Brief Communication

Modified Contact Metallizations for GaP to Provide Barrier Action Against Gallium Migration

W. A. Brantley,[1] B. Schwartz,* V. G. Keramidas, A. K. Sinha, and G. W. Kammlott

Bell Laboratories, Murray Hill, New Jersey 07974

In the chemical oxidation of GaP in aqueous H_2O_2, native oxide thickness quickly reaches a limiting value, in the range of 200-400Å, and does not change with continued exposure to the oxidant (1). In the galvanic oxidation of GaP with ohmic contacts, the cathodic component of the reaction proceeds unhindered at the noble metal ohmic contact. The resulting oxide layers are thick and the ultimate thickness is limited only by the diffusion of the oxidant through the oxide. However, in a number of cases, relatively thin oxides were formed on contacted GaP. It was determined that both Ga and P were present in appreciable

Key words: ohmic contacts, compound semiconductors, barrier metallization, secondary ion mass spectrometry.

quantities on the Au-based ohmic contacts before as well as after oxidation (2).

In a recent investigation (3), we reported the extent of Ga and P migration through the ohmic contact metallizations. The migration principally occurs when the contacts are formed with GaP.[2] During subsequent galvanic oxidation, gallium and phosphorus oxides form on the ohmic contacts, and the presence of these oxides is believed to cause the inhibition of thick oxide growth. In this communication, we report the successful utilization of intermediate layers in the contact metallizations which serve as barriers to gallium migration.

The conventional (4, 5) contact metallizations for GaP LED's were evaporated on <111>-oriented GaP wafers. The p-contact consisted of a Be-Au alloy, and these films were deposited on GaP having $N_A - N_D \gtrsim 5 \times 10^{17}$ cm^{-3}. The n-contact consisted of a Si-Au alloy, and these films were deposited on GaP having $N_D - N_A \gtrsim 3 \times 10^{17}$ cm^{-3}. Specimens were alloyed at 600°C for 5 min to obtain ohmic contacts.

A thin titanium or tungsten film was considered to have promise as a barrier to gallium migration because no gallium interdiffusion at 500°C into thin titanium (6) or tungsten (7) films on GaAs could be detected by 2 meV $^4He^+$ backscattering. In addition, experiments had indicated (8) some effectiveness for Ti/Pt films in reducing gallium migration through gold-based contacts to GaAs.

Accordingly, three modified metallization schemes for GaP were investigated, in which the following layers were deposited successively over the initial Be-Au or Si-Au layer: (*i*) Ti/Au, (*ii*) Ti/Pt/Au, and (*iii*) W/Ti/Au. (The outermost layer in each case is gold.) The tungsten (9) and gold depositions for (*iii*) were performed in different stations, so that a titanium layer had to be included to provide adhesion which would otherwise be marginal between gold and tungsten films exposed to air. Specimens for groups (*i*), (*ii*), and (*iii*) were alloyed in two different manners. For half of the specimens, the Be-Au or Si-Au film only was alloyed with GaP at 600°C for 5 min, followed by deposition of the remaining layers. For the other half, the entire composite metallization was alloyed with GaP at 600°C for 5 min, after deposition of all the layers.

The effectiveness of the modified metallizations for reducing the gallium migration was evaluated by secondary ion mass spectrometry[3] (SIMS) (10-12), using O^+_2 ions as the primary sputtering species. With this technique, relative comparisons of the extent of the gallium migration through the metallizations can be obtained. The $^{69}Ga^+$ secondary ion signals from the outermost gold films were compared at some arbitrary depth such as 1000Å where the near-surface signal enhancement (12, 13) resulting from the presence of a surface gallium oxide is no longer significant (3). Absolute gallium concentrations were not established, due to the lack of appropriate chemical standards and possibly different sputtering rates for the various gold matrices. Because the SIMS apparatus has a much lower sensitivity for phosphorus (as $^{31}P^+$) than gallium, the effectiveness of the modified metallizations for reducing the phosphorus migration was not investigated.

The $^{69}Ga^+$ signals at an estimated 1000Å depth for the various specimens are summarized in Table I. These signals are normalized to a value of unity for a reference specimen consisting of a pure gold film on a quartz substrate. The data are presented in a decade format, where each entry is the logarithm of the upper limit of the decade(s) within which the relative Ga^+ signal values lie.

[2] The term "formed" is employed to denote any heat-treatment process for achieving ohmic contacts.

[3] SMI-300, Cameca Instruments, Incorporated, Elmsford, New York.

Table I. Gallium migration through contact metallizations on GaP

Metallization group	Relative $^{69}Ga^+$ signal at 1000Å depth*
I. Reference specimen: pure gold on quartz substrate	0
II. Conventional (4,5) alloyed p- or n-contact	5-6
III. Ti/Au over Si-Au or Be-Au	
A. Only Si-Au or Be-Au alloyed	1-2
B. Entire metallization alloyed	6
IV. Ti/Pt/Au over Si-Au or Be-Au	
A. Only Si-Au or Be-Au alloyed	2-3
B. Entire metallization alloyed	
1. Be-Au initial layer	1
2. Si-Au initial layer	3
V. W/Ti/Au over Si-Au or Be-Au	
A. Only Si-Au or Be-Au alloyed	2
B. Entire metallization alloyed	5-6

* These values are logarithms of the upper limit of the decade(s) within which the relative Ga^+ signal values lie. For example, an entry of 3 corresponds to a relative signal between 101 and 1000. All the relative Ga^+ signals are normalized to that for the reference specimen which has been assigned a value of unity (and thus a logarithm of 0).

It is evident that the near-surface gallium concentration is considerably decreased for some of the modified metallizations in Groups III through V, compared to that for the conventional alloyed contacts to GaP in Group II. In general, the most efficient barrier to gallium migration was obtained if the Ti/Au, Ti/Pt/Au, or W/Ti/Au layers were deposited after the underlying Si-Au or Be-Au layer was alloyed with GaP. No significant effect on gallium migration was found for variation of deposition rates for the Si-Au and Be-Au layers by an order of magnitude. For these specimens, there appear to be no noteworthy differences in barrier action for the three different structures. However, microstructural imperfections in the alloyed Si-Au or Be-Au layers, observed with the scanning electron microscope, may diminish the effectiveness of the barrier layers. A note of caution is also necessary for the simple Ti/Au metallization; when Ti/Au couples are aged in air, titanium migrates along the gold grain boundaries and subsequently forms an oxide layer on the surface of the gold (14).

On the other hand, if the entire composite structure was instead alloyed with GaP, no barrier to gallium migration was provided by the metallizations containing the W/Ti or titanium layers. However, with this alloying procedure, the near-surface Ga^+ signals for the Ti/Pt/Au modified metallizations were comparable to those for the efficient barrier structures where only the initial Si-Au or Be-Au films were alloyed with GaP. Inferior behavior for the alloyed Ti/Pt/Au films deposited over a Si-Au initial layer, compared to that when deposited over a Be-Au layer (*cf.* Group IVB), may be associated with microstructural imperfections, which were more prevalent for the Si-Au films. (The near-surface gallium signal was not measured in these regions.)

The effective barrier action of the alloyed Ti/Pt/Au metallizations in Group IVB is unexpected in view of the extensive gallium migration through the alloyed Ti/Au metallizations (Group IIIB) and since it is known (15) that gallium migration occurs freely through platinum films on GaP. It may be that interaction between platinum and gallium or, instead, among titanium, platinum, and gallium [with the possible formation of intermetallic compounds (16) in either case] impedes the gallium. The reason for the gallium barrier effectiveness of the alloyed Ti/Pt/Au films remains to be established.

Two different multilayer metallization approaches thus may be possible to reduce the near-surface gallium concentration in ohmic contacts to GaP. One approach is the deposition of appropriate metal layers, after alloying the initial Si-Au or Be-Au layer with GaP, to provide a barrier to gallium migration. An alternative approach involves alloying the entire composite metallization, whereby the migrating gallium is

trapped by interacting, and possibly forming intermetallic compounds, with an intermediate layer. The former approach is considered more attractive in view of possible adverse effects of intermetallic compounds on mechanical properties of the contact films and on potential device reliability in general.

Acknowledgments

The authors are grateful to R. K. Lewis and B. Autier of Cameca Instruments for performing the SIMS analyses, to P. A. Barnes and R. T. Hepplewhite for use of their thin-film deposition facilities, to T. E. Smith and L. J. Smith for assistance in performing the depositions, and to E. F. Labuda for helpful discussions.

Manuscript received April 4, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Bell Laboratories.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

JUNE 1975

C. V. King—Acheson Medalist

David A. Vermilyea[1]

Dr. David A. Vermilyea delivers introductory remarks about the Acheson Award Medalist.

The Acheson Medal and Prize is awarded not more than every two years for "distinguished contributions to the advancement of any of the objects, purposes, or activities of The Electrochemical Society." This is the twenty-third Acheson Medal to be awarded.

In the short time available it is not a simple matter to provide an adequate picture of the long and distinguished career of Dr. King, and it is even more difficult to convey an impression of the man himself to those who do not know him. I shall mainly attempt a very brief outline of his scientific, educational, and industrial careers and of his contributions to The Electrochemical Society.

First, with respect to his work in science, education, and industry, he was off to a good start with a formal education which started at Indiana University, moved through Columbia University, and finished with a post doctoral stay at Copenhagen with Professor Brønstead. He next spent three years as an instructor at Columbia, and then moved to New York University where he spent the next 35 years of his academic career. While there he taught inorganic and physical chemistry and, with his co-workers, he published more than 70 papers in solution electrochemistry, ionic transport, acid-base catalysis, homogeneous kinetics, corrosion, inhibition and ion exchange at surfaces. He coauthored the book "Experiments in Physical Chemistry." He trained more than 100 graduate students. He became a fellow of the New York Academy of Sciences, a fellow of the American Association for the Advancement of Science, was admitted to the Fellowship of the American-Scandinavian Foundation, and became a member of Sigma Xi and Phi Lambda Upsilon. In addition to The Electrochemical Society, he is a member of the American Chemical Society, the National Association of Corrosion Engineers, the Instrument Society, the Vacuum Society, and the Cryogenic Society.

Following his acquisition of the title "Emeritus"—he did not retire—he became president of the American Gas and Chemical Company, a post he still holds.

[1] Introductory remarks by David A. Vermilyea, General Electric Company, Schenectady, New York, on the occasion of the presentation of the Acheson Medal Award to Cecil V. King on October 15, 1974 at the New York, New York, Meeting of the Society.

The company specializes in leak detection and industrial pollutants; Dr. King has two patents on leak detection. I asked Dr. King how the company was named, and was told that the name was deliberately selected to permit the Company to do nearly anything.

Let us turn to Dr. King's contributions to The Electrochemical Society. He has been Chairman of the Corrosion Division and Chairman of the New York Chapter, and has been very active in both that Division and that chapter. He was editor of the *Journal of The Electrochemical Society* from 1954 to 1968, and was President of The Electrochemical Society from 1971 to 1972. Among his many contributions to the Society one stands out in my mind as being unique, namely, his many editorials in the *Journal of The Electrochemical Society* during his years as editor. I can remember reading these witty, cogent, informative, thoughtful editorials with great relish. Many were on Society matters, often pertaining to publications, but many were on a great variety of other subjects. They all contributed greatly to my own understanding of these subjects and stimulated my thoughts significantly. As an example of the breadth of his interests, consider the following titles, a few selected from the more than 100 he wrote: The St. Lawrence Seaway, Our National Highways, Dielectric Materialism, Future of Mankind, Inflation, Russian Literature, Of Satellites and of Men, Wisdom, Bell for St. Michaels, Growing Up Absurd, What Are We Teaching Our Students?, How Long to Boil an Egg?, Las Cucaraches y las chinchas, Salty Waters, Science Fiction, Search For Life on Earth. Truly, our lives have been enriched by these editorials; I recommend their rereading.

Dr. King did not spend all his time on his scientific, educational, and industrial careers and working for the Society. He has become an expert in golf, chess, ping pong, and croquet, and even now, I'm told, he still plays an occasional game of football. At least once he fell through the ice while skating at Chatham, and was soaked to the skin. He spent much time with his family in a variety of activities and trips which involved many experiences they will all long remember. For instance, an early trip to Indiana was made in a car which boiled over regularly every 100 miles on the Pennsylvania Turnpike, necessitating frequent trips with a mason jar down embankments to streams for water. Dr. King was a parent who believed that the rod should not be spared. I'm told that he once sprained his thumb chastising his son Peter. He likes homemade beer. He is a violin player and a trumpet player, and plays trumpet duets. He is a PUNdit. He likes the story of the moron who sat up all night trying to figure where the sun went when it went down. Finally it dawned on him!

Although these comments do not do him full justice, I hope that you have some picture before you of the twenty-third Acheson medalist, the man and his career. And now, "For distinguished contributions to Solution Chemistry and to The Electrochemical Society" it is my very great pleasure to present this Acheson gold medal, a bronze replica thereof, and a check for $2000 to one of the great men of electrochemistry, Dr. Cecil V. King.

Research in Review[2]

Cecil V. King

Dr. Cecil V. King presents the Acheson Medal Award Address.

I was introduced to electrochemistry in the laboratory of Professor Oliver W. Brown at Indiana University, in 1917. We learned to electrodeposit copper quantitatively from solution, and found that stirring made the deposition go much faster. One method of stirring was to place the beaker in a solenoid coil. We made our own potentiometers by stringing a resistance wire along the laboratory bench, making contact with alligator clips, and measuring distances with a meter stick. One of my assignments was to make a fused quartz tube by burying a carbon rod in quartz sand and heating it electrically. This was done in the university powerhouse beside a large switchboard, and it was tempting to close one more switch to be sure the carbon rod was hot enough. The quartz tube was perfect, but part of the campus was without light or power for a while.

Professor Brown had a set of lead-acid storage cells which he maintained would last at least 30 years if he could care for them personally.

During that year I learned the names AQUA-DAG and OIL-DAG, even then registered trade names of the Acheson Company; DAG standing for Deflocculated Acheson Graphite.

One of my nominators for the Acheson Award mentioned that my first research was done with ova, and that I started in a modest way with pigeon eggs. The facts are, that when I got out of college I was much interested in the ova that are served with bacon for breakfast, and was willing to do whatever I was told to earn them. And the eggs to be studied were not pigeon eggs, but hybrid African ring dove eggs. Is there an analogy with crow's eggs compared to pheasant eggs under glass?

This work was done in the laboratory of Dr. Oscar Riddle at the Carnegie Experimental Station on Long Island, and there was much to be learned. For example, the birds could be fed calcite crystals, but they put aragonite crystals in their egg shells. I first learned of the superiority of the female over the male with respect to adverse conditions. One of my duties was to prepare oxygen-rich or -deficient atmospheres in which to incubate the eggs; fewer eggs hatched under these abnormal conditions, and the proportion of surviving females was greater than normal. Higher or lower than normal incubation temperatures had a similar effect.

I also learned how easy it is to operate on a bird, or a hen, and insert a capsule containing a message in the upper oviduct; the capsule serves as a yolk, receiving an albumin coating and a shell. The birds recover immediately from such an operation. This is evidently the procedure used to obtain a large egg with a small egg inside, both complete with yolks and shells, as has been demonstrated on television.

Let me review some background material for my doctoral research. In the early 1900's several investigators studied binary compound formation between acids and such oxygen-containing compounds as esters, aldehydes, ketones, and ethers. The criterion of compound formation was the familiar maximum in the binary freezing point curve, at the composition of the compound. Earlier investigators had often postulated that changes in slope of physical property-composition curves could indicate compound formation. The eminent Russian chemist Dmitri Mendeleev examined the specific gravity of ethyl alcohol-water mixtures and decided that three compounds must be formed [*Trans. Chem. Soc. (London)*, **51,** 778 (1887)]. The compound $C_2H_5OH \cdot 12\ H_2O$ could be isolated at $-17°$, he said, and $C_2H_5OH \cdot 3\ H_2O$ at the temperature of "solid carbonic acid anhydride;" the compound $C_2H_5OH \cdot H_2O$ required a still lower temperature. Of course no one since has been able to isolate any alcohol-water compounds, and the freezing point curves show no maxima. At about $-17°$ the appearance of the ice crystals formed on freezing changes noticeably, and this is probably what Mendeleev observed.

Professor James Kendall, my research sponsor, had students isolate acid-ester compounds as a means of studying the mechanism of ester hydrolysis. James Booge studied three compounds which had sharp melting points, *i.e.*, they were stable at least at and below their melting points. He measured the freezing points of benzene solutions of the separate components and of equimolar mixtures. The results indicated that in the aprotic solvent the compounds were somewhat, but not fully, dissociated.

My research was essentially to repeat this work with water as the solvent. There was no evidence of any acid-ester compound remaining; the freezing points of equimolar mixtures of ethyl acetate and trichloroacetic acid, for example, were strictly the sum of those of the components; and the effect of the ester on the conductance of the acid was due to the increased viscosity.

Such negative results do not exclude the view that trace amounts of fleeting compounds are involved in the kinetic mechanism of ester hydrolysis. But the negative results are to be expected on the basis of the Brønsted acid-base theory; water is a far stronger base than ethyl acetate, or the trichloroacetate ion, and neither can compete for protons in the presence of water. In aqueous acetic acid the acetate ion can retain most of the protons, but an ester cannot compete in base strength even with the acetate ion.

Considerations similar to these led Brønsted to formulate his acid-base theory. The evidence was equally available to many other chemists who failed to review and correlate it.

To explain my eventual interest in metal dissolution and inhibition, it is necessary to introduce some background. After a year in Brønsted's laboratory my interest centered in the study of reaction kinetics and catalysis in dilute solution, and the interpretation of salt effects on the rates. One system, for example, was the peroxydisulfate oxidation of various compounds with silver ion as catalyst. The reaction with oxalate looks as if it should be especially simple

$$C_2O_4^= + S_2O_8^= \rightarrow 2CO_2 + 2SO_4^=$$

Without a catalyst the reaction is extremely slow. Small amounts of silver ion speeded it up, but the rates were not reproducible; two experiments run side by side perhaps differing by 200%. With excess peroxydisulfate the reaction was autocatalytic, not

[2] Acheson Award Address delivered on October 15, 1974 at the New York, New York, Meeting of the Society.

just at the start but until the oxalate was used up; the CO_2 pressure in the apparatus increased faster and faster up to the end. This behavior indicates that an intermediate accumulated in the solution; trivalent silver ion has often been suggested. It was later shown elsewhere that purity of the water is important in these experiments; traces of copper from a copper still probably enhance the silver ion catalysis.

Eventually we became aware of experiments on general acid and base catalysis. For example, it was shown in Brønsted's laboratory that the nitramide decomposition

$$NH_2NO_2 \rightarrow N_2O + H_2O$$

is catalyzed not only by hydroxyl ion, but by other basic ions and molecules as acetate ion and aniline molecules. The mutarotation of glucose and the enolization of acetone were found subject to both general acid and general base catalysis. It was found that a plot of log rate constant *vs.* log base (or acid) strength constant was linear, indicating a rate law

$$k_m = G(K_A)^x$$

where x is the slope of the log-log plot and the constant G is characteristic of the reaction. Brønsted and Kai Pedersen were able to formulate a derivation of this equation, based on reasonable intermediate formation in the Brønsted-Bjerrum sense. Actually the equation needs a simple statistical correction depending on the charge type of the catalyzing species.

We studied in detail two cases of general acid catalysis: the decomposition of diazoacetate ion and of azodicarbonate ion

$$N_2CHCOO^- + H_2O \rightarrow N_2 + CH_2OHCOO^-$$

$$2N_2(COO)_2^= + 2H_2O \rightarrow N_2 + N_2H_4 + 2CO_3^=$$

In both cases the Brønsted relation was obeyed over the range of acid strength from H_2O to H_3O^+, a range of 10^{18} in strength constants. The azodicarbonate reaction is so sensitive that it was necessary to use extremely weak acids like sucrose, maltose, acetoxime, in alkaline solutions. In both cases the slope of the log-log lines, the exponent x, was approximately 0.8; a similar value of x had been found in the nitramide decomposition, but in the acid catalyzed glucose mutarotation the value of x was about 0.3.

A similar study of the decomposition of diazomalonate was rather disappointing. The reaction uses up hydrogen ion

$$N_2C(COO)_2^= + H_3O^+ \rightarrow N_2 + CO_2 + CH_2OHCOO^-$$

In strong acids the rate is approximately proportional to the acid concentration and it was expected that the rate would be low in weak acid buffers. Actually, in 0.1M acetic acid, 0.1M sodium acetate the decomposition was as fast as in 0.1M perchloric acid. The reaction showed general base catalysis, and several anionic and neutral bases were studied. Since hydrogen ions are used up the analysis of the measured rates was difficult and the range of base strengths was limited. A Brønsted slope of 0.27 was indicated for some of the bases, but H_2O did not fall on the line.

With this background we proceed to the study of metal dissolution. Around 1930 Martin Kilpatrick published experiments on the rate of dissolution of rotating magnesium cylinders in weak and strong acids. As he described a preliminary experiment: in 0.1M HCl, hydrogen was evolved at the rate of 0.5 cm^3/min. In 1.7M formic acid, 0.1M sodium formate the hydrogen ion concentration is half as great but the hydrogen evolution was about 100 cm^3/min. This might indicate that weak acid molecules react directly with the metal and the Brønsted relation for general catalysis might apply. The log-log points for several acids, including hydrogen ion, fell near a straight line with a slope of about 0.08, much lower than for any case of homogeneous catalysis.

Brønsted and Kane at about the same time measured the rate of dissolution of sodium from its amalgams in acids. Their conclusion was that diffusive transport of strong acids to the amalgam was rate-controlling, but that with extremely weak acids the slow chemical reaction controlled the rates.

Since metal dissolution offered the possibility for further studies of acid reactivity, we decided to study zinc dissolution. Since the reaction in pure acids was known to be erratic, depending on the amount and nature of impurities in the metal and their effect on hydrogen evolution, the effect of oxidizing depolarizers was investigated. It was found that nitrates or hydrogen peroxide were equally suitable, giving the same rates when added (in excess) to hydrochloric acid; in such solutions zinc dissolved at about the same rate as magnesium did with or without the additives. A log-log plot of rate *vs.* acid strength constants was similar to the plot for magnesium, with a slope of 0.05. Very weak acids such as ammonium ion, fell far below the line.

Our conclusion, of course, was that the observed rates were those of convective and diffusive transport of acid to the metal surface, as had been postulated many years earlier by a number of investigators. The diffusion layer theory was developed by Nernst and by Brunner in 1904. Van Name and his co-workers at Yale University (1910-1916) had perhaps carried out the most extensive and convincing experiments with several metals dissolving in ferric and other solutions where no special depolarizers were needed.

In our first experiments we used rotating zinc disks but soon abandoned them in favor of cylinders so that the entire surface would have equal velocity with respect to the solution. We operated in the turbulent region and had no idea that V. Levich at about the same time was solving the hydrodynamic problem of flow for disks rotating in the nonturbulent region. The rotating disk and later the ring disk have of course been extremely useful in many problems. The hydrodynamic relations for the rotating cylinder have not been solved, but the dimensionless group analysis has had useful applications in turbulent flow experiments.

If diffusion of acid or other reagent to the metal surface is rate controlling, then theoretically one cannot learn anything about the reaction mechanism. For example, one does not know whether a weak acid molecule reacts directly, or gives up its proton to a water molecule, allowing the H_3O^+ ion to react. One would suspect the latter, since the H_3O^+ diffuses faster and new ionic equilibria are established almost instantly. When I was asked if I considered the metal dissolution an electrochemical process, I replied that it was an oxidation-reduction with electron transfer, but we did not know if that transfer took place at every collision with the metal surface. I should have realized at once that since the metal usually becomes rough, evidently some spots do dissolve faster than others; there are anodic and cathodic sites on the surface and a considerable flow of electrons within the metal.

In some cases, notably nickel dissolving in acidified ferric and ceric solutions, while the rates are transport controlled, the metal becomes extremely rough and there may even be undercutting and spallation of nickel particles. The roughness also increases the turbulence in the solution at a given rotational speed. This was observed and treated by Makrides and Hackerman.

Some of the metal cylinders acquire a gray or black coating during dissolution. This was observed with zinc and cadmium, and even with magnesium in certain alcohol-water mixtures. In some experiments with cadmium we removed the coating by wiping gently with filter paper. Microanalysis showed nothing but cadmium. Since such fine particles could hardly have been formed by undercutting and there was no visible spallation, we must conclude that cadmium, already dissolved, can replate on the surface.

In the course of the metal dissolution experiments it became necessary to measure many diffusion coefficients of the acids and other reagents since values were not available in the literature. These measurements were carried out in cells with two compartments separated by fritted glass disks, as pioneered by McBain. As an offshoot of these experiments one student made diffusion measurements with acid in one compartment, base in the other, neutralization occurring within the porous disk. Another student was able to make cylinders of benzoic acid and measure the rate of solution in sodium and potassium hydroxides, neutralization taking place within the diffusion layer. Addition of phenolphthalein gave a self-indicating endpoint.

It was expected that with a fixed degree of stirring, the dissolution rates would be proportional to the diffusion coefficients of the reagents. The plots were linear within experimental error, but did not extrapolate to the origin, as if a reagent which could not diffuse could still dissolve the metal. A log-log plot was linear and showed that the diffusion coefficients should be raised to about the 0.7 power. This indicates that the "effective diffusion layer" thickness is not the same for all reagents but is related to the diffusion coefficients.

We were able to measure the dissolution rates of thin wires of zinc, cadmium, and copper in suitable reagents and compare them with heat dissipation from a thin platinum wire which was heated electrically and show that the heat transfer coefficients and thermal diffusivity could be included in the same relation.

Having studied the dissolution of several metals under convective-diffusive control, it was natural to try to inhibit such dissolution. Only a few of these attempts will be mentioned here. It was found that as little as 0.005% of certain surfactants, such as sodium dioctyl sulfosuccinate, could reduce the dissolution rate of iron, zinc, or cadmium in acid nitrate solution from 100 mg in a few minutes to 3 or 4 mg in the same time. However, more surfactant did not block the surface much more, and addition of other inhibitors did not help.

Cupferron and neocupferron form very insoluble complexes with ferrous and ferric ions, and it was thought that they might be strongly adsorbed on an iron surface and form an impervious film. It soon became obvious that iron first dissolved, then the chelate precipitated on the metal surface to form a barrier layer which inhibited dissolution only as long as excess cupferron was present. Since these compounds are not very stable in acid solution, inhibition could be maintained for only a few hours and eventually the iron began to pit.

Experiments on the rate of dissolution of silver in ferric salt solutions showed that silver ion, formed in the reaction or added separately, had an inhibiting effect. The presence of silver and ferrous ions reduces the driving potential for the reaction, and the inhibition could be explained quantitatively as due to adsorption of silver ion on the metal. These results led to a serious study of metal ion adsorption on metals: if dilute silver nitrate is allowed to trickle down through a column of finely divided silver, pure water comes out at first. The advent of radioactive isotopes naturally led to studies of exchange as well as adsorption.

Our research program was made possible and in fact was made mandatory by the large number of master's and doctoral candidates at New York University starting in the 1920's. It was promoted by the helpful attitude and support of the university, and by the availability of government financial assistance after 1946. I am grateful for the cooperation of scores of students, most of whose work has not been mentioned here.

Alkaline Primary Cells[1]

S. Ruben*

Ruben Laboratories, New Rochelle, New York 10801

I would like to relate some history and development of sealed zinc/mercuric oxide alkaline cells. Thirty-two years have passed since the work on sealed zinc/mercuric oxide alkaline cells was initiated, and its history may be of interest.

At the start of World War II there was a need for transreceiver batteries having the ability to withstand tropical conditions with high capacity per unit volume, and maintain a low voltage drop during their effective discharge life.

In 1942 the work initiated at my laboratory utilized the experience obtained in the mid thirties in developing the hermetically sealed C-bias cell and the dry electrolytic capacitor. The bias cell had as its anode a cadmium container separated by a grommet and crimped to the cathode composed of a sintered disk of vanadium pentoxide, sealing in an enclosed gel electrolyte of ammonium glyco-borate. The first sealed alkaline cell structure utilized the type of capacitor structure shown in Fig. 1, with a wide area rolled anode and close spacing to its cathode for low internal resistance (Fig. 2). The cathode in the rolled structure was a 2 mil sandblasted steel strip coated with a layer of cupric oxide and graphite, bonded with a 5% polystyrene solution. This coated strip was rolled at high pressure, producing a low resistance flexible cathode layer. The spacers were a combination of an ionically conductive cellophane layer as a barrier in contact with the oxide to prevent migration of cathode particles, and an absorbent nylon gauze element in contact with the zinc. A dusting of mercuric oxide was applied to the anode before winding, so as to cause amalgamation of its surface when in contact with the alkaline electrolyte. In order to reduce solubility of the cupric oxide in the potassium hydroxide electrolyte, a solidified high concentration electrolyte was used and impregnated into the rolled unit at the electrolyte melting point. After impregnation and electrolyte solidification, the unit was fastened to a composite insulating top. The cupric oxide coulombic capacity and its voltage of 1.06 was not adequate, and other oxide coatings such as mercuric oxide, manganese dioxide, cadmium oxide, and silver oxide were comparatively tested. The mercuric oxide (1.34V) produced the best over-all results. Since the main object was to provide a sealed alkaline cell with maximum capacity per unit volume, the design was changed to one using a steel can cathode in the bottom of which a densely pressed mixture of mercuric oxide and micronized graphite was consolidated. The anode was composed of a spirally wound corrugated zinc strip with an intervening absorbent cotton paper spacer. The winding was in an offset manner, so that the corrugated zinc extended at one end, and paper at the other. Corrugation of the anode was found essential, since it provided space for the zinc oxide produced at the anode when the cell was discharged. After impregnation of the wound unit and its porous spacers, the anode was amalgamated by applying a measured quantity of mercury to the exposed turns of the corrugated zinc, providing an amalgamated junction with zinc top contact without local galvanic action. The barrier was a microporous dialysis paper disk, and other barriers such as sintered magnesium oxide were also used. The potassium hydroxide electrolyte was zincated by dissolving zinc oxide at a temperature of about 100°C.

In order to obtain maximum anode area, another type of rolled anode was used in which zinc was sprayed onto one side of cellophane strip with a "Schori" gun, producing a powdered porous layer of zinc. This was corrugated, wound, and amalgamated in the same manner as the solid zinc strip, but did not make suitable cells because of impurities derived from the spraying equipment. In later cells, the use of pressed

powdered zinc amalgam served the same purpose without the impurity factor.

The most important development for producing sealed alkaline cells was the development of the coulombmetrically balanced cell having equivalent anode and cathode capacities. Since the hydrogen deposition potential is 0.989V and the container overvoltage is 0.15V, the sum of both is less than the zinc half-cell potential of 1.332V in the electrolyte, so that any residual unoxidized zinc would cause hydrogen generation at cathode on continued application of load after the oxygen content of the depolarizer was exhausted. It also basically required that the anode top contact be composed of a nonconsumable but amal-

gamatable material such as copper or tinned steel. In order to compensate for errors in the required measured weights of the anode and cathode materials, an excess amount of cathode was used, in most cases the addition of a small per cent of electrolytic manganese dioxide sufficing. On larger cells an added safety factor against possible gas producing impurities in the cathode materials is applied by using a pressure-vented structure with an outer steel container separated by a cardboard tube which absorbs any electrolyte that may be vented.

Natural manganese ore, on account of its ferrous content, was found to produce dendritic growth on the zinc that caused internal discharge. The available large scale supply of pure manganese dioxide has made possible sealed manganese alkaline cells which, while not having the small voltage change of mercuric oxide during discharge and being of lower capacity per unit volume, have lower cost and are produced on a high volume scale.

Figures 3, 4, and 5 show the relation of capacity to the geometry of the present three types of sealed zinc mercury cells; corrugated wound anode, pressed powder anodes in flat or button form, and pressed powder cylindrical anode cells.

Technique for the Measurement of the Viscosity of a High Vapor Pressure Organic Electrolyte

H. Y. Kang and P. Bro

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

A capillary flow viscometer was developed to measure the viscosity of high vapor pressure organic solvent electrolytes over a wide temperature range. Inert electrodes and associated circuits were used to observe the passage of the meniscus through the viscometer. The viscometer was kept inside a sealed aluminum container to minimize the pressure differential between the test solution and the ambient and to contain the high vapor pressure solutions if the viscometer should rupture. Measurements were made on sulfur dioxide/organic solvent electrolytes containing lithium bromide at temperatures between $-60°$ and 70°C and at vapor pressures to 15 atm. The viscosity varied between 0.6 and 22 cp, being higher the lower the temperature and the lower the SO_2 concentration. The activation energy calculated from the temperature effect was about 4 kcal/mole for electrolyte compositions close to those used in Li/SO_2 batteries. The data indicated the occurrence of strong ion/solvent interactions in this system.

The rate capability of high energy density lithium batteries depends more strongly on the transport properties of the electrolyte than does that of an alkaline battery because of the generally low electrolytic conductivity of organic solvent electrolytes. The search for high-rate lithium batteries is, therefore, in part a search for suitable high-conductivity organic electrolytes. An important property that affects the conductivity of a solution is the viscosity of the medium in which ionic transfer takes place, and the analysis of the conductivity of organic solvent electrolytes requires the availability of viscosity data.

The sulfur dioxide/organic solvent electrolytes have a high conductivity and a low activation energy for ionic transfer over a wide temperature range, and they provide an interesting model system on which to study the structural and other factors that affect the solution conductivity. The measurement of the transport properties of the sulfur dioxide electrolytes poses a problem because of the high vapor pressure of the electrolyte. Concentrated SO_2 solutions have vapor pressures approaching that of pure SO_2, *i.e.*, close to 15 atm at the highest temperature of interest for battery applications. When we were confronted with the need for viscosity data on the sulfur dioxide/organic solvent electrolytes, we found no available viscometer suitable for such high vapor pressure solutions and had to adapt a conventional capillary viscometer to our needs. The modified viscometer is described in this report, together with some experimental data on a sulfur dioxide/organic solvent electrolyte containing dissolved lithium bromide. The chosen electrolyte compositions are representative of the solutions used in lithium/sulfur dioxide batteries.

Key words: capillary viscometer, density, lithium batteries, Li/SO_2 battery electrolyte.

Experimental Techniques

Viscometry.—The viscometer is shown schematically in Fig. 1. It was made of Pyrex and consisted of two compartments, A and B, connected with a capillary tube, C, and a side tube, D. Three metallic probes, P_1, P_2, and P_3, are located in A. The glass-to-metal seals were made with a tungsten wire and uranium glass, and the wire tips were gold plated to prevent corrosion by the electrolyte. At the bottom of the B compartment, the glass tube was sealed to Kovar K which was, in turn, soft soldered to a threaded brass ring, F. The viscometer was tightly screwed into the bottom of the aluminum pressure cell, E_2, with O-rings placed as shown to prevent any leakage of electrolyte from the viscometer. The probes P_1 and P_2 were connected to a triggering circuit by the feed-throughs, G_1 and G_2, on the container E_2, and probe P_3 was grounded to the aluminum container. The aluminum pressure cell, E_1 and E_2, was sealed as indicated to prevent leakage of SO_2 gas to the atmosphere should the viscometer be broken by the high vapor pressure. The viscometer was filled at low temperatures via port H and then sealed. The container was kept with the A compartment down until the desired temperature had been reached, then the viscometer was inverted to allow the electrolyte to flow through capillary C. When the meniscus of the electrolyte passed probe P_1, the electrical connection between P_1 and P_3 through the conductive electrolyte was broken which triggered the timer. When the meniscus passed P_2, the stopping trigger circuit stopped the timer. The trigger circuit is shown in Fig. 2. It was used in conjunction with a Beckman Berkeley Di-

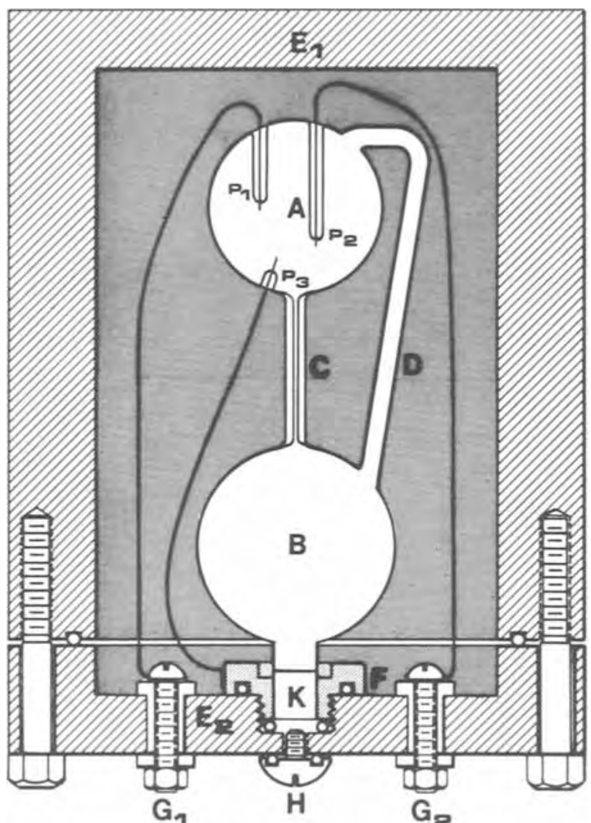

Fig. 1. Schematic diagram of viscometer (refer text)

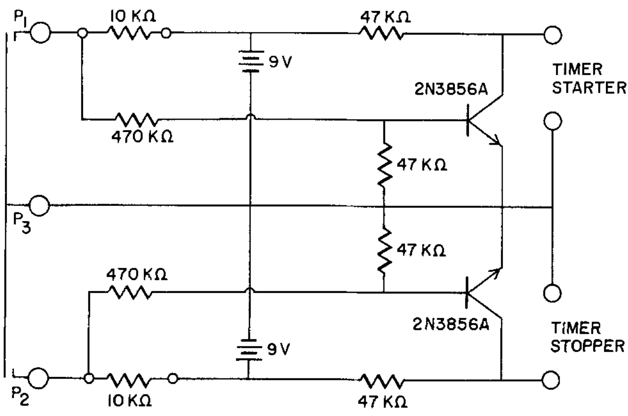

Fig. 2. Trigger circuit

vision Model 7360 Universal Timer Unit. The viscometer was kept in a vertical position by aligning the capillary section with the center line of the aluminum vessel, and the latter, in turn, was supported on a horizontal surface. Vibrations were reduced to a minimum by turning off the compressor on the refrigerator during the actual measurements and by removing any other sources of vibration from the proximity of the viscometer work area. No significant thermal drifts occurred during the refrigerator off-periods.

A Statham Model SP-60-1 Temperature Test Chamber was used for the temperature control of the viscometer. A check on the rate of change of the temperature of the electrolyte inside the viscometer while controlling with the Statham Chamber was carried out using a calibrated iron-constantan thermocouple. The electrolyte reached a temperature within 5°C of the set temperature in 30 to 45 min, then gradually approached the set point temperature in 60 min, and stabilized at that temperature within ±1.5°C. At least 90 min was allowed for thermal equilibration prior to each measurement.

The viscosity of the mixed acetonitrile-propylene carbonate-sulfur dioxide solvents with no LiBr was measured by determining the efflux time visually. Due to the low conductivity of these solvents, the triggering mechanism could not be used. A thick glass bell was pressed tightly onto the bottom part of aluminum cell E_2 (see Fig. 1) in place of E_1. Then the viscometer was connected to a handle installed in a Blue M Versa-Range Test Chamber (window provided) that could be used to turn the viscometer from the outside. At each temperature the flow of the liquid was observed visually and the flow time was measured by operating the Berkeley Timer manually. The calibration of the viscometer is discussed in a following section.

The efflux time was measured three to five times for each determination. The standard deviation of the measurements ranged from about 1% at room temperature to about 5% at 70°C and −60°C. Typical data are listed in Table I. In addition to the error in efflux time, the error in the viscometer constant introduced during the calibration (estimated to be about 3%) and the error in the density (about 1%, see the following section) contribute to the error of the viscosity values. The error of the viscosity measurements was estimated from the linear contributions of these factors to be ±5% at room temperature and ±10% at −60° and 70°C.

Density measurements.—The density measurements were made with 10 ml Pyrex pipettes with 0.1 ml subdivisions. A small bulb was blown at one end of the pipette, and the volume of the attached bulb up to the first subdivision mark was calibrated with distilled water. The coefficient of thermal expansion of the glass was used to calculate the pycnometer volume at other temperatures, but the change was less than 1% and no thermal corrections were used. The sample electrolyte was injected into the tube through a septum attached at the other end of the pipette while the tube was chilled in a dry ice bath. The tube was then flame sealed at the top. The weight of the sample electrolyte was determined by weighing the original tube, the sealed tube with the sample, and the piece of glass removed during the sealing operation. To prevent the hazards that might be caused by a possible rupture of

the tube due to the pressure buildup at elevated temperatures, the density tube was placed in a thick-walled Pyrex tube plugged with a stopper. The volume of the electrolyte was read at various temperatures in a Blue M temperature chamber provided with a window. The temperature of the Blue M chamber was determined with a Fisher certified thermometer inside the chamber. Each measurement was made 30 min after the temperature reading had stabilized within ±1°C of the control temperature. The composition of the sample electrolytes other than the stock solutions was calculated from the density of the solutions at the acetone/dry ice temperature and the amount of the stock solution used to prepare the given volume of the electrolyte at the dry ice temperature. The error of the density measurements was estimated to be ±1% based on the errors of the weighing and the volume readings.

Materials.—Eastman Kodak practical grade propylene carbonate was fractionally distilled at reduced pressure, and the distillate at 120°-122°C/1.0 mm was collected.

Eastman Kodak practical grade acetonitrile was dried over molecular sieve 4A and then fractionally distilled in an atmosphere of argon. The water content of the purified solvents was less than 20 ppm as determined by infrared spectroscopy. The Foote Mineral lithium bromide, anhydrous (99.6% pure), was dried in a vacuum oven at 150°C for approximately 48 hr before use. The purified solvents and the lithium bromide were stored in an argon atmosphere dry box.

The desired amounts of LiBr, acetonitrile, and propylene carbonate were weighed and mixed in a volumetric flask in the argon atmosphere dry box. The sealed flask with the mixture was taken out of the dry box and SO_2 gas was slowly admitted to the mixture. A cold water bath (10°C) was used to minimize evaporation of the solvents and to enhance SO_2 dissolution. When the volume of the solution reached the calibration mark on the volumetric flask the amount of SO_2 that had been introduced was determined by weighing. The solution thus prepared was used as a stock electrolyte solution from which other electrolytes were made by diluting the stock electrolyte solution with liquid SO_2 in a dry ice cold bath as illustrated in Fig. 3. A given amount of the stock solution was poured into volumetric flask A which was connected to the line at joint J_1, and cooled in a cold bath C. SO_2 gas was added to the stock solution through the three-way stopcock S_1 and tube T_2 until the meniscus of the electrolyte reached mark M. Pressure buildup in flask A was avoided by opening S_2. The sample electrolyte was transferred to the vacuum jacketed burette B through tube T_1 by closing S_2 and pressurizing A with argon admitted through S_1. The sample electrolyte was injected into the viscometer or the pycnometer through the hypodermic needle N. The ingress of moisture from the outside air to the cold solution inside A was limited by attaching drying tubes to stopcocks S_1, S_2, and S_3. The portion of tube T_1 that joined A and B was wrapped with glass wool to minimize heat transfer to the cold electrolyte during its transfer from A to B. The water content of final electrolyte varied between 150 and 200 ppm as determined by Karl Fisher titrations (no cell was available for infrared absorption measurements on the high vapor pressure electrolyte).

Experimental Results

The densities of the various solutions are shown in Fig. 4 and 5 and their compositions are given in Table II. At each temperature between −60° and 70°C the density increased linearly with the LiBr concentration, except below 1.0 weight per cent (w/o) LiBr where it increased as a higher degree function of the LiBr concentration. The density of the solutions decreased linearly as the temperature increased, the temperature coefficient of expansion being slightly greater for the more concentrated LiBr solutions. It may be noted

that the mass ratios of the non-LiBr constituents remained the same for all the data points shown in Fig. 4.

As the SO_2 concentration increased for a constant mass ratio of the other constituents the density increased approximately as a second degree function of the SO_2 concentration between 30 and 90 w/o of SO_2. As expected, the density decreased as the temperature increased for a given composition, and it was approximately linear in the temperature between $-60°$ and 70°C.

The viscosity data for the same solutions are presented in Fig. 6 and 7. The viscosity increased linearly with the LiBr concentration at each temperature except in the range below 0.1 w/o LiBr where nonlinearity was observed. At 20°C the viscosity changed from 0.58 cp for the pure solvent mixture to 1.05 cp for the 5.1 w/o LiBr solution, and at -60°C it changed from 1.41 to 2.40 cp, respectively, over the same concentration range. The viscosity decreased as the temperature increased, the change being more pronounced at the lower temperatures.

The SO_2 was quite effective in reducing the viscosity of the electrolyte, especially in the low temperature range; the rate of change being greater than that of a simple exponential function of the SO_2 concentration. At -60°C the viscosity decreased from 21.6 to 2.0 cp as the SO_2 concentration increased from 28 to 89 w/o. At 0°C it changed from 2.5 to 1.1 cp over the same concentration range. The viscosity remained a nonlinear function of temperature over the SO_2 concentration range studied, decreasing as the temperature increased.

Discussion

The viscosity technique.—The basic theory of viscosity measurements by kinematic instruments can be derived from the Poiseuille-Hagenbach equation (1)

$$\eta = \frac{\pi R^4 (P_o - P_1) t}{8Vl} \quad [1]$$

where η is the viscosity, V is the volume of the liquid flowing through the capillary tube of length l and inside radius R in time t, and P_o and P_1 are the pressures at the two ends of the liquid column. Equation [1] assumes a steady, laminar flow with no slip of an incompressible, Newtonian fluid. Departures from these conditions in actual viscometers necessitate the introduction of correction factors, and Eq. [1] becomes

$$\eta = \frac{\pi R^4 h_m g d t}{8V(1+b)} - \frac{MVd}{8\pi(1+b)t} \quad [2]$$

where h_m is the mean height of the liquid column during the flow, g the acceleration due to gravity, d the density of the liquid, and M and b the coefficients for the Hagenbach and the Couette corrections, respectively. The pressure difference between the two ends of liquid, $P_o - P_1$ in Eq. [1], is replaced by $h_m gd$ in Eq. [2].

The most important correction in designing a viscometer is the correction for the nonsteady flow which is expressed as the second term in Eq. [2] (kinetic energy or Hagenbach correction). The numerical coefficient M is introduced to account for the particular shape of the capillary ends, and it is close to unity. It is seen from the kinetic energy correction term that it can be reduced most easily by decreasing the rate of flow and by using a small efflux volume. In the present viscometer the efflux volume was kept small by making the distance between probes P_1 and P_2 small ($V \approx$ 1.5 ml).

A low rate of flow is important not only to prevent departures from steady-state flow but also to assure laminar flow conditions. In the flow of liquids through uniform tubes, turbulence may be expected for Reynolds numbers above about 2000. The size of the capillary was chosen to give a Reynolds number below 300. However, there is a practical limit to the extent to which the radius of the capillary may be decreased because of the sensitive dependence of the reproducibility of the data on the presence of dust particles in the fine capillary and because of the difficulty involved in transferring liquid from compartment B to A prior to

each measurement. A compromise was adopted by employing a capillary radius of about 0.04 cm (Reynolds number about 100).

The Couette correction coefficient b relates to the viscous energy dissipated at the entrance and at the exit of the capillary. This correction is of minor importance experimentally if the kinetic energy correction term is negligible, since the viscometer can be calibrated with a standard fluid of known viscosity without considering the complications due to the second term in Eq. [2]. The present viscometer design minimizes the loading error common with the Cannon-Fenske viscometers. Any differences in the volume of liquid discharging through the Cannon-Fenske viscometer will be reflected in the mean driving fluid head h_m. However, in our viscometer (an Ubbelohde type) the loading error is practically eliminated since the mean head is not dependent on the liquid level in the lower reservoir B, but terminates at the junction of the capillary with bulb B. This is made possible by gas pressure equalization between the lower and upper bulbs through the side tube D.

Another error may arise from the surface tension difference between the calibrating liquid and the sample electrolytes. In the present viscometer surface tension will affect not only the adhesion of the liquid to the walls of the bulbs but also the adhesion of the liquid to the probes P_1 and P_2, and thus the error due to surface tension is more significant than with other viscometers. This error was reduced by calibrating the viscometer with a low vapor pressure stock solution whose viscosity was determined separately with a certified Cannon-Fenske viscometer. The efflux times of the standard electrolyte through both the new viscometer and the certified viscometer were measured at several temperatures to obtain the required calibration data.

The construction of the confining vessel and the contact structures appeared to be satisfactory and gave trouble-free operation of the unit. Although the actual pressures did not exceed about 15 atm, it is reasonable to think that the viscometer can be used at higher pressures. However, it may be necessary to provide a means of pressure equalization either by the use of a pressurized inert gas or a volatile inert solution inside the confining vessel external to the viscometer tube if pressures much above 15 atm are involved.

The solution properties.—It is our intention to discuss the solution properties in some detail at a later time in conjunction with the conductivity of the SO_2 electrolyte, and we limit this section to a few brief remarks on the viscosity data.

The electrolyte chosen for the viscosity measurement was selected because of its usefulness in Li/SO_2 batteries. Each solution component serves a useful function in these batteries. The SO_2 is the active depolarizer, the acetonitrile forms a complex with the lithium bromide and causes it to dissolve in the sulfur dioxide to give a highly conductive solution, and the propylene carbonate inhibits the reactivity of lithium toward acetonitrile and sulfur dioxide. Since the SO_2 concentration decreases during discharge, it was of interest to determine the viscosity over an appreciable SO_2 concentration range.

The data correlated well as a function of the specific volume of the solutions, Fig. 8, according to the Batschinski equation as written by Hildebrand (2)

$$\frac{1}{\eta} = K\frac{\bar{v} - V_o}{V_o} \qquad \bar{v} = \frac{1}{d} \tag{3}$$

where η is the viscosity, d the solution density, V_o the empirical constant (specific volume of "hole-free" liquid), and K the empirical constant. The fluidity ($1/\eta$) was an almost linear function of the free volume ($\bar{v} - V_o$) of the solution over the entire temperature range for all the solutions. Slight deviations from

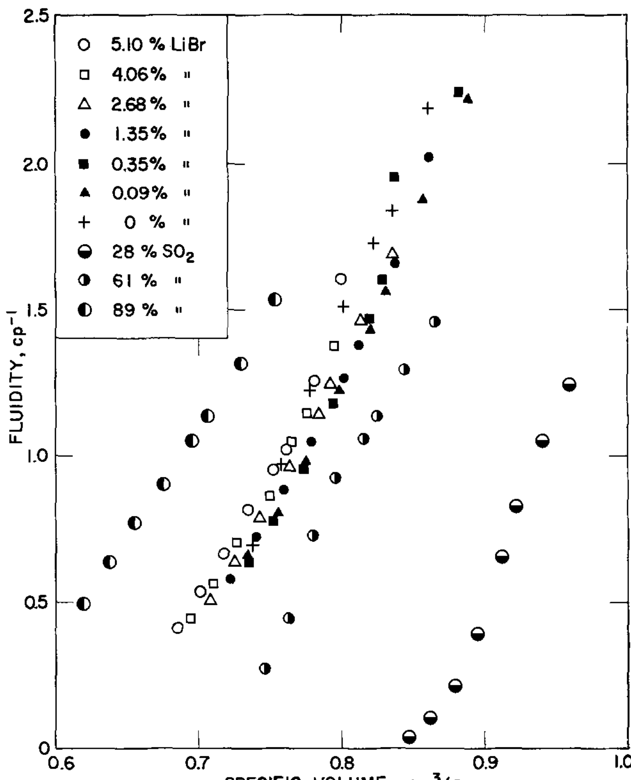

Fig. 8. The free volume theory correlation of the electrolyte viscosity.

linearity occurred in the region of the smaller specific volumes, *i.e.*, at the lower temperatures. Interestingly, solutions with different LiBr concentrations defined the same fluidity/specific volume curve to a first approximation. The SO_2 concentration, however, displaced the curves noticeably. The greater the SO_2 concentration, the more the fluidity curves shifted toward the smaller specific volume range. The effect of the SO_2 concentration on the constants in the free-volume viscosity equation is given in Table III.

The specific volume constant V_o approached the specific volume of liquid SO_2 (0.61 cm^3/g) at the melting point of SO_2 as the concentration of the SO_2 increased. This is in reasonable agreement with the model considerations on which the free volume viscosity equation is based (3).

The viscosity data reflected the strong solvent/solute interactions thought to occur in the SO_2/AN/PC/LiBr solutions. Apart from the low LiBr concentration range, the viscosity was linear in the LiBr concentration, Fig. 6

$$\eta/\eta_o = 1 + BC \tag{4}$$

where η_o is the viscosity of solvent, C the LiBr molar concentration, B the empirical constant; and the value of B was found to be $B = 0.79 \pm 0.02$, independent of the temperature. This value is characteristic of nonaqueous electrolyte solutions containing small ions (4). The dominance of the linear concentration term in the Jones-Dole equation above is taken to signify strong solvent/solute interactions (5), presumably the solvation of Br^- by acetonitrile and sulfur dioxide in this case.

Table III. The effect of the SO_2 concentration on the free volume equation constants (Eq. [3])

SO_2 concentration (w/o)	K (1/cp)	V_o (cm^3/g)
28	10.1	0.85
61	6.4	0.70
75	6.2	0.66
89	5.0	0.57

The same general conclusion may be derived from Einstein's equation for the viscosity of dilute solutions of uncharged spherical molecules (6)

$$\eta/\eta_0 = 1 + 2.5\,C\overline{V} \quad [5]$$

where $\overline{V}$ is the molar volume of solute species, from which $\overline{V} = 316$ cm^3/mole for LiBr in the SO_2/AN/PC solvent. Since the sum of the ionic volumes of Li^+ and Br^- is about 19 cm^3/mole, it is apparent that the ions must be strongly solvated in this solution.

The data may also be analyzed in terms of an Arrhenius type of activated process (3, 7, 8) despite some doubts about the validity of such a model for momentum transfer (9).

As the concentration of LiBr increased from 0 to 5% (weight) the activation energy increased from about 2 to 4 kcal/mole, Table IVA.

SO_2 exerted a more pronounced effect on the activation energy; Table IVB. At low SO_2 concentrations, the activation energy was close to 44 kcal/mole, and at high SO_2 concentrations it approached 3 kcal/mole or less. This pattern reflects the highly beneficial effect of the SO_2 on the transport properties of the SO_2 electrolyte used in the Li/SO_2 batteries. The changes in the activation energy also reflect the complicated interactions that occur between the dissolved species and the solvents in these solutions.

89	3.4

* AN/PC/SO_2 mass ratio: 1.95/1/10.6.
** LiBr/AN/PC mass ratio: 1/3.3/1.7.

Conclusions

The capillary flow viscometer was found to function satisfactorily for the high vapor pressure SO_2 organic solvent electrolyte over the temperature and pressure range explored in these experiments: −60° to 70°C and pressures below 15 atm.

A high concentration of SO_2 in the electrolyte decreased the solution viscosity markedly, and the viscosity increased linearly with the LiBr concentration at temperatures between −60° and 70°C. This functional dependence indicated the occurrence of strong solvent/solute interactions in the SO_2 electrolyte.

The effect of the temperature on the viscosity agreed reasonably well with that expected from the free volume theory of momentum transfer.

Lead-Acid Batteries: Use of Carbon Fiber-Lead Wire Grids at the Positive Electrode

J. L. Weininger* and C. R. Morelock

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

Conducting carbon fibers were introduced into the positive grid of the lead-acid battery in a structure which resembled a grid of pipecleaners. The carbon fibers are compatible with the environment of the positive electrode of the cell. In conjunction with Pb-Ca-Sn alloy wires or pure lead wires, the fibers prolong the cycle life of the battery, increase the high discharge rate capability, and can decrease the weight of the battery. Scanning electron microscopy showed the function of the carbon fibers to be an extension of the lead wire grid, thereby participating in the solution-precipitation mechanism of the electrode reaction. For comparison, a grid with glass fibers was also studied.

In most applications of the lead-acid battery, the factors limiting performance and lifetime of the battery are utilization of the active material. adhesion of this material to the grid of the positive plate, and corrosion of the grid structure. Furthermore, an improvement in the energy density of the battery requires an increase in the utilization of the active material and a decrease in the weight of structural materials, especially of the grid.

The work described here deals with an attempt to achieve these ends with a radically different positive grid, as compared with the conventional cast or expanded lead grids. In the new structure, carbon fibers are combined with lead wires. The fibers interlock with each other and with the lead grid. This combined grid could still be pasted with active material and treated in the conventional manner to produce positive plates by curing, forming, and cycling. The purpose of the addition of carbon fibers was to (*a*) strengthen the lead grid, (*b*) improve the adhesion of the active material to the grid, and (*c*) reduce the resistive path from the metallic substrate to the site of electrochemical activity owing to the conductivity of the carbon fibers, thereby improving utilization.

In this report an experiment to prove the compatibility of carbon fibers with the lead-acid battery environment is described, as are the design and preparation of the grid and the performance of cells in which the carbon fiber-lead wire combination serves as the positive grid.

Use of Carbon Fiber at Positive Plate

It is common practice to improve conductivity of electrodes in galvanic cells by addition of carbon blacks or various grades of graphite. However, carbon fibers have not yet been used in the lead-acid cell. The pyrolyzed polyacrylonitrile (PAN) fibers used in this work have a conductivity in the range 0.86×10^{-3} to 2.5×10^{-3} mho/cm which compares to the values of 2.2×10^{-5} mho/cm for metallic lead and 1×10^{-3} and 4×10^{-3} mho/cm for α-PbO_2 and β-PbO_2, respectively. For this application, it was necessary to prove that the fibers can stand up to the strongly oxidizing conditions of the positive electrode. To test the stability of carbon fibers in this environment, an expanded grid of Pb-0.065% Ca-1.0% Sn alloy (St. Joe Minerals Corporation, RDP-16) was wound with carbon fibers (Hercules, Type A). This electrode was placed in 1.28 sp gr H_2SO_4 and was maintained potentiostatically at 1.40V *vs.* a Hg/Hg_2SO_4 reference electrode. The test lasted the equivalent of more than 700 cycles, if it is assumed that the plate must stand this high voltage for 20 min in each cycle. After 234 hr, the carbon fibers had lost their metallic grayish surface sheen and some colloidal carbon was suspended in the solution. There was no measurable weight loss which may have been compensated by oxidation of the surface with nascent oxygen. The texture of the surface observed in the scanning electron microscope (SEM) was not changed during the experiment. Instead, almost all fibers were at least partly split parallel to their long axis (Fig. 1). This would not interfere with their functioning as an extension of the positive lead grid. Furthermore, as will be seen later, during the actual operation of the lead-acid cell, the fibers became thoroughly covered with the active electrode material so that their exposure to acid, adsorbed oxygen, and to oxidizing potentials was less severe in the battery than during this compatibility test.

Grid Preparation

Figure 2 shows three substrates (grids) for electrodes of lead-acid cells. On the right is a lead-plated

copper screen and on the left an expanded RDP-16 alloy grid which were used, respectively, for negative and positive electrodes. In the center of the figure is a combination of lead wires and carbon fibers, framed in RDP-16 alloy. The horizontal strands of the grid are structures resembling pipecleaners. They consist of two twisted RDP-16 alloy wires which hold the carbon fibers in place. During the twisting operation, while the wires are twisted, the carbon fibers are caught and aligned radially to the pipecleaner. Each 360 degree turn of the wire strand, about two complete twists, contains approximately 1000 carbon fibers. Their radial orientation is ideal for gripping the active battery material during and after pasting and curing. Figure 2 shows one of the first pipecleaner grids. The ends of wire strands were pressed between frames of 0.018 in. RDP-16 sheets which were welded on the outside of the frame.

Experimental Results

Four cells were assembled with identical components except for the positive plates to be examined. In each cell the positive electrode was placed in a Daramic (W. R. Grace Company) separator bag and was sandwiched between two negative electrodes of larger combined capacity than that of the positive. The grid of the control cell consisted of RDP-16 alloy with a 500/1 expanded grid pattern. The cells Pb/C-2 and Pb/C-3 had carbon fiber/lead wire grids; that of Pb/C-3 is shown in Fig. 2. Finally, as a further check on the utility of carbon fibers, the fourth cell, Pb/G-1, had a positive grid in which the carbon fibers were replaced by glass fibers.

The plates were pasted and cured in the conventional manner. Their weights, dimensions, and additions of H_2SO_4 and water during pasting are given in Table I. The larger weight of fiber structures was due to the excess weight of the lead frame in which the fiber grid was anchored.

Formation of the plates was also performed in the customary manner at charge rates of C/20 for 24 hr in 1.05 sp gr acid, followed by C/24 for 20 hr in 1.28 sp gr acid. Before each charging step the plates were soaked in the acid electrolyte for 1-2 hr.

The cells were cycled at constant current to cut-off voltages of 2.70V on charge and 1.75V on discharge. With these conditions the charge rate varied with cycle life, but except for the first few cycles, during which the capacity decreased rapidly, the rates were approximately C/2 for the control and Pb/C-2 cells and C/4 for Pb/C-3 and Pb/G-1. For the latter pair of cells the rate was changed to C/6 after 40 cycles.

The experimental results are plotted in Fig. 3-5. Figure 3 gives the cell voltage as a function of time for the first two cycles for all four cells. Figure 4 shows the variation of discharge capacity up to cycle 25 and Fig. 5 extends this to the end of cycle life.

There is a large decrease in discharge capacity between the first and second cycle (Table II, Fig. 3). Although this has also been observed to a lesser extent with negative electrodes (1), it is much more pronounced with the positive electrodes. After the first discharge there was little difference between the plates containing carbon fibers or glass fibers until after cycle 25 (Fig. 3a and 4), but there was a large difference between these plates and the control electrode even in the second cycle, particularly at high discharge rates (Fig. 3b and 4).

A broad band of slowly decreasing values in Fig. 4 indicates small differences between individual fiber electrodes which can be attributed to the automatic

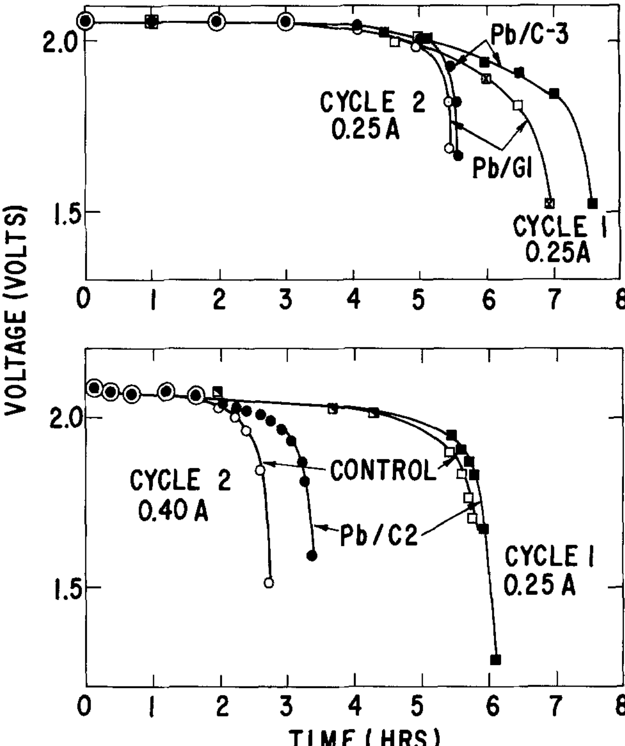

Fig. 3. Voltage-time plots during discharge of cycles 1 and 2. a, Top; b, bottom.

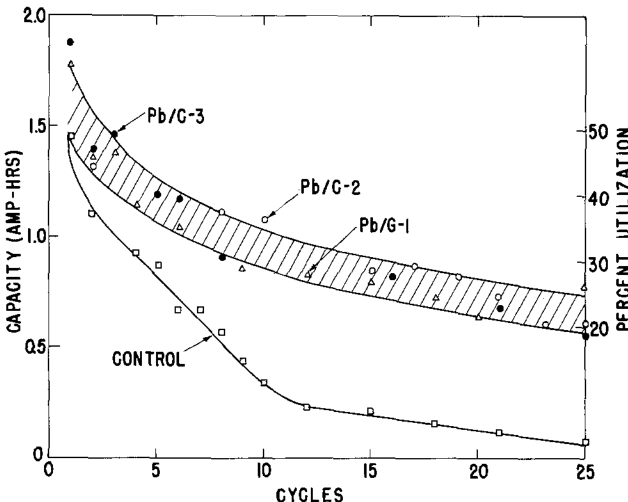

Fig. 4. Capacity and per cent utilization for first 25 cycles

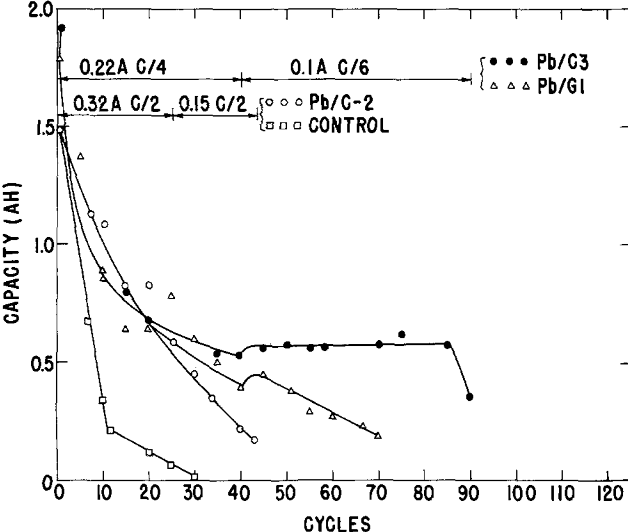

Fig. 5. Capacity during total cycle life

cycling equipment. However, the control cell, based on the expanded RDP-16 alloy grid, deteriorated rapidly and failed after about 10 cycles. This control cell and cell Pb/C-2 were cycled at the high rate of C/2. The other cells were cycled at C/4, and then at C/6, the change having been made to explore the possibility of prolonging cell life of Pb/C-3 and Pb/G-1 by decreasing the rate of charge and discharge (Fig. 5). This was the case for the electrode containing the carbon fibers, which showed superior charge acceptance over that with glass fibers after about cycle 30-35. This became more pronounced with increased cycle life. Pb/C-3 lasted 90 cycles and Pb/G-1 about 50 cycles before falling below the arbitrary limit of 0.50 A-hr capacity.

The serviceable life of the carbon-fiber cell Pb/C-3 is illustrated in Fig. 6 by the potential measurements of the individual electrodes against a Hg/Hg_2SO_4 reference electrode during the charge portion of cycle 81. Gas evolution occurred at approximately the same stages for both electrodes. It started at about 4 hr, became pronounced after 5 hr and predominant for the last 20-30 min of the 6-hr charge. The corresponding potential-time curves for discharge were more linear, with smaller time dependence, almost to the end of discharge, at which time the potential decayed rapidly.

An inset in Fig. 6 shows the typical coup de fouet or Spannungsberg which has been observed at the beginning of charging a previously completely discharged positive electrode (2). This phenomenon has been attributed to resistance polarization. In cell Pb/C-3 the potential maximum of the coup de fouet varied with charge current as follows: 1368, 1310, and 1264 mV, respectively, for currents of 150, 100, and 75 mA. The approximately linear relation of these values would be characteristic of an insulating $PbSO_4$ film on the positive electrode with resistance of the order of 1 ohm.

Examination of cell components at the end of cycle life showed few changes in the negative electrodes which were still functioning normally. The carbon-fiber electrodes had retained much of the active positive material, but in the case of the expanded grid, adhesion was so poor that the cell could not be taken apart without losing from the grid whatever material still adhered to it. This is shown in Fig. 7.

Table II. Performance of positive grids

	Control	Pb/C-2	Pb/C-3	Pb/G-1

Scanning Electron Microscopy (SEM)

The appearance of the positive plates after use (Fig. 7) indicated that adhesion of the active material was improved by the use of carbon fiber-lead wire grids. SEM further helped to elucidate the role of the carbon fibers in the positive plate. It showed that the active material was distributed uniformly between individual

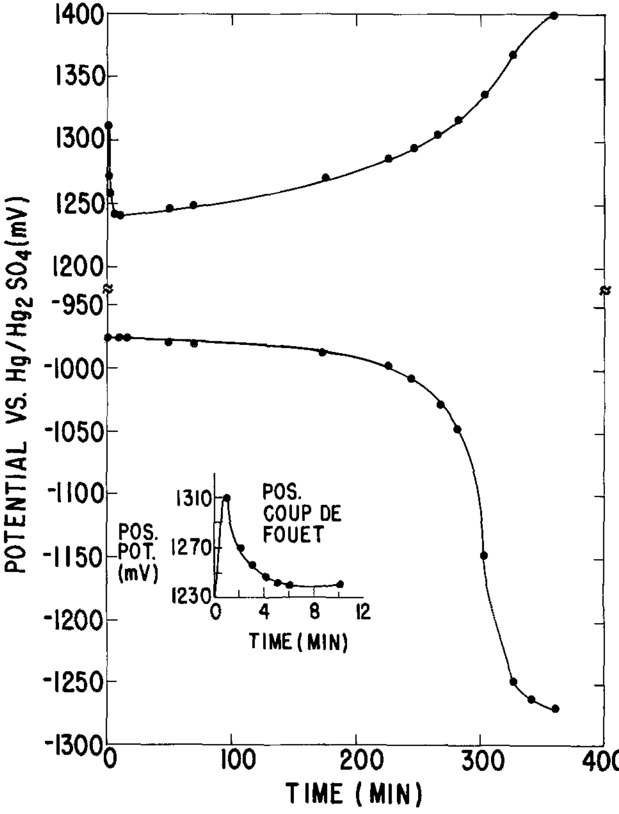

Fig. 6. Electrode potentials vs. Hg/Hg_2SO_4 reference electrode, cell Pb/C-3, cycle 81.

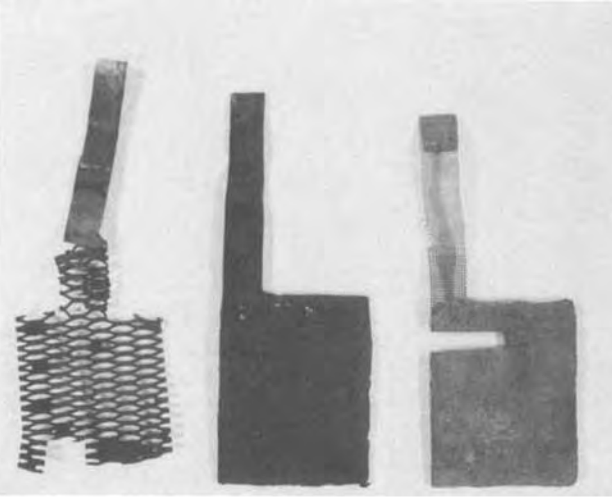

Fig. 7. Grids of Fig. 2 after use in the control cell (left), in cell Pb/C-2 (center), and as negative counterelectrode (right).

carbon fibers and that the fibers acted as nucleation sites for growth of the active material. For example, Fig. 8 shows a single carbon fiber which is heavily encrusted with $PbSO_4$ crystals. This barnacled appearance was typical of the deposits on the fibers. A similar deposit and growth were found at a bundle of fibers taken from the positive plate of cell Pb/C-3 (Fig. 9). Individual $PbSO_4$ crystals, their aggregates, and nucleation sites at the carbon fibers can be seen.

The materials in Fig. 8 and 9 were taken at the end of the useful life of cell Pb/C-3 so that they may have been very nearly inactive. However, a completely passivated $PbSO_4$ deposit is shown in Fig. 10 where the large crystal size rules out any effective electrode reactions. Conversely, where the deposit is still active, different smaller crystal structures, typical of PbO_2 were found (see Fig. 15 below).

The insulating glass fibers in cell Pb/G-1 were useful to the extent that they added structural support to the active material. But unlike the carbon fibers, they did not provide a substrate for crystal growth. This is shown in Fig. 11, which is a view of many isolated, but closely spaced, glass fibers. That they are not covered with active material is clearly shown in

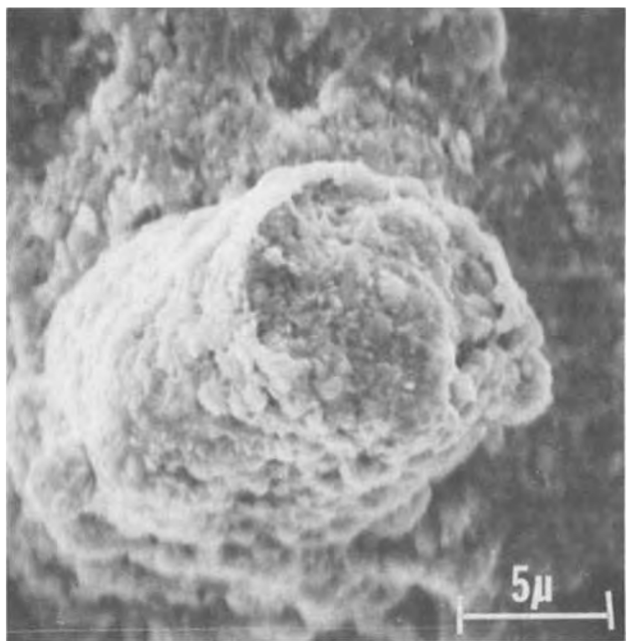

Fig. 8. Carbon fiber with deposit of positive active material

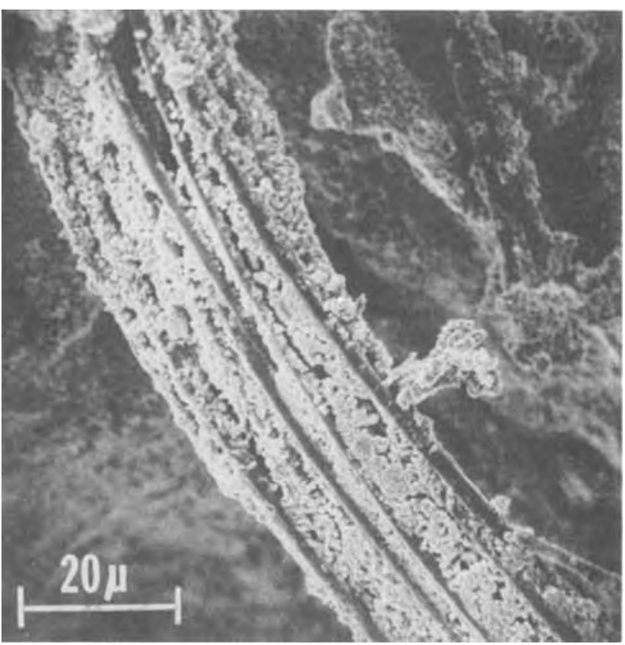

Fig. 9. Bundle of carbon fibers, each 3μ thick, with positive active material, at end of cycle life of cell Pb/C-3. Note growth characteristics of solution-precipitation mechanism.

the enlargement of one of the central glass fibers of Fig. 11 in Fig. 12.

Another interesting SEM observation, not directly related to the use of carbon fibers, is that of the passivated layer on the Pb/Ca/Sn alloy wire of the fiber-wire grid. Figure 13 is the cross section of the wire, originally 0.043 cm in diameter, at the end of experiment Pb/C-3. Two layers of active material adjacent to the wire are noted. They have different color and texture. The inner, lighter layer is made up of large $PbSO_4$ crystals. It is believed to be the corrosion layer which has the passivating effect on cell operation. Figure 14 is the enlargement of the central portion of the SEM of Fig. 13. The $PbSO_4$ crystals are densely packed, but considerable porosity is maintained, even in the corrosion layer. The darker, finer

textured active material of the positive plate, located to the right of the central portion of Fig. 13, is shown in the enlargement of Fig. 15. The porosity and crystallite sizes in Fig. 15 are typical of active PbO_2 material.

Discussion

Use of alloyed lead and carbon fibers.—In the present work the main objectives of improving the cycle life of positive plates and of the utilization of the positive active material were combined with the search for a suitable Sb-free grid structure. The new grid structure makes use of conducting carbon fibers as an extension of a Pb-Ca-Sn alloy wire grid. This combination, resembling a grid of pipecleaners, results in greater strength, better adhesion of the active material, and longer cycle life of the positive electrode.

Two important aspects of the contribution of the carbon fibers are: (*a*) their relatively ordered, radial arrangement, with respect to the Pb or Pb alloy wire grid, and (*b*) their electrical conductivity. The former leads to an intimate combination of carbon fibers and active material on a microscopic scale providing nucleation sites for growth of the active material. This is made possible by the conductivity of the carbon fibers which allows the fibers to act as extension of the grid (see below).

Performance of test cells.—Figures 4 and 5 show the longer lifetime of the carbon-fiber cells Pb/C-2 and Pb/C-3 than those of the control cell and the glass-fiber cell Pb/G-1. The control cell had a positive substrate of expanded Pb-Ca-Sn alloy with an expansion

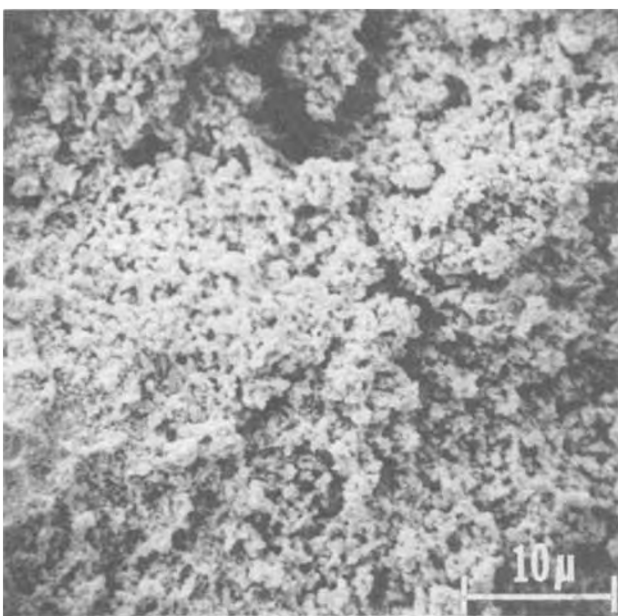

Fig. 15. Enlargement of a portion of Fig. 13 which contained the more porous, darker layer. The active material of the positive electrode.

pattern that resembled slightly that of the conventional cast grid (Fig. 1). But the lack of adhesion of the active material (see Fig. 7) was the decisive factor in the poor performance of the control cell, particularly with the rigorous cycle regime of 100% depth of discharge. The glass-fiber cell kept pace with the carbon-fiber cell for approximately the first 25 cycles (Fig. 3 and 4), showing a similar structural improvement of the positive electrode, due to the incorporation of fibers. In the later stages of cycle life, when previously active sites were passivated, the advantages of the carbon-fiber grid became more pronounced (Fig. 5). They can be related to the mechanism of the electrode reactions, discussed below.

The better cycle life of cells, containing positive electrodes with carbon fibers, is evident from the data represented in Fig. 5. This preliminary finding holds out hope that the life of a specialty "maintenance-free" battery with Pb-Ca-Sn grid wires can be brought up to the level of heavy-duty batteries, employing antimonial lead grids.

Electrode design.—The grid design incorporating fiber electrodes was intended to prove the feasibility of the carbon-fiber grid structure. It did not constitute a design for best performance, utilization, or energy density. There was excessive weight in construction of the lead alloy frame and of the cell as a whole. Furthermore, another observation indicated that the life of cells containing carbon fibers was not limited by the usual factors contributing to deterioration of the positive plate, such as lack of utilization, passivation, or shedding of active material. Instead, an extraneous introduction of a resistive contact, produced by corrosion of the alloy at points of contact between the ends of the carbon-lead pipecleaners and the lead alloy frame, may have been responsible for lower capacity in the later cycles of Pb/C-3. The contacts were made by pressing and cold-welding the ends of the pipecleaner strand between two frames of Pb alloy and melting the outside edges of the frames. Optical microscopy showed that this connection was not leakproof. The acid electrolyte seeped into the cracks between the two frames and corroded the contact points. It is, therefore, quite plausible that with a better design of the grid frame, for example, by anchoring the ends of the carbon fiber/lead wire strands in a suitable material, better results will be obtained with an advanced electrode design.

Utilization of positive material.—The decrease in the utilization of the positive material from 50-60%, encountered in the first cycle, to approximately 40-47% in the second cycle (see Table II) is disappointing. It may be tentatively ascribed to the passivation of the Pb-Ca-Sn alloy which over the life of the cell is pronounced. It is illustrated in the SEM's of Fig. 13 to 15.

Some methods of carbon-fiber grid construction do not depend on the mechanical strength of the lead alloy. It is then possible to use pure lead wire for the carbon-fiber grid. This may be an advantage electrochemically and economically, but the same sulfation problem and, hopefully, the same remedies that apply to the Pb-Ca-Sn alloy will also apply to pure lead.

High rate discharge.—Electrodes containing carbon fibers will have a better capability to deliver power at high rates. This conclusion is again based on the concept of extending the grid by means of the carbon fibers into the active material. The effect of sulfation will be alleviated insofar as the carbon fibers act as an active electrode surface. Also, more utilization and capacity at higher current drain may be obtained than with conventional grids. This is shown to some extent by the discrepancy of the performance of cells Pb/C-2 and of the control cell, between the first cycle at C/6 discharge rate (small difference) and the second cycle at C/3 (considerable advantage to the cell containing the carbon fiber).

Scanning electron microscopy.—SEM studies of active constituents of the lead-acid cell were first described by Hughel and Hammar (3) who showed many interesting SEM's of positive and negative materials in various stages of charge. Since that publication, SEM has become a powerful and popular tool in battery research. It has recently been described for the negative electrode of the lead-acid cell (1). In the present work, the function of the carbon fibers as conducting substrates in positive plates was also elucidated by SEM. This is discussed in connection with the solution-precipitation mechanism of the electrode reactions.

Solution-precipitation mechanism.—Evidence for this mechanism is derived from SEM's. Figure 9 shows the crystal growth and nucleation sites on carbon fibers, whereas in the comparable construction with glass fibers (Fig. 11) no such crystal growth occurred. The reaction in question may take place even before cycling, during the formation of the positive active material which is discussed in detail by Pavlov and co-workers (4).

During formation, Pb(II) ions have a limited solubility in equilibrium with tribasic lead sulfate

$$3PbO \cdot PbSO_4 \cdot H_2O + 2H_2O = 4Pb^{2+} + SO_4^{=} + 6\,OH^-$$

This may be followed by (*a*) direct precipitation of the sulfate

$$Pb^{2+} + SO_4^{=} = PbSO_4$$

or (*b*) by oxidation and subsequent precipitation of α or β PbO_2, depending on the acidity at the site of PbO_2 precipitation

$$Pb^{2+} = Pb^{4+} + 2e^-$$

$$Pb^{4+} + 2H_2O = PbO_2 + 4H^+$$

The existence of this solution-precipitation mechanism is particularly important for the proper distribution of active material in the carbon-fiber grid. There are approximately 1000 strands to a single tow of the carbon fibers, each of which has a very small diameter. Consequently, during pasting, the carbon fibers cannot be expected to be individually coated. Only later during formation and cycling can it be expected that the carbon fibers will be uniformly covered with the active material.

Conclusions

A new positive grid structure has been developed which, by means of carbon fibers, extends the active lead wire grid into microscopic contact areas with the active material. The resulting performance of lead-acid cells with these grids shows longer cycle life and better capability at higher discharge rates than control cells made with expanded Pb-Ca-Sn alloy or cells in which the carbon fiber is replaced by glass fibers.

Acknowledgment

The authors wish to express their appreciation to P. C. Lord with whom the basic invention of the carbon fiber-lead grid was a joint effort; to F. W. Secor who designed and prepared the test cells; and to M. D. McConnell for the scanning electron microscopy.

Anodic Behavior of Silver in Alkaline Solutions

D. B. Gibbs, B. Rao, R. A. Griffin, and M. J. Dignam*

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A1

ABSTRACT

The anodic behavior of silver was investigated under controlled diffusion conditions in alkaline solutions. Experiments were carried out under linear flow control and also using a rotating disk electrode. The electrical and optical properties of the silver oxide films were measured. On the basis of these results, we point out the difficulties involved with surface roughness in interpreting diffusion layer kinetics. Finally, we suggest a mechanism for Ag_2O film formation under stirred conditions, involving dissolution of silver followed by precipitation, the rate-controlling step for which is nucleation of steps on the oxide surface.

Interest in the anodic behavior of silver in alkaline solutions (1-3) has been stimulated in recent years by the widening using of silver/silver oxide electrodes in storage batteries. The plateaus on the potential-time charging curves obtained at constant current have been associated (4) with the formation of Ag_2O, AgO, and other higher oxides. The first anodic product is Ag_2O which may be grown to several thousand angstroms in thickness (5). Its growth is terminated rather abruptly with the rapid increase of electrode potential to be followed by the formation of AgO and possibly higher oxides, before oxygen is eventually evolved. The physical and chemical properties of these silver oxides have been reviewed in detail by Allen (6) and MacMillan (7).

This paper is concerned primarily with the investigation of the initial electrode process, namely the formation of Ag_2O. A mechanism for the formation of this oxide would in general consist of a series of elementary steps involving solid-state point defects as well as species in solution and on the electrode surface, and would include reactions both within the film and at the interfaces. It was found that the kinetic behavior of silver electrodes was profoundly influenced by surface conditions (5) and it would thus seem that further studies should be carried out on smooth well-defined surfaces. The earlier work of the galvanostatic investigation (5) of both etched and electropolished silver electrodes in aqueous Ag_2O saturated NaOH solutions, included an examination of the effect of stirring of the electrolyte. The results were explained by postulating that at least two different mechanisms were involved in the Ag_2O film formation: one a dissolution-precipitation process and the other a direct interfacial reaction. Evidence for this hypothesis came from observations such as: (*a*) the apparent existence of two different overpotentials about 40 mV apart for oxidation, (*b*) the marked dependency of current efficiency on stirring, particularly at low current densities, and (*c*) the very different appearance of films formed under stirred and unstirred conditions, the former having a transparent glassy appearance, the latter a dull opaque one. In this work an attempt is made to examine further this hypothesis through the use of both a flow system and a rotating disk electrode. In addition, the electrical and optical properties of the films formed are determined, both to provide additional information on which to base kinetic arguments and also for reasons of intrinsic interest.

Experimental Details

The experimental procedure used involved a flow system, with adjustable flow rates, designed to circulate the electrolyte solution past the electrode surface at very high speeds. A schematic of the system is shown in Fig. 1. The system was constructed entirely of plastic materials (Teflon, polypropylene, and high density polyethylene) since the experiments involved the use of concentrated alkaline solutions. A Teflon lined pump P circulated the solution from a storage reservoir S through the cell C and a flow meter F. The flow meter was calibrated by measuring the time needed to pump a given volume of the solution through the system for a given manometer deflection. The flow rate was variable over a range of 25 to 100 ml sec^{-1}.

The storage reservoir S was placed in an outer tank containing water thermostated at 27°C. Through the

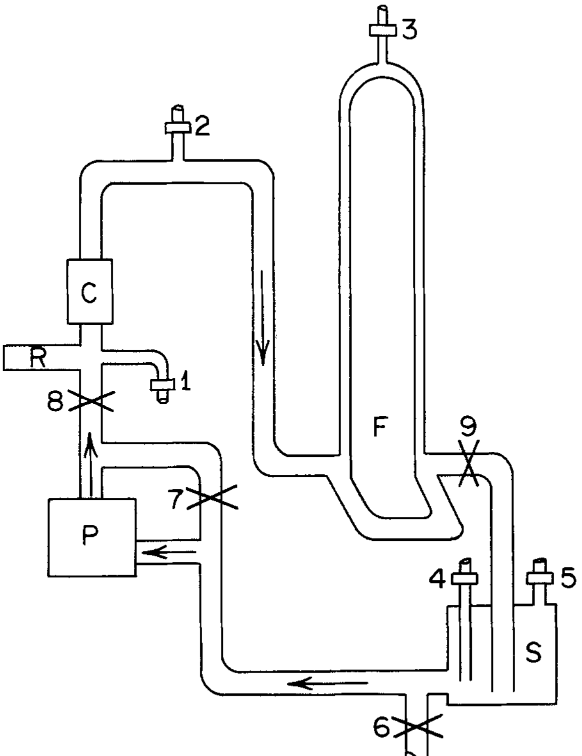

Fig. 1. Schematic of the flow system: C, polypropylene cell; R, reference electrode chamber; P, pump; F, flow meter; and S, storage tank.

top of the tank were sealed two tubes, for nitrogen inlet (a porous polyethylene gas dispenser) and an outlet such as to provide isolation from the atmosphere. Two auxiliary electrodes were also installed in the tank, one of platinum gauze and the other of silver foil, used for the preelectrolysis of the solution. A Hg/HgO microelectrode prepared on a piece of platinum foil (3) was used as the reference electrode. The nitrogen used in the system was purified by passage through vanadous chloride solution and amalgamated zinc (8) followed by a bubbler containing 0.7*N* NaOH solution.

The electrochemical cell was designed to place the test electrode in the center of a rectangular flow channel with counterelectrodes at each side as shown in Fig. 2(a). The pieces are from top to bottom: polypropylene tubing (main flow line) joined by a sleeve to a tapered end piece, electrode locater, center piece locater, and finally a tapered end piece joined by sleeve to the tubing. The center piece plan is shown in Fig. 2(b). The counterelectrodes N consisted of silver plates covered with anodically formed Ag_2O. Electrical contacts were made by sharpened silver wires which were forced against the back of the electrodes and sealed into the cell walls using first molten polypropylene and then reinforcing with epoxy cement. The electrical contact to the test electrode was made by a sharpened silver wire, this time sealed into the tight fitting polypropylene plug H. The electrode locaters [Fig. 2(c)] were small annular disks with three grooves to accommodate the ends of the electrodes and served to keep the test electrode at the center of the channel and parallel to the counterelectrodes. The center hole of each locater had a diameter just small enough to support the test electrode and prevent it from being swept downstream during the operation of the system. With the present cell, flow velocities ranging from 100 to 400 cm sec^{-1} could be produced.

The electrolyte was prepared from analytical grade NaOH and was found to contain 0.8% by weight of carbonate. The electrolyte was saturated with Ag_2O either by adding the powdered oxide into the electrolyte solution or by the anodic oxidation of the silver auxiliary electrode and subsequent agitation of the solution with the use of a mechanical shaker. Oxygen was removed from the solution by bubbling prepurified nitrogen for several hours. The test electrode was punched from 0.13 cm bright rolled silver sheet (99.95% pure) in the form of paddles with a blade approximately 2.54 × 0.63 cm and with a handle of 0.18 cm. Following a preliminary annealing in flowing hydrogen at 500°C for 1 hr, the electrodes were electropolished in a cyanide bath (10). They were rinsed in running distilled water and subjected to a further annealing in hydrogen at 500°C for 1 hr. The geometrical area of the electrode was 4.4 cm^2.

Fig. 2. Details of polypropylene cell. (a) Cross sectional view of the cell. (b) Central part of the cell: T, test electrode; N, counter electrode; and H, plug with lead for test electrode. (c) Electrode locater, L.

The rotating disk electrode (Pine Instrument Company) experiment was carried out employing a demountable electrode assembly (9) as shown in Fig. 3. Silver electrodes (99.95% pure) 1 cm in diameter and 0.6 cm thick were imbedded in a thermoplastic. These were metallographically polished to 0.25μ and then subsequently electropolished (10) to remove the worked layer. The rotational speed was varied from 0-10,000 rpm. Electrolyte preparation and other procedures were similar to that used in the flow system.

For studying the effect of roughness on the diffusion layer kinetics, silver electrodes for use in the rotating disk assembly were prepared in two different ways. In the first, electrodes mounted in the rotating head were metallographically polished and subsequently electropolished, then a silver film was deposited on the top of the polished surface by vacuum evaporation. In the second method, circular optical flats made of Pyrex were seated into the face of the rotating disk electrode assembly and silver film was deposited on the exposed face of the optical flat by vacuum evaporation. Electrical contact with the film was made by means of a fine silver wire protruding through a small hole (10μ diameter) in the center of the optical flat. The electronic equipment consisted of a standard galvanostat/potentiostat combination built with a set of operational amplifiers.

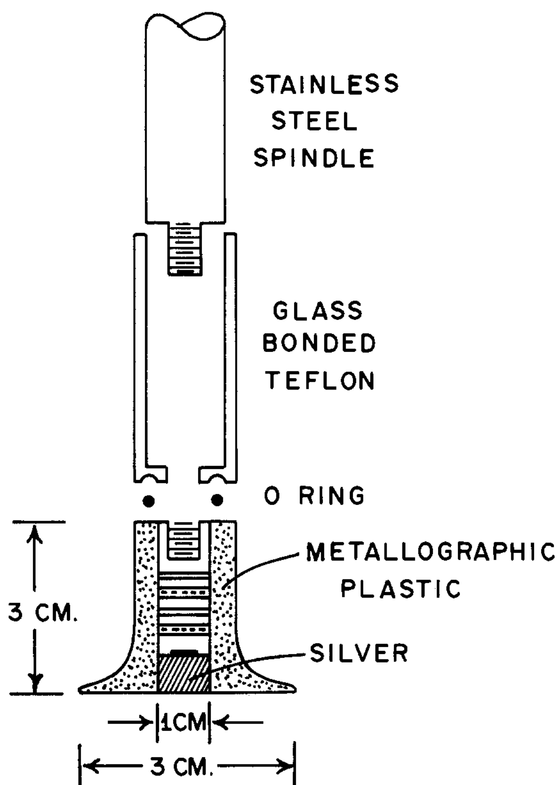

Fig. 3. Rotating disk electrode with demountable head suitable for electrical and optical measurements.

The optical studies consisted of direct reflection spectroscopy in the infrared region to observe lattice vibrational modes and ellipsometry in the visible spectral region to determine the thickness and optical constants of the silver oxide films. A Perkin-Elmer 350 spectrophotometer (0.35-217μ) and a Beckman IR-11 spectrophotometer (12-150μ) were used to obtain the specular reflectance spectrum of the silver oxide films. Also, for the sake of comparison, transmission spectra of Ag_2O powder were recorded. The ellipsometric measurements were carried out, using a method involving light intensity measurements (11), over the wavelength region 4000-7000Å.

In addition, electrical measurements were carried out on the oxide films. These were done by subjecting the system Ag/anodic oxide/Al to measurements of direct current *vs.* voltage, and capacitance (10^6 Hz) *vs.* d-c polarizing voltage. For this purpose a uniform square grid of superpurity aluminum spots of 0.04 cm was evaporated on to the silver oxide surface to provide electrical contacts. The type of charge carrier was identified at room temperature by means of thermoelectric measurements. The sign of the thermoelectric power for the oxide film was determined by observing the sign of the potential developed between a heated probe against that of a room temperature probe on adjacent aluminum spots.

Results

Electrochemical studies.—In the absence of stirring, a freshly installed silver electrode was found to assume an initial open-circuit potential of about 0.20V *vs.* Hg/HgO reference electrode and then slowly increased toward the reversible Ag/Ag_2O potential of 0.244V. This was however speeded up under stirring conditions and remained stable at that value. Figure 4 shows a typical oxidation-reduction curve of potential *vs.* time at 27°C for silver in Ag_2O saturated alkaline solution. The general shape of the anodic curve was found to be unaffected by stirring. The cathodic curves were always recorded in the absence of stirring, since otherwise reducible species such as silver in solution and residual oxygen would be transported to the electrode,

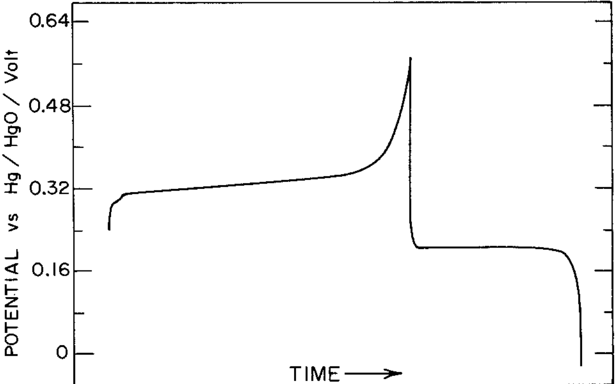

Fig. 4. Oxidation and reduction curves for Ag_2O film formation under a flow rate of 350 cm sec^{-1} at 27°C oxidation: i = 0.33 mA cm^{-2}, time = 7.6 min reduction: i = 0.39 mA cm^{-2}, time = 4.3 min.

making meaningful reduction measurements impossible. The cathodic curve normally consisted of only one plateau and always exhibited a distinct abrupt drop toward hydrogen evolution, which was taken to signify the end of Ag_2O film reduction. It was, however, found that it is essential to saturate the electrolyte with Ag_2O, otherwise the electrochemically formed oxide film tended to dissolve in the electrolyte. Examination of the Ag_2O film formed under rapid stirring conditions showed it to have a smooth shiny finish, compared to those formed under unstirred conditions, which were dull brown in color.

The plot of current efficiency (defined as the ratio of the reduction charge to the oxidation charge) *vs.* total current density is shown in Fig. 5. At median current densities, the measured current efficiencies were less than 100%, and independent of whether the electrode was reduced immediately following oxidation or whether a period of open-circuit stirring was allowed before reduction. The experimental points in Fig. 5 are represented fairly well by two intersecting straight lines. A more or less similar behavior was observed with the rotating electrode system. The intersection of the two lines falls near 0.25 mA cm^{-2}, the current density noted by Dignam *et al.* (5) to be unique. Below this current density, the current efficiency falls off precipitously and would appear to reach a value of zero at about 0.06 mA cm^{-2}.

Mean film thicknesses were calculated from the number of coulombs needed to reduce the films, assuming unit roughness factor and using bulk density (6) values for the Ag_2O. The limiting film thickness as calculated was found to be a decreasing function of current density, as shown in Fig. 6. The reduction charge (proportional to the film thickness) and current efficiency for silver oxide films at varying current densities and different flow rates are shown in Table I.

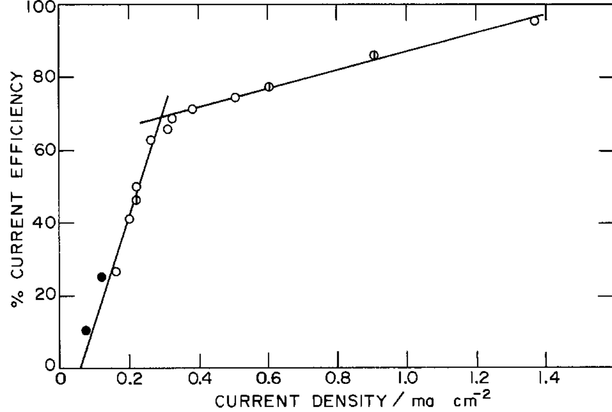

Fig. 5. Current efficiency for Ag_2O formation as a function of current density under a flow rate of 350 cm sec^{-1} and at 27°C.

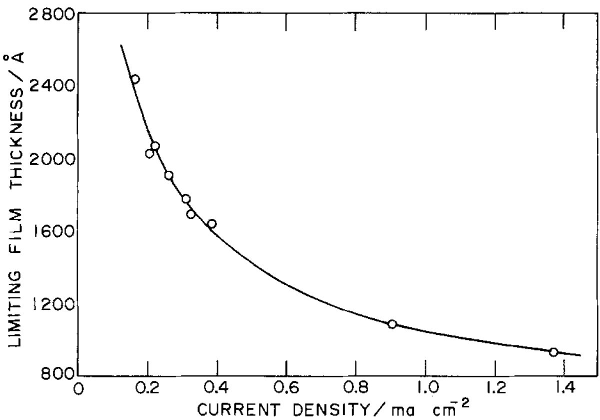

Fig. 6. Limiting film thickness as a function of current density under a flow rate of 350 cm sec^{-1} and at 27°C.

Examination of the amount of charge required for reduction shows clearly that the limiting film thickness is independent of flow rate over the entire range investigated in our experiments. Thus Ag_2O film formation ceases when a certain thickness has been reached, independent of the contribution of the dissolution process. As regards current efficiency data for unstirred conditions, the efficiency is very high at all current densities, but has dropped significantly by the time a flow of 150 cm sec^{-1} is reached. Thus it would appear that at least for the range of flow rates accessible here, the current efficiency is independent of flow rate except at very low flow rates.

The dependence of current efficiency on the per cent complete formation of Ag_2O film is given in Table II. These results indicate that the efficiency is independent of film thickness. The linear segments of the anodic potential *vs.* time curves were extrapolated to zero time. The resulting potential intercept, η_o, is seen to be approximately constant at about 60 mV (Table III) except at very low current densities where it drops rapidly with decreasing current.

The current efficiency for film formation may be written as

$$\text{C.E.} = i_f/(i_f + i_s) = i_f/i \quad [1]$$

where i_f is the current density associated with film formation and i_s that for metal dissolution. Their sum i is the total current density. The film current density i_f can be calculated as the product of total current density and current efficiency, the values of i_s being subsequently found by subtraction. The results are shown in Table III. While i_f increases regularly with current density, being nearly zero at the lowest current density, i_s is virtually constant ($\sim$ 0.1 mA cm^{-2}) except at the lowest current densities. Indeed, the variation of i_s with i is very similar to that of η_o with i described earlier. It was further found that oxidation reduction cycling does not appreciably affect the current efficiency. However, limiting film thicknesses calculated were somewhat greater (~30%) which suggests some surface roughening has occurred. This observation is consistent with earlier studies (5).

Diffusion layer studies.—The results of diffusion layer studies using rotating silver disk electrodes prepared by vacuum evaporation on both smooth and rough surfaces suggest that roughness effects might be a problem in obtaining reproducibility in the system $Ag/Ag_2O/(Ag_2O$ saturated aqueous NaOH) under anodic conditions. This conclusion was verified by the results of the study of redox reactions as a function of rotational speed for both smooth and rough electrodes. The behavior of the rotating disk electrodes under both potentiostatic and galvanostatic conditions as a function of angular velocity were determined in three different electrolytes. Figure 7 shows the result for I_3^--I^-, for a rough Ag rotating disk electrode under cathodic conditions. Thus under potentiostatic control the limiting current density is found to vary in direct proportion to $\omega^{1/2}$, where ω is the angular velocity, a result expected on the basis of the hydrodynamic theory (12), since diffusion layer thickness is predicted to vary in inverse proportion to $\omega^{1/2}$. A similar behavior was observed for the case of $Fe(NO_3)_3$-$Fe(NO_3)_2$ under anodic conditions.

In contrast, the electrodes were found to behave very differently under conditions in which the minor constituent is generated at the electrode surface, such as $Fe(NO_3)_3$-$Fe(NO_3)_2$ under cathodic conditions and Ag_2O saturated NaOH under anodic conditions where $Ag(OH)_2^-$ is presumed to be generated at the electrode surface. Thus the rough electrode surfaces (*i.e.*, those surfaces formed by silver evaporation onto metallographically polished surfaces) show very little change in overpotential with rotational speed under galvanostatic conditions (Fig. 8), while relatively smooth electrode surfaces (*i.e.*, those formed by silver

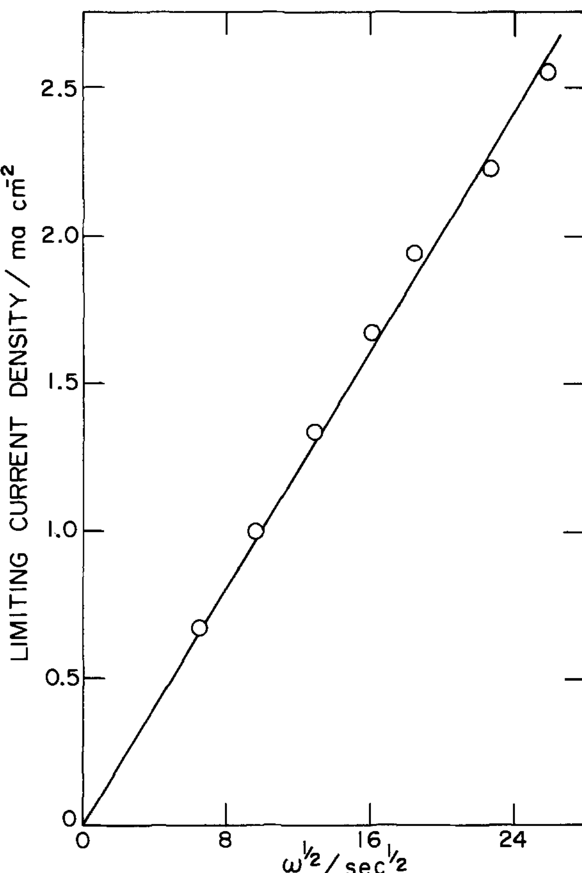

Fig. 7. Limiting current density as a function of the rotational speed using a rough silver rotating disk electrode under cathodic conditions for the redox system I_3^--I^-.

evaporation onto optically polished Pyrex flats) display a substantial change, though much less than that predicted theoretically.

A plausible, though not entirely convincing, explanation of these results follows: If the surface is rough on a scale of the order of the hydrodynamic boundary layer thickness, then under rotation, the electrolyte lying in the valleys on the surface will be more or less stagnant compared with that in the vicinity of the peaks. Thus a hydrodynamic layer will be formed extending from the bulk of the solution up to a plane defined approximately by the positions of the peaks on the surface. Species diffusing up to the electrode to undergo electrochemical reaction will have to diffuse through this boundary layer before reacting at the mountain peaks. If this description is correct, then the roughness should not affect the diffusion kinetics significantly under these conditions, *i.e.*, the species diffusing up to the surface, *e.g.*, I_3^--I^- under cathodic conditions and Fe^{+2}-Fe^{+3} under anodic conditions. If, on the other hand, the diffusing species are generated at the electrode surface and diffuse into the bulk of the solution, they must not only diffuse through the hydrodynamic boundary layer but also through a portion of the stagnant layer lying in the valleys. As the rotational speed will not alter the thickness of the stagnant layer, the rougher the surface, the less the effect of rotational speed on overpotential or current density as the case may be, in agreement with the data presented for the case of Ag electrodes (with varying roughness characteristics) in Fig. 8 and for the case of Fe^{+3}-Fe^{+2} under anodic conditions.

Optical measurements.—The optical results for the silver oxide films consisted primarily of ellipsometric data. From these measurements the ellipsometric parameters $\overline{\Delta}$ and $\overline{\psi}$ for the film free surface, and Δ and ψ for the oxide film covered surface were calculated at each wavelength (13). In order to determine the thickness and the spectrum of optical constants of the oxide film, we have used a procedure described elsewhere (14). The method involves the expansion of the complex dielectric constant of the film as a series of Lorentzian functions (15), the Lorentzian function parameters and the film thickness being chosen to minimize the variance (sum of the square differences between the measured and calculated values) of the optical measurements. Three Lorentzian functions were used in the expansion of the dielectric constant, so that a total of ten parameters was used to fit the experimental data for a range of trial film thickness values. For a typical case, the film thickness corresponding to the minimum variance 960Å, is to be compared with 1015Å, the thickness of the film determined by coulometric reduction (16) assuming bulk density and unit roughness factor. Figures 9 and 10 show the

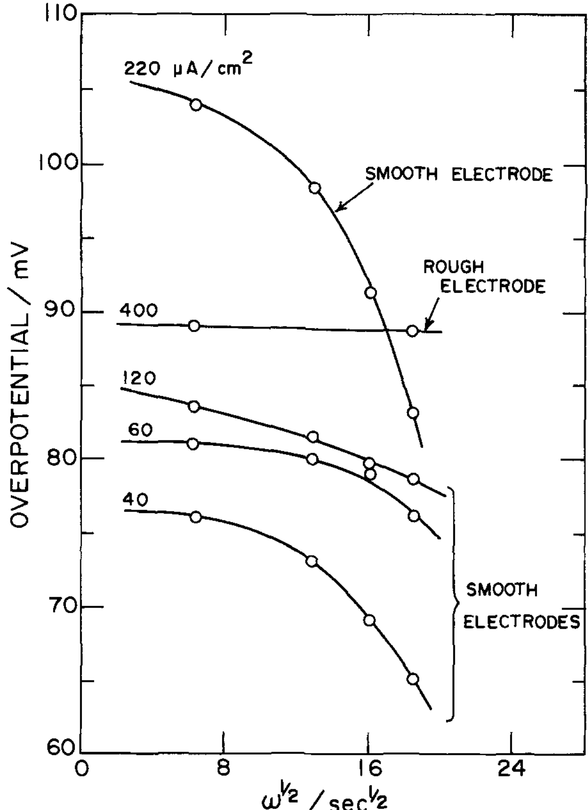

Fig. 8. Overpotential vs. rotational speed for both rough and smooth silver rotating disk electrodes under anodic conditions in Ag_2O saturated NaOH electrolyte solution.

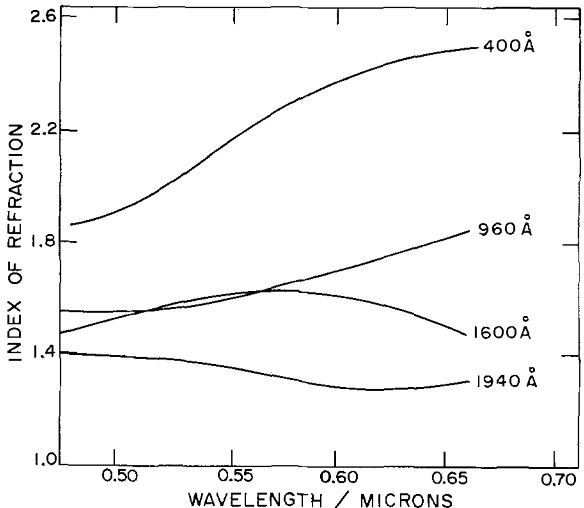

Fig. 9. Spectrum of refractive index for selected silver oxide films.

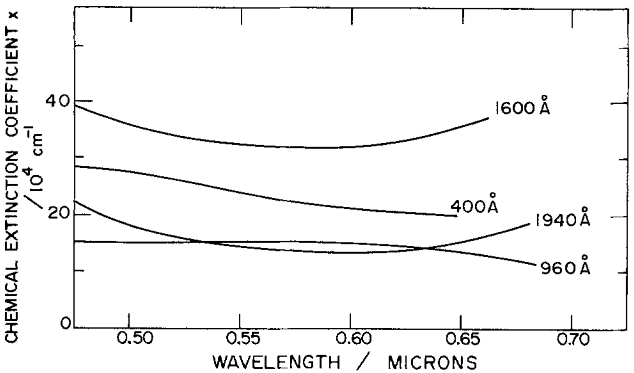

Fig. 10. Absorption spectrum for selected silver oxide films

resulting spectra of the refractive index and chemical extinction coefficient. The Ag_2O film exhibits broad absorption features, an indication of its semiconducting properties. In addition, the infrared and far infrared reflectance spectra of the Ag_2O film were found to agree with the transmission spectrum of chemically prepared Ag_2O, in its main features.

Electrical measurements.—The d-c current-voltage characteristics for a Ag_2O film formed at 0.2 mA cm^{-2} to a thickness of 450Å is shown in Fig. 11. The results indicate ohmic behavior for silver biased with a positive voltage with specific resistivity ($\sim 3 \times 10^7$ ohm-cm) being close to that for bulk Ag_2O (6). For silver biased with a negative voltage, however, the film appears to be blocking up to electrical breakdown. In contrast, the results for the oxide film formed at 0.017 mA cm^{-2} show almost perfect ohmic behavior for both positive and negative electrode bias and a much lower specific resistivity ($\sim 10^4$ ohm-cm) (Fig. 12). An explanation for the very different electrical behavior of the films formed under high (0.2 mA cm^{-2}) and low

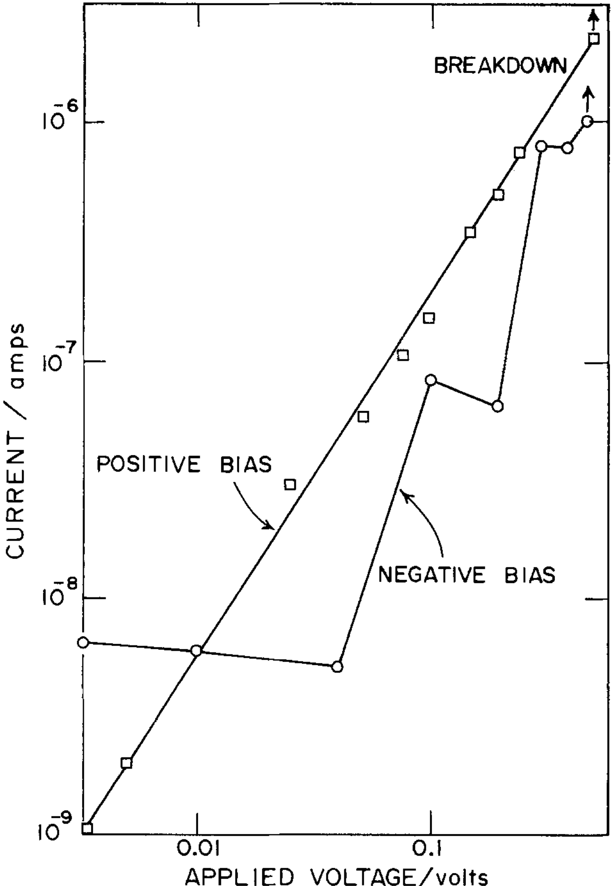

Fig. 11. Direct current-voltage curves for a 450Å thick Ag_2O film formed at 0.2 mA cm^{-2} in 0.3*N* NaOH solution.

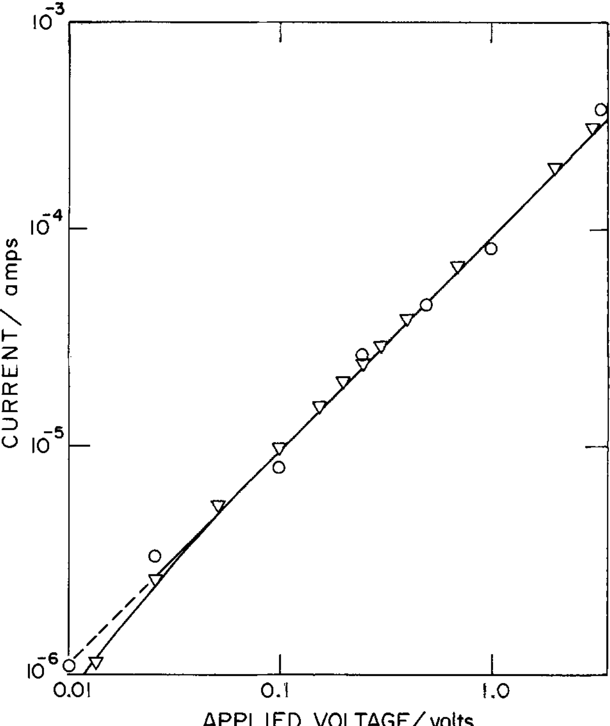

Fig. 12. Direct current-voltage characteristics for a Ag_2O 1260Å film formed at a current density of 0.017 mA cm^{-2} in a 0.3*N* NaOH solution.

(0.017 mA cm^{-2}) current densities follows: The two current densities used differ by a factor of ten, and thus in the case of the film grown under high current densities, a larger concentration gradient of the diffusing species exists in the film, remitting in it nonsymmetrical electrical behavior, in contrast with the film grown under appreciably lower current densities. Further, the specific resistivity ($\sim 10^4$ ohm-cm) is substantially below that accepted for Ag_2O powders. The capacitance-voltage characteristics for films formed at 0.2 mA cm^{-2} are displayed in Fig. 13. The lack of symmetry for positive and negative bias is indicative of asymmetry in the film itself. The thermoelectric power for films formed as above was found to be negative, a result expected for n-type semiconductors. To confirm the results the method was checked against both n- and p-type sections of silicon, in both cases the expected result being obtained. This is a surprising result as Ag_2O has generally been regarded as metal-deficient and hence p-type analogous to Cu_2O.

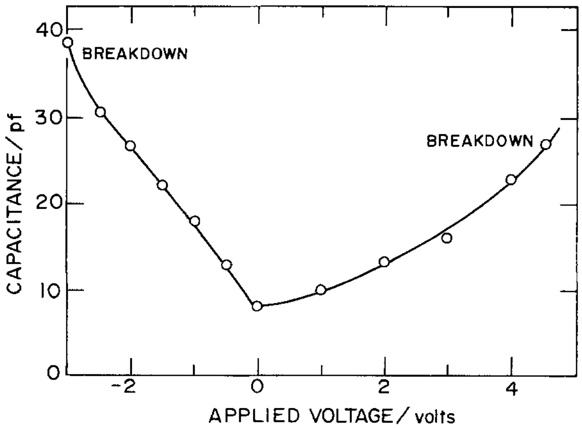

Fig. 13. Capacitance (1 MHz) vs. d-c polarizing voltage for the system Ag/anodic oxide/Al, the anodic oxide Ag_2O being 450Å thick, formed at a current density of 0.2 mA cm^{-2} in 0.3*N* NaOH solution.

We suggest that perhaps the n-type properties are conferred upon the film by the presence of colloidal silver.

Discussion

In this section we attempt to correlate some of the experimental observations in order to obtain an insight into the nature of the Ag/Ag_2O electrode.

A plot of current densilty i *vs.* $1/X_L$ (where X_L is the limiting films thickness) was clearly nonlinear, but a plot of the form i *vs.* $1/(X_L - A)$ (where A is a constant) produced an excellent straight line (Fig. 14). In this plot, the intercept has been set equal to zero and the optimum value of A was found by a least squares procedure to be 695Å. This suggests that diffusion within the film determines the limiting film thickness, though the presence of the constant A does pose a problem. It is possible that it arises due again to surface roughness.

Since current efficiency was found to be independent of film thickness, one is led to the conclusion that the pathways for Ag_2O film formation and metal dissolution share a common step in transport through the film, and differ only in the reaction path at the film solution interface. The most obvious mechanism which satisfies this condition is one in which film formation occurs entirely by a dissolution precipitation mechanism. The relevant equations for such a mechanism, when it is further assumed that the rate-controlling step for film growth is the nucleation of step sites on the oxide film, take the following form (17)

$$i_s = i_s^o[e^{\eta_o/V_s} - 1] \quad [2]$$

and

$$i_f = i_f^o e^{\eta_o/V_s} e^{-V_f/\eta_o} \quad [3]$$

where i_f is the current density associated with film formation, i_s is the current density for metal dissolution, η_o is the overpotential, $V_s = kT/e$ (k being the Boltzmann constant, T the absolute temperature, and e the electronic charge), $V_f = \pi\rho^2 a/kTe$ (ρ being the step free energy per unit length and a is the area per molecule in the oxide surface), i_s^o is a constant (equal to $DFCo/\delta$, where D is the diffusion coefficient for the dissolved ionic silver species, Co is the bulk concentration, and δ is the diffusion layer thickness), and i_f^o is a constant which contains the preexponential factor for step site nucleation. The total current density, made up of i_s and i_f defined in terms of Eq. [2] and [3], was fitted to the measured current efficiency and overpotential, using an optimization procedure (18) involving a three parameter fit (i_s^o, i_f^o, and V_f). Figures 15 and 16 show the fit of the current efficiency and the overpotential, respectively. The fit for the current efficiency *vs.* current density is extremely good, that for the overpotential within experimental scatter. The scatter in the overpotential arises in part from the fact that the experimental points represent different electrodes, leading to at least a 10 mV uncertainty in the overpotentials. From the value of i_s^o, and assuming a value for the diffusion constant of 10^{-5} cm² sec⁻¹, the diffusion layer thickness was calculated to be 0.008 cm in good agreement with that predicted under stirred conditions (19). From the value for the film crystallization parameter, V_f, the step free energy per unit length was calculated to be 4.4×10^{-6} erg·cm⁻¹ in good agreement with the value quoted for a standard situation involving nucleation of steps on the surface (17). Further, the surface free energy per square centimeter, σ, is related to ρ through the approximate equation

$$\sigma \simeq \rho/r \quad [4]$$

where r is the step height in centimeters and ρ is the step free energy per unit length. Taking r to be the unit cell length, σ is calculated to be 120 ergs·cm⁻², a value which closely matches that for ionic crystals (20).

In conclusion we suggest a mechanism for the Ag_2O film formation under stirred conditions, involving dis-

solution of silver followed by precipitation, the rate of which is controlled by the formation of steps on the oxide surface. We point out the difficulties involved with surface roughness in interpreting diffusion layer kinetics, difficulties which led to the previous erroneous interpretation of the kinetics as arising from two mechanisms for film formation. The electrical properties point to the interesting semiconducting nature of these oxide films, grown under the stated conditions, with the optical properties being consistent with those of an electronic conducting material.

The Anodic Oxidation of Hydrogen on Platinized Tungsten Oxides

III. Mechanism of H_2 Oxidation on Platinized Lower Tungsten Oxide Electrodes

B. S. Hobbs and A. C. C. Tseung

Department of Chemistry, The City University, London EC1V 4PB, England

ABSTRACT

The anodic oxidation of hydrogen at platinized electrodes of the lower tungsten oxides (WO_y, where $2 < y < 3$) occurs via a route involving hydrogen tungsten bronze formation on the surface of WO_3 film

$$2Pt + H_2 \rightarrow 2Pt - H \rightarrow 2Pt + 2H^+ + 2e$$

$$xPt - H + WO_3 \rightarrow H_xWO_3 + xH^+ + WO_3 + xe$$

Initial performance of the platinized lower tungsten oxide electrodes is lower than the corresponding WO_3 electrodes. However, their performance improves with time as the surface is converted to WO_3 rich layers until a limiting thickness is reached. The bulk of the lower tungsten oxide is then protected from further oxidation and does not participate in the over-all electrode reaction. It does, however, provide a conducting pathway to the current collector, even under flooded hydrogen-starved conditions, thus ensuring long-term stability in performance as compared with platinized WO_3 electrodes.

The anodic oxidation of hydrogen at platinized WO_3 electrodes occurs by a synergistic mechanism involving predissociation of molecular hydrogen on the platinum, followed by migration of H atoms into the WO_3 lattice to form hydrogen tungsten bronzes ($H_x\ WO_3$). These "bronzes" subsequently undergo electrochemical oxidation (1, 2). This paper is concerned with hydrogen electrode reactions on platinized mixtures of the lower tungsten oxides, WO_y, where $2 < y < 3$. There is a prolific number of these oxides quoted in the literature, but from a crystallographic standpoint only three stable compounds exist: β-oxide ($W_{20}O_{58}$), γ-oxide ($W_{18}O_{49}$), and δ-oxide (WO_2) (3-5). All other compounds are either metastable or consist of mixtures and solid solutions of these three phases and α-oxide (WO_3). The lower tungsten oxides are nonstoichiometric n-type semiconductors with electrical resistivities decreasing from about 1 ohm-cm for WO_2 to a minimum of 0.1

Key words: electrocatalysis, H_2 oxidation, lower tungsten oxides, stability.

ohm-cm for $WO_{2.75}$, then rising sharply to 2×10^5 ohm-cm as the composition tends to WO_3. Colors depend on stoichiometry and particle size, but normally vary from brown WO_2 through red-violet $W_{18}O_{49}$ to blue $W_{20}O_{58}$. These oxides are insoluble in acid solutions due to the formation of a protective WO_3 film, their standard potentials being below hydrogen (6). The electrochemical literature (6) quotes standard potential values for W_2O_5 and does not apparently consider the true phases, $W_{18}O_{49}$ and $W_{20}O_{58}$. Three distinct equilibria are identified

$$W + 2H_2O = WO_2 + 4H^+ + 4e \quad E^\circ\ -0.119V$$

$$2WO_2 + H_2O = W_2O_5 + 2H^+ + 2e \quad E^\circ\ -0.031V$$

$$W_2O_5 + H_2O = 2WO_3 + 2H^+ + 2e \quad E^\circ\ -0.029V$$

It is very likely that true equilibrium is not obtained in electrochemical systems and that the W_2O_5 phase represents a metastable oxidation state. Whatever the nature of the oxides, it is recognized that tungsten electrodes in contact with water progressively oxidize at the surface in a stepwise manner, eventually forming a WO_3 outer layer (7-9). The thickness of this layer increases with anodic polarization, but the crystalline bulk remains essentially unchanged.

In view of the close crystallographic relationship between WO_3 and the lower tungsten oxides and the possible existence of a WO_3 surface film, it is likely that a similar synergic mechanism for hydrogen oxidation exists with Pt/WO_y as for Pt/WO_3. Two reaction pathways are possible with the lower oxides: (*i*) Migrating H atoms from the Pt form bronzes of the type H_xWO_y which then undergo anodic oxidation as for H_xWO_3. (*ii*) Bronze formation is restricted to the surface layers of WO_3 to give H_xWO_3, with the WO_y crystallite bulk merely acting as a conducting support.

The following investigations were carried out to establish the mechanism of H_2 oxidation at platinized lower tungsten oxide electrodes, using the techniques developed for Pt/WO_3 (1, 2).

Experimental

Preparation and analysis of lower tungsten oxides.—WO_3 impregnated with 0.8% by weight Pt (1) was heated in a stream of hydrogen at 300°C for 2 hr and cooled to room temperature before admitting air. The product, a blue powder, was identified by x-ray diffraction and thermogravimetric oxidation in air. No further reduction of the oxide occurred on prolonged heating under the conditions of temperature, hydrogen pressure, and flow rate. The reduced powder was used for composition studies in hydrogenated slurries with $5N$ H_2SO_4 as described for WO_3, using x-ray diffraction and chemical analysis (1).

Electrode preparation and testing.—A series of platinized WO_3 hydrophobic electrodes were prepared with varying platinum loadings between 0.100 and 0.007 mg cm^{-2}. Preparation of electrodes having similar physical structures and platinum crystallite morphology, but varying widely in their Pt loadings, has been described (2). Tungsten oxide loadings were 10 mg/cm^2. Electrodes were tested in a "floating electrode cell" after converting the WO_3 to lower tungsten oxides by heating the electrodes at 300°C in H_2 as above. The electrolyte was $5N$ H_2SO_4 at 25°C. The purification of materials for these tests is described in Ref. (1) and (2).

Polarization curves were measured under 1 atm of flowing H_2. Background corrosion currents were also measured by replacing the H_2 with white spot N_2. The reduced oxides gave higher initial corrosion currents than Pt/WO_3 electrodes, *ca.* 1 mA/cm^2 maximum between 0-600 mV *vs.* RHE, compared to 0.1 mA/cm^2 for Pt/WO_3. These currents, however, decreased to the Pt/WO_3 level after an hour or so and must have included contributions from the conversion of immediate surface layers to WO_3.

Results and Discussion

Composition of tungsten oxide electrocatalyst.—The reduced WO_3 was a blue powder, stable in air at room temperature, and unaffected by boiling acidic dichromate solution. On heating in air at 400°C, it reverted to a pale yellow solid identified by x-ray diffraction as WO_3. From weighings before and after thermal oxidation, an empirical formula of $WO_{2.87(\pm 0.02)}$ was calculated which approximates to the phase $W_{20}O_{58}$. The x-ray pattern exhibited marked line broadening, rendering identification difficult. Subsequent BET measurements confirmed a decrease in average particle size from 0.11 to 0.10 μm during the reduction.

A slurry of the reduced platinized oxide in $5N$ H_2SO_4 absorbed 0.22 moles hydrogen per mole oxide. This product was easily reoxidized to $WO_{2.87}$ by warm air and acidified dichromate solution. X-ray diffraction patterns of the hydrogenated product were identical to the original $WO_{2.87}$, although line broadening made accurate measurements impossible.

A coarser sample of WO_3 used as the starting material had better x-ray line definition. The H_2-reduced product had an empirical formula of $WO_{2.84}$, in fair agreement with the finer material. The x-ray pattern was complex and not characteristic of any one tungsten oxide phase. It probably consisted of solid solutions of lower tungsten oxides, and none of the strong WO_3 lines were present. The hydrogen uptake of this powder in $5N$ H_2SO_4 slurries was only 0.09 moles per mole oxide, *i.e.*, half the finer material, and no change was detected in the x-ray pattern.

From BET surface area measurements, it was estimated that the amount of H_2 absorbed by both fine and coarse powders was considerably more than that required for monolayer coverage, indicating migration into the bulk of the crystallites. But the absence of a measurable change in diffraction pattern after hydrogenation supports the hypothesis that bronze formation is confined to immediate, oxidized surface layers of WO_3 which are not detectable and that the existence of lower oxide bronzes is doubtful.

Anodic oxidation of hydrogen.—The electrochemical behavior of the lower tungsten oxide electrodes differed from WO_3 electrodes with regard to the long term stability of electrode performance. Table I compares typical long-term characteristics of WO_3 and lower oxide electrodes. The reduced oxide electrodes underwent improvement with time and eventually achieved a steady performance after a few days. The performance of WO_3 electrodes, however, progressively decayed with time.

The stabilized performances of lower tungsten oxide hydrogen electrodes were very high and comparable with initial performances of WO_3 electrodes (Fig. 1). Thus a synergic mechanism is indicated.

The participation of the tungsten oxide in the electrode reaction may be confirmed as for WO_3 (2) by measuring the performances of a series of electrodes having similar catalyst morphologies and electrode structures, but varying in their Pt loadings. A plot of performance against Pt loading, for these electrodes is characteristics of an "active" support (Fig. 2). This plot is also characteristic of Pt/WO_3 electrodes in hav-

Table I. Typical life characteristics of platinized WO_3 and lower tungsten oxide electrodes

ing a cutoff point at which the ratio of WO_3 to Pt particles falls below unity (2).

These results do not differentiate between the two possible reaction pathways for the lower tungsten oxide supports. A deeper insight into the exact mechanism is provided by considering further the performance/time variations exhibited by tungsten oxide electrodes.

The attainment of a stable performance with lower tungsten oxide electrodes was achieved within several hours by subjecting them to anodic pretreatments. The most convenient method of anodic treatment was to leave the electrodes at open circuit with oxygen fed to the gas compartment. Optimum performances were achieved in about 3 hr with this treatment (Fig. 3). Oxygen evolution also speeds the attainment of a stable performance, but the gassing had deleterious effects on the electrode structures and final performances were lower.

This behavior supports the findings of the compositional studies that WO_3 and its bronzes are the "active" agents in platinized tungsten oxide hydrogen electrodes. The anodic treatment would result in faster growth of the WO_3 film with corresponding improvements in performance. Optimum performance would then correspond to the stage at which the WO_3 film reached the limiting thickness controlled by the oxidation conditions. The possibility of the increased performance being due to anodic oxidation of impurities can be dismissed since no improvement in performance was observed when similar pretreatments were carried out on platinized electrodes of WO_3, boron carbide, or tantalum carbide.

The progressive decay in Pt/WO_3 electrode performance requires an explanation. Several possibilities exist:

(*i*) Poisoning by impurity adsorption on the Pt can be discounted since it should apply equally to lower oxide electrodes and other substrates studied, *i.e.*, B_4C and TaC.

(*ii*) WO_3 has a slight solubility in sulfuric acid solution (6), forming tungstate ions which may discharge onto and poison the Pt surfaces. A similar effect has been reported by Radovici and Totir with MoO_3 substrates in acid media (10). However, the effect should equally apply to the lower oxide electrodes which form WO_3 layers on anodic treatment. Performance of hydrogen cured electrodes was also unaffected when left in contact for several days with an electrolyte presaturated with WO_3

(*iii*) The aqueous PTFE dispersion used to wetproof the electrodes (2) contains a surfactant to stabilize the suspension. It is possible that a higher proportion of this material remained in the WO_3 electrodes, which were cured in static air at 300°C (2), than in the lower oxide electrodes cured in flowing H_2 at the same temperature. The hydrophobicity of the WO_3 electrodes would therefore be lower and render them more susceptible to "flooding" with electrolyte, producing a higher degree of gas mass transfer polarization. However, a WO_3 electrode cured in flowing nitrogen had exactly the same decay pattern as those cured in static air.

A "spent" WO_3 electrode was regenerated, almost to its original performance, by washing in distilled water and drying in static air at 300°C (Fig. 4). Continued operation of the electrode resulted in more rapid loss of performance, and successive "resuscitations" became less effective; after the third cycle, performance after resuscitation was actually worse. The reasons for this behavior could be many, thus steam may be forming in the catalyst pores causing disruption of the elec-

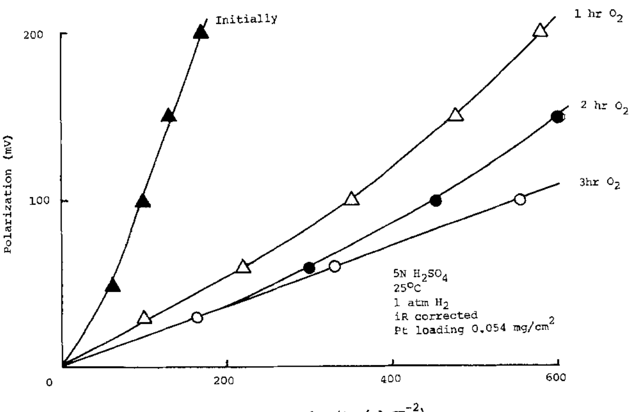

Fig. 3. Effect of O_2 treatment at 0°CV on a lower tungsten oxide electrode performance.

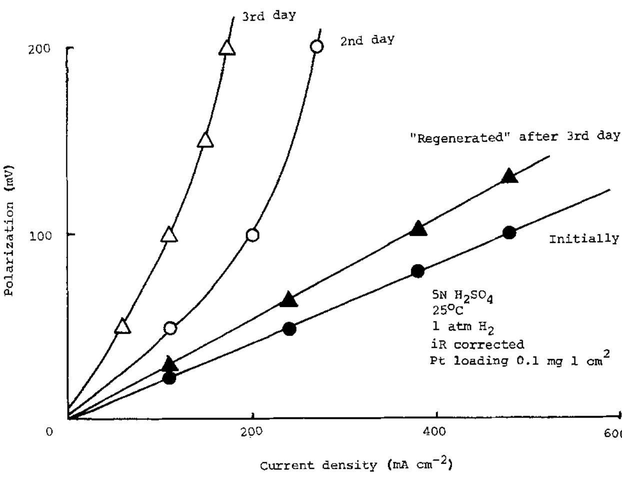

Fig. 4. Pt/WO_3 electrode performance decay and effect of first regeneration after third day.

trode structure, sintering may be reducing the activity of the components, etc. Nevertheless, it is clear that flooding is a major cause of performance decay in WO_3 electrodes. There is no reason to suspect that the lower tungsten oxide electrodes were any more resistant to flooding. The explanation of their improved long-term performance characteristics must therefore lie with their ability to cope under flooded conditions.

The lower tungsten oxides are more resistant to oxidation of their crystalline bulk than tungsten bronzes of the type H_xWO_3. Thus the blue oxides prepared in this work were unaffected by air or boiling dichromate solution, whereas the hydrogen bronzes revert rapidly and completely to WO_3 in either of these conditions (1). Similar effects were noted during anodic polarization under nitrogen. In a flooded catalyst aggregate, the bronze oxidation rate may exceed the hydrogen supply and the value of x in the H_xWO_3 will diminish with a corresponding reduction in conductivity. With WO_3 electrodes, oxidation can penetrate deeply in the crystallite bulk causing severe ohmic polarization of the electrode. The lower oxides, however, are more resistant to bulk oxidation which does not proceed beyond the layer formed during anodic pretreatment. Although the flooded portion of the catalyst aggregate is subject to a degree of gas concentration polarization, the electrical conductivity of the electrodes is not so markedly reduced.

A Rutherford Scattering Study of Catalyst Systems for Electroless Cu Plating

I. Surface Chemistry of Mixed Pd, Sn Colloids

Ronald L. Meek*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Rutherford ion backscattering has been used to obtain quantitative data on the surface concentration of Pd and Sn on substrates catalyzed with Pd-Sn colloid solutions. The alteration of these catalyzed substrates due to subsequent processing solutions, *i.e.*, the accelerator and electroless Cu bath, was also examined. The early stage of catalyst deposition saturates at a few monolayers of particles. The Pd/Sn ratio at this stage is $\lesssim 1$. The accelerator solution partially removes extraneous Sn and leaves a final average Pd surface coverage of $2\text{-}4(10)^{15}$ atom cm^{-2} independent of initial value. The Pd/Sn ratio at this stage is ~ 3. The Pd/Sn ratio in the catalyst core particle on which Cu deposition takes place is ~ 6. Sn lost into the electroless Cu bath is codeposited on subsequent samples.

Electroless copper plating of insulating substrates is widely used in printed circuit and decorative plating technology. Sensitization of the substrate, usually with Pd-Sn catalyst solutions, is required to provide catalytic sites for initiation of the autocatalytic electroless plating reaction (1). At present, very little useful quantitative data is available characterizing the behavior of these catalyst systems.

In the past, catalysis has been accomplished by sensitization in $SnCl_2$ solutions followed by activation in $PdCl_2$ solutions but, in recent years this process has been somewhat supplanted by the use of mixed Pd-Sn colloids. This paper will be concerned only with the Pd-Sn colloidal solutions and the process utilizing separate sensitization and activation will be examined separately (2).

Recent publications (3, 4) have questioned the colloidal nature of the solutions of interest. However, the experiments of Cohen and West (5, 6) indicate their colloidal nature, and, insofar as possible, the present results will be interpreted in terms of their model which is based on Mössbauer spectroscopy results. In a separate paper (7), we will combine results obtained by Rutherford backscattering, transmission electron microscopy, and Mössbauer spectroscopy, as well as discuss apparent disagreements with other published results. Suffice it to say here that when experimental methods, which have the inherent capability of re-

* Electrochemical Society Active Member.

Key words: catalysis, electroless plating, Pd-Sn colloids, printed circuit processing.

vealing colloidal particles in the ~20Å size range, are applied, the colloidal nature of the catalyst is revealed.

The purpose of the present study is to obtain quantitative information on the amount of Pd and Sn present on catalyzed surfaces and to examine the interaction of these catalyzed surfaces with the solutions used in subsequent process steps.

Experimental Details

Solution preparation.—In order to insure relevance to real life production situations, the catalysts used were prepared from commercial concentrates. The S catalyst solution was prepared by mixing 33 ml H_2O, 33 ml conc (37%) HCl, and 33 ml Shipley 9F conc.[1] The M solution was made up by mixing 55 ml H_2O, 20 ml conc HCl, and 25 ml MacDermid 9070 concentrate.[2] As prepared, the S solution contains 0.38 g/liter Pd and the equivalent of 33 g/liter Sn^{++} as $SnCl_2 \cdot 2H_2O$, while the M solution contains 0.29 g/liter Pd and 13 g/liter Sn^{++}. Pd was determined spectrophotometrically and Sn^{++} via titration.

Substrate catalysis is followed by immersion in an accelerator solution such as dilute fluoroboric acid. The accelerator used in the present work was prepared by mixing $5H_2O$ to 1 Shipley 19 accelerator concentrate.

The early stage of electroless Cu plating on the various catalyzed substrates was studied using the MacDermid 9072 D bath with mechanical agitation at room temperature. In all cases, fresh solutions were prepared immediately before use and kept in clean polyethylene containers. Each step, catalysis, acceleration, and plating, is normally followed by a rinse. In this work a standard rinse of 30 sec in DI water was selected and the results were established to be independent of rinse time for times greater than 15 sec.

Substrates were prepared for analysis by immersing 1 cm² samples in 100 cm³ of the appropriate solution, or series of solutions, with gentle stirring. They were then carefully dried by placing the sample edge on filter paper and immediately (within 15 min) examined. Substrate selection and the surface analytical technique are discussed in the following subsection.

Rutherford ion scattering.—Backscattering of high energy (2 MeV) He^+ ions has been fruitfully applied to a number of problems in surface, interface, and thin-film analysis (8, 9). Details of the technique as used by the author may be found elsewhere (10). Through conservation of energy and momentum, the energy of a backscattered ion yields the mass of the atom from which it scattered. Through the well-established Rutherford scattering cross section, the number of backscattered ions yields the number of scattering atoms. Thus, the technique qualitatively and quantitatively identifies the nature of the surface and near-surface layers.

It should be emphasized that the Rutherford scattering event takes place between nucleii well inside the innermost electron shell so that the information obtained is independent of the chemical state of the atoms. That is, essentially one identifies and counts the number of atomic nuclei. Depth information may be obtained due to the fact that an ion scattered from an atom of given mass at some depth into the substrate will possess a lower energy than will an ion scattered from an identical atom at the surface of the substrate due to the inelastic (electronic stopping) energy loss as the ion enters into and exits from the material.

Cleaved graphite substrates (~1 cm²) were chosen for the present study.[3] A scattered ion spectrum from a control (untreated) substrate is shown in Fig. 1. The low mass of C eliminates substrate interference and, furthermore, graphite may be obtained in a very pure form. By using a freshly cleaved surface, unwanted surface impurities can be minimized. The surface peaks in Fig. 1 correspond to O [$5(10)^{14}$ atoms cm^{-2}] and P and Si (~10^{14} cm^{-2}).

A typical spectrum from a surface layer produced by immersion in a catalyst solution and rinsing is shown in Fig. 2. Here O [$3(10)^{15}$ cm^{-2}], Cl (10^{15} cm^{-2}), Pd [$3(10)^{15}$ cm^{-2}], and Sn [$3.5(10)^{15}$ cm^{-2}] can be clearly seen. Results with other substrates, *e.g.*, epoxy-glass composites, were found to be roughly equivalent when the real to apparent surface area ratio is taken into account.

The substrate area examined by the ion beam is 0.78 mm². The statistical counting error in a given measurement is typically 3% for heavy mass impurities (Cu, Pd, Sn) and 10% for light masses (O,Cl). During the experiments it became apparent that significant differences (a factor of two) can exist from point to point on a given substrate. Thus 3-5 separate measurements were made at randomly selected points on a given sample. Throughout this paper, bars on data points indicate the point to point variation found, not

an error bar. Of course, surface concentration variations on a smaller scale, smaller than the beam spot size, may be even greater. Two or more samples treated in the same way gave equivalent results within the point to point variations just mentioned.

Results and Discussion

Catalyst.—Figure 3 shows Pd and Sn surface concentration *vs.* time in the S catalyst solution. In the early stages ($t \lesssim 100$ sec) the Pd or Sn increases roughly as the square root of time, but begins to saturate at about $5(10)^{15}$ Pd cm^{-2} and $8(10)^{15}$ Sn cm^{-2}. Note that not only is there a significant point to point variation in the Pd and Sn concentration, but also there is a considerable variation in the observed Pd/Sn ratio. Figure 4 shows similar data for the M solution. In this case the Pd and Sn values at a given time are

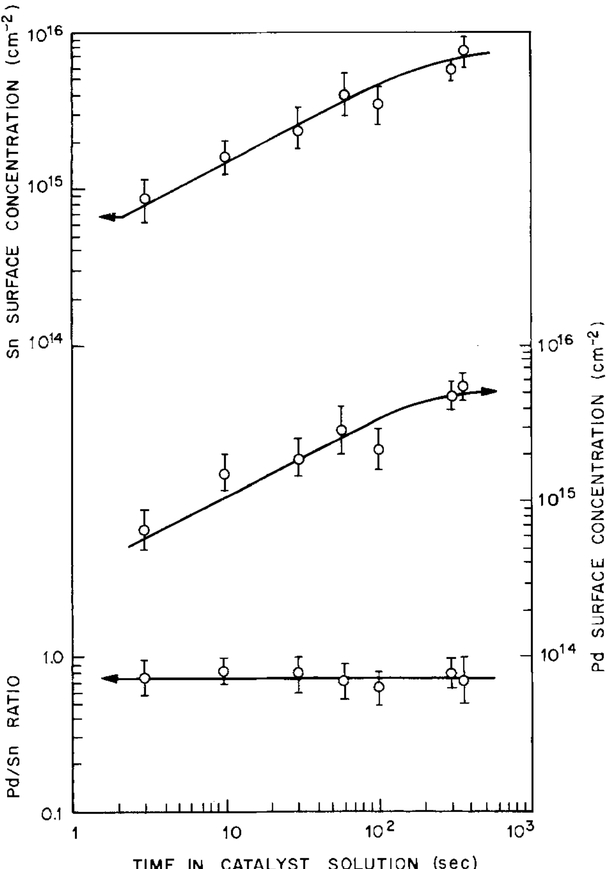

Fig. 3. Pd and Sn surface concentration vs. immersion time in S catalyst solution.

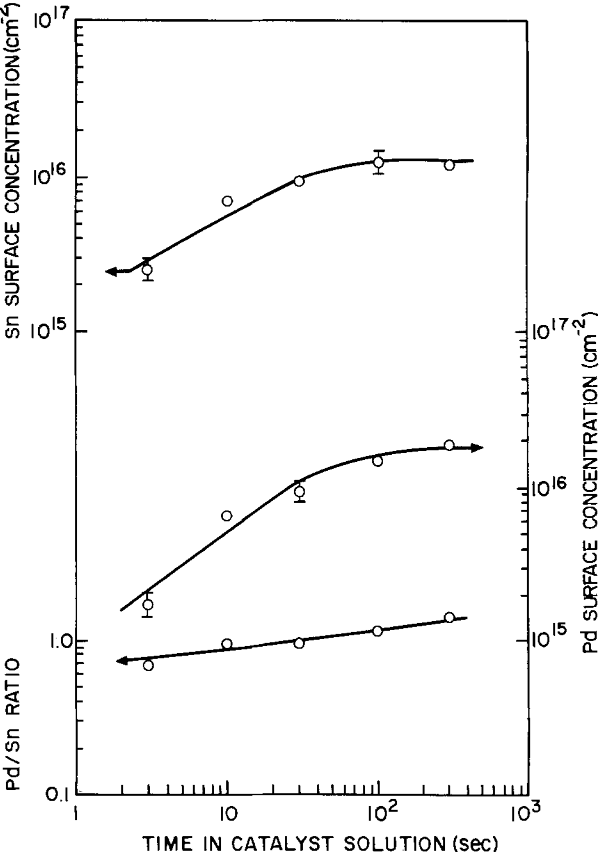

Fig. 4. Pd and Sn surface concentration vs. immersion time in M catalyst solution.

larger than for the S solution and there is considerably less point to point spread.

The Cl and O surface concentrations were also determined. The O/Sn ratio is essentially unity while the Cl/Sn ratio is about 0.3.

It will be convenient to discuss the results of this study in terms of adsorption of colloidal, Pd-containing catalyst particles. Because of the large excess of Sn present in the solutions, adsorption of other species may also be important and, furthermore, we must expect Sn to be deposited due to hydrolysis during the rinse step. The extent to which this is an influence is examined in Fig. 5. Twenty g/liter $SnCl_2 \cdot 2H_2O$ was added to the M solution so that the excess Sn concentration was the same as for the S solution. Little change is apparent in the surface coverage values except for a slightly reduced Pd concentration and Pd/Sn ratio at the longest times. Thus we have some confidence in interpreting the data in terms of adsorption of the Pd-Sn catalyst.

Cohen and West (5, 6) have stated that the Pd catalyst particles consist of a Pd-Sn alloy core in which the Pd/Sn ratio is about 6 surrounded by a divalent Sn stabilizing sheath which is probably $SnCl_3^-$ ions. The over-all diameter of these colloidal particles was judged to be about 20Å and the over-all Pd/Sn ratio to be in the range 0.5-1, depending on particle size (5, 6).

The square root of time dependence for early times suggests that the adsorption is diffusion controlled. The solutions were gently stirred, but it should be noted that even if the external flow is fully turbulent, for times such that the mass transfer boundary layer thickness is less than the distance from the surface to which the turbulent fluctuations penetrate, the mass flux to the surface will be essentially independent of fluid motion effects. Using periodic viscous sublayer theory (11, 12) and the usual turbulent boundary layer theory (13), it can be estimated that this is the case as long as the free stream velocity is less than about 10 cm/sec, which is appropriate for these ex-

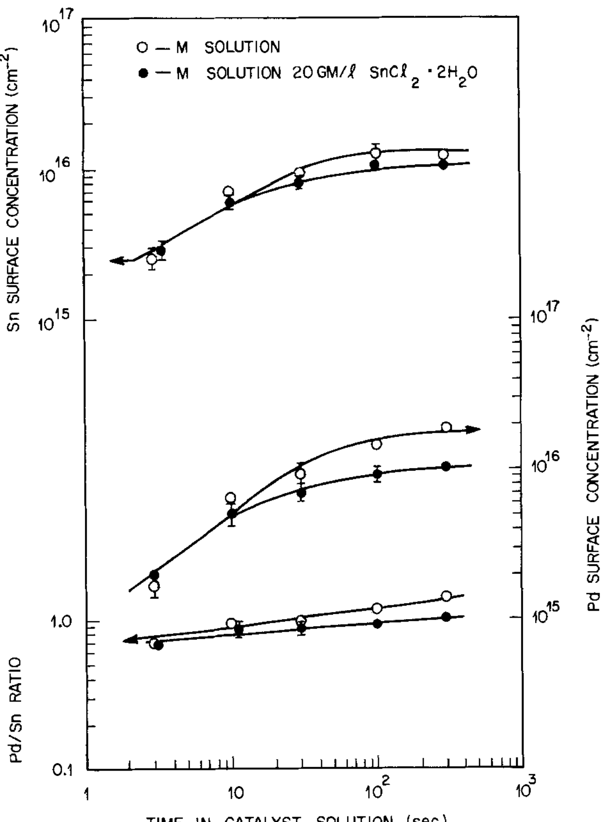

Fig. 5. Comparison of Pd and Sn surface concentration vs. catalysis time for M solution with and without added $SnCl_2 \cdot 2H_2O$ (20 g/liter).

periments. For short times, such that adsorption dominates desorption, the Pd surface concentration, n_{Pd}, is related to the bulk solution concentration, C_{Pd}, the effective diffusivity, D, and time, t, by

$$n_{Pd} = C_{Pd}(Dt)^{1/2} \quad [1]$$

Using the Stokes-Einstein equation (14), the diffusivity for a colloidal particle of the expected size (20Å) may be estimated as 10^{-6} cm² sec⁻¹. Then from the above equation

$$n_{Pd(S)} = 1.3(10)^{15}t^{1/2}$$

and

$$n_{Pd(M)} = 0.9(10)^{15}t^{1/2}$$

for the S and M solutions, respectively, where n has units of atom cm^{-2} and t is in seconds. The experimentally observed coefficients are $4(10)^{14}$ and $(10)^{15}$, respectively; the differences are probably within the approximations involved.

If the adsorbed material is regarded as being entirely the catalyst particles, the observed Pd/Sn ratio may be used to deduce an apparent particle size based on the model developed by Cohen and West (5, 6). We will assume that the particle is spherical, in agreement with TEM observations (7), and that the Pd/Sn ratio in the core is 6 (5, 6). Then the number of Pd atoms in the core is

$$\frac{6}{7}\frac{4\pi r_c^3}{3V}$$

where r_c is the core radius and V is the volume occupied by an atom in the core (14.7Å³) (5). Similarly the number of Sn atoms in the core is

$$\frac{1}{7}\frac{4}{3}\frac{\pi r_c^3}{V}$$

and the number of Sn atoms in the stabilizing sheath is

$$\frac{4\pi r_c^2}{\Delta^2}$$

where Δ is the characteristic dimension of the divalent Sn group in the sheath (4Å) (5). That is, the total diameter of the particle, d, in terms of the particle's over-all Pd/Sn ratio is

$$d = \frac{\left(\frac{7V}{\Delta^2}\right)\left(\frac{Pd}{Sn}\right)}{1 - \frac{1}{6}\left(\frac{Pd}{Sn}\right)} + 2\Delta \quad [2]$$

Apparent particle sizes deduced in this way are presented in Table I for comparison to ultracentrifuge (6) and TEM (7) observations. Furthermore, it would appear from Fig. 3 and 4 that the S solution has a somewhat smaller and more variable particle size, that is, a smaller and more variable Pd/Sn ratio, than does the M solution; again in agreement with the observations and arguments of Cohen and West (6). Also, Fig. 5 indicates that the apparent particle size deduced in this way is not much affected by changing the excess Sn concentration in solution. It can be noted that the presence of Sn as species other than the Pd-Sn colloid serves to decrease the apparent particle size estimated from Eq. [2] so that the values in Table I must be thought of as lower limits.

For particles approximately 20Å in diameter, coverage of the surface with one layer of particles would correspond to about $5(10)^{15}$ Pd atoms cm^{-2}. Thus the saturation surface coverage is equivalent to a few layers of particles. The fact that considerably more O than Cl is found implies that most of the Sn in the stabilizing layer, or Sn adsorbed as species extraneous to the catalyst particle itself, has been converted to oxides or hydroxides in the washing and drying steps. Recent Mössbauer results (7) show that, in fact, essentially all Sn, except that in the Pd-Sn core, is in the form of hydrous stannic oxide at this stage.

Accelerator.—Figures 6 and 7 show the change in Pd and Sn surface concentration observed when catalyzed substrates are treated with the accelerator solution. In all cases, the Sn concentration decreases by a factor of from 3 to 10. For substrates catalyzed in the S solution, there is only a slight decrease in the Pd concentration. For the M solution, however, the Pd concentration also decreases significantly, by a factor of about 3 in Fig. 7 for example. Note that in all cases, the final Pd concentration is about $2\text{-}4(10)^{15}$ cm^{-2}; that is about one monolayer of particles according to the arguments in the preceding subsection. Five to ten minutes in the accelerator are in general sufficient to reduce the Sn concentration to its asymptotic value. After treatment in the accelerator solution, the O/Sn ratio is about 3 and the O/Cl ratio increases to about 6 for both catalysts. In all cases the Pd/Sn ratio rises to roughly 3. It thus appears that the accelerator both removes Sn in the stabilizing sheath and perhaps changes the chemical state of the remaining Sn. If all Sn in the sheath were removed we would expect a Pd/Sn ratio of 6, based on the model (5). As will be seen, one does achieve this ratio during electroless deposition. The purpose of an accelerator solution is thought to be to remove the Sn sheath, or any other Sn species extraneous to the core particle itself, thus exposing the catalytically active core particle. The present accelerator, HBF_4, seems to be only partially successful in achieving this objective on these substrates.

Table I. Colloidal particle size (Å)

Solution	From surface Pd/Sn ratio*	Ultracentrifuge (6)	TEM (7, 15)
S	10-16	10-20	~20
M	13-18	10-20	~20
M + $SnCl_2$	12-16	—	—

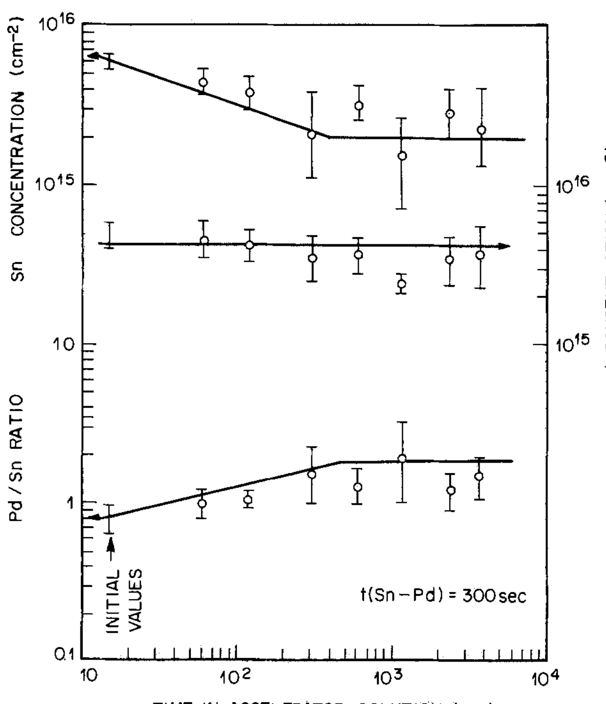

Fig. 6. Pd and Sn surface concentration vs. accelerator time for a S solution catalysis time of 300 sec.

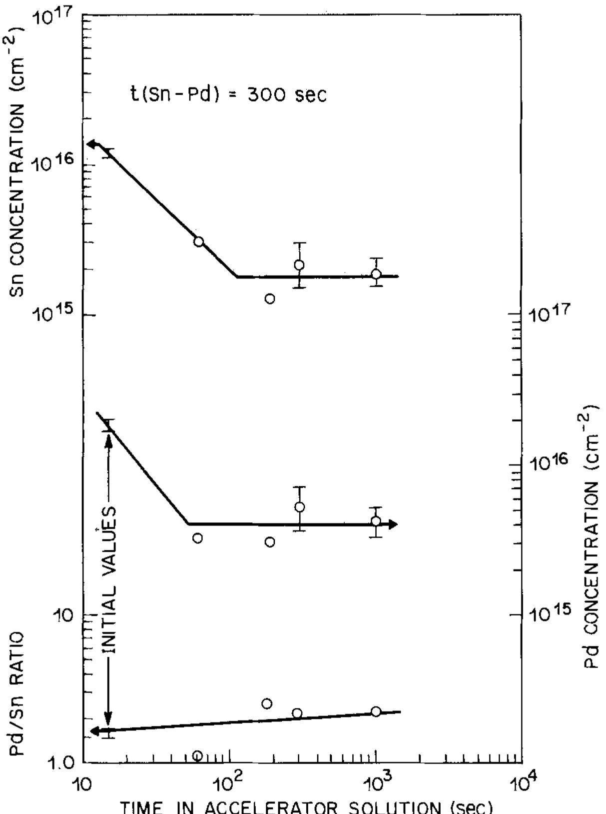

Fig. 7. Pd and Sn surface concentration vs. accelerator time for a M solution catalysis time of 300 sec.

Electroless copper.—Figure 8 shows the high energy portion of the Rutherford scattered ion spectrum from a substrate which had been briefly immersed (30 sec) in the electroless Cu bath after catalysis. This material system (Cu, Pd, Sn) is well suited to study by ion scattering because of the convenient mass (energy) separations between Cu, Pd, and Sn. Not only can the three peaks be easily resolved, but also the peak for scattering from Cu occurs at a lower energy than from

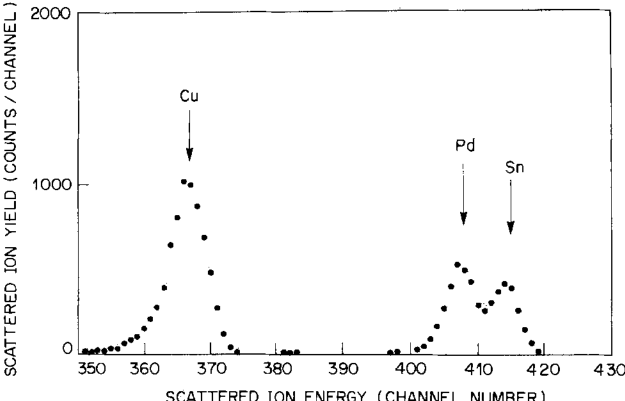

Fig. 8. Scattered ion spectrum from sample for which $t_{catalyst(S)} = 300$ sec, $t_{accelerator} = 60$ sec, and $t_{Cu} = 30$ sec.

Pd or Sn so that the processing can be allowed to proceed to significant Cu thickness (~1000Å) while still allowing observation of the Pd and Sn peaks.

Figures 9 and 10 show copper coverage data (as atoms cm^{-2} or equivalent average thickness) *vs.* time in the electroless Cu bath. The line labeled 2.2 Å/sec is the rate at which this bath plates Cu on Cu as determined by a method which will be described later. It can be seen that the accelerator solution may or may not accelerate the initial metal plating rate. Reducing the catalysis time to 10 sec results in a rather long (~10^3 sec) initiation time for significant plating to begin; *i.e.*, $>10^{15}$ Cu atom cm^{-2}. For surfaces in the S solution for 300 sec (Fig. 9) the Cu coverage for times of 30 sec or less is greatest for intermediate accelerator times. For greater plating times, equivalent thickness >100Å, the data converge to the Cu on Cu line. Microscopic observation indicates complete coverage also occurs at about this stage. For the M catalyst solution, Fig. 10, the largest Cu coverage values for short times

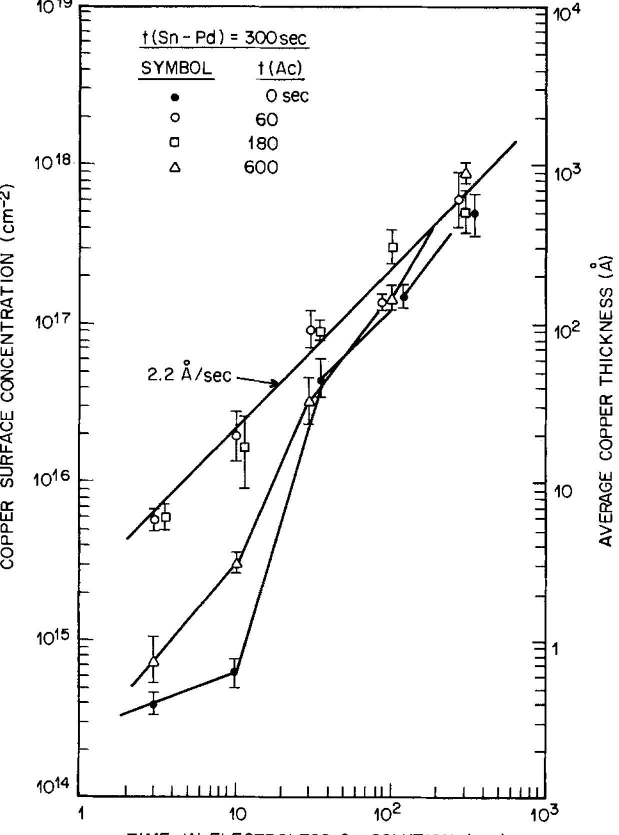

Fig. 9. Copper surface concentration vs. time in electroless Cu solution for a S solution catalysis time of 300 sec and various accelerator solution times.

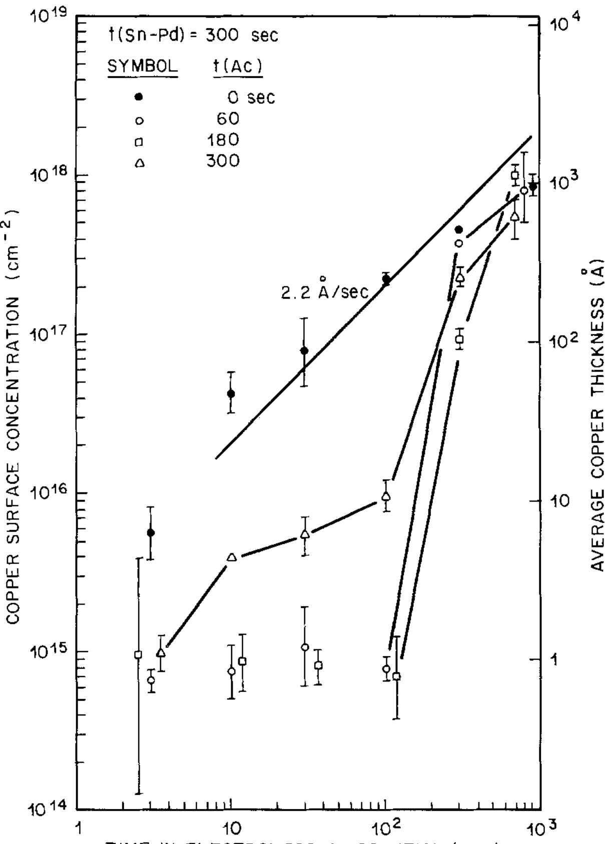

Fig. 10. Copper surface concentration vs. time in electroless Cu solution for a M solution catalysis time of 300 sec and various accelerator solution times.

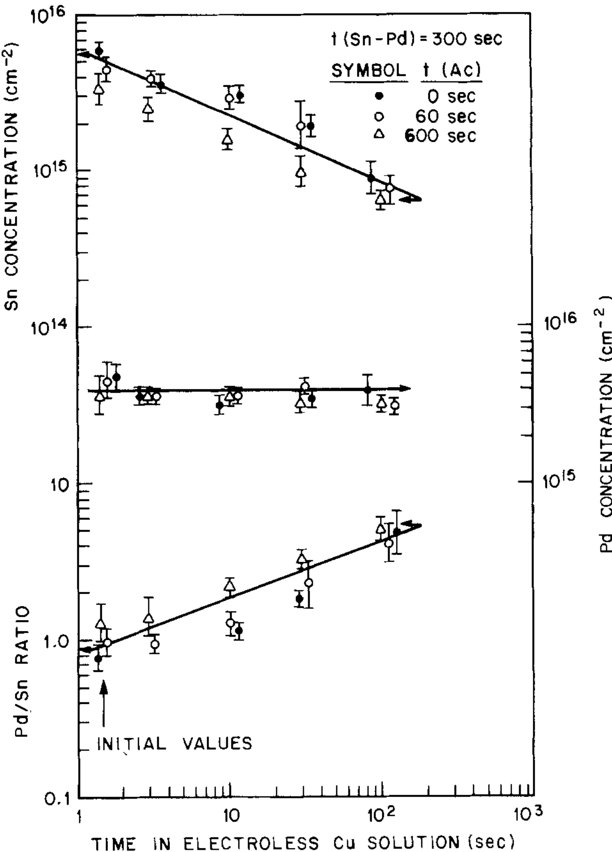

Fig. 11. Pd and Sn surface concentration vs. time in electroless Cu for a S solution catalysis time of 300 sec and various accelerator times.

correspond to no accelerator at all. It will be recalled from the previous discussion that the surfaces catalyzed in the M solution lose Pd in the accelerator step so that the zero accelerator time sample has a considerably greater Pd concentration (~3X) than do the other samples. It can also be noted that there is a considerably greater (100 sec as opposed to 10 sec) initiation time apparent in Fig. 10 than in Fig. 9. This may relate to particle size and distribution differences. In any case, the effects of the accelerator treatment appear rather complex and probably include removal of catalyst particles, partial removal of the stabilizing sheath and other excess deposited Sn, and perhaps chemical changes.

Figures 11 and 12 give the Pd and Sn surface concentrations corresponding to the samples represented in Fig. 9 and 10 for the S and M catalyst solutions, respectively. There is no evidence of significant decrease in Pd concentration, but the Sn concentration does further decrease so that by the time the catalyst particles are covered the Pd/Sn ratio has risen to 6/1; that is, only the core particle remains. The reduction of Sn surface concentration implies that Sn has been lost into the electroless Cu bath; the implication of this result is discussed further below. It was also found that the Cl peak completely disappears after the first stage of Cu plating (3 sec); the O peak cannot be meaningfully interpreted because of surface oxidation of copper.

It can also be noted that the present results are not in accord with the supposition that a well-defined Pd_3Sn compound is the catalytically active species (15). This and other apparent discrepancies with some of the published literature will be discussed in more detail elsewhere (7).

Figure 13 is the scattered ion spectrum for a sample which had been plated to a mean equivalent Cu thickness of ~500Å. The arrows labeled Cu, Pd, and Sn denote the channel numbers (energies) for scattering from Cu, Pd, and Sn at the surface. The Pd peak has been shifted to lower energy, *i.e.*, the Pd lies at the Cu-substrate interface. As discussed above, this shift

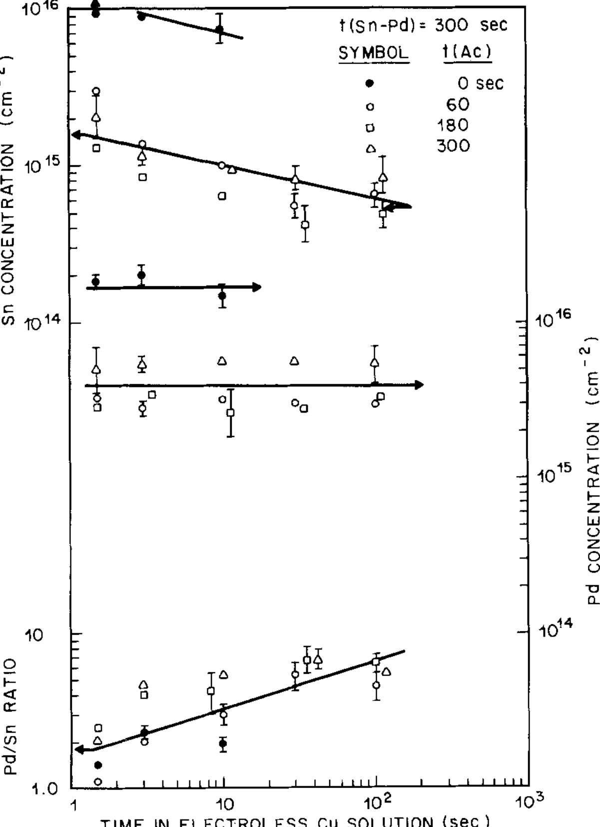

Fig. 12. Pd and Sn surface concentration vs. time in electroless Cu for a M solution catalysis time of 300 sec and various accelerator times.

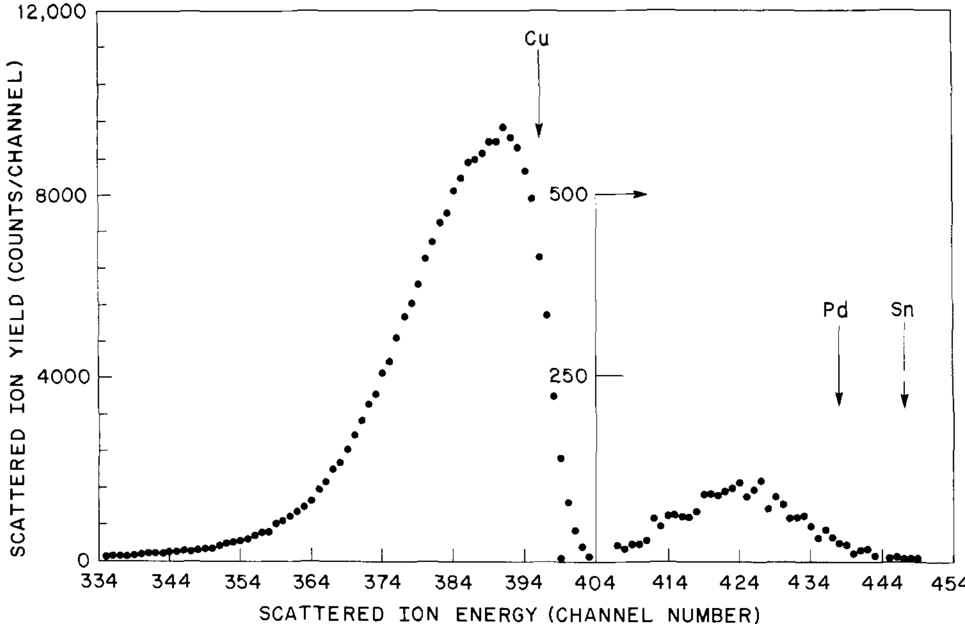

Fig. 13. Scattered ion spectrum for a sample for which $t_{catalyst(S)}$ = 300 sec, $t_{accelerator}$ = 60 sec, t_{Cu} = 300 sec.

is due to the loss in energy as the ion penetrates into and exits from the overlying Cu layer. The broadening of the Pd peak and the low energy edge of the Cu peak is due to nonuniformity of the Cu film over the area examined by the beam. This nonuniformity is estimated to be 25-50% of the mean Cu thickness in the range from a few hundred to a few thousand angstroms. (Slit-scattering and straggling also contribute to this broadening but are not of significance here.) In this particular spectrum, definition of the Sn peak has been lost in the broadened Pd peak. The shift in the Pd peak with increasing Cu thickness may be used to monitor the plating rate for Cu on Cu. That is, the Pd is used as an interface marker. It is in this way that the line labeled 2.2 Å/sec on the previous figures was determined. For longer times, the plating rate can be determined by weight-gain methods, with the same result.

In the experiments discussed thus far, care was taken to use fresh solutions. Figure 14 shows the result observed when a sample was plated for 100 sec in a bath which had been used to process about ~10 previous samples. Although the Pd peak is shifted down a few channels, that is, it is at the interface, a sharply defined Sn peak is apparent at the surface; *i.e.*, on top of the Cu. Figure 15 shows the result when the Cu bath is allowed to become even further contaminated with Sn. Here the mean Cu thickness is about 1000Å and approximately 5% Sn has been codeposited with the Cu. The Sn contamination at this stage is estimated to be ~10 ppma. Further study of the effects of metallic impurities is now underway. It may be of interest to note that it has been found that Pb was also codeposited when an electroless copper bath was inadvertently contaminated with Pb.

Other substrates.—The experimental observations obtained when the S solution was used to catalyze a variety of substrates appropriate to printed circuit board fabrication are similar to those obtained using graphite substrates. Surface roughness measurements on the substrates indicated that the data are in reasonable quantitative agreement with the graphite substrate data when this factor is taken into consideration. However, important effects on surface coverage *vs.* time, for example, cannot be ruled out if the substrate is charged or perhaps otherwise chemically active.

Catalyst aging and contamination.—Cohen and West have shown that the presence of enough divalent Sn to form a stabilizing sheath around the core particle is necessary and sufficient for the solution to be stable with respect to oxidative coagulation (5, 6). Oxidation due to atmospheric aging and the presence of transition metal ions has been examined.

For the aging experiments, the S and M solutions were prepared and kept in sealed polyethylene containers. This serves to cut down evaporation losses, but the containers are rather permeable to oxygen. Periodically, samples of the solutions were withdrawn and their catalytic behavior was examined. The life, defined as the time when the colloid coagulates and precipitates out of solution, was determined to be 12 ± 1 week for the S solution and 8 ± 1 week for the M

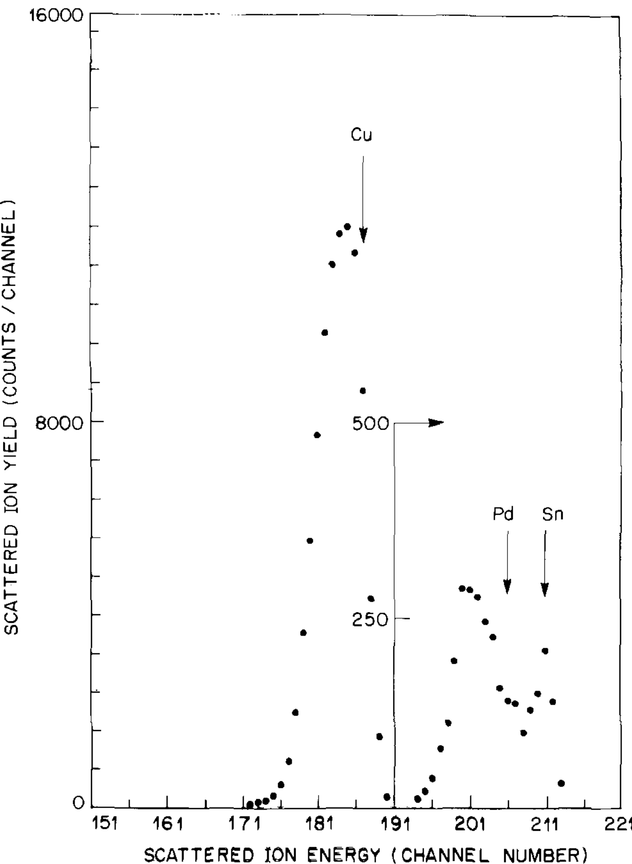

Fig. 14. Scattered ion spectrum from a sample for which $t_{catalyst(S)}$ = 300 sec, $t_{accelerator}$ = 180 sec, t_{Cu} = 100 sec. Electroless copper solution had been used to process ~10 previous samples.

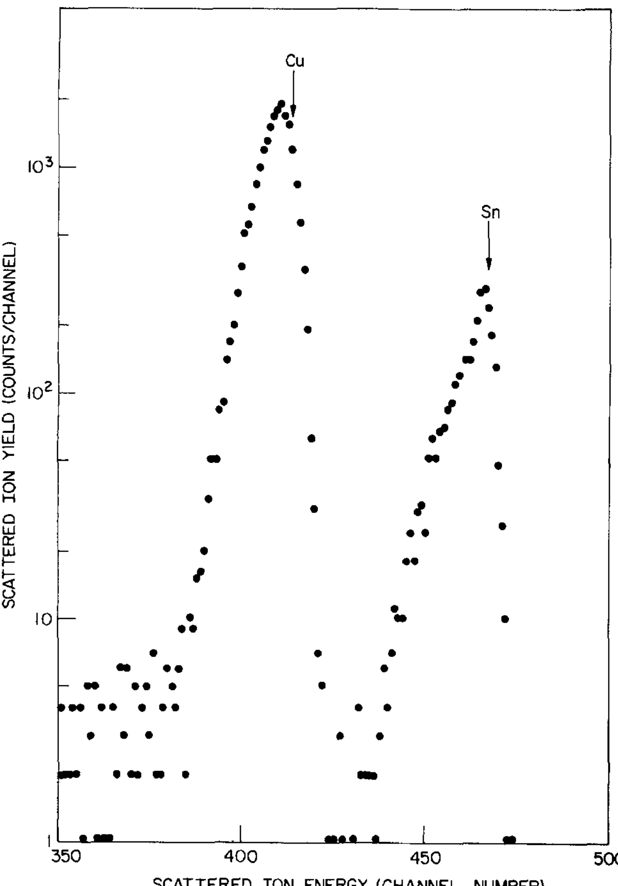

Fig. 15. Scattered ion spectrum from a sample for which $t_{catalyst(S)}$ = 300 sec, $t_{accelerator}$ = 180 sec, t_{Cu} = 300 sec. Electroless Cu solution had been used to process ~50 previous samples. Shows ~5% Sn codeposited with Cu.

solution. This result is in accord with the larger divalent Sn content of the S solution. The catalytic activity, in terms of amount of Pd and Sn adsorbed and in terms of the plating behavior, was unchanged at least up to 90% of the life of the solutions. Thus it is concluded that degradation of the solution does not occur progressively, but rather suddenly when nearly all the Sn^{+2} is oxidized to Sn^{+4}. It should also be noted that in production environments these solutions can remain stable for many months when suitable replenishment schemes are used to maintain concentrations near nominal values.

The effect of addition of Cr ions in the +3 and +6 valence states has also been studied. When Cr is added as the dichromate ion, the S and M solutions will tolerate 800 and 300 ppma Cr, respectively.

The reaction

$$Cr_2O_7^{=} + 3Sn^{+2} + 14H^+ \rightleftharpoons 2Cr^{+3} + 3Sn^{+4} + 7H_2O$$

has a large negative free energy change (16), and $3Sn^{+2}$ ions are oxidized for every $Cr_2O_7^{=}$ ion added. The S solution, *e.g.*, contains 0.14 mole $Sn^{+2}l^{-1}$ so that one would expect to need 0.05 mole $Cr_2O_7^{=}l^{-1}$ to coagulate the solution. The experimental value is 0.07 mole $Cr_2O_7^{=}l^{-1}$.

In the case of trivalent Cr ions, the reaction

$$2Cr^{+3} + Sn^{+2} \rightleftharpoons 2Cr^{+2} + Sn^{+4}$$

has a positive free energy change (16) so the reaction does not proceed as written to any great extent. Experimentally it is found that at least 10^4 ppma Cr^{+3} can be added without adverse effect.

Also, it is found that when the $Cr_2O_7^{=}$ added is less than that necessary to cause oxidative coagulation, no significant changes in catalytic activity are noted. Any adsorbed Cr on the sample surfaces is less than the detection limit (< 10^{14} Cr cm^{-2}) for 400 ppma Cr^{+6} added or 2000 ppma Cr^{+3} added.

Conclusions

Rutherford scattering has been used to quantitatively measure adsorption from Pd, Sn colloid catalyst systems, and the behavior of the adsorbed material during subsequent steps in the electroless deposition sequence. The present findings are in general agreement with the colloidal model of Cohen and West (5, 6) insofar as it is possible to interpret the results on that basis. The early stages of catalyst adsorption appear to be diffusion controlled and obey at $t^{1/2}$ dependency. The particle sizes deduced (10-20Å) are in agreement with other work and it appears that a few monolayers of particles lead to saturation.

The effect of the accelerator solution appears to be rather complex. Although it does partially remove the excess Sn, its use may or may not accelerate the initial plating rate. The Pd surface concentration found after the accelerator treatment is in the range $2\text{-}4(10)^{15}$ Pd atoms cm^{-2} regardless of the solution used for catalysis times greater than 30 sec, so that there is little point in using solution concentrations or treatment times which give significantly greater Pd surface coverage after the catalysis step. Accelerator times of 10 min are sufficient to remove all Sn which can be removed in HBF_4. The primary virtue of the accelerator treatment appears to be to reduce subsequent contamination of the electroless copper bath with Sn.

The early stages of electroless copper plating have also been studied. In this process, the remaining excess Sn is removed and the copper plates over the core particle in which the Pd/Sn ratio is approximately 6. Tin lost into the bath may be subsequently codeposited into the Cu layer on succeeding samples.

Catalyst aging and contamination (with Cr^{+3} and Cr^{+6}) indicate that oxidative coagulation is precipitous rather than progressive in nature.

Acknowledgments

Hydrodynamic Studies of Bubble Effects on the *IR*-Drops in a Vertical Rectangular Cell

F. Hine,* M. Yasuda, R. Nakamura, and T. Noda

Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466, Japan

ABSTRACT

The bubble effects on the resistivity of solution under various conditions of electrolysis was examined with a rectangular cell, in which hydrogen evolution took place from a stainless steel cathode in dilute caustic soda solution. The resistivity of electrolyte containing hydrogen bubbles was a function of the current density, the operating temperature, the flow rate of solution, and the geometry of channel. An experimental equation was obtained.

Bubble effects on the terminal voltage of electrolyzer are important, especially at high current densities. Increase in the resistivity of electrolyte due to suspensions of nonconducting particles has been studied by La Rue and Tobias (1), and Tobias has also described a theoretical treatment of the effect of gas on the current distribution in a vertical cell (2). Hine *et al.* studied the *IR*-drops in the chlor-alkali cells, and discussed preferable geometry and arrangement of the graphite anode for the horizontal cell (3-7).

Gardiner stated that the apparent resistivity of the brine between the graphite anode and the amalgam cathode of the Olin E-11 cell was practically free of chlorine bubbles when the anode-to-cathode gap was more than 0.13 in., whereas the resistivity of brine was affected by bubbles if the gap was narrow (8). MacMullin pointed out that the vertical-type diaphragm cell such as the Hooker cell is a "good pump," because gas lift near the anode enhances circulation of the brine and it causes significant reduction of the *IR*-drop between two electrodes (9, 10). The cell voltage of the amalgam-type chlorine cells operated at high flow rate of mercury cathode is relatively low even at high current densities, because chlorine bubbles under the graphite anodes are removed quickly (11, 12).

Electrolytic cells with gas evolution are important not only with respect to chlor-alkali cells but some others such as the water electrolyzer. The *IR*-drop due to involvement of bubbles in the brine is a major factor of high voltage in chlor-alkali cells. The water electrolyzer stores a certain amount of electrolytic solution, but, in some cases, the cell is operated with forced flow of solution along the electrode. The *IR*-drop depends on the flow rate in the latter case (13-16). Agitation of solution with bubbles enhances the mass- and heat-transfer in the cell (17-24).

Experimental Procedure

Electrolysis of dilute NaOH solution with a rectangular cell under flow conditions has been carried out, and the effects of hydrogen bubbles on the *IR*-drop have been investigated.

A rectangular cell, made of Lucite resin, 240 mm long and 10 mm wide is shown in Fig. 1. The anode-to-cathode gap can be changed with spacers 2, 3, 5, and 7 mm thick.

The working cathode of AISI 304 stainless steel is 10 mm wide and 16 mm long and is placed at the center of the cathode compartment. At both sides 2 mm from the working cathode, the auxiliary cathodes (10 mm wide and 40 mm long) are arranged so as to yield uniform current distribution on the test electrode.

The anode screen, also Type 304 SS, is covered by a PVC fabric diaphragm and is parallel to the cathode.

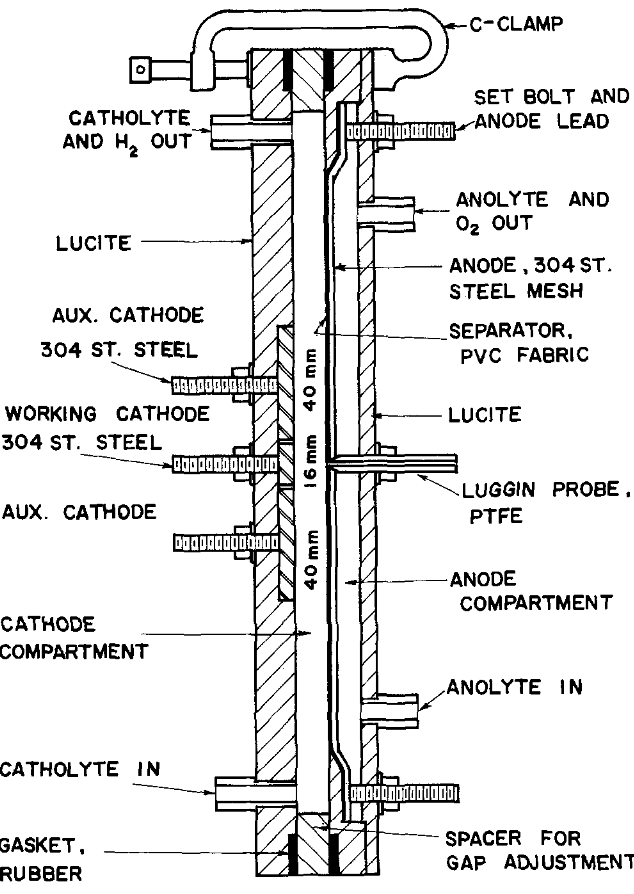

Fig. 1. Experimental cell in vertical position

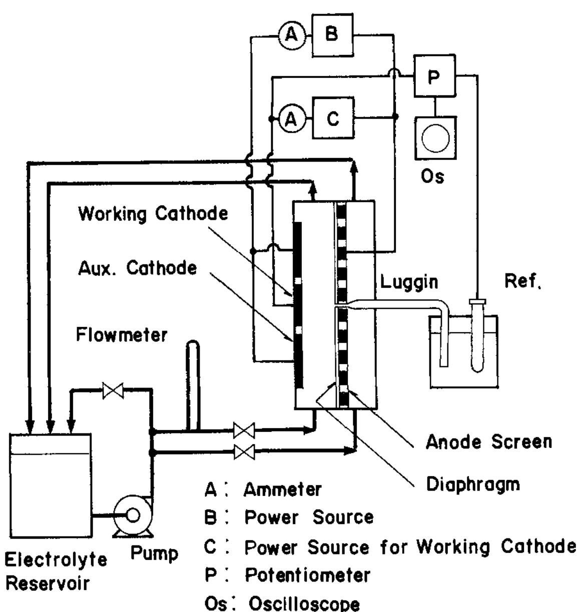

Fig. 2. Flowsheet of system

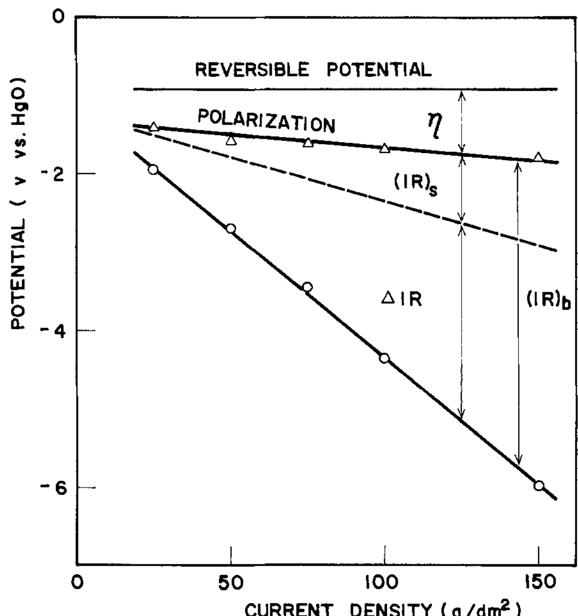

Fig. 3. Potential *vs.* current density curves. l = 2 mm, t = 30°C, u = 10 cm/sec.

A Luggin probe made of PTFE resin is screwed and pressed to the back side of a diaphragm from the anode compartment, and is connected to a reference electrode consisting of Hg/HgO/1.75*N* NaOH. The *IR*-drop between the Luggin and the working cathode is determined by means of the current interruption technique. The auxiliary electrodes are polarized at an equal current density with the working cathode by a separate d-c power source.

The flowsheet of the system is shown in Fig. 2. The electrolytic cell is placed vertically. Caustic soda solution (1.75*N* NaOH) is pumped up from the thermostated reservoir to the cell bottom and flows through the channel under controlled rate. The solution returns to the reservoir of about 50 liters in volume, where hydrogen and oxygen are purged. Properties of a 1.75*N* NaOH solution employed are shown in Table I.

Results and Discussion

An example of the voltage balance between the working cathode and the Luggin probe is shown in Fig. 3. The hydrogen overvoltage is relatively small compared to the *IR*-drops in the solution containing bubbles, $(IR)_b$. The broken line shows the estimated *IR*-drop in the solution free of bubble, $(IR)_s$, which is also small in comparison to $(IR)_b$. The ratio of $(IR)_b$ to $(IR)_s$ is proportional to the normalized resistivity, ρ/ρ_0, where ρ and ρ_0 are the conductivity of solutions with and without bubbles, respectively.

Figure 4 shows the *IR*-drop *vs.* flow rate at given current densities. The thin lines show the estimated $(IR)_s$. The voltage reduces with the increase of flow rate, especially at high current densities, and tends to the corresponding $(IR)_s$. At low flow rate, less than 10 cm/sec, the *IR*-drop fluctuated and bubbles were swept out intermittently from the electrode due to natural convection. The *IR*-drop was not linear to the current density in the solution containing bubbles. It was also a function of the temperature. The *IR*-drop was low due to increase in the conductivity and to decrease of the viscosity at high temperature ranges.

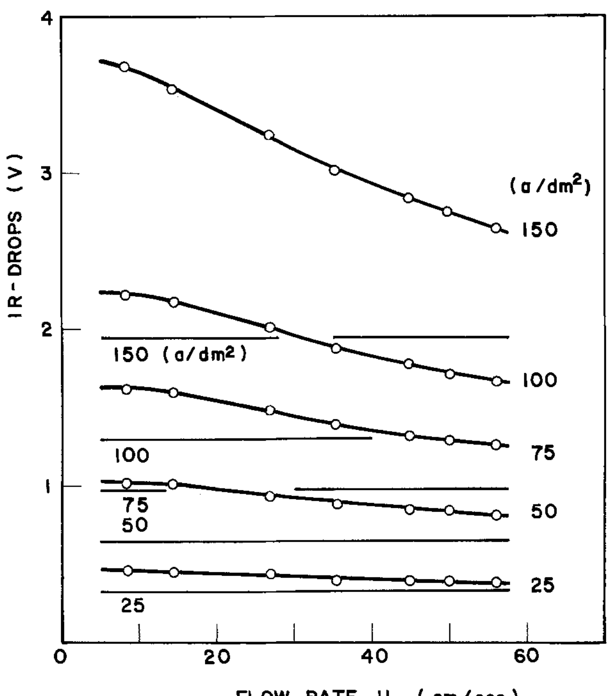

Fig. 4. *IR*-drop *vs.* flow rate curves. l = 5 mm, t = 50°C

The *IR*-drop *vs.* cathode-to-diaphragm gap showed the S-shaped curve (Fig. 5). The thin lines show $(IR)_s$ as reference. In the wide channel, such as a 10 mm gap, the *IR*-drop is close to $(IR)_s$, whereas it becomes large in the narrow channel. There is a maximum of ρ/ρ_0 at about 2-3 mm in gap.

The normalized resistivity is a function of the ratio of gas flow to liquid flow, V_g/V_l, the ratio of gap width

Table I. Properties of a 1.75*N* NaOH solution

	Temperature, °C						Reference

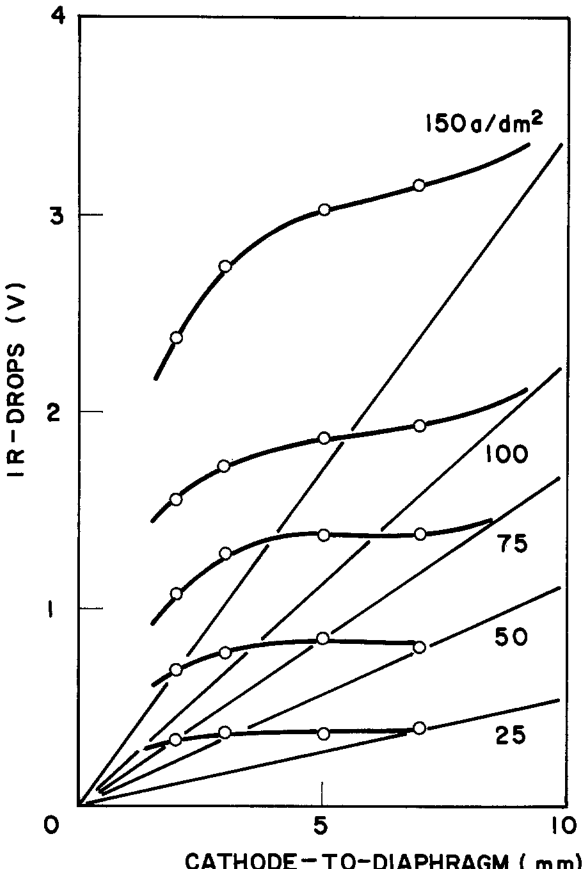

Fig. 5. *IR*-drop *vs.* distance curves. $t = 60°C$, $u = 20$ cm/sec

to electrode width, l/L, and the Reynolds number, Re, as follows (25)

$$\frac{\rho}{\rho_0} = K \left(\frac{V_g}{V_l}\right)^{\alpha} \left(\frac{l}{L}\right)^{\beta} (\mathrm{Re})^{\gamma} \quad [1]$$

where Re is assumed to be

$$\mathrm{Re} = \frac{D_{eq} u d}{\mu} \quad [2]$$

Equivalent diameter, D_{eq}

$$= \frac{4 \times \text{(Sectional area of channel)}}{\text{Total length of wall of section}}$$

$$= \frac{4Ll}{2(L+l)} = \frac{2l}{1+l} \quad (\because L = 1 \text{ cm}) \quad [3]$$

where K, α, β, and γ are the coefficients. The area of gap is lL cm², and the approach velocity of liquid is u cm/sec. The flow of liquid is, therefore, $V_l = lLu$. On the other hand, the volume rate of gas, V_g in cm³/sec, is represented as follows

$$V_g = \left(\frac{i}{2F}\right)\left(\frac{RT}{p_{H_2}}\right) LH \quad [4]$$

where LH is the total cathode area in cm². The hydrogen partial pressure, p_{H_2} in atm, is as follows

$$p_{H_2} = 1 - p_{H_2O} \quad [5]$$

where p_{H_2O} is the water vapor pressure on NaOH solution (see Table I).

Figure 6 shows the logarithmic plots of ρ/ρ_0 *vs.* Re under given conditions of l/L and the temperature. It is somewhat complicated that V_g/V_l varies with the solution flow, also the kinematic viscosity, μ/d, would change with the void fraction, ϵ. It is impossible to change those two factors separately. The higher the temperature in a narrow channel the larger is the ρ/ρ_0.

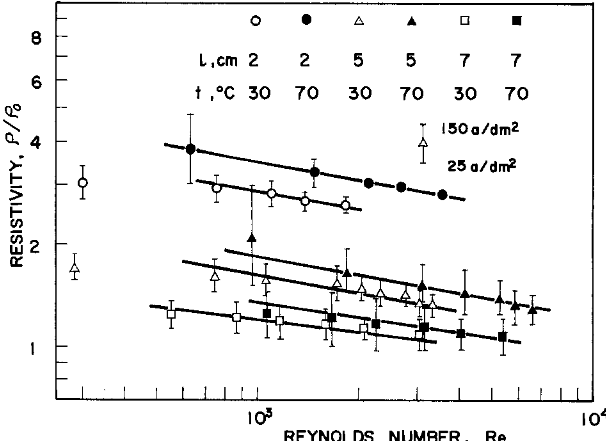

Fig. 6. Resistivity *vs.* Reynolds number. Average slope, $\gamma = -0.18$.

At high current densities, the ρ/ρ_0 becomes large. The plots in this figure are the average values of the data shown by the bar under given conditions. The slope of the curve is small: $\gamma = -0.18$, and is almost independent of the gap width and the temperature.

The (ρ/ρ_0) *vs.* (l/L) is shown in Fig. 7, where the slope, β, is -0.65. The (ρ/ρ_0) *vs.* (V_g/V_l) is shown in Fig. 8. The Re is not specified in this figure, because the V_g/V_l contains some influences of Re as stated above. The slope α is 0.12 and is almost independent of l.

With use of those coefficients, Eq. [1] has been applied for all the data, but we have found some deviations. On the other hand, Fig. 9 is a trial of the plots of Eq. [6], where (V_g/V_l) involves the influence of Re. This equation fits the data quite well rather than Eq. [1]

$$\frac{\rho}{\rho_0} = K_1 \left(\frac{V_g}{V_l}\right)^{\alpha} \left(\frac{l}{L}\right)^{\beta} \quad [6]$$

where K_1 is a coefficient.

The void fraction due to holdup of bubbles is as follows

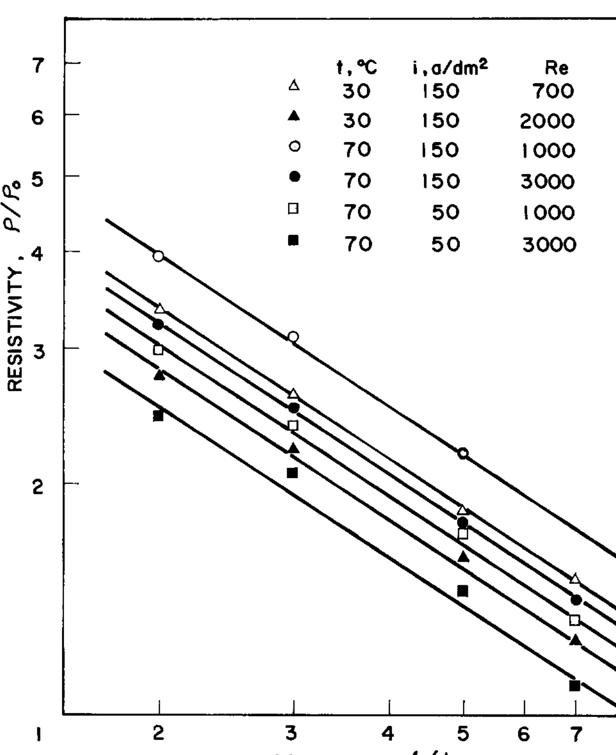

Fig. 7. Resistivity *vs.* gap width. Average slope, $\beta = -0.65$

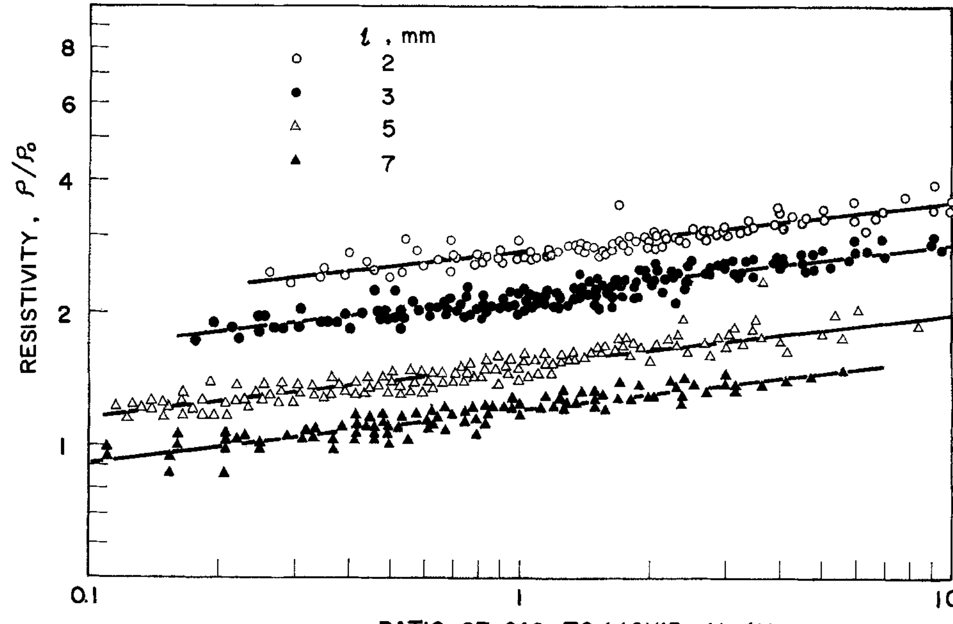

Fig. 8. Resistivity vs. ratio of gas flow to liquid flow. Average slope, $\alpha = 0.12$.

$$\text{Void fraction} = \frac{\text{Bubble volume}}{\text{Solution + bubbles}} \quad [7]$$

The bubbles generated at the upper stream of the channel may disturb the working cathode, and the flow of gas halfway up is $V_g/2$. Therefore

$$\epsilon = \frac{V_g/2}{V_g/2 + V_l} = \frac{V_g/V_l}{V_g/V_l + 2} \quad [8]$$

Substituting this into Eq. [6], we have

$$\frac{\rho}{\rho_0} = K_1 \left(\frac{2\epsilon}{1-\epsilon}\right)^{\alpha} \left(\frac{l}{L}\right)^{\beta} \quad [9]$$

La Rue and Tobias have shown an equation (1)

$$\frac{\rho}{\rho_0} = (1-\epsilon)^{-3/2} \quad [10]$$

This equation differs from Eq. [9], probably due to conditions of the brine flow. Equation [10] was obtained with the assumption of uniform distribution of bubbles in the anode-to-cathode gap. Under flow conditions, on the other hand, a major part of bubbles is crowded in the vicinity of the electrode surface, and the solution flows away in the center of channel. Figure 10 shows simple models of the distribution of bubbles across the gap. With Eq. [10], the (ρ/ρ_0) is represented as follows (25)

$$\frac{\rho}{\rho_0} = \left(1 - \frac{\epsilon}{\lambda}\right)^{-3/2} \lambda + (1-\lambda) \quad [11]$$

and

$$\frac{\rho}{\rho_0} = \frac{(1-2\epsilon)^{-1/2} - 1}{\epsilon} \quad [12]$$

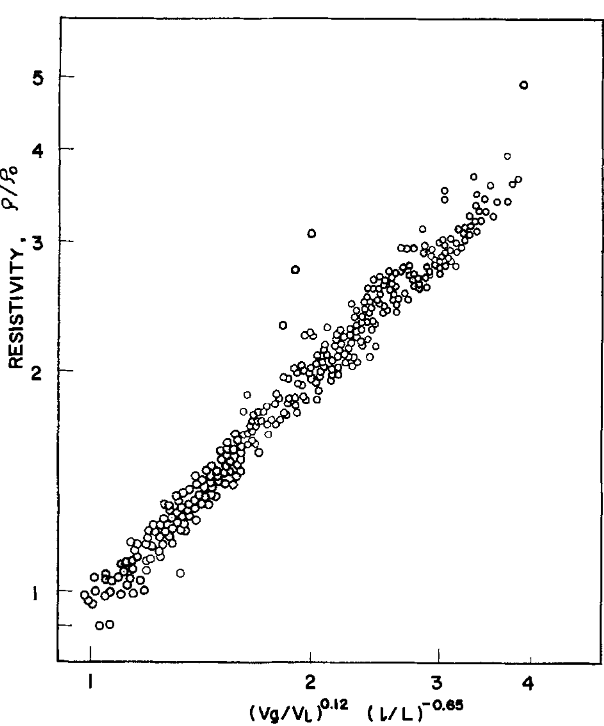

Fig. 9. Resistivity represented by Eq. [6]. $K_1 = 1.03$

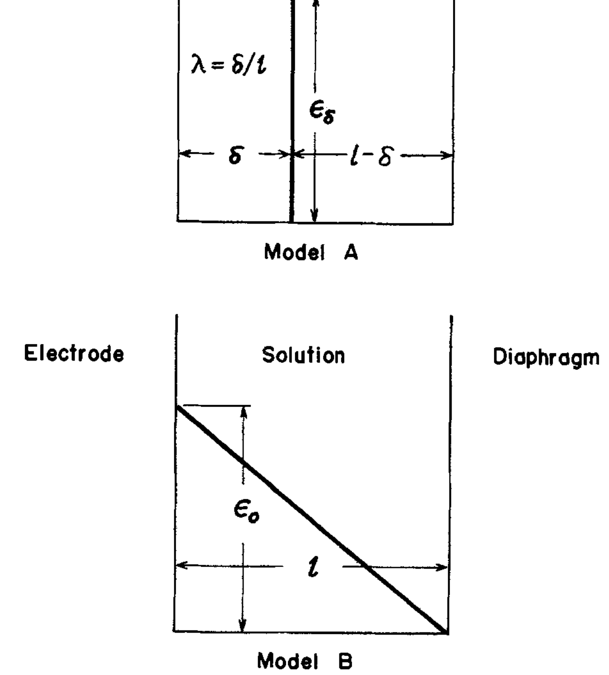

Fig. 10. Two models of the distribution of bubbles across the gap. ϵ_δ, void fraction of crowded zone, δ. ϵ_0, void fraction at electrode surface.

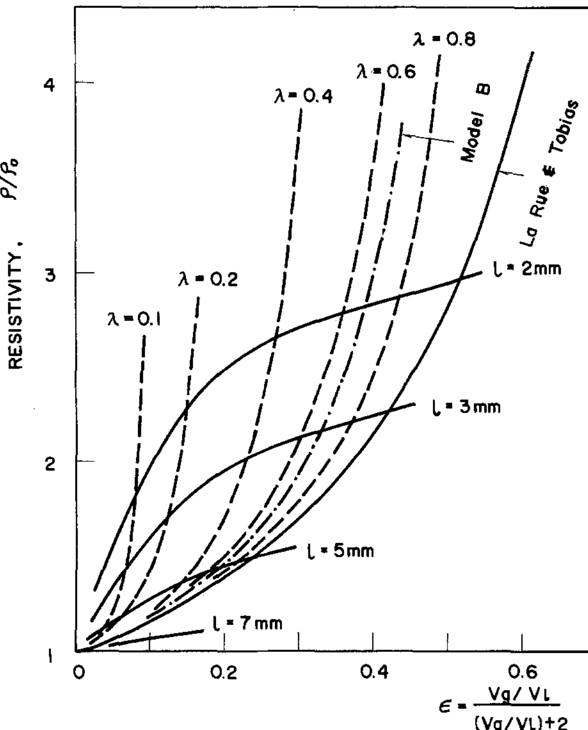

Fig. 11. Resistivity vs. void fraction. MacMullin equation,

$$\rho/\rho_0 = \left(1 - \frac{\epsilon}{\lambda}\right)^{-3/2} \lambda + (1 - \lambda)$$

for models A and B, respectively, where $\lambda = \delta/l$, and δ is a crowded zone in model A. Those curves are still concave as shown in Fig. 11, and differ from the experimental data labeled l.

It is assured that a part of the electrode surface is covered with the "fixed layer" of gas bubbles, which depends on the operating conditions such as current density and temperature. The actual current density at the working surface of electrode thus increases, and the IR-drop near the electrode surface and the overvoltage become large compared to the predicted values in the case of uniform distribution across the gap. Those phenomena would be significant in the narrow channel.

The "fixed gas layer" would differ somewhat from the models shown in Fig. 10. Suppose the gas is fixed into a layer, δ_1 cm, at the electrode surface, and the solution in the remaining layer, $(1 - \delta_1)$, contains gas dispersion. The ρ/ρ_0 is shown by the equation

$$\rho = \rho_f\left(\frac{\delta_1}{l}\right) + \rho_l\left(1 - \frac{\delta_1}{l}\right)$$

or

$$\frac{\rho}{\rho_0} = \frac{\rho_l}{\rho_0} + \left(\frac{\rho_f + \rho_l}{\rho_0}\right)\left(\frac{\delta_1}{l}\right) \qquad [13]$$

where ρ_f and ρ_l are the resistivity of the fixed layer and of the remaining layer, respectively. The second term of the right-hand side is large enough compared to the first term in the narrow channel, and hence, the ρ/ρ_0 is dependent largely on the gap width. In a wide channel, on the other hand, the second term diminishes. The ρ becomes small and uniform. The IR-drop across the wide gap can be represented by $i\rho_l l \cong i\rho_0 l$. It would be a major reason of why the plots in Fig. 11 appear below the curve by La Rue and Tobias at large l and ϵ.

Experiments described above were carried out with the rectangular channel under controlled flow conditions. The electrode surface is covered by fine bubbles, and hence, the overvoltage increases significantly. The resistivity of the solution near the electrode is very large due to dispersion of fine bubbles. The resistivity of the solution containing bubbles depends largely on the geometry of the channel and the bubble size as well as the void fraction. It is evident from Eq. [13] that the tighter the spacing of the channel the larger is the resistivity, especially in the narrow channel, which is important from the viewpoint of practical electrolysis.

In conclusion, the bubble effects on the terminal voltage depend on a variety of operating conditions and the cell geometry. The apparent resistivity of the solution containing bubbles is a function of those factors as well as the void fraction. Differences between our experimental data and the theory by La Rue and Tobias have not been clarified.

A New Approach to the Analysis of Chemiluminescence Transients from Step Experiments

Larry R. Faulkner*

Department of Chemistry, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A study has been made of problems associated with extracting fundamental parameters from chemiluminescence decay curves generated by electrochemical step experiments. Emphasis is placed on the use of data obtained early in the transient, and a new approach based on curve fitting is advanced. A general ST mechanism provides the fitting function, and the Marquardt algorithm plays the key role in implementing the fit. However, a perimeter search routine has been developed to remove the unreliability that the Marquardt algorithm displays with noisy decay curves. The effectiveness of the entire procedure has been tested on sets of noisy transients, and fitting precision is reported as a function of the size and time domain of the data base, the noise level, and the percentage of S emission in the over-all luminescence. The effects of error in the calibration of absolute luminescence measurements are also discussed.

Studying light emission in single pulses from electrochemical step experiments has been an important aid in understanding chemiluminescent electron transfer processes. These experiments involve a planar working electrode which is held initially at rest in a solution of the electrochemical precursors to the reactants that will ultimately yield luminescence. To begin, the potential is stepped to the mass-transfer-limited region for creation of the first reactant. For example, the cation radical of rubrene might be generated from the parent hydrocarbon in a benzonitrile solution. The width, t_f, of this forward step might range from 10 sec to 10 μsec. It is terminated by switching the potential to a value in the mass-transfer-limited region for creation of the second reactant (*e.g.*, the rubrene anion radical). Thus, the two reactants diffuse together near the electrode and yield luminescence, which appears as a pulse that decays by a nonexponential form. Often this reverse step has a width equal to t_f, and it is nearly always ended by a return to the original rest potential.

Feldberg was early in pointing out the diagnostic utility of the luminescence transient (1, 2). He presented treatments of S- and T-route cases (see below), and showed that one should usually obtain a linear plot of the form

$$\log \omega_i = a_i + b_i(t_r/t_f)^{1/2} \quad (t_r/t_f \geq 0.2) \qquad [1]$$

where ω_i is proportional to intensity and t_r is time measured into the second step from its start. The slope, b_i, of this "Feldberg plot" was shown to be sensitive to the type of light producing mechanism (2). A number of experimental studies have pursued these ideas (3-7).

Later Cruser and Bard adopted the Feldberg format for their study of the effects of reactant instability on the shapes of light decay curves. Their publications include both theoretical analysis and experimental results (8, 9).

More recently, Bezman and Faulkner added some refinements to Feldberg's reaction schemes, and they showed that certain aggregates of rate and efficiency parameters could be evaluated from a_i and b_i, if absolute luminescence measurements were available (10, 11). They later constructed a suitable apparatus and reported data for several systems (11-13).

Analyzing experimental results by linearizing the light transient has been very convenient, especially for the limited amounts of information one can obtain by oscilloscopic recording. Even so, the procedure carries several important drawbacks:

(*i*) Only data for $t_r/t_f \geq 0.2$ are examined. For still earlier times, the decay is rapid, hence the intensities that are actually studied are low compared to those that can be recorded, and they have relatively poor signal-to-noise ratios.

(*ii*) Obviously a linearized curve can yield only two parameters; hence, studies that are restricted to the later time domain cannot deal with ST systems, which require at least three parameters for description (see below).

(*iii*) Eliminating the short-time intensities, which decay in a more complex fashion than the later ones,

* Electrochemical Society Active Member.

Key words: chemiluminescence, electrogenerated chemiluminescence, curve fitting, Feldberg treatment.

reduces the opportunity for critical comparisons with theory, even with S- and T-route systems, for which the linear approach is, in principle, valid.

(*iv*) The parameters a_i and b_i are synthetic intermediates with no fundamental meaning of their own. They must be related to mechanistic variables in an imperfect manner via working curves.

(*v*) The need for linearity in the transformed decay curve limits the generality of the interpretive procedure. Complications introduced into the mechanisms for light generation often yield intensities that cannot be linearized in the usual format, hence quantitative comparisons with theory become difficult.

All of these problems are remedied by the new approach to transient analysis that is described below. Virtually the entire decay curve is used, without logarithmic transformation, in a curve fitting algorithm that can accept a general fitting function. The function used for this work describes light emitted from an ST system in a manner much like the one advanced by Feldberg (2). Sets of noisy synthetic decay curves have been used to assess the performance of the algorithm, and it is shown below that this procedure is a realistic approach to the evaluation problem.

A Generalized ST Mechanism

Prior knowledge of the functional form of any kinetic transient is a prerequisite for evaluating fundamental parameters from it, hence a presumed fitting function must be derived from a postulated mechanism. The analysis below is based on the following scheme

$$R^+ + R^- \xrightarrow{\phi_s} {}^1R^* + R \qquad [a]$$

$$R^+ + R^- \xrightarrow{\phi_t} {}^3R^* + R \qquad [b]$$

$$R^+ + R^- \longrightarrow 2R \qquad [c]$$

$${}^3R^* + {}^3R^* \xrightarrow{k_s} {}^1R^* + R \qquad [d]$$

$${}^3R^* + {}^3R^* \xrightarrow{k_t} {}^3R^* + R \qquad [e]$$

$${}^3R^* + {}^3R^* \xrightarrow{k_g} 2R \qquad [f]$$

$${}^3R^* \ (+Q) \xrightarrow{1/\tau} R \qquad [g]$$

$${}^1R^* \ (+Q) \longrightarrow R \qquad [h]$$

$${}^1R^* \xrightarrow{\phi_f} R + h\nu \qquad [i]$$

The notation here duplicates that used previously (10). In general, ϕ's, τ's, and k's represent branching efficiencies, lifetimes, and rate constants according to usual practice. Note, however, that τ is the triplet lifetime in the absence of triplet-triplet annihilation and that $k_a = k_s + k_t + k_g$. This mechanism represents the generation of light via two parallel paths: The emitting singlets ${}^1R^*$ may be produced directly in electron transfer (the S route, reactions [a] and [i]) or indirectly through triplet intermediates (T route, reactions [b], [d], [e], [f], and [i]).

Feldberg's treatment of this scheme involves the presumption that events [a]-[i] take place in a reaction zone to which the ion radicals are fed by diffusion (2, 10). The over-all redox reaction rate, N (moles/sec), is then fixed by the diffusion process. The linkage between light emission and the redox rate is expressed (10) by

$$\omega_i = \beta - (\beta^2 + \alpha\beta\omega_n)^{1/2} + 0.5\alpha\omega_n + \gamma\omega_n \qquad [2]$$

where ω_i and ω_n are dimensionless variables proportional to light intensity and redox reaction rate, respectively. They are defined explicitly in the symbols list. The first three terms describe light emission from the T route via two aggregate parameters $\alpha = \phi_f\phi_{tt}\phi_t/(1 - g)$ and $\beta = \phi_f\phi_{tt}ft_f/8k_a(1 - g)^2\tau^2C$. Here $\phi_{tt} = k_s/k_a$, $g = k_t/2k_a$, f is a dimensionless reaction zone thickness [in units of $(Dt_f)^{1/2}$], and C is the bulk concentration of the substrate from which $R^{\dot{+}}$ and $R^{\dot{-}}$ are generated. S route emission is registered in the fourth term, where $\gamma = \phi_s\phi_f$. The efficiency parameters α and γ are potentially useful because they contain the excitation yields, but β is of little value (10).

In general the redox rate function ω_n is obtained from a digital simulation of the experiment (1, 10), and it can be used directly as the numerical array. For this study, however, it was obtained in an analytical form by linearizing it to determine the longest-lived exponential, subtracting that term from each numeric ω_n, then repeating the process twice more with the residues from the preceding subtraction steps. Figure 1 displays about 10% of the information used in the third (and most uncertain) stage of this process for ω_n data based on an infinite redox rate constant. The result

$$\omega_n = 4.70 \exp[-3.272(t_r/t_f)^{1/2}] + 11.4 \exp[-11.35(t_r/t_f)^{1/2}] + 34.9 \exp[-34.6(t_r/t_f)^{1/2}] \qquad [3]$$

closely approximates the numeric form for $t_r/t_f \geq 0.005$. The three terms were obtained from simulations involving 2,500, 10,000, and 100,000 iterations/step, respectively.[1] At shorter times, additional exponential terms contribute, but they are of no consequence to this work. The first term is better recognized in Feldberg's linear format (1)

$$\log \omega_n = (0.672 \pm 0.002) - (1.421 \pm 0.003)(t_r/t_f)^{1/2} \qquad [4]$$

which is valid for $(t_r/t_f) > 0.5$.

The functions [2] and [3] describe the intensity-time relationship for a light pulse generated in the step format, provided the assumptions involved in deriving [2] are valid. They have been considered in the literature (10), and only the presumed steady state in ${}^3R^*$ needs reexamination here. The use of data taken early in the curve, where intensity changes are rapid, makes it necessary to support this approach. Thus, a comparison was made of the light intensities predicted by that approximation and by the integrated rate equation (10) for ${}^3R^*$. For these calculations, f was taken as $(\tau'/t_f)^{1/2}$, where $1/\tau' = 1/\tau + k_a[{}^3R^*]$. [See Ref. (10).] For a realistic case, $t_f = 1$ sec. $\phi_t = 0.1$, and $\tau = 10^{-4}$ sec, and the two predicted intensities become equal within 2% by the time $t_r = 30$ μsec. Longer time constants characterize systems with lower ϕ_t or longer τ. A worst case can be taken as $t_f = 1$ sec, $\phi_t = 0.001$, and $\tau = 10^{-2}$ sec, and it features an 8% discrepancy after 10 msec. In the algorithm proposed below, data are considered only for $t_r/t_f > 0.01$, hence it is likely that the steady-state treatment is always valid for the data analysis as long as $t_f > 0.1$ sec. For experiments

[1] During the review of this manuscript, Professor J. T. Maloy pointed out that the oscillations in ω_n could be eliminated by equating the dimensionless redox rate constant, kt_fC, with the number of iterations/step in a given simulation. One can further argue that such a procedure is the most appropriate method to obtain ω_n for diffusion controlled conditions. It gives rise to the analytical rate-time function

$$\omega_n = 4.74 \exp[-3.275(t_r/t_f)^{1/2}] + 11.99 \exp[-11.604(t_r/t_f)^{1/2}] + 37.34 \exp[-36.33(t_r/t_f)^{1/2}].$$

This function deviates from the numeric data set by 0.4% at the most and 0.2% on the average. It deviates from [3] by 0.5% at the most and 0.3% on the average. The two analytical representations give virtually identical precision in fitting operations.

The smoothness of ω_n from Maloy's approach is noteworthy, however. For example, one obtains an analog to Fig. 1 that is absolutely straight and noise free from $0.07 \leq (t_r/t_f)^{1/2} \leq 0.13$. When fitting operations involve numeric (rather than analytical) ω_n, the smoothness is a great advantage.

Fig. 1. The residue of ω_n following subtraction of the two longer-lived exponentials in Eq. [3]. The circles represent approximately every tenth value of ω_n produced by a simulation involving 100,000 iterations/step. The oscillatory behavior of ω_n is an artifact arising from the discrete nature of the concentration arrays in the simulation. The line is a plot of the shortest lived exponential in Eq. [3].

of shorter duration or for very inefficient systems, one might have to consider the more exact approach.

Strategy for Evaluating Parameters

The heart of the proposed method for extracting information from decay curves is the Marquardt curve fitting algorithm (14, 15). Like other least squares methods, it seeks the minimum point on the surface $\chi^2(\alpha, \beta, \gamma)$, which is defined as

$$\chi^2(\alpha, \beta, \gamma) = \sum_{\substack{\text{all} \\ \text{points}}} [\omega_i(\alpha, \beta, \gamma) - (\omega_i)_{\text{meas}}]^2{}_n/\sigma_n{}^2 \quad [5]$$

The sum in [5] covers the whole array of measured intensity-time pairs $[(\omega_i)_{\text{meas}}, t_r/t_f]_n$, and the weighting factor σ_n is proportional to the standard deviation in the intensity of the nth point.

The Marquardt algorithm requires as input a working point, *i.e.*, some set (α, β, γ). The shape of the χ^2 surface at that point is examined, and the routine adjusts the three parameters in a manner that yields a smaller $\chi^2(\alpha, \beta, \gamma)$. The new working point is then used as input for another cycle, and the whole procedure continues until the working point arrives at a minimum on the χ^2 surface.

This procedure is accurate and efficient. If one supplies a data set which is calculated from given α, β, and γ values via [2], it will report exactly those values regardless of what initial point is chosen. Unfortunately, the reliability is much worse when noisy data are used because the noise introduces into the χ^2 surface shallow secondary minima that can serve as traps. They usually are located fairly near the true result, but our observations include cases in which the fitting results are erroneous by an order of magnitude in one or more parameters. In the presence of noise, then, fitting operations using only the Marquardt algorithm are imprecise, sometimes grossly incorrect, and may yield results that depend strongly on one's choice of the initial working point. It is a key aspect of this work that the Marquardt procedure has been supplemented to improve its reliability.

The improvements are derived from a second routine which is executed after a first pass through Marquardt's algorithm. Since the working point that exists on entry to this routine defines a minimum in χ^2, one cannot easily use surface contour there to obtain a better working point. Instead, the approach is to search a perimeter of 26 selected points surrounding it. These points are the set $(\alpha + u_1\delta\alpha, \beta + u_2\delta\beta, \gamma + u_3\delta\gamma)$ where $u_i = 0, \pm 1$. The increments $\delta\alpha/\alpha$, $\delta\beta/\beta$, and $\delta\gamma/\gamma$ do not exceed 0.5, but they are usually large enough that χ^2 for some peripheral point is larger than that at the working point by factors from 2 to 10. Selecting them so helps to ensure that the perimeter will extend over the ridges defining the secondary traps in the χ^2 surface. If one or more of the peripheral points has χ^2 smaller than the working point, then the best of these is taken as the new working point, and a new perimeter search is made. When the improvement is within the fitting tolerance, the iteration is stopped, and a final pass through the Marquardt algorithm is made. Its output is taken as the best fit to the data.

The perimeter search is inefficient and accounts for about 70% of the typical fitting time; but it virtually eliminates gross errors, it improves fitting precision markedly, and dependences in the final fit on the initial guess became quite rare. For a 150 point array of data, a program written in Fortran IV for a Data General Nova 820 minicomputer requires about 3 min for execution.

This fitting procedure is prefaced by several other operations. In our implementation, data from experiments or from calculations of trial synthetic curves exist on tape cassettes in an array which contains 501 intensities corresponding to times 0.002 unit apart in the range $0 \leq t_r/t_f \leq 1$. These data are first subjected to a 7-point quartic smooth for $0 \leq t_r/t_f \leq 0.06$ and a 19-point quartic smooth for $t_r/t_f > 0.06$ (16, 17). Since a 501 point array is unmanageably large for the fitting operation, some selection of points must be made. In much of the work reported below, the data sent to the fitting algorithm were taken at even time intervals over the range $0 \leq t_r/t_f \leq 1$. Better precision is attained when they are selected at intervals as even as possible in a $(t_r/t_f)^{1/2}$ format, hence this procedure was adopted for the version now being used for experimental work. Data for $t_r/t_f \leq 0.01$ are discarded. The weight σ_n for any given point is taken as the average of the smoothing corrections made for it and for the two selected points immediately adjacent to it.

Following smoothing and point selection, the Feldberg parameters are determined, and the ratio of ω_i at $t_r/t_f = 0.05$ to that at 0.2 is calculated. A comparison

of these three indices of curve shape with those in a large catalog of data from theoretical curves permits one to enter an initial working point that is not too far from the final value.

Performance

To characterize the precision that could be expected from this procedure, a study of fitting performance has been made for synthetic curves which first were calculated from [2] and then had noise superimposed upon them. The sets of deviations making up the noise were Gaussian, and the deviations in any set ranged from $3\sqrt{2}\sigma$ to $-3\sqrt{2}\sigma$, where σ was the standard deviation of the distribution. One could change the absolute noise level by altering σ. Two kinds of noisy curves were studied: (*i*) For most work, ω_i was perturbed in a manner such that σ/ω_i was constant. Thus the noise falls with the intensity decay, and the signal-to-noise ratio is constant. (*ii*) A few studies involved the application of a constant noise level, expressed as $(\sigma/\omega_i)_{t_r/t_f=1}$, to the entire curve. In this case, the signal-to-noise ratio worsens as the decay proceeds.

Performance has been defined for variations in several operating parameters, including the number of data points used in the fit, the range of times over which the points are taken, the noise level, and the fraction of S route emission. In addition, the effect of an error in calibrating absolute emission measurements has been examined. The results are as follows:

Number of data points.—Figure 2 portrays the precision of determining α, β, and γ from a set of five noisy transients all of which had the same noise level and the same true values of those parameters. Precision is expressed for each parameter as $\overline{\Delta}$, the relative average deviation from the mean fitting result. In every case the mean was within $\overline{\Delta}$ of the true value.

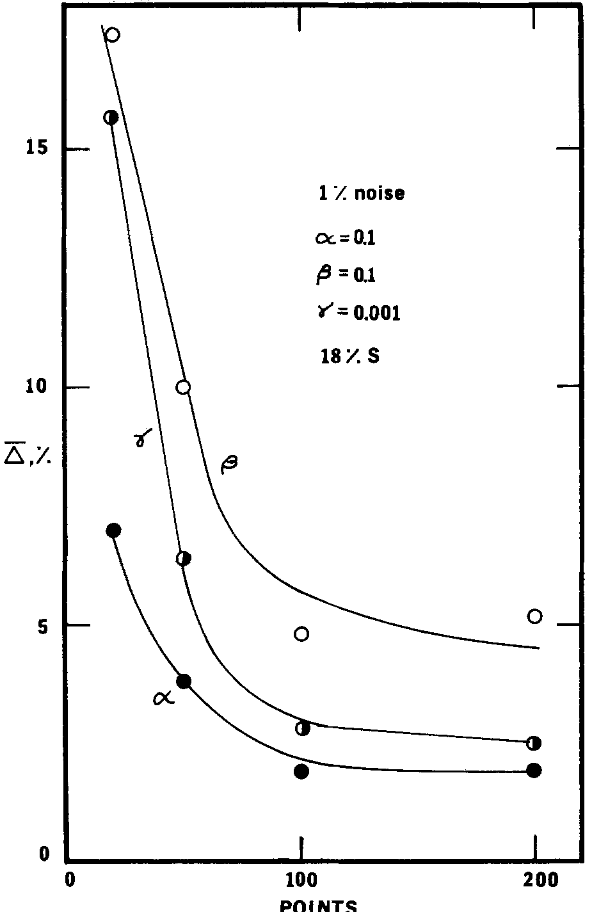

Fig. 2. Relative average deviations in fitting α, β, and γ vs. size of the data array. Noise is of type (*i*).

