where $N(x)$ is the base dopant concentration at depth x; Q_b is the quantity of base dopant per cm^2 surface; D_b is the normal base diffusivity at the emitter diffusion temperature; and t_b is the base diffusion time (drive-in) corrected to the equivalent time at the emitter diffusion temperature.

After the emitter diffusion and assuming uniform enhancement, χ, the nonpushed-out base is given by

$$N_1(x) = \frac{Q_b}{\sqrt{\pi D_b (t_b + t_e)}} \exp\left\{ -\frac{x^2}{4D_b(t_b + t_e)} \right\} \quad \text{[A-2]}$$

while the pushed-out base is

$$N_2(x) = \frac{Q_b}{\sqrt{\pi D_b (t_b + \chi t_e)}} \exp\left\{ -\frac{x^2}{4D_b(t_b + \chi t_e)} \right\} \quad \text{[A-3]}$$

where t_e is the emitter diffusion time. (It is assumed that no loss or gain of base dopant occurs during the emitter diffusion.)

At the base-collector junctions the base concentrations are equal to the substrate doping level N_s, *i.e.*, $N_1(b) = N_2(c) = N_s$. Therefore, from Eq. [A-2] and [A-3]

$$\frac{t_b + \chi t_e}{t_b + t_e} = \exp\left\{ \frac{1}{2D_b} \left[\frac{b^2}{t_b + t_e} - \frac{c^2}{t_b + \chi t_e} \right] \right\} \quad \text{[A-4]}$$

The left-hand side of Eq. [A-4] can be rewritten as

$$1 + \frac{(\chi - 1)t_e}{t_b + t_e}$$

where the term $\frac{(\chi - 1)t_e}{t_b + t_e}$ is positive and generally less than unity. Taking logarithms of both sides of Eq. [A-4] and using the series expansion for $\ln(1 + x)$, *i.e.*, $\ln(1 + x) = x - x^2/2 + x^3/3 \ldots -1 \leq x < 1$, then

$$\frac{(\chi - 1)t_e}{t_b + t_e} \approx \frac{1}{2D_b} \left[\frac{b^2}{t_b + t_e} - \frac{c^2}{t_b + \chi t_e} \right] \quad \text{[A-5]}$$

where only the first term in the series has been retained because the other terms are small. Rearranging Eq. [A-5] gives

$$b - c = \frac{t_e}{(b + c)t_b} [2D_b\chi(\chi - 1)t_e + 2D_b(\chi - 1)t_b - \chi b^2 + c^2] \quad \text{[A-6]}$$

Now assume that $\delta << 2b$, where δ is the amount of push-out and equals $(c - b)$; this is a less restrictive approximation than that of Hu and Yeh (6). Then $b + c = 2b + \delta \approx 2b$ and terms in δ^2 can be ignored. Equation [A-6] then becomes

$$\delta = \frac{t_e(\chi - 1)}{2b(t_b + t_e)} [b^2 - 2D_b\chi t_e - 2D_b t_b] \quad \text{[A-7]}$$

Now

$$N_s = N'_{bo} \exp\left\{ -\frac{b^2}{4D_b(t_b + t_e)} \right\}$$

where N'_{bo} is the nonpushed-out base surface concentration. Therefore

$$\frac{b^2}{t_b + t_e} = 4D_b \ln(N'_{bo}/N_s)$$

and using this in Eq. [A-7] gives

$$\delta = \frac{2D_b(\chi - 1)t_e \ln(N'_{bo}/N_s)}{b} \left\{ 1 - \frac{2D_b\chi t_e}{b^2} - \frac{2D_b t_b}{b^2} \right\}$$

This formula gives the amount of push-out in terms of the base diffusion parameters D_b, N'_{bo}, b, t_b, and the emitter diffusion parameters χ and t_e.

Ion Implanted Profiles from Two Point Spreading Resistance Measurements

T. E. Hendrickson

Solid State Electronics Center, Honeywell Incorporated, Plymouth, Minnesota 55441

ABSTRACT

A modified form of the Schumann and Gardner approach to correction of spreading resistance data, appropriate for a two point geometry, is given. Plotting the results of a numerical evaluation of "unilayer" theory yields a universal correction curve, useful for hand calculation. As an example of the use of this plot, consideration is given to the cases of 150 and 300 keV boron implants in (100) silicon.

Several authors have presented work based on numeric evaluation of three point spreading resistance data (1-3). More recently, however, the two point configuration (see the insert in Fig. 1) has become widely accepted. Owing to a fundamental difference in the quantities measured, modifications must be made to the basic three point formula. The formula thus obtained differs in form from that reported previously (1).

In contrast to other profiling techniques, spreading resistance data may be readily obtained from currently available commercial equipment.[1] The primary task is therefore one of accurately determining the appropriate correction factors (CF) to be applied. The work presently described represents the application of the simplest "unilayer" theory to the case of ion implanted layers. Correction factors determined in this fashion can be conveniently displayed in a "universal" plot suitable for hand calculation.

Correction Factors (CF)

In the three point geometry, current is forced through two probes while the voltage is measured between one of these points and a third probe "floating" with the body of the semiconductor. Detailed consideration of this geometry leads to the formula

$$V_{\text{measured}} = V_{\text{spreading}} + V_1(2s) - 2V_1(s)$$

where $V_1(r)$ is the surface potential, relative to the probe tip, at a distance r; and s is the probe tip spacing. For the case of the two probe geometry, the measured voltage takes the simpler form

$$V_{\text{measured}} = 2(V_{\text{spreading}} - V_1(s))$$

Applying the general formula for $V_{\text{spreading}}$ and $V_1(r)$ developed by Schumann and Gardner (1) yields the form

$$R_{\text{spreading}} = \frac{V_{\text{measured}}}{2\,I_{\text{measured}}} = \frac{\rho_2}{2r_o}\left\{\frac{4}{\pi}\int_0^\infty \left(\frac{1+Ke^{-2hx}}{1-Ke^{-2hx}}\right)\left(\frac{J_1(x)}{2X^2} - \frac{J_o(Sx)}{4X}\right)\sin(x)\,dx\right\}$$

where J_1, J_o = Bessel functions; $K = \rho_1 - \rho_2/\rho_1 + \rho_2$; $S = s/r_o$; r_o = effective radius of the probe tip; s = probe spacing; $h = d/r_o$; d = thickness of the layer; and ρ_1, ρ_2 = resistivities of the layers (see Fig. 1). The term in brackets is normally labeled the correction factor. Use is made of this quantity through the relationship

$$\rho_{\text{corrected}} = \rho_2 = (2\,r_o R_{\text{spreading}})/\text{CF}$$

Where the quantity $2r_oR_{\text{spreading}}$ is obtained directly from a calibration chart (4) is is hereafter referred to as ρ'.

The form for the correction factor given here is that appropriate for two layers [referred to elsewhere as the unilayer theory (1)] of resistivity ρ_1 and ρ_2 and thicknesses ∞ and d, respectively. Since the background layer (ρ_1) is assumed to be of semi-infinite extent, its corrected resistivity is set equal to the measured resistivity taken from the calibration chart. Calculation of CF for a given value of ρ_2 then proceeds in the following manner:

1. Set ρ''_2 equal to ρ'_2 and CF equal to 1.
2. Calculate CF′ from the corresponding value of K (*i.e.*, $K = \rho_1 - \rho''_2/\rho_1 + \rho''_2$).
3. If CF′ is not within 0.5% of CF, set CF equal to CF′, ρ''_2 equal to ρ'_2/CF′, and repeat step 2.
4. If CF′ is within 0.5% of CF, set $\rho_{2\,\text{corrected}} = \rho'_2$/CF′.

This procedure will yield values for CF self-consistent with the definition of K. Normally four to five iterations yield the desired accuracy.

Values for CF computed in the above-described fashion with s and r_o set equal to 85 and 4μ,[2] respectively, are plotted in Fig. 1. This plot has been made in a form convenient for hand calculation by plotting CF *vs.* the dimensionless parameter ρ defined as the ratio ρ'_2/ρ'_1. The layer thickness (d) is used as a running parameter.

To use Fig. 1, correction is begun at the deepest portion of the profile and carried forward toward the surface. The general outline to be followed is (see Fig. 2):

1. Divide the profile into a set of equally spaced data points, beginning at the deepest point of the profile and continuing toward the surface.
2. Compute the ratios $\bar{\rho}'_1/\bar{\rho}'_o$, $\bar{\rho}'_2/\bar{\rho}'_1$, . . . , $\bar{\rho}'_n/\bar{\rho}'_{n-1}$, where ρ'_n represents the average of all data points contained in an interval of width d centered about the point ρ_n.
3. Find the appropriate values of CF from Fig. 1 and compute

$$\rho_{n\ \text{corrected}} = \rho'_n/\text{CF}\ (\bar{\rho}'_n/\bar{\rho}'_{n-1})$$

The above outlined procedure is simple and direct, allowing for ease in hand computations. Use of this form of "tabular look-up with averaging" yields a rapidly executing alternative to the more lengthy multilayer approach (3). Averaging lengths can be readily varied according to the depth of the profile, however experience has shown the limits $0.75\mu \geq d \geq 0.15\mu$ to yield the best results.

Results

Corrected (dashed) and uncorrected (solid) resistivity curves are given in Fig. 2 for the case of a boron implanted layer in (100) p-type silicon. The implant was performed at an energy of 300 keV and dose of 10^{14}/cm^2 through 680Å of thermally grown SiO_2 An-

Key words: unilayer theory, hand computations, channeling.

[1] The ASR-100 Mazur Automatic Spreading Resistance Probe purchasable from Solid State Measurements, Inc. was used in this work.

[2] This value for r_o was obtained by finding the radius of the smallest circle entirely enclosing the probe markings on an SEM.

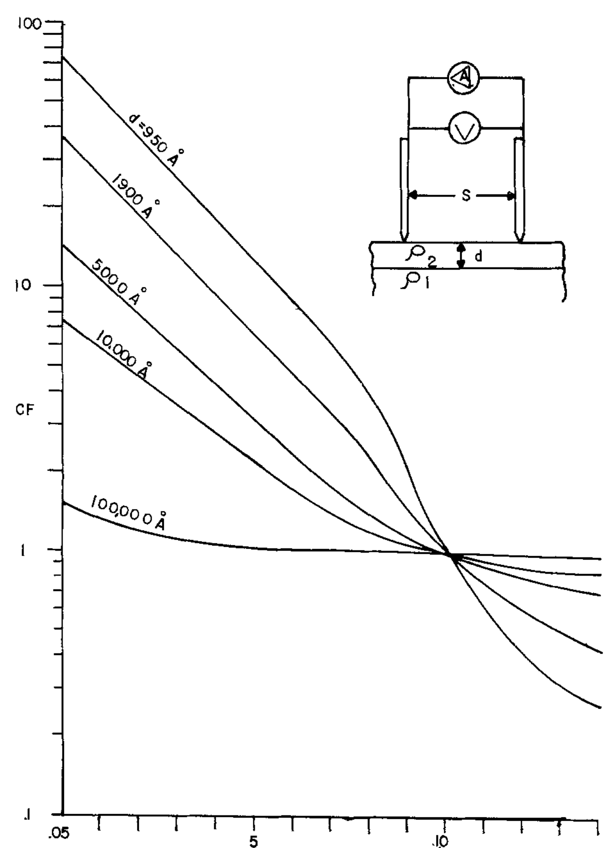

Fig. 1. Correction factor (CF) plotted as a function of the dimensionless parameter $\rho = \rho_2/\rho_1$ with thickness used as a running parameter. The curves are given for $s = 85$ and $r_0 = 4\mu$.

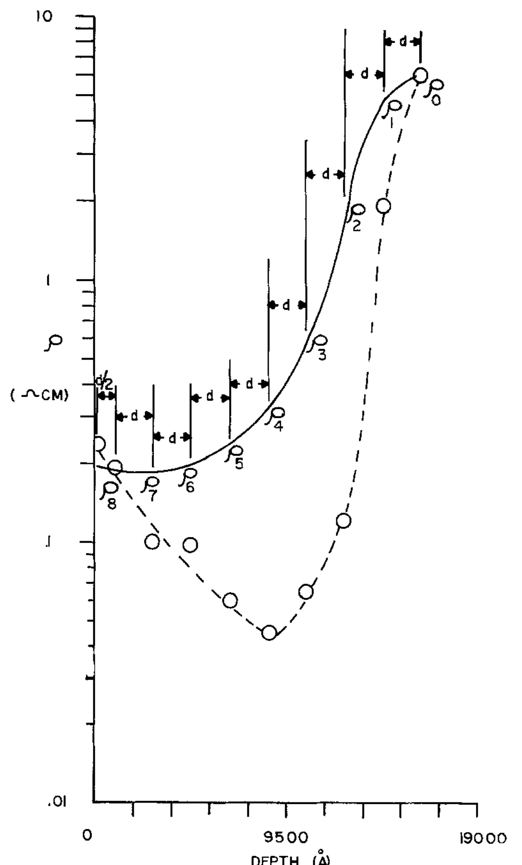

Fig. 2. Uncorrected (solid line) and corrected (dashed line) resistivity vs. depth curves for the case of boron implanted (energy = 300 keV; dose = $10^{14}/cm^2$) into (100) silicon through 680Å SiO_2.

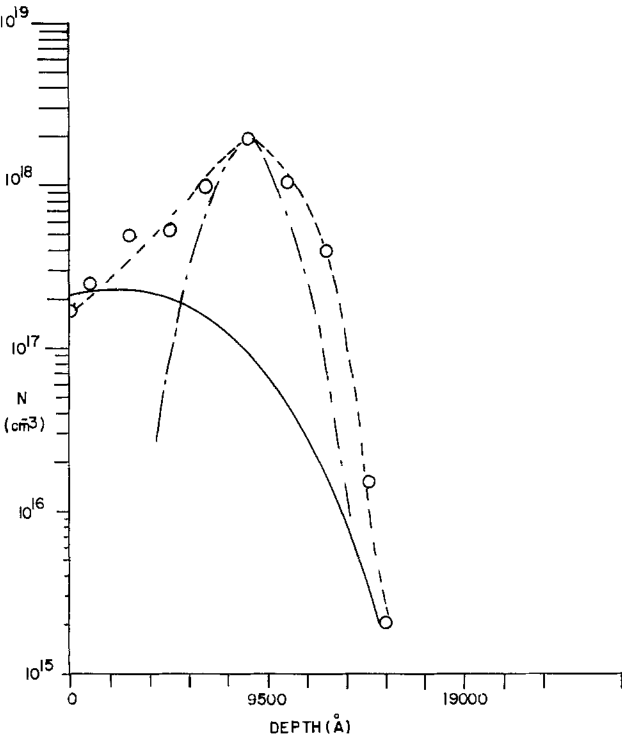

Fig. 3. Uncorrected (solid) and corrected (dashed) doping profiles obtained from Fig. 2. Also given is the shape predicted by the LSS theory (——— – – ———).

nealing was performed at 950°C for 25 min in dry N_2. Comparison of the two curves graphically demonstrates the "masking" of the implant peak by the uncorrected data.

Converting these curves into doping profiles results in the plot of Fig. 3. Also plotted here is the distribution predicted by the LSS theory.[3] Notice that the measured range is in close agreement with theory, as is the peak concentration ($\sim 1.98 \times 10^{18}/cm^3$ empirical *vs.* $2.1 \times 10^{18}/cm^3$ theoretical). In contrast to this, the empirical curve displays a much larger value for the projected straggle (ΔR_p). A close fit to the data presented here is given by $\Delta R_p = 1460Å$ (curve not shown) which is in reasonable agreement with values observed by other authors (5) (typically 900-1300Å). The somewhat larger value found here is most likely ascribable to either an anomalously high diffusion rate during the post-implantation anneal, or errors introduced during correction of the profile [owing to the absence of an exponential tail normally observed in such implants (6), it seems reasonable to assume that the correction procedure has smeared this feature into the normal Gaussian shape thereby increasing $\Delta R_{p\ measured}$]. The relatively high surface concentration ($\sim 2 \times 10^{17}/cm^3$) observed appears to represent a real phenomenon observable in all implants performed to date.

A second example of an ion implanted boron layer is given in Fig. 4. This implant was performed analogously to the first with an energy of 150 keV and dose of $10^{14}/cm^2$. Perhaps the most salient feature observable in this profile is the pronounced appearance of a channeled peak in the profile (note: though only one channeled point was chosen for correction, in all 8 actual data points were found to lie along this portion of the curve). This channeled peak was found to be present for all those implants performed at 200 keV or less, through ~700Å SiO_2. Agreement with the LSS theory (dashed curve) was found to be excellent for this implant.

Referring back to Fig. 3, notice that both the 150 and 300 keV implants show a definite surface inversion at

[3] Allowance has been made for field-enhanced diffusion during the post-implantation anneal.

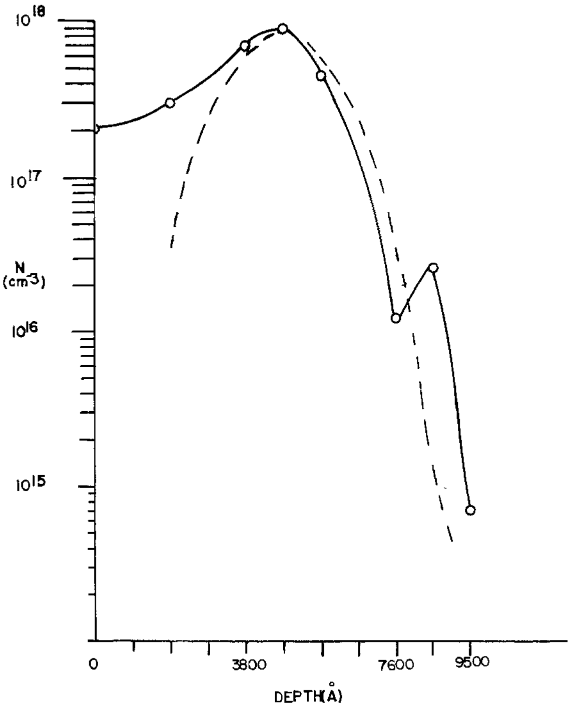

Fig. 4. Corrected profile for a 150 keV boron implant (solid) vs. that obtained from the LSS theory (dashed).

a doping level of approximately $2 \times 10^{17}/cm^3$. Speculation on the origin of this surface layer has lead to the proposal that a p-type impurity normally present in the material has been gettered by the damage sites. Such an observation would appear consistent with results obtained by other authors (7).

Conclusion

Two point spreading resistance data have proven to be a reliable means of profiling ion implants when corrected by a modified form of the Schumann-Gardner approach. Correction factors computed from unilayer theory yield profiles consistent with work performed previously by other authors. Certain effects, most notably channeling and unexpected surface inversion, seem readily discernable by this technique.

ABSTRACT

Liquid phase epitaxial growth is studied using interface demarcation during growth by transmitting current pulses across the substrate solution interface. This approach permits the investigation of the growth interface morphology and the determination of the instantaneous microscopic growth rate and epitaxial growth efficiency for any time of the cooling cycle. It is shown that the growth interface can be subject to significant transient morphological perturbations which are not necessarily reflected in the surface morphology of the epitaxial layers.

While liquid phase epitaxy (LPE) is recognized as one of the most important techniques for the production of high quality electronic materials and structures, many aspects of the basic growth process are as yet unexplained and subject to various interpretations. The microscopic growth rate variations associated with a particular cooling rate for any given system have to date only been approximated from layer thickness determinations (1-4). Reliable data on solute diffusivity, which are required to theoretically explain the microscopic growth behavior, are as yet unavailable (5, 6). In addition, the nature of transient growth conditions during the initial part of the cooling cycle is as yet unresolved. Furthermore, incomplete knowledge of the growth and segregation controlling parameters is responsible for our inability to predict effective distribution coefficients, hence desired layer compositions are achieved on the basis of empirical growth procedures. Also unresolved to date is the mode of epitaxial solution growth on substrates of low-index surface orientation (2, 7). The experimental determination of the growth mode is of more than theoretical importance, since the segregation behavior and thus the composi-

* Electrochemical Society Active Member.

Key words: epitaxy, gallium arsenide, dopant segregation, growth rate.

tion of the epitaxial layer in the facet growth mode is controlled by the lateral growth rate rather than by the microscopic growth rate normal to the established growth interface (8-10). In this context it is important to realize that the functional dependence of the effective segregation coefficient on experimental variables for facet growth is still unknown (11).

The purpose of the present study was to investigate the microscopic growth behavior during LPE of GaAs (Te-doped) by means of interface demarcation. This technique, originally applied to the quantitative study of melt growth (12), was applied recently also to solution growth of InSb (13). Interface demarcation is achieved by transmitting periodic current pulses across the solid-liquid (S-L) interface. Each pulse, depending on the direction of current flow, leads to Peltier cooling or heating at the growth interface (14) (for the duration of the pulse) and thus to temporarily accelerated or decelerated growth (or even dissolution). The temporary growth rate change, which is uniform over all parts of the growing epitaxial layer if the current density is uniform across the interface, results in an alteration of effective dopant segregation. This yields a precise demarcation of the growth interface by producing dopant concentration striations that are readily revealed by cleaving the wafer and etching the exposed cleavage plane. Using current pulses of known repetition rate, it is thus possible to determine the microscopic growth rate from the spacing of the induced striations. It is furthermore possible to study the interface morphology from beginning to end of the growth experiment and to establish the relationship between growth and surface morphology of the epitaxial layer.

Experimental Procedure

The LPE experiments were carried out under flowing H_2 in a horizontal graphite boat (Fig. 1). The top part of the boat, containing a Te-doped Ga-As solution, was electrically isolated by a BN slider from the bottom part containing the GaAs substrate. Uniform electrical contact to the bottom surface of the substrate [(100) orientation, n-type, Si-doped to $10^{18}/cm^3$] was achieved by wetting the back side of the substrate with liquid Ga. The top and bottom sections of the boat were connected with stainless steel rods to a programmable d-c power supply. After the system was brought to the desired temperature (typically 850°C), substrate-solution contact was established by moving the slider into the appropriate position, and cooling was initiated at a rate of 0.25°C/min. During cooling, current pulses of up to 20A (13.3 A/cm^2) and of a duration ranging from 0.1 to 8 sec were transmitted at time intervals ranging from 1 to 10 min. After completion of a growth experiment, the solution was isolated from the epilayer by moving the slider into its original position. The wafer was subsequently cleaved along a (110) plane, and the cleaved face was etched for 30 sec in an AB etching solution (15) (8 mg $AgNO_3$, 1g CrO_3, 1 ml HF, 2 ml H_2O) and then examined by interference contrast microscopy.

In preliminary experiments it was observed that the transmission of current pulses of either polarity, corresponding to current flow from seed to solution or the reverse, resulted in effective interface demarcation. The thermal effects associated with demarcation were measured with a Chromel-Alumel thermocouple (not shown in Fig. 1) located 1.2 mm from the edge of the S-L interface. To determine the sign of the Peltier coefficient and the relative contributions of Joule heating and of Peltier heating or cooling, four 2-sec current pulses of +5.35, −5.35, +2.67, and −2.67 A/cm^2 were successively applied across the S-L interface (a + sign indicates that the solution has a positive polarity with respect to the substrate). The resulting temperature effects are shown in Fig. 2.

It is seen in Fig. 2 that the pulse of +2.67 A/cm^2 resulted in a temperature increase, while the pulse of −2.67 A/cm^2 caused a temperature decrease. The occurrence of the temperature decrease shows that at this current density Peltier cooling and heating ($=PI$) exceeded Joule heating ($=I^2R$), which tends to raise the temperature regardless of current polarity. From the observed relationship between the thermal effects and current direction, the Peltier coefficient is positive, according to the sign convention of Ref. (16). For pulses of ±5.35 A/cm^2, it is seen in Fig. 2 that the temperature increased for both current directions, although the increase was appreciably greater for the positive pulse. At this current density Joule heating had become dominant, because of its dependence on I^2, although the relative magnitude of the Peltier effect was still large enough to have a significant influence on the temperature change. The dominance of Joule heating was observed for current densities exceeding about 3 A/cm^2. In experiments of GaAlAs, however, it has been demonstrated that under certain conditions substantial net cooling can be achieved by the Peltier effect even at high current densities (17).

Results and Discussion

In the experiments described here the polarity of the current pulses was positive, so that both Peltier heating and Joule heating occurred at the growth interface. The resulting demarcation effects are visible in Fig. 3, which is a photomicrograph of a cleaved and etched GaAs LPE layer. During the growth of this layer, 25 current pulses of 13 A/cm^2 and 0.5 sec duration were transmitted at 5 min intervals. The width of the observed demarcation bands is in all instances about 3 μm, independent of the temperature, which decreased from 851° to 815°C during the experiment. Since the solubility of As in liquid Ga decreases from approximately 3.8 to 2.6 atomic per cent over this temperature range (18), it must be concluded that the current-induced growth is not an equilibrium process. The formation of demarcation bands is attributed to temporary dissolution of a thin region of the LPE layer, due to the heat generated at

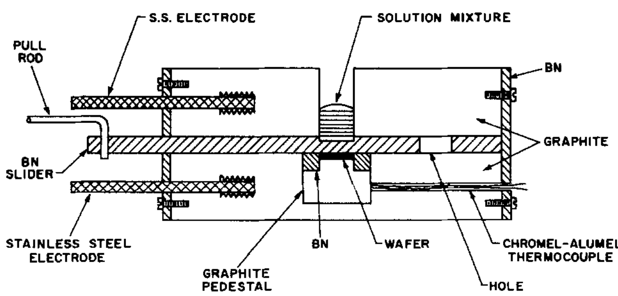

Fig. 1. Schematic diagram of boat used for LPE growth of GaAs with interface demarcation.

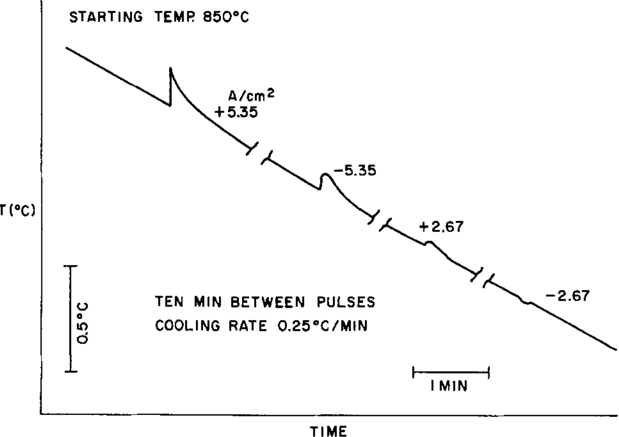

Fig. 2. Temperature-time profile for LPE experiment, showing the temperature changes associated with the transmission of current pulses across the solid-liquid interface.

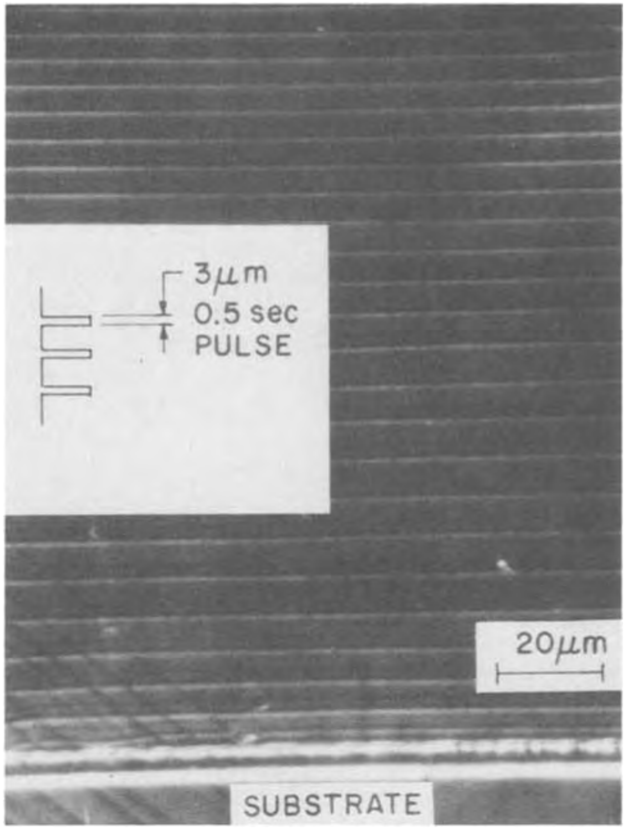

Fig. 3. Photomicrograph of a cleaved and etched GaAs layer grown by LPE with interface demarcation. During growth, 25 pulses of 0.5 sec duration were transmitted at 5 min intervals.

the S-L interface, followed by very rapid regrowth of this region after termination of current flow; Te segregation varies with growth rate and the etching rate of the cleavage plane is a function of the Te concentration. (No demarcation lines could be observed in undoped GaAs.) This interpretation is consistent with the constant width of the demarcation bands, since the amount of heat generated per pulse was constant and the heat of fusion and heat capacity of GaAs can be assumed constant over the temperature range of the experiment. However, it does not explain the observations in other experiments where it was found that the width of the demarcation bands is not changed appreciably by variations of approximately one order of magnitude in pulse duration or pulse height.

Detailed information concerning LPE growth can be extracted from experimental results such as those in Fig. 3. The amount of material deposited over any temperature interval can readily be determined, since the demarcation bands delineate the S-L interface and each current pulse results in a signal on the recorded cooling curve (as illustrated in Fig. 2). Figure 4 is a plot of the epitaxial layer thickness as a function of growth temperature, obtained from the spacing of consecutive demarcation lines in Fig. 3. It can be seen in Fig. 4 that the experimental points very accurately follow the curve shown, which was obtained from the phase diagram (18). According to the phase diagram, a maximum layer thickness of 153 μm GaAs (on a 1.5 cm^2 substrate, from a solution containing 4.5g Ga and 0.383g GaAs) can be achieved by growth from solution over the temperature interval from 851° to 815°C. The measured average layer thickness was 149 μm, indicating that the growth efficiency in this particular case was close to 100%. A growth efficiency of 100% cannot be expected if growth is diffusion controlled, since this growth mode implies the existence of an arsenic concentration gradient perpendicular to the S-L interface. The results in Fig. 4 would suggest that growth occurs without the establishment

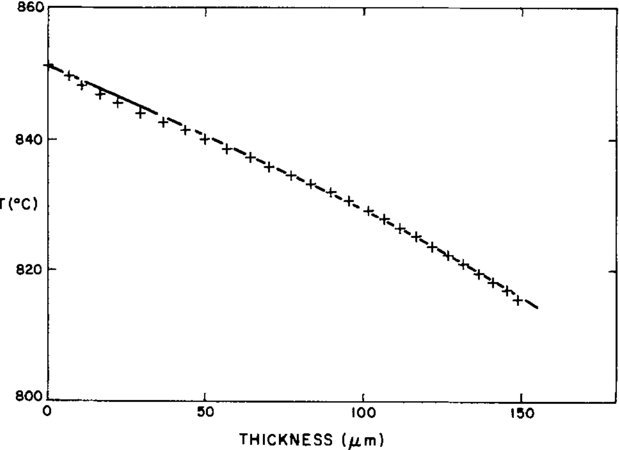

Fig. 4. Plot of LPE layer thickness vs. growth temperature. The data points, based on Fig. 3, follow the phase diagram, which is represented by the solid line.

of a substantial diffusion boundary layer. Etching experiments indicate the absence of random segregation inhomogeneities. It must therefore be concluded that thermal convection effects cannot readily account for the apparent decrease in the thickness of the diffusion boundary layer. On the other hand, it cannot be assumed that the equilibrium conditions prevailing during current-controlled LPE at the growth interface are identical with those encountered during conventional LPE.

It has been suggested (2, 7) that the surface morphology of an epitaxial layer corresponds to the morphology of its growth interface; thus, a flat surface is taken as indicative that growth proceeded with a flat interface. On the other hand, Ref. (19) has shown that the surface of the top layer in a GaAlAs/GaAs heterojunction laser is rather disturbed compared to the underlying interfaces. Figure 5 shows clearly that neither of these relationships can be assumed *a priori*, since here the top surface is flat while the underlying demarcation lines reveal a pronounced localized depression in the growth interface. In this case, the interface morphology remained basically unchanged over a growth period of 30 min (from 844° to 835°C), but there is a pronounced difference in morphology between the final surface and the last demarcation line. This observation suggests that surface morphology is significantly affected by growth during solution wiping. It was established that the solution was wiped off completely from the surface of the epitaxial layer. The surface morphology is therefore unrelated to

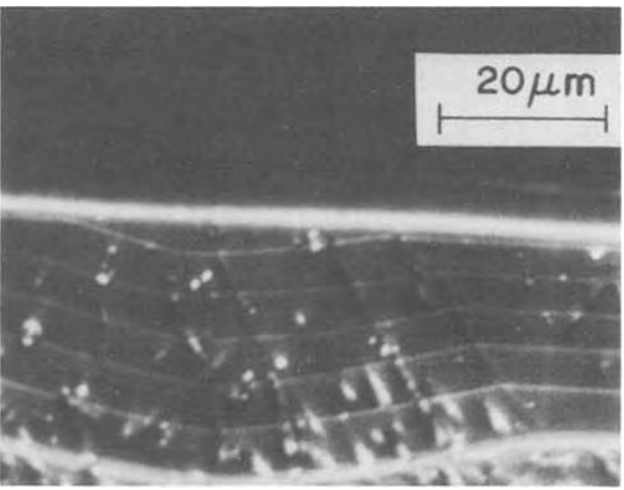

Fig. 5. Photomicrograph of a GaAs LPE layer. It can be seen that the surface flatness does not reflect the shape of the S-L interface (as depicted by demarcation lines) during growth.

residual solution left on the surface and cannot at this time be explained adequately. The presently observed wiping effects cannot be generalized, but they indicate potential complications arising from wiping in LPE systems.

Another application of interface demarcation to the study of LPE growth is illustrated in Fig. 6. In this experiment, a pit in the substrate surface created a local perturbation on a flat, possibly facet-type, growth interface. It took 18 μm of epitaxial growth (about 25 min) before the 2.5 μm deep pit was eliminated. In some other cases, however, the change from an irregular interface to a straight one took place within a short period.

Local retardation of the growth of an LPE layer is shown in Fig. 7. Of the nine demarcation lines observed, eight were formed by current pulses at intervals of 5 min, while the uppermost line was generated by interrupting the growth momentarily by separating and subsequently recontacting solution and wafer. Figure 7 indicates that locally no epitaxial growth had taken place over a distance of about 220 μm. This local retardation of growth persisted over a steadily decreasing area for a period in excess of 20 min. It is clear from Fig. 6 and 7 that during LPE growth a pit may result in the final surface if growth is restricted to thin layers (as is customary for certain devices). In the experiment shown in Fig. 7, it took 45 min of growth before the retardation was overcome and a flat growth interface was formed. The area under the delineated pyramid was formed at an increased growth rate and can be expected to constitute a significant segregation discontinuity. In this area the average growth rate normal to the angle of inclination is calculated to be approximately 35% higher than that in the (100) direction. The orientation of the growth interface varies, and no specific set of low-index growth planes can be identified. The exact cause of the local inhibition of growth is unknown, but it is suggested that oxides or major defects in the substrate are responsible. While the present experiments are not exhaustive, they indicate clearly that smooth substrate-epilayer interfaces and smooth final layer surfaces are no assurance that LPE growth has proceeded in an unperturbed manner.

Summary

The presently reported experiments show that interface demarcation through current pulsing can be applied successfully to the quantitative study of liquid phase epitaxy. It has thus been shown that transient changes in the growth interface morphology, which are not necessarily reflected in the surface morphology of the epitaxial layer, may occur. Such transients may result in significant compositional inhomogeneities. While the experimental results were obtained on thick epitaxial layers, the observations should apply as well to thin layer growth.

Low Temperature Deposition of Metal Nitrides by Thermal Decomposition of Organometallic Compounds

Kozoh Sugiyama, Sangryul Pac, Yasutaka Takahashi, and Seiji Motojima

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kagamigahara, 504 Japan

ABSTRACT

Decomposition reaction of dialkylamides of boron, silicon, tin, titanium, zirconium, niobium, and tantalum was investigated. The amides of transition metals decomposed to the corresponding nitrides at 300°-500°C, whereas those of boron, silicon, and tin yielded elemental deposits at higher temperatures. In the deposition of titanium nitride from titanium tetrakis(dimethylamide), two optimum temperatures at 400° and at 800°C in nitrogen or hydrogen atmosphere were found, but in argon only low temperature deposition was possible. The low and high temperature processes are discussed in relation to mass spectral analysis of the exhaust gases formed at various decomposition temperatures of titanium amide.

Metal nitrides are well known to have outstanding physical and chemical properties and have been prepared by the reactions of metal halides or hydrides with nitrogen + hydrogen or ammonia, or of metals with nitrogen (1). These reactions usually require temperatures higher than 1000°C, which have limited the application of the nitrides as the useful coatings on many materials. Therefore, their preparation at lower temperature, where deformation of substrate materials can be avoided, should be important.

Recently, the use of organometallic compounds as the starting materials for the vapor deposition of some inorganic compounds such as oxides has been reported (2). Dialkylamides of metals are of particular interest with respect to the fact that they have direct metal-nitrogen σ-bonds, and controlled thermal decomposition of these organometallics could result in the deposition of the corresponding nitrides at temperatures much lower than the conventional preparation techniques mentioned above. With this in mind, the thermal decomposition of dialkylamides of various metals is investigated, and a detailed examination of the decomposition products including organic compounds was performed using titanium tetrakis(dimethylamide) as a representative compound.

Experimental

Materials—Metal dialkylamides used in this study were prepared according to the modified method of literature (3) from lithium dialkylamides and the corresponding metal chlorides and were supplied to be used for the decomposition reaction after identification with infrared, NMR, and mass spectra (4). Silicon tetrakis(dimethylamide) was found to include about 75% of chlorotris(dimethylamino)silane but was used without further isolation. Argon, hydrogen, and nitrogen were refined by passing over titanium sponge heated at *ca.* 800°C and phosphorus pentoxide, successively. Helium and other Guaranteed Grade reagents were used without further purification.

Decomposition reaction of the amides—An apparatus used for the decomposition reactions is shown in Fig. 1. An amide saturated in a carrier gas (argon, hydrogen, or nitrogen) at a suitable temperature, where it is thermally stable (in most cases below 100°C except for silicon amide; 140°C), was introduced onto a substrate [about 10 × 10 mm²: quartz, graphite, stainless steel (Ni 18, Cr 8), or copper plate] which was mounted on a SiC heater in a reaction tube (quartz; inside diameter 25 mm). The reactor was cooled by water flow from the outside in order to avoid the deposition on its inside surface. Temperature of the substrate was measured by an Alumel-Chromel thermocouple (uncorrected) and was regulated using a regulator (Chino Electric Company, Model E-500). After the decomposition reaction, the furnace was cooled in an atmosphere of flowing carrier gas to room temperature. Most substrates were used after polishing with an emery paper. The surface of the copper plate was cleaned by heating in air and subsequent steeping in methanol. The films on the substrate were examined *in situ* on the substrate by x-ray diffraction (Rigaku Electric Company, Type 2040), scanning electron microscopy (JEOL, Model U3), and partly by x-ray microprobe analysis (JEOL, Model JAX-5 CHD).

Key words: metal-dialkylamides, nitrides, thermal decomposition.

Analysis of the exhaust gas—The exhaust gas formed in the decomposition of an amide was analyzed by gas chromatography (F.I.D.; Apiezon L column, 1.0m; 20°C) and by bubbling through a benzene solution of naphthylisocyanate which reacts to form urea derivatives of the corresponding amines. Detailed analysis was performed by a mass spectrometry. Helium gas, which was used because it does not interfere with detection of fragments with low molecular weights, was saturated with the vapor of titanium tetrakis(dimethylamide) or the silicon analogue and was passed through a quartz furnace (inside diameter 15 mm) heated from the outside at a given temperature. The gas formed was first collected in a gas reservoir, before it was introduced into the spectrometer (JEOL, JMS-01SG).

Evaluation of quantity of vapor transported of titanium tetrakis(dimethylamide).—Titanium amide is so sensitive to moisture and oxygen that it is difficult for us to determine the quantity transported by a

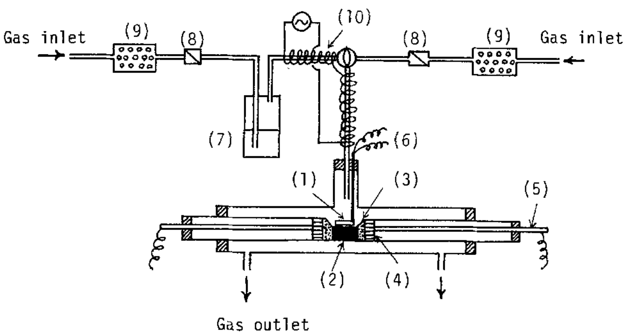

Fig. 1. Schematic diagram of the apparatus used for the decomposition of amides. 1, Substrate; 2, SiC heater; 3, carbon powder; 4, graphite; 5, iron rod; 6, a-c thermocouple; 7, amide saturator; 8, flow meter; 9, titanium sponge; 10, Nichrome heater.

carrier gas. However, this compound has been reported to react with carbon disulfide giving the stable complex, titanium tetrakis(N,N-dimethyldithiocarbamate) (5). Thus, by bubbling the carrier gas (nitrogen) saturated with the titanium amide at 90°C into a benzene solution of carbon disulfide and collecting the red precipitates by filtration, the quantity of the amide transported was calculated from the weight of the precipitates as 0.032 mg/ml (N_2).

Results

Decomposition products.—When the vapor of titanium tetrakis(dimethylamide) saturated in nitrogen gas was introduced onto a quartz substrate which was heated at 400°C, it decomposed resulting in brownish coatings. Their x-ray diffraction showed broad peaks, which are fully consistent with those of titanium nitride as shown in Fig. 2. The peaks became more pronounced when annealed in argon atmosphere at 800°C for 10 min. The high temperature decomposition products were yellow-colored and had sharper x-ray diffraction peaks (see Fig. 2). The low and high temperature products were inert to hydrochloric acid and sulfuric acid but were etched partly by nitric acid and soluble in aqua regia, being consistent with the chemical properties of titanium nitride. The x-ray microprobe analysis of the product obtained at 400°C shown in Fig. 3 suggests a homogeneous nitride which contains a small quantity of carbon, particularly in the grain boundaries. The lowest formation temperature was about 250°C.

The decomposition reaction was evident in hydrogen as well as in nitrogen. On the other hand, in argon atmosphere the nitride deposition was observed analogously at lower temperature reaction (about 400°C) but was very poor at temperatures higher than 700°C.

The decomposition reaction of other amides was investigated in a similar manner, and the products are listed in Table I, together with their lowest formation temperatures. The amides of transition metals such as titanium, zirconium, and niobium gave the corresponding nitrides. Their x-ray diffraction patterns are reproduced in Fig. 2. Tantalum amide gave the grayish deposits which had x-ray diffraction peaks Cu-Kα 2θ = 36.2°, 41.9°, and 61.0° (relative intensity 100:70:30) which were not consistent with available data of tantalum compounds. Therefore, we could not identify the products.

On the other hand, amides of boron and tin did not yield a nitride at any temperature in the range 300°-1000°C but gave the elements themselves. Boron was obtained above 700°C in the brown films and was identified by x-ray diffraction and the easy dissolution in nitric acid. Tin was formed at 300°-1000°C as gray coatings, which were clearly identified by the x-ray diffraction analysis (30.2°, 31.6°, 43.5°, and 44.5°). In the decomposition of silicon amide which was found to consist of both silicon tetrakis(dimethylamide) and monochloride (nearly 1:3, see experimental section), white powder and homogeneous yellowish or brownish coating were obtained at 800°C, below which no depositions occurred. The

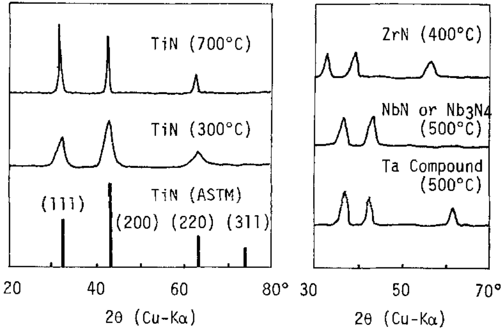

Fig. 2. X-ray diffractions of deposits formed on quartz

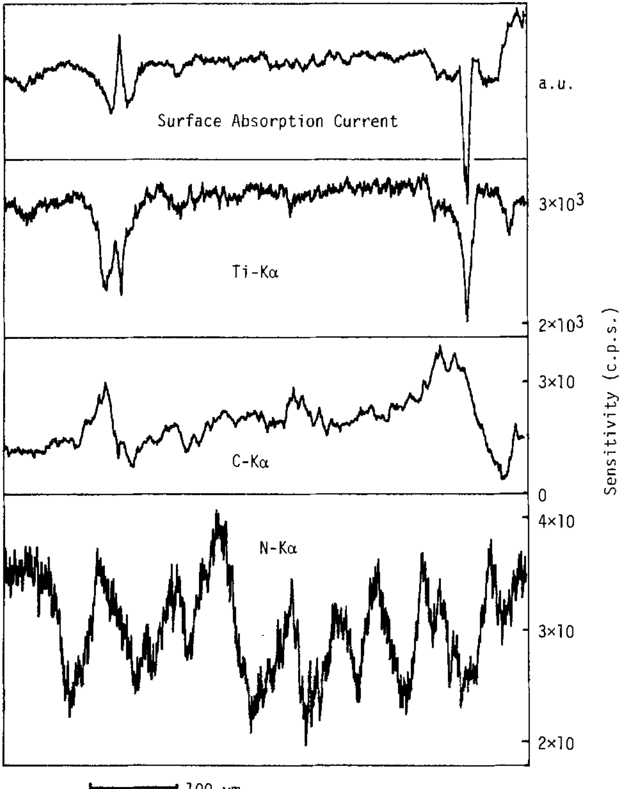

Fig. 3. X-ray microprobe analysis of the deposits obtained from $Ti(NMe_2)_4$ on quartz at 400°C in nitrogen.

former was identified as ammonium chloride by infrared spectrum and x-ray diffraction. The latter adhered tightly on the quartz substrate and exhibited no x-ray diffraction peaks, indicating an amorphous material. Its infrared spectrum showed the presence of an amino-group ($\nu_{N\text{-}H}$ 1400 cm^{-1}) (6). Its further heating at a higher temperature (1100°C) in argon released a small quantity of ammonia, suggesting that the deposit contained silicon amide. It was oxidized gradually in air at 1300°C to give a blue-colored product. In figuring the weight increase after the oxidation, silicon content in the product was estimated to be at least 80%. It was soluble partly in hydrofluoric acid, partly in 20% sodium hydroxide, and partly in hydrofluoric acid + nitric acid. Therefore, it can be assumed that the brownish product from silicon alkylamide contains a few compounds such as silicon, silicon nitride (or amide), and silicon carbide. But, the result of the oxidation reaction strongly suggests that silicon is a major product. Thus it is of great interest that the decomposition of the amides of the main group elements has a tendency to result in the corresponding elements themselves rather than the nitrides, being in striking contrast to that of transition metal amides.

Table I. Metal dialkylamides, decomposition products, and the lowest formation temperatures of nitrides

Amide	Product	Lowest formation temp (°C)	Remarks
$Ti(NMe_2)_4$	TiN	250	Reddish brown (low) or yellowish (high temperature) coatings
$Ti(NEt_2)_4$	TiN	350	
$Ti(N\text{-}n\text{-}Pr_2)_4$	TiN	500	
$Ti(N\text{-}n\text{-}Bu_2)_4$	TiN	600	
$Zr(NMe_2)_4$	ZrN	400	Pale brownish coatings
$Zr(NEt_2)_4$	ZrN	500	
$Nb(NEt_2)_5$	NbN or Nb_4N_3	500	Black coatings
$Ta(NEt_2)_5$	Unidentified	(500)	Grayish coatings
$Si(NMe_2)_4$*	Si, SiC and $Si(NH_2)_n$	(800)	Brownish coatings
$Sn(NMe_2)_4$	Sn	(300)	Grayish coatings
$B(NMe_2)_3$	B	(600)	Dark brownish coatings

* It includes about 75% of $ClSi(NMe_2)_3$.

Temperature dependence of deposition.—The lowest formation temperatures of nitrides shown in Table I are remarkably low compared with those in the conventional chemical vapor depositions. The amides having a higher molecular weight or of heavier elements are apt to decompose at higher temperatures. The temperature dependence of the deposition was studied in more detail using titanium tetrakis(dimethylamide) and tetrakis(diethylamide) as representative compounds. The results in nitrogen are shown in Fig. 4 and 5, respectively. The maximum yields were found at about 400°-500°C and at a temperature above 800°C in either compounds, when hydrogen or nitrogen was used as a carrier gas. In the case of argon carrier, however, the nitride deposition occurred analogously at lower temperatures but was extremely suppressed at higher temperatures. The titanium nitride content in the deposits was evaluated from titanium oxide (TiO_2) formed by oxidation in air, and is shown also in Fig. 4 and 5. These results strongly suggest that the different mechanisms can take part in the low and high temperature decompositions. Table I indicates that the amides of the main group elements gave deposits at higher temperatures than those of transition metals.

Analysis of the exhaust gases.—In order to clarify the processes of deposition, the exhaust gas of the decomposition reaction was examined by gas chromatography, mass spectroscopy, and chemical analysis. When the exhaust gas formed by the decomposition of titanium tetrakis(dimethylamide) at the optimum condition (400°C) in nitrogen was bubbled into a benzene solution of naphthylisocyanate, white crystals which were identified as pure dimethylnaphthylurea by NMR and infrared spectra, m.p. and thin layer chromatography were separated, indicating a selective formation of dimethylamine. Its yield was found to decrease with the increasing decomposition temperature. The gas chromatographic analysis showed at least three peaks, one of which was identified as dimethylamine.

Detailed analysis of the gases obtained at the decomposition temperatures 300°, 600°, and 800°C in helium atmosphere was performed using a mass spectroscopy, and the results are shown in Fig. 6, in which the relative intensities of fragments to a fragment m/e 78 (unidentified) are shown. This figure indicates that at lower temperatures the elimination of dimethylamine was dominant and that at temperatures above 600°C further degradation could take place. The formation of hydrogen and methane became significant at 800°C, which indicates an occurrence of a full decomposition of the complex. In contrast, the deposition yields of titanium nitride were maximum at about 400°C and at a temperature higher than 800°C, and a minimum of 600°C (see Fig. 4 and 5).

The temperature dependence of the composition of the exhaust gas of silicon dimethylamide was similar to that of titanium dimethylamide, as shown in Fig. 7. In the case of silicon amide, however, the deposition was found only at a temperature above 700°C. The difference between the behavior of silicon and titanium amides may be related to the stability of an intermediate of the reaction. The main fragments in the mass spectra of silicon and titanium complexes are summarized in Table II. In the case of the former, bis(dimethylamino)siliconium ion was observed at high abundance, but the analogous fragment ion of titanium was absent, suggesting the higher stability of low valent silicon species.

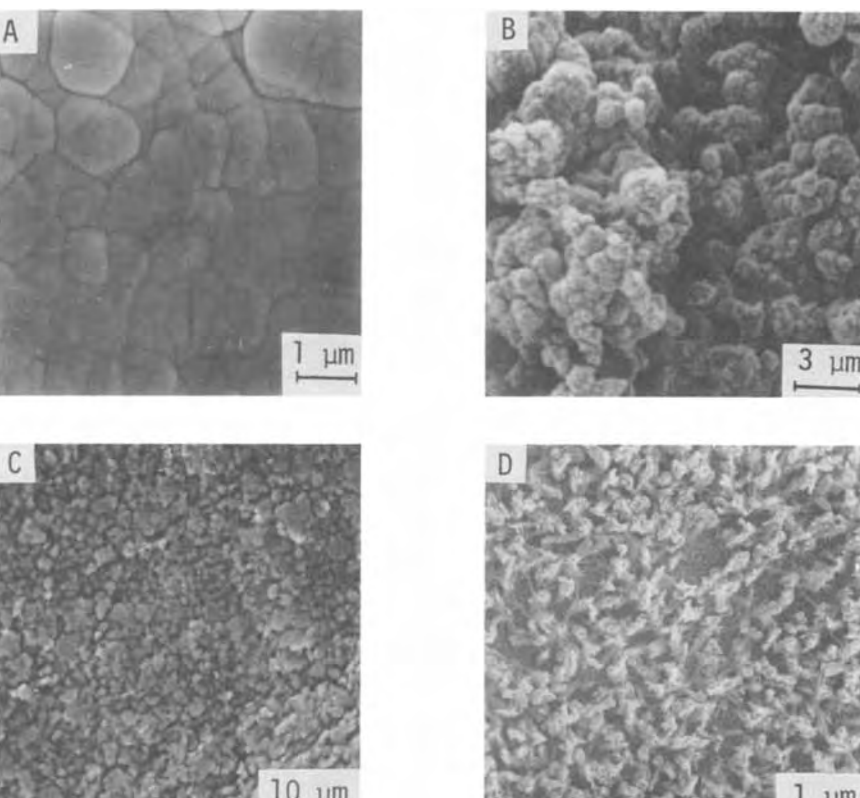

Fig. 8. TiN deposits formed on quartz. A, 300°C, low deposition; B, 300°C, high deposition; C, 800°C; D, 1000°C).

Properties of deposits.—In Fig. 8, the scanning electron micrographs of a typical titanium nitride deposited on a quartz substrate are shown. The grain sizes of the nitride obtained at a lower temperature were larger than those at a higher temperature. The x-ray diffraction pattern of low temperature deposits was quite similar to that of powdered titanium nitride except for considerable broadening, but the high temperature deposits had a larger intensity of (111) peak (see Fig. 2). Figure 8 demonstrates that the high temperature deposits are partly crystallized.

The deposition onto some other substrates such as graphite, copper, and stainless steel was also examined. The deposition rates on these substrates were found to be 0.25 mg/cm^2·min (about 15% yield for the amide introduced), thus being faster than on the quartz substrate (0.15 mg/cm^2·min). This difference might be due to the thermal conductivity of the substrates rather than their chemical nature such as a catalytic action of the surfaces. The adherence of the deposits to graphite and copper substrates seemed preferable to that of stainless steel and quartz. The deposits on the two latter substrates were often found to peel off. A cross section of the titanium nitride deposited on a quartz at 300°C is shown in Fig. 9. At the interface between the nitride and the surface of the quartz, no other layers were found, suggesting that the nitride did not react with quartz at the deposition condition. The color of the nitride was brownish or dark yellowish at low temperature but became yellowish at a high temperature, being similar to the appearance of a typical titanium nitride.

A qualitative electrical conductivity measurement (four terminal method) showed that the nitride had a resistivity 10^{-2} ohm·cm at room temperature, which is not in agreement with that of normal nitride (21.7 $\times$ 10^{-6} ohm·cm) (7), probably due to imperfect coatings, the contamination of some impurities (in particular at the grain boundaries), and the existence of fine cracks.

Table II. Mass spectra of $M(NMe_2)_4$ (M = Si and Ti)*

Fragment ion**	Intensity (%)	
	Si	Ti
$M(NMe_2)_4$	44.7	22.0

† Molecular ion of chlorotris(dimethylamino)silane involved and a fragment ion formed by its fragmentation.

Discussion

The deposition processes of metal nitrides from the corresponding amides can be expected to vary with temperature. At low temperature, the deposition was independent of the atmosphere, but at high temperature, the process was affected by the atmospheric gas, and the deposition was suppressed in argon. Mass spectral results of the exhaust gas indicated that the

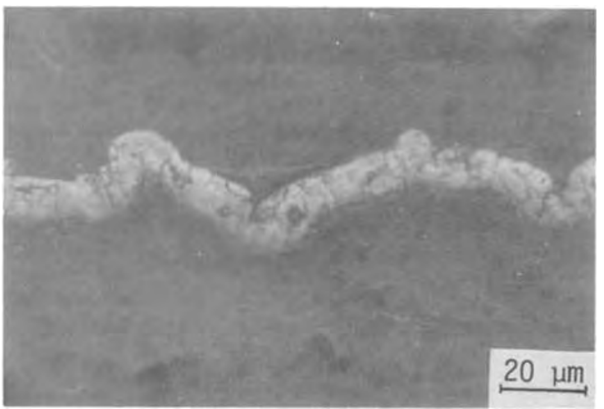

Fig. 9. Cross section of TiN films deposited on quartz at 300°C

low temperature decomposition gave mainly amine, but the high temperature caused a full degradation of complexes. Therefore, the following decomposition schemes might be assumed

$$\text{Low temperature: } M(NMe_2)_4 \rightarrow M(NMe_2)_3 \rightarrow M(NMe_2)_2 \rightrightarrows MN_x$$

$$\text{High temperature: } M(NMe_2)_4 \rightarrow \text{Metal species} + \left\{\begin{array}{l} H_2 \text{ and/or} \\ \text{N compounds} \end{array}\right. \nearrow MN_x$$

In the low temperature process, the amides may decompose through a successive elimination of amine fragments to give a low valent metal amide, followed by subsequent elimination of alkyl groups to yield the corresponding nitrides. A nitrogen atom originally bound to the metal may remain in the product without any separation through the reaction. Meanwhile, at high temperatures a complete degradation of the amides is preferable, followed by a recombination of metallic species formed with nitrogen compounds or by a further reduction with hydrogen, affording the nitrides. When argon is used in this reaction, it may dilute the concentration of nitrogen species or hydrogen to make the formation of the nitrides difficult. In a hydrogen atmosphere, splitting of the N-C bonds may be accelerated. These tentative schemes can explain the existence of two maxima in the temperature dependence of deposition. The optimum conditions were concluded to exist at approximately 400°C and at a temperature higher than 800°C in low and high temperature depositions, respectively.

At a medium temperature (about 600°C), the complete decomposition may take place, but this temperature is too low for nitride formation by subsequent recombination reactions. The amides of a main group elements may be so thermally stable that the successive reaction is difficult to occur. Therefore, they can decompose only at a high temperature to the elements. This selective element formation (the representative case was tin from tin dimethylamide) may be attributed to the easy reduction of the amides to zero valent species in comparison to the transition metals such as titanium.

In the case of titanium, zirconium, and niobium compounds, the corresponding nitrides which contain a small quantity of carbon were obtained. Although the product from the tantalum amide could not be identified, it is supposed that it is to be a kind of nitride. In spite of a larger ratio of carbon to nitrogen in the starting materials the selective formation of nitrides suggests that the nitrogen atoms originally linked are important for it, although the thermodynamic data also indicate the nitride formation to be easier than the carbide (8).

Unfortunately it was difficult to obtain a perfect homogeneous coating over the surface of the substrates even when the careful experiments were performed, probably due to very low thermal stability of the amides. However, this defect may be corrected in a procedure of reduced reaction pressure.

ABSTRACT

Liquidus and solidus data are presented for the 800°, 850°, and 900°C isotherms in the In-rich corner of the In-Ga-As phase diagram. A simple solution model gives excellent agreement with the solidus data, but describes the liquidus more poorly than desired.

The $In_xGa_{1-x}As$ mixed crystal system has attracted considerable interest for possible use in infrared optoelectronic devices. By choosing the appropriate InAs mole fraction x, a room temperature bandgap between 1.425 (0.87 μm) and 0.36 eV (3.4 μm) can be obtained. As part of a recent study of the liquid phase epitaxial (LPE) growth and characterization of this material (1), a number of liquidus and solidus measurements at 850°C in the In-rich corner of the In-Ga-As phase diagram were described. In the present work, we report liquidus and solidus data for the 800°, 850°, and 900°C isotherms extending all the way to the In-As binary cut.

Early work on the In-Ga-As phase diagram was reported by Stringfellow and Greene (2), who compared their calculations with some of Ewing's unpublished solidus data. Panish (3) measured liquidus temperatures between 700° and 1170°C for several solution compositions along the 0.25 and 0.55 atom fraction Ga concentration lines of the phase diagram. A number of liquidus and solidus points near 700°C were obtained by Antypas (3), who also derived a phase diagram for the system in fair agreement with his measurements. Additional liquidus and solidus points below 800°C in the In-rich corner were measured by Wu and Pearson (5). They obtained good agreement between their calculated phase diagram and measurements over a limited compositional range (1) by adopting a composition-dependent interaction parameter.

Panish and Ilegems (6) have compared the results of these workers and have suggested a new set of parameters in a phase diagram calculation for the In-Ga-As system. It was shown by Nahory *et al.* (1), that a small change in one of these parameters would permit excellent agreement between their own calculated and measured solidus isotherms at 850°C, although agreement for the liquidus was poorer than desired. As will be shown below, this conclusion holds true as well when the more extensive data reported here are included.

Experimental Procedure

The LPE apparatus consisted of a quartz reaction tube mounted in a horizontal furnace. The furnace temperature was electronically controlled to within ±0.1°C. Liquidus measurements and layer growth were carried out in a palladium purified, flowing H_2 ambient, using a graphite boat and slider assembly. Solution temperature measurements were made by means of a thermocouple situated just below the solution well in the boat.

Accurately preweighed 99.999+% pure Ga and In, and undoped polycrystalline InAs were used in order to obtain desired solution compositions. The Ga and In were cleaned in HCl, and the InAs in a 10% Br: methanol solution before being weighed. Growth was obtained on 111B (As) faces of GaAs substrates which had been sawed, lapped, cleaned, and degreased and finally etched in a 10% Br:methanol solution immediately before being loaded into the boat.

Liquidus temperatures were determined *in situ* by the method of direct, visual observation of the solutions just prior to epitaxial growth. Briefly, the method consists of first heating to dissolve and mix all components thoroughly, and then cooling the solution sufficiently to form an $In_xGa_{1-x}As$ crust. The liquidus temperature T_L is reached when, upon further heating, the last bit of this ternary solid crust is observed to dissolve in the ternary liquid. Details of the adaptation of the method to our apparatus have been described elsewhere (1).

The use of an open, flowing H_2 system resulted in a measurable loss of As by evaporation, which was observable by a reduction of T_L with time. The liquidus temperature of the original melt was readily determined, however, by measuring T_L as a function of time and extrapolating back to zero. The uncertainty in T_L introduced by this procedure was negligibly small at 800°C, but increased with T_L and arsenic concentration, becoming significant (~10°) at 900°C along the In-As cut. An absolute temperature calibration of the system was obtained at 960.8°C by observing the melting of silver in the same well usually used for the growth solutions.

After the determination of T_L for a particular solution, epitaxial growth of a layer several micrometers thick was carried out. The substrate was moved under the growth solution, cooled through several degrees at a rate between 0.25° and 1°C/min, and then slid out from under the solution again. It was possible to nucleate $In_xGa_{1-x}As$ directly on the GaAs 111B substrates with x as large as 0.15, although for x larger than about 0.08, such layers exhibited many defects as a result of the large lattice mismatch with the substrate.

Solidus compositions were determined by electron microprobe analysis for most of the grown layers. An electron beam accelerating potential of 15 keV was used, producing x-ray fluorescence to an effective depth of approximately 1.3 μm. Indium L-alpha, gallium L-alpha, and arsenic K-alpha x-ray intensities were measured simultaneously using wavelength dispersive spectrometers. X-ray intensity ratios were determined by direct comparison with stoichiometric GaAs and InAs crystal standards and converted to chemical composition with the aid of a computer program (7). At least ten spots, approximately 5 μm in diameter, were probed on each layer, and in each case the lateral variation of x was less than 3% of its average value.

Results and Discussion

The liquidus temperatures T_L and solidus compositions x are summarized in Tables I, II, and III for solutions with T_L in the vicinity of 800°, 850°, and 900°C,

respectively. The compositions of these solutions are specified by the atom fractions X^l of In, Ga, and As, which were measured to better than 1 part per thousand. The estimated uncertainty in T_L, which is attributable to the procedure used in correcting for As evaporation, is given in the tables. The solidus compositions are not given for every solution because in some cases a layer could not be grown on the GaAs substrate (*), and in other cases no microprobe analysis was performed (—). A number of the solutions listed in Table II were previously reported (1).

The solution compositions of Tables I, II, and III are also shown on the phase diagram of Fig. 1, by open circles, closed circles, and open squares, respectively. The solid curves are the 800°, 850°, and 900° isotherms obtained by interpolation between the data points. The curves agree well with Panish's (3) data where they intersect the $X^l_{Ga} = 0.25$ and 0.55 cuts and with the two 795°C data points of Wu and Pearson (5). Agreement with the InAs data of Liu and Peretti (8) (along the $X^l_{Ga} = 0$ cut) is also well within the experimental error. The solidus compositions are plotted against X^l_{Ga} for the three temperatures in Fig. 2.

As described above, a small change of one of the interaction parameters in the model suggested by Panish and Ilegems (6) permitted Nahory et al. (1), to obtain theoretical results at 850°C in excellent agreement with their own solidus measurements, although in rather poor agreement with their liquidus data. This model treats the $In_xGa_{1-x}As$ solid as a strictly

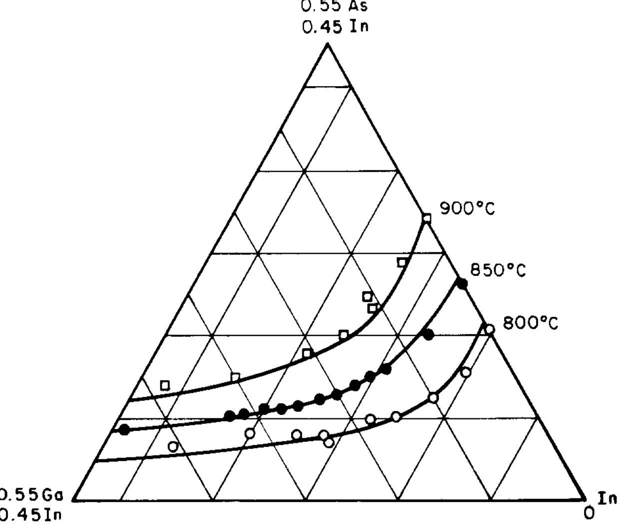

Fig. 1. Liquidus isotherms at 800° (open circles), 850° (solid circles), and 900°C (open squares) in the In-rich corner of the In-Ga-As system. The points correspond to measured solutions and the curves are interpolated for the three temperatures.

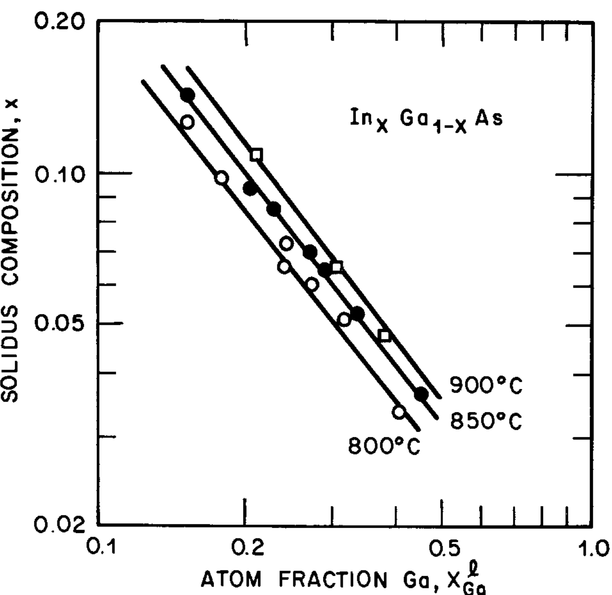

Fig. 2. Solidus isotherms at 800° (open circles), 850° (solid circles), and 900°C (open squares) as functions of X^l_{Ga} in the In-Ga-As system. The solid curves have been calculated to fit the data points.

regular solution of the binary compounds InAs and GaAs, and the liquid as a simple solution of In, Ga, and As. Details of the calculation are given in the Appendix. Present attempts to optimize all the interaction parameters of this model to simultaneously fit the experimental liquidus and solidus isotherms of Fig. 1 and 2 were not successful, indicating that the model is a good approximation but not quite adequate. The best over-all fit was obtained using the parameters given in Table IV, which are the same as those used by Nahory *et al.* (1), and differ from those of Panish and Ilegems (6) only in the value of $\beta_{InAs\text{-}GaAs}$, which was increased from 3000 to 3450 cal/mole. The computed solidus curves, which are the nearly straight lines drawn in Fig. 2, are in excellent agreement with the data at all three temperatures, as can be readily seen from the figure.

For the liquidus data, a comparison of the measured curves (solid) with those calculated (dashed) using the parameters of Table IV is shown in Fig. 3. The solidus curves for $x = 0.05$, 0.10, and 0.15 (coincident

measured and calculated) have also been replotted in Fig. 3 from the solidus isotherms of Fig. 2. Agreement between experiment and theory for the liquidus is good along the In-As cut, but the curves differ by as much as 20°C elsewhere. It would appear that a more complex model than the present simple solution treatment is required.

APPENDIX

Phase Diagram Calculation

We follow Panish and Ilegems (6) in treating the In-Ga-As system. The $In_xGa_{1-x}As$ solid is considered to be a strictly regular solution of the binary compounds InAs and GaAs, and the liquid to be a simple solution containing In, Ga, and As mole fractions X^l_{In}, X^l_{Ga}, and X^l_{As}. Then

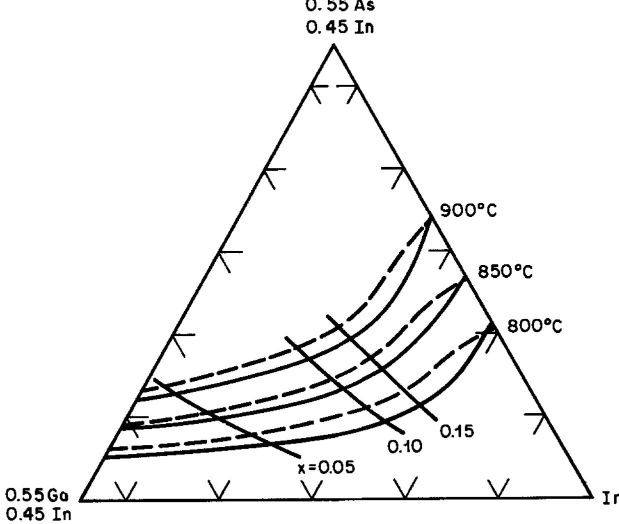

Fig. 3. Comparison of experimental liquidus isotherms from Fig. 1 (solid) with isotherms calculated using the model described in the text and the parameters of Table IV (dashed). The solidus curves for x = 0.05, 0.10, and 0.15 are replotted from Fig. 2.

$$\gamma^s_{GaAs}(1-x) = \frac{4\gamma^l_{Ga}\gamma^l_{As}}{\gamma^{sl}_{Ga}\gamma^{sl}_{As}} X^l_{Ga}X^l_{As} \exp\left[\frac{\Delta S^F_{GaAs}}{RT}(T^F_{GaAs}-T)\right] \quad [A\text{-}1]$$

and

$$\gamma^s_{InAs}x = \frac{4\gamma^l_{In}\gamma^l_{As}}{\gamma^{sl}_{In}\gamma^{sl}_{As}} X^l_{In}X^l_{As} \exp\left[\frac{\Delta S^F_{InAs}}{RT}(T^F_{InAs}-T)\right] \quad [A\text{-}2]$$

where

$$X^l_{In} + X^l_{Ga} + X^l_{As} = 1 \quad [A\text{-}3]$$

The γ^l and γ^s are activity coefficients of the element in the liquid or the binary compound in the solid, respectively, the superscript sl signifies the stoichiometric liquid, ΔS^F is the entropy of fusion and T^F the fusion temperature of the binary solid.

The activity coefficients for the solid are related to the interaction parameter β by

$$RT \ln \gamma^s_{GaAs} = \beta_{InAs\text{-}GaAs}x^2 \quad [A\text{-}4]$$

and

$$RT \ln \gamma^s_{InAs} = \beta_{InAs\text{-}GaAs}(1-x)^2 \quad [A\text{-}5]$$

The activity coefficients for the liquid are related to the interaction parameters α by

$$RT \ln \gamma^l_{Ga} = \alpha^l_{Ga\text{-}As}(X^l_{As})^2 + \alpha^l_{Ga\text{-}In}(X^l_{In})^2 + (\alpha^l_{Ga\text{-}As} + \alpha^l_{Ga\text{-}In} - \alpha^l_{In\text{-}As})X^l_{In}X^l_{As} \quad [A\text{-}6]$$

$$RT \ln \gamma^l_{In} = \alpha^l_{In\text{-}As}(X^l_{As})^2 + \alpha^l_{Ga\text{-}In}(X^l_{Ga})^2 + (\alpha^l_{In\text{-}As} + \alpha^l_{Ga\text{-}In} - \alpha^l_{Ga\text{-}As})X^l_{Ga}X^l_{As} \quad [A\text{-}7]$$

$$RT \ln \gamma^l_{As} = \alpha^l_{Ga\text{-}As}(X^l_{Ga})^2 + \alpha^l_{In\text{-}As}(X^l_{In})^2 + (\alpha^l_{Ga\text{-}As} + \alpha^l_{In\text{-}As} - \alpha^l_{Ga\text{-}In})X^l_{Ga}X^l_{In} \quad [A\text{-}8]$$

An iterative computer program is used to solve for the equilibrium liquid and solid compositions at a given temperature $T = T_L$ using Eq. [A-1]-[A-8]. The input parameters T^F, ΔS^F, α, and β used in the present work are given in Table IV. The simple solution approximation for the liquid requires that the α's be independent of composition, although they are functions of temperature. The limitation that the solid be a strictly regular solution requires that the interaction parameter β be a constant.

The Deformation of Anodic Films during the Plasma Anodization of Al-Si Structures

J. J. H. Reche[1] and D. L. Pulfrey

Electrical Engineering Department, The University of British Columbia, Vancouver V6T 1W5, Canada

Although the insulator/semiconductor combination of SiO_2/Si has proved very successful in semiconductor device technology, other combinations are of interest for particular applications. For example, Al_2O_3 on Si would appear to be of interest in devices requiring good radiation resistance (1), low mobility of incorporated impurities, *e.g.*, Na^+ (2), low surface state density (3), and increased oxide dielectric constant (~8 *vs.* ~4). Memory action in metal Al_2O_3-Si FET's has also been observed (4). The Al_2O_3 film can be deposited in a variety of ways, *e.g.*, pyrohydrolysis of $AlCl_3$ (4), decomposition of Al-alkoxides (5), pyrolytic deposition from AlB_3 (6), rf sputtering (7), and

plasma anodization (1, 3). The latter method is considered here and results are presented indicating that severe deformation of the anodic oxide film can occur during anodization.

Anodization in an rf oxygen plasma was carried out utilizing the apparatus described in Ref. 8. The substrates used were (1-1-1) p-type silicon, 3-5 ohm-cm, and were etched in buffered HF and dried in nitrogen immediately prior to insertion in the vacuum chamber. The vacuum system had a liquid nitrogen trap and was operated at a base pressure of about 10^{-5} Torr. 99.999% grade aluminum was thermally evaporated from tungsten coil filaments onto the unheated substrates. The film deposition rate was approximately 100 Å sec^{-1} and the mass deposited was monitored by a quartz crystal oscillator used as a microbalance. Film thicknesses were checked using a Sloan "angstrometer," Model M-100.

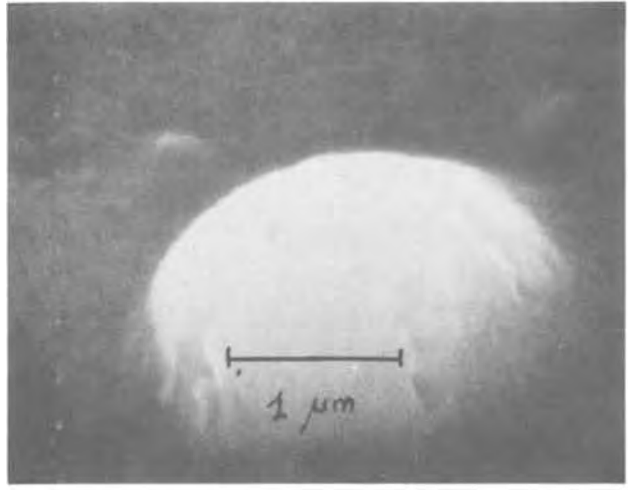
The data presented in this note refer to two samples anodized at a constant current of 16 $mAcm^{-2}$. Sample A had an aluminum film of initial thickness 450Å and was anodized to slightly past the point at which *in situ* reflectance measurements (9) indicated, assuming homogeneous anodization, all the metal had been converted to oxide. Sample B's initial aluminum film thickness was 1650Å and this was anodized until the Al_2O_3 was approximately 1000Å thick.

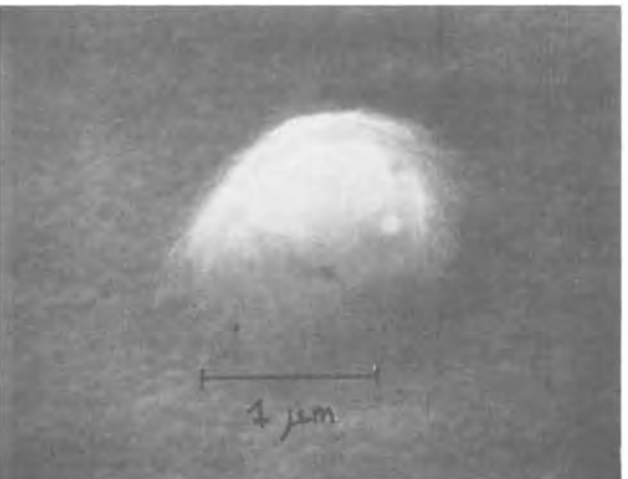
Figure 1 shows a scanning electron microscope (SEM) micrograph and electron microprobe results for a section of the anodic film on sample A. Small hillocks are clearly visible on the two topographical photographs and these can be identified in Fig. 1 b (ii) as aluminum-rich regions. The hillocks are not thought to be related to structure in the as-deposited aluminum film as a SEM micrograph of an unanodized sample, deposited at the same time as sample A, revealed only very fine structure with any small visible features being spatially unrelated to the hillocks shown in Fig. 1.

Figure 2 shows SEM micrographs of a variety of hillocks and extrusions resulting from the anodization of sample B. Electron microprobe data from the same portion of sample B are shown in the four photos of Fig. 3. The four extrusions shown are clearly of a high aluminum content, yet possessing little or no oxygen or silicon. The dark vertical trails on the silicon x-ray image recording are the result of shadowing effects due to the low angle of the x-rays emitted by the silicon.

From the data presented it would appear that during anodization migration of aluminum in the metal film occurs and accumulation at sites of the order 10-20 μm apart develops. If anodization is continued for a long enough time (which will only be permitted by a thick enough metal film) these accumulations or hillocks of aluminum actually rupture the overlying anodic film and extrude.

The cause of the mass transport is unlikely to be electromigration (10), a source of failure in some IC's using aluminum interconnects and current densities $>10^6$ $A\text{-}cm^{-2}$, as the mass transport is in the direction of electron current flow (*i.e.*, opposite to that observed here) and, furthermore, the current densities are not high enough. *E.g.*, even if all the anodization current is assumed to flow through the hillocks, the current density would only be of the order of 10 $A\text{-}cm^{-2}$. A more probable cause is the presence of a film with high compressive stresses (the aluminum) under another film with lower diffusion rates (the aluminum oxide).





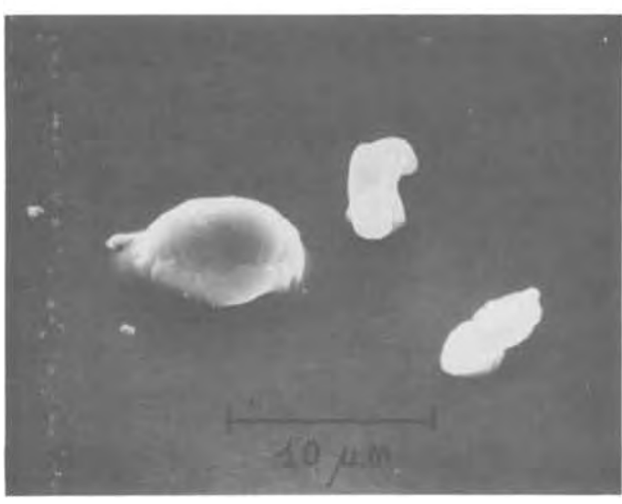


Fig. 2. Scanning electron microscope micrographs showing hillock formation and aluminum extrusions in sample B

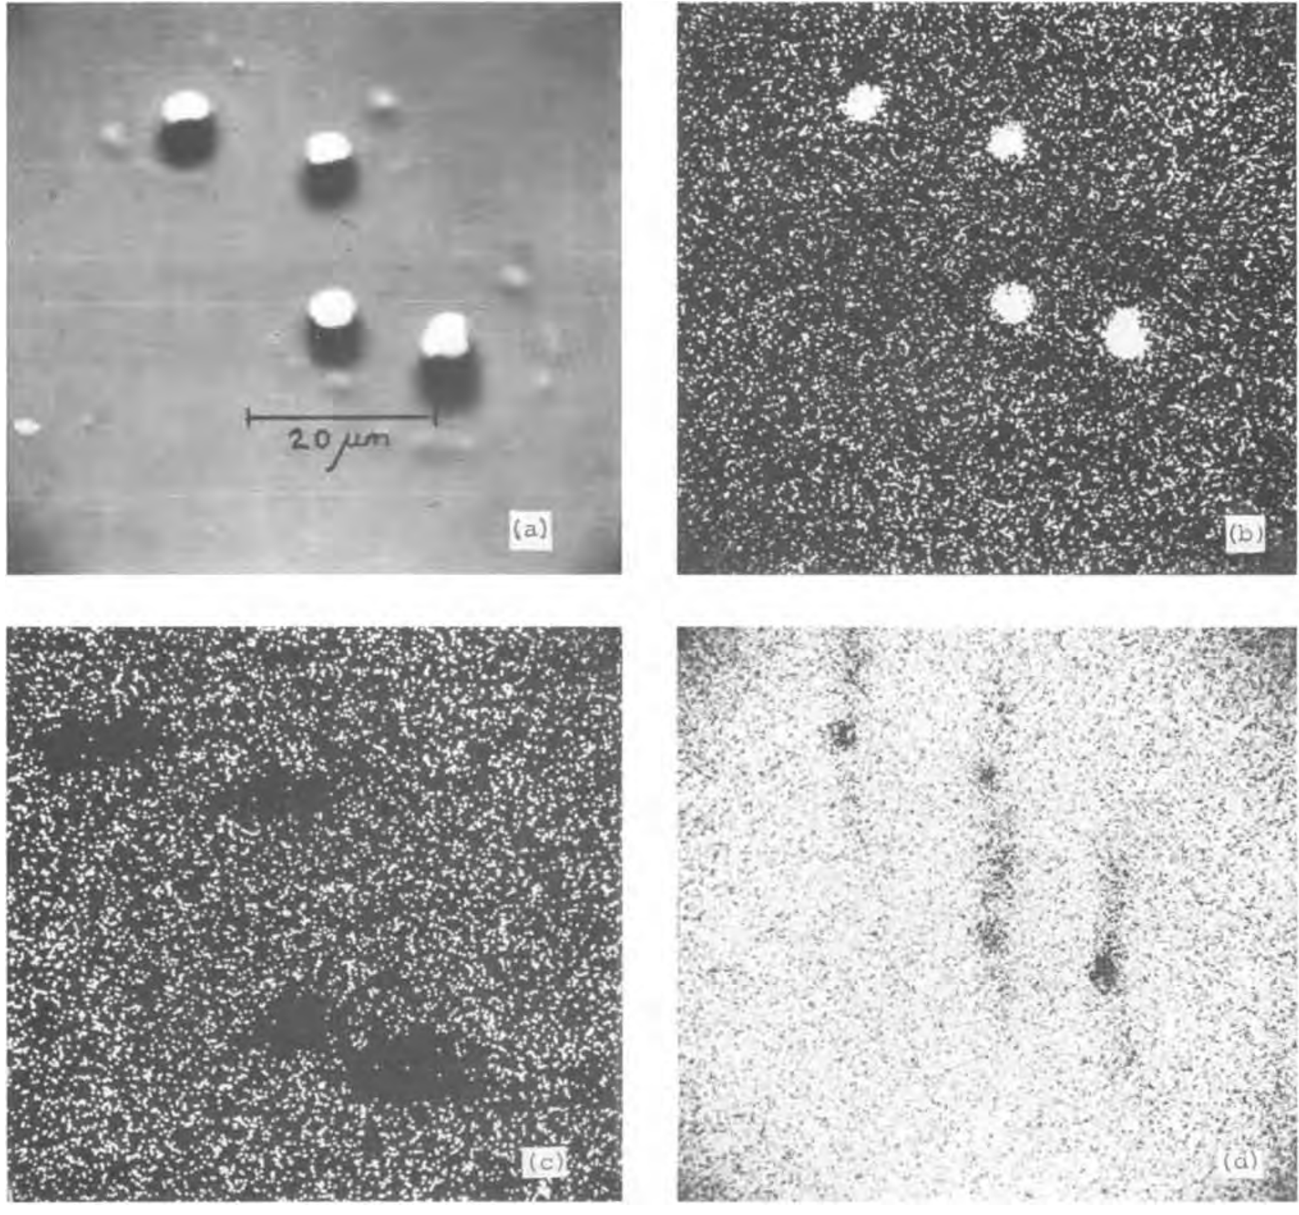

Fig. 3. Electron microprobe analysis of region of sample B: (a) backscattered electron image (topography); (b) aluminum x-ray image; (c) oxygen x-ray image; (d) silicon x-ray image.

The mechanism of stress relief is shown schematically in Fig. 4 and is similar to that treated theoretically by Chaudhari (11). In the case of compressive biaxial stress in the aluminum, the film will seek relief through the path of least resistance, *i.e.*, push the covering anodic film upwards. Although the oxide will accommodate some deformation by manifesting itself in hillocks, a crack will eventually occur, thus opening a path for stress relief by extrusion of the aluminum toward the free surface.

The presence of biaxial stress in the aluminum film could be due to growth defects, differential thermal expansion, temperature gradients, tensile stresses in the aluminum oxide film, and electrical stresses. In aluminum films internal stresses originating during vapor deposition have been shown (12) to cause hillocks, but this type of deformation does not seem relevant in the present case as SEM micrographs of unanodized aluminum films revealed no hillocks and, furthermore, annealing of the aluminum film prior to anodization did not prevent aluminum oxide film deformation on subsequent anodization. Stress analysis of d-c plasma-grown aluminum oxide (13) indicates the presence of stresses which are most probably tensile as the film apparently contracts in the presence of an anodizing field. In the present case evidence of tensile stresses in the anodic film was provided by the almost complete removal of the film if the anodization field was suddenly removed when either the current was high or the oxide was thick. This can be contrasted to silicon oxide films which appear (8) to relieve stress by forming "bubbles." In the present work no film deformation was ever observed to develop after anodization.

In conclusion it would apear that the hillock and film rupture phenomena are well explained by Chaudhari's (11) model, and that the biaxial compressive forces in the aluminum film result from a combination of some of the factors discussed above, with the presence of an anodizing field being a necessary ingredient.

Microscopic Mechanisms of Growth of Dark Line Defects in Double Heterostructure Lasers

J. A. Van Vechten*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

Petroff and co-workers have studied the growth of dark line defects, DLD's, in GaAs-GaAlAs double heterostructure lasers (1). They claim to have established that the DLD dislocation network begins to grow in the p-alloy layer a variable distance from the active layer, grows only under recombination, and gradually propagates into the GaAs active layer via a climb mechanism. Although some still dispute these claims, the author accepts them. If one does accept them, then one must conclude that the more elementary defects which coalesce to form the DLD dislocation network must be nonradiative recombination centers, NRC's, acting via a configuration coordinate mechanism so as to exhibit recombination enhanced diffusion (2). One must further conclude either that the NRC's are much more prevalent in the alloy than in the binary, or that the concentration in the binary is not sufficient to degrade the device. The propagation of the NRC's toward the active layer should then result from a gradient in chemical composition. [If the rate of recombination in the p-alloy region within a diffusion length of the active layer is at least 0.1% that in the active layer in the devices studied, then the expected rate of enhanced diffusion is adequate. It seems reasonable that such a rate should obtain in this region as a result of the impurity absorption of light from spontaneous emission and the tail of the lasing mode, the passage of Auger electrons from the active region, and the imperfect reflection of electrons at the actual p-p junction. This hypothesis is supported by the observation that the rate of degradation continues to increase above the lasing threshold (3).]

To test these conclusions the existence curve of GaAs, Fig. 1, and the concentration of the various native defects in GaAs and $Ga_{0.65}Al_{0.35}As$ were calculated using the author's prescription for estimating the energies of formation of vacancies and antisite defects in zincblende type semiconductors (4, 5). (See Table I.) The equilibrium concentrations of the various elementary native defects in the three layers of the p-p-n devices for 800°C growth in contact with the appropriate liquids (6-9) are listed in Table II. For the alloy layers, the dielectric theory of the electronic structure of alloys (10) and the defect parameters estimated previously (4, 5) were used. The defect ionization energies were assumed to be the same in the alloy

Table I. Theoretically predicted enthalpies and entropies of various reactions involved in the growth of the actual imperfect crystal (4, 5, 9). ΔH_{cv} and ΔS_{cv} denote the enthalpy and entropy of the fundamental bandgap and are fitted to the observed temperature dependence of that gap (5)

Reaction	ΔH, eV	ΔS, k
$Ga(l) = Ga_{GA}^{x} + V_{As}^{x}$	1.827	−2.12
$As(l) = V_{GA}^{x} + As_{As}^{x}$	1.632	−3.36
$O = V_{GA}^{x} + V_{As}^{x}$	4.66	2.20

Key words: GaAs, laser degradation, dark line defects, III-V nonstoichiometry.

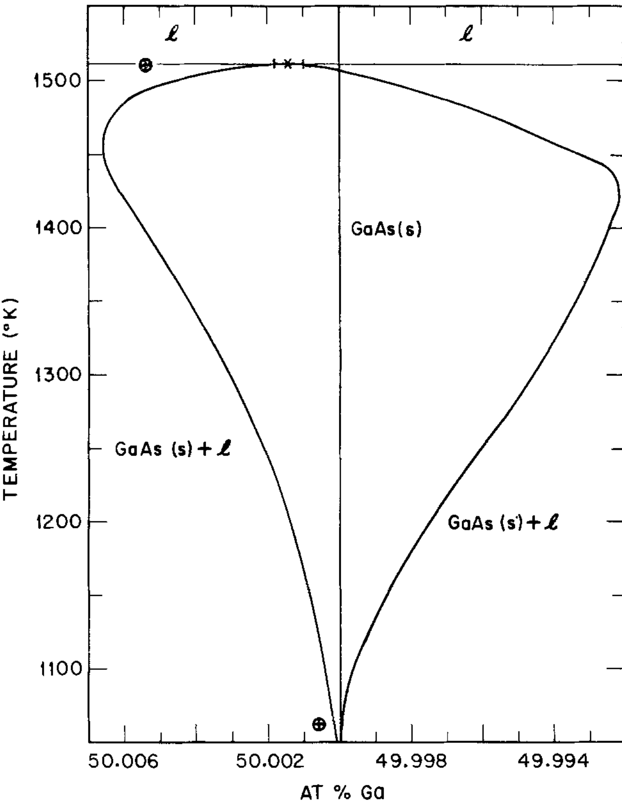

Fig. 1. Predicted existence curve for GaAs and one experimental datum due to Kim (14), x, at the congruent melting point. Also shown are the results of the stoichiometry calculation of Logan and Hurle (15) at the congruent melting point and at 800°C, ⊕.

and the binary and that for V_{As} in GaAs was taken to be the same fraction of the gap as was assumed for V_P in GaP (5). The ionization energies for V_{Ga} were slightly adjusted from the corresponding estimate to match the radiation-induced defect having levels denoted E3 and H1 by Lang and Kimerling (11).

The present theory was previously used (5) to calculate an existence curve for GaP which was in good agreement with experiment (12). It also offered an explanation for the observed dependence of the concentration of native NRC's on growth conditions (13). The theory indicated the dominant NRC to be a complex, $V_{Ga}^-P_{Ga}^{+2}V_{Ga}^-$, formed during cooling from the equilibrium distribution of point defects present during growth.

The existence curve for GaAs, Fig. 1, calculated here using the liquid phase activities of Thurmond (8) and heats of formation of Ilegems and Panish (9), may be compared against one reliable measurement at the congruent melting point (14). The calculated composition at that point is 50.0013% Ga in agreement with Kim's value of 50.0014 ± 0.0005% Ga for float zone material. Kim's one other measurement, on solution-grown (750°-950°C) material, indicates the material to be much more Ga-rich, 50.0077%, than the calculated

Table II. Calculated equilibrium concentrations of defects in the three layers of the double heterostructure layers studied by Petroff *et al.* (1). The parameters in Table I and 800°C LPE growth (7, 9) are assumed

	n-GaAlAs × 10^{16}/cm^3	p-GaAs × 10^{16}/cm^3	p-GaAlAs × 10^{16}/cm^3
Ge_{As}^-	—	120	100
Ge_{Ga}^+	—	20	1
Te_{As}^+	1000	—	—
$V_{Ga,Al}^-$	0.2	0.01	0.01
V_{As}^+	0.8	2.2	19
As_{Ga}^{+2}	2×10^{-5}	0.08	0.01
Ga_{As}^{-2}	257	9.4	0.46
Al_{As}^{-2}	235	—	0.42

equilibrium value. The author suspects that the material was not at its equilibrium composition due to the trapping of Ga-rich liquid inclusions during the growth of that material. The one other calculation of the existence curve of GaAs, that of Logan and Hurle (15), predicted the equilibrium composition at 800°C to be very close to that calculated here (Fig. 1). Indeed, it would be very difficult to construct any thermodynamic model for GaAs which predicts a large deviation from stoichiometry at such a low temperature. However, Logan and Hurle's calculation for the congruent melting point is substantially more Ga-rich than either the present calculation or Kim's experiment (see Fig. 1).

As the crystal cools, the reaction

$$Al_{Al}^x + V_{As}^+ = V_{Al}^- + Al_{As}^{-2} + 4e^+ \quad [1]$$

and the corresponding Ga_{Ga} reaction will occur as the V_{As}'s migrate to the nearest neighbor sites. Therefore, the number of $V_{As}^+Al_{As}^{-2}V_{As}^+$ complexes which may form as the material cools is not limited by the number of Al_{As} present during growth but may be limited by the number of V_{As} present. Assuming, as in Ref. (5), that these complexes are the primary fate of the native defects formed at growth, we estimate their concentration for equilibrium growth to be 5×10^{15} cm^{-3} in the n-alloy, 1.1×10^{16} in the p-GaAs active region, and 7×10^{16} in the p-alloy, where they are about evenly divided between $V_{As}^+Al_{As}^{-2}V_{As}^+$ and $V_{As}^+Ga_{As}^{-2}V_{As}^+$.

Just as $V_{Ga}^-P_{Ga}^{+2}V_{Ga}^-$ and not $V_P^+Ga_P^{-2}V_P^+$ is the dominant NRC in GaP, the author believes $V_{As}^+Al_{As}^{-2}V_{As}^+$ and not $V_{As}^+Ga_{As}^{-2}V_{As}^+$ nor $V_{Ga}^-As_{Ga}^{+2}V_{Ga}^-$ will be the dominant NRC in this case, at least for recombination via the configuration coordinate mechanism. (They would seem about equally effective for an Auger mechanism, but this mechanism could not produce RED and so would not cause the DLD dislocation network to grow.) This follows from the fact that Al, like P, is much lighter than Ga and As and so should experience a larger attempt frequency, transition matrix element, and tunneling probability in the various recombination modes. The lighter mass should also lead to a lower barrier for migration.

Therefore, in the equilibrium growing condition model developed so far, the recombination enhanced diffusion of NRC's should begin in the p-alloy near the active region because that is where the requisite native defects will occur during growth. Assuming that the $V_{As}^+Al_{As}^{-2}V_{As}^+$ NRC's tend toward the threading dislocation due to its strain field, we see that the resulting dislocation network will propagate by climb (atomic diffusion) as the Al_{As}^{-2} atoms are injected into the dislocation and pipe-diffuse toward the active layer under the gradient in composition. This pipe-diffusion of Al will eventually produce $V_{As}^+Al_{As}^{-2}V_{As}^+$ NRC's in the active layer so that the DLD will propagate there.

The shortcoming of this equilibrium model is that the calculated concentration of mobile NRC's in the p-alloy layer, 3.5×10^{16} cm^{-3}, is about two orders of magnitude smaller than the empirically estimated concentration (1). Indeed, transient capacitance spectroscopy measurements of similar alloy material show large concentrations of nonradiative deep traps which vary in a manner not easily describable in terms of equilibrium growth thermodynamics (16).

Two alternate explanations for the growth of DLD's are known to the author. Woolhouse (17) proposed that they are produced by electromigration of atoms along the dislocation in opposite directions in n- and p-type material. This explanation has the attraction of not requiring any large concentration of grown-in defects and does not address the problem of slow degradation in the absence of threading dislocations. This model would seem to require that the DLD grow at the p-n junction and not in the p-alloy layer some variable distance from the active layer, as is reported (1). The

other proposal made by Petroff and Hartman (1) is that nonradiative recombination at the threading dislocation produces vacancies which cause the DLD network to grow, and interstitials which pipe-diffuse away along the threading dislocation. This proposal does not explain the location of the DLD network or the slow degradation in the absence of a threading dislocation and seems to be inconsistent with the highly convoluted appearance of the network that does grow (18). Thus, both these alternate explanations seem to be irreconcilable with the reported observations (1).

The conclusion that alloy material of these layers is, in fact, not grown close to its equilibrium stoichiometry is supported by the observation of Kim (14) on material solution-grown at similar temperatures and rates. If the laser material is as metal-rich as the solution-grown samples Kim measured, the concentration of V_{As}^{+} and Al_{As}^{-2} present could easily be large enough to produce sufficient NRC's to account for the subsequent growth of the DLD.

Added Note

Petroff and Hartman (1) concluded that the DLD were vacancy-type dislocation networks because they found small dislocation loops lying within the network to exhibit vacancy-type contrast in the electron microscope. After submission of this paper, Hutchinson *et al.* (19) published the results of a more extensive electron microscopy study of similar lasers and concluded that the dislocation loops of the DLD were mainly interstitial in character. The lasers observed in this latter study differed from those examined by Petroff *et al.* in that they contained 5% Al in the active layer while Petroff's were pure GaAs.

On the basis of the present model of the degradation, one might expect the DLD to originate in the active layer of the 5% Al lasers rather than in the p-alloy layer. Hutchinson *et al.* (19) tentatively concluded that this was the case with their samples. Reconsideration of pure GaAs lasers reaffirms the conclusion that the DLD's originate in the p-alloy layer (20).[2]

However, it now seems likely that the DLD dislocation loops are mainly interstitial in character in both types. Therefore, it is appropriate to point out that the NRC proposed here could cause either an interstitial or a vacancy-type network to grow depending upon whether As (*i.e.*, V_{As}^{+}) or Al pipe-diffuses more rapidly down the threading dislocation. This is easily seen if we assume the threading dislocation to be an edge dislocation of excess metal atoms. [The true nature of the threading dislocation has not yet been determined (20), but this simplifying assumption is consistent with Kim's observation of a gross excess of Ga in GaAs solution-grown at similar rates and temperatures (14).] If the Al atom from the $V_{As}Al_{As}V_{As}$ complex pipe-diffuses away, then, as assumed above, the remaining V_{As}'s cause a vacancy-type loop to grow by eating away at the extra plane of metal atoms. If the V_{As} pipe-diffuses away, *i.e.*, if As pipe-diffuses in, then the remaining Al_{As} causes an interstitial loop to grow because these atoms would add to the extra plane of metal atoms. From the results of Hutchinson *et al.* (19), one may conclude that the latter is the dominant process.

[2] G. M. Blom, in a private communication, has observed DLD networks originating in the n-alloy layer as well as in the p-alloy layer, but not in a pure GaAs active layer. As long as the material is not grown near equilibrium, this does not contradict the present conclusions about the equilibrium.

The author would also like to note that Van der Sande and Peters have observed (21) defect clusters in LEC GaAs having the same length, width, orientation, and concentration as that here predicted for the $V_{As}Ga_{As}V_{As}$ complexes under LEC conditions, *i.e.*, at the congruent melting point.

Correspondence between Nonradiative Dark Spots, Microplasma Emissions, and Dislocation Pits in GaP:N Light-Emitting Diodes

Takashi Kajimura, Kunio Aiki, and Jun-ichi Umeda

Central Research Laboratory, Hitachi, Limited, Kokubunji, Tokyo 185, Japan

Though many investigations have been carried out to relate the luminescence efficiency of light-emitting diodes (LED's) to crystal imperfections in melt-grown crystals and epitaxially grown wafers (1-5), little work has been done on completed LED's, which seems to give more direct information on the diode performance. In this paper, we report on a clear one to one correspondence between nonradiative dark spots under forward bias, microplasma emissions under reverse bias, and dislocation etch pits in GaP:N LED's.

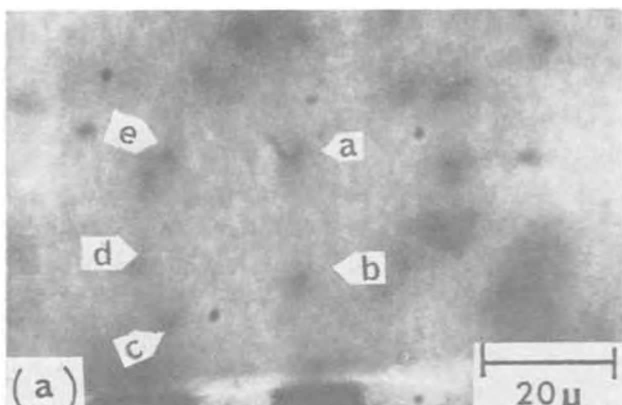
Experimental

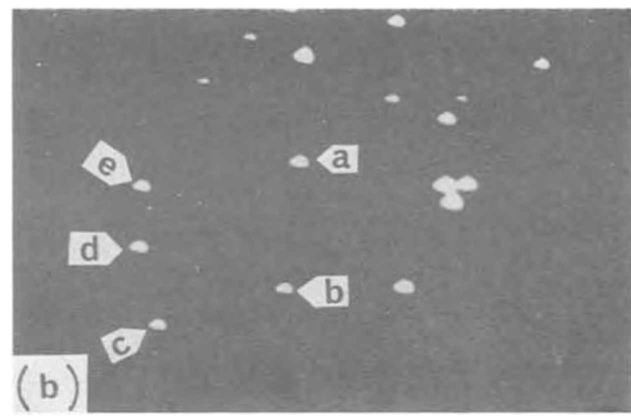
Diodes investigated in this experiment were fabricated from S- and N-doped liquid-phase epitaxial (LPE) wafers grown on LEC substrates. The p-n junctions were made both by Zn diffusion into the wafer and by LPE growth of a Zn- and N-doped layer upon the wafer. Electroluminescence in the forward biased diode was observed at a d-c current density of 8 A/cm^2. Light emission in the reverse biased diode was observed by applying current pulses in order to minimize the heating effect. The amplitude of each current pulse was 50 A/cm^2. The duration and repetition rate were $\sim$8 μsec and $\sim$25 kHz, respectively. Black wax was applied to each side face of the diode chip to avoid internal scattering of light which obscures the image. An etch pit study was performed using AB etchant (6) for the {111}P surface. For the {100} surface, thermal etching was used.

Key words: dislocation, electroluminescence, microplasma, III-V compounds, LED, GaP.

Results

A light emission image in the forward biased diode, which was made by Zn diffusion into n-LPE layer grown on {111}P LEC substrate, is shown in Fig. 1(a). Nonradiative dark spots with a radius of 2-3μ, which is the same order of magnitude as the diffusion lengths of carriers in the GaP LPE layer, and with a density of $\sim 5 \times 10^5$/cm^2 are seen in the picture. In the case of reverse bias, emission spots originating from the microplasma were observed. Figure 1(b) shows the reverse biased image of the diode. The microplasma emissions appear at positions where the nonradiative dark spots did (see a-e in Fig. 1). The etch pit pattern of the surface of the diode is shown in Fig. 1(c). The etch pits observed are D-pits (2) which are caused by dislocations in the crystal. In Fig. 1(c) D-pits appear where the dark spots (and microplasma emissions) did. These results show that the nonradiative dark spots were caused by the dislocations in the LPE layer, and the emission spots due to microplasma appear at positions where the dislocations cross the p-n junction. Dark spots appeared at the positions where D-pits did without exception in diodes investigated. There are a few positions where microplasma emissions did not appear in Fig. 1. This shows that the breakdown voltages





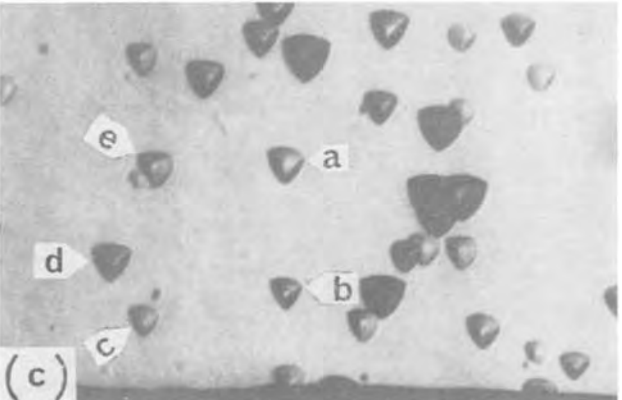


Fig. 1. (a). An electroluminescence image of a GaP:N LED in the forward bias. The density of the nonradiative dark spots is 5×10^5/cm^2. Typical nonradiative dark spots are shown by a $\sim$ e. (Comparatively small and black spots in the figure are due to dusts in the optical system and should be distinguished from the inherent nonradiative spots.) (b). A reverse biased image of the diode. Microplasma emissions appear at the positions of the dark spots. (c) The etch pit pattern of the diode surface.

at the positions are higher than the ones at the other positions.

Rozgonyi *et al.* (1, 3) reported that dislocations, by themselves, are of secondary importance to the luminescence efficiency and decorated dislocations, which only occur when there is a high density of S-pits (2, 3), can be a significant factor in GaP. However, Fig. 1 shows that dislocations are important to the luminescence efficiency of GaP LED's, even if there is a low density of S-pits.

Similar results were obtained in diodes made by double layer growth. There were, however, some positions where dark spots (and emission spots due to microplasma) appeared, but no etch pits appeared in these diodes. This shows that some of the dislocations in the n-layer do not propagate into the p-LPE layer in LPE growth. From the photoluminescence image of the {110} cleavage face of a LPE layer made by the double layer growth, it was found that some of the dark lines which are caused by dislocations and extend from the substrate towards the LPE surface stopped at the p-n junction and did not propagate into the p-LPE layer. These dislocations may be pinned by some kinds of crystal imperfections (for example, precipitates).

The density of the dislocation in the LPE layer varied 2×10^4-$7 \times 10^5/cm^2$ from wafer to wafer. From the radius and the density of the nonradiative dark spots, it was found that the dislocations lower the luminescence efficiency of the diode by 0.3-20%. The same results were also obtained for the {100} wafers.

Fabrication Techniques for Tungsten Cat Whisker Infrared Antennas

Bor-long Twu

Department of Electrical Engineering and Computer Sciences, Electronics Research Laboratory, University of California, Berkeley, California 94720

Metal-insulator-metal tungsten cat whisker point-contact diodes have been used as mixers in the far infrared, infrared, and near infrared regions (1). At 10.6μ wavelength the ability of the device to detect radiation arises from the diode's nonlinear current-voltage characteristic (2). In work to be reported elsewhere, we have described the antenna properties at 10.6μ wavelength in some detail (3). A particularly interesting finding is that the effective antenna length is not determined by the over-all length of the tungsten wire, but rather by the length of the etched away portion which is produced in the electrochemical etching process. In general, the antenna length affects the number of lobes, the positions of maxima and minima, and the directivity in the antenna pattern. In this note we report a technique by means of which conical antennas with different lengths in the range between ~40 and ~170μ can be fabricated in a reproducible way.

The electrochemical etching technique that we have used is already known to many workers in the field, but to our knowledge it has not been published, and therefore it will be summarized here. A 25μ diameter tungsten wire, after being soldered to a BNC connector, is dipped into NaOH solution to a depth of approximately 0.5 cm to act as anode. A sheet of pure platinum is used as cathode. The etching process occurs when a direct current is passed between the tungsten wire and the platinum sheet. The tungsten wire is continuously etched away near the solution surface until the weight of the immersed part causes it to break and drop off, leaving a sharp conical tip. An electrical circuit is designed to turn off the etching current as soon as the immersed wire drops off, in order to prevent further etching and consequent dulling of the tip. Typically, it takes from ~30 sec to a few minutes to etch 25μ tungsten wires. A similar technique involving alternating current and KOH solution is also known (4).

The etching apparatus consists of the etching cell, controlling circuit and power supply, tungsten wire holder mounted on a vertical micropositioner for controlling the tungsten wire position as it is dipped into the etching solution, an inclining stereomicroscope of 90X magnification for viewing the etching process, and a compound microscope of 40X, 100X, 400X, and 1000X different magnifications for examining etched conical tips.

Micrographs of 25μ tungsten wires with tips ranging in length l from 40 to 170μ are shown in Fig. 1 and Fig. 2. These tips were produced by using etching solutions with different concentrations ranging from 0.75 to 0.1875*N*. It is interesting that the final length of the conical tip can be controlled effectively within ±15% accuracy by varying the concentration. To etch 75, 100, and 125μ wires, more concentrated solutions are needed. We have not attempted to produce tips with controllable lengths on these thicker wires, although it appears to be possible.

Especially for shorter tips, unexpected irregular shapes do occur occasionally. By watching the process through the stereomicroscope, the reason can be determined. During the first few seconds, initial oxidation of the tungsten wire is rapid. This causes gas bubbles to be formed. The bubbles are then attracted to the tungsten wire surface. The result is the appearance of ir-

Key words: electrochemical etching, tungsten, cat whisker, infrared antenna.

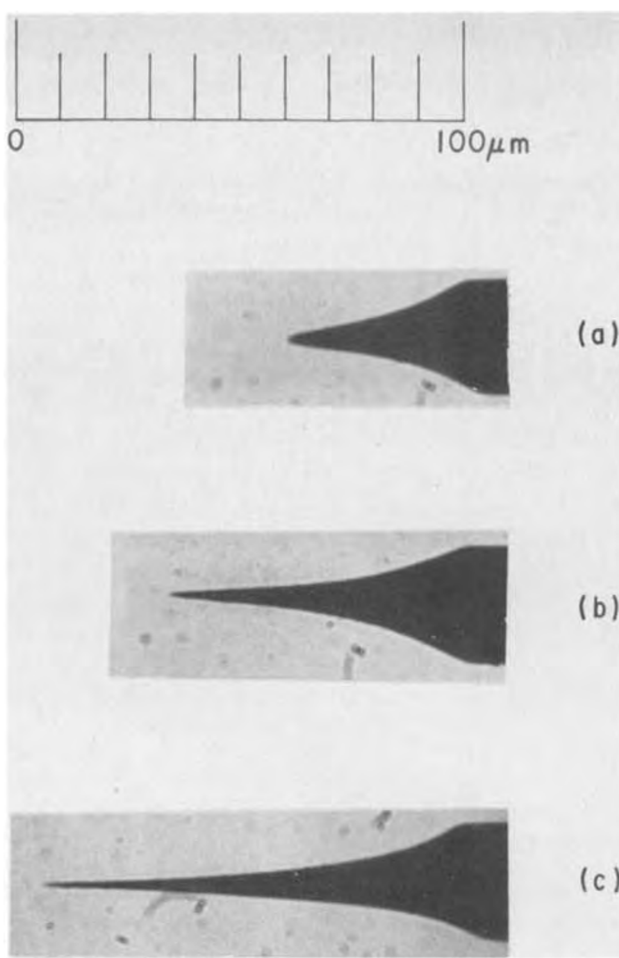

Fig. 1. Micrographs of direct current, electrochemically etched tips of 25μ diameter tungsten wires by using NaOH with different concentrations. (a) 0.75*N* NaOH, I = 40μ. (b) 0.5*N* NaOH, I = 67μ. (c) 0.375*N* NaOH, I = 93μ.

regular bumps on the tips, since places covered by bubbles are protected from the etching solution. An easy way to get rid of bubbles is to divide the etching process into steps. First, the tungsten wire is dipped into the solution and direct current passed as usual for ~15 sec. Bubbles are formed and attached to the wire. Then the wire is raised out of the solution to interrupt the etching process. The bubbles are left at the surface of the solution and dissipate. The etched wire is then dipped into the solution again to approximately the same depth as in the first step by means of the micropositioner. Current is passed again and the etching process resumed. No more bubbles are observed to form. Without bubbles attached to the tungsten wire surface, the tip etching processes were always reproducible.

In conclusion, we report a fairly easy method to fabricate tungsten cat whisker antennas with controllable lengths in the range from 40 to 170μ. Similar techniques may also find applications in field emission microscopy.

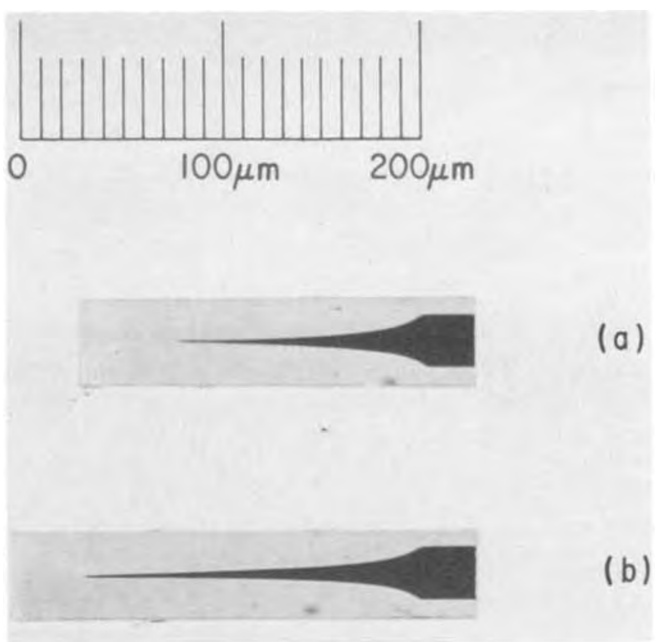

Fig. 2. Micrographs of longer tips of 25μ diameter tungsten wires. (a) 0.25*N* NaOH, I = 125μ. (b) 0.1875*N* NaOH, I = 170μ.

The availability of tips with different lengths and cone angles allows one to vary these parameters in situations when they can be expected to influence the antenna behavior or other useful characteristics.

Semi-Empirical Calculation of Depletion Region Width in n^+-p Silicon Solar Cells

E. Y. Wang and R. N. Legge

Department of Electrical Engineering, Wayne State University, Detroit, Michigan 48202

In recent calculations (1) of the short-circuit current contributed by the n^+ diffused region in n^+-p silicon solar cells, we have found that the results are extremely sensitive to the depletion region width occurring in the n^+-region. To obtain the depletion region width in usual treatments of a solar cell junction, assumptions of either abrupt or one-sided step, or linear approximations (2, 3) are used. More recently an exponential charge density approximation (4) was used to obtain the width. In this note we extend the width calculation for impurity distributions of complementary error function and the Gaussian function, in addition to the exponential function. In combination with experimental width values deduced from capacitance measurements at zero bias, we can determine numerically the width occurring in both n^+ and p regions. It should be emphasized here that diffusion anomalies observed in the shallow n^+-p junction of a solar cell may result in an impurity profile which is a mixture of the aforementioned distributions (5).

Results

Depletion region width measurements.—The capacitance measurement circuit used to determine the depletion width is shown in Fig. 1. The a-c source and the current-sensitive pre-amplifier are part of a PAR 124 lock-in amplifier. The output of the lock-in signal is related to the conductance at zero bias. The junction capacitance at zero bias can be obtained by simply measuring the current 90° out of phase. Table I summarizes the capacitance results for various silicon solar cells.

Calculations.—The basic assumptions used in the calculations are: (*i*) one dimensional analysis using the abrupt space-charge edge approximation, (*ii*) charge neutrality condition in whole depletion region, and (*iii*) fully ionized impurity atoms in both n^+ and p regions.

Key words: depletion region width, solar cell, capacitance measurement.

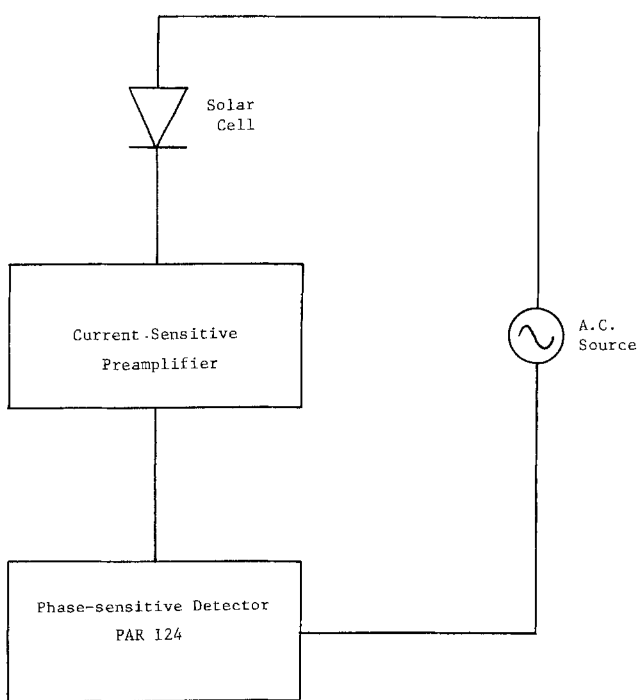

Fig. 1. Schematic circuit diagram for capacitance measurement

Table I. Junction capacitance and corresponding widths of silicon solar cells

Base material resistivity	Junction capacitance in μf per cm²	Depletion region width (W) in μm
10 ohm-cm	0.0145	0.75
1 ohm-cm	0.038	0.28
0.1 ohm-cm	0.106	0.098

Under the above conditions we have charge neutrality in the whole depletion region

$$\int_{d_n}^{x_j} [N_D^+(x) - N_A^-(x)]dx = \int_{x_j}^{d_p} [N_A^-(x) - N_D^+(x)]dx \quad [1]$$

where x_j is the metallurgical junction depth where the space-charge density is zero. The depletion region widths occurring in the n^+ and p regions, respectively, are $x_j - d_n$, $d_p - x_j$. $N_D^+(x)$ is the positive donor ion density and $N_A^-(x)$ is the negative acceptor ion density. Notations are illustrated in Fig. 2.

In a conventional n^+-p silicon solar cell, $N_A^-(x)$ is constant, and the value of the constant depends on the doping level of the base material. For 10 ohm-cm solar cells $N_A^-(x)$ is about $1.3 \times 10^{15}/\text{cm}^3$. $N_D^+(x)$ depends on the type of diffusion profile and is given as $N_D^+(x) = N_D^+(O)f(x)$ where $N_D^+(O)$, the surface concentration, is taken as 10^{20} cm^{-3} and $f(x)$ is the functional form of the impurity profile (erfc, Gaussian, or exponential). Table II lists $N_D^+(x)$ functions for the three impurity profiles used in our calculations. The constant argument in the functional form is directly related to the surface concentration we choose.

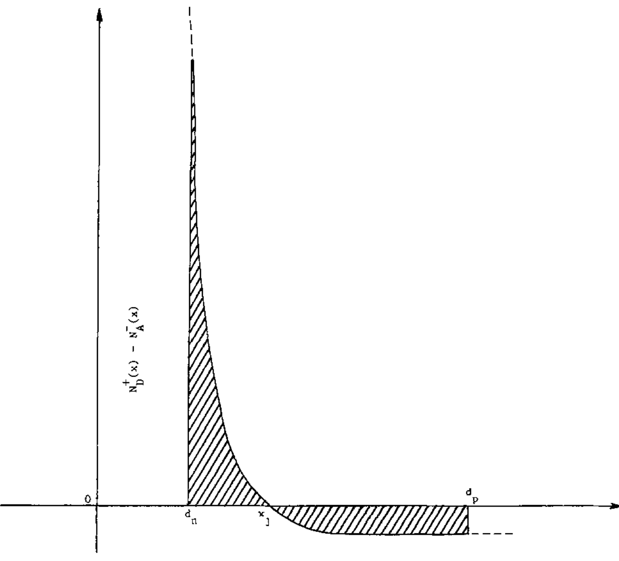

Fig. 2. Illustration of impurity distribution in n^+-p silicon solar cell.

Table II. Functional form for three impurity profiles

	10 ohm-cm	1 ohm-cm	0.1 ohm-cm
Complementary error function	$\text{erfc}\left(3.07\frac{x}{x_j}\right)$	$\text{erfc}\left(2.68\frac{x}{x_j}\right)$	$\text{erfc}\left(1.986\frac{x}{x_j}\right)$
Gaussian	$\exp -\left(3.34\frac{x}{x_j}\right)^2$	$\exp -\left(2.97\frac{x}{x_j}\right)^2$	$\exp -\left(2.3\frac{x}{x_j}\right)^2$
Exponential	$\exp -11.178\frac{x}{x_j}$	$\exp -8.806\frac{x}{x_j}$	$\exp -5.298\frac{x}{x_j}$

Table III. Summary of results for 10 ohm-cm cells with $N_D^+(0) = 10^{20}$ cm^{-3}, $N_A = 1.3 \times 10^{15}$ cm^{-3}, and $w = 0.75$ μm

The total space-charge width, W, obtained from the capacitance measurements is given as

$$d_p - d_n = W \qquad [2]$$

By solving Eq. [1] and [2] simultaneously, d_n and d_p values can be obtained. The value of $N_D(d_n)$ thus obtained can then be used to find the built-in potential $V_B = \frac{kT}{q} \ln \frac{N_A N_D(d_n)}{n_i^2}$. The results for three different values of base material resistivity and a range of x_j values are presented in Tables III to V.

Discussion

The calculated width values are within $\pm 1\%$ error. This is because we are numerically balancing the charge neutrality in Eq. [1] within $\pm 1\%$. The experimental determination of the width used for Eq. [2] is well within $\pm 2\%$. Therefore the total possible error in this semi-empirical calculation is less than $\pm 3\%$. The results show that depletion region widths in the Gaussian and complementary error function impurity distribution in the n^+-region for 10 ohm-cm cells is about 10% or less of the total width, depending on x_j values. For an exponential impurity distribution, the percentage of the total width occurring in the n^+-region is even higher (up to about 20%). In the usual one-sided step approximation, it is assumed that the entire width occurs in the p- region. For 1 ohm-cm and 0.1 ohm-cm base material cells, the $x_j - d_n$ values can be comparable with the $d_p - x_j$ values. In fact, the $x_j - d_n$ value will dominate for some x_j values.

In conclusion, the results have shown that the $x_j - d_n$ and $d_p - x_j$ values have quite a variation for different impurity profiles. Therefore caution should be exercised in choosing a proper impurity profile for determining some of the device parameters in shallow junction devices such as solar cells and high frequency transistors, where accurate values of $x_j - d_n$ and $d_p - x_j$ are needed.

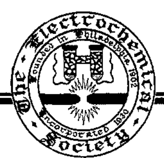
Brief Communications



Identification of the U.V. Irradiation Product in Nematic Chlorostilbene Imaging Processes

K. F. Nelson, W. E. Haas,* and J. E. Adams

Research Laboratories, Xerox Corporation, Webster, New York 14580

In a previous article (1), we described an imaging process based on the photochemical degradation of the nematic *trans*-chlorostilbenes. In that process, the nematic-isotropic transition temperature (T_{n-i}) was selectively lowered in those regions exposed to u.v. irradiation. The depression of T_{n-i} was attributed to a u.v. generated impurity tentatively identified as the *cis* isomer of the parent compound.

In order to positively identify the impurity element, liquid column chromatography was employed to first separate the u.v. generated impurity from the host material. A 20 mm diameter column was packed to a height of 400 mm with silica gel slurried in reagent grade hexane. Nematic *trans*-4-butyl-α-chloro-4'-ethoxystilbene (BCES), which had been irradiated in spectroscopic grade hexane at a wavelength of 300 nm, was then passed through the column. The first-eluted material, the u.v. generated impurity, crystallized at room temperature following solvent evaporation (mp = 46°-50°C) and did not have a mesomorphic phase. The second-eluted material was pure *trans*-BCES having the same nematic temperature range as the non-irradiated, original BCES. Following several irradiation/separation sequences, several hundred milligrams of a single impurity (verified by thin layer chromatography) had been separated for analyses.

* Electrochemical Society Active Member.

Key words: liquid crystals, stilbenes, ultraviolet, imaging.

Figure 1 shows the absorption spectra of *trans*-BCES and the separated impurity. A comparison with similar spectra, Fig. 2, of *trans*- and *cis*-α-chloro-4-methylstilbene (2) indicates that the isolated impurity is indeed *cis*-BCES. Table I shows the results of elemental analysis and molecular weight determinations of *trans*-BCES and of the impurity material compared with the calculated values for *trans*-BCES. The composition and molecular weight of the impurity molecule is, again, indicative of the *cis* isomer of BCES.

Table I.

Material	%C	%H	%Cl	%O	Molecular weight
trans-BCES*	76.29	7.36	11.26	5.08	314.861
trans-BCES**	76.10	6.89	11.79	5.20	340
impurity**	75.85	6.95	11.91	5.29	330

* Calculated values.
** Determined by Galbraith Laboratories, Incorporated, Knoxville, Tennessee.

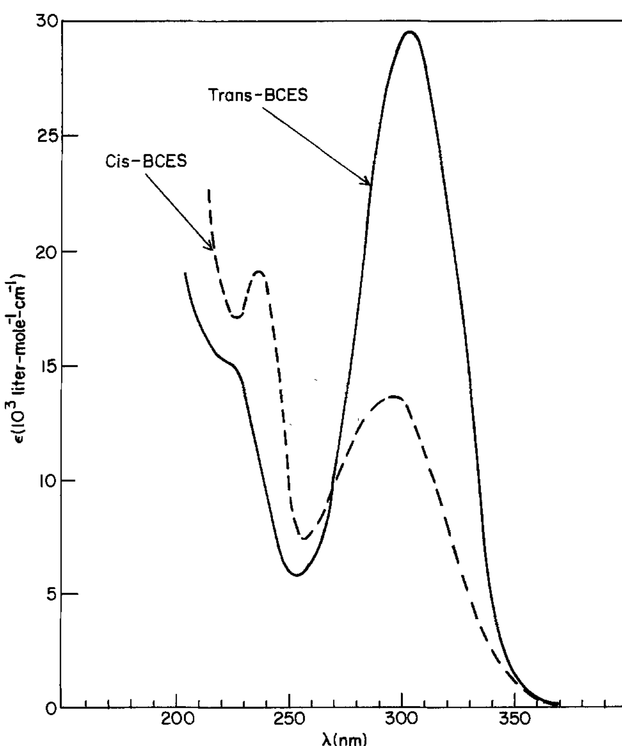


Fig. 1. The u.v. absorption spectra of *trans*-BCES and the separated impurity, *cis*-BCES, in cyclohexane.

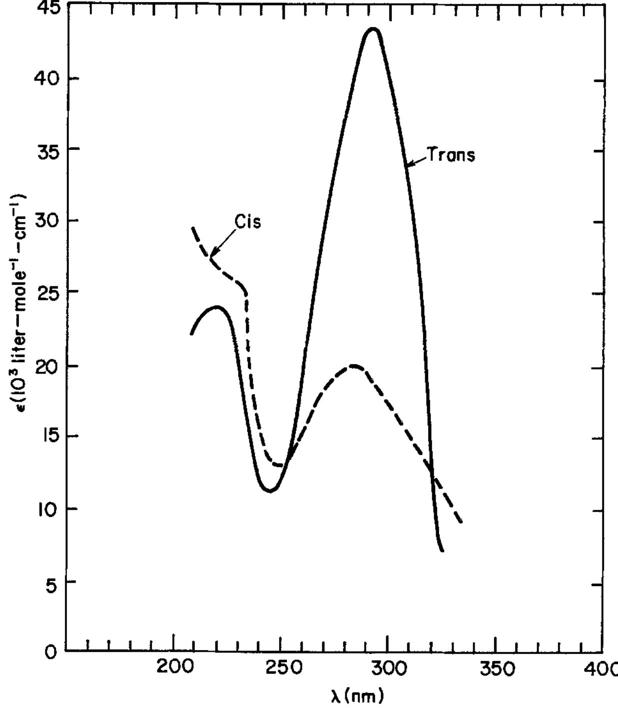

Fig. 2. The u.v. absorption spectra of *trans*- and *cis*-α-chloro-4-methylstilbene [after McDonald and Schwab, Ref. (2)].

Finally, proton nmr spectra showed a down-field shift in the resonance of the vinyl hydrogen of the impurity molecule compared to the vinyl hydrogen resonance in *trans*-BCES. A similar shift is observed in *cis*-stilbene compared to *trans*-stilbene. We conclude that the impurity generated by u.v. irradiation of *trans*-BCES is the isomer, *cis*-BCES.

Simple Method for Separating Completed Diodes from Semiconductor Wafers

J. Klatskin and A. Rosen

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

Finding ways of cutting processed semiconductors into individual diodes or transistors is a major time-consuming activity for process designers. One problem, for instance, has been the separation of completed Trapatt diodes so they could be packaged. Many designers use techniques such as wire sawing, diamond sawing, etching, laser cutting, and scribe and break separation.

Problems associated with these methods, excluding the cost of the equipment involved in cutting, include low yields due to damage along the edges of the completed devices, as well as inadvertent fractures of the device itself.

Wire sawing requires a cutting medium such as oil, or a tenacious diamond mixture which retains the shavings on or near the device. In addition to metal contamination, the substance used presents cleaning problems.

Diamond sawing requires a large capital investment, without solving fine-line requirements ($<$ 1 mil).

Etching introduces contaminants, which can ruin an otherwise good device. Etching is a lengthy process, often up to 2 hr, and the masking material seldom holds that long.

Scribe and break separation often causes damage due to breaks along lines not defined by the scribe. Unintentional breaks come about because the natural cleavage line to scribe line angle is too large.

An analysis of the methods and the review of their associated problems have led to an improved process for cutting a semiconductor wafer into individual devices of desired geometrical configuration.

A metal film is deposited on the support side of a semiconductor material. Photoresist is applied and processed, forming the device regions by a pattern of

Key words: diodes, Trapatt, heat sink.

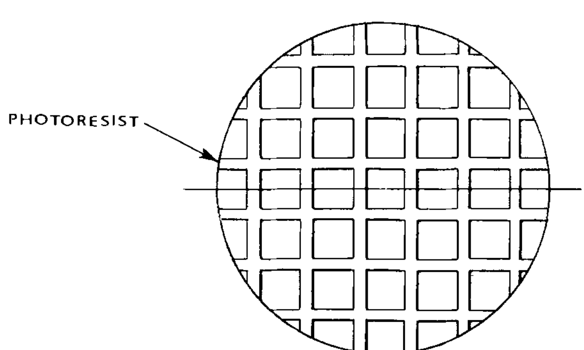

Fig. 1. Photoresist defining the device regions. The type of photoresist used is dictated by the design requirement. AZ111 has been used successfully and, for forming a thick base, dynachem thick film resist has been utilized.

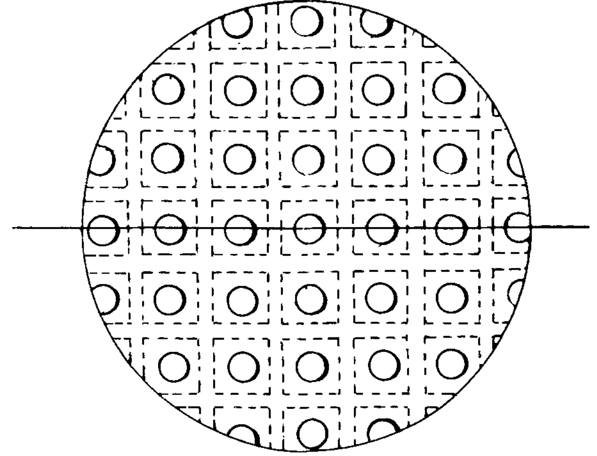

Fig. 2. Alignment of each device within the defined regions

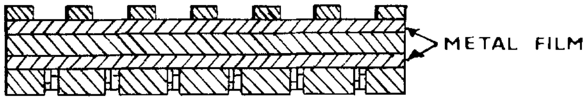

Fig. 4. Wafer prior to etching for diode fabrication

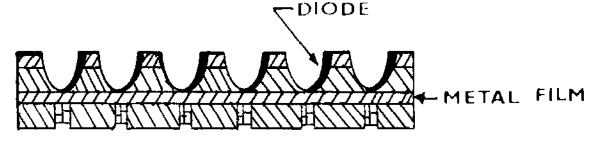

Fig. 5. Completed wafer with diode formed above each heat sink ready for separation.

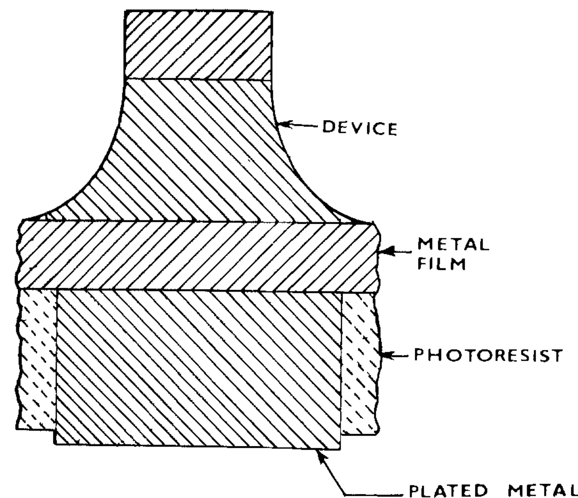

Fig. 6. The separated device, in this example a diode

intersecting strips (Fig. 1). A layer of metal, such as copper or gold, is plated within each device region (Fig. 2). This forms a base for mounting or bonding in a package. The opposite side of the semiconductor wafer is selectively etched down to the metal film. The mechanics of etching diodes completes both the structure formation of the diode and material removal in one step. Different device structures could require a masking procedure.

Separation of each device takes place by fracturing the thin metal film along the strips of photoresist (Fig. 3-6). The presence of photoresist at this point is not required, and removal is possible prior to separation.

This process has increased device yields while saving the manhours normally required in the dicing operation.

Electrochemically Etched Tunnels in Gallium Arsenide

M. M. Faktor, D. G. Fiddyment, and M. R. Taylor

Post Office Research Department, Dollis Hill, London, NW2 7DT, England

The purpose of this communication is to convey information about the deep and extensive tunneling of n-type gallium arsenide which can occur under certain, well-defined conditions of anodic dissolution. Tunnel formation in gallium arsenide was first reported by Krumme and Straumanis (1), and similar features have more recently been observed by Chase and Holt (2) on jet-etched gallium phosphide.

Anodic dissolution of (100), (110), and (111) faces of n-type GaAs slices in flowing 10% aqueous KOH solution was carried out as described previously (3, 4). The slices were obtained from various sources and possessed lapped or sawn surfaces which, before use, were mechanico-chemically polished in bromine-methanol (5). The material examined was doped with either Si or S giving carrier concentrations in the range 10^{16} - 10^{18} n cm^{-3}.

The principal result was that tunnel formation occurred only when anodic dissolution was carried out in the dark, or at high anode potentials in the light where the current is in excess of its "saturation" value. Under the latter condition, the "light" current closely approaches the "dark" current (Fig 1).

The polarization behavior shown in Fig. 1 has previously been reported and discussed by Ambridge *et al.* (3, 4). The existence and magnitude of the "dark" current and the "light" current above saturation at high potentials are not adequately understood, though explanations have been advanced (7, 8). No simple correlation was found between the "dark" current level and either the doping level or structural defects in the material. The latter were investigated by etching studies (9), x-ray topography, and transmission electron microscopy. In all cases the tunnels were found to run in <111> directions, as demonstrated by angle measurements on cleaved surfaces and on tunnel entrances using optical and scanning electron microscopy, and confirmed by infrared transmission microscopy. On (110) specimens, some tunnels intersected the surface forming channels. Typically, tunnels were some 150 μm long, and of equilateral triangular section with a width of 5 μm (after anodization for 2 min at 2 mA cm^{-2} and at a potential of 0.7V with respect to a saturated calomel electrode). The tunnel directions were such that they terminated in (111)B (arsenic) planes (1). Order of magnitude calculations showed that anodic dissolution was confined to tunnels with little general leveling of the exposed surface occurring.

Key words: gallium arsenide, anodic dissolution, etch pitting, tunneling, preferential adsorption.

Examination of anodically etched (100) specimens by optical and scanning electron microscopy indicated the general evolution of the surface morphology; the first sign of tunnel formation being the appearance of single triangular pits, or adjacent pairs of triangular pits extended parallel to <110> directions. Yamamoto and Yano (6) have recently observed similar surface features. We would like to emphasize that such features are in fact the entrances to the deep and narrow <111> tunnels mentioned earlier. Subsequent anodic etching enlarges these surface features. In the case of triangular pit pairs, rectangular features are formed. Coalescence and further enlargement leads eventually to large square pits [Fig. 10 of Ref. (5)]. The underlying complex of tunnels, frequently accompanied by branching, is dramatically revealed by infrared transmission microscopy, as demonstrated in Fig. 2 on a (111)A sample.

Although occasionally tunnels intersect the surface along impurity bands or other defects, this was by no means the general rule. In fact tunnels were generated in dislocation-free material, which on a macroscale at least, was uniformly doped. Furthermore transmission electron microscopy of dislocation free material did not reveal either columnar precipitates or any defects which could be construed as tunnel guides (10). Apparently bulk heterogeneities are not responsible for tunnel formation or their guidance.

Preferential adsorption on (111)B faces was strongly indicated by measurements of the band bending poten-

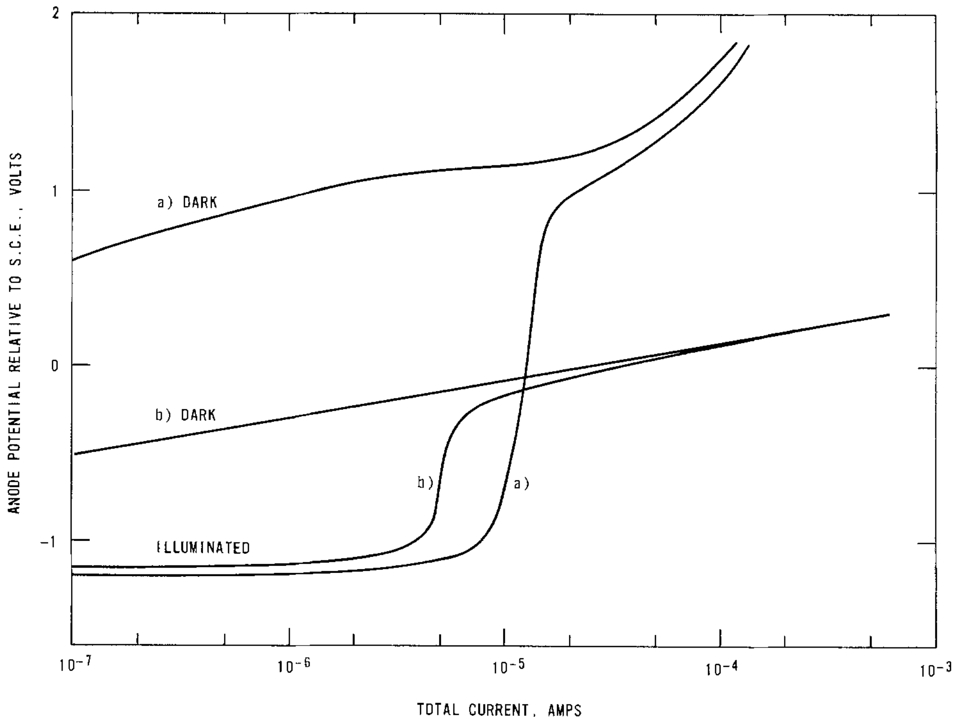

Fig. 1. Typical polarization plots for n-type GaAs of doping level 3.8×10^{16} n cm^{-3} (a) and 1.9×10^{18} n cm^{-3} (b). The curves tend to merge when the current exceeds its saturation value.

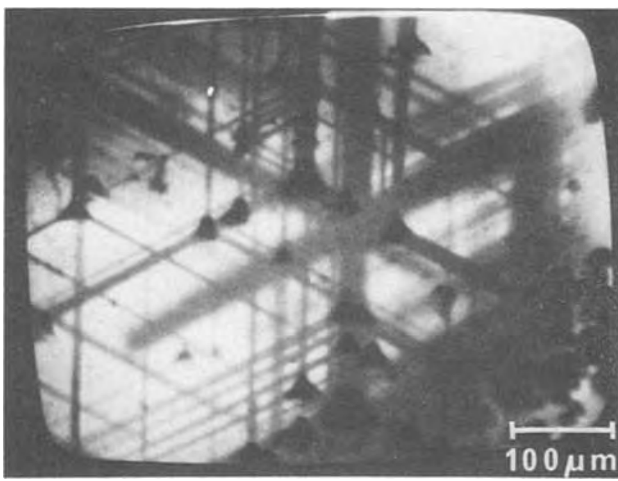

Fig. 2. Combined transmission and reflection infrared micrograph of an anodically etched (111)A (Ga) surface showing tunnels (gray) and tunnel entrances and surface details (black). The <111> tunnels are projected on to the (111)A surface in <211> directions. (Doping level 2×10^{17} n cm^{-3})

tial (11) on surfaces of different orientation (see Table I). The Schottky-Mott expression (4) was used to determine the band bending potential. Such adsorption may well lead to the appearance of surface states of energies suitable for communication with electrons in solution, and resultant preferential attack in these regions. The dark current would then be mainly due to the catalytic action of the adsorbent.

Table I. Band bending potential as a function of orientation for n-type Si doped GaAs (carrier concentration 2×10^{17} n cm^{-3})

Orientation	Band bending potential (V)	
	In the dark	In the light
(111)A	1.83 ± 0.05	1.67 ± 0.05
(111)B	2.41 ± 0.05	2.07 ± 0.05
	2.38 ± 0.05	2.13 ± 0.05
(110)	2.06 ± 0.05	1.82 ± 0.05
(100)	2.04 ± 0.05	1.82 ± 0.05

Finally it is worth mentioning that if current values are kept beneath saturation, then smooth surfaces result from anodic dissolution under illumination with light of frequency greater than 3.46×10^{14} sec^{-1} (4). This corresponds to a bandgap energy of 1.43 eV at 300°K. Using light of energy which spans the bandgap, it is possible to reveal banding due to doping variations and if one confines the current to below saturation, no pits appear. It is a useful, as yet qualitative technique, for looking at doping inhomogeneities in n-type GaAs (3, 4).

Doping of Silicon by Neutron Irradiation

H. A. Herrmann and H. Herzer

Wacker-Chemitronic, Burghausen, Germany

In the manufacture of high power devices such as thyristors and special diodes, there is a great demand for homogeneously doped n-type silicon. In our efforts to reduce striations in dislocation-free float-zone silicon (1), we rediscovered a quite interesting method which was used in the field of nuclear particle detectors.

In nuclear physics experiments for the detection of high energy particles, the application of silicon junction counters has become a standard way of measurement. Due to the range of high energy particles, deep depletion layers are necessary that are dependent on the concentration of free charge carriers and the applied voltage. For that reason, only ultrapure silicon with a very high resistivity can be used for the production of high quality silicon radiation detectors.

Besides using ultrapure silicon, two methods are known to increase the resistivity of the bulk material: (*i*) compensation by lithium drift technique (2) and (*ii*) compensation by doping of silicon with neutron irradiation, called transmutation doping (3-5).

Contrary to the lithium drift which is a well-known technique for production of highly compensated silicon, transmutation doping has not been so successful. In this case compensation is achieved by use of the nuclear reaction $^{30}Si + n \rightarrow {}^{31}Si + \gamma \rightarrow {}^{31}P + \beta$. The reason for this technique has never become significant

Key words: dislocation-free silicon, striations, transmutation doping, thermal neutrons.

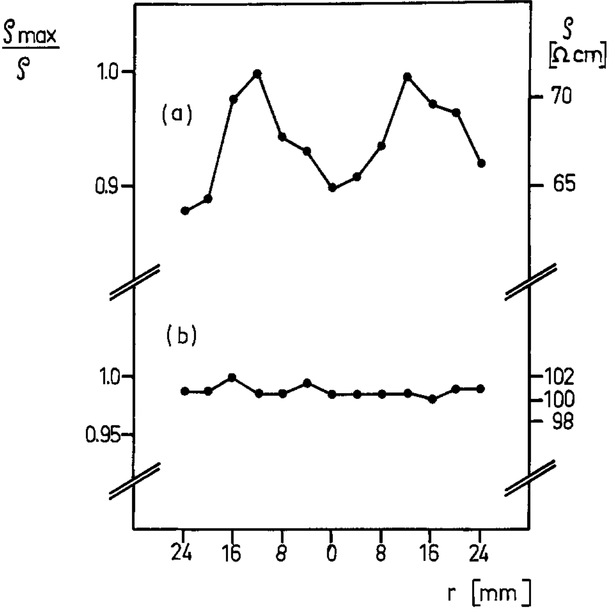

Fig. 1. Radial resistivity variations: (a) standard material (b) neutron transmutation doped.

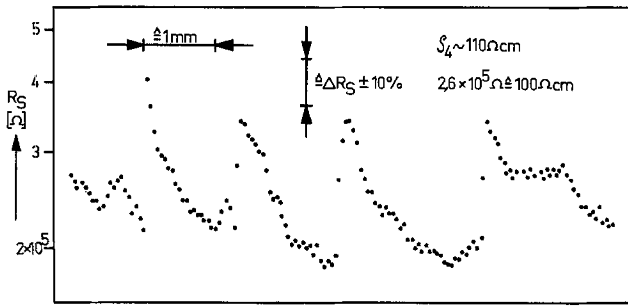
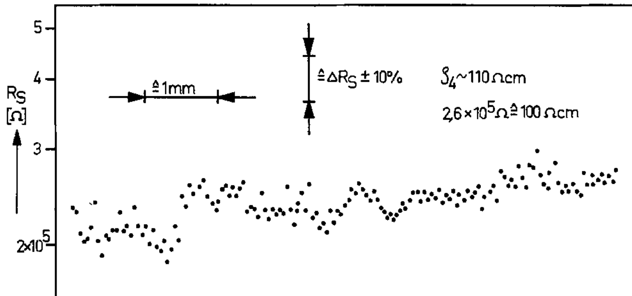
Fig. 2. Spreading resistance profiles: (a) conventional technique, (b) improved growth technique, and (c) neutron transmutation doping





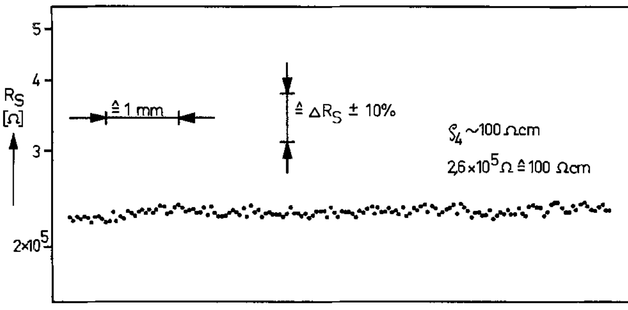


Fig. 3. Sections of Fig. 2

has to be seen in the lack of uniformly doped p-type silicon as the starting material.

We have now recognized that for the application in the lower ohmic range, *i.e.*, between 100 and 500 ohm-cm, the nuclear reaction is an excellent method to dope silicon homogeneously. Starting with undoped polycrystalline silicon which is purified by several vacuum passes, the influence of grown-in dopants can be neglected. The final resistivity is represented by the number N of transmutated ^{30}Si isotopes which can be calculated from the equation

$$N = N\square \cdot \sigma \cdot \phi \cdot t$$

where $N\square = 0.15 \times 10^{22}$ cm^{-3} gives the number of ^{30}Si isotopes, $\sigma = 110$ mbarn is the neutron capture cross section, ϕ is the thermal neutron flux, and t is the irradiation time. The irradiation is performed in the core of a nuclear reactor where $\phi \approx 5 \times 10^{13}$ cm^{-2}·sec. To achieve resistivities between 100 and 500 ohm-cm, typical irradiation times are between 20 and 100 min.

After the neutron bombardment, the silicon lattice is damaged due to the different interactions between silicon nuclei and neutrons, recoil atoms after neutron capture, high energy heavy particles created by fast neutron induced transfer reactions, high energy β and γ radiation, etc. The damage requires subsequent annealing treatments as it is known from ion implantation (6, 7). At a temperature of about 700°C, full electrical conductivity can be obtained. Figure 1 shows the four point probe measurement of a neutron transmutation doped silicon compared to conventionally grown standard material. The radial resistivity variation is markedly reduced to about 2%. Figure 2 represents the spreading resistance profiles of samples grown by (*a*) conventional technique, (*b*) improved growth technique, and (*c*) neutron transmutation doping. Figure 3 shows sections of Fig. 2 which demonstrate most clearly the advantage of constant resistivity in the microscopic range.

The results indicate that transmutation doping may be a rather good technique for production of homogeneously doped silicon material. Up to now, the influence of fast neutrons and high energy β and γ radiation seems to be negligible. Further work must be undertaken to establish whether transmutation doping will play a dominant role in addition to the standard methods for growing silicon crystals.

Effects of Temperature on the Kinetics of Passive Film Growth on Iron

C. Lukac,[1] J. B. Lumsden, S. Smialowska,[2] and R. W. Staehle*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Ellipsometry was used to investigate the effects of temperature and potential on the growth kinetics of passive films on iron exposed to a pH 8.6 borate buffer solution. It was found that over the temperature range of 0°-80°C the growth kinetics could be described with an equal degree of confidence by either logarithmic, inverse logarithmic, or a modified form of inverse logarithmic kinetics. None of the existing models for film growth were found to be completely consistent with the temperature and potential dependencies of the growth constants.

There have been several ellipsometric studies (1-8) of the passive film formed on iron in near-neutral solutions. These investigations have shown that the film thickness is directly proportional to the applied potential and that film growth can be described equally well by either inverse logarithmic or logarithmic kinetics. Thus, it has not been possible to identify the model which represents the growth of this film from existing results. This investigation was undertaken to assess possible distinguishing features which might corroborate one of the proposed models for film growth. This was approached by measuring the temperature dependence of film thickening.

