$V, the anodic current approaches exponential dependence on the overpotential as the electrode is made more anodic. The averaged data in this region are accurately described by

$$i = i_0(e^{v/b_a} - e^{-v/b_c}) \quad [1]$$

While in Eq. [1] b_a resembles an anodic Tafel constant, divided by 2.303; b_c, the analogous cathodic constant; and i_0, an exchange current density (38), this comparison is inappropriate due to the markedly anomalous values of these constants as seen in Table II and to the dissimilarity between this process and

those traditionally described by the Tafel relation. This region is analyzed in detail in Fig. 4, showing graphical evaluation of the three constants at each experimental temperature. Above 50V the behavior changes abruptly, with a limiting current, i_s, being attained. The current-overpotential behavior in this region resembles that of a simple electrode experiencing concentration polarization (38)

$$v = b_a \ln (i/i_o) - RT/\mathbf{F} \ln (1 - i/i_s) \quad [2]$$

The saturation current, i_s, is readily chosen by inspection. On increasing the overpotential the current does not remain constant, however, but at overpotentials greater than approximately 80V increases ever more rapidly with potential. Behavior in this region closely follows

$$i = \frac{i_s}{1 - (v/v_a)^c} \quad [3]$$

derived empirically for avalanche phenomena (39). The parameters v_a and c are readily determined from the applicable data by plotting log $(1 - i_s/i)$ *vs.* log v. The curves in Fig. 3 were drawn according to Eq. [1], [2], and [3] using the values of the empirical parameters given in Table II.

Discussion

It is well established that during potentiostatic anodizing of valve metals in appropriate electrolytes growth of barrier-type oxide terminates at a thickness in proportion to the applied potential difference. The average field in such films is thus independent of the applied potential difference, neglecting any potential drops other than that across the barrier oxide, and for aluminum in aqueous ammonium tartrate is of the order of (13 Å-$V^{-1})^{-1}$ or 7.7×10^6 V-cm^{-1} (29). This field represents a steady state in which a finite ionic flow through the barrier oxide occurs in equilibrium with the rate of dissolution of the barrier oxide at the oxide-electrolyte interface (16). A portion of the dissolved oxide is precipitated as porous oxide (16, 28, 31). Ionic flow through the oxide is clearly dependent on the field within the oxide as well as the concentration gradient, while the rate of dissolution is dependent on the field near the oxide-electrolyte interface. The functionality in the latter case is not established (16). The simplest explanation of Haas's data (29) is that the field is homogeneous throughout the oxide and that transport processes other than a field-dependent diffusional flow are unimportant. In such a model the ionic contribution to the terminal leakage current would necessarily be independent of the applied potential difference. This, alone, is not in conflict with the data shown in Fig. 2 and 3 inasmuch as the observed variation in total current could be attributed to electronic processes. However, the minimum ionic current that must flow in this system to maintain the observed porous film growth is of the order of 8 μA-cm^{-2} (28, 31), substantially higher than the minimum total current observed. It is, thus, feasible to conclude that the steady state is substantially different from the state of films previously studied as cited in the foregoing. Maximum anodizing times previously reported were of the order of 90 min (31), approximately the time required to reach the current minimum in the transient reported in Fig. 1.

At present there are virtually no data concerning the morphology, defect structure, and transference numbers characteristic of steady-state films grown in barrier-forming electrolytes, providing a very poor base on which to propose a model. Young (12) has derived an expression for the field in an anodic film at steady state, assuming that the current is ionic and diffusion limited. Neither restriction may be justified, *a priori*, in this case. Butler (40) has discussed the equilibrium distribution of potential and space charge in oxide on the basis of Boltzmann statistics; Devereux and deBruyn (41) have provided detailed solutions to the Poisson-Boltzmann equation that may be applied to this case. However, the expected Boltzmann distribution of charge in highly polarized anodic films is trivial; in the presence of very large potential differences necessarily all carriers in the film will reside at the film boundaries. The field within the oxide will then be constant, with a discontinuity at each boundary, and smaller in magnitude than the apparent average field. This is possible only to the extent that a barrier to carrier flow across the interface exists. In the absence of such a barrier there would be no buildup of interfacial charge and the field within the oxide would be simply equal to the potential difference across the film divided by the film thickness.

The authors have assumed in interpreting the i-v characteristics depicted in Fig. 2 and 3 that they are not an artifact of specimen preparation. That is, an obvious interpretation of the substantially constant current region between overpotentials of approximately 50 and 150V is that the current is governed by a field that is independent of applied potential, *i.e.*, film thickness is proportional to overpotential. The diminished current below 50V could be interpreted as a manifestation of the initial equilibration of the electrode at 30V (overpotential $\approx$ 32V). If the barrier layer formed in this operation were assumed capable only of growing, when higher anodic overpotentials are applied, and not thinning under the action of lower overpotentials, then clearly the small currents at low overpotentials would be due to a reduced field in the oxide. This does not appear to be the case, however. Not only does the onset of the constant current region occur at a significantly higher overpotential than 32V, but the reversibility of the process as shown in Fig. 2 clearly demonstrates that the stable leakage current is determined only by the overpotential and is independent of the potential history of the specimen. This observation

admits to two interpretations: either the film assumes a thickness characteristic of the applied overpotential and independent of the potential history, or the leakage current is independent of specimen thickness. In support of the former interpretation, Fig. 5 shows transmission electron micrographs of a film formed at an overpotential of 32V and a similar film subsequently stabilized at 12V. Clearly in the latter case a thinning process has occurred which may loosely be described as a growth and coalescence of pores. Although such thinning in neutral tartrate environments has not been previously observed, it appears to be a logical extension of similar processes that have been noted in acidic media (16, 42, 43). Not only has pore formation been noted in neutral tartrate electrolytes (28, 32), especially under current decay conditions (44), but, as previously noted, a number of authors find the anodic behavior of aluminum in "barrier-forming" electrolytes entirely similar to that in "pore-forming" electrolytes except for the rate at which pore development occurs (14, 16, 32). It is suggested that the proposed barrier layer thinning on reduction of the anodic overpotential occurs by an unbalance of the equilibrium, existing at steady state, between growth and dissolution of the barrier layer. This may result in the initiation and growth of pores into the barrier layer, or to the deepening of existing pores by dissolution of the barrier layer at the bases of such pores. The status of porous layer formation at steady state has not yet been established. Goruk *et al.* (9), citing Renshaw's (45) work in citrate environments, expect pore formation to be dependent on current density. Hoar and Yahalom (32) note that pores initiate only when the field at the surface drops to a low enough value to permit protons to enter the film against the field. This is entirely consistent with barrier layer thinning by pore formation when the overpotential is reduced, but leaves open the question of porous layer growth over and above that required for barrier layer thinning. The authors do not regard the extent of the porous layer as an important issue in the present context, however, since the pores are highly conductive and, thus, can have little direct effect on leakage current.

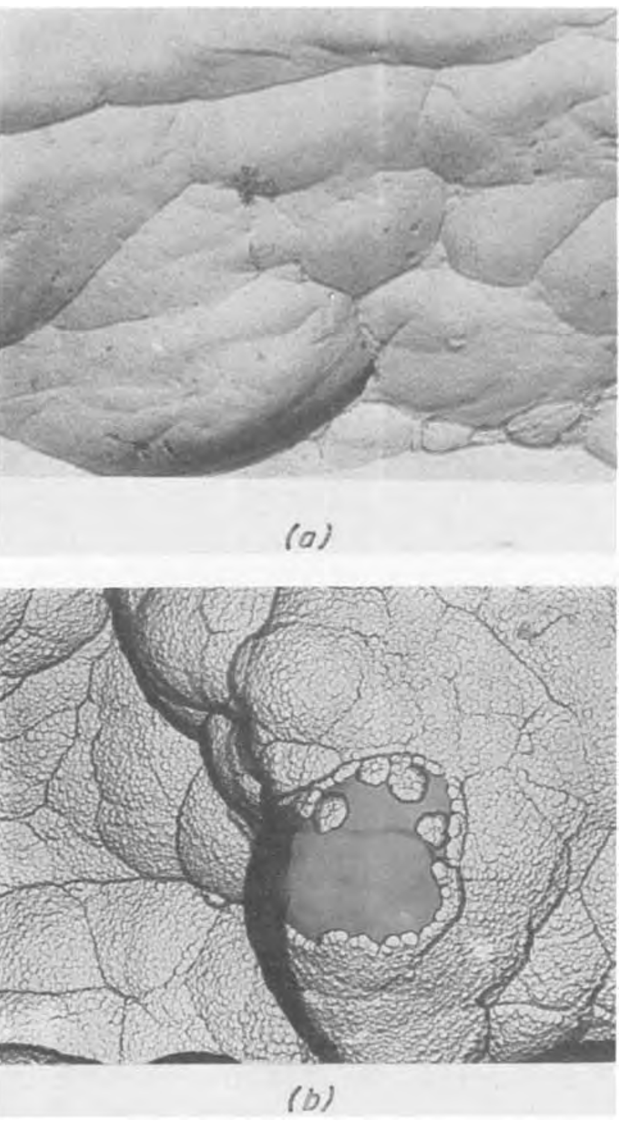

Fig. 5. Transmission electron micrographs of the anodic oxide formed on aluminum in 1M ammonium tartrate at 30°C on anodizing (a, upper) for 45 min at 30V (≈ 32V overpotential) and (b, lower) at 10V (12V overpotential) until steady state obtained. Magnification 23,500X.

The authors thus propose that the *i-v* behavior shown in Fig. 2 and 3 is characteristic of a barrier layer whose thickness is determined by the applied overpotential. The functional relation between thickness and overpotential is nonobvious, however, except in the intermediate potential region, approximately 50-150V, where the current is substantially independent of potential. In this region it is logical to propose that the barrier layer thickness is proportional to the overpotential and that interfacial potential drops (*i.e.*, "space" charge effects as discussed previously) are negligible. Under these circumstances the field in the oxide would be independent of potential and a diffusion-limited leakage current would be constant, consistent with observation. As the overpotential is reduced, however, any potential differences across either oxide interface would become increasingly significant, especially if these differences are substantially independent of the overpotential as would be the case if local equilibrium exists at the interfaces. Thus the field in the oxide would no longer be constant, but would decrease with the potential, yielding a reduced diffusion current in agreement with observation. While the form of the *i-v* characteristics below 50V is not amenable to easy interpretation, the two exponential terms clearly arise from simultaneous occurrence of both forward and reverse conduction and are consistent in form with either a field-dependent diffusion-limited process, as discussed above, or a potential-dependent interfacial transfer process as current limiting. In either case the exponential coefficients are anomalous with respect to expected values. The authors are presently unable to offer a discussion based on potential-dependent interfacial transfer processes that offers as many points of consistency with observation as does the proposal that current is field dependent and diffusion limited.

Zahavi and Yahalom (46-48) have examined anodic breakdown of oxide films in considerable detail, viewing it as an avalanche process initiated at the oxide-electrolyte interface at adequately high potentials. Full scale avalanching is preceded by short-lived sporadic discharges at the interface; presumably this phenomenon gives rise to the marked increase in anodic current in the overpotential region preceding failure and described by Eq. [3].

The temperature dependence of the exponential coefficients, b_a and b_c, is shown in Fig. 6; it, as well as the magnitudes of the constants, is anomalous in comparison to Tafel behavior. Young (49, 50) has discussed at length anomalies in the Tafel slopes observed during growth of anodic films on niobium and has attributed them to space charge effects arising from a nonuniform distribution of cations "frozen-in" during film formation. In view of the distinction between growth and steady state, however, as well as the greater degree of anomaly seen in the present study, such an explanation would not seem directly applicable.

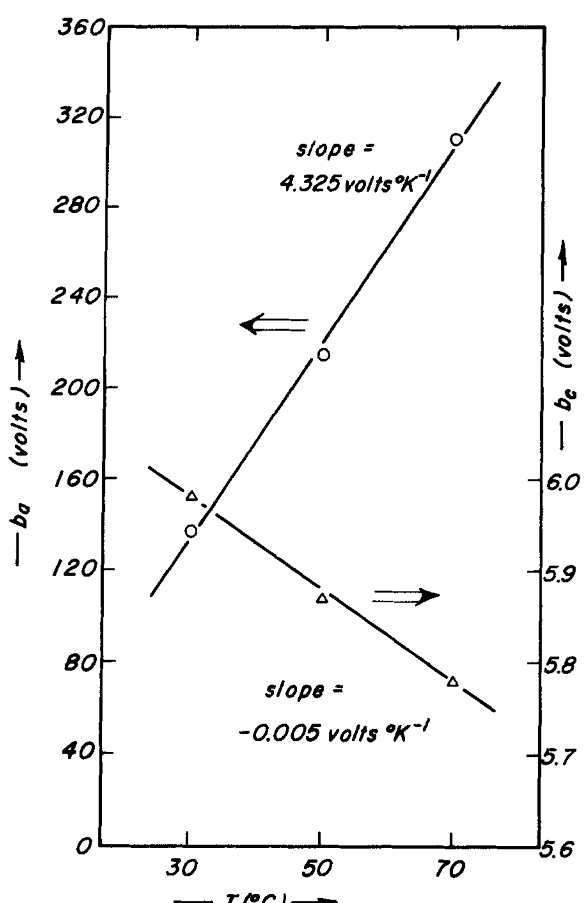

Fig. 6. "Anodic" and "cathodic" exponential coefficients vs. temperature.

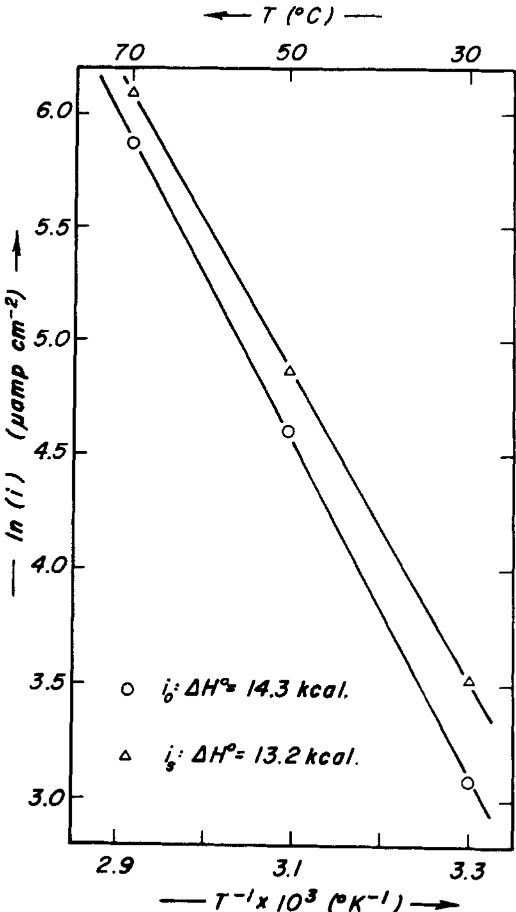

Fig. 7. Arrhenius plot of "exchange current," i_o, and "saturation current," i_s.

Arrhenius plots for the "exchange current," i_o, and the "saturation current," i_s, are shown in Fig. 7. The Arrhenius slope for each process should represent the sum of the enthalpy of formation of the carrier and that for the activated state of the carrier pertaining to that process. Values of 14.3 and 13.2 kcal-g-atom^{-1} are seen for the exchange current and the saturation current, respectively. These values are essentially identical, suggesting that the same transport mechanism is limiting in both the low and intermediate potential regions. Furthermore, the values are small in comparison to the bandgap of the oxide, 7 eV (160 kcal) (51) suggesting that the carrier state is ionic rather than electronic. In the light of the foregoing discussion the authors propose that the current-limiting mechanism at steady state is ionic diffusion over the anodic overpotential range of 0 to approximately 80V and that, while above 50V the field is substantially constant independent of overpotential, at lower overpotentials the field is significantly reduced by charge polarization within the oxide.

Acknowledgments

The authors express their appreciation to the National Science Foundation for its generous support through grants No. GK 20017, "The Role of Environment in the Mechanical Behavior of Passive Films," and No. GH 35580, "Environment-Affected Properties of Oxide Films as Related to Defect Structure." Numerous supporting statistical and regression computations were carried out using the facilities of the University of Connecticut Computer Center. The authors gratefully acknowledge the contributions of Professors M. A. Melehy and J. H. Tripp, Departments of Electrical Engineering and of Physics, respectively, University of Connecticut, derived through several lengthy discussions, as well as those of the anonymous reviewers for this JOURNAL, which enabled a substantial improvement in the discussion.

Fluorescence of Eu^{3+} in Sodium Phosphotungstate Glasses

R. Reisfeld, H. Mack, A. Eisenberg, and Y. Eckstein

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

Sodium phosphotungstate glasses of various ratios of P_2O_5/WO_3 were doped by 1.0 weight per cent Eu^{3+}. Fluorescence spectra were measured on excitation to 394 and 464 nm. On excitation to 394 nm the ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ emissions and the amount of splitting of the $^5D_0 \rightarrow {}^7F_1$ transition are dependent on composition of the glass and conditions of glass preparation. It is concluded that two different types of Eu^{3+} sites exist in phosphotungstate glasses. One type is this in which Eu^{3+} is surrounded by phosphate and tungstate tetrahedra at random. In the other type, Eu^{3+} is incorporated into microcrystallites. It is shown that Eu^{3+} may serve as a spectroscopic probe for microphase separation. It is also suggested that phosphotungstate glasses doped by Eu^{3+} can substitute Eu^{3+}-doped tungstate crystals for fluorescence purposes.

Tungstate crystals doped by rare earth ions are known to be good laser materials. Recently, it has been shown by the present authors (1, 2), for series of rare earth doped different oxide glasses, that the glasses have similar optical characteristics as the crystals, the main difference being in the inhomogeneous broadening and higher oscillator strengths. In most glasses studied, the excitation of the rare earth ions is achieved by direct absorption to the electronic levels of the dopant, while in the case of tungstate crystals, transfer of excitation energy from the matrix is also observed. The latter process can increase the brightness of fluorescence.

It was the purpose of this work to prepare tungstate glasses which were expected to have some of the optical properties of tungstate crystals. Technically, preparation of such glasses is much easier than that of the corresponding crystals. Since pure tungstate glasses are very unstable, and an addition of P_2O_5 is highly effective in stabilizing and widening the glass forming region (3), mixed sodium-phosphotungstate glasses, containing Eu^{3+} ions, were prepared.

Key words: microphase, microcrystallites, fluorescence probe for microphase separation.

Experimental

The starting materials were WO_3 (Hopkin and Williams, Limited), Na_2HPO_4 analytical "Frutarom," and Eu_2O_3 (Molycorporation) 99.99% purity. Glasses containing 1 weight per cent (w/o) of Eu^{3+} and varying concentrations of WO_3, Na_2O, and P_2O_5 were prepared by melting the mixture at 950°-1050°C in a platinum crucible in air. The various concentrations of the oxides in the mixture are given in Table I. The melting times varied from 9 to 120 min. The melts were either quenched rapidly (henceforth called fast cooling rate) or allowed to cool slowly in the crucible until the liquid became viscous and then poured on the tile (henceforth referred to as slow cooling rate). The time of heating and the rate of cooling as well as the rela-

tive concentrations of WO_3 and $Na_2O \cdot P_2O_5$ affect the emission characteristics of Eu^{3+} as a result of microphase separation.

Results and Discussion

The emission spectrum of Eu^{3+} was measured by excitation at 394 and 464 nm. These bands have the highest intensity in the excitation spectrum of $^5D_0 \rightarrow {}^7F_j$ emission of Eu^{3+}. The emission spectrum of Eu^{3+} in glasses with varying ratios of WO_3 to $2Na_2O \cdot P_2O_5$ is presented in Fig. 1. As seen from this figure, on excitation at 394 nm differences are observed between glasess containing 68 and 75 w/o of WO_3 in the ratio of the relative intensities of $^5D_0 \rightarrow {}^7F_2$ (at 613 nm) to $^5D_0 \rightarrow {}^7F_1$ (at about 590 nm) and in the splitting of these transitions.

For the sake of the arguments which will be applied below, we defined the resolution of the $^5D_0 \rightarrow {}^7F_1$ transition as the sum of the areas of the two components of this transition divided by the minimum intensity between them. In the case of glass, where no distinct splitting was observed (*e.g.*, 68 w/o WO_3 in Fig. 1), the $^5D_0 \rightarrow {}^7F_1$ transition was resolved into two gaussians peaking at the same wavelengths as those of $^5D_0 \rightarrow {}^7F_1$ transition in the sample containing 75 w/o WO_3, where we observed a defined splitting (presented in Fig. 1). The resolution between the two gaussians was done as described above. At 464 nm, no splitting is observed and the ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ remains constant with the changing of the concentrations of WO_3. The ratio and resolution for glasses of varying amounts of WO_3 prepared at constant temperature (1050°C), constant heating time (60 min), and slow cooling rate are given in Table II for excitation at 394 nm.

Table II. Dependence of the $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ and the spectral resolution of $^5D_0 \rightarrow {}^7F_1$ transition on the WO_3 content (after 60 min of heating at 1050°C and slow cooling rate). Excitation 394 nm.

WO_3 (w/o)	$\frac{^5D_0 \rightarrow {}^7F_2}{^5D_0 \rightarrow {}^7F_1}$	Resolution	
60	10.47	2.0	glass
63	8.42	2.0	
65	6.62	4.0	microcrystallites
66	5.52	4.6	
67	9.92	2.0	glass
68	10.16	2.0	
69	10.74	2.0	
70	4.67	3.19	microcrystallites
72	2.90	4.76

78	3.02	4.02	
80	9.15	1.57	

High ratio of $\frac{^5D_0 \rightarrow {}^7F_2}{^5D_0 \rightarrow {}^7F_1}$ and low resolution are characteristic of a glass.

Low ratio of $\frac{^5D_0 \rightarrow {}^7F_2}{^5D_0 \rightarrow {}^7F_1}$ and high resolution are characteristic of microphase separation.

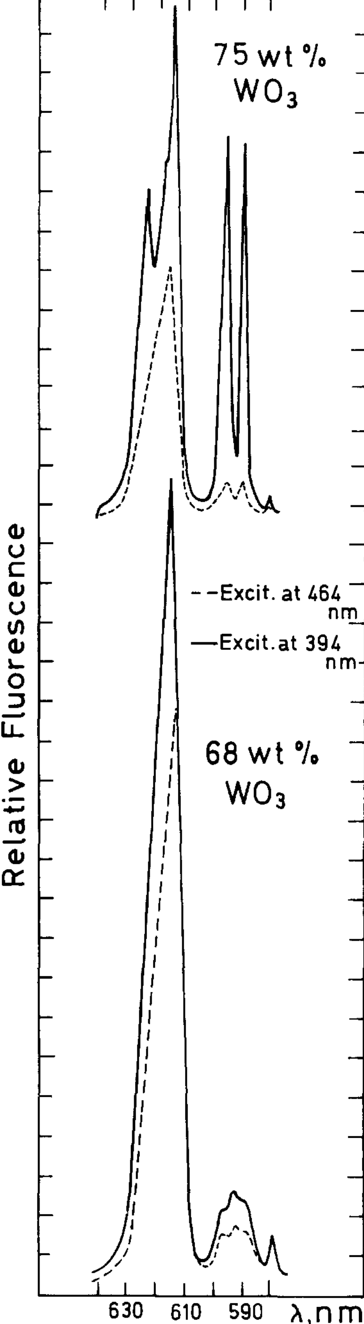

Fig. 1. Emission spectra of 1 w/o Eu^{3+} in $xWO_3 \cdot y(2Na_2O \cdot P_2O_5)$ glasses. The ratio of peak areas of Eu^{3+} $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ transitions under 394 nm excitations which are given in Table II and Table III is 3 for the 75 w/o WO_3 sample and 10.16 for the 68 w/o WO_3 sample. The resolution of the $^5D_0 \rightarrow {}^7F_1$ transition in the two samples is 9 and 2, correspondingly.

The differences in the emission spectra of Eu^{3+} produced by the two different excitation wavelengths is explained by the existence of different types of Eu^{3+} sites in the tungstate glass. One type of Eu^{3+} site is that in which the ion is surrounded by phosphate tetrahedra and tungstate octahedra intermixed at random. Such an arrangement is typical for glasses, hence the site symmetry is the lowest, as evident by the high ratio between $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ transitions and the highest inhomogeneous broadening. The $^5D_0 \rightarrow {}^7F_2$ is known to be "hypersensitive" on the site symmetry in which Eu^{3+} is incorporated as it is originated from forced electric dipole transition, while $^5D_0 \rightarrow {}^7F_1$ is a magnetic dipole transition and much less sensitive on site symmetry. This picture is similar to that of Eu^{3+} in phosphate glasses (4).

We suggest that the other type of Eu^{3+} site, for which the ratio of $^5D_2 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ transition is

* $\Delta\nu$ is the half-bandwidth of the short wavelength component of Eu $^5D_0 \rightarrow {}^7F_1$ transition for the microcrystallites and half-width of the unresolved $^5D_0 \rightarrow {}^7F_1$ band for the glasses.

about 3-6.5, is Eu^{3+} incorporated into microcrystallites of tungstate. This suggestion is based on the similarity of the emission spectra of Eu^{3+} excited at 394 nm to Eu^{3+}-doped $Na_{0.5}Y_{0.5}WO_4$ crystals (5). As seen from Table III, the half-bandwidth of the short wavelength component of the $^5D_0 \rightarrow {}^7F_1$ transition of Eu^{3+} in such tungstate crystallites is about 50 cm^{-1} compared to the half-bandwidth of this unresolved band in glasses which is about 380 cm^{-1}. A similar increase of the bandwidths with increasing randomness of the Eu^{3+} sites has been also observed by Van Uitert: 1.5 and 5 cm^{-1} in pure $CaWO_4$ and 4 and 11 cm^{-1} in $Na_{0.5}Y_{0.5}WO_4$ for the Eu^{3+} $^5D_0 \rightarrow {}^7F_2$ transition (5). The fact that even in the polycrystallites of Eu^{3+} tungstates the smallest ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ transitions observed was 2.9 indicates that the polycrystallites do not possess a center of inversion, and thus resemble Eu^{3+}-doped tungstate crystals (5).

At 394 nm excitation, the fluorescence of Eu^{3+} in the crystallite sites is predominant, while at 464 nm excitation the fluorescence of Eu^{3+} in the glass forms makes the main contribution. At about 400 nm, the tungstate has an absorption edge and, therefore, at this excitation the Eu^{3+} ions embedded in the crystallites are mainly excited (probably by energy transfer from tungstate to Eu^{3+}). At 464 nm, the Eu^{3+} is excited directly into its electronic levels and since the oscillator strengths of the glass are higher than that of the crystals, the emission from the glass is predominant. The higher oscillator strength of Eu^{3+} in glasses are due to the forbidden $f \leftrightarrow f$ transitions which are more permissible as a result of the total absence of symmetry in glass. At the appropriate concentration of WO_3, when only a glass structure exists, there was no difference in the spectral behavior of Eu^{3+} in the two excitations.

The appearance of microcrystallites should depend on conditions which promote crystallization, such as (*i*) a definite ratio of WO_3 to $2Na_2O \cdot P_2O_5$, (*ii*) slow cooling rate at which an equilibrium can be achieved between the glass and the microcrystallites, and (*iii*) the doped microcrystallites may be formed by diffusion of Eu^{3+} into the tungstate phase when the temperature is low and the time insufficient for a thorough mixing of the glass and the crystalline phases. This can be observed in all concentrations of WO_3 (with the exception of a 50 w/o WO_3 mixture), since it is not an equilibrium process.

The influence of melting conditions on the appearance of microcrystallites, as reflected by a small ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ transitions, high resolution and a small half-bandwidth of the $^5D_0 \rightarrow {}^7F_1$ band when excited at 394 nm, is summarized in Table II and Table III. From Table II we see that at conditions in which an equilibrium may be achieved, the only limiting factor for the appearance of the microcrystallites is the ratio between WO_3 and $2Na_2O \cdot P_2O_5$. The concentration regions of the glass phase and microcrystallite phase are marked in Table II. From Table III we conclude that the conditions for glass or microcrystallite formation are the following: If the concentration ratio of WO_3 to $2Na_2O \cdot P_2O_5$ is characteristic for glass, then after proper heating time, which is needed for achieving the equilibrium, a glass will be formed. This time is 11 min for a 50 w/o WO_3 mixture and 50-60 min for mixtures containing 68-72 w/o WO_3. At concentrations of WO_3 in which the equilibrium conditions favor the appearance of microcrystallites, a slow cooling rate will enable it to reach an equilibrium and microcrystallites will be formed. This can be seen in the mixture containing 75 w/o WO_3 (Table III).

In summary, the fluorescence spectra of Eu^{3+} can serve as a probe for the indication of microphase separation and the materials presented in this work can, in some cases, substitute in tungstate crystals.

ABSTRACT

It was established that ideal, diffusion-controlled, steady-state segregation, never accomplished on earth, was achieved during the growth of Te-doped InSb crystals in Skylab. Surface tension effects led to nonwetting conditions under which free surface solidification took place in confined geometry. It was further found that, under forced contact conditions, surface tension effects led to the formation of surface ridges (not previously observed on earth) which isolated the growth system from its container. In addition, it was possible, for the first time, to identify unambiguously: the origin of segregation discontinuities associated with facet growth, the mode of nucleation and propagation of rotational twin boundaries, and the specific effect of mechanical-shock perturbations on segregation. The results obtained prove the advantageous conditions provided by outer space. Thus, fundamental data on solidification thought to be unattainable on earth because of gravity-induced interference are now within reach.

Structural and compositional control during solidification of materials is impeded by gravity-induced effects in the melt. Thermal gradients necessary for crystal growth lead, in the presence of gravitational forces, to thermal convection which in general causes uncontrolled variations in the solidification rate and in diffusion boundary layer thickness; such variations lead directly to periodic and/or random microscopic and macroscopic segregation inhomogeneities. Furthermore, in the presence of gravity, establishing steep thermal gradients, frequently required to prevent constitutional supercooling, is often impossible and consequently interface breakdown is unavoidable.

Gravity effects are, thus, primarily responsible for the present lack of reliable solidification data and the existing gap between theory and experiment. Consequently, crystal growth and associated segregation phenomena are still based on empiricism, and the properties and performance of solids are not at their theoretical limits.

Gravity-free conditions made accessible through the space program provide a unique opportunity to obtain reliable crystal growth data and, therefore, to advance our quantitative understanding of solidification processes; in addition this program makes possible the exploration and assessment of the potential of outer space for materials processing.

Indium antimonide was chosen for the presently reported Skylab experiment because its relatively low melting point (525°C) made the experiment compatible with the available electrical power. In addition, chemical etching, the only high-resolution technique available, at the time, for the study of segregation inhomogeneities on a microscale, had been developed on InSb to its most advanced level.

The experiments performed during the Skylab-III and -IV missions included the growth of undoped, tellurium-doped, and tin-doped indium antimonide. The present report is concerned primarily with results obtained on tellurium-doped InSb.

Objectives

The objectives of growing Te-doped InSb in Skylab were to assess the advantages of zero-gravity environment, to obtain basic data on solidification, and to explore the feasibility of electronic materials processing in outer space. Thus, the experiment was designed to achieve solidification under diffusion-controlled, steady-state conditions and to investigate the associated growth and segregation behavior on a micro- and macro-scale. Direct comparison of growth and segregation on earth and in space was to be achieved by melting and resolidifying in space a portion of each crystal growth on earth.

Experimental Approach

Crystal growth apparatus.—The InSb growth experiment was carried out in the "multipurpose furnace" (Fig. 1). The furnace provided for three tubular cavities into which three stainless steel cartridges containing the crystal growth assemblies were inserted. Heat levelers, lateral heat-shields, and the heat extractor plate insured controlled heat flow from the heating element to the heat extractor plate through the crystal. Melting was initiated at the end of the crystal (to be referred to as hot end), located inside the heating element and the crystal-melt interface was advanced to the desired position (back-melting) by appropriate power input. Regrowth, in turn, was achieved by controlled power reduction.

Crystal preparation and assembly.—Indium antimonide used for ground-based tests and the Skylab experiment was synthesized in the Electronic Materials Laboratory at M.I.T. The single crystals for the experiment were pulled from the melt in the <111> direction by the Czochralski technique. The as-grown crys-

tals (approximately 1.8 cm in diameter and 17 cm long) were centerless ground to a diameter of 1.4 cm, and cut to a length of 11 cm. The cylindrical crystals were etched in modified CP-4, 3 parts (48%) HF + 5 (conc) HNO_3 + 3 (glacial) CH_3COOH + $10H_2O$, to remove surface damage and reduce their diameter to the desired value. Each crystal was subsequently inserted between graphite spacers into a quartz ampul of 3 mm wall thickness. The diameter of every crystal was 0.13 mm smaller than the inside diameter of its ampul.

The spacer at the hot end had a peripheral cylindrical cavity to provide additional space for the melt in case unforeseen surface tension effects under zero gravity conditions resulted in increased clearance between the regrown crystal and the quartz wall; the cylindrical graphite spacer at the other end of the crystal (to be referred to as cold end) was designed to enhance heat transfer from the crystal to the heat extractor plate. The crystals were positioned in the ampuls so that their B <111> direction coincided with the regrowth direction.

All ampuls were repeatedly flushed with purified helium and evacuated to 10^{-7} Torr prior to sealing. The crystals were anchored near their cold end to the ampuls by means of a small depression in the quartz wall formed by local heating of the evacuated ampuls.

Each sealed ampul was encapsulated in an evacuated stainless steel cartridge; one set of three cartridges containing an undoped crystal, a Te-doped crystal ($\sim 10^{18}/cm^3$), and a heavily Sn-doped crystal ($\sim 10^{20}/cm^3$) was used for the zero gravity growth experiment (Skylab-III mission). A second set intended for backup purposes was eventually used in an unscheduled additional experiment in space (Skylab-IV mission). A sealed ampul and its metal cartridge used in the Skylab experiment are shown in Fig. 2.

Crystal growth procedure in space.—Skylab-III mission experiment.—The samples were inserted into the multipurpose furnace and back-melting was initiated by turning on the power. The desired back-melting was achieved in 120 min. Then the system was kept at temperature for a period of 60 min (thermal soak), to achieve thermal equilibrium in the system and homogenization of the melts.[1] Subsequently, a cooling rate of 1.17°C/min was established by controlled power reduction at intervals of 14.4 sec. Four hours after initiation of regrowth the power was turned off and passive cooling to the ambient temperature took place. The thermal history of the growth system (hot-end temperature) obtained from a Chromel/Alumel thermocouple in the furnace is shown in Fig. 3.

Skylab-IV mission experiment.—The remelting and thermal soaking procedure was identical with that of the Skylab-III experiment. However, in this, originally

[1] A soaking period of 180 min was originally specified for this purpose; however, an inadvertent power shortage necessitated the reduction of the soaking period to 60 min.

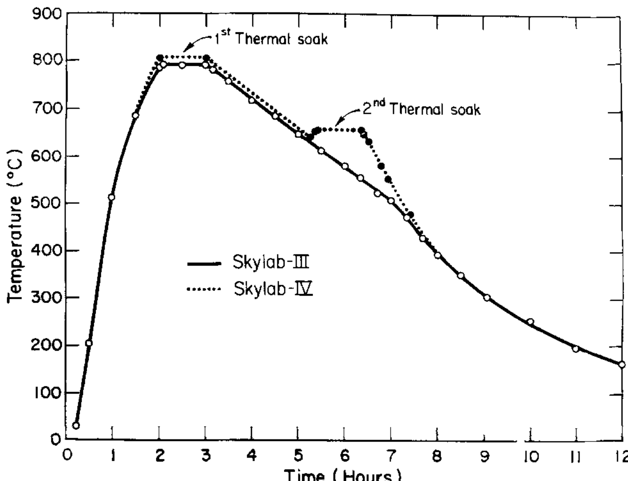

Fig. 3. "Hot-end" temperature cycles for Skylab-III and Skylab-IV experiments as obtained from a Chromel/Alumel thermocouple.

unscheduled, experiment the growth system was subjected to a mechanical shock by striking the furnace assembly at a predetermined time; furthermore, the constant cooling rate of 1.17°C/min was interrupted 140 min after initiation of regrowth and a second thermal soaking period of 60 min was introduced by maintaining the furnace power at a constant level. The power was subsequently turned off and the system was allowed to reach ambient temperature (see Fig. 3). These changes in the growth procedure were intended to provide time reference markings in the crystal and to obtain data on the dependence of transient segregation on growth rate.

Results and Discussion

Morphological characteristics.—The extent of regrowth achieved during the Skylab experiment was virtually the same for all crystals (about 6 cm) and in excellent agreement with theoretical calculations and ground-based testing; in each crystal the regrowth interface was clearly delineated (see for example Fig. 2).

All crystals were separated from their containers, without affecting their morphological characteristics, by dissolving the quartz ampuls in 48% HF.

The Te-doped InSb crystals grown in the two Skylab missions are discussed individually since they exhibit seemingly significant differences in morphological characteristics.

Tellurium-doped InSb grown in Skylab-III.—This crystal was of the same diameter as the earth-grown segment (seed); two portions of the crystal corresponding to the early and late stages of growth are shown in Fig. 4 and 5, respectively. The surface of the

Fig. 2. crystal has a dull appearance which indicates that during growth it did not establish contact with the confining quartz wall. This conclusion is reinforced by the absence of the peripheral cavities which generally characterize growth under confined geometry.[2]

The surface of the regrown crystal in the vicinity of the seed (Fig. 4) exhibits several bands of differing width oriented normal to the growth direction. These bands were identified as the external boundaries of rotational twins (see below) which are frequently encountered in InSb grown in the <111> direction.

Conspicuous in Fig. 5 is the presence of irregularly spaced "surface ridges" oriented preferentially in the direction of growth (left to right). The ridges are shiny at the top indicating contact with the quartz wall; they are, on average, 25 μm high and increase in width toward the hot end of the crystal. Over the last 10 mm of the crystal the ridges become irregular and branch out. The regions between the ridges exhibit, in general, the characteristics of growth from free (unconfined) melts. In some isolated areas inclined lines, which have the appearance of stress-induced defects, originate at the surface ridges. These defects were shown to be confined to the surface region and to have no detectable effects on the growth and segregation behavior of the system. To the authors' knowledge, the phenomenon of surface ridge formation has not been previously observed in solidification under confined geometry; it is further discussed below.

Tellurium-doped InSb grown in Skylab-IV.—As seen in Fig. 6, regrowth, following the thermal soaking period, proceeds (left to right), in this case, first with decreasing and then essentially constant crystal diameter. With continuing growth the crystal diameter decreases again, then increases and assumes a constant value of 12.8 mm (right-hand side of Fig. 6) which is the same as that of the ID of the confining quartz ampul. (The reasons for the differences in diameter between the two Te-doped crystals in the early stages of regrowth are discussed below.)

From volume considerations, it is concluded that the increase of the crystal diameter coincides in time with the initial contact of the melt with the graphite spacer at the hot end of the quartz ampul. Since crystal growth over the first 30 mm proceeded with a decreased diameter, and solidification of InSb is accompanied by a volume expansion of 12.9%, the volume available to the residual melt is less than during the Skylab-III experiment at the same time in growth. Thus, toward the final stages of solidification some melt was ultimately forced into the peripheral cavity available in the hot-end graphite spacer. Indium antimonide solidified in the spacer cavity weighed 2.52g. Accordingly, the total available volume for the melt in the ampul itself (excluding the volume of the cavity in the graphite spacer) was occupied after the crystal had reached a length of 34 mm, *i.e.,* 5 mm after the crystal diameter reached its maximum value. Since the clearance between the spacer and the quartz wall was less than 0.25 mm, the melt was under substantially increased pressure during the last 25 mm of growth. This increased pressure, however, did not lead to forced wetting between the melt and the quartz wall since contact between the crystal and the wall remained confined to the surface of the irregularly spaced ridges as in the Skylab-III crystal.

The surface characteristics of the crystal grown with a diameter smaller than the ID of the ampul are typical of free-surface solidification. They are identical with those encountered between the surface ridges in the Skylab-III crystal and are similar to those observed on crystals grown by the Czochralski technique on earth.

Figure 7 shows the surface characteristics of the crystal portion grown with constant reduced diameter at a distance of about 10 mm from the initial regrowth interface; the surface irregularities are the same as those commonly observed in nonfaceted crystal growth from the melt. In addition, randomly spaced lines oriented normal to the <111> growth direction are visible. These lines are not continuous over the whole periphery and are confined to the three relatively flat portions of the crystal surface. They are not present on the centrally located "white" band which was identified as a rotational twin (see also below).

The crystal portion with a reduced diameter does not exhibit surface ridges observed on the previously discussed crystal; surface ridges do appear as the crystal diameter increases and approaches the value of the ID of the ampul. Details of surface ridge patterns are

[2] It is of interest to note that the surface of the Sn-doped and undoped crystals grown in Skylab was shiny and exhibited peripheral cavities indicating intimate contact (wetting) of the melt with the confining quartz wall.

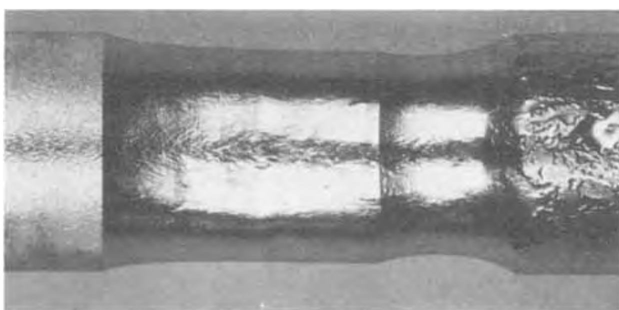

Fig. 6. Te-doped crystal grown during the Skylab-IV mission; note decrease in crystal diameter upon initiation of growth; surface ridges appear on right-hand side after crystal diameter reaches its maximum constant value. Magnification 4.8×.

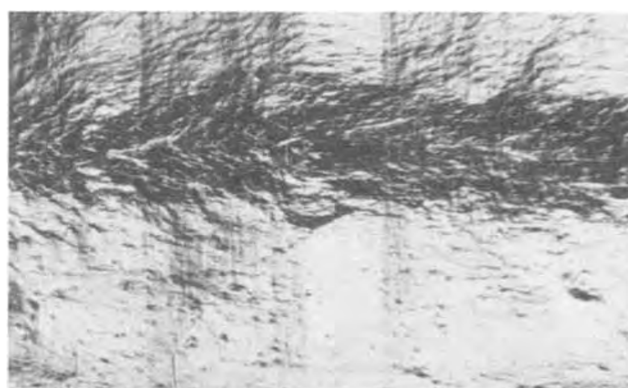

Fig. 7. Part of Te-doped crystal shown in Fig. 6; surface characteristics are typical for unconfined solidification; note random distribution lines normal to the growth direction; rotational twin is visible (white band). Magnification 19×.

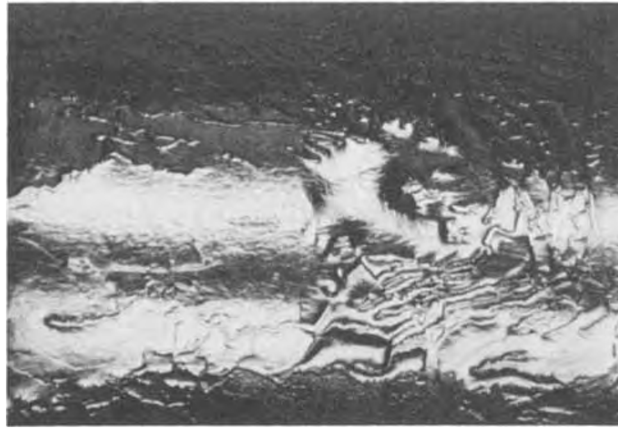

Fig. 8. Surface ridge patterns formed after crystal reached maximum constant diameter during Skylab-IV experiment; note discontinuity in surface morphology associated with second thermal soaking (see text). Magnification 21×.

shown in Fig. 8. The ridges in this crystal are of the same height as those on the crystal grown in Skylab-III (~25 μm). Here again they have no measurable effect on growth and segregation in the bulk of the crystal; they appear, however, less oriented along the growth direction and more branched. From the propagation patterns of these ridges, it is concluded that they are not the result of anomalous solidification, but, rather, that they are formed on the melt prior to solidification.

So far all attempts to account for ridge formation on the basis of known phenomena, such as wetting and convection induced by surface tension gradients, have met with fundamental inconsistencies.

Bulk characterization.—The bulk characterization of the space-grown crystals was aimed primarily at the growth and segregation behavior employing various analytical techniques. For this purpose the crystals were sectioned as shown in Fig. 9.

Dopant segregation.—The analysis of dopant segregation by high resolution differential etching was carried out on longitudinal sections of (211) surface orientation (see Fig. 9). All crystal sections were polished with Syton and etched for 40 sec in a solution of 1HF(48%) and $1CH_3COOH$ (glacial) + $1KMnO_4$ (saturated aqueous solution); they were subsequently rinsed, dried in purified nitrogen, and studied by means of interference contrast microscopy.

Dopant segregation during growth under the influence of gravity and under zero gravity conditions is evident in Fig. 10 where a portion of earth-grown (upper part) and space-grown crystal (lower part)

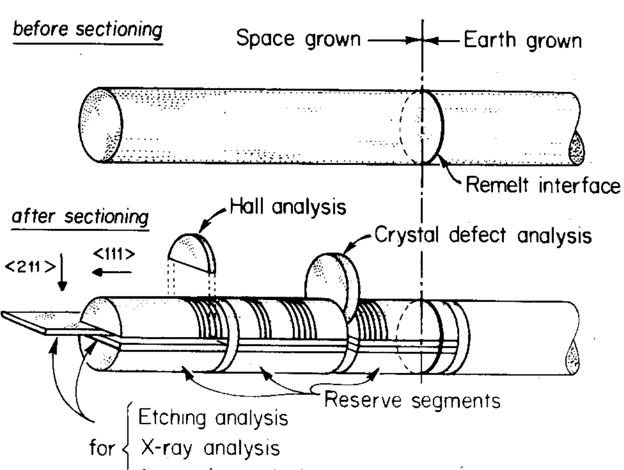

Fig. 9. Sectioning scheme for analysis of space-grown crystal

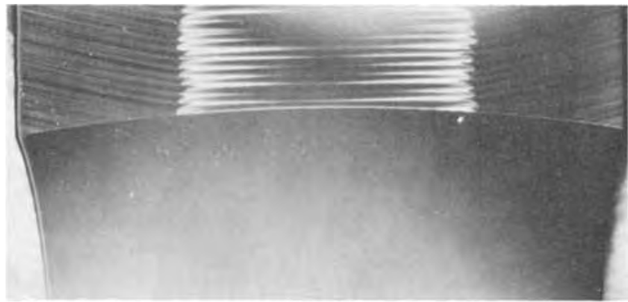

Fig. 10. Etched cross section (under dark field illumination) of crystal grown during Skylab-IV mission; space-grown region (bottom), in contrast to earth-grown region (top), exhibits no compositional inhomogeneities. Magnification 12×.

is shown. It is further seen that the regrowth interface morphology, established during thermal soaking, is concave (viewed from the melt). The sharp demarcation line separating the earth- and space-grown segment is the result of an abrupt decrease in Te concentration which is dictated, for initial regrowth, by the thermodynamic characteristics of the system, *i.e.*, the distribution coefficient, k_o of Te in InSb is less than one ($k_o = C_S/C_L < 1$, where C_S and C_L are the concentration of Te in the solid and the melt, respectively).

The microscopic segregation behavior for the peripheral and the central part of the crystal in the vicinity of the regrowth interface is shown in Fig. 11 and 12, respectively. Pronounced segregation fluctua-

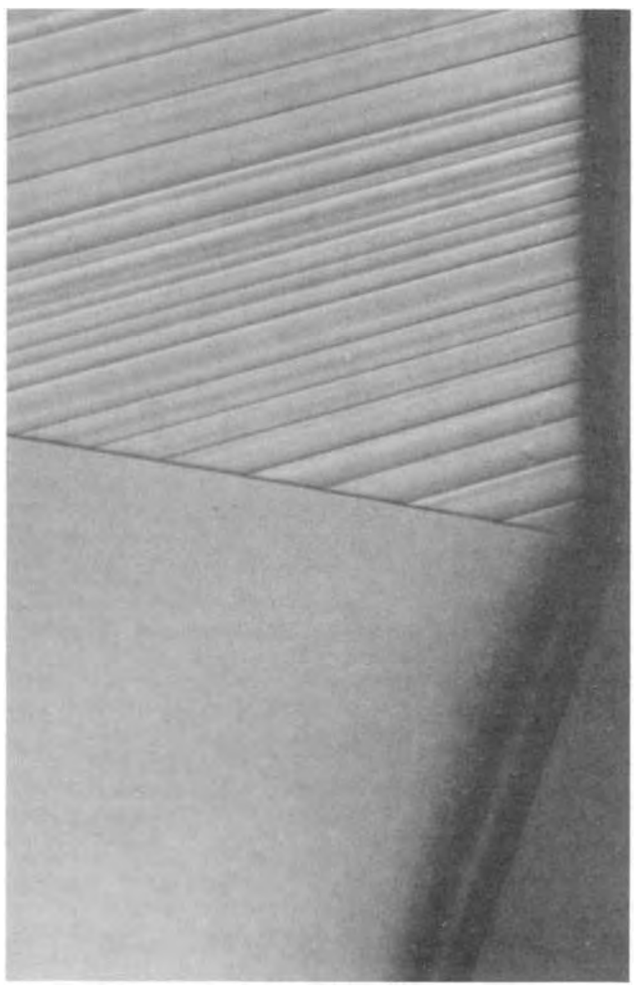

Fig. 11. Dopant segregation characteristics near the periphery of initial regrowth interface (right-hand side of Fig. 10). Magnification 300×.

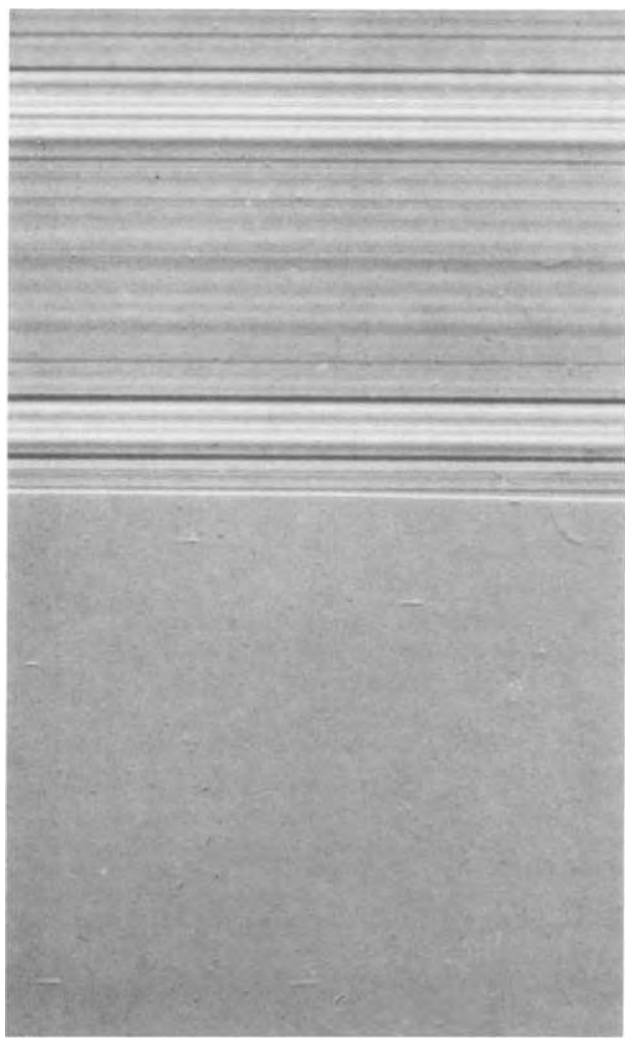

Fig. 12. Dopant segregation characteristics near the central region of initial regrowth interface of crystal grown during Skylab-IV mission. Magnification 580×.

tions (compositional inhomogeneities) in the earth-grown segment reflect irregular variations in growth conditions which are due to rotation effects (Czochralski pulling) and to uncontrolled gravity-induced thermal convection in the melt. No microscopic compositional fluctuations are present in the crystal segment grown in space. The segregation behavior in the equivalent region of the crystal grown during the Skylab-III mission was identical to the behavior presented above.[3]

According to theory, the area of the space-grown region shown in Fig. 12 must be part of a segregation transient (not revealed by etching) over which the dopant concentration increases continuously until, in the absence of convection, it reaches the same value as that of the dopant concentration present in the bulk of the melt; at this point steady-state segregation conditions are established and the dopant concentration in the solid remains constant except at the very terminal stage of solidification.

Quantitative dopant segregation analysis.—Since one of the major objectives of the Skylab experiment was to achieve steady-state segregation, quantitative dopant concentration analysis of the transition region was undertaken by means of Hall-effect measurements and ion-microprobe scanning.

Hall-effect measurements were carried out by the Van der Pauw technique on square samples measuring $2 \times 2 \times 0.5$ mm. Silver contacts were evaporated at the four corners of each sample and were annealed at 350°C for 2 hr to ensure ohmic behavior. Subsequently, gold wire leads were soldered with indium onto the contacts. More than thirty individual Hall-effect measurements (at different field strengths) were carried out on each sample to optimize the validity of the data. The reproducibility of the results was better than 1%. Twelve successive crystal slices were cut from the crystal grown in the Skylab-III mission as shown in Fig. 9. Two adjacent Hall-effect samples were chosen from each slice, in most instances near the central part of its straight edge. From some slices the Hall-effect samples were taken adjacent to the central location since twin or grain boundaries were present.

The compositional (carrier) profile together with the corresponding resistivity and carrier mobility obtained at 77°K are shown in Fig. 13. (Room temperature data, as expected, were found to be similar to those shown in Fig. 13 in view of the relatively high level of carrier concentration.)

The carrier concentration curve (N_{space}) in Fig. 13 shows clearly the decreased dopant concentration in the initial part of the space growth region, as predicted from theory; it delineates further the transient region in which the dopant concentration increases steadily and reaches its maximum value at a distance of about 0.5 cm from the regrowth interface. Beyond this distance the dopant concentration remains constant for the entire crystal length analyzed (5 cm). It is, thus, shown that steady-state segregation and homogeneous dopant distribution were achieved under zero gravity conditions.

In the ground-based tests performed in an identical experimental configuration and under "stabilizing thermal gradients," the dopant profile (N_{earth}) indicates clearly a steadily increasing dopant concentration, as seen in Fig. 13, which reflects the presence of slow convection caused by unavoidable lateral thermal gradients. The adverse effects of this type of convection cannot be revealed by high resolution etching, since no abrupt fluctuations in composition take place.

The ratio of the dopant concentration in the initially grown region and in the steady state-grown region is a direct measure of the equilibrium distribution coefficient, k_o, which cannot be reliably determined on earth. Unfortunately, the low spatial resolution of Hall-effect measurements does not permit, at this time,

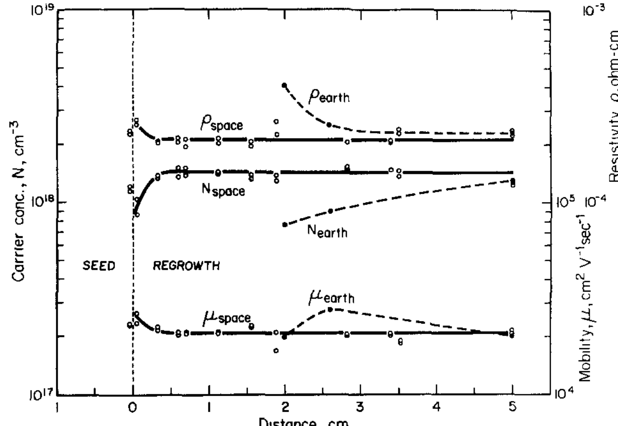

Fig. 13. Carrier (dopant) concentration profile obtained from Hall-effect measurements for Te-doped crystal grown during Skylab-III mission (N_{space}) and for Te-doped crystal grown during ground-based testing. The position of the original regrowth interface for both crystals is indicated by the vertical dashed line. Due to the presence of many twin and grain boundaries in the InSb grown during the ground-based testing, no meaningful Hall-effect measurements could be carried out in the vicinity of the regrowth interface.

[3] The use of Czochralski-grown seed material was necessitated because no single-crystal seed material can be obtained by the gradient freeze technique in confined geometry due to pronounced volume expansion during solidification.

the accurate determination of k_0. From the width of the region of transient segregation and the associated compositional change, the diffusion coefficient of the dopant in the melt can be determined, provided the microscopic growth rate is known and constant; this condition was not met in the present experiment, since only the nominal growth rate is known.

It should be pointed out that the observed variation in carrier concentration between adjacent Hall samples is not surprising since extensive twinning took place in this InSb crystal. In addition to twinning, growth under confined geometry leads to high dislocation densities which account for the measured, relatively low, carrier mobilities. It is of interest to note that in the crystal grown during the Skylab-IV mission, with a smaller diameter than that of the quartz ampul (unconfined solidification) the dislocation density was found to be 40% smaller than that in the earth-grown segment.

The compositional profile in the Skylab-III crystal was in parallel subjected to ion microprobe analysis since this technique was expected to provide a similar sensitivity as the Hall-effect measurements but a resolution in the micron range. The results obtained are consistent with the Hall-effect measurements; however, due to the relatively low yield of sputtered Te-ions, the linear resolution and accuracy were found to be limited. Thus, the precision of the ion-microprobe analysis with a scanning beam of 25 μm was only of the order of $\pm$16%.

Intentionally introduced segregation discontinuities.— As pointed out earlier, the growth process during the Skylab-IV mission was perturbed 90 and 140 min after initiation of the cooling cycle by a mechanical shock and by an arrest of cooling, respectively; the cooling arrest was sustained for a period of 60 min. These perturbations were intended to introduce time reference markers in the crystal and to study their specific effect on segregation behavior under steady-state conditions.

Etching analysis of the crystal revealed the presence of only two distinct segregation discontinuities manifested as curved lines, extending over the entire cross section of the crystal, 15 and 28.8 mm from the initial regrowth interface. As seen from the sketch in Fig. 14, the first discontinuity coincides with an abrupt decrease in crystal diameter and is of relatively low intensity as viewed in interference contrast. The second discontinuity was formed after the crystal had reached its maximum constant diameter and is very pronounced, as seen in Fig. 15.

The nature of these segregation discontinuities was investigated by double beam interferometry. As seen in Fig. 16a, the first perturbation (15 mm from the initial regrowth interface) resulted in a small and localized increase in tellurium concentration; on the other hand, the second perturbation (Fig. 16b) resulted in a pronounced segregation discontinuity (decrease) which persisted for an extended period of time. Thus, this second discontinuity is unambiguously identified as a transient segregation region associated with regrowth following thermal soaking, while the first, short-lived, segregation discontinuity is attributed to the mechanical shock.

Identification of the two segregation discontinuities permits their use as time markers for the determination of average microscopic growth rates in two different portions of the crystal. Thus, the average growth rate from the initial regrowth interface to the first discontinuity, 90 min into growth, is found to be 2.8 μm/sec and the growth rate from the first to the second discontinuity is 4.6 μm/sec. The average growth rate over the first 2.88 cm of growth (see Fig. 14) is 3.4 μm/sec.

The above growth behavior is consistent with theory: for the thermal configuration in the multipurpose furnace the thermal gradient in the melt is expected to decrease with continuing solidification and consequently the growth rate must correspondingly increase.

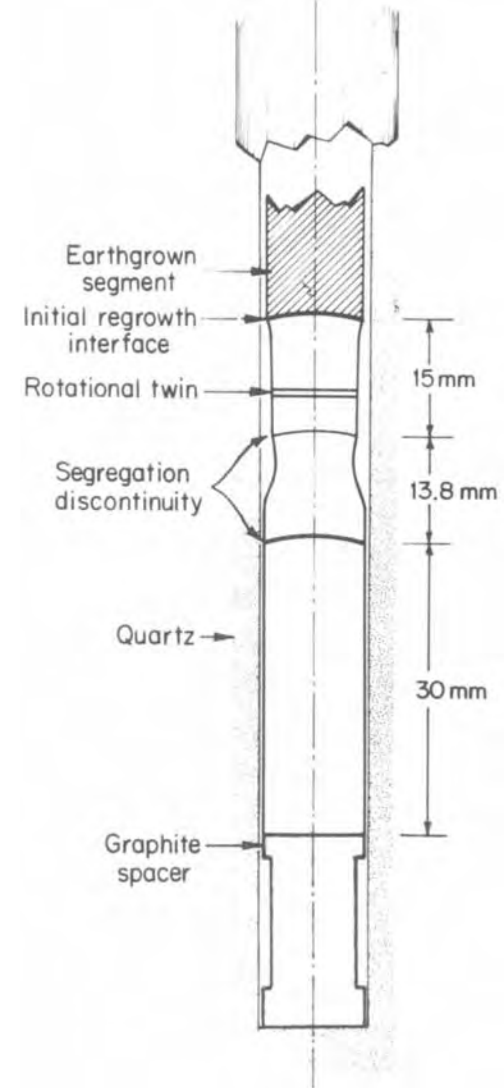

Fig. 14. Cross section of crystal grown during Skylab-IV mission

Fig. 15. Dopant segregation discontinuity caused by cooling arrest and thermal soaking during growth in Skylab-IV mission. Magnification 400×.

It is of interest to note that the fringe deflection at the second compositional discontinuity (Fig. 16b) is constant over the entire crystal diameter. Since the fringe deflection is proportional to the concentration change across the discontinuity and since the dopant concentration in the initial regrowth portion at the discontinuity (following thermal soaking) must be constant across the crystal diameter, it must be concluded that the tellurium concentration in the crystal above the discontinuity, which is constant along the

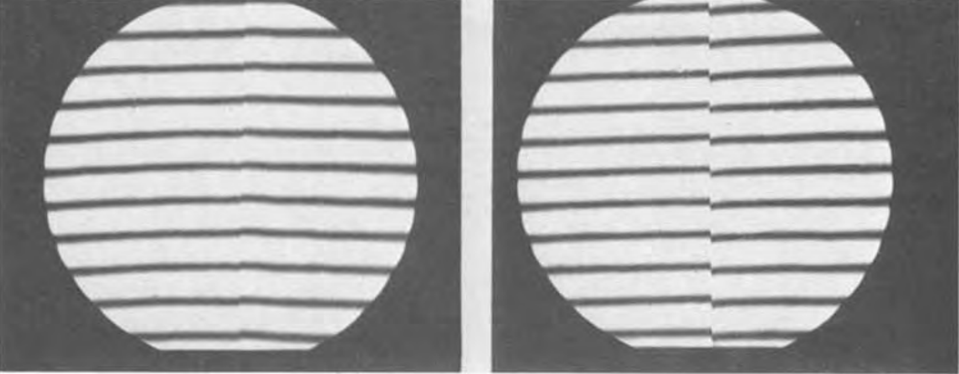

Fig. 16. Double beam interferograms of segregation discontinuities as revealed by etching (a, left) caused by mechanical shock and (b, right) caused by regrowth after thermal soaking (see text).

growth axis (fringes parallel to the growth axis), must also be constant in the radial direction.

Crystal morphology.—As discussed earlier, the surface morphological characteristics of both space-grown crystals indicate that the Te-doped InSb melt does not wet the confining quartz wall. Accordingly, the contact angle between the seed and the melt at the peripheral contact line is controlled by the interfacial tensions of the three phases involved and the meniscus of the melt (which determines the shape of the growing crystal) becomes a function of the radius of curvature of the crystal-melt interface. The decrease in crystal diameter observed during the early stages of growth in the Skylab-IV experiment (Fig. 6) is, thus, a direct consequence of the pronounced concave configuration of the crystal-melt interface (as viewed from the melt) brought about by the thermal characteristics of the system.

The ensuing gradual change to constant crystal diameter reflects the decrease in lateral heat transfer (due to the increasing distance of the growing crystal from the quartz wall) which results in an increase of the radius of curvature of the regrowth interface. The second decrease in crystal diameter, which coincides with the intentional, mechanical-shock perturbation, is attributed to a deformation of the melt (stretching toward the hot end) which established a melt meniscus leading to decreasing crystal diameter. The subsequent increase in the diameter of the crystal is due to the fact that the volume available to the growth system becomes limited.

In the Skylab-III experiment the radius of curvature of the initial growth interface was significantly larger than in the Skylab-IV experiment, apparently due to inadvertent differences in the heat transfer characteristics of the two cartridges; accordingly, the crystal diameter in the Skylab-III experiment conformed to the size of the confining quartz wall.

Peripheral facet effect.—Basic thermodynamic parameters are responsible for the fact that during growth of InSb in the <111> direction a facet is generally formed at the growth interface. Since facet formation is associated with kinetic supercooling, the facet is centrally located at convex interfaces and peripherally at concave interfaces (as viewed from the melt). It is generally believed that dopant segregation within facets is controlled by the lateral layer growth rate which is sensitive to thermal perturbations and gravity-induced convection.

Consistent with the above considerations, peripheral facet formation is observed in both space-grown crystals (Fig. 17) since in both experiments the growth interface assumed concave morphology (Fig. 14). The well-defined segregation discontinuities on the facet grown region cannot, however, be explained on the basis of thermal and/or convective perturbations in the melt since segregation in the nonfaceted bulk of the crystals was found to be homogeneous.

The observed segregation effects in the peripheral facet can be explained by considering that kinetic supercooling for peripheral facet formation assumes its highest value at the outermost part of the growth interface, which thus becomes the location with the highest probability for nucleation of lateral layer growth. Under these conditions, any perturbation, such as a vibration or the arrival of a foreign particle at the peripheral three-phase contact line may trigger nucleation of lateral layer growth and, thus, result in the formation of the observed segregation discontinuities. Their magnitude (intensity) is seen to decrease with decreasing supercooling from the periphery to the interior. Furthermore, depending on their magnitude, the facet segregation discontinuities extend more or less into the adjacent off-facet region; accordingly, it must be concluded that a finite amount of kinetic supercooling is associated with growth adjacent to facet regions. There is some evidence that the randomly spaced lines visible on the surface of the grown crystal (Fig. 7) correspond to the external boundaries of the presently discussed facet segregation discontinuities.

It should be pointed out that the same type of facet segregation discontinuity has been observed superimposed on compositional inhomogeneities in facet regions of earth-grown InSb; their origin could not, however, be explained.

Rotational twinning.—The bands of varying width appearing on the left-hand side of the crystal grown during the Skylab-III experiment (Fig. 4) were identified as the external boundaries of $(\bar{2}11)$ rotational twins. Each band is the result of two consecutive rotations by 60° of the (111) plane normal to the growth direction.

Analysis of the rotational twins on etched crystal segments of (211) surface orientation (Fig. 18) shows that some propagate across the entire crystal, some terminate within the crystal, and others deteriorate to grain boundaries, eventually leading to breakdown of the single-crystal matrix.

In view of the concave interface morphology, nucleation during growth is essentially restricted to the outermost peripheral part of the growth interface, as

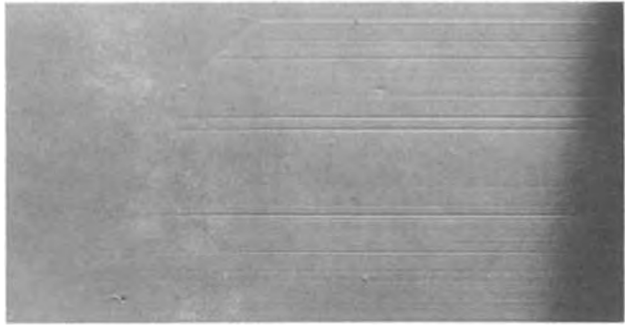

Fig. 17. Peripheral facet growth with segregation discontinuities in crystal grown during Skylab-IV mission. Magnification 300×.

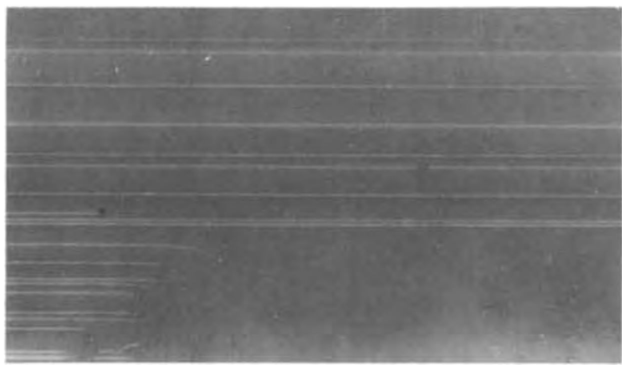

Fig. 18. Cross section of crystal grown during Skylab-III mission exhibiting rotational twinning (see also Fig. 5). Magnification 12×.

discussed previously. Rotational twin formation initiated by a nucleus having a 60° misorientation within the growth plane can thus be explained as the result of misoriented nucleation at the crystal periphery.

Because of inherent thermal asymmetry in the multipurpose furnace, the concave growth interface morphology is to some extent inclined to the growth direction. Therefore, any misoriented nucleus formed at the lowest part of the three-phase contact line (periphery of the growth interface) encounters no constraints in propagating and results in the formation of a twin boundary which crosses the entire crystal. Nucleation at any higher part of the periphery, however, can propagate only through part of the crystal, since a varying fraction of the plane of propagation has solidified already in the original orientation. Considering that a twin boundary cannot terminate within the crystal, its direction of propagation must change to form a curved grain boundary which may either terminate at a subsequently nucleated twin boundary or lead to a polycrystalline matrix (see Fig. 18). It is of interest to note that the tendency of twin formation is strikingly reduced (only one rotational twin was observed) in the crystal grown with reduced diameter during the Skylab-IV experiment.

Summary

The present InSb experiment proves unambiguously the uniqueness of zero-gravity conditions for obtaining fundamental data on crystal growth and segregation associated with solidification. Furthermore it demonstrates striking advantages of processing materials in space.

Specifically the following results and conclusions were obtained for the first time:

Ideal steady-state growth and segregation (exclusively diffusion controlled) were achieved leading to three-dimensional chemical homogeneity on a microscale over macroscale dimensions (several centimeters in the present case); the transient segregation profile was determined; limitations in the experimental arrangement and in the presently available microanalytical techniques do not permit, at this time, the extraction of fundamental data pertinent to solidification.

Surface tension effects led to phenomena previously never observed and theoretically not predicted: the Te-doped melt, not wetting the quartz wall, solidified with a free surface (unconfined) configuration. Under forced contact conditions, the growth system remained essentially isolated from its container through the formation of narrow surface ridges. It was also shown that surface tension effects in space remained localized on the surface and did not affect growth and segregation in the bulk.

In the absence of convective interference it was possible to identify segregation discontinuities associated with facet growth and to explain their origin on the basis of spurious nucleation. The absence of convective interference permitted, further, the determination of the mode of nucleation (formation of misoriented nuclei at the three-phase boundary line) and propagation of rotational twinning.

A mechanical-shock perturbation intentionally introduced during growth was identified in the crystal and found to cause a localized increase in dopant segregation; this dopant discontinuity was used as a time reference for the determination of the average macroscopic growth rate.

On the basis of the present results it is apparent that fundamental data necessary for bridging the gap between theory and experiment can be reliably obtained in the absence of gravity and that outer space presents a unique opportunity to science and technology.

Acknowledgments

The authors wish to express their appreciation to the National Aeronautics and Space Administration, and particularly to the Staff at the Marshall Space Flight Center for their uncompromising efforts, cooperation, and enthusiastic support during all stages of the experiment. They are indebted to Dr. K. M. Kim for carrying out much of the ground-based testing, to Drs. J. R. Carruthers and J. Colbey for stimulating discussions, and to Mr. W. J. Fitzgerald and J. Baker for their skillful assistance with the characterization program. Finally, the authors are grateful to Dr. R. K. Lewis and the CAMECA Instruments, Incorporated. for their generosity in carrying out Ion-Microprobe Analyses of the crystal.

Properties of SiO_2 Grown in the Presence of HCl or Cl_2

ABSTRACT

Effects associated with the incorporation of chlorine during the thermal growth of SiO_2 (500-1400Å) on <100> Si are investigated as a function of additive species (HCl, Cl_2), additive concentration, and oxidation temperature (900°-1150°C). Chlorine profiles are measured mainly by nuclear backscattering spectroscopy, and oxide thicknesses and refractive index changes by ellipsometry. The highest chlorine concentrations in unannealed oxides always occur at the Si-SiO_2 interface. Under otherwise similar conditions, the use of Cl_2 results in higher, more evenly distributed chlorine levels (up to 1.2×10^{21} at cm^{-3}). The incorporated chlorine is gradually removed by annealing at temperatures in excess of 1100°C, as well as under conditions where further oxide growth takes place without the presence of HCl or Cl_2. Additional oxide formation in steam effectively removes all the incorporated chlorine. MOS capacitors made from oxides grown in HCl or Cl_2 show fixed charge levels lower than 10^{11} cm^{-2} and mobile charge levels less than 10^{10} cm^{-2}. When biased at high fields (>6 MV/cm) significant shifts in the flatband potential of Si were observed. Chlorine-grown oxides exhibit positive and negative shifts attributed to a mobile species; the smaller negative shifts in HCl oxides are attributed to interface states. Other electrical data of intentionally Na-contaminated HCl oxides suggest that only a constant fraction of the Na is trapped.

Recent reports on the beneficial electrical effects (1-8) of small additions of chlorine-containing species to the oxidative atmosphere during the thermal oxidation of silicon wafers have in turn led to studies in which the effects of the additive on the oxide growth were examined (9-12). It was thus found (11) that changes occur in the SiO_2 growth rate which are quite complex and depend not only on the additive species used (HCl, Cl_2) but also on the oxidation temperature. Of major concern with respect to the long-term dielectric stability is whether chlorine or its compounds are actually incorporated into the growing oxide layer; some analytical results published on this subject (9, 10, 13) point to the presence of substantial amounts of chlorine, and also indicate a surprisingly high mobility of these chlorine atoms in the dielectric matrix under the conditions present during Auger electron analysis (9). The purpose of this article is to present results of a more detailed and quantitative analysis of the incorporation of chlorine into SiO_2 during thermal oxidation of silicon, as well as on some electrical properties of such oxides.