Table I. Effect of data base time domain on fitting precision[a]

Time domain	$\overline{\Delta\alpha}$(%)	$\overline{\Delta\beta}$(%)	$\overline{\Delta\gamma}$(%)
$0.01 \leq t_r/t_f \leq 1$	1.9	4.8	2.8
$0.1 \leq t_r/t_f \leq 1$	3.0	7.8	3.2

[a] 100 points; type (*i*) noise at 1% level; true curve: α = 0.1, β = 0.1; γ = 0.001; 18% S.

The noise was of type (*i*) described above, and its standard deviation was 1% of the intensity ω_i. In peak-to-peak terms, this level is 3-5% of ω_i throughout the time domain. For the particular combination of α, β, and γ taken here, the S route supplies 18% of the total emission. Performance improves markedly with increases in the data set when the number of points is below 100. However, the slight improvement obtained with still larger sets has led us to settle on 100 or 150 points for the analysis of real data.

Time domain.—Table I shows the effect on $\overline{\Delta}$ values of taking data later in the transient. Deleting the early information has disadvantages enumerated above, but it may be necessary whenever the step rise time or the validity of the steady-state approximation becomes a problem. The fitting procedure remains useful if one retains some information for $t_r/t_f \leq 0.2$, but raising the lower bound on t_r/t_f causes increases in $\overline{\Delta}$ values. Note that the increases are much larger for α and β than for γ. This situation derives from the T route's sensitivity to $[^3R^*]^2$, and it emphasizes the importance of the early information for evaluating T route parameters and the later data for determining the role of the S pathway.

Errors in the absolute measurement of ω_i.—It is not a trivial task to calibrate a detector to yield absolute measurements, and disagreement continues over the validity of calibration procedures. It is therefore important to determine the effect on the fitting outcome of a constant multiplicative error in all values of ω_i. The general rule can be found from Eq. [2]. Note that if a given set ω_i is associated with the given parameters α, β, and γ, then the set of intensities $k\omega_i$, which has the same shape as ω_i if k is constant, must be associated with $(k\alpha, k\beta, k\gamma)$. The important conclusion is that the curve shape depends only on the ratios of α, β, and γ. The ratios of the parameters, hence the percentage of S emission, can be determined even from relative measurements of intensity. Absolute data are needed if the magnitudes of the parameters are wanted, and any error factor in evaluating ω_i will show up identically in all three parameters. Tests with the fitting procedure have borne out this expectation.

Contributions from the S route.—Figure 3 depicts fitting precision as a function of S route contribution to the total emission arising from an ST system. For a constant relative noise level, $\overline{\Delta}$ values hardly depend at all on the absolute magnitudes of α, β, and γ. As one expects, the ability to define α and β deteriorates as one moves to larger S participation, and γ shows the opposite trend. When the S contribution is between 10 and 90%, both important parameters, α and γ, seem adequately defined.

Noise level.—The deterioration in precision with increasing noise is shown in Fig. 4, where the abscissa expresses the standard deviation of superimposed noise of type (*i*) as a percentage of ω_i. The efficiency parameters α and γ are sufficiently well defined to make the fitting procedure worthwhile even at a 5% level (15-25% peak-to-peak), and Fig. 3 suggests that they generally will be so for pure S or pure T cases and for ST systems with S contributions ranging from 10-90%.

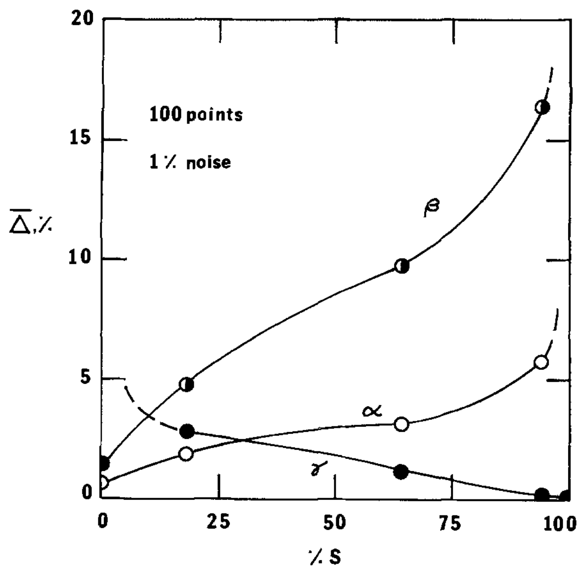

Fig. 3. Relative average deviations in fitting α, β, and γ vs. percentage contribution of S-route luminescence to total emission. Noise is of type (*i*).

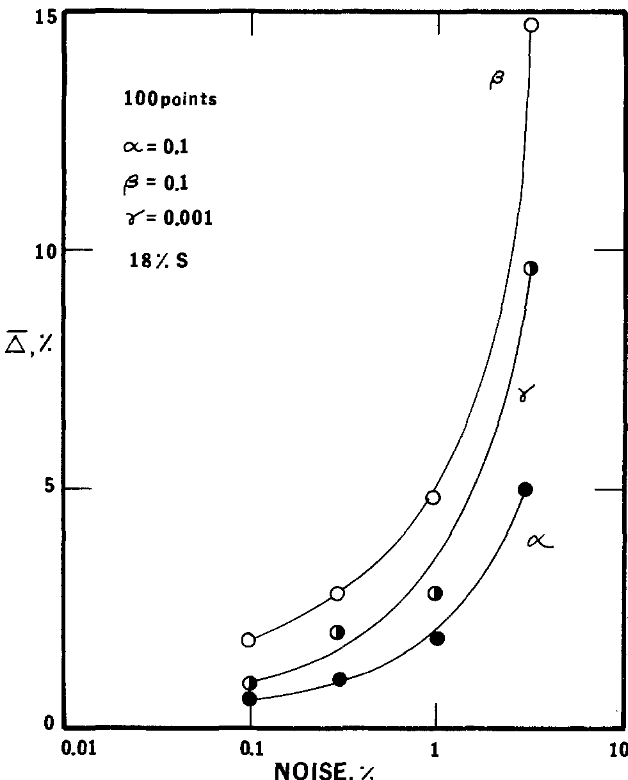

Fig. 4. Effect of noise level on fitting precision. Noise is of type (*i*).

A brief study dealt also with noise of type (*ii*) For $\alpha = 0.1$, $\beta = 0.1$, and $\gamma = 0.001$ (18% S) and for σ being 50% of ω_i at $t_r/t_f = 1$, $\bar{\Delta}$ values for the three parameters were 0.3, 1.8, and 6.4%, respectively. When σ was 200% of ω_i at $t_r/t_f = 1$, these figures rose to 0.9, 5.7, and 23%. The importance of the early emission for determining T route parameters is again demonstrated: For 50% noise of type (*ii*), the precision in α and β is comparable to that obtained with noise of type (*i*) at a level of 0.1%; yet γ is only as precise as with a 2-3% level of type (*i*).

Conclusion

The foregoing paragraphs demonstrate the viability of this procedure for transients having noise levels no larger than those considered here. Such signals are experimentally realistic. In work with the rubrene homomolecular ion annihilation in benzonitrile, we record transients with noise patterns resembling type (*ii*) with a 50% level. Thus, it seems reasonable to use this approach with real data, and efforts along that line are in progress. Being able to examine an entire transient with precision will make a rigorous test of the theory behind [2] possible for the first time. If it or a successor is found to be valid, the fitting approach should prove worthwhile for routinely extracting information about excitation efficiencies.

LIST OF SYMBOLS

A	electrode area, cm^2
a_i, b_i	intercept and slope of Feldberg plot
C	concentration of reactant precursor, moles/cm^3
D	diffusion coefficient of reactant precursor, cm^2/sec
f	width of reaction zone along diffusion axis (dimensionless) (2, 10)
g	$k_t/2k_a$
I	absolute light intensity, einstein/sec
k_a	$k_s + k_t + k_g$
k_s, k_t, k_g	rate constants for triplet-triplet annihilation
N	redox reaction rate, mole/sec
t_f	duration of the forward step, sec
t_r	time measured into the reverse step from its start, sec
α	$\phi_f\phi_{tt}\phi_t/(1-g)$
β	$\phi_f\phi_{tt}ft_f/8k_a\tau^2(1-g)^2C$
γ	$\phi_f\phi_s$
σ_n	standard deviation in the measurement of the nth ω_i value
σ	standard deviation of the distribution of absolute noise deviations
τ	lifetime of $^3R^*$ in the absence of triplet-triplet annihilation
ϕ_f	fluorescence efficiency of $^1R^*$
ϕ_s	singlet yield of electron transfer
ϕ_t	triplet yield of electron transfer
ϕ_{tt}	k_s/k_a
χ^2	index function for fitting, see [5]
ω_i	$It_f^{1/2}/AD^{1/2}C$
ω_n	$Nt_f^{1/2}/AD^{1/2}C$

ABSTRACT

Theoretical correction and instrumental compensation of charging current are discussed for both conventional and derivative chronopotentiometry. Experimental results indicate that either correction or compensation is effective in reducing the error due to charging the electrical double layer, but that best results are obtained by application of both techniques. In diffusion-controlled systems, derivative chronopotentiometry shows significant advantages over conventional chronopotentiometry.

Relationships governing chronopotentiometry in its simplest form have been derived, and the technique has been discussed in some detail (1-5). The relationships given in the references do not include the unavoidable complication of double-layer charging, probably the most serious problem encountered in chronopotentiometry. Because of this, it is often difficult to obtain a highly precise correspondence of experimental results and theoretical predictions. Despite these problems, the chronopotentiometric technique offered sufficient promise of utility to encourage our examination. Most of our efforts have been in the evaluation of derivative chronopotentiometry (6) and its comparison with the conventional technique. In this paper, we report the instrumentation required for derivative chronopotentiometry, its application to simple systems, and a comparison of derivative and conventional results. Included are suggestions for obtaining chronopotentiometric data corrected for the effects of double-layer charging.

Conventional Chronopotentiometry

Application of the Sand equation (3) requires that all current supplied to the cell be used in the faradaic process. In reality this requirement is never met. A part of the current supplied is used in charging the electrical double layer. This has the effect of decreasing the amount of charge available for the faradaic process. In addition, the double-layer capacity is potential-dependent and the rate of potential change is highly nonlinear so that the fraction of current devoted to the charging process is not constant. These two effects produce not only a lengthening of the apparent transition time beyond its predicted value based upon the value of the applied current, but also a distortion of the potential-time curve. These effects become most important at short times (high current densities) and low concentrations.

Considerable effort has been expended in recent years in attempts to obtain chronopotentiometric data unperturbed by double-layer charging (7-9). One approach to the distortion problem has been the suggestion that instrumental compensation, usually requiring positive feedback, be used (10). A promising instrumental method, evaluated in this work, is based upon the fact that the rate of double-layer charging is a function of the rate of potential change. Electronic differentiation of the potential-time curve produces a voltage signal proportional to dE/dt, and a portion of this signal is converted to a current which is then added to the applied current by positive feedback (6). The fixed proportion of the differentiator output which is used for feedback is based on the double-layer capacitance in the potential range of interest. Further details are given in the instrumentation section.

The various graphical and potential-interval techniques and correction approaches have been compared by others (11). After considerable investigation, we have chosen to base our estimate of the conventional transition time upon the measuring technique suggested by Noonan (12) (Fig. 1) and the correction model suggested by Bard (13). Noonan defines the initial time ($t = 0$) as the intersection of tangents to

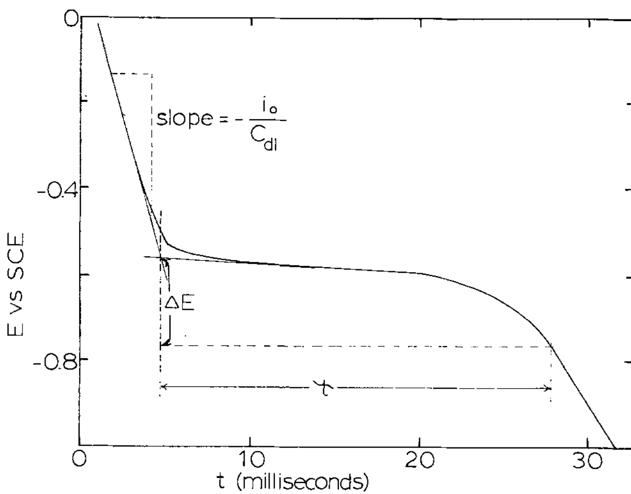

Fig. 1. Noonan technique for measurement of transition time and double-layer capacitance.

* Electrochemical Society Active Member.
Key words: dropping mercury electrode (dme), current compensation, positive feedback.

the initial, rapid potential change and the initial portion of the plateau region of the potential-time curve. The uncorrected transition time, τ, is then defined as the time interval from this point to the time at which the potential has changed by 200 mV. The choice of potential interval magnitude is somewhat arbitrary, but the interval must be large enough to ensure that the surface concentration of electroactive species approaches zero. Of course, the larger the interval the more nonfaradaic charge is included in the measurement, and the greater the probability that more highly potential-dependent regions of double-layer charging will be encountered. No charging correction is obtained in the measuring technique itself. This is accomplished by treating the data in the manner suggested by Bard, who utilized a split current model

$$i_o = i_F + i_{dl} + i_{ads} \quad [1]$$

where i_o = total applied current density; i_F = faradaic current density; i_{dl} = double-layer current density; and i_{ads} = adsorption current density. The model assumes that the component currents comprising i_o are all constant throughout the experiment. In the absence of adsorption, the equation becomes after substitution

$$i_o = n\mathbf{F}(\pi D)^{1/2}C/2\tau^{1/2} + C_{dl}\Delta E/\tau \quad [2]$$

where C_{dl} = average double-layer capacitance per cm^2 over interval ΔE volts and τ = measured transition time. A useful form of this equation is

$$i_o\tau = n\mathbf{F}(\pi D)^{1/2}C\tau^{1/2}/2 + C_{dl}\Delta E \quad [3]$$

$$i_o\tau = AC\tau^{1/2} + B$$

where A = true chronopotentiometric constant = $n\mathbf{F}(\pi D)^{1/2}/2$ and $B = C_{dl}\Delta E$. Thus, if the model is applicable, a plot of $i_o\tau$ *vs.* $C\tau^{1/2}$ should yield a straight line with a slope of A and an intercept of B for a series of data obtained at varying current densities. Once B is known, it may be applied in various ways to correct chronopotentiometric data. Corrected individual chronopotentiometric constants can be calculated from Eq. [4]

$$A = (i_o\tau - B)/C\tau^{1/2} = (i_o\tau^{1/2} - B/\tau^{1/2})/C \quad [4]$$

Corrected individual values of τ (as $\tau^{1/2}_{corr}$) can be calculated from Eq. [5]

$$\tau^{1/2}_{corr} = AC/i_o = \tau^{1/2} - B/i_o\tau^{1/2} \quad [5]$$

An alternative method of determining B was suggested by Noonan (12); in this method, one measures the slope of the initial, sharply changing segment of the chronopotentiometric potential-time curve just prior to its breaking over to the plateau region (Fig. 1). The slope is related to the double-layer capacity by

$$\text{Slope} = i_o/C_{dl} \quad [6]$$

The value of C_{dl} thus calculated is used with the known ΔE over which τ is measured to yield a value of B. This value can be used in the same ways as outlined above. This procedure is most useful in kinetically complicated systems.

The Noonan-Bard approaches were used with the results given below. Details as to the specific mode of correction used are given in the Results and Discussion section.

The assumptions, explicit and implicit, in the Bard model have been discussed in some detail in the work of de Vries (14), Nicholson (11), and Rodgers and Meites (15). Their more complex treatments of the double-layer effect indicate that the Bard model is open to some criticism on both theoretical and physical grounds. While these criticisms may be valid, in our hands the model does yield data substantially free of double-layer error and in close agreement with theoretical predictions. It is possible that this occurs because of fortuitous cancellations of errors contained in the model; nonetheless, the model appears to provide a simple, empirical method for obtaining chronopotentiometric data substantially free of charging error.

Derivative Chronopotentiometry

In derivative chronopotentiometry, the chronopotentiometric potential-time curve is electronically differentiated as a function of time. The differentiator output, dE/dt, can be displayed *vs.* time or potential. During the chronopotentiometric trace, dE/dt reaches a minimum which is quantitatively related to the transition time. For a cathodic process dE/dt is a negative quantity while for an anodic process it is a positive quantity. The term minimum here refers to the minimum of the absolute values of the derivative. Previous published work in derivative chronopotentiometry is rare. The derivative concept has been applied to cyclic chronopotentiometry (16), and Peters and Burden (6) have derived the theoretical relationship between the transition time and the minimum in the dE/dt curve. Noonan (12) deals with the technique to a limited extent; others have reported initial attempts to apply the technique to submicroformal concentrations (17) and to multicomponent systems (18).

For reversible systems, Peters and Burden derived the following expression

$$(dE/dt)\min = -27RT/8n\mathbf{F}\tau = -0.08664/n\tau \quad \text{at } 25°C \quad [7]$$

The authors claim that this equation provides the first theoretically justifiable method for the evaluation of transition times and point out that the minimum in the dE/dt function is relatively insensitive to double-layer charging. Although this is true and, as a result, derivative chronopotentiometric data are less distorted by double-layer effects than conventional data, it is evident that the experimentally determined dE/dt function retains a double-layer charging term. We have chosen to treat the derivative data in a similar fashion (Bard model) to that chosen for conventional data. As mentioned above, the Bard model assumes a constant ratio of i_F/i_{dl} over the chronopotentiometric curve. Although this can only be approximately true over the entire chronopotentiogram in the conventional technique, the ΔE over which the derivative is taken is much smaller. Thus, the derivative technique is performed using conditions which more nearly approach those postulated in the model. As a consequence, insofar as the model is applicable at all, it should be more applicable to the derivative than to the conventional technique. Results are given below.

Use of the derivative approach is not without its price. The original instrumentation used by Peters and Burden is severely limited in its ability to yield data over a broad time range. Expanding the time range of the instrumentation required some added complexity compared to conventional chronopotentiometry. Most of the additional complexity is directly traceable to the well-known difficulties of electronic differentiation.

More serious disadvantages are those associated with the nature of the charge-transfer process. Theoretical chronopotentiometric transition times depend only upon mass-transfer properties; in principle, the detailed nature of the potential-time curve does not affect τ. Derivative chronopotentiometry, however, requires differentiation of the potential-time curve; thus, relating $(dE/dt)_{min}$ to τ requires a detailed knowledge of the degree of reversibility of the electrochemical process. In addition, IR drop (uncompensated resistance) may be more important in the derivative method than in the conventional technique. Despite some problems, the work we report here and in succeeding papers will, we believe, demonstrate the continued utility of the chronopotentiometric technique and the potential of the derivative approach.

Instrumentation

Several different chronopotentiometers have been built in this laboratory which represent various stages of development from the instrument descrbed previously (16). The major differences in these instruments are in the characteristics of the amplifiers used, the devices used for switching, and in the number of differentiators employed.

In all the instruments the same basic galvanostat circuit has been used with the test electrode connected to the summing point (at virtual ground) and the counterelectrode connected to the output of the galvanostat amplifier (Fig. 2). The reference electrode is connected to the input of a second amplifier which is used as a voltage follower. The output of the follower serves as the potential output of the instrument and is also connected to one or two differentiators and the voltage sensors of the control circuit. In the earlier instruments, the current source for the galvanostat was an operational amplifier with output voltage limited by a pair of Zener diodes connected back to back. In the latest instrument, regulated power supplies are used for the current sources.

To control the potential of the working electrode prior to the application of the current step, the cell connections are not changed but the summing point of the galvanostat is disconnected from the current sources and connected to the movable tap of the voltage divider (R_3) between the + or − supply and the output of the follower. The galvanostat amplifier then controls the voltage of the cell so that the tap of the voltage divider is at ground potential. The potential control is quite effective if no cell current flows at this desired potential. If cell current does flow at this setting, the nominal electrode potential will be in error since current will be drawn from the voltage divider; however, the potential control is adequate for most purposes and, in any event, the output of the follower will indicate the electrode potential plus a small fraction of the total *IR* drop in the cell. This circuit has the advantage that the cell is connected to the galvanostat and follower amplifiers at all times and thus switching transients are minimized.

In order to perform chronopotentiometry with a dropping mercury electrode, some device must be employed to synchronize the drop action so that the current step is applied at a reproducible time in the drop life and, hence, on a reproducible electrode area. For this purpose a drop-detaching solenoid is actuated by the cycle timer. The detacher must be designed so that the drop will be dislodged without causing significant continued oscillation of the capillary. The solenoid is mounted in a jig which also holds the capillary. The capillary is held in a semicircular groove by an elastic band or metal spring. The spring tension is just sufficient to return the capillary to its original position. The back side of the groove is covered with a section of rubber tubing to damp the recoil motion when the capillary is reseated. The solenoid may be positioned in the jig so as to obtain the minimum necessary amount of capillary movement when the solenoid is actuated.

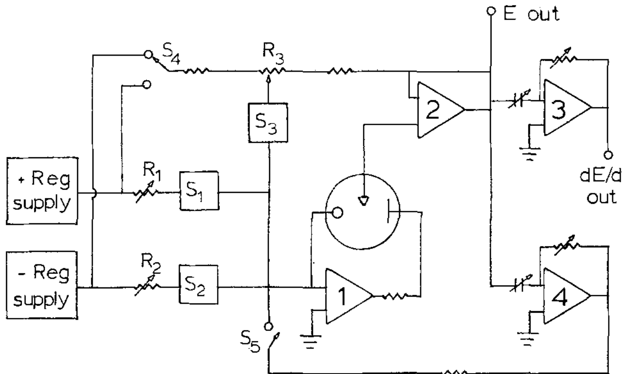

Fig. 2. Schematic diagram of chronopotentiometer. Amplifiers: 1, galvanostat; 2, voltage follower; 3, readout differentiator; 4, feedback differentiator; see text for other details.

A master timing and control circuit is used to actuate the drop detaching solenoid and to control the input switches to the galvanostat amplifier. When the timer pulses the solenoid, the current control switches, S_1 and S_2, are set nonconducting and the potential-control switch, S_3, is set conducting. At the end of the predetermined delay time, the potential control is switched off and either S_1 or S_2 is made conducting so that a cathodic or anodic current is switched into the input of the galvanostat amplifier to start the chronopotentiometric process. The magnitudes of the anodic and cathodic currents are set independently with R_1 and R_2. When the electrode potential, as represented by the follower output, reaches a preset limiting value, a voltage-sensing circuit reverses the states of S_1 and S_2, thus reversing the direction of cell current. When the electrode potential reaches a second preset limiting value, both S_1 and S_2 are again set nonconducting and S_3 is set conducting to restore potential control. Alternatively, when the second limiting potential value is reached, the states of S_1 and S_2 are again reversed so that another chronopotentiometric cycle is started. In this way, cyclic chronopotentiometry can be performed. At the end of the cycle time, the drop-detaching solenoid is pulsed again and a new cycle is started. A push-button switch is also provided to serve as a manual start for experiments on stationary electrodes. In this series of instruments, the switching elements have ranged from toggle switches through mercury-wetted relays and diode gates to MOS field-effect transistors.

Operational amplifier differentiators are used to obtain the *dE/dt* readout and as a signal source for the positive feedback loop used for compensation for the cell capacitance current. A series of differentiator time constants is selectable by switching the input capacitor and feedback resistor. Careful attention to the frequency response of the circuit is necessary to obtain a stable, fast, low noise differentiator. Both a series resistor in the input of the circuit and a parallel capacitor in the feedback loop of the differentiator are necessary. These are switched together with the input capacitor and feedback resistor. In addition, it is necessary to use Zener diodes in a low impedance feedback loop which comes into use when the differentiator output voltage nears its limit. If this is not done, the summing point of the differentiator circuit will leave virtual ground when the limiting output voltage is reached. The circuit recovers very slowly from this condition, especially if a chopper-stabilized amplifier is used.

For derivative readout it is desirable to have a differentiator circuit with a rise time at least two orders of magnitude faster than the transition time being measured. This requires a fast amplifier for transition times of less than a msec. On the other hand, for charging-current compensation, the rise time of the differentiator must be slower than that of the galvanostat-cell circuit; otherwise, the entire circuit will break into oscillation. Thus, it is clear that optimum results can be obtained only if different differentiators are used for readout and feedback. Only one of the instruments used in these studies had two differentiators and the quality of some of the results obtained with the other instruments was curtailed by this omission.

Due to the evolutionary nature of our instruments, still in process, we prefer not to supply specific values of circuit elements in this paper. Interested readers may contact us for further details of specific circuit elements.

Results and Discussion

The first results discussed are conventional. By "conventional" is meant the usual experiment in which the chronopotentiometric potential-time curve, as opposed to its derivative, is the waveform of interest. In all

cases the measurement of τ was made using the 200 mV interval technique discussed above. Both cadmium and lead systems, of varying concentrations, were examined; the supporting electrolyte was 1.0M KNO_3 in all cases. The conventional results obtained are presented in Tables I and II. In these tables, the column heading "microfarads compensation" refers to the amount of positive feedback utilized, a larger number meaning higher current feedback. The range of τ gives the longest and shortest transition time observed for a given set. The quantity $i\tau^{1/2}/C$ is given as a range in the table, but note that the ranges are somewhat larger than would be obtained using a graphical method for τ measurement; our reasons for adopting the potential-interval measuring technique are given above. The intercept and slopes given are the values obtained by applying the Bard model to the chronopotentiometric data. In all cases this is a plot of $i\tau$ *vs.* $C\tau^{1/2}$ where τ is the measured transition time, C is concentration of electroactive species, and i is the applied current chosen instrumentally. Such a plot corresponds to Eq. [3] with all terms multiplied by the electrode area, a, and yields a slope of $i\tau^{1/2}/C$ and an intercept on the $i\tau$ axis which equals $aC_{dl}\Delta E$. Thus, the slope, insofar as the model applies, should be equal to the average value of $i\tau^{1/2}/C$ obtained by correcting individual values of experimental $i\tau/C$, using the procedure outlined previously, and should be equal to the true chronopotentiometric constant multiplied by the electrode area. The intercept value provides a value of C_{dl}. In all cases the slopes and intercepts were obtained by least squares computer analysis, rather than by hand plotting. The column headed $i\tau^{1/2}/C$ (corrected) presents the average of Bard-corrected values thus obtained. Note that slopes and corrected values are in good agreement, implying not only linearity of the data but also close adherence to the Bard model. The number of values given is the actual number of individual values to determine the range and average reported for each set. The number of points used for the over-all average does not always agree with the total due to the statistical procedure of eliminating points whose standard

* For units, see Table I.

deviation is greater than 2σ. In the summary column are presented chronopotentiometric constants in conventional units; also presented are values of C_{dl} calculated from intercepts. Observe the close agreement of corrected chronopotentiometric constants and C_{dl} over a wide range of concentrations and τ's and with different values of compensation.

The conventional chronopotentiometric results obtained for the lead system are presented in Table I. Detailed examination of the results in Table I reveals a number of salient features. For no compensation, the values of $i\tau^{1/2}/C$ obtained increase drastically, not only with decreasing τ in a single concentration but also with decreasing concentration; in the absence of double-layer charging, this value should be constant. For example, the values obtained for 10^{-3}M range from 14.1 to 19.4, whereas for 10^{-4}M the range is 21.8-67.5. These results are expected and are in agreement with the observations of other workers. On the other hand, even with zero compensation, the corrected values are virtually constant within experimental error. A second feature is that exhibited by the results obtained using positive feedback. Generally, as compensation increases (increasing feedback current), the range of uncorrected $i\tau^{1/2}/C$ values decreases within each concentration studied, but does not decrease sufficiently to indicate that electronic compensation alone can provide completely corrected data; a Bard correction is still necessary. An interesting result is revealed by the data for the 10^{-4}M solution at compensation 0.7; the negative intercept obtained indicates "overcompensation" and is a further suggestion that electronic compensation alone is inadequate in conventional chronopotentiometry.

The third salient feature of the data in Table I is revealed by examination of corrected values of $i\tau^{1/2}/C$; virtual constancy in the quantity is obtained over the concentration range studied. Although the trend is not statistically meaningful, corrected values obtained with zero compensation are slightly larger than those obtained with positive feedback; yet, too high a level of compensation can be used, as evidenced by the negative intercept discussed above. Therefore, it would appear that, if conventional chronopotentiometry is used, the optimum approach is to use some compensation and to invoke the correction system by Bard. A somewhat less optimum approach is to use no compensation, but to use only the correction technique; this aproach would provide data usable for most applications. Data obtained at the concentration levels and transition times of Table I are virtually useless without correction, and electronic compensation (positive feedback) further improves the data. At higher concentrations (2-10 mM), it may be possible to obtain corrected data using only electronic compensation, but at these higher concentrations and at longer transition times correction is often unnecessary. The success of the correction approach and of the application of electronic compensation has particular significance in kinetics studies where theoretically predicted behavior must be obtained; the significance of these results in analytical application is dealt with in a later paper of this series. The fourth important feature of Table I is revealed in examination of the values of $i_0\tau^{1/2}/C$, the chronopotentiometric constant. Values of the quantity, calculated using the corrected value of $i\tau^{1/2}/C$ and the electrode area, are in good agreement with values previously obtained in our laboratories under more favorable concentration and transition time conditions and, thus, much less subject to double-layer charging error.

The conventional chronopotentiometric results obtained for the cadmium system are presented in Table II. The results in set A of the table are illustrated in Fig. 3. These results confirm and strengthen the conclusions and observations obtained using the lead results. They are also useful in the comparison of derivative and conventional approaches given below. In addition, a few important features require comment. Observe that the cadmium system is somewhat more well behaved than the lead in that the ranges of experimental $i\tau^{1/2}/C$ are somewhat smaller. This is probably due to the smaller average double-layer capacitance encountered in the cadmium system, where reduction occurs at -0.6V *vs.* SCE, than that encountered in the lead system where reduction occurs at -0.4V *vs.* SCE. In fact the electronically compensated (0.6 μF) but uncorrected values of $i\tau^{1/2}/C$ obtained in 10^{-3}M $Cd(NO_3)_2$ compare rather favorably with corrected values. The data in Table II also provide some indication, as do the data of Table I, that zero-compensated data yield larger values of corrected $i\tau^{1/2}/C$ than do compensated data; again, the trend may not be statistically meaningful. Finally, note that constancy in $i\tau^{1/2}/C$ is achieved over a wide range of transition times.

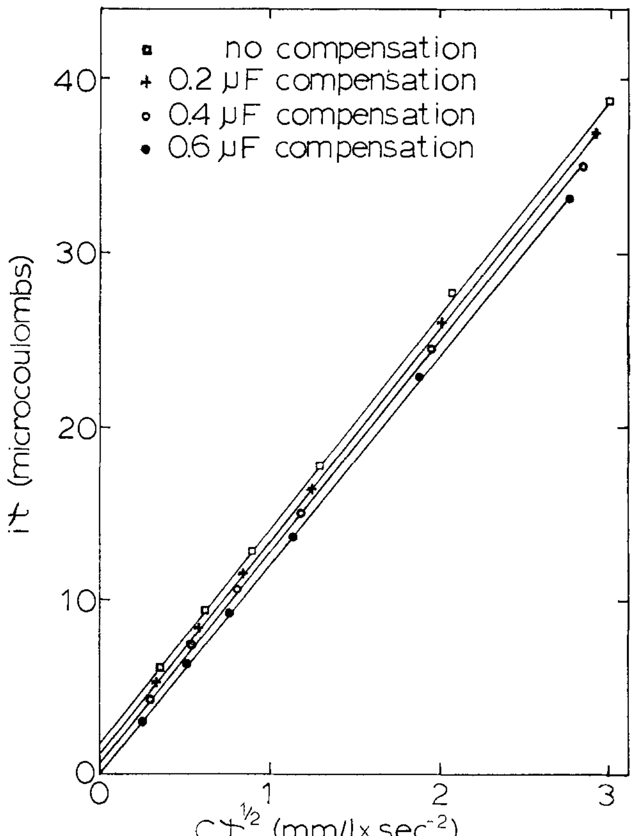

Fig. 3. Bard plots for Cd^{2+}, Set A of Table II

Derivative chronopotentiometric results are presented in Table III. Note that the concentration of cadmium is low and thus provides a good test of the derivative technique compared to the conventional approach. Calculated transition times in the table were obtained from Eq. [7] presented earlier. Actual differentiator readout is a potential waveform, the minimum of which permits calculation of (dE/dt)min by the relationship

$$(dE/dt)\text{min} = -E_{\text{min}}/R_fC_i \qquad [8]$$

where R_f and C_i are the respective values of the feedback resistance and input capacitance of the differentiator circuit. The quantity $i\tau$ is the product of the calculated experimental transition time and the controlled current chosen instrumentally. Other quantities in the table were determined as in Tables I and II. Observe that each entry in Table III is a single data point, whereas the entries in Tables I and II are averages of several measurements. Set A of Table III are uncompensated (no positive feedback) results. Note that the uncorrected values of $i\tau^{1/2}/C$ show a definite trend towards higher values as τ decreases; although the

			Slope $\frac{i\tau^{1/2}}{C}$ = 12.3; Intercept = 0.012		

trend is present, the values are more nearly constant than equivalent conventional results presented in Table II. Corrected values of $i\tau^{1/2}/C$ are constant, and the value of the chronopotentiometric constant obtained (420) is in fair, though not excellent, agreement with the value of 436 (Table II) obtained conventionally with a different instrument and cell more than a year earlier. Set B of Table III are results for the same concentration of cadmium as in Set A, but were obtained using optimum compensation (*i.e.*, use of as much positive feedback as possible without introducing observable distortion of the conventional chronopotentiometric waveform). Note that, in the case of Set B, corrected and uncorrected data are virtually identical; this result suggests that the derivative technique does indeed provide data significantly less affected by double-layer charging than does conventional chronopotentiometry. These results were obtained with an instrument having only one differentiator for both readout and feedback.

Conclusions

These results are encouraging in that they confirm the utility of electronic compensation (positive feedback) and the Bard correction approach in removing double-layer charging error from chronopotentiometric data and, thus, extend application of the technique downwards to lower concentrations and shorter transition times using either the conventional or derivative technique. Although optimum results can be achieved using derivative chronopotentiometry, positive feedback, and the correction system, those electroactive species exhibiting irreversible charge transfers can still be studied using the conventional technique with feedback and correction. Further, should the use of positive feedback be undesirable or inconvenient, good results can still be achieved using conventional or derivative results with correction.

Electrode Kinetics of Antimony in Acidic Chloride Solutions

L. L. Wikstrom,* N. T. Thomas,* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The kinetics of the electrode processes of antimony in KCl-HCl solutions have been investigated. The rest potential of antimony in acidic chloride solutions can be expressed empirically by the equation

$$E^e = 0.182 - 0.060\,pH + 0.020 \log [Sb(III)]$$

and is attributed to the redox reaction

$$Sb + 2H_2O = HSbO_2 + 3H^+ + 3e$$

The empirical rate equations for the electrodissolution and electroreduction reactions near the rest potential are

$$I_a = \overrightarrow{k}_a [OH^-][Sb(III)]^{-1} e^{2FE/RT}$$

and

$$I_c = \overleftarrow{k}_c [H^+]^2 e^{-FE/RT}$$

The rate of electrodeposition of Sb(III) can be expressed as

$$I_{c,\,dep} = \overleftarrow{k}_{c,\,dep} [H^+][Sb(III)] e^{-FE/2RT}$$

A mechanism which is consistent with the experimental results is proposed.

Although there has been interest in antimony as a reference electrode, electrocatalyst for electrochemical energy conversion and inhibitor in the corrosion control of iron and steel (1), there has been little work on the kinetics of electrodissolution and electroreduction of antimony. The use of antimony as a reference electrode has focused studies on the thermodynamic properties and open-circuit electrochemical behavior of antimony and antimony oxides. Stock, Purdy, and Garcia (2) and Ives and Janz (3) have reviewed this work.

Park and Beard (4, 5) surmised that the rest potential of antimony was determined by the redox reaction

$$2Sb + 3H_2O = Sb_2O_3 + 6H^+ + 6e^- \quad [1]$$

with the equilibrium potential following the relation

$$E^e = 0.152 - 0.059\,pH, \text{ volts} \quad [2]$$

The Sb_2O_3 was assumed to be a surface film on the antimony electrode and formed antimonyl ions (SbO^+) in strong acid solutions by the reaction

$$Sb_2O_3 + 2H^+ = 2SbO^+ + H_2O \quad [3]$$

Although Bishop and Short (6) and Stock, Purdy, and Garcia (2) obtained the same redox potential, they attributed it to different reaction steps. Bishop and Short (6) suggested $Sb(OH)_3$ as an intermediate, while Stock, Purdy, and Garcia (2) suggested Sb^{+3} as an intermediate. These investigators report that the experimental rest potential was more noble than the theoretical value but approached it as oxygen was removed from the system. Schuhmann (7), and Robert and Fenwick (8) report $E^\circ = 0.15V$ for the Sb/Sb_2O_3 reaction in deaerated perchloric acid and acidic chloride solutions, respectively. On the other hand, Tourkey and Musa (9) report about a 0.1V higher value for E° and conclude that the value, $E^\circ = 0.15V$, can only be obtained with finely divided antimony. Schuhmann's actual measured rest potential of antimony in deaerated perchloric acid was 0.212V (7). He attributed this rest potential value to the Sb/SbO^+ redox reaction. According to Schuhmann, the SbO^+ forms as given in Eq. [3]. It should be noted that Cotton and Wilkinson (10) question the existence of SbO^+.

Bishop and Short (11) investigated the electrochemistry of antimony in oxygenated 0.03M KCl (pH = 7). They attributed the potential controlling process at low cathodic currents and high oxygen concentrations to

$$2Sb + 3H_2O = Sb_2O_3 + 6H^+ + 6e^- \quad [1]$$

and at high anodic current densities to

$$Sb_2O_3 + 2H_2O = Sb_2O_5 + 4H^+ + 4e^- \quad [4]$$

Similarly, from galvanostatic charging transients, El Wakkad and Hickling (12) suggested that antimony oxidized to Sb_2O_3 at low currents and to Sb_2O_5 at high currents. However, they surmised that although the antimony electrode was covered by a porous Sb_2O_3 film, Sb_2O_5 was formed by direct oxidation of antimony.

Huq, Rosenberg, and Makrides (13) investigated the anodic dissolution of single crystal antimony in 1M $HClO_4$ (pH = 0.04). In acid solution an anodic Tafel slope of 120 mV was obtained. An active-passive transition was observed at 0.40V *vs.* SHE with a critical current density of 4.5×10^{-3} A/cm². Passivation was attributed to the formation of Sb_2O_5. In a further study (14) these investigators obtained a Tafel slope of 180 mV and an exchange current density of 2×10^{-6} A/cm² for the hydrogen evolution reaction on antimony in 1M $HClO_4$.

This paper reports on kinetic studies of the electrooxidation and electroreduction processes at the antimony electrode and the electrodeposition of Sb(III) on Sb in acidic chloride solution.

Experimental

A common 3-electrode electrochemical cell was used for this investigation. The electrolyte was deaerated with prepurified nitrogen which was passed through scrubbers before entering the cell. All experiments were performed with the cell and scrubbers in a glove box filled with prepurified nitrogen gas. Temperatures were maintained at 23° ± 1°C.

Electrical connections were made with shielded leads and BNC connecters. A Kepco power supply was used for long galvanostatic pulses. Differential capacitances

* Electrochemical Society Active Member.

Key words: electrodissolution, electrodeposition, polarization.

were determined by the d-c pulse method with the Rutherford pulse generator and a specially constructed cathode follower. The potential transients were measured and recorded with a Type 564 Tektronix oscilloscope. Potentiostatic polarization was performed with a Wenking potentiostat.

Saturated calomel electrodes were used as reference electrodes which were in contact with the electrolyte close to the electrode surface through a Haber-Luggin capillary. Potentials were measured with either a Keithley 621 or 603 electrometer.

The antimony electrodes were prepared from a bar stock of 99.9996% antimony. All electrodes were cut with a carborundum wheel with water used as the lubricant. The cylindrical electrodes were drilled and tapped dry. The exterior surfaces were ground with the carborundum wheel and then with carborundum paper 4/0 to a cylindrical shape. The planar electrodes were 1 cm × 1.5 cm and the cylindrical electrodes were 0.63 cm diam. × 0.75 cm length. The planar electrodes were cut flat with a carborundum wheel and soldered to a platinum wire passed through a 6 mm Pyrex tube. The electrode was masked with purified paraffin wax except for one surface of the antimony. The cylindrical electrode assembly was rotated at 500 rpm (V_t = 35 cm/sec) while the planar electrode was stationary.

Just prior to immersion into the electrolyte, the electrode was etched in CP-4A (HNO_3, 5 parts; 48% HF, 3 parts; acetic acid, 3 parts) for 4-8 sec, washed, and immersed in distilled water and then placed immediately in the cell.

All solutions were prepared from C.P. grade chemicals: B & A HCl, KCl, and Sb_2O_3. Solutions of constant ionic strength of unity were used throughout the investigation. All solutions were prepared from 1*N* HCl with the desired *p*H obtained by the addition of KOH. The *p*H values of 0, 1, and 2 were investigated.

After immersion of the electrode in the electrolyte, the system was held at open circuit for at least 2 hr before polarization. During the 2 hr period, the rest potential was monitored and recorded. If, at the end of the 2 hr period, the potential drift was in excess of 2 mV/hr, the system was kept at open circuit until the drift was 2 mV/hr or less. After a steady-state rest potential was observed, the electrode was polarized.

Two-minute current steps were used to polarize the antimony electrode. The 2 min steps were chosen since it was observed that an apparent steady-state was achieved for both anodic and cathodic currents after about 90 sec. At each absolute value of current density, anodic polarization was first obtained and then switched to cathodic polarization. This same procedure was followed with each increasing increment of current density.

Results

Sb/Sb(III) reaction.—The dependence of the rest potential on the *p*H, as shown in Fig. 1, is

$$\frac{\partial E^e}{\partial pH} = -0.06V \quad [5]$$

An E^e *vs.* log Sb(III) plot shows that

$$\frac{\partial E^e}{\partial \log Sb(III)} = 0.02V \quad [6]$$

Except for the extreme negative potential region where mass transfer effects become important, the polarization data obtained with stationary and rotating electrodes were identical. Figures 2 and 3 show the polarization behavior of antimony in 1M Cl^- of *p*H = 0, 1, and 2 solutions in the absence and presence of Sb(III), respectively. The anodic dissolution increased with increase in *p*H. On the other hand, both the rates of the cathodic reaction near the rest potentials and at large negative potentials decreased with increase in *p*H. Near the rest potential the anodic and cathodic Tafel slopes in both the absence and presence of Sb(III)

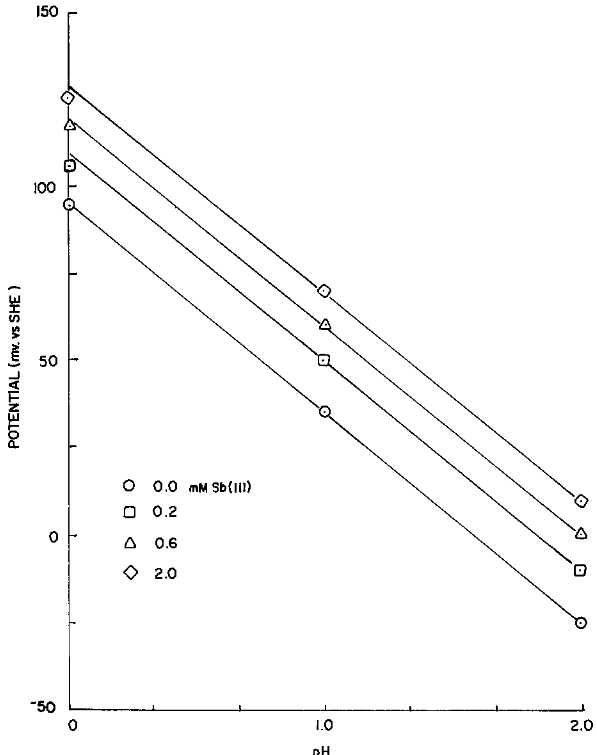

Fig. 1. Rest potential of antimony in acidic chloride solutions vs. *p*H.

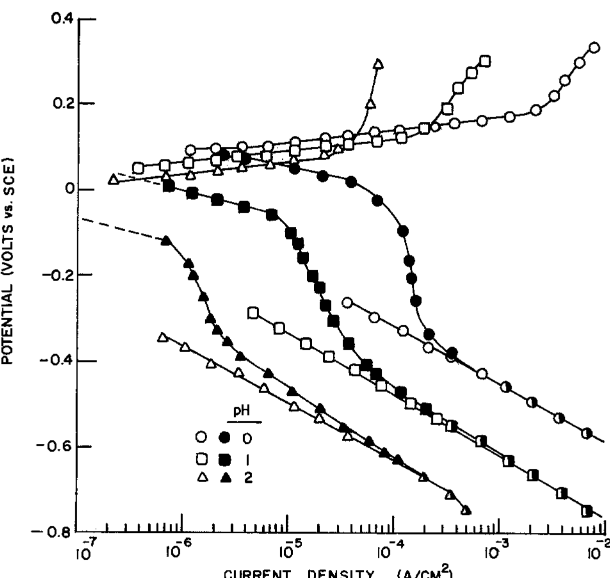

Fig. 2. Effect of *p*H on the polarization of antimony in acidic chloride solutions.

are 30 and 60 mV/decade, respectively. Figure 4 shows some typical results of the effect of Sb(III) on the polarization behavior of antimony. It is shown that anodic dissolution decreased with increase in the concentration of Sb(III) while the rate of the cathodic reaction near the rest potential was independent of the Sb(III) concentration, *i.e.*

$$\frac{\partial \log |I_c|}{\partial \log [Sb(III)]} = 0 \quad [7]$$

This latter result suggests that the electroreduction process near the rest potential is not electrodeposition of Sb(III) from the bulk solution. Figure 5 shows the variation of the cathodic reaction in this same region with *p*H

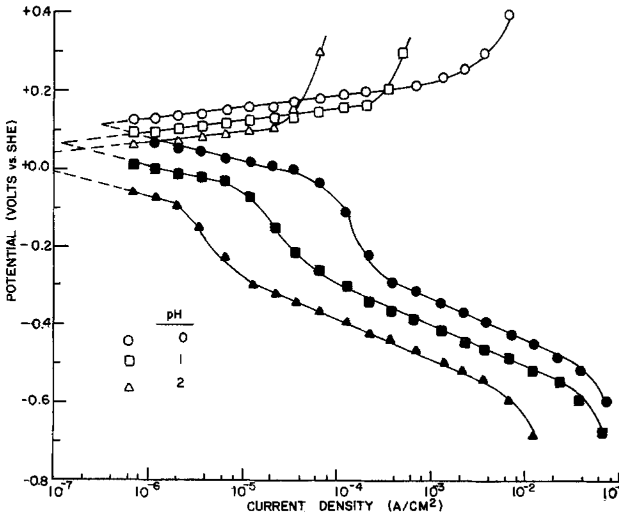

Fig. 3. Effect of pH on polarization of antimony in acidic chloride solutions 0.6 mM Sb(III).

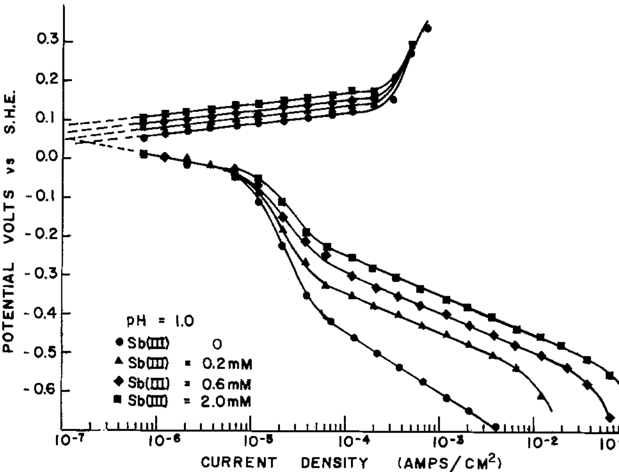

Fig. 4. Effect of Sb(III) on polarization of antimony in pH = 1 solutions.

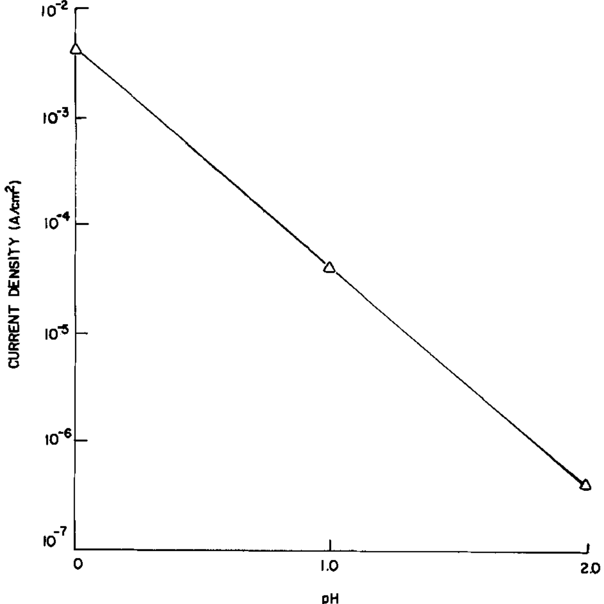

Fig. 5. Reaction order of electroreduction of antimony near the rest potential with respect to pH. −0.1V.

$$\frac{\partial \log |I_c|}{\partial pH} = -2 \quad [8]$$

The dependence of anodic dissolution on pH and Sb(III) concentration is

$$\frac{\partial \log I_a}{\partial pH} = 1 \quad [9]$$

and

$$\frac{\partial \log I_a}{\partial \log[Sb(III)]} = -1 \quad [10]$$

as shown in Fig. 6 and 7, respectively.

The variation of the exchange current density of the electrode reaction near the rest potential with pH, as shown in Fig. 8, is

$$\frac{\partial \log I_o}{\partial pH} = -1 \quad [11]$$

A log I_o *vs.* log [Sb(III)] plot shows that

$$\frac{\partial \log I_o}{\partial \log[Sb(III)]} = -\frac{1}{3} \quad [12]$$

From the experimental results given above, the rate of the anodic and cathodic reactions near the rest potential can be written in the following empirical form

$$I_a = \overline{k}_a[OH^-][Sb(III)]^{-1} e^{2FE/RT} \quad [13]$$

and

$$|I_c| = \overline{k}_c[H^+]^2 e^{-FE/RT} \quad [14]$$

Electrodeposition of Sb(III).—The cathodic Tafel region at the higher negative potentials in Fig. 2 shows hydrogen evolution on antimony by discharge of hydrogen ions with a Tafel slope of 130 mV/decade and a reaction order of one. The closed points represent the descending polarization curves, and the open points represent the ascending ones.

Figure 4 shows the codeposition of hydrogen ions and Sb(III) at the higher negative potentials. The rate of electrodeposition of Sb (III) can be readily obtained by substracting the rate of hydrogen evolution from the rate of codeposition. The cathodic polarization curves thus obtained representing electrodeposition of Sb(III) have Tafel slopes of 110 mV/decade. The dependence of electrodeposition of Sb(III) on pH and the concentration of Sb(III) is shown in Fig. 9 and 10, respectively. These results indicate that

$$\frac{\partial \log |I_{c,dep}|}{\partial pH} \approx -1 \quad [15]$$

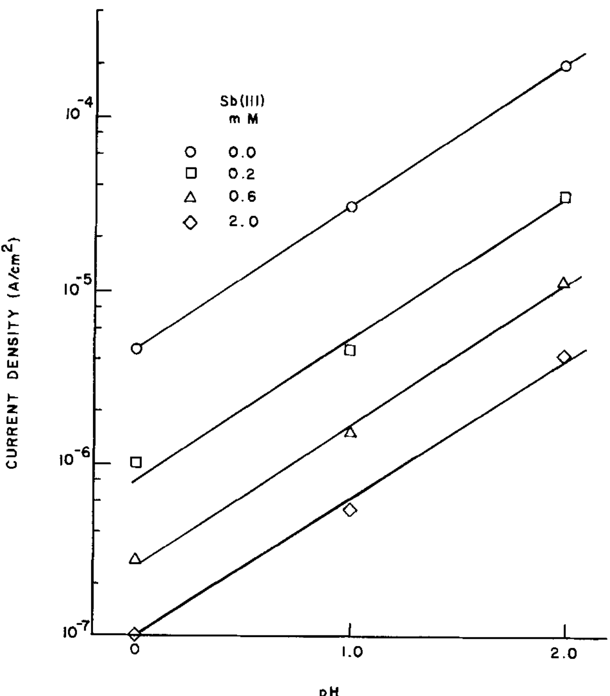

Fig. 6. Reaction order of electrodissolution with respect to pH. 0.1V.

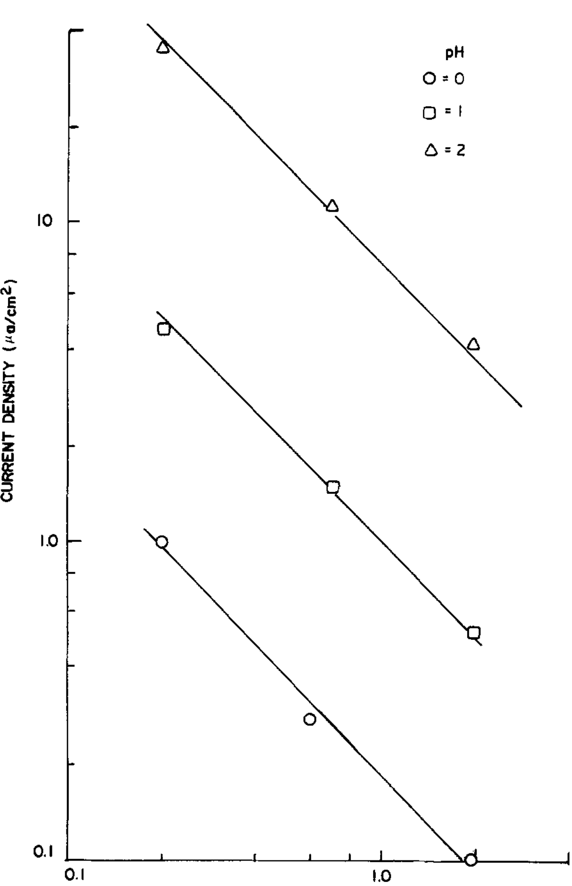

Fig. 7. Reaction order of electrodissolution with respect to Sb(III) concentration. 0.1V.

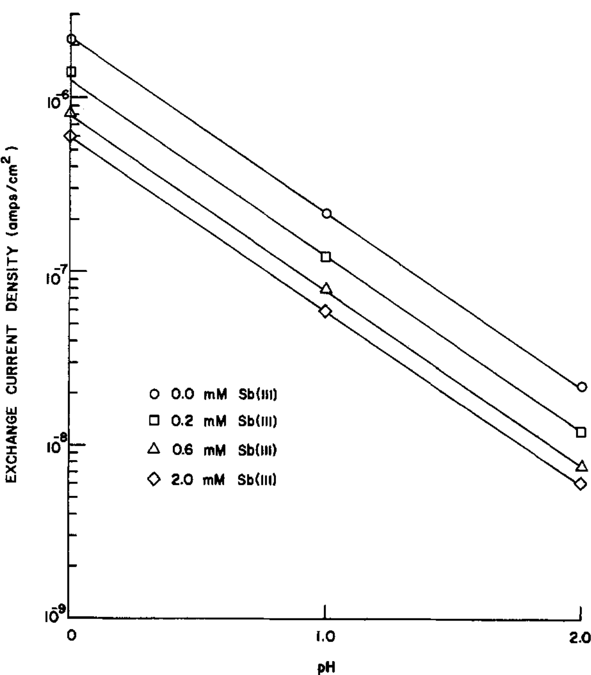

Fig. 8. Exchange current density of Sb/Sb(III) reaction *vs.* *p*H

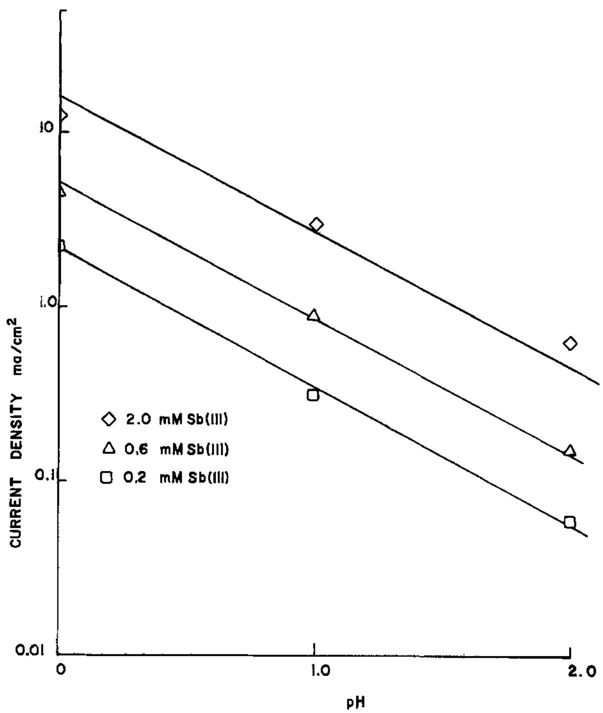

Fig. 9. Reaction order of electrodeposition of Sb(III) with respect to *p*H. —0.4V.

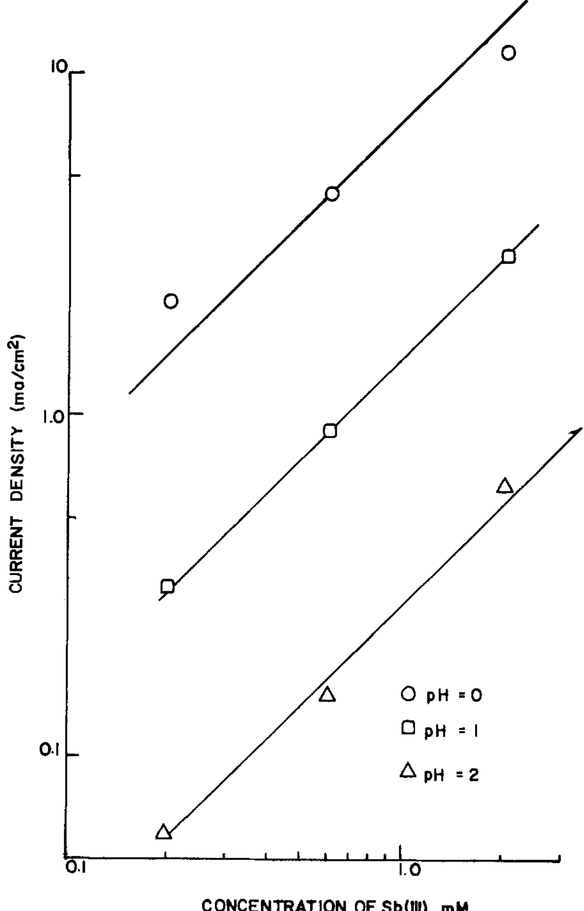

Fig. 10. Reaction order of electrodeposition of Sb(III) with respect to Sb(III) concentration. —0.4V.

and

$$\frac{\partial \log |I_{c,dep}|}{\partial \log [Sb(III)]} = 1 \qquad [16]$$

Thus, the rate of electrodeposition of Sb(III) in acidic chloride solutions can be expressed empirically as

$$I_{c,dep} = \overline{k}_{c,dep} [Sb(III)][H^+] \exp - (\mathbf{F}E/2RT) \qquad [17]$$

Discussion

Thermodynamic considerations.—Pourbaix (1) reports that $HSbO_2$ is the predominant Sb species in aqueous solution between *p*H = 1-11. The Sb/$HSbO_2$ redox reaction

$$Sb + 2H_2O = HSbO_2 + 3H^+ + 3e^- \quad [18]$$

has an equilibrium potential

$$E^e = E^o + (RT/3\mathbf{F}) \ln [HSbO_2] + (RT/\mathbf{F}) \ln [H^+], V \quad [19]$$

where E^o is 0.23V. Equation [14] shows that

$$\frac{\partial E^e}{\partial\, pH} = -0.060V$$

and

$$\frac{\partial E^e}{\partial \log [Sb(III)]} = 0.020V$$

in accord with the experimental results (Eq. [5] and [6]). The values of E^e calculated for Eq. [19] are compared in Table I with the measured rest potentials, E^e_{obs}, and the rest potentials determined by the intersection of the experimental anodic and cathodic Tafel lines, E^e_x. It is seen that the rest potentials were about 50 mV less than the equilibrium potentials calculated from Eq. [19].

If it is assumed that the observed rest potential of antimony in acidic chloride solutions, which can be expressed empirically as

$$E^e = 0.182 - 0.060pH + 0.020 \log [HSbO_2], V \quad [20]$$

is the equilibrium potential of the redox reaction, Eq. [18], the standard electrode potential, E^o, can be determined. These values are presented in Table I. The mean value of E^o is 0.182V. Therefore, ΔG^o (Eq. [18]) = 12.6 kcal/mole and $\Delta G^o_f(HSbO_2)$ = −100.8 kcal/mole. Latimer (15) determined the free energy of formation of $HSbO_2$, $\Delta G^o_f(HSbO_2)$ = −97.5 kcal/mole, from the solubility and the free energy of formation of Sb_2O_3.

The rest potential of antimony in the absence of Sb(III) in the supporting electrolyte can also be attributed to the above redox reaction. The incipient oxide, Sb_2O_3, on the electrode surface forms $HSbO_2$ by the following reaction

$$Sb_2O_3 + H_2O = 2HSbO_2 \quad [21]$$

The concentration of $HSbO_2$ at the electrode-electrolyte interface can be determined from Eq. [20]. These interface concentrations of $HSbO_2$, $[HSbO_2]_i$, for solutions of pH 0, 1, and 2 not containing Sb(III) in the bulk solution, are given in Table I.

Mechanism of the Sb/Sb(III) reaction near the rest potential.—The experimental data indicate that the over-all electrochemical reaction is

$$Sb + 2H_2O = HSbO_2 + 3H^+ + 3e^- \quad [18]$$

To interpret the experimental kinetic data in light of the above over-all reaction, the following mechanism is proposed for the anodic reaction

$$Sb + H_2O = SbOH + H^+ + e \quad [A]$$

$$SbOH + H_2O = Sb(OH)_2 + H^+ + e \quad [B]$$

$$Sb(OH)_2 + Cl^- = Sb(OH)_2Cl + e \quad [C]$$

Table I. Electrochemical parameters

pH	[Sb(III)] mM	E^e	E^e_x (mV vs. SHE)	E^e_{obs} (mV vs. SHE)	E^o_{calc}	$[HSbO_2]_i$ μM
	0		95	80		44
	0.2	156	105	100	179	
0	0.6	166	118	105	183	
	2.0	176	125	115	179	
	0		35	30		40
	0.2	97	50	50	183	
1	0.6	107	60	60	184	
	2.0	117	70	70	183	
	0		−25	−35		35
	0.2	38	−10	−10	182	
2	0.6	48	0	0	183	
	2.0	58	10	15	182	
					avg = 182	

$$Sb(OH)_2Cl + Sb = HSbO_2 + SbCl + H^+ + e \quad [D]$$

$$SbCl + H_2O \rightarrow HSbOHCl \quad [E]$$

$$HSbOHCl + H_2O = Sb(OH)_2 + 2H^+ + Cl^- + e \quad [F]$$

$$Sb(OH)_2 = HSbO_2 + H^+ + e \quad [G]$$

If step [E] is the rate determining step, the rate of electrodissolution of antimony is

$$r_a = k_{a,(E)}\theta_{SbCl} \quad [22]$$

By assuming reaction steps [A], [B], [C], and [D] are at quasi-equilibrium, the surface coverage of $Sb(OH)_2$, $\theta_{Sb(OH)_2} \rightarrow 1$, and the surface coverages of the other surface intermediates SbOH, $Sb(OH)_2Cl$, SbCl, and Sb(OH)Cl, are very small, the kinetic equation for electrodissolution can be obtained from Eq. [22]

$$I_a = \overline{k}_a[OH^-][HSbO_2]^{-1}e^{2\mathbf{F}E/RT} \quad [23]$$

Similarly, if step [E] is the rate determining step for electroreduction, the corresponding rate can be expressed as

$$r_c = k_{c,(E)}\theta_{HSbOHCl} \quad [24]$$

By assuming reaction steps [G] and [F] are at quasi-equilibrium and that surface coverages of the surface intermediates are the same as above, the kinetic equation for electroreduction near the rest potential can be derived from Eq. [24]

$$I_c = \overline{k}_c[H^+]^2e^{-\mathbf{F}E/RT} \quad [25]$$

Thus, Eq. [23] and [25] show that the proposed mechanism for electrodissolution and electroreduction of antimony in acidic chloride solutions near the rest potential is consistent with the experimental results which can be expressed by the empirical relations, Eq. [13] and [14], respectively.

Mechanism of the electrodeposition of Sb(III).—Reaction steps [G] to [A] also comprise the mechanism for the electrodeposition of Sb(III). However, in this case, reaction step [G] is assumed to be the rate determining step. Thus, the rate of electrodeposition can be expressed as

$$r_{c,dep} = k_{c,dep}[HSbO_2][H^+]e^{-\beta\mathbf{F}E/RT} \quad [26]$$

If $\beta = \frac{1}{2}$, the kinetic equation for electrodeposition of Sb(III) can be obtained from Eq. [26]

$$I_{c,dep} = \overline{k}_{c,dep}[HSbO_2][H^+]e^{-\mathbf{F}E/2RT} \quad [27]$$

Equation [27] shows that the proposed mechanism for the electrodeposition of Sb(III) is consistent with the experimental data correlated by the empirical expression, Eq. [17].

On a Model for the Electrocrystallization of Zinc Involving an Autocatalytic Step

I. Epelboin,* M. Ksouri, and R. Wiart

Groupe de Recherche n°4 du C.N.R.S. "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

The model presented involves the autocatalytic step $Zn^{2+} + Zn^{+}_{ads} + e^- \rightleftarrows 2Zn^{+}_{ads}$ and the adsorption at the interface of three species, hydrogen, an anion, and the Zn^{2+} cation which can be complexed. The model is compared with results obtained, after eliminating the influence of convective diffusion, during the electrocrystallization of zinc in: (*i*) an acid sulfate solution, (*ii*) a Leclanché cell electrolyte, and (*iii*) an alkaline zincate solution commonly used in accumulators. The experimental results are in good agreement with the model, although the three electrolytes are markedly different. The model accounts indeed for the variation of the electrocrystallization efficiency with the current, for the appearance of multiple steady states revealed by S-shaped current-potential curves, and for the existence of an inductive faradaic impedance characterized by at least three time-constants.

The study of the electrocrystallization of zinc is now of high interest, mainly because this metal is more and more employed in electrochemical generators. In this paper, basing ourselves on a kinetic study of the electrocrystallization of zinc in several acidic and basic electrolytes (commonly used for industrial purposes), we shall propose a reaction model for the electrocrystallization of this metal in such electrolytic media.

Several mechanisms have been proposed for the electrocrystallization of zinc at acidic *p*H's. According to certain authors (1), the adatoms resulting from the simultaneous transfer of two electrons diffuse on the surface before being incorporated into the crystal lattice. Other authors (2-5) believe on the contrary that charge transfer occurs from the bivalent metal ion Zn^{+2}, which can either be solvated or form a complex in the electrolyte, in two successive monoelectronic steps involving a monovalent intermediate Zn^{+} which can also form complexes with certain anions (4, 5)

$$Zn^{2+} + e^- \rightarrow Zn^{+}$$

$$Zn^{+} + e^- \rightarrow Zn$$

Although the reaction mechanism of the electrocrystallization of zinc is still a matter for discussion, it now seems accepted that the adsorption of hydrogen plays an important role in acidic medium. As a matter of fact, hydrogen evolution takes place within the same potential range as for zinc deposition (6) and it is known that hydrogen is always present in zinc electrodeposited from acid solutions (7). In addition, the polarization curve which characterizes the electrocrystallization of this metal considerably depends on the electrolyte *p*H (5, 8, 9).

In very alkaline medium, the electrolytic deposition of zinc is known to occur mainly from zincate ions $[Zn(OH)_4]^{2-}$ (10-12). In addition, it is generally accepted that charge transfer occurs in several steps, but the mechanism of the over-all reaction

$$[Zn(OH)_4]^{2-} + 2e^- \rightarrow Zn + 4\,OH^-$$

is still under discussion. As a matter of fact, the reaction schemes differ in the number and the nature of the hydroxyl species involved as reaction intermediates (13-16).

In the case of the electrocrystallization of zinc from a Leclanché cell electrolyte, it is known that, when the influence of mass transfer is cancelled out, three different current density values correspond to a given potential value (17). Consequently, these multiple steady states cannot be attributed, as in the case of iron passivation in sulfuric acid medium, to a coupling between mass transfer and heterogeneous reactions (18-20).

The above-mentioned reaction mechanisms of the electrocrystallization of zinc are based only on the idea of elementary interfacial steps associated with simple activation processes; therefore, it is highly probable that they are not sufficient to predict the existence of multiple steady states. Now, in homogeneous kinetics, it is known that the presence of an autocatalytic reaction in the reaction scheme can give rise to instabilities and to continuous oscillations of the system (21) and can be the origin of multiple steady states (22, 23). This is the idea we based ourselves on, and therefore the model of heterogeneous reactions relative to the electrocrystallization of zinc, which is put forward in this paper, involves by analogy an autocatalytic reaction.

In zincate solutions as well as in certain acidic media such as the Leclanché cell electrolyte, it is known that several complexed ions are in chemical equilibria. In the model we shall describe, the heterogeneous reactions which occur at the interface will be only considered, whereas the chemical reactions taking place in

* Electrochemical Society Active Member.

Key words: multiple steady states, faradaic impedance, efficiency, rotating disk electrode, heterogeneous reactions.

the homogeneous solution will be neglected. The good agreement between this model and the experimental results justifies such an approximation.

Theoretical

The model we shall describe is based on a coupling between heterogeneous reactions one of them being autocatalytic, *i.e.*, of the form $A + X \rightleftarrows 2X$, where A and X are reacting species.

Let us consider that the following reactions take place at the interface

$$H^+ + e^- \xrightarrow{K_1} H_{ads} \quad [a]$$

$$H^+ + H_{ads} + e^- \xrightarrow{K_2} H_2 \quad [b]$$

$$Zn^{2+} + Zn^+_{ads} + e^- \underset{K'_3}{\overset{K_3}{\rightleftarrows}} 2Zn^+_{ads} \quad [c]$$

$$Zn^+_{ads} + H_{ads} \xrightarrow{K_4} H^+ + Zn \quad [d]$$

$$Zn^+_{ads} + e^- \xrightarrow{K_5} Zn \quad [e]$$

$$Zn^{2+} + H_{ads} + e^- \xrightarrow{K_6} H_{ads} + Zn^+_{ads} \quad [f]$$

Reaction [a] corresponds to the hydrogen adsorption and reaction [b] to the hydrogen evolution. This evolution the mechanism of which is not well known on zinc may also occur through the recombination $H_{ads} + H_{ads} \rightarrow H_2$, so that reaction [b] must be considered only as a possible path.

The Zn^{2+} ion, which may be either complexed or solvated in the electrolyte, is adsorbed through the autocatalytic reaction [c] and also through reaction [f] which is catalyzed by H_{ads} and this adsorption gives the intermediate Zn^+_{ads}, which may also be complexed. From this intermediate, reduction to the metal finally occurs through the chemical reaction [d] and through the electrochemical reduction [e].

In order to simplify the calculations, the reverse reactions of [a], [b], [d], [e], and [f], which may occur at low cathodic polarizations, have been neglected. As a matter of fact, the coupling of reaction [a] to [f] is sufficient to cause multiple steady states of the interface (24). Reactions [a]-[f] imply that both the intermediate adsorbed Zn^+_{ads} species and the adsorbed hydrogen H_{ads} exist at the interface. Now, it is known that the reactions which lead to the corrosion and to the anodic dissolution of zinc can involve the adsorption of anions such as OH^- (25, 26). That is the reason why we shall also take into account the following reaction which corresponds to the reversible adsorption of an anion A^- the nature of which may depend on the electrolyte

$$Zn + A^- \underset{K_7}{\overset{K'_7}{\rightleftarrows}} ZnA_{ads} + e^- \quad [g]$$

Equations of the system.—Using a method already described in detail in the case of electrocrystallization of nickel and cobalt in acidic medium (27), we first establish the balance of mass and electrons at the interface. To this end, we shall accept the following hypotheses:

1. The three species H_{ads}, Zn^+_{ads}, and ZnA_{ads} adsorb according to the Langmuir isotherm. Their surface concentrations are $\beta_1\theta_1$, $\beta_2\theta_2$, and $\beta_3\theta_3$, respectively; θ_1, θ_2, and θ_3 are the coverage fractions; and β_1, β_2, and β_3 represent the maximal surface concentrations related to a total coverage of the electrode by the corresponding species.

2. The electrochemical rate constants K_i and K'_i vary with the cathodic potential V according to Tafel's law: $K_i = k_i \exp(b_iV)$ for the cathodic reactions and $K'_i = k'_i \exp(-b'_iV)$ for the anodic reactions where $b_i = \alpha_i\mathbf{F}/\mathcal{R}T$ and $b'_i = (1 - \alpha_i)\mathbf{F}/\mathcal{R}T$; α_i, $\mathbf{F}$, $\mathcal{R}$, and T represent the transfer coefficient of the cathodic reaction, the Faraday constant, the ideal gas constant, and the absolute temperature, respectively.

With these hypotheses, the equations accounting for the variation of the system with time, can be written as

$$\beta_1 \frac{d\theta_1}{dt} = A_1(1 - \theta_1 - \theta_2 - \theta_3) - A_2\theta_1 - A_4\theta_1\theta_2 \quad [1]$$

$$\beta_2 \frac{d\theta_2}{dt} = A_6\theta_1 - A_4\theta_1\theta_2 + (A_3 - A_5)\theta_2 - A'_3\theta_2^2 \quad [2]$$

$$\beta_3 \frac{d\theta_3}{dt} = A'_7(1 - \theta_1 - \theta_2 - \theta_3) - A_7\theta_3 \quad [3]$$

$$\frac{J}{\mathbf{F}} = (A_1 - A'_7)(1 - \theta_1 - \theta_2 - \theta_3) + (A_2 + A_6)\theta_1 + (A_3 + A_5)\theta_2 - A'_3\theta_2^2 + A_7\theta_3 \quad [4]$$

where J is the current density and where

$$\left.\begin{array}{ll} A_1 = K_1[H^+] & A_2 = K_2\beta_1[H^+] \\ & A_3 = K_3\beta_2[Zn^{2+}] \\ A'_3 = K'_3\beta_2^2 & A_4 = K_4\beta_1\beta_2 \\ & A_5 = K_5\beta_2 \\ A_6 = K_6\beta_1[Zn^{2+}] & A_7 = K_7\beta_3 \\ & A'_7 = K'_7[A^-] \end{array}\right\} \quad [5]$$

Steady-state current potential curve.—Under steady-state conditions the coverage fractions can be expressed by the following equations

$$\theta_1 = \frac{A_1(1-\gamma)(1-\theta_2)}{A_1(1-\gamma) + A_2 + A_4\theta_2} \quad [6]$$

$$\theta_2^3 + B\theta_2^2 + C\theta_2 + D = 0 \quad [7]$$

$$\theta_3 = \gamma(1 - \theta_1 - \theta_2) \quad [8]$$

where

$$\gamma = \left(1 + \frac{A_7}{A'_7}\right)^{-1} \quad [9]$$

The coefficients in Eq. [7] are

$$B = \frac{A_1(1-\gamma) + A_2}{A_4} - \frac{A_1(1-\gamma) + A_3 - A_5}{A'_3} \quad [10]$$

$$C = \frac{A_1}{A'_3}(1-\gamma)\left(1 + \frac{A_6}{A_4}\right) - (A_3 - A_5)\frac{A_1(1-\gamma) + A_2}{A'_3A_4} \quad [11]$$

$$D = -\frac{A_1A_6}{A'_3A_4}(1-\gamma) \quad [12]$$

Under these conditions, the steady-state current density is

$$J_s = 2\mathbf{F}\,[\theta_2(A_5 + A_4\theta_1) + A_2\theta_1] \quad [13]$$

and the efficiency η of the electrocrystallization is

$$\eta = \frac{\theta_2(A_5 + A_4\theta_1)}{\theta_2(A_5 + A_4\theta_1) + A_2\theta_1} \quad [14]$$

When adequate values are employed for the parameters A_i and b_i, it can be found that there exists a potential range within which Eq. [7] has three real roots between 0 and 1, to which correspond three values of θ_1 and θ_3, also between 0 and 1, and three values of J_s. We then obtain an S-shaped curve for the dependence of current density on the steady-state potential, similar to curve 1 in Fig. 1(a). Curve 1 has been computed using the values for parameters A_i and b_i indicated in the caption to Fig. 1(a). On the other hand, curve 2 in Fig. 1(a), which corresponds to a different set of parameters, is no longer S-shaped. Curve 2 has been

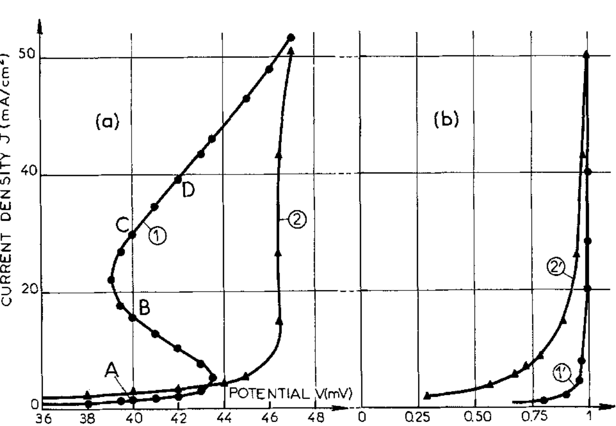

Fig. 1. Simulation of the influence of pH (a), on current density-potential curves with respect to an arbitrary origin, and (b), on current density-deposition efficiency curves. Curves (1) and (1′) have been calculated taking the following values for parameters b_i (in V^{-1}): $b_1 = 19.3$, $b_2 = 29.3$, $b_3 = 33.8$, $b'_3 = 4.8$, $b_5 = 38.6$, $b_6 = 19.3$, $b_7 = 19.3$, $b'_7 = 19.3$ and, at $V = 0$, for parameters A_i (in $cm^{-2}\ sec^{-1}$): $A_1 = 0.16591\ 10^{-6}$, $A_2 = 0.3\ 10^{-9}$, $A_3 = 0.8763\ 10^{-7}$, $A'_3 = 0.1229\ 10^{-6}$, $A_4 = 10^{-7}$, $A_5 = 0.54\ 10^{-7}$, $A_6 = 10^{-10}$, $\gamma = 0.1$. Curves (2) and (2′) have been calculated from the same set of parameters by multiplying A_1 and A_2 by 10.

obtained from curve 1 by multiplying by 10 the parameters A_1 and A_2, which simulates a decrease of a unity in the pH. Consequently, a decrease of the electrolyte pH tends to eliminate the multiple steady states of the interface. Correlatively, we can see from Fig. 1(a) that a decrease in the pH shifts the current-potential curve towards higher cathodic polarizations, which corresponds to an inhibiting effect of adsorbed hydrogen.

Calculation of the coverage fractions shows that when the current increases, θ_1 decreases whereas θ_2 increases, which means that the adsorbed H_{ads} species are progressively replaced by Zn^+_{ads} species. In addition, it was found that the anion coverage θ_3 first increases, and then decreases, with increasing current.

Figure 1(b) shows the variation of the efficiency η of the metal deposition with current. In order to simulate a variation of pH, curves 1′ and 2′ have been computed using the values of the parameters corresponding to curves 1 and 2, respectively. Figure 1(b) reveals that η, which is lower than 1 due to hydrogen evolution, increases with increasing current and tends to 1. In addition, a decrease of a unity in the pH leads to a decrease in η at a given current density.

Electrode impedance.—The faradaic impedance Z_f of the electrode is calculated using a method described elsewhere (27) which consists in linearizing Eq. [1]-[4] for small sinusoidal variations $\Delta V = |\Delta V| \cdot e^{j\omega t}$ from conditions for steady state. We thus obtain Eq. [15]-[18]

$$\frac{1}{Z_f} = \frac{\Delta J}{\Delta V} = \left(\frac{\partial J}{\partial V}\right)_{\theta_i} + \sum_i \left(\frac{\partial J}{\partial \theta_i}\right)_V \cdot \frac{\Delta\theta_i}{\Delta V} \quad [15]$$

$$(j\omega\beta_1 + A_1 + A_2 + A_4\theta_2)\frac{\Delta\theta_1}{\Delta V} + (A_1 + A_4\theta_1)\frac{\Delta\theta_2}{\Delta V} + A_1\frac{\Delta\theta_3}{\Delta V} = A_1b_1(1 - \Sigma\theta_i) - A_2b_2\theta_1 \quad [16]$$

$$(A_4\theta_2 - A_6)\frac{\Delta\theta_1}{\Delta V} + (j\omega\beta_2 + A_4\theta_1 + 2A'_3\theta_2 + A_5 - A_3)\frac{\Delta\theta_2}{\Delta V} = A_6b_6\theta_1 + (A_3b_3 - A_5b_5)\theta_2 + A'_3b'_3\theta_2^2 \quad [17]$$

$$A'_7\frac{\Delta\theta_1}{\Delta V} + A'_7\frac{\Delta\theta_2}{\Delta V} + (A_7 + A'_7 + j\omega\beta_3)\frac{\Delta\theta_3}{\Delta V} = -[A_7b_7\theta_3 + A'_7b'_7(1 - \Sigma\theta_i)] \quad [18]$$

The first term in Eq. [15] corresponds to the transfer resistance R_t and can be calculated from Eq. [4]

$$\frac{1}{R_t} = \left(\frac{\partial J}{\partial V}\right)_{\theta_i} = \mathbf{F}[(A_1b_1 + A'_7b'_7)(1 - \Sigma\theta_i) + (A_2b_2 + A_6b_6)\theta_1 + (A_3b_3 + A_5b_5)\theta_2 + A'_3b'_3\theta_2^2 + A_7b_7\theta_3] \quad [19]$$

Terms $\left(\frac{\partial J}{\partial \theta_i}\right)_V$ are also deduced from Eq. [4]

$$\left(\frac{\partial J}{\partial \theta_1}\right)_V = \mathbf{F}(A_2 + A_6 - A_1 + A'_7) \quad [20]$$

$$\left(\frac{\partial J}{\partial \theta_2}\right)_V = \mathbf{F}(A'_7 + A_3 + A_5 - A_1 - 2A'_3\theta_2) \quad [21]$$

$$\left(\frac{\partial J}{\partial \theta_3}\right)_V = \mathbf{F}(A_7 + A'_7 - A_1) \quad [22]$$

Terms $\Delta\theta_i/\Delta V$ are obtained by solving, using the Cramer method, the linear system formed by Eq. [16], [17], and [18].

By taking account of the electrochemical double-layer capacity C_d considered in parallel with Z_f, we finally obtain the electrode impedance Z

$$\frac{1}{Z} = \frac{1}{Z_f} + jC_d\omega \quad [23]$$

With certain values of the parameters, Z is inductive at low frequencies. As an example, we represented in Fig. 2 the impedance R-jG diagrams calculated at points A, B, and C of curve 1 in Fig. 1(a). These diagrams were obtained using the values of parameters A_i and b_i already employed to establish the current-potential curve, and the values of the parameters A_7, β_1, β_2, β_3, and C_d which are indicated in the caption to Fig. 2. On each diagram, where the parameter is frequency in Hertz, the capacitive semicircle corresponds to the circuit formed by the capacity C_d in parallel with the transfer resistance R_t. At low frequencies, the faradaic impedance Z_f, which is then inductive, prevails and three time-constants corresponding to the relaxation of the coverage fractions θ_1, θ_2, and θ_3, are observed. The limit of Z_f at zero frequency coincides with the polarization resistance R_p, given by the slope of the steady-state current-potential curve. As shown in Fig. 2, this resistance is either positive (points A and C) or negative (point B).

Figure 2 reveals that with the values chosen for the parameters, the three time-constants remain clearly different when current varies. This is not always the case. Thus, by attributing for example to parameters β_1, β_2, and β_3 another set of values (indicated in the caption to Fig. 3), we can see that the shape of the impedance diagram changes when the current varies, and the three time-constants become more or less clearly separated. The diagrams depicted in Fig. 3 have been calculated at points A, B, and D in Fig. 1. We can see that the three inductive loops clearly appear at point B, where the polarization resistance is negative, whereas at points A and D only two inductive loops can be observed.

Experimental

Electrolytic solutions and electrolysis cell.—In order to compare the theoretical model with our experimental results, we chose three types of electrolytes which are commonly used in zinc industry. One of them, (1M Na_2SO_4 + 1.5M $ZnSO_4$) is used in the metallurgy of zinc; the pH of this medium is varied by addition of small amounts of H_2SO_4. To vary the pH of the second acidic medium (2.67M NH_4Cl + 0.72M $ZnCl_2$, which is a Leclanché cell electrolyte), we added small amounts of NH_4OH or of HCl. The third electrolyte, we chose, was an alkaline medium (7M KOH

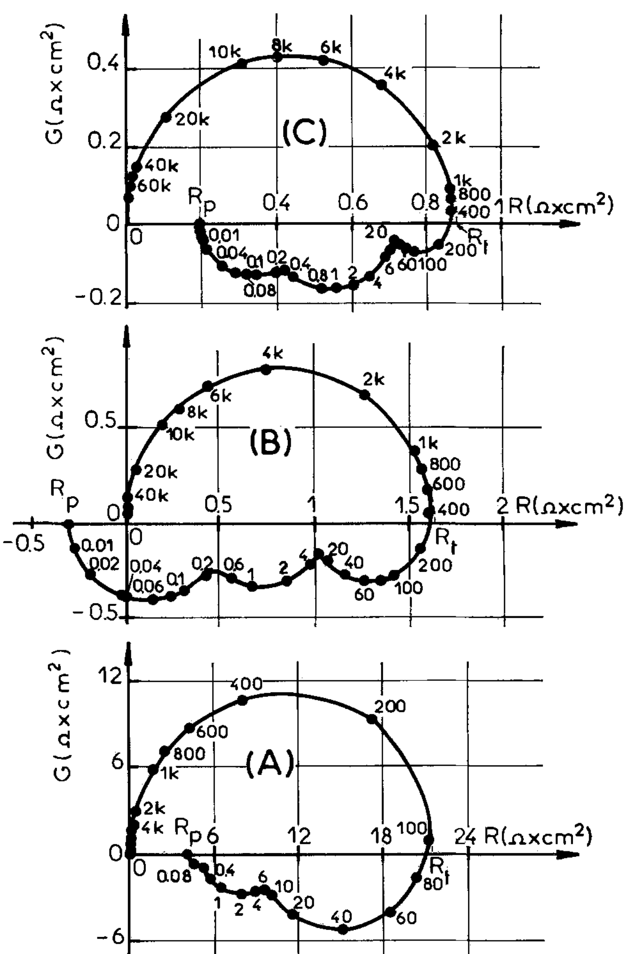

Fig. 2. Impedance diagrams simulated at the same potential (=40 mV) as for points A (3 mA/cm²), B (15.5 mA/cm²), and C (30 mA/cm²) of Fig. 1(a) by introducing the following parameters: C_d = 25μF/cm², β_1 = 1.36 10^{-7} at·g·cm^{-2}, β_2 = 9.067 10^{-11} at·g·cm^{-2}, β_3 = 8.10^{-9} at·g·cm^{-2} and at V = 0: A_7 = 4.62 10^{-9} cm^{-2} sec^{-1}.

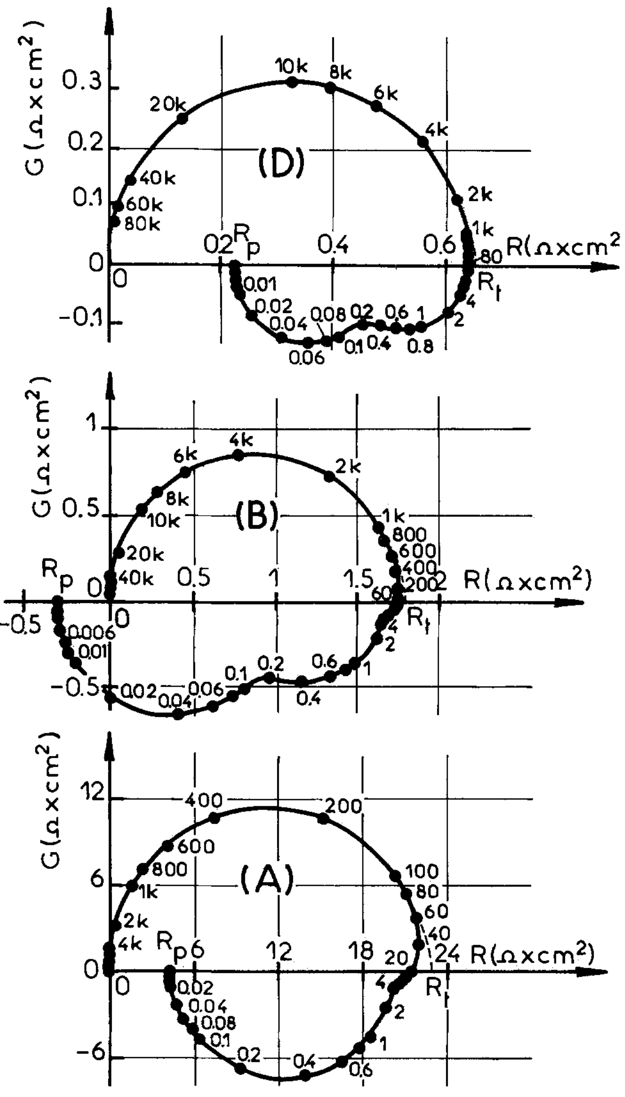

Fig. 3. Impedance diagrams simulated at points A (40 mV, 3 mA/cm²), B (40 mV, 15.5 mA/cm²), and D (42 mV, 39 mA/cm²) of curve 1 in Fig. 1(a) by introducing the following parameters: C_d = 25 μF/cm², β_1 = 2.72 10^{-7} at·g·cm^{-2}, β_2 = 1.904 10^{-8} at·g·cm^{-2}, β_3 = 2.72 10^{-10} at·g·cm^{-2}, and at V = 0: A_7 = 4.62 10^{-9} cm^{-2} sec^{-1}.

+ 0.5 to 1.24M ZnO) employed in accumulators. The most concentrated ZnO solutions were prepared by dilution and cooling of ZnO solutions in 21M KOH previously obtained by heating (14). All the solutions were prepared with twice ion-exchanged water and "Merck" compounds of analytical purity.

During the electrolysis, the electrolyte was maintained at 26° ± 0.5°C. The atmosphere in the cell remained inert by argon bubbling. The anode was generally a cylinder of zinc of high purity (99.999%). In the most acidic solutions ($pH \leq 2$), it was replaced by a platinum gauze in order to avoid chemical attack, and the anodic and cathodic compartments were separated by a sinter wall. Besides, at pH = 5.2, we have verified that the plotting of the current-potential curve and the measurement of the impedance do not depend on the nature of the anode (zinc or platinum) in our experimental conditions. In all cases, the reference electrode was immersed in the electrolyte, and consisted of two compartments separated by fritted-glass. The compartment containing the calomel electrode was filled with a KCl saturated solution, the other one contained the electrolyte of the cell.

Metal deposition was performed on the cross section of a zinc cylinder having an area of 0.28 cm². The wall of the cylinder was isolated from the electrolyte with a coat of a "Specifix" type resin. The electrode was rotated uniformly round a vertical axis and constituted a rotating disk whose speed could range from 0 to 5000 rpm. This speed was always sufficiently high so that the current-potential curve was independent of the rotation speed, *i.e.*, of the transfer by convective diffusion of the chemical species towards the electrode.

In order to obtain a reproducible plotting of the current-potential curve, the electrode surface was polished by emery paper (600 grade) before each deposition, then immersed into a nearly 50% HCl solution for some seconds. It is finally rinsed with twice ion-exchanged water and used immediately after.

Plotting of the current-potential curve and measurement of the impedance.—Considering that during the electrocrystallization of zinc the current varies very rapidly with the cathodic polarization (28, 29), the plotting of the $I(V)$ current-potential curve and the measurement of the impedance have been performed under galvanostatic conditions. Provided that the applied electrolysis current remain sufficiently low, dendritic growth of zinc is avoided (30, 31) and steady-state conditions for the electrocrystallization of the metal are maintained. As a matter of fact, the recording of the electrode-potential as a function of time reveals, after a short-time variation of potential (about 1 min), a plateau which defines the steady-state potential. The lower the current, the more extended the plateau is; particularly, at current lower than 10 mA, this plateau is longer than 15 min. In order to obtain the potential V, the steady-state potential was measured and corrected for ohmic drop (term in R_eI,

where R_e is the resistance of the electrolyte between the cathode and the reference electrode). This ohmic drop term has been determined using an interruptor method (32) and, also, from the high-frequency limit of the impedance. The accuracy was better than 4% and was sufficient to reveal an S-shaped current-potential curve. Each curve, which has been recorded both with increasing and decreasing values of current intensity, shows no hysteresis effects.

The electrode impedance was obtained by superimposing on the direct current a sinusoidal alternating current of small amplitude. Measurements were performed with a correlation transfer function analyzer (Solarton JM 1600 + JX 1639) connected to a wide-band galvanostat built in our laboratory (33). Such a device allows an easy measurement of the electrochemical impedance between 10^{-3} Hz and 50 kHz. As a matter of fact, it is necessary to measure the interface impedance up to its zero-frequency limit in order to reach the elementary steps of any electrochemical reaction (27, 34, 35). Now, most of the impedance measurements relative to a zinc electrode have hitherto been performed at frequencies higher than a few hundred Hertz (1, 36) or at a few ten Hertz (37-40), and therefore they only lead to the double-layer capacity and the transfer resistance.

Efficiency of the electrocrystallization.—To perform a reproducible electrocrystallization of the metal, it is indispensable not to dry the electrode before the electrolysis, and this prohibits any weighing of the electrode before the experiment. The efficiency measurements have therefore been carried out using an electrode constituted by a Johnson-Matthey (99.999%) copper disk kept in electric contact with the zinc rotating cylinder by means of a thermoplastic coat.

After electrolysis, the disk was separated from the zinc cylinder. The amount of the zinc deposit is equal to the difference between the weight of the copper disk covered by the deposit and that of the disk after dissolution of the deposit by 50% HCl. Before each weighing, the disk was rinsed with ethyl acetate, then dried under vacuum. Weighings were performed with a "Cahn Division" electrobalance and allowed us to determine the electrocrystallization efficiency η to better than 0.5%.

Results

The acid sulfate solution.—In Fig. 4(a) we represented the current-potential curves obtained when the influence of mass transfer is eliminated in the case of the acid sulfate solution (1M Na_2SO_4 + 1.5M $ZnSO_4$) at two different pH values. The curves were recorded with currents lower than 10 mA, which is the limit beyond which conditions are no longer those for steady state. At a pH of 4.3, curve 1 is S-shaped, and multiple steady states are observed at potentials between −1.045 and −1.049 V/SCE. At a pH of 2, however, the current-potential curve is single valued and is shifted towards higher cathodic polarizations.

At low cathodic currents, the electrocrystallization efficiency η is an increasing function of current. For example, at pH = 4.3, it can be seen in Fig. 4(b) (curve 1') that the efficiency is equal to 0.97 at 1 mA and that it remains nearly equal to unity as soon as the current becomes higher than 2 mA.

With such an electrolytic medium, the shape of the impedance diagrams is similar to that we already obtained with the Leclanché cell electrolyte (29). At high frequencies, the faradaic impedance is shunted with the double-layer capacity, and the impedance becomes reduced to the electrolyte resistance R_e. At frequencies higher than about 100 Hz, there appears a capacitive loop whose shape is nearly a semicircle and which corresponds to the circuit formed by the double-layer capacity in parallel with the transfer resistance R_t.

At low frequencies, the impedance is inductive and is characterized by three time-constants; Fig. 5 gives an example of the variation of the impedance diagrams ($Z = R - jG$) with current at pH = 4.3. Diagrams (K), (L), and (M) correspond to points K, L, and M on curve 1 in Fig. 4. The electrolyte resistance R_e is taken as origin of the R-axis in the complex plane and is equal here to 9.0 ± 0.1 ohms. Extrapolating the capacitive loop leads to the transfer resistance R_t. This loop also allows us to calculate the double-layer capacity which has an average value of 40 $\mu F/cm^2$ for diagrams (K) and (L), and of 50 $\mu F/cm^2$ for diagram (M). At low frequencies, all three diagrams lead to three well-defined time-constants, since they show clearly three inductive loops. For example, dia-

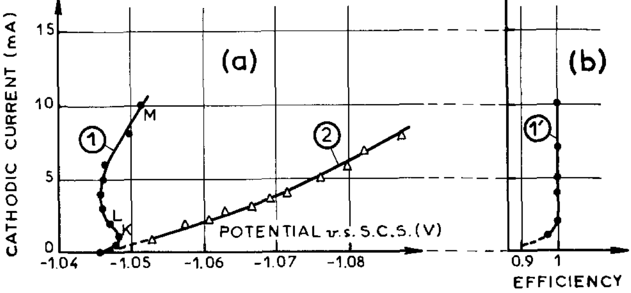

Fig. 4. Influence of the pH on the steady-state current-potential curves (a) and influence of the current on the deposition efficiency (b) for the electrocrystallization of zinc obtained with the following electrolyte: (1M Na_2SO_4 + 1.5M $ZnSO_4$) and a rotating disk electrode (area 0.28 cm^2; rotation speed Ω, 3000 rpm) at 26° ± 0.5°C: Curve 1 and 1', pH = 4.3 ± 0.1; curve 2, pH = 2.0 ± 0.1; K, I = 2 mA, V = −1.0485 V/SCE; L, I = 3 mA, V = −1.047 V/SCE; M, I = 10 mA, V = −1.0515 V/SCE.

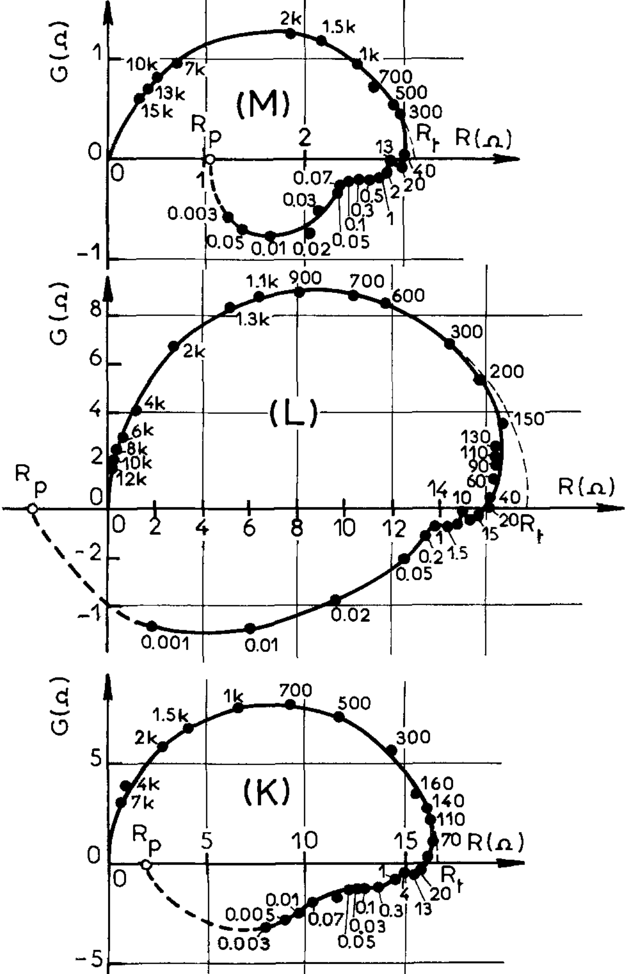

Fig. 5. Complex impedance $Z = R - jG$ corresponding to the electrocrystallization of zinc under the same conditions as for points K, L, and M of curve 1 in Fig. 4 (frequency in Hz).

gram (L) shows three loops located within the 0-1, the 1-10, and the 10-40 Hz frequency ranges approximately. Finally, by extrapolating each diagram at zero frequency, we find the polarization resistance; in particular extrapolation in diagram (L) actually leads to a negative resistance.

The Leclanché cell electrolyte.—With this electrolyte we can determine the current-potential curve under conditions for steady state as long as the current remains lower than about 20 mA. In addition, electrode rotation speeds higher than 1000 rpm no longer have an influence on the current-potential plots. Figure 6(a) shows the current-potential curves obtained at two different values of pH. Curve 1, recorded at $pH = 5.2$, is S-shaped and is characteristic of multiple steady states between -1.057 and -1.059 V/SCE. As in the case of the acid sulfate solution, the multiple steady states disappear when the pH decreases; this is why the curve becomes single valued at $pH = 2$ (curve 2). In addition, contrarily to the case of the acid sulfate solution, a decrease of the pH gives rise to a shift of the current-potential curve towards lower cathodic polarizations.

As in the case of the acid sulfate solution, an increase of the efficiency η is found when the current increases. This variation is illustrated in Fig. 6(b) where the three current-efficiency curves correspond to 5.2, 2, and 0.5 pH values, respectively. It can be seen that for a given current value, the more acid the solution the lower the efficiency. For example, at $pH = 5.2$, η becomes equal to unity as soon as the current exceeds 2 mA (curve 1′), whereas at $pH = 0.5$ it is still equal to 0.97 for a current of 20 mA (curve 3′).

Figure 7 shows the variation of the impedance diagrams with the current at $pH = 5.2$. Diagrams (N), (P), and (Q) correspond to points N, P, and Q on curve 1 in Fig. 6a. In this medium, which is more conducting than the acid sulfate electrolyte, the electrolyte resistance is equal to 2.8 ± 0.2 ohms. The average value of the capacity shunted by the transfer resistance is equal to 50, 40, and 200 $\mu F/cm^2$ at points N, P, and Q, respectively. At low frequencies, impedance becomes inductive, and three relaxation processes are observed. As a matter of fact, three time constants are clearly shown on diagram (P), whereas they are not as well separated on diagrams (N) and (Q) where only two inductive loops can be seen.

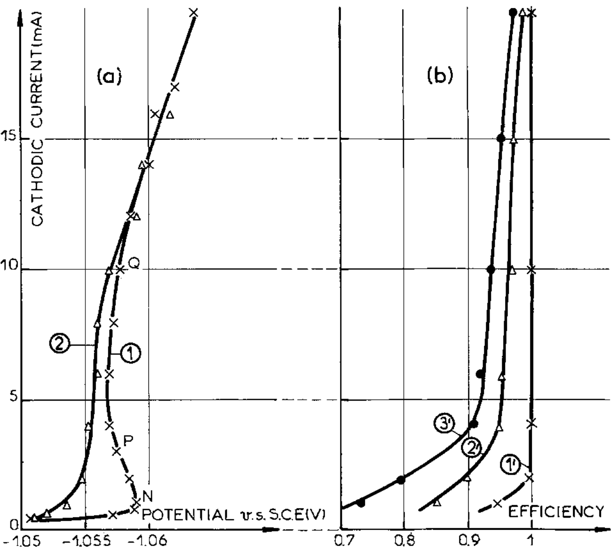

Fig. 6. Influence of the pH (a) on the steady-state current-potential curves, and (b) on the current deposition efficiency curves recorded during the electrocrystallization of zinc from a Leclanché cell electrolyte (0.72M $ZnCl_2$ + 2.67M NH_4Cl) with a rotating disk electrode (area, 0.28 cm^2; rotation speed Ω, 3000 rpm) at 26° ± 0.5°C. Curves 1 and 1′, $pH = 5.2$; curves 2 and 2′, $pH = 2$; curve 3′, $pH = 0.5$. N, $I = 1$ mA, $V = -1.059$ V/SCE; P, $I = 3$ mA, $V = -1.0575$ V/SCE; Q, $I = 10$ mA, $V = -1.0575$ V/SCE.

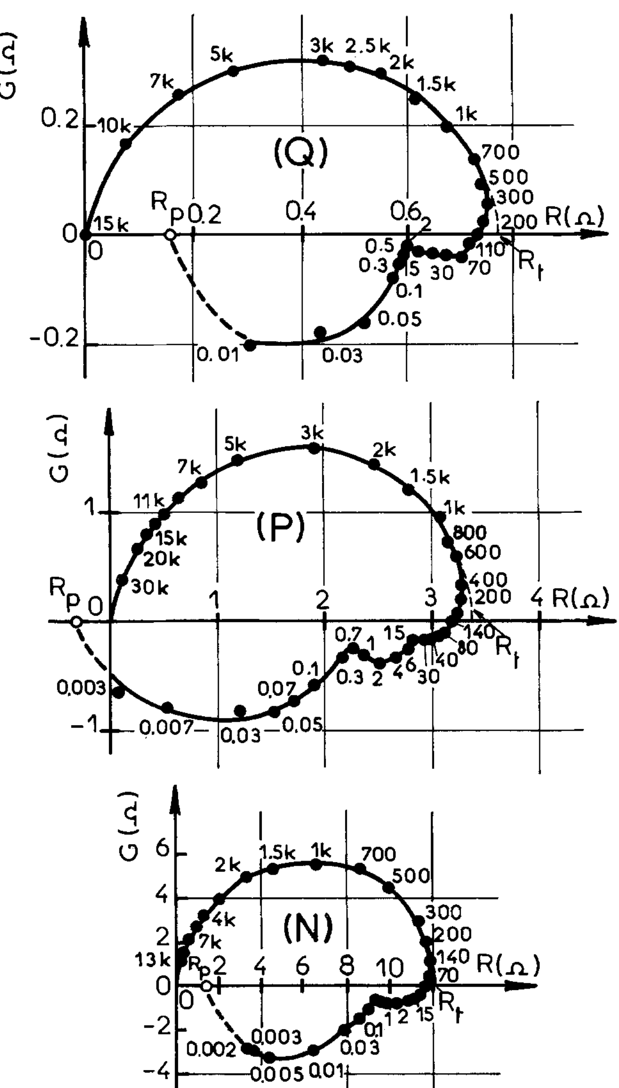

Fig. 7. Complex impedance $Z = R - jG$ corresponding to the electrocrystallization of zinc under the same conditions as for points N, P, and Q on curve 1 in Fig. 6(a) (frequency in Hz).

The alkaline zincate solution.—Curves 1 and 2 in Fig. 8 represent the steady-state current-potential curves obtained after eliminating the influence of mass transfer with the alkaline zincate solution at two different zinc oxide concentrations (1.24 and 0.5M, respectively). These curves reveal that, in alkaline medium like in acidic medium, the electrocrystallization of zinc is markedly activated when the cathodic polarization increases. This activation is more and more important as the concentration of zinc becomes higher in the electrolyte. The dependence of the current-potential curve on concentration is similar to that we observed with the Leclanché cell electrolyte (29).

The impedance diagrams obtained in alkaline medium are also similar to those obtained in acidic medium. As a matter of fact, the mean values of the double-layer capacity as calculated from diagrams (I), (J), and (H) in Fig. 8, which correspond to points I, J, and H, are close to those determined in acidic medium, since they are equal to 40, 60, and 30 $\mu F/cm^2$, respectively. Moreover at low frequencies, three relaxation processes presenting an inductive character are most frequently found here as shown by the three inductive loops which clearly appear on the three diagrams as in the case of acidic solutions. However, the three diagrams reveal a further faradaic time-constant as shown by a fourth loop which is either inductive [diagram (I)], or capacitive [diagram (J) and (H)].

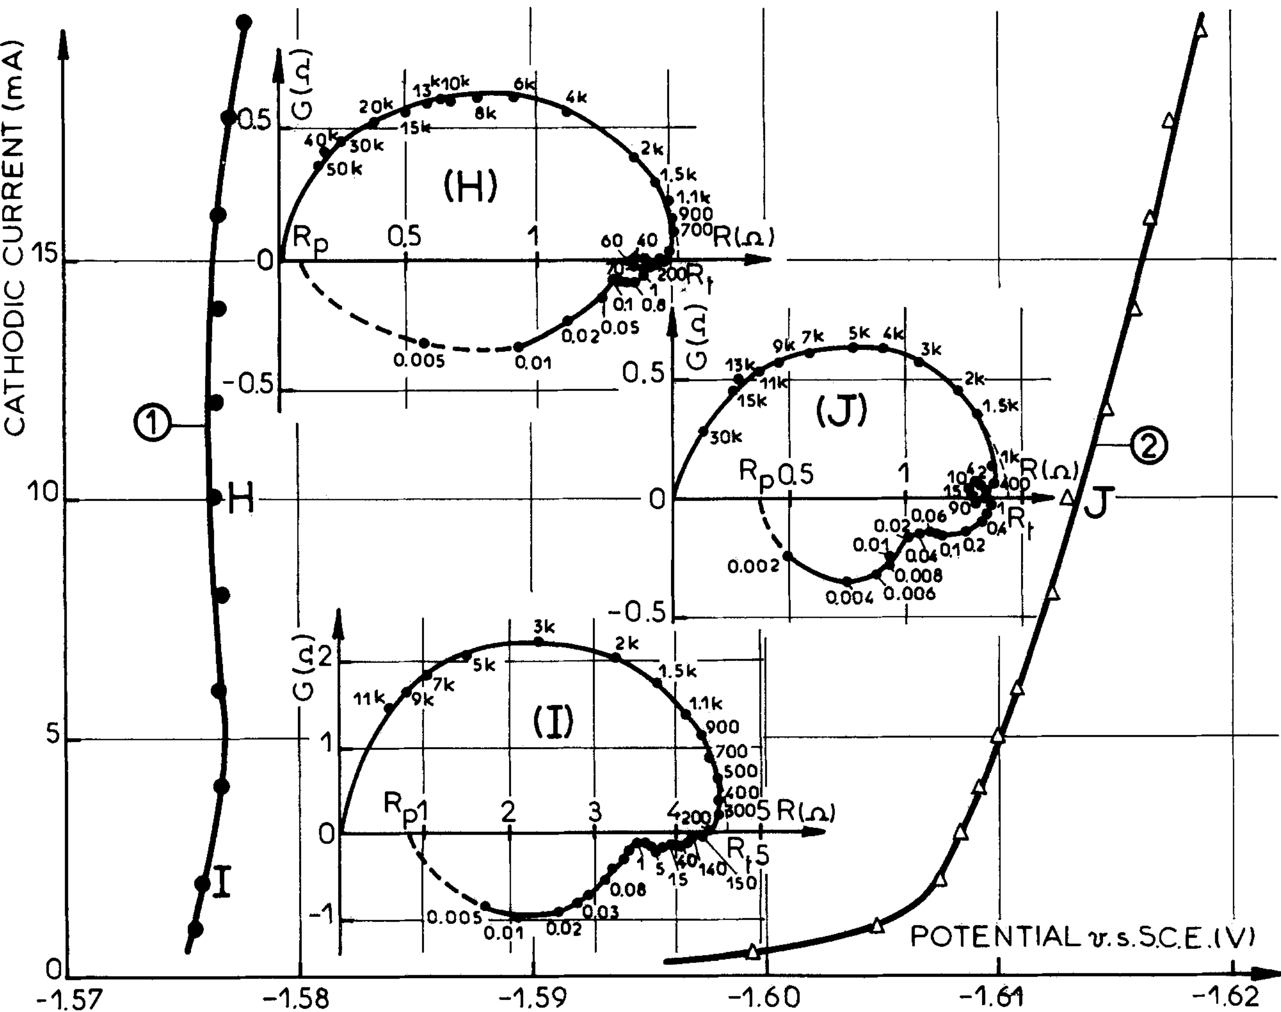

Fig. 8. Influence of the concentration x of ZnO in 7M KOH on the steady-state current-potential curves relative to the electrocrystallization of zinc obtained with a rotating disk electrode (area, 0.28 cm^2) at 26° ± 0.5°C. Curve 1, x = 1.24M, rotation speed Ω = 3000 rpm; curve 2, x = 0.25M; Ω, 5000 rpm. H (10 mA, −1.576 V/SCE); I (2 mA, −1.5755 V/SCE); J (10 mA, −1.613 V/SCE). Impedance diagrams (H), (I), and (J) obtained under the same conditions as for points I, J, and H (frequency in Hz).

Let us finally note that, with such alkaline electrolytes, the efficiency η increases with increasing current in a manner analogous to that in acidic medium. For example, at a zinc oxide concentration of 0.5M, the influence of the current on η is similar to that represented in Fig. 4b: η is equal to 0.98 with a current of 1 mA and becomes equal to unity as soon as the current is higher than 2 mA.

Discussion

Our experimental results have been obtained by: (*i*) eliminating the influence of mass transfer, (*ii*) correcting the current-potential curve for the ohmic drop term related to the electrolyte resistance, and (*iii*) measuring the faradaic impedance of the interface up to very low frequencies. Our experimental results agree, on the whole, with the model proposed and confirm that the mechanism of electrocrystallization is more complicated in alkaline medium than in acidic medium. As a matter of fact, in alkaline medium, the impedance diagrams reveal not only the three inductive loops predicted by the model but also a fourth faradaic time-constant (Fig. 8). This leads us to believe that, in fact, the electrocrystallization of zinc from zincate ions involves at least four adsorbed species at the interface, unless chemical reactions between different complex species are the origin of a further time-constant, as in the case of the cupri-cuprochloride reduction on a platinum electrode (41).

It is evident that the hypotheses upon which our model is based and which concern the behavior of the interface and the mechanism of adsorption, are over simplified. In particular, assimilating the active surface of the electrode with an ideal plane by neglecting all roughness at a macroscopic level as well as at that of atomic steps, constitutes a rough approximation. Now, it is known that the roughness of zinc deposits depends on the current value (42); a change of the roughness with the electrode polarization might therefore influence the values of the time-constants. However, the time-constants measured here, even the highest one, do not seem to be caused by a slow relaxation of the electrode area, as shown by a recent attempt to establish such a relationship in the case of the Cu/$CuSO_4$ interface (43). Therefore, the most probable cause for this time-constant remains a coverage process, at least in the present study.

In addition, the hypotheses accepted here do not take account of the extreme mobility of adsorbed hydrogen and of its penetration into the metal. These approximations might explain why, in order to calculate the magnitude of the highest time-constant measured and compare it to the experimental results, it is necessary to choose a relatively high value of the coefficient β_1, since this value is 100 times as great as the surface concentration $\beta_0 = 2.72 \ 10^{-9}$ at·g·cm^{-2} of the zinc atoms in the compact plane (0001), where the interatomic distance is 2.659Å. On the other hand, the values of β_2 and β_3, relative to Zn_{ads} and ZnA_{ads}, chosen for a good agreement between our model and experiment are close to or lower than β_0.

It is known that the Leclanché cell electrolyte may contain several complex ions (6) but the structure of the charged species that adsorb remains unknown. It

is possible that a change of the pH entails a change of another parameter such as the concentration of Zn^{2+} and A^- ions. Therefore, it is not surprising that a decrease of the pH for such an electrolyte can alter the electrolysis conditions in a way different than the condition which is simulated simply by increasing parameters A_1 and A_2 (Fig. 1a). Thus, with an electrolyte of this type, a decrease of the pH gives rise to a decrease of the cathodic polarizations at low current values (Fig. 6a) which is contrary to the inhibiting effect of hydrogen adsorption predicted by our model. On the other hand, with the acid sulfate solution, which is known to form complexes with zinc much less readily than the Leclanché cell electrolyte, a decrease of the pH actually entails an increase of the inhibiting effect of hydrogen adsorption (Fig. 4a), which is in good agreeement with our model.

Experimentally, it is observed that a decrease in the concentration of zinc in the electrolyte leads to a shift of the steady-state current-potential curve towards more cathodic polarizations, and simultaneously cancels out the multiple steady states. Such an influence was shown up in basic medium (Fig. 8) as well as in acidic medium (29). It is not obvious that this influence can be interpreted in terms of the model described in this paper. As a matter of fact, with the set of parameters used to simulate curve 1 in Fig. 1(a), a decrease of the concentration of Zn^{2+} (corresponding to a decrease of parameters A_3 and A_6) does not tend to make the curve single valued. This might be due to the choice of the relative values of parameters A_i and b_i employed to perform the simulation. Considering the complexity of this type of model, due to the number of parameters and the nonlinearity of the equations of the system, it is very difficult to make sure that a given set of parameters is optimal, even if these parameters can account for the magnitude of the electrolysis current and the components of the faradaic impedance. As a matter of fact, because it is not possible to fit the theoretical parameters to the experimental results and because the nature and the concentration of the Zn^{2+} and A^- ions are not well-known, the values of the quantities K_i and β_i specific of each electrolyte cannot be determined.

Besides, it might be possible that the concentration effect be interpreted more satisfactorily in terms of a different coupling between the heterogeneous reactions. For example, when the reaction [f] is replaced by another one such as $Zn^{2+} + e \rightarrow Zn^+_{ads}$, it becomes possible to simulate the effect of the concentration of zinc in the electrolyte on the steady-state current-potential curves. Unfortunately, with such a new coupling of heterogeneous reactions, an increasing of parameters A_1 and A_2 simulates no more the inhibiting effect of hydrogen adsorption.

The reaction model presented here agrees with certain basic facts relative to the electrocrystallization of zinc experimentally performed with very different electrolytic media, although it presents some imperfections probably due to the relatively simple hypotheses on which it is based.

This model takes account of the influence of hydrogen evolution on the efficiency η of the electrocrystallization of zinc. The variation of η with current, which is observed experimentally, agrees entirely with the theoretical variation depicted in Fig. 1(b). As a matter fact, both in acidic and in alkaline medium, η is actually an increasing function of current [Fig. 6(b)]. In addition, the experimental variation of η with the electrolyte pH is also in good agreement with our theory, since the experimental values confirm that a decrease of the pH leads to a decrease of the efficiency at constant current [Fig. 6(b)].

The model, which involves an autocatalytic interfacial step, also predicts the appearance of multiple steady states of the interface which are revealed by an S-shaped current-potential curve. In agreement with the model, after eliminating the influence of convective diffusion, we showed up such curves with the two acidic electrolytes [Fig. 4(a) and 6(a)] and also with the alkaline medium we investigated (Fig. 8). Moreover, a decrease of the pH, in the case of the Leclanché cell electrolyte as well as the acid sulfate solution, cancels out the multiple steady states, and the current-potential curve becomes single valued [Fig. 4(a) and 6(a)]. This effect is also in good agreement with the behavior predicted by our model.

The shape of the impedance diagrams we obtained experimentally is also in conformity with the theoretical model. In fact, with the two acidic media, and even with the alkaline medium where a further time-constant appears, an inductive impedance can be measured at low frequencies and three time-constants are revealed. These time-constants correspond to the relaxation of the partial coverages of the electrode by the three adsorbed species predicted by the model. Finally, the variation of the impedance diagrams with current in acidic medium also agrees with the model. As a matter of fact, according to the values of the parameters used to simulate the interface impedance, we may predict a more or less clear separation of the three time-constants when the current varies. For example, the variation of the diagrams verified with the Leclanché cell electrolyte supports the simulated variation (Fig. 3). Similarly, the diagrams recorded with the acid sulfate solution (Fig. 5) agree with those calculated (Fig. 2).

Obviously, relaxation experiments are indirect methods for detecting intermediates in electrode reactions and cannot give an unambiguous picture of what intermediates are involved (44). Nevertheless, other experimental results confirm the outstanding role played by the autocatalytic step in the reaction mechanism of the electrocrystallization of zinc. So, it has been shown that the interactions between the interfacial reactions [a] to [f] and the surface diffusion of the Zn^+_{ads} adions can give rise to a distribution of the current-density on the electrode (45). This spatial structuration of the electrode accounts for the appearance of spongeous, compact or dendritic deposits which are observed successively when the current intensity increases, both in acidic and alkaline electrolytes. Consequently, the model is able to make a correlation between the morphology of the electrodeposits and the heterogeneous reactions.

Conclusion

The model for the electrocrystallization of zinc presented in this paper reveals that several species such as hydrogen, certain anions, and Zn^+ are involved. It also allows one to show the outstanding role played in the mechanism of the electrocrystallization of zinc by an autocatalytic step during which a monovalent intermediate is formed. Comparison of the model with the experimental results obtained with three markedly different electrolytes shows up the importance of this autocatalytic step both in acidic and in alkaline medium, despite the probably different nature of the chemical species implied in the three media investigated. As a matter of fact, not only does our model account for the influence of hydrogen adsorption on the efficiency of electrocrystallization, but it also explains the appearance of multiple steady states and the existence of an inductive faradaic impedance characterized by at least three time-constants. This type of model allows one to calculate, from the elementary steps occurring at the interface, parameters such as the electrocrystallization efficiency, the electrolysis current, and the various components of the faradaic impedance. This opens promising outlooks for the study of the electrocrystallization of zinc because it is perhaps possible to relate one or several of the parameters defined here to certain properties specific to the interface.

Manuscript submitted Sept. 17, 1974; revised manuscript received May 27, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

LIST OF SYMBOLS

A_i and A'_i — defined by Eq. [5], $cm^{-2}sec^{-1}$
b_i — $\alpha_i \mathbf{F}/\mathcal{R}T$, V^{-1}
b'_i — $(1 - \alpha_i)\mathbf{F}/\mathcal{R}T$, V^{-1}
B — defined by Eq. [10], dimensionless
C — defined by Eq. [11], dimensionless
C_d — electrochemical double layer capacity, **F**
D — defined by Eq. [12], dimensionless
F — Faraday's constant, 96,500 coulombs/g-equivalent
G — imaginary part of the electrode impedance Z
I — current intensity, A
J — current density, A cm^{-2}
J_s — steady-state current density, A cm^{-2}
j — $\sqrt{-1}$
$(K_i)_{i=1\text{-}3,5\text{-}7}$ — electrochemical rate constants of cathodic reactions
$(K'_i)_{i=3,7}$ — electrochemical rate constants of anodic reactions
K_4 — chemical rate constant, $cm^2\ sec^{-1}$
R — real part of the electrode impedance Z
R_e — electrolyte resistance
R_p — polarization resistance
R_t — transfer resistance
$\mathcal{R}$ — ideal gas constant
T — temperature, °K
t — time, sec
V — cathodic potential, V
Z — electrode impedance
Z_f — faradaic impedance
α_i — transfer coefficient of the cathodic reactions
β_i — maximal surface concentrations, at·g cm^{-2}
γ — defined by Eq. [9], dimensionless
η — efficiency of the electrocrystallization, dimensionless
ω — angular frequency, rad. sec^{-1}
θ_i — coverage fractions

Brief Communication

Calculation of Diffusion Coefficients from Rotating Disk Electrode Data

Stanley Bruckenstein*

Department of Chemistry, State University of New York, Buffalo, New York 14214

Levich's equation (1)

$$i_o = 0.62048\, n\, \mathbf{F}\, \mathrm{Sc}^{-2/3} (\nu\omega)^{1/2} C^b \quad [1]$$

relates the convective-diffusion limiting current density, i_o, to the number of electrons exchanged per molecule of electroactive species, n; to the Faraday constant, $\mathbf{F}$; to the kinematic viscosity, ν; to the rotation speed, ω; to the bulk concentration, C^b; and to the Schmidt number, Sc. In turn, the Schmidt number is a function of ν and the diffusion coefficient, D

$$\mathrm{Sc} = \nu / D \quad [2]$$

Newman (2) derived an improved version of Eq. [1] and obtained

$$i_o = \frac{0.62048\, n\, \mathbf{F}\, \mathrm{Sc}^{-2/3} (\nu\omega)^{1/2} C^b}{1 + a\, \mathrm{Sc}^{-1/3} + b\, \mathrm{Sc}^{-2/3}} \quad [3]$$

where $a = 0.2980$ and $b = 0.14514$. Equation [3] is accurate to 0.1% for $\mathrm{Sc} > 100$ as compared to a numerical treatment of this problem. If we denote D_L as the diffusion coefficient that would be calculated from a set of experimental data using Eq. [1], and D as the diffusion coefficient given by Eq. [3], it follows that

$$D = D_L [1 + a\, \mathrm{Sc}^{-1/3} + b\, \mathrm{Sc}^{-2/3}]^{3/2} \quad [4]$$

From Eq. [4] we see that D_L is always smaller than D. Table I presents the dependence of D/D_L upon Sc.

Table I. D/D_L vs. Schmidt number

D/D_L	1.108	1.100	1.090	1.080	1.070	1.060	1.050	1.040	1.030
Sc	100	124	165	228	330	509	851	1608	3685

Their ratio varies significantly from one over the entire range of Schmidt numbers likely to be encountered. Current practice involves a number of successive approximation techniques and graphical methods (3, 4) for evaluating D using Eq. [3].

The purpose of this note is to demonstrate that no graphical or successive approximation procedure is required when using Newman's rotating disk relationship. A simple algebraic manipulation leads to an analytical solution for Sc, from which D is calculated.

Equation [3] may be written in the form

$$J = \frac{\mathrm{Sc}^{-2/3}}{1 + a\, \mathrm{Sc}^{-1/3} + b\, \mathrm{Sc}^{-2/3}} \quad [5]$$

where

$$J = \frac{i_o}{0.62048\, n\, \mathbf{F} (\omega\nu)^{1/2} C^b} \quad [6]$$

hence

$$J^{-1} = \mathrm{Sc}^{2/3} + a\, \mathrm{Sc}^{1/3} + b \quad [7]$$

which is a quadratic function of $\mathrm{Sc}^{1/3}$. Its solution is

$$\mathrm{Sc}^{1/3} = \left(J^{-1} - b + \frac{a^2}{4} \right)^{1/2} - \frac{a}{2} \quad [8]$$

and the explicit expression for D is

$$D = \nu [(J^{-1} - 0.122939)^{1/2} - 0.1490]^{-3} \quad [9]$$

The evaluation of D using Eq. [9] poses no particular computational problem and will yield a result whose accuracy is limited only by that of Eq. [3].

Thermal Oxidation of Silicon

In Situ Measurement of the Growth Rate Using Ellipsometry

M. A. Hopper,*[,1] R. A. Clarke,[2] and L. Young*

Department of Electrical Engineering, University of British Columbia, Vancouver 8, British Columbia, Canada

ABSTRACT

The formation of oxide films on resistively heated silicon in dry oxygen was followed *in situ* using a computer controlled ellipsometer. For (111) silicon surfaces two distinct growth regions were observed. Our results on the growth above 300Å were found to agree with previous investigations. For films 200Å or less (for which little previous data exist) the kinetics did not obey any existing model of the growth process. The rate of growth of the oxide on (111) surfaces in the 20-200Å region was investigated from 700° to 950°C and at oxygen pressures between 50 and 1200 Torr. A possible explanation of the thin film kinetics is given and its relation to the thick film data is discussed.

Because the production of oxide films on silicon by thermal oxidation is of importance to the semiconductor industry, many studies have been made on various aspects of the process. Despite this, the mechanism is not fully understood, partly because of lack of experimental data. In particular, kinetic data for films less than 300Å in thickness are limited. The purpose of the present work was to help fill this gap by using an automated ellipsometer to observe the growth of the films *in situ* on the hot substrate. Some form of *in situ* film measurement process is desirable for this range of thickness and it turns out that the thermal radiation from the specimen does not interfere with the ellipsometric technique.[3]

Investigation of the thermal oxidation process of silicon in oxygen gas is complicated by its sensitivity to impurities and additions, some of which (H_2O, Cl_2) are important in the production of films for electronic devices. Papers on the oxidation process in pure dry oxygen mostly fall into two categories: those on the formation of the first few layers of oxide, say up to 50Å, mostly at temperatures below 600°C, and those dealing with relatively thick films at relatively high temperatures. Continued growth at any reasonable rate above 300Å requires temperatures above 800°C.

In the thick film region Deal and Grove (1) made a comprehensive study of the thermal oxidation of silicon in dry oxygen and reported that the dependence of the oxide thickness L, on the oxidation time, t, for oxides greater than 230Å, could be described by the equation

$$\frac{L_2}{k_p} + \frac{L}{k_l} = t + \tau \qquad [1]$$

where k_p and k_l are the parabolic and linear rate constants. A relation of the form of Eq. [1] may be interpreted as resulting from a growth mechanism where the oxidizing species diffuses through the oxide film (giving rise to the parabolic term) and reacts with the silicon at the silicon-oxide interface (giving the linear term). Equation [1] could not be applied to the data below 230Å as the growth rate in that region was greater than that predicted by fitting the equation to the thicker film data. In the region below 50Å the growth law is uncertain. Fehlner (2) has shown that his data, and that obtained by earlier investigations [*e.g.* Goodman and Breece (3)] in the very thin film region, can equally well be described by several alternative growth laws. He has, in addition, pointed out the effect of certain impurities on the kinetics in the thin film region.

Only van der Meulen (4) and Smith and Carlan (5) have given thickness-time data over the thickness range 30-300Å. The results given by these authors show significant differences.

Experimental

All oxidations were carried out in a stainless steel vacuum chamber fitted with windows to allow optical probing of the sample surface. Attached to the chamber through the appropriate valves was a sorption pump, a titanium sublimation pump, and two sputter-ion pumps. The system pressure could be reduced routinely to less than 10^{-8} Torr and into the 10^{-10} Torr range if the integral baking heaters were employed. A residual gas analyzer pumped by a separate ion pump was attached to the chamber through a variable leak valve to allow the composition of the oxidizing atmosphere to be monitored during an oxidation. Oxidations were carried out at pressures between 50 and 1200 Torr, these pressures being measured with a calibrated integrated circuit piezoresistive strain gauge (National Semiconductor LX 1603) mounted in a small chamber connected to the oxidation cell by large diameter, high vacuum valve. This gauge has an accuracy of ±10 Torr but changes in pressure of the order of 2 Torr can be detected.

[3] Dr. van der Meulen has informed us of a concurrent project using the same technique in his laboratory.

The silicon substrates used in this investigation were cut from standard 2 in. diameter Monsanto wafers of the appropriate orientation and doping. The samples, in the form of strips 3 cm long and 3 mm wide, were chemically cleaned using the acid-peroxide process (6) and given a HF dip before having platinum contacts sputtered on to each end. The samples were then clamped to the sample holder (made of Inconel sputtered with platinum where the sample made contact with the holder), which was designed to allow the samples to be heated directly. The sample holder was fixed to a high vacuum, high current feedthrough which was fitted onto the oxidation chamber using a bellows connector. This arrangement allowed the position of the sample to be adjusted so that the optical beam probed the center of the sample.

The computer controlled nulling ellipsometer is similar in general construction to that described by Ord and Wills (7). A Rudolph ellipsometer (Type 43603-200E) was modified by the addition of stepping motor drives on the analyzer and polarizer. Anti-backlash gears were used with one motor step giving the optical element a rotation of 0.01°. A difference in design from that of Ord and Wills is that absolute, brush-type shaft encoders were used to read the analyzer and polarizer angles. The light source used with the instrument was a He-Ne laser, wavelength 632.8 nm, and the quarter-wave plate, a Babinet-Soleil compensator, was placed between the polarizer and the input window of the oxidation chamber. The ellipsometer was aligned using the procedure given by Aspnes and Studna (8). The retardation of the compensator was determined by the method of McCrackin (9). An angle of incidence of 70.0° was used for all measurements, this angle being fixed by the cell and the requirement that the light beam pass normally through the oxidation cell windows. Comparison between the two zone average measurements of the ellipsometric parameters of the sample, when measured in and out of the cell (both before and after the oxidation), gave the correction required to adjust measurements made in the cell for any window birefringence. A method for determining the correction has been described by Azzam and Bashara (10).

To ensure a reproducible starting surface before carrying out an oxidation the sample was heated to 1200°C for 30 sec in a vacuum better than 10^{-7} Torr and allowed to cool to room temperature. This procedure removes the thin oxide film that forms on the etched silicon surface on exposure to air. This "flashing" technique was found to be the only reliable way of removing this oxide while maintaining an optically flat surface. The surface prepared in this way did not remain oxide free if left for any extended period at 10^{-8} Torr. From changes in the optical parameters no more than a monolayer of oxygen appeared to react with the surface if left under these conditions for a few hours. Details of an extensive investigation of the optical properties of silicon surfaces and various techniques of oxide removal will be described elsewhere.

Starting with the "clean" flashed surface, ultra high purity Matheson oxygen was admitted to the system until the desired pressure was reached. The sample was then heated by the passage of d-c current from a constant current power supply. During the oxidation the ellipsometer completed a null every 3 sec allowing an almost continuous monitoring of the oxide thickness-time relation to be determined. The temperature of the sample during the oxidation was measured with an optical pyrometer having an effective wavelength of 650 nm. The true sample temperature could be determined from the observed sample temperature by applying the appropriate emissivity correction. As this correction is intimately connected with the optical constants of the silicon it is discussed in the appropriate section below.

Results

Temperature dependence of the optical constants.— During an oxidation, changes in the ellipsometric parameters, Δ and Ψ, for the hot silicon surface were recorded. Analysis of this optical data to obtain the thickness-time relation for oxide growth is possible only if the refractive indices of the silicon ($\bar{n}_s = n_s - ik_s$) and the oxide ($\bar{n}_f = n_f - ik_f$) are known at the oxidation temperature. The temperature dependence of these indices may be estimated for 632.8 nm from certain ellipsometric data.

A silicon surface covered by a film of oxide of thickness such that the value of Δ for the system is close to 180° has certain unique features. For this surface the Ψ value depends mainly on n_s and to a lesser extent on k_f, whereas changes in Δ arise from changes in k_s, n_f and the thickness of the oxide film. By making ellipsometric measurements on at least two samples (each with a different oxide coverage) in this region, changes in n_s with temperature can be distinguished from changes in the other parameters.

Figure 1 shows the ellipsometric results obtained when silicon samples covered with approximately 18Å (a) and 2810Å (b) are heated. This experiment was performed in vacuo to prevent growth of oxide during the course of the measurements. The figure also shows three curves of the Δ-Ψ locus that would be traced out on the growth of a film of index $\bar{n}_f = 1.46 - i0.0$, on a substrate for n_s equal to 3.9, 4.1, and 4.3, respectively. k_s was assumed to be less than 0.2. The experimental points X_1 and X_2 correspond to the same apparent temperature (900°C) as measured by the optical pyrometer. Determination of the actual temperature of the sample at these points requires estimation of the emissivity correction.

The spectral emissivity, e_λ, and the reflectance, R_λ, at a wavelength λ for a medium which absorbs the radiation are related (11) by the expression

$$e_\lambda = 1 - R_\lambda$$

The value of R_λ for an oxide-covered surface depends on the optical constants of the substrate and the thickness and refractive index of the oxide layer (12). R_λ is also related to the ellipsometric parameters Δ and Ψ. Vedam *et al.* (13) have shown that R_λ is not sensitive to oxide coverage, for a film within 100Å of that required to make $\Delta = 180.00°$. This observation, which can be checked by computation of R_λ for the films used to obtain the data shown in Fig. 1, implies that X_1 and X_2 correspond to the same surface temperature. As the effective wavelength of the optical pyrometer is close to the wavelength used with the ellipsometer, the refractive index of the surface, actually n_s, is taken to

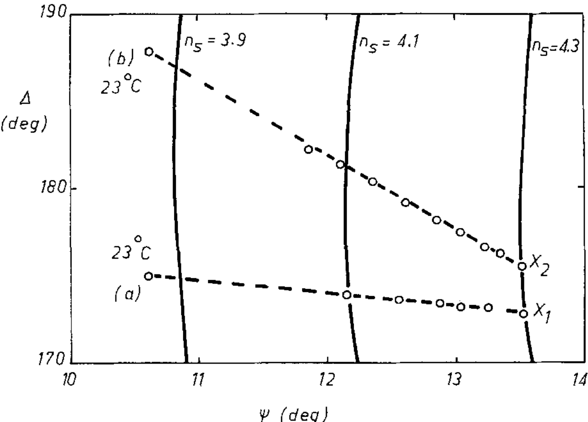

Fig. 1. Changes in Δ and Ψ with temperature for silicon samples covered with (a) 18Å and (b) 2810Å of oxide. Points X_1 and X_2 correspond to a temperature of 930°C. The solid curves show the computed Δ, Ψ locus for the growth of a nonabsorbing film, of index 1.46, on a substrate having the indicated index.

be 4.30 for points X_1 and X_2. Using the relations given by Sato (14) the emissivity at this temperature was estimated to be 0.61. For an observed temperature of 900°C this emissivity implies a true surface temperature of 930°C. The resistivity of the sample was also used to estimate changes in the temperature of the silicon. The data of Fulkerson *et al.* (15) being used to relate temperature and resistance. For temperatures below 700°C where the optical pyrometer cannot be used to probe the surface temperature, resistivity measurements alone were used.

The temperature dependence of n_s, determined from our results given in Fig. 1, is plotted in Fig. 2. The temperature dependence we obtain is the same as that reported by van der Meulen and Hien (16) and is consistent with the infrared results of Lukes (17) and the emissivity measurements of Sato (14). The ellipsometric results of Ibrahim and Bashara (18) are quite different from our results as seen when their data are plotted on Fig. 2 (dashed curve). The differences are probably due to an overestimation of the surface temperature by Ibrahim and Bashara because of their method of measuring temperature (a thermocouple in contact with the substrate heater).

The results given in Fig. 1 show that the value of n_s for silicon for any particular temperature is independent of the thickness of the oxide film on the surface. This result also implies that the absorption coefficient of the oxide, k_f, is negligible at all temperatures used in this work.

The refractive index of the oxide and its temperature dependence can be estimated by performing ellipsometric measurements similar to those described above with the silicon covered by between 1000 and 1800Å of oxide. The value of n_f was found to increase from 1.458 at 23°C to 1.467 at 930°C. These results are in good agreement with published values of the refractive index of fused silica (19).

Other quantities which might change on heating an oxide-covered silicon sample are the film thickness, L, and the absorption coefficient of the substrate, k_s. Changes in these two quantities result in essentially similar changes in Δ and Ψ for a film of any thickness and are thus difficult to determine separately using ellipsometric measurements alone. Assuming that the thermal expansion coefficient of the oxide is identical to that of fused silica (19), and knowing the variation of n_s and n_f with temperature, we can estimate how k_s varies with temperature. In addition the room temperature value of $k_s = 0.023$, as determined by the bulk transmission measurements of Philipp (20), has to be assumed. With these assumptions the value of k_s at 930°C was determined at many oxide thicknesses. A consistent value of 0.172 ± 0.003 was measured for all oxides greater than 100Å. For thinner oxide films the apparent value of k_s decreased with decreasing thickness. At 18Å of oxide k_s has the value of 0.140. The reason for this low value in the thin film region is uncertain but may be associated with the composition of the thin oxide film. Backscattering results of Sigmon *et al.* (21) and ESCA measurements made in this laboratory (to be published) indicate that the oxide close to the silicon-oxide interface is silicon-rich having a composition closer to SiO than SiO_2.

From the thick film measurements the variation of k_s with temperature was determined using the above assumptions. These results are summarized in Fig. 3.

Oxidation kinetics for (111) silicon.—Oxidation of (111) silicon surfaces was investigated at temperatures between 650° and 950°C in oxygen atmospheres between 50 and 1200 Torr. To illustrate the general characteristics that we observe in all our experiments the data for both 870° and 930°C at 760 Torr oxygen are discussed in detail. Under these conditions the oxide grows to 1000Å in a reasonable period of time, and sufficient data can be obtained for films less than 100Å to allow an accurate comparison of the growth rate in the thick and thin film regions to be made.

The thickness for both the 870° and 930°C runs in 760 Torr oxygen increased smoothly with time. The thickness-time data obtained from fitting the ellipsometric measurements for these runs are given in Fig. 4. Only every fifth point obtained is plotted in this figure. Examination of the results summarized by Fig. 4 shows that there is no region of oxide thickness where the oxide grows linearly with time. The data are curved

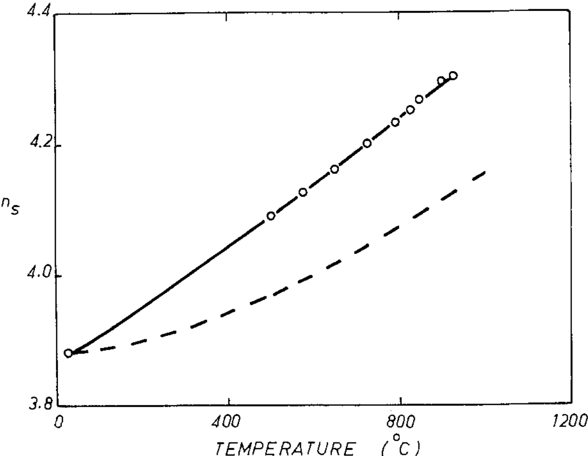

Fig. 2. Temperature dependence of the refractive index of silicon at 632.8 nm. The dashed line shows the relation between n_s and T given by Ibrahim and Bashara (17).

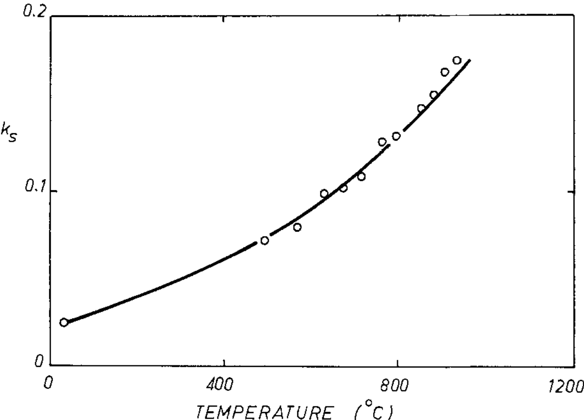

Fig. 3. Temperature dependence of the absorption coefficient of silicon at 632.8 nm. Experimentally estimated values of k_s are plotted as circles.

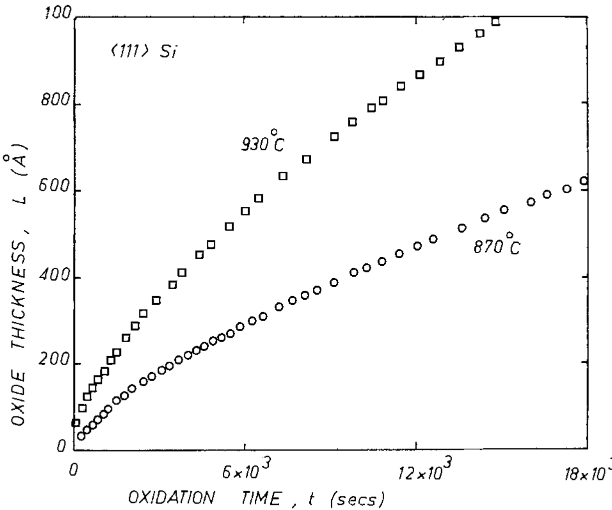

Fig. 4. Thickness-time dependence observed for oxidation of (111) silicon at 870° and 930°C in 760 Torr dry oxygen.

over the whole region investigated. Guided by approaches used by previous workers we attempted to fit the thickness-time data for each run in such a way that meaningful kinetic parameters could be estimated. This procedure proved unsuccessful as no single expression, that can be given a useful kinetic interpretation, was found that adequately describes our data over the whole range of thickness covered. As we have many data points in every thickness range it was decided that the growth rate could be determined directly by appropriate differentiation of the thickness-time data.

To facilitate comparison with theory (see the Discussion section) it is more useful to determine the thickness dependence of the inverse of the growth rate rather than the growth rate itself. For an oxide of thickness, L, at time, t, dt/dL is determined using the following procedure. All data lying within ± 50Å of the point are least squares fitted with an expression of the form $t = \sum_{i=0}^{\lambda} c_i L^i$. Once the values of c_i have been estimated, it is an easy manipulation to determine dt/dL at the point. This procedure is applied over the whole thickness range available.

The thickness dependence of dt/dL obtained using the above procedure, for the oxidation runs summarized by Fig. 4 is given in Fig. 5. The error bars shown on the 870°C data indicate the spread in dt/dL expected, at 100 and 500Å, if the only error involved in obtaining this data was an uncertainty of ± 2°C in the temperature of the substrate. Figure 5 shows dt/dL increasing with increasing oxide coverage for any particular oxidation. The 930°C data show that above 300Å, dt/dL increases linearly with L.

In Fig. 6 the variation of dt/dL with L for films less than 200Å in thickness is plotted. Both the 870° and 930°C data appear linear in this region, the slope in the thin film region being greater than that found for the thicker films. This characteristic behavior was found for all oxidations of (111) silicon carried out in this investigation.

As we have found two distinctly different regions of oxidation behavior, our results for the dependence of the oxide thickness on time for (111) silicon are best summarized in the following manner. Below 200Å the time t is related to the oxide thickness L by the relation

$$t = a_0 + a_1 L + a_2 L^2 \qquad [2]$$

and above 300Å by

$$t = b_0 + b_1 L + b_2 L^2 \qquad [3]$$

For (111) silicon surfaces oxidized in pure dry oxygen at 760 Torr the temperature dependence of the parameters a_0, a_1, and a_2 are given in Table I. In the thick film region b_0, b_1, and b_2 have the values -1222.5 sec, 19.41 sec-Å^{-1}, and 1.86×10^{-2} sec-Å^{-2}, respectively, at 870°C and -634.8 sec, 7.38 sec-Å^{-1}, and 8.4×10^{-3} sec-Å^{-2}, respectively, at 930°C. Our measurements indicate that all these values are independent of the doping of the silicon substrate (0.1 and 10 ohm-cm n-type and 10 ohm-cm p-type samples were tested).

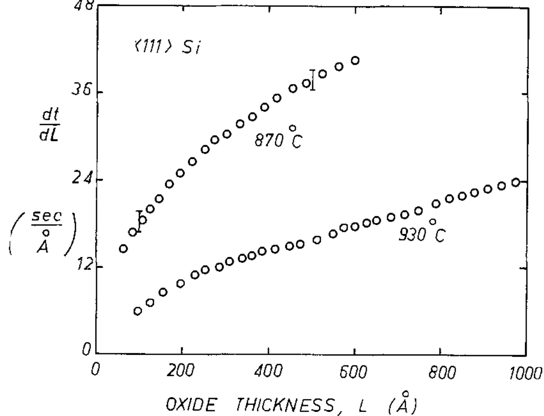

Fig. 5. Dependence of the inverse of the growth rate on oxide thickness for (111) silicon at 870° and 930°C in 760 Torr dry oxygen.

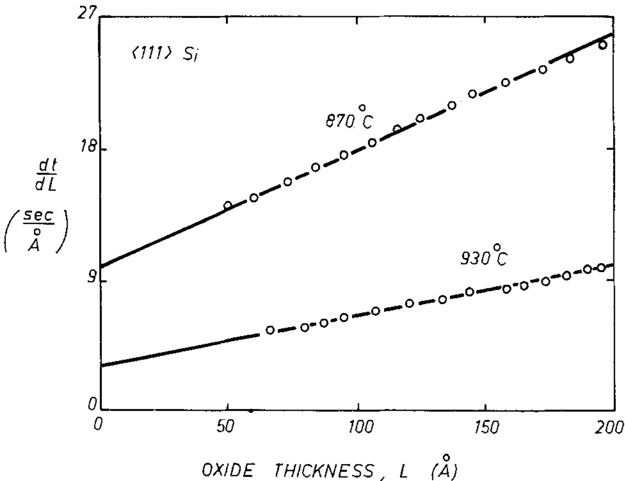

Fig. 6. Increase in the inverse of the growth rate with oxide thickness for films less than 200Å for the data shown in Fig. 5.

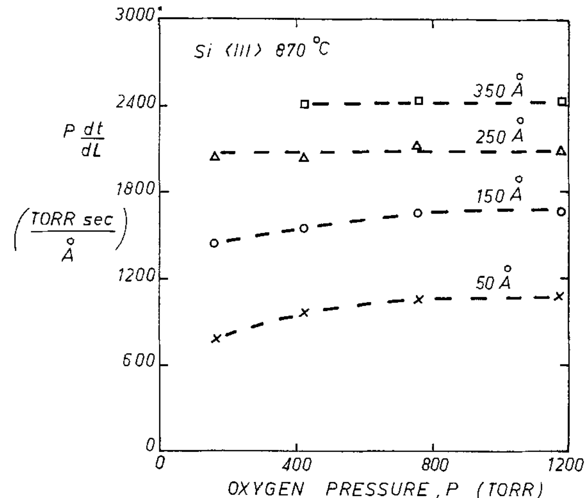

Fig. 7. Dependence of the inverse of the growth rate on oxygen pressure for (111) silicon at 870°C as a function of oxide thickness.

The dependence of the oxidation rate on the pressure of the reactive gas often is of considerable use in elucidating the mechanism of the oxidation reaction. In the present case the pressure dependence is far from simple. To illustrate this pressure dependence it is convenient to plot $p \cdot dt/dL$ (at a particular oxide thickness) against p, where p is the oxygen pressure.

The results obtained for a (111) silicon surface at 870° are presented in this way in Fig. 7. The value of $p \cdot dt/dL$ is independent of pressure above approximately 300Å. Below this thickness $p \cdot dt/dL$ decreases

Table I. Temperature dependence of growth parameters of (111) Si at 760 Torr oxygen for films less than 200Å

Temperature (°C)	a_0 (sec)	a_1 (sec-Å^{-1})	a_2 (sec-Å^{-2})
720	−4386.0	251.7	0.621
780	−576.0	58.5	0.268
832	−216.0	24.0	0.0654
870	−162.6	10.0	0.0396
930	−92.4	3.0	0.0174

with decreasing pressure. The curve fitting parameters in Eq. [2] and [3] were determined where possible at all the pressures investigated. The pressure dependence of a_1 and a_2 was found to be rather complex, these parameters both vary approximately as $p^{0.8}$ at 870°C.

Oxidation of (100) silicon.—Oxide growth on (100) silicon surfaces is far slower than that on the (111) surface. The change of dt/dL with thickness found for an oxidation of a (100) surface at 870°C at a pressure of 760 Torr oxygen is shown in Fig. 8. For comparison the data obtained under similar conditions for the (111) surface is also given in the figure. An almost linear increase in dt/dL, below 200Å, with thickness was found and the parameters a_0, a_1, and a_2 have the values 246.0 sec, 17.1 sec-Å^{-1}, and 0.0806 sec-Å^{-2}, respectively. The second linear section of the dt/dL *vs.* L plot was not observed until the oxide is more than 600Å thick. The temperature dependence of oxidation of (100) surfaces has not been extensively investigated.

Discussion

The rate of growth of an oxide film on silicon during thermal oxidation in dry oxygen was found to show a complicated dependence on oxide thickness. In general agreement with the results of Deal and Grove (1) we find that growth in the thin film region differs markedly from that of thicker films. Deal and Grove applied the linear-parabolic law (Eq. [1]) to (111) silicon oxidation only for oxides thicker than 230Å, growth of thinner films being faster than that predicted by their general formula. They gave no explanation of the thin film kinetics, but the present results on (111) surfaces indicate that the thickness above which the kinetics show the characteristics of the Deal and Grove model varies with temperature and oxygen pressure.

The model of oxidation in the thick film region involves the diffusion of the oxidizing species through the oxide layer and reaction at the silicon oxide interface. These two processes are essentially in series, the over-all rate being controlled by the slowest process at any temperature. Under interface control the growth rate, dL/dt, is constant. If diffusion limits the growth rate $dL/dt \propto L^{-1}$. When the two growth rates are comparable

$$\frac{dt}{dL} = b_1 + 2b_2L \qquad [4]$$

where b_1 and b_2 are related to the rate constants. Equation [4] is the differential form of Eq. [3]. Comparison with Eq. [1] gives $b_1 = 1/k_l$ and $b_2 = 1/k_p$.

For thick oxide films (>300Å) we find dt/dL increases linearly with L. From the slope of dt/dL *vs.* L plots we can estimate a value of k_p. Our results for k_p at 870° and 930°C for 760 Torr oxygen are in good agreement with the data given by Deal and Grove. The pressure dependence of k_p provides information

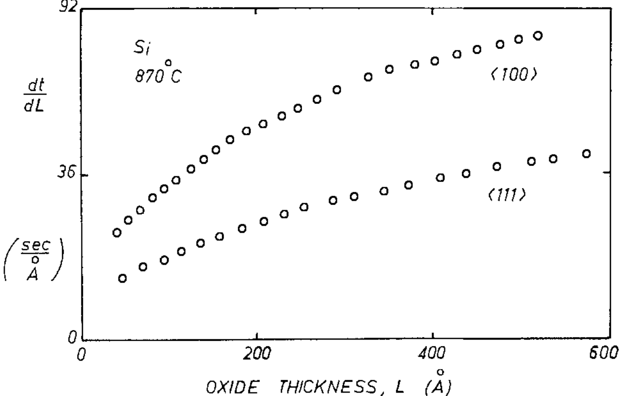

Fig. 8. Comparison of the oxide thickness dependence of the inverse of the growth rate obtained with (111) and (100) silicon at 870°C in 760 Torr oxygen.

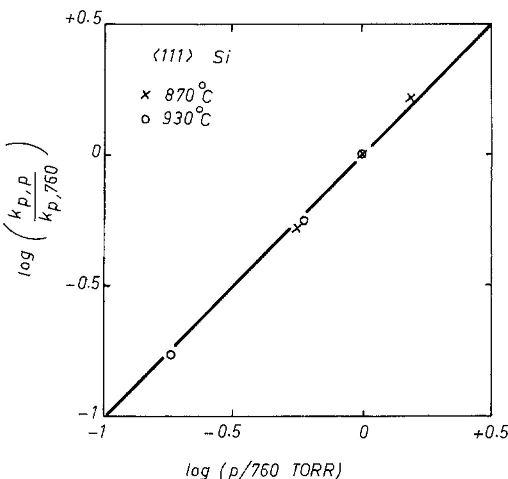

Fig. 9. Pressure dependence of the parabolic rate constant, k_p, estimated from the growth rate for films thicker than 300Å on (111) silicon at 870° and 930°C. For each temperature the value of k_p measured at 760 Torr oxygen ($k_{p,760}$).

on the nature of the diffusing species. Figure 9 shows our results for the pressure dependence of k_p at both 870° and 930°C. In this plot the values of k_p are normalized to the 760 Torr value of this constant for the temperature of interest. This procedure eliminates the effects of temperature allowing the pressure dependence to be compared directly. The data clearly indicate that k_p depends linearly on oxygen pressure. Deal and Grove observed that k_p showed a linear pressure dependence for temperatures above 1000°C. According to Wagner (22) a linear dependence of this parameter, which is related to the diffusion coefficient, implies that the diffusing species is either O_2 or O_2^{n-}.

The linear rate constant, k_l, is apparently known with far less certainty than is k_p. Deal and Grove give values of k_l from 700° to 1200°C. Revesz and Evans (23) in their study of oxidation in dry oxygen above 900°C obtain values of k_l that are quite different from those of Deal and Grove. The activation energy for the k_l data of Revesz and Evans is only half that measured by Deal and Grove. We can estimate the corresponding k_l value from our thick film fits. This gives values of k_l that are smaller than those given by both Deal and Grove and by Revesz and Evans but they show the temperature dependence observed by Deal and Grove. k_l was found not to vary linearly in oxygen pressure, but appears to vary as $p^{0.6}$.

We would question whether the method used to obtain k_l, by simply fitting the thick film data, actually provides a measure of the rate constant of the process occurring at the interface. Admittedly this value is sensitive to surface orientation, as seen by the results given in Fig. 8, which is an indication that it is related to the nature of the surface, but the value obtained may also reflect some influence of the processes that occur in the thin film region.

In his study of thin film oxide growth van der Meulen (4) measured the thickness-time dependence of both (111) and (100) silicon surfaces from 700° to 100°C for thicknesses up to 300Å. Our thickness-time data generally agree with those given by van der Meulen, but the kinetic parameters cannot be compared as he assumed that the thick film value of k_p (given by Deal and Grove) could be applied to the thin film region. Our results do not agree with the measurements of Smith and Carlan (5) and the complex growth they observed is unexplained.

Two explanations of the "fast" growth found for films less than 200Å have been advanced. One, due to Revesz and Evans (23) invokes the existence of a process in which the normal diffusion is effectively

short circuited by "fast" diffusion through "microchannels" that are presumably about 200Å in length. This model should tend to enhance the effect of the linear rate constant in the thin film region which makes dt/dL independent of thickness until the film is sufficiently thick to obey the bulk diffusion model. dt/dL, however, changes more rapidly with thickness for thin films than it does above 300Å. To obtain an adequate description of the thin film process, the Revesz and Evans model needs further development.

To explain some of the results of van der Meulen, Ghez and van der Meulen (24) have proposed a reaction process for the interface oxidation which modifies the form of the linear-parabolic equation. Using the expressions given by Ghez and van der Meulen we have computed the thickness dependence of dt/dL predicted by their assumptions. The effect of this modification to the model of the interface process is to decrease the dependence of dt/dL on L for thinner films, thus contradicting the present experimental results.

The observation that dt/dL increases linearly with L over the range 20-200Å has not been observed previously in silicon. It is interesting to note that the slope of the dt/dL *vs.* L plot for thin films is approximately twice what it is above 300Å at the same temperature, while the intercept for $L = 0$ is half the thick film value.

From Eq. [2] we can write

$$dt/dL = a_1 + 2a_2L$$

Assuming a_1 and a_2 correspond to some physical process, their temperature dependence should be governed by an Arrhenius-type law. Figure 10 shows how a_1 and a_2 vary with $1/T$ for oxidation of (111) silicon at 760 Torr oxygen. These results show that a_1 and a_2 do vary as expected with temperature, but have almost identical activation energy, about 1.95 eV.

The existence of two linear segments in the dt/dL *vs.* L plots, and the behavior of the thin film slope, suggests that oxidation of silicon might be proceeding by two parallel paths. Each process involved would have to have both an interface reaction and a diffusion-limited step. The diffusion coefficients for the two processes, and thus the "parabolic" rate constants, must differ sufficiently that one dominates in the thick film region.

The growth rate for two such parallel independent processes is

$$\frac{dL}{dt} = \left.\frac{dL}{dt}\right|_1 + \left.\frac{dL}{dt}\right|_2$$

where

$$\left.\frac{dL}{dt}\right|_i = \frac{1}{A_i + B_iL}$$

Fig. 10. Temperature dependence of the rate parameters a_1 and a_2 (see text) obtained from oxidation data for film growth below 200Å on (111) silicon in 760 Torr dry oxygen.

The over-all value of dt/dL is thus

$$\frac{dt}{dL} = \frac{A_1A_2 + (B_1A_2 + B_2A_1)L + B_1B_2L^2}{(A_1 + A_2) + (B_1 + B_2)L} \qquad [5]$$

where A_1 and B_1 refer to one process and A_2 and B_2 to the other. For certain values of these parameters Eq. [5] has interesting limiting behavior. For $A_1 \sim A_2$ and $B_1 << B_2$, at thin films where $B_1B_2L^2 << B_2A_1L$ and $B_2L << A_1 + A_2$

$$\frac{dt}{dL} = \frac{A_1A_2}{A_1 + A_2} + \frac{A_1}{A_1 + A_2} \cdot B_2L \qquad [6]$$

and for thick films ($L \to \infty$)

$$dt/dL \propto B_1L$$

Under these assumptions this type of model predicts that dt/dL increases with L and the slope of the dt/dL *vs.* L plot decreases as thickness increases. Under the given assumptions this model might explain the experimental dt/dL *vs.* L plots.

A possible explanation of the two parallel processes arises from the studies of Jorgensen (25). At high temperatures with a porous metal electrode attached to the oxide he has shown the growth rate of the oxide could be increased or decreased by applying a current of appropriate polarity. This experiment, as analyzed by Raleigh (26), indicates that both ionic and molecular motion might be possible in these oxide films. The existence of both ionic and molecular motion diffusion could be the reason for our observed rate data. As the diffusion coefficient and activation energy for these two processes are not necessarily equal, these processes might contribute to the over-all growth rate in a manner similar to that summarized by Eq. [5].

The parallel reaction model described above does explain, at least qualitatively, the over-all shape of the experimental dt/dL *vs.* L plots. No attempt was made to fit the data using a relation having the form of Eq. [5] because some of our results indicate that even this fairly complex model might not be a complete description of the oxidation process.

In the model leading to the growth rate given by Eq. [5] we would expect that the two diffusion processes would be independent of silicon surface orientation. For any oxidation temperature B_1 and B_2 (in Eq. [5]) should thus not differ for (111) and (100) surfaces. The interface parameters, A_1 and A_2, can differ for different orientations but the ratio $A_1(111)/A_1(100)$ and $A_2(111)/A_2(100)$ should be similar. From these observations, and assuming the validity of Eq. [6], the slope of the dt/dL *vs.* L plot (d^2t/dL^2) in the thin film region should be the same for both (111) and (100) surfaces at any fixed temperature. Experimentally we find. at 870°C, that d^2t/dL^2 for a (100) surface is more than twice as large as the corresponding (111) value.

Two other experimental results are difficult to reconcile with the present theory. The first of these is the observation that the kinetic parameters a_1 and a_2 (in the thin film region) both vary approximately as $P^{0.8}$ with oxygen pressure for a (111) surface at 870°C. This result is surprising and it is not obvious how the theory would account for this behavior. Secondly, the results for the temperature dependence of a_1 and a_2 at fixed oxygen pressure are unusual. Both these parameters were found to have the same activation energy.

Despite these unexplained results the mechanism of two parallel competing processes appears to be the only model of the oxidation that can describe the general characteristics of the rate behavior we observe experimentally. Further studies on this model are required to determine whether it can be modified to account for all the experimental results.

Conclusions

The use of an *in situ* technique to follow the rate of growth of an oxide film on silicon in dry oxygen shows

the existence of two distinctly different regions of oxidation behavior. Oxidation appears to proceed in one manner from 20 to approximately 200Å of oxide coverage and in a different manner at greater oxide thicknesses. The thickness above which characteristic thick film behavior is observed was found to vary with temperature, oxygen pressure, and silicon substrate orientation. No earlier kinetic description of the process adequately describes the observed results. A mechanism is proposed that qualitatively accounts for the general behavior of the oxidation kinetics.

Concentration Dependence Curves of Y_2O_2S:Eu

Lyuji Ozawa* and Herbert N. Hersh*

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

Concentration dependence curves for Y_2O_2S:Eu over a range of excitation conditions have been determined for transitions from the $^5D_0$ to various ^7F levels. It is shown that the optimum Eu concentration for the $^5D_0 \rightarrow {}^7F_2$ transition is lower for cathode-ray excitation than for photoexcitation. The absorption spectrum of Y_2O_2S:Eu has also been determined; it suggests the possibility that the change in optimum concentration might be qualitatively explained in terms of a preferential increase in reabsorption of the $^5D_0 \rightarrow {}^7F_2$ emission, however the calculated average population increase does not seem to be large enough to provide quantitative validation.

The optimum activator concentration of cathodoluminescent phosphors is an important practical and theoretical parameter in discussing the efficiency of a phosphor. In rare earth activated phosphors the optimum activator concentration occurs at different values for different types of excitation, *e.g.*, cathode-ray excitation, host photoexcitation, and direct activator photoexcitation (1). For direct photoexcitation of the activator, one can obtain the true concentration dependence curves only where the radiation is weakly absorbed. For phosphors with high optical absorption coefficients, the optimum activator concentration shifts to lower concentrations due to a decrease in penetration depth of the exciting radiation with activator concentration (1). For a wide range of activator concentrations (10^{-6}-10^{-2}), the concentration dependence curves of phosphors excited by cathode-rays are almost identical to the curves obtained for host photoexcitation (because apparently the same mechanisms are involved in the excitation process), except for the fact that the optimum concentration under cathode-ray excitation is always slightly lower (2).

Since host photoexcitation is usually very superficial (penetration depth <1 μm) whereas cathode-ray excitation is deeper (penetration depth >1 μm) and increases with cathode voltage, the smaller value of the optimum concentration for cathodoluminescence has been hypothesized as being due to de-excitation at the surface of the phosphor particles (3-5) or to radiationless sinks which interfere with the energy transfer process between the excited host and activators. In those experiments the total phosphor luminescence has usually been measured rather than the spectral intensities of the individual lines.

The transition probabilities between the states of Eu^{+3} ion in crystal are determined by the selection rules and crystal parameters; they are independent of the energy transfer process involved in the phosphor (such as surface de-excitation and radiationless sink), of excitation conditions, and of phosphor temperature. Thus, for each of the $^5D_0$ luminescences, the same normalized concentration dependence curve is expected.

* Electrochemical Society Active Member.

Key words: absorption, saturation, cathodoluminescence.

However in the present work it has been found that all of the $^5D_0$ concentration dependence curves are not the same. By analyzing the normalized curves and the absorption spectrum one can obtain qualitative intimations of the presence of nonthermal populations of some of the terminal states of the activators.

Experimental

The study was made using Y_2O_2S:Eu phosphor in which conditions are simpler and better defined than in other Eu^{+3} activator phosphors. This arises because of more easily identified luminescence lines which make spectroscopic studies and interpretation relatively simple and unambiguous.

The preparation of the Y_2O_2S:Eu phosphors has been described elsewhere (6). To obtain the concentration dependence curves, the spectral luminescence intensities were measured on powder samples which were packed in planchettes to a depth of 2 mm. For cathodoluminescence measurements, the samples were excited in a demountable cathode-ray apparatus under steady-state excitation conditions at 1 μA beam current per 5 mm spot diameter (= 5 μA/cm). Photoluminescence and excitation spectra were obtained with Perkin-Elmer Fluorescence Spectrometer MPF-3. The host photoexcitation intensity was estimated to be 10 $\mu W/cm^2$ on the phosphor surface. The luminescence intensities of selected lines of Eu^{+3} luminescences were determined from the amplitudes of the recorded luminescence spectra.

Measurements were also made using a 19-in. tricolor television picture tube under pulsed, high excitation conditions. The picture tube was mounted in a production television chassis, which was driven by a signal generator. The anode voltage was a nominal 30 kV. The current densities were calculated from the anode current and beam size (7). To ensure that the phosphor dot on the screen was excited in a regular television scanning mode, *i.e.,* 50 nsec pulses every 1/30 sec, a single scanning line was used. This was accomplished by blanking the entire raster except for one scanning line at the center of the screen. To increase the pumping rate, multiple excitation (8) was used: by shrinking the vertical raster, the raster line separation becomes smaller than the electron beam diameter, and hence each phosphor dot was multiply excited by the scanning beam, with a 60 μsec interval between excitations. The degree of multiple excitation depends on the ratio of the beam diameter to the shrunken raster height.

Results

It was found that there are some differences in the concentration dependence curves of the luminescences from one emitting level to the various lower levels, ^7F, on which the transitions terminate. Concentration dependence curves for the $^5D_0$ emitting level to the ^7F levels are reported here but similar results also occur for the $^5D_1$ and $^5D_2$ levels.

Figure 1A shows the normalized concentration dependence curves for host photoexcited luminescence. Note the difference between the $^7F_2$ curve and the $^7F_1$ and $^7F_0$ curves; the optimum activator concentration, C_{opt}, is 2 mole per cent (m/o) for the $^7F_0$ and $^7F_1$, and 4 m/o for the $^7F_2$. Under cathode-ray excitation, C_{opt} for the $^7F_2$ luminescence shifts to a lower value, 2.5 m/o (Fig. 1B) and the curve closely approaches the $^7F_0$ curve. The $^7F_1$ and $^7F_0$ curves are hardly affected in going from host photoexcitation to cathode-ray excitation.

The $^7F_4$ curves for host photoexcitation (not shown) are close to the $^7F_1$ curves and are only slightly shifted by cathode-ray excitation. The $^7F_3$ curves were not studied because of their weak intensities; the $^7F_5$ and $^7F_6$ luminescences were not in the range of our interest.

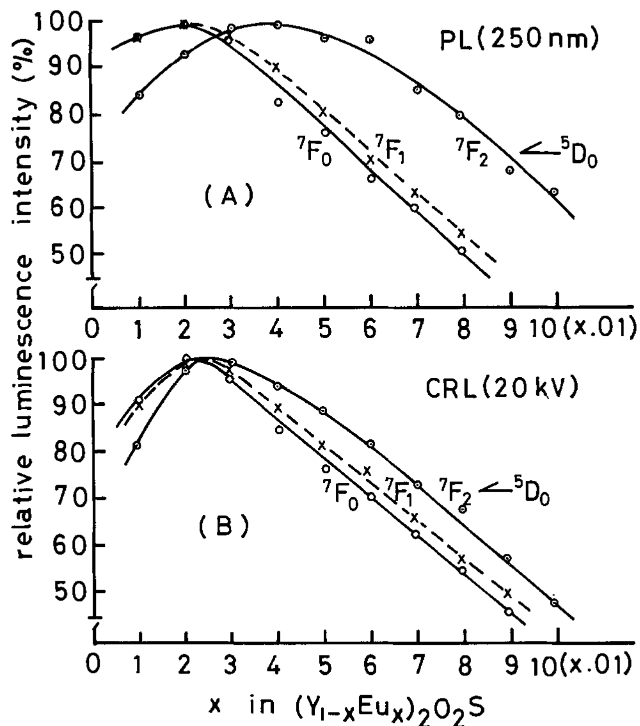

Fig. 1. Concentration dependence curves of $^5D_0 \rightarrow {}^7F_0$, $^7F_1$, and $^7F_2$ luminescences for host photoexcitation (A) and for 20 kV cathode-ray excitation (B).

Discussion

A difference in the maxima of the concentration dependence curves for the $^5D_0 \rightarrow {}^7F_2$ luminescence using cathode-ray and photon excitation has been observed. This shift of C_{opt} with the type of excitation cannot be explained by the bulk-to-surface effect (9) (surface de-excitation of the ^5D emitting state), because this would not differentially affect the individual ^7F terminal levels. Thus, the relative $^5D \rightarrow {}^7F$ luminescence intensities would not be expected to change by this mechanism, and the normalized concentration dependence curves should be the same for each terminal level. Thus another explanation must be sought.

Since the relative luminescence intensities from the $^5D_0$ emitting level should be independent of excitation conditions, the difference may possibly be explained by a quenching mechanism involving the ground ^7F states.

A phenomenon commonly overlooked in cathodoluminescence studies is the possible reabsorption of the luminescence. Reabsorption by the activator is a general phenomenon operating in all phosphors to limit the photon yield (10, 11) but it has not been considered in cathodoluminescence, possibly because no absorption band in the spectral region of the luminescence has been reported in practical phosphors.

Boltzmann population of ^7F states.—The excitation spectrum for the $^5D_0 \rightarrow {}^7F_4$ luminescence at 707 nm is given in Fig. 2. This spectrum is equivalent to the absorption spectrum because the absorptions are weak. Optical absorption only occurs from states populated by electrons. At $T = 0°K$, the $^7F_0$ state is fully populated. At higher temperatures the population is also distributed in the $^7F_1$ to $^7F_6$ states in accordance with the Boltzmann distribution law. The Boltzmann population at room temperature is computed as 0.1 for each $^7F_1$ state and 0.0016 for each $^7F_2$ state. It is clear that at room temperature no absorption will occur from the $^7F_3$ and $^7F_4$ in unexcited phosphors because the Boltzmann populations of these levels are negligible.

At room temperature, strong absorption from the $^7F_0$ and $^7F_1$ state and two weak absorptions from the $^7F_2$ state are seen in Fig. 2. These results indicate

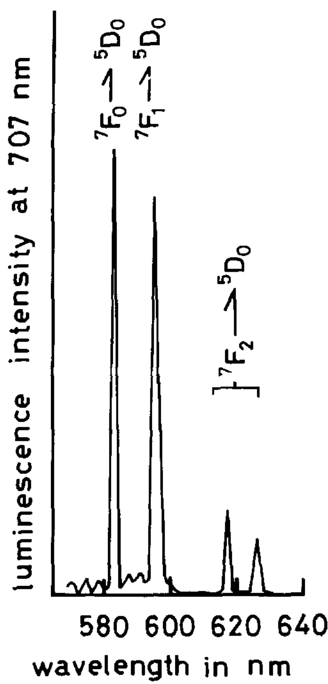

Fig. 2. Excitation spectrum for 707 nm ($^5D_0 \rightarrow {}^7F_4$) luminescence of Y_2O_2S:Eu phosphor.

that reabsorption of the $^5D_0 \rightarrow {}^7F_{0,1,2}$ luminescences exists at room temperature.

The absorption intensity of the $^7F_2$ is about 20% of the intensities for the $^7F_0$ and $^7F_1$, although the Boltzmann population is about 10^{-3} of the $^7F_0$ state. This fact indicates that the absorption coefficient for the $^7F_2 \rightarrow {}^5D_0$ transition is about two orders greater than the coefficient for the $^7F_{0,1} \rightarrow {}^5D_0$ transitions. Because of the low Boltzmann population (0.0016) and high absorption coefficient for the $^7F_2$ state, the absorption from the $^7F_2$ should be more sensitive to the change in the population than the $^7F_1$ and $^7F_0$. This conclusion seems to be supported by the facts that the $^7F_0$ and $^7F_1$ dependence curves (Fig. 1) are not affected in going from photon to cathode-ray excitation and that only the $^7F_2$ curves shift to lower values with cathode-ray excitation.

Cathode-ray pumped population.—One may compute the average cathode-ray (CR) pumped population as follows: Assuming that the penetration depth of 20 kV electrons is 6 μm (6×10^{-4} cm) (12), the excitation effective volume, Δ, of the phosphor particles is calculated to be 6×10^{-4} cm^3 for a circular homogeneous beam of 0.5 cm diameter. The Eu^{+3} ions/Δ are calculated as

$$\frac{\Delta x\,(\text{density of phosphor}) \times N \times (\text{Eu ions in molecule})}{\text{molecular weight}} \quad [1]$$

where N is Avogadro's number. For 5 m/o europium this corresponds to 7.4×10^{17} ions/Δ. Taking the center-of-gravity of five $^7F_2$ states as 1000 cm^{-1} above the ground state, the fractional thermal excitation at room temperature ($T = 300°K$, $kT = 206$ cm^{-1}) is 0.0078. Because the population quickly thermalizes among the five $^7F_2$ states, the fraction for each $^7F_2$ state is $0.0078/5 = 0.0016$. Thus, the thermal population of each $^7F_2$ state is

$$7.4 \times 10^{17} \times 0.0016 = 1.2 \times 10^{15}\ \text{Eu}^{+3}\ \text{ions}/\Delta \quad [2]$$

Under steady-state CR excitation, the rate equation of the population for each $^7F_2$ state is

$$\frac{dn}{dt} = \dot{N} - n/\tau = 0 \quad [3]$$

Therefore, the average population, n, for the average lifetime τ of the $^7F_2$ state is given by

$$n = \dot{N}\tau \quad [4]$$

where $\dot{N}$ is the average number of $^5D_0 \rightarrow {}^7F_2$ luminescence transitions per second as calculated by Eq. [5]

$$\dot{N} = \frac{(\text{input power}) \times (\text{power efficiency of luminescence})}{\text{photon energy of luminescence}} \quad [5]$$

The input power for steady-state CR excitation of 20 kV, 5 μA/cm^2 is 0.1 W/Δ. Assuming that the luminescence photon energy is 2 eV and the efficiency of the $^5D_0 \rightarrow {}^7F_2$ transitions for the CR excitation is 0.06 W/W, one can get 1.8×10^{16} transitions/Δ-sec. Each downward transition populates one of the $^7F_2$ states. This excess population would thermalize very quickly among the five $^7F_2$ states, so that $\dot{N}$ for each $^7F_2$ state would be

$$\dot{N} = \frac{1.8 \times 10^{16}}{5} 3.6 \times 10^{15}\ \text{Eu}^{+3}\ \text{ions}/\Delta\text{-sec} \quad [6]$$

Unfortunately we could not measure the lifetime of the ^7F states. The reported decay times for the ^5D luminescence under CR excitation are shorter in going to order of the $^5D_0$, $^5D_1$, and $^5D_2$ (13) and the decay time of the $^5D_0$ luminescence is about 500 μsec (13, 14). If τ for the $^7F_2$ is about 100 μsec (10^{-4} sec), the CR pumped population is computed as

$$\dot{N}\tau = 3.6 \times 10^{15} \times 10^{-4} = 3.6 \times 10^{11}\ \text{Eu}^{+3}\ \text{ions}/\Delta \quad [7]$$

Thus, the computed CR population (10^{11} ions) is too small to perturb the thermal population (10^{15} ions), even if the calculation is made for one-tenth the electron penetration depth (5).

The CR pumped population can be increased by increasing the beam current density. An increase in the steady-state beam current density results in a significant increase in phosphor temperature. We have measured the luminescence intensities from the phosphor screen of a 19-in. color television picture tube (30 kV) as a function of beam current density (to avoid a temperature increase). The results obtained with two extremes of the pulsed excitation (30 Hz and 15 kHz) on the picture tube screen are shown in Fig. 3.

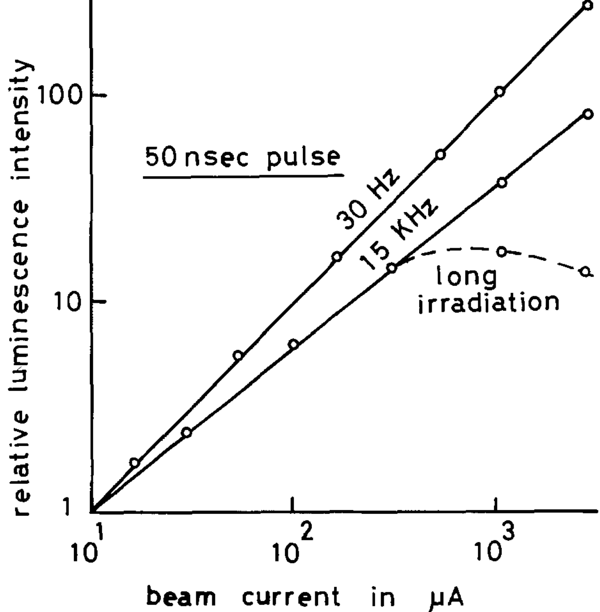

Fig. 3. Relative $^5D_0$-$^7F_2$ luminescence intensities of Y_2O_2S:Eu phosphor on 19-in. tricolor television picture tube screen as a function of beam current. The phosphor dots on the screen are excited by 50 nsec pulses at 1/30 Hz and 15 kHz, respectively. Quenching (dashed lines) only occurs for long CR irradiation under multiple excitation conditions at high beam current.

The phosphor dot (0.3 mm diameter) in the 19-in. television picture tube is instantaneously excited for 50 nsec by a single horizontal scan. The instantaneous excitation intensity for 50 mA/cm^2 corresponds to 1500 W/Δ or 6 × 10^{15} Eu^{+3} ions pumped in each $^7F_2$ state/Δ under steady-state excitation. When the phosphor screen was excited by 50 nsec pulses every 1/30 sec using a single scanning line, all of the luminescence intensities increased linearly with beam current up to 3 mA [estimated as 70 mA/cm^2 current density on the phosphor screen (7)]. No change in the relative $^5D_0$ luminescence intensities was observed. Under multiple excitation, sublinear response (0.9 slope for the $^5D_0$ luminescence) and quenching at high beam current (dashed lines) for long CR irradiation were observed. No change in the relative $^5D_0$ luminescence intensities was observed in the straight line region. The quenching was enhanced on increasing the degree of multiple excitation and the CR irradiation time. Therefore, the quenching is related to reabsorption of the luminescence because the relative intensities of the $^5D_0$ luminescence were markedly changed in this region; the $^7F_2$ was quenched more than the $^7F_1$. Longer CR irradiation with a short pulse interval heats up the phosphor temperature, resulting in an increase in the thermal population of the $^7F_1$ and $^7F_2$ states.

The temperature rise for continuous CR excitation in this study (20 kV, 5 μA/cm^2) is too small to change the thermal population of the $^7F_2$ state. The phosphor temperature rise during the steady CR excitation can be determined accurately by measuring the $^5D_1/^5D_0$ luminescence intensity ratio of Y_2O_2S:Eu phosphor (15). Because this ratio measurement uses an internal reference method, the accuracy is high enough to determine the temperature difference within a few degrees centigrade. For the measurement it is convenient to select two luminescence lines located at 583 and 587 nm which are $^5D_0 \rightarrow {}^7F_0$ and $^5D_1 \rightarrow {}^7F_3$ transitions, respectively (15). No change in the ratio was detected for steady CR excitation in this study. Thus, the change in the $^7F_2$ curves is also hard to attribute to a thermal effect.

Concluding Remarks

We have shown that the concentration dependence curves of Y_2O_2S:Eu depend on the mode of excitation. The absorption spectrum (Fig. 2) shows the existence of reabsorption of luminescence. However, our calculations allow one to conclude that the decrease of the optimum activator concentration of the $^5D_0 \rightarrow {}^7F_2$ luminescence in going from host photoexcitation to steady-state cathode-ray excitation (Fig. 1) cannot be attributed to the increase in absorption due to the change in the average population in the $^7F_2$ state caused by CR pumping or temperature rise. It may be necessary to consider the instantaneous population, or otherwise to clarify the energy transfer mechanism from host to activators, before one can calculate theoretical concentration dependence curves for host excitation.

Acknowledgment

The authors wish to thank Dr. M. Stevens for his cathodoluminescence measurements on the picture tube screen and Ms. H. Stanczyk for her assistance in preparation of samples.

Low Carbon Contamination of Epitaxial Germanium Films Produced by Pyrolysis of Alkyl Germanium Compounds

Y. Avigal,[1] D. Itzhak, and M. Schieber[2]

Department of Materials Science, School of Applied Science and Technology, Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

Thin films of Ge produced by the pyrolysis of alkyl germanium tetramethyl germanium and tetraethyl germanium compounds have been studied for their rates of deposition, crystallinity, and carbon contamination. The pyrolysis reaction has been found to be of first order, and the activation energies have been found to vary with concentration of the alkyl germanium compound between the limits of 25-30 kcal/mole for both tetramethyl and tetraethyl germanium. The morphology and crystallinity of the films vary with the chemical and crystalline structure of the substrate. Good quality and uniform films are produced on monocrystalline germanium substrates preetched *in situ* with HCl gas. The carbon contamination is found to be strongly dependent on the substrate material, and it varies between 25 ppm for germanium and 200-50,000 ppm for tungsten substrates.

Pyrolysis and oxidation of alkyl silicon compounds for the chemical vapor deposition of SiC or SiO_2 have been studied recently in our laboratories (1, 2). The experiments have shown that the pyrolytically dissociated silicon tends to combine with the carbon from the alkyl radical to form SiC, and it is also contaminated with large amounts [up to about 7 weight per cent (w/o)] of free carbon (1, 3). The tendency to form SiC is attributed to the larger chemical affinity of Si for C. Since GeC is known to be unstable, it is expected that the pyrolysis of alkyl germanium compounds would lead to the formation of pure germanium. It was therefore considered interesting to study the expitaxy of germanium by pyrolysis of alkyl germanium compounds and to compare the carbon content of the resulting deposits with the carbon found in films grown by pyrolysis of alkyl silicon compounds (1, 3). The rates of deposition and the morphology of the grown films were also studied and are reported here.

Homoepitaxial thin films of germanium are usually deposited by hydrogen reduction of $GeCl_4$ (4-7) or by the pyrolysis of GeH_4 (8-12). Chemical transport with iodine is limited to close systems only, and direct vacuum sublimation (13-15) is limited by the high cost of the equipment and the difficulty of controlling the deposition process. Heteroepitaxial films of germanium on various substrates are usually deposited by the pyrolysis of GeH_4 (16-20). The main disadvantages of $GeCl_4$ and GeH_4 as sources for deposition are their high chemical reactivity at room temperature, which makes them highly corrosive ($GeCl_4$) or flammable (GeH_4) and also causes difficulties with the purification process (21). Alkyl germanium compounds have the advantages of being noncorrosive, nonhazardous, and easy to purify.

Experimental Procedure and Rates of Deposition

The alkyl germanium compounds used in the present investigation have been tetramethyl germanium $(CH_3)_4Ge$ (TMG) and tetraethyl germanium $(C_2H_5)_4Ge$ (TEG) purchased from Alpha Chemicals. The vapor pressure of these compounds is not available from the literature and, therefore, has been determined dynamically for TEG and statically for TMG (1). The results are shown in Fig. 1. The substrates used for crystallinity studies of epitaxy were single crystals of (111) Ge whereas substrates of polycrystalline tungsten were used for studies of deposition rates and carbon contamination. The diluent gases were high purity H_2 and He (Matheson) which was further purified *in situ* in one laboratory (1).

The experimental procedure of deposition is similar to the one used for SiC and is described elsewhere (1, 3). The relations of deposition rates and deposition parameters have been studied by measuring the rate of increase in weight, R, as a function of the tungsten substrate temperature (Fig. 2 and 3) and the molar fraction of the alkyl germanium which was regulated either by the flow rate through the saturator or by its temperature (Fig. 4 and 5). It can be seen from Fig. 2 and 3 that for both TMG and TEG a measurable deposition rate starts at about 700°C, increases with the temperature of the substrate, and tends to stay constant at around 1000°C. While in the case of TMG hydrogen was used exclusively as the gas diluent, in the case of TEG depositions, either hydrogen or helium were used as the gas diluent. Figure 3 shows that R is unchanged by the gas diluent, a behavior which is different from the case of the alkyl silanes (1) where R is strongly dependent on whether the diluter is H_2 or He.

The different behavior between the pyrolysis of alkyl silane and alkyl germanium compounds in the presence of H_2 is an indication that H_2 does not participate chemically in the deposition of the films of Ge. In comparing the units of Fig. 2 and 3 it is interesting to note that R for TMG is much larger than R for TEG

at about the same conditions of deposition. The linear relations of Fig. 4 and 5 indicate a first order for the over-all reaction of deposition. An Arrhenius plot of log R *vs.* T^{-1} is shown in Fig. 6 for both TMG and

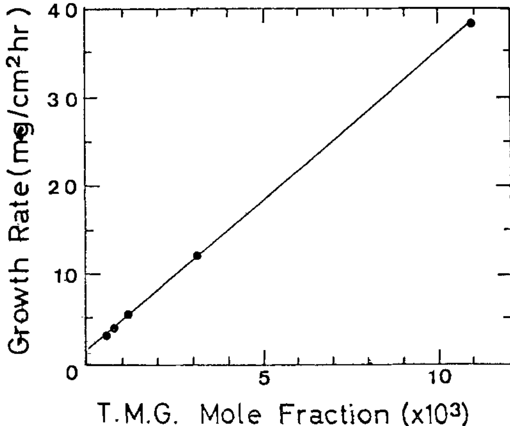

Fig. 5. Growth rate vs. mole fraction of TMG in H_2. All experiments were performed at a constant temperature of 850°C of the tungsten substrates. The total gas flow is 1.5 liters/min.

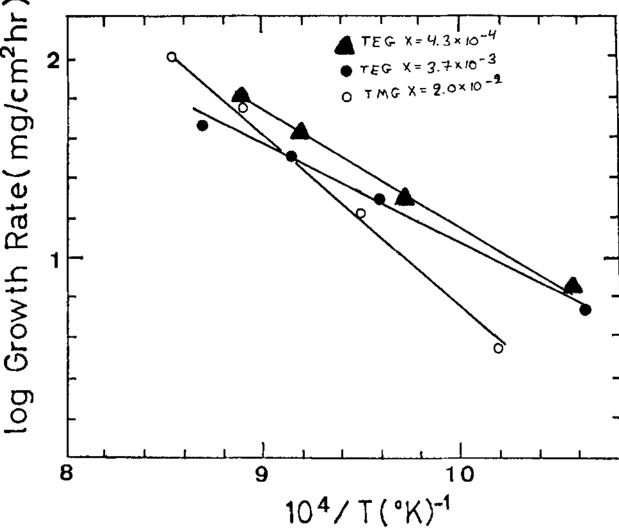

Fig. 6. Arrhenius plot of the log of growth rate vs. inverse temperature of the tungsten substrates for TEG at a molar fraction of 4.3×10^{-4} and 3.7×10^{-3} and for TMG at a molar fraction of 2.0×10^{-2} on H_2. The total gas flow is 1.5 liters/min.

TEG, and for two different values of the molar fraction X for TEG. The activation energies calculated from these plots are 31.6 kcal/mole for TMG for $X = 2.0 \times 10^{-2}$, and 31.3 and 25.0 kcal/mole for $X = 4.3 \times 10^{-4}$ and 3.7×10^{-3}, respectively, for TEG.

Characterization of the Films

The Ge thin films grown on (111) Ge and polycrystalline tungsten have been characterized using scanning electron microscopy (SEM), electron diffractions, and microchemical analysis of the carbon content. An optical examination shows that all films of Ge grown in H_2 were metallic in appearance and shiny, whereas the films grown in He showed various degrees of gray coloring.

The morphology determined by the SEM examination varies according to the deposition temperature and also the nature and the pretreatment procedure of the substrate. Lower temperatures of deposition, *e.g.*, 750°C, show relatively poor quality films. The dendritic appearance of the Ge on polycrystalline tungsten at 750°C (Fig. 7a) is changed at 850°C to a polygonal type of growth (Fig. 7b) whose lateral sites still increase further if the substrate has been preetched in HCl (Fig. 7c). The homoepitaxial film on (111) Ge (Fig. 7d) shows irregular shaped steps of growth. Raising the substrate temperature to about 850°C and etching with HCl *in situ* improved the morphology of the grown films, as can be seen in Fig. 7e and f, respectively. HCl

f. On (111) Ge at 850°C with HCl preetching

Fig. 7. SEM micrographs of Ge films about 10 μm thick deposited by the pyrolysis of TEG on H_2

in situ etch did not give any substantial improvement for films grown at 750°C.

The crystallinity of the grown films has been studied both by x-ray Laue low angle diffractions, transmission electron microscopy (TEM) diffractions, and reflection electron diffractions (RED). Films of about 10 μm thick were deposited on (111) Ge for these measurements which showed the single crystallinity of the homoepitaxial layer of Ge grown both on H_2 or He atmosphere.

The films grown on polycrystalline tungsten substrates also show an appearance of twinned (111) single crystalline deposits. However, this is due to the natural tendency of Ge to grow as twins in the (111) plane.

The carbon contamination of the films grown on cleaned tungsten and (111) Ge substrates has been analyzed microchemically, as reported previously for SiC films (1). The carbon content of blank substrates treated in a similar way as the ones covered with Ge films was subtracted from the total carbon content of the samples. Etching with HCl *in situ* was not used for carbon concentration studies. The epitaxial films of Ge on (111) Ge contained no more than about 25 ppm of carbon. It was seen, however, that the tungsten substrate influenced the results and that the carbon contamination was much higher, varying between 800 to 4700 ppm. This is probably due to the tendency of W to form WC, as in the case of SiC, which causes the production of free carbon during the pyrolysis of the alkyl radicals. The results of the carbon contamination are summarized in Table I. Table I shows that no clear cut correlation can be found between the carbon concentration and the deposition temperature, the mole fraction of the alkyl germane and the chemical identity of the alkyl germane. This is in contrast to the case of alkyl silanes where such correlations were found. The only factor which we found to affect the carbon concentration is the nature of the diluent gas, where the carbon concentration is higher for depositions performed in He rather than in H_2.

Discussion

Comparing the results obtained in the present investigation with those reported for the heteroepitaxy of SiC (1) we can conclude that the alkyl compounds have a tendency to deposit free carbon whenever they can form with a given element a stable carbide. Since Ge does not form a stable carbide the homoepitaxial layers of Ge have a low carbon content. Alkyl germanium deposits less carbon in the presence of H_2 than in He. Hydrogen promotes the reaction similar to the behavior of alkyl silicon (1), preventing the decomposition of the alkyl radical R into free carbon

$$R\cdot + H_2 \rightarrow RH + H\cdot$$

It can be concluded that the optimum conditions of growth of thin films of Ge, starting from alkyl germanium, are as follows: (*i*) use a substrate composed of elements which do not tend to form a stable carbide; (*ii*) preetch the substrate *in situ* with HCl; (*iii*) deposit in the presence of H_2; (*iv*) use higher temperatures of deposition in excess of 850°C, in order to promote lateral growth and thus increase the over-all growth rates; and (*v*) use higher molar fractions of the alkyl germanium which increase the rates of growth without giving any clear indication that it would also cause an unwanted increased contamination of carbon in the grown films.

Table I. Weight percentage of carbon, C (w/o), at various deposition temperatures, T(°C), and molar fractions, (× 10^3), diluting gases, and transporting alkyl germanium, found in Ge on polycrystalline tungsten films

Number	Transporting agent	Diluting gas	Molar fraction × 10^3	T (°C)	C (w/o)[a]
G50	TMG	He	1.30	880	4.71
G52	TMG	He	1.30	980	4.42
G23	TEG	He	0.44	1060	2.65
G32	TMG	H_2	2.00	790	0.10
G47	TMG	H_2	11.00	890	0.21
G40	TMG	H_2	2.00	900	0.11
G26	TEG	H_2	0.43	760	0.33
G24	TEG	H_2	0.43	890	0.08
G30	TEG	H_2	3.7	900	0.46

[a] The analysis of carbon has been performed on both the substrates covered or not covered with films of Ge. The uncovered substrates were analyzed as blanks and their carbon content was subtracted from the total amount of carbon determined on the film. Expressing in weight percentages it can be seen that the total carbon content varies between 0.1 to 5% and is larger in films of Ge produced in a He rather than an H_2 atmosphere.

Acknowledgments

The authors are indebted to Mr. R. Levin for performing the microchemical carbon analyses. This paper is part of the Ph.D thesis of Y. Avigal submitted to the Hebrew University.

Manuscript submitted Oct. 21, 1974; revised manuscript received March 20, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Observations on Si Contamination in GaP LPE

O. G. Lorimor, S. E. Haszko, and P. D. Dapkus

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Silicon has long been known to be an unintentional impurity often present in GaP; however, the concentration of the Si and its effects have not been known. It has been observed that the net donor concentration in undoped LPE layers fluctuates from $\sim 1 \times 10^{16}$ cm^{-3} $\lesssim N_d - N_a \lesssim$ 2-4 $\times 10^{17}$ cm^{-3} for different growth runs when growth is in ~ 1 atm of H_2. This background $N_d - N_a$ is attributed to unintentionally present Si donors. The Si concentrations in these as well as S- and Zn-doped layers as determined by ion microanalyzer measurements range from $\sim 6 \times 10^{16}$ cm^{-3} $\lesssim X^s{}_{Si} \lesssim 2 \times 10^{18}$ cm^{-3} with the typical value being $\sim 5 \times 10^{17}$ cm^{-3}. In the undoped layers $X^s{}_{Si}$ often exceeds $N_d - N_a$. The variations in both background $N_d - N_a$ and $X^s{}_{Si}$ are attributed to variations in the oxygen level of the gas ambient which is inversely related to the $X^s{}_{Si}$. An important reaction resulting in Si contamination is H_2 reduction of the quartz used in the construction of the LPE growth system. With a growth sequence designed to grow both a Zn- and oxygen-doped p-layer onto an undoped n-layer in the same growth run, SiO_2 precipitates have been observed in the p-layer near the p-n junction. The identification of these precipitates as SiO_2 is further proof of the high levels of Si contamination that can occur during LPE growth. Minority carrier lifetimes for Si-doped LPE layers with $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3} are considerably longer than have been obtained by doping with S or Te. The increased lifetime is attributed to either a reaction involving Si which results in the reduction in the concentration of an important nonradiative center or the fact that the usual dopants S and Te themselves are involved in a nonradiative center.

For several years it has been known that Si is often found as an unintentional impurity in GaP (1); however, this Si contamination has received little attention, especially in the LPE layers used in LED's. In this paper we review both previous work and present additional data which together provide a better understanding of Si contamination resulting from LPE growth.

Early work by Trumbore *et al.* (2) studied Si incorporation into intentionally Si-doped samples. One observation was that emission spectroscopic measurements always yielded a higher value for the Si concentration than did a spectrophotometric (a chemical separation followed by a spectroscopic measurement) determination. They felt that the spectrophotometric analysis was more accurate and so weighed those data points more heavily in their analysis. However, the same data were later reinterpreted (3) by suggesting that the spectrophotometric method yields the isolated Si (or Si-Si pairs) in solid solution while the emission spectroscopic (as well as electron microprobe) method yields the total Si content including Si in the form of some second phase (*e.g.*, SiO_2) or complex which is insoluble in the reagents used to dissolve the GaP for the spectrophotometric analysis. Thus, there is early evidence that the incorporation of Si into GaP may be complicated in that the total Si concentration in GaP may exceed that truly in solid solution.

More recently, it has been observed that the background net donor concentration, $N_d - N_a$, measured in LPE layers grown in a quartz dipping system from both 1000° and 900°C have varied nonsystematically (4) from $\sim 1 \times 10^{16}$ cm^{-3} to 2-4 $\times 10^{17}$ cm^{-3}. C, Si, S, and N have been identified in these layers from photoluminescence or optical absorption measurements (5). The S and N concentrations are typically $\lesssim 5 \times 10^{15}$ cm^{-3} as determined by optical absorption. This implies that Si, for which no concentration could be determined by optical absorption, is the donor providing the measured background $N_d - N_a$.

Key words: LED, light-emitting diodes, liquid phase epitaxy.

To investigate Si incorporation further two crystal growth runs were made where radioactive Si was used as a dopant. In one experiment an LPE layer was grown from 925°C from a melt containing 0.01 atom per cent (a/o) radioactive Si (5). The net donor concentration, $N_d - N_a$, was 1.6×10^{18} cm^{-3} while the total Si concentration, $X^s{}_{Si}$, was 1.7×10^{19} cm^{-3}. The total Si concentration exceeds $N_d - N_a$ by a decade.

In the second experiment, the melt was undoped except that a small piece of irradiated quartz with an area of ~ 1 cm^2 was floated on the surface of the melt. The 15g melt was held at 800°C in a H_2 atmosphere for 2½ hr. After this treatment, the melt contained 2.3 μg of Si from the irradiated piece of quartz. This amount of Si in the melt would Si dope an LPE layer so that $N_d - N_a \approx 3 \times 10^{16}$ cm^{-3}. However, considering that the temperature is low compared to that normally used for GaP LPE, and the small size of the piece of the "hot" quartz compared to the total area of quartz in the system, 2.3 μg of Si is judged to be quite a high level of contamination. Thus, Si from the quartz used in the growth systems can contaminate the melt.

There is direct evidence for the presence of Si in many undoped LPE layers. Trumbore (3) has studied Si in GaP using the ion microanalyzer. By using a few highly Si-doped samples whose Si concentration could accurately be measured by other analytical techniques, an absolute calibration for Si was obtained. The Si concentrations in a number of undoped crystals grown under varying conditions were measured. These results are shown in Table I along with two additional samples (the last two) recently studied. In obtaining these values for the Si concentration in the solid GaP, $X^s{}_{Si}$, it is assumed that the entire positive ion signal at mass 28 is due to Si^+ ions. The minimum Si concentration that could be detected was $\sim 2 \times 10^{17}$ cm^{-3}.

The primary observation that can be made from Table I is that Si concentrations vary from sample to sample from 6×10^{16} cm^{-3} to over 10^{18} cm^{-3}. As with the background $N_d - N_a$ found in undoped layers, the variation of $X^s{}_{Si}$ from sample to sample is in general

Table I. Si concentrations in GaP LPE layers as measured by the ion microanalyzer

Crystal	Growth conditions: (temp, boat material, gas ambient)	Dopants	$N_d - N_a$ (cm^{-3})	X^s_{Si} (cm^{-3})
1-474	900°C, pyrolytic C, H_2	N	6.5×10^{16}	1×10^{18}
1-471	900°C, quartz, H_2	S,N	2×10^{18}	2×10^{18}
2-388	1000°C, BN, H_2	—	—	8×10^{17}
2-432	1000°C, quartz, H_2 (melt prebaked in vacuum)	N	1.1×10^{16} (p)	4×10^{17}
2-430	1000°C, quartz, H_2	S,N	4.7×10^{17}	2×10^{17}
1-468	900°C, quartz, H_2	—	2.5×10^{16}	6×10^{16}
2-364	900°C, BN, H_2	N	—	2×10^{18}
X-112873	1000°C, quartz, H_2	—	3.5×10^{17}	4×10^{17}
X-120473	1000°C, quartz, He	—	2×10^{16} (p)	$\lesssim 2 \times 10^{17}$

nonsystematic. Although one might expect less Si to enter the melt when the boat material is BN or C rather than quartz, Table I shows no such correlation. Instead X^s_{Si} appears to fluctuate randomly. The last two samples in Table I were grown under as nearly leak-free conditions as possible. Less Si was found in the sample grown under an ambient of high purity He compared to the sample grown under H_2. However, one cannot quantitatively compare the relative Si concentrations in these two samples because of the relatively high detectability limit of the ion microanalyzer compared to their Si concentrations. A general conclusion from the data in Table I is that values of X^s_{Si} in the mid-10^{17} cm^{-3} range appear to be quite common when the ambient is ~1 atm H_2.

We propose that the Si enters the melt from the quartz used in the construction of the LPE system when the ambient is ~1 atm H_2. The large variations observed in X^s_{Si} and background $N_d - N_a$ are attributed to the effects of varying water vapor pressure resulting from inadvertent and fluctuating air leaks in the gas system. (The oxygen that is admitted by an air leak is assumed to be essentially entirely converted to H_2O by the ~1 atm of hot H_2.)

For a system consisting of the liquid Ga melt, the quartz reactor tube, and the H_2 and H_2O gases, we consider the following reactions which result in Si contamination of the melt

$$H_2(g) + SiO_2(s) = SiO(g) + H_2O(g) \quad [1]$$

$$SiO(g) + 2Ga(l) = Ga_2O(g) + Si(l) \quad [2]$$

$$H_2O(g) + 2Ga(l) = Ga_2O(g) + H_2(g) \quad [3]$$

Making the usual assumptions such as ideal dilute solutions, we obtain from reactions [1]-[3]

$$K_1 = \frac{p_{SiO}p_{H_2O}}{p_{H_2}} \quad [1a]$$

$$K_2 = \frac{p_{Ga_2O}\gamma_{Si}X^l_{Si}}{p_{SiO}} \quad [2a]$$

$$K_3 = \frac{p_{Ga_2O}p_{H_2}}{p_{H_2O}} \quad [3a]$$

The general effect of increasing the water vapor is to decrease the Si contamination of the melt. Figure 1 illustrates this effect by the solution of Eq. [1a]-[3a]. X^l_{Si} is shown as a function of the inlet partial pressure of water in the gas stream, $p^i_{H_2O}$. $p^i_{H_2O}$ is determined by the oxygen entering the gas stream through leaks as well as any other source of water or oxygen present in the inlet gases. Table II gives the values of the reaction constants used in these calculations. At the higher values of $p^i_{H_2O}$, the reduction of the quartz is negligible and thus $p_{H_2O} = p^i_{H_2O}$ with the consequence $X^l_{Si} \propto (p^i_{H_2O})^{-2}$. X^l_{Si} saturates at the lower values of $p^i_{H_2O}$ at a value determined by the reduction of the quartz. One should note that, in equilibrium, X^l_{Si} can be quite large, $> 10^{-3}$ atom fraction, at both 900° and 1000°C. Values of $X^l_{Si} \approx 1 \times 10^{-4}$ are sufficient to

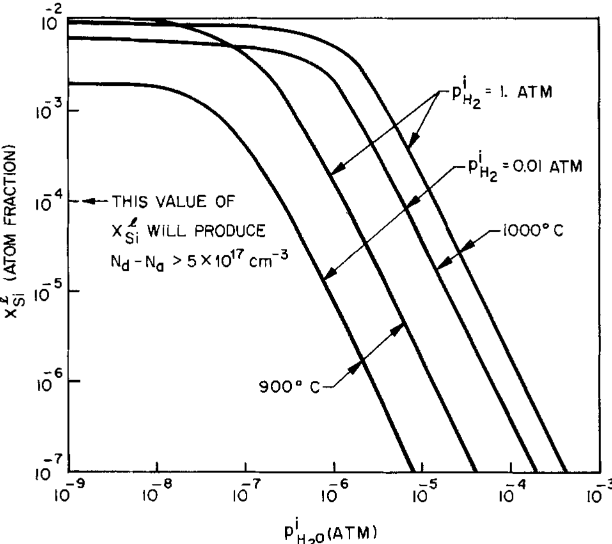

Fig. 1. Concentration of Si in the melt, X^l_{Si}, as a function of inlet water vapor partial pressure, $p^i_{H_2O}$.

dope an LPE layer so that $N_d - N_a > 5 \times 10^{17}$ cm^{-3} (2).

However, the rate at which Si enters the melt is highly dependent upon the growth conditions, $p^i_{H_2O}$, and the boat material. Calculations have shown that the rate of Si contamination for a nonquartz boat where the Si must be transported to the melt via the vapor is much slower than for a quartz boat where the Si may dissolve directly into the melt (6, 7). These calculations also showed that for a quartz boat, 1 atm H_2, and $p^i_{H_2O} \lesssim 10^{-5}$ atm equilibrium is not reached for typical LPE growth times. However, the actual rate at which these reactions approach equilibrium may differ from that calculated as the idealized assumptions used in the calculations are most likely not entirely met experimentally. However, the generalized conclusions that Si contamination occurs faster in quartz boats than inert boats and that equilibrium is not reached for low values of $p^i_{H_2O}$ for typical LPE growth times are most likely true experimentally. Thus, the very high levels of X^l_{Si} shown in Fig. 1 for low values of $p^i_{H_2O}$ are probably not attained experimentally.

There is one final piece of evidence for high levels of Si contamination in GaP LPE layers. When unintentionally doped n-layers were grown followed by an oxygen-doped p-layer in the same growth run, precipitates were often observed in the p-layer at the p-n junction. The n-layer was first grown from 1020°C under ~1 atm of H_2. After n-growth the furnace was held at constant temperature and the H_2 ambient replaced by ~0.9 atm He, ~0.1 atm H_2, ~2 × 10^{-3} atm Zn, and ~1 × 10^{-2} atm O_2 at the inlet to the reactor tube. After allowing 1 hr for equilibration of the melt, the furnace is heated ~2° to melt back a small amount of the n-layer and then cooled for p-growth.

Figure 2 shows an SEM photograph using secondary electron emission of one of these precipitates. The p-region is lighter than the n-region due to voltage enhancement of the secondary emission. Using the

energy dispersive x-ray unit, a strong Si signal as well as background Ga and P signals were identified with the electron beam on the precipitate. We judge these precipitates to be largely SiO_2. (Oxygen and all the lighter elements are not detected with the x-ray unit.) This conclusion is reached because these precipitates are not produced if O_2 is deleted from the same growth procedure, and elemental Si will not precipitate from a Ga+P melt at 975°C for Si concentrations in the melt $\leq 15\%$ (8).

During n-growth the melt becomes heavily contaminated with Si via reactions [1]-[3]. During the equilibration period, the introduction of oxygen causes the Si to be precipitated from the melt as SiO_2. These SiO_2 precipitates evidently grow on the surface of the n-layer which results in their hemispherical shape. Eventually, the melt is almost entirely depleted of Si and precipitate growth stops. The precipitate acts as a mask during the meltback and thus is sitting on the mesa of n-layer. If n-growth is under 1 atm He, no precipitates are observed, indicating that the Si contamination of the melt is greatly reduced compared to growth in an H_2 ambient.

It is felt that these precipitates have not been present in earlier LPE studies because a unique growth cycle is required to produce them. First the melt must be heavily contaminated with Si and then the oxygen must be added. If the oxygen were added initially, the melt would not become Si contaminated as the large concentration of oxygen dissolved in the melt causes X^l_{Si} to be very small.

The presence of these precipitates is strong evidence that the melt was highly Si contaminated during n-growth. Typically the density of these precipitates is $\sim 10^5$ cm^{-2} and $\sim 5\mu$ diameter over a growth area of ~ 2 cm^2. If they were solid SiO_2, the total weight of Si in the precipitates is ~ 20 μg. This amount of Si is a lower limit on the total Si contamination of the melt as it is highly unlikely that all, or perhaps even most, of the SiO_2 precipitates out onto the n-layer which is at the bottom of the melt. For example, the density of SiO_2 is ~ 2.5 g/cm^3 compared to 5.6 g/cm^2 for Ga, with the consequence that the SiO_2 particles should float to the surface. This ~ 20 μg of Si represents a minimum $X^l_{Si} = 1 \times 10^{-5}$ atom fraction in the 5g melt used in these experiments. A deliberate addition $X^l_{Si} = 1.0 \times 10^{-5}$ atom fraction to the melt is sufficient to dope to $N_d - N_a = 3 \times 10^{17}$ cm^{-3} when growth is from 900°C. Consequently, it is observed again that the unintentional Si-contamination level is sufficient to produce $N_d - N_a$ = several $\times 10^{17}$ cm^{-3}. The total Si concentration in these LPE layers is undoubtedly much higher.

Intentionally Si-doped crystals with $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3} grown in the dipping system from both 900° and 1000°C were found to have long minority carrier lifetimes compared to those which could be obtained with other dopants. Figure 3 shows the minority carrier lifetimes (τ) as determined from the green-PL time decay (9), as a function of $N_d - N_a$ for Si, S, Te, and undoped LPE layers. The values of τ for the S, Te, and undoped LPE layers are the highest which were measured during several years of LPE growth. It should be noted that these lifetimes are substantially longer than those reported for similar crystals doped with nitrogen.

For $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3} the value of τ for Si-doped material is larger than the correspondingly S- or Te-doped layers by at least a factor of 2. At lower doping densities the dopant dependence of τ decreases. At $N_d - N_a \lesssim 1\text{-}2 \times 10^{17}$ cm^{-3} it appears that the addition of Si has little, if any, effect upon the lifetime. However, $N_d - N_a \approx 1\text{-}2 \times 10^{17}$ cm^{-3} is just the background value often measured and that has been attributed to unintentional Si doping in a nearly oxygen-free system. An undoped layer should probably be more properly called a lightly Si-doped layer.

From Fig. 3, we can conclude that the defect limiting the minority carrier lifetime in the S- and Te-doped samples where $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3} does not consist of Si alone or Si-intrinsic GaP defect complexes. If it did, the corresponding Si-doped samples would not be expected to have a longer lifetime. Instead it appears that the Si, through a reaction in the Ga melt or during impurity incorporation, is reducing the concentration of the defect limiting τ. One of the simplest but most likely possibility is that the Si in the melt is reducing the oxygen in the melt via $Si(l) + 2\,O(l) = SiO_2(s)$. An important nonradiative recombination center in the LPE layer involving oxygen is then being reduced in concentration. Deliberate doping with 10 to 30 ppm oxygen has been observed to reduce both τ and the electroluminescent efficiency of green-emitting LED's (11). In other work, a complex involving Si and oxygen has been observed to be an important nonradiative center when large concentrations of O_2 were added to Si-doped melts (5). Consequently, if the reduction in O_2 concentration of the melt results in the longer minority carrier lifetimes, one should be able to add to the melt an impurity which has a strong affinity for oxygen but is not incorporated into the

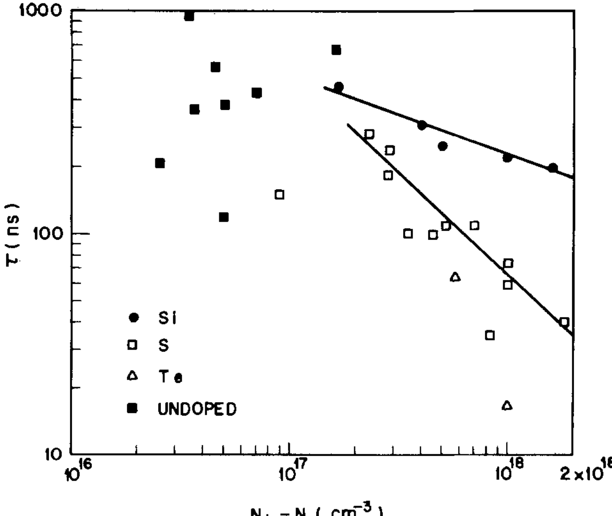

Fig. 3. Minority carrier lifetime as a function of net donor concentration for S-, Te-, and Si- doped LPE layers.

GaP in an appreciable concentration as a means of increasing the minority carrier lifetime. A second possibility is that the shorter lifetimes for $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3} in the S- and Te-doped crystals is that the Te and S themselves are involved in the defect limiting the lifetime. In this case, when Si is used as the n-dopant this defect is eliminated.

Discussion and Summary

The background net donor concentration in LPE layers, which is attributed primarily to Si donors, has been observed to fluctuate from $\sim 1 \times 10^{16}$ cm$^{-3} \lesssim N_d - N_a \lesssim$ 2-4 $\times 10^{17}$ cm^{-3}. This behavior is attributed to variations in the oxygen partial pressure (actually H_2O) in the gas ambient which in turn varies the oxygen content of the melt and thus the Si content of the melt via the reaction

$$2\,O(l) + Si(l) \rightarrow SiO_2(s)$$

The lower the oxygen content of the gas stream, the lower the oxygen in the liquid Ga and the higher the concentration of Si in the melt, and a higher resultant $N_d - N_a$. Thus, a high ($> 1 \times 10^{17}$ cm^{-3}) value of $N_d - N_a$ is to be expected in undoped LPE layers grown in an oxygen-free system for growths under $\sim$1 atm of H_2.

Measurements of the Si concentration in unintentionally Si-doped layers with the ion microanalyzer give absolute numbers for the Si concentration. Fluctuations have been noted in X^s_{Si} from layer to layer which do not correlate with the boat material. Thus, it appears that Si contamination through H_2 reduction of the quartz in the LPE growth system is an important mechanism for Si contamination. The fact that less Si contamination was observed when growth is under 1 atm He compared to 1 atm H_2 is consistent with this conclusion. The observed fluctuations in X^s_{Si} often result in values higher than $N_d - N_a$. In a crystal lightly doped with radioactive Si, X^s_{Si} exceeded $N_d - N_a$ by a decade.

Precipitates of SiO_2 have been observed which are further evidence of Si contamination during LPE growth. A rough estimate shows that the Si contained in these precipitates is consistent with that required in the melt to dope the LPE layers to the 10^{17} cm^{-3} levels.

Measurements of the minority carrier lifetimes of intentionally Si-doped layers have been made. For $N_d - N_a \gtrsim 5 \times 10^{17}$ cm^{-3}, these values of τ, $\sim$200-350 ns, are the longest that have been achieved by any means at these doping densities. At lower doping densities it appears that the lifetimes of the Si-doped layers should be comparable to those of the undoped layers. We attribute these long lifetimes in the Si-doped layers to the effects of Si reactions in either the melt or the LPE layer which reduce the concentration of defects which are responsible for limiting τ to the usually observed values. The most probable reaction is the reduction of oxygen in the melt through the formation of SiO_2.

One should note that the large concentrations of Si (10^{17} cm^{-3} range) that often occur in LPE layers not intentionally Si doped are apparently not limiting τ to values less than several hundred nanoseconds. This amount of Si may even be beneficial by causing the reduction in concentration of another defect which is more important in limiting τ. However, in green-emitting LED's, the simultaneous doping of the n-layer with N precludes the use of Si as a dopant (16). The Si and N react in the melt forming Si_3N_4 until the melt is depleted in one of the dopants, which, in practice, is Si. In red-emitting LED's Si should be a superior n-dopant to Te, which is now commonly used (17, 18).

ABSTRACT

The redistribution of As, Sb, and Ga implants into silicon during wet oxidation was investigated by MeV He backscattering and channeling techniques. Oxidation produces an accumulation of nonsubstitutional As and Sb at the interface of the advancing oxide front. In contrast, the implanted Ga accumulates at the front surface of the oxide layer. In subsequent diffusion all three species are highly substitutional at concentrations at or below the solubility. Loss of As and Sb is minimal during oxidation or subsequent diffusion; however, for Ga diffusion encapsulation with Si_3N_4 was required.

A number of papers has been published describing the redistribution of diffused impurities (1-4) in Si in an oxidizing ambient. The results of these investigations have shown that n-type impurities accumulate at the oxide silicon interface while p-type impurities are depleted from the substrate.

The purpose of the present investigation was to study the influence of the oxidation process on the distribution and lattice location of a number of implanted dopant species in Si. Since the use of heavily implanted layers is increasing in silicon technology we were interested in determining whether or not the segregation of impurities at a SiO_2/Si interface was different in implanted samples as compared to published work on diffused samples. Based on studies of gettering of heavy metal ions in damaged layers (5) it might be anticipated that Group V dopants, for example, would show enhanced segregation at the interface between damaged Si and SiO_2. Also because oxidation is used to consume the disorder caused by high-dose heavy-ion implants, it is essential to gain information about incorporation of impurities in these oxide layers. It has been reported, for example, in As implants that the As is driven into the Si by use of a high-temperature oxidizing ambient (6).

In the present work, As and Sb were chosen for the n-type species because of their difference in solid solubility. Ga was chosen as a p-type dopant having a similar solid solubility to that of Sb. The thickness of the thermally grown SiO_2 layers was chosen to consume an amount of Si greater than the projected range of the implanted species. Low temperature wet oxidation was used to minimize diffusion of the impurities during the oxidation cycle. Backscattering techniques were used to determine the depth distribution of implanted impurities and channeling was used to determine lattice locations.

Experimental Techniques

The silicon wafers used for this investigation were n-type, 2-4 ohm-cm resistivity of <111> orientation with a low damage surface preparation. Arsenic implantations were performed at 200 keV with doses of 1-2 $\times$ 10^{16} cm^{-2}. The crystals were oriented in a random direction to the beam and the substrate was initially at room temperature. The gallium and antimony implantations were done at 80 keV with doses between 10^{15} and 1.6 $\times$ 10^{16} cm^{-2}. The annealing in a nonoxidizing ambient was carried out in dry N_2. Thermal oxidation was performed in steam between temperatures of 850° and 1000°C. The carrier gas was pure O_2.

The oxide growth rate has been found previously to depend on the concentration of the impurity species (7, 8). For implanted Si samples, it has been found that the oxide growth rate depends on both impurity concentration and residual damage (9, 10). In both implanted and diffused cases, the change can be characterized by a change in the linear rate constant, the parabolic rate constant remaining roughly the same.

In our case, the oxide thicknesses were determined by backscattering and ellipsometry measurements. For a steam oxidation at 850°C, oxides of about 2400Å were grown in 30 min for a well annealed 2 $\times$ 10^{16} cm^{-2} As implant. This thickness is about twice that grown on low concentration n-type Si. For the case of Sb a similar behavior is found. These results are in agreement with those found by Nomura *et al.* on Sb and P implanted Si. The thickness of our oxide layers grown on the Ga implanted samples were found to be about 10-20% less than that of a nonimplanted 2 ohm-cm n-type sample.

Channeling and backscattering measurements were made with 2 MeV $^4He^+$ ions. The backscattered particles were detected by a surface barrier detector mounted at an angle of 168° to the incident beam direction. For the conversion of energy depth, the stopping cross sections of Ziegler and Chu (11) were used.

Experimental Results

Arsenic implantations.—The implanted distribution was first measured by backscattering, then the samples were oxidized and the distribution remeasured both with the oxide layer and with the layer etched away. Channeling measurements were also performed on annealed samples without the oxide layer. Typical results obtained are shown in Fig. 1. Here, the upper portion of the figure is the random spectrum for a sample implanted with 10^{16} As/cm^2. The lower portions are spectra taken after oxidation and subsequent oxide removal, respectively.

It can be seen in Fig. 1a, that the broad plateau with a front edge at 1.13 MeV is due to particles backscattered from the Si and the peak at 1.55 MeV corresponds to As. The peak of this As distribution is located approximately 50 keV below the surface position (1.61 MeV) and corresponds to a projected range value of approximately 1100Å (12).

After oxidation of the sample the As distribution (solid curve) is found to shift to lower energies (1.38

MeV in Fig. 1b) and to narrow in width. The step observed in the Si spectrum represents scattering from Si in the SiO_2 layer. The width (ΔE) of the Si step is directly related to the thickness of the SiO_2 layer. The shift of the As signal is also directly related to the depth of the As below the surface. Comparison of the width of the oxide layer and the position of the As indicates that the As is located at the Si/SiO_2 interface. Less than 5% of the As atoms are located within the outer regions of the SiO_2 layer as indicated by the sum of the counts in the energy interval 1.4-1.6 MeV.

More details on the width of the As distribution can be obtained by removing the SiO_2 layer. The As signal in Fig. 1c for the oxidized and stripped sample appears at an energy corresponding to the As surface position. The integrated number of counts of the As signal is reduced by about 20% which indicates that there is little loss of the As during the oxide removal in HF. Channeling measurements show the absence of any residual oxide layer within our experimental sensitivity (*i.e.*, less than 5×10^{15} oxygen/cm^2). The FWHM of this measured As signal corresponds to that of the system resolution. From this result we can determine that the As is confined in a layer which is less than 200Å wide. Tilting the sample by 60° to double the depth to energy conversion did not produce a significant shift in the major portion of the As spectrum confirming that the location of the As is at the silicon surface.

The solid points in Fig. 1c represent the As profile obtained after annealing the sample at 1000°C for 20 min in dry N_2 with the oxide layer in place. Diffusion of the As profile is observed to extend more than 4000Å below the surface. The integrated signal from the As after the diffusion was found to be 5% less than that of the original implant. From this we conclude that little As was lost during the oxidation and diffusion.

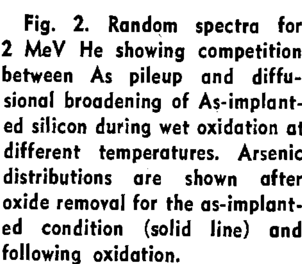
During the thermal oxidation of As-implanted Si, the As distribution is determined by the pileup of As at the advancing oxidation front coupled with some diffusion which leads to a spreading away from this front (1). The distribution and lattice location of As are illustrated in Fig. 2 for three samples that had oxide layers grown at 850°, 920°, and 1000°C.

The spectra in Fig. 2 were taken after the oxide layer was removed and are compared with the original distribution (solid line). The 850°C sample (Fig. 2a) exhibits a narrower As distribution after oxidation than the original implant caused by the pileup effect. The aligned <111> yield is ~75% of the random yield which indicates that the majority of the As is nonsubstitutional after the oxidation.

The As distribution for the sample oxidized at 920°C (Fig. 2b) has a deeper profile and an aligned yield which exhibits peak at the surface. About two-thirds of the As located near the surface is substitutional with an increasing component extending deeper into the crystal. The 1000°C sample has an even deeper distribution which extends 3000Å below the surface and an even higher substitutional component.

Antimony implantations.—Similar to the results obtained with As implantations, Sb is pushed deeper into the sample by the advancing oxide front. The backscattering spectra for 1.2×10^{16} cm^{-2} Sb implanted at 80 keV and then oxidized at 850°C is shown in Fig. 3. The distribution of the implanted Sb before oxidation is located with the peak at about 370Å below the surface corresponding to R_p (13). After oxidation the major portion of the Sb is located near the Si/SiO_2 interface. Less than 5% of the Sb is found within the oxide layer, the majority of which is found near the oxide surface. There is a loss of greater than 90% of the Sb during oxide removal. This indicates that either the Sb atoms are incorporated within the SiO_2 layer at the interface, or that the Sb atoms reside at the interface and are removed by HF.

After oxidation, the Sb can be diffused deeper into the Si. The depth distribution of the Sb following oxidation at 850°C and subsequent diffusion in dry N_2 at 1050°C is shown in Fig. 4. With the oxide cap in place, the spectra in Fig. 4 indicate that the majority of the Sb remains near the interface. The deeply penetrating distributions within the Si represent diffusion



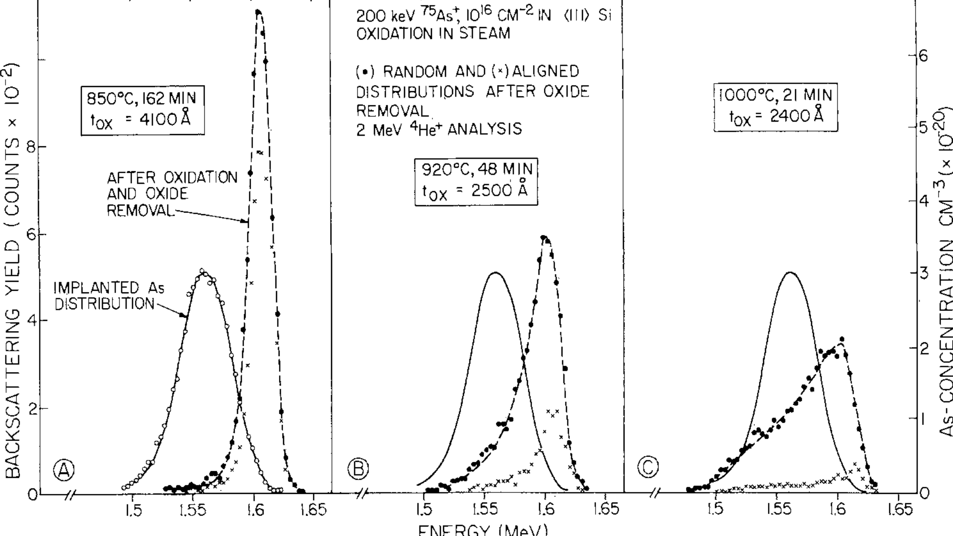


Fig. 2. Random spectra for 2 MeV He showing competition between As pileup and diffusional broadening of As-implanted silicon during wet oxidation at different temperatures. Arsenic distributions are shown after oxide removal for the as-implanted condition (solid line) and following oxidation.

of the Sb by standard mechanisms. Removal of the oxide cap reduced the Sb peak at the surface indicating that Sb is located at the interface but did not change the depth distribution for the deeper component. The origin of the depth scale in Fig. 4 was placed at the break of the two profile parts.

The solid curves are calculated for an erfc distribution using an Sb surface concentration C_0 of 3.4×10^{19}/cm^3 and a diffusion coefficient $D = 8.0 \times 10^{-15}$ cm^2-sec^{-1} (14). These values are representative of the bulk solubility and diffusion coefficient of Sb in Si. The concentration at this point corresponds to the equilibrium solubility of Sb in Si (15). The data points and the calculated curves are in reasonable agreement suggesting that the Sb distribution is determined by bulk diffusion processes. Channeling effect measurements performed on these samples indicated that greater than 85% of the Sb atoms below the surface are on substitutional sites while the Sb atoms located near the surface are predominantly nonsubstitutional.