In order to correlate with the experimental data we review briefly here the four major models for interpreting film growth on metal surfaces. The first of these is the inverse logarithmic model proposed by Mott and Cabrera (9). This model assumes field assisted cation diffusion according to which the potential drop, V, across the film remains constant while the field, V/X, decreases as the film thickens. The rate-determining step is assumed to be the surmounting of the potential barrier, W, between the metal-oxide interface. The rate of film growth is given by the expression

$$\frac{dx}{dt} = u_o \exp\,(qaV - W)/kT \qquad [1]$$

where

$$u_o = Na^4\nu \qquad [2]$$

N is the number of mobile ions per unit volume of oxide; a is the jump distance; q is the charge on the ion; W is the activation energy; ν is the phonon frequency. If the absolute reaction rate theory is used, $\nu = (kT/h)$. Mott and Cabrera give an approximate integration of Eq. [1] as

$$1/x = \frac{kT}{qaV}\ln\frac{x_i^2 kT}{qaVu_o} + \frac{W}{qaV} - \frac{kT}{qaV}\ln t \qquad [3a]$$

Key words: iron, passivity, film, ellipsometry, corrosion.

or

$$1/x = A - B\ln t \qquad [3b]$$

The quantity, x_i, is the average film thickness over the range considered.

Recently, Ghez (10) has examined the integration of Eq. [1]. According to his results the inverse logarithmic kinetic expression derived by Mott and Cabrera is not an asymptotic solution to this equation. His basic objection is the approximation of X by X_i. He obtains as a solution the expression

$$1/x = \frac{kT}{qaV}\ln\frac{kT}{qaVu_o} + \frac{W'}{qaV} - \frac{kT}{qaV}\ln\frac{t + t_o}{x^2} \qquad [4a]$$

or

$$1/x = A' - B'\ln\frac{t + t_o}{x^2} \qquad [4b]$$

Sato and Cohen (11) have proposed a model which rationalizes logarithmic kinetics. According to their suggestion, film growth proceeds by the field assisted place-exchange of metal-oxygen pairs. All such pairs in a given row normal to the surface are assumed to exchange places simultaneously. This model gives a growth rate

$$\frac{dx}{dt} = 2\,\alpha(T)\exp\frac{\mathbf{F}V}{2RT} - \frac{xW_o}{a\nu RT} \qquad [5]$$

which integrates to

$$x = \frac{a\nu RT}{W_o}\ln\frac{W_o\alpha}{a\nu RT} + \frac{a\nu\mathbf{F}V}{2W_o} + \frac{a\nu RT}{W_o}\ln\,(t_o + t) \qquad [6a]$$

or

$$x = C + D\ln\,(t + t_o) \qquad [6b]$$

where a is the lattice constant, ν the stoichiometric number, W_o the chemical potential between a cation in the activated state and the normal state in any lattice layer, and

$$\alpha(T) = \beta T\exp\delta/T \qquad [7]$$

Here β and δ are constants independent of potential and temperature.

Fehlner and Mott (12) have described logarithmic growth differently. They suggest that the structure of the film changes with thickness so that the potential drop across the film increases as the film thickens in such a way that the field remains constant. With this assumption the activation energy is of the form $W_o + \mu x$; therefore

$$\frac{dx}{dt} = A \exp\left[-(W_o + \mu x)/kT\right] \quad [8]$$

and

$$x = kT/\mu \ln \mu A/kT - W_o/\mu + kT/\mu \ln (t + t_o) \quad [9a]$$

$$x = C + D \ln (t + t_o) \quad [9b]$$

In the results reported here we have determined the thickness of the passive films on iron as a function of time, potential, and temperature using ellipsometry. The results have been analyzed in terms of the above three models of film growth.

Experimental

A schematic diagram of the cell used is shown in Fig. 1. This was a double-walled glass vessel having optically flat Pyrex windows and a capacity of 500 ml. The cell consisted of a Luggin capillary leading through a wetted, closed stop-cock to a saturated calomel reference electrode. The temperature of the solution was measured by a thermometer positioned 2 cm from the sample. Temperature control was maintained by circulating ethylene glycol through the jacket. The cell was connected to a double-walled 2 liter reservoir where the electrolyte was deaerated by bubbling with prepurified helium; the temperature of the solution was raised or lowered as desired before it was admitted to the cell.

The iron specimen was a 99.99% zone-refined rod with a threaded hole for the electrical connection. It was mounted in a Teflon holder and had an exposed area of 0.32 cm^2.

The solution used was an equivolume mixture of 0.15*N* H_3BO_3 and 0.15*N* $Na_2B_4O_7$ (*p*H 8.7). Measurements were made at 0°, 20°, 35°, 50°, and 80°C. The solutions were deaerated by bubbling prepurified helium for at least 24 hr.

The ellipsometer was a Rudolph & Sons, Type 43603-200E. A Keithley Model 4145 picoammeter was used to measure the output from the photomultiplier tube (RCA 1P21). All measurements were made using the 5461Å mercury green line.

Before placing the sample in the cell, it was mechanically polished to a ¼ μm finish using diamond paste. The specimen was then cleaned, degreased, and electropolished in a solution consisting of 20 parts glacial acetic acid to one part 20% perchloric acid. Next the sample was washed with double-distilled water and then with reagent grade methanol, dried, and placed in the cell.

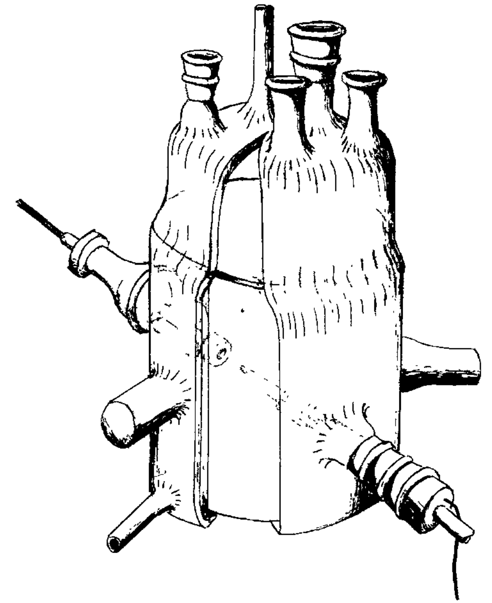

Fig. 1. Schematic of the ellipsometric-electrochemical cell

The specimen was first cathodically reduced at a constant current density of 40 μA/cm^2. Cathodic reduction was continued until the optical constants of the film-free surface were obtained. The passive film was then formed potentiostatically by switching directly from the cathodic potential (approximately −1.0V SCE) to the desired potential in the passive region. The sample was polarized approximately 1 hr at each potential; measurements of the ellipsometric parameters were made at 10 min intervals. This procedure was repeated 3-5 times at each potential.

The optical constants obtained for the film-free surface are in satisfactory agreement with those found by others as shown in Table I. These values also compare favorably with those measured by Yolken and Kruger (13) for a film-free surface in an ultra-high vacuum.

A cathodic current density of 40 μA/cm^2 was used to reduce the film since at this current density it could be removed within 10-15 min. The final potential attained was close to that established by others (6-8) for this system as "the optical reference state."

It was found to be unnecessary to change the solution after cathodic reduction in order to avoid the effects of ferrous ions. Several measurements were made following the procedure of replacing the solution after reduction, excluding oxygen, while maintaining the surface at the reduction potential. The steady-state results were the same as those for the unrefreshed solution.

Results

The current-potential curves for iron exposed to the borate buffer solution with the range of temperatures 0°-80°C are shown in Fig. 2. These curves were obtained by scanning at a rate of 20 mV/min. There was no measurable change in *p*H over this temperature range.

The optical constants of the film were determined using the first-order approximation of the ratio of the Fresnel reflection coefficients (16). Thus, if the film thickness is less than 50-100Å, the change in both of the ellipsometric parameters $\delta\Delta$ and $\delta\psi$ is directly proportional to the thickness. This implies that $\delta\Delta$ and $\delta\psi$ are related linearly. The $\delta\Delta$ *vs.* $\delta\psi$ curve for films formed a 20°C is given in Fig. 3. This is the least squares curve and was found to be linear at the 95% confidence level by the F ratio test. The standard deviation of the slope was 4.6%. It is not possible to obtain unique values for the optical constants using this curve. This is one of the inherent problems associated with the ellipsometric technique when working with semiconducting films of unknown thicknesses. The difficulty arises since there are three unknowns (the

thickness, the index of refraction, and the absorption coefficient), and only two experimental parameters, Δ and ψ. Accordingly, the real part of the refractive index was assumed to be 2.6 and the imaginary part was determined by fitting a theoretical curve, which was calculated using the exact equations (17), to the least squares curve. The curve which gave the best fit corresponded to the optical constants 2.6 (1-0.19*i*). As shown in Table I these optical constants are in good agreement with those rationalized by others at room temperature.

The same procedure was used to find the optical constants at each temperature. A minimum of seventy points was used to obtain each curve. The standard deviations in the slope of the δψ *vs.* δΔ curves ranged from 2.2% for 35° to 7.8% for 80°. The values of the optical constants for each temperature are given in Table II. All are the same within error except those determined for films formed at 0° and 35°C. The imaginary parts of the optical constants for these films are substantially smaller than those formed at other temperatures.

80	2.60	0.20

The least squares curves of the reciprocal of the film thickness *vs.* log t and log t/x^2 and the film thickness *vs.* log t are shown in Fig. 4, 5, and 6. Plots are given as a function of potential for films formed in solutions at 0°, 35°, 50°, and 80°C. Results were also obtained at 20°C but are not shown. Each of these curves were found to be linear well within the 95% confidence level using the F ratio test. The confidence level of the fit was approximately the same for all three models.

Table III gives the values of the constants A, B, A', B', C, and D where

$$1/x = A - B \ln t \quad [8]$$

$$1/x = A' - B' \ln t/x^2 \quad [9]$$

and

$$x = C + D \ln t \quad [10]$$

The quantity $1/B$ *vs.* potential is plotted in Fig. 7 and $1/B'$ *vs.* potential in Fig. 8. These show that B and B' are directly proportional to potential and that the proportionality constant, m (the slope), is temperature dependent. There is some scatter in these results; nevertheless, the least squares analysis indicates that the correlation for the set of data for each temperature is linear at the 95% confidence level.

The results of Fig. 9 show the slopes of the curves in Fig. 7 and 8, m_1. A least squares analysis of the data gives a linear relationship. This is in accordance with Eq. [3] and [4], *i.e.*

$$B = B' = kT/qaV \quad [10]$$

These correlations show that B and B' are inversely proportional to V and directly proportional to T in agreement with the Mott-Cabrera model.

It should be pointed out that the applied electrochemical potential, which is that given in Fig. 7 and 8, is not the potential drop, V, across the film. However, it differs from V only by an additive constant. Thus, the only effect of plotting the electrochemical potential instead of V is a shift in the axis. This assumes

that the potential across the double layer remains constant.

The jump distance, a, was calculated using the slopes in Fig. 7 and 8 since $m_1 = kT/qa$. These values are given in Table IV. Figure 10 shows the the jump distance as determined using inverse logarithmic kinetics as well as a' from the modified inverse logarithmic kinetic model decreases linearly with temperature.

Figures 11 and 12 show that A and A' are linearly related to the inverse of the potential with a temperature dependent slope, m_2. This potential dependence is in accordance with Eq. [3a] and [4a] since $\ln x_i^2kT/qaVu_o$ is a slowly varying function of T and V over the ranges considered. The temperature dependence of the slopes, m_2, is shown to be linearly related to the temperature in Fig. 13. This indicates that A and A' are directly proportional to the temperature.

The constant D appears to behave in a random fashion with potential; therefore, it was assumed to be potential independent. The average values are given in Table III. Figure 14 indicates that D_{av} gives a good linear correlation with temperature. This is in accordance with the constant field model. From the slope the value 9.42×10^8 is obtained for μ.

The Sato-Cohen model gives D as

$$D = \frac{a\nu RT}{W_o} \quad [11]$$

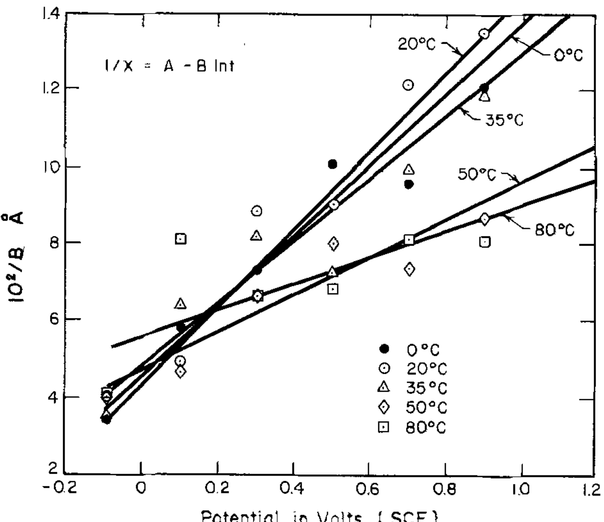

Fig. 7. The reciprocal of the rate constant B vs. applied potential.

where W_0, the activation energy, is split into an enthalpy ΔH_0 and an entropy ΔS_0 term (8, 18). Thus

$$D = \frac{a\nu RT}{\Delta H_0 - T\Delta S_0} \quad [12a]$$

or

$$1/D = \frac{\Delta H_0}{a\nu RT} - \frac{\Delta S_0}{a\nu R} \quad [12b]$$

Figure 15 shows that $1/D$ is proportional to $1/T$.

The constant C is proportional to the potential as shown in Fig. 16. From Eq. [6a] and [6b] the slopes of Fig. 16 are given by

$$m_3 = \frac{a\nu F}{W_0} \quad [13a]$$

or

$$1/m_3 = \frac{\Delta H_0}{a\nu F} - \frac{T\Delta S_0}{a\nu F} \quad [13b]$$

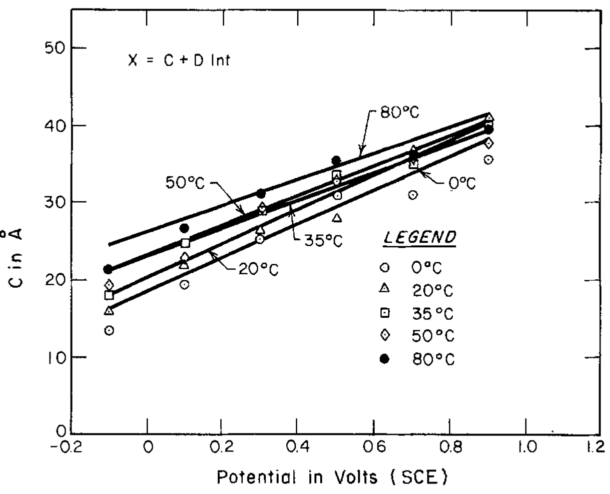

Fig. 16. The values of the rate constant C at various applied potentials.

Figure 17 shows that $1/m_3$ is proportional to T in accordance with the Sato-Cohen model. Also from Eq. [6a] and [6b] the intercepts of Fig. 16 are a function of temperature

$$b = \frac{2a_{\nu}RT}{W_o} K \qquad [14a]$$

or

$$1/b = \frac{\Delta H_o}{2sxRk}\frac{1}{T} - \frac{\Delta S_o}{2a\,Rk} \qquad [14b]$$

The intercepts $1/b$ are linearly related to $1/T$ as shown in Fig. 18. This assumes that K is a slowly varying function of T.

Discussion

These results have shown that the dual nature of the growth kinetics of passive films on iron observed

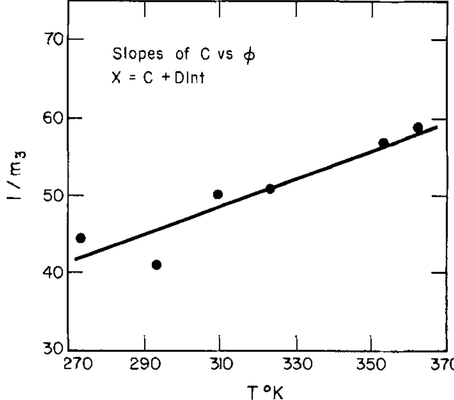

Fig. 17. The relationship between the reciprocal of the slopes of the C vs. applied potential curves and temperature.

by others at room temperature (1, 4) in borate solutions also apply over the temperature range from the near freezing point to the near boiling point of the solution. In addition, plots of the inverse thickness *vs.* log t/x^2 also give straight lines over the potential and temperature ranges considered. However, it should be pointed out that it is not possible to determine which type of kinetics is applicable by merely plotting a graph when the film thickness varies over a small range of values. This can be illustrated by eliminating the logarithmic terms of Eq. [3b] and [6b] giving

$$\frac{1/A - X}{BX/A} = \frac{C - D}{D} \qquad [15]$$

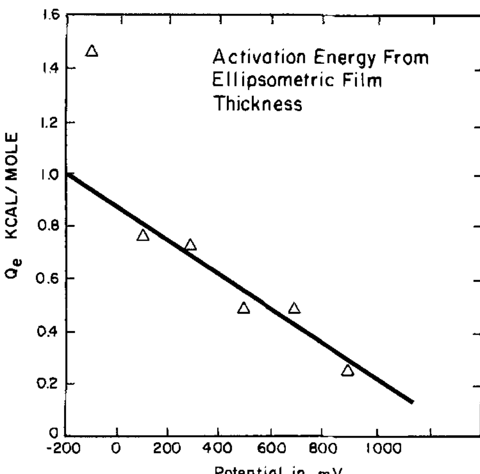

Fig. 20. The coulombic film thickness vs. $1/T$

Thus

$$1/A = C \quad [16]$$

and

$$BX/A = D \quad [17]$$

if the change in X is small. In the same manner it can be shown that

$$B = B' \quad [18]$$

and

$$A = A' - \frac{B}{X} \ln X^2 \quad [19]$$

for small changes in X.

The temperature and potential dependencies of the time-independent constants B and B' were found to be consistent with the Mott-Cabrera and modified Mott-Cabrera kinetics, respectively, *i.e.*, directly proportional to temperature and inversely proportional to potential. In addition, the jump distance, a, was found to vary linearly with temperature such that

$$a = 25.7 - 0.0633T \quad [20a]$$

in the case of the Mott-Cabrera model and

$$a' = 19.2 - 0.0462T \quad [20b]$$

for the modified Mott-Cabrera model. Thus, expressing a as $a_o - pT$, the constants B and B' take the form

$$B = B' = \frac{kT}{qaV} = \frac{kT}{8(a_o - pT)V} + C_1(T) \quad [21]$$

The values for the jump distance, a, are quite large below 100°C. It is difficult to explain these large values within the framework of the assumptions of Mott and Cabrera. Kruger and Calvert have obtained similar values for the jump distance at room temperature (1). They rationalized their results within the Mott-Cabrera model by assuming the film to be composed of two layers with only the outer layer capable of supporting fields of sufficient strength to pull cations across the film. They assumed that the actual value of the jump distance was the product of the apparent value and the fraction of the film which was nonconducting; they estimated that this fraction was approximately 1/3. This assumption and Eq. [20] lead to the conclusion that the thickness of the dielectric outer layer increases with increase in temperature. However, there still exists an inconsistency since there is a critical temperature at which the jump distance becomes zero. These temperatures are 406° and 457°K for Eq. [20a] and [20b], respectively.

Both the Mott-Cabrera and the modified Mott-Cabrera models give additive constants A and A', respectively, which are inversely proportional to potential across the film and directly proportional to temperature. However, experimentally

$$A = \frac{1}{\eta} (10.86 \times 10^{-2} - 2.46T \times 10^{-4}) + C_2(T) \quad [22a]$$

$$A' = \frac{1}{\eta} (11.05 \times 10^{-2} - 2.81T \times 10^{-4}) + C'_2(T) \quad [22b]$$

where the overpotential η has been defined relative to the corrosion potential, −770 mV (SCE). Such a dependence on temperature is not in agreement with the above models. It is interesting to note that there exists a temperature at which A and A' become independent of potential. The temperatures are 441° and 393°K for A and A', respectively. These temperatures are not far from the critical values found for a and a'.

One can explain the temperature dependent constants in Eq. [21] and [22], which are the ordinate intercepts in Fig. 7, 8, 11, and 12, as resulting from the potential drop across the film being temperature dependent. However, an examination of the intercepts on the potential axis of the $1/B$ vs. ϕ curves suggests that this may not be the complete explanation. These are the potentials at which field dependent growth begins. The values of the intercepts were found to be −498, −403, −660, −1037, and −1743 mV for 0°, 20°, 35°, 50°, and 80°C, respectively. Similar values were obtained for the $1/B'$ vs. ϕ curves. It is difficult to rationalize the low values obtained for 50° and 80° since the corrosion potential is −770 mV and independent of temperature.

The constant D was found to have a temperature dependence which is consistent with the Sato-Cohen model for film growth. From Eq. [12b] and the least squares equation for the curve in Fig. 15, it was found that ΔS_o = 14.8 cal/deg mole and ΔH_o = 7.19 kcal/mole; where the lattice constant, a, has been assumed to be 2Å and ν to be 3.

In Fig. 16 the constant C was shown to be proportional to the applied potential with a temperature-dependent slope, m_3, in accordance with Sato-Cohen model. The reciprocal of the slopes is proportional to the temperature and related to the enthalpy and entropy as given by Eq. [13b]. Figure 17 shows that $1/m_3$ is proportional to the temperature. The least squares line is

$$1/m_3 = 0.181T - 7.44 \quad [23]$$

The signs are the reverse of those in Eq. [13b]; further, ignoring the signs, the calculated value for the enthalpy is 4310 kcal/mole and that for the entropy is 104 kcal/mole, which are unrealistic numbers.

The activation energies have been determined using the Mott-Cabrera model and are shown in Table IV. The energy W has been determined from the expression given by Mott and Cabrera for the limiting thickness X_L

$$X_L = Va'q/(W - 39kT) \quad [24]$$

where X_L is the film thickness when the growth rate is 10^{-5} Å/sec. This quantity was calculated by differentiating the expression giving the film growth as a function of time and solving for X when $dX/dt = 10^{-5}$ Å/sec. The other quantities in this expression are the same as those in Eq. [1]. The values of W were determined for each temperature using

$$W = 1/p + 39kT \quad [25]$$

where p is the slope of the X_L vs. qaV curve; qaV was determined from the expression

$$qaV = kT/B \quad [26]$$

The values of W, given in Table IV, are approximately the same as those obtained by Kruger and Calvert (1) at room temperature.

From expression [24] there exists a temperature, T_c, such that

$$39T_c = W \quad [27]$$

above which rapid growth will occur. Using the mean value of W, 2.08 eV, T_c was found to be 620°K.

The activation energy, W', was determined using (from Eq. [4a])

$$A' = \frac{kT}{qaV} \ln \frac{kT}{qaVu} = B' \ln B'/u \qquad [28]$$

where

$$u = u_o \exp - (W/kT) \qquad [29]$$

therefore, W' can be determined from the slope of the ln u *vs.* $1/T$ curve. The value of W' was found to be 1.74 eV for 900 mV and 1.63 eV for 300 mV. The average of these two values is 1.68 eV as shown in Table IV.

The activation energy, Q_e, was also calculated using Arrhenius plots of the ellipsometric film thickness after 1 hr of polarization *vs.* $1/T$. The values obtained for Q_e at each potential have been plotted against potential in Fig. 17. This plot illustrates that Q_e decreases linearly as the potential is increased or

$$Q_e = W' - mV \qquad [19]$$

where V is the potential drop across the film.

Likewise, an activation energy, Q_c, can be determined from an Arrhenius plot of the coulombic film thickness after 1 hr of polarization *vs.* $1/T$. This was done for 700 mV by assuming that the passive film was Fe_2O_3 with a density of 5 g/cm^3 and a roughness factor of one. A value of 2500 cal/mole was obtained whereas, a value of 500 cal was obtained for Q_e at the same potential. If it is assumed that the difference between the coulombic film thickness and the ellipsometric film thickness is due to film dissolution, then

$$Q_c - Q_e = Q_{diss}$$

where Q_{diss} is the activation energy for film dissolution. This gives a value of 2 kcal/mole for Q_{diss}.

In essence it was found that none of the proposed models for passive film growth are completely consistent with the observed temperature and potential effects. The time-independent constants A and A' of the two expressions for inverse logarithmic kinetics are inversely proportional to potential in accordance with Eq. [3a] and [4a]; however, the temperature dependence is not in accordance with these equations. The constants B and B' of the same kinetic expressions have temperature and potential dependences which are consistent with Eq. [3a] and [4a]; but assumptions have to be made in explaining the large value of the jump distances a and a' obtained from these constants. Also, the values obtained for the potentials corresponding to the onset of field-dependent growth are difficult to rationalize. The effects of temperature on D of Eq. [6b] were found to be exactly those of the Sato-Cohen model; yet although temperature and potential of dependences C are in accordance with the Sato-Cohen model proportionally, the signs in the functional relationship are not correct physically. Thus either the existing models do not postulate the correct mechanism, or they are in need of modification.

A Limitation to the Mixed Potential Concept of Metal Corrosion

Copper in Oxygenated Sulfuric Acid Solutions

T. N. Andersen,[1] M. H. Ghandehari,[2] and H. Eyring

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

The corrosion of copper in oxygenated sulfuric acid solutions was studied by means of weight-loss and polarization curves. At a given potential, the rate of copper dissolution is greater in the presence than in the absence of oxygen reduction, which is contrary to the conventional theory of mixed potentials. An explanation of this phenomena is proposed on the basis of chemical attack by dissolved oxygen on the Cu^+ ions which are intermediates in the electrochemical copper oxidation scheme. The model is further verified by results of varying the solution agitation rate, acid strength, and oxygen partial pressure.

In 1938 Wagner and Traud (1) put forth the principle of superposition of electrochemical partial processes and applied it to mixed potentials. According to this principle, the rate of a faradaic process is independent of other faradaic processes occurring simultaneously at the electrode and thus depends only on the electrode potential. Thereby the polarization curves for independent oxidation and reduction processes may be added to predict the over-all rates and potentials which exist when more than one reaction occurs simultaneously at an electrode. Several studies have been reported which verify the above superposition (or mixed potential) principle. Wagner and Traud (1) showed the independence of dissolution of Zn amalgam of the simultaneous H_2 evolution process. They also found H_2 oxidation and reduction of several oxidants on Pt to be mutually independent. Glassner and Kimball (2) found the rate of Cd dissolution in dilute acid to be dependent on the Cd potential but independent of the rate of simultaneous H^+-ion reduction. Petrocelli (3) verified the independence of Al dissolution, at given potential, on the simultaneous reduction of ceric (Ce^{+4}) ions.

From such findings as referenced above, the independence of partial electrode reactions has been generally assumed in most recent discussions of metal corrosion in electrolyte solutions [*e.g.*, see Ref. (4-6)]. Application of the mixed potential theory to corrosion is valuable in clarifying the rate-determining processes and thus in suggesting solutions to the corrosion. It is also valuable in predicting corrosion phenomena from the polarization curves for the partial processes. These polarization curves may be obtained in the potential region of the corrosion by one or more of the following methods: (*i*) by measuring the rate of metal dissolution directly from electrode weight-loss or ion concentration changes in the solution; (*ii*) by removal of the depolarizer (*e.g.*, O_2) and measuring the rate of metal dissolution directly as the electric current; (*iii*) by measuring the rate of cathodic reduction on a nonreactive metal such as Pt, to approximate the reduction on the active metal [see Ref. (3)]; or (*iv*) by measuring the polarization curve for depolarizer reduction at potentials so negative of the corrosion potential that metal oxidation can be neglected; the resultant Tafel line is then extrapolated to the corrosion region to yield the desired polarization curve.

Key words: copper, corrosion, mixed potential.

Certain limitations are recognized in developing polarization curves by each of the above methods. Weight-loss measurements require more time than is desirable, and changes in the surface as well as metal loss through spalling is possible. The kinetics of O_2 or H^+-ion reduction differs for different metals, so it is desirable to directly study the metal of interest. Therefore, determination of polarization curves directly and extrapolation to the corrosion potential appear to be a desirable approach. This approach is not valid if the catalytic properties of the surface change with potential over the range of interest. It is also not valid if the rate-determining step and hence the Tafel slope for any process changes in the potential range through which the polarization curve is extrapolated.

In the present work we have found a further limitation to the extrapolation of polarization curves (and to the theory of mixed potentials in general) which does not appear to have been stressed previously; *i.e.*, the opposing partial processes are not independent, if the intermediates of one process react with the reactants of the opposing partial process to produce new reaction paths with lower reaction barriers than those of the isolated processes.

This limitation was discovered during the course of attempting to quantitatively apply the theory of mixed potentials to the corrosion of Cu in oxygenated H_2SO_4 solutions. Thus, extrapolation of the polarization curve for Cu dissolution in N_2-saturated solution to the corrosion potential in O_2-saturated solution yielded a corrosion rate which is less than 0.1 of the observed value. Further study of this phenomena revealed that oxygen attacked the intermediate of the copper dissolution (*i.e.*, Cu^+ ions) and thus short-circuited the electrochemical dissolution path.

Experimental

Corrosion studies.—Because of differences in the kinetics and rates in the published literature (7-12), it was necessary to develop corrosion data to support the polarization tests. For this purpose samples of high purity copper sheets, 1 cm^2 in area, were covered on one side and on the edges with silicone rubber (Dow-Corning Silastic); these were placed in a 600 ml cell containing 200 ml of 2M H_2SO_4. The solution was stirred at a constant rate and O_2, air, or high-purity N_2 was purged through the solution during each experiment. The sample was removed at different time intervals, washed with doubly distilled water and acetone, dried in an oven, and then weighed to deter-

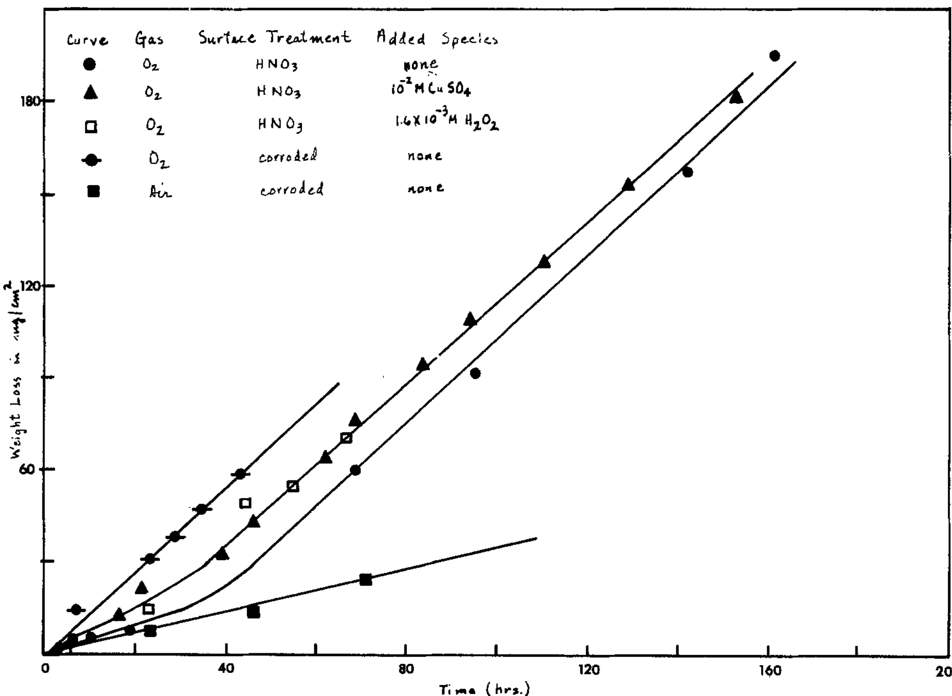

Fig. 1. Copper corrosion in stirred, 2M H_2SO_4 under various conditions.

mine the amount of Cu dissolved. For many of the tests the same sample was then put back in the cell and the corrosion continued. Each weight-loss measurement required approximately ½ hr and an entire corrosion test lasted from 6 to 160 hr. The concentration of H_2O_2 was measured at various corrosion times by means of the titanium sulfate colorimetric method (13) in the following manner: 2 to 4 ml of 0.008M titanium sulfate was added to the same amount of corrosion solution, and the maximum absorption peak at about 410 nm was compared to that of standard H_2O_2 solutions in 2M H_2SO_4. The Cu surface was prepared, prior to each test, in one of two ways: (*i*) leaching it with a few drops of HNO_3 or (*ii*) by corroding it for 40 hr in O_2-saturated 2M H_2SO_4. Corrosion tests were performed on Cu at open-circuit and at potentiostatically polarized conditions.

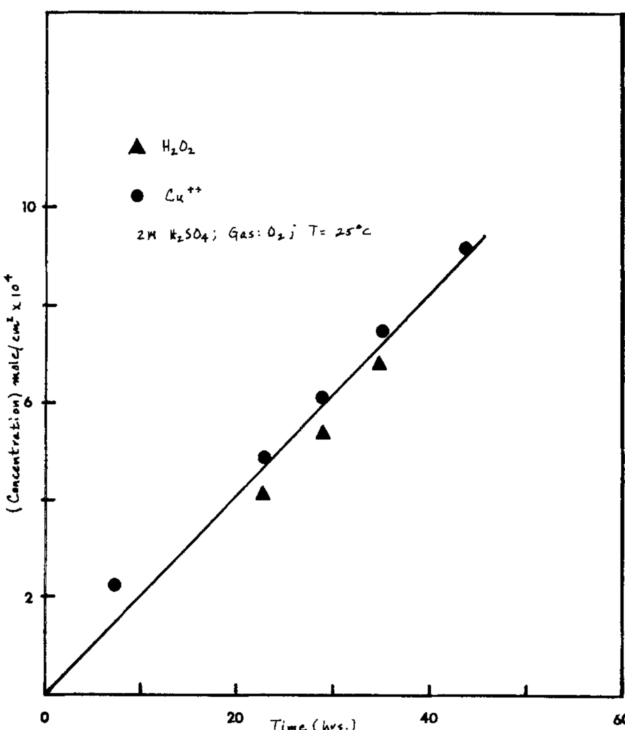

Fig. 2. Rate of copper dissolution and simultaneous hydrogen peroxide buildup during Cu corrosion at open circuit.

Polarization curves.—Cathodic and anodic polarization curves were determined by manual potentiostatic means. These curves were obtained by stepping the potential every few minutes and recording the resultant current. Also for anodic polarization the electrode was potentiostated for times from 4 to 24 hr and the current was recorded continuously and integrated. For this same period the copper weight loss was measured. Electric currents were checked for accuracy by inserting a standard resistor in the circuit and measuring the potential across it.

Results

Open-circuit corrosion tests.—Copper weight loss *vs.* time curves under various conditions in 2M H_2SO_4 are shown in Fig. 1. For the HNO_3-pretreated surface the corrosion rate increased with time until approximately 40 hr, after which the rate was approximately constant. When an already corroded sample was placed in a fresh corroding medium, the rate was constant from the beginning of the experiment and corresponded to the rate after 40 hr on the HNO_3-pretreated electrode (cf. Fig. 1).

The stable products of corrosion were H_2O_2 and Cu^{+2} ions which formed in equimolar amounts at times less than 40 hr (cf. Fig. 2). At longer times, the rate of Cu weight-loss continued at the same rate but the rate of H_2O_2 production decreased. This indicates that further reduction of H_2O_2 to H_2O or catalytic decomposition of the H_2O_2 occurs. These results contrast with those from previous corrosion studies of Cu in oxygenated H_2SO_4, in which it was generally assumed that H_2O is the final product (7, 10-12). In most such studies no direct tests for H_2O_2 formation were conducted.

To further investigate the effects of the products on the rate of corrosion, measurements were conducted in solutions which initially contained H_2O_2 and Cu^{+2} ions at concentrations observed toward the end of a typical test. From the results of these tests (see Fig. 1) it also is concluded that product Cu^{+2} ions at $C \leq 0.01M$ and H_2O_2 at $C \leq 1.6 \times 10^{-3}M$ have no effect on the corrosion.

The corrosion curves for Cu in O_2- and air-saturated solutions are both shown in Fig. 1; weight loss in N_2-saturated solutions was negligible. The corrosion currents are 1.15 and 0.29 mA/cm^2 in O_2 and air, respectively, which indicates that the rate is approximately first order with respect to oxygen concentra-

tion. Corrosion potentials of 0-10 mV (*vs.* SCE) were noted in O_2- and air-saturated solutions, whereas the open-circuit potential in N_2-saturated solution (with no added Cu^{+2} ions) was approximately −50 mV. The addition of Cu^{+2} ions shifted the open-circuit potentials in N_2 or O_2 in a positive direction.

Corrosion tests were carried out in both O_2-saturated 2M H_2SO_4 and 0.2M H_2SO_4. The rate in the 2M H_2SO_4 was 1.15 mA/cm² and that in the 0.2M H_2SO_4 was 0.82 mA/cm². In both cases the Cu^{+2} ions and H_2O_2 were formed in nearly equimolar amounts.

To test the role of agitation in the mechanism, tests were run in O_2-saturated 2M H_2SO_4 without stirring and at a faster rate than the "standard" stirring rate employed in most of the tests. The corrosion current densities obtained were 0.5 mA/cm² for no stirring, 1.15 mA/cm² for the standard stirring rate, and 1.43 mA/cm² for the rapid stirring rate. This indicates that at the standard conditions the corrosion is either partially or wholly controlled by diffusion. Inasmuch as the limiting diffusion current for O_2 reduction at the standard stirring rate was 1.6 mA/cm², which is substantially more than the corrosion rate of 1.15 mA/cm², the corrosion is only partially diffusion controlled and is hence partially reaction controlled. The positive effect of acid strength on the corrosion rate also indicates that the corrosion is partially reaction controlled.

Polarization tests.—Polarization curves were measured from open-circuit to potential regions substantially positive and negative of the open-circuit potential region. This was done to produce Tafel curves for Cu oxidation alone and O_2 reduction alone; these curves then could be extrapolated to the same potential (*i.e.*, to the corrosion potential in O_2-saturated solution) as a test of the mixed potential theory. If the curves extrapolated to the observed corrosion potential (0-10 mV) and at the current density observed in the corrosion tests, then the mixed potential theory would be considered applicable.

Figure 3 shows the cathodic Tafel plot for Cu in O_2-saturated 2M H_2SO_4 and the anodic plot for Cu in N_2-saturated 2M H_2SO_4. The copper surface was precorroded and hence corresponded to that in the linear corrosion region of Fig. 1. The plots were obtained by manual potentiostatic means with an allowance of approximately 5 min per point. The solutions were stirred at the same standard rate as in the case of the corrosion studies represented by Fig. 1 and 2. Both of the curves in Fig. 3 were repeatable in position and shape.

The anodic curve which corresponds solely to Cu oxidation consists of a Tafel line similar to those obtained in previous investigations (14-17). The cathodic curve is atypical of conventional O_2-reduction curves as the current increases to a maximum and then decreases to a minimum before increasing to the O_2 limiting diffusion current, $i_{O_2,l}$, and to the region of H_2 evolution. From the open-circuit potential to the current minimum on the negative side of the hump, both O_2 reduction and Cu dissolution occur. From the current minimum to $i_{O_2,l}$, O_2 reduction is the only significant reaction and thus equals the measured current. In a previous study (18) the region of the current maximum (hump) was investigated and the hump was identified as the result of cathodic passivation. The surface at the hump allows O_2 to be reduced with a greater rate constant than that at more negative potentials. Accordingly, the curve at current densities just less than $i_{O_2,l}$ cannot be extrapolated to the corrosion potential, E_{cor} (10 mV), to yield the corrosion current, i_{cor}, as the resulting current is too small. Rather the O_2 reduction characteristics at potentials positive of the hump would need to be extrapolated to predict i_{cor}.

Apart from problems on the cathodic side of E_{cor}, the anodic polarization curve in N_2-saturated solution fails to yield i_{cor} at E_{cor} but rather yields a value of i_{cor} which is only approximately 0.1 the value of 1.15 mA/cm² obtained from copper weight-loss measurements. Therefore the anodic polarization curve in N_2-saturated solution cannot be used to deduce the corrosion rate in oxygenated solutions.

Copper dissolution rates in N_2 vs. O_2 saturated solutions.—To further clarify this phenomena four different kinetic currents were obtained at various potentials: (*i*) The weight loss of Cu in N_2-saturated solution was obtained and converted to the corresponding 2 electron current, $i(Cu,N_2)$; (*ii*) the meter-derived current corresponding to the above test, $i_a(N_2)$, was obtained, (*iii*) the weight loss of Cu in O_2-saturated solution was obtained and converted to the current $i(Cu,O_2)$; and (*iv*) the meter-derived current in test (*iii*), $i_a(O_2)$, was obtained.

To obtain each current, at a given potential, the Cu was potentiostated for 4-24 hr. Inasmuch as the electric currents at the higher overvoltages ($\eta \geq 40$ mV) increased with time, the current was recorded and averaged to yield the effective meter values. Current densities corresponding to weight-loss results were based on 2 electrons per dissolved Cu atom because

[a] Average of all tests at given potential.

+2 is the only oxidation state for Cu in sulfate solutions in significant concentration [*e.g.*, cf. Ref. (19) and (20)]. The results of tests (*i*) = (*iv*) are given in Table I. Each test was repeated up to four times; both the individual and average values are listed. The values are arranged such as to show paired values from the same test of $i_a(N_2)$ *vs.* $i(Cu,N_2)$ and $i_a(O_2)$ *vs.* $i(Cu, O_2)$; *i.e.*, the first values listed at a given potential are from the same test [*e.g.*, 0.12 for $i_a(N_2)$ and 0.18 for $i(Cu,N_2)$], the second are from the same test, etc.

The following trends are evident: (*a*) $i(Cu,O_2) > i_a(O_2)$; the difference is substantial. (*b*) $i(Cu,N_2) > i_a(N_2)$; the difference is small. (*c*) $i_a(O_2)$ is slightly less than $i_a(N_2)$ and $i(Cu,N_2)$ at 10 mV; $i_a(O_2)$ becomes indistinguishable from the currents in N_2 at slightly more positive potentials; at the most positive potentials studied, $i_a(O_2)$ is larger than the currents in N_2.

The effects of varied stirring and acid strength are shown in Table II. It is apparent that both the rate of Cu weight loss, $i(Cu,O_2)$, and the anodic current density, $i_a(O_2)$, increase with increases in stirring and acid strength. The anodic polarization results in N_2-saturated solution were shown in a previous study (14) to be independent of stirring rate.

Discussion

That Cu dissolution is faster in O_2- than in N_2-saturated solution at a given potential is an anomaly compared to the previously described systems (1-3) and to the conventional theory of mixed potentials (1). To explain the present results we propose the following simultaneous reactions

$$Cu \rightleftarrows Cu^+ + e^- \quad [1]$$

$$Cu^+ \rightarrow Cu^{+2} + e^- \quad [2]$$

$$Cu^+ + 1/2\, O_2 + H^+ \rightarrow Cu^{+2} + 1/2\, H_2O_2 \quad [3]$$

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad [4]$$

The Cu^+ ions in Eq. [1]-[3] are transient intermediates which exist in significant concentrations only in the adsorbed state or very near the electrode surface.

Steps [1] and [2] alone constitute the mechanism for anodic Cu oxidation in N_2-saturated solutions, as manifest by test data in Table I and Fig. 3. A well-defined Tafel line is noted with values given by

$$b_a = dE/d \log i = 35\text{-}40 \text{ mV} \quad [5]$$

Previous investigators [see Ref. (14-17)] have obtained similar results which are interpreted in terms of Eq. [1] being in quasi-equilibrium followed by the rate-determining charge-transfer step, Eq. [2].

The faster rate of Cu dissolution, at a given potential, in the presence of O_2 rather than N_2 follows from step [3]. This step represents the attack by O_2 and H^+ ions on the intermediate Cu^+ ions. Thereby Cu is dissolved while exchanging only one electron with the electrode, although the final product is still the Cu^{+2} ion. Equation [4] is the electrochemical reduction of O_2 at the Cu surface.

The measured reactions of Table I are related to the proposed mechanism as follows:

$$i(Cu,N_2) \simeq i_a(N_2) = 2i_2 \text{ [3]} \quad [6]$$

$$i_a(O_2) = i_1 + i_2 - i_4 = 2i_2 + i_3 - i_4 \quad [7]$$

$$i(Cu,O_2) = 2i_2 + 2i_3 \quad [8]$$

The total O_2 utilization or H_2O_2 production current is given as

$$i_{H_2O_2} = i_3 + i_4 \quad [9]$$

From Eq. [6]-[9] and the results given in Table I the values for the reactions [2], [3], and [4] were calculated. The values for $2i_2$ and $2i_3$ (the components of Cu dissolution), $i_3 + i_4$ (the total O_2 consumption current), and i_4 are shown in Table III at various potentials. The value for $2i_2$ was taken as the average of $i(Cu,N_2)$ and $i_a(N_2)$. Average values for $i_a(O_2)$ and for $i(Cu,O_2)$ were used in Eq. [7] and [8].

The calculated value for i_3 increases with a positive increase in potential as the theory predicts. This is because the concentration of Cu^+ ions is increased as the

[3] Although $i(Cu,N_2)$ is slightly larger than $i_a(N_2)$, we consider them to be identical in this treatment. The reason for the small difference was not established but may be expected to arise from a combination of phenomena which includes dissolution of Cu^+ ions (20), mechanical loss from the electrode, and errors of up to 3% in the measured current. Inasmuch as the differences in $i(Cu,O_2)$ and $i_a(N_2)$ [or $i(Cu,O_2)$ and $i(Cu,N_2)$] are much larger than those between $i(Cu,N_2)$ and $i_a(N_2)$, the latter differences are of no consequence with regard to the qualitative conclusions of this paper.

Table II. Effects of varied stirring and sulfuric acid strength on results

E (mV)	$[H_2SO_4]$ (M)	Rate of stirring	$i_a(O_2)$ (mA/cm²)	$i(Cu,O_2)$ (mA/cm²)

equilibrium of reaction [1] is shifted with a positive increase in potential. Although the data are not adequate to produce a reliable Tafel slope, it is observed that i_3 yields a slope between 60 and 100 mV which is reasonable for partial rate control by O_2 diffusion and part by chemical reaction. The value of i_4 decreases with a positive shift in potential, but the Tafel slope is much less well defined than that for i_3. The apparent negative value of i_4 at 80 mV is further indication of the limitation in data precision.

The total oxygen consumption, $i_3 + i_4$, is approximately constant for $E \geq 30$ mV, at a value equal to or slightly less than the O_2 limiting diffusion current (which is measured as 1.6 mA/cm^2 at the rate of stirring employed in Table III). From Table III it is observed that i_3 is the predominant path for Cu dissolution at and near open-circuit potentials while the purely electrochemical path, i_2, is predominant at the more positive overpotentials. The path i_3 is the predominant reaction for O_2 consumption or H_2O_2 production at the more positive potentials; at and near open circuit i_4 is as large or larger than i_3.

The effects of stirring and acid strength on $i_a(O_2)$ and $i(Cu,O_2)$ (see Table II) are clarified by Eq. [7] and [8] and the fact that $i_3 >> i_4$.

The present model explains not only the differences in Cu dissolution rates in O_2- and N_2-saturated solutions, but also the effects on the corrosion rate of stirring rate, acid strength, and O_2 partial pressure, and the lack of effect of Cu^{+2} ions. This model also correlates anodic electrochemical results with corrosion data.

The present results and interpretation are in accord with the kinetics of corrosion of Cu by oxygenated HCl solutions (10, 21) and with the kinetics of anodic oxidation of Cu in HCl solutions (22, 23). In these cases the product is Cu^+. The rate constant of the reaction $Cu \rightarrow Cu^+$ is so rapid that the rate-determining step during anodic dissolution is the diffusion of Cu^+ products away from the electrode (24, 25). In sulfate solutions the Cu^+ ions are not stable in solution and must be removed mainly by further oxidation steps (Eq. [2] and [3]) which become rate determining. In weakly acidic sulfate solutions the Cu^+ ions are removed by precipitation of Cu_2O (24).

Although the present model does not specifically take anions into account, it is not inconsistent with the observation of Robertson *et al.* (10) that the corrosion rate of Cu is different in the presence of Cl^- than of $SO_4^=$ ions and that the relative anion effects change with pH. In the present work, corrosion tests were made in 2M HCl at open circuit. The corrosion rate was 0.25 mA/cm^2 (compared to 1.15 mA/cm^2 at 2M H_2SO_4); the corrosion potential was -260 mV (SCE) compared to $+10$ mV in the case of 2M H_2SO_4. This difference in corrosion rates is qualitatively explicable on the basis of potential, but may also depend on effects of anionic specific adsorption on the reaction rates for the given mechanism.

Although the partial processes for Cu oxidation and O_2 reduction in H_2SO_4 solutions are interdependent, the present model does not indicate such interdependence of reactions for Cu in oxygenated HCl. This is because Cu^+ is the final product and thus there is no vulnerable intermediate. Data obtained by Miller and Bellavance (21) indicate that this is indeed the case. The rate of Cu dissolution from either N_2- or O_2-saturated 0.1M HCl-1M NaCl was the same at a given potential [data from Fig. 4 and 5 in Ref. (21) were compared].

From the present results one would suspect that some other multivalent metals would behave similarly to Cu, in dissolving via the route of consecutive electron transfer, such that the mixed potential theory does not apply to corrosion of them. Although the pertinent potentiostatic data has not been located, dissolution of metals via ions of suboxidation states is supported by test results of Epelboin and co-workers and Davidson and co-workers [*e.g.*, cf. Ref. (25-29) and others listed in the review by Garreau (30)]. These investigators observed that various metals are anodically dissolved in certain solutions with an electron loss per atom less than the conventional one [*e.g.*, Al was found to dissolve with the withdrawal of only 2-2.7 electrons per atom in aqueous solutions containing halide, nitrate, chlorate, bromate, and perchlorate ions (25)]. Although the above phenomena is believed by some authors to be due to metal disintegration [cf. work of Straumanis and co-workers in Ref. (31-33) and in other works referenced in the abovementioned review article (30)], the suboxidation state finds support in numerous test results (25-30).

An Ellipsometric Investigation of the Underpotential Deposition of Lead on Gold

Jean Horkans,*,[1] B. D. Cahan,* and Ernest Yeager*

Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

Potential scanning ellipsometry has been used to examine the wavelength and potential dependence of the optical constants of the lead layer formed on Au by underpotential deposition from Pb^{2+} solution. The two main current peaks in the voltammetry curves of the system can be identified with two different states of the surface film. Neither state has optical constants resembling those of bulk Pb. Both films have an ellipsometrically determined thickness of 1.5Å. The large wavelength dependence of the optical constants of the films indicates a strong interaction of the lead adlayer with the surface layer of the Au substrate. The ellipsometric data are consistent with a model in which the layer formed on the surface at less cathodic potentials is primarily ionic and at cathodic potentials undergoes a transition to a metal-like lead adlayer.

Optical reflectance techniques have given useful information about the phenomenon of underpotential deposition[2] (UPD) and the nature of the surface lead layers formed on gold at potentials anodic to the reversible potential of lead (2-4). The use of modulated specular reflectance techniques, in conjunction with electrochemical and surface-specific methods, to investigate UPD is discussed in an earlier paper (4). The information obtained by these specular reflectance methods, although important to a better understanding of the electrode-electrolyte interface, is largely of a qualitative nature. More quantitative information may be gained by the use of ellipsometric techniques, which are capable of determining the optical dielectric constant of a surface or a surface film.

Ellipsometry has not previously been applied to the study of the UPD phenomenon, in part because of the slowness of manual ellipsometry and the expense of automation. Recently, a potential scanning ellipsometric technique has been developed (5-7) in order to allow changes in the ellipsometric parameters to be rapidly measured. Three ellipsometric parameters Δ_o, Ψ_o, and reflectivity are determined, thus allowing the determination of the complex refractive index and thickness of an absorbing film using a three layer model [*i.e.*, the substrate, film, and solution of the interface as discussed in Ref. (5)]. This method has been applied in the investigation of the UPD of lead on gold. The dependence of the optical constants of the lead film on both electrode potential and wavelength has been investigated. In addition, the effective optical film thickness was determined.

Experimental

The ellipsometric system and cylindrical optical electrochemical cell are the same as used by the authors in earlier studies with potential scanning ellipsometry (5-7). The light intensity is recorded during three identical linear voltage scans with a given offset from null of the polarizer of the ellipsometer and three different settings of the analyzer. Since the functional dependence of the light intensity on the three surface parameters, Δ_o, Ψ_o, and reflectivity R, is known, the voltage dependence of $\delta\Delta_o$, $\delta\Psi_o$, and $\delta R/R$ can be determined from the three light intensity transients, as described earlier (5-7). The parameters Δ_o and Ψ_o are related in a straight-forward manner to p_o and a_o, the characteristic null polarizer and analyzer settings, which will be used here. The relationships between p_o and a_o and Δ_o and Ψ_o are given in Ref. (6) or (8). The method is described in detail in Ref. (5).

The complex refractive index $\hat{n} = n - ik$ and the thickness of the surface film have been determined by a modified form of the unconstrained minimization techniques used in earlier studies of oxide layers on Pt (7), using a simple, three layer model of the interface (*i.e.*, assuming a film with sharp boundaries with the substrate and the solution both having bulk optical constants). For each of a series of film thicknesses, chosen by the user, the unconstrained minimum is found for the function F

$$F = (\delta\Delta_{om} - \delta\Delta_{oc})^2 + (\delta\Psi_{om} - \delta\Psi_{oc})^2 \quad [1]$$

where the subscript m denotes the measured value of each parameter and c denotes the value calculated from the assumed dependence of Δ_o and Ψ_o on the film optical constants and thickness. At each thickness, the n and k determined in this manner are used to calculate $\delta R/R$ (using the Fresnel equations). The thickness at which this calculated $\delta R/R$ is equal to that determined experimentally is taken to be the film thickness and the n and k determined from Eq. [1] at this thickness are taken as the film optical constants.

The electrodes were Au films of 0.5-1μ thickness evaporated on glass microscope slides with a thin sputtered Nb undercoat to give adhesion. The preparation of the electrodes has been described elsewhere (5, 9). The Nb undercoat was found not to interfere with the optical or electrochemical measurements (9). Although all measurements reported here were done with evaporated Au electrodes, Adzic, Cahan, and Yeager (4) have found that evaporated Au prepared in this manner and the 111 orientation of single-crystal Au give similar results in electrochemical and reflectance studies of the UPD of Pb.

Key words: underpotential deposition, monolayer metal films, ellipsometry, lead on gold.
[2] Lorentz *et al.* (1) have recently published a review of the various techniques for the study of UPD and discussed the structure and kinetics of the formation of UPD layers.

The Au vapor deposited films behave similarly to a highly oriented bulk Au.

The electrolyte was 1*M* $HClO_4$ prepared from reagent grade acid and triply distilled H_2O, the second distillation being from basic permanganate solution. The Pb^{2+} solution was prepared from Johnson Matthey Specpure $Pb(NO_3)_2$. All solutions were deaerated with N_2 gas from which CO_2 and O_2 had been removed by passing through molecular sieves. A N_2 atmosphere was maintained in the cell at all times. The squareness of the voltammetry curve in the double layer region, before the addition of Pb^{2+}, was taken as an indication of cleanliness.

An α-Pd hydrogen bead reference electrode was placed near the surface of the working electrode. A stable reference potential was maintained even in the presence of Pb^{2+} in solution. (All potentials will be quoted *vs.* NHE). The counterelectrode was a thin-walled (0.005 in.) tube of Pd-Ag alloy, sealed at one end, with H_2 gas at 1 atm inside the tube.

Results and Discussion

The linear sweep voltammetry curve for Au in 1*M* $HClO_4$ + $5.0 \times 10^{-3}M$ Pb^{2+} is shown in Fig. 1. The entire potential range shown is anodic to the reversible potential of bulk lead metal. Two distinct peaks I and II are observed with shoulders and smaller peaks also evident. The shape of the pronounced cathodic peak II differs from that reported by Adzic, Yeager, and Cahan (4) using similar electrodes, probably as a result of differences in the voltage range over which the potential was swept. In any event, this peak is surprisingly narrow in both studies. There is evidence of fine structure, including the extraordinarily sharp spike in the cathodic sweep.

The shape of these voltammetry peaks has been discussed by Adzic *et al.* (4). The more anodic peak I is broad and undoubtedly due to the adsorption of lead species on the gold surface. The remarkedly narrow peak II has been explained (4) on the basis of a surface phase transition in which lead adions condense into patches to form a predominantly metallic layer. Evidence that this peak does not involve the direct adsorption of lead from solution is to be found in the observation that this peak is not under diffusion control under conditions where peak I is under pure diffusion control. With this explanation, the charge under the peak II must then correspond to the release of compensating negative charge in the ionic double layer attending the change of the adsorbed layer from ionic to predominantly metallic character.

This explanation has been challenged by Schmidt and Wüthrich (10) on the basis that their data for lead adsorption on gold obtained with the twin electrode-thin layer technique (11) did not reveal any deviation from a linear relation between the amount of lead adsorbed and charge passed through the electrode at the potential corresponding to the narrow peak. Adzic *et al.* (12), however, question whether Schmidt and Wüthrich would have necessarily been able to see the small deviation from linearity in view of the small amount of charge observed under the corresponding peak in their voltammetry curves, which was much smaller than in the work of Adzic *et al.* (4) or in the present work. The use of an acetic acid-acetate buffer system in their thin layer cell experiments may also have caused complications.

The UPD of Pb on Au has also been studied by Vicente and Bruckenstein (13) using rotating ring-disk methods. Although most of their investigations were done in Cl^- solutions, they claim qualitatively similar results in ClO_4^- solution. These authors suggest that peak II is only observed after all the available sites associated with peak I have been filled, and observe that bulk Pb is not deposited until a monolayer of lead species is deposited at underpotentials, an observation in agreement with the results of Adzic *et al.* (4).

The optical changes caused by the UPD of lead on Au are highly dependent on wavelength. The potential dependences of $\delta R/R$, δp_o, and δa_o at 456 and 652 nm are shown in Fig. 2 and 3, respectively. The zeros of the ordinates for these curves have been adjusted to correspond to the values at 0.45V. At 456 nm (Fig. 2) on the blue side of the adsorption edge of Au (which occurs at 500 nm), both voltammetry peaks are attended by large increments in reflectivity. The δp_o curve shows a shape similar to $\delta R/R$. At this wavelength, δa_o is small and is positive for the more anodic current peak but negative for the more cathodic peak. At 652 nm (Fig. 3), on the red side of the adsorption edge of Au, a decrease in reflectivity is observed for both peaks. The shape δp_o does not vary drastically as a function of wavelength, although the magnitude

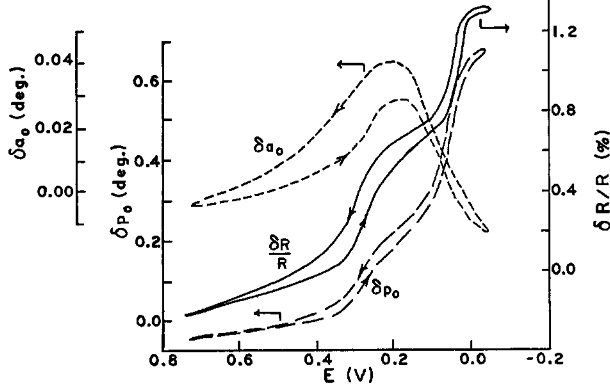

Fig. 2. Potential dependence of $\delta R/R$ at $\alpha = \pi/4$ (——), δp_o (— —), and δa_o (- - -) for Au in 1*M* $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. Wavelength 456 nm, angle of incidence 65°, sweep speed 20 mV/sec.

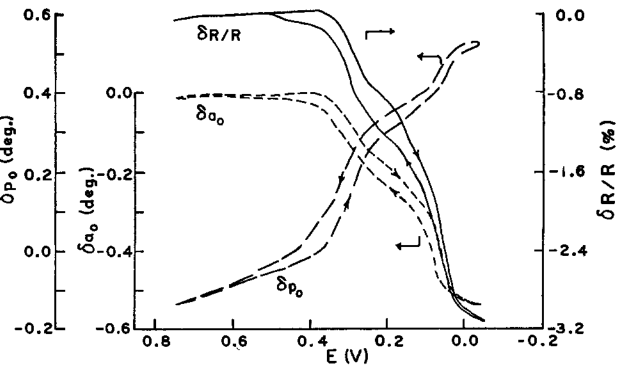

Fig. 3. Potential dependence of $\delta R/R$ at $\alpha = \pi/4$ (——), δp_o (— —), and δa_o (- - - -) for Au in 1*M* $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. Wavelength 652 nm; other conditions same as for Fig. 2.

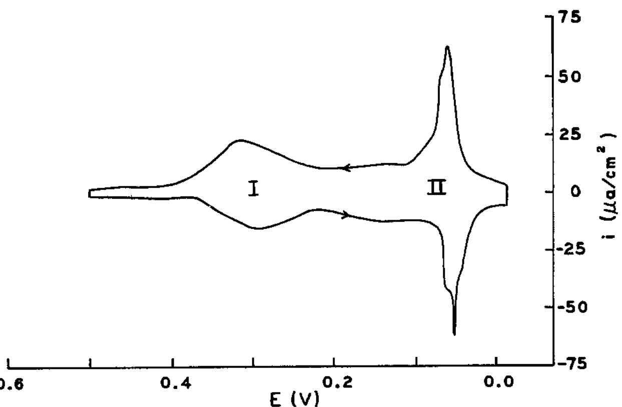

Fig. 1. Linear sweep voltammetry of Au in 1*M* $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. Sweep speed 20 mV/sec.

of the change differs. At this wavelength δa_o is large and is negative at all potentials.

The apparently large hysteresis in the δa_o *vs.* E curve at 456 nm (Fig. 2) is actually no larger than that of the other two parameters; the scale for δa_o is much expanded. However, any hysteresis at potentials anodic to 0.4V is rather surprising. At such anodic potentials, the voltammetry curves indicate that most of the lead has been desorbed. The adsorption-desorption process would not be expected to be under diffusion control in this section of the voltammetry curves at a sweep rate of 20 mV/sec in $5 \times 10^{-3}M$ Pb^{2+}. Vicente and Bruckenstein (13) have observed a similar result, in that their ring currents showed desorption of species from the disk in potential regions where the disk current indicated no faradaic processes. They suggest that this current is caused by desorption of Pb(II) adsorbed during the oxidation of underpotential lead. Possible alternative explanations are that the process is under kinetic control or that some type of aging process occurs.

The calculation of the optical properties of the adsorbed lead layer using a three-layer model requires the determination of the changes in p_o, a_o, and R relative to a film-free, two-layer reference state. The problems associated with the selection of such a reference state have been discussed elsewhere (7). In the present study, the changes in p_o, a_o, and R upon formation of the lead layer were taken to be the difference between the value of each parameter at the electrode potential of interest and its value extrapolated from the portion of the curve (scanning in the cathodic direction) in which no lead is adsorbed (anodic to 0.4V). This is essentially equivalent to taking the difference between the value of the parameter at a given potential in the presence and absence of Pb^{2+} ions in solution.

The wavelength dependence of $\delta R/R$, δp_o, and δa_o for the lead layers formed by the more anodic and more cathodic peaks are shown in Fig. 4 and 5, respectively. The reflectivity change shows the wavelength dependence observed by Adzic *et al.* (4). The measured $\delta R/R$ curve crosses zero at 505 nm in Fig. 4 and 492 nm in Fig. 5. The difference is significant; measurements at 502 nm show that the first peak causes an increase in reflectivity and the second peak causes a decrease. For both films. δp_o is everywhere positive and shows a peak at ~470-500 nm, which is rather near the absorption edge of Au at ~500 nm. The value of δa_o is small and positive in the blue, becoming large and negative in the red.

The thickness and optical constants of the UPD lead layers were determined by the procedure described in the experimental section. The function F of Eq. [1] is minimized and the calculated value of $\delta R/R$ is matched to the experimentally measured value. The

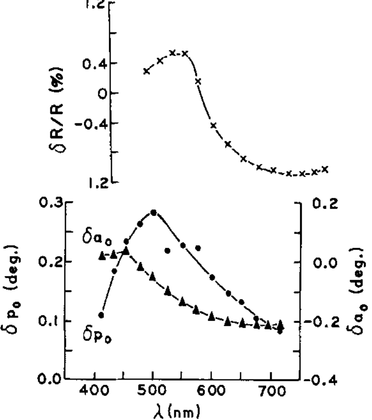

Fig. 4. Wavelength dependence of $\delta R/R$, δp_o, and δa_o for Au in 1M $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. Layer formed by more anodic current peak (0.15V in cathodic sweep). Angle of incidence 65°.

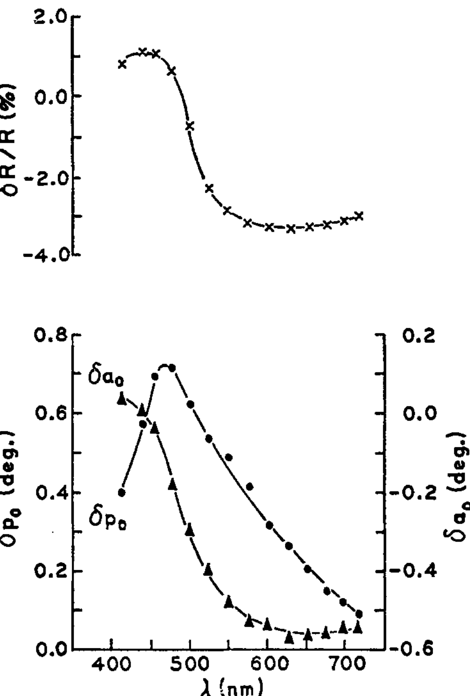

Fig. 5. Wavelength dependence of $\delta R/R$, δp_o, and δa_o for Au in 1M $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. Layer formed by more cathodic current peak (−0.05V in cathodic sweep). Angle of incidence 65°.

two potentials at which these calculations were done were 0.15 and −0.05V in the cathodic sweep; these potentials were chosen to be after the completion of the voltammetric peaks I and II, respectively. At both potentials, the film thickness t of 1.5Å minimized the difference between calculated and measured $\delta R/R$ values over the entire wavelength range studied. The measured and calculated values of $\delta R/R$ are in good agreement, within the precision with which the changes in a_o, p_o, and R are known from the experimental measurements, at all wavelengths examined for the film at +0.15V and at wavelengths shorter than 500 nm at −0.05V. At longer wavelengths than 500 nm at −0.05V, the difference between the observed and calculated $\delta R/R$ values was somewhat greater (5% of the measured $\delta R/R$ values). This may be due to some inadequacy of the three-layer model in this wavelength region, where the film formation probably substantially affects the optical properties of the surface of the Au substrate. Such failures of the three-layer model have previously been encountered with Au in this wavelength region (7) due to the presence of the adsorption edge of Au at 500 nm. Consequently, the values of the optical constants above 500 nm in Fig. 7 may be somewhat in error.

The precision with which the t values could be determined at each wavelength is estimated to be ±0.3Å with the precision of the measured values of $\delta R/R$ being the limiting experimental measurement in the present work. While the precision with which any one value of t could be determined is rather limited, the average of the values at 14 wavelengths at each potential is expected to have a standard deviation of 0.1Å. Consequently no appreciable change in the ellipsometric thickness occurs between +0.15 and −0.05V despite the fact that the total charge associated with the film formation almost doubles.

The wavelength dependences of the optical constants of the film are shown in Fig. 6 and 7 for +0.15 and −0.05V, respectively. In both cases, very large dependences of n and k on wavelength and very high values of k are observed for the film. results that would not be expected if the film resembles Pb metal. Since the optical constants of Pb are not available in

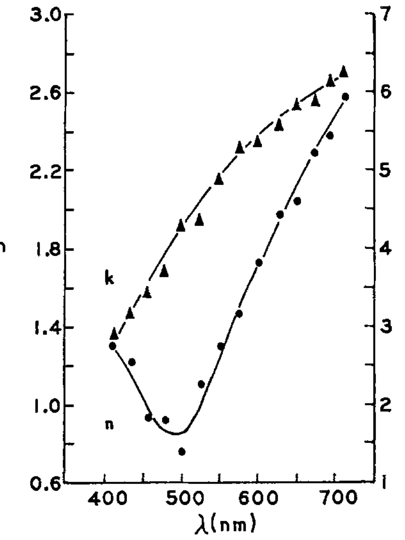

Fig. 6. Optical constants of lead film deposited by more anodic current peak (0.15V in cathodic sweep) on Au in 1M $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+}. ($t = 1.5Å$.)

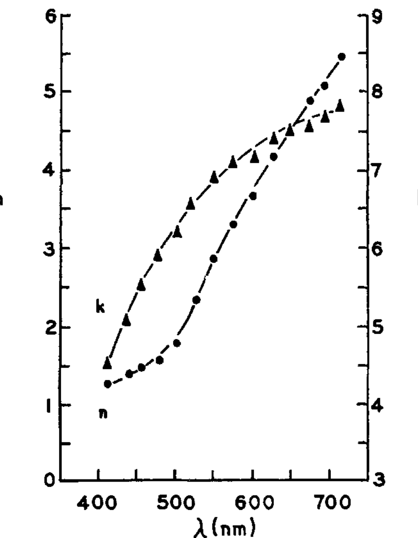

Fig. 7. Optical constants of lead film deposited by more cathodic current peak (—0.05V in anodic sweep) on Au in 1M $HClO_4$ with $5 \times 10^{-3}M$ Pb^{2+} ($t = 1.5Å$.)

the literature, a rough determination of the optical constants of bulk Pb metal has been made in this wavelength region using conventional null balance ellipsometry (Fig. 8). Although the Pb surface used undoubtedly had an oxide film and lacked the desired flatness, neither the absolute values of n and k nor their wavelength dependence should be grossly in error. None of the conclusions presented here is directly dependent on the data of Fig. 8, which are presented only for purpose of comparison with Fig. 6 and 7.

The absolute significance of the n, k, and t values of the film is not clear in view of the strong interaction of the adsorbed lead species with the gold substrate and also complications associated with surface roughness. Nonetheless, there is no question that a very pronounced change has occurred in the optical constants and hence the structure of the surface layer between +0.15 and —0.05V. The real and imaginary components of the refractive index are much higher at —0.05V and the minimum in the real component has disappeared. The imaginary component of the dielectric constant, given by $\epsilon'' = 2nk$ is far higher over the entire wavelength range, indicating much higher surface conductivity. This supports the view that the pro-

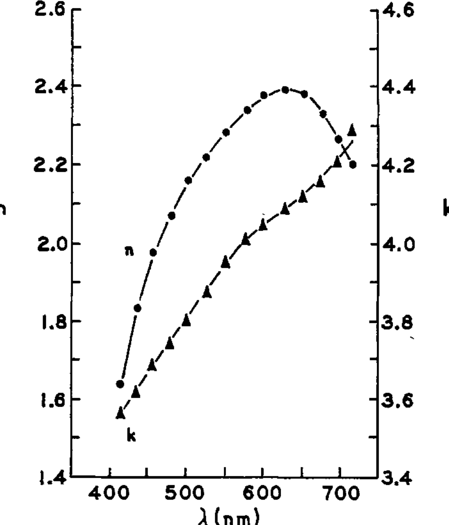

Fig. 8. Optical constants of Pb metal in air

nounced voltammetry peak II at +0.05V corresponds to a change of the film to a more metallic-like layer, with strong interaction of the lead orbitals with the band structure of the gold, as was proposed by Adzic, Cahan, and Yeager (4) on the basis that peak II is too sharp for an adsorption process and is not under diffusion control. It is difficult to reconcile such changes in the optical constants as evident between Fig. 6 and 7 and the constancy of the thickness t with the proposal of Schmidt and Stucki (14) that peak II corresponds to the formation of a metal layer more distant from and less strongly bound to the substrate.

Even at +0.15V, the values of the optical constants of the film and their wavelength dependence in Fig. 6 are indicative of a gross modification of the surface electronic properties of the gold electrode and hence of very strong interaction of the adsorbed species with the gold surface. This is at variance with the view of Schmidt and Wüthrich [see, *e.g.*, Ref. (10)] that only simple ionic adsorption of Pb^{2+} ions is involved but in accord with the proposal of Adzic *et al.* (4) that partial charge transfer occurs with voltammetry peak I. Kolb, Przasnyski, and Gerischer (15) have also recently expressed the view that underpotential deposition involves partially charged adatoms and present arguments for such based on the correlation of the underpotentials with the difference in work functions of substrate and deposit.

The sharpness of the voltammetry peak II, its insensitivity to diffusion control, the constancy of the effective ellipsometric thickness, and the pronounced change in the optical constants together support the explanation that the lead ions are first adsorbed with partial charge transfer but still primarily as ions at relatively anodic potentials and then at a more cathodic potential the layer undergoes a phase transition corresponding to a condensation into patches of predominantly metallic character.

The Effect of Oxide Dissolution on the Electrodepositing of Dispersion-Hardened Co and Ni-Al_2O_3 Alloys

G. R. Lakshminarayanan, E. S. Chen, and F. K. Sautter

Watervliet Arsenal, Watervliet, New York 12189

ABSTRACT

The solubilities of γ- and α-Al_2O_3 particles have been investigated in dilute H_2SO_4 and in watts-type plating electrolytes of cobalt and nickel. The effects of the presence of Al^{3+} ions in the plating solutions on the properties of electrodeposits of cobalt and nickel have also been studied. The results show that γ-oxide is more soluble than α-oxide, the solubility increases with decreasing solution *p*H and increasing temperature. Aluminum contents of up to 0.04 weight per cent (w/o) in cobalt and 0.02 w/o in nickel were found and the room temperature yield strength values increased to about 40% for cobalt and 20% for nickel deposits. The effects on the yield strength values of Co-Al_2O_3 and Ni-Al_2O_3 alloys due to the presence of Al^{3+} ions in their respective plating electrolyte-oxide suspensions are also discussed.

The preparation of dispersion-hardened alloys by electrodeposition is attaining increasing importance in view of the many advantages this method offers for a variety of applications. In this method, submicron oxide particles are suspended in a conventional plating electrolyte and during plating the particles are codeposited with the metal matrix. A number of investigations dealing with the preparation and properties of these alloys have been reported from this (1-6) and other laboratories (7-12). The submicron oxide particles suspended in the plating solution are generally assumed to be inert although some of them do undergo dissolution in the plating solution over a period of time. In our experience with cobalt electrolytes in which γ-Al_2O_3 was suspended over a period of time, we have observed through spectrographic analysis that an appreciable amount of aluminum was present in the solution. The primary way aluminum could have been introduced in the solution was by the partial dissolution of oxide. The contribution of this or the effect of it in the electroforming of alloys would be of interest particularly if the dissolved aluminum is incorporated in the deposit as a basic metal hydroxide. The present investigation deals with studies relative to the solubility characteristics of γ-Al_2O_3 and α-Al_2O_3 in different electrolytes, the possibility of incorporation of aluminum in the electrodeposited cobalt and nickel and its effect on the strength properties of the deposits. In addition the effects of the presence of aluminum ions in the plating electrolyte-Al_2O_3 suspension on the strength properties of electrodeposited cobalt-Al_2O_3 and nickel-Al_2O_3 alloys were also studied.

Experimental

Materials.—All chemicals were of reagent quality grade and were used without further purification. Two different aluminum oxides, γ-Al_2O_3 (0.03μ, Cabot Corporation) and α-Al_2O_3 (0.3μ Adolf Meller Company) were used to prepare the suspensions. The γ-oxide suspensions were dispersed with ultrasonic agitation to break up the agglomeration in the electrolyte.

Equipment.—*p*H measurements were made using both a Beckman Electroscan 30 in the *p*H mode of operation and a Digital *p*H meter (Leeds and Northrup) and dilute H_2SO_4 was used to adjust the solution *p*H. The surface area of the oxides was obtained by a Micromeritics Surface Area Analyzer (13) using nitrogen as an adsorbate. The design of this instrument is such that one can obtain the surface area of the samples directly and rapidly. The analyses of Al in solutions were carried out using both an atomic absorption spectrophotometer (Perkin-Elmer) and a Beckman Model Du spectrophotometer. For the atomic absorption spectrophotometer nitrous oxide-acetylene was used as an oxidizer (14) and the absorption of solution containing aluminum ions was measured at 390 mμ. When using a Beckman Du spectrophotometer, the method (15) selected was based on the extraction of aluminum 8-hydroxy quinolate by chloroform and measuring the optical density of the resultant yellow extract at 395 mμ. The oxide content in the Co-Al_2O_3 and Ni-Al_2O_3 deposits was obtained by dissolving the deposits in 50% HNO_3 and separating the oxide with Millipore filters. The oxides were then dried for an hour at 95°C and weighed on a microbalance.

Preparation and measurement of properties of the deposits.—Cobalt, nickel, Co-Al_2O_3, and Ni-Al_2O_3 alloys were deposited from their respective plating baths on a brass shim stock (0.003 in.) and the brass substrate was anodically dissolved in a KOH-K_2CO_3 solution. These deposits were cut into tensile specimens and their yield strength (0.2% offset) at room temperature was measured using an Instron tensile

Key words: electrolyte-oxide suspension, solubility of oxide, yield strength.

testing machine. A Leitz metallograph microscope was used to examine microstructural features of the deposits. Hardness values were also obtained from the above instrument fitted with the Leitz hardness tester operated at 50 and 100g load capacity.

Results and Discussion

Solubility of oxides in suspensions.—The addition of oxides to the electrolyte influences the solution *p*H to a different degree depending on the initial *p*H of the electrolyte. From Fig. 1 it is seen that the *p*H of electrolytes is raised significantly within minutes after the addition of γ-Al_2O_3 followed by a slow variation of *p*H with time. Several investigators (16, 17) have observed this type of behavior and from the kinetic studies of oxide-solution interface it has been suggested that the initial rapid change of *p*H is due to the establishment of primary equilibrium of the surface with the potential determining ions (H^+, OH^-) and that the slow variation of *p*H was partly due to the solubility of the oxide leading to various secondary reactions such as hydrolysis, complex formation, dissociation of complexes, and so on.

In the plating solutions where oxide particles are suspended the partial dissolution of oxide introduces aluminum ions in the solution. Periodic adjustment of the plating solution *p*H through the addition of acid would further contribute to increase the dissolution of oxide. The concentrations of Al obtained as a function of time in different solution *p*H are shown in Fig. 2-4, for dilute H_2SO_4-γAl_2O_3, dilute H_2SO_4-αAl_2O_3, Ni watts-γAl_2O_3, and Co watts-γAl_2O_3 suspensions, respectively. In Fig. 2, in order to make proper comparison of the solubility of γ-Al_2O_3 and α-Al_2O_3 whose surface areas are different (γ-Al_2O_3, 98.2 m^2/g; α-Al_2O_3, 20.6 m^2/g) and whose concentrations in dilute H_2SO_4 suspensions are different (γ-Al_2O_3, 25 g/liter and α-Al_2O_3, 100 g/liter) the concentration of Al is represented based on the amount of oxide dissolved per square meter surface area of the respective oxide.

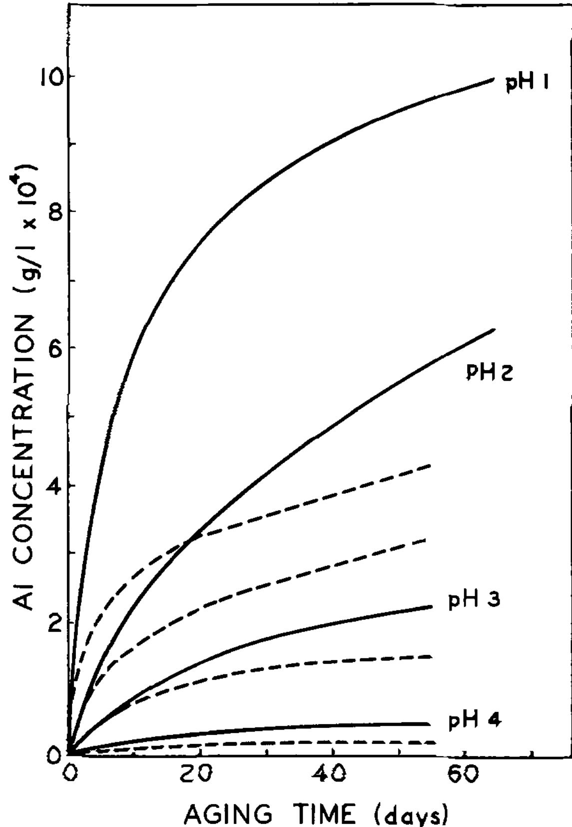

Fig. 2. Concentration of Al in solution of different *p*H due to the solubility of oxide at room temperature as a function of solution aging. Solid lines correspond to γ-oxide and dotted lines correspond to α-oxide. Since the surface areas of the oxides are different and different amounts of oxides in solution were used, the concentration of Al represented is per square meter of the surface area of the respective oxide.

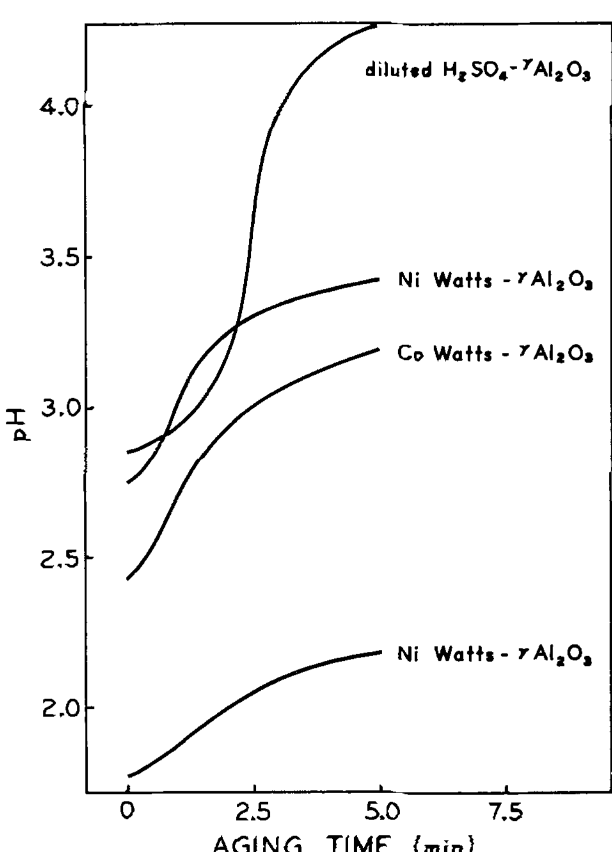

Fig. 1. Variation of *p*H at 25°C due to the addition of γ-Al_2O_3 (25 g/liter) in different electrolytes with time. A Beckman Electroscan 30 was used to scan the variation of *p*H with time.

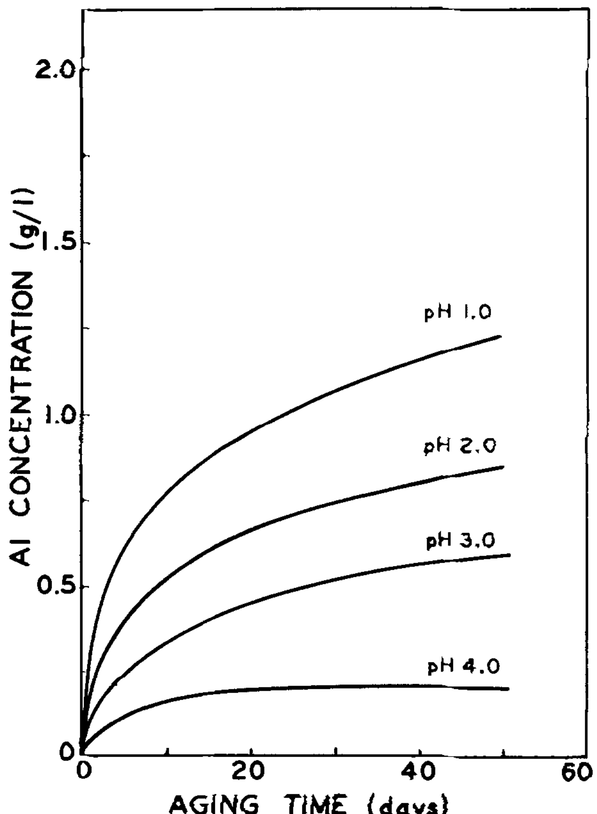

Fig. 3. Concentration of Al in nickel watts-γAl_2O_3 (25 g/liter) suspensions of different *p*H due to the solubility of oxide at room temperature as a function of solution aging.

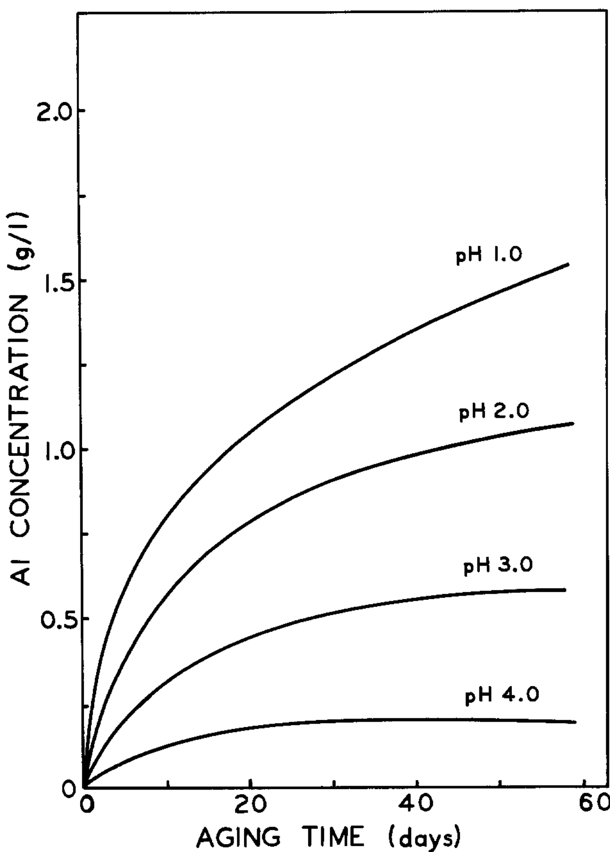

Fig. 4. Concentration of Al in cobalt watts-γAl_2O_3 (25 g/liter) suspensions of different pH due to the solubility of oxide at room temperature as a function of solution aging.

From Fig. 2. it is apparent that the rate of dissolution of both γ- and α-oxides is initially high and decreases with aging time especially at pH 1.0 and 2.0. The amount of oxide dissolution is also strongly dependent on the solution pH and is large at pH 1.0. At a high pH value the solubility is low and is possibly limited by the solubility product of aluminum hydroxide. The crystalline nature and the size of the oxide have a definite influence on the dissolution characteristics, in that α-Al_2O_3 is much less soluble at comparable pH values than γ-Al_2O_3. The solubility characteristics of γ-Al_2O_3 in nickel watts and cobalt watts solutions as a function of pH and solution aging (Fig. 3 and 4) are very similar to those observed in dilute H_2SO_4-γAl_2O_3 suspensions in that greater solubility at low pH and lower solubility at high pH values were observed.

An increase of solution temperature increases the solubility of the oxides in suspensions. For example, the concentrations of aluminum in $NiSO_4$-γAl_2O_3 suspensions (pH 2.0) at room temperature and at 53°C were found to be, respectively: 0.008 and 0.30 g/liter after 1 hr; 0.013 and 0.36 g/liter after 2 hr; 0.035 and 0.46 g/liter after 6 hr. Since cobalt and nickel plating are usually carried out at higher temperatures (40°-50°C), the concentration of aluminum ions due to the dissolution of γ-oxide in the plating solutions can be expected to be considerably higher over a period of time.

Cobalt watts and nickel watts plating solutions.—In order to investigate the effects of presence of aluminum ions in a watts-type cobalt or nickel plating bath on the properties of the Co or Ni electrodeposits, a series of deposits were obtained under different plating conditions as shown in Table I. It has to be pointed out that only small amounts of Al [max 0.04 weight per cent (w/o)] were found in the deposits. Since Al cannot be cathodically discharged, it has to be incorporated in the deposits as a basic metal hydroxide (18). It has been observed that in nickel plating (19) the cathode film has a pH value as high as 6 or 7 and at

Table I. Effect of variation of aluminum ion concentration in the plating solutions on the inclusion of aluminum with cobalt and nickel deposits

	Al content in deposits Cobalt	Nickel
Concentration of Al^{3+} ions in plating solutions:		
0.5 g/liter	No Al	
1.0 g/liter	Traces	
1.5-4.5 g/liter	Al (0.002-0.04 w/o)	Al (0.002-0.022 w/o)

* Plating solutions: Cobalt watts solution contains 310 g/liter of $CoSO_4 \cdot 7H_2O$, 31 g/liter of $CoCl_2 \cdot 6H_2O$, and 25 g/liter of boric acid; nickel watts plating solution contains 330 g/liter of $NiSO_4 \cdot 6H_2O$, 45 g/liter of $NiCl_2 \cdot 6H_2O$, and boric acid 37.5 g/liter. Aluminum ions were introduced in the plating solutions as $Al_2(SO_4)_3 \cdot 18H_2O$. Plating conditions: pH 1.0-4.0; current density 4ASD; temperature 40°C for Co and 50°C for Ni.

this high pH region aluminum ion can become hydrolyzed to $Al(OH)_3$ and subsequently included in the deposit. There is no definite trend between the Al inclusion in the deposit and the aluminum ion concentration in the plating solution except deposits from baths containing less than 1.0 g/liter Al ions showed no or only trace inclusion of Al while from baths containing larger amounts of Al ions (1.5, 2.5, 4.5 g/liter) the Al content in the deposits varied up to about 0.04 w/o. No definite trend was observed for Al inclusion in the deposits with respect to variations of the pH of the plating solution.

An examination of microstructures of electrodeposited cobalt and nickel (Fig. 5 and 6) with Al revealed interesting features. It is seen from Fig. 5 that the coarse grained columnar structure of cobalt is modified and a finer grain structure results when Al is included. A similar trend was observed for nickel containing Al (Fig. 6). As a result of the fine grained structure the Knoop hardness values obtained using a 100g load showed an increase from 270 for pure Co to 403 for Co with 0.04 w/o Al while for nickel it varied from 250 to 290 with 0.02 w/o Al. One possible explanation for the finer structure could be that the reaction product at the cathode layer, $Al(OH)_3$, may be preferentially adsorbed at the active sites (edges, corners, half-crystal position) and thus inhibits normal growth (repeatable step process). The metal atoms are forced to enter the crystal lattice at less active sites on the cathode. Thus formation of new crystallization nuclei is more frequent, the number of nuclei consequently leading to a fine grained structure.

The effects due to the presence of aluminum in cobalt and nickel deposits on their respective strength values are illustrated in Fig. 7 and 8. The yield strength values of both the as-plated and hydrogen-annealed (800°C, 1 hr) samples of cobalt and nickel increased with an increase in aluminum content. For example, an inclusion of about 0.04 w/o of Al in cobalt deposits has increased the yield strength value of the as-plated sample to about 40% over that of pure cobalt and an inclusion of about 0.02 w/o of Al in nickel deposit increased the yield strength value by almost 20% over that of pure nickel. The higher strength of the deposits with aluminum is thus seen associated with finer grained structures (Fig. 5 and 6).

Cobalt watts-γAl_2O_3 and nickel watts-γAl_2O_3 plating solutions.—To assess the effects of presence of aluminum ions in the plating solutions of cobalt or nickel with oxides on the yield strength values of their respective deposits, a series of deposits were prepared with varying amounts of aluminum sulfate in the bath and the yield strength values of both the as-plated deposits and deposits annealed in hydrogen (800°C, 1 hr) are reported in Table II. It can be seen that the codeposition of oxide with cobalt increases the yield strength values of the as-plated sample from 34.8 to 48.3 kg/mm² while no significant change was observed for nickel deposits with the codeposition of oxide. Annealed Co-Al_2O_3 and Ni-Al_2O_3 deposits, however, re-

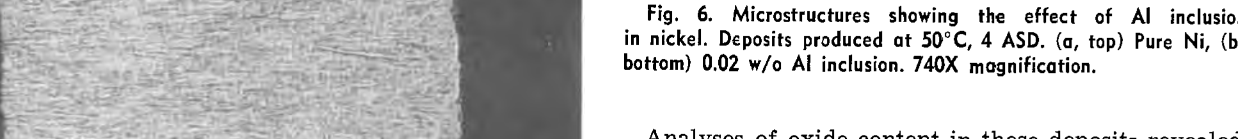

Fig. 5. Microstructures showing the effect Al inclusion in cobalt. Deposits produced at 40°C, 4 ASD. (a, top) Pure Co, (b, center), 0.02 w/o Al inclusion, (c, bottom), 0.04 w/o Al inclusion. 740X magnification.

tained higher strength values over that of pure metals annealed under identical conditions due to dispersion strengthening effects of oxide particles. In fact it is interesting to note that high temperature annealing of the $Co-Al_2O_3$ deposits increased the yield strength value while a decrease in yield strength value was observed for $Ni-Al_2O_3$ deposits. The presence of aluminum ions in the plating solution increased the yield strength values of the as-plated $Co-Al_2O_3$ alloys slightly while somewhat of a decrease in yield strength values was observed for nickel deposits in the presence of aluminum ions in the plating solution.

Fig. 6. Microstructures showing the effect of Al inclusion in nickel. Deposits produced at 50°C, 4 ASD. (a, top) Pure Ni, (b, bottom) 0.02 w/o Al inclusion. 740X magnification.

Analyses of oxide content in these deposits revealed some interesting features. As seen in Table II a general decrease in oxide content was observed for both $Co-Al_2O_3$ and $Ni-Al_2O_3$ deposits with increases in aluminum ion concentration in their plating baths. It is well known that the strength of dispersion-hardened alloys increases with oxide content in the deposits. It has been noted earlier by Sadak and Sautter (5) that a decrease of about 33% in oxide content in $Co-Al_2O_3$ deposits (prepared from a plating bath containing no added aluminum ions) resulted in 10-12% decrease in yield strength. In the present study, the $Co-Al_2O_3$ alloys obtained from the plating bath containing added aluminum ions have a slightly higher yield strength than those obtained from the plating solution without added aluminum ions. The fact that a slightly higher yield strength was obtained for $Co-Al_2O_3$ deposits in spite of a decrease in oxide content (up to about 33%) can be attributed only to the presence of aluminum ions in the plating solution. The increase in yield strength of $Co-Al_2O_3$ deposits due to the presence of aluminum ions in the plating bath is very similar but only smaller than those observed for cobalt deposits prepared from plating baths with added aluminum ions (Fig. 7). Unlike $Co-Al_2O_3$ deposits, a decrease in yield strength was observed for $Ni-Al_2O_3$ deposits that were obtained from plating baths containing added aluminum ions (Table II), the oxide content in these deposits decreased up to 37%. The effect of added aluminum ions in the nickel watts-Al_2O_3 bath on the yield strength of the deposits is quite different than those observed for deposits from nickel watts bath

Concentration of γ-Al_2O_3 for cobalt bath, 25 g/liter and for nickel bath, 25 g/liter; aluminum ions were introduced in the plating solutions as $Al_2(SO_4)_3$, $18H_2O$. Deposits were annealed in hydrogen atmosphere and the yield strength values are the average of 4-6 specimens.

(Fig. 8) where an increase in yield strength was observed. Apparently, the presence of added aluminum ions to the plating solutions of cobalt and nickel containing Al_2O_3 and no oxide has different effects on the deposits and their respective yield strength values.

Summary

The solubility of aluminum oxide in electrolytes and the effects of the presence of aluminum ions in cobalt and nickel plating solutions on the properties of electrodeposits have been investigated and the results are summarized as follows:

1. Both γ and α aluminum oxide show definite solubility in aqueous electrolytes of low pH, the dissolution being more pronounced for γ-oxide. The oxide dissolution increases with decreasing solution pH and increasing temperature.
2. Trace amounts of Al (up to 0.04 w/o) included with cobalt and nickel refine the structure of cobalt and nickel and increase the yield strength and hardness of the deposits; the effect is more pronounced for cobalt than for nickel deposits.
3. The presence of aluminum ions in the plating bath used for the electroforming of dispersion hardened Co-Al_2O_3 alloys contributes to an increase in the yield strength of the as-plated deposits while a decrease in yield strength is observed for Ni-Al_2O_3 deposits.

Flow-Through Porous Electrodes

Richard Alkire* and Brian Gracon**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Experimental limiting current data obtained on two systems of known configuration clarify conditions under which internal mass transfer restrictions control the current distribution and collection efficiency of flow-through porous electrodes. At sufficiently low flow rates, the limiting current is controlled by the rate of reactant supply to the electrode. A theoretical model is developed which includes mass transfer, ohmic, kinetic, and geometric parameters. The model succeeds in predicting limiting current behavior over a wide range of operating conditions. A simple algebraic criterion is suggested for estimating the limiting current and collection effectiveness of flow-through porous electrodes.

Because electrochemical reactions are heterogeneous, porous electrodes have come into widespread usage in order to provide large reaction rates per unit volume. Although the interior surface area of porous electrodes can be exceedingly large, dilemmas nevertheless arise which can restrict the effectiveness of the large interior surface area. For example, limitations may be encountered owing to the ohmic resistance of the electrolyte or to mass transfer limitations on the supply of reactants.

In recent years, the need for improved reactor designs to accomplish high rate electrolysis has led to the development of new reactor configurations as well as methods for scale-up and prediction of performance. Several recent publications discuss promising configurations which provide for enhanced mass transfer rates (1, 2, 3). A few of these configurations have also been recommended for the development of new electro-organic synthesis routes (4, 5). The following investigation directs attention toward one particular electrode configuration, namely, flow-through porous electrodes in which the current flows along the same spatial direction as the flowing electrolyte.

The literature on porous electrode investigations up to mid-1974 has been reviewed quite thoroughly (6). In the recent past, a number of investigators have focused attention on mass transfer limitations which arise within the porous electrodes under certain operating conditions. The extensive publications of Sioda (7) are especially noteworthy since they establish experimental procedures as well as theoretical methods for data analysis. Additional studies have appeared which account for mass transfer effects in specific electrochemical systems such as electro-organic synthesis reactions (8), metal deposition (9, 10, 11), and dissolution systems (12). These electrochemical studies provide the framework upon which the present investigation rests.

Correlations of mass transfer rates within packed beds have been investigated by traditional chemical engineering methods as noted in Ref. (6). In addition to works cited therein, the studies of Satterfield and Cortez (13), and Mandelbaum and Böhm (14) are also noteworthy since they reported correlations at low flow rates as found in most porous electrode systems. In addition, McMaster and Gilliland (15) have recently examined the influence of porosity variations which may lead to channeling and thereby cause loss of effectiveness.

The purpose of the present investigation is, on the one hand, to investigate experimentally the region of operating conditions where mass transfer restrictions affect behavior and, on the other hand, to develop a general mathematical model for flow-through porous electrodes which is applicable over wider ranges of parameter space than previous theories.

Apparatus

The flow circuit shown in Fig. 1 was used. The anode, located in a side chamber upstream from the porous electrode compartment, was a platinum sheet of approximately 20 cm^2. Saturated calomel reference electrodes were placed in side chambers on either side

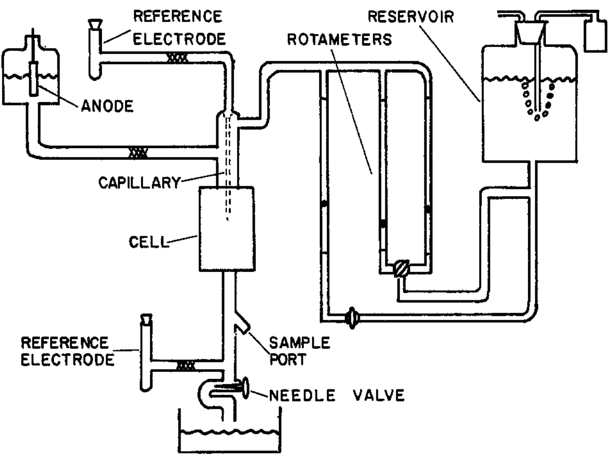

Fig. 1. Flow circuit

of the porous electrode; a glass capillary extended from the upstream SCE compartment to within 1 mm of the upstream face of the porous electrode. Downstream from the porous electrode, samples of electrolyte were withdrawn through plastic tubing to avoid galvanic displacement reactions.

The porous cathode electrode was fabricated from disks of 100-mesh platinum screen (wire diam 0.003 in.) stacked in the electrode holder (Ref. 7) as indicated in Fig. 2. The stack of disks (12 mm diam) was supported around the edge by a piston which pressed the stack against a 26-gauge platinum contact wire on the lip in the cell block. The electrical resistance of the contact was less than 0.05 ohm. The Lucite cell block was connected to the glass flow system through standard taper joints with seamless Teflon sleeves.

In order to assure that the flow within the porous electrode was uniform over the entire cross section, auxiliary experiments were conducted by depositing copper (from acidified sulfate solution) onto the screens. Observation of the deposit distribution indicated that the deposits were uniform over the cross section provided that a porous glass disk was placed downstream from the working electrode.

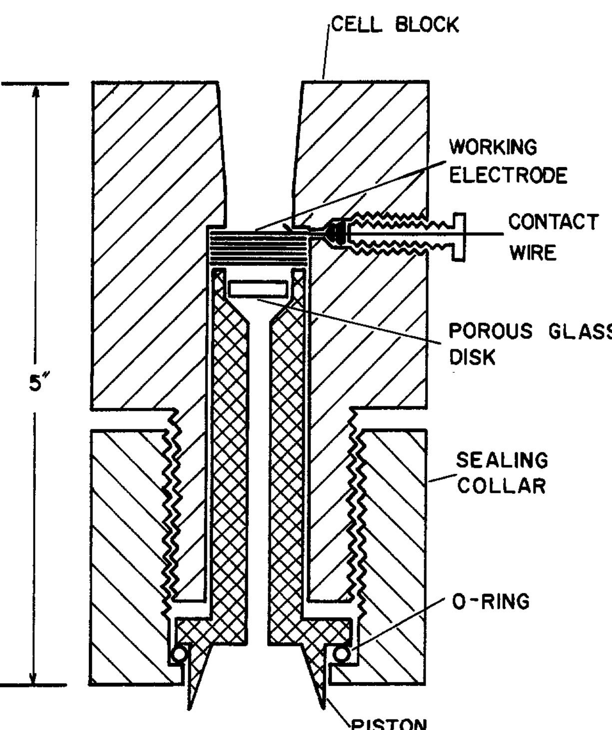

Fig. 2. Diagram of porous electrode cell holder

Current to the porous electrode was supplied by a potentiostatic source (Wenking 68TS3) with use of the upstream reference electrode. Potentials throughout the system were measured with a high impedance multipoint recorder (Leeds and Northrup Speedomax).

Two electrolytic solutions were employed, both of which used deionized, distilled water (conductivity 4×10^{-6} mho/cm). The first solution consisted of 1.0M KCl with equimolar concentrations of potassium ferricyanide and potassium ferrocyanide. Owing to the light sensitivity, nearly all parts of the flow system were shielded from light. The potassium ferricyanide concentration was determined by an iodometric titration method which was found to be accurate to within 1%. The second solution consisted of 0.002M $CuSO_4$ in 1.5M H_2SO_4. The copper concentration was determined by colorimetric determination with neocuproine (16).

Procedure

Electrolytic solution was prepared from AR chemicals and deaerated by nitrogen flow for one hour prior to use. The metal disks were punched from screen (Unique Wire Weaving Company), soaked in trichloroethylene, air-dried, soaked in NaOH (25 g/liter), rinsed, soaked in warm concentrated nitric acid, and rinsed. The electrode was assembled under water to eliminate bubbles, placed in the flow circuit, and rinsed with copious amounts of electrolytic solution.

The flow rate was measured both with rotameters and by collecting measured volumes. The needle valve permitted flow rate control to within 2% of the mean value reported.

Steady-state polarization curves were determined by current measurement at various applied potentials. The steady-state current was attained within three residence times. In some cases, but not all, while operating at the limiting current condition, electrolyte samples were withdrawn from both sides of the porous cathode and were subsequently analyzed to determine reactant concentration.

The measured potential difference between the working and upstream reference electrodes was corrected in order to remove the ohmic contribution external to the porous electrode. For this purpose, the distance between the upstream reference capillary tip and the porous electrode face was measured optically. It was found that the potential gradient in the upstream solution, determined by varying the capillary position, corresponded to a value of electrolyte conductivity which agreed to within 5% of that value determined independently in a conductivity cell. The capillary tip was positioned 1 mm from the upstream face of the porous electrode in order to avoid interference with the fluid flow.

The current distribution within the porous electrode was determined from the deposit distribution obtained with the acid copper system. Electrolysis was conducted under limiting current conditions for a measured period of time. Subsequently, the electrode was disassembled. The amount of copper on each screen was determined by nitric acid stripping followed by copper-ion measurement using the neocuproine method (16).

Results and Discussion: Experimental

The properties of the electrochemical systems investigated are compiled in Table I. Table II contains the geometric properties of the porous electrodes. The electrode porosity was determined by weighing. The electrode length, determined by measurement through the transparent cell wall, was accurate to within 0.1 mm. The specific surface area given in column four of Table II was estimated by a method which is known to predict values which are somewhat high (27). As will be discussed later, it was found that agreement between experimental data and theoretical predictions could be obtained if the specific surface area was

4.0	40	64	260	210
7.0	60	72	223	180

reduced by a multiplier of 0.81; the "adjusted value" of the specific surface area is given in the last column in Table II.

Figure 3 illustrates a typical set of polarization curves; all voltages reported are *vs.* SCE and have been corrected for ohmic drop external to the porous electrode. In subsequent discussion, attention will focus solely on the limiting current plateau region. The dependence of limiting current upon velocity, given in Fig. 3, is shown in Fig. 4 along with similar data obtained at two other reactant concentrations. It is seen that when the limiting current for each system is normalized by the corresponding reactant concentration, the data fall on a single curve which assures that mass transport processes control electrode behavior.

The effect of electrode thickness on limiting current is shown for a range of velocities in Fig. 5. At low flow rates, all the data for a given chemical system converge to a single curve which corresponds to the equation

$$i_{lim} = nFc_i^o v \quad [1]$$

The solid lines in Fig. 5 correspond to Eq. [1] for the two systems studied. At high flow rates, all curves approach similar slopes but the value of limiting current depends upon electrode length. For flow rates between about 40-1200 ml/min, the slope is about one-third; for still higher flow rates, the slope increases to approximately one-half. These data indicate that for low flow rates, the limiting current depends upon the rate of reactant supply in accord with Eq. [1]. At higher flow rates, on the other hand, the limiting current depends upon another type of mass transfer process occurring within the interior of the porous electrode; that is, reactants entering the porous region experience difficulty in reaching the interior surface. As a consequence, the limiting current depends upon reactor length.

The effectiveness of the porous electrode in removing reactant species may be defined as

$$\begin{matrix}\text{collection} \\ \text{effectiveness}\end{matrix} \equiv CE = \frac{c_i^o - c_i^x}{c_i^o} \quad [2]$$

It was determined experimentally that the reactions under investigation proceeded with a current efficiency of 100%. Therefore, by a materials balance, Eq. [2] can also be written as (7)

$$CE = \frac{i_{lim}}{nFc_i^o v} \quad [3]$$

By direct experimental measurement of c_i^x, the downstream electrolyte concentration, it was found that determination of the collection effectiveness, or limiting degree of conversion, by Eq. [2] agreed to within 1% of that value determined independently by Eq. [3]. Referring again to Fig. 5, it is seen that those data which lie below the solution line, Eq. [1], correspond to conditions where the collection effectiveness is less than unity. Under these conditions, owing to internal mass transfer resistance, there exists a plume of reactants which cannot reach the interior surface and which therefore escape from the reactor.

Figure 6 provides current distribution data from the copper deposition system operated at several solution velocities and electrode lengths. The data are normalized by the total deposit weight so that a uni-

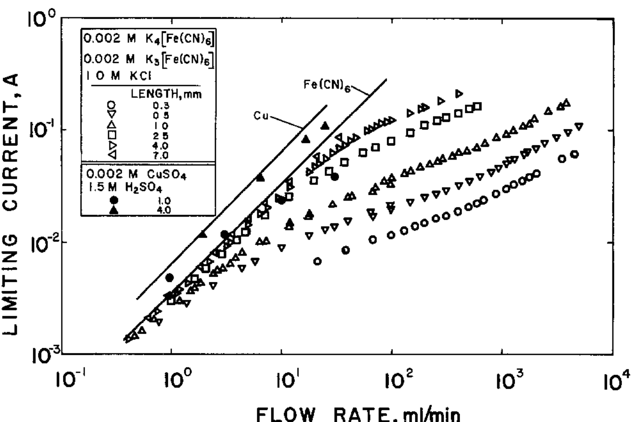

Fig. 5. Dependence of limiting current upon flow rate and electrode length.

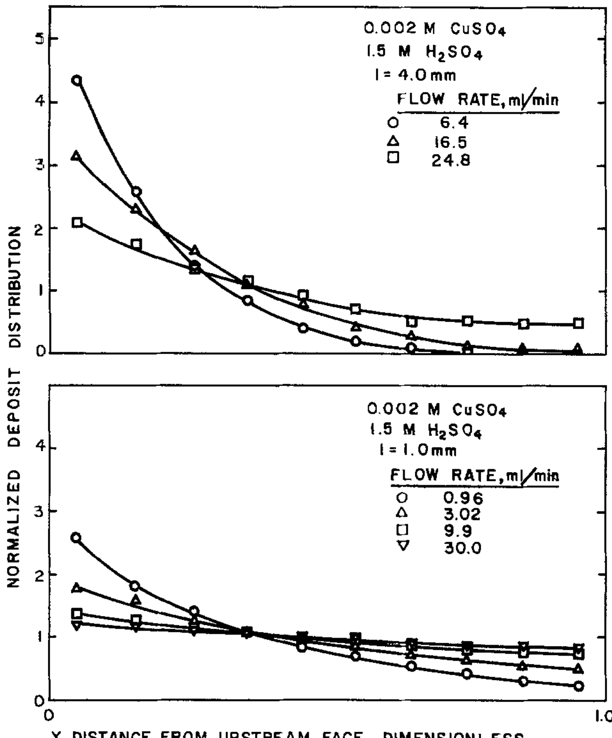

Fig. 6. Dependence of current distribution upon flow rate and electrode length.

form distribution corresponds to an ordinate value of unity. At low flow rates, the limiting current distribution is quite nonuniform and indicates that there is little reaction in the downstream portions of the electrode; these data indicate that the reactant is consumed within the electrode to such extent that there is very little reactant remaining in the electrolyte on the downstream regions. At high flow rates, the limiting current distribution is nearly uniform, indicating that mass transfer from the flowing electrolyte to the solid interior surface controls behavior, and that the mass transfer coefficient is independent of position within the porous electrode.

Theoretical

The foregoing experimental program has provided a firm basis upon which to develop a theoretical model for predicting the behavior of flow-through porous electrode systems. As indicated in the literature survey section, several models have been proposed which are valid over limited ranges of operating conditions. In what follows, a more general model will be developed which is capable of predicting behavior over wide ranges of operating conditions and which includes charge transfer, ohmic resistance, convection, and diffusion (dispersion) in addition to internal mass transfer limitations. Only behavior at the limiting current condition will be investigated below. A more extensive theoretical investigation will be the subject of future papers.

The porous electrode to be modeled is of uniform thickness, l, and is of uniform specific surface area throughout. The counterelectrode is upstream; solution enters the porous electrode at position $y = 0$ and exits at position $y = l$. These conditions correspond to the experimental configuration shown in Fig. 1 and 2.

Since rigorous calculations are cumbersome, several assumptions have been adopted which conform closely to the foregoing experimental systems: (*i*) electrolysis proceeds in the steady-state without structural changes or insulation effects occurring at the electrode; (*ii*) only one electrochemical reaction occurs; (*iii*) conduction within the electrolytic solution obeys Ohm's law, and migration effects are negligible; (*iv*) the porous electrode is of uniform potential throughout; (*v*) convection through the porous electrode takes place by forced plug flow without channeling effects, and there are no diffusion limitations exterior to the porous electrode; (*vi*) internal mass transfer processes, localized near the solid interior surface of the porous electrode, may be characterized by a mass transfer coefficient which is independent of location; and (*vii*) the pores of the electrode are sufficiently small that the model may be written in one-dimensional form wherein heterogeneous electrode reactions appear as pseudohomogeneous source terms. Although these assumptions limit the model, most of them may be altered to suit particular applications.

The stoichiometry of the electrode reaction is defined by

$$\sum_i \nu_i M_i^{z_i} = ne^- \quad [4]$$

For the redox system of ferro- and ferricyanide, the reaction rate expression is assumed to be

$$j(y) = i_o \left\{ \left(\frac{c_1^s(y)}{c_1^o}\right) \exp\left(\frac{\alpha_a n\mathbf{F}\phi(y)}{RT}\right) - \left(\frac{c_2^s(y)}{c_2^o}\right) \exp\left(\frac{-\alpha_c n\mathbf{F}\phi(y)}{RT}\right) \right\} \quad [5]$$

Owing to mass transfer processes occurring near the interior solid surface, however, the surface concentrations which appear in Eq. [5] may be substantially different from reactant concentration in the "core" of the flowing electrolyte filament. The local concentration difference between surface and "core" are related through the mass transfer coefficient

$$j(y) = \frac{nk_i\mathbf{F}}{\nu_i}(c_i - c_i^s) \quad [6]$$

In this work, the mass transfer correlation of Wilson and Geankoplis (21) will be used over the range of low flow rates for which it is valid

$$k_i = \frac{1.09}{\epsilon} \frac{1}{Sc^{2/3}} \left(\frac{\mu}{d_p}\right)^{2/3} L^{1/3} \quad [7]$$

The internal mass transfer process is assumed to be localized near the solid surface; the species balance which incorporates diffusion, convection, and reaction is therefore

$$D_i \frac{d^2c_i}{dy^2} - v\frac{dc_i}{dy} = k_i a\,[c_i(y) - c_i^s(y)] \quad [8]$$

In the electrolyte phase, the potential field obeys Ohm's law

$$i(y) = -\kappa \frac{d\phi}{dy} \quad [9]$$

The current in the solution, $i(y)$, varies with position owing to electrochemical reaction

$$\frac{di}{dy} = -a\,j(y) \quad [10]$$

Combination of Eq. [9] and [10] gives

$$\frac{d^2\phi}{dy^2} = \frac{a}{\kappa} j(y) \quad [11]$$

The model is completed by specification of the boundary conditions.

At $y = 0$

$$\phi = \phi_a, \quad c_i = c_i^o \quad [12]$$

At $y = l$

$$\frac{d\phi}{dy} = \frac{dc_i}{dy} = 0 \quad [13]$$

In order to reduce the number of independent parameters, the following dimensionless quantities are defined

$$Y = \frac{y}{l} \qquad C_i^s = \frac{c_i^s}{c_r}$$
$$C_i = \frac{c_i}{c_r} \qquad \Phi = \frac{F\phi}{RT} \qquad [14]$$

With these groupings, the equations of the model yield the dimensionless system parameters

$$\xi = \frac{i_o a l^2 n F}{\kappa RT} \qquad \gamma_i = \frac{c_i^o}{c_r} \qquad \chi = \frac{i_o a l^2}{n F c_r D_r}$$
$$\zeta = \frac{vl}{D_r} \qquad \Gamma = \frac{k_i a n^2 F^2 l^2 c_r}{\kappa RT} \qquad \pi_i = \frac{D_i}{D_r} \qquad [15]$$

In the discussion section below, attention will turn to a physical interpretation of each of these parameters and the role they play in determining the behavior of the system.

In the foregoing dimensionless notation, the equations which define the model are

$$\Phi'' = \xi \left\{ \frac{C_1^s}{\gamma_1} \exp(\alpha_a n \Phi) - \frac{C_2^s}{\gamma_2} \exp(-\alpha_c n \Phi) \right\}$$
$$\pi_i C_i'' - \zeta C_i' = \frac{\chi \Gamma}{\xi} (C_i - C_i^s) \qquad [16]$$
$$\Gamma(C_i - C_i^s) = \nu_i \xi \left\{ \frac{C_1^s}{\gamma_1} \exp(\alpha_a n \Phi) - \frac{C^s_2}{\gamma_2} \exp(-\alpha_c n \Phi) \right\}$$

Each "prime" superscript denotes differentiation with respect to the dimensionless spatial variable Y. The boundary conditions become

$$\Phi(o) = \Phi_a$$
$$\frac{d\Phi(1)}{dY} = \frac{dC_i(1)}{dY} = 0 \qquad [17]$$
$$C_i(o) = \gamma_i$$

Once the potential and concentration distributions are found by solving the model equations, the current distribution within the porous electrode may be found from the dimensionless form of either Eq. [5] or Eq. [6] which are, respectively

$$\beta J = \xi \left\{ \frac{C_1^s}{\gamma_1} \exp(\alpha_a n \Phi) - \frac{C_2^s}{\gamma_2} \exp(-\alpha_c n \Phi) \right\} \qquad [18]$$

$$\beta J = \Gamma(C_2^s - C_2) \qquad [19]$$

The above equations have been derived for a redox system. The same general approach may be used to develop a model for metal deposition reactions by replacing Eq. [5] with the reaction rate equation

$$j(y) = i_o \left\{ \exp\left(\frac{\alpha_a n F \phi}{RT}\right) - \frac{c_2^s}{c_2^o} \exp\left(\frac{-\alpha_c n F \phi}{RT}\right) \right\} \qquad [20]$$

Models have been developed which use both Eq. [5] and [20] in order to analyze the experimental data reported above.

Method of Solution

The solution of the model equations was carried out on a digital computer with a finite difference numerical procedure. The equations were first linearized about a trial solution and then written in finite difference form. The resulting set of simultaneous tridiagonal matrices was then inverted with use of an IBM 360 computer (28). Solutions of the nonlinear equations were obtained by iteration on the approximate linear solution; convergence was usually achieved within seven iterations.

Table III. Dimensionless parameters of systems under study

Comparison of Theory with Experiment

The foregoing theoretical model was tested over the range of limiting current conditions for which experimental data have been reported above. It was found that excellent agreement was obtained by arbitrarily adjusting the specific surface area by a multiplier of 0.81. This adjustment is not large in comparison with the accuracy of the method employed in estimating the original values (27). With this single minor adjustment, the values of dimensionless system parameters which correspond to the experimental systems are given in Table III. Calculations with these values were compared by three different methods with experimental data as follows.

Figure 7 provides the comparison for limiting current *vs.* flow rate for several reactor lengths. The agreement is excellent over the entire flow range for which the mass transfer correlation is valid (Re < 55). At the highest flow rates investigated, the slope changes from one-third to one-half; the Reynolds number at which this change occurs corresponds to the upper limit of validity of the mass transfer correlation used. At such flow rates, a different mass transfer correlation could be used (29); however, the range of high flow rate and low collection effectiveness is perhaps of scant interest for most industrial applications.

A second method of comparison was made by using Eq. [3] to determine collection effectivenesses as shown in Fig. 8. Direct experimental measurement of collec-

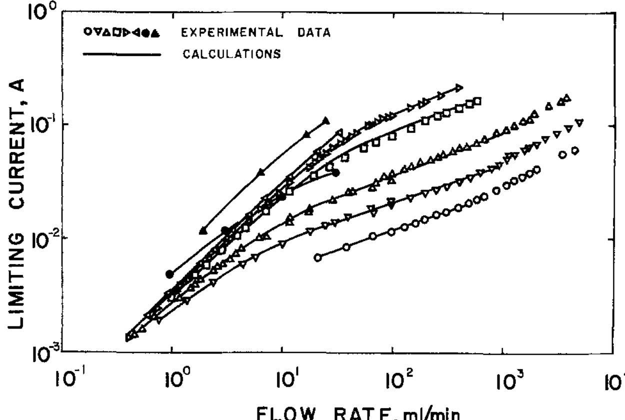

Fig. 7. Comparison of experimental limiting current data (Fig. 5) with theoretical calculations.

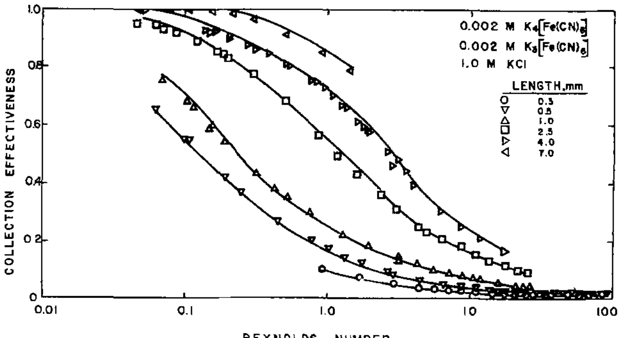

Fig. 8. Comparison of measured collection effectiveness with theoretical calculations.

tion effectiveness, by concentration determinations, was found to agree within 1% of the values calculated from the limiting current with Eq. [3]. These data indicate that the collection effectiveness falls from unity to zero in about three orders of magnitude of flow rate. An approximate method for estimating the maximum flow rate for which all reactants are collected is provided in the discussion section which follows.

Current distributions predicted for the acid copper system are given in Fig. 9; these calculations may be compared with experimental data under the same conditions in Fig. 6. The general trends of the calculated distributions agree with the trends of the experimental data: at low flow rates the upstream portions of the porous electrodes are more reactive, but, at high flow rates the current distribution is more nearly uniform. However, the experimental distributions are more nonuniform than those predicted on a theoretical basis. Since operation at the limiting current is purely mass transport controlled, the factors which may contribute to the discrepancy would include only those associated with the mass transport phenomena, namely, diffusion, convection, and internal mass transfer. Although the diffusion process may be influenced by dispersion of fluid packets within the bed, or nonplug type flow, the effect of such a process would be opposite to that observed; that is, the experimental distributions would be more uniform than theoretically expected. The accuracy with which the concentrations and velocities are measured is sufficient to assure that the discrepancy is not due to errors in estimating the system parameters. It is suggested that the mass transfer coefficient is not constant, as assumed, but varies with position within the bed.

Errors regarding the form of the mass transfer coefficient are critical only insofar as the internal mass transfer process dominates electrode behavior. For example, predictions of behavior below the limiting current would not be expected to depend upon the mass transfer coefficient. Because the experimental data at high flow rates ($Re >> Re_{cr}$) are in excellent agreement with calculations, it is clear that the value of the average mass transfer coefficient is correctly modeled. The disparity between Fig. 6 and 9 indicates the need for additional studies on local mass transfer processes within packed beds operated at low flow rates.

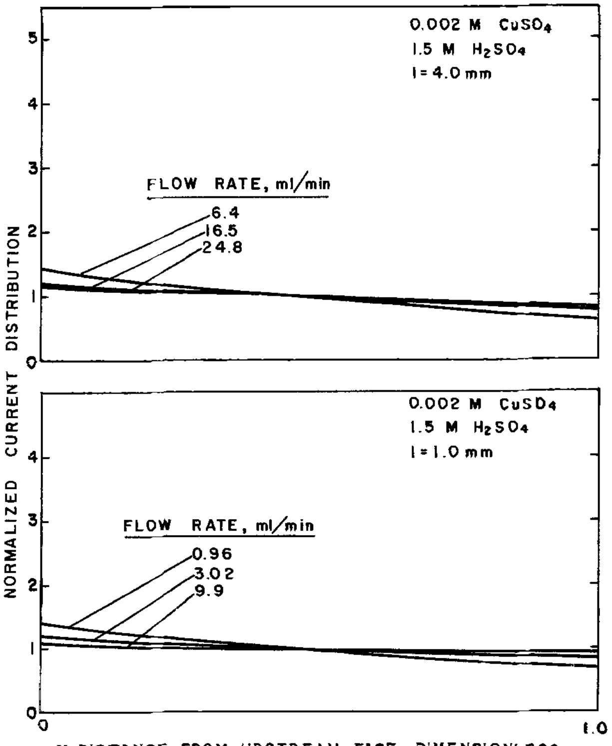

Fig. 9. Theoretical current distribution calculations to be compared with expeimental data in Fig. 6.

Discussion: Theoretical Model

In this study, calculations with the theoretical model have been reported only under limiting current conditions. The model is also capable of predicting behavior below the limiting current insofar as its parameters contain information about charge-transfer, ohmic resistance, diffusion, electrolyte flow, internal mass transfer resistance, and geometric properties. The agreement obtained in this study between experiment and theory, however, justifies further discussion of several qualitative aspects of the model. In the following paragraphs, a physical interpretation of the dimensionless parameters is provided. In addition, several examples are given to illustrate how the model can be employed to define regions of parameter space within which previously published limiting cases can be used to predict system behavior.

The parameter ξ contains the ratio i_o/κ and thereby indicates the relative importance of electrolyte resistance and charge-transfer resistance. In the absence of other phenomena, a value of ξ greater than unity corresponds to conditions under which the current distribution within the porous electrode is nonuniform owing to low solution conductivity. The parameter χ contains the ratio i_o/D and thus indicates the relative importance of diffusion *vs.* charge-transfer resistance; in the absence of other effects, a value of χ greater than unity indicates that the current distribution will be nonuniform owing to slow diffusive transport of reactants to the interior regions. The parameter ζ indicates the relative importance of electrolyte convection (by plug flow) with respect to diffusional transport; if ζ is sufficiently large, limitations on reactant supply depend upon convection processes, not diffusion. The parameter Γ is a dimensionless mass transfer coefficient and describes the ease with which reactants are transported to the solid surface once they have entered the porous region; a small value of Γ indicates the situation wherein reactants experience great difficulty in moving from the "core" of the flowing electrolyte filaments to the solid surface where reaction occurs.

Each of these dimensionless parameters indicates the relative importance of two effects. In general, however, more than two effects may be important in controlling electrode behavior. However, the relative magnitude of the parameters with respect to each other can be employed to estimate which particular effects are the most important for any particular electrode design. The following paragraphs provide four examples. It is worthwhile to note that the following discussion does not require solutions of the differential equations which define the model; that is, algebraic knowledge of the parameters alone is sufficient to provide a great deal of intuitive insight into the behavior of complex electrochemical systems.

(i) Role of electrolyte conductivity.—Concentration variations within the porous electrode are negligible under conditions of rapid diffusion, high flow rates, and large mass transfer coefficients ($\chi << 1$, $\zeta >> 1$, and $\Gamma >> 1$). Under these conditions, the parameter ξ controls the uniformity of reaction within the porous electrode. When ξ is large, the conductivity is sufficiently low that the potential distribution, and thereby the current distribution, is nonuniform (30). Many of these special cases have been applied to battery systems (6); the same approach also applies to resistive electrodes (31).

(ii) Role of diffusion.—Reactants may experience difficulty in penetrating into interior regions of an electrode when convection rates are low ($\zeta < 1$), even though the potential distribution would otherwise be uniform ($\xi < 1$). For steady-state behavior under these conditions, the parameter χ controls the current distribution. Large values of χ indicate that diffusion from

the electrode face is insufficient to supply interior regions, thus leading to a nonuniform current distribution. Many specific cases have been applied to battery systems (30-34) as reviewed in Ref. (6).

The relative importance of solution conductivity *vs.* diffusional limitations is given by the ratio ξ/χ.

(iii) Role of convection.—By flowing electrolyte through the porous electrode, high rates of reaction can be sustained provided that ohmic resistances do not limit behavior. Calculations conducted with the above model (35) have indicated that for $\zeta < 10^{-1}$, pure diffusion controls and the situation under *(ii)* above obtains; for $\zeta > 10^4$, the convection is sufficiently rapid that the electrolyte is of uniform concentration so that comments under *(i)* above pertain. For intermediate values $10^{-1} < \zeta < 10^4$, more complex behavior is obtained (6, 30, 36, 37).

All convection models published to date assume plug flow within the pores. In the absence of internal mass transfer limitations, the maximum current which can be obtained with a flow-through porous electrode is given by Eq. [1] which, in dimensionless notation is

$$\beta_L = \frac{\gamma\xi}{\chi}\zeta \qquad [21]$$

Equation [21] indicates that, under these operating conditions, the limiting current is linearly proportional to the convective velocity and is independent of the electrode length. In addition, the collection effectiveness is unity at the limiting current for all flow rates.

(iv) Role of mass transfer.—It may not be possible to attain the maximum current predicted by Eq. [21] if mass transfer processes within the pores are sluggish (small Γ) (6-10), in which case the limiting current is given by

$$i_{\rm lim} = n\mathbf{F}lakc_i^o \qquad [22]$$

or

$$\beta_L = \gamma\Gamma \qquad [23]$$

By combining Eq. [21] and [23], the collection effectiveness under mass transfer control is

$$CE = \frac{\Gamma\chi}{\zeta\xi} \qquad [24]$$

Equations [21] and [23] correspond to the low flow and high flow asymptotes shown in Fig. 7. By combination of Eq. [7], [21], and [23], the Reynolds number at which the asymptotes intersect is found to be

$$\mathrm{Re}_{cr} = \left[\frac{\Gamma^* \chi\, d_p}{\mathrm{Sc}\,\xi\, l}\right]^{3/2} \qquad [25]$$

For Re $<<$ Re_{cr} the discussion given in *(iii)* above applies. For Re $>>$ Re_{cr}, the discussion given in *(iv)* can be used to predict behavior. For Reynolds numbers in the range $0.10\ \mathrm{Re}_{cr} < \mathrm{Re} < 10\ \mathrm{Re}_{cr}$, the algebraic relations given above are not suitable for accurate predictions.

Conclusions

The experimental data reported above have led to clarification of different regimes of mass transport phenomena which control the limiting current density of flow-through porous electrodes. At low flow rates, the limiting current is controlled by the rate of reactant supply to the upstream face of the electrode and the current distribution is rather nonuniform within the electrode. At high flow rates, the limiting current is controlled by the rate at which reactants are transported to the reactive surface once they have entered the electrode pores, and the current distribution is uniform provided that secondary reactions do not occur. Whereas data on limiting current and collection effectiveness are in excellent agreement with theoretical predictions, the measured current distributions at low flow rates are more nonuniform than predicted by the theoretical model. In order to investigate the discrepancy, experiments with the use of sectioned porous electrodes are suggested for more convenient current distribution data acquisition.

A qualitative discussion of the theoretical model illustrates the important point that, without solving any mathematical equations whatsoever, a great deal of intuitive insight can be gained from knowledge of the dimensionless parameters characteristic of the system. With the dimensionless parameters, one can determine what physical phenomena are most likely to control electrode behavior: charge-transfer, diffusion, convection, mass transfer, or conduction phenomena. The dimensionless parameters provide scale-up criteria by which data from different experimental systems may be correlated. In addition, knowledge of the relative magnitude of the parameters aids in determining under what conditions simpler models of limiting cases can be employed instead of the foregoing general model.

The model described herein is based on assumptions which naturally affect its applicability. However, in order to apply the model to other systems, a significant number of the assumptions may be removed or substantially altered without major complication of the calculational procedure. In particular, the model may be expanded to investigation of multiple electrode reactions, heterogeneous plus homogeneous scavenger reaction systems, and channeling effects owing to porosity variations.

The investigation reported here has served both to unify diverse previous efforts at predicting porous electrode behavior and also to establish a firm basis for further investigations of more complex electrochemical systems.

The Gibbs-Helmholtz Equation and the EMF of Galvanic Cells

I. Inapplicability to Liquid-Liquid Junction Potentials

Abner Brenner*

N-Q Electrochemical Research Corporation, Reston, Virginia 22070

ABSTRACT

Measurements were made of the temperature coefficient of the emf of a type of concentration cell in which the emf was generated solely by liquid-liquid junctions. The data fit the Henderson equation very well but not the Gibbs-Helmholtz equation. The discrepancy between the values of ΔH, computed from the Gibbs-Helmholtz equation, and the values measured calorimetrically is shown to be calculable from ionic mobilities. In addition, data are presented showing that the sum of the thermoelectric powers of the three junctions (including a liquid-liquid junction) is equal to the isothermal temperature coefficient of the emf of the cell.

This is the first of three papers dealing with the precision of the Gibbs-Helmholtz equation when applied to the emf of galvanic cells.

This paper deals with the measurement of the isothermal temperature coefficient of liquid-liquid junction potentials. To my knowledge this is the first time that such measurements have been reported and, therefore, the data should be of interest for that reason alone. (Incidentally, the data reported in the literature for the temperature coefficients of liquid-liquid junctions are actually thermoelectric powers.) A matter of even greater interest is that of Gibbs-Helmholtz equation did not fit the data.

In the second paper, several sets of data dealing with the emf of various types of galvanic cells, with and without liquid-liquid junctions, were taken from the literature and examined with respect to the Gibbs-Helmholtz equation. I found that the discrepancy of the Gibbs-Helmholtz equation was in many instances greater than the expected experimental error.

In the third paper the cause of the discrepancy between the value of ΔH obtained via the Gibbs-Helmholtz equation and the value obtained calorimetrically was investigated for various types of cells,

My interest in investigating the precision of the Gibbs-Helmholtz equation came about indirectly. We had been measuring by thermal means the reversible heat effects at liquid-liquid junctions (1), during the passage of direct current, with the rather naive idea of thereby obtaining a knowledge of the liquid junction potential (which idea, however, did not materialize), In addition, we measured the thermoelectric power, dE'/dT, of the junctions. According to an accepted thermodynamic relation, the value of $j \cdot T \cdot dE'/dT$ (where j is 23,050 cal/V) should equal the calorimetrically determined heat Q_{rev}, but we found a large discrepancy. This suggested to me that the Gibbs-Helmholtz equation might not apply to liquid-liquid junctions. After a different kind of measurement (to be described herein) had shown this indeed to be the case, I became interested in studying the precision of the Gibbs-Helmholtz equation when applied to galvanic cells in general.

In my study of the literature of the Gibbs-Helmholtz equation, I found that the equation had been accepted as precise by the early electrochemists on the basis of scanty, imprecise measurements, mostly made before 1900. In no textbook or even in the treatise of Helmholtz (2) himself did I find any limitation to the application of the equation other than the customary statement that certain variables of the system must be held constant. I believed that a study of the precision of the equation, when applied to more recent data, would be useful in the application of the equation.

Key words: Gibbs-Helmholtz equation, concentration cells, liquid junction potentials, Henderson's equation, temperature coefficient of emf of liquid junctions, thermoelectric power of liquid junctions, heat of dilution of liquid junctions.

Background

In the early development of the thermodynamics of galvanic cells, the emf of the cell was considered to be determined entirely by the enthalpy of the chemical reaction. This was known as Thomsen's rule and, indeed, it held rather well for some of the simple cells, such as the Daniel cell. Subsequently, between 1860 and 1880 various investigators showed experimentally that the emf of a cell was sometimes greater and sometimes less than that calculated from the enthalpy change of the reaction, as measured in a calorimeter.

Nearly all textbooks on electrochemistry make a point of sharply exposing the fallacy of Thomsen's rule. The texts, however, are unjust in being so critical of Thomsen, because the great Helmholtz, himself, originally also subscribed to Thomsen's rule, until the researches mentioned above led him to change his view. Helmholtz, thus, became aware that the entropy change of the reaction was also involved in determining the emf of the cell and in 1882 published a paper (2) dealing with the relation, which was discoverd at about the same time by Gibbs (3), now known as the Gibbs-Helmholtz equation.

The Gibbs-Helmholtz equation is a combined statement of the first and second laws of thermodynamics. It is derived from the equation

$$\Delta F = \Delta H - T \cdot \Delta S \qquad [1]$$

and when applied to a galvanic cell has the form

$$E = \frac{-\Delta H}{nj} + T \cdot dE/dT \qquad [2]$$

dE/dT being the isothermal temperature coefficient.

A galvanic cell which is operated reversibly at constant temperature evolves or absorbs heat from the surroundings. This reversible heat Q_{rev} is given by the expression

$$Q_{\text{rev}} = T \cdot \Delta S = nj \cdot T \cdot dE/dT \qquad [3]$$

in calories per mole of reaction. If the cell absorbs heat, which represents an increase of entropy ΔS (in this case the cell tends to become colder on adiabatic operation), this absorbed heat is given out in the form of electrical energy. Consequently, the cell delivers more energy than corresponds to the enthalpy change. The reverse is true if the cell evolves heat.

In checking the validity of Eq. [2], it is advantageous to use cells in which the ΔH term is small compared to the $T \cdot dE/dT$ term, which latter is the one of interest. It is expedient, therefore, to use concentration cells, since their enthalpy change is relatively small being derived from heats of dilution compared to that of cells involving a chemical reaction.

Experimental Measurements of Liquid-Liquid Junction Potentials and Their Temperature Coefficients

Procedure for Measuring Isothermal Temperature Coefficients

The measurement of the isothermal temperature coefficient of the emf of a liquid junction potential requires that the emf itself be capable of measurement and at two different temperatures. However, except for a certain special situation—in which a concentration cell with transference can be set up in two different ways: (*i*) with electrodes reversible with respect to the anion and, (*ii*) with electrodes reversible with respect to the cation—the liquid junction potential cannot be measured because in a cell it is always accompanied by the two emf's arising from the two electrode-electrolyte interfaces of the cell.

To eliminate the uncertainty occasioned by the electrode-electrolyte interface, a novel type of concentration cell was used containing three liquid-liquid junctions and two equal and opposite electrode-electrolyte systems. The emf's of the latter cancelled each other and, consequently, the emf of the cell came entirely from the liquid-liquid junctions. A typical cell is the following

$$Hg, HgCl|KCl, M_1||KCl, M_2||HCl, M_3||KCl, M_1|HgCl, Hg$$

Concentration cells in which the emf was produced only by the liquid-liquid junctions were first used by Müller (4) about 100 years ago. Nernst (5) also used them, except that his cells had four liquid-liquid junctions, instead of three.

A schematic diagram of the concentration cell which I used for measuring the temperature coefficient of the emf of liquid-liquid junctions is shown in Fig. 1. These cells will hereafter be referred to as the "tri-junction" cells. The tri-junction cell consisted of two identical reference electrodes A and A′ which were calomel or mercury-mercurous sulfate electrodes. The same electrolyte was used in A, A′, B, and B′. The other two electrolytes were C and D. The three junctions were formed in the long tubes by the pairs of electrolytes flowing together from B′ and C, C and D, and D and B. The method of forming the flowing junctions is discussed in a subsequent paragraph. The entire cell was maintained at a uniform temperature. Consequently, the emf's produced by the reference electrodes A and A′ annulled each other since they were equal and opposite. The emf of the cell was produced entirely by the aforementioned three liquid-liquid junctions. Furthermore, dilute solutions were used so that the heats of dilution of the liquids would be small.

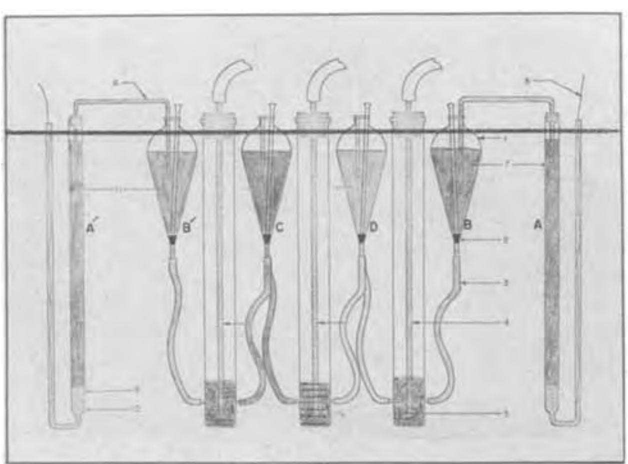

Fig. 1. Apparatus for measuring the isothermal temperature coefficient of liquid junction potentials. Entire apparatus at uniform temperature T_1 and then at T_2 in separate experiments. 1. separatory funnel; 2, rubber plug acting as valve; 3, flexible tubing; 4. glass tube for withdrawing waste liquid at conclusion of experiment by means of a water aspirator; 5. mixed liquids; 6. bridge (agar gel); 7. potassium chloride solution; 8. wire lead to potentiometer; 9. mercurous salt; 10. mercury; 11. potassium chloride solution, same as 7.

The temperature coefficient of the emf of the three liquid junctions, collectively, was obtained by measuring the emf of the cell at temperature intervals of 10°C, mostly in the range between 15° and 55°C, although a few measurements were made at 0°C. If the individual liquid-liquid junction potentials followed the relation of Eq. [2], then the sum of the emf's of the three junctions (which was the quantity actually measured) should also follow the relation.

Since the temperature coefficients of these cells were small, a high precision was required in measuring the emf of the cells. Therefore, the emf had to be both constant and reproducible. The production of constant and reproducible liquid junction potentials is a familiar problem in electrochemistry. Initially, I tried a method devised by Lakhani (6) in which the junction of two electrolytes was formed by the mutual impingement of jets (about 1 mm in diameter) of each electrolyte. This method did not result in adequate constancy of the liquid junction potential, as the fluctuations amounted to tenths of a millivolt. However, when the discharged electrolytes in the mixing chamber (see Fig. 1) rose to a height sufficient to cover the impinging jets, the emf became constant and reproducible to a few hundredths of a millivolt.

The entire cell shown in Fig. 1 was immersed in a thermostat, constant to about 0.1°, to a depth such that the electrolytes were below the level (indicated by a line in Fig. 1) of liquid in the thermostat. Deep vessels insured that the electrolyte in the jets remained at the same temperature as the bulk of electrolyte in the tap funnels. Oil was used in the thermostat, because the conductivity of water resulted in parasitic voltages being picked up by the electronic galvanometer.

In performing an experiment, the closures (consisting of a rubber stopper at the end of a glass rod) were removed from the throats of the tap funnels, thus allowing the electrolyte to flow and form jets in the mixing chambers. The rate of flow of solution was about 25 ml/min. The emf was not sensitive to the rate of flow. As soon as the jets became covered with electrolyte, emf measurements of the cell were made. Measurements could be made for about two minutes before the supply of electrolyte in the tap funnels was exhausted. Voltages were measured on a microvolt potentiometer with an electronic voltmeter, sensitive to 1 μV, serving as null instrument. At the conclusion of the experiment, the electrolyte which had collected in the mixing chambers was removed by a water aspirator.

To prevent the liquid in the reference electrodes A and A′ from being drawn into the tap funnels B and B′ as the solution in the latter was lowered, the electrolyte bridges contained an agar-agar gel. In an actual experiment only two flowing junctions were used instead of three, as three such junctions were difficult to manage and required too much space in the thermostat. Therefore, instead of a flowing junction, the connection between the two electrolytes B′ and C was made by a bridge containing an agar-agar gel. Since the two electrolytes B′ and C were different concentrations of the same electrolyte (either potassium chloride or magnesium sulfate), the liquid junction potentials were smaller than those of the other junctions; furthermore, the agar-agar bridge, by independent experiments, was found to afford adequate con-

stancy and reproducibility. In these experiments the reproducibility of measurements on cells which had a small emf of 10 mV or less was about 0.02 mV. The reproducibility of measurement on the cells with an emf of about 25 mV was about 0.1 mV. Since measurements were made at temperatures 10° apart, this made the precision of measurement of the temperature coefficient of the emf about 1×10^{-5} V/°C. This precision is equivalent to a possible error of about 3 mV in the calculated emf or to an error of about 70 cal/mole for univalent salts.

Results of Measurements of the Temperature Coefficients of Liquid Junction Potentials

The results of the measurements on the tri-junction cells are given in Table I. To make a check of the validity of the Gibbs-Helmholtz equation, it is customary to compare the value of the enthalpy ΔH_{emf} calculated via the Gibbs-Helmholtz equation

$$-\Delta H_{emf} = nj\left(E - T \cdot \frac{dE}{dT}\right) \quad [4]$$

with the calorimetrically measured value ΔH_{cal}. In these experiments with the tri-junction cells the enthalpy change is a heat of dilution, and at present there is no method in the literature for calculating the heat of dilution at a liquid-liquid junction. Therefore, it is necessary to digress at this point for the purpose of developing a formula for calculating the heat of dilution.

Calculation of the heat of dilution at a liquid-liquid junction.—The derivation of a relation for calculating the heat of dilution between two solutions S and S′ is patterned after the derivation of the Henderson equation (7) for liquid-liquid junction potentials. Note that the Henderson equation involves only the Nernst equation and does not involve the energy derivable from the heat of dilution.

As is the case with the Henderson derivation, the energy derived from the heat of dilution depends on the net transfer of solute across the boundary of the two solutions under the influence of the current, and this in turn depends on the transference number of the ions. Between two solutions S and S′ there must be a region in which the composition of the solution varies from that of S to that of S′ and, consequently, the transference number of all of the ions must change continuously throughout this region. In the special case that all the cations and anions had the same transference number, the movement of solute to the left would be exactly cancelled by movement to the right; consequently, there would be no net contribution of energy. For example, in a potassium chloride solution the K ion and the Cl ion have about the same mobility and the liquid junction potential between two solutions of differing concentration is small.

The basic relation for the heat of dilution at a liquid-liquid junction is

$$\Delta H_{cal} = \Sigma\,[t_i \cdot d(\Delta H) + t_i' \cdot d(\Delta H')] \quad [5]$$

where t_i and t_i' are the varying transference numbers of the ions of MX and M′X′, respectively; ΔH is the partial molal heat of dilution resulting from the transfer of one mole of MX from solution S into solution S′; and $\Delta H'$ is the partial molal heat of dilution resulting from the transfer of one mole of M′X′ from solution S′ into solution S. The summation is for the four ions M, X, M′, and X′, having the mobilities U, V, U′, and V′, respectively.

All of the intermediate compositions of solutions between S and S′ can be considered to be obtainable by making up a unit volume of solution consisting of a fraction (x) of S′ with the fraction $1 - x$ of solution S. Solution S has the concentration C of MX, and solution S′ has the concentration C′ of M′X′.

The method of the derivation is to express the transport number of each ion as a function of the mixing fraction x. For a given x, the generalizer concentration of the salt MX is represented by C_i where

$$C_i = C(1 - x) \quad [6]$$

This is also the concentration of the ions M^+ and X^- Similarly, for the salt M′X′, the generalized concentration C_i' is

$$C_i' = C'x \quad [7]$$

The current-carrying ability of each ion is equal to the product of mobility and concentration, and the total current-carrying capacity of the solution at x is

$$CU(1 - x) + CV(1 - x) + C'U'x + C'V'x \quad [8]$$

or

$$C(U + V) + x[C'(U' + V') - C(U + V)] \quad [9]$$

or

$$a + bx \quad [10]$$

where

$$a = C(U + V);\ b = C'(U' + V') - C(U + V);\quad a + b = C'(U' + V') \quad [11]$$

The transference numbers of the ions U, V, U′, and V′ at x are, respectively

$$\frac{CU(1-x)}{a+bx};\ \frac{CV(1-x)}{a+bx};\ \frac{C'U'x}{a+bx};\ \text{and}\ \frac{C'V'x}{a+bx} \quad [12]$$

Consider now that the heat of dilution, ΔH_m, due only to the ion M^+:

$$\Delta H_m = \Delta H \int_{x=0}^{x=1} \frac{CU(1-x)dx}{a+bx} = UC \cdot \Delta H \left[\int_{x=0}^{x=1} \frac{dx}{a+bx} - \int_{x=0}^{x=1} \frac{x \cdot dx}{a+bx}\right] \quad [13]$$

	* →									

* Arrow gives the direction of the conventional flow of current through the cell when the electrodes are shorted.
** J_a, J_b, and J_c designate the three liquid-liquid junctions.
† $-\Delta H_{emf}$ designates the enthalpy obtained *via* the Gibbs-Helmholtz equation (see Eq. [4]). The cell emf's are for 30°.

Integration of Eq. [13] and substituting in the limits gives

$$\Delta H_{\mathrm{m}} = \frac{C \cdot \mathrm{U} \cdot \Delta H}{b^2} \left[(a + b) \cdot \ln \frac{a}{a + b} + b \right] \quad [14]$$

The heat of dilution due to the ion X having the mobility V would be similar to Eq. [14] with V substituted for U. The net heat of dilution for MX would be the difference due to the two ions M and X

$$\Delta H_{\mathrm{mx}} = \frac{C \cdot (\mathrm{U} - \mathrm{V}) \cdot \Delta H}{b^2} \left[(a + b) \cdot \ln \frac{a}{a + b} + b \right] \quad [15]$$

The net heat of dilution, $\Delta H_{\mathrm{m'x'}}$, for the transfer of a mole of salt M'X' from solution S' to S is similarly computed

$$\Delta H_{\mathrm{m'x'}} = C'(\mathrm{U'} - \mathrm{V'}) \cdot \Delta H' \int_{x=0}^{x=1} \frac{x \cdot dx}{a + bx} \quad [16]$$

Integration of Eq. [16] and substituting in the limits gives

$$\Delta H_{\mathrm{m'x'}} = \frac{C'(\mathrm{U'} - \mathrm{V'}) \cdot \Delta H'}{b^2} \left[a \cdot \ln \frac{a}{a + b} + b \right] \quad [17]$$

For conciseness in writing, let

$$\alpha = C(\mathrm{U} + \mathrm{V}) \cdot \Delta H \quad [18]$$

$$\beta = C'(U' + V')\Delta H' \quad [19]$$

$$\delta = \ln \frac{a}{a + b} \quad [20]$$

The net heat of dilution of the four ions is the difference of Eq. [15] and [17]

$$\Delta H_{\mathrm{mx}} - \Delta H_{\mathrm{m'x'}} = \frac{\alpha - \beta}{b^2} [b + a \cdot \delta] + \frac{\alpha \cdot \delta}{b} \quad [21]$$

Ion mobilities are the important quantities which are required for making the calculations both of the heats of dilution, as just described, and of liquid junction potentials (by means of the Henderson equation) as described in the following section. However, it is not necessary to know the true mobility of an ion; it is sufficient to know what MacInnes (8) calls the "mobility of an ion constituent" given by the relation

$$\mathrm{U_i} = t_{\mathrm{i}} \cdot \Lambda_{\mathrm{i}} / \mathbf{F} \quad [22]$$

where Λ_i is the equivalent conductivity of the compound at the concentration in question. Furthermore, since Eq. [21] is homogenous with respect to ion mobilities, it is not necessary to deal with **F** in Eq. [22], and the quantity actually substituted for the mobility of the ion constituent in Eq. [21] is

$$\mathrm{U_i} = t_{\mathrm{i}} \cdot \Lambda_{\mathrm{i}} \quad [23]$$

The values of the equivalent conductivities and transference numbers required for the calculation of the heats of dilution and for the calculation of liquid junction potentials (in the next section by means of the Henderson equation) were obtained from the Landolt-Börnstein tables (9).