Experimental

For our studies chem-mechanically polished silicon wafers ([100]-oriented, 1¼ in. diameter, p- and n-type, 2 ohm-cm) were used. They were cleaned by a standard process (14); usually subjected to a clean-up oxidation to remove surface damage in oxygen at 1050°-1100°C to form ~ 2000Å of SiO_2; recleaned; blown dry in filtered, purified nitrogen; and placed in a double-walled quartz oxidation tube through which the oxidizing mixture was passed.

Thin SiO_2 films (500-1400Å) were grown on these wafers at temperatures ranging from 900° to 1150°C, in dry-oxygen containing up to 9 volume per cent (v/o) HCl (HCl oxides) or 3 v/o Cl_2 gas (Cl_2 oxides). The HCl and Cl_2 were 99.99+% pure. In most cases an effort was made to obtain films of approximately 1000Å: this was an almost optimum thickness for analysis by nuclear backscattering spectrometry. In some cases, the O_2-HCl, or O_2-Cl_2 gas mixture was used only during an initial or a final stage of the oxidation process before or after a regular oxide was grown in pure O_2 in another furnace. Relatively little attention was given to the use of H_2O as the oxidant as it has been reported (1, 13) that oxides grown in H_2O-HCl or H_2O-Cl_2 do not show any improvement over regular steam-grown oxides. However, some experiments were performed in which HCl or Cl_2 oxides were further oxidized in steam before being analyzed for the presence of Cl in the film. It has been found (11) that the oxidation process in quartz furnace tubes can be influenced by lingering traces of HCl and especially of Cl_2 long after additions to the oxidant have been halted. When using a particular furnace tube, it was therefore always subjected to an overnight bake in nitrogen at high temperature (1100°-1150°C) to ensure the removal of traces of earlier additives.

The effectiveness of the HCl additions in removing impurities was also demonstrated in the following way: the inside of a high purity quartz furnace tube, that had been used for six months, was rinsed with acid to remove deposits at several locations and the resultant solutions were analyzed by emission spectroscopy. Significantly higher amounts of impurities were detected downstream, close to the mouth of the furnace tube. A typical result is listed in Table I. This shows the effectiveness of the removal from the hot zone of metals as halides, that condense at the cooler end of the tube. However, it also illustrates the contamination risk present in the area through which wafers normally are loaded and unloaded.

Oxide thicknesses were measured ellipsometrically following earlier reported procedures (14). It has been

demonstrated (15) that the SiO_2 thickness can also be obtained directly from the nuclear backscattering spectrum by integration of the oxygen or silicon signal. Because of the fact that rather thin SiO_2 films were used in the present investigation, and in view of possible distortion of the oxygen signal at 2.6 MeV, the ellipsometric determination was thought to be more reliable. It was found that the oxides formed were generally quite homogeneous in thickness across a wafer (to within 1-2%); nonuniformities were encountered only in Cl_2 oxides grown at temperatures in excess of 1000°C. From the ellipsometric measurements on oxides with thicknesses ranging from 1000-1400Å, we could also determine with a high degree of accuracy the influence of the halide additive on the oxide refractive index. The results indicate systematic variations, not only as a function of additive concentration but also as a function of the oxidation temperature (Table II). The latter variations may be due to a difference in stress built-in during cooling; the shifts from a standard value with halide concentration are thought to be real, and not caused by an increase in surface roughness or by a slight optical absorption in the dielectric film. They probably are caused by a slight change in the density of the SiO_2 film, as a function of the growth conditions. Shifts measured in the Cl_2 oxides were more ambiguous since corrosion of the silicon surface did sometimes occur visibly at oxide thicknesses around 1000Å.

Auger analyses (9) showed instabilities in the profile of the incorporated chlorine and eventual desorption into the vacuum of the AES system. Further data were obtained using x-ray fluorescence spectroscopy (XFS), electron microprobe analysis (EMA), and nuclear backscattering spectroscopy (NBS). In all cases, particular care was taken to check for transient effects such as were found in the Auger experiments. However, no indication of the occurrence of such instabilities was found. Sometimes, wafers oxidized at the same time were evaluated by several analytical and electrical techniques. However, NBS was most extensively used, because of its rather unique ability to determine both quantitatively and nondestructively an impurity profile as a function of depth into the oxide. Hence, a somewhat detailed description of its application to the present case is given in the next section. Results of the various analyses are given in the later sections of this article.

Nuclear backscattering spectroscopy.—Several review articles on the use of this technique have recently been published (16, 17). The essential features pertaining to the analysis of thin oxides are shown in Fig. 1. The insert displays schematically the elastic collision between a ^4He ion projectile and a target nucleus, which results in the backscattering of the ^4He toward a semiconductor detector that gives a signal proportional to the energy of the impinging ion. The Cl impurity atoms are heavier than the SiO_2 matrix atoms, so they absorb less energy. Thus the ^4He ions backscattered from Cl atoms are more energetic than those scattered by Si or O atoms. These

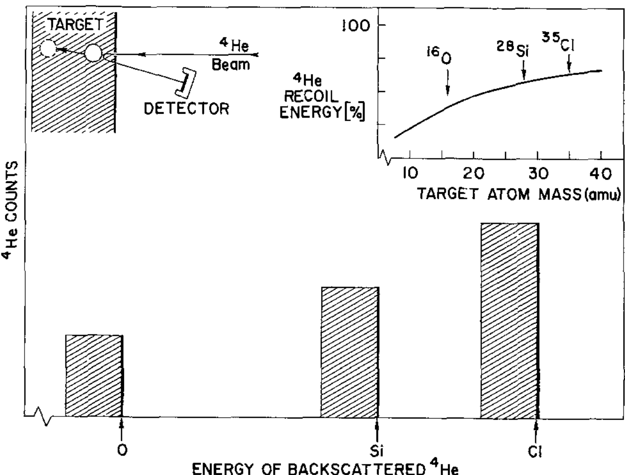

Fig. 1. Relative energy of backscattered ^4He atoms as a function of the target nuclei.

major energy changes allow a differentiation between Cl, O, and Si in the target. Smaller changes in ^4He energy are used to obtain impurity depth profiles. At 2.6 MeV, the ^4He ion moves much faster than the target electrons, making the target matrix appear as an electron sea. When traversing this matrix, the ^4He projectile loses a small, but detectable amount of energy which can be converted to sampling depth by using tables of specific energy loss of ^4He ions in matter (18).

Since the target is a compound, Bragg's rule (19) must be used in the energy loss determination. The applicability of Bragg's rule to SiO_2 has recently been verified experimentally to within a few per cent (20). However, it was found during the present investigation, that reliable depth values of the Cl impurity could be confirmed by using the technique of Chu *et al.* (21). As shown in Fig. 2, the depth δx_{Cl} is calculated from

$$\delta x_{Cl} = d_{SiO_2}(\delta E_{Cl}/\Delta E_{Cl}) \quad [1]$$

where d_{SiO_2} is the ellipsometrically determined film thickness, δE_{Cl} is the energy difference between the Cl signal from the surface (cf. Fig. 2) and that from a depth x in the film, and ΔE_{Cl} is the energy difference between the Cl signals from the surface and from the bottom of the SiO_2 film. Values of ΔE_{Cl} can be calculated from the value of ΔE_{Si} measured in the same spectra

$$\Delta E_{Cl} = \Delta E_{Si}([S]_{Cl}/[S]_{Si}) \quad [2]$$

where the [S] factors (22) may be easily calculated from tables (18). For backscattering from Si or Cl target atoms in an SiO_2 matrix the ratio of the [S] factors is near unity ($[S]_{Cl}/[S]_{Si}$ = 1.01) and rela-

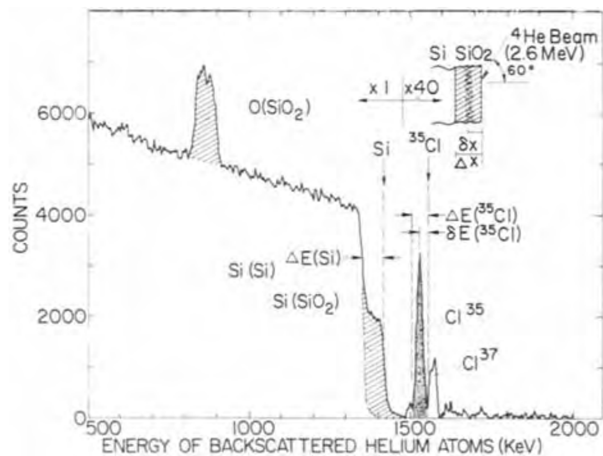

Fig. 2. Spectral distribution of ^4He atoms backscattered from a thin SiO_2 film (Cl doped) on a Si substrate.

tively insensitive to errors in the absolute energy loss values.

Experimentally, a ^4He incident energy of 2.6 MeV kept the Cl and Si signals well separated provided that the SiO_2 thickness did not greatly exceed 1000Å. This thickness still permitted an oblique angle of incidence ($\phi = 60°$) of the beam onto the target, which doubled the apparent thickness and thus increased the accuracy of the Cl profile. It was noted in an earlier study (10) that the analysis of ^4He backscattering profiles of Cl in SiO_2 is complicated by the isotope ratio in natural Cl (^{35}Cl:^{37}Cl = 76:24). At the high values of the incident energy used in the present investigation, the two Cl isotopes can be separated into individual profiles. To obtain the impurity distribution use was made mainly of the ^{35}Cl profile, corrected for isotopic abundance. With the 17 keV detector resolution of the instrument used, it is estimated that the final depth resolution of the spectra was approximately 200Å.

Results and Discussion

HCl oxides.—Analysis by NBS of HCl oxides always results in similarly shaped chlorine concentration profiles, regardless of the SiO_2 thickness, the growth temperature, or the ambient HCl concentration during oxidation. A typical example of a measured profile and the evaluation in terms of constituent signals is shown in Fig. 3. The chlorine concentration is lower than the limit of detection (approximately 3×10^{19} at. cm^{-3}) in the top of the layer and then increases toward a maximum near the Si-SiO_2 interface. It seems evident that chlorine is incorporated directly at the Si-SiO_2 interface during oxidation. During further oxide growth, as the distance between the previously trapped chlorine and this interface increases, the chlorine is slowly released and perhaps replaced by oxygen atoms. As discussed before, an upper thickness limit of approximately 1100-1200Å exists above which SiO_2 films can no longer be analyzed for chlorine with NBS. Our data therefore do not permit quantitative conclusions on the Cl-incorporation over a wide range of oxide thicknesses. However, it was found elsewhere, using XFS, that the total amount of chlorine incorporated in HCl-oxides grown at 1000°C is roughly proportional to the film thickness (165-4240Å) (23). From the observed shape of the Cl concentration profile, we conclude that this correspondence cannot simply be explained on the basis of a larger number of sites available to chlorine atoms. It also has to reflect a higher level of incorporation at the Si-SiO_2 interface and perhaps a slower rate of removal of the incorporated species as the oxide thickness increases. Such an increasing chlorine concentration is consistent with the silicon surface corrosion that is observed only underneath much thicker oxides (11-13). The parallel reactions of the O_2 and the HCl with the silicon apparently compete kinetically, and as the oxygen flux decreases with increasing SiO_2 thickness more chlorine is incorporated. The subsequent removal of chlorine is caused by the greater thermodynamic stability between the Si-O and Si-Cl bonds. Finally, the concept of a relatively high mobility of the chlorine carrying species during growth of HCl oxides is in agreement with the results of other experiments described later in this paper.

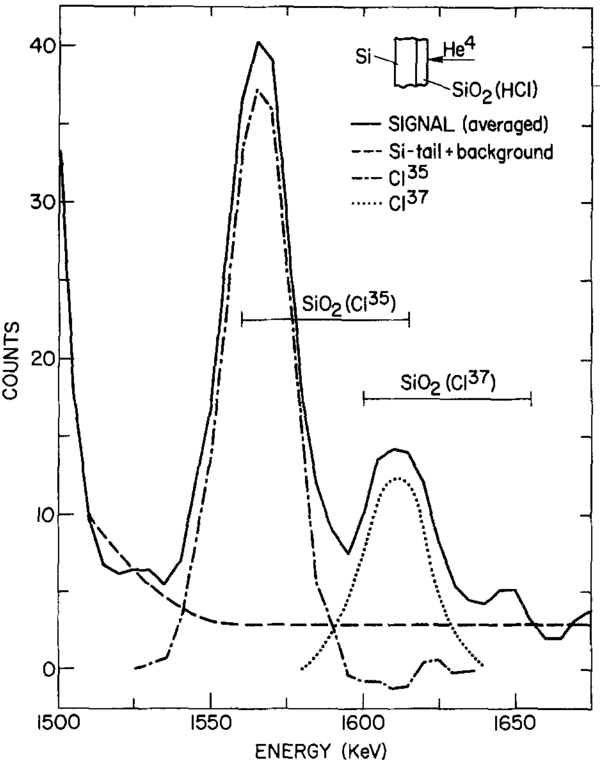

Fig. 3. Chlorine distribution as a function of depth in an HCl oxide (1150°C, 9 v/o HCl, 780Å). The measured signal has been separated into background and chlorine isotope profiles. The calculated energy range for both chlorine isotopes in the oxide film is indicated. Note: In all figures, the energy of the ^4He atoms backscattered from a given isotope decreases as the distance to the SiO_2-vacuum interface increases.

Regardless of the angle of incidence (ϕ) of the exciting beam upon the target sample, the backscattered helium atoms were analyzed and counted in energy increments of 5 keV. For different angles of incidence these sampling intervals therefore correspond to different thicknesses. Analysis of a number of HCl oxides at $\phi = 0°$ and 60° showed the maximum concentration to be higher by a factor 1.5-1.7 for the smaller sampling increments ($\phi = 60°$). This illustrates the steepness of the maximum in the chlorine concentration as a function of position in the oxide layer. Peak chlorine concentrations ($\phi = 60°$) and average concentrations are listed in Table III as a function of oxidation temperature and ambient HCl concentration.

Cl_2 oxides.—NBS profiles of Cl_2 oxides show the chlorine distribution to be less prominently peaked than was the case for the HCl oxides. In fact, a number of analyses indicate a distribution that is homogeneous within the margin of error (Fig. 4). This is the main qualitative distinction between Cl_2 and HCl oxides, but it leads once again to the conclusion that incorporation takes place upon formation of the oxide. Analysis results for peak and average chlorine concentrations are listed in Table IV. A comparison with Table III shows that the incorporation of chlorine in Cl_2 oxides takes place at a much higher level, especially if the additive concentrations are considered. The more homogeneous distribution in this group of oxides can also be gauged from these tables.

The wider, more even chlorine distribution in Cl_2 oxides (as compared with HCl oxides) indicates a slower rate of removal of incorporated chlorine during further growth. As is seen below, annealing in N_2 leads to similar behavior for both types of oxide, and additional growth in steam reduces the original oxide chlorine level effectively to zero in all cases. Thus, the higher rate of removal in the HCl oxides may well reflect the presence of appreciable amounts of H_2O in

the oxidizing ambient, even though the oxide growth rate itself does not seem to be affected (11).

Annealing experiments.—It has been reported (24) that annealing of HCl oxides in an inert ambient at temperatures in excess of 1100°C results in a loss of Na neutralization in such films. To correlate such effects with the actual degree of chlorine incorporation, NBS profiles were obtained for Cl_2 and HCl oxides of comparable thickness (~1000Å) before and after various annealing treatments in vacuum and in N_2. It was found that vacuum annealing for 60 min at 100°C did not result in a measurable decrease in oxide chlorine concentrations, and such treatments were not pursued any further. High temperature annealing results are shown in Fig. 5 (HCl oxides) and 6 (Cl_2 oxides). In both cases little if any significant decrease in the chlorine profile is seen to occur after annealing for 60 min at 1100°C. Annealing at 1200°C, however, results in the loss of approximately 50% of the built-in chloride, while at the same time the original profile is considerably changed in shape. Even if allowance is made for some uncertainty in the as-measured profiles, it appears that the chlorine originally incorporated closest to the $Si\text{-}SiO_2$ interface is removed most efficiently in the HCl oxides. Kriegler has argued that proximity of built-in chlorine to that interface is a precondition for Na neutralization, and it is therefore not surprising that such annealing at 1200°C causes a complete loss of passivating properties of the oxide.

Sequential growth studies.—In an effort to better understand chlorine motion through the SiO_2 films, a number of oxides were grown in two steps, *i.e.*, the oxidative ambient and (sometimes) temperature were changed by transferring the sample to a different furnace after an initial oxidation. The conditions are listed in detail in Table V. It must be recalled that oxide growth occurs at the $Si\text{-}SiO_2$ interface so that the outer oxide is formed in the first step.

Samples 1-4 were prepared to explore possible differences in chlorine incorporation when HCl or Cl_2 are added during only part of the oxide growth process. When the initial oxide is grown in 100% O_2 (sam-

Table V. Overview of sequentially grown oxides

Sample No.	Step 1 T_1 (°C)	Step 1 Ambient (v/o)	d_1 (Å)	Step 2 T_2 (°C)	Step 2 Ambient (v/o)	d_2 (Å)	d_{tot} (Å)
1	1150	100 O_2	900	1150	91 O_2 + 9HCl	108	1008

ples 1 and 2), the chlorine was found to be incorporated in the general area of the oxide layer grown during the second step. Little qualitative difference is therefore observed between the chlorine profile in sample 1 and that in the regular HCl oxides discussed earlier. On the other hand, the distinction is obvious for the films grown with Cl_2 added to the ambient: the chlorine in sample 2 is located only in the part of the oxide that is closest to the Si-SiO_2 interface, whereas in regular Cl_2 oxides the incorporation takes place over a much wider range. Experimental broadening of the profiles makes it difficult to judge whether incorporation in samples 1 and 2 has occurred solely within the second layer. Assuming, however, that this is indeed the case, it is calculated that for the HCl oxide $(Cl)_{avg} = 5.6 \times 10^{20}$ at. cm^{-3} and for the Cl_2 oxide $(Cl)_{avg} = 6.1 \times 10^{20}$ at. cm^{-3}. These concentrations do compare closely to the values of $[Cl]_{max}$ measured on one-step oxides grown under the same conditions (Tables II and III). Measurements on samples 3 and 4 which had their final oxidation take place in 100% O_2 showed that the chlorine incorporated during the first oxidation step followed the SiO_2-Si interface during the second step and afterward was located mainly in the layer grown in this last step. Considerable loss of chlorine to the atmosphere did apparently occur (60-70%), since the concentrations calculated on basis of the amount detected and the width of the first layer were quite low.

Samples 5 and 6 were grown to greater thickness in steam after the initial growth in O_2 + HCl or O_2 + Cl_2. This caused the chlorine to be removed almost completely (>90%). This process apparently proceeds quite rapidly as the time necessary to grow the additional (steam) oxide was relatively short: 2½ min for sample 5, 4 min for sample 6.

Electrical analysis.—To gain insight into the electrical effects associated with chlorine incorporation in SiO_2, two types of experiments were performed. In the first group, otherwise uncontaminated oxide samples were grown in O_2 + HCl or O_2 + Cl_2, metallized, and tested by MOS capacitance-voltage techniques. In the second series of experiments such oxides were intentionally contaminated with Na in an effort to relate the halogen incorporation quantitatively to sodium neutralization efforts reported earlier (3, 4, 13, 24, 25).

The electrical stability of the silicon surface potential under bias was measured to determine the effects of the incorporated chlorine. Capacitance-voltage plots are an excellent measure of the concentration of charged species and their spatial distribution in silicon dioxide (26). As such they are very sensitive to charge motion. In order to make these measurements, an array of aluminum capacitor dots was evaporated onto the silicon dioxide. Oxides grown in either HCl or Cl_2 show exceptionally low oxide charge ($<10^{11}$ charges/cm^2). As previously reported (5, 13), these oxidation additions have proven effective in reducing the charge levels obtained with oxidation in pure O_2.

Under bias at room temperature, however, the Cl_2 oxides were electrically unstable. Both positive and negative flatband voltage shifts were seen and they were of opposite sign as the applied electrode voltage. These shifts were indicative of considerable mobile charge ($\sim 10^{12}$ charges/cm^2) and they were much larger than the mobile charge levels ($<10^{10}/cm^2$) normally found. The fact that positive as well as negative voltage shifts were seen demonstrated: (*i*) that the charges must have originated from the bulk of the oxide film rather than at an interface, and (*ii*) that both negative and positive charges were involved. Apparently neutral centers were initially present within the oxide and were ionized by the applied voltage. Charge of one sign moved in the field in order to give the dipole charge that resulted in a flatband voltage shift. Unfortunately it was not possible with these measurements to determine the sign of the mobile species. It was noted that the level of mobile charges (as calculated from the ratio of the flatband voltage shift to the oxide thickness) seen here was $\sim 10^{12}$ cm^{-2} and thus considerably less than the amount of incorporated Cl ($\sim 10^{16}/cm^2$). Either only a small fraction of the Cl becomes charged under bias or the separation of positive and negative charges is extremely small. For instance, 10^{16} charges/cm^2 with positive and negative centers 0.1Å apart would give the same flatband voltage shift as 10^{12} charges/cm^2 that were 1000Å apart. If the charge separation were actually less than an angstrom one might expect a very significant relaxation when the applied field is removed. Some relaxation is indeed seen but many hours are required for the flatband voltage shift to decay even 10-20%. Furthermore with the Cl uniformly incorporated, the separation between positive and negative centers would be small regardless of the separation of the charge centroids, and some relaxation might be expected in any case.

As a test of field-induced chlorine motion, metal (Pt)-oxide (Cl_2 oxide)-silicon capacitor structures were biased while *in-situ* backscattering profiles were measured. No Cl shift was detected with fields of ±6 MV/cm even though electronic currents and flatband voltage shifts were substantial.

The transient flatband voltage was monitored to help determine the kinetics of charge ionization and motion in Cl_2 grown oxides. A typical flatband shift *vs.* $(time)^{1/2}$ is given in Fig. 7 for several applied bias voltages. The Al(−) bias polarity was chosen for most measurements to keep any positively charged contaminants like Na^+ at the metal-SiO_2 interface where they do not contribute to the flatband voltage. With this bias, a positive flatband shift corresponds to the negative charge center being closer to the silicon than the positive center. A negative flatband voltage shift cannot be explained by charge motion under the influence of the applied field and is commonly referred to as a negative bias instability; models have been proposed (27-30) to account for this behavior, but very little is known about it. The abscissa is $(time)^{1/2}$ since both diffusion-limited (26) and emission-limited processes (30-32) should give linear plots with this scale. Clearly the observed behavior is very complex; nevertheless it is qualitatively reproducible in Cl_2 grown oxides. The magnitudes of the shifts are merely larger when more Cl_2 is incorporated during oxidation. At a moderately high applied voltage (60V in Fig. 7) we observe a negative shift, primarily occurring at short time. At very high voltages the flatband voltage initially increases with time. When an intermediate voltage is used the flatband first goes negative and then positive like the lower curve in Fig. 8. Instead of continuing to increase indefinitely or saturate at higher voltages, ΔV_{FB} decreases at long times. The onset and the rate of this decrease is accelerated by higher applied voltage. This final mode is characterized by distorted

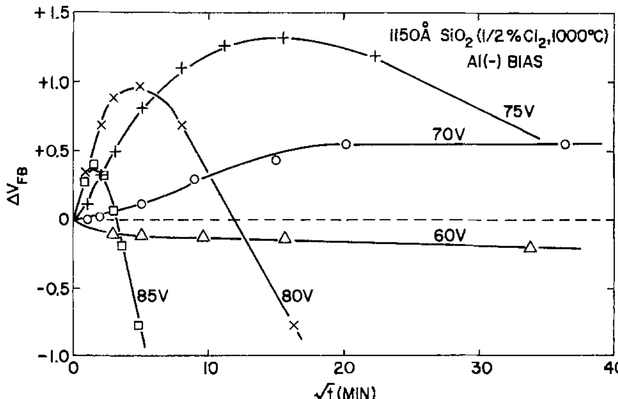

Fig. 7. Time dependence of the flatband voltage shift for an 1150Å SiO_2 film (1000°C, 0.5% Cl_2). The aluminum electrode was biased negatively.

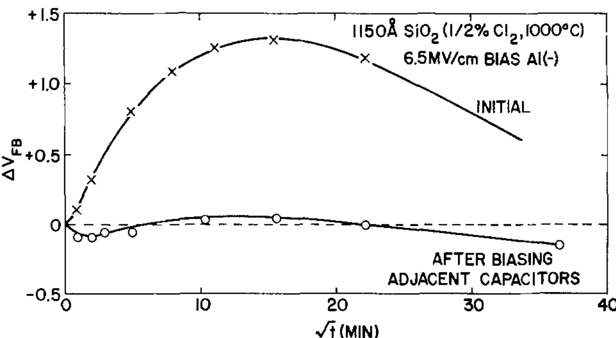

Fig. 8. Change in flatband voltage transient as a result of stressing capacitors adjacent to the capacitor of interest.

rather than parallel shifts in the capacitance-voltage curves. This distortion is characteristic of interface state generation. Thus the flatband voltage of Cl oxides has three components: an initial negative or delayed positive shift, a positive shift, and a negative voltage shift with time. The first component is most pronounced at moderately high fields (6 MV/cm) and the last at very high fields (8 MV/cm). The mechanism of the first component is unknown; mobile charge motion can explain the second; and interface state generation dominates the third.

In addition to having very complex kinetics, the flatband voltage of Cl_2 oxides exhibits a proximity effect. Measurements were made of individual capacitors (32 mils diameter) in a larger array (intercapacitor spacing was 80 mils). Flatband voltage shifts were reproducible provided that a capacitor on a virgin wafer was tested even after several months of room temperature storage. When several capacitors on a wafer were biased, however, the flatband shifts were greatly reduced in magnitude (see Fig. 8). Note that all three components of the flatband instability are still present after adjacent capacitors had been biased. This effect was first observed with Na neutralization measurements on HCl oxides. Metal-oxide-semiconductor capacitors on freshly prepared wafers were able to neutralize large amounts of sodium ($\sim 10^{13}/cm^3$); however, very little was neutralized ($\sim 10^{12}/cm^2$) on wafers where adjacent capacitors were biased. Again storage could not explain the effect; it was a direct result of the bias.

On the other hand, the flatband voltage shifts seen with HCl grown oxides were all negative (see Fig. 9). The shifts could be extremely large but did not become appreciable unless a very high electric field was applied (over 6 MV/cm for the extreme case of a film grown in 9% HCl at 1150°C). More thorough examination of the C-V curves showed considerable distortion; the method of Gray and Brown (33) was used to confirm the generation of interface states during this high field biasing. At the low fields typically encountered

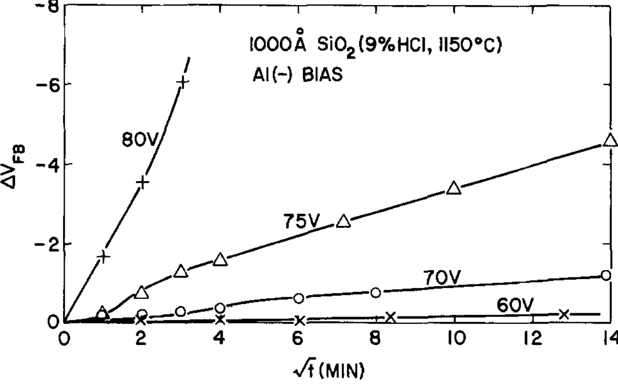

Fig. 9. Time dependence of the flatband voltage shift for a 1000Å SiO_2 film (1150°C, 9% HCl). The aluminum electrode was biased negatively.

with FET gate dielectrics ($\sim$2 MV/cm), HCl oxides were no less stable than conventionally grown oxides.

Sodium neutralization in halogen grown oxides was studied for the purpose of establishing a possible correlation with the amount of incorporated chlorine. Several important and previously unreported observations were made. First, different methods to measure the amount of neutralized sodium gave different results. For example, flatband voltage shifts after a bias-temperature stress gave different values for the amount of neutralized Na than did reversible charge time (Q-t) measurements of the mobile charge after initially neutralizing some of the charge. Second, using (Q-t) measurements, the amount of neutralized and immobile sodium appeared to be a fixed fraction of the total amount present. In 9% HCl oxides grown at 1150°C only about 1/3 of the total sodium was immobile from 10^{12}-10^{14} $Na^+ \cdot cm^{-2}$. Even though sodium might be neutralized (as measured by C-V) it is not necessarily immobile (since Q-t reveals the presence of mobile charged species) and still presents a potential stability problem. Limited data suggest that the effect of oxidation temperature and halogen concentration is merely to change the ratio of immobile to total sodium. This finding is in sharp contrast with the hypothesis that the halogen oxides contain a certain number of trapping sides and all sodium is neutralized until the Na concentration exceeds the trap concentration. The qualitative results of Kriegler showing the degree of neutralization to increase with halogen concentration and oxidation temperature were verified; the immobile Na concentration (Q-t measurements) does indeed increase with the peak Cl concentration. However, this increase appears to be sublinear and the amount of neutralized Na is never more than a small fraction of the amount of chlorine incorporated ($<1\%$). Based on these and earlier data it is apparent that the sodium neutralization is a complex phenomenon and requires more information before a meaningful model can be postulated.

Summary

A study was made of the chemical and electrical properties of thin SiO_2 films (500-1400Å) grown at temperatures ranging from 900°-1150°C under addition of small amounts of HCl (0-9 v/o) or Cl_2 (0-2 v/o) to the oxygen ambient. Chlorine is known to be incorporated into such oxides and it was found that the oxide refractive index depends on the growth conditions.

Nondestructive measurement of the chlorine concentration profile took place by nuclear backscattering spectroscopy using He^4 ions as the bombarding species. Under otherwise similar growth conditions (time, temperature, additive concentration), more than ten times as much chlorine was incorporated into Cl_2 oxides than into HCl oxides. For both additives incorporation increased with oxidation temperature and percentage added. No chlorine incorporation could be measured in the silicon substrate ($[Cl] < 3 \times 10^{19}$ cm^{-3}). The highest average oxide concentration was 5 atomic per cent in a sample grown in 2% Cl_2 at 1150°C. In HCl oxides the maximum concentration is found at the Si-SiO_2 interface; as the distance from this interface increases, a rapid decrease in the concentration occurs and the oxide near the surface contains little if any chlorine. In Cl_2 oxides, on the other hand, the peak at the Si-SiO_2 interface is much broader and it appears as if a fairly even distribution exists throughout most of the film. Accordingly, peak and average concentrations are quite similar for Cl_2 oxides, but not for HCl oxides.

Annealing in N_2 shows that the incorporated chlorine is slowly removed at temperatures between 1100° and 1200°C. Experiments in which HCl or Cl_2 was present only during part of the oxidation process show the chlorine to disappear from the oxide very rapidly by subsequent oxidation in steam.

Electrical measurements were made on MOS capacitors using HCl or Cl_2 oxides. At low applied fields, such oxides had lower charge levels than control oxides; at high fields (> 6 MV/cm) different types of electrical instability were observed. One type was ascribed to a mobile species in Cl_2 oxides. Interface state generation also contributed to the instability at very high fields (> 8 MV/cm). Sodium neutralization was monitored in Na-contaminated HCl oxides by measuring the amount of mobile charge; the results indicated that only a fixed fraction of the sodium is trapped regardless of the initial concentration.

Bipolar Charging of Low Density Polyethylene under Corona Discharges

I. B. Jordan

Université Laval, Québec, Canada G1K 7P4

ABSTRACT

Low density polyethylene films 25-100 μm thick were corona-charged between parallel-plane electrodes under d-c fields ranging from 0.4 to 2 MV/cm. These films were studied for their electret properties in air at atmospheric pressure and room temperature by measuring the external residual field 1 min after charging. Observations show that there is a limit to the dipole effect in polyethylene depending upon the charging voltage and upon the delay of measurement after charging. This limit is determined by an increase of the rate of injected charge decay with the initial charge density.

Charge trapping in polymers can be achieved by a variety of methods; among them are thermal procedures (1), simultaneous application of heat and an electric field, application of a breakdown field (2), electron bombardment, and corona discharge (3). Application of corona discharge under high electric stress is of more practical interest in the case of low density polyethylene because of the use of this material as a high voltage insulation and its deterioration under corona discharges. Low density polyethylene offers no advantage from the point of view of electret production because of its relatively low stability (4).

Key words: electret, polyethylene, charge, corona, air.

Experiments

The observations reported here were made on thin films (25, 50, and 100 μm thick) of commercial low density polyethylene having a density of 0.92 g/cm^3 and a melting point of about 115°C. An infrared transparency spectrum of the material is shown in Fig. 1. Samples 5 × 5 cm were placed between circular electrodes 3.7 cm in diameter (Fig. 2). An insulating ring spacer was inserted between the upper electrode and the film for most of the measurements. Several films could be charged simultaneously, as shown in Fig. 3. After charging for a given period of time, the insulating spacer was removed, the upper electrode was

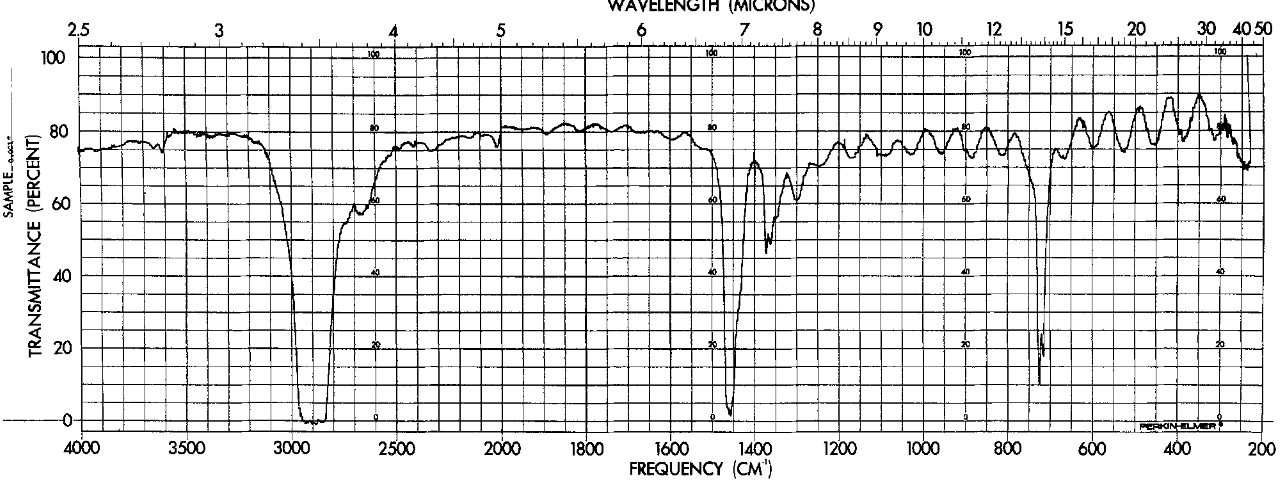

Fig. 1. Infrared spectrum of a sample of polyethylene film 25 μm

brought into contact with the film, and the electrodes were externally short-circuited for 30 sec. Then the residual field was measured at the polymer surface using an electrostatic fieldmeter (Monroe Electronics). Measurement of desorption current was made with a sensitive d-c meter (Boonton Electronics).

All investigations were carried out in air at atmospheric pressure, room temperature (22°-24°C), and a relative humidity of about 25%.

Results

Measurements were first made with an insulating ring 37 μm thick inserted between the sample and the upper electrode. The residual field measured after charging increased with duration of applied voltage, with a time constant of the order of 10 min. This constant did not change appreciably with sample thickness; therefore a charging time of 15 min was used in all further tests. The infrared spectra have shown that the decrease in transparency resulting from corona-induced oxidation did not exceed 5%.

The exposure time having been determined, the dependence of the residual field upon the charging voltage was investigated. The residual field, as measured 1 min after voltage removal, initially increased with charging voltage, reaching a maximum value (Fig. 4) which depended upon the sample thickness, and thereafter decreased. Maximum field was not influenced significantly by the insulating spacer thickness. However higher corona pulses were observed with longer gaps, leading more easily to sample breakdown under higher stresses. The residual field did not change when the sample was charged without a spacer, but the number of the sample breakdowns was as high as in the case of thicker dielectric inserts.

For obvious reasons it is very difficult to make a direct study of an air layer sandwiched between a polyethylene film and a metal electrode. Capacitance measurements can however give valuable information about the mean thickness of this layer. For this purpose silver electrodes were vacuum deposited on both sides of a 25 μm-thick sample. The capacitance between these electrodes, measured at 1 kHz, was in accordance with the sample thickness and dielectric constant, and did not change significantly when a sample was subjected temporarily to a high electric stress. The behavior of a polyethylene film sandwiched between plain brass electrodes was completely different. First, the measured capacitance was 3.5 times lower than in the previous case. This could be attributed to the presence of air layers having an average thickness of 12 μm on each side of the film. Second, the thickness of these layers decreased to 7 μm when a sample was put under 2 kV for a few seconds.

Residual field was not influenced by the electrode material as far as tests with brass, steel, and aluminum electrodes may be considered conclusive. However, it was influenced by surface smoothness; higher charge

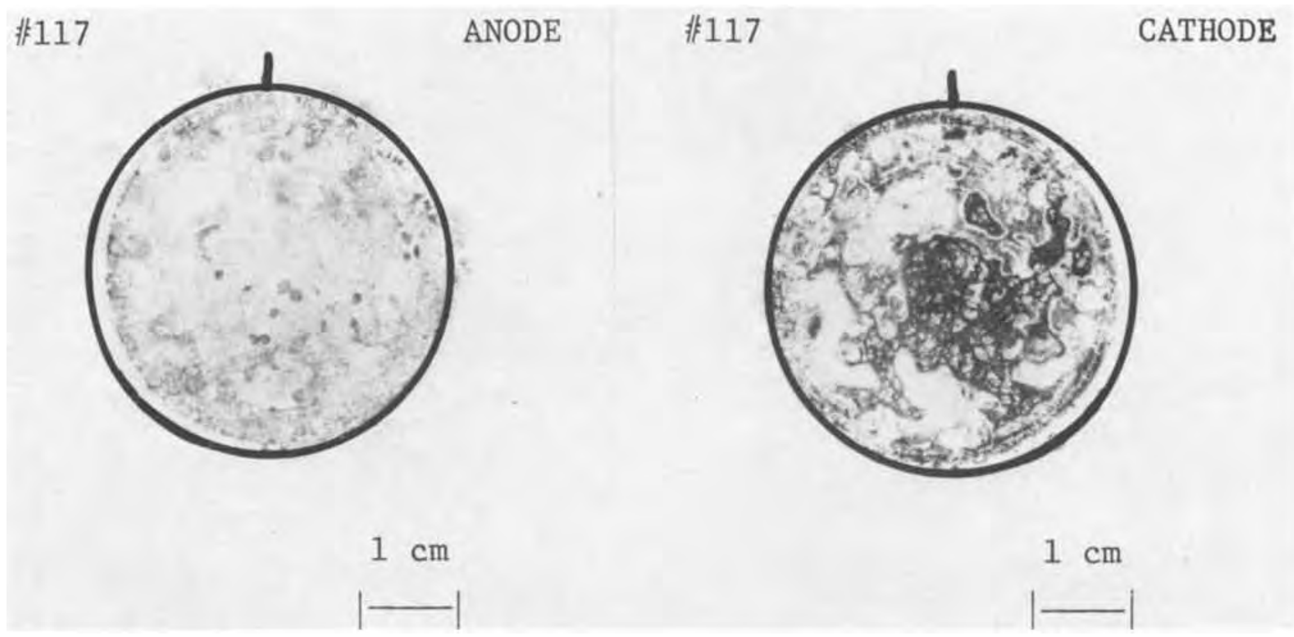

Fig. 5. Lichtenberg figures of both surfaces of a 50 μm thick sample. Formation voltage, 4 kV

densities were for the most part obtained with rough electrode surfaces.

Finally, the temperature influence was investigated. Electrodes and samples were kept under voltage for 15 min at constant elevated temperatures, ranging between 25° and 80°C, then cooled rapidly to ambient temperature before voltage removal and sample short-circuiting. This process did not yield any higher residual fields, despite the fact that the charging current increased from $5 \cdot 10^{-10}$A at 25°C to $2 \cdot 10^{-6}$ at 80°C (film 25 μm under 2 kV). However a large scatter of values was observed.

It became clear therefore that the residual field is the result of charge injected by corona discharges. The charging was not symmetrical. At lower voltages (on the rising slope of curves in Fig. 4) the positive homocharge prevailed, whereas at higher voltages (on the falling slope) the opposite was true in most of the cases.

In order to get further insight into the charging mechanism, Lichtenberg dust figures of both surfaces were made with a mixture of Neon Red and Saturn Yellow fluorescent pigments of Day-Glo Color Corporation. An orthochromatic film was used for the photographs (Fig. 5). The black surfaces (red in reality) correspond to negatively charged regions, whereas the gray half-tones correspond to positive areas (yellow on a color film). The pictures show the heterogeneity of the charging process. Both surfaces display the presence of positively and negatively charged regions. However the prevailing charge on a given side had the same polarity as the adjacent electrode during the charging process.

Two additional investigations were undertaken to explain the peculiar form of the residual field curves (Fig. 4): a study of temporal field decay, and a measurement of desorption current transients. Results of the first study are shown in Fig. 6. The charge decay depends evidently on charging voltage, and different curves may cross each other. This phenomenon was discovered by Ieda, Sawa, and Shinobara (5) in polyethylene samples with small amounts of surface active agents.

Results of the second study are given in Fig. 7. The discharging current of samples charged under voltages below 2 kV flowed in a direction opposite to the direction of the charging current, whereas a current inversion was observed in samples subjected to higher stresses. The voltage corresponding to the appearance of homocurrent depended upon the electrode surface condition. For smoothly polished electrodes the current reversal appeared only at higher voltages. With rough electrodes the homocurrent was observed even after charging at 1.5 kV.

Discussion

When a low density polyethylene film is inserted between parallel-plate electrodes, two air layers about 10 μm thick usually remain trapped between the film and metal electrodes. Thicknesses of these layers decrease under applied voltage due to attractive electrostatic forces between electrodes. These air layers are of course far from being uniform and their heterogeneity probably increases with the beginning of corona activity as could be deduced from the dust figures (Fig. 5). This activity appears at a potential difference close to Paschen's minimum, since the pd value under atmospheric pressure is close to critical. Below corona onset the desorption current transients (Fig. 7) exhibit only the presence of heterocharges. These charges are deposited on the polyethylene surface and also at the interfaces between amorphous and crystalline regions

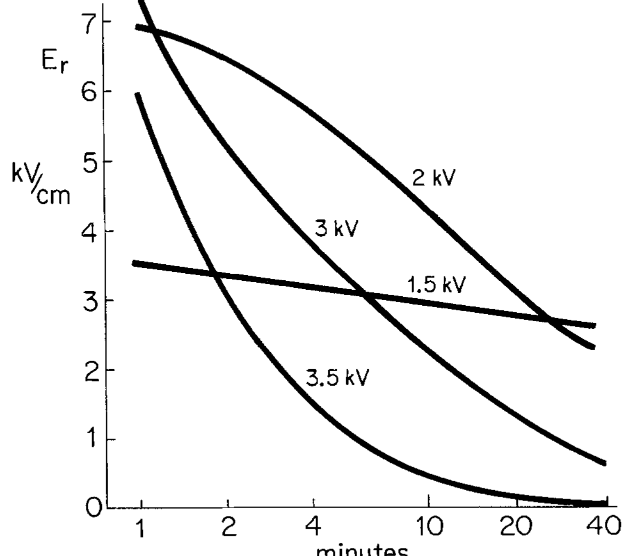

Fig. 6. Field decays at polyethylene samples 25 μm thick after charging under various voltages. Charging time of 15 min followed by 30 sec of short-circuiting.

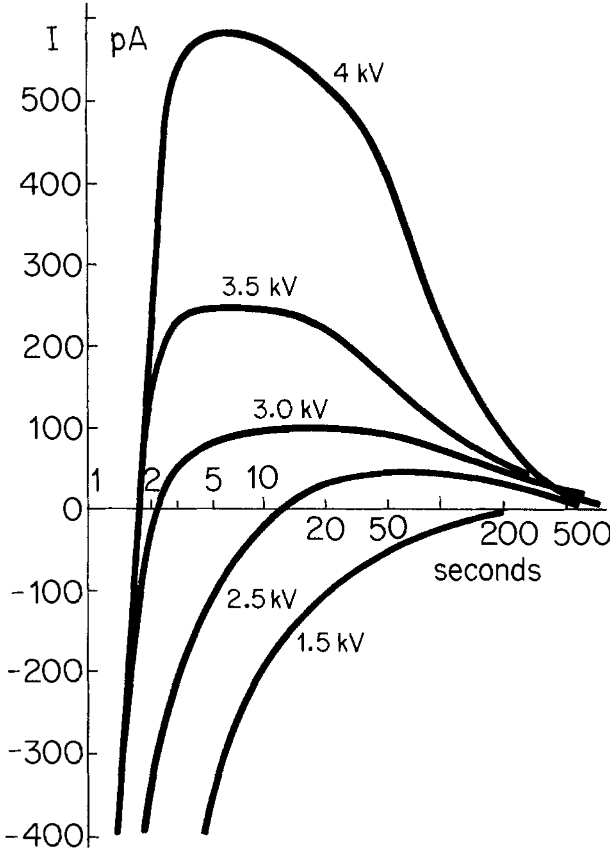

Fig. 7. Desorption current transients of polyethylene samples 25 μm thick after charging under various voltages.

of polymer (low density polyethylene under investigation was about 50% amorphous).

Charge injection from ionized air layers became important under voltages exceeding 1 kV (in our investigations the onset voltage was independent of sample thickness). This was manifested by the appearance of a residual field (Fig. 4) and by desorption current inversion (Fig. 7). Figure 7 shows that amplitude of the homocurrent increases exponentially with applied voltage. Therefore the charge densities and the residual field should also increase with the voltage. But the homocurrent in samples subjected to high stress reaches its peak in a few seconds after voltage removal and then decreases with a rate depending upon applied voltage. Figure 6 indicates that the higher the charging voltage and the initial injected charge density, the faster is the residual field decay. Therefore the residual field measured 1 min after voltage removal reaches its maximum as shown in Fig. 4 and then decreases again. There is also a second factor limiting the residual field increase in thicker samples, air ionization at the sample surface.

Conclusions

Investigation of desorption current of corona charged low density polyethylene shows two distinct charging processes: heterocharge moving towards electrodes after short-circuiting, and homocharge injected by corona discharges in air and moving through polymer after external field removal. Under low stress, only heterocharge is observed. At higher voltages the homocharge becomes dominant. Drift of this charge is strongly influenced by initial charge density; it decays more rapidly when the initial injected charge density is high. This phenomenon, and crossing of field decay curves (Fig. 6), are responsible for the peculiar form of residual field curves (Fig. 4) measured some time after charging voltage removal. Density of injected homocharge depends upon the corona activity and indirectly upon the electrode surface condition.

High Resolution Tungsten Patterning Using Buffered, Mildly Basic Etching Solutions

T. A. Shankoff and E. A. Chandross

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Prior to this work, commonly available chemical etches for tungsten were difficult to use for high resolution patterns because of their incompatibility with available positive and negative photoresists. Rapid attack by basic hydrolysis made the use of positive resists impossible and the use of negative resists difficult. It was found that solutions of $K_3Fe(CN)_6$ which were buffered in the mildly basic *p*H range of 7.5-9.5 etch tungsten as fast as the previously used highly alkaline KOH-$K_3Fe(CN)_6$ etches (*p*H 13-14) but are far better in the practical fabrication of tungsten-based integrated circuits. These etches can be used to delineate patterns of high resolution (1-2 μm range) limited only by the photolithography, with no evidence of failure of either positive or negative photoresists.

Until the present time practical chemical etches for tungsten have involved strongly alkaline solutions of an oxidizing agent, *e.g.*, H_2O_2 in aqueous NH_3 (1) or $K_3Fe(CN)_6$ in aqueous KOH (2). The use of any metal as a conductive layer in a semiconductor device is dependent on pattern definition using standard photolithographic technology. Previous etchants suffered from either low etch rates at room temperature and/or too rapid attack of the photoresist material. All commonly available positive photoresists are rapidly hydrolyzed in aqueous alkaline solution, *e.g.*, whereas AZ-1350 is actually dissolved away at *p*H 14 in less than 1 min, it loses its insulating ability at *p*H 12 in 1-2 min through loss of adhesion. Thus, for example, in recent work (3) it was found that the KOH-$K_3Fe(CN)_6$ system was unusable for defining circuits if the photoresist (both positive and negative) was exposed to the solution for as little as half a minute. Even KMER and KTFR fail during this time in the 5% KOH solution recommended (3). Since chemical etching rates were reported to be in the order of 30 Å sec^{-1}, for practical purposes this system is unattractive. Because of this, electrochemical etching techniques have been used to obtain etching rates commensurate with resist lifetime in the KOH-$K_3Fe(CN)_6$ system (3).

Our approach to this problem was to seek a means of reducing the basicity of tungsten etching solutions to a range compatible with long protective lifetimes for both negative and positive photoresists, and yet maintain chemical etching as a viable means of tungsten pattern delineation.

Experimental

Reagents, materials, and equipment.—All reagents used were of the highest purity commercially available. Deionized water was used for all experimental work. Etchants were generally not filtered prior to employment.

The following equipment was used in the work: Coleman Model 37A *p*H Meter for all *p*H measurements; Cary Model 14 for spectroscopic work; Headway Research Photoresist Spinner EC101; Thayer and Chandler Airbrushes, Models C and E; and Teflon-coated tweezers for all etching rate data.

Etching techniques.—Samples of SiO_2/Si (0.5 cm^2) overcoated with tungsten (2500Å: resistivity 15-25 μohm-cm) were etched by rapid hand agitation using 40 mliters of etchant in a 50 mliter beaker. The etching end point was taken as the visual disappearance of the last trace of tungsten from the sample.

Key words: tungsten etching, tungsten photolithography, tungsten metallization, tungsten processing.

High resolution etching of 1¼ in. wafers was done by spraying etchant with a Thayer and Chandler Model C or E Airbrush, using 25-50 lb $in.^{-2}$ air pressure, onto a photoresist (AZ-111 or KMER) patterned tungsten coated SiO_2/Si wafer spun at 100-1500 rpm on a Headway Model EC101 Photoresist Spinner. The airbrush was held 4-6 in. above and was centered on the wafer. Towards completion of etching the sample was inspected visually and etched for 5-10 sec intervals to completion. Final microscopic observation prior to resist removal was always made to ensure complete etching. Etching was stopped with distilled water and the sample was dried by spinning at 7000-8500 rpm. Two inch diameter wafers were etched in a similar manner with excellent results across a wafer. To compensate for the increased area, several spray nozzles (each covering a portion of the wafer) are directed at the rotating wafer.

Analytical.—It was found that 5.7 moles of $K_3Fe(CN)_6$ reacted with one mole of tungsten by determining the maximum weight of tungsten metal powder which could be dissolved in an etching solution. By using the molar extinction coefficient (4) of 290 at the $Fe(CN)_6^{-4}$ absorption maximum of 3250Å it was found that 0.1M $Fe(CN)_6^{-3}$ yielded 0.096M $Fe(CN)_6^{-4}$ in the exhausted etchant. Acidification of the exhausted etchant according to the method in Remy (5) produced the faintly yellow precipitate characteristic of the simple tungstate anion WO_4^{-2}.

Results

Development of buffered chemical etchants.—It has been established (6) that tungsten metal is passive to chemical attack in acid solution. More recently, data have been obtained (7) which show that the metal is electrochemically inactive at *p*H $\leqq$ 6 and undergoes oxidation at *p*H $\geqq$ 6.5. There are exceptions to this finding (8, 9), however; for example, concentrated aqueous HF-HNO_3 solutions attack the metal readily. Practically speaking it is clear that chemical etches for tungsten should operate in alkaline solutions. The important question is: How alkaline does the etching solution need to be in order to support tungsten oxidation and dissolution?

The initial set of experiments was directed at determining the minimum KOH concentration which could be used in the conventional KOH-$K_3Fe(CN)_6$ system with satisfactory etching results. The etch rate data for the system are presented in Fig. 1. It is seen that relatively rapid etching can be done by this system, but only at high *p*H values. When the *p*H is reduced to anything approaching a value compatible with positive

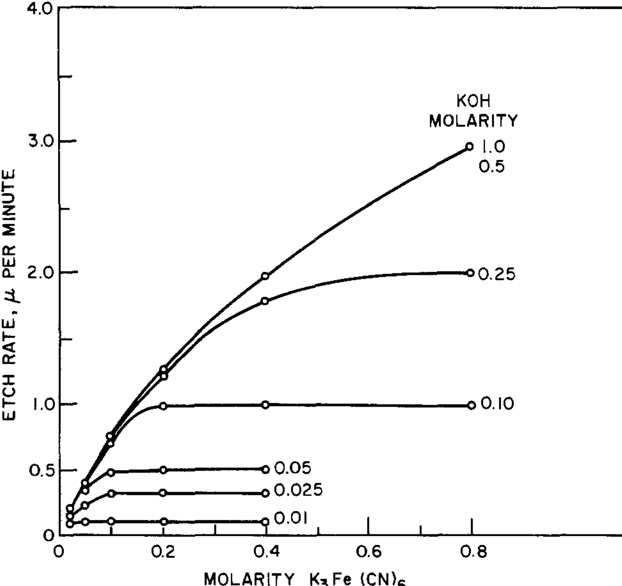

Fig. 1. Plot of tungsten etch rate vs. $K_3Fe(CN)_6$ concentration for various KOH concentrations.

photoresist stability ($pH < 12$, $< 0.01M$ KOH), very slow rates are obtained. Moreover, we found that samples etched in 0.01-0.025M KOH, 0.05-0.8M $K_3Fe(CN)_6$ solutions showed very nonuniform etching; etching always tends to occur from a photoresist-tungsten edge into a feature so that fine resolution patterns are lost before coarse features are resolved. In Fig. 2, a photomicrograph of an Ealing test chart etched into tungsten which was protected by 0.5 μm KMER using 0.02M KOH-0.5M $K_3Fe(CN)_6$ as the etchant, it can be seen that much metal remains in the very coarse 30 and 40 μm lines while the fine sets of lines are resolved. Moreover, overetching of the 2.0, 1.5, and 1.3 μm lines in the upper left of the pattern has become evident.

The trends evident in Fig. 1 make it obvious that further *p*H reduction by dilution of the strong base, KOH, would be futile. We felt that a reasonable approach at this point was to substitute weak bases for KOH in order to assess the effects of further *p*H reduction. A common practice for improving etch capacity while maintaining constant concentrations of certain etchant components is to include complexing agents for the metal in question. Ethylenediamine (en) was selected for the dual role of *p*H reduction and complexation. Even though there is a dearth of reported

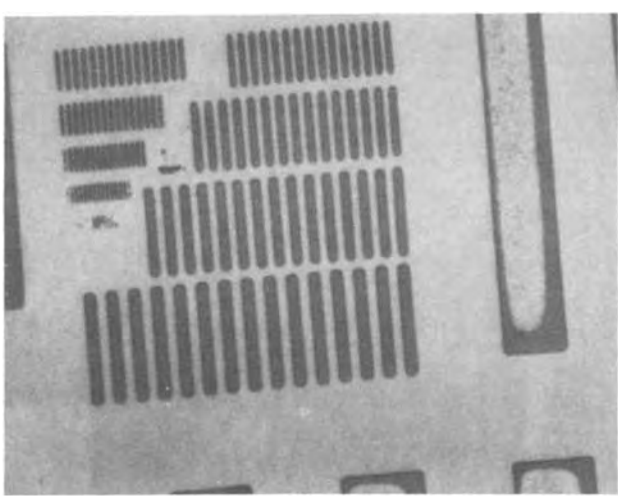

Fig. 2. Photomicrograph of an Ealing test pattern etched into tungsten using an etchant composed of 0.02M KOH and 0.5M $K_3Fe(CN)_6$. Note tungsten remaining in 30 and 40 μm lines and overetched small features.

amine-W^{+6} chemistry (W^{+6} is formed in the etch process) it was hoped that this strong ligand for inorganic cations might facilitate etching by complexing transiently formed species intermediate between W^0 and W^{+6}.

It was found that a solution of 0.01M $K_3Fe(CN)_6$ brought to *p*H 12 with en (1M) etches tungsten at the rate of 4600 Å min^{-1}, compared with a *p*H 12 KOH-$K_3Fe(CN)_6$ rate of 1000 Å min^{-1}. The data in Table I were obtained in an attempt to understand further the role of a weak base in the ferricyanide etching of tungsten. It can be seen that there is a fairly constant etch rate at *p*H 12 for the weak bases.

It was found that lowering the *p*H by dilution of the weak base leads to much the same result as reducing the *p*H by decreasing the KOH concentration; etch rates rapidly fall to very low values and nonuniform etching once again becomes a problem. It was subsequently discovered that etching rates of weak base-ferricyanide etchants could be maintained at a high level, while the *p*H is drastically reduced, by partially neutralizing the base with an acid to produce a buffered etching solution. This important finding is evident in the data tabulated in Table II, which shows the etch rate to be independent of *p*H over the range from unbuffered weak base (en at *p*H 12) to a *p*H value as low as 7.5, for constant $K_3Fe(CN)_6$ concentration. The same holds true for other common weak bases. There seems little reason to attempt to replace ferricyanide with an alternative oxidant. The innocuous nature of this chemical coupled with the lack of other oxidants which function adequately in basic solution governed this decision.

Mechanism of etching.—A logical explanation of the above results can be advanced by considering the chemistry of tungsten removal by a basic oxidizing solution. We can write Eq. [1][1] for the etching of tungsten metal by an aqueous ferricyanide solution at any *p*H

$$W^\circ + 6Fe(CN)_6^{-3} + 4H_2O \rightarrow WO_4^{-2} + 6Fe(CN)_6^{-4} + 8H^+ \quad [1]$$

It is obvious from Eq. [1] that the generation of H^+

[1] That 6 moles of $K_3Fe(CN)_6$ react for each mole of W° and that $Fe(CN)_6^{-4}$ is quantitatively formed in the redox reaction from $Fe(CN)_6^{-3}$ has been verified by the use of gravimetric and spectroscopic analysis. The presence of a simple tungstate (WO_4^{-2}) after oxidation as opposed to some more complex meta- or paratungstate has been established experimentally according to standard analytical procedure (5).

Table I. Etch rate data at pH 12 for aqueous 0.1M $K_3Fe(CN)_6$ solutions of several bases

Base	Molarity	Etch rate (Å min^{-1})
1. NH_3	5.0	5800
2. Ethylene diamine	1.0	4600
3. Piperidine	0.2	4800
4. KOH	0.01	1000

* The pH was lowered by the gradual addition of HCl to the etchant.

locally at the tungsten surface will potentially lead to acid passivation of tungsten. If sufficient base is present to neutralize the acid generated by dissolution of the metal the surface will remain active. The important factor is the ability of the etching solution to neutralize the acid and maintain the *p*H at a high enough value to prevent passivation. This does not depend on the hydroxide ion concentration but depends only on the concentration of Bronsted base and the rate at which the protons are removed from the metal-solution interface. Thus at a given *p*H a high concentration of weak base (*e.g.*, an amine) may, depending on the kinetics, be much more effective than the corresponding low concentration of OH^-. Buffered solutions are effective because they have a high capacity for absorbing protons while maintaining the *p*H essentially constant. The buffering suppresses the hydrolysis of the weak base, thus keeping the OH^- concentration low while the solution still has a large capacity for rapidly neutralizing acid.

Description of representative systems.—We have studied several prototype etching systems which are based on the developmental work just described. Our initial work on the buffered systems was with en-HAc-$K_3Fe(CN)_6$ maintained above the obvious passivation limit seen in Table II. We subsequently substituted HCl since a strong acid provides larger buffer capacity in the basic range than a weak one, when coupled with a weak base. The etch rate data presented in Fig. 3 are for various permutations of concentration for the system en-HCl-$K_3Fe(CN)_6$ at *p*H 8.0. Remember that raising the *p*H to higher values has no effect upon the etch rates in these systems. The data in Fig. 4 are for

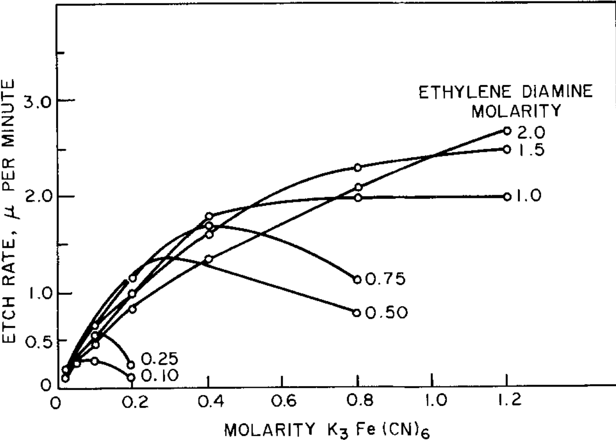

Fig. 3. Plot of tungsten etch rate *vs.* $K_3Fe(CN)_6$ concentration for various ethylene diamine concentrations at *p*H = 8.0.

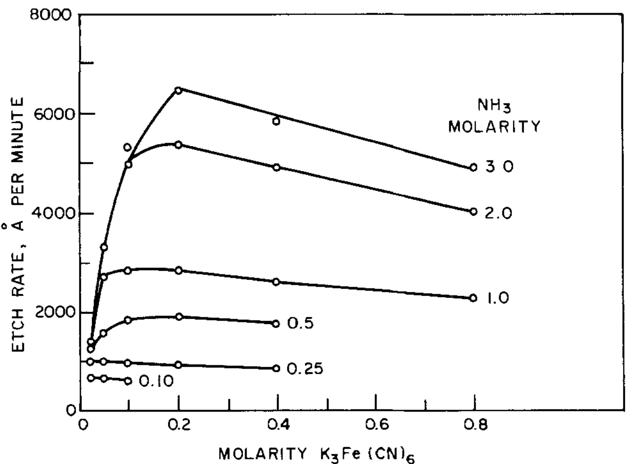

Fig. 4. Plot of tungsten etch rate *vs.* $K_3Fe(CN)_6$ concentration for various NH_3 concentrations at *p*H = 8.0.

the closely related system NH_3-HCl-$K_3Fe(CN)_6$, or NH_3-NH_4Cl-$K_3Fe(CN)_6$, also maintained at *p*H 8.0.

In an attempt to determine whether a conventional inorganic buffer system could be substituted for the buffered amine systems, we obtained rate data for the KOH-KH_2PO_4-$K_3Fe(CN)_6$ system at *p*H 8.0. These data are given in Fig. 5. The parameter of buffer concentration refers to the molarity of KH_2PO_4 in the solution. Note, that to achieve *p*H 8, it is necessary to add 0.92 moles of KOH to each mole of KH_2PO_4. While the etch rates for this system do not approach those for en-HCl-$K_3Fe(CN)_6$ or even those for NH_3-NH_4Cl-$K_3Fe(CN)_6$, this system has important advantages which recommend it for routine tungsten etching. In the first place the weak amine base systems are unstable and some formulations must be used within 1-2 hr of preparation. Secondly, the etch rates are constant over a wide range of buffer and $K_3Fe(CN)_6$ concentration, which is not the case for the en and NH_3 systems. Thus, this system is less sensitive to error in etchant preparation than the others. It is obvious that the employment of related weak bases and inorganic buffering systems should yield similar results.

Discussion

Mechanism.—It is not completely clear why the etch rate data behave as they do. It is readily seen that the maximum etching rate obtainable for a given base at constant base concentration follows the base ionization constants or base strengths without exception: KOH > piperidine > en > NH_3 > HPO_4^{-2} (HPO_4^{-2} is the base in the KOH-KH_2PO_4 system) > pyridine. While this is the case, the differences in rate cannot be quantitatively explained on this basis alone. We can make quantitative rate comparisons on the systems as follows: KOH, en, NH_3, HPO_4^{-2}, pyridine, have relative rates of 200:60:10:3:1. For example, KOH is said to be three times as effective as en because the maximum etch rate possible for 0.1M KOH at any $K_3Fe(CN)_6$ concentration is 10,000 Å min^{-1} while that for 0.1M en is 3000 Å min^{-1} (see Fig. 1 and 3). The ionization constants and relative ionization (at 1 molar concentration) are 1 (100%), 9×10^{-5} (1%), 1.5×10^{-5} (0.4%), 10^{-7} (0.03%), and 1.4×10^{-9} (0.004%) for KOH, en, NH_3, HPO_4^{-2}, and pyridine, respectively. The relative rates of 60:10:3:1 for the weak bases are reasonable when compared to the ionization percentages which might be interpreted as reflecting the importance of free OH^- to etching. As a group, however, the weak bases have rates close to the completely ionized KOH. Thus while the etch rates for weak bases are within a factor of three of that obtained for KOH, the absolute OH^- concentration is only 1% of that of the KOH solution. As emphasized above it is the dynamic ability of the solution to neutralize protons which is important rather than the absolute OH^- concentration. The amines are not quite as effective as is OH^-, as judged from the rate data, and this difference may be due to small differences in the rates of reaction with the actual acidic species.

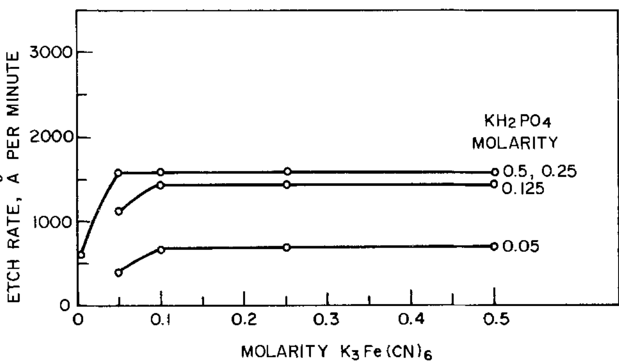

Fig. 5. Plot of tungsten etch rate *vs.* $K_3Fe(CN)_6$ concentration for various KH_2PO_4 concentrations at *p*H = 8.0.

The similarity of the rates for mono- and difunctional amines suggests that coordination of metal ions is not important in the dissolution of tungsten. If it were so, en would be expected to be much more effective than the monofunctional amines. Further, we measured the etching rate *vs.* $K_3Fe(CN)_6$ concentration for 0.5M solutions of KOH, piperidine, en, and ammonia. The maximum rate in the amine solutions was highest for piperidine which is the strongest base of the three amines. This result suggests that coordination is not important in the dissolution of tungsten.

Etchant composition.—It is our observation that as long as the etch rate curves are in the ascending region of etch rate, then any etchant composition is useful and apparently equivalent as far as etching patterns are concerned. Once the concentration of $K_3Fe(CN)_6$ gets too far in excess of the base concentration needed to support tungsten dissolution then nonuniform and unpredictable etching results. Thus, for example, 0.5M en neutralized to pH 8 with HCl can be used with good results only up to 0.2M $K_3Fe(CN)_6$. Beyond this point the oxidation proceeds faster than surface depassivation and hard to remove oxidation products, which impede the etching process, become evident. This observation is consistent with our early finding that 0.01M KOH solutions produce nonuniform etching. In the case of the KOH-KH_2PO_4-$K_3Fe(CN)_6$ system which has a wide region of constant etch rate, these problems do not show up as clearly as in the weak systems having steep etch rate curves.

Since the etch rate data above pH 7.5 show no significant dependence on pH and since the etchants can easily be prepared to $\pm$ 0.1 pH unit, then the use of the etchant at some pH safely above 7.5 is suggested, *e.g.*, pH 8.0. The KOH-KH_2PO_4-$K_3Fe(CN)_6$ system exhibits long shelf life if the etchant is stored in an amber bottle and its activity is assured if its pH remains above 7.5. Certain of the more concentrated en-HCl-$K_3Fe(CN)_6$ and NH_3-NH_4Cl-$K_3Fe(CN)_6$ etchants are quite unstable, while the more dilute compositions (etch rates $< 10,000$ Å min^{-1}) should be used within a few hours of preparation.

We have included typical etching results in Fig. 6. Figure 6a shows the AZ-111 photolithograph and etching of an Ealing test pattern using 0.25M KH_2PO_4, 0.24M KOH, and 0.1M $K_3Fe(CN)_6$, while Fig. 6b shows a CCD-L pattern etched using 0.5M en, 0.5M HCl, and 0.1M $K_3Fe(CN)_6$. The finest resolved Ealing line is 1.25μ in the photolithograph, while the smallest feature in the CCD-L pattern is 2.5μ wide. Tungsten samples 2500Å thick were etched using the spinning wafer spray etching technique described in the next section.

Etching technique.—Unless there is uniform exchange of etching products with fresh etching solution at the metal surface, obvious nonuniform etching occurs which is especially evident on 2 in. wafers. Every attempt must be made to minimize this nonuniformity consistent with the size of a device feature and the degree of undercutting that one can tolerate. Thus, where overetching of a 10 μm feature in a 2000Å thick tungsten film by 100% will hardly be noticeable, the same treatment of a 3 μm feature may be unwarranted.

We have found that while coarse patterns in the 25 μm range can be etched using almost any technique that one chooses, 1-10 μm devices are best etched by spraying. We further suggest that some attempt be made to minimize spray pattern nonuniformities. Our best results have been obtained using single or multiple atomizing spray nozzles either centered on (1 nozzle) or uniformly distributed ($>$ 1 nozzle) over a wafer rotating 4-6 in. beneath the nozzle(s). Generally, one can achieve results with undercutting of no greater than 0.25 μm per feature edge in 3500Å thick tungsten films across a 2 in. wafer.

Etching rates.—The etch rates presented here are for beaker hand-agitated etching at room temperature of small samples of sputter deposited tungsten films. They should be used only as a guide since etch rates vary with technique. In general those which involve the most vigorous movement of etchant to and from the metal surface produce the fastest etch rate. Thus, for example, certain spray techniques give rates 3-5 times as fast as those reported in this memorandum. We have found that in the range 20°-45°C a 10°C rise in temperature approximately doubles the etch rate.

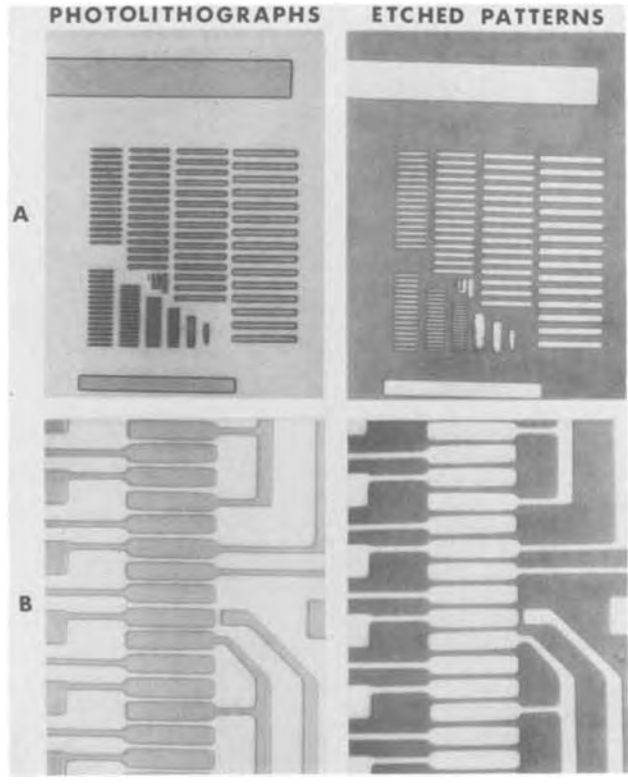

Fig. 6. Typical patterns etched into 2500Å of tungsten and initial photolithography. A, Ealing test pattern etched using 0.25M KH_2PO_4-0.24M KOH-0.1M $K_3Fe(CN)_6$; smallest resolved set is 1.25 μm. B, CCD-L metallization pattern etched using 0.5M ethylene diamine-0.5M HCl-0.1M $K_3Fe(CN)_6$; gaps are 2.5 μm wide.

An etchant composition which furnishes adequate rate commensurate with the tungsten thickness being etched and ample time for unhurried etching is suggested for routine work.

Selection of photoresists.—There has been no evidence of degradation of any photolithograph either by direct attack or by loss of adhesion at feature edges using any of the prototype systems described earlier (pH 8). All photoresists, both positive and negative, are apparently satisfactory.

Summary

It has been found that a method of achieving satisfactory tungsten etching solutions is to replace the strong base in the KOH-$K_3Fe(CN)_6$ etching system by a buffer solution. This solution can be of any composition that functions in the mildly basic pH range (7.5-9.5). Thus buffered solutions obtained by neutralization of a weak base by a strong acid or by reaction of a strong base with a mono-basic weak acid (KOH-KH_2PO_4) are effective. We have shown that the etching rate in these systems generally follows the ionization constant or base strength.

As long as there is sufficient H^+ absorbing capacity in a particular etching solution the rate of etching depends only on the concentration of oxidant, $K_3Fe(CN)_6$. If this criterion is satisfied, uniform and reliable tungsten etching is easy to achieve. If the ability to absorb H^+ formed in tungsten oxidation becomes insufficient, then the oxidation is no longer the rate determining step and nonuniform, unpredictable etching occurs

owing to buildup of hard-to-dissolve oxidation products at the etching surface.

The three prototype systems studied [en-HCl-$K_3Fe(CN)_6$, NH_3-NH_4Cl-$K_3Fe(CN)_6$, and KOH-KH_2PO_4-$K_3Fe(CN)_6$] are all capable of excellent etching of high resolution tungsten device circuits as long as the selected composition meets the criterion of H^+ absorbing capacity. We tend to favor KOH-KH_2PO_4-$K_3Fe(CN)_6$ (even though it furnishes the lowest etching rates) for general work owing to its long shelf life and relative independence of component concentrations. Where speed is required or thick tungsten samples (> 5000Å) must be etched, then the en-HCl-$K_3Fe(CN)_6$ system is recommended, provided the user is aware of the short shelf life of the etchant.

The gentle nature of $K_3Fe(CN)_6$ coupled with the near-neutral pH of etchant operation makes these systems completely compatible with all presently available photoresists.