Gallium implantations.—Figure 5 represents 2 MeV ^{4}He backscattering spectra for a sample implanted at 80 keV with 1.2×10^{16} Ga/cm^2 before (solid curve) and after (dashed curve) oxidation. In this figure the vertical and horizontal axes of the Ga component were expanded. In the implanted sample, Ga is distributed with a peak about 500Å below the surface. After oxidation, the gallium distribution is shifted toward the surface and the total amount of Ga decreases by about 20%. The high energy edge of the Ga distribution appears at the sample surface as shown in Fig. 5 and nearly all the remaining Ga is incorporated within the oxide layer. The left-hand portion of Fig. 5 shows the change in the Si spectrum observed after oxidation. The same features are found

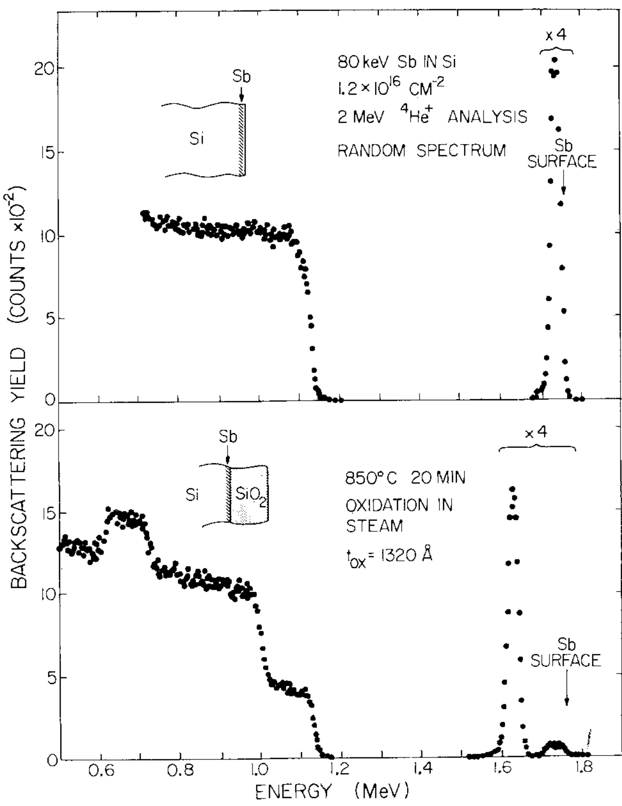

Fig. 3. Backscattering spectra for 2 MeV He$^+$ on Sb-implanted silicon before and after wet oxidation at 850°C. 20 min.

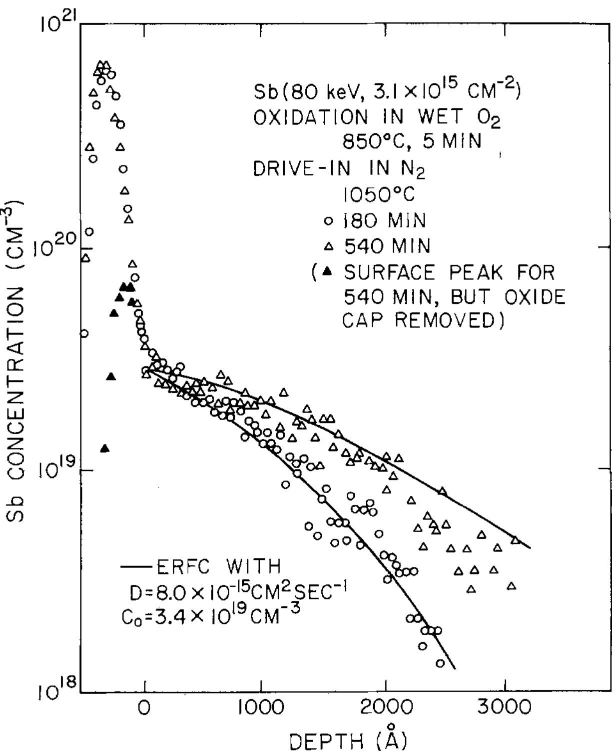

Fig. 4. Sb-drive-in diffusion profiles following wet oxidation at 850°C, obtained by 2 MeV He backscattering on samples with oxide layer in place. Solid triangles show reduction of Sb surface concentration after oxide removal.

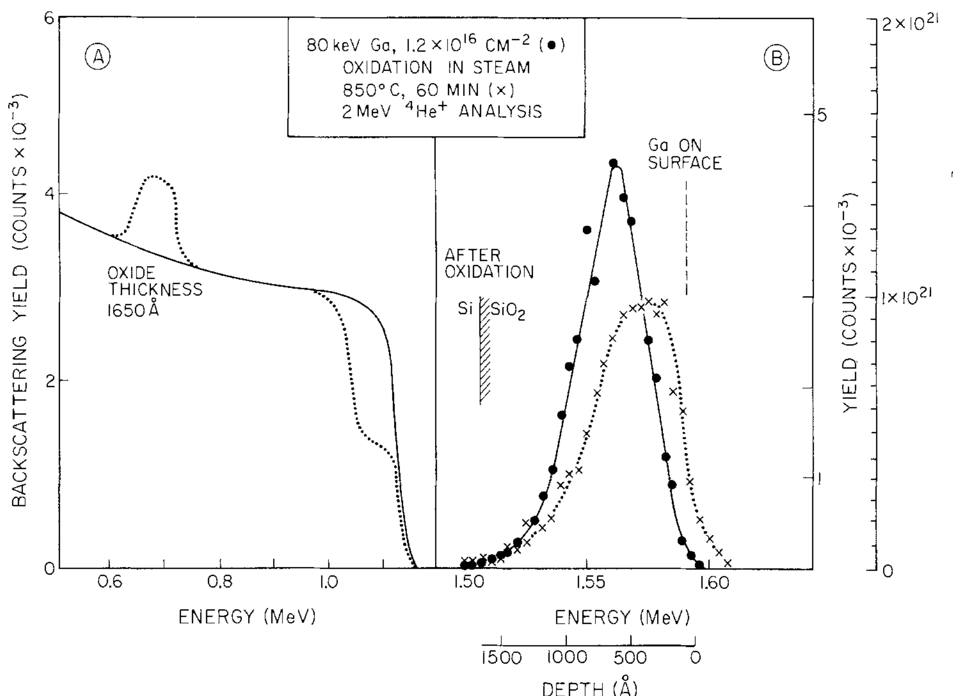

Fig. 5. Random spectra for 2 MeV He on Ga-implanted silicon before and after wet oxidation at 850°C, 60 min. Both the energy and yield scales are expanded for the Ga component. The depth scale is determined for Ga in SiO_2.

as in the case of an As-implanted sample (Fig. 1b) except that the oxide layer is thinner.

Wet oxidation at 850°C was carried out on samples implanted at 80 keV with doses of 0.6-1.2 $\times$ 10^{16} Ga/ cm^2. For all samples there was a shift in the Ga concentration to the oxide front surface and a loss of 20-35% of the total amount of Ga. The maximum concentration of Ga in the Si following these diffusions was less than 8 $\times$ 10^{18} cm^{-3}, well below the thermal equilibrium solubility. These results indicate that the Ga is incorporated in the oxide layer. This oxidation cycle is not suitable to act as an encapsulating layer for Ga drive-in diffusions.

As an alternative encapsulating layer, Si_3N_4 was deposited by reactive sputtering. Figure 6 shows random and aligned backscattering spectra for a sample annealed at 1050°C for 45 min after the Si_3N_4 was removed. An almost constant depth distribution for the Ga is observed over the accessible depth (7000Å). The concentration of the Ga is between 3 and 3.5 $\times$ 10^{19} cm^{-3} which is comparable to the equilibrium solubility at this temperature (15). The dashed curve represents the calculated erfc diffusion distribution using bulk values (14). The disagreement between the experimental data and the calculated curve indicates the enhancement of the Ga penetration during the anneal. The aligned spectrum for this sample indicates that more than 80% of the Ga is on lattice sites.

Discussion and Speculation

Since the diffusion coefficients (extrapolated) of As and Sb in SiO_2 are ~1/10-1/100 of that in Si at the temperatures of 805°-1000°C, the pileup of these two impurities at the oxidation interface will be a function mainly of the oxidation temperature. At higher temperatures (> 1000°C) the diffusion velocity of As and Sb is higher than the oxidation front velocity and they diffuse away from the advancing oxidation front. In the case of As the diffusion coefficient is known to be concentration dependent (16) so the transition between pileup and diffusion may be also expected to depend on total implanted dose.

For the As there appears, even at 850°C, a substitutional component (Fig. 2) indicating that substitutional incorporation in the lattice is starting to take place. However, for Sb there is no evidence for substitutional incorporation at 850°C. We believe that for both Sb and As the dopant accumulates at the interface. Although the evidence is indirect for Sb it is rather clear for As. This speculation disagrees with the recent findings of Chou *et al.* for phosphorus in Si.

The situation is much less clear for Ga. Competition between the oxidation of the Ga and Si can lead to the formation of $(Ga_2O_3)_x \cdot SiO_2$. Presently, we have no direct evidence that the Ga accumulation at the outer surface of the SiO_2 layer is caused by the oxidation of the Ga.

It is evident (Fig. 6) that encapsulation of the implanted sample with Si_3N_4 can prevent the interaction of oxygen with Ga. The anomalous feature of our data is the enhanced penetration of the Ga under the Si_3N_4 layer. We speculate that this is due to lattice strain caused by the mismatch of the expansion coefficients between Si_3N_4 and Si.

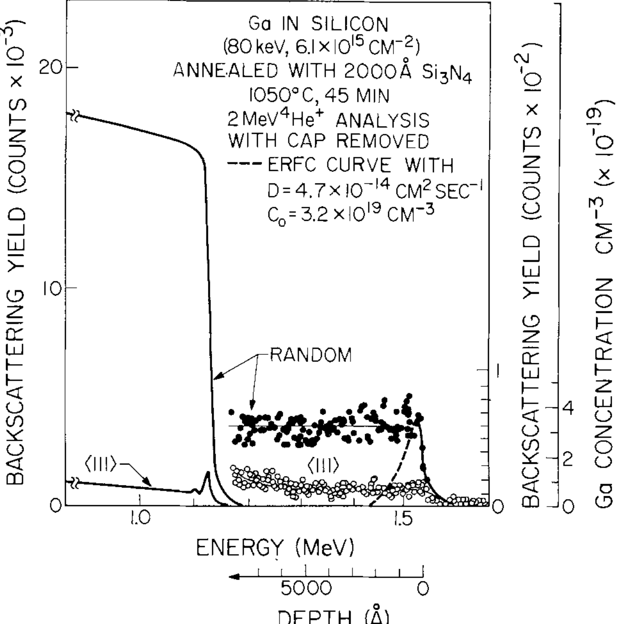

Fig. 6. Backscattering spectra for 2 MeV He+ on Ga-implanted silicon after drive-in diffusion at 1000°C, 45 min using sputtered Si_3N_4 as a protective encapsulating layer.

Summary

The most pronounced feature of the low temperature oxidation of As and Sb implanted samples is the pileup effect where the implanted dopant accumulates at the advancing oxide interface.

For As, the low temperature oxidation results in a nonsubstitutional accumulation at the advancing oxide front. At higher oxidation temperatures (920°, 1000°C) the As profile exhibits diffusional broadening and an increased substitutional component. The backscattering data show that the maximum concentration of As in Si to that in SiO_2 is greater than a factor of 50. It is found that less than 5% of the As is lost during the oxidation.

For the Sb case a somewhat greater amount (up to 10-20%) is found in the SiO_2 layer. There is also a pileup of Sb at the front surface of the oxide layer. With the oxide layer in place, the Sb at the interface acts as a diffusion source. The resultant diffusion profiles follow an erfc distribution, described by bulk values of the Sb concentration and diffusion coefficient. Channeling effect measurements showed that the diffused Sb profile was highly substitutional.

For the case of As, we find that the As is incorporated in the Si at the interface. This result differs from that of Chou *et al.* (4) for thermal oxidation of phosphorus-doped Si. They found that a phosphorus-rich layer was located in the SiO_2 film near the interface but not in the silicon substrate. Our results for Sb show that the Sb either resides in the oxide layer near the interface or is at the interface and dissolved by HF.

In contrast to the results with implanted Sb and As the implanted Ga accumulates at the front surface of the oxide layer and therefore does not act as a diffusion source. The maximum Ga concentration in Si was less than 8×10^{18} cm^{-3}, well below the value for the equilibrium solubility. As an alternative procedure we found that sputter-deposited Si_3N_4 acted as a protective cap layer during drive-in diffusion. The Ga concentration at the surface was at the thermal equilibrium solubility and channeling effect measurements showed that the Ga was highly substitutional. However, the penetration is anomalously deep.

Acknowledgments

The authors wish to acknowledge the assistance of Jim Hansen of Hewlett-Packard, who provided As-implanted samples and of E. Pasztor from the implantation group at the Central Research Institute for Physics, Budapest, who provided Ga and Sb implants. We wish to thank Fred Eisen for helping us by providing cap layers. Investigations of the Fabrication of Thin Silicon Films for Microwave Semiconductor Transit Time Devices

Jürgen Freyer

Institut für Allgemeine Elektroechnik der Technischen Universität München, 8 München 2, Germany

ABSTRACT

The fabrication of thin silicon films for microwave semiconductor devices is investigated using polishing and etching methods. With the described bubble etching method the thickness of the Si film can be monitored during etching. Si-films with a thickness down to 3 μm could be fabricated with this process. The etched films are free of strain and etch pits and are sufficiently plane parallel as required by microwave transit devices. The fabrication of an MnM Baritt diode and a double diffused Impatt diode without substrate is given as example.

For application in microwave semiconductor devices very thin semiconductor layers or films are useful, for example for Impatt, Baritt, or pin diodes. The thickness of these films varies between 2 and 10 μm depending on the application. For Impatt diodes without any substrate [MnM-Impatt diodes (1)] silicon films with a thickness of 4 μm are required for X-band

Key words: etching, polishing, Impatt diodes, Baritt diodes.

frequencies. For Baritt diodes in the same frequency range the film thickness must be about 8-10 μm (2, 3). The semiconductor layers in any case have to be plane parallel, free of strain and of dislocations, and without any damage at the surface. To meet these requirements the fabrication of thin silicon films was investigated by polishing and etching methods.

Polishing

In order to achieve the required thin silicon films the reduction of the thickness first was performed by polishing. The base, the polish, and the pressure on the silicon slice during polishing could be varied. Plane glass plates and Pellon cloths on plane glass plates were used for the base. The Pellon cloths had different degrees of hardness. The polish was Al_2O_3 powder (0.25 μm ϕ), diamond paste (1 μm ϕ), and Lustrox.[1] The apparatus used for thinning slices was the same as for conventional mechanical lapping and polishing and was similar to that used by Mash *et al.* (4) who fabricated silicon slices down to 10 μm. Thinning was also performed using a vibration polishing machine. Above 10 μm the thickness of the films can be measured with an accurate dial gauge, below 10 μm the thickness must be measured by the aid of the transparency colors of the silicon because the pressure of the dial gauge would damage the thin film.

In Table I the results from polishing are summarized for two thickness ranges of the films: 10-15 and 4-6 μm. In the last two rows in Table I the results using a vibration polishing machine are also listed. The surface of these polished slices often is not plane but convex and has an orange skinlike structure. The dislocation density caused by polishing was high on all polished films and became higher if the pressure on the silicon slices during polishing was exceeded.

Etching

The polished silicon slices show many disadvantages for many applications for solid-state devices; *i.e.*, the dislocation density caused by polishing is high at the polished surface and the slices are often crumbly especially for very thin films. Therefore, in the following work the silicon slices are thinned only by etching. Unvala *et al.* (5) describe a large-scale process for the fabrication of thin semiconductor layers but the thickness of the layers is limited to about 20 μm. Theunissen *et al.* (6) developed a preferential electrochemical etching process with which very thin silicon films can be fabricated. One disadvantage, however, is that a special doping structure of the initial material is needed and that an additional layer has to be etched away.

Generally bubbles of gaseous reaction products at the surface of the slices to be thinned lead to nonuniform etching. One method to remove these bubbles is the use of a rotating beaker. The results of this method are also listed in Table I. In the following an etching method is described which is especially sensitive for the fabrication of thin films (<10 μm). The etching process is similar to that published by Stoller *et al.* (7) who fabricated slices with a thickness less than 25 μm. With this described bubble etching method thin films down to 3 μm could be attained. The determination of the thickness is performed during etching and the thickness is monitored by means of the transparency colors.

Figure 1 shows a schematic cross section of the etching apparatus. The apparatus consists of a Teflon or polyethylene vessel which at the bottom has a thin polyethylene plate perforated with many holes 0.1 mm in diameter. Carbon dioxide is blown through these holes under low pressure. In this way bubbles rise into the upper volume which is filled with the etching solution. The silicon slice which is fixed on a quartz plate with beeswax is slowly rotated in this etching solution to ensure uniform etching.

To investigate the etching process more in detail several parameters were varied: the ingredients of the etching solution, the pressure and the rate of flow of carbon dioxide, respectively, and the rotation velocity of the sample. If the sample is not rotated a concave surface results; on the other hand a convex surface is obtained if the silicon sample is only rotated and if the rotation velocity is too high. It has been found that the etched films are plane if the sample is alternatingly rotated and not rotated during etching and if the ratio of the rotation time to the time without rotation is 2:1. In this case the rotation velocity has a value of 8 rpm. Similar to the rotation of the sample the pressure respectively the rate of flow of the gas influences the plane parallelism of the film. A high rate of flow brings a lot of whirls into the etching solution and a too low flow is not sufficient to remove the gaseous reaction products from the surface: in both cases a nonuniform etching results. A rate of flow of 4 liters/min gave the best results with the described etching apparatus.

The ingredients of the etching solution normally have no influence on the plane parallelism of the

[a] The determination of the thickness during etching is difficult.
[b] + = good, ○ = medium, − = bad.

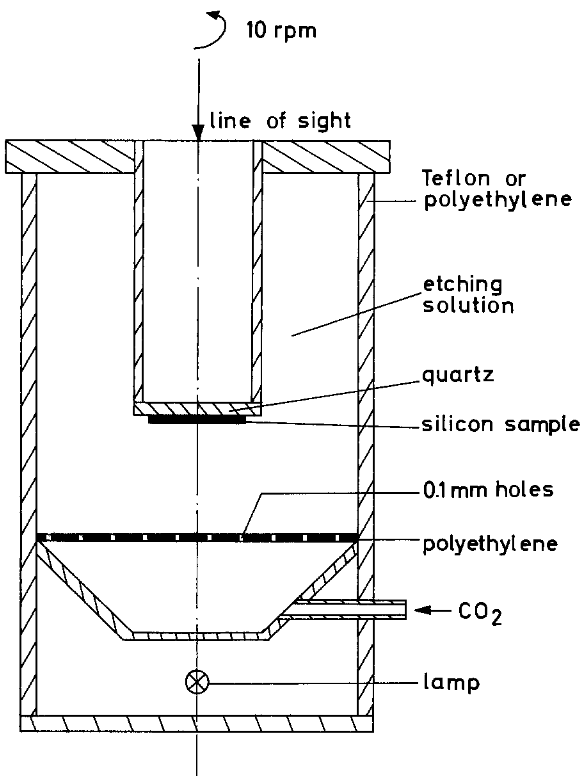

Fig. 1. Schematical cross section of the etching apparatus for the fabrication of thin silicon films.

sample but on the surface behavior. As etching solution only a mixture of nitric acid and hydrofluoric acid was used. Other additional ingredients such as glacial acetic acid often lead to bad surface characteristics such as high etch pit density and passivation layers. The etching solution used with the described bubble etching method consists of a mixture of 10 parts HNO_3 (65%) and one part HF (50%) resulting in an etching rate of 12-15 μm/min depending on the material, *i.e.*, on the dislocation density of the material.

The thickness of the silicon films is monitored during etching by means of the transparency colors. For calibration, thin silicon films were fabricated and their thicknesses were measured by the aid of a microscope. In this way each thickness can be coordinated to a transparency color. Using the apparatus shown in Fig. 1, the color changes from brown to light yellow in a thickness range of 15-1 μm can be observed. The etching process can be stopped immediately when the color corresponding to the desired thickness appears.

With the aid of this bubble etching process silicon films with a thickness down to 3 μm could be fabricated reproducibly. The deviation of the plane parallelism is less than 0.3 μm over the whole area of the silicon film (the used silicon slices had an area of approximately 1 cm^2), even if the initial material has a thickness of approximately 200-300 μm.

Device Fabrication

Normally silicon epitaxial wafers with a total thickness of approximately 200 μm are used as initial material for the fabrication of microwave semiconductor transit time devices. The entire substrate and part of the epitaxial layer are etched away until the desired thickness of the silicon film is reached. It is advantageous to use epitaxial wafers because the exact doping concentration of the epi-layer can be obtained easily, the epitaxial layer is plane and free of damages, and no additional dislocations at the surface are generated by polishing.

Baritt diodes and Impatt diodes have been produced using the thin films fabricated with the described bubble etching method. For MnM Baritt diodes (for X-band frequencies) silicon layers in the thickness range of 7-10 μm are needed. On both sides of the n-layer a Schottky contact is performed and after plating a heat sink on one side, standard photoresist technology is applied on the other side for separating the diodes by mesa etching. By the aid of the thin silicon films it was possible to investigate the behavior of MnM-Baritt diodes (2) which can find application as local oscillators for communication systems.

In a similar fabrication process double-diffused X-band Impatt diodes without any substrate have been fabricated. The initial silicon films had a thickness of 6-7 μm and were simultaneously diffused on one side with p^+ and on the other side with n^+. By this means it was possible to fabricate Impatt diodes with two very abrupt junctions. The advantage of such a structure in comparison to a diode with epitaxial transitions is a smaller series resistance and a resulting higher efficiency and power output (8). The efficiency of these diodes could be increased from 6.5 to 11.5% at a power output of 0.8W.

Conclusion

The fabrication of thin films for microwave semiconductor devices has been investigated. Thin silicon films which satisfy the requirements for microwave transit time devices such as plane parallelism, good surface characteristics, and a minimum of dislocations can be obtained by the bubble etching method. The minimum thickness of the slice was 3 μm even if the initial material has a thickness of more than 200 μm. The measurement of the thickness is performed by the aid of the transparency colors of the silicon during etching. With these thin silicon films MnM-Baritt diodes and double diffused Impatt diodes without any substrate have been fabricated.

Diffusion of Ion-Implanted B in High Concentration P- and As-Doped Silicon

Richard B. Fair* and Paul N. Pappas

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

The diffusion of ion-implanted B in Si in the presence of a uniform background of high concentration P or As has been studied by correlating numerical profile calculations with profiles determined by secondary-ion mass spectrometry (SIMS). Retarded B diffusion is observed in both As- and P-doped Si, consistent with the effect of the local Fermi-level position in the Si bandgap on B diffusivity, D_B. It is shown that D_B is linearly dependent on the free hole concentration, p, over the range $0.1 < p/n_{ie} < 30$, where n_{ie} is the effective intrinsic electron concentration. This result does not depend on the way in which the background dopant has been introduced (implantation predeposition or doped-oxide source), nor the type of dopant used (P or As).

In earlier papers (1, 2) the theory was discussed that the diffusion of B in Si is controlled by donor-type monovacancies. This model predicts that the diffusivity of B increases linearly with B concentration for $C_B > n_i$ when the concentration of n-type dopants, C_N, is $<< n_i$. The combined observations of many workers verify this fact. It has also been demonstrated (2) that the diffusivity of B in uniform As-doped Si ($C_N \approx 1.5 \times 10^{20}$ cm^{-3}) is retarded approximately linearly with the decrease in the normalized hole concentration, p/n_i, also predicted by the donor-type monovacancy model. Some ambiguity may exist in interpreting these results, since the retarded diffusion of B in Si in the presence of a diffusing As layer has been attributed to other effects (3, 4). Therefore, additional data have been obtained by implanting and diffusing B into uniform P- and As-doped Si layers. Retarded B diffusion in both P- and As-doped Si has been observed, consistent with the theory of a Fermi-level-controlled concentration of donor-type vacancies which directly affect B diffusivity. The significance of this result is that transistor modeling programs must take this first-order effect into account, since the diffusion of B in the presence of n-type dopants is invariably encountered. Examples of numerically calculated B diffusion profiles in n-type Si are presented in which the local diffusivity is determined from the local hole concentration, p. Heavy-doping effects (5) on the Fermi-level calculation are included. These calculations are compared with experimental profiles obtained by secondary-ion mass spectrometry (SIMS) analysis.

Experimental

Ion-implantation and doped-oxide source diffusions were both used to introduce P and As into Si slices. Silicon slices [(100) orientation, 1 ohm-cm, p-type] were implanted with 5×10^{15} cm^{-2}, 50 keV P, and then were diffused at 1050°C for 45 min in a N_2/O_2 ambient. In other slices, arsenic implantations were performed (5×10^{15} cm^{-2}, 50 keV), and these samples were diffused at 1050°C for 2 hr, also in N_2/O_2. In both cases, ~600Å of SiO_2 grew on the Si surface, which was retained through the subsequent B implantation. P- and As-doped oxide depositions were performed on another group of Si slices, and diffusions were performed in O_2 at 1050°C for 2 hr. The oxide sources were etched off in HF prior to the subsequent B implantations.

B was implanted into all of the slices at 1×10^{15} cm^{-2}, 50 keV. Diffusion was performed at 1050°C for 23 min in N_2. The B and n-type dopant diffusion profiles were determined by mass analysis of secondary ions ejected from the samples by 15 keV oxygen ion bombardment (predominantly O_2^+) using a Cameca IMS-300 Ion Analyzer. Secondary ions were selected and counted using an AS-200 multichannel analyzer. The analyzer data were converted to impurity concentrations by measuring the depths of the sputtered holes in the samples, and from calibration achieved by knowing the total implanted dose in the Si. For the diffused P and As profiles, spreading resistance measurements were used to establish the surface concentrations and, thus, the calibration for the SIMS data.

Analysis

The coupled diffusion equations for C_B and C_N have been described previously (3, 4). These equations were solved numerically by transforming them into explicit differential-difference equations and by integrating with respect to time by the Runge-Kutta technique. Since the B was implanted to a known dose in all cases, the accuracy of the numerical results was checked by the equation

$$\int_0^\infty C_B(x, t)\, dx = \int_0^\infty C_B(x, 0)\, dx \qquad [1]$$

which stipulates the conservation of the total B concentration.

The local B diffusivity was calculated according to the equation

$$D_B = D_i(p/n_{ie}) \qquad [2]$$

where $pn = n_{ie}^2$ [effective intrinsic electron concentration at the diffusion temperature (5)], D_i is the intrinsic diffusion coefficient

$$p/n_{ie} = \exp(-(E_F - E_{Fi})/kT) \qquad [3]$$

is the normalized free hole concentration, and E_F is the local Fermi level. Calculations of E_F have been made by Jain and Van Overstraeten, taking into account band-tailing and impurity-band formation (heavy-doping effects). Their results have been approximated over limited concentration ranges and for three diffusion temperatures are

1000°C

$$E_F = -0.4 + 0.074 \ln\left(\frac{C_N}{10^{19}}\right) + 0.041\left(1 - \frac{C_B}{10^{20}}\right) \qquad [4]$$

1100°C

$$E_F = -0.35 + 0.083 \ln\left(\frac{C_N}{3 \times 10^{19}}\right) + 0.036\left(1 - \frac{C_B}{10^{20}}\right) \qquad [5]$$

* Electrochemical Society Active Member.

Key words: boron diffusion, cooperative diffusion, profile calculations, secondary ion mass spectrometry.

1200°C

$$E_F = -0.36 + 0.077 \ln\left(\frac{C_N}{3 \times 10^{19}}\right) + 0.03\left(1 - \frac{C_B}{10^{20}}\right) \quad [6]$$

for $10^{19} < C_N < 5 \times 10^{20}$ cm^{-3} and $0 < C_B < 2 \times 10^{20}$ cm^{-3}. The intrinsic Fermi level is calculated from the equation

$$E_{Fi} = -\frac{E_g(T)}{2} - 0.0133\left(\frac{T}{300}\right) \quad [7]$$

where $E_g(T)$ is the silicon bandgap given by

$$E_g(T) = 1.156 - \frac{7.02 \times 10^{-4}T^2}{(T + 1108)} \quad [8]$$

Results

An example of B diffusion in Si with a prediffused P layer (R_S = 46 ohms/□, x_J = 1.5 μm, doped-oxide source) is shown in Fig. 1. The agreement between the SIMS data and the calculated final P and B profiles is quite good. The B diffusivity calculated during the final time increment of the Runge-Kutta integration is also shown plotted as a function of depth. The resulting B profile when diffusion was performed in a P implanted-diffused sample is shown in Fig. 2. The average P doping over the B-doped region was ~1.5×10^{20} cm^{-3}. As a result, even less relaxation of the implanted B has occurred than is shown for the case in Fig. 1. The average diffusivity of the B in Fig. 2 was ~1.5×10^{-14} cm^2/sec which is 0.2 times D_i. These results show unambiguously that the B diffusivity is reduced by the presence of the P.

The sensitivity of the redistribution of the implanted B layer to background n-type doping is illustrated in Fig. 3. The calculated curves show the final B profiles following a 1050°C, 23 min diffusion for several uniform background concentrations of n-type dopant. The SIMS data were taken from a slice with a prediffused P layer (R_S = 16 ohms/□, x_J = 2.1 μm, doped-oxide source).

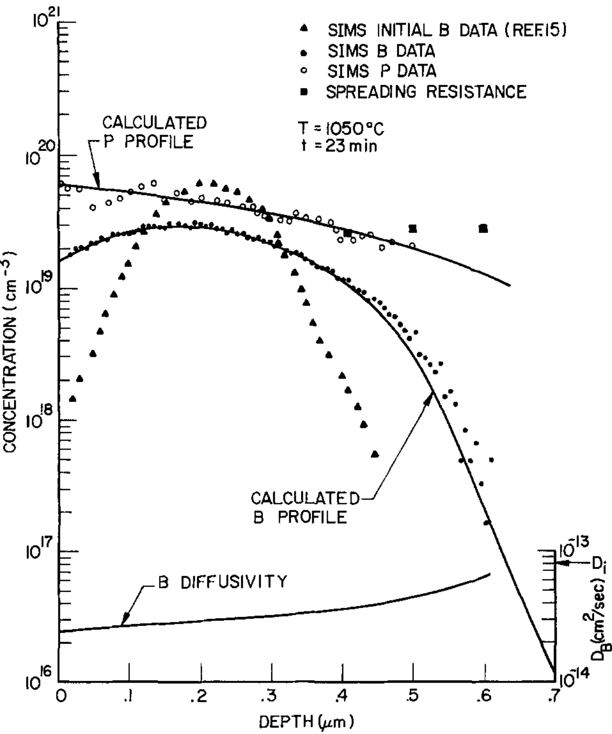

Fig. 1. Experimental SIMS data of as-implanted B (1×10^{15} cm^{-2}, 50 keV: ▲ data), the subsequently diffused B (1050°C, 23 min in N_2: ● data), and the background P doping (○ data) introduced from a doped-oxide source (1050°C, 2 hr in O_2) before the B implant. The calculated B and P profiles are shown as well as the calculated B diffusivity as a function of depth.

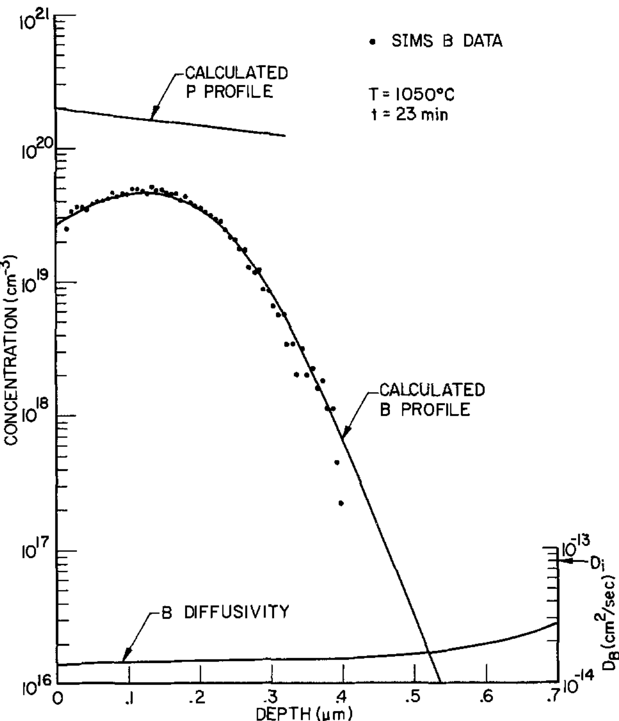

Fig. 2. Experimental SIMS data of B implanted through 600Å of SiO_2 (1×10^{15} cm^{-2}, 50 keV) and diffused at 1050°C for 23 min in N_2. The background doping is implanted P (5×10^{15} cm^{-2}, 50 keV), diffused at 1050°C for 45 min prior to the B implantation. Calculated profiles and the B diffusivity are also shown.

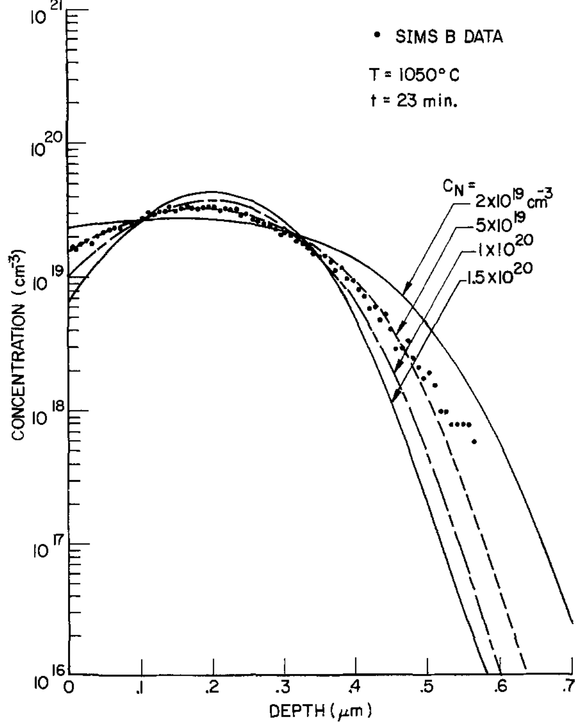

Fig. 3. Calculated B profiles as a function of n-type background doping, C_N. Experimental SIMS data of B (1×10^{15} cm^{-2}, 50 keV) diffused at 1050°C for 23 min in N_2 in a P-diffused (doped-oxide source) background (R_S = 16 ohms/□, x_J = 2.1 μm, $C_N \simeq 5 \times 10^{19}$ cm^{-3}).

For the case of B diffusion in the presence of As, experimental and calculated profiles are shown in Fig. 4. The As was implanted and then diffused in this sam-

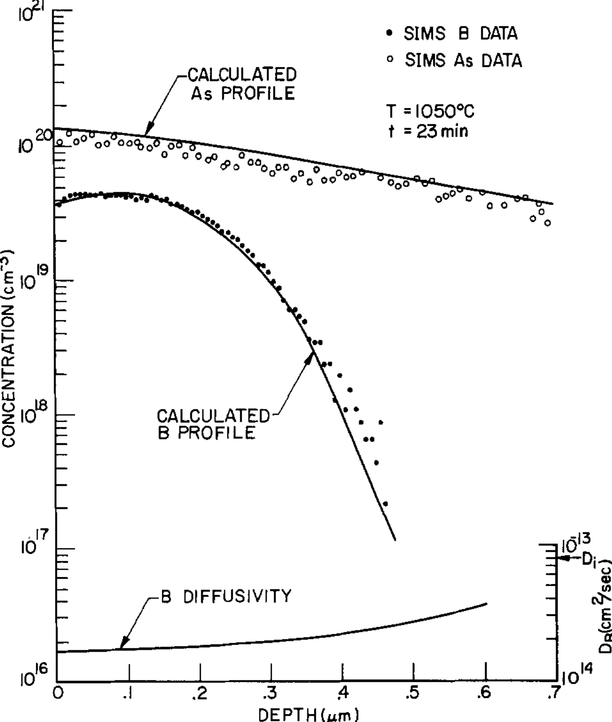

Fig. 4. Experimental SIMS data of B implanted through 600Å of SiO_2 (1×10^{15} cm^{-2}, 50 keV) and diffused at 1050°C for 23 min in N_2. The background doping is implanted As (5×10^{15} cm^{-2}, 50 keV), diffused at 1050°C for 2 hr prior to B implantation. Calculated profiles and the B diffusivity are also shown.

ple. A similar reduction in the B diffusivity is observed.

To summarize the published results on B diffusion (and Ga diffusion), normalized diffusivity is plotted *vs.* p/n_{ie} in Fig. 5. The data representing B diffusion in n-type Si (this study) were obtained by averaging D_B and p/n_{ie} over the diffused B regions. Also included is the data of Crowder *et al.* (2) (Δ and ⬡) which has been corrected in terms of the p/n_{ie} ratio which takes into account the effects of heavy doping on band structure. The type of n-type dopant background is indicated next to each data point. By considering the previously published data (1) from B diffusions into lightly doped substrates, it can be seen

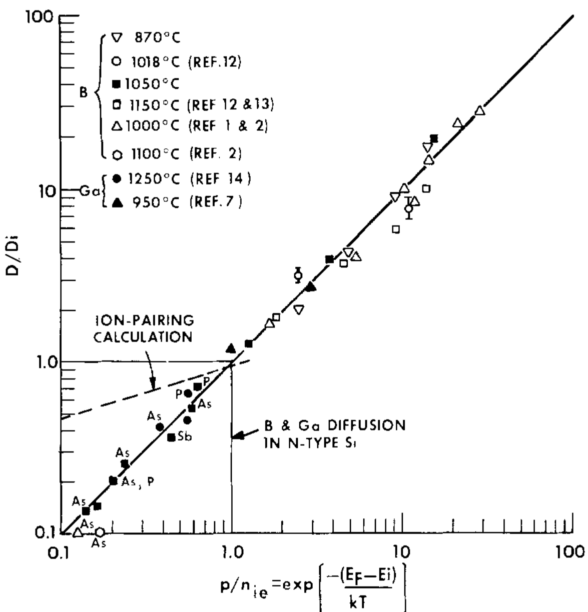

Fig. 5. Diffusivity of boron and gallium in silicon as a function of the normalized hole concentration.

that D_B/D_i is linear with p/n_{ie} over 2½ orders of magnitude. These latter data are plotted by assuming that $n_{ie} \simeq n_i$, since it has been shown that heavy-doping effects on band structure are less pronounced in degenerate p-type Si as compared with degenerate n-type Si (6). All of the data shown (for $p/n_{ie} > 1$) were obtained from B diffusions with surface concentrations less than 2×10^{20} cm^{-3}. Above this concentration, heavy-doping effects certainly should not be neglected.

Also shown in Fig. 5 is previously published Ga diffusivity data. These results indicate that Ga diffusion in Si is also controlled by the position of the Fermi level in the bandgap, which was pointed out by Makris and Masters (7). These authors concluded that a donor-type vacancy is probably responsible for Ga diffusion in Si.

Discussion

Arguments supporting the donor-type monovacancy diffusion model have been previously discussed (1, 2, 7). The data reported in this paper provide additional support for the concept of a simple, positively charged defect being responsible for B diffusion in Si when the diffusion ambient is a nonoxidizing ambient. The additional influence of Si self-interstitials extrinsically generated at an oxidizing Si surface have been discussed previously (1, 8). The conclusion that the donor-type monovacancy is the primary defect which controls B diffusion is based on the following observations:

1. Both quenching and diffusion experiments indicate that the dominant native defect in high temperature silicon has an entropy of ~$5k$ (k = Boltzmann constant). This value is much too large for simple neutral monovacancies or interstitials, nor can the existence of divacancies, semivacancy pairs, or similar complexes be used to explain this result (9). However, the entropy of ionization of the vacancy is quite large at high temperatures. Thus, the large entropy associated with the dominant defect can be accounted for by the entropy of formation of the neutral vacancy ($1.1k$) plus the ionization entropy of the vacancy ($5.1k$), which is within the experimental uncertainty of the measured value (10).

2. The defect involved in atomic diffusion could not be a self-interstitial because the energy of formation of interstitials is too large and their migration is too rapid and athermal (10).

3. The existence of a vacancy in the Si lattice will cause a perturbation such that states will be split from the valence and conduction bands of the surrounding atoms a few tenths of an electron volt into the bandgap (10). Thus, the energy levels associated with simple donor- and acceptor-type vacancies are such that at high temperatures both V^+ and V^- would be more numerous than neutral vacancies.

4. The quenching experiments of Elstner and Kamprath (11) indicate that an energy level exists at E_v + 0.37 eV associated with donor-type complexes in p-type Si samples. The effect of vacancy association should shift the ionization energy of the donor level by only a small amount. Assigning the E_v + 0.37 eV level to a V^+ vacancy means that above 800°K, V^+ is the dominant charge state of the monovacancy in p-Si.

It was pointed out earlier (1) that one other mechanism could possibly account for retarded B diffusion in highly doped n-type Si-ion pairing. For this situation the B diffusion coefficient can be expressed as (3)

$$\frac{D_B}{D_i} = \frac{1}{2}\left[\frac{C_B - C_N + \dfrac{1}{\Omega}}{2\left[\dfrac{1}{4}\left(C_B - C_N - \dfrac{1}{\Omega}\right)^2 + \dfrac{C_B}{\Omega}\right]^{1/2}} + 1\right] \quad [9]$$

where $\Omega(T)$ is the ion-pairing equilibrium constant. Using the charge neutrality condition, Eq. [9] can be rewritten as

$$\frac{D_B}{D_i} = \frac{1}{2}\left[\frac{A + \frac{1}{\Omega}}{2\left\{\frac{1}{4}\left(A - \frac{1}{\Omega}\right)^2 + \frac{C_B}{\Omega}\right\}^{1/2}} + 1\right] \quad [10]$$

where

$$A = \frac{n_{ie}[(p/n_{ie})^2 - 1]}{(p/n_{ie})} \quad [11]$$

The experimental data in Fig. 5 show that D_B/D_i is independent of temperature and n-type dopant. However, $\Omega(T)$ is dependent on both of these variables ($\Omega(1050) = 1.1 \times 10^{-20}$ for the $[As^+B^-]$ pair, while $\Omega(1050) = 1.25 \times 10^{-20}$ for the $[P^+B^-]$ pair). Also, the parameter A depends on temperature. Equation [10] is plotted in Fig. 5 for the $[As^+B^-]$ pairing condition at 1050°C. It can be seen that this phenomenon cannot be used to explain the data.

The B diffusivity expresed explicitly in terms of C_B and C_N can be obtained by substituting Eq. [4] or [5] or [6] into Eq. [3], depending on the temperature (valid only over the concentration ranges indicated). For example, plots of D_B/D_i (or p/n_{ie}) *vs.* C_B for values of C_N are shown in Fig. 6 for diffusions performed at 1000°C.

Conclusions

The diffusion of ion-implanted B in the presence of a uniform background of n-type dopant (P and As) has been studied. In the absence of any previously observed cooperative-diffusion effects (3, 4) (electric-field interaction, ion-pairing, vacancy transients, etc.), a retarded B diffusion has been observed to be consistent with the local Fermi-level position in the Si bandgap, as determined by the net free hole concentration. The native defect most likely responsible for the diffusion of B is the donor-type monovacancy with a level at $\sim E_v + 0.37$ eV.

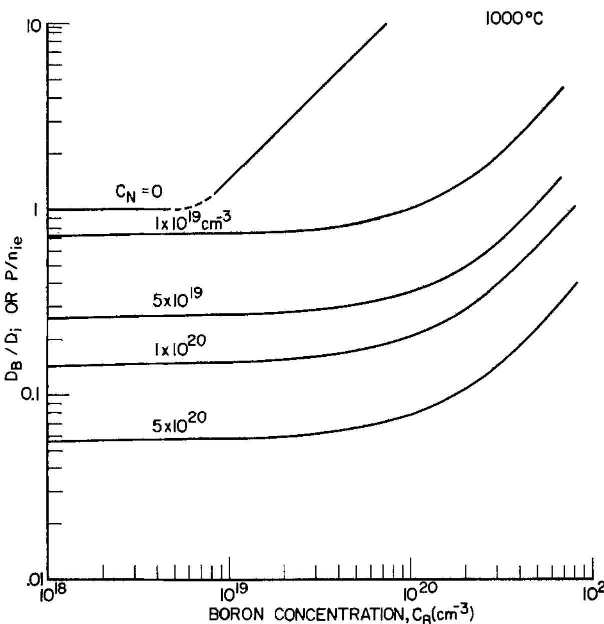

Fig. 6. Boron diffusivity *vs.* concentration at $T = 1000°C$ for several values of n-type background doping density.

Numerical calculations of B diffusion profiles in which the B diffusivity is locally determined from the equation

$$D_B = D_i\, p/n_{ie} \quad [2]$$

with p/n_{ie} given by Eq. [3] have yielded good agreement with profiles experimentally determined by the SIMS analysis. The results did not depend on the way in which the background dopant had been introduced (implantation predeposition or doped-oxide source), nor the type of background dopant used (P or As).

Acknowledgments

The authors would like to thank Mr. J. D. Abbott of the Western Electric Company for performing the SIMS measurements.

Phase Diagram of Al-Ga-In-As Quaternary System

Kazuo Nakajima, Kozo Osamura, and Yotaro Murakami

Department of Metallurgy, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT

The phase diagram of the Al-Ga-In-As quaternary system has been determined experimentally for several Al isoconcentration sections. The liquidus data were obtained by DTA, and the solidus data were determined from liquid epitaxial layers grown on GaAs substrates by using EPMA. The phase diagram was calculated by using a simple solution model. Most of the nine interaction parameters necessary for the present calculation are the same as those used in the corresponding binary and ternary phase diagrams, and the remaining three parameters, Ω^l_{GaAs}, $\Omega^s_{AlAs\text{-}InAs}$, and $\Omega^s_{GaAs\text{-}InAs}$, were determined by fitting each calculated phase diagram to the experimental data.

It has been reported that various, closely lattice-matched heterojunction devices based on quaternary III-V solid solutions are possible which permit the independent variation between lattice constant and bandgap (1). Several devices based on such systems have been reported, for example, $Ga_xIn_{1-x}P_yAs_{1-y}$/InP photocathode emitter (1, 2), $Al_xGa_{1-x}P_yAs_{1-y}/GaP_yAs_{1-y}$ heterojunction lasers (3), and $Al_xGa_{1-x}As_ySb_{1-y}/GaAs_ySb_{1-y}$ heterojunction lasers (4, 5). For producing these devices, the accurate knowledge of their quaternary phase diagrams is desired.

The GaAs-Al_xGa_{1-x}As double heterostructure device is presently one of the most important of the III-V mixed crystal systems, because very low threshold semiconductor lasers can be made from it which can operate continuously at room temperature. At the region of the heteroboundary, however, stresses remain at room temperature due to the different lattice constants of the two layers involved (6). These interface stresses are the primary factors that shorten the lifetime of the lasers. It is possible to get a good match between the lattice constant of the different constituent layers of the diodes by the addition of a fourth component P or In, that is, by making such structures as

$$GaAs/Al_xGa_{1-x}P_yAs_{1-y}/Al_vGa_{1-v}P_wAs_{1-w}/Al_xGa_{1-x}P_yAs_{1-y}$$

or

$$GaAs/Al_xGa_{1-x}As/Al_yGa_zIn_{1-y-z}As/Al_xGa_{1-x}As.$$

It is difficult, however, to grow the alloys with exactly controlled compositions with the first system, because the addition of a small amount of P substantially raises the melting temperatures of the alloys, the vapor pressure of phosphorus in the alloys is very high, and the atomic ratio of P to As in the quaternary solid solutions varies rapidly with a small change of As concentration in the liquid (7). Consequently, because of their low melting temperatures and the fact that there is only one volatile component, As, it is better to use the second system for growing crystals with closely controlled compositions

In the present paper, the experimental and calculated phase diagrams of Al-Ga-In-As system were determined to facilitate the preparation of closely lattice-matched heterojunction devices.

Experiments and Results

Liquidus.—Differential thermal analysis was used for the determination of the liquidus isotherms of the Al-Ga-In-As system. In this work, the materials used were semiconductor grade Ga, In, Al, and GaAs. The required amounts of these materials were sealed under vacuum into a fused silica capsule as reported earlier (8). The capsule was held above the melting point of GaAs, then cooled at a constant rate of 3.0°C/min. After it had been cooled below an inflection point, T_c, that was observed in the cooling curve, it was again heated with a constant heating rate of 3.0°C/min to above an inflection point, T_h, that was observed in the heating curve. The temperature, T_h, was read from the foot point on the higher temperature side of the peak due to the latent heat of fusion of the solid in the heating curve. It is considered that the last solid completely dissolves and the evolution of the heat finishes off slightly below this point. The temperature, T_c, at which a primary crystal appears in the melt, tends to be lower than the equilibrium liquidus temperature due to the supercooling effect. Therefore, in the present analysis, an average of T_c and T_h was taken to be the transformation temperature. These temperatures are listed in Table I.

In solutions containing X^l_{Al} = 0.001, 0.002, and 0.005. the liquidus at the cross sections of $X^l_{As}/(X^l_{Ga} + X^l_{In} + X^l_{As})$ = 0.05, 0.10, and 0.20 are shown in Fig. 1, 2, and 3, where X^l_i represents the atomic fraction of the element i in the liquid. These Al compositions were taken from the previously calculated phase diagram to permit growth of Al_xGa_{1-x}As (x = 0-0.3) epitaxial layers within a reasonable temperature range. These figures show that addition of Al to the melt raises the liquidus and decreases the solubility of As in the liquid.

Solidus.—$Al_xGa_yIn_{1-x-y}As$ epitaxial layers were grown onto Cr-doped or Te-doped GaAs (100) or (111)A substrates from quaternary solutions to determine the solidus isotherms. The apparatus consisted of a horizontal furnace, a fused silica tube, and a sliding graphite boat. At the start of a run, the apparatus was heated rapidly to 50°C above the starting temperature of the growth and maintained there for about 1 hr. It was then cooled with a constant cooling rate of 1.0°C/min. At the desired growth temperature, the substrate was brought into contact with the solution by moving the slider. The growth ranges were 805°-775°C and 905°-875°C. After the growth, the solution was separated from the seed by sliding the boat, then the apparatus was rapidly cooled to room temperature. Layer thicknesses were in the range of 20 to 30 μm.

Ga and In concentrations were determined on cleaved sections of epitaxial layers with EPMA. A scanning electron microscope equipped with an energy-dispersive x-ray analyzer was used. An electron beam energy of 25 keV was used and the peak energy of the Ga-Lα emission bands was measured. GaAs and InSb were used as the EPMA standard for Ga and In, respectively. The measured relative x-ray intensities were normalized by performing the atomic number, absorption, and fluorescence corrections.

The quaternary layers on GaAs substrates were single crystal. The surfaces of the layers grown from 800°C were generally smoother than those from 900°C. The layers grown from the liquidus containing $X^l_{In} > 0.3$ showed uneven surfaces and generally were polycrystalline. The condition of the surfaces was not influenced by Al concentration in the liquid within the range of the present experiments. The variation of the crystal composition was due to the depletion of Al in the melt near the growing interface during cooling. The composition of the layer near the interface between the GaAs substrate and the epitaxial layer was adopted as the solidus composition of the primary precipitated crystal.

The solidus isotherms in equilibrium with the quaternary liquids containing $X^l_{In} < 0.4$ and X^l_{Al} = 0.001, 0.002, and 0.005 were determined. The solidus data values are listed in Table II. Figures 4 and 5 show the solid solubility isotherms for Al in the quaternary liquids at 800° and 900°C, respectively. These solidus isotherms show that the lower the growth temperature, the larger the distribution coefficient for Al becomes. Figures 6 and 7 show the solid solubility isotherms for In in the quaternary liquidus at 800° and 900°C, respectively. These isotherms indicate that the higher the growth temperature and the lower X^l_{Al}, the larger the distribution coefficient for In becomes.

Discussion

This experimental phase diagram showed that the solubility of In in the solid was very small and almost linearly dependent on X^l_{In}, and that the distribution

structure and whose lattice is matched with that of

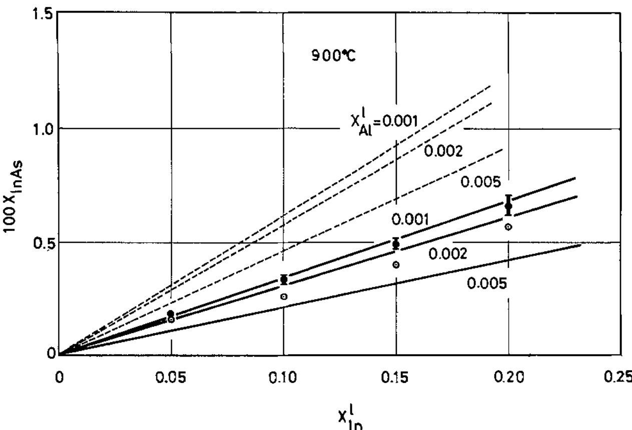

Fig. 7. 900°C InAs solidus isotherms in the Al-Ga-In-As system at X^l_{Al} = 0.001 and 0.002. ●, X^l_{Al} = 0.001; ⊙, X^l_{Al} = 0.002. - - - - - and ——— represent the calculated solidus for the first (I) and second (II) sets of parameters given in Table III, respectively.

$Al_xGa_{1-x}As$ can be easily prepared by using the information contained in the phase diagram. That is, the desired amount of In can be easily dissolved in the solid at the appropriate Al composition.

The Al-Ga-In-As phase diagram was calculated by treating the quaternary liquid and solid as a simple solution (11, 12) in which the interaction parameters are approximated by a linear temperature dependent function. The basic equations given by Huber (13) expressing the chemical equilibrium between the pseudoternary solid of the type $A_xB_yC_{1-x-y}D$ and the quaternary liquid were used. These equations are useful for the calculation of the III_A-III_B-III_C-V_D type phase diagram because the solid of the type $A_xB_yC_{1-x-y}D$ is completely analogous to the pseudobinary solid. The reasonable values found in the literature were used as the interaction parameters necessary for the calculation. These values are listed in Table III. The calculated results represented by dashed lines in Fig. 1-7, however, did not agree well with every experimental one. For obtaining the reasonable agreement, the values of three parameters, Ω^l_{GaAs}, $\Omega^s_{AlAs\text{-}InAs}$, and $\Omega^s_{GaAs\text{-}InAs}$, had needed to be changed as $\Omega^l_{GaAs} = 6100 - 9T$, $\Omega^s_{AlAs\text{-}InAs} = 4800$, and $\Omega^s_{GaAs\text{-}InAs} = 4800$ cal/mole, but the implication of the magnitude of these parameters presented here is not clear. The calculated results are represented by solid lines in Fig. 1-7. Figure 8 shows the liquidus isotherms and the AlAs and InAs solidus isotherms on the entire cross section of 0.2 atom per cent Al in the liquid which are calculated by using such changed parameters. Figure 8 summarizes the results of Fig. 4-7.

Table III. Thermodynamic input data for phase diagram calculation

The diagram was calculated for two sets of interaction parameters. Each set is consisted of nine parameters. Six are common parameters in two sets and the remaining three parameters, Ω^l_{GaAs}, $\Omega^s_{AlAs\text{-}InAs}$, and $\Omega^s_{GaAs\text{-}InAs}$, are not. The first and the second sets are marked with I and II, respectively.

ABSTRACT

The high-temperature oxidation behavior of a HfB_2 + 20 v/o SiC composite was investigated in the temperature range 1200°-1550°C and in oxygen partial pressures at 1400°C ranging from 2.6×10^{-9} to 3.3×10^{-1} atm. Oxidation kinetics in pure oxygen were parabolic, with the rate constants exhibiting linear Arrhenius behavior. The rate of oxygen consumption is described by $k_p = 1.62 \times 10^7 \exp(-106{,}000/RT)$ $g^2\text{-cm}^{-4}\text{-hr}^{-1}$ in the range 1350°-1550°C. The oxide scale formed in this range consisted of an inner HfO_2 layer in series with an outer SiO_2 layer. The oxidation rate was found to be controlled by initial short-circuit oxygen diffusion through the HfO_2, followed by volume diffusion through the SiO_2 scaling layer. Below 1350°C, rapid oxidation kinetics were observed, HfO_2 being the primary scale constituent.

Interest in diboride composites stems from their potential use in high-temperature oxidizing environments. These materials hold promise due to their chemical inertness, thermal-shock resistance, retained strength at high temperature, and oxidation resistance. Early studies by Kaufman *et al.* (1) on the oxidation of undoped diborides showed the oxidation resistance of HfB_2 to be superior to that of its Zr, Ti, Ta, and Nb counterparts based on a comparison of the total diboride recession after a 1 hr exposure to oxygen at temperatures ranging from 1300°-2000°K. Later, Kaufman *et al.* (2) and Berkowitz-Mattuck (3) studied the oxidation rate of HfB_2 and ZrB_2 as a function of temperature and oxygen partial pressure in order to determine the mechanism of oxidation. The oxidation kinetics were observed to obey a parabolic rate law, and oxygen diffusion through the scaling layer was found to be rate determining. More recently, Clougherty *et al.* (4) investigated the oxidation behavior of HfB_2 and ZrB_2 containing additions of SiC as a function of temperature only, and total diboride recession was measured after 1 hr of oxidation. The SiC addition was found to increase the oxidation resistance; however, kinetic data were not obtained.

The oxidation of ZrB_2 and ZrB_2 + 20 v/o SiC has been investigated by Tripp *et al.* (5-7) as a function of temperature and oxygen partial pressure using thermogravimetric techniques. The oxidation reaction was found to be controlled by diffusion through a SiO_2 scaling layer. In the present investigation, the oxidation behavior of HfB_2 + 20 v/o SiC was studied as a function of temperature and oxygen partial pressure. The oxidation resistance of the HfB_2 + SiC composite was compared to that of its constituent components as well as its zirconium counterpart in order to define the rate-determining oxidation mechanism.

Experimental

The diboride composite used in this study was prepared by Man Labs, Inc. under contract with the Air Force Materials Laboratory. The HfB_2 + 20 v/o SiC powders had been hot pressed at 2200°C under a pressure of 3000 psi for 90 min, and the resulting billet was 88% dense. Coupons (~ 1 × 0.5 × 0.1 cm) were cut from the billet, ground with 600-grit SiC paper, and ultrasonically cleaned in acetone and methanol.

Oxidation kinetics were determined using an oxygen-consumption technique (5-7) which is very useful for studying oxidation where one or more of the reaction products is volatile at sample temperature but condensable at lower temperatures. With this technique the volatile species are collected on the walls of a cold alumina crucible which is suspended over the sample, and the weight of the sample plus crucible is monitored continuously with time. In this way the weight gain due to the oxygen used to form both the solid and volatile products can be measured. The measurement of sample weight change alone does not give a true indication of the reaction kinetics because sample weight gains and losses occur simultaneously. In the present work nonvolatile HfO_2 and SiO_2 are formed as well as volatile B_2O_3 and SiO. The CO and CO_2 which are formed as oxidation products cannot be condensed on the cold crucible; however, their weight is only 10-15% of the total weight change.

The kinetics of total oxygen consumption were studied using a Cahn RH electrobalance having a capacity of 100g and a sensitivity of ± 2 μg. The balance assembly has been described previously (5, 8). The diboride specimen and crucible were preheated for ~ 15 hr in Ar at 500°C in the balance assembly. The furnace was then quickly heated to the desired temperature and the oxidant (O_2, O_2/Ar, or CO/CO_2) admitted into the furnace chamber until the desired total pressure was reached. In all cases the oxidation experiments were conducted in flowing gas at ~ 60 cm^3 (STP)/min.

Postoxidation analysis of the specimens consisted of x-ray analysis for determining scale constituents, microprobe analysis for elemental distribution, and optical and scanning electron microscopy for scale morphologies.

Results

Oxidation in pure oxygen.—The oxidation behavior in pure oxygen was studied in the temperature range 1200°-1550°C; the results of a typical experiment are shown in Fig. 1. In all experiments parabolic behavior was observed after an initial transient period, the initial rapid kinetics being due to short-circuit diffusion (see Discussion section). Scaling rate constants com-

puted from the slopes of the parabolic plots are given in Arrhenius form in Fig. 2. The activation energy for oxidation in the range 1350°-1550°C is 106 kcal/mole with

$$k_p = 1.62 \times 10^7 \exp(-106{,}000/RT)\ g^2\text{-}cm^{-4}\text{-}hr^{-1}$$

The scaling rate increases abruptly below 1350°C due

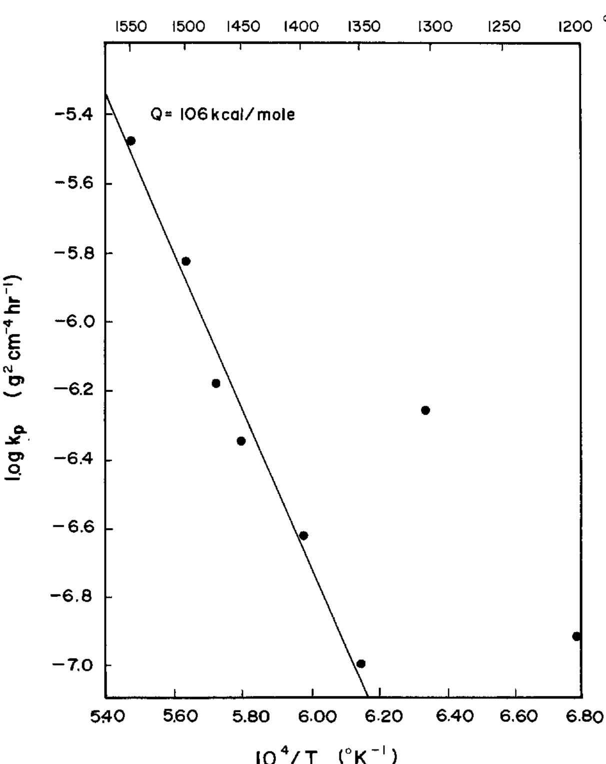

Fig. 2. Arrhenius plot of parabolic rate constants for total oxygen consumption of HfB_2 + SiC in 250 Torr O_2.

to selective oxidation of the HfB_2 with very slow attack of the SiC. Only small amounts of SiO_2 were found on the samples oxidized at these low temperatures. Therefore, the beneficial effect of the addition of SiC appears to be lost in this temperature range.

Figure 3 is an optical micrograph of the polished cross section of a sample oxidized for 24 hr at 1400°C in 250 Torr oxygen. The scale formed consists of an amorphous SiO_2 layer on top of a HfO_2 layer and is typical of those formed in the high-temperature region. The HfO_2 is porous and of uniform thickness, the dark regions being a combination of voids and SiC particles. The matrix beneath the scale contains a uniform distribution of SiC particles and no SiC depletion is observed.

X-ray diffractometer analysis of the oxidized specimens indicated that monoclinic HfO_2 and tetragonal $HfSiO_4$ are the primary scale constituents. The expected amorphous silica hump and cristobalite peak could not be found with this technique. The location of the scale constituents was obtained using the electron-beam microprobe. Figure 4 is a microprobe scan of the sample oxidized at 1400°C. The zone between 19 and

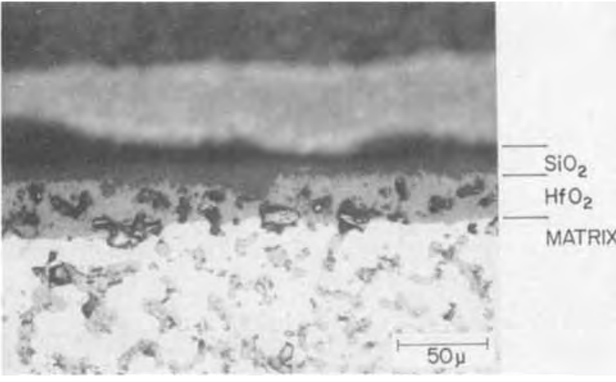

Fig. 3. Optical micrograph of a HfB_2 + SiC specimen oxidized at 1400°C in 250 Torr O_2 for 24 hr.

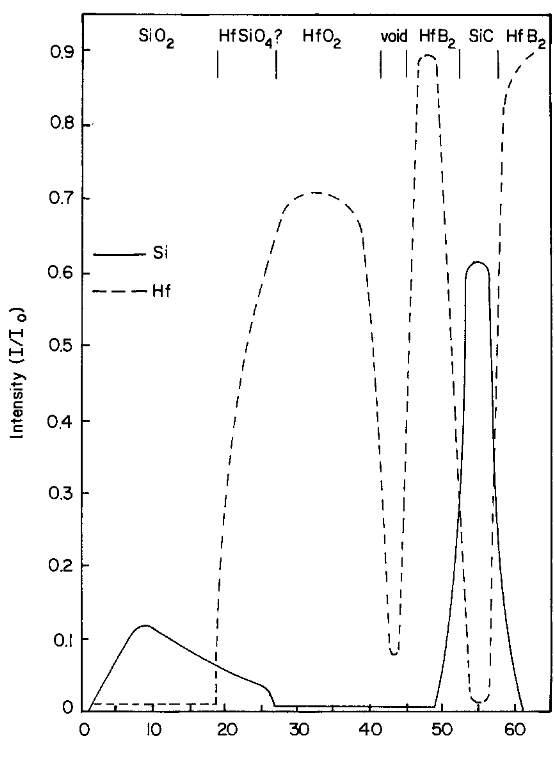

Fig. 4. Electron-beam microprobe scan of a HfB_2 + SiC specimen oxidized at 1400°C in 250 Torr O_2 for 24 hr.

27μ may be $HfSiO_4$; however, since the intensity of the Hf peak varies throughout this range, the thickness of the $HfSiO_4$ cannot be determined. The $HfSiO_4$ probably exists as a very thin reaction layer between the SiO_2 and HfO_2 scaling layers. No B was found in the microprobe scans of the scales, suggesting that B diffuses through the scale and vaporizes as B_2O_3 at the scale-ambient interface.

Oxidation at reduced oxygen partial pressures.—The oxygen partial pressure dependence of the rate of oxygen consumption was investigated at 1400°C. Reduced oxygen partial pressures in the range 3.6×10^{-9} to 3.3×10^{-1} atm were established with premixed O_2/Ar and CO/CO_2 gas mixtures obtained from Air Products and Chemicals, Inc., the total system pressure being maintained at 250 Torr. A parabolic plot of the data is presented in Fig. 5. Oxidation kinetics are slower than parabolic in the O_2/Ar mixtures except at a P_{O_2} of 3.2×10^{-4} atm where rapid linear oxidation kinetics are exhibited. At this P_{O_2} active oxidation of the SiC occurs, with gaseous SiO being formed as the reaction product. A weight gain, rather than a weight loss, is observed because the volatile species is collected as SiO_2 on the cold crucible surrounding the HfB_2 + SiC sample. The rate of oxygen consumption is found to increase with decreasing P_{O_2} in O_2/Ar gas mixtures down to 3.2×10^{-4} atm. Below this pressure CO/CO_2 gas mixtures were used, and the trend is reversed. The oxidation kinetics are parabolic in CO/CO_2 mixtures as in pure oxygen, suggesting that the reaction is diffusion controlled; however, the oxidation rates at the low oxygen partial pressures established by these mixtures are much higher.

Figure 6 is a light micrograph of the sample oxidized at a P_{O_2} of 3.2×10^{-4} atm. As expected, the SiO_2 scale is absent, and a thick HfO_2 layer has formed. The SiC particles have been depleted in the matrix due to rapid active oxidation. This micrograph is in contrast to that of the sample oxidized in pure oxygen (Fig. 3)

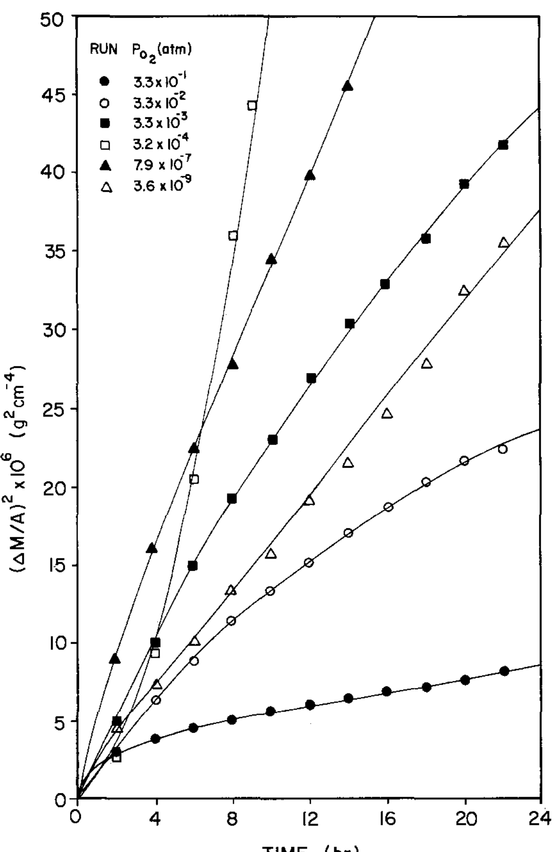

Fig. 5. Total oxygen consumption of HfB_2 + SiC as a function of oxygen partial pressure at 1400°C: ● O_2; ○, ■, □ O_2/Ar; ▲, △ CO/CO_2.

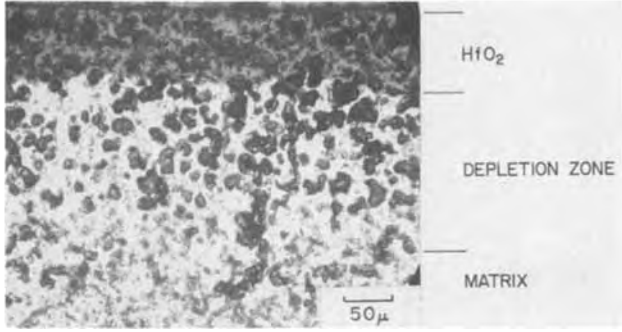

Fig. 6. Light micrograph of a HfB_2 + SiC specimen oxidized at 1400°C in 975 ppm O_2/Ar (P_{O_2} = 3.2×10^{-4} atm) for 24 hr.

where no such depletion zone is present. Figure 7 is a comparison of scanning electron micrographs of these two specimens oxidized at 1400° in a P_{O_2} of 3.3×10^{-1} and 3.2×10^{-4} atm. The HfO_2 scale formed at the higher P_{O_2} appears to be more coherent than that formed at the lower P_{O_2} which contains pores and pinholes through which SiO escaped during oxidation.

Light micrographs of samples oxidized in CO/CO_2 mixtures are shown in Fig. 8. The HfO_2 scale formed on these samples has a greater thickness than that formed in pure oxygen, and globules of SiO_2 rather than a coherent layer are formed on the HfO_2 layer. No active oxidation of the SiC particles was found, as evidenced by the absence of a SiC depletion zone near the matrix-oxide interface.

Discussion

The parabolic oxidation kinetics observed in pure oxygen indicate that the oxidation reaction is diffusion controlled. Oxidation may be controlled by one of several mechanisms, including inward diffusion of oxygen through either the HfO_2 or SiO_2 layer or outward diffusion of Si, C, or B through the HfO_2 or SiO_2. If the oxidation mechanism is via oxygen transport through the HfO_2 scale, the oxidation rate and activation energy for oxidation should agree with previous results for Hf and HfB_2 oxidation. The rates of oxidation for HfB_2 + SiC, HfB_2, and Hf in 250 Torr O_2 are compared in Fig. 9. In order to compare the oxidation kinetics for the three materials, the rates of HfO_2 formation were computed from the experimental parabolic rate constants, assuming that the diboride materials oxidize stoichiometrically according to the reactions

$$HfB_2 + 5/2\,O_2 = HfO_2 + B_2O_3 \quad [1]$$

and

$$HfB_2 + 0.36SiC + 3.04\,O_2 = HfO_2 + 0.36SiO_2 + B_2O_3 + 0.36CO \quad [2]$$

The low-temperature (600°-1200°C) data by Smeltzer and Simnad (9) for Hf oxidation were extended into the range of interest. For the oxidation of Hf and HfB_2, the agreement in rates of HfO_2 formation and activation energies is quite good, which suggests that the oxidation mechanism is the same for the two materials. However, the SiC addition to the HfB_2 significantly alters the kinetics and activation energy for oxidation. Although volume diffusion of oxygen through the HfO_2 layer has been found to control the oxidation of Hf (9) and HfB_2 (3), this mechanism is not rate determining during the oxidation of HfB_2 + SiC.

If the oxidation of HfB_2 + SiC is controlled by diffusion of oxygen through the SiO_2 scaling layer, the activation energy and kinetics of oxidation should agree with those of other silicon-based materials. Generally activation energies of 28-30 kcal/mole are reported for silicon oxidation in the range 800°-1200°C (10-12). However, in recent investigations on the oxidation of silicon (13) and hot-pressed silicon carbide (14-16), activation energies of ~ 70-115 kcal/mole were reported. In Fig. 10 the oxidation kinetics of HfB_2 + SiC are compared with those for SiC oxidation obtained by the present authors (15, 16). The rates of SiO_2 formation were compared for the two materials using the stoichiometric oxidation reaction (2) and

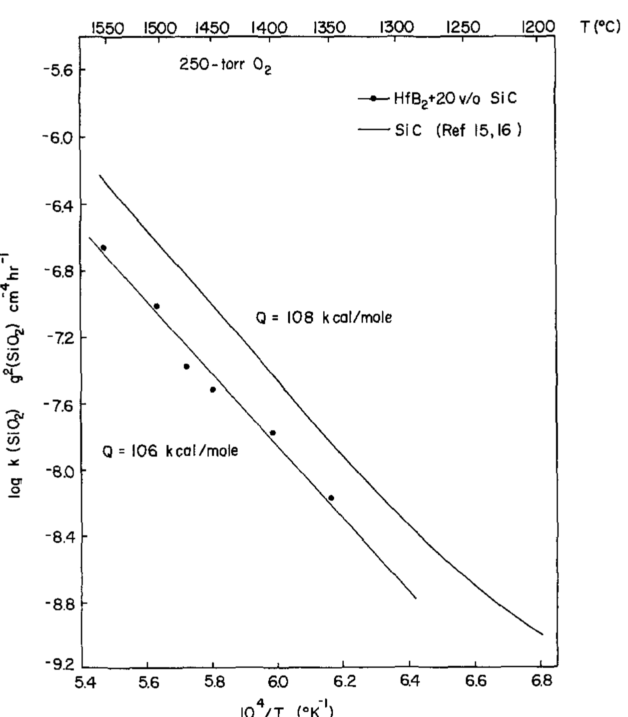

Fig. 10. Comparison of the rates of SiO_2 formation during oxidation of HfB_2 + 20 v/o SiC and hot-pressed SiC in 250 Torr O_2.

the reaction

$$SiC + 3/2\, O_2 = SiO_2 + CO \quad [3]$$

The agreement in rates and activation energies is excellent, confirming that the oxidation mechanism is the same for the two materials. Therefore, outward diffusion of B through the scale is eliminated as a possible rate-controlling mechanism. For SiC oxidation a mechanism involving outward diffusion of C was shown to be unlikely. Instead, volume diffusion of oxygen through the scale was found to be rate controlling, the valence of the oxygen species being indeterminate (15-16). Thus, in pure oxygen, the oxidation mechanism of both HfB_2 + SiC and SiC is inward diffusion of oxygen through the silica scale.

Some question arises as to the manner in which the external SiO_2 scale forms atop the internal HfO_2 layer. The optical micrographs and microprobe scans of the oxidized specimens reveal the presence of SiC particles in the HfO_2 layer. It is believed that a number of these particles are present at or near the ambient HfO_2 interface following the initial transient oxidation period and that the SiO_2 which subsequently forms on the SiC particles spreads laterally across the HfO_2 surface forming a protective layer. In view of the similarity between the oxidation behavior of SiC and that of HfB_2 + SiC, it appears that any rate-controlling mechanism involving outward Si diffusion through the HfO_2 layer is improbable.

The oxygen partial pressure dependence of the oxidation rate is quite different for SiC and HfB_2 + SiC. At reduced oxygen partial pressures in O_2/Ar gas mixtures, the oxidation rate of SiC was parabolic and increased with P_{O_2}. In the present investigation the rate decreased with increasing P_{O_2} in the same mixtures. The rapid rate of oxidation at a P_{O_2} of 3.2×10^{-4} atm has already been interpreted in terms of active oxidation of the SiC particles in the HfB_2 matrix. However, at larger oxygen partial pressures, no evidence for active oxidation through depletion of the SiC particles was found. The downward curvature of the parabolic plots at these pressures suggests that the oxidation rate is controlled by oxygen diffusion along short-circuit paths through the HfO_2 layer, the number of paths decreasing with time. Such short-circuit diffusion has been observed and interpreted by Smeltzer *et al.* (17) for the initial oxidation of Zr and Hf. If the rate of SiO_2 formation decreases with decreasing P_{O_2}, as observed for SiC oxidation, it will take longer to form a coherent SiO_2 layer at reduced P_{O_2}, and the short-circuit diffusion found initially in pure oxygen will occur for a longer period of time. Therefore, in O_2/Ar mixtures the oxidation mechanism is essentially the same as it is in pure oxygen except that the period of short-circuit diffusion is extended.

In CO/CO_2 gas mixtures the oxidation rates were parabolic after a brief transient period, decreased with decreasing P_{O_2}, and were larger than in pure oxygen. The SiO_2 formed in these mixtures appeared as globules and was not protective. Although the cause of the globule formation is not clear, volume oxygen diffusion through the HfO_2 layer is believed to be rate determining in these mixtures. Active oxidation of the SiC particles was not observed in CO/CO_2 mixtures. In these mixtures the partial pressure of CO in the gas surrounding the sample is large causing the active oxidation reactions

$$SiC + 2SiO_2 = 3SiO + CO \quad [4]$$

and

$$2CO_2 = SiO + 3CO \quad [5]$$

to be retarded or driven to the left.

The rates of total oxygen consumption of HfB_2 + SiC and ZrB_2 + SiC composites in 250 Torr O_2 are compared in Fig. 11. The 1400°C data for the ZrB_2-based composite are those of Tripp *et al.* (7) converted to a parabolic plot. The initial rapid oxidation kinetics of the two composites are controlled by short-circuit

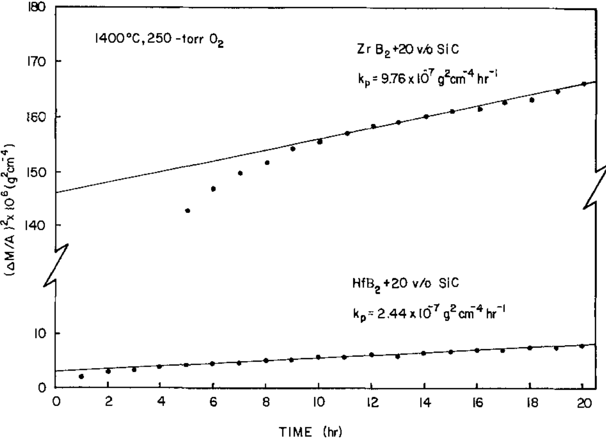

Fig. 11. Comparison of the rates of total oxygen consumption for HfB_2 + 20 v/o SiC and ZrB_2 + 20 v/o SiC at 1400°C in 250 Torr O_2.

diffusion through the inner HfO_2 or ZrO_2 scales; however, the reason for the large difference in initial oxidation rates is unknown. After ~ 10 hr the oxidation rate of the ZrB_2 + SiC composite is only a factor of four larger than that of the HfB_2 + SiC. Since each composite contains ~ 26-27 m/o SiC, the stoichiometric oxidation reactions are essentially the same for the two materials. Hence, the rates of silica formation during oxidation can be compared directly and agree well within one order of magnitude. The oxygen partial pressure dependences of the oxidation rates are also similar. Therefore, the same mechanism, initial short-circuit oxygen diffusion through the HfO_2 or ZrO_2 followed by oxygen diffusion through the SiO_2 scaling layer, controls the oxidation of the two materials.

Kinetics of Phosphorus Predeposition in Silicon Using $POCl_3$

P. Negrini, D. Nobili, and S. Solmi

C.N.R.—LAMEL, Via Castagnoli, 1, 40126 Bologna, Italy

ABSTRACT

Phosphorus predeposition in silicon using a $POCl_3$ source and oxidizing conditions has been studied over a wide range of temperature (850°-1200°C) and doping gas compositions, by determining the total and electrically active dopant and the thickness of the surface oxide. The dependence of the fraction of electrically inactive phosphorus on temperature, time, and doping gas composition was studied; and it is reported that phosphide precipitation takes place in the course of the predeposition. These observations lead to the conclusion that the flux of phosphorus is not limited by the solubility of this element in silicon, and this is confirmed by the results of the study of the kinetics, which are reported. They show that the rate-determining process of phosphorus predeposition and the associated oxide growth is the diffusion across the oxide layer. The amount Q of dopant predeposited in an isothermal process increases with a parabolic time law

$$Q = \sqrt{K_0 \exp\left(-E_K/kT\right) \cdot t}$$

and a similar behavior is observed for the oxide thickness

$$X_0 = \sqrt{B_0 \exp\left(-E_B/kT\right) \cdot t}$$

It is shown that E_K and E_B are constants in a wide range of experimental conditions, and the dependence of K_0 and B_0 on gas composition is reported. A method, based on surface resistivity measurements after drive-in, which provides quantitative determinations of the predeposited phosphorus in satisfactory agreement with activation analysis, is reported in the Appendix.

A considerable amount of information exists in the literature on the electrical properties of phosphorus-doped layers in silicon as a function of the main parameters of the predeposition process (1-4).

It has been noticed by several authors that only a fraction of the predeposited phosphorus is electrically active and that it changes with subsequent heat-treatments (5, 6). Several hypotheses, among which is that of precipitation, have been put forward to explain the phenomenon (7, 8).

In silicon device technology, predeposition is generally followed by heat-treatments (drive-in, oxidation, annealing) which can therefore result in an unpredictable change of the amount of electrically active dopant.

In industrial practice this uncertainty is by-passed by using standard procedures for device production.

Determination of the total phosphorus content as a function of the main parameters of the predeposition thus has practical interest and is a necessary procedure for an analysis of the kinetics of this process.

Further, determination of the functional relations between the physical and chemical variables and the electrically active and total dopant can contribute to clarifying the nature of the electrically inactive phosphorus.

Key words: silicon, phosphorus oxychloride, kinetics of predeposition, phosphorus precipitation.

Experimental

Low dislocation density (< 500 cm^{-2}), (111) oriented, boron-doped, Czochralski-pulled silicon of nominally 1 ohm·cm, about 300 μm thick, has been used in our experiments. Slices, produced by Wacker, were mirror finished on one side.

Predeposition experiments were carried out under oxidizing conditions in an open tube furnace[1] having an internal diameter of 55 mm. Temperature uniformity in the flat zone of the quartz tube ($\sim$ 30 cm) was kept within ± 0.5°C.

Experiments were run at 850°, 920°, 1000°, 1100°, and 1200°C using a $POCl_3$ source kept at 24°C (corresponding to a vapor pressure of 34 Torr).

The predeposition atmosphere consisted of high purity nitrogen bubbled through the phosphorus oxychloride source and mixed, before entering the furnace, with the main carrier gas (nitrogen plus high purity oxygen).

[1] B.T.U. Engineering Corporation, Model DC. LH1.

A set of experiments has been carried out at various partial pressures of dopant, always keeping the ratio between $POCl_3$ and O_2 constant; another set by changing only oxygen partial pressure and a third set by changing only that of $POCl_3$. In any case the total gas flow was kept constant (1580 ml/min) by adjusting the main nitrogen flow. Calibrated flow meters[2] were used to control the predeposition atmosphere.

Prior to each deposition a 5 min warm-up period was given without the flow of dopant and, afterwards, a further 3 min flushing as a health precaution.

Extraction from the furnace was, unless specified, rapid (about 1 sec). Specimens were left to cool in an air stream, and a quartz boat of low thermal capacity was used.

The thickness of the phosphorus glass formed during the predeposition was accurately measured by a Talystep (maximum sensitivity 20Å) by making at least 10 determinations for each specimen.

We have determined both the electrically active and the total content of phosphorus. As discussed in the Appendix the latter quantity has been measured by neutron activation analysis and electrical resistivity after suitable drive-in. These were carried out at 1100° or 1200°C in a N_2 + 10% O_2 atmosphere, after removal of the phosphorus glass in dilute hydrofluoric acid.

Both after predeposition and drive-in processes sheet resistivity was measured by the four-point probe technique; five distinct determinations were executed on each specimen after removing oxide with dilute HF. At least three specimens were processed for each experimental point.

The presence of precipitates in predeposited specimens has been checked both by transmission electron microscopy (TEM) using an Elmiskope 101 electron microscope, and by x-ray topography using a Lange camera and $CuK_{\alpha 1}$ radiation.

TEM observations have been carried out on the polished side after thinning the slice by etching the opposite surface with a jet technique. Also the specimens for x-ray topography were chemically thinned to eliminate the damaged lapped side.

Results and Discussion

Total and electrically active predeposited phosphorus. —We report first the values of Q and Q_{el} (total and electrically active phosphorus) for a predeposition time of 27 min at 920°C. In Fig. 1 these quantities are plotted *vs.* the concentration of $POCl_3$ at a constant O_2 concentration of 5.7%.

In Fig. 2 the values of Q and Q_{el} are reported *vs.* the concentration of O_2 at a constant $POCl_3$ concentration of 0.27%.

In Fig. 3 we report the values for a simultaneous change of O_2 and $POCl_3$ keeping constant the ratio of their concentrations (~ 21.5).

In the composition range considered our data of Q_{el} are in qualitative agreement with those reported earlier (1) and show that this quantity is relatively insensitive to the variables under control. On the contrary, Q is a sensitive property which decreases as the concentration of oxygen rises, increases with that of $POCl_3$, and increases also, but less steeply, with their simultaneous increase. In any case the ratios Q/Q_{el} turn out to be larger than 1.

For a more comprehensive analysis of this effect in the range of experimental conditions typical of device technology we report in Fig. 4 the ratios Q/Q_{el} as a function of time for predeposition processes at 850°, 920°, 1000°, 1100°, 1200°C at constant gas composition (5.7% O_2 and 0.27% $POCl_3$). In Fig. 5 the ratios Q/Q_{el} are reported for processes at the above-mentioned temperatures and at a constant predeposition time (27 min) as a function of O_2 and $POCl_3$ concentrations, simultaneously increased.

[2] Fischer and Porter.

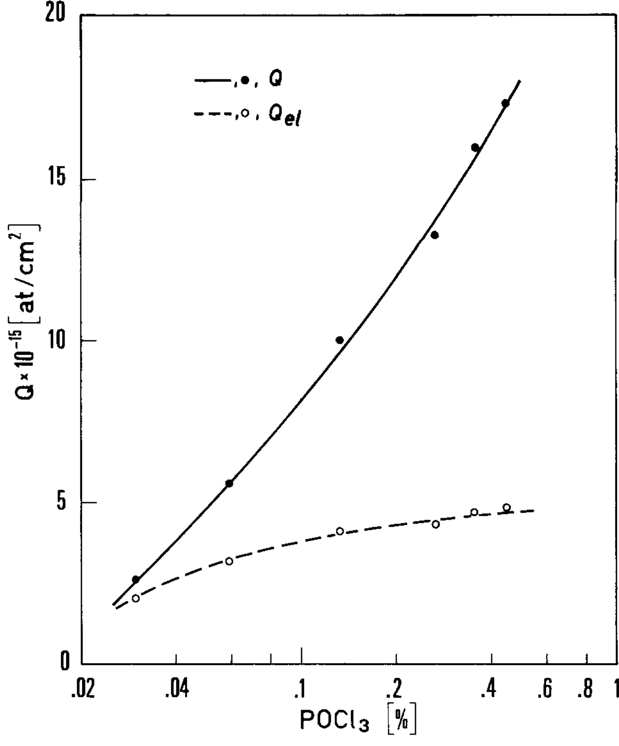

Fig. 1. Total, Q, and electrically active phosphorus, Q_{el}, *vs.* $POCl_3$ concentration, in constant time (27 min) predepositions at 920°C. Oxygen concentration is constant (5.7%).

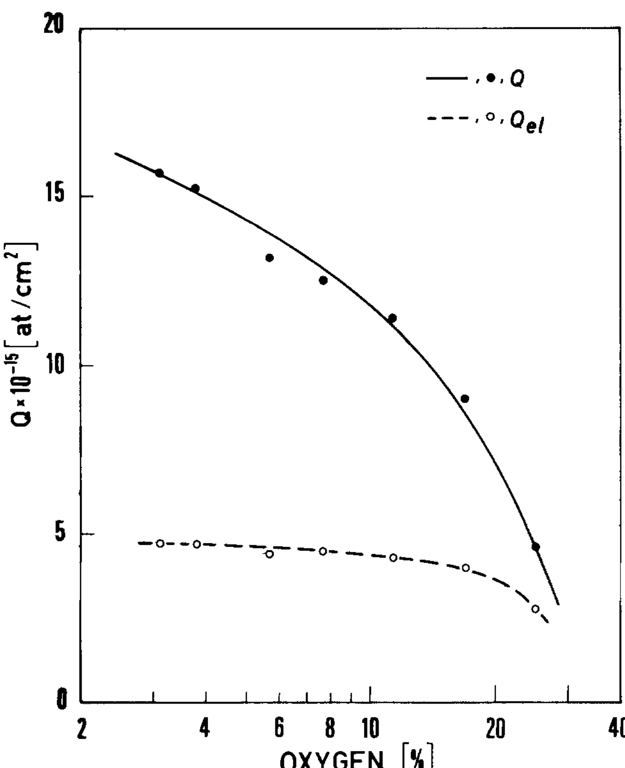

Fig. 2. Total, Q, and electrically active phosphorus, Q_{el}, *vs.* oxygen concentration, in constant time (27 min) predepositions at 920°C. $POCl_3$ concentration is constant (0.27%).

These results confirm that the situation evidenced by comparing electrical profiles and chemical data is verified in a wide range of experimental conditions: *i.e.*, the amount of phosphorus determined by resistivity measurements after predeposition is systematically lower than the total, and the discrepancy can be very large. They show that the ratio increases with increasing concentration of $POCl_3$ and decreasing tempera-

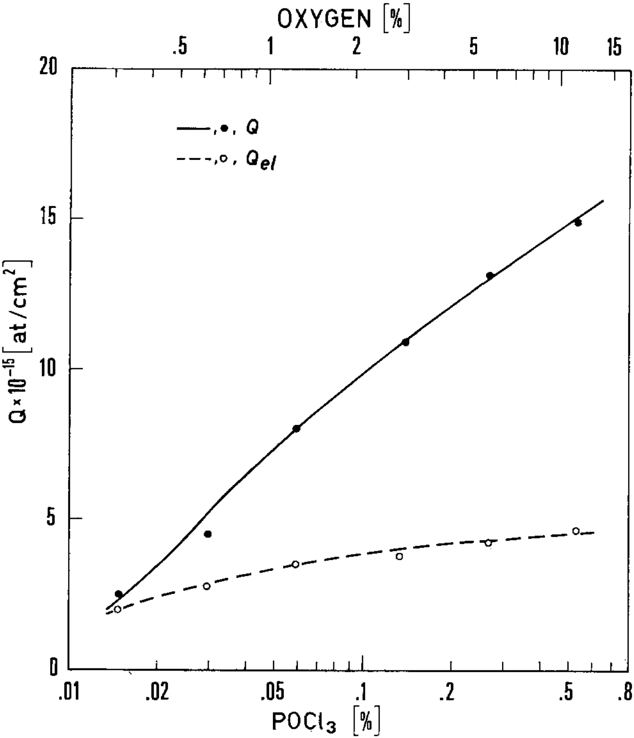

Fig. 3. Total, Q, and electrically active phosphorus, Q_{el}, vs. $POCl_3$ and oxygen concentrations increased keeping constant their ratio (~21.5). Conditions of predepositions are the same as for Fig. 1 and 2.

tures. Further, these ratios keep nearly constant after an initial time which increases with decreasing temperature.

We have determined, by changing the time of extraction from the furnace from 1 to 60 sec, that these ratios are unaffected by the extraction rate.

TEM and x-ray topography examinations carried out using the techniques described have shown evidence of precipitation taking place in the course of the predeposition process.

This phenomenon can account for the electrical inactivity of at least part of the phosphorus. Qualitatively, the amount of the precipitated phase increases as the ratio Q/Q_{el} rises.

A detailed study on the morphology and structure of the precipitates will be presented in a separate paper (10).

We report in Fig. 6 and 7 typical examples of the precipitates observed: the particles in the former look like those observed by Jaccodine (7); the precipitates

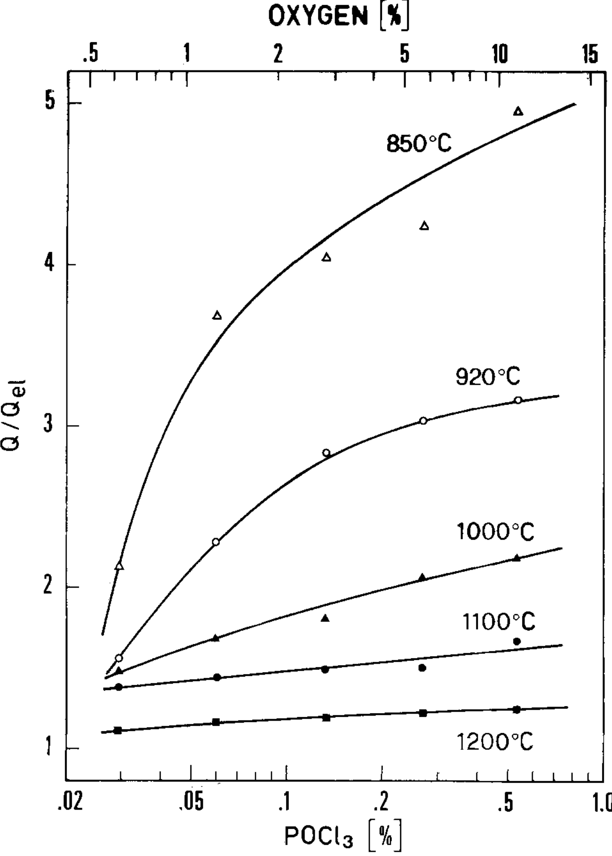

Fig. 5. Ratio Q/Q_{el} between total and electrically active phosphorus vs. $POCl_3$ and oxygen concentration increased keeping constant their ratio (~ 21.5). Predeposition time is constant (27 min).

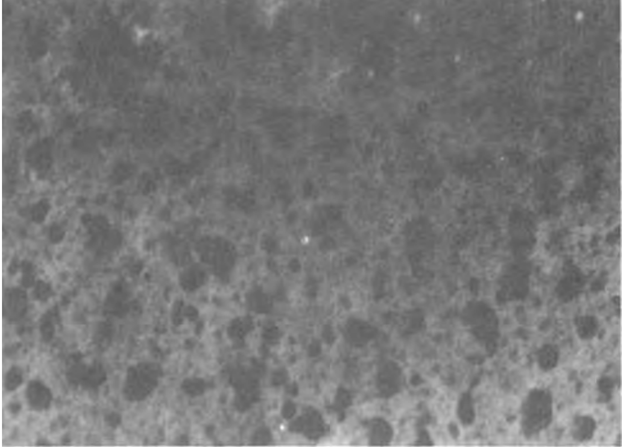

Fig. 6. Electron micrograph showing dotlike particles of silicon phosphide in a 1000°C, 22 min predeposited silicon wafer. 130,000X.

in Fig. 7 are plateletlike, similar to those observed by Levine *et al.* (11).

It has been verified by systematic observations carried out after anodic oxide stripping that the precipitates are not confined to the surface but lie within the diffused region.

Further, it has been shown, by changing the time of extraction from the furnace from about 1 to 60 sec, that both the structure and density of the precipitates are unaffected by the extraction rate. This is in agreement with the above-mentioned result that Q/Q_{el} is unaffected by the extraction and is a further evidence that precipitation takes place in the furnace.

The presence of these precipitates shows that in a wide range of conditions, typical of device technology, the chemical potential of phosphorus at the glass-silicon interface and in the adjacent Si matrix can

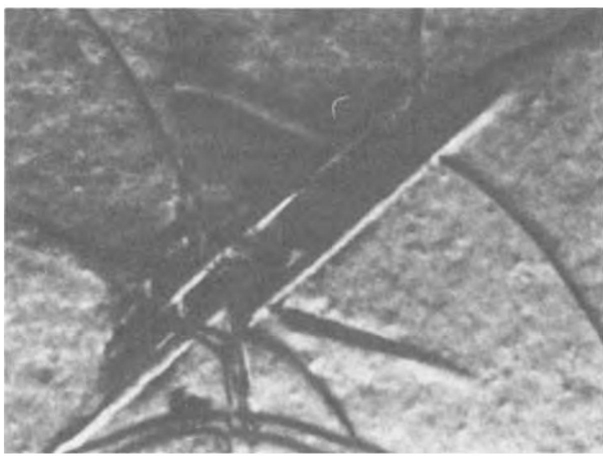

Fig. 7. Electron micrograph showing platelets of silicon phosphide in a 920°C, 42 min predeposited silicon wafer. The precipitates are parallel to <$\bar{2}$20> direction. 50,000X.

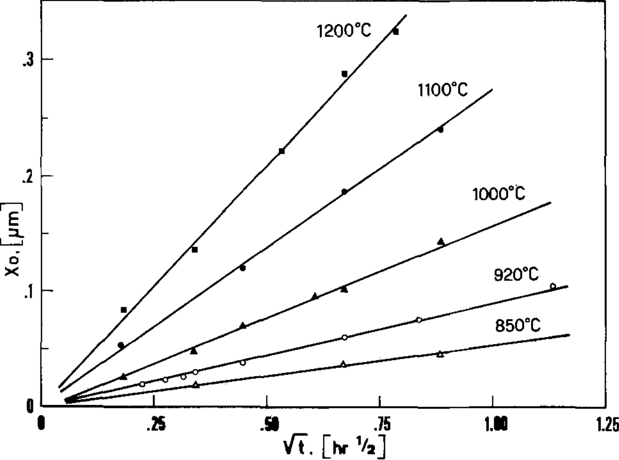

Fig. 9. Parabolic increase of the oxide thickness with predeposition time. $POCl_3$ and O_2 concentrations are 0.27 and 5.7%, respectively.

overcome the value corresponding to the solubility limit. A supersaturated solid solution of phosphorus in silicon is formed and precipitates can nucleate inside the silicon matrix.

It is important to point out that these precipitates act as sinks for the dopant, therefore, the flow of phosphorus across the glass-silicon interface is not limited by the primary solid solubility of this element in silicon.

Kinetics of oxide growth and of phosphorus doping.—To obtain information about the kinetics, the values of the total phosphorus content Q and of the oxide thickness X_o resulting from predeposition experiments at given doping gas compositions have been determined as a function of time t at different temperatures, 850°, 920°, 1000°, 1100°, and 1200°C. In Fig. 8 we report the Q data obtained with $POCl_3$ and O_2 concentrations of 0.27 and 5.7%, respectively. The corresponding thicknesses X_o of oxide are reported in Fig. 9. In spite of the indetermination in the predeposition time due to the experimental procedure, the plots extrapolate well to the origin. These results show, at all temperatures, a parabolic oxide growth $X_o = \sqrt{Bt}$; a similar kinetics $Q = \sqrt{KT}$ is observed for phosphorus. B and K are coefficients which depend, as discussed below, only on temperature and gas composition.

The process of doping, as well as the oxide growth go through several consecutive steps. A detailed treatment of the thermal oxidation of silicon is reported by Grove: the reacting species must be transported

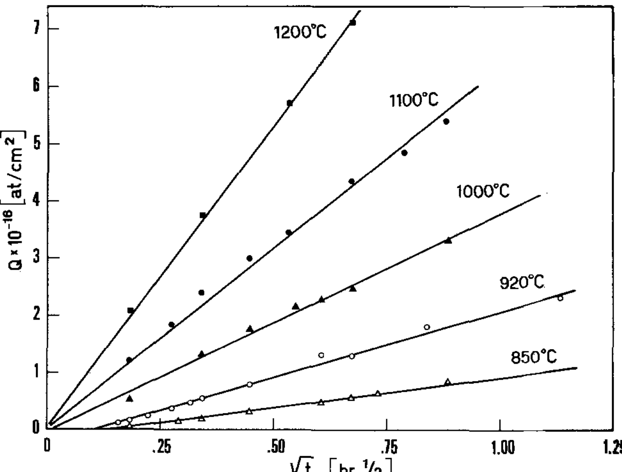

Fig. 8. Parabolic increase of the amount of phosphorus with predeposition time. $POCl_3$ and O_2 concentrations are 0.27 and 5.7%, respectively.

from the bulk of the gas to the oxide surface, diffuse across the oxide layer, and then react at the Si surface. In the steady state the fluxes corresponding to each step are equal and the kinetics is controlled by the slowest one. This treatment leads to the conclusion that a parabolic growth results from a diffusion limited process (9). Our data fit with the following rate equation

$$\frac{dQ}{dt} = \frac{D(C_o - C_i)}{x(t)} \quad [1]$$

where D is the diffusion coefficient, C_o and C_i the steady-state concentration of phosphorus at the gas oxide and at the oxide silicon interface, respectively, and x the oxide thickness, which increases parabolically with time. This indicates that also in case of phosphorus diffusion the passage across the oxide is the controlling step.

These conclusions can be verified by observing the effect of thin, preformed oxide films on the velocity of these processes.

In diffusion-limited conditions, with an initial oxide thickness x_i, the law of oxide growth becomes (9)

$$x = \sqrt{Bt + x_i^2} \quad [2]$$

and the integral of Eq. [1] results

$$Q = Q_o \left[\sqrt{1 + \left(\frac{x_i}{x_o}\right)^2} - \frac{x_i}{x_o} \right] \quad [3]$$

where Q_o and x_o are, respectively, the amount of predeposited phosphorus and the oxide thickness resulting from the process with $x_i = 0$.

For Eq. [3] to be valid C_o and C_i must attain their steady values in a negligible time; this is a further reason for keeping $x_i << x_o$.

We have carried out constant time (27 min) predepositions at 920° and 1000°C on slices with x_i up to about 300 and 500Å, respectively. Doping gas conditions were kept the same as in Fig. 8 and 9. The oxide films had been obtained by thermal oxidation at 920°C in a dry oxygen atmosphere.

We report in Fig. 10 the experimental values of $Q(x_i)$ together with those of the thickness $(x - x_i)$ of the newly formed oxide as a function of the thickness x_i of the preformed oxide. A very good agreement is observed between these and the theoretical curves obtained by Eq. [2] and [3], respectively; they are verified in a wide range up to $x_i = ½\ x_o$. This confirms the validity of the simplified model in Eq. [1] and that both phosphorus predeposition and oxide growth are limited by diffusion across the oxide layer. Both processes show an exponential temperature dependence

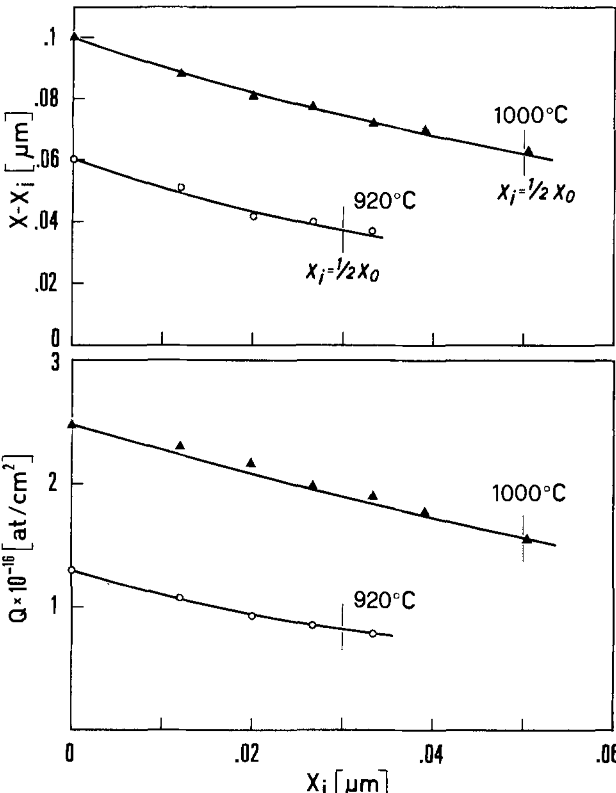

Fig. 10. Experimental values and calculated curves of predeposited phosphorus and of the associated oxide growth, reported vs. the thickness x_i of preformed oxide layers. Constant time (27 min) predepositions at the same doping gas compositions as in Fig. 8 and 9.

which can be analyzed by considering the values of the coefficients B and K.

We have verified by further experiments that the exponential factors keep constant in a wide range of gas compositions. In Fig. 11 and 12 are reported Arrhenius plots of B and K values, respectively, obtained by constant time (27 min) predepositions carried out at 850°, 920°, 1000°, 1100°, and 1200°C. The concentration of $POCl_3$ was varied in the range between 0.06 and 0.53%, by keeping constant the $O_2/POCl_3$ ratio (21.5). In the whole temperature range, B turns out to have the general form $B = B_0 \exp(-E_B/kT)$ with $E_B =$ 1.7 eV.

A similar relation $K = K_0 \exp(-E_K/kT)$, valid up to 1100°C, is observed in Fig. 12 with $E_K = 2.2$ eV.

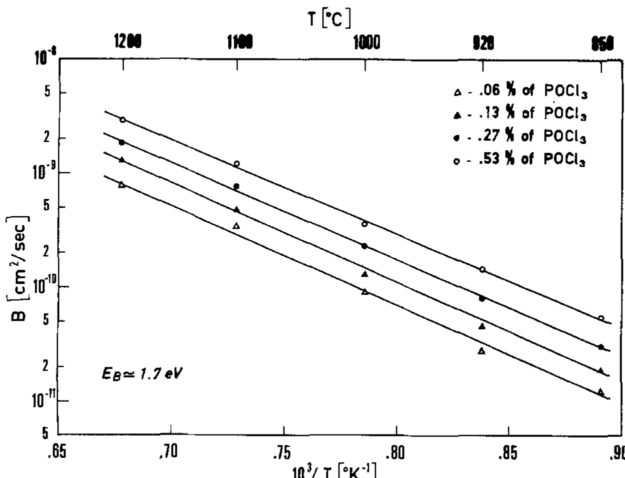

Fig. 11. Dependence on temperature and on doping gas composition of the coefficient B. The ratio $O_2/POCl_3$ is kept constant (21.5).

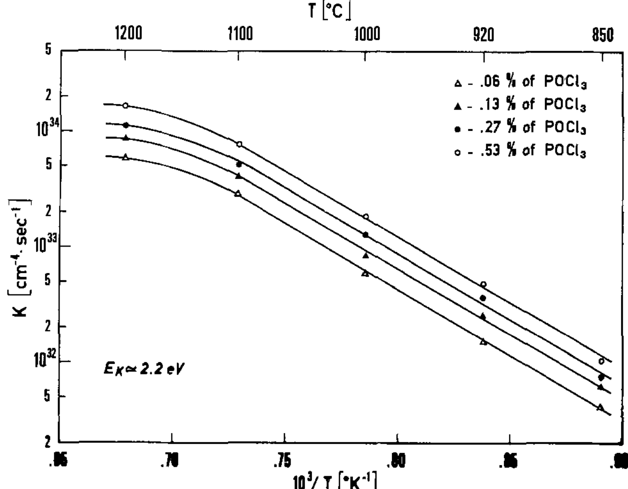

Fig. 12. Dependence on temperature and on flux composition of the coefficient K, compositions are the same as in Fig. 11.

Only the pre-exponential factors B_0 and K_0 depend on gas composition and decrease with decreasing oxygen and $POCl_3$ concentrations.

The energy term in the temperature dependence of Q results ½ $E_K = 1.1$ eV; lower than the corresponding term of Q_{el} (about 1.6 eV) resulting from our experimental data. The latter value is in agreement with those calculated by the data in literature (6, 9, 12, 13). This accounts for the increase of the ratio Q/Q_{el} with decreasing temperature observed in Fig. 4, and confirms that Q and Q_{el} depend on distinct phenomena.

We have shown that the total phosphorus content Q is limited by diffusion across the oxide layer; on the other hand Q_{el}, as reported in literature, is limited by the solubility and diffusivity of the dopant in silicon (9).

Finally, we notice that in our experimental conditions both Q_{el} and Q turned out to be fairly reproducible.

From statistics we have determined that the fractional standard deviation, $\sigma = \frac{1}{\overline{X}} \sqrt{\frac{\Sigma_1^n (\overline{X} - X_j)^2}{n-1}}$, were 1.5 and 3% for Q_{el} and Q, respectively, in slices processed together. For different predepositions carried out in the same conditions we have obtained for Q_{el} and Q values of σ of 4 and 9%, respectively.

A more extensive study on the correlation between gas composition and the properties of the oxide phase is under way and the results will be reported.

Conclusions

A simple method which provides a satisfying precision for the quantitative determination of phosphorus predeposited in silicon, is the measurement of surface resistivity after suitable drive-in. The results of this technique, described in the Appendix, are in good agreement with those obtained by activation analysis.

In a wide range of experimental conditions typical of device technology using a $POCl_3$ source, the amount of electrically active predeposited phosphorus Q_{el}, is lower than the total dopant content Q. The fraction of electrically inactive dopant increases with the rising concentration of $POCl_3$ and decreasing temperature.

The electrically inactive phosphorus is due, at least in part, to phosphide precipitates within the diffused region. Precipitation takes place in the course of the predeposition process, therefore these precipitates act as sinks for the dopant. As a consequence the flux of phosphorus is not limited by the primary solid solubility of this element in silicon.

Study of the kinetics has shown that the rate-determining process of both phosphorus doping and the as-

sociated oxide growth is diffusion across the oxide layer.

Phosphorus predeposition follows a parabolic law $Q = \sqrt{Kt}$; a similar behavior $X_o = \sqrt{Bt}$ is observed for oxide thickness.

The relations $K = K_o \exp(-E_K/kT)$, with $E_K \simeq$ 2.2 eV, and $B = B_o \exp(-E_B/kT)$, with $E_B \simeq 1.7$ eV, are satisfied over a wide range of temperature and flux compositions. The pre-exponential factors K_o and B_o increase with the concentrations of oxygen and $POCl_3$.

APPENDIX

The amount of phosphorus predeposited in silicon can be accurately determined by activation analysis.

We have verified, according to the observations formerly reported by Tannenbaum (5), that it is possible to derive the same information by electrical measurements carried out after suitable drive-in.

As a prior step we have established the agreement between chemical and electrical profiles.

Our determinations were carried out on silicon slices processed in parallel at different predeposition and drive-in temperatures and times. Chemical profiles have been obtained by neutron activation analysis and an automated technique (14). The electrical profiles were obtained by conventional anodic oxide stripping and resistivity measurements (5). The dependence of mobility on concentration was considered based on accurate measurements carried out in our laboratory (15).

To avoid out-diffusion of phosphorus we have tried two procedures with good results. The first consisted of depositing a film of SiO_2 about 1 μm thick by sputtering; subsequent drive-in was performed in nitrogen.

The same results have been obtained, more simply, by performing the drive-in process in an oxidizing atmosphere ranging from pure O_2 to N_2 + 10% O_2. This last composition has been adopted.

The amount of phosphorus lost turned out to be negligible; this is because the phosphorus segregation coefficient between SiO_2 and Si is very small (9) and the diffusivity of phosphorus is much smaller in SiO_2 than in Si (16).

Our determinations have shown that after suitable drive-in, as detailed below, the chemical and electrical profiles coincide fairly well.

Further, if the out-diffusion of phosphorus is inhibited by using the above techniques, the integral of the chemical profile after predeposition agrees with those of the profiles, chemical as well as electrical, after drive-in.

A typical example of our results is reported in Fig. 13.

The determination of the amount of predeposited phosphorus by analysis of the electrical profile is very tedious and time consuming. As a further step we have verified that a rapid technique which provides satisfying precision is the measurement of the surface resistivity after suitable drive-in.

The surface resistivity is given by the well-known relation

$$\rho_s = \frac{1}{e \cdot \int_0^{X_j} [C(x) - C_B] \cdot \mu(x)\, dx} \quad \text{[A-1]}$$

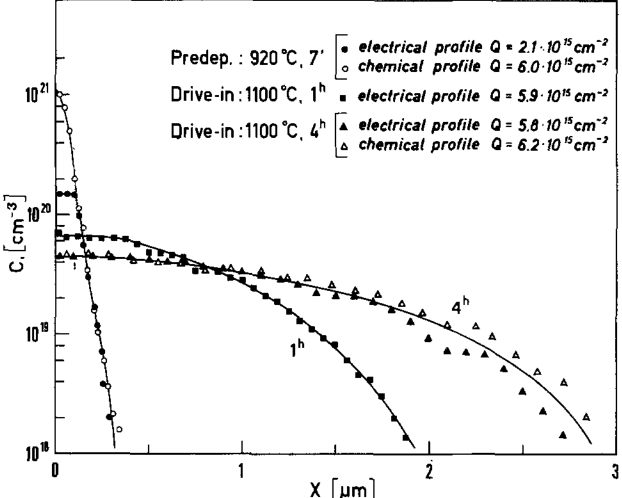

Fig. 13. Chemical and electrical phosphorus profiles after predeposition and drive-in. The latter has been carried out in N_2 + 10% O_2 atmosphere.

where $C(x)$ is the concentration of the diffused dopant, C_B the concentration in the bulk (which was negligible in our experiments), X_j the junction depth, μ the electron mobility, which depends on the total impurity concentration, and e the charge of the electron.

Defining an "effective mobility" by the ratio

$$\mu_{eff} \equiv \frac{\int_0^{x_j} C(x) \cdot \mu(x)\, dx}{\int_0^{x_j} C(x)\, dx} \quad \text{[A-2]}$$

where

$$\int_0^{x_j} C(x)\, dx = Q$$

one obtains

$$\rho_s = \frac{1}{e \cdot \mu_{eff} \cdot Q} \quad \text{[A-3]}$$

which allows determination of the content of dopant Q by a simple measurement of the surface resistivity, provided that the values of μ_{eff} are known. Actually for concentrations above 10^{19} at./cm^3 phosphorus mobility depends only slightly on the concentration (15, 17).

This results in values of μ_{eff} which are nearly independent of the process of predeposition and drive-in,

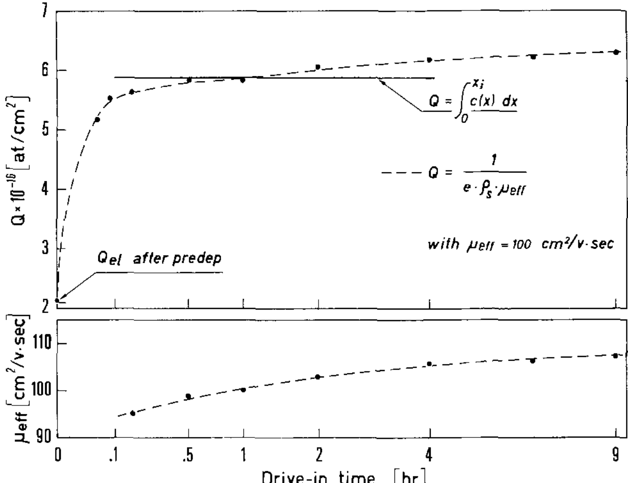

Fig. 14. Experimental determination of the apparent total phosphorus content vs. the drive-in time, assuming a constant value of μ_{eff}. In the lower part of the figure the real effective mobility, as deduced from the knowledge of the total diffused charge Q (solid line), are reported vs. the drive-in time.

Table I

Predeposition temp (°C)	Drive-in temp (°C)	Drive-in time (min)
850	1100	30
920	1100	30
1000	1100	60
1100	1200	30
1200	1200	30

provided that most of the dopant is in regions of the profile with concentration exceeding 10^{19} at./cm^3.

By Eq. [A-2] we have calculated the value of μ_{eff} for all the specimens whose profile has been determined.

The value after predeposition was 95 cm^2/V·sec, fairly independent of the conditions of the process.

Further, we have verified that, provided the surface concentration of the dopant keeps high, the "effective mobility" depends only slightly on the conditions of drive-in, our mean value being about 100 cm^2/V·sec.

As a typical example we report in Fig. 14 our results for specimens having received a predeposition treatment of 7 min at 920°C followed by drive-in at 1100°C. The plot reports μ_{eff} *vs.* time of drive-in, calculated by Eq. [A-3] using the known value of Q. The values of Q calculated by using a constant value of $\mu_{eff} = 100$ are also shown.

Initially Q increases rapidly with time, corresponding to the formation of new active dopant; subsequent changes in the calculated values of Q are slight corresponding to increases in μ_{eff} with modifications in the distribution of the dopant.

It is noticed in Fig. 14 that a more than 50 times increase of the heating time results in a change of Q of about 10%. These results show that, above a given time, the conditions of drive-in suitable for the determination of Q, are not critical.

Experiments like those in Fig. 1 have been carried out to determine the temperature and time of drive-in for the different predeposition processes. The conditions chosen for the present work are reported in Table I.

Anisotropy of Spontaneous Macrostresses in Ferromagnetic Films Induced by Magnetization

I. Anisotropic Macrostresses in Films of Nickel and Iron-Nickel Alloy Deposited in a Magnetic Field

M. Perakh (M. Ya. Popereka)*

Graduate School of Applied Science, The Hebrew University of Jerulsalem, Jerusalem, Israel

ABSTRACT

When depositing nickel and iron-nickel alloy films in a magnetic field parallel to the substrate, the spontaneous macrostresses in the films are anisotropic. The absolute magnitude of the stresses can, depending on the composition of the alloy and the deposition conditions, be either substantially smaller or larger than in films deposited without the application of such a field. In layers of nickel electrodeposited from a solution free of organic inhibitors, the tensile macrostresses acting along the lines of a magnetic field are larger than those acting across the lines of a field. The introduction of saccharin into the solution effects an inversion of the influence of the magnetic field on the macrostresses: the tensile macrostresses acting across the lines of the field are now larger than those acting along these lines. In alloy films having a negative magnetostriction, the tensile stresses along the lines of the field are smaller than those across the lines. A change in the sign of the magnetostriction leads to an inversion of the field effect on the stresses: in alloys with a positive magnetostriction, the tensile macrostresses acting along the field are larger than those acting across it.

In ferromagnetic films obtained in vacuum by oblique incidence of the atom beam, the planar macrostresses possess a definite degree of anisotropy (1-3). However, the above means of precipitation is not the only source of the anisotropy of macrostresses. Thus, McDonald (4) has already pointed out that films deposited in a magnetic field possess an anisotropic component of macrostresses in the direction of the field.

The creation of anisotropy of the macrostresses by a magnetic field (or, more accurately, by magnetization) is interesting, first, because of the possible contribution of macrostresses to magnetic anisotropy, and second, because its study may develop an understanding

* Electrochemical Society Active Member.

Key words: internal stress, measurement of anisotropic stress, anisotropy of magnetic films, electrodeposition of nickel and nickel-iron alloys, influence of magnetic field on electrodeposition.

of the origin of spontaneous macrostresses. The contribution made by spontaneous macrostresses to the uniaxial magnetic anisotropy of films, the composition of which is about 83% nickel and 17% iron, and the magnetostriction coefficient which is in the order of -10^{-5}, has been previously reported (5).

The purpose of this work was to measure spontaneous anisotropic macrostresses in iron-nickel films of a wide range of compositions and to investigate the basic behavior of the phenomenon (to which Part I of this work is dedicated), and to attempt to form a quantitative interpretation of the phenomenon (see Part II) (6).

Experimental

Two methods were used to measure spontaneous macrostresses in electrolytic films of an iron-nickel alloy. The first used an alternate bending of two mutually perpendicular flat substrates (3, 7), one directed along and the other across the line of the field. The deflections of the substrates were registered automatically by a highly sensitive device, roughly identical to the one previously described (8). The substrates were polished copper plates of 1.5 mm thickness, on the lower side of which the film was deposited, while the upper side was kept outside the electrolyte. The computation of the absolute magnitude of real [not the average over the film thicknesses (1, 4)] macrostresses was made according to the following formulas (7)

$$\sigma_x = \frac{1}{3}\frac{E_o d^2}{l^2(1-\mu_o^2)}\left(\frac{df_x}{dt} + \mu_o\frac{df_y}{dt}\right);$$

$$\sigma_y = \frac{1}{3}\frac{E_o d^2}{l^2(1-\mu_o^2)}\left(\frac{df_y}{dt} + \mu_o\frac{df_x}{d\tau}\right) \quad [1]$$

where E_o is Young's modulus of elasticity, μ_o is Poisson's ratio of the substrate material, l is the length of that part of the substrate covered by the film, d is the thickness of the substrate, f_x and f_y are the deflections of the free ends of the substrates directed along (x axis) and across (y axis) the lines of the field. Magnitudes df_x/dt and df_y/dt are determined by graphical differentiation of the "deformation curves," *i.e.*, the relationship of deflections f_x and f_y, recorded on the diagram tape, to the film thickness.

In addition, a second method was specially developed which, although more laborious, measures σ_x and σ_y simultaneously using only one sample, as compared to two required by the first method; the second method enables a stricter control over the similarity of conditions for measuring σ_x and σ_y. Because of its tediousness, the second method was chiefly used to check the results. It is based on the spontaneous tension-compression (in two mutually perpendicular directions) of the flat substrate covered on both sides by the film being studied. A device schematically pictured in Fig. 1 was used. Fixture 1 fixes one corner of the flat substrate 2 to the Teflon frame 3, which is being inserted into the guides 5 of the carriage 6. The device is placed on the table of a microhardness meter. A diamond indentor is used to make imprints A and B_x on the substrate opposite the reference marks C_1 and C_2 on part 7 which is fixed to carriage 8. Frame 3 with the substrate 2 is then turned through 90° and carriage 6 is used to fix imprint A opposite mark C_2; carriage 8 is used to introduce mark C_1 in the field of vision of the microscope, and imprint B_y is made opposite it on the substrate. Then, frame 3 (without the flat table 4) is placed in the cell, where the film being studied is grown on both sides of the substrate until it reaches the required thickness. After that, frame 3 with the substrate and film (and with table 4) is again inserted into guides 5. Screw 9 is used to move carriage 6 in the grooves of carriage 8 until imprint A coincides with reference mark C_1 (or C_2). Carriage 8 is moved in the grooves 10 by turning screw 11 until mark C_2 and imprint B_x (or, correspondingly, C_1 and B_y) appear in

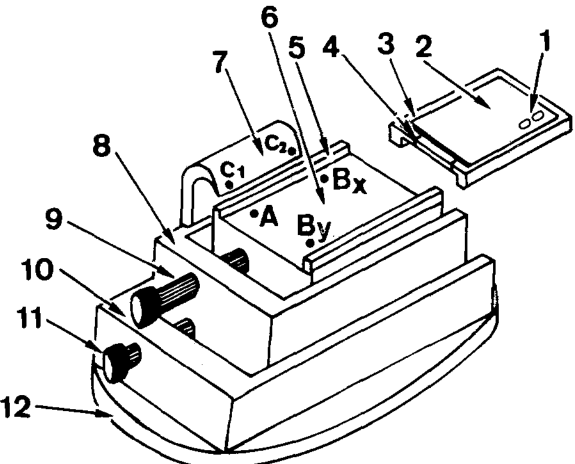

Fig. 1. Diagram of device for the measurement of anisotropic spontaneous macrostresses in films according to the method of biaxial tension-compression of the substrate plate. See text for explanation of numbers; 4, supporting table used to press the indentor into the sample.

the field of vision of the microscope. Stresses in the film produce a deformation of the substrate: the distance between imprint A and imprints B_x and B_y change by magnitudes Δ_x and Δ_y. The above deformations (*i.e.*, the distance between C_2 and B_x or between C_1 and B_y after the deposition of the film) are measured using a measuring eyepiece (graduation 0.2 μm).

In order to obtain the dependencies Δ_x *vs.* t and Δ_y *vs.* t (t is the thickness of deposit) it is needed to repeat the procedure described, specifying in every run the definite thicknesses $t_1, t_2, \ldots, t_n$. Thus, although the σ_x and σ_y are determined by this method simultaneously and error due to the difference in experimental conditions while measuring these magnitudes separately is eliminated, error due to the use of a series of consecutive runs of measurement needed to obtain one "deformation curve" is greater than it is by using the first method (margins of error indicated in Fig. 2 and 3 correspond in all cases to maximum error obtained in series of specimens by using both methods).

The measurement base l (*i.e.*, the distance between C_1 and C_2) was 3 cm. The substrates were plates of copper (thickness 25 μm). The substrate deformed freely as the film was deposited. For such conditions, the computation of the absolute magnitude of actual macrostresses is made according to the formula (7)

$$\sigma_x(t) = \left[\frac{E_o d}{1-\mu_o^2} + \frac{E_1 t}{1-\mu_1^2}\right]\frac{1}{l}\frac{d\Delta_x}{dt} + \left[\frac{E_o\mu_o d}{1-\mu_o^2} + \frac{E_1\mu_1 t}{1-\mu_1^2}\right]\frac{1}{l}\frac{d\Delta_y}{dt} \quad [2]$$

and a similar equation for σ_y, which is obtained by replacing indexes x by y and vice versa. In Eq. [2], E_1 is the modulus of elasticity, μ_1 Poisson's ratio for the material of the film, t the sum total thickness of deposit on both sides of the substrate. Magnitudes $d\Delta_x/dt$ and $d\Delta_y/dt$ are determined by graphical differentiation of the experimental deformation curves Δ_x-t and Δ_y-t. The Young's modulus and Poisson ratios for substrates and deposits were determined using the method previously described (9).

While using the two-cantilever technique, stress is determined simultaneously with the film's growth in a magnetic field, thus the magnetostrictive deformation does not affect the results. When use is made of the second method described, the specimen is taken out of the magnetic field before strain measurement, thus a magnetostrictive deformation is added algebraically to that caused by stress. However, the difference of stresses determined using both methods described, did not exceed the margins presented in Fig. 2 and 3. Hence, the

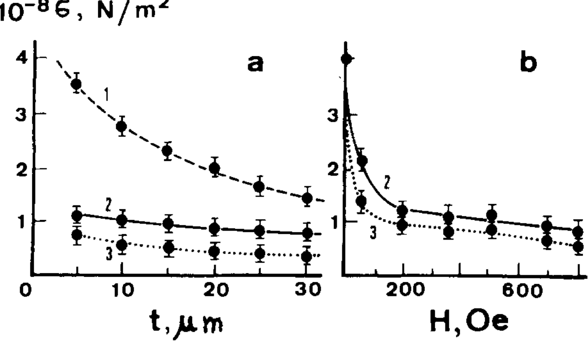

Fig. 2. Dependence of spontaneous macrostresses in electrolytic nickel films on the film thickness (a) and on the intensity of the technological magnetic field, used while the film is growing, parallel to the substrate (b). Curve 1, Stresses in the film deposited without a field; curve 2, macrostress along, and curve 3, across the field lines. For (a), curves 2, 3, H_T = 520 oe. For (b), curves 2 and 3, t = 10 μm.

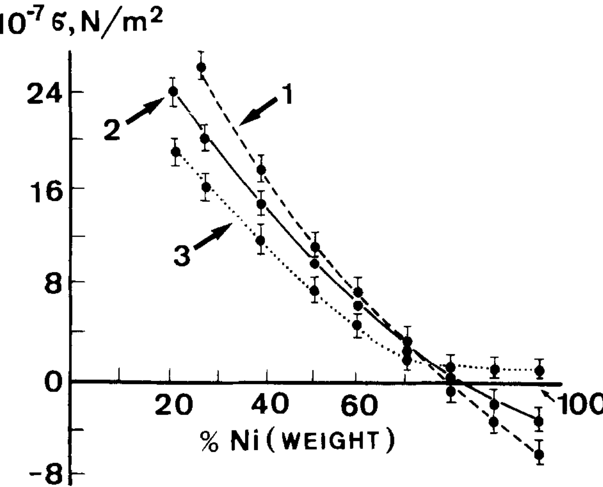

Fig. 3. Dependence of spontaneous macrostress in iron-nickel alloy films on composition. Curve 1, Stresses in films deposited without a field; curve 2, stresses along, and curve 3, across the field lines (300 oe). Film thickness 10 ± 0.2 μm.

regularities stated in this paper cannot be ascribed to the ordinary magnetostriction itself. Indeed, the coefficient of magnetostriction, for instance, for nickel is about $\lambda_s = -3.4 \times 10^{-5}$, while the initial strains discovered in nickel films were about $(0.5 \div 2) \times 10^{-3}$; the difference of strains appearing in two mutually perpendicular directions was up to 3×10^{-4}, which is almost ten times more than a maximum possible magnetostrictive strain in one direction. Moreover, the difference of strains, longitudinal and transverse, respectively, which are due to the magnetostriction, must be of the same sign regardless of operating conditions; actually, the difference of stresses longitudinal and transverse, respectively, changes its sign when, for instance, saccharin is introduced into the solution. Therefore, it is not the ordinary magnetostrictive strain which is responsible for the phenomenon described below.

The compositions of the solutions and the deposition conditions used to prepare the films under investigation are given in Table I.

The temperature of the specimen while measuring the stress using the second method was kept quite identical to that while depositing.

The thickness of the films was measured on an "Ultraoptimeter" (graduation scale 0.2μ). The rectangular cell was placed between the poles of the electromagnet (homogeneous field up to 10^3 oe). Uniformity of thickness of the deposited film over the substrate was ensured by special limiters (11) of the electric field in the electrolyte.

Table I. Conditions of the deposition of nickel and iron-nickel films

Figure	Composition of solution, g/liter		Current density, A/dm²	pH	Temperature, °C
2	$NiSO_4 \cdot 7H_2O$	300	3	2.3	20 ± 0.25
	$NiCl_2 \cdot 6H_2O$	80			
	H_3BO_3	40			
3	($NiSO_4 \cdot 7H_2O$ + $FeSO_4 \cdot 7H_2O$)	294*	2	2.3	20 ± 0.25
	H_3BO_3	30			
	Rochelle salt	25			
	Saccharin	1			

* The ratio of the nickel and iron salts in the solution was changed (10) in order to obtain an alloy of the required composition (including 100% nickel).

Results and Discussion

Many properties of films studied were reported elsewhere (17, 18). Particularly, in these films, neither crystallographic texture nor the "columnar" structure were observed.

The characteristic experimental data are shown in Fig. 2 and 3. Let us note some of the basic features of the regularities thus discovered:

1. When depositing nickel and iron-nickel alloy films in a magnetic field, the spontaneous macrostresses are anisotropic.

2. In films of nickel deposited from a solution not containing organic inhibitors, the tensile stresses along the line of field (σ_x) are larger than the tensile stresses across the field (σ_y), Fig. 2. In nickel films deposited from a solution containing saccharin (as also in films deposited from the same solution without the superposition of a magnetic field), compressive macrostresses are registered in the direction of the lines of the technological magnetic field, while in the direction perpendicular to the field, tensile macrostresses are observed (Fig. 3).

The macrostresses observed in the experiment may be considered (12-14) as the algebraic sum of stresses of both signs, created independently. Hence, the above observation can be interpreted by assuming that the tensile macrostresses across the magnetic field are larger than those acting along the field. (The latter are in this case so small that they are exceeded by independently emerging compressive stresses and, as a result, excess compressive stresses are registered.) Thus, the introduction of saccharin into the solution leads to an inversion of the field's effect on macrostresses.

3. In films of iron-nickel alloy deposited from a solution containing saccharin and possessing a negative magnetostriction, the macrostresses along the lines of the field are smaller than those acting across it. Conversely, the macrostresses along the lines of the field are larger than the stresses across it in films of alloys possessing a positive magnetostriction (those containing less than ~ 81% nickel). Thus, a change of the sign of the magnetostriction leads to an inversion of the field effect on macrostress.

4. When depositing nickel and iron-nickel films in a magnetic field, the mean arithmetic magnitude of the stresses acting in both directions changes greatly as compared with those in films obtained without the superposition of a field. Such a change can greatly exceed the difference between the stresses acting along and across the field. Depending on the composition of the alloy and the deposition conditions, the mean magnitude of the stresses obtained by deposition in a magnetic field can be considerably smaller or larger than that obtained by the deposition without the superposition of a field.

An interpretation of items 1-3 will be proposed in Part II of this work (6). A full explanation regarding item 4 will not be attempted here. However, several

hypotheses could be proposed to explain the possible causes of this phenomenon. It has been found (15) that by depositing iron films in a magnetic field, a change occurred in the density of the crystal defects of the film. Indeed, this density of defects is one of the main factors determining the macrostress level (12-14). Changes in density of the defects may depend on changes in the amount of hydrogen (16) reduced together with the metal and adsorbed on the crystals of the growing film. Adsorption of hydrogen has a major effect on the surface tension of the crystal, thereby changing the condition of the outflow of defects and with it, the macrostress level (12). Causes of the changes in amount of hydrogen reduced together with the metal during deposition in a magnetic field are as yet unclear. (It may be that the magnetic field changes the height of the potential barrier being negotiated by the discharging hydrogen ion.)

Acknowledgments

The experiments, the results of which are given in this report, were carried out with the valuable assistance of B. S. Zolotkovskii. to whom the author wishes to express his sincere gratitude.

Anisotropy of Spontaneous Macrostresses in Ferromagnetic Films Induced by Magnetization

II. Dislocation Model of the Anisotropy of Spontaneous Macrostresses in Films Grown in a Magnetic Field

M. Perakh (M. Ya. Popereka)*

Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

A model of the appearance of anisotropy of the spontaneous tensile macrostresses in films grown in a magnetic field is considered. The model is based on the idea that the microscopic areas along the lines of the edge dislocations interact (as a result of magnetostriction) with the magnetization. This interaction effects the partial orientation of the dislocation lines and that of the normals to them, lying in the slip planes. This orientation appears during the growth of the film crystals in the magnetic field. In the system of partly orientated dislocations, the withdrawal of a fraction of them to the surface of the crystals creates a tendency for anisotropic reduction of the volume. This tendency is hampered by the adhesion of the film to the substrate, creating an anisotropic state of stress. The calculated values of anisotropy are close to the experimental observations; the equation derived offers an explanation for the principal experimental regularities.

In Part I of this work (1), the results of the measurement of anisotropic macrostresses in films of nickel and iron-nickel alloy electrodeposited in a magnetic field were described, and the regularities observed in the experiments were stated. In this report, attempts are made to interpret the phenomena described in Part I. The consideration is based on a model (2-4), ac-

* Electrochemical Society Active Member.

Key words: dislocations in electrodeposits, anisotropy of internal stress, theory of stress, influence of magnetic field on electrodeposition.

cording to which a definite fraction of the tensile macrostresses results from the tendency of crystals in the film to decrease their volume. This tendency is due to the egress of a fraction of the growth dislocations from the volume of the crystals to the surface. Since adhesion of the film to the substrate prevents the decrease of volume, a plane state of stress sets in.

The assumption that the withdrawal of dislocations may contribute to the creation of spontaneous macrostresses in growing films (2-4) was confirmed by later experiments, the principal results of which can be summarized as follows:

1. Direct determinations of the density of dislocations, p_0, in films [see for example (5)], gave results coinciding with the values of p_0 postulated to correlate the formulas with experimental data (2-4).

2. It was found that measures applied to the films to facilitate the escape of dislocations (for example, cathode polarization of the film in an electrolyte (6), which decreases its surface tension) increase spontaneous tensile macrostresses. This falls in with the predictions of the theory (2-4).

3. Direct observation by means of electron microscopy of high resolving power made it possible to observe the withdrawal of individual dislocations from a newly formed crystal of the film during the latter's growth (7). Observation confirmed the existence of the postulated mechanism (2-4).

4. A spontaneous decrease of the density of the stacking faults was reported (8, 9), *i.e.*, a removal from the crystal of partial dislocations. This process, which occurs in electrodeposited copper films, is characterized by an activation energy of ~0.37 eV, which is lower than that for the motion of vacancies (~0.7 eV). The latter was thus not observed. The enumerated data give grounds to believe that the concept (2-4) can be used to interpret experimental data.

At the same time, it should be noted that the withdrawal of dislocations cannot be the only (and in many cases, not even the main) factor responsible for the appearance of spontaneous tensile macrostresses. Indeed, the presence of dislocations with a density of p_0 (the Burgers vector being b) brings about an increase in the specific volume of the crystal by magnitude (10)

$$\theta \cong 2\, p_0\, b^2$$

If the density of dislocations decreases as a result of the withdrawal of a fraction, κp_0, of them (where $\theta < \kappa < 1$), a linear strain (along an arbitrary axis) of the order of $1/3\ \kappa \cdot 2pb^2$ will result. To this linear strain (which is due to the adhesion of the film to the substrate) corresponds a linear macrostress of the order

$$\sigma \cong E \frac{1}{3} \kappa \cdot 2p_0 b^2$$

where E is the modulus of elasticity of the film material. The computation of σ, using the above relation and based on experimental values (5) of p_0 at $\kappa \sim 0.1$, shows that for some films (*e.g.*, for copper, antimony, manganese, tin, etc.) the withdrawal of dislocations may be responsible for the magnitudes of tensile macrostresses, observed experimentally. At the same time, for some other films (*e.g.*, for chromium, iron, nickel, cobalt), the escape of dislocations, judging from the above relation, can account only for a part (*ca.* 0.1-0.3 of the total) of the observed values of the stresses. This indicates that there must also be other mechanisms responsible for the creation of tensile macrostresses [for example, the outflow of vacancies (11), phase and structural changes, interdiffusion on the interface, etc.].

This paper attempts to show that the mechanism of the withdrawal of dislocations should be regarded as the main reason for the creation of the anisotropic component of tensile macrostresses, as applies to films grown in a magnetic field.

In close-packed structures (which include, in particular, nickel and iron) vacancies are practically isotropic defects. The annihilation of vacancies or their removal from the crystal, assumed, for example, to be one of the main causes of the appearance of macrostresses (11), can therefore hardly explain the creation of the anisotropic component of them. The assumption that the withdrawal of a fraction of the dislocations is the cause of the appearance of macrostresses, however, makes it possible, owing to the anisotropic nature of the dislocations themselves, to propose a model for the creation of anisotropic macrostresses for films grown in a magnetic field.

In this model neither the origin of edge dislocations nor their types, nor any other particular properties of dislocation are essential. Only three facts are to be employed for the consideration, namely, (*a*) that presence of dislocation causes an increase in the volume; (*b*) that a partial egress of dislocations occurs; and, consequently, (*c*) that this egress causes an anisotropic change in volume, which is due to the anisotropic structure of dislocations.

Computation of the Orientation of the Dislocation Lines by Magnetization

Figure 1 shows a model of a segment AB of an edge dislocation line (DL), which segment is of unit length and has a definite orientation. The escape of such a segment from the crystal causes linear dilatation in the direction of the normal (NSP) to the dislocation line, which normal lies in the slip plane. In the direction of DL, the dislocation withdrawal will cause no dilatation. In an arbitrary direction, coinciding neither with DL nor with NSP, the escape of the segment under consideration will cause a dilatation, the magnitude of which is equal to the projection on the given direction of the dilatation observed along NSP. Thus, the level of the macrostresses acting in the given direction is determined by the statistically averaged orientation of the normal NSP to the dislocation line.

Crystalline anisotropy leads to the formation, within a single grain, of some predominant orientations of DL and NSP. However, in a polycrystalline body the orientation of the dislocations, as averaged for the body, is random. The superposition of a magnetic field, while the crystal is growing, creates the additional factor of anisotropy. The area of the lattice adjacent to the line of dislocation interacts in the ferromagnetic body with magnetization, owing first to the existence, along the line of dislocation, of demagnetizing fields and second, to magnetostriction. [According to calculations, for example (12), the intensity of the magnetostrictive interaction is by two orders of magnitude greater than that of the magnetostatic.] Energy of the interaction of the dislocation with magnetization must depend on the angle θ, which is formed between DL and the magnetization vector M, and angle ϕ, formed

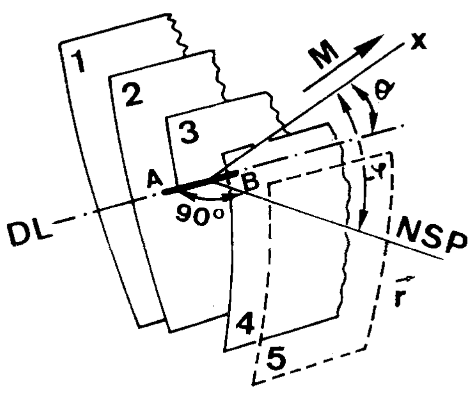

Fig. 1. Schematic presentation of edge dislocation. 1-5, Atomic planes; DL, line of dislocation; NSP, normal to dislocation line in the slip plane. The x-axis is directed along the vector of magnetization, M.

between NSP and M (Fig. 1). Considering the magnetostrictive interaction as the main factor, let us write the energy of the interaction between the dislocation and magnetization in a form similar to that introduced by Néel (13, 14) and Taniguchi (15), for anisotropic groups of point defects, the only difference being that in our case, the role not of one, but of two angles ϕ and θ must be taken into account

$$E(\theta, \phi) = K_1\left(\cos^2\phi - \frac{1}{3}\right) + K_2\left(\cos^2\theta - \frac{1}{3}\right) \quad [1]$$

where K_1 and K_2 are the constants of the postulated interaction. The sign of these constants is determined by the sign of the magnetostriction. Their magnitude depends on the magnetization and on the coefficient of magnetostriction of the given material. The value of $2(K_1 + K_2)/3$ is equal to the energy of the interaction between the dislocation and the magnetization when DL as well as NSP are perpendicular to the magnetization (Fig. 1). (The constants K_1 and K_2 are introduced here phenomenologically; the evaluation of their physical nature is beyond the scope of our task.)

In order to select the distribution law of dislocations, according to energies of their interaction with magnetization, let us take into account the following considerations.

1. The "solution" of the dislocations in the film may be considered as a rather "dilute" one: even at a dislocation density of $\sim 10^{12}$ cm^{-2}, a line of dislocation is encountered on an average of once in every $\sim 10^3$ "regular" atom planes.

2. It is known (10) that the dislocations are nonequilibrium defects. Indeed, the presence of dislocations in crystal increases simultaneously the free energy and the entropy of the latter. The increase of free energy, however, due to distortions in the crystallographic order, is considerably larger than the decrease due to the increase of entropy; the appearance of dislocations always increases the free energy. Thus the dislocation density does not depend on temperature: because of a large elastic energy connected with dislocation existence (which is much greater than the heat energy: $W >> kT$), thermal fluctuations are not able to create a new dislocation.

The presence of an additional factor, magnetization, causes the distribution of dislocation lines according to angles θ and ϕ. This distribution could depend on temperature, as the energy of interaction between dislocation and magnetization, as well as the rotation energy of dislocation segments, are lower than the heat energy, and naturally, than W. Hence, as far as the distribution of dislocation line segments upon θ and ϕ is concerned, a behavior of a quasi-equilibrium system might be inherent in the "solution" of dislocations. This makes it possible to postulate the applicability of the Boltzmann formula to the distribution of dislocations according to angles θ and ϕ.

At the same time, it might be expected that the entropy of dislocation segment rotation is considerably small. The ratio of magnetoelastic energy to the entropic term TS can scarcely be estimated at present for the case of dislocation rotation. If this ratio is large enough, this factor could annihilate the dependence of dislocation line directions on temperature. On the other hand, however, the consideration of possible distribution functions have shown that the distribution differing from that of Boltzmann could give a much smaller stress anisotropy as compared with an observed one.

Hence, in order to estimate whether the mechanism assumed can ensure the level of stress anisotropy observed, let us postulate the Boltzmann law for distribution of dislocation line directions upon θ and ϕ. Introducing such a postulate, the distribution function is

$$\rho(\theta, \phi) = A \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta) \quad [2]$$

where A is a constant to be determined from the normalization conditions, while

$$\alpha_1 = \frac{K_1}{kT}; \quad \alpha_2 = \frac{K_2}{kT} \quad [3]$$

where k is the Boltzmann constant, T the absolute temperature.

Let us now imagine that all segments DL, every one of unit length, are transferred to the beginning of the coordinates, while the orientation of every one of them is preserved. The ends of all these segments will now lie on a sphere of a unit radius, as shown in Fig. 2. Since the density of the dislocations in films is considerable (10^{10}-10^{12} cm^{-2}) (3, 7), let us replace the actual discrete distribution of the unit segments DL with a quasi-continuous one. Let us now consider a film built up in an intense field, sufficiently intense for magnetic saturation. In this case, the magnetization will coincide during growth of the crystals throughout the volume of the film, with the direction of the technological magnetic field, so that the x-axis is directed along that field.

On an element of the sphere under consideration (Fig. 2), having an area of $dS = 1 \times 2\pi \sin\theta d\theta$, terminate $\rho_1(\theta) 2\pi \sin\theta d\theta$ of segments DL, where $\rho_1(\theta)$ is the quasi-continuous function of the distribution of dislocation line unit segments according to angle θ. The magnitude $\rho_1(\theta)$ can be computed if each such segment is matched with a unit vector of the normal to DL in the slip plane. Imagining a transfer of all these unit vectors to the beginning of the coordinates, we shall obtain a picture identical to that in Fig. 2, the sole difference being that instead of angle θ we shall have angle ϕ.

Figure 3 shows that if θ remains constant, ϕ can be changed within the limits of $\pi/2 - \theta$ to $\pi/2 + \theta$. Then, if $\rho(\theta, \phi)$ is the function of the distribution of the NSP unit vectors, according to angle ϕ at a fixed θ, we shall obtain for $\rho_1(\theta)$ the following

$$\rho_1(\theta) = 2 \int_{\pi/2-\theta}^{\pi/2} 2\pi \sin\phi\, \rho(\theta, \phi)\, d\phi \quad [4]$$

Taking into account Eq. [2] and [4], we shall find the total number of NSP unit vectors (or, equally, of the unit DL segments) equal to the dislocation density in the film crystal

$$p_0 = 8\pi A \int_0^{\pi/2} \sin\theta \int_{\pi/2-\theta}^{\pi/2} \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta) \sin\phi\, d\theta d\phi \quad [5]$$

The dilatation along the x-axis is determined by the sum of the projections on the x-axis of all the random orientated NSP unit vectors. Projection of each unit vector on the x-axis depends on the magnitude of $\cos\phi$ (Fig. 3). Then, considering Eq. [5] as a condi-

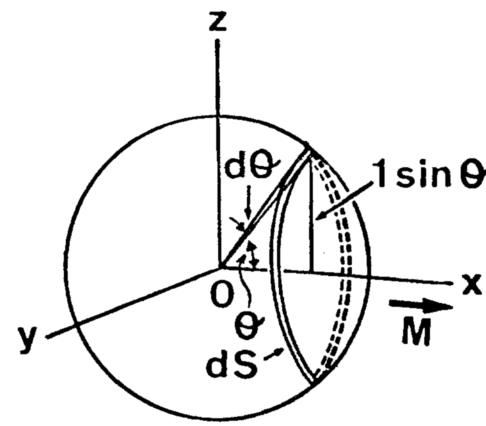

Fig. 2. Diagram illustrating the computation of distribution functions. The x-axis is directed along the magnetization, the z-axis along the normal to the film.

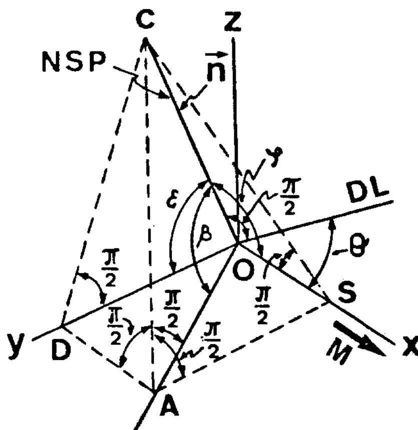

Fig. 3. Diagram for the computation of p_o^x and p_o^y parts of the density of the dislocations, the outflow of which results in the emergence of anisotropic macrostresses along the x and y axes.

tion for normalization for A, we shall find the sum of the projections of all NSP unit vectors on the x-axis

$$p_o^x = \frac{p_o \int_0^{\pi/2} \sin\theta \int_{\pi/2-\theta}^{\pi/2} \sin\phi \cos\phi \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta)\, d\theta d\phi}{\int_0^{\pi/2} \sin\theta \int_{\pi/2-\theta}^{\pi/2} \sin\phi \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta)\, d\theta d\phi} \qquad [6]$$

The dilatation along the y-axis is determined by an identical expression, where however, instead of $\cos\phi$, we write $\cos\epsilon$ (the angle ϵ is shown in Fig. 3). Figure 3 shows that

$$\cos\epsilon = \sqrt{\cos^2\beta - \cos^2\phi} \qquad [7]$$

For fixed ϕ and θ, β can change within the range 0 to ϕ. The value of β does not affect the energy of the interaction between the dislocations and magnetization, so that all values of β within the above limits are equally probable. The average magnitude of $\cos\epsilon$ in that case is

$$\overline{\cos\epsilon} = \frac{1}{\phi}\int_0^{\phi} \sqrt{\cos^2\beta - \cos^2\phi}\, d\beta \qquad [8]$$

Thus, for the sum of the projections of all NSP unit vectors on the y-axis we shall obtain

$$p_o^y = \frac{p_o \int_0^{\pi/2} \sin\theta \int_{\pi/2-\theta}^{\pi/2} \sin\phi \left[\frac{1}{\phi}\int_0^{\phi} \sqrt{\cos^2\beta - \cos^2\phi} \cdot \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta)\right] d\theta d\phi d\beta}{\int_0^{\pi/2} \sin\theta \int_{\pi/2-\theta}^{\pi/2} \sin\phi \exp(-\alpha_1 \cos^2\phi - \alpha_2 \cos^2\theta)\, d\theta d\phi} \qquad [9]$$

We shall assume (13-15) that the energy of the interaction between the defect and magnetization is considerably lower than the heat energy

$$\alpha_1 = \frac{K_1}{kT} << 1; \qquad \alpha_2 = \frac{K_2}{kT} << 1 \qquad [10]$$

Then, replacing the exponents in Eq. [6] and [9] by the first members of the corresponding series, we shall reduce the denominators of both expressions [6] and [9] and the numerator in [6] to table integrals; the numerator of [9] can be found by numerical integration. As a result of the computation of the integrals in [6] and [9], we obtain

$$p_o^x \cong 0.425\, p_o \frac{1 - 0.4\alpha_1 - 0.125\alpha_2 + 0.057\alpha_1\alpha_2}{1 - 0.563\alpha_1 - 0.25\alpha_2 + 0.042\alpha_1\alpha_2}$$

$$p_o^y \cong 0.425\, p_o \frac{1 - 0.244\alpha_1 - 0.211\alpha_2 + 0.039\alpha_1\alpha_2}{1 - 0.563\alpha_1 - 0.25\alpha_2 + 0.042\alpha_1\alpha_2} \qquad [11]$$

From expression [11] it will be seen that for $\alpha_1 \neq 0$ and $\alpha_2 \neq 0$, the sums of the NSP vector unit projections on the x-axis coinciding with the direction of the field, and the y-axis, normal to the technological field, differ from one another. This makes for different dilatations in the directions of the indicated axes and, hence, also for different macrostresses.

Computation of Macrostresses in the Films Growing in a Magnetic Field

Let us compute the macrostresses σ_x in the direction of the x-axis and σ_y in the direction of the y-axis.

Let p_R be the density of dislocations which are preserved in the crystal after the process of their outflow has stopped. Let p_R^x be the sum of the projection of all the NSP unit vectors, normal to the lines of the "remaining" dislocations, on the x-axis, and let p_R^y be the same for the y-axis. Then, the decrease of the sum of projections of the NSP unit vectors on the x-axis (as a result of the outflow of a part of the dislocations) will amount to $\Delta p_x = p_o^x - p_R^x$, and on the y-axis, $\Delta p_y = p_o^y - p_R^y$. If W_o is the linear energy of the dislocation, the withdrawal of a part of the dislocations will bring about a decrease of the total dislocation energy in the crystal by $W_o \cdot \Delta p$, where $\Delta p = p_o - p_R$.

Let us now introduce a coefficient q

$$q(\Delta p_x + \Delta p_y) = \Delta p \qquad [12]$$

Thus, for example, if $p_R^x/p_o^x = p_R^y/p_o^y = p_R/p_o$, we obtain from [11] the following

$$q^{-1} = 0.425 \frac{2 - 0.644\alpha_1 - 0.336\alpha_2 + 0.096\alpha_1\alpha_2}{1 - 0.563\alpha_1 - 0.25\alpha_2 + 0.042\alpha_1\alpha_2} \qquad [13]$$

In this case, the decrease of the total energy of the dislocations (as a result of their partial withdrawal) can be presented as $\Delta W = W_o q(\Delta p_x + \Delta p_y)$, where part of the decrease of energy to the amount of $W_o q \Delta p_x$ is connected with a change in the sum of the projections of all NSP unit vectors on the x-axis and part $W_o q \Delta p_y$ on the y-axis.

On the other hand, in the event of a plane state of stresses with stresses σ_x and σ_y, the potential energy corresponding to the elastic deformation along the x-axis is (16)

$$\frac{1}{2}\sigma_x\epsilon_x = \frac{1}{2}\sigma_x\left[\frac{1}{E}(\sigma_x - \mu\sigma_y)\right] = \frac{1}{2E}(\sigma_x^2 - \mu\sigma_x\sigma_y) \qquad [14]$$

(ϵ_x and ϵ_y are the strains along the x and y axes); for the y-axis it will be

$$\frac{1}{2}\sigma_y\epsilon_y = \frac{1}{2E}(\sigma_y^2 - \mu\sigma_y\sigma_x) \qquad [15]$$

where E is Young's modulus of the elasticity and μ Poisson's ratio of the film material.

While the dislocations, which outflow from the crystals, carry away the energy in amount ΔW, only a fraction χ of ΔW is converted to macrostress energy; the

rest of ΔW, expressed as $(1 - \chi)\Delta W$, is scattered as heat. The estimation of a value χ will be proposed in the discussion. As to the nature of this quantity, it scarcely can be explained at this stage of theory's development. Hence, we must be limited by the introduction of, instead of ΔW, a magnitude $\chi\Delta W$ in following relations. Then, the energy balance is

$$\chi W_o q \Delta p_x = \frac{1}{2E}(\sigma_x^2 - \mu\sigma_x\sigma_y)$$

$$\chi W_o q \Delta p_y = \frac{1}{2E}(\sigma_y^2 - \mu\sigma_y\sigma_x) \quad [16]$$

The solution of the system of equations in [16] provides formulas

$$\left.\begin{aligned}\sigma_x &= \sqrt{\frac{\chi q W_o E}{1-\mu^2}}\cdot\sqrt{\mu^2\delta p_{xy} + 2\kappa_x p_o^x + \sqrt{(\mu^2\delta p_{xy} + 2\kappa_x p_o^x)^2 - 4(1-\mu^2)\kappa_x^2 p_o^{x2}}} \\ \sigma_y &= \sqrt{\frac{\chi q W_o E}{1-\mu^2}}\cdot\sqrt{\mu^2\delta p_{yx} + 2\kappa_y p_o^y + \sqrt{(\mu^2\delta p_{yx} + 2\kappa_y p_o^y)^2 - 4(1-\mu^2)\kappa_y^2 p_o^{y2}}}\end{aligned}\right\} \quad [17]$$

into which the following notations are introduced

$$\delta p_{xy} = -\delta p_{yx} = p_o^x - p_o^y; \quad \kappa_x = \frac{\Delta p_x}{p_o^x}; \quad \kappa_y = \frac{\Delta p_y}{p_o^y} \quad [18]$$

[The sign in front of the inner square root in both equations [17] is determined by letting α_1 and α_2 approach zero and comparing formulas [17] to the corresponding ones for the isotropic case (2-4).]

Discussion

Relations [17], taking into account formulas [11], make it possible to explain the experimental regularities stated in Part I (1) (section on Results and Discussion, items 1-3).

1. If $\alpha_1 \neq 0$ and $\alpha_2 \neq 0$, *i.e.*, according to Eq. [11], $p_o^x \neq p_o^y$, from relations [17] is it evident that σ_y must differ from σ_x. The obtained result shows how the small energies of magnetic interaction control the large energies of elastic deformation: even if K_1 and K_2 are small and, hence, the orientation of the dislocation lines and the normals to them are not substantial, the high density of the dislocations makes this small degree of orientation sufficient for the creation of a measurable anisotropy of the macrostresses.

For a quantitative evaluation of the anisotropy of the macrostresses being induced by the above mechanism, let us assume that in Eq. [11], $\alpha_1 \cong \alpha_2 \cong 0.1$ which is within the admissible limits given in Eq. [10]. We then obtain from [11]: $p_o^x = 0.437p_o$, $p_o^y = 0.444p_o$. In nickel films electrodeposited in a magnetic field, the tensile macrostresses are of an order of (1): $\sigma \sim 2 \times 10^7$ N·m^{-2}. Let us assume, for example, that ~ 0.02 of the initial density of dislocations is removed from the crystal, *i.e.*, $p_R \cong 0.98p_o$. Then, by taking the limit of Eq. [11] for $\alpha_i \to 0$, we obtain: $p_R^x = p_R^y \cong 0.425p_R \cong 0.425 \cdot 0.98p_o$; and from relations [17] and [19]: $\sigma_x = \sqrt{\chi q}\cdot 1.25 \times 10^9$ N·m^{-2}, $\sigma_y = \sqrt{\chi q}\cdot 1.4 \times 10^9$ N·m^{-2}. In order to correlate the calculated σ_x and σ_y with the experimental ones, we have to assume that $\chi q \cong 1.5 \times 10^{-3}$. From [13] it can be seen that the factor q, introduced by relation [12], is of the order of ~ 1. Hence, there must be: $\chi \cong 1.5 \times 10^{-3}$. Thus, if less than 1% of the energy of the dislocations, which was removed from the crystal, converts to the energy of the macrostresses, the postulated mechanism will ensure the level of macrostresses observed in experiments. Here, the anisotropy of the macrostresses caused by the partial orientation of the dislocations in the magnetic field is also of the same magnitude as the experimental one (in the above example $\sigma_y/\sigma_x \cong 1.12$).

2. When the sign of the magnetostriction changes, the constants K_1 and K_2 and, hence, also α_1 and α_2, change their sign. As can be seen from Eq. [11] and [17], when $\alpha_1 > 0$ and $\alpha_2 > 0$ we obtain $\sigma_y > \sigma_x$. When $\alpha_1 < 0$ and $\alpha_2 < 0$ there is an inversion, $\sigma_y < \sigma_x$, which corresponds to the inversion observed experimentally when the sign of the magnetostriction was changed (1).

3. Equations [11] and [17] also provide an explanation for the effect of saccharin on the anisotropy of macrostresses of the films studied here. It has been observed (1) that saccharin inverts the influence of the magnetic field on the macrostresses. Since, as was postulated, K_1 and K_2 and with them also α_1 and α_2 (see Eq. [10]) characterize the magnetostrictive interaction, the magnitude of the coefficient of magnetostriction λ_s determines the absolute values α_1 and α_2. It is known (17) that the stresses affect the magnetostriction λ_s substantially. But introduction of saccharin into the solution leads to a considerable increase in the defect concentration and raises the microstress level. [For example, in a nickel film the introduction of saccharin into the solution raises the microstresses by more than 5-fold (18).] This must greatly alter the absolute values of α_1 and α_2. On the other hand, from Eq. [11] and [17], it will be seen that a change in the absolute value of α_1 and α_2 can bring about an inversion of the relation between σ_x and σ_y. For example, at $\alpha_1 \cong 10^{-3}$, $\alpha_2 \cong 2 \times 10^{-3}$, we obtain from [11]: $p_o^x > p_o^y$ and hence, according to [17] also $\sigma_x > \sigma_y$. If, however, $\alpha_1 \cong 3 \times 10^{-3}$, $\alpha_2 \cong 2.5 \times 10^{-3}$ then $p_o^x < p_o^y$ and correspondingly $\sigma_x < \sigma_y$.

Thus, the regularities of the anistropy of macrostresses, observed in films of nickel and iron-nickel alloy deposited in a magnetic field and described in Part I of this work (1), can be explained on the basis of the above concept.

Adoption of the dislocation model of the creation of the macrostresses, as well as of their anisotropy, does not exclude the possible role of other mechanisms. However, from the above discussion, it is seen that a considerable part of the anisotropy of macrostresses could very likely be ascribed to the effect of the partial withdrawal of dislocations from the film crystals and to the partial orientation of dislocations under the influence of technological factors (as in the case under consideration, the magnetic field).

Manuscript submitted Dec. 2, 1974; revised manuscript received May 7, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Technical Notes

Vapor Deposition of High P_2O_5 Content Binary Phosphosilicate Films on Silicon

J. Wong* and M. Ghezzo*

General Electric Company, Research and Development Center, Schenectady, New York 12301

The stability enhancement of Si devices by binary phosphosilicate glass (PSG) films as gettering sources for metallic impurities (1-7) and passivation layers (8-12), and the utilization of these materials as n-diffusion sources for the fabrication of p-n junctions in Si (13-15) have been demonstrated by a number of authors. Much of the preparation, material characterization studies, and device application of PSG so far has been confined to films with less than 20 mole per cent (m/o) P_2O_5 (16-24). High P_2O_5 content phosphosilicate glasses are of considerable interest, especially in studies such as structural aspects of this type of material (25) which require systematic property investigations across the whole composition of the binary system.

In this paper, we report the vapor deposition of binary PSG films with composition ranging from one end component to the other using a PH_3-SiH_4-O_2-Ar (or N_2) reaction system at substrate temperatures in the range 300°-400°C. The rate of deposition and film composition has been investigated systematically as a function of temperature and concentration of reactive and carrier gases.

Experimental Procedure

Ten ohm-cm p-type (111) oriented silicon wafers, 2.5 cm in diameter and 0.05 cm thick, were used as substrates for film deposition. These were heavily etched in a conc HNO_3-conc HF solution (3:1 by volume), rinsed thoroughly in distilled water, and spin-dried prior to deposition. The phosphine and silane sources used were semiconductor grade obtained from the Matheson Company as a calibrated 1% mixture in Ar. Union Carbide ultrapure grades of O_2, Ar, and N_2 were used as the oxidizing medium and carrier gases, respectively, in the CVD process. The gas-flow system and vertical reactor used in the present study are similar to those used for the study of arsenosilicate film reported earlier (26).

Depositions were made at substrate temperatures of 300°, 350°, and 400°C controlled to within ±2°C. All flow meters were calibrated with the corresponding gases or mixtures using two Brook flow calibrators having capacities of 0-70 and 0-1000 cc. In all depositions, the molar ratio of O_2 to total hydride in the reactive mixture was maintained at about 10 to assure complete oxidation of both PH_3 and SiH_4, which theoretically requires an O_2/hydride ratio varying from 1 to 1.25 depending on composition across the PSG system.

Deposition rate was conveniently determined by continuously recording the color of the film *in situ* during deposition and using the color thickness chart devised by Tenney and Ghezzo (22b) from the data of Pliskin and Conrad for thermal SiO_2 (27) to plot film thickness *vs.* time of deposition. The actual thickness of PSG films may be 5-10% (see error bars in Fig. 1-3) lower than that obtained by color because of the higher refractive indices of PSG films (1.50-1.60 depending on composition) (28) compared to a value of 1.46 for thermal SiO_2. Interestingly enough, it was found experimentally that by reducing the substrate temperature to 300°C and using a high flow rate of PH_3 with Ar, but not N_2, as carrier gas, a pure P_2O_5 film can be reproducibly vapor deposited at a fairly high rate. The uniformity of the P_2O_5 film can be greatly improved by first coating the bare Si substrate with a 200Å layer of SiO_2 prior to the P_2O_5 deposition.

Film compositions were determined by electron microprobe analysis for silicon and phosphorus using high purity, undoped samples of silicon and gallium phosphide, respectively, as standards. Films containing 20 m/o P_2O_5 and higher are hygroscopic; to protect these high P_2O_5 content films from moisture attack during handling, a thin covering layer (~300Å thick) of SiO_2 was deposited *in situ* immediately after the PSG deposition by simply turning off the PH_3 supply. For films containing 50-100 m/o P_2O_5, a double covering layer was necessary in order to avoid cracking (due to thermal stress) of the covering layer when cooled from the deposition temperature to room temperature. The double covering layer consisted of a 20 m/o PSG film (~300Å thick) followed by a pure SiO_2 layer (also ~300Å thick). When stored in a desiccator,

Key words: thin dielectric glass films, preparation.

moisture attack on the underlying binary film can be obviated for as long as a week which is indicated by the reproducibility of the infrared spectrum of the as-deposited film and absence of the OH absorption in the 3μ region. The accuracy of the microprobe technique was estimated to be within ±3% or better for all films.

Results and Discussion

Deposition rate.—The deposition rate of PSG films has been studied as a function of the mole fraction of PH_3 (x_{PH_3}) in the hydride mixture, substrate temperature, and gas flow conditions. Figure 1 shows the results obtained at 400°C by varying the flow rate of PH_3 (1% in Ar) in the range 0-900 cc min^{-1}, while holding constant flow rates of O_2, SiH_4 (1% in Ar), and carrier gas Ar at 40, 100, and 2800 cc min^{-1}, respectively. The deposition rate increases monotonically with x_{PH_3} and exhibits a maximum at $x_{PH_3} \sim 0.8$.

At lower substrate temperatures, higher flow rates of reactant gases are necessary in order to facilitate deposition rate measurements within a reasonable time scale. The results at 350° and 300°C in the N_2 system are shown in Fig. 2 and 3. In the range $0 \leq x_{PH_3} \leq 0.45$, the flow rate of PH_3 (1% in Ar) was allowed to increase, while those of O_2, SiH_4 (1% in Ar), and N_2 were held constant at 40, 400, and 2800 cc min^{-1}, respectively. Again, the deposition rate increases with x_{PH_3}. In the range $0.5 \leq x_{PH_3} \leq 1.0$, the flow rate of PH_3 (1% in Ar), O_2, and N_2 were held constant at 473, 40, and 2800 cc min^{-1}, respectively, while that of SiH_4 (1% in Ar) was progressively lowered to obtain high x_{PH_3} values. In this range the deposition rate decreases monotonically to zero with increase in x_{PH_3} (Fig. 3).

However, when Ar was used instead of N_2 as the carrier gas at 300°C, a maximum similar to that shown in Fig. 1 was again observed at $x_{PH_3} \sim 0.85$. At $x_{PH_3} = 1$, the deposit rate in the Ar system shown in Fig. 3 could be maintained at ~1300Å min^{-1} under the gas flow conditions of 473, 40, and 2800 cc min^{-1} for PH_3 (1% in Ar), O_2, and Ar, respectively. The deposition corresponds to that of a pure P_2O_5 film. The above data for the N_2 system shown in Fig. 2 and 3 clearly indicate an inhibitive effect of N_2 on the deposition of PSG film in the region of high x_{PH_3} values. In the absence of further detailed kinetic data, it could only be speculated that N_2 may retard the generation of oxygen free radicals that are necessary to initiate the oxidation of PH_3; complex with intermediate species, thus preventing further oxidation to higher oxides; or terminate chain propagation in the polymerization process.

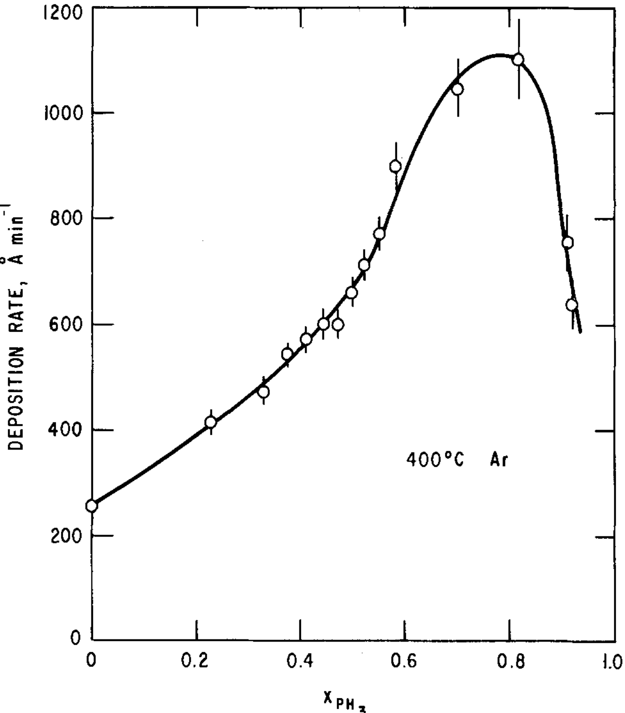

Fig. 1. Deposition rate of PSG films at 400°C vs. x_{PH_3}. The flow rates of O_2, SiH_4 (1% in Ar), and Ar were held constant at 40, 100, and 2800 cc min^{-1}, while that of PH_3 (1% in Ar) was made to vary so as to obtain the corresponding x_{PH_3} in the hydride mixture.

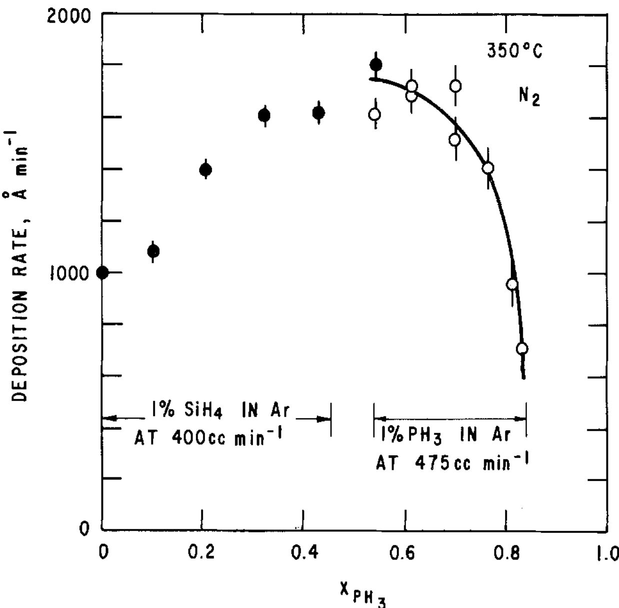

Fig. 2. Deposition rate of PSG films at 350°C vs. x_{PH_3} in N_2. Flow rates in cc min^{-1} for $0 \leq x_{PH_3} \leq 0.42$: $O_2 = 40$, $SiH_4 = 400$, $N_2 = 2800$, and PH_3 variable; for $0.5 \leq x_{PH_3} \leq 0.83$, $O_2 = 40$, $PH_3 = 473$, $N_2 = 2800$, and SiH_4 variable. Flow rates of both SiH_4 and PH_3 are those of the 1% mixtures in Ar.

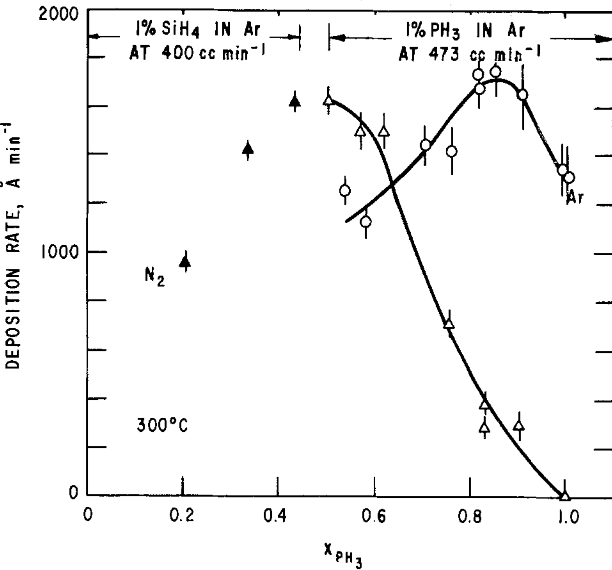

Fig. 3. Deposition rate of PSG film at 300°C vs. x_{PH_3}. Flow rates in cc min^{-1} for $0.2 \leq x_{PH_3} \leq 0.43$: $O_2 = 40$, $SiH_4 = 400$, $N_2 = 2800$, and PH_3 variable; for $0.5 \leq x \leq 1.0$: $O_2 = 40$, $PH_3 = 473$, N_2 or Ar $= 2800$, and SiH_4 variable. Flow rates of both SiH_4 and PH_3 are those of the 1% mixtures in Ar.

Deposition of pure P_2O_5 films.—The above systematic study of the rate of deposition of PSG films from the PH_3-SiH_4-O_2 system leads to a formulation for depositing a pure P_2O_5 film at low substrate temperature and high PH_3 flow rate. Pure P_2O_5 films deposited on bare Si substrates are rather nonuniform in thickness as shown by the color distribution of the deposit. It was found experimentally that by depositing a thin layer of CVD SiO_2 (~200Å thick) on the bare Si sub-

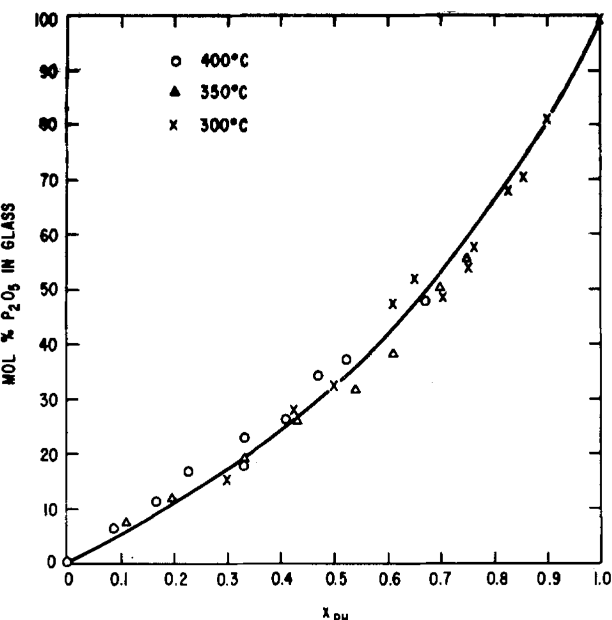

Fig. 4. Film composition determined by electron microprobe analysis vs. x_{PH_3} at various deposition temperatures. The line is calculated by using the formula m/o $P_2O_5 = \frac{x_{PH_3}}{2 - x_{PH_3}}$.

strate prior to the P_2O_5 film, uniformity of the latter was greatly enhanced. This "priming" procedure enables reproducible deposition of very uniform P_2O_5 films.

Film composition.—Compositions of PSG film prepared under the above-mentioned substrate temperatures and gas flow conditions have also been determined. It was found that the amount of P_2O_5 that can be incorporated in the film depends strongly on x_{PH_3} and substrate temperature. The results are given in Fig. 4 in which the film composition in m/o P_2O_5 is plotted *vs.* x_{PH_3} at various deposition temperatures. The points represent the data obtained by electron microprobe analysis after having been corrected for the respective covering layers, while the curve corresponds to those calculated from the molar concentration of PH_3 and SiH_4 in the reaction mixture using the formula: m/o $P_2O_5 = x_{PH_3}/(2 - x_{PH_3})$ which assumes stoichiometric oxidation of each hydride component. Within ±5 m/o or better, composition of CVD PSG films can be expected to follow that determined by the relative concentrations of the hydride components in the presence of excess O_2. Furthermore, in the range 0-20 m/o P_2O_5, the microprobe data agree well with those obtained from the infrared data of Tenney and Ghezzo (22) using the intensity ratio of the P = 0 band and Si-O band at 1320 and 1100 cm^{-1} as a composition calibration of PSG films deposited from the same reaction system in the range 300°-700°C.

The amount of P_2O_5 that can be incorporated in the PSG films increases with decreasing substrate temperature in agreement with the findings of Tenney and Ghezzo (22), as well as the more recent data of Shibata *et al.* (29). At 400°C, the maximum concentration is about 50 m/o P_2O_5 (see Fig. 4 for the data point at 400°C). Increasing the amount of PH_3 gas (hence x_{PH_3}) will lead only to heavy fuming at the gas-substrate interface, indicative of vaporization loss of reaction products, especially P_2O_5. This probably gives rise to the drop in deposition rate beyond $x_{PH_3} = 0.8$. When the substrate temperature was lowered to 350° and 300°C, the concentration of P_2O_5 in the film can be extended to ~60 and even to 100 m/o P_2O_5 as shown in Fig. 4. The decrease in P_2O_5 concentration in the film with increasing substrate temperature appears to be due to a decrease in the sticking coefficient of the P_2O_5 component with temperature. That this is the case is substantiated by direct observation of a progressive decrease in thickness (Fig. 5 inset) of a pure P_2O_5 film deposited initially at 300°C as it was being heat-treated *in situ* in the reactor from 325° to 550°C holding the temperature constant for 3 min at 25°C intervals. Accordingly, the infrared spectrum of the heat-treated film shows a decrease in intensity in all the corresponding absorption bands (Fig. 5). The vibrational spectra and structural analysis of these CVD PSG films will be given in a subsequent paper (30). In fact, the occurrence of the band at 1300 cm^{-1} which is characteristic of the P = 0 vibration and its persistence in the spectra of all as-deposited binary PSG films suggest that the oxidation product of PH_3 under the present CVD conditions is indeed phosphorus pentoxide.

Summary

Binary phosphosilicate glass films of varying composition across the binary system have been prepared by a CVD technique using a PH_3-SiH_4-O_2 reaction system at low substrate temperatures (300°-400°C). The deposition characteristics of these films may be summarized as follows: (*i*) The P_2O_5 content in the film increases monotonically with the mole fraction of PH_3 (x_{PH_3}) in the hydrides mixture in the presence of excess O_2. (*ii*) At 400°C film composition is restricted to no higher than 50 m/o P_2O_5. Higher P_2O_5 content PSG films can be deposited by lowering the substrate temperature to 300°C, at which a pure P_2O_5 film may be deposited using only PH_3-O_2 and Ar, but

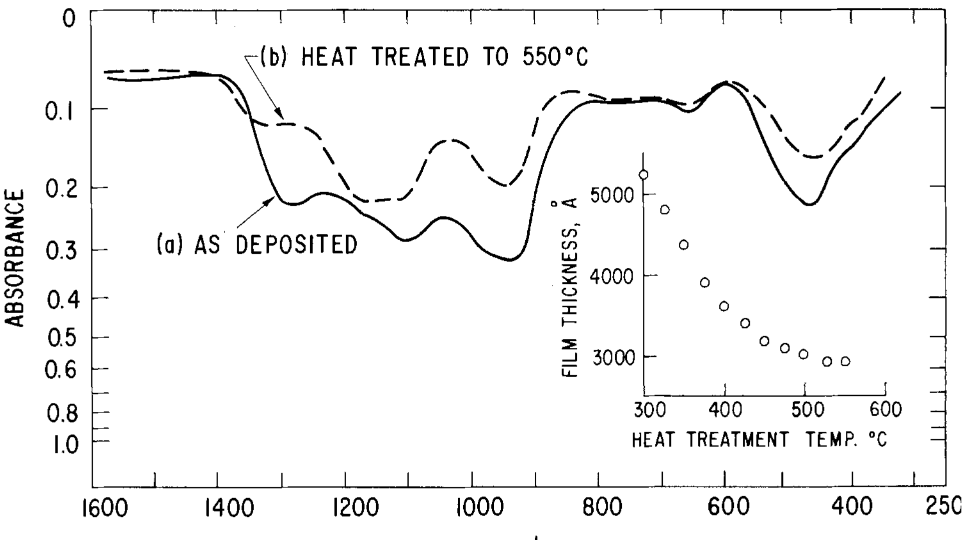

Fig. 5. Room temperature infrared transmission spectra of pure P_2O_5 films deposited on silicon (a) as-deposited and (b) heat-treated to 550°C. The priming layer of SiO_2 and double covering layer have been compensated accordingly on a reference Si substrate. Inset is a plot of film thickness vs. *in situ* heat-treatment temperature.

not N_2, as the carrier gas. (*iii*) The deposition rate increases initially with x_{PH_3} at all temperatures studied. A maximum rate at $x_{PH_3} \sim 0.8$ is observed in the Ar system, but not the N_2 system. (*iv*) Deposition of high P_2O_5 content films, *i.e.*, at $x_{PH_3} > 0.5$, appears to be inhibited by the presence of N_2.

Acknowledgment

The authors would like to thank P. Sargent for technical assistance and M. McConnell for performing the microprobe analysis.

Manuscript submitted March 4, 1975; revised manuscript received May 6, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Silicon Nitride Films by Direct RF Sputter Deposition

G. J. Kominiak

Sandia Laboratories, Albuquerque, New Mexico 87115

Silicon nitride, because of its chemical stability (1), is of considerable importance in the electronics industry for use in passivating semiconductor surfaces (2, 3), as a barrier to diffusion in silicon device technology (2, 4-10), and in MNOS device technology (11-16). Nonelectronic applications of silicon nitride layers include: the formation of glass to metal seals (17), a proposed antireflection coating for a solar-thermal collector (18), and as an electrode insulator in high temperature electrochemistry (19).

Among the several methods which have seen general use for the deposition of amorphous layers of silicon nitride are: the pyrolysis of silane in the presence of gaseous nitrogen compounds (4, 20-30), rf and microwave discharge induced CVD (31-34), ion beam techniques (35), and reactive sputter deposition from a high-purity silicon target (36-39). The most common method of film formation appears to be the CVD techniques.

A disadvantage to the pyrolysis schemes is the high substrate temperatures needed (500°-1000°C) (28-30). Glow discharge induced CVD methods alleviate this disadvantage since deposition occurs at temperatures below 100°C (34). These low temperature films appear to have residual hydrogen content (40), which may limit their usefulness. Direct rf sputter deposition of silicon nitride films from a pressed powder target of silicon nitride has been avoided because of the difficulty in obtaining high purity targets (40), the danger of silicon oxide incorporation into the films because of gases trapped in the target (41), and variations in stoichiometry in the resulting films due to dissociation reactions at the target (42). Gregor (43) has reported that reproducible films of silicon nitride may be sputtered from a nitride target, but only at high rf power levels.

Here we report the formation of transparent thick films (up to 10μ) of silicon nitride by direct rf sputter deposition. These films are prepared at low rf power levels from an Si_3N_4 target using a mixture of argon and nitrogen.

Experimental

The silicon nitride films were directly sputter deposited on water-cooled substrates of silicon, fused SiO_2, gold, platinum, and T-12®[1] infrared windows using an MRC IC[2] grade Si_3N_4 target. The depositions were carried out in a conventional planar rf sputtering system. The substrates were biased by inserting a tuning network between the substrate holder and

Table I.

Target voltage (kV)	Input power (watts)	Lattice absorption (cm^{-1})	Refractive index	Etch rate (Å/sec)
1.0	300	870	2.08	~8
1.2	450	850	2.00	~15
1.5	700	830	1.90	~20
Bulk	—	935	2.1	—
CVD	—	830	2.0-2.06	1.5[20]
Glow discharge CVD (low temp)	—	870	1.75-2.18	100[40]

ground (44). Gas mixtures were admitted and adjusted to the operating pressure with the high vacuum valve open in an effort to maintain a high gas throughput. Low throughput resulted in films with considerable oxygen (26) content as evidenced by a distinct infrared absorption band at 1100 cm^{-1}. A nitrogen concentration in the discharge gas of <20% produced films which were silicon rich, while a percentage greater than ~25% gave clear adherent films but severely reduced the deposition rate. The principal variable in this investigation was the target voltage (input power) (45). The substrate circuit was tuned for +20V bias and held constant from run to run.

The width and position of the lattice absorption band (46, 47), the index of refraction (46, 48), the ultraviolet absorption (40), film density, and the etch rate (48) were used to evaluate the quality of the film.

Results

Figure 1 shows the infrared absorption spectrum (curve A) of a 2000Å film of silicon nitride deposited in argon-20% nitrogen at a target voltage of 1 kV (P_{in} ~ 300W). The lattice absorption is fairly broad with the maximum occurring at 870 cm^{-1} as compared to ~830 cm^{-1} for CVD material (4, 25) (curve B) and ~935 cm^{-1} for bulk silicon nitride (curve C) (4, 6). As these films were shown to be amorphous by x-ray diffraction, the shift in lattice absorption to lower frequencies may be attributed to bond stretching in the amorphous film (4, 36). Increasing the target voltage to 1.5 kV (P_{in} ~ 700W) resulted in a general increase in the infrared absorption in the range 1000-1200 cm^{-1} and a shift in the maximum to ~830 cm^{-1}. The shift in the band maximum may be attributed to porosity (49) or an increased bond strain in the resulting films (50). These infrared properties were obtained only if the target was presputtered for approximately 1 hr prior to film deposition. Proceeding without presputtering gave rise to films with additional absorption bands at ~3300 cm^{-1} (N-H) (40) and ~2100 cm^{-1} (Si-H) (33, 40). This is comparable to low temperature glow discharge CVD coatings (40). In this case, the hydrogen probably originated as an adsorbed impurity in the target surface (41).

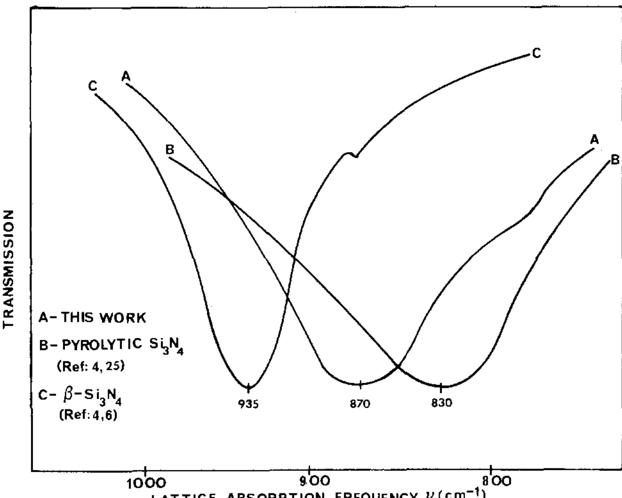

Fig. 1. Position of lattice absorption band. A, Direct sputter Si_3N_4; B, CVD Si_3N_4; C, bulk Si_3N_4.

For measurements of refractive index and optical absorption, Si_3N_4 layers were deposited on chromium-coated soft glass and fused silica, respectively. The chromium layer was opaque and was partially masked during nitride deposition to facilitate measurement of the optical constants of both the chromium substrate and the nitride layer. The refractive index was measured at λ = 5461Å using an ellipsometer and the energy gap was calculated from the position of the ultraviolet absorption edge.

Silicon nitride films deposited at 1 kV (P_{in} ~ 300W) exhibited an index of refraction of 2.08 (bulk — 2.1) (36); the optical gap was ~ 5 eV. Increasing the target voltage to 1.5 kV (P_{in} ~ 700W) reduced the refractive index to 1.90 and increased the energy gap to ~ 5.5 eV. These results along with an increase in infrared absorption in the vicinity of ~ 1100 cm^{-1} are suggestive of oxygen incorporation in the 1.5 kV deposit. Examination of these films by sputter-Auger spectroscopy indicated the presence of ~ 9 atomic per cent (a/o) oxygen. In addition, the films produced at high target voltages were uniformly absorbing in the visible. This absorption is probably a result of damage caused by particle bombardment of the film during growth (51-55).

The density, as determined by weight gain, of 10μ thick nitride films deposited at 1 kV, was ~ 3 g/cm^3. This is comparable to that found for films produced by other techniques (56).

The room temperature etch rate in 48% hydrofluoric acid was found to range from 8 Å/sec for films deposited at 1 kV (300W) to ~ 20 Å/sec for films deposited at 1.5 kV (700W). As preliminary investigation of the composition of these films did not indicate large changes, the variation in etch rate may be related (at least in part) to changes in internal stress with deposition conditions (57, 58).

Summary

Thick (~ 10μ), transparent films of amorphous silicon nitride were deposited at low temperatures (< 100°C), at rates of 30-60 Å/min by direct rf sputtering of a Si_3N_4 target. The films were prepared using a mixture of Ar/20% nitrogen as the sputtering gas. Nitrogen levels < 20% result in films which are silicon rich, while concentrations > 25% drastically reduce the deposition rate. The density and optical properties of the films were comparable to those of pyrolytic and glow discharge CVD deposits. Contrary to the results of Gregor (43), these properties tend toward those of crystalline material when deposited at low rf power levels. Increasing the input power by a factor of ~ 2 broadens the lattice absorption band and further shifts its position to longer wavelengths. Simultaneously, the films become absorbing in the visible, and the index of refraction decreases from 2.08 to 1.90. Along with changes in optical properties, the power increase during deposition results in an increase in the 48% HF etch rate of approximately a factor of 3.

Growth of GaN Thin-Films from Triethylgallium Monamine

J. E. Andrews

Research Triangle Institute, Research Triangle Park, North Carolina 27709

and M. A. Littlejohn

North Carolina State University, Raleigh, North Carolina 27607

Vapor phase deposition of gallium nitride from organometallic compounds and NH_3 offers the possibility of lower growth temperatures compared to Ga-halide compounds due to the weaker Ga-organic radical bonds compared to the Ga-halide bonds (1). Lower growth temperatures could be desirable since the dissociation temperature of GaN has been reported to be as low as 600°C (2), depending on the growth conditions (3).

Although GaN growth was obtained from trimethylgallium [$Ga(CH_3)_3$], (4) triethylgallium monamine [$Ga(C_2H_5)_3 \cdot NH_3$] was selected over $Ga(CH_3)_3$ for

Key words: organometallic compounds, epitaxial growth, diethylgallium amide.

several reasons. First, a nitrogen atom is already bonded to the Ga atom, and although this is a weak bond, some Ga-N pairs may survive long enough to be incorporated into the film growth without an external source of N. Second, it is not pyrophoric as are both triethylgallium and trimethylgallium. Finally, this compound is a liquid at room temperature, providing slightly more convenient handling than $Ga(CH_3)_3 \cdot NH_3$ which is solid (mp 31°-32°C) (5).

Published information on the physical and thermodynamic properties of $Ga(C_2H_5)_3 \cdot NH_3$ was not available. Only one commercial source is known to date.

Preparation of $Ga(C_2H_5)_3 \cdot NH_3$

The $Ga(C_2H_5)_3 \cdot NH_3$ used in this research[1] was prepared by saturating $Ga(C_2H_5)_3$ with NH_3 at -10°C. The material so formed was reported to be pale yellow and apparently underwent a slow decomposition, possibly by the reaction

$$Ga(C_2H_5)_3 \cdot NH_3 \rightarrow Ga(C_2H_5)_2 \cdot NH_2 + C_2H_6$$

Distillation resulted in further decomposition with C_2H_6 positively identified as a by-product. Upon completion of the decomposition, the product was easily distilled in a vacuum of 0.25-0.4 mm Hg. The material's reported boiling range was 64°C/0.25 mm Hg-83°C/0.4 mm Hg, and an analysis indicated the material to be predominantly diethylgallium amide.

The as-received material was colorless and "air-sensitive." Several droplets of the liquid turned into a white waxy-type substance when exposed to air over a period of approximately two days at room temperature. H_2O was nearly immiscible with the liquid and converted, at least ten times its own volume of the liquid into a beige-colored solid substance over a period of several days at room temperature.

Growth System Description

The growth system constructed for this research used a horizontal steady-state flow, 5 cm ID, cylindrical quartz reactor heated with a 700w Type FM305 Hoskins furnace. The reactor was operated at atmospheric pressure with a N_2 carrier gas stream for reactant vapor transport.

The triethylgallium monamine source material was shipped in a pressurized (N_2 gas, 12 psig), stainless steel sample cylinder and connected to the growth system shown in Fig. 1 directly over the bubbler. The bubbler is Pyrex and is connected to the stainless steel tubing through a Kovar glass-to-metal seal. The entire system was evacuated and the lines baked out from the gas supplies toward the vacuum system (reactor was removed and vacuum system was connected in its place) to aid the desorption of O_2 and H_2O from the interior tube walls. The system was evacuated, sealed

[1] Prepared and characterized by Dr. T. F. Jula and Dr. Bernd Schneider, Ventron Corporation, Alfa Inorganics, following essentially the technique described on p. 172 of Ref. (4).

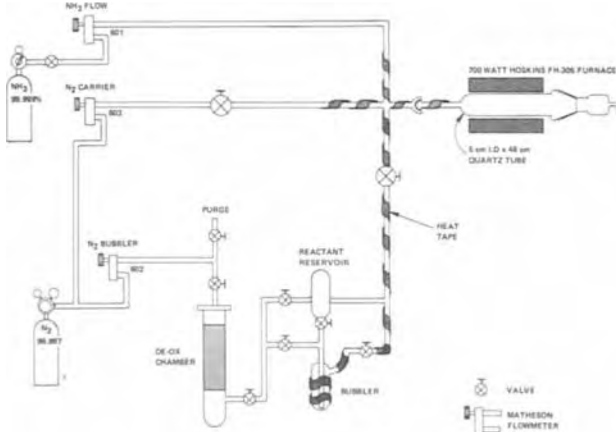

Fig. 1. GaN growth system

off, and leak-back rate measurements made to verify system integrity.

The N_2 tanks were rated at 20-30 ppm O_2 and required the addition of a de-oxygenation catalyst[2] and chamber (Fig. 1) to reduce this impurity to the sub-ppm levels. It should be noted that the system shown in Fig. 1 was designed to afford the maximum protection to the source material from O_2 and H_2O contamination. This precaution was essential in prolonging the useful life of the source material.

After several runs were made, the source material became noticeably darker and more viscous. The vapor pressure apparently decreased (based on a decrease in the deposition rate), and the films grown did not appear to be as transparent as those grown during the first run with fresh source material. Preliminary tests were carried out to characterize the vapor evolved from the material remaining in the bubbler.

Source Material Characterization

The purpose of this characterization was twofold: first, to establish a temperature range over which the vapor pressure was reproducible and stable; second, to identify the vapor being introduced into the furnace and to obtain some indications as to the nature of the decomposition or reaction path.

A cold trap was designed and constructed which allowed the chemical vapors that normally enter the reactor (Fig. 1) to be collected for analysis. The trap was fitted with a septum so that the material could be withdrawn with a syringe for transfer to the liquid inlet of an AEI MS-12 mass spectrometer. A thermoelectric cooler was used to lower the trap temperature to -20°C.

The material was collected by vacuum transfer from the bubbler to the cold trap. The bubbler was maintained at 130°C during sample collection, and in 20 min approximately 1 cm of material was collected. Continued heating eventually left a dry, tan-colored residue in the bubbler.

The material collected consisted initially of a white precipitate and a clear, colorless liquid. It took approximately 2 hr after the trap was brought to room temperature before the precipitate apparently dissolved, again leaving a clear, colorless liquid in the trap. This material had the same appearance as the fresh source material.

Mass spectra were obtained on the clear liquids both before and after the precipitate dissolved. These spectra are shown in Fig. 2. The two mass spectra were completely different, indicating that a reaction had taken place. The molecular fragments from the clear liquid collected initially did not contain Ga. The mass spectrum taken after the precipitate dissolved does show Ga-containing fragments, with the heaviest fragment (286-288-290 amu) tending to support the existence of a diethylgallium amide dimer. The diethylgallium amide dimer, if a constituent of the original source material, would be consistent with the supplier's analysis that indicated the existence of diethylgallium amide initially. The relative abundance ratios of the Ga^{69} and Ga^{71} isotopes were used to identify Ga-containing fragments.

Subsequently, vapor pressure stability of the collected material *vs.* temperature was studied by evacuating the cold trap and monitoring the pressure at the trap inlet. Above 71°C the pressure was erratic due apparently to the occurrence of a reaction. At 71°C or below, the pressure was well behaved; this was used as a basis for defining a maximum working temperature for the source.

Film Properties

Nearly transparent, yellow deposits were obtained on (0001) and $(1\bar{1}02)$ single crystal α-Al_2O_3 substrates with deposition rates up to 2 μ/hr, with 0.5 μ/hr being typical. These films were analyzed with x-ray and re-

[2] Alfa De-OX supplied by Ventron Corporation, Alfa Inorganics.

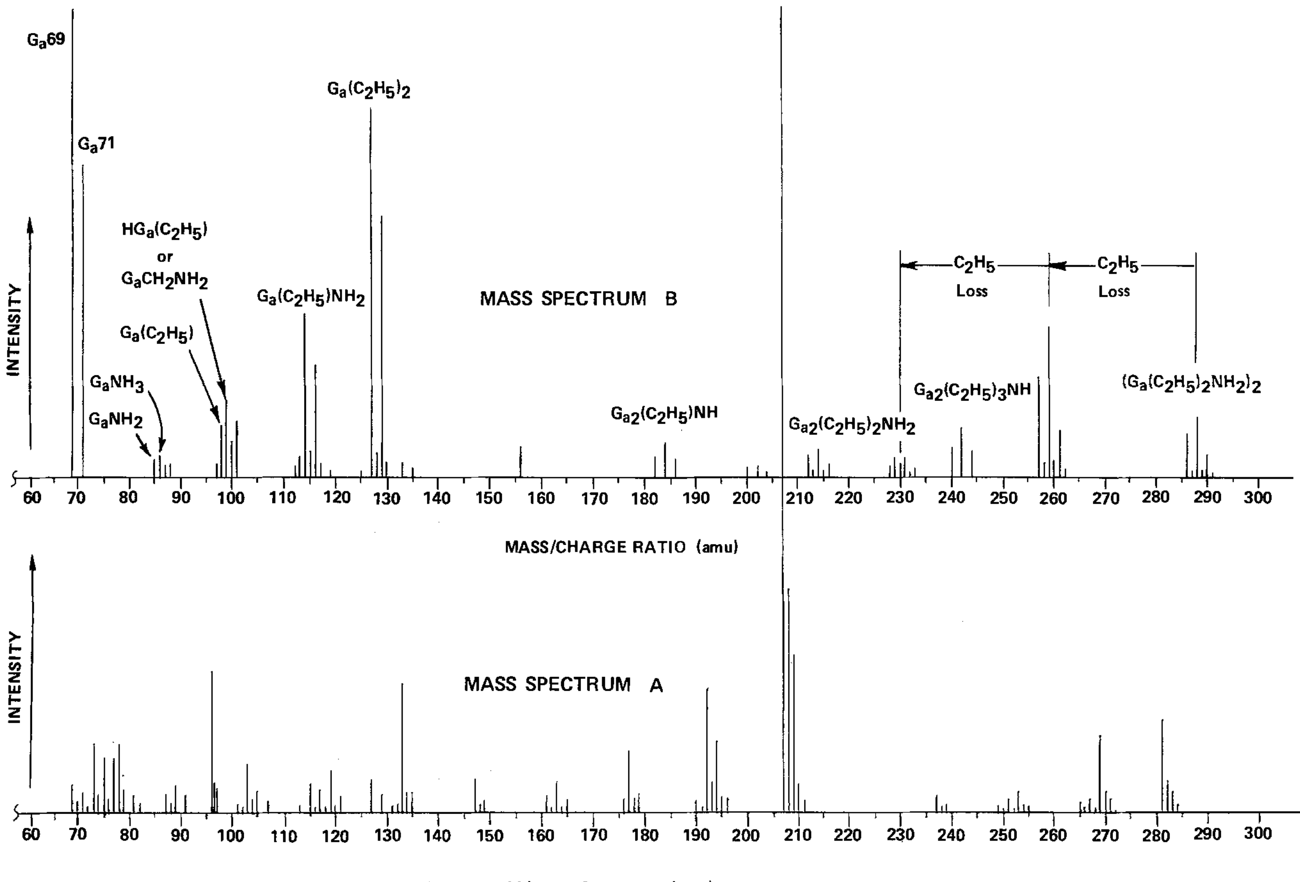

Fig. 2. Mass spectra of source material collected from bubbler

flection electron diffraction techniques and found to have a wurtzite structure with a c/a ratio of 1.63 and interplanar spacings corresponding to those published for GaN in the ASTM powder diffraction data analysis.

The GaN films were n-type with electron concentrations ranging from $5 \times 10^{14}/cm^3$ to $7 \times 10^{19}/cm^3$. Hall mobilities from 20 to 30 cm^2/V-sec can and have been routinely obtained, with the highest Hall mobility observed to date being 34 cm^2/V-sec, $n = 1.5 \times 10^{19}/cm^3$, (room temperature data) for films grown at 800°C. Growth at 600°C yielded high resistivity films ($\sim 10^3$ ohm-cm) with carrier concentrations in the $10^{15}/cm^3$ range, but the Hall mobilities were low due in part to poorer quality substrate surface finishes used in that sequence of runs.

A more comprehensive report on the evaluation of the films grown to date will be published.

Summary

In summary, the triethylgallium monamine used in this research did lead to the growth of thin epitaxial layers of GaN. The preliminary analyses of the source material indicate that it is diethylgallium amide [$Ga(C_2H_5)_2 \cdot NH_2$] and probably exists as a dimer. $Ga(C_2H_5)_3 \cdot NH_3$ decomposition to $Ga(C_2H_5)_2 \cdot NH_2$ during preparation or in the bubbler does not preclude GaN growth since this is expected to be an intermediate step in the decomposition process that leads to the formation of GaN. However, this change and further decomposition in the bubbler makes vapor pressure control difficult. Heating the material to not more than 71°C does permit reasonably stable reactant vapor pressures suitable for thin film growth.

Acknowledgments

The authors want to thank Dr. J. R. Hauser and Dr. J. W. Harrison for their helpful comments and suggestions which contributed to the writing of this paper. Also, we are indebted to Dr. T. F. Jula and Dr. Bernd Schneider for their preparation of and discussions on the properties of this compound. Finally, we gratefully acknowledge the financial support of the Office of Naval Research.

Elimination of Random Compositional Inhomogeneities in Czochralski Grown Silicon

A. Murgai, A. F. Witt,* and H. C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Thermal conditions were achieved, in a standard Czochralski system, under which the random compositional inhomogeneities in silicon crystals are consistently eliminated. This growth configuration was obtained for the generally employed rate of seed rotation (ranging from 3 to 30 rpm) by establishing pronounced thermal asymmetry through the introduction of an off-centered heat sink above the melt.

In earlier studies on the microsegregation in Czochralski grown semiconductor crystals, random compositional fluctuations were attributed to turbulent thermal convection (1); they were also found to become more pronounced with increasing melting point of the material grown (2). Thus, it was shown that the formation of these microsegregation inhomogeneities is readily suppressed by seed rotation of moderate rates in InSb and germanium crystals. In silicon, however, grown at the commonly used pulling rates and rates of seed rotation, random compositional inhomogeneities are invariably present (3).

The thermal configuration achieved is of fundamental importance as it permits the quantitative study of the effects of seed rotation and of crucible rotation on growth and segregation without interference from turbulent convection; moreover, it now becomes possible to determine quantitatively the effect of turbulent convection on segregation and growth behavior.

The reported results were obtained in a standard Czochralski system, with design features, including interface demarcation (4), for an extensive study of growth and segregation behavior of silicon. In this system a graphite resistance heater was used (7 cm in diameter and 16 cm long) in conjunction with a concentric cylindrical tantalum heat shield (14 cm in diameter and 11 cm long). Silicon melts up to 75g were employed. Numerous crystals grown invariably exhibited the familiar random compositional inhomogeneities. The thermal configuration leading to microsegregation free of random convection effects was first obtained after introducing a stainless steel pipe 5 mm in diameter (wall thickness, 0.5 mm) running horizontally through the water-cooled furnace wall to a distance of 3 cm from the rotational axis and bent downwards with its end located 2 cm above the upper rim of the crucible. Growth experiments under various thermal conditions indicated that the presently reported critical thermal configuration may be achieved not only by establishing asymmetric heat loss from the melt (as described above), but also through pronounced asymmetric heat input, *i.e.*, by displacing the crucible containing the melt from the rotational axis of the growth system. A quantitative characterization of the thermal conditions leading to segregation without interference from thermal convection is in progress.

The microsegregation in silicon before and after the modification of the thermal configuration is shown in Fig. 1(a) and 1(b). It is seen that the random compositional fluctuations present in Fig. 1(a) are eliminated in Fig. 1(b). The widely spaced lines of Fig. 1(b)

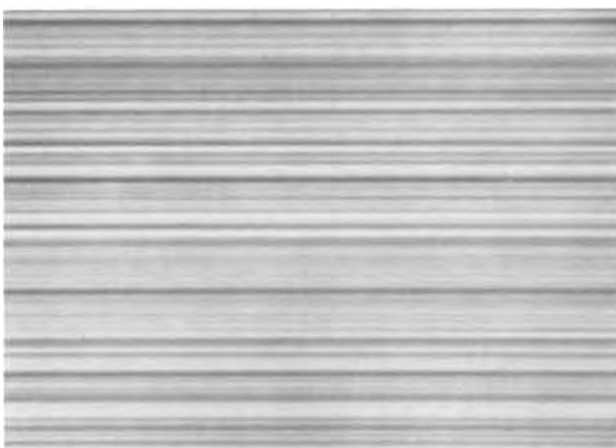
Key words: silicon, crystal growth, dopant inhomogeneities.



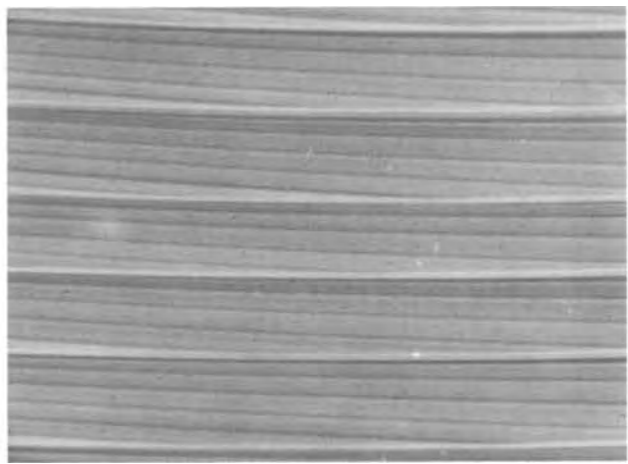


Fig. 1. Microsegregation in Czochralski type silicon (Sb doped to $5 \times 10^{18}/cm^3$) pulled at a rate of 3.4 cm/hr with seed rotation (5 rpm). Figure 1(a, left) shows the normal segregation behavior, characterized by the appearance of random nonrotational striations caused by thermal convection. Figure 1(b, right) shows the segregation behavior in silicon grown under the presently reported thermal conditions; periodic rotational striations now become well defined and random striations are eliminated. The number of rate striations (fine lines between successive rotational striations) introduced at 1 sec intervals reveal that the crystal segment remaining after backmelting for each rotational cycle (12 sec) corresponds to about 4 sec of growth. The samples were etched in 1 part [25g CrO_3 in 50 cm^3 H_2O] + 1 part HF (conc) by successive immersions for periods of 5 sec (total etching time 1 min).

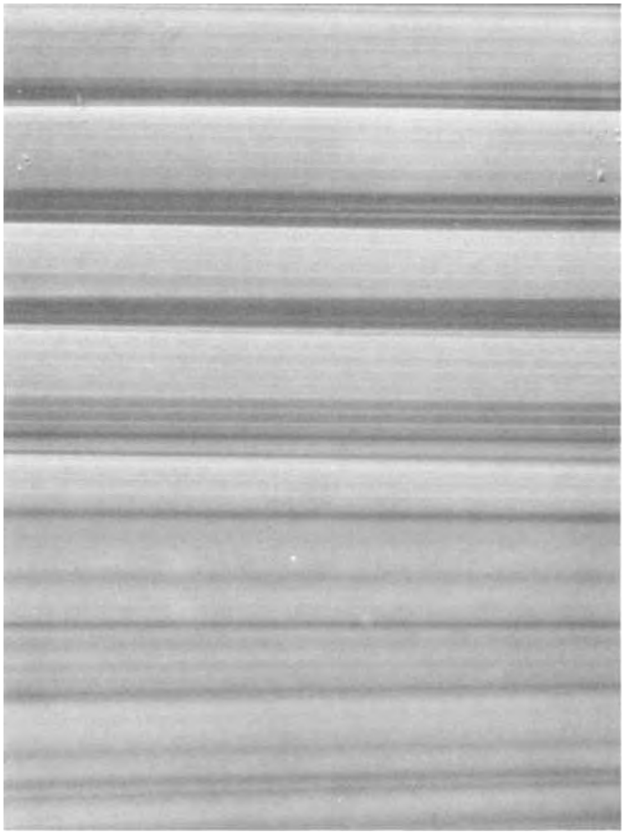

Fig. 2. Microsegregation behavior in silicon pulled under the presently reported thermal configuration. Note the abrupt transition from forced convection controlled segregation (top portion) to thermal convection controlled segregation (bottom portion) which occurred as the melt level was decreased and the aspect ratio exceeded the value of 2.5.

were introduced by interface demarcation, employing current pulses of 10 A/cm^2 at 1 sec intervals. These rate striations show clearly the existence of pronounced thermal asymmetry and the occurrence of periodic rotational backmelting during growth. With the given thermal configuration, growth without convective interference was reproducibly achieved for aspect ratios (d/h) of the melt less than 2.5. For the crucible employed (5 cm in diameter), these aspect ratios correspond to melt heights greater than 2.1 cm. As the melt height decreased below 2.1 cm, it was found that the growth system changes abruptly to the normally encountered conditions associated with turbulent convection controlled growth and segregation. The critical aspect ratio (2.5) was found to be independent of the pulling rate and of the diameter of the crystal grown. The segregation behavior above and below the critical aspect ratio is shown in Fig. 2.

It is of interest to note that temperature measurements in the melt, with a thermocouple located 0.5 cm below the initial growth interface, indicated the presence of pronounced irregular temperature fluctuations (up to $\pm 8°C$) of frequencies up to 5 Hz during growth both above and below the critical aspect ratio. In the light of the observed growth and segregation, the detailed study of the thermal configuration and the prevailing thermohydrodynamics of the melt should be of fundamental significance.

The reported thermal asymmetry effect on microsegregation in silicon now makes it possible to isolate forced convection from thermal convection effects and to investigate quantitatively their respective influence on growth and segregation.

The Catalytic Activity of Platinum Supported on Carbon for Electrochemical Oxygen Reduction in Phosphoric Acid

H. R. Kunz and G. A. Gruver

Power Systems, Division of United Technologies Corporation, South Windsor, Connecticut 06074

ABSTRACT

An experimental program was conducted to determine the catalytic activity of high surface area platinum supported on carbon for the electrochemical reduction of oxygen in phosphoric acid. The Tafel slope at 160°C in 96 weight per cent phosphoric acid was found to be approximately 90 mV/decade. The exchange current per unit of real surface area of the supported platinum was found to be approximately the same as that of platinum black or a flat platinum sheet if the effect of electrode prepolarization is considered. Additional tests at other temperatures indicated that the Tafel slope varies as $RT/\mathbf{F}$ and is similar in sulfuric and phosphoric acid at the same temperature. The prediction that a double Tafel slope exists when oxygen diffusional resistance becomes significant in a Teflon-bonded porous electrode was confirmed.

Although a considerable amount of experimental work had been done to determine the Tafel slope and exchange current for the electrochemical reduction of oxygen in acidic electrolytes, uncertainty still existed concerning the true value of these quantities for high surface area platinum when supported on carbon. These uncertainties were present for a number of reasons.

First, the experimental data on Tafel slope were not in good agreement. For example, the data of Vogel and Lundquist (1) at 120°C in 85% phosphoric acid indicated a Tafel slope of 60 mV/decade for platinum black, whereas the data of Appleby (2) indicated a Tafel slope of 80 mV/decade at 116°C in 85% phosphoric acid in what he considered to be an oxide-free platinum sheet. Vogel and Lundquist indicated that this difference could be due to a true difference between the catalytic properties of the two surfaces or due to impurities on the platinum when tested as a smooth surface.

Secondly, the measured temperature effect on Tafel slope was not consistent. Appleby found the Tafel slope in 85% phosphoric acid to be equal to $RT/\mathbf{F}$ on a flat sheet. However, Vogel and Lundquist found the Tafel slope in 85% phosphoric acid at 120°C to be approximately 60 mV/decade and about equal to that in 50% phosphoric acid at 70°C and 20% sulfuric acid at 70°C.

Thirdly, the data of Vogel and Lundquist for platinum black in phosphoric acid was obtained at potentials above 0.9V with respect to a hydrogen reference electrode in the same electrolyte. This was necessary because diffusional resistance to oxygen migration through the electrolyte within the platinum black was found to occur at lower potentials. The Tafel slope was not measured in phosphoric acid at potential levels significantly lower than 0.9V. Since a change in the oxidation state of the platinum surface occurring in the vicinity of 0.9V might cause a change in the mechanism for oxygen reduction (3), extrapolating a linear Tafel line to lower potentials is not justifiable. An extensive study of the surface oxidation state of platinum has been made by Conway *et al.* (4-6).

Fourth, a measurement of the Tafel slope for platinum supported on carbon is difficult at potentials above 0.9V because of the mixed potential caused by oxidation of platinum and carbon.

Finally, if a high surface area platinum supported on carbon is considered, the catalytic properties can be affected by the size of platinum crystallites and the support. Small crystallite sizes of the supported platinum as compared to those of platinum black might affect the Tafel slope and exchange current. Also, a catalytic interaction between the platinum and carbon might be present for small platinum crystallites.

Because of the uncertainties that existed concerning the true activity of high surface area supported platinum for the reduction of oxygen in acidic electrolyte, a theoretical and experimental program was undertaken to clarify this situation.

Theory

A number of theoretical studies have been performed on Teflon-bonded platinum black electrodes. Brown and Horve (7) derived a model based on cylindrical platinum agglomerates and applied this to cathodes operating in potassium hydroxide electrolyte. This model was also used by Giner (8). Kosinski (9) applied this model to phosphoric acid electrolyte and found the model capable of rationalizing the platinum black data of Vogel and Lundquist using a Tafel slope of 65 mV/decade at 120°C in 85% phosphoric acid. This value was essentially the same as that extracted by Vogel and Lundquist.

The use of such a theoretical model is definitely limited because of the number of fitting parameters

Key words: platinum, oxygen reduction, phosphoric acid, cathode theory, Tafel slope.

that are needed to rationalize the experimental data and the assumptions that are made in the model. Tafel slope, exchange current, agglomerate diameter, agglomerate porosity, agglomerate tortuosity, and electrolyte film thickness surrounding the agglomerate are all fitting parameters. Nevertheless, a great deal of information can be obtained about the operating characteristics of electrodes through the use of a theoretical model.

At low levels of current and high potentials, the polarization of an electrode is controlled by a mixed potential between the reduction of oxygen and oxidation of carbon, platinum, and possible impurities (10). As the current is increased, the polarization should follow the Tafel line of the electrochemical reaction if the currents are high enough to make mixed potential effects negligible and other losses are adequately small. These include the losses associated with oxygen, ion, and electron migration to the reaction site. This region of the data can be used to obtain the Tafel slope and exchange current.

Once the centers of the majority of agglomerates start to experience a significantly reduced oxygen activity, the polarization curve starts to follow a slope which is twice the Tafel slope, in the absence of significant ohmic polarization and electrolyte concentration gradients. If a wide distribution of agglomerate sizes is present, a wide transitional region will exist with slopes between the Tafel slope and double Tafel slope. The current at which the polarization curve changes from a single to a double Tafel slope can be used to obtain a measure of an average agglomerate size.

This model was extended to Teflon-bonded electrodes containing supported platinum in order to get a better understanding of their operation. The resulting equations are similar to those derived previously for unsupported catalyst. When all of the electrode polarization is that associated with the finite rate of the electrochemical reaction, the Tafel equation results in the form

$$i = W_{Pt} S_g i_o e^{\alpha N \mathbf{F} \eta / RT} \quad [1]$$

where i = electrode current density, A/cm^2 frontal area; W_{Pt} = platinum loading, g/cm^2 frontal area; S_g = platinum surface area, cm^2/g; i_o = exchange current, A/cm^2 Pt real area; α = transfer coefficient; N = number of electrons in the rate-determining step, equiv./mole; $\mathbf{F}$ = Faraday constant, coulomb/equiv.; η = polarization, V; R = gas constant, joule/mole°K; T = temperature, °K.

When the ability of oxygen to diffuse through the electrolyte in a porous cylinder of supported catalyst is also controlling, the following equation results for suitably large values of

$$\frac{R_{agg}}{2}\left(\frac{S_g W_{Pt} i_o \tau e^{\alpha N \mathbf{F} \eta/RT}}{N\mathbf{F}L D_{O_2}\alpha_{O_2}\theta}\right)^{1/2}:$$

$$i = \frac{2W_{Pt}}{R_{agg}}\left[\frac{N\mathbf{F}D_{O_2}\alpha_{O_2}S_g i_o}{\rho_s W_{Pt}/W_s}\cdot\frac{\theta}{(1-\theta)\tau}\right]^{1/2} e^{\alpha N \mathbf{F}\eta/2RT} \quad [2]$$

where R_{agg} = agglomerate radius, cm; L = electrode thickness, cm; W_s = support loading, g/cm^2 frontal area; $D_{O_2}\alpha_{O_2}$ = oxygen diffusivity-solubility product, mole/cm sec; ρ_s = support density, g/cm^3; θ = agglomerate porosity; τ =agglomerate tortuosity.

As demonstrated by Eq. [1], the theory of supported platinum electrodes indicates that in the Tafel region the current at a given potential varies linearly with the catalyst loading if the catalyst specific activity is constant. In the double Tafel region described by Eq. [2], however, if the carbon loading is fixed and the platinum specific activity is fixed, the current at a given potential should vary with the square root of the platinum loading. Therefore, it was concluded that, if experimental data could be obtained over a wide range of platinum loading, the variation of current with loading could be used to determine whether the single or double Tafel slope is occurring. The Tafel slope could therefore be obtained. Since as the catalyst loading is reduced the relative importance of the diffusional resistance to oxygen in the catalyst layer is diminished, it was thought that experimental data on Tafel slope would become available at lower levels of potential, in the range of 0.7V. This potential is significantly below that at which a change in the oxidation state of the platinum occurs.

Such a test series was therefore performed in this study together with investigations of the effect of temperature in phosphoric acid and the effect of changing the electrolyte to sulfuric acid. The latter tests were run to determine whether or not the Tafel slope varies with $RT/\mathbf{F}$ as found by Appleby and to compare results with those of other investigators. Experiments were also performed on cathodes with reduced Teflon content to increase the effective agglomerate size. A well-defined double Tafel slope was hoped to result in these experiments and therefore confirm the findings obtained in the study in which platinum loading was varied. Finally, some experiments were performed on a flat platinum sheet to obtain data at temperatures higher than those investigated by Appleby.

Experiments

The electrodes used in this study contained platinum supported on Vulcan XC-72 (Cabot Corporation). The nitrogen BET surface area of this support was measured and found to be about 220 m^2/g. Platinum was deposited upon this carbon and it was fabricated into Teflon-bonded electrodes.

Electron micrographs of this carbon-containing platinum are shown in Fig. 1 and 2 for untested specimens. Figure 1 is a "bright field" micrograph in which the platinum appears as dark particles overlaid on the semitransparent carbon. In Fig. 2 the white spots are "reflections" arising from (111) platinum (same sample field as in Fig. 1). This micrograph confirms that the dark spots in Fig. 1 are in fact platinum. Platinum

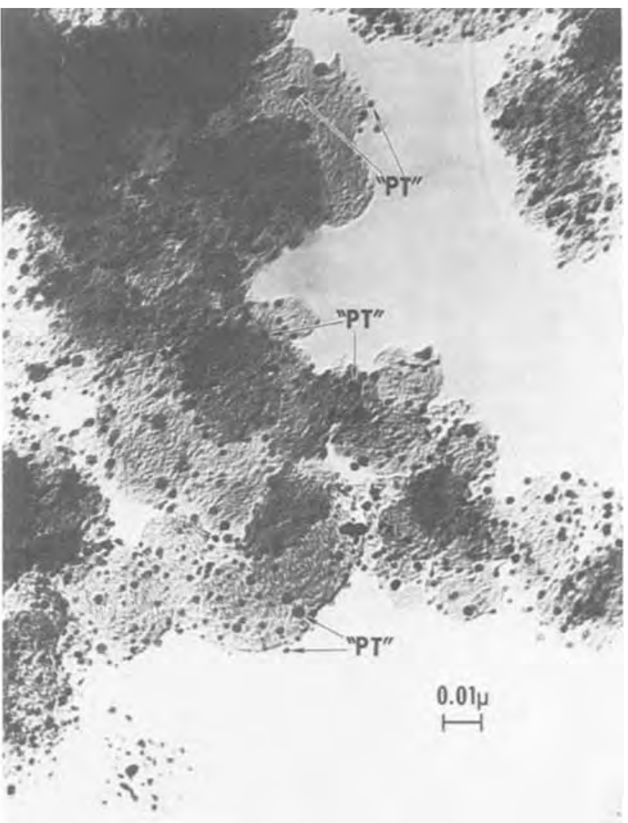

Fig. 1. Electron photomicrograph of platinum supported on Vulcan XC-72 (bright field).

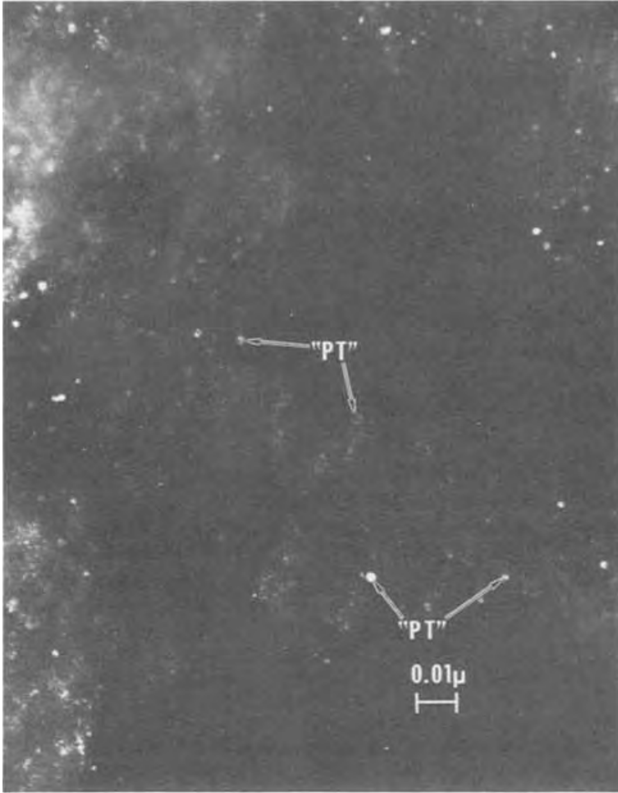

Fig. 2. Electron photomicrograph of platinum supported on Vulcan XC-72 (dark field).

crystallite sizes were measured from these micrographs and found to result in a platinum surface area of approximately 130 m^2/g, assuming the particles to be spherical and all of the platinum surface exposed. The range of surface areas from micrographs of other samples of this catalyst was 109-175 m^2/g.

Platinum surface areas were also measured electrochemically using hydrogen adsorption in sulfuric acid for samples of electrodes containing about 0.25 mg Pt/cm^2. These areas were found to be about 60-70 m^2/g after the electrodes had been tested. These areas are considerably lower than the areas calculated from platinum crystallite sizes measured using the electron microscope micrographs.

The difference in surface areas obtained from the micrographs and from hydrogen adsorption might be due to a number of reasons. For example, some of the platinum crystallite surface is in contact with the carbon and might be blocked with respect to hydrogen adsorption. In addition, part of the platinum area is lost due to recrystallization, part might not be adequately wet by electrolyte to act as effective catalyst, and some might be in poor electronic contact. Since the important platinum area with respect to the determination of catalytic activity is that which is used in an electrode, a typical area of 70 m^2/g was used in the rest of this study.

The supported platinum was fabricated into electrodes using Teflon 30 (E. I. du Pont de Nemours & Company). A photograph of the cross section of an electrode is shown in Fig. 3. Figure 4 shows an electron micrograph of a microtomed section of a catalyst layer. The Teflon and the carbon can be seen to be present in distinct segregated regions.

Electrodes were tested in a glass half-cell apparatus as 1 cm^2 floating electrodes as shown in Fig. 5. The catalyst layer was located facing the electrolyte with the carbon paper facing upward toward the reactant supply. A platinum black hydrogen reference electrode operating in the same electrolyte was used in conjunction with a Luggin capillary. The counterelectrode was a platinum screen enclosed in a separate electrolyte

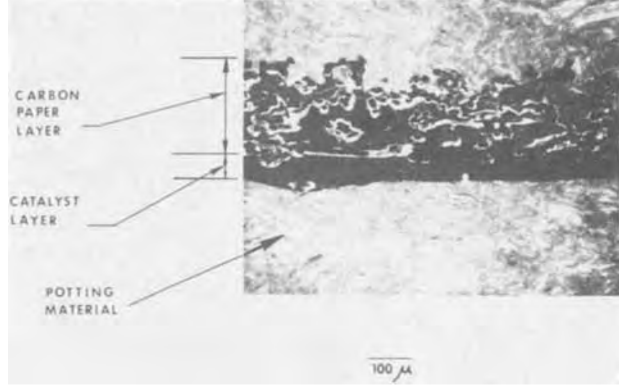

Fig. 3. Optical photomicrograph of an electrode cross section

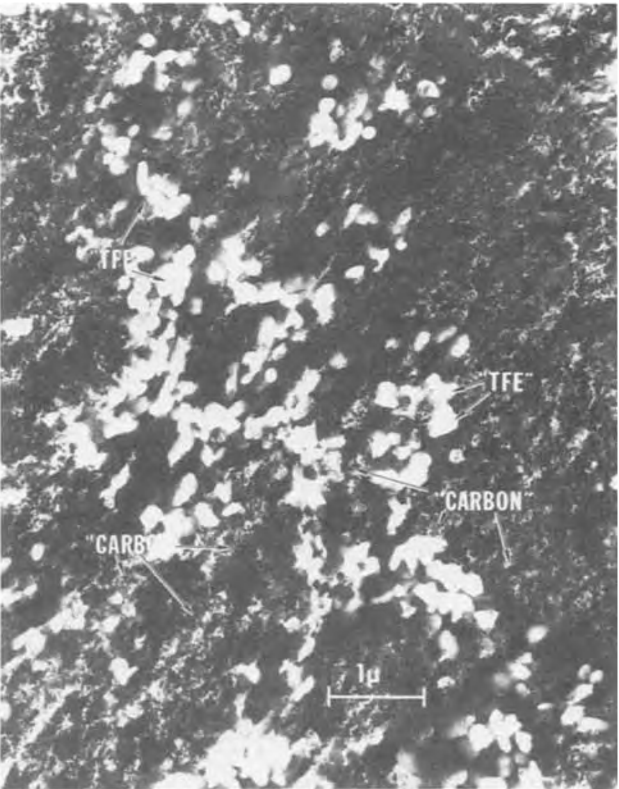

Fig. 4. Electron photomicrograph of an ultramicrotomed section of an electrode catalyst layer.

region. Current was collected from the top of the working electrode using a platinum spring. The volume of electrolyte in the apparatus was approximately 30-40 ml. Both Baker and Adamson reagent grade H_3PO_4 and acid which had been electrochemically cleaned by absorption of impurities on platinum black at hydrogen potential were used. Temperature was controlled using an electrically heated mantle surrounding the electrolyte vessel with the sensing thermocouple in the electrolyte. Electrode potentials, E^*, were measured relative to a hydrogen reference electrode in the same electrolyte and were corrected for external resistance by using a current interrupter. Load currents were supplied by a constant current source and were measured using a precision 1% resistor located in the counterelectrode line. Electrode voltage and current were monitored using either an electronic digital voltmeter accurate to 0.2% of full scale (1.999V) or an electromechanical voltmeter accurate to 0.5%. Reactant gases were saturated to provide a water vapor pressure in equilibrium with the electrolyte.