In calculating the heats of dilution for the liquid junctions, it was necessary to know the net partial molal heat of solution ΔH involved in transferring a mole of compound MX from solution S into solution S', which contains compound M'X'; and similarly, one must know $\Delta H'$ for the transfer of a mole of M'X' from solution S' into S, which latter contains MX.

Since data on the partial molal heats of dilution of compounds in solutions containing other salts are not available, some approximations had to be made. First of all, in the dilute solutions used in these experiments, the difference between two partial molal heats of dilution does not differ much from the difference between two integral heats of solution for which much data are available. Also, another approximation had to be made with regard to the range of concentration of the dilution, inasmuch as the compound MX was transferred from solution S (where its concentration was C) into solution S' in which its concentration was zero, although the concentration of M'X' was C'. It was assumed that the heat effect was the same as if MX had been transferred from a solution of concentration C into a solution of concentration C' (the same as the concentration of M'X').

The heats of dilution (10) used in the calculations of the data in Table II and the ranges of concentration are as follows

HCl	0.20-0.01N	170 cal
KCl	0.30-0.01N	4 cal
H_2SO_4	0.20-0.01N	2160 cal
$MgSO_4$	0.30-0.03N	372 cal
Li_2SO_4	0.30-0.03N	285 cal
LiCl	0.30-0.03N	103 cal

Presentation of the data.—Table I gives the data for the four tri-junction cells. The quantity of most interest in the table is the enthalpy ΔH_{emf} calculated *via* the Gibbs-Helmholtz equation (Eq. [4]). These values (in the last column of the table) are to be compared with the calorimetric values given in Table II.

In Table II are given the heats of dilution which were calculated for each of the three junctions, J_a, J_b, and J_c. The net heat of dilution for the cell (ΔH_{cal}) is given in column five. Although the heat of dilution at most of the junctions is appreciable, the net heat of dilution for a cell is smaller than might be expected, because the heat of dilution at one of the junctions opposes the heat effects at the other two. In column six of Table II the values of ΔH_{emf} (from the last column of Table I) are reproduced for comparison with ΔH_{cal} in the preceding column five. In column seven the difference between the two values of the enthalpy are given. This difference will be referred to as the "discrepancy" of

Table II. Heat of dilution in tri-junction cells (derived from calorimetric data) compared with ΔH_{emf} obtained *via* the Gibbs-Helmholtz equation. Also, comparison of the Gibbs-Helmholtz discrepancy in ΔH with the discrepancy calculated *via* the Henderson equation.

* Calculated from calorimetric data. See Eq. [21].
** Derived from Gibbs-Helmholtz equation. See Eq. [4].
† Discrepancy calculated via the Henderson equation. See Eq. [31].

the Gibbs-Helmholtz equation and has the form

$$\text{Discrepancy} = -\Delta H_{\text{emf}} + \Delta H_{\text{cal}} \qquad [24]$$

It is apparent that the discrepancies given in column seven of Table II are large, much too large to be attributed to experimental errors or to uncertainties in the approximations used in the calculation of the values of ΔH_{cal}.

Calculation of the Gibbs-Helmholtz discrepancy from ionic mobilities.—To add weight to the view that the Gibbs-Helmholtz discrepancy is *bona fide* and not a result of experimental error, I shall now show that the discrepancy can be calculated with a fair degree of precision from simple electrochemical data obtained from the literature (9).

The first step in the demonstration is to show that the experimental data closely follows the Henderson equation (7), which is

$$E_L = \frac{RT}{F} \cdot \frac{C(U - V) - (U' - V')C'}{C(Uw_c + Vw_a) - C'(U'w_c' + V'w_a')} \cdot \ln \frac{C(Uw_c + Vw_a)}{C'(U'w_c' + V'w_a')} \qquad [25]$$

where E_L is the liquid junction potential, w_c and w_a are the valences of the cation and anion in one salt, w_c' and w_a' are the valences of the ions of the other salt, and the other symbols have the same meanings as in Eq. [8] and those following.

The calculated emf's and their temperature coefficients for the three junctions of each of the four cells are given in Table III. It is seen that the calculated emf for a cell, given in column D, agrees well with the experimental emf given in column G. Also, the calculated temperature coefficients given in column K agree reasonably well with the experimental values in column L.

A refinement may now be introduced. Since the Henderson equation does not include the energy derived from the heat of dilution, it is reasonable to add this energy (see column five of Table II) in the form of its voltage equivalent, as given in column E of Table III, to the Henderson liquid junction potentials in column D of Table III. This gives the more nearly correct calculated values of emf listed in column F, which are the sum of the emf's in columns D and E. On an average, the calculated emf's in column F are about 2.5 mV higher than the experimental values in column G, which is a discrepancy within experimental error.

The second step in the demonstration is to set up an equation for the emf of the tri-junction cells which is experimentally valid. This is done simply by adding to the usual equation for the emf of a cell the Henderson equation, which will be represented by RTZ

$$E = -\Delta H_{\text{cal}} + T \cdot \int \frac{\Delta C_p}{T} dT + RTZ \qquad [26]$$

In this discussion we do not know the value of the heat capacity term, but in view of the reasonable agreement between the experimental and calculated values of emf it would appear that the contribution to the emf might be a few millivolts.

The third step in the demonstration is to derive an expression for the Gibbs-Helmholtz discrepancy, as follows. Equation [26] is differentiated and a substitution made, as in the derivation of the Gibbs-Helmholtz equation, to yield the following

$$E = -\Delta H_{\text{cal}} + T \cdot \frac{dE}{dT} - RT^2 \cdot \frac{dZ}{dT} \qquad [27]$$

The Gibbs-Helmholtz equation is

$$E = -\Delta H_{\text{emf}} + T \cdot \frac{dE}{dT} \qquad [28]$$

The Gibbs-Helmholtz discrepancy is obtained by subtracting one equation from the other and rearranging terms

$$\text{discrepancy} = -\Delta H_{\text{emf}} + \Delta H_{\text{cal}} = -RT^2 \cdot \frac{dZ}{dT} \qquad [29]$$

Since Z is the part of the Henderson equation that contains the ionic mobilities, it is seen that the discrepancy is due to the variation of the ionic mobilities with temperature.

The expression $RT^2 \cdot dZ/dT$ can be simplified by utilizing the Henderson equation for the liquid junction potential, E_L, in the abbreviated form

$$E_L = RTZ \qquad [30]$$

On differentiating Eq. [30], one obtains

$$RT^2 \cdot \frac{dZ}{dT} = T \cdot \frac{dE_L}{dT} - E_L \qquad [31]$$

where E_L is the emf calculated from the Henderson equation and given in column D of Table III, and dE_L/dT is the temperature coefficient, based on the Henderson equation for two different temperatures, and given in column K of Table III.

The last column of Table II gives the values of the Gibbs-Helmholtz discrepancy calculated according to Eq. [31]. These values agree reasonably well with the experimental values of the discrepancy given in the next to the last column of Table II.

Discussion of the Gibbs-Helmholtz discrepancy.—Scarpa (11) was the first to suggest that the Gibbs-Helmholtz equation is not accurate when applied to concentration cells. He did no experimental work but

** Sum of columns D and E.

† Calculated by means of Henderson's equation.

based his belief on the following theoretical considerations. If the solutions in a concentration cell were so dilute that there was no entropy change on operation, then the Gibbs-Helmholtz equation simplifies to

$$E = KT \qquad [32]$$

where K is a constant. This result, however, is inconsistent with the Nernst equation for the emf of concentration cells because the Nernst equation involves the product of T and a transport number, and the latter is not a constant but varies with temperature.

The fact that the Gibbs-Helmholtz discrepancy can be very simply calculated, as shown in the last column of Table II, in my opinion, leaves little doubt that the equation is not exact when applied to liquid junction potentials. The examples in this paper are not unique, as in the second paper of this series, a similar calculation is made for a more conventional type of concentration cell with transport.

Since the Gibbs-Helmholtz equation is not exact, this means that the equation from which it was derived

$$E = -\frac{\Delta H}{n\mathbf{F}} + T \cdot \Delta S \qquad [33]$$

is not exact. More specifically, the source of error is in the term $T \cdot \Delta S$ which does not adequately describe the reversible heat generated in the operation of a galvanic cell. Or stating the matter in a different way, there does not exist in nature a quantity ΔS with the mathematical properties that thermodynamicists have associated with it.

The Nernst Equation and the Thermoelectric Power of Liquid-Liquid Junctions

Since in the past the thermoelectric power of a liquid-liquid junction has been confused with the isothermal temperature coefficient, I have considered it worthwhile to extend this paper a little, both to resolve this confusion and to include some of our measurements of thermoelectric power.

Nernst (5) in 1889 had shown a remarkable analytical insight, not only in satisfactorily explaining the complex phenomenon of liquid junction potentials, but also in deriving a formula for calculating them. Nernst's equation was improved by Henderson (7).

It is both ironic and paradoxical that Nernst, himself, was not successful in validating his equation with respect to the temperature coefficient of the emf of liquid-liquid junction potentials, although he made a try at it. The reason for the failure was that his student, Duane (12), measured the thermoelectric power of the junctions instead of the isothermal temperature coefficient of the emf of the junction. But perhaps he should be forgiven for this error, since there is no way to measure the isothermal coefficient of a single junction. Needless to say, the agreement of the experimental results of Duane with the Nernst equation was very poor and a fair proportion of the lengthy publication was used in an effort to explain the cause of the discrepancy.

The difference between the measurement of an isothermal temperature coefficient of emf for a cell and the measurement of a thermoelectric power can be seen by comparing Fig. 1 with Fig. 2 which shows an idealized apparatus for measuring the thermoelectric power of a liquid-liquid junction. The two similar reference electrodes A and A′ were at the same temperature T_1, hence their emf's annulled each other and did not enter in the emf of the concentration cell. The electrolyte in B and B′ was the same as that in A and A′. The electrolytes C and C′ were the same. Two similar

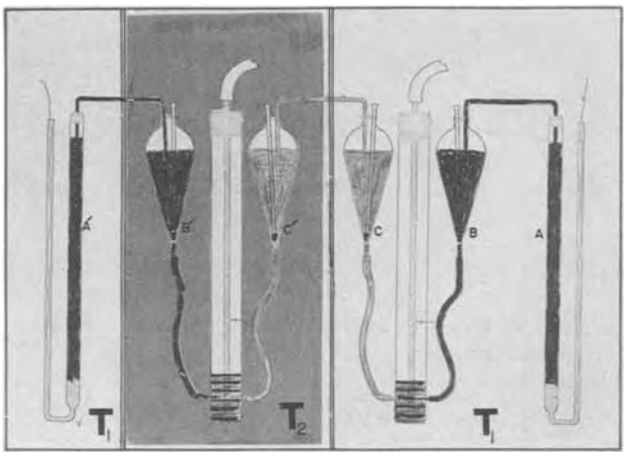

Fig. 2. Apparatus for measuring the thermoelectric power (false temperature coefficient) of liquid junction potentials.

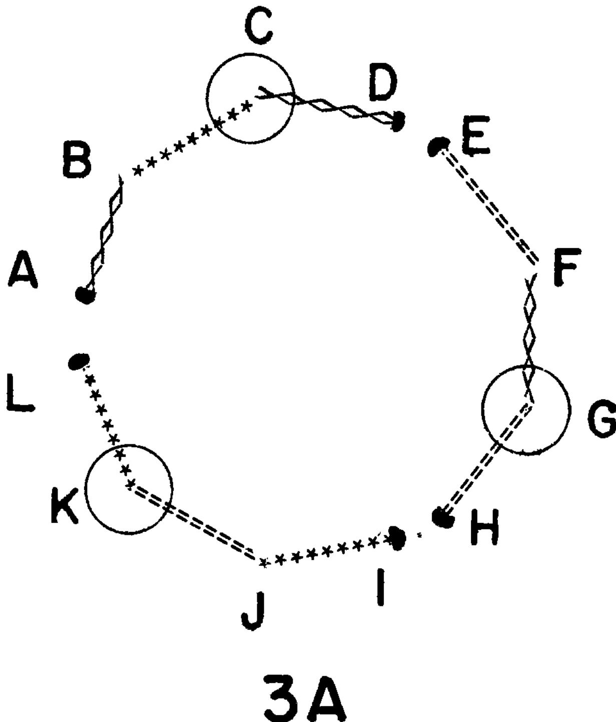

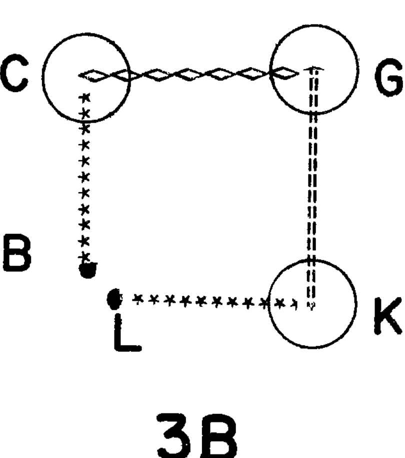

Fig. 3. Demonstration that three different thermocouples formed from three different materials, taken two at a time, when connected into a complete circuit with one set of junctions at T_1 and the other set at T_2 do not generate an emf. KL, AB, and BC represent the three different materials. The area encompassed by the circles represents temperature T_2 and the rest of the material outside the circle represents T_1. The three thermocouples are AD, EH, and IL in 3A. The circuit in A is equivalent to the circuit in 3B in which the junctions C, G, and K are all at the same temperature.

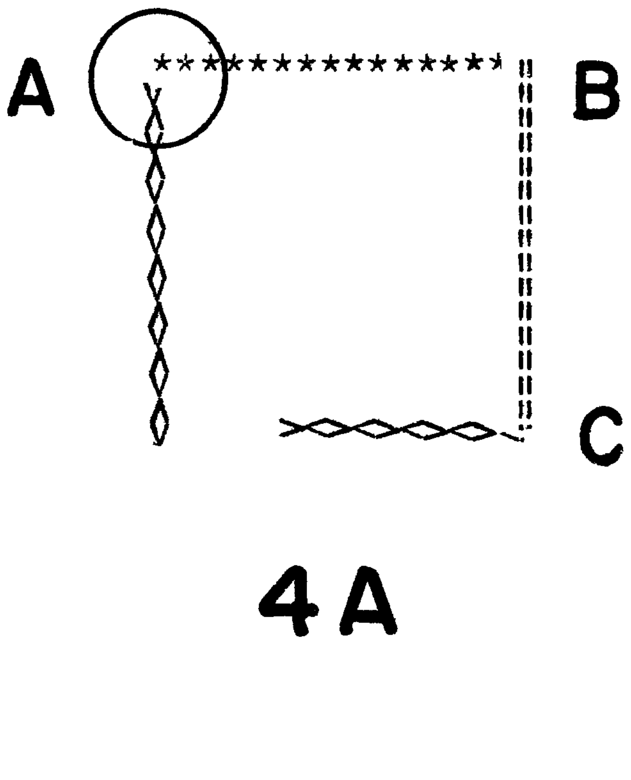

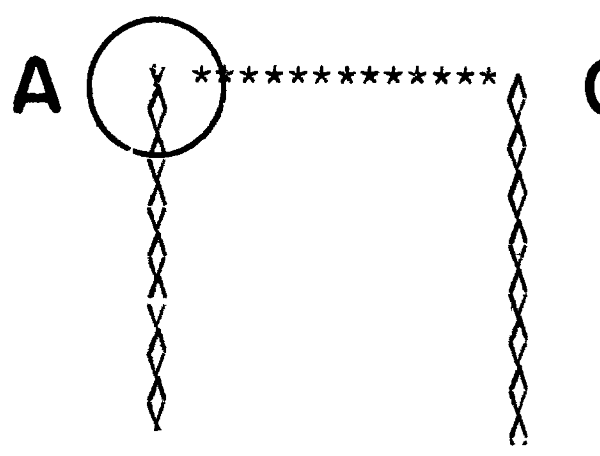

Fig. 4. Demonstration that a circuit (4A) composed of three materials connected to yield three junctions, A, B, and C, with only one junction at temperature T_2, is equivalent to a simple thermocouple (4B) with two junctions, A and C.

liquid-liquid junctions were formed between electrolytes B and C at temperature T_1 and between electrolytes B′ and C′ at temperature T_2. The emf of the cell was due to the difference in temperature between the two junctions B′C′ and BC. The cell constituted a thermocouple and the laws of thermocouples are applicable to it. The setup used by Nernst and his students was similar to the arrangement in Fig. 2, except that no means were provided for flowing junctions. It may be noted that the thermoelectric power of the junction could be determined with a cell having only one liquid-liquid junction by operating it at two different temperatures, for if a reversible electrode were put into C or C′, the system then could be considered as two identical cells, A′ — C′ and C′A. The sum of the voltages of the two cells divided by the temperature difference is the same as the thermoelectric power of the liquid-liquid junction.

To complete this discussion of temperature coefficients, I shall show that there is a simple relation between the isothermal temperature coefficient of the emf of a cell and the thermoelectric power of a junction. Brenner (13) has suggested that the thermoelectric power of a junction of a reversible electrode in an electrolyte is the sum of two terms, one representing the thermocouple effect and related to the Peltier coefficient Π by the equation

$$\frac{\Pi}{T} = \frac{dE_1}{dT} \qquad [34]$$

the other representing the entropy change associated with the change of state

$$\Delta S = \frac{dE}{dT} \qquad [35]$$

It is a law of thermocouples that in a complete circuit at constant temperature the sum of the thermoelectric powers due to the Peltier coefficient must vanish. Hence, in the summation of the thermoelectric powers of all of the junctions in a cell, that portion which is related to the Peltier coefficient vanishes for a complete cell, and the remainder of the sum is equal to the isothermal temperature coefficient of the emf of the cell

$$\sum \frac{dE'}{dT} = \frac{dE}{dT} \qquad [36]$$

isothermal for the cell.

The summation is for every junction in the cell and dE'/dT is the thermoelectric power of a junction.

Since I have not seen Eq. [36] in the literature, in Table IV, I have given some data to demonstrate its validity. The cells contain two electrode-electrolyte junctions and one liquid-liquid junction. The data on the thermoelectric powers and on the isothermal temperature coefficients were obtained in my laboratory, with the assistance of Jean Berkeley, by methods similar to those described in the earlier parts of this paper. The data have not been published previously.

The sum of the thermoelectric powers of three junctions, including the liquid-liquid junction, is given in column D of Table IV. The sum is to be compared with the experimentally measured isothermal temperature coefficient of the cell given in column E. The difference between the values in the two columns averages about 1.3×10^{-5} V/°C, which is within experimental error.

Acknowledgments

This investigation was one of the author's "extracurricular" interests and as such did not require specific support. However, the ideas involved were a spinoff from the author's program of Electrochemical Calorimetry which the Research Division of the Atomic Energy Commission sponsored at the National Bureau of Standards from about 1958 to 1964. For this support the author wishes to express appreciation to A. R. Van Dyken of the Chemistry Branch, Division of Research of AEC. Also, the author wishes to acknowledge the laboratory assistance of Jean J. Berkeley in the initial phases of the laboratory work with the concentration cells.

Manuscript submitted Dec. 18, 1973; revised manuscript received June 9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976. A portion of this paper was Paper 188 presented at the Cleveland, Ohio, Meeting of the Society, May 1-6, 1966.

Publication costs of this article were partially assisted by the N-Q Electrochemical Research Corporation.

The Gibbs-Helmholtz Equation and the EMF of Galvanic Cells

II. Precision of its Application to Concentration Cells

Abner Brenner*

N-Q Electrochemical Research Corporation, Reston, Virginia 22070

ABSTRACT

The Gibbs-Helmholtz equation is usually tested by comparing the enthalpy, ΔH_{emf}, of the cell reaction obtained by means of the equation with the calorimetrically determined enthalpy, ΔH_{cal}. A survey was made of three such tests in the literature. An examination of the precision of the correspondence between ΔH_{emf} and ΔH_{cal} was made using concentration cells without transference, containing either hydrochloric or sulfuric acid. The enthalpy change was a partial molal heat of dilution. With dilute solutions of hydrochloric acid the agreement was satisfactory. With strong solutions of hydrochloric and of sulfuric acid the differences amounted to a hundred calories or more. In sulfuric acid concentration cells with transference the difference amounted to several hundred calories. The differences for these cells are shown to be due mainly to the variation of the transference number of the hydrogen ion with temperature. On this basis, the discrepancy of the Gibbs-Helmholtz equation is easily calculated.

In Part I of this series of papers it was shown that the emf of liquid-liquid junctions did not follow the Gibbs-Helmholtz equation, although it followed the Henderson equation within experimental error. The cells used in this investigation were an unusual type in which the emf was derived solely from liquid-liquid junctions. The results of Part I raised the issue of the precision of the Gibbs-Helmholtz equation when applied to conventional types of galvanic cells.

The data in this paper is in two parts. The first part is a brief survey of some of the tests of the Gibbs-Helmholtz equation reported in the literature. In the second part and main treatment of data, the precision of the Gibbs-Helmholtz equation was investigated with respect to concentration cells containing either hydrochloric or sulfuric acid. The raw data were taken from the published results on simple galvanic cells. These were combined so as to form concentration cells. The reason for investigating concentration cells is that the precision of the tests was improved, as shown in the subsequent discussion.

The Gibbs-Helmholtz equation was discussed in Part I, however, a little reiteration is necessary. The second law applied to galvanic cells can be stated in the form

* Electrochemical Society Active Member.

Key words: Gibbs-Helmholtz equation, concentration cells.

$$E = -\Delta H/nj + Q_{rev}/nj \quad [1]$$

where j is approximately 23,050 (cal/V-**F**) and Q_{rev} is the quantity of heat either absorbed or evolved when a cell operates reversibly.

The Gibbs-Helmholtz equation is

$$E = -\Delta H/nj + T \cdot dE/dT \quad [2]$$

Comparison of the two equations shows that $T \cdot dE/dT$ should be equal to the voltage equivalent of the reversible heat, that is Q_{rev}/nj.

The usual manner in which the Gibbs-Helmholtz equation is checked is to calculate ΔH from Eq. [2] using the experimentally obtained values of E and its temperature coefficient. This particular ΔH will henceforth be referred to as ΔH_{emf}. Then, ΔH_{emf} is compared with the value of ΔH (henceforth referred to as ΔH_{cal}) obtained by calorimetry.

The most direct check of the Gibbs-Helmholtz equation would be to measure calorimetrically the reversible heat absorbed or evolved in the working of a cell and to compare this with $T \cdot dE/dT \times nj$. Unfortunately, this kind of calorimetric measurement is difficult and has been done on only a few occasions.

Survey of the Tests of the Gibbs-Helmholtz Equation in the Literature

Typical of the early investigations of the Gibbs-Helmholtz equation is that of Bugarszky (1) whose paper was published in 1897. He measured the emf of cells having mercury-mercurous salt electrodes, such as the following

$$\text{Hg, HgCl} \left| \begin{matrix} \text{KCl,} & 0.01N \\ \text{KNO}_3, & 1.0N \end{matrix} \right\| \begin{matrix} \text{KBr,} & 0.01N \\ \text{KNO}_3, & 1.0N \end{matrix} \left| \text{HgBr, Hg} \right. \quad [3]$$

Although the cells had a liquid-liquid junction, the potential of the latter was presumably suppressed by the use of potassium nitrate in both sides of the cell at a 100-fold higher concentration than the working electrolyte.

The following is a summary of the results obtained with ten different cells. The discrepancy between the value of ΔH_{cal} and ΔH_{emf} (calculated from the Gibbs-Helmholtz relation) ranged between 40 and 2300 cal with an average of about 660 cal.

In 1909 Mellencamp (2) published the results of an investigation of the Gibbs-Helmholtz relation. His work is of special interest and unique in that it is the only investigation in the literature specifically directed toward demonstrating that the Gibbs-Hemholtz equation held for concentration cells in which the emf was partly derived from the heat of dilution of the electrolyte. His cells all had liquid-liquid junctions, and since he did not mention them in his calculations, it is apparent that he assumed that the law held for such cells.

Mellencamp's original data are presented in Table I. Three out of the four experiments show a deviation of 20 cal or less between the heat of dilution derived from the use of the Gibbs-Helmholtz relation and that measured calorimetrically. The percentages of error (for the three experiments) based on $2j \cdot T \cdot dE/dT$ are 1% or less. These results, taken at their face value, show as precise an agreement of the Gibbs-Helmholtz relation as can be expected on the basis of the experimental errors involved.

However, I have made a careful examination of Mellencamp's experimental procedures and calculations and have come to the conclusion that the excellent agreements that he found were fortuitous and must have resulted from the canceling of various errors.

Although Mellencamp measured voltages with a precision of 10^{-5}V, the accuracy of his measurements of emf could not have been that high because of three experimental faults: (*i*) he did not use flowing liquid-liquid junctions; (*ii*) the liquid junctions were not at the same temperature as the electrolytes in the cells; and (*iii*) the emf measurements were made after a period of hours or even days, during which time considerable diffusion must have occurred across the liquid-liquid junction, thus altering the emf of the cell with time.

Another reason that the close agreements found by Mellencamp cannot be valid is that the calorimetric data that he used in his comparisons were not of high accuracy. The data that he used, given in column A of Table I, differ significantly from more recent data, given in column A of Table II. For example, for experiments 1 and 4 the values of ΔH_{cal} differ by 190 and 160 cal, respectively.

Mellencamp should not be criticized for the inaccuracy of the calorimetric data available at that time. However, he is culpable in neglecting two important details in the calculations. First of all, Mellencamp used the integral heats of dilution instead of partial molal heats (partial molal quantities were not even mentioned). Second and most serious, he did not take into

Table I. Mellencamp's original data (2) on the comparison of the heat of dilution computed from emf of cells with that obtained calorimetrically. The electrodes of all cells were amalgams.

[2] D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Baily, and R. H. Schumm, Editors, "Selected Values of Chemical Thermodynamic Properties," Technical Note 270-3, National Bureau of Standards, Washington, D. C. (1968).

consideration the electrical migration of ions across the liquid-liquid junction. This migration reduced the amount of salt transported per Faraday from one compartment of the cell to the other.

In Table II this latter omission has been rectified by multiplying the heat of dilution by the transference number of the anion to give a more nearly correct value for the calorimetrically derived heat of dilution resulting from the passage of current. Comparisons of these corrected values of ΔH_{cal} with Mellencamp's values of ΔH_{emf} derived from his emf measurements on the cells show an average discrepancy of 330 cal and an average percentage error of 32% based on the value of $2j \cdot T \cdot dE/dT$.

The third and last example of a test of the Gibbs-Helmholtz equation that I have taken from the literature utilizes the data of Gerke (3). Gerke measured the emf and the temperature coefficient of the emf of cells of which the following two are typical

$$\mathrm{Hg, HgCl \mid HCl\ (1M) \mid Cl_2 (1\ atm)}$$

$$\mathrm{2Hg + Cl_2 \rightarrow Hg_2Cl_2} \quad [4]$$

$$\mathrm{Pb(Hg) \mid PbCl_2 + HCl\ (1M) \mid PbCl_2 + AgCl, Ag}$$

$$\mathrm{Pb + 2AgCl \rightarrow PbCl_2 + 2Ag} \quad [5]$$

Gerke did not examine the relation of his data to the Gibbs-Helmholtz equation but was concerned with testing the third law of thermodynamics. However, his data was used by MacInnes (4) to illustrate the Gibbs-Helmholtz equation. The five examples cited show discrepancies ranging from 30 to 2600 cal with an average discrepancy of 870 cal. If the large discrepancy of 2600 cal is omitted, the average discrepancy was about 440 cal.

In contrast to these discrepancies, Gerke's results (based on the temperature coefficient of the emf of the cells) agreed with the third law within 30 cal. This indicates that his measurements of the temperature coefficients of emf were accurate. If such measurements are generally accurate, it would throw the onus of the large discrepancies of hundreds of calories observed in the tests of the Gibbs-Helmholtz equation (as shown by the data of Bugarszky, Mellencamp, and Gerke) on either the inaccuracy of conventional calorimetric measurements or on the imprecision of the equation, or on both.

Gibbs-Helmholtz Equation Applied to Concentration Cells without Transference

The simplest and most accurate way in which to check the precision of the Gibbs-Helmholtz equation is to use concentration cells having no liquid-liquid junctions. These cells are formed by connecting together two of the same kind of simple cells, similar in all respects except for a difference in the concentration of the electrolyte, with the added specification that one electrode be reversible with respect to the cation, the other reversible with respect to the anion. For example, the two cells

$$\mathrm{H_2 \mid HCl, conc\ C_1 \mid Cl_2} \quad [6]$$

$$\mathrm{H_2 \mid HCl, conc\ C_2 \mid Cl_2} \quad [7]$$

can be connected together to give the concentration cells

$$\mathrm{Cl_2 \mid HCl, conc\ C_1 \mid\mid H_2 \mid\mid HCl, conc\ C_2 \mid Cl_2} \quad [8]$$

or

$$\mathrm{H_2 \mid HCl, conc\ C_1 \mid\mid Cl_2 \mid\mid HCl, conc\ C_2 \mid H_2} \quad [9]$$

It makes no difference as to the order in which the simple cells are connected. Cells [8] and [9] yield the same reaction and the same emf.

The simple cells of the type used by Gerke would not yield a concentration cell because the composition of the electrolyte does not change on operation of the cell. For example, the cell formed by connecting two cells of the type of Eq. [4]

$$\mathrm{Cl_2 \mid HCl, conc\ C_1 \mid\mid Hg, Hg_2Cl_2 \mid\mid HCl, conc\ C_2 \mid Cl_2} \quad [10]$$

appears similar to Eq. [8], above. However, passage of current through this cell simply results in the transfer of chlorine from one end of the cell to the other. This involves no energy, hence this cell should have no emf.

The passage of 1**F** of current through the concentration cells [8] or [9] results in the transfer of one equivalent of HCl from the solution at higher concentration to the solution at the lower concentration. The enthalpy change, ΔH_{cal}, involved in the working of the cell is equal to the difference between the partial molal heats of solution of HCl in solutions of concentration C_1 and C_2. The electrical energy developed by the cell comes from two sources: the aforementioned enthalpy change, ΔH_{cal}, and the heat, Q_{rev}, reversibly absorbed from the surroundings. This latter portion of energy is the quantity with which this paper is essentially concerned, and the matter to be decided is whether Q_{rev} is exactly equal to $nj \cdot T \cdot dE/dT$ as required by the Gibbs-Helmholtz equation.

In dealing with concentration cells without transference, it is unnecessary to actually electrically connect two simple cells such as Eq. [6] and Eq. [7] for the purpose of making measurements. It is sufficient to simply subtract the emf's of the temperature coefficients, or the ΔH_{cal} of the simple cells (for which data are reported in the literature) to arrive at the corresponding data of emf etc. for the concentration cells such as Eq. [8] or Eq [9].

It is now necessary to justify the expedient of using concentration cells to explore the precision of the Gibbs-Helmholtz equation, as is done in this paper, instead of dealing with simple cells, as used by Bugarszky and others. As noted above, the quantity of importance in this quest is the reversible heat, Q_{rev}, and it is the more accurately determined (*via* Eq. [1]) the larger it is relative to ΔH_{cal}. In simple cells Q_{rev} may range widely in magnitude, but in many instances it amounts to only from one-third to one-tenth of the magnitude of ΔH_{cal}. In concentration cells the enthalpy change, ΔH_{cal}, is of course much smaller than in simple cells, but this is not the matter of importance. The improvement of the precision of the test using concentration cells results from the situation that the magnitude of Q_{rev} is closer to that of ΔH_{cal} than in the case of simple cells. Although in the concentration cells, also, the ratio of Q_{rev} to ΔH_{cal} may vary over a wide range, in many instances Q_{rev} is of the same magnitude as ΔH_{cal} and may be larger; it seldom is smaller than one-third the size of ΔH_{cal}.

Another important source of the improved precision of the test, using concentration cells, is that in the subtraction of the values of emf and ΔH_{cal} obtained for simple cells (to derive the values for concentration cells) some errors cancel out. For example, if only the difference of two voltages was to be determined, the zero point of the instrument would be of no consequence. As a concrete example of the manner in which taking differences improves precision, I have compared the data of Sturtevant (5) with that of Rossini (6) for the partial molal heats of dilution of hydrochloric acid over the range 0.01 to 3.24*M*. The values for 12 concentrations of HCl differed by an average of 53 cal. However, if for each investigator's data, the 0.25*M* solution were taken as the reference value from which the values of the other concentrations of solutions were subtracted (which would be done with concentration cells as discussed above), then the two sets of data differed only by an average of 17 cal. This is a threefold improvement in precision. Going a step farther, if the comparison were made over the more limited range of 9 concentrations between 0.16 and 3.24*M*, the average difference between the two sets of data was only 10 cal.

The comparison of ΔH_{cal} with ΔH_{emf} to obtain a measure of the precision of the Gibbs-Helmholtz equation (or a comparison of Q_{rev} with $nj \cdot T \cdot dE/dT$) does not involve any judgment as to whether or not the equa-

tion is an exact law of nature. To make such a judgment would require an exact knowledge of the experimental error so as to be able to determine whether the discrepancies were within or greater than the experimental error.

It is my opinion that not enough information is available to determine the experimental error. Nevertheless, even a rough estimate is of value as a guide, even though no conclusions should be based on it.

The experimental error has two sources: the measurement of emf and the calorimetric measurements. The emf of a cell is generally measured with a precision of 10^{-5}V or better. The heat equivalent of this error per mole ($nj \cdot 10^{-5}$) would be less than a calorie, hence not significant. A larger error is involved in the determination of the term $nj \cdot T \cdot dE/dT$. The temperature coefficient of emf is usually determined by measurement of emf's ten degrees apart and the precision of dE/dT might be 10^{-6}V. Since T is usually about 300, the value of $j \cdot T \cdot dE/dT$ might be in error by about 7 cal.

With regard to calorimetric measurements, the above comparison of the data of Sturtevant with that of Rossini gave a precision of about 17 cal on a relative basis for the partial molal heat of dilution of hydrochloric acid. The sum of the errors involved in the test of the precision of the Gibbs-Helmholtz equation *via* HCl concentration cells would thus be about 24 cal (17 + 7). This amount is not far from the precision of 30 cal that Gerke found in his test of the third law, which involved measurements of both temperature coefficients of emf and heat capacities of elements. As an estimate of the experimental error in the tests involving the HCl concentration cells, a value of 30 cal seems reasonable.

A measure of the calorimetric error involved in the determination of the heats of dilution of sulfuric acid is not available, as in the case of HCl, because there are not two different sets of data covering a wide range of concentration. The papers of Kunzler and Giauque (7) and of Giauque, Hornung, Kunzler, and Rubin (8) do not give an estimate of the precision of measurement of the partial molal heat of dilution of sulfuric acid. A statement in the latter paper implies that the precision should be better than 100 cal. Data, however, are given to the nearest calorie. Without more data to go on, I suggest 100 cal as the total experimental error involved in the test of the Gibbs-Helmholtz equation *via* sulfuric acid concentration cells. This is equivalent to considering that the error in the measurement of the relative partial molal heats of dilution of sulfuric acid is not greater than 1%.

Concentration Cells without Transference Containing Either Hydrochloric or Sulfuric Acid

In this section I have investigated the precision of the Gibbs-Helmholtz equation with respect to concentration cells constructed from simple cells for which data were reported in the literature. I have combined the simple cells in many different fashions to form concentration cells in which the ratios of the concentrations varied widely.

The data on the hydrochloric acid cells were taken from four sources. The concentration of acid covered the range from 0.001 to about 15*M*.

Table III contains data on concentration cells constructed from the simple cells measured by Bates and Bower (9)

$$H_2 \mid HCl, M_1 \mid\mid Ag, AgCl \mid\mid HCl, M_2 \mid H_2 \quad [11]$$

These concentration cells had electrolytes in the dilute range of 0.0001-0.1*M*. The comparisons are based on the partial molal heats of dilution of both Rossini (6) and Sturtevant (5). The difference between the calorimetric ΔH_{cal} and the value of ΔH_{emf} (derived from the Gibbs-Helmholtz relation) is about 9 cal on the average, based on Rossini's data and about 30 cal, based on Sturtevant's data. These differences are within the experimental error of 30 cal which I had suggested. Quite apart from their use *vis-à-vis* the Gibbs-Helmholtz equation, these cells have an interest in themselves. In contrast to the other concentration cells examined, their reversible heat (given by $j \cdot T \cdot dE/dT$) is 10 or 20 times greater than the enthalpy change due to heat of dilution. Thus these cells function mainly as heat engines.

[1] ΔH_{emf} = Partial molal heat of dilution computed from the emf of the cell and dE/dT.
[2] ΔH_{cal} = Partial molal heat of dilution obtained by calorimetry.

The HCl concentration cells presented in Tables IV, V, and VI differ from those in Table III in possessing a more concentrated electrolyte. At least one compartment of the cell had an HCl concentration of 3.0*M* or higher.

The data in Table IV are based on the simple cell data of Harned and Ehlers (10) and those in Table V are based on the data of Akerlof and Teare (11). The concentration cells were of the same type as in Table III (see Eq. [11]). The average difference between ΔH_{cal} and ΔH_{emf} in Table IV is about 40 cal and in Table V about 76 cal. The data in Table V covers a higher range of HCl concentration (3-15*M*) than the data in Table IV (0.001-4*M*).

The results in Table VI are based on the data of Cerquetti, Longhi, and Mussini (12). Their simple cells differ from those on which Tables III-V are based in that the positive electrode was a chlorine electrode instead of a silver-silver chloride electrode. The concentration cell constructed from the simple cells is

$$H_2 \mid HCl, M_1 \mid\mid Pt, Cl_2, Pt \mid\mid HCl, M_2 \mid H_2 \quad [12]$$

The data of Table VI gives an average difference of 250 cal between ΔH_{cal} and ΔH_{emf}. This large difference may be partly due to a lack of precision in drawing a

tangent to the curve of emf *vs.* temperature at a temperature of 25°, since the authors' data did not have values below this temperature.

The researches of Harned and Hamer (13) on the thermodynamics of aqueous sulfuric acid solutions yield another large amount of accurate data for examining the precision of the Gibbs-Helmholtz equation. Their data cover the range of concentration from 0.005 to 17.5*M*. Cells of the type

$$H_2 \mid H_2SO_4, M \mid Hg_2SO_4, Hg \quad [13]$$

were used for concentrations of acid above 0.05*M* and cells of the type

$$H_2 \mid H_2SO_4, M \mid PbO_2, PbSO_4, Pt \quad [14]$$

for acid concentrations below 0.05*M*. With their data for the simple cells it was possible to obtain similar data for the following concentration cells

$$H_2 \mid H_2SO_4, M_1 \mid\mid Hg_2SO_4, Hg \mid\mid H_2SO_4 \mid M_2 \cdot H_2 \mid [15]$$

or

$$H_2 \mid H_2SO_4, M_1 \mid\mid PbSO_4, PbO_2, Pt \mid\mid H_2SO_4, M_2 \mid H_2 \quad [16]$$

In Table VII the difference between the partial molal heats of dilution of sulfuric acid at two concentrations has been calculated from the data of Harned and Hamer (13), *via* the Gibbs-Helmholtz equation. This quantity, ΔH_{emf}, is compared with the similar quantity, ΔH_{cal}, obtained from the calorimetric data of Giauque and co-workers (8) for the range of acid concentration from 1.0 to 17.5*M* and from the data of Young (14) for the lower range of concentration.

In Table VII data are given for two sets of concentration cells: one set of cells with a compartment containing 0.05*M* sulfuric acid and the other set with a compartment containing 1.0*M* sulfuric acid. The average deviation of the ΔH_{cal} values from the ΔH_{emf} values (derived *via* the Gibbs-Helmholtz equation) is about 225 cal for the first set of concentration cells and 147 cal for the second set of concentration cells. Some of the differences were larger than 300 cal.

Sulfuric Acid Concentration Cells with Transference

Hamer (15) measured the emf and the temperature coefficient of the emf of the following cell in which there is transference of sulfuric acid from one compartment to the other during the working of the cell

$$Hg, Hg_2SO_4 \mid H_2SO_4, M_1 \mid\mid H_2SO_4, M_2 \mid Hg_2SO_4, Hg \quad [17]$$

The objective of Hamer's research was to determine the transference number of the ions of sulfuric acid as a function of concentration and temperature, and he did not use his data to check the precision of the Gibbs-Helmholtz equation.

For testing the precision, the calorimetric value of the partial molal heat of dilution of sulfuric acid, ΔH_{cal}, must be known for comparison with ΔH_{emf}. This requires a measurement that was not needed for the concentration cells without transference, namely the transference number, t_+, of the hydrogen ion. The rea-

son for this is that in the working of a cell with liquid-liquid junctions and with electrodes reversible with respect to the anion, the passage of 1**F** of electricity through the cell results in the transport of only t_+ equivalents of sulfuric acid from one compartment to the other. To obtain the heat effect resulting from the passage of 2**F** through the cell, the difference between the partial molal heats of dilution for concentrations M_1 and M_2 must be multiplied by t_+. This has been done, using Hamer's values for t_+, to yield the values of ΔH_{cal} given in Table VIII.

In this table the values of ΔH_{emf} obtained by applying the Gibbs-Helmholtz equation to Hamer's data are compared with ΔH_{cal} derived as mentioned in the preceding paragraph. The average discrepancy is about 600 cal, which is considerably larger than that for cells without transference.

Calculation of the Gibbs-Helmholtz Discrepancy from the Transference Number of the Hydrogen Ion

In Part I of this series, I showed that the Gibbs-Helmholtz discrepancy could be calculated from data on the variation of ionic mobilities with temperature, by using Henderson's equation. A similar treatment of the data on sulfuric acid concentration cells with transference permits the Gibbs-Helmholtz discrepancy to be easily calculated from the variation of the transference number of the hydrogen ion with temperature, which, of course, in the final analysis means that the discrepancy is due to variation of ionic mobilities with temperature.

The calculation in the case of the sulfuric acid concentration cells is more straightforward and convincing than that with the liquid-liquid, tri-junction cells, because the calorimetric effects (partial molal heats of dilution of sulfuric acid) are accurately known and did not have to be calculated as was done with the tri-junction cells. Furthermore, the data on the variation of transference number of the hydrogen ion with temperature were directly available from Hamer's (15) publication.

The derivation of the Gibbs-Helmholtz discrepancy is as follows: The passage of 1**F** of electricity through the cell with transport results in the transfer of t_+

[1] Each of the 7 sections in the above Table represents the results for 3 concentration cells, as noted under M_1 and M_2, considered connected in series.

equivalents of sulfuric acid from one side to the other. Consequently, the emf, E_t, of the cell is considered as equal to that of the cell without transport, E, multiplied by t_+, which is the transport number of the hydrogen ion

$$njE_t = njE \cdot t_+ = t_+ \left(-\Delta H_{cal} + T \int \frac{C_p}{T} d\tau + KT \cdot \ln \cdot f_c \right) \quad [18]$$

where j is approximately 23,050 cal/V-**F**. The last term represents some form of the Nernst relation for emf with f_c representing some function of concentration of sulfuric acid in the two sides of the cell.

Differentiation of Eq. [18] gives

$$nj \cdot \frac{dE_t}{dT} = \frac{dt_+}{dT} \left(-\Delta H_{cal} + T \int \frac{C_p}{T} dT + KT \cdot \ln \cdot f_c \right) + t_+ \left(-\frac{d(\Delta H_{cal})}{dT} + T \cdot \frac{C_p}{T} + \int \frac{C_p}{T} dT + K \cdot \ln \cdot f_c \right) \quad [19]$$

Note that

$$-\frac{d(\Delta H_{cal})}{dT} + T \cdot \frac{C_p}{T} = 0 \quad [20]$$

Multiplying both sides of Eq. [19] by T gives

$$njT \cdot \frac{dE_t}{dT} = T \cdot \frac{dt_+}{dT} \left(-\Delta H_{cal} + T \int \frac{C_p}{T} + dT + KT \cdot \ln \cdot f_c \right) + t_+ \left(T \cdot \int \frac{C_p}{T} dT + KT \cdot \ln \cdot f_c \right) \quad [21]$$

Rewrite Eq. [21] so as to place the $t_+(\quad)$ term on the left

$$t_+ \left(T \int \frac{C_p}{T} dT + KT \cdot \ln \cdot f_c \right) = njT \cdot \frac{dE_t}{dT} - T \cdot \frac{dt_+}{dT} \left(-\Delta H_{cal} + T \int \frac{C_p}{T} dT + KT \cdot \ln \cdot f_c \right) \quad [22]$$

Substitute the left side of Eq. [22] into Eq. [18] for E_t using the values on the right side of Eq. [22] and at the same time substitute the terms in the parenthesis on the right side of Eq. [22] for their value given by Eq. [18] which is njE_t/t_+. This yields a simple equation for E_t in terms of temperature coefficients

$$njE_t = -t_+ \cdot \Delta H_{cal} + T \cdot \frac{dE}{dT} nj - T \cdot \frac{dt_+}{dT} \cdot \frac{E_t}{t_+} \cdot nj \quad [23]$$

Note that in the cell with transport, the heat effect for the passage of 2**F** is $t_+ \cdot \Delta H_{cal}$, hence the Gibbs-Helmholtz discrepancy is given by the equation

$$\text{discrepancy} = -\Delta H_{emf} + t_+ \cdot \Delta H_{cal} \quad [24]$$

To derive the expression for the discrepancy, subtract the Gibbs-Helmholtz equation, Eq. [25] from Eq. [23] and rearrange terms to yield Eq. [26] for the discrepancy

$$njE_t = -\Delta H_{emf} + njT \cdot \frac{dE_t}{dT} \quad [25]$$

$$\text{discrepancy} = -T \cdot \frac{dt_+}{dT} \cdot \frac{E_t}{t_+} \cdot nj \quad [26]$$

Table IX gives the values of the discrepancies, which have been calculated from Eq. [26] using data for E_t, t_+, and dt_+/dT obtained from Hamer's publication (15). In my opinion, the agreement is satisfactory except for the first entry in the table.

Table IX. Gibbs-Helmholtz discrepancy calculated from the variation of the transference number, t_+, of the hydrogen ion with temperature (see Eq. [26]) with data obtained from Hamer (15).

Conc range of H_2SO_4 (M)	$-\Delta H_{cal}$, cal	E_t, V	t_+	dt_+/dT	Discrepancy Calc, cal	Discrepancy Exp, cal

Summary and Discussion

1. The absolute value of ΔH_{emf} was generally larger than that of ΔH_{cal}.
2. In dilute solutions of HCl the discrepancies were small and within experimental error.
3. The discrepancies for the concentrated solutions of HCl and most of the sulfuric acid concentration cells were more than 100 cal and in some instances a few hundred calories, which, in my opinion, is greater than the experimental error.
4. The largest discrepancies occurred with sulfuric acid concentration cells with transference.
5. The discrepancies for the sulfuric acid cells with transference were readily calculated on the basis of the variation of the transference number of the hydrogen ion with temperature.

The discrepancies of the Gibbs-Helmholtz equation have been calculated for two different types of concentration cells. In Part I of this series it was calculated for tri-junction cells in which the emf was generated entirely by liquid-liquid junctions. In this paper, Part II of the series, it was calculated for a conventional type of concentration cell with transport. The importance of these calculations is that they show that for at least two types of cells, the discrepancy is a genuine phenomenon and not an experimental error.

To preserve the sanctity of the Gibbs-Helmholtz equation (which is a laudable crusade, since so much has been based on it), the theorists can prohibit application of the equation to any cell with a liquid-liquid junction. However, this seems a bit *ex post facto*, because at least up to this moment, the data derived from the sulfuric acid concentration cells with transference have been considered as thermodynamically acceptable. In treating of the use of such cells for obtaining transference numbers, MacInnes (16) stated that, "Although thermodynamically sound this method for obtaining transference numbers has not attained the accuracy of the recent moving boundary or Hittorf methods." The general acceptability of the data from such cells is further illustrated by the inclusion of Hamer's data on the transference numbers of the hydrogen ion in sulfuric acid (derived from the cells with transference) in the standard reference works, such as the Landolt-Börnstein (17).

If the sulfuric acid cells with transference are accepted as thermodynamically correct, there seems to be no reason why the tri-junction cells with three liquid-liquid junctions should not also be acceptable. Furthermore since the Gibbs-Helmholtz discrepancy could be calculated for them, this would seem to put them in the same thermodynamically acceptable class as the sulfuric acid concentration cells with transference.

However, even if the cells with a liquid-liquid junction are excluded from participation in the Gibbs-Helmholtz equation, the theorist must still face the situation that the discrepancies of many of the cells without transference are rather large. These might be dismissed on the basis of a large experimental error. However, even this crutch is swept away, because in Part III of this series I shall show that the discrepancies for the sulfuric acid cells without transference can be explained or even roughly calculated on the basis of a shift of equilibrium with temperature. In the final analysis, the variation of ionic mobilities and of transference numbers with temperature is caused by a shift of equilibrium.

In view of the foregoing discussion, it seems to me simpler to deal with the Gibbs-Helmholtz discrepancies by accepting the situation that the equation for the emf of a galvanic cell

$$njE = -\Delta H + T \cdot \Delta S \qquad [27]$$

is not accurate and that it must be specifically modified or supplemented as required for each individual cell.

ABSTRACT

Two chronopotentiometric waves were observed for the electrochemical reduction of molybdate in the presence of zinc chloride, with quarter-wave potentials of −1.5V and −1.75V *vs.* the Pt(II)/Pt reference electrode, respectively. It was observed that an increase in the molybdate concentration causes a decrease of the first transition time indicating a chemical reaction between $ZnCl_2$ (which is reduced at −1.5V) and Li_2MoO_4 in the melt forming $ZnMoO_4$ which is sparingly dissociated in LiCl-KCl eutectic. The equilibrium constant for the observed reaction was calculated. X-ray powder diffraction patterns of the reduction product of $ZnMoO_4$ have been obtained.

Laitinen and Propp (1) have shown that the electrochemical reduction product of K_2CrO_4 in LiCl-KCl eutectic containing dissolved $MgCl_2$ is a single compound of formula $Li_xMg_yCrO_4$, where $x + 2y = 5$. Laitinen and Hanck (2) observed that the reduction of chromate in the presence of Zn(II) was shifted from −1.0V *vs.* Pt(II)/Pt reference to −0.5V. Analysis of the deposit indicated the composition to be $LiZn_2CrO_4$. Laitinen and Popov (3) also observed that when chromate is reduced in the presence of $NiCl_2$ at 500°C the deposit approaches the composition $LiNi_2CrO_4$.

The purpose of the present research is to characterize the insoluble electrode deposit formed when Li_2MoO_4 is reduced in the presence of $ZnCl_2$ in LiCl-KCl eutectic. The knowledge gained through this study will contribute to the over-all understanding of molybdate electrochemistry (4, 5) and should aid the interpretation of the mechanism of the electrochemical reduction of Li_2MoO_4 in LiCl-KCl eutectic.

Experimental

Solvent.—The eutectic mixture of potassium chloride [41 mole per cent (m/o)] and lithium chloride (59 m/o) at 450°C was used as a solvent system. The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Incorporated, Champaign, Illinois. The method of purification has been described (1).

Apparatus.—The instrumentation and equipment used in this study have been previously described (1-5).

Electrolytic cell.—The cell used in this experiment has been previously described (6). Within this cell and under an atmosphere of dry, oxygen-free argon, the solvent was allowed to collect into the fritted compartments which were used as experimental cells. At the end of the experiment the volume of each compartment was determined by titrating its chloride content, and making calculations from the known density of the melt at 450°C.

Electrodes.—The reference electrode was a platinum foil in contact with platinum(II) solution. This reference electrode has been shown to be reproducible and nonpolarizable over a long period of time (7). The Pt indicator electrode used in this study has been previously described (1-5). The electrode had a geometric area of 0.5 cm^2 and was constructed so that the glass-metal seal was always kept above the level of the melt. The platinum gauze electrodes used to prepare samples of the film, as well as the carbon electrode which served as counterelectrode in all electrochemical investigations in the melt, were constructed as described by Propp (1).

Chemicals.—All chemicals used in this study were reagent grade. $ZnMoO_4$ was prepared by fusion of ZnO and MoO_3 at 700°C (8) as well as by the methods described by Schultze (9), Carriere (10), and Jander (11). The product was light rose in color and has been identified by x-ray and chemical analysis as $ZnMoO_4$. Those chemicals containing water of hydration were vacuum dried at 110°C before being added to the melt. Solid chemicals were added to the melt by means of a small glass spoon. A blanket of argon was kept over the melt at all times to exclude oxygen and water vapor. The purification train used in purifying the argon has been described (1-5).

Experimental techniques.—Samples of the electrode deposit resulting from the reduction were obtained by constant current electrolysis using platinum gauze electrodes. Before their insertion in the melt solution, the gauze electrodes were cleaned in boiling, concentrated HNO_3, rinsed with distilled water, and dried at 130°C for 20 hr. After the material had been deposited on the electrode, the electrode was allowed to cool, washed with deionized water, and dried at 120°C. The deposits were then dissolved in 5 ml of concentrated nitric acid by heating on a hot plate. The zinc content of the solution was conveniently determined by a simple EDTA titration with Eriochrome Black T as the indicator. The molybdenum content of the deposit was determined by addition of an excess of Pb^{2+} which was backtitrated with EDTA using xylenol orange as the indicator. The total molybdenum was also obtained by amperometric titration with lead, a procedure developed by Aylward (12). The lithium content was determined using flame photometry, observing the Li emission at 670.8 nm. X-ray powder diffraction patterns were obtained using an 11.47-cm camera loaded with Ilford Type G x-ray film and exposed to Ni filtered CuK α radiation. The Cu tube was mounted in a Norelco generator. Chloride was determined by the Volhard method.

Results and Discussion

$ZnCl_2$-Li_2MoO_4-LiCl-KCl system.—Under certain conditions one chronopotentiometric wave is observed for the reduction of Li_2MoO_4 at $-1.75V$ *vs.* the Pt(II)/Pt reference electrode. This reduction was found to be diffusion controlled over the time interval investigated. Chronopotentiograms were obtained over the concentration range ($5.3 \times 10^{-3}M$ Li_2MoO_4-$153.3 \times 10^{-3}M$). The average value of $I\tau^{1/2}/C$ calculated from the chronopotentiometric results is 175 A sec$^{1/2}$ mole^{-1} cm^3, which agrees with the results obtained earlier (4, 5).

Chronopotentiometry of $ZnCl_2$ in the absence of Li_2MoO_4 revealed a wave with a quarter-wave potential of $-1.5V$ *vs.* the Pt(II)/Pt reference electrode. Diffusion control was shown by the constancy of $I\tau^{1/2}/C$ at 800 ± 4 A sec$^{1/2}$ mole^{-1} cm for four different concentrations ranging from $8.34 \times 10^{-3}M$ to $125 \times 10^{-3}M$ at three different current densities. The above value of $I\tau^{1/2}/C$ was used as a calibration factor for evaluating Zn(II) concentration in calculating the formation constant of $ZnMoO_4$.

The effect of Zn(II) on the reduction of Li_2MoO_4 was demonstrated by successively increasing the concentration of Li_2MoO_4 at constant Zn(II) concentration as shown in Fig. 1. Two chronopotentiometric waves were observed. The first wave has a quarter-wave potential at $-1.5V$ *vs.* the Pt(II)/Pt reference electrode corresponding to the reduction of Zn(II) and the other at $-1.75V$ corresponding to the reduction of molybdate. It was observed that an increase on the molybdate concentration in the melt causes a decrease of the first transition time and at the same time an increase of the second transition time. The quantitative variation of the transition time constant was tested by running duplicates of three current densities at different Li_2MoO_4 concentrations. The decrease of $I_0\tau^{1/2}$, for the reduction step at $-1.5V$, with increasing Li_2MoO_4 concentration, is demonstrated in Table I.

The chronopotentiometric data for the second reduction are presented in Table II.

The data in Tables I and II can be quantitatively interpreted in terms of an equilibrium

$$Zn^{2+} + MoO_4^{2-} \rightleftarrows ZnMoO_4$$

$$K = \frac{[Zn\,MoO_4]}{[Zn^{2+}][MoO_4^{2-}]} = \frac{X}{(C_{ZnCl_2} - X)\,(C_{Li_2MoO_4} - X)}$$

The results, given in Table III indicate that $K = 30.1 \pm 2.9$, as calculated from the data in Table I.

$ZnMoO_4$-LiCl-KCl system.—In order to examine further the electrochemical reduction of Li_2MoO_4 in the presence of $ZnCl_2$, chronopotentiograms of $ZnMoO_4$ in molten LiCl-KCl were obtained.

Qualitatively, two chronopotentiometric waves occur in the case of $ZnMoO_4$ reduction with quarter-wave potentials at $-1.5V$ and at $-1.75V$ *vs.* the Pt(II)/Pt reference electrode.

The Sand equation was tested by running duplicates of four current densities at five different $ZnMoO_4$ concentrations. The dependence of $I_0\tau^{1/2}$ on C is demonstrated in Table IV for the first wave and in Table V for the second reduction.

The data in Tables IV and V can be quantitatively interpreted in terms of an equilibrium

$$ZnMoO_4 \rightleftarrows Zn^{2+} + MoO_4^{2-}$$

In order to compare the results given in Table IV for the system $ZnMoO_4$ with those obtained for the system Li_2MoO_4-$ZnCl_2$ one can write for the above equilibrium

$$K = \frac{[ZnMoO_4]}{[Zn^{2+}][MoO_4^{2-}]} = \frac{(C_{ZnMoO_4} - X)}{X^2}$$

possible to monitor the electrode potential only at −1.65V *vs.* Pt(II)/Pt reference electrode using current densities of 10, 20, 30, and 40 mA/cm^2. Examination of the cathode showed only one type of solid product, a dark brown solid which adhered to the surface of the electrode. Following electrolysis, the samples were washed with distilled water and dried at 130°C.

Qualitatively, the electrode deposit was found to contain Li, Zn, and Mo. Samples of the deposit were analyzed by the methods described. Table VII summarizes the composition of four samples of deposit prepared under identical conditions. If it is assumed that the deposit contains only Li, Mo, Zn, and O, one obtains the empirical formula $Li_2Zn_{0.5}MoO_4$ or $Li_4ZnMo_2O_8$. On the other hand it is not possible from the data given in Table VII to obtain the exact oxidation state of Mo, both because it was supposed that $O^=$ weight percentages add up to 100% of the sample weight and because some $ZnMoO_4$ may be incorporated into the deposit during the electrolysis. $ZnMoO_4$ is not soluble in water or any other suitable solvent. X-ray diffraction studies were therefore carried out on the dried sample.

Table VII. Typical analysis of $ZnMoO_4$ deposit prepared at constant current

	A	B	C	D

1.5876	50
1.4904	40
1.4576	40

The "d" spacings and relative intensities of the diffraction pattern are presented in Table VIII. The "d" spacings were not comparable with any known Mo or Zn compound listed in the ASTM files.

From the preceding study of molybdate reduction in which the product $Li_5Mo_2O_8$ was identified (4), the simplest reduction mechanism for the formation of $Li_4ZnMo_2O_8$ would involve the reduction of MoO_4^{2-} to MoO_4^{3-}, which is then incorporated into a crystal lattice with Li^+ and Zn^{2+}, in the appropriate ratio. In the absence of Zn^{2+}, both MoO_4^{2-} and MoO_4^{3-} are involved in the final product.

Kinetics of Electrogenerative Hydrogenation over Platinum Black Electrocatalyst

Stanley H. Langer* and George P. Sakellaropoulos*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

The kinetics of the electrocatalytic hydrogenation of ethylene at positive potentials has been studied over polytetrafluoroethylene-bonded, porous platinum black electrodes in perchloric acid electrolyte. Pore diffusion was generally not a significant factor except at low concentrations of reactants. Steady-state kinetic parameters and deuterium exchange results suggest that surface reaction of hydrogen with ethyl radicals is rate limiting. A mechanistic model is proposed and examined in terms of Temkin adsorption of hydrogen atoms in the low potential region ($<0.18V$). Strong Langmuir adsorption of ethylene appears to take place for all mechanisms considered. The energy production of the electrogenerative reactor is favored by high electrolyte concentration, high alkene partial pressure, elevated temperatures, and increased catalytic loading.

Few electrocatalytic reactions have been well characterized; the frequent referral to hydrogen and oxygen electrode reactions, and not many others, in the context of "electrocatalysis" is symptomatic of this situation. The electrocatalytic nature of electrogenerative hydrogenation and the availability of significant amounts of information on the process from earlier investigations (1-6) stimulated a study of the kinetics of the hydrogenation reaction at an ethylene electrode with porous platinum black electrocatalyst. Such kinetic information should provide an additional basis for comparison with conventional catalytic hydrogenation (7-10) and with other reactions, which utilize these and similar electrodes for generation of current.

This electrogenerative process involves the operation of a hydrogen electrode against a hydrogenating olefinic electrode separated by an aqueous, acidic, barrier electrolyte phase (1-3). The external circuit between the electrodes is regulated to allow operation at varying voltages and currents generated by the reacting species. The olefinic electrode operates at positive po-

* Electrochemical Society Active Member.

Key words: ethylene, catalysis, porous electrodes, deuterium exchange.

tentials relative to the hydrogen electrode. The study here differs from a number of others [some of which we mentioned earlier (1-3)] in that hydrogen *per se* is not placed in the olefin chamber during the electrochemical reaction. Davitt and Albright (11) and Fujikawa *et al.* (12) carried out some related studies using sulfuric acid electrolyte in which ethylene is more soluble than in the perchloric acid of our system. The open-circuit voltage of the present system differs significantly from that of other workers using sulfuric acid electrolyte (11, 12) and from systems where gaseous hydrogen is present (4-6, 12). We chose perchloric acid because it is a strongly ionized electrolyte which tends not to be adsorbed. Furthermore, there is the advantage of dealing with a univalent acid.

The electrogenerative reactor allows a relatively reproducible, controlled steady-state investigation of the catalytic process with a constant composition electrolyte. The use of porous electrodes calls for caution in the interpretation of the kinetics, but makes the results applicable to macro current operation.

Experimental

Cell—The free electrolyte cell is shown in Fig. 1. The electrolyte chamber of polytrifluorochloroethylene, with a capacity of about 4.5 ml of electrolyte, had two small ⅛ in. ports to allow filling and removal of electrolyte. A groove at the upper end of this chamber minimized the accumulation of gas bubbles between the two electrodes. Polytetrafluoroethylene sheet gaskets were found to effectively prevent electrolyte leakage during prolonged cell operation. The assembly was held together with four 3/16 in. diameter stainless steel bolts. Polypropylene screen spacers were used to press the electrodes uniformly against platinum screen current collectors. No stainless steel parts came in contact with the electrolyte. Excess gas was fed continuously at the back of each electrode at a rate that would not affect the cell polarization.

Electrodes.—American Cyanamid polytetrafluoroethylene-backed, polytetrafluoroethylene-bonded, platinum black, commercial porous electrodes were used (13, 14). These electrodes are supported on tantalum screen and are gas permeable, liquid impermeable. LAA-2 electrodes contain 9 mg Pt/cm^2 electrode area (13). Type LAA-25 carry a catalyst load of 25 mg Pt/cm^2. The LAA electrodes were used in direct contact with free electrolyte with an exposed geometric area of 5.07 cm^2. The platinum black had a surface area of 20-25 m^2/g (3, 15).

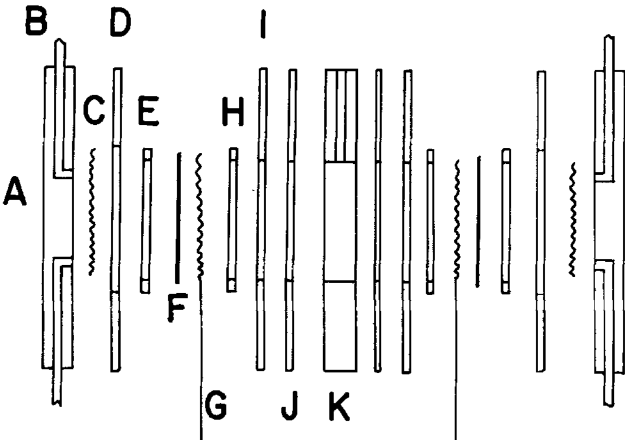

Fig. 1. Exploded view of static free electrolyte cell. A, Lucite face plate, 2.5 in. square, 0.25 in. thickness; B, stainless steel tubing, ⅛ in. diameter; C, polypropylene screen spacer, 1 in. diameter; D, I, Viton-A gaskets, 1/16 in. thickness; E, polytetrafluoroethylene ring gasket, 1.25 × 1 in. diameter, 1/16 in. thickness; F, porous platinum-polytetrafluoroethylene electrode, 1.25 in. diameter; G, current collector, platinum screen 45 × 45 mesh, 1.25 in. diameter; H, Viton-A ring gasket, 1.25 × 1 in. diameter, 1/16 in. thickness; J, polytetrafluoroethylene film gasket, 0.002 in. thickness; K, electrolyte chamber, KEL-F, 0.25 in. thickness, with ports.

Flow system.—An all-glass and Teflon auxiliary gas system was used, Fig. 2. Both sides of the cell could be purged with nitrogen or hydrogen, and ethylene could be introduced to the cathode without exposing the electrodes to the atmosphere. Nitrogen and ethylene were prepurified by being passed through alkaline pyrogallol solution and over packed beds of calcium sulfate and Molecular Sieves 13X or 4A. All gases were saturated with water before entering the cell to minimize electrolyte evaporation. Gas samples were collected at the cell exit and analyzed by gas chromatography (Carle 8000, Basic Gas Chromatograph with a Porapak QS aluminum column, 6 ft long, ⅛ in. diameter). Sampling bulbs and handling techniques were similar to those used earlier (3).

Materials.—Commercial prepurified nitrogen and hydrogen were employed. Ethylene, C.P. grade, and an ethylene standard mixture, 10.27%, in prepurified nitrogen were obtained from the Matheson Company. The ionic strength of all perchloric acid (A.R., Baker Chemical Company) electrolyte solutions were made up to 2*N*, assuming complete ionization, by adding lithium perchlorate (A.R., Alfa Inorganics-Ventron).

Electrical system.—A load box (with 1-1000 ohm variable resistors) was used to control the cell current. The current was occasionally stabilized with a constant current supply (Quan Tech, Model 151B). Currents were measured with an accurate ammeter (Sensitive Research Instrument Corporation, Polyranger S). Cell voltage was measured with a calibrated digital voltmeter (United Systems Corporation, Digitek 201). The cell internal resistance was measured before each run, with hydrogen flowing over both electrodes, with a milliohmmeter (Keithley Instruments, Model 503).

Procedure.—Elimination of oxygen and impurities from the cell and good electrocatalyst pretreatment were essential for reproducible results. The following procedure allowed repeated reproducible results to within 5%. After cell assembly, the electrolyte compartment was filled slowly through one of the electrolyte compartment ports to avoid air bubble formation. The ports were stoppered with polyethylene plugs to eliminate oxygen diffusion into the cell. The anodic and cathodic gas compartments were purged with nitrogen for 20 min. Hydrogen was then passed through both electrode compartments for at least 15 min while shorting the cell. During this time period, the current from the cell was normally less than 1 μA and the open-circuit voltage (OCV) effectively zero. At the end of the hydrogen pretreatment of the electrocata-

lysts, the internal resistance of the cell was measured and was found constant for at least 5 min. Other experiments showed that the cell internal resistance, R_{int}, remained constant throughout each experiment; IR-correction using the measured R_{int} or a Kordesch-Marko bridge agreed within 2-3 mV. The cathode compartment was flushed with nitrogen for 10 min before ethylene was allowed to contact the cathode. The flow rate of all gases was normally about 8 ml/min at atmospheric pressure. For ethylene mixtures other than 1.0 and 0.10 atm, additional nitrogen was introduced continuously into the ethylene stream. By bubbling the gas mixture through two gas-washing bottles in series, complete mixing was achieved. Gas chromatographic (GC) analysis of samples, before and after each run, ensured the constant composition of the mixture to within ±0.002 atm. Open-circuit voltage was stabilized within 20-30 min as indicated by a change of less than 2 mV/5 min. Preliminary polarization runs removed any remaining traces of oxygen or impurities. All data represent steady-state values, normally achieved after about 3 min at any specified current, and after at least two preliminary polarization runs. Results obtained with a variable resistor load or a constant current supply were practically identical. Gas samples were obtained after 10 min operation at steady state and they were analyzed by GC immediately. The hydrogen electrode did not polarize more than 8 mV/decade, measured against a hydrogen reference electrode in the same electrolyte. The IR-free cell voltage was corrected for the anode polarization and the ethylene electrode potential is given with reference to the NHE. All current densities are based on exposed electrode area.

Results

In the course of operation of the ethylene-hydrogen cell in the region of 0.52-0.25V, high polarization at the ethylene electrode is observed which does not obey either a linear or logarithmic current relationship. At lower potentials, Tafel behavior with a slope of 0.035V is found at the cathode as shown in Fig. 3. As the concentration of H^+ or C_2H_4 is decreased, some change in the Tafel slope occurs before a limiting current is attained. After correction for concentration overpotential associated with the limiting current, the Tafel slope attains its intrinsic value of 0.035V except for acid concentrations below 0.2N for which a slope of 0.055V is observed (Fig. 4). At ethylene partial pressures below about 0.10 atm, Nernstian hydrogen transport and evolution (2) becomes significant after a limiting current seemingly is observed, as shown in Fig. 5. In our earlier studies (1-3) we did not report results for the concentrations at which limiting currents might be observed.

If nitrogen flow is substituted for ethylene in the cathode compartment, some hydrogen ions can discharge at positive potentials relative to the normal hydrogen electrode (NHE) because of the Nernst or concentration driving force (2). For reference purposes here, a hydrogen-nitrogen cell was run under our experimental conditions with results shown in Fig. 3. For a given cathode potential, the current of the H_2/N_2 cell is about two orders of magnitude less than the current of the H_2/C_2H_4 cell, for comparable electrolyte concentrations. Therefore, the hydrogen evolution reaction (HER) normally can be neglected in the Tafel region of ethylene hydrogenation.

Using the data reported in Fig. 4 and 5, it is possible to estimate a reaction order with respect to either reactant with the assumption of a simple exponential rate expression

$$\left[\frac{\partial \log i}{\partial \log C_J}\right]_{T,E,C_{K\neq J}} = j \qquad [1]$$

Here i represents current density, C bulk concentration of a specific reactant, and j is the order of the reaction with respect to reactant J. The straight lines of Fig. 6 support the applicability of Eq. [1] for H_3O^+ concentrations higher than 0.2N in each potential region studied. Tafel plot deviations do not allow determination of reaction orders at potentials corresponding to current densities below 0.5 mA/cm². Use of electrodes with higher catalytic loads (25 mg Pt/cm²) results in a significant decrease in cell polarization with parallel shift in Tafel lines as shown in Fig. 3.

The temperature effect on the reaction rate has been determined in our laboratories by Feiz (16). From these results, an apparent activation energy can be calculated for the temperature range of 25°-70°C using data at three temperatures. This as well as other ki-

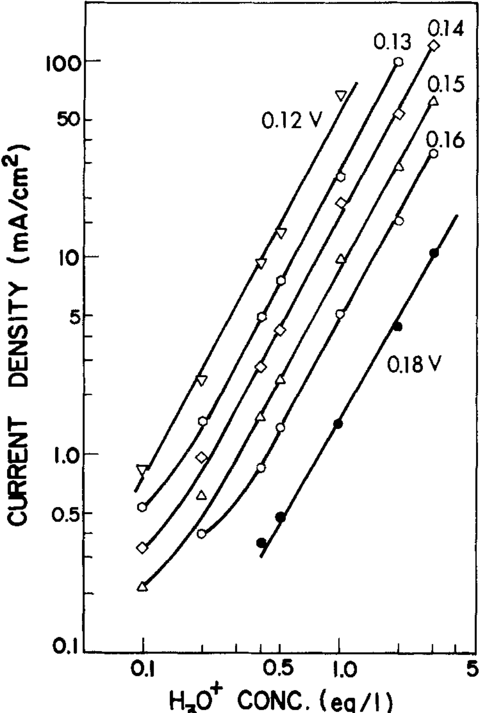

Fig. 6. Rate dependence on electrolyte concentration and electrode potential. Platinum electrode, 9 mg/cm^2; $P_{C_2H_4}$, 1 atm. Temperature, 25°C.

netic data related to our system are presented in Table I for the ethylene electrode. The surface rate constant for zero potential referred to NHE, k_0, and the calculated standard exchange current density at unit concentrations are based on the exposed geometric surface area of the electrode of 5.07 cm^2. The data of Table I given for the HER are based on the hydrogen concentration cell for which some experimental data are represented in Fig. 3.

Discussion

Catalyst utilization.—Heterogeneous catalytic studies over porous catalysts are often complicated by the superimposition of pore diffusion effects on the reaction kinetics. The direct measurement of reaction rate as current in an electrochemical cell, however, presents a distinct advantage over conventional catalytic investigations. Comparative analysis of the results from the electrochemical cell for systems with well-established mechanisms might, in simple cases, resolve some ambiguities regarding pore diffusion. The HER was chosen for this purpose.

The Volmer-Tafel mechanism is generally accepted for the HER, where either hydrogen atom recombination on the surface or diffusion of molecular hydrogen away from the electrode are believed to be rate limiting with platinum electrodes (17-20). The Tafel slope and reaction order observed here with respect to H^+

Table I. Kinetic parameters for ethylene hydrogenation and hydrogen evolution over platinum black at positive potentials and 25°C

Parameter	Ethylene	Hydrogen (23)
Tafel slope (V)	0.035	0.033
Reaction order in H^+	1.9	1.9
Reaction order in C_2H_4	0.1	—
Catalyst load exponent	1.5	−1.5
Apparent E_a (at 0.17V), (kcal/mole)	2.5	—
Rate constant, k_0, (cm^4 mole^{-1} sec^{-1})	8.0×10^{-4}	2.8×10^{-6}
Standard exchange current density, i_o, (A/cm^2)*	1.9×10^{-18}	5.4×10^{-1}

* Based on unit concentrations of reactants. $i_o = nFk_0 \exp(-\alpha E^\circ F/RT)$.

or H_3O^+ differ only slightly from those expected on theoretical grounds from planar electrodes. Since ethylene molecules would reach the catalytic sites from the gaseous side of the pore, diffusion of H_3O^+ to the same catalytic site is expected to be fast for the ethylene-hydrogen system as well. All observations (reaction orders, Tafel slopes) indicate that the observed kinetics have not been complicated by pore diffusion at electrolyte concentrations higher than 0.2*N*. This is reasonable, given the very open porosity and the short pore length of the electrodes (13, 15). Increase of the Tafel slope (Fig. 4) and straight line deviations (Fig. 6) at low acid concentrations are probably a result of hydronium ion pore diffusion limitations. At high electrolyte concentrations and intermediate currents, it is expected that the active electrocatalytic area would remain approximately constant. With careful use, the activity of our electrodes remained unchanged even after 100 hr of use under varying experimental conditions.

Catalysis enhances the rate of reaction according to the relation

$$\left[\frac{i_1}{i_2}\right]_{E,T,C_J} = \left[\frac{W_1}{W_2}\right]^{1.5}_{E,T,C_J} \quad [2]$$

for our two catalytic loadings where i_1, i_2 are current densities corresponding to catalytic loads W_1 and W_2, respectively. Energy recovery from the cell is significantly improved at high catalytic loads, since the operation potential is higher at any given current density.

Maintaining a constant ionic strength in the electrolyte regardless of H_3O^+ concentration should make it possible to neglect any potential drop across the diffuse layer supported by the observed relation $(\partial E/\partial \ln C_{H^+})_i = RT/F$ at constant temperature and ethylene partial pressure (21). Use of strong electrolytes $HClO_4$ and $LiClO_4$ is further advantageous, since lithium and perchlorate ions tend to adsorb less than many other ions on electrodes and catalyst poisoning is minimized. The solubility of C_2H_4 in the electrolyte is low thus avoiding "chemical shorting" of the cell. Attempting to use a similar procedure for maintaining ionic strength with sulfuric acid is more complicated since the ionization constants of the first and second hydrogens are significantly different as is well known but not always appreciated.

Limiting currents.—The slight solubility of ethylene has little effect on its mass transport to active catalytic sites because of the nature of the polytetrafluoroethylene-treated electrodes. The ethylene limiting currents, which are observed only at lower partial pressures, are enhanced by the porous electrode structure (22). Electrolyte limiting currents, i_L, are observed for hydronium ion concentrations less than 0.4*N* in acid. The dependence of i_L on each reactant bulk concentration $C_{J,\infty}$ is not linear but it is given by

$$i_{L,J} \propto C^{\gamma}_{J,\infty} \quad [3]$$

where γ varies between 1.4 and 1.5. This behavior will be discussed further in the future, in view of similar results with other electrocatalysts.

Open-circuit voltage.—The open-circuit voltage seems to follow Nernstian behavior with respect to H_3O^+, while ethylene partial pressure has little if any effect (Fig. 7). The value of 0.52V at atmospheric pressures agrees with that observed earlier by us (3) and Fujikawa *et al.* (12). It appears that ethylene adsorbs strongly at OCV with almost full surface coverage even at relatively low ethylene partial pressures. This is further supported by the rapid approach to OCV at the end of each run (0-0.3V in about 1 min). Hydrogen is removed from the surface in the low voltage region readily by chemical reaction and desorption of the ethane formed.

Kinetic model.—The kinetic rate equation at intermediate current densities (> 0.5 mA/cm^2) is of the

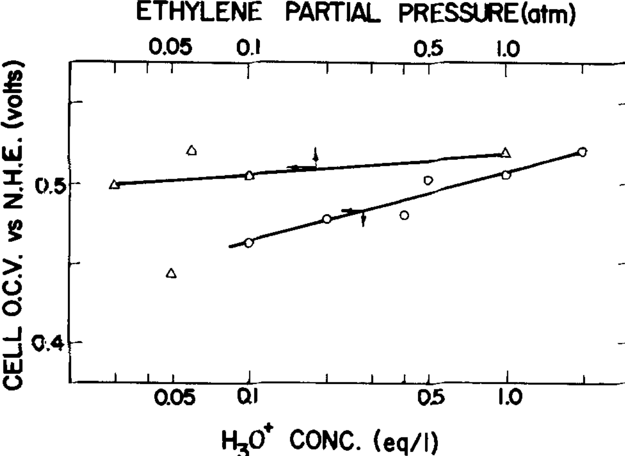

Fig. 7. Dependence of cell open-circuit voltage on acid concentration and ethylene partial pressure. △, 2N $HClO_4$; ○, $P_{C_2H_4}$ = 1 atm.

form

$$i = n\mathbf{F}k_0 P_{C_2H_4}{}^0 C^2{}_{H^+} \exp(-2E\mathbf{F}/RT) \quad [4]$$

This is a close approximation of the experimental kinetic equation

$$i = n\mathbf{F}k_0 P_{C_2H_4}{}^{0.1} C^{1.9}{}_{H^+} \exp(-1.7E\mathbf{F}/RT) \quad [4a]$$

after neglecting the small differences in reaction orders. The rate constant at zero potential *vs.* NHE, k_0, would depend only on temperature in an Arrhenius-type relation.

The approximation of 2 for the exact transfer coefficient determined from the Tafel slope of Table I is justified in view of the results for the simpler well characterized HER (Table I). The 20% discrepancy between Tafel slopes obtained from using Eq. [4] and [4a] is about what one can expect in comparing actual kinetic results with an idealized model. Equation [4a] reproduces the electrode polarization of Fig. 4 and 5 in the Tafel region quite satisfactorily (within 10%). If k_0, obtained by extrapolation using Eq. [4a], is used with the approximate Eq. [4] to predict current densities, somewhat lower reaction rates result than observed experimentally, with Tafel curves shifted to lower potentials by 10-15 mV. This is expected, since the approximation for the transfer coefficient can change the extrapolated value of k_0 by about an order of magnitude.

In interpreting the kinetic results, it must be remembered that it is unlikely that two hydrogen atoms would add to the ethylene molecule simultaneously. Therefore the Tafel slope and the reaction order in H_3O^+ (Table I) are consistent with a rate-limiting step involving the addition of the second hydrogen, qualitatively in agreement with an earlier deuterium study of the addition reaction to ethylene (3). Those data recently have been reevaluated with only one partial change (value of q) in the qualitative picture of the course of the reaction on the electrocatalyst (23). Normally such information is not available from simple kinetic studies. The analysis is based on Kemball's model (24), according to the following scheme where **X** represents either hydrogen isotope

$$C_2X_4 \underset{1/(1+p)}{\overset{p/(1+p)}{\rightleftarrows}} [C_2X_4] \underset{r/(1+r)}{\rightleftarrows}$$

$$[C_2X_5] \xrightarrow{1/(1+r)} C_2X_6 \quad [5]$$

$$[C_2X_4] + H \xrightarrow{1/(1+q)} [C_2HX_4] \quad [6]$$

$$[C_2X_4] + D \xrightarrow{q/(1+q)} [C_2DX_4] \quad [7]$$

$$[C_2X_5] + H \xrightarrow{1/(1+s)} C_2HX_5 \quad [8]$$

$$[C_2X_5] + D \xrightarrow{s/(1+s)} C_2DX_5 \quad [9]$$

Brackets indicate an adsorbed species and p, q, r, and s are the model parameters representing probability ratios: p is the probability of adsorbed ethylene forming ethyl radicals, relative to the probability of ethylene desorbing; q is the probability of adsorbed ethylene acquiring a D-atom, relative to the probability of acquiring an H-atom; r is the probability of an ethyl radical reverting to ethylene, relative to the probability of reacting to form ethane; and s is the probability of an ethyl radical acquiring a D-atom, relative to the probability of acquiring an H-atom. The values of the parameters p, q, r, and s can be estimated, from the isotopic product distribution, using nonlinear regression analysis (3, 16, 23). Results are presented in Table II. A rough estimate of the rate of some steps can be made using the relations of Eq. [5]-[9]. These results are given in Table III. The monotonic increase of p with decreasing potential reflects the increase in ethylene conversion with increasing current. However, the first addition step is about an order of magnitude faster than the second one, while formation and reversal of ethyl radicals is in quasi-equilibrium. Parameters q and s are indicative of the selectivity of each step for D- or H-atom addition. If a statistically probable addition occurred on the surface, based on total hydrogen isotopes present, both parameters would have a value of 0.5. High values of q indicate a preference for deuterium over hydrogen in the first addition. At high positive potentials surface coverage by a hydrogen isotope is expected to be low. Since this model does not specify the origin of D or H, a predominant direct addition of D^+ from the deuterated electrolyte seems probable. As potential decreases, D-addition becomes less selective, but it tends to remain higher than H-addition. The model cannot distinguish between a concerted electron transfer such as

$$[C_2X_4] + D^+ + e \rightleftarrows [C_2DX_4] \quad [10]$$

or a preceding electron transfer

Table II. Statistical parameters for Kemball model

$[C_2X_5] \xrightarrow{+D} C_2X_5D$	0.472	0.220	0.131	0.108	0.092	0.100

$$[C_2X_4] + e \rightleftarrows [C_2X_4^-] \quad [11]$$

$$[C_2X_4^-] + D^+ \rightleftarrows [C_2DX_4] \quad [12]$$

The selectivity of the second addition step (parameter s) varies with the potential at which addition occurs. At 0.22V (sample A), ethyl radicals seem to acquire D atoms preferentially which presumably originate from the electrolyte. The selectivity changes radically at lower potentials to favor H-addition over D-addition. For a deuterated electrolyte this can be explained by a surface reaction, such as

$$[C_2X_5] + [H] \rightarrow C_2HX_5 \quad [13]$$

or

$$[CX_3 - CX_2] + [CH_2 - CH_2D] \rightarrow CX_3CHX_2 + [CH_2 - CHD] \quad [14]$$

or surface reorganization involving a reaction of a labeled ethyl radical with an impinging ethylene molecule (3).

Based on the observed kinetics and the deuterium study under similar operating conditions, the following mechanistic model is proposed for reaction at platinum black porous electrodes at potentials less than 0.18V

$$z\sigma + C_2H_4(g) \rightleftarrows \sigma_z[C_2H_4] \quad [I]$$

$$\sigma_z[C_2H_4] + H^+ + e \rightleftarrows \sigma_{z-x}[C_2H_5] + x\sigma \quad [II]$$

$$\sigma + H^+ + e \rightleftarrows \sigma[H] \quad [III]$$

$$\sigma_{z-x}[C_2H_5] + \sigma[H] \xrightarrow{\text{rds}} C_2H_6 + (z - x + 1)\sigma \quad [IV]$$

where σ represents an active catalytic site, z the number of catalytic sites for adsorption of ethylene, and x the sites released by ethyl formation.

For examining this general mechanism, kinetic expressions are derived below assuming: (*i*) σ adsorption of ethylene, $z = 2$, $x = 1$ (3, 25), and (*ii*) π adsorption, $z = 1$, $x = 0$ (8, 25). The problem in testing the mechanism further is in choosing a model for the adsorption isotherms of the reactants and intermediates with appropriate assumptions.

Hydrogen adsorption on platinum in acidic electrolytes has been studied by Breiter and co-workers (26, 27). The heat of adsorption of hydrogen from 1*N* $HClO_4$ varies significantly and approximately linearly with surface coverage, θ_H, for $\theta_H > 0.2$ (26). This, and logarithmic dependence of θ_H on hydrogen pressure suggest that at intermediate coverages Temkin hydrogen adsorption on platinum could be operative. The observed relative invariance of the free energy of adsorption with surface coverage was apparently a result of a compensation effect between the enthalpy and entropy of adsorption (26).

Adsorption of ethylene on platinum from an $HClO_4$ solution has also been found to be strong by Gilman (28) and independent of temperature or potential. However, we as well as Fujikawa *et al.* (3, 12) find no evidence for a significant acetylene surface intermediate for the experimental conditions. No data are available on the free energy and heat of adsorption from $HClO_4$. Small variation of these parameters with potential has been reported for sulfuric acid (29). We have expressed our reservations regarding this electrolyte (3). But, if this result is accepted in contrast to hydrogen adsorption, then hydrogen would impose its potential-surface coverage characteristics on the system. Then, a Temkin isotherm for hydrogen adsorption would be appropriate, with a potential dependence of surface coverage by hydrogen atoms. Such an isotherm should be applicable for potentials at which $0.2 \leq \theta_T \leq 0.8$, where θ_T is the total surface coverage of the electrocatalyst (30).

For Temkin adsorption a total surface interaction energy $f(\theta)$, can be defined

$$f(\theta) = \sum_J r_J\theta_J \quad [15]$$

where θ_J is the surface coverage of species J with a free energy of adsorption r_J (30). The free energy of activation for adsorption of species J will then be

$$\Delta G^{\neq}_J = \Delta G^{\neq}_{o,J} + \lambda_J x_J f(\theta) \quad [16]$$

where $\Delta G^{\neq}_{o,J}$ is the free energy of activation for adsorption at zero coverage, x_J is the number of surface sites required for adsorption, and λ_J an interaction parameter similar to a transfer coefficient. In general, $0 \leq \lambda_J \leq 1$ with $\lambda_J \simeq 0.5$ for activated adsorption with a symmetric potential energy barrier, and $\lambda_J = 0$ for nonactivated adsorption.

Assuming quasi-equilibrium for all other steps except the rate-limiting one, we can write for σ adsorption of ethylene, $z = 2$, $x = 1$ (step I)

$$C_E(1 - \theta_T)^2 \exp\{-[\Delta G^{\neq}_{o,I} + \lambda_I 2f(\theta)]/RT\} = \theta_E \exp\{-[\Delta G^{\neq}_{o,-I} - (1 - \lambda_I)2f(\theta)]/RT\} \quad [17]$$

or

$$K_I C_E(1 - \theta_T)^2 \exp[-2f(\theta)/RT] = \theta_E \quad [18]$$

where C_E is the bulk concentration of ethylene, K_I an equilibrium constant for step I, at zero coverage, and θ_T is total fractional coverage by all species. Similar expressions can be written for steps II and III

$$K_{II}\theta_E C_{H^+} \exp(-E\mathbf{F}/RT) \exp[f(\theta)/RT] = \theta_{EH}(1 - \theta_T) \quad [19]$$

$$K_{III}C_{H^+}(1 - \theta_T) \exp(-E\mathbf{F}/RT) \exp[-f(\theta)/RT] = \theta_H \quad [20]$$

where θ_H and θ_{EH} represent the fractional surface coverage of H-atoms and ethyl radicals, respectively. With step IV as rate limiting, the rate of reaction will be

$$i = n\mathbf{F}r_{IV} = n\mathbf{F}k^{\circ}_{IV}\theta_H\theta_{EH} \exp[(1 - \lambda_{IV})2f(\theta)/RT] \quad [21]$$

where r_{IV} is the rate of step IV. Since the chance of ethyl radical reversal is high (large parameter r), the steady-state surface concentration of ethyl radicals is expected to be small compared to surface H-atoms in the low potential region. Variations in surface coverage by H-atoms (Eq. [20]) is much more dependent on the exponential terms than on θ_H, θ_T. Therefore, Eq. [20] can be simplified (30) to

$$\exp[f(\theta)/RT] \simeq K_{III}C_{H^+} \exp(-E\mathbf{F}/RT) \quad [22]$$

Similarly θ_H and θ_{EH} can be neglected in Eq. [21]. By substituting Eq. [22] into Eq. [21], the final expression for the rate equation is obtained

$$i = n\mathbf{F}k^{\circ}_{IV}[K_{III}C_{H^+} \exp(-E\mathbf{F}/RT)]^{2(1-\lambda_{IV})} \quad [23]$$

A similar result is obtained for $z = 1$, $x = 0$ assuming π adsorption of ethylene (25). Nondissociative adsorption of ethane would be expected to be nonactivated or possibly not take place. Then Eq. [23] becomes

$$i = n\mathbf{F}k^{\circ}_{IV} K^2_{III}C^2_{H^+} \exp(-2E\mathbf{F}/RT) \quad [24]$$

Equations [24] and [4] are identical, if

$$k_0 = k^{\circ}_{IV}K^2_{III} \quad [25]$$

This is a result of the assumption of Temkin adsorption for hydrogen and significant adsorption of ethylene which may be governed by a Langmuir adsorption isotherm.

Langmuir adsorption for both ethylene and hydrogen with the assumption of strong ethylene adsorption and less strongly held hydrogen can also explain the observed kinetics. Equations [18]-[20] will still hold with $f(\theta) = 0$. For θ_E close to unity, then, the unoccupied fractional surface is

$$1 - \theta_T \simeq (K_I C_E)^{-1/2} \quad [26]$$

The rate equation takes the form

$$i = n\mathbf{F}r_{IV} = n\mathbf{F}k^{\circ}_{IV}K_I K_{II}K_{III}C_E C^2_{H^+}(1 - \theta_T)^2 \exp(-2E\mathbf{F}/RT) \quad [27]$$

or

$$i = n\mathbf{F}k^{\circ}_{IV}K_I K_{II} K_{III} C_E C^2_{H^+} (K_I C_E)^{-1} \exp(-2E\mathbf{F}/RT) \quad [28]$$

or

$$i = n\mathbf{F}k^{\circ}_{IV}K_{II}K_{III}C^2_{H^+} \exp(-2E\mathbf{F}/RT) \quad [29]$$

Low values of parameter s indicate that ethyl radical disproportionation (Eq. [14]) could be important. The rate equation would be for Langmuir adsorption of ethylene and $z = 1$, $x = 0$

$$i = 2n\mathbf{F}k^{\circ}_D\theta^2_{EH} = 2n\mathbf{F}k^{\circ}_D[K_I K_{II} C_E C_{H^+} \exp(-E\mathbf{F}/RT)]^2(1-\theta_T)^2 \quad [30]$$

where k_D is the rate constant for Eq. [14]. For strong ethylene adsorption then

$$1 - \theta_T \simeq (K_I C_E)^{-1} \quad [31]$$

$$i = 2n\mathbf{F}k^{\circ}_D K^2_{II} C^2_{H^+} \exp(-2E\mathbf{F}/RT) \quad [32]$$

Kinetic experiments do not make it possible to discriminate from among Eq. [24], [29], and [32], all consistent with experimental results. It is possible that two of these mechanisms operate concurrently or at different potentials.

The three rate expressions developed here all involve some type of prior equilibrium before the rate-determining step. Two expressions involve hydrogen adsorption and all involve the ethylene ↔ ethyl interconversion. The relatively small activation energy for the over-all hydrogenation reaction then is a result of the interaction of the energy of activation of a rate step, k°_{IV} or k°_D, and heats for prior equilibria, hydrogen adsorption, and/or ethyl formation. The latter are presumably negative.

The hydrogenation kinetics found here (Eq. [4]) are in agreement with those obtained in a number of studies of platinum in heterogeneous catalysis (7, 10) but not others (9). Despite the fact that surface reaction rate is limiting under standard atmospheric operating conditions in the electrogenerative reactor heretofore (1-3), reactant concentrations may be decreased to determine order or so that mass transport of either may be rate limiting. The potential of operation is generally oxidizing for hydrogen so that the equilibrium surface concentration of hydrogen atoms must be considerably less than that found with conventional catalysis on a platinum surface. The mechanism proposed involves two different types of hydrogen addition: one electrochemical (a proton and an electron) and one essentially chemical (involving a preceding electrochemical step). If this mechanism is valid, it would seem possible that a similar mechanism may operate in heterogeneous catalysis under some conditions. The net addition of two hydrogen atoms would be involved. The mechanism of the first addition essentially could involve a proton and an electron, while the second addition would result from addition of an adsorbed hydrogen atom.

Competitive adsorption of ethylene and hydrogen, absence of electrolyte and of electric fields in gas-phase catalytic hydrogenation do make comparison with electrogenerative hydrogenation difficult. The reported kinetic parameters (7) vary widely from system to system. However, it is interesting to note that recalculated results of Bond *et al.* (8) for ethylene deuterogenation over Pt-on-alumina are in good agreement with our results (3, 23) at low potentials where conditions are most comparable. It has been stated (8) that the Kemball model parameters, obtained by trial and error, give only an approximate fit with the experimental product distribution so that the further application of nonlinear regression analysis (Table II) seemed appropriate. The agreement with samples D-F is surprisingly close.

Heat of activation.—By differentiating Eq. [4] and [24] with respect to temperature at constant potential, the heat of activation of step IV at zero potential, $\Delta H^{\circ\neq}_{IV}$, can be related more quantitatively to the apparent activation energy, E_a, for the Temkin adsorption

$$\Delta H^{\circ\neq}_{IV} = E_a - 2\Delta H_{o,III} - 2\mathbf{F}E \quad [33]$$

Similarly, for Langmuir adsorption the heat of activation is

$$\Delta H^{\circ\neq}_{IV} = E_a - \Delta H_{o,II} - \Delta H_{o,III} - 2\mathbf{F}E \quad [34]$$

and for ethyl radical disproportionation

$$\Delta H^{\circ\neq}_D = E_a - 2\Delta H_{o,II} - 2\mathbf{F}E \quad [35]$$

$\Delta H_{o,II}$ is not known for platinum electrodes. Twigg (31) has estimated that the enthalpy change is 1-10 kcal/mole for the first H-addition over nickel in the gas phase. Although these values have been based on different heats of adsorption of C_2H_4 and H_2, they can be used for a rough approximation to estimate $\Delta H^{\circ\neq}_{IV}$. Obviously, for $\Delta H_{o,II} = -1$ kcal/mole, the activation enthalpy calculated from Eq. [34] or [35] is too low for a surface reaction limiting step. Using $\Delta H_{o,II} = -10$ kcal/mole and $2\Delta H_{o,III} = -23$ kcal/mole (26) the activation enthalpy has been estimated for both adsorption types, Table IV.

The change in E_a and $\Delta H^{\circ\neq}_{IV}$ is expected since the Tafel plots were not linear above 0.16V for these experiments (16). Very low E_a at high potentials is indicative of strong ethylene adsorption in this region [see also Gilman (28)]. Since surface coverage by hydrogen should be low, ethyl radical disproportionation possibly could contribute to ethane formation above 0.2V. Below this potential, hydrogen adsorption increases and a transition region is observed before adsorption of hydrogen atoms prevails.

It is important to realize that electrogenerative hydrogenation takes place on catalytic electrodes under conditions less drastic than those encountered in conventional fuel cell operation with hydrocarbons. Nevertheless, knowledge on the utilization of catalysts in electrogenerative hydrogenation might be applicable to fuel cell operation. This is particularly true if it is remembered that the addition of the second hydrogen is the reverse of the probable rate-determining step in hydrocarbon combustion in a fuel cell.

Conclusions

Kinetic results can be obtained for some reactions on porous electrocatalysts *in situ*, for mechanistic investigations. By studying results for well-characterized reactions, such as those for hydrogen evolution, some questions regarding pore diffusion can be resolved. In the investigated electrogenerative hydrogenation of ethylene on platinum black, pore diffusion apparently did not affect the kinetics except at low reactant concentrations. Further catalysis at the electrode surface decreased cell polarization and increased energy output of the cell.

The over-all electrochemical reaction rate was essentially independent of ethylene partial pressure and second order in hydrogen ion concentration. Isotopic exchange provided additional insight into the reaction mechanism, particularly on steps preceding the rate-limiting one. A general mechanism can be proposed for electrogenerative hydrogenation on platinum black electrocatalyst, involving simultaneous electrochemical addition of electrons and protons to adsorbed ethylene

Table IV. Estimated heat of activation of limiting step for Temkin and Langmuir adsorption (25°-70°C). (See text)

		$\Delta H^{\circ\neq}_{IV}$ (kcal/mole)		
			Langmuir adsorption	
Potential (V) *vs.* NHE	E_a (kcal/mole)	Temkin adsorption	H-addition	Disproportionation
0.200	1.5	15.3	13.8	12.3
0.170	2.5	17.6	16.1	14.6
0.145	4.9	21.2	19.7	18.2

molecules, followed by the rate-limiting, surface reaction of ethyl radicals and hydrogen atoms. Temkin hydrogen adsorption can determine the kinetic and electrochemical behavior of this system below 0.18V. At higher potentials, where hydrogen atom surface coverage is low, strong Langmuir adsorption of ethylene and ethyl radical disproportionation probably control the reaction. The similarity between conventional catalytic and electrogenerative hydrogenation deserves further investigation. The nature of the results obtained for electrogenerative hydrogenation indicates the reaction to be suitable for characterizing platinum black electrodes.

Electrochemistry of Potassium Chromate in Molten Zinc Chloride-Potassium Chloride Eutectic

M. L. Deanhardt[1] and K. W. Hanck*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27607

ABSTRACT

The electrochemistry of K_2CrO_4 in an equimolar $ZnCl_2$-KCl eutectic at 300°C was investigated by chronopotentiometric, chronoamperometric, and neovoltammetric techniques. The reduction occurs as a single, irreversible, diffusion-controlled step yielding an insoluble electrode deposit that would not undergo electrochemical oxidation. The value of $nD_{ox}^{1/2}$ at 300°C was found to be $(3.46 \pm 0.10) \times 10^{-3}$ eq-cm/mole-sec$^{1/2}$. The charge transfer step was found to be totally irreversible; $\alpha = 0.57$ and $k_{h,f}$ (at 1.2V) $= 4.46 \times 10^{-4}$ cm/sec. Chemical analyses were performed to determine the composition of the electrode deposit. The deposit appears to be an unstoichiometric compound of the general form $K_xZn_yCrO_z$ where x, y, and z depend upon the conditions of the electrolysis. A mechanism consistent with the observed results is proposed.

The electroreduction of chromate has been the subject of extensive investigation by Laitinen and coworkers because of its use as a depolarizer in thermal batteries (1-5). Their studies were carried out in LiCl-KCl, a neutral, nonoxidizing solvent. With the addition of acidic $ZnCl_2$ to the LiCl-KCl solvent, the reduction of chromate is shifted to more positive potentials (4). A mechanism involving the formation of a Zn(II)-Cr(IV) adduct as a reaction intermediate was proposed to account for the positive shift in potential.

Recently acidic solvents such as the chloroaluminate melts have gained popularity as solvents for electrochemical studies (6-8). Low oxidation states of metals are usually more basic than the higher oxidation states and are stabilized through formation of an acid-base adduct with strongly acidic solvents. Several such states have been observed in chloroaluminates.

In attempting to further characterize the Cr(IV) species proposed by Hanck and Laitinen we sought a solvent acidic enough to stabilize Cr(IV) yet not so acidic as to introduce complications from $Cr_2O_7^{2-}$. Consequently we have elected $ZnCl_2$-KCl as a solvent over the more acidic chloroaluminate melts. The reduction of chromate in LiCl-KCl containing $ZnCl_2$ is free of side reactions and yields a stoichiometric reduction product, $LiZn_2CrO_4$, over a wide range of preparative conditions (4); the influence of $AlCl_3$ on the reduction of chromate in LiCl-KCl, on the other hand, has not been fully explored.

Experimental

Reagents and solvent preparation.—Anhydrous K_2CrO_4 was obtained by drying reagent grade K_2CrO_4 (J. T. Baker) at 110°C for 1 hr and storing over $Mg(ClO_4)_2$ a few days before use.

The $ZnCl_2$-KCl eutectic was prepared by vacuum drying reagent grade $ZnCl_2$ (J. T. Baker) and reagent grade KCl at 150°C for 48 hr. The two dried salts were mixed in a 1:1 mole ratio under a nitrogen atmosphere and stored over $Mg(ClO_4)_2$ in a vacuum desiccator. To prevent hydrolytic decomposition of $ZnCl_2$, anhydrous HCl (Air Products electronic grade) was slowly passed through the salt mixture for 30 min during which the temperature was raised from room temperature to 450°C; fusion occurred at 230°C. The temperature was maintained at 450°C for 1 hr in order to rapidly decompose any organic matter present, then the temperature was lowered to 300°C. Argon was passed through the melt for 4 hr to expel excess HCl. Finally the melt was filtered through a medium porosity, sintered glass frit directly into the electrochemical cell and maintained under vacuum for 4 hr.

The purity of the $ZnCl_2$-KCl solvent was carefully examined using chronopotentiometry. Both anodic and cathodic residuals were sharp; at an applied current of 5 mA/cm^2, 150 msec were typically required for the potential to shift from the rest potential to the cathodic limit of the solvent. The anodic limit of the solvent is due to the oxidation of chloride; the cathodic limit is due to the reduction of Zn(II); the useful potential range of the solvent is 1.5V.

Apparatus.—The molten salt furnace, temperature controller, and cell assembly have been previously described (9).

Current-time and voltage-time curves were obtained with a Princeton Applied Research Corporation Model 173 potentiostat/galvanostat. A triangle wave generator constructed using the circuit of Bull and Bull (10) was interfaced with the Model 173 to obtain linear sweep voltammograms.

Data were digitized with an IBM system/7 data acquisition computer which was linked to the IBM 370/165 computer located at the Triangle Universities Computation Center. The laboratory instruments were interfaced to the computer by means of logic circuits constructed on a Heath Schlumberger Model EU-801 analog/digital designer. In some cases data were collected with a Tektronix 502-A oscilloscope equipped with a Model C-12 oscilloscope camera.

Controlled current depositions of the reduction product were obtained with the PAR 173 galvanostat.

Electrodes.—A zinc rod (0.125 in. in diameter; Alfa Inorganics, 99.95% Zn) in equilibrium with the equimolar $ZnCl_2$-KCl solvent was used as the reference electrode. The counterelectrode was a rod of spectroscopic grade graphite (0.125 in. in diameter; Ultra Carbon Corporation).

Platinum flag electrodes (area approximately 0.5 cm^2) were used as working electrodes. Construction and area determination of these electrodes have been previously described (4). Platinum gauze electrodes (52 mesh) served as working electrodes in the electrode deposit analysis.

Analytical procedures.—The following analytical procedures were used in the preparation and analysis of the electrode deposits.

Platinum gauze electrodes were cleaned in boiling $HClO_4$, rinsed with deionized H_2O, dried, and weighed to the nearest microgram. After deposition the deposits were reweighed and dissolved in $HClO_4$ according to the procedure described by Propp (11).

Key words: molten salt, chromite, chromium(IV).

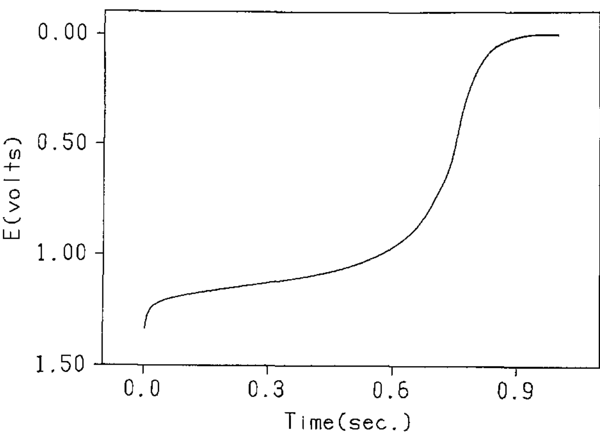

Fig. 1. Potential-time curve for the chronopotentiometric reduction of K_2CrO_4. Current density = 14.98 mA/cm². [K_2CrO_4] = 29.93 mM.

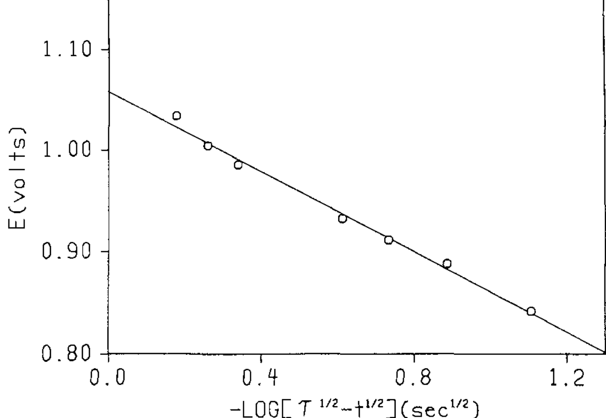

Fig. 2. Potential time analysis. [K_2CrO_4] = 30.59 mM. Current density = 10.14 mA/cm².

The deposits were found to contain chromium, zinc, and potassium. Chromium was determined by a coulometric titration with electrogenerated Cu(I) using a biamperometric endpoint as described by Meier, Myers, and Swift (12).

Zinc was determined by a spectrophotometric titration (750 nm) with EDTA using Eriochrome Black T as an indicator.

The potassium content was determined by flame photometry.

The deposits were analyzed for chloride by oxidizing the deposits with ammonium hexanitratocerate(IV) and coulometrically titrating with electrogenerated Ag(I) (13).

Results and Discussion

Electrochemical measurements.—The reduction of K_2CrO_4 in the $ZnCl_2$-KCl solvent involves a single reduction step with the formation of an insoluble product which adheres to the electrode. This insoluble product was not oxidizable in the observable potential range, therefore double step techniques could not be used to deduce the reduction mechanism. Three single step techniques, chronopotentiometry, chronoamperometry, and neovoltammetry where chosen to study the electrochemical reduction. Cyclic voltammetric experiments were attempted but very little useful information could be obtained because the i-E curves were extremely broad with poorly defined maxima. All electrochemical measurements were made at 300°C.

Digitized chronopotentiograms of K_2CrO_4 in the $ZnCl_2$-KCl solvent were taken at several different concentrations and current densities using a 2 msec sampling interval. Transition times were limited to a range of 0.2-2.0 sec in order to minimize double layer effects and convection. A typical chronopotentiogram of the reduction is shown in Fig. 1. A fresh electrode was used for each chronopotentiogram. Transition times were measured using the method of Delahay and Berzins (15) and corrected for double layer effects by the method of Bard (16).

The range of concentrations and current densities studied are shown in Table I. The reduction was found to obey the Sand equation; a linear regression analysis of $I_o\tau^{1/2}$ *vs.* [K_2CrO_4] indicates a diffusion controlled process with $I_o\tau^{1/2}/C$ being 0.295 ± 0.009 mA-sec$^{1/2}$/cm²-mM. From this slope $nD_{ox}^{1/2}$ was calculated to be (3.46 ± 0.10) × 10^{-3} equiv.-cm/mole-sec$^{1/2}$.

We have also investigated the reduction of $K_2Cr_2O_7$ in the $ZnCl_2$-KCl solvent. The results indicate that the diffusion coefficient of dichromate, as expected, is slightly smaller than that of chromate. The rest potential of solutions of dichromate was significantly higher than that observed for chromate and very close to the oxidation limit of the solvent. Similar results were observed in molten LiCl-KCl (11). The reduction of dichromate was not pursued further but the differences in electrochemical behavior between CrO_4^{2-} and $Cr_2O_7^{2-}$ indicate that dichromate is not formed when chromate is added to the acidic solvent.

Plots of E *vs.* log ($\tau^{1/2} - t^{1/2}$) were found to be linear indicating a totally irreversible charge transfer step. An example of such a plot is shown in Fig. 2. From the average slope of these plots we calculate α = 0.57. From the average intercept, the forward heterogeneous charge transfer rate constant $k^o_{h,f}$ was calculated to be 327 cm/sec, referred to the zero of the potential scale (Zn^o/equimolar $ZnCl_2$-KCl). The reduction of K_2CrO_4 occurs at ~1.2V *vs.* the zinc reference electrode; at E = 1.2V, $k_{h,f} = 3.27 \times 10^{-4}$ cm/sec.

Chronoamperograms of the reduction of K_2CrO_4 provided an independent method for the determination of $nD_{ox}^{1/2}$. The electrode potential was stepped from the rest potential to 0.5V; plots of I *vs.* $t^{-1/2}$ were found to be linear as predicted by the Cottrell equation. Using a linear regression analysis, values of $nD_{ox}^{1/2}$ were obtained from the slopes of the regression lines as shown in Table II. The chronoamperometric values of $nD_{ox}^{1/2}$ agree within experimental error with the value obtained from the chronopotentiometric data.

Recently, the "semi-integral" technique has been applied to linear sweep voltammetry (17-21). Plots of the semi-integrated current *vs.* potential have two basic advantages over the normal voltammetric plots. First the semi-integral technique provides an easier method for obtaining quantitative data from the voltammetric measurements. Second the semi-integral technique provides a convenient way of removing effects of solution resistance from the analytical data.

Digitized linear sweep voltammograms of K_2CrO_4 were taken at several different sweep rates from ~1 to ~10 V/sec; the potential was scanned from the rest

Table I. Chronopotentiometric data

[K_2CrO_4] (mM)	$I_o\tau^{1/2}$ (mA-sec$^{1/2}$/cm²)	Range of I_o (mA/cm²)
10.45	3.21	4.69-9.29
28.66	8.61	11.55-18.33
44.20	13.73	19.08-24.32
78.90	24.38	28.63-38.61
116.90	34.27	39.53-49.50

Table II. Chronoamperometric data[a]

[K_2CrO_4] (mM)	$nD_{ox}^{1/2}$ (equiv.-cm/mole-sec$^{1/2}$)
9.81	(3.50 ± 0.08) × 10^{-3}
78.90	(3.45 ± 0.08) × 10^{-3}
116.90	(3.42 ± 0.12) × 10^{-3}

[a] Uncertainties quoted in this paper are 95% confidence intervals.

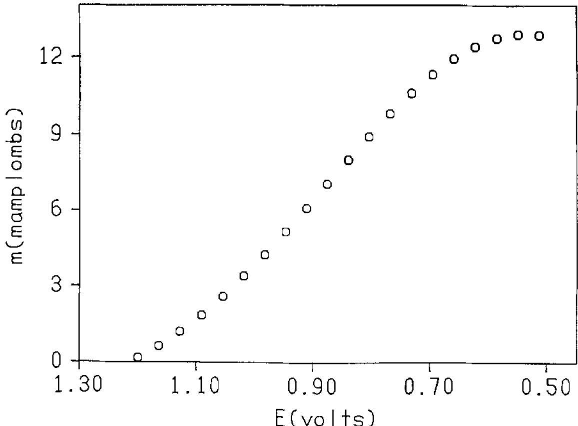

Fig. 3. Neovoltammogram for the reduction of K_2CrO_4. $[K_2CrO_4] = 78.90$ mM. Sweep rate = 3.61 V/sec. Electrode area = 0.488 cm².

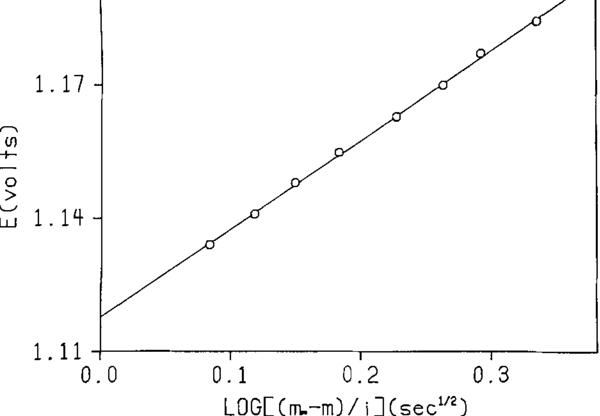

Fig. 4. Relationship between potential and semi-integrated current. $[K_2CrO_4] = 78.90$ mM. Sweep rate = 3.61 V/sec. Electrode area = 0.488 cm².

potential to 0.5V. The semi-integrated currents, $m(t)$ were calculated using the algorithm described by Grenness and Oldham (18). Blank neovoltammograms were taken of the pure solvent to correct for nonfaradaic effects. Effects of uncompensated solution resistance were corrected using positive feedback resistance compensation provided on the PAR 173 potentiostat.

One of the neovoltammograms is shown in Fig. 3. At a sufficiently negative potential the semi-integrated current reaches a limiting value, $m(\infty)$ given by

$$m(\infty) = nFACD_{ox}^{1/2} \quad [1]$$

Using several neovoltammograms and Eq. [1] the average value of $nD_{ox}^{1/2}$ was calculated to be $(3.45 \pm 0.19) \times 10^{-3}$ equiv.-cm/mole-sec$^{1/2}$, which is in good agreement with the chronopotentiometric and chronoamperometric values (Table III).

Plots of E vs. log $[(m_\infty - m)/i]$ were found to be linear indicating a totally irreversible charge transfer step (20). An example of such a plot is shown in Fig. 4. A transfer coefficient of 0.57 was obtained from the slope. From the intercept, the heterogeneous charge transfer rate constant $k_{h,f}$ was calculated to be 4.46×10^{-4} cm/sec at $E = 1.2$V. As can be seen in Table III, the $k_{h,f}$ obtained from the chronopotentiometric data is lower than that obtained from neovoltammetry. This discrepancy is probably due to the effects of uncompensated solution resistance on the chronopotentiograms where positive feedback resistance compensation was not possible.

Characterization of the electrode deposit.—Electrode deposits were prepared by constant current electrolysis using the method outlined by Propp (2) and analyzed for chromium, zinc, and potassium as previously described. The potential was never allowed to become more negative than 0.5V during the deposition process; the concentration of chromate was 0.15*M*. Approximately 100 μequiv. of deposit was formed on each electrode using five current densities ranging from 0.5 to 10 mA/cm². The area of the platinum gauze electrodes was determined by a chronoamperometric technique using a standard $K_3Fe(CN)_6$ solution. The results of the deposit analysis are shown in Table IV.

The effective number of electrons transferred was determined by

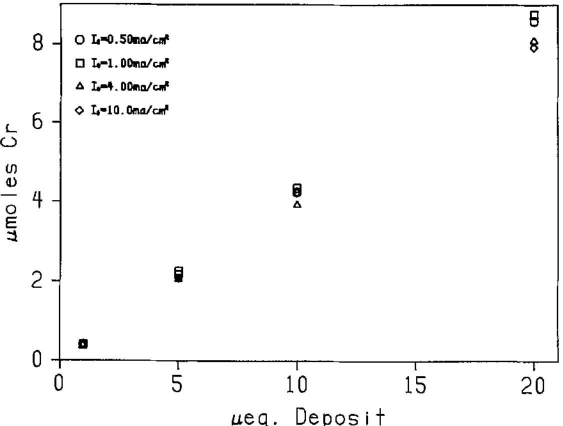

Fig. 5. Relationship between micromoles of chromium and microequivalents of deposit.

$$n_{eff} = \frac{\mu\text{equiv. deposit}}{\mu\text{moles Cr found}} \quad [2]$$

The oxygen to chromium ratio in each deposit was calculated using a charge balance and assuming the oxidation states of potassium, zinc, and chromium to be I, II, and VI − n_{eff}, respectively.

Deposits formed with high current densities were found to be hygroscopic, green in color, and not strongly attached to the gauze electrodes. The per cent of sample weight accounted for by the empirical formulas in Table IV was ~92-100%, where the remaining weight is assumed to be H_2O. Chloride could not be detected in any deposit. The low current depositions were very stable when exposed to the atmosphere, black in color, and adhered strongly to the gauze electrodes.

Additional experiments were performed to determine if the deposit composition varied with the amount of deposit formed on the electrode. Deposits ranging from 1 to 20 μequiv. were formed at several current densities and analyzed for Cr and Zn by atomic absorption. The results are shown in Fig. 5 and 6. A straight line passing through the origin was obtained for each current

Table III. Comparison of data obtained from the various electrochemical techniques

Technique	$nD_{ox}^{1/2}$ (equiv.-cm/mole-sec$^{1/2}$)	α	$k_{h,f}$ (at $E = 1.2$V) (cm/sec)
Chronopotentiometry	$(3.46 \pm 0.10) \times 10^{-3}$	0.57	3.27×10^{-4}
Chronoamperometry	$(3.46 \pm 0.05) \times 10^{-3}$	—	—
Neovoltammetry	$(3.45 \pm 0.19) \times 10^{-3}$	0.57	4.46×10^{-4}

Table IV. Deposit analysis

Current density (mA/cm²)	n_{eff}	Empirical formula	Formula wt
0.5	2.39	$K_{0.07}Zn_{1.18}CrO_{3.02}$	180
1.0	2.39	$K_{0.11}Zn_{1.56}CrO_{3.42}$	213
2.0	2.33	$K_{0.12}Zn_{1.71}CrO_{3.60}$	226
4.0	2.50	$K_{0.17}Zn_{2.18}CrO_{4.02}$	265
10.0	2.79	$K_{0.32}Zn_{2.15}CrO_{3.92}$	268

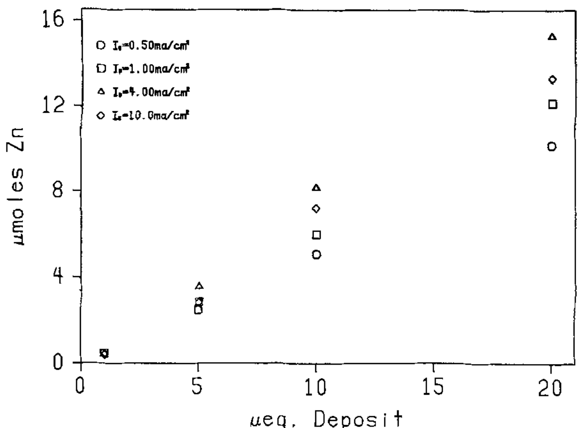

Fig. 6. Relationship between micromoles of zinc and microequivalents of deposit.

density. The excellent linearity of these plots strongly suggests that neither Cr nor Zn is being trapped by the deposit. These results are consistent with the n_{eff} and Zn/Cr ratios shown in Table IV.

ESR and magnetic measurements have been made on several of the deposits (22). The ESR measurements clearly indicate the presence of Cr(III) in the deposits. Specific magnetization and thermomagnetic analysis indicate that the deposits are ferromagnetic; the saturation magnetization and Curie temperature vary with deposit composition. Similar results have been reported for oxides formed by the thermal decomposition of chromium trioxide (23, 24).

X-ray powder diffraction studies indicate that the deposits have a diamond cubic lattice (DC) with a unit cell edge of 8.43Å. This phase is slightly larger than the DC phase of pure Cr_2O_3 which has a unit cell edge of 8.36Å.

Reduction mechanism.—The composition of the electrode deposit depends on the current density applied during the electrolysis. A reduction mechanism consistent with the results of Table V is shown below

$$\begin{array}{ccc} x + 2y = 2 & & x + 2y = 3 \\ (K_xZn_yCrO_3)_s & & (K_xZn_yCrO_3)_s \\ \uparrow & & \uparrow \\ CrO_3^{2-} + O^{2-} & & CrO_3^{3-} + O^{2-} \\ \text{path A} \uparrow\downarrow & & \text{path B} \uparrow\downarrow \\ CrO_4^{2-} + 2e^- \rightleftharpoons CrO_4^{4-} & + & e^- \rightleftharpoons CrO_4^{5-} \\ \text{path C} \downarrow & & \text{path D} \downarrow \\ (K_xZn_yCrO_4)_s & & (K_xZn_yCrO_4)_s \\ x + 2y = 4 & & x + 2y = 5 \end{array}$$

At high current densities the total time of the electrolysis is small. This would tend to limit the decomposition reactions of paths A and B and favor the depositions of paths C and D. Due to the large overvoltage at very high current densities, path D would be favored over path C. At low current densities the total time of electrolysis is very large providing more time for the chemical reactions of paths A and B to occur. Due to the small overvoltage at very low current densities, path A would be favored over path B. Table V summarizes the changes in deposit composition predicted to occur as preparative current density is changed; these predictions are experimentally verified in Table IV.

Table V. Compositional changes with electrolysis current

Current density	$(x + 2y)$	n_{eff}	O/Cr
Very low	2	2	3.0
Low	2 to 3	2 to 3	3.0
High	4 to 5	2 to 3	4.0
Very high	5	3	4.0

The mechanism for the reduction of K_2CrO_4 in the presence of Zn(II) in molten LiCl-KCl involves a three electron process with CrO_4^{4-} formed as a transitory intermediate (4). Our data indicate that Cr(IV) is sufficiently stable in $ZnCl_2$-KCl to prevent complete reduction to Cr(III) unless high current densities are used. This infers the presence of a stronger Cr(IV)-Zn(II) interaction than in LiCl-KCl containing $ZnCl_2$. The source of this increased interaction is undoubtedly the high acidity of the $ZnCl_2$-KCl solvent. Weakly basic solutes display more alkaline properties in acidic than in neutral solvents, consequently the acid-base adduct Zn(II)-Cr(IV) is more stable in $ZnCl_2$-KCl than in LiCl-KCl containing $ZnCl_2$.

The loss of oxide at low current density (path A) is also a consequence of the acidity of $ZnCl_2$-KCl. Acidic Zn(II) species would be expected to rapidly react with oxide to produce zinc oxychloride. This may, in fact, divert significant quantities of CrO_4^{4-} from the second electron transfer to path A.

This mechanism is consistent with the results obtained from the electrochemical measurements. Due to the high current densities and short time intervals of the chronopotentiometric analysis, the value of n_{eff} is approximately 3 as indicated in Table V. The small uncertainty in the value of $nD_{ox}^{1/2}$ also indicates a constant value of n. Using $n = 3$, the value of D_{ox} is $(1.33 \pm 0.08) \times 10^{-6}$ cm²/sec.

The kinetic data suggest an irreversible charge transfer step in the reduction sequence. The oxygen coordination remains tetrahedral in the first reduction step and changes from tetrahedral to octahedral in the second reduction step (4). Therefore the second step is slower than the first and is considered to be the irreversible, rate-determining step. It should be pointed out that due to the chemical reactions involved in the reduction mechanism, it may be possible that the irreversible shape of the chronopotentiograms and neovoltammograms is due to a reversible electron transfer reaction with a rapid following chemical reaction. Using only single step techniques as described here, it was virtually impossible to distinguish between these two cases.

Conclusions

Molten $ZnCl_2$-KCl is a useful moderately acidic solvent for electrochemical investigations. The electroreduction of K_2CrO_4 in $ZnCl_2$-KCl involves a moderately stable Cr(IV) intermediate and produces an insoluble electrode deposit which is ferromagnetic at room temperature.

Technical Note

Electromotive Force Measurements in Molten Lithium-Magnesium Alloys

Marie-Louise Saboungi* and Milton Blander

Chemical Engineering Division, Argonne National Laboratory, Argonne, Illinois 60439

In the development of high-energy lithium alloy/metal sulfide cells, investigations of lithium alloys as the active material in the negative electrode appear to be desirable. The aim of such investigations is to identify those lithium alloys that perform better than the Li-Al electrode presently used (1). The choice of an optimum alkali metal alloy electrode for new battery systems requires the availability of data on the thermodynamic behavior of a large number of systems. The paucity of such data led us to start measurements in order to fill this gap and to gain fundamental insights into the thermodynamic properties of alkali metal alloys.

We report here electromotive force measurements of molten lithium-magnesium alloys using the cell

Li (liq, in Feltmetal)	LiF-LiCl (eutectic) or LiCl-KCl (eutectic)	Li-Mg (liq)

The results of our measurements may be combined with data from the measured Li-Mg phase diagram (2) to calculate the thermodynamic properties of solid Li-Mg alloys at the solidus. Earlier, magnesium vapor pressure measurements over Li-Mg melts were made by Mashovets and Puchkov (3) at only five compositions. The concentration dependence of their deduced excess chemical potential is quite unusual; consequently, more detailed investigations appeared to be needed to check their conclusions.

Experimental

Materials.—Lithium metal (99.97% purity) was obtained from the Foote Mineral Company, Philadelphia, Pennsylvania, in the form of 1 lb ingots sealed in cans under an argon atmosphere. Bright metal pieces were melted and floating impurities were skimmed off at about 200°C under a purified helium atmosphere; part of the remainder was passed through a pinhole at the bottom of a heated tantalum vessel. Small drops (0.1-0.3g) of lithium were obtained and only those with the brightest surfaces were used in this study.

Magnesium metal (99.98% purity) was obtained from Brooks and Perkins, Livonia, Michigan, in the form of cylindrical rods. The oxide coating was removed by dipping the rods in a dilute solution of HCl.

Anhydrous purified LiCl-KCl eutectic mixture was supplied in 200g ampuls by the Anderson Physics Laboratory, Champaign, Illinois. The LiF-LiCl eutectic mixture was prepared by weighing the appropriate amounts of predried reagent grade solids [30 mole per cent (m/o) LiF and 70 m/o LiCl], placing them into a fused silica vessel and melting the mixture. Chlorine gas was passed through the molten eutectic, after which the excess chlorine was removed by bubbling helium through the melt.

Apparatus and procedure.—The experimental arrangement of a typical cell is indicated in Fig. 1. A porous beryllia crucible (high purity grade) from National Beryllia Corporation, North Bergen, New Jersey, contained the molten electrolyte in which was immersed the pure lithium anode. This crucible, which served as a barrier to separate the two electrodes, was 20 mm in diameter and 2.4 mm in thickness; its pore size was about 50 μm. The BeO cup was presoaked in the molten electrolyte to wet it so as to minimize possible chemical attack by molten lithium. Cairns *et al.* (4) noted that the purity and manner of preparation of beryllia have a strong influence on its resistance to attack by lithium.

The molten lithium-magnesium electrode (positive electrode) was contained in a 100 mm diameter tantalum crucible. The reference electrode consisted of porous stainless steel Feltmetal (Type 347 SS, approximate area 1 cm^2) soaked in pure lithium at 500°C. At this temperature, the lithium wets the metal with such tenacity that no loss of lithium due to dewetting occurs when the lithium reference electrode is submerged in the electrolyte. The porosity (the pore size is about 35 μm) of the Feltmetal from Brunswick Corporation, Milford, Connecticut, was quoted as approximately 80%. Tantalum leads were used to connect

* Electrochemical Society Active Member.

Key words: lithium, magnesium, alloys, activity, electromotive force, alkali-metals.

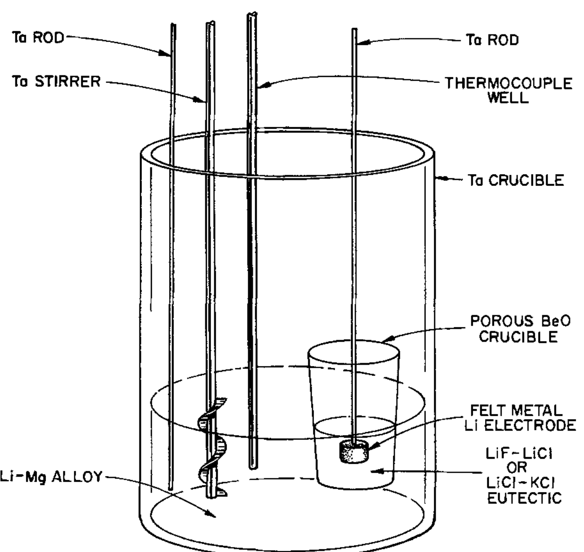

Fig. 1. Schematic of the cell

both electrodes to a digital voltmeter (Dana Model 5000, input resistance greater than 10^{10} ohms). The entire assembly was set in a furnace well which was attached to a helium-filled glove box; all operations were carried out completely inside the glove box. The procedure for purifying the helium is described elsewhere (5); the impurities in this atmosphere consisted of 0.1-0.5 ppm of water while oxygen was undetected (limit of detection 1 ppm).

The temperature was measured with a calibrated (Pt-Pt10%Rh) thermocouple protected by a tantalum well. For each run, the temperature was held constant within a three degree range. The composition of the alloy was kept homogeneous (and the temperature uniform) by vigorous stirring with a tantalum stirrer. Because of the small amount of the electrolyte, the salts in the BeO crucible were not stirred; no significant loss of lithium from the reference electrode was apparent. The emf of the cell with two pure lithium electrodes was measured first. The bias potential was always less than 0.2 mV and when checked remained constant for several hours. The composition of the melt in the tantalum crucible was then changed by adding successive weighed amounts of magnesium. The dissolution of the magnesium in the alloy was immediate, and the emf of the cell became stable (to within 0.2 mV) for as long as the composition and the temperature were held constant, often for hours and sometimes overnight. After temperature cycling, the emf generally returned to within 0.1 mV of the initial value.

The choice of electrolyte in collecting these data depended on the temperature of the cell. For temperatures lower than 773°K, the LiCl-KCl eutectic mixture (mp 625°K) was used. For temperatures greater than 773°K, the LiF-LiCl eutectic mixture (mp 774°K) was used in order to ensure the stability of the cell.[1]

The use of a large amount of alloy (40-50g of lithium) appears to be significant in minimizing the effects of self-discharge, *i.e.*, the transfer of lithium from the reference electrode to the alloy. Finally, it should be pointed out that at these temperatures, the solubility of metallic Li in the electrolytes is less than 1 m/o (8).

Results and Discussion

Compositions of molten alloys, emf data, and activities of lithium, at four temperatures, are given in

Table I. Emf results at four temperatures

Table I. The emf values, E, are corrected for the bias potential.

The activities of lithium, a_{Li}, in the alloys calculated from the relation

$$E = -\frac{RT}{\mathbf{F}} \ln a_{Li} \qquad [1]$$

(R is the gas constant, and $\mathbf{F}$ is the Faraday constant) are plotted in Fig. 2. In the molten alloys, deviations from ideality are small and negative. The activities of lithium in solid alloys at the solidus can be calculated by combining these results with the phase diagram. The data for the solidus are somewhat uncertain, which lends uncertainty to our values of the activities of Li in solid alloys. We chose for our calculations the phase diagram as given by Hultgren *et al.* (2) (Fig. 3). The ratio of the activities of lithium in the molten alloy (liquid lithium is the standard state) to the activity of lithium in the solid alloy (hypothetical solid lithium is the standard state) in equilibrium with the liquid is given by

$$\ln \frac{a_{Li}}{a'_{Li}} = \frac{\Delta H_f}{R} \left(\frac{1}{T_m} - \frac{1}{T} \right) \qquad [2]$$

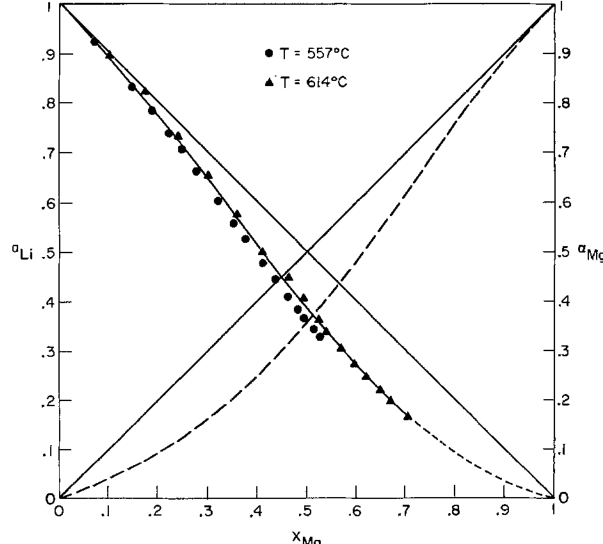

Fig. 2. Activities of Li and Mg in the Li-Mg system. ● a_{Li} measured at 557°C; ▲ a_{Li} measured at 614°C; — — — a_{Mg} calculated at 614°C.

[1] At temperatures greater than 773°K, it was observed experimentally by us and by others (1, 6) that the lithium metal reduces KCl to potassium metal, which condenses mainly on the cooler sections of the well and the electrode leads. This effect can be understood from simple thermodynamic considerations. The standard free energy of the reaction

$$Li + KCl(l) \rightleftharpoons K + LiCl(l)$$

is about 3 kcal mol^{-1} at 800°K according to JANAF Tables (7). Even at 723°K, the vapor pressure of potassium in this mixture is noticeable (about 1 Torr).

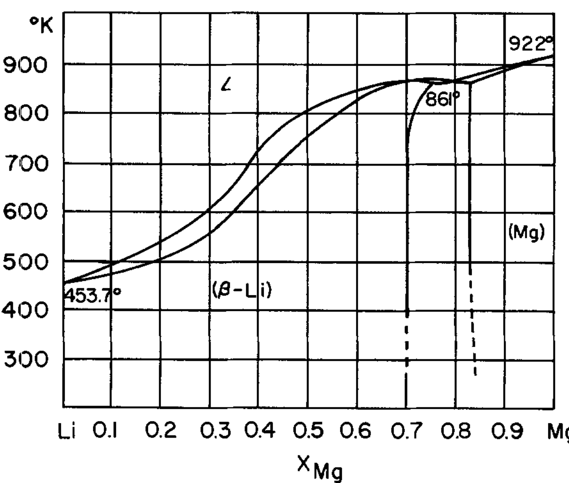

Fig. 3. Phase diagram of the Li-Mg system (2)

The prime denotes solid lithium as standard state, ΔH_f is the enthalpy of fusion of lithium (0.7171 kcal mol^{-1}), and T_m is the melting point of lithium (453.69°K) (7). The excess chemical potential of lithium in the molten alloys (μ_{Li}^{xs}) is

$$\mu_{Li}^{xs} = RT \ln \gamma_{Li} = -\mathbf{F}E - RT \ln X_{Li} \qquad [3]$$

where γ_{Li} is the activity coefficient and X_{Li} is the atom fraction of lithium. By assuming that μ_{Li}^{xs} is independent of temperature, the activities of lithium at the liquidus may then be calculated. Values of μ_{Li}^{xs} at 830° and 887°K differ somewhat. However, this small difference is about the size of the combined uncertainties; it is, therefore, reasonable to assume that μ_{Li}^{xs} is independent of temperature. The composition of the solid alloy in equilibrium with the liquid is given in column 2 of Table II. The values of the activities of solid and liquid lithium at the solidus and liquidus (2), respectively, at temperatures ranging from 500° to 870°K, are given in columns 3 and 4 of Table II.

As with the liquids, deviations from ideality at the solidus are relatively small and negative. At higher temperatures and lower atom fractions of lithium, activity coefficients of lithium in the solid alloy are lower than in the liquid. This is a necessary consequence of the reported maximum in the liquidus and solidus curves in the phase diagram (Fig. 3). At this maximum, we have $\gamma_{Li} > \gamma'_{Li}$ but $\gamma_{Mg} > \gamma'_{Mg}$ where the prime denotes the solid alloy. Thus, if the reported phase diagram is correct, the differences in activity coefficients (and activities) of each component in the liquid and solid have opposite signs at the maximum.

The data at 887°K (Table I) were utilized to calculate the activity coefficients of magnesium from the Gibbs-Duhem relation

$$\ln \gamma_1 = \frac{-X_2}{X_1} \ln \gamma_2(X_2) - \int_{X_1=1}^{X_1=X_1} \frac{\ln \gamma_2}{X_1^2} dX_1 \qquad [4]$$

where component 1 is Mg and component 2 is Li. Experimental values of ln γ_2 were fit by a least-squares method to an equation of the form $\ln \gamma_2 = A X_1^2 + B X_1^3 + C X_1^4$. The coefficients A, B, and C were then used to numerically calculate the integral in Eq. [4]. The calculated activities of magnesium for T = 887°K are plotted in Fig. 2. As with Li, the deviations from ideal solution behavior of Mg appear to be relatively small.

Table II. Estimated values of the activity of Li* in solid Li-Mg alloys at the solidus

T(K)	X'_{Li}	a'_{Li}	a_{Li}
500	0.80	0.80	0.87
600	0.65	0.54	0.66
700	0.56	0.40	0.53
800	0.44	0.28	0.40
850	0.36	0.18	0.27
870	0.30	0.12	0.17

* The concentrations, X'_{Li}, are atom fractions at the solidus. Activities in column 3 are relative to a hypothetical solid lithium as standard state and activities in column 4 are relative to liquid lithium.

Table III. Excess chemical potentials of magnesium and lithium (cal mol^{-1})

( ) Extrapolated.

Our calculations for the excess chemical potentials of Li and Mg at 887°K, given in columns 2 and 3 of Table III, respectively, differ considerably from those of Mashovets and Puchkov (2, 3) at 887°K given in columns 4 and 5 of Table III. The results of these experimenters were derived from magnesium vapor pressure measurements at only five concentrations, and no information was given on the reproducibility of their results. We believe that the large asymmetry and the unusual concentration dependence of the excess chemical potentials of Mashovets and Puchkov, as well as the small number of measurements, place their results in some doubt. The small deviations from ideality of our results at all concentrations are consistent with the small difference in electronegativities and the small difference in molar volumes between Li and Mg.

Acknowledgments

We would like to acknowledge the help of F. J. Martino and R. M. Yonco in preparing the lithium, and Dr. J. R. Selman for valuable discussions.

This work was performed under the auspices of the U.S. Energy Research and Development Administration.

Manuscript submitted May 22, 1975; revised manuscript received Aug. 15, 1975. This was Paper 36 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Argonne National Laboratory.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 121, No. 11 and 12; November and December 1974; and Vol. 122, No. 1, 2, 3, 4, and 5; January, February, March, April, and May 1975.

A Palladium Hydride pH Electrode for Use in Buffered Fluoride Etch Solutions

R. Jasinski (pp. 1579-1584, Vol. 121, No. 12)

J. V. Dobson, B. R. Chapman, and D. Start:[1] There is some ambiguity in the Jasinski paper concerning the effect of purging the electrolyte with air. The sentence "no distinguishable effect of purging with air" may mean to the uninformed that no difference was observed between bubbling (purging) or stirring the electrolyte. Alternatively, it may suggest that no effect was found with purging the electrolyte at all. The results shown in Fig. 1 from our own more extensive studies show that some significant "bubbling effect" is obtained with the palladium hydride electrode in addition to a stirring effect. Thus in Fig. 1 a change in cell emf is found for bubbling with nitrogen or air and also with stirring.

The use of a 20 mV criterion for determination of composition and lifetime of the electrode may result in errors of 2-3 days for some electrodes, *e.g.*, Fig. 3 in the paper under discussion. There are two ways of overcoming the difficulty in accurately determining the lifetimes (and composition) of palladium hydrogen electrodes of long lifetimes. First, the use of long lengths of very thin palladium wire supported on a former enables the relative resistance to be determined.[2] For long wires the desorption rate of hydrogen or lifetime is inversely proportional to the radius and is independent of the length.[3] Second, if large rods of wire are employed, the general Eq. [1] derived in an earlier paper[2]

$$T = \frac{0.766 \frac{dr}{dt} (t + S)a}{i_a} \qquad [1]$$

may be used to determine the lifetime and predict the charging conditions for an electrode. T and i_a are the charging time (hr) and current density (A/cm^{-2}); t, the lifetime in the $\alpha + \beta$ phase; S, the [H]/[Pd] α-max composition; and dr/dt the desorption rate (hr^{-1}). Further details are given in our paper.[3]

We find it difficult to understand why the pH of the electrolyte should have any effect at all on the lifetime let alone a trend to increase with increasing pH. The data in Table III in the paper under consideration show a decrease in lifetime above pH 3. An increase in lifetime by decreasing the surface area exposed to the electrolyte by sleeving, for example, has been shown dramatically in several recent papers.[4]

The minimum dependence of "stirring effect" on [H]/[Pd] (stated incorrectly throughout the paper as [Pd]/[H]) composition is only partly true from the given data. For example, Jasinski's Table IV suggests that there is an optimum composition of 0.49 at least for pH 8, though not pointed out in the paper. A decided optimum composition is clearly shown from the results of some of our studies which are shown in Fig. 2. We have converted and replotted the data obtained for the Jasinski paper. It is seen that for our system, a wire-wound coil of 0.025 in. (8-10 ohm) diameter wire whose electrical resistance was monitored, an optimum value would be $r = R/R_0 = 1.23$, while the Jasinski data would give a value of r around 1.48.

The profound discrepancy thus detected may be partly reconciled by Jasinski's uncontrolled arbitrary choice to make measurements of stirring effect after

10 min. We have found, Fig. 3, a considerable change or lowering in stirring effect with time after charge.

Finally, we get the impression from the discussion that there is a suggestion of a loss of a Pd H species from the electrode surface into the bulk electrolyte. It may be instructive to recall that Troost and Hautefeille[5] oversimplified the problem of structure by suggesting the formation of discrete Pd_2H. Later work[6] has made it clear that the $\alpha + \beta$-phase is a mixed phase system of variable H/Pd composition. It would appear, therefore, that a discrete Pd-H compound dissolving into the electrolyte would be contrary to the formation of a nonstoichiometric mixed phase system. Desorbed hydrogen on the electrode surface could of course be dissolving into the bulk electrolyte, thereby reducing the electrode composition.

R. Jasinski:[7] Constructive criticism is always appreciated, and I wish to apologize for any difficulty Dobson *et al.* have had in understanding my paper. The point of my work, as stated in the introduction, was to develop a practical *p*H electrode which was usable in a corrosive, commercially important silica etchant. This was done by maximizing the content of palladium hydride in the electrode structure and by minimizing the rate at which it was lost to the surroundings.

Now to the specific criticisms. On the "ambiguity ... concerning the effect of purging ...," the complete sentence in the Experimental Section reads: "There was no distinguishable effect of purging the test solutions with air *vs.* stirring in an open beaker after first saturating with air." This still seems to me to be a relatively unambiguous description of the general electrode behavior that I observed under the experimental conditions I described. It is possible to devise a situation where stirring will be less effective than bubbling in maintaining the bulk dissolved air concentration at the electrode surface. Also, if bubbles of air are delivered to the electrode surface to increase the availability of oxygen "depolarizer" at the surface, greater shifts in potential will be observed. Such potential shifts would also be particularly large if the hydride concentration of the electrode were particularly low, as with Dobson's wires.

Next, I stated in my paper, that the 20 mV criterion used to define electrode life was indeed arbitrary, but was nevertheless adequate for comparing electrode lifetimes of minutes with electrode lifetimes of days. Dobson *et al.* are perfectly entitled to desire a more rigorous criterion for electrode life. Thin wires do not give long electrode lifetimes (days) as I have shown. Accurate measurements of electrical resistance for large rods of metal are difficult, and would indicate an average hydride concentration, at best, rather than the operative surface concentration. I did find it difficult to correlate my data published in 1974 with Dobson's equations published in 1975 (Dobson's Eq. [1] and Ftn[3]). It is instructive to note, however, that our two correlation equations are of the same sense, *i.e.*, the electrode life in the $\alpha + \beta$ phase (*a*) is proportional to the total charge put into the electrode (in the $\alpha + \beta$ phase), minus that left in the α-phase, and (*b*) is inversely proportional to a desorption rate (dr/dt). I have, in effect, attempted to establish a proportionality between this desorption rate of Dobson and the surface area of the electrode exposed to the solution. Some proportionality is to be expected since one mechanism for the loss of palladium hydride phase is chemical reaction with dissolved oxygen.

One possible "why" for the *p*H effect is postulated (not proved) at the end of the paper and so labeled: "that this process is the acid catalyzed recombination of palladium hydride to yield H_2." The possibility of different oxygen solubilities according to electrolyte is also raised in the final paragraph of the paper.

The use of the "sleeve" in the work of Dobson, Dagless, and Thirsk, was to retard the rate of absorption of H_2 by palladium once sufficient hydride has been formed to generate the potential of the palladium $\alpha + \beta$ phase. Indeed this technique is analogous to the reverse situation described in my paper that of increasing the life of the electrochemically formed $\alpha + \beta$ phase, in the absence of H_2, by restricting the surface area of the palladium electrode presented to the solution for reaction. Unfortunately I did not have the reference at the time of preparing my paper.

I do stand corrected on the use of {Pd}/{H}, rather than {H}/{Pd}.

Considering the complicated chemistry and poorly defined mass transport conditions in the solution and in the palladium phase during these stirring experiments, I fail to appreciate the profound significance based on such results of an enhanced stability for an intermediate {H}/{Pd} composition.

The time of stirring in my paper was 1 min, not 10 min. The stability of potentials with the palladium rods was such that little change in potential was noted after longer periods of time. The data presented in the paper unambiguously demonstrated the point (Table IV in the paper under discussion) stated clearly as "stirring dependence is dependent upon PdH content of the electrode." Such a dependence is entirely reasonable in view of reaction between PdH at the electrode surface with dissolved oxygen, followed by diffusion of hydride from the bulk of the electrode to the surface to replace the hydride removed. A low PdH content in the electrode must yield a low diffusion gradient and hence a low rate of transport of hydride from the bulk to the surface. As indicated in the references quoted in my paper, this diffusion coefficient is also about an order of magnitude slower in palladium than for ions in solution.

Finally I must apologize for giving Dobson *et al.* the impression that I have suggested the dissolution of Pd or PdH species from the electrode into the electrolyte. This was not my intent and is not stated. The work of Troost and Hautefeille (Dobson Ftn[5]) was published in 1874 not in 1974; Ftn[6b] is page 1229 not page 1220.

I do wish to thank Dobson *et al.* for their interest in my paper.

Supersaturated Zincate Solutions

W. Van Doorne and T. P. Dirkse, pp. 1-4, Vol. 122, No. 1)

A. G. Briggs, N. A. Hampson, and A. Marshall:[8] We wish to point out in connection with the above-mentioned paper that the constitutions of the supersaturated potassium zincate solutions are dependent upon

[8] Department of Chemistry, University of Technology, Loughborough, LE11 3TU, England.

the time which has elapsed between the preparation of the saturated solution and the structure determination.[9] This point appears to have been omitted from a number of past investigations in this area. However, we have recently been able to show that some of the anomalies observed from time to time have a satisfactory explanation when the above time dependence is taken into account.[10]

The Effect of Solvent on the Electrochemistry of Iron

A. L. Bacarella and A. L. Sutton (pp. 11-18, Vol. 122, No. 1)

K. Schwabe:[11] It is well known that the acidity of inorganic acids measured by the thermodynamic values ptH or pwH increases strongly with respect to the solutions in water of equal concentration at high contents of organic solvents especially ethanol.[12] Therefore it is not surprising that Bacarella and Sutton receive an increasing corrosion current of iron at constant concentration of H_2SO_4 with rising content of ethanol. The dependence of the potential of the iron electrode on the ethanol content can also be explained by the increasing acidity. But it is quite impossible to found an absolute acidity scale on these measurements and to define the absolute acidity as proposed by the authors.

This definition is based on the assumption of Grunwald *et al.*[13] who postulated the same medium effect for similar solutes (degenerate coefficient). As proved by Wynne-Jones[14] this postulate is not right. Surely it cannot be used for H_2SO_4, and therefore the degenerate coefficients, calculated by Bacarella and Sutton for ethanol and mixtures of ethanol-water are not correct. That means that the "diffusion potential $E_L{}^S$ cannot be calculated with the help of these coefficients. The cell used by Bacarella and Sutton gives no possibility to estimate the diffusion and phase boundary potentials. But it is quite improbable[15] that they are 0 mV with $0.5M$ H_2SO_4 in water, and 140 mV in ethanol as shown in Fig. 1 of the paper being discussed. So the proposal of Bacarella and Sutton cannot be accepted as a new absolute measure for acidity.

A. L. Bacarella and A. L. Sutton:[16] In our publication, we have shown that using the junction potentials $E_L{}^S$ estimated by Gutbezahl and Grunwald,[17] a very satisfactory interpretation of the iron dissolution and hydrogen evolution reactions on zone-refined iron in hydrogen saturated acidic ethanol-water media was obtained. It was also shown that by using the junction potentials provided by Popovych and Dill,[18] a satisfactory fit to the data was not obtained.

Schwabe suggests that the junction potentials in EtOH-HOH solvents are not larger than those between similar electrolytes in water. We interpret this to mean that the junction potentials are therefore small for all EtOH-HOH solvents, and can be neglected. Again, with such an assumption a satisfactory interpretation of the experimental data cannot be made.

It was also stated that it is not surprising that the corrosion current of iron at constant H_2SO_4 concentration increased with increasing ethanol content of the solvent. Unfortunately, our observation was that the corrosion current decreased with increasing ethanol content, as shown in Fig. 2 and 3 of our paper. Also, Fig. 7 shows a very satisfactory fit to the data for the corrosion current, log $i^s{}_{(corr)}$ (corrected for coverage), as a function of *p*A. Here, the *p*A of the solution was determined from the potential of the Pt/H_2 electrode, and using the junction potentials provided by Gutbezahl and Grunwald.[17]

It is also stated that Wynne-Jones[14] has proved that the basic assumption (the activity postulate) upon which the estimation of the junction potentials is made is not right. This is, of course, not so and suggests that the "activity postulate"[19] is not understood. Indeed, if such ratios of the acid dissociation constants of the anilinium, toluidinium, and ammonium salts are made with respect to anilinium as the reference acid, it is observed that the curves are not necessarily parallel; some increase, some decrease, and some remain essentially unchanged with increasing ethanol content of the solvent. For these acids, however, a quantitative correlation of the dissociation constants was made using the activity postulate.