Metal Vapor Effects on Chemical Reactions in an Argon Plasma

Paul Meubus*

Department of Applied Sciences, Université du Québec à Chicoutimi, Chicoutimi, Quebec, Canada

ABSTRACT

In order to illustrate the effect of metal vapors on chemical reactions carried out at high temperatures, the example has been taken of propane cracking in an argon plasma, yielding acetylene. The reaction takes place in the homogeneous phase, in the presence of iron vapor. Molar ratios propane/argon of 1.5 and 6.0% have been used, associated with 0.25, 0.75, and 1.00% iron/argon molar ratios. It is observed that the reaction temperatures required for obtaining the maximum conversion of propane into acetylene are considerably lowered in the presence of iron vapor, attaining then 3200°-4200°K while, all other conditions being equal, except for the presence of iron vapor, these temperatures are of the order of 5000°-6500°K. The latter conditions also lead to maximum conversions of propane into acetylene which are of the order of 40% while these conversions attain 100% when iron vapor is present. Possible mechanisms are suggested, relating the results observed either to a catalytic effect generated by condensing iron particles, or to a photosensitization process by which excited iron vapor emissions around 3000.7 and 5328.5Å contribute to the stabilization of acetylene and C_2H precursor during the quenching stage, thus avoiding the decomposition of these species into solid carbon and hydrogen.

It is the purpose of this study to show by an example how a metallic vapor may alter the chemical kinetics of a given reaction taking place in a plasma gas. The case investigated is the formation of acetylene from propane cracking in the presence of iron vapor, the plasma matrix being argon. Acetylene production from lower hydrocarbons like methane, ethane, and propane have been studied and the reaction kinetics is well known (1, 2) so that possible changes brought by the introduction of iron vapor are more easily evaluated.

Iron is supplied to the argon stream by means of an iron wire 1 mm in diameter, which is introduced into the plasma gas at a given rate. Propane is then injected into the resulting mixture and a small plasma volume is delimitated within which the average temperature is recorded by means of the hydrogen lines H_α and H_β. Reacted gas samples are then drawn through a cooled probe for gas chromatography analysis. An interpretation of the results observed is given, based on catalytic effects resulting from the condensation of the metal vapor, and also based on possible photosensitization effects related to the iron spectroscopic emissions around 3000.7 and 5328.5Å as explained later in the text.

Apparatus and Mode of Operation

The power supply, control panels, and plasma torch have been described elsewhere (3). As shown in Fig. 1, the reactor is made up of a plasma torch and of a set of cooled copper probes used for metal injection (G), propane injection (H), and reacted products sampling. The probes G and H are provided with a welded tungsten refractory tip whose purpose is to facilitate injection of the metal and propane into the plasma gas. The iron injection rate is adjusted by means of a controlled speed driving wheel entraining an iron wire 1 mm in diameter. The wire emerges through the cooled probe G within the plasma where it evaporates and turbulent mixing occurs so that

Key words: argon plasma, metal vapors, chemical reactions, photochemical effects, catalytic effects.

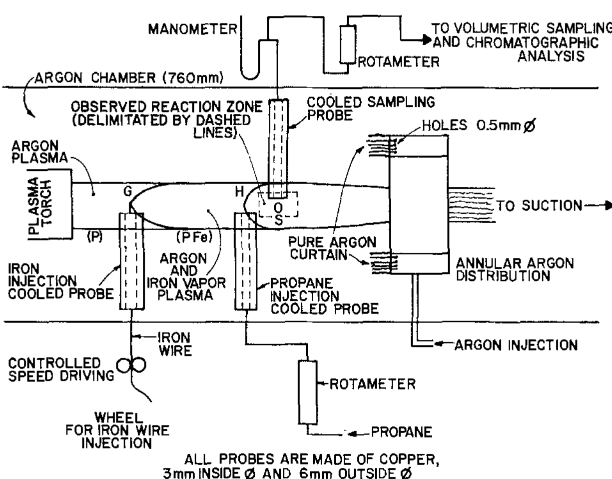

Fig. 1. Plasma reactor

about 3 cm downward from G, a homogeneous mixture of argon-iron vapor is available within which propane is injected at a given rate.

The probes are installed in such a way that their vertical axis of symmetry is contained in the vertical plane of symmetry of the plasma jet (which is of cylindrical symmetry) and they are positioned at, respectively, 0.7 (G), 3.8 (H), and 4.8 cm (sampling probe) from the plasma torch outlet. The probes' tips horizontal surfaces (for G and H) coincide with the horizontal plane of symmetry of the plasma. This positioning of the probes ensures an adequate reproducible plasma surrounding the injection parts. While in operation, three sections may be distinguished in the plasma: (*i*) an argon section (P), (*ii*) an argon + iron vapor plasma (PFe), and (*iii*) the reaction zone within which a small volume S can be delimitated, care being taken that chemical equilibrium is attained at the prevailing temperature. Temperatures are recorded by means of spectroscopic measurements related to the atomic hydrogen lines H_α and H_β, using the well-known lines intensity ratio method (4).

Also, reacted gas samples are withdrawn through a cooled probe always under the same negative pressure and gas flow rate so that the quenching conditions can be accurately controlled. The samples are analyzed for acetylene and H_2 which are, for all practical purposes, the only gas constituents found in all cases as products of reaction. A Pye Unicam 104 with a 20% Squalane on Chromosorb P column is used for flame ionization detection of the hydrocarbons, while a Fisher Hamilton 29 supplied with a Molecular sieve 13× determines the hydrogen content of the sample. Since the refractory tips already mentioned provide conditions of homogeneous region within the considered reactor volume S, the following relation can be written

$$\frac{\text{moles } C_2H_2}{\dfrac{\text{moles } C_2H_2 + \text{moles } H_2}{4}} = \frac{\text{moles } C_2H_2}{\text{mole } C_3H_8} \qquad [1]$$

a value of 1.5 for this ratio being equivalent to 100% C_2H_2 yield for the reaction

$$2C_3H_8 \rightarrow 3C_2H_2 + 5H_2 \qquad [2]$$

where the acetylene and hydrogen concentrations are obtained from a sample analysis for a given test, the total content of hydrogen being used for the determination of the initial amount of propane. In order to avoid any contamination of the plasma flame byproducts of reaction that may accumulate in the surrounding chamber, an annular distributor supplies a curtain of pure argon around the reaction site (see Fig. 1).

Before starting an experiment, the chamber was filled with argon and the pressure was maintained at 760 mm Hg. The plasma argon flow rate was kept constant at 0.2 g-moles/min while, respectively, 0.3 $\times 10^{-2}$ and 1.2 $\times 10^{-2}$ g-moles/min propane were used. Variable amounts of iron were injected in the pure argon section P (Fig. 1), ranging from 5 $\times 10^{-4}$ up to 19 $\times 10^{-4}$ g-moles/min iron, calculated on the basis of iron wire feed rate. While sampling the products of reaction, the quenching rate was adjusted until optimum acetylene yield was obtained. The adjustment was made by means of suction application and the flow rate of gas withdrawn was obtained from a rotameter reading thus avoiding any misleading conclusion resulting from pressure reading alone.

Results

The optimum quenching conditions were found practically equivalent in all cases and resulted in quenching times of about 10^{-3} sec. The argon flow rate was 2 $\times 10^{-1}$ g-moles/min. The values given for iron injection rates are those corresponding to the iron wire speed and they are discussed later.

With a propane flow rate of 0.3 $\times 10^{-2}$ g-moles/min in 0.20 g-moles/min argon, an injection of 5.0 $\times 10^{-4}$ g-moles/min of iron resulted in an acetylene yield approaching 100% propane conversion, the latter never exceeding 40% without added iron. Further, the most favorable temperature for the production of acetylene achieved was reduced from 6500° to 3500°K. When the iron rate was increased to 19 $\times 10^{-4}$ g-moles/min, the maximum yield dropped back to 40% propane conversion into acetylene at a temperature of 4500°K. The data from these experiments are presented in Fig. 2 and Table I.

When a propane flow rate of 1.2 $\times 10^{-2}$ g-moles/min in 0.2 g-moles/min argon was used, the addition of 5 $\times 10^{-4}$, 15 $\times 10^{-4}$, 19 $\times 10^{-4}$, and 0 g-moles/min iron resulted in temperatures for maximum acetylene yield obtention of, respectively, 3000°, 3800°, 4200°, and 5000°K, the propane conversion into acetylene attaining nearly 100% for all the iron flow rates used, against 65% when no iron was present in the reacting medium. As a result, and within the limits of the experimental conditions, the higher propane flow rate used was related to lower optimal tempera-

tures required for maximum acetylene yield at the various iron flow rates tested, the temperature drop being around 500°K for equivalent iron flow rate conditions.

Finally, it was observed that the iron injection rate did not affect, for all practical purposes, the maximum acetylene yield (nearly 100%) obtained when keeping a propane flow rate of 1.2 × 10^{-2} g-moles/min, while a drop in maximum yield from around 100% down to 40% was observed, using a propane flow rate of 0.3 × 10^{-2} g-moles/min with, respectively, 5 × 10^{-4} and 19 × 10^{-4} g-moles/min iron. Figures 3, 4, and 5 show the results described while Table I summarizes the data from these experiments.

In order to obtain reference conditions, a number of experiments were carried out with respective propane flow rates of 0.3 × 10^{-2}, 0.7 × 10^{-2}, and 1.2 × 10^{-2} g-moles/min in 0.20 g-moles/min argon, no iron being used. In this way, a curve was derived showing the increase in maximum acetylene yield at decreasing maximum temperatures when the propane flow rate was increased. At about 3000°K (extrapolated), a maximum of 73% propane conversion into acetylene is obtained. This should be the limiting value attainable for nearly pure propane in the homogeneous phase at atmospheric pressure, and a molar ratio carbon over hydrogen (C/H_2) equal to 0.75 (corresponding

to propane). Such a conclusion is derived from the slow variation of maximum acetylene yield as a function of optimal temperature and propane flow rate, and also from the fact that the sublimation temperature of carbon is 3200°K for a pure C-H_2 system at atmospheric pressure and $C/H_2 = 0.75$ (1). This limiting value of 73% conversion should be compared with a nearly 100% conversion in the presence of iron vapor. The representative curves are shown in Fig. 6.

Discussion

Suggested reactions.—Equilibrium composition calculations have been made for the carbon-hydrogen system above 2000°K (1, 2, 5), considering a large range of total pressures and C/H_2 molar ratios. The plasma formed consists, in the homogeneous phase (the one we are interested in here), of the polymeric forms of carbon vapor C_1, C_2, and C_3, of atomic and molecular hydrogen, as well as of a number of radicals and molecules. The main reactions leading to the formation of acetylene should be

$$C_2 + H_2 \rightarrow C_2H_2 \quad [3]$$

and a quench mechanism has been postulated (1) whereby C_2H should act as a precursor for C_2H_2 formation so that

$$C_2H + 1/2\ H_2 \rightarrow C_2H_2 \quad [4]$$

Reverting back to Fig. 2 and 3 related to propane flow rates of 0.3×10^{-2} g-moles/min and 1.2×10^{-2} g-moles/min, it is observed that the maximum acetylene yields occur, as an average, at 3200° and 4200°K when, respectively, 5×10^{-4} and 19×10^{-4} g-moles/min iron vapor are injected into the reacting medium. However, reference to the work of Baddour and Blanchet (1, 5) leads to the conclusion that for the conditions of the present study (atmospheric pressure; $C/H_2 = 0.75$), acetylene is nearly maximum at 3200°K, its concentration being about two times higher than C_2H. On the other hand, the precursor C_2H goes through a maximum at 4200°K, being at least an order of magnitude higher than the acetylene concentration. Taking these facts into account, some possible mechanisms for the reaction involved are now suggested.

Catalytic effects resulting from condensed iron particles.—Acetylene is liable to be adsorbed on the {100} and {110} planes of face-centered cubic metals of which γ iron is an example. Desorption should then proceed through hydrogenation (6) and formation of ethylene. Thus, for a carbon-metal bond, one obtains

$$H_2 + \underset{\displaystyle Fe}{\underset{|}{HC}} = \underset{\displaystyle Fe}{\underset{|}{CH}} \xrightarrow[\text{bond rupture}]{\text{carbon-iron}} H_2C = CH_2 + Fe \quad [5]$$

However, very small amounts of ethylene are found in the products of reaction so that if any catalytic process of the kind described is susceptible to occur, acetylene could be desorbed, for instance, by the catalyst surface irradiation with photons of the appropriate energy, the desorption taking place at a temperature low enough for avoiding subsequent decomposition of acetylene

$$\underset{\displaystyle Fe}{\underset{|}{HC}} = \underset{\displaystyle Fe}{\underset{|}{CH}} \xrightarrow{h\nu} HC \equiv CH + Fe \quad [6]$$

As a matter of fact, there is a growing interest in this type of mechanism on the catalytic effects of metals and metal oxides (7).

Considering now the case of C_2H which has been related to maximum acetylene yields obtained around 4200°K, a reaction similar to that described by Eq. [6] can be considered, except that desorption should now occur by partial hydrogenation

$$1/2\, H_2 + \underset{\displaystyle Fe}{\underset{|}{HC}} = \underset{\displaystyle Fe}{\underset{|}{\overset{\bullet}{C}}} \xrightarrow{h\nu} HC \equiv CH + Fe \quad [7]$$

Equations [6] and [7] are the distinct reactions which should explain the variations of maximum yield obtained when, respectively, acetylene or C_2H predominate in the system. Equation [7] is a function of hydrogen concentration and should therefore be favored by an increase in propane flow rate, thus explaining why, for a given amount of iron present, the reaction implying C_2H leads to higher yields when the propane flow rate is raised from 0.3×10^{-2} up to 1.2×10^{-2} g-moles/min. On the other hand, acetylene stabilization from conditions prevailing around 3200°K should not depend on hydrogen concentration, following Eq. [6] and therefore, should not be affected by propane flow rate (Fig. 2 and 3).

It should be pointed out that the γ iron crystalline form is obtained between 906° and 1401°C, the fusion temperature of iron being 1530°C. Below and above this temperature range, the α iron body-centered cubic form is obtained, which is less liable to lend itself to acetylene adsorption. While it is doubtful that the γ form be always obtained, it may be expected that the rapid quenching rate will introduce defects in the particles structure, making them suitable for the adsorption processes involved.

Possible photochemical effects resulting from the presence of iron vapor.—By analogy with observed photosensitization effects occurring between acetylene and mercury atoms (8, 9), it is possible to consider a photochemical energy exchange process, generated by appropriate iron lines, which may oppose the decomposition of an acetylene molecule during the quenching process so that the yield of propane conversion into acetylene is improved. For instance, the reaction leading to an excited state of the acetylene molecule could occur if the iron excitation state is high enough. Thus

$$C_2H_2 + Fe^* \rightarrow (C_2H_2)^* + Fe \quad [8]$$

$$(C_2H_2)^* + M \rightarrow (C_2H_2) + M \quad [9]$$

The similar reaction

$$C_2H_2 + Hg^* \rightarrow (C_2H_2)^* + Hg \quad [10]$$

has been proposed earlier (8), using the 2537Å mercury radiation as the excitation source. The energy coupling takes place by means of a photosensitization effect. In the case of the present study, for reaction temperatures of 3200°-4200°K, the short u.v. emission from iron vapor is not high enough for allowing any resonant energy interchange since the latter should occur for acetylene at 1540Å and downward (10). As a result, if Eq. [8] describes an actual situation, here again energy should be exchanged by a process of photosensitization.

Another photosensitization reaction between iron and acetylene is suggested by a similar reaction studied in the case of mercury (8)

$$C_2H_2 + Fe^* \rightarrow C_2H + 1/2\, H_2 + Fe \quad [11]$$

Reaction [11] could also oppose the decomposition of acetylene into solid carbon and hydrogen. From Ref. (1) one obtains, for C_2H_2

C_2H_2

$$\Delta H^\circ_{(0)f} = 54.33 \text{ kcal/g-mole } (2.36 \text{ eV}) \quad [12]$$

$$\Delta H^\circ_{(3200)f} = 48.36 \text{ kcal/g-mole } (2.09 \text{ eV}) \quad [13]$$

and, if the energy transfer during photosensitization is entirely used for internal energy increase of the acetylene molecule, then photons are required whose associated wavelength is

$$\lambda_1 = \frac{hc}{E_1} = \frac{6.62 \times 10^{-27} \times 3.0 \times 10^{10}}{2.36 \times 1.602 \times 10^{-12}} \times 10^8$$
$$\lambda_1 = 5330\text{Å} \quad [14]$$

This value is purely indicative of the excitation level required by iron vapor and emissions of higher energy are available from iron vapor at the prevailing temperatures.

$\Delta H^\circ_{(0)f}$ for the radical C_2H may be obtained from chemical bond strength considerations (11), while data from Bauer and Duff (12) are used for an approximate evaluation of $\Delta H^\circ_{(4200)f}$. Then

C_2H

$$\Delta H^\circ_{(0)f} = 95.5 \text{ kcal/g-mole } (4.14 \text{ eV}) \quad [15]$$

and

$$\Delta H^\circ_{(4200)f} = 90.0 \text{ kcal/g-mole } (3.91 \text{ eV}) \quad [16]$$

From the heats of formation given in [13] and [16], the enthalpy of reaction for Eq. [11] should be approximately 51.6 kcal/g-mole at 3200°K. As a result, the wavelength associated with the photons required for reaction [11] to take place should be of the same order of magnitude as the one related to the photons required for Eq. [8], both reactions taking place around 3200°K.

Considering now the case where the radical C_2H prevails in the medium at around 4200°K, a mechanism could be written on the basis of a similar structure between the radical and acetylene, with the possible formation of an iron complex

$$C_2H + Fe^* \rightarrow (C_2H)^* + Fe \quad [17]$$

$$(C_2H)^* + H_2 \rightarrow (C_2H_2)^* + 1/2\, H_2 \quad [18]$$

de-excitation taking place at a temperature low enough so that the decomposition reaction into solid carbon and hydrogen does not take place. Referring to [15], and assuming that the photosensitizing energy is absorbed only for increase in internal energy, the wavelength corresponding to the photons required for Eq. [17] should be

$$\lambda_2 = \frac{hc}{E_2} = \frac{6.62 \times 10^{-27} \times 3.0 \times 10^{10}}{4.14 \times 1.602 \times 10^{-12}} \times 10^8 = 3000\text{Å} \quad [19]$$

A number of iron lines are emitting with a fairly high intensity around the wavelengths defined in rela-

tions [14] and [19] and two representative lines of these groups are observed at 5328.5 and 3000.7Å. The assumed photosensitization effects imply energy transfer by means of collisions between excited iron atoms and acetylene molecules as well as C_2H radicals. It may be conceived that, while the gas is withdrawn for sampling, it is still exposed to plasma radiation (Fig. 1) since most of the quenching takes place at the inlet of the sampling probe where iron is present up to 0.13% (vapor pressure at 1800°C) at 1800°C. The cooled iron vapor can be excited, prior to conveying its energy: (*i*) by resonance absorption of 3000.7 and 5328.5Å photons emitted from the plasma, and (*ii*) by collision with metastable argon atoms (12) resulting in reactions of the kind (Penning effect)

$$Ar^* + Fe \rightarrow Fe_+ \qquad [20]$$

$$Fe_+ + Fe \rightarrow 2Fe^* \qquad [21]$$

In view of the experimental results obtained, it seems that high iron vapor concentrations favor the formation of acetylene at higher temperatures (around 4200°K), this indicating that an emissive power high enough in quanta of wavelength 3000.7Å is required for allowing the occurrence of reaction [17]. On the other hand, such an emission density is probably liable to decompose acetylene instead of exciting the molecule, thus decreasing the probability of acetylene formation. This should explain, to a certain extent, the curves appearing on Fig. 2-5, the effect of propane flow rate variation at 4200°K being understood from Eq. [18].

Propane cracking in an argon plasma without iron vapor.—The experimental results show that an increase in propane flow rate increases the conversion into acetylene and decreases the temperature required for maximum conversion. In this case, the yield is essentially a question of quenching rate keeping the acetylene and C_2H precursor formed at high temperature from decomposition into solid carbon and hydrogen. In this respect, the amount of hydrogen present at the start of the quenching process will affect the quenching rate since it is well known that around 4000°K down to 2000°K, the thermal conductivity of hydrogen considerably increases (13). A higher initial propane flow rate results in higher concentrations of hydrogen present in the gas mixture at elevated temperatures, thus improving optimal quenching conditions with resulting higher optimal quenching conditions with resulting higher acetylene yields. However, the hydrogen effect is limited to an upper propane concentration value beyond which no further change is observed in acetylene yield.

These considerations lead to a possible interpretation of Fig. 6 which, in conjunction with Fig. 2-5 also shows that the maximum possible acetylene yield remains around 30% below the maximum value (nearly 100% yield) obtained when cracking is carried out in the presence of iron vapor.

Spectroscopic considerations.—The assumption has been raised in this work of photochemical excitation of iron vapor in relationship with photosensitization reactions involving acetylene and the C_2H radical. It is of interest to evaluate the power emitted from excited iron at 3000.7 and 5328.5Å since these emissions or similar ones could be responsible for part of the effects observed.

The emission intensity for a given spectral line can be written (4)

$$I = \frac{2}{3} \times 10^{16} \frac{hc\, gf\, N_o\, e^{-E/kT}}{\lambda^3 Z_o(T)} \qquad [22]$$

or, in terms of quanta emission rate

$$Q = \frac{2}{3} \times 10^{16} \frac{gf\, N_o\, e^{-E/kT}}{\lambda^2 Z_o(T)} \qquad [23]$$

N_o being here a function of temperature and concentration P of the total number of particles for a given species (iron in this case) injected into the plasma gas. The function $Z_o(T)$ in Eq. [22] or [23] can be evaluated from the energy levels related to the atomic species whose concentration is N_o and the latter is obtained from the following equations, first ionization only being considered

(*a*) Saha equation

$$\frac{N_+ N_e}{N_o} = K = 2 \frac{Z_+(T)}{Z_o(T)} \left(\frac{2\pi m_e kT}{h^2} \right)^{3/2} e^{-E_i/kT} \qquad [24]$$

(b) Species conservation

$$N_+ + N_o = P \qquad [25]$$

(*c*) Assumption of first ionization only

$$N_+ = N_e \qquad [26]$$

From Eq. [24], [25], and [26], one obtains with the restriction that $N_o \leq P$

$$N_o = \left[\frac{(K + 4P)^{1/2} - K^{1/2}}{2} \right]^2 \qquad [27]$$

which is then substituted in Eq. [22] or [23] with the appropriate constants for the given electronic transitions. As a result, I or Q may be obtained for a number of temperatures.

Applying these calculations to the present study, emission power for iron at 3000.7Å and 5328.5Å was calculated, at various temperatures, for an argon flow rate of 0.2 g-moles/min and iron vapor flow rates p, respectively, equal to 10^{-5}, 10^{-4}, and 1.5×10^{-3} g-moles/min. The total iron particles concentration P (atoms + ions) per cm^3 of plasma gas was calculated from

$$P = \frac{6.02 \times 10^{23} \times 273}{0.2 \times 22{,}400} \frac{p}{T} \qquad [28]$$

The value for E_i in Eq. [24] related to iron as well as the energy levels for atomic and singly ionized iron required for calculating $Z_o(T)$ and $Z_+(T)$ were obtained from Ref. (14) and Table III shows the values of $Z_o(T)$, $Z_+(T)$, and K for various temperatures. The other spectroscopic parameters required for iron were taken from Ref. (4). Then

$\lambda_1 = 5328.5$Å

$$Q_1 = \frac{2}{3} \times 10^{16} \times 156 \times \frac{1}{(5328.5)^2} \frac{N_o\, e^{\frac{-3.23 \times 11{,}600}{T}}}{Z_o(T)} \qquad [29]$$

and

$\lambda_2 = 3000.7\text{Å}$

$$Q_2 = \frac{2}{3} \times 10^{16} \times 46 \times \frac{1}{(3000.7)^2} \frac{N_o\, e^{\frac{-4.20 \times 11{,}600}{T}}}{Z_o(T)} \quad [30]$$

The results obtained for Q_1 and Q_2 at various temperatures and iron flow rates are shown in Fig. 7 and 8. The same figures also indicate that, at the average iron flow rates used in the present study, the rate of quanta emitted following Eq. [29] and [30], at, respectively, 3200° and 4200°K, should be of the order of 10^{20} quanta/cm^3-sec. The maximum amount of acetylene or C_2H present in the reaction medium amounts to approximately 10^{15} particles/cm^3. As a result, a quantum efficiency of around 0.1%, for the proposed photochemical mechanisms, should be sufficient, this including particles concentration and capture cross-section effects, the latter being not known. It should be mentioned that all the iron used is not actually introduced into the plasma and some preliminary work made in this laboratory should indicate that between 1 and 10% of the iron is incorporated in the plasma.

Conclusion

The cracking reaction of propane in an argon plasma at atmospheric pressure has been studied in the presence of iron vapor. Comparing the results obtained with those related to mixtures of argon and propane alone, all conditions being identical except for the presence of iron vapor, it is observed that the reaction temperature required for maximum yield is considerably decreased, dropping from 5000° to 6500°K when iron vapor is not present, down to 3200° to 4200°K in the presence of this metal vapor and depending on the latter concentration as well as on the initial propane flow rate adopted. In most cases when iron is present, except for small propane and high iron vapor flow rates, the acetylene yield is nearly 100%, while the maximum attainable propane conversion without iron is of the order of 70%.

An interpretation of the results obtained is given in terms of catalytic effects resulting from the minute condensing iron particles. Also, by analogy with mercury photosensitization effects in relationship with the acetylene molecule, an energy transfer mechanism is suggested which involves resonance energy absorption by the iron vapor during the cooling stage, or iron vapor excitation by metastable argon atoms, followed by energy exchange through particles collision. Iron emission around 3000.7 and 5328.5Å should be responsible for enhanced acetylene production from, respectively, excited acetylene species and, for instance, excited complex [C_2H-iron]* molecules. De-excitation should occur at temperatures low enough for avoiding the decomposition of acetylene into solid carbon and hydrogen. The results observed could be the consequence of a combination of the mechanisms proposed, although further work is required for casting more light on the actual mechanisms involved.

ABSTRACT

Activities and activity coefficients of indium and tin in their amalgams were determined by means of potentiometric measurements in the temperature region 150°-200°C. The equilibrium potential of indium amalgam was far less noble than that of tin amalgam. In the case of tin amalgam, the activity coefficient decreased rapidly with temperature, but the difference between the normal amalgam potential and the standard electrode potential, E^*, was kept practically constant. On the other hand, in the case of indium amalgam the activity coefficient was kept nearly constant, but the value of E^* increased fairly. The temperature dependence of the activity coefficient was discussed in relation to the type of the amalgamation reaction. Indium amalgam was considered as a simple mixture of indium and mercury and tin amalgam was regarded as a complex such as Sn_xHg_y which was dissolved in a simple mixture of tin and mercury.

In previous papers (1-9), we studied manufacturing processes for production of high purity tin and indium from tin ores containing a small amount of indium and from electrolytic baths containing indium ions used for electrolytic refining of tin. A fused salt electrolysis with amalgam, which is performed in a fused salt electrolyte by the use of an amalgam as an anode and the pure metal as a cathode, was proposed as a new metallurgical method of production of high purity indium from a mixed amalgam of tin and indium (7-9). Through these investigations it was found that the potential of indium amalgam was far less noble than that of tin amalgam at high temperature (180°C) in fused salt, while indium amalgam was more noble than tin amalgam in aqueous solution at room temperature. Therefore, only indium was dissolved by the anodic reaction into the fused salt from the mixed amalgam of tin and indium, whereas only tin was dissolved in an aqueous solution at room temperature. Thus, it was suggested that amalgamated metals behaved in a different manner at high temperature from those at low temperature. Activities and activity coefficients of indium (10-13) and tin (14-16) in their amalgams at around room temperature have been measured by many workers. However, they have scarcely been investigated at high temperature except a few reports (15, 17).

The present work deals with determination of activities and activity coefficients of indium and tin in their amalgams at high temperature. The results were compared with those obtained at around room temperature and the thermodynamic properties of indium and tin amalgams are discussed.

Experimental

Materials and apparatus.—Metals used in this study were 99.99% purity. Chemicals were guaranteed reagents.

A Pyrex H-type cell (Fig. 1) was used for potentiometric measurements. The amalgam and fused indium well were connected with platinum wire. Emf measurements were carried out in the temperature region 150°-200°C in a bath thermostated within ± 0.5°C. A universal digital meter Type 2502 (internal resistance > 10^9 ohm, Yokogawa Electric Works) was employed in all potential measurements.

[1] Present address: Argonne National Laboratory, Argonne, Illinois 60439.

Key words: tin amalgam, indium amalgam, activity coefficient, high temperature.

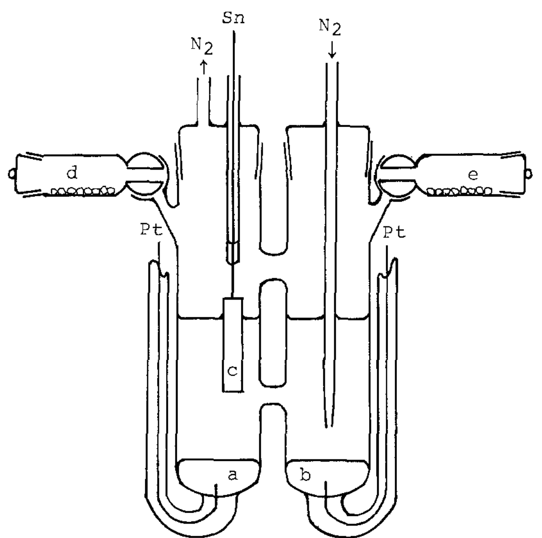

Fig. 1. Schematic diagram of H-cell. In the case of tin amalgam, mercury is used for a and b, tin for c, d, and e. In the case of indium amalgam, mercury is used for b and indium for a and e. Both c and d are not in use.

Experimental procedure.—Anhydrous indium (I) chloride was prepared with indium metal and mercury (I) chloride by the method of Clark (18). Aluminum chloride was reduced to powder in a dry-box, and then heated for 15 hr at 90°C *in vacuo* to remove hydrogen chloride and moisture (8). Powdered sodium chloride was dried for 2 hr at 250°C and tin(II) chloride for 2 hr at 100°C *in vacuo*. The fused salts consisting of 51.6 mole per cent (m/o) aluminum chloride, 43.8 m/o sodium chloride, and 4.6 m/o indium(I) chloride and of 53.5 m/o aluminum chloride, 45.5 m/o sodium chloride, and 1.0 m/o tin(II) chloride were used as cell electrolytes for potentiometric measurements of indium and tin amalgams, respectively. These salts were preheated in bubbling nitrogen for 10 hr at 180°C in order to form a single phase and to remove a very small amount of hydrogen chloride. These were cooled to room temperature and reduced to powder, and then charged into the legs of the emf cell under a nitrogen atmosphere.

Indium was cut to obtain the fresh surface with a grease-free stainless steel cutter and then used as soon as possible. Tin was degreased with benzene and methyl alcohol, and then rinsed with concentrated sulfuric acid for 30 sec. It was then rinsed with distilled water and methyl alcohol and dried *in vacuo* immediately before use.

Under a nitrogen atmosphere, all emf measurements were carried out in a cell containing electrodes of a pure metal of tin or indium and an amalgam of a known concentration of tin or indium. The amalgam was produced by dissolving weighed metallic tin or indium (d or e in Fig. 1) in mercury (a or b in Fig. 1) under a nitrogen atmosphere after the salts were fused, and agitated for 10 min.

Results and Discussion

Activities and activity coefficients of indium and tin in their amalgams.—The activity ($a_{M\text{-}Hg}$) and activity coefficient ($\gamma_{M\text{-}Hg}$) of a metal M in the amalgam at high temperature were measured by applying the method of Butler (11).

The cell is described as

$$M \mid M^{n+} \mid \text{amalgam} \qquad [\alpha]$$

The electromotive force ($E_{M\text{-}Hg}$) of the cell is given by Eq. [1]

$$\begin{aligned} E_{M\text{-}Hg} &= [E^o_{M\text{-}Hg} - (RT/n\mathbf{F})\ln (a_{M\text{-}Hg}/a_{M^{n+}})] \\ &\quad - [E^o_M - (RT/n\mathbf{F}) \ln (1/a_{M^{n+}})] \\ &= (E^o_{M\text{-}Hg} - E^o_M) - (RT/n\mathbf{F}) \ln a_{M\text{-}Hg} \end{aligned} \qquad [1]$$

$E^o_{M\text{-}Hg}$ and E^o_M denote the normal amalgam potential and the standard electrode potential, respectively. As long as the composition of the fused salt and the temperature are kept constant, $(E^o_{M\text{-}Hg} - E^o_M)$ is given as a constant. Therefore, Eq. [1] is reduced to

$$E_{M\text{-}Hg} = E^* - (RT/n\mathbf{F}) \ln a_{M\text{-}Hg} \qquad [2]$$

$$= E^* - (RT/n\mathbf{F}) \ln X_{M\text{-}Hg} \cdot \gamma_{M\text{-}Hg} \qquad [2']$$

where E^* is a constant and $X_{M\text{-}Hg}$ the mole fraction of the amalgam. Equation [2'] is rearranged to

$$E_{M\text{-}Hg} + (RT/n\mathbf{F}) \ln X_{M\text{-}Hg} = E^* - (RT/n\mathbf{F}) \ln a_{M\text{-}Hg} \qquad [3]$$

$E_{M\text{-}Hg}$ is determined against $X_{M\text{-}Hg}$ at a constant composition and temperature of the fused salts. The value of the left-hand side of Eq. [3] is plotted against $X_{M\text{-}Hg}$. If $\gamma_{M\text{-}Hg}$ is defined to approach unity at the infinitely dilute amalgam, the extrapolation of the amalgam concentration toward zero gives the value of E^*. Thus the activity and activity coefficient of a metal in the amalgam are calculated by Eq. [4].

$$a_{M\text{-}Hg} = X_{M\text{-}Hg} \cdot \gamma_{M\text{-}Hg} = \exp(n\mathbf{F}/RT)(E^* - E_{M\text{-}Hg}) \qquad [4]$$

Activities and activity coefficients of indium and tin in their amalgams obtained at 150°, 160°, 180°, 190°, and 200°C are listed in Tables I and II. In order to visualize the change of the activities with temperature values of $a_{Sn\text{-}Hg}$ determined in this work are shown in Fig. 2 together with those[2] of Bonnier *et al.* (14) and $a_{In\text{-}Hg}$ in Fig. 3 together with values of Butler (11). In the case of tin amalgam as shown in Fig. 2, the activities and activity coefficients became extremely small at high temperature. It was also seen from Fig. 2 that $\gamma_{Sn\text{-}Hg}$ was nearly constant at a given temperature below 50°C, because the curve of $X_{Sn\text{-}Hg}$ *vs.* $a_{Sn\text{-}Hg}$ was approximately linear at the temperature. In the case of indium amalgam (Fig. 3), the activities and activity coefficients changed very little with temperature (especially at low concentration). Therefore, it is seen from these results that the temperature coefficient of $\gamma_{M\text{-}Hg}$ depended upon the amalgamated metals.

The temperature dependence of activity coefficients and thermodynamic properties of amalgams.—It is considered that the remarkable difference of the temperature dependence of $\gamma_{In\text{-}Hg}$ and $\gamma_{Sn\text{-}Hg}$ is favorable to separate indium from a mixed amalgam of tin and indium by means of the fused salt electrolysis with

[2] The values may be smaller if they are calculated by our method.

[a] The value of saturated amalgam with excess solid tin present.

amalgam. In the following section the difference is discussed on the basis of thermodynamics.

If the reaction of a metal ion with a mercury electrode is described as follows

$$M^{n+} + ne + Hg = \text{M-amalgam} \quad [\beta]$$

the electrode potential (E'_{M-Hg}) is generally represented as follows (19)

$$E'_{M-Hg} = E^o_{M-Hg} - (RT/n\mathbf{F}) \ln (a_{M-Hg}/a_{M^{n+}}) = E^o_M + E_s + (RT/n\mathbf{F}) \ln a_{sat} + (RT/n\mathbf{F}) \ln a_{M^{n+}} - (RT/n\mathbf{F}) \ln a_{M-Hg} \quad [5]$$

where a_{sat} denotes the activity of a saturated amalgam with the metal M. E_s is defined as $-\Delta F/n\mathbf{F}$ provided that the change in free energy of the following reaction is given as $-\Delta F$

$$xM(S) + yHg = M_xHg_y(S) \quad [6]$$

where S represents a solid state and M_xHg_y a compound of metal M with mercury. In addition, E_s is regarded as the electromotive force of a cell which consists of electrodes of a metal and an amalgam saturated with the metal; M | M^{n+} | M-amalgam(sat). If the equilibrium potential of the reaction [β] is measured against the electrode potential of the metal M and if the temperature and the composition of the fused salt are equal to those in the cell [α], the following equation is derived from Eq. [2] and [5]

$$E'_{M-Hg} - E^o_M - (RT/n\mathbf{F}) \ln (1/a_{M^{n+}}) = E_{M-Hg} \quad [7]$$

Insertion of Eq. [7] into Eq. [5] leads to

$$E_{M-Hg} = E_s + (RT/n\mathbf{F}) \ln a_{sat} - (RT/n\mathbf{F}) \ln a_{M-Hg} \quad [8]$$

Therefore, from Eq. [2] and [8] we obtain

$$E^* = E_s + (RT/n\mathbf{F}) \ln a_{sat} \quad [9]$$

Values of E_{M-Hg} and E^* for indium amalgam and tin amalgam were determined, and are listed in Tables I and II. The values of E^*, $(E^* - E_{M-Hg})$, $\exp(n\mathbf{F}/RT)(E^* - E_{M-Hg})$ and ratio of a_{M-Hg} (temperature change, 30°C) at the mole fraction of 0.0111 for tin amalgam and of 0.0180 for indium amalgam are shown in Table III. In the case of tin amalgam the activity ratio was given as 1.39, while the ratio was 1.01 for indium amalgam. The value of a_{M-Hg} was greatly affected by E^* as shown in Table III.

In the case of indium amalgam the change of E^* with temperature was close to that of E_{In-Hg}. However, in the case of tin amalgam the change of E^* was extremely smaller than that of E_{Sn-Hg}. These tendencies were observed over the whole range of the amalgam concentration studies as shown in Tables I and II. Then it is concluded that the difference between the changes of activities (or activity coefficients) of indium and tin in their amalgams with temperature was due to the variation in the change of E^* of these amalgams with temperature. Such a conclusion was confirmed by the temperature dependence of E^* between 25° or 30°C and 180°C, which is shown in the third column of Table IV. The change in E^* with temperature for indium amalgam is extremely larger than that for tin amalgam.

Fig. 2. Activities of tin in the amalgam. ——— Bonnier *et al.* (14), —○—○— present work.

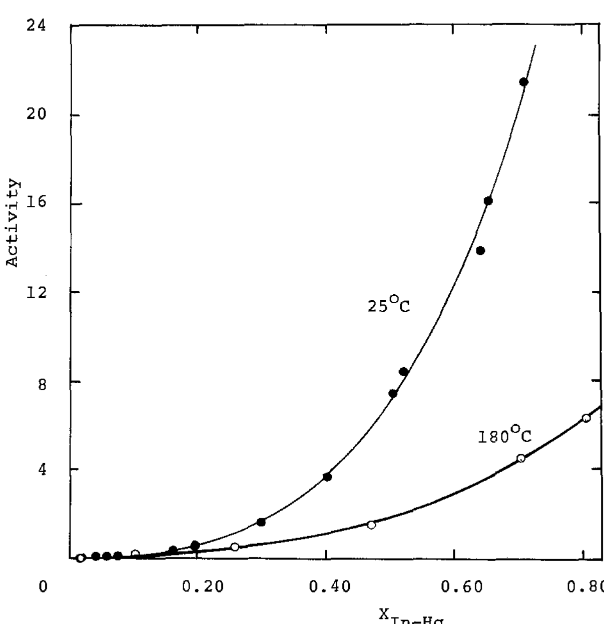

Fig. 3. Activities of indium in the amalgam. —●—●— Butler (11), —○—○— present work.

Table III. Measured and calculated values of each term at a given temperature

Amalgam (X_{M-Hg})	Temp. (°C)	E^* (mV)	E_{M-Hg} (mV)	$E^* - E_{M-Hg}$ (mV)	$\exp(nF/RT) \times (E^* - E_{M-Hg})$	Ratio of a_{M-Hg} (temp. change, 30°C)
Tin amalgam	150	−56.4	+24.0	−80.4	0.0121	1.39
(0.0111)	180	−56.8	+35.7	−92.5	0.00872	
Indium amalgam	160	+78.0	+228.0	−150.0	0.0179	1.01
(0.0180)	190	+84.3	+245.0	−160.7	0.0178	

In order to consider the change in E^* with temperature, $(RT/n\mathbf{F}) \ln a_{sat}$ and E_s at 25°, 30°, and 180°C were calculated by the use of Eq. [9] and are listed in Table IV. The change in E_s for both tin and indium amalgams with temperature were very small, *i.e.*, 3.1 and 0.1 mV, respectively. Furthermore, the values of E_s for indium and tin amalgams were approximately zero at both 25° or 30°C and 180°C.

Types of amalgamation reactions of indium and tin amalgams.—Information obtained above is discussed separately on indium and tin amalgams.

1. Indium amalgam.—Thermodynamic properties of indium amalgam observed are summarized as follows: (*i*) The change of a_{In-Hg} with temperature was very small at a given concentration (especially at low concentration). (*ii*) E_s was practically zero and independent of temperature. (*iii*) E^* varied with temperature.

From the Gibbs-Helmholtz equation, we lead to

$$\Delta H = \Delta G + T[\partial(-\Delta G)/\partial T] = -T^2[\partial(\Delta G/T)/\partial T] \quad [11]$$

When the relation $\Delta G = RT \ln (a_1/a_2)$ is inserted into Eq. [11] and a differential version is used, the change of the activity ratio with temperature is represented as the following equation

$$d \ln (a_1/a_2)/dT = -\Delta H/RT^2 \quad [12]$$

where a_1 and a_2 are activities, and $\Delta H = \Delta H_2 - \Delta H_1$. Subscripts show the states 1 and 2. Since the change of the activity of indium in the amalgam with temperature is very small, we obtain

$$\Delta H \simeq 0 \quad [13]$$

On the other hand, Kirchhoff's law gives the following relationship

$$\Delta H_T = \Delta H_0 + \int_0^T \Delta C_p \, dT \quad [14]$$

Combining Eq. [13] with [14], we obtain

$$\int_0^T \Delta C_p \, dT \simeq 0 \quad [15]$$

According to Kubaschewsky (20) ΔC_p's of indium and mercury are very small and independent of temperature, *i.e.*, 7.24[3] and 6.61 cal/deg·mol, respectively. Thus, it is expected that ΔC_p of indium amalgam is also small provided that there is no special interaction between indium and mercury in the amalgam. Therefore, it seems reasonable to assume that indium amalgam is a simple mixture of indium and mercury. In addition, this assumption satisfactorily explains the property (*ii*), because it is considered from Eq. [15] that both the value of ΔF[4] and the change with temperature are small.

[3] As an amalgamated indium is liquid, a value of fused indium is quoted. This value is nearly independent of temperature below 527°C.

Table IV. Calculated values of each term at a given temperature by using Eq. [9]

Amalgam	Temperature (°C)	E^* (mV)	$(RT/n\mathbf{F})\ln a_{sat}$ (mV)	E_s (mV)
Tin amalgam	30[a]	−56.2	−54.7	−1.5
	180	−56.8	−58.4	+1.6
Indium amalgam	25[b]	+26.3	+26.4	−0.1
	180	+82.5	+82.5	0

[a] Calculated from data of Bonnier *et al.* (14).
[b] Calculated from data of Butler (11).

Bros (21) and Kleppa (22) found that ΔH of indium amalgam was approximately constant against temperature. Butler (11) assumed that indium amalgam was a regular solution in his study of ΔS of indium amalgam at room temperature. These studies support our consideration. Thus, it is concluded that indium amalgam is the simple mixture of indium and mercury.

2. Tin amalgam.—The thermodynamic properties of tin amalgam are summarized as follows. (*i*) E_s was nearly equal to zero and varied very little with temperature. (*ii*) γ_{Sn-Hg} was approximately constant with the concentration change at a constant temperature below 50°C. (*iii*) γ_{Sn-Hg} largely changed with temperature. (*iv*) E^* was practically independent of temperature.

As shown in Fig. 2, a_{Sn-Hg} varied largely with temperature. Therefore, it would be expected that ΔF and ΔH of tin amalgam varied largely with temperature. Kozin (15) found that the change in ΔF of tin amalgam with temperature was large. The fact that E_s was nearly independent of temperature is inconsistent with these results. According to the general treatment (19) as stated in the previous section, all metal atoms in a saturated amalgam must exist as M_xHg_y. However, indium amalgam can be regarded as a simple mixture of indium and mercury rather than In_xHg_y as we pointed out. Smallman (23), Halder (24), and Folley (25-27) reported that Tl_2Hg_5 was formed in a simple mixture of thallium and mercury and the amount of Tl_2Hg_5 varied with the temperature and concentration of thallium amalgam. Namely, all metal atoms in an amalgam do not always exist as M_xHg_y. In such cases results obtained may not be satisfactorily interpreted by the general treatment.

The amalgamation reactions of metals may be divided into three types as follows

$$xM^{n+} + xne + Hg \rightarrow M_xHg_y$$
[A compound M_xHg_y is formed in mercury] [A]

$$M^{n+} + ne + Hg \rightarrow M(Hg)$$
[A simple mixture of metal M and mercury] [B]

$$(x+1)M^{n+} + (x+1)ne + Hg \rightarrow M_xHg_y(M(Hg))$$
{A compound M_xHg_y is dissolved in a simple mixture of metal M and mercury} [C]

where mercury exists in large excess. Compounds of tin with mercury such as $SnHg_2$, SnHg, Sn_2Hg, Sn_3Hg, Sn_4Hg, and Sn_5Hg were reported and heat capacities of these compounds were estimated to be large (28). Hinzner (29) also suggested that Sn_xHg_y is formed when tin dissolves in mercury. Therefore, if it is assumed that the amalgamation reaction of tin belongs to the type (C), *i.e.*, Sn_xHg_y exists in Sn(Hg), and moreover, that a large portion of tin exists as Sn_xHg_y, we can conclude that: (*I*) $-\Delta H$ of tin amalgam largely changes with temperature, because a complex com-

[4] It should be noted that ΔG can be rewritten in terms of ΔF at constant pressure and volume. Therefore, in the following section, discussion is made in terms of ΔF instead of ΔG.

pound such as Sn_xHg_y has a large heat capacity and in general the heat capacity of such a compound is a function of temperature (20), and (*II*) $\gamma_{Sn\text{-}Hg}$ is practically independent of the concentration of tin amalgam [the property (*ii*)], because a large portion of tin in the amalgam exists as Sn_xHg_y and the interaction between Sn_xHg_y and Sn_xHg_y may be much smaller than that between Sn and Sn in the amalgam.[5] However, $\gamma_{Sn\text{-}Hg}$ is slightly affected with the concentration change, because tin in the amalgam may not exist entirely as Sn_xHg_y and the interaction between Sn_xHg_y and Sn_xHg_y is not negligible. These tendencies may become strong at high temperature.

From the above (*I*), it is considered that $\gamma_{Sn\text{-}Hg}$ decreases rapidly with temperature [the property (*iii*)]. Thus, the results can reasonably be explained by assuming that the amalgamation reaction of tin belongs to type [C].

As described above, the fact that indium is separated from the mixed amalgam of tin and indium is attributed to the wide variation of $\gamma_{Sn\text{-}Hg}$ and to the approximately constant $\gamma_{In\text{-}Hg}$ with temperature. It can also be concluded that the difference is ascribed to the different amalgamation reaction type, *i.e.*, indium amalgam belongs to type [B] and tin amalgam to type [C]. On the other hand, it should be noted that the temperature dependence of E^* (*i.e.*, $E^o_{M\text{-}Hg}$) has a great influence on that of $E_{M\text{-}Hg}$. Because $E_{M\text{-}Hg}$ is affected not only by the change of $\gamma_{M\text{-}Hg}$ (and $a_{M\text{-}Hg}$) with temperature but also by the change of $E^o_{M\text{-}Hg}$ with temperature as described by the following equation

$$E_{M\text{-}Hg} = E^o_{M\text{-}Hg} - (RT/n\mathbf{F}) \ln (a_{M\text{-}Hg}/a_{M^{n+}}) \quad [16]$$

The relationship of the temperature dependence of E^* to the amalgamation reaction type is under investigation, and the results will be published shortly.

Conclusion

The reason why indium is separated effectively from a mixed amalgam of tin and indium by means of the fused salt electrolysis with amalgam was investigated. The potential of indium amalgam was far less noble than the potential of tin amalgam at high temperature, because $\gamma_{Sn\text{-}Hg}$ decreased rapidly with temperature (and E^*_{Sn} was kept practically constant), while $\gamma_{In\text{-}Hg}$ was approximately constant (and E^*_{In} increased fairly). From the temperature dependence of the activity coefficient, we concluded that indium amalgam is the simple mixture of indium and mercury (type [B]), whereas tin amalgam contains a complex such as Sn_xHg_y dissolved in a simple mixture of tin and mercury (type [C]).

[5] It is known that metal M in an amalgam is very active and compound M_xHg_y in the amalgam is stable (30).

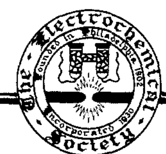
Technical Notes



Effect of the Rate of Cooling on the Emission of CaS:Ce Phosphor

D. R. Vij and V. K. Mathur

Department of Physics, Kurukshetra University, Kurukshetra, India

Calcium sulfide phosphors are among the earliest phosphors to be synthesized in the laboratory. The bright emission and persistent afterglow of these phosphors led to their extensive investigations by the "Lenard School" (1). However, due to inadequate techniques employed in their synthesis, the resulting phosphors were of poor reproducibility and were found to be unstable against atmospheric carbon dioxide and water vapor. Successful attempts have since been made to synthesize calcium sulfide phosphors which are stable as well as reproducible (2-4).

We have been able to synthesize (5) a stable and reproducible CaS:Ce phosphor from $CaSO_4$. The reduction of $CaSO_4$ by carbon and the incorporation of activator (Ce) in the host lattice of CaS is achieved in a single process of firing at a comparatively lower temperature of 900°C in the presence of a flux. Later it was discovered by us that due to the hygroscopic nature of the flux it absorbed water vapor from the atmosphere and thereby impaired the emission properties of the phosphor. Surprisingly enough the flux could be removed by washing with water, and the phosphor product thus obtained did not show any deterioration in its emission properties even after a few weeks exposure to the atmosphere.

We have studied thermoluminescence (5), thermally stimulated conductivity (6), and spectral characteristics (7) of these phosphors. The emission of CaS:Ce phosphor consists of a green and a yellow band. It was observed (7) that at lower concentration of cerium, the green emission is predominant, while at higher concentration, the yellow emission is enhanced at the expense of green emission. Lehmann and Ryan (8), however, state that the intensity ratio of the two bands is independent of all preparational parameters. These authors synthesized the CaS:Ce phosphors by the method of Wachtel (4) and further found that the addition of chlorine enhances very much the emission of the phosphor. Smith (9) succeeded in synthesizing these phosphors without the addition of any flux (in our method, a flux is essential for the synthesis of the phosphor) or even without the addition of any chlorine, which according to Lehmann is an essential ingredient for their bright emission. Smith observed the effect of a varying Ce^{+++} concentration on the emission similar to the one reported by us (7) but unlike the observations of Lehmann and Ryan (8).

We wish to report here the effect of the rate of cooling of the charge after firing, which is one of the interesting parameters (10) among many found to affect the emission of the CaS:Ce phosphor.

Experimental

The CaS:Ce phosphor was synthesized by the method developed by Bhawalkar (11). A charge was prepared by mixing 5g of $CaSO_4 \cdot 2H_2O$ powder with 1.5g of anhydrous Na_2SO_4. An appropriate quantity of carbon, slightly in excess of that needed to reduce $CaSO_4$ completely, was added to this charge. Cerium was added in the form of a solution of $Ce(NO_3)_3 \cdot 6H_2O$ in triply distilled water. The percentage of Ce was varied from 0.02 to 1.0 by weight of $CaSO_4 \cdot 2H_2O$.

After proper mixing, the whole charge was fired in a Salamender graphite crucible at 900°C in a muffle furnace for 2 hr. Additional carbon was fired in a separate crucible in the muffle furnace to create a reducing atmosphere in the furnace. Finally, after firing, the mass was crushed to a fine powder. Flux was removed by washing of the powder in boiling double distilled water for 2-3 min, and it was dried at 150°C. The phosphor thus prepared was found to be stable and unaffected by the moisture in the atmosphere.

CaS:Ce(0.08%) was the most intense green emitting phosphor (10). The effect of rate of cooling after proper firing was evaluated on this sample. After firing of the above mentioned charge for 1 hr, the whole mass was brought out of the furnace, crushed to powder to ensure proper reduction in the interior volume of the charge. At this stage, it was divided into two parts and again placed in the furnace in two separate crucibles. After firing for one more hour, the charge of one of the crucibles was brought out and crushed immediately. If this is not done and the charge is allowed to cool as such, the outer crust of the mass would cool down while the interior volume of the hot mass still remains at high temperature. By crushing, the whole mass cools homogeneously at a faster rate. The other part of the phosphor placed in another crucible was left as such in the furnace. It was cooled with the average rate of 50°C/hr.

To observe the emission, the samples were excited by short wave UVS-12 lamp which predominantly emits 3650A radiations. The emission was observed with the help of a constant deviation spectrometer, to which was attached a photomultiplier tube, Type 1P21. For TL studies, the phosphor was excited to saturation using u.v. radiations. The heating of the phosphor was started after 90 sec of decay. The rate of heating was 0.25°C/sec. The resulting TL was measured with the help of 1P21 photomultiplier. The details of experimental setup are described elsewhere (5).

Results

The emission spectra of slow and fast cooled samples of CaS:Ce(0.08%) are shown in Fig. 1. As is obvious from the curves, the slow-cooled sample exhibits brighter emission (see curve-I, Fig. 1) than the fast-cooled one (see curve-II. Fig. 1). Both the bands in the green and yellow regions are of higher intensity in the slow cooled sample.

In Fig. 2 the thermoluminescence curves of the two samples are plotted. In this case the effect of rate of cooling is opposite to that of emission, *i.e.*, the slow-cooled sample gives rise to low intensity of TL (see

curve-I, Fig. 2) as compared to the fast-cooled one which emits higher intensity of TL (see curve-II, Fig. 2).

Discussion

At the temperature of firing the lattice has a large density of defects which tends to "freeze" during fast cooling. It is well known that these defects give rise to trapping centers in sulfide phosphors. On the other hand if the phosphor is cooled slowly, the lattice would have sufficient time to adjust itself and come to an equilibrium state corresponding to that particular temperature. This results in a smaller density of defects and consequently of traps. The above mentioned facts are borne out by the thermoluminescence studies reported in Fig. 2. It is seen that the area under the glow curve of the fast-cooled sample (curve-II) is more than the area under the glow curve of the slow-cooled sample. It may therefore, appear that the smaller density of defects in a slow-cooled sample results in well-defined luminescent centers increasing thereby the probability of radiative transitions. Therefore, it appears that for higher emission efficiency, the samples should be cooled very slowly.

Acknowledgments

The authors wish to acknowledge the keen interest shown by Prof. N. Nath during the course of these studies. One of the authors (D.R.V.) also acknowledges the financial assistance from the Council of Scientific and Industrial Research, India, in the form of a Senior fellowship during the tenure of the work.

Infrared-to-Visible Conversion in YOF:Yb^{3+}, Ho^{3+} and YF_3:Yb^{3+}, Ho^{3+} Phosphors

J. Wojciechowski, I. Pawelska, R. Grodecki, and L. Szymanski

Institute of Electron Technology, Al. Lotnikow 32/46, Warsaw, Poland

In recent years there has been much interest in phosphors that emit visible radiation when excited with infrared radiation from Si-doped GaAs electroluminescent diode source (1).

These phosphors, in general, contain Yb^{3+} ions absorbing infrared radiation of about 1 μm and transferring excitation in two or more sequential steps to activator ions.

The most frequently used sensitizer-activator systems are: for green and red radiation, Yb^{3+}-Er^{3+}, and for blue radiation, Yb^{3+}-Tm^{3+}. Green radiation can also be obtained with Yb^{3+}-Ho^{3+} system, but the efficiency of Ho^{3+} activated phosphors is smaller in comparison with Er^{3+} activated phosphors. This is the reason why the Yb^{3+}-Ho^{3+} system is the object of investigation only in a small number of papers (2, 3) and processes of energy transfer, stepwise excitation, and radiation deexcitation are not fully explained.

In this paper some comments on the dynamics of infrared-to-visible conversion in the Yb^{3+}-Ho^{3+} system are given and also some advantages of Ho^{3+} activated phosphors are shown.

Key words: anti-Stokes luminescence, Yb^{3+}-Ho^{3+} system, excitation processes, visible emission.

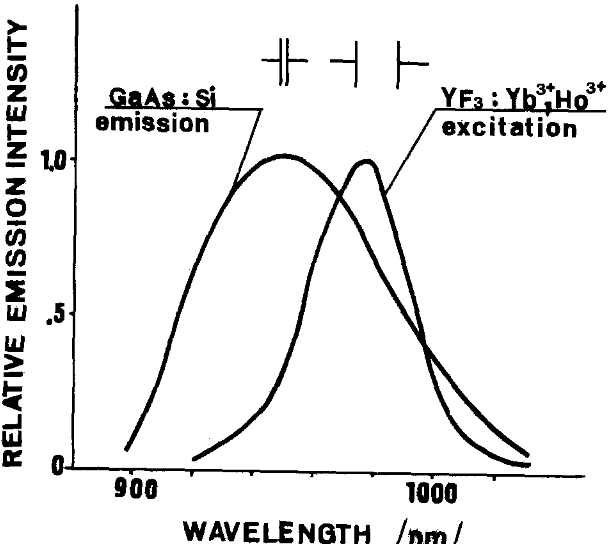

Fig. 1. Excitation spectrum of YF_3:Yb^{3+},Ho^{3+} compared with emission spectrum of Si-GaAs diode.

Experimental Procedures

Samples of phosphors were made according to the usual methods. As starting materials very high purity oxides were used: Y_2O_3 (6*N*), Yb_2O_3 (5*N*), and Ho_2O_3 (4*N*).

YOF:Yb^{3+},Ho^{3+} phosphor was made according to the method described by Matsubara (4) and YF_3:Yb^{3+},Ho^{3+} phosphor was made in a similar manner, but in this case the possibility of oxidation was thoroughly eliminated. The temperature in a furnace was about 1100°C. Ho^{3+} activated phosphors were compared with YF_3:Yb^{3+},Er^{3+} phosphor prepared in the same way. As a rule samples of composition $Y_{0.80}Yb_{0.198}Ho_{0.002}OF$, $Y_{0.80}Yb_{0.198}Ho_{0.002}F_3$, and $Y_{0.80}Yb_{0.19}Er_{0.01}F_3$ were used.

As an infrared radiation pump source, an Si-doped GaAs diode was used, with 2% efficiency and peak emission at 950 nm.

The excitation source for infrared excitation spectra was 800W tungsten-iodine light suorce.

Results and Discussion

The excitation spectrum of YF_3:Yb^{3+},Ho^{3+} for green emission is shown in Fig. 1. The excitation resolution is indicated. In Fig. 1 also shown is the emission spectrum of the Si-GaAs diode.

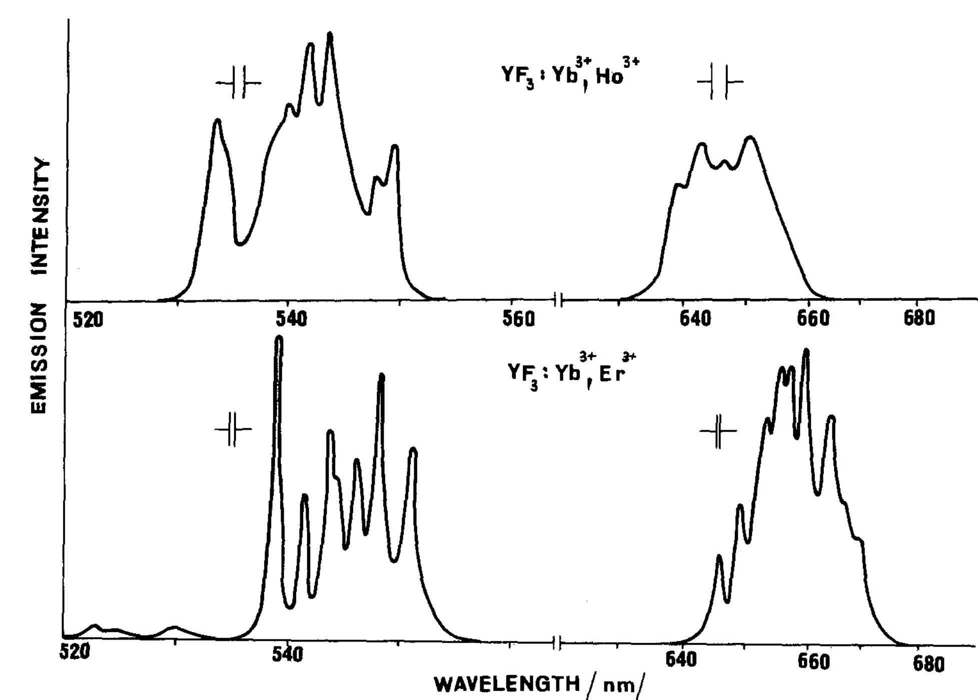

Fig. 2. Visible radiation spectra of YF_3:Yb^{3+},Ho^{3+} and YF_3:Yb^{3+},Er^{3+}.

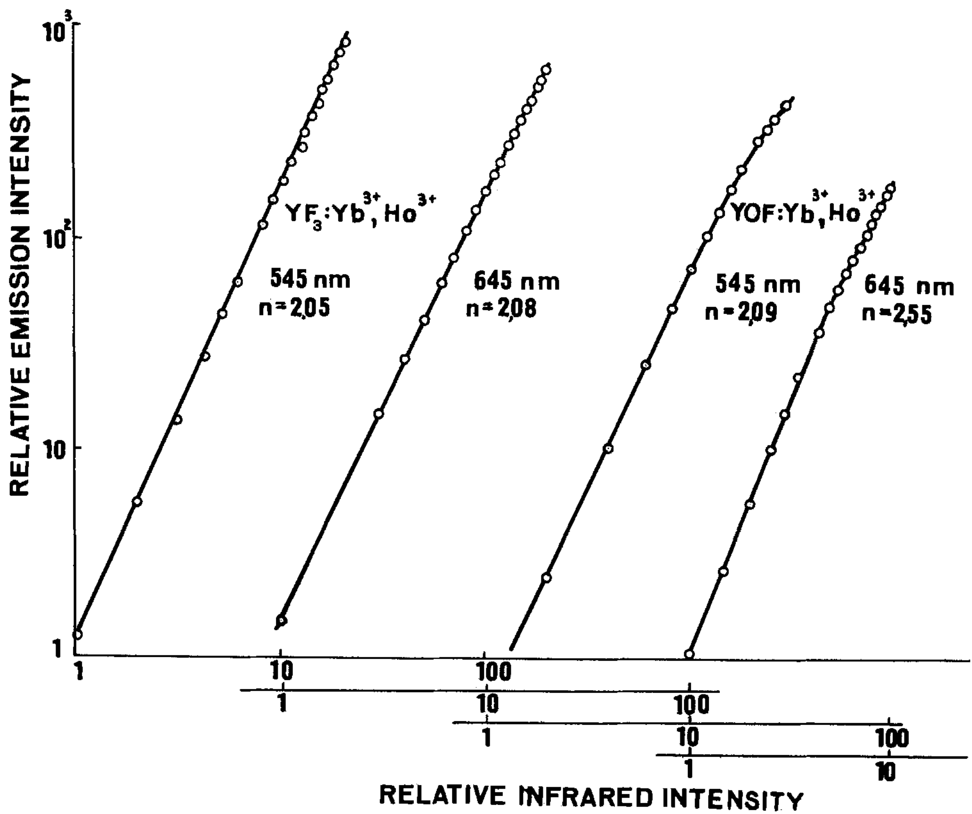

Fig. 3. Dependence of green and red emission from $YF_3:Yb^{3+}$, Ho^{3+} and $YOF:Yb^{3+},Ho^{3+}$ on Si-GaAs infrared pump intensity.

The excitation spectrum consists of a narrow band, with peak at 975 nm. Investigation of other compositions $YOF:Yb^{3+},Ho^{3+}$ and $YF_3:Yb^{3+},Er^{3+}$ indicates that this property is generally true for all systems investigated. Differences in shape of infrared excitation spectra are very small.

Visible radiation spectra of phosphors excited by the Si-doped GaAs diode are shown in Fig. 2. In upper

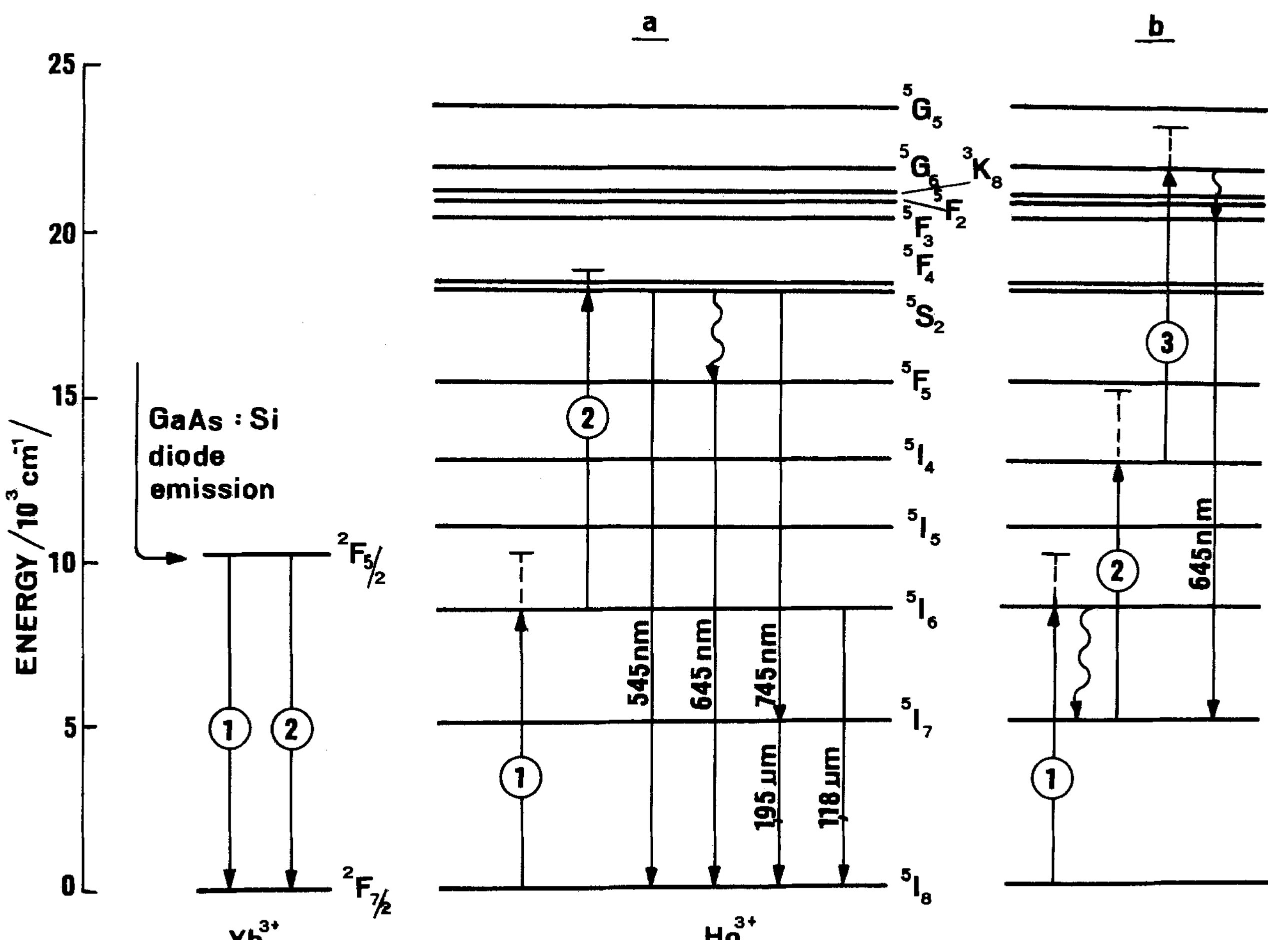

Fig. 4. (a). Infrared-to-visible conversion in $YF_3:Yb^{3+},Ho^{3+}$. (b). Three-photon excitation of red emission in $YOF:Yb^{3+},Ho^{3+}$.

part of this figure radiation spectra of $YF_3:Yb^{3+},Ho^{3+}$ are given, in lower part, that of $YF_3:Yb^{3+},Er^{3+}$. In all cases strong green emission is observed.

In $YF_3:Yb^{3+},Ho^{3+}$ phosphor the green emission is in a series of lines between 530 nm and 555 nm, near the peak of the normal eye sensitivity. Some weak lines (not to scale on Fig. 2) are also observed near 645 nm.

The intensity of green and red emission varies almost proportionately to the square of the infrared pump power (Fig. 3). This indicates that the excitation process involves two successive transfers of energy from Yb^{3+} ions, as shown in Fig. 4a. A phonon-assisted transfer from Yb^{3+} to the $^5I_6$ state of Ho^{3+} is followed by second transfer exciting Ho^{3+} to the $^5S_2$, $^5F_4$ states. Green emission arises from transitions from the $^5S_2$ state to the $^5I_8$ ground state. Weak red emission arises according to the $^5F_5 - {^5I_8}$ transition.

Visible emission is accompanied by very weak emission in the infrared, near 745 nm, 1.18 μm and 1.95 μm. Emission at 745 nm arises from transitions from $^5S_2$ to $^5I_7$ state. Emission at 1.18 μm is given as a radiative decay to the ground state from $^5I_6$, after first energy transfer from Yb^{3+} ion. Intensity of this radiation varies linearly with infrared pump intensity. Emission at 1.95 μm corresponds to the transition from $^5I_7$ to $^5I_8$ and can arise as a consequence of multiphonon transition from $^5I_6$ to lower lying state or can be combined with 745 nm radiation.

In $YOF:Yb^{3+},Ho^{3+}$ phosphor the visible spectra are similar in shape, in comparison with $YF_3:Yb^{3+},Ho^{3+}$ spectra, but in the oxyfluoride the dependence of emission intensity on infrared pump power gives a slope of about 2.55 for the red emission. This indicates contributions from both two- and three-photon processes.

The most probable three-photon excitation process of red emission is shown in Fig. 4b. The first step of excitation is from $^5I_8$ to $^5I_6$ and then a multiphonon decay to $^5I_7$ follows. After the next two steps of excitation shown in Fig. 4b the 645 nm emission results from the $^5F_3$ to $^5I_7$ transition.

Another three-photon excitation process can also be considered which would be followed by excitation of higher lying states, *e.g.*, $^5G_4$ and $^5G_5$. But probably such is not the case because visible and ultraviolet radiation at wavelengths shorter as 530 nm is not observed. Such blue and ultraviolet light in the Yb^{3+}-Er^{3+} system was observed by Johnson and his coworkers (5) as the consequence of the three- and four-photon excitation.

Next, from our measurements of emission spectra the red-to-green ratio of the emission can be estimated. The red-to-green ratio of the emission from $YF_3:Yb^{3+},Er^{3+}$ is about 35 times greater than the red-to-green ratio of the emission from $YF_3:Yb^{3+},Ho^{3+}$ and about 4 times greater than the ratio of the emission from $YOF:Yb^{3+},Ho^{3+}$. Accordingly, the radiation from $YF_3:Yb^{3+},Ho^{3+}$ seems pure green, whereas the radiation from $YF_3:Yb^{3+},Er^{3+}$ is slightly yellower. The possibility of obtaining pure green emission seems advantageous in some technical applications.

It is worth adding here that in $YOF:Yb^{3+},Ho^{3+}$ phosphor the green-to-red ratio of the emission does not depend on Yb^{3+} concentration, as it is seen in $YOF:Yb^{3+},Er^{3+}$ phosphor (4).

Acknowledgments

The authors would like to thank Professor B. Paszkowski and Dr. B. Mroziewicz for encouragement in work and fruitful discussions. They thank Dr. B. Darek for offering some Si-GaAs diodes. The valuable technical assistance of Mr. M. Grabinski is also acknowledged.

The Influence of Leakage Current on Concentration Profile Measurements

P. Kramer, C. de Vries, and L. J. van Ruyven

Semiconductor Development Laboratory, N. V. Philips' Gloeilampenfabrieken, Nijmegen, Netherlands

The capacitance-voltage technique (CV) is a standard method for obtaining the profile of electrically active impurities in semiconductors (1). The method has been automated to create the possibility of routine materials evaluation (2, 3) and many investigators have studied the necessary corrections to obtain the true impurity concentration as a function of depth (4, 5). Besides the above corrections which have a more fundamental nature, Copeland has calculated the correction necessary for test samples consisting of a Schottky barrier test diode on a wafer, due to the extension of the depletion layer under reversed bias (6).

This report describes an additional requirement of a practical nature arising from the reverse current irregularities, quite commonly observed in Schottky diodes (7), prepared by an evaporated metal dot or a confined mercury column (8). Although in most cases the magnitude of the reverse current stays well within the limits for correct measurements (9), it will be shown that even then sudden changes can alter the result substantially. This effect can be in particular very misleading if the samples themselves have large variations in impurity concentration. as is the case in ion implanted material.

Any experimental arrangement requires of course a second contact, which introduces a series resistor with or without a parallel capacitor (see Fig. 1). This series resistor acts as a d-c voltage divider and therefore its value should be small compared to the resistive part of the test diode impedance (9). This requirement, which can be written in conductance form as $G_d/G_s << 1$, is usually fulfilled. Therefore the apparent car-

Key words: impurity profile, diode-capacitance, leakage current, series resistance, silicon.

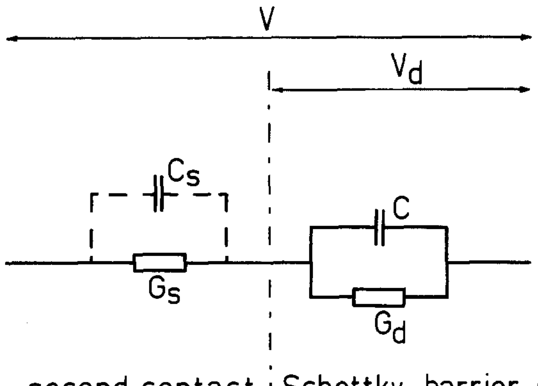

Fig. 1. Diagram of a reversed diode. C = capacity, G_d = parallel conductance, G_s = series conductance.

rier density does not need to be corrected for this small error in voltage, but a sudden change in the sample conductance itself in combination with this series conductance can cause substantial errors. It can be shown that the final result is strongly dependent on the derivative of the conductance with respect to voltage.