No prepolarization of electrodes was performed in general since this might introduce errors in the steady-

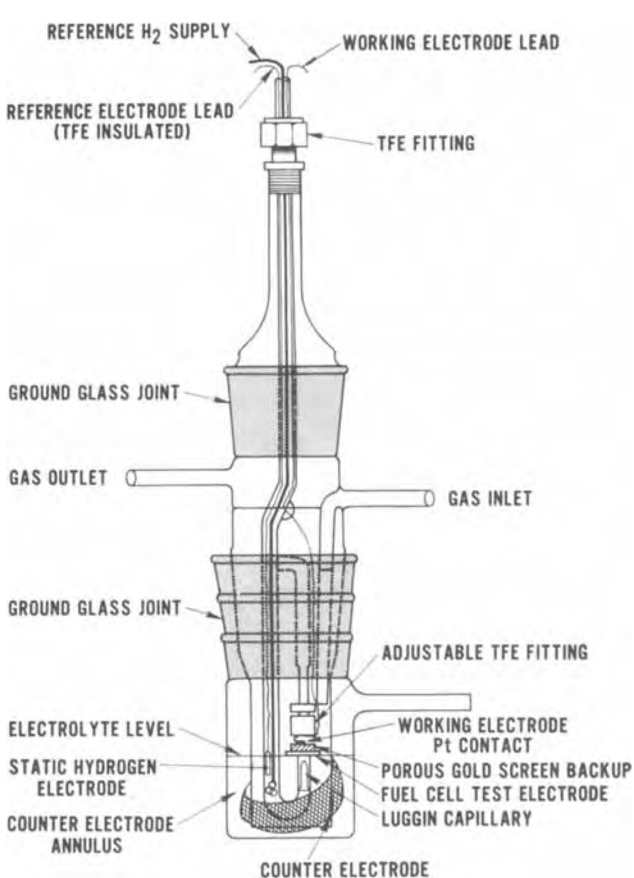

Fig. 5. Half-cell apparatus

state activity due to possible effects of phosphate anion adsorption and the extent of adsorbed oxygen coverage (11). Data were obtained by both increasing current in steps and decreasing current in steps through the potential range of interest, about 0.9-0.7V. Little difference in results was found. Potentials in this range were stable for at least 5 min. Data at higher potentials changed somewhat with time due possibly to anion desorption, platinum oxidation, or mixed potential effects due to oxidation of the carbon, platinum, and possible impurities. Data at high current densities changed with time due to possible electrode heating. Some experiments were performed on a flat platinum sheet to investigate the effect of prepolarization since both Appleby and Vogel and Lundquist incorporated prepolarization treatments.

Results

As discussed in the Theory section, a number of separate experimental studies were conducted to evaluate the activity of platinum. The first of these involved an investigation of the effects of a variation of the platinum loading with a constant carbon loading with phosphoric acid electrolyte. Others involved investigations of the effect of temperature and of operation with sulfuric acid rather than phosphoric acid. In addition, electrodes were evaluated in which definite diffusional losses had been introduced. A final investigation involved tests on flat sheets in order to obtain an extension of the data of Appleby to higher temperatures. The results obtained in these various investigations are presented in the following sections.

Variation of platinum loading.—A series of electrodes were prepared containing 15, 1.5, and 0.15 weight per cent (w/o) platinum applied to Vulcan XC-72. The weight per cent of Teflon in the supported catalyst and Teflon mixture was held constant at 50%. These weight per cents of platinum resulted in platinum loadings of about 0.25, 0.025, and 0.0025 mg/cm², respectively. These platinum loadings were verified by chemical analysis.

Each one of these electrodes was tested as a floating electrode in the half-cell apparatus on both oxygen and air at atmospheric pressure at 160°C in unpurified 96% H_3PO_4. Graphs of the experimental data for these various electrodes are presented in Fig. 6 through 8.

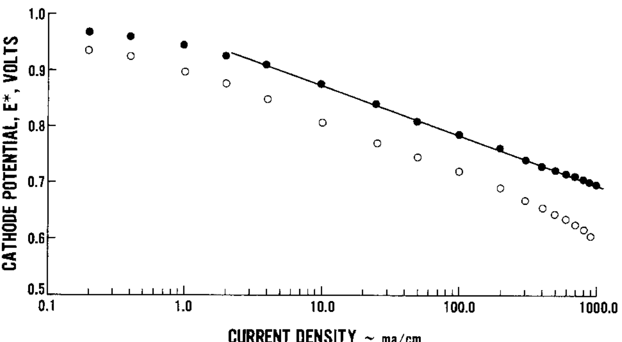

Fig. 6. Cathode performance for 0.25 mg Pt/cm² supported on Vulcan XC-72 at 160°C in 96% H_3PO_4. ●, Oxygen; ○, air. A straight line with a slope of 90 mV/decade has been drawn through the oxygen data.

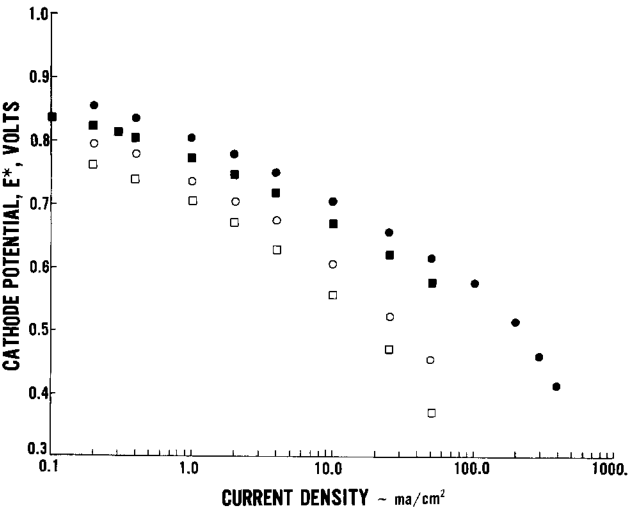

Fig. 8. Cathode performance for 0.0025 mg Pt/cm² supported on Vulcan XC-72 at 160°C in 96% H_3PO_4. ●, Oxygen; ○, air; with high concentration platinum solution. ■, Oxygen; □, air; with low concentration platinum solution.

During the fabrication of the electrodes with the loadings of 0.025 and 0.0025 mg Pt/cm^2, two different concentrations of the platinum catalyzation solution were used. This was done in order to investigate whether or not the small quantity of platinum was being uniformly distributed throughout the Vulcan. The data presented in Fig. 7 and 8 show that adequately uniform catalyzation of the Vulcan had been achieved.

By investigating Fig. 6-8 some of these electrodes can be seen to demonstrate a straight line variation of cathode potential with the logarithm of current density over a range of potential below 0.9V. As discussed in the Theory section, if the variation of current at a given potential varies linearly with platinum loading in a straight line region, the straight line region represents a region in which the Tafel slope is occurring. If the variation of current at a given potential varies with the square root of the loading, this straight line region is a double Tafel region rather than a single Tafel region. For this reason a graph was made of current density at 0.7V cathode potential *vs.* loading. This graph is shown in Fig. 9. As can be seen in this figure, all the experimental points fall along an approximate straight line with a slope of 45°, thereby showing a linear dependence between the current at a given potential and the loading. The straight line segments on the performance curves of these various cathodes in the range of 0.7-0.9V therefore represent the true single Tafel slope for the reduction of oxygen. The value of this slope is approximately 90 mV/decade.

The possibility existed in this investigation that a systematic change in the electrode structure might be occurring as the platinum loading is being changed, thereby leading to an erroneous conclusion. To eliminate this possibility, an electrode was fabricated containing no platinum with the same quantity of Vulcan as was used in the study in which the platinum content was varied between 0.25 and 0.0025 mg/cm^2. This electrode was subsequently catalyzed with 0.25 mg Pt/cm^2 and resulted in essentially the same experimental results as the electrode which was precatalyzed with 0.25 mg Pt/cm^2. Therefore, no systematic effect of electrode structure was present in the data.

The theory of fuel cell electrodes indicated that the limiting current should not depend on the platinum loading for a given carbon loading. However, the experimental data obtained here indicated limiting currents on air of approximately 2000 mA/cm^2 for the 0.25 mg/cm^2 loading, 1300 mA/cm^2 for the 0.025 mg/cm^2 loading, and 110 mA/cm^2 for the 0.0025 mg/cm^2 loading. This result at first indicated that perhaps the results for the lowest loading were not being interpreted correctly. However, a theoretical investigation of oxygen diffusion through the electrolyte film surrounding the agglomerate to single platinum crystallites on the surface of the agglomerate indicated that, with this loading, an additional diffusional resistance of oxygen in the electrolyte was present due to the scarcity of the platinum crystallizates on the surface of the agglomerate. This additional diffusional resistance was calculated to be absent at the low currents and high potentials occurring in the range of data that was being used to evaluate the variation of current at a given potential with platinum loading. Therefore, the fact that the limiting current declined with loading is probably of no consequence.

A variation of the platinum specific area with loading would also affect the variation of electrode performance with loading. The platinum specific area might be expected to increase as the loading is reduced. This would tend to make the variation of current at a given potential vary in less than a linear manner with loading in the Tafel region, just as the presence of a diffusional resistance would. Therefore, the variation of platinum specific area with loading is probably not causing this linear dependence. The specific area could not be measured electrochemically for the loadings of 0.025 and 0.0025 mg/cm^2 because of the greater relative capacitive effect of the Vulcan.

Variation of temperature.—A series of tests was performed on the 0.25 mg Pt/cm^2 cathode to determine the variation of the Tafel slope and the current at a given potential with temperature. These tests were run using both unpurified 96% H_3PO_4 and purified and unpurified 85% H_3PO_4 in the half-cell apparatus. The cathode performance data are presented in Fig. 10 and 11. Figures 12 and 13 present a comparison with the experimental data of Appleby. The data on Tafel slope obtained with unpurified 85% H_3PO_4 in this study are in good agree-

ment with the data of Appleby for purified acid at temperatures above 95°C. This agreement could be due to the smaller effect of electrolyte impurities on the larger platinum surface area in the fuel cell electrode used here compared to that of the flat sheet used by Appleby. Below 95°C, the Tafel slope obtained with the fuel cell electrode in unpurified and purified 85% H_3PO_4 is in agreement with the data of Appleby for unpurified electrolyte. This increase in Tafel slope at lower temperatures for the fuel cell electrode is probably due to an increase in the relative importance of electrolyte impurities at lower temperature. With unpurified 96% H_3PO_4, the Tafel slope was 90 mV/decade at 160°C, was relatively insensitive to temperature, and showed a trend similar to that of Appleby for unpurified 85% H_3PO_4. This result might be caused by an increase in the effect of impurities in the more highly concentrated electrolyte.

In the comparison of the variation of current at a given potential with temperature with the variation found by Appleby, the area of the platinum on the fuel cell electrode was considered to be 70 m^2/g. Using this value of surface area, the value of current at a given potential can be seen to be in fair agreement with the data obtained by Appleby for 85% H_3PO_4. The data obtained in this study at 96% H_3PO_4 were somewhat higher than that obtained with 85% H_3PO_4.

Tests using sulfuric acid.—Tests were run in 20% H_2SO_4 at 70°C on a sample of a 0.25 mg Pt/cm^2 electrode that demonstrated 90 mV/decade Tafel slope using 96% H_3PO_4 at 160°C. These data are presented in Fig. 14. The data with H_2SO_4 can be seen to indicate a slope of about 65 mV/decade at the currents at which 90 mV/decade occurs with H_3PO_4. The limiting current for air in H_2SO_4 was about 2500 mA/cm^2, a value near that using H_3PO_4. Since the diffusivity-solubility products of oxygen in these two electrolytes are probably of the same order, the same mechanisms are probably controlling performance in the two electrolytes in the 65 and the 90 mV/decade slope ranges. Therefore, the type electrode tested here is probably activation limited with a slope of 65 mV/decade for H_2SO_4 and 90 mV/decade for H_3PO_4. This 65 mV/decade is about what would be expected in H_3PO_4 at 70°C if the Tafel slope varied as $RT/\mathbf{F}$, that is, linearly with temperature as predicted by theory with constant transfer coefficient. This data with H_2SO_4 are shown in Fig. 12 and compares well with Appleby's data with phosphoric acid at the same temperature. It should be noted, however, that the absolute performance level with sulfuric acid was less reproducible than that with H_3PO_4.

Flooded electrode tests.—An electrode was fabricated with 5 w/o Teflon using 15 w/o platinum supported on Vulcan. A small percentage of Teflon was used to cause the electrode to flood with electrolyte and thereby introduce diffusional losses. This electrode was tested in the half-cell apparatus at 160°C in unpurified 96% phosphoric acid and the data are shown in Fig. 15. A slope of 180 mV/decade resulted for almost 2 decades on oxygen. This value is twice the 90 mV/decade slope and indicates that the single Tafel slope is probably 90 mV/decade.

Flat plate tests.—A platinum sheet electrode was submerged in unpurified 96% H_3PO_4 in the half-cell apparatus at 160°C with oxygen over the electrolyte. The data for this electrode are shown in Fig. 16 both with and without oxygen bubbling over the surface of the sheet. Data are also presented both with and without polarization of the electrode to 500 mV prior to the obtaining of each data point. The higher performance obtained with prepolarization is probably due to the desorption of anions or impurities occurring during the prepolarization. Appleby found a similar effect by prepolarizing to 50 mV. This electrode can be seen

to have resulted in only a short Tafel slope region. A straight line was drawn through the data obtained using prepolarization to 500 mV and bubbling oxygen and an exchange current calculated. The exchange current, corrected to 1 atm oxygen pressure, is plotted in Fig. 17 where good agreement with an Arrhenius-type extrapolation of Appleby's data can be seen.

Discussion

All the experimental data obtained in this study indicate that the true Tafel slope for the reduction of oxygen in 96% H_3PO_4 at 160°C in the range of potentials below 0.9V is approximately 90 mV/decade.

The series of electrodes that were fabricated with various platinum loadings with a constant carbon loading indicated a linear dependence between current at a given potential and the platinum loading. This result indicated that the performance of these electrodes was controlled only by the activity of platinum. Since these electrodes had a slope on semilogarithmic coordinates of 90 mV/decade this slope is the Tafel slope.

The test sequence that was conducted to investigate the effect of temperature variation with 85% phosphoric acid resulted in data in good agreement with the results obtained by Appleby on a flat platinum sheet above 95°C. The Tafel slope varied as RT/F and is equal to 90 mV/decade at 160°C.

The tests using H_2SO_4 indicated a Tafel slope of 65 mV/decade with 20% H_2SO_4 at 70°C. This Tafel slope is in agreement with that found by Appleby at the

Fig. 17. The straight line represents a fit to the experimental data.

same temperature in 85% H_3PO_4. Therefore, the rate-limiting reactions for the reduction of oxygen in H_2SO_4 and H_3PO_4 are most likely the same. The flooded electrode tests indicated a double Tafel slope of 180 mV/decade, again confirming that the Tafel slope is 90 mV/decade for H_3PO_4 at 160°C.

The experiment conducted on a flat platinum sheet was in good agreement with an extrapolation of Appleby's data. The platinum specific activity obtained from a flat platinum sheet was found to be in fair agreement with the experimental results obtained with platinum supported on carbon as shown in Fig. 17. This means that, down to the range of platinum crystallite sizes obtained with the supported platinum in this study, no large change in the properties of the platinum are occurring with respect to activity. Also, there is apparently no large interaction between the platinum and the carbon with respect to platinum activity.

However, one set of experimental data must still be rationalized, that of Vogel and Lundquist. They found that at 120°C with 85% H_3PO_4 the Tafel slope was apparently 60 mV/decade on platinum black. These experimental data were fit by Kosinski (9) using the cylindrical agglomerate model to obtain a Tafel slope of 65 mV/decade. In order to rationalize the platinum black data of Vogel and Lundquist, additional calculations were performed to determine whether the newly determined Tafel slope in this experimental study could be used to fit their experimental cathode performance curves.

The Tafel slope determined by Appleby for a platinum sheet was used so that the number of fitting parameters was reduced to essentially four: the exchange current, the agglomerate diameter, the agglomerate porosity, and the electrolyte film thickness. Since Vogel and Lundquist's data were obtained at 120°C, a Tafel slope of 82 mV/ decade was used in the fitting of their experimental data. A comparison of their experimental data with the results obtained by fitting the cylindrical agglomerate model is shown in Fig. 18 and 19. Figure 18 shows a comparison between the calculated and experimental results of cathode potential *vs.* current density for one catalyst loading. Figure 19 shows the comparison of current densities *vs.* catalyst loading for various cathode potentials. As can be seen from these figures, an excellent fit was obtained. A comparison between the results of the cylindrical ag-

glomerate model and the experimental data using a 65 mV/decade slope obtained previously by Kosinski are shown in Fig. 20 and 21. As can be seen from these figures, an excellent agreement was obtained in this case also.

The comparison between the results of the cylindrical agglomerate model and the experimental data was somewhat better for the 65 mV/decade case at potentials greater than 0.9V. However, since the surface oxidation state of platinum changes above approximately 0.9V, no conclusion can be reached as to which fit of Vogel and Lundquist's data is the better. The value of the exchange current obtained using the 82 mV/decade value of Tafel slope was added to Fig. 17. As can be seen, this value of exchange current for the platinum black electrode is in good agreement with Appleby's results for a flat sheet. A measured surface area of 24 m²/g was used for the platinum black. Both fits of the experimental data lead to reasonable values of agglomerate diameter, agglomerate porosity, and electrolyte film thickness.

Experimental data obtained on an electrode fabricated using platinum supported on Vulcan XC-72 were also fit using the cylindrical agglomerate model to determine if reasonable values of fitting parameters would be obtained. Data were obtained at 160°C so a Tafel slope of 90 mV/decade was used. A comparison of the results of the cylindrical agglomerate model with the data using only the exchange current, the agglomerate diameter, porosity, and electrolyte film thickness as fitting parameters are shown in Fig. 22. Good agreement resulted in this case.

The value of exchange current, corrected to 1 atm oxygen pressure, was added to Fig. 17. This value is lower than the value expected based on the results for 96% H_3PO_4 on a flat sheet. This difference can be partially attributed to the absence of prepolarization in the supported platinum electrode test as shown in Fig. 16. Other reasons for the results of the supported platinum electrode exchange current being low might be that regions of the Teflon-bonded catalyst were excessively flooded by electrolyte, that some regions of the Teflon-bonded electrode were in poor ionic or electronic contact, that slight surface roughness existed on the flat sheet (assumed to be 1.0), and that a slight effect of platinum crystallite size is present. A lower value of current in the supported platinum electrode in 85% H_3PO_4 can also be seen in Fig. 13.

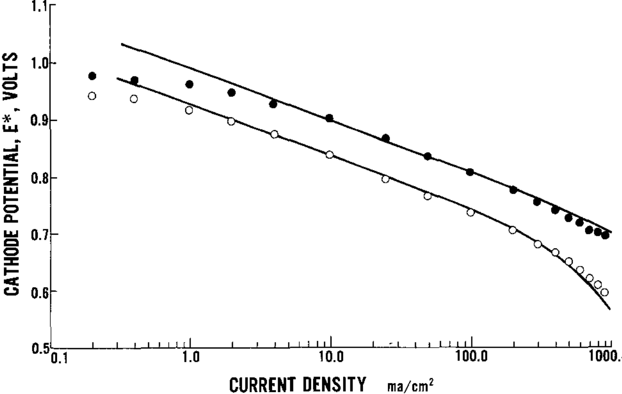

Fig. 22. Comparison of data of the present study with the calculated results of the cylindrical agglomerate model at 160°C in 96% H_3PO_4; 0.31 mg Pt/cm². ●, Oxygen; ○, air. Values of parameters used in the calculations: exchange current = 2.4×10^{-8} for oxygen; exchange current = 0.73×10^{-8} for air; Pt surface area = 70 m²/g; agglomerate porosity = 0.60; agglomerate length = 0.0382 mm; agglomerate diameter = 1.6μ; tortuosity = 1.0; electrolyte film thickness = 0.20μ; electrolyte conductivity = 0.57 $(\text{ohm-cm})^{-1}$; oxygen diffusivity-solubility product = 0.63×10^{-11} mole/cm-sec; density of carbon = 2.0 g/cm³.

The values of the agglomerate diameter, porosity, and electrolyte film thickness for the supported platinum electrode were also reasonable considering the electron micrographs obtained for this type of electrode shown in Fig. 4. The agglomerate diameter appears to be somewhat small. This might be due to an effect of the carbon and/or Teflon on the diffusivity-solubility product of the oxygen in the electrolyte.

Again, a slight deviation between the predicted results using the model and the experimental data occurred above 0.9V. However, this might be expected in this case due to mixed potential effects caused by carbon, platinum, or impurity oxidation or perhaps a change in the catalytic properties of the platinum.

The fact that the cylindrical agglomerate model can be used to fit the experimental data for both the platinum black electrodes of Vogel and Lundquist and the supported platinum electrodes in this study does not confirm results obtained in this study but merely indicates that experimental data on both these types of electrodes can be rationalized using the results of this study. In all probability, the Tafel slope and exchange current for platinum black, platinum supported on carbon, and a flat platinum sheet are all the same, since the results obtained for platinum black and platinum supported on carbon are in such good agreement with the flat sheet results.

Conclusions

The following conclusions can be made from the results obtained in this study.

1. Platinum with an area as high as about 70 m²/g when supported on carbon has approximately the same specific activity as a flat platinum sheet if the effect of electrode prepolarization is considered.

2. The specific activity of platinum black is most likely the same as that of a flat platinum sheet.

3. Crystallite size is relatively unimportant with respect to specific activity for oxygen reduction in the range of crystallite sizes studied and carbon does not interact significantly with the platinum.

4. The experimental data of Appleby are valid with respect to platinum activity in the potential range below 0.9V.

5. The mechanism for oxygen reduction is the same over a temperature range from 70° to 160°C for purified 85% phosphoric acid and is probably the same in both sulfuric and phosphoric acid. The Tafel slope varies as $RT/\mathbf{F}$.

6. Data above approximately 0.9V for platinum on carbon catalyzing pure oxygen reduction are confused by at least mixed potential effects and therefore cannot be used to obtain Tafel slope information for application to lower potential levels.

7. Data obtained for platinum black above approximately 0.9V indicate that possibly a change in mechanism for oxygen reduction may be occurring, perhaps through a change in the oxidation state of the surface.

8. Because the catalyst surface area for supported platinum determined using the electron microscope is larger than the electrochemical area and because the activity of the supported catalyst is somewhat lower than that anticipated using the data of Appleby, some of the catalyst in the supported platinum electrodes may be ineffective due to poor electronic or ionic paths.

Acknowledgments

The authors wish to thank Dr. A. Kaufman, M. Katz, and S. Organ for their assistance in the experimental phases of this work. The assistance of J. Kosinski in the theoretical studies and D. Pilney in the investigations with the electron microscope are also acknowledged.

Rate Capability and Electrochemical Stability of Carbon Fluorine Compounds in Organic Electrolytes

Herbert F. Hunger* and Joseph E. Ellison

Power Sources Technical Area, U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

ABSTRACT

Polarization measurements of cathodes containing various carbon fluorine compounds, CF_n ($n = 0.24$-1.5), as the active depolarizer material were made in 1M $LiClO_4$-propylene carbonate at 298°K. The polarization (free of ohmic iR drop) was measured, using the periodically interrupted sine wave pulse current technique. The open-circuit potentials and polarization data were analyzed, considering their mixed potential character. The two major factors that influenced the data were the C/F ratio and the electrode compression pressure. With graphite fluorides, activation polarization was prevalent and Tafel behavior was observed ($b = 0.12$). The exchange currents were low, peaking at $n = 0.93$ with 10^{-22}A. From the exchange currents, the cathodic currents at the mixed potentials were computed. For $n = 0.93$, a value of about $7 \cdot 10^{-10}$A was obtained, indicating a depolarizer shelf life of about 10^6 years. Compounds with higher rate capabilities, such as polymeric, perfluorinated, and polycyclic hydrocarbons, show a very short shelf life by oxidizing rapidly the organic solvent. The experimental behavior of such compounds can be explained by the mixed potential theory. Shifts in open circuit, mixed potentials to more positive values are predicted for compounds with higher rate capability and can be observed experimentally.

The energy densities of lithium organic electrolyte batteries with graphite fluorides as depolarizers can reach 150 W-hr/lb; their rate capability, however, is limited to about 5-10 mA/cm^2 at room temperature. This limitation is mainly due to a relatively high polarization at the cathode at these current densities. The shape of the cathodic polarization curve indicates strong activation polarization (1). It would be desirable to decrease this overvoltage in order to obtain higher energy densities and rate capabilities in lithium batteries using carbon fluorine compounds as the cathodic material. Therefore, in our study, the polarization behavior of carbon fluorine compounds with various compositions and structures was investigated, but limited to a one solvent-electrolyte system.

Experimental

The electrochemical measurements and associated handling of cell materials were carried out in a dry lab in pure, dried argon or helium atmosphere. The water vapor level was between one and five parts per million.

Solvents and electrolytes.—The solvent employed in this investigation was propylene carbonate, purified by vacuum distillation. The electrolyte used in this study was one molar solution of anhydrous lithium perchlorate in propylene carbonate.

Depolarizer materials.—Graphite fluorides, covering the composition range from tetracarbon monofluoride to polycarbon monofluoride, were investigated as cathode materials. These materials were obtained from Rice University. Their preparations and purities have been described previously (2). Further, polymeric carbon fluorine compounds were investigated, such as the oxygen crosslinked polymers of perfluoro anthracene, perfluoro decacyclene, perfluoro phthalocyanine, and fluorinated paracyanogene. These compounds were prepared and characterized for the U.S. Army Electronics Command by Professor Lagow of MIT (3).

Preparation of electrodes.—The cathodes were prepared by a dry press technique. This involves preparing a dry cathodic depolarizer mixture of 80 weight per cent (w/o) depolarizer, 15 w/o graphite (spectroscopic grade), and 5 w/o Teflon powder. About 0.3g of the mixture were pressed into a highly porous nickel matrix of 10 cm^2 cross section. Both anode and reference electrode consisted of lithium foil pressed onto a nickel screen.

Electrochemical cell.—The electrochemical cell was assembled by placing the cathode, surrounded by a separator, between two lithium electrodes identical in size to the cathode. One of the lithium electrodes served as the anode and the other as the reference electrode. The cell design has been described in detail previously (1).

Electrochemical measurements.—Since the cathode polarization measurements included a substantial resistance polarization, it was essential to separate the resistance polarization component from the others. For that purpose, the periodically interrupted sine wave pulse current technique, invented by Kordesch and Marko, was chosen for polarization measurements free of the ohmic iR drop (4).

The circuit used in the measurements is shown in Fig. 1. The electrochemical cell C is connected with a load circuit (D_1) and two voltage measurement circuits (S_3 positions a and b). A gating switch circuit (D_2 and D_3) permits the cathode potential to be measured, free of the ohmic iR drop, during the brief

* Electrochemical Society Active Member.

Key words: graphite fluorides, mixed potential, perfluoro anthracene, perfluoro decacyclene, perfluoro phthalocyanine.

period of current interruption (1/120 sec). The selection of the circuit components had to consider the higher cell voltages and the ohmic resistance characteristics of the lithium batteries which influence mainly the choice of the transformers (T_1 and T_2), the components in the gating switch circuit, and the condenser, C_V, parallel to the voltmeter. The latter had to be adjusted to the time constant of the voltage measurement circuit (S_3 position a).

Thus quasi steady-state current-cell voltage and current-cathode potential curves of lithium/graphite fluoride cells, including or excluding the ohmic *iR* drop, could be measured. In the case of polymeric carbon fluorine compounds as depolarizers, galvanostatic discharge curves were measured.

Results and Discussion

Standardization of cathode preparation.—Before a study of the kinetics of various graphite fluorides was started, the cathode preparation technique had to be optimized and standardized. It was found that the major two factors influencing the performance of the cathode were the carbon to fluorine ratio and the compression pressure applied in preparing the cathodes. The compression pressure was varied within the range of 400 to 30,000 lb/electrode. Using the dry press technique a pressure of about 2000 lb/in.^{2} yielded graphite fluoride cathodes with the lowest polarization up to 5 mA/cm^2.

Mixed potential theory of CF_n reduction.—The key to the analysis of the polarization data was the mixed potential theory of CF_n reduction. The open-circuit potential of graphite fluoride cathodes is a mixed potential, the reduction of graphite fluoride being the cathodic reaction and solvent oxidation being the anodic reaction (1). The electrochemical behavior of carbon fluorine compounds is shown schematically in terms of the mixed potential theory in Fig. 2. E_{CF} is the potential of a carbon fluoride cathode *vs.* a lithium reference electrode, computed from thermodynamic data. It is numerically identical to the electromotive force of a corresponding lithium-carbon fluoride cell. The emf of such cells, covering the composition range from $CF_{0.24}$ to $CF_{1.13}$, have been determined recently by Professor Margrave and co-workers at Rice University (2). The values range from 5.23 to 4.56V at 298°K. Note that the potentials decrease with increasing fluorine content in the compounds. There are three current-potential curves shown in Fig. 2, covering three cases of CF kinetics, slow, medium, and fast. E_S is the oxidation potential of the organic solvent. The average potential of graphite electrodes in 1M $LiClO_4$-PC is 2.56V *vs.* lithium. Tiedemann has found that the potential of a completely discharged $(CF)_n$ electrode is approximately 2.5V *vs.* lithium (5). A_s is the solvent oxidation and C_s the solvent reduction curve.

The open-circuit potential of a CF electrode, *e.g.*, E_m, is a mixed potential and a function of its state of discharge (1). Experimental E_m values, ranging from 2.56 to 3.36V, have been observed with poly carbon monofluoride at 298°K. The variations are caused by the type of CF used and by the electrode compression pressure.

A mixed potential, E_m, is established when the cathodic current of CF reduction and the anodic current of solvent oxidation are equal. The open-circuit potential, E_m, is thus a function of the kinetics of the partial electrode processes (6, 7). According to the principle of the additive composition of all partial electrode processes, we should observe experimentally the interrupted curve, C_{exp}. The theoretical curve for CF reduction and the experimental curve are, however, practically identical between E_m and E_s due to the smallness of the solvent oxidation current.

CF_n cathode polarization data.—In Fig. 3, polarization data, free of ohmic *iR* drop, of graphite fluoride cathodes are shown. The polarization here is defined as the difference between the cathode potential, calculated from thermodynamic data, and the cathode potential at a given current measured *vs.* the lithium reference electrode. Each data point was taken after quasi steady state, defined by a change of less than ±5 mV/5 min, was reached. The average error in the polarization data, *e.g.*, for $CF_{0.93}$, for the 0.15 to 50 mA range was 38 mV or less than 1.8% at polarizations between 2.5 and 2.74V. At higher current densities, above 2 mA/cm^2 (20 mA), a slow, continuous increase in polarization with time was observed. In these cases, the initial data points taken are shown in the graph. The upper two curves (Fig. 3) are for white CF [dry press technique and wet preparation technique (1)] and the lower two curves for gray CF (dry press technique, two different metal current collectors).

A range of linear behavior with a slope of about 0.12V/decade of current can be observed. The deviations at higher currents from linearity could be due to blocking of parts of the inner surface area of the electrodes with reaction products, mainly lithium fluoride; the deposition will be proportional to current and time. Since no limiting currents have been observed up to 100 mA, any concentration polarization can be neglected due to its smallness.

Exchange currents of CF_n reduction.—From the linear part of the polarization curves, the exchange currents, i_o, for cathodic CF reduction could be computed, using the following equation

$$E_{CF} - E_i = 0.116 \log i_c - 0.116 \log i_o \quad [1]$$

Values of exchange currents for various graphite fluorides are shown in Table I. The highest exchange

Table I. Exchange currents of graphite fluorides CF_n in 1M $LiClO_4$-PC at 298°K for about 2% discharge of the cathodes

n	i_o (A)	$(i_m)_c$ (A)	E_m (V)	τ (Y)
0.237	$3 \cdot 10^{-26}$			
0.55	$8.9 \cdot 10^{-23}$			
0.93	$1 \cdot 10^{-22}$	$6.9 \cdot 10^{-10}$	3.09	$3.05 \cdot 10^{+4}$
0.96	$2.2 \cdot 10^{-23}$			
1.0	$6.4 \cdot 10^{-24}$			
1.09	$3.6 \cdot 10^{-24}$	$3.39 \cdot 10^{-11}$	3.05	$9 \cdot 10^{+5}$

current was observed with $CF_{0.93}$. Considering the inner surface areas of the graphite fluorides (2), which range from 230 to 270 m^2/g, the exchange current density for gray CF should be in the order of $1.7 \cdot 10^{-28}$ A/cm^2 and that of white CF about $5.4 \cdot 10^{-30}$ A/cm^2; however, blocking of active, inner surface area by compression during electrode preparation has to lead to higher exchange current densities.

Electrochemical stability of CF cathodes.—From the exchange currents, the cathodic currents of CF_n reduction at the mixed potentials, $(i_m)_c$ (third column, Table I), could be computed via Eq. [2]

$$E_{CF} - E_m = 0.116 \log (i_m)_c - 0.116 \log i_o \quad [2]$$

For gray CF we obtain $(i_m)_c = 6.9 \cdot 10^{-10}$A. This value is significant in that it relates to the electrochemical stability of the CF cathode on open circuit. A cathodic current at the mixed potential of about 10^{-11}A corresponds to a depolarizer shelf life, τ, (last column, Table I) in the electrolyte of about 10^6 years.

It can be estimated that hypothetical compounds with a higher rate capability than gray CF, *e.g.*, with exchange currents of $(i_o)_{CF_n} = 10^{-12}$ or 10^{-7}A, would have, based on the computed $(i_m)_c$, a far shorter depolarizer shelf life in the electrolyte of about 3 years or 1 day, respectively.

In computing the depolarizer shelf life of such compounds from i_m, we have to consider the shift in E_m due to the faster kinetics of the CF_n reduction. E_m, i_m, and consequently τ, can be computed from the two equations [3] and [4] with two unknowns E_m and i_m

$$E_m - E_s = 0.12 \log i_m - 0.12 \log (i_o)_s \quad [3]$$

$$E_{CF_n} - E_m = 0.12 \log i_m - 0.12 \log (i_o)_{CF_n} \quad [4]$$

As mentioned earlier, E_s was found experimentally to average 2.56V. The exchange current of the solvent $(i_o)_s$ could be determined indirectly from i_m, *e.g.*, for $CF_{1.09}$, under assumption of activation control, using Eq. [3], E_m being the mixed potential of $CF_{1.09}$; $(i_o)_s$ was also determined directly by measuring the anodic oxidation of propylene carbonate at $CF_{1.09}$. With 1M $LiClO_4$-PC at 25°C, a Tafel slope of 0.12 was found and an $(i_o)_s$ of 10^{-16}A; $(i_o)_s$ determined indirectly was about 10^{-15}A.

E_{CF_n} can be estimated using Eq. [5] (2) and [6]

$$G°_{298} = -(104.2n + 1.158) \text{ (kcal mole}^{-1}) \quad [5]$$

$$E°_{CF_n} = G°_{298}/n \cdot 23.053 \quad \text{(V)} \quad [6]$$

The polymeric carbon fluorine compounds, mentioned earlier, fall apparently into the category of high rate depolarizers by showing initially a far better kinetics than white CF, but also a strong reactivity with the organic solvent. Figure 4 shows the cathodic reduction of polymeric carbon fluorine compounds and of white CF. The discharge was performed galvanostatically at 1 mA/cm^2. In the figure the cathode potential measured *vs.* a lithium reference electrode is plotted *vs.* the discharge time in minutes. Oxygen crosslinked perfluoro anthracene, perfluoro decacyclene, perfluoro phthalocyanine, and fluorinated paracyanogene showed initially about 1V higher discharge potentials than poly carbon monofluoride. After a certain time, however, reactions between depolarizer and solvent consume the cathodes. Highly soluble depolarizers, such as oxygen crosslinked perfluoro anthracene, show inferior discharge behavior.

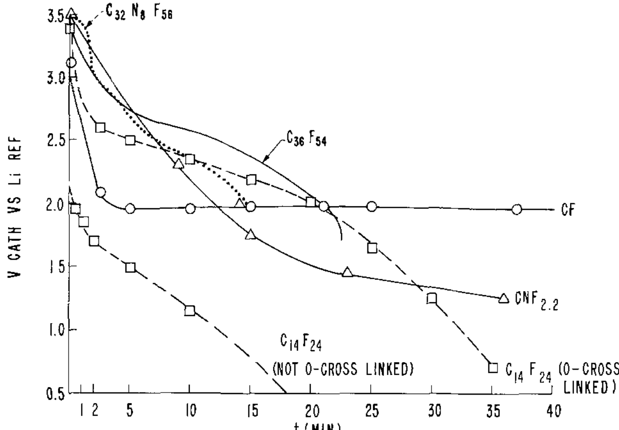

Fig. 4. Cathodic reduction of polymeric carbon fluorine compounds compared with CF (1 mA/cm^2). 1M $LiClO_4$-PC, 30°C. $C_{14}F_{24}$ perfluoro anthracene (oxygen crosslinked), $C_{36}F_{54}$ perfluoro decacyclene (oxygen crosslinked), $C_{32}N_8F_{56}$ perfluoro phthalocyanine (oxygen crosslinked), $CNF_{2.2}$ fluoro paracyanogene, CF poly carbon monofluoride.

A more detailed explanation of the experimental behavior of these compounds is submitted: When the cathode is submerged for the first time in the electrolyte, reduction takes place initially at a high rate, corresponding perhaps to an $i_o = 10^{-7}$A, at a mixed potential of about 3.95V. For 100% bulk utilization of the depolarizer, a time of about 1 day would be required; for depletion of active species at the surface, however, far less time would be required. This depletion will change the kinetics to a slower one, *e.g.*, to an $i_o = 10^{-12}$A. A mixed potential of about 3.62V would be the consequence. This would approximately correspond to the starting points of our discharge experiments in Fig. 4. Drawing a cathodic current of 10^{-2}A at about 3.32V would result in a fast consumption of the remaining active depolarizer material which is indicated in Fig. 4 by a strong drop in discharge potential.

The mixed potential theory predicts a shift in E_m to more positive potentials for compounds with faster reduction kinetics (see Fig. 2). This could be observed experimentally in the case of oxygen crosslinked perfluoro anthracene, perfluoro decacyclene, perfluoro phthalocyanine, and fluoro paracycanogene. The mixed potentials of these compounds measured *vs.* a lithium reference electrode are given in Table II.

Such compounds could make excellent depolarizers with higher rate capabilities if solvents and electrolytes could be found that would be stable to oxidation by the compounds. The theoretical energy capacities of these compounds exceed those of graphite fluorides, 2050 W-hr/lb of cell reactants *vs.* 1785 W-hr/lb.

Manuscript submitted Nov. 13, 1974; revised manuscript received May 20, 1975. This was Paper 25 presented at the New York, New York, Meeting of the Society, Oct. 13-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Table II. Mixed potentials of polymeric carbon fluorine compounds in 1M $LiClO_4$-PC at 298°K *vs.* the lithium reference electrode

Compound	E_m (V)
$CF_{0.93}$	3.09
Oxygen crosslinked perfluoro	
Anthracene $C_{14}F_{24}$	3.46
Decacyclene $C_{36}F_{54}$	3.47
Phthalocyanine $C_{32}N_8F_{56}$	3.47
Fluoro paracyanogene $CNF_{2.2}$	3.58

High Conductivity Solid Electrolytes

Double Salts of Substituted Organic Ammonium Halides and Cuprous Halides

Anthony F. Sammells,* Jack Z. Gougoutas,[1] and Boone B. Owens*,[2]

Gould Incorporated, Gould Laboratories, St. Paul, Minnesota 55165

ABSTRACT

Copper solid electrolytes have been synthesized by the solid-state reaction between substituted organic ammonium halides and cuprous halides. High conductivity electrolytes were found with both high and low symmetry organic ammonium halides, indicating that high symmetry in the latter need not be necessary in this class of electrolytes. Initial experiments with these materials in galvanic cells and coulometers indicated some instability.

Many of the highly conducting solid electrolytes investigated over the past decade have been silver ion conductors. The most conductive of these, $RbAg_4I_5$, has a conductivity of 0.27 $ohm^{-1}\cdot cm^{-1}$ at ambient temperatures (1) and has found application in galvanic cells (2). Silver electrolytes have also been synthesized through compound formation between AgI and various substituted ammonium halides (4, 5) and also between AgI and sulfonium iodides (6). The single-crystal structures of certain of these unique phases have been investigated (7-11) to determine the structural features that permit fast ion diffusion in solids. It was observed that the iodide ions form face-sharing polyhydra (generally tetrahedra), with the silver ions situated within these polyhedra. On the average there are two or three vacant sites per silver ion, thus permitting ready diffusion through the faces of the polyhedra.

Because of the similar properties of Ag^+ and Cu^+ together with the much lower cost of copper compared to silver, it has been of considerable interest to synthesize copper electrolytes with ionic transport properties analogous to those of the above referenced silver electrolytes. Such materials were recently reported to exhibit ionic conductivities as high as 0.045 $ohm^{-1}\cdot cm^{-1}$ (12-13).

In the present investigation, following procedures similar to those of Takahashi, Cu^+ ion conducting solid electrolytes were synthesized by the combination of NN'-dimethyltriethylenediamine dibromide + cuprous bromide, NN-dihydrotriethylenediamine dibromide + cuprous bromide, and N-hydrohexamethylenetetramine chloride + cuprous chloride, in good agreement with the results of Takahashi *et al.* (12, 13).

The organic cations that are presumably stabilizing the high conductivity phase in the above three electrolytes have both high symmetry and a saturated cage-type structure. In order to determine whether ionic conduction is limited to the hydrohalides of triethylenediamine and hexamethylenetetramine and their derivatives, and investigate the relative importance of high symmetry, the cage-type structure, and the onium nitrogen atoms, we have investigated several other systems. Our choice of substituents for the most part has been empirical since no crystallographic structural information is available to suggest those molecular features which the organic moeity should possess in order to form an ionically conducting phase. The possibility of ionically conductive cuprous halide phases being stabilized by quinuclidine, quinuclidone, pyridinium, dimethylpiperizine, NN',NN'-diethylenedipyrilidinium, and 1-adamantanamine halides was investigated.

Conductivity measurements have been reported both at 1000 Hz and ∞Hz. Extrapolation to ∞Hz was made to eliminate the faradaic impedance ΔR, which may be proportional to the square root of frequency (14, 15).

$$\Delta R = kf^{-1/2}$$

where f is frequency and k a proportionality constant. The measured resistance R_m will contain both the bulk electrolyte resistance R and any faradaic impedance effects that may exist at the interface

$$R_m = R + \Delta R = R + kf^{-1/2}$$

The error caused by ΔR was minimized by extrapolating the measured resistance to infinite frequency.

The conductivity-temperature function was determined for some of these electrolytes and activation energies reported. The stability of these electrolytes under a potential was evaluated by fabricating galvanic cells with copper anodes and various cathodes, including $CuBr_2$, MoO_3, V_2O_3, tetrapropylammonium tribromide, tetrabutylammonium tribromide, and triethylenediamine dibromide.

Experimental

Electrolyte syntheses.—3-quinuclidone hydrochloride, quinuclidine hydrochloride, and 1-adamantanamine were obtained from Aldrich Chemical Company. Triethylenediamine was purchased from Eastman Kodak Chemical Company. Cuprous chloride and bromide were very carefully purified by recrystallization from the appropriate halogen acid, followed by wash-

ing with glacial acetic acid, and ethanol. While still moist with ethanol, the cuprous halide was stirred with tetrahydrofuran and rapidly transferred to a round bottom flask, where the remaining solvent was removed under vacuum. After solvent removal the cuprous halides were not exposed to the atmosphere in any subsequent operation.

The electrolyte materials were synthesized under a nitrogen atmosphere by intimately mixing the appropriate mole quantities of cuprous halide and organic material in a round bottom flask, using sufficient ethanol to make a slurry. The ethanol was then vacuum distilled. After thorough washing and drying the materials were transferred to a dry box where they were pressed into pellets at 57,000 psi. These pellets were then heated under the conditions illustrated in Table I. After the solid-state reaction, the pellets were transferred to a dry box, ground up, and repressed at 57,000 psi into conductivity cells of the configuration Cu,E/E/Cu,E (E is the electrolyte). The electrodes consisted of powdered copper intimately mixed with electrolyte in the weight ratio 2:1. Some of the conductivity cells were annealed under high purity nitrogen to remove any excess halogen that may be present. However, attempts to anneal the electrolytes containing quinuclidine and 3-quinuclidone resulted in deterioration of these materials.

Synthesis of electrolyte components.—NN'-dimethyltriethylenediamine dibromide.—Methyl bromide (2 moles) was reacted with triethylenediamine (1 mole) in benzene. The product was recrystallized from tetrahydrofuran. [Br: found 51.70%, calculated 52.98% (13).] This material was also prepared from NN'-dimethylpiperidine and 1-2-dibromoethane.

NN'-dihydrotriethylenediamine dibromide.—Triethylenediamine was reacted with an excess of a 47% aqueous HBr solution. The solution was allowed to stir overnight; the product was recrystallized from EtOH/water. [Br: found 57.4%, calculated 58.39% (13).]

N-hydrohexamethylenetetramine chloride.—Hexamethylenetetramine was reacted with 1 mole equiv. of 47% aqueous HBr in ethanol and was recrystallized from ethanol. [Cl: found 19.37%, calculated 20.11% (12).]

Quinuclidine hydrobromide.—Quinuclidine hydrochloride was treated with 1M NaOH, stirred with $MgSO_4$, and then reacted with a slight excess of HBr. The product was recrystallized from ethanol. (Br: found 40.94%, calculated 41.66%.)

Quinuclidine methylbromide.—As above except treated with 3 moles methylbromide. The product was recrystallized from ethanol. (Br: found 37.70%, calculated 38.83%.)

3-Quinuclidone hydrobromide.—This material was synthesized by passing quinuclidone hydrochloride through an anion exchange resin (amberlite IR-45) and the product was recrystallized from ethanol. (Br: found 40.18%, calculated 38.46%.)

Pyridinium bromide.—This extremely hygroscopic salt was prepared by titrating an aqueous solution of pyridine with 47% aqueous HBr. After evaporation of the solvent, the solid was recrystallized from acetone/ethanol. (Br: found 45.17%, calculated 41.66%.)

NN'-dimethylpiperizine dihydrochloride.—NN'-dimethylpiperizine was treated with 2 moles of aqueous hydrochloric acid. Crystals were obtained by concentration of the solution and were recrystallized from ethanol. (Cl: found 34.74%, calculated 37.96%.)

NN',NN'-diethylenedipyrrolidinium dibromide.—Pyrrolidine was reacted with ethylenedibromide, the solution was clarified using NORITE (activated charcoal) and the product was recrystallized from iPrOH. [Br: found 45.28%, calculated 44.94% (16).]

Synthesis of cathode materials.—Tetramethylammonium tribromide.—Tetramethylammonium bromide was reacted with bromine in carbon tetrachloride. The excess bromine was pumped off.

Tetrabutylammonium tribromide.—Tetrabutylammonium was reacted in carbon tetrachloride with a 0.05 mole Br_2/CCl_4 solution (14).

Triethylenediamine dibromine complex of.—Triethylenediamine was dissolved in benzene and was stirred with excess bromine in benzene. The yellow product was filtered, washed with benzene, and air dried. The product was recrystallized from glacial acetic acid.

Experimental measurements.—Cell resistances were measured at frequencies between 500 and 20,000 Hz using a General Radio 1608A impedance bridge with an external Hewlett-Packard 209A oscillator. The measurements were made on cells maintained in an inert atmosphere. The cell voltages were measured with an HP3430A digital voltmeter. X-ray powder diffraction patterns were run on a GE XRD-6 x-ray spectrometer using $CuK\alpha_1$ lines.

Table I. Conductivity results

Electrolyte	Conductivity $ohm^{-1} \cdot cm^{-1}$ at 25°C				Electrolyte synthesis	Conductivity cell anneal
	1000 Hz		∞ Hz			
	Before anneal	After anneal	Before anneal	After anneal

1-Adamantylamine-HCl-CuCl (80 m/o)	3.1×10^{-7}	1.2×10^{-7}			180°C 16 hr under vac	140°C 8 hr N_2 flow
Triethylenediamine-CuBr (90 m/o)		No conductivity			100°C 16 hr N_2 flow	
Triethylenediamine-CuCl (90 m/o)	1.3×10^{-7}				100°C 16 hr N_2 flow	

Results

The systems reported on are shown in Fig. 1. These are (I) quinuclidine hydrobromide-CuBr, (II) quinuclidine methylbromide-CuBr, (III) quinuclidine hydrochloride-CuCl, (IV) 3-quinuclidone hydrobromide-CuBr, (V) 3-quinuclidone hydrochloride, (VI) pyridinium bromide-CuBr, (VII) NN'-dihydrotriethylenediamine dibromide-CuBr, (VIII) NN'-dimethyltriethylenediamine dibromide-CuBr, (IX) N-hydrohexamethylenetetramine chloride-CuCl, (X) dimethylpiperizine dihydrochloride-CuCl, (XI) NN',NN'-diethylenedipyrrolidinium dibromide-CuBr, (XII) 1-adamantanamine hydrochloride-CuCl, (XIII) triethylenediamine-CuBr, (XIV) triethylenediamine-CuCl.

A typical frequency dependence for a conductivity cell resistance is shown in Fig. 2 for the electrolyte NN'-dimethyltriethylenediamine dibromide-CuBr [94 mole per cent (m/o)]. If we plot cell resistance values at 1 kHz against cell length, the resultant faradaic impedance, as represented by the intercept, is generally several ohms. However, by plotting the extrapolated conductivity values at ∞Hz against cell length, the intercept is at the origin, demonstrating that the impedance effect has been minimized, as shown in Fig. 3. All of our results for both 1 kHz and ∞Hz are summarized in Table I. The highest conductivity found was for NN'-dihydrotriethylenediamine chloride-CuBr (87.5 m/o) at 6.5×10^{-2} $ohm^{-1} \cdot cm^{-1}$ at ∞Hz, which is in reasonable agreement with the value of 4×10^{-2} $ohm^{-1} \cdot cm^{-1}$ at 1000 Hz reported by Takahashi.

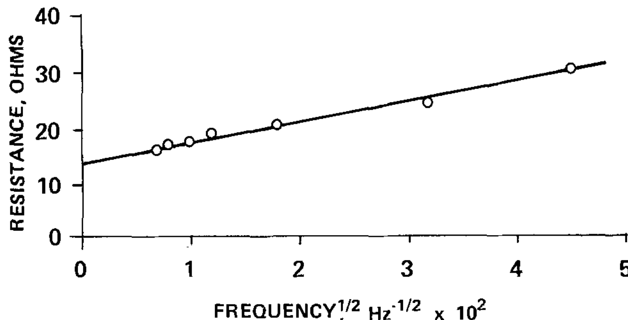

Fig. 2. Frequency dependence for dimethylenediamine dibromide + CuBr(94 m/o).

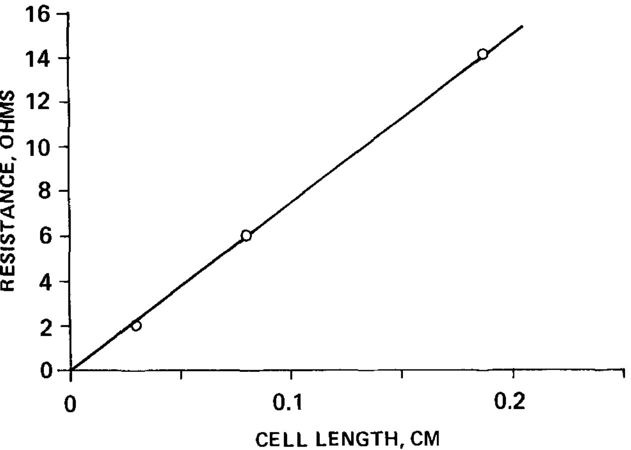

Fig. 3. Cell resistance vs. cell length at ∞Hz for dimethyltriethylenediamine dibromide + CuBr(94 m/o).

The composition dependence of the conductivity was determined for the more conductive systems investigated. The compositions at which maxima occurred are summarized in Table I. The synthesis temperatures chosen were those where new phase materials could be detected from x-ray patterns. The presence of the new phases was then correlated with directly measured conductivity values to find the synthesis temperature at which the most conductive samples were produced.

The optimized stoichiometries for maximum conductivity were quite distinct, but were generally not sharp.

The observed temperature dependence of the conductivity for quinuclidine hydrobromide-CuBr (87.5% m/o) over the temperature range 50° to −20°C is shown in Fig. 4. The slope corresponds to an activation energy of 2.7 kcal/mole. The activation energies observed in the present study varied from 2.7 up to 6.7 kcal/mole as shown in Table II.

X-ray powder diffraction patterns were routinely run on samples of optimized stoichiometry. All samples showed lines characteristic of the starting materials together with, in some cases, new phases, indicating that the phases were not optimized to equilibrium.

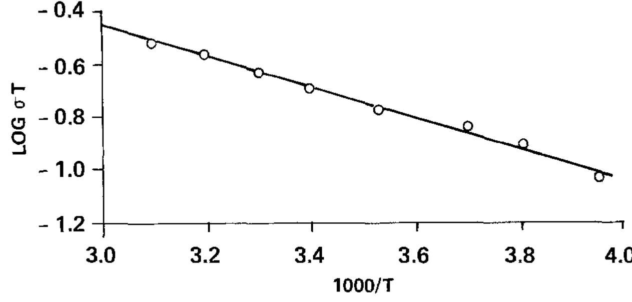

Fig. 4. Conductivity temperature dependence for quinuclidine hydrobromide + 87.5 m/o CuBr.

Table II. Activation energies for copper solid electrolytes

Electrolyte	ΔE, kcal/mole
Quinuclidine-HBr-CuBr (87.5 m/o)	2.68

Cu | 3-Quinuclidone-HCl-CuCl	| $Propyl_4NBr,B_2$	527
Cu | 3-Quinuclidone-HCl-CuCl	| $Butyl_4NBr,B_2$	592

To evaluate the utility of these copper electrolytes in solid-state galvanic cells, various cells were made. Initial voltages are reported in Table III. A load curve for the cell Cu/hexamethylenetetramine-HCl CuCl (87.5 m/o) $CuBr_2$ is shown in Fig. 5. During discharge or upon standing on open circuit, the electrolyte phase in our cells deteriorated and became black in appearance. There was a concurrent loss of cell voltage, possibly due to electronic conductivity in the electrolyte decomposition product.

The plating characteristics of copper in these materials was investigated for a simple coulometer cell. The plate, deplate cycle for the cell Cu/pyridinium bromide-CuBr (87.5 m/o) graphite is shown in Fig. 6.

Some preliminary work was performed on identification of the ionically conductive phase or phases present in these copper electrolytes by the use of single-crystal techniques. Single crystals of a conductive phase of pyridinium bromide-CuBr were prepared from an aqueous solution. A preliminary crystallographic survey of the single crystals suggested an orthorhombic unit cell (a = 11.8Å, b = 14.1Å, c = 13.1Å). The observed density of 3.178 g/cm^3 and unit cell volume agree with a unit cell containing 20 CuBr and 8 C_5H_6NBr.

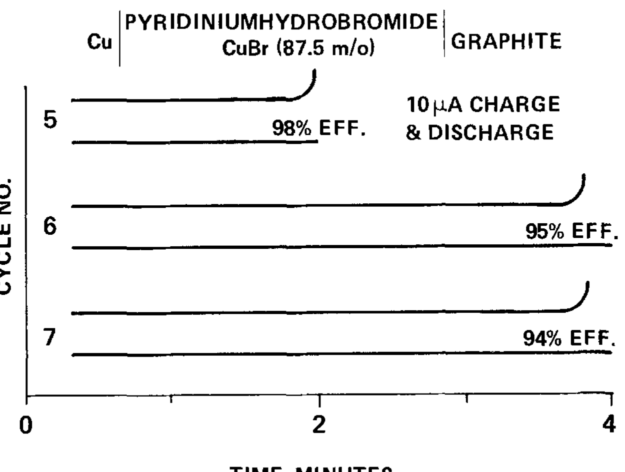

Fig. 6. Application in coulometers

Discussion

The present results indicate that copper ion conducting phases can be stabilized not only by substituted organic ammonium compounds of high symmetry (D_3h) as reported by Takahashi (12, 13) but also by species in which some lowering of the over-all symmetry occurs. High conductivity has been observed for double salts of copper halides with quinuclidine hydrobromide, quinuclidine methylbromide, and quinuclidine hydrochloride, where there is still a high symmetry organic ammonium halide, but one of the "onium" nitrogens of the NN'-dialkyltriethylenediamine halide has been removed. In fact, the conductivity at infinite frequency found for quinuclidine methylbromide-CuBr (87.5 m/o) was close to that observed in this laboratory for NN'-dimethyltriethylenediamine dibromide-CuBr (94 m/o), Table I. The molecular symmetry of quinuclidine may be C_{3v} or C_3, but it was clear that the cation need not contain rotational axes or mirror planes of symmetry perpendicular to the three-fold axis. It also followed that a doubly charged cation was not essential for the formation of a conducting phase.

Asymmetry was introduced into the quinuclidine structure by introduction of an oxygen atom at the three-position, giving the quinuclidone-type structure. High conductivity was found for 3-quinuclidone hydrochloride-CuCl (80 m/o) and 3-quinuclidone hydrobromide-CuBr (80 m/o), showing that highly symmetric organic nitrogen compounds are not necessary for the formation of highly conductive phases.

However, it is possible that the carbonyl group represents only a relatively small perturbation on the cage structure which, accordingly, may be axially disordered at 120° rotational intervals in the crystal structure of the double salt and thereby simulate three-fold symmetry. A crystallographic study of such possible positional disorder in the double salt would be required to clarify this possibility.

The formation of conductive phases with cations not having a cage structure was evaluated in the systems: dimethylpiperizine dihydrochloride-CuCl and NN', NN'-diethylenedipyrrolidinium dibromide-CuBr, the structures of which are shown in Fig. 1, No. X and XI, respectively. No significant conductivity was observed with either of these materials. One might infer from the low conductivity of these two materials that removal of the cage structure from a saturated species such as NN'-dimethyltriethylenediamine dibromide appears to prevent the stabilization of conductive phases. However, by analogy with previous work on silver conductors (8, 10) high conductivity was found with pyridinium bromide-CuBr (87.5 m/o) where the

organic cation has a planer aromatic ring and in particular, three-fold symmetry is absent.

The possible conductivity of the 1-adamantanamine hydrochloride-CuCl system (Fig. 1, No. XII) was investigated by analogy to the electrolyte N-hydrohexamethylenetetramine chloride-CuCl (87.5 m/o) (Fig. 1, No. IX). Conductivities only a little greater than 10^{-7} $ohm^{-1} \cdot cm^{-1}$ were achieved with the samples investigated.

From conductivity measurements the optimum Cu/substituted organic ammonium halide mole ratios were found to be 7:1 for CuBr-quinuclidine hydrobromide, CuBr-quinuclidine methylbromide, and CuBr-pyridinium bromide, close to 6:1 for CuCl-quinuclidine hydrochloride, and 4:1 for CuBr-3-quinuclidone hydrobromide and CuCl-3-quinuclidone hydrochloride. The conductive materials used in these investigations were not single phase, as determined by x-ray diffraction, and optimized stoichiometries may be somewhat contingent upon experimental details used for electrolyte synthesis. Further comment on the stoichiometry of the conductive phase or phases in these electrolytes must await single-crystal structural determinations.

The conductivity of an ionic conductor can be represented by $\sigma = n\mu q$ (17), where n is the concentration of migrating species, μ is the ionic mobility, and q is the charge on the migrating species. Assuming that a univalent copper ion is the migrating species in these electrolytes, q will be essentially constant. The concentration of ions n in these copper electrolytes will vary between one material and another, being dependent on how much ionically conducting phase is present. Therefore, to compare conductivity values between the more highly conductive copper electrolytes might be somewhat erroneous.

The mobility μ of such ionic conductors can be represented by (17)

$$\mu = \mu_0 e^{-\Delta E/kT}$$

where ΔE is the activation energy for ionic migration and the other symbols have their usual significance. The concentration of migrating species n will be difficult to predict in the absence of single-phase material; it may therefore be more meaningful to compare ΔE values obtained from the conductivity-temperature dependence than absolute conductivity values.

The lowest activation energies were found for electrolytes (Table II) stabilized by the quinuclidine structure. The conductivities of these electrolytes are comparable to those found for electrolytes stabilized by NN'-dihydro and dimethyltriethylenediamine dibromide. The activation energies of the latter materials were found to be higher than those of the quinuclidine-CuX electrolytes, which suggests that there may be more mobile copper ions in the latter materials.

The introduction of an oxygen double bond into the three-position of quinuclidine causing the possible loss of symmetry in the 3-quinuclidone increased the activation energy for copper migration from 2.7 kcal/mole for quinuclidine hydrobromide-CuBr (87.5 m/o) to 6.7 kcal/mole for 3-quinuclidone hydrobromide-CuBr (80 m/o). The optimum stoichiometric ratios are also changed from 7:1 to 4:1 indicating a different structure and possibly a different conduction mechanism. The electrolyte 3-quinuclidone hydrochloride-CuCl (80 m/o) was not stable at the temperatures used for temperature dependence measurements, however assuming an activation energy comparable to that found in 3-quinuclidone hydrobromide-CuBr (80 m/o) there must be a high concentration of mobile species available since a conductivity of 2.5×10^{-2} $ohm^{-1} \cdot cm^{-1}$ was recorded at ∞Hz.

These results indicate that high molecular symmetry in the substituted organic ammonium cations is not essential in achieving high conductivity, but does appear to give a lower ΔE value for copper ion migration in the solid phase. For example, the activation energy for NN'-dimethyltriethylenediamine dibromide-CuBr (87.5 m/o) is greater (5.7 kcal/mole) than for NN'-dihydrotriethylenediamine dibromide-CuBr (87.5 m/o) 4.55 kcal/mole), and quinuclidine methylbromide-CuBr (87.5 m/o) is greater (3.6 kcal/mole) than quinuclidine hydrobromide (2.68 kcal/mole). We tentatively conclude that introduction of a larger group on the onium nitrogen atom leads to larger ΔE values. However, the over-all conductivity will be contingent also on the number of migrating species available in the phase that is stabilized as indicated earlier.

All of the copper electrolytes were evaluated in galvanic cells and were observed to lose voltage upon standing on open circuit, with electrolyte deterioration, even when stored in a dry box under an argon atmosphere. With halide cathode materials the initially white electrolyte became black both upon standing and during discharge. This color change appears to be a direct chemical reaction. By pressing pellets of the configuration $CuBr_2$/electrolyte/$CuBr_2$ the initially white electrolyte was observed to become black upon standing, indicating that even in the absence of any voltage breakdown of the electrolyte, a direct chemical path was also available for reaction with the copper electrolyte. This chemical instability was only observed in the stabilized conductive electrolyte phases and not in the organic nitrogen halide compounds used for the electrolyte synthesis. No color change was observed in pellets $CuBr_2$/organic nitrogen halide/$CuBr_2$ upon extended standing. The electrolytes were also stable to copper since conducting cells Cu/electrolyte/Cu were stable over several months without evidence of chemical breakdown.

The chemical change taking place in galvanic cells containing halide cathode materials, probably involves a halide migration which could cause the formation of electron holes, and/or the formation of Cu^{2+} species in the electrolyte, thus explaining the loss of cell voltage. The presence of electron holes in cuprous halides containing an excess of halogen is well known (18, 19). Four cells of the configuration Cu/electrolyte/graphite + electrolyte were charged up initially to around 600 mV; these cells slowly began to lose their charge with the simultaneous decomposition of the electrolyte (detected by the color change), and finally held a voltage of around 350 mV for several months.

In cells using V_2O_5 or MoO_3 as cathode materials, the cell voltage similarly deteriorated with time; however, no electrolyte color change was observed. This indicates that voltage breakdown of the electrolytes is probably occurring leading to some electronic conduction path. Preliminary attempts using x-ray diffraction techniques to identify the electrolyte decomposition products were not conclusive.

The performance of these electrolytes in solid-state coulometers is illustrated by the cell Cu/pyridinium bromide-CuBr (87.5 m/o)/graphite (Fig. 6). The first few cycles charging and discharging at 10 μA showed high coulombic efficiencies, indicating that initially the materials were predominantly Cu^{+} ion conducting; however, upon extended cycling the efficiency began to decrease, probably due to electrolyte breakdown caused by the voltage drop across the cell.

The fact that high ionic conduction has been found in copper electrolytes stabilized by substituted organic ammonium compounds of lower symmetry than previously reported, indicates that such electrolyte phase stabilization is more general than might have previously been thought. From the evidence presently available it would appear that these materials are somewhat unstable when applied in galvanic cells. Whether these copper electrolyte materials can find any useful applications in solid-state devices must await the syntheses or isolation of the phase or phases that are responsible for the ionic conduction, together with the necessary structural determination and stabilization of the electrolytes in cells.

On the Kinetics of the Breakdown of Passivity of Preanodized Aluminum by Chloride Ions

Z. A. Foroulis*,[1] and M. J. Thubrikar

Department of Metallurgy and Materials Science, New York University, New York, New York 10019

ABSTRACT

The kinetics of passivity breakdown and nucleation of pitting of preanodized aluminum by chloride ions has been investigated using aluminum supporting oxide films of reasonably well-known thickness and structure. The kinetics of passivity breakdown at the steady-state, critical pitting potential is influenced by chloride ion concentration, temperature, and oxide film thickness; it was found to be independent of solution *p*H in the range 5-10. It is postulated that passivity breakdown and nucleation of pitting at the critical pitting potential occurs by a process of Cl^- adsorption (assisted by the field at the oxide-solution interface) on the hydrated oxide surface and formation of a soluble, basic chloride salt with the lattice cation which readily goes in solution. This process of localized dissolution of the hydrated oxide film via formation of a soluble, basic, aluminum chloride salt once initiated is likely to continue in an "autocatalytic" fashion until the oxide is locally "penetrated" and dissolution of the substrate metal begins.

The breakdown of passivating oxide films on aluminum, by "aggressive" anions such as chlorides at sufficiently positive anodic potentials is frequently responsible for the failure of aluminum and its alloys in aqueous chloride solutions because it usually leads to severe pitting of the underlying metal. Several mechanisms for the breakdown process have been suggested (1-7). However, there is little experimental information on the kinetics of the oxide film breakdown process which could be used to establish the mechanism of pit nucleation of aluminum by chloride ions. Considerably more research is required to better understand the physical and chemical processes occurring during pit nucleation. In particular, there is considerable need to understand the role of surface films, Cl^- concentration, solution *p*H, and temperature on the kinetics of passivity breakdown and nucleation of pitting.

The work described in this report was undertaken to study the kinetics of pit nucleation of preanodized aluminum by chloride ions, as a function of Cl^- concentration, solution *p*H, and temperature. The purpose of prefilming of aluminum by anodization was to obtain oxide films of reasonably well-known thickness and structure.

Experimental

The electrodes, about 4-7 cm^2 total exposed area were cut from 99.99% pure aluminum. The electrode assembly was similar to the one described previously (8). Surfaces were abraded through 4-0 emery paper and then metallographically polished using 1 and 0.5μ alumina. This surface preparation produced a mirror like surface.[2] Following rinsing in distilled water,

specimens were anodized using two different methods. One method involved constant current anodization in sulfuric acid using 15% w/v sulfuric acid (sp gr 1.84) for various times at 25 mA/cm^2 (20-21V) with a standard rate of stirring. Following anodization, the specimens were sealed in boiling distilled water. In general, the ratio of anodizing time to sealing time in boiling distilled water was 1:30. In some instances, however, longer times of sealing were also used. The unsealed films produced consisted of a thin barrier layer adjacent to the metal and a thick outer porous layer. The oxide film prior to sealing in water is essentially γ-Al_2O_3. During exposure in boiling water, sealing of pores due to hydration of γ-Al_2O_3 and formation of the less dense boehmite, AlO(OH), or $Al(OH)_3$ is well known (9-12). The sealing procedure gives an essentially pore free film (9). The over-all thickness of the oxide films produced by anodization was estimated from values reported by Hoar and Wood (9).

Another method of prefilming of aluminum specimens was constant voltage anodization in 3% ammonium tartrate. In this case different anodizing voltages were used in order to get different film thicknesses. Films formed in ammonium tartrate solution are much thinner, nonporous, and did not require sealing. The oxide films produced by anodization in ammonium tartrate are similar to the air formed oxides and consist essentially of γ-Al_2O_3. The thickness of oxides produced by anodizing in ammonium tartrate solutions were estimated from values reported by Hass (13).

Solutions for the kinetic studies of film breakdown and pit initiation were prepared from distilled water and reagent grade KCl, KOH, and H_2SO_4. The cell design was essentially identical to the one described previously (14). Solutions were deaerated by bubbling prepurified nitrogen prior and throughout each run. Additional purification was done by passing it through copper turnings heated at 500°C. Potential control was obtained by means of an electronic potentiostat. Potentials were measured against SCE using a vacuum tube millivoltmeter (high impedance). Current was measured by recording the potential drop across a standard resistor using a millivolt recorder. Temperature control was achieved either by means of a heat mantle fitted to the lower part of the cell or by using suitable cooling baths.

Since the aim of this investigation was to gain an understanding of the mechanism of nucleation of pitting, it was felt of particular significance to study the kinetics of film breakdown at the steady-state, critical pitting potential. The procedure was to anodically polarize the electrode, in steps of 10 to 20 mV,[3] after a rest period of a few minutes at the open-circuit potential. At each step the potential was kept constant at a given value, while the current was recorded continuously for as long as 24 hr and the electrode was then observed under a low power microscope for pitting. The potential at and above which pitting was observed was taken as the potentiostatic, critical pitting potential, E_c. It was also observed that at and above E_c, the current, after an initial induction period (τ) during which the current remained essentially constant, began and continued to increase with time, eventually reaching current values higher by two or more orders of magnitude. At potentials smaller than the critical, the current generally <1 μA/cm^2, remained essentially constant and pits were not observed. Reproducibility of the critical pitting potential was within about 10-15 mV. All potentials are reported with reference to the SCE.

To gain information regarding the kinetics of film breakdown and pit nucleation at the critical pitting potential, the induction time τ was determined experimentally as a function of Cl^- ion concentration, temperature, oxide film thickness, and solution pH. The induction time τ is defined as the initial period of time (generally a few minutes) at the critical pitting potential during which the anodic current (induction current) is very low and essentially constant, prior to a beginning of a continuous increase of current with time which eventually reaches current values higher than the induction current by two or more orders of magnitude as shown in Fig. 1.

The continuous increase of the over-all anodic current at the critical potential at times higher than τ is attributed to growth of minute pits initiated on a microscale during the induction time. As the minute pits grow the over-all, anodic current density, due to active metal dissolution at the very small pit or pits and the passive current passing through most of the electrode surface which remains passive, continues to increase with time as the size of pits grow and perhaps additional pits nucleate. The localized, anodic current density due to active metal dissolution at the small pit or pits is expected to be higher by several orders of magnitude as compared with the current density passing through the passive surface. It should be mentioned that pits could actually be observed under a low power microscope only after the electrode was maintained at the critical potential for an extended period of time beyond the induction time τ during which pits grew to sufficient size to be visible under the microscope.

In a typical experiment for the induction time determination, the preanodized aluminum electrode was introduced in the cell and its potential was set and maintained at the steady-state critical potential for pitting while the current was recorded continuously. The time required for the current to begin its sharp and continuous increase was measured as τ, the induction time for the oxide film breakdown and nucleation of pitting.

The measurement of the induction time τ for pit nucleation was not very reproducible. The poor reproducibility of the induction time for pit nucleation as seen by the spread of the experimental data points is probably due to several reasons, such as nonuniform thickness of the oxide film produced by anodization due to nonuniform current distribution on the specimen surface (edge effects), small variations in surface finish, and perhaps other oxide surface discontinuities. Since the induction time τ relates to the very precise process of current increase at the critical pitting potential, the relative accuracy of measuring τ is also affected by the uncertainty of 10-15 mV in reproducing the critical pitting potential (15). The reported, induction time data represent clearly defined values using specimens with carefully prepared surface finish, as described previously.

Results and Discussion

A typical experiment showing the variation of current with time at and below the critical pitting potential is shown in Fig. 1. The data were obtained with preanodized aluminum exposed to 3.0M KCl at 25°C.

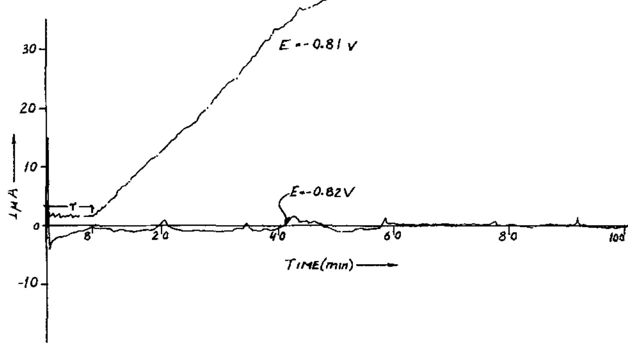

Fig. 1. Typical current-time curve for preanodized pure aluminum electrode potentiostated at −0.81 and −0.82V (SCE) in 3M KCl at 25°C.

[3] Prior to each potential setting, the electrode was subjected to new surface preparation (polishing, anodization, and sealing for specimens anodized in sulfuric acid).

The critical pitting potential in this case was −0.81V (SCE) and the induction time, τ, for pit nucleation was about 8 min. At the lower potential of −0.82V (SCE) the current remained relatively constant and very low and no pits were observed for up to 24 hr.

The dependence of the induction time on chloride ion concentration was measured at 25°C in the concentration range 0.01-3M KCl; the *p*H of these solutions was in the range 5.9-6.1. The data for a series of experiments with preanodized[4] aluminum are plotted in Fig. 2. The data show that the induction time for pit nucleation decreases from about 23 min in 0.01M KCl to about 4 min in 3M KCl. The slope, *n*, of the log 1/τ *vs.* log C_{Cl^-} line is approximately $n \simeq -0.1$ in the concentration range 0.01-1M KCl. At higher chloride ion concentrations the induction time appears to decrease rapidly as indicated by the approximate slope of $n \simeq -0.9$ which was drawn through the available experimental points. One may question the relative accuracy of the slopes drawn through the data points; the significant thing is not the precise value of the slopes but rather the general conclusion drawn from the data that in low Cl^- concentrations there is a very weak dependence of τ on KCl concentration but in higher KCl concentrations there is a tendency for higher dependence of τ on Cl^- concentration.

Temperature as might be expected has also considerable influence on the rate of pit nucleation as indicated by data on the temperature dependence of τ plotted in Fig. 3. This figure shows an Arrhenius-type plot for the temperature variation of τ of preanodized aluminum in 0.1M KCl solution. The plot shows an apparent activation energy of about 6.7 kcal/mole for the pit nucleation process.

The solution *p*H in the range 5-10, at constant chloride ion concentration, was found to have no effect

[4] Unless otherwise indicated, specimens were anodized for 1 min in 15% H_2SO_4 and sealed for 30 min in boiling distilled water.

on the rate of pit nucleation, as measured by the induction time. This is shown with the data plotted in Fig. 4. These data were obtained with preanodized aluminum in 0.1M KCl in the *p*H range 5-10. Solution *p*H was adjusted as required with either H_2SO_4 or KOH.

In order to study the influence of oxide film thickness on the rate of film breakdown and pit nucleation, a series of experiments was carried out with oxide films of a broad thickness range. Most oxide films on aluminum were prepared by anodization in 15% H_2SO_4 followed by sealing in distilled water as described in the experimental section. This procedure produced oxide films in the thickness range 0.8 to about 40μ. Several oxide films of considerably smaller thicknesses, in the range of 260-1300Å, were also produced by anodization in 3% ammonium tartrate solution.

The dependence of the incubation time τ for pit nucleation on the oxide film thickness is shown in Fig. 5. The data show essentially a linear dependence of τ on oxide film thickness. The data plotted in Fig. 5 were obtained in 0.1 and 3M KCl solutions with aluminum preanodized in H_2SO_4 and sealed in distilled water and in 0.1M KCl solutions with aluminum preanodized in 3% ammonium tartrate solution.

Table I shows the dependence of the steady-state, critical pitting potential on the thickness and structure of the oxide film. The data show that the critical pitting potential of specimens covered with oxide films in the thickness range of 0.026-0.130μ is essentially the same within the ±10-15 mV (experimental error) of the average value. However, in the case of much

0.1M KCl 25°C	Anodization in 15% H_2SO_4 and sealed in boiling dist. H_2O	0.79	−0.68

higher oxide film thickness (about 0.79μ) there is clear evidence that E_c increases with oxide film thickness. The apparent increase in E_c with oxide film thickness suggests that with increasing oxide film thickness, due to potential drop (pd) within the oxide film, a higher applied anodic potential is required to attain the minimum pd across the oxide-solution interface which is required to achieve the penetration of Cl^- through the electric double layer at the oxide-solution interface and its adsorption on the hydrated oxide surface.

Following the arguments of Engell and Stolica (16), Hoar and Jacob (17), and Bogar and Foley (18), it is assumed that $1/\tau$ is an approximate estimate of the rate of the limiting process leading to pit nucleation of aluminum. Then the slope of the straight lines in Fig. 2 is interpreted as the order n of the rate-determining step during pit initiation with respect to the concentration of chloride ion in solution.

The very weak dependence of τ on chloride ion concentration in dilute chloride solution, as shown in Fig. 2, and the low apparent activation energy of about 6.7 kcal/mol (Fig. 3) suggest that in dilute chloride solutions the rate-determining step in the process of pit initiation is likely to be a diffusion or adsorption step. Lattice diffusion of chloride ions through the aluminum oxide film via lattice defects or by place exchange of oxide ions and chloride ions would be energetically consistent with the measured activation energy and the weak dependence of τ on C_{Cl^-}, but the diffusion rate itself would be much too slow to account for the induction time observed (19).

If we suppose that the relationship between the concentration of Cl^- adsorbed on the hydrated oxide surface and the bulk solution is that of a Freundlich adsorption isotherm, and assuming that pitting is initiated at the critical pitting potential when a critical concentration of Cl^- is established at one or more sites on the hydrated oxide surface, then $1/\tau$ should be related to the bulk chloride ion concentration C according to the Freundlich adsorption isotherm. The data plotted in Fig. 2 in dilute solutions follow such a functional relationship

$$\frac{1}{\tau} \simeq k_1 C^{1/n'} \simeq k_1 C^n$$

where k_1 and $1/n'$ are constants of a Freundlich-type isotherm and n is the stoichiometric factor described previously.

In higher chloride ion concentrations, the induction time apparently decreases much faster with chloride ion concentration as indicated by the approximate dotted line slope of about $n \simeq -0.9$. The stronger dependence of τ on the bulk chloride ion concentration in concentrated KCl solutions suggests that the rate-determining step in the over-all process of passivity breakdown changes from a step involving adsorption from solution on the hydrated oxide surface to that of a chemical reaction on the hydrated oxide surface which involves approximately one Cl^- per aluminum cation.

The stoichiometric factor n obtained in this study for the pit initiation process of aluminum is considerably smaller than the values of 2.5-4.5 reported by Hoar and Jacob (17) for the breakdown of passivity in 18-8 stainless steel by chloride ion in sulfuric acid solution of pH 2.05, in the potential range of 0.4-0.8V (SHE). These authors also found an apparent activation energy of about 60 kcal/mole for the breakdown of passivity in acidic solutions. Values of n in the range 3.0-11.1 were also reported by Foley and Bogar (18) for pit initiation of aluminum alloys in sulfuric acid solutions containing chloride ions in the pH range 0.0-3.5. Their data on the temperature dependence of the breakdown process give apparent activation energies in the range of 22.9 kcal in pH 0.0 and 12.0 kcal/mole in pH 6.08. Reasons for the considerable difference in stoichiometric numbers n and activation energies between the present study and those of Foley and Bogar (18), Hoar and Jacob (17), and Engell and Stolika (16) are not known. It is assumed, however, that this difference is probably caused by the considerable difference in pH of the solutions used in the various breakdown experiments, and the difference in alloy and passive film compositions. This explanation is consisent with the decreasing stoichiometric number and apparent activation energy reported by Foley and Bogar (18) with increasing solution pH for the passivity breakdown process of an aluminum alloy potentiostated at 0.18V (SCE) in sulfuric acid solution.

General Discussion

Several mechanisms for the action of chloride ions to initiate pitting corrosion have been suggested in the literature. These include: (a) Cl^- penetration of the protective oxide film which covers the metal surface through pores or other weak places (1, 20, 21), (b) competitive adsorption of Cl^- and oxygen or OH^- for sites on the metal surface (22, 23), (c) migration of chloride ions inward through the oxide lattice (4), (d) peptization of the oxide film by a strong negative charge caused by adsorbed anions (5) and by dynamic breakdown-repair mechanism (7). Aluminum provides a good opportunity to evaluate the influence of an oxide on the process of pit initiation since well-known methods are available for preparing oxide films of different thicknesses and structure by anodization.

The results of the present study provide considerable experimental evidence to test the various mechanisms for passivity breakdown and initiation of pitting in nearly neutral solutions by chloride ions.

Chloride ion migration through pores or other weak places in the oxide film (1, 20, 21) followed by competitive adsorption between chloride ions and adsorbed oxygen or hydroxyl ions at the metal/solution interface as a mechanism of pit initiation (22, 23) is an unlikely mechanism for several reasons. Migration of Cl^- through pores or other weak spots in the oxide film as the rate-determining step can be ruled out, since by treating the aluminum specimens as a porous electrode it can be shown (24) that the mass transport limiting current for a porous and a corresponding flat electrode are the same both being determined by mass transport in the hydrodynamic layer outside the electrode. Furthermore, it is considered unlikely that continuous pores through the oxide film to the bare aluminum surface are present in oxide films prepared by anodization in ammonium tartrate or in H_2SO_4 with subsequent sealing.

Competitive adsorption (22, 23) between chloride ions and adsorbed oxygen or OH^- on a bare metal surface is also considered an unlikely mechanism. There is abundant evidence that aluminum metal (even without a thick barrier-type film) in neutral solutions is covered with a thin persistent and fairly protective film of aluminum oxide (25). A dynamic passivity breakdown-repair mechanism (7) which attributes to the Cl^- the role of inhibiting repassivation rather than promoting passivity breakdown, cannot account for the observed increase in induction time τ with the thickness of the oxide film. The passivity breakdown-repair mechanism (7) conceptually is similar to the com-

petitive adsorption mechanism (22, 23) and assumes in essence competitive adsorption between Cl^- and OH^- (or H_2O) on the metal surface as the rate-limiting process of pit nucleation. If this were the rate-limiting process in pit nucleation, the induction time should be independent of the thickness of the oxide film (which must in some way be "penetrated" before Cl^- can adsorb on the bare metal surface). This, of course, is contrary to the data shown in Fig. 5, which indicate that the induction time increases with oxide film thickness.

Migration of chloride ions inward through lattice diffusion, as discussed previously, is much too slow to account for the induction time observed (19).

The kinetic data presented in this paper are consistent with a pit nucleation model (26) which involves field-assisted adsorption of chloride ions from solution on the hydrated oxide surface followed by oxide dissolution as the rate-determining steps in the process of passivity breakdown and pit nucleation of aluminum in nearly neutral solutions. The over-all passivity breakdown and nucleation of pits according to this model involves the following sequence of reaction steps: (*a*) adsorption of Cl^- on the oxide-solution interface under the influence of the electric field (at the oxide-solution interface) in competition with OH^- or H_2O molecules for surface sites on the hydrated oxide surface; (*b*) formation of a basic hydroxychloride aluminum salt with aluminum oxide cations on the hydrated oxide surface, which immediately separates from the oxide lattice and readily goes in solution.

It is suggested that a probable reaction describing formation of such a readily soluble basic chloride aluminum salt is reaction [2]

$$Al(OH)_3 \rightleftarrows Al(OH)_2^+ + OH^- \quad [1]$$

$$Al(OH)_2^+ + Cl^- \rightarrow Al(OH)_2Cl \quad [2]$$

Reaction [1] describes the ionization of the hydrated aluminum oxide surface in nearly neutral solution. This reaction accounts for the positive charge on the hydrated oxide surface as indicated by ζ potential measurements (27-29).

This process of field assisted Cl^- adsorption on the hydrated oxide surface and formation of a soluble aluminum chloride salt leading to localized oxide dissolution will have a high probability of repeating itself at the same site, since at constant anode potential the applied field at the oxide-solution interface will tend to be stronger at the "thinned" point of the oxide film. Thus, the process of localized dissolution of the oxide film via the formation of a basic chloride aluminum salt ($Al(OH)_2Cl$) is likely to continue until the oxide film is locally dissolved; once the oxide film is locally "dissolved," dissolution of the substrate metal begins and the anodic current density at the very small pit or pits increases by several orders of magnitude compared with the current density of the passivated surface.

Localized dissolution of the oxide (leading to pitting of the underlying metal), rather than general dissolution of the oxide film occurs at the critical pitting potential because of the "autocatalytic" character of the localized oxide film dissolution at the critical pitting potential. Once a critical concentration of chloride ions is adsorbed on a particular site on the hydrated oxide surface via this mechanism (26), and one or more, adjacent, aluminum oxide lattice cations are transformed to chloride-containing soluble salts, they are likely to immediately separate from the oxide cations in the lattice and go in solution.[5] The probability of this localized oxide dissolution to continue on the same sites is considerable because of the higher potential drop (pd) at the oxide-solution interface (under constant, applied anodic potential) expected on these sites.

[5] It is worth noting that the solubility of hydrated aluminum oxide cations present in the film without the participation of the activating chloride ions is considerably lower; the very low rate of dissolution in this case is uniform thoughout the oxide surface.

This argument implies that preferential sites for pit initiation are likely to be areas of oxide surface defects such as scratch lines, voids or other surface flaws where the oxide thickness is smaller than in adjacent areas and therefore the pd across the oxide-solution interface is higher (30).

The question may be raised as to why the high field across the oxide film would not rapidly repair the film in areas where it is locally thinned by dissolution and thereby prevent film breakdown. The answer to this lies in the supposition that on the oxide-solution interface a competition exists between Cl^- and OH^- (or H_2O molecules) for oxide surface sites. Once oxide dissolution is initiated via the proposed mechanism, a high probability exists that as aluminum cations advance through the oxide film at the thinned points of the film (under the influence of the field across the oxide film) instead of oxide forming OH^- or H_2O molecules, they are likely to meet Cl^- and OH^- so that a high probability exists for formation of a readily soluble aluminum hydroxychloride salt rather than an insoluble aqueoaluminum complex required for oxide film repair.

In low chloride ion concentrations adsorption of chloride ions, from solution, on the hydrated aluminum oxide surface under the influence of the field at the oxide-solution interface is assumed to be the rate-determining step in the process of passivity breakdown. In higher chloride ion concentrations, the reaction step leading to formation and dissolution of the hydroxychloride aluminum salt on the hydrated oxide surface is likely to become the rate-determining step in the process of pit initiation.

The induction time for passivity breakdown and pit initiation according to the proposed mechanism is a direct measure of the rate of the localized dissolution of the passive aluminum oxide film via the sequence of Cl^- adsorption and formation of a readily soluble chloride containing aluminum salt (Eq. [2]).

On this basis, it is expected that the induction time τ for pit initiation should increase with the thickness of the oxide film. Data plotted in Fig. 5 on the dependence of the induction time for preanodized aluminum on oxide film thickness show that τ increases with oxide thickness following essentially a linear dependence.

The hypothesis in the proposed mechanism that a readily soluble, chloride-containing aluminum salt is locally formed on the solution side of the aluminum oxide surface, once the chloride ions under the influence of the applied anodic potential have penetrated the electric double layer at the oxide-solution interface and adsorbed on the hydrated oxide surface, is consistent with literature data (31, 32) indicating that hydrated aluminum oxides form soluble aluminum salts in acidic or nearly neutral aqueous solutions containing chloride ions.

Rate of Propagation of Growth Layers on Cubic Crystal Faces in Electrocrystallization of Silver

V. Bostanov, G. Staikov, and D. K. Roe*,[1]

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia, Bulgaria

ABSTRACT

The advancement rate of mono- and polyatomic growth steps was measured on perfect, screw dislocation-free cubic faces of silver single crystals during electrocrystallization of silver. For low overvoltages, a linear dependence of the rate on overvoltage was found. It was established that the advancement rate of the steps depends on the surface conditions of the crystal face and is about two times larger on a "fresh" surface than on an "aged" one. It was also found that mono- and polyatomic steps advance with the same rate on a fresh surface. A polyatomic step is considered as a ledge composed of monoatomic steps. The ledge spacing of this composite step was estimated. On the basis of these experimental results as well as on the experimentally determined value of the exchange current of adatoms with metal ions of the electrolyte, it is concluded that the electrolytic deposition of silver in 6M solution of silver nitrate is carried out according to the direct transfer mechanism. The value of the exchange current of the edge atoms at the steps with ions of the electrolyte was determined to be $i_{o,st} = 200$ A·cm^{-2} for an aged surface and $i_{o,st} = 370$ A·cm^{-2} for a fresh surface.

The kinetics of growth of an equilibrium-form, close packed crystal face depends on the rate of advancement of the growth steps on its surface. The theory of electrocrystallization assumes two basic mechanisms of step growth offered by Volmer (1) and Brandes (2): the direct transfer mechanism and the surface diffusion mechanism. According to the first, the ionic transfer onto the crystal surface through the double layer occurs directly at the kink sites of the steps. The ions are discharged and incorporated simultaneously into the crystal lattice. According to the second mechanism the transfer is carried out on completely built areas of the surface. Here the ions discharge and remain adsorbed (adatoms) for a certain period of time. By surface diffusion the adatoms can reach the kink sites and be incorporated into the crystal lattice.

The dependence of the current density, i (A·cm^{-2}), on the overvoltage, η, in the case of surface diffusion was derived for the first time by Lorenz (3) and has the form

$$i = i_{o,ad}[e^{\alpha z F\eta/RT} - e^{-(1-\alpha)zF\eta/RT}] \frac{\lambda_o}{x_o} \tanh \frac{x_o}{\lambda_o} \quad [1]$$

In this equation, $i_{o,ad}$ (A·cm^{-2}) is the exchange current density of the adatoms with the metal ions of the electrolyte; $2x_o$ (cm) is the average distance between the monoatomic steps which can also be given by the total step length L_s (cm·cm^{-2}) per unit area; λ_o(cm), the surface diffusion penetration, is defined by

$$\lambda_o = (zFD_s c^o_{ad}/i_{o,ad})^{1/2} e^{-\alpha zF\eta/2RT}$$

where D_s (cm^2·sec^{-1}) is the surface diffusion coeffi-

* Electrochemical Society Active Member.

[1] Present address: Chemistry Department, Portland State University, Portland, Oregon 97207.

Key words: crystal growth, electrocrystallization, silver single crystal, growth layer propagation.

cient and c^{o}_{ad} (mol·cm^{-2}) the equilibrium adatom concentration.

In the case of direct transfer the dependence of the current density on overvoltage is described by a Volmer-type equation

$$i = i_{o,st}\delta L_s[e^{\alpha zF\eta/RT} - e^{-(1-\alpha)zF\eta/RT}] \quad [2]$$

here $i_{o,st}$ (A·cm^{-2}) is the exchange current density of the edge atoms of the monoatomic step with the metal ions of the electrolyte and δ (cm) is the width of an atomic row in the crystal lattice parallel to the step.

The normal velocity of step growth or the advancement rate of the step v (cm·sec^{-1}) and the current density are connected in the relation

$$v = iv_M/zFhL_s \quad [3]$$

where v_M (cm^3·mol^{-1}) is the molar volume and h (cm) is the height of a monoatomic step. For low overvoltages, under the assumption that the surface diffusion penetration is small as compared to the average step half-distance, $\lambda_o/x_o << 1$, from Eq. [1] and [2] one obtains a linear dependence of the current density on step length and overvoltage

$$i = \kappa L_s \eta \quad [4]$$

where the constant κ (ohm^{-1}·cm^{-1}) is given by

$$\kappa = i_{o,ad}2\lambda_o zF/RT \quad [5]$$

for surface diffusion, and

$$\kappa = i_{o,st}\delta zF/RT \quad [6]$$

for direct transfer. Under these conditions the advancement rate of the steps is linearly dependent on overvoltage

$$v = k_v \eta \quad [7]$$

where the advancement rate constant k_v (cm·sec^{-1}-V^{-1}) is given by

$$k_v = \kappa v_M/zFh \quad [8]$$

Experimental

The advancement rate of growth steps in electrocrystallization of silver was studied on perfect, dislocation-free, (100) crystal faces. These were obtained by the capillary method described in detail earlier (4, 5). The essence of the method is the electrolytic growth of a silver single crystal in a capillary along a definite crystallographic axis. If this axis is <100>, a (100) face would appear as a frontal face of the single-crystal filament. Under specified conditions of electrolysis, the face may fill up the whole cross section of the capillary. These conditions require high purity of the electrolyte, high concentration of silver ions, and, above all, modulation of the direct current of growth with an alternating 50 Hz current. At slow growth conditions of the single-crystal filament (20 mA·cm^{-2}) and a suitably chosen amplitude of the alternating current, the number of screw dislocations intersecting the front face gradually decreases and a perfect face can be obtained.

It was experimentally shown that dislocation-free (100) faces grow by two-dimensional nuclei (5), in agreement with the theory of crystal growth. The critical overvoltage for the nucleation process is about 6 mV, and if an overpotential lower than this value is applied, charge flow through the electrolytic cell is not observed. A potentiostatic pulse with suitable amplitude and duration (*e.g.*, 12 mV, 100 μsec) leads to the creation of only one nucleus. If after the pulse the face remains at a potential lower than the critical overvoltage, current flows through the cell, passing through a maximum and subsequently decreasing to zero. This current is connected with the growth of the newly formed monolayer and is proportional to the length of growing monoatomic step, in accordance with Eq. [4]. The value of the constant κ in this equation may be determined from the current-time curves following nucleation overvoltage pulses which produce different supersaturations. The round shape of the face complicates this task. The experiment is considerably simplified if the crystal face has the shape of an elongated rectangle.

Rate of Propagation and Form of Monoatomic Layers

The capillary method was developed using capillaries with round cross section. Crystal faces filling up the entire cross section and free of screw dislocations can also be obtained in capillaries with a rectangular cross section (*e.g.*, 400 × 100 μm) (6). At constant rate of growth of a monoatamic layer on a perfect face with rectangular form, a plateau should be expected in the current-time curve, since after a definite time interval a step would be advancing along the face with a constant length. This was experimentally confirmed and Fig. 1 represents three characteristic experimental current-time curves at constant overvoltage.

As shown in Fig. 2, the value of the growth current of a monoatomic step with constant length is linearly dependent on overvoltage, according to Eq. [4]. However, to determine exactly the constant κ in Eq. [4], one should know the step length. Besides on the capillary width, the step length depends also on the form of the monoatomic layer, or whether the layer is round or polygonized. If polygonized, it would also depend on the orientation of the layer, *i.e.*, on the orientation of the seed crystal with respect to the capillary cross section. In Fig. 2 the straight line a refers to the case when the long axis of the rectangular section of the capillary is parallel to the crystallographic direction <100>, and the straight line b, when this axis is parallel to the direction <110>. The slopes of both straight lines differ by $\sqrt{2}$. Therefore it can be concluded that

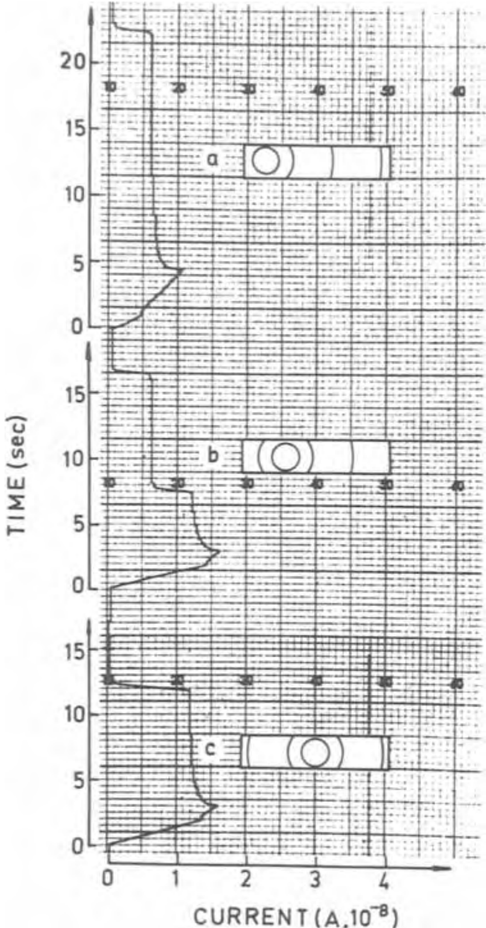

Fig. 1. Current-time curves at 3 mV overvoltage following a nucleation overvoltage pulse on a perfect (100) face with rectangular form (0.1 × 0.4 mm). The probable site of nucleation is schematically indicated in each case.

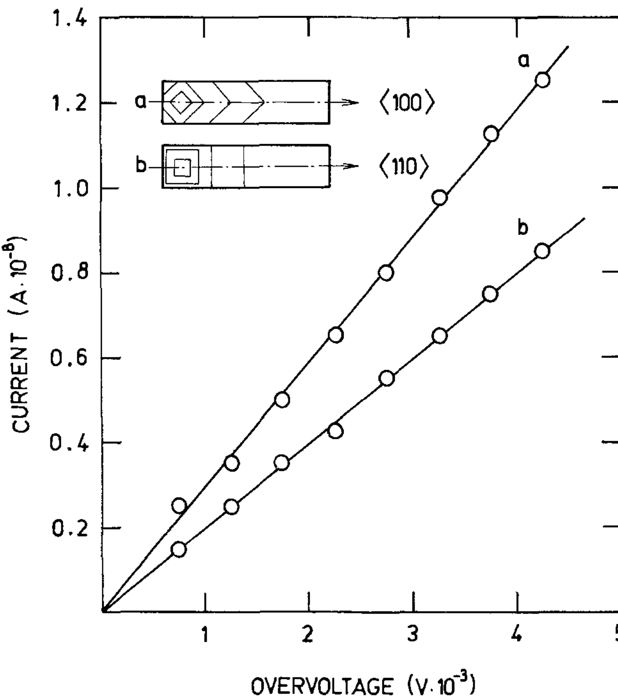

Fig. 2. The stationary value of the current (Fig. 1) as dependent on overvoltage, for two orientations of the seed crystal in respect to the rectangular cross section of the capillary: straight line a, the longitudinal axis of the cross section coincides with the direction 100; straight line b, with the direction 110.

the monoatomic layers are polygonized and have a square form and that the growth steps are parallel to the crystallographic direction <110>. So the step length is known and the constant κ in Eq. [4] can be exactly calculated. At 45°C and in 6M solution of $AgNO_3$ the value obtained is $\kappa = 2 \cdot 10^{-4}$ ohm$^{-1}\cdot$cm^{-1}. The advancement rate constant k_v can be obtained from this constant, according to Eq. [8] and is $k_v = 1.0$ cm·sec$^{-1}\cdot$V^{-1}.

Rate of Propagation of Polyatomic Layers

On a dislocation-free (100) face the rate of propagation of polyatomic layers was now studied. Polyatomic layers sometimes originate after an overvoltage pulse having higher amplitude and longer duration (*e.g.*, 50-60 mV, several milliseconds).

At higher overvoltages a dislocation-free face grows according to the multinuclear, multilayer growth mechanism (7, 8). During the pulse action several tens of monoatomic layers are deposited on its surface. After the pulse the face surface has a complex relief, comprising several lattice planes. Under the action of a low overvoltage applied after the pulse, the face begins to flatten and the current drops slowly to zero.

The crystal face is generally expected to be homogeneous in respect to the process of two-dimensional nucleation. The surface becomes then randomly rough during and immediately after the pulse. In some cases, however, on a specific, more "active" center the nucleation proceeds with a higher rate resulting in a more pronounced hillock at this site. During the subsequent flattening this hillock gives the origin of a polyatomic front of growth. By means of the interference contrast device after Nomarski, this front, if sufficiently thick, is already visible under the microscope as a strip advancing on the face. The current accompanying the process during the flattening stabilizes to a stationary value proportional to the front length and thickness, Fig. 3. This growth front can be considered either as a single polyatomic ledge or as a composite step consisting of several monoatomic layers.

The advancement rate of such steps was measured as described below. After the stabilization of the current at the stationary value two flash light pictures

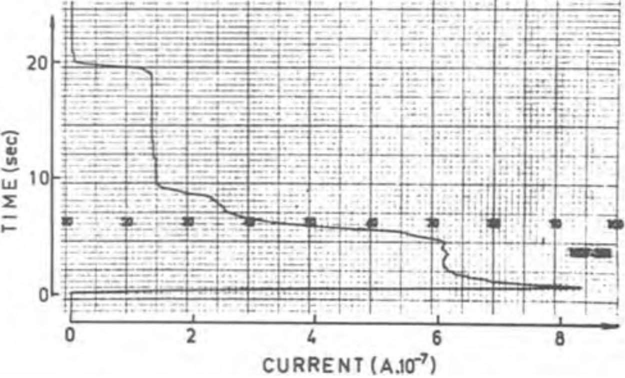

Fig. 3. Current-time curve following an overvoltage pulse with amplitude 60 mV and duration 5 msec on a perfect (100) face with rectangular form. The stationary value of the current results from the growth of a visible in the microscope polyatomic step retaining a constant length.

are taken in sequence on the same frame. With the first flash an electronic chronometer is triggered which is stopped by the second one. A picture made in this way is shown in Fig. 4. Two positions of the growth step are clearly fixed by the two consecutive flash exposures. The distance traveled by the step for the time interval between the flash exposures can be measured quite accurately. The time interval is indicated by the chronometer so that the rate of advancement of the step is directly determined. From the rate of advancement and the stationary value of the current (Fig. 3), the height of the polyatomic step is evaluated.

Using the interference contrast after Nomarski, steps higher than 10Å (equivalent to 5 monoatamic layers) can be visually detected, while steps above 30Å can be photographed, as shown in Fig. 4. It was also found that independently of their thickness, steps up to 80Å advance with the same velocity. A measurable decrease in the velocity is observed only for steps higher than 100Å. Figure 5 shows the dependence of the advancement rate of steps 30-80Å high on overvoltage. From the slope of the straight line the value of the constant k_v in Eq. [7], $k_v = 1.9$ cm·sec$^{-1}\cdot$V^{-1} is obtained. The value of k_v is roughly two times higher than the value obtained for monoatomic steps. This unexpected difference can be explained by the assumption that the polyatomic steps under the conditions of their creation advance on a "refreshed" surface. Immediately before their origination during the high amplitude pulse, several tens of monoatomic layers have been deposited on the face obviously refreshing the surface. This assumption is confirmed by the fact that if the surface prior to the creation of a mono-

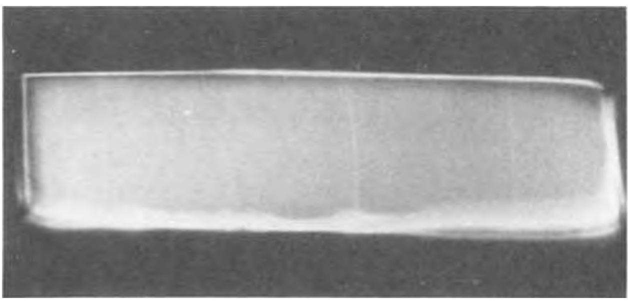

Fig. 4. Two overlapping flashlight photographs of a perfect (100) crystal face in a glass capillary with rectangular form of the cross section (0.1 × 0.4 mm). The two bright strips represent the polyatomic step with height 30Å advancing along the face in the moment of the first and the second photographs.

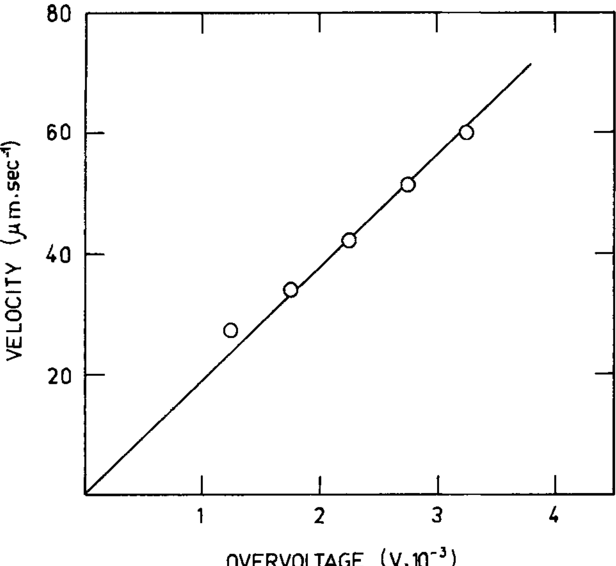

Fig. 5. The dependence of the rate of advancement of polyatomic steps up to 80Å high on overvoltage.

atomic layer is refreshed by a high amplitude pulse as described above, one obtains the curve a in Fig. 6, instead of the curve b observed on an aged surface. It is readily seen that the slope of curve a is nearly two times higher than that of curve b. From the slope of curve a one obtains $\kappa = 3.7 \cdot 10^{-4}$ $ohm^{-1} \cdot cm^{-1}$, and for k_v 1.9 $cm \cdot sec^{-1} \cdot V^{-1}$ which is equal to the value found for a polyatomic step.

It is interesting to note that by the propagation of monoatomic layers the surface is not refreshed. Such a refreshing occurs only when more than several tens of layers are deposited simultaneously.

Ledge Spacing in a Composite Polyatomic Step

As already mentioned, a growing polyatomic step can be considered as a "train" of parallel monoatomic steps By means of the interference contrast device the polyatomic step is seen under the microscope as a darker or brighter thin strip. The width of the strip on this interferential picture is not related in a simple manner to the width of the step train.

The advancement rate of the polyatomic step at constant overvoltage is known. The step height is determined by the rate and the growth current. Then the average ledge spacing can be determined from the time required for disappearance of the ledge into the capillary wall which is strictly parallel to it. This time can be measured from the current drop to zero accompanying the ledge disappearance. As has been demonstrated, the ledges are parallel to the crystallographic direction <110> and advance toward the narrow capillary wall. To orientate the seed crystal so that the direction <110> is strictly parallel to these walls is a very difficult task. This difficulty can be overcome if, instead of in the capillary wall, the ledge is made to disappear in a crystal edge parallel to it. This can be easily achieved if the crystal face filling up the capillary cross section is grown for a specified time by a suitably modulated direct current at which its dimensions begin to decrease. Between the crystal face and the narrow capillary walls crystal edges and dislocation-free (111) faces of small dimensions appear. Figure 7 shows an experimental curve of the current drop recorded at the disappearing of a polyatomic step in a crystal edge. From the curve the average ledge spacing $2x_0$ at the step train is determined to 160Å.

It should be noted that the above estimation indicates the maximum possible value of the average ledge spacing. This distance can in fact be smaller because any deviation of the ledge from a straight line parallel to the edge increases the time of disappearance of the polyatomic steps. For example the curve in Fig. 7 can be obtained from a very steep polyatomic step curved in an arc with a radius of 2.5 mm, *i.e.*, with side wings advancing only 0.5 μm after the central part of the step. It is obvious that it is impossible to determine a curvature of this magnitude and hence it is excluded in the observation conditions of our case. In fact in many cases longer periods of ledge disappearance have been observed which are obviously connected with an already visible curvature or any other irregularity of the ledge.

Mechanism of Electrolytic Deposition of Silver

As shown above, on a "fresh" surface the monoatomic and all polyatomic steps with a height up to 80Å advance with one and the same rate. The average ledge spacing in some of the polyatomic steps does not exceed 160Å. From these two relevant experimental findings a conclusion elucidating the mechanism of electrolytic deposition of silver can be drawn.

The rate of advancement of the growth steps does not depend at all on the step distance if the metal ions are directly incorporated in kink sites along the steps. If the crystal lattice is built up by surface diffu-

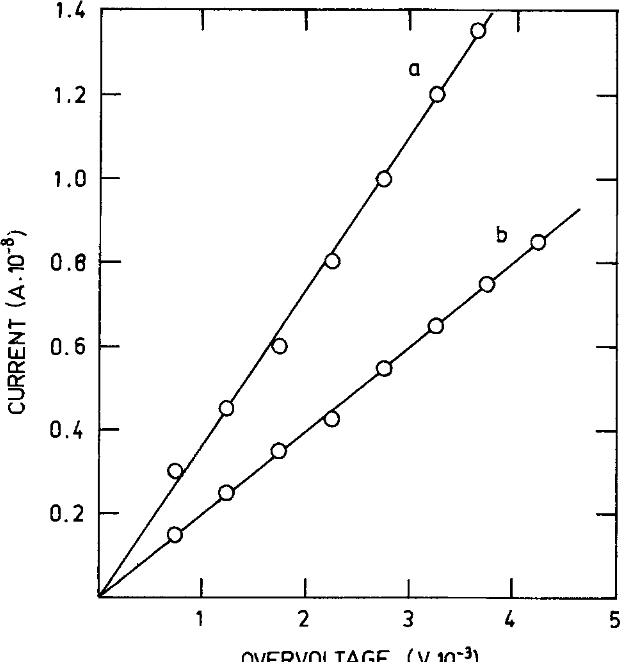

Fig. 6. Current (stationary value)-overvoltage curve at the growth of a monoatomic layer. The straight line a refers to a fresh surface; and b, to an aged surface.

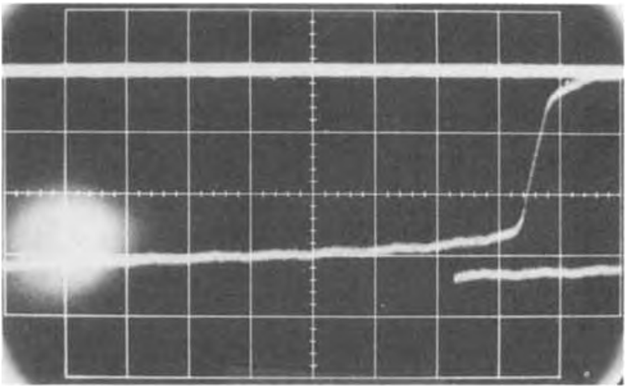

Fig. 7. Curve of current drop to zero, accompanying the disappearance of the polyatomic step in a crystal edge parallel to it. Height of the step, 61Å (30 monoatomic layers); rate of advancement, $48 \cdot 10^{-4}$ $cm \cdot sec^{-1}$ (overvoltage 2.5 mV). Vertical sensitivity, $1 \cdot 10^{-7}$ $A \cdot cm^{-1}$, time base, 20 $msec \cdot cm^{-1}$.

sion of adatoms, the advancement rate of the steps does not depend on the distance between them only if the depth of the surface diffusion penetration is small compared to the average half-distance between the steps, $\lambda_o/x_o << 1$. Obviously, if one assumes the surface diffusion mechanism of deposition of silver, λ_o must be $\leqq 80\text{Å}$

The constant κ of Eq. [4] in the case of surface diffusion mechanism is given by Eq. [5] and contains $i_{o,ad}$ and λ_o. Under experimental conditions similar to ours, the exchange current $i_{o,ad}$ for crystal (100) face has been determined by high frequency impedance measurements on a perfect completely built up aged face and was found to be $i_{o,ad} = 0.06\ A \cdot cm^{-2}$ (9). Preliminary impedance measurements carried out now on a fresh crystal face lead to the conclusion that the value of the exchange current of the adatoms is smaller than the one for aged surface. The value of λ_o is unknown but it is not larger than 80Å. If the constant κ is now evaluated with these values of $i_{o,ad}$ and λ_o, one obtains $\kappa = 3.5 \cdot 10^{-6}\ ohm^{-1} \cdot cm^{-1}$ which is two orders of magnitude smaller than the one experimentally observed here. It follows therefore that the electrolytic deposition of silver occurs almost exclusively by direct incorporation. The contribution of the surface diffusion would not exceed 1%. From the experimentally found values of κ, according to Eq. [6], for the exchange current of the step edge atoms with metal ions in the electrolyte two values were found: $i_{o,st} = 200\ A \cdot cm^{-2}$ for an aged surface and $i_{o,st} = 370\ A \cdot cm^{-2}$ for a fresh one.

This conclusion pertaining to the mechanism of electrolytic deposition of silver was made by Vitanov, Popov, and Budevski (10) on the basis of: (*i*) the results of impedance measurements at high frequency on a (100) face, atomically smooth (9) and with a surface relief defined by spiral growth (10); (*ii*) the results of the experimental check of the theory of spiral growth by the electrocrystallization of silver of a (100) face (11). The value of the exchange current determined by these authors is $i_{o,st} = 170\ A \cdot cm^{-2}$ and refers to an aged surface. This value is very close to the one $i_{o,st} = 200\ A \cdot cm^{-2}$, given here for the same surface.

Compensation of Ohmic Potential Interactions Occurring at Ring-Disk Electrodes

Mani Shabrang* and Stanley Bruckenstein**

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

Pseudocollection and inverse pseudocollection effects caused by potential drops at ring-disk electrodes can be eliminated by positive feedback. A potential proportional to a fraction of the disk electrode current is fed back to the ring electrode potentiostat, eliminating changes in ring potential and current that arise due to the variations of the disk electrode potential and current. Analogously, feedback of a potential proportional to a fraction of the ring current to the disk electrode potentiostat prevents variations of disk electrode potential and current that are due to the variations in ring electrode potential and current. The two positive feedback networks function independently and no *a priori* knowledge of the uncompensated resistance is required.

Many investigators have considered the problems of positive feedback compensation of the ohmic potential drop that exists in an electrochemical cell between the working and the reference electrode (1-10). Roe (11) and Nicholson (12) have summarized recent work on this subject while Smith (13) has reviewed work prior to 1972. In all these studies the ohmic potential drop occurred between the reference electrode and a single working electrode. Two working electrodes exist when a rotating ring-disk electrode (RRDE) is used, and some unique ohmic potential compensation problems can arise in an electrochemical cell having a RRDE.

Recently an equivalent circuit for the uncompensated primary resistances existing at a RRDE was proposed by us (14). The validity of this circuit was veri-

fied, and the circuit is shown within the circled region of Fig. 1. Point T represents the tip of the Luggin capillary leading to the reference electrode. The tip's location in the electrochemical cell determines its effective position on three of the resistors making up the equivalent circuit. In this paper we are concerned with treating the case in which the tip lies on the R_C, the resistance that is common to the current path between the Luggin capillary tip and the two working electrodes, the ring and the disk. In Fig. 1, R_{aux} represents the resistor between the Luggin capillary tip and the auxillary electrode. The total uncompensated resistance between the capillary tip and the disk electrode is $R_C + R_D$, and is $R_C + R_R$ between the capillary tip and the ring electrode. E_D, E_R, and E_{Ref} represent the half-cell potentials of the disk, ring electrode, and reference electrode, respectively, and include all the impedances characteristic of the electrode processes that are occurring. I_D and I_R are the corresponding disk and ring electrode currents, and no current flows through the reference electrode.

Full compensation for the total uncompensated ohmic potential drops between the Luggin capillary and the ring and disk electrodes is not considered in this paper. Full compensation is an elusive concept when dealing with working electrodes that have non-uniform current distributions such as those that can exist at disk, ring, and other electrode geometries. Under such circumstances positive feedback circuitry cannot compensate for the nonuniform potential distribution that is inherent to the electrolysis cell.

The ohmic potential drop dealt with in this paper is associated with the flow of current through resistor R_C, the resistor common to the ring and disk electrodes. The pseudocollection effect (14) is the term we have used to represent the current phenomena occurring at the ring electrode produced as a result of varying uncompensated potential drops associated with a changing disk electrode current. Conversely, the inverse pseudocollection effect coresponds to the current phenomena produced at the disk electrode as a result of varying uncompensated ohmic potential drops produced by varying ring electrode currents.

Appropriate positive feedback compensation has the effect of repositioning the Luggin capillary at point O of Fig. 1 and thus eliminates the pseudocollection effect and the inverse pseudocollection effect. This kind of feedback compensation involves only partial compensation of the total ohmic potential drop and does not give rise to any of the conceptual difficulties associated with full compensation in the presence of a nonuniform current density, nor are there experimental problems of potentiostat stability which arise when full compensation of an ohmic potential drop at an electrode is attempted.

Experimental

Reagents.—Solutions of 0.01*M* sulfuric acid were prepared from triply distilled water and a Baker reagent grade sulfuric acid.

Cell.—The glass cell and the auxiliary equipment are described elsewhere (15, 16).

Electrodes.—The four electrodes used in the experiments were: electrode I, a platinum-ring platinum-disk with a diameter, d_1, of 7.6 mm and ring-inner diameter, d_2, of 8.0 mm and ring-outer diameter, d_3, of 8.4 mm; electrode II, a platinum-ring gold-disk with d_1 = 7.6 mm, d_2 = 8.0 mm, and d_3 = 11.0 mm; electrode III, a gold-ring platinum-disk with d_1 = 7.6 mm,

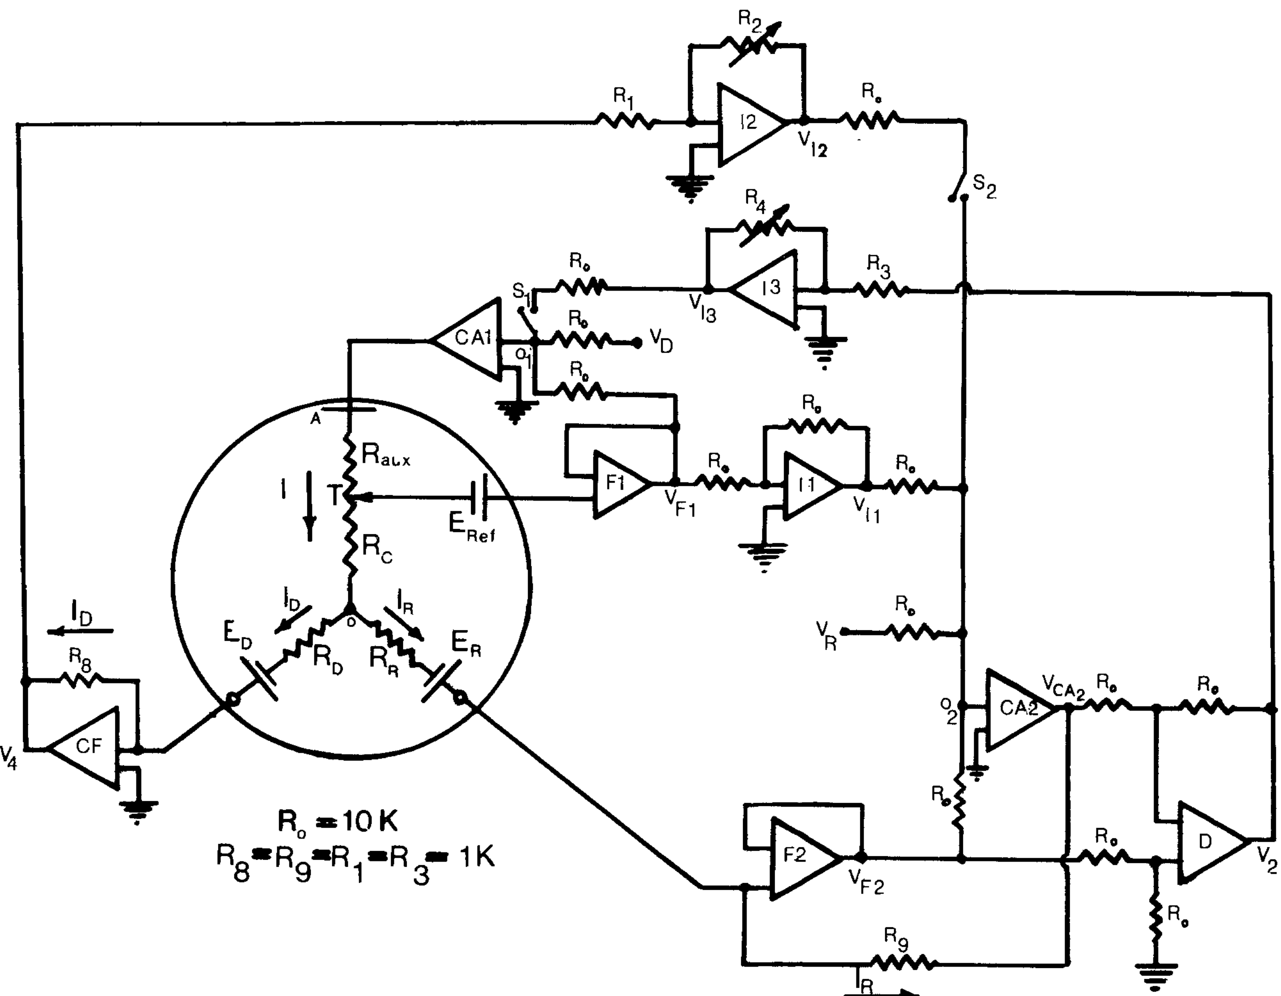

Fig. 1. Conventional four-electrode potentiostat with the additional positive feedback network. The equivalent circuit for the uncompensated ohmic resistance at ring-disk electrodes is enclosed by the circle.

$d_2 = 8.0$ mm, and $d_3 = 11.0$ mm; and electrode IV, a gold-ring gold-disk with $d_1 = 7.6$ mm, $d_2 = 8.0$ mm, and $d_3 = 8.4$ mm. Teflon was used as the insulating material for all electrodes.

These electrodes were electrochemically pretreated before each experiment, as discussed in Ref. (17), and were all polished to a final mirror finish using 0.05μ alumina on Buehler microcloth.

Instrumentation.—A conventional four-electrode analog instrument for independent potentiostatic control of the ring and the disk was used (18-20), and the *I-E* curves obtained were recorded on an EA1, X-Y-Y' 1131 Variplotter, Model 141 A. Analog Devices operational amplifiers were used in the positive feedback networks.

The operational amplifier instrument for independent galvanostatic control of the ring and the disk used for the common resistance measurement is described elsewhere (14).

A Heathkit Model IG-18 function generator was used to supply the a-c signal.

All potentials were measured and reported *vs.* the saturated calomel electrode. Experiments were run at 25°C. The Luggin capillary was positioned, by eye, to lie on the axis of rotation, unless otherwise stated.

Theoretical

Four electrode potentiostat with finite cell resistance.—Consider Fig. 1, which includes the electronic schematic and the ring-disk electrode equivalent circuit. We intend to obtain the expression for the disk electrode potential *vs.* the reference electrode, $E_D - E_{Ref}$, and the ring electrode potential *vs.* the reference electrode $E_R - E_{Ref}$, in terms of various currents and cell resistances, and the voltages applied to control amplifiers CA1 and CA2. It is instructive to consider the original four electrode potentiostatic circuit first, *i.e.*, S-1 and S-2 open, before undertaking the analysis of circuit with positive feedback, since this analysis was not given earlier (18).

No-ohmic drop compensation.—Disk electrode.—If switches S-1 and S-2 are open, the circuit corresponds to a slightly modified version of the original by Johnson, Napp, and Bruckenstein (18). The various relations of interest in obtaining the disk potential control function are:

summing point restraint at CA1

$$V_{F1} + V_D = 0 \qquad [1]$$

and the output of the voltage follower, F1

$$V_{F1} = E_D - E_{Ref} + I_D R_C + I_R R_C + I_D R_D \qquad [2]$$

Defining

$$E_D^* \equiv E_{Ref} - E_D \qquad [3]$$

we obtain

$$E_D^* = V_D + I_D(R_C + R_D) + I_R R_C \qquad [4]$$

and we see that the disk potential contains an uncompensated ohmic resistance, R_C, through which the ring electrode current passes. Changes in the ring current will therefore produce changes in the disk potential even though V_D is held constant. The partial derivative

$$\left(\frac{\partial E_D^*}{\partial I_R}\right)_{I_D} = R_C \qquad [6]$$

is a convenient measure of this resistance, which we term the inverse pseudocollection resistance.

Ring electrode.—The various relations of interest in obtaining the ring electrode potential control functions are the summing point restraint at CA2

$$V_{F2} + V_R + V_{I1} = 0 \qquad [7]$$

the output of voltage follower 2

$$V_{F2} = E_D - E_R - I_R R_R + I_D R_D \qquad [8]$$

the output of I1

$$V_{I1} = -V_{F1} \qquad [9]$$

and the output of F_1 given by Eq. [2] above. Defining

$$E_R^* \equiv E_{Ref} - E_R \qquad [10]$$

and solving for E_R^* using Eq. [2] and [7]-[9], yields

$$E_R^* = -V_R + I_R(R_C + R_R) + I_D R_C \qquad [11]$$

Thus, we see that there is an uncompensated resistance through which the disk electrode current can affect the ring potential. This resistance R_C is given by

$$\left(\frac{\partial E_R^*}{\partial I_D}\right)_{I_R} = R_C \qquad [12]$$

and is termed the pseudocollection resistance.

The pseudo and inverse pseudocollection resistances are identical, hence, the magnitude of the pseudo and inverse pseudocollection effects for a given value of R_C depend on slope of the current-potential curves at the ring and disk electrodes and the remaining uncompensated potential drops at these two indicator electrodes. For example, if the ring electrode is set on the rising portion of a current-potential curve, variations of the disk current produce changes in the ring electrode potential that can be accompanied by large relative changes in the faradaic current.

In addition, the double layer capacity at the ring and disk electrodes can play a significant, even major, role in the case where there are time-varying currents, *e.g.*, the sinusoidal variation of current through a rotating disk electrode (Albery papers) will produce a sinusoidal variation in the ring electrode potential and thus a double layer charging current. The treatment presented above was a d-c analysis, and for simplicity was not presented in a-c terms, although this extension is quite straightforward. The d-c analysis is also used below to discuss the positive feedback circuitry.

Compensation for R_C.—Disk electrode.—Assume switch S-1 is closed. Then Eq. [1] must be replaced by

$$V_{F1} + V_D + V_{I3} = 0 \qquad [13]$$

where

$$V_{I3} = -V_2 \frac{R_4}{R_3} \qquad [14]$$

and

$$V_2 = I_R R_9 \qquad [15]$$

Using Eq. [13]-[15] and Eq. [8] and [13] yields

$$E_D^* = V_D + I_D(R_C + R_D) + I_R(R_C - R_4R_9/R_3) \qquad [16]$$

for the relationship describing the disk potentiostat behavior. Hence, when

$$\frac{R_4R_9}{R_3} = R_C \qquad [17]$$

the inverse pseudocollection effect vanishes. In practice, R_4 is increased from zero, and the magnitude of the effect is seen to decrease to zero and to change sign as R_4R_9/R_3 becomes greater than R_C.

Ring electrode.—Assume switch S-2 is closed at CA2, the summing point condition leads to

$$V_{F2} + V_R + V_{I1} + V_{I2} = 0 \qquad [18]$$

instead of Eq. [7]. Also

$$V_{I2} = -\frac{R_2}{R_1} V_4 \qquad [19]$$

and

$$V_4 = -I_D R_8 \qquad [20]$$

Thus, using Eq. [18]-[20] along with Eq. [8]-[10] yields

$$E_R^* = -V_R + I_R(R_C + R_R) + I_D\left(R_C - \frac{R_2R_8}{R_1}\right) \qquad [21]$$

Hence, compensation from the pseudocollection effects occurs when

$$\frac{R_2}{R_1} R_8 = R_C \quad [22]$$

Again, experimentally, partial or overcorrection (with change in sign) for the pseudocollection phenomena is observed by continuously varying R_2 from zero to larger values.

In both of the derivations for compensation of R_C, note that the position of S-2, when S-1 was closed, or S-1, when S-2 was closed. is irrelevant. The position of the other switch does not affect the statement of Eq. [2], which is common to both derivations even though the values of E_D, I_D, and I_R may be affected. Any change in these quantities is accounted for by the other relationships involved in the derivations. Therefore, one may elect to compensate for either the pseudo or inverse pseudocollection effect, or both, as the experimental needs dictate.

Discussion

Pseudocollection-faradaic processes.—As was shown earlier (14, 21-24) the current of a ring electrode which is potentiostated at "constant" potential can be affected by the currents that pass through the disk electrode. Figure 2 illustrates the pseudocollection phenomena strikingly. The platinum ring electrode has been potentiostated on the rising portion of the hydrogen evolution current (at −0.400V in 0.01*M* H_2SO_4). As the potential of the gold disk electrode is scanned at ± 130 mV/sec, the changing disk electrode currents produce a change in the ring electrode potential. Cathodic disk electrode currents produce more anodic ring electrode currents, and vice versa; as a result of decreasing or increasing the hydrogen evolution current. This result is consistent with the idea of a common uncompensated ohmic resistance, represented by R_C in Fig. 1. This result also indicates the difficulty in detecting an intermediate produced during nonsteady-state disk current conditions if the required ring electrode potential lies on the rising portion of a voltammetric wave, *e.g.*, either the solvent or supporting electrolyte decomposition.

One approach to eliminating the pseudocollection effect was suggested earlier by us (14). The position of the Luggin capillary in the cell determined the value of R_C, and thus by proper positioning (trial and error) the Luggin tip can be placed at point O of Fig. 1 (*i.e.*, $R_C = 0$). In fact if the capillary is brought extremely close to the electrode, the pseudocollection response reverses since the capillary is in effect located on R_D. The results of such an experiment in 0.01*M* H_2SO_4 is shown in Fig. 3. As the Luggin capillary is moved down the axis of rotation toward the disk electrode, the pseudocollection effect becomes smaller (curves b-d), vanishes (at curve e), and reappears with a reversed sign (curves f, g). This result is in accordance with the physical representation of the capillary tip, T in Fig. 1, moving toward point O, through point T and then down R_D toward E_D. Curve e, corresponding to complete compensation ($R_C = 0$), is produced when the capillary is very close to the electrode (≤1 mm) and it requires some patience to locate this point exactly. There are a number of positions of the Luggin which give very little evidence of the pseudocollection effect, but there appears to be only one position that compensates for both the pseudo and inverse pseudocollection effect, which in our equivalent circuit corresponds to locating the capillary precisely at point O.

Figures 4 and 5 demonstrate the behavior of the compensation circuitry in Fig. 1. The faradaic ring electrode reaction in both cases is the evolution of hydrogen at the platinum ring electrode in a supporting electrolyte of 0.01*M* H_2SO_4. Figure 4 illustrates the case of no compensation (curve b) and over compensation (curve c) in which case there is a reversal in the appearance of the ring electrode current shape, as predicted by Eq. [22] when $R_2R_8/R_1 > R_8$. Note that severe overcompensation (by a factor of more than two) does not produce any instability in the circuit.

The circuit response in the vicinity of ideal compensation, *i.e.*, $R_2R_7/R_1 = R_C$, is shown in Fig. 5. Curve d shows no pseudocollection effect, while a ±3% change in the value of R_2 produces a visible pseudocollection response.

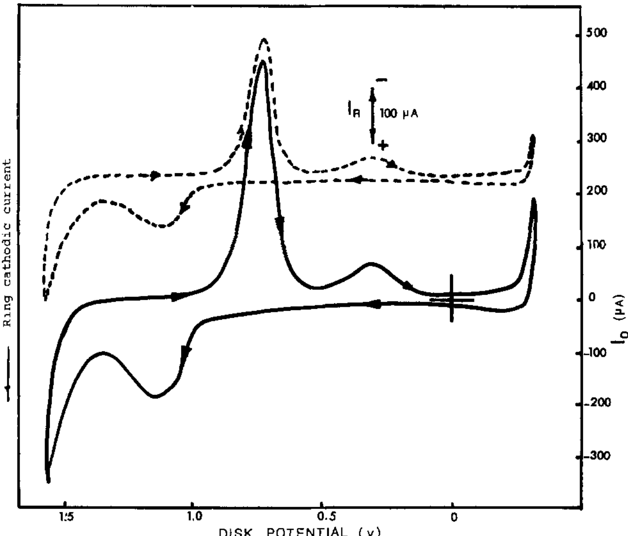

Fig. 2. Pseudocollection effect. 0.01*M* H_2SO_4 using electrode No. 2. Solid curve and dashed curve represent disk and ring voltammograms, respectively. The gold ring electrode is potentiostated at −0.400V, where $2H^+ + 2e$ occurs. Ring current offset arbitrarily from zero. Scan rate = 130 mV/sec; rotation speed = 2500 rpm. There is a trace of platinum left on the gold disk after polishing, and it is visible in the *I-E* curve at ~ 0.4V.

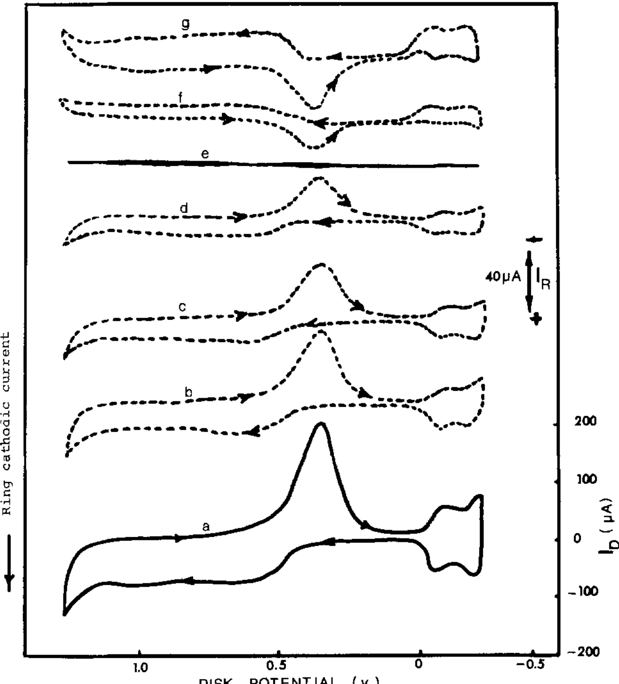

Fig. 3. Pseudocollection compensation by positioning of Luggin capillary. 0.01*M* H_2SO_4 using electrode No. 1. Solid curve and dashed curves represent disk and ring electrode voltammograms, respectively. Ring is potentiostated at −0.370V. All ring current curves are zero offset to allow for current due to $2H^+ + 2e = H_2$. Scan rate = 120 mV/sec; rotation speed = 2500 rpm. The approximate distance of the Luggin capillary tip from the plane of the rotating ring-disk electrode is 1 in., 6, 3, 2, and 1 mm, and a fraction of mm for curves b, c, d, e, f, and g, respectively. The tip has been positioned by eye, on the axis of rotation.

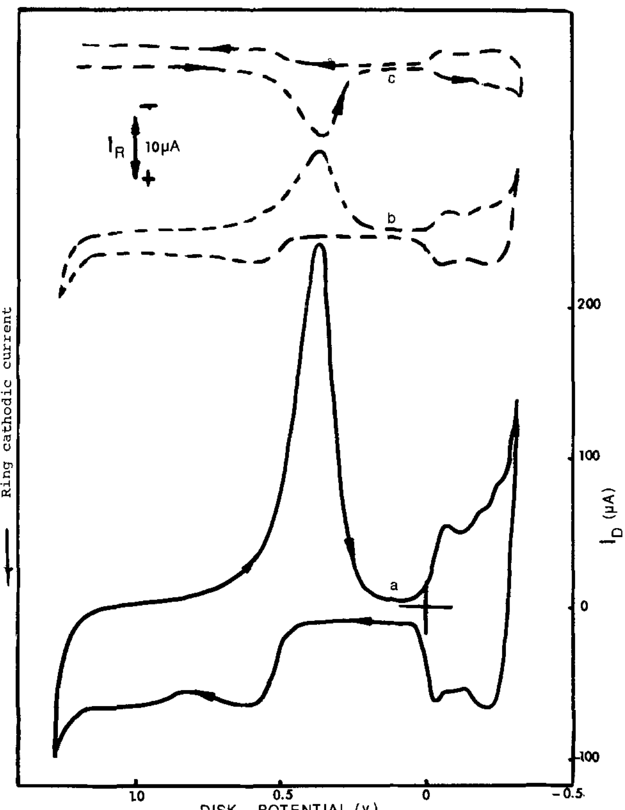

Fig. 4. Pseudocollection compensation by positive feedback. 0.01M H_2SO_4 using electrode No. 1. Solid curve and dashed curves represent disk and ring voltammograms, respectively. Ring is potentiostated at −0.325V. Ring current arbitrarily offset from zero. Scan rate = 130 mV/sec; rotation speed = 2500 rpm. The value of the resistor R_2 is 0 and 90 ohms for curves b and c, respectively.

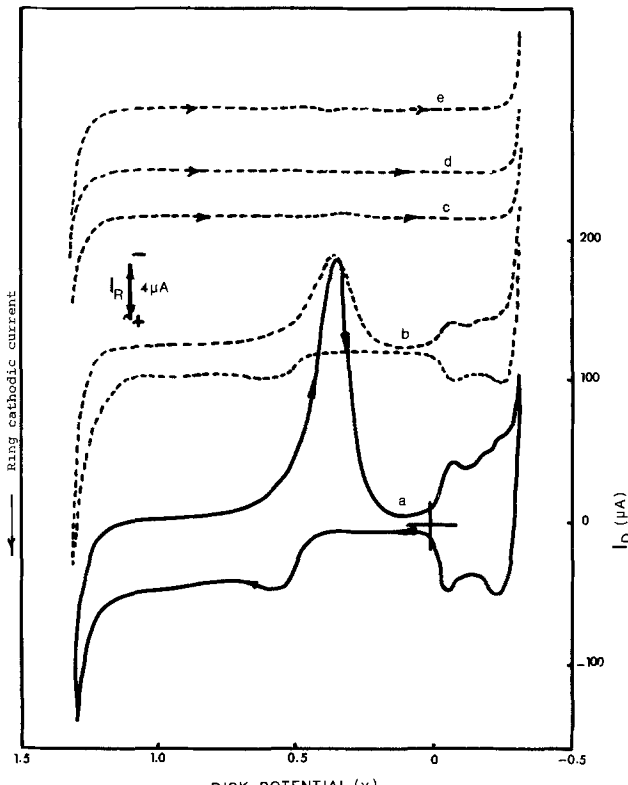

Fig. 5. Pseudocollection compensation by positive feedback. 0.01M H_2SO_4 using electrode No. 1. Solid curve and dashed curves represent disk and ring voltammograms, respectively. Ring is potentiostated at −0.300V. Ring current is arbitrarily offset from zero. Scan rate = 110 mV/sec. Rotation speed = 2500 rpm. R_2 = 0, 32, 33, and 34 for curves b, c, d, and e, respectively. The curves c, d, and e are recorded only when the disk potential is scanned in the cathodic direction.

The pseudocollection resistance ($R_2R_8/R_1 = R_C$) is readily found by varying R_2 and observing the ring electrode current trace in the potential region where the oxidized disk electrode is reduced. Table I presents the results of pseudocollection resistance measurements obtained by this procedure at five different locations of the Luggin capillary. Also listed in Table I are the corresponding values of R_C found using our earlier procedure (14). The agreement between these two methods is excellent.

Inverse pseudocollection.—Another test of the equivalent circuit was performed by interchanging the leads to the ring and disk electrodes, *i.e.*, the ring electrode to the input of F2. The effect of this change to position R_R at the input of CF and R_D at the input of F2. Thus varying the ratio R_2R_8/R_1 compensates the disk electrode potential for effects caused by ring electrode currents passing through R_C, *i.e.*, compensates for the inverse pseudocollection effect.

Table II lists the values of the inverse pseudocollection resistance found by the above procedure at three different locations of the Luggin capillary. Also listed are the values of the pseudocollection resistance found when the disk electrode lead was connected to CF and the ring electrode lead was connected to F2, *i.e.*, the original configuration. The agreement between the pseudo and inverse pseudocollection resistances found in this way is good.

Pseudo and Inverse Pseudocollection Effects: Double Layer Charging Currents

Albery (23) in his a-c studies at the ring-disk electrode noticed that an a-c ring electrode current flows in the ring electrode circuit even when only an a-c double layer charging current flows through the disk electrode and correctly ascribed this phenomenon to an uncompensated ohmic potential drop caused by the disk current flowing through a solution resistance that is coupled to the ring electrode. The equivalent circuit for this situation is shown in the circled region in Fig. 1 in which E_D and E_R should be considered to contain the double layer capacitances of the disk and ring electrodes. Our model contains the Albery *et al.* features and in addition predicts the reciprocal effects of current at one electrode on the other electrode's poten-

tial. The a-c voltage fluctuation across the common resistance, R_C, of Fig. 1, produces potential fluctuations across the ring electrode double layer capacitance, and thus double layer charging currents at the ring electrode. Analogously, as is shown below, an inverse pseudocollection effect can be produced by an a-c current flowing at the ring electrode.

The ring and disk electrode currents involved in these capacitative pseudo and inverse pseudocollection effects are out of phase with each other as a result of the differing value of R_R, R_D, the ring electrode double layer capacitance and the disk electrode to double layer capacitance. Hence, the derivation leading to Eq. [17] and [22] would have to be suitably modified to account for this phase shift. This was not done, since it is seen that if the proper phase shifted fraction of I_D is fed back to the ring control amplifier CA2, the inverse pseudocollection effect can be eliminated. Similarly, by feeding back the appropriate phase shifted fraction of I_R to the disk control amplifier, the inverse pseudocollection effect can be eliminated. The circuit used to accomplish these results is given in Fig. 6, in which a phase shifting circuit P1 and P2 was introduced into the ring and disk current positive feedback loops. P1 and P2 are identical circuits, and have the property of unity gain at all frequencies, shifting the phase of an a-c signal from 180° to 360°, depending on values of the R_P's and C's and the frequency.

In an actual a-c pseudocollection compensation experiment, both R_2 and R_{PD} are adjusted until there is no a-c ring current in the absence of a faradaic process at the disk electrode. The analogous adjustment of R_4 and R_{PR} compensates for the a-c inverse pseudocollection effect.

The results of such a-c compensation experiments at 10, 100, and 200 Hz are given in Table III. The currents listed in parenthesis are the a-c pseudo or inverse pseudocollection currents. The values of R_2R_8/R_1 and R_4R_9/R_3 produce the resistance values necessary to produce the proper amplitude for compensation after adjusting the phase shift resistors, R_{PR} or R_C, as measured by the d-c method in which the faradaic currents flow through the ring and disk electrodes. R_C values measured in this way are given in the last column of Table III, and agree well in all pseudo and inverse pseudocompensation studies.

The positive feedback networks function completely independently of each other when the inverse pseudocollection effect is compensated according to Eq. [17], the pseudocollection phenomenon is unaffected, and visa versa when the condition of Eq. [22] is met. When the conditions of Eq. [17] and [22] are both met, both effects vanish.

Conclusion

The uncompensated common resistance R_C, between the reference electrode and the ring and disk electrodes can be a significant fraction of the uncompensated resistance found at ring-disk electrodes. Pseudo and inverse pseudocollection effects arise due to this common resistance. These effects can be completely eliminated, in both d-c and a-c experiments, by appropriate positive feedback networks, without any noticeable loss of dual potentiostat stability. The positive feedback networks used are our earlier equivalent circuit for the uncompensated resistances occurring at ring-disk electrodes (14) and the success of the positive feedback networks in eliminating pseudo and inverse

Studies in Derivative Chronopotentiometry

II. Analysis of Multicomponent Systems

P. E. Sturrock* and B. Vaudreuil

ABSTRACT

Instrumental compensation for diffusion current of prior steps is investigated for the derivative chronopotentiometry of multicomponent systems. This technique, in combination with the instrumental compensation and mathematical correction for charging current described in a previous paper (1) is applied to the analysis of multicomponent systems by standard addition and titration. As examples, an amount of 0.2 μmoles of cadmium was determined by standard addition in the presence of 100 μmoles of lead and an amount of 2 μmoles of cadmium was titrated with EGTA in the presence of 50 μmoles of copper.

Chronopotentiometry of solutions containing two or more electroactive substances which undergo consecutive electrode reactions suffers the inherent disadvantage that the faradaic current for the second and subsequent components is reduced by the amount of the residual diffusion current from the more easily

* Electrochemical Society Active Member.

Key words: current correction, standard addition, titration, DME.

electrolyzed components. This has the effect of increasing the transition times for the subsequent components. In addition, the shape of the chronopotentiogram for the second component is altered, thus complicating the relationship between transition time and the minimum of the dE/dt curve.

Previous attempts to correct the transition time of the latter component were based on theoretical concentration-transition time relationships derived by Delahay and Mamantov (2) for two consecutive processes and which were extended to multicomponent systems by Reilly *et al.* (3). Sturrock, Anstine, and Gibson (4) derived the theoretical potential-time relationships for multicomponent derivative chronopotentiometry. They found it is possible to evaluate τ for second and third components by using a computer prepared tabulation of a parameter which is dependent on $(dE/dt)_{min}$ for the component in question, and the sum of the transition times for the preceding waves.

The same authors proposed a standard addition type analysis to determine the concentration of the component in question. However, this type of analysis cannot be applied to very dilute solutions or to transition times much shorter than 3 msec because it is impossible to apply a Bard-type separation of faradaic and capacitative currents to correct for double-layer charging.

Bowman and Bard (5), working with stationary electrodes, were able to decrease the effect of a preceding wave by imposing a constant potential between the two waves for a measured time before applying the constant current for the chronopotentiometry of the second component. Extension of the potential step technique was undertaken in the present work in which all experiments were performed on a DME. If the prebias potential is applied for a long enough time, the diffusion current of the first component decays to a small and nearly constant value. If the chronopotentiometric current is applied at any time within the flat portion of the i *vs.* τ curve, the diffusion current can be considered to be constant over the short (1-50 msec) time span of the chronopotentiometric wave. The constant diffusion current, i_d, can be subtracted from the applied current to give the current going toward the faradaic process for the second component, i_f. The value of i_f is used with the observed transition time to calculate the $i\tau^{1/2}/C$ ratio for the second component. The chronopotentiometric constant is stated in terms of a corrected current, rather than a corrected transition time. If the value of i_f is known, or can be held constant, analytical applications are possible.

There are various methods, based on the Cottrell and Ilkovic equations of obtaining a value for i_d. The disadvantage of calculating instantaneous currents by the Ilkovic equation lies in the inaccuracies introduced by the use of so many measured parameters. To reduce the number of experimentally measured parameters involved, a new expression was derived in the course of this work combining the Cottrell and Sand equations. The concentration of electroactive substance in the bulk solution was expressed in terms of the Sand equation, then this expression was substituted for C in the Cottrell equation along with a factor, $\sqrt{7/3}$, to account for the expansion of the drop. The resulting equation is

$$i_d = (2/\pi)(7/3t)^{1/2} i\tau^{1/2} \quad [1]$$

where t is the delay time (the length of time that the growing drop is subject to the prebias before the chronopotentiometric current is applied) and i and τ are obtained from a chronopotentiogram of the first component, without prebias, at time t in the drop life. Essentially, i_d for a single component is calculated from a single chronopotentiogram of that component.

In the course of this investigation, a simpler method was discovered to determine diffusion currents. A prebias potential beyond the first wave is maintained for time t, as the electrode drop grows, then upon switching to galvanostat mode, sufficient current is applied from a continuously variable calibrated source so that the prebias potential is maintained. Under such conditions, the applied current is equal to the diffusion current of the first species. If the applied current is less than the diffusion current, the concentration of electroactive species will increase at the electrode surface and the potential will change in accord with the Nernst equation. Likewise, if too large a current is applied the potential will move in the opposite direction. The diffusion current measured in this way is subtracted from the total current to the next drop of the DME to obtain i_f. A simpler method is to use an uncalibrated, variable current source adjusted to supply just the current necessary to equal the diffusion current and maintain the prebias potential. Then this current can be electronically added to the current, applied to the next drop of the DME so that nominally all the applied current is available for the second faradaic process. In a multicomponent situation where one is trying to measure a transition for a wave on top of several others, this method is superior to the use of the Sand-Cottrell calculation which can be applied only with difficulty to multicomponent systems. It is also superior to the application of the Ilkovic equation which involves summing the diffusion currents for each of the preceding waves. In the new instrumental method, the total residual diffusion controlled current is measured without regard to the number or magnitude of its components.

Experimental Verification of Applied Corrections

The validity of the various corrections proposed was tested on lead-cadmium solutions using potassium nitrate as the supporting electrolyte. The transition for the reduction of lead occurs at approximately -0.4V *vs.* SCE. The reduction wave for cadmium occurs at a potential about 0.2V more negative. Both metals are reduced reversibly, and neither species is known to be adsorbed on a mercury electrode.

Calculation and measurement of diffusion currents.— Diffusion controlled currents for lead were determined by four methods; direct measurement at -0.52V, Sand-Cottrell calculation, Ilkovic calculation based on $D^{1/2}$ obtained from derivative chronopotentiometry, and Ilkovic calculation based on polarographic literature value of $D^{1/2}$.

To 50 ml of 1M KNO_3 supporting electrolyte were added 2 ml portions of 2×10^{-2}M $Pb(NO_3)_2$. The solution was deaerated after each addition and allowed to become quiet. The delay time for switching from prebias to controlled current modes was 2.625 sec into the drop life. The diffusion current was measured by adjusting the calibrated main cathodic current control to exactly maintain the prebias voltage for a period of 50 msec, thus giving a horizontal trace on the oscilloscope. The magnitude of the applied current was read directly from the dial of the current control potentiometer.

To obtain data required for the Sand-Cottrell calculation derivative chronopotentiograms were run on the above solutions with the prebias at -0.2V. Values of $(dE/dt)_{min}$ for the lead wave were converted to transition times. Using delay time, t, equal to 2.625 sec, and combining numerical terms, the modified Sand-Cottrell equation (Eq. [1]) reduces to

$$i_{d(\text{in } \mu A)} = 0.600\ (i\tau^{1/2}) \quad [2]$$

Experimental values of i and τ were used to calculate i_d for solutions with different lead concentrations.

The Ilkovic calculation was based on the following experimentally measured parameters

$D^{1/2} = 0.00290$ cm/sec$^{1/2}$, $t = 2.625$ sec, $m = 2.393$ mg/sec, $C =$ (variable) mmoles/liter

Combining numerical terms, the Ilkovic equation reduces to

$$i_{d(\text{in } \mu A)} = 8.63C \quad [3]$$

When using a literature value of $D^{1/2}$ from polarographic data (6), Eq. [3] becomes

$$i_{d(\text{in } \mu A)} = 9.00C \quad [4]$$

The values of i_d obtained for lead solutions over a concentration range from 7.69×10^{-4}M to 4.38×10^{-3}M are summarized in Table I. Diffusion current is a linear function of concentration of the diffusing species. Values for diffusion currents calculated by the Sand-Cottrell and the Ilkovic equations based on chronopotentiometric $D^{1/2}$ values agree well. However, the diffusion currents obtained by direct measurement were consistently higher by about 6% and in close agreement with the Ilkovic calculation based on literature value of polarographic $D^{1/2}$ (6).

The discrepancy noted in Table I was thought to be due to the depletion of electroactive substance in the vicinity of successive drops. A semiquantitative evaluation of the magnitude of the depletion effect was obtained by examining the changes in successive chronopotentiograms of an electroactive substance as the depleted layer, resulting from a prebias, is replenished by continued diffusion after the prebias is switched off.

A cadmium solution (1.1×10^{-3}M in 1.0M KNO_3) was subjected to a prebias of -0.76V until a steady-state diffusion current (10 μA) was observed at the usual delay time. Then the prebias was switched off manually to coincide as closely as possible to drop detachment. Derivative and conventional chronopotentiograms were run on the next four drops of the DME. With an applied current of 100 μA and an electrode area of 0.0290 cm^2, $\tau^{1/2}$ values were 0.128, 0.145, 0.152, and 0.153 sec$^{1/2}$. The increase in $\tau^{1/2}$ from the first to the fourth drop indicates a corresponding increase in the apparent concentration of cadmium at the electrode surface. Stated in another way, application of a prebias to a DME electrode results in a residual concentration polarization such that the concentration of electroactive species seen by the newly formed drop may be much less than the true bulk concentration. The directly measured diffusion currents presented in Table I were obtained after a steady state of depletion was reached. The same steady-state conditions were used in subsequent work. During the application of the prebias, the situation at the electrode is exactly the same as in polarography and one would expect the Ilkovic equation to be applicable provided polarographic values of $D^{1/2}$ are used.

No depletion effect was observed on any chronopotentiograms run normally, that is, without a prebias beyond the reduction potential for that substance. Chronopotentiograms on the first and subsequent drops were identical for single component systems. For multicomponent systems, with a prebias set between the reduction potentials of the different components, chronopotentiograms of the first few drops were not identical. Discrepancies between first and subsequent drops can be explained by considering the variation of current required to set up the diffusion layer for the more active component. As the current required to set up the diffusion layer decreases, the fraction of the total current which is used for the chronopotentiometric process increases. Once a steady state is reached in the diffusion of the more active component, the chronopotentiograms of the less active component will superimpose so that successive traces on a storage oscilloscope appear as one trace.

Table I. Lead diffusion currents

Conc. Pb (mmoles/liter)	Diffusion current (μA): Direct measurement	Sand-Cottrell calculation	Ilkovic calculation: Chronopotentiometric $D^{1/2}$	Ilkovic calculation: polarographic $D^{1/2}$
0.77	7.3	6.72	6.63	6.91
1.48	13.6	12.8	12.8	13.3
2.14	19.6	18.6	18.5	19.3
2.76	25.2	23.8	23.8	24.8
3.33	30.3	28.6	28.7	30.0
3.87	35.4	33.4	33.4	34.8
4.38	40.1	37.5	37.8	39.4

Contributions to the apparent diffusion current from charging the double layer of the growing drop at the prebias potential are insignificant. For a drop area change of 1% ($\Delta a = 0.0003$ cm^2) and a typical double-layer capacitance of 20 μf/cm^2, charging the double layer required approximately 0.006 μcoul/V. At a prebias of -0.52V over a time of 50 msec, the required current would be

$$i = \frac{0.006\ \mu\text{coul} \times 0.1\text{V}}{0.05\ \text{sec}} = 0.012\ \mu\text{A}$$

This is insignificant compared to the magnitude of the diffusion currents reported in Table I.

Consistency of the chronopotentiometric constant for cadmium in the presence of lead.—A series of solutions which were 3.8×10^{-6}M to 4.3×10^{-3}M in cadmium and 2.0×10^{-3} in lead was prepared by adding portions of solutions which were 1.0×10^{-3}M or 1.0×10^{-4}M in cadmium and also 2.0×10^{-3}M in lead and 1.0M in KNO_3 to a solution which was 2.0×10^{-3}M in lead and 1.0M in KNO_3. A series of chronopotentiograms was run on these solutions using a prebias of -0.52V and instrumental compensation for the lead diffusion current. The diffusion current was checked after each addition and was found to be invariant. The chronopotentiograms were run with and without instrumental double-layer compensation and the transition times measured with the derivative technique (1).

Three sets of chronopotentiometric constants were calculated: from the uncompensated (double-layer) and uncorrected data; from uncompensated (double-layer) data corrected according to Bard (7); and from data compensated (double-layer) instrumentally. The results are shown in Table II. Consistency was achieved for cadmium concentrations as low as 1.66×10^{-5}M both by Bard corrections and by instrumental compensation. For Cd solutions on the order of 10^{-6}M, Bard-corrected results were more consistent than were the instrumentally compensated results. The results from the latter were improved by applying Bard corrections; $i\tau$ *vs.* $C\tau^{1/2}$ plots of the instrumentally compensated data showed a residual double-layer effect of about 0.0036 μcoul. This is one-tenth the double-layer effect in the uncompensated data and becomes insignificant at concentrations of 10^{-5}M and higher, but it consumes significant portions of the very low currents used for lower concentrations.

The lowest current setting available on the instrument used was 1 μA. For a 3.8×10^{-6}M cadmium solution using double-layer compensation, this lowest current yielded a τ of 7.73 msec, too near the lower limit imposed by the speed of the differentiator for an attempt to analyze more dilute solutions. There is reason to believe that with a lower applied current and a more sophisticated double-layer compensator, this concentration limit can be extended to the lower 10^{-6} range and perhaps beyond.

It should be emphasized that in these experiments the amount of lead present was 0.5-500 times the amount of cadmium. Consistency of $i\tau^{1/2}/aC$ was attained despite the large amounts of lead.

Application to Analysis

The concentration of an electroactive substance can be determined by chronopotentiometry by substituting experimental values for the other parameters into the Sand equation and solving for C. The value obtained, however, is subject to considerable error owing to the large number of variables used. Standard addition and titration methods offer a better approach. A series of chronopotentiograms is used to obtain data for the analytical curves.

Table II. Chronopotentiometric constants for cadmium in the presence of 2 × 10^{-3}M lead

Note i = applied current; a = 0.0290 cm^2; $i_t = i - B/\tau$; B for uncompensated data = 0.035 μcoul; B for compensated data = 0.0036 μcoul. Units for $\frac{i\tau^{1/2}}{aC}$ in $\frac{\mu\text{A-sec}^{1/2}\text{-liter}}{\text{cm}^2\text{-mmole}}$.

Constancy of the $i\tau^{1/2}/C$ ratio is a necessity if chronopotentiometry is to be used for standard addition or titrimetric determinations. Either instrumental compensation of double-layer charging or arithmetic corrections as described previously (1) can be used to assure the constancy of $i\tau^{1/2}/C$ over the range of concentration to be spanned during the titration or standard addition. Generally, instrumental compensation will yield values for τ that can be used directly in plotting an analytical curve.

Standard addition determinations.—For a standard addition determination it is essential that a plot of $i\tau^{1/2}$ *vs.* C (which is equivalent to a Bard-type plot of $i\tau$ *vs.* $C\tau^{1/2}$) intercept the C-axis at the point $C = 0$. If double-layer effects are not eliminated by compensation or corrections, the $i\tau^{1/2}$ *vs.* C line may be displaced upward, indicating a higher concentration of the substance than is actually present. As derived in an earlier paper on derivative chronopotentiometry of single component systems (8), double-layer charging can be corrected for by maintaining a constant value for current density and plotting $\tau^{1/2} - \tau_{res}/\tau^{1/2}$ on the ordinate. In order to create a perfectly linear plot, it is necessary to correct for dilution.

If the solution which is being determined contains two or more electroactive species, these species can be determined independently in the same solution. In this study, cadmium was determined in the presence of lead by using the prebias and diffusion current compensation techniques discussed above. As aliquots of a standard cadmium solution are added to the test solution, the concentration of lead present is decreased. Thus the lead diffusion current changes after each Cd addition, and the diffusion current must be checked and the compensation readjusted.

When a sufficient number of additions (3-5) has been made and data obtained for the cadmium standard addition curve, the prebias can be lowered to a potential below the lead wave and aliquots of a standard lead solution added, yielding data for the lead determination. A solution of several electroactive substances can be analyzed by this means as long as the reduction potentials for the substances are separated sufficiently for a prebias to be imposed between the waves.

It is important that the substance which is reduced at a more negative potential be determined first. The additional amount of that substance which remains in the solution as a result of the standard addition acts as supporting electrolyte and does not interfere when the more easily reduced species is determined. If, on the other hand, the more easily reduced species is determined first, the additional amount present in the test solution interferes in the determination of the less easily reduced species. The more of the former present, the more difficult it becomes to compensate for it.

Another precaution is worthy of note. To achieve the best precision, the amount of electroactive substance added in each increment should be of the same order of magnitude as the total amount of that substance initially present. Addition of considerably larger amounts greatly compresses the concentration axis and reduces the precision by which small amounts may be determined. If, on the other hand, the increments are much smaller than the amount to be determined, extrapolation over a long distance adds to the uncertainty of the result.

An example of a two component standard addition determination is presented in Fig. 1. Cadmium in the amount of 0.2 μmoles was determined, in the presence of 100 μmoles of lead, by derivative chronopotentiometry.

Titration using chronopotentiometric end point detection.—Cadmium can be titrated with EGTA ([ethylene bis(oxyethylenenitrate)] tetraacetic acid) in the presence of copper if an ammonia-ammonium buffer of pH 10 is used. The ammonia strongly complexes the copper and masks it for reaction with EGTA. The $Cd(NH_3)_4^{2+}$ complex is weaker and does react with the EGTA. End point detection is difficult, however, because copper interferes with metallo-chromic indicators such as Eriochrome Black-T which is routinely used for the EGTA titration of cadmium.

As EGTA complexes cadmium during the course of the titration, chronopotentiometry can be used to measure the decreasing concentration of uncomplexed cadmium.

As the concentration of cadmium decreases, double-layer effects become prominent. Bard corrections work well to deal with these effects. The τ measured by derivative means which occurs beyond the equivalence point is τ_{res}, the apparent transition time due to double-layer charging (8). It is constant at points well beyond the equivalence point where the concentration of cadmium not complexed by EGTA is essentially zero. If $\tau^{1/2} - (\tau_{res}/\tau^{1/2})$ is plotted *vs.* ml EGTA added, the portion of the titration curve beyond the equivalence point coincides with the x-axis. Thus the point where the extrapolated initial portion of the titration curve intersects the x-axis is taken as the end point.

If volume changes during the titration are significant, volume corrections must be applied, just as they are in the case of standard addition determinations. Chronopotentiometric end point determination lends itself to the use of concentrated titrant which can be added in small volume, eliminating the need for volume corrections. In the vicinity of the end point, titrant can be added in larger increments, so long as several

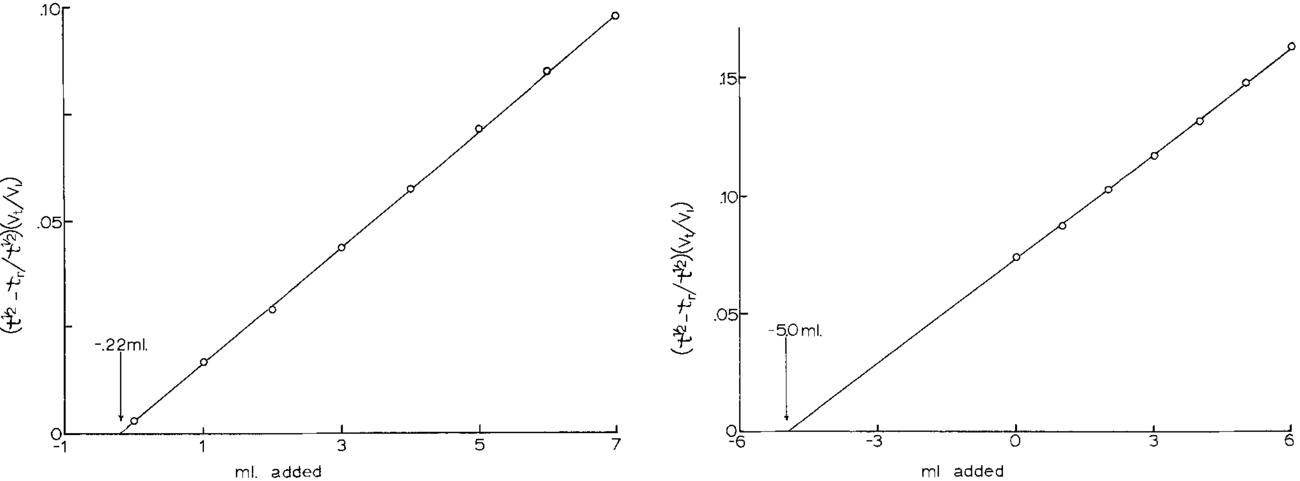

Fig. 1. Standard addition curves: (a, left). 0.2 μ moles of cadmium in presence of 100 μmoles of lead. Addition of 1.0 × 10^{-3} F $Cd(NO_3)_2$. 0.22 μmoles Cd found. (b, right). 100 μmoles lead. Additions of 1.0 × 10^{-2} F $Pb(NO_3)_2$. 100 μmoles lead found.

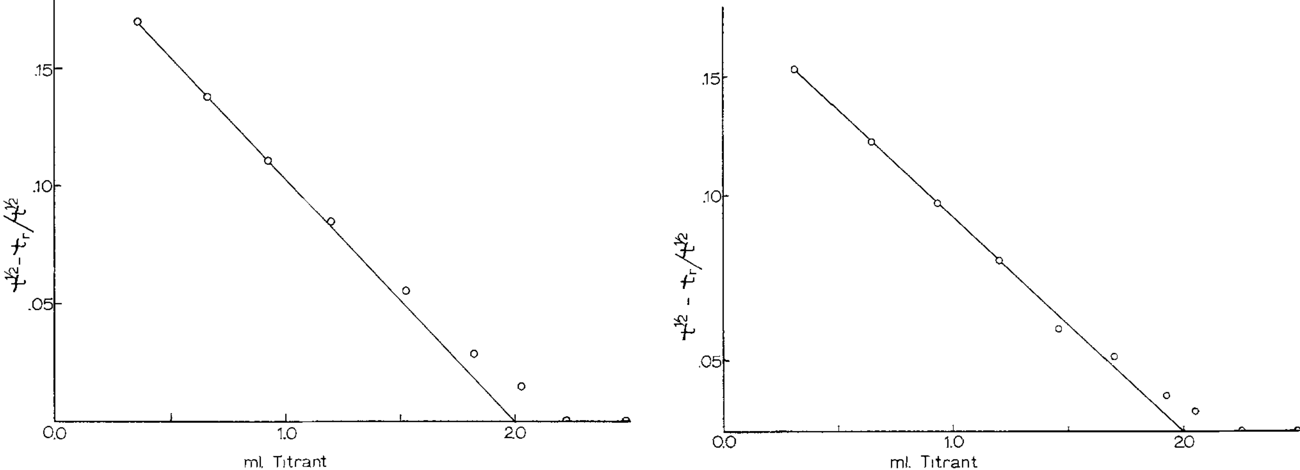

Fig. 2. Titration curves. (a, left). 2 μmoles of cadmium and no copper. (b right) 2 μmoles of cadmium and 50 μmoles of copper

points are obtained in the linear regions before and beyond the end point.

An EGTA solution was standardized against a standard cadmium solution using Eriochrome Black-T and an ammonia-ammonium nitrate buffer of pH 10. A series of identical solutions was made as follows: 1.00 ml standard Cd solution (2 μmoles Cd) was added to 5 ml buffer, 10 ml 1.0M KNO_3, and sufficient water to make 50 ml total. The concentration of Cd in these test solutions was 4.00 × 10^{-5}M. The EGTA titrant was determined to be exactly 1.00 × 10^{-3}M.

The same titration was performed using chronopotentiometry. The chronopotentiometric titration curve is presented in Fig. 2a. For this determination, electrode area = 0.02899 cm^2, current = 30 μA, and prebias = −0.66V. The cadmium-ammonia complex is reduced at −0.8V.

The same procedure was repeated on a new test solution, identical to the preceding one except for the presence of 50 μmoles copper. Diffusion current compensation was used to eliminate interference from the Cu. The titration curve is presented in Fig. 2b.

The results of the two cadmium titrations using chronopotentiometric end point detection are identical to the result of the series of titrations using Eriochrome Black-T, and demonstrate the feasibility of titrating multicomponent mixtures using chronopotentiometry.

The Frequency Response of Limiting Currents to Sinusoidal Speed Modulation at a Rotating Disk Electrode

Koichi Tokuda* and Stanley Bruckenstein*

State University of New York, Buffalo, New York 14214

and Barry Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

When a sinusoidal modulation is superimposed on the rotation speed of a rotating disk electrode, the corresponding modulated current follows the Levich equation closely for sufficiently low ratios of the modulation frequency to the constant center rotational frequency. In this work, the frequency response of the modulated current (amplitude and phase) is derived for the general case and the results experimentally confirmed over a wide range of Schmidt numbers (230-2100 Sc) and modulation to rotational frequency ratios for the reduction of Fe^{+3} to Fe^{+2} in 1.0*M* H_2SO_4 over the temperature range 25°-85°C. Tables are given of the phase and amplitude factors which would be encountered for the normal range of both modulation and solution parameters.

In recent papers (1-6), we have considered various theoretical and experimental aspects of hydrodynamic voltammetry at the rotating disk (RDE) and ring-disk electrodes (RRDE). In these studies, the angular velocity of the RDE, ω, was programmed as a function of time, t, or current, i. With the exception of one study (4) involving step speed change, this work dealt with conditions for which the Levich equation always applied, *i.e.*, a quasi-steady state existed in which the concentration gradients adjacent to the RDE could be described adequately using the instantaneous angular velocity, ω, of the electrode and the von Kármán (7)-Cochran (8) approach. Recently, using the results of Benton (9), we considered the current transient produced by a step change in angular velocity, $\Delta\omega$, of a RDE held at a limiting current. After such a step change in ω, the fluid velocities in the region adjacent to the RDE adjust very rapidly from values characteristic of the initial velocity, ω_o, to those characteristic of the final velocity, $\omega_o + \Delta\omega$, while the concentration profiles adjust somewhat more slowly.

We consider here the problem of describing the limiting, convective-diffusion controlled current at a disk subjected to a rotational velocity program of the form

$$\omega^{1/2} = \omega_o^{1/2}(1 + \epsilon \cos \sigma t) \quad [1]$$

In Eq. [1]

$$\epsilon = \Delta\omega^{1/2}/\omega_o^{1/2} \quad [2]$$

and σ is the modulation frequency in radians/sec. In this paper, we refer to this class of techniques as sinusoidal hydrodynamic voltammetry (SHM) to distinguish it from other uses now being made of the term "hydrodynamic voltammetry (10)."

Equation [1] will describe the experimental situation for all values of ω_o, ϵ, and σ, including those for which the angular acceleration, $d\omega/dt$, is too high for the quasi-steady state assumptions used in our previous studies of a sinusoidal modulation of ω to apply. These broader experimental conditions will produce current responses deviating from those (5, 6) found for Levich-type conditions ($\epsilon\sigma$ small), *i.e.*, the current is not given by

$$i = i_{\omega_o} + \Delta i \cos \sigma t \quad [3]$$

where

$$\Delta i = i_{\omega_o} \Delta\omega^{1/2}/\omega_o^{1/2} = i_{\omega_o}\epsilon \quad [4]$$

and i_{ω_o} is the convective-diffusion limiting current at a constant angular velocity of ω_o.

Instead, as will be shown later, i is given by

$$i = i_{\omega_o} + \Delta i_1 \cos(\sigma t - \varphi_1) + \Delta i_2 \cos(2\sigma t - \varphi_2) + \ldots \quad [5]$$

In our experiments we have determined Δi_1 and φ_1 by appropriate techniques and have therefore restricted the detailed theoretical analysis to the first harmonic term, *i.e.*, to the calculation of Δi_1 and φ_1 as a function of the Sc number. The results for the amplitude response are reported in terms of the dimensionless parameter A

$$A = \Delta i_1/\Delta i \quad [6]$$

where $A \to 1$ as $\sigma \to 0$.

The need to predict values of Δi_1 and φ_1 had been prompted by unpublished studies of certain applications of SHM. These results indicated the desirability of performing experiments at larger values of σ/ω_o than those to which we restricted the earlier work. For example, where potential scanning programs are used, higher modulation frequencies permit using higher scanning rates before undue distortion of Δi_1-E curves is found, shortening experiments, reducing sensitivity to impurity poisoning, and thus leading to a better response to convective-diffusion controlled reactions.

Excellent agreement between the theory for A and φ_1 and experiment has been found for the reduction of Fe^{+3} to Fe^{+2} in 1.0*M* H_2SO_4 over the temperature range 25°-85°C (230-2100 Sc).

Theoretical

The normal component of the fluid velocity, w_o, for an infinite disk rotating at constant angular velocity was first studied by von Kármán (7) and later by Cochran (8). After quasi-steady state is reached, w_o is given by

$$w_o = (\omega\nu)^{1/2} H_o(\eta) \quad [7]$$

where ν is the kinematic viscosity and

$$\eta = (\omega/\nu)^{1/2} z \quad [8]$$

For small η

$$H_o(\eta) = -0.51023\,\eta^2 + 0.33333\,\eta^3 - 0.10267\,\eta^4 + \ldots \quad [9]$$

* Electrochemical Society Active Member.

Key words: hydrodynamic modulation, frequency dependence, convective-diffusion.

where the value of the second derivative of $H(\eta)$ with respect to η at $\eta = 0$ is the one given by Cochran (8).

Sparrow and Gregg (11) analyzed the analogous rotating disk problem for the case in which the angular velocity was a time dependent quantity. Their expression for the instantaneous normal component of the fluid velocity w, was obtained by a series expansion about the value found at quasi-steady state, *i.e.*

$$w = (\omega\nu)^{1/2}\{H_o(\eta) + \beta_1 H_1(\eta) + \beta_2 H_2(\eta) + \ldots\} \quad [10]$$

where

$$\beta_1 = (d\omega/dt)/\omega^2 \quad [11]$$

$$\beta_2 = (d^2\omega/dt^2)/\omega^3 \quad [12]$$

and the $H_i(\eta)$ are axial velocity functions that satisfy the equations

$$H_i(\eta) = \tfrac{1}{2} H_i''(0)\eta^2 = c_i\eta^2 \quad [13]$$

for all i values at small values of η.

The values of the $H_i(\eta)$ functions were given graphically (11) for $0 \leq \eta \leq 20$, and the values of $H_2''(0)$ were given in their Table I. However, the values of higher derivatives at $\eta = 0$ were not given. Using their Table I data, we obtain

$$c_0 = -0.51023$$
$$c_1 = 0.204835 \quad [14]$$
$$c_2 = -0.023112$$

and

$$w = -0.51023(\omega^3/\nu)^{1/2}z^2\{(1 - 0.65327\eta + 0.20121\eta^2) - 0.40144\beta_1 + 0.04530\beta_2\} \quad [15]$$

as a good approximation to w when $\beta_{i+1} \leq \beta_i$. Note that when $\beta_1 = \beta_2 = 0$, Cochran's result, as used by Newman (12), is obtained. It is therefore possible to solve the Levich problem for small oscillations in ω, given its time dependence.

As stated previously, the superposition of a sinusoidal $\omega^{1/2}$ modulation, $\Delta\omega^{1/2}$, about a constant value, $\omega_o^{1/2}$, is advantageous from the experimental viewpoint, and the problem we deal with assumes that

$$\omega = \omega_o(1 + \epsilon \cos \sigma t)^2 \quad [16]$$

It is also convenient to define

$$p = \sigma/\omega_o \quad [17]$$

Thus, the values of β_1 and β_2 are

$$\beta_1 = -2\,\epsilon\, p \sin \sigma t(1 + \epsilon \cos \sigma t)^{-3} \quad [18]$$

and

$$\beta_2 = -2\,\epsilon\, p^2\{\cos \sigma t + \epsilon(\cos^2 \sigma t - \sin^2 \sigma t)\}(1 + \epsilon \cos \sigma t)^{-6} \quad [19]$$

Substituting Eq. [18] and [19] into Eq. [15] and assuming $\epsilon << 1$ yields the expression for the instantaneous normal component of the fluid velocity

$$w = w_o\{1 + \epsilon(a_{01} \cos \sigma t + a_{10} \sin \sigma t) + \epsilon^2(a_{02} \cos 2\sigma t + a_{11}) + \ldots\} \quad [20]$$

where

$$w_o = -0.51023(\omega_o^3/\nu)^{1/2}z^2(1 - 0.65327\eta_o + 0.20121\eta_o^2)$$

$$a_{01} = (3 - 2.6131\eta_o + 1.0060\eta_o^2 - 0.090591p^2)/(1 - 0.65327\eta_o + 0.20121\eta_o^2)$$

$$a_{10} = 0.80288p/(1 - 0.65327\eta_o + 0.20121\eta_o^2) \quad [21]$$

$$a_{02} = (1.5 - 1.9598\eta_o + 1.0060\eta_o^2 - 0.04530p^2)/(1 - 0.65327\eta_o + 0.20121\eta_o^2)$$

$$a_{11} = (1.5 - 1.9598\eta_o + 1.0060\eta_o^2 - 0.13589p^2)/(1 - 0.65327\eta_o + 0.20121\eta_o^2)$$

and

$$\eta_o = (\omega_o/\nu)^{1/2}z$$

However, if $\epsilon < 1$ rather than $\epsilon << 1$, only the amplitude of the second harmonic expression in Eq. [20] will be in error, while the amplitude of the first harmonic with which we are experimentally concerned remains unchanged.

In order to obtain the time dependent convective-diffusion limiting current, the convective-diffusion equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial z^2} - w\frac{\partial C}{\partial z} \quad [22]$$

must be solved for the boundary conditions

$$z = 0 : C = 0$$
$$z \to \infty : C \to C^\circ \text{ (bulk concentration)} \quad [23]$$

$w(z, t)$ given by Eq. [20] and [21] and for steady sinusoidal variations.

Taking into account the form of Eq. [20], a solution of the convective-diffusion equation is

$$C = C^\circ\ u(z, t) \quad [24]$$

where

$$u(z, t) = u_o(z) + \epsilon\{u_{01}(z) \cos \sigma t + u_{10}(z) \sin \sigma t\} + \epsilon^2\{u_{02}(z) \cos 2\sigma t + u_{20}(z) \sin 2\sigma t + u_{11}(z)\} + \ldots \quad [25]$$

Thus, we substitute Eq. [24] and Eq. [20] into Eq. [22], equate the coefficients of all terms having the same time dependence in the resulting expression, and obtain a set of ordinary differential equations involving functions of z. These equations are not written out here but may be simplified by using the dimensionless variable

$$\xi = \{0.51023(\omega_o^3/\nu)^{1/2}/3D\}^{1/3}z = 0.55405\ \mathrm{Sc}^{1/3}\eta_o \quad [26]$$

where $\mathrm{Sc}(\equiv \nu/D)$ is the Schmidt number, and they lead to the set of equations below where the various u's are functions of ξ and the primes represent differentiation with respect to ξ

$$u''_o - f(\xi)u'_o = 0 \quad [27]$$

$$u''_{01} - f(\xi)(u'_{01} + a_{01}u'_0) = bu_{10} \quad [28]$$

$$u''_{10} - f(\xi)(u'_{10} + a_{10}u'_0) = -bu_{01} \quad [29]$$

$$u''_{02} - f(\xi)(u'_{02} + a_{02}u'_0) = 2bu_{20} \quad [30]$$

$$u''_{20} - f(\xi)u'_{20} = -2bu_{02} \quad [31]$$

$$u''_{11} - f(\xi)(u'_{11} + a_{11}u'_0) = 0 \quad [32]$$

where

$$f(\xi) = -3\xi^2 + 3.5372\ \mathrm{Sc}^{-1/3}\xi^3 - 1.9663\ \mathrm{Sc}^{-2/3}\xi^4 \quad [33]$$

The quantity b is defined by

$$b = \{9\nu/(0.51023)^2 D\}^{1/3}p = 3.2576\ \mathrm{Sc}^{1/3}p \quad [34]$$

The boundary conditions become

$$\xi = 0 : u_0 = u_{01} = u_{10} = u_{02} = u_{20} = u_{11} = 0$$
$$\xi \to \infty : u_0 \to 1, u_{01}, u_{10}, u_{02}, u_{20}, \text{ and } u_{11} \to 0$$

It is readily shown that the form of Eq. [25] leads to a current of the form given by Eq. [5].

The limiting convective-diffusion current, i, is defined by

$$i = n\mathbf{F}\pi r^2 D(\partial C/\partial z)_{z=0} \quad [35]$$

or in terms of ξ

$$i = n\mathbf{F}\pi r^2 DC^\circ(d\xi/dz)(\partial u(\xi, t)/\partial\xi)_{\xi=0} \quad [36]$$

where r is the radius of the disk electrode. Combining Eq. [25] and [36] with Eq. [26] yields

$$i = i_{\omega_o} + i_{\omega_o}I(\infty)\epsilon\, a_1 \cos(\sigma t - \varphi_1) + i_{\omega_o}I(\infty)\epsilon^2\{a_2 \cos(2\sigma t - \varphi_2) + a_3\} + \ldots \quad [37]$$

where

$$a_1 = [\{u'_{01}(0)\}^2 + \{u'_{10}(0)\}^2]^{1/2} \quad [38]$$

$$\varphi_1 = \cos^{-1}\{u'_{01}(0)/a_1\} = \sin^{-1}\{u'_{10}(0)/a_1\} \quad [39]$$

$$a_2 = [\{u'_{02}(0)\}^2 + \{u'_{20}(0)\}^2]^{1/2} \quad [40]$$

$$\varphi_2 = \cos^{-1}\{u'_{02}(0)/a_2\} = \sin^{-1}\{u'_{20}(0)/a_2\} \quad [41]$$

$$a_3 = u'_{11}(0) \quad [42]$$

and

$$i_{\omega_0} = 0.6205 n\mathbf{F}\pi r^2 D^{2/3}\nu^{-1/6}\omega_0^{1/2} C^\circ \Gamma(4/3)/I(\infty) \quad [43]$$

The above value for i_{ω_0} is obtained by solving Eq. [27] to obtain

$$u_0(\xi) = I(\xi)/I(\infty) \quad [44]$$

where

$$I(\xi) = \int_0^\xi \exp\left[\int_0^\xi f(x)\,dx\right] d\xi = \int_0^\xi \exp(-\xi^3 + 0.8843\mathrm{Sc}^{-1/3}\xi^4 - 0.3932\mathrm{Sc}^{-2/3}\xi^5)\,d\xi \quad [45]$$

and $I(\infty)$ is given by

$$I(\infty) = 0.89294 + 0.26610\mathrm{Sc}^{-1/3} + 0.12960\mathrm{Sc}^{-2/3} \quad [46]$$

which was obtained by Newman (12) for the correction of the Levich equation and holds for Sc $\geqq$ 100.

The experiments we have performed involve detecting the magnitude and phase of the current at the frequency used to modulate $\omega^{1/2}$; hence we need only solve Eq. [28] and [29] and we have postponed consideration of the behavior of the terms associated with the second harmonic.

Equations [28] and [29] were solved numerically (13) for various values of p in the range 0-1.0 and for selected values of Sc in the range 100-2100. In addition, A and ϕ_1 corresponding to specific experimental Sc values were calculated where required.

The effect of p on amplitude response for selected values of Sc is given in Table I, using the parameter A defined by Eq. [6].

By comparing the coefficients of the $\cos(\sigma t - \varphi_1)$ of Eq. [5] and [37] it is seen that

$$\Delta i_1 = i_{\omega_0} I(\infty)\epsilon a_1 \quad [47]$$

Substituting Eq. [47] and [46] into Eq. [6] yields

$$A = (0.89294 + 0.26610\mathrm{Sc}^{-1/3} + 0.12960\mathrm{Sc}^{-2/3})a_1 \quad [48]$$

The theoretical values of a_1 at constant p and Sc are calculated using the numerical values of $u'_{01}(0)$ and $u'_{10}(0)$ obtained through Eq. [28] and [29] and applying Eq. [38]. The phase shift φ_1 is calculated from Eq. [39] and is given in Table II.

In using Tables I and II, linear interpolation at low Sc values is not accurate. A more sophisticated interpolation technique or graphing of the tabulated values of A and φ_1 is necessary if an error less than that found experimentally is to be achieved.

In the above discussion, both the deviation of hydrodynamics from quasi-steady state and the simultaneous relaxation of the diffusion layer were taken into account. It is of interest to estimate the conditions under which the current response is controlled almost completely by convective-diffusion, *i.e.*, the conditions under which the hydrodynamic situation deviates by only a small percentage from quasi-steady state. Since we propose to obtain only an estimate for this condition, only the large Schmidt number limit for the normal velocity component, obtained from Eq. [15], will be used, *i.e.*

$$w = -0.51023[\{\omega(1 - 0.40144\beta_1 + 0.04530\beta_2)^{2/3}\}^3/\nu]^{1/2} z^2 \quad [49]$$

From Eq. [49] it is seen that small deviations of ω from quasi-steady state are approximately given by $2/3 \times 0.401\beta_1\omega$. Since the deviation in the percentage current error, α, is twice that in angular velocity, it follows that relationship between the error in ω and i is given by

$$\beta_1 = \frac{\dot{\omega}}{\omega^2} = -2p\frac{\sin\sigma t}{(1 + \epsilon\cos\sigma t)^3} \leqq 0.0187\alpha \quad [50]$$

The maximum value of β_1, β_{max}, is

$$\beta_{max} = 2\epsilon p \frac{\sqrt{1 - \left(\frac{1 - \sqrt{1 + 24\epsilon^2}}{4\epsilon}\right)^2}}{\left(\frac{5 - \sqrt{1 + 24\epsilon^2}}{4\epsilon}\right)^3} = 2\epsilon p f(\epsilon) \quad [51]$$

so that the relationship between p, and ϵ and α is

$$2\epsilon p f(\epsilon) \leq 0.0187\alpha \quad [52]$$

Sparrow and Gregg (11) considered the problem of determining under what condition the shear stress would deviate by less than 5% from its quasi-steady state value and found that

$$\beta_1 \leq 0.0834$$

which, by comparison with Eq. [50], corresponds to an α of 4.5%.

Table III gives the values of p *vs.* selected ϵ's which cannot be exceeded if the deviation from hydrodynamic quasi-steady state is not to produce a current error exceeding 4.5%

The significance of Table III is merely that, within specified restrictions on p and ϵ, the total current is determined by convective-diffusion processes rather than by the coupling of convective-diffusion and a deviation from a hydrodynamic quasi-steady state.

Experimental

The motor drive and operational amplifier control systems have been described previously (3, 5). The entire system (mechanical plus electronic) bandwidth for modulation was examined by recording the motor tachometer's voltage amplitude and phase shift with respect to the driving waveform. The latter signal was the sum of a linear voltage ramp and a sinusoidal voltage of constant frequency and amplitude. The ramp voltage was selected to scan the center motor speed, ω_0, from 6.67 Hz (400 rpm) to above 125 Hz (7500 rpm).

Typical tracings of a-c motor reponse to this kind of program are shown in Fig. 1; *e.g.*, at a constant modulation (signal) amplitude of 3 $rpm^{1/2}$ and a frequency of 6 Hz, the tachometer amplitude agrees with the a-c driving signal to ±1% and the phase shift is constant within ±1° at least up to a center speed of 84 Hz (>5000 rpm). The amplitude circuitry in the Dranetz Phasemeter automatically switches ranges during experiments since a constant $\Delta\omega^{1/2}$ at all speeds produces a-c voltages (related to $\Delta\omega$) which typically vary by a factor of more than four. The observed constant phase shift level in each trace is determined solely by modulation frequency, up to the rotational frequencies indicated by the roll-offs in Fig. 1.

All experiments were carried out with combinations of modulation frequency, amplitude, and center rotational speed frequency for which any amplitude and phase errors due to the above sources were well within ±1% and ±1°, respectively. Thus, correction of the modulated disk electrode current response for $\Delta\omega^{1/2}$ variations was eliminated, and a full-wave rectifier circuit was used to obtain the amplitude in Δi-experiments. In these experiments, the amplitude response Δi_1 was determined as a function of p. Extrapolations of the Δi_1 data to $p = 0$ yield the maximum amplitude response, and A values were calculated by dividing

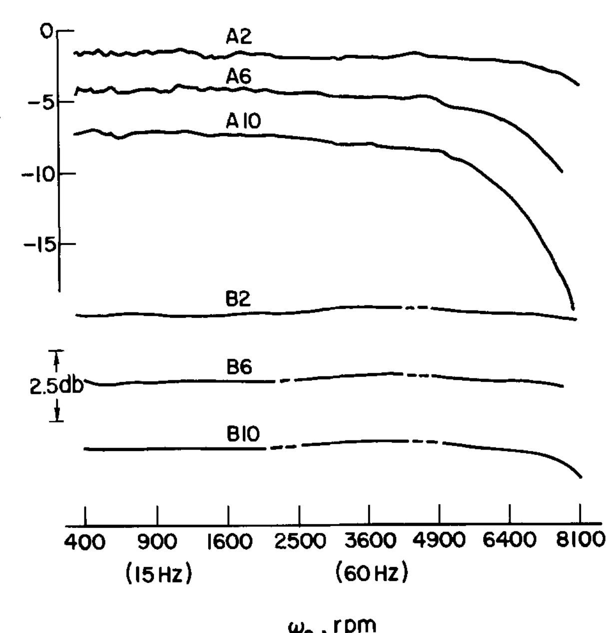

Fig. 1. A-C motor response to sinusoidal modulation. Curves A are phase shift, tachometer *vs.* signal; curves B are log of amplitude ratio, tachometer to signal. Signal amplitude set to constant $\Delta\omega^{1/2}$ of 3 $rpm^{1/2}$; center was scanned from low to high. Fixed frequency of modulation (Hz) indicated by number following A or B. Constant phase shift levels were, for A2, A6, and A10, respectively, −1.6°, −4.3°, and −7.2°, expressed as deviation from the theoretical 180° (no lag) shift. Amplitude plots arbitrarily displaced from common value; dashed regions indicate interruption of measurement due to ranging of phasemeter.

this value into the observed amplitude response at the various p values.

The phase shift of the sinusoidal Δi response relative to the $\Delta\omega$ tachometer output was continuously recorded with a Dranetz Model 305 Phasemeter equipped with a Model 3009A plug-in, after prefiltering each signal with matched 0.64-32 Hz two-pole bandpass amplifiers that introduced <0.5° of phase shift uncertainty. In a typical experiment, ω_0 was scanned from 400 to *ca.* 8000 rpm and back, and the φ data averaged to correct for a small hysteresis related to time constant effects. The experimental abscissas were converted to $p = \sigma/\omega_0$ values and the φ data were used without further reduction.

The electrochemical experiments were all carried out with a 0.313 cm^2 platinum disk electrode and a 2.17 mM Fe^{+3} − 1.0*M* H_2SO_4 solution, prepared from reagent chemicals and triply distilled (the last two from quartz) water. The Sc was varied by performing experiments at 10°C ± 0.5°C increments between 25° and 85°C. The supporting electrolyte kinematic viscosities, ν were determined with a Cannon-Fenske viscometer that was calibrated with water over the 25°-75°C range. The diffusion coefficients for Fe^{+3} were calculated at the various temperatures from the slopes of Levich plots (i_L *vs.* $\omega^{1/2}$) for the limiting current of Fe^{+3} reduction, utilizing the ν values determined independently above and Eq. [46]. Log plots of Sc, D, and ν *vs.* $1/T$°K are shown in Fig. 2.

All data in this paper were obtained at 0.00V *vs.* an unthermostated SCE. This potential was in the limiting current region over the 25°-85°C cell temperature range.

Results and Discussion

The phase shift, φ_1, of the modulated limiting disk current output, Δi_1, produced by $\omega^{1/2}$ modulation at the frequency $f = \sigma/2\pi$ Hz, was directly measured for the reduction of Fe^{+3} to Fe^{+2} in 1.0*M* H_2SO_4, using the constant modulation frequency-ω_0 variation technique described in the Experimental Section. The value of A, however, was, as noted, not calculated directly from the defined value of $\Delta i_1/\Delta i$ but rather from $\Delta i_1/$

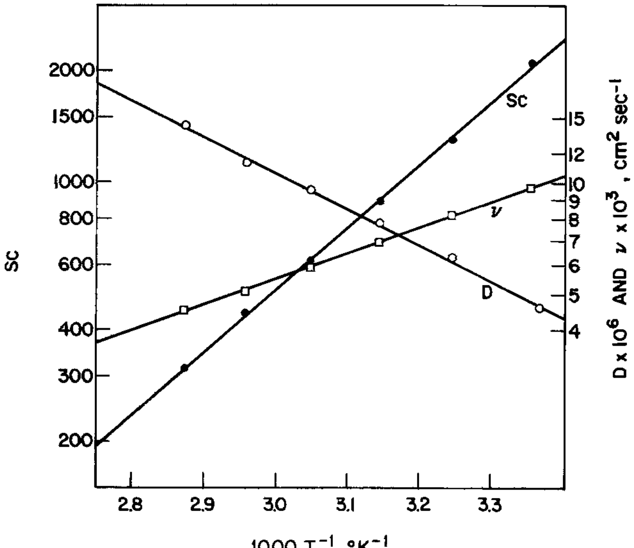

Fig. 2. Log plots of Sc, *D*, and ν vs. 1000/*T*° K.

$(\Delta i_1)_{p\to 0}$ where $(\Delta i_1)_{p\to 0}$ is the extrapolated value of Δi_1 at $p = 0$. Satisfactory agreement between $(\Delta i_1)_{p\to 0}$ and Δi has been established previously by us (5), and the present procedure cancels a number of possible sources of small determinate errors associated with the electronic instrumentation including bandpass, gain, and rectification efficiency.

Theoretical plots and experimental values of A and φ_1 as a function of p for three values of Sc (315, 890, and 2100) are given in Fig. 3 and 4. Other sets of data obtained for different Sc (not plotted) agree equally well with theory. The Sc range illustrated in Fig. 3 and 4 covers the great majority of aqueous solution cases that will be encountered.

Satisfactory experimental tests of the theory for A and φ_1 dependence on Sc for five constant p values from 0.2 to 0.6 are given in Fig. 5 and 6. The theoretical values of A and φ_1 for these particular Sc values may also be accurately obtained by graphical interpolation in the tables of A and φ_1 given earlier, assuring the general experimental usefulness of the tabulations.

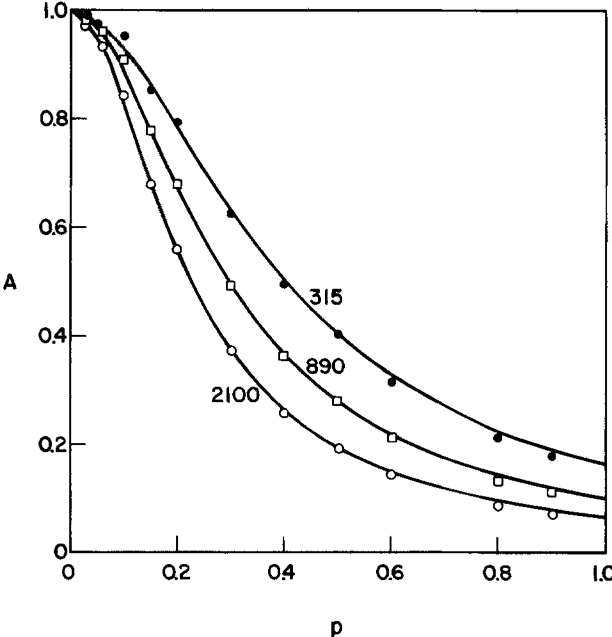

Fig. 3. Amplitude factor *A* as a function of *p* for Sc values of 315, 890, and 2100, as marked. Solid lines are theoretical, points are experimental.

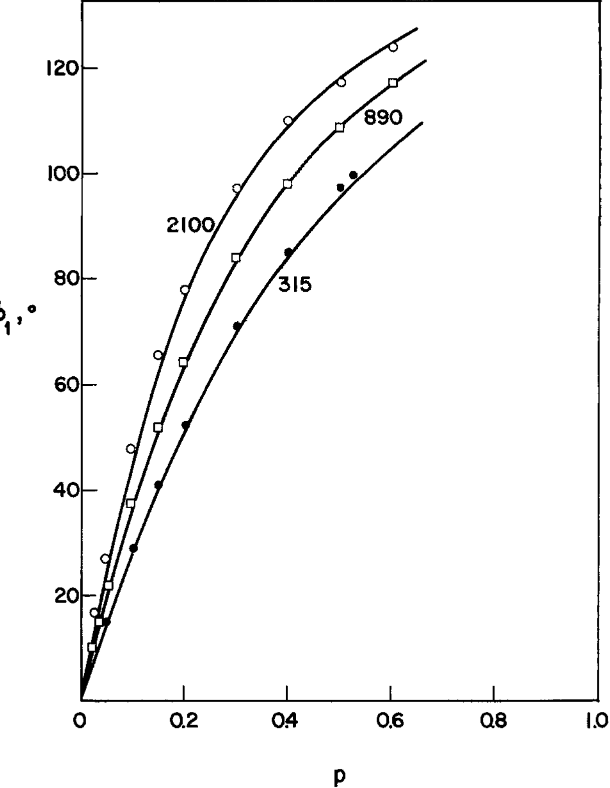

Fig. 4. Phase shift φ_1 as a function of *p* for Sc values of 315, 890, and 2100. Sc values marked. Solid lines are theoretical, points are experimental values.

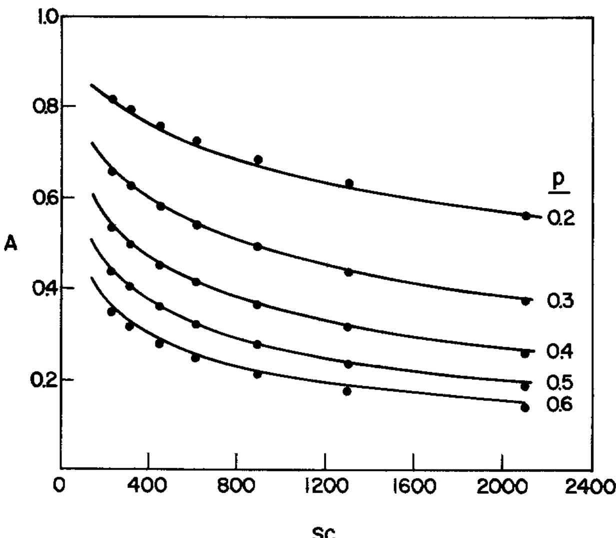

Fig. 5. Amplitude factor as a function of Sc at constant *p*. Values of *p* indicated at right of curves. Solid curves are theoretical, points are experimental.

The criteria of Table III, expressing maximum limits of p and ϵ for which the total current is essentially determined by convective-diffusion processes, have been exceeded in certain of our measurements by a factor of as much as three. Our theory explicitly takes into account the region in which convective-diffusion and hydrodynamics couple. Nevertheless, it was of significance to examine experimentally whether the $p\epsilon$ product at these levels, rather than just p alone, influenced the value of A in a given solution. Therefore, Δi_1 was measured as a function of $\Delta\omega^{1/2}$ under conditions of constant p, while $\Delta\omega^{1/2}$ was varied so that $p\epsilon$ was either always $\leqq 0.04$, exceeded 0.04 at an intermediate value of $\Delta\omega^{1/2}$, or was $\geqq 0.04$ for all $\Delta\omega^{1/2}$. We

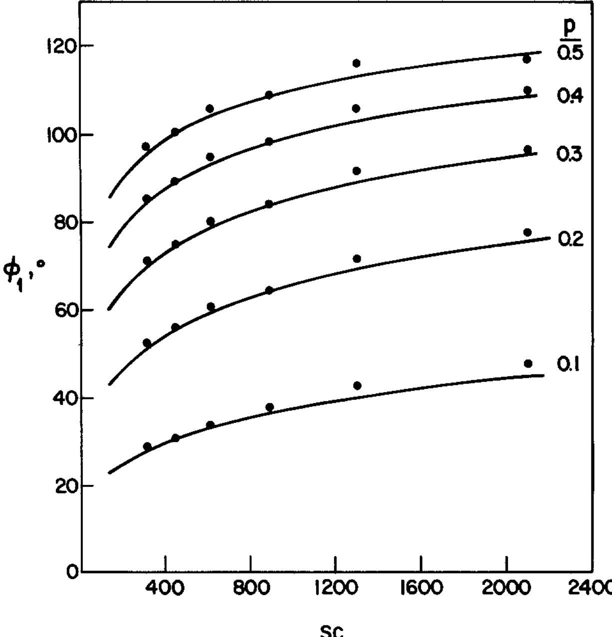

Fig. 6. Phase shift ϕ_1 as a function of Sc for constant p. Values of p indicated at right of curves. Solid curves are theoretical, points are experimental.

chose 0.04 simply as the approximate level of the $p\epsilon$ products collected in Table III.

These results for Fe^{+3} reduction in 1.0M H_2SO_4 are shown in Fig. 7. The points taken for $p = 0.2$ cover $p\epsilon$ from 0.004 to 0.03, those for $p = 0.4$ cover 0.012-0.093, and those for $p = 0.8$ cover 0.04-0.26. All three plots are linear and both the slope ratios (A ratios) and absolute A values are in satisfactory correspondence to the theory given above. Absolute A values were estimated in this case by determining Levich plots of i_{ω_0} *vs.* $\omega_0^{1/2}$ for various $\omega_0^{1/2}$ and comparing the slopes with those of the Fig. 7 plots. By combining Eq. [43] with Eq. [6], a definition of A related to this experimental approach is obtained, *i.e.*

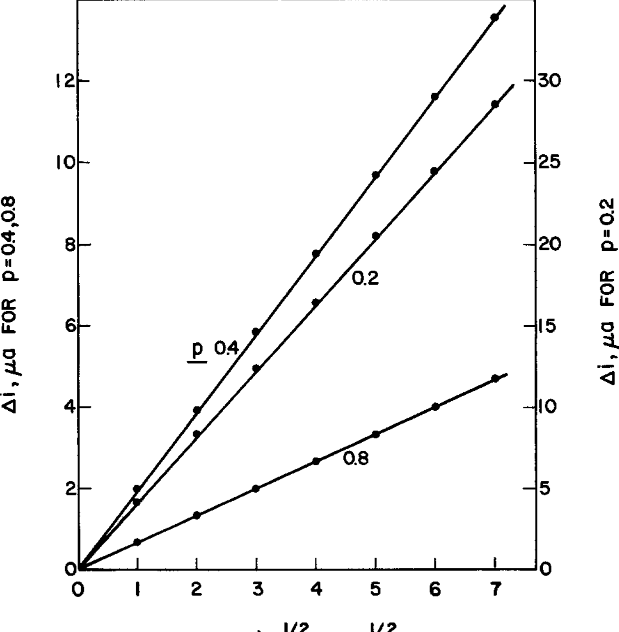

Fig. 7. Δi_1 as a function of $\Delta\omega^{1/2}$ at constant p values of 0.2, 0.4, and 0.8, as marked. Modulation frequency 6 Hz (all curves), center speed held at 30, 15, and 7.5 Hz. Abscissa is convertible to $p\epsilon$ values by multiplication by 0.00472, 0.0133, and 0.0377 for p = 0.2, 0.4, and 0.8, respectively.

$$A = \frac{\Delta i_1}{\Delta\omega^{1/2}} \Bigg/ \frac{i_{\omega_0}}{\omega_0^{1/2}} \qquad [53]$$

Hence, the slopes of the SHM data in Fig. 7, when divided by the slopes of the Levich plots, give the A values for the particular p values.

As far as the SHM technique is concerned, exceeding the $p\epsilon$ criterion for deviation from a hydrodynamic quasi-steady state by even a factor of six appears to have little detectable effect on $\Delta i_1 - \Delta\omega^{1/2}$ plots. This result, predicted by theory, has the significance for practical use of the SHM technique at higher modulation frequencies (larger p) that, to a large extent, much of the loss of current sensitivity associated with a decreasing A factor at higher p values may be compensated by a $\Delta\omega^{1/2}$ increase. At present, the practical limitations of this sort of approach appear to reside mostly in the amplitude and frequency response of the motor system.

The A and φ_1 functions are independent of the concentration of the electroactive species and its n value in the electrode process. This property suggests a method for determining the diffusion coefficient of an electroactive species without *a priori* knowledge of the n value (or concentration), as is required by RDE and other voltammetric steady-state diffusion layer techniques. From the A (or φ_1) *vs.* p data for an unknown system, Sc for the electroactive species can be determined by interpolation in Table II (or I). D can then be calculated from the readily determined kinematic viscosity of the solution. This value of D may be in error by ±10-15%, because of the combination of experimental error and relative insensitivity of the A or φ_1 *vs.* p function to some values of Sc. However, if i_{ω_0} and the electroactive solute's concentration are known, substituting these data and the estimate of D into Eq. [43] will permit determination of the integral value of n, and thence a precise value of D.

Application of the SHM technique to solutions containing two or more electroactive components leads to certain difficulties if phase sensitive detection is used to determine Δi_1. In such mixtures, each electroactive species has its unique value of Sc, and thus a corresponding phase shift. The detection of Δi_1 response for regions on the current-voltage curve involving simultaneous reduction (or oxidation) of more than one species is thus complicated by the varying phase shifts for each component. There are obvious experimental strategems to correct for this difficulty, *e.g.*, manual tuning of the phase shift for each of the components is feasible. However, the variation of phase angles as a function of Sc at constant p, as can be seen from Table I or Fig. 3, is not large. The phase angle effect is modest when compared to the phase angle setting accuracy requirements of lock-in amplifiers. Phase errors of ±10° are necessary for 1½% signal loss and, if the spread of Sc values is not extreme, errors due to this source will probably be small in most practical situations.

It should be noted that, if a tuned filter used to isolate the a-c response to SHM is followed by either full-wave rectification or RMS detection, the phase problem is completely avoided.

The theory presented here does not apply to the case of mixed electron and mass transfer control, which we have already considered for the $p \to 0$ limit (6). There are effects in those situations (further diminishing A and increasing φ_1) which require a more involved treatment.

Technical Note

The Cathodic Reaction of Iron Disulfide Electrode in KCl-LiCl Eutectic Electrolyte

Katsushi Abe and Takewo Chiku*

Toyota Central Research and Development Laboratories, Incorporated, 2-12, Hisakata, Tempaku-ku, Nagoya 468, Japan

The molten salt battery will be given more attention in the near future because of its high specific power and high specific energy. However, in the present state, there are various difficulties involving the battery construction, particularly the risk at high temperature operation from the use of liquid (1) or gaseous (2) active material as the positive electrode.

Vissers *et al.* (3) studied the molten salt secondary cells with iron sulfide as the positive material. This study was useful because it showed that there was no significant deterioration of electrical performance with cell operation.

Tomczuk, Martin, and Steunenberg (4,5) found that metal sulfides, such as nickel or cobalt sulfide, were solid-state materials that could serve as a positive electrode for a molten salt battery, and they proposed that the charge reaction of iron disulfide proceeds by three steps. The present authors have also examined various metal sulfides as solid-state active material for a battery with KCl-LiCl eutectic electrolyte.

It is the purpose of the present note to elucidate the discharge reaction of iron disulfide in KCl-LiCl eutectic electrolyte by a combination of the polarization character and x-ray diffration analyses.

Experimental

The test electrodes were prepared, as shown in Fig. 1, by putting a definite quantity of iron disulfide powder in a hole (3.2 mm diameter, about 3 mm depth) drilled in spectroscopic graphite rod (6 mm diameter, 150 mm length), then filling it with electrolyte salt powder; the lower part of the rod was fixed by baking Aremco alumina adhesive and glazed Pyrex to separate it from the electrolyte except the hole. To prevent iron disulfide from escaping, the hole was sealed by wind-

Key words: iron pyrite, discharge reaction, molten salt electrolyte, high temperature cell.

ing the rod with quartz wool. The iron disulfide powder sample used in this study was a commercial pyrite (99.9% purity) containing only a trace of marcasite as shown by x-ray diffraction analysis.

The 58 mole per cent (m/o) LiCl-42 m/o KCl eutectic electrolyte was prepared by combining reagent grade lithium chloride and potassium chloride in a Pyrex vessel at 400°C, bubbling hydrogen chloride gas for about 1 hr and then high purity argon gas (O_2: ~1 ppm, dew point: −65°C) for several hours. A Pyrex tube 28 mm inner diameter and 150 mm height was used as the electrolysis cell; the anode and the cathode compartments were separated by quartz wool. Figure 1 shows a schematic representation of its construction. The iron disulfide electrodes were discharged and charged at 400°C in the electrolyte with glassy carbon as the counterelectrode. High purity argon gas was made to flow continuously over the electrolyte during the experiments. The electrode potential was measured against a Pt/0.01 mole $PtCl_2$ reference electrode with the supporting electrolyte.

The reaction products used for x-ray measurements were taken from the electrode at various stages of charge and discharge in the following way: The respective electrodes were removed from the circuit and cooled in argon atmosphere, the products extracted from the graphite rods were crushed and pulverized in the atmosphere, then were covered with a thin film of Mylar. No washing or drying procedures were performed so as to prevent any change in the chemical composition.

Results and Discussion

Discharge and charge characteristics.—Figure 2 shows potential/time curves for the iron disulfide electrode with the repetition of discharge and charge cycles at a constant current of 200 mA/cm². The potential curve obtained during the first discharge to −2.0V shows several steps, and similar steps also were obtained in the curve with the subsequent charge to −0.7V, in which open-circuit potential before the discharge was about −0.7V. When repeating the cycle, the corresponding curves have little change in the shapes and the discharge capacities, at least up to 40 cycles. There is an additional step at about −0.8V in the discharge curve. However, judging from the fact that the upper limit of the charging potential was equal to the open-circuit potential at the initial state, the open-circuit potential could not be that of iron disulfide itself.

Figure 3 shows the discharge and charge curves at a constant current density of 100 mA/cm² and open-circuit potentials in various discharge and charge states; a stationary value obtained about 30 min after the circuit was opened at each state served for the open-circuit potential. It is seen that both the open-circuit potential curves in the discharge and charge were composed of four steps, and they are in close agreement with each other. These results suggest that the discharge-charge reaction proceeds through four reversible processes. At this current density, the polarization curve in discharge also shows four distinct steps corresponding to those in the open-circuit potential curve, but the four steps grow less distinct as the discharge current increases.

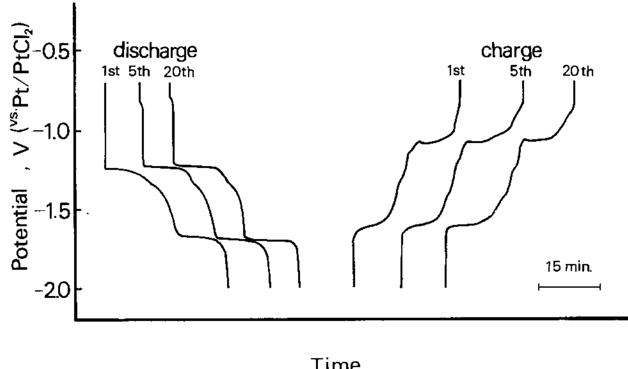

Fig. 2. Typical potential/time curves for FeS_2 electrode in discharge-charge cycling at a constant current density of 200 mA/cm².

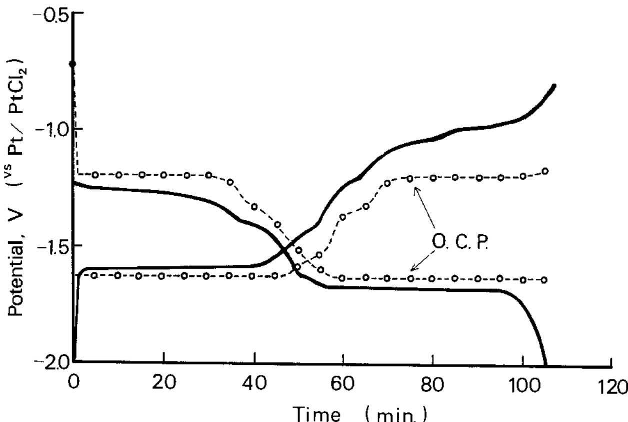

Fig. 3. Discharge-charge curves at a constant current density of 100 mA/cm² and open-circuit potentials in various discharge and charge states, for 20 mg FeS_2 at 400°C.

X-ray diffraction analyses.—Five electrodes, each containing 70 mg of iron disulfide, were placed in the discharge and charge states in the KCl-LiCl electrolyte. Three of them were partially discharged to −1.3, −1.6, or −2.0V at a current density of 50 mA/cm². The fourth electrode was completely discharged to −2.0V intermittently at 25 mA/cm². The last electrode was discharged to −2.0V at 100 mA/cm², then immediately recharged to −0.7V, the level of initial potential, at the same current density. X-ray diffraction analyses were carried out as a function of the depth of discharge. The results are summarized in Table I. As seen from the table, the starting material is pyrite containing a trace of marcasite. Phases gradually decrease with progressive discharge and are eventually exhausted at about −1.6V. At −2.0V, lithium sulfide and iron were observable as the final products. It is noted here that by recharging the electrode, the diffraction peaks of lithium sulfide and iron disappear accompanied by the reformation of pyrite together with a trace of pyrrhotite. However, many unknown peaks were present in the diffraction pattern at the partial discharge states. As shown in the last column

Table I. Results of x-ray diffraction analyses; Co-Kα, 2θ; 30° ~ 80°

No. of sample	Sampling potential (V)		Discharge state (%)	Identified material	Unknown peaks
	Discharge	Charge			
—	—	—	0	Pyrite, Marcasite (trace) ↓ ↓	
1	−1.3	—	35	(Decrease) Marcasite ↓ ↙	(A) (B) ↓ ↓
2	−1.6	—	40	(Not detected)	↓ Decrease (C) ↓
3	−2.0	—	85	Li_2S, Fe	Increase ↓ Decrease
4	−2.0	—	100	Li_2S, Fe	Not detected
5	(−2.0)	−0.7	3	Pyrite, $Fe_{1-x}S$ (trace)	

of Table I, the unknown peaks were divided into three groups denoted by A, B, and C, respectively. These classifications show a partial increase or decrease as the discharge takes place. To ascertain if said peaks may have been caused by atmospheric oxidation or hygroscopicity during the sample preparation, the same examination was carried out with the sample specially prepared in a high purity argon atmosphere. No change, however, was observed in the diffraction pattern.

The results suggest at least that the corresponding substances were formed with the discharge process and that they transform to a stable substance at the final stage. In fact, the unknown peaks disappeared at the complete discharge state, and lithium sulfide and iron, which are considered to be the final products, could only be detected. These results corroborate previous findings that suggested four reversible processes make up the discharge-charge reaction.

Role of Anodic Processes in the Electrolytic Coloration of Alkali Halides

M. T. Montojo[1] and F. Jaque

Departamento de Física, Universidad Autónoma, Cantoblanco, Madrid, Spain

and C. Sánchez

FEMSA, D.E.P. Investigación, Hnos. García Noblejas No. 19, Madrid 17, Spain

ABSTRACT

An investigation has been made into the origin of Zone IV (1) of the current *vs.* time curves obtained during electrolytic coloration of alkali halides with a pointed cathode and a flat metallic anode mechanically pressed against the crystal. Zone IV is not intrinsic and is not due to the crystal volume itself, but is related to processes occurring in the crystal metallic anode interface. Whenever these processes are inhibited, *e.g.*, by using a vacuum evaporated metallic anode, Zone IV is suppressed and intrinsic current *vs.* time curves are obtained. These curves resemble those corresponding to space charge limited currents in insulators and semiconductors. The following anodic processes are mentioned: An electrical arc was produced in the thin and irregular gap between the crystal and the anodic plate. The intensity of the light emitted from this arc correlates with electrical current during Zone IV and the spectral distribution shows a complicated multipeak structure. The number and position of the peaks are quite independent of the alkali halide crystal, anodic material, and gas filling the furnace. Most of the spectrum peaks correspond fairly well in position to those of the air component discharge. The main characteristics of the arc are due to air (water vapor) adsorbed on the anodic crystal surface. A tentative explanation of how this electrical arc can determine the properties of Zone IV is proposed.

Electrolytic coloration has been extensively used as a procedure to create F-centers in alkali halides (2); the number of F-centers produced depending upon the experimental conditions. Experiments are usually carried out at constant temperatures (~350°-700°C) and applied voltages (50-10^3/V). Currently, a pointed cathode and a flat metallic anode machanically pressed against the crystal are used. Atmospheres surrounding the crystals are air, vacuum, or an inert gas.

The evolution of the electrical current through the crystal during the electrolytic coloration has been recorded in KCl and KBr (1, 3, 4). Figure 1 shows an example of this behavior in KBr single crystals. F-center density changes in a parallel fashion, as shown by the dashed curve, although a time lag exists. Four zones appear in the *i-t* curve. Zone I has been accounted for as being due to purely ionic transport (1, 4, 5). This process leads to the formation of an injecting contact at the cathode-crystal interface (6). Once this contact is formed electrons are injected from the pointed cathode into the crystal. Electronic current marks the start of Zone II. The kinetics of this zone in KCl has been explained by Heiland (3) and Karabascheff (7) as due to F-center diffusion. Equations describing the slope of this zone have also been proposed.

In spite of the wide use of electrolytic coloration, several questions relating to its physical mechanisms still remain open. Briefly, these questions relate to: (*i*) The appearance of Zone IV in KBr and KCl which corresponds to an enhancement of the electrical current and F-center density in the crystal. According to Heiland (3) Zone II should be followed by an equilib-

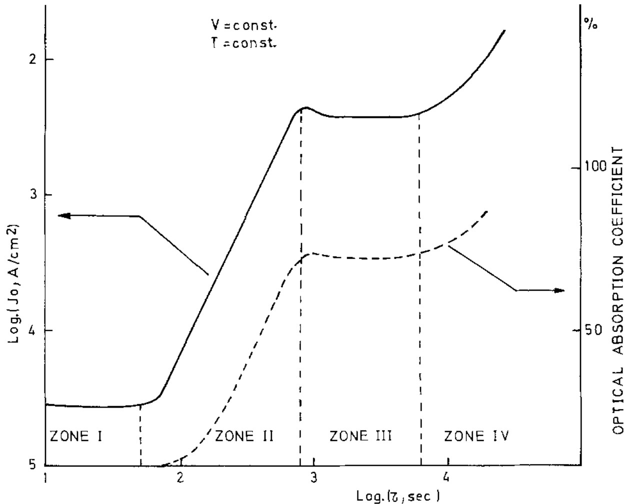

Fig. 1. Electrical current (continuous line) and F-center density (dashed line) *vs.* time during electrolytic coloration of KBr single crystals. [After Andreev *et al.* (1)].

[1] Also: C.I.D.A., Arturo Soria No. 289, Madrid, Spain.

Key words: solid electrolytes, injected carriers, color centers, dielectric breakdown.

rium stage (Zone III) in all cases, and Zone IV should never appear. (*ii*) The F-color cloud starts at the cathode and propagates through the crystal. Pisarenko (8) has observed a coloration starting at the region surrounding the anode after the conductivity increased in Zone IV in KCl crystals at temperatures between 250°-350°C.

Herein are reported some new experimental results in relation to these points. It is shown that Zone IV is exclusively due to processes occurring at the anode-crystal frontier. These processes can be inhibited, therefore suppressing Zone IV. They are responsible for the high current and high F-center concentrations that characterize Zone IV.

Experimental

A vacuum-sealed furnace was used to electrolytically color the crystals. Temperature was controlled with ±1°C and measured with a Chromel-Alumel thermocouple. Experiments were performed in either air, vacuum, nitrogen, or argon atmospheres. A pointed cathode (stainless steel, Pt) and a flat anode (tungsten, aluminum foils, and graphite) were used. In some experiments the anode was a vacuum-evaporated film.

A couple of quartz windows in the furnace allowed for luminescence measurements and photographing the crystals. A high intensity Bausch and Lomb monochromator and an EMI 9558 QB photomultiplier were used in the range 2500-4500Å. Single crystals of KBr, NaCl, KCl, KI, and CsI of ~ 10 × 5 × 5 mm were colored. Other experimental details are described in (4).

Results

In the process of electrolytically coloring KBr single crystals with a stainless steel pointed cathode and a tungsten foil anode mechanically pressed against the crystal, a light emission was detected. The samples were placed between the electrodes in the open air and the sample holder was then introduced into the furnace. Air was evacuated and nitrogen was let into the furnace at a pressure slightly higher than the atmospheric one. The sample was heated and once the working temperature (~350°-550°C) was stabilized, the electric field was turned on in order to color the crystal. Light emission was also measured with other crystals (KCl, KI, NaCl, and CsI), electrodes (platinum point, aluminum foils, and graphite), and atmospheres (air and argon).

Photographs taken during the coloration process proved that in all cases the light is generated at the anode-crystal frontier. The crystal is shown in Fig. 2 with a black line and the pointed cathode is at the top of the picture. The light emitted has a multipeak spectrum as shown in Fig. 3. The width of the lines cannot be considered as a reliable datum due to the monochromator we used. The intensities of the lines were highly dependent on the experimental conditions and no systematic study of this point has been made.

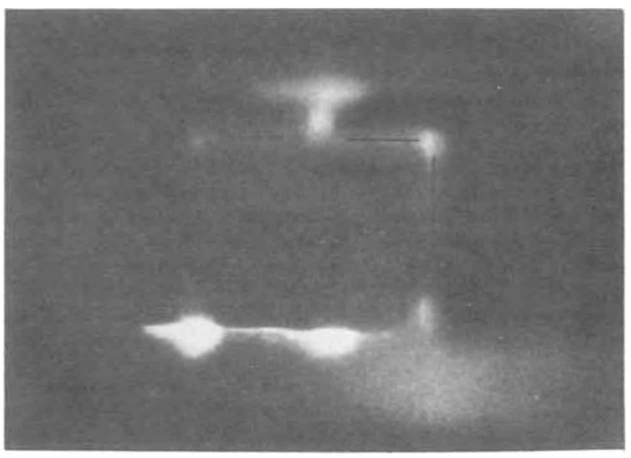

Fig. 2. Photograph of a KBr crystal during coloration in Zone IV shows light emission in the anodic region. The crystal is marked with a black line.

In order to elucidate the possible origin of the electrical arc and the light emission, experiments were performed with different alkali halides, electrodes, and atmospheres. In all cases, the experimental procedure was that described above. The most relevant parameters from the obtained spectra were the peak positions. Table I shows some of the experimental results: the crystal, cathode and anode material, and the atmosphere used in each experiment are indicated. The main air component discharge is also quoted for comparison purposes. It is clear from the table that most of the peak positions are quite independent of the various crystals, electrodes, and atmospheres. In our experiments with KBr and KCl single crystals, we were able to obtain measurements only for wavelengths shorter than ~ 4700Å due to the emission of the furnace walls: A much lower temperature is required to color CsI than to color KBr and KCl. All the wavelengths in the table are affected by an error of ±50Å. At this point it is interesting to note that whenever a graphite anode was used, the peak intensities were much weaker than with an Al or W anode. Furthermore, with air filling the furnace the intensities of all the lines were considerably improved.

The intensity of the emitted light is a function of time during the coloration process: we never detected

Table I. Peak position wavelengths (Å) of the anodic emission spectra obtained by electrolytically coloring different alkali halides with several electrodes and atmospheres. The major lines of the air component discharge are also included. All the values are affected by an error of ±50Å.

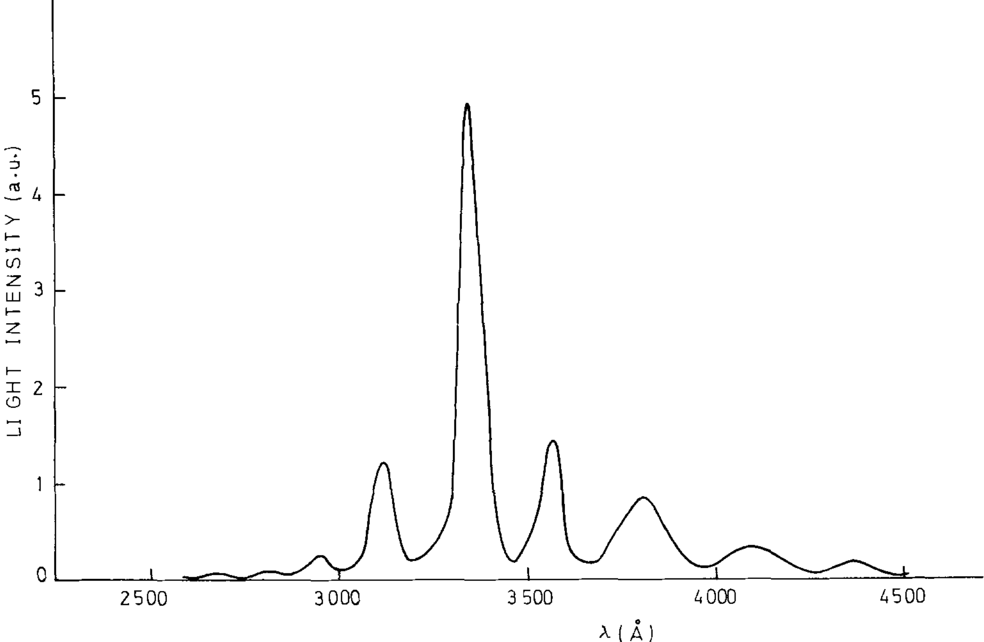

Fig. 3. Spectral distribution of light emitted during electrolytic coloration of KBr with a W foil as anode and nitrogen atmosphere.

light during Zone I of the coloration curve; a very weak emission was measured sometimes during Zone II and at other times during Zone III; but the emission of light was highly efficient during Zone IV. This behavior is depicted in Fig. 4(a) where the evolution of the electrical current (curve A) and the light intensity measured at $\lambda = 3570Å$ (curve B) during the electrolytic coloration of KBr are shown. A time lag between the current and light is observed initially; but in Zone IV both curves rise up proportionally as represented in Fig. 4(b). This behavior appears in all the materials we have studied. The slope of the straight line and the value of the electrical current when there is no light intensity are a function of the experimental conditions, but are more affected by the applied electric field and the sample temperature. It was also noted that at temperatures below 500°C the F-coloration originating at the cathode during Zone II is very weak, but on reaching Zone IV a dense line of coloration from the anode propagates through the crystal and begins its dielectric breakdown when it joins the cathode.

Discussion

It is clear from Fig. 2 that the emission of light during Zone IV of the current-time curve is due to processes occurring in the crystal-anode interface. All the experimental results already described were obtained by using a metallic anodic plate mechanically pressed against the sample; the conventional method used to electrolytically color alkali halides. The experimental procedure followed in all cases was that described above.