Light-Deflection Errors in the Interferometry of Electrochemical Mass Transfer Boundary Layers

F. R. McLarnon, R. H. Muller, and C. W. Tobias (pp. 59-64, Vol. 122, No. 1)

T. Z. Fahidy:[20] In computing light-deflection errors, the authors postulate for basis the convection-free diffusion equation

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} \quad [1]$$

in the boundary layer of a "convectionless" metal deposition cell in electrolysis. Much evidence has been shown lately[21] for the existence of local convective currents in such cells using parallel plane electrodes and one wonders if Eq. [1] has as wide an applicability as inferred from the paper. It appears that if local Peclet numbers are large and convective "loci" are numerous, the more realistic, but still unrigorous, mass balance

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} + v_y\frac{\partial c}{\partial y} \quad [2]$$

would have to be taken as basis for the analysis of errors. The solution to Eq. [2], employing an arbitrary velocity profile $v_y = P(y) = \sum_{k=1}^{N} a_k y^k$ of polynomial form is $c = c_1 + c_2$, where c_1 is the well-known error function solution to Eq. [1] (Eq. [6] in the authors' paper) and c_2 is computed as

$$c_2/c_b = \sum_{k=0}^{N} D^{k-1/2} P^{(2k)}(y) \frac{t^{k+1/2}}{\Gamma(k+3/2)} - \frac{y}{2\pi^{1/2}} \sum_{k=1}^{N} D^{k-1} a_{2k}(2k)! \int_0^t \frac{(t-u)^{k+1/2}}{\Gamma(k+3/2)} \times \frac{1}{u^{3/2}} \exp\left(-\frac{y^2}{4Du}\right) du \quad [3]$$

for times less than the so-called transition time in the theory of unsteady-state convective diffusion. Thus, the authors' analysis seems to apply only to very short times and at very low current densities, *i.e.*, when the condition for the thickness of the boundary layer

$$\delta P(\delta) << D \qquad [4]$$

is satisfied. Do interferometric studies of electrochemical mass transfer boundary layers really satisfy this criterion? It seems logical that one should know, at least approximately, the velocity field in the boundary layer and if it is assumed *a priori* to be zero, a firm base for the analysis of deflection errors will be missing.

F. R. McLarnon,[22] R. H. Muller,[23] and C. W. Tobias:[24] It is well known that, in the absence of forced convection, transport of an ionic species which is consumed at a horizontal electrode facing downward is only by diffusion and migration, because the density gradient established by the electrode reaction is stable. The role of free convection in ionic mass transport with other electrode configurations has already been described and analyzed by the authors 20 years ago. Free convection velocity and concentration fields have been measured by dark field photography and interferometry,[25] and limiting current studies on the same models[26-28] have confirmed the interpretation of optical data.

As stated in the paper under discussion, "Diffusion boundary layers free of convection effects offer a useful model for optical investigation since the concentration profiles are easily derived and experimental results can serve to test the optical calculations." In no way has it been suggested that optical corrections derived for concentration profiles in the absence of convection could serve to accurately predict concentration fields in the presence of various velocity boundary layers.

Clearly, if we had assumed any particular velocity profile, the validity of the computed light deflection errors would be just as restricted as those for the chosen profile. The concentration field in the pure diffusion model in fact can be predicted on theoretical grounds with higher accuracy, and less ambiguity than in the case of forced or free convection. We have reported elsewhere on the excellent agreement between theoretical concentration fields in unsteady-state diffusion and those obtained from corrected interferograms.[29]

Details of the computer-implemented numerical solution of the equations involved in the correction procedure for an arbitrary concentration profile have been published in a journal devoted to physical optics.[30] These calculations showed that the errors incurred are not very sensitive to the exact shape of the entire concentration profile, but depend strongly on the inner regions of the boundary layer, where the concentration changes are large. Therefore, the error estimates derived for the convection-free profiles are useful for obtaining good first estimates of corrections in the presence of flow as well. Results of analysis of interferograms in the presence of flow, performed in this laboratory, are to be published in the near future.

Unified Approach to Cell EMF Calculations

D. Gray (pp. 75-76, Vol. 122, No. 1)

C. P. Keszthelyi:[31] In the paper under discussion, the author provides an important service to the scientific community in general, and electrochemistry (and analytical chemistry) in particular, by pointing out an error in Laitinen's well known text.[32] This is made all the more urgent by the latest edition of the book,[33] which not only leaves the error uncorrected, but further degrades the treatment by using cell potentials given to only two decimal places, whereas the previous edition gave three decimals. It is nevertheless an unwarranted conclusion to suggest that a correct unified approach to cell EMF calculations is something we are lacking at present. What we are faced with is a correct ("unified") approach augmented by some errors published—errors which clearly contradict the correct method.

We are in disagreement with a comment in the paper under discussion, that "Laitinen's is the only major textbook which discusses the problem at length;" perhaps "length" is a subjective term, but we cite the following from three major texts to document that the correct approach is available in published works.

In Ref. (2) given by the paper under discussion,[34] we find the following:

> However, in addition or subtraction of two half-reactions to give a third half-reaction, the free energies, *i.e.*, volt equivalents of the two half-reactions, must be added or subtracted to give the free energies of the third half-reactions.
>
> Example
>
> | | $E°$ | volt equivalents |
> |---|---|---|
> | $Cl^- + 3H_2O = ClO_3^- + 6H^+ + 6e^-$ | -1.45 | -8.70 |
> | $Cl^- = \frac{1}{2}Cl_2 + e^-$ | -1.36 | -1.36 |
> | $\frac{1}{2}Cl_2 + 3H_2O = ClO_3^- + 6H^+ + 5e^-$ | -1.47 | -7.34 |
>
> Thus the volt equivalents for the new half-reaction are -7.34, and since there are 5 electrons for this reaction $E°$ is $-7.34/5$, or -1.47.

In a major text dealing with quantitative chemical analysis[35] we find:

> By application of certain thermodynamic concepts it can be shown that for a redox couple
>
> $$RT \ln K = n\mathbf{F}E°_{cell} = -\Delta G°$$
>
> where $G°$ is the standard free energy change, and the other symbols represent the usual terms in the Nernst equation. By the IUPAC conventions, $E°$ assumes that the given half-cell is the right-hand electrode in a cell having the standard hydrogen electrode on the left; therefore, $E°_{cell}$ is numerically equal to $E°$ associated with the half-reaction in question. Half-reactions may be combined, by addition or subtraction, and the $E°$ of the resulting half-reaction can be calculated by adding or subtracting the free energy changes ($n\mathbf{F}E°$) associated with the half-reactions. Because **F**, the Faraday number, is common to all the free energy changes, the calculations are simplified by the use of $nE°$, the dimensions of which are electron volts.

This paragraph is augmented by two examples which we do not reproduce here to conserve paper.

In a major freshman textbook,[36] the authors unmistakably stir their students in the correct direction:

[31] Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803.
[32] H. A. Laitinen, "Chemical Analysis," p. 286, McGraw-Hill Book Co., New York (1960).
[33] H. A. Laitinen and W. E. Harris, "Chemical Analysis: An Advanced Text and Reference," 2nd ed., p. 224, McGraw-Hill Book Co., New York (1975).
[34] W. M. Latimer, "Oxidation Potentials," 2nd ed., pp. 4-5, Prentice-Hall Inc., Englewood Cliffs, N.J. (1952).
[35] G. H. Ayres, "Quantitative Chemical Analysis," 2nd ed., p. 385, Harper and Row, New York (1968).
[36] W. L. Masterton and E. J. Slowinski, "Chemical Principles," p. 594, W. B. Saunders Co., Philadelphia (1973).

°21.43 Consider the half-reactions

$$\begin{array}{ll} M(s) \rightarrow M^{a+}(aq) + ae^- & E^\circ_1 \\ M^{a+}(aq) \rightarrow M^{b+}(aq) + (b-a)e^- & E^\circ_2 \\ \hline M(s) \rightarrow M^{b+}(aq) + be^- & E^\circ_3 \end{array}$$

a. Write expressions for ΔG° for each of the three half-reactions in terms of E°.
b. Knowing that $\Delta G^\circ_3 = \Delta G^\circ_1 + \Delta G^\circ_2$, derive a relationship that would enable you to calculate E°_3 given E°_1 and E°_2.
c. Use the relationship in (b) to obtain E° for the half-reactions below, using Table 21.1.

$$Fe(s) \rightarrow Fe^{3+}(aq) + 3e^-$$
$$Sn(s) \rightarrow Sn^{4+}(aq) + 4e^-$$

All it takes at this stage is a competent freshman instructor to assure that any encounter by the student with erroneous suggestions[32,33] in later years will be identified by him as such.

We have no intention to belittle the contribution made by the paper under discussion by the above comments; it is indeed cause for concern[37] when a new breed of Ph.D. analytical chemist is surfacing who is aware of the merits of interfacing, automation, computerization, and analog to digital conversion, but is alien to basic freshman-sophomore chemistry.

D. Gray:[38] I did not mean to imply that my development of forming new half-cells from other half-cells is in any way original and it was an oversight on my part not to reference it properly with at least one of the numerous appropriate sources. As I noted in the paper under discussion: "For completeness, the method of combining half-cell reactions to form a new half-cell reaction will be included in the discussion." This trivial case was only inserted in the paper under discussion to avoid any possible confusion of it with the (incorrect) method of combining half-cell reactions to form new cell (not half-cell) reactions. Keszthelyi has apparently confused the two cases and as a consequence he has misunderstood the purpose and the point of the paper under discussion.

Unified Approach to Cell EMF Calculations

D. Gray (pp. 75-76, Vol. 122, No. 1)

R. Parsons:[39] The argument of this article is incorrect because of an erroneous identification of n_{cell} which is, in fact, always equal to n_r n_{ox} (using the notation of the paper under discussion). If n_{cell} were correctly defined as "the number of electrons sent round the external circuit in the completion of unit cell reaction in the form written," then the error should become clear. In fact the definition of n_{cell} given by Gray (the net cell electron change) is vague and misleading.

The standard emf's of the three copper cells used as examples should be as follows:

1. Cu, Pt|Cu^{2+}, Cu^+ ⋮⋮ Cu^{2+}|Cu $E^\circ_1 = 0.184V$
2. Cu, Pt|Cu^{2+}, Cu^+ ⋮⋮ Cu^+|Cu $E^\circ_2 = 0.368V$
3. Cu|Cu^{2+} ⋮⋮ Cu^+|Cu $E^\circ_3 = 0.184V$

and although the cell reaction in each case is

$$2Cu^+ = Cu + Cu^{2+}$$

the completion of this reaction in cells 1 and 3 involves the passage of two electrons round the external circuit, whereas in cell 2 it involves the passage of one electron round the external circuit. Thus the standard free energy change in the disproportionation reaction is -35.5 kJ mole^{-1} whichever way it is calculated from these data.

Thus Eq. [1] is correct and leads to no anomaly, if it is correctly applied. In contrast, the article by Gray would lead to the result that the standard emf's of the three cells 1, 2, and 3 were all 0.368V which would be contrary to experiment.

D. Gray:[38] The primary difficulty here is not what is n_{cell}, but rather what is the thermodynamic nature of E(rev). It is generally conceded, when explaining the different possible cell potentials calculated for the same disproportionation cell reaction involving different half-cell combinations, that E° is not a state (or thermodynamic) function.[40] This is, of course, incorrect. E(rev) is a thermodynamic function which can be simply shown by letting $E(\text{rev}) = f(T, P)$, assuming ideality, and evaluating the second derivatives.

$$\left[\frac{\delta}{\delta P}\left(\frac{\delta E}{\delta T}\right)_P\right]_T = \frac{1}{nF}\left(\frac{\delta \Delta S}{\delta P}\right)_T = -\frac{1}{nF}\left(\frac{\delta \Delta V}{\delta T}\right)_P$$

$$\left[\frac{\delta}{\delta T}\left(\frac{\delta E}{\delta P}\right)_T\right]_P = \frac{\delta}{\delta T}\left(-\frac{\Delta V}{nF}\right)_P = -\frac{1}{nF}\left(\frac{\delta \Delta V}{\delta T}\right)_P$$

Since the second derivatives are equivalent, E(rev) is shown to be a thermodynamic function. One should note that a similar thermodynamic treatment for E(irrev) does not yield equivalent second derivatives (due to the overvoltage) and it is not a thermodynamic function.

Since E(rev) is a thermodynamic function, it is path independent and must yield the same value for a cell reaction regardless of the manner of half-cell construction. Calculating E_{cell}(rev) by assuming that in all cases $n_{cell} = n_{ox}n_r$ leads to nonunique E_{cell} values in certain disproportionation reactions, *i.e.*, Cu^+. In order to maintain the necessary uniqueness of E_{cell}(rev) it is necessary that $n_{cell} \neq n_{ox}n_r$ in these particular disproportionation reactions. This is why I defined n_{cell} in the paper under discussion as "the net cell electron change" which can be easily determined by inspection of the over-all balanced cell reaction, and not as Parsons has done as "the number of electrons sent round the external circuit in the completion of unit cell reaction in the form written." It is intriguing to note that in the paper under discussion a mathematical impasse is reached in these same disproportionation systems (cases II and III) of interest and one cannot show mathematically how n_{cell} is related much less equal to $n_{ox}n_r$.

By evaluating n_{cell} from the over-all cell reaction, one is essentially equating n_{cell} to the "number of equivalents of electricity flowing per mole of reaction as written."[41] This may be a better and less ambiguous way to define n_{cell}. The significant point here is that regardless how n_{cell} is defined, it cannot in general be determined from the contrived half-cell reactions. A trivial consequence of this is that n_{cell} is uniquely defined for a cell reaction.

The Free Energy of Formation of Iridium Oxide by Solid Electrolyte Galvanic Cell

E. S. Ramakrishnan, O. M. Sreedharan, and M. S. Chandrasekharaiah (pp. 328-331, Vol. 122, No. 3)

H. Kleykamp:[42] Ramakrishnan *et al.* have criticized and called into question the results of our paper "Gibbs Energy of Formation of Iridium Dioxide."[43] The objections are baseless. It has escaped their attention that we have used zirconia as the electrolyte and a closed cell arrangement instead of thoria and an open cell as Ramakrishnan *et al.* imputed. Further, we applied both

[43] H. Kleykamp and L. J. Paneth, *J. Inorg. Nucl. Chem.*, 35, 477 (1973).

Fe, FeO and Ni, NiO as reference electrodes and $ZrO_2 \cdot Y_2O_3$ and $ZrO_2 \cdot CaO$ as the electrolyte as we have discussed in quoted previous investigations. No differences resulted in the Gibbs energy values. Ramakrishnan *et al.* cited our experimentally determined Gibbs energy of formation in Eq. [21] of their paper to be

$$\Delta G_f^\circ \langle IrO_2 \rangle = (-61.66 \pm 0.741) + (43.26 \pm 0.956)\, F \times 10^{-3}\, T \text{ kcal/mole}$$

in comparison to their own value to be

$$\Delta G_f^\circ \langle IrO_2 \rangle = -56.76 + 40.41 \times 10^{-3} T \text{ kcal/mole}$$

The presupposed disagreement should not be a pretense for their redetermination of this system. A mistake might have been committed by the authors in copying our results which are given correctly as

$$\Delta G_f^\circ \langle IrO_2 \rangle = -59.42 + 43.26 \times 10^{-3} T \text{ kcal/mole}$$

between 900° and 1200°K (1 cal = 4.184 J). Consequently, their work should be regarded as a confirmation of our results and lays no claim to a higher reliability.

Two objections should be made regarding the validity of their data: (i) the cells mentioned in Eq. [7] and [14] of the paper under discussion are not symmetric. The conducting leads on the right and the left hand sides of the cells consist of Pt/Ir and Pt, respectively, which results in an additional thermal emf and (ii) it might be possible that the system has not attained equilibrium below 1000°K, but this could have been checked easily by polarizing the cells.

E. S. Ramakrishnan, O. M. Sreedharan, and M. S. Chandrasekharaiah:[44] We regret the inadvertent arithmetical error in converting the $\Delta G^\circ \langle IrO_2, f \rangle$ expression of Kleykamp and Paneth.[43] Our Eq. [21] should read

$$^{f}\Delta G_T^\circ (IrO_2)/\text{kcal mole}^{-1} = (-59.42 \pm 0.741) + (43.26 \pm 0.956)\,T \quad [1]$$

Our contention that if the oxygen potential difference between the reference electrode and the electrode of interest is very large (as it was the case with the measurement of Kleykamp and Paneth who have employed Fe, FeO_x reference resulting in the emf of 800-870 mV), the oxygen permeation rates through the electrolyte increases resulting in a possible systematic error in the measured emf. This point has been reiterated recently by Giddings and Gorden.[45] This effect is less in the case of biphase mixture than in case of single phase. Nevertheless it is there. Therefore in the paper under discussion we have employed Cu, Cu_2O and Ni, NiO as the references.

That there exists a higher systematic error in the reported $^{f}\Delta G^\circ$ for IrO_2 by Kleykamp and Paneth compared to our data will become obvious when one compares the third law enthalpy of formation values calculated using the same free energy functions. Kleykamp and Paneth's Table IV[43] presents an estimated change in free energy function, $T\Phi^\circ$ for the reaction

$$Ir(s) + O_2(g) = IrO_2(s) \quad [2]$$

at various temperatures. $^{f}\Delta H^\circ_{298}$ calculated from their $^{f}\Delta G^\circ$ data shows a systematic increase from −241.9 kcal mole^{-1} at 900°K to −236.3 kcal mole^{-1} at 1200°K. They have attributed this variation entirely to the uncertainties in the estimated specific heat of IrO_2. We have recalculated the $^{f}\Delta H^\circ_{298}$ of IrO_2 employing their estimated $T\Phi^\circ$ and our $^{f}\Delta G^\circ$ data and it is shown in Table I.

As can be seen, the spread is from −241.4 kcal mole^{-1} at 900°K to −239.1° at 1200°K, a maximum variation of 2.3 kcal mole^{-1} compared to their 5.6 kcal mole^{-1}. Since the same $T\Phi^\circ$ values are used in both cases, this disagreement cannot be due to the errors of the estimated heat capacity alone but also due to much smaller systematic errors in our measurements. This variation in the calculated $^{f}\Delta H^\circ_{298}$ would be smaller in our case if we had limited our evaluation to the temperature range 950°-1170°K to which our expression for $^{f}\Delta G^\circ(IrO_2)$ (our abstract) was considered valid. Thus, our conclusion in the paper under discussion that the results of our work for the $^{f}\Delta G^\circ$ (IrO_2) is more reliable stands to reason.

Table I. $^{f}\Delta H^\circ$ (IrO_2, 298°K) calculated from the third law

T/°K	$T\phi^\circ$/ kj mole^{-1} [43]	$-^{f}\Delta G^\circ$/ kj mole^{-1} [43]	$-^{f}\Delta H^\circ_{298}$/ kj mole^{-1} [43]	$-^{f}\Delta G^\circ$/ kj mole^{-1}	$-^{f}\Delta H^\circ_{298}$/ kj mole^{-1}
900	156.1	85.8	241.9	85.3_2	241.4_2
1000	172.6	67.4	240.0	68.4_1	240.9_7
1100	188.8	49.5	238.3	51.5_0	240.2_8
1200	204.5	31.8	236.3	34.5_9	239.1_3

In view of the above-mentioned reasons, we take strong objection to Kleykamp's statement, "The presupposed disagreement should not be a pretense for their redetermination of this system." Besides, when we began our galvanic cell investigations in 1972,[46] there was no other galvanic cell results available in the literature for IrO_2 and hence the question of redetermination did not arise.

In their communication,[43] Kleykamp and Paneth describe only their experiments employing Fe, wustite electrode, and yttria-zirconia electrolyte cup in which the sample was sealed. No results obtained with Ni, NiO as the reference with Ir, IrO_2 system are given as claimed in the above comments while we have measured the IrO_2 system with two separate reference electrodes. Hence it is not at all clear what they mean by the statement, "No differences resulted in the Gibbs energy values." In their measurements, the sample was sealed inside the electrolyte cup with glass. There is a possibility that the sealing glass can act as the path for the oxygen permeation between the reference electrode outside and the system sealed inside. Giddings and Gordon[45] have discussed this mechanism at length. This may also add to the systematic error.

In cells [7] and [14] of our paper, there is no asymmetry of the kind indicated by Kleykamp. In both cases, the lead wires were Pt wires on both sides. Only an iridium foil was interposed between Ni and Pt (as also between Cu and Pt) so as to minimize the thermal effects. To check this, the positions of the reference and the Ir, IrO_2 electrode pellets were interchanged and the emf measured did not show any appreciable (<0.1 mV) variation indicating insignificant contributions from the thermal emf.

Their other objection that our measurements below 1000°K were nonequilibrium ones is also incorrect. As described in our experimental procedure, we did subject the emf readings to micropolarizations even for those below 1000°K readings. The time independent emf at any one temperature setting was reproducible within ±0.5 mV. But the scatter from the results of one temperature cycle to another was larger than this. As described in our paper, the change in the slope of emf *vs.* temperature was observed with both references and hence we felt it as real and not due to not attaining equilibrium.

Thus the difference in the results of the two measurements are real and we have to refute the claim made by Kleykamp that our work boils down to nothing but the confirmation of their results and lays no claim to a higher reliability. The results we have reported have much smaller systematic errors and hence are more reliable.

Structural Transformations of the PbO_2 Active Material during Cycling

A. C. Simon, S. M. Caulder, and J. T. Stemmle

(pp. 461-466, Vol. 122, No. 4)

B. Burrows and H. Giess:[47] It was observed by the authors of the paper under discussion that, after formation, PbO_2 had a uniform tightly packed structure which was transformed during cycling into a coralloid structure characterized by large voids and a dense network of PbO_2. It is claimed that this coralloid structure should be ideal for a porous electrode since the dense convolutions of the coralloid structure should provide maximum strength and electrical conductivity and the surfaces of these convolutions should present an enormous surface area while the large voids should enable a free flow of electrolyte. With cycling, however, the capacity of positives in the lead-acid battery decreases rather than increases. To account for this contrary trend three explanations were offered.

The first explanation is in terms of the structure of the $PbSO_4$ formed during discharge. With increase in cycle number it was observed that the $PbSO_4$ deposits in a progressively more closely packed and dense layer on the surface of the dense PbO_2 network thereby passivating the PbO_2. This is not surprising and simply shows that the coralloid structure is, contrary to the authors' claims, not ideal for a porous positive electrode.

The second explanation offered is that the coralloid structure itself is the cause of capacity loss which contradicts the claim that the coralloid structure is ideal.

The third proposed explanation is that an increase in the proportion of "inactive" PbO_2 causes the capacity loss. The existence of this "inactive" PbO_2 has not, however, been unequivocally established. Rather the existence of an electrochemically inert form of PbO_2 in the active mass has been inferred from the authors' NMR[48] and DTA[49] measurements and, even if one admits the existence of "inactive" PbO_2, it has not yet been demonstrated that its concentration can be quantified (either absolutely or relatively) and related to cycle number of a positive electrode.

The observations and conclusions of Simon *et al.*, which we have briefly summarized and commented upon above, indicate the difficulties of interpreting optical and scanning electron micrographs. This is particularly so when one is attempting to understand the nature of the complex changes taking place in a porous battery plate which is subjected to periodical transformations during charge and discharge of the electrodes. Therefore, it is extremely important that any conjectures arising from the examination of micrographs be corroborated with quantitative physical measurements.

In some of our own work, which we have not yet been able to publish, we have systematically investigated the influence of deep cycling on the structure of PbO_2 active mass. Apart from optical and scanning electron microscope observations we have used x-ray diffraction analysis, BET surface area measurements, and porosity and pore size distribution measurements in order to monitor the structural changes during cycling of the active material.

Our measurements show that the BET surface area characteristically decreases from values of ~ 8 m^2 g^{-1} after formation to values of ~ 2 m^2 g^{-1} after 130 cycles. Accompanying this considerable decrease in surface area we have observed small decreases in total porosity and a marked change in the pore size distribution with large pores becoming predominant with increase in cycle number. These quantitative trends were also qualitatively evident in the optical and SEM micrographs and we have observed active mass structures similar to those reported by the authors.

Also if one examines the coralloid structure with a higher magnification than that used in the paper under discussion one can clearly see a crystalline structure. Our own x-ray diffraction work and that of others[50-52] also provides evidence that PbO_2 is recrystallized during cycling. It is this recrystallization and densification accompanied by a decrease in surface area and an increase in the proportion of large pores which we think is the likely explanation for the gradual loss in capacity of positives with deep cycling. In other words the coralloid structure is definitely not an ideal morphology if one is to avoid loss of capacity in positives.

A. C. Simon, S. M. Caulder, and J. T. Stemmle:[53] The remarks by Burrows and Giess in general appear to confirm our observations concerning the changes that take place in the positive active material during cycling. Although we have, unfortunately, no means of judging their work, since it remains unpublished, we can assume from their remarks that they have observed a decrease in surface area, a marked change in pore size toward much larger pores, and also have obtained optical and SEM micrographs of the same structures as we observed and described.

They are not the first to confirm our observations. Mention should be made of the excellent work of Dr. S. Hattori, Dr. M. Yamaura, and their associates at Yuasa Battery Company, Limited in Japan. These investigators have done considerable work in this area of investigation that has not yet appeared in a journal publication although progress reports can be obtained from the International Lead Zinc Research Organization (ILZRO) by reference to project LE-197.

Burrows and Giess are in error in stating that we claimed the coralloid structure to be ideal. The statement made by us was that on the basis of theoretical considerations the structure would appear to be ideal for a porous electrode, but we then went on to state that our experience had demonstrated that it was not.

We suggested three possibilities as reasons why this structure was not as ideal as appearances suggested it should be. The first was that, in the presence of such a structure, the $PbSO_4$, upon repeated cycling, appeared to form a progressively more closely packed and dense layer on the surface of the coralloid structure that effectively passivated the surface before all of the PbO_2 could react. In view of the fact that this was offered as a reason why the coralloid structure was not ideal, the remark by Burrows and Giess are irrelevant. It is not irrelevant, however, that further study since publication of the paper under discussion has led us to the belief that this explanation is incorrect and a passivation by the $PbSO_4$ occurs no more readily with the coralloid microstructure than with any other.

The remarks by Burrows and Giess regarding our suggested second reason why the coralloid structure is not ideal are as irrelevant as those regarding our first statement, and for the same reason, that we have not claimed the coralloid structure is ideal. However the observations made by us regarding the presence of a hard dense core in each coralloid branch are correct and the observation by Burrows and Giess that there is a considerable decrease in surface area following cycling would seem to confirm it. Since they do not give details of their cycling procedure we cannot correlate this decrease exactly with the onset of the growth of the coralloid structure but a correlation certainly seems likely.

As to the remarks by Burrows and Giess concerning inactive positive active material, we consider that we have conclusive evidence that such material does exist. The NMR and DTA evidence that we found,

referenced by Burrows and Giess, is in itself fairly convincing evidence for the existence of an inactive form of PbO_2 but, in addition, studies made of the formation of tetrabasic lead sulfate have shown that a layer of PbO_2 is formed at the surfaces of these crystals that can be clearly demonstrated to be unreactive, since it remains visible as a reticulate structure in both the charged and discharged states of the electrode, indicating that this material takes no part in the reduction process.[54] Only after ten or more capacity discharge cycles does this reticulate structure break up. Moreover, its breakup is accompanied by a large increase in the amount of PbO_2 found as discrete particles in the $PbSO_4$ crystals, indicating that, despite the breakup of the reticulate structure, the inactive PbO_2 has not disappeared but merely has been segregated into smaller, discrete particles that now appear within the lead sulfate crystals.

We do not agree with the final paragraph of the remarks by Burrows and Giess. In the first place, the coralloid structure is in all its transformations still crystalline. It is not clear what they mean by recrystallization, since clearly PbO_2 is regenerated from $PbSO_4$ at each charge portion of a cycle. It is true, however, that the PbO_2 lattice is disordered and may depend on this disorder for its electrochemical activity. If this is true, a more ordered crystal becomes an inactive crystal and this is the mechanism that we have proposed for the loss of capacity. In this process the presence or absence of the coralloid structure is immaterial and we do not see how this can be used to argue that the coralloid morphology should be avoided.

We certainly agree that conclusions arising from examination by microscope should be corroborated with quantitative physical measurements, but it is equally true that erroneous conclusions can be derived from physical measurements in the absence of microscopic examination. In the present case, we see nothing in the physical measurements reported by Burrows and Giess that would necessitate a change in the conclusions that we have reported.

Their concluding statement, "It is this recrystallization . . .," is merely another way of stating what we have previously reported, *i.e.*, inactive material and coralloid structure increase during the loss of life and capacity that accompanies cycling. But neither their results nor ours have yet shown whether the one is caused by the other, or whether the coralloid structure is necessarily undesirable even though it is self-evident that an increase in inactive PbO_2 would be detrimental.

Conduction Characteristics of Polycrystalline Lead Fluoride

C. C. Liang and A. V. Joshi (pp. 466-470, Vol. 122, No. 4)

J. H. Kennedy:[55] The paper by Liang and Joshi presents a substantial amount of data concerning the conductivity of lead fluoride using doping techniques. Several important parameters of the system can be calculated using their data; however, these calculations present some basic inconsistencies which should be considered.

First, one could ask if the nominally pure β-PbF_2 was acting intrinsically. If so, then $n_v = n_i$ and $\sigma_{total} = \sigma_v + \sigma_i = n_v e\mu_v + n_i e\mu_i$. Since the Arrhenius slope gave an activation energy the same as +3-doped PbF_2 (resulting in interstitials), $\sigma_i >> \sigma_v$ and $\mu_i >> \mu_v$. However, at high doping levels assuming Frenkel equilibrium

$$\sigma_i = (D_i + n_v) e\mu_i \cong D_i e\mu_i \quad (D_i = \text{conc of } +3 \text{ doping})$$
$$\sigma_v = (D_v + n_i) e\mu_v \cong D_v e\mu_v \quad (D_v = \text{conc of } +1 \text{ doping})$$

Data from the paper give the following results at 25°C

$$e\mu_v = \frac{\sigma_v}{D_v} = \frac{5.5 \times 10^{-4}}{0.01} = 5.5 \times 10^{-2}$$
(slope of line in Fig. 3)

$$e\mu_i = \frac{\sigma_i}{D_i} = \frac{2 \times 10^{-7}}{0.003} = 6.7 \times 10^{-5}$$
(conductivity from Fig. 7)

and thus it is seen that $\mu_i << \mu_v$. Therefore the conductivity of nominally pure PbF_2 is not intrinsic and must be due to impurities (D_o) leading to a preponderance of interstitials to explain the Arrhenius slope.

If we now assume a Frenkel equilibrium we can write several expressions for the Frenkel equilibrium constant

$$\text{pure} \quad K = [n_i^o]\,[n_v^o]$$
$$\text{nominally pure} \quad K = [D_o + n_v]\,[n_v]$$
$$+3 \text{ doping (interstitials)} \quad K = [D_o + D_i + n_v]\,[n_v]$$
$$+1 \text{ doping (vacancies)} \quad K = [n_i]\,[D_v - D_o + n_i] \quad \text{if } D_v > D_o$$

For nominally pure PbF_2

$$\frac{\sigma_i}{\sigma_v} = \frac{(D_o + n_v) e\mu_i}{n_v e\mu_v} = \frac{6.7 \times 10^{-5}(D_o + n_v)}{5.5 \times 10^{-2}\, n_v} >> 1$$

For comparing D_o and n_v let us assume $\sigma_i/\sigma_v \sim 10$ so that Arrhenius slope only shows Δh_i. Then

$$\frac{D_o + n_v}{n_v} = \frac{5.5 \times 10^{-2}}{6.7 \times 10^{-5}} \times 10 = 8.2 \times 10^3$$
and $D_o >> n_v$

We can now calculate D_o from data in the paper without making any assumptions concerning σ_i/σ_v

$$\text{nominally pure:} \quad e\mu_i = \frac{\sigma}{D_o} = \frac{10^{-7}}{D_o}$$
$$+3 \text{ doping:} \quad e\mu_i = \frac{\sigma}{D_i + D_o} = \frac{2 \times 10^{-7}}{0.003 + D_o}$$

Solving these two equations for D_o gives a value of 0.003. That is, the nominally pure PbF_2 contains 0.3 mole per cent (m/o) of interstitials from impurities. A recalculation for $e\mu_i = \sigma_i/D_o + D_i$ gives the value of 3.3×10^{-5}, but this does not change the situation regarding $D_o >> n_v$. We are now faced with a basic inconsistency. If Frenkel equilibrium is established, these interstitials should react with doped-in vacancies (doping with KF) up to 0.3%. The conductivity should fall with addition of KF until this level is reached and the activation energy should become Δh_v only when $D_v > D_o$. One possible explanation is that equilibrium is not reached and that the product $[n_i][n_v] > K$. This explanation, however, contains its own inconsistencies since the conductivity lines for nominally pure PbF_2 and KF-doped PbF_2 then could not cross as shown in Fig. 5 in the paper under discussion. That is, at high temperatures the mobility of interstitials becomes predominant, and curves b-f in Fig. 5 should begin to track curve a. One could argue that at high temperature reaction occurs between vacancies and interstitials to reach Frenkel equilibrium, but upon cooling the pellets the conductivity and Arrhenius slope for 0.1 and 0.3 m/o KF-doped PbF_2 should now be considerably different than before heating. No mention of such a change was made in the paper and in view of the preparation procedure would not be expected.

Additional calculations can be made but are not meaningful until the question of whether or not Frenkel equilibrium is established. The comments above refer to β-PbF_2, but the results for α-PbF_2 are similar except that D_o is much smaller (*ca.* 0.0004). The arguments presented depend critically on the +3-doping of PbF_2 and these studies should be expanded to cover a larger concentration range and possibly another MF_3 compound. Work in our laboratories has shown a decrease in conductivity when BiF_3 was the dopant with an increase in electronic conductivity. We

[54] Abstract 34, p. 85, Extended Abstracts, Electrochemical Society Fall Meeting, New York, New York, October 13-17, 1974.

[55] Department of Chemistry, University of California, Santa Barbara, California 93106.

also observed a gradual change in Arrhenius slope which might indicate that at low doping levels σ_i and σ_v are nearly equal, because doped-in vacancies are reacting with interstitials present in the nominally pure material. Other explanations are, of course, also possible.

C. C. Liang and A. V. Joshi:[56] Dr. Kennedy calculated the M^{3+} impurity concentration in the nominally pure PbF_2 as being 0.3 m/o and thereby raised the question of basic inconsistencies in the conduction behavior. We shall show in the following that the M^{3+} impurity concentration in the nominally pure PbF_2 is very much lower than 0.3 m/o (in fact, it is much lower than 0.1 m/o) and our interpretation of the PbF_2 conduction behavior is indeed consistent with the experimental data.

In the Kennedy calculation of the M^{3+} impurity concentration, an assumption was made that the 0.3 m/o YF_3 added to PbF_2 was completely dissolved in the β-PbF_2 lattice. In fact, we found that under our experimental conditions the solubility of YF_3 in β-PbF_2 is very much less than 0.3 m/o as shown by the fact that the same value of $1.6 \pm 0.3 \times 10^{-7}$ $(\text{ohm-cm})^{-1}$ was obtained from the room temperature conductivity of β-PbF_2 containing 0.1, 0.3, 0.5, 0.8, or 1.0 m/o YF_3. We did not report these results nor did we attempt to determine the solubility of YF_3 in PbF_2 inasmuch as they were not pertinent to our principal objective which was to determine the defect structures. It was important, however, to recognize that some YF_3 was dissolved in β-PbF_2 as shown by the slight increase in conductivity and that the YF_3 doping did not result in a change in activation energy for β-PbF_2.

The principal objective of our paper was to investigate the defect structures and the results of our investigation clearly demonstrated a Frenkel defect structure in β-PbF_2 as well as α-PbF_2. The defect concentration was not computed inasmuch as we had not obtained enough quantitative information from our YF_3 doping experiments for such a computation. Nonetheless, in view of the question of basic inconsistencies we shall estimate the M^{3+} impurity concentration in the nominally pure PbF_2.

The spectrographic analysis showed that the effective M^{3+} impurity concentration in the commercial PbF_2 was about 150 ppm (0.015 m/o). Even if we took into consideration that such an analysis could be semiquantitative and the results could be off by $\pm 100\%$, the maximum concentration for the M^{3+} impurities would be 300 ppm (0.03 m/o).

If one were to carry out the Kennedy calculation using the YF_3-doped α-PbF_2 results (Fig. 6 in the original paper) and assuming a complete solubility of YF_3 in α-PbF_2, one would obtain a M^{3+} impurity concentration of about 400 ppm (0.04 m/o) in the nominally pure α-PbF_2. It is extremely unlikely that the M^{3+} impurity concentration in β-PbF_2 would be much higher than that in α-PbF_2.

Accordingly, the decrease in conductivity with addition of KF as argued by Kennedy would occur up to 0.04 m/o KF. On the other hand, the conductivity of the 0.1 m/o or higher KF-doped β-PbF_2 is expected to be higher than that of the nominally pure β-PbF_2. Furthermore, the activation energy determined from the Arrhenius plots of the 0.1, 0.3, 0.5, 0.8, or 1 m/o KF-doped β-PbF_2 is for the mobility of fluoride ion vacancies in β-PbF_2.

Bismuth fluoride was also one of the MF_3 used in our studies. We found that the conduction behavior of BiF_3-doped PbF_2 appeared to depend on the electrode material in the conductivity cell. When Pb electrodes were used the total conductivity was much lower and the electronic conductivity appeared to be very high compared to the total conductivity. On the other hand, when graphite electrodes were used we observed a rather normal increase in conductivity.

There are, of course, many explanations for such a behavior. Nonetheless, we do not rule out the simple explanation that Pb reacts with BiF_3 even though the concentration of the added BiF_3 was only 1 m/o or less in our experiments

$$2BiF_3 + 3Pb \rightarrow 2Bi + 3PbF_2 \quad \Delta G = -44 \text{ kcal}$$

$$\Delta G_f(PbF_2) \text{ at } 25°C = -148 \text{ kcal/mole}$$

$$\Delta G_f(PbF_2) \text{ at } 325°C = -138 \text{ kcal/mole}$$

$$\Delta G_f(BiF_3) \text{ at } 25°C = -200 \text{ kcal/mole}$$

$$\Delta G_f(BiF_3) \text{ at } 325°C = -185 \text{ kcal/mole}$$

Electrogenerated Chemiluminescence. XXIII. On the Operation and Lifetime of ECL Devices

D. Laser and A. J. Bard (pp. 632-640, Vol. 122, No. 5)

C. P. Keszthelyi:[57] In the above-mentioned paper, the authors report that in electrogenerated chemiluminescence (ECL) under the usual potential program (cyclic double potential steps to the diffusion plateau) only $\sim 1\%$ of the ions $R^{\cdot -}$ and $R^{\cdot +}$ are quenched by the electrode due to $R^{\cdot -} \rightarrow R^{\cdot +} + 2e^-$ and $R^{\cdot +} + 2e^- \rightarrow R^{\cdot -}$, *i.e.*, only about 2% of the total current is consumed by these processes, a result in good agreement with the present writer's previous result,[58] hence the following discussion raises no critical questions whatsoever in that regard. Although the paper is adequately documented in general (30 literature references plus three "private communications"), it omits one of the prestigious published works in the field. The missing reference[59] states that 34.4% of the Faradaic current is consumed by the two-electron oxidation and reduction processes, and this same value had also been used by Pighin[60] in rubrene electrogenerated chemiluminescence calculations. As both the paper under discussion and the work of Schwartz *et al.*[59] assume stable $R^{\cdot +}$ and $R^{\cdot -}$, the maximum possible efficiency, expressed as Φ_{ecl}, should be the same;[61] yet the former gives $\sim 98\%$, and the latter, 82.8%. Consequently, the general scientific community is faced with some difficulty in selecting a proper value of $\Phi_{ecl,max}$ (or, $\bar{\phi}^{ss}_{coul,max}$) due to a conflict in reported values. It is the purpose of the present discussion to settle that $\sim 98\%$, given by Laser and Bard, is the correct value (or $1.0 \times 100\%$[58]), and the related work[59,60] should be recalculated.

Improved documentation and careful evaluation of published works in ECL[62] can be both revealing and rewarding; for example, the fate of $R^{\cdot +}$ and $R^{\cdot -}$ in typical ECL experiments has been published some time ago,[63] leading to the unmistakable conclusion that "destruction of the ions [is] virtually negligible . . . ,"[64] a conclusion which, for the record, well predates the relevant sections of both the present writer's related publication[58] and the paper under discussion.

60 A. Pighin, *Can. J. Chem.*, **51**, 3567 (1973).

61 It appears unnecessary to develop this point at length here, as the authors of the paper under discussion have done so already. Yet the authors' contention in the original paper is misleading, for $\bar{\Phi}^{ss}_{coul}$ does not approach 98% when two electrodes of equal size are used, unless one counts photons at both electrodes, while counts electrons at only one.

A Correlation Between the Quantum Efficiency of Electrogenerated Chemiluminescence and the Redox Potentials of Rubrene in Various Solvents

A. Pighin and B. E. Conway (pp. 619-624, Vol. 122, No. 5)

C. P. Keszthelyi:[65] In the above-mentioned paper, the authors report electrogenerated chemiluminescence (ECL) efficiency of rubrene in several solvents. In view of the close agreement between some of our rubrene ECL efficiency results[66] and the ones reported in the paper under discussion, the following comments do not attempt to question the direct measurements; however, there are still some disturbing aspects that should be cleared up in as brief a space as possible.

(1) The authors define "quantum efficiency" in ECL in a manner which is inconsistent with previous as well as current "mainstream" usage.[66-71] We should probably stay with $\Phi_{ecl} \equiv$ ECL quantum efficiency $\equiv$ number of photons emitted/radical ion annihilation (usually),[72] if for no other reason, to avoid needless confusion due to redefinition of common terms by every newcomer to the field.

(2) In Fig. 1 in the paper under discussion, the Faradaic current should merge into the capacitive current with a smooth line, following the Nernst equation. The implication of Fig. 1 is that the Faradaic current component drops to zero at ~2.3V, whereas the Nernst equation tells us otherwise, together with "underpotential electrodeposition" experiments.

(3) Based on our experience in the same general area,[73] point No. 11 in Fig. 4 should have been augmented by a few additional measurements. With 1 mM solute concentration the 0.020M TBAP-100 Hz combination is apt to lead to dubious results. It would have been imperative to decrease the rubrene concentration, or the Hz, or preferably systematically vary both. Also, with solutions of this type a potentiostat employing positive *IR* feedback and a three-electrode configuration is a virtual necessity.[73]

(4) On p. 623-624 the authors make a perplexing statement: "... the solvent component (benzene) which tends to produce relatively high ($E_{p,ox} - E_{p,red}$) will also then tend to solvate the radical ions." Benzene is definitely unlikely to preferentially solvate radical ions when other solvent components are also present such as propylene carbonate or acetonitrile. It seems proper to call to the authors' attention the figure reproduced from the 1973 issue of *This Journal*[74]

> it is possible to have preferential solvent interaction as shown in the inset (solid circles represent the more polar component in the heteropolar solvent

$$R^{+} + R^{-} \longrightarrow [R^{+}\cdots R^{-}] \longrightarrow [R\cdots R]^{*} \longrightarrow R + R^{*}$$

> mixture). It has been experimentally observed that use of a heteropolar mixed solvent having the same over-all dielectric constant as a given single solvent leads to higher efficiency than use of said single solvent in ECL.

Whereas a number of important aspects of the creation of electronically excited states by electron transfer and preferential solvation in mixed heteropolar solvents remain open for discussion,[75] one should make certain that we are moving forward with the passage of time, instead of proposing preferential ion solvation by the benzene solvent component.

A. Pighin[76] and B. E. Conway:[77] We regret that our paper disturbed Keszthelyi. However, had he read our paper more carefully and been less dogmatic about his work most of his comments would not have been necessary. Our replies to his comments are, point by point:

(1) Since we have led a 15-man-year investigation of EGCL*[78] over 4 years for display applications,[77-81] we should hardly be called newcomers.

The so-called "mainstream" definition of quantum efficiency of EGCL has at least the following difficulties: (a) it does not consider electrogenerated ions, which do not partake in radical ion annihilation, as contributing to the inefficiency of the EGCL process, *e.g.*, losses due to diffusion, side reactions, potential cycling, etc.; (b) it would consider EGCL produced from the di-ion radicals to be as efficient as that produced from mono-ion radicals, although the former consumes twice as much current; (c) it requires a knowledge of the light-producing mechanism; and (d) for various reasons, *e.g.*, (a) and (b) above, it tends to overestimate the over-all quantum efficiency.

Our definition of EGCL quantum efficiency is free from these difficulties and is more inclusive and more pragmatic. It also gives a more realistic basis for evaluation of quantum efficiency which minimizes corrections.

(2) Experimental points taken at *ca.* 2.3V did follow the Nernst equation and we were not surprised by this. The delineation of the Faradaic current line in Fig. 1 of our paper into the capacitive current line was drawn simply to demonstrate the potential of onset of appreciable Faradaic current. More closely spaced experimental points would have been required to demonstrate the role of the back reaction. However, the purpose of Fig. 1 was, of course, not to demonstrate this well-known, but trivial, effect.

(3) It only takes two precise points to determine a difference. Since the TBAP concentration was varied fivefold and no significant change in ϕ_{coul}, measured over a wide frequency range,[79] was observed, we considered that to be sufficient proof that ϕ_{coul} was independent of electrolyte concentration.

In the paper referred to,[73] Keszthelyi *et al.* equate the relative EGCL intensity to ϕ_{egcl}. ϕ_{egcl} requires knowledge of the Faradaic current (or number of radical ion annihilations). Without this knowledge, it is dangerous for them to conclude by implication that their results show a variation in ϕ_{egcl} with electrolyte concentration. Therefore, this question appears to have been based on a premise which has no substance. Furthermore, he has been wrong previously[82] on the interpretation of quantum efficiency.

The recommendation that we ought to have measured ϕ_{coul} as a function of rubrene concentration and frequency is baffling because such information is given (Fig. 3) in the paper under discussion and our previous paper[79] (Fig. 4) which was referenced, respectively.

As for the need for *IR* compensation, other methods for measuring ϕ_{coul} may require *IR* compensation but

our technique is relatively insensitive to *IR* effects. In our procedure for measuring ϕ_{coul}, *IR* effects will decrease the slope of the extrapolation of the capacitive current line in the current *vs.* voltage plots (Fig. 1) but this effect is obviously small because the change in slope is small and the length of the extrapolation is short. It was observed that both the EGCL and Faradaic current commenced together. Thus, although the redox potentials of rubrene are asymmetrical about the SCE, they were symmetrical about the ground of the driving circuitry. This, together with the fact that EGCL was generated at two equal-area electrodes, resulted in equal quantities of oppositely charged radical ions being produced alternately at both electrodes.

(4) We are fully aware of the paper by Keszthelyi which discusses preferential solvation in EGCL and would like to refer him to our patent[81] in this area which was filed during the previous year.

The charge on rubrene radical ions is well diffused due to delocalization. Its radical ions may be regarded as a large aromatic structure with a small charge density over its central π-bond network which contains 18 carbon atoms. Because of the large space over which the single charge is distributed, the force which will attract and orient polar solvent molecules will be weak. Furthermore, since the radical ions retain some aromatic character, it is reasonable to assume that with an increasing aromatic fraction in the solvent the solvation shell may accommodate some aromatic solvent. It is to be noted that this does not exclude, in this case, some solvation also by the polar component, as recognized in our paper. Keszthelyi appears to insist on an all-or-nothing model of preferential solvation but we do not feel bound by his view.

We feel that our interpretation of preferential solvation is reasonable and thus contributes to the understanding of EGCL. We hold a flexible opinion on this and are prepared to alter our thinking if new evidence should warrant it.

Barrier-Type Aluminum Oxide Films Formed under Prolonged Anodizing

I. Influence of Anodizing Parameters on Film Morphology

Yoon H. Choo* and Owen F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

The morphology of anodic aluminum oxide films formed in neutral aqueous 3% ammonium tartrate was investigated using transmission and replica electron microscopy and transmission stereoscopy. After an initiation period of approximately 90 min, corresponding to the appearance of a minimum in the potentiostatic anodic current, development of a porous structure was observed. The film structure was comparable to that formed in conventional pore-forming electrolytes at shorter times, with approximately polygonal oxide cells, each containing a central pore. Pore depth and diameter both increased in a systematic manner with anodizing time; a hypothetical model relying on field-assisted dissolution of oxide, with local field enhancement due to the pore geometry, is used to explain this dependence. At longer times, the pore depth increases linearly with anodizing time, also consistent with this model and with the observed establishment of a stable pore structure. The stable pore size and oxide cell size are proportional to formation voltage in accord with the geometric argument forwarded to explain pore coalescence and the formation of stable terminal pores.

Anodic aluminum oxide films are commonly classified as porous or barrier-type (*i.e.*, nonporous) according to the electrolyte in which they are formed. Barrier-type films are formed by anodically polarizing aluminum in an electrolyte which exerts little solvent action on the oxide film, *e.g.*, aqueous borate or tartrate, and grow to a limiting thickness in proportion to the applied potential. Porous films, on the other hand, are formed by anodic polarization of aluminum in an electrolyte which exerts appreciable solvent action on the film, *e.g.*, aqueous sulfuric, chromic, oxalic, or phosphoric acids, and tend to thicken indefinitely under constant potential in proportion to the charge passed. The structure of porous films has been characterized by Keller, Hunter, and Robinson (1), and later by O'Sullivan and Wood (2), as a close-packed array of columnar hexagonal cells, each containing a central pore normal to the substrate surface and separated from it by a layer of barrier-type film. The dimensions of these structural features are dependent on the formation potential as well as the electrolyte (2). The barrier film beneath the porous structure is proportional in thickness to the applied potential, the proportionality constant being of the order of 10 $Å\text{-}V^{-1}$ in contrast to the value of approximately 13 $Å\text{-}V^{-1}$ seen in typically barrier-forming electrolytes (3-5).

A number of authors have studied the mechanism of pore formation and growth in anodic films. Keller, Hunter, and Robinson (1) proposed that pore growth occurs by simultaneous formation and dissolution of oxide. This occurs initially at regions experiencing a locally high dissolution rate; Joule heating in the adjacent electrolyte then enhances the process at these sites. While Hunter and Fowle (6) explained pore formation simply in terms of chemical dissolution, Hoar and Mott (7) postulated that the dissolution was field-assisted and, thus, that both formation and dissolution of oxide were enhanced by the locally high field at the pore bases. This mechanism appears most generally accepted at present (2). To explain the observation that pores do not initiate until a barrier-type layer of at least a critical thickness has formed, Hoar and Yahalom (8) have suggested that proton entry into the oxide film is necessary to pore formation and that this is possible, against the anodic field, only when the field has decreased to a value characteristic of the critical thickness. Random local defects in the initial barrier film are seen as important to pore nucleation by Arrowsmith, Culpan, and Smith (9) who studied pore nucleation in films formed on aluminum substrates of varying purities.

Hoar and Yahalom (8) have reported that barrier-type films (formed in 3% ammonium tartrate at pH 7.3, 25°C, 14.4V) and porous films (formed in 15% sulfuric acid, 25°C, 14.4V) both develop their structures after only seconds of anodizing. Several investigators have reported formation of porous-like cellular structures in films formed in borate or tartrate solutions at high formation voltages or prolonged anodizing times. Franklin (10) observed an irregular polygonal cell structure in films formed at 500V in aqueous 3% boric acid-0.05% borax, with the cell diameter proportional to the formation voltage and the cells bulging out into both the electrolyte and the substrate. Stirland and Bicknell (11) confirmed this observation and, through electron diffraction by thinned films, demonstrated that the centers of the cells were amorphous while the edges were $\gamma'\text{-}Al_2O_3$. Hoar and Yahalom (8) reported

Key words: aluminum, anodic oxidation, impedance, porosity.

pore formation in films formed in 3% ammonium tartrate, pH 7.3 at 14.4V for 10 min. Hunter and Towner (12) found a porous layer formed above the barrier layer on aluminum anodized in 3% ammonium tartrate, pH 5.5, for times up to 900 min. The substrate surface after anodizing was seen to have a cellular pattern similar to that seen in the case of porous films. They observed that the barrier layer reached a limiting thickness after 12 min, after which the porous layer formed at a linear rate of about 175 Å-hr^{-1}. Leach and Neufeld (13) observed pore formation in films formed in aqueous borate at pH 9.7 subsequent to attainment of a steady leakage current under constant applied potential. Pore growth was affected both by formation rate and electrolyte temperature.

The present study was undertaken specifically to investigate more fully the porous structure of anodic aluminum oxide formed in barrier-forming electrolytes, and to characterize the effects of the anodizing time and formation potential on this structure. Attention was restricted to aluminum anodized in aqueous 3% ammonium tartrate at pH 7.

Experimental Procedures

High purity aluminum (99.99%) sheet of 2.5 mm thickness was cut into rectangular specimens, 12 x 50 mm, annealed in air at 350°C for 1 hr, and furnace cooled. Specimens were then chemically polished in a solution comprised of 80 volume per cent (v/o) phosphoric acid and 3 v/o nitric acid in water for 20 min, followed by electropolishing in a conventional bath of 20 v/o perchloric acid in ethanol. All anodizing was done in a solution of 3 weight per cent (w/o) ammonium tartrate, reagent grade, in double distilled water; the solution was adjusted to pH 7 by titration with dilute aqueous ammonium hydroxide. Anodizing was performed in a simple cell employing a cylindrical platinum gauze surrounding the anode as cathode; the anodizing time and formation potential employed in this study ranged from 15 min to 48 hr, and from 25 to 100V, respectively. Anodizing was conducted at a constant current density of 1 mA-cm^{-2} until the desired formation potential was obtained; at this point the current was allowed to decay under constant potential for the balance of the experiment. Anodic current was recorded directly with a strip chart recorder.

Upon removal from the anodizing cell, anodized specimens were gently washed, first with absolute methanol and then with double distilled water, then allowed to dry in a gentle air stream. For transmission electron microscopy oxide films were scribed into grid size (2.5 x 2.5 mm) while on the substrate, then removed by the amalgamation method (1). For replica electron microscopy carbon-platinum replicas were prepared from the oxide surface that had been adjacent to the electrolyte, and from the substrate surface. The latter surface was prepared by dissolution of the oxide film by immersing the specimen in a mixture of phosphoric and chromic acids (35 cm^3 85% phosphoric acid and 20g chromic acid per liter of solution) at 90°C for 10 min. Surface features of the aluminum were unattacked by this treatment (1).

Most electron micrographs were taken at the same magnification to facilitate measurement of pore and cell sizes and also to eliminate comparative errors possibly inherent in different magnification settings. Stereopair electron micrographs were taken of given areas of films by tilting the specimen holder ± 5°; this technique enabled measurement of pore depth and barrier layer thickness and permitted clear three-dimensional viewing of the film morphology. Stereopair micrographs, typically at 92,200×, were viewed with a Hilger and Watts SB 185 mirror stereoscope; barrier layer thickness and pore depth measurements were made using a parallax bar, accurate to 0.01 mm.

Results

Current/time transient behavior.—Anderson and Devereux (14) have reported that, on potentiostatic formation of anodic aluminum oxide films in neutral aqueous tartrate solutions, the leakage current decreases continuously to a minimum value characteristic of the formation voltage in 45-90 min. This value is not stable, however, as the leakage current increases beyond this time at nearly an exponential rate for 10-15 hr before attaining a terminal stable value. That report is confirmed by data from this study, shown in Fig. 1, in which anodic current is plotted *vs.* anodizing time for several different formation potentials. Each curve represents a single experiment; therefore, these are typical, rather than average, results. Similar curves are seen for aluminum anodized in pore-forming electrolytes; however, the current minimum may occur after as little as 2 sec anodizing time and the steady-state value after as little as 10 sec (8). The current minimum in pore-forming environments is seen to correspond to pore initiation in accord with the postulate that initiation does not occur until the field has dropped to a level that permits proton entry into the film; the subsequent increase in leakage current reflects thinning of the barrier layer at the pore bases as pore growth proceeds; the steady-state current reflects stability of the barrier film (~10 Å-V^{-1}) and pore growth occurring by addition to the film rather than by subtraction. A similar mechanism is proposed in the present study, with transmission electron microscopy demonstrating pore initiation approximately coincident with the current minimum.

Influence of anodizing time on pore size.—A time sequence of transmission electron micrographs of anodic oxide films formed at 50V is shown in Fig. 2. At 15 min the oxide is seen to be virtually featureless, while at 2 hr definitive pores are seen, the dark edge surrounding each pore indicating diffraction by the pore wall and/or oblique transmission of electrons through the barrier film comprising the pore wall. At 2 hr, pore diameter ranges to 120Å; as anodizing time is increased pore size increases until approximately 32 hr, when it approaches a stable value. It is apparent, especially in the photomicrograph for 8 hr, that as pores grow and coalesce new pores form. Thus, there is a distribution of sizes and shapes at any given anodizing time; for purposes of comparison pore size has been defined herein as the average diameter of the most frequently appearing and fully developed pores. Prior to attainment of a stable value, the pore diameter is seen in Fig. 3 to follow the relation

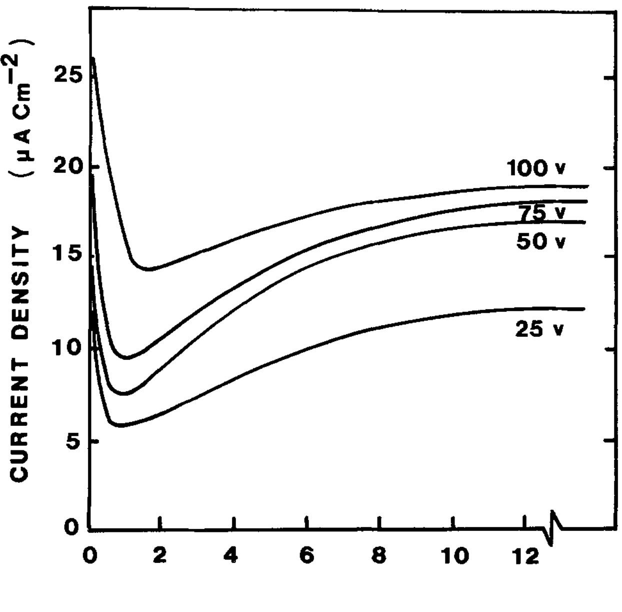

Fig. 1. Current density *vs.* anodizing time for various formation voltages.

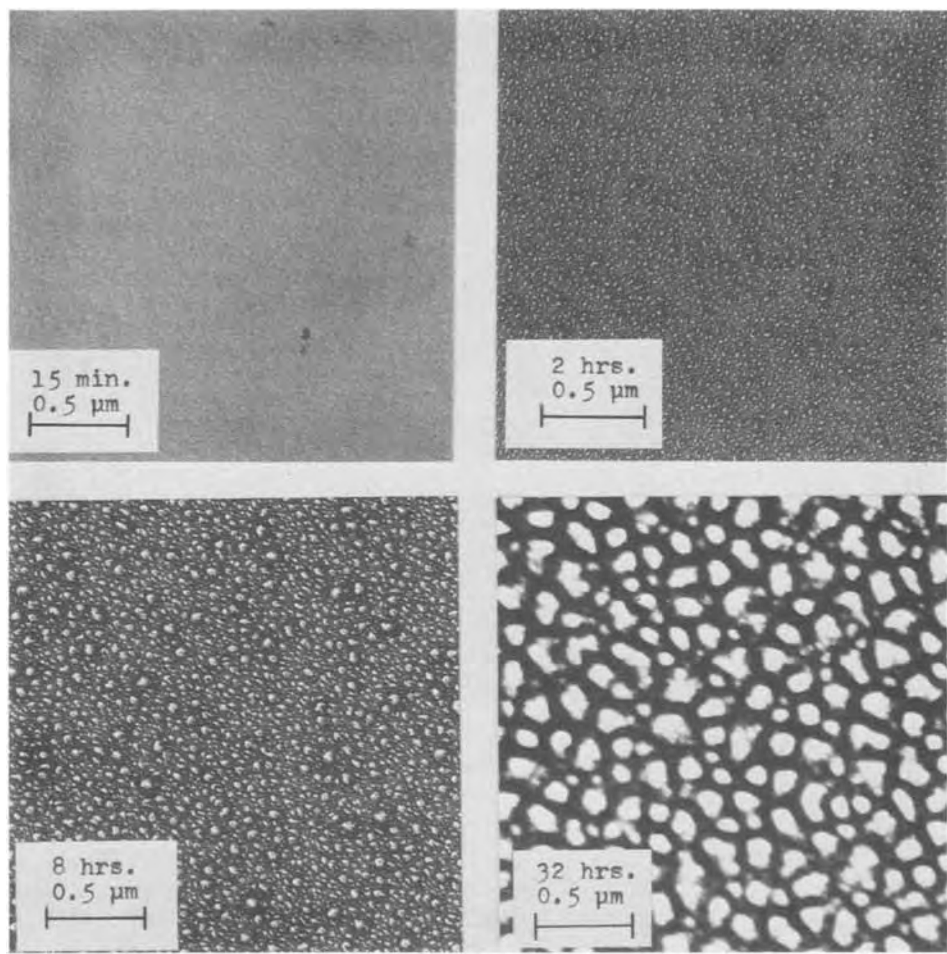

Fig. 2. Transmission electron micrographs of anodic oxide films formed at 50V for various anodizing times.

$$\frac{D}{1.31} - d \ln\left(\frac{D/1.31 + d}{d}\right) = K(t - t_o)$$

to be derived in the Discussion section, where D is the measured pore diameter, d is the barrier layer thickness, t is anodizing time, and t_o is the time required for pore initiation. This expression is closely followed at 50 and 75V, with $K = 9.5$ Å-hr^{-1}. Data taken at 25V deviate from this behavior, possibly due to earlier establishment of a stable pore size. Pore initiation time is of the order of 90 min as noted above.

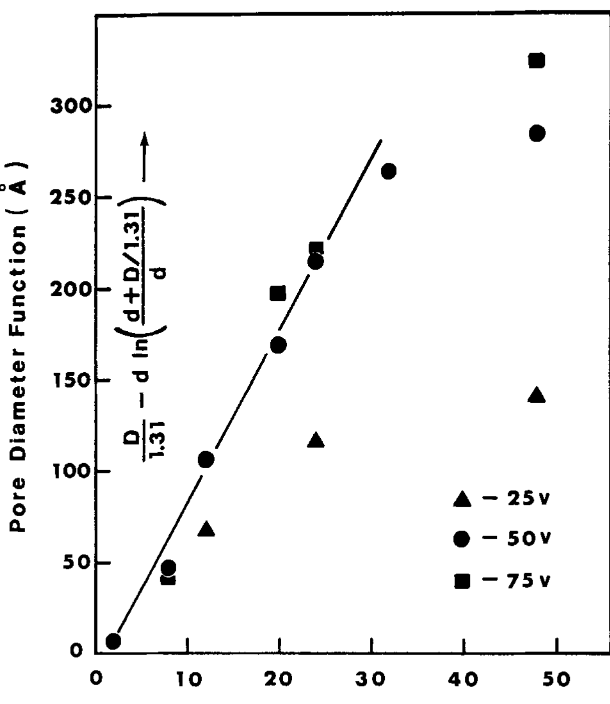

Fig. 3. Pore diameter function *vs.* anodizing time for various formation voltages.

Influence of anodizing time on oxide cell size.—Replica electron micrographs of the aluminum substrate subsequent to anodizing at 75V for various times are shown in Fig. 4; these replicas clearly depict the basal structure of oxide cells comprising the anodic film. There is an initial cell structure which does not change significantly during the first 8 hr of anodizing. It then undergoes rather rapid growth, but attains a maximum size representative of the final structure after 20 hr. This behavior is typical of that seen at other formation potentials.

Determination of the density (*i.e.*, number per unit area) of cells and pores from photomicrographs of comparable specimens indicated a one-to-one correspondence, *i.e.*, to each cell corresponds a pore. Consequently, (pore density)$^{-1/2}$ is approximately equal to the cell diameter. A time sequence of such values is shown in Fig. 5 for films formed at 50V. Clearly, these data lack the simple time dependence of the pore diameter; the cell sizes as computed from pore density represent the average of all cells, whereas the plotted pore diameters are only for fully developed pores. Cell size shows a slow initial growth, but a very marked transition after about 16 hr of anodizing; this may be interpreted as a disappearance of a large number of small cells leaving a relatively stable film structure of large cells only.

Influence of formation potential on terminal pore and cell sizes.—Figure 6 shows transmission electron micrographs of films formed after 48 hr of anodizing at

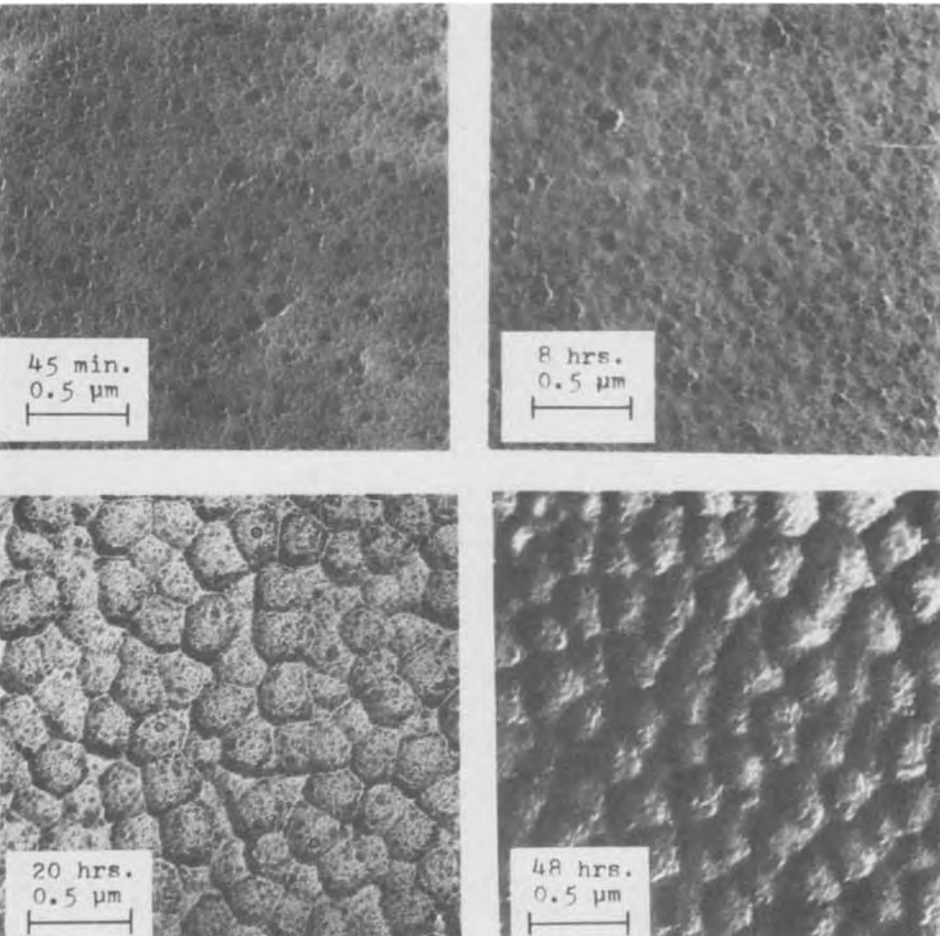

Fig. 4. Replica electron micrographs of substrate surfaces after anodizing at 75V for various times, showing oxide cell formation.

various formation potentials, illustrating the dependence of terminal pore size on formation potential. Figure 7 depicts replica electron micrographs of the corresponding substrates, showing cell size dependence on formation potential. Pore and cell diameters are plotted in Fig. 8, showing a linear dependence of each on formation potential: terminal pore diameter (Å) = 18.5 × formation voltage and terminal cell diameter (Å) = 35 × formation voltage. Directly measured average cell diameters and values computed from pore density are both shown and are comparable. Inasmuch as these are "terminal" there is no significant contribution to the average size from small undeveloped cells.

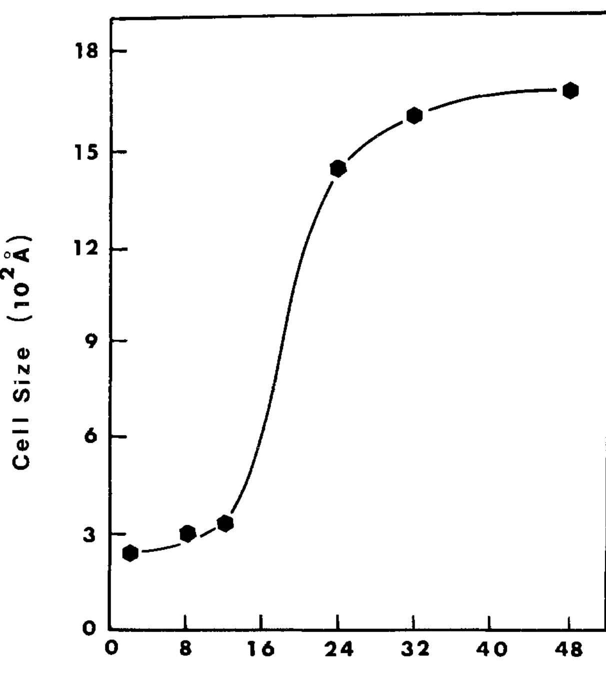

Fig. 5. Cell diameter vs. anodizing time at 50V

Barrier thickness and pore depth measurements.—The barrier layer thickness and the pore depth were determined by use of electron stereomicroscopy. Vertical distances were determined from the equation (15, 16)

$$T = \frac{x}{2M \sin \theta}$$

where T is the vertical distance; x, the measured parallax; M, the over-all magnification; and 2θ, the angle through which the specimen is tilted between exposures. Pore depth was evaluated by measuring the change in distance between features at the pore opening and at the pore bottom; similarly, the barrier layer thickness was determined by examination of features on opposite sides of a nonporous region of film. The relative (vertical) position of such features is readily apparent in stereo viewing. A typical pair of stereo electron micrographs, from a film formed at 50V for 24 hr, is shown in Fig. 9. With use of an appropriate viewer it may be seen that there is a considerable variation in pore depth; this is also evident in Fig. 10. Figure 10 is a cross-sectional view of a film formed under the same conditions employed for Fig. 9; while wet the film was folded over the edge of a specimen grid for viewing through the folded edge. Figure 11 shows average pore depth for several specimens as a function of anodizing time. It is apparent that there is no dependence of the pore depth growth rate on formation potential. As with the pore diameter, the behavior is nonlinear at short times with an abscissa

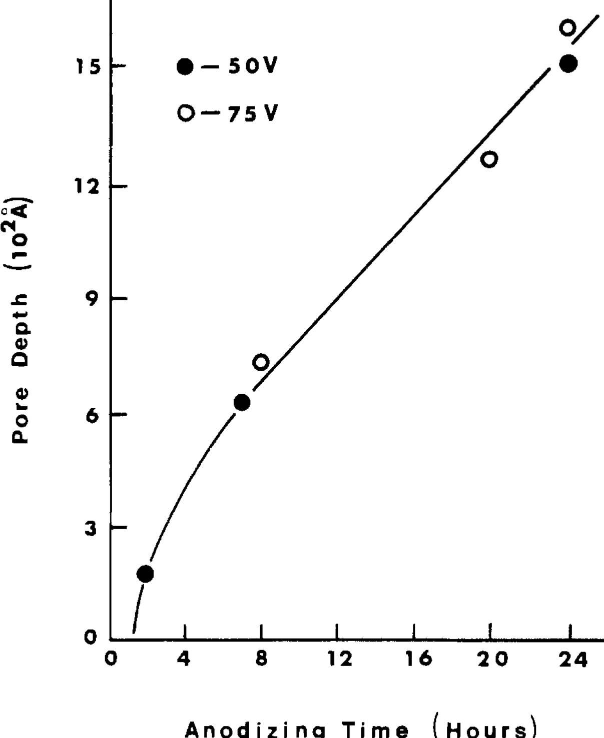

Fig. 11. Pore depth vs. anodizing time at 50 and 75V

intercept of the order of 90 min. The pore depth approaches linearity with time after about 8 hr of anodizing with a growth rate of 54 Å-hr^{-1}. Barrier layer thickness was determined for the pore-free regions of the film shown in Fig. 9; the value measured was 633 ± 45Å or 12.6 ± 0.9 Å-V^{-1}. Due to lack of suitable markers it was not possible to obtain reliable measurements for the thickness at the pore bases.

The power of electron stereomicroscopy is not evident in Fig. 9 unless viewed with a stereo viewer. The film appears as a transparent overlay on the opaque substrate surface. It can be seen that the oxide/electrolyte interface is virtually planar and that to each pore corresponds a pit in the substrate metal. The pore itself is separated from the substrate on all sides by a relatively uniform barrier layer. This layer appears to be somewhat thinner at the pore bases than on the pore walls or in the nonporous region. Furthermore, pores are consistently wider toward the base than at the pore opening. Figure 12 is a schematic representation of the section A-B indicated in Fig. 9, illustrating these points. Especially deep substrate pitting, with corre-

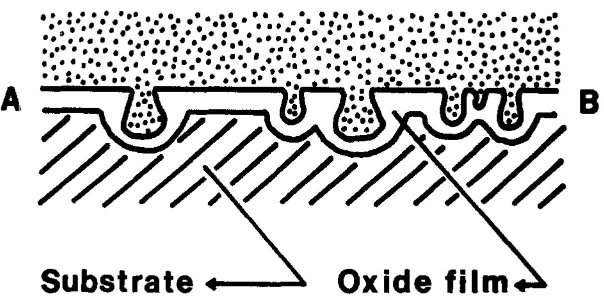

Fig. 12. Schematic representation of cross-section A-B marked on Fig. 9. Approximately to scale.

sponding thick porous layer formation, was observed over grain boundary junctions in the substrate. Such a site is shown in Fig. 13. These structures are, in fact, the "pore colonies" described in detail by Renshaw (17), constituting radial arrays of pores growing outward from a central site. This phenomenon occurs beneath the barrier layer; the two very light spots in the center of the pore colony shown in Fig. 13 are holes in the barrier layer, necessary to continued dissolution of oxide within the colony. Except for these holes the barrier layer over this region is planar and intact.

Discussion

O'Sullivan and Wood (2) have examined in considerable detail the structure of porous aluminum oxide films formed in acidic media and the effect of various anodizing parameters on this structure. Although as noted above other investigators have observed porous structure in films grown in barrier-forming media (8, 10-13) and, indeed, the similarity between films grown in barrier-forming electrolytes and those grown in pore-forming electrolytes (8, 13, 18, 19), no detailed study has previously been performed on the porous structure developed in such media as neutral aqueous ammonium tartrate. The most striking feature of the present study is the degree of similarity between anodic films formed in this electrolyte and those formed in conventional pore-forming environments.

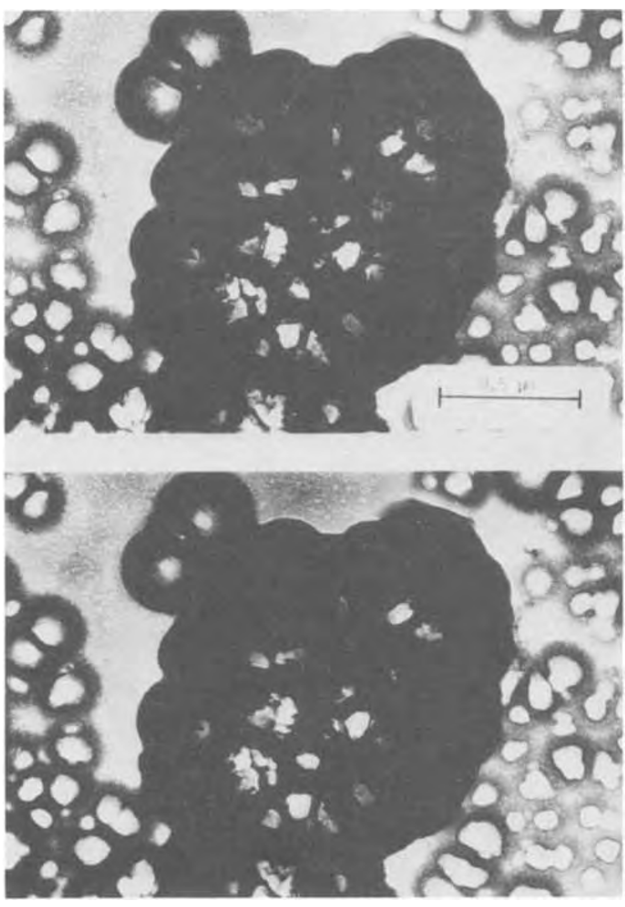

Fig. 13. Stereo transmission electron micrographs of anodic oxide film formed at 50V for 24 hr, showing deep pitting at substrate grain boundary junctions. Tilting angle ± 5°.

Figures 1, 3, and 11 suggest that a period of the order of 90 min elapses prior to initiation of visible pores. According to the mechanism postulated by Hoar and Yahalom (8) the film gradually thickens during this time, the average field finally decreasing to a value that will permit diffusion of protons into the film and initiation of pores. O'Sullivan and Wood (2) do not evoke a critical field for proton diffusion, but suggest that local regions of high current density thicken and spread during this initiation period, leaving relatively thinner sites between them that become pore nuclei. The significance of field-assisted dissolution as the primary mechanism of pore growth is well established (2, 7). It is thus proposed that the field is intensified by a pseudo-spherical geometry of the pore base, causing penetration of the pore and enlargement of its base diameter. The pore wall, being further from the substrate than is the base, experiences only a weak field and dissolves at a proportionately slower rate. Thus the pore base widens as it progresses, creating a pore that may be idealized as a truncated cone whose base is a spherical segment. Similar pore shapes were noted by O'Sullivan and Wood (2), but only under constant current conditions. They attributed this to the increase in voltage with anodizing time and the observation that pore diameter was proportional to voltage. Under constant voltage conditions they observed cylindrical pores terminating in spherical caps. The authors do not believe their findings to be in contradiction to those of O'Sullivan and Wood, but, instead, to represent the drastic difference in time scale of events in barrier-forming *vs.* pore-forming electrolytes, *i.e.,* that the pores depicted in Fig. 9 and 12 are yet in an early stage and that once the pore diameter stabilizes (~32 hr) and the pore depth assumes a linear rate of increase in time the pores will assume a cylindrical shape as indicated by the pore wall uniformity shown in Fig. 2 (32 hr).

O'Sullivan and Wood (2) indicated that rapidly growing pores would alter the field in their vicinity such that adjacent shallower pores would virtually cease to grow. Although these shallow pores would remain, they would become increasingly difficult to resolve optically as the over-all film thickness increased. With both pore diameter and wall thickness proportional to voltage, it followed that the density of pores (per unit area) would also be directly related to voltage. Although the authors do not disagree with the above, they also believe that there is evidence for pore coalescence in Fig. 2 and 9. It is clear that a large pore with the O'Sullivan and Wood "peardrop" shape can undermine a smaller adjacent pore, with eventual collapse of the pore wall separating them. On the other hand, adjacent pores of comparable size may remain essentially stable once oxidation of the substrate metal separating them at the base terminates field-assisted dissolution. Several stages in both the annihilation and stabilizing of pore walls are shown schematically in Fig. 14. Inasmuch as the terminal oxide cell size is 35 $Å\text{-}V^{-1}$ and the terminal pore diameter is 18.5 $Å\text{-}V^{-1}$, the terminal thickness of oxide separating adjacent pores is 16.5 or 8.25 $Å\text{-}V^{-1}$ per cell. Assuming, for want of direct measurement, that the barrier layer at the pore base is comparable to the measured barrier layer exterior to the pores, 12.6 $Å\text{-}V^{-1}$, the cell wall/barrier layer is 0.655, not greatly different from O'Sullivan and Wood's figure of 0.71 for pore-forming media.

Using some simplifying assumptions an estimate of the time-dependence of field-assisted dissolution at the pore base may be calculated. Assuming that the electrolyte is a conductor and the oxide in the basal region of the pore is a portion of a spherical shell, the field

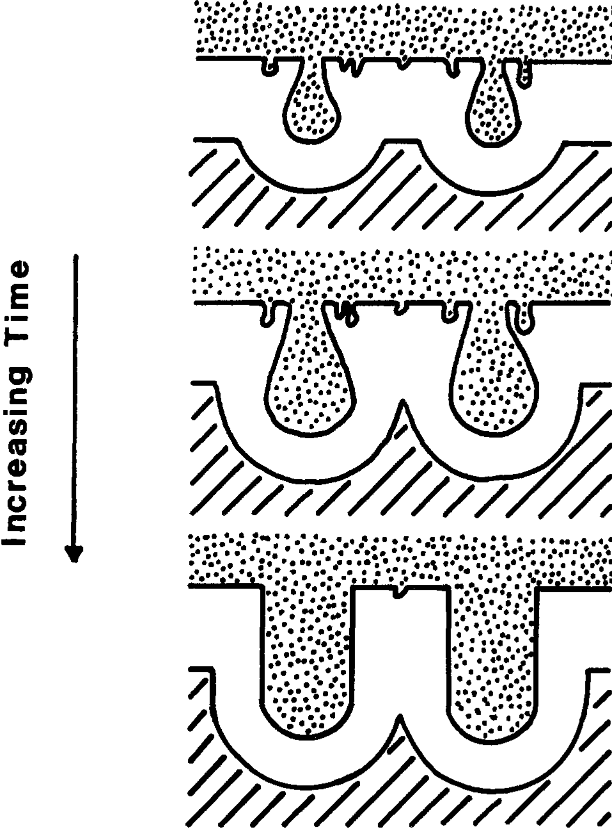

Fig. 14. Schematic representation of pore progression during anodizing, showing coalescence and formation of stable pore walls.

at the oxide/electrolyte interface is

$$E_i = \frac{V}{d}\left(1 + \frac{d}{R_i}\right)$$

where V is the potential drop across the oxide (and thus assumed equal to the formation voltage), R_i is the radius of curvature of the oxide/electrolyte interface, and d is the oxide thickness. The radius R_i is not necessarily the basal pore radius; under steady growth conditions (attainment of terminal pore size) O'Sullivan and Wood (2) demonstrated that normals to the pore axis and pore base defined a minimum angle of

$$\theta = \cos^{-1}\left(\frac{\text{pore radius}}{\text{pore base radius of curvature}}\right)$$

$$= \cos^{-1}\left(\frac{\text{cell wall thickness}}{\text{barrier layer thickness}}\right)$$

which, in their case, was 45°. The authors found this value to be $\theta = \cos^{-1} 0.655 = 49°$ in the present system. Assuming this ratio to be valid during pore enlargement the radius R_i is related to the basal pore diameter D by

$$R_i = \frac{0.5D}{0.655} = \frac{D}{1.31}$$

and the field may be written

$$E_i = \frac{V}{d}\left(1 + \frac{1.31d}{D}\right)$$

Although O'Sullivan and Wood (2) discussed in detail possible mechanisms for field-assisted dissolution, the actual mechanism is unknown as is any empirical dependency on system parameters. Due to this lack, a simple linear dependence of dissolution on field is assumed

$$\frac{dR_i}{dt} = CE_i$$

or

$$\frac{dD}{dt} = 1.31\, C \frac{V}{d}\left(1 + \frac{1.31d}{D}\right)$$

This expression may be integrated to yield

$$\frac{D}{1.31} - d \ln\left(\frac{d + D/1.31}{d}\right) = \frac{CV}{d}(t - t_o)$$

As seen in Fig. 3, this expression is closely followed at 50 and 75V with $CV/d = 9.5$ Å-hr^{-1} or $C = 119.7$ Å^2-hr^{-1}-V^{-1}.

During the period of pore diametral growth the pore depth should be increasing by dissolution at a rate

$$\frac{dh}{dt} = \frac{dR_i}{dt} = \frac{1}{1.31}\frac{dD}{dt}$$

or

$$\frac{h}{D} = \frac{1}{1.31} = 0.764$$

This is readily checked using data from Fig. 3 and 11. The experimental values of the ratio h/D are given in Table I. Thus, the pore depth is seen to increase approximately 108% faster than expected in this simple model. This could be attributed to precipitation of aluminum oxide, dissolved within the pore, on the outer oxide surface. That is, material dissolved from the pore base may simply be transported out of the pore and be deposited on the exterior surface (12, 18, 20), either in hydrous or anhydrous form. The extent to which this occurs is not established; however, the data of Smith (20) show that after the first half-hour of anodizing the aluminum content of the electrolyte ceases to increase, suggesting that despite the continued occurrence of field-enhanced dissolution further aluminum is not removed from the oxide film, but is simply redistributed. Clearly the degree to which this occurs must depend on many factors, among them the pore geometry, relative volume of electrolyte, convective parameters, and solubility parameters. As a rough estimate of the possible magnitude of the effect, the area of the pore base may be compared to the available exterior area. Regarding, for convenience, the pore base as a hemisphere 18.5 Å-V^{-1} in diameter, it has an area of 538 Å^2-V^{-1}. The exterior surface corresponding to each pore is approximately a ring of inner diameter 18.5 Å-V^{-1} and an outer diameter larger by twice the pore wall thickness, or 35 Å-V^{-1}, having an area of 693 Å^2-V^{-1}. Assuming a constant molar volume for the oxide during dissolution and precipitation, the depth increase due to precipitation could be of the order of 538/693 = 0.77, that due to dissolution, or the total depth increase, could be 1.77 of that due to dissolution alone.

An additional estimate of C may be obtained from the observed linear rate of pore depth increase that occurs following stabilization of the pore structure. As above

$$\frac{dh}{dt} = C\, E_i = \frac{CV}{d}\left(1 + \frac{1.31d}{D}\right)$$

Using the empirical values for 50V: $d = 630$Å, $D = 1050$Å, $dh/dt = 54$ Å-hr^{-1}, C is calculated as 381 Å^2-

Table I. Experimentally determined values of h/D

* Measured at 7 hr.

V^{-1}-hr^{-1}, of the same order as the value calculated from the change of pore diameter with time.

It is not easy to be even hypothetically quantitative about the proportionality between terminal pore diameter and formation voltage. The argument regarding the annihilation of small pores, or at least termination of their growth, and the establishment of a stable pore size is qualitative and geometric in nature. For this reason the authors regard the linear relation between formation voltage and pore size as a manifestation of that between formation voltage and steady-state barrier layer thickness. That is, the state at which adjacent pores stabilize diametrically by dissolution of the web of substrate separating them and, hence, do not further enlarge other than in depth is presumably geometrically similar at different formation voltages. Thus, the structural dimensions of the porous oxide would be proportional to the only dimension which is independently controlled, the steady-state barrier layer thickness.

Conclusions

After a detailed electron microscopic examination of anodic films formed on highly pure aluminum in neutral aqueous 3% ammonium tartrate during anodizing times up to 48 hr, it is clear that these films may be distinguished from those formed in conventional pore-forming electrolytes such as sulfuric acid only by the rate at which the porous structure develops, in agreement with previous investigators (8, 18, 19). The mechanism by which pores form in such electrolytes that has appeared most plausible, simultaneous field-assisted dissolution of the oxide and reoxidation (7, 18), offers an equally likely explanation of observations pertaining to pore formation in barrier-forming electrolytes. Indeed, a pore growth rate with time is observed which may, in a semiquantitative way, be explained by the decay of the field at the inner surface of a spherical segment pore base as the pore enlarges, leading to a field-assisted dissolution constant of the order of 120 $Å^2$-hr^{-1}-V^{-1}. A similar order of magnitude, 381 $Å^2$-hr^{-1}-V^{-1}, is estimated from the linear rate of pore depth increase once a stable pore structure is developed. Coalescence of pores during growth is observed and explained by a purely geometrical argument, the undermining of small pores by adjacent, larger pores, and by their decreasing optical significance as the oxide thickens. Similarly, adjacent pores of similar size may form a stable shared pore wall when the substrate separating them has been consumed. Stable pore size and oxide cell size are seen to be proportional to formation voltage and, thus, to the barrier layer thickness as it is customarily defined. This is interpreted as supportive of the concept that the establishment of a stable pore structure is geometrically controlled and, thus, independent of actual dimensions.

The authors found the use of electron stereomicroscopy to provide a powerful tool for structure analysis of thin oxide films. Not only did it provide an accurate means for measuring local film thicknesses and individual pore depths, but provided a clear three-dimensional view of the complex film morphology.

Barrier-Type Aluminum Oxide Films Formed under Prolonged Anodizing

II. Dielectric Characteristics

T. A. Libsch* and O. F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Nonporous anodic aluminum oxide films were potentiostatically formed at 30V and subsequently exposed to neutral aqueous ammonium tartrate for 3000 min at 30V, 10V, and at rest potential. Porous film growth was observed at the formation potential in accordance with Part I. Some factors responsible for the observed stability of the film capacitance and resistance at 30V have been determined by modeling the porous film as a parallel combination of two parallel *RC* circuits. Films tested at 10V thinned slowly by the development of a large number of fine pores at the oxide/electrolyte interface; in addition, pore colonies were observed in the metallic substrate below the thinning film. At rest potential the film developed a nonporous cellular topography, presumably an artifact of a selective dissolution process. The film capacitance at 10V and rest potential has been expressed as film thickness *vs.* time profiles under the assumption of uniform thinning.

A brief survey of the salient contributions to the literature concerning anodic aluminum oxide films is given in the first paper of this two part series (1). While the development of structure in anodic aluminum oxide films at the formation potential, both in pore-forming and barrier-forming electrolytes, is now reasonably well characterized, very little work has been done on the structural changes in such films resulting from reduced potentials. The phrase reduced potential is used here to indicate a film tested for some time at a potential below its formation potential.

O'Sullivan and Wood (2) formed porous aluminum oxide films at a constant potential of 115V for 30 min in 0.4M phosphoric acid at 25°C. Upon reducing the potential to 85V, they observed the following structural changes: (*i*) the barrier layer at the pore bases started to thin immediately, (*ii*) new pores were nucleated in this thinning barrier layer, and (*iii*) these pores increased in diameter until a new steady-state pore population density characteristic of the lower voltage was reached. Renshaw (3) formed 340Å thick nonporous films by anodizing aluminum in 3% ammonium tartrate (pH 5.5) at a constant potential of 25V for 1 min. These films were subsequently tested at a reduced potential of 15V in a 10% chromic acid electrolyte. The nonporous layer was observed to impede the formation of the porous film which normally would be formed in the chromic acid electrolyte. Hemispherical pore colonies, however, the pores of which developed radially from flaws or low resistance pathways present in the nonporous layer, were found to undermine the nonporous film. Edwards and Keller (4) had previously reported pore colony formation beneath barrier-layer anodic aluminum oxide films. These investigators, however, created artificial linear pores by intentionally cracking the nonporous anodic oxide film.

The purpose of the current investigation was to determine what structural alterations occur in preformed nonporous anodic aluminum oxide films upon exposure to neutral aqueous ammonium tartrate for a prolonged period (3000 min) at potentials equivalent to and less than the formation potential and to relate these alterations to changes in the film capacitance and resistance.

Experimental Procedure

Cylindrical specimens were machined from aluminum rod of 99.999% purity, mechanically polished using 240, 320, 400, and 600 grit metallographic papers, and chemically polished (5) by immersion in: (*i*) a 3 weight per cent (w/o) sodium hydroxide solution at 75°C for 1 min and (*ii*) a 50 w/o nitric acid solution at 75°C for 2 min. Specimens were ultrasonically rinsed in double distilled water for 10 min following exposure to each chemical polishing solution. Electrolytes were prepared from reagent grade chemicals and double distilled water. The anodizing electrolyte was an aqueous 0.17M[1] ammonium tartrate solution with pH adjusted to 7 by the addition of several drops of dilute ammonium hydroxide. The testing electrolyte was either the anodizing electrolyte or a neutral 1M ammonium tartrate solution.

The electrode assembly, comprised of two Teflon gaskets compressed against the parallel faces of a prepared specimen, and the electrochemical cell used for anodizing and testing have been described previously (6). The cells were maintained at a constant temperature of 30.0° ± 0.3°C during both anodizing and testing by a conventional water bath. Anodic films were formed by gradually increasing the potential between the specimen and platinum gauze counterelectrode in such a manner that the current remained constant at 0.75 mA/cm^2 until the desired potential of 30V was obtained. This potential was maintained for 45 min, during which time the leakage current normally decayed to less than 20 μA/cm^2; specimens exhibiting leakage currents in excess of this value were discarded. Based on the anodizing constant of 12.0 Å/V reported by McMullen and Pryor (7) for anodic aluminum oxide films formed in neutral ammonium tartrate, this procedure created nonporous films 360Å thick.

These films were tested at 30V, 10V, and at rest potential for a period of 3000 min. In the case of cells tested at 30V, anodizing blended into testing in that the anodizing electrolyte was not changed and the potential was continuous with time. In the case of cells tested at 10V and rest potential, the 30V potential was removed at the conclusion of the anodizing period and the electrolyte changed from 0.17M to 1M. This change was made to correct a problem discovered during testing at 30V wherein the procedure for calculating film dielectric data from cell data, described below, yielded erroneous values at high frequencies in the more dilute electrolyte. At the conclusion of a test, the film was rinsed with double distilled water, air dried, and scribed into small squares which were detached from the aluminum substrate by immersion in a saturated

Key words: aluminum, anodic oxidation, impedance, porosity.

[1] 0.17M ammonium tartrate is equivalent to 3 w/o.

aqueous mercuric chloride solution. Stripped film sections were rinsed twice in double distilled water, mounted on 200 mesh copper grids, and examined in the transmission electron microscope. At 10V, several specimens were tested for times shorter than the 3000 min period in order to construct a sequence of transmission electron micrographs.

During the test period, the dielectric properties of the electrochemical cells were recorded at 0.5, 1, 5, 10, 20, and 50 kHz utilizing a capacitance measuring assembly comprised of a General Radio Type 1310-B oscillator, a Type 1615-A capacitance bridge, a Type 1232-A null detector, and a Sorenson Model QHS 100-.2 power supply. The dielectric properties of cells subjected to 30 and 10V were also monitored for 150 min after the potential was removed at the end of the 3000 min test period.

Results

Calculation of the series resistance of the electrolyte and subsequent correction of the cell data involve the following steps: (*i*) calculation of the series resistance of the cell (R_{s3}) at several frequencies from[2]: $R_{s3} = D_3/\omega C_{s3}$, where ω represents the angular frequency in rad/sec; (*ii*) determination of the series resistance of the electrolyte (R_{s2}) from a plot of R_{s3} *vs.* ω^{-1} at the point where the reciprocal frequency equals zero (8); (*iii*) calculation of the series resistance of the film (R_{s1}) by subtraction of R_{s2} from R_{s3} at any frequency; and (*iv*) calculation of the parallel capacitance (C_{p1}) and resistance (R_{p1}) of the film from the expressions: $C_{p1} = C_{s1}/[1 + (\omega R_{s1}C_{s1})^2]$ and $R_{p1} = [1/(\omega C_{s1})^2 R_{s1}] + R_{s1}$, where the series capacitance of the film (C_{s1}) and that of the electrochemical cell are equivalent.

The dielectric data employed to determine the electrolyte resistance comprised the initial measurements recorded after the application of the testing potential since, at this time, the film may be regarded as having an essentially parallel plate configuration inasmuch as pore development does not commence immediately (1). At longer exposure times such structural alterations may result in nonlinearity of the plots mentioned in (*ii*) above (9).

Figure 1 illustrates the average initial series resistance of electrochemical cells *vs.* reciprocal frequency at each test potential. These plots were constructed from data points (not shown) having reciprocal frequency values of 200 × 10^{-5}, 100 × 10^{-5}, 20 × 10^{-5}, 10 × 10^{-5}, 5 × 10^{-5}, and 2 × 10^{-5} Hz^{-1}. The data points shown in this and subsequent figures are only for the purpose of illustrating typical scatter. Note the high value of electrolyte resistance (y-intercept) and the curvature of the plot at 30V, to be discussed later. The average plots at 10V and rest potential are virtually identical and have not been distinguished. While the error bars on this line encompass the data from both potentials, the data scatter at 10V is significantly greater than that at rest potential for the higher values of reciprocal frequency.

Figure 2 illustrates the average parallel capacitance and resistance of films tested at 30V. As defined here, zero exposure time corresponds to the end of the 45 min anodization; the 30V potential was removed after 3000 min exposure. In this and subsequent figures of film data, the time scale has been expanded by a factor of five at the conclusion of the 3000 min test period. The dashed curve in Fig. 2 shows typical anomalous behavior arising from the correction procedure described above at high frequencies for cells having a low concentration electrolyte. The important characteristics in Fig. 2 are the negligible data scatter, the time stability of the data, and the frequency dependent, but essentially time independent, change in capacitance and resistance upon removal of the potential. Figure 3 shows typical transmission electron micrographs of the anodic oxide film as-anodized and after 3000 min at 30V, illustrating porous film growth in accordance with Part I.

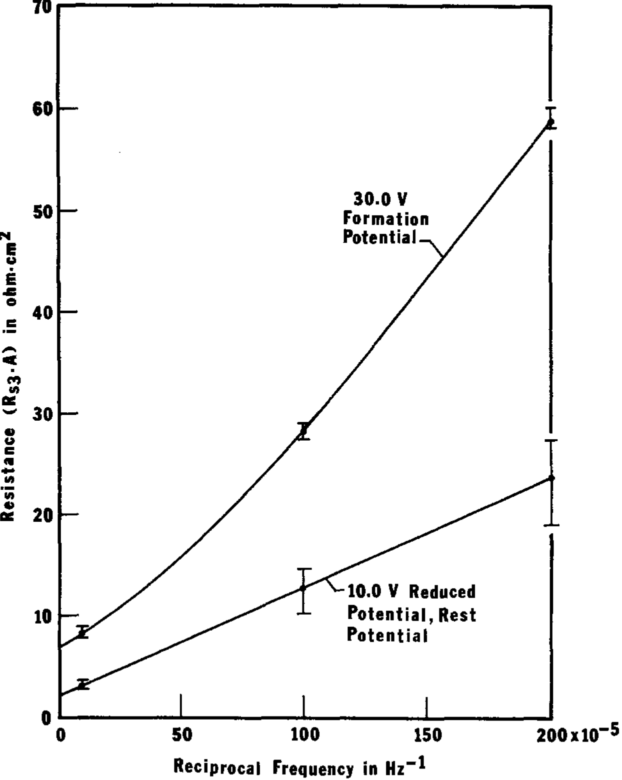

Fig. 1. Average initial series resistance of electrochemical cells tested at 30V, 10V, and rest potential *vs.* reciprocal frequency. Error bars typical.

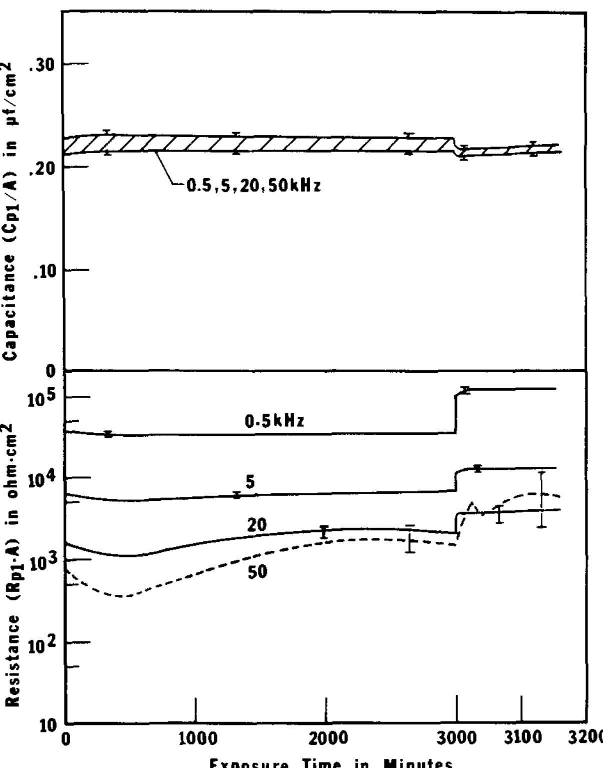

Fig. 2. Average parallel capacitance and resistance of anodic oxide films tested at 30V as a function of exposure time and frequency. The applied potential was removed at 3000 min. Error bars typical.

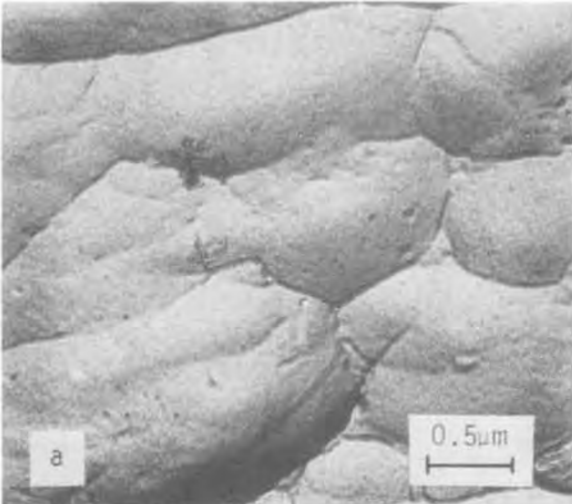
Figure 4 portrays the average parallel capacitance and resistance of films tested at 10V. The important characteristics of this figure are the large data scatter,

[2] The series capacitance (C_{s3}) and dissipation factor (D_3) of the cells were recorded from the bridge readouts.



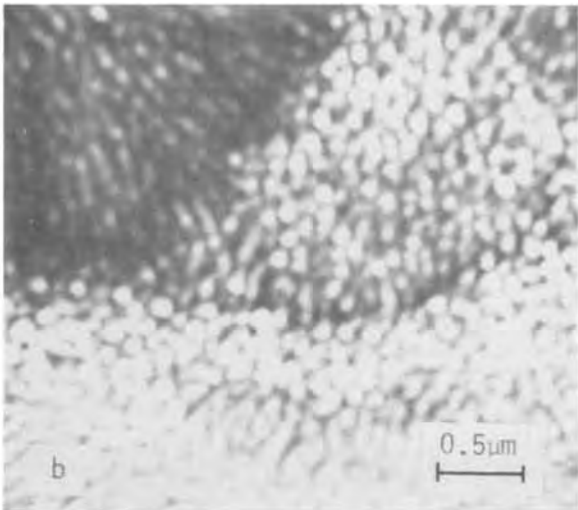


Fig. 3. Transmission electron micrographs of the anodic oxide films: (a) as-anodized, and (b) tested for 3000 min at 30V.

a time dependent increase in capacitance and associated decrease in resistance, and a frequency dependent, but essentially time independent, change in the capacitance and resistance upon removal of the potential that is less than that of cells tested at 30V. As mentioned previously, several specimens were tested at 10V for times shorter than the 3000 min test period in order to obtain a set of transmission electron micrographs illustrating the progressive change in the film structure. Due to the large variation in dielectric data in cells tested at this potential, the micrographs, shown in Fig. 5, have been placed in a capacitance sequence rather than in a time sequence. Figure 3a, which is the as-anodized film, may be considered as the initial micrograph in this capacitance sequence, having a capacitance of 0.202 μf/cm^2 at 0.5 kHz.

Figure 6 illustrates the average parallel capacitance and resistance of the anodic films tested with no applied potential. The important characteristics in this figure are the negligible data scatter and an increase in capacitance and decrease in resistance which are less than those observed in the film data at 10V (Fig. 4). Figure 7 is a typical transmission electron micrograph of the film after 3150 min of testing at rest potential illustrating a different topography and a lack of the dark circular spots which were observed in films tested at 10V (Fig. 5).

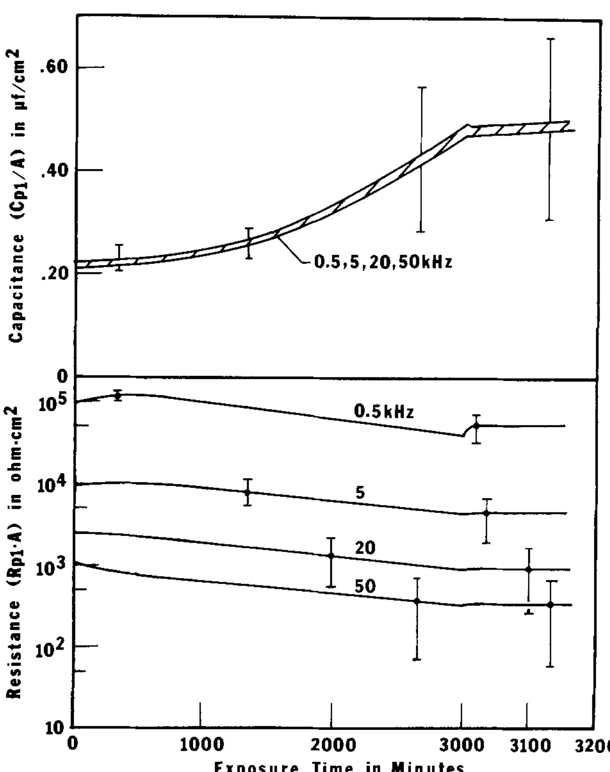

Fig. 4. Average parallel capacitance and resistance of anodic oxide films tested at 10V as a function of exposure time and frequency. The applied potential was removed at 3000 min. Error bars typical.

Discussion

Films tested at the 30V formation potential.—Cell resistance during 30V tests showed a nonlinear dependence on reciprocal frequency, in contrast to measurements at the lower potentials. The linear dependence seen at 10V and at the rest potential is reported as an indication of good cell geometry (9); however, cell geometry per se was a constant parameter in these tests. The curvilinear behavior at 30V may be due to (*i*) field-induced changes in the dielectric properties of the oxide film (10), (*ii*) nonuniformity of the dielectric properties of the oxide with respect to position on the substrate surface, or (*iii*) a significant capacitive contribution from the lower concentration electrolyte used at 30V. (The series resistance of the electrolyte, determined as the infinite frequency intercept in Fig. 1, is 6.89 ohm · cm^2 for the 0.17M electrolyte and 2.08 ohm · cm^2 for the 1M electrolyte.) The data on hand do not permit meaningful comment on the contributions attributable to these factors.

The low concentration electrolyte also caused large frequency dispersions of capacitance and resistance in cell measurements involving freshly anodized films. The previously outlined procedure for correcting for the presence of the electrolyte reduced these dispersions, but proved somewhat inadequate above frequencies of approximately 20 kHz, as shown by the anomalous behavior of the dashed curve in Fig. 2. Similar problems have been encountered using alternate correction methods (6). These problems did not occur with the 1M electrolyte.

Films tested at 30V for 3000 min (Fig. 3b) are observed to possess a high degree of porosity in agreement with previous workers (1, 11, 12). The linear appearance of some pores is due to the irregular substrate features, created by the sodium hydroxide-nitric acid chemical polish. Richardson, Wood, and Breen (13) have examined the surface of 99.99% aluminum at various stages during a similar surface treatment and reported that individual cells or "saucers" were created in the aluminum by the sodium hydroxide solution, with the nitric acid solution removing much of the ridges separating these saucers.

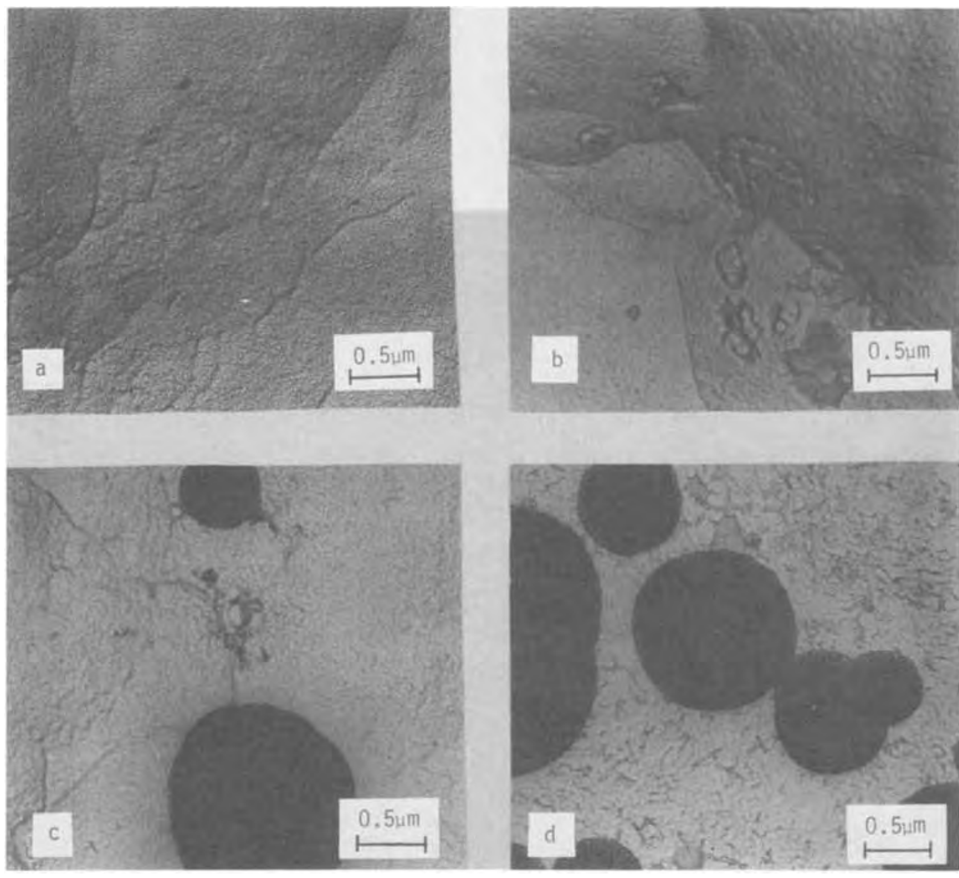

Fig. 5. Capacitance sequence of transmission electron micrographs for anodic oxide films tested at 10V. The parallel capacitance (C_{p1}/A), measured at 0.5 kHz, of the film for each micrograph is: (a) 0.227, (b) 0.272, (c) 0.300, and (d) 0.661.

The initial average series dielectric constant (κ_s) and resistivity (ρ_s) of the anodic film at 30V and rest potential were calculated from the initial average series film capacitance and resistance by the expressions: $\kappa_s = C_{s1}d_o/\epsilon_o A$ and $\rho_s = R_{s1}A/d_o$, where d_o, A, and ϵ_o represent the initial film thickness, the film area, and the permittivity constant, respectively. The dielectric constant and resistivity are often reported in the parallel configuration; κ_s and ρ_s were, therefore, transformed to the parallel dielectric constant (κ_p) and resistivity (ρ_p) by the expressions: $\kappa_p = \kappa_s/[1 + (\omega\rho_s\kappa_s\epsilon_o)^2]$ and $\rho_p = [1/(\omega\kappa_s\epsilon_o)^2\rho_s] + \rho_s$. These values are tabulated *vs.* frequency in Table I. It is noted that Ord, Hopper, and Wang (14) have reported the low frequency dielectric constant of tantalum, niobium, and tungsten oxides to decrease linearly with increasing field, *i.e.*, opposite to the trend for aluminum oxide in Table I. There is, however, no *a priori* reason to expect a decrease.

The authors believe that the potential dependent changes in dielectric data (Fig. 2 and 4) can be explained by the presence of a transitory population of ionic defects. While a significant anodic potential is

applied, there is a finite population of Al^{+3} ions in the oxide, contributing to the a-c as well as d-c conductance. Assuming a constant field across the thickness, it is reasonable to presume that the population density is also independent of position in the film. This population is not stable, however, since under the very high field ($\sim 10^7$ V/cm) the Poisson-Boltzmann space charge would be of negligible thickness. Hence when the potential is removed, the Al^{+3} ion population in the film will be quickly drained to the oxide/electrolyte interface, drastically reducing the a-c and d-c conductance. A similar argument would hold for electronic defects in the film produced by the anodic reaction. The changes in parallel film capacitance and resistance upon removal of the 30V potential (Fig. 2) are listed *vs.* frequency in Table I. These changes have been compared with those which would occur if the potential were removed immediately after its application, *i.e.*, at the time when the film has an essentially parallel plate configuration (compare Fig. 2 and 6). Alterations in the film's structure and distribution of dielectric constant and resistivity account for the minor differences observed.

Dekker and Urquhart (15) have previously determined that the 60 Hz capacitance of porous anodic aluminum oxide films formed by anodizing at a constant current of 8 mA/cm^2 in a 5.4 volume per cent (v/o) sulfuric acid solution are independent of time after 1 min of anodizing; the final film capacitance, however, was reported to be a function of current density and solution concentration and composition. No analysis of these results was attempted, however. In the current investigation, the authors have represented the thickening anodic film by a parallel combination of two parallel *RC* circuits; one circuit representing the porous area of the film, the other the thicker film adjacent to the pores. An a-c circuit analysis (16) for this analog yields for the series film capacitance and resistance: $C_{s1} = -a/bc\omega \sin \theta_1$ and $R_{s1} = bc \cos \theta_1/a$ where

$$a = [(b \cos \theta_2 + c \cos \theta_3)^2 + (b \sin \theta_2 + c \sin \theta_3)^2]^{1/2}$$

$$\theta_1 = -\theta_2 - \theta_3 + \tan^{-1} [(b \sin \theta_2 + c \sin \theta_3)/(b \cos \theta_2 + c \cos \theta_3)]$$

$$b = d_o[1 + (\omega\kappa_s\epsilon_o\rho_s)^2]^{1/2}/\omega\kappa_s\epsilon_o A_1$$

$$c = d[1 + (\omega\kappa_s\epsilon_o\rho_s)^2]^{1/2}/\omega\kappa_s\epsilon_o(A - A_1)$$

$$\theta_2 = \tan^{-1} (1/\omega\epsilon_o\kappa_s\rho_s)$$

$$\theta_3 = \tan^{-1} (1/\omega\epsilon_o\kappa_s\rho_s)$$

The parallel film capacitance and resistance were subsequently calculated from equations previously presented. The parameters d and A_1 represent the film thickness and the area of the pores within the area A. In this model, the fractional area of pores (A_1/A), determined from Fig. 3b to be 0.42, was assumed constant.

The analog presented is not an exact model of the thickening film due to lack of a definitive relation between film thickness and time and the unknown distribution of dielectric constant and resistivity within the oxide. In respect to the former deficiency, the parallel film capacitance and resistance were evaluated as a function of the thickness of the outer porous layer, *i.e.*, $d - d_o$, in lieu of time as an independent parameter. In respect to the latter deficiency, three cases were evaluated: case I, the film has the dielectric constant and resistivity values at rest potential (Table I); case II, the film has the dielectric constant and resistivity values at 30V (Table I); and case III, the film below the pores has the dielectric constant and resistivity values at 30V, while the remainder of the film has the values at rest potential. In case III, κ_s and ρ_s in the expressions for b and θ_2 are those at 30V; κ_s and ρ_s in c and θ_3 are those at rest potential.

Figure 8 illustrates the results of this model; the parallel film capacitance, being virtually identical in each case, has been illustrated only for case III. The parallel film capacitance and resistance of the model are observed to approach a stable value rapidly as the film thickens. The changes in capacitance and resistance of the model at low $d - d_o$ values, which are not present in the film data in Fig. 2, may reasonably be credited to the initial growth and coalescence of pores as reported in Part I (1). Four conclusions concerning the stability of the film data in Fig. 2 can be drawn from the model: (*i*) the film at the pore bases has a thickness controlled by the anodizing constant reported previously, (*ii*) the porous film area dominates the over-all dielectric properties, (*iii*) the uneven distribution of dielectric constant and resistivity contributes significantly to the stability of the data,

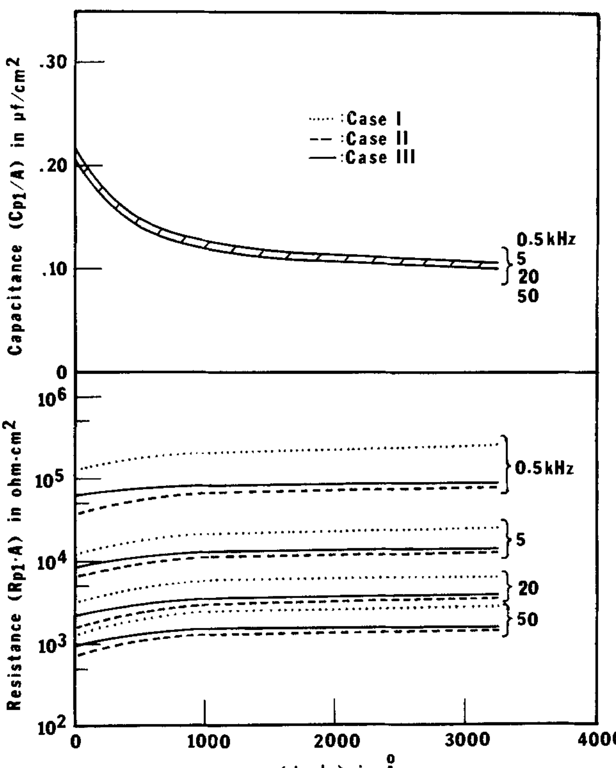

Fig. 8. Results of electrical analog used to represent anodic oxide films tested at 30V. Case I: The film has the dielectric constant and resistivity values determined at rest potential. Case II: The film has the dielectric constant and resistivity values determined at 30V. Case III: The porous film area has dielectric constant and resistivity values determined at 30V, while the thicker film outside the pores has the dielectric constant and resistivity values determined at rest potential.

and (*iv*) a negligible frequency dispersion of capacitance accompanies porous film growth of this type. The minor frequency dispersion of capacitance observed in Fig. 2 is in sharp contrast to that previously reported by Libsch and Devereux (6). In that investigation, nonporous anodic aluminum oxide films tested in acidic electrolytes developed a porous film structure by the radial growth of pores without film thickening. This manner of porous film development creates a significant increase in and a broad frequency dispersion of capacitance.

Films tested at the 10V potential.—The topographical features noted in the films tested at 10V (Fig. 5) are: (*i*) the scalloped form of the film, discussed previously, (*ii*) the development of a large number of small pores at the oxide/electrolyte interface believed to be created by a decrease in the local *p*H value of the electrolyte, caused by the applied field as suggested by Plumb (17), and (*iii*) the development of pore colonies at the substrate/oxide interface (dark circular spots). The pore colonies often, although not always, form below the film at the network of ridges created by the juncture of the saucer shapes on the aluminum surface. These sites in the film may be more defective than average due to impurity concentrations in the substrate or thinner than average due to enhanced oxide dissolution at the small radius of curvature of the ridge peak, resulting in higher anodic current in these regions, effectively lowering the *p*H of the electrolyte adjacent to the film in comparison to the bulk solution. These pore colonies are identical to those observed by Renshaw (3) and similar to those reported by Edwards and Keller (4).

A film thickness *vs.* time profile (Fig. 9) was determined under the assumptions that the film thins uniformly in a parallel plate configuration and that the film dielectric constant is independent of film thickness. The former assumption is expected to be reasonably accurate since the pores at the oxide/electrolyte interface are numerous, *i.e.*, a negligible amount of pore wall material exists at this interface, and the pore colonies at the substrate/oxide interface encompass a negligible area of the film during the majority of the test period. The validity of the latter assumption is clearly difficult to ascertain. The data points in Fig. 9 were calculated from the average 0.5 kHz series film capacitance by the expression $d = \kappa_S \epsilon_0 A / C_{S1}$, the average initial 0.5 kHz series dielectric constant having a value of 9.12. Figure 9 shows that the data obtained at 10V are consistent with an essentially constant rate of thinning of 1.42×10^{-13} m/sec (5.1 Å/hr) following an induction period of approximately 1000 min.

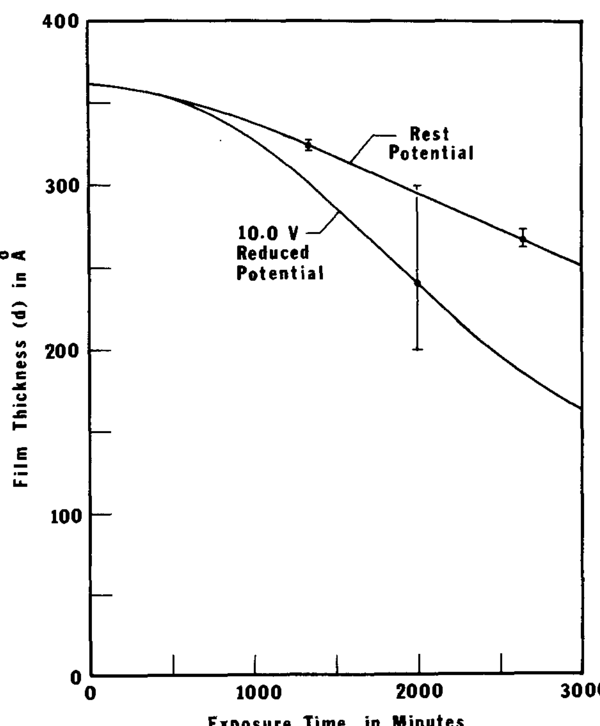

Fig. 9. Average film thickness as a function of exposure time for cells tested at 10V and at rest potential. Error bars typical.

Each of the specimens tested at 10V was examined microscopically to determine the cause of poor reproducibility in the dielectric data (Fig. 4). The two specimens with greater changes were observed to have a greater area encompassed by pore colonies. While the presence of pore colonies is not expected to significantly alter the dielectric behavior, it is indicative of greater film thinning, to which the anomalous dielectric behavior is attributed.

Films tested at rest potential.—The films tested at rest potential (Fig. 7) are observed to have the scalloped shape as in the 30 and 10V cases, to be composed of an array of small apparently nonporous cells, and to be entirely free of pore colonies. The cellular pattern is presumed an artifact of a selective dissolution process rather than a genuine cellular structure as reported by Franklin (18) and Stirland and Bicknell (19) in films formed at high voltage in a boric acid-borax electrolyte. The time-dependent nature of the film data (Fig. 6) contradicts Plumb's (17) statement that neither ammonium tartrate nor potassium sulfate electrolytes will dissolve aluminum oxide by simple contact without current flow.

A thickness *vs.* time profile (Fig. 9) determined under the assumptions and in the manner previously described, shows the average rate of thinning after a 1000 min induction period to be constant at 6.94×10^{-14} m/sec, *i.e.*, approximately one-half the average rate of films tested at 10V.

Summary and Conclusions

Anodic films tested at the 30V formation potential thickened into a porous structure similar to that of porous films formed in aggressive electrolytes; the rate of pore formation, however, being markedly less in accordance with the results of Part I. Films tested at 10V thinned slowly by the development of a large number of fine pores at the oxide/electrolyte interface; in addition, pore colonies were observed to develop at the substrate/oxide interface, primarily at surface irregularities created by substrate preparation. Films tested at rest potential were observed to have a nonporous cellular topography, this topography resulting from a slow thinning process.

The time independent nature of the film capacitance and resistance observed at 30V was examined by modeling the porous film as a parallel combination of two parallel *RC* circuits. The results of this model show that: (*i*) the film at the pore bases has a thickness governed by the anodizing constant, (*ii*) the porous film area dominates the over-all dielectric properties, (*iii*) an uneven distribution of dielectric constant and resistivity contributes significantly to the stability, and (*iv*) a negligible frequency dispersion of capacitance accompanies this type of porous film growth. The capacitance increases and resistance decreases of films tested at 10V and rest potential are consistent with uniform thinning. The thinning rate in both cases was found essentially linear following an induction period of approximately 1000 min, the average rate at 10V (1.42×10^{-13} m/sec) being approximately twice the average rate at rest potential. Potential dependent changes in the capacitance and resistance of the film at 30 and 10V have been explained by the flow of a transitory population of ionic defects to the oxide/electrolyte interface.

Dielectric Anisotropy in Amorphous Ta_2O_5 Films

Peter W. Wyatt

Bell Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

The capacitance of Ta-Ta_2O_5 thin-film capacitors changes by the order of 1% when an electric field is applied across the dielectric. The dependence of capacitance on field is a potentially useful tool for studying the fundamental properties of this device. The capacitance-field curve is asymmetric which suggests that an interface effect might be involved. In this paper it is shown that the *C-E* curve at liquid nitrogen temperature is independent of oxide thickness. This independence holds whether the oxide was produced by simple anodization or by anodization followed by chemical thinning. It is argued that interface effects cannot account for these experimental results, so therefore the *C-E* dependence must result from bulk effects. It is suggested that local structural anisotropy, produced by the ionic current responsible for anodization and frozen in when the field is removed, is responsible for the asymmetry of the *C-E* curve.

Hybrid integrated circuits based on Ta thin films are becoming increasingly important in the Bell System. The Ta film capacitor is one of the major components in many of these circuits. It has long been known that these capacitors are voltage dependent (1), but the dependence is small enough that it would not seriously affect circuit operation in any but the most critical applications. It is, for example, many times smaller in its working voltage range than that of a solid Ta capacitor. Perhaps for this reason the voltage dependence has received little attention. The present study was made in order to use the voltage dependence as a source of information about the physical processes which are active in the capacitor and which determine its performance.

The small-signal capacitance was measured as a function of slowly varying bias voltage for a range of measurement parameters using capacitors made with several variations on the basic process. These experiments clearly indicate that the capacitor responds in several different ways simultaneously when a d-c voltage is applied, which leads to considerable confusion in data analysis. The results are somewhat simplified at low temperature, so this paper is limited to work at liquid nitrogen temperature, 77°K.

Key words: capacitors, anodization, interface, ellipsometry.

This study divides naturally into two segments. The first, presented in this paper, is the question of whether the voltage dependence is produced by effects involving one of the metal-insulator interfaces or alternatively by effects distributed throughout the insulator. We will find that an interface model cannot account for the observed behavior and therefore will conclude that the voltage dependence must arise from bulk processes. Because the capacitance is not symmetric about zero voltage, we will conclude that the anodic oxide is anisotropic despite its amorphous structure. The second segment of the study, to be presented in a later paper (2), considers how many bulk processes are involved and what their properties are.

The next two sections describe sample preparation and measurement. Then a general interface model is introduced, and predictions are derived from it. The pertinent experiments to test these predictions are summarized, and in the last section the disagreement between prediction and experiment is discussed. It is concluded that interface effects cannot account for the data, and a qualitative explanation for the apparent bulk anisotropy is suggested.

Sample Fabrication

A typical sample is shown in cross section in Fig. 1. A Ta film 500Å thick is deposited by d-c sputtering in argon on a glass substrate and oxidized thermally to produce a protective layer of Ta_2O_5. A second Ta film, 5000Å thick, is then d-c sputtered onto this underlay. The Ta contains about 1 atomic per cent (a/o) nitrogen, an impurity which is conventionally added as a dopant in the sputtering gas to improve capacitor performance (3). Sputtering conditions are such as to produce the β (tetragonal) crystal structure (4). The Ta film forms one electrode of the capacitor and is oxidized to produce the dielectric.

The oxidation is done anodically in dilute citric acid [0.01 weight per cent (w/o) in water] at room temperature using a Ta sheet cathode. A constant current of 0.16 mA/cm² is applied until the desired anodization voltage, V_A, is reached, and this voltage is then held constant for a soak period, t_s. Standard values, assumed in Fig. 1, are 230V and 1 hr, but these parameters were varied in the present experiments as discussed below. It is well known that this procedure produces an amorphous stoichiometric film of Ta_2O_5 (5). The nitrogen contained in the Ta is distributed nonuniformly in the oxide (6),[1] but these experiments show that its presence does not affect the $C(V)$ characteristic (2).

The counterelectrode is a round dot of NiCr backed by Au which is evaporated through a metal mask by electron beam heating. The area is 0.1 cm². The resulting capacitor, for $V_A = 230V$ and $t_s = 1$ hr, has capacitance and dissipation factor at 1 kHz of 5.8 nF, and 0.0025, respectively, at room temperature, and 5.5 nF, 0.0012 at 77°K.

[1] Auger analysis by J. M. Morabito indicated about 1 a/o N in the Ta, with the N in the oxide film confined to the 70-80% of the oxide nearer the Ta. This subject is discussed for samples with higher N concentration in Ref. (6).

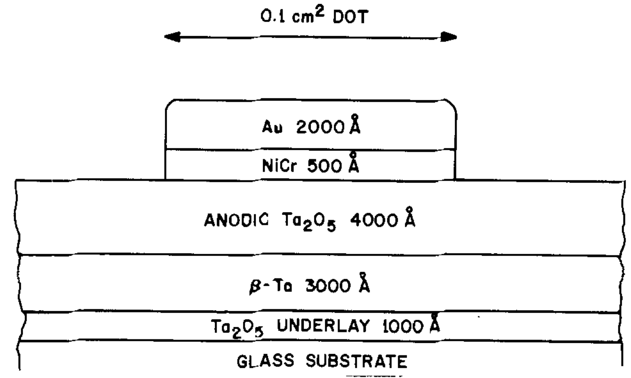

Fig. 1. Cross section of a Ta film dot capacitor

In this study it was necessary to prepare samples of various oxide thicknesses by two different techniques. The first experiment used the usual technique of varying the anodization voltage. The anodization conditions and oxide thicknesses for this experiment are summarized in Table I. Six voltages were used, 50-300V in 50V steps. The current density was the same for all six samples, 0.16 mA/cm². The soak period was varied in proportion to the voltage, with t_s in minutes equal to ¼ the anodization voltage in volts. This is important because the asymmetry of the $C(V)$ characteristic, discussed below, depends on the soak time (2). It means that the fraction of oxide grown at reduced current density is the same for the different thicknesses.

Oxide thickness was measured with an ellipsometer (O. C. Rudolph and Sons, Type 43603-200E) using light with 5461Å wavelength. Polarizer and analyzer readings were taken in zones 1 and 3 (7) and averaged. An optically uniform, nonabsorbing oxide was assumed, and this assumption was confirmed by the observation that the points fall on the same curve for different cycles of the ellipsometric parameters. Fitting the data for six thicknesses to calculated curves gives thicknesses of 900-5400Å with an oxide index of refraction of 2.24 ± 0.02. The Ta film index of refraction is not accurately determined, since many values fit equally well. The value 2.98 − i 3.29 has been taken in this work, since it leads to a calculated thickness which is directly proportional to the anodization voltage, $d = KV_A$, with $K = 18.02 \pm 0.02$ Å/V. Choosing other values of the Ta index does not significantly affect the results discussed here. The index values (8) and K value (6) determined here are consistent with earlier work.

In the second experiment the Ta was anodized as usual, but the oxide was then thinned by chemical etching to produce the desired thickness. The Ta was anodized to 230V with a 1 hr soak period. In order to reduce weak spots, the films were anodically back-etched at room temperature in a solution of 0.02% NH_4Cl in methanol for ~ 15 sec, reaching a voltage of ~ 90V. This treatment does not affect the vast majority of the oxide area, but it penetrates through weak spots and etches the Ta underneath, thus reducing the number of flaws in the finished capacitor (9). The films were then anodized in the citric acid for a second hour at 230V. Thus the total soak period was twice the usual one.

Oxide thinning was done at room temperature in a vigorously stirred solution of 470g of 49% HF plus 190g of NH_4F (nearly saturated) (10). The etchant attacks the glass substrate as well as the Ta_2O_5 and Ta, so it became contaminated with numerous impurities as the experiment progressed, but this had no apparent effect. The etch time for each sample is given in Table II. After thinning and a long rinse in deionized water the samples were anodically back-etched again for ~ 10 sec.

This thinning procedure results in a very uniform oxide thickness, as judged by interference color, over the vast majority of the area. However, the HF-NH_4F etchant attacks flaws in the oxide at a much higher rate, creating pinholes, and then etches some of the Ta underneath. The NH_4Cl backetch is intended to reduce this problem, but it cannot be eliminated. The result is capacitors with very low breakdown voltages.

Table I. Anodization conditions for the first experiment

Anodization voltage (V)	Soak time (min)	Thickness (Å)
50	12.5	900
100	25	1800
150	37.5	2700
200	50	3600
250	62.5	4500
300	75	5400

Table II. Properties of the thinned samples

Dielectric etch time (min)	Dielectric thickness (A)	Reanodization voltage (V)
0	4130	180
20	3430	150
30	2980	130
40	2370	105
45	2010	90

In order to reach the high voltages needed for this experiment, it was necessary to reanodize in citric acid after thinning. Each sample was reanodized for 10 min at a field of 4.4 MV/cm, which is 80% of the 5.5 MV/cm field which exists at the end of the soak period in a standard anodization. (During the constant-current part of the anodization the field is about 6 MV/cm). The reanodization grows new oxide in the weak spots, allowing the measurement to be made, but the field is not high enough to significantly affect the good oxide. This point is considered further in the Discussion section. The good oxide makes up nearly all the area, and hence dominates the capacitance measurement.

The oxide thickness after thinning was measured with the ellipsometer. The points fell on the same calculated curve as the previous samples, indicating that the oxide index of refraction is uniform within $\pm$ 0.04 despite the nonuniform nitrogen distribution. The thickness and reanodization voltage of each sample are given in Table II.

Measurements

Contact to the counterelectrode is made with a gold-plated, blunt-tipped spring probe which exerts very little force. There is no evidence of any damage by this probe, and measurements made on samples with etched patterns, which do not require such a probe, give essentially the same results. The probes are mounted in a Teflon block and connected via coaxial cable to the measurement system. The sample assembly is immersed in liquid nitrogen.

The measurement system is shown schematically in Fig. 2. The General Radio 1654 impedance comparator measures the magnitude and phase of the impedance difference, ΔZ, between the unknown capacitor and a variable RC standard using a small a-c signal. The signal was $1V_{rms}$ at 1 kHz for all samples except for the thinnest oxide ones, where it was $0.3V_{rms}$. The magnitude of the impedance difference is expressed as a percentage of the standard impedance, Z_o. The phase angle is small enough ($\lesssim$ 0.002) that $|\Delta Z/Z_o|$ is essentially equal to $|\Delta C/C_o|$, the normalized change in capacitance. A pair of Kepco OPS 500 power supplies, connected as a bipolar integrator, provide a variable-rate linear ramp voltage from -200 to $+200$V. The voltage rise rate was adjusted to give an approximately constant rate of increase of electric field for samples of all thicknesses. The rise rate has only a very small effect on the $C(V)$ curve (2) so precise adjustment is not necessary. The bias is applied across both the unknown and standard capacitors, but the air and mica standards have such a small voltage coefficient that it need not be considered.

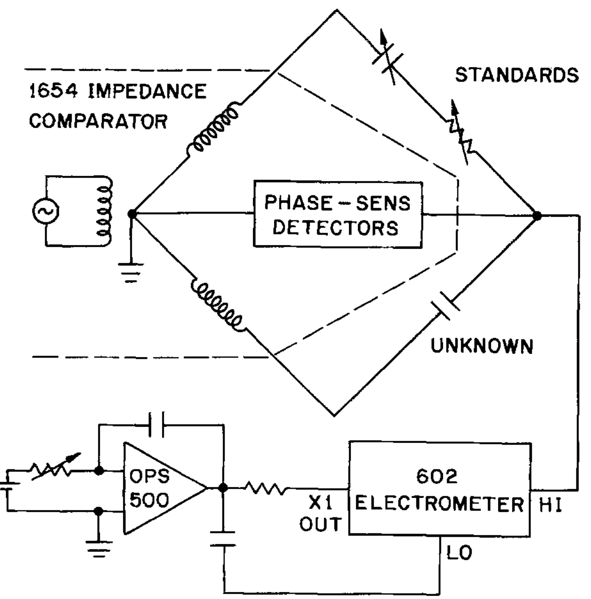

Fig. 2. Schematic diagram of the system used for $C(V)$ measurements.

The bias supply is also connected across the 1654 detector input. A large resistance in series with the supply is required to avoid shorting out the a-c signal. This resistance is provided by the Keithley 602 battery powered electrometer, with the bonus that the d-c current flowing to the capacitors is measured simultaneously. The 602 is connected in such a way that while its a-c impedance is high, producing negligible distortion of the capacitance measurements, the d-c voltage drop across it is very low.

To record a $C(V)$ curve the bias voltage is set to zero, and the impedance comparator is balanced by adjusting the standards. The voltage ramp is then started and the change in impedance recorded as a function of voltage on an X-Y recorder. In addition to the analog recording, the voltage and change in capacitance are also digitized and printed for later computer analysis. It is estimated that the over-all accuracy of the ΔC measurement is on the order of 0.01% of C_o.

Application of a high voltage to a Ta film capacitor produces polarization, part of which decays only very slowly, with time constants the order of hours or even days. Thus it is not practical to measure the full voltage range on one capacitor. Rather, one capacitor is used for positive voltage and another for negative. In each case the measurement starts either at zero voltage or at a small voltage of the opposite polarity.

Typical data at 77°K are given in Fig. 3, traced directly from a pair (one + and one $-$) of X-Y recorder plots. The curve shows the change in capacitance from zero voltage, ΔC, normalized by the zero voltage capacitance, C_o. The x-coordinate is voltage, with Ta positive to the right. These were typical capacitors with V_A = 230V and t_s = 1 hr, measured at liquid nitrogen temperature with a 1 kHz, $1V_{rms}$ test signal and a 1V/sec bias rise rate. One sees that the change in capacitance is the order of $\pm$ 1%, and that it is highly asymmetric about zero voltage, with the asymmetry apparent even at very low voltage.

Interface Model

The asymmetry in the $C(V)$ curve shown in Fig. 3 suggests an interface effect. The MOS capacitor, for example, is highly asymmetric about the flatband point

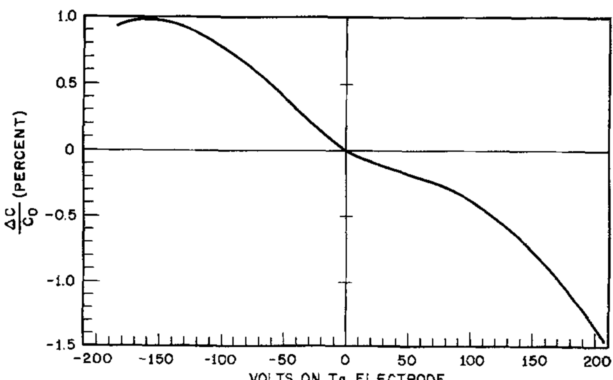

Fig. 3. Typical capacitance-voltage curve for a pair of capacitors anodized at 230V for 1 hr and measured at 77°K with a 1 kHz test signal and 1V/sec bias rise rate.

because the interface between conductive material and the depletion layer, which forms part of the insulator, moves in response to the d-c field. A smilar situation has been reported by Smyth and co-workers in the case of Ta-Ta_2O_5 capacitors which have been heated at 300°-500°C and then measured at room temperature (11). Their observations are explained by noting that at the high temperature the Ta tends to extract oxygen from its oxide, leaving behind vacancies which can act as donors, doping the oxide in the region close to the Ta interface. If the partially localized states associated with these defects are occupied by electrons, the oxide in that region is conductive and it behaves as part of the Ta electrode. If the Ta is biased positively, electrons are removed from these states, and the oxide becomes insulating. Thus the insulating thickness increases when positive bias is applied, and the capacitance decreases.

This effect involves thermal activation of carriers from the defect states, and it disappears below about −40°C (11). Since the present measurements are at much lower temperature and the samples have not been heat-treated, we are definitely not seeing the same effect. However, one can imagine similar effects involving a different type of defect state, perhaps shallower in energy or with substantially higher density, such that thermal activation is not required. In the remainder of this section a general interface model is proposed, and predictions are derived from it which can be tested against experiment. We find a contradiction and thus are forced to conclude that the $C(V)$ characteristic results from bulk, not interface, processes.

The model is shown schematically in Fig. 4. We assume that there exist defect states in the oxide near the Ta interface such that when they are occupied by electrons the oxide in that region is conductive. We define a conductive thickness, d_c, which is the order of 1% of the oxide thickness, d. This is an idealization, since in reality the conductivity must change gradually with position. To be specific one can, following Smyth *et al.* (11), define the interface as the plane at which the local capacitive admittance and local conductance are equal. The conductive thickness will in general depend on the temperature and test frequency, but these parameters are held constant during the present measurements.

The conductive layer thickness is determined by the density of electrons in the interfacial region and the density of defect states which can accommodate them. The density of electrons depends on the electric field, E, in the oxide, so d_c is a function of E, increasing when the Ta electrode is made more negative. For such a structure the capacitance per unit area is

$$C = \epsilon/(d - d_c) \approx (\epsilon/d)[1 + (d_c(E)/d)] \qquad [1]$$

where ϵ is the dielectric constant. Changing the field from E_2 to E_1 causes a change in capacitance

$$\Delta C = C(E_1) - C(E_2) \approx (\epsilon/d^2)[d_c(E_1) - d_c(E_2)] \qquad [2]$$

The normalized change in capacitance, which is the measured quantity, is thus

$$\frac{\Delta C}{C_o} \approx [d_c(E_1) - d_c(E_2)]/d = \Delta d_c/d \qquad [3]$$

This equation is accurate for $d_c << d$.

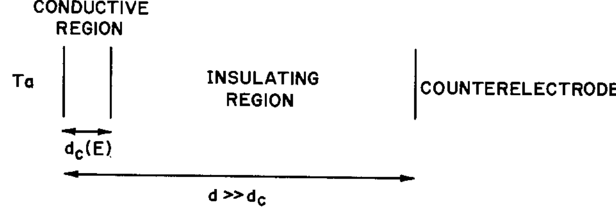

Fig. 4. Interfacial model for the capacitance-field dependence

The measured quantity is thus directly proportional to the change in d_c, with ΔC negative for an increase in field in the positive (parallel to anodization) direction. To account for the observed magnitude of change of C, d_c must be 2 or 3% of d for large negative (opposite to anodization) field, which is easily small enough to make Eq. [3] accurate. The change in d_c is determined by the change in field and by the local density of defect states, which is a function of energy and position. These are the only parameters which explicitly influence Δd_c. In particular, Δd_c does not explicitly depend on d. Thus Eq. [3] seems to indicate an inverse dependence on oxide thickness. However, the density of states is determined by conditions near the Ta interface during anodization and could conceivably vary with the time of anodization, and therefore with d. So to check the validity of Eq. [3] we must first determine the dependence of $\Delta C/C_o$ for a given change in field on d, and then establish whether or not the pertinent properties of the interfacial region change with oxide thickness. These experiments are discussed in the next section.

It has been assumed that the conductive layer is next to the Ta electrode. One could alternatively place it next to the counterelectrode. All the same arguments would apply except that conduction would have to be by positive holes instead of by electrons.

The model thus far is restricted to an infinitely conductive layer whose thickness is modulated by the field. It can be made completely general by allowing both the conductivity and the local dielectric constant near the interface to be modulated by the field. This general model is discussed in the Appendix. The result is, for our present purpose, the same as the simple model above, so reference will be made in the following to Eq. [3] rather than the more general Eq. [A-5].

Experimental Results

The first experiment described in the Sample Fabrication section serves to establish the dependence of $\Delta C/C_o$ on the oxide thickness, d. Six different values of d were produced by varying the anodization voltage. Using the thicknesses determined by ellipsometry the voltage scale of $C(V)$ curves was converted to an average field scale, using $E = V/d$ as the average field. For each thickness and each voltage polarity data from two capacitors were averaged to reduce the effect of sample-to-sample variation. Thus four capacitors were used for each $C(E)$ curve. The curves from all six anodization voltages are given in Fig. 5. They are essentially identical for positive field (parallel to anodization). The two thinnest ones exhibit $\Delta C/C_o$'s for negative field (opposite to anodization) which are ~ 10% greater than the thicker ones.

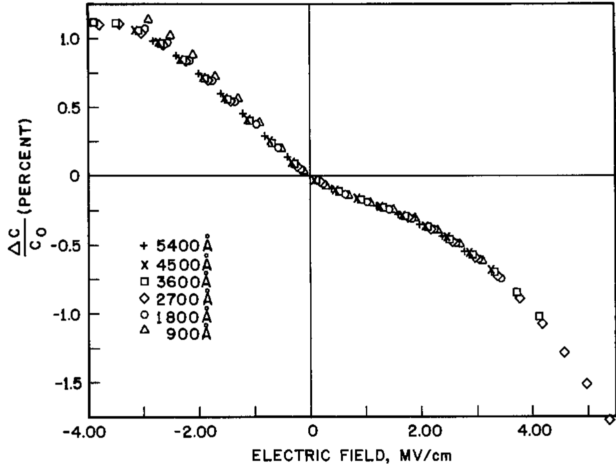

Fig. 5. Capacitance-field dependence for the capacitors of Table I, made with six different anodization voltages.

The inverse dependence on d indicated by Eq. [3] would predict a factor of six difference between the curves for the thinnest and thickest oxides. The observed difference is negligible compared with this factor, so one can for present purposes conclude that the $C(E)$ characteristic is independent of oxide thickness. Recalling Eq. [3], this result indicates that if an interface effect is involved in the $C(E)$ characteristic, then $d_c(E_1) - d_c(E_2)$ must be proportional to d, and hence to the anodization voltage. So in order for the interface hypothesis to be correct, one must assume this proportionality as a second hypothesis.

It was argued before that d_c is determined by local conditions near the interface. These conditions are themselves established during anodization, specifically near the end of the soak period. Once the capacitor is completed these conditions do not change, so d_c for a given field is fixed. One can determine whether d_c depends on anodization voltage by changing d using a method which does not change these local conditions. This was accomplished in the second experiment described in the Fabrication section using chemical thinning of the oxide.

Equation [3] requires that if interface effects influence the $C(E)$ characteristics, then $\Delta C/C_o$ for a given field should be larger than in Fig. 5 in inverse proportion to the fraction of the original oxide thickness remaining. Figure 6 shows that this is definitely not the case. The curves for four different degrees of thinning, up to removal of more than half the initial thickness, are essentially the same as the curve for a sample which was not thinned. Thus the second hypothesis is not obeyed, Eq. [3] does not agree with the true behavior, and the interface model is not correct. Using the general model expressed by Eq. [A-5] leads to the same result. One is therefore forced to conclude that the variation of capacitance with d-c field is produced by bulk effects, that is, physical processes which are distributed at least approximately uniformly through the oxide thickness. The significance of this conclusion is discussed further in the next section.

Discussion

The necessity of reanodization in the thinning experiment casts some doubt on the result. One can imagine that during the reanodization the atoms near the Ta interface might rearrange themselves sufficiently to make the conductive thickness, d_c, the same as it would be for a sample anodized to the smaller thickness and not thinned. That this is extremely unlikely can be shown by several different arguments, some of which are given here.

First, the ionic motion which allows anodization depends exponentially on the field, so a small reduction in the field causes a large reduction in the current density. At 80% of the final anodization field the current is very small, so not much rearrangement of atoms is expected. A check of this assertion is provided by a second thinning experiment in which the sample was reanodized at only 50% of the usual, final anodization field. The result was the same: the $C(V)$ characteristic was the same as that of a sample from the same batch which was anodized to the smaller thickness and not thinned.

A similar argument can be given from a different point of view. The current during reanodization was recorded, so the total charge transferred, and hence an upper bound on the total oxide grown, is known. If we suppose for the moment that the current flowed uniformly over the oxide surface, then the amount of new oxide grown was less than about 11Å. But the current could not have been uniform. Most of it must have gone to the pinholes; otherwise they would not have been repaired and the measurement could not have been made. So a realistic upper bound on the amount of new oxide grown in the "good" oxide area would be perhaps 1Å average thickness. To destroy the effect in question, a layer of $\sim$ 2% of the total thickness, 40-70Å, would have to be rearranged, a highly unlikely result.

As a third argument, we note that if the interface model (Eq. [3]) were correct the slope at zero field of the $C(E)$ curve should be greater for a thinned sample than for one not thinned. The reanodization could reasonably be considered as an extension of the usual anodization soak period. But increasing the soak time causes the slope of $C(E)$ to increase (2), not decrease. So reanodization should tend to amplify the difference between a thinned capacitor and one not thinned, not eliminate it.

It is thus highly unlikely that reanodization would significantly affect the local conditions near the interface. Moreover, if it did, the effect would be the opposite of what is required to destroy the meaning of the experiment. So the conclusion stands: the $C(E)$ characteristic is produced by bulk oxide effects.

The detailed nature of these effects is not clear, but the fact that the $C(E)$ characteristic is asymmetric requires that they be anisotropic. This is somewhat surprising, since the oxide is known to be crystallographically amorphous. Asymmetry in d-c current-voltage curves has been reported by many investigators (12), but there is considerable disagreement as to the cause of this asymmetry. Indeed, some authors deny that it exists at all in properly prepared samples (1, 13). The d-c conduction experiments surely do not demonstrate conclusively that the bulk oxide is anisotropic. Thus, to the author's knowledge, the present capacitance data is the first strong evidence of such anisotropy. Ord, Hopper, and Wang (14) reported from ellipsometric work a linear dependence of oxide thickness on field over a narrow range of field, with the proper sign to account for these results. However Cornish and Young (15), using a similar technique, showed that the dependence is actually quadratic. Both studies used H_2SO_4 as the counterelectrode, which precludes applying negative bias, but it is reasonable to assume that the quadratic dependence is symmetric. Those measurements were at room temperature.

Ord, Hopper, and Wang (14) also reported a large negative dependence of 1 kHz dielectric constant on field (-2.4% per MV/cm). Capacitance-voltage curves taken at room temperature with the samples of the present study indicate that $\Delta C/C_o$ does indeed approach linearity at high field ($\gtrsim$ 4 MV/cm), with a slope approaching the above value. This slope, however, does not extrapolate to low fields, and it does not appear to be directly related to the much smaller ($\sim$ 0.3% per MV/cm) slope observed at low temperature (2). The latter slope, as previously noted, exists even at very low field.

Cornish and Young (15) demonstrated that the index of refraction with an applied field is uniaxially aniso-

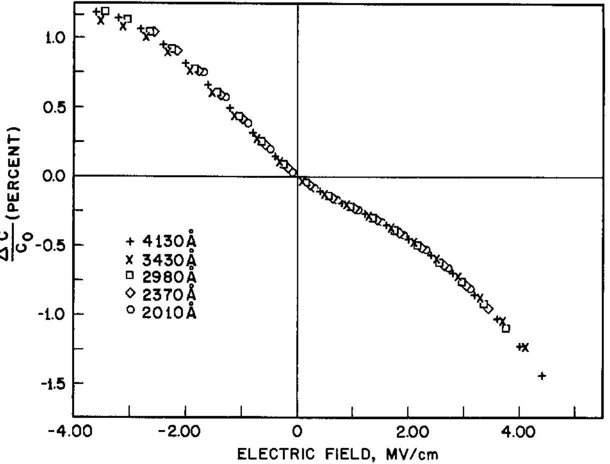

Fig. 6. Capacitance-field dependence for the capacitors of Table II. All oxides were initially 4130Å thick and four of them were chemically etched to the thicknesses shown.

tropic, with the index perpendicular to the field (n_o) larger than the index parallel to the field (n_e). The present work indicates a very different kind of anisotropy, namely that the low frequency dielectric constant with a d-c field parallel to the forming direction is less than with a d-c field antiparallel to it. No such effect was observed in the ellipsometric work (15), so it is probable that the modes which are responsible involve ionic motion, which is too slow to affect the index of refraction at visible light frequencies.