The static conductances G_s and G_d give rise to a small difference between V and V_d, being the applied voltage and the true voltage over the Schottky barrier diode (see Fig. 1). Consequently the ratio between V and V_d differs from unity according to

$$V = \left(1 + \frac{G_d}{G_s}\right) V_d \quad [1]$$

Differentiation of Eq. [1] yields

$$\frac{dV}{dV_d} = 1 + \frac{G_d}{G_s} + \frac{V_d}{G_s} \cdot \frac{dG_d}{dV_d} \quad [2]$$

The real carrier density N_d should be derived from

$$N_d = C^3 \frac{dV_d}{dC} \cdot \frac{1}{q\, \epsilon_0\, \epsilon_r\, A^2} \quad [3]$$

in which q is the electron charge, $\epsilon_0\epsilon_r$ the semiconductor permittivity, and A the diode area. However, assuming $C << C_s$, the actual experiment yields

$$N = C^3 \frac{dV}{dC} \cdot \frac{1}{q\, \epsilon_0\, \epsilon_r\, A^2} \quad [4]$$

because only V can be read from the instrument. If we define N_d/N as the relative error in carrier density we can write, by combining [2], [3] and [4]

$$\frac{N_d}{N} = \frac{1}{1 + \frac{G_d}{G_s} + \frac{V_d}{G_s} \cdot \frac{dG_d}{dV_d}} \quad [5]$$

Equation [5] demonstrates that in addition to the G_d/G_s-correction a third term $\frac{V_d}{G_s} \cdot \frac{dG_d}{dV_d}$ should be taken into account. The effect of this term on the final result will be an abrupt increase and decrease in the apparent carrier density at a sudden change in the slope of the leakage current *vs.* voltage.

A number of silicon slices were analyzed with the aid of an inhouse developed doping profile plotter (10). This plotter measures the capacitance C of a mercury-silicon junction (8) as a function of an exponentially increasing blocking voltage V. An analog computer derives dC/dt and dV/dt and uses these values to calculate the concentration N according to Eq. [4]. The concentration and the leakage current are displayed simultaneously on a double beam X-Y-oscilloscope as a function of blocking voltage or depth, which enables the interaction between apparent concentration and leakage to be studied. The capacitance measurement is carried out with a phase sensitive detector circuit; the measuring voltage amounts to 25 mV rms with a frequency of 10 MHz. The blocking voltage ramp has a repetition frequency of 10 Hz and a peak value of 150V.

In Fig. 2 the concentration N and the leakage current I *vs.* blocking voltage V are given for a mercury contact on a 13μ thick 1.4 ohm-cm N-type epitaxial layer on an N^+ substrate, as displayed by the plotter. It appears that a marked peak in the N-curve coincides with a sharp step in the leakage current curve. In this case the back contact on the slice was about 1 cm^2 of silver paste (Leitsilber 100 of Degussa) with a resistance of about 100 ohms, which may represent the major part of the series conductance G_s, which thus becomes 10^{-2} ohm^{-1}. The back contact has a capacitance of about 2×10^4 pF.

As can be seen from Fig. 2, the static conductance just below 14V (arrow) equals $G_d = 65\ \mu A/14V = 4.65 \times 10^{-6}$ ohm^{-1}. The step at 14V gives an increase ΔI of 70 μA, resulting in a static conductance $G_d = 135\ \mu A/14V = 9.65 \times 10^{-6}$ ohm^{-1} just above 14V, hence G_d is increased by an amount dG_d of 5.3×10^{-6} ohm^{-1}. Assuming from the scope picture that this increase occurs over a voltage increment dV_d of 10 mV, dG_d/dV_d becomes 5.3×10^{-4} ohm^{-1} V^{-1}. Substituting these values in Eq. [5] it follows that $N_d/N = 0.57$. Considering the N-value of about 4×10^{15} at $V = 10$V equal to N_d, N should increase at the leakage step to about 7×10^{15} over an increment of 10 mV. Experimentally, the increase is slower than predicted (see Fig. 2) due to the time constant of the analog computer. Similarly, the sudden decrease of dG_d/dV_d on the top of the leakage step determines the shape of the trailing edge of the concentration peak.

Figure 3 represents a 109 ohm-cm homogeneous P-type slice. The leakage current I begins abruptly at $V = 6$V (arrow), which causes a very pronounced peak in the N-curve. At the right-hand side of this

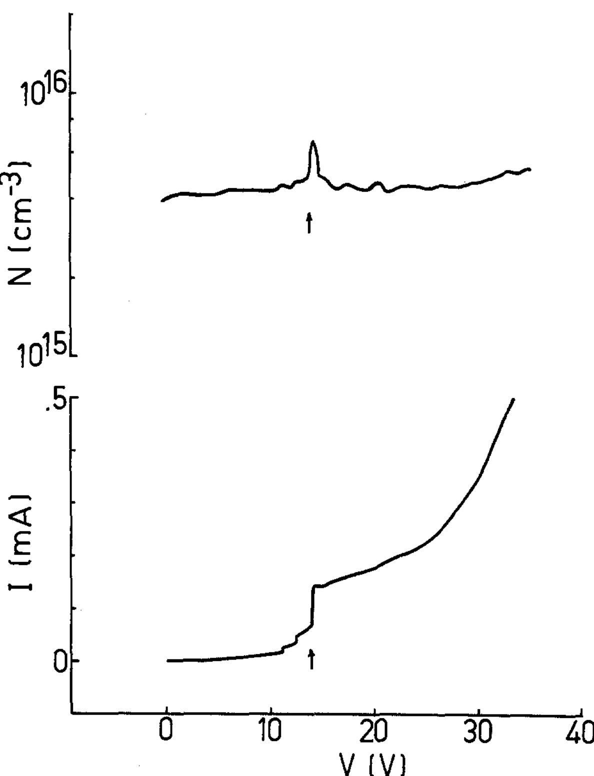

Fig. 2. Curves of apparent concentration N and leakage current I *vs.* blocking voltage V for a mercury contact on a 1.4 ohm-cm N-type epitaxial layer on an N^+ substrate.

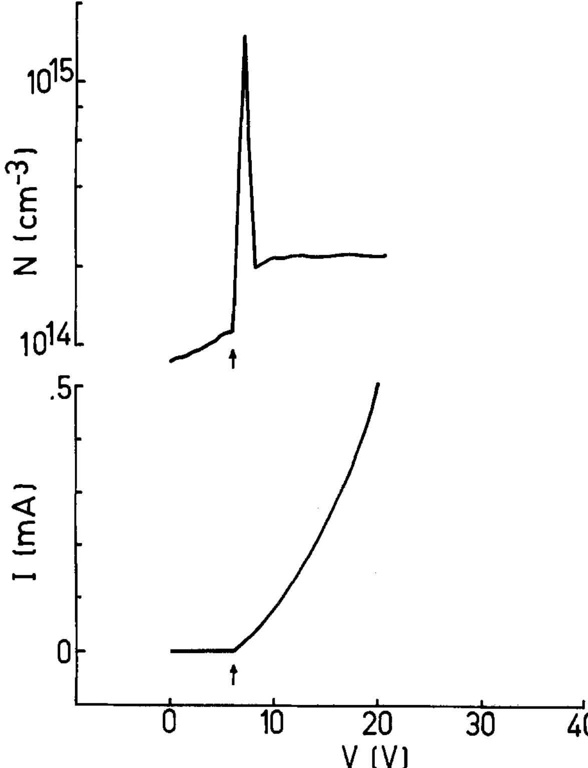

Fig. 3. *N* and *I* vs. *V* curves for a 109 ohm-cm homogeneous P-type slice.

peak the level of N is markedly higher than on the left, which is caused by the persistent increase of G_d at higher voltages. An additional proof of the correlation between the apparent concentration peak and the step in the leakage characteristic is the observation that in case of instability both phenomena always occur simultaneously along the X-axis.

Experiments with a simulating circuit have shown a quantitative confirmation of the phenomenon. This circuit was built up from linear resistors (G_s and G_d), a linear capacitor (C_s), and a low leakage diode (C) according to Fig. 1. G_d was switched on and off at certain values of V, using a mercury switch.

As a result of this study we conclude that an important source of error can be detected if the experimental arrangement is made such that large values of the derivative of the parallel conductance with respect to voltage can be observed. The simultaneous display of the carrier profile and the leakage current turns out to be a practical solution.

Acknowledgments

We would like to express our appreciation to Dr. J. J. Goedbloed and Dr. C. van Opdorp for stimulating discussion and critical comments.

The Origin of the Cubic Rate Law in Zirconium Alloy Oxidation

G. P. Sabol

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

and S. B. Dalgaard*

Westinghouse Nuclear Fuel Division, Pittsburgh, Pennsylvania 15230

The pretransition corrosion kinetics of zirconium and zirconium-based alloys at temperatures of less than about 400°C have been reported (1-3) to deviate from the ideal parabolic behavior characteristic of diffusion control through a thickening homogeneous scale barrier. Reviews of the pertinent work describing the corrosion kinetics have been presented (4, 5), and it appears that the observed rates approach cubic behavior. Moreover, in an extensive test program, Kass (3) has shown that the pretransition kinetics of Zircaloy-2 and -4 are cubic for corrosion in pressurized water in the temperature range studied, 232°-316°C. In this note it is postulated that these cubic kinetics are accounted for by involving mass transfer along grain boundaries and a steadily increasing grain size of the oxide with increasing film thickness.

* Electrochemical Society Active Member.

Key words: zirconium, corrosion, kinetics, cubic, crystallites.

It appears clear from the literature that diffusion of oxygen through the oxide film takes place along preferred paths (6-8), and that these regions of high diffusivity are probably crystallite or grain boundaries (7, 8). From an analysis of $^{17}O_2$ tracer diffusion profiles, Cox and Pemsler (7) have found that the diffusion coefficient of oxygen in ZrO_2 along grain boundaries is greater than that for lattice diffusion by a factor of about 10^4 at 400°-500°C. They conclude, therefore, that all of the oxygen transported through the oxide film during oxidation migrates along grain boundaries and no more than 0.01% is transported via lattice diffusion.

Assuming grain boundary migration as the controlling mechanism, then ideal parabolic kinetics would apply only if the grain boundary area per unit volume of oxide is independent of oxide thickness. However, such is not the case. Recently, the microstructure

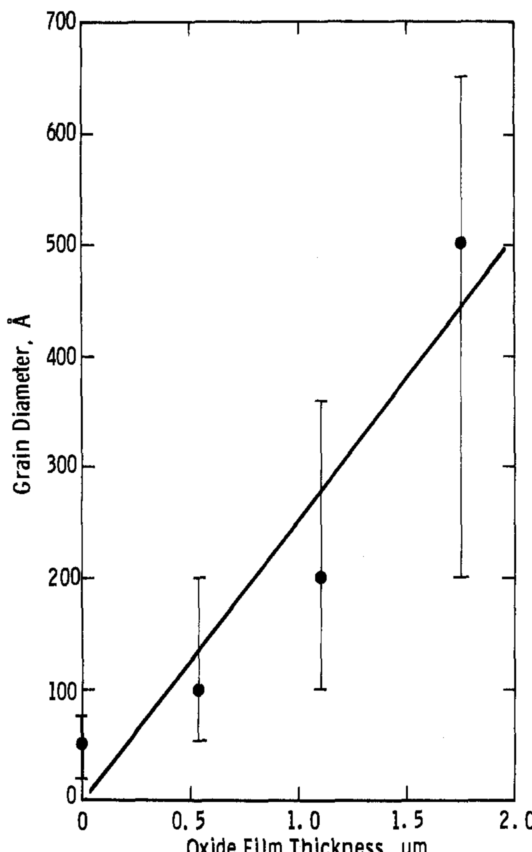

Fig. 1. Grain diameter of the oxide as a function of position in the oxide in the pretransition region for Zircaloy-4. Data taken from Ref. (9) for samples exposed in 360°C water.

of oxide films formed on zirconium alloys has been characterized (9). The grains of the initially formed film were observed to be approximately 50Å or less in diameter, and to retain this size throughout continued exposure in the corrosive environment. This observation is at variance with Cox's suggestion (8, 10) that growth of ZrO_2 crystallites in the oxide by recrystallization may have accounted for variations in the oxidation rate law. Upon increase of the oxide thickness layer crystallites were observed to form at the actively growing metal-oxide interface, and the grain size reached about 500Å at the interface as the film thickness reached 2 μm, the approximate end of the pretransition regime. A plot of the pretransition data reported previously (9) is shown in Fig. 1. The points represent the average grain size of the oxide, and the bars represent the range of sizes observed. Although the data are of insufficient strength to establish the exact relationship between grain size and film thickness, linear behavior is indicated and, therefore, a linear relationship was assumed for simplicity and the line drawn accordingly. Coupling these data with the observation that oxygen migration through the oxide film during low-temperature oxidation takes place primarily along grain boundaries, then, in fact, the kinetics should deviate from parabolic and would be ideally cubic if the linear relationship between grain size and film thickness is valid.

The cubic kinetics can be derived quite easily by setting the rate of film thickening, dx/dt, to be inversely proportional to the integrated resistance to mass transport. In this instance, as the diffusion paths are the grain boundaries, the specific resistance to mass flow is proportional to the film thickness, because the grain boundary area decreases linearly with increasing thickness. Thus, the integrated resistance becomes the square of the film thickness, and the rate of film thickening is given by

$$\frac{dx}{dt} = \frac{k}{x^2}$$

This yields cubic behavior. The actual kinetics would deviate from cubic depending upon the exact relationship between grain diameter and film thickness. Also, volume diffusion at the larger grain size would contribute to deviations. Nevertheless, the present interpretation and analysis lend credence to the postulate that the widely observed cubic rate law in zirconium alloys may be accounted for by progressive increase in the grain size of the oxide.

Conductance-Viscosity Studies on Some Moderately Concentrated Nonaqueous Electrolyte Solutions from –50° to 125°C

II. Solutions of Pr_4NBr, Bu_4NBr, and Bu_4NI in Propylene Carbonate

ABSTRACT

Matching conductance, viscosity, and density data at 25° intervals between −50° and 125°C have been determined and analyzed for moderately concentrated solutions of three quaternary ammonium halides in propylene carbonate. Detailed results are presented for the fitting of experimental data as functions of molal concentration and temperature to appropriate equations by computer least squares procedures. Calculated results related to moles of solvent displaced per mole of solute and also apparent molal volumes indicate the lack of significant ion-solvent interactions in the solutions of the quaternary ammonium salts in propylene carbonate. Additionally, conductance-viscosity products and activation energies of viscous flow and conductance have been calculated and discussed. Throughout the broadly varying experimental conditions over the 175°C range, the conductances of the three salts have been found to be fairly closely proportional to the fluidity, or reciprocal of the viscosity, of the medium.

Conductances and viscosities of moderately concentrated solutions of Bu_4NI, KSCN, and NH_4Br in N,N-dimethylformamide from −50° to 125°C were dealt with in the first article in this series (1). As a supplementary, parallel investigation on other nonaqueous electrolyte solutions over the unusually broad 175°C range, the present conductance-viscosity study relates to solutions of three quaternary ammonium halides in propylene carbonate, a solvent which like DMF has received much attention during the last 15-20 years.

Propylene carbonate or 4-methyl-1,3-dioxolan-2-

one, $H_3C—CH—CH_2—O—C=O$, symbolized by PC, is a commercially available cyclic ester which has become established as a promising electrolytic solvent (2). It has a liquid range extending from −49° to 241°C and is a good solvent for most quaternary ammonium salts, selected alkali metal salts, and organic compounds. PC as a dipolar, aprotic liquid has the following physical properties at 25°C: dielectric constant, 64.9 (3); viscosity, 2.513 cP (4); density, 1.1995 g cm^{-3} (5); dipole moment, 4.94 debyes (6); Kirkwood correlation factor, 1.01 (3).

Other studies dealing with conductances and viscosities of both dilute and concentrated solutions of electrolytes in PC have been reported or summarized (2, 4, 7-10), but none of these have significantly overlapped with the scope of this work. The quaternary ammoium salts were selected primarily because they were found to be among the most soluble common salts in PC at −50°C. The major objective of this study, other than obtaining extensive and valuable new data, was to thoroughly examine and compare matching conductance and viscosity characteristics of moderately concentrated solutions of electrolytes in PC over a very broad temperature range.

* Electrochemical Society Active Member.

Key words: density, propylene carbonate, activation energy, apparent molal volume, ion-solvent interactions.

Experimental

PC (Eastman practical grade) was purified through two fractionations at ~1 mm using a 1m distillation column packed with 6 mm porcelain saddles, each time retaining the middle 75% of the distillate. Values determined for the physical properties of the finally retained PC are in good agreement with comparable data reported by other investigators (4, 5).

Eastman grade Pr_4NBr, Bu_4NBr, and Bu_4NI were dried overnight in a vacuum oven at 45°C and used without further purification. Exploratory solubility determinations revealed that the approximate upper working limits for solubilities in PC at −50°C were 10, 12, and 10 weight per cent (w/o) for Pr_4NBr, Bu_4NBr, and Bu_4NI, respectively. Solutions were prepared in glass-stoppered flasks on a weight basis, in 2% by weight increments of solute, in sufficient quantities to permit separate portions of each solution to be used for the determinations of conductance, viscosity, and density.

The equipment and other procedural details are described in the preceding article (1). All determinations were made in duplicate or triplicate with very good precision except in six cases of conductance or viscosity determinations at the lowest temperatures where differences as great as 1% were observed. Mean values of the experimental data were fitted to various equations with an IBM 360/65 computer using double precision Fortran IV programming. Usually normal least squares analyses were performed; in a few cases, however, a nonlinear least squares program of the type

described by Wentworth (11) was advantageously used to better fit the data for the entire temperature range to viscosity-temperature and conductance-temperature equations.

Results and Discussion

Compilations of extensive experimental data are not presented but suitable equations and constants are provided which permit the calculation of any part or all of the data within designated limits. The number of solutions and exact molal concentrations for each of the three salts in PC are shown in any one of Tables V-VII.

With the single exception for solutions of Bu_4NBr at $-50°C$, the specific conductance (κ) for each salt in PC at each temperature increases with increasing concentration. At $-50°C$, a maximum in κ for Bu_4NBr occurs at a molality of about 0.34. Other investigators have observed maxima in κ for alkali metal salts in PC at 25°C and higher concentrations (2).

Molar conductances were calculated from specific conductances and molar concentrations in the usual manner ($\Lambda = 1000\ \kappa/C$). Molar conductances, viscosities, and densities as similar functions of molality can be described excellently over the concentration range by the following polynomial equation in which $Y = \Lambda$, or η, or ρ

$$Y = c_1 + c_2m^{1/2} + c_3m + c_4m^{3/2} \quad [1]$$

Results obtained from fitting the experimental data by normal least squares analyses to Eq. [1], together with corresponding deviation data, are summarized in Tables I-III. The deviations between experimental and calculated values of each property in no case exceed estimated experimental error.

Both molar conductances and viscosities exhibit exceptionally large changes in values over the 175°C experimental range. For convenient overviews, plots of log Λ *vs.* $\sqrt{m}$ and log η *vs.* $\sqrt{m}$ are shown in Fig. 1 and 2, respectively. In these and other figures, experimental values are denoted by the centers of the symbols (circles, triangles, or squares) whereas calculated values are represented by continuous curves. The isothermal plots of log Λ *vs.* $\sqrt{m}$ in Fig. 1 are linear at the higher temperatures, increase in slope as the temperature decreases, and become slightly nonlinear at

the lowest temperatures. Such plots based on data for concentrated solutions, however, cannot be reliably extraploated to zero concentration to obtain meaningful values of limiting molar conductances. The isothermal plots of log η *vs.* $\sqrt{m}$ in Fig. 2 are similarly shaped but generally inversely related to those in Fig. 1. All plots in Fig. 2 are nonlinear with both the nonlinearities and the slopes of the plots increasing with decreasing temperature.

Two trends are characteristic of the viscosity data for solutions of the quaternary ammonium halides in PC. The temperature coefficient of viscosity increases with increasing electrolyte concentration and the relative viscosity (*i.e.*, viscosity of a solution divided by that of the solvent at the same temperature) decreases markedly with increasing temperature.

Density data, in addition to being necessary for the calculation of absolute viscosities and volume-based concentrations, oftentimes may be used to evaluate

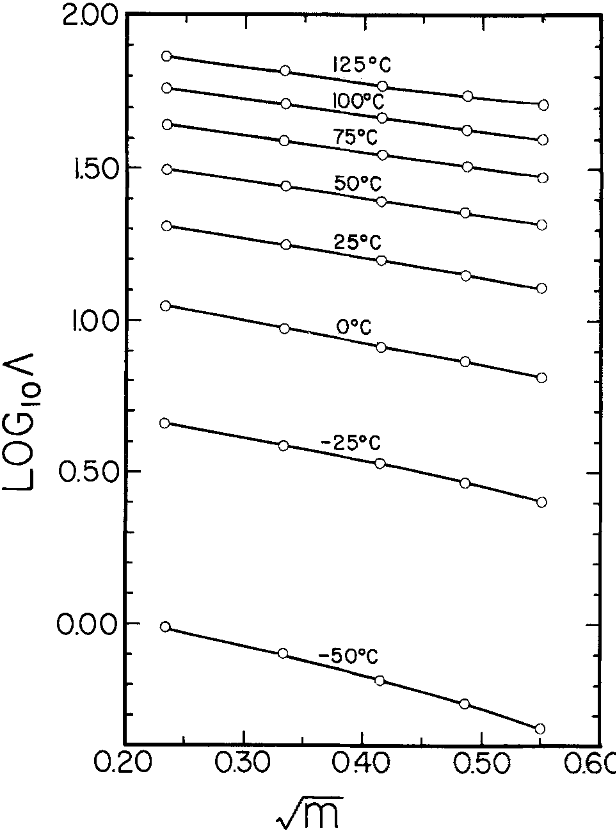

Fig. 1. Logarithm of molar conductance vs. square root of molality for solutions of Bu_4NI in PC.

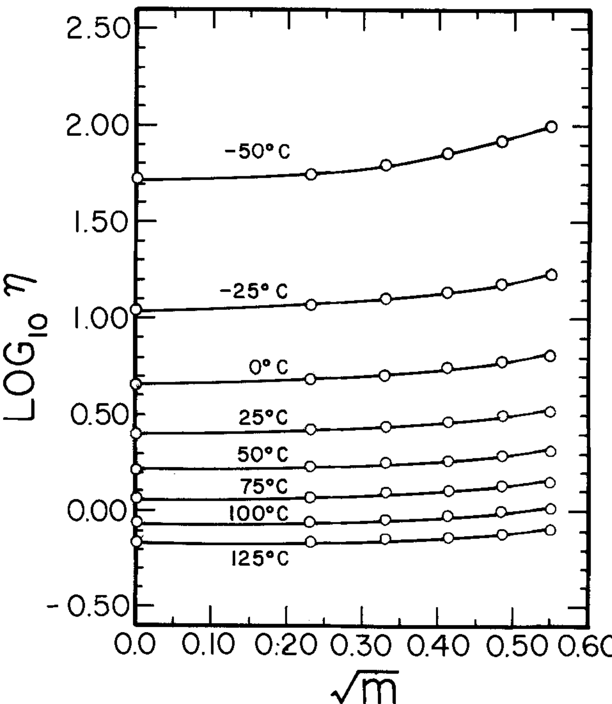

Fig. 2. Logarithm of viscosity vs. square root of molality for solutions of Bu_4NI in PC.

partial molar volumes or other appropriate quantities such as volume displacements which are related to ion-solvent effects. Though fairly accurate density data were determined in this study, the small differences between the densities of the solutions and the solvent (usually <0.0100 g cm^{-3}) precluded the calculation of partial molar volumes which were meaningful to more than two or three significant figures. Alternatively, Jasinski (2) has shown that density data may be used for quantitatively determining the displacement of solvent by solute in solution. The displacement tends to be large if the solvation energy is low and/or the sizes of the ions are large. The moles of solvent (PC) displaced per mole of solute, symbolized by Δ, may be calculated using the following equation

$$\Delta = 1000(\rho_o - \rho)/M_1C + M_2/M_1 \qquad [2]$$

The symbols in this and other equations are defined below in a List of Symbols.

Values of Δ calculated for the various solutions at −50°, 25°, and 125°C are summarized in Table IV. Through observation of the data in this table, three trends in the values of Δ are readily apparent: for any solute at a given temperature, there is little change in Δ with concentration; at a given temperature, Δ increases significantly with increasing sizes of ions; and, for a given salt, Δ decreases noticeably with increasing temperature.

The Δ values in Table IV can be converted to apparent molal volumes for the solute by multiplying the Δ values at −50°, 25°, and 125°C by 79.7, 85.1, and 93.4 cm^3/mole (PC), respectively. The resulting value of 320 cm^3/mole for Bu_4NBr in its most concentrated solution in PC at 125°C is identical with the value calculated by dividing the gram molecular weight of Bu_4NBr by the density of molten Bu_4NBr at 125°C (12). Such behavior is characteristic of an ideal solution in which exact additivity of volumes of components occurs. Using extrapolated density data for supercooled liquid Bu_4NI at 125°C (12), the calculated apparent molal volume for Bu_4NI at 125°C is 329 cm^3/mole, which is 1.3% less than the experimental value of 333 cm^3/mole.

From a slightly modified approach, experimental values for the apparent molal volumes of Pr_4NBr and Bu_4NBr in their most concentrated solutions in PC at 25°C are 238 and 305 cm^3, respectively, which are 5-7% higher than those calculated by dividing the gram molecular weights by available densities of the salts as solids at 25°C (13). These results suggest slight expansion effects accompanying dissolution of such a salt in PC.

The comparisons of experimental and calculated apparent molal volumes for the quaternary ammonium salts in PC indicate an absence of contraction effects which are characteristic of strong ion-solvent interactions. This finding is not surprising, however, since other investigators have previously commented that PC not only closely approximates an "ideal structureless dielectric" solvent (14), but also has poor solvating ability with respect to anions and large cations (15). A conclusion that there is an absence of significant ion-solvent interactions for the solutions of quaternary ammonium salts in PC is completely consistent with the observed results. If the solute ions simply displace the solvent in solution without strong interactions, the values of Δ would be proportional to

Table IV. Moles of propylene carbonate displaced per mole of solute (Δ)

sizes or volumes of the ions and independent of the solute concentration as observed. Furthermore, the value of Δ for such a salt in PC would be expected to decrease with increasing temperature if the temperature coefficient of the density or molar volume for PC were greater than that for the salt, which is substantiated by a comparison of the temperature coefficients for the densities of PC and Bu_4NBr as liquids.

The small decrease in solution density with increasing molality indicates that Pr_4NBr, Bu_4NBr, and, below 100°C, Bu_4NI are less dense than PC. For Bu_4NI-PC solutions at 100°C, and as has been previously observed for KPF_6-PC solutions at 25°C (2), the density does not change with concentration providing evidence that the densities of the solute and solvent are equal. In the specific case in this study, Bu_4NI and PC each have a density of 1.1204 g cm^{-3} at 100°C.

The densities for the PC salt solutions as a function of temperature are described excellently by the following quadratic expression

$$\rho = a + bt + ct^2 \quad [3]$$

Parameters relative to fitting the density data to Eq. [3], along with corresponding very small deviations, are compiled in Table V.

Solutions of the quaternary ammonium salts in PC have fairly low viscosities ranging from 0.7 to 3.7 cP as the temperature decreases from 125° to 25°C. For 0° through −50°C, however, the viscosity increases very abruptly with decreasing temperature. The 0.4122*M* Bu_4NBr solution has a viscosity of 139.7 cP at −50°C, which is 165 times greater than its viscosity at 125°C. This probably results from the thermal energies of the constituent species in solution being too weak to counteract strong dipole-dipole and other electrostatic interactions which would account for high viscosities at low temperatures. Plots of log η *vs.* $1/T$ for three solutions of Bu_4NI in PC, which are typical of all solutions in this study, are shown in Fig. 3. It may be observed from this figure that the similarly shaped plots are nonlinear and that their slopes increase slightly with increasing molality of electrolyte.

Because of the abruptness of the change in viscosity at the lower temperatures in conjunction with the much smaller rate of change in viscosity over the upper 100°C range, it was challenging to find a suitable viscosity-temperature relationship to which the viscosity data could be closely fitted over the entire 175°C range. After other relationships were found to be essentially inapplicable or less than satisfactory, the following equation which was used in the preceding study (1) was employed again not only because of its superior applicability but, importantly, also for theoretical and computational reasons

and viscosity ranges. The average deviation between calculated and experimental values in each case is ≤0.84%; the maximum deviation frequently is less than 1% and never exceeds 1.40%.

Plots of log Λ *vs.* $1/T$ for the same three solutions of Bu_4NI in PC are presented in Fig. 4. The plots are similarly shaped and nonlinear, with their slopes increasing slightly with increasing molality of Bu_4NI. Obviously, the plots in Fig. 3 and 4 are closely, but inversely, related. Such behavior is typical for systems in which molar conductance is closely, but reciprocally, related to viscosity.

Molar conductances, like viscosities, vary greatly over the 175°C range but in an inverse manner. It was, therefore, logical to fit molar conductance data as a function of temperature to the following expression

$$\Lambda = \exp - (\alpha' + \beta'/T + \gamma'/T^2 + \delta'/T^3 + \epsilon'/T^4) \quad [5]$$

Parameters for fitting Λ values to Eq. [5], together with deviation data, are listed in Table VII. The average deviation between calculated and experimental values in each case ≤0.99%; the maximum deviation never exceeds 1.60%. Generally, these results are satisfactory and essentially equivalent to those obtained in the analysis of the viscosity data in terms of Eq. [4].

The deviations for fitting η and Λ data for the PC systems to Eq. [4] and [5] are somewhat larger than those resulting from parallel analyses of data for DMF systems discussed previously (1). This is explained in major part by greater temperature coefficients for η and Λ and experimentally less precise determinations on the PC salt solutions.

Conductance-viscosity (or Walden) products decrease 10-15% with increasing temperature over the 175°C range for any solution and, at any temperature, decrease 20-25% with increasing concentration in the 0.05-0.41*M* range. The general trends in the variation of conductance-viscosity products agree well with observations for other systems (1, 2, 16).

Activation energies of viscous flow and conductance also provide valuable comparison information about conductance and viscosity (or viscous flow) when these are considered as rate processes. In view of common expressions for E_{vis} and E_{con} in conjunction with the temperature relationships for η and Λ used in this study (Eq. [4] and [5]), E_{vis} and E_{con} may be calculated using the following relationships

$$E_{vis} = Rd(\ln \eta)/d(1/T)$$

$$= R(\beta + 2\gamma/T + 3\delta/T^2 + 4\epsilon/T^3) \quad [6]$$

$$E_{con} = -Rd(\ln \Lambda)/d(1/T)$$

$$= -R(\beta' + 2\gamma'/T + 3\delta'/T^2 + 4\epsilon'/T^3) \quad [7]$$

Values of E_{vis} based on Eq. [6] show an approximate broad range of 2,800-10,300 cal; values of E_{con} based on Eq. [7] show a comparable range of 2500-9700 cal. Table VIII contains values of E_{vis} and E_{con} at −50°, 25°, and 125°C for three solutions of each of the salts in PC. As found previously for the DMF systems, the values of E_{vis} and E_{con} generally increase with increasing salt concentration and decreasing temperature. Corresponding values of E_{vis} and E_{con} do not differ very much, but, in every case, $E_{vis} > E_{con}$. Values of

* In calories.

E_{vis}/E_{con}, as shown in Table VIII, are quite close to unity.

Generally, the results of this conductance-viscosity study involving moderately concentrated solutions of three quaternary ammonium halides in PC over a 175°C range reflect that the magnitude of molar conductance is fairly closely related to the fluidity, or reciprocal of the viscosity, of the medium. Activation energies of viscous flow and conductance also have been found to be almost equal for each PC salt solution over the relatively broad spectrum of experimental conditions. The results for the quaternary ammonium halides in PC especially closely parallel those obtained previously for solutions of Bu_4NI in DMF.

LIST OF SYMBOLS

PC	propylene carbonate
Pr	n-propyl
Bu	n-butyl
Λ	molar conductance, ohm^{-1} cm^2 mole^{-1}
η	absolute viscosity of solution, cP
cP	centipoise
t	temperature, °C
T	temperature, °K
R	molar gas constant, cal mole^{-1} deg^{-1}
E_{vis}	activation energy of viscous flow, cal
E_{con}	activation energy of conductance, cal
ρ	density of solution, g cm^{-3}
ρ_0	density of solvent, g cm^{-3}
Y	general variable in Eq. [1]
M	molality, mole kg^{-1}
κ	specific conductance, ohm^{-1} cm^{-1}
Δ	moles of solvent displaced per mole of solute
M_1	molecular weight of solvent, g-mole^{-1}
M_2	molecular weight of solute, g-mole^{-1}
C	concentration of solute in mole liter^{-1}
exp	exponential to base e
ln	logarithm to base e
log	logarithm to base 10
c_1, c_2, c_3, c_4	constants in Eq. [1]
a, b, c	constants in Eq. [3]
$\alpha, \beta, \gamma, \delta, \epsilon$	constants in Eq. [4] and [6]
$\alpha', \beta', \gamma', \delta', \epsilon'$	constants in Eq. [5] and [7]
DMF	N,N-dimethylformamide

Standard Free Energies of Formation of Metal Fluorides by Solid Electrolytic Galvanic Cell Method

I. Metal Difluorides

G. Chattopadhyay, M. D. Karkhanavala, and M. S. Chandrasekharaiah
Chemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400085, India

ABSTRACT

Measurements of $\Delta G°_f$ of FeF_2, CoF_2, and NiF_2 employing single crystals of CaF_2 as the solid electrolyte are presented. From the emf data between 850° and 1050°K of the following cells

$$Pt \mid Fe,FeF_2 \mid CaF_2 \mid NiF_2,Ni \mid Pt \qquad [I]$$

$$Pt \mid Fe,FeF_2 \mid CaF_2 \mid CoF_2,Co \mid Pt \qquad [II]$$

$$Pt \mid Co,CoF_2 \mid CaF_2 \mid NiF_2,Ni \mid Pt \qquad [III]$$

the $\Delta G°_R$ for the corresponding reaction was calculated

$$Fe + NiF_2 = Ni + FeF_2$$

$$\Delta G°_R/cal = -11642 - 6.734T \pm 100 \qquad [1]$$

$$Fe + CoF_2 = Co + FeF_2$$

$$\Delta G°_R/cal = -8704 - 2.952T \pm 100 \qquad [2]$$

$$Co + NiF_2 = CaF_2 + Ni$$

$$\Delta G°_R/cal = -2463 - 4.059T \pm 100 \qquad [3]$$

Combining these results with the best available literature value of $f\Delta G°_T(NiF_2)$, the $\Delta G°_f$ of FeF_2 and CoF_2 were calculated.

$$f\Delta G°_T(NiF_2)/cal\ mole^{-1} = -156079 + 36.33T \pm 500 \qquad [4]$$

$$f\Delta G°_T(CoF_2)/cal\ mole^{-1} = -158542 + 32.27T \pm 600 \qquad [5]$$

$$f\Delta G°_T(FeF_2)/cal\ mole^{-1} = -167721 + 29.60T \pm 600 \qquad [6]$$

The solid electrolyte galvanic cell (SEGC) method is now firmly established as an invaluable source of reliable thermodynamic data for materials at high temperatures (1). SEGC measurements based on CaF_2 as the fluoride ion conducting electrolyte have great potentialities in alloy thermochemistry. The d-block (transition) metal fluorides in general are stoichiometric compounds compared to the significantly nonstoichiometric oxides of the corresponding metals. Hence, the activity data evaluated from the fluoride cells will have smaller uncertainties due to the smaller nonstoichiometry of the coexisting binary compound.

Availability of accurate thermodynamic data for a set of metal fluorides to be used as reference electrodes is a primary requirement before this method can be utilized for alloy activity measurements. Thermodynamic data for such fluoride systems are scant and not very reliable (2). Hence it was decided to investigate three such reference electrode systems, *viz.*, Fe,FeF_2 Co,CoF_2; and Ni,NiF_2. The results are presented here

Experimental

Electrolyte.—The electrolyte was a rectangular piece (16 × 15 × 8 mm) of single crystal, optical grade CaF_2 (Isomet Corporation). The two parallel surfaces were polished flat with carborundum papers before use in each cell assembly. The polished surfaces were transparent.

Materials.—Anhydrous NiF_2 and CoF_2 (Ozark-Mahoning Corporation, total metallic impurities < 200 ppm) were mixed with equal amounts of the respective metal sponge (Chemistry Division, BARC. < 100 ppm metallic impurities) and pressed into pellets. Anhydrous FeF_2 was prepared by fluorination of iron sponge (Johnson-Matthey specpure, impurities < 10 ppm) and then mixed with excess iron powder and pressed into pellets. The phases present were characterized by x-rays before and after the experiment. Usually the green pellets were heated in a stream of anhydrous HF and argon before use. To check whether there was any reaction between CaF_2 and FeF_2, NiF_2, or CoF_2, mixtures of CaF_2 and the respective fluorides were heated in argon for 24 hr and then examined by x-ray diffractometry. No new phases or change in the intensities of CaF_2 peaks were observed indicating the absence of mixed crystal formation or any substantial mutual solubility. Egan and Hues (3) also did not observe any saturation between CoF_2 and CaF_2.

Ultrapure argon gas (> 99.95%) was purified further by passing sequentially over Drierite, anhydrous $Mg(ClO_4)_2$, a column of copper oxide, and copper at 500°C, a molecular sieve trap refrigerated in a dry ice bath, a bed of titanium sponge at 750°C, and finally through another molecular sieve trap refrigerated with dry ice before admitting into the cell. The residual oxygen concentration after purification was below the detectable level by either gas chromatography or mass spectrometry. All connections were made by using oxygen-free high conducting copper tubings with brazed joints. A glass capillary flowmeter connected to the exit side of the cell not only indicated the gas flow rate but also prevented the back diffusion of air into the cell. The details of the flow meter is given elsewhere (4).

Furnace.—Kanthal A wire (1 mm) wound non-inductively on a recrystallized alumina tube (600 mm long, 40 mm diameter) together with another ancillary heater for end heat loss compensation provided an iso-

Key words: fluoride electrolyte, free energies, cobalt fluoride, ferrous fluoride, nickel fluoride.

thermal zone (± 1.0°C) of 5 cm long near the center of the furnace. A SCR proportional temperature controller (Eurotherm type PID) maintained the set temperatures within ± 1.0° for several hours. All temperatures were measured with a calibrated Pt-Pt 10% Rh thermocouple placed close to the electrolyte.

Cell assembly and measuring procedure.—A schematic view of the cell assembly, which was designed to separate the two electrode chambers and to minimize the fused silica surface exposed to the fluoride vapors, is shown in Fig. 1.

The two electrode chambers were separated by pressing the recrystallized alumina tube (A) against the polished surface of the electrolyte block (B). Inner electrode pellet (C) with the platinum disk was placed inside this tube and pressed against the electrolyte surface by means of an alumina tube (D) and a mild steel plug (E). The other electrode pellet (F) with the lead wire connections was pressed against the outer surface of the electrolyte by means of a stainless steel disk (G). This disk was held in position by three stainless steel or nickel wires (H) which were passed through the disk. The tension in these wires was maintained by three stainless steel springs at the cold end of the cell. This entire assembly was placed inside a fused silica tube. The two electrode chambers were separately flushed with purified argon.

The polished electrolyte piece and the electrode pellets were placed separately inside Pyrex tubes and evacuated to 10^{-5} Torr at ambient temperature for several hours to remove all surface adsorbed moisture and they were then kept sealed in a tube until required. The cell assembly was evacuated to 10^{-1} Torr and refilled with purified argon several times in each series before the furnace was brought to its desired temperature. An argon flow rate of 1.5-2.0 liter/hr was usually maintained during the heating and cooling cycle. The emf was recorded over 1-4 hr at each set temperature. Each cell was subjected to several heating and cooling cycles lasting for several days. Reversibility of the electrode processes was established in the usual way (1).

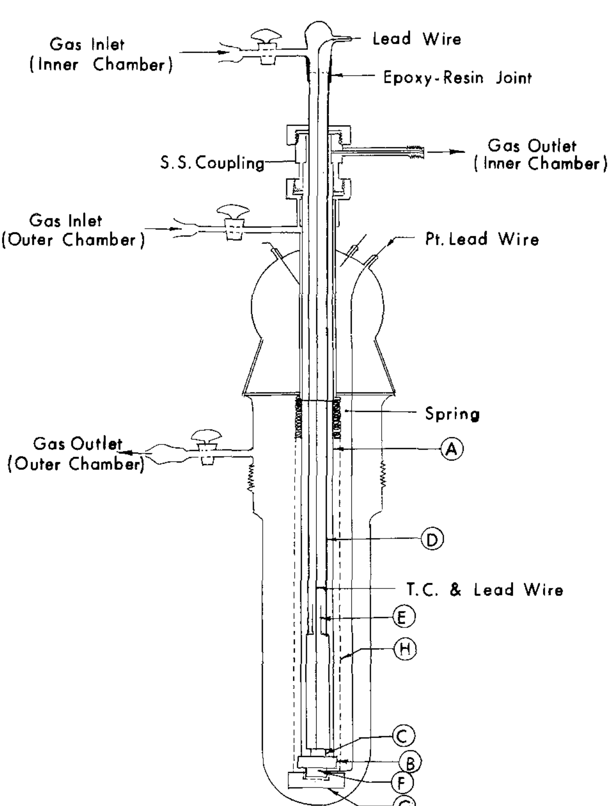

Fig. 1. Cell assembly. A, Outer alumina tube; B, electrolyte; C, electrode (1); D, inner alumina tube; E, mild steel plug; F, electrode (2); G, stainless steel disk; H, stainless steel wire.

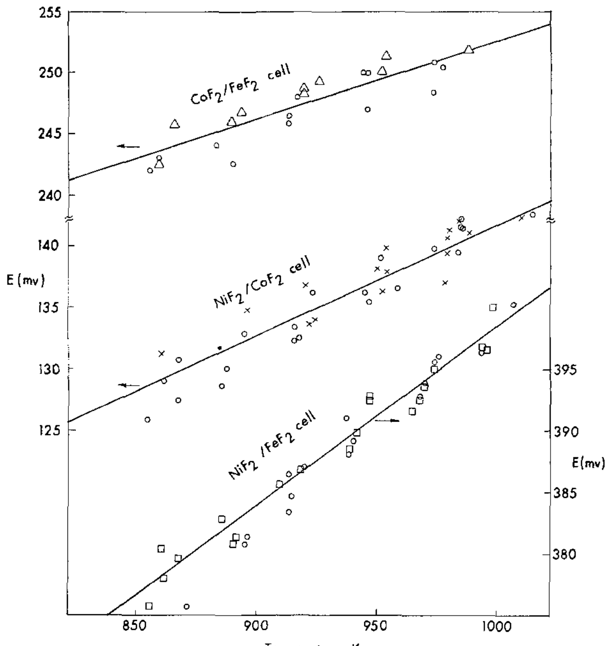

Fig. 2. Emf vs. temperature plot

A thin nickel sheet was placed coaxially on the outside of the silica tube and was earthed to prevent any a-c pickup during the emf measurements. A high input impedance (> 10^{12} ohms) vibrating reed electrometer (Vibron Model 33C) as well as a precision microvolt potentiometer (Leeds and Northrup K5 with electronic d-c null detector) were employed to measure the emf values with a precision better than ± 0.2 MV.

Results and Discussion

The emf of the cells [I], [II], and [III] were measured and the results were expressed by a linear expression using the least squares method. The uncertainties quoted are the standard deviation in E. The temperature dependence of the emf is presented in Fig. 2.

$$\text{Pt} \mid \text{Fe,FeF}_2 \mid \text{CaF}_2 \mid \text{NiF}_2\text{,Ni} \mid \text{Pt}; \quad 850° \leq T \leq 1050°\text{K} \qquad [\text{I}]$$

$$E_{\text{I}}(\text{mV}) \pm 2.0 = 252.4 + 14.60 \times 10^{-2}T \qquad [1]$$

$$\text{Pt} \mid \text{Fe,FeF}_2 \mid \text{CaF}_2 \mid \text{CoF}_2\text{,Co} \mid \text{Pt}; \quad 850° \leq T \leq 1050°\text{K} \qquad [\text{II}]$$

$$E_{\text{II}}(\text{mV}) \pm 2.0 = 188.7 + 6.40 \times 10^{-2}T \qquad [2]$$

$$\text{Pt} \mid \text{Co,CoF}_2 \mid \text{CaF}_2 \mid \text{NiF}_2\text{,Ni} \mid \text{Pt}; \quad 850° \leq T \leq 1050°\text{K} \qquad [\text{III}]$$

$$E_{\text{III}}(\text{mV}) \pm 2.0 = 53.4 + 8.80 \times 10^{-2}T \qquad [3]$$

The internal consistency among the data is excellent as may be seen by comparing the values in the second column of Table I with the corresponding values in the fifth column of Table I.

From the measured emf data, the $\Delta G°_R$ for the following net cell reactions were calculated assuming

Table I. Emf values at some selected temperatures

T/K \ emf (mV)	E_{I} ±2	E_{II} ±2	E_{III} ±2	$(E_{\text{II}} + E_{\text{III}}) = E_{\text{I}}^{\text{calc.}}$ ±4
1000	398	253	141	394
	385*	240*	111*	351*

* Calculated from Skelton and Patterson data (8).

negligible solid solutions

$$Fe + NiF_2 = FeF_2 + Ni \quad [4]$$

$$\Delta G°_{I}/cal = -11642 - 6.734 \pm 100;\ 850° \leq T < 1050°K \quad [4A]$$

$$CoF_2 + Fe = FeF_2 + Co \quad [5]$$

$$\Delta G°_{II}/cal = -8704 - 2.952T \pm 100;\ 850° \leq T \leq 1050°K \quad [5A]$$

$$Co + NiF_2 = CoF_2 + Ni \quad [6]$$

$$\Delta G°_{III}/cal = -2463 - 4.059T \pm 100;\ 850° \leq T \leq 1050°K \quad [6A]$$

Paucity of reliable enthalpy and entropy data for the anhydrous metal difluorides precludes any direct comparison of these $\Delta G°_R$. Only for $NiF_2(s)$, are $f\Delta H°_{298}$ data available from combustion calorimetry (5), as well as low temperature (6) and high temperature (7) heat capacity data. The best available data are $f\Delta H°_{298}(NiF_2) = -157.2 \pm 0.4$ kcal mole^{-1} (5) and $S°_{298} = 17.59 \pm 0.2$ eu (6). Combining these data with the high temperature drop calorimetric results (7), the following expression was calculated for the $f\Delta G°_T(NiF_2)$

$$f\Delta G°_T(NiF_2)/cal\ mole^{-1} = -156079 + 36.33T \pm 500 \quad [7]$$

Expressions [4A] and [7] yielded

$$f\Delta G°_T(FeF_2)/cal\ mole^{-1} = -167721 + 29.60T \pm 600 \quad [8]$$

Similarly, Eq. [7] and [6A] gave

$$f\Delta G°_T(CoF_2)/cal\ mole^{-1} = -158542 + 32.27T \pm 600 \quad [9]$$

The uncertainty in these free energy data is essentially the uncertainty involved in calculating $f\Delta G°_T(NiF_2)$. The experimental inaccuracy in the galvanic cell measurement is much less.

When this work was almost complete, Skelton and Patterson (8) recently reported some of their galvanic cell measurements of metal fluorides. The emf values calculated from their data for the three cells at 900° and 1000°K are also shown in Table I. Besides this report, data for only cell [I] are available to a limited extent. Lofgren and McIver (9) and Bones, Markin, and Wheeler (10) have reported emf values of 375 ± 2 mV and 374 ± 3 mV, respectively, for the cell [I] at 873°K. A value of 384 ± 2 mV was calculated from the equation given for the emf of the same cell by Bagshaw (11) compared to 380 ± 2 mV obtained in the present work. Vecher and Rogach (12) have reported emf data they have measured for the cell $Pt|Mo|Fe,FeF_2|CaF_2|NiF_2,Ni|Mo|Pt$ from which a value of 85.2 ± 2.6 mV was calculated at 873°K. These discrepancies are difficult to account for except that galvanic cell measurements with all fluoride cells require experimentally much more care than the corresponding solid oxide galvanic cell measurements (9, 10).

A probable explanation for the discrepancies may be the difference in the details of cell arrangement, particularly in the separation of the two electrode chambers. Skelton and Patterson (8) have used an open cell stacked pellet assembly where the possibility of gas phase interaction exists.

In the present work as well as in that of Lofgren and McIver (9), and Bones *et al.* (10), the two electrodes were isolated from each other. In those experiments where some gas was able to leak from cathode chamber to anode as a result of some misalignment, the emf was unsteady. This indicates the necessity of isolating the electrode chambers in fluoride cells.

The relative reliability of data from different investigators can best be established by an internal consistency test by measuring the emf of two cells against a common third electrode. Such measurements have not always been reported. The internal consistency check was made in the present work (Table I) and was shown to be good. But as can be seen from the calculated data (Table I), the results of Skelton and Patterson (8) do not fulfil this requirement indicating some source of systematic error. (E_I measured is not in agreement with their $E_I^{calc.} = (E_{II} + E_{III}.)$ It is rather difficult to account for the extremely low value for cell [I] reported by Vecher and Rogach (12). In view of the excellent internal consistency in the present work, the data reported here for $NiF_2(s)$ and $FeF_2(s)$ are considered more reliable.

Acknowledgment

We thank our colleagues, Shri O. M. Sreedharan for his assistance in some of the experimental work and Shri A. S. Kerker for his help in the fabrication of the cell assembly and the gas purification train. We would like to acknowledge our indebtedness to Dr. M. V. Ramaniah, Head, Radiochemistry Division, and his colleagues and to Dr. T. K. Das of Chemistry Division for permitting us to utilize their hydrofluorination/fluorination setup for the preparation of fluorides.

Manuscript submitted April 26, 1974; revised manuscript received Sept. 16, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

The Free Energy of Formation of Iridium Oxide by Solid Electrolyte Galvanic Cell

E. S. Ramakrishnan,[1] O. M. Sreedharan, and M. S. Chandrasekharaiah

Chemistry Division, Bhabha Atomic Research Centre, Bombay 400085, India

ABSTRACT

The ΔG°_f of $IrO_2(s)$ was determined in the range of 950°-1170°K from the measured emf data of the cell

Pt/Ni,NiO/CSZ/IrO_2,Ir/Pt

and the best available data of ΔG°_f <NiO>. The value of ΔG°_f <IrO_2> so calculated from the emf of the cell is

$$\Delta G^\circ_f < IrO_2 >/\text{cal mole}^{-1} \pm 400 = -56760 + 40.41T$$

The enthalpy and the entropy of formation of $IrO_2(s)$ calculated by the second law method at a mean temperature of 1048°K were respectively

$$\Delta H^\circ_{f,1048} < IrO_2 >/\text{cal mole}^{-1} = -56760 \pm 400$$

$$\Delta S^\circ_{f,1048} < IrO_2 >/\text{cal mole}^{-1} \cdot K^{-1} = -40.4 \pm 0.4$$

Platinum-iridium alloys have better mechanical properties compared with pure platinum and hence they are substituted for platinum in many high temperature applications. But the stability and the volatility of IrO_2 and IrO_3 alter the alloy composition during use and thereby affect the strength of the alloy. Accurate thermodynamic data for these iridium compounds at high temperatures would enable one to estimate the iridium loss and make appropriate correction in the alloy composition. The presently available entropy and enthalpy data for $IrO_3(g)$ (1-3) and for $IrO_2(s)$ (4) have large uncertainties which render them unsuitable for this purpose.

The solid oxide electrolyte galvanic cell method has proved to be superior to other methods for obtaining the ΔG°_f for oxides directly at high temperature (5, 6). High sensitivity and better precision and accuracy are the attractive features of this method. The value of ΔG°_f <IrO_2> as a function of temperature was determined between 875° and 1175°K by employing calcia stabilized zirconia (CSZ) as the oxide electrolyte. The results shown below serve to supplement the preliminary data which were published earlier (7).

Experimental

Materials.—$IrO_2(s)$ was prepared by oxidizing iridium powder (Johnson-Matthey specpure quality, total metallic impurities < 200 ppm, mostly other platinum group metals) in dry oxygen at 1273°K for 80 hr. The resulting product was shown by x-ray diffractometry to be essentially $IrO_2(s)$ with only one or two weak lines of Ir(s). The (Ir, IrO_2) electrode pellets made by cold compacting of Ir and IrO_2 (1:1) mixture by weight did not yield reproducible emf data on thermal cycling. Hence a second batch of electrode pellets was made by merely pressing the oxidized sample into disks of 6 mm diameter and 2 mm thick (10 tsi). Sintering them in argon at 775°K for 12 hr before use served to generate the Ir phase *in situ*. The x-ray diffractometric analysis of these sintered pellets established the presence of both Ir and IrO_2 phases.

Cu, Cu_2O, and Ni, NiO reference electrodes were prepared from equimolar powder mixtures of each metal and its oxide. Disks of 6 mm diameter and 1.5 mm thick (10 tsi) were first cold-pressed and then sintered in evacuated, sealed silica tubes for 24 hr at 1200°K.

Pellets of 15 mole per cent (m/o) calcia stabilized zirconia electrolyte (10 by 2 mm thick) were prepared by first decomposing the coprecipitated oxalate in air and then pressing the resultant powder into the disks of required size. The green pellets were first sintered in air at 1700°K for about 750 hr followed by an additional heating of 1 hr at 2100°K. The sintered pellets were polished to a mirror finish with corosil paper before use. In addition, a CSZ tube obtained from Zircoa Corporation (12 in. long, ⅜ in. ID and closed end flat) was used to partially separate the two electrode chambers in all measurements involving $IrO_2(s)$.

Argon of initial purity >99.95% was further purified by passing it sequentially through anhydrous $Mg(ClO_4)_2$, copper oxide (750°K), a trap cooled by dry ice, titanium sponge (500°K), and another trap cooled by dry ice before admitting it into the cell. The flow was regulated at 1-1.5 liters/hr by a calibrated capillary flow meter.

Apparatus and measurement procedure.—A Pt-Rh alloy wire wound noninductively on a sintered alumina tube (16 in. long, 1.5 in. ID) served as the furnace whose temperature was regulated to ± 0.5°K by a SCR controlled proportional controller. The cell assembly was always placed in the 2.0 in. long isothermal zone near the center. The temperature of the system was measured by placing a calibrated platinum-platinum 10 weight per cent (w/o) rhodium alloy thermocouple close to the electrolyte pellet.

An open cell stacked pellet assembly, modified to some extent by the electrolyte tube in some runs, was adopted for emf measurement. The emf was measured with the Leeds and Northrup K-5 potentiometer and Leeds and Northrup 9834 d-c null detector as well as the high input Vibron 33-C electrometer. Each cell was subjected to several heating and cooling cycles and the emf was recorded in both heating and the cooling sequences. Emf measurements were continued for several days in each case. The reversibility of the electrode processes was ascertained in each case by momentarily polarizing the electrodes in the usual way and observing that the original emf was restored within 10 min. For each series the initial equilibration at the highest temperature required from 3 to 4 hr; however, on subsequent changes of temperature, equilibrium emf values were achieved as soon as thermal equilibrium was attained.

Results and Discussion

The reliability of the setup was ascertained first by measuring the emf of the following cells

Pt/Fe, Wustite/CSZ/CoO, Co/Pt [1]

[1] Present address: Department of Atomic Energy, University of Bombay, Bombay, India.

Key words: oxide electrolyte, iridium oxide, free energy.

Pt/Co, CoO/CSZ/NiO, Ni/Pt [2]

Pt/Fe, Wustite/CSZ/NiO, Ni/Pt [3]

The emf data for each cell was expressed by a linear expression

$$E_1/(\text{mV}) \pm 1.0 = 88.0 + 8.20 \times 10^{-2}T; \quad 1175° \leq T \leq 1375°\text{K} \quad [4]$$

$$E_2/(\text{mV}) \pm 1.0 = 17.5 + 6.20 \times 10^{-2}T; \quad 1175° \leq T \leq 1375°\text{K} \quad [5]$$

$$E_3/(\text{mV}) \pm 1.0 = 102.4 + 14.30 \times 10^{-2}T; \quad 1175° \leq T \leq 1375°\text{K} \quad [6]$$

These show very good agreement with the published data as well as an excellent internal consistency of the measurements (Table I).

After establishing reliability, the $\Delta G°_f <IrO_2>$ was evaluated from the measured emf of the cell

Pt/Ir/Ni, NiO/CSZ pellet/CSZ tube/IrO_2, Ir/Pt [7]

between 875° and 1175°K. The partial isolation of the two electrode chambers by the CSZ tube was a necessity without which the gas phase interaction made the emf measurement impossible. This probably was the result of the rather high oxygen dissociation pressure of $<IrO_2>$ (about 10^{-3} atm near 1273°K). A schematic diagram of the cell assembly is shown in Fig. 1.

Five different series of measurements were made. Series A and B (Ir, IrO_2) electrodes made from equal amount mixtures of the oxide and the metal were used. In series A (Ir, IrO_2) pellets made from equal weight mixtures were placed inside the CSZ tube with the Ni, NiO pellet outside it. This cell gave continuously falling emf values, differing by as much as 10-15 mV at the same set temperature within 1½ hr, and eventually reaching almost zero emf at the end of 24 hr of measurement. In series B, the positions of the electrode pellets were interchanged. Though it improved the readings, the emf values at a given set temperature still decreased with time and the cell did not yield reproducible values on thermal cycling. So these data were not included in the free energy calculation. In the remaining three series (C, D, and E), (Ir, IrO_2) pellets of the second batch were used which gave satisfactory results and each cell gave reproducible emf's extending over 5-6 days. Tables II and III present the typical emf data. The least squares treatment of the data yielded the expression

$$E_7/(\text{mV}) \pm 3.5 = 597.9 - 0.0038T; \quad 920° \leq T \leq 1175°\text{K} \quad [8]$$

The emf values and their scatter increased excessively when the temperature was below 920°K. Consequently, values below 920°K were not included in the determination of $\Delta G°_f <IrO_2>$. The plot of emf *vs.* T shows a distinct break in the slope around 920°K (Fig. 2).

Table I. The emf values for the following cells at selected temperatures: E_I, Fe, $Fe_{0.95}$ O/CSZ/CoO, Co; E_{II}, Co, CoO/CSZ/NiO, Ni; E_{III}, Fe $Fe_{0.95}$ O/CSZ/NiO, Ni

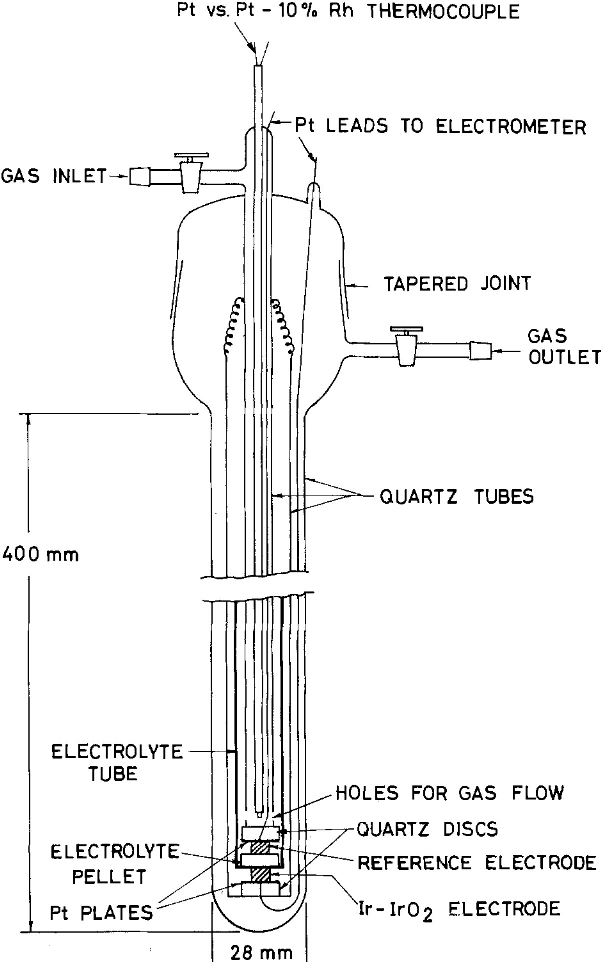

Fig. 1. The cell assembly

The large scatter in the experimental data below this temperature rendered the calculation of slope at lower temperature rather uncertain.

The net chemical reaction of cell [7] for the passage of 4 Faradays of electricity is

$$2 <Ni> + <IrO_2> = 2 <NiO> + <Ir> \quad [9]$$

The available literature data show insignificant mutual solid solution between $<Ni>$ and $<NiO>$ or $<Ir>$ and $<IrO_2>$. Hence

* The two readings were the lowest and the highest during a recording period of 1-1½ hr at any set temperature.

$$\Delta G^\circ_f <IrO_2> = 2\Delta G^\circ_f <NiO> + 4\,\mathbf{F}(E_7) \quad [10]$$

Kellogg (8) recently reevaluated the thermochemical data for $<NiO>$ and $<Cu_2O>$ and the folowing linear expression for the ΔG°_f $<NiO>$ was calculated from his tabulation

$$\Delta G^\circ_f <NiO>/\text{cal mole}^{-1} \pm 50 = -56000 + 20.38T; \quad 900^\circ \leq T \leq 1350^\circ K \quad [11]$$

Substituting this expression for ΔG°_f $<NiO>$ and the expression [8] for the emf in Eq. [10] and rearranging yields

$$\Delta G^\circ_f <IrO_2>/\text{cal mole}^{-1} \pm 400 = -56760 + 40.41T; \quad 920^\circ \leq T \leq 1175^\circ K \quad [12]$$

The enthalpy and the entropy of formation of $IrO_2(s)$ at 1048°K (the mean temperature of measurement) calculated by the second law method was

$$\Delta H^\circ_f, <IrO_2>, (1048^\circ K/\text{cal mole}^{-1}) = -56760 \pm 400 \quad [13]$$

$$\Delta S^\circ_f, <IrO_2>, (1048^\circ K/\text{cal K}^{-1}\cdot\text{mole}^{-1}) = -40.4 \pm 0.4 \quad [13A]$$

A linear extrapolation of Eq. [12] yields 1404.6°K as the temperature at which oxygen dissociation pressure becomes one atmosphere. This temperature is in good agreement with directly measured values of 1396°, 1373°, and 1378°K reported respectively by Schafer and Heitland (2), Cordfunke and Meyer (3), and Bell, Tagami, and Inyard (4). Bell *et al.* (4) have measured the dissociation pressure of IrO_2 by tensiometry and have calculated the enthalpy and the entropy of formation of $IrO_2(s)$ at a mean temperature of 1300°K as -54.0 ± 1.5 kcal mole^{-1} and -39.2 ± 1.5 cal mole^{-1} K^{-1}, respectively. They also have estimated ΔC°_p for the formation of $IrO_2(s)$ by combining C°_p values of Ir(s) and $O_2(g)$ given by Kelley and an estimated C°_p for IrO_2. Assuming this ΔC°_p to be constant in the range of 1300°-1048°K, the ΔH°_f and ΔS°_f of $IrO_2(s)$ at 1048°K was calculated to be $\Delta H^\circ_f = -54.95 \pm 1.5$ kcal mole^{-1} and $\Delta S^\circ_f = -40.06 \pm 1.5$ cal mole^{-1} K^{-1}. There is an excellent agreement between their entropy of formation and the data from present investigation (Eq. [13A]). But the ΔH°_f, 1048°K $<IrO_2>$ calculated from emf data is nearly 1.8 kcal more negative than the corresponding enthalpy data of Bell *et al.* This is also reflected in the slightly higher dissociation temperature (1404.6°K) compared to their calculated value of 1378°K. The uncertainties involved in the tensiometric measurements are reflected in the spread of nearly 25°K in the temperature of dissociation of $IrO_2(s)$ among the three investigators (2-4), all of whom employed essentially the same experimental technique.

To verify the consistency and the reliability of the measurement, the ΔG°_f $<IrO_2>$ was determined with the (Cu, Cu_2O) reference electrode by employing the cell configuration

$$Pt/Ir/Cu,\ Cu_2O/CSZ\ \text{pellet}/CSZ\ \text{tube}/IrO_2,\ Ir/Pt \quad [14]$$

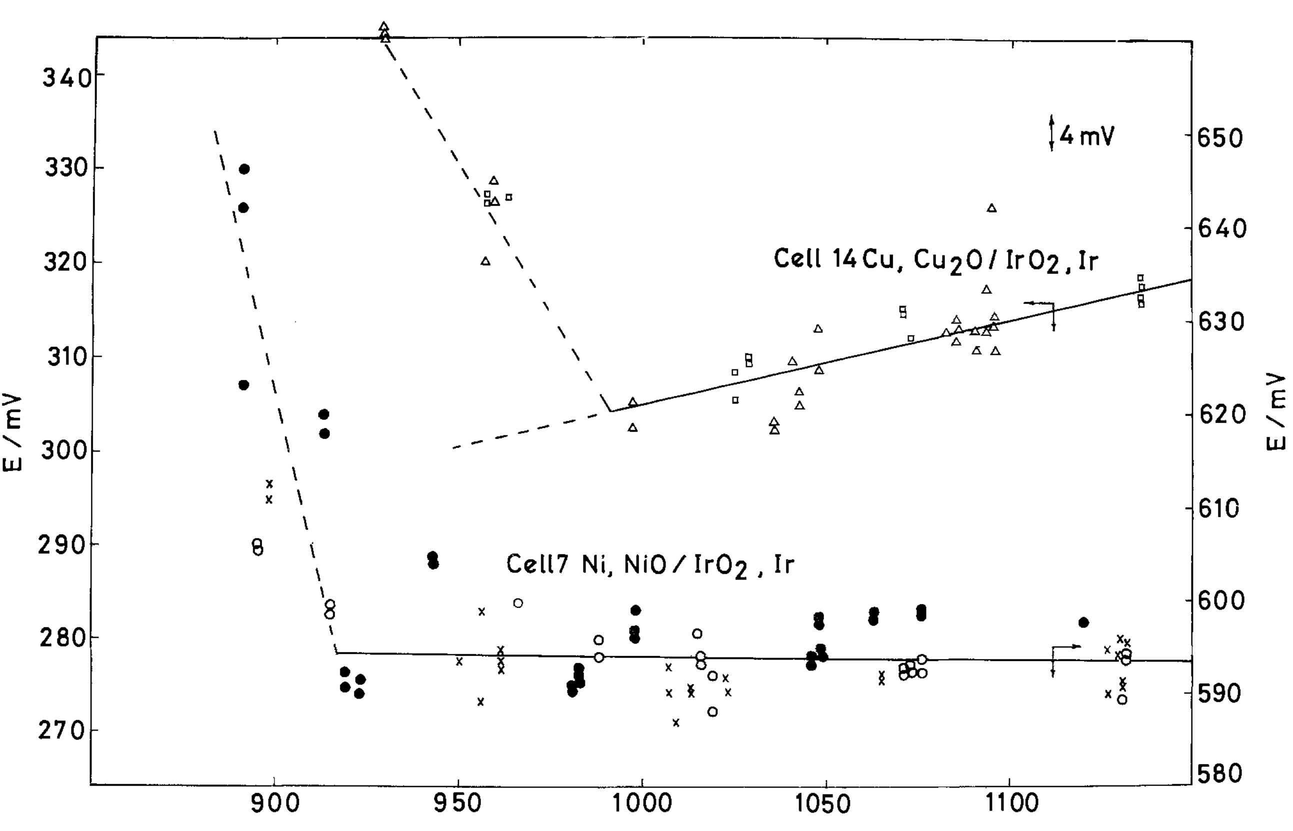

Fig. 2. Emf vs. temperature plot for cell [7] (bottom) and cell [14] (top). ○, **Series C;** ●, **series D;** ×, **series E;** △, **series F;** □, **series G.**

between 970° and 1175°K. The least squares treatment of the data gave the expression

$$E_{14}(\text{mV}) \pm 4.0 = 236.0 + 7.85 \times 10^{-2}T \qquad 970° \leq T \leq 1175°\text{K} \quad [15]$$

The internal consistency of the emf measurements was checked by the direct measurement of the emf of the cell

$$\text{Pt/Ni, NiO/CSZ/Cu}_2\text{O, Cu/Pt} \quad [16]$$

in the temperature range of 950°-1275°K. The emf of this cell was found to be

$$E/\text{mV} \pm 2.0 = 364.0 - 8.0 \times 10^{-2}T \qquad 950° \leq T \leq 1275°\text{K} \quad [17]$$

Combining the emf of cell [7] and cell [14] would yield the expression

$$(E_7\text{-}E_{14}) \pm 7.5 \text{ mV} = 361.9 - 8.23 \times 10^{-2}T \quad [18]$$

for the emf of cell [16]. Thus the internal consistency was established to be good. For example, at 1000°K, expression [18] would yield a value of 279.6 ± 7.5 mV while the corresponding value calculated directly from Eq. [17] is 284.0 ± 2 mV.

The best available value for $\Delta G°_f$ <Cu_2O> (8) between 1000° and 1275°K can be expressed as

$$\Delta G°_f \langle \text{Cu}_2\text{O}\rangle/\text{cal mole}^{-1} \pm 100 = -39848 + 17.04T \quad [19]$$

From Eq. [15] and [19], the following expression for the $\Delta G°_f$ <IrO_2> was calculated

$$\Delta G°_f \langle \text{IrO}_2\rangle/\text{cal mole}^{-1} \pm 500 = -57984 + 41.30T \quad [20]$$

in good agreement with that calculated from the (Ni, NiO) reference (Eq. [12]).

The reproducibility of emf data for cell [7] below 920°K and for cell [14] below 950°K was poor. Besides, in both cases the temperature dependence of emf changed abruptly below these temperatures indicating a possible transformation in the IrO_2 phase. The exact nature of this transformation is not known. A DTA investigation of the IrO_2 pellet indicated a small endotherm peak around 950°K at a heating rate of 36°C/min but not at smaller heating rates. This may be due to any transformation in the IrO_2 phase since none of the other phases involved are known to exhibit any phase transformation. Because of this possible transformation no attempt was made to extrapolate the enthalpy and the entropy data to 298°K.

When this work was completed, a report appeared in the literature (9) in which the $\Delta G°_f$ <IrO_2> was also measured employing SEGC. Kleykamp and Paneth (9), however, have employed (Fe, Wustite) as the reference and apparently stacked open cell arrangements. They gave the following expression for the free energy data

$$\Delta G°_f \langle \text{IrO}_2\rangle = (-61.66 \pm 0.741) + (43.26 \pm 0.956)T \quad \text{kcal/mole} \quad [21]$$

The agreement is not good. For example, at 1048°K, the $\Delta G°_f$ <IrO_2> calculated from Eq. [21] will be (−16.32 ± 0.85) kcal/mole compared with a value of (−14.41 ± 0.40 kcal/mole) obtained from Eq. [13] and [13A].

The discrepancy may perhaps be attributable to difference in the experimental details of the two measurements. Kleykamp and Paneth (9) have used (Fe, $Fe_{0.95}O$) as the reference electrode and yttria doped thoria as the electrolyte. It is generally known (14) that Wustite may react with the electrolyte and form YFe_2O_4 resulting in mixed potential. Secondly, with this reference electrode, the oxygen potential difference is very large and complications (15) may arise due to oxygen transport, particularly in view of relatively high oxygen dissociation pressure of IrO_2. Thirdly, the p-type semiconduction is observed in YDT at $P_{O_2} > 10^{-5}$ atm (16) which is within the oxygen dissociation pressure of IrO_2(s) in this temperature range. The internal consistency of the emf data was not established with one more reference electrode as is normally done. Hence, their more negative free energy of formation (nearly 2 kcal) data may not be acceptable. The break in the emf *vs.* temperature below 920°K which is observed in this investigation is not reported so far. In view of these considerations, the free energy of formation data reported here for IrO_2(s) is considered more reliable.

Acknowledgment

The authors thank Dr. J. Shankar, Emeritus Scientist, BARC, for his encouragement and Dr. M. D. Karkhanavala. Head, Chemistry Division for his suggestions and criticism. We wish to express our indebtedness to many of our colleagues, especially to Shri A. S. Kerkar in the fabrication of the apparatus. One of the authors, E. S. Ramakrishnan, gratefully acknowledges the financial assistance provided by the Department of Atomic Energy, Government of India, by the offer of a predoctoral fellowship during this work.

Conductivity and Crystal Structure of $(C_5H_5NH)_5Ag_{18}I_{23}$ A Two-Dimensional Solid Electrolyte

S. Geller, P. M. Skarstad, and S. A. Wilber

Department of Electrical Engineering, University of Colorado, Boulder, Colorado 80302

ABSTRACT

The solid electrolyte pentapyridinium 18-silver iodide, $(C_5H_5NH)_5Ag_{18}I_{23}$, has a crystal structure which allows the Ag^+ ions to move in only two dimensions, perpendicular to its hexagonal c-axis. The structure consists of face-sharing iodide tetrahedra which provide a network of pathways for diffusion of the Ag^+ ions. Planes of (formally) $[(C_5H_5NH)_3I]^{2+}$ groups, which occupy a considerable proportion of the crystal space, block the motion of Ag^+ ions in the c-axis direction. Crystals of $(C_5H_5NH)_5Ag_{18}I_{23}$ belong to space group $P\overline{6}2m(D^3_{3h})$ with lattice constants $a = 13.62 \pm 0.02$, $c = 12.58 \pm 0.02$Å, and the unit cell contains one formula unit. There are 55 tetrahedral sites for the Ag^+ ions in seven crystallographically nonequivalent sets of sites; as expected, the distribution of Ag^+ ions over these sites is markedly nonuniform. The low specific conductivity of this solid electrolyte is consistent with its two-dimensionality.

The origin of electrolytic conductivity in true solid electrolytes, especially halogenides and chalcogenides, has been propounded in several papers (1-6). To at least some extent, the physical properties of a crystalline solid are related to its structure, by which we mean the arrangement and types of atoms in the material. In the case of solid electrolytes, this relation is vividly recognized when one examines their crystal structures.