It is also evident that a close parallelism exists between the electrical behavior in Zone IV and the anodic processes responsible for the light emission. In order to examine this parallelism more closely, the anodic contact was changed. Crystals with vacuum (10^{-6} Torr)-evaporated metallic (Au, Al) anodes were prepared. The rest of the experimental procedure was as previously described: The same stainless steel or platinum pointed cathode was used. While coloring the crystal with these new anodes, the electrical current passing through the sample was recorded. Curve A in Fig. 5(a)

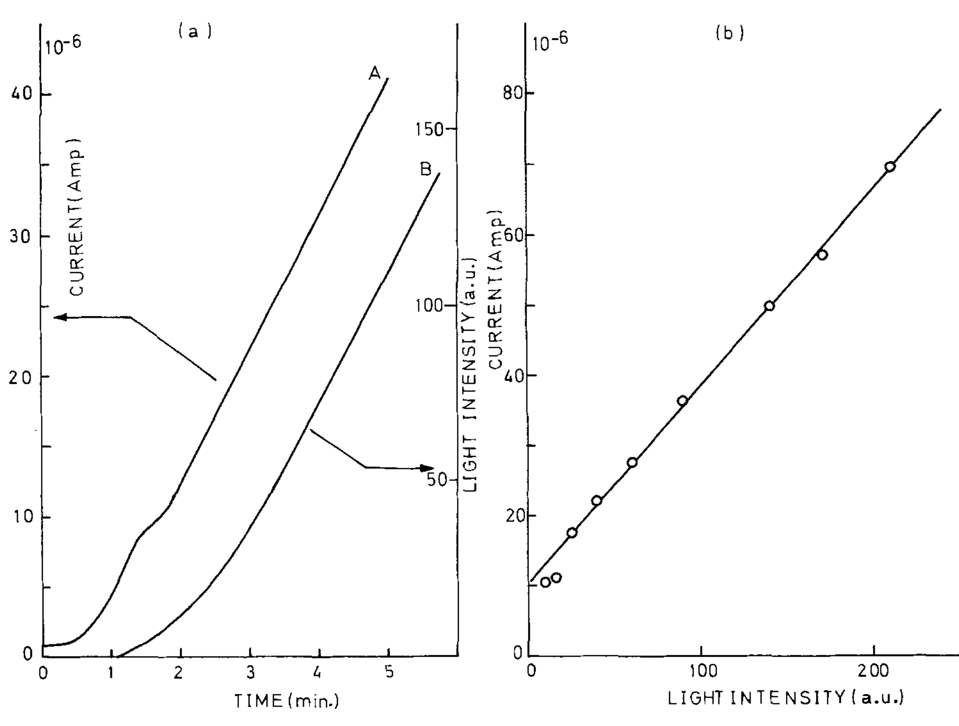

Fig. 4. (a). Electrical current (curve A) and light intensity at $\lambda = 3570Å$ (curve B) during electrolytic coloration of KBr at $T = 422°C$, $V = 600V$. (b) Relationship between current and light intensity.

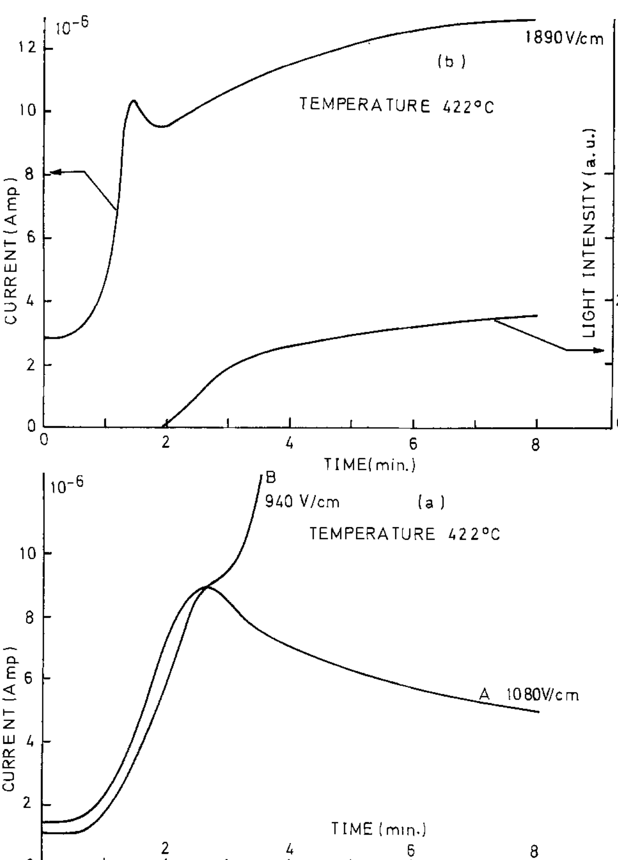

Fig. 5. (a). Electrical current during electrolytic coloration of KBr with a vacuum-evaporated Al film as anode (curve A). The anode was a vacuum-evaporated film.

represents the results obtained. At the same time it must be emphasized that no light emission was detected along the whole coloration process. It is clear from Fig. 5(a) that Zone IV does not appear. The electrical current follows Zones I and II, reaches a maximum, and finally decreases; the difference between the maximum and the final steady value of the current being a function of the applied voltage and the crystal temperature. From these experiments it was concluded that Zone IV of the curves is not intrinsic and is due to the processes occurring in the crystal-anode interface while electrolytically coloring alkali halides by conventional means. If these phenomena are inhibited, at least partially, Zone IV disappears. The anodic processes are not totally avoided by using vacuum evaporated anodes as can be seen from Fig. 5(b) where the applied voltage has been increased to much higher values than those commonly used in these experiments. Current again increases, leading to a very reduced Zone IV. At the same time, a very slight light emission is detected [Fig. 5(b)] proving that both light emission and electrical current in Zone IV have the same origin. For comparison purposes a typical curve obtained with a tungsten foil anode mechanically pressed against the crystal at the same temperature is shown as curve B in Fig. 5(a).

It is worthwhile to note that curve A in Fig. 5(a) closely resembles those obtained in insulators and semiconductors (9) whenever space charge controlled mechanisms are operating. Results regarding the role played by these mechanisms in the electrolytic coloration of alkali halides will be published elsewhere.

As to the physical nature of the processes occurring in the crystal-anode interface, it is clear from Table I that the peak positions of the emission spectra are widely independent of the crystals, electrodes, and gas filling the furnace. On the other hand, a very narrow correspondence (within the experimental error) exists between these values and those shown by the principal lines of the air component discharge (last column of Table I). These two experimental facts, and the evidence that on using vacuum-evaporated anodes there is no light emission, lead to the suggestion that the air (essentially water vapor) adsorbed in the anodic crystal face during the cleaving and the storing of the samples plays a major role in all the described phenomena. This water vapor is probably desorbed during the heating of the sample and retained in the thin and irregular gaps between the crystal and the anodic plate due to the overpressure of the nitrogen (or argon) introduced in the furnace. As a consequence, the main characteristics of the emission spectra correspond to those of the air component discharge. A confirmation of this hypothesis was obtained by the following experiments: with the same primitive flat anode (tungsten or aluminum foils), the crystal holder was introduced into the furnace and the crystal heated in a dynamic vacuum (without introducing inert gas) up to the working temperature, then the vacuum was maintained for some time (~1 hr) before letting nitrogen or argon in. With this procedure we tried to partly eliminate the water vapor adsorbed in the crystal surface. On applying the electric field to color the crystal, curves similar to curve A in Fig. 5(a) are obtained and no light emission exists. Whenever the water vapor retained in the gaps between the crystal and the metallic anode is removed, Zone IV disappears and there is no luminous phenomena. Not all the observed phenomena are due exclusively to this water vapor, no doubt there is some influence from the gas filling the furnace and the electrode materials, but these should be rather small in comparison with the contribution of the adsorbed water vapor.

Regarding the origin of the electrical arc in the crystal anode interface, no clear conclusion can be obtained from these results. According to the shape of the curve in Fig. 1 it can be suggested that during Zone II a high negative space charge accumulates at the crystal anodic face and a very high electric field is produced through the narrow gaps between the crystal and the anode. This suggestion has some experimental support in that the arc appears either during or at the end of Zone II.

Finally, the means by which the electrical arc in the anodic face can give place to Zone IV of the curves should be discussed. The whole process appears to be very complicated, and some speculation seems unavoidable. Our results suggest that water vapor molecules desorbed from the anodic face of the crystal are decomposed by the arcing, and oxygen ions react with the metal plate to produce oxides. In fact, the area of the anodic foil in contact with the crystal shows a very dark stain, clear evidence of a chemical reaction. On the other hand, the principal emission lines that were measured correspond to those of the second ionization of oxygen. One possible mechanism for this decomposition could be

$$M + H_2O \rightarrow M + O^{-2} + 2H^+ \rightarrow MO + 2H^+ + 2e^- \quad \text{(on the metal)} \quad [1]$$

although the whole process must be much more complicated and other quantitative combinations are possible. M signifies the anodic metal (W, Al, Mo). Reactions like Eq. [1] have been observed in different metallic surfaces under the action of an electric arc (10).

In order to account for the high value of electrical current in Zone IV, it is plausible to think that protons liberated in the arc region are injected into the crystal under the electric field existing in the gap. Their high mobility should produce a considerable contribution to the electrical current. Phenomena parallel to those we are discussing now have been shown to take place in some glasses when atmospheric moisture is present (11). Further experimental work is needed before all these possible mechanisms can be confirmed.

The final conclusion in relation to the electrolytic coloration process is that only Zones I, II, and III are intrinsic; Zone IV is not due to the crystal itself. From our results it appears that water vapor adsorbed in the anodic face of the crystal plays an important role in relation to Zone IV of the curve. But it is not yet possible to determine the exact processes taking place in the electrical arc at the anode region.

The Transport of Chromium in Cr_2O_3 Scales in Sulfidizing Environments

G. Romeo,*[,1] H. S. Spacil,* and W. J. Pasko

Research and Development Center, General Electric Company, Schenectady, New York 12301

ABSTRACT

The diffusivity of chromium in Cr_2O_3 scales formed during the oxidation of chromium at 900°-1000°C appears to increase by several orders of magnitude when an initially present oxide scale is exposed to sulfur-bearing atmospheres at low oxygen partial pressure. As a result chromium sulfide scales grow on both sides of the preexisting oxide layer. The transition from oxidation to sulfidation corresponds to a change from parabolic to linear weight gain, indicating that the sulfide growth is controlled by a constant rate of supply of chromium through the oxide to the outer oxide-sulfide interface, under fixed experimental conditions. The sulfidation rate increases with sulfur partial pressure, indicating that chromium transport in the oxide is affected by changes in the defect structure of Cr_2O_3 induced by the presence of sulfur. A model is proposed in which sulfur enters the oxide as an electron donor, thereby increasing the concentration of chromium vacancies and interstitials.

Hot corrosion phenomena of gas turbine superalloys frequently result in the formation of mixed oxide/sulfide scales. Sulfidation has been reported as due to the reaction of the alloy surface with sodium sulfate deposits, considering the sulfate, with a very low sulfur activity, as the only source of sulfur (1). However, the presence of sulfur at an activity above the equilibrium value for sulfide formation would provide an additional mechanism for accelerated corrosion. Such high sulfur activities could arise from local reducing conditions in an otherwise oxidizing environment (2). Internally precipitated sulfides are frequently observed under Cr_2O_3 scales formed on Ni-base alloys. It is then possible that a mechanism involving the transport of sulfur across these scales from a high activity source is responsible for the presence of sulfide particles. The diffusion of sulfur in polycrystalline Cr_2O_3 has been studied by Seybolt (3), who reported a tracer diffusion coefficient of about 1.5×10^{-10} cm²/sec at 1000°C. No mechanism was proposed for the migration of sulfur species through the oxide. A recent paper by Chang *et al.* (4) on the diffusion of S^{35} in hot-pressed α-Cr_2O_3 reported a diffusion coefficient for S^{35} varying from 5.1×10^{-11} to 5.2×10^{-10} cm²/sec in the temperature range 700°-1050°C.

Key words: sulfidation, chromium diffusion, chromium oxide.

In a previous publication (5) we have reported preliminary results on the sulfidation kinetics and scale morphologies of chromium specimens preoxidized and subsequently exposed at 900°C to 10% H_2S-H_2 gas mixtures. This paper summarizes the results of further experiments in which the sulfidation of preoxidized chromium was studied at different partial pressures of sulfur.

Experimental

Rectangular specimens of high purity "iochrome" (99.997%) approximately 1.5 × 0.7 × 0.15 cm were cut from a cast ingot. After a suspension hole was drilled in each, these were wet ground through 600 grit silicon carbide paper and cleaned with acetone and methanol. Finally, their dimensions were measured with a micrometer.

Reaction kinetics were determined by following the weight gain of a specimen with a spring balance, the basic design of which has been described in a previous publication (6). Some modifications were made to this equipment in order to run experiments at low sulfur pressures. These could be attained by bubbling argon or a carbon monoxide/argon mixture through a flask containing molten sulfur. The flask was immersed in a silicone oil bath which was held at temperatures controlled within 1°C. Argon was used as an inert carrier

for sulfur, while carbon monoxide could provide a reducing environment. Gas mixtures of composition ranging from 0.001-10 volume per cent (v/o) hydrogen sulfide in hydrogen were also used as a source of sulfur. Linde commercial mixtures of "ultra high purity" gases were employed directly or appropriately diluted with hydrogen for this purpose. When the sulfur bath was used, the vapor pressure of S_2 was known from the temperature of the bath; by assuming saturation of the argon carrier, the S/CO ratio in the final gas mixture could be specified. With either H_2S-H_2 or CO-S_2 mixtures, the equilibrium sulfur partial pressure can be found by employing thermodynamic data for the relevant species. For the latter mixtures, formation of COS, CO_2, and SO_2 must be considered. Data from the JANAF Tables were used for this purpose (7).

Prior to each sulfidation run the chromium specimen was oxidized isothermally with oxygen at atmospheric pressure at temperatures of 900° or 1000°C, the latter value being chosen to allow the formation of thicker oxide layers. The oxygen flow was then stopped, the reaction cell was purged with argon, and the furnace temperature was adjusted to a value of 900°C prior to sulfidation, with the exception of a few runs carried out at 800° and 1000°C. The temperature of 900°C was chosen for its relevance to gas turbine operations.

After completion of each run the specimens were mounted in epoxy resin and cross-sectioned for metallographic examination and microprobe analysis of the scale. Also, after some runs the scale composition was identified by the Debye-Scherrer method.

Results

As reported elsewhere (5), a dramatic change in reaction rate and mechanism took place when a previously oxidized chromium specimen was exposed to a sulfur-containing atmosphere. Figure 1 shows that the weight gain curve of a specimen exposed directly to a 10% H_2S-H_2 gas mixture at 900°C followed a parabolic rate law, with a rate constant of 52 mg^2-cm^{-4}-min^{-1}, in quite good agreement with the value 92 mg^2-cm^{-4}-min^{-1} reported by Strafford and Hampton for the sulfidation of chromium at 925°C with a 30% H_2S-H_2 gas mixture (8). Figure 2 shows the weight gain curve of a specimen preoxidized and subsequently exposed at 900°C to the 10% H_2S-H_2 gas mixture. In the latter instance, switching from an oxidizing to a sulfidizing atmosphere brought about a change from a parabolic to a linear rate law after an incubation period.

Figure 3 shows an example of scale structure formed after a complete preoxidization and sulfidation run (No. 4 in Table II). Chromium sulfide can be formed on both sides of the oxide layer initially present, with

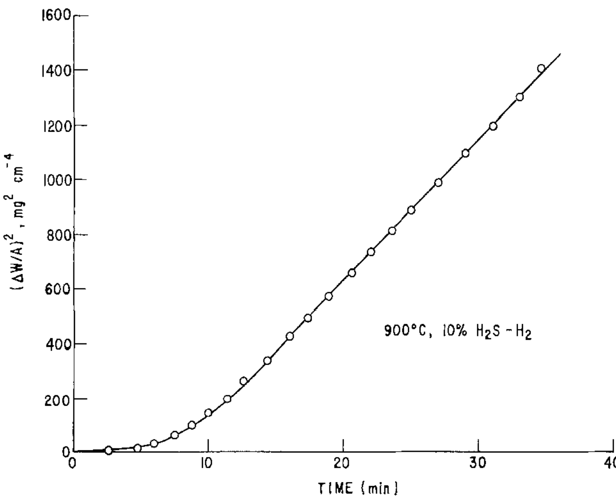

Fig. 1. Parabolic plot of weight gain vs. time for the sulfidation of chromium at 900°C with a 10% H_2S-H_2 gas mixture.

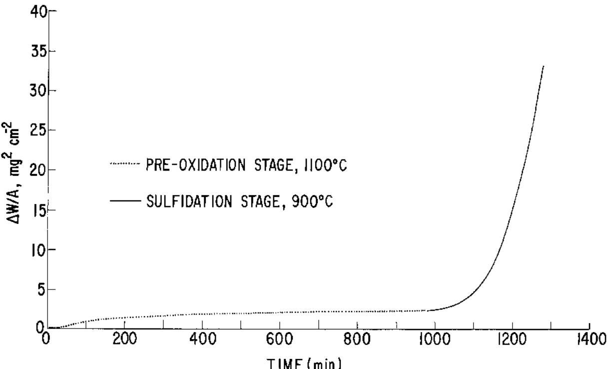

Fig. 2. Weight gain of a chromium specimen first exposed to oxygen at 1 atm and 1100°C, then to a 10% H_2S-H_2 gas mixture at 900°C.

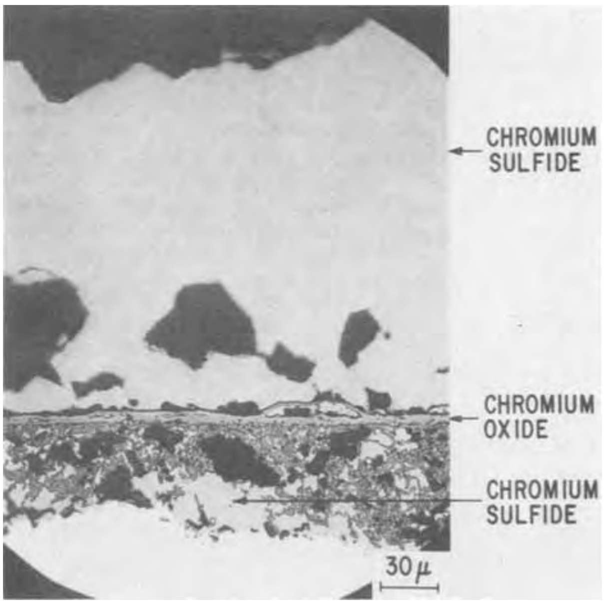

Fig. 3. Scale structure of a chromium specimen preoxidized and subsequently exposed for 20 hr to a 0.1% H_2S-H_2 gas mixture at 900°C.

the outer portion of the sulfide scale much thicker than the inner portion. Although the initial compactness of the oxide layer has been altered by the growth of the inner chromium sulfide layer, a fairly uniform layer of chromium oxide exists between the chromium sulfide scales.

Table I summarizes the values of the linear rate constant k_l obtained during sulfidation for three different thicknesses of pregrown oxide. The sulfidation was carried out in each case at 900°C in a 10% H_2S-H_2 gas mixture. The corresponding weight gain curves have been reported previously (5).

To verify the lower limits of sulfur pressure at which sulfidation does not take place on a preoxidized chromium specimen, similar experiments were also carried out in a much lower range of sulfur pressures. The experimental conditions and linear rate constants are

5	900	0.5	0.2	0.09

summarized in Table II. Figure 4 shows the corresponding weight gain curves, in which time zero is the time at which the sulfidizing mixture was introduced into the reaction cell. Again, after an incubation period which varied with the thickness of the pregrown oxide, sulfidation took place in all cases according to an approximately linear rate law, except for run No. 1 of Table II.

A similar weight gain curve was obtained when the sulfidation stage was carried out using a reacting gas mixture of carbon monoxide bubbled through a sulfur melt held at 175°C. The purpose of this experiment was to observe whether a decrease in oxygen activity in the reacting gas mixture due to a reducing agent other than hydrogen would result in a comparable sulfidation mechanism. Indeed the corresponding weight gain curve, labeled with an asterisk in Fig. 4, followed the same trend as the curves obtained with H_2S-H_2 atmospheres. However, the morphology of the corrosion product was different in this case, as shown in Fig. 5. X-ray and microprobe analysis identified the outer layer of the scale as Cr_3S_4, the dark layer underneath it as a mixture of sulfides and carbides of chromium, and the innermost layer as primarily chromium together with chromium oxide and carbide particles. Saturation of the carrier gas with sulfur was more difficult to accomplish, and the vapor pressure of sulfur in the gas may have been below the nominal value of 10^{-3} atm corresponding to the temperature of the sulfur bath.

Discussion

The equilibrium phases that would be expected at 900°C in the Cr-O-S system are shown in Fig. 6, which is the stability diagram for this system in terms of the chemical potentials of oxygen and sulfur. These chemical potentials are given by $\mu_X = RT \ln p_{X_2}^{1/2}$, where X represents either oxygen or sulfur and p_{X_2} is the equilibrium partial pressure of O_2 or S_2. Data on sulfide stability were obtained from Young *et al.* (9), except for CrS, where an average of data from Young *et al.* with that of Hager and Elliott (10) was used. Data on oxide stability were taken from Elliott and Gleiser (11). The phase "Cr_6S_7" represents an average of data for the phases Cr_5S_6 and Cr_7S_8 reported by Young *et al.*; the equilibrium S_2 pressures for these two phases in equilibrium with CrS and Cr_3S_4, respectively, are sufficiently close to allow treating them as one phase for the present purpose.

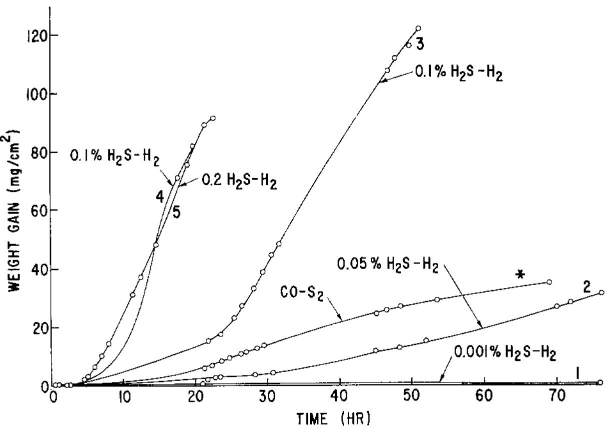

Fig. 4. Weight gain curves of chromium specimens preoxidized and subsequently sulfidized at 900°C with H_2S-H_2 gas mixtures of different composition. The experimental conditions corresponding to the curves labeled with numerals are listed in Table II. The curve labeled with an asterisk corresponds to a sulfidation stage carried out with a $CO-S_2$ gas mixture.

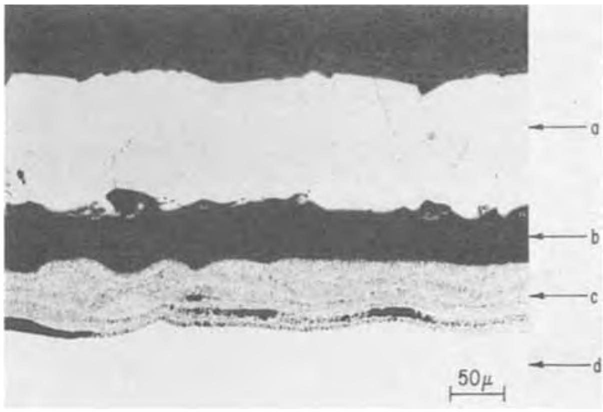

Fig. 5. Scale structure of a chromium specimen preoxidized and exposed at 900°C for about 70 hr to a $CO-S_2$ gas mixture: a, chromium sulfide (Cr_3S_4); b, mixture of sulfides and carbides of chromium; c, mixture of chromium with some oxides and carbides; d, chromium.

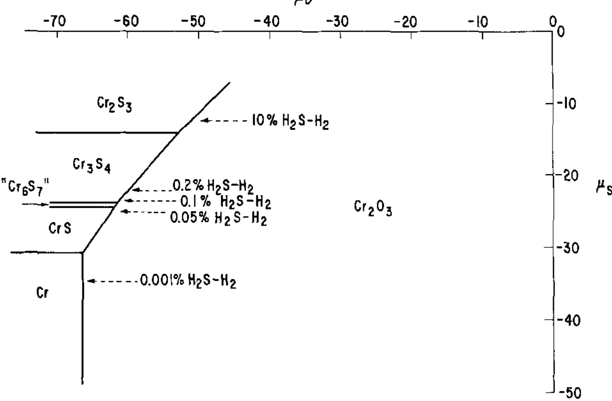

Fig. 6. Stability diagram of the Cr-O-S system at 900°C (μ_O, μ_S in kcal/mole).

Figure 6 also shows the sulfur potentials corresponding to the various H_2S-H_2 compositions of Tables I and II. It is immediately apparent from this figure that the lowest composition of 0.001% H_2S is thermodynamically incapable of forming any sulfide. Thus run No. 1 of Table II would be expected to show no sulfide formation. All other compositions, however, can lead to sulfide formation at oxygen potentials below that of oxide/sulfide equilibrium. Since sulfide was formed, it can be presumed that the oxygen contents of the sulfidizing atmospheres were sufficiently low to satisfy this condition. Direct measurements of the oxygen potential in the sulfidizing atmospheres employed for the experiments summarized in Table I showed that this requirement was met (5).

Figure 3 shows that the oxide scale remains relatively intact during sulfidation even though Fig. 4 would predict conversion of the oxide to sulfide under any combination of sulfur and oxygen potentials that lead to sulfide formation. Since this conversion does not occur appreciably during the sulfidation time periods employed, it can be concluded that transport of oxygen through the external sulfide layer formed during sulfidation is very slow. Further, the linear growth of the sulfide at a rate which is low compared to direct sulfidation (see Fig. 2) suggests that Cr trans-

port through the oxide layer is the limiting step during sulfidation. Thus a probable "reaction path" for the sulfur and oxygen potentials across the reaction products of a specimen during sulfidation is shown in Fig. 7, which is a simplified version of Fig. 6 that does not distinguish between the various chromium sulfides. Point A represents the gas/external sulfide layer interface, point B the external sulfide layer/oxide layer interface, point C the oxide layer/internal sulfide layer interface, and point D the internal sulfide layer/metal interface. Since the sulfidation rate in the presence of an oxide layer is much less than that of direct sulfidation, the sulfur potential gradient in both sulfide layers has been assumed to be nearly zero. Most of the sulfur potential drop then occurs across the oxide layer as shown in Fig. 7.

The mechanism of Cr transport in Cr_2O_3 has not been determined unambiguously. This oxide is a p-type semiconductor, but its electrical conductivity at relatively high oxygen pressures is nearly independent of oxygen pressure, indicating a lack of any strong reaction between O_2 and electron holes (12). The oxidation rate of Cr metal to Cr_2O_3 is likewise essentially independent of oxygen pressure in a similar pressure range, indicating that while Cr diffusion under such conditions may involve a defect mechanism, the defect concentration is not determined by a defect-O_2 reaction (13). Thus Hauffe and Block have proposed that the principal defects in Cr_2O_3 are Cr vacancies, Cr interstitials, and electron holes, formed in accordance with the equilibrium (12)

$$Cr^{3+} \rightleftharpoons V_{Cr}''' + Cr_i^{\cdot\cdot} + h^{\cdot} \qquad [I\text{-}A]$$

where Cr^{3+} is a normal Cr ion on a cation site, V_{Cr}''' is a triply charged (negative) Cr vacancy, $Cr_i^{\cdot\cdot}$ is a doubly charged (positive) Cr interstitial, and $h^{\cdot}$ is a positively charged electron hole.

Kassner *et al.* studied the oxidation of Cr metal and the tracer diffusion of Cr^{51} in Cr_2O_3 at the low equilibrium oxygen pressures generated by H_2-H_2O mixtures (14). They observed an oxygen partial pressure dependence of the oxidation rate and of the tracer diffusion coefficient which led them to propose that the principal defects in Cr_2O_3 are Cr vacancies and electron holes formed in accordance with the equilibrium

$$1/2\ O_2 \rightleftharpoons O^{--} + 2/3\ V_{Cr}''' + 2h^{\cdot} \qquad [I\text{-}B]$$

where O^{--} is a normal O ion on an anion site.

The presence of other cations in Cr_2O_3 would be expected to affect the oxidation rate of Cr metal if these cations were either electron donors or electron acceptors. Reactions [I-A] and [I-B] both indicate that such cations would modify the intrinsic hole concentration and thus Cr diffusivity through changing Cr defect concentration. This effect has been demonstrated

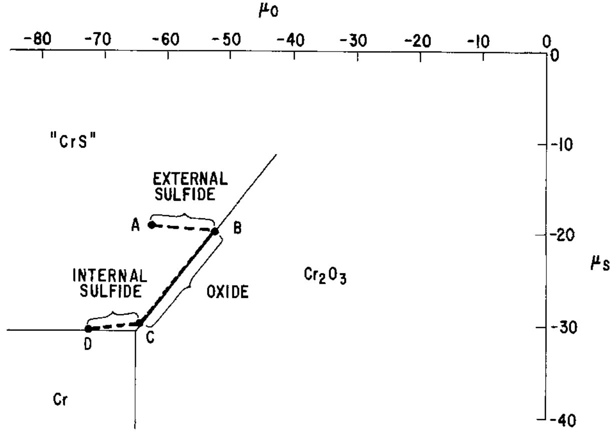

Fig. 7. Schematic reaction path in the Cr-O-S system during sulfidation at 900°C.

as a change in oxidation rate (15). If sulfur were an electron donor in Cr_2O_3, it would likewise be expected to increase the Cr diffusivity in the oxide through decreasing the hole concentration and consequently increasing the Cr defect concentration as either reaction [I-A] or [I-B] are shifted to the right. Konev *et al.* have proposed that sulfur enters NiO as S^- ions rather than S^{--} ions (16). Wagner and his co-workers have also suggested that S^- ions may be the form in which sulfur generally enters into solution in most oxides (4). The sulfur could act as an electron donor according to the equilibrium

$$1/2\ S_2 + O^{--} + h^{\cdot} \rightleftharpoons S^-|_O^{\cdot} + 1/2\ O_2 \qquad [II]$$

where $S^-|_O^{\cdot}$ is a singly ionized sulfur ion on an anion site, and is thus a singly charged (positive) defect with respect to the anion lattice.

The equilibrium constants for reactions [I-A], [I-B], and [II] can be expressed in terms of x_V, x_i, x_h, and x_S which are, respectively, the mole fractions of Cr vacancies, Cr interstitials, electron holes, and singly ionized sulfur ions on anion sites. These equilibrium constants will also involve the oxygen and sulfur activities, which are defined as $a_O = p_{O_2}^{1/2}$ and $a_S = p_{S_2}^{1/2}$. It can be noted that the chemical potentials are then given by $\mu_X = RT \ln a_X$, where X represents either oxygen or sulfur, allowing the activities corresponding to specific phase equilibria to be obtained from Fig. 6.

From reaction [II], the value of x_S is obtained as $x_S = K_{II}(a_S/a_O)x_h$, where K_{II} is the equilibrium constant for reaction [II]. We will assume that in the H_2-H_2S gas mixtures considered in the following analysis that the oxygen activity is sufficiently low to cause $K_{II}(a_S/a_O)$ to be much greater than unity. The vacancy concentrations corresponding to reactions [I-A] and [I-B] can then be obtained as

$$x_V = K(a_S^{1/3}/a_O^{1/3}) \qquad [1\text{-a}]$$

and

$$x_V = K(a_S^{3/4}/a_O^{3/8}) \qquad [1\text{-b}]$$

where K in each instance represents some combination of the equilibrium constants $K_{I\text{-}A}$ and K_{II} or $K_{I\text{-}B}$ and K_{II}. If reaction [I-A] is assumed to take place, then $x_i = x_V$ and Cr transport could occur either through interstitial or vacancy defects. Whether reaction [I-A] or [I-B] is assumed to prevail, however, a Cr defect concentration gradient could exist across the sulfur-containing Cr_2O_3 layer during sulfidation to act as a driving force for Cr transport through this layer.

The sulfur and oxygen activities on each side of the Cr_2O_3 layer during sulfidation of any specimen used in the present work can be obtained from Fig. 6, assuming that a reaction path such as that shown schematically in Fig. 7 applies to the sulfidation process. A general form of Eq. [1-a] or [1-b] is

$$x_D = K(a_S^f/a_O^g) \qquad [2]$$

where x_D is the Cr defect concentration, whether vacancies or interstitials. The outward molar flux of Cr through the Cr_2O_3 layer is then given by the proportionality relationship

$$\Gamma_{Cr} \propto (x_{D,B} - x_{D,C})/m \qquad [3]$$

where Γ_{Cr} is the Cr flux, m is the mass per unit area of the oxide layer, and the subscripts B and C refer to the external sulfide/oxide interface and the oxide/internal sulfide interface, respectively (cf. Fig. 7). Assuming that the linear sulfidation is due primarily to the formation of the external sulfide layer of composition Cr_xS_y, the linear rate constant for sulfidation is given by the proportionality relationship

$$k_l \propto ((y/x)/m)\phi \qquad [4]$$

where the factor ϕ is defined as

$$\phi = (a_{S,B}/a_{S,C})^f(a_{O,C}/a_{O,B})^g - 1 \quad [5]$$

Since k_1, the ratio y/x, and m are experimentally accessible, they can be consolidated into a single parameter, using Eq. [4], defined by

$$k = (x/y)mk_1 \quad [6]$$

Thus the value of k should be proportional to ϕ for any run, or the value of k/ϕ should be constant for all runs in which sulfide was formed at a single temperature of 900°C. The ratio k/ϕ was calculated for each of the runs of Tables I and II. Values for $a_{S,C}$ and $a_{O,C}$ were taken as those corresponding to the $Cr/CrS/Cr_2O_3$ equilibrium of Fig. 6, and remain the same for all runs. Values for $a_{S,B}$ and $a_{O,B}$ as well as for x and y were those corresponding to the appropriate Cr_xS_y/Cr_2O_3 equilibrium of Fig. 6 at the sulfur potential level indicated by the dashed line for each H_2-H_2S composition. Since the absolute magnitude of the ratio k/ϕ has no significance, the value of the ratio was normalized using the average values obtained in arbitrary units of each set of runs treated. Three pairs of values of the exponents f and g were used: $f = 0$ and $g = 0$; $f = 1/3$ and $g = 1/3$; $f = 3/4$ and $g = 3/8$. These represent, respectively, an absence of any influence of sulfur or oxygen on Cr defect concentration, a Cr defect concentration established according to Eq. [1-a], and a Cr defect concentration governed by Eq. [1-b].

Table III summarizes the normalized k/ϕ ratios obtained for each pair of exponents. Averages and variances are also presented. Since the average must be unity for the normalized k/ϕ ratio, the variances are direct indications of how well the three assumed models for the influence of sulfur on Cr diffusivity fit the experimental observations. Either of the models involving the presence of sulfur as an electron donor gives a better fit than the assumption of no interaction between sulfur and Cr defects. It is thus proposed that sulfur enters Cr_2O_3 as an electron donor, thereby reducing the electron hole concentration. This reduction leads to an increase in Cr defect concentration through reactions similar to [I-A] or [I-B]. Such a general model can be qualitative only at present, but it is suggested that a parameter containing an equilibrium constant and both sulfur and oxygen activities, in the form given by Eq. [2], describes the effect of sulfur on the Cr defect composition.

An enhanced Cr diffusivity in Cr_2O_3 due to the presence of sulfur could be either a grain boundary or volume effect. It is not possible to distinguish between these two types of mechanism at this time. Factors which may contribute variations in linear sulfidation rate are deviations from the nominal gas compositions, differences in Cr_2O_3 layer grain size as a result of different oxidation temperatures, and partial disruption of the Cr_2O_3 layer during sulfidation. Thus no more detailed analysis of the data appears warranted.

The single test undertaken with a CO-S_2 mixture (Fig. 4) was performed to show that the observed enhancement of Cr transport through Cr_2O_3 during sulfidation was not uniquely dependent on the use of H_2 to achieve the low oxygen potentials that thermodynamically allow sulfide formation. Figure 5 indicates that the Cr_2O_3 layer was at least partially converted to one or more Cr carbides during this run. While not conclusively demonstrating that neither hydrogen nor carbon is affecting defect equilibria, the result shows that hydrogen is not unique and that the sulfur itself is most probably responsible for the enhanced diffusivity of Cr in Cr_2O_3 exposed to sulfur at low oxygen potentials. Since the reaction products of the specimen were not the same as those of other tests, no attempt was made to treat this test quantitatively.

Table III. Values of ratio of sulfidation parameter defined by Eq. [6] to sulfur and oxygen activity function defined by Eq. [5]. The designation of each run corresponds to numbering in Tables I and II.

	$(k/\phi)/(\overline{k/\phi})$

Average	1.00	1.00	1.00
Variance	± 0.89	± 0.75	± 0.55

Conclusions

Exposure of preoxidized Cr to an ambient atmosphere of sufficiently high sulfur potential and low oxygen potential results in the linear growth of Cr sulfide on both sides of the Cr_2O_3 layer formed during oxidation. Most of the sulfide growth takes place in the external sulfide layer by transport of Cr through the relatively intact Cr_2O_3 layer which is metastable as a result of limited oxygen transport through Cr sulfides. The sulfidation rate in this situation reflects a much higher Cr diffusivity in the Cr_2O_3 than would be expected in the absence of sulfur. A model for the defect equilibria in Cr_2O_3 exposed to sulfur can be formulated, in which sulfur enters the oxide as an electron donor, thereby increasing the concentration of Cr defects.

The Deposition of Tin Oxide Films from a D-C Glow Discharge

D. E. Carlson

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Tin oxide films have been deposited on soda-lime-silicate glass using a d-c glow discharge in atmospheres of $Sn(CH_3)_4$ and O_2, and $SnCl_4$ and O_2. The sodium ions were removed from the surface of the glass during the film deposition by forcing the current to pass through the heated glass substrates. Film properties were studied as a function of atmospheric composition, current density, and deposition time.

Many investigators (1-12) have reported the deposition of thin films on various substrates using a-c and d-c glow discharges in appropriate gases or vapors (typically at a pressure of 0.1-10 Torr). The glow discharge breaks chemical bonds and promotes complex reactions in the gas or gas mixture, and the films result from the deposition of certain reactive components on substrates in the vicinity of the discharge.

Most of the published work involves films deposited on substrates placed in rf or microwave glow discharges. This technique has been used to produce films of organic polymers (2, 3), silicon oxides (4, 5), silicon nitride (5, 6), aluminum oxide (7), amorphous silicon (8, 9), etc. (9, 10). The substrate may or may not be heated depending on the type of film desired.

Much less work (11, 12) has been reported on the deposition of films from a d-c glow discharge. The scarcity of work in this area has been attributed to poor reproducibility of film composition and contamination of the film due to sputtering effects (1, 4). However, the present study shows that good quality tin oxide films can be produced on the cathode in a d-c discharge and that the sputtering action of the discharge can be controlled. Moreover, the d-c technique is simple in practice and readily allows the uniform deposition of thin films over large areas. An additional benefit is gained in the deposition of films on glass substrates since the glass surface will be either ion-depleted (13, 14) or proton-exchanged (15) during the deposition. In either case, the removal of alkali ions from the glass surface allows high quality films to be deposited (14).

Experimental Procedure

The apparatus used in the present study is depicted schematically in Fig. 1. The major components of the system were a vacuum bell jar, a mechanical vacuum pump, and a high voltage d-c power supply (5 kV, 5A). A heating plate was located in the center of the bell jar on a thin-walled, fused silica pedestal. Power for the heater was provided by coupling through an isolation transformer to a variable auto-transformer.

For glass substrates, the bottom was first painted with a conductive coating such as Ag or graphite so that at elevated temperatures the current passed through the glass. The substrate to be coated was then placed on the heating plate with the negative lead (0.005 in. Pt wire) from the power supply in electrical contact with the bottom of the substrate. That part of the negative lead not under the substrate was electrically shielded with a fused silica tube.

The anode was a metal sheet (usually Pt) placed ~2 cm above the substrate. The ceramic spacers that held the anode were several cm to either side of the substrate so that they were outside of most of the glow discharge region. A limiting resistor (10^5 ohm, 100W) was used to stabilize the discharge. The current was monitored by measuring the voltage drop across a 10^3 ohm resistor.

The system was evacuated to a pressure of ~5 mTorr with the substrate hot (200°-550°C) before any gases or vapors were admitted. The procedure for admitting vapors such as tetramethyltin ($Sn(CH_3)_4$) was to freeze a vial of $Sn(CH_3)_4$ in liquid nitrogen while pumping on it. Once a pressure of ~5 mTorr was attained, the sample was warmed until the desired vapor pressure was achieved. The appropriate gases or vapors were sequentially bled into the system, and the pressure during each admission was monitored with a thermocouple vacuum gauge. Since the thermocouple gauge was calibrated for air, a McLeod vacuum gauge was used to measure the pressure after each admission. The total pressure was in the range of 0.5-2.0 Torr for most of the film depositions.

The minimum voltage for deposition of uniform films was determined by adjusting the applied voltage so that the negative glow of the discharge covered the entire cathode substrate. This is the beginning of the regime for the abnormal fall of potential near the cathode (16). Operating at this voltage assures a uniform deposition while minimizing sputtering effects. Increasing the voltage beyond this value will increase the deposition rate, but eventually sputtering effects will decrease the rate and may even prevent film deposition. Normally, a constant current density was maintained during the film deposition. The applied voltage had to be increased during the deposition when a glass substrate was used. (As the depleted region in the glass increased in thickness, the resistance increased.)

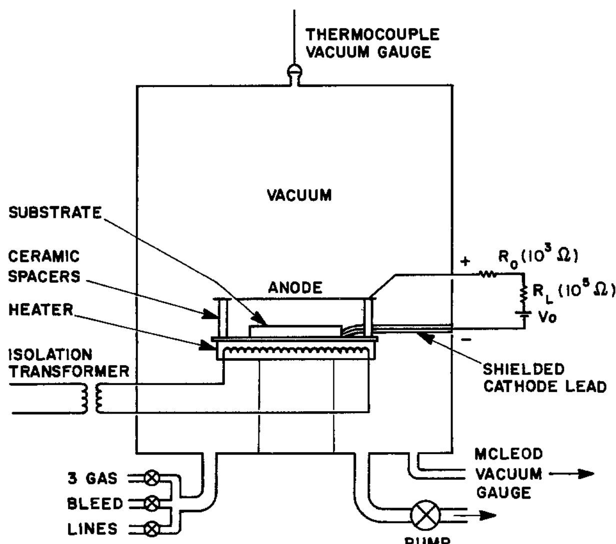

Fig. 1. Schematic diagram of the apparatus used for film deposition from a d-c glow discharge.

Key words: glass, semiconductor, ion-depletion.

The films could be deposited in patterns by using either insulating or conducting masks. Insulating masks perturbed the field distribution in the discharge and generated borders that were not sharp, *i.e.*, the film thickness increased gradually up to a distance of a few mm from the edge of the mask. Conducting masks did not affect the field distribution, and the film edges were sharp to within a few microns. When glass substrates were used, Na was removed from the glass surface beneath both the depositing film and the conducting mask.

Since the edges of the cathode substrates were high field regions, the film thickness varied near the edges. Uniform deposition over the entire substrate was achieved by placing another cathode material around the edges of the substrate. This effectively moved the high field regions of the cathode out beyond the edges of the substrate. For uniform deposition, the total pressure was maintained at $\lesssim 1$ Torr since the discharge tended to localize at higher pressures.

The thickness of various films was measured with a stylus profilometer (Bendix Linear Pilotor, Type RLC). The surface resistivity was measured with an RCA VoltOhmyst or a Keithley Electrometer (Model 610C) after painting parallel stripes on the surface of the film with air-drying Ag paint. The transmission of visible light was measured with a Cary spectrophotometer (Model 14R).

Results and Discussion

Tin oxide films were deposited on soda-lime-silicate glass[1] substrates using d-c glow discharges in vapors of $Sn(CH_3)_4$ and oxygen, and in vapors of $SnCl_4$ and O_2. The inclusion of the glass substrate in the electrical circuit caused the glass surface to be either ion-depleted (13, 14) (for a discharge in $SnCl_4$ and O_2) or proton-exchanged (15) (for a discharge in $Sn(CH_3)_4$ and O_2) during the film deposition. The Na ions were typically removed from the glass surface to a depth of ~2000Å. The removal of Na ions from the glass surface during the deposition gave rise to sodium-free films with excellent optical and electrical properties. Moreover, the Na-depleted region is little affected by thermal treatment below the transformation temperature of the glass (~510°C), so the films should remain Na free during any subsequent thermal processing below this temperature. (The thermal stability of the ion-depleted region is due to the removal of the nonbridging oxygen ions (13) during the film deposition.)

Figure 2 shows how the volume resistivity of films deposited in a discharge of $Sn(CH_3)_4$ and O_2 depended on the composition of the atmosphere. The current density and treatment time were held constant, and the thickness of the films increased as the ratio of $Sn(CH_3)_4$ to O_2 was increased (from 350Å at a ratio of 0.10 to 1250Å at a ratio of 0.23). When the ratio of $Sn(CH_3)_4$ to O_2 was small ($\lesssim 0.10$), the films were fairly resistive ($\rho > 10^{-2}$ ohm-cm). When the ratio of $Sn(CH_3)_4$ to O_2 was large (~0.23), the films were also resistive and acquired a yellowish coloration and became less scratch-resistant. The coloration is probably due to an oxygen deficiency in the films; only ~0.2 atomic per cent (a/o) of C was found in these colored films. When the optimum ratio was selected, films with resistivities of $\sim 3 \times 10^{-3}$ ohm-cm were obtained; these films had a surface resistivity of ~400 ohm/□ (~750Å thick) and an average light transmission as compared to uncoated glass of ~87% (over the wavelength range of 3500-6500Å). Approximately 0.5 a/o of C was present in the most conductive films.

These films were relatively insensitive to thermal cycling and exhibited only 10-20% reduction in conductivity after baking for 24 hr at 400°C in air. (Baking for 1 hr at 550°C caused a decrease of 50%.) If the conduction were due only to donor states arising from

[1] Approximate composition by weight per cent (w/o): 73 w/o SiO_2; 13.5 w/o Na_2O; 9 w/o CaO; 4 w/o MgO; 0.2 w/o Al_2O_3.

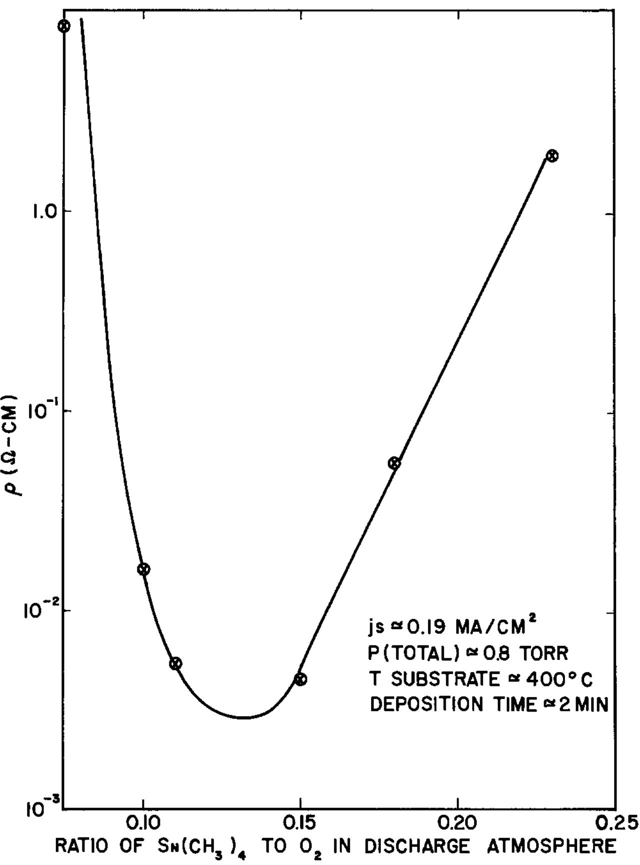

Fig. 2. Volume resistivity of tin oxide films as a function of the ratio of $Sn(CH_3)_4$ to O_2 in the discharge atmosphere.

oxygen vacancies, the resistivity should have increased by more than an order of magnitude (17,18). One possibility is that donor levels are created by the presence of OH groups in the tin oxide structure. The glow discharge is expected to produce OH groups because of the large number of hydrogen atoms per $Sn(CH_3)_4$ molecule and the large per cent of O_2 in the initial discharge atmosphere (~88% O_2).

Figure 3 shows how the film thickness and the surface resistivity varied with time for a discharge in $Sn(CH_3)_4$ and O_2. The deposition rate was ~1200 Å/min for the first 15 sec and slowed to ~225 Å/min after 1 min. The average volume resistivity decreased from $\sim 4 \times 10^{-2}$ ohm-cm at 15 sec to $\sim 10^{-2}$ ohm-cm at 4 min. The composition or stoichiometry of the film varied with thickness since the percentage of Sn in the discharge atmosphere decreased with time.

Figure 4 shows how the surface resistivity of films formed from a discharge in $Sn(CH_3)_4$ and O_2 varied with current density. For low current densities, the deposition rate increased as the current density increased. As the current density (or cathode fall potential) became larger, the deposition rate decreased due to the influence of sputtering. At large current densities ($\gtrsim 1.0$ mA/cm²), film deposition did not occur and the glass surface was slowly sputter etched.

Tin oxide films were deposited on glass substrates at temperatures as low as 200°C using a d-c glow discharge in $Sn(CH_3)_4$ and O_2. These films can be deposited at temperatures much lower than with chemical vapor deposition (CVD) ($\gtrsim 375$°C) (17) because the discharge dissociates the molecules and drives the positive ions to the substrate with appreciable kinetic energies (~10-100 eV depending on the deposition parameters). Thus, the positive ions arriving at the substrate are on the order of 10^3 times "hotter" than the substrate.

The average light transmission and volume resistivity of the best films deposited at 250°C were com-

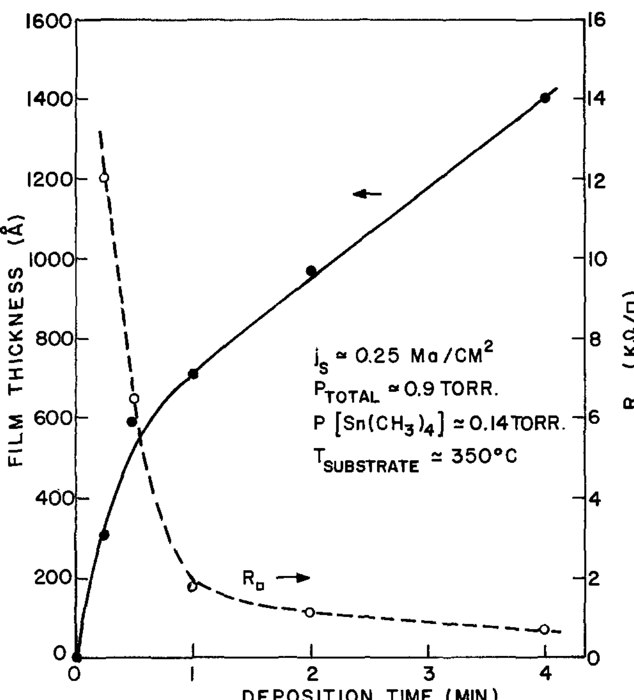

Fig. 3. Thickness and surface resistivity of tin oxide films as a function of deposition time.

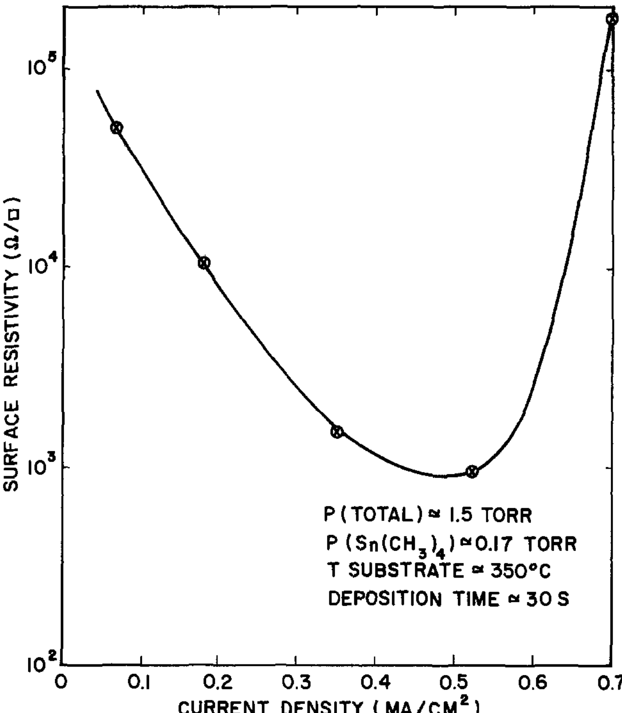

Fig. 4. Surface resistivity of tin oxide films as a function of current density.

parable to those deposited at 400°C. However, the films deposited at lower temperatures appeared to be slightly less scratch-resistant.

As the deposition temperature was reduced, the highest conductivity films were produced at decreasing ratios of $Sn(CH_3)_4$ to O_2. For example, at a deposition temperature of 400°C, the ratio was ~0.13 (Fig. 2), while at 250°C the ratio was ~0.04. A larger ratio was probably necessary at higher temperatures to compensate for the thermal decomposition of some of the $Sn(CH_3)_4$ in the vicinity of the heater coils.

By admitting $SbCl_5$ to an atmosphere of $Sn(CH_3)_4$ and O_2, films with volume resistivities as low as 1.7 $\times 10^{-3}$ ohm-cm were produced. The variation of volume resistivity with varying amounts of $SbCl_5$ in the atmosphere is shown in Fig. 5. Mass spectrometry (solids) showed that the most conductive film contained ~0.33 a/o of Cl and less than 0.06 a/o of Sb. The average light transmission for this film was ~90%.

SnO_2 films were also made from glow discharges in $SnCl_4$ and O_2. For depositions at 400°C, a current density of ~0.2-0.5 mA/cm² was applied for 2 min. The ratio of $SnCl_4$ to O_2 was typically 0.3-0.5 ($P_{total} \simeq 0.8$ Torr) and was not as critical as in the case of $Sn(CH_3)_4$ and O_2 (Fig. 2).

The most conductive films made from a discharge in $SnCl_4$ and O_2 had a resistivity of ~1.5 $\times 10^{-3}$ ohm-cm. These films only showed a 20-40% increase in resistivity after baking for 24 hr at 400°C in air. (Baking for 1 hr at 550°C caused a 70% increase.) The doping must be caused mainly by substitutional incorporation of chlorine (18, 19) since mass spectrometry (solids) showed that the films contained ~1 a/o of Cl. However films that are halogen-doped during spray deposition do not usually show the stability to thermal cycling in air that the discharge-produced films do. For example, films formed by spraying solutions of stannic bromide on hot fused silica showed an order of magnitude increase in resistivity after baking in air for 24 hr at 400°C (20). Films made by spraying stannic chloride solutions on hot glass show similar thermal degradation in air. The films produced by a d-c glow discharge may be more dense than those produced by spraying, and thus halogen diffusion may be reduced in the discharge-produced films.

Electron diffraction by reflection has shown that discharge-produced films have a crystallite grain size less than 100A for deposition temperatures below ~400°C. The grain size was slightly larger in films produced from discharges in $SnCl_4$ and O_2 than those from $Sn(CH_3)_4$ and O_2 for the same deposition temperature.

In conclusion, the present study shows that a d-c glow discharge in the appropriate atmosphere can be

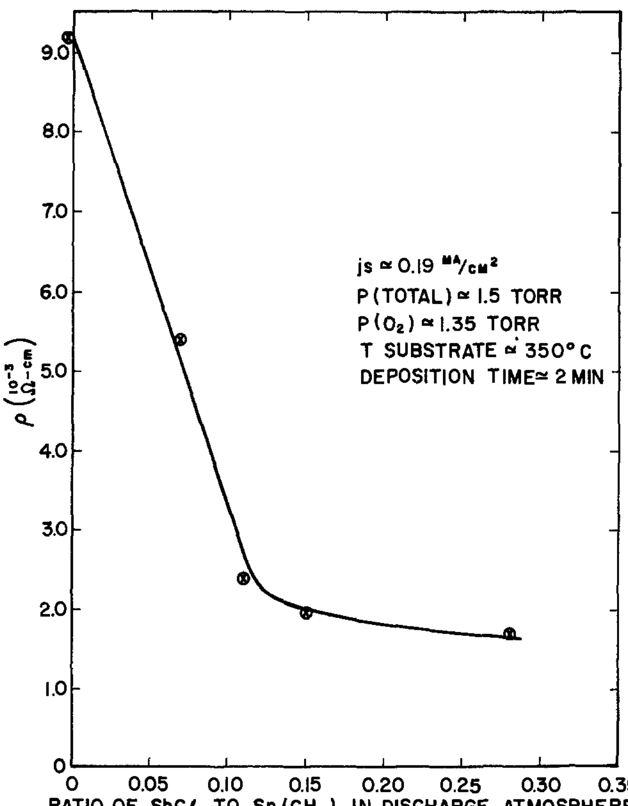

Fig. 5. Volume resistivity of doped tin oxide films as a function of the ratio of $SbCl_5$ to $Sn(CH_3)_4$ in the discharge atmosphere.

used to deposit good quality, tin oxide films on the surface of a soda-lime-silicate glass.

Microstructural and Electrical Properties of Thin PtSi Films and Their Relationships to Deposition Parameters

R. M. Anderson and T. M. Reith

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The intimate relationships among the microstructure, electrical characteristics, and deposition parameters of thin PtSi films deposited on {001}, {011}, and {111} Si wafers are discussed. PtSi morphology and crystallinity fall into several distinct categories, according to substrate surface preparation, deposition conditions, heat-treatment, and electrical performance. *In situ* sputter cleaning before PtSi deposition and formation gives better films. Also, the microstructure and sheet resistance of PtSi are strongly affected when deposition and formation are followed by heat-treatment at temperatures from 400° to 950°C.

PtSi films have recently been the subject of much investigation because of their usefulness in forming near-ideal ohmic and Schottky contacts to both n- and p-type Si (1, 2). The crystallography and morphology of PtSi films have received considerable attention (3-8), as have the kinetics of their formation (9-12). This paper discusses the intimate interrelations of the microstructure of thin PtSi films, their electrical properties, and their dependence on deposition conditions.

Experimental

Preparation of samples.—In the present study we have examined both sputter- and e-beam-deposited PtSi films, although we have concentrated on the former. For the sputter-deposited films, an oil diffusion-pumped vacuum system with a Pt target 30 cm in diameter was used. It had provisions for *in situ* rf sputter cleaning and d-c sputtering of Pt. A Pt-coated stainless steel substrate holder resting on a Cu block with an embedded heating element enabled us to heat the wafers to 450°C before, during, or after Pt deposition (Fig. 1). The *in situ* sputter cleaning, when performed and unless otherwise indicated, was for 2 min at an rf power of 100W and an Ar pressure of 10 mTorr. Figure 2 shows the amounts of Si and SiO_2 removed as a function of time and rf power. The curves were obtained by sputter etching bare and thermally oxidized 3.2 cm Si wafers, which were partially masked with chromium to create a step in the surface. The step height was subsequently measured by use of a Talystep apparatus.

Extrapolation of the appropriate curves indicates that, for 2 min at 100W of rf power, about 75Å of SiO_2 and 175Å of Si are removed. The Pt was d-c sputter deposited with a 2 kV potential applied to the target and at 40-50 mTorr of Ar pressure unless otherwise noted. Various heat-treatments were used to form the PtSi, either *in situ* or externally in dry, flowing N_2. After PtSi formation, any unreacted Pt was removed in aqua regia at 60°-65°C. An oil diffusion-pumped vacuum system with a 180° four-pocket Cu-hearth e-beam source was used for the evaporated PtSi films. The pressure in the deposition system was $1\text{-}5 \times 10^{-6}$ Torr during all evaporations. A spiral-wound tungsten wire heater was used to heat the substrates to ~300°C during deposition. The PtSi was formed externally in dry N_2, and unreacted Pt was stripped in aqua regia.

Key words: electron microscopy, platinum-silicon, electrical measurements.

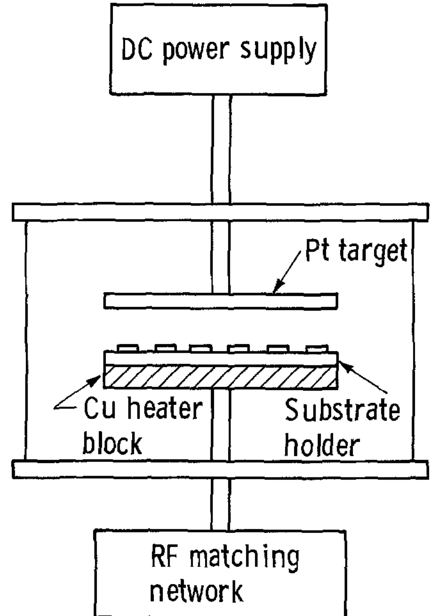

Fig. 1. Pt sputtering system

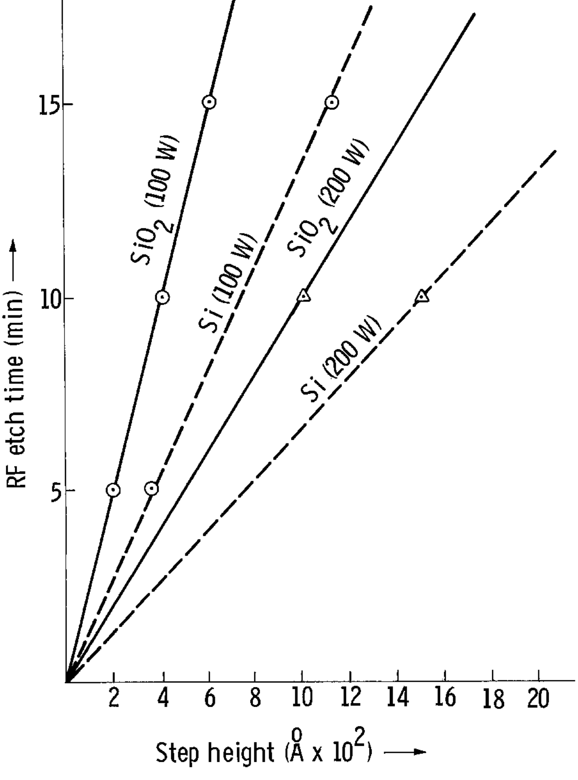

Fig. 2. RF etch time

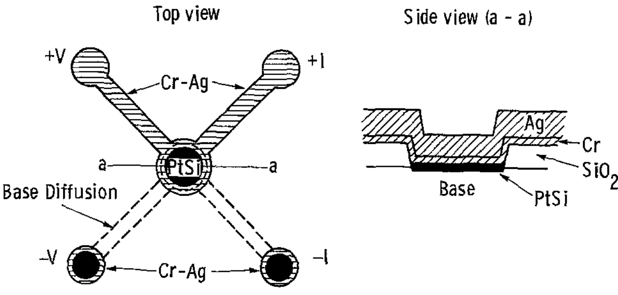
To examine the dependence of PtSi microstructure on the dopant level and species of the Si on which it is formed, and the stability of the compound as a function of high heat-treatment temperature, 500Å of Pt was sputter deposited on the entire surface of several 3.2-cm Si wafers that had been diffused with either boron or arsenic to various dopant concentrations. After the wafers were cleaned by rf sputtering, the Pt was d-c sputter deposited as described previously. The substrates were heated to 450°C during the Pt deposition to form PtSi *in situ*. Any unreacted Pt that may have been present was removed in hot aqua regia. The sheet resistance of films was measured as a function of dopant and anneal by use of an in-line four-point probe apparatus. No attempt was made to convert the measurements into resistivity units, because there was some uncertainty about the total thickness of the PtSi. As before, all heat-treatments subsequent to the *in situ* PtSi formation at 450°C were done in dry, flowing N_2. The resulting microstructures were then examined by transmission electron microscopy (TEM).

To examine the effects of *in situ* rf sputter cleaning, bare 10-20 ohm-cm As-doped Si wafers, 3.2 cm in diameter, were sputter etched for 5 min at 100 and 500W of rf power. These specimens were analyzed by transmission electron microscopy, reflection electron diffraction (RED), low-angle-Laue, Berg-Barrett surface topography, and electron microprobe methods to determine whether any microstructural changes could be induced on the Si surfaces as a result of the *in situ* sputter cleaning. Also, some of the device structures described earlier were sputter cleaned for 15 min at rf power levels of 100 and 200W and examined by scanning electron microscopy (SEM) and electron microprobe analysis to determine whether SiO_2 can be back sputtered from the areas surrounding the opened contacts onto the exposed Si in these contacts by the sputter-cleaning operation. All sputter cleaning performed was either of longer duration or at higher power than would normally be used and hence represented an extreme condition.

Electrical testing procedure.—By use of the test structure shown in Fig. 3, the specific contact resistance of the various PtSi-Si contacts formed was measured. Since the only point in common between the current and voltage loops is the PtSi-Si contact, the measured voltage drop is that which occurs across the PtSi-Si interface, if spreading resistances are neglected. The test structures were defined by standard photolithographic methods. To simulate a typical "base" contact, boron was diffused into 10-20 ohm-cm phosphorus-doped <001> Si wafers. After reoxidation, the measured junction depth was about 0.5 μm, and the surface concentration was 2.4×10^{19} atoms/cm^3. To simulate a typical "emitter" contact, slightly smaller cuts were opened photolithographically on half the devices through the reoxidized SiO_2 above the "bases" and an arsenic diffusion was done. After reoxidation, the junction depth was approximately 0.25 μm, and the surface concentration was 1.1×10^{21} atoms/cm^3. To complete the structures, contact holes 0.05 mm in diameter were etched to expose the doped Si surfaces. After PtSi deposition and formation, 1000Å of Cr and 10,000Å of



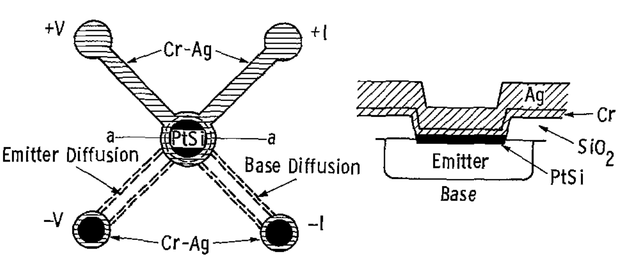


Fig. 3. Electrical test structure

Ag were evaporated through a molybdenum mask 0.1 mm thick to facilitate electrical probing. Unlike Al, Cr (13, 14) will not react with PtSi until temperatures well above those typically encountered in semiconductor device processing are reached. This fact was confirmed by four-point probe resistivity measurements and particle backscattering analysis. All measurements of contact resistance were made with a constant-current source and a digital voltmeter. Finally, HCl was used to stripe the Cr-Ag metallization to expose the electrically characterized PtSi contacts for subsequent TEM analysis.

Transmission electron microscopy specimen preparation.—The electrically characterized wafers were scribed and broken up into specimens, each containing one device, of a size that would fit the specimen holder of the JEM 200A electron microscope. After appropriate masking, the Si was thinned from the backside of the specimen down to the intermetallic film in a mixture of HF-HNO_3-CH_3COOH (1:2:3). Specimens were thinned further, as required, in a Commonwealth ion milling machine.

Results

Microstructure vs. electrical properties.—At this point it would be well to stop and look at what "good" and "bad" PtSi microstructures are like. As we have learned, the key to "good" and "bad" microstructures lies in the cleanliness of the Si surface before Pt deposition. Pt deposited on a clean Si surface will begin to form a satisfactory PtSi film during deposition or subsequent heat-treatments, even without substrate heating. Unreacted Pt on Si films are due primarily to the presence of a contamination layer between the Pt and the Si which prevents the formation of PtSi, even after extensive heat-treatments. Quite often, especially with thin (<150Å) initial Pt depositions, the as-deposited Pt films are not fully coalesced and do not become so after subsequent heat-treatment. Selected area electron diffraction (SAD) of thin, poor Pt on Si films shows randomly oriented Pt diffraction rings superimposed on Si reflections. Subsequent heat-treatment brings no change; the Pt has not reacted with the Si, and the SAD patterns still show Pt rings and Si substrate spots.

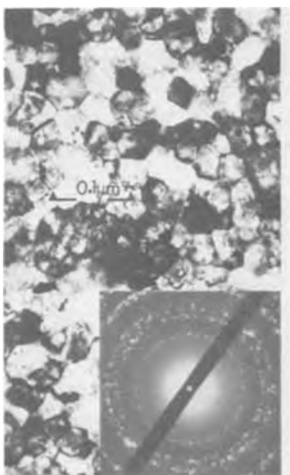
For thicker initial Pt depositions on randomly and unintentionally contaminated Si, the as-deposited Pt films still do not fully coalesce. After heat-treatment these films undergo simultaneous grain growth and void enlargement, producing lacelike Pt films on Si. Whenever the initial Pt deposition fails to show a preferred orientation to the Si wafer, the microstructure observed after heat-treatment is poor, and no PtSi phase forms. Where the contamination film is itself incomplete, allowing islands of more or less continuous PtSi to form, the stress evolved as the PtSi phase shrinks during formation dissipates itself through void enlargement. One obvious observed consequence of the failure to form PtSi over contaminated Si is that when the aqua regia etch for unreacted Pt is applied, the film disappears. Where PtSi forms in islands, the unreacted Pt over contaminated Si is etched away. Any subsequent metallurgy forms a "capacitor," with the contaminant film as a very leaky "dielectric." Moreover, the metallurgy contacts the Si because of the circular channel of bare Si exposed around the islands of PtSi (opened up by shrinkage of the PtSi phase). No electrical data were taken on the very poor Pt on Si films discussed above, because no PtSi phase formed.

The contamination film on the Si was analyzed by x-ray microprobe and ESCA methods. It consists primarily of oxygen (as SiO_2) and carbon films, 50-100Å thick. It builds up in the perimeters of contacts. ESCA has also shown the presence of a thin SiO_2 film (<100Å thick) on top of freshly prepared PtSi films. Heat-treating the PtSi films in air instead of nitrogen results in a surface containing less platinum and more oxygen. The etching in aqua regia may promote the formation and growth of the thin SiO_2 film on the PtSi. This phenomenon has been observed by other investigators (15).

When Pt is deposited on clean Si, but not heat-treated *in situ* or later, the electron microscope shows a continuous Pt film with a very strong <111> preferred orientation to the Si substrate. As was mentioned earlier, this strong orientation is a good indication that a satisfactory PtSi film will form upon heat-treatment. When these films are heated *in situ* in the electron microscope while being recorded in the SAD mode on 16-mm motion picture film, it is possible to edit frames from the sequence and index the SAD patterns. By this method we find that the phases formed are $Pt + Si \rightarrow Pt_3Si \rightarrow Pt_2Si \rightarrow PtSi$. The complete reaction occurs in approximately 20 sec at 450°C. Often one or more rings from the Pt_2Si phase remains in the PtSi phase diffraction pattern despite prolonged heat-treatment.

PtSi films <500Å thick, deposited or heat-treated in the range of 400°-850°C, can have several different morphologies, each with its own associated crystallography and, as will be shown later, concentration of dopant in the substrate. For Si substrates that are less than atomically clean, or high concentrations of Si dopant, we see a continuous, polycrystalline PtSi film, randomly oriented to the Si and having high-angle grain boundaries separating grains that are randomly oriented toward each other. Figure 4a is typical of such a PtSi film. For very clean Si substrates and intrinsic-to-moderate Si dopant levels, the PtSi film is heteroepitaxial to the Si substrate and consists of very small nodules of PtSi, having a high degree of orientation toward each other and separated by discontinuities, or voids, 20-150Å wide. This important result indicates that PtSi, by itself, could not be used as an effective diffusion barrier to prevent interaction between the subsequently deposited device interconnective metal and the substrate. Figure 4b is an example of such a film on a <001> Si substrate; the SAD pattern in the insert exhibits anomalous symmetry, greater than two-fold. These two morphologies are extremes; many morphologies may be observed between these limits.

The results for microstructure *vs.* electrical performance are summarized in Table I. Here the specimens observed are divided into groups as functions of deposition conditions. The specific contact resistance data in the table are the statistical means of the data for the specimens in any particular group. Any difference between the forward and reverse values gives a measure of the contact's departure from ohmic behavior. When an occasional sample in one of the superior



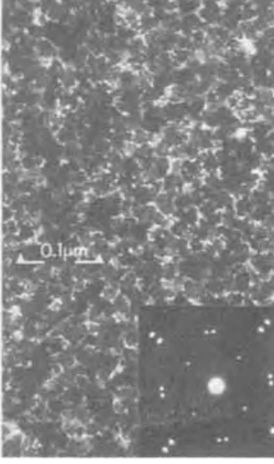


Fig. 4. PtSi morphology: extremes. Corresponding diffraction patterns are shown in the insets. (a, above left) High-angle grain-boundaries; sample is described in Table I, I (base). (b, above right) PtSi nodules; sample is described in Table I, III (base).

Table I. PtSi properties related to deposition parameters

Group	Substrate preparation	Heat-treatment	Diffusion	Specific contact resistance: forward, reverse (ohm-cm^2 × 10^{-5})	Morphology	Crystallinity
I	Chemical cleaning plus sputter cleaning, performed *in situ*	450°C *in situ* during Pt deposition; substrates cooled *in vacuo*	Base	5.48, 6.29	Nodules (300Å), taken as definitive. Internodule voids, 10-50Å. Buildup of larger, thicker nodules in contact hole perimeter (Fig. 5a)	Type A pattern, taken as definitive
			Emitter	0.406, 0.507	Nodules (210Å). Internodule voids, 10-50Å. Nodules have textured surface or internal structure, build up in perimeter	Type A pattern
Ia	Same as I	Same as I	Base	13.6, 13.4	As above except discontinuity in perimeter 2000-3000Å wide, exposing bare Si	Type A pattern in PtSi
			Emitter	0.528, 2.64	Same as base	Type A pattern in PtSi
Ib	Same as I	Same as I	Base	19.1, 19.1	As in group Ia, plus scallops in edge of PtSi area (Fig. 5b)	As in group Ia
			Emitter	0.812, 1.22	Same as base	
II	Same as I	450°C for 20 min *in situ* after deposition	Base	15.2, 15.0	PtSi as in groups I, Ia, and Ib on different samples with no change in contact resistance	Type A pattern mixed with regions of type B pattern
			Emitter	0.771, 0.771	Same as base plus an occasional large void, 500-1000Å	Same as base
III	Chemical cleaning	550°C for 30 min externally in clean furnace	Base	17.5, 17.7	High-angle g.b.* Some large voids. Perimeter effects as in group II	Type C pattern
			Emitter	1.68, 1.68	Same as base	Same as base
IIIa	Same as I	Same as III	Base	13.4, 13.2	Mixed nodules and high-angle g.b., porous	Type B patterns mixed with type C; some unreacted Pt
			Emitter	0.446, 1.91	Same as base but more porous	Type C pattern plus some unreacted Pt
IV	Chemical cleaning	Same as III, but in a contaminated furnace**	Base	102, 81.2	High-angle g.b. Large grains, some voids, etching damage, perimeter effects	Poly PtSi plus unreacted Pt
			Emitter	40.6, 40.6	Same as base; contamination evident	Same as base
Effect-of-thickness samples	Same as I	550°C for 30 min in clean furnace	Base	16.1, 16.1	Two-layer film; nodules next to substrate, and very porous, very small grain layer above (Fig. 5c)	Type A pattern next to substrate; broad, diffuse Pt rings above
			Emitter	1.81, 1.02	Same as base except that nodule layer was thinner	Same as base
Evaporated Pt-I	Chemical cleaning; deposition at 300°C	Same as effect-of-thickness samples	Base	12.4, 12.2	Same as groups Ia and Ib	Same as group Ia
			Emitter	0.790, 0.821	Same as group Ia	Same as group Ia
Evaporated Pt-II	Same as evaporated Pt-I	Same as effect-of-thickness samples	Base	24.8, 24.6	High-angle g.b.;* two-layer structure; etch damage (Fig. 5d)	Poly PtSi below; broad, diffuse Pt rings above
			Emitter	12.03, 11.42 (when PtSi film is present)	Same as base; or, for some samples, Pt did not react with Si and was etched off during the aqua regia step	Same as base or no film at all

* g.b. = grain boundary.
** The furnace was intentionally contaminated with oxygen.

specimen groups had electrical data more typical of one of the contaminated groups, and electron microscopy confirmed the presence of a contaminated or anomalous microstructure, the data for such specimens are presented in a separate statistical subgroup in the table.

For brevity, codes were adopted. In the morphology section, "high-angle g.b." refers to the first limiting case, described above, of a continuous, random, polycrystalline PtSi film with high-angle grain boundaries. "Nodules" refers to the second limiting case of highly oriented, heteroepitaxial, small, discontinuous nodules (lacking grain boundaries) of PtSi; the width of the void between modules is specified in the table. "Poly PtSi"refers to a diffraction pattern of randomly oriented PtSi phase with no preferred orientation. A "type A pattern" is a single-crystal PtSi diffraction pattern consisting of one diffraction zone.[1] A "type B pattern" is a mixture of two or more PtSi diffraction zones, and a "type C pattern" is a mixture of one or more diffraction zones with polycrystalline PtSi rings. The morphology types are illustrated in Fig. 4a and b. For comparison, Table I includes data from thicker sputtered specimens and from films e-beam evaporated and subsequently heat-treated.

Some of the points brought forth in the table merit detailed discussion. The contact perimeter effects that distinguish groups I, Ia, Ib, and II from one another and are illustrated in Fig. 5a and b are due to different degrees of cleanliness in the contact holes combined with the volume contraction, about 500Å, associated with the formation of the PtSi phase. Even when the contacts are sputter cleaned *in situ* before Pt deposition, microanalysis methods often disclose an increased level of chemical etchant residues within 5000Å of the SiO_2 step-down to the Si around the perimeter of the contact hole. When this contamination is present, the Pt immediately adjacent to the SiO_2 step fails to react with the Si, with the result that the aqua regia strip leaves a ring of exposed Si around the contact, as in Ia, or a ring plus scallops, as in Ib. The group I samples occur when the sputter cleaning effectively eliminates the contaminating residue. *In situ* heat-treatment of group II samples in the electron microscope reveals that the Pt on the walls and the top of the SiO_2, having no Si to react with, rapidly diffuses down to feed the reaction in the contact hole perimeter, yielding thicker PtSi nodules in the perimeter. This phenomenon is observed only for sputtered Pt samples in which edge coverage of the oxide step-down is very good. The group II PtSi films had a somewhat poorer heteroepitaxy than the group I films, with an apparently concomitant insensitivity of the specific contact resistance to perimeter effects.

The formal Discussion section will deal with the nodular plus void morphology we attribute to pure PtSi. We believe that the high-angle g.b. morphology is a manifestation of PtSi formed in the presence of low levels of surface contamination that prevents the PtSi from becoming heteroepitaxial to the Si. For PtSi films more than 300-400Å thick, we often see remnants of the Pt_2Si diffraction pattern mixed with diffraction patterns of types A, B, and C. *In situ* heat-treatment in the electron microscope has shown that when the substrate conditions are appropriate for the

[1] The diffraction zone of the pattern is a function of the Si substrate orientation and will be identified along with the n-fold anomalies of the diffraction patterns in the Discussion section.

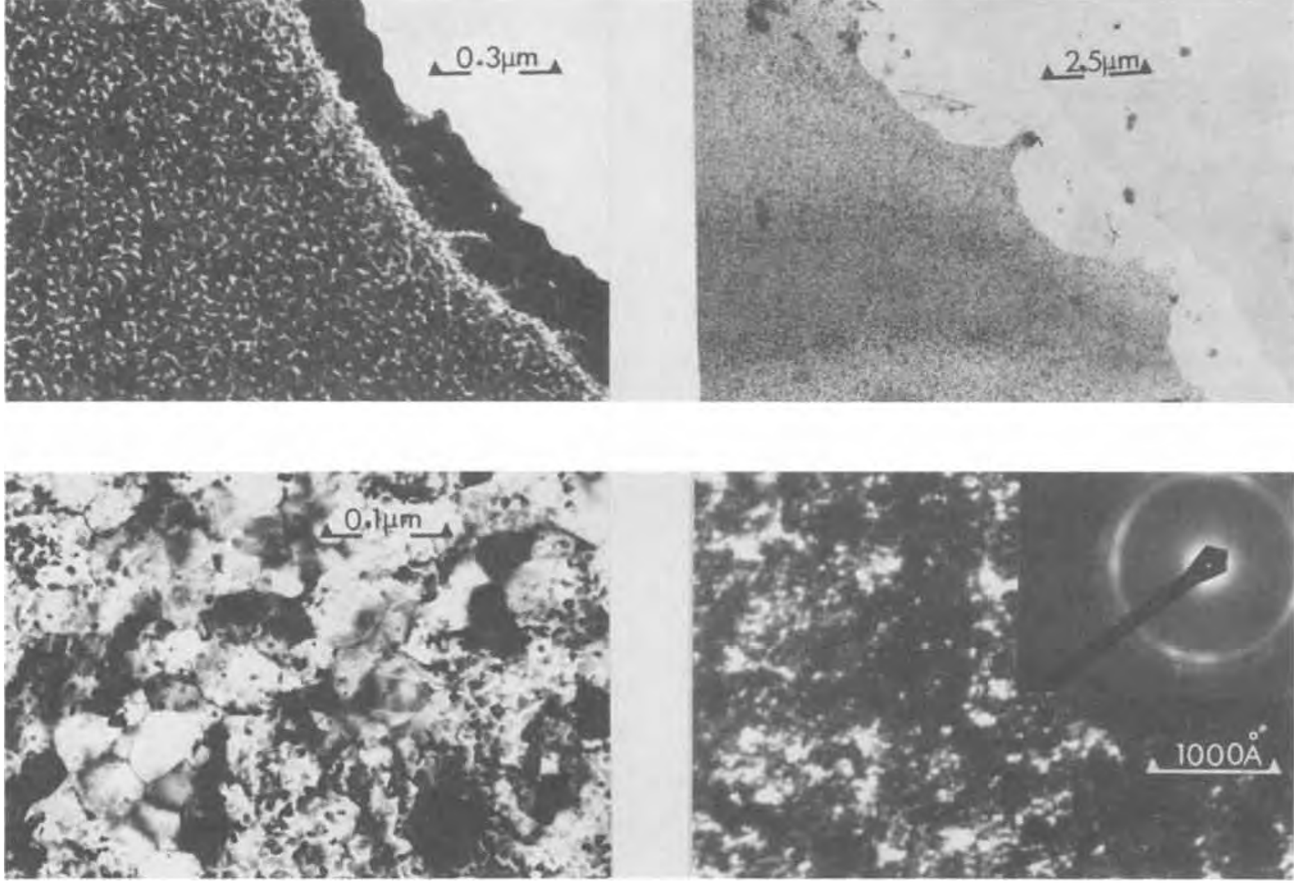

Fig. 5. Anomalies in morphology of PtSi. (a, top left) Buildup of thicker grains of PtSi in perimeter of contact. (b, top right) Opened-up contact perimeter with scallops. formation of high-angle g.b. PtSi, heat-treatment at a temperature of over 500°C for more than 1 or 2 min may induce void growth.

The "effect-of-thickness" samples introduce a new morphological type: the two-layer film. The two discrete layers are detected visually in the transmission and scanning electron microscopes and by their different chemical etching behavior. Both layers yield Pt and Si spectra in energy and wavelength dispersion studies in the x-ray microprobe. As is mentioned in Table I, the layer adjacent to the Si substrate has a nodular morphology that often compares well with the group II samples. The top layer has a very slow etch rate and has a spongelike morphology consisting of grains 50-75Å in size in a matrix that is about 50% small grains and 50% voids. Electron diffraction patterns from the top layer are indexed as fcc Pt, but the Pt rings are very broad and diffuse. On this evidence, we identify the top layer as porous Pt, an etching residue.[2]

For these samples, the heteroepitaxial PtSi nodules are diffusion limited to a maximum thickness of 200-500Å before, presumably, stoichiometric deficiencies cause the PtSi to renucleate in a randomly oriented polycrystalline morphology, as has been observed on unetched specimens. Figure 5c depicts a thick sample that has been thinned from below; the remnants of the nodules can be seen under the large renucleated Pt_xSi_y $(x > y)$ grains. This Pt_xSi_y is attacked by the aqua regia etch to produce porous Pt (Fig. 5d). The thickness of Pt_xSi_y/porous Pt is maximized, for a given Pt thickness, by poor contact hole cleaning and/or higher concentrations of B or As dopants in the Si, as is discussed later.

PtSi formed from evaporated Pt presents a study in contrasts. The evaporated Pt group I samples, which are typical of most of the evaporated Pt-PtSi examined, compare very favorably with sputtered samples of groups Ia and Ib. In all cases, evaporated Pt contacts exhibited deleterious contact perimeter effects. When evaporated Pt-PtSi contacts are made in large lots, with no intentional changes in deposition parameters, electrical tests occasionally reveal wafers with high specific contact resistances. TEM analysis of these wafers reveals the microstructure identified as evaporated Pt group II in Table I. The morphology and crystallinity of evaporated Pt samples in group II combine the worst features of sputtered group IV and the effect-of-thickness samples. Often the perimeter discontinuity expands to the center of the contact, leaving only a small region of PtSi.

The authors believe that the poor quality of the microstructures in the evaporated Pt samples in group II is directly attributable to contamination of the Si contacts. Support for this belief comes from ESCA and SEM/Auger analysis, which reveals higher levels of carbon that presumably are due to residues of chemical cleaning and photoresist left before deposition. Often the high contact resistance of evaporated Pt group II samples can be lowered somewhat by additional heat-treatment before the aqua regia etch. Heat-treatments of up to 2 hr at 550°C were used. This is additional, indirect evidence of contact contamination; one can assume that hydrocarbons in the contacts are breaking down and allowing the Pt to react with the Si.

Dopant C_o dependence.—During our analysis of PtSi thin films, we noted that the microstructure of the PtSi films is sensitive to the dopant species and surface concentration in the underlying Si substrate. As was noted in the section on preparing specimens, the dopant-C_o-dependence PtSi was formed on the seven wafers listed in Table II. The Si dopant species and the range of dopant concentrations were chosen with the aim of encompassing all of the Si-dopant possibilities germane to the production of viable contacts. The 2.0×10^{15} boron wafer is taken as the intrinsic Si case. Sheet resistances were measured on the as-deposited films and after the external heat-treatments as listed in Table II. The heat-treatments were performed after the unreacted Pt strip, to prevent any unreacted Pt present from adding to the volume of PtSi phase formed during the deposition *in situ* heat-treatment. The drop in sheet resistance observed after the heat-treatment at 750° or 850°C is due to the expansion of the heteroepitaxial film via the partial consumption of the thin polycrystalline PtSi (or porous Pt) film overlying the heteroepitaxial nodules. We postulate not that the sheet resistance is lower because of the more perfect microstructure of the PtSi films, but rather that the electrical properties of the films are degraded as the increased heat-treatment temperature drives the finite amount of Pt deeper into the Si at the expense of the stoichiometry of the PtSi films. The films heat-treated at 950°C have been completely recrystallized. The PtSi is now completely randomly oriented polycrystalline, with high-angle grain boundaries and no voids. Paralleling Sinha's findings (8), the polycrystalline PtSi film is covered with discontinuous clusters of agglomerated large grains of PtSi protruding from the smooth film. Note in Table II that the complete absence of stoichiometric heteroepitaxial PtSi in the 950°C samples is invariably accompanied by an increase in sheet resistance.

Space does not permit us to include representative micrographs and diffraction patterns for all of the combinations of Si dopants and heat-treatments reported in Table II. Let us start with the intrinsic (2.0×10^{15}B) Si sample. The as-deposited, two-layer PtSi film has a complete nodule layer over the Si and an incomplete poly PtSi/porous Pt film over the nodules. After heat-treatment at 750°C, there is much less poly PtSi/porous Pt in evidence; after heat-treatment at 850°C, there is none at all in discrete areas on the intrinsic Si. The morphology of the film after the heat-treatment at 950°C consists of protruding large PtSi grains on randomly oriented continuous PtSi film.

The most obvious effect of increasing the Si dopant in the substrate is to improve the coverage of the as-deposited samples by poly PtSi/porous Pt. The As 1.0×10^{19} sample was covered about as well as the intrinsic Si sample, about 50%. On the other hand, the As 1.0×10^{20} and the B 4.0×10^{18} as-deposited samples were 70-90% covered over the heteroepitaxial nodules. At higher dopant levels of either species in Si, the nodules were completely covered with poly PtSi/porous Pt. The microstructural effects of heat-treatment of all the as-deposited films parallel the sequence described for intrinsic Si: at 750° or 850°C the poly PtSi/porous Pt loses its identity as a discrete film, and at 950°C it recrystallizes. The only exception to the general trend was that the As 1.0×10^{21} sample heat-treated at 850°C was partly recrystallized.

Effect of in situ sputter cleaning on the silicon surface.—We have stressed the importance of contact hole

Table II. Sheet resistance (ohm/sq) of PtSi as a function of dopant concentration and heat-treatment. All heat-treatments lasted 1 hr

Dopant	Heat-treatment, °C	Dopant concentration (cm^{-3})		
		2×10^{15}*	5×10^{18}	4×10^{19}
Boron	As deposited	13.50	0.721	0.697
	750	9.36	0.493	0.694
	850	6.50	0.546	0.659

	750	7.67	4.41	4.20
	850	6.90	4.37	4.36
	950	7.74	5.54	5.47

* Taken as the intrinsic case.

[2] A porous reaction occurs when an intermetallic alloy, consisting of a noble metal and a nonnoble metal, is etched: the noble metal is leached from the alloy lattice, leaving the noble metal in a highly disordered state. The remnant lattice will produce a diffraction pattern consisting of broad, diffuse lines. The porous metal product has a spongelike morphology and is not amenable to further etching.

cleanliness on the microstructure of the subsequently deposited PtSi film. We have shown that *in situ* sputter cleaning before Pt deposition produces improved PtSi films and minimizes or eliminates contact perimeter effects. In this section we deal with the side effects of *in situ* sputter cleaning. Specifically, are the SiO_2 surrounding the contacts, and Pt from the nearby Pt fixtures, being backsputtered into the contacts during the cleaning?

TEM analysis of the 100W and 500W sputtered wafers showed contrast effects on the Si that were found to be associated with a rough surface morphology, very small dislocation loops, or the nucleation of a foreign material on the Si surface. Electron diffraction patterns showed single-crystal Si reflections, polycrystalline Si rings, and a ring pattern indexed as Pt.

A part of each sample was analyzed by reflection electron diffraction analysis (RED), comparing the center of the wafer with observations out to the edge. RED showed polycrystalline Si rings, Pt rings, and one ring identified as PtSi on the sample that had not been heat-treated. The only Si single-crystal reflections seen were very weak; this indicates that the thickness of the polycrystalline Si is nearly as great as the depth to which the electron beam from the RED apparatus penetrates into the substrate, about 300Å. The Pt reflections were broadened; this, in turn, indicates that the Pt is very thin. Both the polycrystalline Si and the Pt were more intense near the edges of the wafers than at the centers. Neither the thin polycrystalline Si nor the Pt showed in a low-angle Laue x-ray photograph. A Berg-Barrett surface topograph revealed no surface damage, within the limit of resolution of this method.

In view of the diffraction results, the samples were given a heat-treatment designed to clear up the ambiguity in the TEM observations of the surface. A heat-treatment would cause nucleated Pt to form PtSi with a resolvable size and/or any Si defects, such as dislocation loops, to grow to analyzable dimensions. After a heating cycle that peaked at 750°C after 30 min, TEM revealed isolated islands of PtSi with a strong PtSi <110> orientation relationship normal to the Si. No polycrystalline Si was detected.

For corroboration, the 500W sample was analyzed in the x-ray microprobe for Pt as a step function of distance from the center of the wafer to its edge. Pt was detected from the center out to the edge; its concentration was lowest at the center and peaked approximately 5 mm from the edge. The total counts at each step were low, indicating a very thin layer.

By use of the ESCA and Auger/SEM methods and the x-ray microprobe, we searched for backsputtered SiO_2 in the contact windows that had been sputter cleaned *in situ*. All three analyses confirmed that oxygen and/or SiO_2 were present, along with carbon, in the contact holes. However, the amount of contamination was very close to the above method's detectability limits and to the amount of SiO_2/carbon present on control samples that had not been sputter etched; hence the few monolayers of contamination that we see may well be native oxide films grown on the Si after sputter etching and artifactual carbon contamination induced in the analyzing instrumentation.

Apparently, then, the effect of rf sputter cleaning the Si wafer, if we neglect SiO_2 and carbon contamination, is to introduce a thin layer of polycrystalline Si on the surface (which is probably caused by backscattering or reflection of sputter-etched Si falling back on the surface) and to backscatter some Pt from the Pt-coated sputter-etching cathode and the nearby Pt d-c sputter-deposition cathode. When the samples were heat-treated, the Pt reacted preferentially, with the polycrystalline Si consuming it in the formation of PtSi. No dislocation loops or other line defects were observed in the Si. Although twins and other remnants of the existence of the polycrystalline Si layer could be expected in the heat-treated samples, none was observed.

The presence of backscattered Pt on the Si is desirable (16). The amount and distribution of it can be controlled by manipulation of the sputtering conditions.

The formation of a polycrystalline Si layer is probably not harmful. In fact, it may speed the formation of the PtSi phase.

Excessive sputter etching may produce an amorphous Si layer on top of the polycrystalline Si; however, we found no evidence of such a layer.

Discussion

PtSi diffraction anomalies.—The anomalous greater than twofold symmetry observed in diffraction patterns taken of orthorhombic PtSi was explained in earlier works (11-13). There we identified the epitaxial relationship of PtSi on {100} Si to be PtSi $(\bar{1}10)$ parallel to Si (001) and PtSi [001] parallel to Si [110]. The fourfold symmetry arises from double positioning of PtSi [001]'s on the two cubic <110> of the surface in neighboring PtSi nuclei.

In an illustration, we see that the PtSi on the {100} Si diffraction pattern in Fig. 6a exactly matches the computer plot in Fig. 6b. The computer plot was made by first drawing a PtSi $[\bar{1}10]$ zone (asterisks) and then

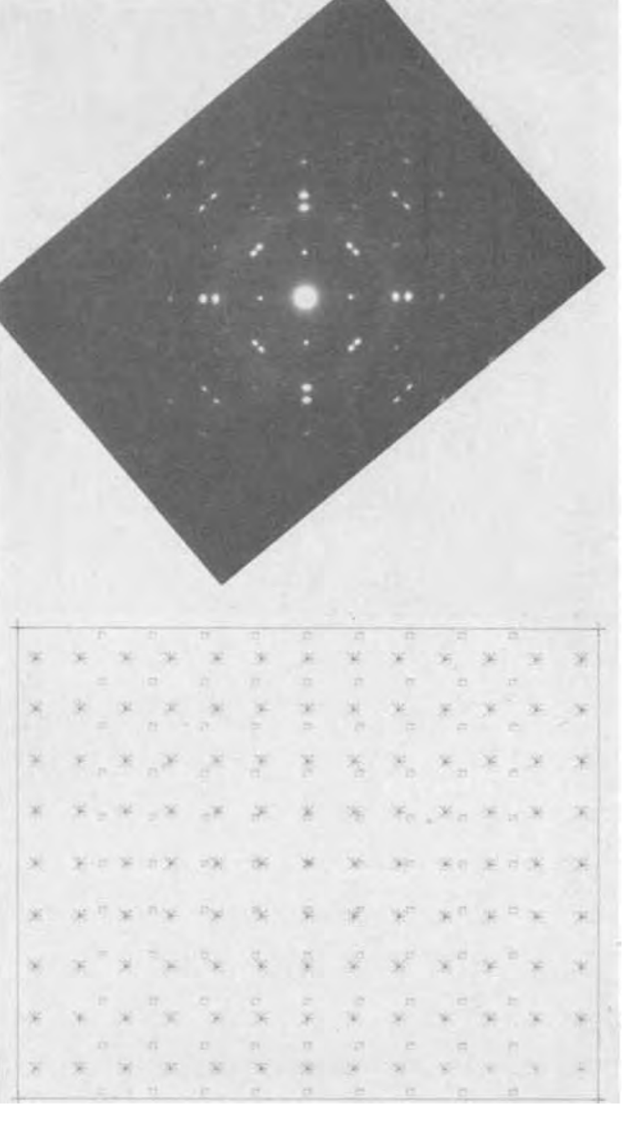

Fig. 6. Comparison of {100} diffraction pattern and computer plot for PtSi on {001} Si. (a) Diffraction pattern. (b) Computer plot, containing two PtSi [110] zones plotted with a 90° mutual rotation.

redrawing the same $[1\bar{1}0]$ zone (squares) after a 90° rotation about the common zone normals. The same explanation applies to the anomalous threefold diffraction patterns observed for PtSi on {111} Si wafers. In this case the PtSi (010) is parallel to the Si (111), and the PtSi [010] is triply positioned on three equivalent <224> of the Si. In Fig. 7 a diffraction pattern and a computer plot are compared as before except that the computer plots the PtSi [010] zone twice after two 60° rotations. The nonmatching reflections plotted by the computer are structure-factor-forbidden PtSi reflections that are present in the [010] zone. Figure 7a also contains oriented Pt_2Si reflections.

For completeness, we have also investigated the epitaxial relationships of PtSi formed on {011} Si substrates. The 150Å of PtSi was formed *in situ* during sputtering with conditions the same as those which produce type A PtSi. The blanket samples exhibited a type A nodule morphology. The diffraction patterns exhibited greater than twofold symmetry, but it was obvious that more than one crystallographic zone was present in the patterns. Figure 8a depicts the morphology of PtSi on {011} Si, and Fig. 8b shows the corresponding diffraction pattern. The heteroepitaxial relationships, obtained from Fig. 8b, are as follows:

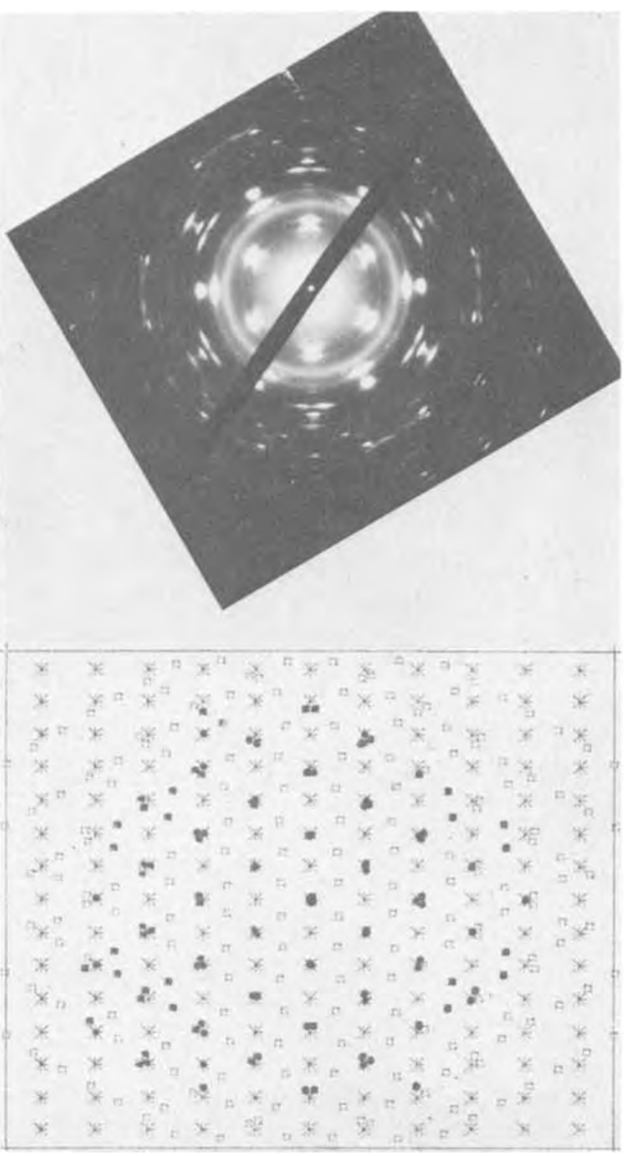

Fig. 7. Comparison of {111} diffraction pattern and computer plot for PtSi on {001} Si. (a) Diffraction pattern, which contains a Pt_2Si reflection that also shows anomalous symmetry. (b) Computer plot, containing three PtSi [010] zones plotted with 60° mutual rotations.

PtSi on {011} Si

Major orientation—double positioning of

PtSi $(13\bar{3})$ | | Si $(01\bar{1})$
PtSi $[30\bar{1}]$ | | Si $[0\bar{2}2]$

Coexisting minor orientations

(a) PtSi $(12\bar{0})$ | | Si $(01\bar{1})$
PtSi $[00\bar{2}]$ | | Si $[0\bar{2}2]$

(b) PtSi $(01\bar{1})$ | | Si (011)
PtSi $[\bar{1}1\bar{1}]$ | | Si [400]

The samples with PtSi on {011} Si were also used to find a solution for another electron diffraction puzzle observed on {001} and {111} Si. When a thin type A film is observed in SAD mode over a thin wedge of Si tilted into perfect zonal orientation, clusters of satellite reflections are formed around the Si matrix diffraction spots (Fig. 9a). Multiple diffraction effects, superlattice formation, and film formation on twinned Si surface regions were suggested as mechanisms for the satellite spot formation (17). Silicon twins primarily across (111) planes; the {011} samples, which have two (111) planes perpendicular to the surface, are ideal vehicles to test the twinning argument.

The assumption of twinning across the two (111) traces in Fig. 9a accounts for all of the anomalous reflections in what appears to be an n/3 relationship to the Si reflections. The close-by satellite reflections are not accounted for in this manner; they are presumed to arise from a combined multiple-diffraction-twinning mechanism, not yet determined, involving the substrate and the heteroepitaxial film. Analogous satellite arrangements for {001} and {111} substrates are seen in Fig. 9b and c.

The one significant conclusion drawn from the identification of the twin reflections in Fig. 9a is that local regions of the Si surface bear twin relationships to one another. Therefore, PtSi films formed heteroepitaxially on one region of Si will bear a twin relationship to PtSi formed on a neighboring, twinned region of Si. This in turn leads to an alternative argument to account for the greater than twofold symmetries observed in PtSi diffraction patterns. For example, the major asymmetry of Fig. 8b, ascribed to double positioning of {133} PtSi zones, could be equivalently produced by forming {133} PtSi over twinned regions of Si. Unfortunately, the Si planes over which the PtSi {133} must be mirrored are the Si (011) and (001), which have not been observed to be Si twinning axes. An attempt to extend the twinning argument to account for the high symmetry of PtSi on {001} and {111} Si wafers is also unsuccessful because the assumption of twinning over the previously reported [111], [123], and [511] Si twinning axes cannot account for the anomalous symmetry.

With the epitaxial relationships established, we can explain the observed morphology of thin, clean, epitaxial PtSi in thicknesses from 100 to 500Å. For PtSi on Si {100} wafers, we would expect an epitaxial PtSi film consisting of grains of PtSi abutting with 90° grain boundaries. Contrary to expectation, the morphology of such a film (Fig. 10a) consists of small disconnected nodules of PtSi with random shapes. This morphology probably arises because large misfit energies make neighboring PtSi nuclei with 90° rotations between PtSi <001> directions unable to coalesce during film deposition or recrystallization.

By carefully tilting a PtSi film on a {100} Si specimen in the goniometer stage of the electron microscope, it was possible to extinguish the PtSi reflections and leave one Si (400) reflection in a selected-area electron diffraction pattern. The Si (400) reflection was used to produce a high-magnification dark-field micrograph (Fig. 10b) of the area seen in Fig. 10a. Here the internodule regions are illuminated. This establishes that the epitaxial PtSi nodules are surrounded by un-

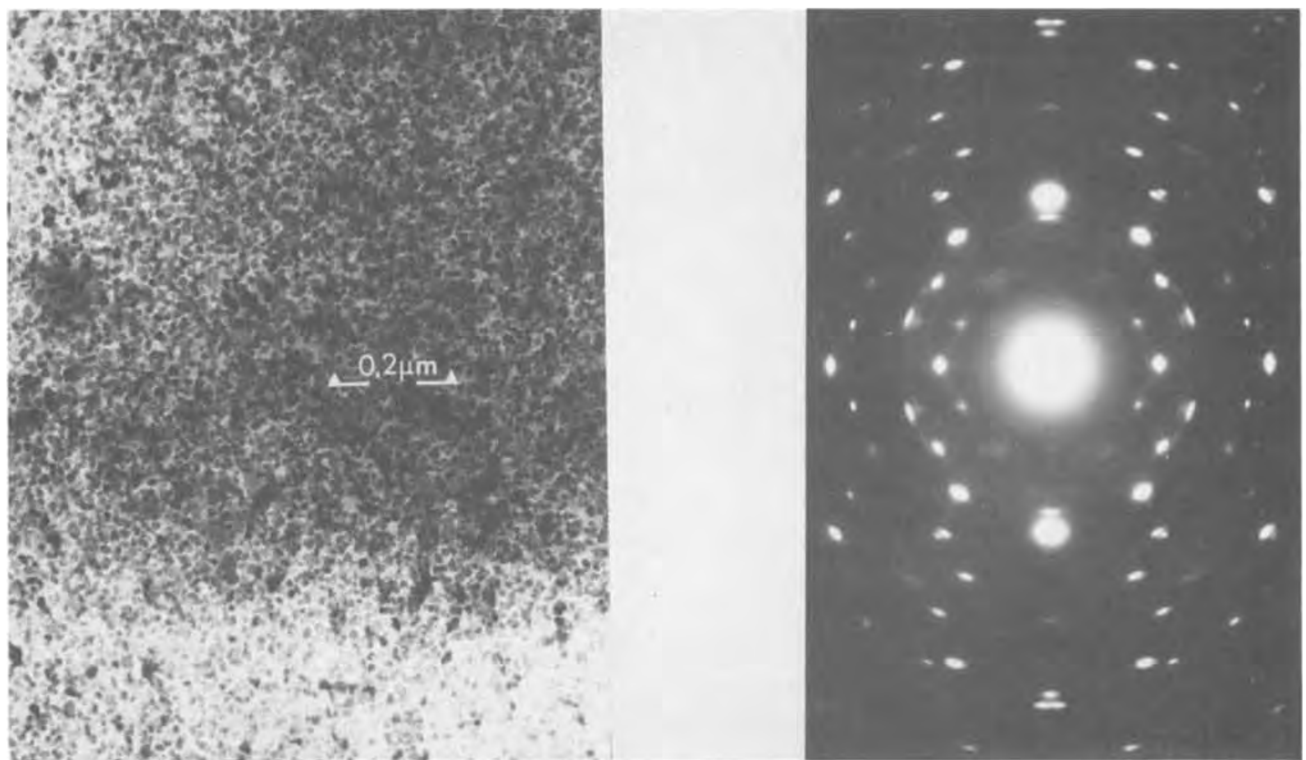

Fig. 8. PtSi on {011}. (a, above left) Nodule morphology. (b, above right) Corresponding diffraction pattern, containing two PtSi [133] zones rotated 180° plus minor orientations.

reacted Si channels approximately 20-30Å wide. Apparently the misfit energy associated with the coalescence of two PtSi nodules oriented 90° with respect to each other overcomes the driving force of the intermetallic phase formation, leaving, presumably, very highly stressed, unreacted Si between nodules.

The same explanation applies to the identical epitaxial PtSi morphology observed on {111} and {110} Si wafers.

Relationship of electrical properties of morphology and crystallinity.—Clearly, the best electrical contacts, *i.e.*, the lowest in specific contact resistance and the closest to ohmic behavior, produce single-crystal PtSi diffraction patterns consisting of one diffraction zone (type A). Morphologically, such structures consist of heteroepitaxial PtSi nodules 200-500Å in diameter separated by voids of 10-50Å, as shown in Fig. 10a. Not surprisingly, the PtSi microstructure that yields the

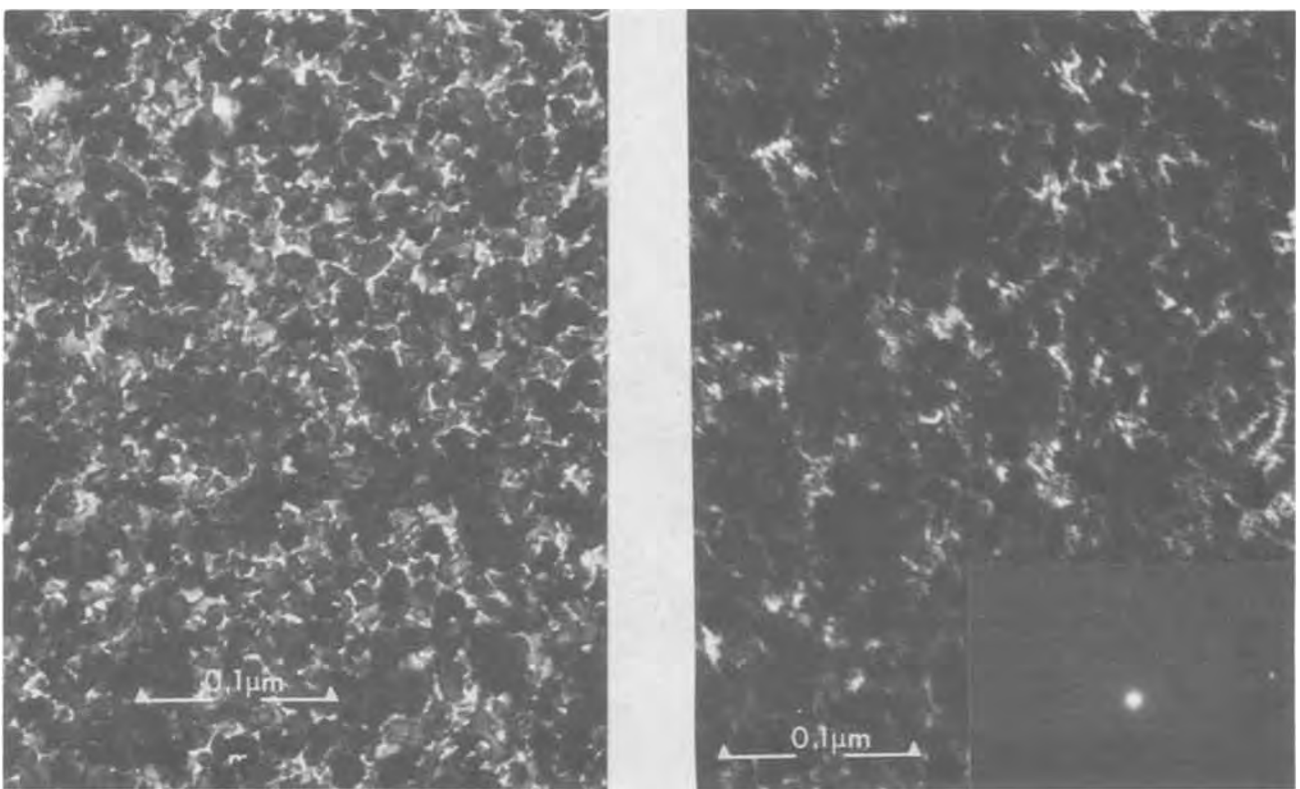

Fig. 10. Unreacted Si between PtSi nodules. (a, above left) Bright-field micrograph. (b, above right) Companion dark-field micrograph taken by use of a Si (400) reflection.

best electrical base contacts also gives the best emitters. Type A PtSi, therefore, appears to be the best from a pragmatic as well as an esthetic point of view.

Relationship of microstructure to deposition conditions.—We have found that the best PtSi films could be formed most consistently by sputter depositing at elevated substrate temperature (~450°C) after *in situ* sputter cleaning. Heat-treating *in situ*, but after rather than during the deposition, produced microstructurally and electrically better contacts than heat-treating externally in a flowing dry N_2 furnace, even with the furnace 100°C higher in temperature. Both methods, however, are inferior to *in situ* heating during deposition.

Chemical cleaning plus *in situ* sputter cleaning also gave consistently better results than chemical cleaning alone. No direct comparison of *in situ* sputter-etched sputter-deposited PtSi and *in situ* sputter-etched, e-beam-evaporated films was made, but sputter depositing should be better, if only because it covers the perimeters of the contact holes better. Perimeter coverage is an extremely important factor when the PtSi is used on lightly doped n-type Si to form a rectifying (Schottky) contact, in which edge effects play a dominant role in reverse-bias operation.

Conclusions

A number of conclusions can be drawn from this study:

1. A direct relationship has been established between the microstructural and the electrical properties of PtSi thin films. We are now able to predict with certainty, by only a microstructural examination, when a PtSi contact will be electrically acceptable. Conversely, we have related unsatisfactory electrical performance to specific microstructures ,which are in turn related to certain deposition conditions; this finding makes it possible to adjust microstructures on the production line on the basis of electrical data.

2. A direct relationship has been established between PtSi deposition parameters and microstructural properties (and hence electrical properties). The best PtSi films, microstructurally and electrically, are formed by sputter depositing Pt while continuously forming PtSi *in situ* at approximately 450°C on Si that has been rf sputter cleaned *in situ*.

3. Sputter cleaning forms a thin layer of polycrystalline Si and deposits a small amount of unreacted Pt on the surfaces of the Si contacts. Neither effect is detrimental; in fact, the formation of polycrystalline Si may aid in the efficient, uniform formation of PtSi.

4. A PtSi film more than 200-500Å thick has two layers. The layer next to the Si substrate often compares well to the best single-layer PtSi. The top layer, after etching, has been identified as "porous Pt" and is poorer microstructurally than the layer beneath. A porous reaction occurs in intermetallic alloys of a noble metal and a nonnoble metal when the latter is leached from the lattice, leaving the noble metal in a highly disordered state.

5. The microstructure and the electrical sheet resistance of a PtSi thin film are sensitive to the dopant species and surface concentration of the Si on which the film is formed, and to subsequent heat-treatment in the range from 750° to 950°C. For a given heat-treatment, the best microstructures are observed on the lowest doped Si, and the lowest sheet resistances on the highest doped Si. For films formed on Si with any dopant species and surface concentration, sheet resistance decreases in the 750°-850°C range, but increases at 950°C because discontinuous clusters of large PtSi grains form and any stoichiometric heteroepitaxial PtSi is completely destroyed.

An ESCA Study of the Oxide at the Si-SiO_2 Interface

R. A. Clarke,[1] R. L. Tapping[2], M. A. Hopper,[*,3] and L. Young[*]

Department of Electrical Engineering and Department of Chemistry, The University of British Columbia, Vancouver, British Columbia, Canada

ABSTRACT

Thermally grown oxide films on silicon were investigated using ESCA (electron spectroscopy for chemical analysis). Evidence was obtained which confirmed previous indications from other techniques that there is a transition layer of about 15 or 20Å thickness next to the silicon. In this layer the oxide changes from SiO close to the silicon to SiO_2 in the rest of the film.

The silicon/silicon oxide interface has a part in controlling the rate of thermal oxidation of silicon (1). Conversely, the atomic arrangement at this interface (which is important in determining several electrical properties of MOS systems) is itself affected by the variables of the oxidation process (2). The aim of the present work was to see what information could be obtained about the composition of the oxide near the interface with ESCA. Using this method, the shift of the 2p electron levels in silicon atoms, due to changes in the chemical environment of silicon atoms in oxide of different oxygen content, was observed. Confirmation of previous evidence from various techniques [including helium ion backscattering (3), secondary ion spectroscopy (4, 5), and optical reflectance (6, 7)] was obtained showing that there is a silicon-rich layer near the interface.

Experimental Procedures

The x-ray source of the Varian IEE-16 photoelectron spectrometer produces $h\nu = 1254$ eV photons. Absorption of a photon raises an electron from the 2p level of the silicon. Neglecting any loss of energy in escaping from the material, the kinetic energy E_k of the freed electron would be $E_k = h\nu - E_b$ where E_b is the difference in energy between the vacuum level and the 2p level. Electrons thus released will not be collected by the detector if the potential difference across the intervening vacuum is of appropriate sign and slightly greater than E_k/e (where e = magnitude of charge on electron). For this condition to exist, the observable difference in Fermi levels between the two electrodes and their work functions is related by $(E_F{}^d + \phi^d) - (E_F{}^s + \phi^s) = E_k$, where d refers to the detector and s to the specimen. Consequently

$$E_b = h\nu - (\phi^d - \phi^s) - eV$$

where V is the applied voltage (sample positive). Rather than estimate the work function difference, the energy calibration of the electron spectra was accomplished by taking the binding energy of some other known observable level. Either a film of gold was deposited on the sample and the higher energy Au 4f level was taken as 87.5 eV or the 2p line of the bulk silicon was used as a reference. The latter can, of course, be used only if the oxide is not too thick to prevent the escape of electrons from the substrate. Located with respect to the above gold standard, this level was found to be 99.5 ± 0.3 eV for the n-type 10 ohm-cm material which we used. Different values of the energy of the silicon peak were observed for different doping densities (*e.g.*, 98.9 ± 0.2 eV for degenerate p-type silicon and 99.9 ± 0.2 eV for degenerate n-type silicon). This is expected since the work function of the silicon is, of course, changed by doping. In this work we are interested in shifts of the level due to silicon atoms in the oxide. To circumvent complications due to doping as well as to band-bending, all bulk silicon peaks used as a reference were arbitrarily taken as having an absolute energy of 98.9 eV.

The silicon samples were commercially polished n-type (111)-oriented 10 ohm-cm material. They were cleaned by immersion in 1:1 H_2O_2-H_2SO_4, 4:1:1 H_2O-H_2O_2-HCl, and dilute HF and were oxidized in steam or pure oxygen in a quartz furnace tube.

The thickness of the oxide films was estimated using ellipsometry. For very thin films on silicon, thickness and refractive index differences cannot readily be distinguished using ellipsometry. The thicknesses were calculated using 1.458 for the refractive index of the oxide at 6328Å, which was the value found for thicker "dry" oxides. For very thin films of low oxygen content, and also for "wet" oxides, this index will, of course, be slightly in error.

For the ESCA measurements the oxide was removed from the back surface with HF and silver paste was

used to mount pieces of wafer on the gold-plated brass specimen holders.

Since fluorine is a likely contaminant and would cause a shift in the peaks, a search was made but no detectable signals were found from any of the fluorine orbitals. The pressure in the ESCA system was typically 2×10^{-7} Torr.

Results and Discussion

Spectra from silicon with not too thick an oxide contained two peaks, as illustrated in Fig. 1. The lower energy peak is due to silicon atoms in the substrate. The higher energy peak is due to silicon atoms in the oxide and, as shown in Fig. 1, the energy of this "oxide" peak depends on how the oxide was prepared and on its thickness.

The solid curve in Fig. 1 was obtained with a specimen from which oxide had been removed with HF immediately before insertion in the ESCA system. It is believed to have had about 5Å of oxide giving an unresolved peak at 102 eV. Three features of the ESCA spectra will be discussed. These are (*i*) the ratio P defined as the "oxide" peak height divided by the sum of the "oxide" and "silicon" peak heights, (*ii*) the line width of the "oxide" signal, and (*iii*) the energy shift between the "oxide" and the "substrate" peaks.

By defining the quantity P in terms of peak height rather than peak area it is possible to avoid the problem of deconvolving the rather closely spaced oxide and bulk silicon peaks. While not the ideal approach, this definition allows the general trends to be observed as shown in Fig. 2 where P is plotted as a function of oxide thickness for dry and wet oxides. The so-called escape depth from any material was taken to be that depth at which probability of escape of an excited electron is $1/e$ of its value at the surface (8). In silicon (8) this depth was calculated to be 20 ± 5Å. An analysis of Fig. 2 indicates that the escape depth from the oxide is somewhat greater than this. The figure also shows a significant difference between "wet" and "dry" oxides, presumably due to inclusion of H_2O or OH in the former. This difference merely implies less silicon in a thin film containing water than in one not containing water but of equal thickness as determined by ellipsometry assuming the same refractive index.

Figure 3 shows spectra of three films: (*i*) 16Å dry oxide, (*ii*) 16Å grown in O_2 bubbled through water at 95°C, and (*iii*) 29Å grown in steam. All gave the same P. Clearly the line width is larger when there is more water in the oxidation ambient. The increased width, however, is insufficient to account for the extra silicon required to provide an oxide of 29Å.

Figure 4 shows the energy of the oxide peak as a function of film thickness for films grown in dry oxygen at different temperatures. Also shown are data for films etched back in buffered HF to the thickness show from an initial 150Å (produced at 900°C). The figure shows data referred to the substrate silicon peak and also data referred to the gold level. In both cases, the oxide peak shifts with increasing thickness in the direction which, as shown below, corresponds to a change from SiO to SiO_2. Because of the limited escape depth of electrons, the ESCA technique samples only the outer part of the thicker films. However, the etch-back data show that these thicker films have an SiO-like layer near the silicon, similar in composition to the initial thin layers.

To calibrate the shift of position of the ESCA "oxide" peak as a function of composition, measurements were made on powdered fused silicon dioxide and on pow-

dered Linde Corporation "silicon monoxide." It is, of course, well known that SiO is not a stoichiometrically well-defined compound. As a further complication, our ESCA studies showed that our samples of the Linde product contained a small amount of elemental silicon. The spectra of SiO_2 and "SiO" powders are shown in Fig. 5. The order of line positions is reversed from that reported by previous authors (9). However, the theory developed later shows that the order observed by us is to be expected.

One source of error in ESCA measurements is the build-up of charge on insulating samples. Some tests were made to see if charging was occurring. A technique (10) was used in which a gold layer evaporated onto both the powder and the supporting metal block. Charging, if it occurs, is indicated by an asymmetry of the gold line. No charging was observed with the "SiO" or with the oxide-coated silicon wafers. About 0.8V of charging was observed with the SiO_2 powder. The difference between the gold-referenced data and the silicon-referenced data in Fig. 4 are believed due to band-bending effects rather than to charging.

A theoretical treatment is now given which allows the observed differences in energy and line width between the ESCA peaks for "SiO" and SiO_2 to be accounted for, and which, in fact, allows predictions to be made of these quantities for oxide of arbitrary composition, SiO_x. The theory is based on an analysis of the structure of the amorphous forms of SiO_x due to Philipp (6). He noted that the tetrahedral configuration of oxygen around the silicon atoms in SiO_2 is

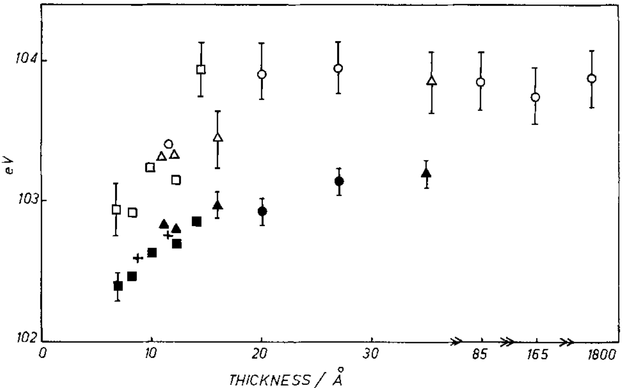

Fig. 4. "Oxide" peak energy as function of oxide film thickness. Open symbols, referred to gold peak; solid symbols, referred to substrate peak. □ and ■ grown at 600°C; △ and ▲ grown at 750°C; ○ and ● grown at 900°C; + etched back from films greater than 150Å thickness.

maintained in SiO_x except that some silicons replace oxygen, the average tetrahedron containing not four oxygens but $(4 - y)$ oxygens and y silicons (with a relation implied between x and y). Any given individual tetrahedron must be one of five kinds (*i.e.*, with $y = 0, 1, 2, 3$, or 4). The proportions of each of the five kinds are shown in Table I for different values of x in SiO_x. Considering only nearest-neighbor interaction, the chemical shift in the 2p level of a given silicon atom will depend on which of the five types of tetrahedron it has around it. It should be understood that the observed peaks represent a superposition of contributions from individual atoms, but that these contributions produce a single peak; the spectrometer does not resolve separate peaks from atoms in each type of tetrahedral coordination. The greater line width found in Fig. 5 with SiO as compared to SiO_2 is, for example, explained in that, in the former, all 5 tetrahedra are present, whereas only one type is present in SiO_2. Also, the shift for SiO will be expected to be less than of SiO_2, as we observed.

From the above theory it should be clear that homogeneous materials of formula SiO_x can be simulated, for the purposes of ESCA, by making heterogeneous mixtures of SiO_2 and "SiO" and hence varying the relative concentrations of each type of tetrahedron so as to produce an averaged peak corresponding to that given by any required homogeneous oxide with $1 < x < 2$.

Figure 6(a) and 6(b) shows the energy and width of the composite line observed with mixtures of various mole fraction χ of Linde "SiO." These confirm the direction of shift in peak energy and line width seen with the separate powders. The lines labeled "theory" in Fig. 6 were calculated for hypothetical SiO_x with x corresponding to a homogeneous oxide of the same over-all composition as our mixtures of "SiO" and SiO_2 The separation between "SiO" and SiO_2 was taken as 1.5 eV and the observed line widths for the separate powders were used together with the proportions of the types of tetrahedra from Table I.

Agreement between theory and experiment in Fig. 6 is substantially improved if the presence of elemental silicon in the Linde "SiO" is taken into account. Based on the height ratio of the two peaks in the "SiO" spectra of Fig. 5, it can be shown that the true values of χ_{SiO} for the mixture are ~20% lower than the values shown. With this correction, for instance, the mole fraction at which equal oxide signal magnitude are obtained from each component of the mixture is seen to be χ ~0.67 both experimentally and theoretically. It should be noted that this is greater than the value of 0.5 that might have been expected for such a condition if one assumed the "SiO" structure contained only a single tetrahedral form as is the case with SiO_2.

Oxide-coated wafers with graded oxide composition would give a line corresponding to some average composition of SiO_x where the averaging process would involve the escape depth. It can be inferred, therefore, from Fig. 4 that the outer 50Å of silicon oxide layers on silicon approaches SiO_2 in composition only for oxide thickness >50Å. The continuing presence at all thicknesses of a thin (15-20Å) transition layer at the oxide-silicon interface of "average" composition SiO

would account for energy shifts in the oxide peaks observed for oxides <50Å.

Conclusions

ESCA studies of the 2p electron spectral line of silicon atoms in thermally grown silicon oxides showed that the width and energy of this line varies with oxide thickness and oxidation ambient. For oxides less than 40Å in thickness, the width of the line increased and the binding energy decreased with decreasing film thickness and with increasing water vapor content in the oxidizing ambient. No effect was found of oxidation temperature and oxide thickness before etchback. Comparison between thermal oxide data and data obtained with mixtures of "SiO" and SiO_2 shows that the oxide at the interface of the Si-SiO_2 structure has the form SiO_x with x increasing from 1 to 2 with increasing distance from the silicon surface up to about 20Å. The transition region is thicker for the steam grown oxides but is of more uncertain Si:O ratio because of the probable presence in the oxide of OH or H_2O. The shifts in the peaks for oxides of different compositions were discussed using Phillip's model for the structure of oxides of the form SiO_x.

Formation and Properties of Porous Silicon and Its Application

Y. Watanabe, Y. Arita, T. Yokoyama, and Y. Igarashi

Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

ABSTRACT

Preparation, properties, and applications of porous silicon film were investigated. Silicon single crystal is converted into porous silicon film by anodization in concentrated hydrofluoric acid at currents below the critical current density. When an n-type silicon was anodized, the silicon surface was illuminated to generate holes which were necessary for this anodic reaction. The growth rate of the film, from n-type silicon, was larger than that from p-type silicon in this experimental condition. The crystalline structure was the same as that of silicon single crystal. A new isolation technique for bipolar integrated circuits was proposed by making use of the properties of the film such that it can be formed several microns thick and oxidized easily to form an insulator. The main feature of the technique is that it provides a means to form thick insulating film inlaid through the n-type epitaxial layer without prolonged heat-treatment. A preliminary experiment was carried out to test the practical usage of the technique.

With the increasing usage of silicon integrated circuits, their fabrication techniques have developed remarkably. However, many problems are left for each fabrication process. Improvement of the isolation process for bipolar integrated circuits is one of the most important and difficult problems. The conventional diffusion method for isolation has various parasitic effects. In addition, the spreading of the isolation region due to sideways diffusion limits the integration density.

Recently, many new structures for isolation have been proposed. Some of them have been considerably successful in avoiding the above mentioned effects. One typical example is the isoplanar technique, in which passive oxide layers are substituted for the usual diffused layers. In this partial oxidation method, however, prolonged heat-treatment is necessary to form thick silicon dioxide films. In the bipolar integrated circuits, the intense heat-treatment has serious problems. For example, when a buried collector exists, the additional diffusion of the buried impurities toward the surface may affect the breakdown characteristics of the fabricated devices.

The authors have also been investigating the isolation technique in silicon integrated circuits and have found a new technique (1) called the IPOS technique. IPOS is an abbreviation of insulation by oxidized porous silicon. The IPOS technique is roughly divided into two processes. The first one is a selective anodization of a silicon epitaxial wafer in hydrofluoric acid. The parts of silicon, where isolation layers are to be formed, are converted into porous silicon, which seems to be the same as the thick anode film reported by Turner and others (2, 3). The other process is a subsequent heat-treatment in oxidizing atmosphere. The porous silicon film can easily be oxidized to a thick insulating film because of its porosity and active nature. Through these processes, isolated islands of silicon single crystal, similar to those of the isoplanar technique, can be formed without long heat-treatment.

There are also two approaches in applying IPOS to the isolation of bipolar integrated circuits, namely n-type method and p-type method. They are shown in Fig. 1. In the former method, the n-type epitaxial layer is directly converted into porous silicon film under illumination. In the latter method, the film is anodized after acceptor diffusion is carried out, as in the usual diffusion isolation. Since the p-type silicon is anodized at lower forming voltage than n-type silicon, only the diffused p-type regions are converted without mask and illumination.

Key words: silicon, IC, porous, anodize, isolation.

This paper describes preparation, properties of the porous silicon film, and isolation process of the n-type method.

Experimental

Preparations and properties of porous silicon films.—Porous silicon films were prepared by anodization of the silicon single crystals in 48% concentrated hydrofluoric acid under constant current densities. The cathode was the platinum.

Since positive holes are necessary for the reaction to occur (2), hole generation was induced by xenon lamp illumination to anodize n-type silicon. The light intensities were 10 ~ 60 mW/cm^2. P-type silicon was anodized without illumination.

At first the growth rates of the porous silicon films were measured with respect to both p-type and n-type silicons. Next, measurements of apparent specific gravities by volumes and weights, observations of film structure by scanning electron microscope, and weight change measurements in an oxidizing atmosphere were performed.

Preparation of samples for testing isolation characteristics.—The structures of the sample is shown in Fig. 2. N on P silicon epitaxial wafers were used. The thicknesses of the n-type epitaxial layers and p-type substrates were, respectively, 2 ~ 4μ and 200μ, and the

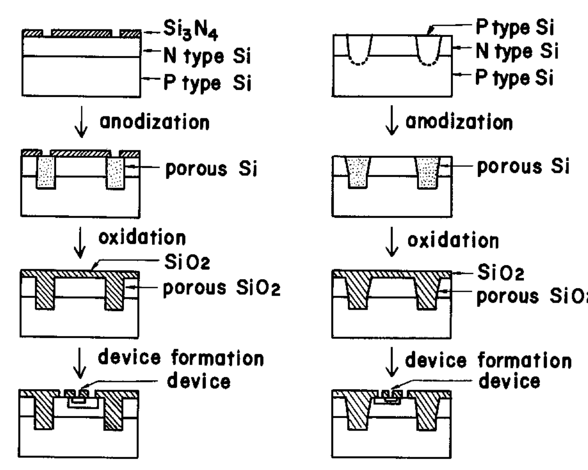

Fig. 1. Two IPOS processes

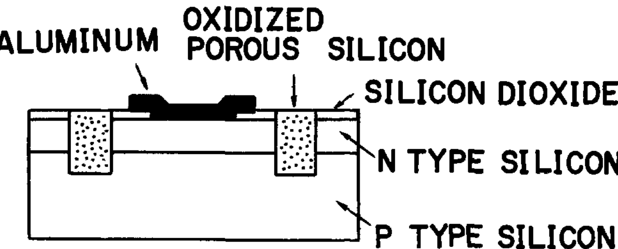

Fig. 2. Structure of the sample for measuring isolation characteristics.

resistivities of the former and the latter were 0.3 ohm-cm and 0.3 ~ 30 ohm-cm, respectively.

For selective formations of porous silicon films to make isolated islands, silicon nitride films were used as hydrofluoric acid-proof mask patterns. The 1500Å thick nitride films were deposited on the wafers by the vapor phase reaction of silane and ammonium, and then were partially removed by the usual photolithographic etch process. On anodization, the silicon portions, where the nitride films had been removed, were converted into porous silicon films.

In order to obtain films of uniform thickness, aluminum films were formed on the back of the wafers by vacuum evaporation to act as equipotential low resistivity contact layers. Moreover, acid-proof wax was coated over the aluminum films to prevent current flow from the films to hydrofluoric acid.

After anodization, wax, aluminum films, and nitride films were removed. The wafers were washed in hot phosphoric acid and boiled in water to improve the film properties. Subsequently, they were heated in a wet oxygen atmosphere to convert the porous silicon films into insulators. Heating was done for 30 min at 1100°C.

The above processes form islands of n-type epitaxial silicon, isolated from each other by the oxidized porous silicon and p-n junctions. Conventional silicon planar technology may then be applied to fabricate the integrated circuits. In this experiment, a metallization process was followed to make ohmic contact directly to the island for testing the isolation properties by the n-type method.

Electrical characteristics measurements.—To investigate the isolation characteristics of the samples, leakage currents and capacitances were measured. As the isolation characteristics in this case are reduced to those of the reverse biased mesa diodes, their d-c leakage currents and capacitances were measured. The frequency used for measuring the capacitances was 1 MHz. All measurements were made at room temperature.

Results and Discussion

Porous silicon film preparation and properties.—Figure 3 shows the relation between the growth rates and the anodizing current densities. The growth rates for n-type silicon were larger than those for p-type silicon for equal current densities.

Though the growth rates were not proportional to the current densities, the total amount of dissolved silicon was proportional to the total electric charge. On the other hand, the film thickness increased in proportion to the square root of the anodizing time. One of these relations is shown in Fig. 4.

The specific gravity of the porous film depends on the anodizing condition. Figure 5 shows the relation of the specific gravities and the current densities. In the case of p-type silicon, specific gravities decreased with current densities. For n-type silicon, however, maxima appeared at about 40 mA/cm² and they decreased with increasing light intensities.

Pore diameters at the sample surface were smaller than 10Å for both p-type and n-type silicon. Those of the inner part of the film were 10 ~ 10,000Å. A cross-sectional view of porous silicon prepared from n-type

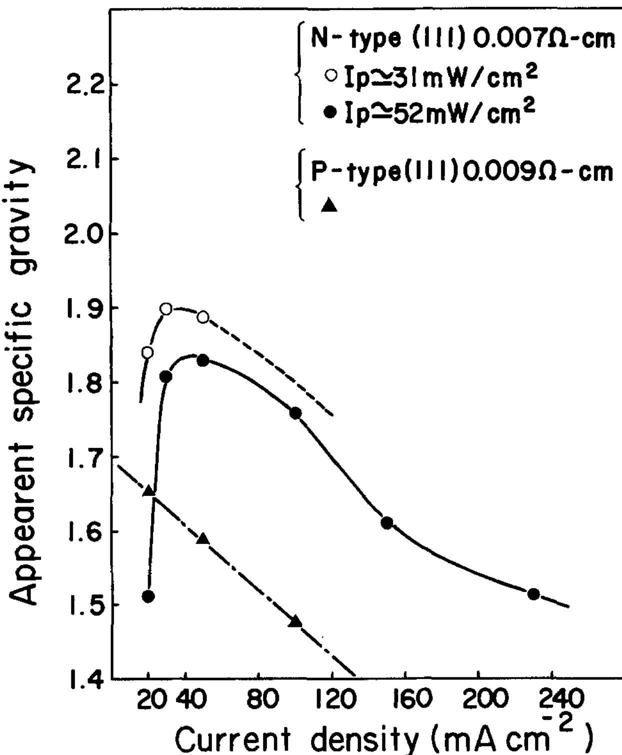

Fig. 5. Relation between apparent specific gravity and anodizing current density of porous silicon film.

silicon with low donor density at small current density is shown in Fig. 6. In this case, the pore diameter was about 1μ. At the surface of the film, however, the pores were very fine.

It is interesting that the crystal structure of the porous silicon was the same as that of the silicon single crystal. This fact was confirmed by x-ray diffraction and electron diffraction. The films are probably a mixture of the unreacted original silicon crystal and the silicon that was the product of the disproportionation reaction of silicon difluoride proposed by Turner (2).

The porous silicon is oxidized very rapidly in oxygen or steam at elevated temperatures. This was confirmed by infrared absorption spectrum and the weight change measurement. Figure 7 shows the relation between weight change of a wafer in which the porous silicon film was formed during oxidation in oxygen at 1000°C and the oxidation time. Most of the weight change occurred in a very short time and, thereafter, no remarkable change was found. This implies that the greater part of silicon in the film was oxidized within a few minutes. There are two reasons why the oxidation velocity is very large. One is the existence of many pores in the film; oxygen and steam can penetrate through the pores. The other is the nature of the film constituents.

Isolation processes.—Figure 8 shows a comparison of the original isolation pattern with the porous silicon pattern. Figure 8(a) is one of the original mask patterns. The width of the isolation zone is 6μ. Figure 8(b) is the porous silicon pattern formed using the above mentioned mask pattern. In this case, the thickness of the film was 6μ. It was observed that sideways spreading of the anodized zone occurred beyond the original zone. The ratio of the spreading width to the thickness of the porous film was about 7:10. This ratio was the same in other anodizing conditions and it is slightly smaller than that of the diffusion isolation.

A cross-sectional view of the isolation region is shown in Fig. 9. In this picture the nail-like line across the n-type layer is the isolation region. When the width of the isolation zone is large, the anodic reaction seems to proceed more rapidly at the edge of the region than at the inner part, due to the current concentration effect.

Current densities suitable for forming proper quality porous films were 200 ~ 400 mA/cm². Proper quality means that the films could be easily oxidized sufficiently deep compared with the thickness of the epi-

taxial layers and have flat surfaces after the oxidation process.

Below 100 mA/cm^2 it was difficult to obtain films that were converted into a high resistivity insulator. This fact is probably in connection with the specific gravities and the pore diameters. On the other hand, at current densities over 500 mA/cm^2 peeling off of the oxidized film occurred and a large surface roughness was observed. In particular, it was marked at the edges of the isolation regions.

Heat-treatment in a wet oxygen atmosphere at 1100°C for 30 min was sufficient to make the porous film prepared at the above mentioned current densities insulating. Under this condition, silicon dioxide film of 0.5μ thick was grown on silicon single crystal. On the other hand, porous silicon films greater than 5μ thick were wholly oxidized as was verified by measurements of leakage currents. There was still slight unevenness at the surface of the oxidized porous silicon. Figure 10 shows a typical example of the surface observed by scanning electron microscopy. The unevenness was also measured by Talystep. It has been confirmed that the interconnecting metallization and photolithographic processes were not affected by this unevenness because their heights were less than 0.5μ and the slopes were gradual. When single crystal silicon is oxidized, the volume of the oxide is about two times that of the original crystal. In the case of the porous film, the ratio of the volume increase is very small because of the porous nature.

Electrical characteristics.—A typical current voltage relation between two islands is shown in Fig. 11. The apparent breakdown voltage was about 210V. This value was larger than that of the diffusion isolation whose breakdown voltage was about 60V, limited by the epitaxial layer resistivity. However, if the isolation process by the IPOS technique were successfully carried out, higher breakdown voltage determined by the resistivity of the substrate of the wafer should be realized. Accordingly, it is considered that the breakdown in this case occurred at the damaged p-n junction parts that were adjacent to the oxidized porous silicon. More detailed leakage current behavior of the same sample is shown in Fig. 12. The current was smaller than 1×10^{-8}A at applied voltages below 100V and increased gradually with increasing voltage. This value is slightly larger than that of diffusion isolation. Most of the leakage current was considered to flow at the same place where breakdown occurred. Leakage of this order does not prevent practical use of IPOS for bipolar integrated circuits. However, in the isolation of the MOS integrated circuits, smaller leakage currents are desired. It is probable that further reduction can be achieved by improving the fabricating processes.

Leakage currents were reduced with the reduction of substrate resistivities. For example, a sample with the substrate resistivity of 0.3 ohm-cm showed an order of 10^{-11}A at 10V.

The relation between capacitances and bias voltages of the sample was measured and the result is shown in Fig. 13. The capacitance was inversely proportional to the cube root of the voltage. This is the same relationship as that of the graded p-n junction. Figure 14 shows the capacitances of two different areas. These

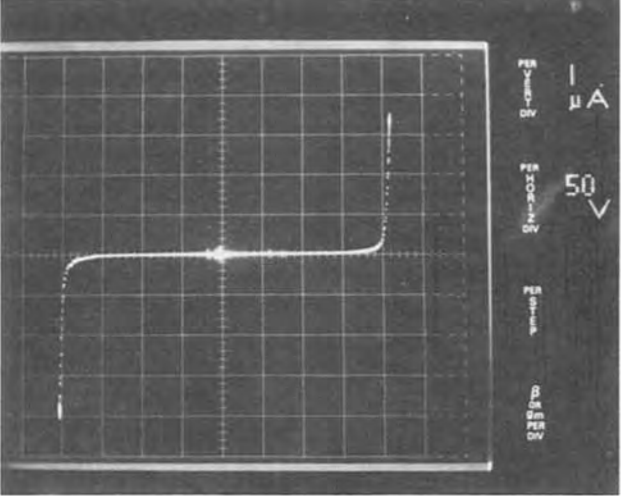

Fig. 11. Current/voltage relation between two islands. Epitaxial layer: 2μ, 0.3 ohm-cm, n-type. Substrate: 200μ, 30 ohm-cm, p-type.

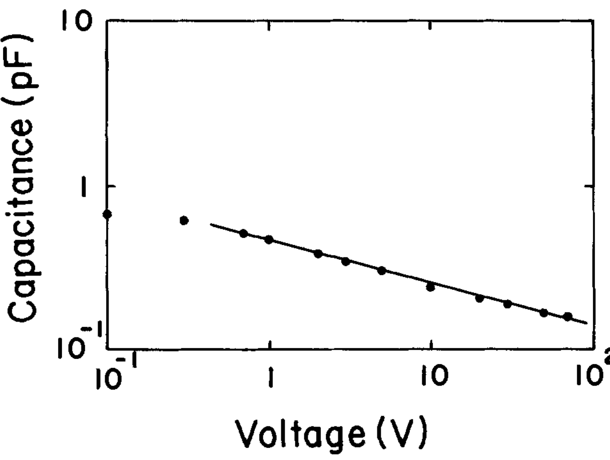

Fig. 13. Capacitance/voltage relation between an island and substrate. Epitaxial layer: 2μ, 0.3 ohm-cm, n-type. Substrate: 200μ, 30 ohm-cm, p-type. Area of island: 10,000μ².

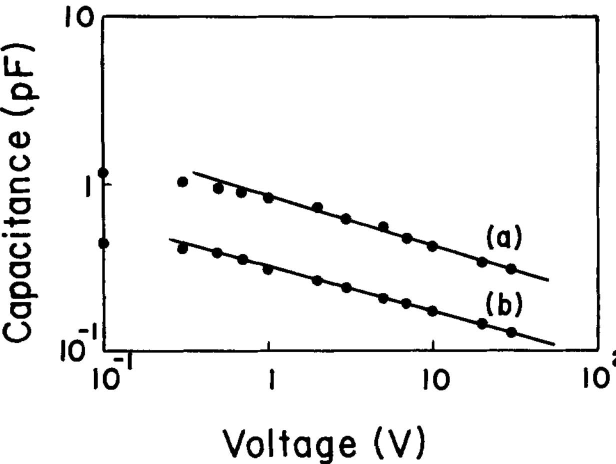

Fig. 14. Capacitance/voltage relations between an island and substrate. Epitaxial layer: 2μ, 0.3 ohm-cm, n-type. Substrate: 200μ, 5 ohm-cm, p-type. Area of islands: (a) 10,000μ², (b) 3600μ².

values agree exactly with the estimated values from the areas of the islands and the substrate resistivities.

From these data, the capacitances of the oxidized porous silicon layers can be considered negligible. It implies that the isolations of small capacitances can be realized using the IPOS technique because the isolation capacitances are only due to the p-n junctions between n-type epitaxial layers and p-type substrates.

As described above, the n-type method IPOS technique can be advantageously applied to bipolar integrated circuits isolation. Though the experimental result concerned only samples whose epitaxial layers were 2μ thick, the same results have also been obtained for those above 4μ thick.

Conclusion

A thick porous silicon film retaining a flat surface was prepared by anodization of silicon single crystal in hydrofluoric acid. The silicon surface was illuminated when the n-type silicon was anodized. The growth rate of the film from n-type silicon was larger than that from p-type silicon. Apparent specific gravity and pore diameter of the film on n-type silicon were affected by the current density and donor density. The crystalline structure of the film was the same as that of silicon single crystal.

The film was oxidized very rapidly in oxidizing atmospheres. A preliminary attempt was made to apply the porous silicon film to bipolar integrated circuits isolation. An oxidation step at 1100°C for 30 min was sufficient to make an insulating film 4μ thick. Small excess leakage current was observed in the sample. Capacitance/voltage relation was similar to that of a graded p-n junction, $C \alpha V^{-1/3}$.

The IPOS technique may be applicable to fabricating not only bipolar integrated circuits, but also MOS integrated circuits. Some problems still remain to be resolved. For example, a lower leakage current is desired for application to MOS devices.

Temperature Dependence of Characteristics of Plastic Film Thermoelectrets

K. Ikezaki, K. Wada, and I. Fujita

Department of Instrumentation, Faculty of Engineering, Keio University, Yokohama, Japan

ABSTRACT

The initial charge and its decay characteristics of Teflon FEP thermoelectrets have been investigated at different polarizing and storage temperatures. The decay of the electrets strongly depends on the polarizing temperature T_p even when they are stored under the same conditions. For low polarizing temperatures, the initial charge is fairly large but it decreases as the polarizing temperature increases. After it reaches a minimum value at $T_p \simeq 100°C$, it increases again with T_p. On the other hand, for low T_p the residual charge which is measured 60 min after polarization, is small in spite of the fairly large initial charge and it increases with T_p. From these experimental results, it is concluded that the polarizing temperature plays an essential role for charge stability in electrets. Observed temperature dependence of the initial charge and its decay characteristics are discussed briefly.

Recently plastic film thermoelectrets have been investigated owing to the practical interest in the electret microphone (1). For several plastic film electrets, the time variation of the surface charge was studied as a function of the storage temperature for estimating the lifetime of electrets (2).

Usually, most of the values of surface charge densities reported in the literature are order of $10^{-9} \sim 10^{-10}$ coulomb/cm^2. In these electrets with relatively low charge densities, effects of molding and stripping charges also become important (3,4). In these electrets charge reversal often takes place. The effect of storage temperature on the charge reversal was investigated for various electret materials (5, 6). Pillai *et al.* (3,7) investigated the effect of polarizing temperature on initial charge and its decay characteristics for polyvinylchloride and polyvinylacetate electrets. The importance of polarizing temperature and electric field is also pointed out in the thermoelectrets of polyvinylchloride and polymethylmethacrylate (8). Recently, Perlman and Unger (9) studied the polarizing temperature effect on charge trapping in Teflon film electrets with the use of the thermally stimulated current technique (10). They reported that both molecular motion and thermal excitation are important for charge release. With the use of the thermally stimulated current technique, Takamatu and Fukada also studied the polarizing temperature effect (11, 12).

For practical purpose, however, it is desirable to produce electrets having large charge density, and to study forming conditions for good electrets is useful not only for deeper understanding of basic mechanisms of electret phenomena but also for practical application of electrets. To get a practical film electret with large homocharge, several techniques have been developed (2, 13, 14). In the present paper, initial charge and its decay characteristics are studied in thermoelectrets of Teflon FEP film which are polarized at various polarizing temperatures with use of the technique of dielectric insert (14).

Experimental

The electret material used in this investigation is a film of Teflon FEP (copolymer of tetrafluoroethylene and hexafluoropropylene) of 12μ in thickness. A film sample and a disk of soda glass (0.75 mm thick) metallized on one face were placed between brass electrodes of a polarizing holder. As shown in Fig. 1, this glass disk was inserted between the sample and the negative electrode in order to obtain an electret with a large homocharge without arcing during the polarization process (14).

Electrets were obtained as follows: a sample was heated to a polarizing temperature T_p and then a polarizing voltage V_p (800V) was applied across the electrodes. After 10 min under the electric stress at the temperature of T_p, the sample was cooled down to room temperature under the same electric stress. The cooling process took about 40 min. In order to exclude a confusing contribution of unstable charges which stay on the surface of electrets, after polarization all electrets were kept for 5 min between brass electrodes short-circuited, and then the net surface charges were measured by the vibrating electrode method developed by Reedyk and Perlman (15). The decay characteristics of the surface charges for various storage temperatures were observed as a function of storage time t_s by measuring the surface charges of electrets which were stored in free (unshort-circuited) at a temperature of T_s.

Key words: Teflon FEP, polarizing temperature, initial charge, residual charge.

Results

The time variations of the surface charge were investigated for the samples which were polarized at various temperatures. Since the decay of the charge on the anode surface of the sample was almost the same as that of the cathode except for some irregular behavior, the charge on the cathode surface was chiefly investigated.

The net surface charge observed in this study was a homocharge and the charge reversal did not take place.

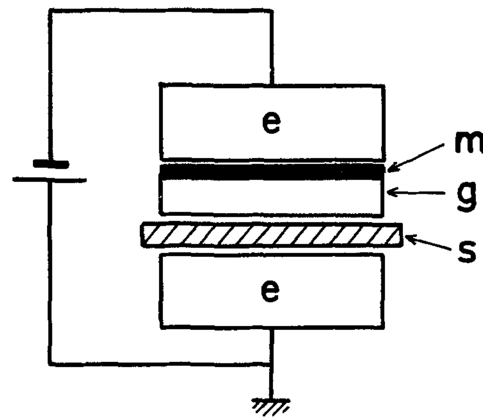

Fig. 1. Electrode assembly. e, Brass electrode; g, glass disk; m, metal layer.

Observed values of the initial surface charge scattered from sample to sample even when the electrets were produced under the same conditions, and the electrets slightly differed in their decay characteristics. Therefore, normalized decay curves were determined from the several measurements as shown in Fig. 2. For various polarizing temperatures, the normalized decay curves are shown in Fig. 3 and 4. As is seen from these figures, the decay characteristics of Teflon FEP electrets are nonexponential and they strongly depend on T_s and T_p. Mean values of the initial charge densities on the anode and cathode surfaces, $\sigma_+(0)$ and $\sigma_-(0)$, and their mean errors are presented in Fig. 5. Their values were determined by taking averages of 12-34 samples which were polarized under the same conditions (12 samples for $T_p = 60°C$, 34 for $T_p = 80°C$, 26 for $T_p = 110°C$, 25 for $T_p = 140°C$, and 14 for $T_p = 180°C$). In Fig. 5, the values of $\sigma_-(60)$ defined as residual charge on the cathode surface after storage of 60 min at T_s, are also plotted against T_p for various storage temperatures. These values of the residual charge were determined from the mean values of $\sigma_-(0)$ and the normalized decay curves.

Discussion

In electrets there are two kinds of surface charge (16), a homocharge and a heterocharge. The heterocharge is due to the volume polarization and it decays more rapidly as compared with the homocharge in many electrets (17). The electrets which are produced with a suitable dielectric insert as in this study, have a large homocharge (2, 13, 14). This homocharge is thought to be due to the discharge in the air gap between the sample and the polarizing electrodes (18-22). The charge produced by this discharge is then trapped by the various trapping sites in the sample. In real electrets there are many kinds of traps. The kinds of traps and the trap densities depend on several factors such as the physical and chemical properties of the material used and the polarizing conditions of electrets. In addition to these facts, in real electrets the heterocharge may be present. Therefore, the decay characteristics of the surface charge become complicated and cannot be expected to obey strictly a simple exponential function. In many electrets, however, the decay form is found to be quasiexponential: After decay has taken place for some time, the subsequent decay can be expressed by a simple exponential curve (17).

For our Teflon FEP electrets, it is found from Fig. 2-4, that the decay curves of the surface charge consist of two components: an initial fast decay component and the subsequent, slow and somewhat exponential component. Similar decay curves have been reported in the electrets with high homocharge (2, 13). As is

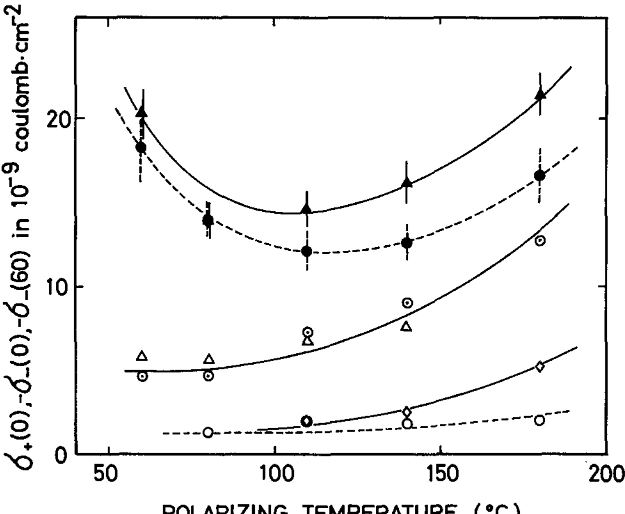

Fig. 5. Effect of polarizing temperature on the initial and residual surface charge densities of Teflon FEP thermoelectets. ●, σ_+ (0); ▲, σ_- (0); △, σ_- (60) at $T_s = 80°C$; ⊙, σ_- (60) at $T_s = 100°C$; ◇, σ_- (60) at $T_s = 120°C$; ○, σ_- (60) at $T_s = 150°C$; where, σ_+ (0) and σ_- (0) are initial charge densities on the anode and the cathode surfaces, respectively, and σ_- (60) is residual charge density on the cathode surface which is measured after storage of 60 min at various storage temperatures.

seen from Fig. 2-4, relative values of these components vary depending on T_s and T_p. In general, the fast component is more remarkable in electrets polarized at low T_p and stored at high T_s than in electrets polarized at high T_p and stored at low T_s. This T_p-dependence of the charge trapping was recently investigated by Perlman and Unger (9). They observed that the curves of thermally stimulated currents in electro-electrets of Teflon vary depending on the polarizing temperature and the current spectra shift toward higher temperature with increasing sample temperature during polarization. This peak shift in thermally stimulated current spectra was also observed by Takamatu and Fukada (11, 12). They found that there are two kinds of peaks in thermally stimulated current spectra in polyvinylidenfluoride, polyethylene, and polytetrafluoroethylene thermoelectrets. For one kind of peaks, the peak position does not depend on polarizing temperature and it locates at low temperatures (most of these peaks appear below 0°C). For the other kind of peaks, the peak position is T_p-dependent and peaks appear at the temperature several degrees higher than that of polarizing temperature. From these facts it is suggested that polarizing temperature plays an essential role for charge trapping in electrets.

Figure 5 shows T_p-dependence of the initial charges. It is almost the same on both anode and cathode sides but the surface charge on the cathode side is slightly larger. In Teflon FEP electrets, negative charges seem to be more stable than the positive. The initial charges on both sides have large values for low T_p and they decrease as T_p increases. After the charges have minimum values at $T_p \simeq 100°C$, they increase again with T_p and have large values for high T_p. On the other hand, the residual charge becomes large with increasing T_p.

In our electrets, the homocharge is thought to be produced by the following process (18, 19): Applying a voltage between electrodes increases the field in the air gap. Eventually, this field will exceed the breakdown strength of the air gap and the spray discharge will occur. The homocharge deposition by this spray discharge continues until the surface density of the deposited charge attains a certain threshold value which reduces the field in the gap below breakdown and quenches the discharge. In order to discuss qualitatively the observed T_p-dependent initial charges and their decay characteristics, we make an assumption for simplicity that there are two kinds of charge traps in our electrets, low energy traps and relatively deep traps. Then, a part of the homocharges produced by the spray discharge is held in the two kinds of traps, σ_1 in shallow traps and σ_2 in deep traps. The remainder of the spray charges contributes to a forming current or to an unstable charge σ_0 which stays on the surface of the sample and easily escapes while the electret is kept for 5 min between the electrodes short-circuited or handled prior to measurements. Since the quenching of the discharge in the air gap is determined only by the threshold value of the deposited charge and it does not depend on the kind of traps in which the charge falls, just after polarization the total value of $\sigma_0 + \sigma_1 + \sigma_2$ is thought to be constant and independent of T_p as long as the polarizing voltage remains constant.

Observed T_p-dependent behavior of the electrets is explained as follows on the basis of an idea that the relative values of σ_0, σ_1, and σ_2 vary depending on T_p.

For electrets polarized at low temperatures, the charge trapped in the shallow traps predominantly contributes to the initial charge. Therefore, at high storage temperature the detrapping rate from the shallow traps is large and the surface charge rapidly decreases in the initial part of the decay. In this case the residual charges are small in spite of the large initial charge.

For electrets polarized at high temperatures, emission probability from the shallow traps increases and the equilibrium net trapping rate by the shallow traps decreases. For this reason the unstable charge σ_0 may be large and the initial charge becomes small.

When the polarizing temperature T_p is much higher, the contribution from the charge held in the shallow traps becomes smaller and smaller due to increase of detrapping probability, but the charges released from the shallow traps migrate much more easily at high T_p and are retrapped more easily by the deeper traps. As a result, the charge held in the deep traps contributes much more to the threshold charge density which quenches the spray discharge. Therefore, the initial charge becomes large again and the residual charge also increases with T_p. In this case the initial rapid decay is not observed.

The charge retrapping was reported by Sessler and West (13). From analysis of thermally stimulated currents, they found that charges in polyethyleneterephthalate and Teflon FEP electrets are subjected to considerable retrapping. This charge retrapping is also supported from the following experiment. Two kinds of electrets were polarized under the same V_p and T_p but different polarizing time t_p, 3 hr and 10 min, respectively. Figure 6 shows charge decay curves of these electrets. As is seen from Fig. 6, the initial charge of the electrets polarized with applying V_p for 3 hr is larger than the electrets polarized with applying V_p for 10 min, and these two kinds of electrets show quite different decay characteristics. In the electrets with t_p of 3 hr, no initial rapid decay is observed and the residual charge is larger. As the polarizing time increases, emitted charges from the shallow traps have much more chance to be retrapped by the deeper traps, so that the unstable component σ_0 decreases and the ratio of σ_2 to σ_1 becomes large even when the values of V_p and T_p are kept constant. This results in a larger initial charge and no initial rapid decay, as is found for the electrets with a long t_p in Fig. 6.

Although the detailed natures of the two kinds of traps are not clear at this stage, the charge σ_1 may be loosely bound on the surface of an electret and decay chiefly by surface recombination. On the other hand, it is found from Fig. 5 that, when T_s is 120° or 150°C, the values of the residual charges decrease abruptly in comparison with the cases of T_s = 80° and 100°C. This suggests that the deep traps may be associated with the motion of the main chain of Teflon FEP because the glass transition temperature of the film is about 130°C (23).

Summary

The observed results are summarized as follows.

1. The initial charge density and its decay charac-

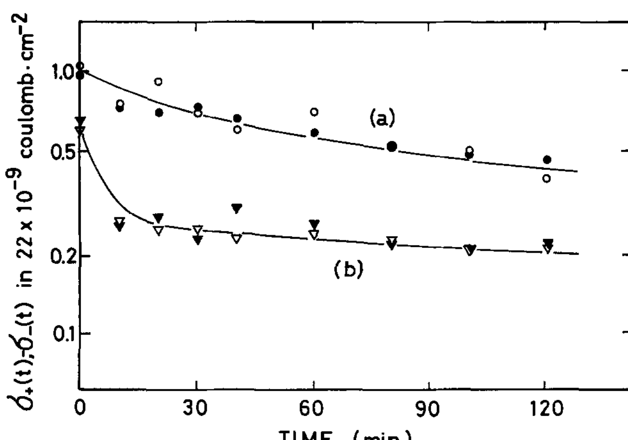

Fig. 6. Effect of polarizing time on charge decay of Teflon FEP thermoelectrets (average over 3 electrets). The storage temperature T_s is 100°C. Curve (a), t_p = 3 hr, T_p = 75°C, V_p = 800V. Curve (b), t_p = 10 min, T_p = 75°C, V_p = 800V. ○, ▽, Surface charge densities on the anode surface. ●, ▼, Surface charge densities on the cathode surface.

teristics of Teflon FEP thermoelectrets strongly depend not only on the storage temperature but also on the polarizing temperature.

2. The decay curves of the electrets are nonexponential and they consist of two components, a fast decay component and a slow component.

3. For electrets polarized at relatively low T_p, the fast decay component becomes remarkable. In this case the surface charge is predominantly held in shallow traps and the residual charge density is small in spite of its large initial charge density.

4. As the polarizing temperature increases, the initial charge density decreases and it has a minimum value when the polarizing temperature is around 100°C.

5. For electrets polarized at T_p higher than about 100°C, the relative amount of the charge trapped by deep traps becomes large, and both initial and final charges increase with T_p.

6. To get a stable electret, the polarizing temperature should be high enough to produce many deep trapping sites and the polarizing time should be long enough for charge retrapping by deeper traps.

The Formation and Structure of Anodic Films on Beryllium

M. T. Shehata* and Roger Kelly*

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

The present, as well as previous, work on the anodizing of Be confirms that most electrolytes yield films characterized by one or more of being porous, being subject to extensive dissolution, or being crystalline. This includes electrolytes based on the following: aqueous KOH, a CrO_3-HNO_3 mixture, aqueous Na_2CO_3, $(C_2H_5)_2HPO_4$, a $(C_2H_5)_2SO_4$-H_2SO_4 mixture, acetic acid. Significantly different results are obtained with ethylene glycol which is saturated with Na_2HPO_4 or KH_2PO_4 or both Na_2HPO_4 and Na_2SO_4. The films are then nonporous, as shown by scanning electron microscopy. They are formed with negligible dissolution, as follows by implanting the Be with 30-keV Kr^{85} before anodizing and noting the loss of activity during anodizing. They are nominally amorphous, as inferred by reflection electron diffraction, though crystallize to hexagonal BeO at a temperature lying somewhere below 300°C. It will be shown in a subsequent paper that the films formed in an ethylene-glycol-based electrolyte can be quantitatively removed and that Be can therefore be microsectioned.

Anodic films on metals are often classified as porous or nonporous. Nonporous films, which are the more usual, are normally found to form in electrolytes in which the oxide has a low solubility, and to grow until they reach an almost limiting thickness which, for a given time scale, is proportional to the applied potential. They are characterized by a high resistivity and by conduction which is mainly ionic in character. Nonporous films are often amorphous though there are many exceptions, including Sn (1) and Zr (2, 3) in general and Mo (4), Ta (4, 5), Ti (3, 5), U (6), V (4), and W (4) under particular conditions.

On the other hand, electrolytes in which the oxide is somewhat soluble are occasionally found to support the growth of porous films which increase more or less indefinitely in thickness while the applied potential varies slightly or not at all. They are characterized by a low resistivity. Though normally described as "crystalline," they are variously amorphous [Al anodized at room temperature (5)] or crystalline [Be (7, 8), probably Sn (9, 1)].

* Electrochemical Society Active Member.

Key words: beryllium, anodization, thin films, anodic sectioning.

Films formed on Be have invariably been found to show one or more of the characteristics of a porous film. Thus no films at all were obtained with some dilute aqueous electrolytes (7, 8). Those formed with HNO_3, CrO_3, or mixed CrO_3-HNO_3 were crystalline (7, 8) and had thicknesses up to ~400 nm (7) or more (10). Those formed with ammonia in ethylene glycol appeared to have had a low resistivity and to have been subject to dissolution (7, 8), while use of 0.5M Na_2CO_3 resulted in crystalline films (11).

The object of the present work was to attempt to form anodic films on Be which, unlike those of previous work, were simultaneously nonporous, formed with minimal or no dissolution, and nominally amorphous. This goal was achieved, such that films could be formed under conditions when the potential drop across the film was about 19×10^8 V/m and the efficiency at 30V for fixed current was 0.95 ± 0.02. Beryllium can thus be made to anodize in a similar manner as with most other metals (Table I). The formation of such films is in principle of importance in the understanding of anodic oxidation from an electrochemical point of view, but we regard it of greater interest to work on diffusion or on ion-solid collisions. It leads first of all to a microsectioning technique, thence to the possibility of studying diffusion and ion depth distributions in Be (12). It leads secondly to the possibility of studying secondary particle emission from BeO in a manner similar to what was done with Al_2O_3 (13).

Experimental

The specimens used throughout this work were polycrystalline Be foils with dimensions of approximately 25 × 12.5 × 0.25 mm and with purities claimed to be 99.5%. They were obtained from Ventron Corporation (Alpha Products). After an initial polishing with a series of increasingly fine SiC papers, the specimens were given further treatment consisting either of chemical polishing [in 5 weight per cent (w/o) sulfuric acid, 75 w/o phosphoric acid, 7 w/o chromic acid, and 13 w/o water] or else of mechanical polishing using 6 μm and 1 μm diamond paste with kerosene as a lubricant. For experiments where reproducible flat surfaces were required, the specimens were finally anodized and sectioned 5 times. The anodizings were carried out at 50V in ethylene glycol which is saturated in both Na_2HPO_4 and Na_2SO_4 and will be subsequently called "electrolyte A." The sectionings were accomplished by exposing the films to 10% KOH for 1 min (12). Such treatment may be assumed to remove submicroscopic irregularities, though this matter will be investigated explicitly in work now underway.

All anodizings were performed at room temperature (~22°C) using a power supply such that limits to both the current and potential could be preset (Hewlett-Packard Model 6186B). The cathode was made of platinum gauze in the form of a cylinder with an inside diameter of 25 mm. Potentials refer to the total value from anode to cathode rather than to the value across the oxide film. For electrolyte A and a current of 3 mA/cm² these values differ by ~5V (as determined using a Ni wire near the Be as a probe), though with none of the results to follow is this of importance. The anodizings were carried out in unstirred electrolytes and without protection from air, and the electrolytes were therefore discarded after 5 or 6 anodizings or 1 hr, whichever came first.

The extent of metal dissolution during anodizing was determined using a depth-distribution technique due to Giani (1). Kr^{85}, which is beta-active, was implanted in Be at 30 keV to a dose of 2×10^{15} ions/cm², and the activity was noted before and after anodizing. The experimental depth distribution of such an implant is shown in Fig. 1 (12) and enables the retained activity fraction to be expressed as a depth. Such a depth is a lower limit to the metal loss during anodizing the lower-limit aspect entering due to the possibility of film formation by outward migration of Be, thence to a burying of the marker in the manner shown by Pringle (14) for Ta.

Table I. Comparison of fields and efficiencies for anodizing various metals

Metal	Electrolyte	Field to form a 50-V film (10^8 V/m)	Efficiency at constant current of 2 or 3 mA/cm²	Ref.
V	Mainly acetic acid	2.8	0.95	19, 23
Mo	Mainly acetic acid	2.9	0.95	17, 23
Nb	Aqueous	3.4	~1.0[a]	16, 24
Zr	Aqueous	4-6	0.50	25
W	Mainly acetic acid	4.6	0.96	16, 23
Ta	Aqueous	6.2-6.6	0.99	20
Al	Aqueous	8.7-9.1	0.90	20
Be	Electrolyte A	19.0	0.95 ± 0.02	here, Eq. [1]

[a] Not for constant current.

Results

Dilute aqueous electrolytes.—It was concluded by Levin (8) that no film at all is formed on Be in 1% H_2SO_4 or 1% KOH, though 1% HNO_3 led to crystalline BeO if the current density was high enough. Survey experiments undertaken in the course of the present work have largely confirmed these results, except for an indication of film formation with 1% KOH. This follows from the V-t and I-t behavior (Table II).

To provide new information on the use of dilute aqueous electrolytes the depth-distribution technique was applied. Unacceptable extents of metal dissolution during anodizing were revealed (Table II).

CrO_3-HNO_3.—A CrO_3-HNO_3 mixture consisting of 200 g/liter of CrO_3 in 10% HNO_3 is known to yield crystalline films with Be, which grow in thickness linearly with time while the current remains constant (7,8). Anodic films have also been obtained using as electrolyte 20% aqueous CrO_3 (10, 15). The results were interpreted in terms of the initial formation of a nonporous layer of small but constant thickness fol-

lowed by a thick film which could be shown to be porous.

We have undertaken a limited number of additional experiments using the CrO_3-HNO_3 electrolyte of Ref. (7, 8). The *V-t* behavior, as shown in curve A of Fig. 2 and also in Table II, suggests (though does not prove) that thick, porous films are formed. The extent of porosity was investigated explicity by means of scanning electron microscopy. The results, given in Fig. 3 show clearly the porous nature of the films, the scale of the porosity being 100-1000 nm. The extent of metal dissolution during anodizing was determined by the depth-distribution technique and found to be significant (Table II)).

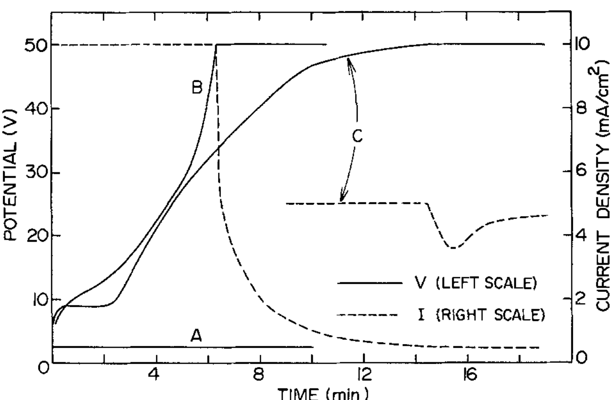

Fig. 2. Typical *V-t* and *I-t* curves for the anodization of Be in CrO_3-HNO_3 (curve A, always 30 mA/cm²), 0.5M Na_2CO_3 (curve B), and $(C_2H_5)_2HPO_4$ (curve C). Solid lines: *V-t*, with potential as in scale at left. Dashed lines: *I-t*, with current as in scale at right.

In conclusion, the anodic films formed on Be with the CrO_3-HNO_3 electrolyte of Ref. (7, 8) have none of the properties which were desired regarding porosity, dissolution, and structure.

Na_2CO_3.—Heusler (11) was able to form films on Be with an electrolyte consisting of 0.5*M* Na_2CO_3. The films were crystalline, could be formed up to a thickness of ~250 nm (at 200V), and were accompanied by oxygen evolution.

We have sought to obtain additional information on the use of 0.5*M* Na_2CO_3. The *V-t* and *I-t* behavior, as shown in curve B of Fig. 2 and also in Table II, suggests (though does not prove) that nonporous films result. The extent of porosity was again investigated by scanning electron microscopy. The results, given in Fig. 4, show that the films are mainly nonporous, but with evidence for both local and general dissolution. Metal dissolution during anodizing occurred to a significant extent (Table II).

The use of 0.5*M* Na_2CO_3 as the electrolyte for anodizing Be is thus unsatisfactory in the present context for two reasons: the dissolution and the crystallinity. Porosity, on the other hand, is not a problem.

Nonaqueous electrolytes.—An indication that nonaqueous electrolytes may be of interest with Be is found in work by Kerr and Wilman (7). They established, using a 25 g/liter solution of ammonia in ethylene glycol, that 30 nm thick amorphous films could be

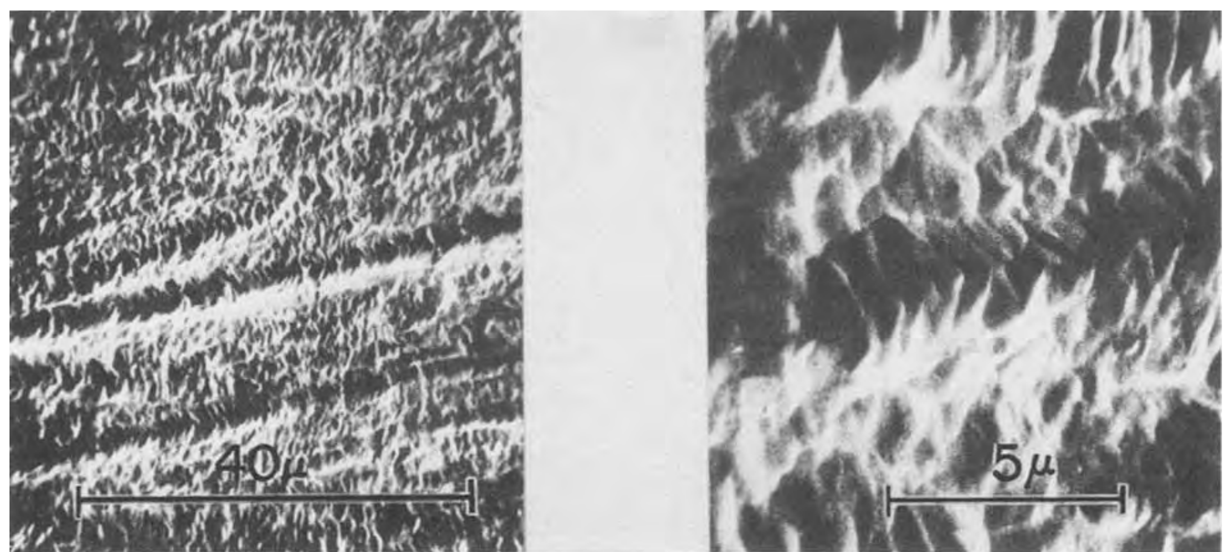

Fig. 3. Scanning electron micrographs with different magnifications of film formed by anodizing Be in CrO_3-HNO_3 for 2 min at 30 mA/cm². The films are markedly porous, the scale of the porosity being 100-1000 nm.

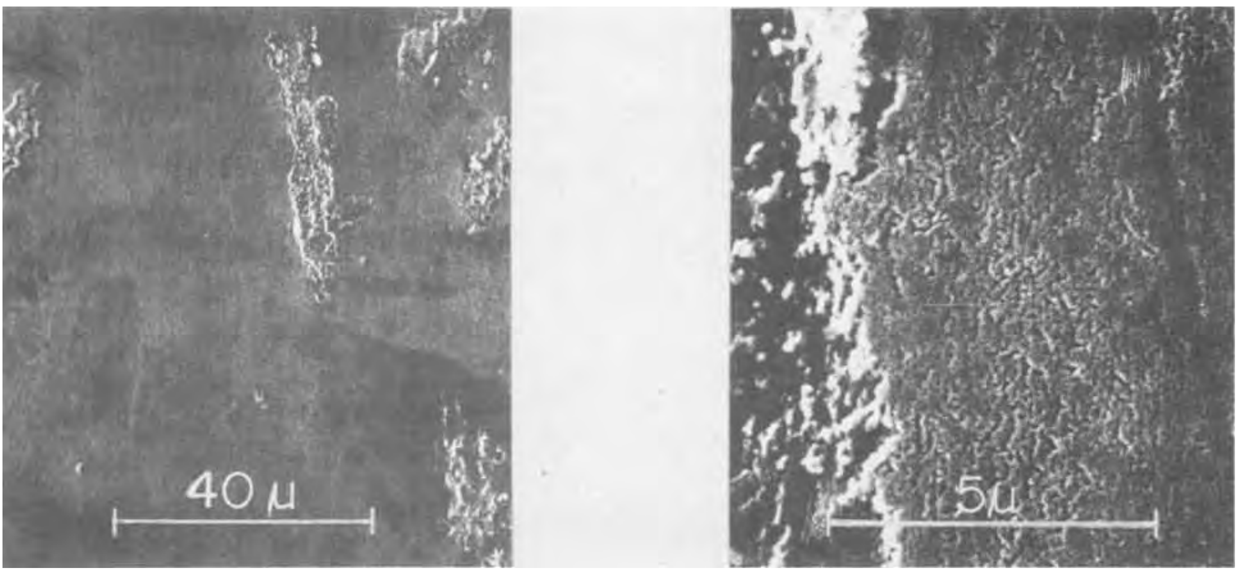

Fig. 4. Scanning electron micrographs with different magnifications of film formed by anodizing Be in 0.5M Na_2CO_3 for 15 min with a preset current of 10 mA/cm^2 and a preset potential of 50V. The films are mainly nonporous, though show features suggestive of both local and general dissolution.

formed. Unfortunately, the current remained roughly constant, as if the films were not insulating or alternatively were dissolving.

In the present work we have investigated nonaqueous electrolytes of four types.

(i) $(C_2H_5)_2HPO_4$. Anodizing Be in diethyl phosphate results in a V-t curve suggestive of a nonporous film but an I-t curve leading to the converse conclusion (curve C of Fig. 2 and also Table II). To gain further information, the extent of metal dissolution during anodizing was determined and found to be unacceptably high (Table II).

(ii) $(C_2H_5)_2SO_4$-H_2SO_4. A mixture of 75% $(C_2H_5)_2SO_4$ and 25% H_2SO_4 has been successfully used in the anodic sectioning of Nb and Ta (16). Anodizing Be in this electrolyte results in V-t and I-t curves of nonideal type (Table II). The electrolyte is implied by this to be unsatisfactory, and this conclusion was confirmed by finding similar metal dissolution to occur during anodizing as with diethyl phosphate (Table II).

(iii) Acetic acid. An acetic-acid based electrolyte, consisting of acetic acid, $Na_2B_4O_7 \cdot 10H_2O$, and water, is one of the few which permits Mo (17) and V (18.19) to be anodized. Its use with Be appeared at first sight encouraging in view of the V-t and I-t behavior (Table II); however, unacceptable metal dissolution occurs (Table II).

(iv) Ethylene glycol. More satisfactory results were obtained with ethylene glycol which has been saturated with certain salts. As seen in Fig. 5, the choice of Na_2CO_3 (curve A) or Na_2SO_4 (curve B) as the salt is unsatisfactory owing to the low value of dV/dt, whence an implied low efficiency. The choice of Na_2HPO_4 (curve C) or KH_2PO_4 or both Na_2HPO_4 and Na_2SO_4 (curve D and also Table II), however, results in V-t and I-t curves similar to those found when nonporous films are formed on Nb, Ta, V, or W (16, 19). We will subsequently refer to the electrolyte consisting of ethylene glycol saturated with both Na_2HPO_4 and Na_2SO_4 as "electrolyte A".

Anodizing efficiency with electrolyte A.—Experiments of two kinds were done to determine the anodizing efficiency with electrolyte A. First of all, Be thicknesses inferred by integrating I-t curves with expanded time scales, such as those shown in curves A and B of Fig. 6, were compared with true Be thicknesses obtained gravimetrically by stripping the films in 10%

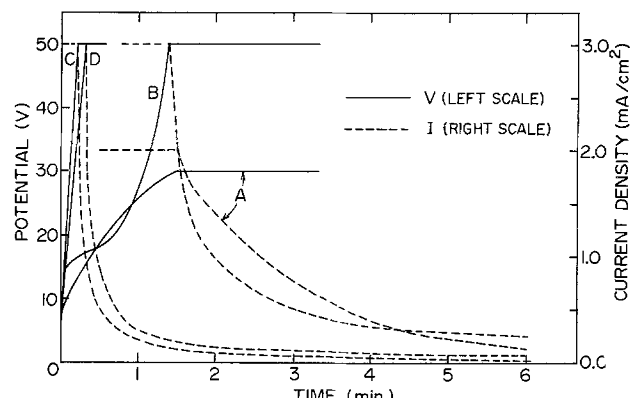

Fig. 5. Typical V-t and I-t curves for the anodizing of Be in ethylene-glycol-based electrolytes. Curve A: ethylene glycol saturated with Na_2CO_3 (abnormally low dV/dt). Curve B: ethylene glycol saturated with Na_2SO_4 (abnormally low dv/dt). Curve C: ethylene glycol saturated with Na_2HPO_4 (no anomalies). Curve D: ethylene glycol saturated with both Na_2HPO_4 and Na_2SO_4 (electrolyte A, no anomalies). Solid lines: V-t, with potential as in scale at left. Dashed lines: I-t, with current as in scale at right.

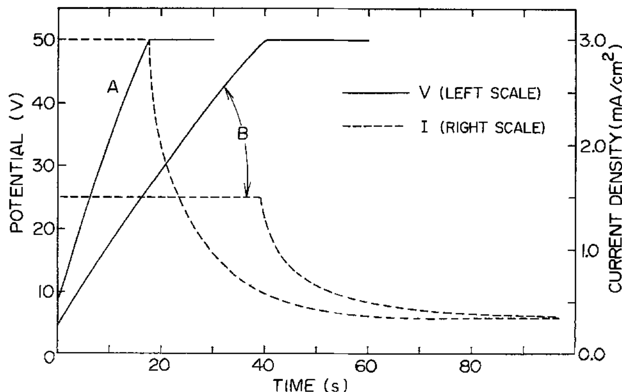

Fig. 6. Like curve D of Fig. 5 but plotted with an expanded time scale. An appropriate analysis of such curves is shown to yield the anodizing efficiency for conditions both of constant current and of constant current followed by constant potential.

Table III. Anodizing efficiency for Be using electrolyte A

Preset potential (V)	Anodizing time (sec)	Charge passed[a] (C/m^2)	Be thickness from Faraday's law[b] ($\mu g/cm^2$ of Be)	True Be thickness from Eq. [1] ($\mu g/cm^2$ of Be)	Anodizing efficiency
25	55	454 ± 10	2.12 ± 0.05	1.50 ± 0.08	0.71 ± 0.04
50	65	920 ± 30	4.29 ± 0.14	2.90 ± 0.15	0.68 ± 0.04

[a] Given by the total area under *I-t* curves as in Fig. 6 for an initial current density of 3.0 mA/cm^2. Repeated 3 times for each present potential.
[b] Calculated assuming an efficiency of 1.00.

KOH for 1 min. The true thicknesses are shown elsewhere (12) to be given by the relation

$$\text{thickness} \approx 0.1 + (0.056 \pm 0.003) \times V\ \mu g/cm^2 \text{ of Be} \quad [1]$$

which is valid provided the preset current is 3 mA/cm^2 and the current is allowed to drop, following the attainment of the preset potential, for 45 sec. The results, summarized in Table III, indicate an efficiency of ~0.7, valid for conditions of fixed current followed by fixed potential.

The dependence of dV/dt on the total current I can be used to estimate the efficiency under conditions of fixed current. The basic relation, which remains valid even if (as in the present work) the IR drop in the electrolyte is not corrected for, is

$$\frac{dV}{dt} \propto i_1 = k(I - i_2 - i_3) \quad [2]$$

where i_1 is the ionic current, i_2 is the electronic current (which usually causes oxygen evolution), and i_3 is the current leading to film dissolution (20). Accordingly, a second group of experiments was carried out. The primary data were as in Fig. 6, and from these plots of dV/dt at 30V *vs.* I as in Fig. 7 were constructed. The intercept with the current axis represents the nonionic current density, namely

$$i_2 + i_3 = 0.15 \pm 0.05\ mA/cm^2 \quad \text{(at 30V)}$$

when I is 3 mA/cm^2. The efficiency follows as 0.95 $\pm$ 0.02 and is thus markedly greater for fixed current than for fixed current plus potential. This result is understandable if it is remembered that the contribution of $i_2 + i_3$ will depend on the total anodizing time (19) and the times were ~15 sec at fixed current but 65 sec at fixed current plus potential.

A slight curvature in the rising portions of the curves in Fig. 6 will be noted. We have not studied this effect in detail and therefore cannot say whether it is due to a change (with V or t) of the field in the anodic film or of the efficiency. The discrepancy between $i_2 + i_3$ = 0.15 mA/cm^2 and the leakage current in Fig. 6, 0.35 mA/cm^2, becomes less for longer times.

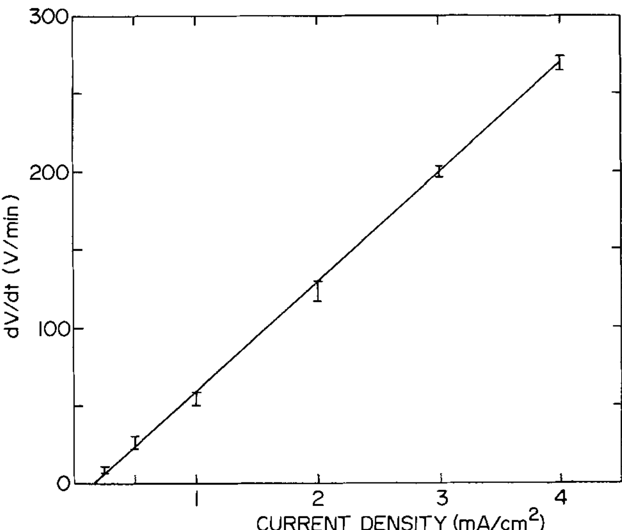

Fig. 7. *dV/dt* **at 30V** *vs. I* **for the anodization of Be in electrolyte A. Given that** *dV/dt* **is proportional to the ionic current as in Eq. [2], these curves serve to separate the total current of 3 mA/cm^2 into an ionic part of 2.85 $\pm$ 0.05 mA/cm^2 and a nonionic part of 0.15 $\pm$ 0.05 mA/cm^2.**

Porosity, dissolution, and crystallinity with electrolyte A.—Figure 8 shows scanning electron micrographs obtained for a film formed on Be and electrolyte A. Comparison with Fig. 3 and 4 suggests a significant freedom from porosity.

The depth-distribution technique showed that the metal dissolution during anodizing was essentially zero (Table II). Electrolyte A differs in this respect from all others that were examined. Stated in other terms, the dissolution current, i_3, is evidently less important than the electronic current, i_2, in lowering the anodizing efficiency to ~0.7 for conditions of fixed current plus potential.

Figure 9a shows a reflection electron diffraction pattern typical of a film as formed with electrolyte A.

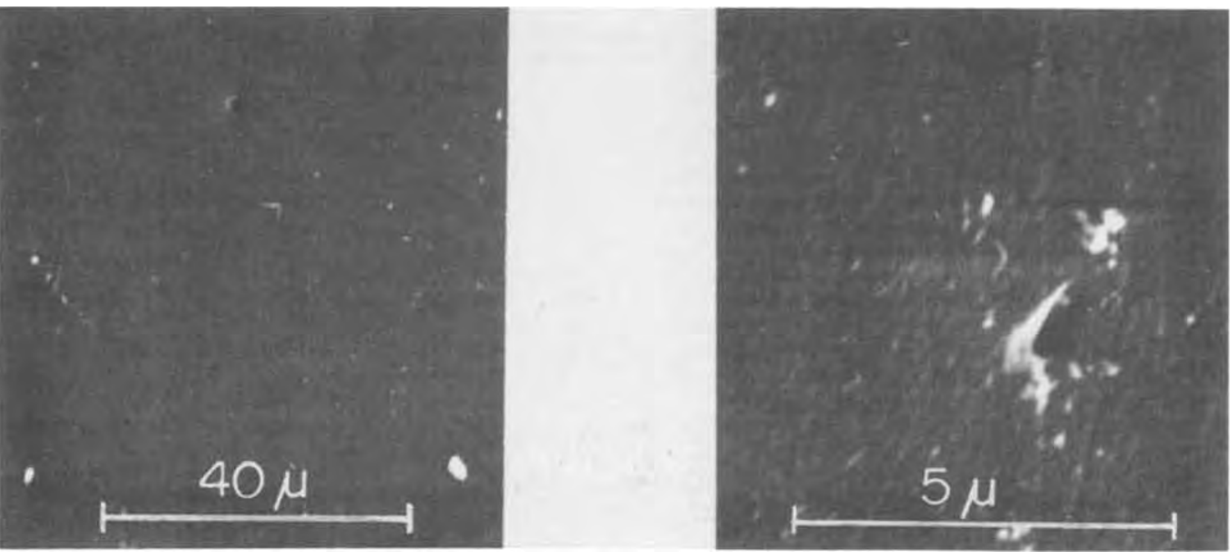

Fig. 8. Scanning electron micrographs with different magnifications of film formed by anodizing Be in electrolyte A for 1.5 min with a preset current of 3 mA/cm^2 and a preset potential of 50V. The films are significantly free from porosity.

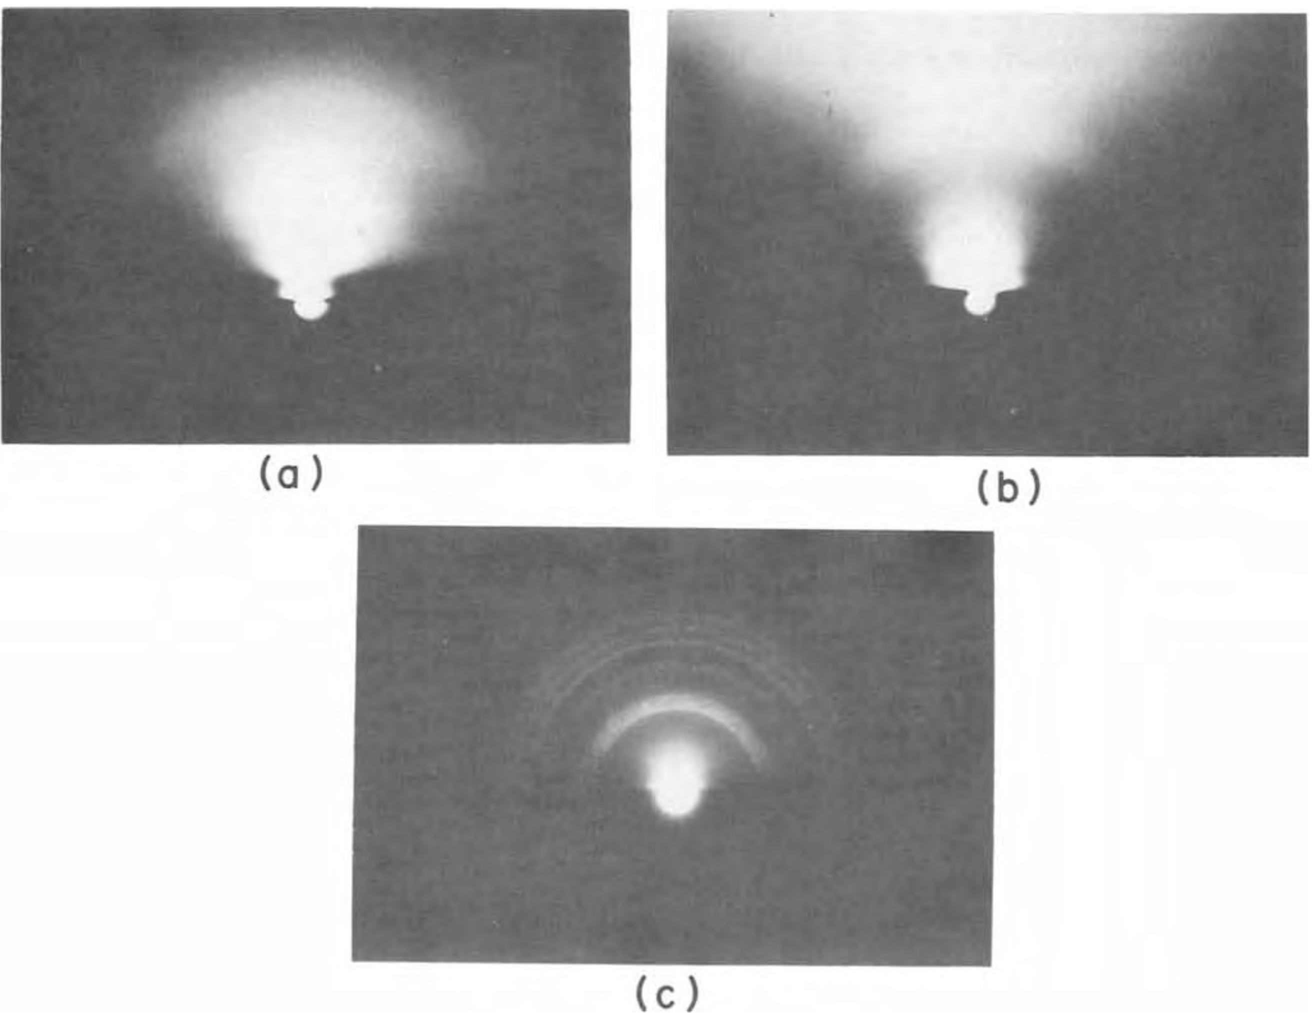

Fig. 9. Reflection electron diffraction patterns taken at 60 or 80 kV of film formed by anodizing Be in electrolyte A for 1.5 min with a preset current of 3 mA/cm^2 and a preset potential of 50V. Image (a): as-formed film, showing halos such as are conventionally ascribed to an amorphous structure though can also arise from microcrystallites having sizes of 1-2 nm. Image (b): film heated for 30 min in a vacuum of 1×10^{-4} Pa at 300°C, showing the halos to have split into diffuse rings. Image (c): film heated for 30 min in vacuum at 600°C, showing sharp rings identifiable as hexagonal BeO.

The film is nominally amorphous. After heating the films for 30 min in a vacuum of about 1×10^{-4} Pa at 300°C (Fig. 9b) or 600°C (Fig. 9c), the diffraction patterns revealed increasing degrees of crystallinity, such that the heating at 600°C led to overt polycrystallinity. The rings were identifiable as those of hexagonal BeO.

Discussion and Conclusions

Type of film.—The results presented here have shown that the behavior of Be with regard to anodizing is much like that of Al (5) and Sn (1. 9). Porosity, dissolution, and crystallinity can be varied almost at will depending on the electrolyte, with over-all results as in Table IV. The most interesting electrolytes would appear to be those consisting of ethylene glycol saturated with Na_2HPO_4 or KH_2PO_4 or both Na_2HPO_4 and Na_2SO_4 (electrolyte A). The V-t and I-t behavior suggested that a voltage-dependent limiting film thickness was obtained (Fig. 5 and 6). The films were found to be nonporous (Fig. 8) and dissolution to be undetectable (Table II). The films were nominally amorphous, with a crystallization temperature lying somewhere below 300°C and with the crystallization product consisting of hexagonal BeO (Fig. 9). Their structure thus more nearly resembled the chemically precipitated BeO studied by Kerr (21) than the anodic films obtained in previous work (7, 8, 11). Anion incorporation in the anodic film from the electrolyte, such as that demonstrated with Ta (16, 22) may or may not have played a role and will be investigated in subsequent work.

Anodizing efficiency.—The anodizing efficiency using electrolyte A was determined in two ways: from Faraday's law and from dV/dt. Use of the former gave a value of ~0.7, valid for conditions of fixed current

Table IV. Summary of Be anodizing

Electrolyte	Film?	Current at fixed potential	Porous?	Dissolution?	Crystallinity
1% H_2SO_4 or 1% HNO_3	No	Constant		Yes	
1% KOH	Yes	Falls slowly		Yes	
CrO_3-HNO_3 mixture	Yes	Constant	Yes	Yes	Crystalline (7)
0.5M Na_2CO_3	Yes	Falls rapidly	No	Yes	Crystalline (11)
$(C_2H_5)_2HPO_4$	Yes	Nearly constant		Yes	
$(C_2H_5)_2SO_4$-H_2SO_4 mixture	Yes	Constant or nearly constant		Yes	
Mainly acetic acid	Yes	Falls rapidly		Yes	
Electrolyte A	Yes	Falls rapidly	No	No	Nominally amorphous

followed by fixed potential. Use of dV/dt gave a value of 0.95 ± 0.02, valid at 30V for fixed current. Efficiencies of less than unity will arise whenever electronic current, i_2, or dissolution current, i_3, play a role. The lack of dissolution (Table II) shows that i_2 is the more important in the present case. We attribute this role of electronic current to the relatively low thicknesses of the anodic films formed on Be (Eq. [1]) such that the resulting fields across the films are higher than with most other metals (Table I).

Anodic sectioning of Be.—The present work constitutes the first instance in which Be has been anodized under controlled conditions, the important feature being the choice of electrolyte. We will in a subsequent paper (12) treat the converse of film formation, namely the quantitative removal of films. This leads first of all to a microsectioning technique, thence to the possibility of studying diffusion and ion depth distributions in Be. We note in this connection that Be is a particularly interesting material for depth-distribution work in view of its low mass. Film removal also has a purely electrochemical interest, in that it leads to explicit information on efficiencies such as that in Table III.

Photoluminescence of Epitaxial ZnSe Layers Grown on Ge

F. Chernow, G. F. Ruse, and G. W. Eldridge

Department of Electrical Engineering, University of Colorado, Boulder, Colorado 80302

ABSTRACT

The epitaxial growth of ZnSe on (100) Ge using the close-spaced transport process is described. Substrate temperature of 575°C and source temperatures of 675°C yield 10μ single-crystal layers in 10 hr. The Ge substrate provides a nonreplenishable, chemical transport agent and the epitaxial layer thickness is limited to approximately 10μ. As-grown epitaxial layers show excellent photoluminescence structure at 77°K. As-grown layers exhibit high resistivity, annealing in Zn vapor at 575°C reduces the resistivity to 10-100 ohm-cm. Zinc vapor annealing quenches the visible photoluminescence.

The literature on the epitaxy of ZnSe on Ge is relatively large. Growth techniques include vacuum deposition (1-3), chemical vapor transport (4), close-space vapor transport (5), and close-space, chemical vapor transport (5). The pair of semiconductors is particularly attractive for electronic applications such as transistors with wide bandgap emitters (6, 7) due to the small lattice mismatch and low concentration of interface states achievable (8). Vacuum-deposited layers exhibit strain and adhesion problems that may make them unacceptable for devices (1, 2). Chemical transport techniques lead to incorporation of substantial halogen concentrations which create donors and comparable densities of deep acceptors (4, 5, 9). The close-spaced growth process using pure H_2 gas and undoped ZnSe sources minimizes doping and compensation in a configuration that is inherently clean and efficient (10).

The present work was motivated by a need to prepare ZnSe substrates suitable for ion-implanted electroluminescent devices. Required characteristics include morphography adequate for ion implantation,

Key words: close-spaced transport.

low doping to minimize the dose required for compensation, and high luminescence efficiency. Layers grown using the close-space technique were examined for morphology and macroscopic uniformity, behavior under Zn vapor annealing, and photoluminescence structure. Photoluminescence measurements provide information on both the defect structure of the ZnSe layer and a suggestion of its electroluminescence potential. Little has been reported on the photoluminescence of ZnSe epitaxial layers and the reported results are somewhat disappointing (4).

Experimental Procedure

Growth system.—The close-space transport system employed in this work is shown in Fig. 1. This configuration is similar to that described by Hovel and Milnes (5). The insert in Fig. 1 shows the actual growth region. The high purity quartz crown establishes the source to substrate separation and aids in controlling the vapor pressure over the substrate. Slots cut in this crown provide access for the flow gas. Several variations in the access area were used, but no dependence of the growth behavior on this area could be determined. The source and substrate are clamped by high purity, low porosity carbon blocks which act as absorbers heated by external 600W tungsten-iodide lamps. These susceptors are supported by high purity quartz tubes. Thermocouples inserted in these tubes are used to monitor the temperatures of the susceptors and control the power to the lamps. Dual, digital, set point indicators, current modulators, and SCR power circuits control the substrate temperature (T_{sub}) and the source-substrate temperature difference (ΔT). Rapid response with little or no overshoot and temperature control of better than 1°C was easily achieved.

A gas flow and mixing system was designed to accommodate HCl chemical transport growth as well as the work described here. It was constructed of Monel, Type 316 stainless steel, and inert plastics. This system

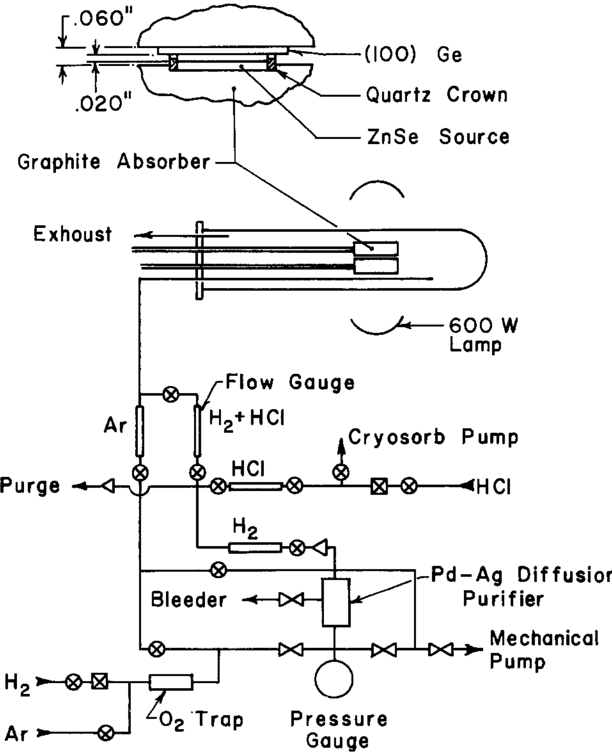

Fig. 1. ZnSe growth system. Graphite absorbers are 1½ in. diam × 7/16 in. thick; Ge substrates are 1/2 in. square, and the ZnSe growth region is 0.34 in. in diameter. Gases are vented through bubblers to prevent back diffusion. For H_2 + HCl growths pure H_2 flows through the Ar flow gauge and a large fraction of the initial H_2 + HCl mixture is dumped at the purge port in order to obtain low HCl concentrations.

was made leak tight to within the 10^{-10} atm-cm^3/sec sensitivity of a helium leak detector. The hydrogen flow gas used during the growths was palladium-diffusion purified. Electronic grade HCl and prepurified argon were employed. Argon was used as a continuous flushing gas when the systems were not in use. (Several glass envelope-susceptor systems were constructed; each system was used exclusively for particular substrate and flow gas combination except where it is noted otherwise.) Systems were open to the atmosphere for source or substrate replacement for a few minutes at most. Prior to growth, the growth region was baked at 350°C in flowing H_2 for a minimum of 1 hr.

Substrate and source preparation.—Substrates were prepared from 2/3 mm thick, (100) oriented germanium wafers. The Ge was nominally undoped (40-100 ohm-cm, p-type). The dependence of epitaxial layer morphography on substrate surface structure was complicated by selective Se etching of the Ge during growth. The best results in terms of ZnSe uniformity and surface morphology were obtained when the substrates were mechanically polished using 1μ Al_2O_3 and then etch polished using concentrated NaOCl on a low nap pad (11). This produces optically flat, scratch-free Ge surfaces. A final etch in dilute I_2-HF to remove 3-5 mils was used to reduce surface damage resulting from the polishing procedure.

Since the close-space transport is very efficient, approximately twenty 10μ thick growths can be made before the source-substrate gap changes appreciably. The work described here is the result of two separate source charges of which each were used twenty times. Sources were prepared from two, separate, high purity, melt grown, ZnSe single crystals purchased from Eagle-Picher Industries. Both crystals had high dark resistivity and both contained numerous grain boundaries. Emission spectroscopy analysis of the as-received crystals revealed an impurity concentration of 540 ppm (500 ppm Si, 20 ppm Fe) in the first crystal and an impurity concentration of 70 ppm (50 ppm Si, 20 ppm Fe) in the second crystal. These emission spectroscopy estimates exclude copper which was measured by atomic absorption at 87 and 0.4 ppm, respectively. The first crystal was ground down to ~50μ grains to form a "crushed-crystal" source. The second crystal was cut and polished to fit the quartz crown to form a "single-crystal" source. Surface damage and contamination were removed by etching in H_2SO_4-$K_2Cr_2O_7$ in the latter case (12). No chemical analysis was performed on the completed sources.

Analysis techniques.—Surface morphography was observed using a 27-1250× microscope with a Nomarski phase-contrast attachment. The front surface of the ZnSe layer was always examined; in some cases the ZnSe layer was removed by etching in 5% bromine in methanol to permit examination of the Ge substrate for etching by Se vapor during growth (5). Samples were cleaved for microscopic examination to determine the thickness of the ZnSe layers. Uniformity of both the growth and substrate etching were also noted. Crystallinity of the ZnSe layers was examined using Laue x-ray reflection and glancing, high energy, electron diffraction techniques. As a consequence of the thin layers ($\leq$10μ) and good lattice match, the x-ray data is dominated by reflections from the substrate.

Several samples were annealed in a Zn vapor atmosphere at 575°C. No attempt was made to protect the Ge substrate from attack by the Zn vapor, and this precluded annealing in liquid Zn (5). The samples were placed in high purity quartz ampuls with a weighed quantity of metallic Zn (99.9995% pure) sufficient to achieve the Zn_l-Zn_g equilibrium at the annealing temperatures while minimizing the quantity of excess, liquid Zn (13, 14). The ampuls were evacuated to 10^{-6} Torr and sealed. Annealing was performed for times between 1 and 36 hr. The ampuls were inserted into a

preheated furnace and quench-cooled upon removal. Annealed samples were examined for cracks and peeling which would indicate stress and adhesion problems. Four terminal resistivity measurements were performed, and the ZnSe layer was etched back in steps and the resistivity measurement repeated to determine the uniformity of the induced conductivity.

Ultraviolet-stimulated luminescence measurements were performed to assess the quality of the ZnSe epitaxial layers. Samples were clamped to a cold finger in an evacuated Dewar and held at liquid nitrogen temperature. Light from a high pressure, 100W mercury lamp was filtered (Corning No. 7-51) to remove visible components and focused on the sample. The spectrum was resolved using a double pass monochromator and detected using a photomultiplier with an S-10 photocathode. None of the spectra were corrected for system response.

Experimental Results

Growth.—T_{sub} and ΔT were varied from 550° to 800°C and 5° to 125°C, respectively, to determine optimum growth conditions. Optimum conditions for this case are defined as best surface morphography, best crystal structure, with acceptable growth rate. The optimum conditions were $T_{sub} = 575°C$, $\Delta T = 100°C$ at a hydrogen flow of 300 cm^3/min.

Ten micron thick films were grown in 10 hr under optimum conditions. Increasing T_{sub} leads to severe pitting of the Ge substrate while almost no pitting was observed under optimum conditions. There is always evidence of Ge etching in the area where the quartz crown makes contact with substrate. At the inside diameter of the crown, erosion reaches depths of a few microns. This erosion decreases continuously toward the outside diameter where isolated, square etch pits are found. No etching is observed outside the crown except in the immediate neighborhood of the slots. Decreasing ΔT increases substrate pitting as well as reducing the growth rate. For $T_{sub} = 575°C$, ΔT must be greater than 50°C for the ZnSe thickness to exceed the erosion depth of the substrate. As T_{sub} is increased, ΔT must also be increased for this condition to be met. Increasing ΔT above 125°C leads to faceting and macroscopic nonuniformity of the layer but HEED and x-ray analysis indicated that all the epitaxially grown films were single crystal.[1] T_{sub} must exceed 500°C to achieve usable growth rates.

It has not been possible to define a ZnSe growth rate for this configuration. Increasing the growth time from 10 to 20 hr does not increase the layer thickness by more than 20%. Similar evidence for saturation of the layer thickness is found when the growth time is reduced. Any conclusions, however, must be qualified due to a ±20% uncertainty in the layer thickness under supposedly identical conditions.

The first series of growths were performed using the crushed crystal source. A Nomarski photograph of the ZnSe layer produced in run No. 12 is shown in Fig. 2a. The source had been used for 54 hr growing time prior to this run without replenishment. Earlier runs show projecting yellow needles as well as the uniform epitaxial layer. The density of dendritic needles decreases continuously to zero over the first 75 hr of source use. There also appears to be some improvement in the uniformity of the continuous layer with each succeeding growth.

Figure 2b is a Nomarski photograph of a ZnSe layer produced using the single-crystal source after 144 hr of prior use. In contrast to the powder source results, dendritic growth appears in only the first epitaxial layer and no further systematic changes occur in the morphography of the epitaxial layers.

[1] Experiments were performed to determine the growth rate for the single crystal to polycrystal transition at the optimum substrate temperature. Addition of 0.6% HCl leads to a growth rate of 30 μ/hr and induces this transition. This agrees with a linear extrapolation of the transition data for ZnSe epitaxy on (100) Ge presented by Calow et al. (2).

Photoluminescence.—Figure 3 shows the visible photoluminescence spectra of a series of ZnSe layers

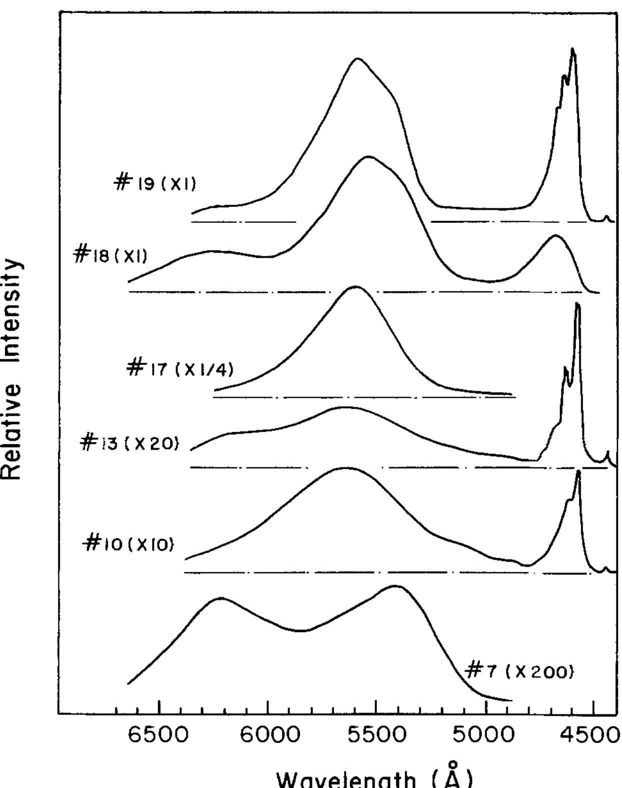

Fig. 3. Luminescence of ZnSe layers grown from a crushed-crystal source. The numbers in parentheses are the scaling factors used to multiply the intensity of the original data in preparing this figure. The relationship between run number and the accumulated hours of source use is No. 7, 20 hr; No. 10, 39 hr; No. 13, 65 ½ hr; No. 17, 107 hr; No. 18, 119 hr; and No. 19, 131 hr. Run No. 17 employed a GaAs substrate.

grown using the crushed-crystal source. The chronological sequence of the growths is indicated by the run number; all of these growths were performed with approximately optimal parameter values. There is also a reduction in dendritic growth in this progression. The dendritic growth was brushed off the sample prior to taking the spectra shown in Fig. 3. Etching to remove any residue of the dendrites did not alter the spectra.

The evolution of the luminescence from layer to layer using the same source is too complex to be described completely by Fig. 3. The epitaxial layers grown when the source is new are of relatively poor quality and the luminescence is characterized by a broad, weak line peaking between 5900 and 6100Å. As the source is used, epitaxial layers exhibit a 5400Å line of increasing intensity followed by the gradual appearance of a line at 6240Å and simultaneous decrease in the intensity of the 6000Å line (No. 7). In turn, the 6240Å line decays and what appears to be an unresolved pair of lines at ~6000 and ~5625Å grows in intensity. Still later growths from the same source result in epitaxial layers that exhibit a reduction in intensity of the 6000Å line with no change in the 5625Å line. Appearance of the blue emission band at 4560-4720Å and the line at 4450Å occurs with extinction of the 6000Å band (No. 10). Continued use of the source leads to epitaxial layers that show increased intensity and better resolution in the blue emission band (No. 13).

Run No. 17 was performed on a GaAs substrate. A 5μ epitaxial ZnSe layer was grown on the (100) GaAs substrate in 10 hr. T_{sub} and ΔT were maintained at 575° and 100°C, respectively. In contrast to normal procedure, neither the growth tube nor the ZnSe source were changed. Figure 3, No. 17 shows substantial intensity enhancement and line width reduction of the 5625Å line. No other lines were observed in the spectrum. Run No. 17 was followed by additional growths on germanium substrates using the same source and growth tube. The 6240Å red band and a structureless blue band reappears in No. 18. Figure 3, No. 19 indicates a return to the spectrum shown in Fig. 3, No. 13. Later runs show that the return to the original spectra is erratic and slower than might appear from the data appearing in Fig. 3, No. 18 and 19.

Figure 4 details the behavior of the blue emission. The phonon-assisted emission series seen in the run No. 13 sample has been identified as resulting from a free to bound transition by Dean and Merz (15). The LO phonon energy implied is 30.5 ± 1 meV in agreement with published results (15, 16). The blue emission band for the run No. 18 sample is typical of ZnSe with high Al and Na concentrations (16). The line at 4450Å is a combination of unresolved I_1, I_2, and I_x lines (17).

ZnSe layers grown from single-crystal sources show similar luminescence spectra with notable exceptions. The structure of the blue emission changes in an erratic manner from growth to growth and never develops the detail observed in the spectra of the epitaxial layers grown from the powdered source. The 4450Å line is observed in all epitaxial layers from the onset of use of the source. Layers grown during the initial runs show the ~5600Å band and blue emission in the 4560-4720Å range is absent. The broad 6000Å emission band may appear alone or with a line at approximately 5400Å. Other epitaxial layers exhibit a 6240Å emission band appearing with a line peaking anywhere between 5600 and 5400Å. The 4560-4720Å blue emission is present only when the 6000Å band is absent. Luminescence intensity in epitaxial layers grown from both sources is comparable.

Although growth of ZnSe epitaxial layers using HCl as a chemical transport agent is not the subject of this paper, some reference to the luminescent spectra obtained is useful. Layers grown using single-crystal sources and less than 0.1% HCl in H_2 show a green emission band centered at 5300Å. At higher HCl concentrations the layers show a broad 6000Å band and the blue emission is either structureless and very weak or absent. The photoluminescence spectra indicate no persistent contamination of the ZnSe source as a result of using HCl. Cutting off the HCl flow yields epi-

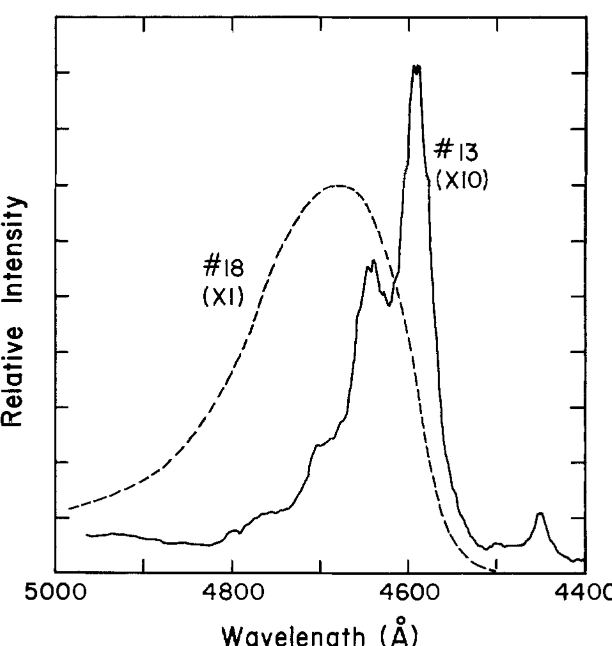

Fig. 4. Detail of blue luminescence of ZnSe layers. The spectra of the layer obtained from run No. 13 is typical of those obtained from runs No. 12 through No. 16. Run No. 18 was preceded by one run on a GaAs substrate. The numbers in parentheses are scaling factors for the data as defined in Fig. 3.

taxial layers showing 6240 and 5400Å emission bands and good blue emission in the following growth.

Sources used in HCl also show ~6200 and ~5400Å emission bands but do not show either intense or highly structured blue emission. Examination in regions with and without exposed grain boundaries shows that most of the emission originates at the grain boundaries. Small shifts in the peak wavelengths and changes of the line width of both the 6200 and 5400Å band demonstrate that the higher intensity observed at grain boundaries is not due to scattering. Unused source wafers do not exhibit uniform luminescence intensity or structure except that blue emission is usually not present. Sources used in H_2 only show a single, weak luminescence band peaking at 5400Å.

Zinc annealing.—All as-grown epitaxial layers exhibit resistivities greater than 10^8 ohm-cm as measured with a four-point probe. Uncertain junction isolation between the n-type epitaxial layer and the p-type substrate sets this value as a lower limit. Annealing in saturated Zn vapor at 575°C for 18 hr reduces the resistivity to 10-100 ohm-cm. Etching studies indicate that the conductivity modification is uniform throughout the epitaxial layer thickness. Similar changes are observed upon annealing ZnSe source crystals under the same conditions. These results are typical of bulk ZnSe (15). In contrast to bulk ZnSe crystals annealed under these conditions, ZnSe epitaxial layers grown on Ge by H_2 transport show no visible photoluminescence at 77°K. Etching experiments demonstrate that this absence persists throughout the layer. Annealing in saturated Zn vapor at 575°C for times such that the resistivity is reduced to the 10^4 ohm-cm range results in a fourfold reduction in luminescence intensity and broadening of the blue emission lines.

It might be hypothesized that photoluminescence is killed by a deep trapping and recombination center. Hovel has reported a Ge-ZnSe heterojunction switching device that depends on the presence of deep traps (18). Measurements on these annealed samples do not show switching behavior strongly suggesting that deep traps are not present.

Annealed samples did not exhibit lifting or cracking. In contrast to other ZnSe-Ge epitaxy studies employing different deposition techniques and/or thickness, this work did not show an adhesion or stress problem that can be revealed by annealing.

Discussion

Approximately 10μ thick ZnSe layers can be grown on (100) Ge using the close-space technique without using a chemical transport agent. Nonlinearity in the growth rate confirms Hovel and Milnes' observation that Ge itself acts as a chemical transport agent (15). Hovel and Milnes also obtained no growth on GaAs (B surface) under conditions similar to those used here; *i.e.*, $T_{sub} = 590°C$, $\Delta T = 110°C$, and 0.02% HCl in H_2. (HCl should increase the growth rate but we have not observed measurable increases at this low concentration.) In contrast, a 5μ thick ZnSe layer was obtained ($T_{sub} = 575°C$, $\Delta T = 100°C$, and pure H_2) on (100) GaAs using a source that had been used for repeated growths on Ge. Although conditions are not identical, the most probable explanation for the discrepancy is persistent Ge contamination of the source powder. Parker *et al.* obtain Ge concentrations of 50-100 ppm in ZnSe epitaxial layers grown by HBr transport on ~500°C Ge substrates (4), and Hovel and Milnes demonstrate that this Ge is provided by Se rather than halogen etching of the substrate (5). It must be concluded that under optimum growth conditions, when there is no visible etching under the ZnSe layer, the $GeSe_x$ concentration is replenished via etching at the quartz crown-substrate interface. Etching in only this region implies very low Zn and ZnSe mobility on the substrate surface and very fast reaction of H_2Se with the exposed Ge. Slightly higher substrate temperature at this interface may also enhance the selectivity of the etching.

Gradual changes in the morphography of layers grown from the crushed-crystal source and absence of similar changes in layers grown from the single-crystal source can be explained by several models. The large surface area of the crushed-crystal source, uncertain thermal contact, and latent heat of vaporization may cooperate to yield supersaturation and dendritic and atypical growth. Morphography improves as smaller grains are consumed or "fused" together to reduce the surface area and improve thermal contact. It is also possible that the ZnSe source surface must equilibrate at nonstoichiometric Zn and Se concentrations in order to achieve stoichiometric deposition. The higher impurity concentration of the crushed-crystal source may have an adverse effect on morphography. Crushing ZnSe also exposes grain boundary surfaces and the impurity concentration on these surfaces is expected to be higher than the bulk. Repeated sublimation from these surfaces may lead to successively purer epitaxial layers.

The photoluminescent spectra of the best epitaxial layers is superior to both that previously reported for epitaxial layers (9, 19) and the source crystals employed in this work. "Superior" in this case refers to the dominance and structural detail achieved in the blue emission region. Blue emission has been identified with Na acceptors (16), but the origin of Na has not been established in this case. Emission spectroscopy reveals no Na in the ZnSe sources and 2 ppm Na in the graphite absorbers. The Ge substates were not analyzed.

The consistent reduction of the long wavelength emission of layers grown from the crushed-crystal source and the erratic behavior of this emission in layers grown from the single-crystal source suggests that with the exception of the 5625Å line these lines are associated with chemical impurities originating preferentially from grain boundaries in the source. An abnormally high concentration of chemical impurities at grain boundaries is expected and examination of the source luminescence confirms a higher concentration of optically active defects at grain boundaries. Crushing the source exposes these high impurity concentration regions so they are sublimed and incorporated in the early grown epitaxial layers. Single-crystal sources release these impurities for incorporation as sublimation and preferential sublimation at grain boundaries exposes impurity pockets. This model requires that these impurities do not both diffuse freely along the grain boundaries and sublime preferentially at the source surface.

Only speculative identifications can be made as to the specific origin of the long wavelength lines. The luminescence band at 6000Å is thought to be equivalent to the self-activated blue luminescence center in ZnS (20). The S-10 photocathode response distorts the luminescence data in this wavelength range. Correction for the S-10 response brings the center wavelength and the linewidth of the 6000Å band into agreement with the self-activated emission band reported by Jones and Woods (21). This center has been suggested to consist of a Zn vacancy associated with a halogen or a Group III donor (22). Appearance of this line in layers grown in high HCl concentrations suggests the halogen donor is responsible.

Cu has been associated with emission bands at approximately 5300 and 6300Å (19, 22-24). Aven and Halstead observed green emission in compensated ZnSe:Cu:Cl and red emission in ZnSe:Cu:Al containing excess Cu (22). Cl does not appear to be optically active in the former case while an optically active Cu-Al complex appears to form in the latter case (22, 25). Similar processes may lead to the 5300Å band in layers grown using low HCl concentration and reappearance of the 6240Å band after contamination of the growth apparatus with Ga (19). Correction for the

S-10 photocathode response bring the center wavelength and the linewidth of the 6240Å band into agreement with the copper-red emission band reported by Jones and Woods (21). The relative behavior of layers grown from the two sources is not consistent with the initial Cu concentrations, however.

Both the 5625Å line in layers grown from the crushed crystal and the 5600-5440Å line in layers grown from the single crystal appear to be the so-called yellow self-activated luminescence (26, 27). Variability in the peak in the latter case is thought to be due to a varying defect concentration.

The ZnSe source material used for this study is similar to that employed by Dean and Merz and by Chatterjee *et al.* in regard to both electrical and photoluminescent behavior (15, 16). Prior to Zn vapor annealing the epitaxial layers also exhibited similar photoluminescent behavior. The initial conductivity of the epitaxial layers and their response to Zn vapor annealing is also similar. Dean and Merz annealed their ZnSe samples in Zn vapor to create or enhance the Q and $Q^{F \to B}$ emission lines (15). This procedure should reduce the Zn vacancy concentration. Chatterjee *et al.* indicate that Na substituting for Zn is responsible for the Q emission series (16). The presence of substitutional Na must be accompanied with a reduction in Zn vacancies if the blue emission is to be enhanced. If not, the deeper Zn vacancies would tend to dominate the photoluminescence and lead to longer wavelength emission. The epitaxial layers show no visible photoluminescence when Zn is vapor annealed to achieve similar electrical properties. This implies either that a killer center involving Ge impurities is formed or that the optically active centers are gettered by the substrate.

Approximately 75 hr of firing the source powder at the growth temperature is an impractical method for stabilizing and purifying the source material. Even this preparation does not achieve surface morphography comparable to that obtained using a single-crystal source. It is possible that prefiring single-crystal sources in liquid zinc would make these sources more uniform and achieve some purification by a solvent extraction process (28).

Some form of chemical analysis of the epitaxial layers would have been helpful in explaining the luminescence data. The luminescence is a complex function of the concentrations of more than one chemical species in general, and these concentrations may lie in the range of 1 ppm or less in ZnSe (27).

Poly(Vinyl Arene Sulfones) as Novel Positive Photoresists

M. J. Bowden and E. A. Chandross

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The synthesis and photosensitivities of a number of copolymers of sulfur dioxide and various arylethylenes are described. Irradiation with ultraviolet light causes chain scission and increases the solubility of these polymers; thus they function as positive photoresists.

All commercial positive photoresists appear to depend on the same photochemical process, *viz.*, the rearrangement and hydration of a quinone diazide to form a carboxylic acid which solubilizes the resist in mild alkali (1). Process operations using these materials have not been entirely satisfactory. The resist solutions are complex mixtures and batch to batch variation in properties can make developing procedures unsatisfactory. Positive resists have limited chem-

Key words: polysulfones, positive resist, photoresist.

ical resistance to etching solutions and are readily soluble in alkaline etchants. Certain difficulties also arise when positive resists are used in conjunction with gallium arsenide substrates since the substrate is attacked by the developing solution, leading to marked undercutting of the resist and attendant loss of resolution.

We have investigated a new type of positive photoresist, analogous to the recently described electron-sensitive olefin-sulfur dioxide copolymers, $\left[-CH_2-\underset{R}{CH}-SO_2-\right]_n$, where R is an alkyl group (2). This group of polymers does not absorb ultraviolet light in a useful region of the spectrum ($\lambda > 250$ nm) and it is not possible to sensitize photodegradation. We thought that polysulfones containing R = aromatic hydrocarbon should show photochemical cleavage of the benzylic carbon-SO_2 bond. Related photochemical reactions are known for cyclic sulfones (3). We have found that the copolymers of arylated olefins, such as styrene, and sulfur dioxide are sensitive to ultraviolet light that is absorbed by the hydrocarbon moiety and that these copolymers function as positive photoresists with useful differential solubility.

Styrene is known to form a 2:1 copolymer with sulfur dioxide under certain conditions (4). We chose this material for our initial studies and found it to be sensitive to ultraviolet light absorbed by the pendant benzene rings (*ca.* 265 nm). The solubility of this polymer is increased by irradiation, indicating that chain scission is the principle mode of degradation as in the electron beam resists; thus it functions as a positive photoresist. The sensitivity is rather low because the absorbance is weak and lies in a region where there is relatively little output from the high pressure mercury arc lamp.

In order to increase the photosensitivity of this type of polymer we replaced some or all of the benzene groups with larger aromatic hydrocarbon systems having greater ultraviolet absorbance at somewhat longer wavelength. The systems studied are summarized in Table I. The sensitivity presumably depends not only on the aforementioned factors but also on the inherent instability of the polymer and the mechanism of photodecomposition.

The most promising member of this class of compounds was a terpolymer based on styrene, acenaphthylene and SO_2, whose sensitivity was about 500 mj cm^{-2} for ultraviolet light in the wavelength region 200-400 nm. This paper reports a more detailed investigation of the properties of this resist.

The photochemical reaction appears to proceed most readily from the excited singlet state as triplet sensitization, *e.g.*, benzophenone was extremely inefficient. This may reflect the energy required to break the carbon-SO_2 bond which is comparable to the triplet energy of the naphthalene group (60 kcal $mole^{-1}$). These polymers decompose at elevated temperatures and the photochemical reaction may be a hot ground state thermal reaction.

The acenaphthylene section of the polymer contains the grouping $-CH-CH-SO_2$ which has the aryl group attached to two atoms of the main chain. We believe that the increased sensitivity of this polymer over the related vinylnaphthalene polymer is due to the strain introduced by the five-membered ring of the acenaphthylene group.