In the amorphous oxide the surroundings of some of the ions are asymmetric. When a field is applied the displacement of a given ion depends on the shape of the barrier on the downfield side. If the potential in that direction rises rapidly (a high barrier), the displacement is less than if it rises slowly (a low barrier). Hence an ion in an asymmetric site makes a smaller contribution to the polarization if the barrier downfield is high than if it is low.

The motion of ions during anodization is exceedingly complex and is not understood (16, 17). If the dynamics are such that there is a preference for ions to be located in sites with a high barrier on the downfield side, then asymmetry of $C(E)$ in the observed direction would result. There is no independent evidence that such a preferred orientation exists, but the following arguments suggest a way in which it might develop.

An ion in an asymmetric site will stay there longer during anodization if the barrier downfield is high than if it is low. Pringle (16) has suggested as a result of work with radioactive markers that the charge transfer event does not consist simply of one ion jumping betwen adjacent sites, but rather involves simultaneous motion of a small group of both Ta and O ions. In this view, when an ion leaves its site the surrounding ions are rearranged and the symmetry of the site is likely to be changed. A site with a low barrier downfield is more likely to lose its ion and therefore is more likely to be rearranged. Thus its lifetime is shorter and, in equilibrium, the density of such sites is expected to be less than that of sites with a high barrier downfield. So, based on this simple physical picture of ionic current flow, one expects to find a preferred orientation in the direction required to explain the observed asymmetry.

Summary

It has been shown that the low temperature capacitance-field characteristic of Ta film capacitors is independent of oxide thickness and of chemical thinning of the oxide. The characteristic is asymmetric, suggesting that an interface mechanism is likely. A general interface model, however, cannot account for the experimental results. One is therefore forced to conclude that a bulk mechanism is responsible. That is, the variation of the capacitance must result from processes which are distributed throughout the oxide, not localized near the metal interfaces. It is suggested that structural anisotropy resulting from the dynamics of ionic conduction during oxide growth produces the observed asymmetry. To the author's knowledge, this is the first strong evidence of such anisotropy in amorphous Ta_2O_5.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Bell Laboratories.

APPENDIX

Referring again to Fig. 4, the conductive layer has thickness d_c, dielectric constant ϵ_c, and conductivity σ_c. All of these depend on the field, E, as well as local variables including but not limited to the density of defect states. We retain the idealized sharp interface between $\sigma > \omega\epsilon$ (conductive) and $\sigma < \omega\epsilon$ (insulating). The insulating layer has parameters d_i, ϵ_i, and σ_i. The total thicknes is constant, $d = d_i(E) + d_c(E)$, and we neglect any field dependence of ϵ_i and σ_i.

The model thus consists of two capacitors in series, each with admittance per unit area

$$Y_j = (j\omega\epsilon_j + \sigma_j)/d_j \qquad [A\text{-}1]$$

The total admittance is

$$Y \equiv Y_cY_i/(Y_c + Y_i) \qquad [A\text{-}2]$$

and the normalized change in admittance on changing the field from 0 to E is

$$\Delta Y/Y_o = [Y(E) - Y(0)]/Y(0) = \frac{Y_i(E)}{Y_i(0)} \cdot \frac{1 + Y_i(0)/Y_c(0)}{1 + Y_i(E)/Y_c(E)} - 1 \qquad [A\text{-}3]$$

We know that $d_c << d_i$, $\sigma_c \geqq \sigma_i$, and $\epsilon_c << \epsilon_i$. So $Y_c >> Y_i$, and we find

$$\frac{\Delta Y}{Y_o} \approx \frac{Y_i(E)}{Y_i(0)}\left[1 + \frac{Y_i(0)}{Y_c(0)} - \frac{Y_i(E)}{Y_c(E)}\right] - 1 = \frac{Y_i(E) - Y_i(0)}{Y_i(0)} + Y_i(E)\left[\frac{1}{Y_c(0)} - \frac{Y_i(E)}{Y_i(0)}\frac{1}{Y_c(E)}\right] \qquad [A\text{-}4]$$

Putting in the definition of Y_j yields

$$\Delta Y/Y_o \approx [d_c(E)f_1(E) - d_c(0)f_2(0)]/d_i(E) \qquad [A\text{-}5]$$

where

$$f_1(E) = 1 - [d_i(0)/d_i(E)][j\omega\epsilon_i + \sigma_i]/[j\omega\epsilon_c(E) + \sigma_c(E)]$$

and

$$f_2(0) = 1 - [j\omega\epsilon_i + \sigma_i]/[j\omega\epsilon_c(0) + \sigma_c(0)]$$

If $\sigma_c \to \infty$ we recover Eq. [3] for the simplified model. Note that within the accuracy of this discussion $d_i = d$, making f_1 and f_2 the same function. This function, f, is dependent on the constants ω, ϵ_i, and σ_i, and the functions ϵ_c and σ_c. These functions and d_c are determined by the applied field and by local structural and chemical conditions. Neither f nor d_c is explicitly a function of the oxide thickness. Thus just as in the simple model we apparently have an inverse dependence on oxide thickness, which might be modified if local properties (including but now not limited to the density of defect states) near the interface are dependent on how much oxide has been grown.

Epitaxial Deposition of Silicon in Deep Grooves

R. K. Smeltzer*[,1]

Texas Instruments, Inc., Semiconductor Research and Development Laboratories, Dallas, Texas 75222

ABSTRACT

An epitaxial silicon growth technique to preferentially deposit into and refill deep, vertically walled, orientation-dependent etched grooves in (110) silicon was developed. All of the common silicon chlorides can be used with the addition of HCl to the deposition system. A mask on the top surface of the substrate is not needed with this selective deposition technique. After refill of the deep grooves, even with variable depths, a planar surface is created. A thermodynamic analysis of the experimental conditions was carried out, and it shows that all of the various experimental conditions successfully used are about equally shifted from equilibrium.

Selective deposition into depressions or onto a surface to create protrusions has been investigated because of its application to devices and circuits. Also, selective epitaxy studies have been useful in efforts to understand deposition processes. In general, chemically vapor deposited layers tend to contour the surface of a bare substrate, although other factors, such as the orientation dependence of deposition rate may produce a deposited surface contour altered from the original surface contour. The only selective silicon deposition technique which is in use requires a mask on the substrate to prevent growth except on the substrate within mask openings. Selective growth occurs at low supersaturations of the desired material, and for the case of silicon deposited from a chloride source, the addition of HCl to the system has been used (1, 2).

The basic purpose of this paper is to show that well-controlled preferential deposition into deep surface depressions can be achieved, at least for certain geometrical configurations and a particular substrate orientation, without use of a mask on the substrate. A maskless epitaxial technique has been developed to preferentially deposit defect-free silicon into very deep, narrow, orientation-dependent etched grooves in a (110) silicon substrate with very little deposition on the top surface of the slice. The present purpose for the development of this technique is the fabrication of vertical p-n junction solar cells (3).

A previous investigation (4) had demonstrated that preferential epitaxial deposition into shallow surface depressions in a bare substrate could be achieved by a particular choice of gas phase composition in the reactor. It was shown that with concentrations of $SiCl_4$ in H_2 higher than the composition at which the maximum growth rate occurs on a flat surface, wide shallow depressions will tend to fill to produce a flat surface. A basic limitation of the high $SiCl_4$ concentration approach to preferential deposition is that the Si/Cl ratio is fixed. The work discussed in this paper shows that the use of low silicon halide concentrations with the addition of HCl to the reactor offers a high degree of control for preferential deposition into deep surface depressions in (110) silicon wafers.

Experimental Details

The epitaxial deposition experiments described in this paper were carried out with 1 ohm-cm (110) silicon substrates, which had 2 cm long, vertically walled, orientation-dependent etched grooves. To produce the substrates, conventional photolithographic methods were used to open lines in thermally grown oxide on the slices, and the silicon was etched in a nominal 42.5% $KOH:H_2O$ solution. The oxide etch mask was removed after the orientation-dependent etch. The grooves were oriented approximately parallel to the set of intersections between one set of (111) planes, which intersect the surface vertically, and the (110) surface of the slice. An important factor in the achievement of reproducible epitaxial depositions is the accurate control of the groove width. Since it has been recently shown (5) that the undercutting etch rate of the nominal (111) walls of grooves in (110) silicon is a very sensitive function of the misorientation of the walls, accurate mask alignment to about $\pm$ 0.2° was required. The etched grooves occupied a 4 cm^2 area in the center of 1½ in. diameter slices with a packing density of 500 grooves/cm. Typically, the grooves were 100 μm deep and 10 μm wide, although other dimensions were also used to characterize the effects of groove geometry on the epitaxial deposition process. For a later discussion, it is important to note that the ends of the grooves are terminated by one of the (111) planes which makes a 35° angle with the (110) surface. Consequently, near the ends of the grooves, the groove depth linearly decreases to zero.

The depositions discussed in this paper were done in an rf heated reactor operated at atmospheric pressure. The vertical deposition chamber is a 9.5 cm diameter fused silica tube. The gas inlet is at the top and the outlet is at the bottom. A bottom plate, which seals to the reaction tube, has a feedthrough for rotation of the graphite susceptors. Two different susceptor arrangements were used with similar results. In one case, the substrates were located on the top of small cylindrical susceptors, which rotated around their own axis and around the axis of the reaction tube. Three susceptors,

whose total cross-sectional area occupied 60% of the cross-sectional area of the reaction tube, were used. With this arrangement, the substrates directly faced the incoming gas flow. In the other susceptor arrangement, the substrates were located on the side of a solid susceptor such that the wafers were tilted about 15° from the vertical. The cross section of the bottom of the solid susceptor occupied 87% of the cross-sectional area of the reaction tube. This latter susceptor design was more convenient, and it was used for most of the deposition experiments.

The adjustment of the Si/Cl ratio, which was done by the addition of HCl to the H_2-silicon chloride systems, is the key factor which produces preferential deposition in deep grooves. Although the epitaxial refill process was demonstrated with $SiCl_4$, $SiHCl_3$, and SiH_2Cl_2, the H_2-$SiHCl_3$-HCl system was more extensively investigated. Prior to deposition, the substrates were heated in H_2 at 1220°C for 5 min. This prebake, rather than a HCl vapor etch, was used because a vapor etch preferentially removed silicon from the top corners of the grooves and produced nonvertical groove walls. Since the groove walls are etched surfaces, the absence of the vapor etch should not be detrimental to the deposition of defect-free material. After the H_2 bake, the substrate temperature was adjusted and deposition started by the simultaneous introduction of metered amounts of $SiHCl_3$ and HCl. The effect of substrate temperature, which was measured with an optical pyrometer and corrected for the emissivity of silicon and a 10°C error due to the reactor wall, and gas flow rates are discussed in the next section.

Experimental Results

Depositions from the H_2-$SiHCl_3$-HCl system onto deep grooved slices were investigated with a variety of gas flow conditions. For comparison purposes, a few depositions were also carried out with no HCl in the reactor, and Fig. 1 shows a slice cross section from a 4 min epitaxial deposition done near 1140°C with 0.45% $SiHCl_3$ in H_2. The cross section shown in Fig. 1 and the cross sections in other photomicrographs except Fig. 2b are from slices with grooves with a 20 μm center-to-center spacing. The photomicrographs show (111) cleavage planes which are about 19.5° from the perpendicular to the grooves. The cross sections were briefly etched to reveal the boundary between the p-type substrate and the n-type deposit. Not surprisingly, conventional deposition conditions with a deep grooved slice yielded a faster growth rate on and near the top of the silicon columns than on the side walls of the grooves away from the top. With a longer deposition time, the silicon deposit bridged the grooves at the top and left large voids in the deposit. Note, however, that significant deposition did occur on the groove bottoms.

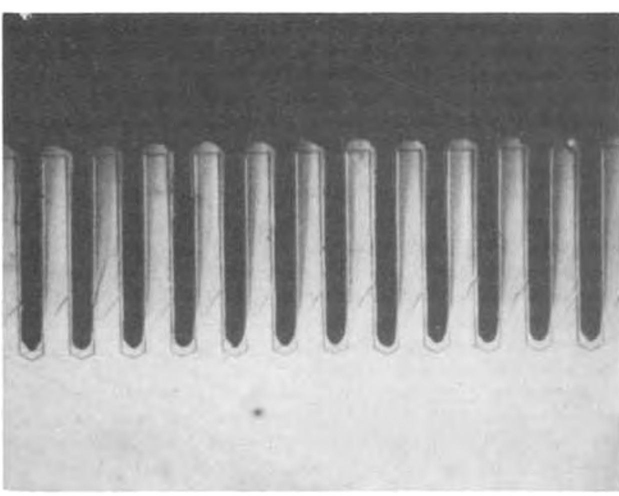

Fig. 1. Stained cross section from a p-type (110) deep grooved substrate with a 4 min, n-type epitaxial layer deposited at 1140°C from 0.45% $SiHCl_3$ in H_2. The groove center-to-center spacing is 20 μm.

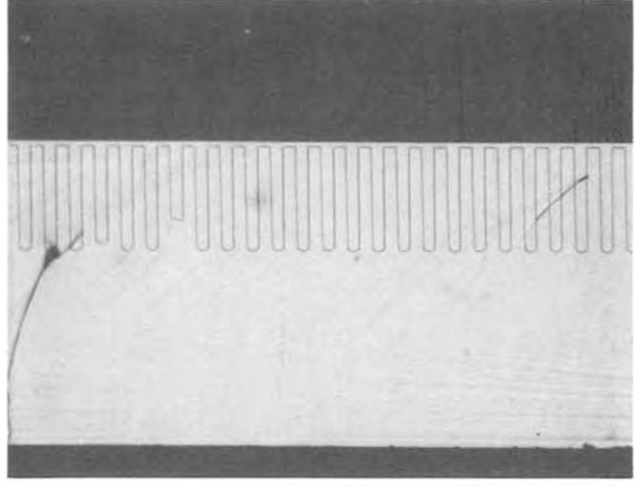
In contrast to the result illustrated by Fig. 1, it was demonstrated that preferential deposition into deep grooves in (110) silicon can be done with the addition of HCl to the common silicon halide systems. With HCl added, etching or a reduced growth rate occurred near the top of the grooves as in conventional silicon depositions onto a flat substrate with HCl added to the system. However, the addition of HCl to the system did not produce a reduced growth rate near the groove bottoms. Near the critical conditions for which no net deposition occurs on a flat substrate, it was possible to completely refill deep grooves without voids. The photomicrographs in Fig. 2 show two stained cross sections from refilled slices. Neither defect-sensitive etches nor x-ray topographical studies revealed defects in refilled epitaxial silicon deposited with the critical gas concentrations discussed below.

A particularly important characteristic of refilled slices is the planar top surface of the deposit, as shown by both examples in Fig. 2. A surface perturbation does not occur even near a shallow groove such as shown in Fig. 2a. A planar surface occurs because of the very small amount of silicon deposited on the top of the silicon columns during the refill. In addition, cross sections from slices with grooves only partially refilled show facets at the top corners of the grooves



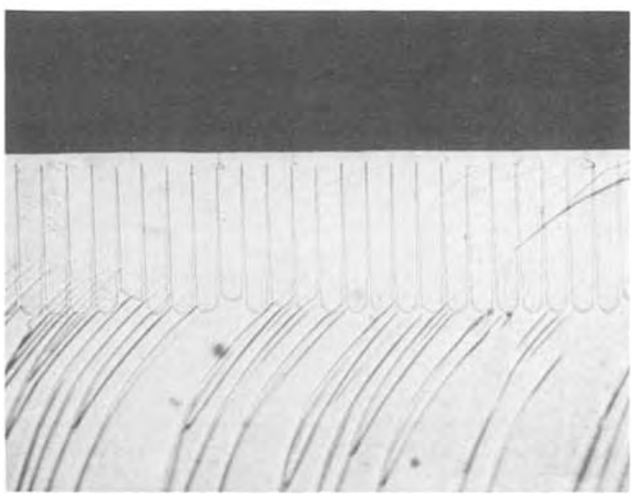


Fig. 2. Stained cross sections from two epitaxially refilled silicon slices. Deposition conditions were: (a, top) 45 liters/min H_2, 0.2 liter/min $SiHCl_3$, 1.0 liter/min HCl, 1140°C substrate temperature and (b, bottom) 45 liters/min H_2, 0.3 liter/min $SiHCl_3$, 1.2 liters/min HCl, 1140°C substrate temperature. Groove center-to-center spacings are: (a) 20 μm and (b) 10 μm.

similar to those in Fig. 1; with HCl added to the system, however, the facets terminate very near the top corners of the silicon columns during most of the deposition. After deposition has completely filled the grooves, growth predominately occurs to fill in the volume between these facets. The result is a planar top surface about 5 μm above the original substrate surface. This tendency to produce a planar (110) surface after refill may also be related to a previous observation (6), which indicated that (110) planes yield a more planar surface in selective epitaxy than other common planes.

The refill of vertically walled grooves without voids suggests either that the deposition rate on the walls increases with depth into the grooves or that growth on the groove bottom is much faster than growth on the walls. To investigate the growth characteristics within the grooves, depositions during which the dopant was cycled on and off were done. Figure 3, which is a photomicrograph of a stained cross section from a deposition during which the dopant was cycled on and off every 6 min, shows that, in fact, the deposition rate on the groove walls does increase with depth. Figure 3 shows six distinct regions, and the growth rate within the grooves, except near the bottoms and the tops, appears to increase approximately linearly with depth. A planar top surface occurred during the fifth 6-min interval of growth. To determine the effect of small temperature variations on the growth within grooves, one deposition with cycled doping was done with a temperature gradient across the substrate. Experimentally, the temperature gradient was obtained by slightly elevating the substrate from the susceptor at one point. It was observed that the slope of the growth profiles was strongly temperature dependent, and consequently, as discussed below, the refill process itself is very temperature sensitive.

The deposition characteristics of the epitaxial refill process were also investigated with regard to the effect of different groove dimensions. A few substrates with 90 μm deep grooves were found to contain grooves with widths in the range from 9 to 30 μm. From photomicrographic measurements, it was estimated that the deposition time required to completely fill variable width grooves is approximately proportional to the width.

In contrast to the variable width case, it was found that for grooves of equal width, the time needed to completely fill grooves of variable depth is approximately independent of the depth. It was observed, for example, that substrates with 200 μm deep grooves require at most a 10% longer deposition time to fill the grooves than substrates with 100 μm deep grooves. It was also found that for substrates with 100 μm deep grooves, no top surface perturbation results from the presence of a few shallow grooves. Additionally, with dopant alternation, it was observed that the deposition rate was faster on the walls near the bottom of deep grooves compared with shallow grooves, and by the time the grooves were almost filled, an equal volume of silicon was needed to fill the remaining volume in both deep and shallow grooves. Figure 4 illustrates the observed depth independence of the epitaxial refill process more dramatically. This photomicrograph is from a cross section near the edge of a 2 cm × 2 cm array of grooves, where the groove ends are terminated by one of the (111) planes which make a 35° angle from the (110) surface. The grooves shown in Fig. 4 are therefore not uniformly shallow for any distance. Side wall growth rate measurements taken from this refilled slice are, however, consistent with measurements taken from other slices with shallow grooves extending over long distances. Figure 4 also shows that the initial growth rate on the bottom of terminated grooves was the same as the initial growth rate on the side walls near the bottom; this is understandable since both surfaces are (111)-type planes. In contrast, the growth rate in nonterminated, double faceted grooves was initially faster on the bottom than on the side walls. The depth independence of the epitaxial refill process is important because top surface planarity can be achieved even with variable depth grooves within one substrate.

The epitaxial depositions discussed above were done with the H_2-$SiHCl_3$-HCl system at 1140°C. Various concentrations of $SiHCl_3$ up to 2.4% were used, and, in all cases, a critical HCl concentration was found which produced defect-free refill. Figure 5, which gives the HCl/$SiHCl_3$ concentration ratio as a function of the $SiHCl_3$ concentration, summarizes the experimental conditions which were used. The solid circles represent the conditions which yielded good refilled silicon; these gas concentrations were routinely used for refill depositions. The open circles represent deposition conditions which did not produce good refill. With excessive HCl the deep groove deposition was very slow and etching of the top surface of the substrate occurred. With too little HCl, the deposition rate near the top of the grooves was too fast and voids were left in the refilled silicon. It was not possible to define a critical range for the HCl/$SiHCl_3$ parameter at any $SiHCl_3$ concentration, and this suggests that, if a critical range exists, it is within the reproducibility of flow meter settings. From the depositions with the various $SiHCl_3$ concentrations, it was found that the adjustment of the Si/Cl ratio by the addition of HCl to produce defect-free silicon, always resulted in the same deposition time. About 40 min was needed with each of the four, well-established deposition conditions given in Fig. 5. On this basis it was concluded that no increase in epitaxial refill rate can be obtained with higher silicon chloride concentrations. The effect of the total H_2 gas flow on the refill process was also determined from a few ex-

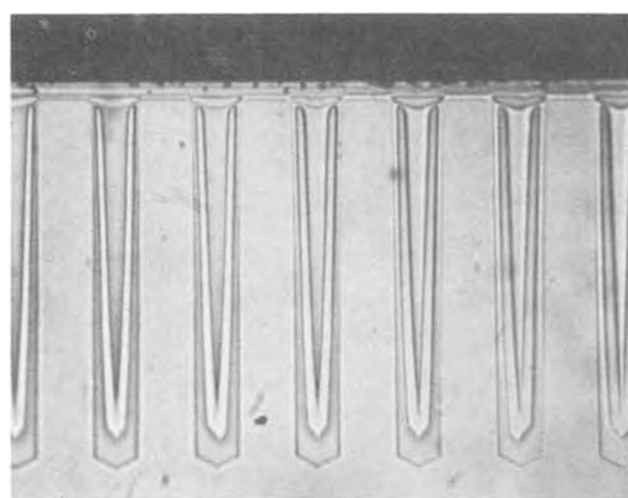

Fig. 3. Cross section from a refilled silicon slice with deposition profiles obtained by dopant alternation every 6 min and subsequent staining of the cross section. The groove center-to-center spacing is 20 μm.

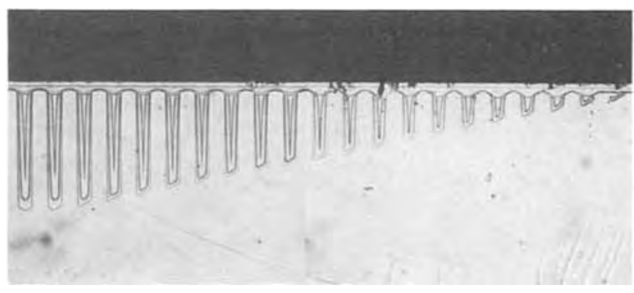

Fig. 4. Cross section from a refilled slice near the groove end terminations to illustrate the groove depth independence of the epitaxial refill process.

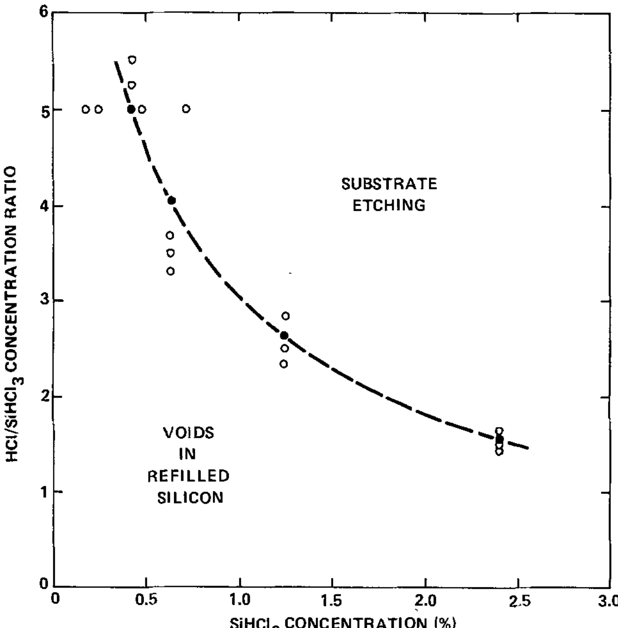

Fig. 5. Deposition conditions used for epitaxial refill experiments at 1140°C with 45 liters/min H_2. Four critical gas concentrations, defined by ●, refilled grooves without producing voids in the deposited silicon or etching of the substrate. The grooves were 2 cm long, 10 μm wide, and 90 μm deep.

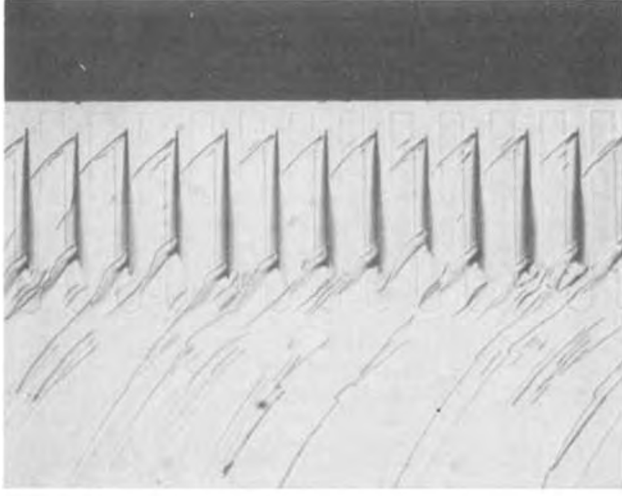
periments. Total H_2 flow rates greater than or less than about 45 liter/min reduced the refill deposition rate.

The cross sections shown in Fig. 6 are representative of the effect of deposition temperature variations on the epitaxial refill process. For a particular set of gas concentrations which produced defect-free silicon at a particular deposition temperature, a higher temperature produced a faster deposition rate near the top of the substrate and left voids in the refilled silicon. Conversely, a lower temperature tended to produce an etching condition and the refill rate was slow. From examinations of slice cross sections it appeared that a low substrate temperature was equivalent to an excess of HCl and that a high temperature was equivalent to a deficiency of HCl.

In addition to the use of $SiHCl_3$, $SiCl_4$ and SiH_2Cl_2 were evaluated for epitaxial refill depositions. The H_2-$SiCl_4$-HCl system near 1200°C yielded results similar to the H_2-$SiHCl_3$-HCl system at about 1140°C. Similar deposition times and characteristics were obtained. In an effort to reduce the deposition temperature, H_2-SiH_2Cl_2-HCl was also investigated for refill depositions. Deep grooves can be filled without voids near 1080°C; however, a planar top surface was not obtained, at least for depositions terminated with a 10 μm, average film thickness above the original substrate surface. Deposition times are about the same with SiH_2Cl_2 as with the other halides. The deposition temperature is much less critical with SiH_2Cl_2, and a 10°C variation does not appear to affect the refill characteristics. The usefulness of SiH_2Cl_2 for refill depositions may be limited, however, by the nonplanar surface obtained after the grooves are filled.

Discussion

From the experimental observations, which are summarized in the previous section, insight into certain features of the epitaxial refill process and an understanding of the role of some parameters have been obtained. There is evidence that the thermal conditions in the substrate are important from two viewpoints. First, as in any silicon halide deposition system, the Si/Cl ratio near the substrate is a very sensitive function of the substrate temperature. As a consequence, the epitaxial refill process is very temperature sensitive, especially with the use of $SiCl_4$ and $SiHCl_3$. In



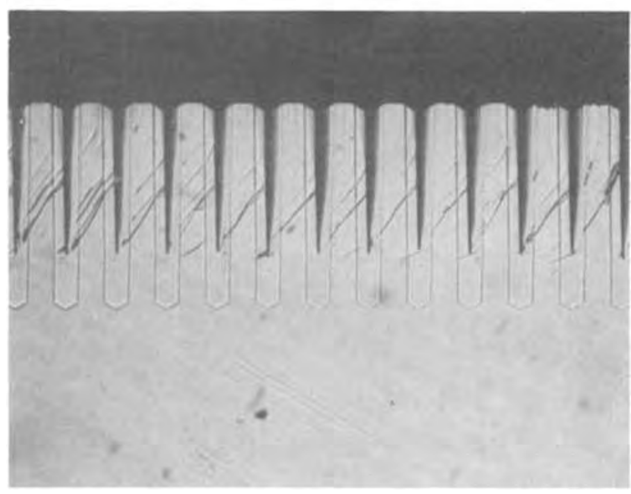


Fig. 6. Cross sections from silicon slices after deposition at two different temperatures with critical gas concentrations for 1140°C (a, top) 1150°C and (b, bottom) 1130°C.

agreement with previous observations (7, 8) from conventional epitaxial studies, however, refill from SiH_2Cl_2 is much less temperature dependent than refill with the other chlorides. Second, there is evidence which suggests that the temperature gradient within the substrate is important in the refill technique. Refill deposition experiments in both a horizontal reactor and a vertical domed reactor with the gas inlet at the bottom did not produce deposited silicon without voids. Groove wall deposition profiles observed on samples from experiments done in a horizontal and a domed reactor showed that the growth rate on the groove walls did not measurably increase with depth into the grooves. It is hypothesized that the reactor used for the successful refill experiments produces a larger temperature gradient in the groove walls than the other two reactors, since the incoming gas impinges directly, although not perpendicularly for one of the susceptor arrangements, onto the substrates. It is concluded, therefore, that the temperature distribution within the deep grooved substrate is critical to the epitaxial refill process, and that a large temperature gradient such that the groove bottoms are at the highest temperature is required to produce defect-free refilled silicon.

The adjustment of the Si/Cl ratio by the addition of HCl to the reactor is the key factor in the epitaxial refill technique. Based simply on the observations, it appears that the HCl tends to preferentially attack corners. More significant, however, may be that the growth conditions used for the refill depositions should produce silicon transport from the top of the substrate down into the grooves. From an analysis (9) which

gives the silicon content in the gas phase as a function of the Cl/H ratio and from the data in Fig. 5, the transport direction, which is the direction to lower the Si/Cl ratio, is from low temperature to high temperature for the deposition conditions used in this work. If the gas conditions are stagnant within the deep grooves, then deposition at the bottoms would act as a driving force for silicon-bearing species to enter the grooves.

The thermodynamic analysis of the Si-Cl-H system (9) has been used to analyze in more detail the critical epitaxial refill gas concentrations. Table I gives both experimental and equilibrium Si/Cl ratios as a function of the Cl/H ratio for the four critical deposition conditions given in Fig. 5 and for two well-established deposition conditions with the H_2-SiH_2Cl_2-HCl system. Of particular interest is that the critical epitaxial conditions are all about equally shifted from equilibrium. For defect-free epitaxial refill, the value of the difference between the experimental and equilibrium Si/Cl ratios is about 0.075. Based on the analysis, critical deposition conditions to refill grooves can probably be predicted for a variety of silicon systems and temperatures.

The experimental observations which indicated that a low substrate temperature is equivalent to an excess of HCl and that a high substrate temperature is equivalent to a deficiency of HCl are consistent with the above analysis. With the low Cl/H ratios used for the refill depositions, both an excess of HCl and a low substrate temperature result in a difference between the experimental and equilibrium Si/Cl ratios less than the critical value. Since a smaller difference between the two ratios means that the system is closer to equilibrium, a slow growth rate or etching of the substrate occurs. Conversely, a deficiency of HCl and a high substrate temperature result in a difference between the experimental and equilibrium Si/Cl ratios greater than the critical value. Therefore, deposition is too fast and the deposit tends to bridge the grooves at the top of the substrate. From the experimental observations, the analysis given here is applicable only to the growth near the top of the substrate. Deposition in the groove bottoms was less sensitive to the small temperature and HCl concentration changes.

The groove depth independence of the epitaxial refill rate is another important aspect of this process. A very simple phenomenological model, illustrated in Fig. 7, explains the observations. Growth profiles are shown in three equal width grooves based on four assumptions: (*i*) a zero growth rate at the top corner, (*ii*) a linearly increasing growth rate with depth, (*iii*) an equal growth rate at any depth independent of the total groove depth, and (*iv*) a bottom growth rate equal to the growth rate on the walls at the bottom. Under these conditions, Fig. 7 shows that growth profiles in deep grooves eventually correspond to the profiles in shallow grooves. Consequently, all of the grooves will be completely filled in the same time interval. The four assumptions used to derive the growth profiles in Fig. 7 are very reasonable in view of the experimental observations. The first three agree with observations and measurements from slice cross sections. Figures 3 and 4 show that the fourth assumption is only correct for grooves with a single (111) plane termination on the bottom. However, the results

obtained in Fig. 7 are only slightly influenced by the bottom growth rate assumption, since, as the grooves fill, side wall growth dominates over bottom growth. Similarly, the exact shape of the groove bottoms is also not important in the model. It is likely that this model for deep groove refill does not apply to grooves with depths less than the width. For grooves with depths greater than the width, however, the growth rate model illustrated by Fig. 7 is appropriate. Exactly why the deposition conditions produce the particular growth profiles remains to be determined.

Conclusion

An epitaxial growth process which produces preferential deposition of silicon in deep, vertically walled, orientation-dependent etched grooves in (110) silicon without a mask on the top of the substrate was developed. With the optimum deposition conditions, the growth rate on the groove walls increases with depth into the grooves so that the grooves are completely filled without voids or defects in the deposited silicon. Even with variable groove depths within a substrate, a planar top surface is produced after the grooves are filled. The key factor in this chemical vapor deposition technique is the adjustment of the Si/Cl ratio, which is conveniently done by the addition of HCl to the reactor. All of the deposition conditions successfully used are shifted about equally from equilibrium, since the difference between the experimental and equilibrium Si/Cl ratios is about the same for all of the depositions. It was also concluded that a temperature gradient within the substrate is critical to the epitaxial refill process.

This silicon deposition technique, which preferentially deposits into and fills orientation-dependent etched grooves in a substrate, may be useful in a number of ways. In essence, it is a method to reconstruct a silicon slice with alternate regions with different properties. Some new structures with unique characteristics are possible.

CVD-BN for Boron Diffusion in Si and Its Application to Si Devices

Makoto Hirayama and Katsufusa Shohno

Department of Electronics, Sophia University, Chiyoda-ku, Tokyo, 102 Japan

ABSTRACT

Amorphous and polycrystalline boron nitride (BN) films were deposited on n-type Si substrates using a B_2H_6-NH_3-H_2 system. During deposition of the BN film, boron diffuses into the Si; a BN film deposited at temperatures below about 1000°C acts as an infinite diffusion source of boron in Si. The maximum values of boron surface concentration give solid solubility of boron in Si at each temperature. A thin layer of BN (below 80Å) gives a surface concentration of boron in the range between 10^{16} and 10^{20} cm^{-3}, by varying the heat-treatment conditions. Amorphous BN decomposes easily when heated in a nitrogen atmosphere. This can be used for planar diode processes using only one photomask. An MIS-memory diode with Al-BN-SiO_2-Si structure, shows an anomalous C-V shift due to the formation of borosilicate glass between BN and SiO_2.

Boron is the most common doping element for p-type Si in the present semiconductor technology. For boron diffusion in Si, many kinds of diffusion sources are used: boron trioxide (1), boron trichloride (2), boron tribromide (2), borosilicate glass (3), and boron nitride disks (4). A large number of experimental and theoretical works have already been published. Rand and Roberts (5) used CVD-BN as an insulator thin film for a varistor device, and also showed that a boron diffusion layer was formed in the Si substrate. In this paper, physical and chemical properties of CVD-BN thin films and methods to obtain boron diffusion layers with high and low surface concentrations are described. As examples of the use of CVD-BN in present planar technology, a Si planar diode process and an MIS-memory diode are shown.

Experimental Procedure

The experimental apparatus is schematically shown in Fig. 1. Deposition is carried out in a quartz reaction chamber with dimensions of 25 × 40 × 400 mm. Diborane (B_2H_6) diluted to 5% in hydrogen and ammonia (NH_3) are used as reactant gases and high purity hydrogen is a carrier gas. The flow rates of reactant gases are kept at 30 cm^3/min and that of hydrogen is 2000 cm^3/min throughout the experiments. Deposition temperatures of the Si substrate are changed in the range of 700°-1250°C. The growth rate of the film at 700°C is about 500 Å/min. Mirror-polished n-type Si wafers (P-doped) with resistivities of 3 ~ 5 ohm-cm are used.

The surface of a deposited film is observed by an optical microscope. Reflection electron diffraction is used for an investigation of crystalline properties of the films. The deposited films are also studied by infrared absorption before and after heat-treatment in an appropriate ambient gas.

In order to measure pinhole density of the deposited films, Si wafers are etched to make pits through any pinholes that may exist in the film. Wafers are boiled at 110°C in APW solution, which has 17 cm^3 of ethylenediamine, 3g of pyrocatechol, and 8 cm^3 of deionized water. Then the samples are boiled for 30 min in a hot solution (~130°C) with equal volumes of phosphoric acid and deionized water for complete removal of the deposited films. The pinhole density of the film is measured by counting the number of etch pits in the Si wafer under an optical microscope.

Although boron diffusion layers are formed during deposition of the film, the total diffusion time was varied from 10 to 3000 min to get diffusion depth from

Key words: CVD-BN, boron diffusion, planar diode, memory diode.

about 0.2 to 5 μm. The diffusion depth is measured by spherical drilling and staining (6). To obtain the boron surface concentration in Si, an average resistivity of the boron diffusion layer is measured by four-point probe and Irvin's plots (7) of resistivity *vs.* impurity concentration. To determine the boron profile, the change of the sheet resistivity is measured by repeated anodic growth and removal of silicon dioxide layers (8). Anodic oxidation is carried out in a solution with 3 parts propylene glycol and 2 parts phosphoric acid at a d-c applied voltage of 100V. The thin silicon dioxide layer (~200Å) is removed with HF. After every fourth anodization-HF cycle, a measurement is made of the sheet resistivity. The thickness of silicon removed was determined by an interference microscope.

Results and Discussion

Properties of boron nitride.—Typical reflection electron diffraction patterns are shown in Fig. 2. These faint ring patterns are obtained from films which were deposited at temperatures near 1000°C. The film is polycrystalline boron nitride, with hexagonal structure, whose lattice parameters are measured as a = 2.51Å and c = 6.68Å. These values are in good agreement with those given by Pease (9). On the other hand, the faint ring patterns changed to hollow ring patterns as the deposition temperature was decreased below about 1000°C. This means that the films obtained below 1000°C are amorphous. Films obtained in this experiment are identified as boron nitride (BN).

An infrared absorption spectrum of the film also shows that it is boron nitride. For infrared spectroscopy, the back side of a Si substrate was chemically etched smooth to prevent diffuse reflection. The absorption peak from the film appears at 7.3 μm, as shown in Fig. 3. This agrees well with the value of the B-N stretching vibration previously reported by Brame *et al.* (10). This value of the B-N vibration is independent of deposition temperature. For films of the same thickness, the magnitude of absorption band changes according to the deposition temperature. This is due to the number of the B-N stretching vibrations and also depends on a crystallization of the films.

The surface of the film is quite smooth and no structural features can be observed on films deposited in the temperature range of 700°-1250°C. The BN film is transparent and shows interference colors.

The BN film is chemically stable and cannot be attacked by any etching solution except hot phosphoric acid. A solution of equal volumes of deionized water and phosphoric acid is heated to its boiling point (~130°C). The etch rate of a film deposited at 700°C is about 80 Å/min. Although the etch rate becomes small for a film deposited at high temperatures, BN films 2000Å thick, which we usually use, can be completely removed when boiled for 30 min in the solution.

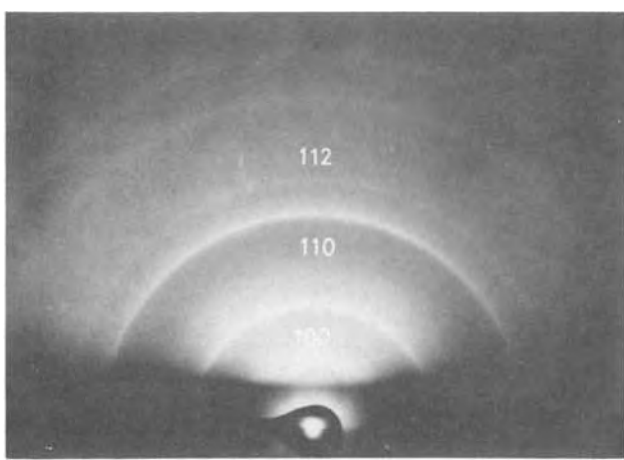

Fig. 2. Typical electron reflection diffraction patterns from a BN film deposited at 1200°C.

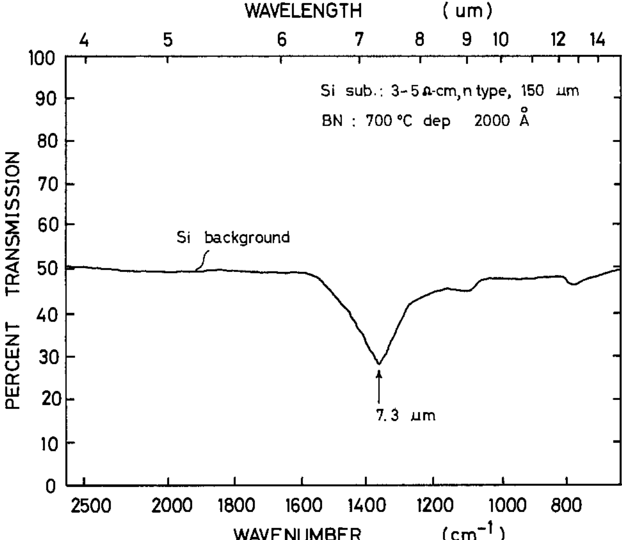

Fig. 3. Infrared absorption spectrum of a BN film deposited at 1000°C on a Si substrate.

Plasma dry etching is also useful, especially for selective removal of BN films by the use of well-known photoresist processes. Experimental results are shown in Fig. 4. The rf power (at 13.7 MHz) was set as small as possible to avoid attack of the Si substrate. Deposition temperatures over about 1000°C, where the etch rate of the film decreases with increasing deposition temperature, correspond to the temperature range where a polycrystalline BN film is obtained.

Pinhole density was below 10 cm^{-2} for 500Å films deposited at 700°C. When the film was thicker than 500Å, defects could not be found on the Si substrate.

Polycrystalline BN films deposited at temperatures over about 1000°C are thermally stable. Changes in the polycrystalline patterns were not observed even after long heat-treatment in hydrogen or nitrogen for several tens of hours at 1250°C. However, amorphous BN films deposited below about 1000°C are unstable and easily decompose during heat-treatment in nitrogen or hydrogen. For example, a 500Å BN film deposited at 700°C completely decomposes after heat-treatment in nitrogen at 1100°C for 3 hr, after which the bare Si surface appears. The change from an amorphous to a polycrystalline form due to heat-treatment was not observed on the patterns by reflection electron diffraction.

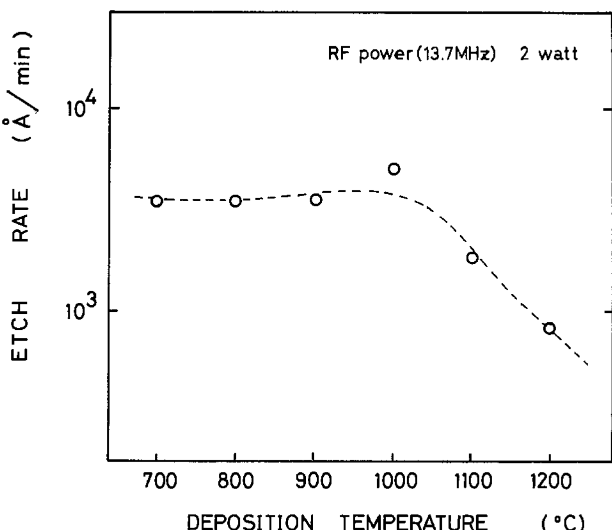

Fig. 4. Plasma etch rate vs. deposition temperature of a BN film.

Al-BN-Si structures with 1000Å of BN were prepared for measurements of dielectric constant, resistivity, and dielectric strength of the BN film. An a-c bridge at 1 MHz was used for measurement of diode capacitance to determine the dielectric constant of a film. The dielectric constant of a BN film has a value that depends on the deposition temperatures. For an amorphous film deposited at a temperature below about 1000°C, the dielectric constant is 3.3 ~ 3.5, while for a polycrystalline film deposited at temperatures over about 1000°C it is 4 ~ 6. From the ohmic region in the V-I characteristics of a diode, resistivity of the film was determined to be in the range 10^9 ~ 10^{10} ohm-cm. Breakdown voltages of 80 ~ 150V give a dielectric strength of 0.8 ~ 1.5 × 10^7 V/cm for the films. The values of resistivity and dielectric strength do not depend on the deposition conditions of the film.

Boron diffusion in Si.—During the deposition of a BN film on an n-type Si substrate, a boron diffusion layer can be formed. The boron surface concentration *vs.* deposition temperature is shown in Fig. 5. When deposition temperatures are below about 1000°C, the boron surface concentration C_s is about 10^{20} cm^{-3}. C_s increases with deposition temperature, and does not depend on deposition time of the BN film. This means that an amorphous BN film deposited below about 1000°C acts as an infinite diffusion source of boron. However, as the deposition temperature is increased over about 1000°C, the boron surface concentration decreases to about 10^{18} ~ 10^{19} cm^{-3}. In this temperature range, the film has a polycrystalline form.

A BN film deposited below about 1000°C can be used to obtain the highest value of boron surface concentration at each temperature. After the films were deposited on n-type Si substrates at 700°C, the samples were heated in a hydrogen atmosphere. Values of boron surface concentrations are plotted in Fig. 6 for various heat-treatment temperatures. The curve in this figure seems to give the solid solubility of boron in Si at each temperature. It corresponds to that reported by Vick *et al.* (8).

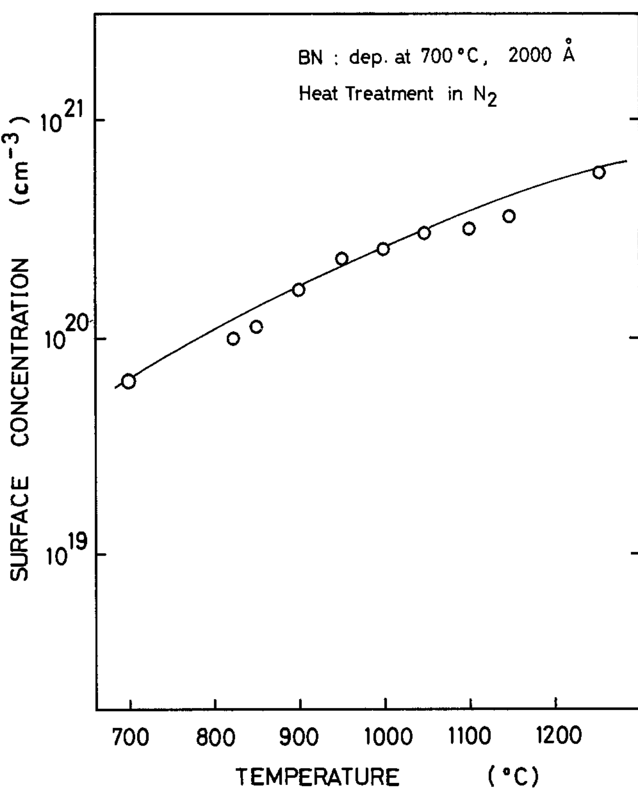

Fig. 6. Maximum values of boron surface concentration at each temperature of heat-treatment (boron solid solubility in Si).

Assuming a complementary error function profile, the boron diffusion coefficient was calculated from the measured values of boron surface concentration, diffusion depth, and diffusion time. Figure 7 shows values of the diffusion coefficient obtained *vs.* the reciprocal of

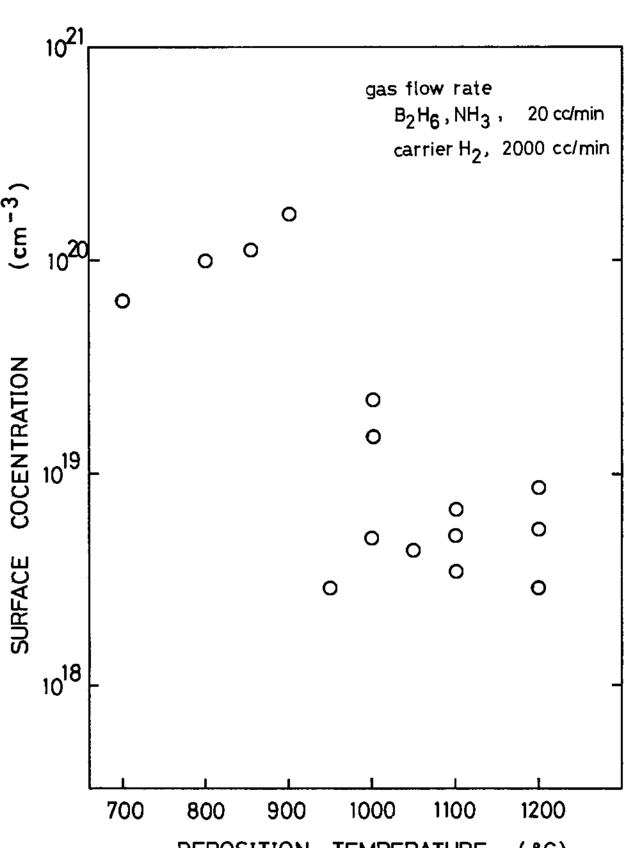

Fig. 5. Boron surface concentration *vs.* deposition temperature of a BN film.

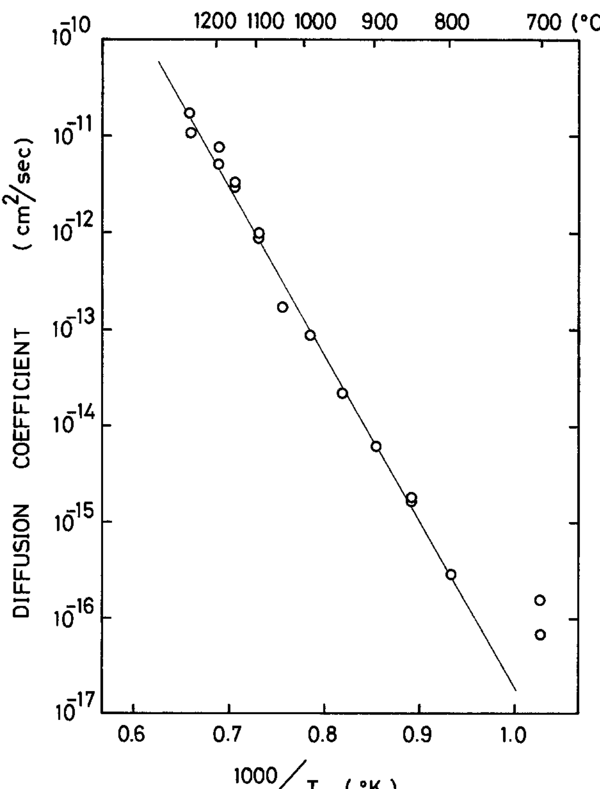

Fig. 7. Diffusion coefficient of boron in Si *vs.* reciprocal absolute temperature.

absolute temperature. The straight line is represented by $D = 26.5 \times \exp(-88{,}900/RT)$. The activation energy of 88.9 kcal compares to with that of 85 kcal reported by Fuller *et al.* (11) and 81 kcal reported by Kurtz *et al.* (1). When the boron surface concentration is over 10^{19} cm^{-3}, it was pointed out by Vick *et al.* (8) that the boron profile deviates from a complementary error function. Our experiments do not show a measurable deviation from a complementary error function.

In order to obtain a lower boron surface concentration than that of solid solubility in Si, a thin layer of BN can be used. As a thin diffusion source, the BN film was deposited at 700°C for 10 sec. The film thickness was estimated to be about 80Å, and the boron diffusion layer which was formed during the deposition was less than 25Å. Heat-treatment for the boron diffusion was carried out in hydrogen or nitrogen. Relationships between diffusion depth, boron surface concentration, and heat-treatment time are shown in Fig. 8. During heat-treatment for 20-800 min at a temperature of 1100°C, the BN decomposed and the bare Si surface appeared. In Fig. 8 the diffusion depth is proportional to the square root of the heat-treatment time, and the boron surface concentration is inversely proportional to the square root of the heat-treatment time. This means that diffusion conditions with a finite amount of impurity on the Si surface are satisfied.

There is another way to obtain a low boron surface concentration. After the BN film was deposited (for 10 sec at a temperature of 700°C), the samples were heated in steam for 3 min at a temperature of 1100°C. The BN film changed to a borosilicate glass. In the next step heat-treatment for boron diffusion was carried out in a nitrogen atmosphere. Relationships between diffusion depth, boron surface concentration, and heat-treatment time are shown in Fig. 9. Diffusion depth is proportional to the square root of the heat-treatment time. On the other hand, boron surface concentration decreases more slowly than the inverse square root of the heat-treatment time. This means that the boron is still supplied from the borosilicate glass during the heat-treatment in nitrogen.

Formation of a borosilicate glass by rapid thermal oxidation in steam was confirmed with infrared absorption. Results are shown in Fig. 10. The absorption peak due to B-N stretching vibration is at 7.3 μm, as shown in Fig. 3. After rapid thermal oxidation in steam, absorption peaks appeared at 7.2, 9.2, and 12.5 μm. The last two peaks at 9.2 and 12.5 μm correspond to those established for silicon dioxide (12, 13). The broadening of the adsorption peak at 7.3 μm due to thermal oxidation is apparent. The small change of the peak from 7.3 to 7.2 μm means that the peak at 7.2 μm is due to a new vibrational mode. The new peak at 7.2 μm

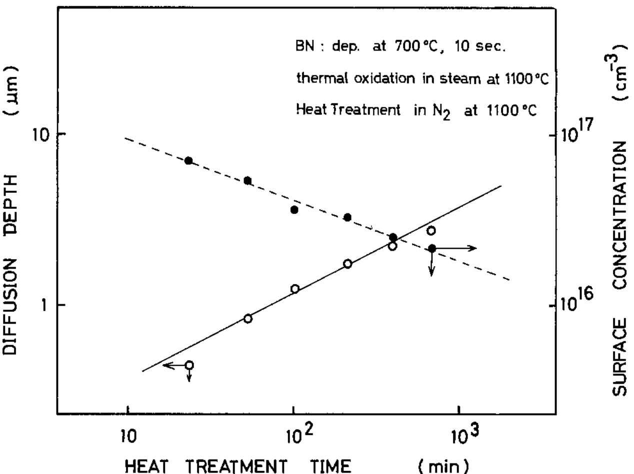

Fig. 9. Diffusion depth and boron surface concentration vs. heat-treatment time when the sample was rapidly oxidized in steam before diffusion.

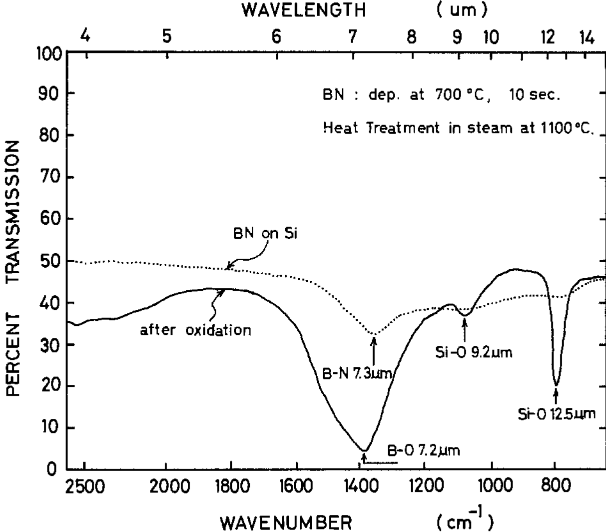

Fig. 10. Infrared absorption spectrum of the borosilicate glass formed by rapid thermal oxidation of a thin BN film on silicon.

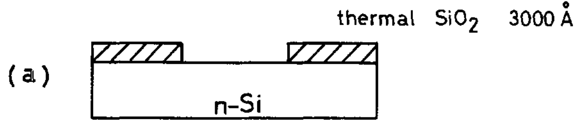
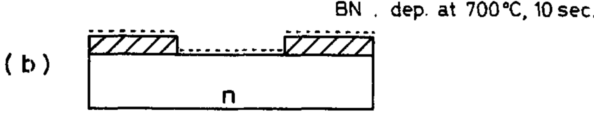
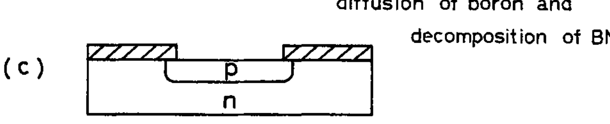
agrees with that due to the B-O stretching vibration (14, 15).

Simple planar diode.—A BN film deposited at 700°C as a diffusion source decomposes easily when heated in a nitrogen atmosphere. This can be used for a planar diode. Schematic diagrams of the processes are shown in Fig. 11. N-type 5 ohm-cm Si wafers are thermally oxidized to about 3000Å, and windows of 1 mm diameter opened in the silicon dioxide. Next, a BN film is deposited for 10 sec at 700°C. To diffuse the boron and decompose the BN in the windows, the samples were heated in a nitrogen atmosphere at 1100°C for 120 min. Boron diffused into the Si through the windows, and a bare Si surface appears in the windows. The diffusion depth of boron is about 3 μm, and the boron surface concentration is about 8×10^{18} cm^{-3}. Nickel can be deposited directly by electroless plating on the bare Si surfaces of the windows. Nickel was also plated on the back face of the Si wafers to make an ohmic contact. Thus, we can simply make planar diodes by the use of only one photomask. A sharp avalanche breakdown is observed in the reverse direction. The breakdown voltages are in the range of 115 ~ 120V, which are expected values from the diffusion depth and the resistivity of Si substrates (16).

MIS-memory diode.—An interesting application of the BN film is as an insulator in an MIS-memory diode. In studying this application, it was found that the







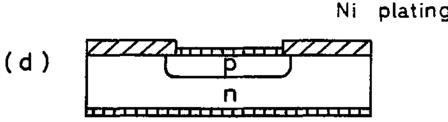


Fig. 11. Schematic diagram of the processes of a simple planar diode using a BN film as a diffusion source.

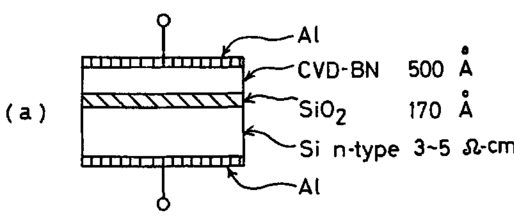
Al-BN-SiO_2-Si structure, shown in Fig. 12(a), exhibited an anomalous shift in C-V characteristics. An experimental device was fabricated as follows. An n-type 5 ohm-cm (100) Si wafer was thermally oxidized in a pure dry oxygen for 3 min at 1050°C. The thickness of silicon dioxide obtained was about 170Å. A BN film of about 500Å was then deposited at a temperature of 700°C. Finally, Al was evaporated to make an electrode on the BN film, using a metal mask with windows of 0.3 mm diam. No additional heat-treatment was necessary to observe a shift in C-V characteristics.



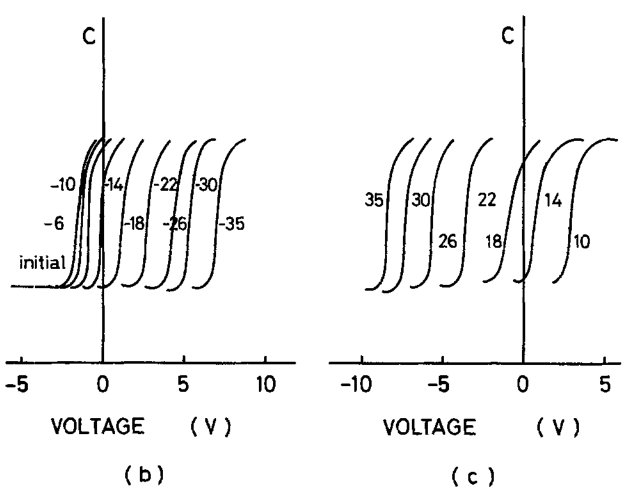


Fig. 12. (a) Schematic diagram of Al-BN-SiO_2-Si structure, (b) typical C-V curves when a negative voltage is applied to the Al electrode, (c) typical C-V curves when a positive voltage is applied to the Al electrode.

Typical C-V characteristics are shown in Fig. 12(b) and (c). When a negative voltage of more than 10V is applied to the Al electrode, the C-V curve begins to shift in the positive direction. The length of the applied voltage pulse was kept at 1 sec throughout this experiment. The C-V shift saturates at an applied voltage of about −35V. Next, we applied a positive voltage to the Al electrode. The C-V curve then begins to shift in the negative direction. The C-V shift saturates again when the voltage applied to the Al electrode is more than 35V.

The direction of these shifts is opposite to those observed for well-known MNOS (17) and MAOS (18) devices. These C-V shifts might be due to polarization of the borosilicate glass which would be formed between the BN film and silicon dioxide layers during deposition of the BN film. Formation of the borosilicate glass is confirmed by the infrared absorption spectrum.

Conclusion

BN films can be deposited on Si substrates by thermal reaction in a B_2H_6-NH_3-H_2 system. When the deposition temperature is below about 1000°C, the film is amorphous. When the deposition temperature is over about 1000°C, the film is polycrystalline with a hexagonal structure. The surface of the BN film is smooth, with a pinhole density below 10 cm^{-2} for a 500Å thick film deposited at 700°C. Boiling phosphoric acid can remove the BN film from a Si substrate; gas plasma dry etching is also useful for removal of the BN film.

BN deposited at a temperature of 700°C easily decomposes when heated in a nitrogen atmosphere. This can be used to fabricate a simple planar diode using only one photomask. The formation of borosilicate glass was confirmed by observing its characteristic infrared absorption spectrum for samples where the BN film was deposited on a thermally grown SiO_2 layer. This can be used for an MIS-memory diode with an Al-BN-SiO_2-Si structure. Such a structure shows an anomalous shift of its C-V curve with applied voltage.

During deposition of BN films, boron diffuses into the Si substrates. BN films thicker than 500Å deposited below about 1000°C act as infinite diffusion sources of boron. When these films are used as diffusion sources, the maximum values of boron surface concentration correspond to the solid solubility of boron in Si at each temperature. A thin BN film (about 80Å deposited at 700°C) gives a surface concentration of boron in the range between 10^{16} and 10^{20} cm^{-3} by varying the prediffusion heat-treatment conditions.

{332} Ga Habit Planes Formed on GaAs during Br_2:CH_3OH Etching

L. A. Koszi and D. L. Rode

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

This paper describes the different habit (stop) planes formed when GaAs substrates are etched in various concentrations of a Br_2:CH_3OH etching solution. It was previously found that concentrations less than 1% Br_2 in methanol yielded {111}Ga habit planes. Concentrations in excess of this amount were investigated and it was discovered that a different set of planes was preferred. Changes in etch pit shapes and mask orientation preference show that these new planes are the {332}Ga planes. The change from {111}Ga to {332}Ga habit planes is a result of increased Br_2 concentration. Initial results of the electrochemical etching properties of Br_2:CH_3OH solutions are also presented. These initial results show that with proper biasing of the sample and solution, the Br_2:CH_3OH etch becomes isotropic.

Dilute mixtures of bromine in methanol are commonly used for free chemical etching and chemical/mechanical polishing of GaAs to achieve smooth, defect-free surfaces. The dependence of etch rate on crystallographic orientation, among other factors, has been studied by Gatos (1) and Moest (2) who find {111}Ga[1] habit planes for this solution with bromine concentrations less than 1% by volume. Similar results were obtained by Tarui, Komiya, and Harada (3) who used this property to chemically etch vee-shaped trenches in (100)GaAs through long rectangular windows formed in an Al_2O_3 mask. In this case, the long axis of the window must be aligned parallel to the $[01\bar{1}]$ to expose the (111) and (111) planes as sides of the vee. These workers pointed out the expected linear dependence of the vee depth (d) on mask window width (w), *i.e.*, $d = w/\sqrt{2}$.

The above work utilized bromine concentrations of less than 1.3% by volume of bromine in methanol. We have obtained similar results at these concentrations. However, during experiments with bromine concentrations above this amount, up to and including 20% Br_2:CH_3OH, we have noted enhanced undercutting of our etching mask window (SiO_2) and the formation of facets along the side of the vee trench leading to a scalloped appearance of the walls which form the trench.

Further experiments* are described below which show that the habit planes at bromine concentrations of 5% Br_2:CH_3OH and higher are {332}Ga planes. With the higher concentration etchant, unfaceted vee-shaped trenches on (100)GaAs are obtained if the long axis of the window mask is aligned parallel to the $[02\bar{3}]$ or $[03\bar{2}]$. The apex of the vee is then inclined away from the normal to the $(01\bar{1})$ cleavage plane by 11.31° and the walls of the vee subtend an angle of 79.52°.

* Key words: chemical etchants, selective etching, gallium arsenide.

[1] The [111] direction is taken to be a positive normal to a (111)Ga surface in agreement with the convention which denotes (111) and $(\bar{1}\bar{1}\bar{1})$ as Ga and As surfaces, respectively.

Results

Br_2:CH_3OH etching was performed at room temperature on polished wafers of boat-grown, Si-doped GaAs with $n = 2 \times 10^{18}$ cm^{-3}. The substrates were subsequently coated with a 5000Å vapor deposited SiO_2 film into which the etching mask pattern was photolithographically defined. Using the "pinhole alignment method" described earlier by Tarui *et al.* (3) the desired mask orientation with respect to the $[01\bar{1}]$ was determined. The SiO_2 etching mask consisted of a fan-shaped pattern shown in Fig. 1. Each leg of the fan, where the SiO_2 had been removed, was 25.4 μm wide and the legs were arranged in 10° increments over a 90° field. A centrally located leg of the pattern was aligned normal to the $(01\bar{1})$ cleavage plane.

A fan etched in a 0.1 volume per cent (v/o) Br_2 in CH_3OH mixture for 25 min confirmed the Tarui *et al.* results (3). Our results are shown in Fig. 2. Note, in the scanning electron micrograph of the surface, the formation of a vee-shaped trench occurs along the center $[01\bar{1}]$ leg only. The other legs form reverse mesa structures discussed by Tarui *et al.* (3). The formation of rectangular etch pits in oxide pinholes was also noted and expected.

A sample was also etched in 5% Br_2:CH_3OH for 15 min. Scanning electron micrographs of the results are shown in Fig. 3. The formation of a vee-shaped trench was noted not only in the center leg of the fan, aligned normal to the $(01\bar{1})$, but also in the legs oriented at ±10° to this normal. Note the formation of scalloped walls in the center leg. Other legs were observed to be "reverse-mesa" geometries.

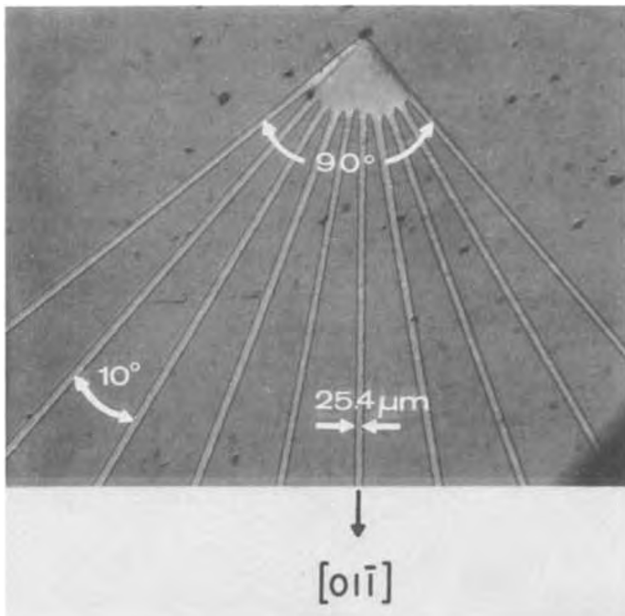

Fig. 1. The alignment and geometric sizes are shown in this photograph of the fan pattern delineated on the (100) surface of a GaAs substrate.

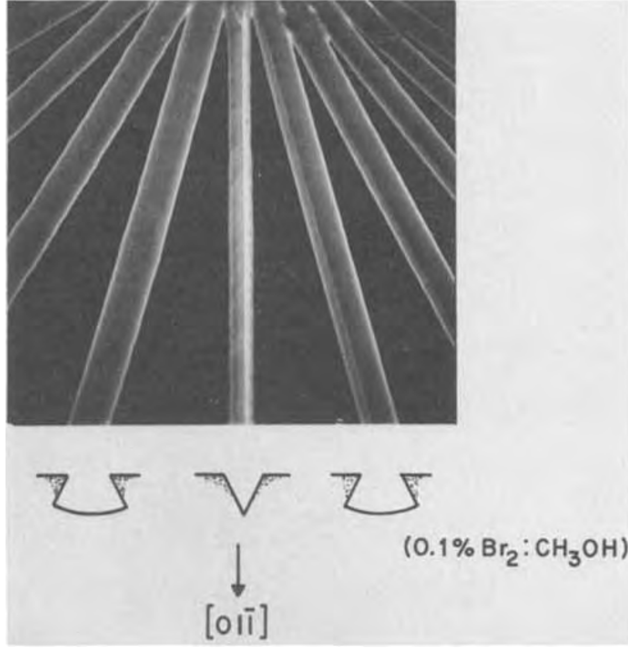

Fig. 2. This photograph shows the results of etching the fan pattern in a 0.1% Br_2:CH_3OH solution. Trench cross sections are also shown.

Another important difference between the two concentrations can be seen in the resultant geometries of the etch pits formed in the oxide pinholes. Two micrographs of these etch pits formed by the 0.1% (a) and 5.0% (b) Br_2:CH_3OH solutions are shown in Fig. 4. The long sides of the diamond-shaped pit, produced by the 5% solution, form an 11° angle with a line bisecting the two acute angles of the diamond. This line lies perpendicular to the (01$\bar{1}$) cleavage plane. This difference in etch pit geometry is due to the delineation of a set of habit planes other than the {111}Ga planes. The planes forming the sides of the diamond-shaped etch pits were found to be the {332}Ga planes.

To confirm the results mentioned above, two slices were etched in a 5% Br_2:CH_3OH solution. The first slice had windows (125 μm wide on 508 μm centers) aligned perpendicular to the (01$\bar{1}$) and the second slice had windows aligned 11.3° off the normal to the (01$\bar{1}$). To reiterate, the 11.3° angle is the angle of intersection between the apex of the vee trench, formed by {332}Ga planes, and the normal to the (01$\bar{1}$) cleavage plane. The walls of the resultant vee in the second slice would then be the {332}Ga planes. If these walls are smooth as opposed to the scalloped walls of the vee trench of the first slice, then one can infer that the higher concentration solution prefers the {332}Ga planes.

The micrographs in Fig. 5 show the results of the etching of the two slices in the 5% Br_2:CH_3OH solution. Micrograph (a) depicts the resultant trench produced in a window aligned perpendicular to the (01$\bar{1}$) while micrograph (b) shows the trench formed in the window aligned parallel to the [02$\bar{3}$] direction which is 11.3° off the [01$\bar{1}$] axis. The scalloped walls of the top figure show the delineation of planes which are not perpendicular to the (01$\bar{1}$). The smooth walls of the lower figure show the resultant and preferred {332}Ga habit planes.

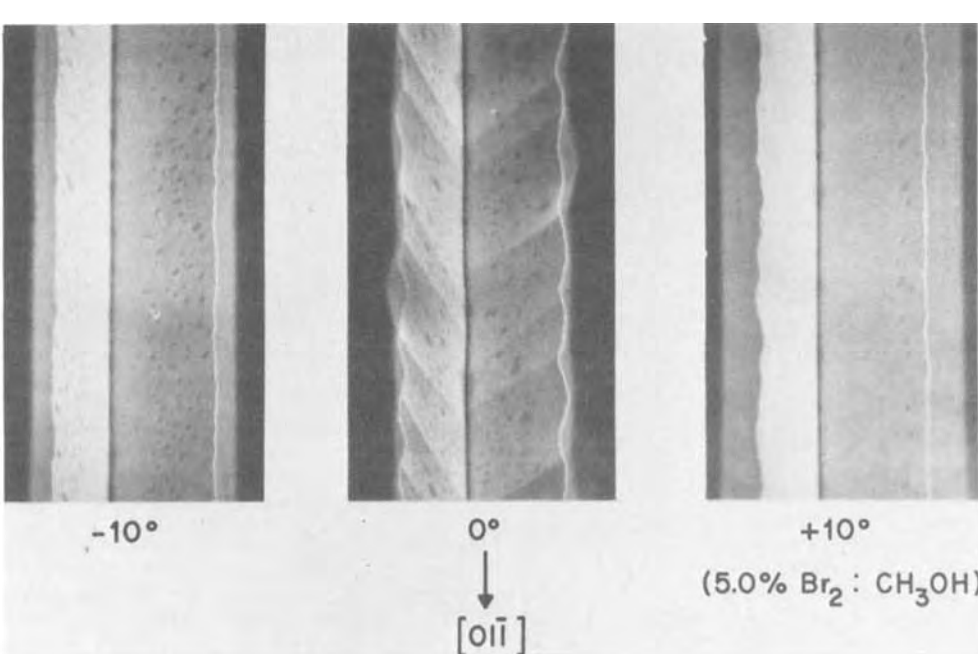

Fig. 3. These three scanning electron micrographs show the shape of the three legs of the fan pattern etched in 5% Br_2:CH_3OH. Note the center leg which is aligned parallel to the [01$\bar{1}$] has serrulated walls while the two trenches aligned ±10° to it are smooth.

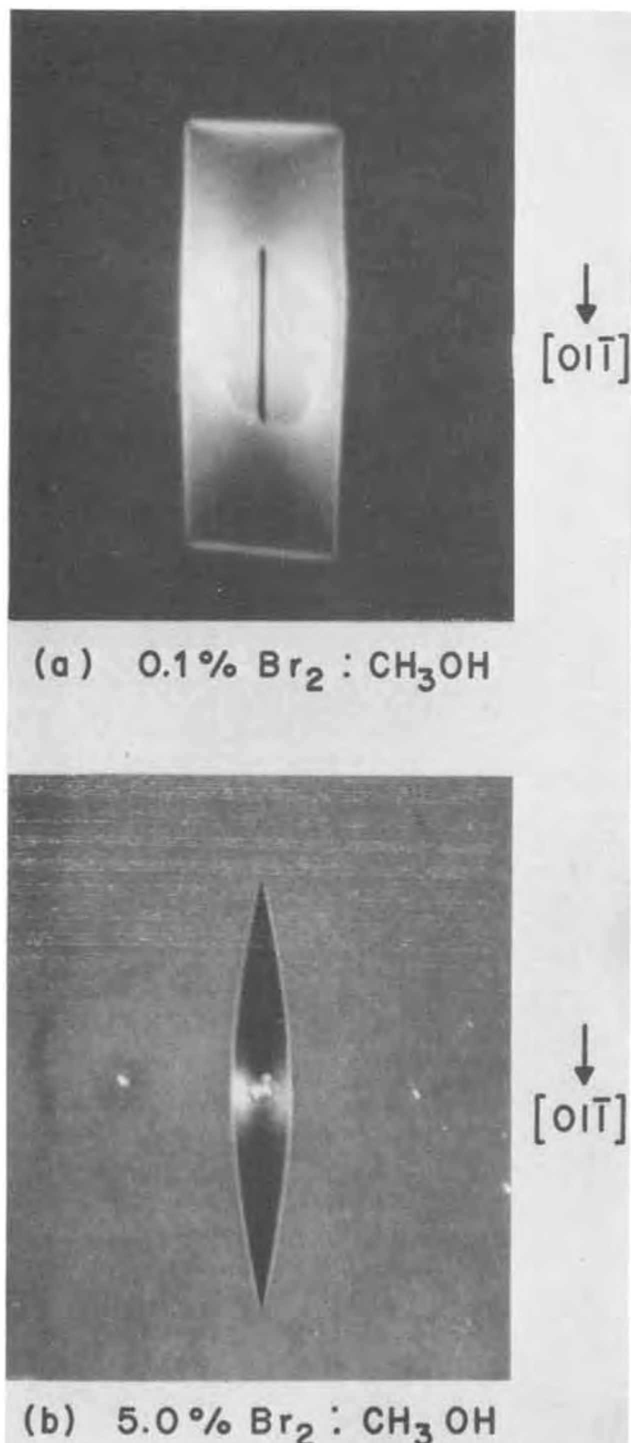

Fig. 4. Pinholes etched by a 0.1% (a) and 5.0% (b) Br_2:CH_3OH solution are shown in these scanning electron micrographs.

A cleave through the [023̄] aligned windows and subsequent measurement of the angle formed between the intersecting walls should give a result relating to the angle of intersection of the {332}Ga planes. However, since the cleave does not pass through the vee perpendicularly, the projected angle of the apex onto the (011̄) cleavage plane is calculated to be 80.6° instead of the angle 79.52° between (3̄3̄2) and (332). The measured angle was found to be 79° ± 2. Had the planes been (111)Ga the corresponding angle is calculated to be 70.53°. This evidence confirms the interpretation that {332}Ga habit planes appear with etching in 5% Br_2:CH_3OH.

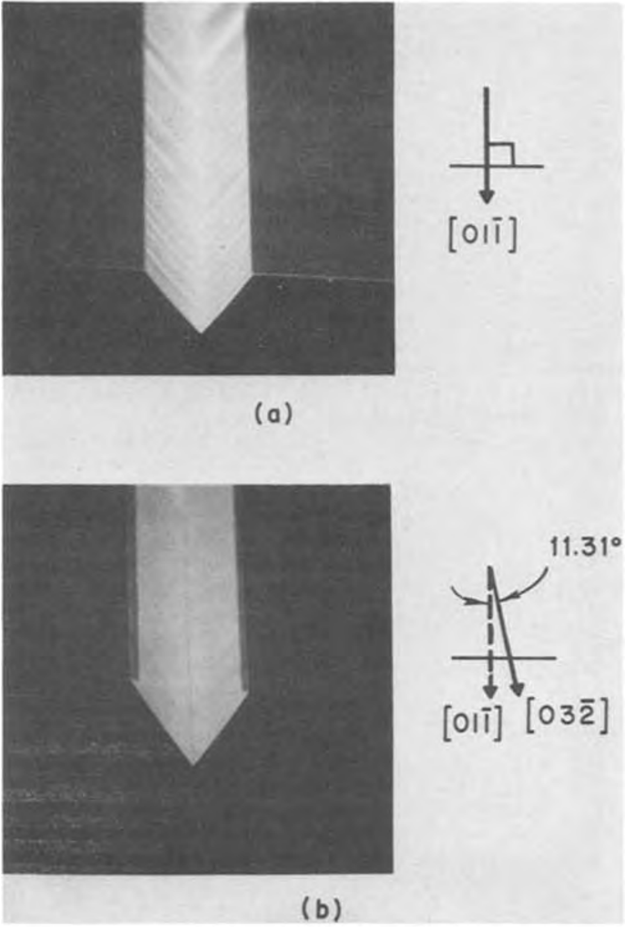

Fig. 5. The formations of vee trenches by a 5% Br_2:CH_3OH are shown in these scanning electron micrographs. The windows were aligned (a) perpendicular to the (011̄) and (b) 11.3° off the normal to the (011̄) plane. Note the serrulated walls of the top photograph.

The shifting of habit planes due to concentration changes is felt to be related to chemical potentials. Etching with concentrations up to 20% were tried in hopes of shifting the habit planes to the {110} planes. These experiments all yielded the same results as the 5% solution. However, it was found that above 1% the solution is reasonably conductive. Hence, experiments with electrical bias applied to the slice during etching with a 5% solution of Br_2:CH_3OH were performed. The procedure and initial results of etching the fan-shaped pattern are presented below. An ability to shift to other planes by means of an applied bias proved fruitless. However, the Br_2:CH_3OH etch was made isotropic with the application of a positive bias to the slice.

Electrical experiments were conducted using GaAs substrates (n-type) which had a fan mask delineated in an SiO_2 layer on the substrate. Electrical access to the sample was made via a spark contacted Sn-Au wire to an area near the edge of the slice. After the unmasked surface was mounted to a glass slide, a liberal coating of wax was applied to cover the wire contacted area to prevent electrical shorting to the etching solution. The samples were then negatively or positively biased during etching in a 5% solution of Br_2:CH_3OH.

Figure 6(a) shows the results obtained with negative bias (−6V). The photograph on the left shows the control slice etched in the same solution, but without bias. Although no difference in the crystallographic properties of the etching solution were noted, a decrease in etching rate resulted with the negative bias. The photograph on the right shows the results of the biased sample. Both samples were etched for 20 min.

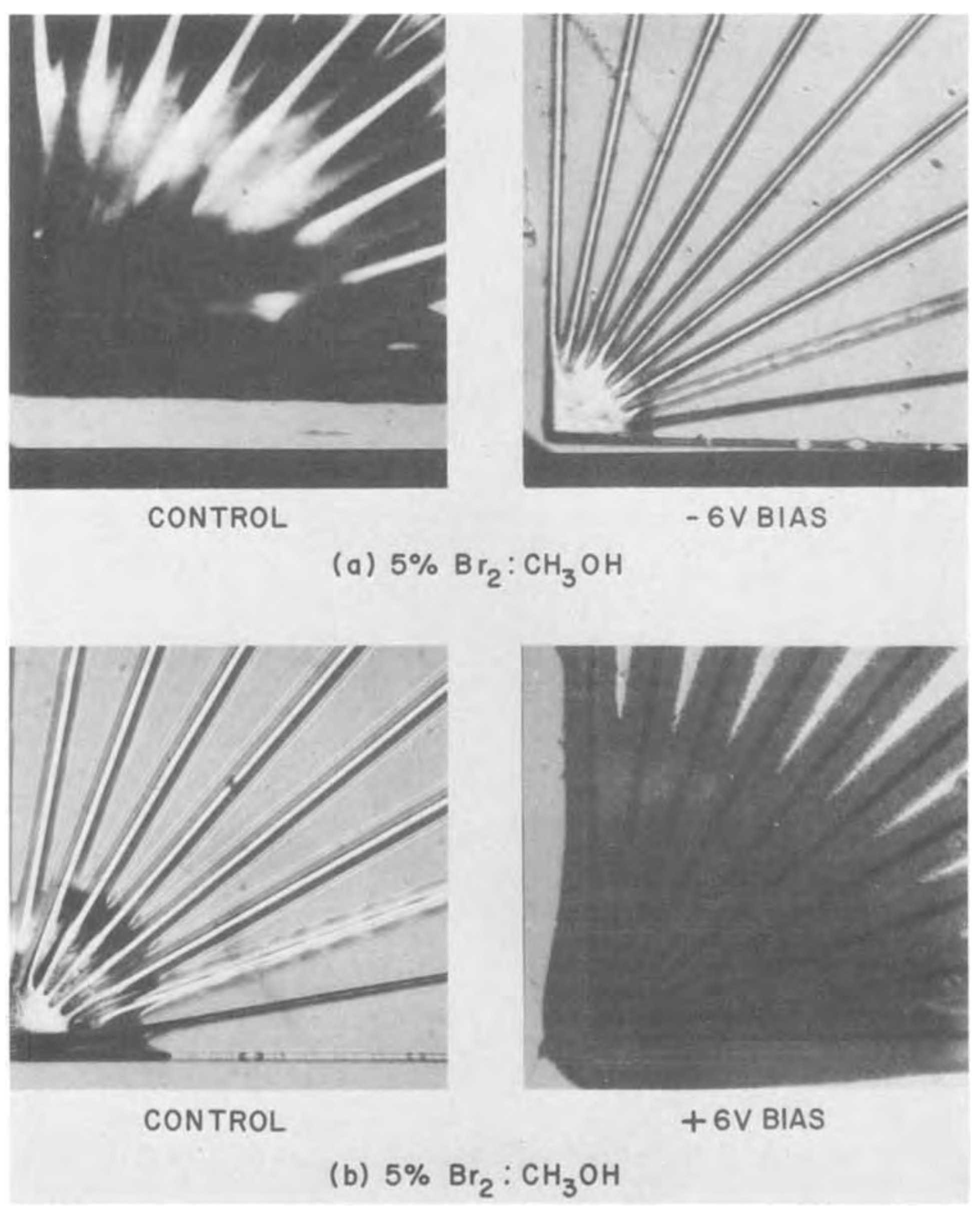

Fig. 6. These photographs show the results of electrically biasing samples during a 5% Br_2:CH_3OH etch of fan shaped patterns.

Figure 6(b) shows photographs of a control (left) and a sample etched for 2 min in a 5% solution with a positive (+6V) bias applied. Note the exaggerated undercutting and increased etch rate of the biased sample. The results were expected. However, note the change in trench shape due to the etchant with the sample biased at a positive potential. Figure 7 shows the etched fan (a) and a photograph of a cleave through the legs to show the trench geometries (b). Figure 7(c) shows the type of etch pits formed with a positive bias applied to the sample during etching. Note that they are circular! These facts suggest that the etch has become isotropic. The application of a higher potential (+40V) produced crystallographically shaped vee trenches with reverse-mesa shaped dendrites superimposed over isotropic trenches.

Conclusion

Using fan-shaped windows delineated into an etching mask and etching with various concentrations of Br_2:CH_3OH, we were able to observe the characteristics of the resultant trenches along different orientations. At concentrations greater than 1% by volume, a change was noted in the number of legs which formed vee trenches, and the wall smoothness of these trenches. Legs oriented at $\pm 10°$ (to the original vee formed at lower concentrations) flipped from reverse mesas to vee trenches. A change in the characteristic shapes of etched pinholes was also noted as the concentration of Br_2 was increased. Lower concentrations formed predicted rectangular pits while pits at higher concentrations were diamond shaped.

Angular measurements from the fan pattern and diamond-shaped etch pits suggested that the habit planes for the higher concentrations were {332}Ga planes. The etching of smooth walled vee trenches, 11.3° off the normal to the $(01\bar{1})$ cleavage plane, supported this assumption. Measurements of various angles formed by these offset trenches confirmed the observation that Br_2:CH_3OH concentrations greater than 1-2% by volume prefer the {332}Ga planes as principal habit planes. At concentrations greater than 1-2%, the Br_2:CH_3OH etching solution was found to be conductive. It was also found that the application of an electrical bias to the sample during etching produced interesting results. A negative bias reduced the etching rate without changing the crystallographic properties of the Br_2:CH_3OH etch. The use of a positive bias produced two changes in the etchant's properties: (*i*) increased etching rate, and (*ii*) a change in the shape of the resultant etch pits and trench geometries suggesting that the Br_2:CH_3OH is isotropic in this case.

Polycrystalline Silicon on Coated Steel Substrates

T. L. Chu,* H. C. Mollenkopf, and Shirley S. Chu

Institute of Technology, Southern Methodist University, Dallas, Texas 75275

ABSTRACT

Steel is the most economical substrate for the deposition of silicon. At temperatures used for the chemical vapor deposition of silicon, however, a barrier layer must be used to prevent the diffusion of iron from the substrate into the silicon layer. Tungsten was found to be ineffective as a diffusion barrier when silicon was deposited by the thermal decomposition of silane at 900°C and above. Borosilicate deposited by the oxidation of a silane-diborane mixture was found to be an effective barrier at temperatures up to 1150°C. Silicon deposited on borosilicate/steel substrates is polycrystalline. The microstructure and crystallographic properties of silicon depend strongly on the substrate temperature, deposition rate, and extent of doping. Silicon layers deposited at low temperatures and high rates consist of small crystallites with a strong preferred {110} orientation, while those deposited at high temperatures and low rates consist of larger crystallites with more random orientation. Silicon p-n junctions deposited on borosilicate/steel substrates show poor electrical characteristics because of the high concentration of grain boundaries, and solar cells have low conversion efficiencies.

Polycrystalline silicon has found increasing applications in device technology during the past few years. For example, polycrystalline silicon film deposited on an oxidized single crystalline silicon substrate has been used for the fabrication of p-channel field-effect transistors, and the characteristics of these transistors were very similar to those of control devices fabricated from single-crystalline silicon (1). The deposition of polycrystalline silicon on silicon dioxide-silicon structures is also an important process in the fabrication of silicon-gate MOS structures and for dielectric isolation in single-crystalline silicon devices (2, 3). The structural and crystallographic properties of polycrystalline silicon for the silicon-gate and dielectric isolation are not as critical as those for the field-effect transistor since polycrystalline silicon is not in the active region of the devices in the former case.

The recent interest in the utilization of solar energy by photovoltaic converters, under the impetus of the energy crisis, has stimulated considerable research and development on the fabrication of solar cells for terrestrial applications. The use of polycrystalline silicon layers on suitable substrates appears to be a promising approach for the fabrication of low-cost solar cells. Ideally, these substrates should be of low cost, light weight, high electrical conductivity, high heat capacity, and low chemical reactivity toward silicon at high temperatures, and they should have a thermal expansion coefficient similar to that of silicon. Such substrates have not been found. In this work, steel was selected as the substrate for the deposition of silicon since it is readily available in sheet form at low cost, \$0.10-0.15/lb. The thermal decomposition of silane in a gas flow system was used for the deposition of silicon. The experimental procedure used for the deposition process and the properties of deposited silicon layers are summarized in this paper.

Necessity for Diffusion Barrier in the Silicon-Steel System

The deposition of silicon by the thermal decomposition of silane in a gas flow system should be carried out at substrate temperatures above 700°C to obtain reasonable deposition rates, 1 μm/min or higher. However, the use of high temperatures is not compatible with the silicon-steel system. A major difficulty is that the thermal expansion coefficients of most low-cost steels are 3-4 times higher than that of silicon. Also, silicon and iron diffuse rapidly into each other at high temperatures. The phase diagram of the iron-silicon system indicates the existence of four silicides, Fe_3Si, Fe_5Si_3, FeSi, and $FeSi_2$, which have metallic properties (4). The deposition of silicon on steel at temperatures above 800°C was found to produce a solid solution of iron disilicide in silicon. To minimize the diffusion of iron, a diffusion barrier must therefore be applied to the surface of steel substrates before the deposition of silicon. The diffusion barrier may also be used to buffer the effects of the large difference in the thermal expansion coefficients of silicon and steel.

A metallic diffusion barrier is preferred for solar cells so that the substrate can serve as an ohmic contact. On the basis of various metal-silicon and metal-iron phase diagrams (4) tungsten was selected. Tungsten is readily deposited by the hydrogen reduction of tungsten hexafluoride (5), and its thermal expansion coefficient (4.2×10^{-6} °C^{-1}) is very similar to that of silicon (3.6×10^{-6} °C^{-1}). In addition, the usefulness of silica (amorphous silicon dioxide) as a diffusion barrier was investigated, as silica is known to be capable of preventing the diffusion of many impurities into silicon (6). Since the thermal expansion coefficient of silicon is several times smaller than those of silicon and iron but can be increased by the addition of boron oxide, the use of borosilicate as a diffusion barrier was also studied. Both silica and borosilicate are readily deposited by chemical reactions, silica by the oxidation of silane (7) and borosilicate by the oxidation of a silane-diborane mixture (8). The composition of borosilicate can be adjusted to have a thermal expansion coefficient similar to that of silicon.

Deposition of Silicon on Coated Steel Substrates

U.S. Steel Vitrenamel I, a low carbon steel sheet used for porcelain enameling applications, and Armco silicon steel, with a large grain structure for use in transformers, were selected as substrate materials. The deposition apparatus is shown schematically in Fig. 1. The flow of various gases was controlled by appropriate valves and measured by flow meters. Hydrogen purified by diffusion through a palladium-silver alloy was used as a diluent in all deposition reactions. The reaction tube was made of fused silica and had an ID of 55 mm. The substrates were supported on a silicon-carbide-coated graphite susceptor, which was heated externally by an rf generator. Prior to the deposition process, the substrates were heated in hydrogen at 900°-1000°C to remove the iron oxide film from the surface.

The deposition of tungsten was carried out at 750°-900°C using hydrogen and tungsten hexafluoride flow rates of 20 liters/min and 8-20 ml/min, respectively.

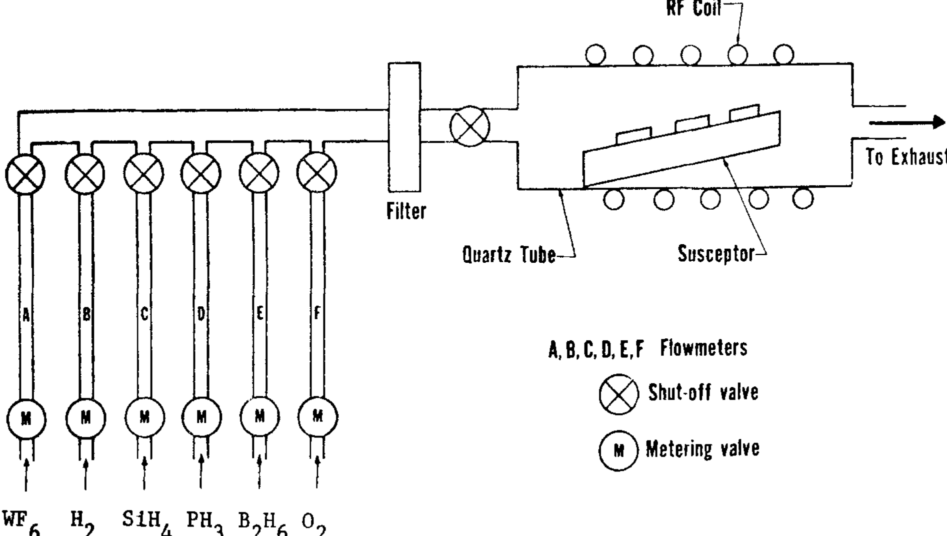

Fig. 1. Schematic diagram of the apparatus for deposition of diffusion barriers and silicon on steel substrates.

Tightly adherent layers of tungsten were obtained at deposition rates of 0.3-0.8 μm/min. When the deposition of tungsten was followed by the deposition of silicon at 900°C or above using hydrogen containing 0.1-0.5% silane at a flow rate of 20 liters/min (9), the deposit always exhibited a grain structure similar to that of the substrate, and centimeter-size crystallites were obtained on silicon steel substrates. However, the silicon was always n-type with very low electrical resistivity, less than 10^{-3} ohm-cm by spreading resistance measurements, and chemical analysis also showed the presence of iron. Thus, the deposit consisted of a solid solution of iron disilicide in silicon, showing that tungsten was not able to prevent the diffusion of iron at 900°C and above. This is due presumably to the polycrystalline nature of deposited tungsten, where the diffusion rate of iron along the grain boundaries is considerably higher than that through the bulk. As the temperature of silicon deposition was decreased, the electrical resistivity of the silicon increased. The silicon deposited at 800°C, for example, was n-type with a resistivity of about 1 ohm-cm, indicating that the diffusion of iron was considerably reduced. Figure 2 shows the vertical cross section of a silicon/tungsten/USS Vitrenamel I specimen prepared at 800°C, where the columnar structure of tungsten is apparent.

The deposition of silica in steel substrates was carried out at 800°-900°C using hydrogen, silane, and oxygen flow rates of 20 liters/min, 25 ml/min, and 250 ml/min, respectively. Silica films of 3-5 μm thickness were adherent to the substrate and served as a good barrier against the diffusion of iron, as indicated by the high electrical resistivity of silicon subsequently deposited at 1100°C. However, cracks were sometimes observed in the silica film, due presumably to the large difference between the thermal expansion coefficients of silica and steel. This difficulty was overcome by adding diborane to the reactant mixture to deposit borosilicate as the diffusion barrier. At temperatures above 450°C, the B_2O_3/SiO_2 molar ratio in borosilicate is very similar to the B_2H_6/SiH_4 molar ratio in the reactant mixture (8). To obtain borosilicate with a thermal expansion coefficient similar to that of silicon, the B_2H_6/SiH_4 molar ratio should be approximately 1:5. Using hydrogen, silane, diborane, and oxygen flow rates of 20 liters/min, 25 ml/min, 5 ml/min, and 250 ml/min, respectively, the deposition rate of borosilicate was approximately 0.25 μm/min at 900°C. At lower flow rates of silane and diborane, the deposition rate was directly proportional to the flow rates of the hydrides.

Following the deposition of borosilicate on steel substrates, silicon was deposited at 900°-1150°C at rates of 0.2-2 μm/min. Tightly adherent layers were obtained in all cases. Figure 3 shows the mechanically polished and chemically etched (Sirtl etch, 10 sec) vertical cross section of a silicon/borosilicate/USS Vitrenamel I specimen prepared at 900°C, where the thicknesses of borosilicate and silicon are approximately 5 μm and 55 μm, respectively. The grain structure in silicon is revealed by etching. Silicon deposited without intentional doping was n-type with an elec-

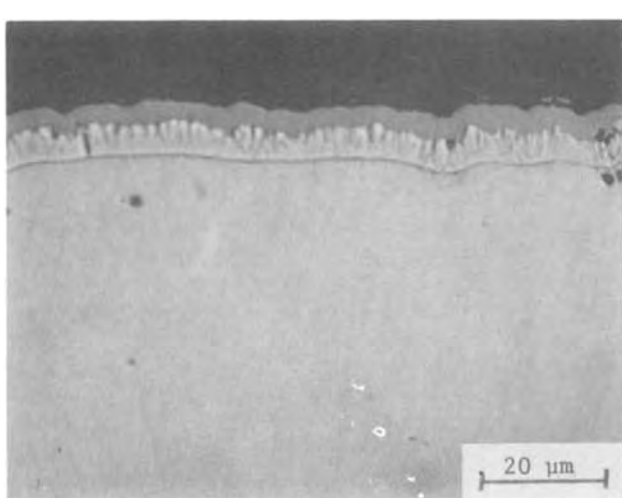

Fig. 2. Vertical cross section of a silicon/tungsten/USS Vitrenamel I specimen prepared at 800°C.

trical resistivity of several hundred ohm-centimeters; this high electrical resistivity could be due to grain boundaries and may not be a good measure of the dopant concentration.

Silicon specimens deposited on borosilicate/steel substrates at 900°-1150°C were analyzed by the ion-probe mass spectrometric technique using an O_2^+ beam to sputter-etch the surface of the specimen. The concentration of iron was found to be below the detection limit, about 1 ppm. Although the ion beam removed only the surface layer of silicon, any iron present should have been uniformly distributed due to the high diffusion coefficient of iron in silicon at the deposition temperatures used.

Properties of Polycrystalline Silicon on Borosilicate/Steel

Since borosilicate deposited on steel is amorphous, silicon deposited on borosilicate/steel substrates is similar in properties to silicon deposited on silicon dioxide or silicon nitride (10-12). Its microstructure was found to depend strongly on the substrate temperature, deposition rate, and extent of boron doping. In general, silicon deposited at low temperatures and high rates without intentional doping consists of small crystallites. The size of crystallites increases with increasing deposition temperature, decreasing deposition rate, or the incorporation of high concentrations of boron (10^{20} cm^{-3}, for example). Figure 4 shows the micrographs of mechanically polished and chemically etched surfaces of four silicon films of about 20 μm thickness deposited under various conditions. Undoped silicon deposited at 900°C at a rate of 2 μm/min showed a fiber-like structure (Fig. 4A). When the deposition rate was reduced to 0.2 μm/min, small crystallites of less than 1 μm size dominated (Fig. 4B). The size of the crystallites was increased appreciably by doping with a high concentration of boron (Fig. 4C) and was further increased by increasing the deposition temperature to 1000°C (Fig. 4D). The largest crystallite was about 5 μm in size, and the crystallite size also increased with increasing thickness of the silicon layer. Furthermore, diborane was found to enhance the deposition rate of polycrystalline silicon as reported by others (13).

The crystallographic properties of many silicon layers deposited on borosilicate/USS Vitrenamel I substrates at 900°-1150°C and at 0.2-2 μm/min containing various concentrations of dopants were examined by the x-ray diffraction technique using CuK_α radiation. Polycrystalline silicon powder of random orientations is known to show three strong diffraction peaks associated with {111}, {220}, and {311} reflections, with 2θ values of 28.4°, 47.3°, and 56.1°, and relative intensities of 100, 60, and 35, respectively (14). The {220}/{111} intensity ratio in the diffraction spectra of the silicon layers was found to vary considerably with deposition conditions. In general, very large {220}/{111} intensity ratios were observed in layers deposited at low substrate temperatures, high deposition rates, and low concentrations of dopants. This ratio decreases with increasing substrate temperature, decreasing deposition rate, or the introduction of a high concentration of dopants (boron or phosphorus). Two extreme cases are shown in Fig. 5. Figure 5A shows the diffraction spectrum of an undoped silicon film deposited at 900°C at a rate of 2 μm/min; the {220}/{111} intensity ratio is approximately 1000, indicating that the crystallites show a strong {110} preferred orientation. Figure 5B shows the spectrum of a 0.002 ohm-cm boron-doped silicon film deposited at 1100°C at a rate of 0.2 μm/min; the {220}/{111} intensity ratio is approximately 2.5, indicating that the crystallites are more randomly oriented.

The conductivity type and electrical resistivity of silicon films on borosilicate/USS Vitrenamel I substrates were readily controlled by using diborane and phosphine as dopants in the reactant mixture (9). Many p-n junctions were prepared by varying the dopant concentrations during deposition. An example of the resistivity profile of such a structure, obtained by using a spreading resistance probe along the angle-

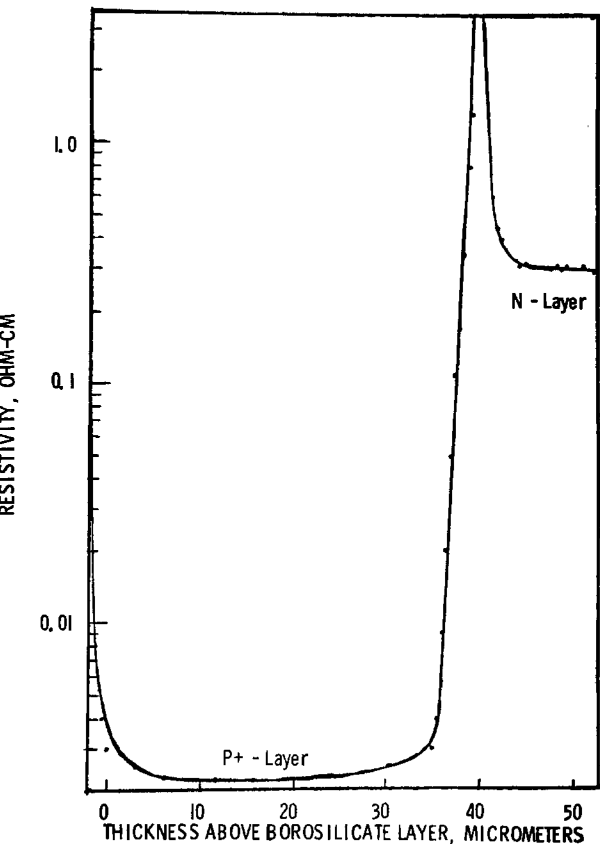

Fig. 6. Resistivity profile of polycrystalline silicon in an n-silicon/p$^+$-silicon/borosilicate/USS Vitrenamel I structure.

lapped surface of a specimen (15), is shown in Fig. 6, where the specimen was prepared by successively depositing 5 μm of borosilicate (not shown), 35 μm of 0.002 ohm-cm p-type silicon, 5 μm of undoped silicon, and 10 μm of 0.3 ohm-cm n-type silicon on an USS Vitrenamel I substrate. The initial, relatively thick, boron-doped silicon layer was used to improve the microstructure of silicon in the junction region. Using masking and etching techniques, mesa diodes of 0.5 mm diameter were isolated. The electrical characteristics of a typical diode are shown in Fig. 7. The "n" value calculated from the forward characteristics is about 3.9 as compared with 1.5-1.9 for single-crystalline silicon p-n junctions at low voltages; this high "n" value is presumably related to the carrier recombination at grain boundaries. The grain boundaries also contribute to the relatively high reverse current. Because of the poor junction characteristics, solar cells fabricated from the structure n$^+$-silicon/p-silicon/p$^+$-silicon/borosilicate/USS Vitrenamel I were found to have low conversion efficiencies, less than 0.5%.

Summary

Borosilicate has been found to be an effective barrier against the diffusion of iron into silicon at temperatures up to 1150°C. Silicon has been deposited on borosilicate/steel substrates at 900°-1150°C by the thermal decomposition of silane. The deposited silicon is polycrystalline, and its microstructure and crystallographic properties are affected by the substrate temperature, deposition rate, and extent of doping. Silicon layers deposited at low temperatures and high rates consist of small crystallites with a strong preferred {110} orientation, while those deposited at high temperatures and low rates consist of larger crystallites with more random orientations. Silicon p-n junctions deposited on borosilicate/steel substrates exhibit poor electrical characteristics, and solar cells have low conversion efficiencies.

Low Surface Concentration of Boron in Silicon by Diffusion Through Silicon Dioxide

W. von Muench and C. Gessert

Institut A fuer Werkstoffkunde, Technische Universitaet, D-3000 Hannover, Germany

ABSTRACT

It is shown that the diffusion of boron through a thin silicon dioxide layer can be used to control the surface acceptor concentration in silicon within the range from 5×10^{15} to 2×10^{20} cm^{-3}, with the junction depth varying from 0 to 15 μm. The diffusion constant of boron in SiO_2 was determined to be $D_1 = 3.4 \times 10^{-6} \exp(-2.60 \text{ eV}/kT)$ cm^2/sec, for a boron surface concentration of about 2×10^{19} cm^{-3}. Examples for the technical application of this method are briefly discussed.

Silicon dioxide is extensively used for masking purposes in the silicon planar technology. Consequently, the main objective of the early work on impurity diffusion in silicon dioxide was an examination of those experimental conditions for which the limit of complete masking is reached (1, 2). In the technology of III-V compounds, on the other hand, the method of diffusion through a thin protective layer has served mainly to eliminate surface erosion problems (3, 4). It was pointed out also that diffusion through a solid layer into a semiconductor body can facilitate the generation of specific impurity concentration profiles (5). More recently, it was observed that a thin (~100Å) layer of silicon dioxide grown by hot nitric acid cleaning of silicon wafers may have a significant influence on the impurity surface concentration obtained by subsequent diffusion from a solid source layer (6, 7). The diffusion of gallium through silicon dioxide films into silicon was studied recently by MOS techniques (8). It is the purpose of this contribution to demonstrate the possibility of achieving surface concentrations in the 5×10^{15} to 2×10^{20} cm^{-3} range with good reproducibility by diffusion of boron through a silicon dioxide layer of appropriate thickness. This technique is useful especially for devices comprising regions with low and high surface concentrations of the same conductivity type (or shallow and deep p-n junctions).

There are numerous experiments on boron diffusion reported in the literature. A survey on these results has been published recently by Ghezzo and Brown (9). The resulting figures for the diffusion coefficient of boron in silicon dioxide are covering a very large range (*e.g.*, activation energy from 2.38 to 3.58 eV). While some of the discrepancies may be properly explained in terms of a concentration dependent diffusivity, it is felt that the various experimental conditions (*e.g.*, type of source) must also be taken into account in an assessment of the diffusivity data. In view of the particular nature of the source material employed by the authors (boron-doped silicon powder), a redetermination of the diffusion constant of boron in silicon dioxide and a comparison with published data seemed to be useful.

Key words: boron diffusion, silicon dioxide, junction depth, sheet resistivity.

Theory

The one-dimensional theory for the diffusion of impurities from a semi-infinite high-diffusivity source (gas phase) through a partially masking layer into a semiconductor body has been developed previously (2). With notations according to Fig. 1a one obtains the following expression for the diffused impurity concentration in silicon

$$C_2(x,t) = m(1-a)C_o \sum_{n=0}^{\infty} a^n \operatorname{erfc}\left[\frac{(2n+1)x_o}{L_1} + \frac{x}{L_2}\right] \quad [1]$$

where m is the distribution coefficient, D_1 the diffusion coefficient in silicon dioxide, D_2 the diffusion coefficient in silicon, and $L_1 = 2\sqrt{D_1 t}$, $L_2 = 2\sqrt{D_2 t}$, $a = (m-r)/(m+r)$, $r = \sqrt{D_1/D_2}$ (t = diffusion time).

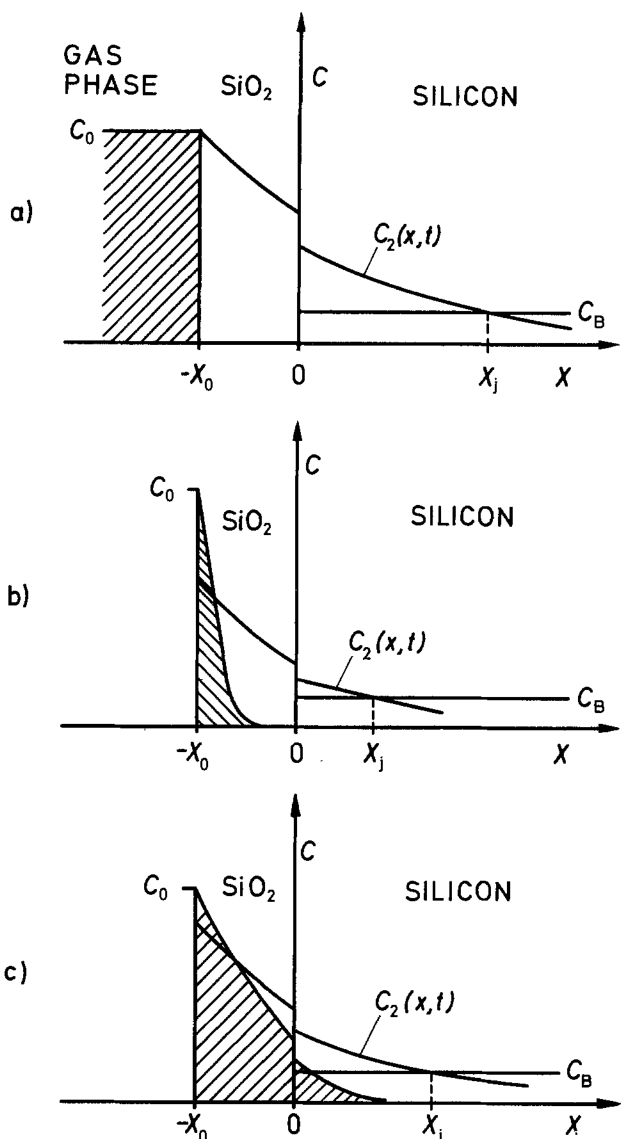

Fig. 1. Impurity concentration profile to be obtained by diffusion through silicon dioxide. (a) Diffusion from gas phase. (b) Diffusion with shallow predeposition. (c) Diffusion with deep predeposition.

If the bulk contains a uniform impurity concentration C_B of opposite conductivity type than the diffusant, a p-n junction will result at a depth x_j which is determined by setting $C_2\ (x,t) = C_B$ in Eq. [1]. For the condition of almost complete masking, *i.e.*, $x_o/L_1 > x_j/L_2$, $x_o/L_1 > 0.7$, only the zero order term needs to be retained in the summation. This yields a simple relationship between the junction depth and the oxide thickness

$$x_j = -\frac{1}{r}x_o + L_2 \arg \operatorname{erfc} \frac{C_B}{m(1-a)C_o} \qquad [2]$$

from which r may be deduced. Plotting x_j *vs.* x_o for a series of diffusion experiments with varying temperature, one obtains the difference of the activation energies of the diffusion in silicon dioxide (E_1) and in silicon (E_2)

$$E_1 - E_2 = \left(\frac{1}{kT_2} - \frac{1}{kT_1}\right)^{-1} \ln \frac{r^2(T_1)}{r^2(T_2)} \qquad [3]$$

In practice, the diffusion from an infinite gaseous source is often employed during the initial stage of the diffusion process only. In this case, a thin solid source is formed within the top layer during the predeposition step; a redistribution of impurities then takes place during the main diffusion cycle (Fig. 1b). Due to the limited amount of impurity atoms available in this case, the concentration C_2 will be lower than predicted by Eq. [1]. Alternatively, a prolonged predeposition may produce an impurity distribution according to the hatched area of Fig. 1c. The main diffusion will then yield a final distribution which is close to that of Eq. [1] if the total diffusion time is of the same order of magnitude as the predeposition time.

Experimental

N-type silicon wafers of (111) orientation were carefully cleaned in organic solvents, boiling nitric acid, and distilled water. These wafers were oxidized at 1050°C in a dry oxygen stream with a flow rate of 12 liters/hr. The oxidation time was varied between 20 and 180 min in order to produce oxide layers in the 500-1800Å range. The oxide thickness was measured with a "Dektak" surface profile measuring instrument (Sloan Corporation) with an estimated accuracy of ±10Å for SiO_2 layers up to 1000Å and ±25Å for thicker SiO_2 layers. The boron predeposition step was performed in a sealed quartz system with a powdered silicon/boron source ($N_A = 2 \times 10^{20}$ cm^{-3}). Experiments for the reevaluation of the boron diffusion coefficient in SiO_2 were carried out in the 1000°-1200°C temperature range, the diffusion time (1-20 hr) being adjusted to yield a junction depth sufficiently large for evaluation. The bulk donor concentration was 5×10^{14} cm^{-3}.

The generation of low-concentration boron diffused layers in silicon requires a two-step process. The electrical data of the bulk silicon and the predeposition conditions pertaining to the four series of experiments (A-D) described in this paper are summarized in Table I. The main diffusion (drive-in step without external source) was performed in an open-flow system at 1150° C with a slightly oxidizing ambient (50 liters/hr nitrogen plus 0.5 liter/hr oxygen). The diffusion time ranged from 1 to 128 hr. Standard four-point probe and beveling techniques were employed to determine the sheet resistivity and the junction depth.

Results and Discussion

The experimental relation between the normalized junction depth, $x_j/\sqrt{t}$, and the normalized oxide thickness, $x_o/\sqrt{t}$, is plotted in Fig. 2. From the straight lines fitting the experimental data one obtains the boron diffusion constant D_1 and the activation energy E_1 according to Eq. [2] and [3]. Using recently published data for the boron diffusion in silicon by Fair (10) it is concluded that the diffusion constant of boron in silicon dioxide is

$$D_1 = 3.4 \times 10^{-6} \exp\ (-2.60\ \text{eV}/kT)\ \text{cm}^2/\text{sec}$$

with a boron/silicon source (2×10^{20} boron atoms/cm^3). This result is compared in Table II with literature data, taken from the summary compiled by Ghezzo and Brown (9). In Table II the diffusion constants are

Table I. Electrical data of bulk silicon and diffusion conditions for experimental series A-D

	A	B	C	D

D	0.5-10	$10^2\text{-}10^4$

The results of two-step diffusion experiments, with parameters according to Table I, are shown in Fig. 3-6. A wide range of diffusion depths and sheet resistivities can be accomplished by properly selecting the experimental conditions. For an arbitrary pair of x_j and $\rho_\square$ (within some limits compiled in Table III) one can find the appropriate diffusion procedure from one of the figures (Fig. 3-6). This includes the fabrication of closely compensated layers in the 10^5 ohm/□ range.

The low resistivity limit is set by the source impurity concentration.

The experiments on which Fig. 3 and 4 are based (series A and C) were performed with a low-temperature (1000°C) predeposition step, yielding an impurity profile according to Fig. 1b. This type of predeposition is appropriate for the generation of very shallow, low impurity concentration p-layers. Series B and D (Fig. 5 and 6), on the other hand, involve a high-temperature (1150°C) predeposition step. A shallow junction is formed during the predeposition, which moves farther into the bulk silicon during the drive-in step (Fig. 1c). This type of diffusion can produce sheet resistivities in the 200-400 ohm/□ range, as required for the base region of junction transistors.

Applications

The technique of boron diffusion through a partially masking silicon dioxide layer is most useful for those devices which require a low concentration p-type region or two regions with different doping levels (or a shallow and a deep p-n junction). A reduction of fabrication costs for integrated circuits may be achieved by the simultaneous generation of the base regions, diodes, and resistors (with partially masking oxide) and the isolation frames (without oxide). Figure 7 describes the sequence of fabrication steps for the transistor region of an integrated circuit.

Exploratory logic circuits have been produced by the above described technique, with diffusion parameters according to Table IV. Figure 8 shows an angle lap through a transistor region, including the isolation frame which was produced in the same diffusion step as the base. A current amplification of 100 at $I_c = 5$ mA was obtained with boron diffusion through SiO_2 and standard ($POCl_3$) emitter diffusion techniques.

High-sensitivity photodetectors for ultraviolet radiation require a very shallow junction and a diffused impurity surface concentration which slightly exceeds

The Diffusion of Ion-Implanted Arsenic in Silicon

Richard B. Fair* and Joseph C. C. Tsai

Bell Laboratories, Reading, Pennsylvania 19603

ABSTRACT

In order to characterize implanted-diffused As layers in Si and to develop general processing information, impurity profiles were determined by secondary ion mass spectrometry (SIMS) and differential conductivity measurements. An analysis of these profiles is given which has yielded information regarding the diffusion of As and the electrical quality of these implanted-diffused layers. It is shown that implanted-diffused As profiles with $C_{TO} \geqq 1 \times 10^{20}$ cm^{-3} can be described by a Chebyshev polynomial approximation to the diffusion equation with concentration-dependent diffusivity. The diffusion of As is not dependent upon the furnace ambient, but As pile-up within 200-400Å of the Si surface does occur during diffusion in an oxidizing atmosphere. It is also shown that implanted-diffused As layers show higher electrical activity for diffusion temperatures below 1100°C than layers diffused from chemical sources. For implanted As layers in which the peak concentration is greater than the solubility limit, the fraction of electrically active As increases at a rate proportional to $t^{1/3}$.

When As is diffused into Si from chemical sources such as doped oxides or solid As in evacuated ampuls, chemical reactions occur in the Si which create inactive As complexes, thus limiting the solubility of the electrically active As (1). It has been suggested that vacancies are involved in these complexes (1, 2) because of the strong cooperative diffusion effects that exist between sequentially diffused As and B layers in Si (3). However, it was recently pointed out that cooperative diffusion effects between As and B are reduced to an electric-field interaction when the source of As is an ion-implanted As layer in the Si (4). The results of that study suggested that As complexes appear to be formed very rapidly during implantation or annealing, and the existence of such complexes is dose dependent.

Since these initial studies were performed, a large amount of ion-implanted-diffused As profile data have been measured in an attempt to study the characteristics of As ion predepositions as diffusion sources. These data in conjunction with Hall mobility measurements have also aided in the construction of a resistivity *vs.* electron concentration curve for As in Si that is more accurate than Irvin's curve (5) at concentrations $> 10^{20}$ cm^{-3}. In addition, general relationships describing the important profile parameters have been derived (6).

In the next section the experimental details of this study will be described. An analysis of the experimental results will follow which will cover total As profile shapes, As diffusivity, and electrical activity.

Experimental

Profile determination.—Silicon of <100> orientation, p-type, 0.2 ohm-cm bulk slices and As-doped n-type epitaxial Si, 0.6 ohm-cm (8-11 μm thick) on p-type 8 ohm-cm substrates was used in the present study. All As implantations were performed at 50 keV in the dose range 1×10^{15} to 2×10^{16} cm^{-2}. The implantations were directed in a random orientation (slices tilted ~8° toward the ion beam). All diffusions of the as-implanted samples were performed in N_2 or O_2 over the temperature range 900°-1200°C and in wet O_2 at 1050°C. After diffusion, the slices were divided, one-half for differential conductivity profile measurements and the other half for profile measurements by secondary ion mass spectrometry (SIMS).

Details of the differential conductivity measurements have been given elsewhere (7, 8). Anodizations were generally performed at 100V in a mixture of tetrahydrofurfuryl alcohol and potassium nitrite (9). 200 ±20Å of Si was removed for each oxidation step as measured on an ellipsometer.

The in-depth total As profiles were determined by mass analysis of secondary ions ejected from the samples by 15 keV oxygen ion (predominantly O_2^+) bombardment using the Cameca IMS 300 Ion Analyzer (8). AsO^- secondary ions were selected and counted using an AS-200 multichannel analyzer. The analyzer data was converted to As concentration *vs.* depth by a method previously described (8). Calibration was achieved by knowing the total implanted dose in the Si.

Resistivity vs. electron concentration.—In order to convert the differential conductivity data into concentration of electrons (electrically active As concentration), Hall mobility measurements were obtained on samples that had been profiled. In addition, the data of Müller *et al.* (10) (Hall measurements on As-implanted samples) and the data of Fistul' (11) and Logan (12) (Hall measurements of As-doped samples) were converted to resistivity *vs.* electron concentration, where it was assumed that μ_H (Hall mobility) equals μ_c (conductivity mobility). This assumption should be valid under conditions of degeneracy (11). These data are shown in Fig. 1. Also shown are direct resistivity measurements taken on well-annealed As-implanted samples that had been profiled by SIMS as well as by the differential conductivity method on profiles which gave 100% electrical activity. The concentration values associated with these data are the total local As concentration. Thus, none of the data in Fig. 1 have been determined by Irvin's curve (5), which is shown plotted for comparison. It can be seen that Irvin's curve underestimates the free-electron concentration in As-doped Si layers by as much as 30% over the range $10^{20} < n < 4 \times 10^{20}$ cm^{-3}. This is probably due to the fact that Irvin used total phosphorus con-

centration *vs.* resistivity data in order to establish this portion of his curve (5). A polynomial fit for the As data is given in Appendix B.

Analysis of Results

Total As profiles.—Implanted-diffused As.—The results of the experimental determination of total As profiles in Si are shown in Fig. 2 where concentration data normalized to total As surface concentration, C_{TO}, are plotted *vs.* normalized junction depth (x_J was selected as the depth at which C falls to 0.01 C_{TO}). These data represent implantations at 50 keV (dose range 2×10^{15} to 2×10^{16} cm^{-2}) which were diffused at 1000°-1200°C for various times. It can be seen that most of the data can be described in total concentration, C (cm^{-3}), and depth, x (cm), by the simple equation (13)

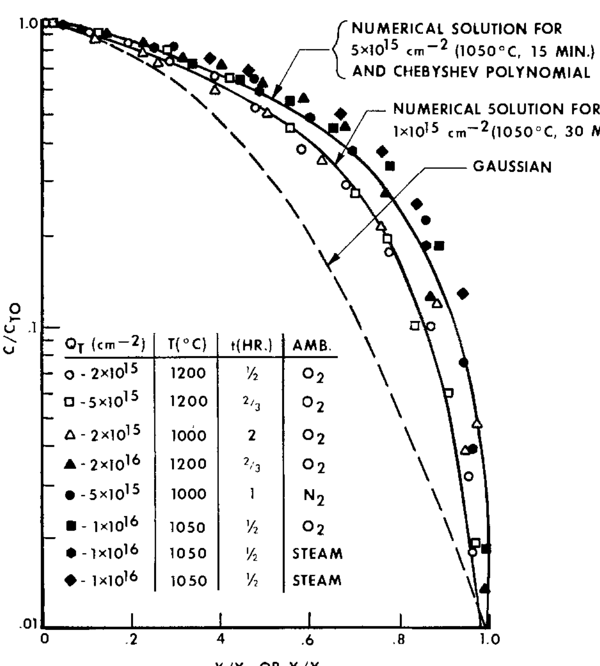

Fig. 2. Normalized total As profiles of implanted-diffused layers in Si. The numerical solutions to the diffusion equation are compared to the polynomial approximation for two different implant doses.

$$\frac{C}{C_{TO}} = 1 - 0.87Y - 0.45Y^2 \quad [1]$$

where

$$Y = x(8C_{TO}D_i t/n_i)^{-1/2} \quad [2]$$

D_i and n_i are the intrinsic As diffusivity and intrinsic electron concentration at the diffusion temperature, respectively. Equation [1] was originally used as a Chebyshev polynomial approximation to the solution of the diffusion equation with linear concentration-dependent diffusivity and constant surface concentration (14). For the diffusion conditions studied the arsenic surface concentration is a slow varying function of diffusion temperature and time, hence, a constant surface concentration of arsenic can be assumed as a first order approximation.

When Eq. [1] is compared to high accuracy numerical solutions of the diffusion equation describing the relaxation of an implanted gaussian impurity distribution, it is found that if the diffusivity is expressed as (assuming 100% electrical activity)

$$\frac{D}{D_i} = \frac{2C}{n_i}, \text{ for } C >> n_i \quad [3]$$

then Eq. [1] agrees exactly with the numerical results. Equation [1] was derived using the *D vs. C* expression of Eq. [3].

A more exact expression for As diffusivity in the absence of As complexing is (15)

$$\frac{D}{D_i} = h\left(\frac{1+\beta f}{1+\beta}\right) \quad [4]$$

where

$$h = 1 + \frac{C}{2n_i}\left[\left(\frac{C}{2n_i}\right)^2 + 1\right]^{-1/2} \quad [5]$$

is the self electric-field enhancement factor (2 factor in Eq. [3])

$$f = \frac{C}{2n_i} + \left[\left(\frac{C}{2n_i}\right)^2 + 1\right]^{1/2} \quad [6]$$

and $\beta \cong 100$ for positively charged donor impurities (15). The factor f is approximately linearly proportional to the ionized donor concentration, C_A, when $C_A = C >> n_i$, and Eq. [4] reduces to Eq. [3] at high concentrations.

The result of using Eq. [4], [5], and [6] in the numerical solutions is that the As profile shape is not uniquely described by Eq. [1], but is a function of the surface concentration (or implant dose and diffusion time and temperature). The normalized solution of the diffusion equation for a 5×10^{15} cm^{-2}, 50 keV As implant diffused at 1050°C for 15 min ($C_{TO} = 2.5 \times 10^{20}$ cm^{-3}) is shown plotted in Fig. 2. This solution agrees almost exactly with Eq. [1]. However, the normalized solution for a 1×10^{15} cm^{-2}, 50 keV As implant diffused at 1050°C for 30 min ($C_{TO} = 7.4 \times 10^{19}$ cm^{-3}) deviates from Eq [1], but it describes those data of the first 3 sets of points in the insert of Fig. 2, with C_{TO} of 4×10^{19} to 1×10^{20} cm^{-3}. In Fig. 2, the remaining data were taken from profiles for which $C_{TO} > 1 \times 10^{20}$ cm^{-3} and they are represented by the polynomial approximation. As C_{TO} approaches n_i, the diffusion coefficient becomes independent of concentration and the As profile approaches a gaussian distribution.

Chemical source As diffusion.—In contrast to the well-behaved, reproducible As profile from ion implanted-diffused samples, the normalized total concentration profiles from constant As surface concentration chemical sources (doped oxides and ampuls) are shown in Fig. 3 for comparison. The difficulty in obtaining a general profile shape for a given C_{TO} for these profiles lies in the complicated properties of the As diffusion coefficients which are affected by the formation of As complexes and by the background substrate con-

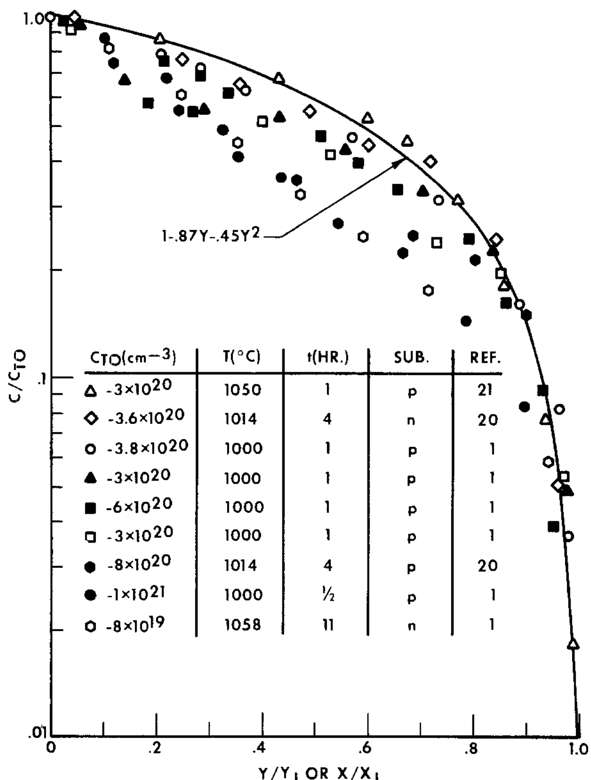

Fig. 3. Normalized total As profiles of diffused layers from chemical sources.

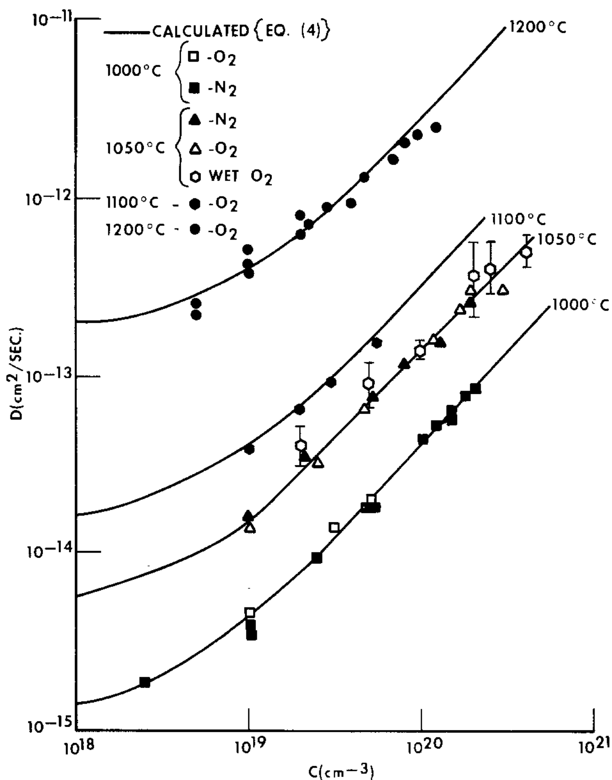

Fig. 4. Arsenic diffusivity vs. total As concentration for several diffusion temperatures.

ductivity type (1). It has been reported previously (4) that rapid annealing of As complexes of high dose ion-implanted As layers occurs, and the As diffusion from such layers is, therefore, better behaved.

Diffusion coefficient.—The intrinsic arsenic diffusivity, D_i.—In order to determine the concentration-dependent diffusion coefficients from the measured As profiles and, thus, check the validity of Eq. [4], it was necessary to develop an expression for diffusivity that was applicable to a redistributing impurity of fixed total concentration, Q_T. Since the Boltzmann-Matano analysis requires diffusion from a constant surface concentration, it cannot be applied to diffusion from an ion-implanted source. As shown in Appendix A for diffusion from a predeposited source (*i.e.*, a delta function)

$$D = \frac{-C(x_o,t)\,(x_o + x_{ox})}{2t \left.\dfrac{dC}{dx}\right|_{x_o}} \qquad \text{[A-16]}$$

where D is the diffusivity at a depth x_o from the surface, and x_{ox} is the thickness of the SiO_2 that is grown during the As diffusion process.

Equation [A-16] has been applied to determine D *vs.* the concentration of total As from the measured implanted-diffused profiles, and these results are shown in Fig. 4 for the diffusion temperature range 1000°-1200°C. For diffusions performed in O_2 and wet O_2, the oxide thicknesses were measured following diffusion, and these values were used in the calculations of D. It can be seen that the As diffusivity in Si does not depend on the diffusion ambient.

From Eq. [4] values of D_i were obtained which best described the data in Fig. 4. These results are shown as a function of diffusion temperature in Fig. 5. Also shown are the diffusivity data from Chan and Mai (16) obtained by driving-in low concentration As predeposited layers, and the D_i value at 900°C of Baldo *et al.* (17) from As ion-implanted layers. It can be seen that the temperature dependence of these data is given by the expression

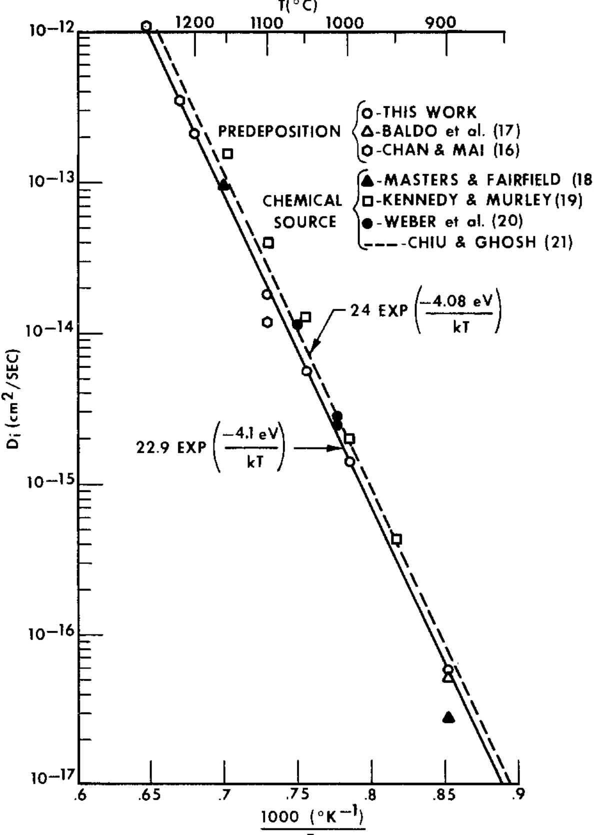

Fig. 5. Intrinsic diffusion coefficient of As as a function of temperature.

$$D_i\Big|_{PD} = 22.9 \exp\left(\frac{-4.1\ \text{eV}}{kT}\right) \qquad [7]$$

where the subscript PD refers to "predeposition." Dif-

fusion coefficient data (18-20) from studies on As chemical sources are also shown in Fig. 5. These data can be compared with the expression for D_i obtained by Chiu and Ghosh (21)

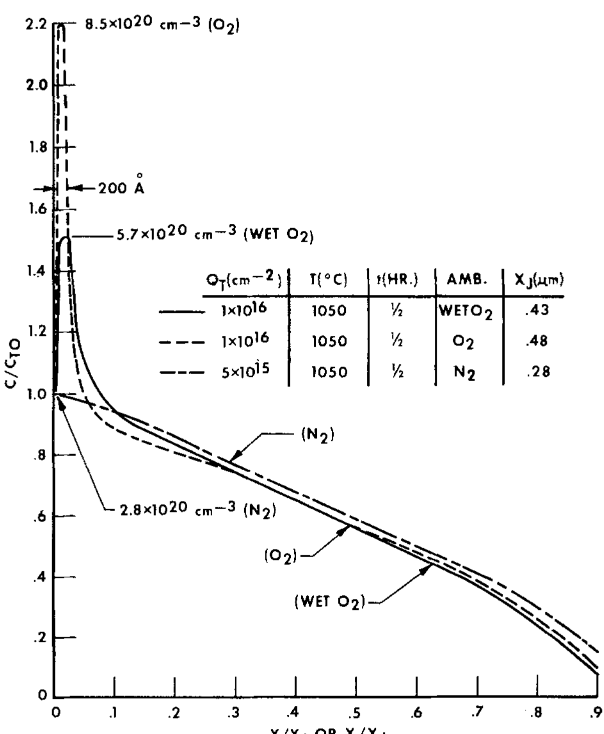
$$D_i \Big|_{CS} = 24 \exp\left(\frac{-4.08 \text{ eV}}{kT}\right) \qquad [8]$$

where the subscript CS refers to "chemical source." It is not clear at this point whether the differences between $D_i|_{PD}$ and $D_i|_{CS}$ are significant or not.

Diffusion ambient effects.—Comparisons among the measured total As profiles for samples which have been diffused in wet O_2, O_2, and N_2 are shown in Fig. 6. In order to show the As profiles near the surface clearly, normalized coordinates with linear scales have been used. The complete profiles in Si and SiO_2 for the two samples of 1×10^{16} cm^{-2} dose (50 keV) which were diffused in oxidizing ambients are shown in Fig. 7 (22). The following observations can be made from Fig. 6 and 7:

1. Arsenic atoms "pile-up" within 200-400Å of the Si surface during diffusion in an oxidizing ambient. 4000Å of SiO_2 were grown in the wet O_2 ambient, and 5.9×10^{14} cm^{-2} As was nonuniformly segregated into the SiO_2 [SIMS measurement (22)]. 500Å of SiO_2 were grown in the O_2 ambient and only 1.4×10^{13} cm^{-2} As was segregated into the SiO_2. A segregation coefficient of $m = 800$ for both oxidation ambients at 1050°C was observed which agrees well with the thermodynamic calculations (23). Consequently, the segregation of As into the SiO_2 does not significantly reduce the As doping in the Si. However, As pile-up is significant since the integrated concentration in the surface pile-up region is $\sim 1.5 \times 10^{15}$ cm^{-2} for both O_2 and wet O_2 oxidations of the 1×10^{16} cm^{-2} implanted samples.

2. The junction depth of the wet O_2 diffused As profile is ~10% shallower ($x_J = 0.43$ μm) than the junction depth of the dry O_2 diffused As ($x_J = 0.48$ μm) at $C = 10^{18}$ cm^{-3}. However, from Fig. 4 it can be seen that the diffusion coefficient is independent of the diffusion ambient. Additional data are presented in Fig. 8 where the junction depths of measured As profiles are plotted *vs.* an expression which contains implant dose,



Q_T(cm^{-2})	T(°C)	t(HR.)	AMB.	X_J(μm)
—— 1×10¹⁶	1050	½	WET O₂	.43
– – – 1×10¹⁶	1050	½	O₂	.48
— — — 5×10¹⁵	1050	½	N₂	.28

Fig. 6. Normalized implanted-diffused As profiles diffused in wet O_2, O_2, and N_2.

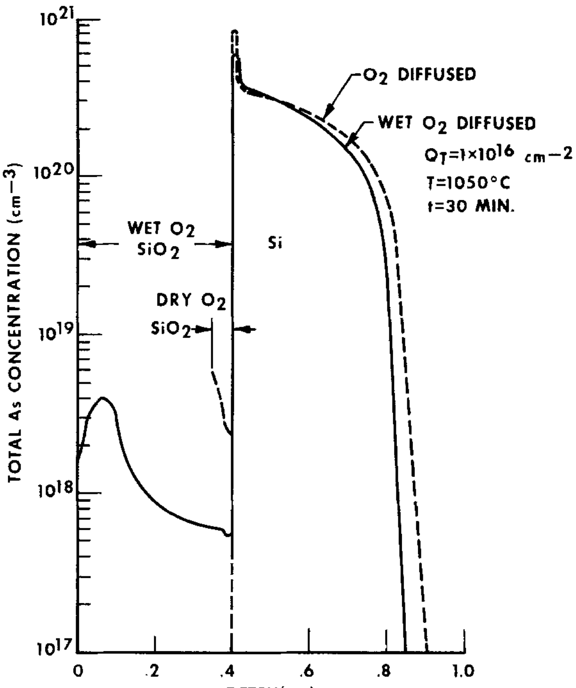


Fig. 7. Total implanted As profiles diffused in O_2 and wet O_2

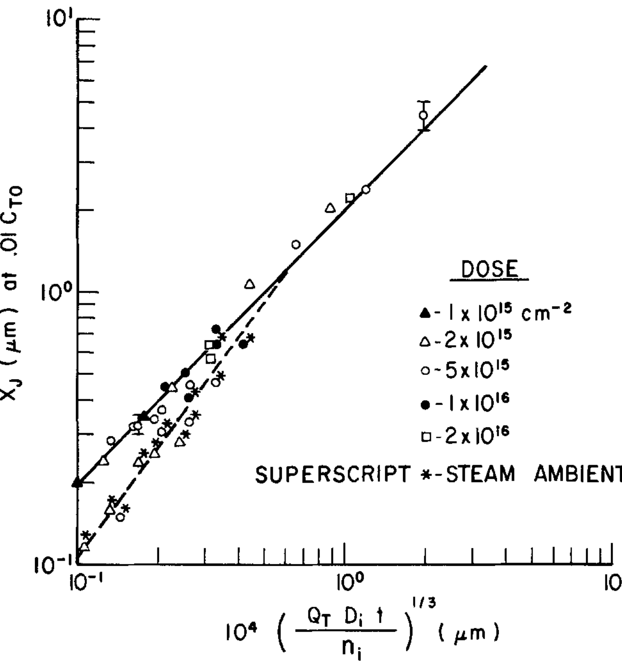

Fig. 8. Time, temperature and implant dose dependence of junction depth of implant-diffused As layers in Si. The effect of As diffusion in a wet O_2 ambient is illustrated.

diffusion time, and temperature (13). The data represent diffusions in the temperature range of 1000°-1200°C in N_2, O_2, and steam (wet O_2). It can be seen that shallower junction depths are obtained for diffusions performed in wet O_2 up to ~1 μm from the Si surface. For the case of dry O_2, the influence of the moving, oxidizing surface boundary on the junction depth can be neglected.

Electrical Activity

It has been pointed out previously that the fraction of As that is electrically active in an implanted-diffused layer in Si is greater than in a layer diffused from a chemical source (4). This is due to the fact that in a well-annealed implanted layer, As complexes ap-

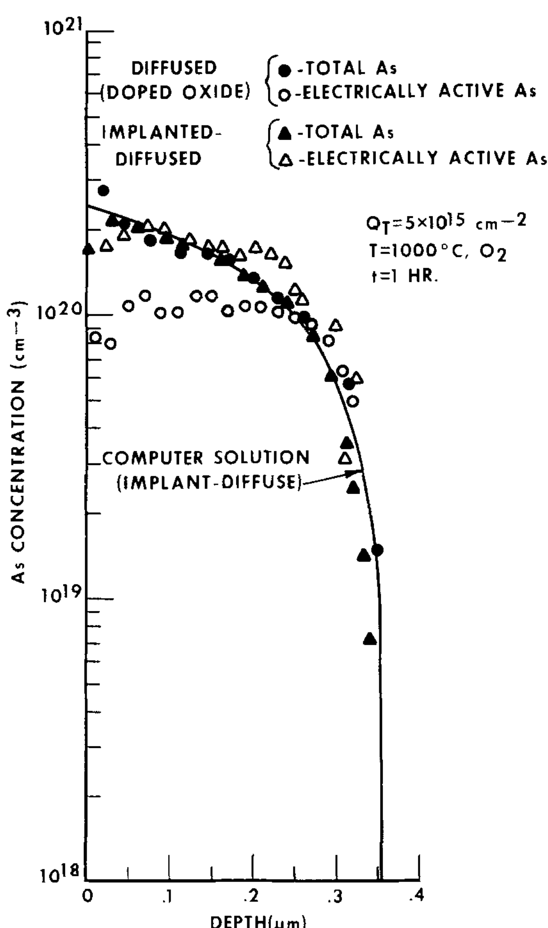

Fig. 9. Comparison between diffused and implanted-diffused As profiles in Si. The numerical solution to the diffusion of an implanted layer is also shown.

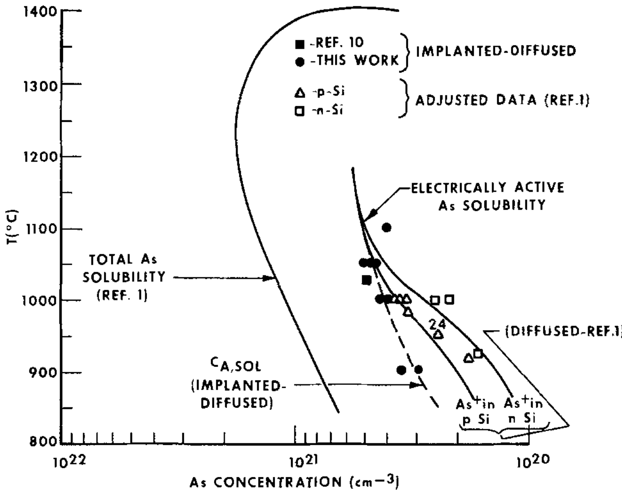

Fig. 10. Solid solubilities of As in Si for diffusion from chemical sources and non-implanted sources. The solid lines denoting solubility of electrically active As are calculated from Ref. (1).

parently are not formed. An example is shown in Fig. 9 where a diffused As layer (doped oxide source) with a total concentration of 5.06×10^{15} cm^{-2} As is compared with an implanted As layer (5×10^{15} cm^{-2}) which was diffused to the same junction depth as the doped oxide-diffused layer (1000°C, 60 min in O_2 ambient). It can be seen that the total As data practically coincide except near the surface. These data were determined by neutron activation and anodic stripping (●), and SIMS (▲). In addition, the theoretical solution of the redistribution of the implanted As layer is shown to agree very well with these data. However, the concentration data obtained from these diffusions by the differential conductivity method and Fig. 1 show a large disparity, reflecting differences in electrical activity between the diffusion from a chemical source and an implanted source. For the chemical-source diffused layer, $Q_A/Q_T \cong 0.65$, while $Q_A/Q_T \cong 1$ for the implanted-diffused layer.

A general conclusion that As^+ is more soluble in implanted-diffused layers than in chemical-source diffused layers in Si is illustrated in Fig. 10. $C_{A,SOL}$ values determined from diffused As implants for which complete activation had not yet been achieved are plotted *vs.* diffusion temperature (● and ■ data). Also shown are the calculated As^+ solubility curves and data for As diffused layers from Ref. (1). These curves and data have been adjusted in accordance with the revised resistivity *vs.* concentration curve in Fig. 1 (△ and □ data correspond to diffusion into p- and n-type Si substrates, respectively). It can be seen that below 1100°C, As^+ is more soluble in implanted-source layers than in a chemical source layer. This result is further evidence of the absence of As complexes in implanted-diffused layers. However, as it will be shown below, complete activity only occurs in high dose implants after diffusion for some period.

Time behavior of electrically active As.—For the case of diffusion of an As-layer in Si, the integrated As concentration is related to the surface concentration, C_{io}, and the depth by the equation (13)

$$Q_i = K_i C_{io} x_J \quad [11]$$

where K_i is a numerical constant ($0.5 \lesssim K_A \lesssim 1$ for electrically active As and $K_T \cong 0.53$ for total As profiles). The ratio of Q_A (active As) to Q_T (total As) is

$$\frac{Q_A}{Q_T} = \frac{K_A C_{AO}}{K_T C_{TO}} = K' \frac{C_{A,SOL}}{C_{TO}} \quad [12]$$

where it is assumed that C_{AO} is limited to the solubility limit $C_{A,SOL}$, and $K' = K_A/K_T$.

It can be shown that

$$C_{TO} = 0.94 \left(\frac{Q_T^2 n_i}{D_i t}\right)^{1/3} \quad [13]$$

hence, Eq. [12] becomes

$$\frac{Q_A}{Q_T} = 1.06\, K' C_{A,SOL} \left(\frac{D_i t}{Q_T^2 n_i}\right)^{1/3} \quad [14]$$

for $Q_A/Q_T \leqq 1$. Equation [14] indicates that complete electrical activity will be achieved initially for a redistributing As layer when $C_{TO} \leqq C_{A,SOL}$. The increase of Q_A/Q_T from some initial value less than one is $\propto t^{1/3}$, where t is the diffusion time. The use of Eq. [14] is restricted to As layers for which, initially, $C_{TO} > C_{A,SOL}$.

Using the revised resistivity *vs.* concentration curves shown in Fig. 1, electrically active As profiles were obtained on implanted layers that had been diffused at various times. The Q_A/Q_T data as a function of time are shown in Fig. 11 where Q_A/Q_T is plotted *vs.* $C_{A,SOL} \cdot (D_i t/Q_T^2 n_i)^{1/3}$ for $K' = 1$. Values of $C_{A,SOL}$ were obtained from Fig. 10. Reasonable agreement with the measured data is obtained.

The $t^{1/3}$ relationship for Q_A/Q_T can also be obtained from the results of Ohkawa *et al.* (24). The experimental conditions for their data were an ampule prediffusion at 950°C for 30 min into 1 ohm-cm p-type Si to a total As concentration of 9.5×10^{15} cm^{-2}, and drive-in diffusions without the presence of the source at 950°C in N_2 for 1.5 to 31.5 hr.

The $C_{A,SOL}$ was 1.9×10^{20} cm^{-3} which agrees with a previously reported result (1). In order to calculate

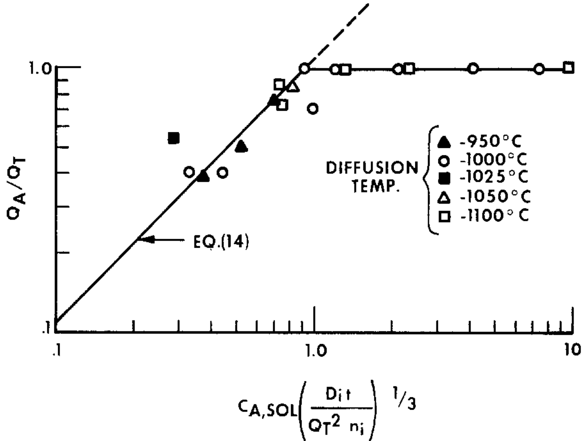

Fig. 11. Fraction of activated As as a function of diffusion time, temperature, and solubility.

the increase of Q_A/Q_T with time for a 950°C drive-in with $D_i = 3.2 \times 10^{-16}$ cm²/sec, Eq. [14] becomes

$$\frac{Q_A}{Q_T} = 2.1 \times 10^{-2}\, t^{1/3} \quad [17]$$

Ohkawa's data and the calculated values from Eq. [17] are shown in Table I, and good agreement is observed.

Electrically active As profiles.—The distribution of electrically active As in Si will have the same shape as the total As profile (Fig. 2) when all of the As in the diffusing layer is active ($C_{A,SOL} \geqq C_{TO}$). However, when $Q_A/Q_T < 1$, the active As concentration is limited to the $C_{A,SOL}$ value, and the active As profile will be quite flat. This effect is shown in Fig. 12, where the data shown were obtained from differential conductivity measurements and the resistivity *vs.* concentration curve of Fig. 1. Nevertheless, the majority of electrically active As profiles that are formed by the diffusion of an implanted layer have a shape that can be approximately represented by Eq. [1], as shown in Fig. 2 and Fig. 12 (▲-data represents a completely activated As layer).