The main characteristics of a true solid electrolyte[1] are (*i*) a large ratio of available sites for the mobile cations (current carriers) to the number of available cations, and (*ii*) networks of passageways resulting from the face-sharing of anion polyhedra. There are corollaries to these: if the available sites are comprised of two or more crystallographically nonequivalent sets, then almost certainly the distribution of the carriers over the available sites will not be uniform. It should be clear that if sites are not crystallographically equivalent, they cannot be energetically equivalent, and of course, the distribution of carriers will depend on the site energy differences. Simplicity and numerous interconnections of passageways will give higher specific conductivities; $RbAg_4I_5$ which has the highest room temperature specific (electrolytic) conductivity (7, 8) has the best network of passageways (1). The passageways should be interconnected, preferably in three dimensions to facilitate the movement of the carriers. The larger the proportion of crystal space occupied by these channels, the smaller will be the restriction on the motion of the carriers.

Contrary to some views, it is misleading to refer to the sites for the carriers in true solid electrolytes as "defects." A Na^+ or Cl^- missing from its appropriate site, or one or the other in an (inappropriate) interstitial position in a NaCl crystal at thermodynamic equilibrium, is rightly called a "defect." An ideal NaCl crystal is one which has none of these defects. On the other hand, an ideal solid electrolyte of the type discussed here is characterized by cation disorder. The probability of occupancy within a set of crystallographically equivalent sites is exactly the same for each of the sites in the set, whereas the probabilities of occupancy of sites in crystallographically nonequivalent sets are very likely to be different. On the average, there will always be a large number of empty sites in an ideal solid electrolyte. Electrolytic conductivity in a crystal of NaCl is in a real sense accidental, resulting from annihilation and creation of defects that would not be present in an ideal crystal. Electrolytic conductivity in a true solid electrolyte is an inherent property of the crystal resulting from the nature of the crystal structure as described in the preceding paragraph.

There are now two known solid electrolytes in the pyridinium iodide-AgI system. Details on $(C_5H_5NH)Ag_5I_6$ have been published (4, 5). The other, namely, $(C_5H_5NH)_5Ag_{18}I_{23}$, is the subject of this paper. The particularly interesting feature of $Py_5Ag_{18}I_{23}$[2] is that it is a two-dimensional solid electrolyte. In this respect, it has some relation to the β-aluminas (9), which to date are the only other reported two-dimensional solid electrolytes.

The paper contains two main parts, one concerned with the results of conductivity measurements, the other the crystal structure determination. Finally, we hope to bring out the relation between the structure and the observed conductivity.

Conductivity

Experimental.—The pyridinium iodide was kindly given to us by Dr. B. B. Owens. The silver iodide was Research Organic-Inorganic Chemical Company, Grade A.R., advertised to be 99.9% AgI. All the conductivity measurements were made on pellets of polycrystalline material. The polycrystalline compound was made by weighing appropriate amounts of pyridinium iodide and silver iodide into an agate mortar (total weight, approximately 4g), mixing well, and forming a 3/8 in. pellet of the material by compressing at 50 tsi. The pellet was sealed into a tube filled with argon and the tube placed in an oven at 85°C for 5 days. The tube was opened, the pellet reground and reformed, resealed into a tube filled with argon, and again placed in the oven at 85°C for about 2 days. An x-ray powder photograph of the specimen was taken with CuKα radiation to check for extraneous phase.

The density of the material was determined by measuring the length and diameter of a good pellet and weighing the pellet. Values of 4.23-4.26 g/cm^3 were obtained. Good pellets were obtained with some difficulty. The description of the procedure for making the pellet is long and tedious so we will omit it with the thought that anyone doing this kind of work will have a personal technique (possibly better than ours) for producing a good pellet. It is important, of course, that the density be close to the x-ray density (4.32 g/cm^3

Key words: solid electrolyte, silver ion conductor, conductivity, crystal structure.

[1] For discussion purposes, we refer specifically to mobile cation solid electrolytes.

[2] We use the convention $(C_5H_5NH)^+ \equiv Py^+$.

for this material as will be shown later), that the edges of the pellet be sharp, and that there be no cracks in it.

The equipment (Fig. 1) used to measure the conductivity is somewhat similar to that used by Mrgudich (10) in his measurements of conductivity of AgI. The pellet is mounted between two silver electrodes with mercury amalgamated surfaces. The four high-wattage resistors mounted directly on the aluminum bar supporting the electrode assembly heat the specimen by conduction through the aluminum support sleeve and pyrophyllite electrical insulating sleeve. Temperature is controlled by a variable d-c power supply and measured with the thermocouple inside a small cavity in the end of one of the electrodes.

A one kHz, ±25 mV square wave signal was applied by means of a potentiostatic circuit[3] (8, 11) (Fig. 2) which also provides an output proportional to the current flowing through the load. The potentiostat maintains the load output at the same voltage as that of the input reference signal regardless of the instantaneous load current. The operational amplifier is a Type 307, which can provide peak currents of approximately 15 mA. The two measuring outputs from the potentiostat are connected to the Tektronix 5A19N differential amplifier plugged into a Tektronix Type 5103N oscilloscope. Measurements of current are made alternately with load output across the pellet and with the load output across a precision 10 ohm resistor. Correction (1.03 ohms) was made for the resistance of leads and electrodes. Contact resistance was found to be negligible; measurements made on specimens of different thicknesses resulted in good agreement of log σT *vs.* $1/T$ plots.

Results.—A plot of log specific conductivity multiplied by absolute temperature (σT) *vs.* reciprocal temperature is given in Fig. 3. At room temperature, the conductivity is 0.008 (ohm-cm)$^{-1}$, about an order of

[3] For application to polarization measurements, the potentiostatic circuit can also produce positive or negative voltage steps of 0-1V with 6 μsec rise/fall time imposed on a bias of 0-2V. Contact bounce noise is eliminated by using a mercury-wetted relay in the stepping circuit.

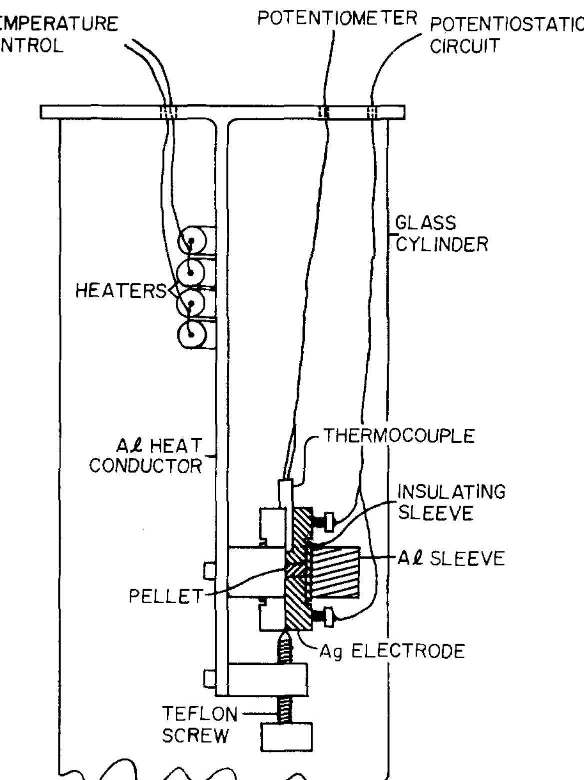

Fig. 1. Heater and electrode assembly for conductivity measurements. Part of the electrode assembly is sectioned to show the arrangement of the sample pellet between the electrodes.

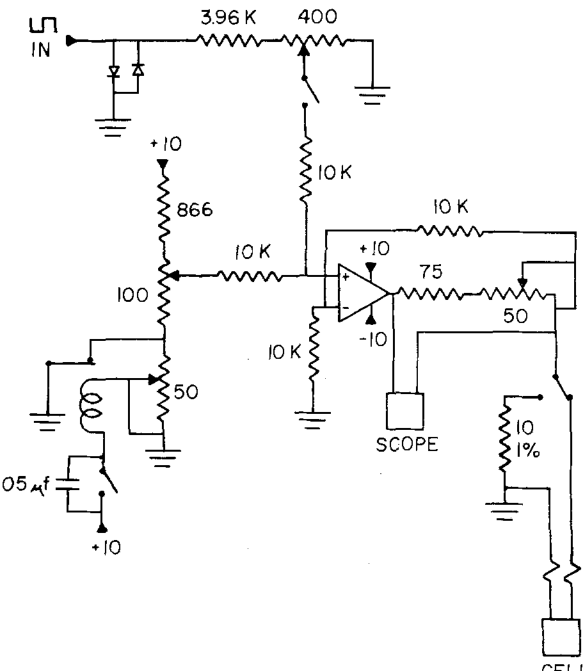

Fig. 2. Potentiostatic circuit

magnitude lower than that, 0.077 (ohm-cm)$^{-1}$, of $(C_5H_5NH)Ag_5I_6$ (5). The slope of log σT *vs.* $1/T$ (Fig. 3) gives an average Ag^+ ion activation enthalpy of motion of 4.6 kcal/mole or 0.21 eV, about the same as for the high temperature (> 50°C) region of $(C_5H_5NH)Ag_5I_6$ (5).

Crystal Structure

Experimental.—Crystals of $(C_5H_5NH)_5Ag_{18}I_{23}$ were grown by Espinosa using the gel method [see Ref. (12)]. X-ray photographs taken with a Buerger precession camera show that crystals of $(C_5H_5NH)_5Ag_{18}I_{23}$ have diffraction symmetry 6/mmm. There are no sys-

tematically absent reflections, implying that the crystal structure belongs to one of the following space groups (13): $P\bar{6}m2(D^1_{3h})$, $P\bar{6}2m(D^3_{3h})$, $P622(D^1_6)$, $P6mm(C^1_{6v})$, $P6/mmm(D^1_{6h})$.

A crystal was ground to a sphere of 0.10 mm radius with a sphere grinder (14) similar to that described by Schuyff and Hulscher (15). [Both are modifications of the Bond sphere grinder (16)]. The crystal was aligned along the c-axis. Initial lattice constants were determined from the precession camera photographs and refined after mounting on the single-crystal diffractometer. The lattice constants are $a = 13.62 \pm 0.02$, $c = 12.58 \pm 0.02$Å. The unit cell contains one $(C_5H_5NH)_5Ag_{18}I_{23}$; the formula weight is 5261.002; the cell volume is 2021.0Å^3. These give an x-ray density of 4.32 g/cm^3. As mentioned above, values of measured density were 4.23-4.26 g/cm^3 in good agreement with the x-ray value.

The intensity data were collected with a Buerger-Supper diffractometer operated automatically with a Nova 1200 computer. Interface between computer and diffractometer and the programming was carried out in our laboratory by S. L. Langer. MoKα radiation and balanced Zr and Y filters were used. The data collected were those of independent reflections included between $2\theta = 10°$ and $45°$. Each reciprocal lattice point was scanned at a rate of 2.5°/min over the range (1.50 + 0.5 Lp) degrees, where Lp is the Lorentz-polarization-Tunell factor (17). Background counts were taken at the beginning and at the end of the scan interval at 1/6 the scan time of each scan.

Intensities of data beyond $2\theta = 45°$ were not significant. Within the range $10° \leq 2\theta \leq 45°$, 729 independent reflections were measured; of these, 190 were below the 200 count threshold.

Some of the data processing is done by the Nova computer. The final output on paper tape and the teletype printout consists of the relative squares of the structure amplitudes for both the Zr and Y filters. These results are processed with the CDC 6400 computer to give the net relative squares of the structure amplitudes. The corrections on the intensity data are those for background, absorption, and Lorentz-polarization-Tunell factor.

The linear absorption coefficient, μ, of $(C_5H_5NH)_5Ag_{18}I_{23}$ for MoKα radiation is 140 cm^{-1}; from which for $R = 0.10$ mm, $\mu R = 1.40$. For the data used, the difference between maximum and minimum absorption correction is 7.9%.

Determination and refinement of the structure.—As indicated in the beginning of this paper, we know that a solid electrolyte must have face-sharing polyhedra formed by the anions. Further, we know that the iodides tend to form icosahedra[4] with an iodide at the center. At first, we were under the impression that the formula contained one less AgI than it finally turned out to have. This is another case [see Ref. (3)] in which the solution of the crystal structure led to the correct formula.

After consideration of all the probable space groups, a model was devised in space group $P\bar{6}2m$ in which 22 iodide ions form a two-dimensional network of face-sharing tetrahedra. Packing considerations require that three of the pyridinium ions lie in cavities in the iodide structure centered at positions 3g with $x \approx 0.63$ (13, p. 296). Two rotationally disordered pyridinium ions lie on the $\bar{6}$ axes at $z \approx \pm 0.20$. This arrangement was seen to leave space for an additional iodide ion at (0, 0, ½). As a starting point for the refinement the 18 silver ions were assumed to be distributed uniformly over sites near the centers of the 55 iodide tetrahedra of the model structure. (It should be emphasized however, that we knew that finally the distribution would not be uniform.) The pyridinium ions on the $\bar{6}$ axes are required to be rotationally disordered by the site symmetry of positions 2e of the space group (Table II). Thus to simplify the calculation, the pyridinium ring was approximated by a regular hexagonal ring of carbon atoms with C—C distance equal to 1.39Å [see Ref. (4)]. The "bisecting"[5] orientation (Fig. 4a) was first assumed by analogy with the structure of $(C_5H_5NH)Ag_5I_6$ (4); again packing considerations make this orientation more probable than the "parallel" orientation or than further rotational disorder. In the "bisecting" orientation, the ring is defined by atoms in position 12*l* at $(x, 2x, z)$, $x \approx 0.059$. The x-parameter could not be refined, but it was allowed to vary; it was never significantly different from the starting value. The z-parameter was refined.

[4] This is not the case for $(C_5H_5NH)Ag_5I_6$, however.
[5] The "bisecting" orientation is the one in which the hexagonal a and b axes bisect the line joining two carbon atoms.

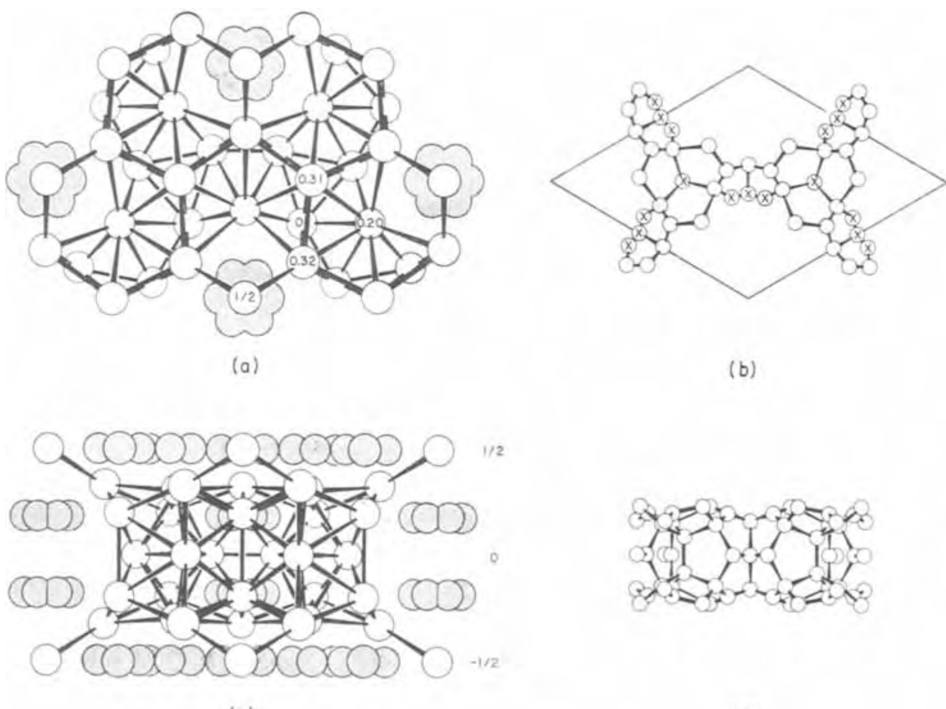

Fig. 4. a. Top view of iodide ion arrangement in $Py_5Ag_{18}I_{23}$; the pyridinium ions (stippled) on the hexagonal axes are also shown. b. Top view of Ag^+ ion paths in $Py_5Ag_{18}I_{23}$; the equilibrium Ag^+ ion sites (located at or near iodide tetrahedra centers) are shown; × indicates connection between upper and lower halves of the Ag^+ path network within the conducting layer; see also Fig. 4d. c. Side view of the iodide arrangement in $Py_5Ag_{18}I_{23}$; the pyridinium ions (stippled) in the ±½c levels of the unit cell are shown; these together with the I^- ions at ±(0, 0, ½) block movement of Ag^+ ions in the c-axis direction. d. Side view of the Ag^+ ion paths in $Py_5Ag_{18}I_{23}$.

Table I. Final values of I^- and Ag^+ ion parameters[a]

Ion	Position	Multiplier	x	y	z	$10^4\beta_{11}$[b]	$10^4\beta_{22}$	$10^4\beta_{33}$	$10^4\beta_{12}$	$10^4\beta_{13}$	$10^4\beta_{23}$

Ag^+C[c]	12l	0.01	0.6380	0.1994	0.1321						

[a] Numbers in parentheses are standard errors and pertain to the last digit in all cases.
[b] The expression for the thermal factor is $\exp - (h^2\beta_{11} + k^2\beta_{22} + l^2\beta_{33} + 2hk\beta_{12} + 2hl\beta_{13} + 2kl\beta_{23})$.
[c] Positional parameters for the Ag(l)c site are calculated values for the point equidistant from the four iodides defining the tetrahedron. The multiplier given for this site was determined by difference.

The orientation of the pyridinium ions on the $z = \frac{1}{2}$ plane was indicated by the shape of the cavity (see Fig. 4a) formed by the surrounding iodide ions. The centers of the pyridinium rings are almost directly above and below the iodide ions in positions I(i)B (Table I), and the two mirror planes of the pyridinium ion coincide with the mirror planes of the space group (13, p. 296). The shape of the pyridinium ion (18) is very close to that of the cavity in the proper orientation; thus the nitrogen atoms lie near the iodide atoms in the $z = \frac{1}{2}$ level. For clarity, the pyridinium ions in these cavities have been omitted from Fig. 4a.

Positional parameters for the atoms in the ordered pyridinium ions were derived from the structure of this ion in pyridinium chloride (18). In the calculations these pyridinium ions (excluding hydrogen atoms) were considered to be rigid bodies (19) centered at positions 3g: (x, 0, ½; 0, x, ½; $\bar{x}$, $\bar{x}$, ½); x converged to the value 0.628, with a standard error of 0.004.

The refinement was carried out by iterative least squares calculations (20).[6] In the refinement, the Ag^+ ion multipliers[7] were varied (for determination of the Ag^+ ion distribution) as well as all possible positional and anisotropic thermal parameters (with the aforementioned restrictions on the pyridinium ions). It was not possible to vary all parameters at once in the early stages of the calculations because of substantial parameter interaction (21), particularly between Ag^+ ion multipliers and thermal parameters. In most of the iterations, refinement was facilitated by constraining the total Ag^+ ion content to 18 per unit cell. In the final cycle, this constraint was removed and all parameters were varied except scale factors and positional and thermal parameters of Ag(l)C. The final value of the Ag(l)C multiplier was 0.05 with limits of error ±0.06. This implies that the Ag^+ ion occupancy of this site is not significantly different from zero. The remaining multipliers for the Ag^+ ion sites converged to the values shown in Table I. These total 1.49; when multiplied by 12, the number of points in general positions, we obtain 17.9 Ag^+ ions per unit cell. In Table I, we have arbitrarily assigned to Ag(l)C the multiplier 0.01 to bring the total Ag^+ ion content per unit cell to 18. The achievement of convergence of the iodide and Ag^+ ion parameters and of the correct Ag^+ ion content, the latter without constraint, gives additional confidence in the general model proposed for solid electrolytes (see above).

[6] A version of the basic ORFLS program (20) modified by J. A. Ibers and R. J. Doedens was used.

[7] $\text{Multiplier} = \dfrac{\text{number of atoms in particular set of positions}}{\text{number of equipoints in general set of positions}}$.

The final value of the discrepancy factor $R = \Sigma \,|\,|F_o| - |F_c|\,| / \Sigma\, |F_o|$, where F_o is the observed and F_c the calculated structure amplitude, is 0.065 and the standard deviation of a structure amplitude with unit weight is 1.39. Excluding scale factors, pyridinium ion parameters and parameters of the nearly empty Ag(l)C sites, 68 variable parameters were fitted to the data.

In the least squares calculations, the atomic scattering factors used were those of Cromer and Waber (22); correction was made for the real parts of the anomalous dispersion (23). The observed data were weighted according to the formula

$$\sigma = \frac{1}{\sqrt{w}} = 1 + 0.025\,[F_o - 15.0 + |F_o - 15|] + 10\exp(-F_o/15)$$

A table showing the comparison between the observed and calculated structure amplitudes is available.[8] Tables I and II list the final values of the structure parameters.

Interionic distances.—Interionic distances and standard errors calculated (24) from the refined coordinates and the final variance-covariance matrix of the least squares calculation are given in Table III. To facilitate the understanding of the structure, the surroundings of each crystallographically independent

[a] Distances involving the Ag(ℓ)C site were calculated for the position equidistant from the four iodides defining the tetrahedron.

atom are given, even though considerable repetition occurs.

Following the order given in Table III, the iodide ions have 6, 9, 8, 10, and 11 near neighbor iodide ions and, respectively, 5, 3, 4, 2, and 2 near neighbor pyridinium ions. Thus, considering only the large iodide and pyridinium ions, the coordination numbers of the iodide ions are 11, 12, 12, 12, and 13. The average iodide-iodide distances, in the same order, and their limits of error (3σ) are 4.849 ± 0.012, 4.682 ± 0.012, 4.529 ± 0.015, 4.680 ± 0.012, and 4.708 ± 0.012Å. For comparison, the nearest neighbor I-I distance in zinc-blende type AgI (25) is 4.59Å. Average I^--I^- distances in the seven crystallographically nonequivalent tetrahedra range from 4.588 to 4.703Å. One I^--I^- distance I(j)-I(j) across the vertical mirror plane of the space group is unusually short, 3.984(8)Å. The remaining I^--I^- distances range from 4.280(4) to 4.993(6)Å.

Average Ag^+-I^- distances in the crystallographically nonequivalent iodide tetrahedra range from 2.82 ± 0.18 to 2.91 ± 0.05Å. Four of the seven mean Ag^+-I^- distances are significantly longer than the value 2.80Å in the zinc-blende type AgI; none is shorter. Those with average distance significantly longer are Ag(l)A, Ag(l)B, Ag(h), and Ag(f) which are occupied 42, 53, 45, and 60% of the time, respectively. The three other silver sites have lower occupancies; consequently higher error limits are associated with their Ag^+-I^- distances.

Each pyridinium ion on the $\overline{6}$ axis is surrounded by thirteen iodide ions and one symmetry related pyridinium ion. These pyridinium rings are 4.4(2)Å apart along the c-axis (Fig. 4c). Among the thirteen iodides surrounding a pyridinium is the one at (0, 0, ½), which lies 4.07Å from the center of the pyridinium ring with I-(C, N) distances of 4.30(8)Å. Three I(i)A and three I(i)B iodides form a puckered hexagonal ring about this pyridinium; distances to nearest carbon (nitrogen) atoms are 3.56(4) and 3.843(7)Å, respectively. The remaining six iodide ions surrounding the pyridinium are I(j) ions lying in the mirror plane at $z = 0$; the nearest I-(C, N) distance is 4.65(4)Å.

The pyridinium ions on the $z = ½$ plane are surrounded by 13 iodide ions. I(i)B ions lie directly above and below the centers of the rings. Distances from ring atoms to nearest surrounding iodides are C-I(i)A, 3.8Å; C-I(b), 3.7Å; C-I(i)A, 3.6Å; N-I(b), 3.7Å.

Description of the structure.—See Fig. 4. Eighteen of the twenty-three iodide ions lie at the vertices of four hemi-icosahedra. These occur in two pairs, each pair sharing a (triangular) face in the basal hexagonal plane. Four of the iodide ions lie in the centers of what would be the complete icosahedra. The basal plane I^- ions are in positions 6j, while the remaining vertices of the hemi-icosahedra are occupied by I^- ions in two sets, A and B of positions 6i. The ions at centers occupy positions 4h. The twenty-third iodide ion is not involved in the icosahedra or in any way with the passageways for the Ag^+ ions. In fact, this situation is thus far unique in AgI-based solid electrolytes.

An icosahedron has twenty triangular faces, and the hemi-icosahedron, ten. Thus the I^- ions on the three-fold axes, in positions 4h, form ten I^- ion tetrahedra in each hemi-icosahedron, for a total of forty iodide tetrahedra. These tetrahedra provide the three sets of 12l and the one set of 4h Ag^+ ion sites. Fifteen tetrahedra are formed between the hemi-icosahedra providing the 6i, 6j, and 3f sets of Ag^+ ion sites. Thus there is a total of 55 tetrahedra for 18 Ag^+ ions per unit cell.

The arrangement of tetrahedra is such that they form a network of passageways (1-6) which extends throughout the crystal essentially parallel to the (001) plane. The Ag^+ ions can migrate through these passageways in a manner similar to those described in previous papers (1-6). Sequences may be found by examination of Fig. 4 and Table III. Every Ag^+ ion passageway through the crystal includes at least two of the Ag(l)C positions in each unit cell. Passageways can be found which bypass each of the six other symmetry sets of equilibrium Ag^+ positions.

As in the cases of other AgI-based solid electrolytes, not all the tetrahedra share all their faces with other tetrahedra. Table III shows that the Ag(l)A tetrahedron shares one face with an Ag(l)B tetrahedron and one with an Ag(l)C tetrahedron; the remaining faces open to pyridinium ions. The Ag(l)B tetrahedron shares faces with only three other tetrahedra: those of Ag(l)A, Ag(l)C, and Ag(i). Ag(i) and Ag(j) tetrahedra each share faces with only three other tetrahedra. Ag(l)C, Ag(h), and Ag(f) tetrahedra share faces with four other tetrahedra.

The equilibrium Ag^+ ion sites near the centers of the iodide tetrahedra are shown in Fig. 4b and d; the lines connecting the sites indicate jumps through the faces of the tetrahedra shown in Fig. 4a and c. Positions indicated by x in Fig. 4b are connections between the upper and lower identical halves (related by the mirror plane at $z = 0$) of the Ag^+ network within the conducting layer. While the multiply-connected nature of the network in directions perpendicular to the c-axis is evident in Fig. 4a and b, the complete absence of connections across the mirror planes at $z = ½$ is clearly shown in Fig. 4c and d. Layers of formal composition $[(C_5H_5NH)_3I]^{2+}$ are interposed (at $z = ½$) between conducting slabs; there are no passageways for Ag^+ migration across these layers. Thus Ag^+ ions are confined to passageways within two-dimensional slabs of the structure.

Alternatively, the iodide structure can be regarded as composed of quasi-icosahedra with iodides at eleven vertices centered about the 6j iodides. Atoms of the pyridinium ions on the $\overline{6}$ axes lie near the twelfth vertices of completed icosahedra. Since 6j iodides occupy both center and vertex positions of any icosahedron, successive icosahedra interpenetrate, the center of one being a vertex of the next. These interpenetrating icosahedra form slabs which extend throughout the crystal; all the iodide tetrahedra in the structure lie within these slabs. The icosahedral arrangements and the predominance of tetrahedra in the iodide structure suggest a similarity of the conducting region of this solid electrolyte to alloy structures even if not the full analogy observed for $RbAg_4I_5$ with β-Mn(1). Parts of two quasi-icosahedra are apparent in Fig. 4c on either side of the central mirror plane; twofold axes of these polyhedra are approximately normal to the plane of the figure.

Discussion

We have now presented the details on the results of conductivity measurements and of the crystal structure determination. Both are necessary to a clear understanding of the behavior of this solid electrolyte. Unfortunately the crystals are too small to enable us to make quantitative directional conductivity measurements on them. However, because thus far all halogenide and chalcogenide solid electrolytes adhere to the model propounded (1-6), we can infer from the crystal structure that $(C_5H_5NH)_5Ag_{18}I_{23}$ is a two-dimensional solid electrolyte.

For the hexagonal crystal, we have (26) that the conductivity

$$\sigma = \sigma_1 \sin^2\theta + \sigma_3 \cos^2\theta$$

where θ is the angle between the direction in which the conductivity is being measured and the c-axis, σ_1 is the conductivity in the basal plane, and σ_3 is the conductivity along the c-axis. The average of $\sin^2\theta$ over a hemisphere is 2/3, from which, because $\sigma_3 = 0$, $\sigma_1 = 1.5\langle\sigma\rangle$. Thus for $(C_5H_5NH)_5Ag_{18}I_{23}$, $\sigma_1 = 0.012$ (ohm-cm)$^{-1}$ at room temperature.

It is of interest to compare briefly the other solid electrolyte in the PyI-AgI system, namely $(C_5H_5NH)Ag_5I_6$ (4, 5), with the one discussed here. A top view of the crystal structure of $(C_5H_5NH)Ag_5I_6$ at −30°C is shown in Fig. 5. As the temperature increases, Ag^+ ions increasingly move into the tetrahedra which are empty in the figure. $PyAg_5I_6$ has three-dimensional passageways for Ag^+ ion diffusion; details

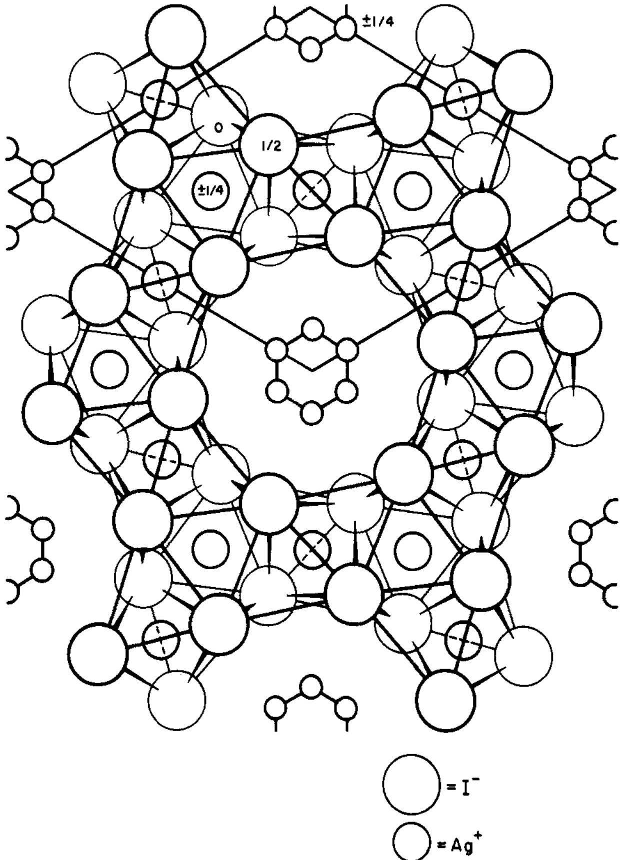

Fig. 5. Top view of the crystal structure in $PyAg_5I_6$ at −30°C. As temperature increases, Ag^+ ions increasingly move into the tetrahedra which are empty in this figure [fom Ref. (1)].

on these passageways have been given elsewhere (4, 5). At room temperature, the conductivity is 0.077 (ohm-cm)$^{-1}$ (5), almost an order of magnitude higher than that, 0.008 (ohm-cm)$^{-1}$, of $Py_5Ag_{18}I_{23}$. However, at 50°C, $PyAg_5I_6$ has a transition from a region of low disorder to a region of high disorder, where the average enthalpy of activation of motion, h_m, is 0.21 eV. This is the value found for the average enthalpy of activation of motion of $Py_5Ag_{18}I_{23}$ between room temperature and 100°C. At 55°C the average specific conductivities of $PyAg_5I_6$ and $Py_5Ag_{18}I_{23}$ are 0.29 and 0.015 (ohm-cm)$^{-1}$, respectively. Sodium β-alumina, a material which is also a two-dimensional solid electrolyte, does not attain a high conductivity until relatively high temperature; at 100°C, for example (27), $\sigma_1 = 0.077$ (ohm-cm)$^{-1}$; for $Py_5Ag_{18}I_{23}$ it is 0.05 (ohm-cm)$^{-1}$.

The two-dimensional solid electrolyte implies lower concentrations of Ag^+ ions and equilibrium sites. In $Py_5Ag_{18}I_{23}$ these are, respectively, 0.89 and 2.72×10^{22} cm^{-3}, whereas in $PyAg_5I_6$ they are 1.07 and 3.65×10^{22} cm^{-3}. The lower values for $Py_5Ag_{18}I_{23}$ occur simply because the crystals must contain ions or atoms which block the motions of the current carriers in one of the crystal dimensions. The solid electrolyte, $RbAg_4I_5$, which has the highest room temperature conductivity (7, 8), has a ratio of Ag^+ ions to equilibrium sites of 16/56 or 0.287, whereas the ratio for $PyAg_5I_6$ (at temperatures > 50°C) is 10/34 or 0.294 and for $Py_5Ag_{18}I_{23}$, 18/55 or 0.327.

Another way to look at this is to compare the relative space occupied by the face-sharing polyhedra for the two crystals. Table IV gives the volume of each tetrahedron associated with each crystallographically nonequivalent Ag^+ ion site in $Py_5Ag_{18}I_{23}$. The net volume occupied by all the face-sharing tetrahedra is 638.3Å^3; this is 31.6% of the total volume of the unit cell and therefore of the crystal.

Table IV. Tetrahedral site occupancy and volume

Site	Number of jumps*	Occupancy, %	Volume tetrahedron, Å^3
Ag(f)	4	60	11.83
Ag(h)	4	45	11.51
Ag(i)	3	18	11.19
Ag(j)	3	30	11.27
Ag(l)A	2	42	11.62
Ag(l)B	3	53	12.23
Ag(l)C	4	1	11.32

* See Table III for jump distances.

In $PyAg_5I_6$, the volumes at room temperature are: for the f-type tetrahedron 11.74Å^3; for the m-type tetrahedron 10.70Å^3; and for the octahedron 40.32Å^3. The total space occupied by the polyhedra is $(6 \times 11.74 + 24 \times 10.70 + 4 \times 40.32)$Å^3 = 488.5Å^3. The unit cell volume is 931.2Å; thus the face-sharing polyhedra which provide the passageways for Ag^+ ion diffusion occupy 52.5% of the unit cell volume and therefore of the crystal. This may be slightly misleading, because the octahedra have 3.4 and 3.8 times the volumes of f- and m-type tetrahedra, respectively. Perhaps the octahedra are not that much more important than the tetrahedra, although they do form straight channels along the c-axis. However, the tetrahedra alone occupy 35.1% of the unit cell.

The volume of a regular tetrahedron is $0.11785a^3$ where a is the side. A side of 4.59Å (an I-I distance in zinc-blende type AgI) gives a volume of 11.40Å^3. In $Py_5Ag_{18}I_{23}$, the weighted average volume of the tetrahedra is 11.62Å^3. In $PyAg_5I_6$ the average volume of the tetrahedra alone is 10.92Å^3. The volume of the m-tetrahedron is very small; even at 125°C it is still only 11.18Å^3, accounting perhaps for the low occupancy of these sites even at higher temperatures. For example, at room temperature, 23°C, these sites are only about 5% occupied, and at 125°C, only about 18% (5).

In $RbAg_4I_5$ (1), there are three different types of tetrahedra: one of multiplicity 8, the other two of multiplicity 24. The volumes are 11.87, 12.41, and 11.52Å^3. The total space occupied by the 56 tetrahedra is 669.3Å^3 which is 47.1% of the volume of the unit cell. $[(CH_3)_4N]_2Ag_{13}I_{15}$ has eight crystallographically different sets of tetrahedra (3). In this case we will estimate the net volume occupied by the tetrahedra. There is small variation in the total volume if we assume an average volume of between 11.6 and 11.9Å^3. The net volume of the tetrahedra in the triply primitive cell will vary from 1427 to 1464Å^3. The volume of the triply primitive cell is 3748.1Å^3 and the space occupied by the face-sharing tetrahedra is estimated to be 38.1-39.1%.

The above indicates that the conductivity is related to the total volume occupied by the diffusion pathways. In Table IV, there is an indication that there is a direct relation between tetrahedron size and occupancy; however, this relation does not hold well for $RbAg_4I_5$. Occupation of next nearest neighbor Ag^+ ion sites must also play a role. As to the magnitude of the conductivity, simplicity of the network and the existence of bottlenecks must also be important.

Conclusions

The crystal structure of $(C_5H_5NH)_5Ag_{18}I_{23}$ shows that it is a two-dimensional solid electrolyte. Such a solid electrolyte is apt to have a substantial amount of crystal space occupied by the ions or atoms which block diffusion. As a result, the conductivity of such materials is inherently low.

Put positively, the results and comparisons given here demonstrate that three-dimensional pathways for diffusion of the ionic carriers are most favorable for high conductivity solid electrolytes. Simplicity of the network and numerous pathways apparently enhance the conductivity.

ABSTRACT

Two new silver solid electrolytes, having high ionic conductivity, have been found in the systems AgI-Ag_3AsO_4 and AgI-Ag_3VO_4. The most remarkable advantage of these electrolytes is their excellent stability in iodine and moisture. The possibility of using these solid ionic conductors in silver-iodine solid-state batteries has also been investigated.

Recently Takahashi and co-workers (1) reported the discovery of silver solid conductors based on the combination of silver iodide with silver oxyacid salts. In particular they studied the systems AgI-Ag_3PO_4, AgI-$Ag_4P_2O_7$, and AgI-Ag_2WO_4 finding intermediate compounds which have the characteristics of high ionic conductivity silver solid electrolytes with average structures. The properties of these electrolytes are summarized in Table I.

The electrolytes are of interest for practical applications since they show a much greater stability in moisture and iodine atmosphere than $RbAg_4I_5$, which is the silver ion conductor with the highest conductivity at room temperature and has been so far the electrolyte used the most in the development of solid-state batteries (2, 3). Therefore we considered it important to extend the study examining the systems AgI-Ag_3AsO_4 and AgI-Ag_3VO_4. In both the systems, intermediate compounds, at 80 mole per cent (m/o) AgI, having high ionic conductivity, have been ascertained by conductivity and x-ray studies. The electrochemical properties of these two new solid electrolytes and their possible use in solid-state batteries have been investigated and the results are reported in this work.

Experimental

Silver iodide was prepared by precipitation, gradually adding an aqueous solution of KI to a solution of $AgNO_3$. The resulting product was washed several times with distilled water and acetone and then dried under nitrogen. Silver arsenate was prepared by precipitation, mixing an aqueous solution of $Na_2HAsO_4 \cdot 7H_2O$ with a solution of $AgNO_3$. The precipitate was washed with distilled water and acetone and dried under nitrogen. The x-ray diffraction patterns of Ag_3AsO_4 so obtained agreed with those reported in the literature.

Silver vanadate was obtained following the procedure of Moser and Brandl (4). An aqueous solution of $AgNO_3$ was added to a saturated solution of NH_4VO_3 also containing CH_3COONa and concentrated ammonia. After precipitation, the solution was boiled to remove excess of NH_3. The precipitate was washed with distilled water and acetone and then dried under nitrogen at 110°C for 20 hr. The composition was ascertained by silver chemical analysis using the Volhard method.

All the chemicals used were reagent grade type.

The new phases were obtained by intimately mixing weighed amounts of AgI and Ag_3XO_4, where X was As and V. The mixture was melted under vacuum or dry nitrogen and cooled at room temperature. The resulting products were ground and pressed at 2500 kg/cm² into pellets of 1.16 cm² surface with an average thickness of 0.15 cm for the electrochemical measurements.

The total conductivity was determined using as electrodes mixtures of silver and electrolyte (1/2 weight ratio), according to a procedure generally adopted in solid electrolyte technology to reduce contact polarizations. The resistance of the resulting cells of the type

$$Ag,Ag_7I_4XO_4 \qquad [I]$$

was measured with a 1 kHz impedance bridge.

The electronic conductivity was checked with Wagner's method and analysis (5), polarizing the cell

$$Ag/Ag_7I_4XO_4/graphite \qquad [II]$$

under voltages less than the decomposition potential of the electrolytes with the graphite acting as the blocking electrode.

The silver transport number in both the new solid conductors was obtained by Tubandt's method (6) using a cell composed of separable layers. Also in this case, to reduce contact resistance, electrodes formed by a mixture of silver and the electrolyte were used.

The solid-state batteries were assembled by pressing the electrolyte and a thin layer of the cathode into a single pellet. This pellet was placed in a plastic container, having gold-plated terminals, to which was then added a mixture of silver and the electrolyte (anode), also in form of a pressed pellet. As cathode, the iodine-perylene (I_2-P, 1/1 mole ratio) charge transfer complex, obtained with a method already described (7), was used.

The polarization and discharge curves were obtained and recorded using standard equipment.

Results and Discussion

Takahashi and co-workers (1) stated that in the system AgI-Ag_3AsO_4 there are no high conductivity

Table I. Properties of silver solid conductors of the silver iodide-silver oxyacid salt type at 25°C, reported by Takahashi and co-workers (1)

compounds. No explanation or experimental data however were given to support what has appeared to us an anomalous behavior considering the similarities between the PO_4^{3-} and the AsO_4^{3-} groups. We therefore reexamined the system and found an intermediate compound having high conductivity, as indicated by the maximum, at 80 m/o AgI, in the conductivity-composition plot reported in Fig. 1.

Results of x-ray analysis of this compound, which may be tentatively written as $Ag_7I_4AsO_4$, confirm the conductivity evidence, since the most intensive lines of AgI and Ag_3AsO_4 are not present in the pattern, as shown in Table II.[1]

The Arrhenius plot of $Ag_7I_4AsO_4$, shown in Fig. 2, is linear in the temperature range from 20° to 100°C. At 25°C the conductivity is 0.004 (ohm cm)$^{-1}$. From the slope of the plot an activation energy of about 4 kcal/mole is obtained. This value is typical of solid conductors having an "average structure" in which the mobile ions are statistically distributed in a large number of sites in the lattice. To determine the nature of the mobile ions, Tubandt's method was used (6). The results obtained from a series of samples under various conditions and reported in Table III show that the ionic conductivity through $Ag_7I_4AsO_4$ is solely due to silver ion movements.

The fact that the silver transport number is one is an indication that the electronic contribution of the total conductivity of $Ag_7I_4AsO_4$ is low. This has been further confirmed by Wagner's analysis (5). The results obtained indicated that the electronic conductivity of the electrolyte is less than 10^{-8} (ohm cm)$^{-1}$ at 25°C.

The decomposition potential of the electrolyte was determined from the current-voltage curve, reported in Fig. 3, of a cell similar to cell [II], with the graphite electrode maintained positive. The results are reported in Table IV, where the properties of $Ag_7I_4AsO_4$ are summarized.

[1] Note added in proof: It has to be mentioned, however, that the x-ray spectra are of difficult interpretation since the peaks are very broad. This could indicate a glass-like structure for the electrolytes.

$Ag_7I_4VO_4$	0.20	−5.1	+0.2	+4.65	4.83	
$Ag_7I_4VO_4$						1.01 ± 0.03

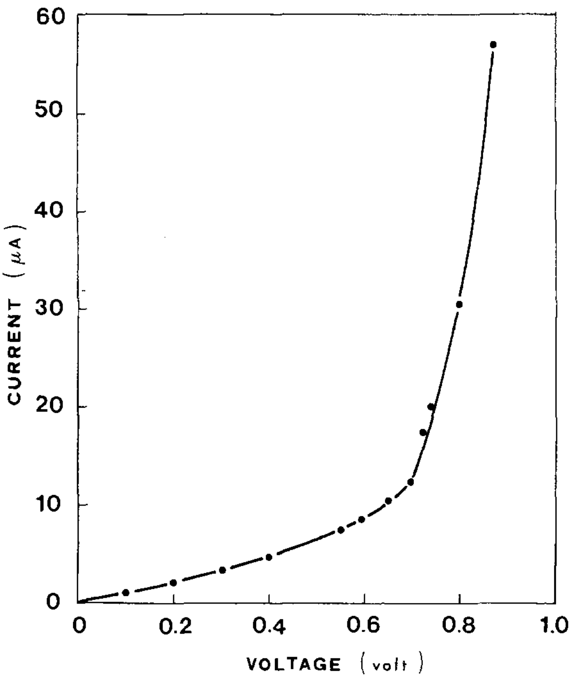

Fig. 3. Decomposition potential of $Ag_7I_4AsO_4$ at 25°C

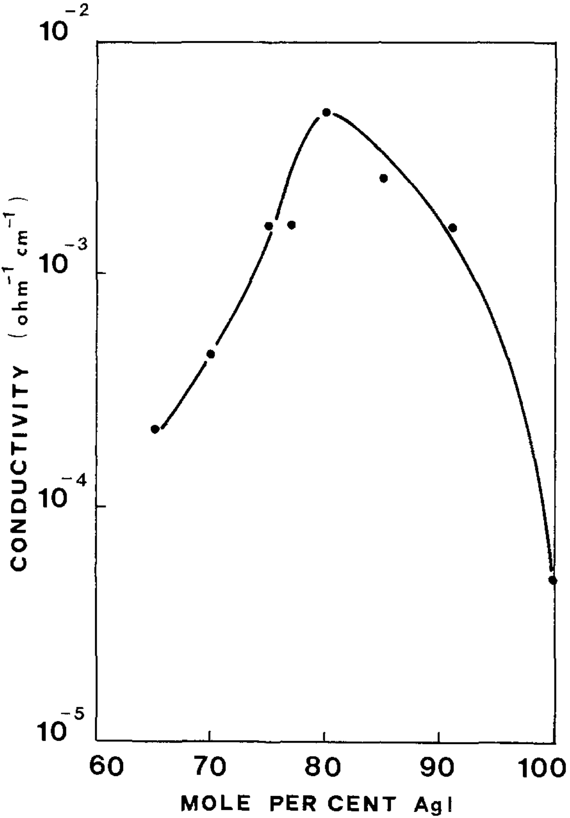

Fig. 4. Composition dependence of the specific conductivity in the system AgI-Ag_3VO_4 at 25°C.

Also in the silver iodide-silver vanadate system there is an intermediate compound with high conductivity, as shown by the maximum of 0.007 $(ohm\text{-}cm)^{-1}$, at

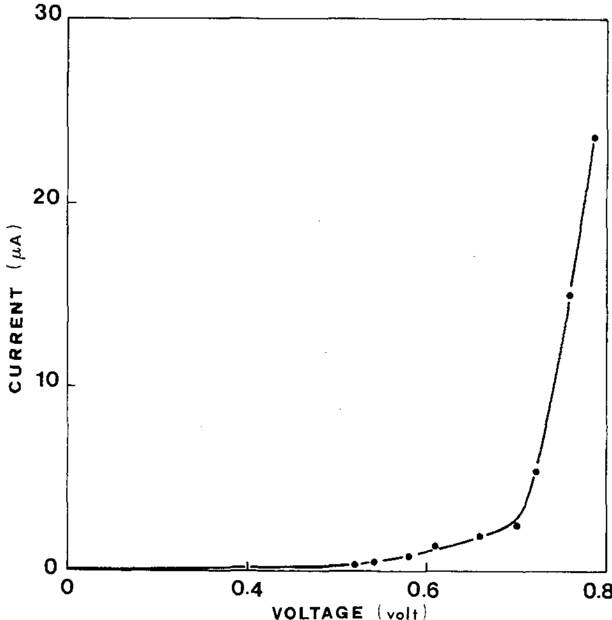

Fig. 5. Decomposition potential of $Ag_7I_4VO_4$ at 25°C

about 80 m/o AgI, in the conductivity-composition plot reported in Fig. 4. The existence in the AgI-Ag_3VO_4 system of a new electrolyte, which may be tentatively written as $Ag_7I_4VO_4$, was also ascertained by x-ray analysis (see Table II).

From the Arrhenius plot of the electrolyte, linear in the temperature range from 20° to 100°C (see Fig. 2), an activation energy of about 4 kcal/mole is derived. This value implies that $Ag_7I_4VO_4$ also has an average structure.

The charge carrier in the electrolyte has been determined as being silver ion by Tubandt's method (6). Typical results, reported in Table III, indicate in fact that the silver transport number is one within the experimental error. The ionic character of the conductivity of $Ag_7I_4VO_4$ has been confirmed by the low value of the electronic contribution, 10^{-8} $(ohm\text{-}cm)^{-1}$ at 25°C, found by Wagner's analysis (5).

From the current-voltage curve of a cell similar to cell [II], shown in Fig. 5, the decomposition potential of the electrolyte has been determined. Its value is reported in Table IV, where the properties of $Ag_7I_4VO_4$ are summarized.

The conductivity of the two new electrolytes here described is lower than that of the solid conductors listed in Table I, but is high enough to make $Ag_7I_4AsO_4$ and $Ag_7I_4VO_4$ of interest for practical applications. This interest is increased by the great stability shown by the electrolytes in moisture and iodine atmosphere. An example of this excellent behavior is the fact that the resistance of a cell similar to cell [I], maintained in an atmosphere of more than 60% humidity, did not show appreciable changes for several days. Furthermore in Fig. 6 are shown the changes in resistance of cells of the type

$$C/Ag_7I_4XO_4/I_2,C \qquad [IV]$$

The resistance initially increases about 15% and then stabilizes to a constant value. A cell similar to [IV], having $RbAg_4I_5$ as electrolyte, would have shown, for the same period of time, a progressive increase in

Table IV. Properties of $Ag_7I_4XO_4$ silver solid electrolytes at 25°C

Electrolyte	Color	Density at 2.5 kg/cm² (g/cm³)	Total conductivity $(ohm\text{-}cm)^{-1}$	Electronic conductivity $(ohm\text{-}cm)^{-1}$	Silver transport number	Decomposition potential (V)
$Ag_7I_4AsO_4$	Red-violet	5.3	0.004	10^{-8}	1.01 ± 0.03	0.68
$Ag_7I_4VO_4$	Orange-brown	5.0	0.007	10^{-8}	1.01 ± 0.03	0.70

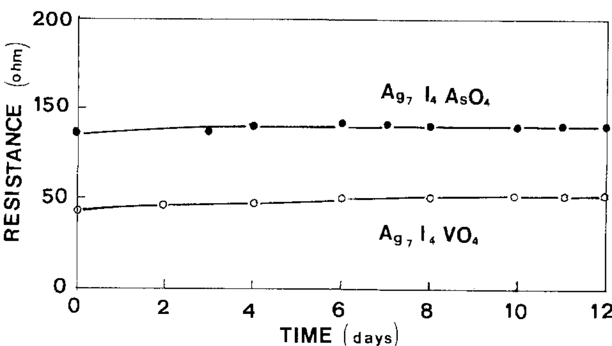

Fig. 6. Changes of resistance of cell [IV] at 25°C

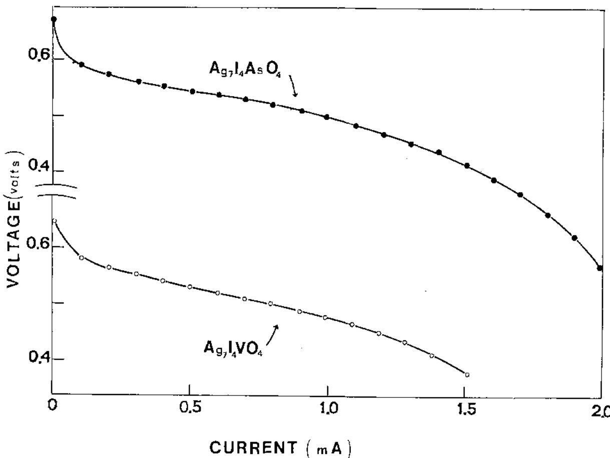

Fig. 7. Polarization curve of cell [V] at 25°C

resistance up to 200% (1). The reason for this difference is probably that in these electrolytes there is not the solubility and diffusion of iodine which was found in $RbAg_4I_5$ (8). Furthermore the new silver conductors here reported should be, at room temperature, thermodynamically more stable than silver rubidium iodide, which undergoes a water-catalyzed decomposition reaction below 27°C (9). To ascertain this definitely, thermodynamic studies, such as the emf of formation cells and phase diagrams, should be carried out for the $Ag_7I_4XO_4$ electrolytes. These studies are in progress in our laboratory.

The applicability of $Ag_7I_4AsO_4$ and $Ag_7I_4VO_4$ for the development of silver-iodine solid-state batteries has been tested by assembling the cell

$$Ag/Ag_7I_4XO_4/I_2\text{-}P \qquad [V]$$

which had, both in the case of arsenate and vanadate, an open-circuit voltage (OCV) of 0.67V at 25°C. This value may be compared with the thermodynamic one (0.687V at 25°C) related to the process

$$Ag + \frac{1}{2} I_2 = AgI \qquad [VI]$$

considering the reduced iodine activity in the cathode (7).

The polarization curves, shown in Fig. 7, indicate that cell [V] may sustain discharge current densities of the order of 1 mA/cm^2 without serious polarization. The feasibility of $Ag_7I_4AsO_4$ and $Ag_7I_4VO_4$ in solid-state power sources is finally confirmed by the typical discharge curves of cell [V], reported in Fig. 8 and 9. The structure and the energetic characteristics of these batteries are reported in Table V. The specific energy density is low, as is typical of solid-state power sources (2). It must be kept in mind, however, that batteries [V] have been assembled only as laboratory

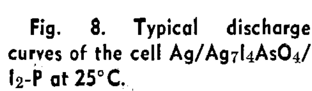

Fig. 8. Typical discharge curves of the cell $Ag/Ag_7I_4AsO_4/I_2$-P at 25°C.

prototypes and, therefore, their performances may certainly be improved by optimization of the cell's geometry. This was of course beyond the scope of this work which was carried out primarily to examine the electrochemical properties of the intermediate, highly conductive compounds in the systems $AgI-Ag_3AsO_4$ and $AgI-Ag_3VO_4$.

Critical Potentials for Stress Corrosion Cracking of 63-37 Brass in Ammoniacal and Tartrate Solutions

H. Uhlig,* K. Gupta,* and W. Liang*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The critical potentials below which SCC of 63-37 brass does not occur in a cupric ammonium test solution are measured as a function of pH, dissolved Cu concentration, and in the presence of the inhibiting ions: Cl^- and Br^-. They are also measured in presence of various metal ammonium complexes other than the Cu complex and for alkaline tartrate solution. Possible mechanisms are discussed.

Many papers have appeared proposing mechanisms for stress corrosion cracking (SCC) of brass since the time of the first reference (1) in 1906 mentioning the phenomenon itself. To this day, the various proposed viewpoints differ widely, and the search continues. The situation has not been helped by some investigators who occasionally confuse intergranular corrosion, not requiring a tensile stress, with stress corrosion cracking which does. For example, moist sulfur dioxide, SO_2, is sometimes stated as causing SCC of brass, but it probably causes slower intergranular corrosion instead, which, so far as the accumulated evidence shows, operates by a different mechanism. Lynes (2), for example, listed several corrosive media including acid sulfates and chlorides that cause slow intergranular corrosion of brass. but he demonstrated that rapid SCC occurs only in electrolytes containing cupric complexes of ammonia. This was true whether or not a given solution causes intergranular corrosion in absence of stress.

Pickering and Byrne (3) recently described the appearance of cracks in dynamically strained 70-30 brass in acid sodium sulfate solution anodically polarized to 0.24V (SHE) which they reported to be an instance of SCC. There was no cracking at constant applied load. Although having the outward appearance of SCC, it is suspected that their observation instead is still another example of intergranular corrosion accelerated by anodic polarization and made visible by the widening of surface grain boundaries during plastic deformation of the metal. It would seem to be a reasonable conclusion that whenever a corrosive medium induces intergranular corrosion in absence of stress (*e.g.*, brass in acid salts) the appearance of surface cracks in dynamic strain tests should not be taken as unequivocal evidence of stress corrosion cracking.

The apparent intergranular stress corrosion cracking of pure Cu in 15*N* aqueous NH_3 + 2.5 g/liter of

* Electrochemical Society Active Member.
Key words: brass, ammoniacal solutions, tartrate solutions, inhibitors, stress-sorption cracking.

Cu reported by Pugh *et al.* (4) was repeated and interpreted as intergranular corrosion not requiring stress by Uhlig and Duquette (5). The reported SCC of 99.9% Cu wires, 0.254 mm diameter, stressed beyond the elastic limit in 0.05*N* cupric acetate by Escalante and Kruger (6) may have still another interpretation. Either the observed oxide cracking was an instance of SCC, as was reported, or it represented alternatively a weakening of the highly stressed thin cross section of metal by its gradual conversion into Cu_2O which then failed mechanically. A reported longer failure time of their 99.999% Cu specimens when thicker (although still thin) in cross section (0.71 mm), suggests that mechanical failure probably describes the situation. This interpretation is also supported by the well-established fact that heavy sections of Cu sheet as used in practice may oxidize but are not observed to undergo SCC when exposed to acetate solutions.

The various theories proposed to explain SCC of α-brass include: (*i*) electrochemical dissolution of alloy along "active paths" at the base of a notch or crack (7-9); (*ii*) progressive fracture of an oxide or other type reaction product film covering the alloy surface (9-13); or (*iii*) reduction of metal bond strength by an adsorbate (14, 15), called by one of us "stress-sorption cracking" (16). Some authors have placed emphasis on metallurgical factors such as dislocation arrays as being responsible for crack-sensitive paths (8, 17), whereas others have emphasized that factors of the environment such as pH or applied potential determine whether the observed fracture path is intergranular or transgranular (15, 18). Over and above such detail, it is important to recognize, as Lynes emphasized, that the usual stress corrosion cracking of brass, if it is to occur at all, requires a specific environment, limited, by and large, to ammonia and the amines, or in some instances to nitrogen oxides and nitric acid vapors which convert by reaction with the brass surface to corresponding ammonium compounds (19). Johnson and Leja (14) showed in addition that bona fide intergranular stress corrosion cracking can occur in alkaline citrates and tartrates, which, like ammonia, form copper complexes. Otherwise, the commonly encountered electrolytes, no matter how corrosive, are not likely to cause stress corrosion cracking.

As in the case of austenitic and ferritic stainless steels (20-22), of mild steel (23), and of high strength low alloy steels (24), there exists a critical potential below which SCC of brass does not occur in an otherwise damaging environment. The significance of such a potential to the previously proposed mechanisms of SCC for brass needs evaluation. Critical potentials are presently measured and interpreted for a variety of ammoniacal solutions and also for a tartrate solution; in addition, attention is directed to the question of whether Cu in solution is required for SCC, or whether other ammonium complex ions can be equally damaging.

Experimental

Material for test specimens consisted of cold-rolled (20% reduction) commercial 63-37 brass supplied by courtesy of Bridgeport Brass Company. The analysis is: 62.65% Cu, 0.01% Sn, 0.012% Pb, 0.023% Fe, 0.01% Cd, balance Zn. The sheet 0.041 in. (0.104 cm) thick was sheared to specimens measuring 1 3/4 × 3/16 in. (4.5 × 0.5 cm). After smoothing the edges with 600 grade emery paper, the specimens were degreased in boiling benzene, then pickled in 45 volume per cent (v/o) HNO_3 for 30 sec at room temperature. They were bent beyond the elastic limit into the form of a C having a final span of 1 7/16 in. (3.7 cm) and held to this dimension between insulating holders of the zirconium test apparatus at constant flow stress as maintained by remote spring loading. Failure times were recorded by an electric clock. The test apparatus was similar to that described earlier for measuring stress corrosion cracking of stainless steels (21) and hydrogen cracking of ferritic alloys (25).

The test solutions were made up of stock solutions of $CuSO_4$ and $(NH_4)_2SO_4$ mixed just prior to the test. The composition conformed approximately to that recommended earlier by Mattsson (18), and by Johnson and Leja (14) for producing minimum failure times; it consisted of 0.05*M* $CuSO_4$ and 1.0*M* $(NH_4)_2SO_4$ of *p*H 6.5 adjusted using NH_4OH. Solutions at room temperature were usually stirred mildly by bubbling air through them.

Controlled potential runs made use of a Wenking potentiostat connected to a saturated calomel reference electrode via a salt bridge to the test solution. The salt-bridge capillary was located near the maximum bend of the test specimen. The electrical connection to the specimen was made by a Teflon coated copper wire fastened to the specimen through a hole drilled at one end. Two platinum electrodes located on either side of the test specimen served as auxiliary electrodes. In general, the critical potential below which failure by SCC did not occur for at least 50-100 hr was reproducible to within 5 mV. The corrosion potential measured by simple immersion of the stressed or unstressed specimen (no difference) was usually recorded at the time of failure.

Results

The effect of *p*H on times to failure is shown in Fig. 1. A minimum in the region of *p*H 6.5 confirms previous data reported by Johnson and Leja (14).

The effect of applied potential on failure times at *p*H 6.5 is shown in Fig. 2. The critical potential below which failure does not occur within at least 50 hr is 0.095V SHE or −0.147V SCE. This value is consistent with limited and more approximate values reported by Sircar *et al.* (15) and by Lahiri *et al* (26). It also approximates the value reported for 70-30 brass in 15*N* aqueous NH_3 by Pugh and Green (27).

Minimum time to failure is observed at 0.27V SHE. At more noble potentials, time to failure again increases, reaching >50 hr at about 0.31V. At the latter potential an appreciable anodic current density causes uncertainty in the potential measurements because of high alloy dissolution rates and consequent thinning of the specimens, contrary to the situation at 0.095V where dissolution of the specimen is suppressed by the accompanying cathodic current.

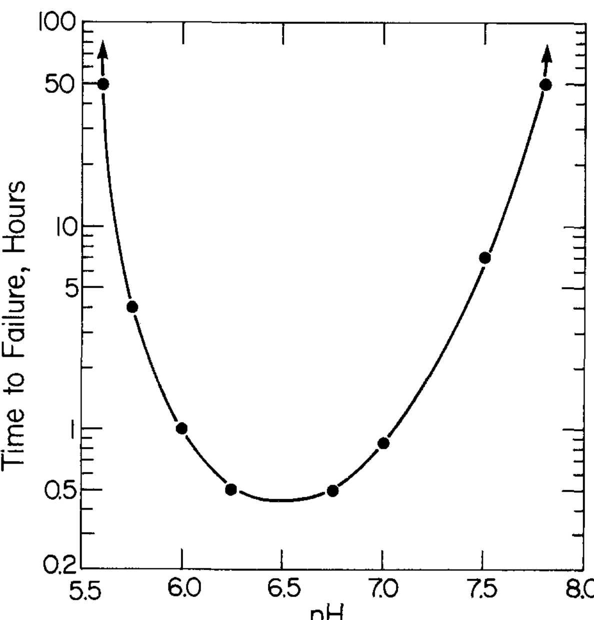

Fig. 1. Effect of pH of 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$ on time to failure of 63-37 brass at room temperature.

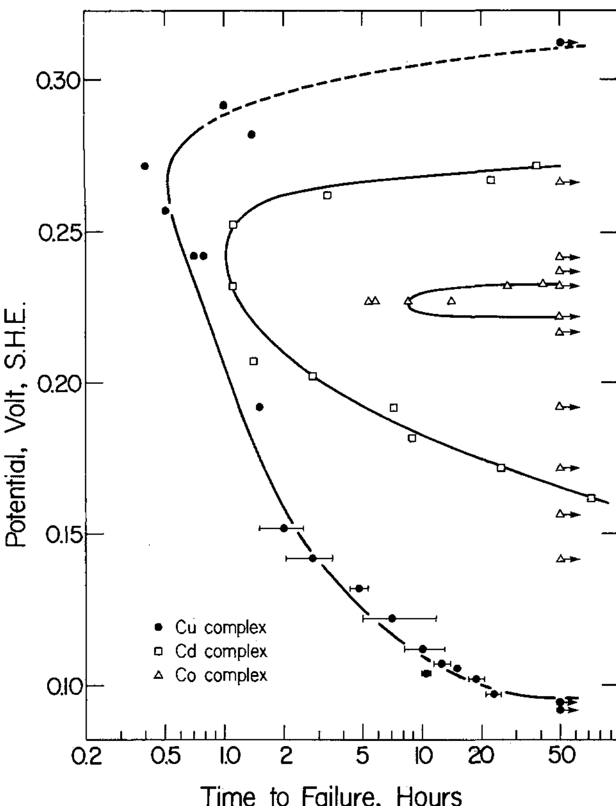

Fig. 2. Effect of applied potential on time to failure in 0.05M $CuSO_4$, $CdSO_4$, or $CoSO_4$, 1M $(NH_4)_2SO_4$, pH 6.5 at room temperature.

At moderately higher *p*H values, the corresponding critical potentials as well as the corrosion potentials are shifted to less noble values, as shown in Fig. 3. As shown later, and also by previous measurements for the stainless (20-22) and carbon (23, 24) steels, should the corrosion potential become active to the corresponding critical potential, failure is not observed. According to Fig. 3, this situation is projected to a *p*H of about 8 and is supported by corresponding long times to failure at *p*H 7.8, as shown in Fig. 1. At *p*H values below 6.0, it is likely that the corrosion potentials fall outside the potentials for minimum failure time. This could not be checked because measurements of critical potentials in the acid range are obscured by a high uniform anodic dissolution rate of the alloy, and hence are not reported.

The effect of annealing the present cold-rolled brass (20% reduction) at 300°C for 1 hr is to shift the critical potential in the noble direction by about 18 mV without much change in the short times to failure. However, severe cold-rolling (20-93% reduction) is reported by Edmunds (28) to appreciably increase the resistance of 70-30 brass to failure when stressed either parallel or perpendicular to the rolling direction. Robertson *et al* (29) reported a similar beneficial effect on SCC resulting from cold-working a 1.9% Ni, 0.6% Si-Cu alloy tested in ammonia. The effect of severe cold-rolling on the critical potential could not be checked using the present thin gauge material; these measurements remain to be done.

The effect of higher temperatures is to decrease times to failure in accord with an approximate Arrhenius relationship (Fig. 4). The apparent average activation energy is 10 kcal/mole corresponding more likely to a chemical rather than to a diffusion limiting process in the solution. This value agrees with that of 9.9 kcal/mole reported by Pugh *et al.* (30) for 70-30 brass in a so-called tarnishing solution consisting of 8 g/liter Cu in 15*N* aqueous NH_3. Johnson and Leja (14) reported for 69.5% Cu-30.5% Zn brass in 0.04*M* Cu, 1.5*M* total NH_3, *p*H 6.8 solution, a variable activation energy ranging from 4 to 11.5 kcal/mole.

The times to failure in 1*M* $(NH_4)_2SO_4$, *p*H 6.5 as a function of dissolved Cu are shown in Fig. 5. The effect of decreasing Cu concentration is to shift the critical potential in the noble direction and the corrosion potential in the active direction (Fig. 6). The extrapolated values show an intersection at 0.003*M* $CuSO_4$ indicating that, at this concentration and below, spontaneous cracking of brass in simple immersion tests is not expected nor is it observed. Decreasing copper concentration increases failure times, in accord with data previously reported by Althof (31) and by many subsequent investigators. The reason for the dependence on dissolved Cu concentration is now made clear in terms of converging critical and corrosion potentials.

Addition to the ammonium sulfate test solution of various cations which form ammonium complexes and variation of the Cu concentration but keeping total metal concentration at 0.05*M*, has no appreciable ef-

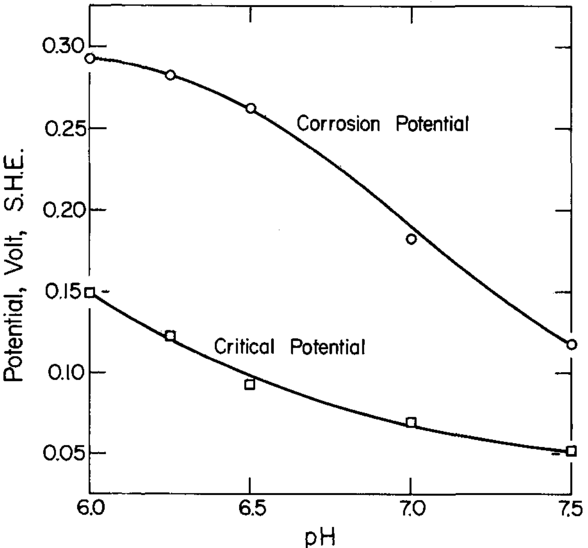

Fig. 3. Effect of pH of 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$ on critical potential and corrosion potential at room temperature.

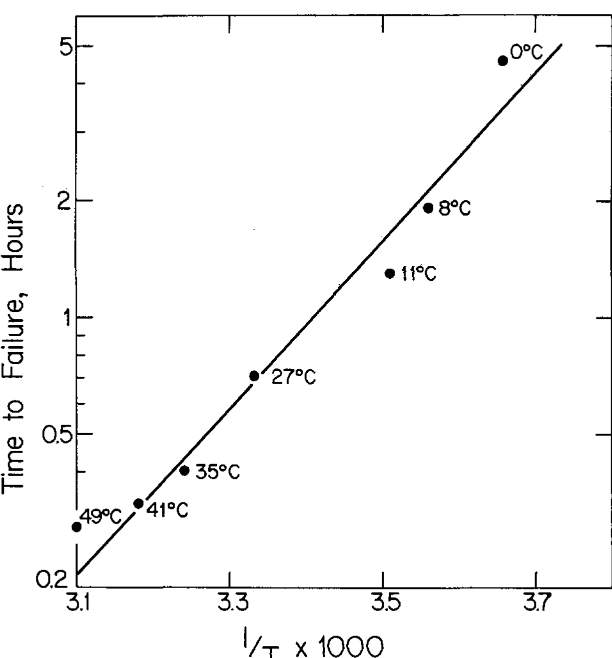

Fig. 4. Effect of temperature on time to failure in 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$, pH 6.5.

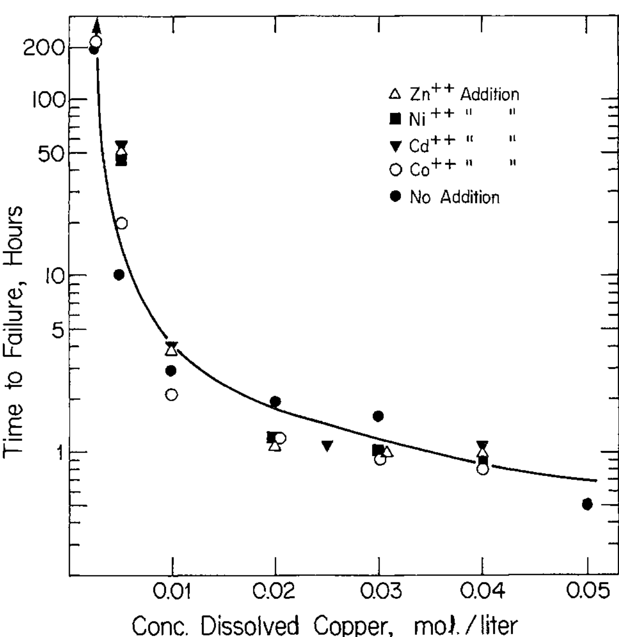

Fig. 5. Effect of dissolved copper in presence of other metal sulfates on time to failure in 1M $(NH_4)_2SO_4$, pH 6.5 at room temperature. Total metal concentration is maintained at 0.05M, except for the solutions containing Cu only.

fect on times to failure (Fig. 5). Furthermore, 0.05M of any such extraneous cation in absence of dissolved Cu does not spontaneously induce SCC. Extraneous cations, however, are able to induce failure under conditions of anodic polarization with or without occasional renewal of the test solution in order to avoid accumulation of Cu salts. The data supposedly show, as Pugh and Green (27) concluded earlier from results obtained in a copper-free ammoniacal test solution, that SCC of brass occurs in absence of dissolved Cu provided that the prevailing potential is favorable. However, the noble values of the favorable potentials, accompanied by continuous anodic dissolution of the brass, makes it impossible to avoid accumulation of dissolved Cu at the specimen surface. This is also true of measurements made in the present non-Cu ammonium complex solutions, hence dissolved Cu in some amount is present in all instances at the time of failure. Whether dissolved Cu is or is not necessary to failure, the apparent critical potentials in the initially Cu-free solutions, in absence of other factors, should all be approximately the same, but, in fact, they are not. It appears, therefore, that failures can occur independent of an initially dissolved Cu concentration. but not independent of whatever heavy metal ammonium complex is present. It is found, for example, that the critical potentials for 0.05M Zn^{++} or Cd^{++} in 1M $(NH_4)_2SO_4$, pH 6.5 solutions are both about 0.16V SHE, but for 0.05M Co^{++} it is 0.22V SHE. The corresponding critical potential for 0.05M Ni^{++}, for which the $(NH_4)_2SO_4$ concentration was reduced to 0.5M in order to avoid precipitation of Ni salts, is 0.14V. Data for the Cd^{++} and Co^{++} test solutions are included in Fig. 2. For Co^{++} test solution, the damaging potential region is so narrow that it is easily missed experimentally. Anodic protection (>50 hr) occurs only 10 mV above the critical potential at and below which cathodic protection is observed. For Cd^{++} test solution, a similar spread of potential between cathodic and anodic protection is equal to 110 mV and for the Cu^{++} test solution it is still greater and equal to 215 mV.

It was found that some anions, *e.g.*, Cl^- and Br^-, added to the usual test solution inhibit the cracking process. Acetate, NO_3^-, and ClO_4^- ions, on the other hand, have less or no inhibiting effect, as shown in Fig. 7. The effect of Cl^- and Br^- is to shift the critical potential in the noble direction, and the corrosion potential in the active direction. The approximate concentration observed at the merger of the two potentials corresponds to the optimum minimum concentration of halide ion imparting inhibition (Fig. 8). The optimum minimum concentration for NaCl is 0.04M and for NaBr it is only 0.005M.

It was also of interest to determine whether SO_4^{--} is an inhibitor in view of the report by McKinney and Hermance (32) describing failure of Ni-brass telephone exchange components by SCC in the Los Angeles amosphere known to be high in nitrogen oxides and nitrates, but not in New York City where the higher sulfate content of the atmosphere presumably inhibits similar failures. The failure time of brass in 0.05M $Cu(NO_3)_2$, 2M NH_4NO_3, pH 6.5 was 0.85 hr, and with added 1M Na_2SO_4, it was 0.70 hr, showing no inhibition. It is possible, therefore, that SO_4^{--} actually inhibits the reduction of NO_3^- to NH_4^+ by the corrosion reactions occurring on a brass surface, the presence of NH_4^+ being necessary to SCC. This possibility deserves investigation.