Experimental

Poly(styrene-acenaphthylene sulfone) (PASS).—A solution of acenaphthylene (8.75g, 0.057 mole) in freshly distilled styrene (30g, 0.29 mole) containing azobisisobutyronitrile (0.1g) and dimethylformamide (5 ml) was degassed by several freeze-thaw cycles. Sulfur dioxide (*ca.* 50g, 0.8 mole) was added and the flask was sealed. It was immersed in a water bath at 50°C for 72 hr. The polymer was precipitated by pouring the viscous mixture into a large excess of methanol. It was redissolved in dioxane and reprecipitated into methanol and then dried under vacuum at room temperature.

The elemental analyses of various batches of the polymer are given in Table II. The u.v. absorption spectrum is shown in Fig. 1. Acenaphthene groups in the polymer are responsible for the absorption in the 290 nm region and their concentration can be determined from the u.v. spectrum.

Sensitivity.—The polymers were dissolved in Kodak Photoresist Thinner (methoxyethyl acetate) and films were spun on Si/SiO_2 substrates using a Headway photoresist spinner. Films were baked for 30 min at 200°C. The films were irradiated through a mask with collimated light from a 200W high pressure mercury arc source. The light was filtered through a Corning 7-54 filter which transmits the 220-400 nm region of the spectrum. The intensity, measured with a thermopile, was 20 mW cm^{-2} at the resist surface.

Following exposure, the irradiated areas of the film were spray-developed with a 60 (dioxane)/40 (isopropyl alcohol) mixture. This developer did not attack the remaining film.

Resolution was checked by exposing the resist through a contact mask and developing the image as described. The resist was then postbaked (30 min at 200°C) and the substrate was etched in buffered HF.

Results and Discussion

Polymerization.—Styrene and sulfur dioxide form a 2:1 copolymer under the conditions used in our experiments. The addition of acenaphthylene (AcN) markedly reduces the over-all polymerization rate. Elemental analyses of the terpolymer indicated that acenaphthylene is incorporated into the chain in either $-Sty-AcN-SO_2-$ or $-Sty-Sty-AcN-SO_2-$ sequences interspersed between the $-(Sty)_2-SO_2$ sequences of the normal copolymer. The marked retarda-

* Values shown in parentheses are theoretical values based on assumed composition.

tion of the over-all rate indicates a kinetically unfavorable addition reaction to acenaphylene and of the acenaphthylene radical to SO_2. Thus the reaction must be carried out at moderate temperatures in order to obtain reasonable yields of product. The upper limit will, however, be determined by reversibility of the addition of SO_2 (ceiling temperature considerations) which tends to reduce its incorporation into the polymer. The rate retardation by acenaphthylene also results in a substantial reduction in molecular weight. This, alone, reduces the photosensitivity which is dependent on the rate of separation of molecular weight distributions; this rate is dependent on the initial molecular weight (5).

We found that cationic homopolymerization could sometimes occur readily in these systems but that it could be suppressed by the addition of small amounts of dimethylformamide. The amide was added routinely to avoid this undesired side reaction.

Film properties.—It was observed that, upon spray developing the exposed areas of the substrate, the unexposed areas developed a "frosted" appearance after extended spraying. This was not observed in the exposed areas which developed normally. Microscopic examination of the frosted regions showed that a myriad of semimicro cracks had developed in the film. In several cases, the film had markedly pulled away, exposing large areas of substrate. Some photomicrographs of these regions are shown in Fig. 2. This effect was only observed in films with thickness > 300 nm. At thicknesses ≤ 300 nm, the resists developed normally, leaving the unexposed film completely intact.

Several reasons may be advanced for this phenomenon. It was thought that the effect could be due to residual stress in the film which was not annealed during prebaking (the resists were initially prebaked at 100°C). It is generally considered advisable to prebake above the glass transition temperature in order to remove residual stress from the film. The T_g, as measured by differential thermal analysis, was found to be 186°C. Thermal degradation of the resist did not occur until 275°C. TGA and DTA analysis results are shown in Fig. 3. Some decrease in the tendency of the resist to crack was observed on increasing the prebaking temperature to 200°C but it was never entirely eliminated.

It appears that the reason for cracking of the film lies in the extreme brittleness of the film. It was not even possible to cast a film on mercury for infrared

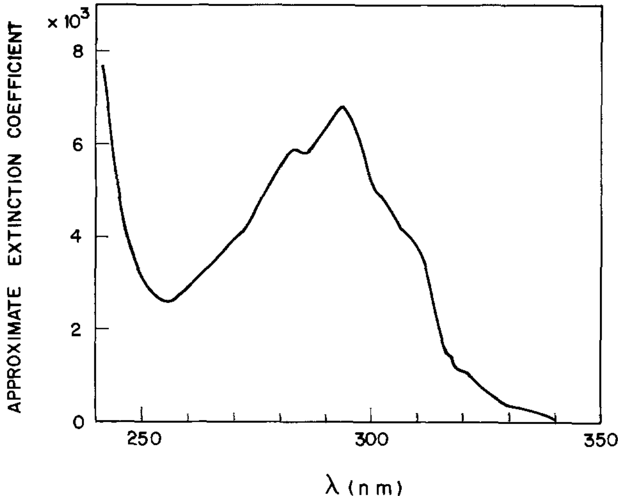

Fig. 1. U.V. absorption spectrum of poly(acenaphthalene styrene) sulfone.

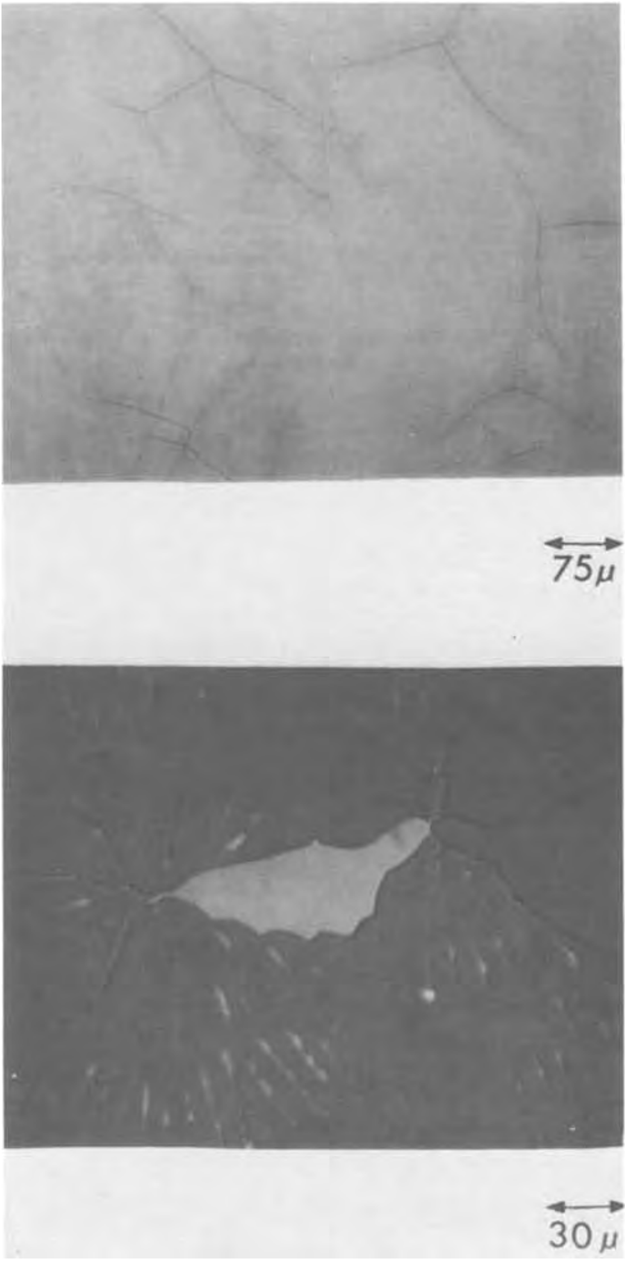

Fig. 2. Micrograph of "frosted" unirradiated regions of developed film showing development of microcracks.

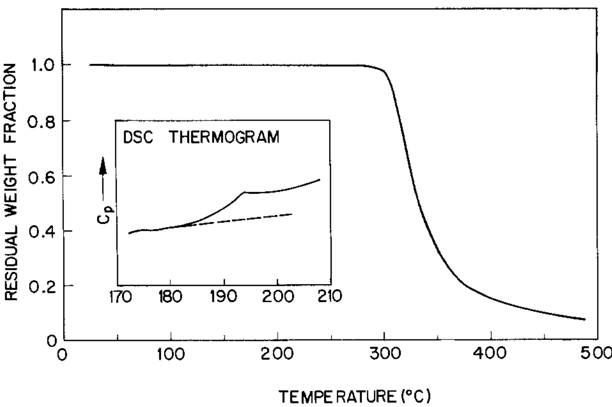

Fig. 3. TGA and DTA curves for PASS

measurement without the film breaking up during the final states of solvent evaporation.

Accordingly, attempts were made to "plasticize" the film by incorporating other groups into the polymer chain. The most practical approach was to attach groups to the *para* position of the polystyrene units in the chain. A typical approach is outlined below

$$\underset{[I]}{CH=CH_2-C_6H_4-CH_2Cl} + RO^-Na^+ \rightarrow \underset{[II]}{CH=CH_2-C_6H_4-CH_2OR} \quad R = C_5H_{11}, C_8H_{17}$$

These films did not crack under prolonged spraying by developing solutions. Unfortunately, the polymer derived underwent cross-linking during u.v. irradiation, presumably through cleavage of the ether bond and cross-linking to another chain.

It may be possible to obviate the cracking problem by increasing the molecular weight of the initial polymer. The addition of acenaphthylene to the mixture of styrene and SO_2 markedly reduces the over-all rate of polymerization and degree of polymerization of the resultant mixture. Reasonable yields of PASS were obtained where the initial mole ratio of styrene to acenaphthylene was 5/1. Acenaphthylene did not form a polysulfone by itself.

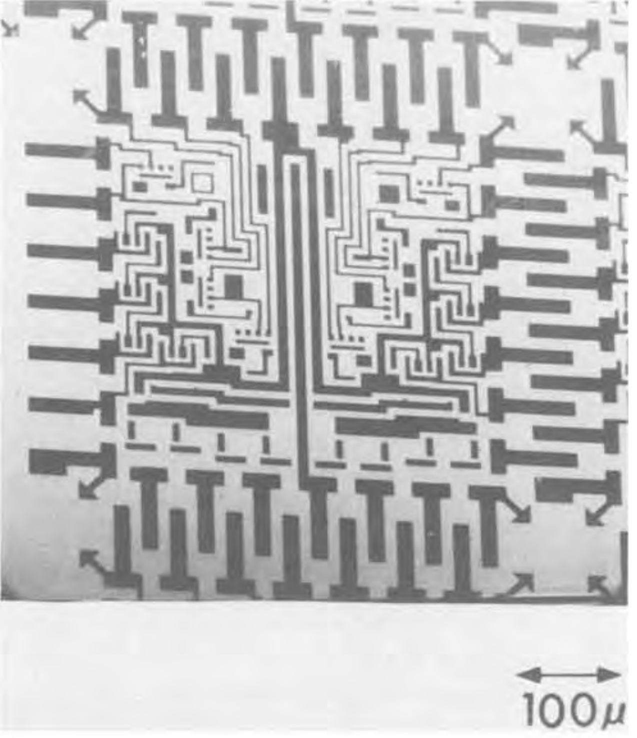
Resist evaluation.—The following results were obtained using sample PASS No. 4 which is a 11/5 copolymer of vinyl aryl groups/SO_2 with two acenaphthalene units per eleven vinyl aryl groups. Evaluation was made on films of 300 nm thickness.

As can be seen in Fig. 1 acenaphthene absorbs strongly at 294 nm with a tail extending out to 330 nm. Exposures were accordingly made through the Corning 7-54 filter which transmits the 220-400 nm region of the spectrum. The sensitivity under these conditions was 500 mJ cm^{-2}. It was found that the sensitivity of the polymer film was unaltered by a 1 mm Pyrex filter (cutoff $\lambda \sim 285$ nm). When the absorption peak of acenaphthene is matched against the ouptut of the Hg lamp, it appears that the photochemical reaction is primarily due to the Hg line at 313 nm. Since more than half of the light passed by the 7-54 filter lies outside the polymer absorption band, the sensitivity at this wavelength is <200 mJ cm^{-2}. This may be compared with a value of ~ 60 mJ cm^{-2} for the AZ positive photoresists (6).

PASS is an excellent etching mask against buffered HF. Some patterns etched in SiO_2 are shown in Fig. 4.

Conclusions

The major drawback to these resists is the region of the spectrum over which they absorb. Admittedly, they are sensitive enough, but they only use a small fraction of the output of the Hg lamp. In addition, one would need to use quartz optical systems for collimating the light, etc. However, for those special situations where current available materials are unsatisfactory, as in the patterning of gallium arsenide, it is felt these resists offer a viable alternative.



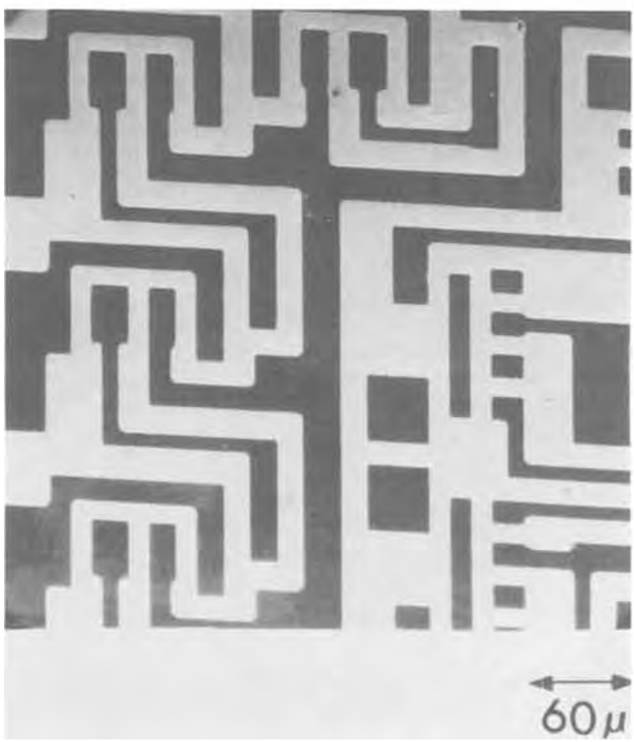


Fig. 4. Micrographs of test patterns etched in SiO_2

It would obviously be desirable to extend the sensitivity into the 365 nm region of the ultraviolet where the lamp output is high and glass optics are usable. Studies directed toward this goal are underway.

Acknowledgments

We thank Mrs. A. H. Schiebel for synthesizing the alkoxystyrene monomers, H. Bair for the DTA measurement, and E. D. Feit for the use of his irradiation apparatus.

Comparison of Group IV and VI Doping by Implantation in GaAs

D. Eirug Davies, J. K. Kennedy, and C. E. Ludington

Air Force Cambridge Research Laboratories, Air Force Systems Command, Bedford, Massachusetts 01730

ABSTRACT

Factor important in attaining higher n-type conductivity on implanting GaAs have been investigated. These are reflected in a comparison of Group IV and VI dopants where the difference in behavior can be ascribed to the different sublattice occupation. The importance of Ga outdiffusion with SiO_2 encapsulated layers is seen on incorporating Ga within the oxide prior to initiating any heat-treatment. For sulfur, the electrical activity is doubled by the presence of the oxide gallium. Such an oxide is detrimental for implanted Si^+ layers and indicates that some Ga outdiffusion is desirable. Presumably the same applies and inadvertently occurs with the traditionally simpler p-type implants. The annealing of S^+ and Se^+ implants with a dose-dependent, optimum annealing temperature differs significantly from Si^+ which requires higher annealing for comparable doping. The advantage gained by implanting Group VI dopants at elevated temperatures is not as pronounced with Si and in this respect Si resembles the p-type dopant Zn which does not exhibit any strong dependence on implantation temperature.

One of the limiting factors in GaAs technology is the difficulty of forming thin, heavily doped n-type regions. In diffusion, problems can arise in working with arsenic overpressures and through many of the dopants reacting chemically with the GaAs wafer surface. When the dopants are introduced by implantation, it is difficult to get a substantial fraction electrically active and uncompensated. Details of early implantation work have been given by Allen (1) while more recent results are summarized by Eisen (2).

Both Group IV and VI elements can be used for n-type doping in GaAs. While Group VI elements are n-type dopants on the As sites, Group IV elements are amphoteric and in contrast exhibit n-type conductivity on the Ga sites. Thus, implanted Group IV and VI ions might be expected to behave somewhat differently and particularly during postimplantation annealing.

An area that has received considerable attention in investigating n-type implants is surface encapsulation. Such a layer is required to prevent thermal erosion that otherwise occurs during annealing. The simplest dielectric to apply is SiO_2 and though it fulfills its initial intent of containing the arsenic, Ga will outdiffuse into the oxide (3). While this Ga loss may be detrimental for Group VI dopants, a certain concentration of Ga vacancies so formed could conceivably benefit Si and other Group IV dopants.

All Group VI dopants exhibit better conductivity when implanted at elevated temperatures, in addition to the usual postimplantation annealing. Foyt *et al.* (4) reported the most efficient Se doping as occurring at the upper end of the room temperature to 500°C range investigated. Better Te doping was obtained by Harris *et al.* (5) when implanting at 150°C rather than at room temperature. For S, an increase in utilization as dopants occurs ~150°C (6), coinciding with the temperature required to avoid lattice disorder (7), and no further improvement occurs at higher temperatures (up to 500°C). As no significant reduction in compensation occurs on implanting hot (6), the inferior room temperature results are attributed to the failure of these ions when so implanted to act as substitutional dopants on the arsenic sublattice. Thus, Group IV elements would not necessarily exhibit the same behavior with regard to implantation temperature in becoming n-type dopants on Ga sites. In this respect, Si or Sn might be expected to follow p-type dopants such as Zn which does not show any great dependence on implantation temperature (8, 9).

Here, S, Se, and Si have been implanted with the intent of comparing and contrasting their annealing behavior. Earlier work on compensation has indicated that even though annealing occurs at 225° and 525°C, this compensation arising from irradiation defects is still only partially recovered at least up to 600°C (10). As a consequence, any n-type doping regardless of the dopant implanted will require annealing to well over 600°C. Annealing temperatures used on this study range from 700° to 900°C. The influence of Ga loss into SiO_2 has been investigated by the use of oxides containing an initial quantity of Ga prior to any outdiffusion. Some implants have also been annealed using Si_3N_4 and AlN instead of SiO_2. Finally, the implantation temperature dependence of Si, taken as representative of the Group IV dopants, is compared to the Group VI dopant behavior.

Key words: GaAs doping, implantation, surface encapsulation.

Experimental

Epitaxial GaAs grown by the hydride vapor phase method has been used in the present work. It is grown 2° off the <100> direction and to a thickness of 1-1½ μm. The doping is held $\lesssim 10^{15}$ cm^{-3} and will have negligible effect compared to the implanted conductivity to be investigated. Any dependence of the implanted electrical activity on the initial material is minimized by confining the work to this epitaxial material which is grown as required under near identical conditions. In contrast, some earlier Si implants into chrome-doped bulk GaAs exhibited carrier concentrations and mobilities that were only around 75% of what is generally attainable with the epitaxial layers.

The SiO_2 used as a surface encapsulant is spun on from an alcohol solution.[1] Following an HF cleaning treatment the oxide is applied and spun at 3000 rpm. The oxide is baked at 180°C and film thicknesses are generally ~1700Å. The gallium-SiO_2 layers are similarly applied using oxides meant primarily to be Ga sources for diffusion into silicon and containing Ga to concentrations of 10^{21} cm^{-3}. The Si_3N_4 and AlN are sputtered on (using targets of the same composition and not reactively). The AlN contains considerable oxide while the Si_3N_4 is relatively pure. Wafer deterioration becomes physically apparent with the oxide encapsulation after heat-treatment to 875°-900°C. Si_3N_4, on the other hand, can withstand temperatures up to at least 925°-950°C.

The encapsulating layers are generally applied prior to implantation and so protect the GaAs during both implantation and postannealing. Most of the S^+ implants to be reported were carried out at 500°C while temperatures within the 200°-300°C range were used for both Se and Si. It should be noted that as there is no advantage in implanting S^+ at 500°C rather than at 200°-300°C (6), the lower temperatures should also be preferred for S^+ (and particularly if implanting prior to applying the surface encapsulant were required).

All the implants have been performed at 1 MeV. Other than one series of S^+ implants at 3×10^{14} cm^{-2} a dose of 10^{14} cm^{-2} has been used throughout. SiH^+ has been implanted instead of Si^+ to avoid contamination from other mass 28 species. Annealing is carried out in a nitrogen ambient for 10 min. For performing Hall measurements tin contacts are alloyed into the implanted layer and no contracting problems are encountered at the dose levels mentioned.

Results

Table I compares the electrical activity resulting from sulfur implants when SiO_2 containing Ga, "pure" SiO_2, and Si_3N_4 are used as the encapsulants. The variation in implantation temperature (170°-360°C) should have minimal effect on the resulting activity. All the samples were implanted to a dose of 10^{14} cm^{-2} and then similarly annealed at 825°C for 10 min. It will be observed that the highest active concentration is given by the Ga-SiO_2 encapsulated layer, indicating that the presence of Ga has a direct bearing on the resulting activity. Si_3N_4, though better than straight SiO_2, does not at present measure up to Ga-SiO_2. Some implants were also undertaken with AlN as the protective layer but the corresponding activity was much lower with only $1\text{-}2 \times 10^{13}$ cm^{-2} becoming electrically active. It should be borne in mind that as no information has been obtained on the relative effectiveness of the encapsulants in retaining the as-implanted distributions, the increase in integrated (sheet) concentrations may also reflect some profile widening.

[1] Commercially available from Emulsitone, Whippany, New Jersey.

Table I. Doping efficiency of 10^{14} S^+ cm^{-2} implants annealed at 825°C with different encapsulants

Encapsulant	$T_{impl.}$ (°C)	R_s (ohm/□)	μ(cm²/V-sec)	N_s(cm^{-2})
Ga-SiO_2	360	51	3100	4.0×10^{13}
	170	57	2750	4.0×10^{13}
Si_3N_4	240	81	3100	2.5×10^{13}
SiO_2	299	99	3150	2.0×10^{13}
	240	127	2050	2.4×10^{13}

The annealing temperature of 825°C used in Table I is near the optimum annealing temperature for 10^{14} cm^{-2} S^+ implants. This can be seen in Fig. 1 where both the sheet carrier concentration and the mobility are shown as a function of annealing temperature. The maximum concentration of 3.6×10^{13} cm^{-2} is lower than the 4×10^{13} cm^{-2} value given in Table I for similarly capped (Ga-SiO_2) implants. The reduction presumably arises from the 500°C implantation temperature used in Fig. 1 and which is marginally close to the onset of a deterioration in activity that occurs on implanting at temperatures $\gtrsim$ 500°C (6).

The improvement in mobility at 750°-800°C despite the accompanying rise in free carrier concentration suggests that considerable defect annealing is occurring. Relocation of S onto substitutional sites alone would lead to increased impurity scattering and a reduction in mobility. The maximum mobility of 3000 indicates a high degree of damage recovery. These mobilities correspond to 10^{18} cm^{-3} doping in bulk GaAs.

It is presumed that the fall off in conductivity that occurs above 825°C is surface related. The activity still attainable at higher temperatures for Si_3N_4 encapsulated Te implants (7) suggests that certain dielectrics may not be as restrictive as SiO_2 in this respect. More clarification is required, however. The same optimum annealing feature is followed at higher doses as can be seen in Fig. 2 for a 3×10^{14} cm^{-2} dose level. At 800°C both the carrier concentration and mobility are close to what was obtained from the 10^{14} cm^{-2} implant with similar annealing. The mobility then falls to reflect the higher active carrier concentration and, despite using similarly applied Ga-SiO_2, the optimum annealing condition of 800°-825°C in Fig. 1 shifts to 850°-875°C.

Similar annealing features are exhibited by Se^+. This is shown in Fig. 3 where Se^+ has been implanted to doses of 10^{14} cm^{-2} at 250°C and annealed with SiO_2 containing Ga. The highest activity occurs at the same annealing temperature seen in Fig. 1 with sulfur. The mobilities are generally lower than those already observed for sulfur and what can be obtained from Si^+ implants.

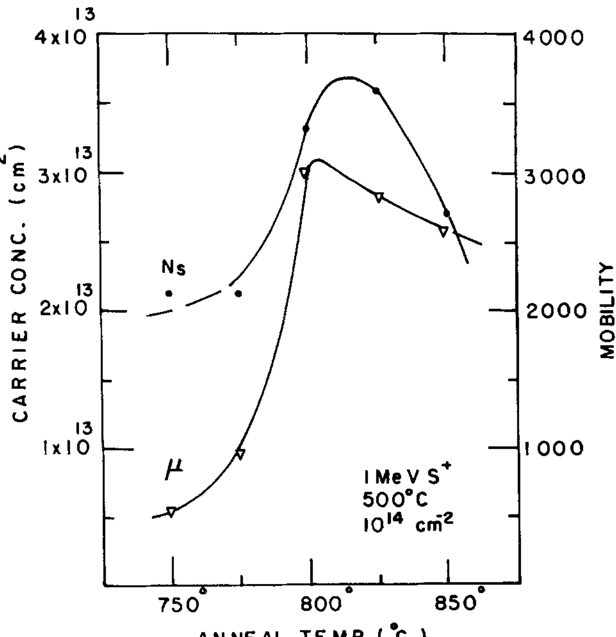

Fig. 1. Dependence of the sheet carrier concentration and mobility on annealing temperature for sulfur encapsulated with Ga-SiO_2.

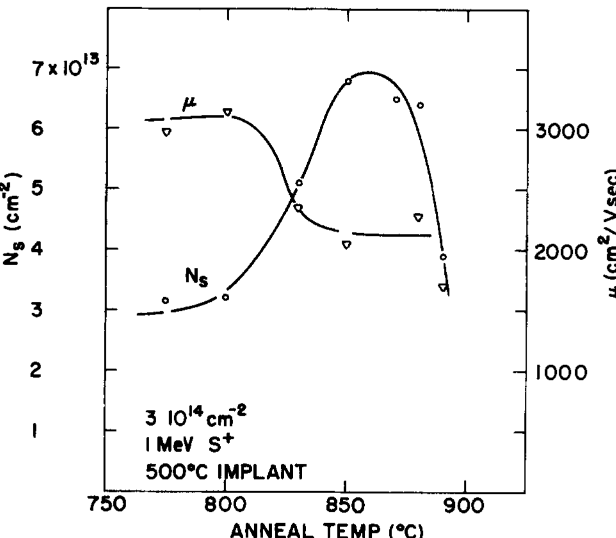

Fig. 2. Annealing of sulfur showing the higher temperatures required for the heavier 3×10^{14} cm^{-2} dose level.

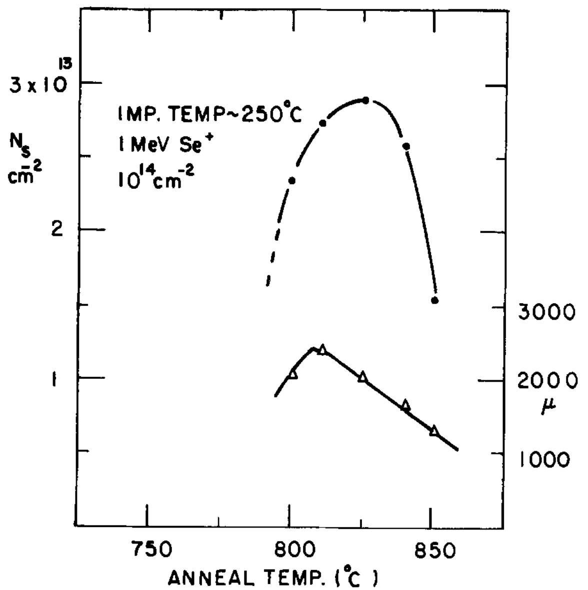

Fig. 3. Annealing of selenium-implanted layers passivated with Ga-SiO_2.

Turning to Group IV dopants, the influence of various dielectric coatings on the annealing of Si^+-implanted layers is shown in Table II. Doses of 10^{14} cm^{-2} were implanted at 250°-300°C and then annealed to 800°C. Contrary to the behavior with S^+, the presence of Ga within the oxide now becomes detrimental to achieving high electrical activity. It thus appears again that Ga-SiO_2 reduces the out-diffusion of Ga but here, unlike with S^+, such an out-diffusion seems desirable. The Si_3N_4 and AlN annealed layers are intermediate between the two oxide extremes.

Table II. Doping efficiency of 10^{14} Si^+ cm^{-2} implants annealed at 800°C with different encapsulants

Encapsulant	$T_{Impl.}$ (°C)	R_s (ohm/□)	μ(cm^2/V-sec)	N_S(cm^{-2})
Ga-SiO_2	260	496	2100	0.6×10^{13}
	300	340	2300	0.8×10^{13}
AlN	290	149	3000	1.4×10^{13}
	250	142	2600	1.7×10^{13}
Si_3N_4	270	139	2500	1.8×10^{13}
SiO_2	290	99	3000	2.1×10^{13}
	240	87	3000	2.4×10^{13}

The 800°C annealing for the implants of Table II is not the most ideal for Si. This is illustrated in Fig. 4 where it can be seen that Si does not exhibit the 800°-825°C optimum temperature observed earlier with both S^+ and Se^+ at the same 10^{14} cm^{-2} dose. These Si^+ implants, at 220°-240°C, were annealed using Ga-free SiO_2. The sheet carrier concentrations up to 3.6×10^{13} cm^{-2} (R_s = 52 ohm/□) are limited by the temperature which the oxide can withstand and which presently is ~900°C. Possibilities for improvement include overcoating the oxide with a nitride layer which would withstand higher temperatures or going to an oxynitride layer which may allow some Ga out-diffusion.

The corresponding mobilities together with those of other Si^+ layers annealed with various oxides including As-SiO_2 are shown in Fig. 5. An improvement occurs at ~825°C but this stage is not as pronounced as that seen ~775°C with S^+ (Fig. 1).

The effect of implantation temperature on S, Se, and Si layers can be seen in Table III. All ions have been implanted above 150°C as well as at room temperature. The sulfur results are taken from earlier work (6) while those for Se are in agreement with Foyt *et al.*

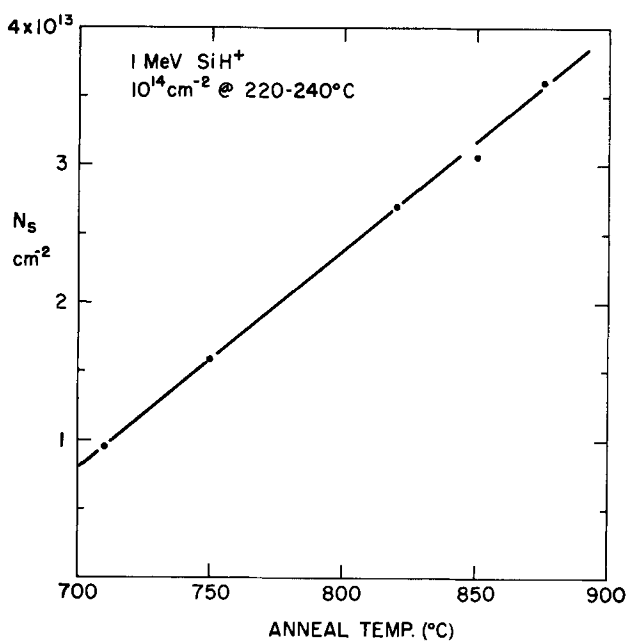

Fig. 4. Annealing of silicon with SiO_2 as the encapsulant

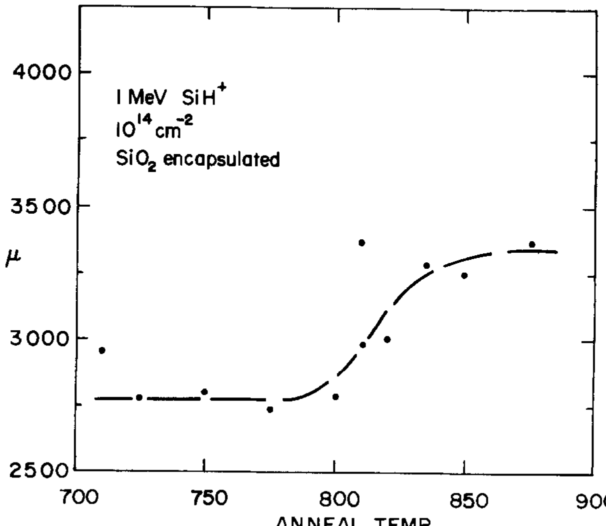

Fig. 5. Dependence of mobility on annealing for silicon implanted layers.

Table III. Effect of implantation temperature on S^+, Se^+, and Si^+ electrical activity

Ion	$T_{Impl.}$ (°C)	T_{Anneal} (°C)	Encapsulant	μ(cm^2/V-sec)	N_S(cm^{-2})	Heated N_S / R.T. N_S
S	360	825°	Ga-SiO_2	3100	4.0×10^{13}	2.5
	20	825°	Ga-SiO_2	3000	1.6×10^{13}	
Se	280	825°	Ga-SiO_2	2050	2.9×10^{13}	3.2
	20	825°	Ga-SiO_2	1650	0.9×10^{13}	
Si	235	825°	As-SiO_2	2750	2.2×10^{13}	1.2
	20	825°	As-SiO_2	2700	1.9×10^{13}	
Si	295	810°	SiO_2	3000	2.3×10^{13}	1.3
	20	810°	SiO_2	3350	1.8×10^{13}	

(4). The most significant factor is the relative insensitivity of Si to implantation temperature. It is clear that Si becomes substitutional more readily than the Group VI dopants when implanted at room temperature.

The comparatively lower activity in Table III that is shown for Si^+ arises through annealing at similar temperatures to the S^+ and Se^+ layers rather than at the more ideal higher temperatures indicated by Fig. 4. Both SiO_2 and As-SiO_2 have been used in annealing these Si^+ implants. It may be noted that incorporation of As within the oxide does not produce any improvement comparable to that obtained for S with Ga-SiO_2. It appears that As loss is not a problem, in agreement with Gyulai *et al.* (3) who established from backscattering measurements that Ga alone out-diffuses through SiO_2.

In summary, significant differences arise in the behavior of implanted S^+ or Se^+ and Si^+. These differences are attributed to Group VI and Group IV dopants occupying different sublattice sites. Incorporation of Ga into SiO_2 resulted in a marked improvement with S^+ implants but was detrimental to achieving high conductivity with Si. It is concluded from such behavior that the gallium within the oxide at least partially inhibits the gallium loss from the wafer surface. Further, some Ga loss seems desirable in the case of Si^+ and presumably the same applies and inadvertently occurs on implanting Group II p-type dopants which can in general be more readily rendered electrically active (2). The annealing characteristics of S and Se with an optimum annealing temperature contrast sharply with Si which requires higher annealing temperatures to achieve similar doping levels. Finally, the substantial difference in the electrical activity resulting from implanting Group VI elements at room temperature and $\gtrsim 150°C$ does not apply to Si. In this respect Si resembles Zn which does not exhibit any strong dependence on implantation temperature.

Vapor-Phase Etching and Polishing of Gallium Arsenide Using Hydrogen Chloride Gas

Rajaram Bhat,* B. Jayant Baliga,**,[1] and Sorab K. Ghandhi†

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Vapor-phase etching of (100) and $(\bar{1}\bar{1}\bar{1})$ GaAs substrates has been conducted in HCl-H_2-AsH_3 gas mixtures. Specular surfaces, suitable for epitaxy, were obtained for substrates doped with Cr, Te, Si, and Zn when the substrates were etched at temperatures above 870°C. It is shown that the etching reaction is mass-transport limited at these temperatures for both (100) and $(\bar{1}\bar{1}\bar{1})$ surfaces. At lower temperatures, faceting results from the unequal etch rates for the different orientations. Etch rates of 0.02-14 μm/min were obtained in this study.

The capability for *in situ* etching of substrates has often been incorporated in systems for vapor-phase epitaxy to insure a clean and damage-free surface prior to growth. It is an inherent feature of gallium arsenide epitaxial systems utilizing arsenic trichloride but details of the etching step are not available. Lin, Chou, and Miller (1) have studied the vapor-phase etching of $(\bar{1}\bar{1}\bar{1})$ and (100) gallium arsenide using hydrogen-water vapor mixtures. Shaikh, Chou, and Donaghey (2) have studied hydrogen chloride etching of (100) gallium arsenide in a hydrogen-arsine ambient. The emphasis in their study was on the modeling of the mass transfer process to account for the etch rates observed experimentally. HCl etching of Si-, Te- and Sn-doped (100) GaAs surfaces has been studied by Moon and James (3) using Auger electron spectroscopy but no details of the surface morphology were published.

In this paper we wish to report studies conducted on the vapor-phase etching of a variety of gallium arsenide substrates using anhydrous hydrogen chloride gas in a hydrogen and arsenic ambient. High quality surfaces, with etch rates ranging from 0.02-14 μm/min, were obtained for (100) and $(\bar{1}\bar{1}\bar{1})$ substrates, at temperatures exceeding 870°C. The etching reaction for all orientations was mass-transport limited at these temperatures. Under these conditions the partial pressure of arsenic did not significantly influence the etch rate or surface morphology, provided sufficient arsenic was present to prevent decomposition.

Experimental Conditions

Apparatus.—Etching was carried out in a 50 mm ID, 37 cm long, rf heated, horizontal quartz tube. A 50 by 25 by 13 mm graphite susceptor, coated with pyrolytic graphite, was placed approximately 16 cm from the input end of the reaction chamber, at an angle of 7° to the direction of gas flow. Temperature was monitored using a Pt/Pt-13% Rh thermocouple enclosed in a quartz sheath and inserted into the susceptor. The temperature was verified using infrared pyrometric measurements. Gases were delivered to the reaction chamber through stainless steel tubing, except in the case of HCl where Monel tubing was used to minimize contamination. The apparatus was similar to the one used for the growth of III-V compounds (4).

Gases.—The purity of the hydrogen chloride gas was found to have considerable effect on the quality of the etched surface. Electronic grade hydrogen chloride gas obtained from Matheson Gas Products[2] resulted in poor surfaces under all experimental conditions. Similar difficulties have been reported by Amick, Roth, and Gossenberger (5) in the etching of germanium. Etching with electronic grade HCl, diluted to 1% in six-nines purity hydrogen,[3] gave excellent results. The arsine gas used in this investigation was either a 2% mixture in five-nines purity hydrogen[2] or a 10% mixture in six-nines purity hydrogen.[3] Ultrahigh purity hydrogen,[2] passed through a deoxidizer and molecular sieve,[4] was used as the carrier gas.

Substrates.—Most experiments were performed with boat-grown, (100) oriented, Te-doped GaAs as the substrates.[5] Some investigations were also conducted using boat-grown (100) Cr- and Zn-doped[5] GaAs, $(\bar{1}\bar{1}\bar{1})$ Te-doped,[6] Zn-doped,[6] Cr-doped,[6] and Si-doped[7] GaAs substrates. All wafers were obtained chemi-mechanically polished on one side. The wafers were degreased in methanol, etched in Caro's etch [$10H_2SO_4$ (97%):$1H_2O_2$ (30%):$1H_2O$] for 2 min at room temperature, rinsed in deionized water, and blown dry in filtered air after a final rinse in methanol. This procedure ensured a featureless, damage-free surface prior to *in situ* etching. More elaborate cleaning procedures, such as successive boiling in trichloroethylene, acetone, and methanol were attempted with no significant improvement in the quality of the etched wafer.

Procedure.—Substrates measuring 5 by 6 mm were placed centrally on the susceptor. The system was first purged with prepurified argon (2 liters/min) for 15 min, followed by a 5 min purge with ultrahigh purity hydrogen (3 liters/min). The susceptor was then heated to the etching temperature after introducing the required amount of arsine to prevent decomposition of the GaAs substrate. Substrates were maintained in hydrogen for 15 min at the etching temperature. This step served to remove traces of oxide on the gallium arsenide substrates and resulted in improving the quality of the etched surfaces. HCl gas was then introduced at the desired rate of flow and the substrates were usually etched for 2 min. The system was maintained at the etching temperature for 3 min, after the HCl gas was shut off. Typical flow rates were 3-18 ml/min for arsine gas,[8] 250-8100 ml/min for hydrogen, and 0.1-5 ml/min for HCl gas.[8] Typical etch rates ranged from 0.02-23 μm/min at 900°C.

[8] In this paper, flow rates for AsH_3 and HCl are all quoted in terms of the actual arsine and hydrogen chloride content of the diluted gas.

Etch rate definition and determination.—Figure 1 shows the decrease in substrate thickness with increasing etch time for a typical etching experiment. The decrease in GaAs substrate thickness is seen to be a linear function of time, for times less than approximately 5 min. The deviation from linearity for etch times greater than 5 min is due to the loss of planarity of the substrates. Based on these considerations, it was decided that all measurements of etch rate would be made for an etch period of 2 min. Since the etch rate was constant for this period, it was defined in terms of the substrate thickness removed per unit time. The change in substrate thickness was obtained gravimetrically.

Experimental Results

Temperature.—The effect of temperature on etch rate was determined for (100) and $(\bar{1}\bar{1}\bar{1})$ oriented, Te-doped GaAs substrates using a flow of 900 ml/min of hydrogen, 3 ml/min of arsine, and 2 ml/min of HCl gas. Under these conditions, the etching reaction of (100) GaAs substrates was mass-transport limited at temperatures above 850°C and kinetically controlled below this temperature with an activation energy of 1.25 eV/molecule. The etching reaction of the $(\bar{1}\bar{1}\bar{1})$ GaAs substrates was mass-transport limited at temperatures above 870°C and kinetically controlled below this temperature with an activation energy of 1.85 eV/molecule. As expected, equal etch rates were observed at temperatures above 870°C, as shown in Fig. 2. [The data in Fig. 2 have not been corrected for the change in linear velocity with temperature (6)].

Surfaces of both (100) and $(\bar{1}\bar{1}\bar{1})$ GaAs substrates etched below 870°C became increasingly faceted, with the simultaneous formation of either etch pits or hillocks,[9] due to the unequal etch rates for different substrate orientations. Above 870°C, where the etch rates for the different orientations were equal, etched (100) and $(\bar{1}\bar{1}\bar{1})$ substrate surfaces were featureless, as seen in the photomicrographs of Fig. 3 and 4.[10]

Chemical polishing of semiconductor substrates occurs when the etch rate for all crystallographic orientations is equal. This is achieved when the etching reaction is mass-transport limited, provided that the adsorption of the etchant on the substrate surface is independent of perturbations present on the surface (7).

[9] Distinguished by scanning electron microscopy.
[10] In this paper, all photomicrographs were taken using the Nomarski interference contrast technique.

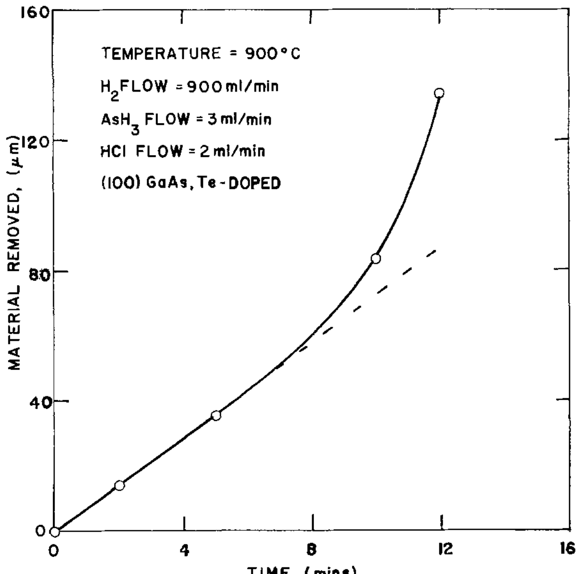

Fig. 1. Change in thickness of the wafers as a function of time

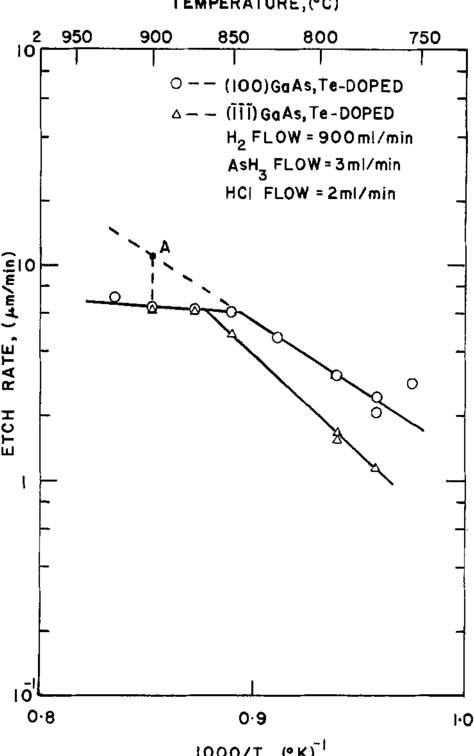

Fig. 2. Effect of substrate temperature on etch rate

The latter condition is apparently met during the vapor-phase etching of GaAs by HCl gas.

Hydrogen flow.—Figure 5 shows the variation of etch rate with hydrogen flow at 900°C for (100), Te-doped GaAs. In these experiments, the arsine and HCl gas flow was varied in proportion to the hydrogen flow to keep their partial pressures constant at 3.3×10^{-3} atm and 2.22×10^{-3} atm, respectively. It is seen that the etch rate varies linearly as the square root of the hydrogen flow for flows below 2.5 liters/min. This is because the etch rate varies directly with the rate of transport of HCl atoms to the substrate under mass-transport limited kinetics. This rate of transport varies directly with the boundary layer thickness at the substrate, and hence as the square root of the hydrogen flow under laminar flow conditions. At higher flows the etch rate saturates at 10.7 μ/min. This independence of etch rate at high hydrogen flow indicates the etching mechanism has become kinetically limited. If the data representing kinetically controlled etching shown in Fig. 2 is extrapolated to 900°C (point A), the value of the etch rate obtained is indeed the same as the observed saturated value.

The rate of transport of As to the GaAs surface decreases with decreasing hydrogen flow due to the increase in the boundary layer thickness. Consequently, substrate decomposition can be expected to occur at low hydrogen flows. This was indeed found to be the case for hydrogen flow rates below 0.45 liter/min. Verification of this fact was carried out by heating substrates under the above conditions without performing HCl etching. Surfaces of the HCl etched and the heated substrates were found to have similar features for identical hydrogen flow rates.

Arsine flow.—The effect of arsine flow on etch rate and surface quality under mass-transport limited conditions was investigated at 900°C using a hydrogen flow of 900 ml/min. It was found that at least 3 ml/min of arsine was required to prevent the decomposition of the substrate. For arsine flows between 3 and 18 ml/min, there was no appreciable change in surface quality, and the etch rate did not change within experimental error. Under similar flow conditions at 790°C,

Fig. 3. Effect of temperature on the surface morphology of (100) Te-doped GaAs etched at (a, top left) 750°C, (b, top right) 825°C, (c, bottom left) 850°C, and (d, bottom right) 900°C.

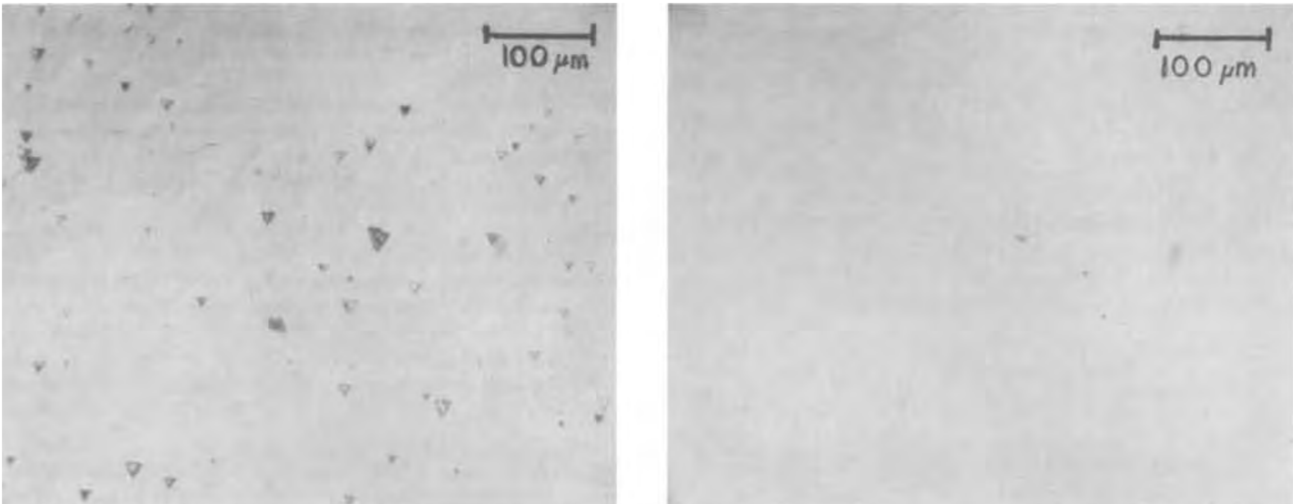

Fig. 4. Effect of temperature on the surface morphology of $(\bar{1}\bar{1}\bar{1})$ Te-doped GaAs etched at (a, left) 790°C and (b, right) 900°C

where the etching was kinetically controlled, the etch rate was found to decrease with increasing arsine flow.

HCl flow.—Figure 6 shows the etch rate of (100), Te-doped GaAs substrates as a function of the HCl gas flow. These experiments were conducted at a temperature of 900°C using a total hydrogen flow of 900 ml/min and an arsine flow of 3 ml/min. The etch rate was found to vary superlinearly with HCl concentration. Similar nonlinear dependence of the etch rate on etchant gas flow, under mass-transport limited conditions, has been observed in the vapor-phase etching of Si (8, 9) and Ge (6). Ideally, under mass-transport

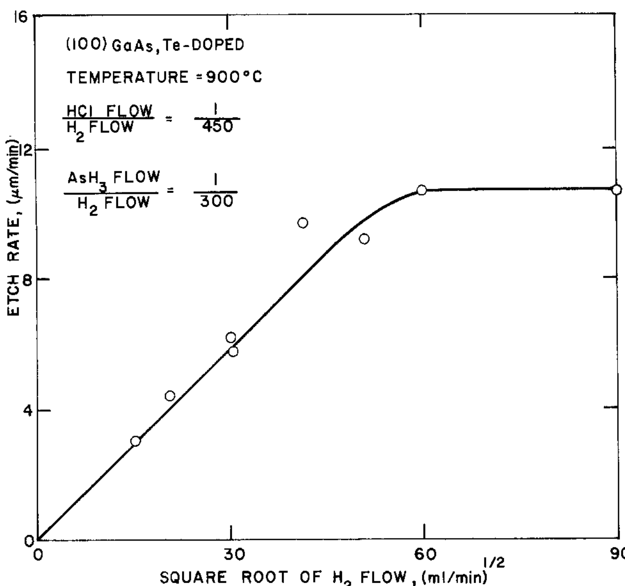

Fig. 5. Effect of hydrogen flow on etch rate

limited conditions, the etch rate should vary parabolically with the etchant concentration at low etchant partial pressures (9).

Orientation and dopant type.—The etch rate and the surface quality of (100) and $(\bar{1}\bar{1}\bar{1})$ GaAs substrates with different dopants were also evaluated. The etch rate observed for Zn- and Cr-doped (100) and Si-,[11] Zn-, and Cr-doped $(\bar{1}\bar{1}\bar{1})$ GaAs substrates, under both mass-transport limited and kinetically controlled conditions, was the same as for their Te-doped counterparts. Therefore, the etch rate is insensitive to the type of dopant incorporated in the GaAs.

[11] Si-doped (100) GaAs was not available to us at the time this investigation was carried out.

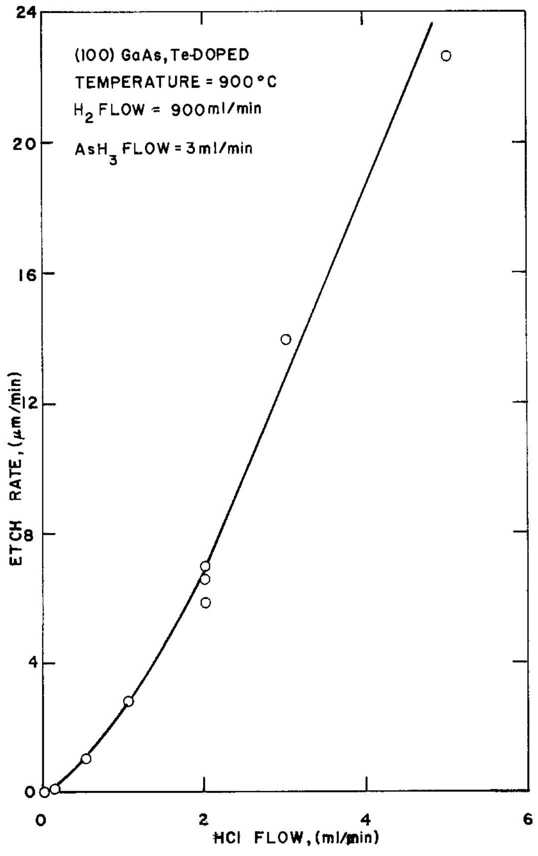

Fig. 6. Effect of HCl gas flow on etch rate

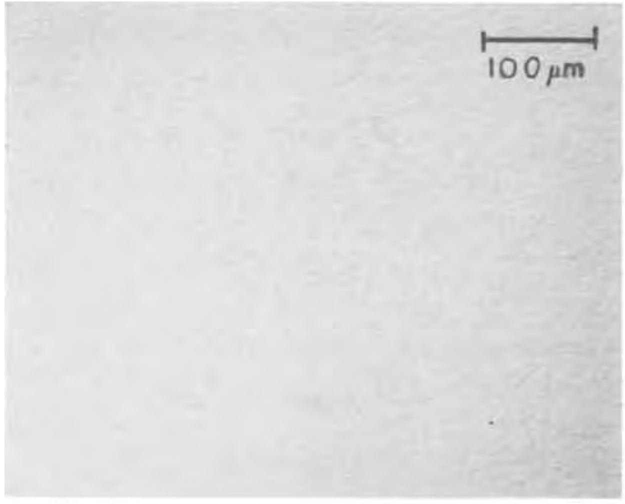
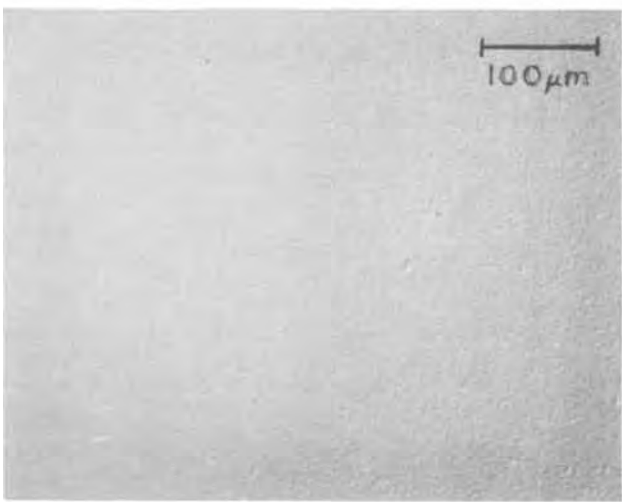
All substrates etched at 900°C using a hydrogen flow of 900 ml/min, arsine flow of 3 ml/min, and a HCl gas flow of 2 ml/min were specular to the unaided eye. However, the quality of etched (100) Cr-doped and $(\bar{1}\bar{1}\bar{1})$ Si- and Cr-doped GaAs substrate surfaces was inferior to those obtained with Te- and Zn-doped GaAs substrates under microscopic examination (Fig. 7). This





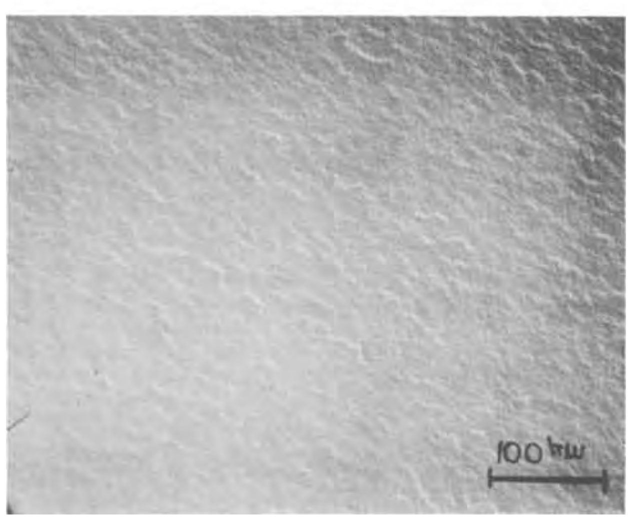


Fig. 7. Surface morphology of etched (a, top) Si-doped, $(\bar{1}\bar{1}\bar{1})$ GaAs, (b, center) Cr-doped, (100) GaAs, and (c, bottom) Cr-doped, $(\bar{1}\bar{1}\bar{1})$ GaAs substrates. Temperature 900°C, H_2 flow 900 ml/min, AsH_3 flow 3 ml/min, HCl gas flow 2 ml/min.

difference in etching behavior is believed to be due to greater inhomogeneities in the doping and dislocation densities in Cr- and Si-doped substrates.

Conclusions

Vapor-phase HCl etching of GaAs substrates can be performed to yield specular surfaces, suitable for epitaxy, with etch rates ranging from 0.02 to 14 μm/min, for (100) and $(\bar{1}\bar{1}\bar{1})$ Cr-, Te-, Zn-, and Si-doped GaAs substrates. A necessary condition for obtaining specular surfaces is that all orientations have the same etch rate. This condition is achieved at sufficiently high temperatures where the etch rate is mass-transport limited for all orientations. The quality of etched (100) and $(\bar{1}\bar{1}\bar{1})$ Si- and Cr-doped substrate surfaces was inferior to those obtained for Te- and Zn-doped GaAs substrates.

Chemical Processes in Vapor Deposition of Silicon

I. Deposition from $SiCl_2H_2$ and Etching by HCl

Vladimir S. Ban* and Stephen L. Gilbert

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Chemical processes occurring in the vapor deposition of silicon from $SiCl_2H_2$ and in the etching of silicon by HCl were studied by means of a mass spectrometer coupled to the CVD reactor. This setup was successfully used for the qualitative and quantitative analysis of the composition of the vapor phase in the Si-Cl-H system. Species found in the vapor phase were H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$, and their partial pressures were measured as a function of temperature, value of the Cl/H ratio, and of the chemical nature of the initial gaseous mixture entering the reactor. The experimentally determined partial pressures were compared with the equilibrium partial pressures of vapor species, calculated from the newest thermochemical data for the Si-Cl-H system. On the basis of these results we discuss the nature and the extent of chemical processes in systems studied.

The chemical vapor deposition (CVD) of thin layers of silicon is among the most important processes in the electronic industry. For this purpose, various Si-containing gases are used, *e.g.*, SiH_4 or various chlorosilanes such as SiH_3Cl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$. Typically, a mixture consisting of approximately 1% of Si-containing gas and 99% of carrier gas, usually H_2 or He, is introduced into the CVD reactor, where it comes into contact with substrates placed on a hot susceptor. The deposition of a layer of Si then takes place on these substrates through chemical reactions, the nature of which depends on experimental conditions, such as temperature, partial pressures and nature of the gaseous mixture, reactor geometry, etc. The purpose of this article is to discuss our studies of chemical processes leading to the deposition of Si. In particular, we studied the deposition of Si from $SiCl_2H_2$ as well as the reverse of this process, *i.e.*, the HCl etching of Si. Dichlorosilane, $SiCl_2H_2$, is becoming an increasingly important starting material for the deposition of Si-layers (1).

* Electrochemical Society Active Member.

Key words: mass spectrometry, CVD, thermodynamics, kinetics.

In general, CVD processes in any system can be understood through the chemical thermodynamics of that system. Thermodynamical calculations should in principle yield information on the feasibility of CVD processes, possible efficiencies of these processes, and on the expected structure and composition of the product. However, in order to apply thermodynamics correctly, one has to know the following about the systems: (*a*) the composition of the condensed and gaseous phases under all experimental conditions; (*b*) the magnitude and the nature of possible kinetic effects, the existence of which may determine the applicability of thermodynamics to the system in question; and (*c*) a set of reliable and consistent thermochemical data should be available.

In growth of Si from $SiCl_2H_2$ and in etching of Si by HCl, the pertinent system is Si-Cl-H. Thermodynamical calculations were applied to this system previously (2, 3). These calculations predicted the composition of the vapor phase, as well as the efficiency of the deposition of Si under various experimental conditions. However, neither the applicability of thermodynamics to the system nor the results of cal-

culations were experimentally verified. One could therefore suspect that the actual situation in the CVD reactor is perhaps different from the situation predicted by calculations. In this paper, we present results of the experimental qualitative and quantitative determination of the composition of the vapor phase and, in view of these results, discuss the applicability of thermodynamics to the system. The experimental and the calculated values of partial pressures are compared, and the nature and the extent of deviations from thermochemical equilibrium, *i.e.*, the role of kinetics, are assessed.

The determination of the composition of the vapor phase was done by means of a time-of-flight mass spectrometer connected directly to the CVD reactor. This method was successfully employed in studies of CVD of various III-V compounds (4-6).

Instrumental

Although the essential part of the mass spectrometer-CVD reactor setup has been described previously (4), we shall briefly review the main points as well as describe modifications made for the study of the Si-Cl-H system.

The reactor used in our studies is a tubular reactor with hot walls, similar to the reactor used in synthesis of III-V materials. This reactor is quite different from reactors normally used in deposition of Si-films, but it nevertheless enabled us to study the pertinent chemical processes. The deposition of Si took place either on the quartz wall of the reactor or on the layer of Si deposited there in previous experiments. Similarly, the HCl also reacted with this deposit in the etching experiments. The residence time of the gas phase as well as the Si area exposed to the gas phase was larger than in the normally used horizontal reactor used for CVD of Si. This should actually facilitate the attainment of chemical equilibrium in the system without altering the nature of reactions. The reactor was heated by a 4-segment tubular furnace. Measurements described here were done in the temperature range of 800°-1300°K. The length of the hot zone could be varied by switching one or two of the segments off. Gases were fed into the reactor through a combination of calibrated Fischer and Porter flow meters and Matheson electronic mass flow transducers. In this way, it was possible to introduce known amounts of $SiCl_2H_2$, HCl, H_2, or He into the reactor, and create a starting mixture of desired composition. There are also provisions for usage of $SiCl_3H$ and $SiCl_4$ in the reactor, but this will be described in another publication.

The reactor is connected to the mass spectrometer via a small quartz capillary. In this way, it is possible to sample hot vapor from the reactor under normal CVD conditions, *i.e.*, 1 atm and temperatures of over 1000°C. The capillary is maintained at the temperature of the sampled gas and since it is made from the same material, *i.e.*, quartz, as the reactor, no interactions different from those in the reactor would occur in the capillary. The capillary reduces pressure from 1 atm in the reactor to 10^{-5} Torr in the mass spectrometer. From it emanates a stream of hot gas directly into the ion source of the mass spectrometer. Since a mean free path at the pressure of 10^{-5} Torr is much longer than the distance between the capillary and the ion source (*ca.* 12 cm), most molecules enter the source without undergoing any interactions in the area between the capillary and the source. We therefore believe that the sample entering the mass spectrometer is representative of the gaseous phase in the CVD reactor. The mass spectrometer can be calibrated for quantitative studies. One can introduce into the reactor gaseous mixtures where partial pressures of constituents are known, *e.g.*, mixtures of $SiCl_2H_2$ and H_2, or HCl, $SiCl_2H_2$ and H_2, and then relate peak intensities in the mass spectra to corresponding partial pressures.

Schematic representation of the mass spectrometer-reactor combination is given in Fig. 1.

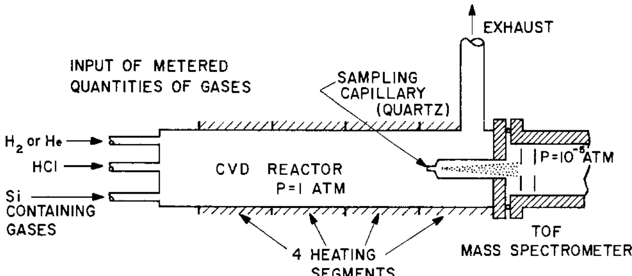

Fig. 1. Schematic representation of the system mass spectrometer-CVD reactor.

Thermodynamical Calculations

Calculations of equilibrium partial presures of vapor species in the Si-Cl-H system have been done by several authors (2, 3, 7) and we shall describe the method only briefly. Basically, one deals with a 3-component system, where the gaseous phase is in equilibrium with the solid phase, *i.e.*, silicon. Therefore, according to the Gibbs rule, the system has three degrees of freedom. These are pressure, temperature, and a compositional variable Cl/H. This Cl/H ratio remains constant throughout the deposition process because neither Cl nor H atoms are added or removed from the system during the deposition (or etching) of Si. Its value is determined by partial pressures of gases in the initially introduced mixture. From the previously referenced works, we learned that the following eight species are most abundant in the Si-Cl-H system: H_2, HCl, SiH_4, SiH_3Cl, SiH_2Cl_2, $SiHCl_3$, $SiCl_4$, and $SiCl_2$. Other possibly existing species, such as Cl, Cl_2, Si_2Cl_6, etc., would be present in negligible amounts only. In order to calculate equilibrium partial pressures of the eight species mentioned above, one must have a set of eight independent, generally nonlinear equations, which specify relationships between these species. Six of these equations represent chemical equilibria between species

$$Si_{(s)} + 4HCl_{(g)} \rightarrow SiCl_{4(g)} + 2H_{2(g)} \quad [1]$$

$$K_{p(1)} = \frac{P_{SiCl_4} \cdot P^2_{H_2}}{a\text{Si} \cdot P^4_{HCl}}$$

$$Si_{(s)} + 3HCl_{(g)} \rightarrow SiCl_3H_{(g)} + H_{2(g)} \quad [2]$$

$$K_{p(2)} = \frac{P_{SiCl_3H} \cdot P_{H_2}}{a\text{Si} \cdot P^3_{HCl}}$$

$$Si_{(s)} + 2HCl_{(g)} \rightarrow SiCl_2H_{2(g)} \quad [3]$$

$$K_{p(3)} = \frac{P_{SiCl_2H_2}}{a\text{Si} \cdot P^2_{HCl}}$$

$$Si_{(s)} + HCl_{(g)} + H_{2(g)} \rightarrow SiClH_{3(g)} \quad [4]$$

$$K_{p(4)} = \frac{P_{SiClH_3}}{a\text{Si} \cdot P_{HCl} \cdot P_{H_2}}$$

$$Si_{(s)} + 2HCl_{(g)} \rightarrow SiCl_{2(g)} + H_{2(g)} \quad [5]$$

$$K_{p(5)} = \frac{P_{SiCl_2} \cdot P_{H_2}}{a\text{Si} \cdot P^2_{HCl}}$$

$$Si_{(s)} + 2H_{2(g)} \rightarrow SiH_{4(g)} \quad [6]$$

$$K_{p(6)} = \frac{P_{SiH_4}}{a\text{Si} \cdot P^2_{H_2}}$$

The activity of Si is represented by a; $a = 1$.

The remaining two equations specify the Cl/H ratio and state that the total pressure in the system is 1 atm

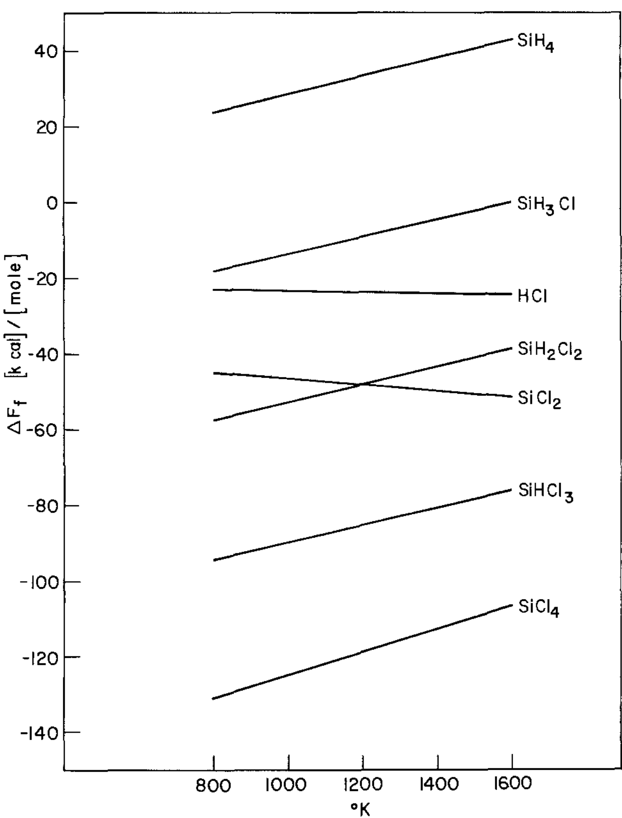

Fig. 2. Free energies of formation of important gaseous species in the Si-Cl-H system in the temperature interval of 800°-1600°K.

$$Cl/H = \frac{4P_{SiCl_4} + 3P_{SiCl_3H} + 2P_{SiCl_2H_2} + 2P_{SiCl_2} + P_{SiClH_3} + P_{HCl}}{2P_{H_2} + P_{SiCl_3H} + 2P_{SiCl_2H_2} + 3P_{SiClH_3} + P_{HCl} + 4P_{SiH_4}} \quad [7]$$

and

$$P_{SiCl_4} + P_{SiCl_3H} + P_{SiCl_2H_2} + P_{SiClH_3} + P_{SiCl_2} + P_{SiH_4} + P_{HCl} + P_{H_2} = 1 \quad [8]$$

Of course, when growing Si from a mixture of $SiCl_2H_2$ and H_2 partial pressures of all other species are initially equal to zero.

In order to find values of $K_{p(1\text{-}6)}$, the most convenient data to have are free energies of formation, ΔF_f, of all species in the temperature interval of interest. Values of ΔF_f of all species were calculated from thermochemical data for the Si-Cl-H system recently collected by Hunt and Sirtl (3). Figure 2 shows values of ΔF_f *vs.* temperature in the form of the so-called Ellingham diagrams (8).

Once values of K_p's were known, we calculated the equilibrium partial pressures of all eight species, using a simple iterative method on a time sharing computer. In these calculations, the Cl/H ratio was set to be 10^{-3}, 10^{-2}, 10^{-1}, and 10^{0}; the temperature was varied from 800° to 1600°K, in increments of 200°K. Results of calculations are given in Table I.

Thermodynamical calculations can also be used to determine the theoretical efficiency of the deposition process. The efficiency can be defined as

$$\eta = \frac{[Si/Cl]_{in} - [Si/Cl]_{eq}}{[Si/Cl]_{in}}$$

where $[Si/Cl]_{in}$ is the ratio of Si to Cl atoms in the starting mixture, and $[Si/Cl]_{eq}$ is this ratio in the equilibrium mixture. A negative value of η means that etching of Si is taking place in the system.

Experimental Results

Mass spectra of chlorosilanes.—Since the determination of the mass spectra of Si-containing gases in our setup is being reported elsewhere (9), we only briefly discuss this topic here. Vapor species in the reactor were identified by means of the attached mass spectrometer. The analysis is complicated by the fact that mass spectra of various chlorosilanes should be quite similar, due to the fragmentation of parent molecules by the ionizing electrons. We determined mass spectra of $SiCl_4$, $SiCl_3H$, $SiCl_2$, and $SiCl_2H_2$ in our experimental setup. A mixture containing 1% of these gases in He or H_2 (this change produces no difference in spectra) was introduced into the reactor and mass spectra were taken at room temperature, where no chemical reactions which would change the mixture occurred. The observed intensities of major peaks in these mixtures did not differ by more than 15%, thus indicating that our experimental setup is about equally sensitive for all chlorosilanes. Mass spectra of $SiCl_2$ were deduced from the high temperature mass spectrometry of $SiCl_4$-He mixtures where the only present vapor species were $SiCl_4$, $SiCl_2$, and He. Mass spectra of $SiClH_3$ were not determined, but as the calculations have shown, this should be a scarce species, and besides, using the analogy with other chlorosilanes, one could deduce its mass spectra with a fair degree of accuracy.

In determination of these spectra, 70 eV ionizing electrons were used. No corrections due to differences in ionization cross section of various species, possible mass discrimination of the instrument, etc., were applied, since we were primarily interested in the relative intensities of various peaks under our experimental conditions. Mass spectrum of $SiCl_4$ agrees reasonably well with the published data (10). Mass spectra of SiH_4, HCl, and H_2 are known. Results of the determination of mass spectra of $SiCl_4$, $SiCl_3H$, $SiCl_2H_2$, and $SiCl_2$ are graphically represented in Fig. 3. From the relative intensities of various peaks, one can calculate relative abundances of various species in the

vapor phase; *i.e.*, one can perform the qualitative and the quantitative analysis of the vapor phase in the reactor.

Determination of partial pressures.—The qualitative and quantitative analysis results in determination of partial pressures of all detected species. Effects of temperature and of the Cl/H ratio, as well as possible effects of the nature of starting mixture on values of partial pressures of various species were studied. Measurements were done at 1000°, 1200°, and 1300°K; Cl/H ratios of 10^{-2}, 10^{-1}, and 10^{0} were used. Mixtures with identical values of Cl/H ratio were prepared in two ways: by mixing pure $SiCl_2H_2$ with H_2, or by mixing the appropriate amounts of $SiCl_2H_2$ and HCl with H_2. The exact amounts mixed are given in Table II. In this way the effect of the nature (*i.e.*, of the presence or the absence of HCl) of starting mixture on the composition of the vapor phase could be studied. In cases of Cl/H = 10^{0}, either pure $SiCl_2H_2$ or pure HCl were introduced into the reactor. Of course, the deposition of Si will occur in the former, and the etching of Si will occur in the latter case, but the composition of the vapor phase in contact with solid Si should nevertheless be the same, providing that chemical equilibrium has been established.

Mass spectra of initial mixtures at room temperature contained only peaks characteristic for the gases comprising the mixture in question. At elevated temperatures new peaks appeared indicating the appearance of new species in the vapor phase. Under our experimental conditions, the following species were found to exist in appreciable amounts: H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$. Species such as $SiClH_3$ and SiH_4 were not detected; Si_2Cl_6 was detected but only in very small amounts. The last three species were therefore ignored in the quantitative determination of partial pressures. When different Si-containing species coexist in the vapor phase, some of the peaks in the mass spectra comprise contributions from more than one species. For example, if the relative intensity of the peak with $m/e = 133$ is 100 and the relative intensity of the peak with $m/e = 170$ is only 25, one concludes that this gas mixture contains $SiCl_4$ (as evidenced by the existence of the peak at $m/e = 170$) and also $SiCl_3H$, because ratio of intensities of peaks with $m/e = 133$ and $m/e = 170$ is larger than in the mass spectrum of pure $SiCl_4$ (see Fig. 3) This means that some other species must contribute to the peak with $m/e = 133$. From Fig. 3 it is obvious that this can be only $SiCl_3H$. The relative amounts of $SiCl_4$ and $SiCl_3H$ can be obtained in this way. Once the relative amounts of $SiCl_4$ and $SiCl_3H$ are known, one proceeds to determine the relative amount of $SiCl_2H_2$ by substracting the contribution of $SiCl_3H$ to the peak with $m/e = 99$. The relative amount of $SiCl_2$ is determined from the intensity of peak at $m/e = 63$, after substracting contributions from $SiCl_4$, $SiCl_3H$, and $SiCl_2H_2$ to this peak. After the above procedure is completed, one obtains ratios of partial pressures of $SiCl_3H$, $SiCl_2H_2$, and $SiCl_2$ respective to the partial pressure of $SiCl_4$. We shall illustrate this on the previously given example, where relative intensity of $m/e = 133$ was 100, and of $m/e = 170$ was 25, respectively. The contribution of the $SiCl_4$ spectrum to the peak at $m/e = 133$ can be obtained by multiplying the ratio of relative intensities of $m/e = 133$ and $m/e = 170$ in the pure $SiCl_4$ spectrum with the relative intensity in the spectrum of the mixture

$$\frac{I_{133(SiCl_4)}}{I_{170(SiCl_4)}} \times I_{170(mix)} = \frac{100}{53} \times 25 = 47.2$$

The contribution of $SiCl_3H$ to the peak at $m/e = 133$ can be obtained by subtracting 47.2 from 100, *i.e.*, its contribution is 52.8. Since partial pressures of species are proportional to mass spectrometric intensities, one has

$$\frac{47.2}{52.8} = \frac{P_{SiCl_4}}{P_{SiCl_3H}} = 0.89$$

and one can express P_{SiCl_3H} in terms of P_{SiCl_4}

$$P_{SiCl_3H} = 1.12\, P_{SiCl_4}$$

This procedure can be repeated for $SiCl_2H_2$ and $SiCl_2$, so that partial pressures of these species are also expressed in terms of P_{SiCl_4}.

The partial pressure of HCl was determined through direct calibration. Intensities of HCl peaks in the mass spectra were measured at temperatures of interest in mixtures containing only HCl and H_2 in known proportions. Since Si was not present in these experiments, no reaction could occur in the reactor and measured HCl intensities can be directly correlated with the partial pressure of HCl.

Now one can proceed with calculations of actual values of partial pressures of $SiCl_4$, $SiCl_3H$, $SiCl_2H_2$, $SiCl_2$, and H_2 from mass spectrometric data. Partial pressures must satisfy Eq. [7] and [8]. Expressing partial pressures of all present chlorosilanes in terms of P_{SiCl_4} and neglecting mass spectrometrically nondetectable species, Eq. [7] and [8] can be written as

$$\frac{\text{Cl}}{\text{H}} = \frac{4P_{SiCl_4} + 3aP_{SiCl_4} + 2bP_{SiCl_4} + 2cP_{SiCl_4} + P_{HCl}}{2P_{H_2} + aP_{SiCl_4} + 2bSiCl_4 + P_{HCl}} \quad [9]$$

and

$$P_{SiCl_4} + aP_{SiCl_4} + bP_{SiCl_4} + cP_{SiCl_4} + P_{HCl} + P_{H_2} = 1 \quad [10]$$

where a, b, and c are mass spectrometrically obtained ratios connecting partial pressure of $SiCl_4$ with partial pressures of $SiCl_3H$, $SiCl_2H_2$, and $SiCl_2$, respectively.

Since P_{HCl} is known from calibration experiments, we deal with the system of two linear equations containing two unknowns, *i.e.*, P_{H_2} and P_{SiCl_4}. After solving for P_{H_2} and P_{SiCl_4} one obtains P_{SiCl_3H}, $P_{SiCl_2H_2}$, and P_{SiCl_2} from known values of a, b, and c, respectively.

In Fig. 4(a)-(e), the experimentally determined partial pressures of vapor species are compared with calculated partial pressures at corresponding temperatures and Cl/H values. Lines represent the temperature variation of calculated partial pressures of pertinent species; Cl/H $= 10^0$ for the top line, Cl/H $= 10^{-1}$ for the middle, and Cl/H $= 10^{-2}$ for the bottom line. Square symbols are to be compared with the top line, triangular symbols with the middle, and circular symbols with the bottom line. Open symbols represent values of partial pressures in mixtures where HCl was not initially present; the full symbols represent partial pressures in mixtures where HCl was initially present. The reproducibility of these data from experiment to experiment is about ±20%.

Discussion

In this section we discuss the nature and the extent of chemical reactions occurring in the system. From the presence of H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiClH_3$, and $SiCl_4$, one can conclude which reactions occur.

The drop of partial pressure of entering $SiCl_2H_2$ and the appearance of HCl in the system infers the following reaction (reverse of reaction [3]) by which the deposition of Si occurs

$$SiCl_2H_{2(g)} \rightarrow Si_{(s)} + 2HCl_{(g)} \quad [11]$$

The HCl created in this way reacts with the Si deposit to form other thermodynamically stable species; $SiCl_4$, $SiCl_3H$, and $SiCl_2$ are formed via reactions [1], [2], and [5], respectively. Reactions of equilibration between various vapor species can be also considered, *e.g.*

$$SiCl_2H_{2(g)} \rightarrow SiCl_{2(g)} + H_{2(g)} \quad [12]$$

$$SiCl_3H_{(g)} \rightarrow SiCl_{2(g)} + HCl_{(g)} \quad [13]$$

$$SiCl_{4(g)} + Si_{(s)} \rightarrow 2SiCl_{2(g)} \quad [14]$$

$$SiCl_{4(g)} + H_{2(g)} \rightarrow SiCl_3H_{(g)} + HCl_{(g)} \quad [15]$$

It is possible to draw some conclusions about the mechanism and the kinetics of the above reactions by referring to Fig. 4(a)-(e). The comparison of calculated with equilibrium partial pressures shows that deviations from equilibrium exist, but their nature varies from species to species. In almost all instances P_{SiCl_2} and $P_{SiCl_2H_2}$ are higher than their equilibrium values; P_{HCl} is also higher except for Cl/H $< 10^{-1}$. On the other hand, P_{SiCl_4} is almost always lower than the equilibrium value, and P_{SiCl_3H} is also lower for $T >$ 1000°K. From these observations, one can conclude that the creation of species which require more HCl molecules to form (*i.e.*, reactions [1] and [2]) proceeds slower than the creation of species which require less HCl (*i.e.*, reactions [3] and [5]). This suggests a dearth of HCl molecules at the Si surface, which could be caused either by the poor transport of HCl to the surface or by the poor adsorption of HCl at the surface. The increase of P_{HCl} by the addition of pure HCl to the gas phase increases the transport of HCl to the surface, but nevertheless, the relative abundance of vapor species does not change significantly. At higher Cl/H ratios one observes that the abundance of HCl in the vapor is higher than equilibrium data predict. This points toward the poor adsorption of HCl on silicon surface. The consequence is that species requiring more HCl for their formation (*i.e.*, $SiCl_3H$ and $SiCl_4$) will form less readily than species such as $SiCl_2$, which need only two HCl molecules for their formation. Recently, Robinson and Goldsmith obtained Si growth from mixtures of $SiCl_2H_2$ and HCl, where HCl content was so high that thermodynamic calculations predicted etching of Si rather than its growth (11). This indicates that in their system the reaction of HCl with Si also did not reach equilibrium.

The incomplete dissociation of $SiCl_2H_2$ (reaction [3]) could also contribute to the relatively high $P_{SiCl_2H_2}$. It is also possible that reaction [12] occurs in the system. This reaction is thermodynamically more feasible at our experimental temperatures than other homogeneous gas reactions, *i.e.*, reactions [13], [14], and [15]). Most likely, neither reactions [13], [14], and [15], nor their reverse reactions occur to a significant extent in our system. If they did occur, one would observe a strong dependence of P_{SiCl_4} and P_{SiCl_3H} on the presence of free HCl in the reactor. This has not been observed. We thus conclude that events on the Si surface were the principal factor in determining the composition of the vapor phase. A similar conclusion was reached by crystal growers, who consider Si deposition up to about 1250°K as surface kinetics controlled (12, 13). Our mass spectrometric data indicate that these deviations from thermochemical equilibrium also reflect themselves in the composition of the vapor phase. Nevertheless, all major species predicted by thermodynamic calculations have been detected, and in most cases, their measured partial pressures are of the same order of magnitude as the equilibrium values.

It was already mentioned that one can calculate the efficiency of the Si deposition process by comparing values of Si/Cl ratio in the initial mixture with the Si/Cl in the equilibrium mixture at some given temperature. The efficiency obtained in this way is the theoretical efficiency of the Si-deposition process. The comparison of the initial Si/Cl ratio with the Si/Cl ratio determined from mass-spectrometric values of partial pressures yields the experimental efficiencies. The Si/Cl ratio is defined by the following equation

$$\frac{\text{Si}}{\text{Cl}} = \frac{P_{SiCl_4} + P_{SiCl_3H} + P_{SiCl_2H_2} + P_{SiClH_3} + P_{SiH_4} + P_{SiCl_2}}{4P_{SiCl_4} + 3P_{SiCl_3H} + 2P_{SiCl_2H_2} + P_{SiClH_3} + 2P_{SiCl_2} + P_{HCl}} \quad [16]$$

Of course, in the initial mixtures, only $P_{SiCl_2H_2}$ and P_{HCl} (when present) should be considered; in the determination of the value of Si/Cl from the experimental data, the partial pressures of undetected species such as $SiClH_3$ and SiH_4 are considered to be equal to zero. In Table III, the experimental and the theoretical efficiencies are listed. Efficiencies are expressed in terms of percentage of the introduced Si converted into the solid Si. From data in Table III, it can be seen that, in general, the experimental efficiencies are significantly lower than theoretical ones in cases of lower temperatures and Cl/H values. The experimental efficiencies approach theoretical values with increasing temperatures and Cl/H values. In some cases, they are even higher than the theoretical efficiencies. This can be explained by the already discussed low rates of the HCl-Si interaction. If the deposition of Si from $SiCl_2H_2$ proceeds at higher rates than the back-etching of the deposit by HCl, a net accumulation of Si larger than the equilibrium amount will occur, leading to the observed higher than theoretical efficiencies. This is consistent with data in Ref. (11).

Fig. 4. Comparison between the calculated and the experimental partial pressures of detected species. Lines represent calculated temperature variations of partial pressures with Cl/H value as a parameter. Square symbols are to be compared with the top line (Cl/H $= 10^0$), triangular symbols with the middle (Cl/H $= 10^{-1}$), and circular symbols with the bottom line (Cl/H $= 10^{-2}$). Full symbols represent partial pressures in mixtures where HCl was initially present; the open symbols represent partial pressures in mixtures where HCl was not initially present.

In experiments where pure HCl was introduced into the reactor (*i.e.*, Cl/H $= 10^0$), the etching of the previously deposited Si occurred. The efficiency of etching can be obtained by comparing the experimentally determined amount of Si in the gas phase with the corresponding calculated amounts. Such comparison yields that the HCl-etching is 80, 64, and 71% efficient at 1000°, 1200°, and 1300°K, respectively. This again confirms the observation that the extent of HCl-Si interaction is lower than calculated.

Summary and Conclusions

The presented study of the chemical processes in deposition of Si from $SiCl_2H_2$ and of etching of Si by HCl is summarized in this section.

1. The mass spectrometer-CVD reactor setup has been successsfully used for the qualitative and quanti-

tative analysis of the vapor phase in the Si-Cl-H system.

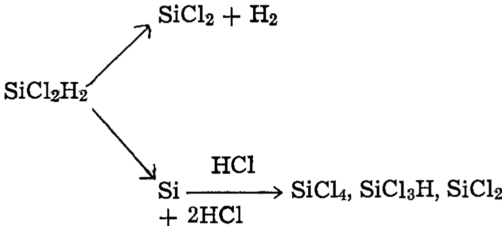
2. Mass spectra of $SiCl_4$, $SiCl_3H$, $SiCl_2H_2$, and $SiCl_2$ have been determined.

3. Species found in the vapor phase were H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$, and their partial pressures were measured as a function of temperature, value of the Cl/H ratio, and of the chemical nature of the initial gaseous mixture entering the reactor.

4. The equilibrium partial pressures of all vapor species present in the Si-Cl-H system were calculated from the newest and most consistent set of thermochemical data available.

5. The comparison between the calculated and the experimentally determined partial pressures indicates that there are certain deviations from the thermochemical equilibrium which reflect themselves in the composition of the vapor phase. Notably, partial pressures of HCl, $SiCl_2$, and $SiCl_2H_2$ tend to be higher, and partial pressures of $SiCl_3H$ and $SiCl_4$ lower than the corresponding equilibrium partial pressures. Nevertheless, under most of our experimental conditions (particularly when $T > 1200°K$), the measured and the calculated partial pressures were of the same order of magnitude. The equilibrium calculations thus provide useful information on the composition of the vapor phase and on the deposition and etching of Si, although the complete equilibrium situation has not been established.

6. The main chemical reactions occurring in the reactor are summarized by the following scheme



The incoming $SiCl_2H_2$ decomposes either to $SiCl_2$ through a loss of two H atoms or to Si through a loss of two HCl molecules; other species are then formed by the HCl-Si interaction.

7. From the nature and the extent of the deviations from the equilibrium, one concludes that their possible causes are the retarded HCl adsorption on Si and the incomplete dissociation of $SiCl_2H_2$.

8. The calculated and the experimentally determined efficiencies of the deposition and etching processes were compared and found to be similar when $T > 1000°K$ and $Cl/H > 10^{-2}$.

Chemical Processes in Vapor Deposition of Silicon

II. Deposition from $SiCl_3H$ and $SiCl_4$

Vladimir S. Ban*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Chemical processes occurring in the vapor deposition of silicon from $SiCl_3H$ and $SiCl_4$ were studied by means of a mass spectrometer coupled to the CVD reactor. Species identified in the vapor phase were H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$. Their partial pressures were measured at temperatures of 1000°, 1200°, and 1300°K; the Cl/H value was 10^{-1}. Values of these partial pressures were compared with the calculated equilibrium partial pressures for the Si-Cl-H system, as well as with partial pressures determined in the deposition of Si from $SiCl_2H_2$. On the basis of the obtained results, we discuss the nature and the extent of chemical processes occurring during the deposition of Si from $SiCl_4$ and $SiCl_3H$.

In the preceding paper of this series (1), the chemical processes occurring in the deposition of Si from $SiCl_2H_2$ and in the HCl-etching of Si were discussed. The topic of the present paper is chemical processes occurring in the deposition of Si from $SiCl_3H$ and from $SiCl_4$. Both of these gases are important sources for the deposition of Si on the industrial scale.

In principle, the deposition of Si from all chlorosilanes should proceed in identical manner, because in all cases one deals with the Si-Cl-H system. The rate and the efficiency of the deposition, as well as the composition of the vapor phase should be uniquely determined by specifying the temperature, the total pressure, and the Cl/H ratio in the system, providing that the thermochemical equilibrium has been established. In reality, however, significant differences in the rate and the efficiency of Si deposition from various chlorosilanes have been observed (2). This implies that certain deviations from the thermochemical equilibrium occur, and that the nature of the input gas affects the deposition.

We studied possible causes and the extent of these effects by experimentally determining the composition of the gas phase by means of a mass spectrometer in a manner described previously (1). The deposition from $SiCl_3H$ and from $SiCl_4$ are compared with the deposition from $SiCl_2H_2$ discussed in Ref. (1). Values of the experimentally determined partial pressures will also be compared with the previously calculated equilibrium partial pressures of vapor species in the Si-Cl-H system (1). On the basis of these comparisons, we shall discuss chemical processes occurring during the Si deposition and the effect of the nature of the input chlorosilanes on these processes.

Experimental

The mass spectrometer-CVD reactor combination has been described in Ref. (1). Controlled amounts of $SiCl_3H$ or of $SiCl_4$ were introduced into the reactor by means of the Tylan Source I Vaporizer Controller. The $SiCl_3H$ and $SiCl_4$ were drawn from 50-lb tanks. Gases were of semiconductor grade purity and supplied by the M&T Chemicals Inc. The Matheson electronic mass flow transducers were used to introduce known amounts of carrier gases, such as H_2 or He, into the reactor. Therefore, partial pressures of Si-containing gases in the input mixtures were known.

The composition of initial mixtures was adjusted so that Cl/H = 10^{-1}. For the case of $SiCl_3H$-H_2 mixture, the Cl/H ratio is given by the following expression

$$\mathrm{Cl/H} = \frac{3P_{\mathrm{SiCl_3H}}}{P_{\mathrm{SiCl_3H}} + 2P_{\mathrm{H_2}}} \quad [1]$$

* Electrochemical Society Active Member.

Key words: mass spectrometry, CVD, thermodynamics, kinetics.

The corresponding expression for the $SiCl_4$-H_2 mixture is given by

$$\mathrm{Cl/H} = \frac{4P_{\mathrm{SiCl_4}}}{2P_{\mathrm{H_2}}} \quad [2]$$

In the above expressions, $P_{\mathrm{SiCl_3H}}$, $P_{\mathrm{SiCl_4}}$, and $P_{\mathrm{H_2}}$ are the partial pressures of these gases at their entrance into the reactor. The $SiCl_3H$-H_2 mixture was prepared by combining flows of 100 cm³/min of $SiCl_3H$ with 1450 cm³/min of H_2. In the case of $SiCl_4$-H_2 mixture, 132 cm³/min of $SiCl_4$ was mixed with 2640 cm³/min of H_2.

The effect of replacing H_2 by He as a carrier gas was also studied. For this purpose, 132 cm³/min of $SiCl_4$ was mixed with 2640 cm³/min of He. Partial pressures of gases in this mixture will be compaerd with partial pressures in the mixtures containing H_2.

Results

Following the method described in Ref. (1), one can determine the qualitative and the quantitative composition of the vapor phase by means of a mass spectrometer. Briefly, various vapor species can be identified by their characteristic mass spectra. Values of partial pressures can then be determined from the mass spectrometrically measured relative amounts of various species and the specified Cl/H ratio and the total pressure in the system, which is 1 atm. Vapor species detected in the Si-Cl-H system, when either $SiCl_3H$ or $SiCl_4$ was used in the initial mixture, were: HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, $SiCl_4$, and H_2. In the Si-Cl-He system, only $SiCl_2$, $SiCl_4$, and He were detected. In Table I, the experimentally determined par-

tial pressures of vapor species present in the $SiCl_2H_2$-H_2, $SiCl_3H$-H_2, and $SiCl_4$-H_2 mixtures as well as the calculated equilibrium partial pressures in the Si-Cl-H system are listed. For all cases, Cl/H ratio is 10^{-1}; pressure values for temperatures of 1000°, 1200°, and 1300°K are listed. In Table II we compare the equilibrium and the experimentally determined partial pressures in the Si-Cl-He system at the above temperatures.

Discussion and Conclusions

Results listed in Table I permit one to compare the deposition of Si from various chlorosilanes. There are some noticeable differences. At T = 1000°K, most of the $SiCl_4$ remains undecomposed, and practically no deposition of Si occurs. This is consistent with the relatively high stability of $SiCl_4$ in comparison with other chlorosilanes (1) and with the observed lower growth rate of Si from $SiCl_4$ (2). Differences between the deposition from $SiCl_2H_2$ and from $SiCl_3H$ are smaller. With increasing temperatures, the values of pressures of vapor species become more similar for all three chlorosilanes and also closer to the calculated equilibrium partial pressures. In other words, the system approaches thermochemical equilibrium. However, at T = 1300°K, one still notices differences between the equilibrium and the experimental partial pressures. In particular, partial pressures of species containing two or less chlorine atoms (*i.e.*, HCl, $SiCl_2$, and $SiCl_2H_2$) tend to be higher than their equilibrium values, while partial pressures of $SiCl_3H$ and $SiCl_4$ tend to be lower than their equilibrium values. It is not clear whether the partial pressure of the incoming $SiCl_4$ indeed drops below its equilibrium value, or if this small deviation (~15%) is caused by the uncertainties of temperature measurement and/or of the thermochemical data used. Similar results have been reported in Ref. (1), and results described here provide some additional information which basically supports our previous discussion, where we concluded that the adsorption of HCl on the Si surface is retarded. In the case of growth of Si from $SiCl_4$ which occurs via the following reaction

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \qquad [3]$$

four molecules of HCl are supplied. It seems that their residence time at the Si surface is short and that they desorb easily. This would lead to the relatively smaller probability of forming, say, $SiCl_3H$ where three molecules of HCl are needed

$$Si + 3HCl \rightarrow SiCl_3H + H_2 \qquad [4]$$

than of forming $SiCl_2$ or $SiCl_2H_2$ where only two molecules of HCl are needed

$$Si + 2HCl \rightarrow SiCl_2H_2 \qquad [5]$$

or

$$Si + 2HCl \rightarrow SiCl_2 + H_2 \qquad [6]$$

Nevertheless, all of the above reactions occur and the resultant partial pressures of all vapor species at $T >$ 1200°K are never more than a factor of 3 or 4 apart from the equilibrium partial pressures.

The equilibrium partial pressures in the Si-Cl-He were calculated by employing the following system of three equations

$$P_{SiCl_4} + P_{SiCl_2} + P_{He} = 1.0 \qquad [7]$$

$$\frac{Cl}{He} = \frac{4P_{SiCl_4} + 2P_{SiCl_2}}{P_{He}} = 0.2 \qquad [8]$$

and

$$SiCl_{4(g)} + Si_{(s)} \rightarrow 2SiCl_{2(g)};\ k_p = \frac{P^2_{SiCl_2}}{aSi \cdot P_{SiCl_4}} \qquad [9]$$

The first of these equations specifies the total pressure in the system, the second one the Cl/He ratio, and the third one the chemical reaction involving the Si-containing gaseous species. In Eq. [9], aSi represents the activity of solid silicon; aSi = 1.0. Values of k_p at 1000°, 1200°, and 1300°K were calculated from thermochemical data given in Ref. (1).

The results of these calculations are given in Table II, along with the experimentally determined partial pressures of $SiCl_2$, $SiCl_4$, and He. An inspection of Table II shows that $SiCl_4$ does not react at $T \leq$ 1000°K. At higher temperatures, significant amounts of $SiCl_2$ are detected, indicating that reaction [9] takes place. At 1200° and 1300°K the observed partial pressures are relatively close to the equilibrium pressures. Again, the P_{SiCl_4} appears to be slightly below the equilibrium value, but the extent of these deviations is smaller than the uncertainty in experimental temperatures and thermochemical data. Both P_{SiCl_2} and P_{SiCl_4} are considerably higher than the corresponding pressures in the Si-Cl-H system. This is so because, due to the absence of hydrogen, species such as $SiCl_2H_2$, $SiCl_3H$, and HCl cannot form. It is quite probable that in the Si-Cl-H system, where reactions such as [4], [5], and [6] are possible, reaction [9] occurs to a smaller extent.

Finally, we shall discuss the efficiencies of the Si deposition from $SiCl_3H$ and from $SiCl_4$. These efficiencies can be obtained by comparing the Si/Cl ratios of the initial mixture with ratios at elevated temperatures. The same method was used in Ref. (1). In Fig. 1, the experimentally obtained efficiencies (full lines) are compared with the deposition efficiencies available under the equilibrium conditions (dotted lines). These efficiencies give the amount of Si deposited as percentages of Si introduced into the system. One notices that in the case of $SiCl_3H$, the experimental efficiencies run close to the theoretical efficiencies. In the case of $SiCl_4$, the theoretical and experimental efficiencies are significantly lower. At $T <$ 1100°K, actual etching of the previously deposited Si takes place when $SiCl_4$-H_2 mixture with Cl/H = 10^{-1} is introduced into the system. Of course, in the Si-Cl-He system, etching occurs at all temperatures via the reaction [9]. The upper curves in Fig. 1 represent the theoretical and the experimental efficiencies of the deposition of Si from $SiCl_2H_2$. These results are taken from the previous paper and indicate that for the given temperature and Cl/H ratio of the initial mixture, $SiCl_2H_2$ is the most efficient source of Si among the chlorosilanes examined.

The presented work could be summarized as follows:

1. Chemical processes in the deposition of Si from $SiCl_3H$-H_2 and $SiCl_4$-H_2 mixtures with Cl/H = 10^{-1} were examined by the mass spectrometer at temperatures of 1000°, 1200°, and 1300°K.

2. Vapor species detected at elevated temperatures were H_2, HCl, $SiCl_2$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$; their partial pressures were measured and compared with partial pressures detected in $SiCl_2H_2$-H_2 mixtures and

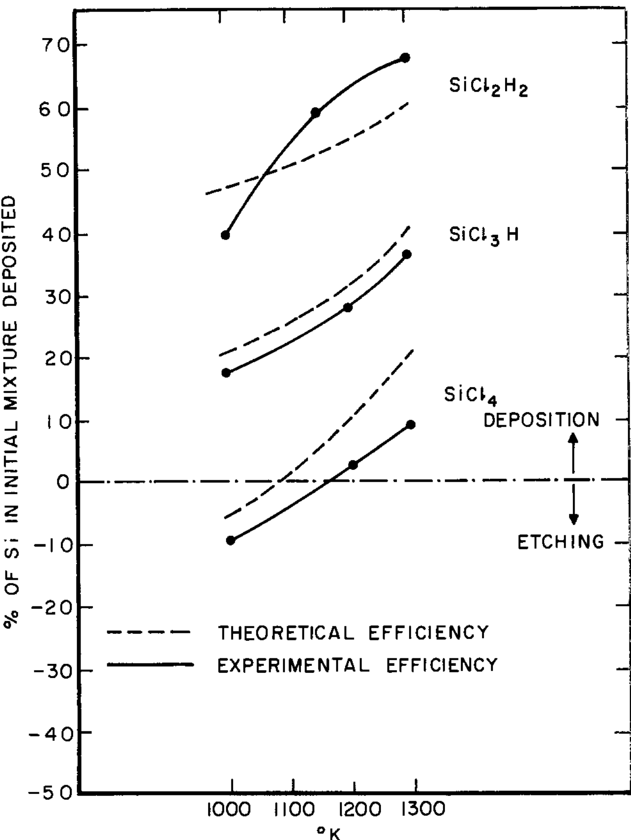

Fig. 1. Theoretical and experimental efficiencies of deposition of silicon from $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$ in temperature interval of 1000°-1300°K; Cl/H = 10^{-1} in all cases.

with the calculated equilibrium partial pressures.

3. In the Si-Cl-He system, $SiCl_4$, $SiCl_2$, and He were present in the vapor and their partial pressures were measured and compared with the calculated equilibrium partial pressures for this system.

4. Measured values of partial pressures indicate that there are some significant deviations from the thermochemical equilibrium in the system, especially at lower temperatures where $SiCl_4$ remains largely undecomposed; at $T > 1200°K$, partial pressures resemble more closely the equilibrium partial pressures, particularly in the Si-Cl-He system.

5. The calculated and experimentally determined efficiencies of the deposition of Si from $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$ were compared and found to decrease in order η-$SiCl_2H_2$ > η-$SiCl_3H$ > η-$SiCl_4$.

A Solid-State Galvanic Cell Study of the Ti_2O_3,Ti_3O_5 Equilibrium

Ronald G. Sommer*[,1] and E. David Cater

Department of Chemistry, University of Iowa, Iowa City, Iowa 52242

ABSTRACT

The chemical potential of oxygen of the coexisting phases Ti_2O_3,Ti_3O_5 was found to be given by $\Delta\overline{G}_{1/2\ O_2}$ (Ti_2O_3,Ti_3O_5) = $-86{,}030 + 15.30T(K) \pm 180$ cal (1 std dev.) from a study of the cell Nb,NbO/YDT [7.5 weight per cent (w/o) yttria]/Ti_2O_3,Ti_3O_5 between 1022° and 1495°K. In the evaluation of the data obtained for the above cell the relationship $\Delta G°_f$(NbO) = $-99{,}870 + 21.51T(K) \pm 150$ cal (1 std dev.) which was determined from a study of the cell Nb,NbO/YDT (15 w/o yttria)/Fe,Fe_xO between 1089° and 1426°K was used. The data for Ti_2O_3,Ti_3O_5 correlate well with calorimetric measurements at lower temperatures and vaporization studies at higher temperatures.

This paper presents a study of the equilibrium chemical potential of oxygen in the coexisting solid phases Ti_2O_3,Ti_3O_5 from 1022° to 1495°K by a galvanic cell technique. For convenience idealized formulas are utilized in this paper for the various solid phases except where their actual nonstoichiometric compositions are of interest. The solid phases in the Ti-O system are of considerable interest because of the wide range of nonstoichiometry and unusual defect ordering near O/Ti = 1 (1, 2) and the multitudinous array of phases Ti_nO_{2n-1} based on crystallographic shear in the composition range O/Ti from 1.667 to 2.00 (1, 3, 4). At the time this work was begun thermodynamic data from calorimetric measurements were available for presumably stoichiometric TiO, Ti_2O_3, Ti_3O_5, and TiO_2 [references summarized in JANAF (5)]. Knudsen cell and mass spectrometric studies at temperatures above about 1700°K had explored the nature and thermodynamics of the vaporization processes (6-8) of the phases from O/Ti = 1.0-2.0. Several thermodynamic discrepancies and uncertainties existed in the literature, arising from uncertainties regarding effects of nonstoichiometry and heats of transition. Equilibrium gravimetric studies involving gas-solid equilibria have

* Electrochemical Society Active Member.

Key words: thermodynamics, titanium oxides, niobium monoxide, yttria-doped thoria.

been reported for systems with O/Ti ratios greater than 1.67 (Ti_3O_5), but this technique has not been successfully applied to systems with the low oxygen potentials found in O/Ti < 1.67 (9, 10).

The present work was undertaken to provide thermochemical information on the intermediate oxide phases Ti_2O_3 and Ti_3O_5 by an equilibrium technique, in the range of temperatures between the calorimetric and vaporization studies and at lower oxygen potentials than could be explored with gravimetric techniques. Of particular interest was the question of whether the calorimetric data on stoichiometric materials were valid when extrapolated to higher temperatures where the coexisting phases might exhibit significant nonstoichiometry.

The use of solid oxide electrolyte galvanic cells for the direct determination at elevated temperatures of the chemical potential ($\Delta\overline{G}_{1/2\,O_2}$) or partial pressure ($P_{O_2}$) of oxygen of two phases which coexist in some metal-oxygen system is by now well known (11, 12). Prior to the recently published, extensive study of the Ti-O system with yttria-doped thoria (YDT) electrolyte cells by Suzuki and Sambongi (9), the two-phase region Ti_2O_3,Ti_3O_5 had not been investigated via this technique, although a galvanic cell study of the adjoining two-phase region Ti_3O_5,Ti_4O_7 had been performed by Vasil'eva and Shaulova, along with studies on higher oxide phases (13). A measurement of the difference in oxygen potential of the electrodes "Ti,TiO" and "TiO,Ti_2O_3" with a calcia-stabilized zirconia (CSZ) electrolyte cell attempted by Hoch *et al.* (14) was of questionable value because of incorrect assumptions about the Ti-O phase diagram and the useful region of CSZ. In the region O/Ti > 1.6, emf and gas-solid equilibrium studies have been surveyed by Suzuki and Sambongi (9) and critically reviewed by Merritt *et al.* (10).

The determination of $\Delta\overline{G}_{1/2\,O_2}$ for the region Ti_2O_3,Ti_3O_5 has been carried out in this laboratory via a study of the cell Nb,NbO/YDT (7.5 w/o yttria)/Ti_2O_3,Ti_3O_5. Although the equilibrium partial pressures of oxygen exhibited by these electrodes, on the order of 10^{-25} and 10^{-22} atm at 1000°C, respectively, are very low, Etsell (15) indicates that the average ionic transport number ($\overline{t_i}$) of the YDT electrolyte for such a cell is greater than 0.99 at 1000°C.

A preliminary investigation of the cell Nb,NbO/YDT (15 w/o yttria)/Fe,Fe_xO (x indicates the boundary composition of iron-saturated wüstite) was performed in order to evaluate the emf apparatus and redetermine $\Delta G°_f$(NbO). The majority of the emf data that have been reported for this cell are in excellent agreement (16, 17).

Experimental

Materials used in preparing electrodes were niobium and niobium pentoxide powders, both of 99.8% purity, and titanium powder of 99.5% purity from A. D. MacKay, Inc., hydrogen-reduced iron powder of Fisher Certified Reagent grade (labeled "95.8%" via an analysis which did not include oxygen), Matheson, Coleman, and Bell reagent grade iron oxide (Fe_2O_3) of 99% purity, and Baker Analyzed Reagent titanium dioxide powder, whose analyzed-for impurities totaled 0.0581%. X-ray powder diffraction was used to identify phases present in electrode and electrolyte materials.

Dense, ⅛ in. thick, ½ in. diameter disks of metal-to-oxide mole ratio 5:1, pressed at 3 kbar, functioned as the electrodes in the Nb,NbO//Fe,Fe_xO cell. The NbO phase was prepared by sintering the appropriate mixture of Nb,Nb_2O_5 at 1300°C for 12 hr in an inductively heated tungsten crucible within an evacuated quartz-walled chamber. The Fe,Fe_xO electrode was generated *in situ* from an Fe,Fe_2O_3 disk by holding the cell at 750°C overnight prior to any emf measurements.

The coexisting phases Ti_2O_3,Ti_3O_5 were prepared by vacuum sintering the appropriate mixture of Ti + TiO_2 at 900°-1500°C for 12 hr. The O/Ti ratio was found to be 1.63 both before and after use, by combustion in air at 1000°C to a product taken to be stoichiometric TiO_2. A mechanically sound Ti_2O_3,Ti_3O_5 disk could not be made, so the Ti_2O_3,Ti_3O_5 powder was packed into a flat-bottomed, 7.5 w/o YDT tube to function as the upper electrode in the Nb,NbO//Ti_2O_3,Ti_3O_5 cell. The tube had a nominal wall thickness of 1/16 in. and outside diameter of ½ in. A new electrolyte disk and the previously used Nb,NbO electrode completed the cell.

Powders obtained by crushing Zircoa (Zirconium Corporation of America, Solon, Ohio) slipcast YDT electrolyte tubes were used in preparing electrolyte disks of nominal composition 7.5 and 15 w/o yttria. Isaacs (18) has discussed the impurity level of such YDT. The disks were pressed at 3 kbar and densified by sintering in vacuum at 2000°C for 4 hr followed by firing in air at 1200°C. Disks of ½ in. diameter and ⅜ in. thickness, of densities 9.2 and 7.2 g/cm³ [103 and 92% of theoretical density (19)] were obtained.

The 7.5 w/o YDT tubes received from Zircoa were found by x-ray diffraction to contain detectable amounts of a second phase identified as thoria. However, the second phase was not detected in the electrolyte disks prepared by us.

The emf apparatus is shown in Fig. 1. A cell was supported in the inductively heated tantalum furnace tube and electrical contact to each electrode was made by a disk of platinum foil to which the bead of a platinum, platinum-10% rhodium thermocouple was attached. All insulators and cell supports were of recrystallized alumina. Springs at the top and bottom pushed the assembly together. A second concentric tantalum tube within the furnace tube shielded cells from the high frequency field. The environment of the cell and furnace was a clean dynamic vacuum, routinely 10^{-6} Torr.

A Rubicon precision potentiometer alone, or in combination with a Cary Model 31-CV vibrating reed electrometer, with appropriate filtering (14, 20) to remove high frequency signals, was used to measure emf's. No interference by the high frequency field was observed in cell emf measurements reported here. Cells containing the Ta,Ta_2O_5 electrode had been found to display high emf's within this apparatus when the induction coil was energized (20), presumably because of rectification by tantalum oxide films on tanta-

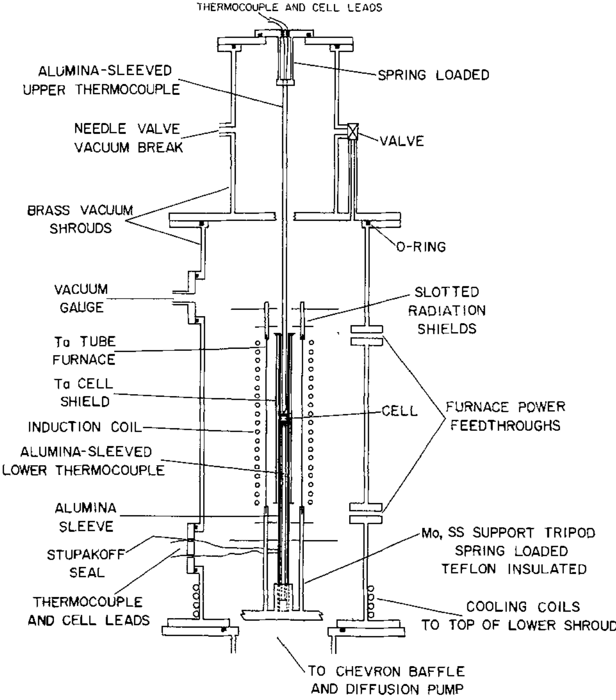

Fig. 1. High temperature inductively heated emf apparatus

lum. Temperatures have an estimated precision of ± 1° and uncertainty of ± 4°. The latter estimate includes an observed temperature gradient of from zero degree at 1100°K to 4° at 1400°K. Two runs were made with each cell. The emf data were taken after equilibration at temperatures both sequentially increased and decreased. Equilibration times were from 1.3 to 25.6 hr with the majority less than 3 hr. Both cells were still operating excellently after a total time at 900°K or above of approximately one week.

Apparently reversible, and clearly reproducible, emf's were displayed by the cells. Somewhat less scatter in the cell emf's, and also distinctly shorter equilibration times, were evident above about 1250°K. The Fe,Fe_xO electrode of the cell Nb,NbO/YDT/Fe,Fe_xO literally welded itself to the electrolyte disk, with staining of the YDT occurring to a depth of 80 μm. Others (21, 22) have previously reported similar phenomena. An electron microprobe study was made of a section sliced perpendicularly through the Fe,Fe_xO-YDT interface. Although the study was somewhat inconclusive due to excitation of the elements by secondary x-rays produced within the sample, no convincing evidence was obtained for diffusion of Fe into the electrolyte or Y into the Fe,Fe_xO disk. No gradient of Y, Fe, or O was detected near the interface and no evidence was found for formation of other phases such as the $YFeO_3$ reported by Worrell (21).

In the study of Ti_2O_3,Ti_3O_5, considerable coloration was developed by the YDT. However, no evidence was obtained for formation of any new phase such as, for example, $YTiO_3$ (23).

Results and Discussion

The data obtained in this laboratory for the cells Nb,NbO/YDT (15 w/o yttria)/Fe,Fe_xO and Nb,NbO/YDT (7.5 w/o yttria)/Ti_2O_3,Ti_3O_5 are plotted, respectively, in Fig. 2 and 3.

The raw data for the cell Nb,NbO//Fe,Fe_xO from 1089° to 1426°K when fit by an unweighted least squares analysis yield

$$E(\text{obs, mV}) = (797.9 \pm 5.6) - (0.1312 \pm 0.0044)T(\text{K}) \quad [1]$$

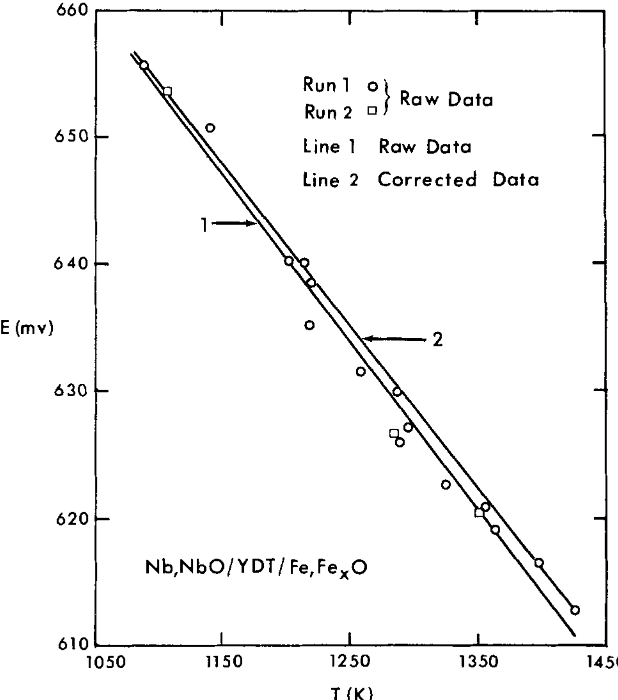

Fig. 2. Emf of cell Nb,NbO/YDT(15 w/o yttria)/Fe,Fe_xO vs. temperature. Line 1, least squares fit to data as measured (Eq. [1]); line 2, least squares fit to data adjusted for solubility of O in Nb (Eq. [2]).

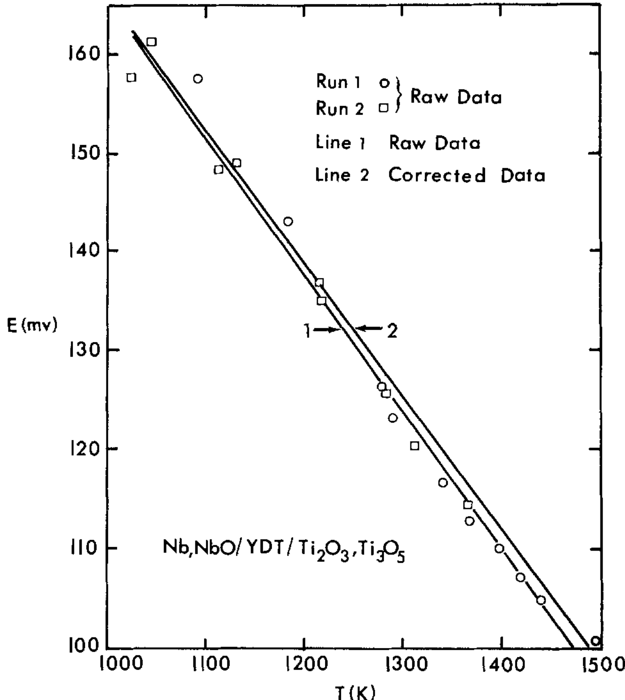

Fig. 3. Emf of cell Nb,NbO/YDT (7.5 w/o yttria)/Ti_2O_3,Ti_3O_5 vs. temperature. Line 1, least squares fit to data as observed (Eq. [7]); line 2, least squares fit to data adjusted for solubility of O in Nb (Eq. [8]).

To obtain the standard free energy of formation of NbO, the emf data were corrected point by point for the solubility of oxygen in niobium, giving

$$E(\text{corr, mV}) = (794.3 \pm 5.7) - (0.1275 \pm 0.0044)T(\text{K}) \quad [2]$$

Uncertainties in slopes and intercepts in these and subsequent equations are standard deviations. The emf's have standard deviations about the line of ±1.7 and ±1.8 mV in [1] and [2], respectively. The correction for oxygen solubility was made by using Bryant's solubility data (24) and assuming that Henry's law is valid for oxygen dissolved in niobium, while Nb obeys Raoult's law. Thus

$$E(\text{corr}) = E(\text{obs}) - (RT/n\mathbf{F}) \ln X_{\text{Nb}} \quad [3]$$

This correction amounts to at most 1.8 mV at 1426°K.

Correspondingly, from the Nernst relation $\Delta G = -n\mathbf{F}E$

$$\Delta G^\circ_{1/2\,O_2}(\text{cell}) = (-36{,}640 \pm 260) + (5.88 \pm 0.20)T(\text{K}) \pm 80 \text{ cal} \quad [4]$$

The value of Faraday's constant $\mathbf{F}$ was taken to be 23.061 cal/mV-equiv. Using the relationship for the free energy of formation of the iron-rich wüstite phase from 873°-1600°K derived by Steele and Alcock (25) from the work of Darken and Gurry (26)

$$\Delta G^\circ_f(Fe_xO) = -63{,}235 + 15.63T(\text{K}) \pm 125 \text{ cal mole}^{-1} \quad [5]$$

it was found that

$$\Delta G^\circ_f(\text{NbO}) = -99{,}870 + 21.51T(\text{K}) \pm 150 \text{ cal mole}^{-1} \quad [6]$$

for 1089°-1426°K.

Tabulated in Table I are values of ΔG°_f(NbO) which were calculated from the above relationship, from a study representative of the literature on the same cell, that of Ignatowicz and Davies (27), values from Worrell's results (21) based on cells different from the one studied here, along with those published by JANAF Thermochemical Tables (17). Also tabulated for comparison are values of $\overline{\Delta G}_{1/2\,O_2}$ for the coexisting

** Corrected as herein for the solubility of oxygen in niobium.

phases Nb,NbO calculated from Eq. [1] and [5]. Worrell's first relationship was derived from $\Delta G°_f(NbO_2)$ (28) and $\Delta G°_f(Fe_xO)$ (29) obtained from reviews in the literature along with data from the cells $NbO_2,Nb_2O_{4.8}//Fe,Fe_xO$ and $NbO,NbO_2//NbO_2,Nb_2O_{4.8}$. His second relationship was derived from the same $\Delta G°_f(NbO_2)$ (28) and data from the cell Nb,NbO//NbO,NbO_2. JANAF (17) has adopted $\Delta H°_{f,298}$ based on the average of those from seven equilibrium (emf) studies. Five of these, including that of Ignatowicz and Davies (27), were of the cell Nb,NbO//Fe,Fe_xO. Worrell's data (21) for the cell Nb,NbO//Ta,Ta_2O_5 were also used. It is evident that the values tabulated for $\Delta G°_f$(NbO) in Table I agree within better than 1% for 1100°-1400°K. Note that $\Delta G°_f(Fe_xO)$ of Steele and Alcock (25) and that adopted by Blumenthal and Whitmore (29), which was used by Worrell (21) and by Ignatowicz and Davies (27), agree within 33 cal in this range. JANAF (17) has tabulated $\Delta G°_f(Fe_{0.947}O)$, incorrectly implying a constant lower phase boundary composition for wüstite (26, 30), which are approximately 100 cal more negative than the other data. Giddings and Gordon (30, 31) in presenting the latest analysis on oxygen activities and phase boundaries of wüstite and of the use of Fe,Fe_xO electrode, prefer the equation for $\Delta G°_f(Fe_xO)$ of Rizzo *et al.* (32), which gives values at 1100° and 1400°K, respectively, 220 and 80 cal more positive than those chosen here.

The excellent agreement of our results for $\Delta G°_f$(NbO) with those in the literature is taken as evidence that our apparatus and technique are giving valid results, and that the Nb,NbO electrode is a suitable reference for measurements on Ti_2O_3,Ti_3O_5.

The raw data for the cell Nb,NbO//Ti_2O_3,Ti_3O_5 from 1022° to 1495° plotted in Fig. 3 were fit by unweighted least squares to obtain

$$E(\text{obs, mV}) = (303.6 \pm 5.0) - (0.1382 \pm 0.0040)T(\text{K}) \quad [7]$$

while the data corrected for the solubility of oxygen in niobium via Eq. [3] fit the relationship

$$E(\text{corr, mV}) = (300.1 \pm 5.0) - (0.1346 \pm 0.0040)T(\text{K}) \quad [8]$$

The standard deviation of E about the lines in [7] and [8] is ± 2.3 mV. Correspondingly

$$\Delta G°_{1/2\,O_2}(\text{cell}) = (-13{,}840 \pm 230) + (6.21 \pm 0.18)T(\text{K}) \pm 110 \text{ cal} \quad [9]$$

and

$$\Delta \overline{G}_{1/2\,O_2}(Ti_2O_3,Ti_3O_5) = -86{,}030 + 15.30T(\text{K}) \pm 180 \text{ cal} \quad [10]$$

for 1089°-1426°K. For internal consistency our Eq. [6] for $\Delta G°_f$(NbO) was used in deriving this equation.

Tabulated in Table II are values of $\Delta \overline{G}_{1/2\,O_2}$ (Ti_2O_3,Ti_3O_5) which were calculated from the above relationship, from the graphically presented emf data of Suzuki and Sambongi (9) for the cell $TiO_{1.6}$// Cr,Cr_2O_3, and from the recently revised JANAF Thermochemical Tables (17) for Ti_2O_3(c) and $Ti_3O_5(\beta)$. Suzuki and Sambongi have published the only previous study of Ti_2O_3,Ti_3O_5 by emf techniques. They used the cells $TiO_{1.6}$/YDT/Cr,Cr_2O_3 and Ta,Ta_2O_5/YDT/$TiO_{1.6}$ in a flowing argon atmosphere from 940° to 1740°K. Here, $TiO_{1.6}$ represents several compositions in the range $1.560 < O/Ti < 1.648$ in the Ti_2O_3,Ti_3O_5 two-phase region. They intercompared their Ta,Ta_2O_5 and Cr,Cr_2O_3 reference electrodes directly by means of the cell Ta,Ta_2O_5/YDT/Cr,Cr_2O_3, and both were measured against Fe,Fe_xO from 990° to 1520°K. Unfortunately their emf data and thermodynamic results for the Ti-O system are presented only graphically and they give no indication of how the lines in their figures were drawn among the data points. Their Eq. [20] for $\Delta G°_f(Fe_xO)$ taken from Ref. (20) contains two typographical errors. Numerous inconsistencies exist among their figures and equations. By carefully measuring their published figures and deriving equations from these measurements, we obtained the following equation which we believe to be the best representation of their data for the Ti_2O_3,Ti_3O_5 equilibrium

$$\Delta \overline{G}_{1/2\,O_2}(Ti_2O_3,Ti_3O_5) = -86{,}418 + 15.82T(\text{K}) \text{ cal} \quad [11]$$

As shown in Table II, our free energies and those of Suzuki and Sambongi (9) for oxygen in Ti_2O_3,Ti_3O_5 are in excellent agreement. This supports the validity of both sets of measurements, because different reference electrodes, physical arrangements, and equilibration procedures were employed. Above 1773°K their emf's rapidly dropped because of reaction of the $TiO_{1.6}$ electrode and YDT electrolyte pellets.

The data in Table II calculated from the JANAF Tables (17) for Ti_2O_3(c) and $Ti_3O_5(\beta)$ are derived principally from calorimetric measurements on stoichiometric material. Our emf results agree well (within about 1% in $\Delta \overline{G}_{O_2}$) with these. JANAF ($\alpha$-$Ti_3O_5$ table) (17) notes that the graphical emf data of Suzuki and Sambongi and "the authors' self-consistent data for the reference couples" yield ΔH and ΔS for the reaction

$$3/2\, Ti_2O_3(\alpha,\beta) + 1/4\, O_2 = Ti_3O_5(\alpha,\beta) \quad [12]$$

consistent with JANAF's adopted values. In addition, third law values of $\Delta H°_{298}$ for reaction [12], calculated from Suzuki and Sambongi's data, were in agreement with combustion calorimetric data.

Two further comments should be made in comparing the emf results to the JANAF data. First, use of the JANAF table for $Fe_{0.947}O$ with the emf data would reduce the small differences of Table II by approximately 0.1 kcal per ½ mole O_2. Secondly, $\Delta \overline{G}_{1/2\,O_2}$ for the reference electrode Cr,Cr_2O_3 obtained in Suzuki and Sambongi's work (9) is systematically more positive than the data adopted for that system obtained by JANAF (17) by about 800 cal from 1000° to 1500°K. JANAF apparently did not use the emf work of Suzuki and Sambongi in drawing up their Cr_2O_3 tables, although Suzuki and Sambongi's data on Ti_2O_3,Ti_3O_5 were used by JANAF. However, both we and Suzuki and Sambongi have referenced our cells ultimately to the same free energies for Fe,Fe_xO (25) so that their Cr,Cr_2O_3 and our Nb,NbO couples are in a sense only intermediate standards. JANAF (17) utilized other data of Suzuki and Sambongi's taken with the Cr,Cr_2O_3 reference electrode in drawing up tables for Ti_4O_7. Suzuki's oxygen potentials for oxide pairs in $1.67 < O/Ti < 2.0$ are in agreement with those determined by Merritt *et al.* (10) near 1300°K.

It appears from our results that the upper phase boundary (upb) composition of the Ti_2O_3 phase in equilibrium with the Ti_3O_5 phase from 1089° to 1426°K is not appreciably different from the stoichiometric composition. This is inferred because oxygen potentials we obtained from the equilibrium mixtures agree with those calculated from JANAF (17) for the stoichio-

metric compounds. Ti_3O_5 was shown to be a line phase by Merritt *et al.* (10) near 1300°K from their gas-solid equilibration studies. Vaporization studies above 1800°K by Gilles and Wahlbeck and their co-workers (6-8) showed that Ti_3O_5 vaporizes congruently at the stoichiometric composition, and the reported partial pressures of oxygen for Ti_3O_5 and Ti_2O_3,Ti_3O_5 are compatible with the JANAF extrapolation of lower temperature data for the two stoichiometric compounds. Hence it appears that the upb of Ti_2O_3 deviates little from the ideal composition up to the melting point, and that the phase width $1.49 \leq O/Ti \leq 1.51$ suggested by Andersson *et al.* (33) is not unreasonable and may be too generous.

This conclusion is in marked contrast to the range $1.425 < O/Ti < 1.585$ around Ti_2O_3, shown by Suzuki and Sambongi in their Fig. 14 from 1273° to 1873°K. Their suggested composition range was deduced from a statistical thermodynamic argument patterned after Anderson (34), but the defect model they used is physically unrealistic, the calculated upb is richer in oxygen than $TiO_{1.56}$, one of their two-phase mixtures, the P_{O_2} values at the TiO_{1+x}-Ti_2O_3 phase boundary used in their calculations are probably (15) too low for valid measurement using YDT, and the resulting P_{O_2} at the proposed upb is inconsistent with either our or their emf data. Their suggested composition range for Ti_2O_3 is thus unrealistic.

In conclusion it seems reasonable to accept the thermodynamic data for Ti_2O_3 and Ti_3O_5 as tabulated by JANAF (17), because this recent compilation successfully correlates calorimetric, emf, and vaporization data over a very large range of T and P_{O_2}.

More precisely stated, the JANAF tabulation presents smoothed enthalpy, entropy, and free energy functions from somewhat discordant calorimetric measurements (35, 36), extrapolated to higher temperatures. These may be combined with free energy data from high temperature equilibrium (emf and vaporization) studies to obtain $\Delta H°_{298}$ for the solids which agree satisfactorily with the calorimetric values. However, if P_{O_2} is to be calculated, we recommend direct use of the high temperature equilibrium data, for example, our Eq. [10]. This is because a discrepancy of ±1% in $\Delta\overline{G}_{1/2\,O_2}(Ti_2O_3,Ti_3O_5)$ at, say, 1300°K corresponds to ±14 mV in cell potential, or ± 50% in P_{O_2}.

One remaining source of discrepancy between the emf and tabulated data is the transition from α to β Ti_3O_5 at 450° ± 20°K, for which JANAF (17) estimates $\Delta H°_t = 3.17 \pm$ kcal mole^{-1}, because of some uncertainty in the drop calorimetric measurements (35, 36) and a DTA study (37).

Acknowledgments

This paper is based on a thesis submitted to the University of Iowa by Ronald G. Sommer in partial fulfillment of the requirements for the Ph.D. degree, December 1974, and was reported in part at the 10th Midwest Regional Meeting of the American Chemical Society, Iowa City, November 1974. The work was supported in part by the USAEC through contract AT(11-1)-1182 with the University of Iowa and in part by the National Science Foundation under grant No. GP-33457. We are greatly indebted to Mr. Yasuyuki Ishikawa for translating the article by Suzuki and Sambongi. Dr. F. D. Ingram and Mary Jo Ingram of the Department of Physiology and Biophysics kindly performed the microprobe analysis of our samples.

Manuscript submitted Feb. 24, 1975; revised manuscript received May 19, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Corning Glass Works.

Mechanisms of Decomposition of Organochromium Compounds in the CVD Process. Cycloheptatriene Chromium Tricarbonyl

T. J. Truex, R. B. Saillant, and F. M. Monroe

Ford Motor Company, Dearborn, Michigan 48121

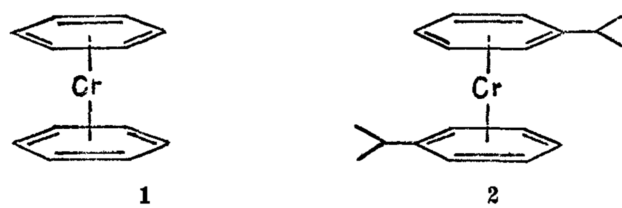
ABSTRACT

A general method for studying the decomposition of organometallic compounds in the low temperature chemical vapor deposition (CVD) process is described. Gas chromatographic and mass spectral analyses have been used to identify volatile by-products from CVD reactions and determine their relationship to deposit composition. The technique, in conjunction with ^{13}C labeling experiments, has been used to determine the mechanism of decomposition of cycloheptatriene chromium tricarbonyl [$(C_7H_8)Cr(CO)_3$]. $(C_7H_8)Cr(CO)_3$ pyrolyzes at temperatures $>$ 300°C to give deposits containing mainly chromium and carbon with small amounts of oxygen present. Reactions involving the CO ligands, including CO disproportionation, make only minor contributions to deposit composition with the majority of deposited carbon ($>$85%) resulting from reactions involving the cycloheptatriene ring. The use of thermogravimetric analysis and differential scanning calorimetry to screen potential CVD compounds is described.

We have undertaken a program to evaluate the use of organometallic compounds in the low temperature chemical vapor deposition (CVD) process for two reasons: to develop general methods for studying the mode of decomposition of these compounds, and to determine the detailed mechanism(s) of decomposition of selected organochromium compounds.

The use of new organometallic compounds (1) for low temperature ($<$ 550°C) CVD provides the potential of depositing metals, oxides, carbides, or nitrides on light metals, glass, and other materials not resistant to glow temperatures. The development of this process depends upon an understanding of the relationship between process variables (chemical and physicochemical) and deposit compositions and properties (2). In particular, an understanding of the mechanisms of decomposition of organometallic compounds could explain the origins of deposit compositions and conceivably indicate ways to control these compositions.

Several organochromium compounds have been used in the past to deposit chromium, chromium carbide, and/or chromium oxide by the CVD process. Lander and Germer (3) and also Owen and Webber (4) studied the decomposition of chromium hexacarbonyl, $Cr(CO)_6$. Deposits containing varying amounts of Cr, Cr_3C_2, and Cr_2O_3 were obtained depending upon reaction conditions. Decompositions using the bis(arene)-chromium(O) compounds, bis(benzene)chromium(O) **1** (5), and bis(cumene)chromium(O) **2** (6) also produced carbide deposits of varying compositions. Of the latter two systems, the bis(cumene)chromium(O) compound has been the most extensively studied. It decomposes at substrate temperatures between 325° and 550°C producing chromium carbide deposits containing 8-12 weight per cent (w/o) carbon. Mechanistic studies on this compound have been precluded due to the unavailability of pure starting material. Chemical decomposition of commercially available bis(cumene)chromium(O) in this and other laboratories (7) reveals that it is a mixture of bis(arene)chromium(O) compounds containing benzene, cumene, diisopropylbenzenes, and triisopropylbenzene. Recently there has been a report of the preparation of pure bis(cumene)-chromium(O) (8) which we hope to utilize for the preparation of pure samples for mechanistic studies.



A third class of organochromium complexes which has received little attention as a potential source of CVD compounds is the arene chromium tricarbonyls **3** (9). These compounds are of particular interest for mechanistic studies because they incorporate structural features of both the $Cr(CO)_6$ and bis(arene)-chromium(O) systems. Thus, decomposition studies of these systems could reveal reactions involving the CO

Key words: chemical vapor deposition, organochromium, deposit composition, DTA/DSC analyses.

ligands leading to oxide and/or carbide formation as suggested for the metal hexacarbonyls of Cr, Mo, and W (3) and/or carbide formation from decomposition of the arene ligands as implied from results on the bis(arene)chromium(O) systems (5, 6).

3 **4**

Differential thermal analysis (DTA), differential scanning calorimetry (DSC), and preliminary plating studies on a series of arene chromium tricarbonyl compounds (*vide infra*) had also indicated that cycloheptatriene chromium tricarbonyl 4 (10) was a promising candidate for study. It is only slightly air-sensitive under ambient conditions, but thermally decomposes at temperatures > 300°C. It is easily sublimed at 70°C and 1.0 mm pressure.

Results are reported on the mechanism of decomposition of cycloheptatriene chromium tricarbonyl. In addition, general procedures for studying the decomposition of organometallic compounds are presented.

Experimental Procedure

Chemicals.—All organometallic compounds were obtained from Strem Chemicals Incorporated, Beverly, Massachusetts. Comparison of observed melting points, solution infrared, nmr, and mass spectra with literature data indicated all compounds were pure as received.

Apparatus and procedure.—A diagram of the experimental apparatus is shown in Fig. 1. The glass (Pyrex) or aluminum substrate was attached to a graphite block which was heated inductively. The substrate temperature was recorded by a thermocouple imbedded in the block. The pressure was measured with a thermocouple gauge. Condensable gaseous by-products were collected in cold traps at liquid N_2 (−196°C), Dry Ice/acetone (−76°C), or ice-methanol (~ −20°C) temperatures. Noncondensable gaseous by-products were collected in a 1 liter evacuated glass bulb and then pumped via a Toeppler pump into a 50 cm^3 volume.

DTA and DSC were performed under an N_2 atmosphere using a du Pont Model 900 analyzer.

The condensable by-products in the CVD reactions were analyzed by separating the components using a gas chromatograph interfaced with a mass spectrometer. These analyses were done at Shrader Analytical and Consulting Laboratories, Incorporated, Detroit, Michigan.

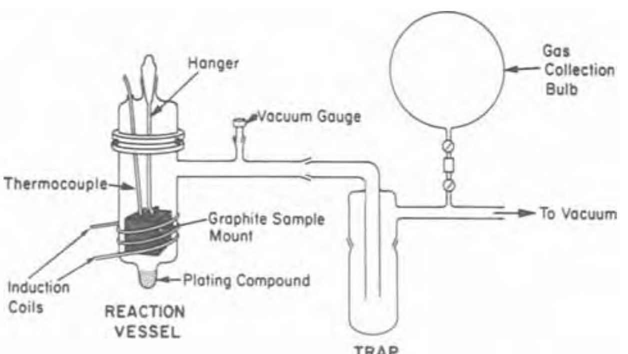


Fig. 1. Schematic diagram of apparatus for studying the mechanisms of decomposition of organometallic compounds.

Mass spectral analyses of the noncondensable gaseous by-products were performed using an Aero Vac Model AVA/61 residual gas analyzer. This instrument was calibrated for intensity *vs.* partial pressure for samples of air, CO, CO_2, H_2, CH_4, and C_2H_4.

Deposit compositions were determined by electron microprobe analyses.

In a typical plating run the following procedure was used. The reaction vessel was charged with the plating compound, the substrate/graphite holder was attached and the apparatus evacuated to the desired pressure. The induction furnace was then turned on and the substrate heated to the plating temperature. After the substrate temperature was stabilized, a preheated oil bath was placed around the bottom of the reaction vessel causing the complex to sublime. The condensable by-products were collected in the cold trap as described above. Noncondensable gases were collected in a 1 liter evacuated flask as described previously. All of the experiments with cycloheptatriene chromium tricarbonyl were done with a sublimation temperature of 70°C and a pressure of ~0.3 mm Hg on glass (Pyrex) or aluminum substrates.

^{13}CO labeling experiment.—The ^{13}CO exchange reaction described below is similar to that used to prepare the substituted compounds $(C_7H_8)Cr(CO)_2X$, where X is triphenylphosphine or triphenylphosphite (11). 6.84g (30 mmole) of cycloheptatriene chromium tricarbonyl was dissolved in 150 ml of degassed cyclohexane (distilled under N_2 from CaH_2). This was placed in a Vycor reaction vessel, with care taken to exclude air, and attached to a vacuum line. After several freeze-thaw cycles under vacuum, 100 cm^3 at 0.7 atm of 90% enriched ^{13}CO (Stohler Isotopes Incorporated) was introduced. The exchange reaction was allowed to proceed at room temperature under 3500Å irradiation for 36 hr. The reaction was then stopped, the solution frozen, and the gases above it replaced with a fresh supply of 90% enriched ^{13}CO (100 cm^3 at 0.5 atm). The reaction was then allowed to proceed an additional 36 hr under the same conditions as above. At the end of this period the gases above the solution were again replaced with a fresh supply (350 cm^3 at 0.36 atm) and irradiation continued for a final 36 hr. The solution was filtered under N_2 and the product isolated by evaporation *in vacuo*. The extent of enrichment was determined by mass spectroscopic analysis. The parent ion region was analyzed for increases due to ^{13}CO-containing species and the ratio of ^{13}CO and ^{12}CO was determined by analysis of the $m = 29$ and $m = 28$ peaks. The reaction can be followed qualitatively by monitoring the appearance and growth of a ^{13}CO stretching band at 1855 cm^{-1} (cyclohexane solvent) in the infrared spectrum. Two samples of labeled compound were prepared; one contained 7.5% ^{13}CO and the other 8.7% ^{13}CO.

Results and Discussion

Selection of potential CVD compounds.—The quick and systematic evaluation of potential CVD compounds is a continuing problem for new materials. DTA and DSC show promise as reliable screening techniques which provide sublimation and decomposition data. A linear correlation was observed, Fig. 2, when the initial decomposition temperatures were plotted against the minimum plating temperatures[1] under CVD conditions. The less-than-unity slope results from the difference between the DTA/DSC measurements and our criterion for "initial plating." These data led to the study of cycloheptatriene chromium tricarbonyl. In the future, these DTA/DSC studies will be extended to a number of other classes of compounds to determine if the observed correlation persists.

Experimental procedure and rationale.—Figure 3 represents the interaction between product and process

[1] For CVD this is necessarily qualitative and arbitrary. For our purposes it is the minimum substrate temperature at which a uniform opaque deposit forms during 30 min of reaction time.

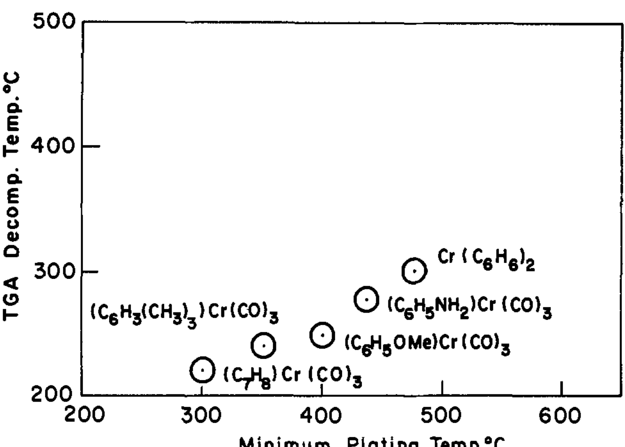

Fig. 2. Plot of DTA/DSC decomposition temperature vs. minimum CVD decomposition temperature.

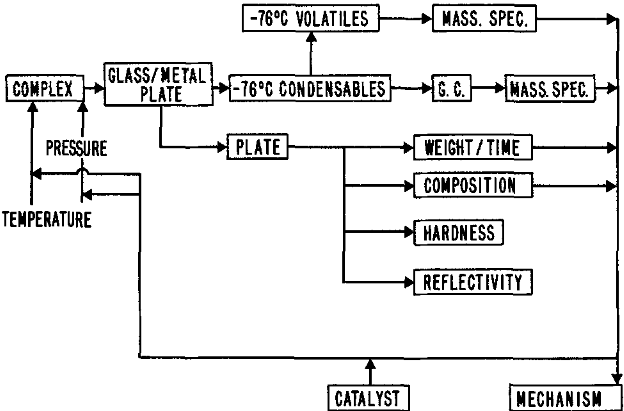

Fig. 3. Schematic representation of relationship between products and process variables in the CVD process.

variables. In this study we have controlled the pressure, and the substrate and sublimation temperatures. For a given set of these variables a deposit is formed which can be analyzed for different properties, some of which are shown. The property of interest for this study was coat composition. The reaction by-products can be experimentally separated into condensables and noncondensables by varying trap temperatures and analyzed as described in the experimental section. This procedure allows the correlation of deposit properties (composition) and reaction by-products with plating compound and variables from which a mechanism can be deduced.

The principle behind this approach is mass balance. Thus, a change in deposit composition must be accompanied by corresponding variations (molecular and/or concentration) in reaction by-products. Isotopic labeling has also been used in the present study to complement mass balance information and unambiguously identify specific carbon sources.

Results of decomposition studies on cycloheptatriene chromium tricarbonyl $(C_7H_8)Cr(CO)_3$.—$(C_7H_8)Cr(CO)_3$ is a slightly air-sensitive red crystalline solid which must be stored in an inert atmosphere but can be handled in air for short periods of time without noticeable decomposition. Its volatility is high enough that adequate sublimation rates are obtained at temperatures $\geq$70°C. Rapid pyrolysis of $(C_7H_8)Cr(CO)_3$ occurs at temperatures $\geq$300°C. The temperature range which produces uniform, smooth, continuous, adherent, mirror-bright films is 350°-450°C. Below 350°C some spontaneous peeling of the film from Pyrex glass substrates is observed (this problem has not been encountered with aluminum substrates) and above 500°C formation of a black sooty material in the reaction chamber indicates that some of the vapor decomposes before it reaches the hot substrate. Although all deposition studies were conducted at a sublimation temperature of 70°C and a pressure of 0.3 mm Hg, it is probable that the optimum substrate temperatures will change as a function of other variables. We have not explored this possibility in detail but have instead chosen to vary substrate temperature while holding all other variables constant in an attempt to simplify the mechanistic analysis. The substrate temperature range studied was 300°-600°C.

The deposited films were analyzed for Cr, C, and O by electron beam microprobe analyses. The results show that deposits formed from $(C_7H_8)Cr(CO)_3$ decomposition in the 300°-600°C range contain mainly chromium and carbon with smaller amounts of oxygen. Average chromium and carbon contents [atomic per cent (a/o)] as a function of temperature were as follows:

300°C	63.6 a/o Cr	28.4 a/o C
400°C	62.4 a/o Cr	32.5 a/o C
500°C	58.8 a/o Cr	36.0 a/o C
600°C	59.1 a/o Cr	32.1 a/o C

Although quantitative oxygen analyses were not performed on all samples, in the analyzed samples oxygen accounted for the remainder of the film. In addition, no foreign elements other than chromium, carbon, or oxygen were detected in any of the films. These results show a fairly uniform composition throughout the temperature range with somewhat higher oxygen contents at both extremes of temperature. A poorly defined x-ray pattern was obtained for one deposit laid down at 600°C. The pattern could be associated with Cr_7C_3 although some known lines were absent. All other film deposits were amorphous. This type of behavior has been noted previously in chromium carbide films deposited at low temperatures (6b) where it was observed that annealing leads to crystallization. This has not been tried with films produced by $(C_7H_8)Cr(CO)_3$ decomposition since the major interest has been in as-deposited films. Of primary interest is the source of the deposited carbon and oxygen found in these films.

The variation in condensable by-products for $(C_7H_8)Cr(CO)_3$ decomposition in the temperature range 300°-600°C is shown in Fig. 4. The relative proportion of the major component, cycloheptatriene, steadily decreases as the deposition temperature is increased. However, the relative proportions of benzene, toluene, cycloheptadiene, and styrene increased with temperature. The benzene and cycloheptadiene concentrations pass through maxima at ~500°C. This may indicate secondary reactions involving decomposition of these compounds above 550°C. Benzene decomposition has been noted in other CVD studies at temperatures >500°C (5b).

The major component of the noncondensable by-products was CO, with the second largest component being H_2 [~10-15 molecular per cent (m/o) of the noncondensable gas fraction]. Minor components of methane and ethylene were observed together with trace amounts of CO_2 (0-2 m/o) and C_2 and C_3 hydrocarbons. It was noted that the relative compositions of the noncondensable by-products do not vary in a significant manner throughout the 300°-600°C temperature range.

The appearance of the different chemical species found in the condensable by-products implies that the net chemical reactions presented in Fig. 5 are taking place during decomposition. Only benzene formation involves a loss of carbon and is therefore a possible source of deposited carbide. The other reactions involve no net change in carbon or, as in the case of styrene, the addition of one carbon atom. The carbon loss through benzene formation is ~7-10 a/o between 300°-400°C and ~20-30 a/o at decomposition temperature >450°C. Since styrene formation, and the associated carbon addition in this reaction is ~0-2 m/o throughout the decomposition temperature range, the

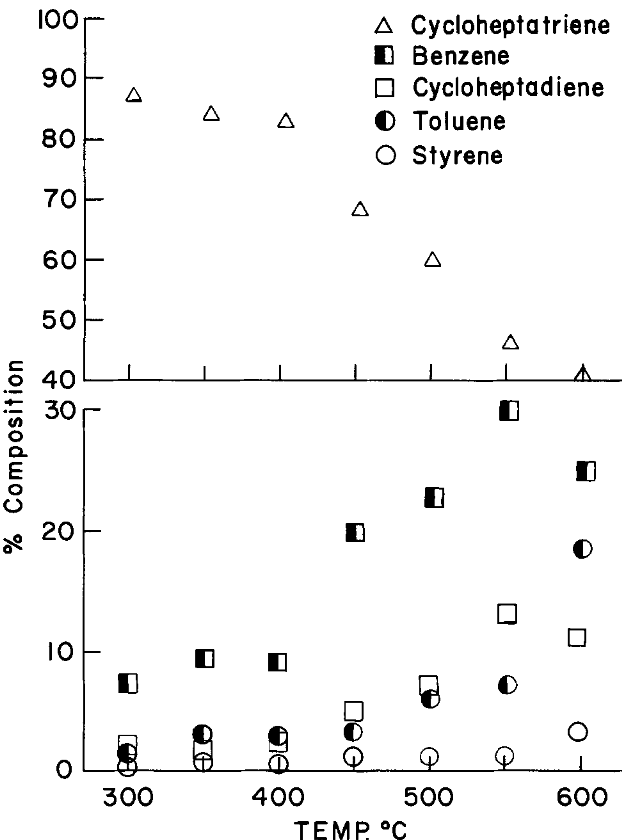

Fig. 4. Variation of condensable by-products for $(C_7H_8)Cr(CO)_3$ decomposition in the temperature range 300°-600°C.

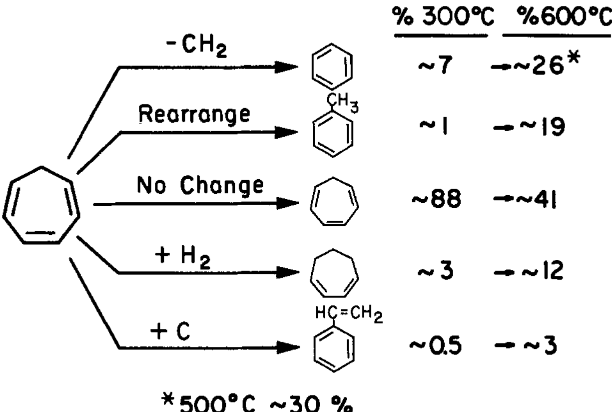

Fig. 5. Chemical reactions implied by the formation of condensable by-products in $(C_7H_8)Cr(CO)_3$ decomposition

majority of the carbon freed in the benzene reaction is available for carbide formation. Thus, below 400°C the benzene reaction can account for ~25-30% of the deposited carbon and above 400°C it can account for ~55-95% of deposited carbon.

The noncondensable gas results provide a complement to the condensable by-product conclusions. First, the absence of considerable amounts of CO_2 indicates that the CO disproportionation reaction proposed as a source of carbon formation in the decomposition of other carbonyl containing organometallics (3) is not significantly operative. This does not completely rule out participation of CO in deposit formation by some reaction pathway other than disproportionation. This point will be raised again during discussion of results from ^{13}C labeling experiments. The second point involves the large H_2 component seen in the noncondensable gas fraction. This implies that considerable reaction involving cycloheptatriene is taking place. Part of this is explained by the benzene formation reaction mentioned previously, but this will not account for all of the H_2 observed, especially below 400°C. This, together with the absence of lower hydrocarbons ($<C_6$), suggests that some total degradation of cycloheptatriene is taking place.

Definitive information on the relative participation of CO and cycloheptatriene in deposit formation has been provided by ^{13}C labeling experiments. ^{13}CO labeled cycloheptatriene chromium tricarbonyl was used for deposition studies at 300°, 400°, and 500°C (runs at 600°C were precluded due to interference from gas phase decomposition). The deposits from these runs were then combusted and the CO_2 given off collected and analyzed mass spectrometrically to determine the $^{13}CO_2/^{12}CO_2$ ratio. The results of these experiments are shown in Table I together with the calculated per cent of observed carbide formation coming from reactions involving CO. These data show that the fraction of carbide formation due to CO was a maximum of ~13% at 400°C with average values of 7.3% at 300°C, 10.0% at 400°C, and 2.0% at 500°C. These results confirm the conclusions drawn from the noncondensable gas analyses. Specifically, CO participation in carbide formation is small compared to that of cycloheptatriene. The presence of 5-9 a/o oxide in the deposits could arise from reaction of the oxygen atom in CO with deposited chromium, or from the presence of residual O_2 in the system which has a background pressure of ~1μ.

Conclusions

As part of an over-all program to determine mechanisms of decomposition of organometallic compounds, a study of the decomposition of cycloheptatriene chromium tricarbonyl has been made. $(C_7H_8)Cr(CO)_3$ decomposes at substrate temperatures of ≥300°C to form deposits on glass and aluminum substrates containing mainly chromium and carbon, with lesser amounts of oxygen present. Mechanistic studies utilizing comparisons of deposit compositions and condensable and noncondensable by-products analyses and ^{13}CO labeling studies allow the following conclusions concerning $(C_7H_8)Cr(CO)_3$ decomposition:

(*i*) Reactions involving CO account for less than 13% of deposited carbon in the deposition pressure and temperature ranges studied.

(*ii*) The majority of deposited carbide comes from the cycloheptatriene ring. Two specific reactions appear to account for this. First, transformation of cycloheptatriene into benzene with loss of a carbon atom and one molecule of hydrogen. This reaction is operative to only a minor extent at low temperatures, but at >450°C it can account for ~55-95% of the deposited carbide. Second, total degradation of cycloheptatriene into carbon and hydrogen. This reaction must be operative throughout the temperature range 300°-600°C, but below 450°C it produces the majority of the carbide formed (~70-75%). It should be noted that in separate experiments pure cycloheptatriene was found not to decompose under the deposition conditions used here. This implies that complexation to chromium activates decomposition, or an initially formed chromium deposit catalyzes the decomposition.

(*iii*) Several other reactions of cycloheptatriene which do not contribute to deposit formation were observed. These included formation of toluene, cycloheptadiene, and styrene.

Table I. ^{13}C labeling experiment results

Deposition temperature, °C	Per cent ^{13}CO in $(C_7H_8)Cr(CO)_3$	Per cent ^{13}C in deposit (range)	Per cent of deposited carbon from CO (range)
300	7.5	1.57(1.49-1.67)	7.3(6.1-8.9)
400	7.5	1.74(1.56-1.92)	10.0(7.2-13.0)
500	8.7	1.25(1.10-1.35)	2.0(0.0-3.3)

(*iv*) The presence of small amounts of oxygen in the films suggests some reaction of deposited chromium with oxygen from CO and/or background O_2 in the reaction system.

This study demonstrates the utility of the experimental approach used in determining mechanisms of decomposition of organometallic compounds in the CVD process. In the future these studies will be extended to other arene chromium tricarbonyl compounds and also other classes of organometallic compounds with the goal of developing thermodynamic models for the prediction of decomposition mechanisms of these systems.

Theoretical Aspects of the Peltier Effect on the Temperature Distribution in Crystal Grown by the Czochralski Technique

S. Vojdani, A. E. Dabiri, and M. Tavakoli

Materials and Energy Research Center, Arya-Mehr University of Technology, Tehran, Iran

ABSTRACT

A theoretical treatment is given for the temperature distribution in a Czochralski system with and without the presence of the Peltier effect. The effect of Peltier heating on the crystal diameter during growth is also considered. The results indicate that the Peltier current necessary to control a given diameter of a crystal during intermediate stages of growth is dependent on T_c, the crucible temperature, and h_c, the height of crucible above the melt.

Recently the use of the Peltier effect has been reported for the control of the diameter of pulled Ge crystals (1). The effect has also been used in connection with modulation of dopant segregation in Czochralski-grown InSb (2). The Peltier effect is produced at the solid-liquid interface without time lag and can be reversed by reversing the current through the crystal.

Some theoretical attempts have been made to determine the solid-liquid interface shape (3) and the temperature distribution in the axial direction of a crystal and the melt in a Czochralski crystal growth system (4, 5) by solving computationally the steady-state heat transfer equation. In such computations the convective processes in the melt are generally ignored. In practice crystal rotation in Czochralski technique is introduced to provide a forced convection flow in the liquid, which tends to isolate the interface from thermal convection in the bulk liquid.

The objective of this paper is to investigate theoretically the effect of Peltier heating at a solid-liquid interface on such parameters as temperature distribution in the solid and the melt, temperature gradients in the solid and the melt, and in particular the control of crystal diameter.

Key words: crystal growth, Peltier effect, temperature distribution in solid, Czochralski technique.

Theoretical Method

The crystal growth arrangement used for the present analysis is shown schematically in Fig. 1.

Assumptions made in solving the heat transfer equation are as follows: (*i*) The heat loss from the crystal and the melt is only through radiation. (*ii*) Convection in the melt is neglected. (*iii*) Joule heating due to the Peltier current in the crystal and the melt for normally used current densities ($\sim$20 A-cm^{-2}) is neglected (6).[1] (*iv*) Thickness of the crucible wall is neglected. (*v*) The interface is assumed to be planar.

[1] The resistivity of the solid Ge, ρ_s, at the melting point is $\sim 10^{-3}$ ohm-cm; that of the liquid, ρ_L is about 1/5 this value. Assuming a normally used current density ($\sim$ 20 A-cm^{-2}), the Peltier heat at the interface is 1.7 W-cm^{-2} while the Joule heat in the solid and the liquid within 5 mm of the interface is 0.2 and 0.04 W-cm^{-2}, respectively.

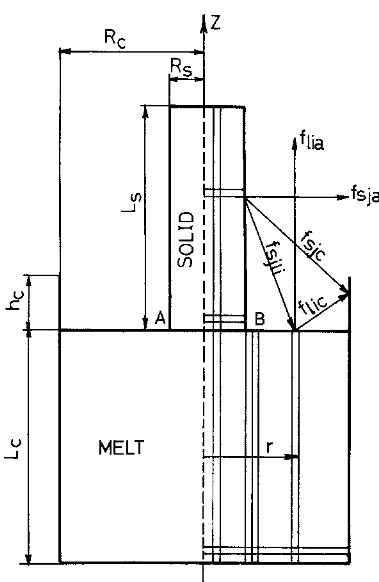

Fig. 1. Schematic diagram of crystal growth arrangement (L_c = 5 cm, L_s = 5 cm, R_c = 2.5 cm, R_s = 1 cm).

Assuming that the steady-state condition for the temperature distribution in the crystal and the melt is governed by the Laplace equation, and using the notation in the Appendix 1, we have

$$\frac{\partial^2 T}{\partial r^2} + \frac{1}{r}\frac{\partial T}{\partial r} + \frac{\partial^2 T}{\partial Z^2} = 0 \quad [1]$$

Subject to the following boundary conditions:
On the crystal axis by symmetry we have

$$\frac{\partial T}{\partial r} = 0 \quad [2]$$

On the crystal side surfaces

$$-K_s \left(\frac{\partial T}{\partial r}\right)_{sj} = q_{sj} \quad [3]$$

where q_{sj} is the net heat flux radiated from a point j on the side surface of the crystal and is given by

$$q_{sj} = \epsilon_s \sigma \left[\sum_{i=1}^{n} \epsilon_l f_{sjli}(T_{sj}^4 - T_{li}^4) + \epsilon_c f_{sjc}(T_{sj}^4 - T_c^4) + f_{sja}(T_{sj}^4 - T_a^4) \right] \quad [4]$$

In the above expression f's are the geometry factors between any two points in the growth arrangement as shown in Fig. 1. The exact calculation of the geometry factors are given in Appendix 2.

Furthermore

$$-K_s \left(\frac{\partial T}{\partial Z}\right)_{Z=L_s} = q_{ti} \quad [5]$$

where q_{ti} is the net heat flux radiated from a point i on the top surface of the crystal and is given by

$$q_{ti} = \epsilon_s \sigma (T_{si}^4 - T_a^4) \quad [6]$$

on the melt free surface

$$-K_l \left(\frac{\partial T}{\partial Z}\right)_{Z=0} = q_{li} \quad [7]$$

where q_{li} is the net heat flux radiated from a point i on the free surface of the liquid and is given by

$$q_{li} = \epsilon_l \sigma \left[\sum_{j=1}^{m} \epsilon_s f_{lisj}(T_{li}^4 - T_{sj}^4) + \epsilon_l f_{lic}(T_{li}^4 - T_c^4) + f_{lia}(T_{li}^4 - T_a^4) \right] \quad [8]$$

and on the solid-liquid interface we have

$$-K_s \left(\frac{\partial T}{\partial Z}\right)_{Z=0} = -K_l \left(\frac{\partial T}{\partial Z}\right)_{Z=0} + LG + Q_P \quad [9]$$

where Q_P is the heat flux given to the interface by the Peltier heating current and is given by

$$Q_P = \alpha I_P T_m \quad [10]$$

Finally on the point A and B of Fig. 1

$$T = T_m$$

Solving Eq. [1] computationally with the above-mentioned boundary conditions, the following results can be obtained: (*i*) temperature distribution inside liquid and solid with and without Peltier effect, (*ii*) temperature gradients inside solid and liquid with and without Peltier effect, (*iii*) crucible temperature for a desired diameter with a given h_c (it should be noted that T_c is not taken as a boundary condition), (*iv*) the amount of Peltier current required to keep the diameter constant (with a given initial h_c), and (*v*) the crucible temperature changes required to keep the diameter constant with a given initial h_c.

Results

As an example Ge has been chosen. The following representative values were used: T_a = 300°K, T_m = 1210°K, $\epsilon_l = \epsilon_s = 0.2$, K_s = 0.24 W-cm^{-1} deg^{-1}, K_l = 0.71 W-cm^{-1} deg^{-1}, $L = 2.16 \times 10^3$ joule cm^{-3}, R_c = 2.5 cm, L_c = 5 cm, R_s = 1 cm, L_s = 5 cm, $\epsilon_c = 1$, $\alpha = 7 \times 10^{-5}$ V deg^{-1}, and G = 1 mm min^{-1}.

Figures 2 and 3 show the temperature distribution and the temperature gradient along the axis of a 5 cm long crystal with and without application of Peltier heating current. With Peltier current employed (24 A-cm^{-2}) no detectable change is observed in temperature distribution or temperature gradient along the axis of the crystal. However when the Peltier current is applied, the T_c must be lowered in order to have the same diameter. Lowering T_c especially for $h_c \geqq 2$ cm has the effect of reducing the temperature difference between the bottom of the crucible and the melt surface along the axis of the crucible. This should tend to reduce convection in the melt. Since even in the presence of Peltier effect and crystal rotation, convection in the melt cannot be completely removed, the result in Fig. 4 can only be approximate. Another effect noticed was the movement of the interface toward the crystal upon the application of Peltier heating.

Control of diameter by Peltier heating.—Figure 5 shows the variation of Peltier current with crystal length for different values of h_c. The curves show that to keep the diameter constant during growth, for a fixed h_c (and therefore T_c), the Peltier current must be increased continuously. The saturation effect seen over longer crystal lengths is related to small variations on total radiation losses from the crystal as the length of the crystal increases. This is shown as a plot of Q_s *vs.* length of the crystal in Fig. 6. It is important to note that the Peltier effect does not change the radiation losses. However since the total area of a crystal increases, therefore the net radiation losses increase and the Peltier effect must compensate this increase of loss. The effect of increasing h_c for a fixed crystal diameter is shown to lower the Peltier current. This is due to decrease of net radiation from the crystal with increasing h_c.

Control of diameter by changing T_c.—Another way to control the diameter of the crystal during growth is to program T_c instead of Peltier current. Figure 7 shows the variation of T_c to keep the diameter of Ge constant with different h_c's.

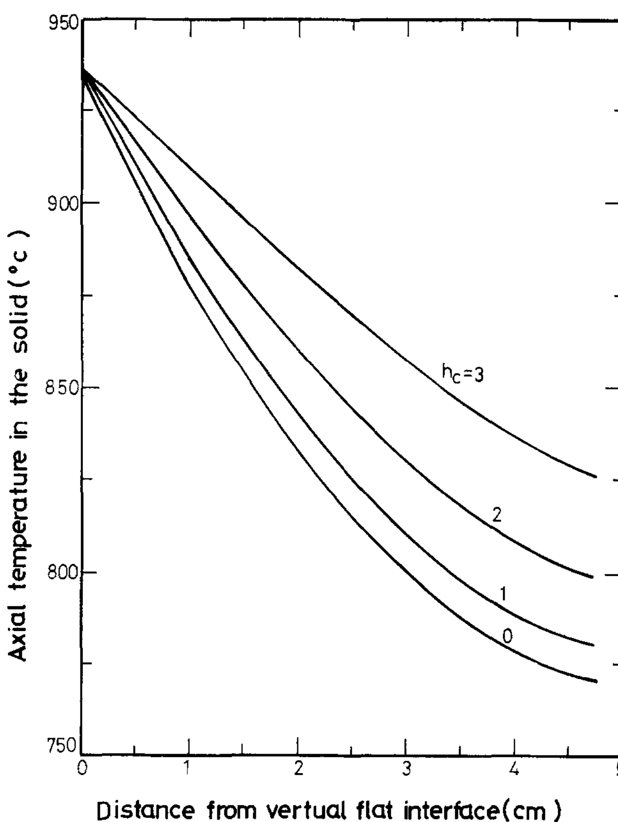

Fig. 2. Axial temperature distribution in the solid *vs.* distance from virtual flat interface.

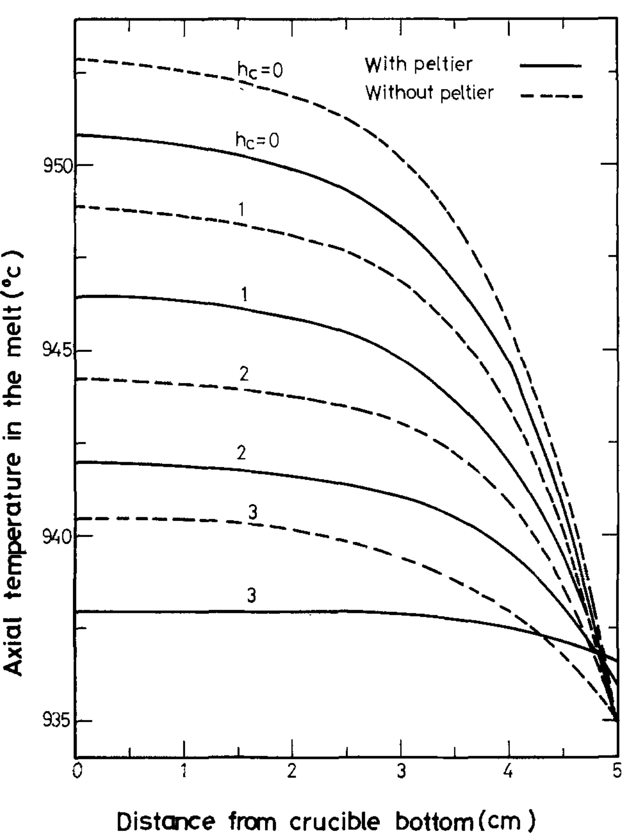

Fig. 4. Axial temperature distribution in the melt *vs.* distance from crucible bottom.

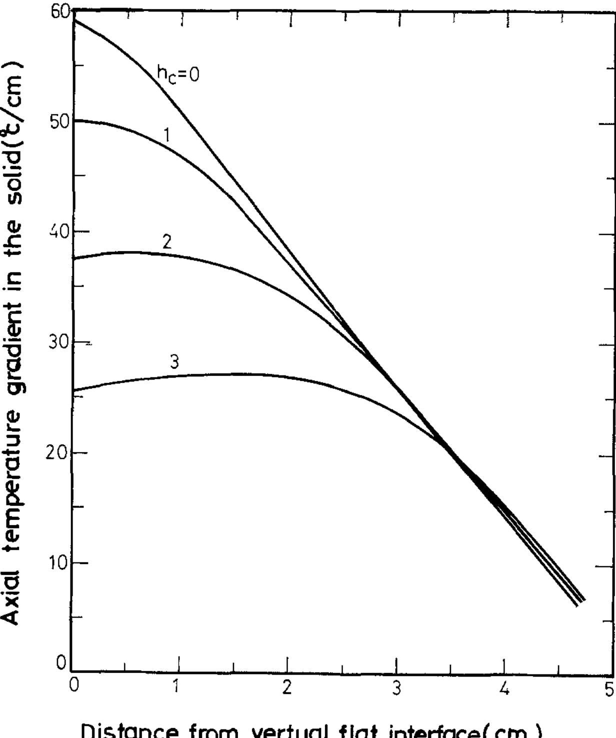

Fig. 3. Axial temperature gradient in the solid *vs.* distance from virtual flat interface.

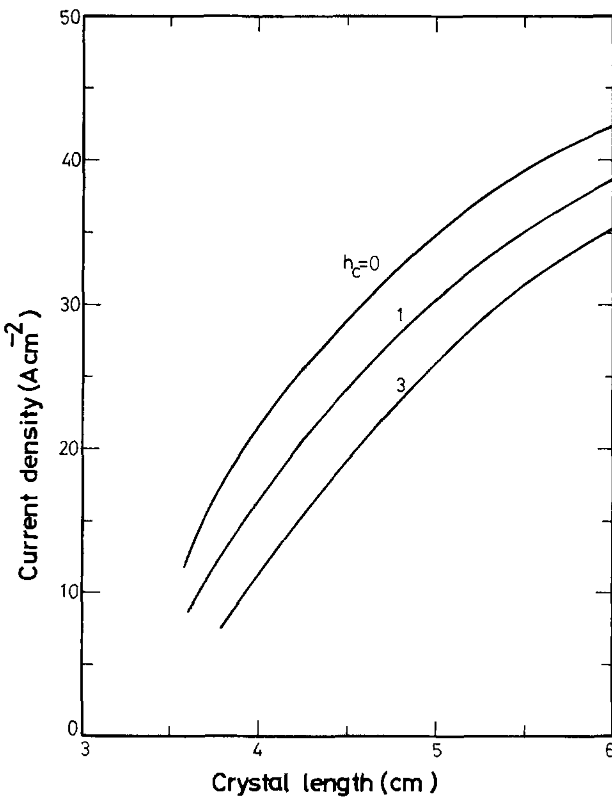

Fig. 5. Variation of current density *vs.* crystal length to control the diameter of the crystal at 2 cm for different h_c.

Conclusion

From the curves shown in Fig. 2-7 it has been demonstrated clearly that:

(*a*) The Peltier heating effect caused at the interface has no appreciable effect on the temperature distribution or gradients in the crystal.

(*b*) For a given diameter and T_c for every h_c the path of increasing the Peltier current to keep the diameter constant can be predicted. It must be noted that for large crystal diameters to keep the Peltier current

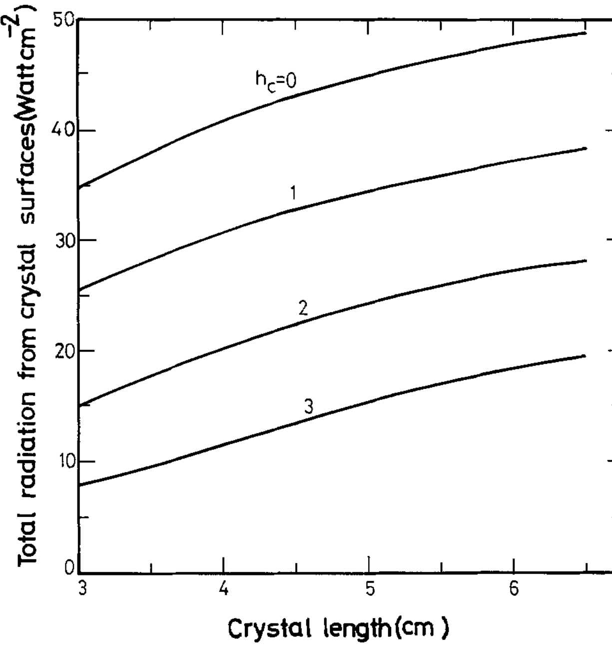

Fig. 6. Variation of total radiation from crystal surfaces with crystal length.

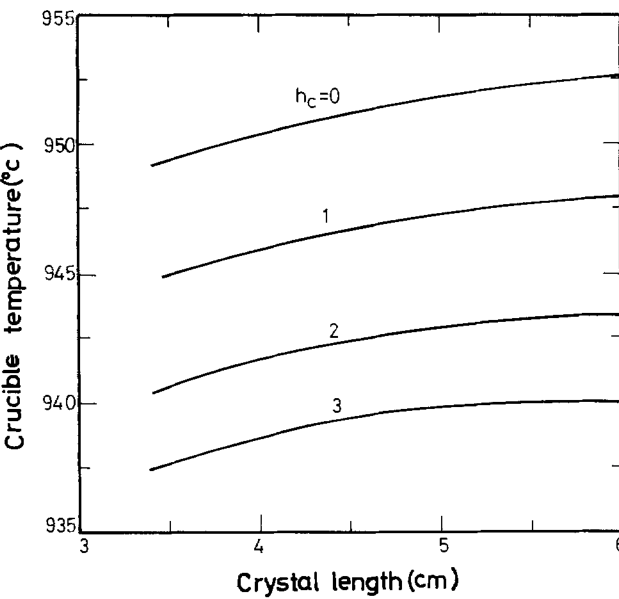

Fig. 7. Variation of crucible temperature with crystal length to control the diameter of the crystal at 2 cm for different h_c.

relatively low for diameter control, higher h_c (essentially an after heater) should be used. The Peltier current necessary for controlling the diameter saturates after, a certain length, a result which is known experimentally.

(c) The same control of crystal diameter can be obtained by changing T_c during growth. This is the process generally used in practice.

Calculation of Geometry Factors

1. $f_{li\to b}$.—The problem is to find the geometry factor of a point li on the melt-free surface and an annulus b. This can be obtained by differentiating $f_{li\to ss}$ (ss denotes solid surface) with respect to Z. $f_{li\to ss}$ is the same as $f_{d\to ss}$. Considering the relations between geometry factors we have

$$2\pi\rho d\rho f_{d\to ss} = 2\pi R_s L_s f_{ss\to d} \quad \text{[A-1]}$$

or

$$f_{d\to ss} = \frac{R_s L_s}{\rho d\rho} f_{ss\to d}$$

but

$$f_{ss\to d} = \frac{\partial f_{ss\to ls}}{\partial \rho}$$

where ls is the subscript for liquid-free surface. From definition of geometry factor, we may write

$$f_{ss\to ls} + f_{ss\to 5} + f_{ss\to(3+4)} = 1$$

but $f_{ss\to ls} = f_{ss\to 5}$ and therefore

$$f_{ss\to ls} = \tfrac{1}{2}\,(1 - f_{ss\to(3+4)}) \quad \text{[A-2]}$$

but

$$f_{ss\to(3+4)} = \frac{R_c}{R_s} f_{(3+4)\to ss}$$

and $f_{(3+4)\to ss}$ is given by (7)

$$f_{(3+4)\to ss} = \frac{R_s}{R_c}\left\{1 - \frac{1}{\pi}\left\{\cos^{-1}\frac{L_s^2 - R_c^2 + R_s^2}{L_s^2 + R_c^2 - R_s^2} - \frac{1}{2R_sL_s}\left[\sqrt{(L_s^2 + R_c^2 + R_s^2) - 4R_s^2R_c^2}\,\cos^{-1}\frac{R_s(L_s^2 - R_c^2 + R_s^2)}{R_c(L_s^2 + R_c^2 - R_s^2)} + (L_s^2 - R_c^2 + R_s^2)\sin^{-1}\frac{R_s}{R_c} - \frac{\pi}{2}(L_s^2 + R_c^2 - R_s^2)\right]\right\}\right\} \quad \text{[A-3]}$$

Substituting Eq. [A-3] into Eq. [A-2], and using Eq. [A-1], we get

$$f_{d\to ss} = f_{li\to ss} = \frac{1}{2\pi}\left[\cos^{-1}\left(-\frac{R_s}{\rho}\right) - \frac{L_s^2 + \rho^2 - R_s^2}{\sqrt{(L_s^2 + \rho^2 + R_s^2) - 4R_s^2\rho^2}}\cos^{-1}\frac{R_s^2(L_s^2 - \rho^2 + R_s^2}{(L_s^2 + \rho^2 - R_s^2)}\right] \quad \text{[A-4]}$$

2. $f_{li\to 3}$.—According to Fig. 8, $f_{li\to 3}$ could be approximated by the following equation

$$f_{li\to 3} = f_{d\to 3} = 1 - f_{d\to 6} - f_{d\to x} \quad [A-5]$$

but

$$f_{d\to 6} = \frac{\partial f_{7\to 6}}{\partial \rho} d\rho$$

and $f_{7\to 6}$ is given by (7)

$$f_{7\to 6} = \frac{h_c^2 + \rho^2 + R_c^2 - \sqrt{(h_c^2 + \rho^2 + R_c^2)^2 - 4\rho^2 R_c^2}}{2R_c^2}$$

$f_{d\to x}$ could be evaluated from Eq. [A-4] where L_s is replaced by x. $\left(x = \frac{h_c}{R_c + \rho} (\rho - R_s)\right.$ if $x < L_s$ and $\left. x = L_s \text{ when } x \geqq L_s\right)$.

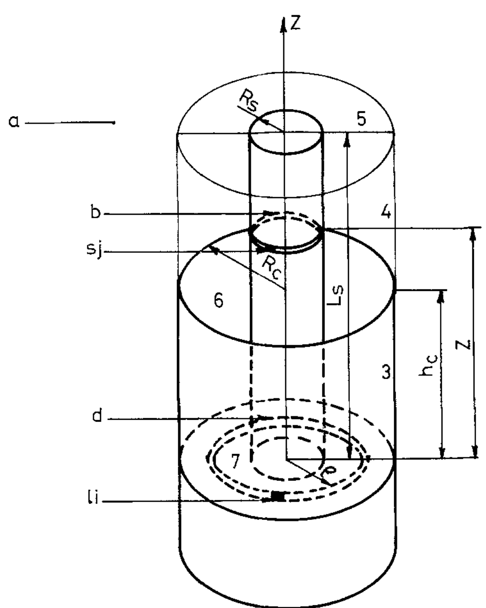

Fig. 8. Schematic diagram of crystal growth arrangement used for calculation of geometry factors.

3. $f_{li\to a}$.—The geometry factor of a point *li* on the melt-free surface and the atmosphere is given by

$$f_{li\to a} = 1 - f_{li\to 3} - f_{li\to ss} \quad [A-6]$$

4. $f_{sj\to d}$.—The problem is to find the geometry factor of a point *sj* on the crystal side and an annulus *d* on the melt-free surface. This can be obtained by differentiating $f_{sj\to ls}$ which is given by (7)

$$f_{sj\to ls} = \frac{1}{2\pi}\left\{ \cos^{-1}\frac{Z^2 - R_c^2 + R_s^2}{Z^2 + R_c^2 - R_s^2} - \frac{Z}{R_c}\left[\frac{Z^2 + R_c^2 - R_s^2}{\sqrt{(Z^2 + R_c^2 + R_s^2)^2 - 4R_c^2R_s^2}} \cos^{-1}\frac{R_s(Z^2 - R_c^2 + R_s^2)}{R_c(Z^2 + R_c^2 - R_s^2)} - \cos^{-1}\frac{R_s}{R_c}\right]\right\} \quad [A-7]$$

5. $f_{sj\to 3}$.—This could be obtained by the following equations

$$f_{sj\to 3} = f_{sj\to 6} - f_{sj\to ls} \quad (\text{if } L_s > h_c)$$

The value of $f_{sj\to 6}$ is obtained from Eq. [A-7] if Z is replaced by $Z - h_c$. And if $L_s < h_c$, then

$$f_{sj\to 3} = 1 - (f_{sj\to 6} + f_{sj\to ls})$$

6. $f_{sj\to a}$.—

$$f_{sj\to a} = 1 - (f_{sj\to ls} + f_{sj\to 3})$$

Technical Note

Mass Spectrometric Analyses of Vapor in Chemical Vapor Deposition of Alumina

Sin-Shong Lin

Army Materials and Mechanics Research Center, Watertown, Massachusetts 02172

Current interest in improving techniques to fabricate a thick layer of translucent to transparent polycrystalline alumina with superior optical properties prompted the present investigation of the vapor phase composition in the preparation of alumina. Previous studies (1-3) relied mostly on analyses of deposits after the completion of a run. The present study extracts gaseous species directly from the deposition reaction, which may furnish basic information concerning vapor molecules existing in the reaction. The sampling of vapors from the process is accomplished by direct injection of these species from the hot furnace into vacuum followed by mass spectrometric detection. Thus the knowledge gained from vapor constituents of the reaction together with examination of the deposits provides valuable information in understanding the chemical deposition process.

Figure 1 shows a block diagram of the sampling device for the chemical vapor deposition of aluminum oxide by hydrolysis-oxidation of aluminum chloride. The experimental arrangement consists of gas inlet lines, a miniature chemical vapor deposition furnace, and a three-stage differential pumping system including a quadrupole mass filter and a modulated beam mechanism. Aluminum chloride is prepared by passing chlorine-hydrogen mixture in a 1:3 ratio over molten aluminum, and water vapor-oxygen mixture in a 1:4 ratio is obtained by bubbling oxygen through water at room temperature. Hydrogen as a carrier gas in the first mixture, reacts with oxygen at temperatures of the deposition to produce more water. Excess oxygen is used to avoid incomplete oxidation of the aluminum chlorides, and water is added not only to serve as a reactant but also to improve transparency of deposited materials. For the deposition reaction, these two gas mixtures are separately introduced into the hot furnace at the same flow rate. The initial flow rates of these gases are in the range of 2-5 cm^3/min.

The miniature furnace is built on the flange of the first chamber of the vacuum system as indicated on Fig. 2. The core of the furnace consists of two high-purity closed-end alumina tubes of ½ and ¼ in. OD in a concentric configuration. On the tip of each tube an orifice is drilled on the axial line. The orifice diameter of the ¼ in. tube is fixed at 0.006 in. and that of the outer ½ in. tube is either 0.04 or 0.06 in. A spacer or collar, cut from a ⅜ in. OD alumina tubing in lengths from ⅜ to ¼ in. is inserted between these two tips to define a hot reaction zone and to serve as a substrate. The spacing between the tips can be reduced to the position of an intimate contact to examine varying extents of the interaction. The heating element is molybdenum wire of a 0.03 in. diameter wound directly around the outer combustion tube. For uniform heating, the winding begins from the orifice edge and extends about 4 in. along the length of the tube. At least two layers of zirconia felt are wrapped around the heating element as insulation. The cylindrical water jacket and the water channel flange are located outside the felt to circulate cooling water. A Pt-10% Rh/Pt thermocouple is placed inside the inner tube near the tip to record temperature and to regulate the heating alternating current supplied to the furnace. The vacuum system, as shown on the right side of Fig. 1, consists of three chambers individually evacuated by three pumping assemblies. The vacuum in the first chamber was maintained at 2×10^{-4} Torr or lower so that a molecular beam could be formed for sampling. The quadrupole mass spectrometer manufactured by Extranuclear Laboratories, Inc., has a high efficiency detection and is designed to operate in a mass range 0-4000 amu. The theory and practice of this sampling technique has been summarized by Milne and Greene (4), and the operation of the present system is given elsewhere (5, 6).

Provision was made to establish and to monitor pressures and flow rates of the reactant gases. The wet oxygen was introduced axially into the furnace through the core of the inner combustion tube and the chlorine-hydrogen mixture was fed into the furnace through the annulus between the inner and the outer combustion tubes. Aluminum metal was placed about 1 in. from the tip of the combustion tube in the annular space so that it melted and reacted with chlorine at temperatures above 600°C to provide aluminum

Key words: aluminum chloride hydrolysis, aluminum chloride oxidation, aluminum-chlorine reaction.

chloride vapors. Since the metal was not placed in a boat, the surface area of molten aluminum tended to decrease after a period of reaction. The experiments were carried out at temperatures from 800°-1400°C, and the pressures of both gaseous mixtures in the furnace were 50-100 mm Hg initially. The pressure of the reaction zone is estimated to be in the range of a few mm Hg. During the run, the Cl_2/H_2 passage tended to clog gradually due to the formation of Al_2O_3 and the displacement of molten aluminum. Consequently the flow rate decreased and the source pressure increased. Alumina deposits resulting from the interaction of the two mixtures were found mostly on the inner cylindrical surface near the exit end of the spacer. All vapors including reactants and products were exhausted into vacuum through the outer orifice for detection. The run was terminated after either the source pressure had reached 1 atm from clogging or a period of 6 hr had elapsed. At the end of a run, gases were shut off and furnace was allowed to cool. The entire furnace was then disassembled and the substrate was separated from the combustion tube.

The extent of the interaction between aluminum and chlorine was examined first. The study was carried out by passing a chlorine-argon mixture over aluminum at temperatures up to 1400°C. Mass spectra were recorded continuously with rising temperatures. The gas-solid reaction begins somewhere around 300°C, and the products from the reaction depend on the surface area of aluminum and the partial pressure of the reactant. Ion species of Cl^+, unreacted Cl_2^+, $AlCl^+$, $AlCl_2^+$, $AlCl_3^+$, $Al_2Cl_5^+$, and a trace of $Al_2Cl_6^+$ were observed at low temperatures. The ions resulting from the dimer, Al_2Cl_6 diminish in abundance as the temperature rises to 900°C. At this temperature all ions containing two Al atoms disappear and no chlorine ions are detected. As the temperature is increased further, $AlCl^+$ becomes more abundant. Finally at temperatures above 1000°C, the monochloride ion becomes the predominant species and in most cases is the only major reaction product observed. The substitution of hydrogen for argon in the gas mixture did not change the reaction products except to produce HCl. Typical abundances of ions observed in the mass spectra are listed in the first half of Table I. The variation of the ion intensities of observed species with the partial pressure of chlorine-argon at 1365°C is illustrated in Fig. 3. At the high end of the chlorine pressure, the chlorine-rich ions are abundant, and at the low end $AlCl^+$ is a dominant ion species.

Prior to the deposition experiments, vapor species existing in argon carrier gas over $AlCl_3$ powders were

Table I. Relative abundances of ion species present in aluminum-chlorine reaction and chemical vapor deposition process of alumina. The magnitudes of signals are obtained directly from strip charts and computer printouts without corrections for the sensitivity and efficiency of the detector. Due to variations in the experimental conditions, the data represent only relative ion intensities in a run

Reaction	Run No.	Gas mixture	Temperature / Pressure	Relative ion intensity: H^+ H_2^+	OH^+ H_2O^+	Al^+	N_2^+ [(a)]	O_2^+	Cl^+	HCl^+	$AlCl^+$	Cl_2^+	$AlCl_2^+$	$AlCl_3^+$	$Al_2Cl_5^+$
Al + Cl_2	111772	Ar/Cl_2 =16/10	475°C 155 mm Hg	—	—	20	—	—	15	—	14	1.2	60	25	16

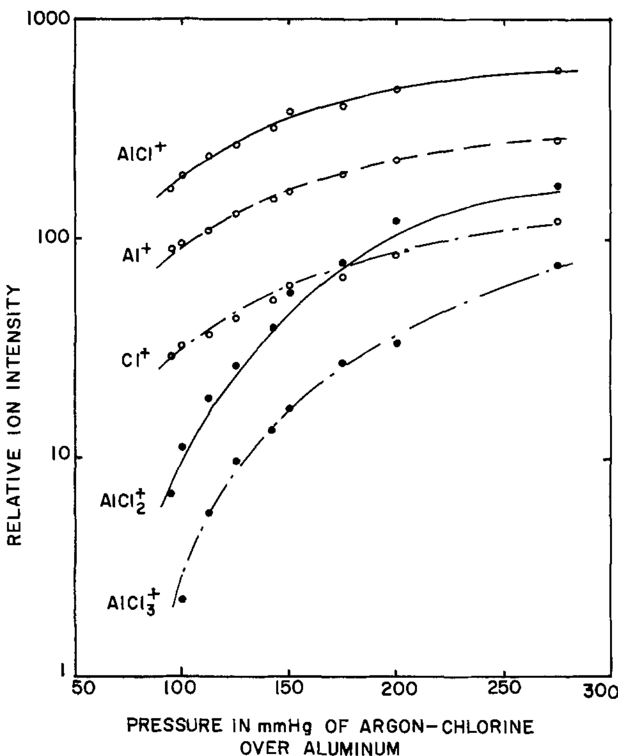

Fig. 3. Relative abundances of vapor ion species in aluminum-chlorine reaction at 1365°C. The data are taken from run 112872, Ar/Cl_2 ratio = 2/1, electron ionization energy = 40 eV, no correction is made for the detection efficiency. The fragmented ions are Al^+ and Cl^+ from AlCl, and $AlCl_2^+$ from $AlCl_3$.

also examined. At low temperatures up to 400°C, $Al_2Cl_5^+$ is the most abundant species, but at 1200°C, only $AlCl^+$ and $AlCl_2^+$ ion molecules exist and are equally abundant.

The mass spectra obtained during the deposition reaction at temperatures of 900°-1400°C reveal only the presence of H^+, H_2^+, O^+, OH^+, H_2O^+, O_2^+, Cl^+, and HCl^+ ions. The typical distribution of ion species is tabulated in the second half of Table II. The relative abundances may vary from run to run due to variation and fluctuation in the experimental conditions. In general there were no ions containing aluminum present, which indicated that the deposition reaction was nearly complete. During the experiments, the mass spectrometer was used repeatedly to scan up to mass 1000 amu to acertain that no large mass ion or cluster ion was present in the deposition system. If there was a high mass ion present, the abundance must be less than 10^{-5} of the most abundant species in the spectra.

Under the condition of the present experiments, the chemical vapor deposition of alumina from aluminum-chloride/hydrogen and water/oxygen is predominantly a heterogeneous process in contrast to the earlier report (3) that vapor phase homogeneous nucleation might take place. If vapor phase homogeneous nucleation had occurred, it would proceed via the random growth of small condensed aggregates and clusters of vapor molecules. The present result reveals the absence of aluminum-oxygen molecular species which are presumably the precursors of the aggregates and clusters, and Al_2O_3 nuclei in vapor phase. One might question the ability of the spectrometer to detect large microparticles from electron impact ionization processes. Since the existence of AlO^+ and Al_2O^+ ion species detected by the spectrometer has been reported (7, 8), there is no reason to suspect that the clusters of Al-O species would not have been detected if they had been present in the system in excess of 10^{-5} of the most abundant species. Perhaps large microcrystals dissociate into Al^+ and large neutral fragments upon electron impact ionization, but this is highly improbable.

Table II. Free energy changes of reactions between aluminum chlorides and water/oxygen in deposition of Al_2O_3 at various temperatures

	Reaction	Free energy change in kcal-mole⁻¹ 1300°K	1500°K	1700°K
[1]	$2AlCl(g) + H_2O(g) + O_2(g) = Al_2O_3(s) + 2HCl(g)$	−235.4	−217.3	−199.5
[2]	$2AlCl(g) + 3H_2O(g) = Al_2O_3(s) + 2HCl(g) + 2H_2(g)$	−151.4	−138.7	−126.4
[3]	$2AlCl(g) + 3/2\ O_2(g) = Al_2O_3(s) + Cl_2(g)$	−228.4	−206.9	−185.9
[4]	$2AlCl_3(g) + 3H_2O(g) = Al_2O_3(s) + 6HCl(g)$	−77.1	−77.8	−78.6

Examples of polycrystalline alumina deposits obtained from this study are shown in Fig. 4. These deposits were obtained from the CVD process under similar experimental conditions except for temperature, which was found to have a dominant influence over the textures of the deposits. The presence of whiskers grown on surfaces of the deposit at T = 1100°C (Fig. 4c) suggests that the surface nucleation is an important reaction mechanism.

The major vapor molecule from the aluminum-chlorine reaction at the present deposition temperature and pressure is AlCl. The exhaust gases from the CVD process of Al_2O_3 are HCl, Cl,[1] O_2, H_2O, and H_2. The over-all deposition reaction should be written according to existing vapors as

$$2AlCl(g) + H_2O(g) + O_2(g) = Al_2O_3(s) + 2HCl(g) \quad [1]$$

and

$$2AlCl(g) + 3H_2O(g) = Al_2O_3(s) + 2HCl(g) + 2H_2(g) \quad [2]$$

[1] The Cl^+ ion intensity was greater than could be accounted for by HCl fragmentation; the monatomic chlorine probably resulted from dissociation of unreacted Cl_2.

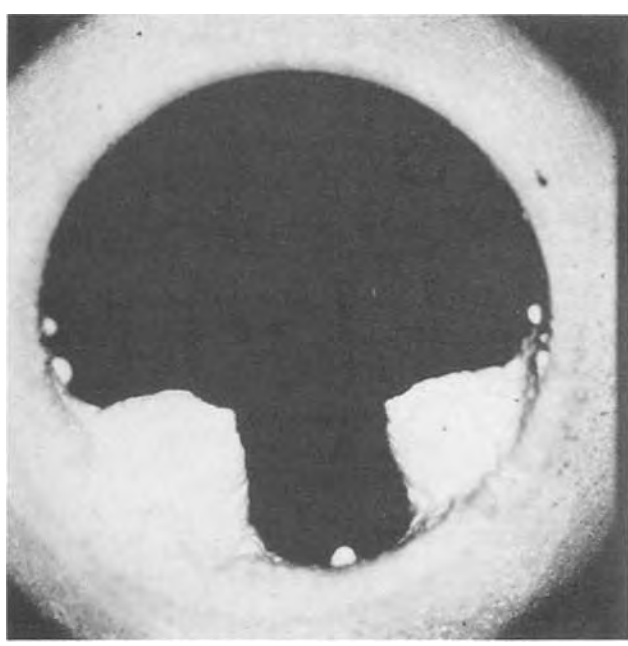

Fig. 4. Microphotographs (×7) of Al_2O_3 polycrystalline deposits obtained from chemical vapor deposition process. The deposits are grown on the cylindrical inner surface of the substates cut from a ⅜ in. OD alumina tube under same gaseous reactants.
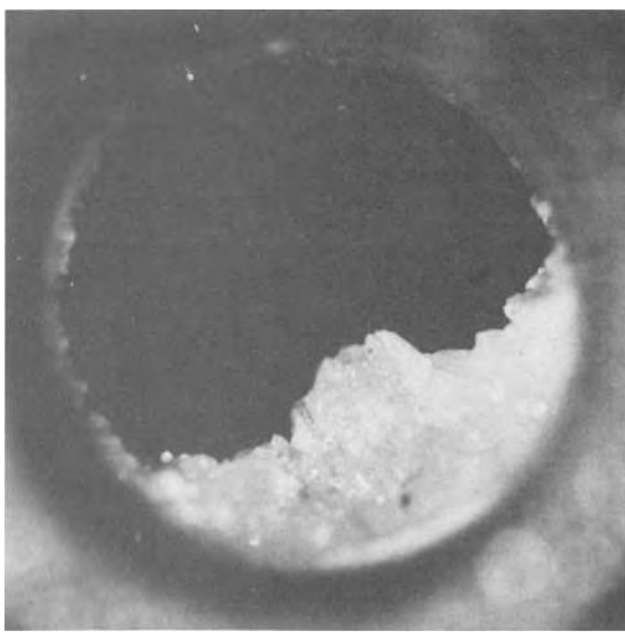
a. White polycrystalline deposits obtained at 900°C. The similar white deposits were also obtained at temperatures above 1300°C and below 900°C.



b. Opaque to transparent alumina obtained at 1000°C.

c. Whiskers on surfaces of opaque deposits obtained at 1200°C.

These reactions occur at the surfaces of substrates and/or Al_2O_3 crystals. The reaction

$$2AlCl(g) + 3/2\,O_2(g) = Al_2O_3(s) + Cl_2(g) \quad [3]$$

is thermodynamically feasible, but the formation of Al_2O_3 from this reaction is neither observed by the previous work (3) nor in this investigation. Table II tabulates the free energy changes of reactions leading to the formation of alumina. For the CVD of Al_2O_3 the first two reactions are both possible. The free energy change of reaction [1] is more negative than that of reaction [2], and reaction [1] seems to be kinetically more favorable because it requires fewer molecules to yield Al_2O_3 on the substrate surfaces. In reaction [1], oxygen is essential in the formation of Al_2O_3. The earlier report (3) proposed the over-all reaction in which $AlCl_3$ is the only major Al-containing reactant

$$2AlCl_3(g) + 3H_2O(g) = Al_2O_3(s) + 6HCl(g) \quad [4]$$

It would have been of interest to duplicate the conditions of the earlier work at higher pressures (3) to confirm the importance of $AlCl_3$ in the reaction; however the very small orifice [*e.g.*, 0.01 cm (5)] necessary to isolate the high pressure region would have plugged with Al_2O_3 almost immediately, making measurements impossible.

At least, judging from analyses of vapor species in the present deposition data and associated experiments, the existence of AlCl molecule at the high temperature of the CVD process is highly probable. Furthermore, nonequilibrium kinetics in the chlorine-aluminum reactions could lead to AlCl vapor formation.

Competitive heterogeneous and gas-phase nucleation reactions leading to the formation of Al_2O_3 are believed to take place in the CVD process. The surface reaction is more favorable in the present experiments. Vapor phase nucleation is almost impossible because of fairly low pressures used in the present investigation. Perhaps vapor phase nucleation would have prevailed in the CVD system at much higher pressures.

Manuscript submitted Aug. 23, 1974; revised manuscript received June 2, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by The Department of the Army.

Low Temperature Thermal Oxidation of Silicon by Dry Oxygen Pressure above 1 Atm

R. J. Zeto,* C. G. Thornton,* E. Hryckowian, and C. D. Bosco

U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

It is widely recognized that the cost, reliability, and performance of integrated circuit devices are adversely affected by the large number of process-induced chemical and physical defects that result from high processing temperatures in the range 950°-1250°C. High thermal oxidation temperatures may also destroy specific desired impurity distributions achieved in previous processing steps. Consequently, there is strong motivation for developing an oxidation process that can produce gate, field, and other masking and passivating oxides at lower processing temperatures for silicon integrated circuit devices. It is also desirable that reduced oxidation temperatures be achieved by a dry oxidation method since problems due to oxide defects and contamination may be more serious for oxides prepared by wet oxidation. Although the use of high pressure steam (1) has long been known as a method for achieving low temperature thermal oxidation, attractive electrical characteristics have not been reported and the method is not generally used. On the other hand, it is known (2) that the oxidation of silicon is accelerated by dry oxygen partial pressures to 1 atm, but to our knowledge there are no oxidation data reported for dry oxygen pressures above 1 atm. On the basis of these considerations, dry pressure-oxidation of silicon is a logial possibility for achieving improved electrical properties *via* accelerated oxide growth and reduced oxidation temperatures.

The purpose of this communication is to report the initial results of experiments which demonstrate that dry pressure-oxidation, P-OX, significantly reduces the required oxidation temperatures of semiconductor silicon used for integrated circuit devices. The rate of oxidation of arsenic-doped (111) silicon at 800°C, 140 atm dry oxygen pressure was measured and compared with conventional (2, 3) thermal oxidation methods. The results are shown in Fig. 1. It is evident that oxide growth by 140 atm dry P-OX at 800°C is faster than either 1 atm dry or wet oxidation at 800°C, and is comparable to 1200°C dry oxidation at 1 atm. The 400°C reduction in dry oxidation temperature by the application of only 140 atm oxygen pressure is remarkable. Since 140 atm pressure (2060 psi) is less than the pressure supplied in conventional pressurized gas cylinders that are widely used and ordinarily handled, the technique is expected to be amenable to practical utilization.

The experimental oxidation system is readily assembled from commercially available components. It consists of a pressurized cylinder of oxygen gas, an oxygen gas pump, a vacuum pump, a cold-seal pressure vessel of the type used for hydrothermal crystal growth, an external resistance furnace, and stainless steel pressure lines. Rectangular samples, 8 × 10 mm, were cut from a 1 in. silicon wafer and positioned in a quartz sample holder at the bottom of a 9 in. quartz tube (Amersil T08) that lined the inside of a 0.5 in. ID pressure vessel (Rene 41 alloy). The pressure-oxidations were conducted in a closed system with separate substrates for each experiment. Temperature and pressure were maintained within ±2°C and ±10 atm, respectively, during the course of the oxidations. Oxide thickness was measured with a Rudolph RR100 ellipsometer. The over-all uncertainty in thickness ranged from ±20Å for thin oxides to a maximum of ±200Å for some of the thicker oxides.

Special attention was given to the potential role of water vapor in the P-OX kinetics shown in Fig. 1. Scientific Gas Company electronic grade oxygen gas, 99.998% minimum purity, less than 3 ppm water vapor, and less than 1 ppm hydrocarbons as methane, was used. The stated moisture level was verified by measurements with a Panametrics Model 2000 hygrometer with a cell probe rated for operation to 5000 psi. Less than 14 ppm H_2O was measured in the exit gas from several overnight experiments. Using an identical hygrometer sensor element, Irene (4) recently compared the thermal oxidation kinetics of silicon at 1 atm oxygen pressure for conditions of less than 1 ppm water vapor *vs.* 20-30 ppm water vapor. This data for (111) silicon at 800°C is shown in Fig. 2 for comparison with the 800°C/140 atm P-OX data. With the ordinate scale used, both of Irene's cases are encompassed by the indicated points in Fig. 2. It was, therefore, concluded that the accelerated oxidation observed in the P-OX experiments was due to the effect

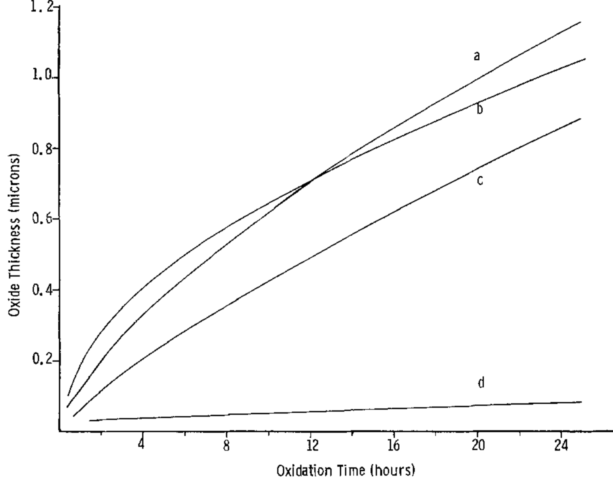

Fig. 1. Comparison of thermal oxidation conditions for (111) silicon: (a) 140 atm dry pressure-oxidation at 800°C, (b) 1 atm dry oxidation at 1200°C, (c) 1 atm steam oxidation at 800°C, (d) 1 atm dry oxidation at 800°C.

Key words: silicon oxidation, dry oxygen pressure, oxide growth, MOS properties, passivation.

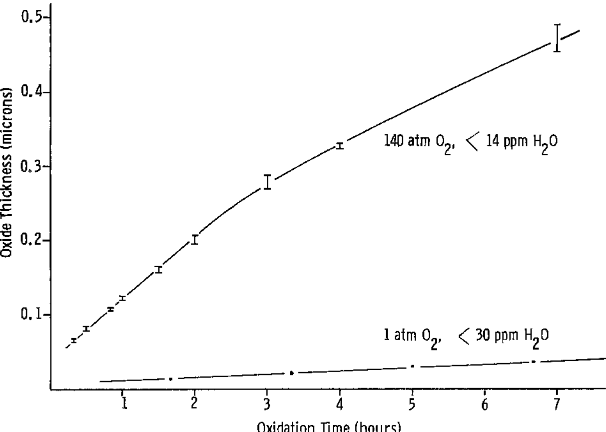

Fig. 2. Comparison of oxidation rate and moisture conditions for 800°C/140 atm P-OX and 800°C/1 atm (4) thermal oxidation of (111) silicon.

of dry oxygen pressure rather than moisture. For the P-OX conditions stated in Fig. 2, the oxide growth rate was linear between 650-2500Å with a value of about 14 Å/min.

Oxides for a wide range of applications in integrated circuit devices can be obtained at reduced temperatures by dry pressure-oxidation. A 1200Å gate oxide can be grown in 1 hr at 800°C/140 atm. Exploratory 3 hr oxidations at other temperature/pressure conditions yielded 4700Å at 800°C/500 atm and 16,000Å at 900°C/500 atm. Additional data on dry pressure-oxidation kinetics and detailed information on the P-OX experimental system will be reported.

According to the model of Deal and Grove (2), the thermal oxidation of silicon is initially reaction-rate limited at the oxide-silicon interface followed by diffusion control of the oxidant through the oxide. The corresponding coefficients in the oxidation equation $x_o^2 + Ax_o = B(t + \tau)$ are given in Table I for oxidation by 1 atm and 140 atm oxygen pressure at 800°C. Both the parabolic, B, and linear, B/A, rate constants are one to two orders of magnitude larger for 140 atm dry oxidation, indicating that both of these stages of the oxidation process are accelerated by pressures above 1 atm. The pressure variation of the coefficients, however, indicates that the pressure-oxidation mechanism is not completely described by the model. The coefficient A is not independent of pressure, and neither the parabolic nor the linear rate constants are proportional to pressure. The pressure-oxidation mechanism will be examined as additional P-OX data are determined.

Table I. Coefficients for the dry thermal oxidation of (111) silicon according to $x_o^2 + Ax_o = B(t + \tau)$ for 1 atm (2) and 140 atm oxygen pressure at 800°C.

Oxidation pressure (atm)	A (μ)	B (μ^2/hr)	B/A (μ/hr)	τ (hr)
1	0.37	0.0011	0.0030	9.0
140	1.03	0.100	0.097	0.45

A pressure vessel was recently put into operation to evaluate the MOS properties of samples prepared by the dry P-OX of 1 in. silicon wafers using clean-room conditions and state-of-the-art procedures. Evaporated aluminum dots were used for electrical contact, and conventional capacitance-voltage measurements were made. MOS structures from initial experiments showed negligible (<0.1V) shift in flatband voltage under bias temperature stress and Q_{ss} values in the range 3-8 $\times$ 10^{10} cm^{-2}. These samples were (111) phosphorus-doped 1-5 ohm-cm silicon with 1000Å oxides prepared by 800°C/150 atm dry P-OX. Previous program effort was directed at an assessment of the dry pressure-oxidation kinetics, and for MOS properties exploratory experiments without clean-room conditions were made at 140 atm, 700°-800°C, with 8 $\times$ 10 mm samples of arsenic-doped silicon. Q_{ss} values in the range 2-7 $\times$ 10^{11} cm^{-2} were obtained, and under bias temperature conditions gross shifts in f tband voltage typical of alkali ion contamination were not present. These results indicate that significant benefits may be transferred to electrical properties by reduced temperature dry oxidation. Experimental conditions and procedures are currently being investigated to optimize electrical properties.

The characteristics of P-OX are advantageous for the preparation of oxide-isolated silicon devices with reduced impurity redistribution during dielectric isolation. This application of P-OX for bulk silicon and silicon-on-sapphire is currently under study. Initial results are promising and are reported separately (5).

Dry Pressure Local Oxidation of Silicon for IC Isolation

S. Marshall, R. J. Zeto,* and C. G. Thornton*

U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

This communication reports the use of dry pressure-oxidation (P-OX) for obtaining oxide-isolated device structures in both bulk silicon and epitaxial silicon on sapphire (SOS). Dry P-OX is a new low temperature oxidation technique which, compared with conventional dry thermal oxidation, reduces required oxidation temperatures as much as 400°C for equivalent oxide film growth. It has been shown, for example, that oxidation of silicon by 140 atm dry oxygen at 800°C is comparable to 1 atm dry oxidation at 1200°C (1).

Localized oxide isolation of silicon devices in integrated circuits utilizes silicon nitride as an oxidation mask (2). In the present work two structures were examined, one in which the Si_3N_4 was deposited directly on the silicon surface and one in which a 500-1000Å conventional thermal oxide was grown prior to the nitride deposition. The nitride was grown by the SiH_4-NH_3 process and was defined by supplemental CVD masking and etching in phosphoric acid. When the intermediate oxide layer was used, silicon areas were exposed by HF etching. The local oxidation process with dry P-OX was explored under a variety of experimental conditions, *i.e.*, 700°-880°C, 140-500 atm oxygen pressure, and oxidation times of 3-24 hr. Optimum pressure-temperature-time conditions have not yet been determined, but at 850°C and 250 atm, the average oxidation rate was about 17 Å/min for <100> silicon. For <111> silicon the rate was 47 Å/min at 850°C and 500 atm. Scanning electron microscopy (SEM) was utilized to reveal the morphology of the P-OX structures.

The application of P-OX to dielectric isolation in bulk silicon and SOS devices is illustrated in Fig. 1, where the nitride mask has been applied directly to the surface of the silicon. Figure 1(a) shows the required oxidized structure as achieved in bulk material by the dry P-OX process at oxidation temperatures where undesired impurity redistribution effects are very small. The oxide thickness is 1μ and was grown in 3½ hr at 850°C and 500 atm. In Fig. 1(b) the oxide extends completely through the 1 μm epitaxial silicon layer of an SOS structure, thus effecting dielectric isolation of adjacent silicon elements. In this case, the oxide happened to be grown in 23 hr at 850°C, 250 atm. A more optimum set of conditions can obviously be chosen from available data (1).

Following the P-OX treatment the structures were well defined, lateral oxidation under the nitride mask was negligible, and cracks in the nitride film were absent. The use of a chromate dislocation etch (3) failed to reveal significant nitride induced defects in the cleaved low temperature pressure oxidized structures examined. This observation is contrasted with results reported in Ref. (2) where application of the nitride directly to the silicon surface resulted in severe dislocation damage under higher temperature oxidation. Thus, an intermediate oxide "buffer" layer may not be needed to avoid undesirable defects at the silicon-nitride interface.

Local pressure oxidation of silicon using a more conventional nitride/oxide/silicon structure is illustrated in Fig. 2(a) and 2(b) for bulk silicon and SOS, respectively. It is evident from a comparison of Fig. 1 and 2 that lateral oxidation underneath the nitride mask is much more pronounced in the presence of an intermediate oxide layer, an observation originally reported by Appels and Paffen (4) for silicon oxidized at 1 atm. The shape of the oxide edge is similar to that reported by Powell *et al.* (5) for silicon oxidized in steam. The experimental conditions for bulk silicon and SOS are the same as reported above for Fig. 1.

The degree of lateral oxidation has an important bearing on device design since lateral oxidation establishes a minimum size for adjacent isolated structures. This point is illustrated in Fig. 3 in which the lateral oxide growth undermines the original 8.5μ width of the nitride mask. The ratio of lateral oxidation L to isolation oxide thickness t for the specific P-OX sample shown in Fig. 2(a) (<111> Si, 500 atm,

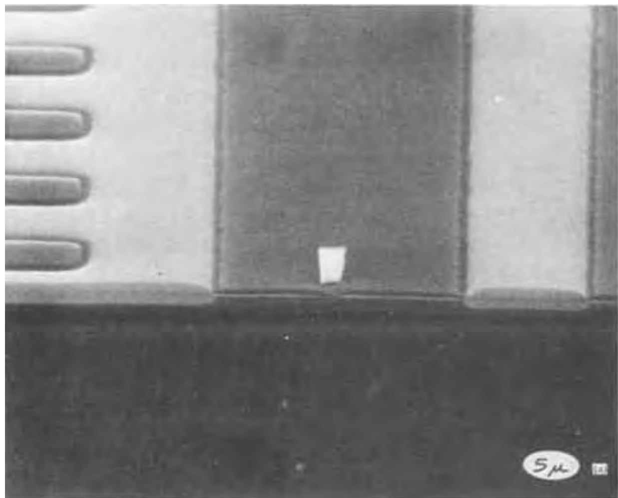

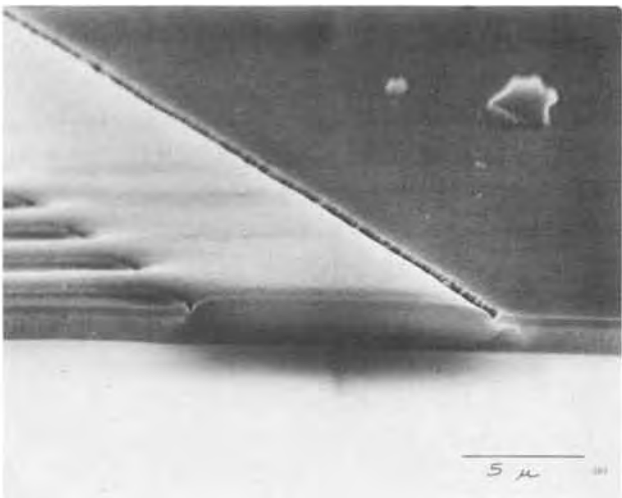

Fig. 1. Dry pressure-oxidation of nitride on silicon structures: (a) Bulk <111> silicon showing 1 μm oxide (light) and masking nitride (dark); (b) 1 μm <100> SOS showing complete dielectric isolation.

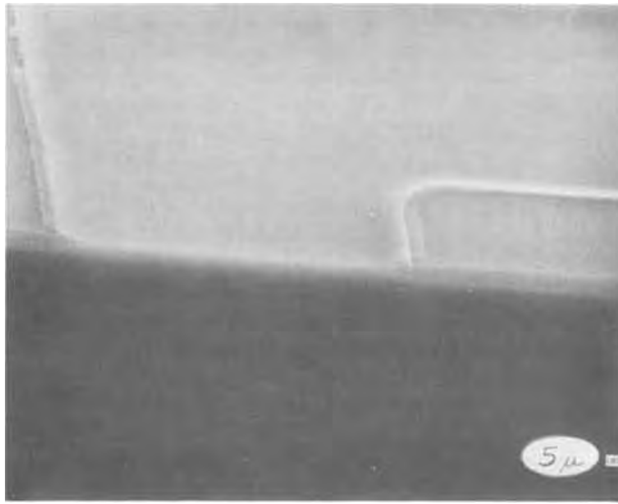

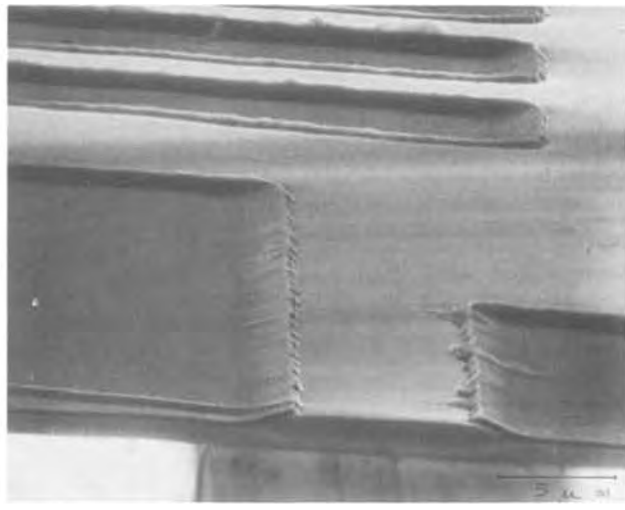

Fig. 2. Dry pressure-oxidation of nitride on thermal oxide on silicon structures: (a) bulk <111> silicon showing 1 μm pressure oxide; (b) 1 μm <100> SOS with 2700Å of silicon remaining. The extent of lateral oxidation is much greater than for the nitride-oxide structures of Fig. 1.

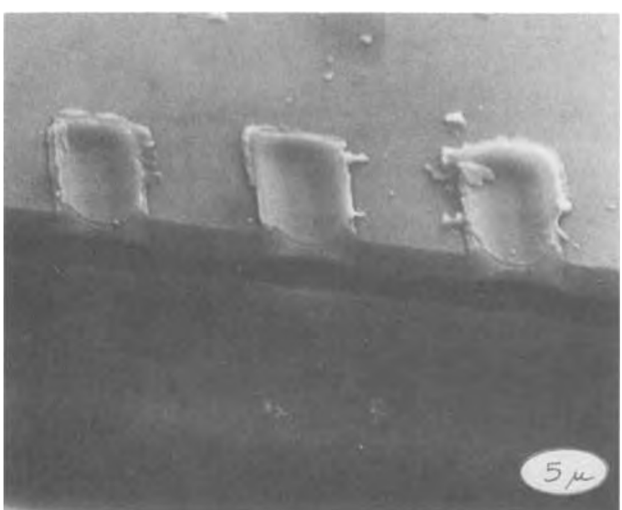

Fig. 3. LOCOS structure showing the limit imposed on device geometry by lateral oxidation beneath the nitride mask. Center to center pad spacing is 12 μm. The initial mask consisted of 8.5 μm wide nitride bars separated by 3.5 μm spaces. The nitride was deposited on 1000Å thermal oxide on bulk (111) silicon.

850°C) is 2.8. For comparison, a ratio of 3.3 is calculated from the data of Powell *et al.* (5) (steam oxidation at 60 atm, 675°C). The P-OX L/t ratio is 2.2 for the <100> SOS sample of Fig. 2(b) (250 atm, 850°C). For equivalent conditions with nitride/oxide/silicon structures it would be expected that the L/t ratio would be higher for high pressure steam due to the high solubility and diffusivity of water in the initially present oxide layer. For either process, selective etching of the silicon prior to the pressure oxidation, as described in Ref. (4) will decrease the oxidation time needed to achieve oxide isolation, reduce the lateral oxidation, and result in a desirable planar surface topography.

Subsequent work in this area will investigate in greater detail the effect of P-OX conditions on the generation of surface defects in nitride masked structures. Consideration will also be given to the oxidation kinetics of the nitride masking film and to the evaluation of "P-OX device" characteristics.

New Method of Manufacturing Sintered-Type Aluminum Solid Electrolytic Capacitor

Sadao Okuma

Department of Applied Science, Tokyo Electrical Engineering College, Tokyo, Japan

The sintered-type aluminum solid electrolytic capacitor has been prepared by a new method, where first either nitrogen or hydrogen gas at 1 atm is used during the sintering of the aluminum powder to form the porous anode, and second either ammonium dihydrogen phosphate or ammonium borate solution is used during the anodization to form the dielectric.

The capacitors prepared by this method gave better characteristic properties than other electrolytic capacitors.

The preparation of the aluminum-sintered anode has been said to be difficult, because aluminum unlike tantalum easily forms a hard oxide at sintering temperature.

The author could prepare the aluminum-sintered anode in this experiment based upon the assumption that adequate sintering would take place in the gaseous atmosphere mentioned above.

This makes us suppose that the aluminum-sintered body has a large surface area with a suitable porous property and the interior surface can be converted to a good dielectric film by the usual anodization techniques.

Consequently, for the manufacture of the sintered-type aluminum solid electrolytic capacitor on this study, it has been understood that both ammonium dihydrogen phosphate as the forming solution and hydrogen gas as the sintering atmosphere gave better dielectric properties, respectively.

If the manufacturing steps are considered, the new method used in this study would be much simpler than the normal vacuum sintering method.

This communication reports a comparison of the characteristic properties with the ones obtained in this study.

Experimental

Materials.—99.98-99.99% pure aluminum powder was obtained from commercial sources. Particle sizes of the aluminum powder were 20, 35-150, 150-200, and 200 mesh, respectively. The binder used for sintering was less than 1 weight per cent (w/o). Gaseous atmosphere during sintering was at about 1 atm pressure. The forming solution was either 3% ammonium borate solution or 0.3% ammonium dihydrogen solution.

Apparatus.—The characteristic properties of the dielectric substance were measured by a Universal Bridge which was manufactured by Yokogawa Electrical Manufacturing Company.

Procedure.—The compacting pressure was either 0.1 ton/5 mm diameter or 0.2 ton/5 mm diameter. The size of the compact was 5 mm diameter by about 5 mm high. The sintering was at 600°C for about 120-180 min in each gas as mentioned above.

The anodization was performed at a constant current of 50 mA until 150V was reached, and the voltage was maintained at 150V until the current dropped to 2 mA.

The total formation time was 120 min. After formation the anodized pellet was washed for 60 min with water, and then dried at 500°C for 60 min.

Manganese dioxide, produced from thermal decomposition of a highly concentrated manganous nitrate solution at 300°C for 60 min, was used to form the interior semiconductor contact.

Finally, colloidal carbon was spread on the coated anode, dried, coated with silver paint, and dried at 500°C for 60 min.

Key words: aluminum, capacitor, sintered-type, solid, dielectric.

Results and Discussion

Table I shows the characteristic properties for the sintered-type aluminum solid electrolytic capacitor manufactured in this study.

In spite of fact that the dielectric constant of aluminum oxide is lower than other dielectric of metal oxide, the sintered-type aluminum solid electrolytic capacitor obtained in this study gave a capacitance of 0.5-7.4 μF.

The capacitance per unit weight of the aluminum solid electrolytic capacitor is 2-40 μF/g. Then anodization voltage to form the aluminum capacitors is much higher than the tantalum, niobium, or zirconium capacitors, and consequently the anodic oxide film is much thicker. Consequently, it can be said that this method was effective enough for the preparation of the dielectric substance.

The dissipation factor of the aluminum capacitor was somewhat inferior to other capacitors; however, it was considered that it might be lowered to some extent by eliminating the naturally formed aluminum oxide. This proposal has not yet been tried. Instead further comparisons were made using either hydrogen or nitrogen gas as the sintering atmosphere and either ammonium dihydrogen phosphate or ammonium borate solution as the forming solution.

First, the dielectric film was formed using each forming solution and then transformed into the sintered-type aluminum solid electrolytic capacitor ac-

* Measured at 4-6V.

cording to above procedure. The characteristic properties of these capacitors were measured.

Figure 1 gives the rate of capacitance change *vs.* frequency (at 20°C) of capacitors prepared in the sintering atmosphere of nitrogen gas as a function of the compacting pressure. Consequently, the element formed from ammonium dihydrogen phosphate solution is better than the one produced from ammonium borate solution.

Figure 2 shows the rate of capacitance and the dissipation factor of the capacitors made in a sintering atmosphere of hydrogen gas.

From these results, hydrogen gas was considered a better sintering atmosphere for it gave more stable dielectric characteristic properties than those prepared in nitrogen (1-3).

Conclusion

This study was carried out with the purpose of increasing the capacitance and the improvement of other characteristic properties of the dielectric substance.

The sintered-type aluminum solid electrolytic capacitors were prepared using either nitrogen or hydrogen gas as the sintering atmosphere and either ammonium borate or ammonium dihydrogen phosphate solution of the forming solution. Measurements were made of the characteristic properties of these capacitors.

The following conclusions can be made:

1. The anode in the capacitor has a large surface area with sufficient porosity to impregnate with manganous nitrate solution.

2. The dissipation factor is somewhat less satisfactory. However, it may be possible to improve it by a surface pretreatment before anodization.

3. Hydrogen gas as the sintering atmosphere and ammonium dihydrogen phosphate solution as the forming solution, each gave better dielectric properties than nitrogen gas and ammonium borate solution.

4. The new method used in this study would be more useful in the industrialization of the sintered-type aluminum solid capacitor than the vacuum mechanism method used hitherto.

Optimal Working Parameters for Some Silver Gas Electrodes

I. Solacolu, Maria Mavrodin-Tărăbîc, and Ioana Onaca

Centre of Physical Chemistry, Bucharest, Romania

ABSTRACT

The effect of oxygen overpressure (200-600 mm Hg), temperature (15°-65°C) and electrolyte concentration (2-9N) were studied on silver gas electrode polarization by dispersional analysis. The values of apparent activation energies were calculated The optimal working parameters were established for different apparent current densities.

Recent studies (1-5) showed the low polarization of silver gas electrodes during oxygen reduction in KOH medium. This study has tried to maximize a set of operating parameters for the silver gas electrodes not previously obtained (6).

Experimental

Electrode preparation and characterization.—The silver gas electrodes, having a DSK type structure, were fabricated by pressing ($2.8 \cdot 10^8$ N/m^2) a homogenous mixture containing 81.25% silver carbonate (less than 5 μm powder) and 18.75% ammonium dicarbonate (40-60 μm powder). The resultant pellets (10 mm diameter, 3 mm thick) were sintered under a hydrogen atmosphere (15 min at 375°C). In a horizontal electric furnace (hydrogen flow rate 2 liters/min, heating 2°C/min, temperature steps, 1 hr at 100°C and 1 hr at 140°C, cooling 3°C/min with 30 min steps at every 100°C).

The microscopic examination showed a uniform distribution of pores in the whole electrode mass. The over-all porosity (as determined by weighing before and after soaking with toluene) was 50.5%.

Polarization measurements.—The study of oxygen reduction in KOH medium on silver gas electrodes was carried out by the potentiostatic technique, previously reported (7, 8). The following equipment was used: a Tacussel potentiostat Type PRT 500 LC (±1 mV precision), an electronic Radiometer Type 22 millivoltmeter (±1 mV precision), a DU 20 milliammeter (±1% precision). The auxiliary electrode was a 99.9% nickel tape, the reference electrode was a saturated calomel electrode. The working cell (120 × 72 × 56 mm) was made from polystyrene. The polarization curves were obtained by applying potential steps of 10 mV at 1 min intervals.

The electrodes were supplied with oxygen at constant overpressure (±2 mm Hg) (6). The working cell was kept at constant temperature (±0.1°C). The electrolyte was prepared from pA KOH (Merck).

The values of the working parameters were varied as follows: oxygen overpressure from 200 to 600 mm Hg (100 mm Hg steps), electrolyte temperature from 15° to 65°C (5°C steps), and KOH concentration from 2 to 9N (1 mequiv./cm^3 steps).

Effect of Changes in Working Parameters

The optimization study established the effect of change of working parameters upon the silver gas electrode polarization at different values of apparent current density between 10 and 70 mA/cm^2. Overvoltage values were obtained by interpolation from polarization curves. $\eta = f_P(P)$, $\eta = f_c(c)$, and $\eta = f_t(t)$ curves were plotted (Fig. 1, 2, and 3).

Effect of oxygen overpressure.—The family of curves in Fig. 1 shows the increase of oxygen overpressure from 200 to approx. 400-500 mm Hg has a favorable effect upon the performance of the studied electrodes whenever the apparent current densities are larger than 10 mA/cm^2. This is explained by an alteration of conditions under which oxygen electroreduction takes place (active surface increase and meniscus thickness reduction) and by the increase of oxygen solubility. The effect is more evident the larger the apparent current density (curves 2, 3, and 4) and the lower the electrolyte concentration (curves 4 and 5) and working temperature (curves 4 and 6). The increasing of oxygen overpressure above 500 mm Hg helps to increase the electrode polarization (more evident in curves 5 and 6).

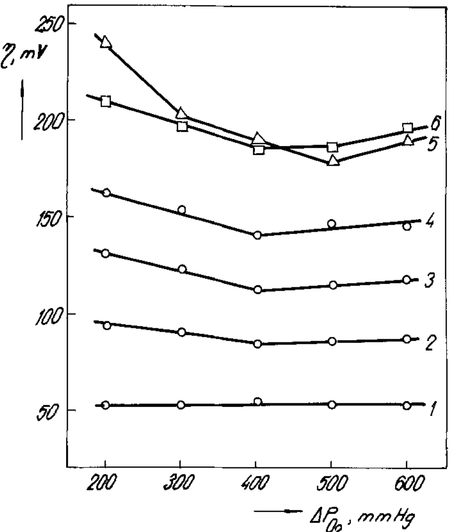

Fig. 1. The effect of oxygen overpressure on electrode polarization. Curve 1, 6N, 55°C, 10 mA/cm^2; curve 2, 6N, 55°C, 30 mA/cm^2; curve 3, 6N, 55°C, 50 mA/cm^2; curve 4, 6N, 55°C, 70 mA/cm^2; curve 5, 4N, 55°C, 70 mA/cm^2; curve 6, 6N, 40°C, 70 mA/cm^2.