Discussion

In spite of the fact that an ion-implanted layer of As in Si diffuses in a well-behaved, predictable manner, there still remain some unanswered basic questions. Why does a solubility limit exist for electrically active As, $C_{A,SOL}$. (Fig. 10) that is ~30% of the solubility of total As. and in what form is the inactive As? Also, during oxidation why does As tend to pile up within a few hundred angstroms of the Si/SiO_2 interface. These questions are briefly considered below.

Solubility of the electrically active arsenic.—The solubility of an impurity in silicon is dependent primarily upon the impurity bonding energy in the Si lattice, provided that the strain energy associated with the impurity in the host crystal is small (as it is for As in Si) (25, 26). Arsenic diffused from a chemical source is known to be highly substitutional in Si (27, 28). For such diffusions, As may be tied up in inactive complexes, or exist as ionized As^+. The fact that definite solubility limits exist for both total As and electrically active As (1, 29) suggests that the inactive As may be more tightly bound in the lattice as was assumed in Ref. (1).

Table I. Rate of change of Q_A/Q_T with time

Q_A/Q_T		
Meas.	Calc. (Eq. [17])	t (hr)
0.23	0.23 [Ref. (1)]	initial
0.43	0.37	1.5
0.63	0.63	7.5
1	1	31.5

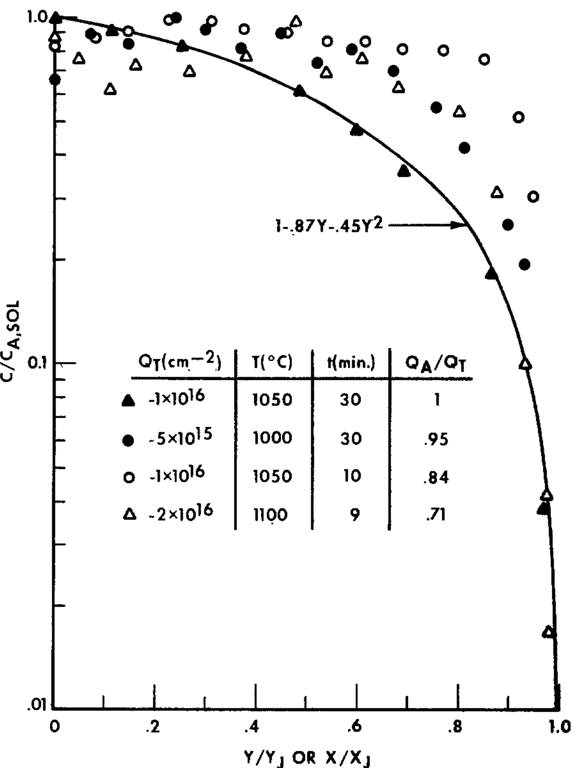

Fig. 12. Electrically active As profiles normalized to $C_{A,SOL}$ for several values of Q_A/Q_T.

For the high-dose ion-implanted As diffusion sources, the implantation of the As creates an amorphous layer in the Si surface region, and epitaxial reordering appears to aid in establishing a high degree of electrical activity, even at low anneal temperatures (550°-650°C). As a result, the solubility of active As^+ is higher in implanted-diffused layers than in comparable layers diffused from chemical sources (see Fig. 9 and 10) for diffusion temperatures <1100°C. Nevertheless, a definite solubility limit, $C_{A,SOL}$, does exist for implanted As^+ in Si that is not dependent upon the presence of complexes, but is related to the solubility considerations discussed above. The structure and nature of the inactive As in As implanted-diffused layers is still not known (4, 10, 17).

Effect of oxidation on As diffusion and pile-up.—Dash and Joshi (30) reported the surface pile-up of redistributing As layers in (111) Si during oxidation. Coincident with As pile-up was the formation of extrinsic stacking faults. Hu (31) has proposed that during oxidation excess interstitial Si atoms are generated which contribute to surface regrowth, nucleate around precipitates to cause stacking fault growth, or displace substitutional impurities near the surface whose enthalpy of interstitial formation is low (Group I, II, and III impurities) (32).

Channeling measurements on As-implanted layers that show pile-up at the surface indicate that some of these atoms are not on lattice sites (10). One possible, but unsupported, explanation for pile-up is that As atoms are absorbed by the growing stacking faults, a process that would effectively remove As from solution in the Si lattice and reduce As diffusivity near the Si surface. On the other hand, it has been observed in this study that much of the As in the surface region is electrically active. The active concentration has not been observed to exceed the solubility limit $C_{A,SOL}$.

It was pointed out earlier that the diffusion of As in Si is independent of the furnace ambient (see Fig. 4). Thus, Si interstitials which may be generated during oxidation (31) do not affect As diffusion, which further supports the vacancy diffusion model for As in Si.

Conclusions

The diffusion of ion-implanted As in Si has been studied by generating As profile data from differential conductivity measurements and secondary ion mass spectrometry. It has been shown that:

1. Implanted-diffused As profiles all have a very similar shape provided $C_{TO} \gtrsim 1 \times 10^{20}$ cm^{-3} (surface concentration after diffusion), which can be described by a Chebyshev polynomial approximation to the diffusion equation (Eq. [1]) with concentration-dependent diffusivity (Eq. [3]). For the general case of the diffusion of any implanted As layer, numerical solutions of the diffusion equation with diffusivity expressed by Eq. [4] give excellent profile calculations.
2. The diffusion of As is independent of the diffusion ambient. Shallower junction depths as measured from the Si/SiO_2 interface are obtained for diffusions in wet O_2 when x_J is less than $\sim$1 μm. This result is not caused by segregation of As into SiO_2 ($m = 800$ at 1050°C), but is due to the moving boundary condition.
3. Implanted-diffused As layers show higher electrical activity for diffusions below 1100°C than comparable layers diffused from chemical sources. For doses sufficiently large so that $C_{peak} > C_{A,SOL}$, rapid activation of As^+ to the solubility limit of $C_{A,SOL}$ has been observed at diffusion temperatures. During diffusion the fraction of electrically active As increases at a rate proportional to $t^{1/3}$, until complete activation occurs when $C_{TO} \simeq C_{A,SOL}$.

APPENDIX A

Diffusion Coefficient Analysis for a Redistributing Layer with Concentration-Dependent Diffusivity

The Boltzmann-Matano analysis (33) is the most suitable method for extracting diffusion coefficients from measured diffusion profiles, provided that the surface concentration of the indiffused species is invariant with time. When the diffusing substance is subject to redistribution, the Boltzmann-Matano analysis may not be used because the time dependence of the concentration is not a function of $x/\sqrt{t}$.

In the case of ion-implantation of impurities into Si, the redistribution of a fixed total amount of impurities is of interest. Thus, the relationship

$$Q_T = \int_0^\infty C(x,t)\,dx \qquad \text{[A-1]}$$

implies a time independence on Q_T which is achieved by the transformation (34)

$$C(x,t) = F(x/\sqrt{t})/\sqrt{t} \qquad \text{[A-2]}$$

where F satisfies the diffusion equation and the boundary conditions

$$C(x,t) = 0 \text{ for } x \rightarrow \infty \qquad \text{[A-3]}$$

$$C(x,t) = 0 \text{ for } x = 0,\ t = 0 \qquad \text{[A-4]}$$

$$C(x,t) = 0 \text{ for } x > 0,\ t = 0 \qquad \text{[A-5]}$$

Conditions [A-4] and [A-5] indicate the initial profile is represented as a delta function.

The one-dimensional diffusion equation with concentration-dependent diffusion coefficient is

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D(C)\,\frac{\partial C}{\partial x}\right) \qquad \text{[A-6]}$$

Defining a new variable, η as

$$\eta = x/\sqrt{t} \qquad \text{[A-7]}$$

and replacing C in Eq. [A-6] with Eq. [A-2] yields an expression in η, $F(\eta)$ and t (34). Adding the limitative hypothesis that D be a function of the ratio $C(x, t)/C_{TO}$ (C_{TO} is surface concentration), where

$$C_{TO} = F(0)/\sqrt{t} \qquad \text{[A-8]}$$

gives rise to the expression

$$-\frac{\eta}{2}F(\eta) = D\left[\frac{F(\eta)}{F(0)}\right]\frac{dF(\eta)}{d\eta} \qquad \text{[A-9]}$$

or

$$-\frac{Cx}{2} = D\left(\frac{C}{C_{TO}}\right)t\frac{dC}{dx} \qquad \text{[A-10]}$$

Thus, the local diffusion coefficient at $x = x_o$ for a diffusion that took t sec is

$$D\left(\frac{C(x_o,t)}{C_{TO}}\right) = \frac{-C(x_o,t)\,x_o}{2t\left.\dfrac{dC}{dx}\right|_{x_o}} \qquad \text{[A-11]}$$

As an example, consider the case where the redistributed impurity has a profile shape described by

$$C(x,t) = C_{TO}\exp\left(\frac{-x^2}{4D_it}\right) \qquad \text{[A-12]}$$

Substitution of Eq. [A-12] into Eq. [A-11] yields

$$D = D_i, \text{ for all } x \qquad \text{[A-13]}$$

It is well known that a redistributing impurity with constant diffusion coefficient will assume a gaussian shape.

For the case of diffusion in an oxidizing ambient where the movement of the Si surface must be considered, the continuity equation becomes

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D(C)\,\frac{\partial C}{\partial x} + vC\right) \qquad \text{[A-14]}$$

where v is the inward velocity of the oxidizing Si surface. Transforming v according to the expression

$$v = \frac{\eta}{\sqrt{t}} \qquad \text{[A-15]}$$

it can be shown in a similar way that the diffusivity becomes

$$D\left(\frac{C(x_o,t)}{C_{TO}}\right) = \frac{-C(x_o,t)\,(x_o + x_{ox})}{2t\left.\dfrac{dC}{dx}\right|_{x_o}} \qquad \text{[A-16]}$$

where $x_{ox} \cong 2\,vt$ is the SiO_2 thickness.

APPENDIX B

Polynomial Fit for Resistivity vs. Electron Concentration in As-Doped Si

In order to provide an analytical description of the resistivity *vs.* electron concentration data in the range $1 \times 10^{19} \leq n \leq 7 \times 10^{20}$ cm^{-3} shown in Fig. 1, a tenth order polynomial was generated. Thus

$$\log\rho = \sum_{i=0}^{10} a_ik^i \qquad \text{[B-1]}$$

where $k = \log n$, $a_0 = -6.633667 \times 10^3$, $a_1 = 7.682531 \times 10^2$, $a_2 = -2.577373 \times 10^1$, $a_3 = 9.658177 \times 10^{-1}$, $a_4 = -5.643443 \times 10^{-2}$, $a_5 = -8.008543 \times 10^{-4}$, $a_6 = 9.055838 \times 10^{-5}$, $a_7 = -1.776701 \times 10^{-6}$, $a_8 = 1.953279 \times 10^{-7}$, $a_9 = -5.754599 \times 10^{-9}$, $a_{10} = -1.316567 \times 10^{-11}$. The fit of this polynomial to the data in Fig. 1 is shown drawn in Fig. 1. The agreement is much better than the fifth order polynomial generated previously by Lee (35).

Kinetics of the Initial Stage of Si Transport Through Pd-Silicide for Epitaxial Growth

Z. L. Liau, S. U. Campisano,[1] C. Canali,[2] S. S. Lau, and J. W. Mayer*

California Institute of Technology, Pasadena, California 91125

ABSTRACT

Backscattering spectrometry and scanning elecron microscopy (SEM) have been used to study the transport of Si from an amorphous Si layer ($\lesssim$ 1 μm) through a Pd-silicide layer ($\lesssim$0.2 μm) onto <100> oriented Si. For a given annealing temperature, two distinct stages of this process have been observed. The initial transient stage starts with island growth of Si and ends with a uniform layer of Si on the substrate. The thickness of the initial transient stage is found to be equal to the thickness of the Pd-silicide layer.

Silicon and Ge can migrate through thin metal films at temperatures below the melting point of any of the components of the system (1, 2). During isothermal heat-treatment of amorphous or fine-grain polycrystalline Si films in contact with metal films, it is observed that the Si dissolves into the metal film and precipitates in crystallite form in the metal film. It has been suggested (1) that the driving force for the amorphous to crystalline transition is due to the higher free energy of the amorphous material as compared to the crystalline form. For the polycrystalline case, Nakamura *et al.* (3) propose that the solid-phase dissolution of small crystallites and reformation of larger crystallites is caused by the tendency to reduce grain boundary areas. In both cases the heights of the crystallites are governed by the thickness of the metal solvent matrix.

As an alternate growth mode involving migration through a metal film, it is possible to form epitaxial layers on a single crystal substrate rather than crystallites in a metal film. It has been pointed out (4) that the conditions of the interface between crystal-substrate and metal-film play a crucial role. For epitaxial growth, the transport of the semiconductors through metal layers is not a sufficient condition; it is necessary to provide a proper interface for nucleation and growth.

Recently, it has been demonstrated (5) that a uniform Si epitaxial layer can be grown on a single crystal Si substrate by solid-state diffusion of Si from an amorphous Si layer through a Pd-silicide layer. During anneal at about 300°C, the deposited Pd layer reacts with both single crystal and amorphous Si on both sides to form a Pd_2Si layer. Then, when annealed at about 500°C, the top layer of amorphous Si is transported through the Pd_2Si layer and grows epitaxially onto the underlying single crystal substrate. Uniform grown Si layers of about 1 μm thickness have been formed this way. X-ray diffraction and channeling techniques have been used to demonstrate that this grown Si is a single crystal layer grown epitaxially on the substrate.

For a given annealing temperature, two distinct stages of this process have been observed; an initial transient stage of rapid transport of Si followed by a

Key words: silicon transport in epitaxy, Pd-silicide.

slower steady-state stage. In the steady-state stage, the transport of Si is linear in time.

In the present work, we have been concerned with the initial transient stages of growth. This aspect of the transport and growth of Si layers has been investigated in this work by 2 MeV $^4He^+$ backscattering spectrometry and scanning electron microscopy.

Experimental Procedures

Commercially available Si single crystal wafers with polished surfaces and <100> orientation were used. The wafers were first cleaned by the R C A process (6), etched in HF, rinsed in high purity water, and then were immediately placed into the vacuum system. The electron-gun evaporation of Pd was performed at a vacuum of approximately 5×10^{-7} Torr at a rate of approximately 5 Å/sec. The source to sample distance was about 25 cm. Typical thickness of Pd evaporated ranged from 300 to 1200Å. Immediately following the evaporation of Pd, a layer of amorphous Si ($\lesssim 1$ μm) was deposited by electron-gun evaporation at a rate of ~ 100 Å/sec.

Anneals were performed in a vacuum quartz-tube furnace. The typical vacuum during anneals was 1×10^{-6} Torr. The precision of the annealing temperatures was ± 1°C and the precision of the annealing times was ± 3 min. The samples were first annealed at 280°C for 0.5 hr for the Pd layer to react with Si to form a uniform Pd_2Si layer (7). After silicide formation, a higher temperature (ranging between 450° and 550°C) anneal was used for the transport and epitaxial growth of Si.

To study this process quantitatively, 2 MeV $^4He^+$ backscattering spectrometry was used. This technique has been described in detail elsewhere (8). Briefly, a 2 MeV $^4He^+$ ion beam is incident on a sample placed in a vacuum chamber. By energy analyzing the He atoms backscattered from the specimen, one can determine the atomic concentration profiles in the sample. The depth resolution is about 200Å for layer thickness ranging between 300-5000Å. The beam size is usually 1-2 mm² therefore a lateral uniformity of at least this dimension is required. In the present study, a solid-state detector of energy resolution of about 20 keV was used to detect the energy of the particles at a backscattered angle of 168°. The layer thicknesses can be calculated from energy loss data and bulk densities as described in the Appendix.

Results

Backscattering spectra of a sample annealed at 280°C for 0.5 hr (formation of Pd_2Si) and the same sample (cut into separate pieces) annealed further at 475°C for 7 different annealing times are shown in Fig. 1. The transport of Si through the Pd-silicide layer can be seen from the spectra of the samples annealed at 475°C. In these spectra the signals of the top amorphous Si layers become thinner and the Pd signals shift to higher energies as compared to the upper spectrum in Fig. 1. This indicates that the Pd-silicide layer moves toward the surface of the sample as the Si migrates through the silicide layer. From the difference in the energy width of the amorphous Si layer in the samples before and after Si transport, one can determine the amount of Si that has been transported. This same information can also be obtained from the shift in the Pd signal to higher energies.

The time dependence of the amount of Si transported is obtained by plotting the amount of Si that has migrated away from the top amorphous layer *vs.* annealing time. Such a transport curve is shown in Fig. 2 for heat-treatment at 475°C of the same samples as those of Fig. 1.

There are two distinct regions in the curve. In the initial stages, the rate is fast, then after a certain transported amount (1800Å in the example shown in Fig. 2) the transport changes abruptly into a slower rate and maintains this rate until the end of the whole process.

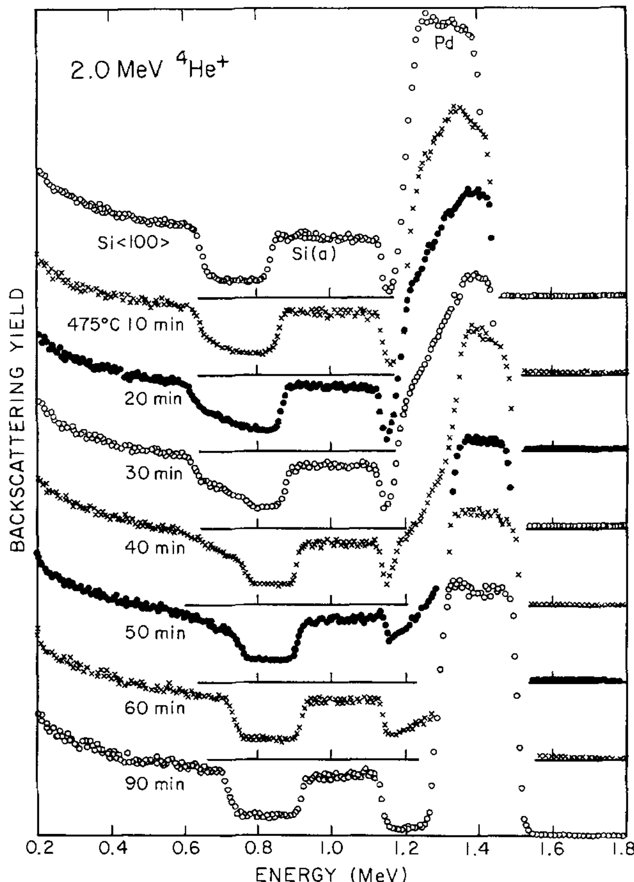

Fig. 1. Backscattering spectra of a sample for different annealing times in the initial transient stage and the beginning of the steady-state stage. The backscattering yield is in a linear scale. The thickness of the Pd_2Si layer is 0.18 μm and that of the amorphous Si layer before transport is 0.63 μm (upper curve).

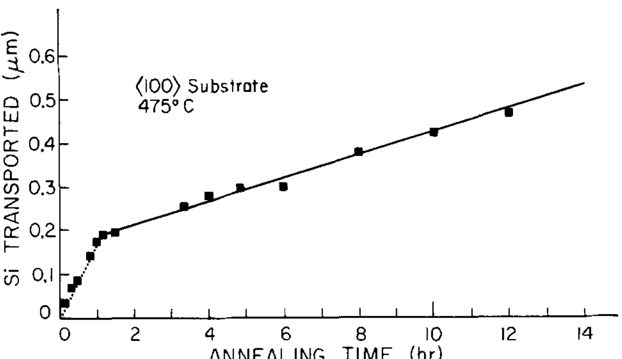

Fig. 2. An isothermal transport curve which shows the time dependence of the transport of Si for the same sample as that of Fig. 1.

The beginning fast period and the subsequent slower period are referred to as the initial transient stage and the steady-state stage, respectively. In the steady-state stage the transport of Si is found to be linear with time. In the initial transient stage the transport rate of Si can also be estimated by a straight line as shown by a dashed line in Fig. 2. From the two slopes of these two straight lines, the transport rate of the initial transient stage is about 8 times faster than that of the steady-state stage. This same ratio is also found for other annealing temperatures.

Similar results have been observed on other samples made at different times and annealed at various temperatures, *i.e.*, the initial transient transport rate is five to ten times faster than that of the steady-state.

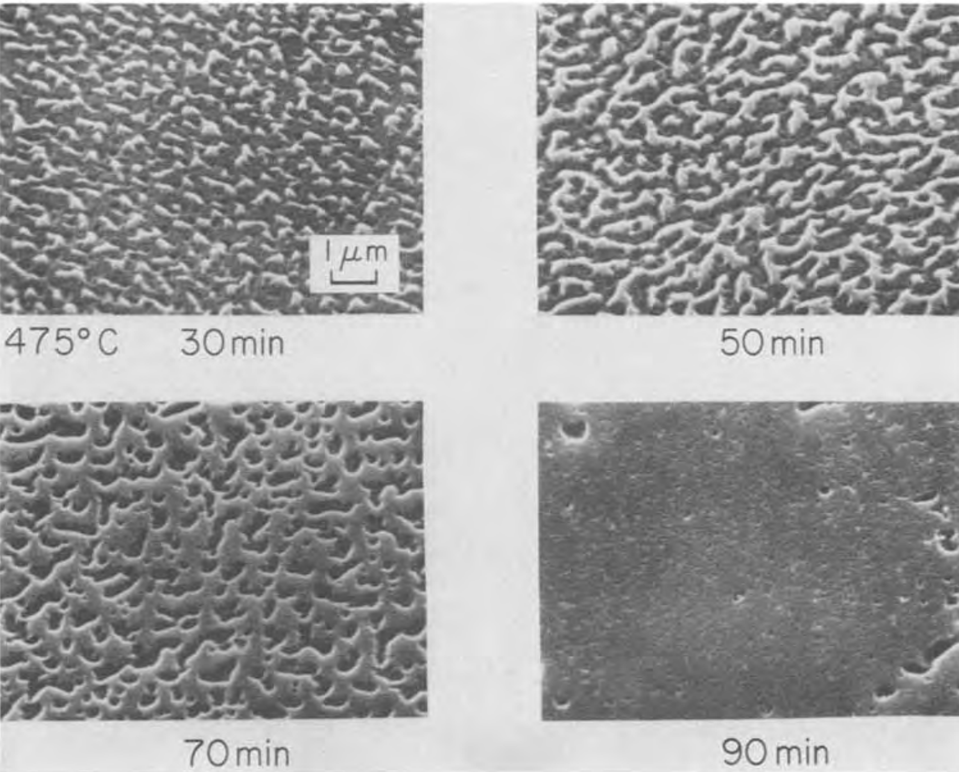

Fig. 3. SEM photos showing Si islands grown on the substrate surface in the initial transient stage and a uniform Si grown layer that is formed just after the completion of the initial transient stage.

The backscattering spectra of samples in the initial transient stage (475°C 10-60 min of Fig. 1) show that the grown Si layers are nonuniform as indicated by the graded slopes of the signal edges corresponding to the interfaces between the grown Si layers and the corresponding Pd-silicide layers. On the other hand, the spectrum of the sample annealed for a longer time (90 min of Fig. 1 which is just in the beginning of the steady-state stage) shows that the surface of the grown Si layer is uniform. The nonuniformity of layer in the transient stage is a general phenomenon observed for Pd_2Si thickness between 0.04 and 0.2 μm and anneal temperature between 440° and 550°C.

To examine the surface nonuniformity in the initial transient stage of the sample used for backscattering measurements in Fig. 1, we put the samples in HF for ~ 10 min for the Pd-silicide and the remaining top layer of amorphous Si to peel off. Thus the grown Si layers on the substrate surfaces were exposed for SEM observations. Figure 3 shows the SEM pictures of the surface view of a time sequence (30, 50, and 70 min) of samples in the initial transient stage and a sample (90 min) just in the beginning of the steady-state stage. These figures show that the growth of the Si starts with islands of dimensions of about 0.2 μm (both in height and in width) and then these islands grow laterally and join themselves. Toward the end of the initial transient stage a uniform Si grown layer is gradually formed. This picture of island growth in the initial transient stage and the transition to a uniform Si grown layer in the beginning of the steady-state stage is consistent with backscattering spectra. Further, the island structures of the grown Si layer have also been confirmed by SEM observations of the cleavage of the samples before being put in HF. This same island growth and transition to a more uniform layer is common to other samples and other annealing temperatures. It should be pointed out that throughout this process the remaining top layer of amorphous Si always remains flat and uniform.

A study of the correlation between the thickness of the initial transient stage of a sample and the thickness of the Pd_2Si layer of that sample has been performed on samples with Pd_2Si thicknesses ranging from 440 to 1820Å. (In all these samples, the thicknesses of the original amorphous Si layer are always about 1 μm.) A correlation between these two thicknesses has been found as shown in Fig. 4. The thicknesses of the Pd_2Si layers of all samples presented in Fig. 4 are also measured from backscattering spectra. The experimental points can be well fitted by a straight line passing through the origin with a slope equal to 1. This shows that for each sample the thickness of its initial transient growth is equal to the thickness of its Pd_2Si layer.

Discussion and Conclusion

In the present study of the transport of amorphous Si through Pd-silicide layers, two distinct regions (initial transient region and steady-state region) have been observed. The initial transient stage has a fast transport rate and is characterized by the island growth structure. At the end of the initial transient stage, the island structure develops into a more uniform grown layer. This process can be described schematically (according to the experimental data of Fig. 1 and 3) as shown in Fig. 5. The thickness of this layer is equal to that of the Pd_2Si layer. The migration rate of Si also changes rather abruptly into a slower rate. In this slower rate region (steady-state stage), the transport of Si is linear with time.

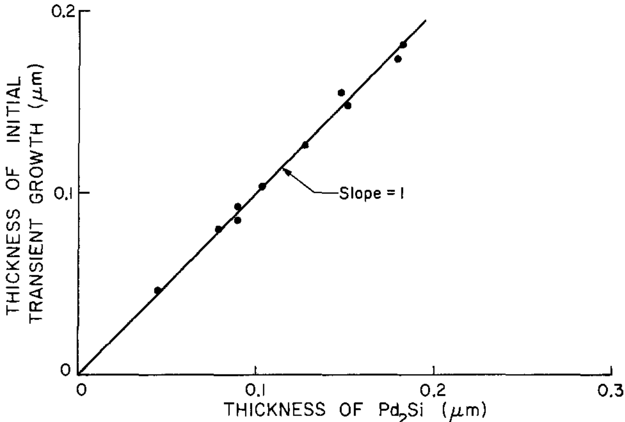

Fig. 4. The linear relation between the thickness of Pd_2Si layer and the thickness of the corresponding initial transient growth.

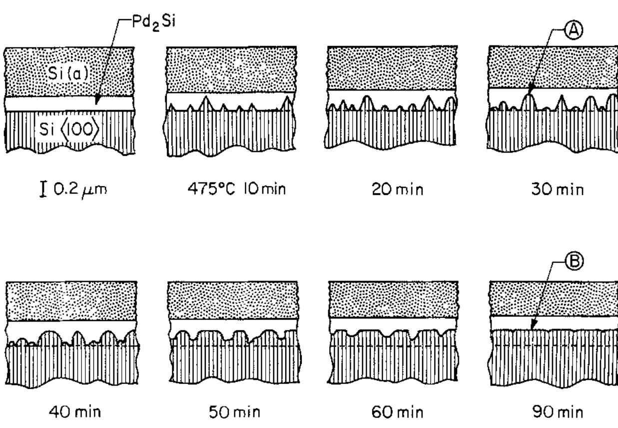

Fig. 5. A schematic picture which describes the growth of islands and the formation of a uniform layer for the sample of Fig. 1.

The Si transport in the initial transient stage can also be approximated by a linear rate which is about eight times faster than that of the steady-state stage. This difference in transport rates is probably due to the island structure in the initial transient stage, which effectively provides many more growth sites.

The equality of the thickness of the initial transient layer and that of the Pd_2Si layer can, perhaps, be rationalized by the following considerations. Initially, small nuclei are nucleated on the substrate surface either randomly or more likely on preferential sites such as defect sites. These nuclei, then grow in size and develop into islands. The height of these islands cannot exceed the thickness of the Pd-silicide layer which is the transport medium. Presumably, the growth of the islands required the incorporation of free Si atoms dissolved in the transport medium. Once these islands (with their height equal to Pd_2Si thickness) are formed, they start to grow laterally and join themselves. During this time, there is no further increase in the height of islands, otherwise there would be an increase of the interfacial energy between the islands and Pd-silicide due to increased interfacial area. In this way, a uniform grown layer of the same thickness as the original Pd_2Si layer can finally be formed. A rather similar phenomenon has been observed recently by Nakamura *et al.* (3) in a study of the dissolution and growth process of polycrystalline Si in contact of Al films. The height of the regrown Si crystals is found to be the same as the thickness of the original Al layer which acts as the transport medium in this case.

The Si transport changes to the steady-state region after the formation of the initial transient layer. As pointed out earlier, this initial transient Si grown layer is uniform and flat. However, there should be some significant differences between the original substrate surface and this uniformly flat surface after the transient stage. Otherwise, instead of changing to the steady-state region, another "initial transient stage" should have been developed on this surface similar to that observed on the original substrate surface. Differences in dislocation densities between the initial transient grown layer and the original crystal substrate, surface morphology, and microstructures are the possible candidates for the difference in growth behavior. In addition, surface conditions caused by polishing, etching, and Pd-silicide formation on the substrate surface are also among the possibilities. Further experimentation to distinguish between these possibilities is now in progress. For example, experiments with substrates of various orientations, different ways of Pd_2Si formation (*e.g.*, evaporation of Pd on a heated Si substrate), metals other than Pd, or even substrates other than Si single crystals may further provide valuable information.

APPENDIX

Depth Scales

From the energy loss studies of $^4He^+$ through materials (9), the thickness of a layer (ΔX) is related to its backscattering spectrum width (ΔE) by

$$\Delta X = \frac{\Delta E}{[S]}$$

where $[S]$ is a depth-scale factor which is determined by the stopping power and the density of the material and the kinematics of the scattering. For convenience, we have assumed bulk densities even for the thin film case (8). Use of a depth scale in atoms/cm² would lead to the same features shown in Fig. 2 and 4. The factor $[S]$ is a slow varying function of ΔX and, for a practical purpose, can be approximated as a constant. For example, when a 2.0 MeV $^4He^+$ beam is incident on a Si layer with a backscattering angle of 168°, $[S] = 46.9$ eV/Å at a depth of 1000Å and 48.9 at 4000Å. For the $[S]$ factor of Pd_2Si layers, the calculation was made from the stopping powers of Si and Pd using Bragg's rule (9). The calculated values are $[S] \doteq 103$ eV/Å when the spectrum width ΔE is measured from the Si signal of Pd_2Si, and $[S] = 115$ eV/Å when ΔE is measured from the Pd signal width. From these values, the thickness of the top layer of amorphous Si of the sample before transport shown in Fig. 1 is determined to be 0.63 µm and thickness of its Pd_2Si layer is 0.18 µm. The thickness of Si that has been transported for the sample annealed 475°C for 90 min shown in Fig. 1 is 0.19 µm.

A careful comparison of the backscattering spectrum of the 475°C for 30 min sample and that of the 90 min sample in Fig. 1, would suggest that the heights of the mountain-shaped islands of the 30 min sample are more than 500Å higher than the thickness of the uniform grown Si layer of the 90 min sample. But actually the height of the islands is very close to (if not exactly equal to) the thickness of the uniform grown layer. The apparent big difference in heights is due to the fact that Pd-silicide and Si have rather different stopping powers for the incident helium particles. (The stopping power of Pd_2Si is about twice as great as that of Si.) This can be easily seen from Fig. 5. If the height of islands is equal to the thickness of the uniform layer, then points A and B are of the same depth from the sample surfaces. But in the backscattering spectra the signal of the point A will appear at a higher energy than that of the point B, because the point A has essentially only Si in front of it, but point B has a thick layer of Pd-silicide displacing a layer of Si of the same thickness.

ABSTRACT

Monosilane was purified with a newly developed ion-exchanged zeolite A, which sorbs phosphine in silane. The phosphine content of silane was determined from electrical resistivity of silicon which was obtained by decomposing silane. Two kinds of silicon samples were used for analysis, *i.e.*, epitaxial films on silicon substrate, and single crystal rods. The electrical resistivity of the silicon rods of p-type ranged between 1×10^4 and 8×10^4 ohm-cm at room temperature, depending on conditions of purification. A surface barrier type solid-state detector, fabricated from this silicon, was evaluated with x-rays and conversion electrons from ^{207}Bi, and showed satisfactory characteristics. Characteristics of the adsorption column were studied with a simulation column by the aid of gas-chromatographic techniques. Optimum conditions were deduced for the operation of the adsorption column.

High purity silicon is used in the fabrication of various elements such as a rectifier for high voltage use and a solid-state detector for x-rays and β-particles. In recent years the demand for it is continuously increasing. Furthermore, a much higher degree of purity is required with increasing needs for elements of higher qualities. The present industrial processes do not meet these requirements.

Usually, semiconductor silicon is obtained by decomposing hydride or by reducing silicon halides. Two processes, *i.e.*, monosilane and trichlorosilane processes, have been industrialized. In order to obtain high purity silicon, the monosilane process is superior to the trichlorosilane one, as can be seen from the following technical considerations:

(*i*) Silane decomposes at 700°-800°C to silicon and hydrogen, which do not cause any corrosion troubles. This is a significant merit in semiconductor technology, since it is possible that silicon is easily contaminated through chemical transport processes of corrosion products.

(*ii*) In a generation process of monosilane, boron hydrides are completely removed from silane by the chemical reaction, $\equiv B + :NH_3 \rightarrow \equiv B:NH_3\downarrow$. Hence, the main residual impurity, which is electrically active, is phosphine, but phosphine is rather easily removed by zone refining. According to our experience, boron content in silicon, prepared from silane, ranges between 0.02-0.01 ppb in atomic ratio, which is very low in comparison with that from trichlorosilane. Phosphorus content in silicon is mentioned in the next paragraph. However, the monosilane process is slightly inferior to the trichlorosilane process in the area of production cost, as far as the present process is concerned.

In the present industrial process, silane is generated by reacting magnesium silicide with ammonium chloride in liquid ammonia solution as

$$Mg_2Si + 4NH_4Cl \xrightarrow[\text{in liq } NH_3]{\text{at } 0°C} SiH_4 + 2MgCl_2 + 4NH_3$$

Impurities generally contained in the evolved gas are highly volatile hydrides (diborane, arsine, phosphine, and methane), carbon monoxide, and nitrogen. Diborane is easily eliminated in the generation step as already mentioned. Arsine is rather unstable and, in our experience, has not caused any problem. It is unavoidable that silane contains traces of CH_4, CO, and N_2. When these gases are decomposed to elements, they give electrically less inactive impurity centers. Hence, the existence of these impurities is not a serious matter, as long as their amounts do not exceed 1 ppm. Phosphine is removed by distillation under reduced pressure at temperatures below the boiling point of silane (−112°C). Phosphine impurity is reduced from about 10 ppm in raw silane to about 0.05 ppb after distillation. This process has some disadvantages. The apparatus for the distillation is complicated and expensive, since liquefied silane, which forms a spontaneously explosive mixture with air, is processed. Fine distillation with a high number of plates is necessary in order to remove phosphine thoroughly from silane. Purified silane is thermally decomposed on a heated substrate of single crystal silicon to yield polycrystalline silicon. Polycrystalline silicon is further purified and single crystallized by means of the floating-zone melting techniques. Resistivity of n-type silicon prepared in this manner ranges from 2000 to 3000 ohm-cm at room temperature. This value is considerably lower than that of the ideally pure silicon, say, 230,000 ohm-cm. Many investigators (1, 2) reported properties of nearly intrinsic silicon which was prepared by techniques of automatically repeated zone-melt refining. The techniques, however, are not suitable to mass production of high purity silicon.

The aim of the present work is to establish the process of the production of high purity silicon, especially, by adsorptive purification of silane. Caswell (3) purified silane with some zeolites, and obtained the p-type silicon with a resistivity of 40-75 ohm-cm. We have developed an improved adsorbent (4). This is an ion-exchanged modification of molecular sieve A, having a composition of (Zn_xK_{12-2x})-A with $2 < x < 4$. The commercially available molecular sieves A are 3A, 4A, and 5A. Adsorptive properties of these zeolites for silane and phosphine are shown in Table I, along with those of a newly developed 4.5A and the concerned zeolite. As can be seen from Table I, 3A and 4A sorb neither silane nor phosphine, while 4.5A and 5A sorb both of them. (Zn_x, K_{12-2x})-A zeolite with $2 < x < 4$, may be classified as 3A as far as its sieving actions for nonpolar and saturated compounds are concerned (5). However, it can sorb polar molecules with diameters slightly larger than its window size. Equilibrium properties of this adsorbent were thoroughly investigated in the preceding paper (5), but the sorption kinetics were only briefly reported. In the present paper we report, in detail, results of the purification

Arsine	−	−	+	−	−

of silane conducted for the purpose of the production of high purity silicon.

Experimental

Adsorbent.—The (M^{II}, K)-A zeolites were prepared by ion-exchanging potassium ion in molecular sieve 3A with divalent cations M^{II}, such as Zn^{2+}, Mg^{2+}, Mn^{2+}. The ion exchange was carried out at 80°C with solutions of $M^{II}Cl_2$ + KCl in 0.2 total metal ion normality. Figure 1 shows adsorptive properties of powdered (M^{II}, K)-A for SiH_4, PH_3, B_2H_6, and AsH_3 as a function of the zeolite composition. One can conclude from this figure that the A-zeolites, having a composition of $(M^{II}{}_xK_{12-2x})$-A with $2 < x < 4$, are useful for the selective adsorption of phosphine from silane. The rates of adsorption of phosphine by these zeolites were measured with a McBain type quartz spring balance. As can be seen in Fig. 2, (Zn, K)-A zeolite surpasses (Mg, K)-A and (Mn, K)-A in the rate of adsorption of phosphine. For these properties, (Zn, K)-A was adopted as the adsorbent for purification in the succeeding experiments.

Experimental apparatus.—Figure 3 shows the flow sheet of the present experiment, *i.e.*, purification of silane by adsorption and decomposition to elemental silicon and hydrogen. The liquefied crude silane, stored in a storage tank T, was evaporated by warming and the silane gas passed through a dehydration column C (2½ in. diameter × 5 ft long) packed with molecular sieve 3A. Adsorption columns A and B are stainless steel tubes 5 ft long and 2½ in. diameter packed with the concerned adsorbent (1/16 in. pellet form) weighing about 2.1 kg. Prior to adsorption measurements, the adsorbent was baked out under a flow of hydrogen (purified through palladium diaphragm) at 400°C for 24 hr. The columns were cooled by standing in air to room temperature, and further to −20° to −30°C by circulating coolant (methanol) through jackets wound on the wall of the column. Silane passed through the column C to A or B at a flow rate of 4 liters · min^{-1} and a pressure of 2.0 atm. The purified silane was introduced into a decomposition furnace, D, and thermally decomposed to polycrystalline silicon onto a silicon wire heated to 820°-880°C. A furnace, E, is used to analyze the sampling gas, and a and b are sampling pipes connected to E and a gas chromatograph G, respectively. The zeolite, which had lost the sorptive ability for phosphine, was regenerated by the same procedure as the activation carried out at the starting step.

The polycrystalline rod obtained was single crystallized in a floating-zone chamber. The rod, before loading, was shaped by mechanical grinding, and its surface was etched with HF-HNO_3 soln. Only one zoning was made under an atmosphere of argon at a positive gauge pressure. Single crystals for the seed had resis-

tivities ranging between 800-2000 ohm-cm at room temperature of n-type, and were held by stainless steel chuck.

Analyses of phosphine in silane.—The concentration of phosphine was measured by two methods. The first was a gas-chromatographic analysis having a sensitivity of 10 vol. ppm. A separation column packed with chromsorb 104 (Johns-Manville) was 3 mm in diameter and 1 m in length, and controlled at 70°C. The second was resistivity measurements of a silicon epitaxial layer deposited from the silane in the furnace E. The apparatus consisted of a stainless steel chamber (30 cm in diameter × 40 cm in height), an oil-free vacuum pumping system, and a gas doser. A vacuum better than 10^{-7} Torr was easily attained after baking-out of the apparatus. The substrate for the epitaxial film was a p-type silicon bar of 0.7 ohm-cm (5 × 5 × 200 mm) with the rod axis parallel to [111]. All faces of the bar were polished with emery, ultrasonically cleaned successively in trichloroethylene, methanol, and acetone, chemically etched, and washed. The rod was held vertically by stainless steel clips and electrically heated. After cleaning the substrate silicon in hydrogen at 10 Torr and 1200°C or so, silane was admitted to the chamber at a pressure between 10^{-1} and 10^{-3} Torr. Most of the epitaxial growth was carried out at 10^{-1} Torr and 1070°C. Under this condition, the growth rate (the thickness of deposited silicon divided by growth time) was about 0.2 μm·min^{-1}.

The epitaxial layer is of n-type while the substrate of p-type, and the thickness of the layer is about 40 μm, so that we are obliged to measure a very high resistance. This limits the measurable range of the specific resistivity, by the four-point probe method, to a value lower than 1×10^3 ohm-cm. To measure the high resistance of a very thin epitaxial layer, we must use the spreading resistance microprobe techniques (6). Then, we can measure the resistivity of the epitaxial layer in a range between 1×10^{-3} and 6×10^4 ohm-cm. The concentration of phosphine in silane is calculated from observed resistivity data, under the assumptions that $([PH_3]/[SiH_4])_g = ([P]/[Si])_s$, and further that the main impurity in solid is phosphorus. These assumptions might be open to some ambiguity, but the impurity concentration thus deduced has a useful meaning in production processes.

Concentration of impurities in single crystal rod.—The concentration of excess donors or acceptors was obtained from the temperature dependence of Hall coefficient, R_H. Furthermore, the concentrations of boron and phosphorus were determined by the frozen-drop method (7) with a sensitivity of 0.01 ppb and an accuracy of 10%. In the present experiments, contents of carbon and oxygen in silicon were not investigated in detail, because both of them cannot be deduced from electric properties. According to infrared spectroscopic analysis, the high purity silicon prepared by the floating-zone refining techniques had impurity oxygen at a lower concentration than 10^{16} atoms/(cm^3 of Si) and carbon ranging from 0.5 to 1.1×10^{16} atoms/(cm^3 of Si).

Results and Discussion

Concentration of impurities in the purified silane.—The resistivity of the silicon layer, which is a decomposition product of the purified silane, is shown in Fig. 4 as a function of the depth from the surface. The vertical arrow in the figure shows the position of the p-n junction which is determined by the stain-etching method. If the experiment could have been conducted ideally, the dotted curve would have been obtained. Several reasons are considered for the discrepancy between the observed and dotted curves. Out-dopings from the substrate may reduce the steepness of the slope in the p-n transition region. The exact shape of the peak cannot be obtained owing to a limited positional resolution of the present microprobe, 1 μm. We cannot claim that contamination from the apparatus

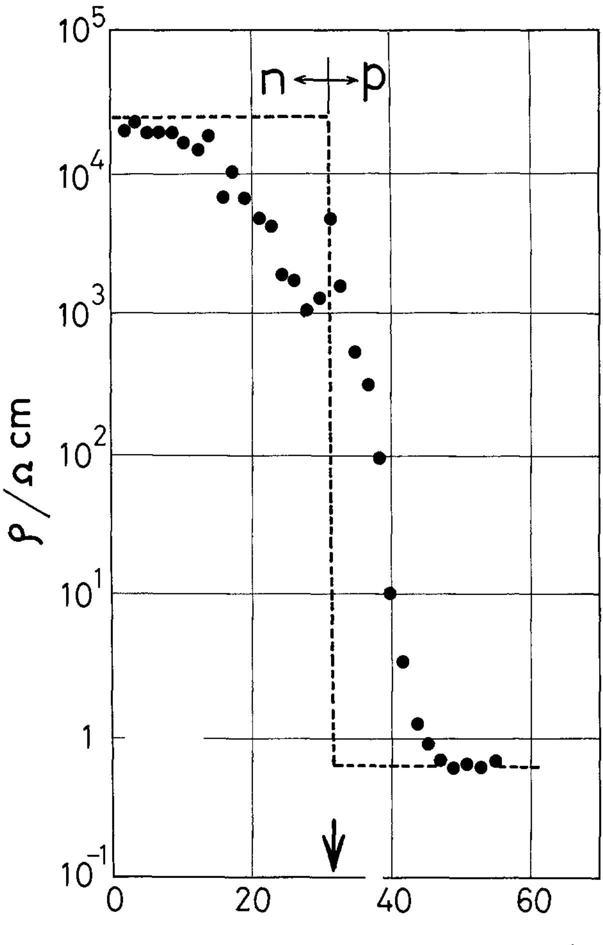

Fig. 4. Profile of the resistivity of the silicon layer deposited onto p-type substrate silicon crystal. Material silane gas was purified with the zeolite at a column temperature of −10°C.

wall is completely excluded. In spite of these shortcomings, the ρ-value at the plateau region becomes a measure of the concentration of phosphine. Applying Irvin's equation (8), we have

$$\text{(donor concentration)} \simeq \text{(concentration of P)} = 5 \times 10^{11} \text{ atoms/(cm}^3\text{ of Si)}$$

Single crystal rods obtained from the polycrystalline silicon were 20-33 mm in diameter and 300 mm in length, and their resistivities at room temperature were greater than 10^4 ohm-cm of p-type without exception. Figure 5 shows a representative curve for the resistivity *vs.* position along the axis of the rod. The part near the seed crystal had a much lower resistivity than that of the middle part. This is attributed to the contamination from the low resistivity seed (600 ohm-cm of n-type). The single crystal silicon rods were of p-type in contrast with the result, obtained in the preceding paragraph, that the epitaxial layer was of n-type. It is considered that phosphorus was efficiently removed but boron was not in the process of the floating-zone melt.

Hall coefficient, R_H, was measured as a function of temperature. The excess donor or acceptor concentration, ΔN, is given by the relation $\Delta N = |N_A - N_D| = 1/R_H \cdot e$, where N_A and N_D are the concentration of acceptor and donor, respectively, and e is the elementary charge. The value for ΔN was 1.9×10^{11} atoms/(cm^3 of Si), as estimated from R_H value in the extrinsic region.

Extrinsic resistivities of the samples ranged between 3×10^4 and 8×10^4 ohm-cm at room temperature. Three measuring techniques—the spreading resistance microprobe, the four-point probe and the bulk

resistance methods—were used for comparison. These results are tabulated in Table II, and the agreement among these results was satisfactory.

Characteristics of the adsorption column.—The concentration of phosphine in the effluent silane is shown as a function of the column temperature in Fig. 6, where the phosphine concentration was obtained from the resistivity of the deposited silicon layer. If the rate of adsorption is so high that the local equilibrium is attained along the column, the effective isosteric heat of adsorption of phosphine by the adsorbent, q_{st}, can be deduced from this figure with the Clausius-Clapeyron equation as

$$q_{st} = 23 \pm 2 \text{ kcal} \cdot \text{mole}^{-1}$$

This heat is slightly smaller than those of ammonia and water (9). The higher purity of the effluent silane is obtained with the decreasing column temperature, up to the point where the assumption of the adsorption equilibrium breaks.

Further studies were carried out by using a simulation column to obtain detailed knowledge in a wider temperature range. The simulation column had a diameter of 4.2 mm and a length of 450 mm, containing 5g of the adsorbent (40-60 mesh particles). A gas mixture of phosphine and silane was passed through the column, and an effluent was directly introduced into a gas chromatograph and analyzed. Since the sensitivity of the detector was 10 ppm for phosphine, the test gas used contained about 350 ppm of phosphine. This composition differs considerably from that used in other experiments at our plant, but we can expect that results of the simulation experiments elucidate the characteristic properties of the adsorbent. The breakthrough curve of the column was measured at temperatures between −78° and 50°C and at flow rates ranging from 60 to 600 mliter · min^{-1}. Results are shown in Fig. 7. In this figure, the concentration of phosphine in the effluent is expressed in a normalized unit (conc of phosphine in the outlet gas/conc of phosphine in the inlet gas). The breakthrough point is defined as the total volume of gas effused before phosphine in the effluent can be detected by the gas chromatography. The breakthrough point increases first with the decreasing column temperature, reaches the maximum value at about −30°C, and then drops steeply, as shown in Fig. 8. Two possible reasons are considered for this drop. The first is concerned with an inherent property of phosphine, that its adsorption may

require some activation energy and become very slow at lower temperatures. The second is that the adsorption of phosphine is reasonably rapid but seriously hindered by coexisting silane at lower temperatures. To make a choice between these two, the breakthrough curve of a mixture of argon and phosphine was studied, and the results are shown by a dotted curve in Fig. 8. In this case, the breakthrough point monotonically increases with decreasing temperatures and is always higher than that in the phosphine-silane system. Consequently, it is concluded that silane hinders the adsorption of phosphine and that its effect becomes serious below −40°C. The effect of the flow rate of the gas was also investigated, with results shown in Fig. 9.

The column, when saturated with phosphine, was regenerated by warming gradually up to 400°C under

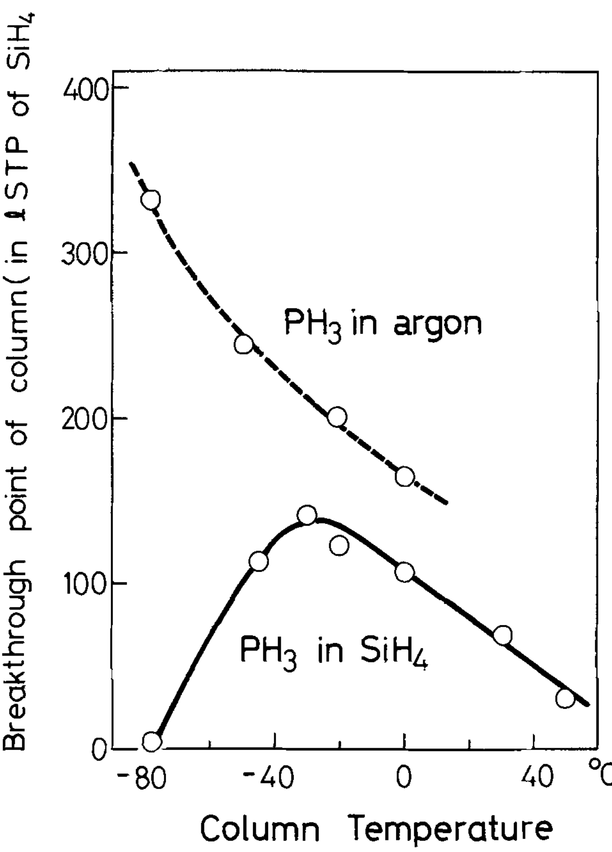

Fig. 8. Breakthrough point of the simulation column expressed as a function of the column temperature. The solid curve is referred to PH_3/SiH_4 system, with a molar concentration of PH_3 of 360 ppm, at a flow rate of 167 ml · min^{-1}; the dotted curve is referred to PH_3/Ar system, with a molar concentration of PH_3 of 370 ppm, at a flow rate of 300 ml · min^{-1}.

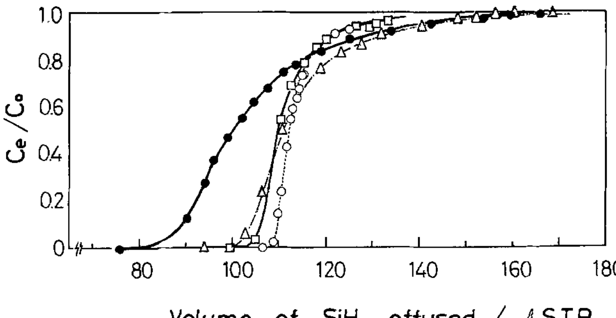

Fig. 9. Effect of the flow rate of the effluent to the breakthrough curve at 0°C. ○, 69 ml · min^{-1}; □, 220 ml · min^{-1}; △, 418 ml · min^{-1}; ●, 582 ml · min^{-1}.

a flow of hydrogen. The adsorption activity of the column was reduced to one-third of its initial value by the first regeneration treatments, and almost lost after three cycles. In contrast with the phosphine-silane system there was no hysteresis on regeneration of the adsorbent in the phosphine-argon system. One possible conclusion is that silane decomposition impairs the adsorption activity of the zeolite in the regeneration process. This means that silane may be sorbed to some extent, and decompose and block the pores on heating. The adsorbed amount of gas in Fig. 1 was obtained by waiting 2 hr for equilibration. Hence, more careful measurements were carried out by waiting 100 hr for equilibration, and it was found that a measurable amount of silane was sorbed very slowly. After pumping out residual silane in a dead space, the zeolite adsorbent was heated to 400°C, hydrogen being evolved in that course. Thus it is concluded that silane competes, though weakly, with phosphine in adsorption, and that the sorbed silane decomposes to hydrogen and silicon by heat-treatments. The product silicon blocks the window to the cavity of the zeolite and hinders the regeneration. It is a considerable demerit that the adsorbent cannot be regenerated. Still, the present process is economical for the following reasons: (*i*) The ratio of weight of zeolite consumed to that of treated silane is very large, that is, the purified silane weighing 200 kg can be obtained from 2 kg of zeolite in one bed; (*ii*) zeolite is far less expensive than a silicon rod; (*iii*) in the adsorption purification process, losses of silane are negligibly small; and (*iv*) adsorption purification is carried out at temperatures between −30° and −20°C, attained by a one-stage refrigerator.

To seek a better adsorbent, we measured adsorption properties of (Mg, K)-A, (Mn, K)-A, and (Zn_xK_{12-2x})-A with $1 < x < 2$, but all of them are inferior to the one discussed herein. With these zeolites, phosphine was sorbed rather slowly, so that an unreasonably long adsorption column may be required to purify silane to the desired degree. Other kinds of zeolites such as (Cd, K)-A, (Ca, K)-A, and (Ni, K)-A, did not satisfy the required conditions.

Characteristics of the high purity silicon.—A surface barrier type detector with a depletion layer thickness of 1 mm was fabricated from high purity silicon (of p-type with a resistivity of 1×10^4 ohm-cm at room temperature). Figure 10 shows a representative spectrum and the full widths at half maximum, measured with the detector at 77°K, for x-rays and conversion electrons from ^{207}Bi. The total system resolution was 5.7 keV at 0.975 MeV with 800V bias on this detector. The same resolution was obtained for a signal from a test pulser, so that the resolution was limited by the electronic circuit used. Consequently, we can say that the intrinsic resolution of the detector is better than the above value.

Conclusion

In the present work, use was made of a conventional floating-zone apparatus and deposition furnace for routine production, so that the apparatus unavoidably caused contamination of the silicon rod. Therefore, the observed purity in the present work gives the lowest limit to the true purity of the treated gas. Ultrahigh purity silicon ($\rho > 10^5$ ohm-cm at room temperature) can be fabricated from silane purified by adsorption on modified zeolite, if use is made of a very clean apparatus specially designed for the purpose.

The high purity silane gas is valuable not only for the production of silicon rods, but also for chemical vapor deposition process. The epitaxial silicon layer with a very high resistivity is useful for some purposes, and the high resistivity polycrystalline silicon layer is required for isolation of electrodes on IC chips. Commercially available silane for CVD, usually, contains n-type impurities (probably, phosphine) and the epitaxial silicon obtained from it has a resistivity of about 200 ohm-cm or lower at room temperature. High

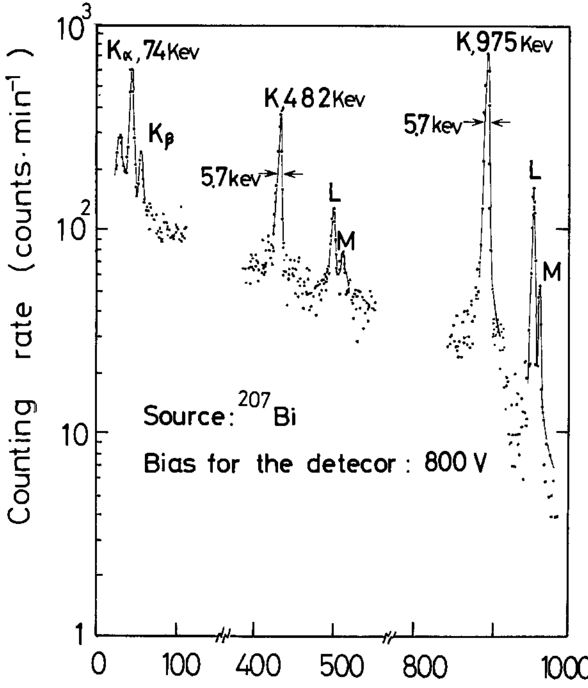

Fig. 10. Spectrum of x-rays and conversion electrons from ^{207}Bi, measured at 77°K with a surface barrier type Si detector having a depression layer of 1 mm thickness.

resistivity layers can easily be obtained by passing such a gas through a small adsorption column of (Zn, K)-A zeolite. This application of zeolite is promising in the production of some types of IC, and is now under investigation.

Reduction of Autodoping

Carl O. Bozler[*,1]

Sperry Rand Corporation, Gainesville, Florida 32601

ABSTRACT

Silicon epitaxial layers are grown on silicon substrates highly doped with arsenic using the pyrolysis of silane. A special technique is used to reduce the autodoping by minimizing impurity evaporation from the back side of the wafer. A comparison of impurity profiles obtained from layers grown under a number of different conditions reveals that autodoping can be reduced still further by increasing the flow rate, decreasing the volume around the susceptor, and decreasing the growth rate. The formulation of a mathematical model helps to describe the interrelation of those three variables. By optimizing the growth conditions, it is shown that the autodoping can be essentially eliminated.

For many silicon devices, especially microwave diodes and transistors, it is desirable to have very abrupt transitions between doping levels. In some cases it is required to have a heavily doped substrate with light doping in an epitaxial layer. Fabrication of such an epitaxial layer where the transition in doping level must occur in less than a micron can be difficult because of dopants coming from the substrate during growth.

Impurities can move from the substrate into the epitaxial layer in two ways. First, they can simply diffuse through the bulk silicon into the layer, and according to Fick's law the impurities will assume a complementary error function distribution (1). Second, impurities can leave the substrate via the gas phase adding to dopants already in the gas. Some of these impurities will then be incorporated into the growing layer. This second impurity transport mechanism, via the gas phase, is generally termed autodoping.

To clarify the events which lead to autodoping, one can divide the growth sequence into two time periods. Before growth begins, there is a period where the substrate is at growth temperature with dopant evaporating from the substrate surfaces reaching some steady-state concentration in the gas phase. The second time period begins with the initiation of growth. The exposed surfaces of highly doped silicon become sealed with a layer of silicon within a few seconds and can no longer contribute to autodoping. No growth occurs

Key words: silicon, epitaxy, autodoping.

on the back surface of the substrate, however, which is more or less in contact with the susceptor, and consequently the back surface continues to contribute to autodoping. There are then two sources for autodoping: the impurities in the gas before growth begins and the impurities evaporating from the back surface during growth.

A number of authors (2-4) have demonstrated that a dramatic decrease in autodoping occurs when the back side of the wafer is coated with SiO_2 prior to epitaxial growth. With the back side of the wafer sealed, the entire wafer becomes sealed after growth begins. The only impurities contributing to autodoping in this case are those which have evaporated from the front surface of the substrate in the period before growth began. It is the pregrowth contribution to autodoping that is investigated in this paper.

Experimental

The system used to grow the epitaxial layers is an Applied Materials Technology AMV 500. The cross section of the reactor chamber in Fig. 1 shows the rotating susceptor which is made of high purity graphite with an over-layer of silicon carbide. The susceptor has a 12.5 cm diameter and is inductively heated. The silicon layers are grown by the pyrolysis of silane at a corrected temperature of 1050°C. Before each growth run, the susceptor is first stripped with hydrogen chloride in hydrogen (1200°C) and then recoated with a fresh layer of undoped silicon.

The substrates are highly doped with arsenic having a resistivity of 0.001 ohm-cm and (111) orientation. They are 3.1 cm in diameter, 0.017 cm thick, and have dislocation counts less than 500/cm^2. They are chem-mechanically polished on one side and chemically etched on the back side to remove lapping strain. The substrates are prepared for epitaxial growth by degreasing in organic solvents followed by 5 min in hot 1:1, NH_4OH:H_2O_2, then 5 min in hot H_2SO_4 saturated with CrO_3, and 5 min in hot 18 megohm water. The wafers are then vapor-etched in the epitaxial reactor with 2% hydrogen chloride in hydrogen (20 liters/min) for 4 min at a corrected temperature of 1200°C. The etch is done immediately prior to film growth and removes about 2μ of silicon.

A very important discovery was made when examining the wafers after etching. During the vapor etch a layer of silicon grows on the back side of the wafer. The layer is 1-2 μm thick and the carrier concentration is approximately 10^{17}/cm^3 at the surface. The reason for this growth during etching is illustrated in Fig. 2. The substrate is 20°C cooler than the susceptor and with the presence of HCl, transport of silicon occurs from the susceptor to the substrate. This layer of silicon seals the back side of the highly doped (5×10^{19}/cm^3) substrate. The effectiveness of the seal was verified by comparing epitaxial layers grown on wafers

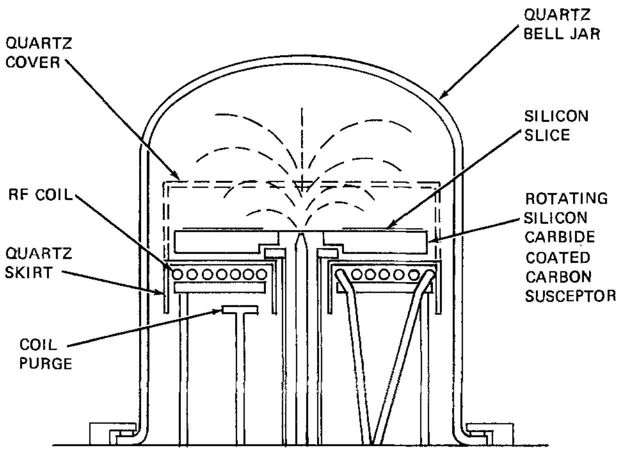

Fig. 1. Silicon epitaxial reactor

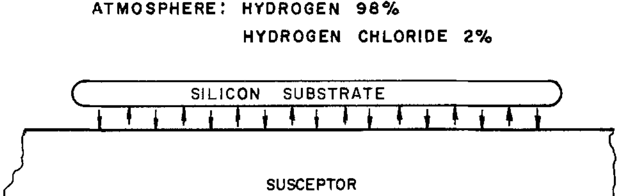

Fig. 2. Transport of silicon from susceptor to substrate

with and without a steam-grown oxide, 10,000Å thick, over the silicon layer on the back side. No detectable reduction in autodoping was observed due to the extra oxide film. This convenient method of sealing the back side of the wafers was used on all of the runs reported here.

After the vapor etch the system is purged for 10 min (various purge times in the range 5-30 min had no effect on the impurity profile) and then epitaxial growth is begun. The hydrogen flow rate was constant throughout the run and except where noted was 20 liters/min.

The silane concentration was varied from 0.01 to 0.1% with the growth rate varying linearly. For the layers grown with a slow growth rate of 0.03 μm/min, a special two-step procedure was used to decrease total growth time. The slow growth rate was maintained for 30 min; then, the silane concentration was increased to give a growth rate of 0.3 μm/min for 7 min. This procedure provided the 3 μm thick film required by the electrical evaluation technique.

Generally, only one substrate was used per experiment except where noted. To reduce the volume around the susceptor from 3 liters to 1 liter, a quartz cover (dotted line in Fig. 1) was added to the reactor for several of the experiments.

The quality of the layers was evaluated with Sirtl etch and they were found free of stacking faults. The film thickness uniformity over each wafer was better than ±2%.

The impurity profile measurements were made using the voltage-capacitance technique (5). Two different procedures were used to form the barrier. One technique was to use a boron predeposition to form a 0.1 μm thick p-layer. Mesas were etched and contact made. The second technique made use of the mercury probe (6). Calibration of the mercury probe was made very accurate by measuring a known standard before each profile measurement. There was excellent correlation between these two techniques.

Results and Discussion

The effect of flow rate and volume around the susceptor on autodoping is illustrated in Fig. 3. The dotted line is the complementary error function determined by time and diffusion constant at growth temperature and represents the part of the doping which would remain if the autodoping were eliminated. The solid curve is the measured impurity profile. Due to the nature of the voltage-capacitance measurement, the position of the impurity profile along the x-axis relative to the interface between substrate and layer was initially unknown. The correct position has been determined by noting that for all the experimental curves the slope above a carrier concentration of 10^{17}/cm^3 is essentially the same as the corresponding complementary error function curve. This implies that autodoping becomes negligible above 10^{17}/cm^3 and that in this range the experimental and complementary error function curves can be matched by shifting the experimental curve in the x-direction. The three experimental curves in Fig. 3 have been matched, and it is evident that by either increasing the hydrogen flow or decreasing the volume, the autodoping is reduced.

It has been found by some (7) that this result could be explained by impurities stored in a stagnant bound-

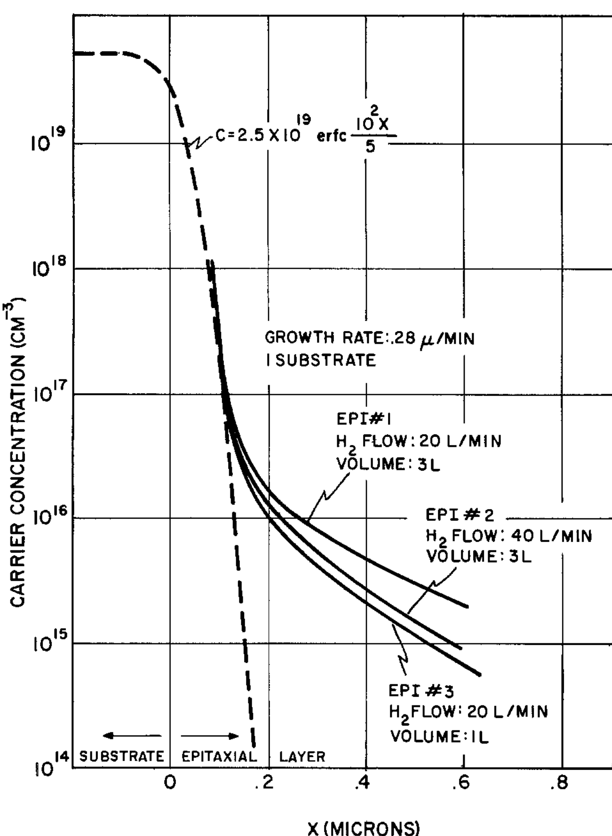

Fig. 3. Impurity profiles showing the effect of volume around the susceptor and flow rate.

ary layer. A special experiment was made to determine the effect of the boundary layer. A fixed quartz wiper was placed over the susceptor in a radial direction so that, with the susceptor rotating, the wiping action would disturb the boundary layer releasing the stored impurities. The clearance between the bottom of the wiper and the top surface of the wafer was ½ mm. The height of the wiper was 1 cm. A layer was grown using the wiper under conditions identical to Epi No. 1 and the profile obtained was indistinguishable from that given for Epi No. 1 in Fig. 3. Therefore for the vertical system used in these experiments the boundary layer is not a major cause of the autodoping.

A second possible explanation of the results in Fig. 3 is that both smaller volume and higher flow cause more rapid impurity dilution. The relation of the growth variables to impurity concentration can be clarified with a model. Consider V to be the volume above the susceptor of Fig. 1 and assume, because of turbulence, that gas entering at flow rate f is completely mixed immediately upon entering. One can describe the impurity concentration in the gas as a function of time with the differential equation

$$C = -\frac{V}{f}\frac{dC}{dt} \quad [1]$$

$$C(0) = C_o$$

It is easy to visualize in the reactor of Fig. 1 that large vortices may exist inside the bell jar above the susceptor. Even though the gas inside a vortex is well mixed a large percentage of pure gas may pass around the outside of the vortex and past the skirt without mixing. To account for this, a mixing factor k less than one is factored into the flow term of Eq. [1]

$$C = \frac{-V}{kf}\frac{dC}{dt} \qquad C(0) = C_o \quad [2]$$

A solution to this equation is

$$C = C_o e^{-\frac{kf}{V}t} \quad [3]$$

Because of the nearly linear relationship between gas impurity concentration and layer impurity concentration, let

$$N_1 = hC \quad [4]$$

where N_1 is that part of the impurity concentration in the silicon which comes from the pregrowth gas impurities and h is the proportionality constant. With the change of variables

$$x = Gt \quad [5]$$

where G is the growth rate. The impurity concentration in the layer as a function of distance is

$$N_1 = hC_o e^{-\frac{kf}{GV}x} \quad [6]$$

In Fig. 4, the impurity profile of epitaxial run No. 1 given in Fig. 3 has been replotted on a contracted x-scale in order to show the impurity level further from the layer-substrate interface. Equation [6] has been plotted also with $k = 0.2$, and one can see that there is some contribution to autodoping in addition to the pregrowth gas impurities. A possible source for this additional autodoping is the walls of the reactor which are relatively cool (300°-700°C). Impurities could condense on the walls in the pregrowth period; then, after growth begins and the impurity concentration in the gas decreases, the impurities on the walls could be released. In Fig. 4 the line having the equation

$$N_2 = B_o \frac{V}{f} e^{-\frac{\eta}{G}x} \quad [7]$$

has been included to represent these released impurities. η does not depend on the volume around the

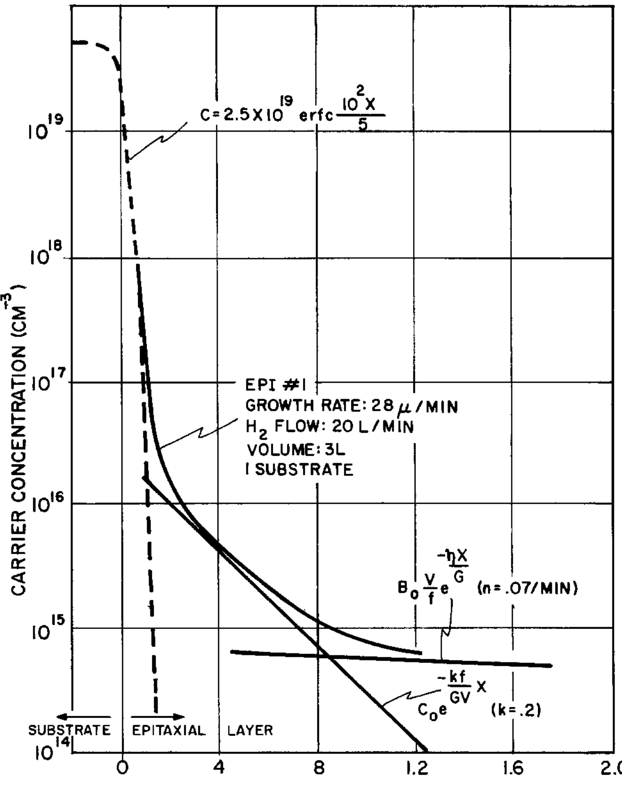

Fig. 4. A comparison of the mathematical model to the measured profile Epi No. 1.

susceptor or the flow rate, but is probably a complicated function of wall temperature and impurity vapor pressure. B_0 is determined by the initial rate of impurity release, and the V/f term represents the effect of flow rate and volume. The total concentration in the film is the sum of Eq [6] and [7]

$$N = hC_0 e^{-\frac{kf}{VG}x} + B_0 \frac{V}{f} e^{-\frac{\eta}{G}x} \quad [8]$$

Even though Eq. [8] is a rather crude model which ignores the effects of diffusion during growth, it has a very good qualitative agreement with several experimental results which follow and is able to predict the requirements for minimum autodoping.

Equation [8] predicts that decreasing the growth rate should have a strong influence in reducing the autodoping. This was indeed found to be the case, as illustrated in Fig. 5. The effect of the low growth rate is to maintain a sealed substrate with a minimal thickness of silicon while allowing time for the impurity level in the gas to decrease. The lower growth rate requires a longer growth time, however, and consequently the impurity diffusion from the substrate into the layer is larger (dotted lines). A comparison of the impurity profile of the 0.03 μm/min layer (Epi No. 5) and Eq. [8] is made in Fig. 6. The values of C_0, B_0, f, η, and V are the same as those used in Fig. 4. The agreement is good with the realization that the increased out-diffusion of impurities from the substrate in Epi No. 5 has covered over the autodoping contributed by pregrowth gas impurities. The impurities designated as coming from the reactor walls now play the most important part.

In addition to growth rate, the one other variable in the system which was found to influence autodoping was the number of substrates on the susceptor, as illustrated in Fig. 7. Increasing the number of substrates increases the autodoping, which is at least in qualitative agreement with the model. The increased surface area of highly doped silicon has the effect of increasing the gas concentration of impurities before growth, which increases the value of C_0 and B_0 in Eq. [8].

Using the model as a guide, an attempt was made to reduce the autodoping as much as possible. A layer

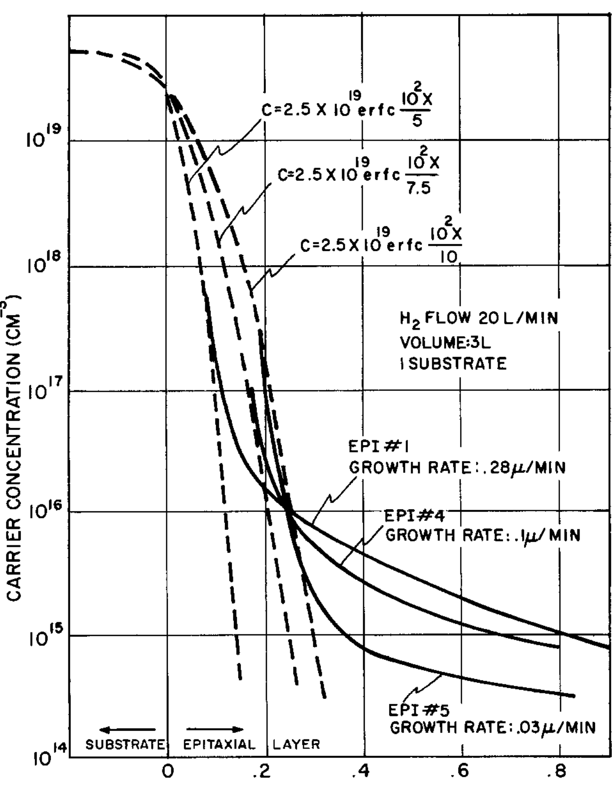

Fig. 5. Impurity profiles showing the effect of growth rate

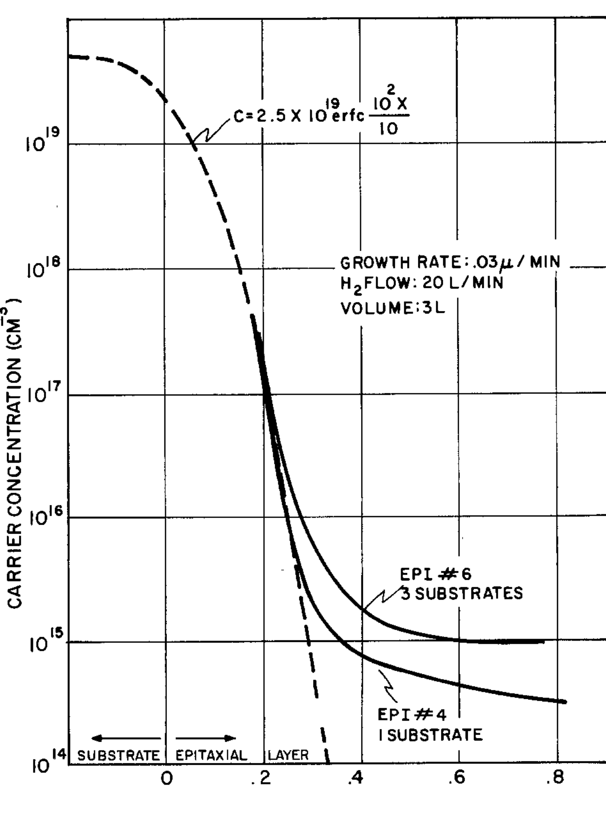

Fig. 7. Impurity profiles showing the effect of number of substrates.

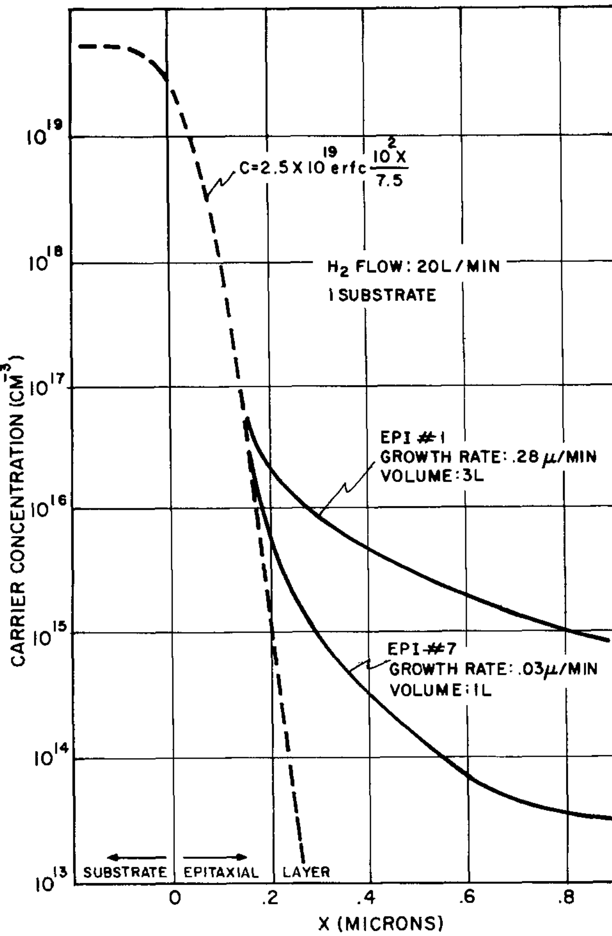

Fig. 8. Impurity profiles showing the result of minimizing autodoping.

was grown using a single substrate, a low growth rate of 0.03 μm/min, and a small volume around the susceptor (1 liter). The result is given in Fig. 8 and compared with Epi No. 1 (the complementary error function for Epi No. 1 has been omitted for clarity). The amount of autodoping has been greatly reduced and has made the transition in doping level very abrupt. The transition is so abrupt that when using the voltage-capacitance technique to measure impurity concentration, there can be appreciable measurement error due to electron redistribution. Using the theoretical data presented by Kennedy (5) on distribution of carriers around hi-low junctions, the remaining autodoping in Epi No. 7 can be accounted for by measurement error.

Although only seven impurity profiles have been given here to describe the results in Fig. 3-8, actually many additional profiles were made of epitaxial layers grown under conditions identical with layers 1-7. Each layer was repeated at least twice and Epi No. 1 has been repeated over twenty-five times. In every case when growth conditions were identical the profile differences were insignificant.

Conclusions

For a specific epitaxial crystal growth system using substrates doped with arsenic, the causes of autodoping have been studied. A mathematical model has been established to help organize the experimental results. With the elimination of autodoping from the back side of the wafer, the important requirements to reduce the remaining autodoping are increased flow rate, decreased volume around the susceptor, decreased growth rate, and decreased number of substrates. It was found possible to meet a combination of these requirements which resulted essentially in the elimination of the autodoping.

Fluoride Ion Contamination and TiO Film Migration in the Ti-Pt-Au Metallization

A. Christou* and H. M. Day*

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

F^- ions exist as probable sources of contamination from the contact etchant and from the platinum etchant during the processing of the Ti-Pt-Au metallization contact system. Annealing up to 200°C has resulted in the formation and migration of a TiO layer as identified in the Si-Ti-Pt-Au structure. Sputter profiles using Auger electron spectroscopy (AES) indicate that the Ti layer has been transformed into a Ti, TiO, O_2 composition. It is shown that the thin oxide film (TiO) passivates the titanium layer. Interdiffusion failures observed were found to be directly dependent on the migration and chemical dissolution of the passivation (TiO) film. These specimens were characterized by random pinhole formation and microcracking as identified with the SEM. Migration of the thin oxide film resulted in the titanium becoming active in a contaminated ion environment. F^- ion contamination was found to provide a more active corrosive environment for pinhole formation. Interdiffusion of gold through the barrier layers increased as F^- ion concentration increased.

A number of investigations on the reliability of semiconductor devices as affected by diffusion controlled processes which take place at metal-silicon contacts have been reported in the literature (1-3). These investigations indicate that halogen ions at silicon and silicide contacts can degrade the low temperature stability of gold/refractory thin film structures. In the present investigation we report (*i*) the effect of F^- ion contamination on the reliability of the Ti-Pt-Au metallization, (*ii*) the effect of oxygen gettered by the titanium on the stability of Ti-Pt-Au test structures, and (*iii*) the pinhole and interdiffusion (Au $\rightleftarrows$ Si) failure mode. F^- ions exist as probable sources of contamination from the contact etchant. In addition to contact contamination, a number of intermetallic compounds are formed in the diffusion couples of the Ti-Pt-Au system (4, 5). These compounds include Ti_3Pt which has been postulated to be the high temperature diffusion barrier to gold-silicon interdiffusion (6). If pinhole formation is accelerated in the presence of a corrosive environment, pinhole formation in the barrier layers can result in a low temperature gold-silicon interdiffusion.

Experimental Techniques

In LSI and microwave transistor metallization applications, an oxide-nitride-oxide sandwich is deposited before the initial emitter diffusion. The upper oxide is photoetched in contact areas and is used as a mask for etching the nitride layer. Contact windows in the silicon are subsequently opened, and after removal of the photoresist, platinum is evaporated for platinum silicide formation. The PtSi is followed by a titanium (for adhesion) and a platinum (gold diffusion barrier) deposition. The gold is then plated onto the beam areas and the titanium is etched resulting in the cross section shown in Fig. 1. Figure 1 also summarizes the various processing steps. The F^- and Cl^- ions are probable sources of contamination from an HF etchant, from the platinum etchant (HNO_3 and HCl), and from the SiO_2 etchant. Test structures with contacts shown in Fig. 1 and with known amounts of F^- ion surface concentration were annealed in a vacuum (1×10^{-5} Torr) at temperatures up to 350°C in order to investigate gold migration, pinhole formation, and microcracking.

A second set of test structures consisting of Ti-Pt-Au deposited on F^- pretreated (100) silicon wafers was used to determine the low temperature 150°-350°C thermal stability of the Ti-Pt-Au system. Radioactive ^{18}F was prepared according to the reaction $^{16}O(\alpha, pn)$ ^{18}F from Li_2O by α-particle irradiation in the Naval Research Laboratory cyclotron (1). The fluorine was extracted in the form of $H_6{}^{18}F$ and added directly to the etch solution. Prior to metallization the silicon wafers were dipped in the etch solution for 10 sec, rinsed, and then monitored at various intervals for verification of fluorine concentration and the absence of other radioactive contaminants such as Na. The variation of the fluorine ion concentration as a function of rinse duration is shown in Fig. 2. Figure 2 shows that wafers pretreated by an additional 1200°C thermal quench also fall on the same curve.

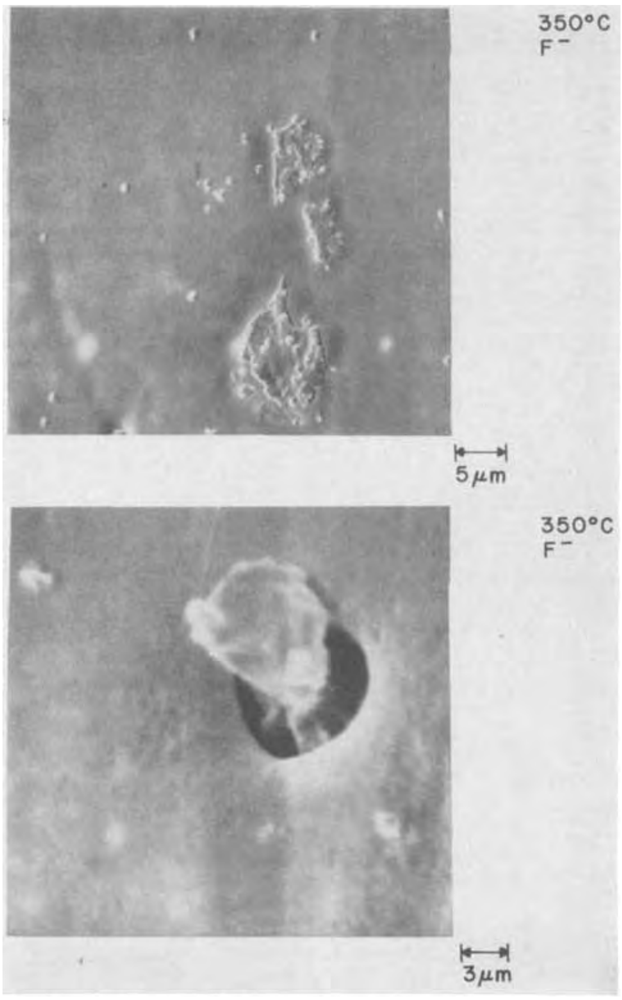

Fig. 3. Pinhole and hillock formation in Ti-Pt-Au test structures as a result of F^- contamination.

The metallizations were sputter-deposited using the techniques reported earlier (7, 8). The titanium, platinum, and gold layers were 1000, 1500, and 3000Å thick, respectively. The metallization structure after heat-treatment was analyzed using scanning electron microscopy and AES. A third set of test structures of Ti-Pt-Au was deposited on oxidized silicon and unoxidized silicon (no F^- contamination) and annealed in vacuum at temperatures between 150° and 350°C.

Results and Discussion

Fluorine contaminated Ti-Pt-Au contacts.—Annealing at 200° and 350°C of the Ti-Pt-Au contact test structures has resulted in pinhole and hillock formation as shown in Fig. 3. The level of F^- contamination of the Ti-Pt-Au contact shown in Fig. 3 was measured to be approximately 1×10^{13} F^-/cm^2. The areal density of etch pits was measured to be approximately $20/cm^2 \times 10^3$, while the hillock density was approximately $10/cm^2 \times 10^3$. Pinhole density as well as hillock density increased as F^- concentration at the contacts increased. From the present investigation, it is believed that fluoride species precipitate at silicon surface defects and subsequent annealing between 200° and 350°C results in enhanced diffusion at silicon defects (1) and the subsequent hillock and pinhole formation in the metallization.

Additional problems identified on the Ti-Pt-Au contact test structure as a result of the F^- ion contamination and annealing at 150°C for 24 hr include: (*i*) pinholes and cracking at contact points between Ti/Si_3N_4 as shown in Fig. 4, and (*ii*) cracks in the Pt layer at the Si_3N_4 shelf and pinholes in the Pt layer as shown in Fig. 5. The pinholes and microcracks can result in diffusion paths between gold and silicon and may initiate a Pt-Si_3N_4 reaction. In addition, titanium and platinum have been found to spread into voids beneath the Si_3N_4 shelf as a result of film discontinuities and compressive loads on these layers. Gold when

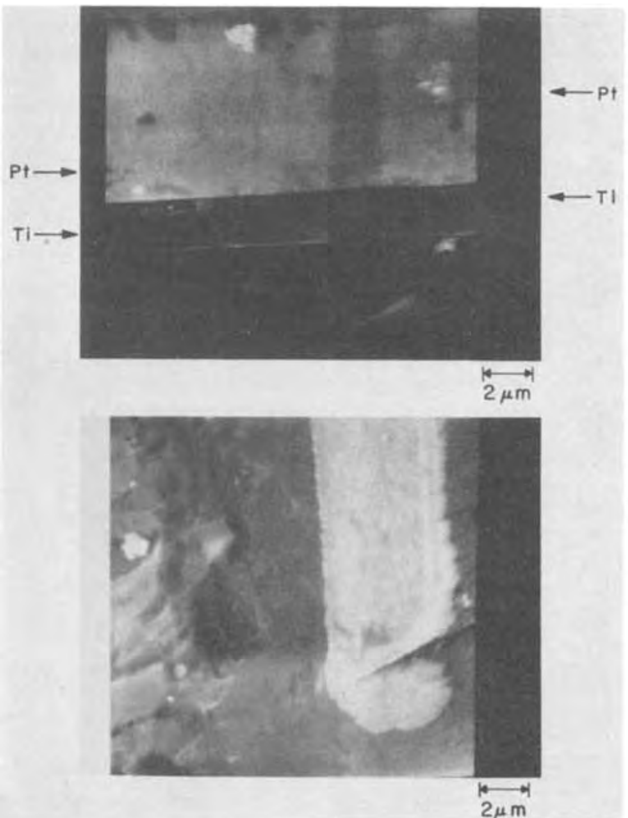

Fig. 4. Pinholes and microcracks found at contact points between Ti/Si_3N_4.

plated into the voids results in gold-silicon interdiffusion at temperatures as low as 150°C.

Migration of titanium and oxygen.—The migration of titanium, oxygen, and TiO was studied as a function of F^- ion concentration and anneal temperature using the sputter profiling technique. The location of the TiO layer was monitored by observing the splitting of the Ti, 387 eV LMM transition. In the as-deposited state, titanium combines with gettered oxygen to form a stable TiO film. Although Ti is a very active metal (10), the thin TiO film passivated the titanium so that it essentially functions as an inert adhesion layer. The initial location of the TiO layer was isolated after 200 min of sputtering. Annealing Ti-Pt-Au (Si substrate) specimens with a 2×10^{12} F^-/cm^2 absorbed layer up to 200°C for 24 hr has resulted in the migration of the TiO layer toward the metal-vacuum interface. The migration of the TiO layer was accompanied by the out-diffusion of titanium and oxygen. Maintaining the anneal temperature at 200°C but increasing the F^- ion concentration to 1×10^{13} F^-/cm^2 has resulted in an increase in the activity of the titanium and a further migration of TiO toward the free surface. The TiO layer was located after 80 min of sputtering. A further increase of the F^- concentration to 5×10^{13} F^-/cm^2 and annealing at 200°C has resulted in the migration of the TiO layer so that it was detected after 40 min of sputtering. The migration of TiO at 200°C is summarized in Fig. 6. Annealing at 350°C for 24 hr has resulted in an accelerated migration of the TiO layer toward the free surface as shown in Fig. 7.

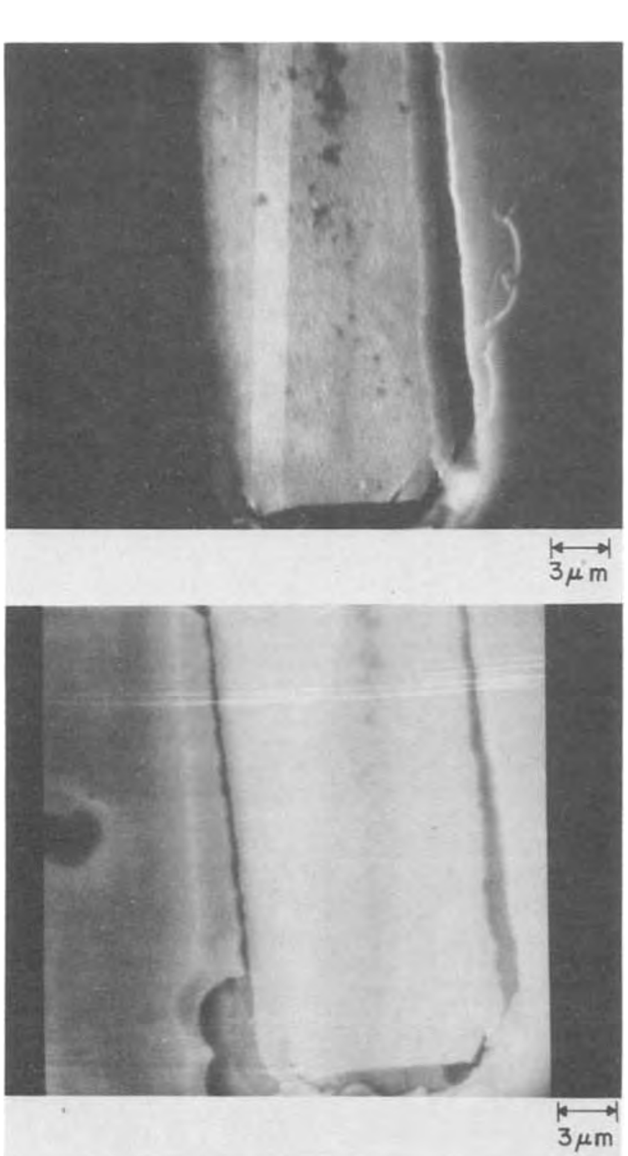

Fig. 5. Microcracking in the Pt layer at the Si_3N_4 shelf

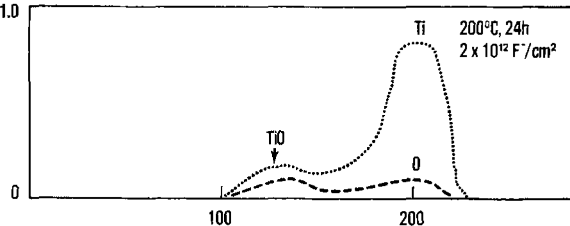
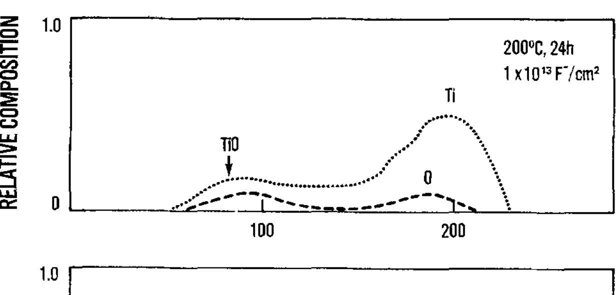
TITANIUM, OXYGEN MIGRATION





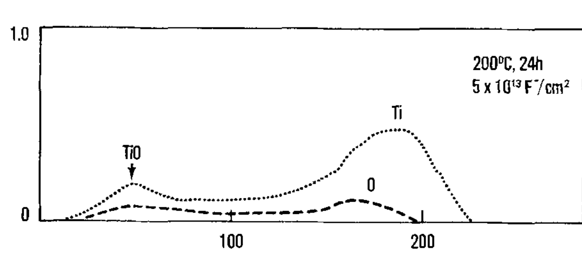


Fig. 6. Migration of TiO at 200°C as a result of F^- ion contamination.

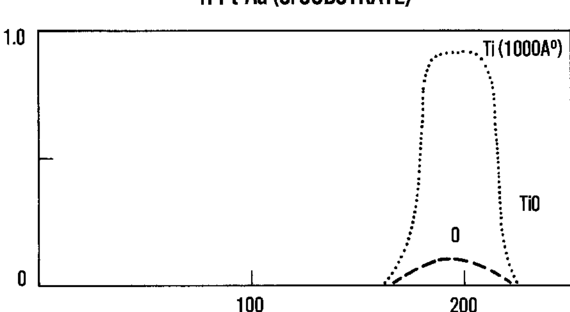
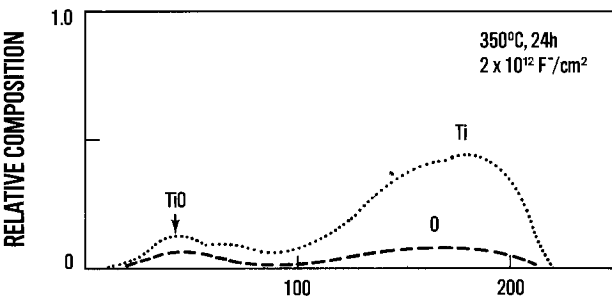
At 2×10^{12} F^-/cm^2 the TiO layer was detected after 80 min of sputtering for the specimens annealed at 200°C, while for specimens annealed at 350°C, the TiO layer was detected after 40 min. At 5×10^{13} F^-/cm^2 and anneal temperature of 350°C, no TiO layer was detected. However, by decreasing the anneal temperature from 350° to 200°C, the TiO layer was detected after 45 min of sputtering for specimens with 5×10^{13} F^-/cm^2 surface concentration. The specimens with no detectable TiO layer, as a result of annealing at 350°C, were characterized by pinhole formation and in some instances by gold-silicon interdiffusion. Therefore the migration of the thin TiO film has resulted in the titanium becoming active and behaving as the anode in a contaminated ion environment. The dissolution of the TiO film leaves the titanium in direct contact with the Au (where Pt is defective) resulting in excessive pinhole formation since Au is not an effective oxygen reducer and cannot maintain the anodic passivation of the titanium.

In the present investigation with ion contaminated Ti-Pt-Au structures, a galvanic cell has been established with F^- ion concentrations as low as 10^{12} F^-/cm^2. The Ti has been attacked preferentially by the Au in the vicinity of either deposited defects in the Pt layer or microcracks in Pt induced by interdiffusion between Pt and Au. Since the reaction occurred with no electrical biasing, the environmental conditions can also be postulated to contain water vapor. Similar multimetallic systems including Ti-Au and Ti-Pd-Au have been investigated using an environmental condition containing chloride ions (9). The corrosion of Ti was found to begin at pinholes in the noble Au coating. Intermediate layers such as Pd were found to effectively improve the corrosion resistance of the bimetallic metallizations.

TITANIUM, OXYGEN MIGRATION
Ti-Pt-Au (Si SUBSTRATE)





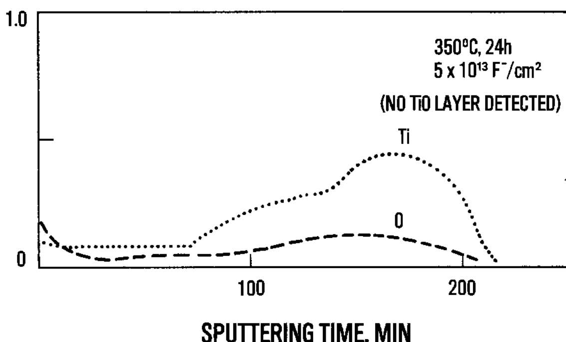


Fig. 7. Migration of TiO at 350°C as a result of F^- ion contamination.

In discussing kinetics, the present investigation has shown that the phenomenon of passivity greatly affects the rate of the reaction. In the case of Ti, the passivity is due to the formation of a thin adherent oxide film which has been identified to be TiO. The oxide film acts as a barrier between the metal and environment and effectively decreases the rate of dissolution involving metal ions. It has been shown that when the passivating film breaks down as a result of increasing fluoride ion concentration, the reaction proceeds rapidly and pinhole formation results. Figure 8 summarizes the kinetics results for 1×10^{13} F^-/cm^2 and 5×10^{13} F^-/cm^2 samples heat-treated at 350°C. The time to sputter to the TiO layer decreased approximately as the square root of the anneal time, thus indicating that the migration of TiO is governed by a diffusion process. The F^- ions can then be assumed to provide sites for the acceleration of the diffusion process. The sputtering time in Fig. 8 was converted directly to film thickness using a separately measured sputtering rate of 22.5 Å/min. The slope of the solid line of Fig. 8 yields a diffusion constant of $D = (\Delta x)^2/4(\Delta t_a) \approx 3.6 \times 10^{-13}$ cm^2/sec. The activation energy for the processes at $T = 200°$ and 350°C was measured to be 1.5 eV. This energy agrees with energy required for the $Ti = Ti^{++} + 2e^-$ reaction (1.63 eV) (10). Therefore, the kinetics

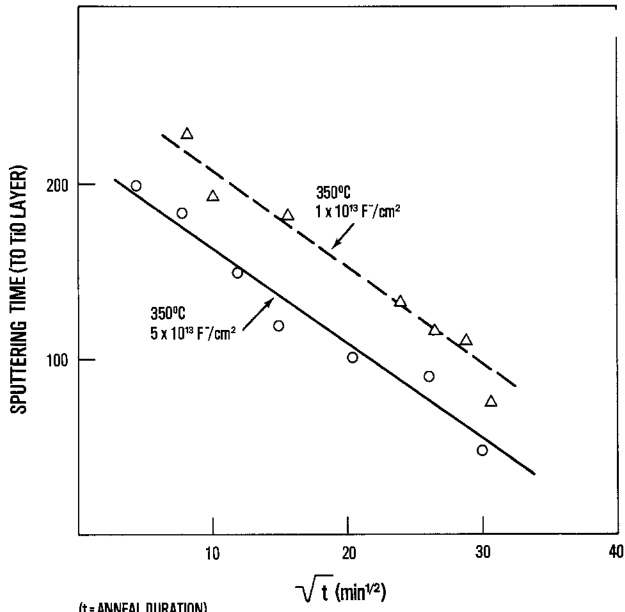

Fig. 8. Summary of migration kinetics for 1×10^{13} F^-/cm^2 and 5×10^{13} F^-/cm^2 samples heat-treated at 350°C.

data indicate that the migration and dissolution of the TiO layer coresponds to a simultaneous Ti corrosion reaction.

Conclusions

The present investigation shows that pinhole failures in Ti-Pt-Au film test structures are directly dependent on the chemical dissolution or migration of the TiO layer. Annealing at 200° and 350°C has resulted in the migration of the TiO layer toward the free surface for ion concentrations between 1×10^{12} and 5×10^{13} F^-/cm^2. Interdiffusion of gold through the barrier layers increased as the F^- concentration increased. The F^- ion contamination has been found to provide a more active corrosive environment for pinhole formation.

Thermal Stability of PtSi Films on Polysilicon Layers

A. K. Sinha, S. E. Haszko, and T. T. Sheng

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A thin-film combination containing PtSi (2000Å)/poly-Si (1000Å) has been considered for application as first-level metallization in large scale silicon integrated circuit devices. The present investigation was made to ascertain the thermal stability of this structure as reflected by changes in microstructure, resistivity, and stresses of these films upon heat-treatment up to 1000°C. The PtSi films (2000Å thick) were formed by sintering Pt on poly-Si at 700°C (15 min) in vacuo or forming gas; the wafers were then coated with 5000Å of Silox SiO_2 and heat-treated at various temperatures. No agglomeration was observed at up to 900°C, although a moderate amount of grain growth did take place. The sheet resistance of these films decreased from ~4 ohm/□ to ~2 ohm/□ after the 750°C anneal, it then increased with increasing annealing temperature to ~16 ohm/□ (900°C anneal). The resistivity increase is tentatively attributed to the accumulation of Si at the grain boundaries of PtSi. At 1000°C, a liquid-eutectic phase was formed. However, the liquid did not "ball-up," *i.e.*, it wetted PtSi and poly-Si, and on cooling, it precipitated relatively large areas of variously oriented single crystals of Si. This recrystallization process led to a sharp decrease in the sheet resistance of PtSi.

With continuing growth of the LSI (large scale integration) technology, several two-level metallization schemes have been investigated for use on SIC's (silicon integrated circuits). A particularly successful scheme, for unipolar devices, involves the application of P- or B-doped poly-Si on the first level (Si-gate technology) (1). In addition to its excellent MOS compatibility, poly-Si can be used to provide low-resistance contacts to doped Si areas on the device. However, doped poly-Si suffers from one major drawback. Its electrical conductivity is rather poor; it has a sheet resistance 10-100 ohm/□ for 5000Å thick lines (2), and this is undesirable for many bipolar LSI circuits and also certain high-speed (*e.g.*, n-channel) unipolar LSI devices. A potential solution to this problem, proposed by Lepselter and others (3), is to utilize a structure containing metal-silicide/poly-Si where the more conducting silicide is formed over previously defined poly-Si lines; the unreacted metal is chemically etched away, generally without the use of a second photoresist step. An attractive system of this type is PtSi on poly-Si, and the present investigation has been concerned with the thermal stability of this structure at temperatures (750°-1000°C) commonly employed to deposit intermediate oxide/nitride layers using chemical vapor deposition. A nearly analogous system comprising thinner PtSi films on single crystal Si was previously

Key words: heat-treatment, LSI metallization, thin films.

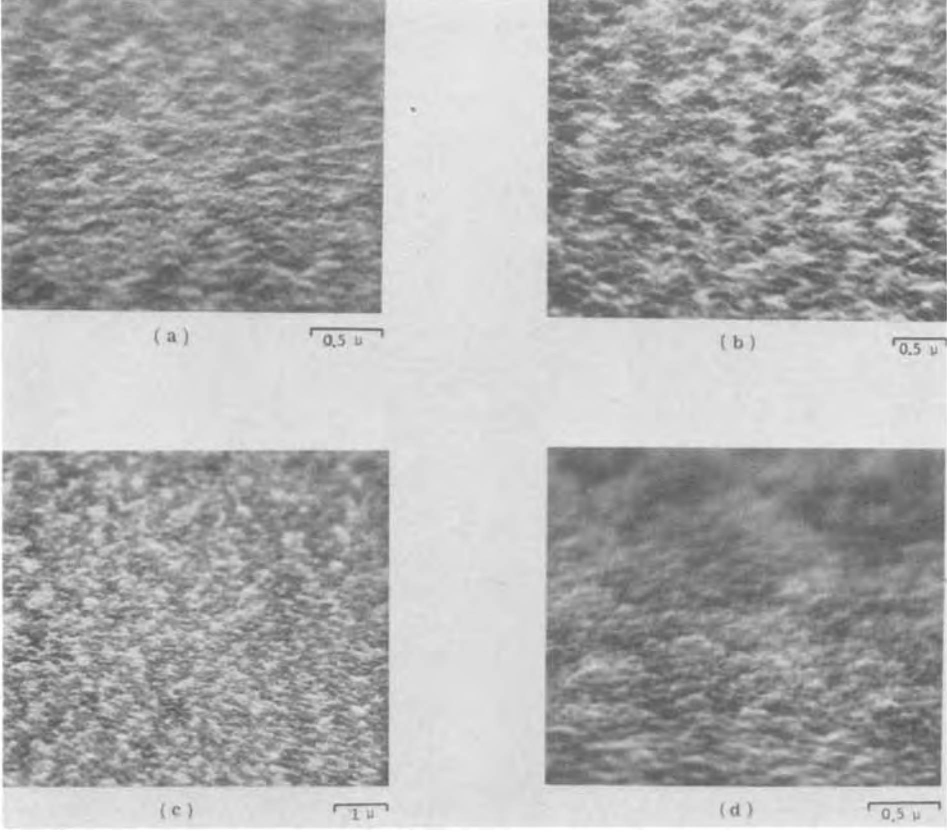

Fig. 1. Scanning electron micrographs of PtSi (2000Å) on poly-Si (1000Å) after various heat-treatments: (a) sintered at 700°C, 15 min, (b) annealed at 750°C, ½ hr, (c) annealed at 800°C, ½ hr, (d) annealed at 900°C, ½ hr.

characterized (4) and it was shown that thin PtSi films (900 and 200Å) agglomerate above 800°C.

Experimental

The substrates for Pt deposition consisted of oxidized Si wafers coated with a 3000Å thick layer of poly-Si which was produced at 700°C in a "Nitrox" reactor (manufactured by Applied Materials Technology, Inc.) using pyrolysis of SiH_4 in Ar/N_2. The poly-Si was lightly doped with B (sheet resistance ~1000 ohm/□) in most cases, but similar results on the thermal stability of PtSi were obtained with poly-Si doped with P to a sheet resistance of 50-100 ohm/□. Immediately prior to metallizing, the poly-Si layer was cleaned by a dip in 50:1 mixture of H_2O:HF for ~1 min (or until its surface turned hydrophobic) followed by DI water rinse and spin-dry. A 1000Å thick film of Pt was deposited using a conventional rf-diode sputtering apparatus (0.2 W/cm²). The PtSi (~2000Å thick) was produced by sintering the Pt/poly-Si combination at 700°C *in vacuo*, or in a reducing ambient such as forming gas. Such ambients were preferred over oxidizing ones in order to minimize any subsequent harmful effects of excessive SiO_2 buildup (5, 6) on or under the PtSi surface. Complete formation of PtSi in these samples was ascertained through x-ray diffraction (7). In order to facilitate subsequent high-temperature annealing studies and also to simulate device structures, the PtSi/poly-Si films were coated with 5000Å of Silox SiO_2 produced at 480°C by reacting SiH_4 and O_2 in Ar/N_2 carrier gas. All the annealing experiments were done in air at temperatures ranging from 750° to 1000°C for ½ hr each. Next, the Silox SiO_2 protective layer was removed by etching in buffered HF and changes in the PtSi layer were evaluated through measurements of sheet resistance (using four-point probe measurements), and stresses [using radius of curvature measurements with an optically levered laser beam (8)], and examination of the microstructure (using scanning and transmission electron microscopy).

Results and Discussion

Wide-film x-ray diffraction patterns showed that the sintered PtSi films were single phase with an (020) type of preferred orientation. The PtSi films were found to be under a relatively large tensile stress of 1.6×10^{10} dyne-cm^{-2}. A tensile stress would be expected on the basis of 10% volume contraction associated with PtSi formation. Subsequent thermal treatments up to 900°C reduced the stress somewhat to 1.1×10^{10} dyne-cm^{-2}.

Figures 1(a) through (d) show scanning electron micrographs of PtSi films (2000Å) on poly-Si after various heat-treatments, namely, (a) sintering at 700°C *in vacuo* for 15 min, (b) annealing at 750°C ½ hr, (c) annealing at 800°C, ½ hr, and (d) annealing at 900°C, ½ hr. In all cases, the PtSi films are continuous and there appears to be no evidence of any agglomeration even at 900°C. By contrast, thinner films of PtSi (900 and 200Å) on single crystal Si show clear evidence of agglomeration at 900°C (4). Although in the latter case, it was shown that the as-sintered PtSi films are associated with surface irregularities of the order of 100Å, the present PtSi films on poly-Si show a much more pronounced degree of granularity and surface roughness (of the order of 1000Å). This increased

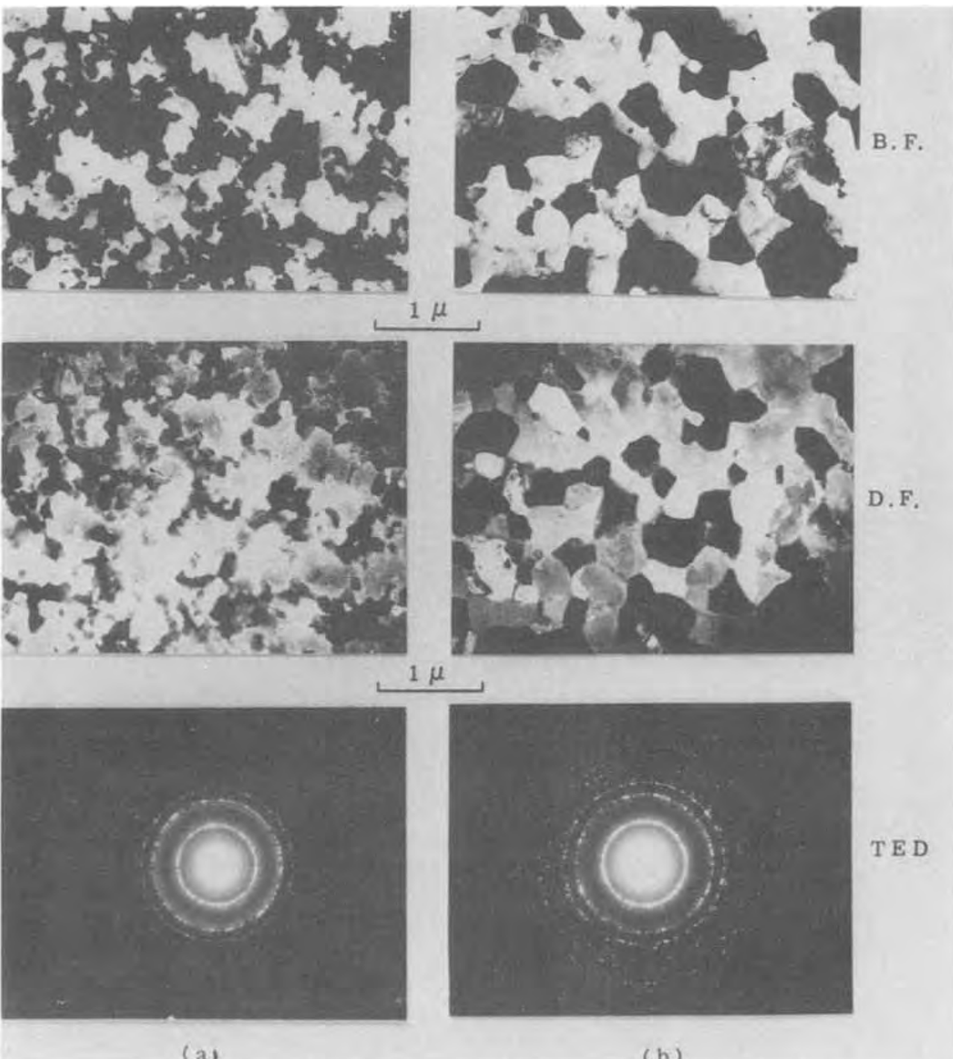

Fig. 2. Transmission electron microscopy results on PtSi films on poly-Si: (a) as-sintered, (b) annealed at 900°C, ½ hr. BF-bright field micrograph, DF-dark field, TED-selected area transmission electron diffraction pattern.

roughness can be partly ascribed to the texture of the underlying poly-Si layer; however, it appears that sintering enhances any surface roughness originally present in the poly-Si and initially replicated by the sputtered Pt film.

Fig. 3. (a) and (b) Bright-field TEM photos of PtSi on poly-Si annealed at 1000°C, ½ hr. (c) TED pattern from lamellar regions of above micrographs.

Detailed information on the microstructure of the films was obtained through examination of the transmission electron micrographs (TEM) of PtSi films (thinned by ion-milling from the poly-Si side), taken in the bright- and dark-field mode, and of the transmission electron diffraction (TED) patterns. Figures 2(a) and (b) show the data for PtSi in the as-sintered state and after annealing at 900°C (½ hr). The grain size of as-sintered PtSi on poly-Si ranged from 1000 to 3000Å whereas after annealing at 900°C, it increased to the 1500-9000Å range. This is also manifested in in-

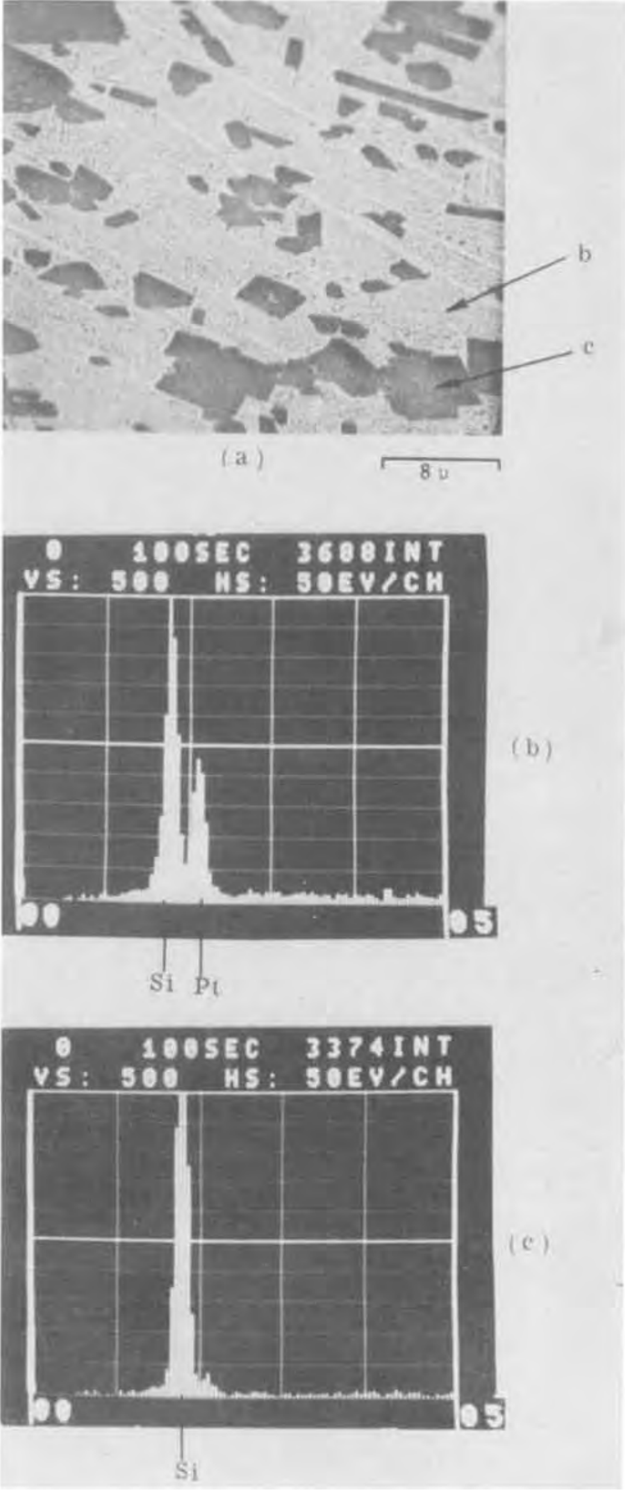

Fig. 4. (a) Scanning electron micrograph of PtSi on poly-Si annealed at 1000°C, ½ hr. (b) and (c) Energy dispersive x-ray analysis of dark and light areas, respectively, of Fig. 3(a).

creased spottiness of the TED pattern for annealed PtSi. The sample annealed at 1000°C showed a two-phase microstructure in the bright-field micrographs [Fig. 3(a) and (b)] consisting of large crystals of Si and a lamellar distribution of PtSi in a Si-matrix. This complex microstructure, which was not apparent in micrographs of the surface replica (because of similar surface texture of PtSi and crystallized Si), is clearly revealed in transmission electron micrographs because of contrast differences between PtSi and Si due to diffraction effects. The selected area TED pattern [Fig. 3(c)] taken from the lamellar regions confirmed the presence of PtSi in these areas.

The unusual microstructure of PtSi/poly-Si samples heat-treated at 1000°C was further investigated using the SEM in conjunction with the energy dispersive x-ray analyzer (EDAX). Figure 4(a) shows the SEM photo where the contrast arises from differences in secondary electron emission coefficients of PtSi (light) and Si (dark) areas. Positive identification of these light and dark areas was made by EDAX analysis whose results are shown in Fig. 4(b) and (c), respectively. The silicon areas in Fig. 4(a) have large geometrical shapes with dimensions of the order of 10μ. The single crystal nature of these areas was ascertained through TED. Figures 5(a) through (d) show the bright-field TEM and selected area TED patterns for various silicon areas. The orientation of Si in the four cases is [001], [111], [110], and [112] which is generally consistent with the macroscopic shapes of these areas.

The formation of relatively large areas of single crystal Si upon annealing PtSi/poly-Si at 1000°C is clearly associated with recrystallization from the liquid eutectic phase (9), and is not due to any grain growth of the poly-Si which would be relatively small at 1000°C (2). The facts that several orientations of Si were observed and that the original PtSi/poly-Si combination was deposited on SiO_2/Si would rule out a simple liquid-phase epitaxial growth of the single crystal Si areas. It is interesting to observe that even liquid formation did not cause significant "balling up"

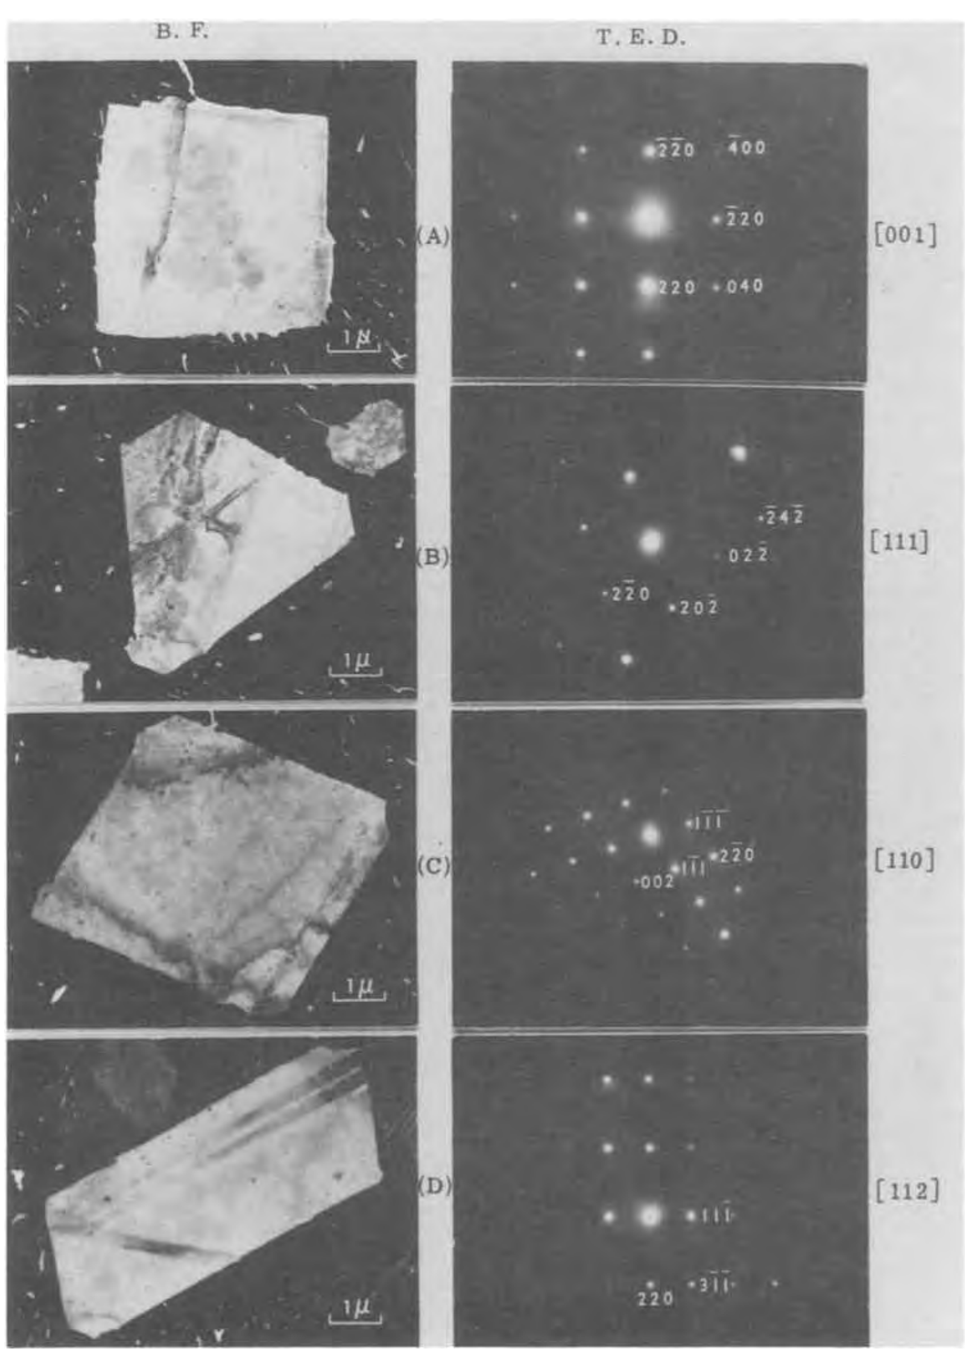

Fig. 5. Bright-field TEM and selected area TED from variously oriented single crystal Si-areas recrystallized from PtSi/Si eutectic: (a) [001] orientation, (b) [111] orientation, (c) [110] orientation, (d) [112] orientation.

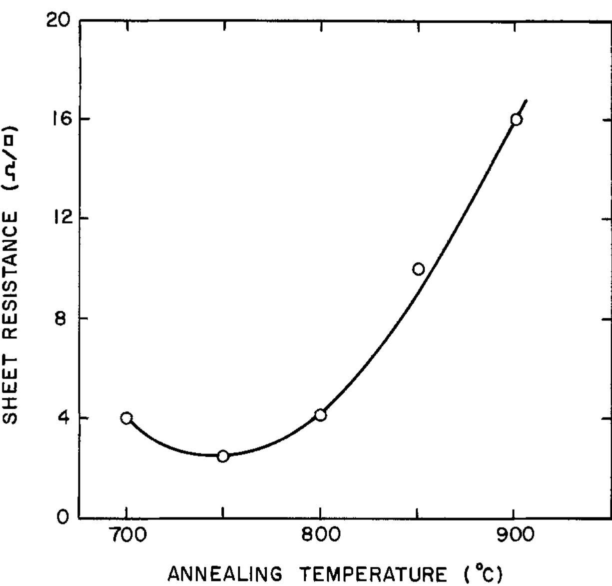

Fig. 6. Sheet resistance of PtSi (2000Å) on poly-Si vs. annealing temperature.

effects; this indicates a very effective wetting action between the liquid eutectic and the PtSi or poly-Si.

The resistivity behavior of PtSi on poly-Si is shown in Fig. 6. The resistivity of as-sintered PtSi on poly-Si is rather high at ~80 μohm-cm (sheet resistance 4 ohm/□) as compared to 17.5 μohm-cm for 900Å thick PtSi on single crystal Si. The sheet resistance decreased by a factor of 2 upon annealing at 750°C; however, with further increase in the annealing temperatures up to 900°C, there was a progressive increase in the sheet resistance to 16 ohm/□. The sheet resistance again dropped sharply to 4.5 ohm/□ for the sample annealed to 1000°C which contained recrystallized PtSi/Si. Since no agglomeration or even grain boundary voids were observed in the samples annealed at 900°C, the observed resistivity increase is somewhat unexpected. We tentatively ascribe this increase to the diffusion and accumulation of small amounts of Si at the grain boundaries of PtSi (10). Further detailed work on the microstructure as well as temperature dependence of resistivity will be desirable to better understand this effect. The sharp drop in sheet resistance following the 1000°C treatment is probably due to the fact that upon recrystallization from the melt, the PtSi grain boundaries are relatively "clean" and free of excessive silicon.

Conclusions

1. Single-phase PtSi films (020 orientation), ~2000Å thick with a sheet resistance of $\lesssim$ 4 ohm/□ and tensile stress of 1.6×10^{10} dyne-cm^{-2} were formed by sintering 1000Å Pt on 3000Å poly-Si.

2. These films can sustain thermal treatment up to 900°C which causes no agglomeration and leads to only moderate grain growth.

3. At 1000°C, a liquid eutectic phase is formed which wets PtSi and poly-Si and, on cooling, precipitates relatively large areas of single crystal Si.

4. The sheet resistance of the PtSi/poly-Si films decreases from ~4 to ~2 ohm/□ after the 750°C anneal; it then increases with increasing annealing temperature to ~16 ohm/□ after the 900°C anneal. Recrystallization upon cooling from 1000°C leads to a sharp decrease in the sheet resistance back to 4 ohm/□.

Acknowledgments

The authors would like to thank A. C. Adams and C. D. Capio for the CVD poly-Si and SiO_2-film depositions, T. E. Smith for the Pt-film deposition, G. Quintana for the heat-treatments, Mildred H. Read for x-ray diffraction work, J. Bindell for his cooperation, and W. R. Dawes, H. J. Levinstein, and R. S. Wagner for valuable discussions.

Properties of Sn-Doped In_2O_3 Films Prepared by RF Sputtering

John C. C. Fan and Frank J. Bachner

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

An rf sputtering process has been used without postdeposition annealing to prepare Sn-doped In_2O_3 films with low electrical resistivity (down to 2×10^{-4} ohm-cm), high visible transmission, and high infrared reflectivity (up to 93% at 10 μm) for applications as transparent conductors and heat mirrors. Substrate heating is accomplished entirely by the electron bombardment intrinsic to rf sputtering, rather than by using an auxiliary resistance heater. The film properties improve with increasing substrate temperature up to 650°C, the maximum employed, and are relatively independent of other sputtering parameters. The electrical and optical properties of the films do not depend significantly on the crystallographic orientation, degree of texturing, or substrate material (glass, fused silica, and single crystal Al_2O_3 and CaF_2).

Transparent heat-mirror films that transmit in the visible and reflect in the infrared are becoming important for radiation insulation and solar energy collection (1-3). Two types of materials have been used for these films: metals with very high infrared reflectivity (approaching 100%) and low enough visible absorption for thin films to be transparent [for example, Au (2) and Ag (4)], and semiconductors with a sufficiently wide bandgap to be transparent in the visible and a high enough free-carrier concentration to have high infrared reflectivity [for example, Sb-doped SnO_2 (1, 5, 6) and Sn-doped In_2O_3 (1, 5, 8)]. To obtain improved films of Sn-doped In_2O_3 for heat-mirror applications, we have studied films prepared by rf sputtering to determine the dependence of film properties on preparation conditions.

The techniques that have been used to prepare Sn-doped In_2O_3 films include chemical spray deposition (1), d-c sputtering (7, 8), and rf sputtering (5-7). In order to obtain satisfactory electrical and optical properties by any of these techniques, it has generally been necessary either to heat the substrate during deposition or to anneal the film after deposition. Either procedure requires fairly high temperatures, typically over 500°C. Our rf sputtering method employs substrate heating rather than post deposition annealing. The main feature of the method is that, by operating at sufficiently high forward power levels, heating is accomplished entirely by the electron bombardment intrinsic to rf sputtering, rather than by using an auxiliary resistance heater in the conventional manner. [Fraser and Cook (8) have produced good films by using the intrinsic heating associated with d-c sputtering, but they did not correlate film properties with substrate temperatures.]

Preparation

Films of Sn-doped In_2O_3 were deposited on a variety of substrates, including Corning CG 7059 glass, fused silica, and single crystals of Al_2O_3 and CaF_2, by sputtering in Ar gas from a 12.7 cm diameter, hot-pressed target of nominal composition In_2O_3-9 mole per cent (m/o) SnO_2. (Targets obtained from Materials Research Corporation, Orangeburg, New York, and from Haselden Company, San Jose, California, gave similar results.) The sputtering apparatus is a commercial rf diode unit with a liquid-N_2 cold-trapped, 15 cm diffusion pump, which is easily capable of achieving a base pressure of 7×10^{-7} Torr.

Figure 1 is a schematic diagram of the target and substrate configuration. The substrate was insulated from the water-cooled, stainless steel substrate platform by means of a Pyrex spacer about 1.6 mm thick. The substrate surface temperature, T_s, was measured with a Chromel-Alumel thermocouple that was mounted on the substrate surface with kaolin-sodium silicate paste, and the assembly was vacuum-baked at 150°C for several hours before being placed in the sputtering system. For CG 7059 glass substrates about 0.5 mm thick, the value of T_s increased reproducibly with increasing rf power, as shown in Fig. 2, reaching over 600°C for 650W, the maximum power used. For a given rf power level, T_s was about 100°C higher with the Pyrex spacer than without it.

Before being used for film deposition, a newly received target was usually sputtered at 200W for more than 10 hr to remove contaminants and to eliminate any differential sputtering effects. After this initial preparation, the target usually yielded reproducible films. The substrates were ultrasonically cleaned in a heated detergent solution, rinsed in ultrasonically agitated, flowing deionized water, and blown dry in N_2 gas. A typical set of sputtering conditions was as follows: target-to-substrate distance = 5.7 cm, Ar pressure = 10^{-2} Torr, Ar flow rate = 0.5 cm^3/min, presputtering at 500W for 15 min, deposition at 500W (deposition rate = 250 Å/min for 15 min).

We have also used other sputtering conditions, including different Ar pressures (5×10^{-3} to 1×10^{-2} Torr), different Ar flow rates (0.25-10 cm^3/min), and different presputtering powers (200-650W). The quality of the films was insensitive to variations in these parameters. Apparently the deposition rate was not critical either. At a sputtering power of 500W, the deposition rate increased to 500 Å/min when the Ar flow rate was changed from 0.5 to 10 cm^3/min, but the properties of the films were similar to those of films grown

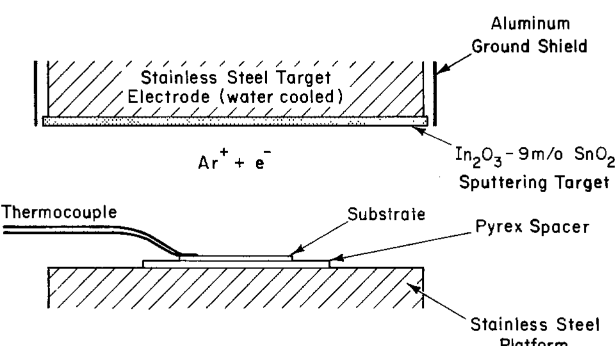

Fig. 1. Schematic diagram of target and substrate configuration in rf sputtering apparatus.

Key words: transparent conductors, solar-energy collection, heat mirrors, thin films.

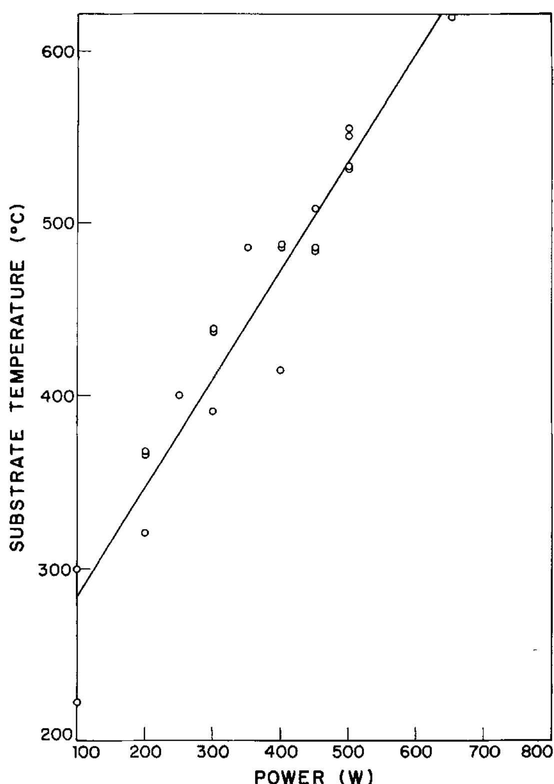

Fig. 2. Substrate temperature with a Pyrex spacer as a function of sputtering power.

at a flow rate of 0.5 cm^3/min. However, as we shall discuss below, film quality was sensitive to changes in the sputtering power. These changes caused changes in deposition rate (*e.g.*, from 150 Å/min at 100W to 300 Å/min at 650W, for the set of conditions listed above) as well as in substrate temperature (Fig. 2) In view of the apparent insensitivity of film properties to deposition rate, we attribute the effect of changes in sputtering power to the resulting changes in substrate temperature. This is confirmed by the fact that several films grown at a sputtering power of only 100W and a substrate temperature of about 500°C (obtained by using an auxiliary heater) are comparable to those grown at 500W with no auxiliary heating.

Characterization Techniques

The individual film-on-substrate samples were generally broken into several pieces so that the films could be characterized in several different ways. A photolithographic technique was used in measuring film thickness. A Cr layer 1000Å thick was sputter-deposited on the film, and stripes were opened in the Cr by applying photoresist, producing a stripe pattern by photolithography, and removing the unprotected Cr by using an etchant consisting of 1000 cm^3 water, 50 cm^3 perchloric acid, and 100 g ceric ammonium nitrate. The sample was then immersed in concentrated H_2SO_4 at 50°-60°C to remove the In_2O_3 film (etching rate ~0.5 μm/hr) wherever it was not masked by Cr. Finally the Cr masking stripes were etched away to expose the In_2O_3 film stripes underneath, and the height of these stripes was measured by microtopography. Most films were from 0.3 to 5 μm thick.

The electrical resistance of the samples was determined by four-point probe measurements, and in many instances confirmed by the van der Pauw technique, which was also used for Hall coefficient measurements. Optical transmission and reflectivity measurements were made from 0.35 to 2.5 μm wavelength with a laboratory-built, normal-incidence spectrophotometer (9) and from 2.5 to 10 μm with a commercial spectrophotometer in which the angle of incidence for reflectivity measurements is about 20°. The crystal structure of the films was examined by x-ray diffractometry. Auger electron spectroscopy was performed on several films, and the compositions of some films were determined by electron microprobe analysis of In and Sn.

Results

Unless stated otherwise, the results described here were obtained for films on CG 7059 glass, and similar results were obtained from measurements made on films deposited on other substrates.

Electrical properties.—Figure 3 shows the resistivity, ρ, measured at room temperature by the van der Pauw method, as a function of sputtering power and substrate temperature. (The substrate temperatures were obtained from the measured power values by using the straight line shown in Fig. 2, which is a least squares fit to the data.) The resistivity measurements were made on films more than 0.20 μm thick, for which resistivity was essentially independent of thickness. The resistivity decreases from about 8×10^{-4} ohm-cm for a substrate temperature of 300°C to about 2×10^{-4} ohm-cm for 650°C. The curve indicates that even lower resistivities could be obtained for higher temperatures, but our sputtering apparatus does not operate effectively at higher power levels. Moreover, the glass substrates would soften above 650°C.

The van der Pauw method was also used to measure the room temperature Hall coefficient (R_H) of the samples. The conductivity is n-type. As shown in Fig. 4 and 5, both the carrier concentration (from the single-carrier expression $N = -1/R_He$) and Hall mobility ($\mu_H = R_H/\rho$) increase with increasing substrate temperature, although the rate of increase becomes smaller above 400°-500°C. For 650°C, $N \approx 7 \times 10^{20}$ cm^{-3} and $\mu_H \approx 40$ cm^2/V-sec.

Optical properties.—Figure 6 shows the transmission and reflectivity measured over the wavelength range from 0.35 to 2.5 μm for a typical film, 0.36 μm thick, that was deposited at a sputtering power of 500W (substrate temperature of about 550°C). In the visible region of the spectrum the transmission is very high

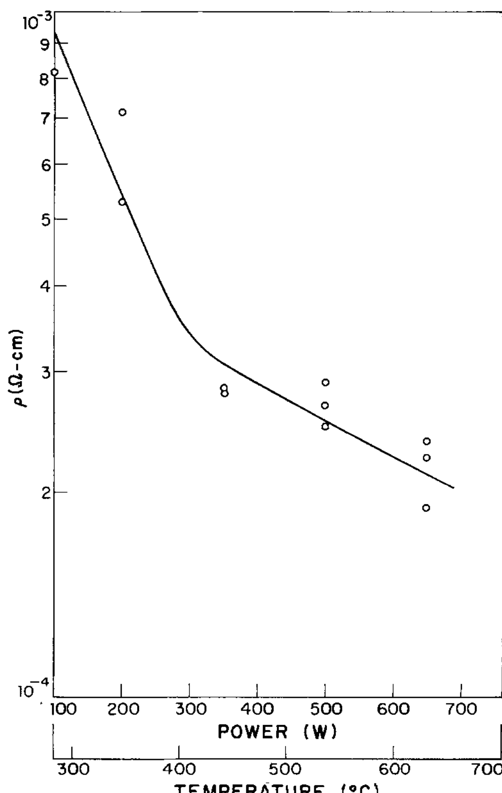

Fig. 3. Resistivity ρ as a function of sputtering power and substrate temperature.

(high enough for interference fringes to be observed) because the reflectivity is low and there is no absorption due to valence-to-conduction-band transitions. At about 1.5 μm the reflectivity increases abruptly (caus-

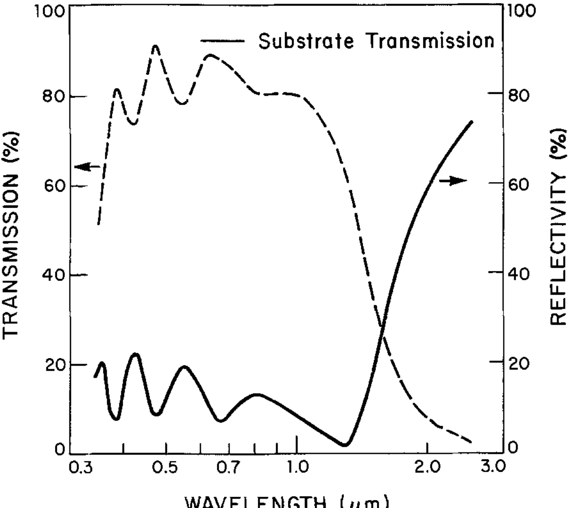

Fig. 6. Transmission and reflectivity as a function of wavelength for a film deposited on CG 7059 glass at sputtering power of 500W. The transmission of the bare substrate is indicated.

ing a corresponding reduction in transmission) because of the plasma effect resulting from the high concentration of mobile carriers. As shown in Fig. 7, as the wavelength increases to 10 μm the reflectivity of this film increases to more than 90%, while the transmission becomes negligible at about 3 μm.

Before the theoretical treatment of these results is presented, it should be noted that the reflectivity of the Sn-doped In_2O_3 films in the infrared increases significantly with increasing sputtering power (*i.e.*, substrate temperature), as shown by the experimental curves for reflectivities at 5 and 10 μm plotted in Fig 8. In addition, the absorption of the films in the visible appears to decrease with increasing sputtering power, although this is less clear because analysis of the data is complicated by the interference fringes and also by the effect of the substrate in this spectral region.

To a good approximation the reflectivity and transmission curves plotted in Fig. 7 can be fitted by using a simple free-carrier model for the photon-energy dependence of the complex dielectric constant, $\epsilon(E)$, which determines the refractive index and extinction coefficient of the film (10). According to this model, in the spectral region of interst $\epsilon(E)$ is the sum of two terms: a constant, ϵ',[1] and an energy-dependent free-carrier term that depends on the carrier concentration (N), effective mass (m^*), and optical mobility (μ_{opt}) (12). The expression for $\epsilon(E)$ is

$$\epsilon(E) = \epsilon' - \frac{E_n^2}{E^2 + iE_cE} \qquad [1]$$

where E_n and E_c are energy parameters given by

$$E_n = \hbar \left(\frac{4\pi Ne^2}{m^*} \right) \qquad [2]$$

and

$$E_c = \frac{\hbar e}{m^* \mu_{opt}} \qquad [3]$$

In using this model to fit the curves of Fig. 7, a multilayer matrix formulation (10) was employed to take account of the fact that the observed reflectivity and transmission values are those of a film-on-glass composite, and a nonlinear minimization routine (13) was

[1] In some recent literature, *e.g.*, Verleur (11), the symbol ϵ_∞ has been used not only in the conventional manner, to represent the high-frequency (optical) dielectric constant, but also to represent an adjustable parameter that is the sum of all contributions to the complex dielectric constant other than those that vary within the spectral region of interest. For clarity, we have adopted ϵ' rather than ϵ_∞ as the symbol for the adjustable parameter.

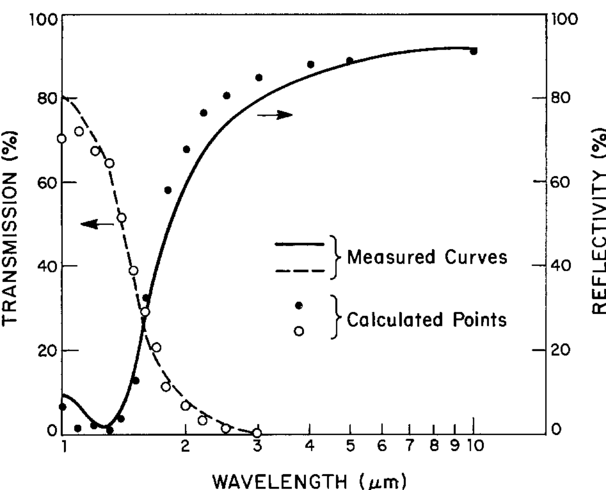

Fig. 7. Measured transmission and reflectivity curves with calculated points. (See text.)

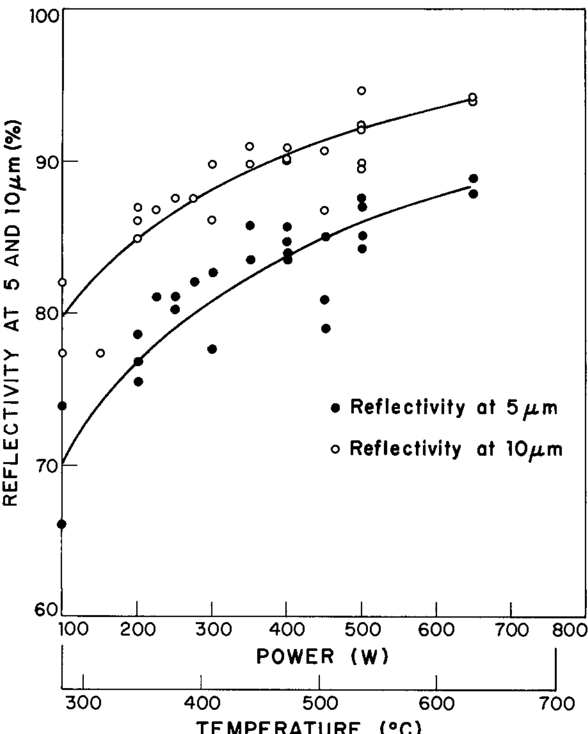

Fig. 8. Reflectivity at 5 and 10 μm as a function of sputtering power and substrate temperature.

utilized to determine the values of the adjustable parameters ϵ', E_n, and E_c that would yield the best fit to the experimental data. The best fit that we achieved by using this procedure is represented by the calculated points that are plotted in Fig. 7. The agreement is quite good, except that in the 2-4 μm region the calculated reflectivity increases somewhat more steeply than the observed.

The values of the adjustable parameters used to obtain the calculated points of Fig. 7 were $\epsilon' = 4.45$, $E_n = 1.64$ eV, and $E_c = 0.075$ eV. Taking the square root of ϵ' gives $n = 2.1$ as the refractive index for wavelengths between the interband absorption edge (~0.35 μm) and the onset of free-carrier contribution, in good agreement with the value of 2.2 found by analysis of the transmission interference fringes shown in Fig. 6. From the value adopted for E_n, together with the concentration $N = 7 \times 10^{20}$ cm^{-3} determined by measuring the Hall coefficient, Eq. [2] gives $m^* = 0.2\ m_o$, where m_o is the free-electron mass. This effective mass is fairly close to the values of 0.3 and 0.55 m_o, respectively, obtained from transport data for films (14) and single crystal samples (15) of undoped In_2O_3. For the effective mass of 0.2 m_o and the value adopted for E_c, Eq. [3] gives an optical mobility of 75 cm²/V-sec, which agrees to within a factor of two with the Hall mobility of 40 cm²/V-sec measured for the same film.

The values for ϵ', E_n, and E_c can be used to calculate the dependence of infrared reflectivity on film thickness. The results obtained for wavelengths of 5 and 10μ are shown in Fig. 9. The reflectivity initially increases with increasing thickness, but becomes essentially constant when the thickness reaches about 0.3 μm. Since the visible transmission and the electrical resistance also depend on thickness for specific applications it is necessary to select the optimum thickness for best performance.

Vossen and Poliniak (6) have reported that Sn-doped In_2O_3 films less than 0.1 μm thick are unstable, but we have prepared films as thin as 0.06 μm (resistance of 150 ohm/sq) that have not shown significant changes in optical and electrical measurements made over a period of several weeks in a laboratory ambient. Figure 10 shows the transmission of a film about 0.12 μm thick (resistance about 55 ohm/sq) that was deposited at a power of 500W.

X-ray diffraction results.—X-ray diffraction measurements were made on films deposited at power levels from 100 to 650W. All the diffraction patterns contain only In_2O_3 peaks, except for one that also contains weak Sn_3O_4 peaks. The film with the two-phase pattern has very poor electrical and optical properties ($\rho \sim 0.5$ ohm-cm, reflectivity ~20% at 10 μm). Because of the presence of the second phase, the properties of this film are not plotted in any of the figures.

The diffraction results are summarized in Table I. The <400> peak is the strongest one observed for the films deposited on glass at 100W (substrate temperature below 300°C). For all films deposited on glass at higher powers (except one at 400W), the <222> peak is the most prominent, as it is in the ASTM powder

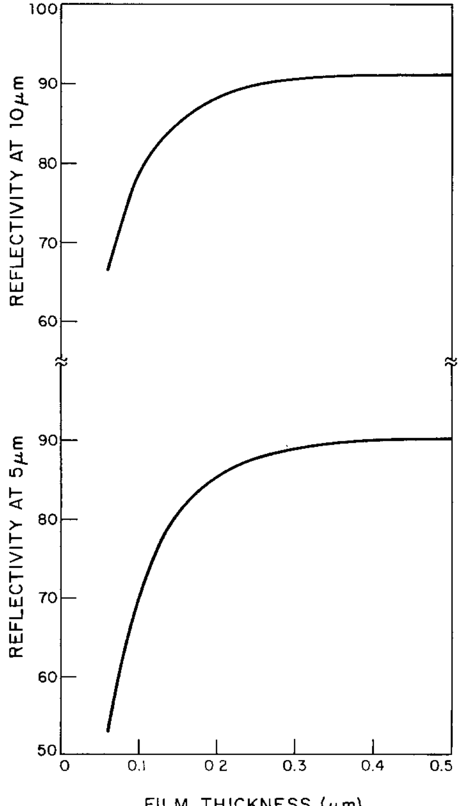

Fig. 9. Infrared reflectivity at 5 and 10 μm calculated as a function of film thickness.

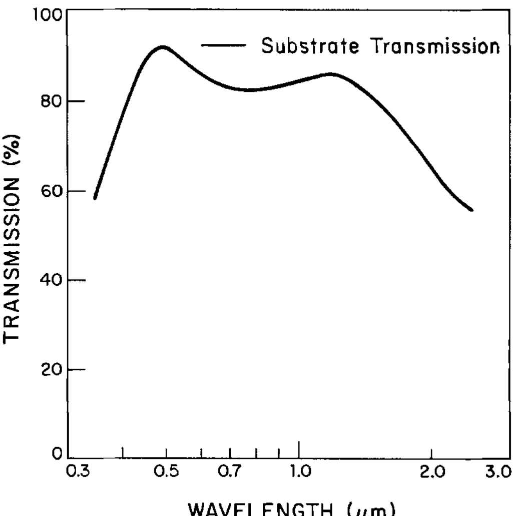

Fig. 10. Optical transmission as a function of wavelength for a film 0.12 μm thick.

pattern for In_2O_3. In fact, for some of the films deposited on glass at 500 or 650W, all peaks other than the <222> are either weak or absent, indicating that these films have a strong <111> texture. For films deposited at 650W on other substrates, only the <222> peak is observed for the film on (111)-face CaF_2, while the strongest peaks for the films on fused silica and (0001)-face Al_2O_3 are the <400> and <332>, respectively. According to our measurements, the electrical and optical properties of the films are not significantly affected by either their principal orientation, their degree of texturing, or their substrate material.