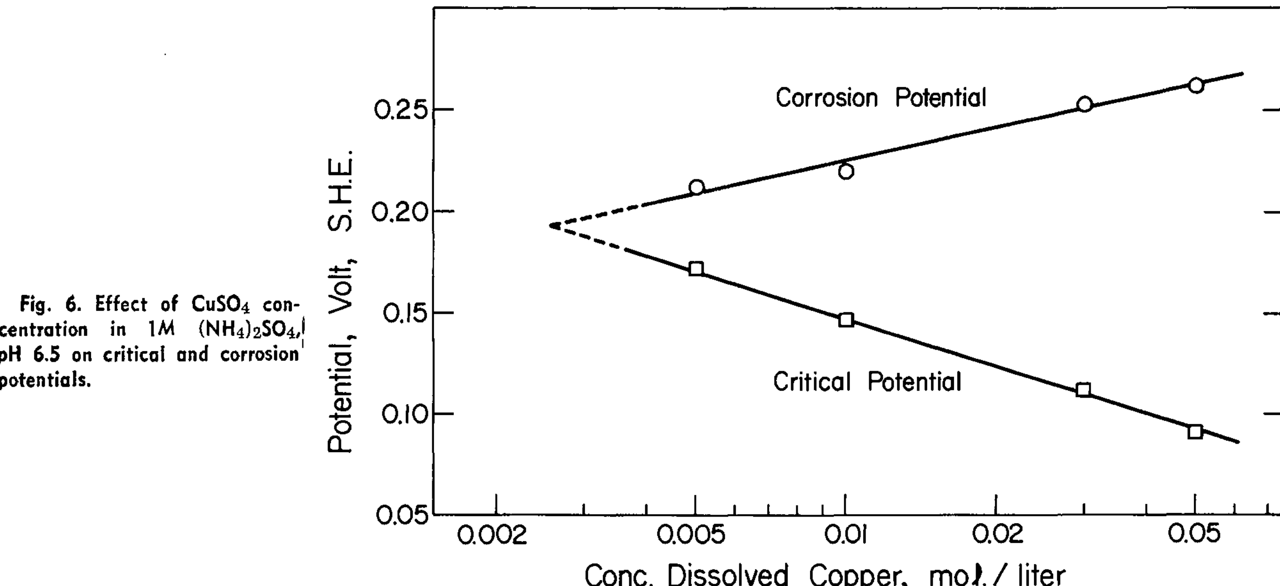

Fig. 6. Effect of $CuSO_4$ concentration in 1M $(NH_4)_2SO_4$, pH 6.5 on critical and corrosion potentials.

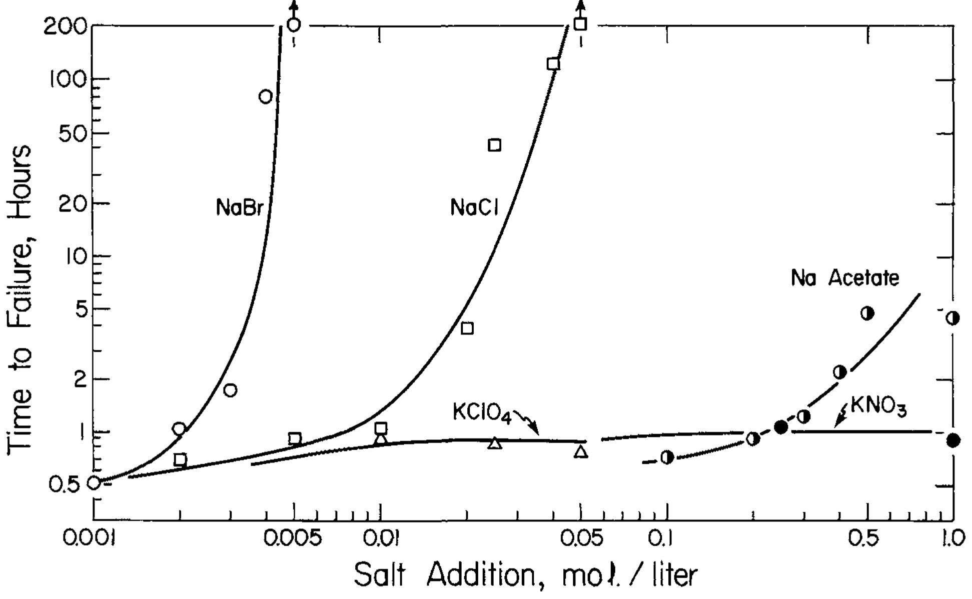

Fig. 7. Effect of various anions on time to failure in 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$, pH 6.5 at room temperature.

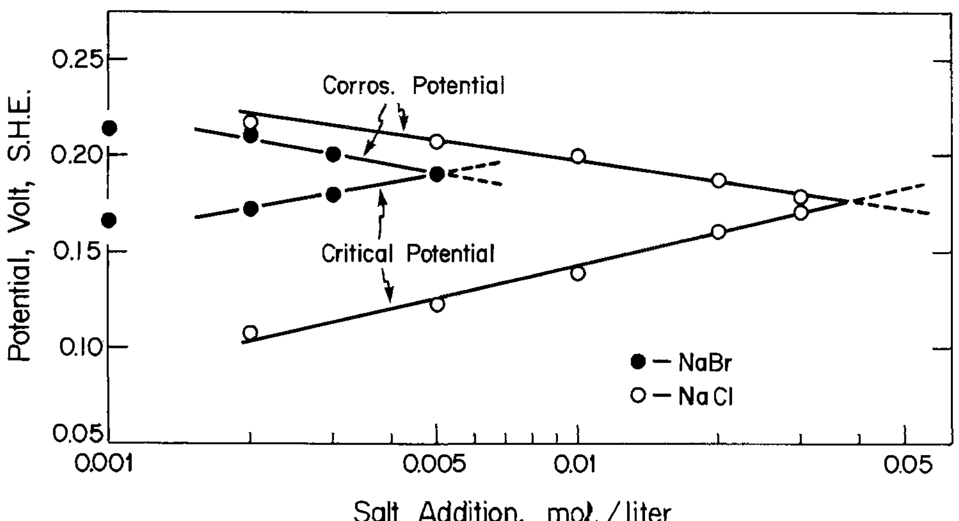

Fig. 8. Effect of NaCl and NaBr additions to 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$, pH 6.5 on critical and corrosion potentials at room temperature.

Finally, data of Fig. 9 show that brass in alkaline tartrates also exhibits a critical potential for SCC, the value being considerably more active than that in ammoniacal solutions. Hence cathodic protection is also possible in tartrate solutions. The values of pH were measured using the glass electrode and hence are only approximate. The alkaline error was reduced, but not eliminated, using potassium instead of sodium tartrates and hydroxides. Qualitatively, an increase in alkalinity of the tartrate solution shifts the critical potential in the active direction.

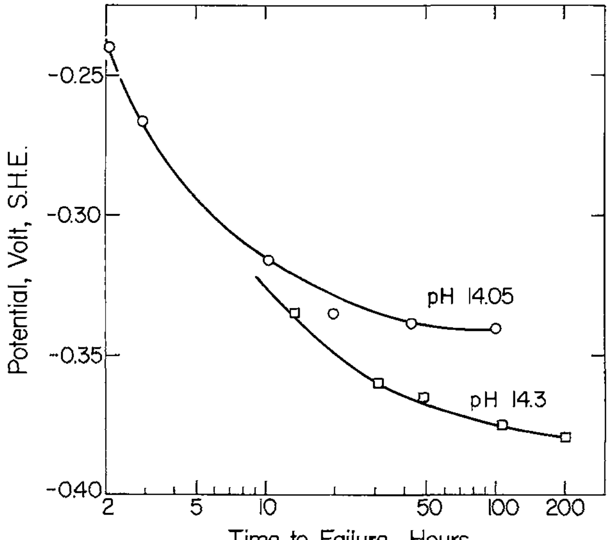

Fig. 9. Effect of applied potential on time to failure in 0.04M $CuSO_4$, 0.5M potassium tartrate at two pH values.

Discussion

It is quite clear that similar to the situation for stainless steels, high strength steels, and mild steels, brass resists spontaneous stress corrosion cracking if the corrosion potential is active to the critical potential. The prevailing potential, alternatively, can be noble to the potential region above which the time to failure again increases (anodic protection). Rapid anodic dissolution of brass may occur simultaneously in the noble region, particularly in the presence of appreciable dissolved Cu.

The critical potential is affected by cold-work of the brass, and by pH, dissolved Cu concentration, and by presence of inhibiting anions. Analogous to other metal systems, it is probably also affected by temperature. Brass undergoing SCC in alkaline tartrate solutions similarly exhibits a critical potential below which failure does not occur within at least 200 hr and probably for much longer times.

The present evidence indicates that dissolved Cu^{++} or some other heavy metal ammonium complex in

some amount is required for the observed failures. This conclusion is supported by the small amount of dissolved Cu^{++} (0.003*M*, Fig. 5) needed for spontaneous failure, and the continuing dissolution of brass at potentials required for failure in non-Cu complex test solutions, all of which are noble to the corrosion potentials. It is also supported by differing critical potentials for failure depending on whether the available ammonium complex contains Cu^{++}, Cd^{++}, Zn^{++}, Ni^{++}, or Co^{++}. Failures are observed in each solution only if the corrosion potential or applied potential is noble to the critical value. It appears that the Cu^{++} complex is the most damaging of the various heavy metal complexes in view of its least noble critical potential, and the ineffectiveness of other complexes in presence of the Cu^{++} complex to change the time to failure (Fig. 5). Necessity for the presence of NH_4^+ has been demonstrated by early investigators and most recently by Lynes (2) and by Sircar *et al.* (15). The two notable exceptions are Cu complex-forming alkaline tartrates and citrates (14).

The effect of increasing *p*H above 6.5 is to shift corrosion and critical potentials resulting in an increase of times to failure. At a *p*H of 6.5 the prevailing corrosion potential coincides with the potential corresponding to minimum failure time (Fig. 2 and 3).

The halide ions Cl^- and Br^- added to the test solution are more effective inhibitors than perchlorates, acetates, sulfates, and nitrates probably because the halide ions or their complexed species more readily adsorb on the metal surface. The marked inhibiting action of small amounts of halide ion is to shift the critical potential in the noble direction and the corrosion potential in the active direction. The latter shift is in accord with a decreased activity of Cu^{++} caused, directly or indirectly, by ionic complexing involving Cl^- or Br^-. Regarding the critical potential, it should be noted that the effect of the inhibiting anions for SCC of mild steel and 18-8 stainless steel is similarly to shift the critical potentials of these metals in the noble direction (20, 23). The explanation for the consistent behavior of inhibitors in this respect is important to any relevant proposed mechanism of SCC. Hoar and Booker (7) earlier found an inhibiting effect of Cl^- on SCC of brass but did not offer an explanation other than to suggest that the surface oxide in its presence was seemingly less compact.

It is difficult to explain the observed critical potentials and the effect of inhibiting anions on the basis of an oxide film fracture model. For example, when the visible oxide film was pickled off presently stressed brass specimens in 6*N* HCl at room temperature for 1 min after exposure for either 0.5, 1.0, 2.4, 3.5, or 5 hr to the usual composition Cu^{++} test solution of *p*H 7.5 (average time to failure is 7 hr), then washed and re-exposed to the same test solution without removal from the test apparatus, there was no major change of failure time. The average total time gradually increased from 7.0 hr for unpickled specimens to 9.1 hr for pickled specimens previously exposed to the test solution for 5 hr. Any fracture of a thick oxide film is obviously unimportant to the mechanism. Supposed fracture of a thin oxide film is also not plausible in light of absence of SCC just below the critical potential of 0.095V SHE, and its occurrence slightly above this potential. The latter value of potential has no obvious relation to the formation or reduction of Cu_2O by the Pourbaix diagram for Cu (33). Moreover, the potential-*p*H diagram for Cu as modified by Mattsson (18) and by Hoar and Booker (7) does not account for the effect of increasing dissolved Cu concentration and of increasing *p*H on observed shift of the critical potential in the active direction. If the estimated thermodynamic activity or other properties of alloyed Zn are invoked to move the equilibrium boundaries in the required direction, any such explanation is obviously not relevant to an explanation of the susceptibility of Cu alloys not containing Zn, *e.g.*, those containing Si, Ni, Sb, As, Al, or P (34).

The relevance of the critical potential to incidence or absence of SCC also casts doubt on any "active path" or metal dissolution model. Uniform corrosion of brass continues just above or below the critical potential, as data of Pugh and Green show (27). If the critical potential is equated to a specific minimum corrosion rate at and above which cracks initiate and grow, it becomes difficult to explain why this supposed rate should be decreased and the critical potential increased by the presence of a small amount, 0.04*M*, of chloride or by only 0.005*M* bromide. Both halide ions form soluble Cu-Zn corrosion products and do not inhibit uniform corrosion of Cu or Zn. Furthermore, it is not plausible to interpret the reduced susceptibility of severely cold-worked brass in terms of a reduced corrosion rate brought about by cold-work.

As in the proposed explanations for SCC of stainless steels, high strength steels, and mild steels, adsorption of the environment on appropriate surface defect sites accompanied by reduction of metal bond strength comes closest to explaining the available facts. This model and the evidence for its support have been discussed in detail in previous publications (35, 36). Johnson and Leja (14) and Sircar *et al.* (15) also favored an adsorption mechanism. It is assumed, accordingly, that surface adsorption on stressed brass of a damaging ammonium complex containing Cu^{++} or another heavy metal ion occurs in sufficient amount above the critical potential, and its corresponding desorption occurs below. Desorption may again take place at still more noble potentials, as is dramatized by the SCC behavior of brass in the Co^{++} test solution. Potentials at which relevant adsorption or desorption takes place understandably varies with the type of ammonium complex. The metal bond breaking process by the adsorbed complex is considered to be analogous to that responsible for nucleation and growth of cracks in, for example, stressed β-brass exposed to moist air (37), in stressed high strength steels exposed to pure H_2 at 1 atm (38), or to moist argon (39), in stressed α-brass exposed to liquid Hg, or in stressed austenitic stainless steels exposed to hot chlorides. If this concept also applies to the present situation, more facts must be made available to clarify which of the possible ammonium complexes containing Cu are the damaging species. It may be one of the well-known stable complexes described in the literature, or, instead, it may be a metastable reaction product of the test solution with brass, the composition of the reaction product being potential dependent. The damaging species presumably must have an over-all apparent negative charge within the damaging potential region because of the more pronounced susceptibility to SCC at potentials just noble to the critical value. Hence, although stable copper complexes are normally positively charged, the responsible species may adsorb accompanied by or combined with an anion or anions. The same situation applies to SCC by Cu complexes involving tartrates and citrates. The inhibiting function of Cl^- and Br^-, accordingly, is probably one of displacing the damaging species by non-damaging adsorbed Cl^- and Br^- or their complexed species. This competitive adsorption process is favored less at more noble applied potentials, a higher concentration of halide ion being necessary for inhibition under these conditions. Competitive adsorption involving Cl^- ions, it should be recalled, was also proposed as describing the inhibiting behavior of extraneous anions in the pitting corrosion of stainless steels (40), aluminum (41), and Ni-Cu alloys (42). However, it should not be concluded from this apparently parallel behavior that the mechanism of SCC necessarily depends on initial pitting corrosion. Adsorption sites for the two processes are quite different, involving a stressed lattice in the one instance, but not in the other.

In accord with the mechanism of stress-sorption cracking, the accountable imperfection network is usually concentrated along grain boundaries or, in the case of transgranular cracking, along the slip planes of stressed α-brass. They mark the sites on which preferred adsorption of the damaging ammonium complex occurs, resulting in cracking. Which direction the crack follows is determined in part by alloy composition and by the degree of cold-work, both affecting imperfection networks, and also by factors of the environment, such as pH. The latter determines the nature of specific Cu complexes in competition with OH^- or other ions available to adsorb on one type of imperfection network over that of another.

A suitable imperfection network is not usually generated in plastically deformed pure Cu, but it is favored by increasing amounts of alloyed Zn. The properties of alloyed Zn, in this regard, are shared by many other alloyed components (34), chemically unrelated as mentioned earlier, which also induce susceptibility. In other words, it is not so much the supposed film-forming or electrochemical properties of alloyed components that induce susceptibility as it is the probable effect of such components on suitable imperfection networks generated during tensile stressing of the alloy.

Along the same lines, shorter failure times at above-room temperatures suggest that, at least in part, more favorable imperfection networks are generated in brass at the higher temperatures. This is analogous to the situation in austenitic stainless steels exposed to $MgCl_2$ solution which fail by SCC only above room temperature.

Conclusions

1. It is confirmed that minimum failure time of 63-37 brass in 0.05M $CuSO_4$, 1M $(NH_4)_2SO_4$ test solution occurs at pH 6.5.

2. The critical potential in the above test solution below which failure time is $>$ 50 hr is 0.095V SHE. This value is shifted in the active direction by increasing pH and by increasing dissolved Cu concentration.

3. The activation energy for SCC in the above test solution is 10 kcal/mole.

4. The minimum dissolved Cu^{++} concentration for spontaneous cracking of 63-37 brass in 1M $(NH_4)_2SO_4$ is 0.003M. Above this concentration the corrosion potential is noble; below it is active to the critical potential.

5. Sodium chloride and sodium bromide, at least 0.04 and 0.005M, respectively, added to the test solution are effective inhibitors of SCC. They shift the critical potential in the noble and the corrosion potential in the active direction; inhibition occurs when the two potentials merge or cross.

6. An ammonium complex containing Cu or some other heavy metal is necessary in some amount for SCC of brass to occur in the $(NH_4)_2SO_4$ test solution. This conclusion is reached from (*i*) the very small concentration of dissolved Cu (0.003M) needed for spontaneous cracking, (*ii*) the continuing uniform corrosion of brass supplying Cu^{++} at the noble potentials required for failures in initially Cu-free solutions, and (*iii*) the distinctly different critical potentials for failures in some of the Cu^{++}, Cd^{++}, Zn^{++}, Ni^{++}, and Co^{++} ammonium complex test solutions.

7. The critical potential in 0.04M potassium tartrate, pH 14, is -0.34V SHE, becoming more active at a higher pH.

8. The present results are interpreted in terms of reduction of metal bond strength by adsorption of a Cu-containing or other heavy metal ammonium complex on appropriate defect sites along grain boundaries or slip planes.

On the Anodic Oxidation of Molybdenum

C. M. Daly and R. G. Keil*

Department of Chemistry, University of Dayton, Dayton, Ohio 45469

ABSTRACT

The anodic oxidation of molybdenum in an acetic acid solution has been studied with regard to the nature of the formed film and the kinetics of film growth. Faradaic methods, ATR spectroscopy, and "open-current" transient methods were utilized. A comparison was made between the anodic oxide film formed on molybdenum and vanadium. The anodic film on molybdenum was found to contain molybdenum in an oxidation state less than +6.

The purpose of this study was to investigate the chemical nature and certain physical properties of anodic molybdenum oxide films formed in a nonaqueous anodizing solution. Young (1) has reported that the hexavalent oxides are not readily soluble in acid solution and when subjected to anodic polarization in acid solution the metals form passivating films of the oxides. Some metals, (*e.g.*, molybdenum and vanadium) do not yield an insoluble anodic oxidation product when anodized in aqueous media and such a film can only be formed in nonaqueous solutions (2). Young has also reported that it is not clear whether anodic metal oxide films might contain cation valencies less than the highest common one.

Recently Johnson *et al.* (3) have studied the mechanism of the anodic dissolution of molybdenum in aqueous sulfate solution as a function of *p*H and salt composition. An anodic dissolution mechanism was proposed which involved the prior oxidation of surface films of molybdenum(V) oxide to MoO_3 and subsequent dissolution by hydrolyzation. This entire mechanism is based, of course, upon the availability of sufficient free water to form soluble molybdic acid.

In addition, Arora and Kelly (4) formed anodic oxide films on molybdenum for radiochemical depth distribution studies. In that work they utilized a nonaqueous solvent reported earlier by Keil and Salomon (2) which had been successfully employed to grow anodic oxide films upon vanadium metal. They make the *a priori* assumption that the anodic oxide formed is in fact molybdenum trioxide. Earlier results have prompted us to make a comparative study of the nature of anodic films upon vanadium and molybdenum using this rather unusual anodizing solution, acetic acid-water-borax.

In this present work, we study the nature of the film on molybdenum using Faradaic methods, attenuated total reflectance (ATR) spectroscopy, and electrical properties of the molybdenum oxide film by use of open-circuit transient analysis. The anodic oxidation of several metals (5-8) has been studied using this method. We were particularly interested in this study, to compare the results obtained through the anodic oxidation of molybdenum with those of vanadium.

Experimental

High-purity (> 99.9%), single-pass, zone-refined molybdenum metal in wire and foil form was used for this work. The molybdenum, obtained from both Materials Research Corporation and Alpha Chemicals, was mounted by methods previously described (2). The molybdenum surface was prepared for anodization by first polishing with a series of emery polishing papers (4, 3, 2, 0, 2/0, 3/0, and 4/0) followed by wet aluminum oxide powder polishing (15.0, 5.0, and 1.0μ) on a rotating felt wheel. The finest aluminum oxide powder utilized was 1.0μ micropolish. Subsequently the electrode was washed first for 15 sec with 1:1 water-nitric acid (70% assay) solution, then with acetone, dried in a stream of nitrogen gas, and immersed in the anodizing solution. In this work we used an acetic acid solution 2.0M in water and 0.02M in sodium tetraborate. The solution had a conductivity of 79 μ(ohm-cm)$^{-1}$. These studies were carried out at 25°C. An ambient of nitrogen was maintained in the reaction flask and the anodizing solution was degassed prior to use.

Under galvanostatic conditions current densities not less than 379 $\mu A/cm^2$ were used. For the open-circuit transient studies a pair of Philbrick SP102 operational amplifiers were used for galvanostat and voltage follower. The output of the voltage follower, which accomplished a power gain, was then fed into the input terminals of a Sanborn Model 7701B oscillographic recorder. These amplifiers operate over a range of ±100V. All potentials were recorded relative to the saturated calomel reference electrode. For the studies at high current densities, an analog to digital converter data collection system was employed. The voltage *vs.* time data was fed into the computer via an audio coupler. Overpotentials were calculated from observed voltages by subtracting the value of the open-circuit potential. Apparent current densities were obtained by dividing the observed current by the macroscopic surface area of the anode.

Faradaic studies.—In an effort to obtain the upper limit of the average valence of the molybdenum ion within the anodic film, quantitative measurements of the charge passed and the amount of molybdenum oxidized were made. The results obtained using this method include gassing, if any, which would result in the actual valence state being substantially lower.

The amount of molybdenum metal present in the anodic oxide was determined using the colorimetric method of Ayres and Tuffly (9) as reported by Snell and Snell (10). The method involved the determination as molybdate in the hexavalent state by phenylhydra-

*Electrochemical Society Active Member.
Key words: anodic oxidation, molybdenum, transients, structure.

zine hydrochloride. The following modifications were incorporated: (*a*) approximately 0.02g of potassium meta-periodate (KIO_4) were added to the phenylhydrazine hydrochloride before boiling took place in order to oxidize the molybdenum present to the hexavalent state, (*b*) the film was quantitatively dissolved by immersing the electrode in 0.5 ml of ammonium hydroxide. A constant current of 2500 μA was used and films were grown to a maximum of 56V. Due to the small surface area of the electrode (0.664 cm^2) consecutive runs were made in the anodizing solution for a cumulative time of approximately 300 sec. The anodizing solution was not changed during these consecutive runs but the electrode was removed after each thin film growth and the stripping modification in part (*b*) above was employed. After the completion of enough runs to reach the time of 300 sec the anodizing solution was removed and reduced to approximately 10 mliters by boiling. This reduced solution was then combined with the ammonium molybdate formed in the stripping process and added to the phenylhydrazine hydrochloride solution. The per cent transmittance was measured at 505 nm in a Perkin-Elmer double beam spectrophotometer. The apparent oxidation state of anodically oxidized molybdenum, defined as the ratio of number of Faradays to grow the film to the number of moles of molybdenum found in the film plus anodizing solution, was then calculated.

ATR spectroscopy.—Infrared spectra were obtained utilizing a Wilk's single beam ATR attachment equipped with a KRS-5 prism. An important step in anodizing (in those instances where a permanent film was desired) was that the specimens be dried with a stream of dry gas (we used nitrogen) immediately following removal from the anodization cell. The molybdenum anodic oxide films, like vanadium, are unstable. This instability is evidenced by changes in the uniformity of the interference colors and occur approximately 15 sec after removal from the anodizing solution if it is kept in a moist atmosphere. This instability is inherent to the oxides of V and Mo and not to the electrolyte. Films formed on Nb or Ta in our laboratory in this electrolyte have the same stability as films formed on these metals using boric acid-borax solutions.

Results

Anodic oxidation in this anodizing solution results in an anodic film which exhibits intense interference colors. The film interference colors observed at various formation potentials are shown in Table I for potentiostatic film growth. Anodization under potentiostatic conditions produced films whose minimum final leakage current was 0.5-1.5 mA/cm^2 and from which some film dissolution did occur even during film growth.

Faradaic studies to obtain an upper valence limit of the molybdenum ion within the anodic film were conducted under galvanostatic conditions. Massive gassing at the anode did not occur. However, it is possible that small amounts of gas were produced. This would cause the actual oxidation state of the metal within the film to be less than the apparent oxidation state. Results showed that the average apparent oxidation state of molybdenum within the film equaled 5.50. It should be pointed out that complete development of the colorimetric complex between the dissolved molybdenum film and phenylhydrazine hydrochloride was not obtained unless periodate was first added to the film solution to be analyzed. The periodate ion oxidizes the molybdenum quantitatively to the Mo(VI) oxidation state.

Table I. Observed interference colors at various formation voltages

Formation voltage, V	Film interference color
6-10	Light yellow
15	Steel blue
25	Light blue
35	Yellow-green
45	Violet
55	Deep violet
65	Emerald green

Additional insight into the nature of the anodic molybdenum film can be gained by viewing the ATR spectra for films produced potentiostatically. Figure 1 shows the ATR spectra of the anodic film as a function of formation voltage. For comparison the spectra published for MoO_3 by Nyquist (11) is given in Fig. 1. Note that there is a definite absorbance of the anodic films at about 1000 cm^{-1} in agreement with the published spectra for MoO_3 but that the broad band centered at 850 cm^{-1} in the standard is either not present or shifted markedly to higher energies in the spectra of the anodic oxide films. We should note that we are comparing a probably amorphous film with a crystalline standard.

The oxide film can be considered to be the dielectric medium of a capacitor whose plates are composed of the substrate metal and the anodizing solution. Under galvanostatic conditions the film carries current in some manner. During an open-circuit transient the differential equation describing the system becomes

$$i + C\,dV/dt = 0 \qquad [1]$$

which relates the ion current through the film, i, with the film capacitance, C, and the voltage decay rate, dV/dt. Measurement of V as a function of t experimentally enables one to determine the equation of dV/dt and ultimately a definitive expression of i as a function of V. Earlier work (5-7) has established that an expression between voltage and time of the form

$$V = k - V_o \ln (t + \theta) \qquad [2]$$

can lead to a field-assisted ionic migration growth mechanism in which the mobile ions jump periodic potential energy barriers. The quantities θ, V_o, and k are parameters which are determined by the particular transient and its initial conditions. For molybdenum, the voltage-time transient fit an equation of the above form. Analysis of the voltage-time trace was performed with the assistance of a digital computer. The computer was fed voltage *vs.* time data. It then performed the following functions: (*a*) it chose from

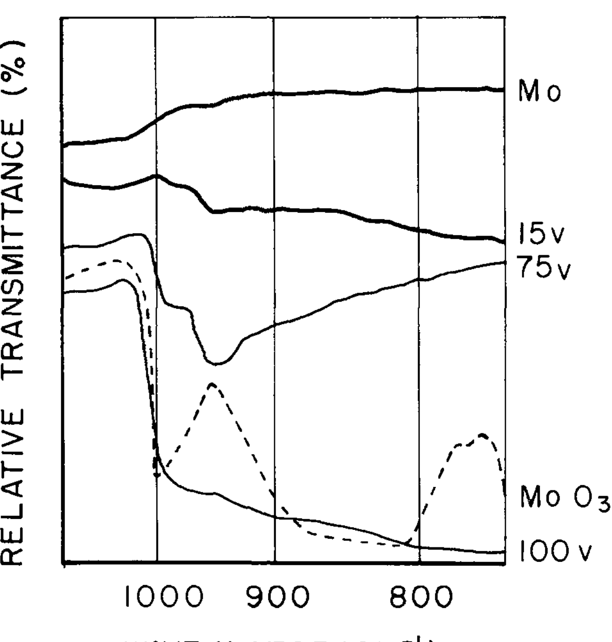

Fig. 1. ATR spectra of anodic oxide films at various formation voltages.

a very large selection the value of θ which produced a minimum standard deviation of all data points when the data were subjected to a linear least square analysis, and (b) it printed out values of k, θ, V_o, and the standard deviation. It can be shown (8) that manipulation of Eq. [2] can ultimately yield as a final result relating i and V, an equation of the form

$$i = i_o \exp (V/V_o) \quad [3]$$

where the exchange current density $i_o = CV_o \exp(-k/V_o)$.

The point is that an equation of this form is the mathematical consequence of the differential equation describing the system and the experimental voltage-time profile. Here i_o and V_o are experimentally determined parameters whose dimensions are the same as i and V, respectively. If time zero equals the commencement of the transient, the transients fit Eq. [2] for times corresponding to 80% of the potential decay at a current density of 3794 $\mu A/cm^2$ and 60% of the potential decay at 1897 and 379 $\mu A/cm^2$. Figure 2 shows the relationship between the parameter V_o and the formation potential. For a given formation current density, V_o is a linear function of the formation potential and all lines nearly pass through the origin. The slope of each line is obviously a function of the formation current density and decreases with increasing current density.

From data analysis, we learned that the value of θ required to fit the transient data to Eq. [3] is quite small, with values ranging from essentially zero to as high as 0.2. A typical value is 0.001. Generally, θ increased with the formation potential of the film. Small values are not unexpected because of the relatively large formation current densities and $\theta = CV_o/i_e$. Figure 3 shows the relationship between the reciprocal capacitance and the formation potential. The reciprocal capacitance is related to θ by the equation $1/C = V_o/i_e\theta$, where i_e equals the film formation current.

Discussion of Results

The results of the Faradaic studies show conclusively that the metal ions in the anodic molybdenum oxide film cannot quantitatively be present in the +6 oxidation state. This point was accented by the fact that full development of the molybdenum-phenylhydrazine hydrochloride was not achieved unless prior to complexation some periodate ion was added. Thus, some of the molybdenum must be present in an oxidation state less than +6 within the film. Also any oxygen evolution (not observed under galvanostatic conditions) would require still lower metal ion valencies. Johnson *et al.* (3) in a study on anodic dissolution of Mo in aqueous acid media postulated that dissolution is probably accomplished through a hydration reaction to form $MoO_3 \cdot H_2O$ (or molybdic acid H_2MoO_4). They further postulated that Mo metal when placed in solution forms a film of approximate composition Mo_2O_5 that completely covers the metal surface. They also noted that the conductive Mo_2O_5 is converted to MoO_3 upon anodic polarization. A major conclusion they made, and with which we agree, is that an equilibrium probably exists between MoO_3 and a lower oxide. We suggest the results from Faradaic experiments and the ATR spectroscopy possibly point to the presence of a lower oxidation state as a major film constituent. Ho and Ord (12) recently followed the formation of mixed inner and outer anodic layer on iron with a following ellipsometer in neutral borate electrolyte. Prediction of our anodic oxidation product upon thermodynamic grounds is further complicated because of the nature of our electrolyte, a difficulty we experienced in earlier work with vanadium (2). The activity of water in the acetic acid solution has not been determined and renders thermodynamic consideration using Pourbaix-type pH *vs.* E(SHE) diagrams (13) difficult. We suggest our data (Faradaic and spectroscopic) at the very least indicate an amorphous film nature and possibly the presence of oxides other than MoO_3. Care must be exercised in these spectral comparison however because we are comparing a probably amorphous (3) film material with a crystalline standard.

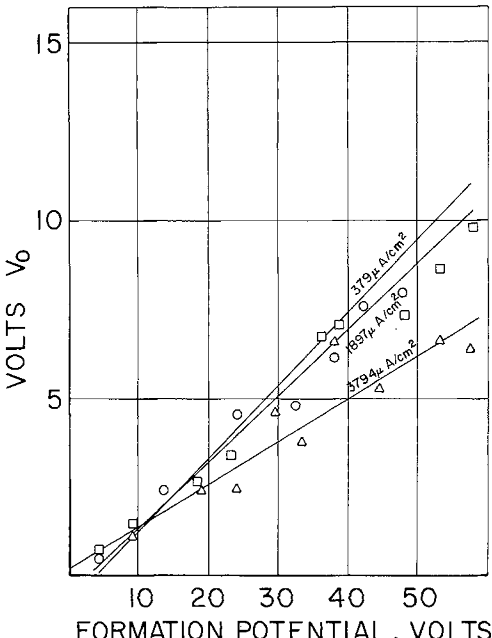

Fig. 2. Dependence of V_o on formation potential for molybdenum in anodizing solution. The formation current density was 379.4 $\mu A/cm^2$ for the data represented by □, 1897 $\mu A/cm^2$ for the data represented by ○, and 3794 $\mu A/cm^2$ for the data represented by △.

An exponential dependence of the current density through the oxide film on the overpotential can be interpreted in terms of an activation-energy-controlled process (1). The theoretical relation for such a process, in the high-field case, is given in its simplest form by

$$i = 2an\nu \exp(-U/kT) \exp(qaE/kT) \quad [4]$$

where a is the half-jump distance of the activation barrier, n the density of charge carriers, ν the frequency of the oscillating ions, U the activation energy for the process, q the effective charge on the mobile ions, and E the electric field at the activation barrier. The other symbols have their usual meanings. Assuming the field at the activation barrier is equal to the average electric field, a comparison of Eq. [3] and [4] may be made which yields the relationship

$$V_o = (kT/qa)D \quad [5]$$

Thus, V_o is proportional to the thickness of oxide layer, D.

The experimental data presented here verify a model of this type. Figure 2 shows that the values of V_o are linearly proportional to the formation potential for a given formation current density over a wide range of values and the lines nearly intersect the origin. This result indicates that a high-field conduction process limits the current through the layer. Data taken for

Table II. Apparent oxidation state of molybdenum anodic oxidation product for various formation voltages grown at a current density of 3762 $\mu A/cm^2$

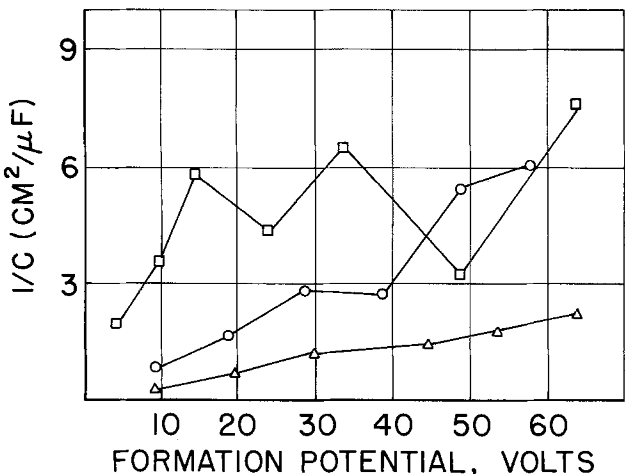

Fig. 3. Dependence of the reciprocal capacitance on formation potential. The formation current density was 379.4 $\mu A/cm^2$ for the data represented by □, 1897 $\mu A/cm^2$ for the data represented by ○, and 3794 $\mu A/cm^2$ for the data represented by △.

different formation current densities fall on lines of differing slopes, indicating that the field in the layer depends on the formation current density. The field in the dielectric may increase with increasing formation current density because of an increase in the ion jump distance at higher formation current densities. For films grown potentiostatically the current decreased to some limiting value which we called the "leakage" current. Our results indicate that the final "leakage current" under potentiostatic conditions equaled 0.5-1.5 mA/cm^2. We presume this is due primarily to a steady-state dissolution of the anodic oxide. Analysis of the electrolyte verifies that some molybdenum is dissolving during film growth. This result is in agreement with those found for vanadium (8). Inspection of the reciprocal capacitance plot, Fig. 3, shows severe scatter of points. Perhaps this is due to the fact that we were using high current densities and consequentially obtained very small values of θ or it may indicate some film porosity.

The results of this investigation on molybdenum are similar to those obtained in an earlier work on vanadium (8). Both metals when subjected to anodic polarization in the acetic acid-water-sodium tetraborate solution, yield a protective film exhibiting intense interference colors rather than anodic dissolution. The anodizing solution is probably unique and works because the water activity is significantly reduced on account of strong intermolecular interactions with acetic acid dimer molecules. Perhaps a comparative study of, say, niobium in aqueous and acetic acid borax solutions would be informative.

The film on molybdenum is not quantitatively MoO_3, but probably exists as a mixed oxide. Ionic conduction during film growth proceeds by the mechanism of field-assisted barrier migration.

Nitrogen Diffusion in Zirconium Nitride

J. G. Desmaison[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

Diffusion of nitrogen in $ZnN_{0.93}$ plates obtained by direct nitridation of 99.995 weight per cent zirconium sheets at 1150°C was studied using the ^{15}N gas-solid exchange technique. These specimens were characterized by chemical analyses, density, lattice parameter, and structural measurements. The diffusion anneals were performed at a nitrogen pressure of 220 Torr and at temperatures in the range 1000°-1200°C. The tracer diffusion coefficient can be expressed as $D^*(cm^2/sec) = 4.08 \times 10^{-6} \exp -36,600/RT$. These results when compared to determinations of the chemical diffusion coefficients obtained from Zr nitriding kinetics demonstrate that nitrogen transport in the polycrystalline solid at temperatures less than 1200°C is associated with a short-circuit diffusion mechanism.

Diffusion studies on metal nitrides have been a subject of limited interest. Indeed, diffusion coefficients have been reported for only a few transition metal nitrides which are chemical coefficients for nitrogen diffusion except for uranium mononitride where tracer diffusion coefficients are available for both nitrogen and the metal species. The purpose of this investigation, accordingly, was to determine the nitrogen tracer diffusion coefficient in zirconium mononitride and to compare this determination to diffusivities obtained from models for the nitridation of zirconium (1-6) and the sintering of this nonstoichiometric compound (7).

Experimental

Sample preparation.—ZrN plates, $2.5 \times 1.5 \times 0.025$ cm, were prepared by nitriding zone-refined Zr sheets, 99.995 weight per cent (w/o) pure, in research grade nitrogen, < 1 ppm O_2, held at 1150°C and 1 atm pressure for periods of 4 weeks. Careful precautions were taken to prevent insofar as possible oxygen contamination of the solids. The Pt boat containing the Zr specimens chemically polished in a 5 volume per cent (v/o) HF-45 v/o HNO_3 aqueous solution was covered with a Zr foil and surrounded with Zr gettering chips.

Sample characterization.—ZrN exists over a broad composition range corresponding to $ZrN_{0.55}$-$ZrN_{1.0}$ (8). The composition of the plates was computed from the weight gain during nitridation, the result being checked by chemical analyses. Nitrogen analysis was conducted using Bollman's modified Kjeldahl method in which the dissolving medium is a stannous-phosphoric acid reagent (9). The zirconium content was deduced from the weight of ZrO_2 obtained by reacting a ZrN sample in oxygen for 24 hr at 1000°C.

The structure was characterized by a combination of metallography, lattice parameter, and density measurements. Specimens mounted in room-setting epoxy resin were polished to 1μ diamond paste with kerosene as lubricant. The HF-HNO_3 etchant was used to reveal grain boundaries. X-ray diffraction traces were made in the high angle region at 1/4° per min using 4° slits and Ni-filtered Cu radiation. The lattice parameters were calculated from the (331), (420), (422), (440), and (511) peaks. In some cases the Debye-Scherrer powder x-ray method was used. Densities were determined by the pycnometric method using xylene as the reference liquid.

Diffusion experiments.—Diffusion rates were determined at constant temperature from the decrements of the ^{15}N isotope concentration in the isotopically enriched nitrogen atmosphere. These experiments were carried out in the apparatus shown in Fig. 1. The Pt-Rh reaction chamber, Fig. 2, was equipped with two winches, one for lowering and raising the quartz crucible containing ZrN powder for oxygen gettering and the other for lowering the Pt crucible containing the ZrN plates to undergo nitrogen exchange. The space between the Pt-Rh and mullite tubes was also gettered of oxygen by means of Zr foil. Following are the precautions taken to prevent oxygen contamination of the ZrN plates. The crucibles, each containing 500 mg of ZrN were introduced into the upper section of the reaction chamber. After nitrogen purging and evacuation of the system, an aliquot of 96 atom per cent (a/o) ^{15}N enriched nitrogen was introduced into the reaction chamber to a pressure of 10-15 Torr. Sufficient normal nitrogen was then admitted to give a pressure of 220 Torr when the system was heated to the diffusion temperature. Argon was introduced into the outer chamber at a slightly smaller pressure. The furnace was then brought up to 850°C and the quartz crucible containing ZrN and the Zr foil lowered into the furnace zone for 12 hr to permit gettering of residual oxygen. The temperature was subsequently increased to that for the diffusion run, the quartz crucible raised from the reaction zone, and two 1 cm^3 gas samples collected to measure the initial ^{15}N concentration. Immediately afterwards the Pt crucible containing the ZrN plates was lowered into the hot zone, the zero time taken when the crucible reached this zone. Gas samples subsequently collected at suitable intervals were analyzed by the mass spectrometric technique.

Tracer diffusion coefficients D^* were calculated from the equation of Carman and Haul (10)

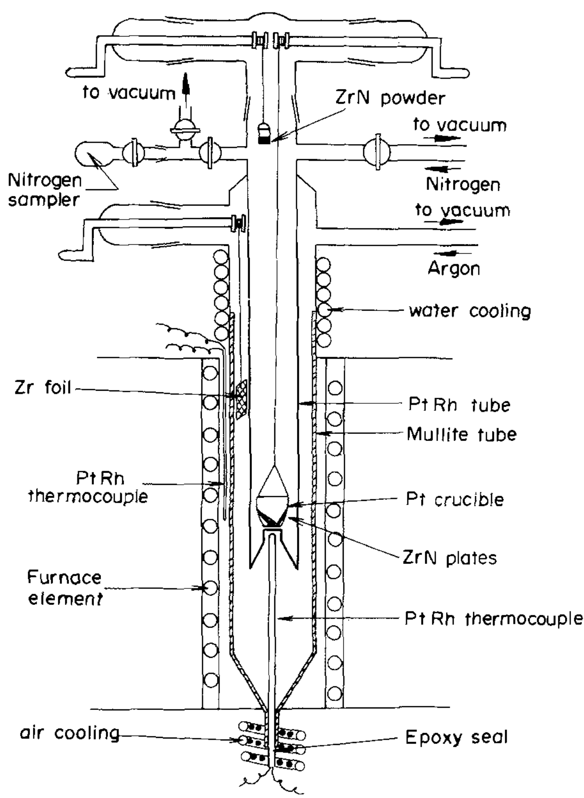

Fig. 2. Reaction chamber and assembly of the diffusion apparatus.

$$\frac{C_t - C_s}{C_g - C_s} = e \text{ erfc } \frac{\sqrt{\tau}}{\lambda} \quad [1]$$

where $\tau = D^*t/l^2$. Here, C_t, C_s, and C_g represent the atom fraction of ^{15}N in the atmosphere at time t, in the solid at time zero (taken as the natural abundance 0.0037), and in the atmosphere at time zero, respectively, l is the half thickness of a ZrN plate, and λ is the ratio of the total mass of nitrogen in the gas phase to that in the solid.

Results

ZrN specimens, which exhibited the golden yellow color of this compound, were in the metal excess range at the atom ratio $N/Zr = 0.93 \pm 0.01$. The lattice parameter, Table I, calculated from diffractometer traces was used to compute the x-ray density given by the expression

$$d_x(\text{g/cm}^3) = \frac{nM}{Na^3} \quad [2]$$

where M is the molecular weight of $ZrN_{0.93}$, N is Avogadro number, a is the lattice parameter, and $n = 4$ is the number of metal atoms in the NaCl-type unit cell. The estimate given in Table I for the fraction of vacant sites in the zirconium sublattice from the small difference of 0.67% between the x-ray and pycnometer densities is questionable (8). Literature data invariably show that $d_x > d_p$, which has been attributed to structural defects such as voids in the polycrystalline solid or the influence of oxygen as an impurity on the defectiveness of the metal sublattice (8, 11, 12).

A smooth surface finish could not be obtained on cross sections of ZrN due to its brittleness. Etching revealed grains of variable size in the 10-30μ range as demonstrated in Fig. 3. Surface examination of the plates showed the existence of small protuberances delineating polygonal surfaces.

In each diffusion run, three or four plates having a total mass close to 500 mg were placed in an inclined position with intervening space in the Pt crucible. Blank runs at 1000° and 1100°C without plates showed no measurable nitrogen exchange. The runs were carried out at temperatures in the range 1000°-1200°C and at 220 Torr nitrogen pressure. Plots of D^*t/l^2 *vs.* time for periods up to 10 hr are given in Fig. 4. Since the plots were linear, diffusion was assumed to be the rate-determining step. The tracer diffusion coefficients were

calculated from the slopes of the best lines and an Arrhenius plot of these evaluations is shown in Fig. 5. The expression for this diffusivity is

$$D^* (\text{cm}^2/\text{sec}) = 4.08^{+88.2}_{-3.9} \times 10^{-6} \exp - (36{,}600 \pm 4500)/RT \quad [3]$$

where the limits are at the 95% confidence level.

The ZrN plates were not discolored during exposures up to 10 hr. At longer times they developed a brownish-green color which darkened with increasing exposure. Powder x-ray photographs contained no new lines but the diffractometer traces of the surface showed a very small extra peak corresponding to the maximum intensity peak of monoclinic ZrO_2.

Discussion and Conclusions

Preparation of ZrN from the metal was carried out under conditions typical of those used in investigations on the nitriding kinetics of zirconium. Since zirconium diffusion is negligible, several investigators (1-5) have analyzed the parabolic kinetics for the nitrogen uptake governing the growth of the ZrN surface layer in terms of unidirectional two-phase ($T < 862°C$) or three-phase ($T > 862°C$) volume diffusion models to obtain an average value for the chemical diffusion coefficient. These values are recorded in Table II and shown by Arrhenius plots in Fig. 6. There are also included diffusivities calculated from the nitriding of $ZrN_{0.76}$ wires (6) and the sintering of ZrN wires of various compositions (7). In this latter investigation, the effective diffusion coefficient determined from the growth of the neck radii and a sintering model was assigned to nitrogen diffusion. The present determination of the tracer diffusivity agrees approximately with several of the

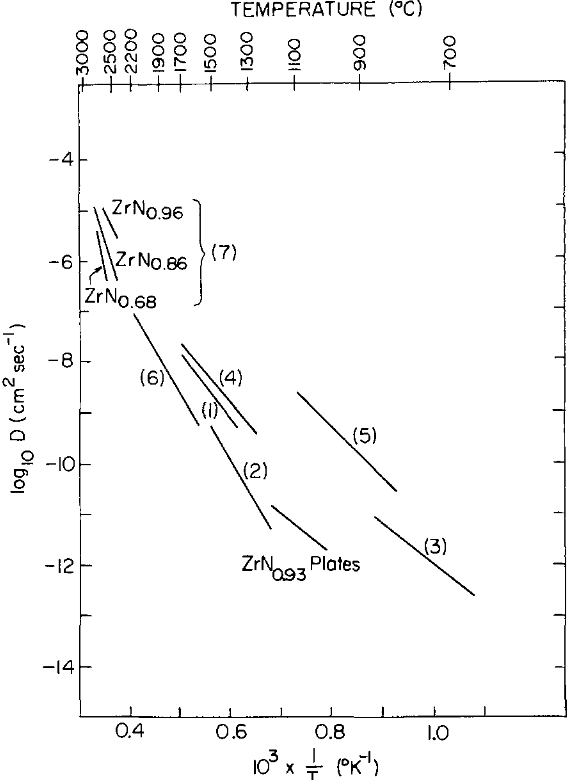

Fig. 6. Present results and those reported in the literature for nitrogen diffusivities of ziconium nitride. The numbers in parentheses refer to the references.

chemical diffusivities obtained from nitriding of the metal. Despite the discrepancies in the determinations, one can conclude that the activation energy and pre-exponential factor for the diffusivities obtained from the different types of measurements increase with increasing temperature. Also, the diffusivities calculated from the sintering results are characterized by an appreciable concentration dependence.

The nitrogen deficiency in the NaCl structured $ZrN_{0.93}$ is essentially caused by the presence of vacancies in the nitrogen sublattice (Table I). One can, therefore, reasonably assume that the zirconium sublattice is fixed and that transport of nitrogen occurs via nitrogen vacancies. Using a Darken-type diffusion analysis for this solid (2, 13, 14), the chemical diffusion coefficient $\tilde{D}$ can be related to the intrinsic coefficient D and the tracer diffusion coefficient D^* by

$$\tilde{D} = D = D^* (\partial \ln a_N / \partial \ln x) \quad [4]$$

In this relationship, a_N and x are the nitrogen activity and the nitrogen-to-zirconium atom ratio, respectively.

In the absence of data on the nitrogen activity as a function of nonstoichiometry one cannot evaluate the activity term in Eq. [4]. Kohlstedt *et al.* (14) have provided, nevertheless, pertinent conclusions on the influence of the carbon activity gradient on carbon diffusion in TiC which exhibits the same type of crystallography and nonstoichiometry as ZrN. The contribution to the activation energy for diffusion from the activity term was estimated to be only ~6 kcal/mole in comparison to the total activation energy for chemical or tracer diffusion of the order of 100 kcal/mole. They, therefore, suggest that when differences of many kcal/mole are reported between the activation energies of $\tilde{D}$ and D^*, like diffusion evaluations from metal carburizing and single-crystal tracer results, the explanation resides in the role of short-circuit diffusion paths in the polycrystalline solid formed rather than in the chemical activity term of Eq. [4].

These conclusions are also consistent with the findings on the nitrogen diffusional properties of ZrN. The evaluation of the tracer diffusivity and those for the chemical diffusivity from metal nitridation investigations at temperatures less than 1200°C were obtained from results on polycrystalline ZrN formed from the metal. This latter temperature is ~0.4 of the melting point of ZrN. Consequently, the low values of the activation energy in the range of 35-45 kcal/mole represent this energy for nitrogen short-circuit diffusion through low resistance structural paths such as ingrown dislocations and grain boundaries. The transition of this energy to values in the 50-80 kcal/mole range at temperatures between 1200° and 2200°C accordingly represents the decreasing influence of short-circuit diffusion as the activation energy becomes that for nitrogen transport by lattice diffusion according to a vacancy mechanism. The activation energies larger than 100 kcal/mole and the high pre-exponential factors obtained above 2200°C in sintering studies, along with the fact that these parameters decrease as stoichiometry is approached, suggest an increasing contribution of Zr diffusion in the mass transport process in the initial sintering of this material (7). Thus the relatively large discrepancies in the nitrogen diffusion coefficients over the lower temperature range results from the different polycrystalline structures of the ZrN solid in each investigation.

Anodic Phenomena in Cryolite-Alumina Melts

I. Overpotentials at Graphite and Baked Carbon Electrodes

E. W. Dewing* and E.Th. van der Kouwe[1]

Arvida Research Centre, Aluminum Company of Canada, Limited, Arvida, Province of Quebec, Canada

ABSTRACT

A method is described for measuring the potential of a working carbonaceous anode with respect to an aluminum reference electrode. The correction for resistance drop is determined by measuring the apparent resistance with a superimposed alternating current and a Kelvin bridge, and at the same time measuring the amplitude of the second harmonic voltage generated, which also gives the Tafel slope. For graphite the Tafel slope is found to be 0.295, but the exchange current varies from 1.5 mA-cm^{-2} for current densities below 0.1 A-cm^{-2} to 5 mA-cm^{-2} above 0.5 A-cm^{-2}. The effect is attributed to changing CO/CO_2 ratio in the gas generated. For baked carbons the same value of the Tafel slope is found, although it applies over a restricted range of current density, and the overpotentials are lower than for graphite. The sheath of gas bubbles rising around the electrode distorts the current flow so that overpotentials at a fixed geometric current density vary with size and shape of the electrode.

One may wonder why yet another paper should be needed on overpotentials at carbon and graphite electrodes in cryolite-alumina melts in view of the amount of competent work already existing. [Thonstad (1) has given numerous references which there is no point in repeating here.] The justification is that we have applied a fresh technique, have obtained a novel result, and have revealed some problems which are, perhaps, more serious than had generally been realized.

The design of an apparatus for such measurements is dictated very largely by the nature of the electrode materials to be investigated. Commercial carbon anodes are made from a petroleum coke aggregate with particles up to 1 cm in diameter; if the surface of a test electrode is to be statistically representative it must have dimensions of the order of 4 cm, and the surface area will be 30-40 cm^2. Since commercial cells work at up to 1 A-cm^{-2}, and it is desired to extend the laboratory work substantially higher, this means that a current of at least 80A is required. There is, unfortunately, no small reference electrode (the equivalent of a Luggin capillary) which can be used, owing to problems with materials of construction; the physically bulky types available must be kept at a distance from the working electrode (to avoid disturbing the current distribution) and this leaves a sizable resistance drop to correct for. If a precision of, say, 10 mV is aimed at, then with 80A total current the resistance must be measured with a precision of about 10^{-4} ohm. This, in fact, turns out to be the major problem. The resistance must be measured at the same time as the cell potential, since it is obviously dependent on the gas bubbles and may be expected to vary with the d-c current; the only possible approach is by superposition of an a-c current and the measurement of the apparent a-c resistance by means of a bridge. This quantity, and previous workers seem to have ignored the fact, contains also the Faradaic resistance of the electrode, and the only way we have found to eliminate it is to go one step further and measure the degree of harmonic distortion of the a-c voltage (*i.e.*, the generation of the second harmonic). Thanks to modern instrumentation this is now relatively easy, and, as is shown below, it not only solves the resistance problem but generates valuable information in its own right.

Key words: cryolite, alumina, graphite, carbon, overpotential, Faradaic rectification, Tafel slope.

Theory

Let the potential V of an electrode be a function, $f(I)$, of the current I. Then the potential at a current $I + h$ (where $h << I$) is given by Taylor's series as

$$f(I+h) = f(I) + hf'(I) + \frac{h^2}{2} f''(I) + \ldots \quad [1]$$

If a small sinusoidal current is superimposed on the direct current, then h can be replaced by $\delta \sin \omega t$, where δ is the amplitude and ω the frequency of the superimposed current. Equation [1] thus becomes

$$f(I + \delta \sin \omega t) = f(I) + \delta \sin \omega t \cdot f'(I) + \frac{\delta^2}{2} \sin^2 \omega t \cdot f''(I) + \ldots \quad [2]$$

The alternating component of the potential is obtained by subtracting the potential corresponding to the d-c current alone and is

$$V_{\text{alt}} = f(I + \delta \sin \omega t) - f(I) = \delta \sin \omega t \cdot f'(I) + \frac{\delta^2}{2} \sin^2 \omega t \cdot f''(I) + \ldots \quad [3]$$

If the substitution $\sin^2 \omega t = (1 - \cos 2\omega t)/2$ is made this becomes

$$V_{\text{alt}} = \delta \sin \omega t \cdot f'(I) + \frac{\delta^2}{4} f''(I) - \frac{\delta^2}{4} \cos 2\omega t \cdot f''(I) \ldots \quad [4]$$

The apparent resistance as observed at the fundamental frequency is simply $f'(I)$ (obtained by dividing the first term in Eq. [4], which is the only one at the fundamental frequency, by the sinusoidal current, $\delta \sin \omega t$). The second term represents Faradaic rectification, but is much too small to observe in the presence of the pseudorandom fluctuations in potential caused by the evolution of gas bubbles. The third represents a sinusoidal voltage of twice the fundamental frequency and amplitude $\sigma = (\delta^2/4) f''(I)$.

Suppose now that, over a limited range of current density (i) and time, the Tafel equation

$$V = a + b \ln i \quad [5]$$

may be used. By this we mean that, over the range of current densities covered by the excursions of the superimposed a.c., and for the time for several such oscillations to take place, the values of a and b are effectively constant. We can replace i, the current

density, by I/A, where I is the total current and A is the effective surface area, again assumed constant for a short period of time, and we can add a resistance term IR, so that

$$V = f(I) = a + b \ln I - b \ln A + IR \quad [6]$$

Differentiation gives successively

$$f'(I) = b/I + R \quad [7]$$

and

$$f''(I) = -b/I^2 \quad [8]$$

It is important to note that A, the effective area, has disappeared from both these derivatives, and R, the resistance, from the second. Experimental values of the second harmonic amplitude (σ) can be obtained, and hence $f''(I)$ from

$$f''(I) = 4\sigma/\delta^2 \quad [9]$$

If Tafel's law is applicable a plot of log $(4\sigma/\delta^2)$ *vs.* log I should have a slope of -2. Once this is established a value of b is calculated; this in turn can be used to correct the apparent resistance for the term b/I to give R (Eq. [7]), and finally IR can be subtracted from the measured V to give the electrode potential.

If Tafel's law is not verified on the log-log plot, then the Faradaic resistance must be determined by numerical integration of the experimental values of $f''(I)$.

We wish to emphasize that, complex though this procedure may be, we are not aware of any other experimental method of determining R. (In principle it can be done by going to frequencies high enough that the Faradaic resistance is short-circuited by the electrode capacity, but it seems that, with the high d-c current densities used here, frequencies of the order of 500 kHz would be necessary, and, with the low values of resistance to be measured, the problem of pickup in the loop formed by the anode and reference electrode leads and the melt seems to be insuperable.)

Experimental

All experiments reported here were made in a melt saturated with alumina at temperatures between 960°-980°C. About 800g of aluminum was added to 3 kg of melt except for two runs where a 20 weight per cent (w/o) Cu alloy was used. The graphite crucible containing the melt was 20 cm OD, 15 cm ID, and 20 cm high, and was heated in a resistance furnace. Temperatures were obtained before a run from a Chromel-Alumel thermocouple immersed in the melt. The temperature had to be watched closely to avoid cooling and crystallization of alumina on the electrode.

Details are given in Fig. 1. The working electrode was screwed onto a 1.6 cm diam copper rod attached higher up to a copper tube. A new anode had the form of a 3.75 cm diam cylinder with a hemispherical end, and a total immersed area of about 50 cm². Due to consumption the anode became somewhat conical in shape, and the average value of D_1 and D_2 was taken as the diameter of the cylinder. The diameter of the hemisphere was taken as D_2. An Inconel rod (2 mm diam) was imbedded in the anode and ran parallel to the copper tube to serve as a potential lead.

The reference electrode consisted of a 0.7 cm ID alumina tube containing aluminum and a tungsten rod (1.5 mm diam) as lead. An opening was cut in the side facing the anode.

The electrical circuit is shown in Fig. 2. The d-c rectifier power supply, capable of giving 1000A at 5V, was connected, via a 0.388 mHenry choke, and a 0.5 mohm current measuring shunt across the cell. In the low current range a 1 ohm resistance was included in the circuit to extend the control steps of the power supply. A potential divider (ratio 100:1100 ohm) reduced the voltage between the anode and reference electrode to bring it within the range of the

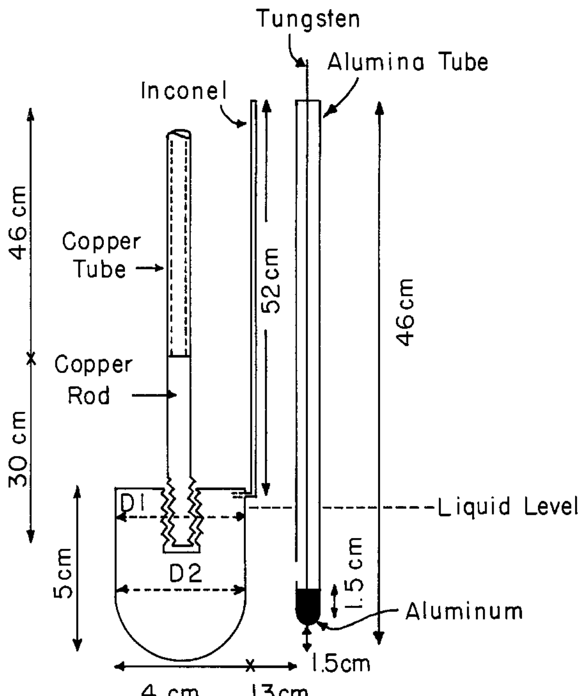

Fig. 1. Dimensions of anode and reference electrode

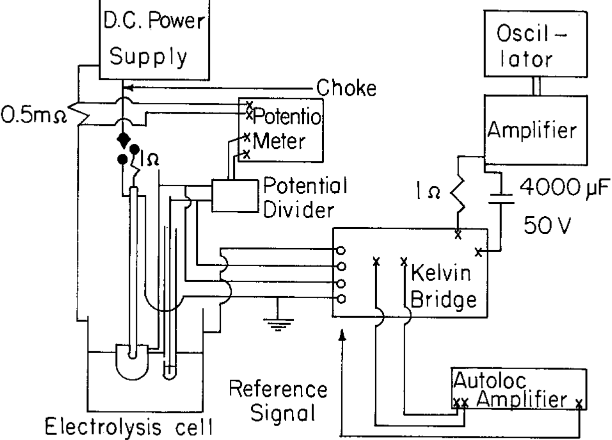

Fig. 2. Electrical circuit

potentiometer used to measure both it and the drop across the shunt.

A modified Kelvin bridge was used to measure the apparent resistance. Its power supply was a Heathkit oscillator and amplifier. To prevent d.c. going through the amplifier a 4000 μF capacitor was placed in series, as was also a 1 ohm resistor to protect the bridge from overloading. The input did not exceed 5V rms. It was essential that the lead to the cell shown in Fig. 2 as grounded should have the lowest practical resistance, and a 60 cm length of 6 gauge flexible cable was found suitable. It was connected to the copper tube supporting the electrode. The bridge was checked against a known resistor and found to give reliable results for frequencies up to 1.5 kHz.

The heart of the a-c measuring system was a phase-sensitive, frequency locked amplifier.[2] This instrument, which has a maximum sensitivity of 10 μV full scale deflection (fsd), is given a reference signal of the frequency of interest, and thereafter is sensitive only to that frequency, ignoring other frequencies, d.c., and random noise. The sole interference comes from odd harmonics of the reference frequency, but they were of

[2] Keithley Instruments Incorporated, 28775 Aurora Road, Cleveland, Ohio 44139, Model 840 Autoloc amplifier.

no concern in this work. By turning a switch the instrument can be operated at twice the frequency of the reference signal, thereby making it ideal for the second harmonic measurements.

The reference signal was taken across the standard resistor (usually 1 ohm) in use in the Kelvin bridge; this ensured that the phase taken as standard was that of the a-c current going through the cell. The magnitude of the current (rms) was next fixed (at either 1 or 0.3A, depending on the d-c current) by using the Autoloc amplifier to measure the drop across the same resistor. Following this the amplifier was used in place of the galvanometer of the bridge.

A run consisted of a series of about 20 voltage, current, resistance, and second harmonic measurements. Each run was started by applying the high currents first, thereby obtaining a steady-state surface. The current densities varied from about 3 to 0.01 A-cm^{-2}.

The resistance measurements were straightforward. The Autoloc amplifier was set to zero phase angle so that it would not respond to any inductive or capacitative components of the impedance, and the bridge was balanced to give zero signal. The second harmonic amplitude was measured across the galvanometer terminals after the bridge was balanced. In this way any second harmonic component contained in the input current was balanced out. The measurement was made at phase angles of 0°, 90°, 180°, and 270° to eliminate interference as far as possible. No successful measurements could be obtained at the highest d-c currents.

After a series of measurements, the current was reversed and run at about 5-10A for a minute or two to depolarize the electrode. The apparent resistance was then measured, and the current was returned to its normal direction. About 20A were passed for a few minutes before taking the electrode out of the bath; if this was not done it was hard to see where the immersion line was. When it was cold the dimensions of the electrode were measured.

Measurements were made on grade ATJ graphite and on baked carbon electrodes of the type used in Soderberg cells. They were made from petroleum coke aggregate heat-treated in a nitrogen atmosphere at 1250° and 1400°C, bonded with pitch, and finally baked at 970°C.

Treatment of Results

Resistances measured on the Kelvin bridge were in the vicinity of 0.01 ohm, and consequently sometimes lay in the X1 range of the bridge and sometimes in the X0.1 range. Despite the fact that tests with known resistors showed that there was no discrepancy on passing from one range to another, it was noticed that results with cells often did show a jump associated with the change of range. To check on this the a-c current and voltage were measured directly with the Autoloc amplifier, and the resistance was calculated to compare with bridge reading. It was found that the resistances on the X1 range were correct while those on the low range were in error, although measurements made with reversed d-c current seemed to be correct. The reason for this behavior is not known, but all measurements made on the low range have been eliminated from the final results.

The amplitude of the second harmonic component was measured across the galvanometer terminals of the bridge in order that the second harmonic distortion existing in the input waveform (~2%) should be balanced out, but owing to the dividing action of the bridge resistors, the full amplitude was not present across the galvanometer terminals. The magnitude of the factor (measured amplitude/input amplitude) was determined by applying a known voltage across the potential input of the bridge and measuring the voltage between the galvanometer terminals. The factor was found to vary from 0.990 to 0.908, depending on the bridge setting.

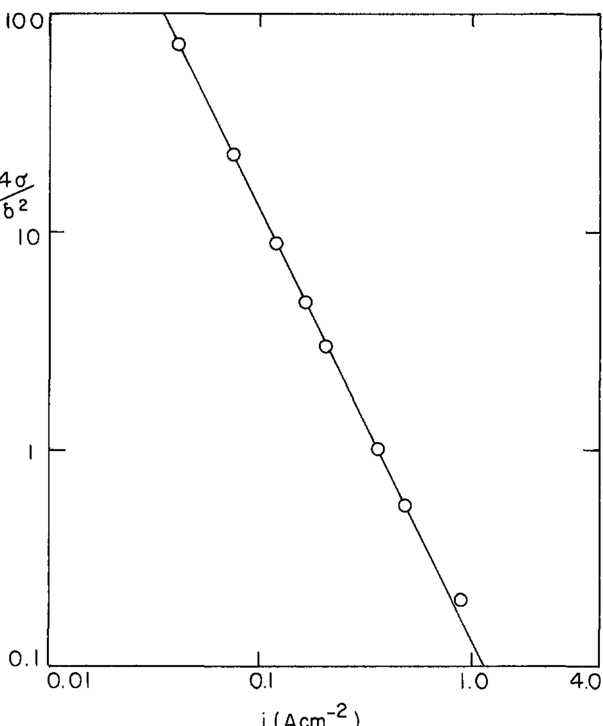

Fig. 3. Second harmonic amplitude (σ) as a function of d-c current density for ATJ graphite.

It was assumed that the genuine part of the second harmonic signal was reversed in sign when the phase was changed 180°. By subtracting algebraically, any part which was not reversed was eliminated. This was done for the 0°-180° pair and the 90°-270° pair, and they were then added vectorially. The resultant was corrected for the calibration factor and the quantity $4\sigma/\delta^2$ found. (Note that a factor of $\sqrt{2}$ is necessary to go from rms values as measured to amplitudes.)

Results

Figure 3 shows, on a log-log plot, values of the quantity $4\sigma/\delta^2$ as a function of current density for one of the runs with graphite. The expectation of a straight line of slope -2, indicating Tafel behavior, is borne out; in this case the statistical value is -1.935 with a standard error of ± 0.014, and the corresponding value of b (Eq. [8] and [9]) is 0.1291 ± 0.0039. The results of the eight runs with graphite are given in Table I. In only one of them was the slope statistically different from -2 (-1.886 ± 0.011). For ease of comparison with the other runs the exchange currents have nonetheless been calculated with a constant value of b (see below). The arithmetic mean value of the slopes is -1.964 with a standard deviation of ± 0.048. This value obviously does not differ significantly from -2, so that Tafel behavior is proven.

Table I. Values of the slope of the log-log plot and b for graphite

Slope	± Standard error	b	± Standard error
−1.987	0.024	0.1512	0.0032
−1.999	0.024	0.1169	0.0023
−2.027	0.019	0.1159	0.0017
−1.935	0.014	0.1291	0.0039
−1.915	0.094	0.1460	0.0083
−1.991	0.013	0.1210	0.0016
−1.886	0.011	*	—
−1.971	0.011	0.1176	0.0014
Mean: −1.964		Mean: 0.1282	

* Since the slope is statistically different from −2, no value of b is calculated

The arithmetic mean value of b is 0.128 with a standard deviation of ±0.015. Whereas the standard deviation of the slopes is comparable with the standard error of individual values, the standard deviation of b is four times greater than the individual standard errors. This implies that the values of b are genuinely different from one another.

With the baked carbon electrodes a different situation is encountered. Whereas with graphite the second harmonic results were independent of frequency in the range 50-520 Hz (the results reported were obtained at 520 Hz), with carbon the values show a frequency dependence, and furthermore the log-log plot is not straight over so wide a range. Figure 4 shows the results of three runs at each of two frequencies for the 1200°C carbon; the straight line is that for graphite. At 49 Hz the results are identical to those for graphite above about 0.7 A-cm^{-2}; at 520 Hz there are deviations both above and below this value. Measurements on the 1400°C carbon were made only at 50 Hz. The deviations (Fig. 5) are markedly less in the low current range than for the 1200° material.

Turning now to the electrode potentials after correction for the resistive drop, Fig. 6 shows the results for graphite, and Fig. 7 those for baked carbons; they are generally similar but about 100 mV lower. Since the melts were saturated with Al_2O_3 the reversible potential (for production of CO_2) is readily calculated from the JANAF Tables (2) as 1.19V at 970°C. Two lines, both with the slope $b = 0.128$ derived from Table I, have been drawn. Although each line fits reasonably well over a range of current densities, it is apparent that there is a discontinuity between 0.2 and 0.5 A-cm^{-2}. This implies that there is a change of exchange current in this region. The exchange currents are plotted in Fig. 8; they have been calculated from the potentials with the average value of b instead of the individual ones since small differences in b make large differences in i_0. The exchange current rises from about 1.5 mA-cm^{-2} for currents below 0.1 A-cm^{-2} to about 5 mA-cm^{-2} for currents above 0.5 A-cm^{-2}. The two runs made with the 20 w/o Cu alloy show somewhat higher exchange currents.

Discussion

It would be very easy, in the absence of the value of b from the second harmonic measurements, to

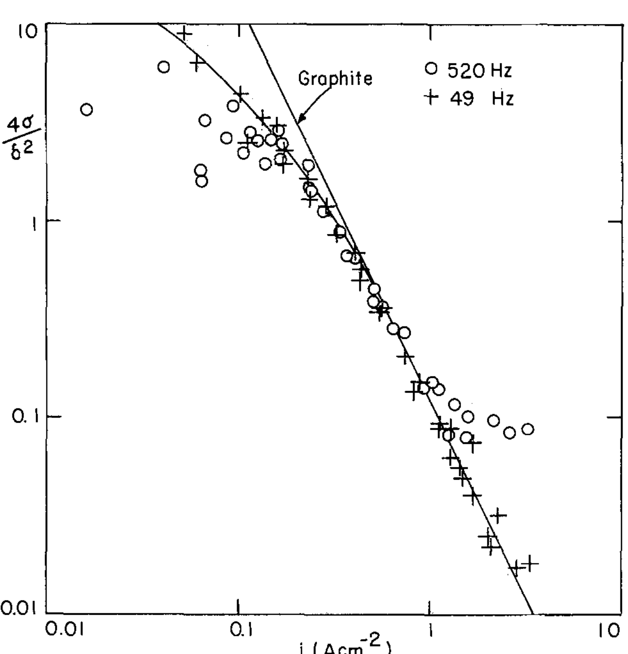

Fig. 4. Second harmonic amplitude (σ) as a function of d-c current density for 1200°C carbon.

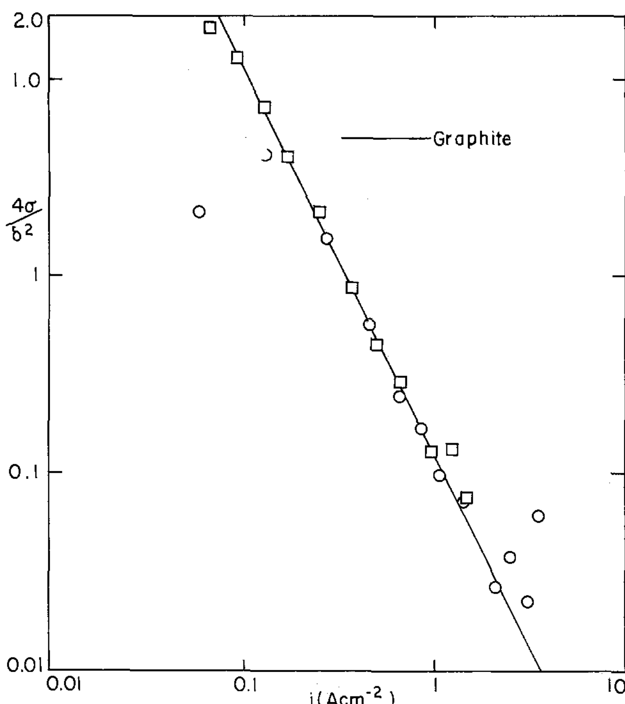

Fig. 5. Second harmonic amplitude (σ) at 50 Hz as a function of d-c current density for 1400°C carbon.