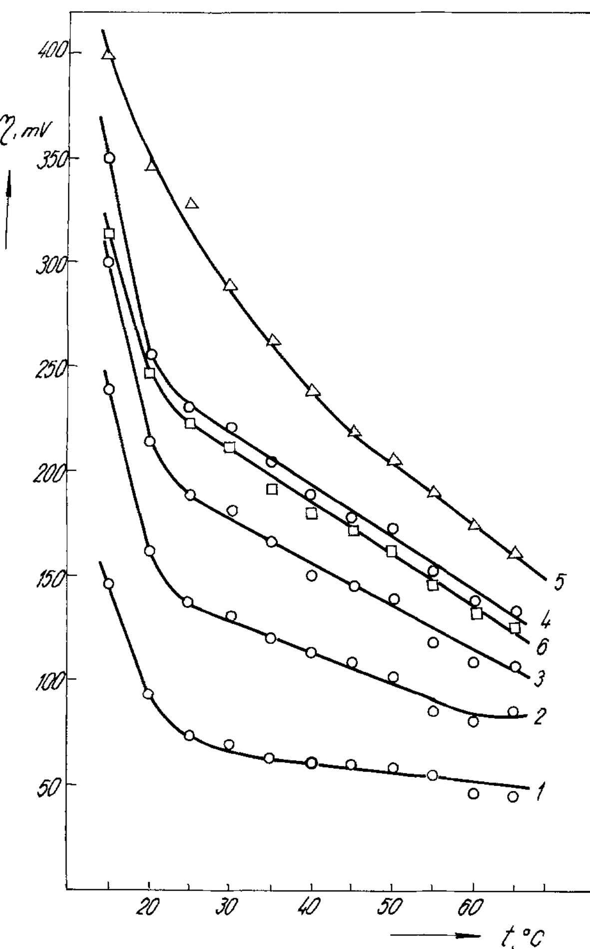

Fig. 2. The effect of electrolyte temperature on electrode polarization. Curve 1, 6*N*, 400 mm Hg, 10 mA/cm^2; curve 2, 6*N*, 400 mm Hg, 30 mA/cm^2; curve 3, 6*N*, 400 mm Hg, 50 mA/cm^2; curve 4, 6*N*, 400 mm Hg, 70 mA/cm^2; curve 5, 4*N*, 400 mm Hg, 70 mA/cm^2; curve 6, 6*N*, 500 mm Hg, 70 mA/cm^2.

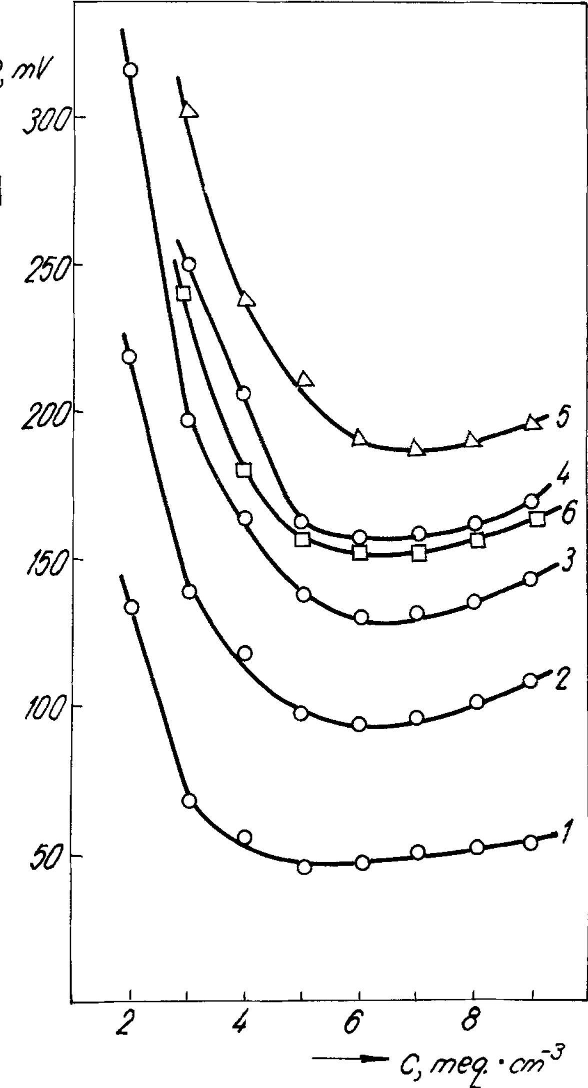

Fig. 3. The effect of electrolyte concentration on electrode polarization. Curve 1, 50°C, 400 mm Hg, 10 mA/cm^2; curve 2, 50°C, 400 mm Hg, 30 mA/cm^2; curve 3, 50°C, 400 mm Hg, 50 mA/cm^2; curve 4, 50°C, 400 mm Hg, 70 mA/cm^2; curve 5, 40°C, 400 mm Hg, 70 mA/cm^2; curve 6, 50°C, 500 mm Hg, 70 mA/cm^2.

Effect of electrolyte temperature.—Examination of $\eta = f_t(t)$ curves in Fig. 2 shows the oxygen reduction in KOH is enhanced by increasing temperature over the range of 15°-65°C. This effect becomes more obvious as the temperature and electrolyte concentration are lowered (curves 4 and 5), and the apparent current density is increased (curves 1, 2, 3, and 4). The behavior of these gas electrodes is accounted for by unlike effects of temperature variation upon electrolyte conductivity (9), solubility of oxygen in KOH solution (10), and diffusion of reacting species and products to/from reaction zone, *i.e.*, oxygen solubility decreases while conductivity and diffusion increase. At apparent current density higher than 10 mA/cm^2, the effect is more obvious over the entire range because, under these conditions, the contribution of concentration and ohmic polarization to the over-all electrode polarizais larger. A plateau is reached as a result of the two effects compensating each other, at 10 mA/cm^2 and temperatures higher than 40°C.

Effect of electrolyte concentration.—The electrode polarization decreases continuously as electrolyte concentration increases over the range of 2-6*N* KOH ($\eta = f_c(c)$ curves shown in Fig. 3). This effect becomes more obvious as the concentration and temperature are lowered (curves 4 and 5) and the apparent current density is increased (curves 1-4). The variation of the oxygen overpressure within the range 400-500 mm Hg has no notable effect upon the $\eta = f_t(t)$ and $\eta = f_c(c)$ functions (curves 4 and 6 in Fig. 2 and 3).

The increase of electrolyte concentration up to approximately 6*N* has a very favorable effect upon the electrolyte conductivity (9), which prevails over the unfavorable effect upon the oxygen solubility (10) (Fig. 3). These two effects are compensated over the range of 6-7*N*. Above this concentration range the electrode polarization increases.

The data presented outline the complexity of the effect of working parameters upon silver gas electrode polarization. The same data show that the optimal parameters depend on the apparent current density (11) for low current densities (approx. 10 mA/cm^2) at KOH concentration 4-5*N*, temperature 45°-55°C, and for apparent current densities higher than 30 mA/cm^2 at KOH concentration 5-6*N*, temperature 55°-65°C.

Apparent Activation Energies

The apparent activation energies (E_{ap}) were calculated from the plots log i_o *vs.* $1/T$. The results are given in Table I.

Examination of data in Table I shows the exchange current increases with increasing electrolyte temperature and concentration. The apparent activation energies decrease as the concentration increases, their lowest values corresponding to 6-7*N* KOH. Values of 4-5 kcal/mol, corresponding to 6-7*N*, prove the electrode process is diffusion-controlled which is in agreement with the literature data (12) obtained for oxygen reduction on coal gas electrodes.

Optimal Working Parameters

To establish the optimal values of working parameters for the different apparent current densities considered (10, 30, 50, and 70 mA/cm²), the polarization data were tested by dispersional analysis in order to eliminate those parameters whose variation had nonsignificant effects. Then, by using a factorial experiment program, the values of the parameters with significant effect were computed in order to minimize the electrode polarization.

Dispersional analysis.—The overvoltages yielded by the gas electrodes under consideration, at various apparent current densities, within optimal working domain are given in Table II.

A 3 factor (A = oxygen overpressure, B = KOH concentration, and C = working temperature) and two, three, and four levels (Table II) model (13) was chosen in order to carry out the dispersional analysis of polarization data. The results are given in Table III.

Examination of Table III shows that for all apparent current densities the effect of variation of factor A and of second order interactions AB and AC is not significant. At 10 mA/cm² the effect of the variation of factor C is significant while, at the other current densities, the effects of factors B, C, and of second order interaction BC are significant. The relatively low dispersion induced by random factors (residual dispersion, s_r) indicates satisfactory accuracy of experimental data and points out the fact that the third order interaction ABC is not significant.

These results were used in building up the interaction table (Table IV) and so figuring out the effect of variation of significant parameters upon the polarization of the silver gas electrodes. The interpretation of these data was done by computing the values of the reliability interval (13) for a significance limit $\alpha = 0.1$.

The data listed in Table IV lead to the following optimal operation zones which are to be further explored in optimization: for 10 mA/cm², concentration KOH 5N, temperature 50°C; for 30 mA/cm², 5N, 60°C; for 50 mA/cm², 6N, 60°-65°C; for 70 mA/cm², 6N, 60°-65°C.

Optimizing.—One considers the regression functions which describe the relation between the significant independent variables, concentration (x_1) and temperature (x_2), and the dependent variable, electrode overvoltage (y)

$$y = b_0 + b_1x_1 + b_2x_2 + b_{12}x_1x_2 + b_{11}x_1^2 + b_{22}x_2^2$$

The calculation of coefficients of regression functions ($b_0 - b_{22}$) for each apparent current density was carried out by starting up with data obtained from a factorial experiment program (13). The steps of 1 mequiv./cm³ and 5°C were considered characteristic to variations working parameters in the optimal zone. The coded values of independent variables correspond to

for 10 mA/cm₂:

$$-1 = 4N; \quad 0 = 5N; \quad 1 = 6N \text{ (for } x_1)$$

$$-1 = 45°\text{C}; \quad 0 = 50°\text{C}; \quad 1 = 55°\text{C (for } x_2)$$

for other C.D.

$$-1 = 5N; \quad 0 = 6N; \quad 1 = 7N \text{ (for } x_1)$$

$$-1 = 55°\text{C}; \quad 0 = 60°\text{C}; \quad 1 = 65°\text{C (for } x_2)$$

To check up the validity of regression function, the overvoltage values (y_{calc}) for each apparent current

	9	1	1	145	143	144.0		144.2		128.8 mV

density were calculated and the deviation of observed values from these calculated (that is the linearity of the regression function) was verified. By equating to zero the partial derivates of regression functions with respect to the two independent variables, a system of two linear equations was obtained for each apparent current density. Solving the system has allowed the establishing of optimal values of independent variables which yield minimum polarization. The results are given in Table V.

Data in Table V show that the electrodes present minimal overvoltage at 400-500 mm Hg oxygen overpressure, 5-6*N* KOH concentration, and different temperatures depending upon current density: 51°C (10 mA/cm^2), 61.5°C (30 mA/cm^2), 64.1°C (50 mA/cm^2), 78.9°C (70 mA/cm^2).

Electrochemical Studies at Silver/Alpha-Silver Sulfide Interfaces

I. The Sulfidation of Silver

C. J. Warde,*[,1] J. Corish, and C. D. O'Briain[2]

Department of Chemistry, University College, Belfield, Dublin 4, Ireland

ABSTRACT

Kinetic measurements have been made in the temperature range 220°-340°C of the growth of α-silver sulfide from three different samples of high purity silver rods. These measurements confirm the parabolic nature of the reaction in the terminal stages although thermodynamic equilibrium is not established at the silver/α-silver sulfide interface. Values for the parabolic rate constant have been derived from the experimental data and are found to be in excellent agreement with values calculated using the modified Wagner theory. New measurements of the partial ionic conductivity of silver ions in α-silver sulfide, accurate values of which are required for these calculations, are also reported. The sulfidation rates were found to be strongly dependent on the particular batch of silver used. Preannealing of the silver samples, which, as revealed by metallurgical examination increased grain size, was shown to produce corresponding changes in their rates of sulfidation.

Because it serves as an excellent model system the reaction between bulk silver and liquid sulfur has attracted much attention in the literature (1-5). The high temperature form of the sulfidation product α-Ag_2S provides fast-ion transport for silver ions and it has been known for some time that the latter stages of the reaction, when the product layer is thick, exhibit parabolic kinetics for which the rate-determining step is the diffusion of the silver ions through the sulfide (1, 6). The differential form of the rate equation may be written simply as

$$dx/dt = k_o/x \quad [1]$$

where x is the thickness of the sulfide layer and k_o is the parabolic rate constant. It is feasible to obtain reliable kinetic data for this system since the problem of the formation of porous product layers may be overcome by introducing, and maintaining a load on, a compacted tablet of α-Ag_2S between the reactants (2). Assuming that the movement of silver through the product layer is an electrochemical process involving the transport of silver ions and electrons and that equilibrium exists at the interfaces, an equation of the Wagner theory of the oxidation of metals (7, 8) may be used to deduce an expression for the parabolic rate constant as follows

$$k_o = \frac{\sigma_{Ag^+}}{c_{Ag}F^2}\{\mu^o{}_{Ag}(Ag_2S) - \mu^*{}_{Ag}(Ag_2S)\} \quad [2]$$

where σ_{Ag^+} is the silver partial ionic conductivity in silver sulfide, c_{Ag} is the number of equivalents of silver/cm^3 of sulfide, $\mu^o{}_{Ag}(Ag_2S)$ the chemical potential of silver in silver sulfide in equilibrium with pure silver, and $\mu^*{}_{Ag}(Ag_2S)$ the chemical potential of silver in silver sulfide in equilibrium with liquid sulfur. Although experimental values of k_o and the k_o values calculated using Eq. [2] were of the same order of magnitude acceptably close agreement was found only at 400°C or above (2, 5). The discrepancies between experimental and theoretical values of k_o at lower temperatures have been shown by Rickert (2) to be due to the fact that thermodynamic equilibrium is not attained at the Ag/Ag_2S interface at temperatures below 400°C. He used the cell

$$Pt \mid Ag \mid AgI \mid Ag_2S \mid Pt \quad [3]$$

the emf, E, of which may be related to the chemical potentials of silver in pure silver $\mu_{Ag}(Ag)$ and in silver sulfide $\mu_{Ag}(Ag_2S)$ by the relationship

$$-FE = \{\mu_{Ag}(Ag_2S) - \mu_{Ag}(Ag)\} \quad [4]$$

to measure any departure from equilibrium occurring at the Ag/Ag_2S interface and found that when the sulfide layer exceeded ~0.5 cm in thickness the potential attained a steady value E^θ. The experimental kinetics of the reaction then agreed with values of the rate constant given by the modified theoretical equation

$$k_o = \frac{\sigma_{Ag^+}}{c_{Ag}F}\{E^* - E^\theta\} \quad [5]$$

where E^* is the emf of the cell

Key words: silver iodide, parabolic rate, partial ionic conductivity, grain size, annealing.

$$Pt \mid Ag \mid AgI \mid Ag_2S \mid S(l) \mid Pt \quad [6]$$

Thus the parabolic rate law was still obeyed in spite of a large, but constant, departure from equilibrium at one of the interfaces (5, 9).

All previous work with this system has been reported by workers using, in any one study, a single type of silver sometimes rather loosely described as simply high purity silver. Involvement with processes of this kind over a lengthy period in this laboratory (9-11) has indicated that differences in the type of high purity silver used might be responsible for observed anomalies in experimental results. This paper reports a systematic and detailed investigation of the kinetics of sulfidation of three different samples of high purity silver in the temperature interval 220°-340°C. The kinetic data have been analyzed by computer and the parabolic rate constants obtained are compared with those calculated using Eq. [5]. The results of new measurements of the silver ion partial ionic conductivity in α-Ag_2S are also reported. These were deemed necessary because of systematic differences between observed and calculated values of k_o, using earlier measurements of σ_{Ag^+} made in this laboratory (11). The effects on the rates of sulfidation when the silver samples were preannealed have been investigated in an attempt to elucidate the factors which govern the behavior of the system.

In the following paper (Part II) measurements of the overpotentials observed during the electrochemical passage of silver from three types of high purity silver across the Ag/α-Ag_2S interface are reported and these again reveal differences in behavior between the samples. Such results are of interest both from a phenomenological point of view and because measurements of this type have been used to explain the kinetics of the sulfidation of silver by liquid sulfur (3, 9).

Experimental

Materials.—The three types of silver used in the basic kinetic measurements were supplied as rods of 6 mm diameter as follows: (*i*) Johnson-Matthey Chemicals Limited, major impurity, copper <5 ppm over-all purity 99.999%; (*ii*) Degussa Feinsilber, major impurity, copper <300 ppm, over-all purity 99.97%; (*iii*) Johnson-Matthey Chemicals Limited, major impurity, copper <50 ppm, over-all purity 99.99%. These samples will be referred to as JM1, D1, and JM2, respectively, and the impurity levels quoted are the result of an analysis carried out by Johnson-Matthey Limited. The behavior of a number of samples of the Degussa Feinsilber used previously by Duffy (11) (to be referred to later as D2) was also examined. The samples were prepared to fit into the apparatus to be described later using a high speed lathe and were then thoroughly degreased (12) using A.R. grade benzene and A.R. grade acetone. The purity of the silver iodide, which was supplied by Sherman Chemicals Limited was checked by testing for electronic leakage through cell [3] at 300°C in an atmosphere of pure nitrogen. After establishment of a cell potential of 100 mV by withdrawal of silver from the Ag_2S tablet, the cell was left on open circuit. A negligible rate of potential drop indicated the absence of electronic leakage. The sulfur was a spectrographically standardized substance of purity 99.999% supplied by Johnson-Matthey Chemicals Limited. The Ag_2S tablets used at the interface were fabricated from silver sulfide rods which had been grown in the laboratory in earlier experiments. These rods were ground to a uniform fine powder using a specially constructed filing machine. Disks of 0.8 mm thickness were then produced by pressing the powder to 6.1×10^3 kg cm^{-2} in a die designed for the preparation of KBr disks for *IR* measurements. Finally tablets of 9 mm diameter and with a 2 mm tag to carry the Ag/AgI probe electrode (see Fig. 1) were punched from these Ag_2S disks. The nitrogen atmosphere used for all experiments was produced from the British Oxygen Company "white spot" product by removal of the residual oxygen with Fieser's Solution (13). The gas line employed also provided for the removal of any traces of hydrogen sulfide using saturated lead acetate solution and for the careful drying of the nitrogen before admission to the reaction assembly.

Apparatus for the kinetic measurements.—The essential components of the system constructed to measure the rate of unidimensional growth of α-Ag_2S and to measure simultaneously the difference in chemical potential of the silver atoms across the Ag/Ag_2S interface are shown schematically in Fig. 1. In contrast to the arrangement used by Rickert (2) it was the sulfide tablet which was rigidly supported. This was done using a platinum disk with a hole in the center which allowed the silver rod being sulfidized to move upwards under continuous spring pressure. The Ag_2S formed by the reaction grew upwards in the glass tube, shown full of liquid sulfur, and thus the level of the $Ag_2S/S(l)$ interface rose. The Ag/AgI probe electrode shown pressed against the tag portion of the Ag_2S tablet was fabricated from a 5 cm piece of 3 mm OD glass tubing drawn to a tip at one end and filled with AgI. A glass spring (not shown) was used to press a piece of silver rod into the AgI and to maintain good contact between the probe and the Ag_2S tablet. The probe together with the platinum support disk formed a cell as shown in Eq. [3] and was used to measure the chemical potential drop for silver atoms across the Ag/Ag_2S interface. The emf of this solid-state cell was measured with a Honeywell 19 Electronik recorder, checked frequently with a vibrating-reed electrometer accurate to 1 mV (Vibron 33C, E.I.L. Ltd.) and a Tinsley potentiometer (accuracy ± 10 μV).

The complete apparatus is shown in Fig. 2. The upper end of the long glass tube which contained the liquid sulfur and the main body of the dial gauge were held at opposite ends of a rigid steel frame. The top of the dial gauge plunger supported a precision glass rod which moved freely through a precision tube and held the silver specimen, which was wedged into a Kovar

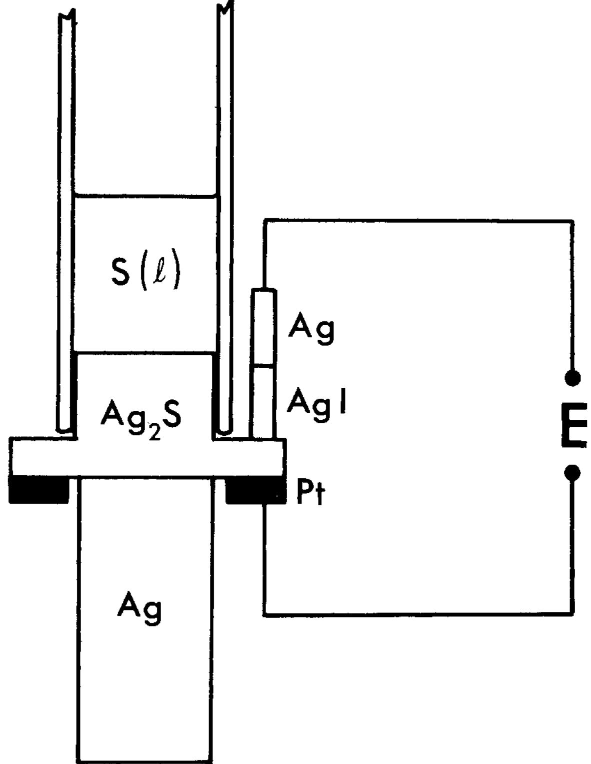

Fig. 1. Schematic diagram of the cell arrangement used to measure the overpotential, *E*, at the Ag/α-Ag_2S interface during the formation of compact α-Ag_2S.

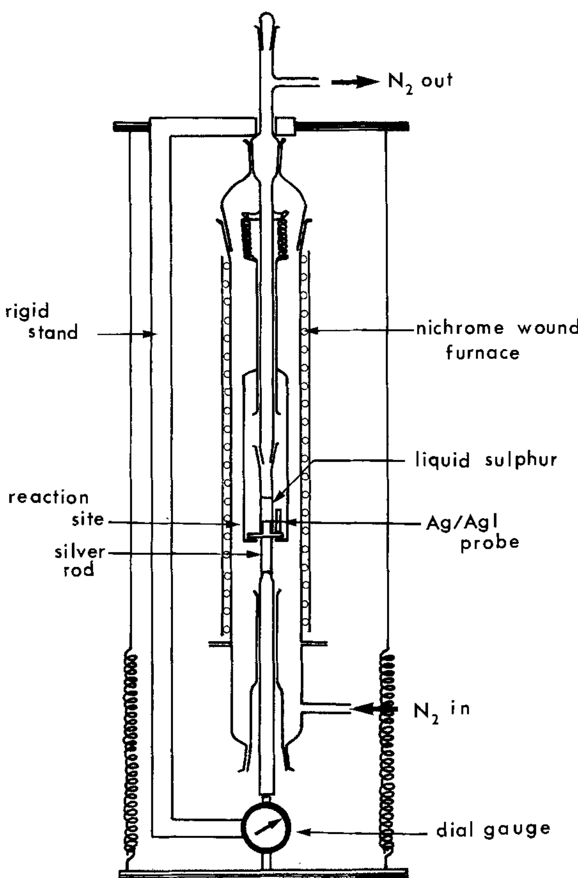

Fig. 2. Over-all apparatus to measure one-dimensional sulfidation of a silver rod by liquid sulfur.

metal to glass seal, against the lower surface of the Ag_2S tablet. The other end of the dial gauge plunger was spring-loaded so that the pressure on the Ag/Ag_2S contact was 6 kg/cm^{-2}. The rate of consumption of silver could be followed by means of the micrometer dial gauge which registered the decrease in length of the silver rod correct to 2.5×10^{-4} cm. The rate of growth of Ag_2S was calculated from this measurement and the accuracy of this procedure was checked periodically by measuring the thickness of the sulfide layer with a cathetometer and finally by measuring the over-all length of the sulfide with a micrometer screw gauge after each experiment. The entire assembly was contained in a wide-bore air-jacketed glass tube which was heated by nichrome strip windings fed from a stabilized voltage source. The temperature at the reaction site was measured by a calibrated Chromel-Alumel thermocouple and was constant to ±1°C over the period of an experiment.

Polishing and etching of silver rods.—Silver samples, as received, after the kinetic runs at 220°C, and after annealing, were mounted in cold-setting resin cylinders. The cylinders were ground, parallel to the axis of the silver rods, on silicon carbide papers (Grades 220, 320, 400, and 600 sequentially). After exposure of an adequate section, polishing and etching were carried out by a procedure recommended by Darling (14). This involved polishing of the samples for 1-2 min on a velvet-covered turntable, rotating at 250 rpm, with "Brasso"[3] employed as a lubricant. After washing, the samples were further lightly polished for 3 min on a velvet-covered stationary smooth glass plate with "Silvo"[3] as lubricant. The surfaces were now etched by applying a solution, comprising one part of 1 weight per cent (w/o) H_2SO_4 and one part of a one-tenth saturated solution of $K_2Cr_2O_7$, to the samples by means of a cotton wool swab. Photomicrogrpahs of the etched surfaces were prepared using a Union Optical metallurgical microscope Model UMG-Bi.

Experimental determination of σ_{Ag^+}.—Measurements of the partial ionic conductivity of α-Ag_2S were made using a modified form of the procedure originally suggested by Hebb (15) and improved by Wagner (16) and later followed by Duffy (11). Cylindrical specimens of Ag_2S 2-3 cm long obtained in the kinetic studies were turned down slightly to a uniform diameter and their cross-sectional area, *a*, determined using a micrometer. They were then made part of the electrochemical cell

$$\mathrm{Ag} \mid \mathrm{AgI} \mid \mathrm{Ag_2S} \mid \mathrm{AgI} \mid \mathrm{Ag} \qquad [7]$$

and two small Ag/AgI probes, made in a manner similar to that described previously were pressed against its side. The distance between these probes, *d*, was measured using a cathetometer. Two platinum probes also touched the specimen, at points on the other side, opposite the Ag/AgI probes. A circuit diagram is shown in Fig. 3. Two AgI tablets were necessary between the Ag_2S specimen and each silver electrode to avoid formation of silver dendrites through individual AgI tablets. The materials used were as described previously for the kinetic measurements. The assembly of tablets and electrodes was contained in an air-jacketed nichrome wound furnace under an atmosphere of purified nitrogen and with temperature at the specimen constant to ±1°C during an experiment. The temperature was measured by a calibrated Chromel-Alumel thermocouple in close proximity to one end of the sulfide rod and a Pt/Pt-13% Rh thermocouple pressed against the other end and agreement between these two thermocouples was within the error quoted at all times. A constant 120V d-c source was used with variable high resistances in series with the specimen to achieve currents in the range 5-10 mA. This arrangement minimized the effects of any slight changes occurring in the resistance of the tablet assembly. If *E* is the potential difference between the two Ag/AgI probes the silver partial ionic conductivity is given by

$$\sigma_{Ag^+} = \frac{i_{Ag^+} d}{Ea} \qquad [8]$$

where i_{Ag^+}, the current under steady-state conditions, was measured using a Cambridge precision microammeter. This experimental arrangement also allowed investigation of the effect on σ_{Ag^+} of changes in the stoichiometry of the silver sulfide. By applying a voltage between one of the platinum probes and one of the silver electrodes, silver could be added to or removed from the sulfide. The associated change in μ_{Ag} (Ag_2S) was determined by measuring the potential difference between the other platinum probe and an Ag/AgI probe.

Results and Discussion

Kinetics of the sulfidation of silver.—In general, if equilibrium at either, or both of the interfaces, Ag/Ag_2S and $Ag_2S/S(1)$, is established only gradually, and the kinetics of the reaction conform to the parabolic law in the later stages, the most satisfactory method (2) with which to represent the experimental data is to plot $(x + x_o)$ *vs.* $(t - t_o)/(x - x_o)$, where t and x represent the time and the thickness of the sulfide layer, respectively. x_o corresponds to t_o and is the least value of x which makes the greatest number of experimental points fit a straight line. The slope of such a plot is $2k_o$, where k_o is the parabolic rate constant and is given by the equation

$$k_o\ (\text{expt.}) = d(x + x_o)/2d(t - t_o)/(x - x_o) \quad [9]$$

The basic experimental data of time and length of silver rod consumed were processed together with the necessary conversion factors by a linear regression computer program, thus yielding values for k_o. Three kinetic plots for D1 specimens are shown in Fig. 4, and it is evident from the similarity of the slopes that at the same temperature the sulfidation rate of identical samples is reproducible. Plots of the overpotential at the Ag/Ag_2S interface as a function of time for the three different kinds of silver at 260°C are shown in Fig. 5. The difference which is evident here between JM1 on the one hand and JM2 and D1 on the other was found to be pronounced at all the temperatures at which measurements were made. The very low overpotentials at the Ag/Ag_2S interface for the former are reflected in high values for the experimental parabolic rate constant as now a greater fraction of the affinity of the reaction is available for the diffusion process. A summary of the experimental values of k_o as given by the computer fit and values calculated using Eq. [5] for the three types of silver used and at all the temperatures at which measurements were made is given in Table I. As is evident there is good agreement between experimental and calculated values in all cases but the rates of sulfidation measured under otherwise identical conditions are strongly dependent on the particular sample of high purity silver under investigation.

Properties of the bulk silver samples which it was felt might be responsible for the present observations were considered to include (*i*) impurity concentration, (*ii*) grain size, and (*iii*) grain orientation. Since all the samples were of a comparatively high purity (*i*) might not appear to be an important factor but it should be noted that the order of ascending steady-state overpotential (and thus of decreasing k_o) was the same as

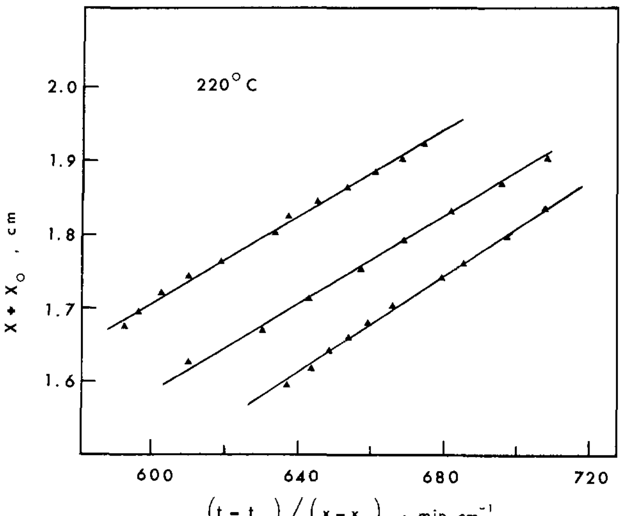

Fig. 4. Parabolic plots for the growth of α-Ag_2S from three separate experiments using samples of Degussa Feinsilber at 220°C.

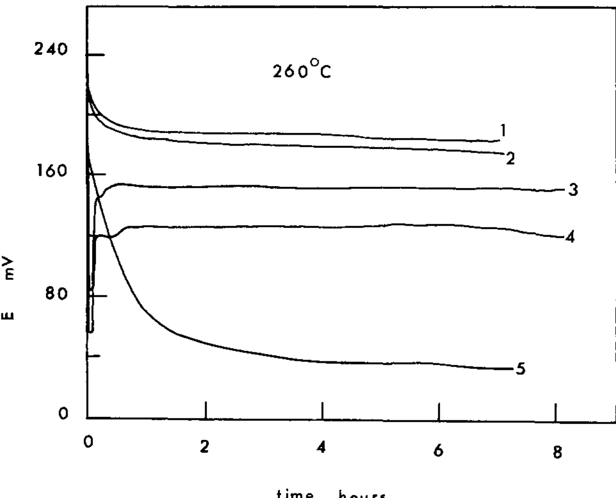

Fig. 5. Overpotential vs. time traces for annealed and unannealed silver samples at 260°C. The samples shown are: curve 1, D1 unannealed; curve 2, JM2 unannealed; curve 3, D1 annealed; curve 4, JM2 annealed; curve 5, JM1 unannealed.

the order of increasing impurity content. To investigate any possible correlation between the grain size and orientation in the bulk silver [(*ii*) and (*iii*) above] and its behavior during sulfidation, a specimen of each type of silver was polished and etched as described earlier. Figure 6(a) shows typical etch patterns observed for as-received samples of JM2 6 mm silver rod. Similar patterns were observed for D1 samples. It was deduced from the elongation of the grains parallel to the rod axis, and the extent of cold working, that the JM2 and D1 rods were drawn at temperatures well below 200°C, the recrystallization temperature for cold-worked silver. In marked contrast the JM1 sample had been drawn at temperatures much higher than 200°C and probably in the 750°-900°C range. As a result the grains were very large, by comparison with the other specimens, and were elongated along the axis of the rod, while the matrix accommodating the grains appeared to be a single crystal. A typical photomicrograph for JM1 silver is shown in Fig. 6(b). Examination of similarly etched samples which had been used in a kinetic experiment showed that recrystallization and grain growth were taking place in JM2 and D1 during the course of a sulfidation reaction even at 220°C [see Fig. 6(c)].

At this stage of the investigation all of the supply of JM1 6 mm rods had been used. It was realized that it would be impossible to reproduce the grain shape, size, and orientation of this silver sample but since it appeared that the extraordinary behavior might well be due mainly to the large grain size an attempt was made to increase the grain size in the JM2 and D1 silver. Annealing of samples of each type of silver was carried out in vacuo at 660°C for 100 hr followed by cooling at 6°C/hr. Some other samples of Degussa Feinsilber

(D2) of the type which had been used by Duffy (11) in his earlier experiments and which was similar with respect to impurity analysis to D1 were also annealed. The results of kinetic experiments using these preannealed samples are shown in Table II where it is evident in all cases that these specimens now exhibit higher values of k_0 and correspondingly lower values of E^θ. The effect of annealing is also shown in Fig. 5 where the overpotential *vs.* time traces for annealed and unannealed samples may be compared. Similar changes in the values of E^θ were observed for the annealed samples at all the other temperatures investigated. The similarity in behavior for the annealed samples D1 and D2 as shown in Table II is significant not only because it indicates just how reproducible these two batches, which were supplied at a four year interval, were, but also because it emphasizes the greater value of k_0 observed at any given temperature for the annealed JM2 samples. In no case, however, did preannealed samples reproduce the kinetic behavior of the unannealed JM1 silver and when the preannealed samples were examined metallurgically it was evident that although the grain size had increased in all cases it was never of the same order of magnitude as that found in the unannealed JM1. Etch patterns for annealed JM2 silver are shown in Fig. 6(d).

Table II. Experimental and calculated parabolic rate constants for preannealed silver samples

Temp (°C)	Sample	E^* (mV)	E^θ (mV)	k_0 (expt.) (10^{-5} cm² sec⁻¹)	k_0 (calc.) (10^{-6} cm² sec⁻¹)
220	D1	220	179	3.06	2.99
	D2	224	184	3.46	2.95
	JM2	223	159	4.53	4.62
260	D1	228	161	5.26	5.38
	D2	228	164	5.43	5.18
	JM2	228	126	7.25	8.18
300	D1	231	146	7.39	7.45
	D2	232	147	7.69	7.47
	JM2	231	101	11.6	11.4
340	D1	235	101	13.0	12.6
	D2	235	113	11.7	11.4
	JM2	235	80	14.3	14.5

This evidence might suggest that the grain size in bulk silver dictated the magnitude of the overpotential at the Ag/Ag_2S interface. However, it must be stated that since the grain sizes in annealed D1, D2, and JM2 were approximately the same and since the observed kinetics of sulfidation of JM2 were quite different from those of D1 and D2 samples, the differences in grain sizes, while obviously a factor, cannot fully account for the differences in behavior of the three types of silver used in this investigation.

The silver partial ionic conductivity.—The need for a new determination of σ_{Ag^+} at the temperatures of the kinetic experiments became apparent when use of the values available in the literature in Eq. [5] produced values for the parabolic rate constant which disagreed systematically with the experimental results. It also seemed important that measurements should be made on α-Ag_2S samples grown from each of the types of silver used in the present investigation. The values of σ_{Ag^+} were determined for cylindrical samples in the apparatus which has been described. Currents of both 5 and 10 mA were passed in each direction through the samples before averaging results to obtain the values shown in the last column of Table III. As well as the samples prepared from each kind of silver the ionic conductivities of sulfide specimens used by Duffy (11) were also measured but no significant differences were observed in any case. The activation energy for the process obtained by fitting to an Arrhenius equation is approximately 1200 cal mole^{-1}. The measurements

Table III. Comparison of values, at various temperatures, of the silver partial ionic conductivity of α-Ag_2S

	σ_{Ag^+} (ohm⁻¹ cm⁻¹)				
Temp (°C)	Rickert Ref. (2)	Duffy Ref. (11)	Ozazaki Ref. (17)	Bartkowiez *et al.* Ref. (5)	Present work
220	3.89	3.41	4.32	3.51	4.11
260	4.08	3.86	4.85	3.94	4.53
300	4.26	4.29	5.38	4.35	4.95
340	4.78	4.71	—	4.74	5.28

were made at the stoichiometry which corresponds to a potential of 100 mV at 220°C for a cell of type [3] but measurements were also made which showed that σ_{Ag^+} was virtually independent (*i.e.*, varied <1% over the attainable range) of μ_{Ag} (Ag_2S) at all temperatures.

Other reported values of σ_{Ag^+} are summarized in Table III. Miyatani (18) has also measured the silver partial ionic conductivity in α-Ag_2S at 183°C using a technique based on the rates of relaxation processes. He reported a value of 2.9 ohm^{-1} cm^{-1} for sulfide close to equilibrium with sulfur and a value of 4.1 ohm^{-1} cm^{-1} for sulfide in equilibrium with silver. Rickert (2) measured σ_{Ag^+} at 200°, 300°, and 400°C but the scatter makes it impossible to deduce an activation energy for the ionic conduction process. Ozazaki (17) employed thin plates of α-Ag_2S in the range 180°-300°C and obtained values considerably higher than other workers. Duffy (11) reported that in the range 190°-350°C σ_{Ag^+} did not vary with μ_{Ag} (Ag_2S) and his activation energy of 1500 cal $mole^{-1}$ is in agreement with that of Barkowiez *et al.* (4). If the values of σ_{Ag^+} given in Table III for any temperature are averaged it will be seen that each value differs from the average by at most 15%. As four experimental parameters are needed to determine σ_{Ag^+} and in view of the varying preparation and shapes of the sulfide samples used such disagreement may not be regarded as unreasonable. A likely source of error would be the presence of pores in the sulfide specimens but this is known not to be a problem with the samples grown as described above and used in the present work. The quality of the agreement between the experimental and calculated rate constants, which is evident in the data of Tables I and II, also lends credence to the values of σ_{Ag^+} determined here.

Conclusions

The terminal stages of the one-dimensional sulfidation of bulk silver by liquid sulfur at 400°C when the rate determining step is diffusion under a near constant concentration gradient has been accepted as one of the best proofs for the correctness of the Wagner theory for such processes (19). It also affords a good example of a chemical reaction rate proportional to the affinity of the reaction. The present work confirms that at temperatures lower than 400°C the parabolic rate law is still obeyed. It is also seen that rate constants in excellent agreement with the experimental values may be calculated using the Wagner equation provided that allowance is made for the departure from equilibrium which now occurs at the bulk Ag/Ag_2S interface. New values for the silver partial ionic conductivity in α-Ag_2S which are necessary for these calculations have also been determined. Further, it has been shown that the extent of the departure from equilibrium at the Ag/α-Ag_2S interface depends on the particular sample of high purity silver being used. Specimens of three samples of high purity 6 mm silver rods have been shown to behave quite differently when exposed to identical experimental conditions. The order of increasing rate constant was found to correspond qualitatively with the order of decreasing impurity concentration but it was also shown that the rate constant could be influenced by preannealing the silver sample to increase the grain size though no clear-cut correlation was found. What is evident however is that some property of the bulk silver must be responsible, at least partly, for the observed differences in behavior and it is obvious that a detailed examination of the Ag/Ag_2S interface is essential so that an attempt may be made to reveal the atomistic mechanism involved in the transfer of silver from bulk silver to α-Ag_2S during the sulfidation reaction. This is especially true in the light of the results of Corish and O'Briain for the transfer of silver from the vapor phase (20) and from silver whiskers (21) to α-Ag_2S. They found that once the silver atoms are free or readily available at active crystal positions they may dissolve readily in the solid without an overpotential. Their work together with the results of a controlled series of experiments involving the electrochemical transfer of silver from different samples of high purity bulk silver to α-Ag_2S will be discussed in Part II which is to follow.

Acknowledgments

We wish to thank Professor H. Rickert, University of Dortmund, for helpful discussions. The assistance of Dr. Eoin P. O'Neill is also gratefully acknowledged.

This work was carried out in partial fulfillment of requirements of the National University of Ireland for the award of the Ph.D. degree to C. J. Warde.

Electrochemical Studies at Silver/Alpha-Silver Sulfide Interfaces

II. Simulation of the Polarization Phenomena Occurring at the Ag/Alpha-Ag_2S Interface during the Sulfidation of Silver

C. J. Warde,*[,1] J. Corish, and C. D. O'Briain[2]

ABSTRACT

Measurements have been made of the overpotentials at the bulk silver/α-silver sulfide interface during the passage of neutral silver, silver ions, and electrons from three different samples of high purity silver across the interface. A semilogarithmic relationship between the overpotential and current density of silver was found in all cases in the temperature range 220°-340°C. In contrast with earlier results this relationship extended to the lowest current densities measured. A more detailed study of the three samples of silver was made at 260°C. The experimental method employed was designed to accentuate any differences between the specimens being used and the relative behavior of these samples has been characterized. A limited number of measurements were also made using preannealed silver samples. Possible reasons for the observed behavior are discussed, and the process is compared to that prevailing during the one-dimensional sulfidation of silver.

By using α-AgI as an auxiliary electrolyte it is possible to investigate fluxes of neutral silver, of silver ions, and of electrons across the phase boundary solid silver/α-Ag_2S. Previous studies of this kind (1, 2) have sought to establish quantitative relationhips between these three fluxes and the chemical potential difference of silver, the electrochemical potential difference of silver ions and of electrons across the interface, respectively. Even although silver and α-Ag_2S are both predominantly electronic conductors the inclusion of α-AgI tablets as electron blocks can ensure that the electric current measured during the passage of silver represents the rate of dissolution of silver at the interface and the process is thus analogous to that pertaining during the anodic dissolution of a metal in an electrolyte solution. The results which have been obtained with this system have shown that while no overpotential was observed during the transfer of electrons, fluxes of either silver ions alone or of equivalent quantities of silver ions and electrons (neutral silver) gave rise to measurable overpotentials which were found to be effectively equal. This overpotential, as might be expected, has therefore been assigned to an ionic polarization. Rickert and O'Briain (1) also reported that a minimum interface potential was required before any significant silver ion flux could occur while above this minimum a semilogarithmic relationship was found between the silver ion current density i_{Ag^+} and the observed overpotential. They represented these results by the following experimental equation

$$i_{Ag^+} = A \exp (B\mathbf{F}E) \qquad [1]$$

where A and B are dependent only on temperature, $\mathbf{F}$ is the Faraday constant, and E the relevant overpotential. The observed overpotentials have been used (3) to make quantitative calculations concerning the unidimensional growth of α-Ag_2S on silver and also the linear growth rate which is observed in the early stages of this reaction (4)

It is now known (5) that the extent of the departure from equilibrium which occurs at the silver/α-Ag_2S interface during the terminal stages of the one-dimensional sulfidation reaction depends on the particular sample of high purity silver being used. Since whatever process does occur at this interface during the reaction is of basic importance in determining the sulfidation rate it was felt that it would be worthwhile doing the electrochemical experiments necessary to reinvestigate the various phase boundary processes but using now three different samples of high purity silver. These samples were chosen to be similar to those used in the sulfidation experiments (5). Since all previous phase-boundary work had employed only one kind of silver preliminary experiments were carried out which showed that the extent of polarization during the transfer of silver ions was, under otherwise identical conditions, dependent on the type of silver being used. This paper reports the results of a series of experiments designed to show clearly any differences in the behavior of these samples and also to seek to establish the effects of using preannealed samples in which the grain size had been increased. A detailed study was undertaken at 260°C and less extensive measurements made at 220°, 300°, and 340°C.

One of the features of the earlier experiments (1, 2) was the use made of the relaxation curves observed when the silver current being withdrawn from the α-Ag_2S in a steady state was switched off. As will be shown later, the fall in overpotential which is observed is due to silver crossing the interface from the silver sample under investigation and a dynamic current density $i_{Ag,dyn}$ may be calculated from the equation

$$i_{Ag,dyn} = \frac{V}{a} \mathbf{F} \frac{dE}{dt} \frac{dc_{Ag}}{dE} \qquad [2]$$

where V is the volume of the sulfide, a the area of the interface, dE/dt is the slope of the relaxation curve at the stage in question and dc_{Ag}/dE (where c_{Ag} is the number of equivalents of silver/cm^3 of the sulfide) may be evaluated from the slope of a subsequent coulometric titration (6) of the sulfide tablet. The curves which result when these calculated dynamic current density values are shown as a function of the overpotential prove to be quite different from the corresponding curves observed under steady-state conditions.

The present reinvestigation includes a detailed study of relaxation curves. To this end the experimental arrangement was designed to allow the lightest sulfide tablets possible to be used and computer curve fitting routines were suitably adapted to calculate the dynamical current density curves. These curves are shown to vary with the particular sample of silver.

Key words: silver iodide, anodic dissolution, overpotential, relaxation curves, annealing.

Experimental

Materials.—The three types of silver used for these experiments were supplied as rods of 3 mm diameter as follows: (*i*) Johnson-Matthey Chemicals Limited, major impurity, copper <5 ppm, over-all purity, 99.999%; (*ii*) Degussa Feinsilber, major impurity, copper <300 ppm, over-all purity 99.97%; (*iii*) Johnson-Matthey Chemicals Limited, major impurity, copper <50 ppm, over-all purity 99.99%. These samples will be referred to as JM1′, D1′, and JM2′, respectively, since they are identical with the samples used in the sulfidation experiments reported in (5) except for their physical sizes. A precision lathe was used to reduce the diameter of each specimen to exactly 2.50 mm for a length of about 4-5 mm from the end to be used in the experiment and the specimens were then degreased as described previously. The silver iodide and silver sulfide used were of the same quality and from the same sources as those described in (5) and their fabrication into the various components utilized in the cell arrangement essential to the present work will be described in the following section. The experiments were again carried out in an atmosphere of oxygen-free nitrogen.

Circuitry.—The basic circuitry is shown diagrammatically in Fig. 1 and was as suggested by Rickert and O'Briain (1). The fundamental element of this system is a cell of the type

$$\text{Pt} \mid \text{Ag} \mid \text{AgI} \mid \text{Ag}_2\text{S} \mid \text{Pt} \quad [3]$$

which may be studied under both equilibrium and dynamic conditions and which employs α-AgI as an auxiliary electrolyte. This compound is an almost pure ionic conductor, its silver partial ionic conductivity beng several orders of magnitude greater than its electronic conductivity. Separate leads (Pt 4, Pt 5, and Pt 6) were used to pass current through the various parts of the cell and also (Pt 1, Pt 2, and Pt 3) to measure the resultant overpotentials at the silver/α-silver sulfide interface. A small Ag/AgI probe pressed against the silver sulfide tablet near this interface and also the platinum probes ensured that the potential measurements were not invalidated by polarization phenomena. When a d-c current is passed between Pt 4 and Pt 6 (S1 left, S2 right) silver ions only cross the silver (Ag1)/α-silver sulfide interface. If, instead, a small voltage is applied between Pt 5 and Pt 4 (S1 right, S2 left) an electronic current only crosses the silver (Ag1)/α-silver sulfide interface. Finally a potential applied between Pt 5 and Pt 6 and positive at Pt 5 (S1 right, S2 right) will cause silver to be withdrawn to Ag3 from the Ag_2S. As the chemical potential of silver in the silver sulfide decreases, silver from the silver sample Ag1 in contact with the sulfide will be found to cross the interface and steady state may be attained in which an equal flux of silver goes from Ag1 into the Ag_2S as leaves this phase through AgI 1 and Pt 5 as silver ions and electrons, respectively. The establishment of the steady state can be assumed once the chemical potential of silver in the Ag_2S, as measured by the silver-silver iodide probe (Ag2/AgI2), remains constant.

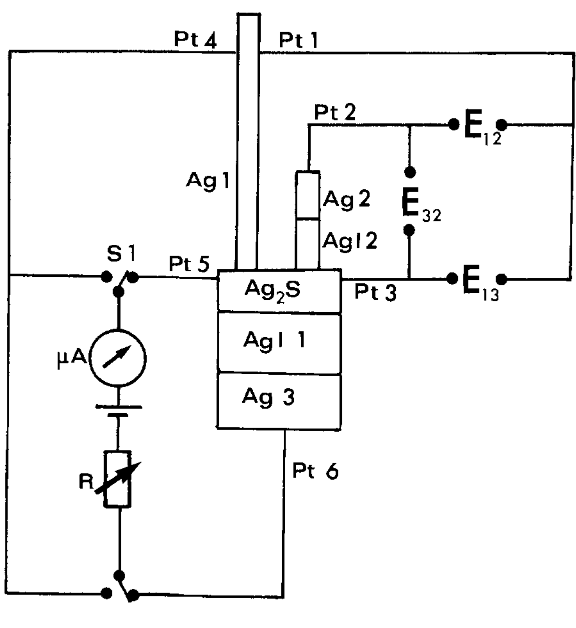

Fig. 1. Basic circuitry to study the transfer of silver across the Ag/α-Ag_2S interface.

Three different overpotentials E_{12}, E_{13}, and E_{32} may be measured when a current of ions, electrons, or neutral silver flows across the Ag/α-Ag_2S phase boundary. These potential differences are the emf's, respectively, of the cells

$$\text{Pt 2} \mid \text{Ag 2} \mid \text{AgI 2} \mid \text{Ag}_2\text{S} \mid \text{Ag 1} \mid \text{Pt 1} \quad [4]$$

$$\text{Pt 3} \mid \text{Ag}_2\text{S} \mid \text{Ag 1} \mid \text{Pt 1} \quad [5]$$

$$\text{Pt 2} \mid \text{Ag 2} \mid \text{AgI 2} \mid \text{Ag}_2\text{S} \mid \text{Pt 3} \quad [6]$$

The analysis of these cells has been discussed in detail previously (1) and these emf's are related to the differences in electrochemical potentials of silver ions and electrons and chemical potentials of silver across the interface by the following equations

$$-\mathbf{F}E_{12} = \eta_{\text{Ag}^+}(\text{Ag}_2\text{S}) - \eta_{\text{Ag}^+}(\text{Ag}) \quad [7]$$

$$\mathbf{F}E_{13} = \eta_{\text{e}^-}(\text{Ag}_2\text{S}) - \eta_{\text{e}^-}(\text{Ag}) \quad [8]$$

$$\mathbf{F}E_{32} = \mu_{\text{Ag}}(\text{Ag}_2\text{S}) - \mu_{\text{Ag}}(\text{Ag}) \quad [9]$$

where μ and η are the chemical and electrochemical potentials, respectively, and the subscripts have their usual meanings. It is also evident from the analysis that the following relationship

$$E_{32} = E_{12} - E_{13} \quad [10]$$

should hold between the measured overpotentials.

Apparatus.—The experimental arrangement of the cells whose operation has been described in the previous section is shown in Fig. 2 (a) and (b). This design evolved after considerable experiment in an effort both to reduce the size of the sulfide tablet to facilitate investigation of the relaxation curves and to increase the reliability of the system over the lengthy time intervals necessitated by the comparative study of the silver samples. The upper AgI tablet shown was pressed under 100 kg cm^{-2} in a specially constructed die with two platinum electrodes embedded in its upper surface. It was then drilled out in the shape shown and rested on a second AgI tablet which was also drilled and which was included to prevent short circuiting caused by dendritic growth of silver through this substance. The Ag_2S disks were 3.4 mm in diameter, 0.25 mm in thickness and each weighed 12.30 ± 0.05 mg. They were punched from a larger tablet which had been compacted at 6.1 × 10^3 kg cm^{-2}. The silver block corresponding to Ag 1 of Fig. 1 and prepared as already described rested on the Ag_2S tablet. Its shape avoided experimental difficulties arising from the occasional failure to exactly center the sulfide wafer and the contact pressure was maintained at 6 kg cm^{-2}, (similar to that used in the sulfidation experiments) via a glass rod which passed outside the apparatus through a precision sliding gas tight seal. The Ag/AgI probe electrode was made from 6 mm glass tubing drawn into a tapering capillary which was cut and ground so that the narrower end could just reach through the drilled hole to the upper surface of the upper silver iodide tablet but no further. One of the consequences of this design was that this Ag/AgI probe was no longer on the same side of the

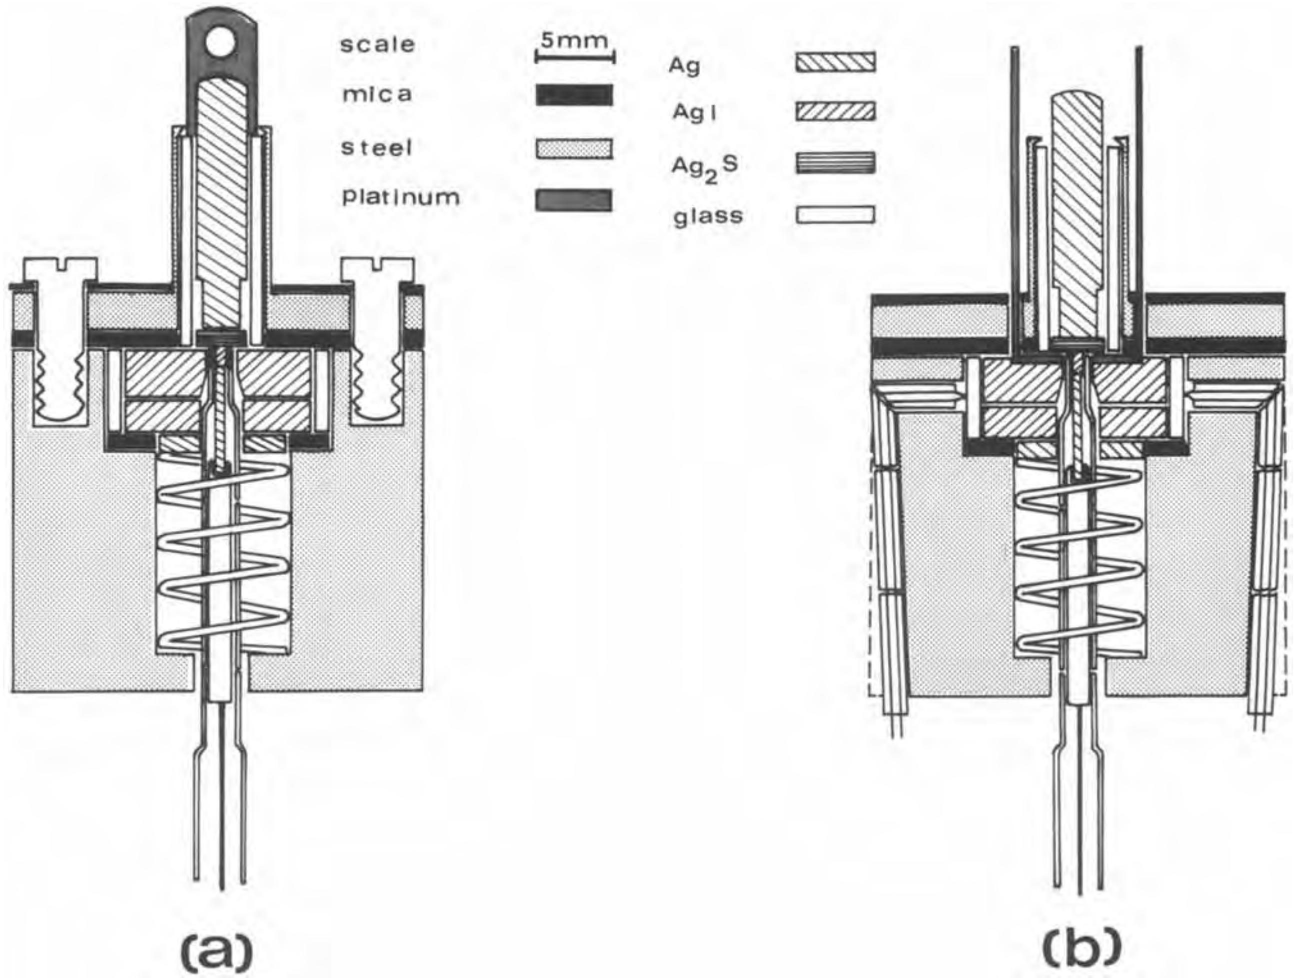

Fig. 2. Cell arrangement shown with the (a) and (b) cross sections at 90°C

α-silver sulfide tablet as was the silver block Ag 1. Fears that this might lead to incorrect measurements of the overpotentials E_{32} and E_{12} were allayed by the solution of the diffusion equation for the system which showed that any concentration gradient across this thickness of sulfide will fall to zero in ~50 msec because of the high value of the diffusion coefficient of silver in α-Ag_2S (6). As shown the cell assembly was held in a steel support unit and the necessary insulation was provided by mica strips. The temperature was measured using a pair of Chromel-Alumel thermocouples and the entire system was held in a 1 in. diameter Kovar joint at the center of an air-jacketed, nichrome wound furnace with temperature control to better than ± 1°C.

Procedure.—A number of procedures have been described previously (1, 2) to establish steady-state conditions at the Ag/α-Ag_2S interface in this type of experiment. Essentially these consisted of withdrawing a large current of silver from the sulfide thus causing silver to flow from the silver rod under investigation into the sulfide. Then when a steady state had been established the current was switched off and the relaxation process observed. These operations were repeated until the relaxation curves indicated that a suitable reproducible contact had been established. The current was then reduced successively thus obtaining new steady states. An alternative method was to commence at a low value of the current after reproducible contact was established and then to switch up the current in steps. These different procedures gave steady-state overpotentials which differed, at the same current density and temperature, by as much as 10-15 mV.

As the main objective of this work was to characterize the relative behavior of the different silver samples, it was obviously desirable to adopt a standard procedure for every experiment. Consequently, it was decided (*i*) to operate each experiment at one fixed current of silver only and at a given temperature and (*ii*) to cause the same quantity of silver to be drawn across the Ag/α-Ag_2S interface in every experiment. The major disadvantage of (*i*) was that it greatly increased the number of experiments required. If there was a buildup of impurities at the phase boundary then (*ii*) ensured that for each sample of silver, the quantity of silver which had crossed the phase boundary when measurements of the overpotentials were made was the same in every experiment. Thus, at a current density of 0.75 A cm^{-2}, the system was operated for 1 hr, at 0.375 A cm^{-2} for 2 hr and so on to 64 hr at 0.0117 A cm^{-2}. The quantity of silver which crossed the interface in every experiment was then a length of 2.9 mm of the silver rod which corresponds to 1 unit in the overpotential traces shown later in Fig. 3. The experimental procedure followed was to withdraw a fixed current of silver from the silver sulfide while E_{32} was monitored continuously using a Honeywell Elektronik 19 recorder. When a steady state was eventually achieved the current density of silver crossing the interface was readily calculable. After the appropriate quantity of silver had crossed the interface, the steady-state values of E_{12} and E_{13} were measured. A relaxation curve of E_{32} *vs.* time was now observed by switching the current circuit off. By switching on again, the steady state could be regained, after an interval which was a function of the current density, and further relaxation curves were taken. The adequacy of the response time of the recorder (F.S.D. <0.5 sec) for the purpose of observing these curves was checked by also using an oscillo-

Results and Discussion

The basic results with respect to the magnitudes of the observed overpotentials are summarized in Table I which gives data at 260°C for the three kinds of silver. The measurements of this kind made in this study show that: (*i*) when electrons alone crossed the Ag/α-Ag_2S phase boundary E_{12}, E_{13}, and E_{32} were all less than 1 mV; (*ii*) when silver ions alone were transported, the measured values of E_{12} were approximately equal to those of E_{32} while E_{13} never exceeded 4% of the E_{32} value; (*iii*) the potential differences during the transfer of equivalent amounts of silver ions and electrons were the same as those observed during the transfer of silver ions alone; and (*iv*) Eq. [8] was, in general, obeyed. These observations are in agreement with the previous work on this system (1, 2) and also with the more recent results of Rickert *et al.* for the Ag/α-Ag_2Se and Ag/α-Ag_2Te interfaces (7). As we shall see later (Fig. 4) the semilogarithmic relationship between the silver current density, i_{Ag}, and the relevant overpotential, E_{32}, found previously is also confirmed but in contrast to the earlier work this relationship was now found to extend to the lowest current densities measured. The detailed results of the comparative study of the silver samples will be discussed in the following sections.

Unannealed silver.—The overpotential traces for the three silver samples at 260°C and at a current density of 0.375 A cm^{-2} are shown in Fig. 3. In the interpretation of these traces it should be remembered that 1.0 units of silver consumed corresponds to 2.9 mm length of the silver rod. These curves are typical of those observed at other current densities and other temperatures and the following general conclusions could be drawn concerning the behavior of the various silver samples. JM1' was characterized by a short induction period at high overpotentials, followed by a rapid drop to near zero E_{32} values and finally, after ~0.25 units

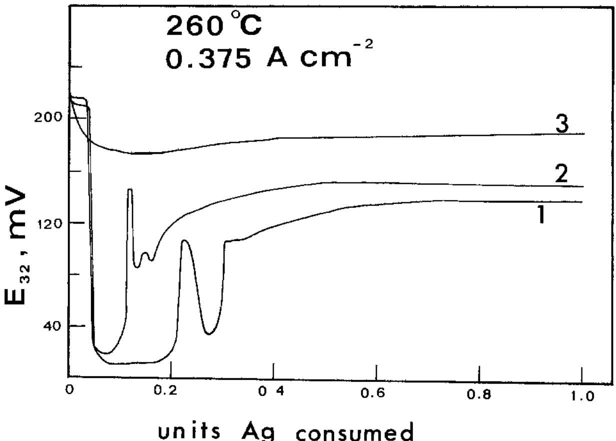

Fig. 3. Overpotential traces at 260°C and a current density of 0.375 A cm^{-2}. The traces shown are: curve 1, JM1'; curve 2, JM2'; and curve 3, D1' samples of silver.

of silver have crossed the interface, by a rapid rise to an overpotential ~20 mV below the steady-state value which was reached typically after 0.6 units had been consumed. The behavior of JM2' differed from that of JM1' in the following ways. Firstly, the overpotentials attained after the rapid drop were not quite so low; secondly, the rapid rise occurred after only about 0.1 units had passed; and thirdly, the steady-state overpotentials were ~20 mV higher than those observed from JM1' at every silver current density measured. The D1' silver was quite different in behavior to the two samples of Johnson-Matthey silver. Virtually no induction period was observed before E_{32} fell to a value which was, at most, 20 mV below the value observed after 1.0 units had crossed the interface. The minimum in E_{32} was observed after ~0.05 units had passed and this was followed by a slow rise until ~0.3 units which was followed in turn by an even slower rise. Even after 1.0 units of silver had been consumed no true steady state was observed ,and E_{32} continued to rise slowly. Furthermore the values of E_{32} now measured were 40-50 mV higher than those observed for the JM2' silver at the same current densities.

The semilogarithmic relationships between the silver current densities, i_{Ag}, and the overpotentials, E_{32}, observed for each of the silver samples after 1.0 units had crossed the interface are shown in Fig. 4. The extent of the bars shown on some of the points represent the limit of any oscillations of E_{32} at the time the overpotential was read. It is most important to emphasize that in contrast to earlier work each point now represents a separate experiment thus confirming both the validity of the relationship shown and also the reproducibility of the differences between the overpotentials observed for each sample. Also in contrast to earlier results (1, 2), the semilogarithmic relationship was now shown to extend to the lowest current densities measured. As is evident from Fig. 4 the slopes of these plots for the various silver samples were almost identical despite the large differences in the magnitudes of the observed E_{32} values. These results are typical of those found at the other temperatures (220°, 300°, and 340°C) at which measurements were made while the effect of temperature on the semilogarithmic plots is shown for D1' silver in Fig. 5.

These results when considered with the fact that the impurity content of JM1' is less than that of JM2' which in turn is very much less than that of D1' lead to a postulate that the abrupt rise from near zero potentials, observed for the first two is due to the buildup of a critical quantity of impurities at the Ag/α-Ag_2S interface. The passage of 0.25 units (*i.e.*, a length of 0.7 mm) is required in the case of JM1' while 0.10 units of the more impure JM2' suffice for the same purpose. This effect is not, of course, observed for the D1' specimens. The major impurity in the three silver samples was copper in concentrations of 5, 50, and 300 ppm, respectively, but in the absence to date of detailed experiments using specifically doped samples no decision can be made as to whether the copper, or some other impurity, perhaps present in trace quantities, was responsible for the sudden rise to higher overpotentials. Since the magnitude of the overpotentials observed here correlate with those reported

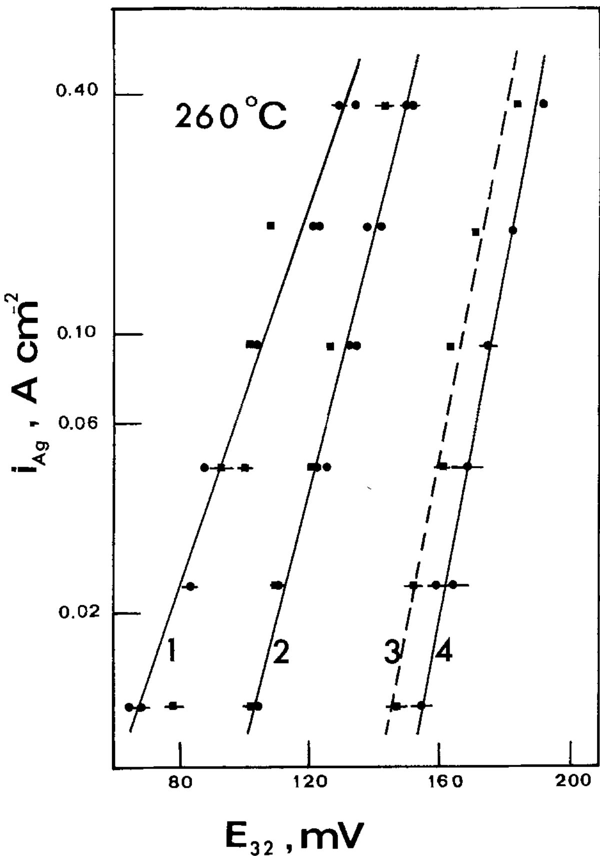

Fig. 4. Semilogarithmic plot of current density vs. steady-state overpotentials at 260°C. Data for unannealed silver (●) and for annealed silver (■) and the lines shown are fitted to the data as follows: line 1, JM1 unannealed; line 2 JM2' unannealed; line 3, D1' annealed; and line 4 D1' unannealed sample of silver.

during sulfidation of comparable silver samples (5) and since it has also been shown that changes in grain size effected by preannealing influence the sulfidation kinetics, a series of phase boundary experiments were now undertaken using annealed silver samples.

Annealed silver.—The annealing of the remaining samples of each type of silver was carried out at 660°C *in vacuo* for 100 hr. A metallurgical examination, as described in (5), followed and indicated that once again the grain sizes had been increased. Because of the limited supply of silver remaining the phase boundary experiments for the annealed samples were confined to measurements at 260°C only. It had been expected, bearing in mind the results of the sulfidation experiments with the annealed samples (5) that there would be a lowering of E_{32} for each of the annealed silver samples. In fact, only very small differences in behavior were observed between these samples and the unannealed specimens. The overpotential *vs.* time traces for JM1' and JM2' annealed samples were quite similar to those shown in Fig. 3 for the unannealed samples while the steady-state overpotentials attained were almost the same as those recorded previously. The pattern of behavior which emerged from these experiments is shown in Fig. 4 where the experimental results for annealed JM1' and JM2' are seen to fall close to the best-fit lines through the unannealed data. In contrast all data for annealed D1' lie consistently lower by ~7 mV and are fitted by the broken line. These results were therefore surprising in view of the sulfidation data (5). In this case it could not be claimed that increasing the grain size in the samples led, in general, to a lowering of the interface overpotential.

Relaxation curves.—The relaxation curves obtained when the current was switched off in the steady state corresponding to each current density measured at 260°C for JM2' silver are shown in Fig. 6. These curves are typical of those observed at all temperatures for both JM1' and JM2' silver. All were perfectly smooth with decreasing slope and the curves for these two kinds of silver were, in general, superposable for the initial 40-50 mV of the drop to zero. The relaxation curves for D1' silver were quite different and that obtained at 260°C from the steady state corresponding to a current density of 0.0117 A cm^{-2} is compared with the curves obtained under identical circumstances for both the Johnson-Matthey samples in Fig. 7. As is evident the curve for D1' silver contained a point of inflection which was also a feature in all the curves for this sample except those originating from the steady states corresponding at each temperature to the

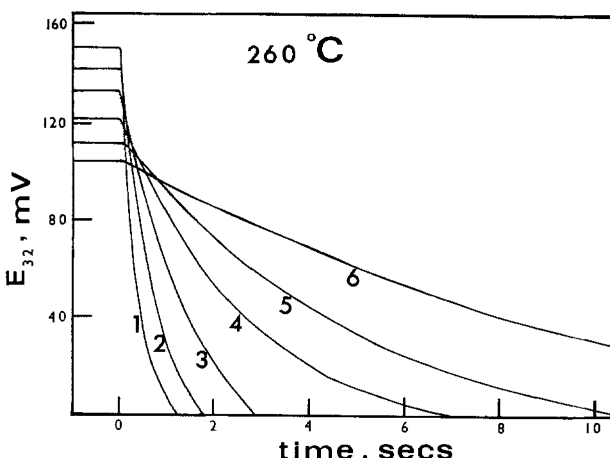

Fig. 6. Relaxation curves at 260°C for JM2' silver. The steady states from which the curves originate result from the following steady-state current densities in A cm^{-2}: curve 1, 0.375; curve 2, 0.1875; curve 3, 0.0938; curve 4, 0.0468; curve 5, 0.0234; and curve 6, 0.0117.

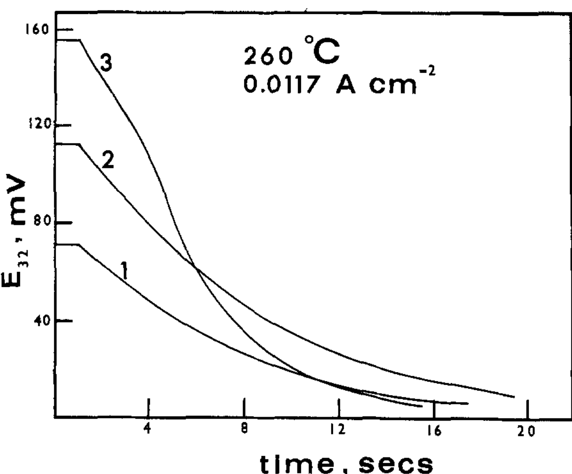

Fig. 7. Comparison of relaxation curves at 260°C from steady states resulting from a current density of 0.0117 A cm^{-2}; curve 1, JM1'; curve 2, JM2'; and curve 3, D1' silver samples.

largest current density (0.375 A cm^{-2}) employed. As it was possible to again attain the same steady state by again switching on the appropriate current further relaxation curves could be observed. These subsequent curves for the Johnson-Matthey samples were found to be quite reproducible, *i.e.*, superposable, but those for the D1' silver were not. In the latter case repeated taking of relaxation curves caused an increase in the degree of inflection with the result that E_{32} fell more rapidly to zero. The relaxation curves of E_{12} for D1' silver also had a point of inflection, while those for E_{13} showed a step which occurred at a time corresponding to just before the onset of inflection in the E_{32} and E_{12} curves. This would suggest the operation of a two-stage relaxation process in the case of the D1' silver, and although there have been indications in earlier work also using Degussa Feinsilber (2) that this might be the case, we can, on the evidence currently available, offer no explanation as to the cause.

To calculate $i_{Ag,dyn}$, the dynamic silver current density across the $Ag/\alpha\text{-}Ag_2S$ interface at any value of E_{32}, coulometric titrations (6) were first carried out on tablets of the same weight as those used in all experiments. These curves were then computer fitted using a polynominal regression routine which also evaluated dE_{32}/dt. A similar program for the relaxation curves evaluated not only the slopes but also the $i_{Ag,dyn}$ at given values of E_{32} using data from the fit to the coulometric curve in Eq. [2]. The dynamic current density curves resulting from the relaxation curves of Fig. 6 are shown in semilogarithmic form in Fig. 8 and once again are typical of the curves obtained for JM1' and JM2' samples at all the temperatures at which measurements were made. Figure 9 shows the $i_{Ag,dyn}$ curves for the relaxation traces of Fig. 7 and the point of inflection for D1' silver now manifests itself as a maximum of current density. The curve itself from 100 mV down approximates to that observable for the relaxation current of a Johnson-Matthey sample from a steady state corresponding to approximately twice the current density. A comparison of Fig. 8 and 9 with Fig. 4 shows clearly that, as had been found previously, the relationship between $i_{Ag,dyn}$ and E_{32} during a relaxation process was quite different from that which existed between the current densities and overpotentials in the steady states. Since the dynamic current densities at the same stage (same value of E_{32}) of the different relaxation processes are quite different it is also evident that the dynamic current density also depends on the steady state from which the relaxation began. Furthermore the relaxation behavior is now also seen to depend on the particular sample of silver being used.

General Summary

The principal results from this investigation of the bulk silver/α-silver sulfide interface show that the interface potentials are dependent, as might have been expected from the sulfidation results (4), on the type of high purity silver used. It has also been shown that the semilogarithmic relationship between the silver current density and the overpotential which had been thought to exist only above certain critical overpotentials (1) in fact extends over the entire current density range measured (*i.e.*, 0.75 A cm^{-2} to 0.0117 A cm^{-2}). The previously observed critical overpotentials below which the overpotential became independent of the current density were used (1) to explain the steady overpotentials observed at the Ag/α-Ag_2S interface during the sulfidation reaction. In view of the new results presented here these steady overpotentials may be explained as follows. The initial stages of the sulfidation reaction proceed rapidly so that by the time steady overpotentials are observed the sulfide layer is reasonably thick. It is obvious from inspection of the parabolic equation [Eq. [1] of Ref (5)] that for the silver flux to decrease by a factor of two, the sulfide layer thickness must have increased by the same factor. This may take a time of the order of hours as, in general, the supposed steady-state is reached after approximately 2-3 hr. When the current density is halved the overpotential, E_{32}, drops by no more than a few millivolts (*e.g.*, at 260°C for D1′ silver E_{32} is diminished by ~8 mV if i_{Ag} is halved). Counteracting this tendency of E_{32} to decrease is the fact, already commented upon, that at a fixed current density E_{32} for D1′ silver continues to rise as more silver crosses the phase boundary. Thus a pseudo steady state may well be observed at the Ag/α-Ag_2S interface during the formation of compact sulfide layers. Further efforts were made, by using preannealed silver samples in which grain size had been increased, to obtain results corresponding to those reported in recent sulfidation experiments (5). These attempts were somewhat surprising since only a small effect was found and that only in the case of D1′ silver. A correlation was found to exist between a possible buildup of impurities at the interface and the magnitude of the observed overpotentials. However, it is felt that a series of experiments in which the impurity levels in the silver are systematically varied will be required before any definite conclusion may be reached as to the precise causes of these overpotentials.

The nature of the polarization is nonohmic while the relaxation behavior indicates that the exact condition of the interface is involved. O'Briain (2) proposed a polarization model based on an activated process, as suggested by Eq. [1], in which a silver ion on a surface site was assumed to have to surmount an energy barrier to reach a similar site on the α-Ag_2S. This model is, however, unacceptable if applied to the data for α-Ag_2S since it requires transfer coefficients appreciably larger than unity. Rickert *et al.* (7) also discussed this model but showed that it was similarly unacceptable for their observations of the Ag/α-Ag_2Se and Ag/α-Ag_2Te interfaces.

Since the net result of the process occurring at the block silver/α-Ag_2S interface is the dissolution of one solid into another any attempt to elucidate the atomistic mechanism must consider the crystal structures of both substances. The α-Ag_2S structure (8) might be expected to be well suited to accept silver since the effective number of available silver sites per unit cell has been estimated at almost six with only four silver ions accommodated (9, 10). As we have already mentioned the interdiffusion coefficient for silver (6) in this solid (~3×10^{-2} cm^2 sec^{-1} at 400°C) is sufficiently high to eliminate concentration gradients rapidly and so the dissolution process may well depend primarily on the particular form in which silver atoms are presented at the sulfide surface. In this respect two previous reports from this laboratory have considered the silver vapor/α-Ag_2S and silver whisker/α-Ag_2S interfaces. Silver vapor (11) impinging on the surface of an α-Ag_2S tablet was found to be incorporated readily into the solid. If the sulfide was made a part of a suitable electrochemical cell then it was found possible using very small overpotentials (<1 mV) to maintain a steady state in which the silver entering the tablet from the vapor phase was balanced by a corresponding electrochemical withdrawal of silver through the cell. The silver whiskers (12) were first grown electrochemically on preferentially nucleated sites on a sulfide tablet and the subsequent transfer of silver across the Ag(whisker)/α-Ag_2S interface was found to occur with the application of very small overpotentials. Typically a current density of 0.5 A cm^{-2} was achieved with overpotentials of ~2.9 mV and 2.2 mV at 220° and 300°C, respectively, which processes would be expected to require overpotentials well in excess of 100 mV for samples of block silver. The very small overpotentials observed at the Ag(whisker)/α-Ag_2S interface, and similar observations have now been made at the Ag(whisker)/α-Ag_2Se interface (13), were attributed to the presence of screw dislocations in the whiskers (14), the situation being analogous to that reported by Vermilyea (15) for the electrolytic growth and dissolution of copper whiskers in solution. It was also emphasized (12) that the special nature of the microcontact expected to be attained at the Ag(whisker)/α-Ag_2S when the whiskers were actually grown *in situ* almost certainly significantly influenced the magnitude of the observed overpotentials. Unfortunately attempts to distinguish the part played in the silver transfer process by the presence of dislocations from that resulting from the nature of the microcontact were not successful. What is clear, however, from the vapor and whisker work is that silver atoms presented either free or at suitable active crystal positions may be very easily incorporated into α-Ag_2S.

The behavior of the bulk silver studied here at the chalcogenide interface is presumably much more complex. The attainment of an adequate microcontact is obviously difficult and since each sample has a different grain size and orientation, and most probably a different defect structure, the facility with which silver atoms are removed from the bulk silver may be expected to vary. These factors will then influence the exact nature of the interface and hence the magnitude of the overpotentials. Our results also indicate that any completely successful model must also take account of the possible influence of a buildup of impurity atoms at the interface, although the role of these impurities is at present less clear.

Acknowledgments

We are grateful to Professor H. Rickert, University of Dortmund, Dr. Eoin P. O'Neill, Westinghouse Research Laboratories, and Dr. Ronald F. Saunders, for many helpful discussions.

This work was in part fulfillment of the requirements for the award of the degree of Ph.D. by the National University of Ireland to C. J. Warde.

Manuscript submitted March 24, 1975; revised manuscript received July 12, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

A State-of-Charge Test for Zinc-Mercuric Oxide Primary Cells

John J. Winter, James T. Breslin, Raymond L. Ross, Herbert A. Leupold, and Frederick Rothwarf

U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

ABSTRACT

A readily instrumented and conducted nondestructive technique to determine the state of charge of zinc-mercuric oxide primary cells has been developed and preliminary results obtained. Measurements of the current *vs.* voltage (*I-V*) characteristics, the a-c impedance, the electronically sampled derivative at different sampling currents and frequencies, and the discharge-time characteristics of the cells as a function of charge expended have been made and reported. The nearly constant slopes of the *I-V* curves above 75 mA were measured graphically. It was found that these slopes have a linear relation to charge expended and can be used as a basis for a simple state-of-charge indicator which determines remaining charge to about 12%. By combining this criterion with a-c resistance measurements the maximum experimental deviation was found to be less than 10% with 90% of the data points deviating less than 6% from the mean linear curve. These studies indicate that this technique constitutes a useful, easily applied state-of-charge test.

There has been a long standing need for a reliable, nondestructive state-of-charge test for many of the most commonly used primary cells. Attempts have been made in the past to link some output characteristic of a cell to its remaining charge, but invariably the resulting relationship was found to be either too insensitive, too internally inconsistent, or too variable from cell to cell. The results of one of the more interesting of these attempts were published by Sandia Laboratories in 1970 (1, 2). This indicator was developed to improve the probability of selecting batteries having a state of charge exceeding 80% of capacity. The calibration curves obtained were extremely sensitive to discharge rates and temperatures as well as storage times and temperatures. In this technique, mercury cells were subjected to a series of large-current, pulsed discharges, each corresponding to a known remaining charge. Certain dimensions of the resulting pulse were measured graphically and combined mathematically to obtain a single parameter which was then plotted against the corresponding charge of the cell. Attempts to apply the Sandia technique to zinc-mercuric oxide primary cells were made at the U.S. Army Electronics Command, Fort Monmouth, New Jersey (3), and Mallory (4) without success, and the experiments were discontinued.

Accordingly, it was decided to investigate the possibility of utilizing the parameters of current *vs.* voltage (*I-V*) curves as state-of-charge indicators. Examples of such curves are shown in Fig. 1. The nearly constant slopes of the *I-V* curves at discharge currents above 75 mA show sufficient sensitivity to state of charge to suggest their utilization as an indicator. Accordingly, it was decided to investigate this possibility as well as the effect of the state of charge on both the cell a-c impedance and differential resistance.

Key words: zinc-mercuric oxide or mercury cells, current voltage (*I-V*) characteristics, state of charge, polarization resistance, internal resistance.

Experimental

Two different types of cell were used: seven RM4R cells denoted A1-A7 and four RM4H cells denoted B1-B4 with nominal voltages of 1.35 and 1.40V, respectively. All cells were discharged at room temperature (22° ± 2°C). The A cells were stored for varying periods of time (2-7 months) at room temperature and the B cells were refrigerated at about 8°C for several months before being tested. A schematic representation of the experimental apparatus is shown in Fig. 2. Only the portion enclosed by the dotted line is needed to obtain the *I-V* curves. The latter are obtained by use of a forced discharge, that is, a discharge through a power supply in the constant current mode. When operated at constant current the power supply behaves as an active variable load to maintain a particular current which is set by manual adjustment of

A State-of-Charge Test for Zinc-Mercuric Oxide Primary Cells

John J. Winter, James T. Breslin, Raymond L. Ross, Herbert A. Leupold, and Frederick Rothwarf

U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

ABSTRACT

A readily instrumented and conducted nondestructive technique to determine the state of charge of zinc-mercuric oxide primary cells has been developed and preliminary results obtained. Measurements of the current *vs.* voltage (*I-V*) characteristics, the a-c impedance, the electronically sampled derivative at different sampling currents and frequencies, and the discharge-time characteristics of the cells as a function of charge expended have been made and reported. The nearly constant slopes of the *I-V* curves above 75 mA were measured graphically. It was found that these slopes have a linear relation to charge expended and can be used as a basis for a simple state-of-charge indicator which determines remaining charge to about 12%. By combining this criterion with a-c resistance measurements the maximum experimental deviation was found to be less than 10% with 90% of the data points deviating less than 6% from the mean linear curve. These studies indicate that this technique constitutes a useful, easily applied state-of-charge test.

There has been a long standing need for a reliable, nondestructive state-of-charge test for many of the most commonly used primary cells. Attempts have been made in the past to link some output characteristic of a cell to its remaining charge, but invariably the resulting relationship was found to be either too insensitive, too internally inconsistent, or too variable from cell to cell. The results of one of the more interesting of these attempts were published by Sandia Laboratories in 1970 (1, 2). This indicator was developed to improve the probability of selecting batteries having a state of charge exceeding 80% of capacity. The calibration curves obtained were extremely sensitive to discharge rates and temperatures as well as storage times and temperatures. In this technique, mercury cells were subjected to a series of large-current, pulsed discharges, each corresponding to a known remaining charge. Certain dimensions of the resulting pulse were measured graphically and combined mathematically to obtain a single parameter which was then plotted against the corresponding charge of the cell. Attempts to apply the Sandia technique to zinc-mercuric oxide primary cells were made at the U.S. Army Electronics Command, Fort Monmouth, New Jersey (3), and Mallory (4) without success, and the experiments were discontinued.

Accordingly, it was decided to investigate the possibility of utilizing the parameters of current *vs.* voltage (*I-V*) curves as state-of-charge indicators. Examples of such curves are shown in Fig. 1. The nearly constant slopes of the *I-V* curves at discharge currents above 75 mA show sufficient sensitivity to state of charge to suggest their utilization as an indicator. Accordingly, it was decided to investigate this possibility as well as the effect of the state of charge on both the cell a-c impedance and differential resistance.

Key words: zinc-mercuric oxide or mercury cells, current voltage (*I-V*) characteristics, state of charge, polarization resistance, internal resistance.

Experimental

Two different types of cell were used: seven RM4R cells denoted A1-A7 and four RM4H cells denoted B1-B4 with nominal voltages of 1.35 and 1.40V, respectively. All cells were discharged at room temperature (22° ± 2°C). The A cells were stored for varying periods of time (2-7 months) at room temperature and the B cells were refrigerated at about 8°C for several months before being tested. A schematic representation of the experimental apparatus is shown in Fig. 2. Only the portion enclosed by the dotted line is needed to obtain the *I-V* curves. The latter are obtained by use of a forced discharge, that is, a discharge through a power supply in the constant current mode. When operated at constant current the power supply behaves as an active variable load to maintain a particular current which is set by manual adjustment of

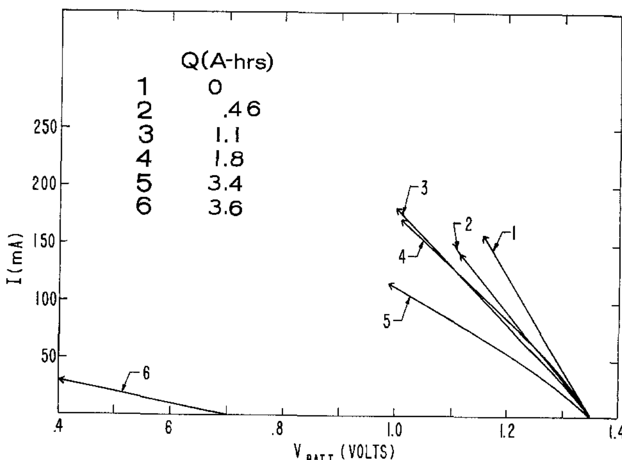

Fig. 1. The *I* vs. *V* curves of cell A6 at different states of charge.

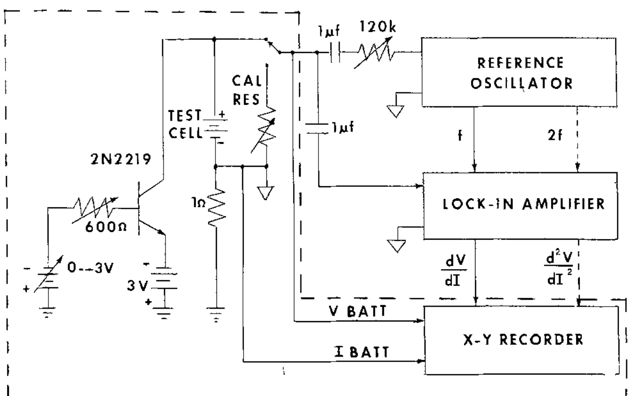

Fig. 2. The circuit employed in the *I-V* as well as the differential a-c resistance measurements.

the bias on the 2N2219 transistor. An *I-V* curve is traced on an X-Y recorder by increasing the current from 0 to 150 mA in 30-40 sec. Cycling times from 25 sec to 2 min yield essentially the same result. Significantly shorter cycling times were not possible due to the time constant of the recorder as well as the erratic response from rapid manual control of the current sweep. If the sweep is interrupted and the current is kept constant, the voltage of a cell having sustained major discharges will initially tend to drift downward. For example, if the sweep is halted at a current of 30 mA, the voltage drifts downward at a rate of about 2.5 mV/sec.

As Fig. 1 illustrates, the slope above 75 mA of the *I-V* curves decreases monotonically with the total charge expended. In general, the slope of each curve varies with current up to about 75 mA, above which it becomes nearly constant. Small local irregularities in the *I-V* curve due to the discrete nature of the electrochemical processes and the inevitable roughness of manual current control made consistent definition of a tangent at a point impracticable. It was, therefore, necessary to measure the slope not of a tangent but of a secant drawn through the curve over a small but finite voltage interval. This procedure effectively smoothed out local irregularities thus permitting definition of an effective d-c differential resistance. The voltage interval (ΔV) chosen was 0.1V and the low current boundary of the interval was taken at 75 mA as illustrated by the dashed triangle in Fig. 3.

The state of charge was usually obtained by starting with new cells and discharging them through fixed loads at currents ranging from 30 to 80 mA, since 80 mA is the upper rating of these cells for practical use. A graphical recording was kept of current *vs.* time so that the charge expended, ΔQ_i, was obtained from the area under the resulting curve. Typical discharges were of the order of 0.4 A-hr. The total charge expended, Q, was obtained by summing all discharges, *i.e.*, $Q = \Sigma_i \Delta Q_i$. The *I-V* curves were obtained at least 16 hr subsequent to each discharge. This interval between discharge and state-of-charge measurement gave the cell time to reach chemical equilibrium and insured consistent results. The 16 hr period was convenient for our measurement schedule and could possibly be shortened to as little as an hour or less. The charge losses ($\sim 7 \times 10^{-4}$ A-hr) associated with the measurement of the *I-V* curves were less than 0.2% of a typical discharge and, therefore, negligibly small. For convenience several cells were sometimes discharged simultaneously by connecting them in series. The series combinations used were A1, A2, A3; B1, B2; and B3, B4.

Plots of slopes, $(\Delta V/\Delta I)_{75}$ *vs.* total discharge Q for several cells are shown in Fig. 4. Note that the relationship is invariant with the discharge rates indicated and between the two different types (A and B) of cells tested. The measurements for A4 and A5 are not included since they were discharged at the abnormally high average currents of 120 and 175 mA, respectively. At the beginning of each discharge of cell A5 the initial current was 250 mA. The current declined gradually to some cutoff value (ranging from 100 to 190 mA) after which the decrease became much more abrupt. As soon as this steep falloff commenced, the discharge was terminated. The average current drain over the discharge period was taken to be 175 mA and is referred to as such in the figures. The discharge current of cell A4 was held constant at 120 mA although maintenance of this value necessitated a slight load decrease in the course of the discharge.

To obtain the differential a-c resistance $(dV/dI)_{AC}$, all of the apparatus of Fig. 2 is employed. A small a-c signal is superimposed on the direct current for which $(dV/dI)_{AC}$ is desired (5). For greater sensitivity the resultant voltage is nulled and measured with a differential lock-in amplifier. The resistance scale was calibrated by substituting a precision wire-wound resistance decade box for the cell. That $(dV/dI)_{AC}$ cannot be used in lieu of the d-c differential resistance $(\Delta V/\Delta I)_{75}$ is clearly illustrated by the curves of Fig. 3 which show that while $(\Delta V/\Delta I)_{75}$ increases by about 50% after a 2.35 A-hr discharge, the corresponding change in $(dV/dI)_{AC}$ is only about 3%. The discrepancy between these measurements appears to be in accord with the literature. Vinal (6), for ex-

[a] $(dV/dI)_{AC}$ is sampled with an alternating current of 10 mA at 0.5 kHz.
[b] $(\Delta V/\Delta I)_{75}$ is specified by a ΔV of 0.1V and a lower current value of 75 mA.

ample, reports his a-c measurements as lower than the lowest values obtained by any d-c measurement. The $(dV/dI)_{AC}$ measurements displayed in Fig. 3 were made at the relatively low frequency of 0.5 kHz. Even at this low frequency $(dV/dI)_{AC}$ is relatively small compared to $(\Delta V/\Delta I)_{75}$. $(dV/dI)_{AC}$ was typically found to vary irregularly from 0.8 to 1 ohm, whereas $(\Delta V/\Delta I)_{75}$ varied linearly with discharge from about 1.2 to 3 ohms up to 90% of capacity. Table I shows how these parameters vary with discharge for a typical cell. Nevertheless, as will be shown in results and discussion section, $(dV/dI)_{AC}$, taken at zero direct current, is a useful parameter when used in conjunction with $(\Delta V/\Delta I)_{75}$. However, $(dV/dI)_{AC}$ should be measured at frequencies above 6 kHz, since in that frequency region its value was found to be independent of current and frequency. Representative values of $(dV/dI)_{AC}$ at this frequency are shown in Table II. A similar observation has been made by others using a-c bridge measurements on dry cells (6) and storage cells (7) except that the minimum frequencies for constant results were lower, 3 and 2 kHz, respectively. In the present series of experiments, most of the a-c resistance measurements were made with a Wayne-Kerr B221 universal bridge and Q221 low-impedance adapter. These measurements were carried out with a sampling current of 2 mA at a frequency of 1592 Hz and are referred to as R_B. Above the cutoff frequency all a-c resistances measured by the authors, as well as those of Ref. (6) and (7), were independent of sampling current, and were, therefore, assumed to represent the true (6) internal resistance of the cell. The 0.5 kHz $(dV/dI)_{AC}$ measurements are useless but the 1.6 kHz R_B measurements are useful estimates of internal resistance.

Results and Discussion

It has already been stated that R_B essentially represents the internal resistance of the cell. The differential resistance $(\Delta V/\Delta I)_{75}$, which we consider to be a d-c measurement, is always larger than R_B, and can be analyzed as a series combination of the ohmic internal resistance of the cell and the current dependent polarization resistance at 75 mA (8-11). The polarization is associated both with exchanges of electrically charged particles between electrode and electrolyte and with changes in concentration of reacting molecules or ions in the vicinity of the electrode surfaces (8). The first component of polarization, which is known as the "transfer polarization," is dependent on the current density at the surface of an electrode and therefore, for a given current, on the electrode's surface area. Since the area is usually related to the amount of active material present at a given time, it reflects the cell's state of charge. The second component or "concentration polarization" depends on the diffusion and reaction rates of the chemical constituents of the cell. Since these processes are also dependent on the amount of active material present, they must also reflect the state of charge of the cell. The internal ohmic resistance, however, may fail to reflect the state of charge of the cell due to offsetting changes in the resistance of the components of the cell (8).

Polarization occurs only when a current flows, and it increases with current. The sign of the polarization is such as to reduce the terminal voltage of a cell during discharge and, therefore, has the same effect as an added resistance. It would seem then, that since it is the polarization resistance, R_P, which varies most strongly with state of charge, it should be the best indicator. If R_B is approximately the internal ohmic resistance at all currents and $(\Delta V/\Delta I)_{75}$ is the d-c differential resistance, then $R_{PB} = (\Delta V/\Delta I)_{75} - R_B$ is an approximation to the polarization resistance at 75 mA. Since R_B is relatively insensitive to state of charge it might seem that its subtraction from $(\Delta V/\Delta I)_{75}$ is unnecessary. This is approximately correct for cells which have been drained at normal currents and have not been otherwise abused. For such cells $(\Delta V/\Delta I)_{75}$ varies linearly with total discharge Q throughout the life of the cell. This is illustrated in Fig. 4 where the nine normally used cells are seen to follow essentially the same relationship from which state of charge can be determined to within about 12%. The sharp change in slope at $Q \approx 3.3$ A-hr indicates the final stage of battery life by reflecting the dramatic increase in the internal resistance during that stage. Figure 5 contrasts the R_B's for the two cells (A4 and A5) which had undergone abnormally high discharge currents with two of the cells which had been drained

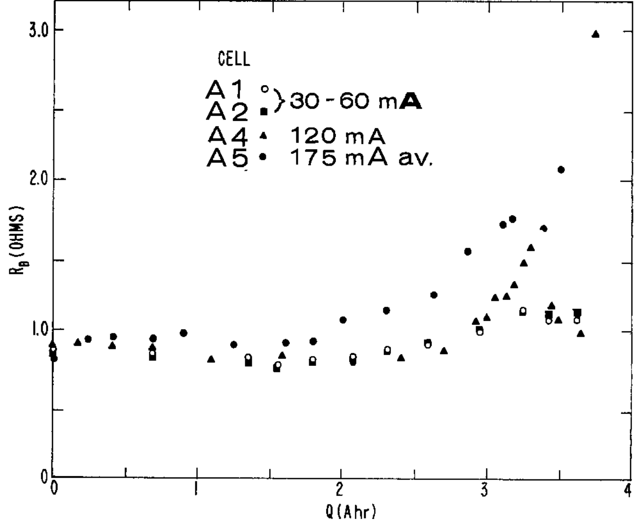

Fig. 5. A universal bridge measurement of the internal resistance of various cells vs. total prior discharge, Q.

normally. The difference is particularly striking for $Q > 1.5$ A-hr, the second half of cell life. Figure 6 illustrates how the plots of $(\Delta V/\Delta I)_{75}$ *vs.* Q for cells A4 and A5 differ from the dashed line which represents the average relationship followed by the other cells. That these differences are due to the aberrant behavior of R_B in cells A4 and A5 is easily corroborated by subtracting R_B from $(\Delta V/\Delta I)_{75}$ for all cells and replotting against Q as in Fig. 7. The loci of points representing cells A4 and A5 now merge with that obtained from the other cells and a single state-of-charge line valid for all cells results. This line is parallel to that defined in Fig. 4. Also, this revised curve shows a linear relationship that extends further into both the high and low Q regions. This is presumably because both the parametric dependence on discharge current and the small variations of R_B with lifetime have been subtracted from $(\Delta V/\Delta I)_{75}$. The simplicity and relative precision achieved by rendering the results in terms of the parameter $R_{PB} = (\Delta V/\Delta I)_{75} - R_B$ are manifest and justify the identification of R_{PB} with the polarization resistance of the cell at 75 mA. The discussion in the experimental section implies that $R_{Pd} = (\Delta V/\Delta I)_{75} - (dV/dI)_{AC}$ for an a-c frequency of 6 kHz would be a slightly better estimate of polarization resistance than R_{PB}. A comparison of the B cell scatter in Fig. 7 and 8 tends to confirm this, particularly at the upper values of Q. R_B must be

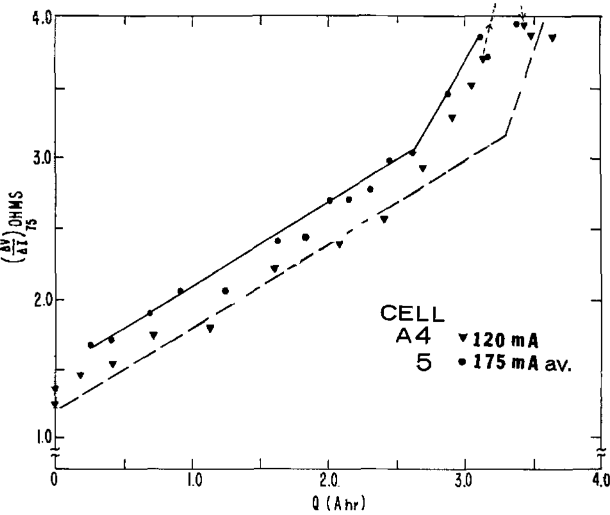

Fig. 6. Illustration of the deviation in $(\Delta V/\Delta I)_{75}$ for cells discharged at abnormally high currents from the dashed, normal state-of-charge graph defined in Fig. 4.

relied upon as the estimate of the internal resistance of the A cells because in some cases no $(dV/dI)_{AC}$ measurements were made and in others the a-c frequency used was too low (0.5 kHz).

The B cells had been refrigerated at about 8°C for a few months then were left at room temperature for an hour before beginning the test sequence. These cells exhibited *I-V* curves which were unstable with respect to recycling of the test current. Successive cyclings (3 or 4) resulted in progressively steeper slopes (implying an increasing state of charge) until a stable value was reached. This stable value was then consistent with the $(\Delta V/\Delta I)_{75}$ of the other cells at full charge. This initial instability occurred only at full charge since the *I-V* curves showed good reproducibility upon recycling for all subsequent measurements. The result seems reminiscent of the gross effect that low temperature (0°C) storage had upon the calibration curves in the Sandia study. In our case, however, the problem is easily dealt with by running multiple *I-V* curves or by making provision for some preliminary cycling before $(\Delta V/\Delta I)_{75}$ is measured.

Conclusions and Recommendations

This report describes sensitive, readily instrumented and conducted state-of-charge measurements made on mercury cells. A linear relationship with a maximum experimental deviation of less than 10% of capacity was found to exist between the polarization resistance, R_P as approximated by $R_{Pd} = (\Delta V/\Delta I)_{75} - (dV/dI)_{AC}$ and the total expended charge, Q. For 90% of the data points the experimental deviation from the mean curve was less than 6%. When applying this procedure, it is advisable to make more than one cycle of the plot of the *I-V* curve to insure obtaining stabilized *I-V* curves of new cells when stored under possibly debilitating conditions. Successive cycling would also serve to eliminate irregularities which occasionally appear in the *I-V* curves, at least when the tracing is manually controlled. The adherence of all eleven cells tested to the same state-of-change criteria despite having been subjected to a variety of discharges and storage environments suggests these criteria may have universal applicability. Further investigation of the limits of applicability by laboratories with the facilities and the need might be apropos.

Manuscript submitted April 23, 1975; revised manuscript received July 21, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by the U.S. Army.

LIST OF SYMBOLS

I or I_{BATT} current through the cell in mA
V or V_{BATT} voltage across the cell in volts
dV/dI or $(dV/dI)_{AC}$ the differential resistance of the cell as measured with a small a-c signal in the kHz range (in ohms)
$(\Delta V/\Delta I)_{75}$ the slope of the I-V curve at 75 mA in ohms also referred to as effective differential d-c resistance
R_B the internal resistance of the cell as measured with an impedance bridge (in ohms)
Q the cumulative total number of A-hr of discharge
R_P polarization resistance in ohms
$R_{PB} \equiv (\Delta V/\Delta I)_{75} - R_B$ and $R_{Pd} \equiv (\Delta V/\Delta I)_{75} - (dV/dI)_{AC}$
R_{PB} and R_{Pd} are experimental approximations to R_P and are in ohms.
A cells are of type RM4R with a nominal EMF of 1.35V.
B cells are of type RM4H with a nominal EMF of 1.40V.

Diffusional Effects in Simulated Localized Corrosion

ABSTRACT

The importance of diffusion was investigated under potentiostatic dissolution conditions with wire electrodes contained in inert supports. The artificial cavities created simulated localized corrosion conditions. Current-time behavior at voltages in excess of the critical pitting potential [>0.5V (SCE)] was examined for nickel and stainless steel specimens in concentrated chloride solutions. The effect of changing the concentration or activity gradient of the dissolving metal cations within the artificial cavity was studied by altering the composition of the bulk solution. Solutions of $FeCl_2$, $NiCl_2$, $CrCl_3$, LiCl, NaCl, $MgCl_2$, and $CeCl_3$ ranging from 0.5 to 10M were used. Mass transfer models were developed for the observed transient and quasi steady-state periods of dissolution.

Localized corrosion can be divided into various stages representing initiation and subsequent dissolution of a metal. Pitting corrosion has been divided into three stages: pit initiation, early growth, and the formation of a stable pit. In the third stage, when the pit becomes sufficiently large, conditions and processes taking place are closely related to those occurring in crevice corrosion. Earlier work (1-3) has suggested that the third stage of dissolution is controlled by diffusion within the occluded cell. Measurements of the rate of corrosion are usually complicated by changing surface areas. To overcome this difficulty, wire electrodes were used to simulate these conditions in the present study. The factors involved during diffusion-controlled stages within localized anodes were investigated and related to the properties and composition of the bulk electrolyte solution. Austenitic stainless steel, nickel, iron, and dilute nickel alloys were studied to emphasize various aspects of the diffusion process.

Mass Transfer Considerations

Localized corrosion is simulated under conditions where the geometry of the system is specified in order that diffusional models can be tested. Basically, wire test specimens are mounted in an inert matrix with one cross-sectional surface exposed to the aqueous Cl^- environment (see Fig. 1). Anodic dissolution of the metal is studied under potentiostatic conditions above the critical pitting potential. The actual dissolution begins with pitting and undermining of the passive oxide film on the metal surface followed by pit growth until the entire cross-sectional area of the metal is dissolving. With an active surface developed each elemental constituent of the alloy undergoes oxidation to form a soluble ionic species, viz.

$$Fe^{\circ} \rightarrow Fe^{2+} + 2e^-$$

$$Ni^{\circ} \rightarrow Ni^{2+} + 2e^-$$

$$Cr^{\circ} \rightarrow Cr^{3+} + 3e^-$$

These ions dissolve under activation polarization control and are free to undergo hydration reactions with water (4) or form complexes with Cl^- ions, but in any case the concentration of each species will begin to increase because of a diffusional limitation between the metal-solution interface and the bulk solution (over distance $l + \Delta$ in Fig. 1). The ionic concentrations (Fe^{2+}, Ni^{2+}, or Cr^{3+}) will continue to increase until a saturation or slightly supersaturated condition exists with respect to the chloride or hydroxychloride complex of that cation. Isaacs (1) has shown that a

resistive layer (presumably metal chloride) then precipitates on the surface. The chloride layer displays ohmic resistance which is controlled by its thickness. During a steady dissolution period, a current equal to the diffusion flux in the solution passes through the layer. The current is determined by the ratio of the potential to resistance which is itself specified by the layer resistivity and thickness. A rapid increase in potential, for example, increases the potential across the layer and is followed by a transient increase in current. The increased flow of ions in the layer causes additional precipitation since the diffusion flux remains effectively independent of applied potential. As the thickness of the layer increases the potential gradient decreases along with the current. Once the chloride layer has formed, it displays a self-regulating effect in balancing the layer current with the diffusional flux in solution (1).

The presence of the layer and the diffusion control define the third stage of localized anodic dissolution, which may be described as a quasi steady state, whereby cations diffuse down a concentration gradient in an aqueous solution. The concentration difference is between the saturated value at the chloride film/solution interface ($x = 0$) and the bulk electrolyte, the distance between which ($x = l + \Delta$) is composed of the depth of the wire (l) in the case of a wire-type electrode and stagnant diffusion layer (Δ).

The diffusional limitations of two types of systems are illustrated by the concentration profiles presented in Fig. 1. Consider case A with a nickel wire dissolving and $NiCl_2$ in the bulk solution. The Ni^{2+} concentration decreases from the saturation concentration (a) at the metal surface ($x = 0$) to the bulk concentration at $x = l + \Delta$. A similar trend can be drawn for Cl^- by applying electroneutrality at any point in the solution. These same ideas can be applied to the localized corrosion of stainless steel, where three ions (Ni^{2+}, Fe^{2+}, and Cr^{3+}) will be diffusing away from the interface. An important example to note in case A is that by increasing only one component of the stainless steel dissolution product the concentration gradient of this component may be decreased, while those of the other components remain the same. If, however, this component is one that predominates in the composition of the chloride film, this would lead to a decreased dissolution rate. If the component does not precipitate to form the chloride layer, increasing its concentration will have no direct effect on the dissolution rate.

Case B illustrates the concentration profiles for a second type of experiment. In this case, either stainless steel or nickel is anodically dissolved in an uncommon cation (M^+) Cl^- solution, *e.g.*, LiCl or NaCl. The Ni^{2+}, Fe^{2+}, or Cr^{3+} ion concentration again varies from the saturation concentration at the metal surface ($x = 0$) to zero at $x = l + \Delta$. The Cl^- ion concentration profile can again be represented by electroneutrality with M^+, Ni^{2+}, Fe^{2+}, and Cr^{3+} ions present. The slight decrease in M^+ from $x = l + \Delta$ to the interface at $x = 0$ is due to a resistance in diffusing toward the metal surface.

Mass transfer models were developed for the early or transient period and the quasi steady-state period of the corrosion process. In either case information concerning the transport properties of the electrolyte solution was required. Specifically, both the dependence of the diffusion coefficient and viscosity on the composition of the solution within the pit should be known. In addition, equilibrium properties, including the solubility and activity coefficient dependence of $NiCl_2$, $FeCl_2$, and $CrCl_3$ on the ionic strength of the solution, are important in determining suitable driving forces for the diffusional processes.

In our experiments, current measurements were made and can be used with Faraday's law to determine mass fluxes. For a constant cross section of wire, the cation mass flux $\dot{N}$ from the interface can be represented as

$$\dot{N} = i/An\mathbf{F} \qquad [1]$$

In addition, the length of wire dissolved during the course of the experiments is given by

$$l = \int_0^t \frac{M_w}{An\mathbf{F}\rho_o} i dt \qquad [2]$$

The positive ion current produced in the oxidation reaction occurring at the metal surface will diffuse through the solution under the influence of two driving forces, namely, concentration gradient and potential gradient, as shown in the Nernst-Einstein equation

$$\frac{i}{An\mathbf{F}} = -D\left[\frac{\partial C}{\partial x} + \bar{C}\frac{n\mathbf{F}}{RT}D\frac{\partial \Phi}{\partial x}\right] \qquad [3]$$

The potential gradient in solution has been shown to be unimportant for the cases being considered (1, 2). In potentiostatic dissolution experiments at fixed voltages from 0.2 to 1V (SCE), Isaacs (1) has shown that almost all the potential drop is contained in a thin resistive layer adjacent to the anode. Frankenthal and Pickering (5) observed similar results showing negligible potentials in solution but attributed the large ohmic drop at the metal-solution interface to the presence of hydrogen bubbles. No bubbles were observed with any of the wire anode systems used in our studies. Therefore, Eq. [3] simplifies to

$$\frac{i}{An\mathbf{F}} = -D\frac{\partial C}{\partial x} \qquad [4]$$

In the cases that follow, cation concentration (or activity) was used as the driving force for diffusion, and all transport properties including D and viscosity μ were assumed constant and uniform. The importance of these effects is discussed later in this paper.

Initial transient period.—During this early period of dissolution, the wire electrode surface is flush with the surface of the cavity ($l = 0$) and semi-infinite

geometries can be used to model the diffusional process that causes the electrolyte concentration to increase at the metal surface. Basically, the time required to reach saturation at the surface can be estimated from a transient model of this type. However, complex factors are operative. The nucleation of active dissolution sites on the wire surface is a microscopic phenomenon with respect to the total cross-sectional area of the wire. Many pits are nucleating and growing on the surface simultaneously. Since only the total current is measured, it would be misleading to assume that the actual current density (i/A) should be based on the total cross-sectional area during this early period when a significant fraction of the surface is not actively dissolving. The current increases as the actively dissolving area of the wire increases until the whole cross section is active and a decreasing current is observed as the system becomes diffusion controlled.

With the current density at the active site known, the mass flux can be specified (Eq. [1]) and used as a boundary condition to solve the transient diffusion equation, which expresses concentration as a function of time and distance into the liquid. Hemispherical and cylindrical geometries of semi-infinite extent were selected to approximate the stagnant liquid diffusion field surrounding the exposed wire surface (see Fig. 1). However, the analysis given in the Appendix closely approximated the observed periods taken to reach the maximum current.

Quasi steady-state period.—Once saturation of the dissolving cation species j occurs at the metal-solution interface (Fig. 2) after the initial period, a quasi steady-state period of diffusional control commences. The situation may be expected to be complex since the interface is actually moving as it recedes into the inert support. Assuming no potential dependence, a transient model involving unidirectional diffusion into a semi-infinite stagnant liquid with a moving boundary was solved and indicated that the measured current $i(t)$ should vary inversely with the square root of time, $\sqrt{t}$. Booth (6) and Danckwerts (7) suggest criteria that can be applied to decide if a quasi steady-state assumption is reasonable. By calculating l^2/D [$\simeq (0.01 \text{ cm})^2/10^{-5} \text{ cm}^2/\text{sec} \simeq 10$ sec] and comparing it with typical experimental time periods of 1000 sec, the transient term can be eliminated without significant error. Under these conditions, the effect of a moving boundary on the diffusional flux is unimportant.

This simplified model was introduced earlier by Isaacs (1) and is reviewed briefly here. Essentially the current density i/A is specified by the Nernst-Einstein equation, Eq. [4], neglecting the mobility term and assuming a linear concentration gradient

$$\frac{i}{A} = \frac{n\mathbf{F}D(C^S{}_j - C^B{}_j)}{l + \Delta} \quad [5]$$

where l, the length of dissolved wire, and Δ, the boundary layer thickness in the solution, constitute the total diffusion path. Substituting Faraday's law, Eq. [2], into Eq. [5] and integrating between $i = i_o$ at $t \simeq \tau \simeq 0$ and $i = i$ at $t > \tau \simeq 0$ yields

$$\left(\frac{i}{A}\right)^{-2} = \left(\frac{i_o}{A}\right)^{-2} + \frac{2M_w t}{n^2\mathbf{F}^2\rho_0 D(C^S{}_j - C^B{}_j)} \quad [6]$$

Equation [6] indicates that the current density varies inversely with $\sqrt{t}$, the identical result obtained for the moving boundary model. In addition, Eq. [6] can be used as a basis for interpreting our experimental current-time results. A plot of $(i/A)^{-2}$ *vs.* t should be linear, and the reciprocal slope $1/S$

$$S = \frac{d(i/A)^{-2}}{dt} \quad [7]$$

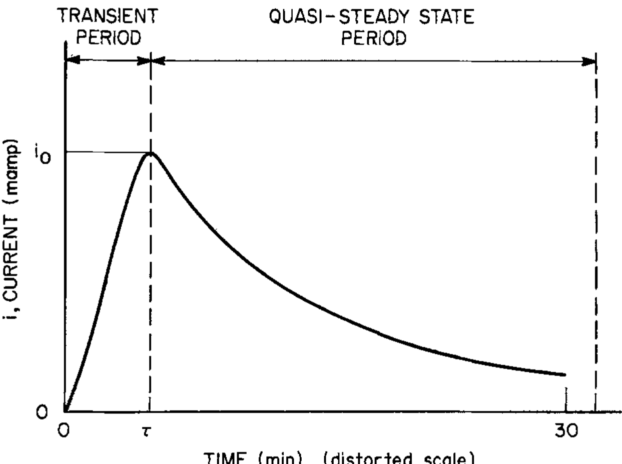

Fig. 2. Current-time plot showing periods of dissolution

should be directly related to the product of diffusivity D and the driving force ($C^S{}_j - C^B{}_j$).

Apparatus and Procedure

Wire electrodes (~0.09 cm in diameter) were embedded in inert polytetrafluoroethylene supports to ensure that a constant cross-sectional area would be exposed to the Cl^- solution throughout the experiment. Initially the surface was mechanically polished with 600 grade emery to the outer surface of the inert support ($l = 0$, Fig. 1). A Wenking potentiostat was used to apply a fixed voltage between the wire test electrode and a saturated calomel reference electrode (SCE). The current was measured in another circuit with an auxiliary platinum electrode as the cathode and the test specimen as the anode. Applied potentials were 0.5-1V, far above the critical pitting potentials for any of the metal chloride systems examined. A Hewlett-Packard Model 700-4A recorder monitored the current as a function of time (Fig. 2) for 20-30 min.

Experiments were performed with aqueous metal chloride solutions at 22°C over concentrations from 0.5 to 10M. Both common-cation ($FeCl_2$, $NiCl_2$, and $CrCl_3$) and uncommon-cation ($LiCl$, $NaCl$, $MgCl_2$, and $CeCl_3$) halide salts were used. In cases where viscosity data were not available a Brookfield synchroelectric viscometer was used to measure values over the solution concentrations studied.

The differences between the two kinds of experiments conducted with common and uncommon cations is illustrated by cases A and B in Fig. 1. In case A, the over-all driving force for mass transfer ($C^S{}_j - C^B{}_j$) could be altered by changing $C^B{}_j$ (j = Ni, Fe, or Cr) as a chloride in the bulk solution, and because all the ions are common to the metal dissolving, $C^S{}_j$ will be a function of only temperature. Alternatively, in case B, $C^B{}_j$ is always zero in the bulk solution and increases to a saturation value corresponding to the presence of uncommon cations (Li, Na, Ce, Mg), which alters the Cl^- activity by changing the Cl^- concentration and mean activity coefficient of the dissolving cation electrolyte.

Results and Discussion

Calculational procedures and data summary.—To evaluate the mass transfer model, the slope of reciprocal squared current density, $(i/A)^{-2}$, plotted *vs.* time t (Eq. [6] and [7]) must be determined from the raw data in the form of current i as a function of time t. A typical set of data is shown in Fig. 3, where the current density is plotted as a continuous function and $(i/A)^{-2}$ plotted from discretely selected points. During some runs, the data show abrupt changes in i over small time periods, especially during the early part of a run when microscopic pit growth is occurring. In most cases, two or three runs at the same set of conditions were sufficient for reproducible slopes; however, when sporadic i-t behavior was observed runs

were repeated. For pure nickel wire in 1M LiCl solutions up to six runs were performed. For the low concentration chlorides, *e.g.*, 0.5M $NiCl_2$, 0.5M $FeCl_2$, and 0.5M $CrCl_3$, up to six runs were also required.

Slopes were calculated by a least square regression applied to discrete values of $(i/A)^{-2}$ taken over the time interval of interest ($\tau < t \leq$ 20-30 min, Fig. 2). Error bounds for the reciprocal slope are based on a 95% confidence level fit of the data averaged over the runs used. The entire set of reciprocal slopes is summarized in Tables I and II for experiments with Type 304 stainless steel (nominal composition Fe 70%, Ni 9%, Cr 18.6%, and C + Mn + Si + Cu + S <3%) and nickel-rich alloy Ni-61 (nominal composition Ni 96%, Mg 0.3%, Fe 0.1%, Si 0.4%, Ti 3%).

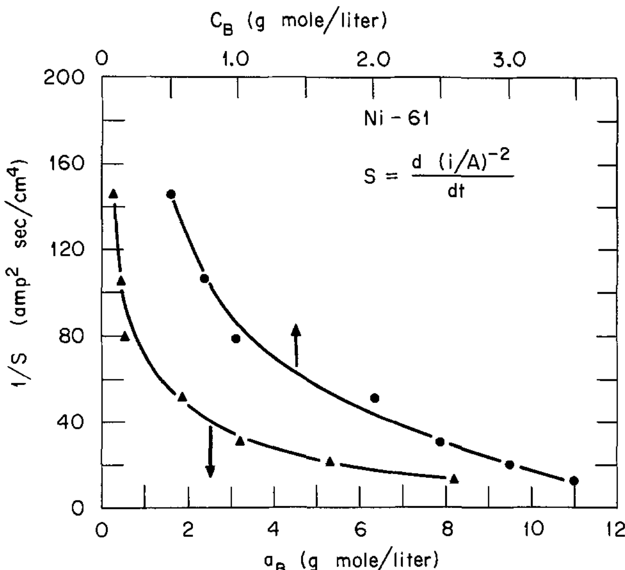

Fig. 4. Common metal cation effect: reciprocal slope $1/S = [d(i/A)^{-2}/dt]^{-1}$ as a function of bulk $NiCl_2$ concentration and activity for nickel dissolution.

Effect of applied voltage.—Earlier experiments on stainless steels demonstrated that the slope $S = d(i/A)^{-2}/dt$ was not affected by changing the applied voltage from 0.35 to 0.85V (SCE). Furthermore, the impedance characteristics of the wire surface strongly suggested that a thin (100Å) layer having a resistivity of approximately 10^8 ohm-cm exists throughout the quasi steady-state period. The potential drop across the resistive layer itself accounts for over 95% of the total voltage drop.

Additional measurements were made at fixed potentials of 0.5, 0.8, and 1V (SCE) for both Type 304 stainless steel and Ni-61 wire electrodes in solutions of identical electrolyte composition. In all cases, the variation of the slope S was within the statistical scatter of the data which again showed rates independent of potential for both stainless steel and nickel. It may also be mentioned that a few measurements with iron wires showed a similar behavior. In addition, step changes in voltage during a run indicated similar slopes after the transient perturbations had damped out. This effect also illustrates the importance of diffusion in controlling the self-regulating nature of the layer's thickness in which the layer adjusts its ohmic resistance to support the cation flux away from the interface (1).

Mass transfer effects during the quasi steady-state period.—The observed linear behavior of reciprocal squared current density, i/A^{-2}, as a function of time t supports the mass transfer model and is consistent with measurements by Novakovski and Sorokina (2) on a similar system. Equation [6] indicates that $1/S$ should vary as $D(C^S{}_j - C^B{}_j)$. If the diffusivity were constant, then for the runs with nickel wire in a $NiCl_2$ solution, $1/S$ should vary linearly with $C^B{}_j$ since $C^S{}_j$ is constant. In Fig. 4, the data from Table II are

plotted over a concentration range from 0.5 to 3.5M $NiCl_2$ and are not linear. The nonlinear behavior shows that Eq. [6] is an approximation and variations not yet considered are brought about by the change in the bulk solution concentration. The first possible improvement incorporates activity rather than concentration as the driving force, where

$$a_{Ni^{2+}} = \gamma_{\pm} C_{Ni^{2+}} \qquad [8]$$

The mean ionic activity coefficients, $\gamma_{\pm}$, were taken from experimental data tabulated by Harned and Owen (8) and extrapolated to higher concentrations by the techniques suggested by Meissner and Tester (9). Unfortunately, no further improvement was obtained (Fig. 4).

Viscosity effects on the diffusion coefficient were found to be significant. Although theoretical correlations for predicting D in concentrated electrolytes are limited (8, 10) several empirical rules can easily be applied. The diffusivity can be expressed in terms of the solution's viscosity η_r relative to pure water at the same temperature and activity coefficient $\gamma_{\pm}$ as (10)

$$D = \frac{D^\circ}{\eta_r}\left(1 + m\frac{d \ln \gamma_{\pm}}{dm}\right) \qquad [9]$$

An integral diffusion coefficient can then be defined as

$$\frac{1}{C^S{}_j - C^B{}_j}\int_{C^B{}_j}^{C^S{}_j} D dC_j \qquad [10]$$

such that the form of Eq. [5] is preserved with D' replacing D. By substituting Eq. [9] into Eq. [10] one can express D' as a function of D°, η_r, and $\gamma_{\pm}$

$$D' = \frac{D^\circ}{(C^S{}_j - C^B{}_j)}\left[\int_{C^B{}_j}^{C^S{}_j}\left(1 + m\frac{d \ln \gamma_{\pm}}{dm}\right)\frac{dC_j}{\eta_r}\right] \qquad [11]$$

To calculate D' requires knowledge of $\gamma_{\pm}$ and η_r as functions of C. This information is usually known for pure aqueous solutions of a single electrolyte over a limited concentration range (8, 11). In the preliminary analysis, the equation was simplified to permit integration using a linear expression for the viscosity and neglecting the $\gamma_{\pm}$ term. For example, for a 4M solution of $FeCl_2$ at 25°C η_r is approximately 8. For a mixed electrolyte consisting of the dissolving cations (Ni^{2+}, Fe^{2+}, and/or Cr^{3+}) and possibly uncommon cations (Li^+, Na^+, Mg^{2+}, etc.) along with the Cl^- ions present, the relative viscosity can be approximated as a linear combination of all species present

$$\eta_r = 1 + \Sigma b_j C_j \qquad [12]$$

where b_j is a constant dependent on the properties of component j. Simplifying the relationship further we assume the dissolving metal cation and uncommon cation can be divided into two terms

$$\eta_r \simeq 1 + bC_j + b^*C^* \qquad [13]$$

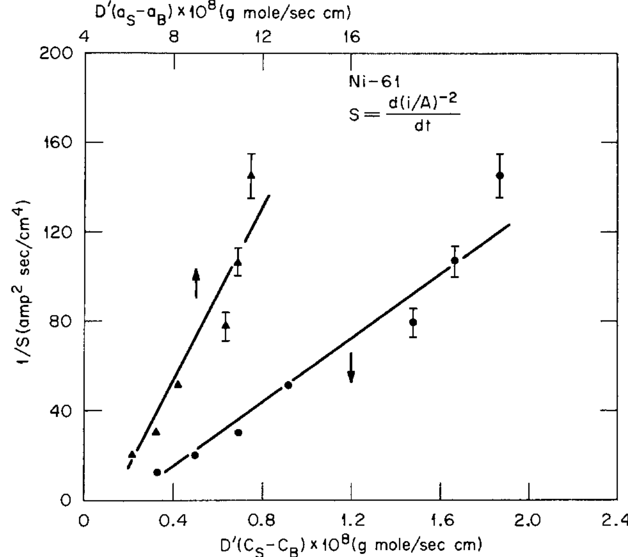

Fig. 5. Common metal cation effect: reciprocal slope $1/S = [d(i/A)^{-2}/dt]^{-1}$ as a function of the product of the integral diffusion coefficient, D', and the concentration and activity driving forces ($C^S - C^B$) and ($a^S - a^B$) for nickel dissolution.

where C_j is the total concentration of dissolving cations as chlorides and C^* is the concentration of the uncommon cations as chlorides. With these simplifications, Eq. [11] can be expressed as

$$D' = \frac{D^\circ}{(C^S{}_j - C^B{}_j)}\int_{C^B{}_j}^{C^S{}_j}\frac{dC_j}{1 + bC_j + b^*C^*} \qquad [14]$$

Integrating with C^* assumed constant gives

$$D' = \frac{D^\circ}{b(C^S{}_j - C^B{}_j)}\ln\left(\frac{1 + bC^S{}_j + b^*C^*}{1 + bC^B{}_j + b^*C^*}\right) \qquad [15]$$

which is essentially a log mean. By using Eq. [15] to replace D in Eq. [6], one can correct D for viscosity changes and then correlate $1/S$ with $D'(C^S{}_j - C^B{}_j)$ or with $D'(a^S{}_j - a^B{}_j)$ (see Fig. 5). For nickel wire in $NiCl_2$ solutions, the relationship is linear within the accuracy of the points given; however, no further improvement is apparent if activity rather than concentration is used as the driving force. For this case a value of $D^\circ = 1.29 \times 10^{-5}$ cm²/sec was used for the diffusivity of $NiCl_2$ in dilute solutions, and the viscosity coefficient $b = 0.86$ liter/mole was obtained from a plot of the viscosity data in Table III by using a linear approximation between concentrations $C^B{}_j$ and $C^S{}_j$. In addition, the C^* term was zero since no uncommon cations were present.

The same improvement in the $1/S$ *vs.* $D(C^S{}_j - C^B{}_j)$ correlation appeared when the Type 304 stainless steel data were used. However, several additional approxi-

mations have to be made concerning the average valence n (Eq. [6]) and saturation concentration for the mixture of dissolving cations (Fe^{2+}, Ni^{2+}, and Cr^{3+}). In this case we assumed weighted average values for stoichiometric dissolution for the given alloy composition. Using $FeCl_2$, $CrCl_3$, and $NiCl_2$ from 0.5 to 2M showed no preferential effect for any one cation. This area does deserve further attention.

Because of a chloride common ion effect, saturation concentrations of $NiCl_2$ decrease as the bulk LiCl concentration increases. Figures 6 and 7 show these effects for nickel samples in LiCl solutions up to 6M. In this case the bulk concentration of Ni^{2+} was essentially zero. Values of $C^S{}_j$ were tabulated by Linke and Seidell (12), and viscosity coefficients ($b^* = 0.20$ liter/mole and $b = 0.86$ liter/mole) were obtained from the data given in Table III. $D°$ was specified as 1.29×10^{-5} cm²/sec. As seen in Fig. 6 the curvature and uncertainty are quite pronounced at LiCl concentrations below 3M. Using the viscosity corrections as before and neglecting the 1M LiCl point since pit initiation was sporadic for this case yielded an improved correlation between $1/S$ and $D'C^S{}_j$ (Fig. 7).

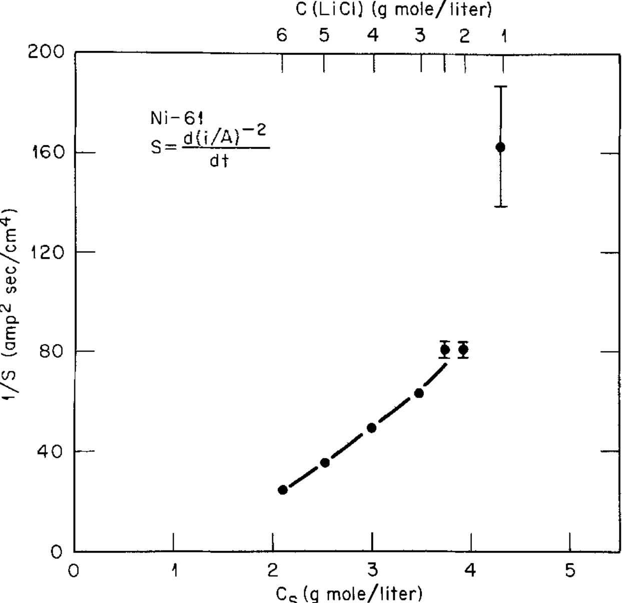

Fig. 6. Uncommon cation effect: reciprocal slope $1/S = [d(i/A)^{-2}/dt]^{-1}$ as a function of $NiCl_2$ saturation concentration C^S in the presence of LiCl solutions for nickel dissolution.

An attempt was made to correlate the LiCl runs for both 304 stainless steel and nickel. The Ni-61 data were plotted as before, and the stainless steel data were modified by incorporating the effects of LiCl on the solubility of the precipitated chloride as a weighted average based on the stoichiometry of the alloy and experimental data for $NiCl_2$ and $FeCl_2$ in the presence of LiCl. The resulting correlation is shown in Fig. 8 and is notably linear over a concentration range up to 10M.

Another verification of the mass transfer model is obtained by comparing the actual value of the reciprocal slope ($1/S$) with the theoretical value (Eq. [6])

$$\frac{1}{S'} = \frac{1}{S(C^S{}_j - C^B{}_j)D'} = \frac{n^2\mathbf{F}^2\rho_o}{2M_w} \qquad [16]$$

For the nickel specimens: $\rho_o = 8.9$ g/cm³, $n = 2$, $\mathbf{F} =$ 96,500 coulombs/equivalent, and $M_w = 58.7$ for Ni^{+2}. Therefore, $1/S' = 0.28 \times 10^{10}$ A² sec² cm⁻³ mole⁻¹. An experimental $1/S'$ value for the case of $NiCl_2$ as the bulk electrolyte was 0.60×10^{10} A² sec² cm⁻³ mole⁻¹ and with LiCl as the bulk electrolyte 0.34×10^{10} A² sec² cm⁻³ mole⁻¹ at $D'(C^S{}_j - C^B{}_j) \simeq 1.2 \times 10^{-8}$ mole sec⁻¹ cm⁻¹.

One further refinement was introduced by graphically evaluating the integral of Eq. [11] to approximate D' for effects of both viscosity and $\gamma_\pm$. Values of η_r were used from Table III, and the derivative $d \ln \gamma_\pm/dm$ was calculated at discrete points by use of experimental data (8) and the empirical charts of Meissner and Tester (9). Only minor improvement was obtained in the correlation.

In conclusion, it has been shown that the major premise of a quasi steady-state period of dissolution being mass transfer controlled is correct. The influence of the type and concentration of chloride salt used for localized corrosion tests of nickel-base and stainless steel alloys can be predicted on the basis of the diffusion model. At low concentrations (less than about 3M Cl^-) all chloride salts should behave similarly and show little concentration dependence. The high concentrations in the localized anode's anolyte itself will dominate the concentration differences and dissolution rates. At intermediate concentrations (around 5M Cl^-), the solubilities of the dissolving chloride layer will be markedly influenced by the chloride activity and its effect on reducing the solubility of the dissolv-

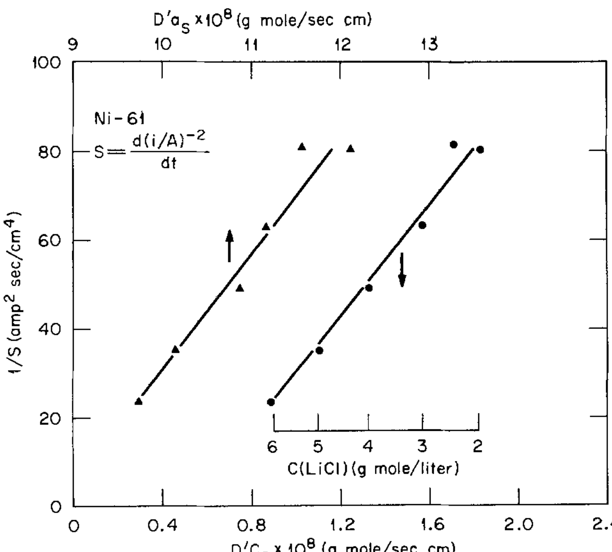

Fig. 7. Uncommon cation effect: reciprocal slope $1/S = [d(i/A)^{-2}/dt]^{-1}$ as a function of the product of the integral diffusion coefficient D', and the saturation concentration or activity of $NiCl_2$ (C^S or a^S) for nickel dissolution.

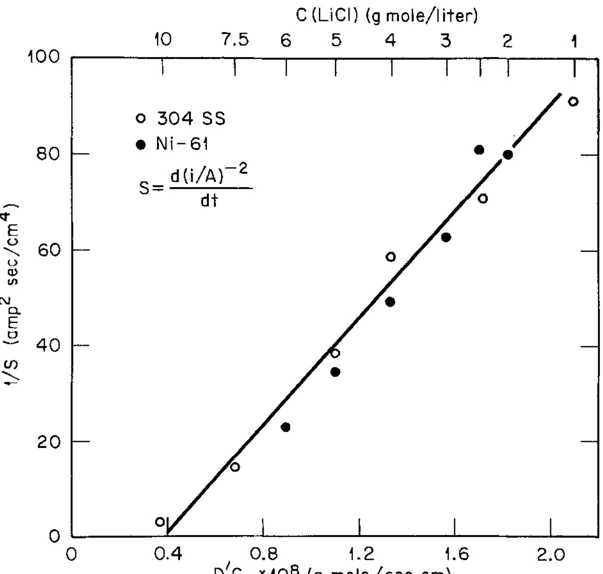

Fig. 8. Uncommon cation effect: reciprocal slope $1/S = [d(i/A)^{-2}/dt]^{-1}$ as a function of the product $D'C^S$ for Type 304 stainless steel and nickel dissolution.

ing metals. At high chloride concentrations the viscosity plays a major role in reducing the diffusion rates; hence the resulting dissolution rates will decrease with increased viscosity of the chloride solution.

Summary

1. Current-time behavior during the quasi steady-state period indicates that anodic dissolution during this period is controlled by diffusion with a concentration driving force ($C^S{}_j - C^B{}_j$).

2. Correcting the diffusion coefficient for viscosity was necessary for accurate interpretation of the mass-transfer model. For the solutions and metals studied, activity and concentration driving forces showed similar results when used in the diffusion model.

3. The chemistry at the metal-solution interface, in particular the effect of foreign ions in influencing $C^S{}_j$, is important in establishing the rate of dissolution.

APPENDIX

Initial Transient Period Model

As a first approximation, the current density and diffusion coefficient during this induction period are assumed constant over the entire surface of the wire. The diffusion equations become

hemispherical geometry

$$D\left(\frac{\partial^2\xi}{\partial r^2}+\frac{2}{r}\frac{\partial\xi}{\partial r}\right)=\frac{\partial\xi}{\partial t} \quad \text{[A-1]}$$

cylindrical geometry

$$D\left(\frac{\partial^2\xi}{\partial x^2}\right)=\frac{\partial\xi}{\partial t} \quad \text{[A-2]}$$

where ξ_j is a dimensionless concentration

$$=\frac{C_j(x \text{ or } r, t) - C^B{}_j}{C^S{}_j} \quad \text{[A-3]}$$

For this system both initial and boundary conditions can be specified.

Initial condition

$$\left.\begin{aligned} C_j(x \text{ or } r, t) &= C^B{}_j \\ \xi_j &= 0 \end{aligned}\right\} \begin{aligned} &\text{at } t = 0 \\ &\text{all } x \text{ or } r \end{aligned} \quad \text{[A-4]}$$

Boundary conditions

1. Prescribed flux

$$\left.\begin{aligned} -D\frac{\partial C_j}{\partial(x \text{ or } r)} &= \frac{i(t)}{An_j\mathbf{F}} \\ -D\frac{\partial \xi_j}{\partial(x \text{ or } r)} &= \frac{i(t)}{An_j\mathbf{F}}\frac{1}{C^S{}_j} = f \end{aligned}\right\} \begin{aligned} &x = 0, r = r_o \\ &t > 0 \end{aligned} \quad \text{[A-5]}$$

2. Semi-infinite approximation

$$\left.\begin{aligned} C_j(x \text{ or } r, t) &= C^B{}_j \\ \xi_j &= 0 \end{aligned}\right\} \begin{aligned} &\text{at } x \text{ or } r = \infty \\ &t > 0 \end{aligned} \quad \text{[A-6]}$$

Equations [A-1] and [A-2] with initial and boundary conditions specified by Eq. [A-4] through [A-6] have been solved previously by Carslaw and Jaeger (13). If $i(t)$ is assumed constant at some characteristic value ($f \rightarrow f_o$) during the early transient period (Fig. 2), then the solutions for ξ_j at the interface are

hemispherical model ($r = r_o$)

$$\xi_j(r_o, t) = \frac{r_o^2 f_o}{D}\left[1 - \exp\left[\frac{Dt}{r_o^2}\right]\operatorname{erfc}\left[\frac{(Dt)^{1/2}}{r_o}\right]\right] \quad \text{[A-7]}$$

cylindrical model ($x = 0$)

$$\xi_j(0, t) = \frac{2f_o}{D}\left[\frac{Dt}{\pi}\right]^{1/2} \quad \text{[A-8]}$$

If f_o can be approximated by measuring the current transient $i(t)$ and specifying the active dissolving area A, then the time required for ξ_j to reach a value corresponding to saturation of a given salt of cation j can be calculated. For example, with a 0.089 cm diameter $\simeq 2r_o$ nickel wire potentiostatically dissolving into a 1M $NiCl_2$ solution assuming $D \simeq 10^{-5}$ cm²/sec, Eq. [A-8] can be solved explicitly for t

$$t = \left(\frac{\xi_j}{2f_o}\right)^2 D\pi = \left(\frac{C_j - C^B{}_j}{2C^S f_o}\right)^2 D\pi \quad \text{[A-9]}$$

For this case $i_o \simeq 8$ mA (8×10^{-3} coulomb/sec), $n = 2$, and the time τ required to reach a saturation concentration of 4.65M $NiCl_2$ would be 2.4 sec assuming that the entire surface area is actively dissolving. Equation [A-7] can be solved by trial and error using Danckwerts (7) graphical solution to a similar problem and yields a value of $\tau = 3.9$ sec for the same set of parameters. At the other extreme, if only one small pit (1 μm in diameter) was dissolving initially, the characteristic current density (i_o/A) would be greater than 10^6 times larger and the value for τ at saturation would be $\sim 10^{-12}$ sec.

Observed transient times were about 2 sec for this solution and type of wire electrode. According to both models τ should be independent of the initial depth l. Several experiments in which the wire electrode was initially withdrawn approximately 1 mm into the cavity resulted in similar values of τ.

All this evidence supports the hypothesis that the cation concentration is rapidly increasing at the surface and forming a thin resistive layer of a chloride or chloride complex as the solution becomes supersaturated. Using a transient diffusion model for this period is an approximation of real behavior. A refined treatment of this problem would apply an initiation and distribution function to describe microscopic pit growth and use this as a boundary condition of a specified time-dependent flux. The measured current $i(t)$ would be a sum over all active sites

$$\frac{i(t)}{A} = \frac{1}{A}\Sigma i(t)_i \quad \text{[A-10]}$$

where $i(t)_i$ would be specified by knowing the growth rate of a microscopic hemispherical pit

$$i(t)_i = n\mathbf{F}\rho_o\frac{dV_i}{dt} = n\mathbf{F}\rho_o 4\pi r_i^2\frac{dr_i}{dt} \quad \text{[A-11]}$$

Relevant analyses of these problems have been published (14).

The Influence of Cyclic Plastic Strain on the Transient Dissolution Behavior of 18/8 Stainless Steel in 3.7M H_2SO_4

T. Pyle, V. Rollins, and D. Howard

Department of Chemistry and Metallurgy, Lanchester Polytechnic, Coventry, England

ABSTRACT

Austenitic stainless steel specimens were subjected to strain cycling using a square strain wave while under potentiostatic control in aqueous 3.7M H_2SO_4 solution. Strains of ±0.025 to ±0.05 were employed at an average strain rate of 0.30 sec^{-1}. The transient dissolution behavior of the steel was investigated at active, passive, and intermediate potentials during both the tensile and compressive parts of the strain cycle. Enhanced dissolution of the metal surface was found to occur during the application of strain, the effect being much more pronounced for tensile strains. Subsequently, at constant strain, the enhanced activity decayed at varying rates depending on potential. The greatest dissolution transients were found to occur at potentials corresponding to the active/passive transition where substantial increases in surface activity were observed with each successive strain cycle.

In a study of the corrosion fatigue behavior of a high carbon steel, Rollins, Arnold, and Lardner (1) deduced that dissolution contributed to crack propagation and was, in the early stages of crack growth, the rate determining factor. Furthermore, they suggested that the anodic activity at the crack tip was enhanced by the plastic strain which occurred during the stress cycle. Recently, Uhlig and Duquette (2) have shown that for mild steel in aqueous solutions there is a critical value of corrosion rate which must be exceeded for the environment to have a deleterious effect on fatigue life.

Pyle, Rollins, and Howard (3) have suggested that such an effect could be explained if reverse slip occurred during cyclic deformation. During the application of stress, slip steps are generated on the surface of the metal by dislocation movement. When the stress is reversed, it is possible that slip could occur in the opposite direction on or close to some of the original slip planes, which could return the steps completely or partially into the surface. If the atoms at the surface of the step were more active than the atoms occupying sites in the plane of the surface, then preferential dissolution at the step face could occur as soon as the deformation started to produce the step and could continue during the life of the step [Fig. 1(a)], until reversal of the load cycle caused the strain to drive the step back into the surface.

Howard and Pyle (4, 5) have shown that the activity of a step face depends upon slip step spacing. The amount of material which will dissolve from the step face is a function of the rate of dissolution and the time of exposure of the step face to the electrolyte.

Key words: corrosion, fatigue, passivity, reverse slip.

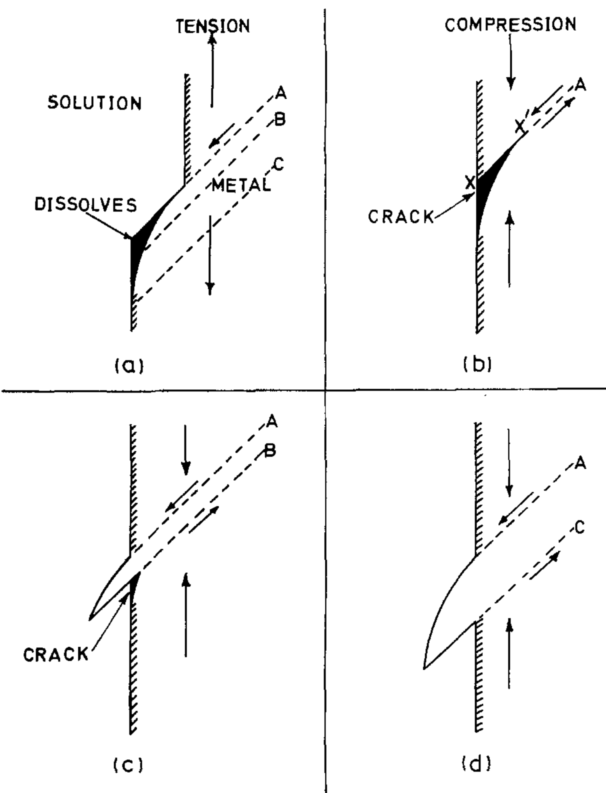

Fig. 1. Crack initiation in corrosion fatigue due to reverse slip

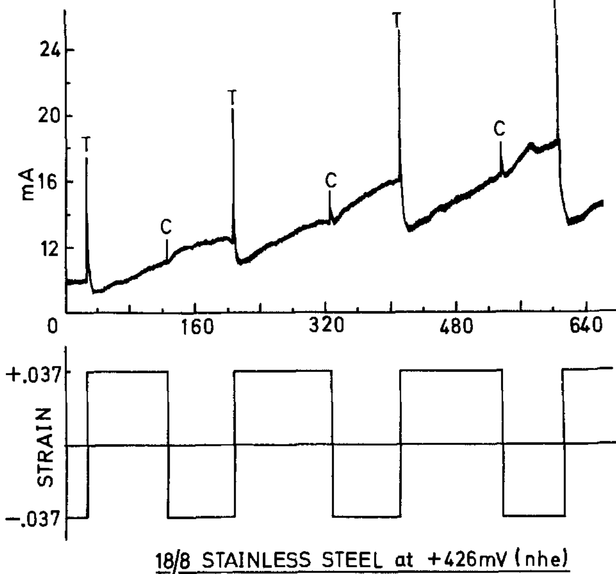

Fig. 2. Strain induced dissolution transients for 18/8 stainless steel in 3% NaCl (pH 3.0), $\pm$ 0.0375 total strain and 0.30 sec^{-1} strain rate.

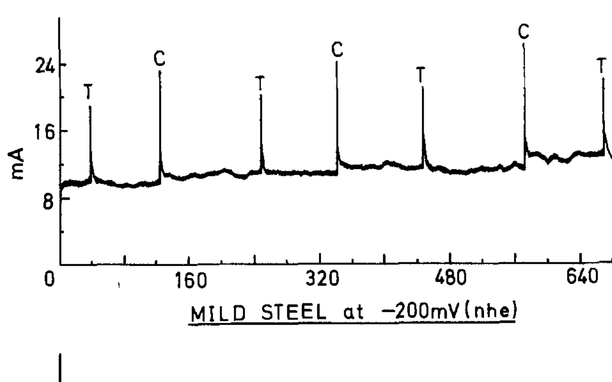

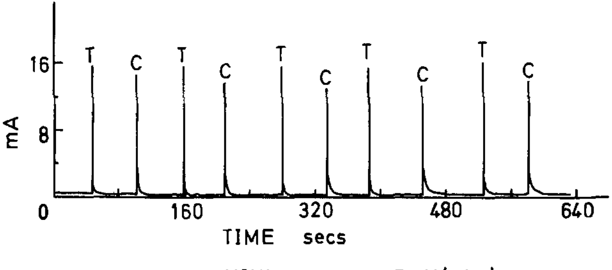

Fig. 3. Strain induced dissolution transients for mild steel and aluminum in 3% NaCl (pH 3.0), $\pm$ 0.0375 total strain and 0.30 sec^{-1} strain rate.

If reverse slip took place along the same slip plane, this would result in the formation of a wedge-shaped crack along the slip plane. The critical rate of dissolution would be that which would remove one atomic layer of atoms in the time that the step was exposed to the electrolyte. If the reverse slip occurred in a different place then it would be necessary for many atomic layers to be removed from the step face if a crack was to develop [Fig. 1(c) and (d)]. The extent of slip reversal and the contribution that this mechanism would make to crack development would depend on the crystal structure and stacking fault energy of the metal concerned. The idea that an increase in anodic activity (6) can be brought about for some metals by dynamic unidirectional strain while the metal is in contact with an electrolyte, has been demonstrated experimentally by several authors (7-11), although the precise mechanism by which it occurs may be open to debate. Smith and Staehle (12) have suggested that strain enhanced dissolution could be due simply to the rupture of surface films and that the speed with which the film repairs itself may play a major role in determining the susceptibility of metals to stress corrosion cracking. As the overpotential for film formation will influence the rate of film nucleation and growth, the potential dependence that is found for stress corrosion cracking behavior would thus be explained. Johansson and Staehle (13) have recently measured the dissolution transients that occur when a metal is suddenly deformed by a fixed amount of strain (0.02 at a high strain rate 2.2 sec^{-1}) and have shown that the magnitude of the charge which passes before dissolution ceases depends markedly upon potential.

However, the influence of cyclic plastic deformation on anodic activity has not been investigated. The results of preliminary tests by the authors on 18/8 stainless steel, mild steel, and aluminum under potentiostatically controlled conditions in 3% NaCl at pH 3 and subjected to a square wave cyclic total strain of $\pm$0.0375 are given in Fig. 2 and Fig. 3. In these tests the strain reversal took 0.25 sec giving an average strain rate of 0.3 sec^{-1}.

The potentials selected for mild steel and aluminum corresponded to the commencement of the active region. The 18/8 stainless steel was held at a potential where it would normally have been passive, but passive film formation was prevented by the presence of chloride ions. In Fig. 2 it is evident that very large increases in the dissolution rate of the stainless steel occurred during the 0.25 sec required to reverse the strain. Similar results were obtained for aluminum and mild steel and in each case the dissolution rate decayed during the constant strain portion of the square strain wave. These initial experiments showed clearly that reversed dynamic strain can greatly enhance dissolution rates in metals during both tension and compression half-cycles. They are important also in that they demonstrate that such effects can occur in conventional engineering materials subjected to reversed strain in a simple aqueous electrolyte at room temperature, i.e., under normal corrosion fatigue conditions.

The relative magnitudes of the transient currents produced in tension and compression for stainless steel were different from those for mild steel and aluminum. It was thought that this difference could be due to the strain characteristics of the metals. Interest was focused on stainless steel also because of the susceptibility of austenitic steels to transgranular stress corrosion cracking and because work by Spähn (14) had shown that the corrosion fatigue properties of 13% Cr stainless steel in solutions of sulfuric acid were markedly dependent on potential. Minimum fatigue life was found at potentials close to the active/passive transition.

It was decided, therefore, to make a more detailed examination of the transient dissolution behavior, under cyclic strain in the range ±0.025 to ±0.05, of an austenitic stainless steel in an aqueous sulfuric acid solution. This paper describes the techniques used in these tests and the results obtained from strain cycling at different strains per cycle and at different potentials relative to the standard hydrogen electrode.

In practice, engineering structures are not subjected to plastic strains, but stress raisers such as notches, inclusions, and pits may locally raise the strain level above the average strain experienced by the structure as a whole. It is at these points that the dissolution effects described in this paper could occur.

Experimental Technique

Strain cycling experiments were carried out on En 58A stainless steel specimens using a Mand servo-hydraulic testing machine for controlled strain cycling and a Chemical Electronics 40V 10A potentiostat to control the specimen potential. The specimen was held in the jaws of the straining frame and surrounded by a glass chamber in which the sulfuric acid was held. Details of the cell are shown in Fig. 4. The electrolyte 3.7M H_2SO_4 was circulated through the cell by a peristaltic pump and was directed onto the exposed surface of the specimen along a tube concentric with the Luggin capillary at a rate of ~0.1 msec^{-1}. The Luggin capillary was spring loaded so that a constant distance of 2.5 mm was maintained between the specimen surface and the end of the capillary despite the slight movement of the surface during the tension and compression cycles of strain. The reference cell for the potentiostat was a saturated calomel cell with a sintered glass base which stood in the 3.7M H_2SO_4. The experiments were of short duration and it was found that the potential of the electrode did not change within this time.

Specimens.—Specimens were machined from a stainless steel having the composition shown in Table I after annealing at 1363°K and water quenching. The specimens which had a gauge length of 11.6 mm and a diameter of 12.5 mm were polished using 220 grade emery paper, finished with crocus paper, washed with distilled water and industrial spirits, and dried in hot air. The specimen gauge length was coated with polythene, and the remainder of the specimen coated with synthetic rubber. The 100 mm^2 area to be exposed to the solution was coated with Lacomite prior to polythene coating. This facilitated the removal of the polythene coating from the center of the gauge length. The exposed surface was then polished with crocus paper to ensure that all traces of the Lacomite and polythene had been removed.

Weight per cent (w/o)	0.12	0.40	1.17	0.02	9.10	17.90	0.80	Trace

Electronic Equipment.—The potentiostat had a rise time of 0.5 μsec and was more than adequate to follow the changes in anodic activity due to straining which occurred over a time period of 0.25 sec. The strain was controlled from an extensometer, which consisted of strain gauges mounted on a high carbon steel U-spring which was located on four pop holes at the extremities of the gauge length *via* perspex pins. The whole of the extensometer was coated in synthetic rubber to protect it from the electrolyte. The strain, load, and current were recorded simultaneously on a Southern Electronics u.v. recorder. A Bryans 2000 X-Y plotter was used to record polarization curves and to provide a second independent recording of potentiostatic current variations with time. The recorders were calibrated against the potentiostat and the Mand extensometer after each run.

Procedure.—After polishing and coating, the specimens were set up in the machine and the electrodes and corrosion chamber arranged as in Fig. 4. The solution, nitrogen-saturated 3.7M sulfuric acid, was added and the pump started. The specimens were held at −460 mV (NHE) for 15 min to clean the surface. During this period, hydrogen was evolved and the current gradually decayed to a constant level. The specimen was then brought to the desired potential for the test at a rate of 1.04 mV sec^{-1}. The specimen potential was then maintained constant for 5 min before the strain was applied to ensure that equilibrium with the solution had been achieved.

In the tests reported, a square strain wave was applied and the first strain increment studied was in tension. The specimen was therefore strained very slowly into compression before switching on the automatic strain cycling control. Two types of tests were run. In the first series, after an increment of strain, the current was allowed to decay back to its original value before the next reverse strain increment was applied. In situations where the decay of the current was slow, a maximum period of 300 sec was allowed before the next half strain cycle. This time corresponded to the slowest cycling frequency that could be obtained with the equipment.

In a second series of tests, specimens were strain cycled using a square wave at 0.2 Hz, irrespective of the degree of decay of the current that had occurred between the reverse strain increments. A series of tests was conducted with the first strain increment in compression. The results obtained were similar to those where the first strain increment had been in tension, *i.e.*, the transient current produced by the tensile strain reversal was larger than that produced by the compressive strain reversal. After each test the load was removed from the specimen and a polarization curve for the strained sample in the solution was determined.

Experimental Results

Tests were carried out at cyclic strains of ±0.025, 0.031, 0.0375, and 0.05 total strain about zero strain

and at different potentials in the range between −8 mV (NHE) and +1042 mV (NHE). References to strain values in the paper refer to total strain (elastic plus plastic). The positions of the chosen potentials relative to the polarization curve for the material in 3.7M H_2SO_4, determined under precisely the same conditions, are shown in Fig. 5.

At the lower potential, −8 mV, the metal was in the active condition while at the higher potential, +1042 mV, the metal was in the passive range. A typical set of current transients obtained at potentials of −8 mV, +262 mV, and +1042 mV is shown in Fig. 6. In these tests the cycling frequency was adjusted to very low levels to ensure that during the initial strain cycles specimens held in the passive region were able to repassivate before the reverse strain half cycle was applied. Values of the peak currents for the transients produced by the tensile half cycles of strain at this low frequency and at 0.2 Hz are shown in Fig. 7-11 for different potentials and strains per half cycle. The results show that, as the metal was strained, a rapid increase occurred in the current required to maintain the specimen at a constant potential, indicating that an increased rate of metal dissolution had occurred. Immediately after dynamic tensile straining ceased, the current commenced to decay and continued to do so while the strain was maintained constant. Although all the current transients had the same general form, it can be seen from Fig. 6 that there were distinct differences both in the magnitude of peak currents and also in the rates of decay of the currents particularly after the application of the tensile half strain cycle. The following main points seem worthy of note:

1. At active potentials, the surface appeared to remain substantially more active for appreciable periods of time after dynamic straining ceased. The current supplied by the potentiostat at these potentials was several times greater than the starting current. If it is assumed that strain occurred by slip at 45° to the surface, a tensile strain of 0.1 would produce an increase in surface area of ~13 mm² equivalent to 0.13 of the original area. If the additional current was concentrated at this new area, it would correspond to a significant increase in the surface activity at these points compared to the normal surface.

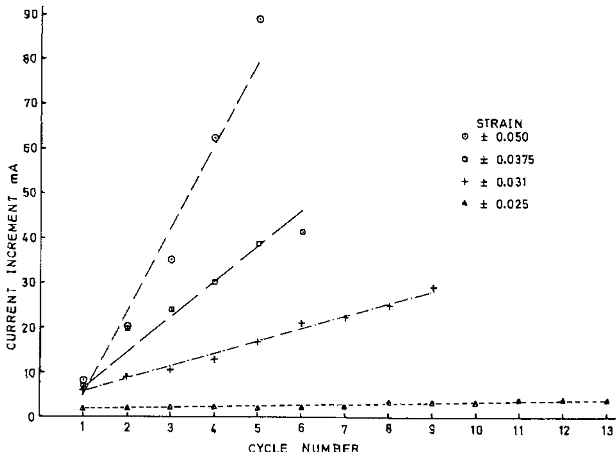

Fig. 8. Variation of dissolution transient peak with strain for 18/8 stainless steel in 3.7M H_2SO_4 at 262 mV, cycled at 0.2 Hz, strain rate 0.30 sec^{-1}.

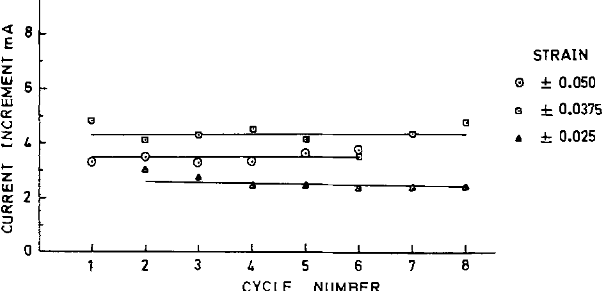

Fig. 9. Variation of dissolution transient peak with strain for 18/8 stainless steel in 3.7M H_2SO_4 at 1042 mV, cycled after interval for repassivation, strain rate 0.30 sec^{-1}.

2. At passive potentials (+1042 mV) the current transients did not vary with successive strain cycles whereas in the active and active/passive transition regions the transient peaks produced in tension increased rapidly with successive cycles.

3. At a potential (+262 mV) where the metal was just passive in the unstrained condition, the surface was able to repassivate within ~5 sec of the first and second tensile strain reversals. Gradually, however, it became increasingly difficult for repassivation to occur and large dissolution currents were found to

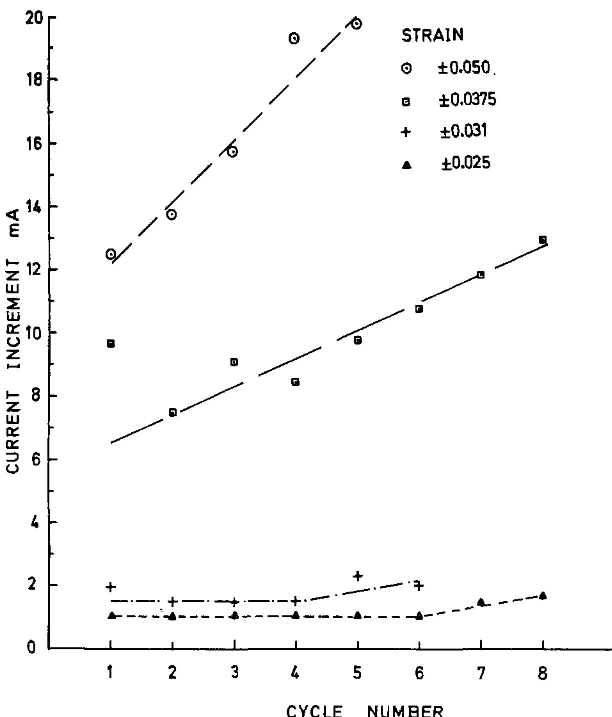

Fig. 10. Magnitude of dissolution transients for 18/8 stainless steel in 3.7M H_2SO_4 at 75 mV, cycled at ~0.0017 Hz, strain rate 0.30 sec^{-1}.

be maintained for appreciable periods of time, *e.g.*, > 60 sec after the tensile strain increment.

4. The current transients produced in compression were significantly smaller than those in tension. (Fig. 3 indicates that this is not so for mild steel in 3% NaCl.)

5. In the active region the peak produced during the compression half cycle diminished with successive cycles until the point was reached when the action of the compressive half cycle was mainly to remove the increased activity remaining after the tension half cycle.

6. At passive potentials the dissolution peaks occurred at approximately 50% of the applied tensile strain at a position corresponding to the maximum strain rate, whereas at active potentials the potentiostat current rose to a maximum close to the point of maximum strain. At potentials corresponding to the active/passive transition the peak position shifted gradually from the point of maximum strain rate to that of maximum strain as the cycle number increased.

In practice, most corrosion fatigue tests are run at a constant cycling speed. The tests at 0.2 Hz represent an initial attempt to examine the influence of controlled frequency cycling on the dissolution transients. Although this speed was low compared to conventional tests it was sufficiently rapid for the second half cycle of strain to be applied before the surface had time to repassivate in the active/passive transition region. Figure 12 reveals that the compressive strain reversal at this frequency acts to remove the transient current produced by the tensile strain.

Discussion

The current transients observed are similar in shape to those shown by Johansson and Staehle (13) although in that work the peak currents occurred at the point of maximum strain. This was due presumably to the higher strain rate, 2.2 sec^{-1}, used by Johansson and Staehle compared with the value of 0.30 sec^{-1} used in these experiments. Johansson and Staehle characterize their transients by measuring the total charge passing in a fixed time. An alternative assessment used in this paper is to measure the peak current and the rate of decay of the peak current which is characterized by a half-life, $t_{1/2}$, which gives a measure of the ability of the surface to repassivate and limit dissolution effects, and may be an important parameter in determining cyclic frequency effects in corrosion fatigue failure.

The sudden increase in the potentiostatic current as the tensile strain was applied suggests that plastic deformation created areas from which dissolution of the atoms occurred more readily than from the unstrained surface. It is apparent that the precise manner in which deformation influenced dissolution depended upon whether the surface was or was not covered by an oxide film and by the ability of such films to reform if they were broken during straining. The results are most easily discussed, therefore, if the behavior of the specimens in the active and passive potential regions are considered before examining the active/

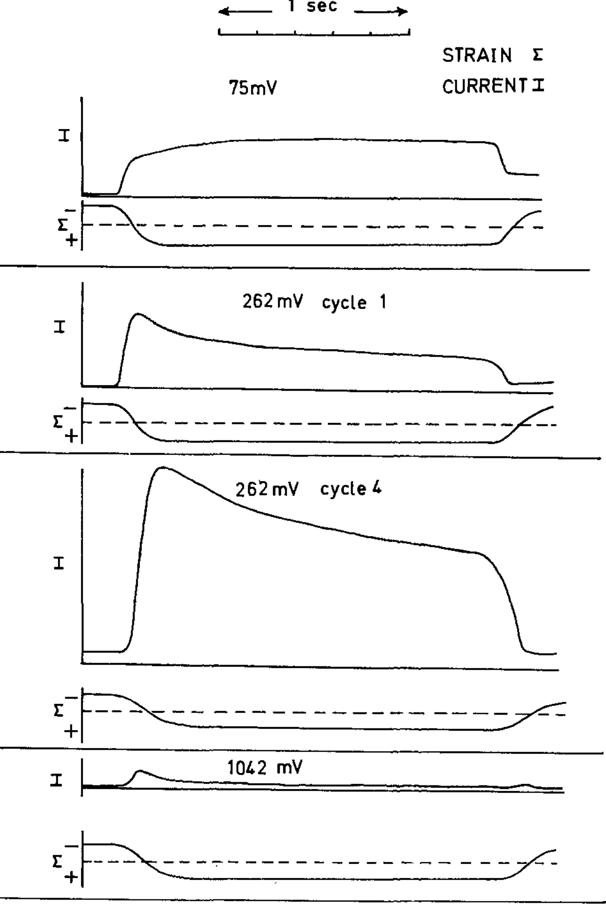

Fig. 12. Typical u.v. recordings of dissolution transients for 18/8 stainless steel in 3.7M H_2SO_4.

passive transition where Fig. 6 indicates that significant changes take place either in the reactivity of the surface or the stability of films formed during repeated strain cycling at these potentials.

The active condition, potentials −8 mV, 75 mV.—At these potentials film formation appears unlikely and the current transients obtained in the first strain cycle varied with the magnitude of the imposed strain (Fig. 10 and 11). Furthermore. the transients showed a rate of increase of the peak current in successive cycles of strain which was dependent upon the applied strain (Fig. 10 and 11). From these results it seems probable that the function of strain was to produce more sites on the metal surface from which ions may dissolve.

Active site formation can occur when a slip step intersects the surface of the metal. Howard and Pyle (5) showed that the rate of dissolution of ions from steps on the surface of a metal was dependent upon the separation between successive steps and reached a maximum rate for steps $> \sim 10^{-4}$ mm. At spacings $> 10^{-4}$ mm, the instantaneous rate of dissolution of ions from a step was $\sim 2 \times 10^3$ ions/surface atom/sec for iron and $\sim 1.2 \times 10^3$ ions/surface atom/sec for nickel compared to rates of dissolution from a smooth surface calculated from Bass' model (4, 15) of 0.52 ions/surface atom/sec. For step sizes $< 10^{-4}$ mm the rate of dissolution will fall rapidly.

Electron microscopic measurement of slip step separation in this type of steel showed that a single tensile strain of 0.05 produced an average step separation of 2×10^{-4} mm. This figure covers a range of spacings, some smaller than 10^{-4} mm, while others were larger than 2×10^{-4} mm. This would give a range of dissolution rates from the different steps and the over-all dissolution rate would represent an average of these rates depending upon the frequency of step separations for a given strain. The effect of this distribution of slip step widths will be that on the initial strain cycle only a proportion of slip steps will be capable of providing sites for rapid dissolution. However, as strain cycling proceeds and the cyclic deformation concentrates slip on specific slip planes, the average slip step spacing will tend to increase, causing an increase in the rate of dissolution from the surface. Measurement of slip step spacings on specimens which had undergone ten cycles of a strain of ± 0.025, *i.e.*, a strain of 0.05 per half cycle, showed an average spacing of 4.5×10^{-4} mm.

The application of a 0.10 strain, moving from a strain of 0.05 in compression to a strain of 0.05 in tension, will produce $\sim 2 \times 10^{12}$ new sites per mm^2 of surface, assuming that the slip steps make an angle of 45° with the plane of the surface. This would produce an additional dissolution rate of $\sim 2 \times 10^{12}$ R ions mm^{-2} sec^{-1} where R is the rate of dissolution of ions per atomic site. If these sites are distributed in steps of $\sim 10^{-4}$ mm separation $R \approx R_{max}$, $\sim 2 \times 10^3$ ions/surface atom/sec for iron (5), and the new surface will dissolve at a rate of 4×10^{15} ions mm^{-1} sec^{-1} or ~ 1.2 mA mm^{-2}. The initial strain appears to produce only one-twentieth of the active sites due presumably to the formation of many finely spaced slip steps. However, as strain cycling proceeds, the progressive increase in the size of the transient current appears to indicate that there was an increase in the activity of the surface which is consistent with the observation that there was a progressive increase in separation of the planes on which slip was occurring. The production of active sites appears to be a reversible process in stainless steel. Figure 12 shows that the transient current was largely removed by the application of the compressive strain. It is possible that this effect was due to reversal of slip during compression along active slip planes produced in tension. There is evidence to suggest that reverse slip occurs in fatigue cycling of single crystals of copper (16, 17). If this did occur during the compressive strain cycle, then it would cause a decrease in the active current as observed and such a process would then contribute to crack development in the manner suggested in Fig. 1. Although previous observations of reverse slip appear to be limited to single crystals of copper, reverse slip was observed in this polycrystalline 18 Cr-8Ni steel during strain cycling.

Figure 13 shows the surface of a stainless steel specimen at 1500× magnification during the first half cycle of strain. Figure 13(a) shows the specimen at zero strain and load, Fig. 13(b) shows the specimen after 0.08 total tensile strain has been applied, and Fig. 13(c) shows the specimen after it has been compressed back to the zero strain position. It can be seen that the slip lines BB′ and CC′ lying on either side of the inclusion A in Fig. 13(b) have nearly disappeared in Fig. 13(c). A new slip line, DD′ is visible and also some duplex slip has occurred towards the center of the field of view.

A slight difference in behavior during compression occurred between the specimen cycled at the low frequency and at 0.2 Hz.

In the latter tests, the application of the compressive strain caused a smooth and continuous decrease in dissolution current. However, in the low frequency tests, the application of the compressive strain always produced a small increase in current before the major decrease occurred. This effect could be due to excessive dissolution during the tensile cycle creating room for dissolution to start on the opposite face, XX′, of the slip plane [Fig. 1(b)] once reverse slip occurs. Because free movement of the electrolyte could not

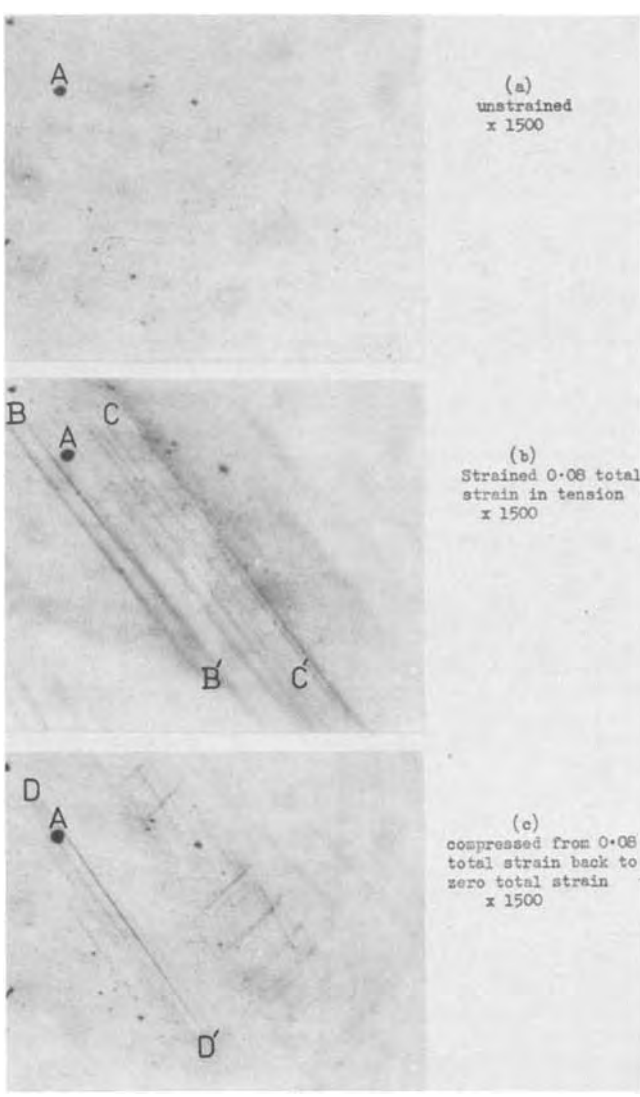

Fig. 13. Showing reversed slip during strain reversal of 18/8 stainless steel.

occur within such a microcrack, concentration polarization would rapidly prevent dissolution from proceeding throughout the compressive strain reversal. The effect of the compressive strain in reducing the dissolution current could alternatively be explained by the closing of cracks opened by the tensile strain. Microscopic examination of the specimens failed to reveal such cracks. It should be noted that the phenomenon was observed during the first strain cycle at a time when the formation of cracks sufficiently large to account for the increase in dissolution current would not be expected.

The passive condition, potentials 642-1042 mV.—In this potential region film formation apparently had an important effect on the current transient. The peak current occurred at the maximum strain rate where the balance between the strain rate and film formation exposed the maximum surface area to the electrolyte. Film formation occurred so rapidly that the surface was repassivated during the application of the tensile strain. Figure 14 shows a typical current transient produced at 1042 mV. The time, $t_{1/2}$, for the peak current to fall to half its peak value at different potentials is shown in Fig. 15 for the first strain cycle of ± 0.0375.

At the active potentials the transient did not decay completely and in many cases the current reached a steady value greater than half the peak value. To obtain a comparison of the rate at which sites were removed at active potentials, a half-life based on the time for the current to fall to a value halfway between the peak current and the final value was taken and plotted in Fig. 15 for the potentials −8 mV and 75 mV. As would be expected, the half-life decreases with increasing potential presumably due to the increased over potential for film formation. At 1042 mV the half-life was found to be dependent also upon the strain per half cycle (Fig. 16). Strains of ± 0.005 produced peak transient currents of ~ 0.1 mA, while strains of ± 0.01 gave peaks of ~ 0.2 mA compared to values in the range 2-4 mA for strains between ± 0.02 and ± 0.05 (Fig. 9). This increase in peak current with strain combined with the reduction in half-life suggests that film formation was related to the amount of dissolution which occurred at the surface; a possible indication that film formation depends on the concentration of metal ions in solution at the interface. However, this effect could also be due to the degree of preferential dissolution of atomic species in the alloy which would change the effective surface composition and alter the repassivation kinetics. Although the precise mechanism of film formation cannot be deduced from these results

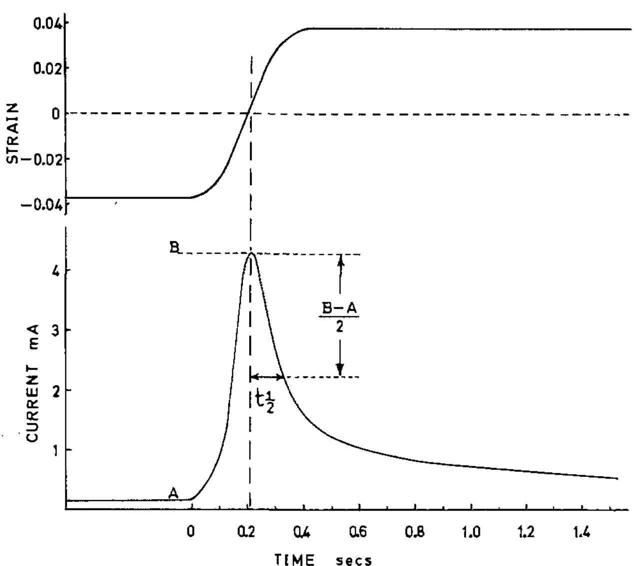

Fig. 14. The measurement of transient half-life, $t_{1/2}$, from a dissolution transient.

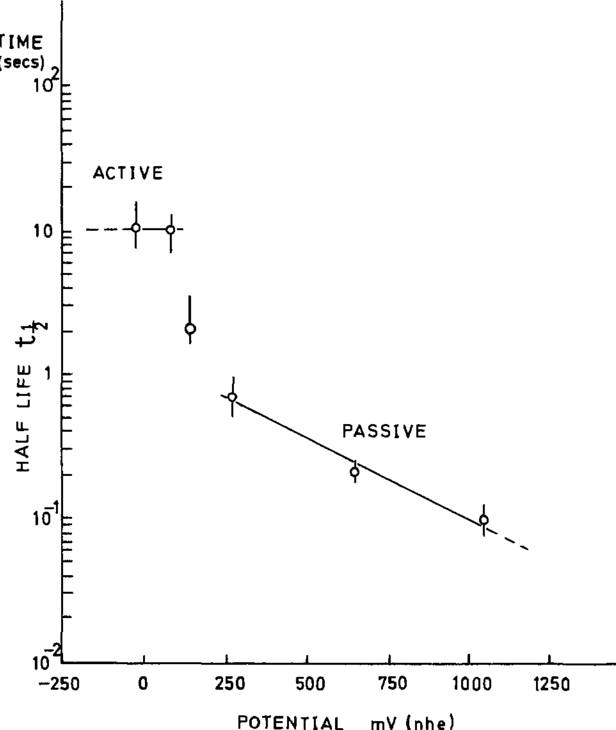

Fig. 15. The influence of potential on transient half-life. Tensile strain reversal from −0.0375 to +0.0375.

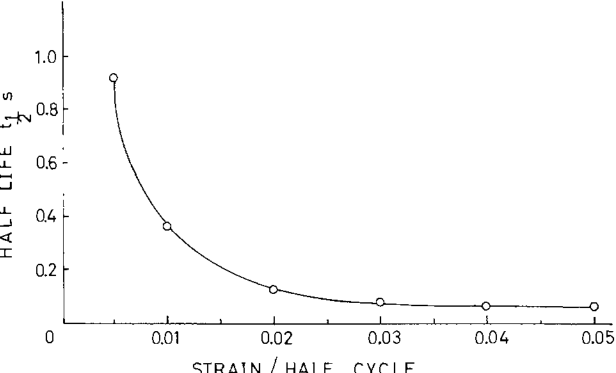

Fig. 16. The influence of strain on transient half-life. 18/8 stainless steel, 3.7M H_2SO_4 at +1042 mV (NHE).

as the half-life is determined by the strain rate as well as the film formation rate, it seems possible that the half-life of the transient taken in conjunction with the peak transient current could be a useful parameter in assessing the sensitivity of the alloy to corrosion fatigue. Furthermore, the half-life of the transient is of importance in considering the influence of frequency on the extent of dissolution per cycle and consequently on the contribution of dissolution to crack development per cycle in corrosion fatigue. Further strain cycles at these potentials did not cause an increase in the magnitude of the peak of the current transient, an indication that strain cycling did not increase the number of active sites. It is to be expected that strain cycling has the same effect on slip deformation as it has at the more active potentials and in this sense a widening of slip planes on which deformation takes place would occur. This would, on the basis of earlier arguments, lead to higher rates of dissolution from these slip step faces. However, it is suggested above that film formation occurs more rapidly at higher dissolution currents and it is possible that any changes in dissolution rate from the surface were compensated for by an equivalent change in the film formation rate. The small size of the current transients produced by compressive

strains indicates that the major proportion of slip produced in the tensile cycle was reversed along the original slip planes. The transient that did occur during compression was probably due either to disruption of the passive film formed on the exposed steps or to some slip along neighboring slip planes which produced fresh steps in contact with electrolyte. The magnitude of the transient peak indicates, however, that these effects were minimal.

The active/passive transitions, potentials 142 mV and 262 mV (NHE).—The most dramatic effects of strain cycling occurred at these potentials. The first current transients at these potentials were of a similar size to those at more noble potentials and occurred at the point of maximum strain rate in the tensile half cycle. In subsequent cycles there was a movement of the peak towards the position of maximum strain which showed the increasing difficulty encountered by the surface in repassivating. The peak values of the tension current transients increased rapidly with cycle number (Fig. 7 and 8) and the surface behavior appeared more characteristic of the active condition although the current peaks were much larger. The increase in peak current/cycle, dI/dN, is shown for tensile strains of ± 0.0375 at different potentials in Fig. 17. A very rapid increase in dI/dN at potentials close to the active/passive transition is evident. If strain enhanced dissolution is a factor in corrosion fatigue failure, then minimum corrosion fatigue properties should occur at these transition potentials. Spähn (14) has demonstrated that this behavior occurs for a 13% Cr stainless steel tested in H_2SO_4. It is clear from Fig. 7 and 8 that values of dI/dN are also sensitive to the magnitude of the applied strain as well as to potential.

From the data we are not able to explain why, after several strain cycles, the surface was unable to completely repassivate or why the rate of formation of the films that were produced slowed sufficiently for the peak to occur at the maximum strain rather than the maximum strain rate. Two possibilities appear feasible. First, preferential dissolution during the first transients could have changed the surface composition removing chromium thus leaving a surface no longer able to form a passive film at these potentials. Changes were observed in the polarization curve where the small peak at 242 mV (NHE) had enlarged considerably after straining in comparison to the main active loop (Fig. 18). There is a peak in the polarization curve of nickel at this potential and it is possible that Fig. 18 is consistent with enrichment of the surface with nickel. The fact that nickel passivates at higher potentials would effectively explain why an increase in

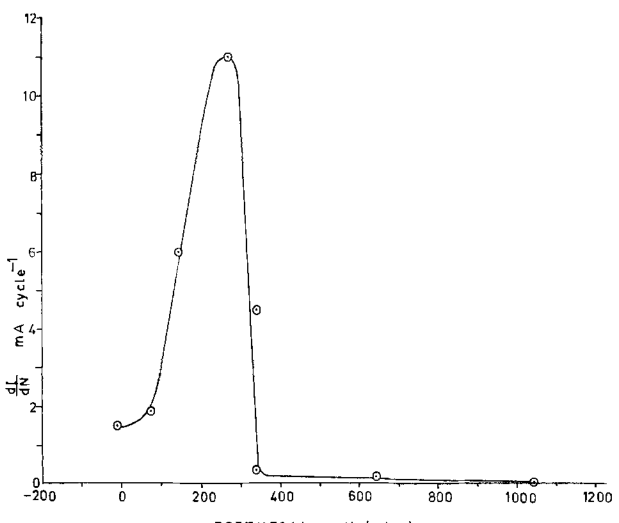

Fig. 17. The variation of the increase in tensile peak current per cycle, dI/dN, with potential. 18/8 stainless steel in 3.7M H_2SO_4, strain cycled ± 0.0375 at a strain rate of 0.30 sec^{-1}.

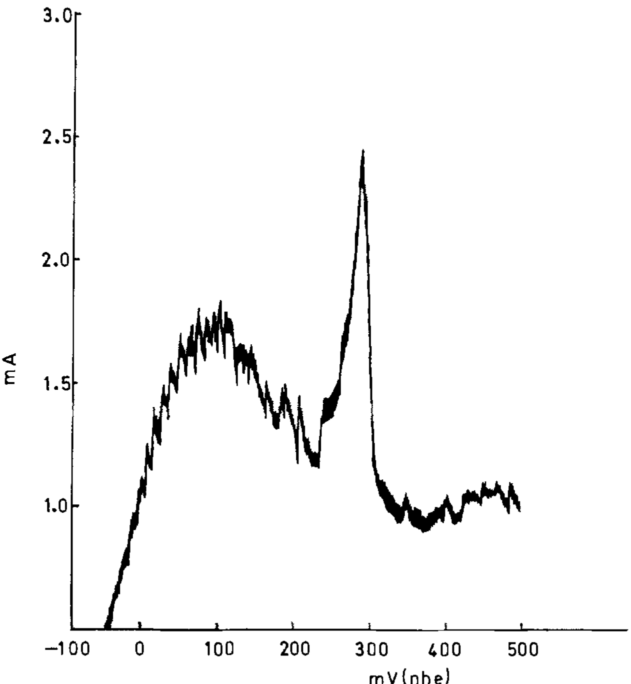

Fig. 18. A typical polarization curve obtained after strain cycling in the potential range —8 mV-242 mV.

the magnitude of the dissolution transient per strain cycle was not observed at more noble potentials. An alternative possibility is that at potentials close to the passivation potential the film is thinner and less stable than at higher potentials and the repeated rupture and reformation of the film during strain cycling makes it more susceptible to failure under tensile elastic strains in subsequent cycles. Rupture of the film in regions where it is not disturbed by slip of the underlying metal could occur and expose additional areas of the surface to the electrolyte which would account for the increase in peak current observed. Repeated fatigue cycling could then generate and extend microcracks in the film during the tensile half cycle and retard repassivation. At a potential of 342 mV (NHE). *i.e.*, slightly further into the passive region, an intermediate type of behavior was observed where initial cycles produced the transition effects but with a smaller value of dI/dN. After three or four cycles, however, there was a sudden drop in the transient magnitude and subsequently the surface behaved as it did at noble potentials and showed only a small value of dI/dN (0.3 mA/cycle). The growth in peak transient then commenced once more as if the changes in the surface brought about by the dissolution caused the surface to oscillate between passive and active transition behavior. An X-Y recording of the transients produced at this potential at ± 0.0375 strain is shown in Fig. 19. This behavior was found to be reproducible and is probably worthy of further investigation.

Conclusion

The experimental work shows that cyclic plastic deformation can induce enhanced dissolution of a stainless steel in contact with sulfuric acid and that these effects are most pronounced during the tensile half of the strain cycle.

The fact that enhanced dissolution is mainly removed by the compressive strain is a possible indication that the slip deformation produced by the tensile strain is reversed along the same slip planes by the compressive strain. The probability that reverse slip occurs in this austenitic stainless steel is supported by micrographic examination of a specimen undergoing cyclic deformation. This suggests that the model of crack formation by slip-dissolution-reverse slip pro-

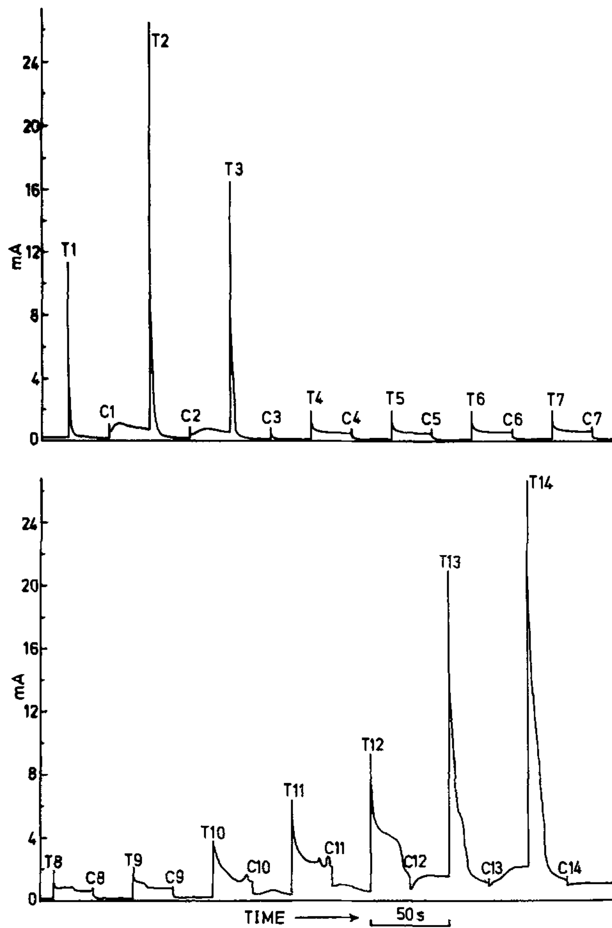

Fig. 19. Dissolution transients for 18/8 stainless steel in 3.7M H_2SO_4 at 342 mV subjected to cyclic strain, ±0.0375 total strain and strain rate 0.30 sec^{-1}.

posed by Pyle, Rollins, and Howard (3) (Fig. 1) could occur in this steel.

The influence of cyclic strain on surface activity is shown to be dependent on the magnitude of the strain and on potential. The greatest effects occur at potentials close to the active/passive transition where substantial increases in surface activity occur with successive strain cycles.

The decay characteristics of strain generated dissolution transients are shown to depend on potential, strain magnitude, and the number of applied strain cycles and indicate that cyclic strain can significantly slow down the rate of film reformation.

Polaromicrotribometry: A Friction Method for the Study of Polarized Metal Solution Interfaces

Application to the Gold Electrode

ABSTRACT

A new adaptation of the technique of mechanical friction is proposed for the study of metal solution interfaces in electrochemistry. The coefficient of friction, especially sensitive to surface-state changes, is measured by means of a micro-slider, which does not disturb the i-v electrochemical curves. This method, called polaromicrotribometry, is easy to employ and of general application. It permits the measurement of electrochemical transient phenomena as well as stationary ones, in aqueous and organic electrolytes. The results obtained using different operating modes are described from the study of gold oxide formation and reduction. Different friction-potential behaviors were found for three different rubbing contacts, against gold in the same electrolyte. Gold/gold friction is elevated at cathodic potentials, indicating metal-metal bond formation, but at anodic potentials friction is reduced by chemisorbed oxygen: the friction-potential curve is in agreement with the current-potential curve. Teflon/gold friction is independent of potential, indicating that in this last case the slider is inert over the potential range studied. As opposed to gold/gold friction, silica/gold friction is low at cathodic potentials, but elevated at anodic potentials with appearance of stick-slip (high static friction). This high static friction is attributed to the electrochemical formation of bonds or bridges which require the presence of an adsorbed oxygen layer. When the electrode is covered by oxygen the friction variations depend only on the applied potential.

Measurement of friction for practical engineering applications is a classical technique of physics. The coefficient of fraction is defined by $f = T/N$, where N is the normal force to the contact surface of two bodies, and T is the tangential force required to cause sliding. Two measures exist: the coefficient of static friction f_s is the force required to initiate sliding, while the coefficient of sliding friction f smaller than f_s, is the force required to keep the bodies sliding on each other. The friction coefficients are ordinarily independent of the force normal to the surface.

Friction and adhesion are phenomena which are very sensible to the physicochemical nature of the contact surface. One quarter of an oxygen monolayer on clean tungsten is sufficient to divide the coefficient of friction by half (1). Conversely any change of friction must be connected to a modification of the surface.

This sensitivity can be explained in the following way. Solids are sticking only on a small part of the apparent contact area (2), and it is on this real contact surface that adhesive forces are working. During the displacement of the slider, the junctions are stretched and broken and then built again; the stronger the adhesive forces the greater the frictional work dissipated. In the presence of adsorbed layers, the slider is always in contact with this superficial layer, and consequently it appears that friction measurement depends directly on the physico-chemical surface state, whatever the scratch behind the slider.

In the case of an electrode which is immersed in an electrolytic solution, adsorption depends on the applied potential and consequently adhesion and friction will depend on this potential.

Key words: friction, electrochemistry, gold electrode, oxidation, tribometry.

The first such friction measurements in electrolytes were those of Edison in 1877 (3) who observed the variation of the coefficient of friction of lead, thallium, and platinum against electrolyte-soaked paper in the presence of electrical current.

Koch (4) in 1879 notes an increase of the friction of platinum against glass (in acidified water) with the applied oxidizing potential. Waitz (5) in 1882 measured friction of gold, palladium, and nickel against glass in different electrolytic solutions, and observed also an increase of friction for anodic potentials and a decrease for cathodic potentials.

Krouchkoll in 1889 (6) reported quantitative measurements of the sliding friction of a platinum brush against glass in an acid electrolyte. The coefficient of friction increased from 0.10 to 0.30 with positive polarization and showed a local maximum at a potential of -120 mV with respect to the rest potential of platinum.

Clark (7) reported the sliding friction of tungsten and platinum wires on a perspex drum in various electrolytes.

Bowden and Young (8) measured the coefficient of static friction of platinum against platinum in 0.1M sulfuric acid. The method involved a small cylinder on a wire in a cell, with the apparatus being tilted at the angle required for the cylinder to slide on the wire at a chosen potential. They observed a maximum of static friction at the point of zero charge (accompanied by an increase in the damage to the surface) which they interpreted as a maximum of adhesion.

Staicopolus (9) measured the coefficient of sliding friction of glass against copper or stainless steel. The sample in the form of a cup was rotated against a spherical fulcrum coupled to a torque measuring de-

vice. He observed the electrocapillary maximum and detected specific adsorption and chemisorption of ionic species from the change in the friction potential characteristics.

Bockris, Argade, and Gileadi (10) applied the method of Bowden and Young, reporting data in the region of pzc for quartz against platinum, gold, silver, and platinum against platinum, silver against silver; they interpreted the variation of static friction in terms of double layer repulsion (11, 12).

In conclusion, it appears that two methods have been used: measurement of static friction with the inclined plane technique (8, 10), measurement of dynamic friction (5, 9).

The first method does not allow friction to be recorded with variation of electrochemical parameters whereas the latter does. However, in this last case the slider is always moving in the same friction track, a fact which is undesirable if the measurement periods are shorter than the time constants of the electrochemical phenomena.

Principle of Polaromicrotribometry

In order to interpret nonreproducible phenomena observed under certain conditions when using polarized platinum electrodes [servo-coulometry (13) and titrimetry (14)] we have attempted for the first time to apply the microtribometric technique (15), previously used for nonliquid environments, to the study of electrode surfaces in electrolytic media (16).

This microtribometric technique is based on continuous measurement of the frictional force between a small test contact and a sample, displaced slowly (a few microns per second). The apparent area of the contact, *ca.* $500\mu^2$, is quite small with respect to the electrode surface, so the perturbation of the electrochemical system is minimized.

Since the contact moves continuously on the new surface, the coefficient measured reflects the state reached by the surface, with any adsorbed layers, with at most a few seconds of response delay if the static friction is controlling, a fraction of a second for measurement of sliding friction. A choice of friction contacts may be made, including insulating materials, *e.g.*, silica, or a metal contact, for study of metal-to-metal friction at controlled electrochemical potential.

It must be noticed, however, that friction causes surface distortion ahead of the slider (plasic deformation and work hardening). Consequently, the relation between friction and current-potential curves may be questionable. In fact, Bagotzki *et al.* (17) have shown that adsorption remains practically unaltered when structural defects are provoked. Moreover all the experiments we have performed confirm a close correlation between friction and intensity-potential curves.

The systematic exploratory work carried out in inorganic (18) and organic media confirmed by the analysis of the layers (19) has established the reliability of this technique. We have thus been able to demonstrate presence of a film, responsible for catalytic properties on electrodes during the Kolbe reaction (20) and the reduction of quaternary ammonium salts (21).

Using the study of gold oxides as a starting point, we hope to show below the possibilities offered by the use of this technique as well as its value for the study of slow transient phenomena whose time constants range from 1 to 3 sec.

Experimental

The polaromicrotribometer is composed of the following elements (Fig. 1). The cell, in the center of the diagram, is supported by an adapter on a microscope-type stage. This can be rotated to any chosen angle; it may be translated sideways by a micrometer screw, and it is translated longitudinally by a motor-driven lathe screw at velocities from 1 to 50 μ/sec.

The friction contact, which presses on the exposed upper surface of the working electrode in the cell, is connected to an arm supported at the virtual axis of an "N" shaped spring support, and is counterbalanced. A pair of inductive transducers is located symmetrically about the end of the first spring blade. Displacement of the friction contact restrained by the force constant of the springs is measured by these transducers, using a 5 kHz carrier-frequency amplifier. The output of this amplifier is displayed on one pen of an XYY' chart recorder *vs.* applied potential or *vs.* time. Pressure on the friction contact is supplied by weights on the platform above the contact. Hertz's theory shows that the radius of curvature of the slider would lead to elastic deformation for loads less than 2g. Actually the elastic range does not exist since the surface asperities always undergo plastic deformation, so the experiments have been conducted with loads from 5 to 10g which correspond to the best sensitivity of the apparatus. The sensitivity of the apparatus is calibrated by connecting a string, balancing the weights, at 45° upwards away from the detector. At this angle, a force exactly equal to the load is applied to the detector. The silica friction contact was a 2.5 mm rod, polished to a tip radius of 2.5 mm. Gold friction contacts used were (*i*) a 3 mm rod polished to a tip radius of 5 mm, and (*ii*) a brush 2.5 mm in diameter, made of 0.5 mm gold wire.

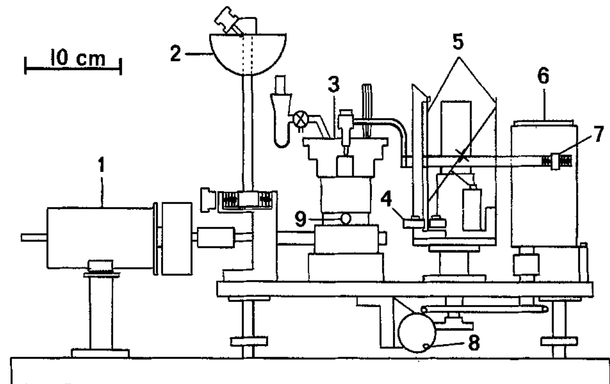

Fig. 1. Polaromicrotribometer. 1, Translation drive motor; 2, protractor for calibration; 3, cell; 4, displacement transducers; 5, spring blades; 6, friction measurement head lift motor; 7, counterbalance; 8, manual height adjustment for the friction contact; 9, micrometer screw for lateral positioning (displacement of the friction contact between successive passes).

The electrochemical cell is drawn in detail in Fig. 2. A saturated calomel (or in some experiments a mercurous sulfate-saturated K_2SO_4) reference electrode is used, with a "stopcock" bridge. The reference electrode and nitrogen inlet tube are supported from the mobile stage. The cell cover is not tight-fitting, since a slot of about 3 cm^2 must be left for the friction-contact motion. It was found that continuous nitrogen bubbling in the cell does not disturb the measurements except at the lowest applied weights. The entire tribometer is inside a nitrogen-filled controlled-atmosphere chamber.

The potentiostat and galvanostat were constructed from $\pm$15V FET input operational amplifiers, with all components of the active feedback loop within the chamber, in order to maintain short leads (22).

Polarization of the working electrode was followed by a Tacussel "Minisis" digital electrometer-pH meter, which also drove the X axis of the chart recorder.

The working electrode was a gold disk, 6.22 mm in diameter, imbedded in a Teflon support machined to fit a 24/40 standard taper joint in the cell bottom. The electrode was polished either with diamond paste (to $\frac{1}{4}\mu$) or with alumina (to 24 hr sedimentation rate) before each experiment. The electrode was not electropolished, since it appeared that grain boundary development was more disturbing to the friction measurement than was the residual surface roughness after mechanical polishing.

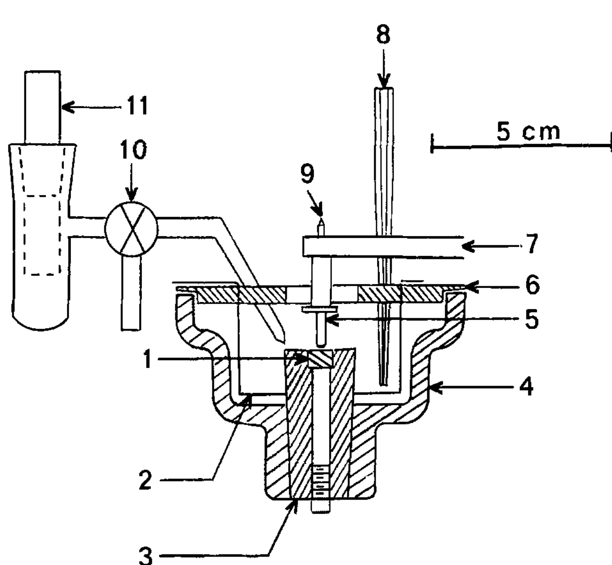

Fig. 2. Electrochemical cell. 1, Sample; 2, wire counterelectrode; 3, Teflon sample holder; 4, Pyrex cell; 5, rubbing contact (silica or gold, etc.); 6, cell cover; 7, arm to force measurement head; 8, nitrogen gas; 9, centering pin for weights; 10, stop-cockbridge; 11, reference electrode.

Electrolytes were, in general, prepared from Merck "Suprapur" reagents and double distilled water or water from a four-cartridge "Millipore" purification system. The studies reported here were conducted in N H_2SO_4 and in N KOH; other studies have been made in H_2SO_4 of lower concentrations, $HClO_4$, H_3PO_4, and NaF electrolytes.

Silica/Gold Friction

Triangular sweep.—When the interface potential is changed linearly with time a curve of friction *vs.* potential such as Fig. 3 results (in N sulfuric acid). The current voltage curve is conventional. The friction curve shows the following regions: a low coefficient at inert potentials, a rise in the coefficient at anodic potentials up to the onset of oxidation (1.35V), and then the violent variations called "stick-slip." In fact, in the "stick-slip" region one can resolve two curves, one for the static coefficient of friction (the peaks) and one for the dynamic coefficient of friction (the average of the peaks and the valleys) (2).

The frictional force measured is somewhat irregular. Deviations of 10% or more around the average value are normal, even with the most carefully cleaned and polished samples.[1] For this reason the friction curves are averaged and replotted pointwise. The curve of Fig. 3 has thus been replotted in Fig. 4, taking for one potential the average values of static and dynamic coefficients of friction of several experiments. The anodic and cathodic friction curves are quite close. We note particularly that, during the cathodic sweep, the coefficient of friction drops well before the electrochemical reduction peak, nearly at the same potential of oxide formation. These experiments show two unexpected results. First the coefficient of friction increases with oxide formation, and second its decrease is not synchronized with the oxide reduction, a fact which will be discussed below.

The hysteresis, or displacement in potential of the coefficient of friction curves between anodic and cathodic sweeps, seen in this series of experiments (Fig. 4) amounts to about 20 mV,[2] while the potential difference between corresponding oxygen coverage fractions on the anodic and cathodic triangular sweeps is about 200 mV.

[1] Increase of friction at the point zero charge was not reliably above experimental deviations.

[2] The initial series (18) had shown an hysteresis of about 100 mV in the Pyrex/gold friction-potential curve.

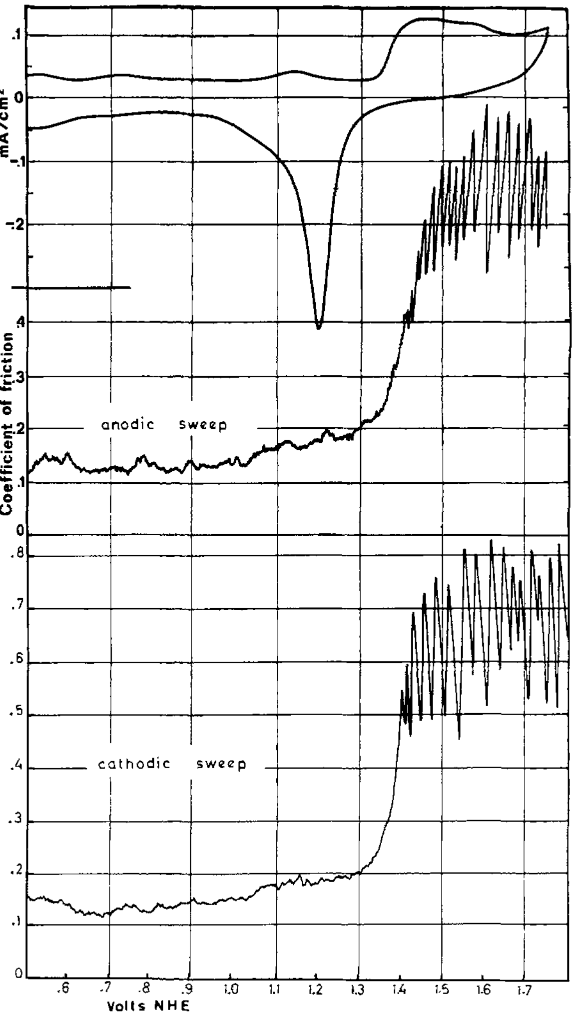

Fig. 3. Silica-gold friction in N sulfuric acid. Triangular sweep, 25 mV/sec, 3g load. Top, I-V curve; middle, coefficient of friction as a function of the interface potential:anodic sweep; and (bottom) cathodic sweep. The beginning of the friction rise is at the same potential as the beginning of oxidation.

In the note published previously (18) it was shown that the friction curve is displaced in potential by approximately 60 mV per pH unit (Fig. 5), as would be expected from the gold oxidation reaction (23).

Galvanostatic sweep.—For comparison with the galvanostatic studies of other authors (24) relating to the mechanism of oxidation at the gold surface, a set of experiments was conducted under galvanostatic control. Only low currents were employed (1-100 $\mu A/cm^2$) in order to resolve the friction curve adequately.

Several curves were run in which, after anodizing at constant current, the current was dropped to zero rather than being reversed. The polaromicrotribometric curves of Fig. 6 show the changes both of the potential and of the coefficient of friction with time, for a current of 20 μA. We see that the "stick-slip" appears at the beginning of oxidation, 1.35V, as under potentiostatic control.

The stick-slip continues after the current is dropped to zero, until the potential is relaxed to below 1.35V. The coefficient of friction increased with potential and oxygen coverage, but decreased with potential at constant coverage. We deduce that the change in coefficient of friction is a function of potential rather than of oxygen coverage. The data from several runs, at different anodic and cathodic currents, were replotted as a friction-potential graph (Fig. 7). Both zero current relaxation and cathodic (galvanostatic) sweep

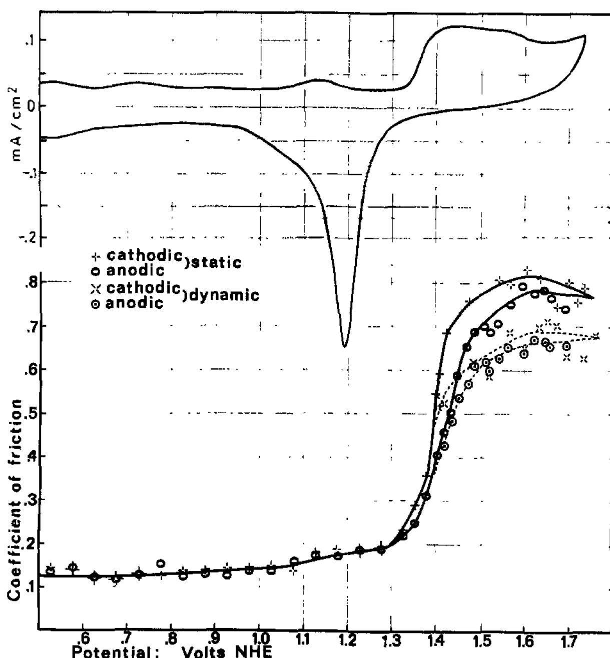

Fig. 4. Silica-gold friction. Triangular sweep, 25 mV/sec, 3g load. Data of Fig. 3 replotted with smoothing: static and dynamic coefficients separated. Top, I-V curve. The coefficients of friction during cathodic sweep decrease substantially before electrochemical reduction of the surface oxide.

points fall on the same curve, *vs.* potential, as does the anodic branch.

Potential jump studies.—The previous results show that at constant oxygen coverage the silica/gold friction is a function of the potential only. This does not exclude *a priori* the possibility of a chemical reaction whose response time is shorter than the response time of the friction measurement apparatus (greater than 1 sec in the stick-slip region). Potentiotribometric curves obtained at sweep speeds from 40 to 150 mV/sec show no significant friction differences. We have therefore come to use a potential-jump method to test for the time constant of the change in friction

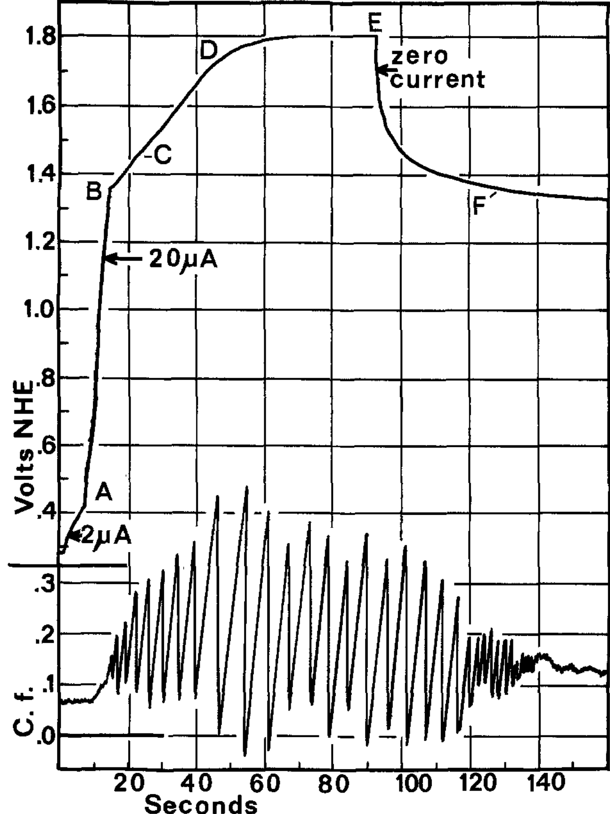

Fig. 6. Silica-gold friction. Galvanostatic control (20 μA = 67 μA/cm² apparent surface). Points A-F discussed in text. "Stick-slip" is visible at all potentials above 1.35V and absent below 1.35V.

with potential. The potential-jump method also helps to obtain more accurate friction measurements at a series of potentials, since one can hold a given potential for several minutes to obtain a better average.

In the anodic series the potential was stepped up, while the friction measurement was being recorded as a function of time, from a reference potential. One such curve is given in Fig. 8, from a series made as a function of polarization time.

It is observed, when the potential is stepped from 1.45 to 1.32V, that the static coefficient of friction decreases instantaneously from 0.40 to 0.25, in spite of the constant value ($\theta \sim 1$) of oxygen coverage fraction (25). The best aveiage friction value, for a period of from 1 to 3 min, was determined, as well as the slope during that time and the instantaneous change observed when the potential was switched. The results are plotted in Fig. 9 and may be compared with the preceding figures. In general, no evidence of change of friction with time could be seen, except at potential extremes in which the relaxation time follows, as closely as can be inferred, the relaxation curve for the electrode current (*i.e.*, the friction may be influenced by the transient overpotentials).

Some difference in the measured values of coefficient of friction was found between the potential jump and the triangular series. The triangular series give higher coefficients of friction than the potential jump series; the cause of the difference has not yet been identified.

Teflon/Gold Friction

The friction of a Teflon rod against the gold surface was found to be independent of interface potential. Neither the oxidation nor reduction of the gold surface produced changes in the coefficient of friction against Teflon which remained at 0.11.

Gold/Gold Friction

Triangular sweep.—After the series of experiments reported above, we began to feel that the silica rubbing

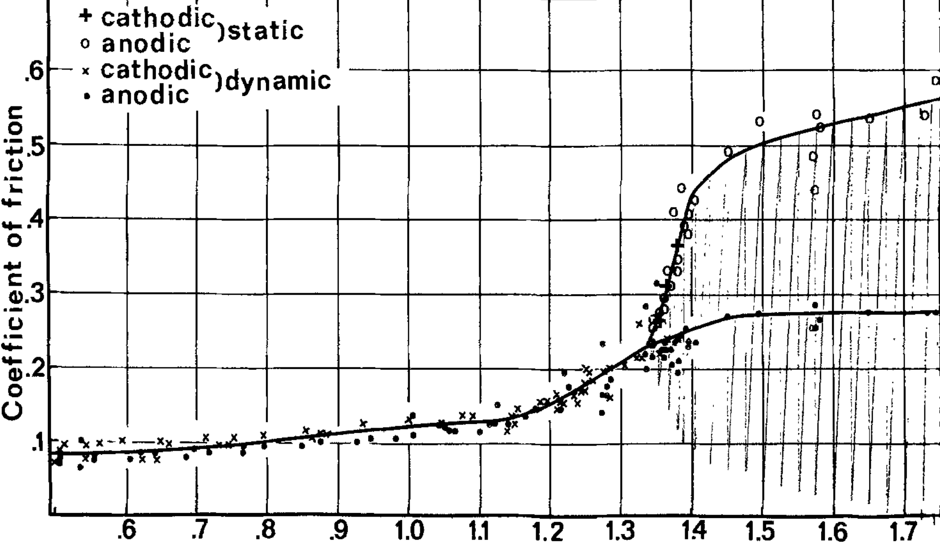

Fig. 7. Silica-gold friction. Galvanostatic control. Average curves, static and dynamic coefficients separated.

contact was not a truly inert sensor, indicating the surface condition of the metallic or oxidized gold.

We found high silica/gold friction at oxidized gold potentials, and low friction at metallic potentials, whereas the *a priori* theoretical expectation (based on high vacuum studies) has been for high friction at a metallic surface, and lower friction at the oxygen-covered surface. The next best indicator to an inert body is a symmetrical system, containing only the gold interfaces. We mounted a gold ball in a Teflon support, to serve as the frictional contact against the gold electrode. Since the gold ball was insulated from the apparatus but was in contact with the electrode, it was supposed that its surface potential would remain the same as that of the working electrode (at much lower contact pressures a noise resulting from irregular contact can be seen in the current response). The friction found for gold against gold was in fact lower in the potential region of oxidation than in the reduced interface region. The stick-slip phenomenon was observed at reducing potentials, as may be expected from metal-to-metal contact (Fig. 10). The cathodic friction curve is displaced with respect to the anodic curve by a potential similar to that between the observed oxidation and reduction peaks.

Potential jump.—The gold/gold friction was also studied using the potential-jump technique. The re-

Fig. 8. Silica-gold friction. Typical potential jumps (potentials as indicated). The lower curve shows the immediate response of the coefficient of friction to the potential jump.

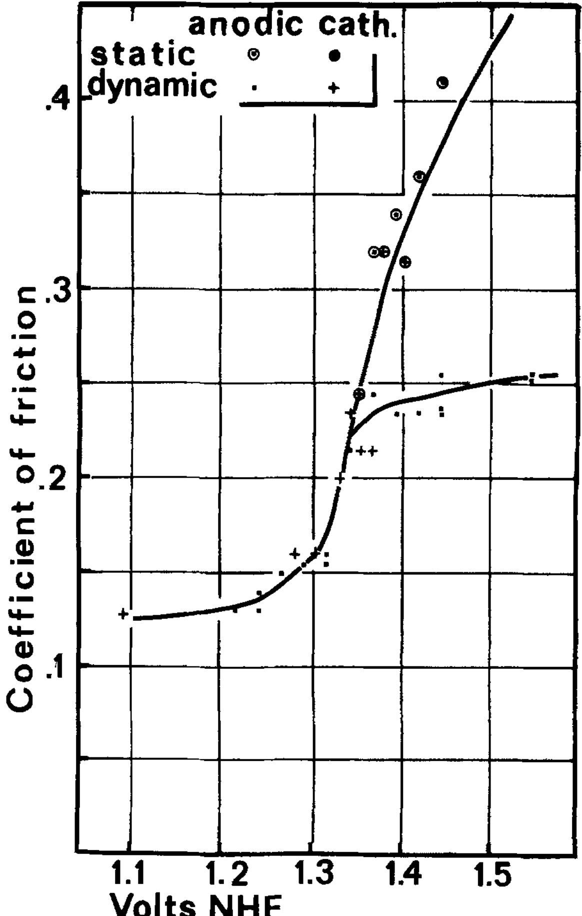

Fig. 9. Silica-gold friction. Averaged potential jump results. Anodic from 1.1V, cathodic from 1.45V.

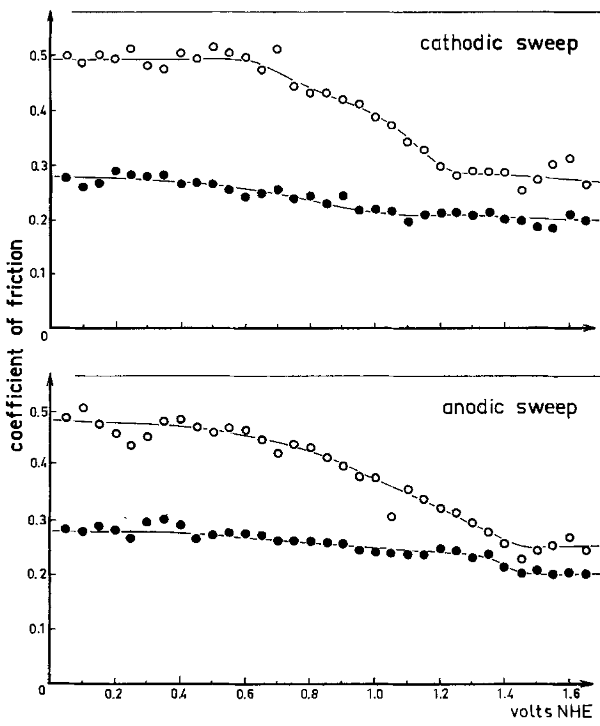

Fig. 10. Gold-gold friction. Triangular sweep, 25 mV/sec static (○) and dynamic (●) mean values. The coefficient of friction is lower at oxidizing potentials than at reducing potentials, the reverse of the gold/silica case.

sults were qualitatively similar, but substantially higher coefficients of friction were obtained than were found in the triangular-sweep experiment.

Discussion

Like previous investigators (4-6) we have seen an elevated coefficient of static silica/gold friction, a region of "stick-slip" at anodic potentials (Fig. 4), with lower friction at cathodic potentials. In contrast, an elevated coefficient of gold/gold friction was found at cathodic potentials (Fig. 10) with lower friction at anodic potentials.

This sticking of one material against another has many of the characteristics of chemical bonding between the materials. Formation of the metallic bond in high-vacuum metal-to-metal friction is classic. At anodic potentials on gold this "welding" is inhibited by chemisorbed oxygen. This results in hysteresis in the gold/gold friction-potential curve comparable to that in the electrochemical current-potential curve for gold.

At cathodic potentials silica does not adhere to gold, since no chemical bond is possible. At anodic potentials, however, silica/gold stick-slip begins at the oxidation potential of gold corresponding to an abrupt static coefficient increase. In the cathodic branch of the triangular sweep, the friction diminishes at nearly the same potential as the anodic increase well before the reduction current peak. In this zone oxygen coverage is constant, hence it follows that static friction only depends on potential.

We thus must propose an eleetrochemically induced reaction between silica and gold to account for this increase in friction related not to oxygen coverage but to electrode potential.

This hypothesis has been tested by the galvanostatic study (Fig. 6) in which the diminution of friction (point F) on potential relaxation after formation of the oxygen coverage, was found at the same potential (1.35V) as its initial increase (point B). That is, the friction changes at points B and F occurred at the same potential but at different oxygen coverages. In the region A-B in that figure the double-layer is charged with little change in friction (0.3-1.35V). In the region B-C the oxygen coverage increases from 0 to 1 (25); in the region C-D the oxygen coverage ratio increases from 1 to nearly 2.[3] Oxygen evolution characterizes the region D-E. During the region E-F the current imposed is zero, so the only change possible in oxygen coverage is due to the loss of 0.3 μA/cm^2 (23) which corresponds to 2% of the coverage during the time scale of the figure. We conclude from the galvanostatic study that for the high-friction (stick-slip) behavior, not just presence of oxygen coverage, but also a potential of at least 1.35V-0.06 pH is necessary.

It appears clearly from these measurements that adhesion is a function of applied potential. The adhesion forces stop at 1.35V, when the oxygen coverage is elevated and for a value which is practically the same as that corresponding to oxide formation.

The chemical bonding of this adhesion is not clear, and we must suppose that there are some bonds between silica and the gold oxide, which depend on potential, and which are stronger as the potential is higher.

If there is a bond formed as a bridge between the two surfaces responsible for the sticking phenomenon, we might postulate that a superficial gold atom may react with the silica surface in a similar manner to its reaction with water

$$\text{Au} + \text{SiOH} = \text{Au—O—Si—} + \text{H}^+ + e^-$$

in comparison with

$$\text{Au} + \text{H}_2\text{O} = \text{AuOH} + \text{H}^+ + e^-$$

Here we write only the first electron of the process, without commitment as to the speed of following electron transfers. One may also postulate a weaker bond if a hydrogen-bond bridge is formed

$$\text{Au—O} \ldots \text{H} \ldots \text{O—Si}$$

We recognize that because of ion size the formation of gold silicate is not a favorable reaction and that this compound is not found in nature, but, as a surface reaction at independent sites, it is possible. A similar friction-potential study is in progress of the silica/platinum friction. The results are similar to those reported here for silica/gold friction.

Conclusions

The polaromicrotribometric technique, though used by only a few researchers, has been well established by the authors cited. We have attempted to improve the technique for use in this study (*i*) so that the rubbing contact always moves over a fresh surface, not deformed by previous passes and (*ii*) by using a contact sufficiently small with respect to the sample surface, to avoid serious shielding or surface disruption effects perturbing the simultaneous electrochemical characteristics correlated with the friction phenomena.

It appears that the coefficient of friction on the gold surface depends on the nature of the sliding contact. Silica-gold friction increases at the beginning of formation of the gold oxide, while gold-gold friction decreases.

In the first case, the friction-potential curves exhibit a greater reversibility than the intensity potential curves, in contrast with the gold-gold friction curves which follow the same variations as the current-potential curves.

At oxidizing potentials, an increase of the static coefficient of silica-gold friction is found. The revers-

[3] Because of the considerable microscopic roughness remaining, we were unable to obtain values of quantity of charge per unit area comparable to the values of Brummer and Makrides (400 μC/cm^2 for oxygen coverage to θ = 1 at 1.45V) (25). Anodic and cathodic charge densities, and the double-layer charging time all exceeded reported values for the flat gold surface by at least a factor of 2, and were not well reproducible between successive polishings of the sample.

ibility of friction curves show that at constant oxygen coverage the static friction only depends upon the applied potential. Other friction curves obtained under galvanostatic control or by the method of the potential jump confirm these results.

We suggest the formation of chemical bonds between silica and the gold oxide surface which depend on the potential.

The Passive Film on Iron: An Application of Auger Electron Spectroscopy

R. W. Revie,*[1] B. G. Baker, and J. O'M. Bockris*

School of Physical Sciences, The Flinders University of South Australia, Bedford Park, South Australia 5042

ABSTRACT

A method has been devised whereby the Auger spectra of films formed under electrochemical conditions can be examined without damage to the film in the transfer from the electrochemical situation. The conditions do not remove water molecules from the film at room temperatures. Application of the method to the passive film on iron shows that this film differs radically in its Auger spectra from that of an air-formed oxide film, or of the passive film after it has been heated to 150°. The change in spectrum from that of the air-formed oxide is associated with the presence of water molecules in the structure of the passive oxide. Examination of the relative intensities of the Auger spectra suggests one water molecule per two iron atoms. The change at 150° results from the removal of this water molecule. The results are consistent with a passive film which is a hydrated ferric oxide with a gel-like structure.

Much work has been done to elucidate the composition and structure of passive films (1). Electron diffraction results have led to the view that the chemical composition of the passive film on iron is γ-Fe_2O_3 (2), but because of the effect of vacuum environments to dehydrate passive films and the additional possible degrading effect of the electron beam, there is a possibility that such studies examined a decomposed passive film and not the passive film as it exists *in situ*.

The development of ellipsometry (3-10) has enabled the knowledge of passive film structure to be increased considerably. It is now known, for example, that the passive film on iron is thick (tens of Å) (2, 11-13), and its refractive index and absorption coefficient have been computed (13, 14). The lattice-like nature of the film before the maximum of the i-V plot (13, 15), the critical thickness at the point of passivation (8, 9, 13, 15), the variation of the film thickness with potential (11, 13), and some aspects of the mechanism of film growth (16) have been established in the past 4-5 years by ellipsometric and transient ellipsometric work.

Although a number of the mechanistic aspects are now becoming established, the description of the passive oxide layer in terms of atomic structure is not clear. Ellipsometry gives the refractive index and absorption coefficient on the surface; however, the interpretation of this information depends on the relation at the surface between polarizability and struc-

Key words: passivity, iron, Auger, spectroscopy, oxidation.

ture, which is insufficiently defined at present. A structural description of the passive layer is needed. Spectroscopic methods give information on surface energy states. Mössbauer spectroscopy has been applied to these films (17-19) and has detected chemical shifts which should be interpretable in terms of the structure of the film. Indeed, such interpretations have been made, but they retain some speculative character in the absence of reliable quantum mechanical calculations connecting such shifts to structure (18, 19).

Another method is Auger electron spectroscopy (20-26). Hubbard *et al.* (27, 28) have used Auger electron spectroscopy to monitor the elemental composition of a platinum surface after exposure to H_2O. These authors found that a layer of water, as shown by the oxygen Auger transition, remains on Pt(100) and Pt(111) surfaces in vacuum after room temperature exposure to water vapor or liquid water. Staehle *et al.* have used Auger electron spectroscopy to study the passive film on stainless steel (29) and on iron (30). The stainless steel studies showed that, with respect to the substrate, the passive film is enriched in Cr and depleted in Fe, Mo, Ni, and Si. The Auger electron spectra on iron passivated in a boric acid-sodium borate buffer, *p*H 8.4, were interpreted in support of previous work (31-34) which suggested that the passive film consists of two distinct structures: an inner Fe_3O_4 layer in contact with the metal and an outer γ-Fe_2O_3 layer.

This paper describes apparatus of a new design which enables Auger electron spectroscopy to be used in the examination of layers formed electrochemically with no intermediate atmospheric exposure. A novel feature of the spectroscope is the use of an analyzer (35, 36) that can be readily constructed in the laboratory using stainless steel mesh and nickel support rods and rings. This equipment has been used to apply Auger electron spectroscopy to the study of passive films formed in solution and unexposed thereafter to the atmosphere. Some initial results obtained using this approach are presented in this paper.

Experimental

Some requirements for the application of electron spectroscopy to the study of electrode processes in solution are that the initial specimen surface be atomically clean; the adsorption of carbon and other misleading contaminants be avoided, *i.e.*, the specimen should not be exposed to the atmosphere between the electrochemical experiment and spectroscopic analysis; the physically, but not the chemically, adsorbed water layer be desorbed during evacuation; and the passivated specimen not be in the spectroscope during bake-out.

It can be shown that during the evacuation, the physisorbed—but not the chemisorbed—water is lost, and therefore, the passive film is not likely to be decomposed. Using the Arrhenius equation

$$\text{rate of desorption} = Ae^{-E/RT} \text{ molecules/site-sec}$$

where A is the pre-exponential factor (10^{12} molecules/site-sec), E is the activation energy of desorption, and T is the temperature. Since $E < 15$ kcal/mole for physically adsorbed H_2O (37), the rate of desorption is >9.3 molecules/site-sec; *i.e.*, the time for 1 monolayer to desorb is <0.1 sec. Thus, the physically adsorbed water is desorbed during evacuation at room temperature. The activation energy for desorption of chemisorbed water from metal oxide surfaces is $\gtrsim$ 20,000 cal/mole and is not expected to desorb during room temperature evacuation in short times of the order of minutes (38-42). To preserve chemisorbed films formed electrochemically for longer times under high vacuum conditions, the specimen should be frozen, *e.g.*, using liquid nitrogen.

The electron beam intensity must be sufficiently small so that degradation of the film by thermal and electron stimulated desorption does not occur. The increase in temperature caused by an electron beam impinging on a bulk metal specimen is negligible. Additional possible effects on an oxide film 50Å thick are also negligible, as may be shown by the temperature drop across the film, calculated, following de Graaf and Oosterkamp (43), from the equation

$$\Delta T = \frac{Wa}{\kappa}$$

where W is the power input per unit area, W/cm^2, a is the electron beam radius, cm, and κ is the thermal conductivity of the sample, W/cm°K. For the electron beam current used in these experiments, $2\mu A$, the voltage, 2 kV, and the area 0.02 cm^2, $W = 0.20$ W/cm^2. Also, the beam radius a is $\sim$0.08 cm and a typical value of the thermal conductivity, κ, for metal oxides (44) is $\sim$0.2 W/cm°K. Then, ΔT is calculated to be $\sim$0.08°K.

The rate of electron induced desorption is given by (45)

$$-dN/dt = nQN$$

where n is the flux of electrons, electrons/cm^2 sec, Q is the total cross section for electron induced desorption, cm^2, and N is the total coverage of the adsorbed species/cm^2. The rate of desorption is determined mainly by Q, which is not known for H_2O adsorbed on Fe. Q for H_2O on W is $\sim 10^{-21}$ cm^2 and for O_2 on W varies from 10^{-19} to 10^{-21} cm^2 (45). It is assumed, therefore, that Q for H_2O on Fe $\lesssim 10^{-19}$ cm^2. Using the values $n = 0.62 \times 10^{15}$ electrons/sec cm^2 (corresponding to the electron current density of 1×10^{-4} A/cm^2) and $N = 0.5 \times 10^{16}$ molecules/cm^2 (monolayer coverage of adsorbed H_2O), $-dN/dt \lesssim 0.3 \times 10^{12}$ molecules/sec, or 6×10^{-5} monolayer H_2O/sec; thus, the time to desorb a monolayer of chemisorbed H_2O is greater than 5 hr.