The values of the cubic lattice constant measured for the films range from 10.17 to 10.27Å, compared with the ASTM value of 10.118Å for bulk In_2O_3. There appears to be no systematic dependence of lattice constant on substrate temperature. Since two films of undoped In_2O_3 deposited on CG 7059 glass at 500W have lattice constants of 10.11Å, close to that of the bulk material, the observed lattice expansion is due to the incorporation of Sn. This suggests that the n-type conductivity of the films is not due to the replacement of In^{3+} ions by Sn^{4+} ions, which are smaller and would be expected to cause a contraction. The observed expansion is consistent with the replacement of In^{+3} ions by the larger Sn^{2+} ions and also with the incorporation of Sn

Table I. X-ray diffraction results for Sn-doped In_2O_3 films

* Small Sn_3O_4 peaks also observed.

ions in interstitial positions. In the latter case, the observed n-type conductivity could result from the excess electrons supplied by the interstitial Sn, without a change in the O/In ratio. (Of the eight available sites around each In^{3+} ion in the cubic In_2O_3 structure, only six are occupied by O^{2-} ions, leaving two positions available for incorporation of interstitial Sn.) Substitution of Sn^{2+} for In^{3+} ions, on the other hand, would decrease the electron concentration so that a stoichiometric deficiency of O would be necessary to explain the n-type conductivity. In this case, the film composition would be represented by the formula $(In_{1-x}Sn_x)_2O_{3-y}$, and the carrier concentration would be proportional to $(y - x)$, since O vacancies should act as donor centers. An accurate chemical analysis of the films could probably help to determine which of the three alternative modes of Sn incorporation actually occurs.

X-ray diffractometer measurements were also made on powdered samples taken from a sputtering target before and after sputtering. As-received targets are yellowish-white in color, but after some hours of sputtering the surface becomes grayish and is speckled with many, small dark areas. The diffraction results show that an as-received target is a two-phase mixture of In_2O_3 and SnO_2, but the diffraction patterns for samples scraped from a sputtered surface contain only In_2O_3 peaks. The decrease in SnO_2 content below the limit of a few weight per cent detectable by diffractometer measurements may be due in part to preferential removal of SnO_2 from the surface by differential sputtering. Electron microprobe analysis of the powder removed after sputtering shows that the darkest regions contain Sn rather than In. This indicates that the darkening of the surface results from the chemical reduction of the SnO_2 phase by loss of O during sputtering, a process that could also contribute to the disappearance of the SnO_2 diffraction peaks.

Electron microprobe and Auger spectrometer studies.—Electron microprobe analysis was used to determine the composition of films deposited at power levels from 100 to 500W. For each film, the weight percentages of In and Sn were measured directly, the weight percentage of O was found by difference (assuming that the concentration of all other elements was negligible), and the atomic percentages were then calculated. The results are given in Table II. With increasing sputtering power the weight percentage of Sn decreased from 4.2 weight per cent (w/o) at 100W to 2.1 ± 0.1 at 450 and 500W, while that of In, 81 ± 1 w/o, was constant within the experimental uncertainty of the microprobe (estimated as ±3% of the measured values). The atomic percentage of Sn and In derived from these results both decreased with increasing sputtering power, while the percentage found for O increased from 54 to 61 atomic per cent (a/o).

The atomic compositions listed in Table II clearly do not have a straight-forward relationship to the carrier concentrations measured for the films as a function of sputtering power. Since O vacancies are expected to act as donor centers, the increase of 7 a/o in the atomic percentage of O found with increasing power should cause a large decrease in carrier concentration,

Table II. Composition of Sn-doped In_2O_3 films prepared by rf sputtering

Sputtering powder (W)	Estimated substrate temperature, T_s (°C)	Weight per cent Sn	In	O*	Atomic per cent Sn	In	O
100	280	4.2	81.6	14.2	2.2	43.6	54.2
200	350	3.3	80.1	16.6	1.6	39.5	58.9

500	550	2.2	79.9	17.9	1.0	37.9	61.1

* Obtained by difference.

but the opposite is observed (Fig. 4). Furthermore, since the O content found for the film deposited at 500W is 1 a/o higher than the stoichiometric composition of 60 a/o, such a film should be either p-type (if the 1 a/o Sn is incorporated as Sn^{2+} ions) or closely compensated (if the Sn is interstitial or incorporated as Sn^{4+} ions). whereas films deposited at 500W are actually n-type with carrier concentrations of about 7×10^{20} cm^{-3}. To a considerable extent these inconsistencies are probably due to the uncertainty in the atomic percentages found for O. For the film deposited at 500W, for example, an increase in the weight percentage measured for In from 79.9 to only 81.0 w/o would cause a reduction in the O content from 61.1 to 59.2 a/o. We conclude that the microprobe measurements are not sufficiently accurate to elucidate the source of current carriers in Sn-doped In_2O_3 films, even though they do give a good measurement of the Sn content. Thus we are unable to determine the significance of the fact that the Sn content decreases with increasing substrate temperature, while the carrier concentration increases.

Auger spectrometer measurements were performed on several films deposited on glass at either 100 or 450W. In these studies, a profile of each film was obtained by recording the Auger spectrum, removing a thin layer from the surface of the film by sputter-etching with 500 eV Ar ions, repeating the Auger measurement, removing another surface layer, and so forth. The heights of characteristic Auger peaks for In, Sn, and O were then read off the spectra and ratios between them calculated. Since the escape depth for Auger electrons is generally less than 20Å, each spectrum reflects the composition of a layer of this depth.

The Auger peak-height ratios obtained for a film deposited at 450W are plotted as a function of the total sputter-etching time in Fig. 11, where they are compared with data obtained in the same manner for a disk prepared by cold-pressing undoped In_2O_3 powder. Similar results were obtained for films deposited at 100W. Since the strongest Auger peak for Sn could not be resolved from the In peak at 424 eV, the variation of the Sn/In ratio is indicated by plotting the ratio of the height of the combined peak at 424 eV to the height of the In peak at 403 eV.

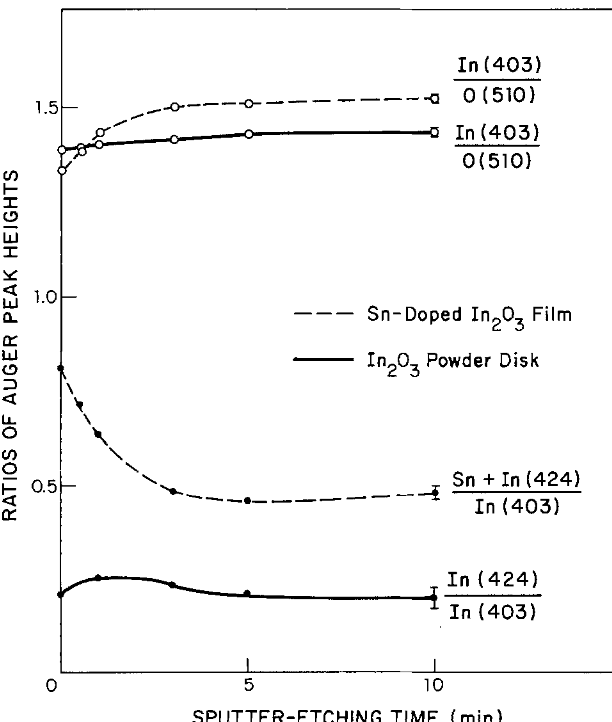

Fig. 11. Auger profiles obtained by sputter-etching a Sn-doped In_2O_3 film and a cold-pressed In_2O_3 disk. The numbers in parentheses are the energies of the Auger peaks in eV.

As shown in Fig. 11, with increasing sputter-etching time the Auger signals for Sn and O in the film, relative to those for In, initially decreased and then became constant. Comparison of the data for the film and the In_2O_3 disk indicates that the Sn/In ratio in the surface layer of the film changed by a factor of about 2, while the O/In ratio decreased by only about 10%, if it is assumed that the composition ratios are proportional to the peak-height ratios. We attribute the observed changes to differential sputtering that occurred during Ar-ion bombardment, as it did during bombardment of the sputtering targets, rather than to compositional inhomogeneities in the as-deposited films.

Conclusions

A one-step rf sputtering process has been used without postdeposition annealing to prepare Sn-doped In_2O_3 films with excellent properties for applications as transparent conductors and as transparent heat mirrors for radiation insulation and solar energy collection. The substrate temperature is the critical preparation parameter: The electrical conductivity, visible transmission, and infrared reflectivity all increase with increasing substrate temperature, as a result of the increases in carrier concentration and mobility. The electrical and optical properties of the films do not depend significantly on the crystallographic orientation, degree of texturing, or substrate material.

There is no reason to believe that the films described here have the best properties that can be achieved when Sn-doped In_2O_3 is deposited by rf sputtering. If films with still higher carrier concentration and/or mobility can be prepared, their properties could be even better. The present results suggest that deposition at higher substrate temperature is one possible means for obtaining improved films. In addition, the Sn/In and O/In ratios in the sputtering target should be changed in order to determine the effects of such changes on the composition and therefore the properties of the films.

Elimination of Oxidation-Induced Stacking Faults by Preoxidation Gettering of Silicon Wafers

I. Phosphorus Diffusion-Induced Misfit Dislocations

ABSTRACT

In the present paper a preoxidation gettering procedure (called POGO) is described which prevents the formation and/or activation of stacking fault nucleation sites during oxidation. In this way the stacking faults and their possible device degrading influences are eliminated at the start of a processing schedule. In addition, the gettering medium is retained through all subsequent high temperature processing, thereby continuing to suppress the formation of stacking faults. The gettering of the nucleation sites, whether they be process induced, such as impurity precipitation, or native to the original crystal growth, such as vacancies or impurities, is achieved by the controlled introduction of interfacial misfit dislocations on the back side of the wafer. The dislocations interact with the stacking fault nucleation sites such that the nuclei diffuse from the active device side of the wafer to the line defects which are confined to within a few microns of the back surface.

The presence of stacking faults introduced during the processing of silicon devices is known to have a deleterious effect on device performance. For example, localized microplasma breakdown (1), increased p/n junction leakage (2), and reduced storage time of CCD devices (3) have all been correlated with stacking fault defects. The stacking faults are most frequently generated during steam oxidation (4, 5). The nucleation sites for these defects have been shown to be related to residual mechanical damage (6), local impurity precipitation (7), and the so-called "swirl" defects (8). The latter two may be either process induced or native to the original crystal growth. Although adequate removal of surface damage is easily achieved with proper etching before polishing, it has not been a simple matter to remove process-induced precipitation or native defects from device wafers. However, progress has been made in reducing the electrical activity of stacking faults once they are formed (2), particularly if the electrical activity is related to precipitation on the stacking fault (9).

In the present paper we describe a process whereby stacking fault nuclei are gettered from the active device side of the wafer by the deliberate introduction of an array of misfit dislocations on the back side of the wafer. The driving force for the generation of the dislocations is the misfit strain gradient introduced into the silicon lattice during an extended phosphorus diffusion (10, 11). The depth and density of the dislocation array can be adjusted by varying the diffusion time and temperature (12). Since the dislocations are interfacial in character they lie parallel to the wafer surface and are confined to within a few microns of the back surface. It is well known that line defects will act as sinks for a variety of point defects such as impurities and vacancies. This gettering action of one type of defect, an interfacial misfit dislocation, for point defects or impurities which act as stacking fault nucleation sites, is the basis for our approach to the elimination of oxidation-induced stacking faults.

* Electrochemical Society Active Member.

Key words: stacking faults, gettering, defects.

The above process has been given the acronym POGO for preoxidation gettering of the other side in order to distinguish it from the commonly used phosphorus gettering (13), back side abrasion (14), and ion implantation damage gettering techniques (15). It is important to point out that there are two essential differences in the POGO procedure. First, the gettering misfit dislocations are generated in the as-received wafers before any device processing is initiated and are intended initially as sinks for native defects which were incorporated during crystal growth or inadvertently introduced during wafer preparation and cleaning. Second, the misfit dislocations are expected to continue to act as sinks for impurities introduced during subsequent high temperature processing. The total effect of these gettering actions is expected to be the gross reduction or elimination of defects near active device regions with a resulting improvement in device properties (MOS storage time, junction leakage, and breakdown).

Experimental Procedures

The gettering results to be described below were obtained on n-type {100} oriented dislocation-free wafers with a nominal resistivity of 5 ohm-cm. The wafers, which were purchased from the Monsanto and Wacker Corporations, were received with a Syton polished front side and chemically etched back side. The Monsanto wafers were from Czochralski ingots while the Wacker were float zone.

Because of wafer-to-wafer variations within a given batch it was necessary to process each wafer such that only half of the back side was gettered before the entire wafer was oxidized. In this way a control was built into each sample. This was accomplished as follows. A thick (1.2-1.5 μm) masking oxide layer was deposited at 480°C on the front and then the back side of each wafer. A low temperature silane process was chosen to insure that no stacking faults were generated. Conventional photolithography was used to strip the oxide from half of the back side while a uniform oxide coating was retained on the front. Phos-

phorus was then diffused into the unmasked half of the wafer at temperatures from 1070° to 1150°C for times of 1-7 hr. Within this temperature range a dense array of misfit dislocations is introduced to a depth of 2μ or more below the P-diffused surface. A $POCl_3$ process with an oxygen flow rate of 110 cm^3/min was used. After stripping of the phosphorus and masking oxides those wafers which were to be evaluated for stacking faults were then oxidized in steam at 1050°C for 110 min to grow about 7500Å of SiO_2.

The various etch pits were delineated in an HF-$K_2Cr_2O_7$ preferential etch as described by Secco D'Aragona (16), hereafter referred to as the Secco etch. During etching the wafers were mechanically rotated for 10 min in an ultrasonically agitated bath to remove about 15 μm from each side of the wafer. Observation of the pits was performed in a Zeiss Ultraphot microscope using Nomarski interference contrast optics.

Three types of each pits are distinguished in oxidized {100} wafers as illustrated in Fig. 1. Emerging dislocations give rise to deep, black pits (D-pits) with a pointed bottom, see arrows D in Fig. 1. Unless a wafer has deliberately had misfit dislocations introduced D-pits are only found near the perimeter of a wafer and are of the slip type, generally attributed to thermal asymmetries during high temperature processing. Saucer pits, see arrows S, are shallow and flat bottomed and are generally associated with stacking fault nucleation sites if they are distributed in a swirl pattern (4, 5, 8). Stacking faults, see arrows SF in Fig. 1, are always aligned along perpendicular <110> directions, horizontal or vertical in all our photomicrographs, and when fully developed often appear like orthogonal arrays of beads.

Experimental Results

Oxidized POGO wafers.—A photomicrograph of the boundary between the phosphorus gettered (PG) plus misfit dislocation (MD) half and the nongettered (NG) half of the back side of a wafer after oxidation and Secco etching is shown in Fig. 2a. The front side of the same wafer, which is shown in Fig. 2b, is discussed below. Enlarged views of the regions surrounding the slip dislocations D_3 and D_1 are shown in Fig. 3a and b.

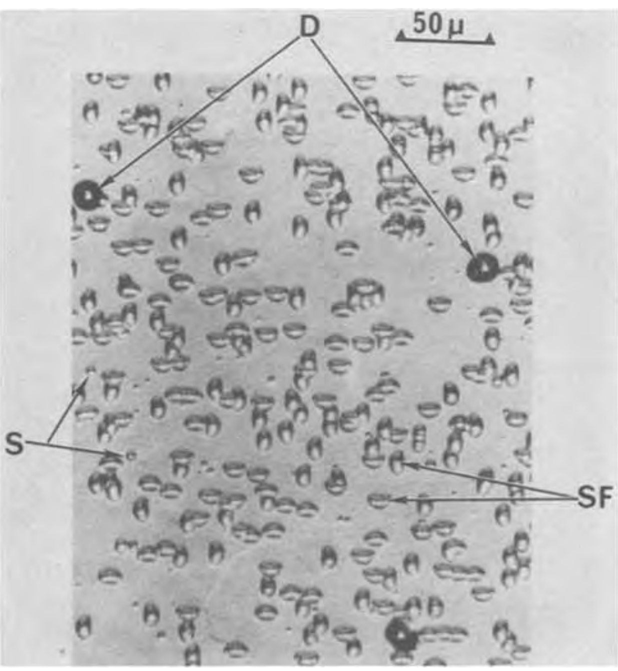

Fig. 1. Optical photomicrograph of etched {100} surface illustrating morphology of dislocations, D, saucer pits, S, and stacking faults, SF.

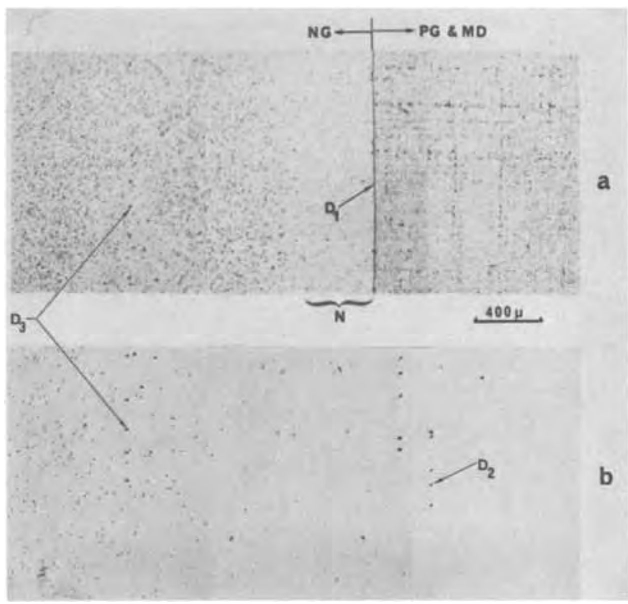

Fig. 2. Back (a) and front (b) etched surfaces of an oxidized Czochralski wafer half of whose back surface was phosphorus gettered (PG) to produce misfit dislocations (MD) while the other half and the front were not gettered (NG). The region N was denuded of stacking faults.

Since the lattice contraction in the PG half of the sample, which was treated for 1 hr at 1150°C, exceeded the threshold strain for generation of misfit dislocations the trace of a cross grid of misfit dislocation is evident to the right of D_1, which is right on the PG/NG boundary line. Only a trace of the misfit dislocation array remains since the removal of 15 μm of silicon during the Secco etch has also removed most of the interfacial MD network from the sample. It has been found that no stacking fault etch pits (SF) exist on that half of the wafer which was gettered, see Fig. 3b; whereas, several millimeters to the left of the PG/NG boundary the SF pit density is $\sim 10^5$ cm^{-2}, see Fig. 3a. We conclude that the phosphorus diffusion plus misfit dislocation process provides a very effective gettering action for those nucleation sites which promote the formation of stacking faults during oxidation.

The range of misfit dislocation gettering action is believed to be at least as large as the region N in Fig. 2a, which is denuded of all SF pits for a distance of $\gtrsim 400$ μm from the PG/NG boundary. Since the wafer thicknesses were ~300 μm for Monsanto and ~450 μm for Wacker material SF gettering effects were also expected on the front side of the phosphorus-treated wafers. This was checked as follows. The same D-pits were located on the front of the wafer under discussion, see arrow D_3 in Fig. 2b, in order to accurately align the PG/NG boundary. Note Fig. 2a and 2b are mirror imaged about a horizontal axis with D_3 the third D-pit in a row of five. It was necessary to use the slip type D-pits for alignment because the misfit dislocations are truly interfacial in character and are confined to the back side of the wafer. Higher magnification photos of front surface regions around the dislocations D_3 and D_2 are presented in Fig. 3c and d. The density of SF pits in the vicinity of D_2 is zero and is representative of the entire volume of the wafer below the misfit dislocation array. This volume has been further checked using transmission x-ray topography to confirm that stacking faults are only present in the NG half of the wafer. The higher density of SF in the back of the wafer, compare Fig. 3a with Fig. 3c, appeared to be related to a local difference in contamination of the back of the wafer.

In addition to the pits, there are also etch hillocks observed, see arrows H_1 and H_2 in Fig. 3c and d, which

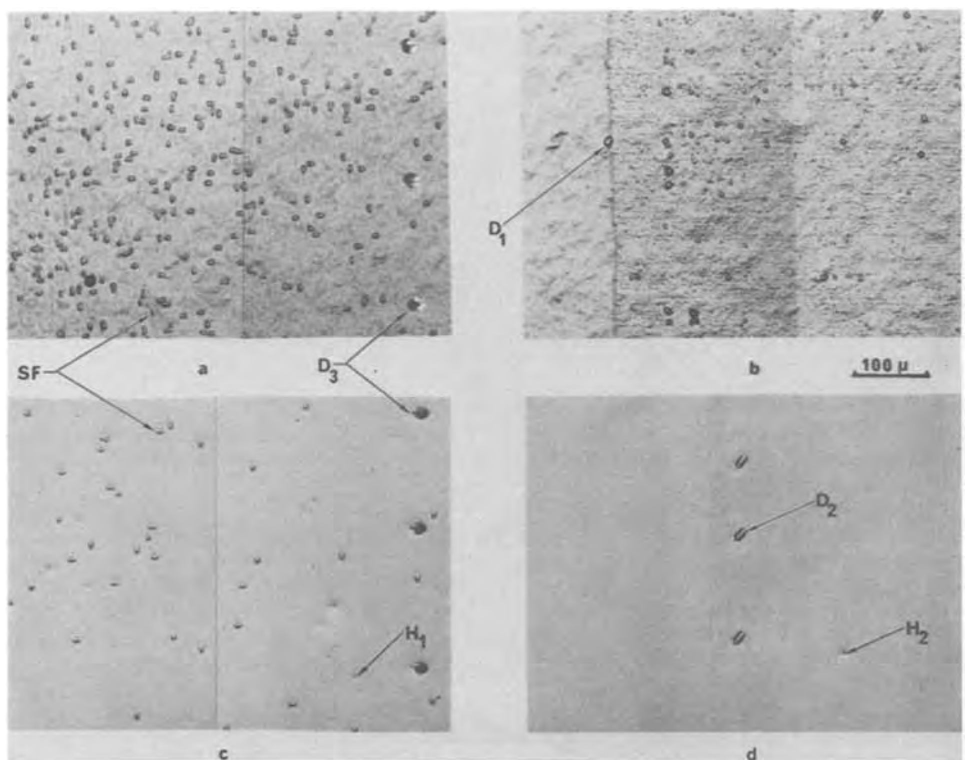

Fig. 3. Higher magnification micrograph of those regions of Fig. 2 surrounding the slip dislocations D_1, D_2, and D_3. H are unidentified hillock defects while the arrows SF point to two separate stacking faults.

may also be associated with a microdefect, perhaps a small dislocation loop, for example. Further etching transforms the hillocks into shallow pits which are similar, but not identical to the S-pits. The hillocks are not observed using x-ray topography, however, transmission electron microscopy studies are under way to help identify the source of the hillocks. Although there is a large reduction in the hillock density across the PG/NG boundary it is nowhere near the 10^4-10^5 cm^{-2} difference observed with the SF pits. However, samples which have been POGO treated for 4 and 7 hr do show a further reduction in hillock density indicating that the gettering action, although slower, is also effective for the hillock defects. Results on a 4 hr POGO sample before oxidation are presented in the next section.

Nonoxidized POGO wafers.—Stacking faults were not generated during the POGO treatment unless there was residual surface damage or localized chemical contamination. Prior to oxidation the gettering action was evident for both S-pits and hillocks. This is illustrated in Fig. 4a, which is the Secco etched PG/NG boundary of the polished side of a Wacker float zone wafer which was phosphorus gettered on half of the back side for 4 hr at 1150°, as described above. The S-pit and hillock densities are both about 10^5 cm^{-2} in the NG region, see the arrows S and H in Fig. 4b, which is an enlarged view of the area marked (b) in Fig. 4a. On the front surface of the wafer directly opposite the POGO treated back side, see Fig. 4c, no hillocks were observed at all and the S-pit density was reduced to $\sim 5 \times 10^3$ cm^{-2}. The ability to eliminate the hillocks completely varied from sample to sample but was always more effective for gettering times longer than 1 hr.

Float zone vs. Czochralski.—Because of the well-documented differences in the oxygen content of float zone and Czochralski material and the possibility that oxygen plays a role in the formation of SF nuclei, a group of five float zone and five Czochralski wafers were gettered simultaneously. However, it was found that the variations in pit density, and other factors such as the occurrence of a swirl pattern, varied just as much within the separate groups of five as they did from group to group. The only consistent observation in the large batch studies was that on the gettered half of any wafer stacking faults, S-pits, and hillocks were either eliminated or reduced in number by several orders of magnitude. It therefore appears that the oxygen concentration is not the predominant factor in the gettering of nucleation sites. This does not mean, however, that oxygen is not important when the stacking faults are actually generated.

Discussion and Conclusions

The experiments and etch pit data presented above demonstrate the existence of a very favorable inter-

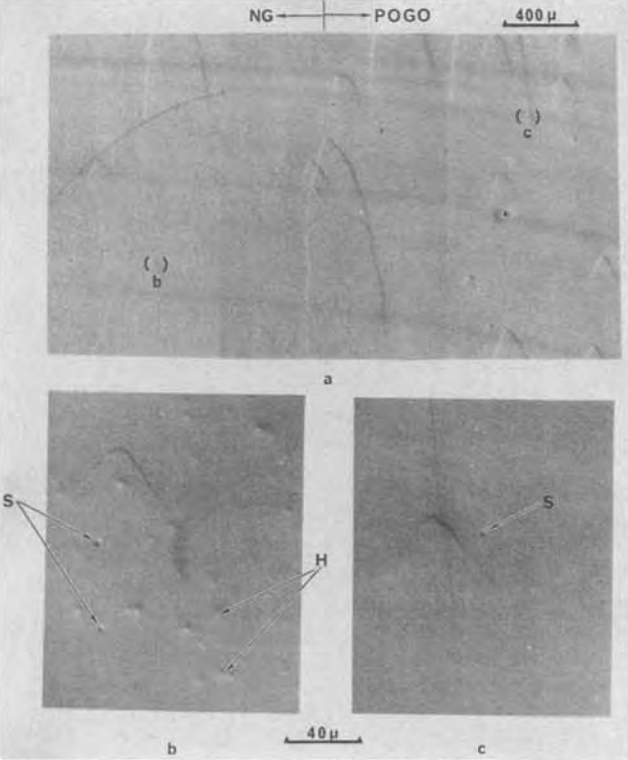

Fig. 4. Etched front surface of an unoxidized float zone wafer preoxidation gettered on half of the other side (POGO). Arrows S and H are saucer pits and hillocks.

action between a phosphorus gettering plus misfit dislocation procedure and the nuclei responsible for oxidation-induced stacking faults. The presence of misfit dislocation was indeed found necessary to achieve the stacking fault elimination. Those samples subjected to a phosphorus diffusion treatment which did not introduce misfit dislocations ($T < 1050°C$) did form stacking faults during oxidation. The role of misfit dislocations is consistent with the extensive literature on line defects acting as sinks for mobile point defects, such as impurities and vacancies. Unfortunately, the precise nature of those point defects (or clusters and complexes thereof) which create an environment for stacking fault formation is not fully understood at this stage of our work. We have, however, schematically outlined the problem as shown in Fig. 5, which is based, in part, on recent work of Pomerantz (17) and de Kock (8, 18, 19).

These workers have demonstrated that interactions which exist between grown-in and process-induced microdefects, whose macroscopic distribution is in the form of a swirl pattern, can be traced back to variations in the microscopic growth rate of the original crystal. Figure 5 identifies two groups of grown-in defects according to whether or not a swirl pattern can be delineated by etching or x-ray topography of Cu or Li decorated samples. Following de Kock we attribute the swirl of S-pits in as-received wafers, stage I in Fig. 5, to a point defect/impurity (PD/i) complex (8), or to collapsed vacancy (8, 20, 23), or interstitial (22) clusters in the form of dislocation loops. If no swirl is delineated we still assume that isolated point defects are distributed in the crystal in a nonhomogeneous fashion. This is based on the observation that swirl defects can be formed by a suitable heat-treatment (24), see process IIB in Fig. 5, of swirl-free wafers. Also, a swirl distribution of stacking faults is observed after steam oxidation, process IIA, in Fig. 5, even if no stage I swirl is delineated by etching (21).

It is well established (8, 17) that metallic impurities introduced during stage II processing can become associated with stage I defects to form stacking faults during oxidation or epitaxial growth. This type of process-induced defect is most certainly gettered by the POGO misfit dislocation and/or phosphorus diffusion treatment itself. Process IIC in Fig. 5 illustrates how swirl and stacking faults can be suppressed in as-received material and, we would expect, in any material which has not previously nucleated stacking faults during processing, *e.g.*, process IIB. However, since stacking faults can be formed under very clean oxidizing conditions the question arises as to whether our gettering procedure is also effective in eliminating stage I defects, *e.g.*, vacancies, copper, or small dislocation loops. The complete suppression of stacking faults in the various material supplied to us indicates that native defect gettering may, in fact, be taking place. In addition, the elimination of the etch hillocks and large reduction in S-pit density discussed above with reference to Fig. 4 is interpreted as a dissolution of stacking fault nuclei. These etch features, although not distributed in a swirl pattern, are very similar in appearance to the A- and B-type native swirl defects recently characterized by Petroff and de Kock (22). Also, preliminary results on POGO treated wafers from the same ingot used by Petroff and de Kock (22) indicates that stacking faults are not formed during subsequent oxidation. It should also be noted that the temperature of these treatments is more than 100°C lower than the recent high temperature argon annealing gettering work done by Shiraki (25). Finally, besides the dissolution or deactivation of native defects, the continued capture of process-induced stacking fault nuclei during subsequent processing cannot be overstated because of the many oxidations and high temperature treatments required in silicon integrated circuit fabrication.

It is hoped that the outline provided by Fig. 5 will serve as a guide to help identify those defects and processes vital to the nucleation of stacking faults. For example, it is occasionally found that swirl and stacking faults are not generated during oxidation of wafers from a specific ingot. Further analysis of these special crystals and their growth history would be most useful in enhancing our understanding of the stacking fault problem. Meanwhile, we believe the POGO gettering process described in this paper, although somewhat empirical, is quite viable and could readily be adapted to several device processing lines.

Acknowledgments

The authors would like to thank V. Morris for carrying out the phosphorus diffusions and oxidations described in this report. Comments on the manuscript and several very enlightening discussions with A. J. R. de Kock, T. E. Seidel, and R. B. Marcus are also appreciated.

Effect of Oxidizing Ambients on Platinum Silicide Formation

I. Electron Microprobe Analysis

T. J. Kingzett and C. A. Ladas*

Motorola Incorporated, Semiconductor Products Division, Mesa, Arizona 85201

ABSTRACT

The effect of oxidizing and inert ambients on the formation and oxidation of PtSi films from 450° to 650°C has been investigated. The presence of O_2 in the annealing furnace ambient during PtSi formation results in the growth of an SiO_2 layer which separates the underlying PtSi from a surface layer of unreacted Pt. The SiO_2 layer acts as a barrier to further silicide formation. In inert ambients, PtSi formation proceeds to completion, and subsequent exposure to O_2 results in the formation of a surface SiO_2 layer. Electron microprobe analysis was used to analyze the composition of the films.

Platinum silicide (PtSi) is commonly used for ohmic or rectifying contacts to silicon (1-3). PtSi is formed from Pt films on silicon substrates at temperatures above 300°C (4) and is reportedly stable up to 800°C (5). Although PtSi formation has been extensively studied (6), certain questions relating to the mechanism of the termination of the reaction as well as the oxidation of PtSi remain unresolved.

Hiraki *et al.* (7) reported that Pt on Si is completely converted to PtSi by annealing at 400°C. Poate and Tisone (8) reported that silicide formation is initiated by diffusion of Si atoms into the Pt film, forming an intermediate Pt_2Si phase which is converted, along with all of the remaining Pt, to PtSi. Rand and Roberts (3) reported that Si diffuses through the Pt along grain boundaries to form a thin SiO_2 layer (~100Å) on the surface of the PtSi film. The oxide formation was attributed to impurities in the annealing furnace ambient.

Several authors (10, 11) have reported the existence of a layer of unreacted platinum on the surface of annealed PtSi films, but do not explain the reason for incomplete silicide formation. Danyluk and McGuire (12) reported that a layer of $PtSiO_4$ is formed between the PtSi and a surface Pt film, and that a native SiO_2 layer on the silicon substrate may interact with the metal in order to form this silicate layer.

In this paper, we report a study of the effect of various ambients on PtSi formation, and of the oxidation of PtSi, both during and subsequent to the annealing process. PtSi was formed by annealing Pt films on Si in oxidizing and inert ambients at temperatures from 450° to 650°C. Oxygen was found to react at the surface of PtSi to form SiO_2. If the Pt film is completely annealed (in an inert ambient) prior to exposure to O_2, then a layer of SiO_2 forms on the surface. If, however, the film is annealed in O_2 or air, then O migrates through the Pt, a layer of SiO_2 is formed at the advancing PtSi-Pt interface, and a layer of unreacted Pt remains on the surface. Analysis of the PtSi films was performed by the electron microprobe method.

* Electrochemical Society Active Member.
Key words: platinum silicide, oxidation, ohmic contacts, electron microprobe analysis.

Experimental

Thin Pt films were deposited on silicon by RF sputtering in argon at 5μ (Hg) pressure and 200W. The silicon substrates were etched in HF and then sputter etched with Ar for 30 sec prior to deposition in order to ensure atomically clean Si surfaces. Two-inch n-type <100> silicon wafers with a resistivity of 0.3 ± 0.05 ohm-cm were used throughout. Pt films of 1300 or 2400Å (±10%) thickness were deposited, and the samples were then annealed in air, nitrogen, oxygen, or argon at temperatures of 450°, 550°, and 650°C.

Electron microprobe analysis was performed with an ETEC scanning electron microscope equipped with a dispersive x-ray spectrometer (13). Quantitative analysis was performed using single crystal Si, sputter-deposited Pt and SiO_2 on silicon as primary standards for silicon, platinum, and oxygen, respectively. A primary electron beam energy of 5 kV was used, and

SiKα, PtMα, and OKα x-ray intensities were used to determine the relative mass concentration of each element in the surface film. The standard correction factor method (14) was employed.

Film thickness measurements were made by DEKTAK (Sloan Instrument Company), CARIS (15), and ellipsometer (16) techniques.

Aqua regia etching of Pt and PtSi was done at 60°C with a 3:1:4 by volume mixture of 37% HCL:70% HNO_3:H_2O. HF etching of all samples was done at room temperature using a 6:1 mixture of 40% NH_4F: 49% HF. Infrared reflectance spectra of SiO_2 films were obtained using a Perkin-Elmer 331 spectrophotometer.

Results

Table I lists the relative mass concentrations [weight per cent (w/o) relative to a standard without normalizing] of Pt, Si, and oxygen in the films produced by annealing samples of 1300 or 2400Å thick Pt on Si in air or oxygen at 650°C for 15 min. The effective electron penetration, or maximum depth of x-ray production, depends upon the energy of the incident electrons, the density of the surface film, and the energy of the electronic transition which results in x-ray emission (17). This depth is approximately 900Å for PtMα, 1000Å for SiKα, and 1300Å for OKα x-rays in PtSi.

The data in Table I show that after annealing in air or oxygen, higher Pt and lower Si concentrations are found in the films than for PtSi, which is 87.45% Pt and 12.55% Si. The presence of a high concentration of oxygen indicates that an oxide layer may have formed. After the samples have been etched in HF, the films display composition closely approximating that of PtSi, and the oxide layer appears to have been removed.

Table I also lists the relative mass concentration of Pt, Si, and O for films annealed in N_2 or Ar for 15 min at 650°C. In this case the Pt concentrations are lower, and Si concentrations are higher than expected for PtSi. A high level of oxygen is also found, again indicating that an oxide formation has occurred. The results of HF etching of each sample are that a film which approximates PtSi remains, and that the oxide layer is removed.

Inspection of the samples following the annealing cycles shows that those samples annealed in O_2 or air appear identical to the original Pt films, but that the films annealed in N_2 or Ar have the darker appearance characteristic of PtSi. By etching the samples annealed in air or O_2 in the HF, a thin metal film, which was insoluble in the etch solution, was removed from the surface. The underlying material then exposed was the darker shade of PtSi. Analysis of the thin metal film recovered from the etch solution established it to be pure platinum in each case. The thickness of the platinum film removed in this manner was found to be ~10-15% of the original sputtered platinum film thickness. HF etching of the samples annealed in N_2 or Ar resulted only in a slight darkening of the surface appearance.

The relative mass concentrations of the Pt, Si, and O in the films annealed at 550° and 450°C for 30 and 45 min, respectively, are listed in Tables II and III. The compositions of the films before and after etching in HF

were found to be essentially the same as for the samples annealed at 650°C, *i.e.*, provided that the annealing time is sufficient, the effect of the various ambients on PtSi formation is unchanged throughout the temperature range studied. In each case, a thin layer of Pt is removed from the surface of the samples annealed in air or O_2, while only a slight darkening of the surface is noted after etching samples which were annealed in Ar or N_2.

The oxide layer on the surface of the samples annealed in N_2 or Ar is probably formed as the hot wafers contact air upon removal from the annealing furnace. This oxide layer, presumed to be SiO_2 is about 100Å thick, and is sufficient to protect the underlying PtSi from attack by aqua regia. If the film is first etched in HF, however, removing the protective SiO_2 film, then aqua regia etches away the PtSi very rapidly. This result is in agreement with previously reported data on the reactivity of PtSi (18, 19).

The oxide layer which is formed on the samples annealed in O_2 or air is also presumed to be SiO_2, but this layer is formed beneath the surface of the Pt film This is due to the migration of O through the Pt, and its subsequent reaction at the surface of the forming PtSi layer to give SiO_2. Extended annealing of the samples does not result in completion of silicide formation, which indicates that the SiO_2 is a sufficient barrier to completion of the reaction.

Figures 1 and 2 are electron micrographs of the unreacted Pt film which is removed from the surface of the sample annealed at 650°C in O_2 (2400Å Pt). The film is resting on the surface of the PtSi following HF etching of the interlayer SiO_2.

Discussion

The model which we propose is that O_2 will react at the surface of a PtSi film to form SiO_2. The thickness of the SiO_2 layer depends upon the time and temperature of exposure to the oxidizing ambient. A 1000Å thick oxide film was grown on the surface of PtSi formed in N_2 by subsequent annealing in O_2 at 650°C. The film was determined to be SiO_2 by *IR* reflectance spectrophotometry.

The SiO_2 layer may result from oxidation of the PtSi or from the reaction of Si atoms which diffuse to the surface of the PtSi film. At this point, either mechanism seems quite reasonable. $\Delta H_{F\,298}$ for the reaction

$$PtSi + O_2 \rightarrow Pt + SiO_2$$

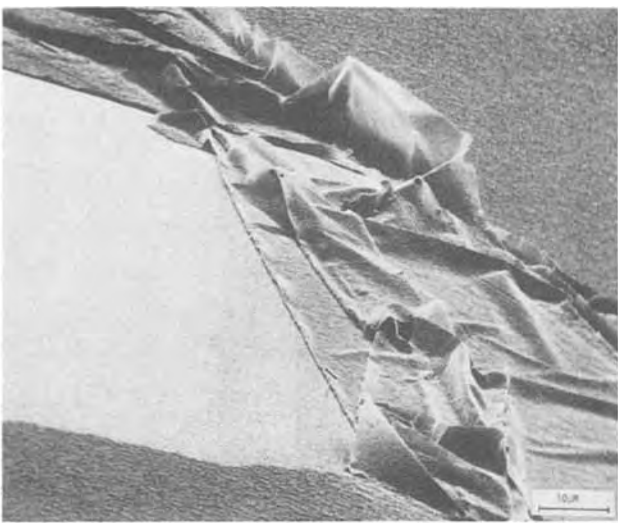

Fig. 1. SEM of Pt film lying on PtSi surface following HF etch

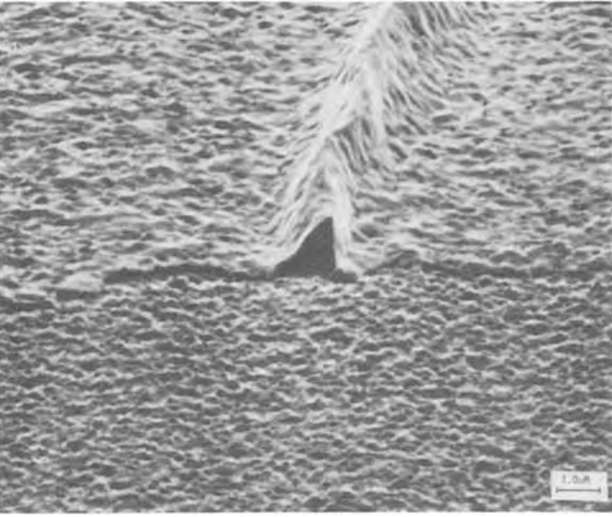

Fig. 2. SEM of Pt film lying on PtSi surface following HF etch

is -211.8 ± 5.5 kcal/mole as calculated from the data of Searcy and Finnie (20, 21). That this reaction does occur at 650°C was verified by forming a PtSi film on a silicon nitride (Si_3N_4) substrate and annealing in O_2. The PtSi was formed by depositing 1000Å each of polysilicon and Pt on the Si_3N_4, then annealing for 15 min in N_2. Silicide formation was verified by electron microprobe analysis. The sample was then annealed in O_2 at 650°C, and an SiO_2 layer formed on the PtSi surface. Etching of the sample in HF removed the SiO_2 film, and 1000Å of Pt remained on the Si_3N_4 substrate.

If the reaction of PtSi with O_2 is the mechanism by which the surface SiO_2 layer is formed, then the free Pt which is a product of the reaction must immediately react with silicon atoms which diffuse through the silicide to reform PtSi. This is shown by the fact that repeated oxidation and HF etching of the resultant SiO_2 produces neither free detectable Pt on the surface of the PtSi nor depletion of the PtSi layer, the silicon substrate being an "infinite source" of the Si atoms.

The formation of the SiO_2 layer below the surface of the Pt on the samples annealed in O_2 or air is due to the migration of O through the Pt as the silicide formation occurs. Although diffusion of O through bulk Pt has not been firmly established, surface absorption and migration of O on Pt surfaces has been reported by many authors (22, 23). Annealing in O_2 or air produces the same result because O_2 is preferentially adsorbed upon and not displaced from Pt by nitrogen (24).

The SiO_2 layer which is formed below the Pt surface is an effective barrier to further silicide formation because it blocks the diffusion of silicon atoms. Oxide layers have been shown to impede silicide formation in other metal films on Si (25). Extended annealing merely results in the formation of a thicker oxide layer. Although the ratio of unreacted Pt to the original sputtered Pt film thickness was relatively constant throughout the range of thicknesses and temperatures studied, this value may vary depending upon the permeability of Pt films prepared by other methods.

In order to confirm that migration of O does occur in the sputtered Pt films, bilayer films of Pt over W (1000Å each) on Si_3N_4 substrates were annealed at 450°, 550°, and 650°C in O_2. In each case, the bilayer films disintegrated upon oxidation of the tungsten. Microprobe analysis of fragments of the films confirmed the formation of tungsten oxide. No oxidation or disintegration of the bilayer films was observed when identical samples were annealed in N_2 over the same temperature range.

It does not appear likely that impurities in the annealing furnace ambient are the cause of the surface oxidation of the PtSi films formed in N_2 or Ar. When Pt films on Si were annealed in Ar contaminated with 1-2% O_2, then incomplete silicide formation resulted, and a layer of unreacted Pt remained on the surface. As in the case of samples annealed in air or O_2, a layer of SiO_2 formed between the PtSi and Pt, which blocked further silicide formation. It is also improbable that a native oxide on the Si substrates is the source of O which forms the oxide layer between the Pt and PtSi. We have observed the formation of this oxide interlayer only if O_2 is contained in the annealing furnace ambient, or if the Pt films are in contact with O_2 for a period of $\sim$150 hr or more prior to annealing in an inert ambient. In the latter case, O_2 which is absorbed by the Pt film prior to annealing is the likely oxygen source.

Hiraki *et al.* (26) report that the amount of SiO_2 grown on the surface of Au films on Si at low temperature is limited due to the diffusion of gold into the silicon. The silicon atoms which are oxidized at the surface of the Au film originate at the Au-Si interface, from which they easily diffuse through the Au film. After all of the Au has interdiffused with the silicon, however, the Au-Si interface no longer exists, and Si diffusion and thus the oxide formation is terminated. In the case of SiO_2 formation on PtSi films on Si, the amount of SiO_2 which may be grown on the surface is not limited in this manner. This is due to the stability of the PtSi film and the preservation of the PtSi-Si interface during oxidation. As much as 10,000Å of SiO_2 has been grown on the surface of a 2500Å film of PtSi by successive oxidation and HF etch cycles in order to remove the SiO_2.

The formation of protective layers of silica on the surface of metal silicides has been frequently cited as the reason for the high oxidation resistance of these materials (18, 19, 27, 28). Reactions of the type

$$MSi_a + (a + b)O_2 \rightarrow MO_{2a} + bSiO_2$$

are commonly accepted as the origin of the silica layer, which may also contain the metal oxide. This was found to be true in the case of the oxidation of titanium disilicide (29).

Summary

PtSi is formed by annealing films of Pt on Si. A layer of SiO_2 is formed on the surface of the PtSi by subsequent exposure to O_2. The thickness of this SiO_2 layer depends upon the time and temperature of formation. The formation of this oxide layer does not result in the formation of a layer of Pt on the surface of the PtSi.

If the Pt films on Si are annealed in air or O_2, then a layer of SiO_2 is formed at the PtSi-Pt interface prior to completion of the reaction. The O migrates through

the Pt and reacts at the advancing PtSi-Pt interface, and a layer of unreacted Pt remains on the surface. The SiO_2 layer is a sufficient barrier to prevent further silicide formation up to 650°C.

ABSTRACT

Auger electron spectroscopy combined with ion sputtering for layer removal and MeV $^4He^+$ ion backscattering spectrometry were used to analyze the depth profile of Pt, Si, and O in platinum silicide layers. Layers formed during heat-treatment at 600°C in an O_2 ambient consisted of an outer layer of Pt on an SiO_2 layer on PtSi. The structure formed in an N_2 ambient followed by heat-treatment in an O_2 ambient consisted of PtSi. In both cases there was a thin SiO_2 layer on the outer surface; in the latter case the SiO_2 layer was appreciably thicker.

The formation of silicide layers has been studied in detail because of their importance in integrated circuit technology. The process steps of evaporation of a metal layer on Si and subsequent heat-treatment to form the metal-silicide layers are easily adapted to device production. A number of analytical techniques have been used to determine the elemental composition as a function of depth, for phase identification, and to provide structural information. For example, Auger electron spectroscopy (AES) combined with layer removal by ion sputtering provides in-depth composition profiles

* Electrochemical Society Active Member.

Key words: Auger electron spectrometry, MeV ion backscattering spectrometry, silicon and thin films.

(1-3). Similar data, but without recourse to ion sputtering, are provided by MeV $^4He^+$ ion backscattering spectrometry (BS) (4-6). Glancing angle x-ray diffraction is used for phase identification and structural information (7) and is often employed (8, 9) with AES or BS techniques for composition analysis.

In most studies of silicide formation, heat-treatments are carried out in vacuum or in inert ambients. Under these conditions silicide layers of uniform thickness and composition can be formed (5, 8, 10). For example, low temperature annealing (200°C) of Pt layers on Si produces a Pt_2Si compound (11). Upon further annealing of this Pt_2Si structure for either longer times or at higher temperatures, additional Si is consumed to produce a PtSi compound (6).

In the preceding paper, Kingzett and Ladas (12) studied the influence of oxidizing ambients on platinum silicide formation using the electron microprobe for analysis. This method provides an average analysis over depths of 1000Å or more in PtSi. The purpose of the present study was to utilize Auger electron spectroscopy and MeV $^4He^+$ ion backscattering to directly measure in-depth composition profiles as suggested by the study of Behrisch *et al.* (13). Backscattering analysis gives absolute depth scales and quantitative compositional data without the requirement of standards. Auger electron spectroscopy provides surface layer analysis and relative concentration of the elemental constituents *vs.* sputtering time. In the present case, Auger analysis is more sensitive to oxygen than backscattering.

Experimental

Sample preparation.—The samples were prepared by Kingzett and Ladas as described in the preceding paper (12).

Auger electron spectrometry and backscattering spectrometry were used to evaluate the structures resulting from two different annealing procedures for silicon single crystal wafers having a 2000Å surface layer of evaporated platinum. The first procedure was to anneal the as-evaporated samples for 20 min in N_2 at 600°C followed by a 10 min postanneal in O_2 at 600°C. The second procedure was a 30 min anneal of the as-evaporated samples in O_2 at 600°C. Four 3 in. wafers were simultaneously prepared for each annealing procedure. After heat-treatment, two wafers of each type were provided to the AES and BS laboratories, respectively. Duplicate analyses for the redundant wafers provided to each laboratory gave similar results. Therefore, it was assumed that similarly prepared samples were identical and no interchange of samples was made between laboratories.

Backscattering spectrometry.—The experimental setup at the California Institute of Technology and analytical method for backscattering spectrometry have been reviewed elsewhere (14). In brief, the technique consists of placing a sample in a beam of mono-energetic helium ions and energy analyzing the particles backscattered out of the sample. Backscattering spectrometry with MeV $^4He^+$ ions provides information on concentration profiles with a depth resolution of about 200Å for layers as thick as 5000Å. With thicker films the depth resolution degrades due to energy straggling of the probing particles in the film. The beam spot is typically 1-2 mm^2, and hence backscattering requires lateral sample homogeneity of at least such dimensions.

Auger electron spectrometry.—A Physical Electronics Model 545 scanning Auger microprobe at the University of Illinois was used for all Auger electron spectroscopic measurements. The samples were mounted on the standard carrousel at 30° grazing incidence to the primary electron beam. The sample chamber residual vacuum was $<1 \times 10^{-9}$ Torr prior to all analyses. Primary electron energies of 6 keV were employed in both the depth profiling and imaging modes. Depth profiles were made by repetitively monitoring the Pt, O, and Si Auger transitions with simultaneous 2 keV Ar^+ ion sputtering for removal of successive atomic layers.

Results and Discussion

Platinum silicide (PtSi) postannealed in O_2 atmosphere.—A sample of PtSi/Si previously formed in N_2 at 600°C for 20 min was postannealed in O_2 at 600°C for 10 min. Surface AES spectra taken prior to ion etching and the AES depth profile of Fig. 1A both indicate Pt depletion at the film surface and the presence of a substantial amount of O and Si. Using the AES data and a sputtering rate determined from the known PtSi thickness, this Pt depleted region is calculated to have a thickness of about 140Å.

Scanning Auger electron micrographs of the surface (Fig. 2) show that there are islands of PtSi surrounded by SiO_2. The fact that the Si is actually present as SiO_2

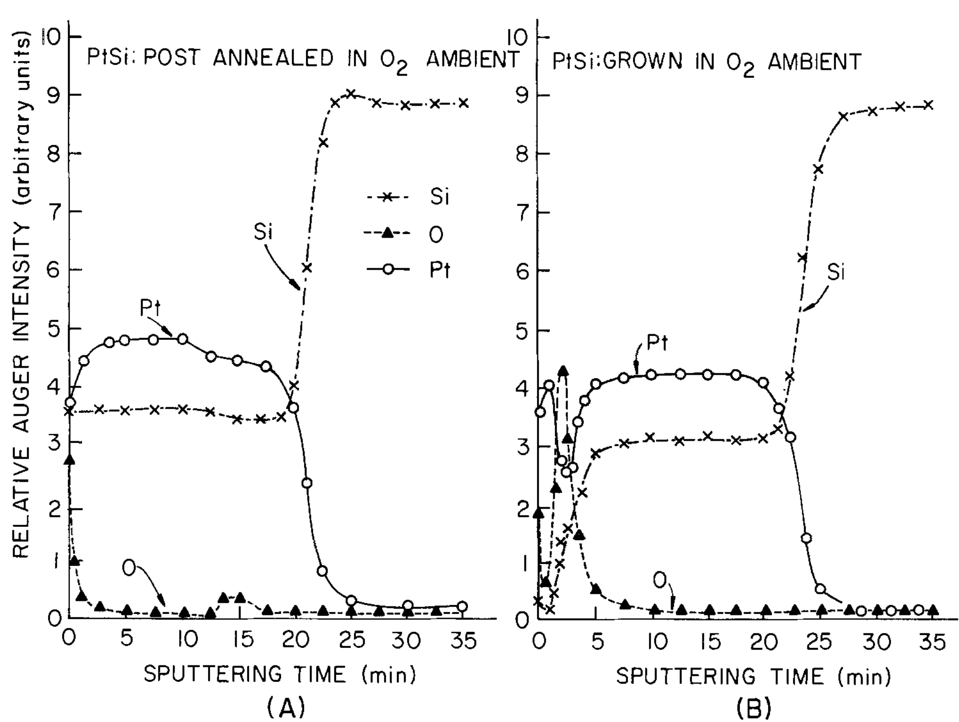

Fig. 1. (A) Pt, Si, and O Auger intensities *vs.* sputtering time from PtSi grown for 20 min in N_2 at 600°C followed by 10 min anneal in O_2 at 600°C. (B) Pt, Si, and O Auger intensities *vs.* sputtering time from PtSi grown for 30 min in O_2 at 600°C. (Note that for both Auger depth profiles data points were taken about 1 min apart. Only representative points are shown on the graphs for clarity.)

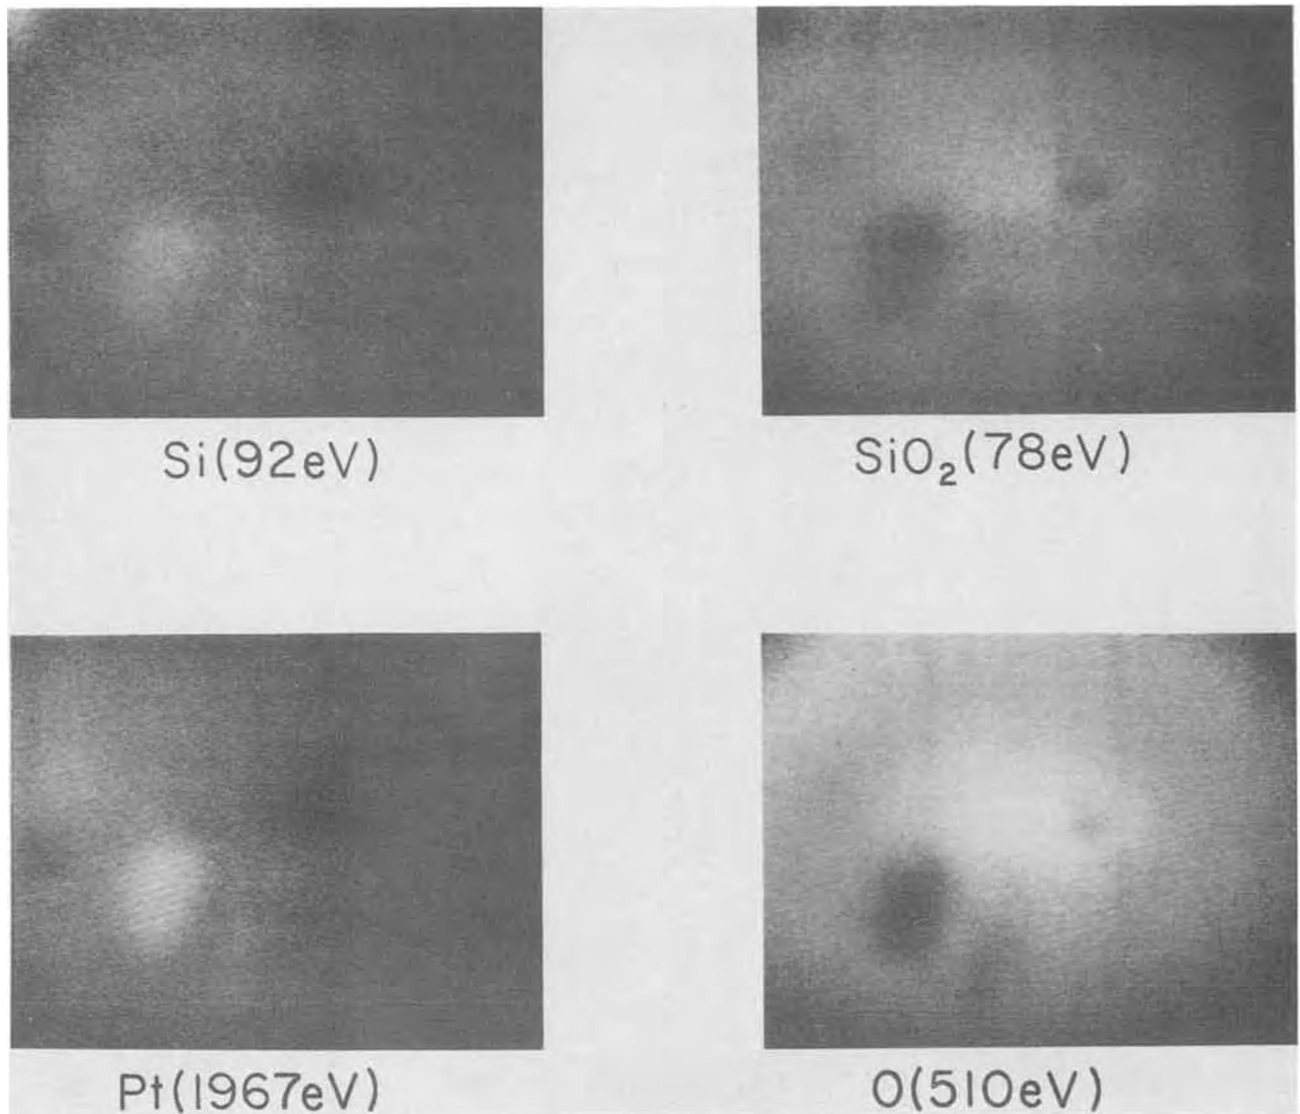

Fig. 2. Scanning Auger micrographs of Si (92 eV), Si (78 eV from SiO_2), Pt (1967 eV), and O (510 eV) taken at 300X for surface of PtSi postannealed in O_2 ambient (same sample as Fig. 1a).

is confirmed by using the Si 78 eV transition which has been shown to arise from a "chemical" spectral energy shift when Si is present as SiO_2 (15).

The backscattering data for similar samples are shown in Fig. 3. The broad peak at high energies centered around 1.7 MeV represents the Pt signal and the broad plateau centered at 1 MeV represents the Si signal from the PtSi layer. The increase in the Pt signal with decreasing energy reflects the change in scattering and stopping cross sections experienced by the analyzing particles (14). Using the measured backscattering yields for Pt and Si, the atomic ratio of Pt to Si is determined to be 1 ± 0.1 across the entire film indicating that the compound PtSi is formed. The data of Fig. 3 show that the silicide layer is uniform in composition with a thickness (assuming bulk density) of 3000Å. For the energy-to-depth conversion, (14), the compilation of Ziegler and Chu was used (16).

Backscattering data in Fig. 3 do not directly indicate the presence of a thin SiO_2 layer at the surface. However, having determined the existence of the thin SiO_2 layer by AES, very careful scrutiny of the BS spectrum suggests a barely perceptible rounding of the high energy edge of the Pt signal. This would indicate the presence of nonuniform surface layers of an energy-absorbing nature (presumably SiO_2). Tilting the sample by 60° with respect to the beam and hence doubling the effective thickness of the silicide layer produces an even more pronounced rounding of the high energy edge. This observation may have been overlooked had the Auger data not been available. From the backscattering data alone, we cannot assign a layer thickness to the SiO_2.

The BS data in Fig. 3 show that the changes in the absolute level of the Pt and Si Auger intensities (see Fig. 1A) are probably due to an instrumental artifact since the Pt and Si intensity ratio as determined by BS and AES is constant within experimental error (±5%) throughout the PtSi layer. The Auger data indicate a small but real oxygen contamination in the PtSi layer. Sensitivity limitations prevent backscattering spectrometry from confirming or denying this observation.

Platinum silicide (PtSi) reacted in O_2 atmosphere.— A sample with 2000Å of Pt on single crystal Si was reacted at 600°C in an O_2 atmosphere for 30 min. The resultant structure was characterized by AES depth profiling and backscattering spectrometry. AES surface spectra and the complete depth profile (Fig. 1B) revealed a very thin (< 50Å) layer of Si and O, presumably SiO_2. Scanning Auger micrographs of this surface oxide region showed no lateral compositional inhomogeneities within the resolution limits of the instrument (5-10 μm). Below this superficial layer, there is a 120Å thick platinum-rich layer calculated using a sputtering rate determined from the known PtSi thickness. Below this Pt-rich region AES data indicated a Pt-depleted, Si- and O-rich layer, pre-

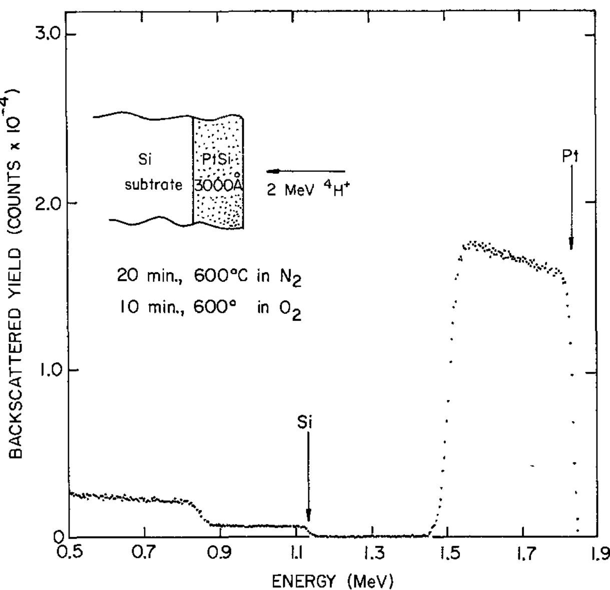

Fig. 3. Backscattering energy spectrum for a sample of Pt/Si annealed at 600°C in N_2 for 20 min and then in O_2 for 10 min.

sumably containing some SiO_2. The Pt intensities did not go to background levels, suggesting this region contains a mixture of PtSi and SiO_2. In a similar manner as before, this region is calculated to be about 200Å thick. The bulk of the reacted film consists of a uniform distribution of Pt and Si. The Pt/Si Auger intensity ratio is the same as for the PtSi film discussed above within ± 5%. It was not possible to use the chemically shifted 78 eV SiO_2 peak to determine that the Si and O present in this sample occurred in this chemical form because of a spectral interference from the very intense and broad Pt peak at 64 eV. As shown in Fig. 1B, a large amount of Pt was present throughout the layer.

The backscattering spectrum for a similar sample as that analyzed in Fig. 1B, is shown in Fig. 4. The thin peak at the high energy edge of the Pt signal indicates the presence of unreacted Pt. The width of this peak corresponds to a thickness of 160Å. The leading edge of the Si signal is shifted to a lower energy indicating that the outer surface is essentially Si-free. The valley

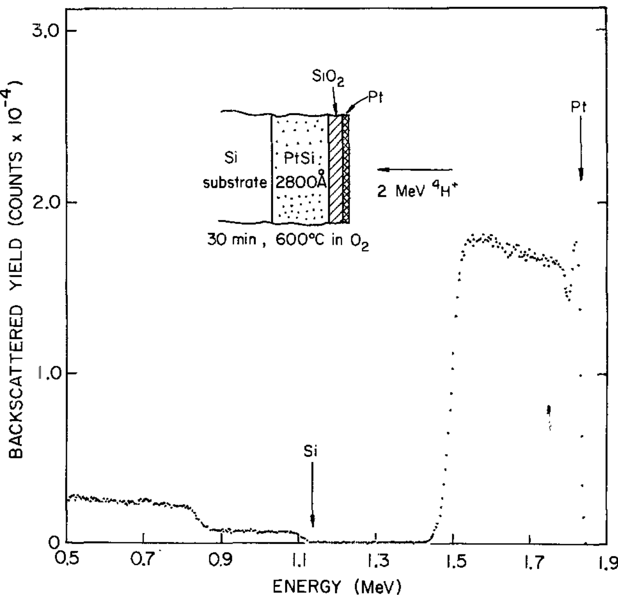

Fig. 4. Backscattering energy spectrum for a sample of Pt/Si grown for 30 min in O_2 at 600°C.

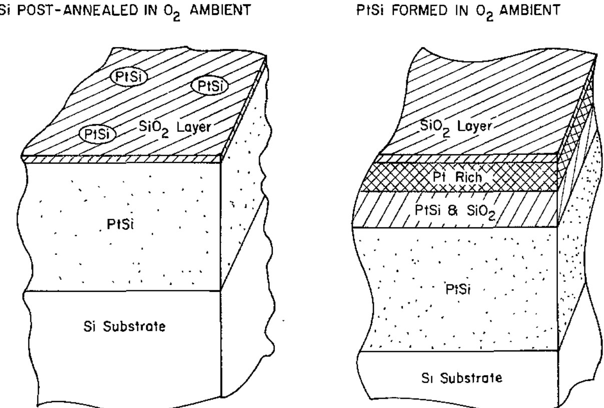

Fig. 5. Schematic representation of the influence of annealing ambients on the composition of PtSi layers. (Not to scale.)

between the thin peak and the broad plateau of the Pt signal represents the presence of an energy-absorbing layer. If the layer is SiO_2, as indicated by Fig. 1B, it would have an average thickness of 400Å. Under tilting conditions which double the effective layer thickness, the valley signal did not drop to the background level, indicating that the SiO_2 layer is nonuniform in thickness. Underneath the surface layers, there is a uniform layer with a Pt to Si ratio of 1 ± 0.1. The thickness of the PtSi layer is 2800Å.

Backscattering analysis of samples annealed in O_2 at temperatures between 400° and 700°C all revealed essentially the same features as that shown in Fig. 4. There is a thin layer of Pt ($\lesssim$ 200Å thick) separated from the PtSi by a thin layer of SiO_2. Although the thickness of the unreacted Pt layer is relatively unchanged, the oxide layer increases in thickness with increasing annealing temperature.

Summary

The results of this work confirm the general composition features deduced by Kingzett and Ladas in the preceding paper. The results of the analysis are shown schematically in Fig. 5. The most pronounced difference between annealing in N_2 and in O_2 ambients is the formation in the latter case of a layer of SiO_2 between PtSi and unreacted Pt.

The comparison of Auger electron spectrometry and backscattering spectrometry points out the merits of using both techniques for the analysis of layered structures. Although backscattering provides a depth scale and composition ratio, it is not sensitive to the presence of oxygen. Auger data requires calibration with samples of known thickness and composition for quantitative depth profiling. Layer erosion rates, for example, are sensitive to the ion beam parameters as well as the target composition itself.

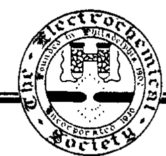
Technical Notes



Silicon Nitride Ledge Removal Techniques for Integrated Circuit Devices

V. D. Wohlheiter*

Western Electric Company, Allentown, Pennsylvania 18103

In order to reduce the silicon area of integrated circuit chips and potentially improve device yield, a nonreoxidized emitter (1) can be utilized. Specifically, a silicon dioxide layer is not grown on the emitter window after the emitter diffusion. However, the combination of this design procedure and the dual dielectric sealed junction technology (2) causes an undesirable silicon nitride overhang to be created. These ledges, if not removed, can manifest reliability problems for all metallization techniques. The scope of this paper is confined to the effects of the dielectric ledges on the titanium-platinum-gold metallization system. This particular overhang was associated with device failures which occurred during the life testing at 325°C. The purpose of this paper is to discuss both the successful and unsuccessful techniques investigated for removing the overhanging dielectric thereby eliminating the resulting integrated circuit failure mode and making the nonreoxidized emitter a reliable design and manufacturable process.

Creation of the Overhanging Dielectric

The mask for the device contact window was formed in the silicon nitride by conventional etching in boiling phosphoric acid using a pattern generated in a layer of CVD silicon dioxide or photoresist on the silicon nitride. The silicon nitride was deposited at 910°C in a diffusion furnace and meets the requirement previously reported (3). However, due to the relative chemical inertness of the silicon nitride film to the fluoride etching solution used to remove the underlying thermal silicon dioxide layers during the contact window opening, a ledge is created as illustrated in Fig. 1 and the actual SEM in Fig. 2. If these ledges are not removed, this structure combined with the gold metallization system can allow a gold-silicon alloy under elevated temperature to form which causes a shorted p-n junction. The dotted lines on Fig. 3 indicate the extent of the gold migration in the contact window. The typical failures appear as gold discolorations in the contact areas.

Experimental Methods to Remove the Ledge

In this study, three basic methods were investigated to reduce or eliminate the dielectric overhang. They were metal masking, thin dielectric with mechanical abrasion, and dielectric thinning. The following paragraphs describe these processes.

Metal masking for ledge removal.—An inert metal was used to mask the top of the dielectric and permit the removal of the overhang by etching from beneath (4). Since the deposition of the inert metal is rather unidirectional, the underside portion of the ledge remains unprotected by metal. By prolonged etching in phosphoric acid, the underside silicon nitride overhang will be attacked and the ledge removed. This method also permits the original thickness of dielectric to be maintained. Since platinum was compatible with the beam lead technology, it was chosen as the masking metal.

However, the results were somewhat unexpected. During the sputtering of platinum, some platinum silicide began to form in the contact window before any other heat-treatment. Upon subjecting the wafers to a sufficient amount of time in boiling 180°C ± 3°C phosphoric acid to remove the overhang, it was noted that some undermining of silicon occurred. This has been illustrated in Fig. 4, and the actual contact structure is shown in Fig. 5. Upon further investigation, it appeared that this attack of the silicon is occurring at the platinum silicide-silicon interface. Since any metal masking technique requires several extra and elaborate processing steps to be added in the device fabrication, this technique was abandoned as a method to remove dielectric ledges for a more cost feasible method. Other inert metals were not investigated for the latter reason.

Thin dielectrics.—Since a 500Å silicon nitride film remains a significant barrier to sodium and also possesses junction sealing capability, it was used in place of the standard 2000Å thick layer. It was expected that the ledge would be abraided away by processing with a mechanically applied force. However, the 500Å silicon nitride film remained intact even after an agitation

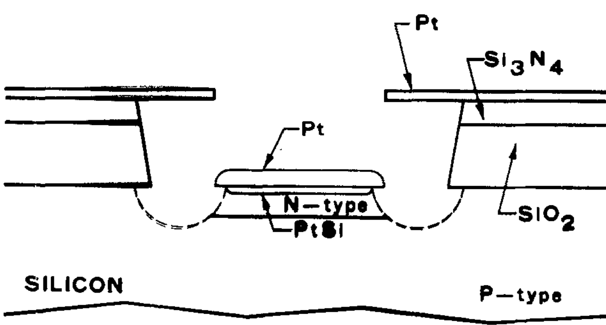

Fig. 4. Preferential etch of silicon-platinum silicide interface

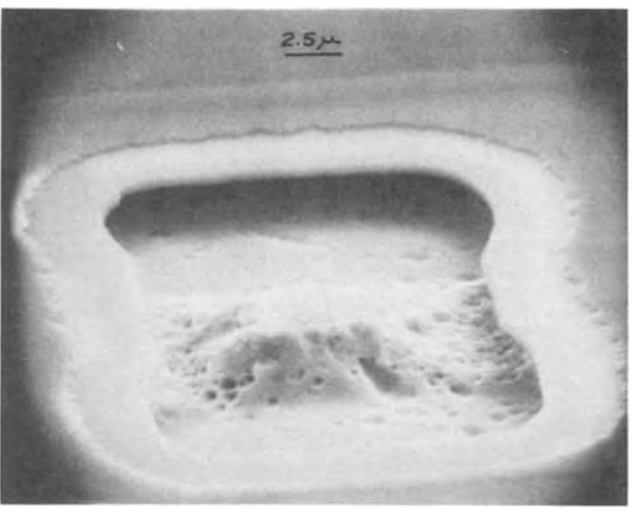

Fig. 5. SEM micrograph illustrating the etched interface

in the etching solution (BHF) for the underlying layer of silicon dioxide. The overhanging ledge was clearly able to withstand the further stresses of water rinsing and spin drying. The condition of the film remained unchanged even after ultrasonic agitation in water and nonionic detergent mixture to insure proper wetting of the sample.

Mechanical abrasion of silicon nitride.—This technique suggested the use of the 500Å thick silicon nitride and removing it by processing it through an automatic silicon wafer scrubbing machine. Figure 6 shows silicon nitride debris clinging to the walls or edges of the contact holes. Ultrasonic cleaning was not normally successful in removing this debris but etching in phosphoric acid after scrubbing produced a clean ledge-free edge as shown in Fig. 7. This method was successful in removing the silicon nitride ledge in some areas, however, variation of breakage across the wafer and lot to lot variables inhibited full adoption as a manufacturable technique.

Dielectric thinning.—A ledge approximately 2000Å thick is created as outlined above. It was then intended to sacrifice one-half of this layer in order to eliminate this ledge (5). The overhang is eliminated by etching since it is attacked from both the top and bottom surfaces. The high temperature phosphoric acid utilized to etch the silicon nitride did cause localized plating of copper or antimony on the heavily doped n-type silicon in the emitter contact windows (6). Attempts were made to passivate the exposed silicon by regrow-

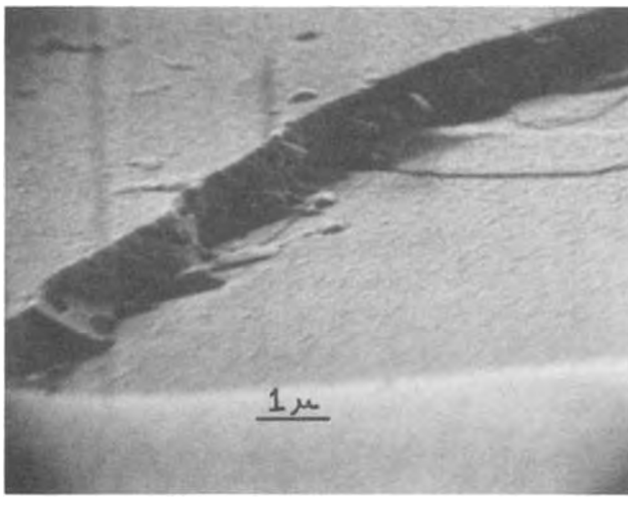

Fig. 6. SEM micrograph of silicon nitride (500Å) ledge after mechanical scrubbing.

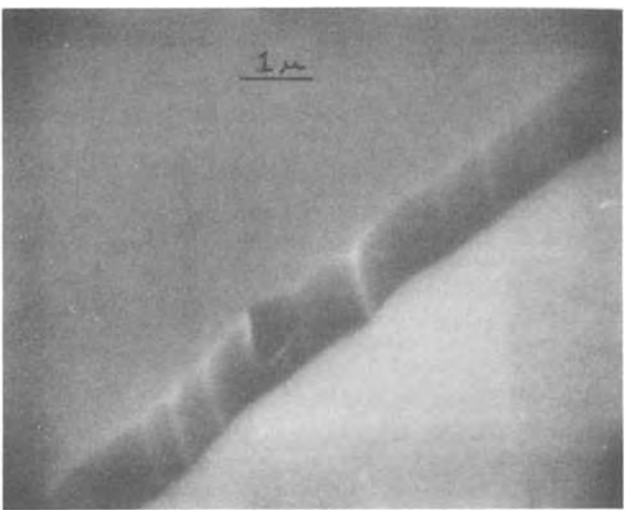

Fig. 7. SEM micrograph of scrubbing debris removed by phosphoric acid.

ing a thin steam oxide in the contact windows. It was found that although the n^+ silicon areas could be protected by reoxidation, the silicon nitride ledge was not always removed during an appropriate time in the phosphoric acid. The silicon nitride etching after the thermal oxidation heat-treatment was erratic, and several minutes were sometimes required in the etchant before the attack would commence. It was presumed that the steam reoxidation treatment converted a thin layer of silicon nitride to silicon dioxide or to an oxynitride that has a significantly reduced etching rate in the phosphoric acid. A similar reaction has been reported by Appels (7) who observed the conversion of approximately 500Å of silicon nitride to silicon dioxide during a 9 hr steam oxidation at 1000°C.

A chemical mixture (8) of concentrated sulfuric acid and phosphoric acid was suggested for etching the silicon nitride that would also, at the same time, effectively passivate the exposed n^+ silicon surfaces. This method oxidized the silicon surface and prevented attack by the phosphoric acid. This etchant mixture was found to be more successful in preventing the selective plating on n^+ silicon and exhibited the same etching rate on silicon nitride as 100% phosphoric acid. While phosphoric acid without the sulfuric acid additive also does reduce plating of n^+ silicon to a significant extent in 160°C, the addition of sulfuric acid is recommended. No plating is apparent on the silicon as can be seen in Fig. 8, and the silicon nitride ledge has been completely removed. The structure shown in Fig. 8 has been etched in a 10% sulfuric acid mixture in phosphoric acid boiling at 160°C. Reliable ledge removal is achieved with a furnace silicon nitride system and the proper control of the temperature of the phosphoric acid.

Fig. 8. SEM micrograph of a contact window with ledge removed

Testing of Thinned Dielectric

To investigate the adverse effect, if any, on the thinned silicon nitride properties, test samples of silicon nitride were deposited on chemically clean, 10 ohm-cm, <111> oriented, polished silicon wafers to thicknesses of 2000Å ± 200Å and 1000Å ± 100Å. The thicknesses were measured with a spectrophotometer. The 1000Å group of silicon nitride was used as the control. The half of the lot with 2000Å of silicon nitride was etched in phosphoric acid to one-half the original thickness while the control remained unetched. Forty-eight aluminum dots, 20 mil in diameter, were evaporated on the surface of the test wafers to form capacitors with silicon nitride as a dielectric. The wafers were subjected to electrical testing which consisted of ramping the voltage and observing the point at which the capacitor exhibited excessive current exceeding 10 μA and below 50V indicating premature breakdown. A calculated value of breakdown voltage for a silicon nitride film of 1000Å is 50-100V. Silicon nitride is reported to have a dielectric field strength of $0.5\text{-}1 \times 10^7$ V/cm (9). The voltage distributions are plotted in Fig. 9 for etched and unetched silicon nitride. The over-all conclusion which can be drawn from these data is that the etched film does remain pinhole-free with adequate dielectric properties for use in beam lead sealed junction integrated circuits. The 10% difference at the 90% point between the etched and unetched can be explained by some variation of the etch rate used for the silicon nitride. Based upon these results, the thinning of silicon nitride can be utilized without fear for loss of film quality. In addition to these breakdown voltage tests, radioactive sodium penetration tests (10) were conducted to evaluate the integrity of the etched film. The results indicated that the thinned silicon nitride continued to act as a sufficient barrier to Na^{++}.

Conclusion

In order to minimize the use of silicon area in device layout and to improve performance, a nonreoxidized emitter structure can be utilized. However, to couple this technique with the dual dielectric, sealed junction technology, it is necessary to eliminate an overhanging dielectric created during processing. The ledge com-

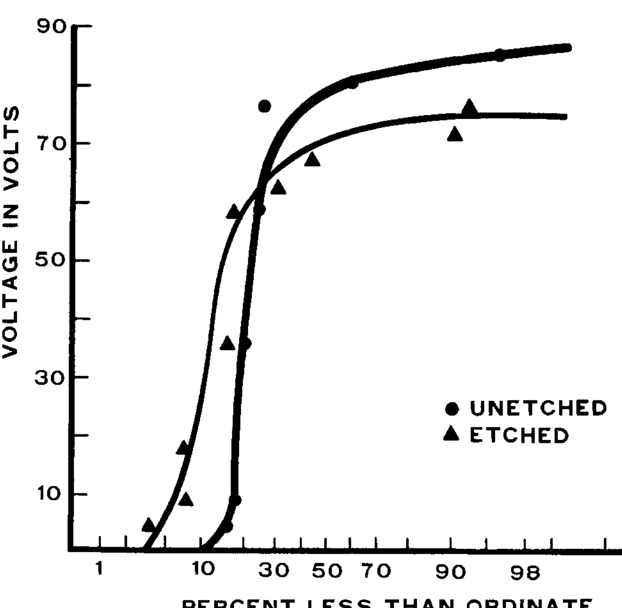

Fig. 9. Breakdown voltage distribution of etched and unetched silicon nitride.

bined with the described metallization can manifest itself as the cause of failures during accelerated aging.

Several types of ledge removal techniques, both successful and unsuccessful, were discussed, which included metal masking, mechanical abrasion, and dielectric thinning.

The most successful method for the removal of silicon nitride was by dielectric thinning. By thinning the dielectric to one-half its original thickness, the ledge is completely eliminated since the etchant, which is a mixture of phosphoric and sulfuric acids, attacks both the top and the bottom of the overhang. Additionally, mechanical damaging of the ledge with a wafer scrubber followed by a short phosphoric acid dip can result in removal of the ledge in certain areas. However, the repeatability of the process was less than adequate.

Calculations of the S_2 and Se_2 Partial Pressure and the ZnS-CdS and ZnSe-CdSe Sublimation Point Diagrams

Warren P. Heim[1] and Kenneth A. Jones

Thayer School of Engineering, Dartmouth College, Hanover, New Hampshire 03755

It is frequently assumed that the only sulfur and selenium molecular specie in the vapor in equilibrium with their II-VI compounds is the dimer. We wanted to determine the temperature range for stoichiometric CdS, ZnS, CdSe, and ZnSe, and their composition range at different temperatures for which the assumption is valid. We did this by plotting curves of the total pressure for a given dimer pressure as a function of temperature, and superimposing the partial dimer pressures in equilibrium with stoichiometric CdS, ZnS, CdSe, and ZnSe that were calculated assuming that the vapor was composed only of dimers.

These plots are shown in Fig. 1 (sulfur) and 2 (selenium). The integers (−5 to 2) on the right-hand side are the powers of the fixed dimer pressures, *e.g.*, $2 = 10^2$ Torr. Since in the regions where the log P *vs.* T curves are horizontal the total pressure equals the dimer pressure, it can be seen that the assumption is valid for CdS up to ~1400°K, for all temperatures that are shown for ZnS, for CdSe up to ~1200°K, and for ZnSe up to ~1700°K. In all instances the limitation is due to the formation of molecules containing more than two atoms at the higher pressures. A significant contribution to the total pressure from the monomers occurs only at the highest temperatures and lowest pressures. It can also be seen that if the assumption is valid for the stoichiometric composition it is valid for all practical excess cation concentrations and is valid over a larger excess anion range at lower temperatures.

The P *vs.* T curves for a fixed dimer pressure, P_2, were calculated using the equations

librium with stoichiometric CdS, ZnS, CdSe, and ZnSe were calculated using the equations

$$\ln P = -\frac{2}{3}\frac{\Delta H_s}{RT} + C_s$$

$$P_2 = \frac{1}{3}P$$

using the data of Shiozawa and Jost (3) which are listed in Table II.

In order to know the composition of the vapor of ternary mixtures to aid us in analyzing platelet growth (4) for the ternary platelets used in our solar cell research, we also calculated the ideal sublimation point diagrams for ZnS-CdS and ZnSe-CdSe at pressures of 10^2, 1, and 10^{-2} Torr. They are shown in Fig. 3 and 4. The diagrams are ideal in that Raoult's law was used, it was assumed that only anion dimers were present, and it was assumed that the constituents form complete solid solutions even though the room temperature structure of the zinc compounds is zinc blende and not wurtzite. The calculations were made by computing the vapor pressures, P_1^0 and P_2^0, of the constituents at a number of temperatures between the sublimation temperatures of the pure constituents and calculating the solid mole fractions, X, from the equation

$$X_1 = (P - P_2^0)/(P_1^0 - P_2^0)$$

and the vapor mole fractions, Y, from the equation

$$Y_1 = X_1P_1^0/P$$

Brief Communication

Liquid-Phase Epitaxial Growth of 6H-SiC by Vertical Dipping Technique

A. Suzuki,* M. Ikeda,* H. Matsunami, and T. Tanaka

Department of Electronics, Faculty of Engineering, Kyoto University, Kyoto 606, Japan

As a method to prepare SiC single crystals for semiconductor devices, liquid-phase epitaxial growth from a Si melt will be more useful than the conventional sublimation method because the growth temperature is lower and the growth process, impurity level, and polytypes may be controlled more easily.

Brander *et al.* obtained epitaxial layers of 6H-SiC up to 100 μm thick at a growth temperature of 1650°C by supporting a substrate crystal on a stock in the Si melt (1, 2). After the growth, they took out the grown crystal from the solidified silicon by cutting the crucible and etching the silicon. However, grown crystals tended to be damaged by stresses induced when the Si melt solidified. In order to solve this problem, we have attempted liquid-phase epitaxial growth of 6H-SiC by vertical dipping technique.

The arrangement for the growth is shown in Fig. 1. The crucible was made of dense and high purity graphite (apparent density 1.60 g/cm^3, ash content 0.02%). Its size was 53 mm in height and 35 mm in outer diameter. In order to avoid evaporation of silicon, we used a graphite lid which had a center hole of 8 mm in diameter. The crucible was filled with a 26g charge of silicon and heated inductively. The gas ambient was Ar flowing at ~200 cm^3/min.

A single crystal of 6H-SiC prepared by the Acheson method was used to make a substrate. The substrate

was prepared by lapping and polishing the {0001} faces of the crystal with diamond paste, and cutting it into pieces of 1 × 1 × 8 mm^3. Then it was rinsed with deionized water. The surface polarity was examined by etch pits with H_2 gas etching at 1550°C for 20 min. The substrate was tied to a graphite holder with molybdenum or tantalum wire. The <0001> direction was set perpendicular to the holder axis. After the silicon was melted, the substrate was dipped to a depth of 2 ~ 3 mm and maintained for 5 hr at a growth temperature between 1550° and 1750°C. The temperature at point A in Fig. 1 was kept 10° ~ 40°C lower than that at point B. After the growth, the substrate was pulled up from the crucible before the Si melt solidified. Residual silicon on the grown layers was removed with a 1:1 mixture of HF and HNO_3. By this dipping technique, the crucible and silicon could be used several times.

Layers 20 ~ 140 μm thick were grown on the {0001} faces after 5 hr growth at 1550° ~ 1750°C. The layer on the Si face was thinner than on the C face with every growth. Each layer was thick near the surface of the Si melt. Figure 2 shows the average thickness as a function of growth temperature. It increased with increasing growth temperature, which may be due to the increase of the solubility of carbon into the Si melt. But above 1750°C etching effects appeared. Fairly even layers were grown at lower growth temperature and with less temperature difference of the crucible.

The appearance of the grown layers was quite different between the Si face and the C face as shown in Fig. 3. The former was relatively smooth and showed a wavy pattern, whereas the latter was composed of small islands.

By taking x-ray oscillation photograph about the <0001> axis of the layer grown at 1700°C, it was found to be a 6H-type single crystal grown epitaxially on the {0001} face of the substrate.

Previously we reported that aluminum and boron impurities were introduced unintentionally from the graphite crucible in our experiments and that they acted as strong luminescent centers at 77K and 300K, respectively (3, 4). We have observed photoluminescence of the grown layers at 77K and 300K. By comparing the spectra with those due to aluminum and boron in various polytypes of SiC reported by other researchers (5, 6), all grown layers were found to be 6H-type.

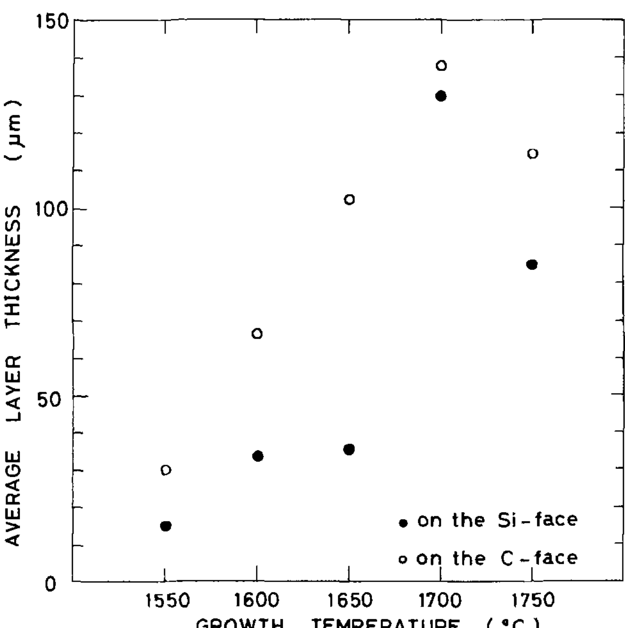

Fig. 2. Average thickness of grown layers on the {0001} faces as a function of growth temperature (5 hr growth).

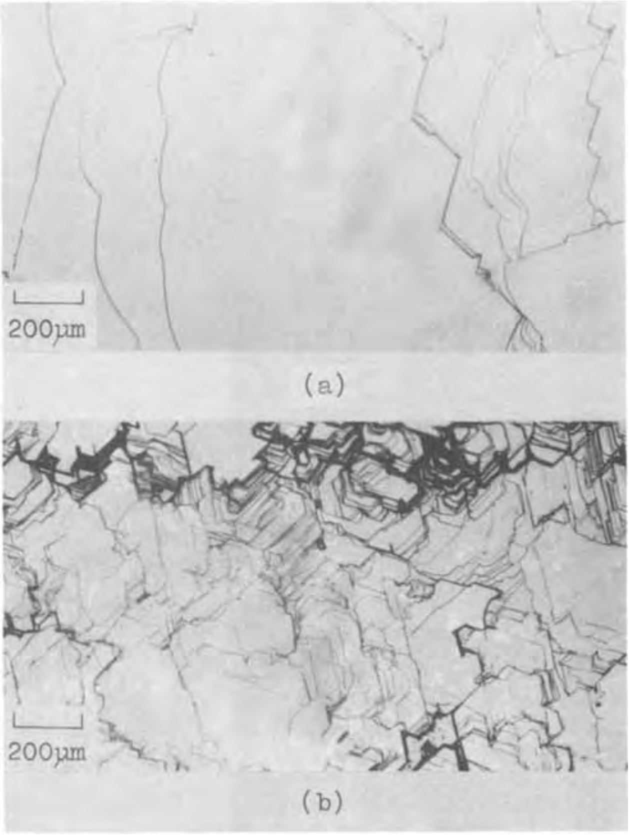

Fig. 3. Grown layers on the {0001} faces after 5 hr growth at 1550°C, (a) Si face, (b) C face.

Pellegrini *et al.* reported liquid-phase epitaxial growth by a similar technique to ours, using the melt of Ti-Si alloy instead of Si (7). They utilized the high solubility of carbon into Ti melt and the low vapor pressure of Ti to obtain thick layers. But thickness of 35 ~ 140 μm at 1600° ~ 1700°C for 5 hr in our experiments is much the same as 120 ~ 150 μm at 1600° ~ 1700°C for 8 hr in their experiments. Moreover, evaporation of silicon was little even in our long run for 120 hr at 1700°C. By using only silicon as a solvent, grown layers may not suffer from undesired impurities.

The Oxidation of Thin Single Crystals of Iron

P. L. Fan and L. O. Brockway (pp. 1534-1537, Vol. 121, No. 11)

J. Manenc:[1] In this very interesting work about oxidation of single crystals of iron, Fan and Brockway give electron diffraction results. They found reflections they were unable to index as Fe, FeO, or Fe_3O_4. Using A.S.T.M. file they chose the compound Fe_4N as the best fitting phase.

I think this interpretation is not valid in view of the results we obtained earlier at IRSID.[2-9] Briefly, we showed that wustite has different structures depending on its departure from stoichiometry and on the heat-treatment. These structures probably correspond to cation vacancy ordering[2-4] resulting in the building of a supercell which gives extra selective spots. The number and the repartition of these spots are a function of the vacancy concentration.

The order can exist in certain circumstances at high temperature as we[8,9] and other people[10] have showed.

It is particularly interesting to compare Fig. 2 of the paper under discussion to Fig. 5 of our paper.[4]

Thus, it is most probable that the reflections attributed to Fe_4N by Fan and Brockway are order spots of oxygen-rich wustite formed at the top of the largest crystals. Moreover, the extra spots always accompany the normal wustite reflections.

Effect of the Rate of Cooling on the Emission of CaS:Ce Phosphor

D. R. Vij and V. K. Mathur (pp. 310-311, Vol. 122, No. 2)

W. Lehmann:[11] The article by Vij and Mathur describes preparation of $CaS:Ce^{3+}$ phosphor at relatively low temperature (900°C) with Na_2SO_4 serving as fluxing agent and without the use of any halide. Since presence of Na and absence of a halide in our own work[12,13] was observed to be just about the worst possible condition under which to prepare this phosphor, we tested once again following the procedure described by Vij and Mathur as closely as possible. The result was a discolored and strongly sintered material with only very weak luminescence (less than 10% of what routinely is available by the halide method) essentially confirming our previous experiences.

At this point, Dr. Mathur kindly supplied a sample of his material (A) for inspection and for comparison to a sample (B) made in our laboratory. Sample A was made with Na_2SO_4 as described, sample B was made with iodine as described in our paper[12] (there is little or no difference between the actions of F, Cl, Br, and I in $CaS:Ce^{3+}$). Both samples contain about 0.03-0.05% of Ce. The following are the most interesting results of this comparison.

1. Routine x-ray analysis indicates no other phase, besides CaS, to be present in either material (limit of detectability: ~ 1-2%).
2. Sample A consists mainly (not only) of remarkably well-developed particles in the size range of about 10 μm despite the low preparation temperature (particles of similar size prepared by the halide method would require at least 1200°C). It is also somewhat more stable in water slurry (pH ≈ 8.5) than material B (pH ≈ 10).
3. The efficiencies of photoluminescence (254 nm u.v.) and of cathodoluminescence (10 kV, low current) of A are approximately 30% of B.
4. The emission spectra of A and B are slightly different; A is shifted by about 0.05-0.06 eV to higher energies (Fig. 1).

We emphasize at this point that the statement "The two peak positions (of $CaS:Ce^{3+}$ made by the halide process) vary only very little with the cerium concentration. . . ,"[12] still is correct. Some measured data are shown in Fig. 2. Comparing the low efficiency of A and the spectral positions of the peaks of its emission bands to Fig. 2 shows a fair agreement with $CaS:Ce^{3+}$, halide containing only 0.001% Ce or slightly more. We interpret this that, probably, less than 10% of all added Ce atoms in A are optically active, *i.e.*, in lattice sites and under conditions where they contribute to luminescence.

An undisputed merit of the preparation procedure used by Vij and Mathur is its simplicity and the lower required firing temperature made possible by the presence of a large amount of Na_2SO_4 flux. However, we still believe Na^+ ions to be detrimental to Ce^{3+} luminescence in CaS. One might wonder whether a

suitable flux could be found containing no alkaline ions.

It is a pleasure to the writer to thank Dr. Mathur for supplying his phosphor sample and for discussion and ready cooperation in this matter.

D. R. Vij and V. K. Mathur:[14] We acknowledge that the efficiency of photoluminescence and cathodoluminescence of CaS:Ce phosphor B (prepared by Lehmann's method) is more than the phosphor A (prepared by our procedure). Under u.v. excitation we found that the efficiency of our phosphor is approximately 40% of that of the sample kindly supplied to us by Dr. Lehmann. However, it is difficult to agree at least in the first instance with his assertion that it is due to the addition of halide in his phosphors. According to spectrochemical analysis of A and B (available to us by the courtesy of Dr. Lehmann), the concentration of Fe is eight times more in A than B. It is well known that Fe is a killer impurity of luminescence. Hence we suggest that the lower efficiency in our case may be due to the presence of higher concentration of Fe. We have tried to eliminate this impurity but without any success so far. It may be mentioned here that we have tried $CaCl_2$ as flux but the samples were found to be of very low efficiency.

The Origin of the Cubic Rate Law in Zirconium Alloy Oxidation

G. P. Sabol and S. B. Dalgaard (pp. 316-317, Vol. 122, No. 2)

B. Cox and R. A. Ploc:[15] The relationship between changes in the crystallite size in the oxide film during growth and the kinetics of oxidation is one of the most important factors yet to be established for zirconium alloy oxidation. It is unfortunate, therefore, that Sabol and Dalgaard present an oversimplified picture which may be misleading to readers.

That the pretransition oxidation kinetics of zirconium alloys are close to cubic is only well established for specimens oxidizing at relatively high temperatures.[16,17] In water at low temperatures (~300°C), the pretransition kinetics are often close to quartic for a large fraction of the time prior to the principal transition in the kinetics at ~30 mg/dm². If the authors study the reference they cited to Kass' work,[18] they will see that many of the exponents quoted in his Table 1 are less than 0.33, even when averaged over the whole oxidation curve. When the data beyond the minor inflection, which occurs in the weight gain curve at ~10 mg/dm², are fitted independently to a curve of the form $\Delta w/kt^n$ the exponents (n) are usually <0.33, for Zircaloy-2 or Zircaloy-4 in their normal metallurgical condition.[19-21] Thus the majority of the pretransition oxidation kinetics in water are usually between a cubic and a quartic, with considerable variation from specimen to specimen (Fig. 1). Similar results have been reported elsewhere.[19-21]

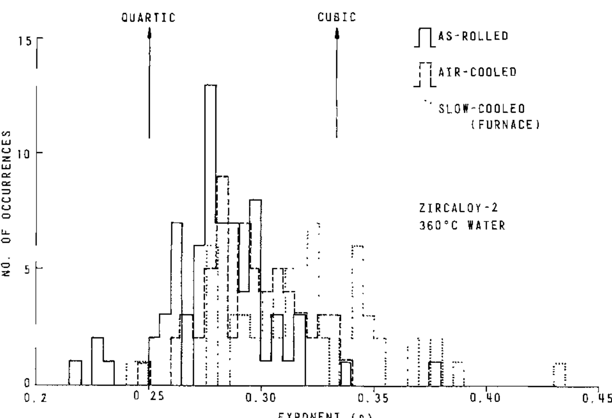

Fig. 1. Histogram of oxidation rate exponents (n).[21] Note that slow-cooling results in poor oxidation resistance.

A quartic kinetic law could be explained by crystallite sizes increasing proportional to the film thickness squared, a dependence to which Sabol and Dalgaard's results show better agreement than the linear dependence they propose to force a fit to cubic oxidation kinetics. In the light of the observed variation in kinetic exponents, however, it is even more important, if an acceptable correlation of crystallite size and kinetics is to be made, that both the crystallite size and the applicable kinetics be derived from the same set of specimens; a correlation which is absent here.

Another factor which Sabol and Dalgaard ignore completely is the influence of the electronic component of the oxidation process on the oxidation kinetics. Theoretically, even for a constant oxide crystallite size (and oxygen ion mobility) as a function of oxide thickness, the rate law will only be parabolic if the electric field across the oxide is constant. This is probably not the case.[22-24] The previously mentioned inflection in the kinetics may be caused by an increase in electronic conductivity (manifested as a sudden drop in the field across the oxide and an increase in the instantaneous oxidation rate) similar to that causing the inflection at ~1 mg/dm² during oxidation in other environments.[22,23] Beyond this inflection in the oxidation curve the field across the oxide is relatively constant and decreases only slowly. Thus, to a first approximation we can consider only the effect of crystallite size and shape on the kinetic law in this region; however, any perturbation caused by changes in elec-

tronic conduction (indicated by changes in the field) will be in the direction of increasing the exponent in the rate law. Thus, the measured oxidation kinetic exponents during a period of decreasing field across the oxide will be higher than would be determined under a constant-field condition.

Sabol and Dalgaard conclude further that the initially formed crystallites of ZrO_2 did not change in size during continued oxidation. Our results[25,26] and those of Roy *et al.*[27] cast doubt on this conclusion. Though complicated by several factors such as nonidentical conditions, our results suggest that at about a film thickness of 500-900Å the oxide crystallites over many prior metal grains change in appearance. Electron diffraction data[26] and transmission electron micrographs[25] strongly support the idea that recrystallization, growth, and re-orientation (possibly caused by grown-in stresses) of the crystallites occur in the early stages of oxidation. The work of Roy *et al.*,[27] which shows that some orientations of crystallites disappear, *i.e.*, that the absolute x-ray intensity of that orientation passes through a maximum as the oxide thickens, rather than merely the relative intensity being reduced, as the oxide continues to thicken, suggests that these processes continue at greater oxide thicknesses. These results require a more extensive exposition than is possible here, or in the reference cited, and further details are currently being prepared for publication.

Let us make it clear in conclusion that we are basically in agreement with the hypothesis for oxygen transport in growing oxide films adopted by Sabol and Dalgaard, having long espoused such an hypothesis ourselves. However, demonstrable proof of the relation between crystallite size in the oxide film and the kinetics of the process requires considerably more care than was shown by these authors in this paper.

G. P. Sabol[28] and S. B. Dalgaard:[29] The purpose of publishing the original technical note was to call to the attention of the scientific community the correlation between the structural aspects of oxide film growth and the observed deviation in kinetics from parabolic towards cubic. It was not the intent of the manuscript to fully explain the details of the corrosion process, but rather to stimulate additional work directed specifically toward the behavior of zirconium in aqueous environments. While we acknowledge that other factors of perhaps equal importance are also involved, it is believed that the structure of the diffusion barrier significantly affects the corrosion kinetics in the pretransition regime.

Rebuttal to specific comments made by Cox and Ploc are the following:

The exponent n in our work was 0.37. This is sufficiently close to the values reported by others [Ref. (1-3) of original paper] that repetition of the kinetic data would have been redundant.

We are well aware that the pretransition corrosion rate is a function of the ionic and electronic resistances of the barrier layer. Furthermore, we believe that these resistances are unique functions of the corrodent as well as the chemical and metallurgical condition of the alloy. Thus, models[22,26,27] based upon observations in electrolytes other than water do not necessarily apply to corrosion in aqueous media.

The disappearance of reflections in transmission electron diffraction patterns with increasing oxide film thickness was taken to indicate either recrystallization or preferential growth by Ploc and Arnal.[26] Our data

[Ref. (9) of original paper] strongly indicate preferential growth rather than recrystallization.

Although Ftn[27], private communication, is difficult to assess, the results referred to were obtained after oxidation in 500° and 650°C oxygen at 30 Torr. These temperatures are significantly greater than those considered in the paper and recrystallization at these higher temperatures is not unexpected.[30] However, the applicability of these results to corrosion in aqueous media at $< 400°C$ is highly questionable.

Oxide Growth on Etched Silicon in Air at Room Temperature

S. I. Raider, R. Flitsch, and M. J. Palmer
(pp. 413-418, Vol. 122, No. 3)

F. P. Fehlner:[31] The paper of Raider *et al.* points up the role of impurities in the oxidation process. They find that at low temperatures an adsorbed layer of impurities can block the attack of oxygen on silicon. Conversely, in the presence of ultraviolet irradiation and impurities, Fehlner has shown that the growth of a dielectric film on silicon can be enhanced.[32]

Another manifestation of the combined effect of ultraviolet light and impurities can be seen during the etching of SiO_2 on Si by dilute HF.[33] This may be relevant to the impurity film observed by Raider *et al.*

Figure 1 shows the thickness of dielectric film present on silicon [6-9 ohm-cm, n-type, (111)] after incremental etching in the dark and under u.v. illumination (medium pressure mercury arc). In the dark, the original SiO_2 film is etched completely away, leaving the silicon surface covered with a film 5-8Å thick. However, under illumination, a surprising event occurs. After the original SiO_2 has been etched away, a new film of unknown composition grows on the silicon. Part of this film can be subsequently removed by further etching in the dark. The results in Fig. 1 argue for carefully controlled etching in the dark of SiO_2 on Si.

[33] Experimental work performed at Signetics Corporation, Sunnyvale, California.

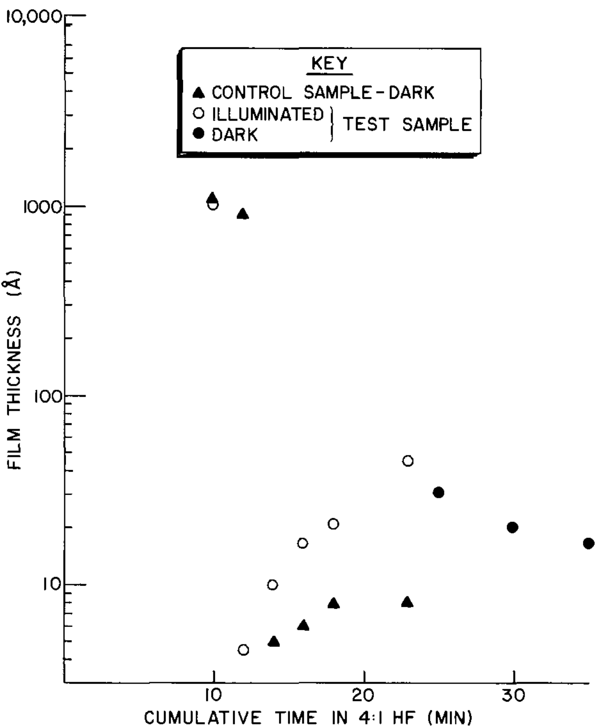

Fig. 1. Dielectric film thickness on silicon originally covered with 8700Å of thermally grown SiO_2 after etching with 4:1 HF. Ellipsometric measurements carried out as described.[32]

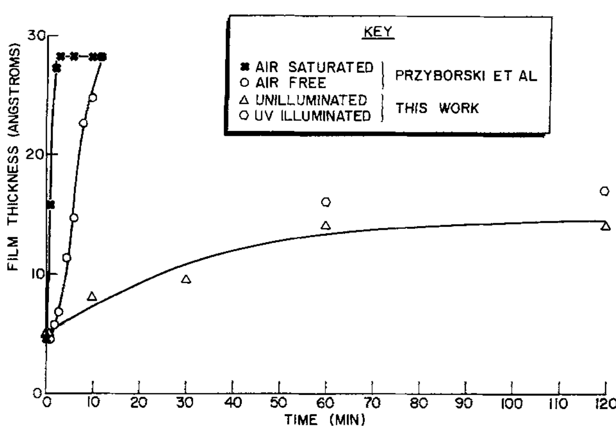

Fig. 2. Thickness of film formed on silicon as a function of time in boiling deionized water.

A second point of interest, which bears on the thickness of film left on etched silicon, concerns the oxide grown on silicon in boiling, deionized water. Etched silicon wafers were exposed to boiling water in equilibrium with the atmosphere for increasing lengths of time. The thickness of film formed on the silicon was then measured. The results are compared with those of Przyborski *et al.*[34] in Fig. 2. The thickness measurements in the present work were made with an ellipsometer, while those of Przyborski *et al.* were done by neutron activation analysis. The difference between the two sets of results is thought to be due to the purity level of the water. In this case also, illumination of the silicon with a high pressure mercury arc led to an increase in film thickness.

These observations, along with those of Raider *et al.* aid in confirming the hypothesis that oxidation is an impurity controlled process.

Simple Theoretical Estimates of the Schottky Constants and Virtual-Enthalpies of Single Vacancy Formation in Zinc-Blende and Wurtzite Type Semiconductors

J. A. Van Vechten (pp. 419-422, Vol. 122, No. 3)

J. Jacobs:[35] J. A. Van Vechten has proposed a theory which predicts, seemingly without exception, the charge carrier type of pure semiconductor compounds in the zinc-blende and wurtzite structure from the quotient of the covalent tetrahedral radii (p-type for quotients <1, n-type for quotients >1). Is this the case for zinc sulfide, too? The quotient here is 1.09.

Blount, Sanderson, and Bube[36] treated zinc sulfide crystals at high temperatures in zinc vapor and in sulfur vapor. According to the discussion of the authors and also that of Morozova and Nikitenko[37] is zinc sulfide after sulfur treatment high ohmic p-type with the position of the Fermi level at $E_v + 1.2$ eV. Probably, the intrinsic disorder situation in zinc sulfide is similar to that in zinc selenide. In this material the activation energy of the carrier concentration in the partial equilibrium corresponds to the distance between the corresponding band and the Fermi level in the high temperature equilibrium under extreme metal or nonmetal conditions. From this we conclude the ionization energies of the isolated doubly ionized intrinsic defects.[38] With this note I would also refer to this possibility to determine the ionization energies of the isolated defects, when experiments were carefully analyzed. The formation of complexes and other phenomena, which disturb this determination, apparently does not occur.

J. A. Van Vechten:[39] Of course, it is true that the position of the Fermi level, E_f, in an undoped semiconductor can be influenced by deviations from stoichiometry induced by heat-treatments in an excess of either the metal or the nonmetal component of the compound. Thus, Blount *et al.*[36] reported that they could drive E_f to about 1.3 eV above the valence band maximum, E_v, by annealing "pure" ZnS in S vapor for 8 days at 891°C. (The starting material contained 1×10^{18} Cu/cm^3, 1×10^{18} Si/cm^3, and 5×10^{17} Mg/cm^3.) E_f was then slightly above a defect level at $E_v + 1.2$ eV, which they associated with the zinc vacancy, V_{Zn}. There is no evidence whether or not the V_{Zn} is present in a complex when observed at, or below, room temperature. This material was then very highly resistive ($\sim 10^{10}$ ohm-cm) p-type.

To the author's knowledge, reasonably highly conductive p-type ZnS has never been produced by any means, although conductive n-type ZnS is common. One may conclude that vacancy self-compensation does prevent the attainment of low resistivity conduction only on the p-type side in Zn. Thus, the correlation between the covalent radius ratio and the side on which vacancy self-compensation restricts conductivity is as predicted in the case of ZnS as well as the other II-VI's. No further inference was intended.

It is further noted that in wider gap materials, such as the alkali halides, vacancy self-compensation restricts conduction on both the n- and p-type sides, although deviations from stoichiometry may be obtained, while in smaller gap semiconductors, like GaSb and GaP, the intrinsic conductivity type (p- and n-type, respectively) may be reversed by doping because self-compensation does not occur until after E_f has reached one band edge or another.

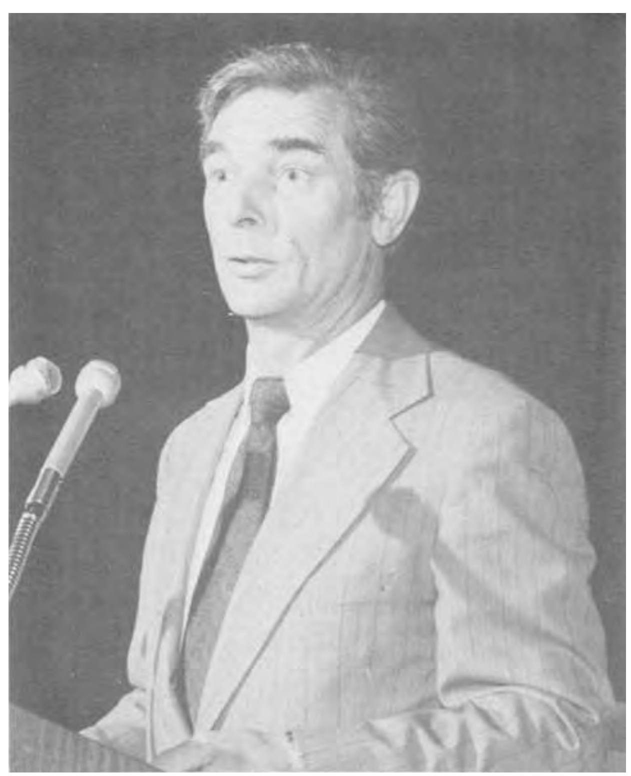
Harry C. Gatos—Solid State Science and Technology Award Medalist

August F. Witt[1]



August F. Witt delivers introductory remarks about the Solid State Science and Technology Award Medalist.

Shortly, Harry Gatos will be the second recipient of The Electrochemical Society Award in Solid State Science and Technology. On the occasion of the award presentation I have the great honor to reflect for a few minutes on Harry's background and technical accomplishments.

To convey to you a real image of his truly outstanding personality I would now have to talk not only about his scientific achievements but also about Harry the poet, the flutist, the violist, the conductor, the educator and, last but not least, about Harry the personal friend. I would have to talk about musical soirees at his home during which he conducted professional musicians performing Mozart and about endless nights spent over the twelfth draft of a publication. I would also have to talk about his family: his son who, at the age of seven, asked me at the beach to do arithmetic with him when I wanted to play ball, and about his daughters who, besides being intelligent, are great young ladies.

Time does not permit me to dwell on this side of Harry's life, so let us look at his biography: Harry was born in Amphissa, Greece, and began his studies in chemistry at the University of Athens where, still an undergraduate student, he functioned as instructor, lecturer, and tutor and wrote his first book on inorganic chemistry at the ripe old age of 22, his second on analytical chemistry at 24, and his third on organic chemistry at 25. In 1946 he was awarded a one-year fellowship for graduate studies in the United States, enrolled at Indiana University and received his M.A. after only 18 months. In 1948 he was admitted to M.I.T., enrolled in the Chemistry Department, and did his graduate work on the passivation of iron in the Metallurgy Department. Only one year after graduation, as research associate at M.I.T., he already did pioneering work on self-diffusion in iron which today is considered one of the classical works on the use of radiotracers for self-diffusion studies.

In 1952 he joined the Engineering Research Laboratory of du Pont where he worked for three years on corrosion and corrosion inhibition of metallic systems. Harry then came back to M.I.T., accepting the position of leader of the chemistry section in the Solid State Group of the Lincoln Laboratory. When the Electronic Materials Group was established, largely on his initiative in 1957, he became its first leader. Besides coordinating and supervising research involving both materials and device oriented groups, initiating new research activities and taking care of administrative details, he found the time to assume the personal responsibility for the growth of a Cr-doped K-cobalticyanide single crystal which was used in the first operational three-level MASER. It was at this time also that he first focused his attention on semiconductor surfaces, semiconductor growth and microsegregation effects, superconductors and high-pressure phase transformation. In 1959 he became Associate Head and in 1964 Head of the Solid State Division of the Lincoln Laboratory. In 1961 he accepted a professorship at M.I.T. which he still holds.

What are his research accomplishments? They are truly outstanding in both quality and quantity, and I can only enumerate. While his leadership abilities forced his attention to the coordination and direction of major research projects and made him devote much of his time to national issues associated with solid-state science and technology, his personal research accomplishments are well documented in over 170 technical publications. During his tenure as Leader of the Electronic Materials Group at the Lincoln Laboratory, the first operation three-level MASER crystal was produced. Soon thereafter his efforts led to an explanation of the polarity effect in III-V and II-VI semiconductor compounds and to a clarification of its implications on the growth characteristics of so-called A and B sur-

[1] Introductory remarks by August F. Witt, Massachusetts Institute of Technology, Cambridge, Massachusetts, on the occasion of the presentation of the Solid State Science and Technology Medal Award to Harry C. Gatos on May 13, 1975, at the Toronto, Canada, Meeting of the Society.

faces which led to a drastic improvement in the growth of defect-free compound semiconductor materials. On the basis of extensive, systematic etching experiments his group identified for the first time α and β dislocations in InSb. He then published the first comprehensive treatise concerned with the etching characteristics of elemental and compound semiconductors. His efforts to bridge the gap between the rigorous formalism used by theoretical physicists and the chemical concepts used by materials scientists in the treatment of semiconductor surfaces led him to the extremely useful concept of "dangling bonds" now generally adopted in the international literature. His research on high pressure phases of compound semiconductors resulted in the discovery of several previously unknown structures, among those the superconducting tetragonal high pressure structure of InSb. He and his collaborators discovered for the first time the existence of nonrotational segregation inhomogeneities in Czochralski-type semiconductors and in a series of publications they subsequently elucidated the microscopic growth and segregation behavior associated with this industrially most important crystal pulling process. Of major impact on the study of semiconductor surfaces was his research effort which led to the development of surface photovoltage spectroscopy and the discovery of a surface piezoelectric effect in noncentrosymmetric semiconductor systems. His most recent accomplishment as head of the Electronic Materials Group at M.I.T. is the development of a quantitative approach to the analysis of crystal growth and segregation on the microscale which is based on the use of growth interface demarcation in combination with high resolution spreading resistance measurements. This work for the first time clarifies previously unexplained discrepancies between theoretical treatments of segregation and experimental results. It also gives direct evidence of convective interference on microsegregation, a phenomenon which had been expected but could only now be unambiguously proven and quantitatively studied.

His current research is concerned with the application of thermo-electric cooling at crystal-solution interfaces for the production of epitaxial layers with controlled composition obtained under constant temperature conditions.

Harry's attitude toward his research is best summarized in a Shakespeare quote:

And now remains
that we find out the cause of this effect
or rather say, the cause of this defect
for this effect defective comes by cause.

Let us now consider the impact of Harry's efforts to advance solid-state science and technology. Harry's internationally recognized outstanding contributions to the advancement of solid-state science and technology are not only his many accomplishments in research. His unique contributions come also from his early realization of the existence of a communications gap between solid-state physicists using rigorous formalism and materials oriented scientists such as metallurgists and chemists operating to a large extent with empirical concepts. This communications gap, in his opinion, relegated electronic materials research for too long to a service function which strongly impeded progress in solid-state technology. Harry's unrelenting efforts to bridge this gap were multifaceted. In his position as leader of the Electronic Materials Group at the Lincoln Laboratory, for which he eminently qualified with his background in chemistry and materials science, he attracted in the mid-1950's outstanding scientists with recognized experimental and theoretical background to electronic materials research and within a few years established an internationally recognized, leading Electronic Materials Research Center. The unique accomplishments of his group in the areas of semiconductor, superconductor, and laser materials and amorphous semiconductors were largely responsible for stimulating similar approaches in other research centers of the United States and the rest of the world.

In his function as chairman of the Electronic Materials Committee of the A.I.M.E. he was instrumental in removing materials research from its isolation by establishing a forum in which electronic materials scientists communicated closely with theoretical physicists and electrical engineers. His efforts led ultimately to the publication of the *Journal of Electronic Materials*. As a member of the Board of The Electrochemical Society he fought for the recognition of the importance of electronic materials research within the realm of the Society's activities. As its elected president in 1967 he strongly supported reorganization of the structure of the *Journal of The Electrochemical Society* which soon thereafter led to the introduction of the subdivision of Solid-State Science and Technology and made the *Journal* one of the most important outlets for publications on solid-state research. Recognizing the importance of surface effects in solid-state research and technology he focused his attention toward surface chemistry and physics and in 1964 founded the journal *Surface Science*. This journal, with strong emphasis on electronic materials, gained within a few years international recognition and constitutes today the most important publication in this field.

In his efforts to advance materials research in solid-state science, Harry recognized significant deficiencies in the educational background of young scientists who had just graduated from outstanding academic institutions. Conspicuous to him was the lack of adequate appreciation for materials on the part of physics and chemistry majors on the one hand and the inadequate solid-state physics background of most majors in metallurgy on the other hand. He resigned as Head of the Solid State Division at the Lincoln Laboratory and assumed a faculty position at M.I.T. with a joint appointment in Metallurgy and Electrical Engineering. He subsequently became instrumental in bringing about changes in the basic curriculum of both departments, changes which have in the meantime been adopted by major academic institutions throughout the United States. He provided, furthermore, the stimulus for the establishment of materials science as a discipline, a concept which is now adopted nationally and internationally.

The Electronic Materials Group at M.I.T., which he founded in 1962, developed into a mecca for scientists in electronic materials from all over the world. (Four of them are currently there doing advanced research and broadening the horizon of his graduate students—needless to say, many of his former graduate students are now actively contributing to the advancement of solid-state science and technology.)

Most recently Harry focused his attention on the potential of zero gravity environment for electronic materials research. He is at this time instrumental in establishing and coordinating a comprehensive exploratory research program aimed at a realistic assessment of the beneficial aspects of outer space conditions on electronic materials processing.

About three years ago Harry told me: "Gus, I'm tired; it is time for me to relax, to lie in the sun and write a book or two." Since then he got deeply involved in space processing, initiated new research activities at M.I.T. concerned with: photo-voltage inversion, the photo-mechanical effect, materials for solar energy conversion, current controlled liquid phase epitaxy, and he is now thinking about a major new involvement in research on the catalytic activity of semiconductor surfaces. Harry, I'm sorry your program for the next ten years is on record—your books must wait.

What else can be said about a man who in twenty years shaped the advancement of solid-state science with forcefulness and determination? I could talk about his accomplishments as chairman and member

on numerous committees, about his national and international awards, about his membership of several academies, about his books and patents—I do not have the time. But I will finally say a word about Harry's great accomplishment which now dates back some 25 years and made all the other accomplishments possible. It was at that time that he succeeded in persuading Dawn to become his wife. It was she who made it possible and still makes it possible for him to operate with efficiency and success, day by day, on a 20 hour work schedule. Congratulations, Harry.

Thank you.

Structure Property Relationships: Key to Solid-State Science and Technology[2]

Harry C. Gatos

Harry C. Gatos presents the Solid State Science and Technology Medal Award Address.

I am deeply honored to be the recipient of the Solid State Science and Technology Award. Having lived the excitement of the explosive and frantic development of solid-state science and technology through the fifties and early sixties, this award, beyond its high status, has special overtones for me. It relates to that electrifying environment in which researchers in the field around the world lived and moved, like fiercely competing athletes bound by the spirit of classical sportsmanship. The field was boiling over: being first to publish on a new result rather than second or third was often a matter of days.

In my research over the years I have been very privileged to work with outstanding colleagues, associates, students, and technical assistants. I am grateful to every one of them. Without their contributions I would not be addressing you today.

In this address I would like first to sketch a historical framework to help view solid-state science and technology in perspective and discuss some of the dominant patterns underlying its growth. Then I will outline the evolution of two of the research themes we have pursued for a number of years. Finally, I would like to share with you some of my views on the future.

[2] Solid State Science and Technology Medal Award Address delivered May 13, 1975 at the Toronto, Canada, Meeting of the Society.

Historical Perspective

The discovery of the transistor has changed the course of science and technology at large more sharply than any other single discovery in history. Semiconductor (solid-state) electronics, an offspring of the transistor, brought into sharp focus the necessity for interdisciplinary research and development on materials. The needs for ultrahigh purity; for large single crystals with high crystalline perfection; for incorporating selected impurity elements at controlled concentration levels in the part per million range; the necessity to know the concentration, mobility, and lifetime of charge carriers; to prepare and understand p-n junctions; to understand and control the surface properties brought together physicists, chemists, metallurgists, and electrical engineers at an unprecedented level of close collaboration. It was this collaboration that proved the striking nonlinear effects of multidisciplinary interactions.

The consequences reached far beyond the rapid development of solid-state electronics and its revolutionary impact on technology. Semiconductors, such as germanium and silicon, familiar only to physicists up to that time, turned out to be a blessed class of materials. They were prepared at purity levels never approached in other material and in single crystal form with nearly theoretical perfection. Consequently, experimental studies became possible at extraordinary stages of refinement. The covalent nature of semiconductors, their well-defined four-nearest neighbor coordination, and their highly directional bonds, made possible elegant theoretical studies. Experiment and theory reinforced each other with an unparalleled effectiveness. The detailed structure of the electron energy bands, the effective masses of the electrical carriers, their transport and scattering characteristics, their interaction with impurity atoms and crystalline defects, and their response to electric and magnetic fields became well-understood realities. Striking experimental developments occurred far more frequently and consistently on semiconductors than in metals or insulators.

Interdisciplinary studies on semiconductor surfaces were intimately interwoven with the study of the bulk. It is perhaps not fully recognized that the discovery of surface states in semiconductors (1947) led directly to the discovery of the transistor. For the first time the study of the electronic and crystalline structure of solid surfaces could be pursued on a quantitative basis.

Semiconductor research led to a situation never before encountered in science and engineering: basic understanding of material overtook materials development and engineering. That is, new fundamental phenomena, properties, and new devices were predicted rather than discovered directly on available materials. For example, basic phenomena such as the cyclotron resonance (which permitted the determination of the

effective mass of the electrical carriers) and numerous devices (including the field-effect transistor) were theoretically described in the context of materials requirements; they reached the experimental stage as the materials requirements were met. In other words, soon after the discovery of the transistor, materials development, rather than basic understanding of materials or device principles, became the slow step in the progress of solid-state electronics. Unfortunately, this situation is still prevalent today.

The contribution of disciplines such as chemistry and metallurgy were certainly basic to the development of solid-state electronics; however, the benefits derived by these disciplines, in return, are not often appreciated. Germanium and silicon (by far the best understood solids) proved unique among all materials for chemical and metallurgical studies and for materials understanding. Purification methods (zone refining) and crystal growth techniques developed for semiconductors were extended to metals, bringing research and development on these materials to a new plateau of refinement. The dislocation theory developed in the early thirties to account for the mechanical behavior of metals was first experimentally verified when edge dislocations in a low-angle boundary configuration were observed in germanium crystals. Screw dislocations and their characteristics were first observed and studied, by infrared microscopy, in copper-decorated silicon crystals; the operation of the Frank-Read source was visually demonstrated in these crystals. Giant strides were made in the understanding of nucleation and growth, solid-state diffusion, segregation phenomena through research on semiconductors. Experimental methods developed for the study of the electronic and crystalline structure, the composition, the stoichiometry and the surfaces of semiconductors were invariably extended to other materials. Finally, the theoretical framework of the energy band structure, electronic transitions, and carrier transport in semiconductors has served as the basis for theoretical advances on metals insulators and other materials.

Through tractable reality, rather than foresight, it was realized that the science and technology of any class of materials (metals, ceramics, glasses, polymers) cannot be fostered within the confines of individual classical disciplines. Materials science and engineering emerged from solid-state electronics as a discipline in itself but linked effectively to the classical disciplines. Solid-state science and technology, rooted also in semiconductor electronics, now encompasses the study and applications of a broad spectrum of materials and phenomena. It interacts intimately and to some extent overlaps with materials science and engineering, with physics and with electrical engineering (Fig. 1).

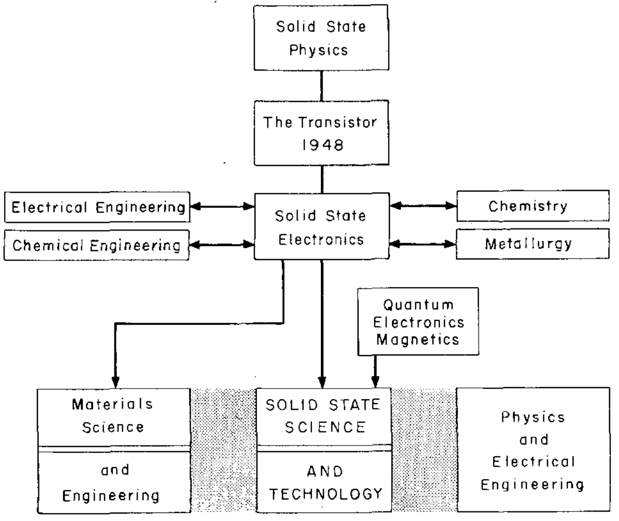


Fig. 1. Solid-state science and technology in perspective

Structure-Property Relationship

Structure-property relationships have been useful for some time in accounting qualitatively for the behavior of solids and in pointing to new directions for the search for materials with improved properties. But they became the driving force of progress in semiconductor and solid-state electronics. Electronic properties are strongly dependent on "structure," *i.e.*, on composition, crystalline structure, lattice defects, and interatomic forces. Because of the unique nature of semiconductors, this dependence can usually be pursued on a quantitative basis: The properties can be experimentally measured reliably and accurately. The "structure" cannot only be experimentally determined, but it can be controlled and varied at will often with high precision; the composition (level of desired impurities) can be controlled in the part per million range; nearly perfect single crystals can be prepared (with zero dislocation density); interatomic forces (strength and nature of bonding) vary in a known way from one semiconductor to another or can be carried at will by controlled alloying.

At the same time, semiconductors lend themselves better than any other solids to the development of theoretical treatments and theoretical calculations. Thus, feedback between theory and experiment has led to an avalanche of new experiments and basic understanding. Device development is also interwoven in the fabric of structure-property relationships. The identification of the "structural" parameter related to specific effects has been the way to device development, to prediction of new devices and new device-functions.

A comprehensive illustration of the interplay between structure-property relationships and progress in the evolution of solid-state science and technology, would certainly make a fascinating and most instructive document. I hope someone undertakes this task some day. I will only touch on it here.

One could start with the studies just preceding the discovery of the transistor. A group, now famous, at the Bell Laboratories was studying metal-semiconductor rectifying contacts; according to theory, the potential barrier in a given semiconductor should be greater (and the rectifying characteristics better), the greater the work function of the contacting metal. But using germanium as the semiconductor the height of the potential barrier was found to be independent of the contacting metal. Through a stroke of genius, this behavior was related to a "structural parameter" of the semiconductor: surface states within the forbidden energy gap; these states trap charge carriers and lead to a surface barrier, characteristic of the semiconductor rather than of the metal-semiconductor contact. Thus, a structure-property relationship was formulated; it set things into motion; the existence of surface states had to be verified. The ingenious field-effect experiment was conceived which not only verified the existence of surface states, but revealed their detailed characteristics. Experiment reinforced theory, and new structure-property relationships with device implications evolved. The transistor was discovered. In turn, its function and improved performance was related to "structural" parameters, *i.e.*, to types, concentration levels, and configurations of dopant impurities and to crystalline perfection. These parameters were identified and studied; their control was improved. Better devices were obtained and new devices were conceived; further refinements in materials were indicated. The study of processing parameters for improving the quality of materials entered the feedback loop. Planar diffusion and epitaxial growth methods, developed for improving the control of dopant concentration, opened the way to integrated circuitry. In parallel experimental techniques for materials characterization were developed to keep pace with the advancing level of materials refinement. Such self-feeding progress through structure-property relationships has no precedent in the history of science and technology. Originally germanium, and subsequently silicon, have

been the materials in this evolution, but certainly not the only ones. Behind the recent precipitous entry of the light-emitting devices (based on III-V semiconductor compounds) into solid-state electronics there is a similar pattern of development (Fig. 2).

Through the evolution of solid-state science, theory has made enormous advances. For example, band-structure theories can determine with remarkable precision the electronic properties of some solids. Theory, however, has not as yet predictive powers in relating the electronic properties to the composition or defect structure of the crystals. Empirical, intuitive and semi-quantitative structure-property relationships will continue to be at least for the foreseeable future, the key to solid-state science and technology.

Tracing the Evolution of Two Research Themes

As I reviewed the structure-property and structure-processing programs I have worked on in the last twenty years, I decided to discuss two of them. I chose them not necessarily because of their greater importance, but because, all these years, they have survived the changes in fashion and the points of diminishing return. The one was initiated to investigate the "structural" parameters responsible for the chemical behavior of semiconductor compound surfaces; the other was initiated to study the processing variables responsible for the composition (dopant distribution) and the defect structure of semiconductors. In the interest of time I will attempt to convey a general impression rather than present a rigorous account of our findings.

Semiconductor Compounds

In 1956, together with Mary Cretella-Lavine, I became involved in the study of the chemical behavior of the $A^{III}B^{V}$ compounds (*e.g.*, InSb), then a relatively new class of semiconductors. Because these compounds have the noncentrosymmetric (crystallographically polar) zinc-blende structure their {111} surfaces must terminate with Group III or A atoms, *e.g.*, In atoms; on the other hand, the $\{\bar{1}\bar{1}\bar{1}\}$ surfaces must terminate with Group V or B atoms, *e.g.*, Sb atoms (Fig. 3). These two types of surfaces are referred to as A and B surfaces, respectively. We observed, as others had, that the etching behavior of the A surfaces is strikingly different than that of the B surfaces (Fig. 4) and that edge dislocation can be revealed, as etch pits, only on the A surfaces (Fig. 5); this behavior was particularly puzzling because the observed etch pits were associated with only one type of edge dislocations, namely, those whose dislocation line consisted of A atoms (α dislocation); dislocations with their line consisting of B atoms (β dislocations) should also be present in these compounds; furthermore, edge dislocations must intersect both A and B surfaces (Fig. 6).

In germanium, Walter Harvey had found that the dissolution rates of the various crystallographic planes,

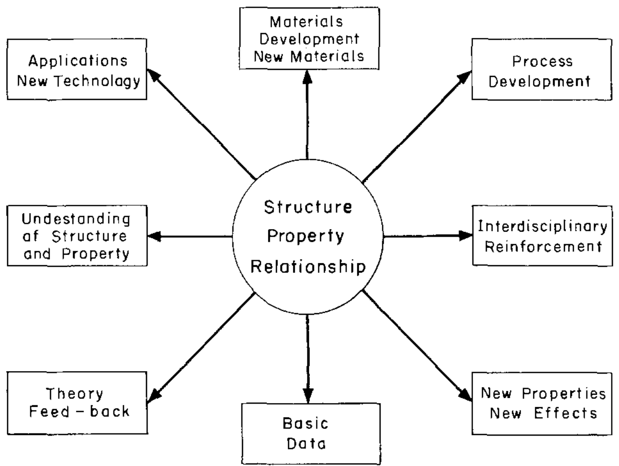

Fig. 2. Dynamics of structure-property relationships

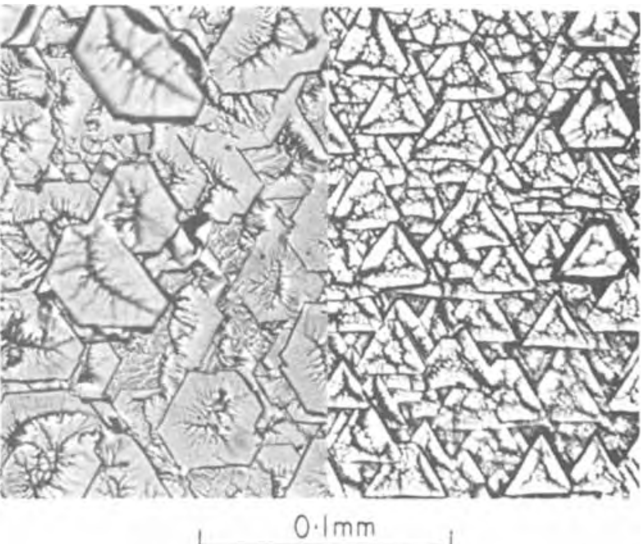

Fig. 4. The A (left-hand side) and B (right-hand side) surface of an InSb wafer etched in Fe^{+++} etchant.

in oxidizing solutions, were related to the density of their dangling bonds. But the density of dangling bonds is the same on the A and on B surfaces. We turned our attention to the nature of the dangling bonds and arrived at the following model: The Group III atoms on the A surfaces cannot have dangling electrons, as they must share their three electrons in forming three bonds with the lattice; on the other hand, each Group V atom on the B surfaces contributes three of its five electrons to the three bonds with the lattice, and thus, must have two (paired) dangling electrons (Fig. 7).

We proceeded to test the obvious implication of this simple model. The B surfaces, whose outermost atoms have two unshared electrons, must react much faster in oxidizing media than the A surfaces whose atoms have no available unshared electrons. From single crystals of InSb we prepared two types of tetrahedral samples, one bounded by A surfaces and the other bounded by B surfaces (Fig. 8). Using such samples we found that indeed the dissolution rate of the B surfaces in oxidizing solutions was an order of magnitude greater than that of the A surfaces. On the basis of this finding, *i.e.*, that the triply bonded B atoms are much more reac-

tive than the triply bonded A atoms, it was relatively straightforward to explain why only α dislocations and

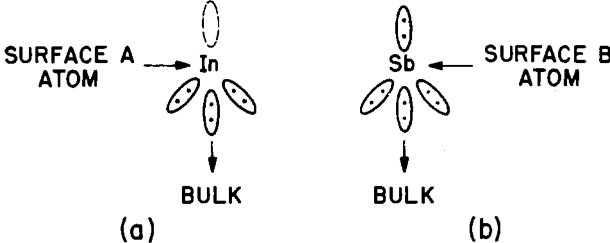

Fig. 7. Atomic model of the A and B {111} surfaces of the $A^{III}B^{V}$ compounds (e.g., InSb). The A surface atoms have no dangling electrons, (a), whereas each B surface atom has two dangling electrons (b).

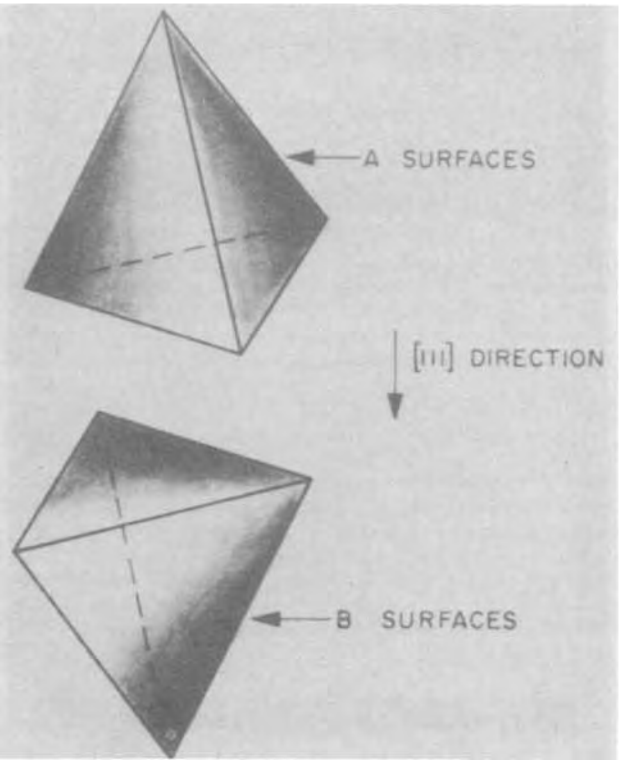

Fig. 8. Two types of tetrahedra of an $A^{III}B^{V}$ compound; one has only A surfaces and the other only B surfaces. Both types are obtained from the same single crystal. Compare geometric relationship of the tetrahedra with Fig. 1.

only on the A surfaces can lead to the formation of etch pits. Our structure-property relationship had survived its first test. But if the presence of unshared electrons was responsible for the high reactivity of the B surfaces in oxidizing media then this reactivity should decrease in the presence of electrophilic chemical compounds which attach themselves to unshared electrons. When we added small amounts of electrophilic organic compounds to oxidizing etchants the reactivity of the B surfaces of InSb decreased and approached that of the A surfaces. Under these conditions, α as well as β dislocations were revealed, through etch pit formation, on both types of surfaces (Fig. 9).

Thus, the presence of two types of dislocations in the $A^{III}B^{V}$ compounds (see Fig. 6) was confirmed by chemical etching. Furthermore, these results provided direct evidence that the formation of dislocation etch pits is controlled by the chemical reactivity of the dislocation and surface atoms; until that time it was generally believed that the strain fields associated with edge dislocations are responsible for the formation of dislocation etch pits.

This early success pointed to a closer examination of the model. The atoms in the III-V compounds are tetrahedrally bonded (diamond structure); can the

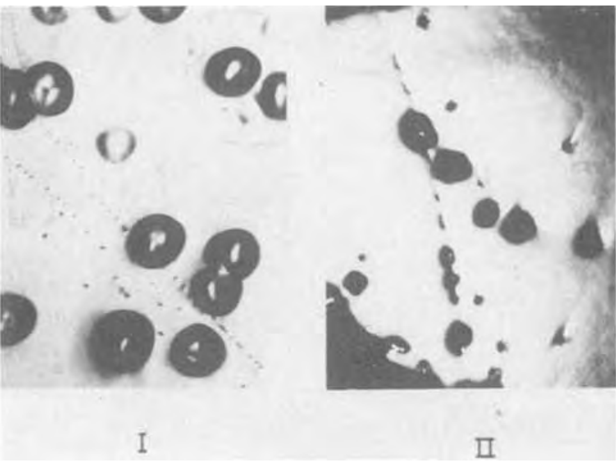

Fig. 9. Dislocation etch pits on the A (I) and B (II) surfaces of an (111) InSb wafer. Two types of pits (small and large) are clearly seen on the A surfaces. A modified CP4 etchant was saturated with stearic acid. 90X.

bonds of the surface atoms maintain this angular configuration? In the case of the B atoms with a pair of electrons occupying the unshared (dangling) tetrahedral orbital, no significant distortion would be expected. However, tetrahedral configuration should not be possible in the case of A surface atoms where there are no electrons in the dangling orbital (see Fig. 7); accordingly, the triply bonded A atoms should exhibit a strong tendency to acquire planar (sp^2) bonding, characteristic of the Group III elements in their compounds with nonmetals. Thus, the A surface atoms should arrive at a distorted configuration, in between tetrahedral and planar; assuming no major surface reconstruction, this distorted bonding configuration must introduce significant strain in the A surfaces in the form of stored elastic energy. The implications of this aspect of the model were pursued.

X-ray diffraction techniques showed indeed that the A surface of a single crystal sample (*i.e.,* InSb) exhibited significant strain in contrast to the B surface. This result was confirmed by much simpler means. After abrading both surfaces in the same way it was found that the depth of damage was much greater in the B surface than in the A surface; clearly, the A surfaces with their stored elastic energy are more resistive to abrasion than the B surface (Fig. 10).

Crystal growth has always been (and still is) basic to semiconductor research and development. In the fifties, the growth of single crystals presented far greater difficulties in the case of compounds than in the case of elemental semiconductors; could the surface structure implications of our bonding model be related to crystal growth? If the A surface was inherently strained, then the B surface of a <111> seed should be more suitable for crystal growth than the A surface. We tested this prediction on the growth of both InSb and GaAs crystals. Single crystals could be obtained only when the B surface of the seed was used. When the A side of the seed was used twinning or polycrystallinity could not be avoided. Paul Moody, who did the experiments, had been growing InSb crystals in the <111> direction for the entire solid-state group at the Lincoln Laboratory. In checking his laboratory notebooks he found that among numerous InSb crystals he had grown before these experiments, only one-half of them were single; he, thus, proved that the probability of using the proper end of a seed coincided with the probability of obtaining single crystals. Since the time of this finding, the B surface of the seed is being used for growing III-V compounds from the melt in the <111> direction. In epitaxial growth also, the B surface is the preferred substrate surface. Furthermore, the elastic stored energy in the A surfaces of III-V compounds is now implicitly taken into consideration in III-V semiconductor layer device structures.

The stored elastic energy on the A surfaces manifested itself directly in thin (111) wafers; such thin (about 10 μm) wafers prepared from single crystals of several $A^{III}B^{V}$ compounds were spontaneously bent (Fig. 11); the elastic strain on the A surfaces overcame the cohesive energy of the wafers. From the radius of curvature of the spontaneously bent InSb wafers, their dimensions and elastic parameters, Rodney Hanneman calculated the elastic stored energy ($\sim 1 \times 10^{-6}$ ergs/g-surface atom) using the classical theory of elasticity; this result was in good agreement with the elastic stored energy he calculated from x-ray diffraction data.

Turning to the electronic properties, the A surface atoms having no dangling electrons should be electron acceptor-type, whereas the B surface atoms should be electron donor-type. The implications of the bonding model on the electronic characteristics of the A and B surface are schematically illustrated in Fig. 12. A direct electronic characterization of III-V semiconductor compound surfaces presented severe experi-

mental difficulties. We arrived, however, at the electronic characterization of the triply bonded A and B atoms through a relatively simple approach: the dislocation lines of the α dislocations consist of triply bonded A atoms and those of the β dislocations consist of triply bonded B atoms (see Fig. 6); accordingly, n-type InSb single crystal samples were deformed so as to introduce either excess In dislocations or excess Sb dislocations; as predicted, the samples with excess In dislocations became less n-type, *i.e.*, the triply bonded In atoms introduced acceptor levels; the samples with excess Sb dislocations became more n-type, *i.e.*, the triply bonded Sb atoms introduced n-type levels.

The class of $A^{II}B^{VI}$ semiconductor compounds (*e.g.*, CdS) had not received nearly as much attention as the III-V compounds in the late fifties. These compounds have the noncentrosymmetric wurtzite or zinc-blende structures; like the III-V compounds, they are characterized by sp^3 (tetrahedral) bonding. The absolute identification of the A and B surfaces had not been carried out. Edward Warekois achieved this identification by x-ray diffraction techniques, on eight II-VI compounds.

As in the case of the III-V compounds, in all II-VI compounds also pronounced differences in etching behavior were observed between the A and B surfaces. These differences were correlated with the x-ray results so that the identification of the A and B surfaces was reduced to simple etching tests. The surface properties of these compounds were also successfully related to the bonding characteristics of the A and B atoms. The stored strain energy due to bonding distortion in the A surfaces was confirmed by the spontaneous bending of thin (00.1) wafers. Most recently the nature of this distortion was theoretically calculated for the Zn surfaces of ZnO from LEED intensity data by other investigators.

In the early sixties Shinji Kawaji undertook to study, in our new electronic materials group at M.I.T., the electronic characteristics of the A and B surfaces of InSb employing field-effect techniques. He and Howard Huff found that surface states present on the A surfaces were characteristic of the triply bonded In atoms and surface states of the B surfaces were characteristic of the Sb atoms consistent with the bonding model. This work clearly showed the significant influence of crystallographic polarity on the electronic behavior of semiconductor compounds. The implications of the bonding model on the electronic characteristics of the A and B surfaces as illustrated in Fig. 12 were directly confirmed later on by other investigators on cleaved (00.1) surfaces of ZnO. In the course of his studies Shinji Kawaji observed quantization of the motion of electrons in the surface region in the presence of electric and magnetic fields; this phenomenon became of significant interest in understanding carrier transport phenomena in semiconductors.

Extensive efforts in our group to study the electronic characteristics of surfaces of high energy gap semiconductor compounds, *i.e.*, GaAs and CdS, led us to the conclusion that the field-effect technique was not applicable to the detailed study of surface characteristics of such semiconductors and that no experimental method was available for the purpose. The experimental approach in this instance, as is often the case, became an end itself rather than a means to an end.

Jacek Lagowski joined the group in the early seventies as Chester Balestra was investigating the electronic characteristics of CdS surfaces by a photovoltage approach employing a method he developed for linear off-null measurements of the contact potential difference (cpd). In exploring the effects of illumination on the height of the surface barrier, they observed that discreet electron transitions from the surface states to the conduction band (surface-state depopulation) and from the valence band to the surface states (surface-state population) could be identified when illumination energies less than those corresponding to the energy gap were employed (Fig. 13). From the values of the surface photovoltage (changes in the surface barrier) as a function of the energy of the monochromatic sub-bandgap illumination, spectra were obtained from which the energy levels of the surface states could be directly determined. Surface photovoltage spectroscopy was born. The transients of the surface photovoltage provided the means for determining the dynamic parameters of the surface states such as occupancy, capture cross section and others. A detailed characterization of the electric configuration of CdS and GaAs surfaces was achieved. A surface photovoltage spectrum of the prismatic surfaces of CdS is shown in Fig. 14, and the data obtained from this spectrum are summarized in Fig. 15.

Jacek Lagowski became interested in reexamining the bonding model on thin (00.1) wafers of CdS. Like the thin wafers of other noncentrosymmetric compounds the CdS wafers were also spontaneously bent.

The insert shows the derivative of surface photovoltage (cpd) with respect to the photon energy at two typical step-like increases in the photovoltage; each peak gives the energy position of a surface state.

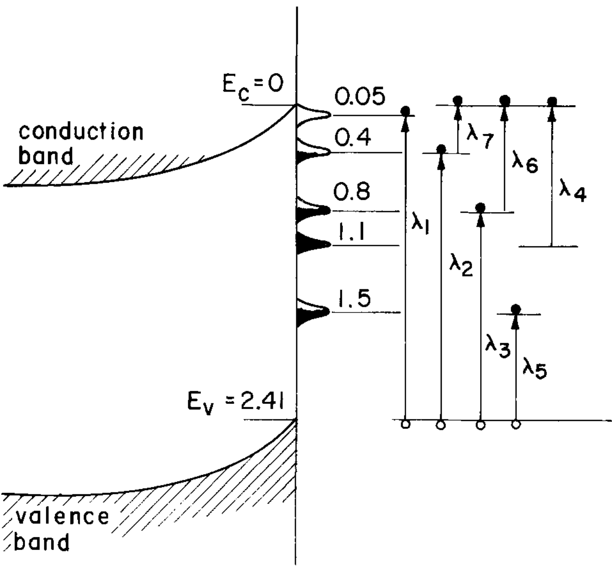

Fig. 15. Energy positions of the surface states in the prismatic surfaces of CdS and the associated electron transitions.

In studying these wafers he observed that illumination with white light led to far greater bending than that caused by stored elastic energy. This behavior represented a new effect associated with light-induced changes in the electric field at the surface (*i.e.*, changes in the surface barrier) and thus, with light-induced surface strains, since CdS is a piezoelectric material. The electric field (and thus the strain components) in the basal surfaces is in opposite directions because a depletion layer is present at both parallel surfaces. Consequently, upon illumination, one surface is under compression and the other under tension, and the wafer undergoes bending. We called this phenomenon the photopiezoelectric effect. The wafers, anchored at one end, were excited to their fundamental-frequency vibration when the electric field was modulated at that characteristic frequency by chopped light (Fig. 16).

It was subsequently found that, under sub-bandgap illumination, the amplitude of the photo-induced vibration underwent changes at illumination energies corresponding to electron transitions from or to the surface states. In fact, the spectra of the amplitude of the vibration as a function of the wavelength of the illumination were virtually identical to the surface photovoltage spectra (Fig. 17). The amplitude of the vibration was found to be very sensitive to the intensity of illumination; light intensities of the order of 10^{11} photons/cm^2/sec could readily be detected. Furthermore, the amplitude of the vibrations was found to be sensitive to very small amounts of ambient gases causing changes in the surface state configuration. Thus, the photopiezoelectric effect constitutes a very sensitive means for photodetection and for the detection of trace amounts of ambient gases.

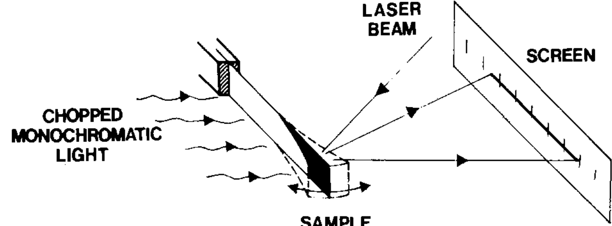

Fig. 16. Experimental arrangement employed in observing and studying light-induced mechanical vibration.

The normal mode of vibration of (111) GaAs wafers with a thickness below 15 μm was found to depend on the surface preparation and the ambient atmosphere. This dependence was attributed to effects directly related to surface stress; accordingly, a new method was developed for determining the surface stress in solids from the natural frequency vibration.