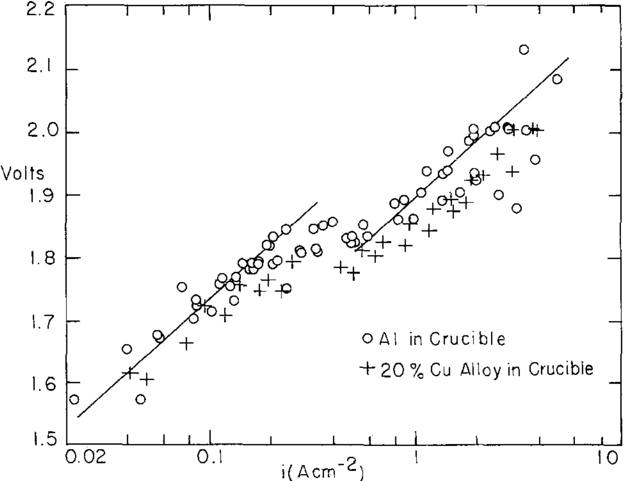

Fig. 6. Current-potential curve for ATJ graphite

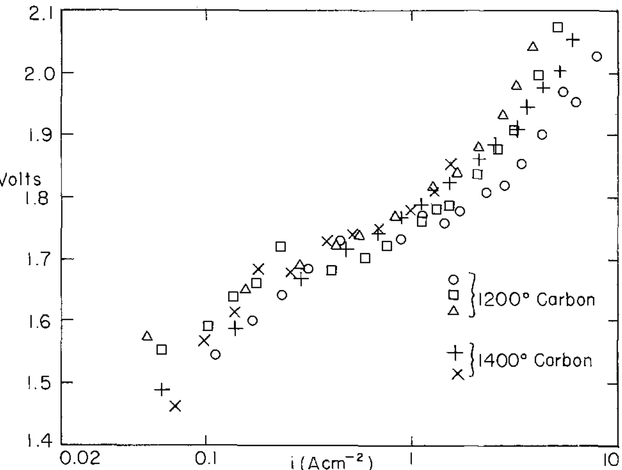

Fig. 7. Current-potential curves for baked carbons

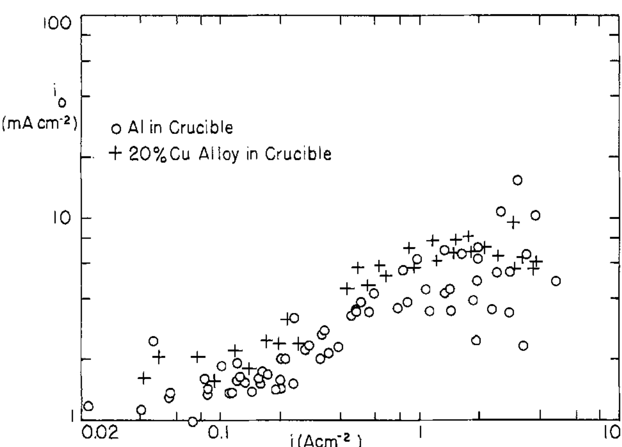

Fig. 8. Exchange current density as a function of current density for ATJ graphite.

draw a straight line of much flatter slope through the points of Fig. 6. This kind of effect is probably the reason for the disparate values of b appearing in the literature.

The decision to add metallic aluminum to the crucible was taken because preliminary experiments had shown that if this was not done quite erratic results were obtained. It is not possible with the present equipment to operate in the absence of aluminum since it is inevitably formed during the electrolysis, and adding it initially was the best way to control the situation. It is, however, quite possible that it is responsible for the change of exchange current shown in Fig. 8. Since there is aluminum in the crucible, there will be dissolved aluminum in the melt, and this gives rise to CO in the gas by the familiar mechanisms responsible for loss of current efficiency. The fraction of CO in the gas will depend on how fast CO_2 is being generated electrolytically; the higher the current the more CO_2 will be available to dilute the CO. It is known that CO is strongly adsorbed on carbon surfaces and acts as a catalytic poison. Studies of the rate of oxidation of carbon by gaseous CO_2 (3) have shown that adsorbed CO inhibits the reaction, and the overpotential measurements of Richards and Welch (4) also showed higher values when the CO content of the gas surrounding the anode was increased. One therefore suspects that the lower exchange current at low current densities is due to the adsorption on the surface of CO produced by reaction of CO_2 with dissolved aluminum. The fact that higher exchange currents are found when an Al-Cu alloy (which will reduce the amount of Al in solution) is used tends to confirm the hypothesis.

The reproducibility of the results obtained with graphite (excluding those from the two runs with the Cu alloy) is shown in Table II. The individual points on the current-voltage curves were interpolated linearly to convenient values of current; no attempt was made to smooth the curves before doing so, although it is quite possible that it would improve reproducibility if a satisfactory procedure could be evolved.

On examining the results for the baked carbons another effect was noticed. The run marked in Fig. 7 with circles is conspicuously low. On seeking what was different, it turned out that it was an electrode

Table II. Interpolated anode potentials for graphite anodes

i (A-cm^{-2})	Mean V	± Std deviation
1.0	1.871	0.043
0.5	1.830	0.010
0.2	1.810	0.017
0.1	1.738	0.019

which had been used several times, and consequently it had a much reduced surface area. This called into question the whole concept of plotting potential against current density. In fact, inspection showed that less scatter was obtained by using total current as the abscissa and not bringing in the area at all.

To try and clarify the situation the data on the 1200° carbon were fitted by regression analysis to the equation

$$\log (\text{total current}) = a_0 + a_1 V + a_2 V^2 + a_3 \log A \quad [5]$$

where A is the electrode area, and the value of a_3 was found to be 0.309 ± 0.057. The proper variable to take is thus

$$\text{total current}/(\text{area}^{0.309})$$

and Fig. 9 shows the result. The scatter is substantially reduced.

The discovery of this area effect raises a number of questions. In the first place, What causes it? The most likely answer seems to lie with the gas bubbles. Although the technique used corrects the voltage for the effect of the electrical resistance caused by the gas around the anode, there is no way of correcting for the fact that the bubbles screen part of the electrode, and that the current distribution is not uniform. Presumably the current concentrates toward the bottom and is limited toward the top by the sheath of gas rising around the electrode. Under these circumstances, an increase in area by lowering the electrode further into the melt may have little effect, since the new surface is at the top and it is largely screened. The data available are not adequate to carry the analysis beyond this purely qualitative picture. It seems that Piontelli and his colleagues have observed a similar effect (5).

The second point which is raised, since we are apparently dealing with a scale effect, is how one transfers the results of laboratory experiments to industrial cells. At the same time, if the gas is having such effects on small, vertical electrodes where it can escape easily, it must be having a drastic influence under a large horizontal industrial anode. At this point, it looks as if study of gas bubbles and how they behave may be of much more practical importance than the overpotentials themselves.

From Fig. 7 it would obviously be impossible to say that there was any significant difference in overpotential between the two baked carbons. From Fig. 9, where the scatter is less, it looks as if there might be, in some ranges of current density. However, in the range 0.5-1.0 A-cm^{-2} used in practice (6.5-13 on the scale at the bottom of Fig. 9) any difference is marginal. Exact statistics are hard to apply, but 20 ± 20 mV would be a fair estimate.

The value of b obtained (0.128 if the Tafel equation is expressed in natural logarithms, 0.295 if in

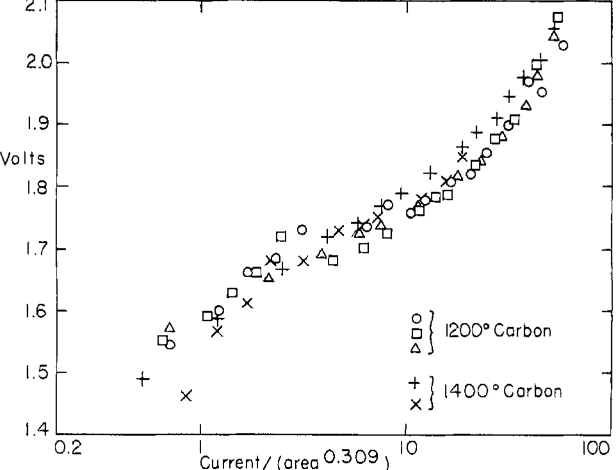

Fig. 9. Current-potential curves for baked carbons

$\log_{10}$) applies to both graphite and the baked carbons used, and, since it was obtained by a method not affected by the presence of gas bubbles, should be of fundamental significance.

The Iodate-Iodine Electrode

Mechanism, Standard Potentials, Related Thermodynamic Data

ABSTRACT

The standard potential of the iodate-iodine electrode enters into the calculation of many other thermodynamic data. The following new values of this E° have been measured: 1.1942V at 25°C, 1.1903V at 37.5°C, 1.1863V at 50°C with an estimated uncertainty (±0.0002V) improved about tenfold over earlier values. Calculated values of related thermodynamic data are given. Agreement, established in 1905, of electrochemical and chemical values for the equilibrium constant of the Dushman reaction has been restored and extended. Thermodynamic difficulties inherent in the cells studied have been successfully handled by approximation-extrapolation methods. The investigation was carried out with the following mechanism as a guide. The electron-transfer steps at the reversible iodate-iodine electrode are assumed to be identical with those at the reversible iodine-iodide electrode. At the former electrode these electron-transfer steps are assumed to be accompanied by the chemical steps that participate in the Dushman reaction.

The standard potential E° for the reaction

$$5/2\, H_2(g) + H^+(aq) + IO_3^-(aq) = 1/2\, I_2(c) + 3H_2O(l) \quad [1]$$

is the standard potential of the iodate-iodine electrode; it is also the voltage reading for the cell

$$H_2(g),\ Pt/HClO_4//HIO_3/Pt,\ I_2(c) \quad [2]$$

operating reversibly under standard conditions with elimination of the potential difference at the junction of the aqueous electrolytes. The early value of E° at 25°C by Sammet (1) has been superseded by that of Lundberg, Vestling, and Ahlberg (2), which is 1.195 ± 0.002V. There appear to be no reliable values for other temperatures.

This standard potential has been used to establish thermodynamic data for iodate ion (2), and it has been combined with that of the iodine-iodide electrode (and with other data) to give the equilibrium constant of the Dushman reaction

$$6H^+(aq) + 5I^-(aq) + IO_3^-(aq) = 3I_2(aq) + 3H_2O(l) \quad K_3 \simeq 10^{46} \text{ at } 25°C \quad [3]$$

This electrochemical determination of K_3 was carried out by Sammet (1), who obtained results at 25°C that agreed to about 10% with the K_3 that he chemically determined. An uncertainty of 0.002V in E° means an uncertainty of about 50% in K_3. The new value of E° spoils the good agreement Sammet found in his classic investigation. Further work is needed, not only to show how closely a complex equilibrium constant like K_3 can be established by these two methods, but also to obtain results for temperatures other than 25°C.

The last matter has become important because the oscillatory decomposition of hydrogen peroxide (3, 4), which is being reinvestigated at 50°C, involves the Dushman reaction. For this and the reasons preceding, an extensive study of the iodate-iodine electrode was made at 25°, 37.5°, and 50°C.

Experimental

Chemicals of the best grade obtainable were used without further purification.

To eliminate the risk of reaction between H_2 and IO_3^-, a cell with liquid junction is mandatory. In Ref. (2), this junction was static, being formed in a three-way stopcock. With the stopcock open, the junction was reproducible and relatively stable; with the stopcock closed, voltage readings changed in a few minutes, probably because of changes in the thin liquid film. In comparative experiments, we found a flowing junction (5) to give steady, reproducible values and to be preferred over a static junction.

Experiments proved the desirability of equilibrating the iodate electrolyte with crystalline iodine outside the cell. Equilibration for at least 24 hr with stirring on a hot plate at 50°C was adopted as standard practice.

* Electrochemical Society Active Member.

Key words: electrode mechanism, iodate-iodine electrode, thermodynamic data, Dushman reaction.

Each cell compartment contained dual, platinized electrodes, each about 1 cm^2 in area. Voltage differences between electrodes in the same compartment were about 0.00001V when cells were at thermostat temperature, which was controlled to less than ±0.1°C.

For reasons to be discussed, temperature-cycling of the cells in the thermostat was used to ensure reliable voltage readings. When each cell compartment and the two electrolyte reservoirs had been filled at the initial thermostat temperature of 50°C, electrolyte flow was started to set up the liquid junction. Voltage readings were then made with a Corning® Model 101 Digital Electrometer, this being a solid-state voltmeter with an input impedance of 10^{14} ohms, which was standardized frequently against a new, saturated Weston standard cell. The cell voltage was monitored until it became steady to within ± 0.0001V over at least an hour. This usually occurred some 10 or 12 hr after the cell had been filled. With a satisfactory cell voltage established at 50°C, the thermostat temperature was lowered to 37.5°C, and the voltage monitoring was repeated to establish the cell voltage at the lower temperature. This typically required 12 hr. Next, the cell voltage at 25°C was similarly obtained. At 25°C, the equilibrating period was sometimes 24 hr long. For most of the final cells, the temperature sequence was then reversed to obtain another set of voltage readings at 37.5° and 50°C. In general, the second reading at each temperature checked the first to within 0.0001V, which is conclusive evidence that the readings were satisfactory. See Fig. 1.

Difficulties. Mechanism

The evaluation of $E°$ for the iodate-iodine electrode is beset with the following difficulties: the liquid-junction potential; the fact that HIO_3 is an intermediate electrolyte, neither weak nor strong (details later); uncertainties in activity coefficients; and unreproducibility of voltage readings, especially at low iodic acid concentrations. Consequently, values of $E°$, instead of being identical, are different for different iodic acid concentration. With increasing dilution, the first three difficulties can become less serious; but voltage unreproducibility then made reliable measurements impossible: results at 0.001*M* HIO_3 were not considered worth reporting in Ref. (2). To resolve this dilemma, a new approach is needed.

The voltage unreproducibility must be due to sluggishness of reaction, chemical, electrochemical, or both, at the iodate-iodine electrode. Reaction mechanisms at electrodes so complex as this are never certain. Nevertheless, some sort of picture is needed. The picture that follows did guide us to experimental conditions under which the iodate-iodine electrode was more nearly reversible so that voltage readings were improved.

Iodine and iodate do not react with each other. Yet kinetic studies have shown the existence of various

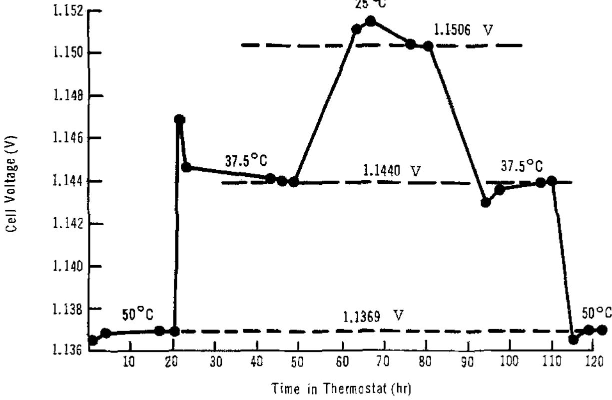

Fig. 1. Final voltage readings as established by temperature-cycling.

compounds, intermediate between I_2 and IO_3^- in oxidation number and with oxygen covalently bonded to iodine; for example, HIO, HIO_2, $H_2I_2O_3$, HI_3O, $I_3O_2^-$, and I_2O_2 are all needed (6) to explain the kinetics of the reverse Dushman reaction, Eq. [3]. None of these oxygenated species is likely to exchange electrons reversibly (that is, with great ease) at an electrode. Still, one cannot have complete equilibrium unless each species in the system is at its equilibrium concentration. We therefore postulate that the equilibrium concentration of each oxygenated iodine species is established chemically as in the Dushman reaction. The hydrolysis of iodine, namely

$$I_2 + H_2O = HIO + H^+ + I^- \quad K_4 = 5.44(10^{-13}) \text{ at } 25°C \qquad [4]$$

is rapid enough (7) in both directions so that reaction [4] is always at equilibrium (8). For present purposes, it is permissible to simplify the kinetic picture by considering HIO, HIO_2, and IO_3^- to be the only significant oxygenated species, and by assuming that they react only with I^- and H^+.

The iodine-iodide electrode is known to be highly reversible (9). This leads to the following mechanism for the iodate-iodine electrode. The electron-transfer processes at the two electrodes are identical and involve no oxygenated species. Complete equilibrium is established at the iodate-iodine electrode through the participation of steps characteristic of the Dushman reaction. To illustrate: one step is

$$HIO_2 + H^+ + I^- = 2HIO \qquad [4a]$$

The occurrence of reaction [4a] will shift the equilibrium of reaction [4]. When this happens, $[I_2]$ and $[I^-]$ will change, and these concentration changes will affect the electron-transfer processes at the electrode.

This picture relies upon the reactions of I^-, a species that appears neither in reaction [1] nor in the Nernst equation for the iodate-iodine electrode. The picture is nevertheless reasonable. Suppose a saturated iodine solution at 25°C is made 0.1*M* in HIO_3. Prior to the HIO_3 addition, $[I^-]$ will be near $10^{-6}M$ (Eq. [4]). At complete equilibrium in the cell, $[I^-]$ will have decreased to, say $10^{-9}M$ (Eq. [3]). This reduction in concentration will have been brought about in large part by the forward Dushman reaction at a rate (10) given by

$$-d[IO_3^-]/dt = -1/5\, d[I^-]/dt = 1.2(10^4)[H^+]^2[IO_3^-][I^-] \text{ mol l}^{-1}\text{ min}^{-1} \qquad [5]$$

When $[H^+] = [IO_3^-]$, this rate is evidently proportional to $[HIO_3]^3$. It is near 10^{-8} mol IO_3^- per liter per minute when $[I^-]$ is near $10^{-9}M$ and $[HIO_3]$ is 0.1*M*. The net rate will of course be much less near equilibrium as the reverse reaction also comes into play. Note that Eq. [5] was actually established at iodide concentrations near $10^{-10}M$, which lends credibility to the present discussion. Note also that the $[HIO_3]^3$ proportionality means a very low forward rate in dilute iodic acid solutions, which is probably the reason for the voltage unreproducibility encountered at $[HIO_3] = 0.001M$ (2).

With increasing temperature, the equilibria in reactions [3] and [4] are shifted so as to increase the concentrations of iodine reaction products such as I^- and HIO. It is reasonable to suppose that the concentrations of other intermediate products (*e.g.*, HIO_2) also increase when this happens. Suppose complete equilibrium exists at an iodate-iodine electrode at 50°C, and the temperature is lowered to 37.5°C. Suppose that the concentrations of the various intermediate compounds readjust themselves slowly to the reduced equilibrium values at the lower temperature. Until they reach these reduced values, the voltage of the cell will be above its equilibrium value for 37.5°C. The same consideration applies when the temperature is subse-

quently lowered from 37.5° to 25°C. It applies in reverse when the temperature is subsequently raised, first to 37.5° and then back to 50°. The behavior just described is actually found: see Fig. 1. This further evidence of slowness of reaction increases confidence in final voltage readings (such as 1.1369 and 1.1440V in Fig. 1) established by temperature-cycling.

Equation [5] shows that increasing $[H^+]$ is the most effective way of increasing the rate of the forward Dushman reaction. It is also evident that complications caused by the liquid junction, by activity coefficients, and by the weakness of HIO_3 will all disappear if $[IO_3^-]$ can be made low enough. The first feature of our approach is to replace cell [2] by cell [6], which is

$$H_2(g),\ Pt/HClO_4(m_1)//HClO_4(m_2),\quad HIO_3(m_3)/Pt,\ I_2(c) \qquad [6]$$

where the concentrations in this and all subsequent cells are molalities (mols solute/kg H_2O) with $m_1 = m_2 + m_3$ in all final experiments. The second feature is to make a series of cell measurements in which m_3 is varied. The third feature is temperature-cycling, already discussed. In this way, we obtain at each temperature a series of measured voltages that are corrected to unit fugacity of hydrogen to give values called E_c. The fourth feature is the calculation, in various ways, of approximate standard potentials called $E°_1$. The fifth feature is the extrapolation of these $E°_1$ data to $m_3 = 0$ to give the final $E°$, which is the standard potential for a hypothetical cell in which the only electrolyte at appreciable concentration is $HClO_4$ at molality m_1.

For the iodate-iodine compartment, the postulated mechanism consists of the iodine-iodide electrode reactions combined with the chemical steps characteristic of the Dushman reaction. This mechanism is in accord with the results of the following experiments: (*i*) Cells with $m_1 = 0.1$ reach their final voltage readings much more quickly than cells with $m_1 = 0.01$, other things equal. (*ii*) The reaching of final voltage readings was not appreciably speeded by early operation of the iodate-iodine electrode as a low-current-density anode or cathode; such efforts might be expected to fail if the only electrochemical processes are those of the iodine-iodide electrode, which is highly reversible (9). (*iii*) The addition of I^- to generate $I_2(c)$ within the cell gave evidence of the presence of intermediate products (*e.g.*, HIO_2) similar to that in Fig. 1. For such a cell, the voltage readings increased steadily until, after 5 hr, they passed those of a cell that was comparable except for having the iodate electrolyte equilibrated as usual with $I_2(c)$. The explanation: when I^- is added, it is rapidly removed according to Eq. [5]. As this occurs, HIO_2 is generated; rapidly at first, more slowly as $[I^-]$ decreases. The reduction of $[HIO_2]$ to its final equilibrium value is slow enough so that it still exceeds this value at 5 hr and beyond. The excess in $[HIO_2]$ does not occur unless I^- is initially added. The cell thus treated has the higher voltage reading so long as this excess exists.

Experimental Results and Extrapolations

Any attempt to calculate $E°$ rigorously from the E_c values is, in our opinion, less likely to give reliable results than the approximation-extrapolation method now to be described. At each temperature, $E°_1$ is calculated in four ways from E_c at each m_3, and each series of calculated values is plotted against m_3 as abscissa. Extrapolation to $m_3 = 0$ then permits selection of the final $E°$ from a consideration of the intercepts on the ordinate axis. The four methods of calculation are

1. $${}_1E°_1 = E_c + (RT/5\mathbf{F}) \ln [H^+]\,[IO_3^-]\,(\gamma_\pm)^2_{HClO_4} \qquad [7]$$

2. $${}_2E°_1 = E_c + (RT/5\mathbf{F}) \ln (H^+)\,(IO_3^-)\,(\gamma_\pm)^2_{HClO_4} \qquad [8]$$

where

$$(H^+) = [H^+] - (HIO_3) \qquad [9]$$

$$(IO_3^-) = [IO_3^-] - (HIO_3) \qquad [10]$$

and

$$K_{11} = (H^+)\,(IO_3^-)\,(\gamma_\pm)^2_{HClO_4}/(HIO_3) \qquad [11]$$

Evidently, the second approximation introduces a correction for the weakness of HIO_3. Brackets denote analytical ("total") concentrations of the enclosed substances; parentheses enclose calculated actual concentrations. The activity coefficient of HIO_3 is taken as unity.

3. $${}_3E°_1 = E_c + (RT/5\mathbf{F}) \ln [(H^+)^6_I\,(IO_3^-)\,(\gamma_\pm)^2_{HClO_4}/(H^+)^5_H] \qquad [12]$$

The subscript I identifies the iodate-iodine compartment of the cell, and the subscript H identifies the hydrogen compartment. Owing to the weakness of HIO_3, $(H^+)_I$ is less than $(H^+)_H = m_1 = 0.1$. Consequently, the voltage is reduced below what it would have been were HIO_3 as strong an electrolyte as $HClO_4$.

4. $${}_4E°_1 = {}_3E°_1 - E_L \qquad [13]$$

Here E_L is the potential at the liquid junction calculated for each cell according to MacInnes (11). Fortunately, E_L is small; it ranges from 0.0023V for $m_3 = 0.05$ to less than 0.0001V for $m_3 = 0.001$.

The following values of $(\gamma_\pm)_{HClO_4}$ were used, all for $m_1 = 0.1$: 0.803 (25°C); 0.799 (37.5°C); 0.795 (50°C). The first is the accepted value for 25°C (12), which was assumed to vary with temperature according to the Debye-Hückel limiting law to give the other two values.

The dissociation constants of HIO_3 were calculated from

$$\log K_{11} = 634.9/T - 2.911 \qquad [14]$$

(T, thermodynamic temperature) which is the equation for the least squares line corresponding to results in the literature (13-16).

The experimental results and the approximate standard potentials are given in Table I.

The variation of $E°_1$ with m_3 is gratifyingly small. The extrapolations will accordingly give reliable standard potentials. To show this, the $E°_1$ values at 50°C for all four approximations are plotted in Fig. 2. The last three methods give lines converging on 1.1863V = $E°$ at 50°C to within 0.0002V (estimated). The first method, which neglects the weakness of HIO_3, must be disregarded.

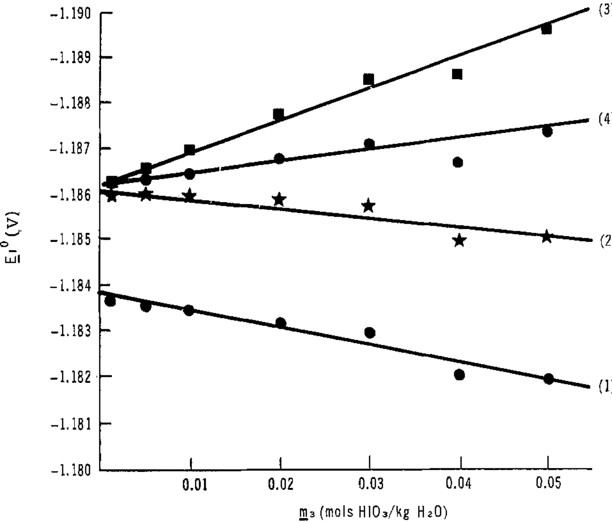

Fig. 2. Extrapolation of approximate standard potentials at 50°C to establish $E° = 1.1863 \pm 0.0002V$.

At the lower temperatures, values of ${}_4E°_1$ at $m_3 = 0.001$ diverged from the chosen straight line by 0.0042V at 25°C and 0.0034V at 37.5°C. This divergence was attributed to sluggishness of reaction not observed at 50°C. It will be remembered that Lundberg *et al.* regarded results for 0.001*M* HIO_3 at 25°C as too unreproducible to report (2).

The results of the extrapolations are given in Table II. At 25°C, the final $E°$ is within the limits, $E° = 1.195 \pm 0.002V$, of Ref. (2); but the estimated uncertainty is tenfold smaller.

Derived Thermodynamic Data

Cell reaction.—Derived data and explanatory notes for reaction [1] appear in Table III.

Dushman reaction.—For reaction [3]

$$\Delta G°[3] = \Delta G°[1] - 5\Delta G°[16] - 3\Delta G°[17] \quad [15]$$

where the bracketed numbers identify reactions, and the two reactions not yet mentioned are

$$1/2\ I_2(c) + 1/2\ H_2(g) = H^+(aq) + I^-(aq) \quad [16]$$

and

$$I_2(aq) = I_2(c) \quad [17]$$

Thermodynamic data for these reactions are given in Tables IV and V, and the data for reaction [3] appear in Table VI.

We must now see how well the new K_3 values agree with those from the chemical determinations by Sammet (1). His chemical determinations, unlike his electrochemical determinations, of K_3 could probably not be improved upon today. When adequate time to reach chemical equilibrium is allowed (Sammet found 5-10 weeks at 25°C and 6-8 days at 60°C to suffice), the chief experimental uncertainty in the chemical determinations is in the determination of $[I_2(aq)]$ at equilibrium. For Sammet's experiments

$$K_3 = [I_2(aq)]^3/(K_{19}/K_{20})^5(H^+)^6(IO_3^-)^6(\gamma_\pm)^{12}_{HIO_3} \quad [18]$$

where the two previously undefined equilibrium con-

NOTES

1. $\Delta G = -nFE°$. $E°$ from experimental measurements of E_c.
2. $\Delta S° = nF\partial E/\partial T$. Quotient is slope of least squares line through values of $E°$ plotted against absolute temperature. Variation of ΔS with T too small to be detected.
3. $\Delta H° = \Delta G° + T\Delta S°$.
4. As is customary, calculated values are reported to more places than is warranted by the estimated uncertainty in the experimental data (Table II).

Table IV. Standard potentials and standard Gibbs energy changes for reaction [16]

Temperature, °K	$E°$ (V) Thermochemical	$E°$ (V) Electrochemical	$\Delta G°$ (cal/mol I-) Thermochemical	$\Delta G°$ (cal/mol I-) Electrochemical
298.15	+0.5383	+0.5355	−12,413	−12,349
310.65	+0.5361	+0.5333	−12,363	−12,299
323.15	+0.5339	+0.5312	−12,313	−12,249

NOTES

1. Thermochemical data calculated in usual way from standard enthalpies of formation and standard entropies of reactants and products in reaction [16]. Data accepted as definitive were used (17).
2. At 298.15°K, $E°$ is Latimer's value (18). For the other temperatures, $E°$ values are calculated from this datum and from the thermochemical value of $\Delta S°$. See Note 2, Table III. Corresponding $\Delta G°$ values obtained as in Note 1, Table III. This procedure should give the best results as the thermodynamic entropy data (17) are more reliable than the heats of formation.
3. The thermodynamic value of $E°$ at 298.15°K exceeds the electrochemical by 0.0028V, an amount considered greater than the uncertainty in the latter. The thermodynamic $\Delta H°f$ for I- is −13.60 ± 0.20 kcal/mole. This uncertainty corresponds to ±0.0087V in $E°$. Perhaps the data in Ref. (16) should be reevaluated.
4. The $\Delta G°$ values in the table are also $\Delta G°f$ values for iodide ion.

Table V. Solubility of iodine, reaction [17]

Temperature, °K	Solubility (mols/liter) × 10³ Gross	Solubility (mols/liter) × 10³ Corrected	$\Delta G°$, cal/mol $I_2(aq)$
298.15	1.3317	1.3151	−3930
310.65	1.9570	1.9277	−3859
323.15	2.7914	2.7460	−3787

NOTES

1. Gross solubility as measured. The smoothed data conform to the equation: $\log s = -(1.239 \times 10^3/T) + 1.279$.
2. The true concentration of dissolved iodine, $I_2(aq)$, is less than the gross solubility owing to reaction [4] and to the formation of I_3^-; that is, $[I_2(aq)] = s - [HIO] - [I_3^-]$. Equilibrium constants from Ref. (8) were used in calculating the corrections.

Table VI. Standard Gibbs energy changes and equilibrium constants for reaction [3]

Temperature, °K	$\Delta G°$ (El) cal/mol IO_3^-	$\Delta G°$ (Th) cal/mol IO_3^-	K_3 (El)	K_3 (Th)
298.15	−63,842	−64,162	6.27×10^{46}	1.08×10^{47}
310.65	−63,854	−64,174	8.37×10^{44}	1.41×10^{45}
323.15	−63,859	−64,179	1.54×10^{43}	2.54×10^{43}

NOTES

1. $\Delta G°$ values calculated according to Eq. [15]. Equilibrium constants from $\Delta G° = -RT \ln K_3$.
2. Values labeled (El) are based on electrochemical data for reaction [16]. See Table IV. We prefer these values.
3. Values labeled (Th) are based on thermochemical data for reaction [16]. See Table IV.
4. As average values for the temperature range shown above, we have calculated:
$\Delta H°$ (El) = 63,639 cal/mol IO_3^-; $\Delta S°$ (El) = −0.68 cal/K·mol IO_3^-;
$\Delta H°$ (Th) = 63,959 cal/mol IO_3^-; $\Delta S°$ (Th) = −0.68 cal/K·mol IO_3^-.

stants are for the reactions

$$AgI(c) = Ag^+ + I^- \quad [19]$$

and

$$AgIO_3(c) = Ag^+ + IO_3^- \quad [20]$$

used by Sammet as a means of establishing a calculable $[I^-]$. Note that a change of 1% in $(\gamma_\pm)_{HIO_3}$ in Eq. [18] changes K_3 by about 12%. We have reevaluated Sammet's chemical results at 25° and 60°C, using the best values (13) of $(\gamma_\pm)_{HIO_3}$ extrapolated as necessary. (Details on request from R. D. Spitz.) The results: $K_3 = 4.59(10^{46})$ at 25°C, the mean of 9 determinations in which $[HIO_3]$ ranged from 0.046 to 0.132M; $K_3 = 1.80(10^{42})$ at 60°C. Extrapolation to this temperature of the K_3 values in Table IV gives $K_3(El) = 7.9(10^{41})$ and $K_3(Th) = 1.3(10^{42})$. Comparison of these values with the new Sammet result, and a similar comparison for 25°C (Table VI) shows good agreement throughout. The comparison does not establish whether the electrochemical (El) or the thermochemical (Th) data for reaction [16] are to be preferred; see Notes 2 and 3 of Table VI.

Other derived thermodynamic data.—The Gibbs energy of formation of $IO_3^-(aq)$ is the standard Gibbs energy change in the reaction

$$1/2\ I_2(c) + 3/2\ O_2(g) + 1/2\ H_2(g) = H^+(aq) + IO_3^-(aq) \quad [21]$$

which is obtainable from $\Delta G°$ for reaction [1] and that for the formation (17) of $H_2O(l)$. The calculated result: $\Delta G°f = -32{,}373$ cal/mol $IO_3^-(aq)$ at 25°C, in satisfactory agreement with the earlier value (2) of $-32{,}251$ cal.

The analogous calculation of $\Delta S°f$ for $IO_3^-(aq)$ gave 22.5 cal/deg/mol $IO_3^-(aq)$, to be compared to thermochemically determined values (19) of 26.9 and 27.7 in the same units. It is well known that voltage measurements cannot often compete with heat-capacity measurements in establishing entropy changes.

Finally, by methods analogous to those used above, calculations were made for the reaction

$$3H_2(g) + IO_3^-(aq) = I^-(aq) + 3H_2O(l) \quad [22]$$

The results for 25°C: $\Delta G° = -150{,}110$(Th) and $-150{,}046$(El) cal/mol $IO_3^-(aq)$ and $E° = 1.0849$V (Th) and 1.0844V (El). As before, the results depend on whether the thermochemical or the electrochemical value for $\Delta G°f$ of I^- is used. The voltages are evidently standard potentials of the iodate-iodide electrode.

Electro-Oxidation of Organic Compounds I

Oxidation of Benzaldehydes at the Dropping Mercury Electrodes

W. James Bover* and Petr Zuman**

Department of Chemistry, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

Benzaldehydes substituted in the meta and para positions with both electron-donating and electron-withdrawing substituents react with hydroxide ions and form geminal diol anions in a reaction $ArCHO + OH^- \rightleftarrows ArCH(OH)O^-$. The height of the anodic waves, recorded with d-c and pulse polarography, decreases with decreasing pH in the shape of a dissociation curve. This has been interpreted as due to the electro-oxidation of the anion $ArCH(OH)O^-$ preceded by the above acid base equilibrium. The source of the second oxygen in the electrolytic formation of benzoic acids in alkaline media is thus the hydroxide ion. Based on the shape of the dissociation curve, oxidation of the dianion $ArCH(O)_2^{2-}$ seems improbable. Under the assumption that the acid-base reaction behaves like a volume reaction, values of rate constants for the anion formation and cleavage were calculated. Half-wave potentials of anodic waves are a linear function of Hammett substituent constants σ.

Benzaldehyde undergoes oxidation by chemical reagents relatively easily (1) but the information on electro-oxidation is rather limited (2). For benzaldehyde in sulfuric acid solutions using a platinum anode, yields of about 30% of benzoic acid were reported (3). As reasons for the observed low yields, further oxidation of the side-chain and oxidative substitution on the ring were considered (3), as well as formation of polymers (3, 4). The formation of the latter was seemingly suppressed when the electrolysis was carried out in an aqueous solution of sodium benzene sulfonate using a nickel electrode in the presence of a cupric oxide catalyst where a 58% yield was found (5). However, under these conditions, competition with the Cannizzaro reaction has been assumed. Considerably higher yields of 95% of anisic acid have been reported (6) for the oxidation of anisaldehyde on a platinum electrode in aqueous sulfuric acid solutions.

The above studies have been carried out under applied current conditions. In another study using controlled potential electrolysis Lund (7) observed on current-voltage steps obtained in solutions of anisalcohol in acetonitrile using a platinum anode two anodic waves and proved that the more positive wave (at +1.63V) corresponded to the oxidation of anisaldehyde. It was also observed that the anisaldehyde wave disappears upon addition of pyridine. No preparative oxidation had been performed at potentials more positive than 1.63V and no evidence for the product formed was given (7).

Polarographic anodic waves of pyridine-4-carboxaldehyde, 2- and 4-nitrobenzaldehyde, 4-cyanobenzaldehyde, and 4-dimethylaminobenzaldehyde in aqueous solutions containing 10-20% ethanol in 0.1-1.0*N* sodium or potassium hydroxide solutions with a dropping mercury electrode were first reported by Volke (8). These studies were later (9) extended to ten substituted benzaldehydes. It has been proved that the polarographic anodic waves, observed in 0.04-1.8M potassium hydroxide, correspond to a two-electron irreversible process. These authors (9) neither described any change in the limiting current with hydroxide ion concentration (which proved to be essential for the interpretation of the mechanism), nor were aware of the establishment of the equilibria between benzaldehydes and hydroxide ions in homogeneous solutions (10, 11).

In the preliminary communication (8), anodic peaks obtained with linear sweep voltammetry were reported which were observed in solutions containing benzaldehydes when a vibrating platinum electrode was used. The presence of such peaks was offered (8) as a proof that mercury salt formation can be excluded as the interpretation of the anodic process. Nevertheless, these anodic peaks have been shown (9) to correspond to oxidation of ethanol, used as cosolvent.

The mechanism of anodic oxidation of benzaldehydes can be considered as speculative. In particular, the source of the second oxygen atom in the resulting benzoic acid has been rather uncertain. Fichter (3) assumed electrolytic formation of atomic oxygen as the oxidizing species, and a radical mechanism (4) was also considered. In the absence of dissolved oxygen in deaerated acetonitrile solution "the formation of carboxyl groups is dubious" (7). The polarographic study (9) assumed electrochemical oxidation of mercury and a surface chemical oxidation of the benzaldehyde involving $HgO \cdot OH^-$.

In the present study we aimed at a contribution to the mechanism of the electro-oxidation of aromatic aldehydes, in particular with respect to the source of the second oxygen atom. Since the anodic waves were observed (8, 9) in alkaline media, it seemed essential to decide whether the addition of hydroxide ions to the benzaldehydes according to equation $ArCHO + OH^- \rightleftarrows ArCH(OH)O^-$ with $K = [ArCH(OH)O^-]/[ArCHO][OH^-]$ [which has been proved to occur in alkaline homogeneous solutions (10, 11)] plays also a role in the generation of the electroactive species, the conjugate base.

The pK values of the studied benzaldehydes (10) together with the preliminary experiments indicated the need to carry out further experiments on electro-oxidation in strongly alkaline solutions in order to achieve conditions under which at least part of the benzaldehyde exists in the form of the conjugate base. For this purpose it was necessary to define the acidity in these strongly alkaline solutions and to find a suitable reference cathode.

Although the acidity scale H_- corresponding to the loss of a proton in concentrated solutions of hydroxides is known (12), it could be used only as a first approximation in the studied reaction which involves the addition of a hydroxide ion. Since the acidity scale (J_-) corresponding to such conditions has not been available from equilibrium data, a new acidity scale J_- has been established (11), based on our values of the dissociation constants K. This acidity function describes the acidity in aqueous sodium hydroxide solutions (up to 13M) for reactions involving addition of a hydroxide ion to a neutral molecule. The use of substituted benz-

Key words: d-c polarography, pulse polarography, acid-base equilibria, hydroxide ion addition, geminal diol anion, benzoic acid, structural effects, substituent effects, Hammett equation.

aldehydes as indicators for the establishment of the acidity function J_- makes this function particularly useful for the study of the effect of acidity on reactions of benzaldehydes and their electrode reactions.

As the reference electrode (cathode) for oxidations in strongly alkaline solutions, a carbon rod electrode immersed in a concentrated sodium hydroxide solution proved (13) most useful in obtaining reproducible anodic waves of substituted benzaldehydes and other related compounds.

Experimental

All of the d-c and differential pulse polarographic curves were recorded on a PAR Model 174 Polarographic Analyzer (Princeton Applied Research Corporation, Princeton, New Jersey) with a Hewlett-Packard 7004B X-Y Recorder. The a-c polarographic curves were recorded on the Cambridge Polarographic Analyzer 82P (Cambridge, England). The capillary employed in these electrochemical experiments with a dropping mercury electrode had the following characteristics: an outflow velocity of 2.49 mg/sec at a 100 cm head of mercury with a natural drop time of 3.18 sec. All capillary characteristics were determined at zero potential (short circuit) in a nondeaerated solution of 1.0M sodium hydroxide in the cell employed for the polarographic measurements.

Current-voltage curves with a rectangular voltage polarization were recorded with the PAR 174 and with a commutator switching device constructed according to the principle suggested by Kalousek (14) and the scheme proposed by Němec and Holub (15) (the device is referred to as a Kalousek commutator). Cyclic voltammograms were obtained with a triangular function generator built by the courtesy of R. N. Adams, which provided a scanning rate range from 250 to 2000 V/min^{-1}. The resulting voltammetric curves were followed on a Tektronic Type 564B Storage Oscilloscope using Type 3A9 and 2A63 Differential Amplifiers and permanently recorded by tracing the curve on graph paper.

A modified Kalousek cell as described in a previous communication (13) was employed for all electrochemical measurements. The reference electrode was a spectroscopic grade carbon rod immersed in either 1.0 or 5.0M sodium hydroxide.

A Corning Digital 112 Research pH-Meter with a combination Sargent glass-calomel electrode (S-30072-15) was employed for pH measurements of the buffers used in the experiments (the meter was standardized using 0.01M borax and saturated calcium hydroxide, pH 9.180 and 12.343, respectively, at 25°C).

A minicomputer (modified PDP-8, Digital Equipment Corporation, Maynard, Massachusetts) and an IBM 360/40 computer were used for the multiparametric curve fitting analyses (16).

Spectrophotometric experiments were performed on a Unicam SP800-A (Pye-Unicam, Cambridge, England) recording spectrophotometer. Matched fused quartz cells (10 mm sample path) were employed in a thermostated cell holder which was maintained at 25° ± 0.1°C by a Mark F. J. (Haake, Berlin) thermostat pump circulator.

Chemicals and solutions.—Most of the aldehydes were supplied by the Aldrich Chemical Company (Milwaukee, Wisconsin). The compounds were checked for purity by recording the relevant melting or boiling points and by recording a gas-liquid chromatogram of an ether solution of the aldehyde.

Preparation of benzaldehyde stock solutions and of the various sodium hydroxide solutions followed the procedures described previously (13). The phosphate buffers pH 10.8 and 11.9 were prepared from an 0.05M dipotassium hydrogen phosphate solution titrated with various portions of 0.1M hydroxide, and the bicarbonate buffers pH 9.9-10.8 were prepared by titration of an 0.05M solution of sodium bicarbonate with 0.1M sodium hydroxide. Piperidine (pK_a 11.12) buffers were also prepared for use in the pH range between 10.2 and 12.0, but their use was limited by the dependence of the oxidation differential pulse current on the concentration of piperidine in the buffer.

Working procedures.—Polarographic current-voltage curves.—Most d-c and differential pulse polarographic measurements were carried out in solutions that were 2×10^{-4}M in aldehyde and contained 2% ethanol. These solutions were prepared by pipetting 0.2 ml of the ethanol stock solution of the aldehyde to 9.8 ml of sodium hydroxide just prior to placing the solution in the polarographic cell. The solution was then deaerated with a stream of nitrogen for a period of 2 min.

The half-wave potentials of anodic waves in 0.1, 0.25, 1.0, 2.0, 4.0, 6.0, and 9.0M sodium hydroxide were measured against the half-wave potential of phthiocol (2-hydroxy-3-methylnaphthoquinone) to avoid corrections for changes in liquid junction potential. Half-wave potentials of the pilot compound were proved to be independent of sodium hydroxide concentration and the compound to be stable except in the most concentrated hydroxide solutions. But even in 9M sodium hydroxide waves can be recorded and half-wave potentials measured. Cathodic waves of phthiocol were recorded before and after the recording of the anodic waves of a series of benzaldehydes for each concentration of sodium hydroxide.

Measurement of the half-wave potential of the reduction wave of phthiocol in 0.1*N* sodium hydroxide against a SCE made it possible to express the half-wave potentials of the anodic waves of benzaldehydes *vs.* SCE (Table I). This procedure was checked by using thallium(I) ions as an internal standard in 1.0M sodium hydroxide. The values of half-wave potentials of the anodic waves of benzaldehydes used by these two independent procedures were practically identical.

The differential pulse polarographic current-voltage curves were recorded using an applied pulse (ΔE) of 25 mV at a scan rate of 2 mV/sec^{-1} and a controlled (forced) drop time of 2.0 sec. Under the condition that (using the PAR-174) the parameters, drop time, potential scan rate, and pulse voltage are kept constant for each run in a pH series, the peak current, Δi_{max}, is directly proportional to the concentration of electroactive species (17, 18). The applied potential was driven from negative to positive values so as to avoid mercury salt contamination of the electrode surface which results when the electrode is polarized at potentials more positive than the initial anodic current rise.

The cyclic voltammograms were recorded for m-cyanobenzaldehyde in 1.0M sodium hydroxide at a scan rate of 12 V/min^{-1}. The Kalousek commutator technique was used for m-cyano- and m-chlorobenzaldehydes in hydroxide solutions at a switching frequency of 1 Hz with the auxiliary potential set on the plateau of the anodic wave. The a-c polarographic curves were recorded in 1.0M sodium hydroxide with an alternating voltage of 10 mV rms at a scan rate of 0.4 mV sec^{-1} and a forced drop time of 1.0 sec.

Results

D-C polarographic curves.—The anodic waves for the substituted benzaldehydes were initially observed in alkaline solutions with d-c polarography using a drop-

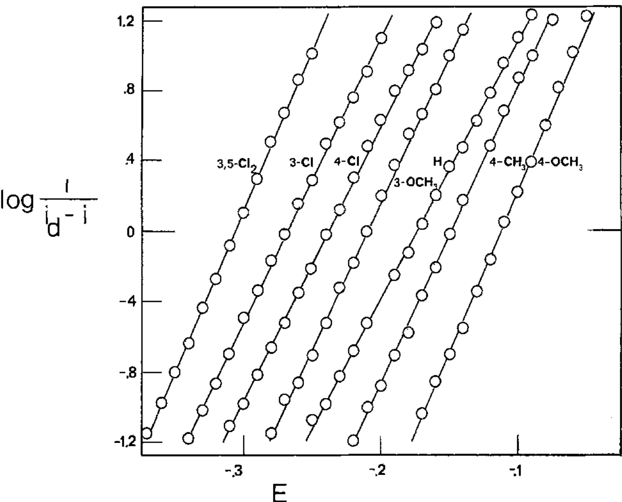

Fig. 1. A plot of the log $i/(i_d - i)$ for the rising portion of the anodic wave vs. the potential (in volts vs. carbon reference electrode) for substituted benzaldehydes. The solutions were all 2×10^{-4}M, 2% ethanol and 1.0M sodium hydroxide at 25°C.

ping mercury electrode and a carbon rod reference electrode as previously described (13). Well-developed waves, enabling measurement of both wave-heights and half-wave potentials were obtained for most aldehydes in 0.1-9.0M solutions of sodium hydroxide [cf. Fig. 2, Ref. (13)]. Anodic waves were well separated from the initial anodic current rise due to oxidation of mercury and were proved irreversible by cyclic voltammetry and the Kalousek commutator technique.

This has been further confirmed by logarithmic analysis (Fig. 1) which shows a linear plot of log $i/(i_d - i)$ as a function of potential with a slope corresponding to βn_b values which vary from 0.86 to 1.08 (Table II).

A decrease of the anodic limiting current at sodium hydroxide concentrations of 1-4M is due to an increase in viscosity (η), as proved from a practically constant value of the product $i(\eta)^{1/2}$. At still higher sodium hydroxide concentrations, the limiting current decreases somewhat more than would correspond to an increase in solution viscosity. This additional decrease which is similar for various substituted benzaldehydes is not in the shape of a dissociation curve. Moreover, the limiting current of benzaldehyde remains diffusion controlled as shown by a linear dependence on the square root of mercury pressure in both 6 and 10M sodium hydroxide, which show, nevertheless, a small negative intercept.

When sodium hydroxide solutions more dilute than about 0.25M and buffers of lower pH values were studied, a shift of the anodic waves to more positive potentials was observed. Since this shift with pH was greater than the shift of the current rise due to mercury dissolution, the waves became less well developed at lower pH values. Below certain pH values (characteristic for each substituted benzaldehyde) the anodic wave was no longer observed. For benzaldehydes with electropositive substituents (*e.g.*, p-methyl or p-methoxy) it was hardly possible to decide whether the absence of the anodic wave was solely due to a potential shift to more positive values than the initial current rise, or whether a decrease in the wave-height occurred as well. For the benzaldehydes with electronegative substituents (*e.g.*, m-nitro or m-chloro, Fig. 2) a decrease in wave-height was indicated on the d-c current-voltage curves, but quantitative measurements were difficult.

An attempt has been made to determine the wave-height of m-nitrobenzaldehyde at pH 11.5-10 by multiparametric curve fitting analysis (16). Even when this approach proved qualitatively the decrease of the limiting current with decreasing pH, uncertainty of the treatment was too large to permit a decision among the possible shapes of the *i*-pH plot. The main source of uncertainty was the change in the course of the residual current in the presence of the benzaldehyde, which made simple subtraction of the residual current for the pure buffer solution insufficient.

Differential pulse polarography.—To confirm the decrease of the current at lower pH values and to obtain reliable values for current, differential pulse polarographic curves (17, 18) of solutions of benzaldehydes were recorded and the peak currents, Δi_{max}, were obtained which were measurable with sufficient accuracy to considerably lower pH values than it was possible to measure the limiting currents of d-c polarographic curves (Fig. 3).

To correct differential pulse polarographic curves which are close to the current rise due to mercury dissolution (last two curves, Fig. 3) for the residual current, use has been made of the symmetry of the peak and the practical independence of the half-width of the peak on peak-height.

Using the construction of the whole peak based on current values accurately measured at more negative potentials (curve 3, Fig. 3), it was possible to obtain

[a] βn_b obtained from the slope of log $i/(i_d - i)$ *vs.* *E* for the rising portion of the anodic wave in 1.0M NaOH recorded automatically (Fig. 1).
[b] From the slope of $E_{1/2}$ *vs.* pH plot (Fig. 5).
[c] For m-chlorobenzaldehyde the following values were found at varying sodium hydroxide concentrations: [OH]: 0.5, 1.0, 1.7, 3.0, 4.0, and 6.0M; βn_b[a]: 0.88, 0.92, 1.09, 0.98, 1.02, and 1.04.
[d] The current values at varying potentials for the log analysis were measured potentiometrically (point by point) using a three-electrode system.

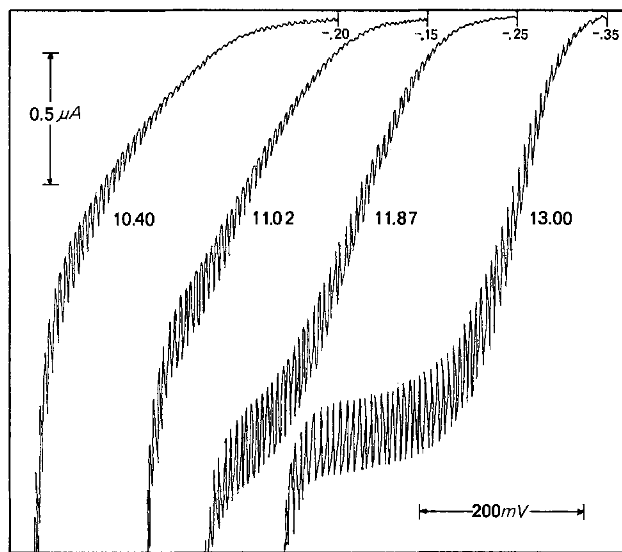

Fig. 2. The dependence of the d-c polarographic current voltage curves on pH for the oxidation of m-nitrobenzaldehyde at the indicated pH values in carbonate (10.40) phosphate (11.02, 11.87) buffers and in 0.1M sodium hydroxide (13.00). All solutions were 2×10^{-4}M in aldehyde and contained 2% ethanol at 25°C. The voltage scanning started from the negative potentials to more positive values.

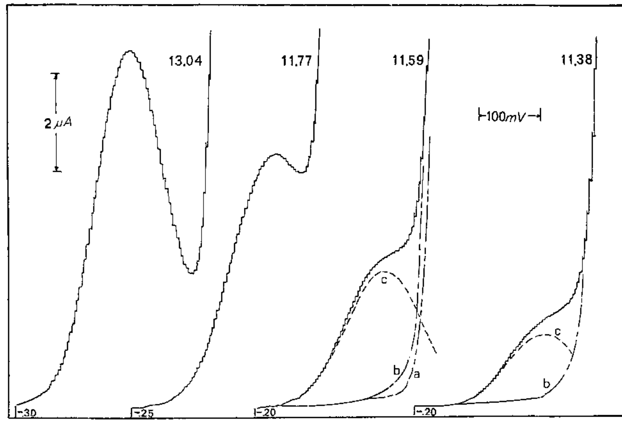

Fig. 3. The dependence of the differential pulse polarographic current-voltage curves for the oxidation of p-chlorobenzaldehyde on pH in solutions of 0.1M sodium hydroxide (pH 13.04) and phosphate buffers (pH 11.77, 11.58, 11.38). The voltage scanning started from the negative to more positive values at the rate of 2 mV/sec. The broken curves correspond (b) to the residual current due to the buffer alone; and (c) to the current resulting from the subtraction of curve (a) from the total limiting current. All solutions were 2 × 10^{-4}M in aldehyde and contained 2% ethanol at 25°C.

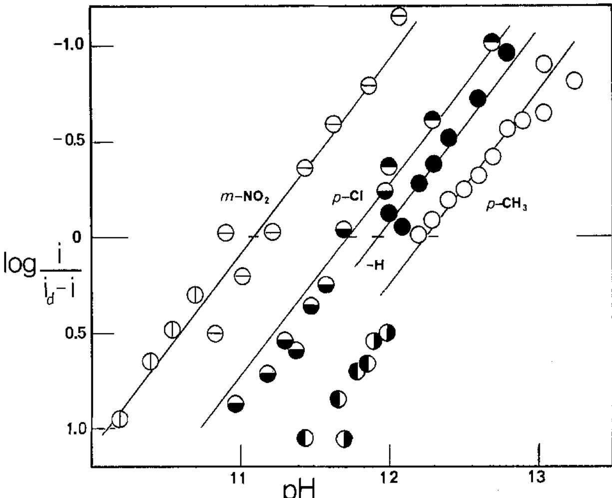

Fig. 4b. The dependence on pH of the log ($i/i_d - i$) where i is the peak current at a given pH and i_d the corresponding diffusion peak current in solutions described in Fig. 4a for some benzaldehydes. The straight lines of unit slope represent the theoretical slope for a monobasic acid dissociation. Symbols for points are the same as in Fig. 4a.

well-reproducible values of Δi_{max} even for less well-developed curves.

Current-pH *plots*.—Reliable values of Δi_{max}, expressed relative to $(\Delta i_{max})_d$ obtained at sufficiently high pH, show a decrease with decreasing pH in the shape of a monobasic acid dissociation curve (Fig. 4a). When log $\Delta i_{max}/[(\Delta i_{max})_d - \Delta i_{max}]$ was plotted against pH (Fig. 4b), a linear plot with unit slope was obtained.

Analogous plots, *i.e.*, $\bar{i}/\bar{i}_d = f$ (pH), are commonly used for the treatment of d-c polarographic currents governed by a rate of an antecedent chemical reaction (19). The theory of such currents for differential pulse polarography has not yet been developed. To prove empirically the possibility of using $\Delta i_{max}/(\Delta i_{max})_d$ instead of $\bar{i}/\bar{i}_d$ for interpretation of pH dependences two approaches have been used: plots of $\Delta i_{max}/(\Delta i_{max})_d$ and

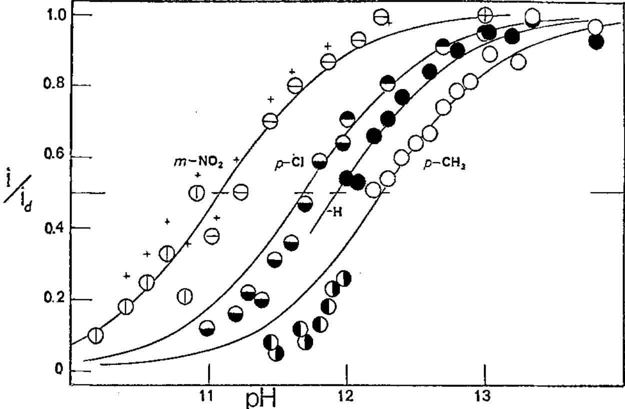

Fig. 4a. The dependence of the differential pulse peak current as a fraction of the corresponding diffusion current on pH for some substituted benzaldehydes. The experimental points represent data obtained for p-tolualdehyde in sodium hydroxide (○) and phosphate buffers (◐); for benzaldehyde in sodium hydroxide (●) and phosphate buffers (◑); for p-chlorobenzaldehyde in sodium hydroxide (◓) and phosphate (◒) buffers; for m-nitrobenzaldehyde in sodium hydroxide (⊕), phosphate (⊖), and carbonate (⦶) buffers. All solutions were 2 × 10^{-4}M in aldehyde and contained 2% ethanol at 25°C. The solid curves have a shape corresponding to a theoretical dissociation curve for a monobasic acid. The values (+) shown on the m-nitrobenzaldehyde curve correspond to those current values obtained with d-c polarography.

$\bar{i}/\bar{i}_d$ against pH have been compared for current-voltage curves of benzoylacetone, which correspond to an irreversible reduction process accompanied by an antecedent volume acid-base reaction (20). Both plots have been found to have the same shape and inflection points (pK'). Furthermore, benzaldehydes, like m-nitrobenzaldehyde where the current in the pH region for which the decrease of the current with pH occurred was measurable both by differential pulse ($\Delta i_{max}/(\Delta i_{max})_d$ and $\bar{i}/\bar{i}_d$, fitted reasonably well a single, continuous curve when plotted *vs.* pH (Fig. 4a). Hence the use of $\Delta i_{max}/(\Delta i_{max})_d$ for treatment in expressions derived for $\bar{i}/\bar{i}_d$ has been substantiated as a first approximation.

Even when we are aware that the differential pulse peak current can also decrease due to a change in the value of the transfer coefficient and the heterogeneous rate constant of the electrode process, all the facts mentioned above indicate that the rate of the chemical reaction is the predominant factor governing the decrease of the anodic current.

Comparison of the curves in Fig. 4a and 4b shows that values of $\Delta i_{max}/(\Delta i_{max})_d$ obtained in phosphate or bicarbonate buffers show deviations toward smaller currents when compared with the theoretical curves plotted to fit values obtained in sodium hydroxide solutions. When recorded in phosphate buffers of constant pH, the value of Δi_{max} decreased with increased phosphate concentration.

Half-wave and peak potentials.—From a comparison of the anodic waves of several benzaldehydes using both d-c and differential pulse polarography under identical experimental conditions, an empirical relationship between the half-wave potential ($E_{1/2}$) and the peak potential (E_p) has been found, *viz.*, $E_p \approx E_{1/2} + 0.025$V.

Plots of $E_{1/2}$ and E_p values *vs.* J_- show three linear sections (Fig. 5). At the lowest and highest pH (or J_-) values a pH independent section is observed; in the intermediate pH range a shift to more positive potentials with decreasing pH occurs. Slopes of this linear section are tabulated in Table II.

The half-wave potentials of substituted benzaldehydes in 1.0 and 2.0M sodium hydroxide [where they are all dependent on concentration of hydroxide ions with practically identical value of $dE_{1/2}/d$pH (Table II)] are a linear function of Hammett substituent constants σ_x (Fig. 6). The reaction constants in 1.0M ($\rho\pi^A = -0.225$V, $r = 0.994$, $SD_\rho = 0.011$) and 2.0M ($\rho\pi^A =$

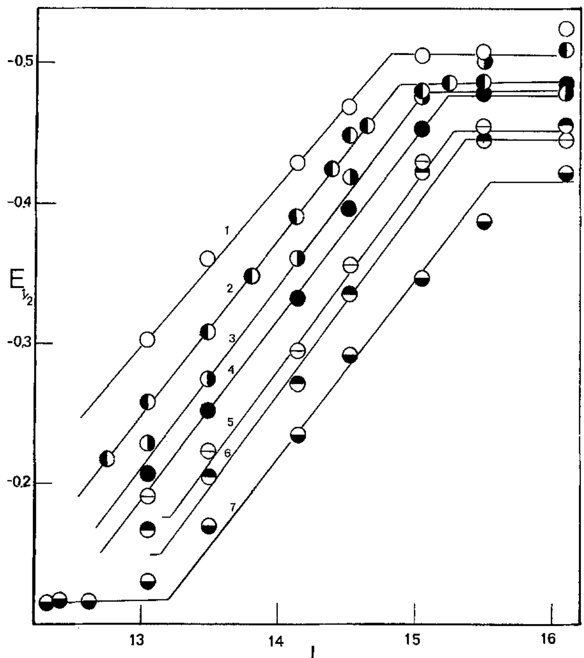

Fig. 5. The half-wave potentials for the anodic polarographic waves are plotted as a function of the acidity function J_- for (1) 3,5 dichloro-; (2) 3-chloro-; (3) 4-chloro-; (4) 3-methoxy-; (5) unsubstituted; (6) 4-methyl; and (7) 4-methoxy-benzaldehydes. Potentials are reported vs. the SCE, and the solutions were $2 \times 10^{-4}M$ in aldehyde and contained 2% ethanol at 25°C.

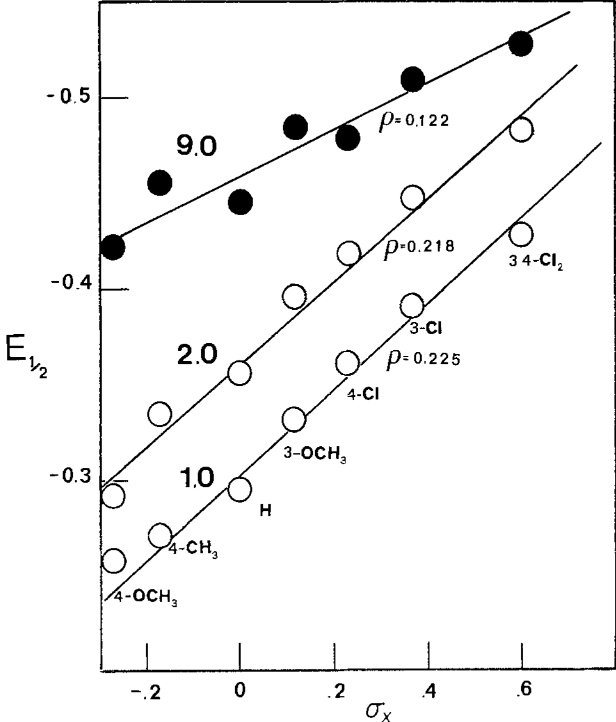

Fig. 6. The dependence of the half-wave potentials for the anodic waves of substituted benzaldehydes in 1.0, 2.0, and 9.0M sodium hydroxide on the Hammett substituent constants, σ_x. All solutions were $2 \times 10^{-4}M$ in aldehyde and contained 2% ethanol. The potentials are reported vs. SCE with $E_{1/2}{}^{H} = -0.294$ for benzaldehyde.

-0.218V, $r = 0.990$, $SD_\rho = 0.014$) are consequently practically identical.

The half-wave potentials in 9M sodium hydroxide (where J_- is equal to 15.97), in an acidity region where all the half-wave potentials are independent of sodium hydroxide concentration (Fig. 5), are also a linear function of Hammett substituent constants σ_x (Fig. 6). The linear plot corresponds to a reaction constant $\rho\pi^B = -0.122$V ($r = -0.954$, $SD = 0.014$). The lower value of the correlation coefficient reflects the smaller value of the reaction constant, but the correlation can be considered good.

Spectrophotometric studies.—Spectrophotometric determinations of equilibrium constants (K) of the reaction $ArCHO + OH^- \rightleftarrows ArCH(OH)O^-$ have been described elsewhere (10). Recent attempts to determine the second dissociation constant (K_2) corresponding to the formation of a dianion in a process of the type $ArCH(OH)O^- \rightleftarrows ArCH(O^-)_2 + H^+$ were unsuccessful even for nitrobenzaldehydes, which have the lowest pK_1 value of the compounds studied (12.79 for para and 13.07 for meta). Hence for nitrobenzaldehydes the value of pK_2 must be at least more than two pK units larger than pK_1.

Discussion

Electroactive forms.—The presence of anodic oxidation waves in alkaline media only (Fig. 2), the decrease of their wave-height with decreasing pH in the shape of a dissociation curve (Fig. 4), and the shift of their half-wave potentials with pH (Fig. 5) indicate that the species ArCHO, which predominates in solutions of benzaldehydes at lower pH values, is not the electroactive form. The fact that mercury does not participate in the anodic process in mercury salt formation has been confirmed by irreversibility of the electrode process as proved by cyclic voltammetry and the Kalousek commutator technique. The absence of mercury in the electrolysis products (13) also confirmed this view.

On the other hand, inflection points of polarographic dissociation curves (pK') roughly parallel the pK values obtained spectrophotometrically for the addition of hydroxide ions (10) (Table III). It has been thus deduced that the species $ArCH(OH)O^-$, the formation of which in alkaline media has been recently proved (10, 11), seems to be the electroactive species which undergoes oxidation to benzoic acid. It was nevertheless necessary to consider the oxidation of the dianion of the geminal diol [$ArCH(O^-)_2$] as an alternative reaction path.

The pH dependence of the limiting current and in particular the dependence of the inflection points pK' on structure of the aldehyde cannot be brought into agreement with the proposed (9) mechanism involving oxidation by $HgO \cdot OH^-$.

The shift of the polarographic dissociation curve to lower pH values than the spectrophotometrically obtained dissociation curve (10), as demonstrated by the smaller values of pK' than pK (Table III) as well as by the kinetic character of the anodic wave when $i < 0.2\ i_d$, indicates that the height of the anodic waves at $pH < pK$ does not correspond to the equilibrium concentration of the electroactive anion in the bulk of the solution, but rather to the rate of formation of this anion (kinetic current).

Reaction scheme.—The simplest reaction scheme, which would be in agreement with the spectrophotometric evidence (10, 11) and would explain the observed change in current with pH (Fig. 4), is a set of reactions [1]

$$ArCHO + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ArCH\begin{matrix} OH \\ O^- \end{matrix} \quad [1a]$$

$$ArCH\begin{matrix} OH \\ O^- \end{matrix} \xrightarrow{E} ArC\begin{matrix} OH \\ {=}O \end{matrix} + H^+ + 2e \quad [1b]$$

$$ArCOOH \rightleftharpoons ArCOO^- + H^+ \quad [1c]$$

Table III. Equilibrium constants ($K_1 = [ArCH(OH)O^-][H^+]/[ArCHO]$) determined spectrophotometrically (pK_{spec}), polarographic dissociation constants (pK' = pH at which $i = 0.5\, i_d$), and rate constants of the reaction $ArCHO + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ArCH(OH)O^-$ at 25°C for substituted benzaldehydes (X-ArCHO) and aromatic heterocyclic aldehydes

In this system the rate of the addition of the hydroxide ion governs the limiting current of the anodic wave, until at sufficiently high sodium hydroxide concentrations the current becomes diffusion controlled.

The scheme will, nevertheless, be compared with two alternative schemes, [2] and [3], where the electroactive form, yielding the benzoic acid as proved by controlled-potential electrolysis (13) is the dianion of the geminal diol

$$ArCHO + OH^- \rightleftharpoons ArCH(OH)(O^-) \qquad [2a]$$

$$ArCH(OH)(O^-) + OH^- \underset{slow}{\overset{k}{\rightleftharpoons}} ArCH(O^-)(O^-) + H_2O \qquad [2b]$$

$$ArCH(O^-)(O^-) \underset{E}{\rightarrow} ArC(=O)(O^-) + 2e + H^+ \qquad [2c]$$

In scheme [2] the slow step would be the abstraction of a proton from an —OH group which does not seem to be in agreement with the experience with similar types of reactions.

Alternatively scheme [3] can be considered

$$ArCHO + OH^- \overset{k}{\rightleftharpoons} ArCH(OH)(O^-) \qquad [3a]$$

$$ArCH(OH)(O^-) + OH^- \underset{fast}{\rightleftharpoons} ArCH(O^-)(O^-) + H_2O \qquad [3b]$$

$$ArCH(O^-)(O^-) \underset{E}{\rightarrow} ArC(=O)(O^-) + H^+ + 2e \qquad [3c]$$

where the addition of the hydroxide ions is the slow step.

When the general treatment for acid-base reactions preceding the electrode process proper (21) is applied to schemes [1]-[3], in all cases the current (i) expressed as a fraction of the diffusion current (i_d) decreases with decreasing pH in the shape of a dissociation curve. The shape of this curve depends on the scheme and on the relative magnitude of the equilibrium constant K_1 characterizing reactions [1a], [2a], and [3a] and the pH at which the polarographic wave is one-half of the diffusion current (pK'). Equations for individual schemes are summarized in Table IV to-

Table IV. Equations for the dependence of current (i) on pH for reaction schemes [1]-[3] for $pK_2 > pK_1$

Scheme	Equation	Conditions	$\frac{d \log (i/i_d - i)}{d\, pH}$
[1]	$i/i_d = \dfrac{0.866\sqrt{kt_1K_w{}^2K_1}\; 1/[H^+]}{1 + 0.866\sqrt{kt_1K_w{}^2K_1}\; 1/[H^+]}$		1
[2]	$i/i_d = \dfrac{0.866\sqrt{t_1kK_w{}^2K_2}\,\dfrac{1/[H^+]^2}{1/K_1 + 1/[H^+]}}{1 + 0.866\sqrt{t_1kK_w{}^2K_2}\,\dfrac{1/[H^+]^2}{1/K_1 + 1/[H^+]}}$	pK' >> pK_1 pK' << pK_1	1 2
[3]	$i/i_d = \dfrac{0.866\sqrt{t_1kK_w{}^2K_1K_2}\,\dfrac{1/[H^+]^{3/2}}{1 + K_1/[H^+]}}{1 + 0.866\sqrt{t_1kK_w{}^2K_1K_2}\,\dfrac{1/[H^+]^{3/2}}{1 + K_1/[H^+]}}$	pK' >> pK_1 pK' << pK_1	1/2 3/2

gether with the slopes of the respective dissociation curves expressed as $d \log(i/i_d - i)/dpH$. In all the systems studied it was assumed that $pK_1 << pK_2$, as is observed experimentally (11).

Since in all experimentally accessible cases the value of pK' was smaller than pK_1, only the shapes of the dissociation curves for the condition $pK' << pK_1$ need to be considered. As the observed dissociation curves all have a slope $d \log(i/i_d - i)/dpH = 1.0$ (Fig. 4b), schemes [2] and [3] which would require steeper dissociation curves with slopes of 1.5 or 2 can be excluded. Hence the pH dependence of the limiting current of the anodic wave indicates that the monoanion of the geminal diol $ArCH(OH)O^-$ is the electroactive form and the working hypothesis (13), that the electroactive form is the dianion, seems less probable.

There is, nevertheless, some evidence available that the detailed mechanism might be more complex than described by scheme [1]. When the value βn_b, obtained from logarithmic analysis of the rising portion of the anodic wave (column 1, Table II) is compared with the value of βn_b obtained from the pH dependence of half-wave potentials (column 3, Table II) under an assumption of the transfer of one hydroxide ion prior to the electrode process proper, a considerable difference is found. It cannot be excluded even when the process appears to be over-all irreversible, that the proton evolution in the electrode process proper affects the half-wave potential, *e.g.*, that the proton abstraction in scheme [1b] precedes the electron uptake. The participation of the electrode surface, proposed by Manoušek and Volke (9) as an antecedent step, cannot be excluded in the proton abstraction step.

Further support for the validity of scheme [1] can be found in the shape of the plot of half-wave potentials as a function of pH. It has been shown recently (22) that a plot consisting of three linear sections as observed in Fig. 5 (with two pH independent sections at the lowest and highest pH values and a linear pH dependent section in the intermediate pH range) corresponds only to systems involving the transfer of one proton or hydroxide ion prior to the electron uptake. Mechanisms which involve two proton transfers (*e.g.*, H^+,H^+,e,e or H^+,e,H^+,e) show plots with four linear sections (with intersections corresponding to the two pK values involved).

In analogy with systems involving antecedent proton transfer and reduction of the conjugate acid (22), it is possible to derive equations for half-wave potentials of systems involving antecedent reaction with hydroxide ions and oxidation of the conjugate base

$$E_{1/2} = E° - \frac{RT}{\beta n_b \mathbf{F}} \ln 0.886\, k_e° \, (t/D)^{1/2} - \frac{RT}{\beta n_b \mathbf{F}} \ln \frac{K}{K + [H^+]} \quad [4]$$

where $K = K_1 K_w$ and other symbols have the usual meaning. For $[H^+] >> K$ then

$$E_{1/2} = E° - \frac{RT}{\beta n_b \mathbf{F}} \ln 0.886\, k_e° \, (t/D)^{1/2} - \frac{RT}{\beta n_b \mathbf{F}} \ln \frac{K}{[H^+]} \quad [5b]$$

or

$$E_{1/2} = \text{const.} + \frac{RT}{\beta n_b \mathbf{F}} (pK - pH) \quad [5b]$$

Similarly at $[H^+] << K$

$$E_{1/2} = \text{const.} = E° - \frac{RT}{\beta n_b \mathbf{F}} \ln 0.886\, k_e° \, (t/D)^{1/2} \quad [6]$$

Finally, in the pH region where the height of the limiting current decreases with decreasing pH (*i.e.*, at sufficiently low pH values) expression [7] applies

$$E_{1/2} = E° - \frac{RT}{\beta n_b \mathbf{F}} \ln \frac{k_e°}{(k_1 D)^{1/2}} \quad [7]$$

where k_1 corresponds to the rate of the addition of the hydroxide ion. Equations [6] and [7] correspond to the pH region where the half-wave potentials are pH independent at low (Eq. [7]) and at high (Eq. [6]) pH values. Equation [5] describes the shift of the half-wave potential in the intermediate pH range. The pH^* values at which right-hand sides of Eq. [7] and [5] are equal corresponds to the value of pK' (*i.e.*, to the pH where $i = i_d/2$). Experimentally found pH^* values were in agreement with pK' values (Table III) for those few compounds for which the value of pH^* was experimentally accessible.

The pH values at which the right-hand sides of Eq. [5] and [6] are equal correspond to the pK value of the antecedent acid-base equilibrium, independent of the characteristics of the electrode, the diffusion coefficient, and the value of $k_e°$.

A comparison of the $pK_{E_{1/2}}$ values obtained from the $E_{1/2}$-pH plots with those values obtained spectrophotometrically (pK_{spec}) (Table V and Fig. 5) shows a small difference for the unsubstituted compound, the para-methyl and para-methoxy benzaldehyde, but larger differences for other substituted aldehydes. This can be attributed to the difference in the value of the equilibrium constant in the bulk of the solution and in the electric field of the electrode.

Further evidence in support of scheme [1] is the comparison with homogeneous oxidations. The geminal diol anion, proposed in scheme [1] as the oxidizable species, was considered (23, 24) as a reactive intermediate in manganate and permanganate oxidations of benzaldehydes in alkaline media, as well as of furfural at pH 11.5-13.5 by permanganate (25). The oxidation of strongly hydrated aliphatic aldehydes, like fluoral or chloral, is assumed at $pH > 6$ also to take place via the geminal diol anion (26, 27).

Moreover, as the oxidations are similarly strongly affected by electron withdrawing groups, the chemical

homogeneous oxidation in alkaline solutions shows a large value of Hammett reaction constant (23, 24) (ρ = 1.83 at pH 12.6). Furthermore, the participation of phosphate and carbonate buffers observed for electro-oxidation has been found (24) also for permanganate oxidation.

Furthermore, addition of a free electron pair of a negatively charged oxygen to the carbonyl double bond in scheme [1] is analogous to the addition of the oxygen of a chromate ion (28, 29) and the proposed intermediate in the chromate oxidation is a derivative of a geminal diol. Moreover, both in scheme [1] and in the chromate oxidation the carbon-hydrogen bond cleavage occurs in the rate-determining step. Position of the hydration equilibria for benzaldehydes has been used also as an argument in the interpretation of substituent effects on chromate oxidation of substituted benzaldehydes (30).

Finally, the oxidation of aldehydes by hydrogen peroxide in alkaline media was interpreted as involving the attack of hydrogen peroxide on geminal diol anion (31).

Solution phenomena.—Deviations of current from the theoretical dissociation curves observed in phosphate and carbonate buffers and the decrease of current with increasing buffer concentration indicate that these buffer components react with aldehydes to produce electroinactive compounds. The possibility of addition of phosphate or carbonate anions cannot be excluded and will be studied in more detail. Sensitivity toward the effect of phosphates increases with the increasing electropositivity of the substituent on benzaldehyde (Fig. 4), *i.e.*, the deviations are greater for p-methyl than for p-chlorobenzaldehyde. For these reasons only the currents measured in sodium hydroxide solutions were taken into consideration for the calculations of the rate constants.

Similarly, currents in sodium hydroxide solutions more concentrated than 4.0M were not considered in finding the best value of the diffusion current (i_d). Since deviations from $i\eta^{1/2}$ = constant in such solutions showed a similar trend for all aldehydes studied, interaction of anions formed with the excess of sodium ions, *e.g.*, to form ion pairs, seems less probable. Changes in the activity of water and changes in the structure of the solvent as well as the structure-breaking properties of concentrated sodium hydroxide solutions can affect the validity of the Stokes-Einstein relation on which the equation $i\eta^{1/2}$ = constant is based.

Rate constants.—To calculate rate constants of reaction [1a] from measurements of polarographic currents, the equation for i/i_d (Table IV) is transformed to Eq. [8]

$$\log k_1 = pK - 2pK' + pK_w - \log t_1 - 2 \log 1.15$$
$$= pK_1 - 2pK' - \log t_1 - 2 \log 1.15 \qquad [8]$$

where pK_1 is the value for the equilibrium constant of reaction [1a] expressed as

$$K_1 = [ArCH(OH)O^-] [H^+]/[ArCHO]$$

and t_1 is the drop time. Hence to calculate the rate constant k_1, it is necessary to determine the polarographic dissociation constant pK' which is defined as pH = pK' for i/i_d = 0.5 (*i.e.*, inflection points of curves in Fig. 4a or the pH value at which the logarithm term in Fig. 4b becomes equal to zero).

Values of pK' based on measurements with d-c and differential pulse techniques at t_1 = 2 sec are summarized in Table III. When the comparison was restricted to those values of pK' obtained in solutions of sodium hydroxide, a linear correlation with the Hammett substituent constants σ_X was found with a reaction constant ρ = 1.87 (r = 0.995).

The calculation of the value of k_1 for the rate constant of the addition of hydroxide ions to benzaldehydes by means of Eq. [8] can be carried out in two ways: either the pK' value is used in combination with the spectrophotometrically determined value of pK_{spec} or with the polarographically determined value of $pK_{E1/2}$, obtained from the $E_{1/2}$-pH plot. When data are restricted to those obtained in sodium hydroxide solutions, both sets of rate constants (log k_1) are a linear function of substituent constants σ_X. The values of the reaction constants ρ are nevertheless different (ρ = 0.95 when pK_{spec} values are used and ρ = 2.94 using $pK_{E1/2}$ values). Values of k_1 calculated from current measurements in phosphate or carbonate buffers show no correlation with substituent constant σ_X.

From the value of k_1 and the measured value of pK it was possible to calculate the value of the rate constant k_{-1} for the reverse reaction by means of Eq. [9]

$$\log k_{-1} = \log k_1 + \log K_w + pK \qquad [9]$$

Similarly as in the previous case, either $pK_{E1/2}$ or pK_{spec} values can be used in the computation of the values of k_{-1} by means of Eq. [9]. The values of log k_{-1} obtained in both cases were a linear function of Hammett substituent constants σ_X, but according to the choice of $pK_{E1/2}$ or pK_{spec} in connection with Eq. [9] the values of log k_{-1} show either a positive or a negative value of the reaction constant, ρ.

Calculation of the rate constant of the addition reaction k_1 can also be carried out by an independent procedure. As has been shown (22), it is possible to use the difference ($\Delta E_{1/2}$) between the values of the half-wave potentials in the two pH regions, where the half-wave potentials are pH independent and follow Eq. [6] and [7], by means of Eq. [10]

$$\Delta E_{1/2} = \frac{RT}{\beta n_b \mathbf{F}} \ln 0.886\ (k_1 t_1)^{1/2} \qquad [10]$$

The values obtained for those compounds where experimental data could have been obtained at low enough pH values, where the half-wave potentials become pH independent are presented in Table V.

The positive value of the reaction constant ρ found for the addition of hydroxide ions to benzaldehydes for values of k_1 obtained using pK_{spec} or $pK_{E1/2}$, which indicates an increase in reactivity with increasing electronegativity of the substituent, is in agreement with the prediction made by Hammett (32) for reactions involving a nucleophilic attack.

Absence of a precedent makes it impossible to predict the sign of the reaction constant ρ for the reverse reaction with rate constant k_{-1}. Hence it is impossible to deduce whether the use of K_{spec} or $K_{E1/2}$ leads to a more reliable value for k_{-1}. This choice between the use of the two equilibrium constants can be made only after some of the values for k_1 or k_{-1} are determined by independent, *e.g.*, relaxation, techniques.

Sensitivity to substituent effects.—Sensitivity of individual quantities characterizing the acid-base and electrochemical properties of benzaldehydes are expressed by the values of the individual reaction constants, ρ (Table VI).

The susceptibility of half-wave potentials of the oxidation of benzaldehydes to substituent effects, expressed by the negative value of the reaction constant ρ_π (Table VI), is similar to that observed for the majority of reductions (33), which also show negative values of the reaction constant ρ_π. Thus the introduction of a substituent, *e.g.*, a p-cyano group, which makes the reduction of the aldehydic group easier (*i.e.*, causes a potential shift to more positive values) results also in a more facile oxidation (*i.e.*, causes a shift to more negative potentials). Nevertheless, an opposite effect, shown by a positive value of the reaction constant ρ_π, would be expected for oxidations where the electron transfer was potential determining, as reported for oxidations of alcohols, phenols, or hydrazines (33). It is thus possible to assume that hydrogen abstraction is potential determining in reaction [1b], similarly as in homogeneous oxidations (28, 29).

Table VI. Summary of the values of reaction constants and corresponding correlation coefficients for various Hammett relationships

Constant (*vs.* σ)	No. of aldehydes studied n	Reaction constant ρ	Correlation coefficient r
pK_{spec}	15	2.76	0.994
$pK_{E_{1/2}}$	7	0.74	0.957
pK'	8	1.42	0.976
$\log k_1$ (using pK_{spec})	5[a]	0.95	0.964
(using $pK_{E_{1/2}}$)	7[a]	2.94	0.995
$\log k_{-1}$ (using pK_{spec}	5[a]	−1.82	+0.972
(using $pK_{E_{1/2}}$)	7[a]	2.50	0.936
$(E_{1/2}{}^{X} - E_{1/2}{}^{H})$	n	$\rho\pi$	r
1.0M NaOH (Region A)	7	−0.225V	+0.994
2.0M NaOH (Region A)	7	−0.218V	+0.970
9.0M NaOH (Region B)	7	−0.122V	+0.954

[a] Values restricted to data obtained in sodium hydroxide solutions only.

The difference between the value of the $\rho\pi^A$ observed in the pH range where half-wave potentials are pH dependent and the value of $\rho\pi^B$ found at such high sodium hydroxide concentrations ($[OH^-] >> K_1$) that it was pH independent, is due to the fact that $\rho\pi^A$ involves the dependence of the acid-base equilibrium constants pK on structure (as expressed by the reaction constant ρ). Relationship [11] will be derived and discussed in some detail elsewhere (34)

$$\rho\pi^A = \rho\pi^B - \frac{RT}{\beta n_b \mathbf{F}} \rho \qquad [11]$$

Conclusions

The source of the second oxygen atom in the electrooxidation of benzaldehydes to yield benzoic acid, which was a source of some confusion and uncertainty (3, 4, 7, 9) has been proved to be the hydroxide ion. The addition of hydroxide ion takes place in a reaction preceding the electrode process proper.

Such a mechanism would make oxidations of benzaldehydes in nonaqueous media by this mechanism impossible. The effects of organic solvents on the values of acidity functions J_- are currently being studied to make an extension of the study of oxidations to these media possible.

The principle of allowing only the smallest structural change in the course of an electrode process would indicate that the dianion $ArCH(O)_2{}^{2-}$ rather than the anion $ArCH(OH)O^-$ would be the electroactive form. The oxidation of the monoanion namely involves a dissociation of the benzoic acid following the electron transfer process. Furthermore, it has been suggested (35) that dianions of the type $ArCH(O_2)^{2-}$ are reactive in some homogeneous reactions of aldehydes. Nevertheless, the shape of the pH dependence of the limiting current strongly indicates that it is the monoanion $ArCH(OH)O^-$ which is the electroactive form. This is supported by the shape of the $E_{1/2}$-pH plots.

Such oxidation processes should not be restricted to benzaldehydes. Extension to heterocyclic aldehydes and anions of strongly hydrated aldehydes and ketones is under study. The assumption that the acid-base process is a volume reaction will be verified by comparison with rate constants of the addition reaction studied by stop-flow and relaxation techniques.

It is rather satisfying that the proposed mechanism is in accordance with mechanisms (23-31) suggested for homogeneous chemical oxidation of benzaldehydes by oxidizing reagents like chromic acid, permanganate, or hydrogen peroxide. It is a further contribution to the observation that chemical and electrochemical reactions under conditions where adsorption is not predominant follow a similar pattern.

Low Temperature Studies of Electrochemical Kinetics

I. Cyclic Voltammetry of Diethyl Fumarate

Roman D. Grypa*,[1] **and J. T. Maloy****

Department of Chemistry, West Virginia University, Morgantown, West Virginia 26506

ABSTRACT

Descriptive, low temperature, cyclic voltammetry studies have been conducted upon diethyl fumarate (DEF) in dimethylformamide (DMF). Temperature variations down to 200°K reveal three, interrelated, reduction processes. The first and second correspond to the formation of $\overline{DEF}$ and $DEF^{=}$; the third is attributed to the reduction of a dimeric product of the initial reduction. Temperature reduction inhibits the formation of this dimeric product while enhancing the availability of $\overline{DEF}$ for reduction to $DEF^{=}$ The extensive formation of $DEF^{=}$ at reduced temperatures appears to be accompanied by a filming of the electrode surface. This suggests that polymerization may proceed through $DEF^{=}$ and may actually be inhibited by the dimerization process. The addition of water enhances the third reduction peak; it also decreases the available cathodic potential range so that this peak becomes lost in background at room temperature. Temperature reduction increases the available potential range so that products of the water-accelerated electrohydrodimerization reaction may be studied.

The electrohydrodimerization (EHD) reactions of 1,2-diactivated olefins have been studied by many investigators. These EHD reactions are of synthetic interest because they are generally regarded as the first step in the formation of the "living" polymer (1). Recent studies (2-4) have also indicated that these reactions may also be used to electroinitiate certain cyclizations.

The olefins used in these studies are of the form

$$\begin{matrix} R_1 & & H \\ & C{=}C & \\ H & & R_2 \end{matrix}$$

where R_1 and R_2 are electron withdrawing groups; these compounds are easily reduced in aprotic media to form relatively stable radical anions.

Baizer and co-workers (1, 2) have carried out numerous studies on these EHD (or electrolytic reductive coupling) reactions on various diactivated olefins. From their voltammetric studies, they determined that the initial reduction of the olefin involved a one-electron transfer to form the radical anion of the parent olefins. Baizer also used macroelectrolysis (2) to find that these diactivated olefins could be used to form cyclic compounds after the dimer dianion was protonated to form the hydrodimer anion. The yields and distributions obtained were highly dependent on the reaction conditions employed.

Bard and co-workers have extensively investigated the possible mechanistic path of the EHD reaction of diethyl fumarate ($R_1 = R_2 = -CO_2Et$; hereafter designated DEF) using double potential-step chronoamperometry (5) and studies of different diactivated olefins at a rotating ring-disk electrode (6). Using working curves obtained through digital simulation, they investigated the path of the reaction and proposed that the EHD reaction of DEF proceeded by a second-order dimerization mechanism. This is contradictory to the results reported by Baizer *et al.* (1), where they presumed the probable mechanistic path to be a second-order electrochemical-chemical-electrochemical mechanism. Further experiments conducted by Bard and Puglisi (6) on different olefins indicated that the second-order dimerization mechanism can be applied to other olefins, so that it is not unique to DEF.

Saveant *et al.* (7) have carried out extensive studies on the EHD reaction of several olefins in nonaqueous solvents to study the kinetics involved in the electrochemical reduction using linear sweep voltammetry. Their results indicated that the dimerization (radical-radical coupling) of two radical anions occurred after an initial one-electron transfer. They measured the variation of the cathodic peak potential of the first reduction peak with respect to the scan rate, the bulk olefin concentration, and the amount of proton source added to these systems. From their observations of the variation of the cathodic peak potential with respect to the scan rate and bulk olefin concentration, they determined that the reaction was not first order, but some type of "bimolecular reaction." The rate-determining step in the EHD reaction for diactivated olefins was determined to be the radical coupling of the two radical anions. This conclusion was similar to the one reached by Bard.

Recent investigations by Klemm *et al.* (3, 4) on the electroreduction of some α,β-unsaturated esters of cinnamic acid, substantiated Baizer's observation that the EHD reaction could be used to synthesize cyclic compounds. On the basis of product analysis, they have proposed that these isolated cyclic compounds were formed by a Dieckmann cyclization of the hydrodimer anion.

Voltammetric studies reported by Bard (5) also indicate that at room temperature DEF exhibits $i_p/v^{1/2}$ behavior characteristics of a dimerization mechanism (8). In his earlier voltammetric studies Baizer observed a marked increase in $i_p/v^{1/2}$ behavior for ethyl cinna-

mate (EC; above structure with $R_1 = -C_6H_5$ and $R_2 = -CO_2Et$) at slow scan rates. (It appears that the caption for Figure 2 in Ref. (1) is in error; from the associated text it appears that the current function decreases with increasing scan rates for EC.) Since this behavior is characteristic of a first-order electrochemical-chemical-electrochemical process, Baizer proposed that the dimerization of EC might be complicated by an additional (first-order) process leading to an electroactive product. No variation in scan rate brought about the resolution of these two competing processes purported to involve the radical anion of EC. The development of low temperature electrochemical techniques by Van Duyne and Reilley (9-11) appeared to offer a means by which these two competing homogeneous reactions could be resolved, provided that the activation energy associated with one of the processes was significantly different from that of the other. This work was initially undertaken, then, in an attempt to resolve the apparent mixed mechanism associated with EC, but not with DEF.

A detailed rate and mechanism study of the low temperature electrochemistry of EC is the subject of a future communication. Because the EHD reactions of DEF had been well studied at room temperature, DEF was selected as an ideal compound to use in the initial experiments extending low temperature techniques to the study of EHD reactions. Since recent interest has been focused on the products of the EHD reaction, these initial experiments were designed to study the complete voltammetry of the DEF system. Temperature reduction has been shown to extend the available background potential limits of the solvent supporting electrolyte system (9); therefore, this technique permits the observation of electrochemical activity at potentials unobtainable conventionally. The results of the cyclic voltammetry experiments employed to characterize the products of the reduction of DEF at a variety of experimental temperatures constitute the remainder of this work.

Experimental

Apparatus.—The electrochemical cell used for low temperature cyclic voltammetry (and subsequent double potential-step chronocoulometry) studies is shown in Fig. 1. The cell was designed with a planar 0.008 cm^2 platinum working electrode, a platinum foil counterelectrode, and a silver wire quasi-reference electrode (QRE). The counterelectrode was made from a rectangle of platinum foil which was wrapped around the outside of a fritted glass cylinder, and attached to a nickel-tungsten lead passing through a 10/30 standard taper inner joint with a detachable connector. The QRE sat in a glass tube which was connected to the cap of the electrochemical cell. Thus, both reference and working electrodes were separated by glass tubing to prevent them from coming into contact with each other or the counterelectrode in the course of any experiments.

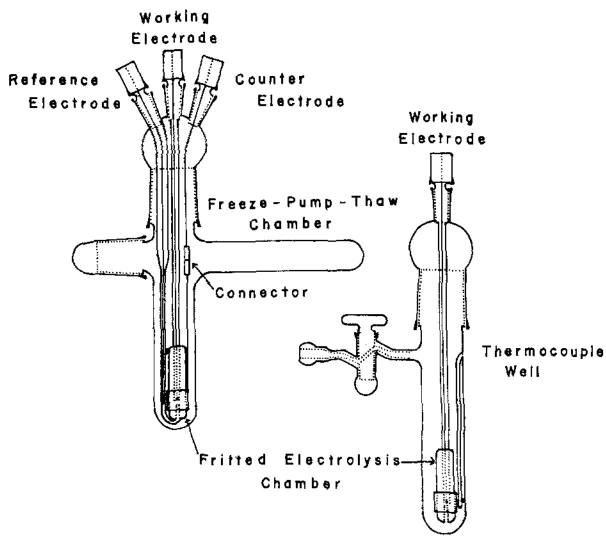

Fig. 1. Electrochemical cell

The cap of this electrochemical cell consisted of a 40/50 standard taper outer joint designed to hold all three electrodes. In addition, it supported the QRE compartment which in turn supported a fritted glass electrolysis compartment, used to separate the working and counterelectrodes. Sealed within this cap was the QRE compartment which was sealed to the base of the QRE joint. The tip of this tube was bent upward and sealed in the center of the bottom of the fritted glass electrolysis compartment in such a manner that the tip extended up into the compartment. The opening on this drawn tip had an inner diameter of 1 mm. When the cell was fully assembled, the distance between the drawn tip and the planar working electrode was approximately 2 mm. This distance was minimized to reduce the uncompensated resistance in the cell.

A double-walled cooling cryostat was constructed from Pyrex so that its inner wall extended above its outer wall to support a machined brass cap; the space between the walls of the cryostat was evacuated. A hole was drilled in the center of the cap to hold the cell firmly in the cryostat and the walls of this hole were lined with a rubber gasket to prevent any damage to the cell. Three smaller holes were drilled in the cap and fitted with copper tubing to serve as entrance and exit ports for the precooled nitrogen gas and thermocouple well.

A cooling system was constructed from a Matheson Gas Products No. 604 flowmeter, a 1900 mliter Dewar flask, a copper cooling coil, and the cooling cryostat. A 3 in. copper cooling coil was prepared from ¼ in. copper tubing. Nitrogen gas was passed from a needle valve through the flow meter into the copper cooling coil which was immersed in liquid nitrogen contained in the 1900 mliter Dewar flask. (Some experiments were conducted at higher than ambient temperatures; to achieve these temperatures, warm water was used instead of liquid nitrogen in this Dewar flask.) After leaving the cooling coil, the cooled nitrogen passed through a glass wool insulated column into the cooling cryostat. The temperature was regulated by adjusting the flow of the nitrogen gas through this system, and monitored by a copper-constantan thermocouple placed either in the cooling cryostat or in the cell.

Thermocouple voltages were amplified from the millivolt level with a noninverting operational amplifier (WC1741) equipped with a trimpot variable resistor so that an exact 1000-fold amplification could be achieved. A Systron Donner multimeter, Model 7050, was connected to the output of the circuit to provide the digital readout of temperature. The amplifier was calibrated with a Heath standard voltage source, Model EU-80A, to assure the linearity of the millivolt converter.

The Princeton Applied Research Model 170 Electrochemistry System was used in all electrochemical experiments. A Perkin-Elmer, Model 137, infrared spectrometer and a Varian T-60 nuclear magnetic resonance spectrometer were used to obtain infrared and NMR spectra of the compounds used.

Reagents.—Highly purified chemicals were required for these electrochemical experiments; therefore, the solvent, supporting electrolyte, and compounds used in these studies were purified and stored carefully. Spectroquality N,N-dimethylformamide (DMF), used as the solvent, was obtained from Fisher Scientific Company, and was purified and stored by the method described by Huret and Maloy (12). Purity was determined through electrochemical experiments. Polarographic grade tetra-n-butyl ammonium iodide (TBAI), the supporting electrolyte, was supplied by Southwestern Analytical Chemicals, Inc. TBAI was

used as received and was stored in a desiccator over Drierite. Diethyl fumarate (DEF) was purchased from Aldrich Chemical Company. It was used as received (99+% pure) and was stored in a desiccator over Drierite. The purity was assured by infrared and NMR spectroscopy. Prepurified nitrogen and 99.995% pure helium were obtained from Air Products and Chemicals, Inc. Both were used as received. These two gases were used in the course of sample and cell preparations. Ordinary house nitrogen was used as the cooling gas and it was not purified because it never came in contact with the sample.

Procedure.—In a typical run, the cell was vacuum-dried and weighed so that concentrations could be determined gravimetrically; in all experiments 0.26-0.27M TBAI was used. After the supporting electrolyte had been dried in the cell, DMF was added to the evacuated cell from an air-tight storage flask under a slight positive pressure of helium. The resulting solution was subjected to five freeze-pump-thaw cycles to remove dissolved oxygen. Sample preparations were then carried out in a glove bag. A DEF solution of known concentration was prepared using the DMF-TBAI solution as the solvent, and an aliquot of this was injected into the remaining solution in the cell. In this manner, 1-5 mM DEF solutions were prepared. The cell was finally evacuated to $\sim 10^{-3}$ Torr, placed in the cryostat, and allowed to stand to permit the solution levels on either side of the fritted surface to equilibrate.

The rest potential of the solution was determined at each experimental temperature by a null balance technique. Positive feedback voltage compensation was used for resistance compensation in the cell. This was set at each current range setting used at every experimental temperature. Single scan and repetitive scan cyclic voltammetry (CV) experiments were performed at a variety of temperatures. After each CV experiment, the solution was allowed to equilibrate for a few minutes to reestablish initial conditions at the electrode.

Results and Discussion

Variable temperature CV experiments were run on all samples. Some especially interesting results were obtained when the entire potential range was scanned. Figure 2 illustrates a number of CV scans which were obtained for the DEF system at different temperatures and scan rates. It can be seen that three significant reduction processes may occur, depending on the scan rate and temperature. At 295°K, the first reduction peak occurred at −0.80V *vs.* Ag-QRE, in agreement with the potential reported by Bard (5); the other two principal reduction peaks occurred at −1.68 and −1.90V *vs.* Ag-QRE, respectively. (A fourth peak may just be detected at potentials slightly positive of the second principal peak at higher temperatures. The height of this peak relative to the first principal peak does not appear to change with changing temperature over the range in which it may be detected; at lower temperatures, however, the second principal peak becomes larger so that this minor peak could not be detected even if the species responsible for it was present in the vicinity of the electrode. This peak has been tentatively assigned to an impurity present in the DEF or a product of the DEF reduction that it is not affected by temperature changes. Because its role in the low temperature electrochemistry of DEF has been judged to be minor, this peak is not discussed further herein.) A decrease in the experimental temperature to 203°K, shifted the first reduction peak to −1.04V *vs.* Ag-QRE and the second reduction peak to −1.90V *vs.* Ag-QRE; the third reduction peak was completely eliminated. These absolute potentials are not too significant because only a silver wire was used as the reference electrode, and no attempt was made to thermostat the reference electrode at room temperature. However, in all of these samples, the first peak corresponds to the well-established, one-electron reduction of the parent olefin R, to form the olefin anion radical

$$R + e^- \rightarrow R^{\overline{\cdot}}$$

The dependence on scan rate and temperature on the formation of the second and third reduction peak is also evident in this figure. At room temperature, a decrease in the scan rate decreases the formation of the product of the second reduction wave and enhances the formation of the third reducible species. A decrease in the experimental temperature enhances the formation of the product of the second reduction wave and decreases the formation of the third reducible species; the species responsible for the third reduction wave apparently disappears at very low temperatures; simultaneously the second reduction wave becomes almost as large as the first wave.

The presence of the third reduction wave only at temperatures where the dimerization rate is rapid

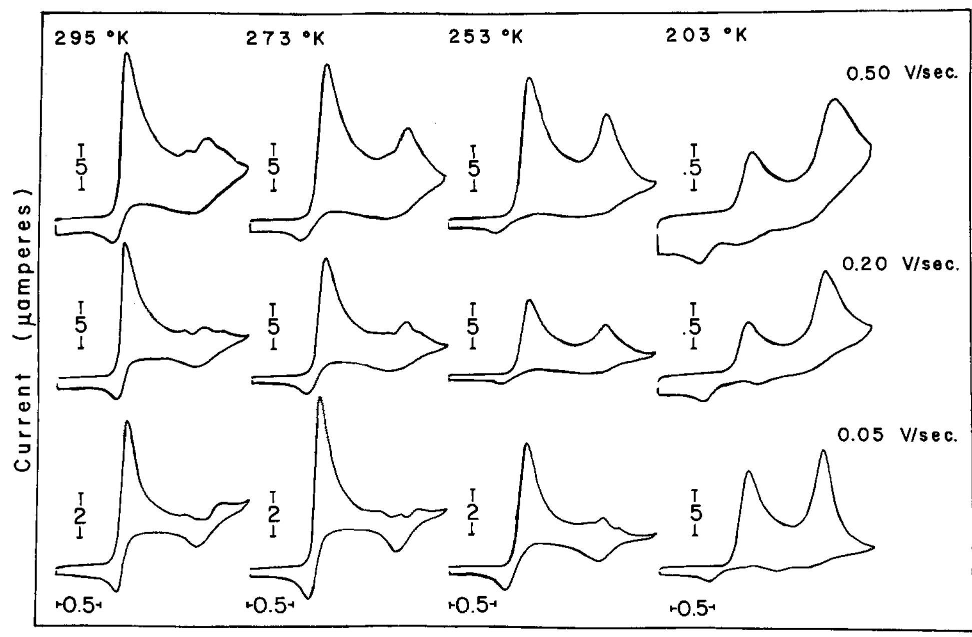

Fig. 2. Complete potential scan cyclic voltammograms for DEF at various temperatures and scan rates. The solution was 3.84 mM in DEF.

seems to indicate that this is due to the reduction of an electroactive product of the dimer dianion, possibly the hydrodimer anion, R_2H^-, such as the one proposed by Baizer (2) or the cyclic compound 2,3,4-tricarboethoxycyclopentane-1-one (C) in a manner similar to that recently suggested by Klemm and Olson (4) through the proposed mechanism

$$R_2^{=} + H^+ \rightarrow R_2H^-$$

$$R_2H^- \rightarrow C + OEt^-$$

However, lowering of the experimental temperature decreases the dimerization rate and stops the formation of this third reducible species. This permits sufficient radical anion, $R\overline{\cdot}$, to populate the diffusion layer to be further reduced to the dianion, $R^{=}$, which is shown by the second reduction wave; that is

$$R\overline{\cdot} + e^- \rightarrow R^{=}$$

This may occur extensively only at reduced temperatures.

Table I shows the dependence of the three reduction processes on the scan rate and temperature for the DEF system. A comparison between the cathodic and anodic peak current heights for the first reduction wave reveals that the peak current ratios which are obtained upon a complete potential scan are different than those obtained when a potential scan is run just past the first reduction peak. The fraction of radical anion which dimerizes to form the cyclic product may be estimated from the value $1 - (i_{pa1}/i_{pc1})$ provided that these peak current ratios are obtained from a potential scan just past the first reduction wave. It may be noted that as the scan rate is increased or the temperature is lowered, the amount of radical anion undergoing dimerization decreases. This is accompanied by a simultaneous increase in the second reduction wave and a decrease in the third reduction wave. The peak current ratios obtained from a complete potential scan indicate that the radical anions formed in the reduction are precursors of the other reducible species. The i_{pa1}/i_{pc1} ratios are considerably less for the complete potential scan than they are for the potential scan just past the first reduction wave. When the potential is scanned just past the first reduction wave, a decrease in the temperature increases the i_{pa1}/i_{pc1} ratio toward a maximum value of 1.0. The rate of reaction governing the disappearance of the radical anion is sufficiently reduced to allow the radical anion to be oxidized back to the parent olefin. However, when a complete potential scan is run, this regular increase is not observed. The third reduction process does not occur at low temperatures, but the products of the second reduction do not undergo oxidation on the reverse scan. This loss of radical anion at low temperature scans through the second reduction process indicates that this process is probably due to the reduction of the radical anion to the dianion; since the dianion (or products formed from it) does not undergo oxidation back to the radical anion, this low temperature reduction removes the otherwise stable radical anion from the diffusion layer.

At high temperatures and slow scan rates, when the amount of dimerization is extensive, the i_{pc2}/i_{pc1} ratio is small. As the extent of dimerization decreases, the i_{pc2}/i_{pc1} ratio increases and the i_{pc3}/i_{pc1} ratio decreases. This occurs when the scan rate is increased or the temperature is lowered. These observations support these contentions: (*i*) a product of the dimerization reaction is responsible for the third reduction wave, and (*ii*) when the amount of dimerization is extensive, very little radical anion remains in the diffusion layer to be further reduced to the dianion. If this analysis is correct, $(i_{pc3}/i_{pc1})/(1 - (i_{pa1}/i_{pc1}))$ should be an approximate measure of the concentration of the species reduced in the third reduction process relative to the concentration of radical anion available from the first reduction for its formation. [This suggestion is valid only if the peak-to-peak time (t_c) for the cyclic voltammetry just past the first reduction wave is similar to the peak-to-peak time (t_c') in the linear sweep voltammetry between the first and third peaks. These times are shown in Table I. At large values of t_c, $d(i_{pa1}/i_{pc1})/dt_c$ is *ca.* -0.002 sec^{-1}; thus, a 5 sec difference between t_c and t_c' represents an error of $\sim$0.01 in the estimation of i_{pa1}/i_{pc1} in the long time linear sweep voltammetry experiment. Similarly, when t_c is

small, $d(i_{pa1}/i_{pc1})/dt_c$ is *ca.* -0.01 sec^{-1}. Typical differences between t_c and t_c' indicate that the error in estimating i_{pa1}/i_{pc1} in the linear sweep voltammetry experiment never exceeds 0.02 through this approximation.] At high temperatures and slow scan rates, even when no current is detected for the second reduction process, the ratio in the last column of Table I never exceeds 0.5. This, of course, would be expected if the third reduction wave is attributed to the one-electron reduction of a dimeric product of the electrogenerated radical anion.

It also appears that the loss of the third peak at low temperatures is accompanied by the loss of the reversible oxidation of the radical anion and the possible formation of a film on the electrode surface. Figure 3 shows repetitive CV scans to a potential just past the first reduction peak superimposed on those run on a complete potential scan. If a potential scan is carried out to a potential which is just past the first reduction process and repetitive CV scans are run, the difference between the cathodic peak current on the first scan and that of the second scan is very small compared to the difference which is observed when a complete CV scan is run in the repetitive mode for the same system. A decrease in the experimental temperature clearly enhances this effect and apparently results in the deposition of a slowly dissolving species on the electrode surface. In the absence of exhaustive electrolysis experiments aimed at product determination, it is unknown whether this species is a saturated hydrocarbon formed by the protonation of the monomer dianion or whether a polymer is being formed.

In Table II evidence is presented that dianion formation results in extensive deposition of product on the electrode surface. This table shows the effect of repeated CV scans on the height of the first cathodic wave. The first column gives the ratio of the first cathodic peak on the second scan i_{pc1}', to that on the first scan, i_{pc1} when the potential scan is carried out just past the first reduction peak. A decrease in temperature results in an increase in this ratio. In the second column, the same ratio is shown for a scan past the peak potential for dianion formation. This decreases with decreasing temperature. At any temperature or scan rate this ratio is reduced when dianion formation occurs. This is illustrated in the third column where the relative change in peak ratio due to dianion formation is given. This effect could be caused either by the depletion of the parent olefin because of the chemical irreversibility of dianion formation, or the deposition of a product of the dianion on the electrode surface. The latter is a distinct possibility; at low temperatures, the initial peak current is not restored when the solution is stirred. Only extensive standing results in the restoration of the initial first wave peak current. This observation would be expected if the formation of the dianion resulted in a slowly dissolving product film on the electrode surface. [This behavior is also illustrated in the full scan cyclic voltammogram at 203°K in Fig. 3. This was obtained after a preliminary potential excursion had resulted in the second process. Even though several minutes had passed between the preliminary voltammogram and the one shown in Fig. 3, the initial current peak was still not restored to the value obtained in the short scan voltammogram. This same effect probably accounts for some of the difficulty encountered in obtaining meaningful peak current ratios at low temperatures. In at least one instance (*cf.* Table I), it is assumed that prior-run filming decreased the magnitude of i_{pc1} relative to that of i_{pc2} so that the ratio of the latter to the former exceeded 1.0. This behavior was observed only at low temperatures when short (*ca.* 5 min) time intervals passed between successive runs.]

Single CV scans just past the first reduction process were also run on this system. In general, an increasing peak separation between i_{pc1} and i_{pa1} was observed as the temperature was lowered. The magnitude of the peak separation (ΔE_p) is shown in Table III in units of RT/F. Increasing peak separation with temperature reduction is to be expected if the reduction of the parent olefin proceeds by a quasi-reversible electron transfer (9). This could also be attributed to

increased cell resistance at lower temperatures; however, "full" iR compensation was employed in all voltammetry experiments at every temperature, and uncompensated iR has been judged to be only a secondary cause of this effect. (One reviewer has suggested that incomplete iR compensation may be the primary cause of the increase in ΔE_p at reduced temperatures and has reported some difficulties in achieving complete compensation with cells employing a QRE in his own laboratory. This is also a distinct possibility in the work reported herein.) The results in Table III also show the dependence of i_{pc1} upon scan rate. At fixed temperature, an increase in scan rate, v, increases i_{pc1} but generally results in a decrease in the $(i_{pc1}/C)(T/v)^{1/2}$ ratio, although this decrease was not found to be strictly monotonic with increasing scan rate (*cf.* representative data in Table III). A decrease of 15-18% in this ratio at constant temperature has been cited as a diagnostic criterion for a dimerization mechanism (7, 13), and this range is typical of the maximum amount of decrease observed with this system. Since the peak ratios in Table III have been temperature-normalized, the differences observed at different temperatures reflect the variation in the diffusion coefficient of DEF with decreasing temperature.

The addition of water to the DMF measurably decreases the usable potential range. At room temperature, water breakdown occurs near the potential where the third reduction process occurs. However, a decrease in temperature sufficiently displaces the breakdown of water to a more negative potential to allow the observation of the third reduction peak.

Water was added to the DMF to determine the effect of a proton source on the reduction of DEF. Figure 4 shows a series of CV scans run in DMF-H_2O over a variety of temperatures. Superimposed on these are CV run in anhydrous DMF. The addition of water increases the relative height of the third reduction peak; this indicates that the formation of the dimeric product is enhanced by the addition of a proton source. The differences between the cathodic peak currents for the first reduction wave in the DEF system in the presence and absence of water is probably due to extensive prior run filming of the electrode that occurs following the formation of the dianion in the presence of additional water. That the addition of water clearly enhances the formation of a dimeric product is shown by the increase of the $(i_{pc3}/i_{pc1})/(1-(i_{pa1}/i_{pc1}))$ ratio listed in the last column in Table I for the DMF-H_2O system compared to the anhydrous DMF system at similar scan rates; still, under no conditions is a value greater than 0.5 observed. However, as the experimental temperature is lowered, the extent of the third reduction process also decreases, while the relative height of the second reduction wave increases. This implies that even though water addition decreases the available potential range, the over-all rate of dimerization may be substantially increased through the addition of the proton source; the reduction of temperature allows the products of the dimerization to be observed before the dimerization reaction is stopped.

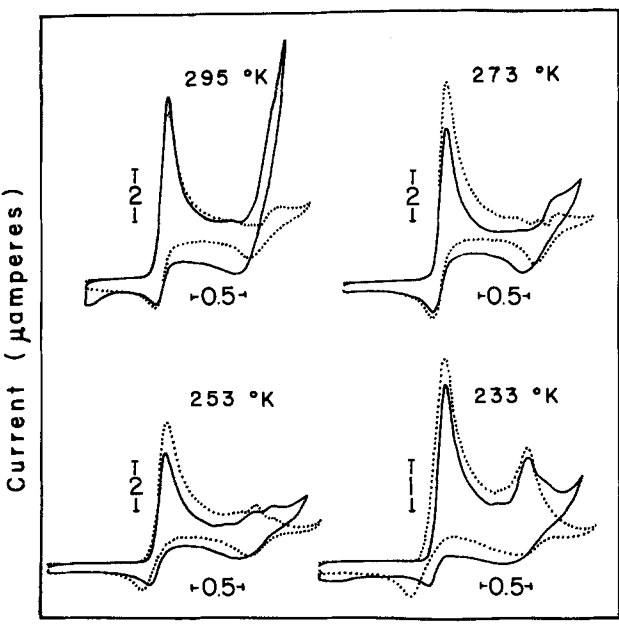

Fig. 4. Effect of water addition on the cyclic voltammetry of DEF. The same DEF solution was used throughout, but different scan rates were employed at different temperatures. ———, Solution contained 53 mM water; . . . . ., anhydrous solution.

The dependence of i_{pc1} on scan rate is similar to that of DEF in anhydrous DMF as shown in Table III. Water addition also decreases the peak separation between the cathodic and anodic peak currents for the first reduction wave.

Conclusion

This work has shown the feasibility of temperature reduction in the study of processes involved in the EHD reactions of DEF. Temperature and scan rate variations have clearly indicated that the formation of the dimeric species inhibits the formation of the DEF dianion. When the dianion is formed, extensive deposition of a product formed from the dianion seems to occur on the electrode surface. If this product film is a polymeric form of DEF, then it would seem that the dimerization reaction, once regarded as the first step in the formation of the polymer, actually inhibits polymerization. This could mean that the product distribution in a bulk electrolysis is temperature dependent; at high temperatures, one would expect extensive dimer formation, while at lower temperatures the formation of a polymer may be anticipated. Variable temperature bulk electrolysis studies are presently being initiated to investigate the temperature dependence of product distribution.

The addition of water increases the rate of the EHD reaction of DEF. It appears that other slow EHD reactions in the absence of water could be forced to react rapidly by water addition. Temperature reduction may significantly retard the rate of proton reduction so that the cathodic background current for these systems may be displaced toward negative potentials at lower temperatures. Evidence presented above indicates that the cathodic range in the presence of water is easily extended by temperature reduction. Thus, water-accelerated EHD reactions may be studied effectively at reduced temperatures. This seems especially important in the study of the product of the third reduction process and its role in subsequent reactions. Since the formation of the species responsible for this reduction is enhanced by water addition, temperature reduction may prove to be essential in the study of this species.

No evidence is presented herein that any observable change in DEF reaction mechanism occurs at reduced temperature. The hitherto proposed dimerization mechanism for DEF appears operative at all temperatures on the basis of the limited CV data presented. Thus, the DEF system should provide a good basis for comparison with the low temperature electrochemical behavior of the EC system. These comparisons will be made in the second paper in this series.

Technical Note

The Effect of Cathodic Treatment on Nickel Dissolution

B. MacDougall and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R9

In recent years, numerous workers have reported two (or more) current peaks associated with the anodic dissolution of nickel in aqueous solutions using both polarization and transient techniques (1-7). A variety of possible explanations have been put forward to account for the existence of more than one current peak for the $Ni \rightarrow Ni^{2+} + 2e$ reaction, but have not been fully substantiated. In the course of an investigation of nickel dissolution in neutral (8) and acid solutions, this multiplicity of current peaks for nickel dissolution was occasionally observed and prompted a study of the relationship between the anodic behavior of nickel and the state of the electrode surface before anodic polarization.

Figure 1(a and b) shows the effect of various cathodic treatments on the subsequent anodic potentiody-

* Electrochemical Society Active Member.

Key words: anodic dissolution, passivity, nickel oxide.

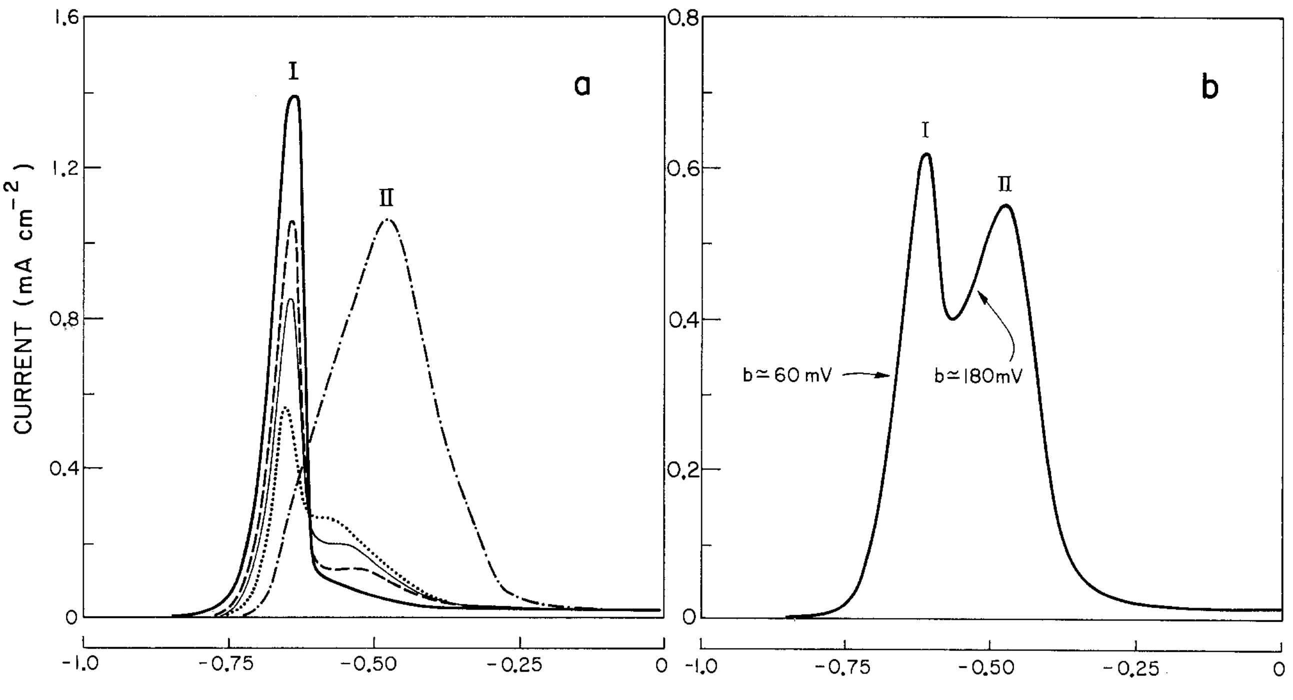

Fig. 1. a, Anodic potentiodynamic profiles at $S = 4$ mV/sec^{-1} on electropolished polycrystalline Ni electrodes in *p*H 3.0 Na_2SO_4 solutions after various cathodic treatments: a(———), 5 min at −1.0V with no N_2 bubbling (the same profile is obtained even after 2 hr of cathodic reduction); b(– – –), 5 min at −1.0V with light N_2 bubbling; c(———), 5 min at −1.0V with vigorous N_2 bubbling; d(. . . .), 10 min at −1.0V with vigorous N_2 bubbling; e(—·—), 1 hr at −1.0V with moderate N_2 bubbling. All potentials quoted in this paper are referred to the Hg_2SO_4 electrode (+0.665V with respect to the standard reversible hydrogen electrode). b, As in (a) above but after 20 min at −1.0V with vigorous N_2 bubbling.

namic sweep behavior of electropolished nickel [see Ref. (8)] in a 0.15*N* Na_2SO_4 (certified ACS)-H_2SO_4 solution of *p*H 3.0. Longer times of cathodic treatment in stirred acid solution or more rapid solution stirring at constant time increases the potential range over which nickel dissolves anodically and, as seen in Fig. 1b, another current peak (*i.e.*, II) is clearly resolved.[1] Figure 1a shows peak II growing from a slight shoulder on peak I in curve (a) to become the predominant peak in curve (e) with peak I now only a shoulder in this latter case. Analysis of the solutions for nickel showed that the charge under both anodic peaks is due to nickel dissolution. An increase in the time and bubbling rate during cathodic treatment shifts the potential of passive film formation to more anodic values with a corresponding increase in the area of peak II. In the absence of N_2 bubbling during the cathodic treatment, the anodic sweep profile displays only a very small peak II, as shown in Fig. 1a (curve a), and is found to be independent of the cathodic reduction potential (even up to $-1.6V$) and time of cathodic polarization. The increased activity of the electrode and growth of peak II is therefore not due to more complete reduction of the prior oxide on electropolished nickel [*cf.*, Ref. (8)].

[1] The appearance and size of peak II is, however, independent of solution stirring during the anodic sweep itself.

Reflection electron diffraction was used to investigate the state of a nickel single crystal surface after the various prior cathodic treatments which gave rise to the subsequent anodic profiles in Fig. 1a. Anodic sweep experiments on the Ni (111) after these cathodic treatments give results similar to those in Fig. 1a for polycrystalline nickel. Figure 2(a-d) shows the diffraction patterns from an electropolished nickel (111) electrode before and after cathodic reduction for 1 hr in a *p*H 3.0 Na_2SO_4 (certified ACS) solution with no N_2 bubbling. Cathodic reduction of electropolished nickel in this solution at $-1.0V$ leaves the surface oxide-free, and upon exposure to the air during transfer to the diffraction apparatus an oxide film forms which has the same diffraction characteristics as the film on electropolished nickel (8). This is also the case for cathodic reduction with light N_2 bubbling for short time periods ($<$ 15 min) or in the absence of N_2 bubbling for extended periods of time (*e.g.*, several hours). With more vigorous N_2 bubbling during the cathodic treatment, the resulting diffraction pattern depends

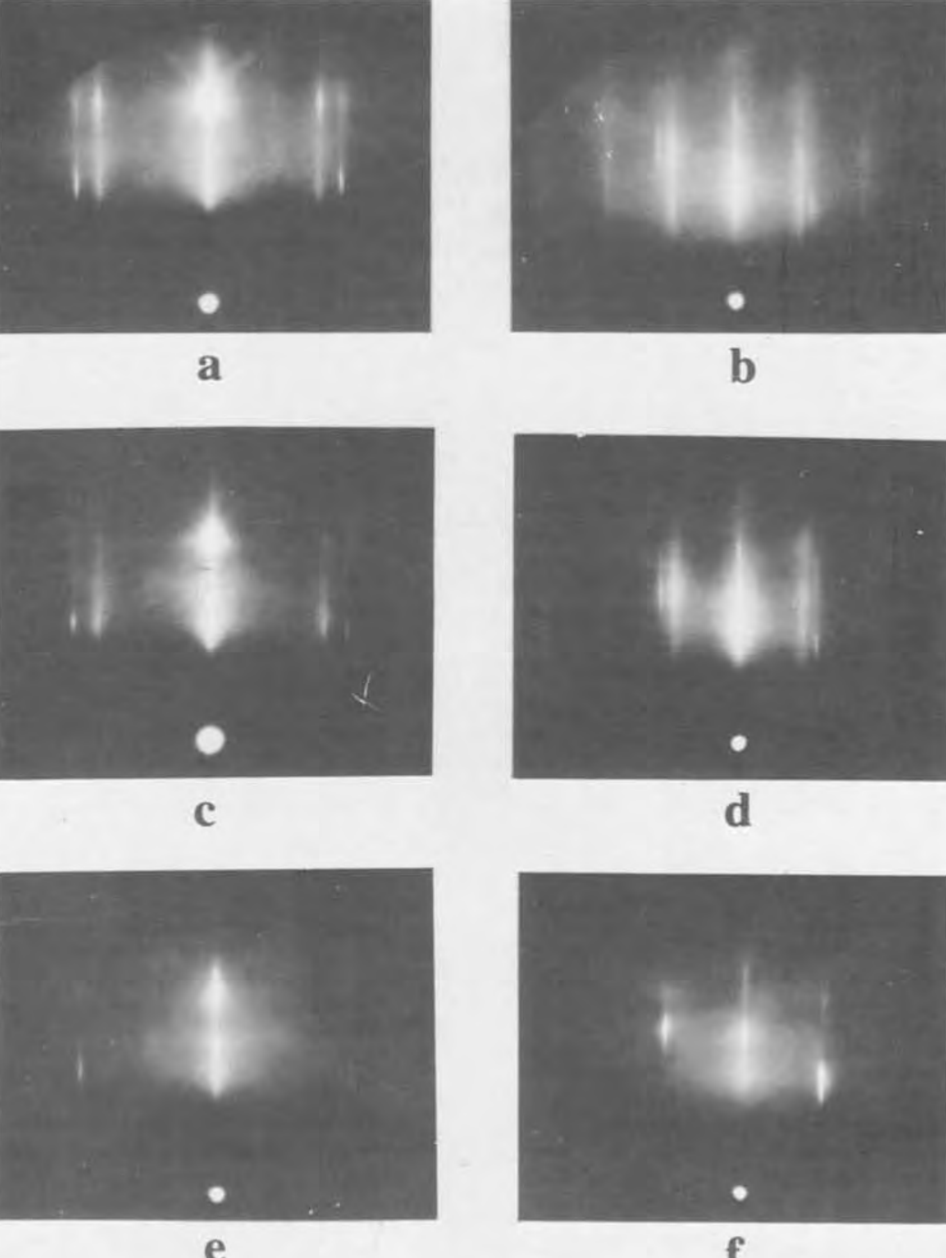

Fig. 2. Reflection electron diffraction patterns from a (111) nickel single crystal, in both the <112> and <110> directions, after various electrochemical treatments: (a and b), electropolished in H_2SO_4; (c and d), cathodic reduction in an unstirred *p*H 3.0 Na_2SO_4 solution at $-1.0V$ with the results being independent of time of polarization; (e and f), cathodic reduction in a vigorously stirred *p*H 3.0 Na_2SO_4 solution (certified ACS) at $-1.0V$ for 1 hr.

on the time but not on the cathodic polarization potential. The increased rate of N_2 bubbling in conjunction with long reduction periods results in a diminishing of intensity of the NiO reflections so that there is an almost complete loss of these reflections after *ca.* 1 hr of cathodic polarization with vigorous N_2 bubbling, as shown in Fig. 2(e and f).

The electron diffraction results in Fig. 2(e and f) indicate that there has been a substantial decrease in the amount of highly epitaxed NiO after cathodic reduction in rapidly stirred solutions and air exposure, and the possibility exists that the oxide has still formed on the surface but in an amorphous configuration. However, oxygen K_α, x-ray emission spectroscopy shows that the amount of surface oxide represented by the diffraction pattern of Fig. 2(e and f) was *ca.* 65% lower than that on electropolished nickel. It would therefore appear that both the nature and extent of peak II during the anodic sweep and the amount of oxide formed by air exposure after cathodic treatment are related to and controlled by the surface coverage of some impurity acting as a blocking agent. Indeed impurity adsorption from solution onto the oxide-free nickel surface is a diffusion controlled process which would be accelerated by N_2 bubbling during cathodic reduction, as is the case here. During a series of potentiodynamic sweeps on a contaminated nickel surface, the effects of the impurity diminish during each successive anodic sweep, *i.e.*, peak II diminishes and peak I becomes predominant, the impurity being removed as Ni dissolves. The time involved during the cathodic sweep at 4 mV/sec^{-1} (*ca.* 4 min for the range in Fig. 1a) is not sufficient to allow large amounts of impurity to diffuse from the solution to the surface again. Although it has previously been shown (9) that large amounts of impurities in the metal itself may extend the potential range of metal dissolution, the present problem is one of adsorption from solution on a high purity nickel metal.

Possible sources of impurity in solution would be the water, acid (H_2SO_4), or salt (Na_2SO_4). The water used in these experiments was prepared by distillation of distilled water from a Corning Still[2] which employs a quartz heating tube. The same results were obtained with water distilled from alkaline permanganate or passed through a series of ion and carbon exchange cartridges. When a pH 3.0 H_2SO_4 solution was used without any added Na_2SO_4 or a pH 3.0 $HClO_4$ solution with 0.15*N* $NaClO_4$ (ACS grade), cathodic reduction with vigorous N_2 bubbling even for several hours did not affect the oxide reflections on subsequent air-exposure. Impurities in the ACS grade Na_2SO_4 would thus appear to be responsible for contamination of the nickel electrodes. Indeed, electron diffraction showed that when ultrapure Na_2SO_4 was used there was no detectable diminishing of oxide reflections even after cathodic reduction for several hours with vigorous N_2 bubbling. Anodic sweeps in the ultrapure Na_2SO_4 solution, after a cathodic treatment which would have given a greatly enhanced peak II in certified ACS Na_2SO_4, instead gave an approximately 30% decrease in peak I but no corresponding increase in peak II, *i.e.*, the potential of passivation was not shifted. The diminishing of peak I in this case is probably associated with what one might call the "ordinary" solution impurity which adsorbs during long time reduction with vigorous N_2 bubbling, even in the pure solutions, and which acts as a surface blocking agent. This latter impurity does not prevent formation of either the highly epitaxed air-formed film on air exposure nor the passive film on nickel during anodic polarization and is therefore different from the more specific impurity in certified ACS Na_2SO_4. Cathodic reduction for shorter times ($\leq$ ½ hr) with N_2 bubbling in the ultrapure Na_2SO_4 solution results in a decrease of peak I of less than 5% and this treatment can therefore be used to produce uncontaminated starting surfaces.

[2] Corning Glass Works, Water Distillation Apparatus Model AG-2.

X-ray emission was used to analyze the various nickel surfaces and their films in an attempt to identify the impurity. No significant impurities were detected by the technique on any of the nickel surfaces. No sulfur was detected on either clean or contaminated surfaces (limit of detection is 0.005 $\mu g/cm^{-2}$) and the carbon content was $<$ 0.01 $\mu g/cm^{-2}$ (*i.e.*, close to the limit of detection) on all surfaces.

An anodic sweep such as that in Fig. 1b can be obtained with the certified ACS Na_2SO_4 where there is good separation between the two peaks, even after peak II has grown considerably. From this sweep profile the Tafel slope for nickel dissolution during peak I is *ca.* 60 mV, *i.e.*, nickel is dissolving from a film-free surface region. However, the Tafel slope of peak II is *ca.* 180 mV and this may be due to nickel dissolution through a barrier-layer film, *e.g.*, the impurity and/or oxide which has begun to grow. A true passive film forms at higher anodic potentials and nickel dissolution practically ceases. Replica electron microscopy of the nickel specimens after considerable nickel dissolution via peak II shows a general roughening of the surface but no pitting is detected. This shows that the specific impurity from the ACS Na_2SO_4 does not act like chloride ion to give localized corrosion and supports the view of nickel dissolution in peak II through a modified barrier-layer type film. This work indicates that the anodic polarization curve of clean nickel has a single sharp dissolution peak and that the extension of the potential range of active nickel dissolution with possible resolution of multiple peaks is probably due to adsorbed impurities.

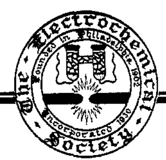
Brief Communication



Infrared Reflectance Spectra (IRRS) of Anodic Oxide Films on Pure Tantalum Formed in Phosphoric Acid

Tsutomu Takamura* and Hirochika Kihara-Morishita

Toshiba Research and Development Center, Tokyo Shibaura Electric Company, Limited, 1 Komukai-Toshiba-cho, Saiwai-ku, Kawasaki, 210 Japan

In previous work, we measured the IRRS of the anodic oxide film of Ta formed in dilute nitric acid and suggested that the growth of the oxide phases was dependent on the forming voltage and that the chemical structure of the film might be changed at around 100V (1). No nitrate anion was incorporated.

When, however, the anodic oxide film is formed in phosphoric acid, the incorporation of phosphorus atoms in the oxide film has been reported by several authors (2-4). Randall *et al.* showed that the content of phosphorus was dependent on both the phosphoric acid concentration of the electrolyte and the current density of anodization (2, 5).

If the amount of incorporated phosphate anion is not low, we can detect it by IRRS. One of the purposes of the present study is to determine the amount of phosphorus incorporated as functions of the forming voltage, the film thickness, and the phosphoric acid concentration of the electrolyte, which will be the aid of the analysis of the formation mechanism.

The authors' purpose is to ascertain the previous findings that both the growth rates of the oxide phases and the chemical structure of the film were dependent on the forming voltage or the film thickness irrespective of the electrolyte and the concentration of the solution.

A thin Ta rolled plate of 99.97% purity was polished chemically with a mixture of concentrated hydrofluoric acid, sulfuric acid, and nitric acid and anodized at a constant current density of 1.0 mA/cm^2 in various concentrations of phosphoric acid aqueous solution. When the voltage reached a desired value, the electrolysis circuit was turned off. The specimens were rinsed with distilled water carefully and dried at room temperature *in vacuo*. IRRS were recorded on a Nihon Bunko (JASCO) IR spectrophotometer in connection with equipment specially designed for the reflection measurement (1) in dried air with an incident angle of 45°. The number of reflections were six.

IRRS of the anodic oxide films on Ta obtained at various forming voltages are shown in Fig. 1. The anodic films gave rise to an intense and very broad absorption band in the region around 900 cm^{-1}, which, by a Gaussian band decomposition (6), could be resolved into three components as seen in Fig. 1. The three components, *i.e.*, 925, 860, and 800 cm^{-1} were always observed for all the oxides irrespective of electrolyte composition, but the 1110 cm^{-1} band was observed only with phosphate, phosphonate, or phosphinate present. In general, inorganic phosphate gives rise to a band due to ν PO_4 in the 1120-1080 cm^{-1} region (7, 8). Accordingly, the band at 1110 cm^{-1} will be assigned to be ν PO_4 of PO_4^{-3} group. Of the three bands in the 1000-750 cm^{-1} region, there are two possibilities of the assignment, *i.e.*, due to the deformation of Ta-OH bond or the stretching of Ta-O band. The former is not probable since no evidence of the presence of O-H group was found in the 3 μm region. On the other hand, the three bands were always observed with a number of Ta anodic oxide films formed in various electrolytes. Therefore, the three bands in the region were assigned to the stretching vibration mode of Ta-O bond. Of course, no band due to the Ta-O deformation mode is expected in these wave number regions (9).

Figure 2 shows how the optical density of each resolved band changes depending on forming voltage or film thickness of the film. As clearly seen in the figure, intensities of the two bands, *i.e.*, 925 and 800 cm^{-1} bands increase linearly with the increase of the anodization voltage, and accordingly, of the film thickness. The rates of their increase, however, change in the 70-90V region where the rates become slow, which were already seen on the anodic oxide formed in dilute nitric acid (1). The intensities of both bands were independent of the concentration of phosphoric acid.

Several causes may be considered for the explanation of these changes in the rates of intensity increase: (*i*) the change of the chemical structure of the film, (*ii*) the slowing down of the growth rates of the oxide phases in the film, (*iii*) the change of complex dielectric constant of the film due to the variation of strain

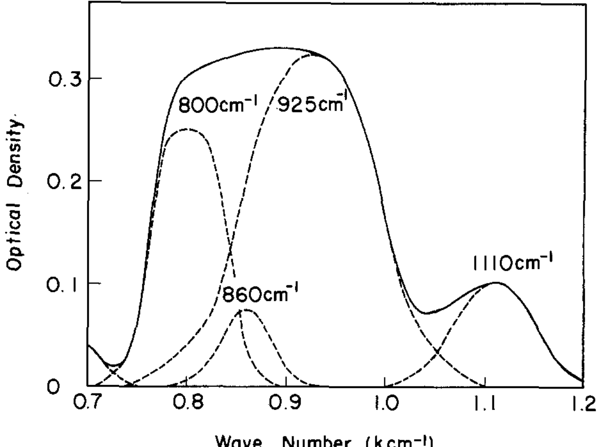


Fig. 1. IRRS and four component absorption bands appearing in the wave number region of 700-1200 cm^{-1} for the anodic oxide films formed on pure tantalum plate which were anodized at 1.0 mA/cm^2 to 300 V in 1.0 $\times$ $10^{-2}N$ H_3PO_4 aqueous solution at 20°C.

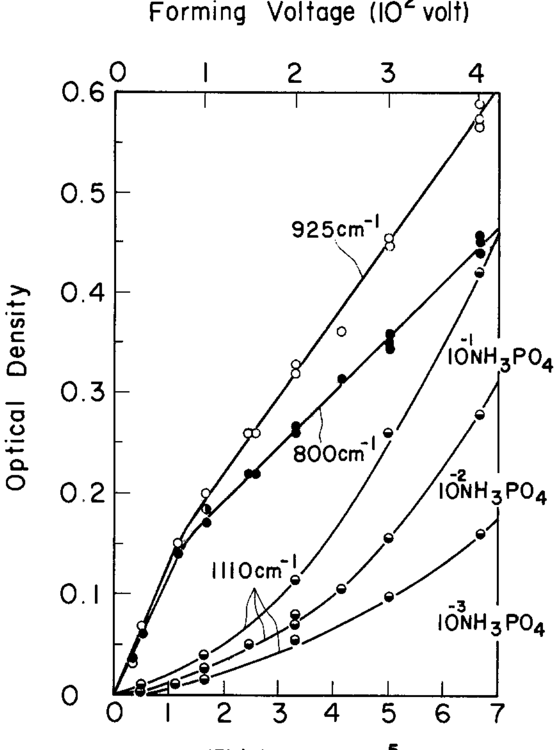

Fig. 2. Dependency of the optical density of each absorption band on the forming voltage and the film thickness of the tantalum anodic oxide film. Three components (925, 860, and 800 cm^{-1}) were examined. The intensity was dependent on [H_3PO_4] of anodizing bath. Higher concentration bath gave higher intensity. Therefore three lines were obtained for one absorption.

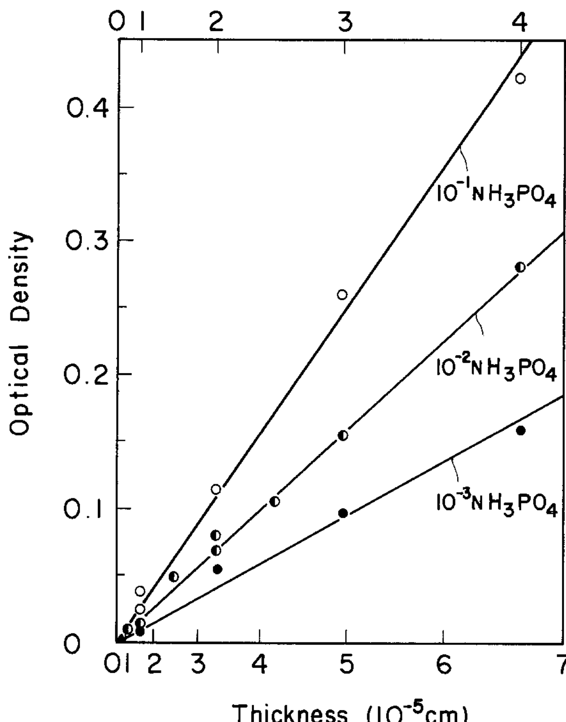

Fig. 3. Quadratic plots of the forming voltage or the film thickness of the tantalum anodic oxide film against the optical density of the 1110 cm^{-1} absorption band.

in the film (10, 11). Further investigation is necessary to determine which cause given above is actually working.

The 1110 cm^{-1} band was intensified more rapidly when the forming voltage was increased (Fig. 3). The band intensity increased linearly against the square of the forming voltage or the film thickness. At constant voltage, it increased logarithmically against the phosphate concentration. At the same time, the 610 cm^{-1} band increased in a similar manner to the 1110 cm^{-1} band. Consequently, these bands will indicate the corresponding phase will contain phosphate.

Manuscript submitted Aug. 7, 1974; revised manuscript received ca. Oct. 18, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by The Tokyo Shibaura Electric Company, Limited.

ABSTRACT

Polycrystalline zirconium samples were oxidized in pure oxygen under atmospheric pressure at temperatures ranging from 700° to 845°C and for times up to 400 hr. The diffusion of oxygen in the metal, beneath the oxide layer formed, was studied using a direct quantitative method of analysis based on the observation of the nuclear reaction $O^{16}(d,p)O^{17x}$. It was found that at a given temperature the oxygen concentration profiles, referred to the oxide-metal interface, may be superimposed after scaling by a factor $\sqrt{t}$. The results may be fitted assuming a concentration independent diffusion coefficient D, the oxygen concentration at the oxide-metal interface being constant and nearly equal to the saturation value, around 30 atom per cent. An activation energy $Q = (49 \pm 1)$ kcal/mole was found for the process. Identical results were obtained in air, showing that, at atmospheric pressure, nitrogen in the air plays a negligible role in the dry corrosion of zirconium.

Zirconium, like other metals such as titanium and hafnium, can form interstitial solid solutions containing large amounts of oxygen (1). Hence, in addition to the formation of an oxide layer (zirconia), the thermal oxidation of zirconium also gives rise to a simultaneous diffusion of oxygen into the metal matrix beneath the oxide. A complete study of the oxidation of zirconium requires these two phenomena to be separated. For the full understanding of the phenomena on the atomic scale, one has to know the profile of the oxygen concentration within the metal as a function of both time and temperature. It is the purpose of this paper to study with a direct method these concentration profiles and the corresponding diffusion process.

Several authors have attempted to establish oxygen profiles in zirconium. Most of the early investigations were based on an indirect determination of the oxygen contents obtained by measuring the microhardness (2-6), or the parameters of the hexagonal Zr lattice (7). However, recent measurements have shown that the relationships between oxygen concentration and both microhardness (8-10) and lattice parameters (11-12) are strongly nonlinear and for the first case not even one to one; thus, the results obtained by these methods have a qualitative character only. In some works the concentration profiles were determined by using more quantitative methods. Thus, Ericsson *et al.* (8) have measured the concentration of zirconium in the Zr-O solid solution by means of an electron probe analyzer and obtained, by difference, the concentration profile of oxygen. Their precision was ±2 atom per cent (a/o); hence amounts of oxygen below 2 a/o could not be detected. More recently Quataert and Coen-Porisini (13) have studied directly the oxygen concentrations by means of an ion probe analyzer. In order to convert their data into depth profiles they had to assume the sputtering rate and ionization probability to be independent of oxygen concentration; moreover they did not attempt an absolute concentration calibration, interpreting only normalized profiles to extract the diffusion coefficient D; finally, due to nonuniform erosion across the ion beam spot their sensitivity for low oxygen contents at depths larger than about $2\sqrt{Dt}$, *i.e.*, 2 a/o, was very poor. However, Ref. [8] and [13] contain the first reliable data from direct measurements of oxygen in the metal matrix, in the 600°-900°C temperature range.

Resorting to an ingenious method Pemsler (14) measured oxygen profiles by observing the rate of dissolution, during an anneal under vacuum at 510°C, of anodic oxide layers deposited on polished sections of specimens, previously oxidized at 850°C. He has assumed that the quantity of oxygen diffused during the anneal under vacuum was, at each point, proportional to $C_s - C$, where C_s represents the saturation concentration of the Zr-O solid solution and C the oxygen concentration to be measured. The quantity of oxygen diffused at each point was deduced from the decrease in the thickness of the anodic layer during the anneal under vacuum, which could be estimated from the change in color of this layer. The concentration profiles so obtained were of the error function type. In interpreting his results, Pemsler must assume that,

after an anneal of 145 min at 510°C, the solid solution Zr-O is saturated at the anodic oxide-metal interface, and that the coefficient of diffusion at this temperature is known and does not depend on oxygen concentration. This method therefore cannot give profiles without *a priori* assumptions; moreover it lacks sensitivity at low concentrations, below about 8 a/o. It gives hence semiquantitative results in terms of the value of C_s which is not measured directly. As will be shown below, several of Pemsler's assumptions are confirmed by the present work: his simple method might hence prove very useful, the more so that it allows one to observe, under the microscope, single grains and to estimate crystal orientation effects on diffusion.

In the frame of a study, using O^{17} as a tracer, of the self-diffusion of oxygen in zirconia growing on zirconium, Cox and Roy (15) have estimated the diffusion coefficient of oxygen in the metal beneath at 400° and 500°C. They used the nuclear reaction $O^{17}(He^3,\alpha)O^{16}$ to detect and locate O^{17} as a function depth. It appears that such nuclear techniques are best suited for direct and absolute concentration measurements for depth profile determinations. For heterodiffusion there is no need to use oxygen isotopes, as O^{16} (99.758% natural abundance) may be readily detected. We resorted to such a method in this work.

The general principles of microanalysis by the direct observation of nuclear reactions have been described in Ref. (16) as applied to O^{16} and O^{18} and more recently in Ref. (17), which contains most of the experimental details on the techniques used here. Specific applications to the study of diffusion processes in zirconium were described in Ref. (18), to which we shall refer here systematically, and which contains the first typical results on oxygen diffusion profiles in zirconium obtained by our group. The $O^{16}(d,p)O^{17x}$ reaction was used. This reaction presents high cross sections below 1 MeV bombarding energies and a low energy accelerator may be used, thus simplifying the experimental setup to some extent. These techniques have been applied also to a study of the physical properties of the Zr-O solid solution, like microhardness (9, 19), lattice parameters (12, 19), and density.

Experimental

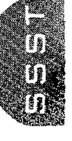
Specimen preparation.—Specimens of rolled Kroll zirconium containing 600 ppm of oxygen have been used. The precise analysis of the impurities is given in Ref. (18). As the initial state of the metal surface has a considerable influence on the kinetics of oxidation (20, 21), a detailed study of various methods of surface preparation was carried out (22). The standard treatment chosen according to this work is briefly described.

Specimens measuring 15 × 10 × 2 mm were polished mechanically under water and then polished chemically in a fluonitric bath (HNO_3 60%, HF 5%, H_2O 35%) for 20 sec. They were then annealed at 800°C for 2 hr in a vacuum of 10^{-6} Torr; a second chemical polishing, similar to the previous one, was then applied, its aim being the elimination of the metal layer contaminated by the diffusion of oxygen during the anneal (22). It must be noticed that such a polishing treatment leaves a superficial oxide layer of about 60Å (22). The oxygen concentration in the bulk of the metal is then the same as the concentration before the treatment (600 ppm), while the grain size is well defined and of the order of 25 μm.

The specimens so prepared were oxidized in pure oxygen under atmospheric pressure, at temperatures of 700°, 750°, 810°, and 845°C, for times up to 400 hr. The treatments were carried out with an automatically stabilized ADAMEL furnace of type Chevenard-Joumier in a 5 cm internal diameter quartz tube. Temperature uniformity in the vicinity of the sample was better than ± 2°C in a 5 cm long zone. The temperature was measured with a precision of the order of one degree using a Chromel-Alumel thermocouple placed near the sample and a MECI pyrometer-potentiometer Type ESPM. Periodic readings indicated ± 1°C long term stability. Ten identical specimens were prepared for each treatment condition: they were ground off to various depths, as in Ref. (18). The depths thus reached were characterized by measuring the decrease of weight of the sample, ΔM, per unit surface, after each grinding operation (see below).

Nuclear analysis.—The general features of the method may be found in Ref. (16-18). We shall summarize here briefly the experimental conditions and describe in more detail a procedure which improves the precision for high oxygen concentrations.

The ground off specimens were bombarded by a 900 keV, 1 μA, beam of deuterons from the 2 MeV Van de Graaff accelerator of the Ecole Normale Supérieure. The beam spot size was 1 mm. The energy spectra of the protons from the reaction $O^{16}(d,p)O^{17x}$ were registered at 165° by means of a 3 cm^2 surface barrier detector at 10 cm. Elastically scattered deuterons were stopped with a 12 μm thick Mylar absorber.



As shown in Ref. (17), the protons contributing to the spectrum originate from the first microns of the sample; the decrease with depth of the oxygen concentration is practically negligible over this surface region for the relatively deep diffusions considered here. Hence the spectra are characteristic of the surface concentration C of the sample under study. Thus one may obtain a series of couples of values (C_j, ΔM_j) for each treatment, from which the profile $C(x)$ may be deduced for the values x_j corresponding to ΔM_j.

The first step consists in calculating C from the spectra. C is conveniently expressed as the oxygen to zirconium atomic ratio O/Zr. If $\beta = O/(Zr + O)$ is the usual "atom per cent" concentration, we have

$$C = \frac{O}{Zr} = \frac{\beta}{1-\beta} \text{ and } \beta = \frac{O}{Zr + O} = \frac{C}{1+C} \quad [1]$$

Figure 1 shows a typical proton spectrum from a Zr-O solution; it represents the number of counts N_i in channel i which corresponds to a fixed energy interval ΔE around the energy E_i. It may be shown (17), that if the statistical spread involved in the proton detection process is neglected, we have

$$N_i = C\Delta x n_{Zr}\sigma[\theta,E_d(x_i)]K \quad [2a]$$