The photopiezoelectric effect should have its reverse counterpart, and it does. Mechanical bending of

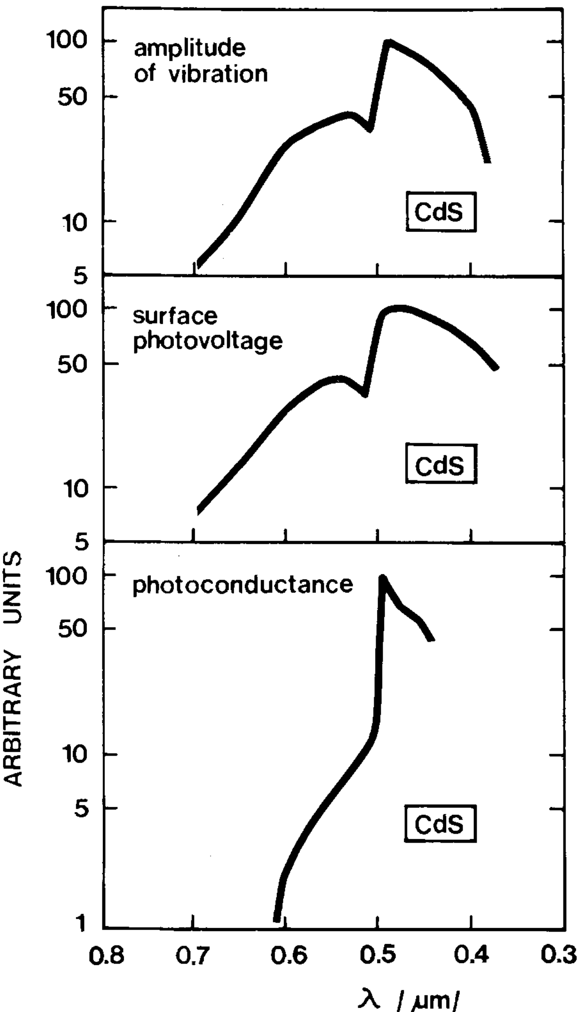

Fig. 17. Typical spectra of the amplitude of the light-induced vibration, surface photovoltage and photoconductance of (00.1) CdS wafers; frequency of light-chopping ≃ 104 Hz.

thin (00.1) wafers of CdS and other crystallographically polar semiconductors was found to cause pronounced changes on the surface barrier. This new effect we called the surface piezoelectric effect: strain due to bending leads to changes of the electric field in the space charge region. Accordingly, the surface piezoelectric effect provides the means for changing the electric field at the surface; it permits field-effect experiments, without an external electrode, and the determination of the surface potential employing a cpd probe for monitoring changes in the height of the surface barrier. Thus, this effect is a powerful complement to surface photovoltage spectroscopy for the electronic characterization of surfaces.

Since in thin wafers of semiconductor compounds the surface barrier is a sensitive function of the radius of bending (or stresses in general) the surface piezoelectric effect is a powerful tool for determining the curvature or changes in curvature of solids or for determining very small stresses.

Surface photovoltage spectroscopy as outlined above or with some modifications is now widely used for the study of surfaces and interfaces in semiconductors or semiconductor device structures.

With the new surge of interest in chemisorption and catalysis, the importance of the surface barrier and surface states of semiconductor catalysts in these processes (recognized about twenty-five years ago) have been brought into sharp focus. At the present, surface photovoltage spectroscopy in conjunction with the surface piezoelectric effect, represent the only direct experimental approach to this problem. The interaction of gaseous species with semiconductor surfaces via surface states and the study of the associated charge transfer can be directly studied with surface photovoltage spectroscopy. The surface piezoelectric effect is uniquely suited for varying at will the height of the surface barrier on a given sample without altering the surface-state configuration. Our preliminary results on the interaction of oxygen and carbon monoxide with ZnO are extremely promising. They could represent the first step towards advancing our understanding of catalytic processes involving semiconductor catalysts.

Relating chemical bonding to chemical, mechanical, structural, and electronic properties of compound semiconductors has led us, for about twenty years, to many directions for fruitful research and applications. Still our original bonding model has not outlived its usefulness.

Crystal Growth and Dopant Segregation

From the very start of solid-state electronics, it was found that the dopant elements were not homogeneously distributed in the single crystals. About twenty-five years later we are still confronted with the same problem. This problem is as acute today as it was then, not because progress has not been made in crystal growth and dopant segregation, but rather because much greater progress has been made in decreasing the size and extending the functions and complexity of semiconductor devices

Like many solid-state groups around the world our group at the Lincoln Laboratory became involved in investigating the origin of dopant inhomogeneities. Periodic inhomogeneities always present in Czochralski-pulled crystals had been found to be associated with the seed rotation, and in fact their period had been shown to be the same as the period of rotation. In the late fifties, with my colleagues at the Lincoln Labratory, we performed a simple experiment; we pulled a segment of an InSb crystal without rotating the seed. The normal rotational inhomogeneities were not present in this segment but inhomogeneities were there (Fig. 18). Their presence indicated temperature fluctuations at the growth interface, but the origin of such fluctuations was quite puzzling.

While a number of groups were theoretically and

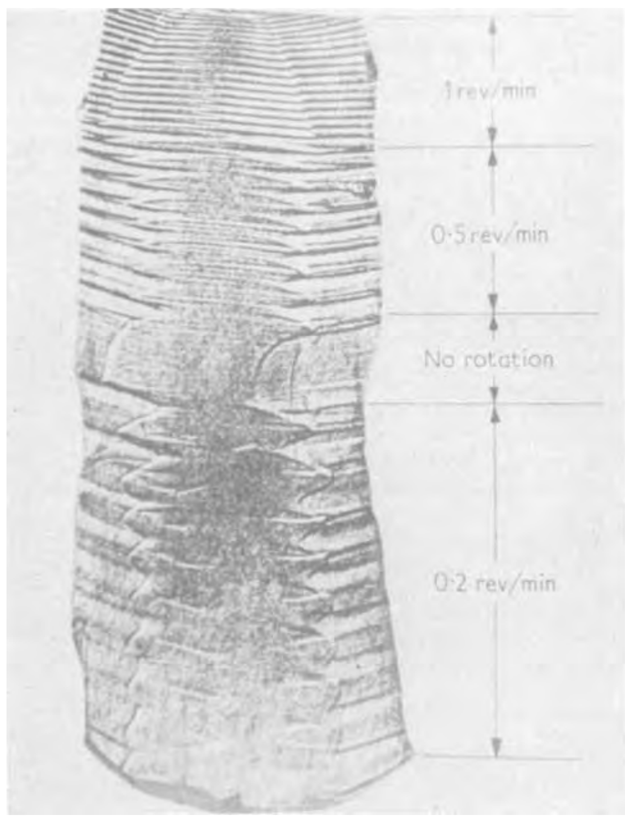

Fig. 18. Longitudinal etched section of a Se-doped InSb crystal. Dopant striations are present in both the rotated and unrotated segments of the crystal. 5X.

experimentally demonstrating temperature fluctuations in melts under thermal gradients, we set out in our new electronic materials group at M.I.T. (1962) to study the nature and origin of dopant inhomogeneities in semiconductor single crystals. We began with InSb primarily because its low melting point minimized experimental complexities. Professor Witt joined the group three years later, was fascinated by the problem, and became a partner in the work and a prime mover.

The main tools for studying dopant inhomogeneities were then, and still are, chemical etching and optical microscopy. Professor Witt began to sharpen these tools and has sharpened them to their limit. With every increase in the resolution of etching and optical microscopy new types of dopant inhomogeneities were being revealed (Fig. 19).

Kenji Morizane devoted his post-graduate years to the study of dopant inhomogeneities in InSb. He developed the first quantitative model showing that, in Czochralski-pulled crystals, grown under seed rotation, the microscopic rate of growth cannot be the same as the pulling rate. It must vary sinusoidally when the thermal axis of the isotherm at the growth interface does not coincide with the axis of rotation, *i.e.,* due to thermal asymmetry in the melt, the microscopic growth rate must gradually increase from a minimum to a maximum and then decrease again to a minimum within each rotational cycle. Thus, the portion of the crystal grown under increased rate is larger than the corresponding portion grown under decreased rate within a given cycle. Consequently, a greater dopant concentration (for a distribution coefficient smaller than one) is expected in the portion grown at an increased rate than in the portion grown at a decreased rate. Thus, a crystal grown under rotation should exhibit impurity inhomogeneities consisting of alternating broad and narrow bands. The narrow bands whose width becomes very small, depending on

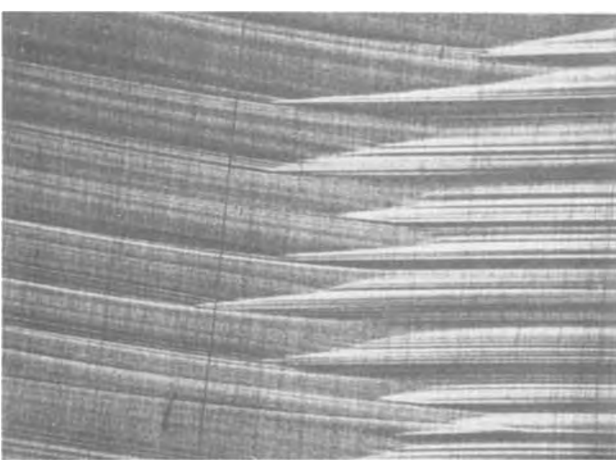

Fig. 19. Etched (211) section of a Te-doped InSb crystal showing the presence of rotational and other types of dopant inhomogeneities. 190X.

the extent of thermal asymmetry, constitute the rotational striations (Fig. 20). The model further predicted that under pronounced thermal asymmetry the microscopic growth rate should assume negative values, *i.e.*, backmelting should take place within each rotational cycle. Indeed, rotational backmelt striations were identified in InSb crystals (Fig. 21).

The Morizane model brought us to an impasse. To pursue the study of dopant inhomogeneities in semiconductor crystals, it was now essential to determine the microscopic growth rate since the pulling rate was shown to be of little relevance; it was also essential to know the dopant concentration on a microscale. At that time there was no method available for determining microscopic growth rates; dopant microprofiling could only be achieved by radio-tracer or other equally complex techniques.

Unexpectedly, we observed in an InSb crystal a type of pronounced dopant striations which had not been observed previously. They were superimposed on the normally observed striations, persisted throughout the crystal and were rather evenly spaced. We suspected that a mechanical vibration of constant frequency was present during the growth of the crystal; its origin was unknown. From the pulling rate and the average spacing of these striations we determined the frequency of the undesirable vibration and traced its origin to a poorly mounted mechanical vacuum pump. This incident turned into an important discovery: We introduced a mechanical vibration of known frequency into the melt (by coupling a vibrator to the crucible) and found that each individual vibration could be identified into the grown crystal as a dopant striation; the normal growth process was not affected. An experimental method for determining microscopic growth rates was now at hand. From the known frequency of the vibration and the separation of the resulting striations in the crystal we could determine the microscopic growth rate throughout the crystal growth process. We called these intentionally introduced striations "rate striations."

Fig. 20. Rotational striations (narrow lines) in a Te-doped crystal of InSb. Although the pulling rate and the rotation rate were maintained constant during growth, the distance between rotational striations is not constant, indicating that the actual growth rate is not the same as the pulling rate. 150X.

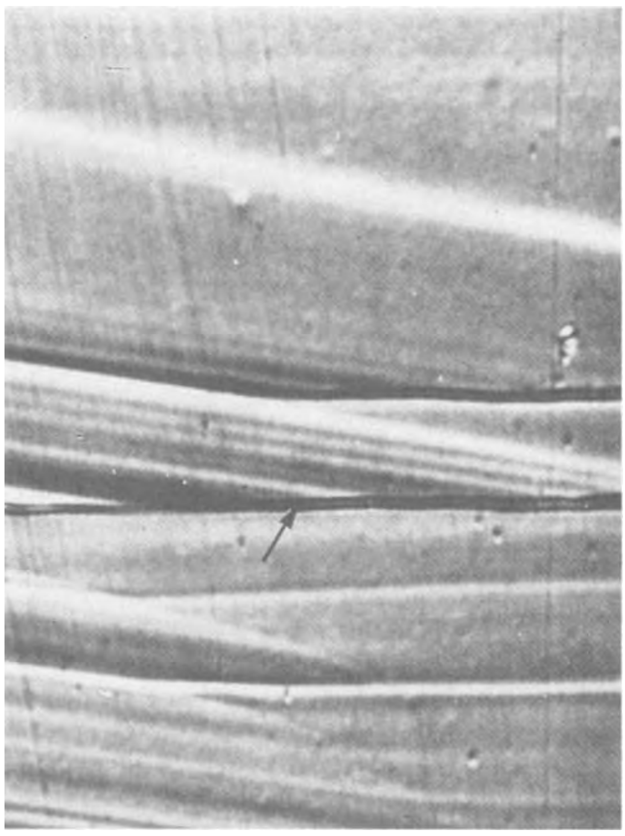

Fig. 21. Rotational backmelt striations (one is indicated by arrow) in a Te-doped InSb crystal. The abrupt termination of nonrotational striations at the rotational striations is caused by the backmelting associated with the formation of the rotational striations. 600X.

We demonstrated that the microscopic growth rate is not the same as the pulling rate and that in fact it varies significantly depending on the thermal conditions prevailing during growth (Fig. 22, 23). The model of Kenji Morizane was proven to be correct. Soon after Ranjit Singh discovered that rate striations could be introduced into the growing crystals, far more advantageously, by transmitting current pulses of known frequency across the growth interface. Each current pulse, depending on its polarity, causes Peltier cooling or heating at the growth interface. The growth rate is thus suddenly increased or decreased for the duration of the pulse (of the order of 30 msec), and a striation is formed in the crystal. Ranjit Singh went on to accomplish experimentally the quantitative study of oscillatory interface instability associated with constitutional supercooling (in germanium crystals grown from heavily doped melts). He determined for the first time the wavelength and phase velocity of this instability and provided a testing ground for theoretical treatments.

Manfred Lichtensteiger refined the technique and showed that the characteristics of the pulse (rise time, duration, and shape) are precisely reflected in the induced striations (Fig. 24). The delineation of the growth interface into the crystal by current pulses provided a new basis for pursuing crystal growth and segregation. We called this technique interface demar-

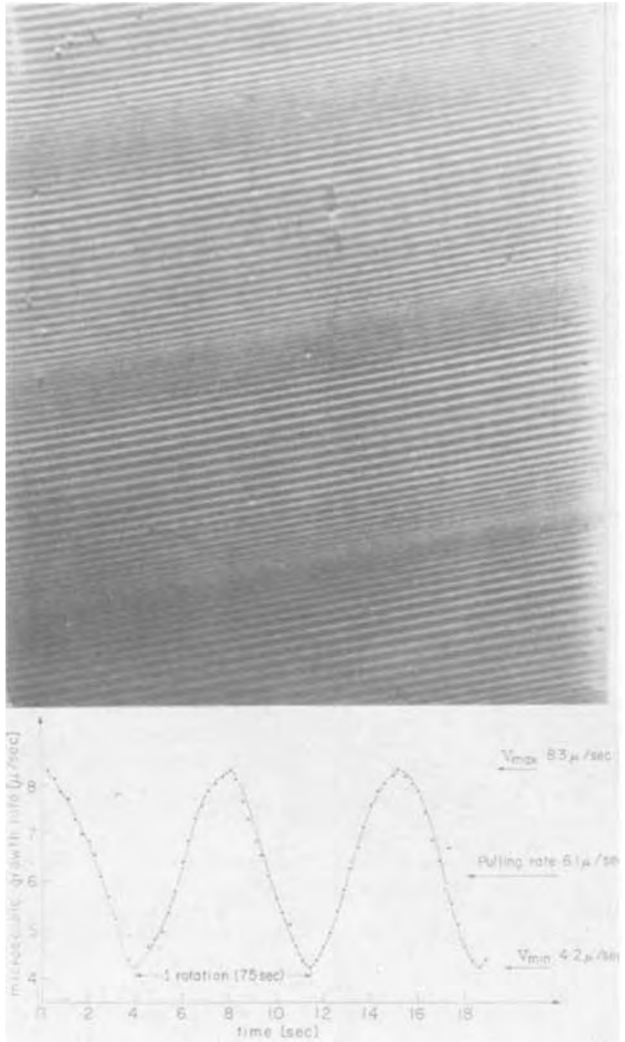

Fig. 22. Cross-section of a Te-doped InSb crystal grown with seed rotation. Rate striations were introduced by a vibration of constant frequency. The variations in the spacing of the rate striations reflect fluctuations in the microscopic growth rate. Rotational fluctuations appear as areas of decreased growth rate (close spacing of rate striations). 550X. The microscopic growth rates of this section are shown in the lower part of the figure.

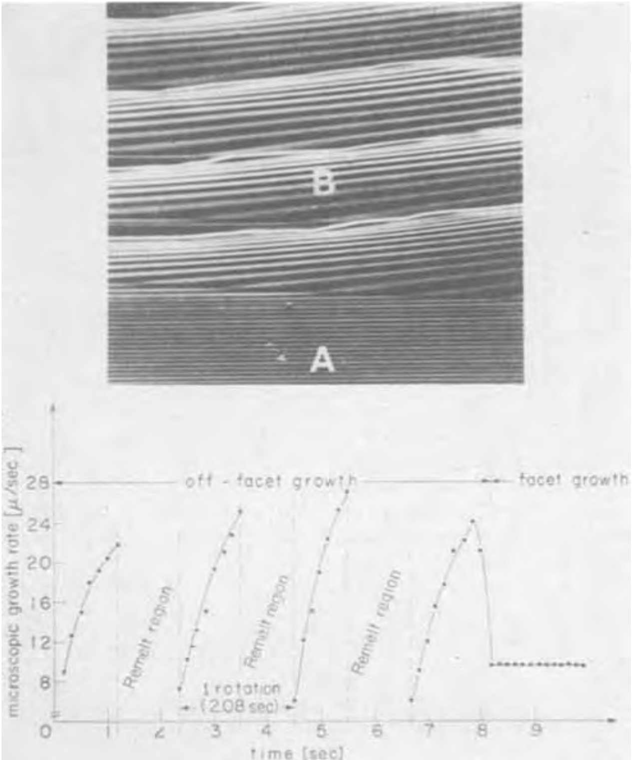

Fig. 23. Cross-section of a Te-doped InSb crystal grown under pronounced thermal asymmetry. The upper part of the crystal segment shown was grown with seed rotation; rotational backmelt striations are visible. The lower part of the segment was grown without rotation; the constant spacing of the rate striations in this part show that thermal asymmetry does not affect the microscopic growth rate in the absence of rotation. 750X. The microscopic growth rates (determined from the rate striations) are shown in the lower part of the figure.

cation. Without interfering with the over-all growth process, the current-induced striations permit not only the determination of the microscopic growth rates, but also they delineate into the crystal the exact morphology of the growth interface at precisely known instances in time. They serve, thus, as time markers for establishing directly cause and effect relationships, in absolute time, between the prevailing growth conditions and the characteristics of the resulting crystal.

Kyongmin Kim established such cause and effect relationships in his InSb growth experiments under destabilizing thermal gradients. He introduced thermocouples into various parts of the melt and recorded continuously the thermal characteristics of the melt during growth. Current pulses, transmitted at known time intervals, delineated the interface into the growing crystal; simultaneously, through electrical induction, the pulses were sensed by the thermocouples and registered on the temperature recording. Thus, after the experiment, the characteristics of any microscopic segment of the crystal could be related to the thermohydrodynamic characteristics of the melt in absolute time. With continuing growth the melt exhibited successively turbulent convection, oscillatory thermal instability, and finally, thermal stability. During turbulent convection the crystal underwent pronounced transient backmelting and the average microscopic growth rate was independent of and up to twenty times greater than the average macroscopic growth rate. In the region of oscillatory instability in the melt the crystal exhibited fluctuations in dopant concentration with a periodicity identical to that of the thermal oscillations in the melt (Fig. 25). Under stabilizing thermal gradients (no temperature fluctuations in the melt), the microscopic and macroscopic growth rates were identical and fluctuations in dopant concentration could not be detected (Fig. 26). A cause and effect relationship between the thermohydrodynamics of the melt and crystal growth was established.

As high resolution etching, interference contrast microscopy and interface demarcation brought us to a new plateau for investigating growth and segregation phenomena, the quantitative determination of compositional variations in the crystals on a microscale became a necessity for further studies. In assessing possible approaches to the problem Ashok Murgai concluded that suitable compositional microprofiling in semiconductors could be achieved by spreading resistance measurements. It had been demonstrated by a number of investigators that the measured resistance by pressing a fine metal probe against a semiconductor could be reduced to the dopant (carrier) concentration of a small volume element in the semiconductor. By traversing the probe (or the semiconductor sample) composition microprofiles, with a resolution of the order of 20 μm, had been obtained.

Manfred Lichtensteiger modified a commercial spreading resistance probe and developed surface preparation techniques so that microprofiling, with a resolution of less than 5 μm, could be obtained on the identical surface on which rate striations were revealed for the simultaneous determination of the

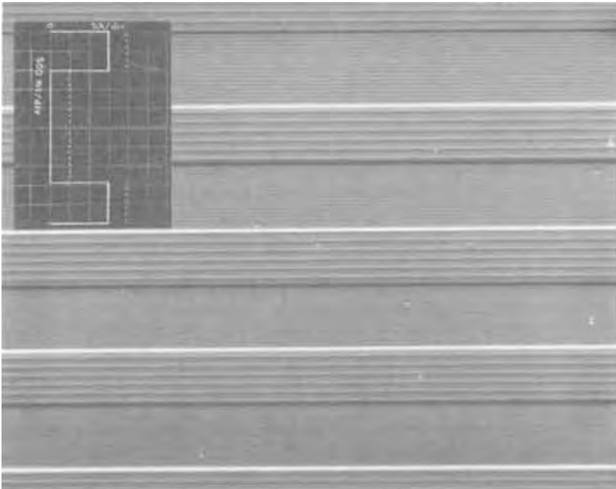

Fig. 24. Cross-section of a Te-doped InSb crystal grown without rotation. As seen from the insert, for 1 sec the crystal was grown with current passing through the interface and for 3 sec without current. Current pulses were of 15 msec duration and a frequency of 6/sec. Each current pulse introduces a well-defined rate striation. It is seen that the separation of the rate striations is much greater in the regions grown with current (they contain six rate striations) showing that the current accelerates crystal growth significantly. The regions grown without current contain eighteen rate striations (the 15 msec current pulses do not perturb the over-all crystal growth process). 800X.

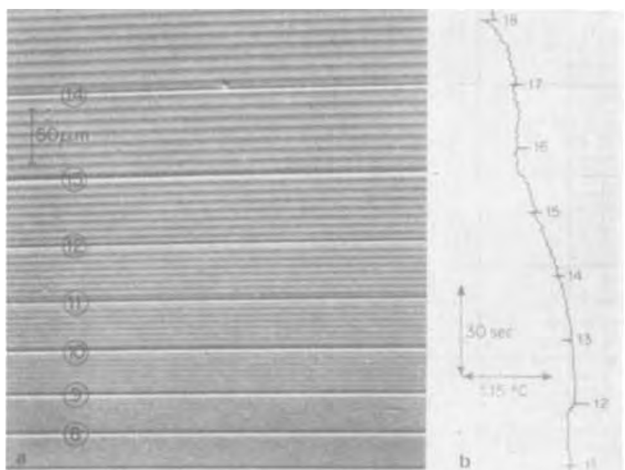

Fig. 25. InSb crystal segment grown in the presence of thermal oscillations in the melt. The time markers introduced by current pulses (at 21 sec intervals) are numbered on the photomicrograph and also on the temperature recording. It is seen that each temperature oscillation in the melt (see temperature recording) causes a dopant striation in the melt; the number of temperature oscillations between two time markers on the temperature recording is identical to the number of dopant striations between the same two markers in the crystal.

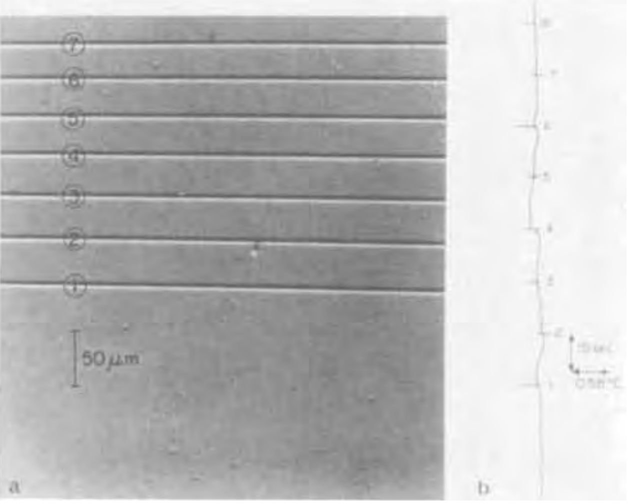

Fig. 26. InSb crystal section grown under thermal stability. No dopant inhomogeneities can be seen. The time markers (indicated by numbers) were introduced by current pulses applied at 21 sec intervals. No temperature fluctuations are indicated in the corresponding temperature recording.

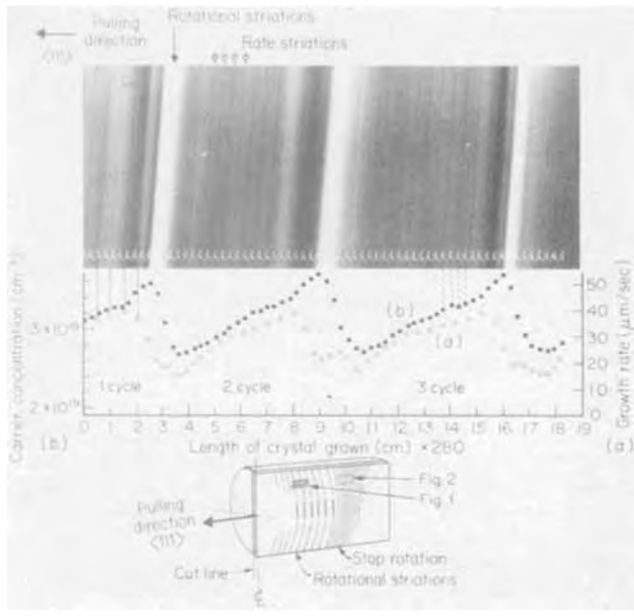

Fig. 27. Segment of a Ga-doped Ge crystal pulled with seed rotation. The microscopic growth rate as determined by the current-induced rate striations are shown in curve (a); the dopant distribution as obtained by spreading resistance measurements at spacings of 10 μm is shown in curve (b); the impact tracing of the spreading resistance probe is visible at the lower part of the photomicrograph.

microscopic growth rates. Thus, the first quantitative microsegregation analysis, relating the dopant concentration to the microscopic growth rates was carried out on germanium crystals (Fig. 27). Theoretical models on microsegregation, available for more than twenty years, could now be tested against experimental results, and conversely crystal growth and segregation could be examined with some confidence in the light of scientific principles. A start was made in bridging the gap between theory and experiment.

Up to that time (about three years ago) we had worked with semiconductors having relatively low melting points (*i.e.*, first with InSb, mp 525°C and then with germanium, mp 938°C), since the experimental complexities increase exponentially with increasing melting point. The study of silicon, the key semiconductor material in solid-state electronics, was the next step. Turbulent convection invariably present in the silicon melt, leading to uncontrolled random dopant fluctuations, was found to interfere with the interface demarcation and, thus, the quantitative study of segregation phenomena in silicon. Very recently, however, Ashok Murgai, by introducing severe thermal asymmetry in the melt, obtained thermal conditions under which forced laminar convection rather than turbulent convection, prevailed at the growth interface (Fig. 28). A quantitative segregation analysis in silicon was completed a few weeks ago (Fig. 29); the results are in good agreement with existing theories and provide a new basis for further theoretical developments. In addition, they elucidate certain aspects of segregation

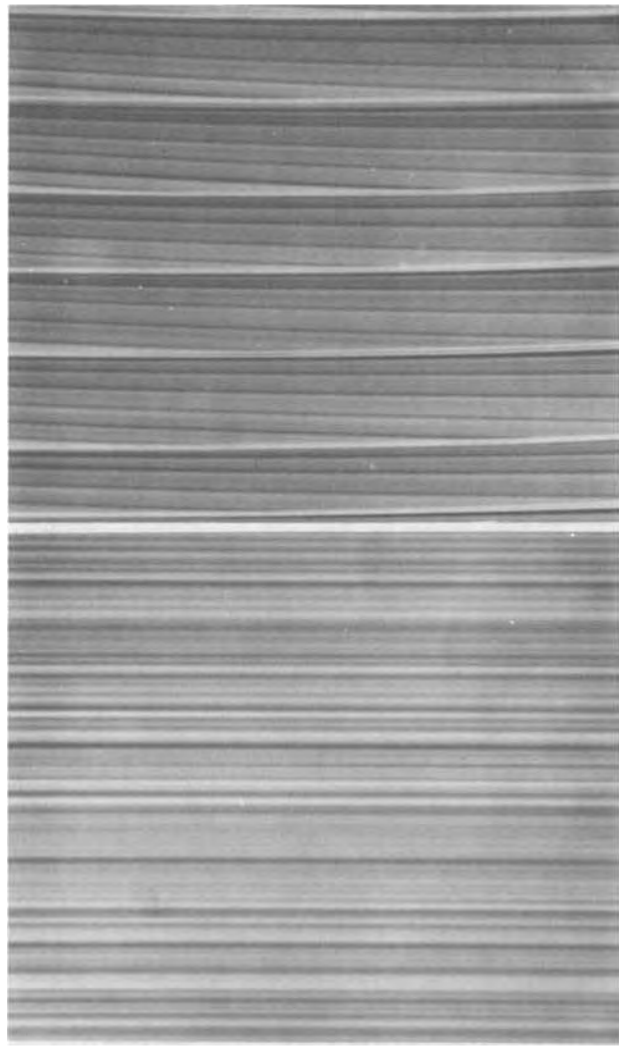

Fig. 28. Microsegregation in Sb-doped silicon grown with 5 rpm seed rotation. Upper photomicrograph shows the normal segregation behavior characterized by random nonrotationol striations caused by convection. Lower photomicrograph shows the segregation behavior in silicon grown under laminar flow conditions at the growth interface; periodic rotational striations now become well defined and random striations are eliminated. The rate striations introduced at 1 sec intervals are clearly visible. 100X.

under turbulent convection invariably present in industrial silicon growth processes.

At this point I would like to outline an application to which interface demarcation has led. Manfred Lichtensteiger's finding, that crystal growth and segregation could be precisely modulated by electric current, indicated that controlled crystal growth could be achieved by passing electric current through the growth interface (Peltier cooling) while the over-all temperature in the growth system (except at the growth interface) was retained constant. This approach appeared particularly attractive for liquid phase epitaxy where the objective is the preparation of thin semiconductor layers with controlled compositional characteristics. It was successfully applied to the growth of III-V compound epitaxial layers. Since the microscopic growth rate responds instantaneously to current density changes and is functionally dependent on the current density, desired compositional profiles can be conveniently achieved.

Outer Space a Unique Dimension in Materials Processing

As I review our work, I see no end to the challenging problems in segregation and crystal growth. We have reduced the reference scale from macro to micro, but we are still in the "macro" end of the microscale.

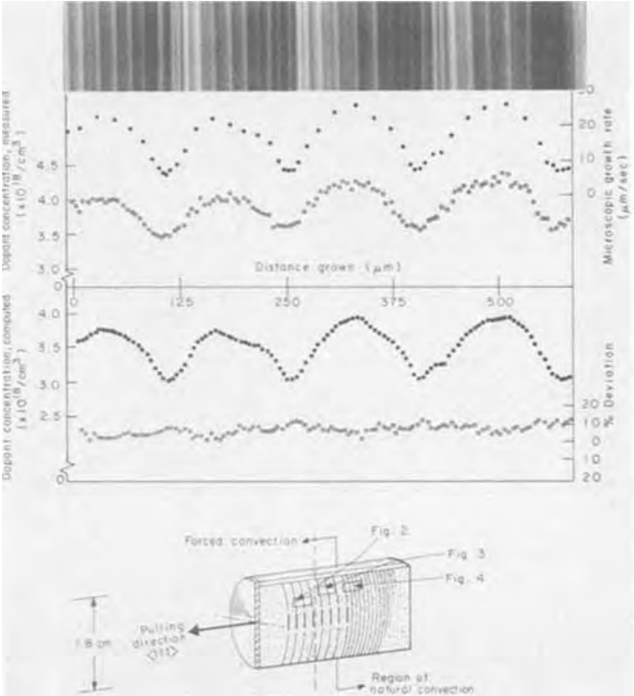

Fig. 29. Microsegregation analysis of an Sb-doped silicon segment pulled with a seed rotation of 5 rpm; rate striations and the impact of the spreading resistance measurements are visible; the uppermost curve (black dots) is the microscopic growth rate plot as a function of distance grown; the second curve from the top is the corresponding dopant concentration. The theoretical dopant concentration computed on the basis of the Burton, Prim, and Slichter model (black dots) and the deviation between the experimental and the theoretical concentration are shown in the lower part of the figure.

We and others will be working, on earth, refining our understanding of segregation and growth for many years to come. However, gravity-induced convection will never permit us to investigate growth and segregation under ideal, strictly diffusion-controlled steady-state conditions. Thus, theoretical predictions on the properties of homogeneous materials on an atomic scale, will essentially remain predictions.

It is incomprehensible to me that experimentation in space has captivated workers in astronomy, spectroscopy, communications, meteorology, and other fields, but has hardly penetrated the skepticism or excited the imagination of the materials community. Experiments in the Skylab mission have provided astronomers, earth scientists, and others with a plethora of original information to keep them challenged for many years. The materials experiments in that mission were almost an afterthought, limited in number and scope of instrumentation. We were fortunate to participate and the results of our simple solidification experiment were beyond our expectations.

We used single crystals of InSb (about 1 cm in diameter and 11 cm long). In space, one-half of each crystal was backmelted and regrown, with the unmelted part of the crystal serving as seed. In this way, the earth-grown seed and the space-grown crystal could be directly compared. As seen in Fig. 30, the compositional inhomogeneities present in the earth-grown seed are eliminated in the crystal segment grown in the absence of gravity; thermal convection was not present in the melt. Growth took place under ideal diffusion-controlled, steady-state conditions, resulting in homogeneous dopant distribution on a macro- and microscale, following a dopant concentration transient as predicted from theory (Fig. 31 and 32). No such homogeneity has ever been achieved on earth, either by nature or by man. In addition, we observed some unexpected new effects associated with solidification

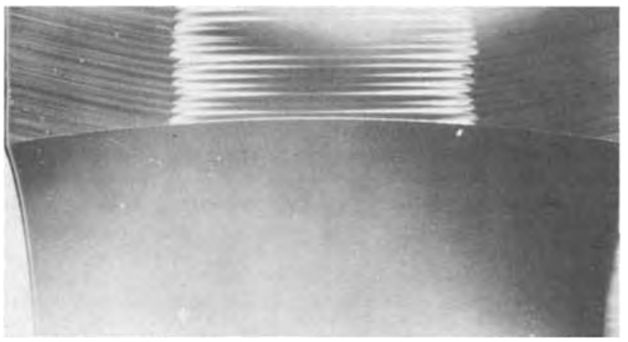

Fig. 30. Etched cross-section of crystal grown in Skylab; space-grown region (bottom) in contrast to earth-grown region (top) exhibits no compositional inhomogeneities. 13X.

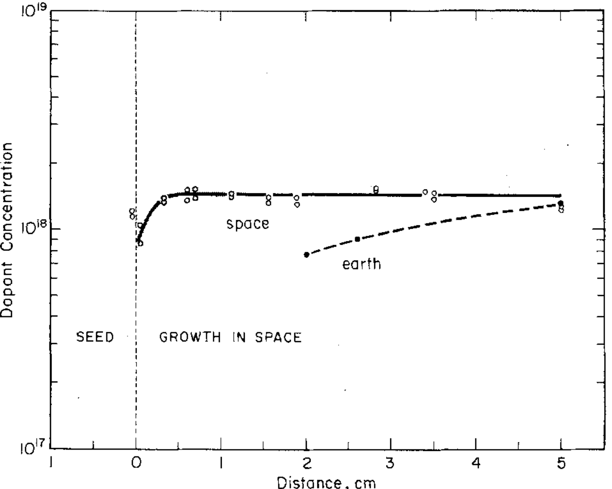

Fig. 31. Dopant concentration profile obtained from Hall-effect measurements for a Te-doped InSb crystal grown in Skylab (the shaded area represents the dopant concentration results obtained with an ion microprobe); the dopant distribution in an InSb crystal grown during ground-based testing is also shown (due to the presence of twin and grain boundaries in this crystal no meaningful Hall-effect measurements could be carried out in the vicinity of the regrowth interface). Note that ideal steady-state, diffusion-controlled, segregation takes place in space.

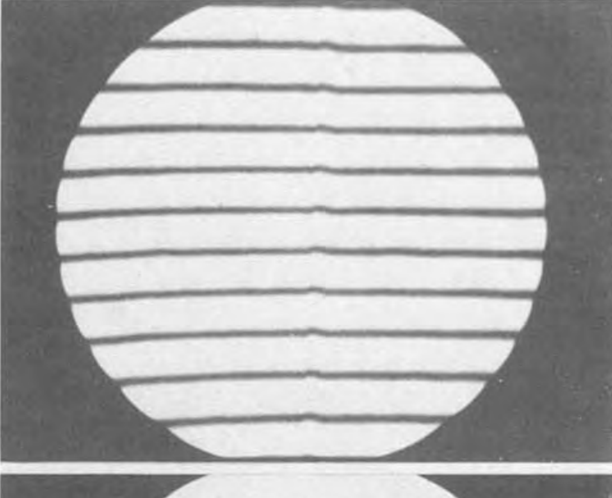
and segregation which we have discussed in a recent publication in *The Journal of the Electrochemical Society.*

On the basis of the first results we have designed a more refined growth experiment, using germanium, for the space mission in July of 1975, which will be carried out jointly by the U.S. and the Soviet Union. Unfortunately, there are no other space missions planned for materials processing until the Shuttle missions, five to six years from now. With intensive participation of the materials community, experiments can perhaps be designed for the Shuttle missions which could represent a turning point in advancing materials and materials processing into new levels of understanding and raise structure-property relationships to a refined, quantitative framework.

Looking into the Future

Solid-state electronics has had a brilliant recent past. It has revolutionized our technology within two decades. It has brought to focus semiconductors, model materials for testing structure-property relationships, for discovering new effects, for breeding theoretical concepts, for discovering new materials and for showing the way to progress in all other classes of materials. It broke the barrier among classical science and engineering disciplines and demonstrated the striking resonance energy of multidisciplinary interactions. It gave birth to materials science, an ideal intermediary for multidisciplinary interactions.



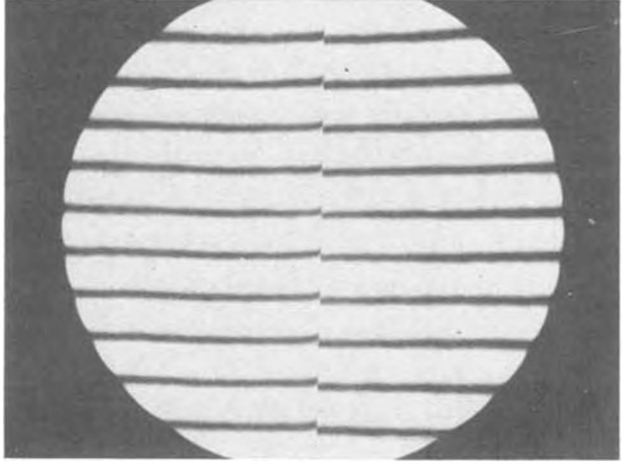


Fig. 32. Double beam interferogram of an InSb crystal grown in Skylab. The interference fringes are straight lines and parallel to each other indicating uniform dopant distribution on a microscale. The segregation discontinuity on the upper interferogram was caused by an intentional mechanical shock during growth; the discontinuity on the lower interferogram was caused by regrowth after an intentional cooling arrest during the growth experiment.

With such a brilliant past, in principle, we cannot expect any less brilliant future for solid-state electronics and for solid-state science. I certainly cannot be specific about the future, but I would like to share with you my views.

Three questions come to mind. (*i*) Will solid-state science and technology progress through improvements and refinements of known materials and through advances in materials processing? (*ii*) Will progress be based on the discovery of new materials and new phenomena? (*iii*) How can the promise of solid-state science and technology be fostered?

At present the limiting step to progress in solid-state science and technology is materials preparation, materials characterization, and materials processing. Future progress then hinges on improvements of known materials and processes. Even in the case of silicon, on which more than 90% of the electronics industry is based, fundamental materials problems still confront us. Compositional homogeneity on a microscale, lattice defects (particularly point defects) and their role in device processing and performance, control and understanding of the electronic properties of surfaces and interfaces in device structures; there are others. Improved capacity, speed, reliability, and cost reduction of integrated and hybrid circuits in the future is intimately related to advances in materials processing.

Light emitting diodes have in the last two to three years made a grand entry into solid-state electronics,

as sophisticated materials technology developed for silicon (for example, crystal growth and p-n junction formation by planar diffusion) was expanded to III-V compounds. Progress in light emitting efficiency throughout the visible spectrum and improvements in cost will broaden immensely the applications of LED's as light sources. But, processing of high energy gap semiconductors and controlled p-n junctions will be the critical steps.

Optical communication of information, voice and pictures, now feasible on a laboratory scale, represent a major quantum jump over present technology in terms of capacity and cost. Here again the existing needs: efficient lasers, modulators, detectors, and low loss glass fibers, are all materials related.

New means for energy generation, an issue of major concern, have been in principle demonstrated: solar energy conversion, new batteries, fuel cells, magnetohydrodynamics, nuclear fusion; their large-scale implementation will certainly be based on improvements in processing electronic and other types of materials.

These are just a few typical instances where future progress is linked to improvements of known materials and processes.

Assessing progress through new phenomena, new materials, and new technologies is not a linear extrapolation process; fundamental or empirical knowledge can be of little help in planning "breakthroughs." On the other hand, it will be naive, at best, to rely for our future on serendipity. New discoveries that have changed the course of civilizations, emerged invariably although unpredictably in well planned, intellectually ripe and stimulating environments. In a recent article[3] it was stated that, "The significance of the wartime semiconductor developments in setting the stage for the invention of the transistor cannot be overemphasized." Another recent article[4] points out that, "It would be well to bear in mind when we begin our attempts to divine the future that the invention of the transistor was not a random event."

In this context I would like to quote from an internal Bell Laboratories document written in the summer of 1945: "Authorization for work. Subject: Solid State Physics—the fundamental investigation of conductors, semiconductors, detectors, insulators, piezoelectrics and magnetic materials. Statement: Communication apparatus is dependent upon these materials for most of its functional properties. The research carried out under this case has as its purpose the obtaining of new knowledge that can be used in the development of completely new and improved components and apparatus elements of communication systems. . . . The modern conception of the constitution of solids that has resulted indicates that there are great possibilities of producing new and useful properties by finding physical and chemical methods of controlling the arrangement and behavior of the atoms and electrons which compose solids." An area of research with great potential on promising materials was selected. A competent group representing the appropriate disciplines was established. Two and one-half years later the transistor was invented. This is a model approach to the discovery of new phenomena, materials and devices. I do not even remotely intend to underplay a major ingredient in this as in other discoveries: the flash of genius. But a flash of genius can only be triggered in the right environment.

The development of solid-state science and technology is linked with structure-property relationships, with the drawing of general principles from specific facts. But the facts have not been and will not be better than the materials; the generalizations, whether they represent predictions, relationships, or theories will always be as good as the facts.

I would like to conclude with a quotation from Thomas Edison, which could be entitled: setting the stage for progress. "My own ambition is to be able to work without regard to the expense. What I mean is that if I want to give up a whole month of my life and that of my establishment to finding out why one form of carbon filament is slightly better than another, I want to do it without thinking of the cost. That galls me. I want none of the rich man's usual toys. I want no horses or yachts—I have no time for them. What I want is a perfect workshop."

Acknowledgments

Since in this address I have only sketched the evolution of two research areas and did not even touch on our research on high pressure transformations, superconductors, and amorphous semiconductors, I have omitted the names and contributions of a large number of my associates and students. This omission in no way reflects a value judgment. In my collaboration with every one of my associates and students I have not only been stimulated and rewarded, but also enriched by their friendship. How can I thank them enough?

I wish to take this opportunity to express my gratitude to the sponsors of our work: The National Aeronautics and Space Administration, the National Science Foundation, the Office of Naval Research, and the M.I.T. Lincoln Laboratory (supported jointly by the U.S. Army, Navy and Air Force).

References

I have chosen not to include references to our work reviewed here, since it has been published principally in readily available journals: *The Journal of the Electrochemical Society*, *Surface Science*, and the *Journal of Applied Physics*. Regarding the work of other investigators mentioned in this address, it is either very well known or it has appeared in the above journals.

Report of the Electrolytic Industries for the Year 1974[1]

Chlorine—Caustic Soda

I. Production.—Chlorine production in the U.S. reached a new record level in 1974 (1, 2). The U.S. 1974 output was 10,872,000 short tons of chlorine and increased 4.3% from 10.42 million tons in 1973. This represents a 10.5% increase over the 1972 production level. Canadian production was 1.07 million tons in 1974 compared with that in 1973 of 1.01 million tons, which is an increase of 6.3% (1, 2).

U.S. chlorine production capacity rose 11.1% in 1974 to 33,300 tons/day on December 1, 1974, compared with 29,982 tons/day a year earlier (2). Canadian capacity increased 6.7% during the year to 3250 tons/day compared with 3045 tons/day in December 1973 (2). During most of the year chlorine producers operated close to an average of 95% of the capacity (4). Three major new brine electrolysis plants came on stream during the year and a total of 13 locations underwent modest expansions, modernizations or replacement of facilities (1, 3) (see Table 1). A plant based on nonelectrolytic oxidation of HCl also came on stream (3). The Chlorine Institute estimates that by January 1, 1976, new plant constructions and expansions of operating facilities at nine locations will boost U.S. chlorine capacity from the 1974 level of 33,300 tons/day to about 35,800 tons/day, an increase of about 7.5% (1). Two projects should raise the present Canadian chlorine capacity of 3250 tons/day by 13.2% during 1975 (1).

In 1974, 69.9% of U.S. chlorine production capacity was in diaphragm cells, 24.8% in the mercury cells, and miscellaneous production from all other sources accounted for the remaining 5.3% (3). In Canada, 64.5% of chlorine production capacity in 1974 was in the diaphragm cell route and the rest in mercury cells (3).

Demand for chlorine in the U.S. was somewhere between 100 and 110% of ability to produce with certain geographic and industrial dislocations. The major hurdles were the availability of power and fuel (1). The national economic downturn first affected chlorine production in December of this year (1).

Due to severe shortages of chlorine and caustic soda and high energy costs, the price of each product increased to the $90/ton level by midyear (5-8) and shortly thereafter to the $100/ton level (9, 10). Toward the end of the year the prices for chlorine were at $120-140/ton (11). Shortage of chlorine appeared to be easing in December (11); however, demand for caustic soda has remained strong with prices in the range of $140-165/ton (4).

The market breakdown for chlorine is as follows (11):

Vinyl chloride (VCM)	20%
Other chlorinated organics	30%
Inorganic chemicals	11%
Pulp and paper	15%
Miscellaneous	17%
Water purification	7%

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.

The material presented herein has been gathered from many sources, as noted in the References, and does not necessarily represent the opinions of the authors.

Vinyl chloride is the largest single product that uses chlorine and factors that affect this industry affect in turn the chlorine industry. Polyvinyl chloride (PVC) output and use stayed at the 400 $\overline{\text{M}}$ lb/month level during the first ten months of 1974; however, in November the consumption slipped 10%, and 22% further in December to 281 million lb (4). This decline in the PVC market late last year was a delayed reaction to trouble in the auto and housing industries (4, 11). After much controversy (14), O.S.H.A. has set strict standards on worker exposure to vinyl chloride (12). The new standard, covering vinyl chloride, polyvinyl chloride, and PVC fabricating facilities, will be implemented in steps (12). After January 1, 1975, vinyl chloride in work-place air must be reduced to 1 ppm averaged over an 8 hr period. Workers may not be exposed to more than 5 ppm averaged over any period for longer than 15 min (12). If these levels cannot be met, employees must be provided respirators. The plastic industry has challenged these standards in courts (12). The effect of these standards on the chlorine industry is unknown. A number of new vinyl chloride monitors have come on the market (13).

The sharp downturn in automotive markets also affected the demand for chlorinated organic products used as degreasing solvents for metals in late 1974 (4). Other markets for chlorine have been less weak than those for organics.

The chlorine shortages in the summer of 1974 for sewage and water treatment were worse than 1973; however, shortages were to ease in early 1975 when new capacity would be on stream (15).

Production of caustic soda reached a record level of 11,400,000 tons in 1974 (16). Demand for caustic soda remained strong throughout the year and markets for caustic soda such as soap and detergent continued to grow at 4-5% per year (4). Mining and metallurgical markets held up well in almost all of 1974 (4). Caustic markets were reacting more slowly and less violently to the economic slowdown in late 1974 compared to chlorine (4). The cutbacks in chlorine production, which are bound to occur, would aggravate the caustic shortage further (4).

II. Developments.—A. Chlorine cells and components.—A number of new cells are available on the market for chlorine producers, many of which were presented at the joint Electrochemical Society and Chlorine Institute meeting held in San Francisco in May 1974, to commemorate the 200th anniversary of the discovery of chlorine by Scheele. Metal anode conversions of chlorine cells continue, as seen in Tables 1 and 2.

Diamond Shamrock's plant at Battleground, Texas, uses cells that have a new expandable dimensionally stable anode and a modified asbestos diaphragm. These cells operate at 40,000-80,000A and have a narrower brine gap between the electrodes which reduces electrical energy consumption to 2300-2500 kW-hr/short ton of chlorine (18). The expandable metal anode is made in a contracted configuration, then expanded against the cathode with the modified diaphragm during assembly of the cell. The modified asbestos diaphragm has given voltage savings of 150 mV and has

Table I. Current changes in chlorine operations (3)

Company and location	Type of cell	Capacity tons/day	Completion date
	A. Production Started		
Diamond Shamrock Corp. LaPorte, Texas	Diamond MDC29 (diaphragm)	1200	November 1974
The Dow Chemical Co. Freeport, Texas	Dow (diaphragm) expansion	1000	September 1974-March 1975

demonstrated life of over 500 days (17). The combination of expandable metal anode and the modified diaphragm is said to save the cell voltage by a total of 300 mV at 1.5 kA/m^2 compared to DSA and asbestos diaphragm (17).

PPG's Glanor bipolar electrolyzers will be used in a 1500 tons/day plant to be built at Lake Charles, Louisiana, by 1977. About 6000 tons/day capacity using this technology has already been licensed (18).

Hooker's 150,000A version of a diaphragm cell has been used at Hooker's 900 tons/day plant at Taft, Louisiana (18). This cell is supposed to have a labor cost advantage over smaller versions (18).

Diamond Shamrock Corporation and du Pont reported on a joint project for demonstration and application of "Nafion" perfluorosulfonic acid membranes for chlorine cells (19-22). Diamond Shamrock is already operating a commercially sized chlorine cell using "Nafion" membranes and is planning to operate a large facility to demonstrate its commercial practice (20, 22, 23). Hooker Chemical has also developed chlorine cells based on "Nafion"-type ion exchange membranes. A 45 tons/day plant has been installed by Hooker for a pulp mill (18, 20) and Hooker plans a 250 ton/day plant for itself (20). At The Electrochemical Society meeting in San Francisco in May 1974, both Hooker and Diamond Shamrock presented papers concerning their development of new cells in which "Nafion" membranes are used (22, 24).

du Pont is also reported (22) to be working with Ionics, Inc., Watertown, Massachusetts, on "Nafion" membranes for chlorine cells for units with less than 100 tons/day capacity (19, 20). Ionics has a system using "Nafion" membranes for on-site chlorine, caustic soda, and hypochlorite generation (19).

Asahi Chemical, Tokuyama Soda, and Maruzen Oil have independently developed a membrane cell process for chlorine production (25, 27). The membrane process is said to produce caustic soda product with less than 100 ppm NaCl and the size of the caustic evaporators is a third the size necessary in the existing diaphragm cell process. The life of the ion-exchange membrane is 4-5 times that of the conventional diaphragms (25). Asahi is reported to be constructing a semipilot plant of 25,000 tons/year caustic soda capacity to be completed in early 1975 (25). The technical data on the Japanese membrane processes are not available as yet (25). The Ministry of International Trade and Industry of Japan which has sponsored the work of Asahi is recommending the membrane process technology for the first phase of the conversion program, away from the mercury cells, which ends in March 1976 (26).

B. Other developments.—Mobay Chemical Company is doubling its HCl electrolysis facility of 200 tons/day at Baytown, Texas, using F. Uhde cells (28).

Kellogg has continued design studies on the recovery of chlorine from HCl by the Kelchlor process, which has resulted in the development of an economic low pressure design (27). This reportedly permits the use of brick-lined towers and Inconel 600 for the oxidizer unit (27). Kellogg has also announced that it has a new variant of the process under development, named Kelchlor II, which can handle either anhydrous or aqueous hydrogen chloride feed (27).

A new quadruple-effect evaporator in the NaOH concentration system requires only 5000-6000 lb of steam/ton of NaOH (18, 29). The steam requirement for the quadruple effect unit is about half the amount required for the double effect units and 20% less than the triple effect units (18, 29).

An absorption-distillation method to liquefy chlorine is ready for licensing by Akzo Zout Chemie Nederland (Hengelo, Netherlands) (23, 30). Chlorine is absorbed in carbon tetrachloride and the solution is distilled. The process presumably consumes less energy than compression and condensation, producing liquid chlorine containing 99.9% chlorine, with a yield of 99.8% (23, 30).

EPA is proposing amendments to the emission standards for asbestos for certain field fabrication operations in new construction. The amended regulations would prohibit the installation of asbestos containing molded insulating materials which are friable, and wet applied insulating materials which are friable after drying (31). Friable asbestos material is defined as any material that contains more than 1% asbestos by weight and can be crumbled, pulverized, or reduced to powder when dry by hand pressure (31).

Asbestos fibers in water can be identified, counted, and measured with a transmission electron microscope equipped with selected area electron diffraction and an energy dispersive spectrometer, according to The Dow Chemical Company (32). The technique was developed to measure asbestos levels, typically 0.001 ppm, in diaphragm cell chlor-alkali plant streams. Almost all of the asbestos fibers from these streams average under 6μ in length and could be filtered out (32).

Employees at an asbestos mine aim to buy the mine from GAF Corporation for $1.25 million (33). The employees of Vermont Asbestos Group, Inc. have won a one year extension of EPA's deadline to install pollution control equipment. Additional equipment and worker safety devices would cost another $1.25 million (33).

Capital expenditures required for environmental controls for the water and air quality standards have boosted the total plant investment by 20% for new plant construction (18). Typical investment for 1000 tons/day diaphragm cell and mercury cell chlorine plants is compared below (17). The direct investment costs are comparable (17). See Table 3.

C. Mercury cells.—No new mercury cell plants were built in 1974 in the U.S. (34). There were a few planned expansions and modernizations, e.g., conversion of Olin's plant at Charleston, Tennessee, from graphite to Marstolin metal anodes (3). One mercury cell plant has been slated for conversion to a diaphragm cell plant in the U.S. and another to a membrane cell process in Canada (3). In the foreseeable future, all new chlorine production capacity will be in the diaphragm cell plants.

The first phase of Japan's conversion program of mercury cells to other cells ending in March 1976, involves 65% of the total capacity, amounting to 3,051,000 tons NaOH/year (26). The second phase ends in March 1978, when facilities for 5,579,000 tons NaOH/year or 100% of the capacity will be converted to diaphragm or membrane process plants from the present mercury cell process (26).

The initial capital investment costs for conversion of mercury cell facilities in Japan have now more than doubled to 800,000 million yen ($2,016 million) due to the dramatic rise in construction costs because of inflation (27). Besides inflation, financial and market factors are also affecting the conversion away from mercury cells and the increase in capacity of the Japanese chlor-alkali industry (27).

Table 3. Capital cost of 1000 short tons/day chlorine plant* (17)

Process item	Capital cost $ millions Diaphragm cell	Mercury cell
Brine area	3.5	5.0
Cell room, excluding license or anode fees	13.0	19.0
Chlorine processing	8.0	8.0
Cell liquor storage	1.5	—
Caustic evaporation	15.0	2.0
Caustic purification	3.0	—
Caustic storage-loading	4.0	4.0
Hydrogen system	1.0	1.0
Utilities	10.0	7.0
General facilities	6.0	6.0
Mercury	—	4.0
Mercury recovery	—	7.0
Total direct investment	65.0	63.0

* U.S. Gulf Coast, 1974-1975 costs.

The formation of mercury butter in mercury cells used in brine electrolysis may be prevented or reduced by using a technique developed by de Nora of Italy (35). Magnets placed in the mercury amalgam circuit retain ferromagnetic particles, *e.g.*, Fe, Ni, suspended in the amalgam (35). The magnets are cleaned periodically (35).

Georgia-Pacific Corp. has completed testing its new process for the recovery of mercury traces from liquid and solid wastes from the chlorine plant at Bellingham, Washington (36, 37). The project was supported partly by EPA. The removal of mercury from the brine sludge by roasting in a six hearth furnace at 1000°-1400°F is said to be 98.3-99.8% efficient and the residual mercury in solids is 0.5-0.7 ppm (37). The waste water is treated with sodium sulfide and filtered; the HgS filter cake containing 15-30% Hg is roasted in the furnace (37). This process is said to be meeting EPA's 0.1 lb/day limit for discharge of mercury (37).

According to USDA's northern regional laboratories, a highly efficient method has been developed for recovering heavy metals from water or up to 10% salt solutions by using a crosslinked starch xanthate in the pH range of 3-11. The metal and starch are recovered by treating with nitric acid. Mercury concentrations are reduced from 100,000 to 3 ppb (42).

Mercury consumption increased by 10% from 54,283 flasks in 1973 to 59,600 flasks in 1974, according to U.S. Bureau of Mines (38, 39). The chlor-alkali producers purchased 16,813 flasks of mercury in 1974 compared to 12,780 flasks in 1973 (39, 41). The domestic production of mercury was 1700 flasks from ten mines in California (65%), Nevada, and Alaska. Secondary production amounted to 9000 flasks. Imports of mercury totaled 51,400 flasks, a 10% increase over 1973 and were received from Canada (30%), Mexico (22%), Algeria (20%), Yugoslavia (11%), and Spain (10%). The seven mercury exporting countries (representing 95% of mercury exports) were planning a base price of $350/flask (40). The mid-year free market mercury price ranged at $270-275 per flask (40).

Other Alkalis and Electrolytic Processes

Caustic Potash.—Caustic potash production in 1974 was 206,252 short tons as 88-92% liquid; this represents an increase of 9% over 1973 production of 188,454 short tons (43, 44).

U.S. production of marketable natural potassium chloride, sulfate, magnesium sulfate, and manure salts was 2.5 million tons of K_2O equivalent, a decrease of 2% in quantity and increase in value by 30% compared with that of 1973 (43).

The government of Saskatchewan removed production controls and the price floor on potash during 1974, and subsequently put into effect a policy of higher taxation and majority participation in future capacity expansions (43, 45). This has resulted in deferral of added capacity by six potash producers amounting to a total of $200 million investment (45).

The price of potassium muriate in bulk f.o.b. Carlsbad, New Mexico, and Saskatchewan, Canada, freight equalized, was quoted in early 1974 at $0.38-0.44/lb; in late 1974 prices were quoted at $0.54-0.65/lb. The caustic potash price after the government controls were lifted was quoted at $4.60/100 lb lots on a 45% basis (46), and in late 1974 it was quoted at $6.00 (47).

Allied Chemical Corporation is planning to shut down its caustic potash production at Solvay, New York (48).

Soda Ash.—Demand for soda ash continued strong in 1974, but total production declined 1.5% to 7.53 million tons. Synthetic (Solvay) soda ash continued its 8 year slump by dropping 9.5% below the 1973 production level to 3.48 million tons. Part of this decrease was the shut-down of PPG Industries 600,000 ton/year synthetic soda ash plant in Barberton, Ohio, in 1973. Existing synthetic plants could manage only an 87% operating rate in the face of strong demand. Natural soda ash production did increase 9.3% to 4.05 million tons, topping the output from synthetic plants for the first time, but this was the smallest annual increase in several years and was not nearly up to the predictions of the producers who were all striving to enlarge their capacities (49, 50).

The main drawback to the construction of additional natural soda ash capacity seemed to be the lack of skilled labor in the relatively undeveloped area. The synthetic soda ash plants are plagued with operating and environmental problems.

The soda ash demand was high, but the producers could not supply about 500,000 tons. There was also a world-wide caustic shortage. Soda ash exports jumped 20% to 530,000 tons in 1974. With the high demand, customers were put on allocation and inventories decreased (50).

The Allied Chemical natural soda ash plant with an annual capacity of 1,100,000 tons came on stream in late 1974 at Green River, Wyoming. In 1975, the FMC Corp. and Allied Chemical natural soda ash plant expansions will bring an additional 1.85 million tons to the industry's capacity, increasing the total to 6.4 million tons.

In March, 1974, the Kerr-McGee Chemical Company announced the selection of a contractor to build their new 1.3 million ton-per-year soda ash plant at Trona, California, at a cost of more than $100 million. Target date for operation has been set as 1977 (51). Kerr-McGee also purchased Stauffer Chemical's plant in West End, California (49).

Texasgulf is expecting to have its one million ton/year natural soda ash plant operating at Grunger, Wyoming, by the third quarter of 1976 (50).

A consortium of five Japanese companies announced intention to develop the natural soda ash resources at Lake Natron in Tanzania (49). Japan's Asahi Glass, Central Glass, Toya Soda Manufacturing, and Tokuyama Soda are planning to build a 1000 ton/day soda ash plant in Australia.

In the face of ever increasing demand and rising costs, the soda ash industry gradually raised its unit costs (52, 53). The average unit value of soda ash, as evaluated by the producers, was about 30% higher in 1974 than the average 1973 price (49). In December, PPG raised soda ash prices to $60/ton in bulk and $74 in bags, f.o.b. Corpus Christi, Texas, from the previous prices of $44 and $58/ton, respectively (54).

A new method of separating sodium minerals from oil shale has been patented by Industrial Resources (U.S. 3,806,044). Nahcolite and dawsonite are separated from shale by froth flotation before the minerals are sent to a shale retort (55).

Sodium Chlorate.—According to the U.S. Department of Commerce data (56), sodium chlorate production in the U.S. in 1974 amounted to 201,453 short tons with a production capacity totaling 235,500 tons (57). Canadian sodium chlorate production was estimated at 138,000 tons for 1974 (58).

In early 1974 the sodium chlorate price was fixed at $135/ton because of government price controls (57). The mid-year price for sodium chlorate was $165/ton (59), and quotes at the end of the year for sodium chlorate were about the same (60).

Engelhard Mineral and Chemical Corp. has developed a line of metal anodes for the production of sodium chlorate (61). The anodes are reportedly a titanium structure with a conductive coating. They demonstrate a lower cell voltage and offer cell design flexibility.

Standard Chemical Limited, a Canadian subsidiary of PPG Industries, will expand its sodium chlorate plant at Beauharnois, Quebec (62, 63). The multimillion dollar expansion in two phases would almost double the production capacity at this location, making it Canada's largest sodium chlorate plant (64). The first phase is expected to be in production by January 1977. The new facilities will include metal anodes using cell technology developed by Standard Chemical and PPG (64). PPG purchased a license for the U.S.

and Canada for using Kema Nord's bipolar electrode technology for sodium chlorate cells last year (57).

Aluminum.—The U.S. aluminum industry sustained another record production year in 1974, with 4,903,000 short tons of the primary metal produced. This represents an 8% increase over the 1973 production level (65). The General Services Administration shipped 509,000 short tons of aluminum in 1974, virtually depleting government inventories (66, 67). The total aluminum supply which includes primary production, secondary recovery, imports and GSA shipments amounted to 7,214,000 short tons in 1974 compared to that of 7,062,000 short tons in 1973 (65).

U.S. shipments of aluminum started to slip midway in the second quarter of 1974 and the demand situation worsened in the third and fourth quarters as the housing and transportation markets, representing 45-50% of the domestic aluminum market, were affected by the national economic slowdown (67). The containers and packaging markets, which account for 30-35% of the total, were strong throughout the year (67). The supply-demand balance was maintained by aluminum production cutbacks (67-69), for which the aluminum industry came under fire from the Council on Wage and Price Stability (67).

The domestic price for aluminum from large producers remained at $0.29/lb through March 29 when controls were lifted and the price was raised to $0.315/lb. The price was raised in succesive amounts to $0.39/lb by September 5, 1974, where it remained for the rest of the year (66). The price of aluminum on an average was about $0.34/lb in 1974 (67). Prices on the major world markets approached $0.46/lb at midyear but softened to a level of $0.35-0.45/lb at the end of the year (66).

Aluminum Company of America (Alcoa) is planning to increase its primary aluminum capacity at Badin, North Carolina, from 120,000 tons/year to 180,000 tons/year by the addition of a third potline. Completion is projected in 1976 at a cost of $50 million (70).

Amax Aluminum Company, owned equally by Amax, Incorporated and Mitsui and Company, will be adding a second potline with a capacity of 87,400 tons/year of primary aluminum at Howmet's Eastalco plant in Frederick, Maryland, at a cost of $85 million (71). The facility will be operated jointly between Howmet and Amax Aluminum. Amax Aluminum is also planning a 287,300 ton/year aluminum plant at Warrenton, Oregon, at a cost of $200 million. The Government approval was sought for the project (71).

In a joint venture, Revere Copper and Brass, Incorporated, and six Japanese firms are studying the possibility of investing $160 million at Revere's aluminum plant at Scottsboro, Alabama, to increase the capacity from 112,000 to 232,000 tons/year, and possibly later to 360,000 tons/year. The Japanese companies will take the increased output (72).

Aluminum Company of Canada and Nippon Light Metals KK of Japan (Alcan's 50% subsidiary) are planning a new subsidiary to produce 100,000 tons/year aluminum in Kitimat, B.C., Canada. Each company will receive half of the output of the plant which will be operated by Alcan (73). Alcan will also add 48,000 tons/year aluminum capacity by 1975 at Arvida, Quebec (74).

Noranda Mines, Limited, of Canada is planning to double the aluminum capacity of the Noranda Aluminum Incorporated, plant at New Madrid, Missouri, from 70,000 to 140,000 tons/year aluminum by mid-1976 (75).

In March 1974, Australia, Guinea, Guyana, Jamaica, Sierra Leone, Surinam, and Yugoslavia formed the International Bauxite Association for the purposes of achieving higher revenues for bauxite and alumina, and maximum vertical integration of their own industries. The United States is traditionally dependent on these countries for greater than 90% of alumina and bauxite requirements (66, 76). Jamaica levied higher taxes on bauxite (76); Guyana, Surinam, and Haiti followed with similar actions (77, 78). These countries are demanding active participation in the bauxite operations of the North American companies (79). Many of the aluminum producers, for this reason, have been looking into alternative materials for bauxite, such as alunite, kaolinite, and laterite (80).

Reynolds Metals Company carried out a full scale test on laterite ore (35% aluminum content) at Hurricane Creek, Arkansas, proving that this ore can be processed in the Bayer process plants without major equipment changes (80).

Pechiney Ugine Kuhlman and Alcan Aluminum, Limited, of Canada have joined efforts in a new venture for the development of a new method for processing nonbauxite ores into alumina (81). The venture will invest $25 million for constructing a pilot plant of 20 tons/day of alumina based on Pechiney's H-Plus technology. PUK has been operating a 1 ton/day alumina laboratory unit since 1971 which can use shale, clays, and sandstone (81). In this process, ores are treated with concentrated sulfuric and hydrochloric acids to produce a crystalline aluminum chloride which is subsequently processed to yield alumina (82).

Alcoa has been operating a pilot plant converting coal wastes into alumina. Coal wastes which contain 28% alumina offer attractive commercial possibilities. Although the process is undisclosed, it is said to be based on conventional chemistry and ready equipment (83). Alcoa and Anaconda have signed an agreement for exchanging information on the alumina extraction technology from sources other than bauxite. Anaconda has operated a pilot plant for producing alumina from clay with a hydrochloric acid process (84).

The Bureau of Mines' Research Laboratory in Nevada is converting 70 lb/hr of domestic alumina clay into 25 lb/hr of alumina, based on a nitric acid leaching process. The project is being sponsored by eight industrial firms and is planned to process alunite, anorthosite, and dawsonite (85).

Another patented method reacts the ore with chlorine at high temperatures to produce aluminum chloride gas which is decomposed on cooling into molten metal (86).

Beryllium.—The over-all production and consumption of beryllium ores in 1974 was relatively unchanged from that of 1973 (87), about 7650 and 9000 short tons, respectively. Bertrandite was produced in Millard County, Utah, by Brush-Wellman, Incorporated. There was no report of any domestic beryl production. Imports of beryl in 1974 were estimated at 1350 short tons, valued at $392,000. Imports were primarily from Brazil and the Republic of South Africa. The other and larger supplier of beryllium products is Kawecki Berylco Industries.

Beryllium is used as the metal, as an alloying agent, and as an oxide. Major uses for the metal are for military and aerospace applications, utilizing light weight and high strength and rigidity, and for nuclear applications where its low thermal-neutron absorption and high-neutron-scatter cross section are required. More than half of the beryllium is used as a beryllium-copper alloy, to which it imparts qualities of strength and resistance to fatigue and corrosion that are superior to those of copper. Molds fabricated from beryllium copper are used to give plastic furniture the appearance of wood-grain surface (87). Beryllium-copper is a substitute for gold in certain contact applications in the electronic and computer fields. Strong growth in consumption also occurred in auto safety devices where beryllium-copper is used for buzzers and relays for seat belts and air-bags (88).

As of November 30, 1974, government stockpile inventories contained 17,986 short tons of beryl (11% BeO equivalent), 7387 tons of beryllium-copper master alloy (approximately 4% Be), and 229 tons of beryllium metal. The stockpile of both beryl and the master alloy was declared surplus. The stockpile objective for beryllium metal is 88 short tons, leaving 141 tons surplus.

As the 1974 boom accelerated, the price of beryllium rod and beryllium-copper alloys increased. The increases were necessary because of higher costs for copper, raw materials, labor, and supplies (89). With the increase in price of aluminum, beryllium-aluminum alloy price also increased per pound of contained aluminum (90). As the boom cooled, prices were also cut, reflecting lower material prices (91). At the end of the year, alloy 25 was quoted at \$3.89/lb and beryllium metal rod at \$106.05/lb.

The Environmental Protection Agency under the Clean Air Act amendments of 1970 has limited beryllium emissions from stationary sources to 10 grams/day (93).

Chromium.—As in earlier years, the U.S. continues to rely solely on imports and purchases from the government stockpiles for chromium requirements. The strong demand that initiated in early 1973 continued throughout 1974. Domestic consumption of chromite was 1,438,400 tons, 4% higher than that in 1973. In the refractory industry, the consumption in 1974 was 12% higher than that in 1973. Chromite usage in the metallurgical industry decreased nearly 3% from the level in 1973 (94).

Imports of chromite totaled 1,170,000 tons, an increase of nearly 26% compared with that of 1973. Imports of chromite from the U.S.S.R. and the Philippines were significantly higher in 1974 than in 1973, while imports from South Africa, Turkey, and Southern Rhodesia exceeded their 1973 levels (95).

The demand for chromium alloys was strong since stainless steel production exceeded two million tons for the first time. Imports of ferrochromium set a yearly record high of 162,000 tons, an increase of 4% over 1973 (94). During the year GSA sold 571,000 tons of refractory grade chromite, 323,000 tons of chemical grade, and 900,000 tons of metallurgical grade. GSA also sold 3182 tons of chromium metal (95).

The strong demand world-wide for chromium and the inflationary pressures raised the chromite and primary chromium product prices (95). South African chromite (44% Cr_2O_3) began the year at \$33-34/long ton delivered in the U.S. Atlantic ports; by June 1, prices quoted were \$47-52/long ton. The Turkish chromite (48% Cr_2O_3), quoted at \$37/long ton early in the year, increased to \$65/long ton in September 1974. The ferrochromium similarly was quoted at \$0.22-0.23/lb chromium at the first of the year and increased to \$0.50/lb by year's end (95). Sodium bichromate was priced at \$0.1725/lb in January 1974, and rose to \$0.2125 by the end of the year (2).

A year-long battle to repeal the Byrd Amendment was terminated when the backers of a Congressional bill withdrew the measure prior to the end of the 93rd Congress (95, 96). The Byrd Amendment is part of a 1971 military procurement law and states that, if the U.S. imports a strategic material from a communist country, it may not refuse to import the material from a noncommunist country. Under this part of the law, chromite ore and ferrochromium have been imported from Southern Rhodesia since early 1972 (95).

Copper.—Preliminary 1974 data indicated that the U.S. mine, smelter, and refinery production and consumption of refined copper were all substantially smaller than in 1973. Strikes at most producing units during portions of July and August and reduced demand for copper in the latter half of the year were factors that adversely affected the level of activity. Imports of copper were an increased supply component as imports of unmanufactured copper increased significantly while exports declined. An additional component of supply in 1974 resulted from the sale or commitment during the months of February through May of all 252,000 tons of refined copper remaining in the national stockpile (97).

Mine production was 1.59 million tons, an 8.4% decline from the preceding year and the smallest quantity since 1971 (98). Principal copper producing states were Arizona with 53% of the total, Utah (15%), New Mexico (13%), Montana (9%), Nevada (5%), and Michigan (4%) (99). Increased operating costs and a drop in copper prices were factors cited in an October announcement by the Anaconda Company of its decision to terminate underground mining at Butte, Montana. In response to the reduced demand for copper, several Arizona producers also made announcements in November and December of decisions to curtail operations (97).

Smelter production from primary materials decreased 10% from the 1973 record high to 1.57 million tons. Refinery production from primary materials was projected to decline 13% to 1.65 million tons. However, production of refined copper from scrap was approximately 495,000 tons compared with 465,000 tons in 1973 (98).

Consumption of refined copper was down 12% to 2.14 million tons from the 1973 record high of 2.44 million tons (98). The first half of the year had a relatively high level of consumption, whereas the second half was significantly lower, reflecting the slump in construction, automobile production, and the general economy.

Stocks of refined copper at primary producers fluctuated around 40,000 tons during the first five months, were drawn down to 23,500 tons during June, increased rapidly to 71,000 in November and 101,300 tons in December, the largest end-of-month level since March 1971 (98, 99). Stocks of copper at brass plants and wire mills were drawn down from 73,000 to 52,000 tons during the first quarter, moved up to 121,000 tons by the end of July, declined to 99,000 tons by the end of September, and closed the year with 144,000 tons (98).

Imports of copper were an increased supply component as imports of unmanufactured copper were 608,000 tons compared with 417,000 tons in 1973, while exports declined from 263,000 to 170,000 tons. The largest trade category, refined copper, had a 55% increase in imports to 310,000 tons and a 33% decrease in exports to 126,500 tons. Imports of blister were indicated to be 207,800 tons compared with 154,100 tons in 1973 (98).

The domestic delivered price for cathode copper was restricted to \$0.687/lb until the removal of price controls at the end of April. The monthly average price then advanced to \$0.812 on May 1 and to \$0.861 on June 1, then, reflecting changing market conditions, was reduced to \$0.83 in September, to \$0.782 in October, and to \$0.758 in November, and \$0.73 in December. The yearly average was \$0.77/lb. Prices on the London Metal Exchange escalated from a monthly average of \$0.921/lb for January to \$1.38/lb for April, followed by an equally rapid descent to around \$0.584 in December. The yearly average on the London Metal Exchange was \$0.931/lb (98).

According to Dravo Corporation, copper smelting costs can be cut by using a top-blown rotary converter process. Test data from an Inco nickel refinery show that energy requirements are only one quarter of those for electric or reverberatory furnaces, or electrowinning (100).

Hydrometallurgical extraction of copper from ores by the Marconaflo process was being carried out by Kaiser Industries and Marcona Corporation. The metal values are extracted in a leaching solution (101).

Anaconda, which is starting up the first commercial plant using its Arbiter fumeless extraction process in Anaconda, Montana, will run pilot plant tests on copper ore from Poland. Results of the tests could lead to licensing negotiations (102).

A flash-oxidation system that continuously produces copper, nickel, and lead from sulfide concentrates will be pilot-planted by American Air Liquide (New York) and other partners. The multistage converting operation is carried out in a single reactor, with continuous feeds of oxygen, concentrates, and flux. The advantages are that energy requirements, slag losses, and

cost of sulfur fixation are each about half as much as in standard processes (103).

A process by cyanide-free copper electroplating is offered by R. O. Hull. The major constituent is copper pyrophosphate with proprietary brightening and leveling agents. It is mildly alkaline and noncorrosive, and does not need any special plating equipment (104). A new electrochemical process that recovers 99% of the copper from leach liquor has been developed by Douglas Bennion and John Newman at UCLA. They believe that the process could be competitive with General Mills' LTX system (105).

Considerable activity was shown during 1974 in the mining of ocean nodules for the copper, nickel, cobalt, and molybdenum values. In January, Kennecott Copper announced a large-scale program aimed at commercial mining of some three million tons of nodules a year by 1980-1981. To achieve this goal, a five-year, $50 million R and D program will be carried out by a five-company consortium of major metal producers, including Rio Tinto-Zinc, Consolidated Gold Fields, Mitsubishi, and Noranda Mines. Key objectives are to build and test a full-scale prototype nodule recovery system capable of handling 10,000 tons/day of nodules, and a demonstration-scale process plant, to handle a minimum of 10 tons and a maximum range of 100 to 150 tons of nodules/day (106).

Likewise, Tenneco's subsidiary Deepsea Ventures has joined forces with a Japanese group of companies, Nichimen, C. Itoh, and Kanematsu-Gosho, U.S. Steel and Union Miniere (Belgium) for the purpose of carrying out a three-year, $20 million program for the development of the deep ocean manganese nodule resource. A 5 ton/day pilot plant will be built in Gloucester, Virginia. Further development will be continued at the Pacific mine site, and Deepsea's hydraulic system will be tested aboard its vessel R/V Prospector (107).

The other American firm interested in the nodules, Summa Corporation of Houston, owned by Howard Hughes has slated tests for its prototype nodule recovery system in 1975 (106). The movements of Howard Hughes "mystery barge" and its activities in the Pacific have made the news media.

An up-to-date account of the activity and organizations interested in deep sea mining was published recently (108). A brief review article on the process technology of extracting copper, nickel, and cobalt from the manganese nodules also appeared (109).

Poland plans to become the world's largest copper exporter, eventually shipping 400,000 million tons/year. Poland's government has approved a $1-billion investment program to enlarge the copper industry. Refined copper production in Poland is expected to reach 206,000 mt in 1974, a 26% gain over 1973 (110).

After suspending initial work in May, Texasgulf has decided to resume building the copper complex planned for Kidd Creek (Timmins), Ontario (111).

Three Finnish companies will build a $575 million extraction and smelting complex for nickel and copper for the Soviet Union in Norilsk, Siberia. The project is due on stream in 1976 and 1977 (112).

Hudson Bay Mining and Smelting Company and Anglo American Corporation of Canada agreed to purchase Lytton Minerals, Limited, interest in the Minas del Otono, S.A., Mexico, which owns the La Verde copper deposit 200 miles west of Mexico City (113).

As 1974 ended, the economic, political, and social factors affecting the world copper trade pointed to a poor year in 1975, with production cutbacks, continuation of price declines, and no viable answers to those problems. In the U.S., several mines cut back production in December in response to depressed copper markets and increasing inventories. Fabricators have also cut production by furloughing mill workers. The CIPEC have agreed to reduce shipments by 10% over the first six months of 1975. They will not cut back production, but will stockpile the copper. Japan is also planning to stockpile copper, but not as much as copper ore contractual commitment would indicate. France was drawing up plans to stockpile copper in 1975 for the first time in history (114).

Lithium.—Lithium carbonate consumption in the aluminum industry in 1974 continued the strong growth trend started in 1972 (115). This growth, combined with a strong demand by other lithium consumers, created a tight supply situation for lithium products last year. In the aluminum industry, the addition of lithium compounds to the potlines lowers the internal resistance of the electrolytic cells, thereby reducing the energy consumption requirements. Lithium also reduces the fluoride emissions. Since both of these factors are important to the aluminum industry, this end use for lithium compounds is expected to grow (115).

In 1974, lithium compounds were produced by Foote Mineral Company, Lithium Corporation of America, and Kerr-McGee in the U.S. (115). Foote Mineral added to the lithium carbonate capacity in 1974 at its Silver Peak, Nevada, operation with the total capacity at 14 million lb/year of lithium carbonate (116) and it is anticipated that output will increase further in 1975 (115). In 1974, Foote Mineral announced the construction of a 12-15 million lb/year lithium carbonate plant at Kings Mountain, North Carolina (117). The project was on schedule for production in 1976 (115). Lithium Corporation of America also inaugurated expansion of production capacity by 12% over 1973 in lithium chemicals at its Bessemer City, North Carolina, operation (118). Lithium Corporation of America also acquired Spartan Minerals Company, a major feldspar processor (119). The tight supply situation of lithium chemicals will ease when Foote Mineral's new plant comes on stream in 1976. Another 8-10 million pounds of lithium carbonate per year operation will be on stream in 1976 at Bernic Lake, Manitoba, Canada.

The total U.S. consumption of lithium chemicals was estimated at 32 million pounds of Li_2CO_3 equivalent in 1974 compared to 30.5 million pounds in 1973. World-wide estimated consumption went up from 49.5 million pounds Li_2CO_3 in 1973 to 53.4 million pounds in 1974 (115).

In early 1974, the quotes for lithium hydroxide were $0.63/lb in bulk quantities (120). In late 1974, the lithium hydroxide price was quoted at $0.87/lb (121). The price for butyl lithium in cyclohexane in early 1974 was $4.80/lb (120), and in late 1974 it was quoted at $7.32/lb (121). Lithium carbonate in early 1974 was quoted at $0.55/lb (119) and by late 1974 the price was quoted at $0.75/lb (121). In late 1974, lithium metal was quoted at $9.38/lb (121).

According to the Bureau of Mines, the U.S. Government has 5.9 million pounds of lithium hydroxide monohydrate in the U.S. General Services Administration stockpile, which was turned over to GSA by the former Atomic Energy Commission (122).

Foote Mineral Company is investing $600,000 for exploration in the Atacama desert for lithium in an agreement with the Chilean Government (123).

In other developments, many research groups are continuing investigations with lithium as an anode material for batteries, since these systems would potentially yield very high energy density (124). Primary organic lithium cells, which are already on the market, are said to be operational from −40° to 160°F, with a shelf life of 10 years and 95 W-hr/lb of energy density. These batteries are finding military applications (124).

Molten salt lithium-sulfur cells, being investigated at ESB, Atomics International, and Argonne National Laboratory, are expected to find applications in "load leveling" or energy storage at power plants and vehicle propulsion (124, 125). Atomics International reported (125) that with a copper sulfide cathode the loss of sulfur from such cells is minimized and over 700 charge-discharge cycles have already been attained. This system indicates an energy density of 60-80

W-hr/lb and would have a cycle life of 2000-3000 cycles.

Magnesium.—Magnesium had a banner year in 1974. Apparent demand far outstripped primary production, even though the plant of the major producer, The Dow Chemical Company, was operating at 105% of capacity at mid-year (126). To ensure an adequate supply of the metal to consumers and to improve inventory levels, The Dow Chemical Company purchased 21,410 tons of magnesium in the latter part of 1973 from the General Services Administration for monthly delivery in 1974 and 1975 (127). The GSA also sold about 4,000 tons of magnesium monthly to other companies (127), until the stockpile was depleted in the second quarter (130).

The American Magnesium Company, Snyder, Texas, with a capacity of 10,000 tons/year, resumed production in the second quarter of 1974 (129). NL Industries, Inc., Rowley, Utah, also produced and shipped a small quantity of magnesium during the first quarter (130).

Northwest Alloys, Inc., a subsidiary of the Aluminum Company of America, is constructing a new magnesium facility at Addy, Washington, for the production of the metal. Startup of this plant is now scheduled for 1976 (178). Norsk Hydro has announced its intention to build a 50,000 tons/year magnesium plant in Mongstad, Norway. Operation of this plant is slated for the early 1980's (131).

According to Nils Hoy-Petersen, Norsk Hydro director and president of the International Magnesium Association, the free world magnesium production should rise to 220,000 tons and consumption to 280,000 tons in 1974 (126).

The Dow Chemical Company has been exploring new technology which is expected to use 50% less power, to be less polluting, and to have lower operating costs than the present technology (126). However, the projected shortages of magnesium encouraged Dow to consider a major new plant on modified present technology rather than wait for new techniques to be proven. Both domestic and foreign sites are being evaluated for a 100 million lb/year magnesium plant to go on stream by 1978 or 1979 (132).

The price of 99.8% purity magnesium ingot in lots of 10,000 pounds or more was progressively raised in five steps from $0.42/lb at the beginning of the year to $0.47 on March 11 (132), $0.55 on May 1 (134), $0.65 on July 1 (126), $0.75 on August 1 (126), and $0.82 on January 1, 1975 (135).

The price of AZ91B alloy, used in die casting and general alloys, also increased correspondingly, and developed a differential of $0.05/lb, with the end-of-year price of $0.87/lb. The increases reflected the large increased costs of electrical energy, increased demand, competitive export markets, and the need to widen depressed profit margins of the materials.

Imports of magnesium metal in all forms in 1974 totaled 5307 tons, while exports of magnesium metal and alloys totaled 46,399 tons (135). American primary production approached 130,000 tons, and consumption 120,000 tons (126).

Manganese.—According to the Bureau of Mines, there was no 1974 U.S. production of manganese ore, concentrate, or nodules, containing 35% or more manganese, and this was the first year since 1880 that no producer shipments were recorded. Ferruginous manganese ore or concentrate, containing 10-35% manganese, was produced and shipped from New Mexico, and the Cuyuna Range of Minnesota (136). The manganese requirements were met by imports and sales from the government stockpile (137).

Consumption of manganese ore was again down from that of 1973 in the U.S. and amounted to 1,645,000 short tons in 1974. Imports of manganese ore this year containing 35% or more manganese were 1,188,000 short tons. Brazil and Gabon continued to supply more than half of this manganese ore and Australia became a significant third (137).

Domestic 1974 production of ferromanganese (high carbon, medium carbon, and low carbon grades) amounted to 582,500 short tons, appreciably lower than that in 1973 (137). The imports of ferromanganese totaling 421,000 tons (327,600 tons Mn content) established a new record. As in 1973, the major ferromanganese suppliers were France and the Republic of South Africa, supplying more than two-thirds of the total. Manganese metal imports for the year amounted to 2507 short tons and originated from South Africa (137).

The General Services Administration released for sale from its stockpile manganese ore, synthetic dioxide, and high carbon ferromanganese (136, 137).

Prices for metallurgical manganese ore containing a minimum of 48% manganese was $1.05-1.15/long ton for the first half of the year and $1.10-1.18/long ton in the second half of 1974 until December when the quote was increased to $1.18-1.38 for the same unit. Prices for ferromanganese after removal of the controls in March were quoted at $270/long ton and by November three subsequent increases brought the price to $400/long ton (136). Prices for the imported ferromanganese went up from $190 at the beginning of the year to $450-460/long ton toward the end of the year. At the end of December 1974, Union Carbide raised the price for ferromanganese to $440/long ton (137). The price for the electrolytic manganese metal went up from $0.3325-0.3725/lb to that of $0.54/lb by mid-November (136). The new South African source of electrolytic manganese metal, Delta Manganese (Pty) Ltd., started production about the middle of the year in Nelspruit in the Transvaal (136). Foote Mineral Company is the distributor for the United States and Mexico, but the initial output was destined for Canada and Europe (136).

Tenneco, Inc., has joined a group of Japanese trading firms, C. Itoh and Company, Nichimen Company, and Kanematsu-Gosho Ltd., in a three-year project to develop and evaluate metal recovery from Pacific Ocean manganese nodules. Tenneco's mining subsidiary, Deepsea Ventures, Inc., will have the responsibility for processing and marketing recoverable manganese. The initial goal is to produce and market 280,000 tons/year of manganese. The assessment program is supposed to cost $20 million over a three-year period. Commercialization would involve $200 million and eventually the group hopes to capture half of the U.S. manganese market. Other recoverable minerals are copper, nickel, and cobalt (136, 138, 139).

Kennecott Copper, as the head of the international group of companies, will continue its research and development program to determine the feasibility of mining sea floor nodules, but with its primary interest on the nickel and copper values. An expenditure of $50 million over a five year period is programmed (136).

The Chemetals Division of the Diamond Shamrock Chemical Company is planning to double, in 1975, its manganese capacity to 17,000 tons/year at Kingwood, West Virginia, at an investment of $6 million (136, 140).

Australia's producer of ferromanganese, Tasmania Electro Metallurgical Company, was reported planning an expansion that would include a new furnace and a sinter machine for feed. Completion was scheduled for late 1975 (136).

A Japanese survey team found substantial deposits of manganese ore, more than 10 million tons, (Tamboa Mines) in the Upper Volta. The ore contains 56% manganese (141).

Nickel.—The U.S. consumption of nickel in 1974 exceeded the high level reached in 1973 and resulted in a tight supply of nickel that lasted throughout most of 1974 according to the U.S. Bureau of Mines (142). The limited availability of nickel was also compounded by delays in the scheduled start-ups at several nickel producing facilities (142). The 1974 U.S. consumption of nickel was 208,107 short tons compared to that in 1973

of 198,461 short tons, according to Bureau of Mines data (143), which represents an increase of about 5%.

The U.S. nickel supply base that began changing in 1973 continued to shift in 1974. Imports of Russian nickel in 1974 continued to increase, doubling the 1973 level. Import data for the year 1974 indicate that the Dominican Republic replaced Norway as the second leading U.S. nickel source behind Canada, and New Caledonia (the French Pacific Islands) took over third place (142, 143).

Bureau of Mines data indicate that the level of activity in the domestic nickel production changed little from that in 1973 (142). Hanna Mining produced about 17,000 tons of nickel from laterite ore, the same as in 1973 (142, 143). The only domestic smelter recovered 12,500 tons of Ni as ferronickel (142). By-product plants recovered 950 tons of nickel in various forms. Other refiners and manufacturing plants recovered 34,000 tons of nickel from scrap (142). Canadian nickel production through the first ten months of 1974 was 10% greater than that for the same period in 1973 and totaled 242,089 short tons (142).

The price of pure nickel increased several times during 1974. The 1973 price of $1.53/lb was raised in early January to $1.62/lb. Falconbridge Nickel Mines, Ltd., and N.C. Trading Company increased the prices on May 16 to $1.85/lb of nickel. International Nickel raised their price to $1.85/lb effective June 28. Falconbridge again on December 1 increased the nickel price to $2.05/lb. The ferronickel prices were raised about 10% in October 1974, to about $2.00/lb of nickel content (142).

Ferronickel increased its market share in 1974 due to record stainless steel production at the expense of pure nickel, while nickel oxide maintained its 1973 market share. The over-all pattern of consumption of nickel remained at about the same levels, with approximately 48% consumed in steels, 22% in other nickel alloys and nickel, and 13% for electroplating (142).

Major exploration and development projects were underway in 1974 in the Philippines, Indonesia, Africa, Guatemala, and Australia. Interest in the United States centers around the possibility of exploitation of copper-nickel deposits located in the Duluth gabbro of Minnesota (142).

Amax Nickel Refining Company has started its nickel refinery at Port Nickel, Louisiana. Full capacity of 80 million lb/year of nickel is now expected to be reached in 1976. Besides nickel, the facility will produce 47 million lb of copper/year, 1.2 million lb of cobalt/year and 100,000 tons/year of ammonium sulfate (144).

Marinduque Mining & Industrial Corporation has started the operation of its $250 million nickel mine and refinery in the Philippines. The designed capacity is for 68.4 million lb/year of nickel with sulfide concentrates and 6.6 million lb/year of nickel and 3.3 million lb/year of cobalt (145).

The Greenvale nickel-cobalt project in Queensland, Australia, is near completion, according to Metals Exploration, Queensland (Pty) Ltd. The facility will have an output of 46 million lb/year of nickel oxide (90%), 7.5 million lb/year of nickel and 2.75 million lb/year of cobalt in the form of mixed sulfides (146).

Agnew Mining Company (Pty) Ltd. and the Australian government are near an agreement for a new large nickel project in Western Australia. The new firm was formed by Western Seleast (Pty) Ltd. and Mount Isa Mines Ltd. (147). Endeavour Oil Company has found a major nickel sulfide deposit at Digger Rocks, in Western Australia, estimated at 520,000 tons of nickel (148).

Societe Metallurgique-Le Nickel Sln. Aquitaine, a joint company formed by Societe Le Nickel and Societe Nationale des Petroles d'Aquitaine, will invest $230 million for a 50% interest in the venture. The new company will take over Societe Le Nickel's mining and other assets in New Caledonia and the refining plant at Le Havre. Production at Doniambo, New Caledonia, will be increased to 75,000 tons/year of nickel (149). Amax, Inc. has acquired a 10% interest in Le Nickel, SA, Paris (147).

The Cie Francaise d'Entreprises Miniers, Metallurgiques et d'Investissements, a subsidiary of Patino, N.V., has received approval from the French government for a nickel mining and processing facility to be completed in 1976, which will produce 18,000 tons/year of nickel as ferronickel (149).

A high recovery nickel extraction (90% extraction efficiency) process is being piloted by Universal Oil Products (UOP) Company's Mineral Sciences Division. The $1.6 million pilot plant will process 5 tons/day of nickel laterite ore, by roasting at 1000°-1800°F with a reducing gas in the presence of SO_2, H_2S, or HCl (150, 151).

The Commonwealth of Puerto Rico and UOP are planning a joint nickel mining and processing venture, based on UOP's extraction technology. UOP will begin a two year evaluation of the project including the pilot plant. The project investment is pegged at $75 million (152, 153).

A process developed by Dartmouth College and Purdue University, called QS Oxygen Process, is being piloted by American Air Liquide of New York with other partners. The process consists of a single reactor with continuous feeds of oxygen, concentrates, and flux and can be used with copper, nickel, and lead sulfide concentrates. The cost for energy, slag, and sulfur fixation are claimed to be 50% of the costs of conventional converters (154).

The U.S.S.R. is operating a metals mining complex on the Taimyr Peninsula, Northern Siberia, where sulfide ores of nickel and other metals are obtained (155). Three Finnish companies will build copper and nickel smelters worth $300 million with annual capacity to handle 550,000 tons of nickel concentrate and 650,000 tons of copper concentrate. The plants will be located at Norilsk in Western Siberia. The project is due on stream in 1976 and 1977 (156, 157).

Sodium.—Metallic sodium production was down an estimated 2.3% in 1974 as compared to the 176,903 tons of metal in 1973. The historic growth rate in production of metallic sodium was 2%/year. About 80% of the metallic sodium went into the manufacture of the gasoline additives, tetramethyl and tetraethyl lead. The shortage of gasoline at the beginning of 1974, the requirement of no-lead gasoline for 1975 model cars equipped with catalytic exhaust systems, and the EPA ruling that most service stations must sell at least one grade of unleaded gasoline were contributing factors in reducing the usage of metallic sodium (158).

The regulations of the Environmental Protection Agency required a reduction in the average lead content of gasoline to 2.00 g/gallon in 1975, 1.70 by 1976, 1.5 by 1977, and 1.25 by 1978. Thus, the regulations could have a direct effect on sodium production over the next four years.

However, PPG, a leading tetraethyl lead producer, filed a petition with the District of Columbia Court of Appeals to invalidate or review EPA's decision to phase down the use of lead in gasoline (159). Ethyl Corporation, also a large producer of tetrethyl lead, appealed the EPA ruling in August, charging that the agency had failed to prove its health case against lead in gasoline and that it had overstepped its bounds in issuing a final phasedown of lead (160). In December, the Federal District Court in Washington, in response to the plaintiffs, the National Petroleum Refiners Association, Ethyl Corporation, PPG Industries, du Pont, and Nalco, overturned EPA's regulation on the phasedown of lead in gasoline, ruling that EPA did not prove that lead emitted from automobiles is a health hazard to humans (161).

Like most industrial items, the prices of antiknock compounds also increased in 1974. Demand for the compounds was strong, despite opposition to its continued use on the part of environmental groups and

government timetables for reduction of lead in gasoline (162).

Titanium.—Industrial demand for titanium metal, which began to strengthen in the last quarter of 1973, continued through 1974 (163). This strong demand and sharply escalating prices featured the titanium markets during 1974.

Production of titanium sponge was 18% greater in 1974 than in 1973 (163). Final deliveries of sponge to the stockpile under GSA contracts were made during the third quarter of 1974. Consumption of sponge and scrap was about 27,000 tons and 10,500 tons, respectively. Production of ingot was about 36,500 tons. Imports of sponge for consumption were about 6800 tons, 30% more than in 1973. Of these imports, 62% came from the U.S.S.R., 30% from Japan, and 8% from the United Kingdom (163). Japanese production was expected not to exceed 9000 tons, 40% gain over 1973 (164). The titanium production rate was limited by shortages of power, labor, replacement parts, and raw materials.

A healthy demand for titanium metal was evident from both the industrial and aerospace sectors (163). Producers of chlorine and caustic soda are increasingly replacing graphite anodes in diaphragm cells with dimensionally stable titanium anodes and switching from the mercury cell process to diaphragm cells. Increased interest was shown by utilities in using titanium for condensers because of resistance to corrosion, erosion-corrosion and fouling, and good heat transfer characteristics. The first all titanium tube condenser for a steam boiler in the U.S. is scheduled to go into operation in June 1975, at New Haven Harbor, Connecticut (165). A major east coast refinery was replacing all of its heat exchanger tubing with titanium tubes (166). Titanium as a specialized construction material was also engineered into desalination plants (164).

The SR-71 prototype aircraft, which crossed the Atlantic Ocean in two hours, was an all titanium plane. The Navy's Grumman F-14 fighter plane was designed with about 25% titanium in its airframe (167).

Gould, Incorporated, has reached agreement with Energy Development Associates (a research and development partnership of Gulf and Western and Hooker Chemical's Oxy Energy Development Company subsidiary) to cooperate in the development of rechargeable zinc-chlorine batteries. Gould will use its powder metallurgy technology to develop a porous titanium electrode, which is not attacked by chlorine. Energy Development has been operating 1-kW-hr, zinc-chlorine batteries, which rely on storing chlorine in the hydrate form. The battery system, with an energy density five times greater than best-available lead-storage batteries, is envisioned for use in peak-load power generation at utilities and in electric cars (168).

The price of domestic sponge increased from \$1.42/lb to \$1.90/lb in mid-year, to \$2.25/lb at the end of the year. The price of rutile increased from \$310.00/short ton as the year began to \$330.00 in March, \$520.00 in June, and \$710.00 in November. Ilmenite similarly rose in price from \$38.00 to \$55.00/long ton. The price of Sorel slag remained at \$60.00/long ton throughout the year (163). It was reported that Japanese sponge will be priced at \$2.85/lb in the first half of 1975 and \$3.05 for the second half (169). The price increases for titanium sponge reflect higher energy and raw material costs.

Because sponge production requires 15-18 kW-hr of electric power to produce a pound of sponge (compared with 6-9 kW-hr for a pound of aluminum), production costs increased with utility rate increases. Freight rates and raw material prices for rutile, chlorine, magnesium, sodium, and argon have also risen sharply (170).

An excellent review on the direct reduction processes for the production of titanium metal was published in 1974 by the National Research Council (171).

Mine production of titanium minerals was about 764,000 tons, a decline of about 1.6% from the 1973 level. The mine of the American Smelting and Refining Company in New Jersey had its first full year of production. Mechanical difficulties at one mine and exhaustion of another property accounted for the decrease. In western Tennessee, Ethyl Corporation conducted an extensive pilot program in anticipation of mining and processing sands of the McNairy formation for their titanium mineral content (163).

Imports of ilmenite increased to 96,000 tons, as heavy shipments from Western Australia began in June. Imports of rutile, both natural and synthetic, decreased to 181,000 tons, off 13% from 1973. Imports of slag were 252,000 tons, 6% more than in 1973. The General Services Administration released 3700 tons of rutile from the stockpile (163).

The demand for titanium pigment, while strong throughout the year, came more nearly into balance with supply than was the case in 1973. Production in 1974 was estimated at 808,000 tons, a 4.7% increase over 1973. E. I. du Pont de Nemours and Company neared completion of its chloride-process facility at Edge Moor, Delaware. du Pont abandoned plans for a pigment plant New Brunswick, Georgia, and took preliminary action toward a similar plant in Mississippi (163).

Kerr-McGee Chemical Company announced plans for 110,000 tons/year of synthetic rutile capacity and a smaller pigment plant at Mobile, Alabama. Sherwin-Williams Company sold its 27,000 ton/year chloride-process pigment plant at Ashtabula, Ohio, to New Jersey Zinc Company in October (163).

Imports of pigment were about 38,000 tons, a decrease of 37% from 1973 levels. Exports during the same period reached 34,500 tons, 63% greater than in 1973. Domestic prices, decontrolled by the Cost of Living Council at the end of May, rose from about \$0.38/lb to about \$0.43 for the highest grade, with similar increases of about \$0.05/lb for lower grades (163).

Australian production of rutile was estimated at 340,000 tons, continuing the decline from the peak year of 1970. Australian ilmenite production, however, was estimated at 775,000 tons, about equal to 1973 production. Current activity in Western Australia may result in increased production of ilmenite in 1975 (163).

Zinc.—The slackening demand for zinc that began in late 1973 continued through 1974. This slackening was principally a result of the turndown in automobile production (1972).

Mine production in 1974 was approximately 494,446 tons, up 3.3% over that of 1973. New York, Missouri, and Tennessee were the principal producing states, accounting for 54% of domestic production. The new Elmwood mine in central Tennessee near Carthage was ready for production. About 25,000 feet of lateral development had been completed. This development confirmed earlier estimates that the deposit consists of approximately 20 million tons of zinc ore grading 4.5-5% zinc. A new mill constructed near the mine site was approaching completion. The concentrator has a capacity for processing 2000-3000 tons/day and will produce a 63% zinc concentrate. A new mine in Utah, developed as a joint venture by two major producers, will be ready for production in 1975 (172, 173).

Smelter production of slab zinc from ore was 546,140 tons in 1974, nearly 15.1% less than 1973 (174).

The decline in domestic zinc smelting capacity was reversed with the announcement of plans to erect two electrolytic zinc smelters, the first in thirty years. Upon completion of the plants, possibly in 1977, domestic capacity will be increased by 340,000 tons annually to over 1 million tons.

National Zinc announced that construction will begin on March 1 on a 50,000 tons/year electrolytic plant in Bartlesville, Oklahoma, replacing a horizontal retort smelter. The \$27 million facility is scheduled for completion by May 31, 1975 (175, 176). The Oklahoma Air Control Board extended permission to operate the

other remaining horizontal retort smelter beyond May 31, 1975, the date now scheduled for closure.

Engelhard Minerals and Chemicals acquired the assets of National Zinc, including the horizontal retort smelter. Engelhard will carry out the zinc producer's previously announced plans to construct an electrolytic zinc facility at Bartlesville (177, 178).

New Jersey Zinc announced the construction of a new electrolytic zinc refinery, with an initial capacity of 80,000 tons/year in 1977 and planned expansion to 160,000 tons/year by 1979, to be built near Clarksville, Tennessee. The company is also planning an extensive modernization program at its vertical retort zinc plant at Palmerton, Pennsylvania (179).

No new primary zinc facilities have been constructed in the U.S. since 1942. The closing of seven outdated smelters has decreased domestic zinc production from a peak of 1.3 million tons in 1968 to approximately 840,000 tons/year at present. Further shutdown scheduled for outdated smelters will reduce domestic primary capacity to about 655,000 tons/year, resulting in increasing dependence on zinc imports (179).

Canadian Electrolytic Zinc is planning to expand its Valleyfield zinc plant from 400 to 620 tons/day (180). Cominco began construction on the Rubiales lead-zinc mine in northern Spain. It is expected to come on stream in 1977, with an annual output of 115,000 metric tons/year of zinc concentrates (181).

General imports of zinc in ores and concentrates increased 20.6% over those of 1973 to 240,043 tons. Receipts from Canada were up, but from other countries—Mexico, Nicaragua, Honduras, Peru, and Australia—were substantially less. Imports for consumption of zinc in ores and concentrates declined approximately 13.1% to 133,728 tons. In 1974, both general imports and imports for consumption of slab zinc were nearly the same at 538,585 and 543,805 tons, respectively, representing decreases of 9.1 and 7.4%, respectively, from 1973. Canada provided about 50% of the slab zinc imports, West Germany 8%, and Australia and Peru each 7% (182).

Consumption of slab zinc decreased almost 14% from that of last year to 1,293,921 tons. Zinc used for galvanizing was down 12.3%, zinc base alloy down 29%, brass and bronze down 10.4%, zinc oxide up 6.6%, and other uses up 4% (182).

The General Services Administration continued to release zinc from the national stockpile as authorized by Public Law 92-283. On December 28, 1973, the President signed Public Law 93-212, which authorized an additional 357,300 tons of zinc for release, thus adding to the previous balance and creating a balance of approximately 415,000 tons of zinc available for commercial disposal. Early in the year, GSA started a new set-aside program by offering 150,000 tons over a period of 1 year with 75,000 tons available for the second quarter of 1974 and 25,000 tons each quarter thereafter. The offers were oversubscribed for the first two quarters in the program, but a turn-around occurred in the fourth quarter of 1974 when only 8360 tons was purchased from the 25,000 tons available. GSA sales of stockpile zinc in 1974 amounted to approximately 270,000 tons, leaving a balance of 166,000 tons authorized for release (172).

Legislation to suspend the duty on imports of zinc concentrates, H.R. 6191, was passed by the House of Representatives and the Senate, but was vetoed by the President because it contained a nongermane tax rider. The bill would have suspended through June 30, 1977, the $0.67/lb import tariff on zinc ores, concentrates, and certain other zinc-bearing materials (172).

The monthly average price of domestic Prime Western zinc ranged from $0.31168/lb for January to a high of $0.39334/lb for October and decreasing to a December average price of $0.3924/lb. The European producer price was raised during the year from $0.3026/lb in January to $0.381/lb in October and $0.3804/lb in December. The London Metal Exchange (LME) price rose from $0.602 to $0.806/lb from January to May, then declined sharply to the average December quotation of $0.3495/lb (173, 174, 183).

These prices are substantially higher than the 1973 prices, when the monthly average price of Prime Western zinc ranged from $0.1866 to $0.2737/lb. The European producer price ranged from $0.1849 to $0.3154/lb, with an average for the year of $0.24/lb. The LME price fluctuated from a low of $0.1753/lb in January to a high of $0.7331/lb in November, with an average for the year of $0.3855/lb (173,174,183).

At the end of the year, the U.S. and foreign zinc markets were seriously affected by the world economic doldrums, resulting in lower demand, oversupply, and decreasing prices. To counteract these adverse conditions, zinc producers have gradually cut production to get supply and demand into balance. European producers have reduced output from 10% to a "significant percentage." Japanese producers cut production 20% from 1973 levels. U.S. producers have not announced any cuts, but some facilities were not running at full capacity (184).

The Bureau of Mines issued a significant document in "The U.S. Zinc Industry: A Historical Perspective," in which the changes in world mine and smelter supply sources of zinc and changes in zinc supply patterns in the U.S. during the last three years are described. The result has been a growing reliance on foreign sources of zinc to furnish an ever increasing portion of expanding domestic requirements. The document also reviews the developments, properties, uses, reserves, technology, production, consumption, imports, and government actions (185).

The Electrical Industry

In 1974, the electric utility industry was swamped with many problems: the flattening of the load growth rate of the use of energy, the high cost of money, lack of adequate return, skyrocketing capital costs of building, high fuel costs, restrictions on western coal, legal delays by environmental intervenors, construction delays, material problems, and new plant cancellations. Because of the conservation program and the recession, for the first time in many years there was a small decline in the total production of electricity. The only segment of the industry which showed an improvement was nuclear generating plants. In contrast to last year, water conditions substantially improved hydroelectric resources particularly in the Pacific Northwest.

In the fall of 1974, President Ford signed into law the bill that formed a federal Energy Research and Development Agency (ERDA) and a Nuclear Regulatory Commission to replace the AEC and the various energy research activities scattered throughout the governmental departments. The President was given the power to appoint the regulatory commissioners, the ERDA administrator, his deputy, and six assistants—one each for fossil energy; nuclear; environment and safety; conservation; solar, geothermal, and advanced energy systems; and national security. The ERDA objective is to guide the energy policies of the nation to attain Project Independence.

In a proclamation which appeared in many major newspapers, a group of 34 scientists, headed by Dr. H. Bethe and including 10 Nobel Prize Laureates, called for oil exploration on the continental shelf and greatly increased use of coal and nuclear energy. They hold that the energy shortage is the most serious problem in the U.S. since World War II, and the U.S. choice is not between coal and uranium, but both.

Howard Drew, of the Texas Electric Service Company, is pessimistic that the U.S. can achieve the goal of self-sufficiency by 1980 (186). He believes that the earliest the nation could possibly reach the goal is 1985, assuming several things that may be difficult to achieve. The assumptions are (*i*) that the nation can cut its growth in energy demand in half (to 2% per year); (*ii*) that the U.S. will be able to double the use of coal as an energy resource (opening 100 new strip mines in the next 11 years); (*iii*) that gas and oil pro-

duction be increased by 25% (drilling hundreds of new offshore oil wells by 1985); and (*iv*) that construction of nuclear power plants be started at the rate of two or three new plants each month for the next 11 years. One of the big problems in reaching the 1985 goal will be the raising of nearly $600 billion in capital needed for new construction.

In the first eight months of 1974, indefinite postponements, cancellations, and scheduled stretchouts in the construction of power plants involved some 65,000 MW through the 1980's, according to a survey of 74 utilities by National Economic Research Associates (187). Of this capacity, some 35,000 MW was nuclear and the balance fossil-fired. This delay of the nuclear power plants could mean the equivalent annual consumption of 400 million bbl of fuel oil, at a cost of $4 billion.

Two recent conferences, one at the Ninth Intersociety Energy Conversion Conference in San Francisco, and the other at the World Energy Conference in Detroit, brought together the recent advances in energy and power R&D, the hydrogen economy, and energy economics. Last March, the first major international conference devoted to the hydrogen economy of the future was held in Miami Beach. Eighteen sessions covered many aspects of the hydrogen economy, from production, storage, transmission, uses, the environment, to legal considerations. In October, the New York meeting of The Electrochemical Society also held sessions on the hydrogen economy.

The interest of power utilities in fuel cells is for baseload, standby generation, or backup power in an environmentally acceptable way. A major advance in the application of fuel cells was made when nine utilities joined with Pratt and Whitney in a financial arrangement to develop a 26 MW fuel cell to generate power. One demonstrator unit will be fabricated and tested by 1975, and, if successful, 56 provisional initial orders by the utilities could be firmed up (188, 189).

A commercial sodium-sulfur battery for load leveling and peaking that could meet a mid-1980 market estimated at 50,000 MW-hr/year was viewed with optimism at a recent Intersociety Energy Conversion Conference meeting (190). Problem areas include extension of cell life by a factor of ten and suitable low-cost, corrosion-resistant materials for containers and current collectors.

U.S. Power Generation.—The following tables give a preliminary summary of the production, installed generating capacity, fuel consumption, and consumption of electrical energy for the twelve-month period, January through December, 1974. For comparison purposes, revised final figures are also given for 1973. The Edison Electrical Institute expects the kW-hr use to rise by 4.5% in 1975 and to average about 7% annual growth during the 1975-1980 period (197).

Power prices are of prime concern to the electrolytic industry. Quadrupled prices of foreign oil and strong demand for low-sulfur coal have forced full escalation clauses in utility contracts. Power that cost 6-8 mills/kW-hr a few years ago now costs 30-60% more. Hydropower prices are also climbing; Bonneville Power Administration is seeking a 39% increase in its present 2.3 mills/kW-hr rate (198, 199). TVA, with more fossil fuel generating plants, is increasing its rates by 53% over 1973 rates.

Table 4. Production of electrical energy in 1974 (191-193) (Billions-kW-hr)

Electric utility	1973	1974	% Change
Coal-fired	848.9	828.3	−2.43
Oil-fired	312.4	292.3	−6.43
Gas-fired	340.2	320.4	−5.82
Nuclear	83.3	106.7	+28.09
Total	1584.8	1547.7	−2.34

Total	1856.4	1808.6	−2.57
Other*	2.7	2.7	0
Total	1859.1	1811.3	−2.57
Private industry	105.7	105.7[e]	0
Grand total	1964.8	1917.0	−2.43

* Includes geothermal, wood, and other sources.
[e] Estimated.

Table 5. Installed generating capacity* (194, 195) (Millions-kW)

Investor owned	1973	1974	% Change
Hydro	21.5	22.1	+2.8
Steam**	305.8	325.6	+7.5
Nuclear	17.8	26.4	+48.3
Internal Combustion	1.4	1.4	0
Total	345.4	375.5	+8.7
Public owned			
Hydro	39.8	40.3	+1.3
Steam**	48.5	51.1	+5.4
Nuclear	1.3	4.2	+22.3
Internal combustion	3.5	3.5	0
Total	93.1	99.1	+6.4
Industry total	438.5	474.6	+8.2
Fuel type			
Hydro	53.7	54.3	1.2
Pumped storage	7.6	8.8	15.8
Fossil fuel	318.3	336.9	5.1
Nuclear	21.1	30.3	43.6
Internal combustion	4.9	5.0	1.9
Combustion turbine	32.9	39.3	19.5
Total industry	438.5	474.6	+8.2

* As of December 31, 1974.
** Includes generation by combustion turbine.

Table 6. Fuel consumption by electric utilities (191)

Fuel	1973	1974	% Change
Coal, million tons	386.6	389.3	−0.08
Oil, million barrels	560.0	527.1	−5.88
Gas, billion of cu ft	3635.8	3413.5	−6.11
Coal equivalent,* million tons	728.6	728.7	0

* Includes equivalent for nuclear, geothermal, wood, and waste.

Table 7. Electric utility sales to ultimate consumers in 1974 (196) (Billions-kW-hr)

Consumer	1973	1974	% Change
Residential	554.2	548.9	−0.96
Commercial	396.9	389.1	−1.97
Industrial	687.2	692.3	+0.74
Other	64.9	63.3	−2.47
Total	1703.2	1693.6	−0.56

An updated analysis of power costs by Arthur D. Little gives nuclear power a 5 mill/kW-hr edge over fossil-fueled plants. In a 1150 MW plant, the annual savings would be nearly $40 million in power generating costs (200).

TVA's fuel expense summary for September 1974, shows that nuclear fuel costs were 1.588 mills/kW-hr and coal fuel costs were 4.632 mills/kW-hr (201). Nuclear fuel costs were equivalent to $3/ton of coal, but coal prices were at $10/ton. The two TVA nuclear plants produce electricity equivalent to burning 20,000 tons of coal/day, three large trainloads (202).

Energy from fossil fuels.—Even before Arab oil embargo in the fall of 1973, it was apparent that current domestic sources of petroleum could not fulfill the requirements demanded by consumers. Petroleum imports steadily increased until the OPEC nations lowered the boom.

In the pre-embargo period, natural gas and oil increased to 65-75% of the total energy, and the contribution of coal gradually decreased, being first displaced in the residential and commercial heating markets. Following World War II, the coal industry lost a large market when the railroads converted to diesel engines. The remaining coal markets were for the production of coke as a fuel, for the rapidly growing utility market, and for large industrial users, such as the cement mills. By 1974, the electric utility industry

consumed 70% of all the coal used in the U.S., while the cement industry consumed 18%.

Prices of coal remained relatively inexpensive and static, about $5/ton up to the end of 1973. Starting in 1973, inflation increased, the field price for natural gas escalated, steep rises in price of imported oil were imposed by OPEC nations, and coal mine productivity declined. As a result of these developments, the price of eastern bituminous coal increased to about $8.50/ton in 1973 and $10/ton in 1974.

The increased price of coal also indicates an increased demand by the utility industry for low-sulfur coal, as well as other industrial uses and exports of coal. At the same time, considerable governmental and industrial interest was shown in converting coal into liquid and gas products for chemicals and heating as substitutes for petroleum products. There are numerous articles in the literature describing the conversion techniques, such as pyrolysis, solvation, hydrogenation, and production of synthesis gas. Excellent reviews of coal conversion technology and coal gasification (203) have been published (204).

A comprehensive survey of established coal-gasification processes as well as new ones was reported by Chopey (205).

The Office of Coal Research is putting emphasis on converting coal into liquefied, clean, storable, transportable fuel that can be burned by central power stations or other big industrial users with minor environmental effects. Energy conversion efficiency is higher for liquefaction than it is for gasification, about 78% *vs.* approximately 60%, respectively. The liquids are more easily stored than gas, big plants could be built to run at optimized output, and production would not have to be synchronized to the demand of a power plant or other big user. Moreover, liquids are more concentrated and can be pumped more economically for greater distance than gas. Liquefaction does not have the heavy demand for water that gasification does, and liquid fuel is more easily pressurized to fire industrial power turbines than gas (206).

During the year, new projects for making gas and oil from coal were started. However, before they go commercial, many economic, equipment, and other problems have to be solved. Despite availability of processes, no construction work had begun and it appeared unlikely that any plant could be completed by 1978. Government approvals, plant sitings, and economics are factors which affect the slow progress toward commercialization (207).

Exxon, El Paso Natural Gas, Texas Eastern Transmission, Northern Natural Gas, Cities Service Gas, and Michigan-Wisconsin Pipeline are among the companies who have announced their intention to build commercial coal gasification plants (207).

Consumers in County Fife, Scotland, are getting synthetic natural gas made from coal. Up to 2.5 million cu ft/day are supplied from a demonstration plant in nearby Westfield. The project is being sponsored by Continental Oil Company and more than a dozen U.S. companies, working in collaboration with British Gas and Woodall-Dickham. The aim of the project is to demonstrate the feasibility of the gasification process developed by Lurgi Mineralotechnik, West Germany, for producing high Btu gas (208).

The effects of electric fields on plants, animals, and soils near and under high voltage transmission lines will be studied by Westinghouse and Pennsylvania State University under contract from the Electric Power Research Institute (209).

The question of the efficacy of installed stack-gas scrubbers was unresolved in the first part of the year. Louisville Gas and Electric was caught in the middle of the dispute between EPA, who issued a directive to install scrubbers, and Federal Power Commission (FPC), who ordered all work stopped on scrubers (210).

Scrubbing efficiency was claimed to be increased by 2.3 times with thiosorbic lime than with conventional lime. Thiosorbic lime has a balanced amount of magnesium oxide to promote high alkalinity in solution (211).

To cope with energy shortages, chemical companies are trying to become at least partially self-sufficient. Dow, Grace, Union Carbide, du Pont, and others are moving into oil and gas exploration by the acquisition of, or joint ventures with, independent exploration companies (212), as well as acquiring coal companies. Grace merged with Blue Diamond Coal (213), Cleary Petroleum, Magness Petroleum, and Amini Oil (214); Ethyl acquired Elk Horn Coal (213); Dow obtained a stake in Magma's geothermal technology and tracts, leased 12 producing wells owned by Quitana Production (215), and bought a 20% interest in McMoRan Exploration (213); and Gulf Resources and Chemical acquired coal reserves in Cambria County, Pennsylvania, and two small oil companies (216). Dow will also participate in a Gulf Coast superport, is planning a fuels and feedstock refinery for Brazosport, Texas, and is lining up ventures in energy-rich western Canada and the Mideast (212).

Connected indirectly to electrical energy is the recovery of the fuel value of oil shale or oil sands. The influence of the oil embargo and the price of Arab oil made the bidding for oil shale leases in western Colorado competitive and the price high (217). The chemical extraction of oil from sands will undergo pilot plant tests at Edmonton, Alberta. The process has shown evidence of higher yield and utility than steam or water (218). The *in situ* combustion to recover oil from tar sands will undergo field testing for feasibility by the Bureau of Mines (219). A one-year study on the feasibility of petrochemicals from the Alberta oil sands will also be made (220).

Project Independence placed reliance of the future energy needs on domestic sources of energy, especially on the vast coal reserves. Estimates indicated that coal production will have to be doubled by 1985 to fulfill its assigned role. One of the many problems in doubling production involves moving that much more coal, since the present transportation system is already strained. Modern technology is making progress to solve the transportation bottleneck.

Overland conveyor systems for transporting coal up to 15-20 miles with capacities of up to 5000 tons/hr are becoming common in the industry (221).

A coal slurry pipeline is operated by Peabody in northern Arizona. The coal is crushed, rod-milled, and wet-ground to 8-mesh. The slurry is formed in the rod mills, from where it is pumped to large storage tanks equipped with mechanical agitators. The 273 mile, 18 in. pipeline is capable of moving 660 tons of coal/hr in a 50% by weight slurry at a flow rate of 4200 gallons/min. Transit time from mine to destination is three days, and the line holds 45,000 tons of coal. Four pumping stations operate at between 1000 and 1500 psi, and require up to 1750 hp (221).

An 800 mile slurry pipeline system from the coal fields in Montana, Wyoming, Colorado, and Utah to the Pacific Northwest is being considered by Northwest Pipeline Corporation. The coal would be slurried with water, which would be recycled to the coal fields. Ultimately, the slurry would be composed of coal and methanol (222).

Consolidation Coal Company has announced a new hydraulic system of moving coal via pipeline from underground mine faces to above-ground preparation plants. Coal from a continuous miner is put through a mobile crusher to obtain a maximum 4 in. size, fed into a mixer where water is added to form a slurry, and sent under pressure through a 10 in. pipeline to the surface. The water is removed from the coal in the preparation plant and returned to the closed-circuit system. Consolidation Coal claims greater productivity, increased tonnage, and many safety advantages (223).

Energy from nuclear sources.—Coal and uranium are in much more abundant supply than oil and gas in the U.S. In view of this, many experts are advocating

that all our power generation should be geared to coal and nuclear energy to conserve oil and gas for other uses. Even the Shah of Iran advocated petroleum uses other than energy. Over the long term, nuclear power should be the base-load, so that coal can be used for synthetic oil and gas, thus augmenting the scarcer supplies of petroleum crude and natural gas. This postulate practically dictates that the breeder reactor be in large-scale commercial operation by 1990 (224).

According to Atomic Industrial Forum, 56 reactors are now operable in the U.S., with a capacity to generate 37,536 MW, nearly 8% of the U.S. total. In 1974, U.S. reactors generated 121 billion kW-hr, saving 183 million barrels of oil or 42 million tons of coal, equivalent to $1.8 billion in foreign trade (225).

However, a mid-year report by the FPC listed 27 nuclear units, originally scheduled for operation in the summer of 1974, that have been delayed. The missing 26,120 MW of power is equivalent to 17 million barrels of oil/month (226).

The Atomic Energy Commission proposed legislation to change the nuclear power plant licensing process. The objective is to decrease the time required for approval and construction of nuclear power facilities from ten to six years, while providing for more effective state and public participation in planning these facilities. To reach the six year period, AEC is requesting authority to approve standardized power plant designs and to establish a list of approved plant sites (227).

For comparison, Sweden has built a nuclear plant in just over four years. Construction of Ringhals 2, an 820 MW pressure water reactor (PWR), began in February 1970, and went critical on June 19, 1974 (228).

Critics and intervenors questioned the availability of existing nuclear-fueled power plants. Three factors should be considered: cost of construction, cost of fuel, and availability. Coal-burning plants are cheaper to build by 30%. The other two factors appear to favor nuclear plants.

The Atomic Industrial Forum reported a 10% drop in nuclear-fuel costs in 1974, while fossil-fuel costs rose by 85%. Fossil fuels, on the average, now cost 11.6 mills/kW-hr, nearly six times the cost of nuclear fuel at 2.0 mill/kW-hr. Average nuclear power plant availability was 68.6% as the year drew to a close, compared to 58.4% for similar-sized fossil plants (229).

In the TVA system, Brown's Ferry Nuclear Unit 1 generated 1.9 billion kW-hr in the third quarter of 1974, equivalent to 650,000 tons of coal. The 1065 MW boiling water reactor (BWR) was available 87% of the time during the quarter, which compares to the average availability for large coal-burning units last year of 72% (230).

Commonwealth Edison reported that the availability of its four large nuclear units averaged 82% in 1974, against 69% for five new 500-800 MW coal-fired units (231).

The Connecticut Yankee 575-MW PWR plant had a capacity factor of 73%, including 88% for the first eleven months of 1974. Compared to equivalent oil-fired generation, the reactor saved its customers over $96 million in 1974 (232).

The average cost of 1 kW-hr from nuclear plants at the end of 1974 was 10.52 mills, compared to 17.03 mills from fossil-fuel plants. The figures included amortized capital allocations. The big savings was in fuel, 2.15 mills in a nuclear plant and 11.25 mills in a fossil-fuel unit (233).

The U.S. uranium enrichment capacity has already been obligated. The projected U.S. and world demand for enriched uranium mandates that the present capacity be enlarged to guarantee a long-term supply for the expanding nuclear power plant market (234, 235). Two groups, CENGEX Associates (236) and Center Associates (237, 238), have shown interest in developing private capacity for enriching uranium by gas centrifuge technology with probable start-up in 1979-1980. Another group, Uranium Enrichment Associates, was studying the current diffusion technology, but initial estimates indicate high capital requirements (234).

A European uranium enrichment plant, involving France, Belgium, Italy, and Spain, is scheduled for completion in 1979. The $1.5 billion plant, based on gaseous diffusion separation, being built at Tricastin in the Rhone Valley, has been increased by an unspecified amount beyond the original level of 9 million separative work units (239).

The U.K.'s fast-breeder reactor prototype went critical in the first quarter of the year. The unit, at Dunrea, Scotland, feeds about 250 MW into the national grid, but its main purpose is to provide practical implications of building a commercial-size unit. Two other prototypes already are operating in Europe, a 150 MW unit in the U.S.S.R. and a 250 MW unit in France (240).

France has built a 250 MW unit and operated an experimental liquid metal, fast-breeder reactor, LMFBR, named Phenix, which produces more plutonium than it consumes as part of the fuel. The U.S. breeder reactor program is mired in red tape. The construction of the reactor, slated to be along the Clinch River near Oak Ridge, Tennessee, and to be operational in the early 1980's, has not started, more than two years behind schedule (241).

The U.S.S.R. also has a BN 350 (350 MW) breeder reactor at Shevchencko. However, this plant was forced to shut down due to tube leaks in three of the steam generators. The plant was operating at 30% of full power at the time of shutdown (242).

Dr. David J. Rose of MIT claimed that burning coal to produce electricity is 100 times more deadly than using nuclear power plants to produce the same amount of energy (243). Health risks from nuclear plants were also called minimal by Dr. Roger E. Lennenman. Radiation levels from nuclear power plants are small compared to normal risks tolerated by society (244). The accidental potential of fission reactors has been exhaustively surveyed recently, and found to be below the risk potential of many industrial processes and natural phenomena (245).

Roughly one-third of Chicago and northern Illinois electricity is now provided by nuclear energy, and the oldest atomic unit has been operating safely for almost 14 years. The state monopoly in France has decided that all new power stations will be nuclear. Twenty nations other than the U.S., including all major industrial powers, are moving ahead on the nuclear power front (246).

In May, Electricite de France ordered 16 Westinghouse PWR's from Frametome (owned 45% by Westinghouse), the largest order ever placed in the history of the nuclear industry. The plants are to go into operation between 1979 and 1982 (247).

Other energy sources.—A number of other energy sources are being developed, including waste combustion, geothermal steam, solar radiation, wave energy, wind power, magnetohydrodynamics, and controlled fusion. Commercial development of these sources require long lead times (except the first two which are already producing energy on a limited scale), and it seems unlikely that any of these sources will contribute materially to the U.S. energy pool before 1985. Controlled fusion is not expected to contribute materially before the year 2000 (248). However, research and development efforts are proceeding in attempts to advance the technology of these methods to generate power economically on an industrial scale.

The energy crisis, the activity of environmentalists for cycling, and the price of fuel have led to the concept of utilizing domestic, agricultural, and industrial wastes as a source of fuel, recovery of ferrous materials, and decrease in weight and volume of the wastes for landfill in the form of ash (249). Many cities, especially St. Louis (244-251) which has been in the forefront in waste combustion for power, and others such as Boston (249, 251), Montreal (249), Chicago (250, 252), San Diego (244), New Jersey (253), New York

(251), Oakland (254), Nashville (255), El Cajon, California (256), etc., have already installed or are committed to the concept of energy from waste. The TVA is also considering production of power from garbage by the "separation process" (257).

One ton of solid waste can provide the same amount of energy as one-third ton of coal, or 65 gal of No. 2 fuel oil, or 8000 cu ft of natural gas. One pound of coal has about 12,000 Btu heating value, whereas wastes average about 4600 Btu (249).

Industrially, Weyerhaeuser has set a goal of becoming energy self-sufficient by 1980 using wastes from their operations. At present, 66% of its energy requirements are obtained from burning black liquor and hogged fuel.

Of the other potential sources of energy, geothermal steam is also producing electrical energy on a limited basis. With the energy crunch and the federal energy research budget including geothermal projects, the activity in geothermal utilization is expanding (259).

The Pacific Gas and Electric Company, which supplies San Francisco, is operating a geothermal field commercially, and is expanding its capacity. In 1976, it will have a capacity of 847,000 kW, far exceeding Italy's 380,000 kW facility (260).

A conceptual design for a 10 MW geothermal electric power plant in Mono County, California, will use the Magnamax power process, an advanced binary cycle for converting thermal energy to electrical energy (261).

An AEC sponsored Geothermal Power Development Conference held in June in Berkeley, California, included papers from AEC and industry (262).

The Dow Chemical Company purchased an interest in the Magma Power Company. Dow will assist in exploration and development of geothermal properties under Magma control and will use Magma's technology to obtain geothermal steam for its chemical plants (263).

The radiant energy received continuously by this planet from the sun far exceeds our present energy needs, or that of the immediate future. A variety of ways have been suggested in which this energy could be used to heat and cool buildings or to generate electricity and synthetic fuels.

NASA is developing an experimental solar collector system to heat and cool a structure that will be built in Hampton, Virginia. Water-filled tubes inside the solar collectors would absorb the solar heat, using it for direct hot-water heating and to operate an absorption refrigeration unit (264). NASA has also applied for a patent on a special absorptive coating for aluminum panels that are used in building a solar energy collector. The coating absorbs about 93% of the total solar heat, but reradiates only 6% of the infrared heat (265).

Continental Oil is testing solar panels as a supplemental power source on a Gulf of Mexico oil production platform. Banks of solar panels absorb sun energy and convert it to electricity for storage batteries that operate warning devices (266).

A photovoltaic solar cell demonstration system was being set up in McLean, Virginia, by Metro Corporation to convert solar energy directly into 1500 kW-hr of electricity annually (267). The system is the first step in a continuing evaluation program. Sandia Laboratories are exploring the possibility of developing photovoltaic cells to produce power at cost equivalent to fossil fuel conversion cells (268). They are also studying the concept for a community powered mostly by solar energy.

The NSF is sponsoring the experimental augmentation of regular heating systems of four schools with solar heating systems (269). A Harvard University-Tyco Laboratories team, also sponsored by NSF, has developed a process for the continuous production of silicon-crystal solar cells. This breakthrough in technology is supposed to cut the cost of a solar array unit capable of producing 1 kW by a factor of 100, to about $350 (265).

PPG is now producing solar energy collector cells, designed for hot water and heating systems of multistory buildings and homes (270). A new Japanese solar battery uses thin film of ultrapure chlorophyll extracted from spinach to generate electricity (271).

In other novel energy schemes, an ocean wave-driven air pump consists of a cylinder submerged in the ocean, through which water rises and falls, pumping air that can power a generator (272).

In a workshop conference, it was concluded that there were no insurmountable obstacles in collecting a part of the energy from Gulf stream currents off the coast of Florida (273).

The University of Edinburgh received a grant to harness ocean wave power to generate electricity. It is claimed that better than 80% of the wave energy could be collected by using the rolling motion of the waves to rotate vanes in partially submerged containers (274).

Methods to recover the energy in tidal waves have been periodically suggested, particularly in the Bay of Fundy and in France. The construction of a dam for a tidal power project is being planned for Mezan Bay in the White Sea in the U.S.S.R. Plans are to install 600 capsule and turbine units, each with 10 MW capacity. The construction method will be similar to that of the first Soviet tidal power unit at Kislaya Guba, on the Barents Sea (275).

The cost of the French 240 MW plant on the Rance estuary was three times as much as a conventional hydropower station (275).

A wind energy conversion system, a series of windmills, could be constructed in the Texas Panhandle by 1985, to produce 500 MW of electrical energy. The windmills could be operating with 20 mph winds 40% of the time in most areas and 50% of the time in some areas of the Panhandle, the windiest region of the U.S. (276).

Both NASA and NSF are funding projects for wind energy conversion systems. Michigan State University, General Electric, and Kaman Aerospace will study the feasibility and design of wind conversion systems (277-279).

Canada's B.C. Hydro, Vancouver, has ordered two small wind-driven power plants from Par Industrial Contractors. The 2000W units, costing $8210 each, will be used in an evaluation study in the spring of 1975 (280).

Windpower systems can generate electricity directly or produce hydrogen by electrolysis of water, and with a storage system the hydrogen can be later used in a fuel cell to produce electricity. Using a computer model to analyze windpower for the New England area, it was found that incremental demand from 1976 to 1990 could be satisfied at a cost of $0.119-0.201/kW-hr. The system would have 173 wind stations with three identical 2 MW generators per station (281).

Magnetohydrodynamic (MHD) power got another boost with an $8 million contract to the University of Tennessee Space Institute to build an intermediate-size MHD plant. The plant, funded by the Office of Coal Research will integrate all components of a direct coal-fired MHD plant and will operate continuously for 100 hr or more (282). Avco also received funding from the same source for development of MHD power systems operating on coal or fuel derived from coal (283).

General Electric reported a breakthrough in MHD efficiency. It converted 20% of the heat produced in a closed-cycle MHD setup into 1800 kW of electricity in a hundredths-of-a-second bursts in a 60 ft shock tube (284).

Manuscript received June 16, 1975. This report was presented at the Industrial Electrolytic Division Luncheon at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Science and Technology—The New Challenges[1]

W. G. Schneider

National Research Council Canada, Ottawa, Ontario, Canada

Science and technology today have attained a fairly high degree of maturity and scientific research has become highly institutionalized. These developments have evolved largely during the decades following World War II. During this period we have seen unprecedented advances in both science and technology. However, as we look to the future there are serious concerns whether the new challenges now facing the nations of the world can be adequately dealt with by simple linear extrapolations. Both the nature and the longer term implications of the new challenges will demand greater R&D initiatives and much greater adaptability by the scientific community than it has been accustomed to in the past.

The new realities.—As we approached the 70's a number of problem areas, which had been formerly of only minor concern, rapidly developed to a degree where they have now become of major concern both nationally and internationally. Some of these areas have reached near crisis proportions. What is equally clear is that many of these problems are closely interrelated and that they have serious long-term implications for man's well-being on this planet.

That having been said, I should make clear at the outset that I do not share most of the "doom and gloom" prophecies with respect to man's survival. Recognizing the problems and their implications, man also has the necessary intelligence, capability, and adaptability to act rationally and to manage his affairs so as to ensure his future well-being. As a result of the broad advances in science and technology over the past few decades, we are in a much stronger position to face up to these challenges, to devise new solutions, and to develop optional technologies for new strategic approaches. This is not to suggest that national and world problems will be solved by science and technology alone, but rather that science and technology will be needed as essential aids in the alleviation of and solutions to such problems.

Because the new challenges I refer to also imply possible serious consequences in the long term as well as in the short term, I prefer to call them the new realities. To be realist rather than alarmist, it is nevertheless appropriate to raise the question whether, in view of past inertia, the nations of the world, as well as the scientific community, have the conviction and the will to respond actively and comprehensively to the new realities.

To be more explicit, I would like to start with the following list of topics which have been identified as problem areas in many countries and which relate directly to our major concerns: (*i*) energy, (*ii*) food, (*iii*) housing and urban problems, (*iv*) industrial development (goods and services, employment), (*v*) environment, (*vi*) materials (resources) and materials recycling, (*vii*) transportation and communications, (*viii*) health, (*ix*) disarmament and peace, (*x*) economic, scientific, and technical aid to less developed countries, (*xi*) oceans, (*xii*) space.

This list is not intended to be in any particular order of importance or priority nor is it necessarily complete. Others might be added, such as economic stability (including trade, monetary problems, inflation, etc.), social justice, public safety and security. These are indeed explicit areas of concern. To some degree also they are implicit in the above list.[2]

In recent years much of the rhetoric on science policies has been concerned with relating scientific research to national goals. In the first instance, that is, without further elaboration, such goals are generally stated in very broad terms, as follows: food, shelter, prosperity, health, peace and security, justice and social welfare.

These could equally well be a statement of international goals. In essence, they reflect basic human needs and no country could long survive if such needs were not met to some minimum standard. When we compare these basic needs with the longer list of topics above, there is a striking overlap and resemblance.

There are several other distinguishing features of the longer list of twelve topics:

(*i*) Most of these areas have become more important or critical in recent years and are likely to be of on-

[1] This is the Electrochemical Society Lecture delivered at the Toronto, Canada, Meeting of the Society, May 12, 1975.

[2] The problem of population should properly be considered as part of the new reality. However, it would seem to belong more in the social or moral domain than in the domain of science and technology.

going concern in future. Frequently a particular topic forms the unique mission of a ministry of national governments.

(*ii*) There is a high degree of inter-connection between these problem areas.

(*iii*) Most of these problem areas are now also of international concern.

(*iv*) All depend heavily on applications of science and technology and will require considerably more R&D investment in future.

To this audience, there is no need to elaborate in detail on each of these topics but certain features are worth mentioning.

Energy.—Although the finite supply of fossil fuels had been frequently pointed out, it took the recent oil embargo to bring home to us an awareness of this fact, as well as of our excessive dependence (and therefore also vulnerability) on this form of energy. Past R&D investments in nuclear energy have provided an alternative form of energy. Other sources of energy will also have to be developed especially from renewable resources.

Food.—Ultimate shortages of food, especially cereals and protein had also been foreseen. The green revolution gave hope of buying time but made heavy demands on fertilizer supplies. Increased food demands were due in part to population increase and in part due to nutritional upgrading of substandard diets. The world now faces the double challenge of increasing food supply while conserving energy, including fertilizers.

Housing and urban problems.—The concerns relating to low-cost housing and a complex of urban problems are well known. The need for energy conservation, for environmental preservation, and for waste and materials recycling are added dimensions.

Industrial development.—In the past, economic viability of a private enterprise could be virtually assured if it had an efficient technology, good management and adequate market access. The ground rules are rapidly altering. Future enterprises will also be required to take into account and be accountable for social costs, environmental costs, energy costs, and material costs. It is doubtful whether many of today's technologies will be able to meet all criteria, and these technologies may have to be modified or alternate techologies may have to be developed. Such new technologies may not necessarily be large-scale technologies. Employment opportunity is an additional factor of growing importance.

Environment.—With today's numerous environmental concerns and risks, it is clear much more basic knowledge and understanding will be required to make environmental impact analyses with confidence. Indeed many environmental risks now of concern were detected only recently as a result of highly sensitive analytical techniques made possible by recent scientific advances.

Materials (resources) and materials recycling.—This is an area which will obviously continue to be science and technology intensive. The new parameters are likely to be energy conservation, materials conservation, substitution, and recycling.

Transportation and communications.—These are the essential service networks required by any nation (and among nations) to move people, goods, and information. Their importance to modern societies has grown enormously with a strong demand for new technologies. Future transportation systems will be required to meet stringent energy consumption standards, environmental acceptability, and urban standards. Electronic communications systems will be required with greater load handling capabilities and as a partial substitute for paper communications.

Health.—With R&D in the health sciences already at a substantial level, new emphasis is likely to be directed toward preventive medicine and health delivery systems.

Disarmament and peace.—This is a topic which requires special comment. At one time referred to as the War Department of national governments, it is currently called the Defense Department. In the new realities, it might better be called the Disarmament and Peace Department. On the one hand we need to question whether present defense theories and postures are becoming outmoded, and on the other hand whether the nations of the world can continue to condone the high wastage of capital, energy, and materials under the guise of defense. Accepting that every nation has a right to defend itself, and that what is regarded as an adequate defense bears an international relativity, the only feasible way to de-escalate mounting defense costs is through mutual and collective agreements among nations. A first goal in this direction must be a total ban on nuclear weapons together with verifiable and enforceable safeguards. The failure to contain the so-called nuclear club and the failure of the Nuclear Non-Proliferation Treaty should now be ample warning that we are drifting along a dangerous course and that a whole new positive approach is needed.

What does all this have to do with science and technology? Today's highly sophisticated defense systems are, of course, heavily dependent on science and technology. It is sometimes suggested that scientists in all countries should refuse to work on weapons technology. Unless a total moratorium could be guaranteed and enforced, such a tactic would be impractical and totally unacceptable, since it would place scientists in an untenable situation of having their motives questioned as unpatriotic. A much more positive approach has a better chance to succeed. An example of this was the contribution made by scientists in developing sensitive detection systems for nuclear explosions anywhere in the world, which led to the acceptance of the partial ban on nuclear tests. Obviously, rather sophisticated safeguard systems would have to be devised to achieve a high level of confidence and an acceptable agreement to ban nuclear weapons. This could be an area of active international collaboration and, if scientists of many countries worked together toward such a common purpose, the chances of success would be greatly enhanced. Such a combined effort could also help to influence attitudes and foster a better climate of understanding and trust. There would appear to be little hope of general disarmament until the problem of nuclear weapons and their delivery systems is resolved on a world scale.

I am not sure whether this is a practical suggestion or not. But I think the scientific community in all countries must seriously ask itself whether there is not some positive role or some new approach which could contribute to the ultimate resolution of this problem. Progress made in the other problem areas I have mentioned may well be negated or diverted unless there is also much more rapid progress toward disarmament and peace.

Economic, scientific, and technical aid to less developed countries.—This is an enormous problem, and in spite of a great deal of discussion and good intentions relatively little progress has been made in reducing the wide disparities between have and have-not countries. It is now widely recognized that to achieve a more stable world community, this gap must be narrowed substantially and more rapidly than has been achieved until now. The difficulties are well known. More effective action programs, together with possible new approaches, are now urgently needed.

Oceans and space.—These are both areas of growing importance. Here, too, the international and political problems are well known and remain to be resolved. It is also clear that the exploitation of the world's

oceans and outer space for the benefit of mankind will require substantial R&D investments.

Implications for science and technology.—How can the scientific community play a more active role in seeking solutions to the above list of problem areas? These are formidable and highly complex problems. Ultimate solutions must of course seek to resolve simultaneously the socio-economic and political aspects. However, with better technological solutions and more technological options available these aspects become much more tractable.

A related question frequently posed is: How can I as an individual scientist or engineer contribute? What research should I do? What research is needed? This points up a major difficulty. Before we can start looking for answers and solutions by doing research, it is necessary to be clear what the question is. Has the question related to a problem been adequately defined and validated? Who should frame the questions and who is best able to do so?.

Such uncertainties, of course, do not arise when we are talking about basic research, but for the major problem areas of concern, they are highly relevant. The fact that these difficulties persist could mean that we lack a sufficient understanding of the problem areas to be able to define the significant questions amenable to research, or that in relation to the questions, we lack promising ideas worth researching, or simply that we have not yet developed adequate ways and means to focus our best talents and capabilities on these problems. Each of these possibilities is no doubt pertinent in particular instances.

Central to these issues is the role of government and its interface modes with the scientific research community. Research and development activities organized on a national scale largely grew out of government initiatives during the last war to mobilize scientific resources for the war effort. A cadre of peer scientists worked closely with various government departments and agencies to evaluate key problems and to formulate significant research requirements. A system for funding research projects through grants and contracts was devised. This system, with but minor modifications, was carried over into peacetime and continues today. Accordingly, government had taken on a major central role not only in funding mission research, but also basic research.

It is also worth noting that during the last war many scientists set aside their own research programs and became primarily problem solvers. What was especially impressive was the effective way in which basic scientists, given strong motivation, successfully became applied scientists and engineers. After the war most of these researchers went back to their prewar pursuits.

During the past thirty years government-funded R&D expanded very substantially. During this period of high affluence and expectation, we have lacked the same strong sense of focus, and the clear articulation of urgent problem areas that was so evident during the war. In this situation and with the rapid buildup of universities and academic research, science tended to become more inward-looking. However, as I mentioned earlier, during this period there had also been very impressive advances in science and technology, and in research capability, which require no defense, and which constitute essential and strategic resources for our future endeavors.

If scientists are to be in a position to respond more effectively to contribute toward the solution of key problem areas, there will need to be a more articulate identification of needs and longer-term objectives by governments. Science policy studies in recent years have attempted to deal with these issues. However, many of these attempts became more preoccupied with structures, budgets, and methodologies, that is, the "how" rather than with matters of substance such as what we should be doing, and why, and relative priorities. It should now be clear that dealing with the latter cannot be accomplished by an external group of planners working in isolation and out of contact with the real world. Action programs of the kind we are considering here can only be developed by having knowledgeable and well-informed scientists working in close consultation and collaboration with government policymakers and decisionmakers.

I am encouraged that we are now beginning to move more positively in this direction and that some of the results of these efforts will soon become apparent. As an example of this approach, many countries, including Canada, are well on the way to developing an integrated national energy R&D program. A similar articulation of objectives and R&D needs and opportunities in other major problem areas is in prospect and is needed to focus our R&D efforts and to permit the scientific community to contribute more effectively to these efforts.

On the other hand, there are also impediments arising from science itself which may inhibit more effective R&D participation on the part of individual scientists. These are matters scientists themselves must take under their purview for they are in the best position to effect changes that are deemed necessary or desirable. These matters touch on the structure and functioning of science as it has evolved over the years.

The strong discipline-orientation of science is usually seen as a handicap because of the apparent mismatch between discipline-oriented research and problem-oriented research. Historically, the development of science took place largely in universities, where it was closely coupled with academic programs. Scientific disciplines were simply a convenience to delineate manageable fields of study. As such, they also became the basis of organizational structures. Our university departments, our scientific societies, and our scientific publications all have a strong discipline basis.

I do not mean to imply that this discipline orientation is now outmoded. In fact, I believe it has served us extremely well and there is at present no obviously superior system to replace it. However, we now also recognize it is not self-sufficient and that other systems, in parallel or in series, will be needed to complement it.

It may be noted that even in basic science as knowledge advanced there has been a considerable blurring of disciplinary boundaries. Modern electrochemistry is an example of this. So are also disciplines such as biology and earth sciences. Numerous hybrid disciplines have also come into being, with their own scientific societies and their own research journals. This fragmentation, particularly of the scientific literature, has been a matter of some concern. On the other hand, there have also been some recent countervailing developments where a related number of scientific societies have joined together in a federation to pursue their common purposes. Examples are the Canadian Federation of Biological Societies and the Canadian Geoscience Council.

As scientific research has become more institutionalized over the years it has also tended to institutionalize its own system of incentives and rewards. Younger scientists sometimes assert that they would like to engage in problem-oriented research, but are concerned whether this might jeopardize their future scientific career. They contend that obtaining research grants and job promotions based on peer review virtually demand a continuous flow of published papers. This is easier to achieve by continuing to research the researchable in a particular specialty than by attempting to pioneer a new field which has as yet no recognized peers and where a research investment of several years may be required before publishable results emerge. There is no doubt that these concerns exist and a better system of incentives and merit recognition will need to be developed.

Looking to the future, what is the R&D picture likely

to be ten or twenty years from now? Because of the gravity of a number of the problems of ongoing national concern, and because of the potential contribution science and technology are capable of making toward alleviating these problems, it is likely that substantially increased R&D expenditures will be made in these areas. This, of course, must be conditional on the availability of competent research manpower in each of these areas as well as promising research ideas. The mounting of significant programs will also require more integrated and cooperative projects with closer collaboration between the government, industry, and university sectors.

In the government and industry sectors the problem of discipline mismatch is a minor one since research teams built around competent specialists required for particular research projects are readily formed. It does, however, pose serious problems in universities where research projects tend to follow disciplinary lines. Indeed, the extent to which universities should engage in mission or problem-oriented research remains a matter of active debate. In view of the many other pressures now being exerted on universities, this is a further question the universities will have to resolve for themselves.

If there are to be substantial new research expenditures in the major problem areas it is likely that a large proportion of new Ph.D. graduates emerging from universities will be required in these areas. This further underscores current discussions as to the most appropriate Ph.D. programs for the future. This is also a matter for which universities have primary responsibility.

In speculating about the future it also seems reasonable to assume there will be no cutback on the present level of effort in basic research to offset in part an increased level of effort in problem-oriented research. But such comparisons may well amount to a somewhat meaningless kind of bookkeeping. In the first place, the value of basic research is no longer in question and the need to support basic research is well recognized by government. The question is only "how much" is needed. New programs in problem-oriented research are very likely to create a demand for more basic research in particular areas. However, this may not necessarily amount to added effort in basic research since the new earmarked research dollars will also be competing for the talents and time of existing researchers in basic research. Accordingly, we may expect the future course of basic research to be strongly influenced by increased R&D effort in the major problem areas. Whether this is beneficial or not in the long term we can only speculate since there is no way of predicting in advance where new opportunities or knowledge gaps are likely to arise.

Finally, I would like to emphasize again the international dimensions of some of the major problem areas. These will demand a more active international cooperation than we have had in the past. Science, because of its universality and the many common links it has already established, provides us with a favorable and strategic base on which to build. Successful cooperation at this level can also serve to foster better mutual understanding, trust, and confidence, thereby facilitating ultimate resolution of the more difficult social and political problem areas.

In summary, the challenges which now face the nations of the world will demand new initiatives and responses from the scientific research community as well as from governments. Both government and the scientific community will need to develop better collaborative interfaces and new approaches in their respective roles. Present day science and technology are in a strong position to contribute significantly to the alleviation of the major problem areas of growing national and international concern. These will demand greater leadership and the focused efforts of highly competent scientists and engineers. In such endeavors we truly serve to further the common ideals and promise of science, namely, the betterment of human life on earth and of all mankind.