Figure 1 shows the apparatus used in the present studies. The high vacuum equipment is separated from the electrochemical cell by a straight-through valve, and a magnetically operated windlass enables the specimen to be transferred directly between the evacuated electrochemical cell and the electron spectroscope.

Figure 2 shows a block diagram of the vacuum system. The system is glass with metal Granville-Phillips valves that can be baked to 450°C. All glass blowing on the UHV side of the system was done using an argon-hydrogen mixture to prevent oxidation of metal parts and to avoid particulate contamination resulting from thermal decomposition of glass (46). When the argon-hydrogen mixture was not used, the sample was contaminated with boron.

In pumping the system from atmospheric pressure, a rotary pump and liquid nitrogen trap were used. During bake-out at 350°C, the system was pumped by a three-stage oil diffusion pump with a liquid nitrogen trap. After bake-out, the system was valved off and the ion pump used. Bake-out was carried out in two stages: a preliminary 1 hr bake-out, after which the iron filaments, the electron gun filament, the ion gauge, and the mass analyzer filaments were degassed, and a final 5 hr bake-out, after which degassing was again carried out. Pressures obtained in the Auger tube were $\sim 10^{-9}$ Torr or less.

The gas handling line, pumped by a two-stage oil diffusion pump with an associated cold trap, allows admission of gases into the UHV system via a break-seal. Gas bottles are connected using screw-on connectors.

The specimens were films of iron ($\sim$1000Å thick) evaporated *in vacuo* from 99.998% iron wire (Koch-Light Laboratories) filaments 0.5 mm diameter. The filaments were degassed at 3A for 30 hr in a vacuum $\sim 10^{-8}$ Torr. Preparation of the electrodes was carried out by evaporation at 4.1A for 30 min on a 99.998%

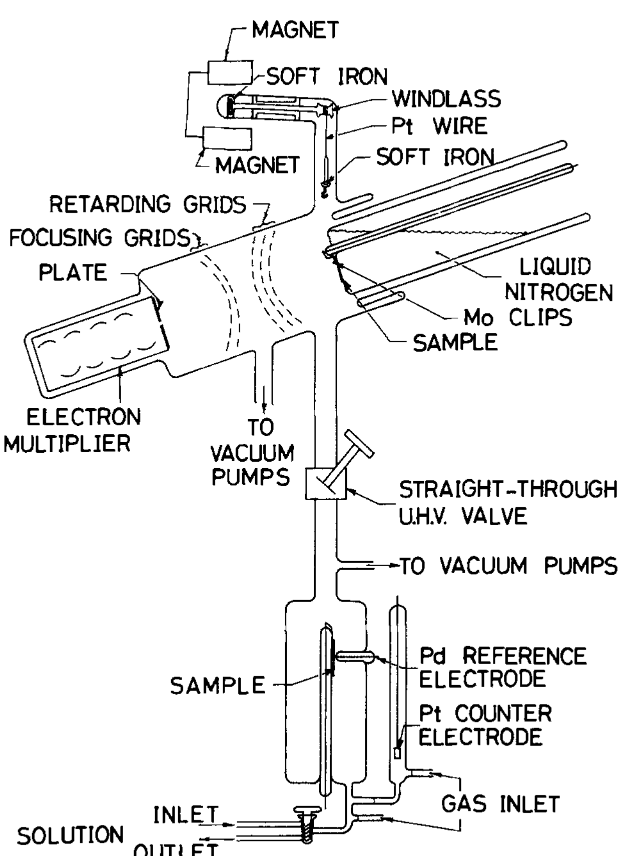

Fig. 1. Apparatus for combined electrochemical studies and Auger electron spectroscopy.

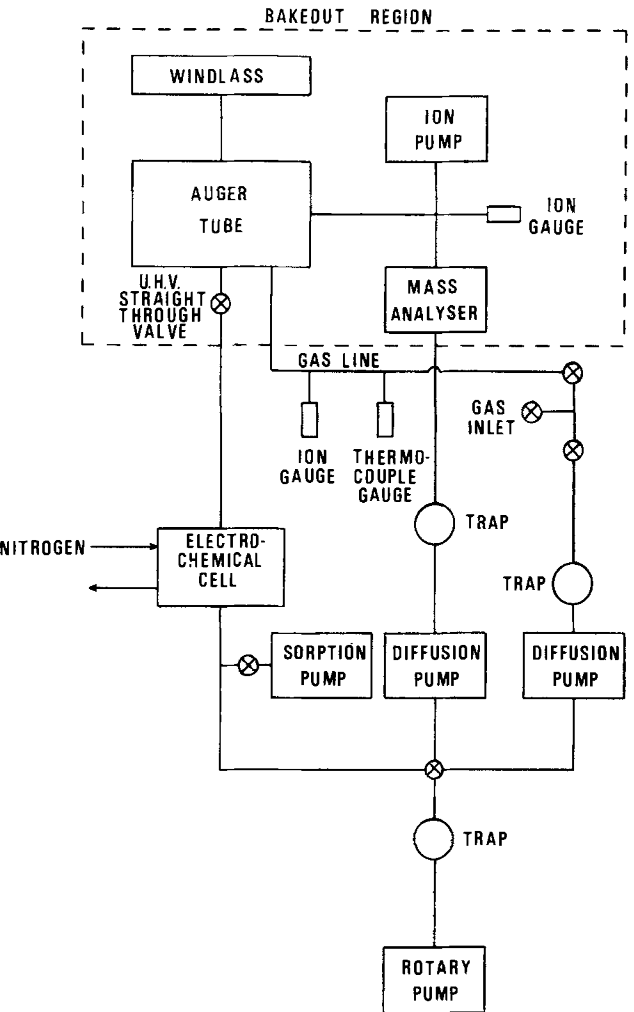

Fig. 2. Block diagram of vacuum system

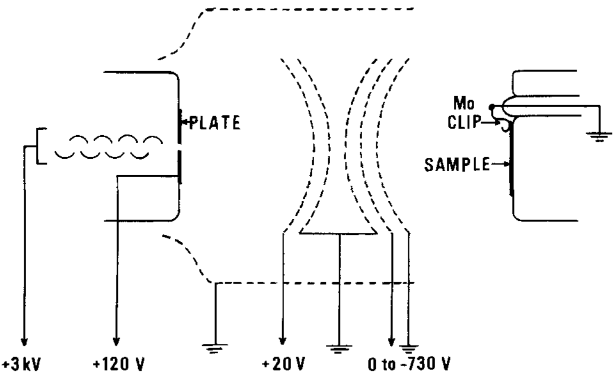

Fig. 3. Electrical circuit for analyzer of Auger electron spectroscope.

iron sheet substrate 1 mm thick, maintained at 0°C by an ice water mixture. This temperature was chosen to reduce the diffusion of impurities from the substrate into the evaporated film. The evaporation temperature was not lowered further because a rough surface would then develop (47).

The electron gun was a commercial television gun modified with a thoriated iridium filament (48, 49) to permit repeated atmospheric exposures. The iridium filament in the electron gun was coated with thoria by cataphoresis in a bath containing 5g of 200 mesh thoria and 0.075g of thorium nitrate to 100 ml of ethyl alcohol (48). The gun, after being prepared in this manner, is operated at 2 kV, and the electron beam impinging on the target has a current density of about 1.0×10^{-4} A/cm^2.

Electron energy analyzers currently used for Auger spectroscopy fall into two main categories (20): cylindrical mirror and retarding field. A cylindrical mirror analyzer (50) employs a pair of co-axial cylinders to focus electrons of a narrow energy band on an electron multiplier. The main disadvantage of the cylindrical mirror analyzer is the critical dependence of the resolution on the size and axial alignment of the incident electron beam on the specimen. The finely focused beam results in a high current density and may damage the surface being investigated.

In the present experiments, a retarding field analyzer was used because the sensitivity and resolution of this type of analyzer are relatively insensitive to the size of the emitting area. It is, therefore, possible to use defocused beams with low current density and still retain a large signal. This practice minimizes desorption and damage at the target surface. The analyzer used 100 mesh, 0.001 in. stainless steel wire retarding and focusing grids, and was based on the principle of Staib's design (35, 36).

Figure 3 shows the circuit used in the analyzer. The specimen, the electron gun, and grid (1) are grounded, so that the primary electrons move in a field-free region. Grid (2), the retarding grid, is swept at 1 V/sec from −20 to −730V. Grids (3) and (4) are grounded, and grid (5), the focusing grid, has a potential of +20V. This grid focuses the retarded electrons on the electron multiplier, which amplifies the current of collected electrons. To improve the focusing further, the plate has a potential of +120V. The wall, which consumes the more energetic electrons that are not retarded, is grounded. To establish the optimum voltage values at which the signal/noise ratio was a maximum, these voltages were varied over large ranges and Auger spectra determined were compared. The multiplier designed for operation at −3000V, has 14 copper-beryllium dynodes and internally mounted resistors.

To obtain high noise rejection, the electronic detection scheme uses modulation and phase-sensitive

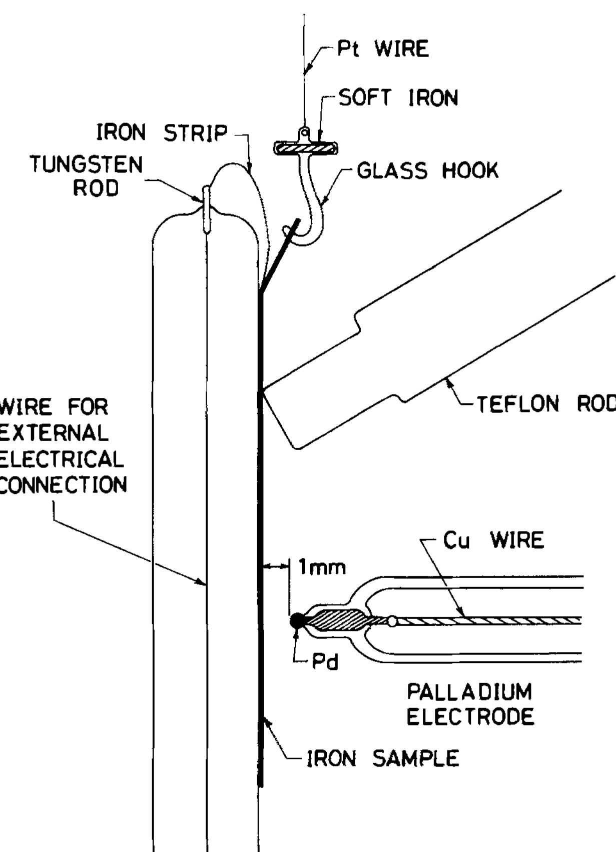

Fig. 4. Iron specimen in electrochemical cell showing palladium electrode (1 mm from specimen surface) and Teflon rod holding specimen on glass support.

detection techniques to modulate the analyzing energy and detect synchronously the current of collected electrons. The retarding grid is given a small amplitude modulating voltage, and the detector is tuned to the same frequency. The modulation voltage used was 3V rms for the low energy spectra and 8V rms for the high energy spectra. These voltages, at a frequency of 183 Hz, were found to give the optimum signal/noise ratio.

The electrochemical cell, located directly beneath the Auger tube, uses a palladium reference electrode (51-53), (Fig. 4), and a platinum auxiliary electrode. The main advantage of the palladium electrode is that it may be inserted directly into the electrolyte, *i.e.*, no Luggin capillary is needed.

The solution used is 425 ml 0.1*N* KOH + 2500 ml 0.1*M* H_3BO_3, diluted to 5000 ml, pH 8.1, which was kept in a storage bottle and transferred to the electrochemical cell as needed via a gas lift pump. The passivation experiments are carried out at +0.300V *vs.* SHE, a potential in the passive region (14). After a passivation experiment has been carried out, the electrolyte is drained from the cell and rinsed three times with de-aerated distilled water. To remove excess water from the specimen surface, the cell is subjected to a preliminary evacuation, first with a rotary pump and then with a zeolite sorption pump. When a pressure of $\sim 10^{-4}$ Torr is reached, the valve between the Auger tube and the electrochemical cell is opened. The windlass is operated so that the hook contacts the specimen and transfers it into the Auger tube. After completing the transfer, the straight-through valve is closed, and the triode ion pump, acting on the Auger tube, regains a pressure $\sim 10^{-8}$ Torr within about 20 min.

The stage on which the specimen is mounted is cooled to −196°C with liquid nitrogen to prevent decomposition of hydrated films under high vacuum conditions. Using magnets the specimen is positioned on the stage and is then held in position with molybdenum clips, which also provide the electrical connection to the specimen. The Auger spectra are then measured and recorded on an X-Y recorder.

Results

Figure 5 shows the low energy spectra obtained (a) from an evaporated film of iron, (b) from a film exposed to O_2 at 10^{-3} Torr for 1 min, (c) from a film passivated for 10 min in a boric acid-potassium hydroxide buffer solution, pH = 8.1, at +0.300V *vs.* SHE, and (d) from a film passivated as in (c) and subsequently heated to 150°C. The iron film as evaporated, Fig. 5 (a), shows a low energy Auger $M_{2,3}M_{4,5}M_{4,5}$[2] transition at 46 eV, whereas the oxidized film, Fig. 5(b), shows two transitions at 42 and 50 eV. The passivated specimen, Fig. 5(c), shows one transition at 50 eV; and the passivated specimen after heating to 150°C, Fig. 5(d), shows two transitions at 42 and 50 eV.

Figure 6 shows high energy spectra for films under the same conditions as Fig. 5. The oxygen *KLL* transition occurs at 508 eV, and the iron $L_3M_{2,3}M_{2,3}$, $L_3M_{2,3}M_{4,5}$, and $L_3M_{4,5}M_{4,5}$ transitions occur at 590, 645, and 695 eV, respectively. The passive film spectrum, Fig. 6(c), shows some carbon contamination as evidenced by the carbon Auger transition at 270 eV.

Discussion

As shown in Fig. 5, oxidation of iron causes a splitting of the 46 eV iron Auger transition into two transitions at 42 and 50 eV. This doublet, characteristic of oxidized iron, has been observed previously by Suleman and Pattinson (54), Ueda and Shimizu (55), and Leygraf and Ekelund (56). The latter authors have suggested that the amplitudes of the 42 and 50 eV peaks are related to the surface concentrations of Fe^{2+} and Fe^{3+}, respectively. It would appear, then, from Fig. 5, that the passive film contains Fe^{3+} and no Fe^{2+}, at least in the first 10A. This conclusion agrees with the results from ellipsometric and electrochemical ex-

[2] *K, L, M*, . . . refer to the principal electronic quantum levels. The subscript 1 refers to s electrons; 2, 3 to p electrons; and 4, 5 to d electrons. It is customary to label Auger transitions in terms of the energy level first emptied, *e.g.*, $M_{2,3}$; the level from which an electron drops to fill it, *e.g.*, $M_{4,5}$; and the level from which the Auger electron is ejected, *e.g.*, $M_{4,5}$, in that order; *e.g.*, a $M_{2,3}M_{4,5}M_{4,5}$ transition.

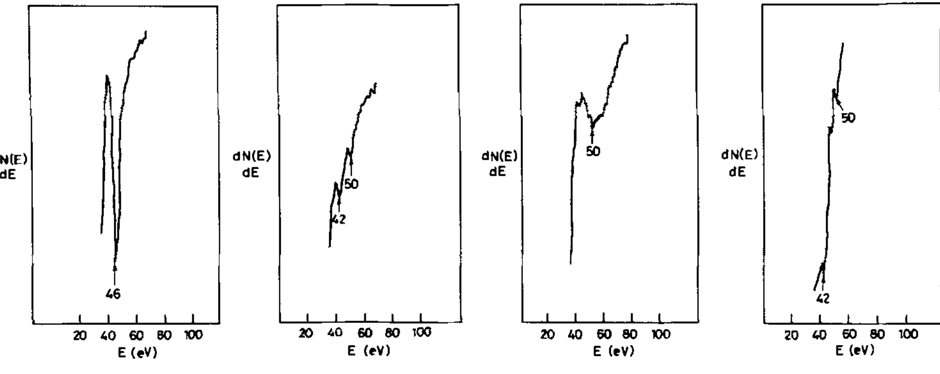

Fig. 5. Low energy Auger spectra of evaporated films of iron: (a) clean film as evaporated; (b) after exposure to O_2 at 10^{-3} Torr for 1 min; (c) passivated in boric acid-potassium hydroxide buffer solution, pH = 8.1, at 0.300V *vs.* SHE for 10 min; (d) passivated as in (c) and subsequently heated to 150°C.

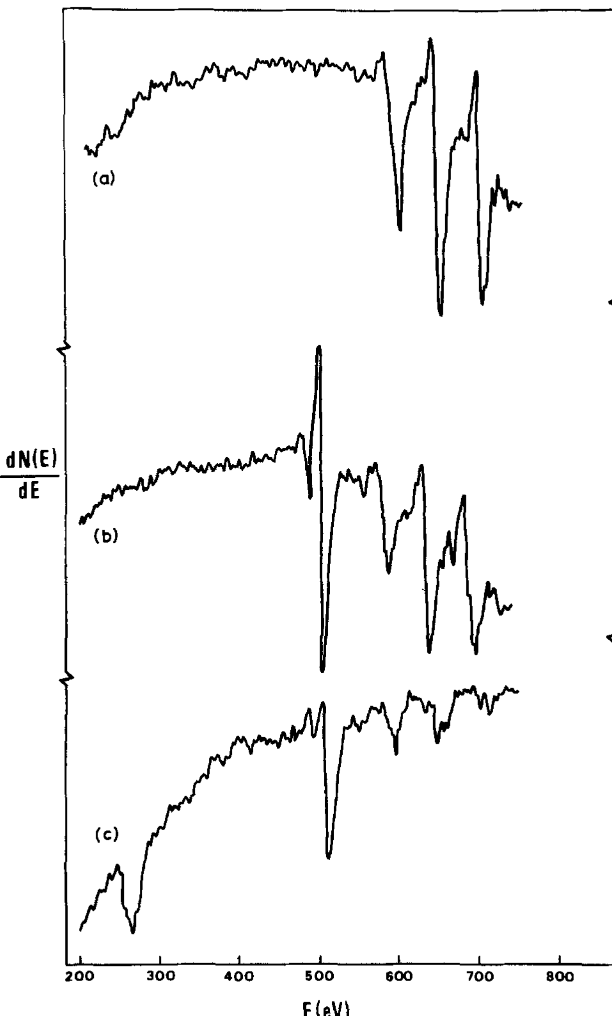

Fig. 6. High energy Auger spectra of evaporated films of iron: (a) clean film as evaporated; (b) after exposure to O_2 at 10^{-3} Torr for 1 min; (c) passivated in boric acid-potassium hydroxide buffer solution, pH = 8.1, at 0.300V vs. SHE for 10 min.

periments carried out by Bockris *et al.* (13, 15) and Sato *et al.* (57).

The carbon contamination shown in the spectrum for the passive film, Fig. 6(c), presumably occurred during exposure to the electrolyte and subsequent evacuation. Such carbon contamination did not occur on the iron during evaporation, Fig. 5(a), since the evaporation was carried out *in vacuo*. The possible effects of carbon contamination on shifts of the 46 eV iron transition were investigated by exposing evaporated films of iron to: (*i*) CO at 10^{-3} Torr in the Auger tube and (*ii*) the evacuated electrochemical cell at 10^{-4} Torr. In both experiments, the surface contamination resulted in no measurable change in the 46 eV transition energy.

The quantitative aspects of Auger electron spectroscopy, *i.e.*, the relation between Auger peak heights and concentration of surface species, have been reviewed in the literature (24, 26, 58-61). The production of Auger electrons depends on the ionization cross section of the inner level which is involved in the Auger process, and on the number and energy of the ionizing electrons. The Auger electron current, I_A, is given by (24, 59, 62)

$$I_A = I_p\sigma(E_p)\Omega N\theta_A \left\{1 - \exp\left(-\frac{d}{\lambda}\right)\right\}^{-1} (1-\omega)r$$

where I_p = primary current on the crystal; $\sigma(E_p)$ = ionization cross section of the inner level at a primary energy E_p; Ω = geometric factor that involves angles of incidence and emission, and the efficiency of collection and transmission of the analyzer, including roughness factor; N = total number of atoms per unit area; θ_A = ratio of species A to the total number of atoms; d = interlayer spacing; λ = mean free path of Auger electron; ω = probability that an x-ray is emitted following ionization of the inner level; $(1-\omega)$ = probability that an Auger process follows the ionization of the inner level; and r = backscattering factor, due to the ionizing effect of secondary electrons.

The data presented by Vrakking and Meyer (63) show that the ionization cross section of the oxygen K level (containing 2 electrons) is 1.0×10^{-19} cm^2 at a primary beam energy of 2 kV. A small extrapolation of their data for the ionization cross sections of $L_{2,3}$ shells (63) gives that for the iron $L_{2,3}$ level [8 electrons including Coster-Kronig transitions (64, 65)[3]] as 1.8×10^{-19} cm^2. Hence, a stoichiometric oxide of FeO would have the sum of the amplitudes of the KLL oxygen Auger transitions, equal to 1.0/1.8 = 0.56 times the sum of the amplitudes of the iron $L_{2,3}$ transitions. Similarly, Fe_2O_3 would have an oxygen transition with the sum of the peak heights $3 \times 1.0/2 \times 1.8 = 0.83$ times the sum of the amplitudes of iron $L_{2,3}$ transitions. Measurement of Auger spectra of the type presented in Fig. (6)b shows that, in fact, the ratio for iron oxidized at room temperature, *i.e.*, Fe_2O_3 (66), is 0.83 ± 0.04 (3 measurements) in excellent agreement with that predicted, 0.83.

These measurements are made with the assumption that the peak-peak height in the derivative spectrum is proportional to the Auger current, I_A, or to the area of the peak; *i.e.*, varying peak widths and modulation voltage distortion are neglected. The accuracy of the measurements may be inferred from the agreement of the theory with the results for the oxidized iron "standard."

Of a total of 6 measurements on the passive film as in Fig. 6(c), the average ratio of the amplitude of the oxygen transitions to the sum of the amplitudes of the iron $L_{2,3}$ transitions was 0.99 with a standard deviation of 0.11; these spectra, therefore, imply an oxygen/iron ratio in the passive film of $r = 0.99 \times 1.8/1.0 = 1.8$, with a standard deviation of 0.2. The oxygen/iron ratio of 1.8 ± 0.2 is higher than that of any known iron oxide.

A layer model may be used to estimate the amount of hydrated water in the passive film. The Auger electron current emerging at the sample surface from molecular layers below the surface is attenuated by the factor $e^{-nd/\lambda}$, where d is the interlayer spacing, λ is the mean-free path of the Auger electrons, and n is the number of layers through which the Auger electrons must pass to reach the surface. The relative contribution of oxygen and of iron to the total Auger current, I_A, may be calculated for a variety of assumed structures. For example, assuming that the passive film on iron consists of layers, each having the composition $Fe_2O_3 \cdot H_2O$, the ratio of the Auger currents due to oxygen and iron is

$$\frac{I_{\text{oxygen}}}{I_{\text{iron}}} = \frac{\frac{2}{3}\left(1 + e^{-d/\lambda} + e^{-2d/\lambda} + e^{-3d/\lambda} + \ldots\right)}{1.8\left(\frac{1}{3}\right)\left(1 + e^{-d/\lambda} + e^{-2d/\lambda} + e^{-3d/\lambda} + \ldots\right)} = 1.1$$

equal, within experimental error, to the ratio of the observed amplitudes of the Auger transitions. It would appear, therefore, that $Fe_2O_3 \cdot H_2O$ is a satisfactory representation of the passive film structure.

This conclusion is in essential agreement with the results of O'Grady and Bockris (18), who found that

[3] A Coster-Kronig transition involves 4 rather than 3 electrons. If the initial ionization occurs in the K shell, an electron from a higher energy level, such as the L shell, will drop to fill the vacant level. A third electron may then drop to fill this vacancy in the L shell, and the Auger electron is then emitted.

their Mössbauer spectroscopic results were consistent with a passive film on iron of a polymeric film of hydrated iron oxide. The Mössbauer parameters match values for the isomer shift and quadrupole splitting of iron-containing polymers, which have a structure containing di-oxy and di-hydroxy bridging bonds between the iron atoms.

Correspondingly, Kudo *et al.* (67) estimated from passivation experiments using tritiated solutions that the total content of water in the passive film on iron in the potential region of +0.04-+1.04V *vs.* SHE was equivalent to $Fe_2O_3 \cdot 1.99\ H_2O$, except in the region of +0.24V *vs.* SHE, where inconsistent results were obtained. These authors (67) mention that the isotope effect was not considered in estimating the amount of bound water and that this would lower the reported values. Calculations based on the reactions

$$2H_2O + M \rightarrow MOH + H_3O^+ + e \quad [1]$$

and

$$2HOT + M \rightarrow MOT + TH_2O^+ + e \quad [2]$$

have been carried out to determine the ratio of the equilibrium constants, K_H and K_T, for reactions [1] and [2], respectively. The ratio K_H/K_T was found to be ~0.01, implying that equilibrium concentration of tritium in the passive film is much greater than that of hydrogen and that tritium measurements may greatly overestimate the amount of bound water in the passive film. Uncertainties in the relative rate constants of hydrogen and tritium (68, 69) place further doubt on the quantitative estimation of the H_2O content of the passive film using tritiated water. These considerations may explain the fact that the results of Kudo *et al.* (67) indicate a higher amount of H_2O than is consistent with the Auger results.

Heating the passivated specimen to 150°C caused the apearance [Fig. 5(d)] of the two Auger peaks, 42 and 50 eV, characteristic of oxidized iron. It may be assumed, then, that such heating causes decomposition of the passive film to iron oxide, perhaps γ-Fe_2O_3, the formation of which O'Grady (19) observed on drying passive iron.

Okamoto *et al.* (70-72) have studied the importance of hydrated water to the corrosion protection of the passive film. These studies indicated, in agreement with the work of O'Grady and Bockris (17-19), that the passive film is a hydrated oxide film having a gel-like structure. Between metal ions in the film, three different types of bridge exist: -M-H_2O-M-, -M-HO-M-, and -M-O-M-. Dehydration of the passive film, *e.g.*, by heating *in vacuo*, destroys bonds of the first two types, changing the passive film to a (less protective) perfect oxide.

Seo, Lumsden, and Staehle also studied the structure of the passive layer on iron (30). Their experimental technique involved a transfer of the sample through the atmosphere. Thereafter, they removed sections of the passive layer by sputtering it progressively and determining the spectrum as a function of depth. The Auger spectra registered by Seo, Lumsden, and Staehle were characteristic of the spectrum shown here [Fig. 5(b)] for air-formed oxide and showed the two peaks characteristic of this body rather than the single peak characteristic of the passive film [Fig. 5(c)]. Seo, Lumsden, and Staehle, however, interpreted their two peaks to be indicative of a duplex structure consisting of γ-Fe_2O_3 and Fe_3O_4. Their interpretation must now be regarded as doubtful.

Conclusions

1. Auger electron spectroscopy may be used for electrochemical studies. It may be important that the films formed electrochemically be stabilized in vacuum by reduction to a low temperature.

2. The high energy Auger electron spectra are consistent with 1 water molecule per 2 iron molecules.

3. Heating the passive film in vacuum causes dehydration and the formation of an oxide.

4. The results are consistent with the model of the structure of the passive layer on iron arising from Mössbauer studies (17-19).

Acknowledgments

The authors express their appreciation to Mr. B. A. Sexton and Miss E. A. Chalmers for experimental assistance. The project was supported by the Australian Research Grants Committee and the Electricity Research Board, to whom the authors are most grateful.

Surface Brightening during High Rate Nickel Dissolution in Nitrate Electrolytes

Madhav Datta and Dieter Landolt*

Materials Department, Swiss Federal Institute of Technology, Lausanne, Switzerland

ABSTRACT

Conditions leading to surface brightening during ECM in passivating electrolytes were investigated by studying high rate transpassive nickel dissolution in acidified nitrate electrolytes under controlled hydrodynamic conditions. The experimental apparatus consisted of a flow channel cell in which constant electrolyte linear velocities between 100 and 1760 cm/sec could be reached. Dissolution experiments were performed galvanostatically at current densities ranging from 0.5 to 30 A/cm^2. Over-all current voltage behavior, current efficiency for metal dissolution and surface appearance were evaluated as a function of applied current density, flow rate, and electrolyte composition. Results indicate that the onset of surface brightening is mass transfer controlled and coincides with the formation of a salt precipitation layer at the anode.

The process of electrochemical machining (ECM) involves anodic dissolution of a workpiece at very high current density under conditions of high electrolyte flow rate and small electrode spacing. Dimensional accuracy and surface finish of the workpiece produced by ECM are intimately related to the nature of the electrolyte and to operating conditions. Passivating electrolytes such as sodium chlorate and sodium nitrate are well suited for electrochemical machining of iron and nickel base alloys because they give good dimensional control and good surface finish (1, 2). The relation between passivation behavior and dimensional control in ECM has been discussed by several authors (3-7) but little is known at present about the processes which determine surface finish in passivating ECM electrolytes.

In ECM practice, surface finish can frequently be improved by increasing current density. Cole and Hopenfeld explained this fact by an electrostatic model (8). According to this, a high potential gradient in the solution leads to preferred metal dissolution at peak sites of a rough surface and thus to leveling. The electrostatic model predicts that surface finish in ECM is independent of dissolution mechanism and of flow rate. This is in contradiction to the findings of Landolt, Muller, and Tobias who studied high rate dissolution of copper in different electrolytes (9, 10) and found that etched surfaces resulted from active dissolution while bright and pitted surfaces resulted from transpassive dissolution. The transition from one dissolution mode to the other depended not only on current den-

* Electrochemical Society Active Member.

Key words: electrochemical machining, transpassive dissolution, nickel, surface brightening.

sity but also on flow rate, indicating that the onset of surface brightening was controlled by mass transfer.

Surface brightening under conventional electropolishing conditions is also controlled by mass transfer (11-15). Hoar and Rothwell (14), who studied copper dissolution in phosphoric acid in a flowing electrolyte, found that the onset of surface brightening coincided with the formation of a salt layer at the anode giving rise to well-defined limiting current plateaus. Their findings have recently been confirmed by Kojima and Tobias (16).

Very little is known about the mechanism of surface brightening of metals dissolving in the transpassive dissolution mode under ECM conditions. Mao and Chin (17) studying the dissolution of steel in sodium chlorate recently suggested that salt precipitation is responsible for the onset of surface brightening. However, they found no effect of flow rate on surface finish, therefore rendering the proposed mechanism questionable. The quantitative study of mass transport processes during transpassive dissolution under ECM conditions is rendered difficult not only by the fast metal dissolution rate which may affect cell geometry and therefore hydrodynamic conditions but also by the possibility of anodic oxygen evolution which can disturb the anodic diffusion layer. To minimize these effects, dissolution experiments have to be carried out at high electrolyte flow velocities using an electrolyte which gives high current efficiencies for metal dissolution. In addition a well-defined cell geometry has to be maintained during the experiments.

The aim of the present paper was to investigate the influence of mass transfer on surface brightening of metals dissolving at high rate at potentials more noble than those corresponding to anodic oxygen evolution. For that purpose, the anodic dissolution of nickel in concentrated acidified nitrate electrolytes was studied in a flow cell allowing for well-defined mass transfer conditions. The present investigation is part of our continuing effort to develop models for predicting the ECM behavior of passivating metals and alloys.

Experimental

All experiments were performed in a flow cell apparatus described in detail elsewhere (18). The electrochemical cell consisted of a rectangular flow channel 0.317 cm wide and 0.053 cm high. A hydrodynamic entrance length of 7 cm upstream from the electrode served for establishing fully developed velocity profiles at the electrodes. Anode and cathode made of Nickel 200 were positioned flush with the channel wall. The electrodes were 1.02 cm long and of the same width as the flow channel. The anode area was thus 0.32 cm^2. The electrolyte was forced through the cell by means of a single stroke piston pump at constant linear velocities ranging from 100 to 1760 cm/sec. Each experiment corresponded to one stroke of the piston after which the pump cylinder was refilled with electrolyte drawn from a 2 liter reservoir. Electrolyte temperature was maintained at 25°C by means of a thermostat. A saturated calomel electrode was used for potential measurements. It was connected to the flow channel by means of a back side capillary positioned upstream from the anode.

Before each experiment, the nickel anode was mechanically polished on 600 carborundum paper, degreased with benzene, and cleaned with soap solution and distilled water. It was subjected to cathodic pre-electrolysis in 1M NaOH solution at 20 mA/cm^2 for 30 sec followed by rinsing with distilled water. The anode was then immediately positioned in the cell. Electrolyte solutions were prepared from analytical grade chemicals and distilled water. Most data reported in this study were obtained in 5M $NaNO_3$ + 1M HNO_3. A strongly acidified solution was employed to reduce local pH changes at the anode due to oxygen evolution.

Except for preliminary experiments which were carried out potentiostatically, all experiments were performed at constant current using a potentiostat (Amel Type 555) in the galvanostatic mode. Current densities applied ranged up to 30 A/cm^2. One series of experiments was aimed at the study of polarization behavior and surface finish. A constant charge was passed corresponding to a maximum depth of dissolution of 10μ. After the experiments, the surface of the anode was observed visually and/or with the aid of a microscope. The surfaces of a few samples were also investigated by means of a scanning electron microscope. Current during the experiments was monitored on a conventional storage oscilloscope (Tektronix Type 5103N), while the anode potential was measured by means of a digital oscilloscope (Nicolet Type 109). In this instrument, the data are first stored in digital form in a memory. They can be displayed in analog or digital form on an oscilloscope screen or recorded on a pen recorder. In a second series of experiments, aimed at the study of the current efficiency for metal dissolution, the amount of charge passed corresponded to a maximum depth of dissolution of 20μ. In these experiments, the current was monitored with the digital oscilloscope while the anode potential was measured with an electrometer (Keithly Type 615). The anode was carefully weighed before and after each experiment, using an analytical balance having a precision of 0.01 mg (Sartorius Model 2474). Before weighing, the samples were cleaned with acetone and dried with air.

Results

The anodic polarization behavior of nickel in 5M $NaNO_3$ + 1M HNO_3 solution is illustrated by the potentiodynamic data of Fig. 1 which were obtained at different electrolyte flow velocities by applying a potential scan rate of 500 mV/sec. The curves exhibit a typical active-passive behavior. The passivation potential is 0.250V *vs.* SCE, the critical current density for passivation is approximately 350 mA/cm^2. This cur-

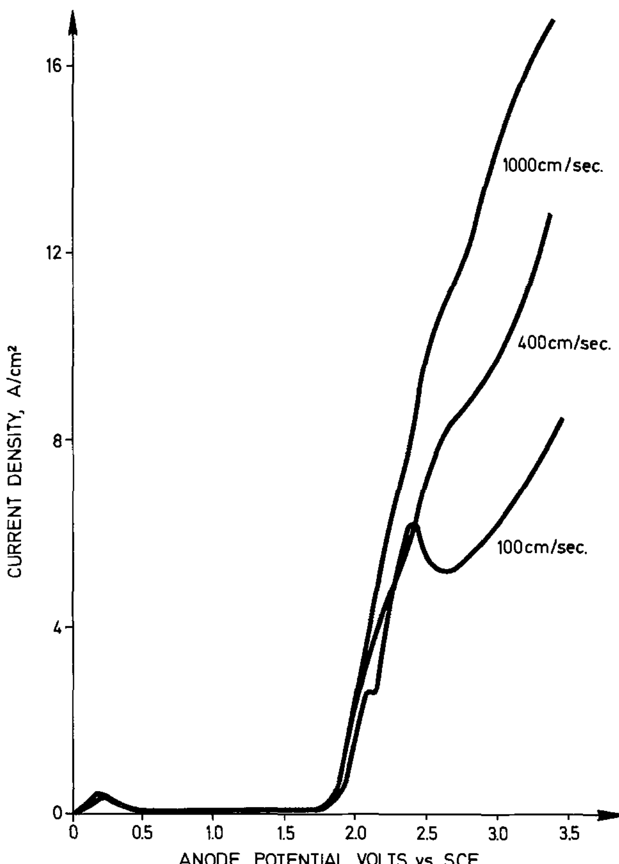

Fig. 1. Anodic potential sweep measurements on nickel in 5M $NaNO_3$ + 1M HNO_3 at different electrolyte flow velocities. Scan rate 500 mV/sec.

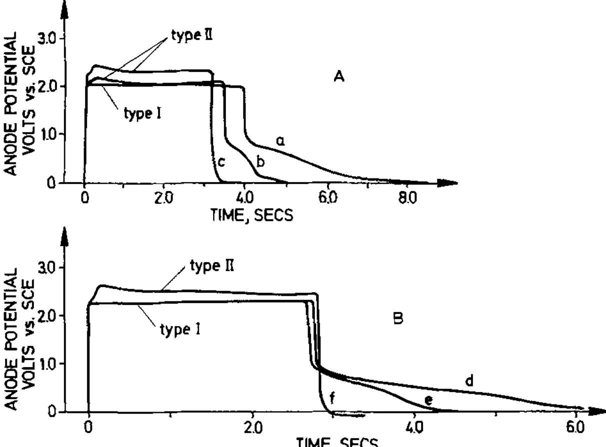

Fig. 2. Anode potential transients in 5M $NaNO_3$ + 1M HNO_3. A: Constant flow rate of 400 cm/sec, current density 7.0 A/cm² (a), 7.5 A/cm² (b), 9.0 A/cm² (c). B: Constant current density of 10 A/cm², flow rate 1760 cm/sec (d), 1000 cm/sec (e), 400 cm/sec (f).

rent density is smaller than those applied in subsequent dissolution experiments (0.5-30 A/cm²) which therefore refer exclusively to the transpassive potential region. The latter corresponds to potentials higher than 1.7V *vs.* SCE. Flow rate has no appreciable effect on the active-passive behavior of nickel in sodium nitrate but it affects the polarization curves in the transpassive potential region (Fig. 1). Because generally large *IR* drops between capillary and anode are present in high rate dissolution studies, current rather than potential was controlled in all subsequent experiments.

The application of a constant current pulse to the anode resulted in two distinct types of potential transients (Fig. 2). At low current densities, steady state was reached almost immediately and the potential stayed constant throughout the run (type I transient). At high current densities, on the other hand, the potential jumped to an initial value, then increased to a maximum before decaying to a more or less steady value (type II transients). Which type of potential transient occurred during an experiment depended not only on the magnitude of the applied current density but also on flow rate. For example, at a flow rate of 100 cm/sec, a type II transient was observed at a current density as low as 4.2 A/cm² while at a flow rate of 1760 cm/sec, a type I transient was observed up to current densities of 20 A/cm².

Upon current switch-off, a potential arrest at approximately 0.8V usually occurred before the original open-circuit potential of 0V *vs.* SCE was reached. The phenomenon is well known for passive electrodes undergoing self-activation, and a thorough discussion of the literature has been given by Vetter (19). The data of Fig. 2 indicate that upon current switch-off self-activation of the anode occurred faster the higher the applied current density and the lower the flow rate. The behavior has been discussed elsewhere (20).

In Fig. 3 initial values and peak values of measured potential transients are plotted as a function of current density for different flow rates. Steady-state potentials of type I transients and initial potentials of type II transients fall on the same straight line. Their value is governed mostly by the *IR* drop between reference electrode capillary and anode. Peak potential values of type II transients lie distinctly higher. The difference between peak potentials and initial potentials is due to the presence of an anodic layer which increases the effective resistance at the anode surface. This layer is different from the usual passive film present on nickel at lower current density because the passive film does not give rise to type II transients.

Two distinctly different types of surface texture resulted from anodic dissolution. One type of surface, typical for a type I transient, appeared grayish-black to the eye and gave the impression of a surface covered by a thick porous film. This impression was not consistent with reality, however. First of all, no deposits could be removed from the black-appearing surface by mechanical or chemical means. X-ray diffraction analysis of a black surface showed only the diffraction pattern characteristic for metallic nickel, but neither oxides nor salts could be identified on the surface. While this does not exclude the presence of a thin passive film [the thickness of passive films on nickel

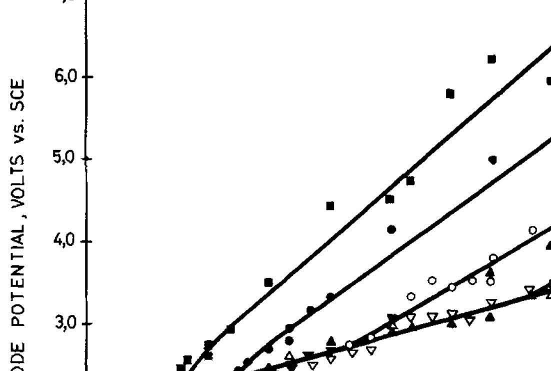

Fig. 3. Over-all anode potential as a function of current density for nickel dissolution in 5M $NaNO_3$ + 1M HNO_3 derived from galvanostatic measurements.

is typically of the order of angströms (19)], it definitely excludes the presence of films of greater thickness. It is therefore concluded that the black surface appearance was due to a finely disperse surface texture of the metal resulting from the anodic dissolution process. A scanning electron micrograph of a typical black-appearing surface is given in Fig. 4.

The second type of surface typical for type II transients appeared bright to the naked eye. Its average surface roughness determined with a mechanical surface tester (Talysurf Model 10) was Ra $= 0.1\mu$ compared to Ra $= 0.75\mu$ for a black-appearing surface. A scanning electron micrograph of a bright surface is shown in Fig. 5. On a microscale, the surface appears almost perfectly flat, except for the presence of some grain boundary attack and of hemispherical pits. Several of the pits exhibit tails pointing in flow direction. It is interesting to note that no effect of flow direction was visible on black-appearing surfaces. On the other hand, bright surfaces not only exhibited pits tailing in flow direction but also so called flow streaks (1). A similar behavior has previously been observed during high rate anodic copper dissolution (10), where the surface texture of etched surfaces showed no discernible influence of flow direction, while bright and pitted surfaces frequently exhibited well pronounced flow streaks. It appears from this that the occurrence of flow streaks in ECM is intimately related to pitting phenomena occurring under brightening conditions.

Surface brightening always started at the down stream end of the anode. Upon increasing current density, it gradually extended over the entire anode surface. The transition in appearance from a black to a bright surface was quite sharp as illustrated by Fig. 6. Because of the clear difference in surface appearance, the fraction of the anode surface that appeared bright could be estimated for each current density and flow rate. The results of such estimations are given in Fig. 7 where percentage brightening has been plotted as a function of current density for different flow rates. The data demonstrate that current density as well as flow rate have a strong influence on surface finish resulting from transpassive dissolution. The onset of surface brightening (Fig. 7) coincides with a change in the slope of the over-all current voltage curve (Fig. 3).

The current efficiency for metal dissolution was determined at various flow rates over a current density

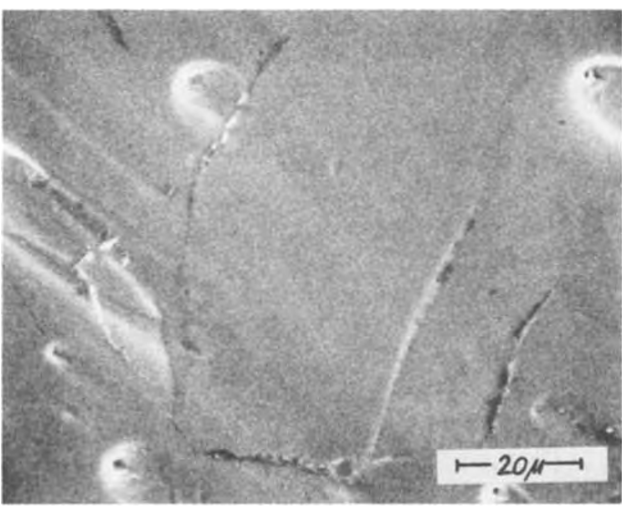

Fig. 5. Scanning electron micrograph of bright surface resulting from dissolution in 5M $NaNO_3$ + 1M HNO_3 at a current density of 25.0 A/cm^2 and a flow rate of 400 cm/sec. Flow direction from upper left to lower right.

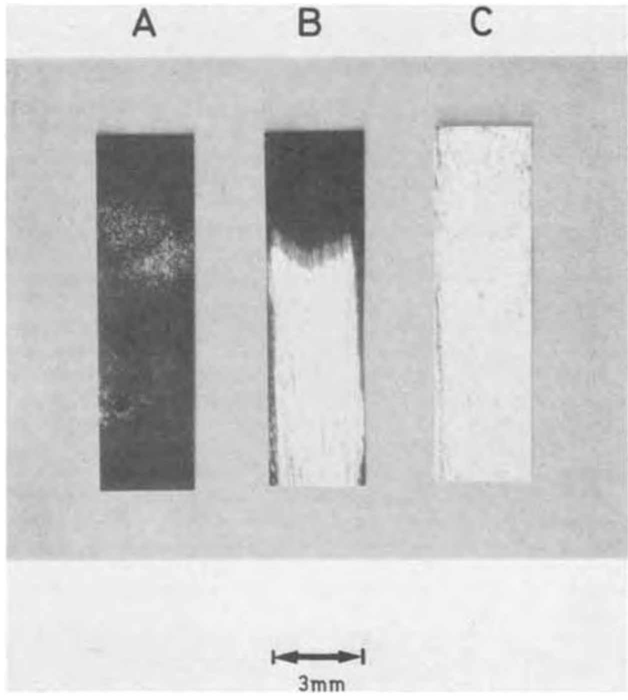

Fig. 6. Photomicrograph of typical nickel surfaces after anodic dissolution showing (A) black surface, (B) partially bright surface, (C) bright surface. Flow direction from top to bottom.

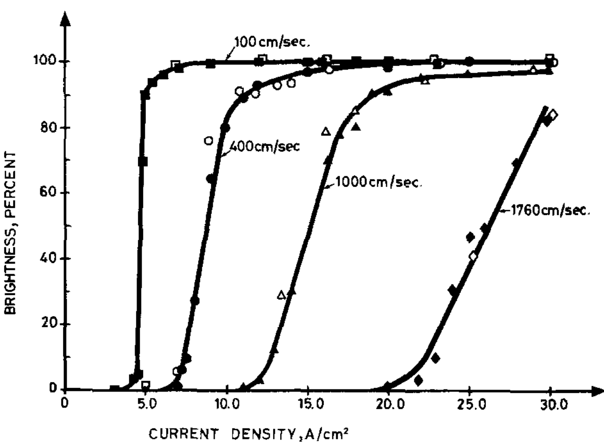

Fig. 7. Percentage of surface area of nickel anode appearing bright as a function of applied current density. Electrolyte 5M $NaNO_3$ + 1M HNO_3. Charge passed: 30 coulombs/cm^2 (■ ● ▲ ◆), 60 coulombs/cm^2 (□ ○ △ ◇).

range from 0.5 A/cm^2 to 30 A/cm^2 by weight loss measurements. Current efficiency values calculated on the basis of Ni^{2+} formation are given as a function of current density in Fig. 8. The dissolution efficiency increases with increasing current density until a maximum of 90-95% is reached. The initial part of the current efficiency *vs.* current density curve is independent of flow conditions, but the current density at which maximum efficiency is attained increases with flow rate. After the maximum, the apparent current efficiency for dissolution decreases slightly and levels off at a constant value of 85-90%.

LaBoda *et al.* (21) recently investigated nickel dissolution in sodium chlorate under ECM conditions. The current efficiency for metal dissolution was measured while simultaneously the anodically evolved gas was collected and analyzed. The authors found that all the current passed could be accounted for by anodic oxygen evolution and divalent nickel ion formation. In the present flow channel system, anodically evolved gas could not be analyzed. However, a few preliminary experiments were performed in a cell without external convection in which the anode gas could be collected. These experiments performed at current densities up to 5 A/cm^2 indicated that divalent nickel ion formation and anodic oxygen evolution are the predominant reactions during transpassive nickel dissolution in sodium nitrate. It is therefore concluded that in the ascending part of the current efficiency *vs.* current density curves shown in Fig. 8 nickel dissolved to the bivalent state, the remainder of the current serving for oxygen evolution. Whether the same holds true for current densities above the current efficiency maximum cannot be decided from presently available data.

Discussion

Mass transport in the present flow channel cell can be described by Eq. [1] and [2] which apply to laminar (22) and turbulent (23) flow conditions, respectively[1]

$$Nu = 1.85\ (ReScD_h/L)^{1/3} \quad [1]$$

$$Nu = 0.022\ Re^{7/8}Sc^{1/4} \quad [2]$$

The Nusselt number Nu is defined by: $i_l D_h / n\mathbf{F}\Delta C D$. The Schmidt number Sc is defined by $Sc = \nu/D$ and the Reynolds number Re is defined by $Re = uD_h/\nu$. In the expressions i_l is the limiting current density, D_h is the hydraulic diameter of the flow channel, L is the length of the electrode, ΔC is the concentration difference between anode and bulk, D is the diffusion coefficient of the transport limiting species, ν is the kinematic viscosity, u is the linear flow velocity of the electrolyte.

[1] Several different dimensionless relations describing heat and mass transport under turbulent flow conditions have been proposed in the literature (23-26). Most of them show Nu to be proportional to $Re^{7/8}$ and $Sc^{1/3}$ or $Sc^{1/4}$ but differ somewhat in the proportionality constant. Equation [2] is used here because previous limiting current measurements in the present apparatus (18) showed it to be in good agreement with experimental data.

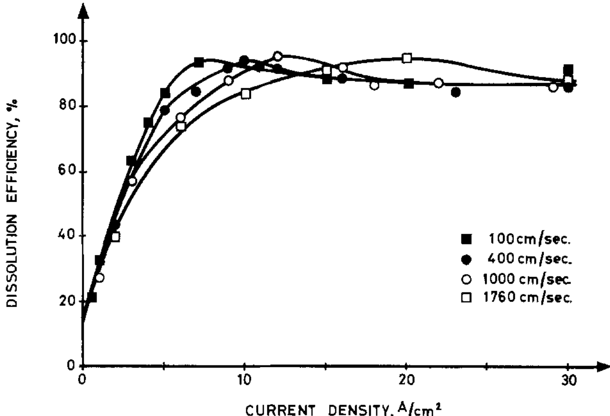

Fig. 8. Current efficiency for nickel dissolution (based on Ni^{2+} formation) in 5M $NaNO_3$ + 1M HNO_3 as a function of applied current density at different flow rates.

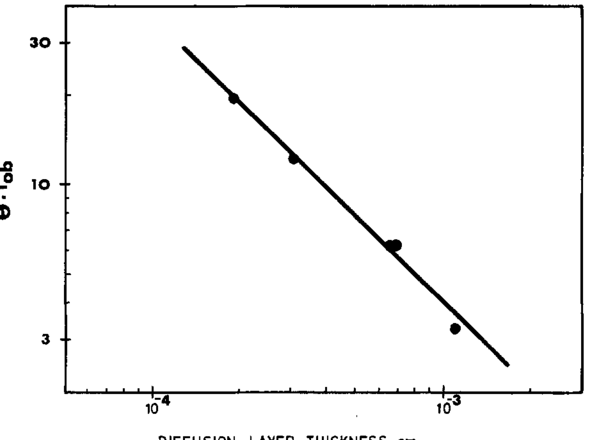

Fig. 9. Onset of brightening during nickel dissolution in 5M $NaNO_3$ + 1M HNO_3 as a function of diffusion layer thickness.

For a mass transport controlled surface brightening process Eq. [3] holds

$$\theta i_{ob} = n\mathbf{F}D\frac{\Delta C}{\delta} \quad [3]$$

Here i_{ob} is the current density at the onset of brightening and θ is the current efficiency for metal dissolution at the onset of brightening. The diffusion layer thickness δ depends on flow conditions and is given by the relation

$$\delta = \frac{D_h}{Nu} \quad [4]$$

In Fig. 9 the product θi_{ob} derived from the data of Fig. 7 and 8 is plotted on a logarithmic scale as a function of δ evaluated from Eq. [1], [2], and [4]. The numerical value of i_{ob} corresponds to 5% of the surface being bright. The kinematic viscosity ν, needed for the calculation of Re and Sc, was determined experimentally (Table I). The numerical value of D needed for the calculation of Sc was assumed to be 9×10^{-6} cm^2/sec. Since in Eq. [1] and [2] Sc appears with the exponent 1/3 and 1/4, respectively, the absolute value of D has relatively little influence on the data of Fig. 9. In particular it does not affect the slope of the straight line shown. The slope determined by regression analysis is -1.0 ± 0.06. This is the same value as predicted by Eq. [3]. Therefore, the onset of surface brightening on nickel dissolving in sodium nitrate solution is mass transport controlled.[2]

According to Hoar (14) and others, electropolishing of metals proceeds in the presence of a precipitated salt layer on the anode surface and is mass transport controlled. The data given above suggest that a similar mechanism applies to high rate nickel dissolution under ECM conditions. To further test this hypothesis, dissolution experiments were performed in acidified nickel nitrate solution of different concentration. The composition of the three solutions employed is given

[2] In the above calculation of δ, it was assumed that anodic gas evolution has a negligible influence on mass transport at the onset of surface brightening. This assumption appears justifiable in view of the high electrolyte flow velocities employed and in view of the high value of metal dissolution current efficiency at the onset of brightening (Fig. 8).

Table I. Physical properties of nitrate electrolytes (25°C)

Electrolyte	Density, g/cm^3	Viscosity, c.p.	Kinematic viscosity, cm^2/sec
5M $NaNO_3$ + 1M HNO_3	1.288	1.868	1.45×10^{-2}
0.5M $Ni(NO_3)_2$ + 1M HNO_3	1.103	1.181	1.07×10^{-2}
2.5M $Ni(NO_3)_2$ + 1M HNO_3	1.387	2.758	1.99×10^{-2}
3.5M $Ni(NO_3)_2$ + 1M HNO_3	1.517	2.169	3.40×10^{-2}

in Table I together with their physical properties which were determined experimentally. In principle, it would have been desirable to use binary nickel nitrate solutions because mass transport data can more easily be interpreted in binary solutions than in mixed electrolytes. However, preliminary experiments had shown that unless the nickel nitrate solutions employed were strongly acid, metal and hydroxide deposition processes at the cathode rendered results unreproducible. In the presence of 1M HNO_3, the cathode remained clean of deposits during the experiments. The solubility of nickel nitrate in 1M HNO_3 was determined experimentally to be 4.14 moles/liter. The concentration of the nickel nitrate solutions of Table I corresponds therefore to 12, 60, and 85% of saturation, respectively.

Figure 10 shows current voltage curves measured at a constant flow rate of 1000 cm/sec in nickel nitrate solutions of different concentration. The data were derived from galvanostatic transients in the same way as described above for sodium nitrate solution. As before, the change in slope in the current voltage curve corresponds to a change from type I to type II transients. The change occurred at a lower current density the higher the nickel nitrate concentration in the bulk and it coincided with the onset of surface brightening. The fraction of anode surface appearing bright is plotted as a function of current density for different nickel nitrate concentration in Fig. 11.

The data clearly show that at a given flow velocity, surface brightening sets in at lower current density the higher the bulk concentration of nickel nitrate. This is qualitatively consistent with a salt film precipitation mechanism of surface brightening. According to this model, the anode surface concentration of nickel nitrate at the onset of brightening corresponds to the saturation concentration and the driving force for diffusion (Eq. [3]) is the concentration difference of nickel ion between anode surface and bulk

$$\Delta C = C_s - C_b \quad [5]$$

The saturation concentration C_s is the same for the three nickel nitrate solutions employed. Therefore, by increasing the bulk concentration C_b, the current density for the onset of brightening becomes smaller.

A more quantitative test of the proposed model is provided by the data of Table II. Here, numerical values of ΔC and C_s for the experiments performed in nickel nitrate solution were evaluated by an iteration procedure. Different values of D were assumed and corresponding C_s values were calculated using the equations given above. The best numerical value for D was presumed to be the one giving identical C_s values for all different nickel nitrate solutions employed. The best value for D was thus found to be 9×10^{-6} cm^2/sec. The ionic diffusion coefficient of Ni^{2+} at infinite dilution evaluated from mobility data (28) is 6×10^{-6}

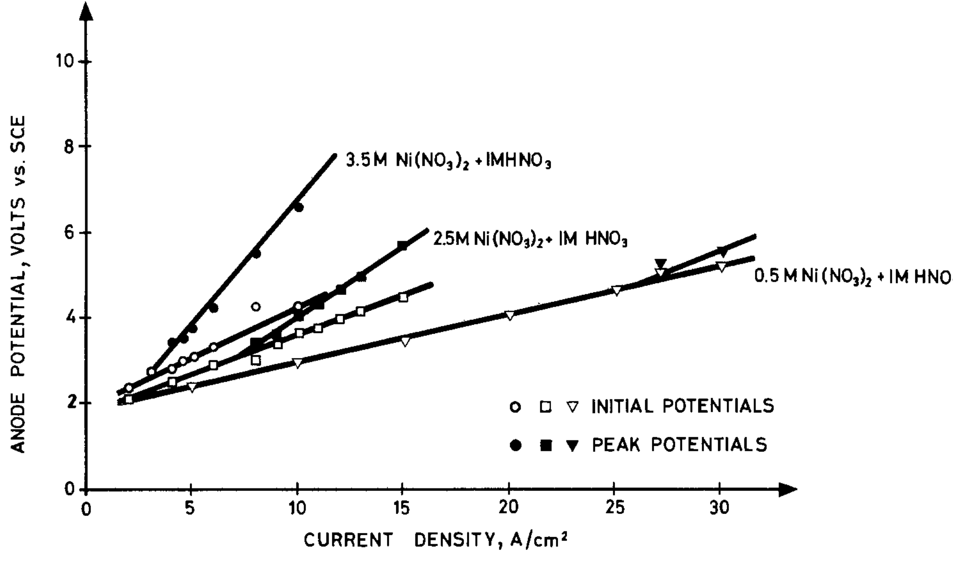

Fig. 10. Over-all anode potential as a function of current density for nickel dissolution in nickel nitrate solutions at a flow rate of 1000 cm/sec.

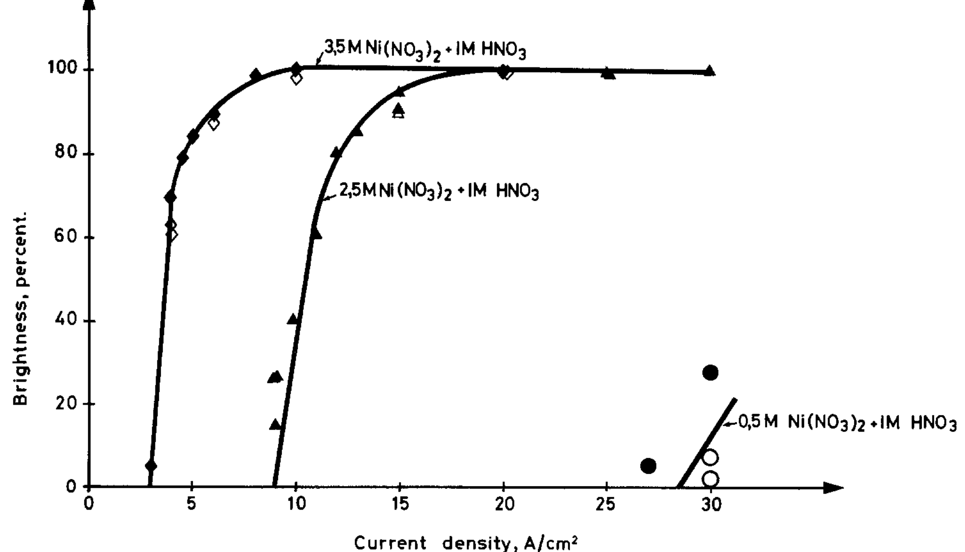

Fig. 11. Percentage of anode surface area appearing bright as a function of applied current density in nickel nitrate electrolytes of different concentration. Flow rate: 1000 cm/sec. Charge passed: 30 coulombs/cm^2 (◆ ▲ ●), 60 coulombs/cm^2 (◇ △ ○).

Table II. Estimation of surface concentration corresponding to onset of brightening in nickel nitrate solutions of different concentrations

Solution	Flow rate (cm/sec)	Reynolds number	Schmidt number	δ (μ)	i_{ob} (A/cm²)	θ (%)	ΔC (moles/liter)	C_s (moles/liter)
3.5M $Ni(NO_3)_2$ + 1M HNO_3	100	269	3378	11.4	1.0	93	0.6	4.1
	1000	2690		5.4	3.0	100	0.9	4.4
2.5M $Ni(NO_3)_2$ + 1M HNO_3	100	460	2209	11.0	2.5	89	1.4	3.9
	1000	4600		3.7	9.0	97	1.9	4.4
0.5M $Ni(NO_3)_2$ + 1M NHO_3	100	855	1189	11.0	9.0*	63	3.6	4.1
	1000	8550		2.5	29.0	88	3.7	4.2
							Average C_s =	4.2

δ, Diffusion layer thickness.
i_{ob}, Current density corresponding to onset of brightening.
θ, Dissolution current efficiency corresponding to the onset of brightening.
ΔC, Concentration difference of nickel ion between anode and bulk.
C_s, Nickel nitrate concentration at anode surface.
* This value corresponds to that of the stoichiometric experiments in which a charge of 60 coulombs rather than 30 coulombs was passed. Contrary to the behavior in other electrolytes employed, the value of i_{ob} in 0.5M $Ni(NO_3)_2$ + 1M HNO_3 varied somewhat with the amount of charge passed during the experiments (cf. Fig. 11).

cm²/sec. The diffusion coefficient employed here is an effective diffusion coefficient which includes the contribution of migration to mass transfer and, therefore, its value has to be higher than that of the ionic diffusion coefficient. The numerical value of D found above, therefore, is very reasonable. It also compares favorably with effective diffusion coefficients reported recently for high rate iron dissolution in chloride media (27). According to the data of Table II, the surface concentration calculated with the given value of D not only is the same for the three nickel nitrate solutions studied but it also lies close to the experimentally determined saturation concentration. This fact provides additional support for the proposed salt film precipitation model.

Summary and Conclusions

Transpassive high rate dissolution of nickel occurs in the presence of two different types of anodic films. At relatively low current densities, the anode is covered by a thin oxide film, the passive film, which inhibits metal dissolution thus causing oxygen evolution to be the main reaction. With increasing current density, the passive film becomes less protective and the relative amount of metal dissolution increases. Dissolved metal ions accumulate at the anode surface to an extent which depends on mass transfer conditions. At a given point, the saturation concentration at the surface is exceeded and salt precipitation can occur. A salt layer, the brightening layer, is formed which manifests itself by an increase in anode potential and leads to surface brightening. The data of the present study suggest that surface brightening during ECM with passivating electrolytes is governed by a similar mechanism as conventional electropolishing.

ABSTRACT

The cathode polarization behavior of copper, zinc, cadmium, and tin in complex baths containing sodium citrate/sodium tartrate additives was investigated. Copper exhibited considerable polarization in baths containing sodium citrate or sodium tartrate. The polarization behavior of zinc, cadmium, and tin was not significantly affected by these additives. Codeposition of zinc, cadmium, or tin with copper was not possible from baths containing no complexing agents. However, studies on the cathode polarization characteristics from baths containing 40 g/liter sodium citrate/sodium tartrate and actual deposition trials revealed that whereas Cu-Sn powder can be codeposited, it was not possible to codeposit Cu-Zn or Cu-Cd powders.

Powder metallurgical alloy products are generally produced by compacting and sintering mixtures of the individual metal powders. Such products are often inhomogeneous, especially when one of the metals is in small proportion, *e.g.*, 90% Cu-10% Sn. Hence there has been a consistent effort to produce alloy powders for the past few decades by several methods such as atomization, alloy disintegration, thermal decomposition, electrolytic deposition, etc. Of these, the electrolytic method is capable of giving homogeneous powders with the desired compacting and sintering characteristics. Surprisingly, codeposition from aqueous baths as a means of producing alloy powders has not received adequate attention. However, some studies have recently been reported on the preparation of Cu-Zn (1), Cu-Ni (2), Fe-Ni (3, 4), Fe-Co (5), and Co-Ni (6) powders by electrodeposition from suitable baths. In this context, cathode polarization studies are very helpful in predicting the possibility of codeposition of metals. The present work is concerned with studies on the cathode polarization characteristics of copper, zinc, cadmium, and tin in complex baths containing citrate/tartrate additives, enabling a prediction to be made of the possibility or otherwise of codeposition of zinc, cadmium, or tin with copper.

Experimental

Anodes.—Graphite plates.

Cathodes.—Plates of electrolytic copper, electrolytic zinc, electrolytic cadmium, and chemical purity tin. All cathodes were polished and degreased before use.

Chemicals.—A. R. Grade $CuSO_4 \cdot 5H_2O$, $ZnSO_4 \cdot 7H_2O$, $3CdSO_4 \cdot 8H_2O$, $SnCl_2 \cdot 2H_2O$, $CuCl_2 \cdot 2H_2O$, NH_4Cl, NaCl, and $Na_3C_6H_5O_7 \cdot 2H_2O$ (sodium citrate), and C.P. grade $Na_2C_4H_4O_6 \cdot 2H_2O$ (sodium tartrate).

The experimental setup for the measurement of cathode polarization, shown in Fig. 1, consisted of a cell having two graphite anodes (covered with anode bags of thick ordinary cloth) and a cathode of the required metal (copper, zinc, cadmium, or tin) dipped in the appropriate electrolyte (1.0*N* $CuSO_4 \cdot 5H_2O$ for copper, 1.0*N* $ZnSO_4 \cdot 7H_2O$ for zinc, 1.0*N* $3CdSO_4 \cdot 8H_2O$ for cadmium, and 1.0*N* $SnCl_2 \cdot H_2O$ for tin) contained in a tank made from methyl methacrylate sheet (trade name: Plexiglas or Lucite in U.S.A. and Perspex in U.K.). The metal electrode, whose cathode polarization was to be measured, was joined via a salt bridge against the standard and saturated calomel electrode. The calomel electrode was connected in series with a high-impedance micro-voltmeter and the cathode of the electrolytic cell via a key as shown in Fig. 1. The instantaneous emf developed was measured at current densities of 0, 1, 2, 4, 6, 8, 10, 12, 14, 16, and 18 ampere per square decimeter (asd).

Similar measurements were taken on all the above baths, but containing, respectively, 10, 20, and 40 g/liter sodium citrate. Experiments were also conducted in a similar way with sodium tartrate as an additive in place of sodium citrate.

The experimental setup used for the deposition of alloy powder was similar to the previous one, except that there was no provision for measurement of cathode polarization. Plates of copper and graphite (covered with thick ordinary cloth) were used as cathode and anode, respectively. The analysis of tin in the Cu-Sn alloy powder was done by the gravimetric method.

Results

Polarization behavior of copper.—The influence of concentration of sodium citrate and sodium tartrate on the cathode polarization of copper in 1.0*N* $CuSO_4 \cdot 5H_2O$ at 30°C is presented in Fig. 2 and 3, respectively. Copper exhibited considerable polarization

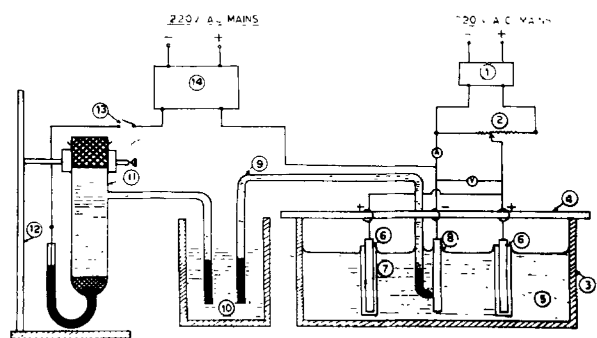

Fig. 1. Schematic diagram of experimental setup used for polarization measurements. 1, 12V battery eliminator; 2, rheostat; 3, Perspex tank; 4, silica rod; 5, electrolyte; 6, graphite anode; 7, anode bag; 8, metal cathode; 9, salt bridge; 10, saturated KCl solution; 11, saturated calomel electrode; 12, stand; 13, two way key; 14, high impedance micro-voltmeter.

Key words: cathode polarization, alloy powder, codeposition, sodium citrate, sodium tartrate, current density.

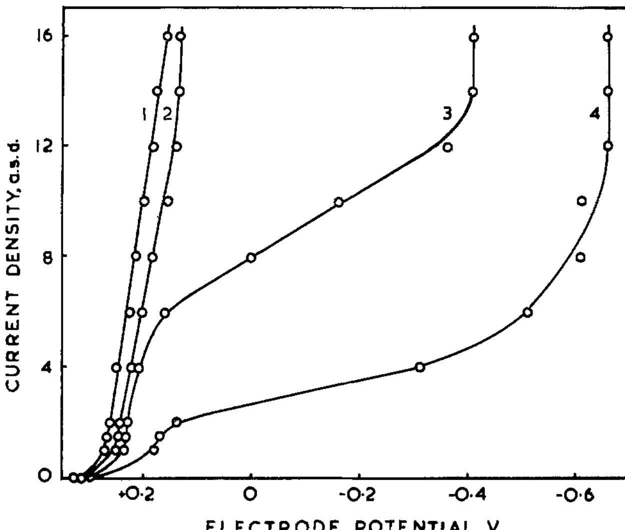

Fig. 2. Effect of concentration of sodium citrate on the cathode polarization of copper in 1.0*N* $CuSO_4 \cdot 5H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; curve 3, 20 g/liter; and curve 4, 40 g/liter.

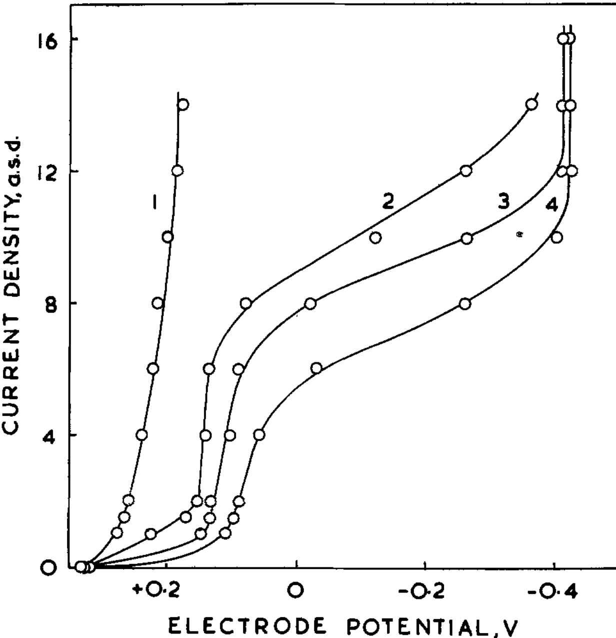

Fig. 3. Effect of concentration of sodium tartrate on the cathode polarization of copper in 1.0*N* $CuSO_4 \cdot 5H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; curve 3, 20 g/liter; and curve 4, 40 g/liter.

in baths containing citrate or tartrate. In all cases, there was a significant amount of polarization at lower curent densities. At lower current densities, plating of copper was observed, whereas at higher current densities copper powder was formed. The transition, plating→powder was characterized by a large and sudden increase in the polarization with only a slight increase in current density. Current densities beyond a certain value had no significant effect on polarization and thus the electrode potential remained constant after a critical value of current density in each case.

Another interesting observation was that the addition of sodium citrate to the bath led to a more pronounced polarization than the addition of a corresponding amount of sodium tartrate, particularly at 40 g/liter concentration. Further, the increase in polarization with increasing addition of the complexing salts was also noteworthy. With both citrate as well as tartrate, addition of over 40 g/liter of the reagent did not very much affect the polarization values. Thus greater additions than this amount were considered unnecessary.

Polarization behavior of cadmium.—The influence of concentration of sodium citrate and sodium tartrate on the cathode polarization of cadmium in 1.0*N* $3CdSO_4 \cdot 8H_2O$ solution at 30°C is presented in Fig. 4 and 5. As in the earlier case, lower current densities had a greater influence on the polarization behavior of cadmium than higher current densities. The critical current density for obtaining a fully nonadherent powdery deposit had been observed to be about 8 asd in all cases. Baths containing sodium citrate showed

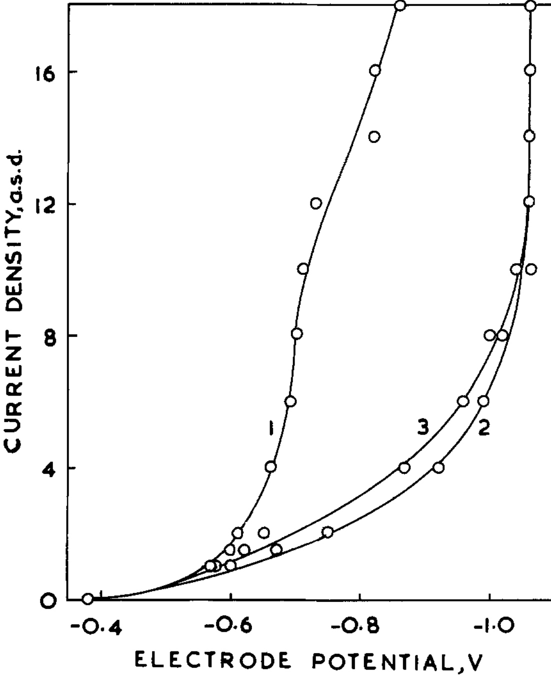

Fig. 4. Effect of concentration of sodium citrate on the cathode polarization of cadmium in 1.0*N* $3CdSO_4 \cdot 8H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; and curve 3, 40 g/liter.

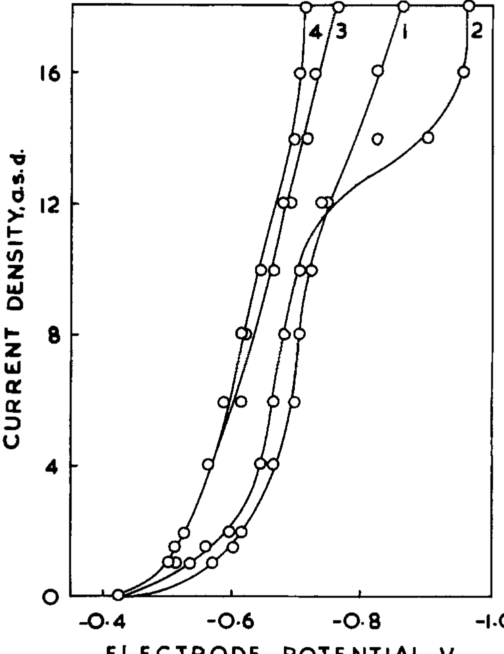

Fig. 5. Effect of concentration of sodium tartrate on the cathode polarization of cadmium in 1.0*N* $3CdSO_4 \cdot 8H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; curve 3, 20 g/liter; and curve 4, 40 g/liter.

considerable polarization in cadmium. Addition of sodium citrate beyond 10 g/liter does not seem to have any significant effect on the polarization of cadmium. In the case of sodium tartrate additions, some depolarization was observed up to about 12 asd. This was seen to persist even at higher current densities, when the amount of tartrate added was 20 g/liter or more. At low concentrations of tartrate (*e.g.*, 10 g/liter) considerable polarization was observed beyond 12 asd.

Polarization behavior of zinc.—The effect of concentration of sodium citrate and sodium tartrate on the cathode polarization of zinc in 1.0*N* $ZnSO_4 \cdot 7H_2O$ at 30° C is presented in Fig. 6 and 7, respectively. The cathode potential of zinc was not significantly changed by the nature or amount of complexing salt. Nonadherent powdery deposits had been observed beyond a current density of about 8 asd.

Polarization behavior of tin.—The influence of concentration of sodium citrate and sodium tartrate on the cathode potential of tin in 1.0*N* $SnCl_2 \cdot 2H_2O$ at 30°C is represented in Fig. 8 and 9, respectively. In this case also, there was not much change in the cathode polarization of tin with addition of complexing agents. Powder formation had been observed at about 8 asd in all cases.

Discussion

Comparative assessment of polarization behavior.—The addition of complex salts had resulted in considerable polarization in the relatively noble metal copper, whereas in the case of the baser metals (*i.e.*, those of zinc, cadmium, and tin) no significant polarization had been observed.

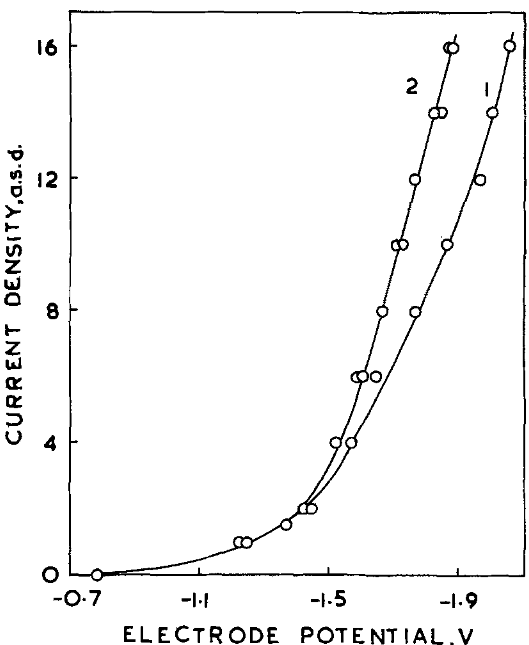

Fig. 6. Effect of concentration of sodium citrate on the cathode polarization of zinc in 1.0*N* $ZnSO_4 \cdot 7H_2O$ solution at 30°C. Curve 1, nil; and curve 2, for both 20 and 40 g/liter.

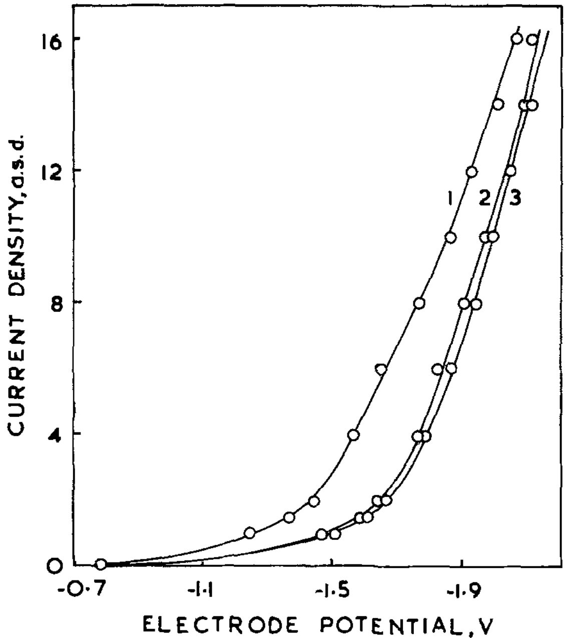

Fig. 7. Effect of concentration of sodium tartrate on the cathode polarization of zinc in 1.0*N* $ZnSO_4 \cdot 7H_2O$ solution at 30°C. Curve 1, nil; curve 2, 20 g/liter; and curve 3, 40 g/liter.

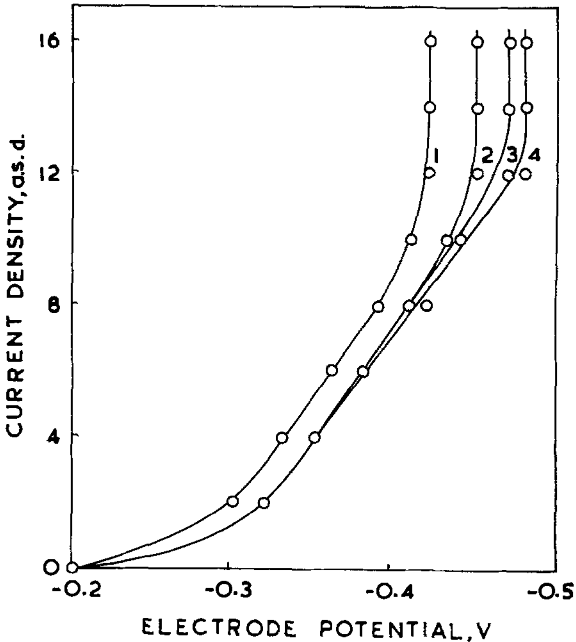

Fig. 8. Effect of concentration of sodium citrate on the cathode polarization of tin in 1.0*N* $SnCl_2 \cdot 2H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; curve 3, 20 g/liter; and curve 4, 40 g/liter.

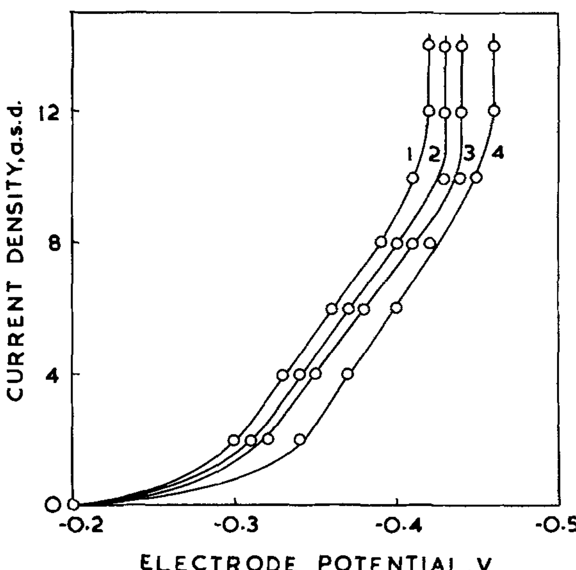

Fig. 9. Effect of concentration of sodium tartrate on the cathode polarization of tin in 1.0*N* $SnCl_2 \cdot 2H_2O$ solution at 30°C. Curve 1, nil; curve 2, 10 g/liter; curve 3, 20 g/liter; and curve 4, 40 g/liter.

Citrates and tartrates can form a variety of neutral, cationic, or anionic complexes, with the cations of common metals, depending on the concentration of the reagents, nature of the bath, its pH, and temperature, etc. (7, 8). Although it is difficult to obtain a quantitative idea of the exact nature of these complexes, a qualitative idea regarding the relative stabilities of complexes of interest in this study can be had from Table I. It can be seen that copper citrate is very much more stable than copper tartrate. This means that baths containing citrate additions will have smaller amounts of free copper ions than baths containing the tartrate additives. In other words, greater polarization is to be expected with copper baths containing citrate addition than with tartrate additions, a conclusion in good agreement with experimental observation.

Generally noble metal complexes are known to be more stable than base metal complexes (in the present case also, it is clear from Table I that copper citrate is more stable than the citrates of base metals cadmium and zinc). This leads to a tremendous decrease in the effective metal ion concentration in the case of the noble metal, whereas the ionic concentration of the base metal is not changed significantly. This is the reason why a more pronounced polarization was observed in the case of copper than in the case of cadmium, zinc, or tin.

Further, it may also be noted from Table I that the stability constants of the complexes of Cd and Zn are not substantially different from those of their sulfates. Hence, with the addition of sodium citrate/sodium tartrate no significant change should be expected in the polarization behavior of these base metals. Experimental observations discussed earlier are in conformity with expected behavior.

Possibility of codeposition of Zn, Cd, or Sn with Cu.—Figure 10 shows the effect of current density on the electrode potential of copper, tin, cadmium, and zinc in the normal solutions of their respective salts, as discussed earlier. It is clear from the above figure that the codeposition of zinc, cadmium, or tin with copper is not possible from baths containing no complexing agents as the curves are far removed from each other and there is no common current density or potential between copper and the others. Figure 11 shows the effect of current density on the electrode potential of copper, tin, cadmium, and zinc in their respective normal salt solutions, containing 40 g/liter sodium citrate at 30°C. The electrode potentials of copper, zinc, and cadmium are not close enough to permit codeposition of copper with either zinc or cadmium from the citrate bath at any current density. But the curve for tin crosses the curve for copper at a current density of 4.5 asd. Thus it may be possible to codeposit tin with copper from baths containing sodium citrate as the complexing agent. These theoretical predictions based on polarization measurements are in conformity with the actual deposition experiments from various baths, because it was possible to codeposit only tin with copper and not the others, as shown in Table II.

Figure 12 shows the effect of current density on the electrode potential of copper, tin, cadmium, and zinc in their respective normal salt solutions containing 40 g/liter sodium tartrate. Zinc and cadmium exhibited similar behavior as mentioned previously and their codeposition with copper was not possible. The curve for tin also does not cross the curve for copper, but they are fairly close to each other above the current density of 12 asd. Thus, from polarization studies, it appears that there is no possibility of codeposition of copper and tin. Experimental observations are in accordance with above prediction in the case of Cu-Zn and Cu-Cd. However, in the case of Cu-Sn, the powder deposit was found to contain some tin, possibly because of the following reasons:

1. The cathode polarization values of copper and tin at high current densities are quite close.
2. What one measures in practice is the value of individual cathode polarization which may be different from the actual cathode polarization on the alloy deposit.

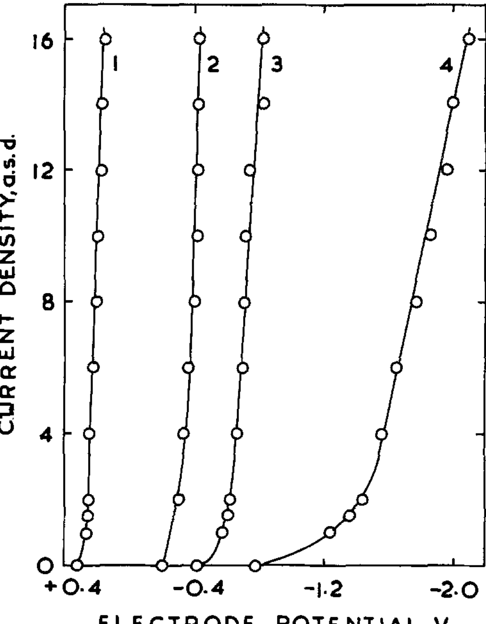

Fig. 10. Effect of current density on the electrode potential of copper (curve 1), tin (curve 2), cadmium (curve 3), and zinc (curve 4) in normal solutions of their respective salts at 30°C.

Zn tartrate	4.8×10^2	7

Table II. Studies on the possibility of codeposition of Cu-Zn, Cu-Cd, and Cu-Sn powders

Trials on codeposition of	Bath composition	Conditions employed			Results
		Anode	Cathode	CD, asd	
Copper and zinc	$CuCl_2 \cdot 2H_2O$ 20, $ZnSO_4 \cdot 7H_2O$ 30, NaCl 20, NH_4Cl 20, $Na_3C_6H_5O_7 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	12.0	No zinc was detected in the deposited powder
	$CuCl_2 \cdot 2H_2O$ 20, $ZnSO_4 \cdot 7H_2O$ 30, NaCl 20, NH_4Cl 20, $Na_2C_4H_4O_6 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	12.0	No zinc was detected in the deposited powder
Copper and cadmium	$CuCl_2 \cdot 2H_2O$ 25, $3CdSO_4 \cdot 8H_2O$ 30, NaCl 20, NH_4Cl 20, $Na_3C_6H_5O_7 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	12.0	No cadmium was detected in the deposited powder
	$CuCl_2 \cdot 2H_2O$ 25, $3CdSO_4 \cdot 8H_2O$ 30, NaCl 20, NH_4Cl 20, $Na_2C_4H_4O_6 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	12.0	No cadmium was detected in the deposited powder
Copper and tin	$CuCl_2 \cdot 2H_2O$ 30, $SnCl_2 \cdot 2H_2O$ 20, NaCl 20, NH_4Cl 20, $Na_3C_6H_5O_7 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	12.0	Tin was detected in the powder deposit
	$CuCl_2 \cdot 2H_2O$ 30, $SnCl_2 \cdot 2H_2O$ 20, NaCl 20, NH_4Cl 20, $Na_2C_4H_4O_6 \cdot 2H_2O$ 40 g/liter	Graphite	Copper	15.0	Tin was detected in the powder deposit

3. As a consequence of the above, it may not be unreasonable to expect some depolarization effects in view of the good alloying ability of copper for tin, thus facilitating codeposition.

Conclusions

The addition of complexing salts (sodium citrate/sodium tartrate) to copper sulfate bath results in considerable cathode polarization of copper. This beneficial effect is more pronounced with sodium citrate. The cathode polarization behavior of zinc, cadmium, and tin were not significantly affected by these additives.

Studies on the cathode polarization characteristics with baths containing 40 g/liter sodium citrate/sodium tartrate and actual deposition trials revealed that whereas Cu-Sn powder can be codeposited, it is not possible to codeposit Cu-Zn or Cu-Cd powder.

A Rutherford Scattering Study of Catalyst Systems for Electroless Cu Plating

II. $SnCl_2$ Sensitization and $PdCl_2$ Activation

R. L. Meek*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

High energy ion backscattering has been used to study the surface chemistry of the sensitization ($SnCl_2$) and activation ($PdCl_2$) processes used to prepare nonconductive substrates for electroless plating. This method of surface preparation is compared to catalysis using mixed Pd-Sn colloidal solutions. While the redox reaction between divalent Sn and Pd may occur during the activation of sensitized surfaces, it is suggested that any zero-valent Pd so produced only becomes catalytically active after a significant (~100 sec) immersion time in the electroless plating solution.

Electroless plating of insulating, *i.e.*, plastic or epoxy glass composite, substrates is widely used in printed circuit and decorative plating technology. In a previous paper (1) referred to hereafter as (I), an ion scattering study of the surface chemistry of the mixed Pd-Sn colloidal system was described. Here, results of an ion scattering study of the older $SnCl_2$-sensitization, $PdCl_2$-activation process (2), which is still widely used, especially in applications where photoselective deposition (3) is desired, are reported.

A number of publications (3-14) which deal with various aspects of this process have recently appeared but there is still considerable controversy regarding interpretation. The Mossbauer spectroscopy work of Cohen *et al.*, (5, 6) allows deduction of a fairly complete picture of the nature of the solutions and of the material deposited on sensitized and activated Kapton surfaces. The active species in the sensitizer which is deposited on the sensitized substrate is a complex Sn colloid consisting primarily of a Sn^{+4} complex core, stabilized by an outer layer of divalent Sn. The colloidal particle diameter is about 25-100Å, depending somewhat on the manner in which the sensitizing solution is prepared (4-6, 10, 11). The divalent Sn is oxidized to tetravalent Sn by exposure to oxygen, u.v. radiation or by dipping the sensitized substrate into the $PdCl_2$ activator solution (3, 5, 6), leading to the supposition that the reaction

$$Sn^{+2} + Pd^{+2} \rightarrow Sn^{+4} + Pd^{o} \quad [1]$$

takes place. It should be emphasized that the Mossbauer spectra (5, 6) show Sn^{+2} and Sn^{+4} after sensitization but only Sn^{+4} after activation. Subsequent work by the author and Cohen on graphite substrates gives qualitatively the same results.

Although the Mossbauer results argue strongly in favor of the correctness of reaction [1], the ellipsometric measurements of de Minjer and v.d. Boom (12), using glass substrates, at first seem to preclude it. They show that no metallic Pd is present after the activation step. On the other hand, ESCA spectra do show the presence of metallic Pd after activation (15). However, it should be noted that Pd^{o} and Pd metal, or even catalytically active Pd, are not necessarily the same thing. For example, isolated, single neutral Pd atoms might not be expected to either have metallic optical properties or to be catalytically active for electroless deposition (16, 17). In fact, some of the present results strongly indicate that the sensitized and activated surface becomes active for deposition only after some relatively long immersion time in the electroless bath. It is therefore proposed that some further change in the chemical state or structure of the material present on the sensitized and activated surface may take place during the early stages of electroless deposition.

Experimental Details

Solution preparation.—Three $SnCl_2$ sensitizing solutions, designated A, C, and W, were used. The A and C solutions were prepared by combining 16g $SnCl_2 \cdot 2H_2O$ with 30 ml HCl and 970 ml H_2O and differ due to the order of mixing (5, 6). For the A solution the $SnCl_2$ was dissolved in H_2O followed by addition of acid, while for the C solution, water and acid were combined followed by addition of $SnCl_2$. According to Ref. (5), the A solution will have the larger colloidal particle size. The W solution, one of the so-called wetting Sn solutions, was formed by adding (7.5g $SnCl_4 \cdot 5H_2O$) then (20g $SnCl_2 \cdot 2H_2O$) and finally (15g $SnCl_2 \cdot 2H_2O$) to one liter of H_2O in the order given with thorough mixing after each addition. All solutions were used between 1 and 2 hr after preparation.

The activating solution was prepared by dissolving 0.2g $PdCl_2$ in 8 ml HCl and diluting to 1 liter with H_2O. The electroless Cu plating solution was the same as that used in (I) and standard H_2O rinse times of 30 sec were used after each process step.

Cleaved graphite substrates (~1 cm^2) were chosen for the present study. [See (I).] The low mass of carbon eliminates substrate interference and, furthermore, graphite may be obtained in a very pure form. By using a freshly cleaved surface, unwanted surface impurities can be minimized. Substrates were prepared for analysis by immersing 1 cm^2 samples in 100 cm^3 of the appropriate solution, or series of solutions, with gentle stirring. They were then carefully dried by placing the sample edge on filter paper and immediately (within 15 min) examined.

Surface analysis.—The high energy ion scattering technique was described in (I). A typical scattered ion spectrum from the surface layer produced by immersion in sensitizing solution C for 300 sec and rinsing is shown as Fig. 1. The peak positions (and yields) correspond to $O[2.5(10)^{16}\ cm^{-2}]$ $Cl[2(10)^{15}\ cm^{-2}]$ and $Sn\ [2(10^{16})\ cm^{-2}]$. $Si(10^{14}\ cm^{-2})$ is a frequently detected surface contaminant on control substrates (1).

The substrate area examined by the ion beam is 0.78 mm^2. The statistical error in a given measurement is typically 3% for heavy mas species (Cu, Pd, Sn) and 10% for light masses (O, Cl). During the experiments it become apparent that significant differences (a factor of three) can occur from point to point on a given

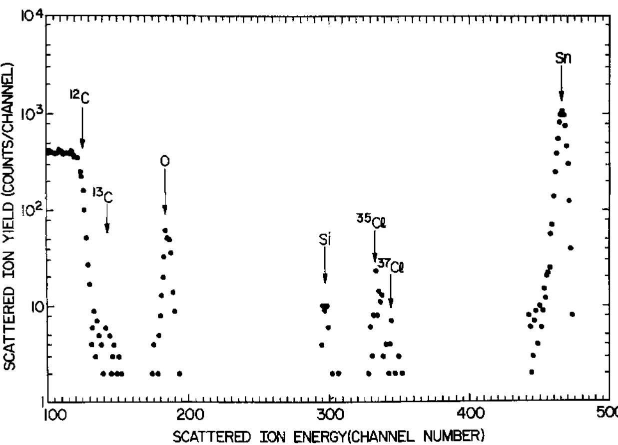

Fig. 1. Typical scattered ion spectrum (scattered ion yield as counts per channel vs. scattered ion energy as channel number) from sensitized ($t_{SnCl_2\text{-}C}$ = 300 sec) substrate.

substrate. Thus 3-5 separate measurements were made at randomly selected points on a given sample. Throughout this paper, bars on data points indicate the point to point variation found, not an error bar. Of course, surface concentration variations on a smaller scale, smaller than the beam spot size, may be even greater. Two or more samples treated in the same way gave equivalent results within the point to point variations just mentioned.

Results and Discussion

Sensitization.—The Sn, Cl, and O surface concentrations found on sensitized surfaces are shown in Fig. 2, 3, and 4 for the A, C, and W solutions, respectively. The amount of each element found is fairly independent of the sensitizing solution used. The fact that the amount adsorbed goes roughly as the square root of immersion time implies diffusion controlled deposition (1) of the colloidal Sn particles; however, one must also expect some deposition due to hydrolysis during the rinse step. After sensitization, the O/Sn ratio is approximately 1.3, while the Cl/Sn ratio is approximately 0.1. The small amount of Cl found is in agreement with the observations of de Minjer and v.d. Boom (12). Experimentally, all of the sensitizer solutions used produced a wetting, hydrophilic, surface on graphite.

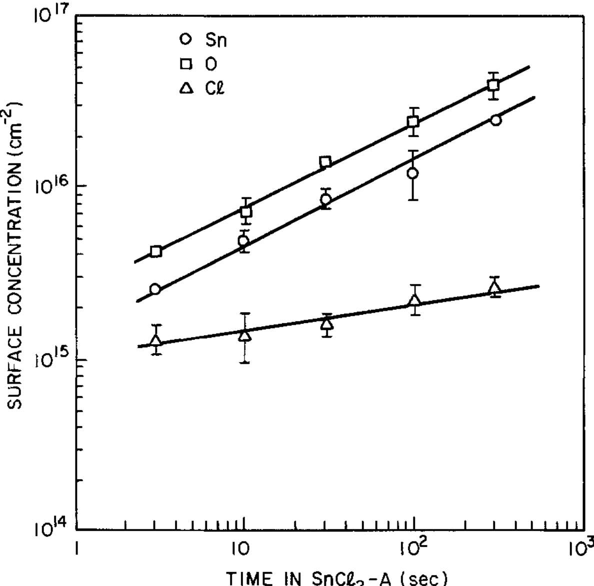

Fig. 2. Surface concentrations of Sn, O, and Cl vs. sensitization time for substrates sensitized in solution A.

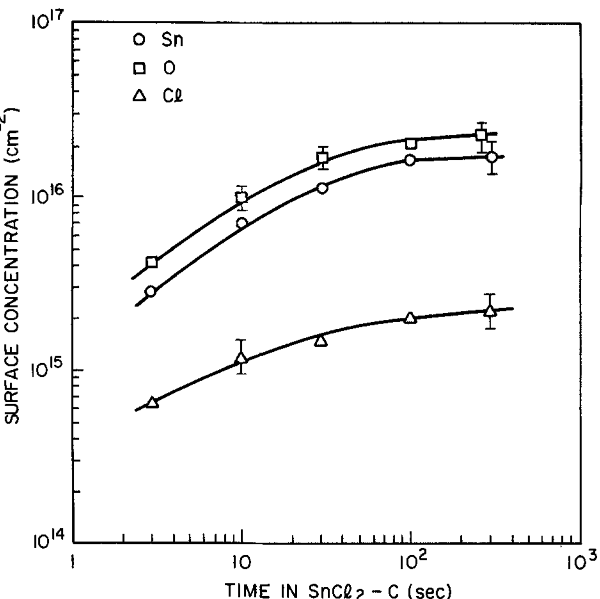

Fig. 3. Surface concentrations vs. sensitization time for sensitizer C.

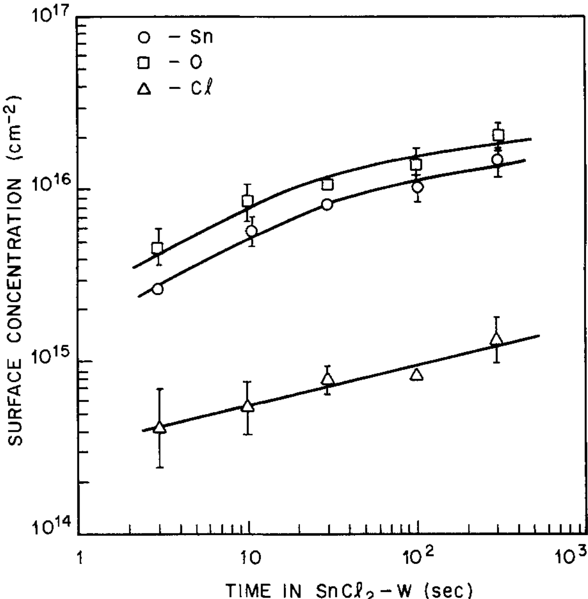

Fig. 4. Surface concentrations vs. sensitization time for sensitizer W.

Activation.—The Pd surface concentrations after immersion in the activator solution are given in Fig. 5 for the A solution. Similar results were obtained using the other solutions. Also shown are the remaining Sn concentrations; the dashed line represents the average Sn concentrations prior to the activation from Fig. 2. It is seen that the Sn concentration decreases slightly but probably not significantly, and that after activation the Pd/Sn ratio is about 0.2. The Mossbauer experiments (5, 6) would suggest that the Pd/Sn ratio should be 0.5 if reaction [1] takes place, if the Sn^{+2}/Sn^{+4} ratio after sensitization is the same as in that work, and if the recoil-free fractions are the same for the Sn^{+4} and the Sn^{+2} species. However, the possibility of a considerable difference in Sn^{+2}/Sn^{+4} ratio is rather likely, since it is known to depend sensitively on the quality of the chemicals used and the exact details of the solution preparation so that the present observations in no way contradict those of Cohen *et al.* (5, 6). Subsequent work by Cohen and the author has reproduced and extended the Mossbauer results using graphite substrates. Furthermore, it is seen that the Pd concentration is independent of time in the activator solution,

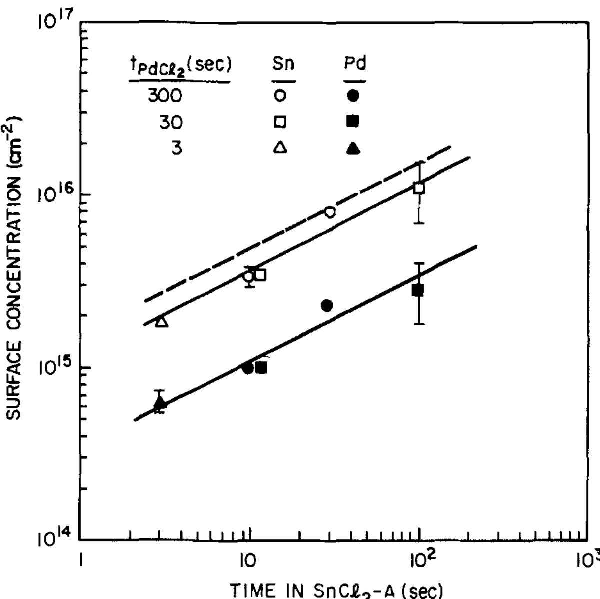

Fig. 5. Surface concentrations of Pd and Sn vs. sensitization time after various activator immersion times for substrates sensitized in solution A.

but rather depends on the time in the sensitizer solution; that is, the Sn concentration; and that the Pd concentration closely follows the Sn concentration. Note also the rapidity of the Pd deposition; it is found in general that 3 sec in the activator leads to the same amount of Pd as 300 sec in the activator. While the Pd concentration is about the same as that found after catalysis in mixed Pd-Sn colloids (1), the Sn concentration is larger or, equivalently, the Pd/Sn ratio is smaller.

After activation, the O/Sn ratio rises to 2 and the Cl/Sn ratio becomes approximately 0.2. The increase in O/Sn ratio is at least in accord with the existence of the redox reaction although it does not prove its existence. The small Cl/Sn ratio observed is not in agreement with the results of Ref. (12), where Cl/Sn ratios in the range 1-6 were found. We have observed such large Cl/Sn ratios, but only if the postactivator rinse is strongly acidic, and then a commensurate increase in Pd is also observed; but the results are very irreproducible (Pd and Cl vary by a factor of ten). It is noted that the possibility of a $Sn_4Pd_2Cl_{14}$ complex proposed in Ref. (12) and (18) is conclusively ruled out both by the present simple atom "counting" techniques and by the Mossbauer experiments which, while not quantitative, show the chemical state; that is, the electronic environment of the Sn atoms.

Electroless plating.—Figure 6 shows the Cu deposition *vs.* time in the electroless solution for the A sensitizer solution. Again similar results are obtained with the C or W solution. The line labeled 2.2 A/sec is the rate at which the bath used plates Cu on Cu (1). The Cu coverage is more or less independent of sensitizer used or time in activator solution, but depends strongly on time in the sensitizer; that is, original Sn concentration. The relatively long ($\gtrsim$ 100 sec) times for significant Cu deposition to take place are in distinction to the short ($\lesssim$ 10 sec) initiation times observed when the mixed Pd-Sn colloid is used to catalyze the surface (1). In fact, for sensitization times $\lesssim$ 10 sec, the Cu plating initiation time is $>10^4$ sec. These observations lend credence to the idea that, after activation, the Pd, while it may be zero-valent, is neither "metal" nor catalytically active. The significance of such long initiation times to processes where the total electroless plating time is only $\sim 10^3$ sec is obvious.

It is of considerable interest to determine the amount of Pd and Sn remaining after electroless deposition.

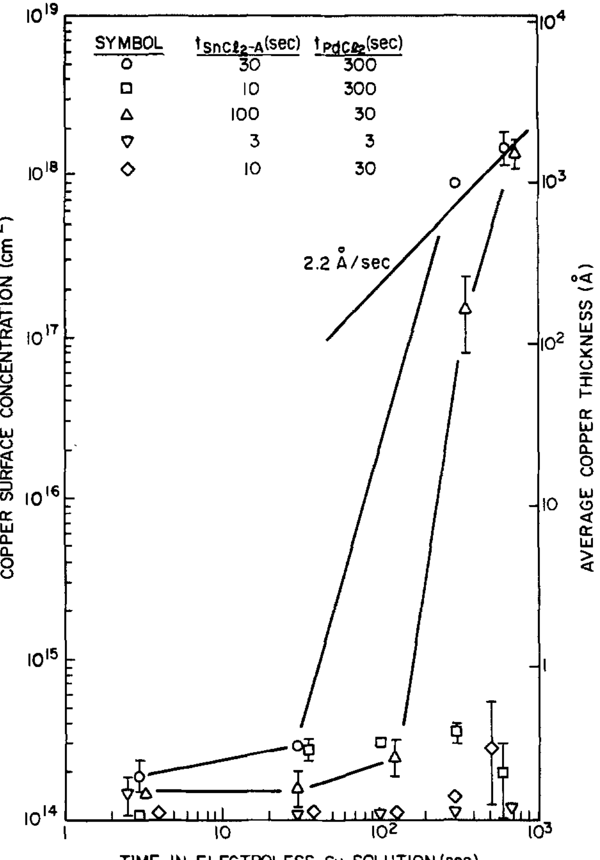

Fig. 6. Copper surface coverage vs. time of immersion in electroless bath for various sensitization (solution A) and activation times.

The data, normalized to initial concentration, for Pd and Sn, corresponding to Fig 6 is given in Fig. 7. While there is some scatter in the data, in general both the Pd and Sn concentrations decrease by about a factor of

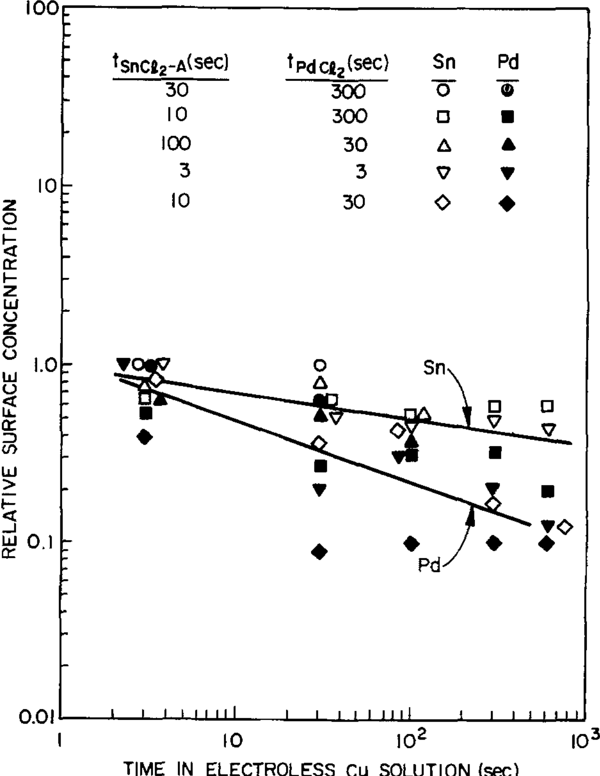

Fig. 7. Normalized Pd and Sn surface concentrations vs. time in electroless bath for samples sensitized in solution A.

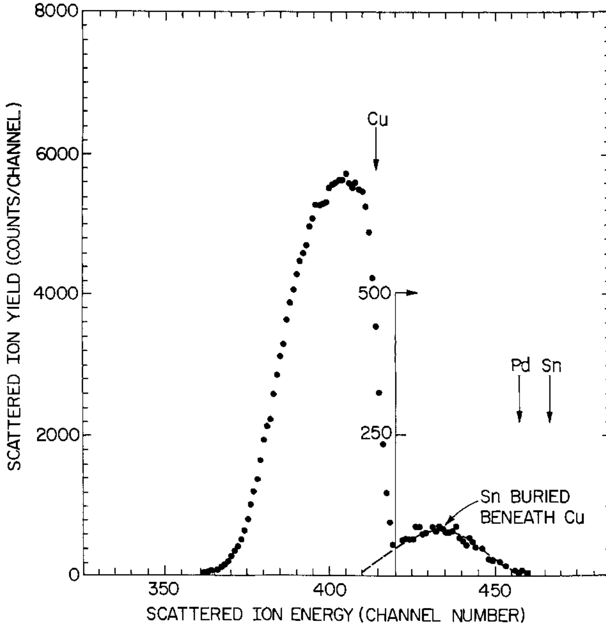

Fig. 8. Typical scattered ion spectrum from a sensitized ($t_{SnCl_2\text{-}C}$ = 30 sec) activated (t_{PdCl_2} = 30 sec) plated (t_{Cu} = 900 sec) sample. The Sn and Pd peaks have been shifted to lower energy; scattering from Pd is completely obscured by scattering from overlying Cu at this stage.

two by the time complete Cu coverage occurs. For catalysis with mixed Pd-Sn colloid solutions, it was found that some Sn was lost into the electroless bath (1). For the present processing even more Sn is lost and also some Pd. It has been demonstrated (1) that Sn lost into the electroless bath may be codeposited; the concern with the possibility of Pd loss into the electroless bath is obvious. It is a general observation of our work that electroless Cu baths which have been used to process sensitized and activated samples are considerably less stable with respect to spontaneous Cu plate-out than are those used to process samples catalyzed by Pd-Sn colloid solutions.

The remaining Pd and Sn are, of course, buried beneath the deposited Cu layer. Figure 8 shows a typical scattered ion spectrum for $t_{SnCl_2\text{-}C} = 30$ sec, $t_{PdCl_2} = 30$ sec, $t_{Cu} = 900$ sec. As discussed in (I), the Sn peak has been shifted to lower energy due to the inelastic energy loss suffered by the scattered ions as they penetrate through and exit from the Cu layer. Again there is considerable difference between the present processing where $\sim 10^{16}$ Sn atoms cm^{-2} and $\sim 10^{15}$ Pd atoms cm^{-2} are found at the Cu-substrate interface and the Pd-Sn colloid catalyst process where $\sim 10^{15}$ Pd atoms cm^{-2} and $\sim 10^{14}$ Sn atoms cm^{-2} are found at the interface.

Some effort has been expended in preventing Pd and Sn loss into the electroless solution and in trying to change the Pd/Sn ratio and reduce the initiation time. Samples which had $t_{SnCl_2\text{-}A} = 100$ sec, $t_{PdCl_2} = 30$ sec were immersed in various 0.2M solutions of the so-called accelerators used after catalysis with Pd-Sn colloids. Results are given in Table I. It is seen that both the Pd and Sn concentrations are reduced, but that the Pd/Sn ratio is practically unchanged. It has also been found that after such treatments no further loss of Pd or Sn into the electroless solution results, but that the long initiation times are not reduced. However, as will be reported separately, a suitable treatment in a basic solution does achieve the desired result.

Conclusions

Sensitization ($SnCl_2$) and activation ($PdCl_2$) is basically different from catalysis by colloidal Pd-Sn solutions. The Pd/Sn ratio is considerably less, more Pd and Sn are lost into the electroless plating solution, and longer times ($\gtrsim 10^2$ sec) are required to initiate the electroless plating reaction than in the case of the mixed Pd-Sn colloid catalyst systems (1).

Table I. Pd and Sn surface concentrations after postactivator immersion in various solutions

Solution	Atoms cm^{-2} Sn	Atoms cm^{-2} Pd	Pd/Sn
—	$1.1(10)^{16}$	$2.8(10)^{15}$	0.23
HCl	$0.36(10)^{16}$	$0.80(10)^{15}$	0.22
HBF_4	$0.53(10)^{16}$	$0.84(10)^{15}$	0.16
NH_4F	$0.62(10)^{16}$	$1.7(10)^{15}$	0.27

The present observations are consistent with, but not proof of, the correctness of the redox reaction involving divalent Sn and Pd during the activation treatment. It is suggested that while the Pd deposited during the activation step may be zero-valent, it has neither metallic properties nor catalytic activity. Rather, it is proposed that the sensitized and activated surface becomes catalytic only after some residence time in the electroless plating solution.

Acknowledgments

Maximum Effective Capacity in an Ohmically Limited Porous Electrode

William Tiedemann* and John Newman*,[1]

Globe-Union, Incorporated, Corporate Applied Research Group, Milwaukee, Wisconsin 53201

ABSTRACT

For large reaction rate constants and negligible change in solution composition, the performance of a porous electrode with solid reactants is governed by the ohmic potential drop within the matrix and solution phases. The cell potential changes with time, at constant current, as the reactants are consumed. Equations are developed which describe this time dependence as a function of electrode porosity and thickness, the electrolyte and solid phase conductivities, specific ampere-hour capacity, separator conductivity and thickness, and current density. These then yield the values of electrode porosity and electrode thickness so as to maximize the capacity for discharge to a given cutoff potential. Treatment of the porous LiAl electrode is presented as an example.

Many models have been proposed to predict the behavior of porous electrodes (1). Current distribution in porous electrodes has been examined in great detail. The correspondence between experiment and theory has been shown to be good for several different systems. The purpose of such models is to develop an understanding of the specific system, as well as to suggest directions for improved performance in the system. The ultimate objective of such investigations is the optimization of the electrochemical cell in question. However, relatively little information is available concerning the optimization of the performance of porous electrodes (1).

Let us consider here the constant-current discharge of an electrode where activation and concentration overpotential are small compared to the ohmic losses in the solution and solid phases. Under these conditions the reaction zone is very thin. The electrode potential changes during discharge because the positions of the reaction zones move as the solid reactant is consumed and also because the conductivities of the phases may be different in the discharged state.

We wish to maximize the capacity which can be utilized at a given current density before the discharge potential drops below a prescribed cutoff potential. An increase in the electrode thickness increases the theoretical electrode capacity, but it also increases the ohmic potential drop because of the increased distances that current must flow. The effective capacity is maximized at that electrode thickness where 100% utilization occurs at the moment that the potential drops to the prescribed cutoff.

Analysis

The system under investigation is a macrohomogeneous porous electrode [as originally proposed by Newman and Tobias (2)] in contact with a porous separator. The treatment presented here is one dimensional as shown in Fig. 1. Only the separator and porous electrode will be considered in this examination. The effects of the free electrolyte and metal backing plate can be dealt with separately.

In this treatment it is assumed that ohmic losses in the system are much larger than kinetic (activation overpotential) losses and losses due to concentration overpotential. This assumption simplifies the analysis. The behavior as well as the performance of the electrode can be determined by calculating the ohmic resistance of the system as a function of time.

* Electrochemical Society Active Member.
[1] Present address: Department of Chemical Engineering, University of California, Berkeley, California 94720.
Key words: electrode thickness, electrode porosity, ohmic loss, optimization, nonuniform current distribution.

The effective resistance of the system shown in Fig. 1, at time zero, can be expressed by (3)

$$R|_{t=0} = \frac{L_s}{\kappa_s} + \frac{L}{\kappa + \sigma} \qquad [1]$$

where L_s and L are the thicknesses of the separator and porous electrode, respectively, and σ, κ, and κ_s are the effective conductivities (1) of the solid electrode matrix, electrolyte contained in the porous matrix, and the electrolyte contained in the porous separator, respectively. The current distribution in the porous electrode becomes nonuniform for large values of the exchange current density, the electrochemically active interfacial surface area, the electrode thickness, or the current density, or for small values of the electrolyte and solid phase conductivities.

As shown by Newman and Tobias (2), the ratio of the electrolyte and solid phase conductivities determines the shape of the current density distribution within a porous electrode. Depending on the value of κ/σ, the current density distribution can be displaced toward the electrode-separator interface, the electrode-backing plate interface, or portioned to these two interfaces, thereby producing a minimum value of the current density within the electrode. As the current distribution becomes highly nonuniform, it approaches a thin reaction zone in nature. We shall approximate the true current density distribution by a narrow reaction zone which can be envisioned to move through the electrode as the available material is consumed. The rate of the reaction and whether it is split between

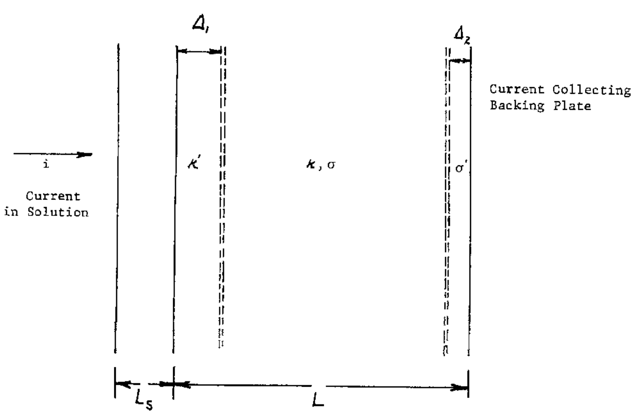

Fig. 1. Schematic representation of a separator and porous electrode of lengths L_s and L, respectively, with finite reaction zones indicated by dashed lines.

the front and back faces of the electrode will be governed by the conductivities of the electrolyte and solid phases.

As these reaction zones consume the available material and penetrate further into the electrode, a discharged region is left behind which may have different electrolyte and solid phase conductivities and thereby alter the over-all resistance of the electrode. We shall assume that concentration changes are small. The porosity of the electrode can change as a result of differences in the partial molar volumes of the reactants and products; also, the electrode can shrink and expand due to these volume changes. It is therefore necessary to alter the expression for the resistance of the system to account for these changes as follows

$$R_{(i,t)} = \frac{L_s}{\kappa_s} + \frac{L - \Delta_1 - \Delta_2}{\kappa + \sigma} + (1+f)\left(\frac{\Delta_1}{\kappa'} + \frac{\Delta_2}{\sigma'}\right) \quad [2]$$

where Δ_1 and Δ_2 are the thicknesses of the reacted zones of the electrode, κ' and σ' are the electrolyte and solid phase conductivities, respectively, of the reacted zone, and f is a constant equal to the fractional increase in electrode thickness resulting from volume changes within the electrode.

The thicknesses of the reacted zones can be expressed as

$$\Delta_1 = \frac{it}{q}\frac{\sigma}{\kappa + \sigma} \quad \Delta_2 = \frac{it}{q}\frac{\kappa}{\kappa+\sigma} \quad [3]$$

where i is the current density, t is time of discharge, and q is the specific electrode capacity. Substituting Eq. [3] into [2] and rearranging yields

$$R_{(i,t)} = \frac{L_s}{\kappa_s} + \frac{L}{\kappa+\sigma} + \frac{it}{q(\kappa+\sigma)}\left(\left(\frac{\sigma}{\kappa'} + \frac{\kappa}{\sigma'}\right)(1+f) - 1\right) \quad [4]$$

The voltage loss in the composite system can be expressed as

$$\Delta V = iR_{(i,t)} \quad [5]$$

and the effective capacity of the electrode at time t as

$$Q = it \quad [6]$$

Using Eq. [5] and [6] to rearrange Eq. [4], we obtain

$$Q = (\kappa+\sigma)\left(\frac{\Delta V}{i} - \frac{L}{\kappa+\sigma} - \frac{L_s}{\kappa_s}\right) q \Big/ \left(\left(\frac{\sigma}{\kappa'} + \frac{\kappa}{\sigma'}\right)(1+f) - 1\right) \quad [7]$$

The total theoretical capacity of the electrode is given by

$$Q_T = qL \quad [8]$$

A qualitative plot of Eq. [7] and [8] is shown in Fig. 2. Dotted lines represent physically inaccessible situations. The effective capacity cannot lie above the value given by Eq. [8] because there is no more active material in the electrode. It cannot lie above the value indicated by Eq. [7] without exceeding the allowable potential loss. The intersection of these equations thus provides the condition at which the usable electrode capacity is maximized. Inspection of Fig. 2 shows that the maximum does not involve a zero derivative of capacity with respect to electrode thickness. Rather, it occurs when 100% of the theoretical capacity is utilized at the same time that the ohmic potential loss rises to the allowable value. The optimum L is given by

$$L_{\text{opt.}} = (\kappa+\sigma)\left(\frac{\Delta V}{i} - \frac{L_s}{\kappa_s}\right) \Big/ \left(\left(\frac{\sigma}{\kappa'} + \frac{\kappa}{\sigma'}\right)(1+f)\right) \quad [9]$$

The thickness of the electrode has now been optimized to maximize the capacity. We now wish to maximize the electrode capacity with respect to porosity. The conductivities given in Eq. [7] can be expressed as

$$\kappa = \kappa_0\epsilon^n, \quad \kappa' = \kappa_0\epsilon_f^n \quad [10]$$

$$\sigma = \sigma_0(1-\epsilon)^n, \quad \sigma' = \sigma_0'(1-\epsilon_f)^n \quad [11]$$

and

$$q = q_0(1-\epsilon) \quad [12]$$

where κ_0 and σ_0 are the bulk conductivities of the electrolyte and solid phases, respectively, ϵ and ϵ_f are the initial and final porosities of the electrode, respectively. The n is a factor lying between 1 and 3 which accounts for tortuosity effects (1). Since the solid product can be a different material from the reactant, the final conductivity σ_0' can be quite different from the initial conductivity σ_0. The initial and final electrode porosities are related by

$$\epsilon_f = 1 - (1-\epsilon)/B \quad [13]$$

where

$$B = (1+f)\frac{(\text{volume of solid reactants}) + (\text{volume of solid inerts})}{(\text{volume of solid products}) + (\text{volume of solid inerts})}$$

Solid inerts should include product species present initially.

Substitution of Eq. [10] through [13] into the optimized form of Eq. [8] gives

$$Q = \frac{q_0(1-\epsilon)(\kappa_0\epsilon^n + \sigma_0(1-\epsilon)^n)\left(\frac{\Delta V}{i} - \frac{L_s}{\kappa_s}\right)}{\left[\frac{\sigma_0(1-\epsilon)^n}{\kappa_0\left(1 - \frac{(1-\epsilon)}{B}\right)^n} + \frac{\kappa_0\epsilon^n}{\sigma_0'\left(\frac{1-\epsilon}{B}\right)^n}\right](1+f)} \quad [14]$$

Differentiating Eq. [14] with respect to ϵ and setting the result equal to zero yields

$$\epsilon^n(1-\epsilon)^{2n}\left(1 - \frac{(1-\epsilon)^2}{B} - \frac{\epsilon}{n}\left(1 - \frac{(1-\epsilon)}{B}\right)\right) + (1-\epsilon)^3\epsilon\frac{\sigma_0}{\kappa_0}\left[\frac{1-\epsilon}{B} - \frac{\left(1 - \frac{(1-\epsilon)}{B}\right)}{n}\right] - \frac{\kappa_0}{\sigma_0'}B^n\left(1 - \frac{(1-\epsilon)}{B}\right)^{n+}\left(\frac{\kappa_0}{\sigma_0}\epsilon^{2n+1}\left(1 + \frac{1}{n}\right) + \epsilon^n(1-\epsilon)^n\left(1 + \epsilon + \frac{\epsilon}{n}\right)\right) = 0 \quad [15]$$

The value of ϵ satisfying Eq. [15] is designated as the optimum porosity, $\epsilon_{\text{opt.}}$.

Equation [15] gives the optimum porosity as a function of the relative conductivities of the electrolyte and solid phases and the system parameters B and n. In the case of $\sigma_0 >> \kappa_0$, Eq. [15] reduces to

$$\epsilon_{\text{opt.}} = 1 - B/(1+n) \quad [16]$$

Discussion

Maximization of the available capacity, as given by Eq. [7] and [8], with respect to porosity yields an optimum porosity, as displayed in Fig. 1. Here we have taken the matrix conductivities σ_0 and σ_0' to be the same in the charged and discharged states, and we have displayed the dependence of the optimum porosity on the conductivity ratio of the bulk matrix and solution phases. The optimum electrode thickness is that for which 100% utilization occurs at the same moment that the ohmic potential loss reaches its allowable value. If concentration and kinetic effects begin to become important, we can expect that the actual curve

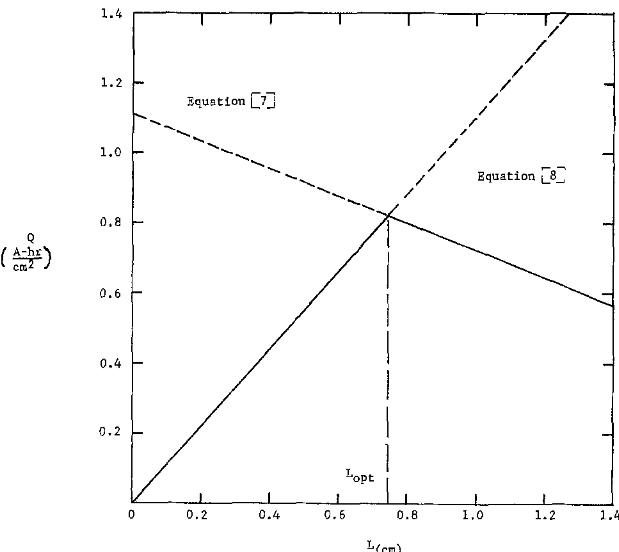

Fig. 2. Effective electrode capacity plotted as a function of electrode thickness, $\kappa = 0.138$ mho/cm, $\kappa' = 0.715$ mho/cm, $\sigma = \sigma' = 20K$, $q = 1.11$ A-hr/cm^3, $\Delta V = 0.1$V, $i = 0.1$ A/cm^2, $f = 0$, $L_S/\kappa_S = 0$.

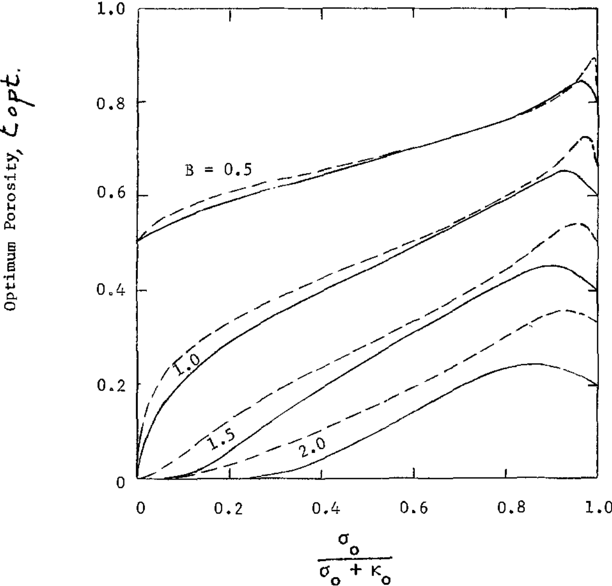

Fig. 3. Dependence of the optimum porosity on the relative conductivities of the bulk matrix and solution phases calculated by Eq. [15], $\sigma_o' = \sigma_o$. Solid curves are for $n = 1.5$; dashed curves are for $n = 2$.

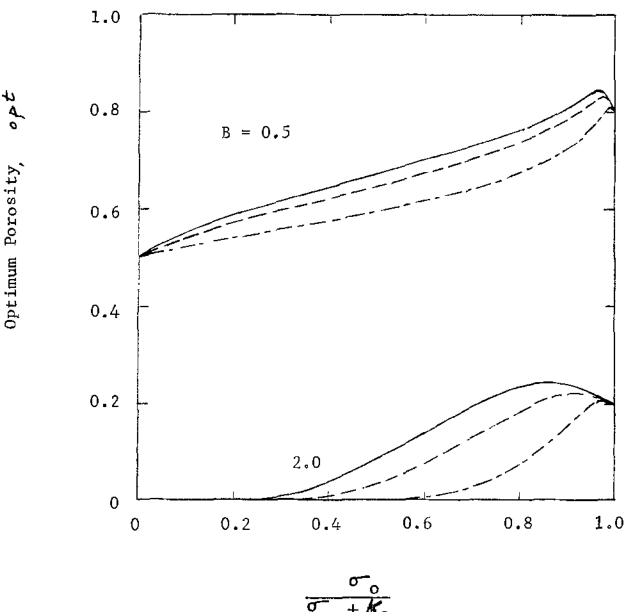

Fig. 4. Dependence of the optimum porosity on the relative conductivities of the bulk matrix and solution phase calculated by Eq. [15], $n = 1.5$. Solid curves are for $\sigma_o'/\sigma_o = 1$; — — — curves for $\sigma_o'/\sigma_o = 0.5$; — - — curves for $\sigma'_o/\sigma_o = 0.1$.

will lie below that of the solid curve generated from Eq. [7] and [8]. In other words, the maximum capacity should lie below that predicted, but the optimum electrode thickness could lie below or above the predicted value.

The optimum porosity curves shown in Fig. 3 are markedly different depending on whether the porosity increases ($B > 1$) or decreases ($B < 1$) during discharge. It is also apparent that the value of n can significantly alter the shape of the curve. Figure 4 shows the effect of different values of the conductivities for the initial and final states of the solid phases on the optimum porosity curves. These results indicate that it is very important to characterize the behavior of a given porous medium in terms of the porosity dependence of the conductivities, the conductivities of the bulk phases, and the volumetric expansion or contraction.

Note that the conditions of the specified discharge, current density and minimum allowable discharge potential in this case, influence the optimization of the electrode thickness. The optimum porosity is independent of these factors for the system treated here.

As an example of the applicability of the model to treat real systems, we select the porous LiAl electrode in molten LiCl + KCl. Since the concentration of Li^+ ions is of the order of 20M, the assumption of minimal concentration gradients is reasonable. The operating temperature of 450°C further supports this assumption, since increased diffusion minimizes concentration gradients. The high temperature and large surface area couple to create very fast kinetics. The relative importance of diffusion in a particle compared with diffusion in the electrolyte phase of a porous electrode has been discussed by Johnson and Newman (3). A criterion to assess the importance of solid-state diffusion within a lithium-aluminum particle can be expressed as

$$S = \frac{3.87(1-\epsilon)i}{n\mathbf{F}CLa^2D} \quad [17]$$

where C is the concentration of lithium in the lithium-aluminum alloy (0.0517 equiv./cm^3), D is the diffusion coefficient of lithium in the lithium-aluminum alloy ($2 \cdot 10^{-10}$ cm^2/sec), a is the specific interfacial area ($2 \cdot 10^3$ cm^2/cm^3), L is the thickness of the porous electrode (1 cm), ϵ is the initial porosity of the electrode (0.2), i is the current density (0.1 A/cm^2), n is the number of electrons transferred in the electrode reaction (1 electron), $\mathbf{F}$ is Faraday's constant (96,500 coulombs/equiv.). For $S < 1$ solid-state diffusion can be neglected. Using the parameters given above $S \approx 0.08$. For the example presently being treated solid-state diffusion can be neglected, however, one should note that decreasing the interfacial surface area (increasing particle size) and operating temperature (decreasing the diffusion coefficient) can greatly increase the value of S. Therefore, application of the model represented in this paper to the LiAl electrode is in harmony with its underlying assumptions.

One curve of Fig. 3 depicts the case of optimum porosity for the LiAl electrode, $B = 2$. For the condition that $\sigma_o >> \kappa_o$, the optimum porosity is equal to 0.2. This value can now be inserted into Eq. [9] to obtain the optimum electrode thickness provided values are assigned to the allowable voltage loss as well as the effect of separator resistance (L_S/κ_S). Using $\Delta V = 0.1$V, $i = 0.1$ A/cm^2, $L_S/\kappa_S = 0.0$, $\kappa_o = 1.54$ mho/

cm, $\epsilon = 0.2$, $f = 0$, $n = 1.5$, and $\sigma_0 = \sigma_0' >> \kappa_0$, we obtain $L_{opt.} \cong 0.713$ cm.

We have not presented results which show the effect of increasing or decreasing electrode thickness. However, one can expect that for electrodes which decrease in thickness as they are discharged the optimum electrode thicknesses will increase and that the opposite would be true for electrodes with increasing thicknesses. For the case of current collected from the front face (separator-electrode interface) instead of the backing plate, or for current collected from both faces, different equations will have to be developed, though their form will be similar. Should the entire cell (two porous electrodes plus a separator) be treated in a similar manner, the effects of changes of the parameters of one electrode will be seen to affect the optimum performance of the other electrode.

ABSTRACT

Potential differences have been measured between the alkali metals and their dilute amalgams in propylene carbonate solutions. The general cell $M(s)|M^+,X^-(PC)|M(Hg)$ has been used where M = Li, Na, K, Rb, and Cs, and $X^- = AlCl_4^-$ or PF_6^-. The emf values measured are in satisfactory agreement with those obtained earlier in other solvents.

In the course of our studies on the thermodynamic properties (1, 2) and the kinetic measurements (3) of the alkali metals in aluminum chloride-propylene carbonate (PC) solution, we have measured the potential difference between the alkali metals Li, Na, K, Rb, and Cs and their respective dilute amalgams.

This is a report of a fragmentary nature which establishes the feasibility for a complete thermodynamic study of the alkali metal amalgams using propylene carbonate as a nonaqueuos solvent.

* Electrochemical Society Active Member.

Key words: lithium amalgam, sodium amalgam, potassium amalgam, rubidium amalgam, cesium amalgam, propylene carbonate.

In the present work we have confirmed some of the emf data of the early pioneering work of Lewis (4-7) and Bent (8-10) and their co-workers, and provided some additional emf data for different amalgam concentrations. We feel that the measurements on potassium, rubidium, and cesium should be especially useful because of the paucity of data for these experimentally difficult systems.

Experimental

Alkali metal amalgams were prepared by weight from triple distilled mercury (Quicksilver Products Incorporated, San Francisco) and alkali metal ribbons (Li, Lithium Corportion of America, 99.9%; Na, Baker analyzed reagent; K, Mallinckrodt; Rb, Alfa Inorganic, m2N+; Cs, United Mineral & Chemical Corporation, New York, 99.8%). The amalgams were prepared inside a dry argon glove box (below 1 ppm water). The electrolytes were prepared from alkali metal chlorides (Mallinckrodt and Alfa Inorganic) and aluminum chloride (Baker, 99.2%) or sodium hexafluorophosphate (Alfa Inorganic, 99%) in propylene carbonate (Jefferson Chemical Corporation, Houston, Texas). The distillation, purification, and preparation of the solutions are discussed elsewhere. Special precautions were necessary for the K, Rb, and Cs cells (1, 2, 11).

Potentials were measured with a high impedance differential voltmeter (John Fluke, Model 887-A), accuracy ±0.005 mV, which was calibrated against an Eppley Laboratory low temperature coefficient standard cell.

The six compartment cells and the electrodes were described previously (1, 11, 12). The potentials were measured between the alkali metals wires, or solidified pools of Rb and Cs in cup electrodes (1, 3, 11), and the corresponding alkali metal amalgams which were placed in cup electrodes. The measurements were repeated every 30 min for the first few hours. The potential drift during the first hour was less than 1 mV for most measurements. The potentials were extrapolated to zero time and represent average values of at least 2 electrodes for each cell. The temperature was maintained at 25° ± 0.01°C for all experiments. In the case of potassium the measurements were repeated for various temperatures up to 50°C within ±1°C.

Results

The potential differences of the general cell

$$M(s) \mid M^+,X^-(PC) \mid M(Hg)$$

(where X^- is $AlCl_4^-$ or PF_6^-) were measured for M = Li, Na, K, Rb, and Cs. The results are summarized in Table I for various amalgam compositions.

Discussion

The results of the present work can be compared with early results. The value of 1.004V for X_{Li} = 0.01907 Li(Hg) agrees with a value of 1.0037V reported by Cogley and Butler (13). The first sodium amalgam measurement (0.843V) satisfactorily agrees with the value of 0.8456V reported by Lewis and Kraus (5) for the identical amalgam composition (X_{Na} = 0.01771). The second value of 0.8319V agrees well with 0.830V calculated after Mussini, Maina, and Pagella (14). However the third value of 0.7347V for X_{Na} = 0.02982 is significantly lower than the calculated value of 0.822V (14). It is believed that the calculated value is the correct one because of the consistency of the data over the entire dilute range (14). It is quite possible that the present value is erroneous due to poisoning of the solid sodium in this particular measurement. The first two Na measurements agree well with the data reported by Hsueh and Bennion (15) and by Bent and Swift (9).

The emf of the potassium cell, 1.0523V, is slightly higher than the value of 1.0481V reported by Lewis and Keyes (6) for the same amalgam composition (X_K = 0.01126). The additional value of 1.0067V for X_K = 0.02271 agrees with 1.01036V calculated from the aqueous solution measurements of Bent and Gilfillan (10). The temperature coefficient of the emf of the X_K = 0.02271 amalgam cell was calculated from data obtained in the temperature range between 25° and 50°C, resulting in the average value of dE/dT = 0.0022 ± 0.001 V/°K. The entropy of solution of potassium in X_K = 0.02271 amalgam is therefore

$$\Delta S = \mathbf{F}(dE/dT) = (96{,}580/4.186)(0.0022)$$

$$= 50 \text{ cal/g-mole°K}$$

The emf value of 1.0766V for Rb(Hg)(X_{Rb} = 0.00539) agrees reasonably with the corresponding value of 1.0745V reported by Lewis and Argo (7) for an identical amalgam composition, and with 1.077V calculated from the aqueous solution measurements of Longhi, Mussini, and Osimani (16).

The cesium amalgam mole fraction in the present work was 0.004551, higher than the composition of the cesium amalgam used by Bent *et al.* (8), X_{Cs} = 0.002827. The value of 1.107V obtained in the present work is indeed lower than the value of 1.121V measured by Bent *et al.* (8) for a more dilute amalgam, and agrees reasonably with the calculated value of 1.100V after Mussini, Longhi, and Riva (17).

The activity coefficient of cesium in its amalgams can now be calculated from the two measurements

$$\log \gamma_{Cs} = (\mathbf{F}/2.303RT)E - \log X_{Cs}$$

where the pure cesium has been chosen as the reference state, and the activity coefficients are based on the mole fraction X of cesium in the amalgam, For both concentrations: X_{Cs} = 0.002827 and X_{Cs} = 0.00454, we obtained $\log \gamma_{Cs} = -16.4$.

The potentials were measured every 30 min for the first few hours and extrapolated to zero time. The time dependent potential drift is due to the reactivity of the alkali metal amalgams, especially lithium amalgam, toward PC. Dousek, Jansta, and Říha (18) report that active lithium reacts with PC freed from impurities with the formation of Li_2CO_3 and propylene. They prove that the Li_2CO_3 layer passivates the solid lithium surface. The decomposition of lithium amalgam in highly pure PC (water content was lower than 0.01 ppm) is even stronger due to surface renewal of the amalgam. The rate of PC decomposition by the alkali metal amalgams decreases sharply in the order Li > Na > K (18). The presence of traces of water in the electrolytic solution (45 ppm) decreases the PC decomposition by the Li-Hg amalgam considerably as it is believed that the amalgam surface is blocked by LiOH (18). Dey (19) also speculates on the film formation in Li-PC systems, and Scarr (20) predicts PC decomposition by Li from thermodynamic considerations.

In the present investigation, the water content was mostly 10 ppm and in some cases up to 50 ppm, and therefore it is quite possible that the protective layer slowed down the chemical decomposition, especially in

Table I. Potential measurements of the alkali metal-alkali amalgam cells

Cell	X, mole fraction	Temp, °C	E, volts

* Doubtful value, see discussion.

the Li amalgam case. Similar behavior of potential drift in nonaqueous cells was observed in PC (1, 21), DMSO (22, 23), DMF (24), and N-MF (25). True cell potentials were obtained by extrapolating to zero time in formamide (26, 27). The general agreement with the previous reliable data justifies the extrapolation procedure in the present work.

In conclusion, this fragmentary study establishes the feasibility of using propylene carbonate for thermodynamic measurements of the alkali metal amalgams.

Technical Notes

Hydrogen Production under Sunlight with an Electrochemical Photocell

Institute of Industrial Science, the University of Tokyo, Roppongi, Minato-ku, Tokyo, Japan

An electrochemical photocell has been reported (1) which consists of titanium dioxide (rutile type) single crystal as an anode, and platinum as a cathode. The photocell works under irradiation with light, leading to oxygen evolution on the anode and hydrogen evolution on the cathode. Quantum efficiencies of the cell increases with an increase in the alkaline concentration in the titanium dioxide anode compartment and in the acidic concentration in the cathode compartment (2). However, the use of polycrystal or amorphous titanium dioxide in place of its single crystal is desired from the practical standpoint of realizing a large scale electrochemical photocell.

Key words: hydrogen production, electrochemical photocell, titanium oxide film.

Among the various methods of forming oxide film on metal, the following three methods were studied in the present work: (*i*) electrochemical formation of oxide film on metal; (*ii*) thermal formation of oxide film in an electric furnace; and (*iii*) thermal formation of oxide film by simple heating.

Electrochemical formation of oxide film on titanium metal.—Formation of anodic oxide film on titanium was carried out potentiostatically or galvanostatically. The electrolyte solutions used were basic (1.0M NaOH) or acidic (0.5M H_2SO_4). Photoelectrochemical behavior of the oxide film electrodes was investigated using a 500W xenon lamp. Maximum photocurrent under anodic polarization of the oxide electrodes was about one-tenth of that on the single crystal rutile

electrodes. Electric resistivity of the semiconductor is desired to be as low as possible in order to effectively separate electrons and holes formed by irradiation with light in the space charge layer of the semiconductor surface. Moreover, the thickness of a photosensitive layer necessary to absorb light quanta is about 1,000 ~ 10,000Å. Therefore these low quantum efficiencies may be attributed mainly to the high resistivity of the oxide film and partly to its thickness being insufficient to absorb all incident light quanta, since the thickness of the oxide film was estimated to be about 3000 ~ 5000Å from its interference color.

Thermal formation of oxide film by means of an electric furnace.—Oxide films were thermally formed on the titanium metal plates at various temperatures in an electric furnace to which oxygen was supplied. The anodic photocurrents obtained with these oxide film electrodes were nearly the same as those films formed electrochemically. On the other hand, when a reducing atmosphere was maintained during the oxide formation in the electric furnace, the anodic photocurrents slightly increased. In the case of TiO_2 single crystal, photoelectrochemical behavior depends on the degree of the reduction treatment, because its electric conductivity related to the amount of the oxygen vacancies in the crystal may govern the probability of the recombination between the electrons and holes created by the irradiation with light (3). Further detailed investigations will be reported elsewhere.

Thermal formation of oxide by a gas burner.—A plate of titanium was heated in a fire of town gas. Oxide could be easily formed on titanium metal. Temperature of fire on Meker burner or Bunsen burner was varied between 1100° and 1400°C. Thickness of the formed oxide film seemed greater than those formed by electrochemical oxidation or thermal oxidation in the electric furnace. Anodic photocurrents on these oxide electrodes were nearly as large as those obtained with the single crystal rutile electrode. Figure 1 shows current-potential curves in 1M NaOH in relation to the temperature of heating for 5 min. These high photocurrents might be due to both the thickness of the oxide being enough to absorb the incident light quanta and the low resistivity of films. The crystal structure of the oxide was found by x-ray diffraction analysis to be the rutile type. Observation of the surface by an electron microscope revealed that the oxide was not a perfect crystalline structure. In the present experiments, the titanium oxide films formed in a flame temperature between 1300° and 1350°C for several minutes showed good photoelectrochemical behavior.

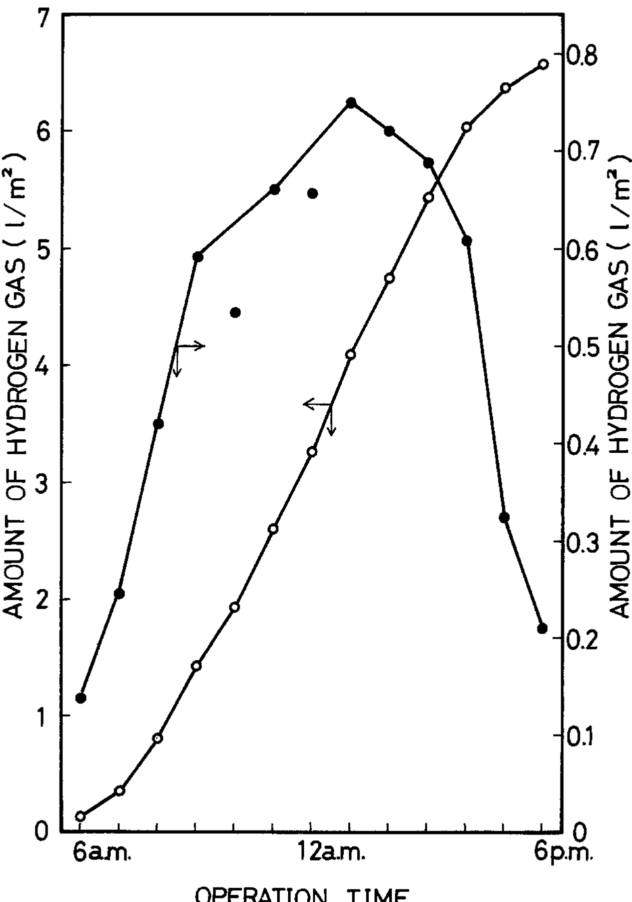

Fig. 3. Hydrogen evolution by the electrochemical photocell under the sunlight. ○: Total amount of hydrogen evolution, ●: hourly evolution.

Hydrogen production under the sunlight.—As described above, the titanium oxide electrodes made by these three methods showed different photoelectrochemical behavior, even when they were irradiated with the light of the same intensity. These differences are probably due to the electric conductivity of the oxide films, and partly to the thickness of the films.

It is possible to prepare, by a simple heating, titanium dioxide film on titanium metal plate which shows pronounced photoelectrochemical activity. The anodes studied were prepared by heating the titanium metal with a surface area of 85 × 100 mm with nine Bunsen burners. Figure 2 shows the geometric arrangement of the electrochemical photocell using twenty anodes coated with titanium dioxide film. The cell consisted of five platinum cathode and titanium dioxide anode units in which four anode plates of the above dimension were connected in parallel. The cell contained alkaline solution in the anodic compartments and acidic solution in the cathodic compartments. Separation between the anodes and cathodes was made with an agar salt bridge saturated with potassium chloride. In this arrangement, a potential drop through the solution or the salt bridge was not found. The total anodic surface area (Fig. 2) was about 0.17 m^2. Figure 3 shows the relationship between the operation time and the volume of the hydrogen collected under irradiation with the sunlight on a clear summer day. The intensity of the sunlight measured by means of Toshiba Photocell Illuminometer SPI-1 was about 110,000 lux from 11 A.M. to 2 P.M. We collected 1.1 liter per day using this photocell (6.6 liters of H_2 per m^2 of titanium dioxide). The combustion heat of this hydrogen is calculated to be 20 kcal/m^2 per day. The mean incident energy of the sunlight at the surface of the earth in Japan was reported (4) to be about 3000 kcal/m^2. As we measured the characteristics of the photocell in August, the incident energy of the sunlight might be larger than the mean one. The energy conversion efficiency of the photocell to the total sunlight energy is estimated to be more than 0.4%. As the energy ratio of the sensitive region of the titanium dioxide against the over-all spectral region of the sunlight may be below 10%, the quantum efficiency in the intrinsic absorption region becomes much larger.

Intricate-Pattern ECM on Ferrous Alloys

Mitchell A. LaBoda* and James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

In the electronics industry, the necessary circuit components are fabricated from various metals supported on a variety of substrates by generating the required, highly intricate patterns in the metal through a photomechanical method known as pattern etch machining (1-5). In a parallel development, another metal removing process known as electrochemical machining (ECM) (6, 7) has been investigated and evaluated which is based on controlled, high rate, anodic corrosion reactions. The ECM process can be used in a number of operations including plunge cutting, sizing, finishing, deburring and electrochemical grinding; but perhaps, the greatest advantage of this process is its speed in a replication application. This report describes the details of this ECM method and some of the underlying electrochemistry involved.

Experimental

The ECM fixture is composed of the cathode tool, the anode work piece, and all cell housing parts which are required to obtain a proper and uniform flow of electrolyte between the electrodes. In Fig. 1, the assembled fixture used in pattern ECM is shown; whereas in Fig. 2, a cross-sectional view of the fixture assembly is given. Essentially, the fixture consists of two machined blocks of brass separated from one another by an insulating layer of epoxy plastic. In operation, the two halves of the fixture were held together with insulated "C"-clamps and made leak-proof with an "O"-ring.

The cathode.—The top half of the fixture (50 mm × 150 mm × 20 mm) serves as the cathode. Two cross-hatched patterns (19 mm × 31.75 mm) of 12.6 lines/cm (32 lines/in.) were etched to a depth of 0.13 mm in the flat ground face of the brass block by a photomechanical method. Next, a layer of epoxy (2 mm

Key words: ECM, ferrous alloys, pattern ECM, $NaClO_3$ electrolyte.

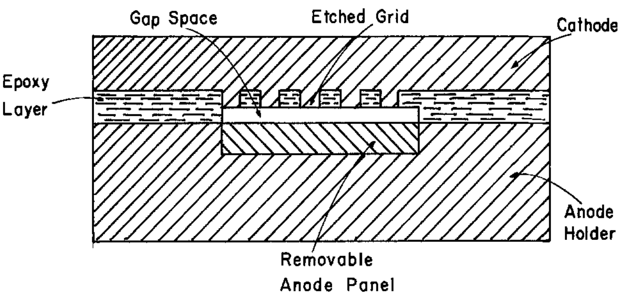

Fig. 2. Cross-sectional view of fixture for pattern ECM

thick) was applied to the etched face of the brass block; and after sufficient hardening of the plastic layer was achieved, the epoxy face was flat ground to within 0.45 mm of the cross-hatched face. A separate end mill machining operation was used to remove the plastic layer covering the two areas of the cross-hatched patterns. In this way, the exposed faces of a cross-hatched pattern of equally spaced lines are obtained and a gap space of 0.45 mm is formed between this cathode cutting face and the anode.

The anode.—The bottom half of the fixture (50 mm × 150 mm × 25 mm) serves as the anode holder. In the flat ground face of the holder, a cavity was machined which exactly accommodated the sample (20 mm × 90 mm × 1 mm); and on either side of this cavity, slots (5 mm × 80 mm × 10 mm) were machined as seen in Fig. 1 to provide a flow of electrolyte through the gap space between anode and cathode. Brass fittings were connected to the slots to serve as inlet and outlet ports for the electrolyte. A groove to hold the sealing "O"-ring was machined around the perimeter of the holder face.

The anode itself (the sample to be machined) was a mild steel panel (20 mm × 90 mm × 1 mm).

The ECM machining system.—The electrolyte required for the pattern ECM of steel was a solution of $NaClO_3$ (350 g/liter) which was pumped through the fixture by a turbine pump at flow rates ranging between 2 and 4 liters/min at a pressure of 1.4 atm and with the direction of flow perpendicular to the long axis of the sample. Direct current was supplied by a low voltage rectifier with a capacity of 0-3000A at 0-30V.

Procedure.—The sample panel was placed in the cavity of the anode holder and the cathode was clamped in place by an insulated "C"-clamp. After connecting the inlet parts to the pump and the outlet parts to the electrolyte reservoir, the $NaClO_3$ solution was pumped through the fixture. A preset voltage of 5V was applied between anode and cathode. Then ECM was carried out for up to 9 sec after which the current and solution flow was shut down so that the solution flow could be reversed by outside valving. Finally, ECM was continued with reverse electrolyte flow for the same length of time.

Results and Discussion

In the course of this work, it was found that the gap space between cathode and anode is a critical parameter. A steel panel blank is shown in Fig. 3A, and in Fig. 3B, the pattern machined in the panel by pattern ECM at a gap space of 0.45 mm shows washed out features. By flat grinding the plastic layer on the cathode, the gap space can be made narrower. At a gap space of 0.20 mm (Fig. 3C), an acceptably sharp pattern is obtained. The depth of this cut was 0.05 mm in Fig. 3C, but cuts of 0.1 mm can be obtained with only a small loss of resolution.

Dependency of the resolution of the pattern on gap space can be understood in terms of the passivation of steel in strongly oxidizing electrolytes. It was suggested (8-10) that the ECM process takes place in the

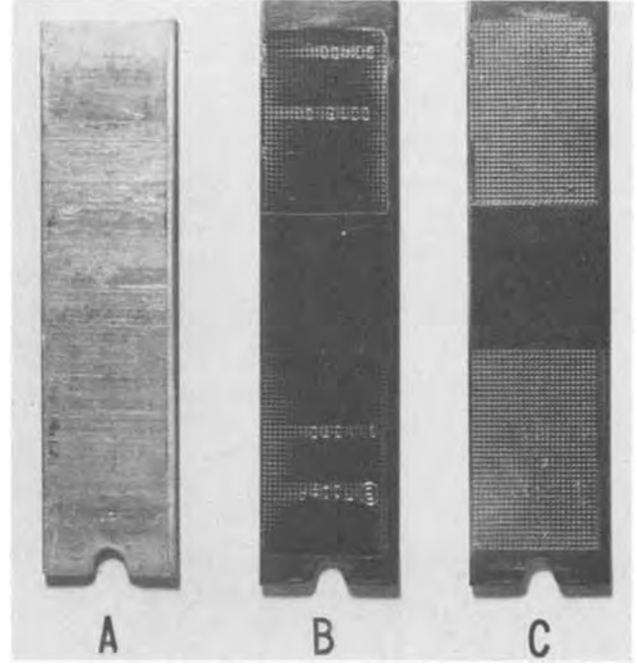

Fig. 3. The test panels of mild steel, 20 mm x 90 mm x 1 mm: (A) the blank; (B) a washed out pattern because of wide gap space or excessively high applied potential; (C) a sharp pattern obtained at a gap space of 0.20 mm, at a preset applied voltage of 5V, and a solution flow rate of 2 liters/min.

transpassive region where breakdown of the passive film on steel in $NaClO_3$ solution occurs and high rates of metal removal take place.

For a given applied voltage, V, across the anode and cathode, the potential, E, controlling the metal-removal process at the anode is determined by the relationship, $E = V - IR$, where I is the current passed and R is the ohmic resistance of the solution path. At sites on the anode directly opposite the exposed metal sites on the cathode, the current path is short, the IR is small, E is large so that the process occurs in the transpassive region (8) and high metal removal rates occur. For the high currents passed (of the order of 50 A/cm^2), even a small value of R can result in a large value of IR. Consequently, at sites remote enough from the exposed cathode sites, the IR becomes so large that the value of E is shifted towards less noble values where the process enters the passive region (8). Under these conditions, metal removal virtually ceases.

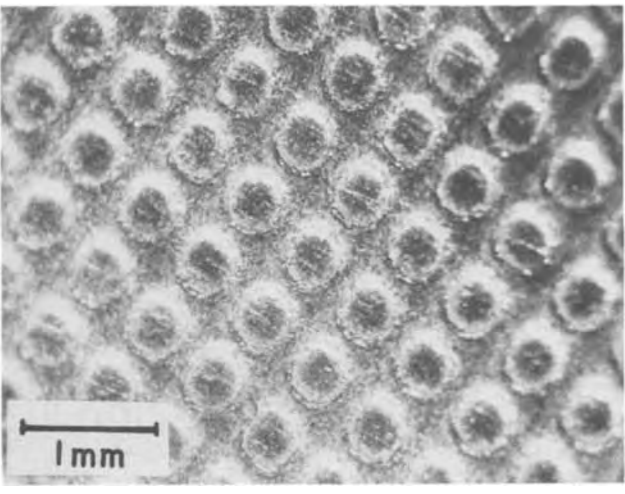

Fig. 4. Photomicrograph of pattern of 12.6 lines/cm (32 lines/in.) machined by pattern ECM in steel with $NaClO_3$ electrolyte.

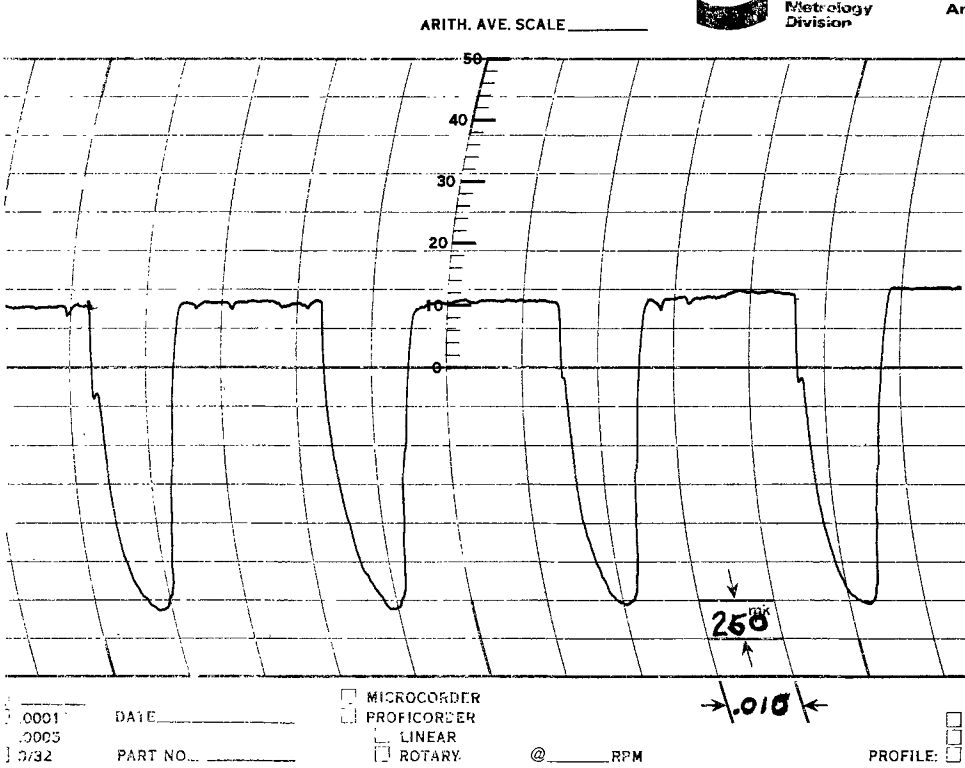

Fig. 5. Proficorder trace of a 12.6 lines/cm (32 lines/in.) pattern machined by ECM to a depth of 0.051 mm in mild steel in 18 sec; X-axis = 2.5×10^{-3} mm/div; Y-axis = 6.25×10^{-5} mm/div. The trace shows the uniformity of depth and land-to-groove ratio obtained on steel in $NaClO_3$ solution.

Conversely then, there may be some metal removal from anode sites which are only slightly removed. For this reason, the imprints of dots are rounded rather than square as noted in the photomicrograph of the machined pattern in Fig. 4. The proficorder trace in Fig. 5 shows that the tops of the dots are quite flat with tapering of the sides.

When the gap space is increased, V must be raised to maintain E at the same value if the same current density at the anode is desired since the current path has been lengthened. At this larger gap space, however, the percentage difference between the direct and remote current paths becomes less and the increase in IR may not be large enough for the remote current paths to cause a passivation of the remote anodic sites. Because some metal removal can take place at these remote sites, a washing out of the pattern can occur as in Fig. 3B.

Another sensitive parameter is the applied voltage, V. If V is too large, the IR of even the longest current paths may not be great enough to lower E into the passive region. Washing out of the pattern occurs in this case, also. One must operate at a value of V so that E is not too far removed from the point corresponding to the passive-transpassive transition of the polarization curve (8). The polarization curve for iron and steel in $NaClO_3$ solution has a relatively sharp transition from the passive to the transpassive region (8) which makes it possible (12) to obtain excellent control of dimensions at high metal removal rates and good surface finish.

The optimum operating values for V and the solution gap distance are found by trial and error. In general, as the pattern becomes finer V must be lowered and the gap space must be reduced because the difference between the direct and remote solution paths must be maintained as great as possible. Some modification of the solution flow rate may be required, but this parameter has less influence on the resolution of the pattern.

The pattern in Fig. 3C was produced in a total machining time of 18 sec at $V = 5V$ and a flow rate of 4 liters/min.

As can be seen from Fig. 5, the width of the ECM'd cut was 0.25 mm. The width of the cathodic grid line employed in the ECM cutting was 0.13 mm. Thus, in these experiments it appears that the overcut, the ratio of the ECM'd line width to the cathodic line width, is about 2. This ratio could be reduced to obtain finer patterns by either reducing the gap space or by reducing the cathodic line width, but each would present attendant difficulties.

On the Electrocatalytic Activity of Electrodeposited Palladium on Pyrolytic Graphite

Ikram Morcos*

Hydro-Quebec Institute of Research Varennes, Quebec, Canada

Data on the reduction of oxygen at the palladium electrode in both alkaline and acidic media have already been reported in the literature (1-5). In alkaline medium, Sobol *et al.* (1) obtained current-potential plots, which show limiting currents, that gradually deviate from theoretical Levich plots, with the increase in the rotation rate of the disk electrode. In acid medium, the reduction currents were found to decrease steadily with time until their values become significantly lower than the corresponding values in alkaline medium.

In the present communication experimental results are presented to show the difference between the electrocatalytic activity toward oxygen reduction of both bulk palladium electrodes and electrodes prepared by the electrodeposition of a palladium layer on pyrolytic graphite substrates. Current-potential curves were obtained as a function of the disk rotation speed on both types of electrodes by slow scanning voltammetry in acid and alkaline media.

The current-potential curves obtained in oxygen-saturated 0.1*N* KOH solution in the potential range between 0.2 and −0.5V (Hg/HgO) show on both palladium surfaces linearly shaped limiting current at rotation speeds between 400 and 10,000 rpm. Plots of the limiting current *vs.* the square root of rotation speed are compared in Fig. 1 with the corresponding theoretical Levich plot for an over-all 4-electron oxygen reduction process. It is seen from Fig. 1 that the electrodeposited palladium has a higher electrocatalytic activity than the bulk palladium and that the difference in the activity increases with the increase in rotation speed.

The difference in the electrocatalytic activity was found to be even more significant in acid medium. Higher current densities (notice that the apparent area is not the same) and greater rotation dependence were observed on the electrodeposited surface. The difference in the electrocatalytic activity persisted regardless of the magnitude of the starting potential and the rate at which the potential was scanned. Figures 2 and 3 show the current-potential characteristics of both palladium electrodes in an oxygen-saturated 1.0*N* H_2SO_4 (ultra pure grade) at different rotation speeds, and a very slow scanning rate of 0.025 V/min to assure the attainment of steady state. Notice that the limiting currents which are under both diffusion and kinetic control are observed on the electrodeposited palladium but not on the bulk electrode.

The interpretation of these observations must take into account the dispersed nature of the palladium deposit on pyrolytic graphite. The present data, however, suggest that the deposited palladium may have different intrinsic electrocatalytic properties which are

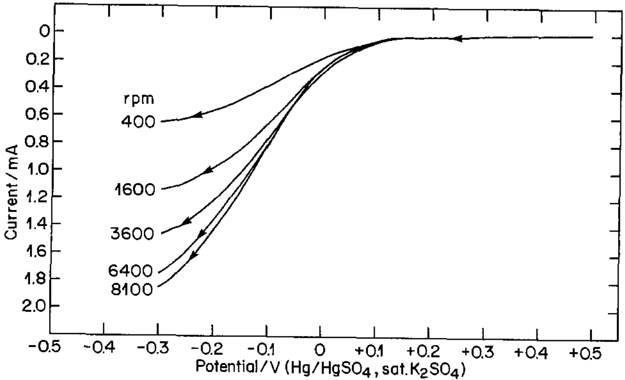

Fig. 2. Current-potential curves for O_2 reduction on a palladium surface electrodeposited on pyrolytic graphite at different rotation speeds in O_2-saturated 1.0*N* H_2SO_4 solution. Potential scanned at a rate of 0.025 V/min in the cathodic direction. Electrode area is 0.338 cm^2.

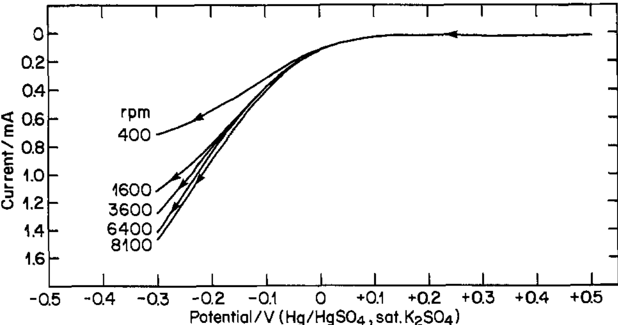

Fig. 3. Current-potential curves for O_2 reduction on a mechanically polished bulk palladium electrode at different rotation speeds in O_2-saturated 1.0N H_2SO_4 solution. Potential scanned at a rate of 0.025 V/min in the cathodic direction. Electrode area is 0.478 cm^2.

not accounted for by the mere increase in true surface area. Voltammetric experiments in helium-saturated solutions indicate a variation in the characteristics of oxygen adsorption on both palladium surfaces. An investigation of the actual mechanism of oxygen reduction on both palladium surfaces is presently being carried out with the aid of the rotating disk electrode with ring. Differential capacity and electron scanning microscope techniques are used to detect variation in surface area and structure. A study of the electrochemical nucleation of palladium on pyrolytic graphite and possible correlation with the observed electrocatalytic aspects is also in progress.

Complex Ions and Corrosion

R. T. Foley*

Department of Chemistry, The American University, Washington, D.C. 20016

It is indeed remarkable the extent to which environmental effects are ignored in the development of corrosion mechanisms and concepts related to the passivity of metals and alloys. The specific anion effect in stress corrosion cracking has been well documented in the corrosion literature. Yet proposed mechanisms for stress corrosion cracking are put forth which incorporate purely mechanical phenomena. In the development of passivity mechanisms, including the formation of passive films, the composition of the electrolyte has been given virtually no consideration except in so far as it provides protons and hydroxyl ions. Yet the breakdown of passivity is often tied to specific ion adsorption and the chloride ion is attributed with unique properties that are evident for this ion in no other area of chemistry.

The purpose of this communication is to reexamine the role of environmental effects, specifically anion effects, with the view of establishing a concept that will be a useful and guiding principle describing the influence of anions in corrosion and passivity.

It is first desirable to characterize the actual environment in which a metal cation finds itself as it passes from the atomic to the ionic state. In most situations of concern to corrosion investigators the environment in which the metal cation finds itself at the instant of ionization is one of a concentrated aqueous electrolyte. This point has been well demonstrated experimentally, particularly during the last decade. A few of these observations wherein the composition of the environment at the actual corrosion site has been described may be cited.

Significant concentration gradients exist in the electrolyte resident in crevices formed on Fe-Cr alloys (1).

There is a build up of metal ions and a decrease in pH (to 1.7 from initially neutral solutions) in the electrolyte in the advancing crack of the stress-corroding specimen (2).

In crevices formed on Type 304 stainless steel by the action of a differential aeration cell in seawater the pH falls to 1.2-2.0 and the ferrous ion concentration increases (3).

The chloride ion concentration builds up in the anolyte of a corrosion cell developed on the surface of steel corroding in dilute solutions of sodium salts of weak acids (4).

The wide-spread occurrence of such conditions in real corrosion situations has led to the concept of the "occluded corrosion cell" (5). The general finding is that in these real corrosion sites the electrolytic solution is quite concentrated and is often of very low pH.

The consequence of this real environment (the concentrated electrolytic solution) becomes immediately apparent. The metal atom, as it passes from the metallic lattice and is ionized is immediately surrounded by an ion atmosphere of negatively charged species located at relatively close distances. This is evident from the simplest calculation employing Avogadro's number to calculate the geometrical distribution of ions in a solution of a given molarity. For example, in a one molar solution of $FeCl_2$ the closest neighbor distance is 8.2Å; for a two molar solution the distance is 6.5Å. This distribution, of course, was specifically recognized in the development of the Debye Hückel theory (6) for ionic solutions as well as the Gouy-Chapman model (7) for the double layer. The assumption is made that the central (positive) ion is, on a time average basis, surrounded by a negatively charged atmosphere. The radius of this interionic atmosphere is calculated from the Debye-Hückel equation for a bi-uni aqueous electrolyte ($FeCl_2$) as 5.56Å for a 0.1M solution and 1.76Å for a 1M solution.

The existing theories dealing with the structure of concentrated solutions leave much to be desired but one of the most reasonable and most useful concepts

* Electrochemical Society Active Member.

Key words: corrosion, complex ions, passivity, concentrated solutions, electrolytes.

is that proposed by Bjerrum (8, 9) and extended by Kraus and Fuoss (10). The ion-pair theory would identify a minimum (distance) in the plot of the distribution of oppositely charged ions about a central ion. For a uni-univalent electrolyte this distance of separation is approximately 3.57Å, for a bi-uni electrolyte the distance is 7.14Å. According to Bjerrum, ions approaching closer to the central ion than this minimum distance are considered to be associated and to exist as "ion-pairs." These are species that are completely ionized but for symmetrical electrolytes have no net charge, *i.e.,* would not migrate in an electric field. In dealing with concentrated solutions it is obvious that the statistical probability of a metal cation and an anion being within this critical distance is quite high. Ion pairing, according to the Bjerrum theory is favored by (*i*) higher valence cations and anions and (*ii*) a lower dielectric constant, two conditions that obtain adjacent to a metal strip immersed in a corrosive solution.

The net conclusion to be drawn from these considerations is that in the interfacial region, adjacent to the corroding metal, specific cation-anion species must exist. It might be argued that such close approach to the metal would make adsorption quite probable, but it is not necessary to postulate any adsorption process to draw the conclusion that anions must participate directly, in the chemical sense, in the dissolution reaction.

Any mechanism that is proposed for passivity or to describe the anodic dissolution process of a metal must start with a realistic count of the ions available for adsorption or interaction. Thus, the inhibition of the dissolution of iron by iodide ions has been correlated with the adsorption of iodide ions on iron as expressed by a Langmuir adsorption isotherm which established the concentration-dependency of the reaction (11). Such an experimental study recognized the need to take into account the available concentration of iodide ions. Further, such considerations must be prerequisite to the development of any corrosion mechanism. Consider, then, a solution of NaCl, one molar in concentration with a *p*H of 1. The concentrations of chloride ions and hydroxide ions are 1 molar and 10^{-13} molar, respectively. It would be very difficult to support a mechanism involving the competitive and preferential adsorption of hydroxide ion over chloride ion when the chloride/hydroxide ratio is 10^{13}.

From these rather basic considerations and from a consideration as well, of literature reports on iron corrosion and passivity one is led to the concept that the anions present in the environment must enter directly into the dissolution and passivation process. It is proposed that this is accomplished by the formation of specific metal-anion species, complexes, that are transitory in some cases, stable and insoluble in others, but in all cases are an essential part of the process.

Because of the transitory nature of these complexes it is difficult to obtain direct experimental evidence for their existence. However, there are a number of lines of evidence supporting this concept and these may be cited.

1. The direct spectrophotometric observation of iron-anion species produced by the dissolution of iron in acid solutions containing various anions (12). Under oxidizing conditions each anion yields a specific spectrum.

2. The feasibility of assigning specific ions to either the anodic or cathodic part of the corrosion process (13). Thus sulfate ion is involved in the cathodic process whereas chloride ion is involved in the anodic.

3. The effect that specific anions have on the functioning of inhibitors (13), e.g, chloride ion interferes with "anodic" inhibitors but not "cathodic."

4. The differences in activation energies observed for the corrosion of iron in acid solutions containing different anions (14). The measurements were at constant *p*H (*i.e.,* constant OH^- concentration). Not only the rate but the activation energies are different.

5. The observation that the adsorption of chloride ion and sulfate ion on iron is interdependent, may be competitive or synergistic (15).

6. The anodic corrosion current for iron in various electrolytes is a function of the anion in solution, perchlorate > sulfate > chloride > acetate > nitrate (16).

7. The inhibition of iron corrosion in very concentrated ferrous chloride solution (17).

8. A stoichiometric order of reaction existing with chloride ions in the pitting initiation reaction on passive iron (18) or stainless steel (19).

9. The dependence of electrochemical reaction order for the dissolution of iron in concentrated solutions on the chloride concentration (20).

Other lines of evidence may be cited. But the burden of evidence indicated that any mechanism of passivity, or any mechanism for metal dissolution, must include a consideration of the formation and existence of metal-anion complexes. Moreover, the rate of dissolution or degree of passivity must be correlated with the stability of these complexes.

Growth and Structure of Nickel Oxide on Nickel Crystal Faces

N. N. Khoi,* W. W. Smeltzer,* and J. D. Embury

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

The structures of films of NiO 300Å-15μ thick formed on (100), (110), and (111)Ni crystal faces at temperatures in the range 500°-800°C were investigated by electron microscopy and x-ray diffraction. The oxide was initially polycrystalline but rearranged as the oxide thickened to major epitaxial relationships with the metal substrate. These relationships were characterized by coincidence between the close-packed directions of the metal and oxide; the number and type of oxide orientations were correlated with the number of close-packed directions in the metal faces. Oxide thicker than 1μ exhibited preferred {100} and {111} orientations. The oxide on (100) and (111)Ni exhibited the highest preferred orientation and a duplex layer structure consisting of equiaxed crystallites in the inner layer and columnar ones in the outer layer. These findings are rationalized in terms of a diffusional model for the growth of these oxide layers in which the reaction rate is determined by boundary and lattice diffusion of nickel through nickel oxide.

The growth kinetics of nickel oxide films and scales on nickel at temperatures less than 1000°C have been shown by several investigators to be related to the oxide morphologies developed (1-12). For both polycrystalline nickel and a variety of single-crystal orientations the rates of metal oxidation have been interpreted in terms of the character and number of easy diffusion paths such as dislocations and boundaries in the oxide. The oxidation rate is enhanced most in comparison to the rate expected solely from lattice diffusion when the easy diffusion paths in the oxide are high angle boundaries between crystallites of small diameter. This type of behavior extends to scales of the order 10μ in thickness due to the relatively small value of the nickel lattice diffusivity and the small size of the nickel oxide grains.

Herchl *et al.* (7) recently determined the oxidation kinetics of (100), (110), and (111)Ni faces at oxide thicknesses encompassing both the film and scale formation regions at temperatures in the range 500°-800°C. The kinetics were interpreted by a model wherein nickel transport occurred by boundary and lattice diffusion. In the present investigation, a structural study of the crystallite and grain sizes, orientations, and textures has been made of the films and scales formed on the (100), (110), and (111) faces in order to obtain a more complete understanding of these variables on the magnitudes of oxidation rates.

Experimental

Electropolished cylindrical specimens, 1 mm thick $\times$ 13 mm diameter, were prepared from 99.999 weight per cent (w/o) Ni crystals to within $\pm 2°$ of a crystallographic plane by metallographic and electropolishing techniques (13). Four specimens were simultaneously exposed by means of winches using platinum wire and quartz rods in a quartz reaction tube suspended vertically in a furnace controlled to $\pm 2°$C. These specimens were subjected initially to a vacuum anneal at 3×10^{-6} Torr for 18 hr at 800°C whereupon they were raised from the furnace and exposed at room temperature to research grade oxygen containing <2 ppm H_2O. After setting the furnace at the reaction temperature, the specimens were lowered by means of the winches and exposed to oxygen at 400 Torr pressure for various time periods. Oxide thicknesses were determined by weight gains of the specimens to a precision of ± 0.5 $\mu g/cm^2$ (1 μg O/cm^2 = 62Å NiO). Throughout this paper the thickness of an oxide film was deduced from the weight gain measurement assuming uniform thickness. For films >2000Å thick a considerable degree of nonuniformity was observed and the thinner regions of these films were examined by transmission electron microscopy (TEM) for films of average thickness up to 5000Å.

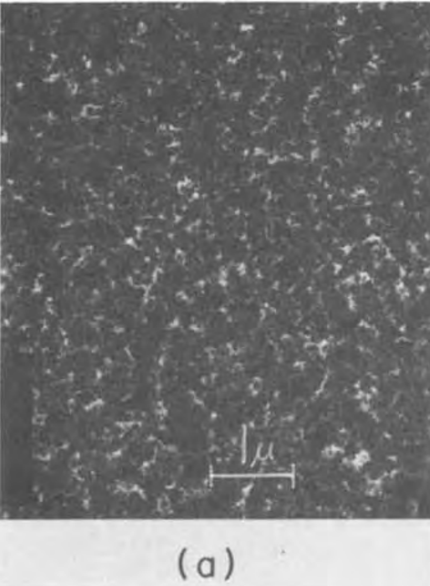
Films <5000Å thick were stripped from the metal using a saturated solution of iodine in methanol (5) and examined using bright field (BF), dark field (DF), and selected area diffraction (SAD) in the transmission electron microscope. Scanning electron microscopy (SEM) was used to study oxide cross sections >1μ thick prepared by mounting specimens in room setting epoxy resin with two strips of stainless steel arranged parallel to the oxide surface and polishing to 1μ diamond paste. The oxide structure became revealed upon anodic etching in a 1:1 HF-acetic acid solution at a potential of 3-5V for 1-5 min.

Preferred orientations of the oxide within scales were determined by reflection x-ray diffraction (XRD) using the inverse pole figure method proposed by Harris (14). This method consisted of a comparison of the integrated intensity of peaks from scales to those from randomly dispersed oxide obtained by counting the pulses from a rotating specimen at each peak maximum. The texture coefficient of a (hkl) plane then is

$$P_{hkl} = \frac{I_{hkl}/I_{r,hkl}}{\frac{1}{n}\sum I_{hkl}/I_{r,hkl}} \quad [1]$$

* Electrochemical Society Active Member.

Key words: NiO films and scales, NiO structures and growth.



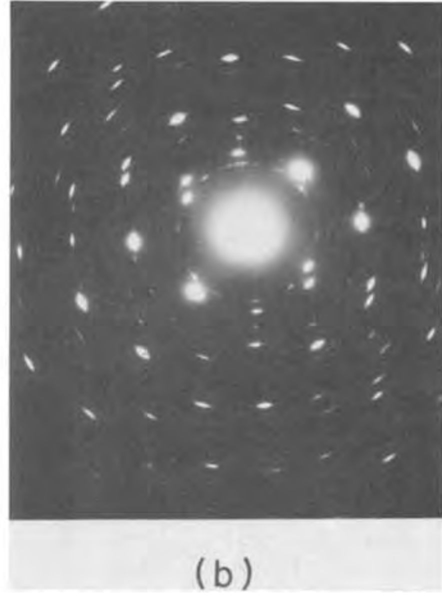


Fig. 1. TEM micrographs of 350Å NiO film formed on (100)Ni. (a) BF, (b) SAD pattern.

where I_{hkl} and $I_{r,hkl}$ are integrated intensity from peaks of the textured and randomly oriented oxide, respectively, and n is the number of peaks examined.

The average size of the crystallites in films up to 3000Å thick were determined by TEM using the DF technique. The distribution of the crystallites was plotted as a fraction of crystallites *vs.* size and the average crystallite size calculated from this distribution for each film. A similar procedure was adopted to determine the average size of grains in scales $>1\mu$ thick by the SEM technique.

Results

TEM.—The structure of films in the range 300-3000Å was determined using BF, DF, and SAD methods. It was not possible to observe directly the orientation relationships between the film and the metal substrate or to know the relative position of the film once it was removed from the substrate. Thus any relationship between the film and the substrate must be deduced from the TEM and compared with models of oxide growth and previous experimental evidence in order to develop a consistent description of the oxide growth process. However, the TEM observations do permit observations of the relative frequency of various crystallographic orientations in the oxide film, the relationship between these structures, and the distribution of the crystallites within the film. In complex cases composed of mixed orientations it is difficult to describe the spatial distribution of crystallites due to the occurrence of double diffraction and the difficulties inherent in the use of intensity variations in the SAD patterns. Observations from 300-5000Å NiO films formed at 500°C are shown as BF, DF, SAD micrographs in order of increasing thickness.

(100)Ni: The uniformly thick films were composed of 300-400Å size crystallites in the early oxidation stages which gradually increased to 700-900Å size after 8 hr exposures. Some crystallites were randomly oriented as evidenced by weak polycrystalline SAD patterns but most were of the type (100), (110), and (111) with fewer cases of (211) and (233).

Figure 1 shows a 350Å film which consists of crystallites 300-400Å in size. Some randomly distributed crystallites contributed a faint ring pattern as illustrated in the SAD pattern. Most crystallites, nevertheless, exhibit (100), (110)NiO//(100)Ni. The DF micrographs from a variety of reflections from both SAD patterns showed that the (100) and (110) oriented crystallites are randomly distributed. The SAD pattern in Fig. 2 from another section of this film represents (111), (211), (233)NiO//(100)Ni. The structure of films up to 1000Å thick did not change appreciably with the exception that (100)NiO became more pronounced.

(110)Ni: The most striking features of the films were the large number of structures accompanied with twins and dislocations. For example, within areas of an isolated film, diffraction patterns were obtained showing a mosaic structure, twins and crystallites exhibiting up to six different orientations. Eleven orientations were actually identified, ten of which can be divided into two sets. The first set was (100), (110), (111), (211), (311), (322), (411), (433)NiO||(011)Ni and the second set was (210), (310)NiO||(110)Ni. In addition some evidence was found for the (123)NiO orientation parallel to the (110)Ni face. These orientations changed with increasing film thickness and a trend similar to that for the oxide on (100)Ni was established since films up to 700Å thick exhibited a large number of oxide orientations including high index planes. These latter planes disappeared as the oxide thickened and in films exceeding 2000Å low index planes were predominantly observed.

For illustrative purpose, electron micrographs of a 500Å film are shown in Fig. 3 and 4. The BF and SAD

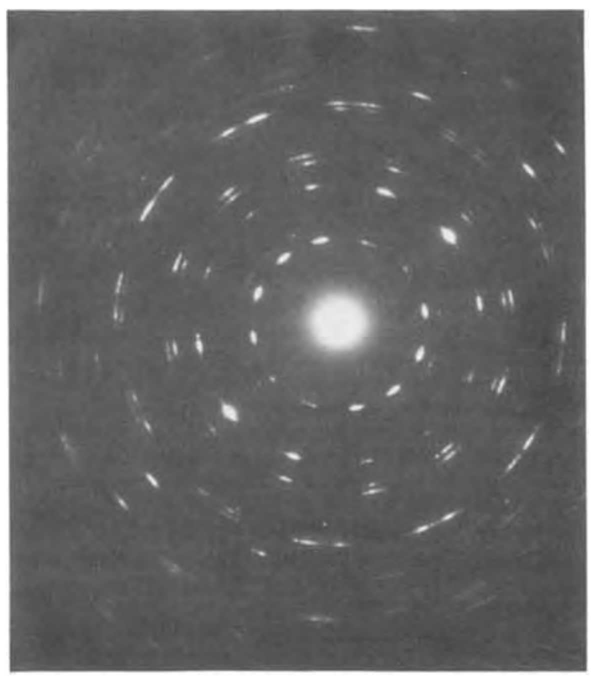

Fig. 2. SAD pattern of 350Å NiO film formed on (100) Ni

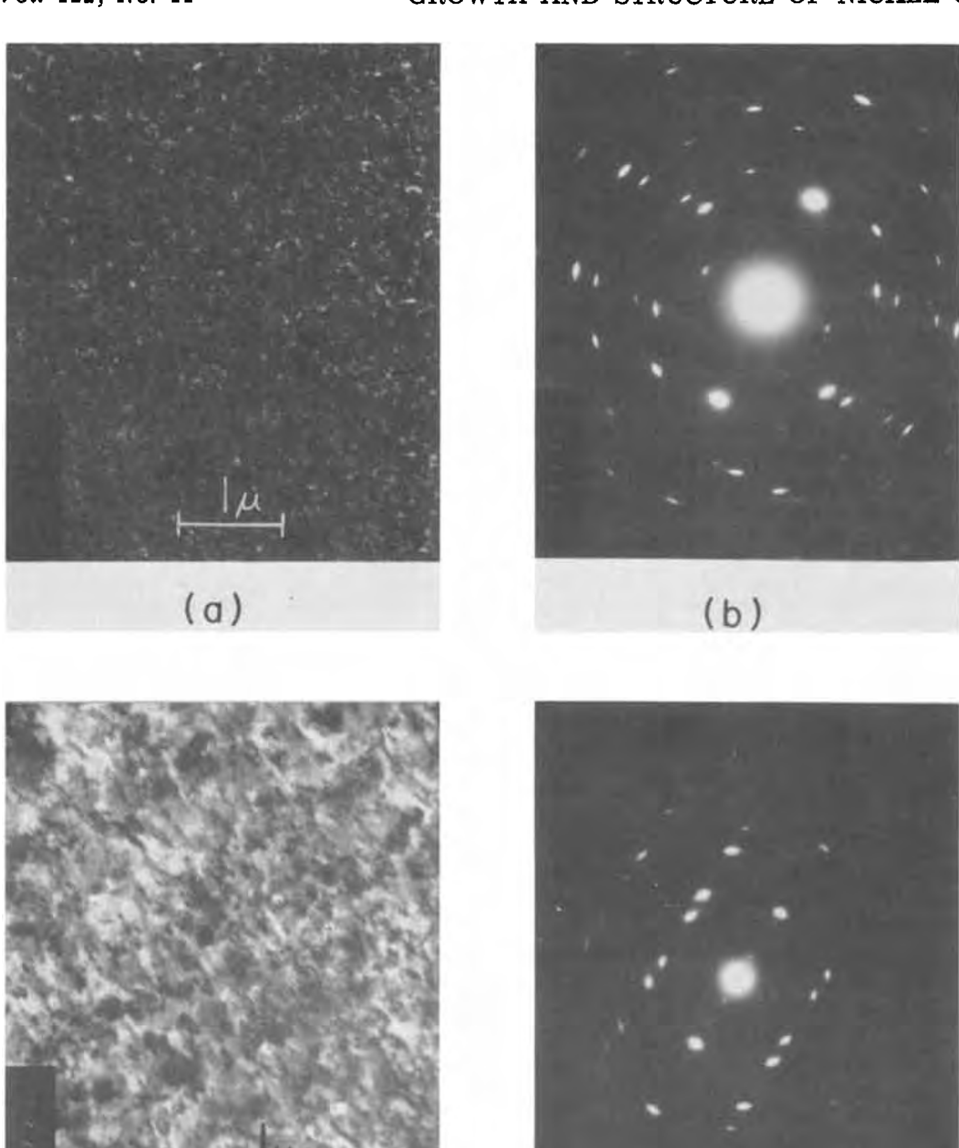

Fig. 3. TEM micrographs of 500Å NiO film formed on (110)Ni. (a) BF, (b) SAD pattern, (c) BF, (d) SAD pattern.

micrographs in Fig. 3(a) and (b) reveal that the film is composed of relatively uniform sized crystallites which when indexed contain oxide with (111), (211), (311), (321), (322), (411), (433)NiO||(110)Ni. In Fig. 3(c) and (d), the BF micrograph does not reveal twin plates, but the SAD pattern shows that twinning of crystallites has occurred as this composite pattern is obtained by rotating the (110) Relp 180° around the $[11\bar{1}]$ direction. Such rotation around a twin axis perpendicular to the electron beam shows, moreover, that the twin boundary lies perpendicular to the plane of the oxide film. The (100)NiO crystal pattern shown in Fig. 4 from another film section corresponds to a mosaic structure in which the crystallites are arranged to each other by very small misorientations. Films >1000Å were irregular and contained dislocations.

(111)Ni: The structure of films on this surface were similar to those on (100)Ni. Five orientations were observed and the presence of a mosaic structure or twins was not detected. An interesting feature was the multiple occurrence of the same orientation including up to six (211) and (233)NiO planes in a single SAD pattern. The multiple orientations (111), (211), (233)NiO||(111)Ni could be divided into two sets A and B characterized by $[0\bar{1}1]$NiO||$[0\bar{1}1]$Ni(A) and $[0\bar{1}1]$NiO||$[11\bar{2}]$Ni(B). The orientation (011)NiO||(111)Ni satisfying $[0\bar{1}1]$NiO||$[0\bar{1}1]$Ni was also observed. The B set disappeared in films >1000Å and the (233) and (211) of the A set were seldom observed. 3000Å films also evidenced some polycrystallinity.

These features are illustrated by the following micrographs. Properties of a 500Å film are shown in Fig. 5(a) and (b); the crystallites are indexed as (011), (211)NiO||(111)Ni with faint reflections arising from the (310) orientation. There are two (211) orientations: one shares a common close-packed direction (cpd) with (110) oxide and the other is rotated 30°. Figure 5(c) shows a 1300Å film containing (011) and (211)NiO and dislocations. The 3500Å film shown in Fig. 6 is irregular with evidence of both preferred orientation and polycrystallinity.

NiO crystallite size distribution: TEM was used to determine the size of crystallites in films up to 1000Å thick formed at 500°C during exposures extending to 6 hr. The distributions and the average size of the crystallites as a function of exposure time are illustrated by the plots in Fig. 7 and 8. These parameters

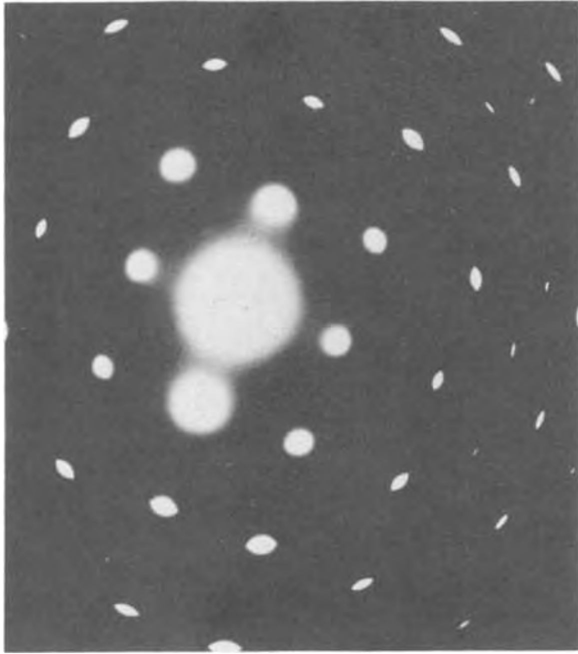

Fig. 4. SAD pattern of 500Å film formed on (110)Ni

did not appreciably change within 30 min. Subsequently the crystallites on each metal face grew at characteristic rates which decreased with time.

XRD.—The textures were determined of scales 1-15μ thick formed at temperatures in the range 500°-800°C. Line broadening by strain and particle size was negligible in agreement with previous findings (6, 15). Accordingly Eq. [1] was used to determine the oxide texture based on the examination of seven reflection peaks. Typical results are shown in Table I and the resulting major oxide orientations are plotted *vs.* scale thickness in Fig. 9. The oxide on (100)Ni exhibited strong (100) and (111) orientations. The oxide on (110)Ni developed a (100) preferred orientation whilst the oxide on (111)Ni showed a (111) preferred orientation.

SEM.—A scale on (100) or (111)Ni exhibited a duplex morphology characterized by layers of equiaxed columnar grains as shown in Fig. 10, which was not found in the scale on (110)Ni. The inner layers of duplex scales exhibited a small degree of porosity. This duplex morphology revealed differences depending on whether the oxide was formed at high or low temperature: at 800°C the boundary between the layers was diffuse since the size of grains in each layer was not much different; whereas, at 600°C a well-defined boundary occurred since the grains in the outer columnar layers were distinctly larger. Average grain sizes and the relative layer thicknesses are recorded in Table II. The grains grew during oxidation at rates increasing with temperature and the oxide grain size on the Ni faces tends to be in the order (110) > (111) > 100.

Discussion

NiO morphology.—The oxide formed on the three metal faces was composed of aggregates of crystallites exhibiting orientations which appear to be determined both by the orientation of the metal surface and by subsequent growth mechanisms since the orientations changed with thickness as summarized in Fig. 11. In order to rationalize the influence of the substrate a model is proposed based on the parallelism between cpd's in the film and substrate. In Fig. 11, lines drawn across the Ni and NiO symbols are close-packed directions and the angle between the lines represents the angle between these directions. The family of oxide crystallographic planes lying parallel to the metal surface is shown in a brace, the number before this brace representing the number of observed equivalent orientations.

(100)Ni can be characterized by two cpd's 90° apart. Five different oxide orientations were observed in thin films. Most crystallites with orientations (100), (011), (111), (211), (233)NiO||(100)Ni can be rationalized by the relationship $[0\bar{1}\bar{1}]$NiO||$[0\bar{1}\bar{1}]$Ni. The (211) and (233) orientations, nevertheless, occur in multiples of six: two can be considered to have the directions $[0\bar{1}\bar{1}]$NiO||[011]Ni and the remaining four have <011> NiO at ±30° from the Ni cpd. The (111), (100)NiO-Ni epitaxial relations have been previously reported based on reflection electron diffraction from films retained on this metal face (13). The reported two (111) sets are equivalent. The most noticeable change is the disappearance of several orientations with increasing oxide thickness until only the (100) and (111) planes and polycrystallinity remain. These (100) and (111) preferred orientations in scales probably developed from the presence of these oriented crystallites in the films.

Eleven different oxide orientations were found in the films formed on (110)Ni which only contains one cpd. Ten of these orientations can be divided into two sets. The first set is (100), (011), (111), (211), (311), (322), (411), (433)NiO||(110)Ni characterized by $[0\bar{1}1]$NiO||$[0\bar{1}\bar{1}]$Ni and the second set is (210), (310)NiO||(110)Ni satisfying [001]NiO||[001]Ni. ally (123)NiO||(110)Ni satisfied [11$\bar{1}$]NiO||[001]Ni. The epitaxial relations for the (100), (011), and (211) oxide planes have been previously reported (16). The (210), (310), and (123) orientations were seldom observed. The remaining eight orientations were frequently found and all contain at least one cpd which can lie parallel to the Ni cpd. Several of these orientations represent high index planes and of these only the (411) has been reported (16). Previous reflection x-ray diffraction work has indicated that the oxide on this face was polycrystalline (6). Also a 110 fibering-type structure has been reported (17) which probably refers to the series of planes including the high index planes found here sharing a common <110> direction. Gradual changes in orientation were only observed as the oxide thickened and the (100) orientation which finally dominated in a thick scale must have developed during oxide growth since it was not a major orientation in films.

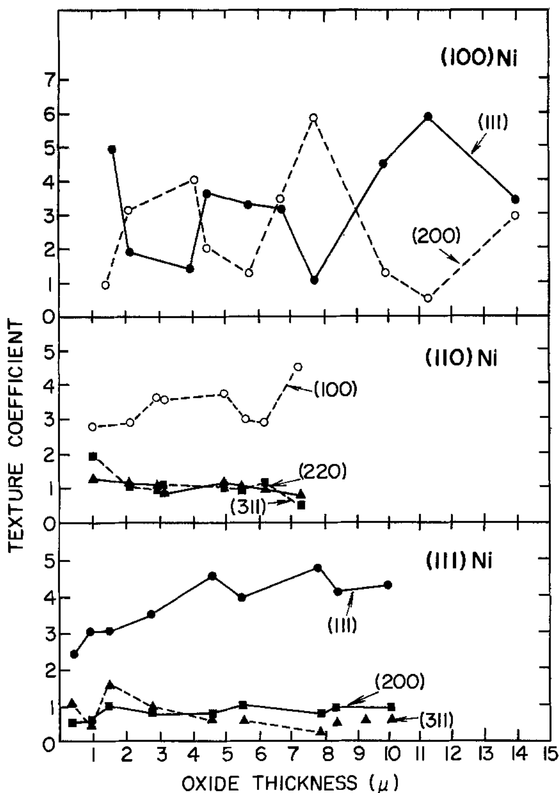

Fig. 9. Texture coefficients of NiO scales formed on (100), (110), and (111)Ni.

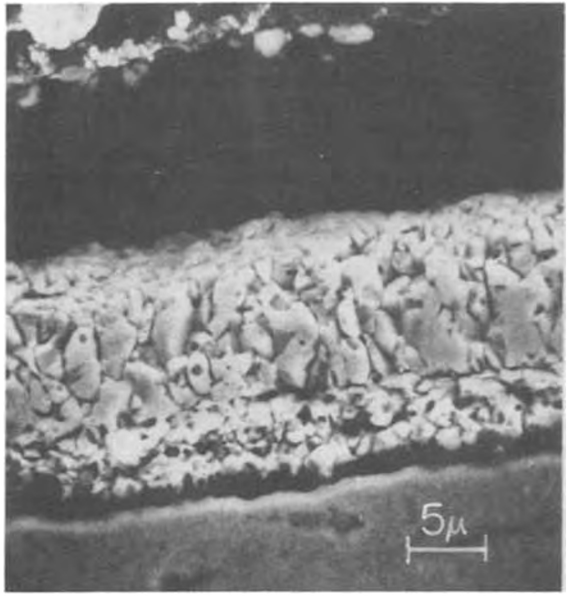

Fig. 10. SEM cross section of NiO scale formed on (100)Ni oxidized at 800°C for 120 hr.

(111)Ni is characterized by the maximum number of three cpd's 60° apart. Five different oxide orientations were observed and of these (111), (211), (233)NiO|| (111)Ni satisfy the epitaxial relations [0$\bar{1}$1]NiO|| [0$\bar{1}$1] or [11$\bar{2}$]Ni which have been previously established (2, 6, 12). An interesting feature was the occurrence of up to six equivalent orientations of (211) and (233) planes containing but one cpd which connotes the strong crystallographic influence of the metal. Three orientations lie with the cpd 60° apart and parallel to a (111)Ni cpd; the remaining three meet parallelism of the cpd with the <112>Ni directions (16). Since the oxide developed a (111) preferred orientation with increasing thickness, its growth corresponded to that of oxide on (100)Ni in that a major orientation observed in the film continued to develop as a preferred orientation during scale growth.

Table II. Average NiO grain size and thickness ratio of layers in duplex scales

* The average grain size in a duplex scale was determined from outer layer.
† The average grain size determined from top view of specimen.

The average size of the oxide crystallites was 300-400Å during an initial 30-40 min at 500°C and they subsequently grew to grains which were not of substantially different size on each metal face (Fig. 8 and Table II). The scale on (100)Ni exhibited the highest preferred orientation and most distinct columnar structure. This feature and the frequent observations of structural changes in less oriented oxide on (110) and (111)Ni accompanied with dislocations are common to findings of recrystallization and grain growth in solids (19).

These results lead to the consideration of general findings for overgrowth phases on solids. It is known that the degree of oxide polycrystallinity in films formed on Ni faces is dependent on the method of surface preparation and that the oxide formed at room temperature can rearrange upon heating the specimens in oxygen to 600°C (12). At the experimental pressure of 400 Torr, in this investigation, a nickel surface was subjected at room temperature to oxygen at least 10^{20} larger than the dissociation pressure of nickel oxide. Such large supersaturations as encountered here often lead to nucleation and growth of many, small, randomly oriented crystallites of the overgrowth phase on a substrate (20, 21). The films formed on the Ni faces exhibited some polycrystallinity upon raising the nickel specimens to the reaction temperature and allowing oxidation to proceed. Subsequently oxide rearrangement readily developed at the metal surface leading to epitaxial restraints since nickel diffuses outward during oxide growth. Because epitaxial relations in many film-substrate systems can often be correlated with the close-pack rule of parallel alignment of cpd's between the phases (22), one is led to inquire whether the number of cpd's in a Ni face influence the type and number of oxide orientations. (100) and (111)Ni possess two and three cpd's, respectively, and only five oxide orientations, all of them low index planes, were observed. The most dominant was the parallel orientation of cpd's. (110)Ni has only one cpd and eleven oxide orientations were observed. Thus the presence of only one cpd defined a less rigid condition for orienting oxide and to its relatively slow crystallographic change. Finally, the twinning which was frequently observed in this oxide with the twin boundary perpendicular to the plane of the oxide film may have arisen from the less rigid crystallographic restraints

leading to rapid growth of specific oriented crystallites.

Any influence of the metal substrate according to these considerations decreases with increasing oxide thickness. Consequently a stage is attained in which crystallite orientations become dependent on growth parameters. Some crystallites become randomly dispersed in films 1000Å thick and contributed to the commonly observed ring diffraction patterns. Since a growth mechanism now dominates a prefered orientation develops if the major orientations parallel to the metal surface in the films are the preferred growth planes. Such type of oxide growth occurs on (100) and (111)Ni. (110)Ni did not exhibit, however, a strong preference for a particular type of oxide orientation in thin films even though the scales showed a (100) preferred orientation. A (100) preferred orientation has also been observed to develop in scales on polycrystalline nickel (23-25). It would thus appear that (100) and (111) planes of nickel oxide lying parallel to the metal surface act as preferred growth planes due to preferential incorporation of adsorbed oxygen into nickel oxide resulting from the outward flux of nickel. The microstructures of the scales formed on (100) and (111)Ni exhibited the stronger preferred orientations and two distinct layers. These findings are also consistent with the development of a preferred orientation initially by epitaxial constraints and finally by growth parameters.

NiO growth kinetics.—Herchl *et al.* (7) found that the growth kinetics of the films and scales on these three Ni faces grew at a rate dependent on the metal crystallographic orientation. They therefore assumed a model wherein nickel migrated in nickel oxide by boundary and lattice diffusion to interpret the reaction kinetics. The present results on structural properties of the films and scales can be shown to substantiate these considerations.

Figure 12 demonstrates that the parabolic oxidation rate constants of both polycrystalline and single-crystal nickel at temperatures less than 900°C are much larger than values expected from calculations assuming lattice diffusion [the full lines in this graph represent the temperature coefficient of the parabolic rate constant estimated from nickel tracer diffusion in NiO crystals using the Wagner theory (31)]. Caplan *et al.* (10) have shown for polycrystalline nickel, moreover, that the values for the parabolic rate constant and its activation energy at temperatures less than 900°C are larger and

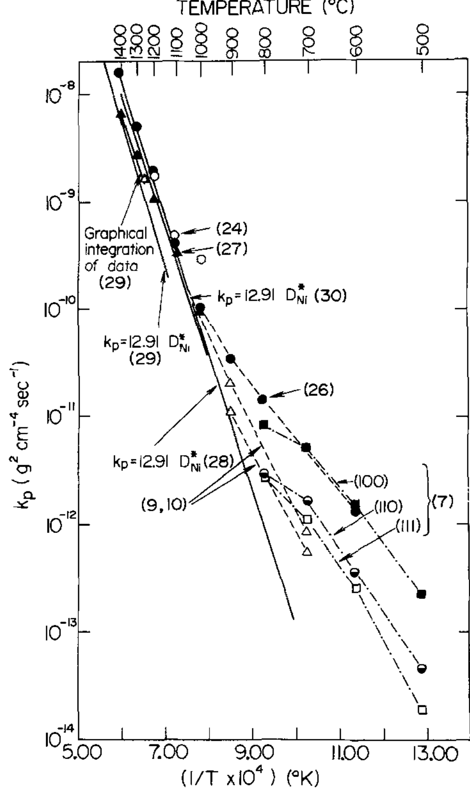

Fig. 12. The temperature coefficient of the parabolic oxidation constants for nickel oxide growth on nickel polycrystalline and crystal faces (>99.995% pure). The reference numbers correspond to those in the text. The solid lines represent calculated values using nickel tracer diffusion coefficients from Ref. (28-30) and the Wagner expression for the parabolic rational rate constant (31).

smaller, respectively, the finer the grain size of the oxide. We therefore express the effective diffusion coefficient for nickel in nickel oxide formed on a metal face as a weighted sum of the diffusivities for lattice and boundary diffusion (5)

$$D_{\text{eff}} = D_L(1 - f) + D_B f \qquad [2]$$

where f is the fraction of diffusion sites in the boundaries. A modified parabolic rate equation

$$x^2 = 2\Omega D_L \Delta c \int_0^t (1 + f D_B/D_L)\, dt \qquad [3]$$

represents the oxidation kinetics upon utilizing the approximation of a linear compositional gradient across the oxide. In this equation, x is the oxide thickness, Ω is the volume of oxide per metal ion, and Δc is the concentration difference across the oxide. NiO is of rock-salt structure so that anisotropy of oxidation with crystallographic orientation of a metal surface would be explained if the magnitude of the boundary diffusivity and/or the fraction of short-circuit sites depend on the NiO morphology on each crystal face. Assuming that the density of short-circuit diffusion paths decrease by the competitive growth of the oxide grains according to the following relations

$$f(t) = 2d/\mathfrak{D}_t; \quad \mathfrak{D}_t^2 - \mathfrak{D}_o^2 = Gt \qquad [4]$$

Eq. [3] becomes

$$x^2 = 2\Omega D_L \Delta c \int_0^t \left\{ 1 + \frac{2 D_B d}{D_L(\mathfrak{D}_o^2 + Gt)^{1/2}} \right\} dt \qquad [5]$$

In these equations, $\mathfrak{D}_t$ is the mean grain diameter after time t, $\mathfrak{D}_o$ is the initial grain diameter, d is the boundary width, and G is the grain growth constant. Equation [5] was placed in the following form for graphical analysis of experimental results (7)

$$1/(dx^2/dt - k_p)^2 = (\mathfrak{D}_o^2/A) + (Gt/A) \qquad [6]$$

where $A = [2k_p D_B d/D_L]^2$, $k_p = 2D_L\Omega\Delta c = 6D_{Ni}$ where D_{Ni} is the self-diffusion coefficient of nickel in NiO. The resulting good fit of Eq. [5] by this method to the oxidation kinetics of (100) and (111)Ni are shown in Fig. 13 and 14. Oxide growth on (110)Ni could not be interpreted by Eq. [6] as the oxidation curves for this metal face showed abrupt changes in slope due to increased reaction rates resulting from oxide spalling and cracking (7).

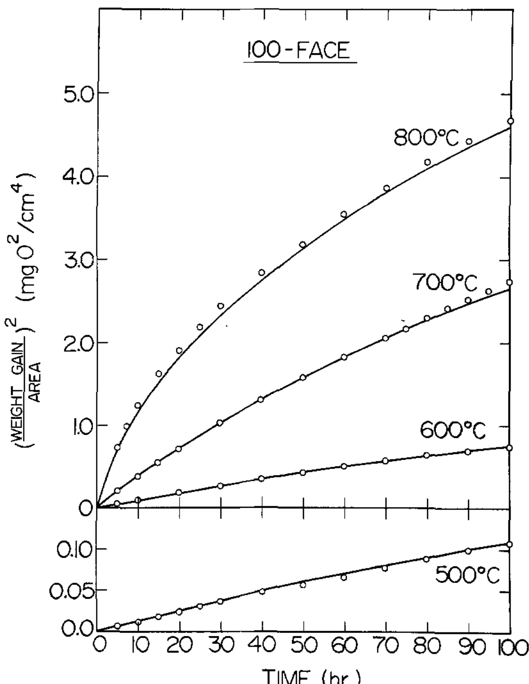

Fig. 13. The experimental results and the curves calculated by Eq. [5] for the growth of NiO on (100)Ni.

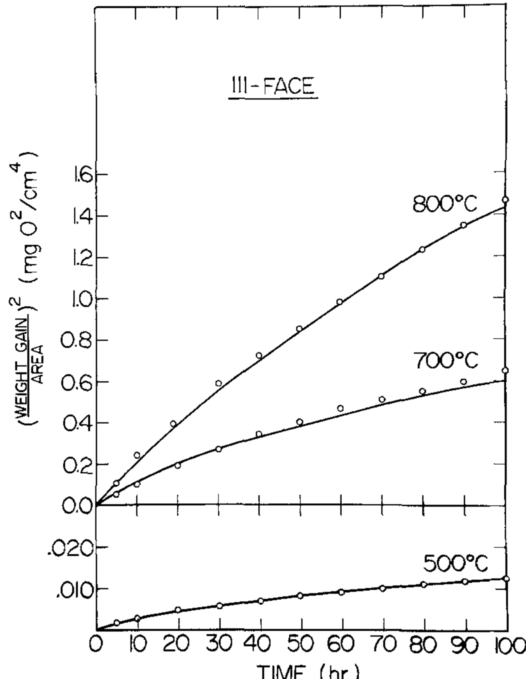

Fig. 14. The experimental results and the curves calculated by Eq. [5] for the growth of NiO on (111)Ni.

Equation [3] can be expressed as

$$\frac{dx^2}{dt} = (k_p)_{\text{eff}} = k_p + (k_p)_B f(t) \qquad [7]$$

where $(k_p)_{\text{eff}}$ is the rate constant determined from the tangents to the oxidation curves plotted x^2 *vs.* t and $(k_p)_B = 2\Omega D_B \Delta c$ is the parabolic constant for oxide growth by boundary diffusion. Thus, $(k_p)_B$ can be calculated using values of k_p and $f(t) = 2d/\mathfrak{D}_t$ obtained from the average crystallite and grain sizes determined by TEM and SEM assuming $d \sim 10\text{A}$. Values calculated for $(k_p)_B$ and the ratio of the diffusivities D_B/D_L by this method are recorded in Table III and the temperature coefficient of $(k_p)_B$ is given in Fig. 15.

Since the values of D_B/D_L are of the order 10^4-10^7, rapid boundary diffusion of nickel led to a large enhancement in oxide growth compared to that expected from lattice diffusion only. This enhancement is so large that $(k_p)_B f(t)$ remains as the leading term determining the effective parabolic constants even in the scaling range where the oxide is 1-15μ thick. The activation energies of 31 and 35 kcal/g-atom for oxide growth on (100) and (111)Ni by boundary diffusion, respectively, equal approximately one-half the activa-

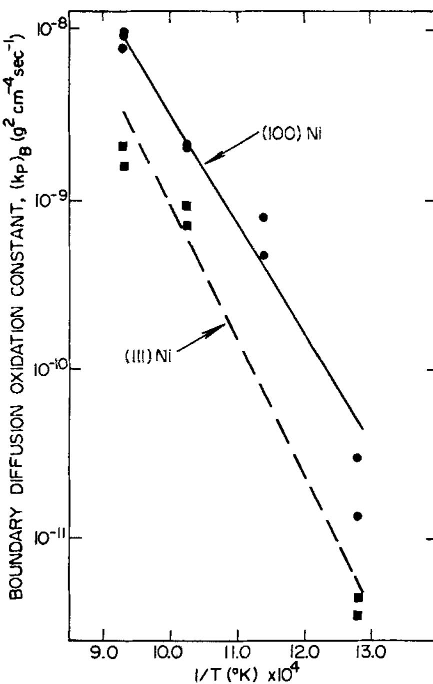

Fig. 15. Arrhenius plots of the parabolic constants for oxide growth by nickel boundary diffusion $(k_p)_B$ on (100) and (111)Ni.

tion energy of 61 kcal/g-atom for nickel lattice diffusion in nickel oxide (29). The values of grain size (Table II) and $(k_p)_B$ (Table III) for (100) and (111)Ni illustrate that differences in both of these quantities determine the degree of oxidation anisotropy with metal face. The differences in the magnitude of $(k_p)_B$, nevertheless, give rise to the most substantial effect. Hence, the influence of oxide orientation or texture on the value of the nickel boundary diffusivity largely accounted for the oxidation anisotropy of (100) and (111)Ni under the conditions of experimentation.

Conclusions

NiO up to 15μ thick formed on (100), (110), and (111)Ni at temperatures in the range 500°-800°C consisted initially of small crystallites which grew to grains with increasing exposure. A number of oxide orientations were found; the most preferentially oriented film developed on (100) and (111)Ni consistent with the close-pack rule for parallel alignment of cpd's between the substrate and an overgrowth phase. (100) and (111) textured scales developed on the metal faces due initially to epitaxial constraints and finally by the mechanism of oxide growth. These findings substantiate a model for oxide growth and oxidation anisotropy with metal orientation in which boundary diffusion of nickel significantly accounts for reactant migration through the films and scales. The differences in the rate of nickel migration was determined most predominantly by the types rather than the different densities of boundaries in the textured oxide on the metal faces under the conditions of exposure.

Oxidation of Titanium Thin Films

W. D. Sylwestrowicz

Fairleigh Dickinson University, Madison, New Jersey 07940

ABSTRACT

Titanium thin films were exposed to an oxidizing argon atmosphere in the temperature range from 30° to 400°C. In specimens exposed to the temperature above 300°C two stages were observed. Initially, resistance increased linearly with time and temperature coefficient values were positive. After prolonged exposure resistance increased exponentially with time, and negative temperature coefficients were observed. It is suggested that this behavior results from a progressive oxidation at grain boundaries. When oxidation is complete through grain boundaries to the substrate, conduction is then dependent on a tunneling process through the semiconducting titanium oxide leading to the observed exponential temperature and time of exposure dependence.

With progressive miniaturization of integrated and thin film circuits, the extremely small dimensions of the components introduce a number of new problems related to material stability and reliability. One of them is the effect of environment on the components of integrated circuits. Since the thickness of compounds may be of the order of a few hundreds atoms, environmental effects which might be negligible in bulk materials, can in such cases be of the utmost importance. In devices where thin films of gold are used as conductors on glass or ceramic substrates, titanium is often used as the bonding agent between gold and the substrate. It is well established that pure titanium is an efficient oxygen getter (1). Before undertaking an investigation of the effect of corrosive environments on gold-titanium metallization, it was thought desirable to conduct a study of the effect of temperature and humidity on the oxidation of titanium thin films and the results of this investigation are here described.

The theoretical aspects of growth and structure of the oxide films formed on the bulk metals were thoroughly discussed by Uhlig (2). Mindel and Pollack (3) investigated oxidation of the bulk titanium at room temperature.

Recently Smith published a paper (4) on oxidation of a titanium specimen exposed to different oxygen pressures at temperatures between 25° and 400°C. He expected to separate processes simultaneously occurring during oxidation of the titanium surface with the use of Auger spectroscopy, ellipsometry, and measurements of surface potential differences. It is not intended to discuss here this interesting paper, but it will be of interest to indicate some fundamental differences between Smith's work and what has been presented here. The thin films used in this work were about 1000Å thick, while those in Smith's (4) work were about 0.8 mm thick. The exposure time was of the order of 800 hr against 2 hr in Smith's experiments. In Smith's experiments, tests started with a clean specimen surface (annealing at 600°C and 5×10^{-10} Torr vacuum). In the experiments described below, the specimen surfaces were covered with the initial oxide layer.

Key words: titanium, oxidation, thin films.

Essentially in the experiments described here, we are dealing with thin film samples while in the Smith experiments we are dealing with a bulk sample, and therefore a considerably longer exposure in the present tests produced effects which had no time to develop in the relatively short exposure of the bulk sample used by Smith.

It should be noted that the experiments described below are designed for investigations of the effects resulting from the long exposures and are not concerned with the initial layer of titanium oxides formed in the first few hours of exposure. Since the experiments are conducted on the thin films of titanium, the obtained results are not necessarily applicable to the bulk material.

Experimental Results

Experiments were conducted for the conditions shown in Table I. Titanium specimens which measured 3 cm in total length, 1.525×10^{-2} wide and 750Å thick,

* h = thickness of titanium layer.
† Initial tests were conducted in wet argon with water vapor pressure 200 Torr.

were tested in the temperature range from 30° to 400°C in: (*a*) argon atmosphere (argon 99.9999% purity), (*b*) argon atmosphere with added water vapor, (*c*) argon atmosphere with added water vapor and oxygen, and (*d*) argon atmosphere with added oxygen.

Water vapor pressures in Table I refer to the pressures at the inlet to the furnace. High oxygen content indicates about 30% of oxygen by volume of oxygen. Specimens were prepared by electron beam gun deposition of titanium of 99.97% purity covered by a 5000Å thick gold layer. Sodium-free Corning 7059 glass (barium aluminum silicate) was used as a substrate. Specimens were obtained by etching with diluted solution of potassium iodine and iodine using the photoresist technique. The specimen's thickness was measured by the stylus-step method with the use of the Talysurf instrument made by Taylor Hobson. The accuracy of measurement is about 10Å for film up to 1000Å thick. Finally the gold layer was removed with the exception of the pads to which connecting gold wires were attached by compression bonding. Pressure after titanium evaporation was about 10^{-6}-10^{-7} Torr and before evaporation, 10^{-8} Torr. The experimental setup was arranged in such a way that specimens could be tested simultaneously in six furnaces heated individually to different temperatures. These furnaces were inserted into a constant temperature chamber and this arrangement permitted close temperature control in tests of long duration, and control of water vapor pressure. Dry or wet argon, with or without addition of oxygen, was fed from a common source through each furnace. The argon used was of 99.9999% purity.

In tests with specimens of lots I and II (Table I) only one specimen was tested at each condition (temperature and atmosphere). In tests with specimens of lots III and IV three specimens were tested simultaneously at each temperature. Since observed changes for these specimens were similar, the data for only one specimen are given with the exception of specimens tested at higher temperatures. For most of these specimens experimental data are given. The resistance of the specimens was continuously recorded by drawing a current of 0.01 mA through the specimens and measuring the voltage change. In addition the resistance of specimens was periodically measured directly.

The following notations are used in this paper: R_o = electrical resistance of a specimen at room temperature before the tests; R_r = electrical resistance of a specimen at room temperature after the test; R_t = electrical resistance of a specimen at test temperature T after time t of exposure; and R_T = electrical resistance of a specimen at test temperature T at the end of the test.

In the first series of tests, with specimens of lot I, specimens were exposed to two atmospheres: pure argon and pure argon with an addition of water vapor. These tests showed a marked difference between specimen No. 1 tested in wet argon and specimen No. 3 tested in dry argon at temperatures 300° and 325°C, respectively (Fig. 1). The second series of tests, with specimens of lot II, was supplementary to the first series and designed for the investigation of specimen behavior in the range of temperatures between 100° and 250°C (Fig. 2). At the end of these tests oxygen was added to specimens No. 6 and 9 exposed to dry argon atmosphere (Fig. 2). These specimens were tested at 245° and 165°C, respectively. The third series of tests, specimens of lot III and IV, was designed after taking into consideration the results of the previous tests and was intended to confirm conclusions drawn from these tests. An additional factor, the thickness of the specimens' layer, was also introduced (specimens of lot IV). The third series of tests was conducted in two stages. In the first stage, specimens were exposed to wet argon and oxygen (about 1/3 by volume) atmosphere at temperatures below 300°C (Table I). In the second stage, the same specimens were tested at temperatures above 300°C. The exceptions were specimens No. 20 and 17 tested at 90° and 170°C, respectively. In this stage specimens were exposed initially to the same, wet, highly oxidizing argon atmosphere as in the first stage but after 106 hr of exposure water vapor was cut off from the system and the atmosphere was composed only of high purity argon and oxygen.

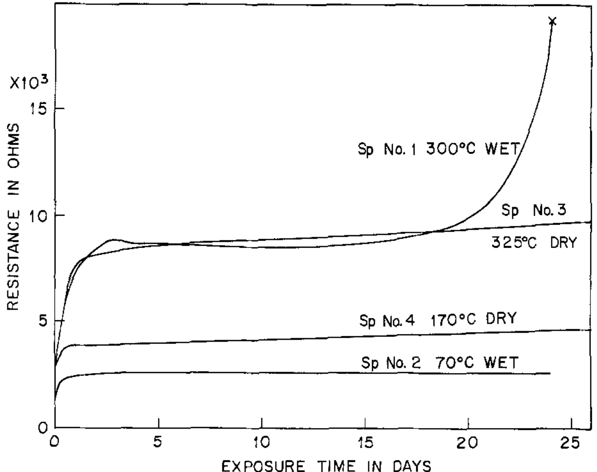

Fig. 1. Change of the electrical resistance with time of exposure time of specimens tested at different temperatures in dry or wet argon.

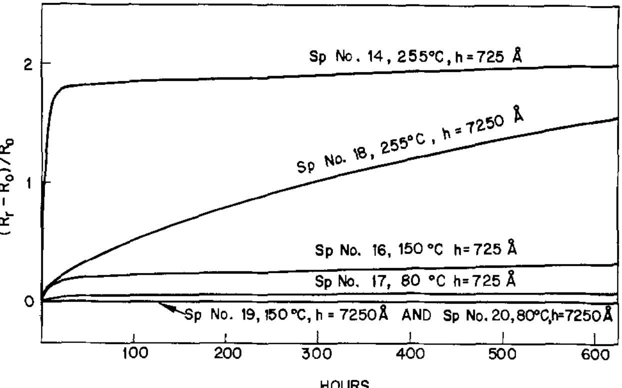

Fig. 2. Changes of electrical resistance (R_t — R_o) with time of exposure of specimens tested in two ranges of temperatures in dry and wet argon. Also the effect of oxygen addition to dry argon atmosphere is shown. The changes are normalized to the initial specimen resistances (R_o) at room temperature.

Discussion

In the thin film titanium specimens exposed to the highly oxidizing atmosphere (1/3 of oxygen by volume), even at a temperature as low as 80°C (specimen No. 17, Table II), some oxidation can be observed, but after the initial rise, resistance of the specimens becomes stable and continuous exposure (in the time of this study) does not further affect resistance of the specimens. This observation is valid for all specimens heated up to 255°C (specimens No. 14, 16, and 17, Fig. 3).

When specimens were exposed to the high purity argon atmosphere (dry or wet) at temperatures below 150°C, no noticeable change in resistance was observed (specimens No. 2, 5, 10, and 11, Table II).

In specimens exposed to the highly oxidizing atmosphere and at temperatures above 300°C, the resistance increases in two stages. Initially the increase is nearly linear (in what follows it will be linear), and then exponential. The time of exposure during which resistance increases linearly depends on temperature (Fig. 4). In this interval of exposure the resistance at room temperature (R_r) increases faster than resistance at the test temperature (R_t). Somewhere close to the end of the period of linear increase of resistance,

the value of the resistance at room temperature (R_r) becomes equal to the resistance at test temperature (R_t). From this point the linear dependence of resistance changes to an exponential dependence (Fig. 4 and 5). In this range some tests were interrupted periodically, specimens cooled to the lower temperatures, and resistance measured. The results are shown in Table III and Fig. 6. It can be seen from Fig. 6 that the resistance depends exponentially on the reciprocal of temperature, and the specimen behaves as a semiconductor exhibiting a negative thermal coefficient of resistance $R_T - R_r < 0$ [1] (Table II, Fig. 6). In the last stage, increases in the resistance were too fast to be accurately monitored.

As shown in Table II, the linear dependence of resistance ends when the resistance has increased by a factor of 3-4. This observation cannot be explained on the basis of a surface oxide layer gradually increasing in thickness. Since the resistivity of titanium oxides (5) is many orders of magnitude larger than that of titanium, the major part of the current would flow through the titanium layer and be largely unaffected by the properties of the titanium oxide layer until oxidation was essentially completed.

However, the observed resistance change can be explained by assuming that oxidation occurs through the grain boundaries into the bulk of the grains.[2] The rate of oxygen diffusion through the grain boundaries in thin films is not known but it is expected to be much faster than through the bulk of the grains.

It can be proposed that diffusion of oxygen, through grain boundaries, is responsible for the formation of a network of titanium oxides along grain boundaries. This would result in a local reduction of the metallic cross section of the film and in an increase of resistance. When titanium oxide penetration to the sub-

[1] This cause of the observed change of sign of the temperature coefficient of resistance was suggested by R. J. H. Voorhoeve.

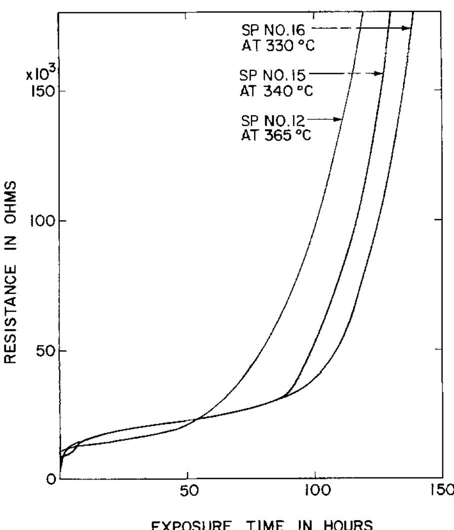

Fig. 4. Dependence of resistance on time of exposure of specimens No. 12, 15, and 16 exposed initially to a humid, highly oxidizing atmosphere then to a highly oxidizing but dry atmosphere. Test temperatures: 365°, 340°, and 330°C, respectively.

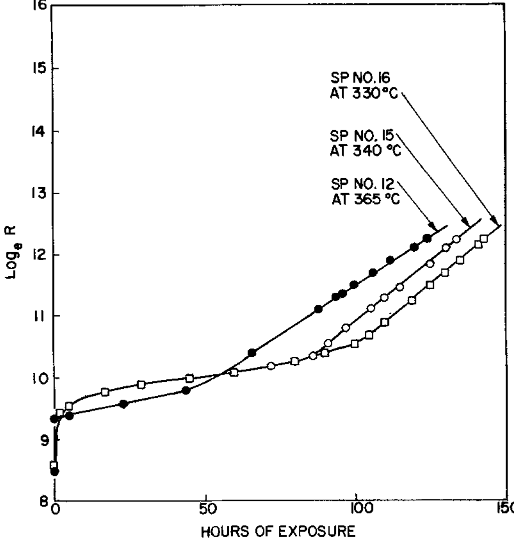

Fig. 5. Dependence in semilogarithmic scale of resistance on time of exposure of specimens No. 12, 15, and 16 exposed initially to a humid oxidizing atmosphere then to an oxidizing but dry atmosphere. Test temperatures: 365°, 340°, and 330°C, respectively.

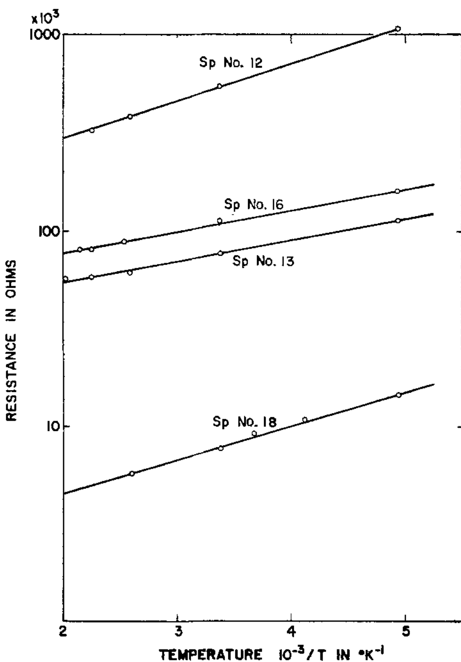

Fig. 6. Dependence of resistance on the reciprocal of temperature of specimens exposed at higher temperatures to oxidizing atmosphere.

strate is completed the linear dependence of resistance changes to the exponential

$$\rho = Ce^{E/KT} \quad [1]$$

The observed negative temperature coefficient of resistance is attributed to the formation of titanium oxides.

Once a titanium oxide network is formed around grains, the current must tunnel through the thin layers of titanium oxides at each boundary and the total specimen resistance consists of the sum of resistances of titanium oxide thin films at grain boundaries (of few interatomic spacings) in series with the sum of resistances of each titanium grain. A tunneling effect should be expected in such a configuration. In this model an exponential temperature dependence of resistance is expected, in agreement with the experiment (Fig. 6). Also the resistance should depend exponentially on the width of the barrier, in this case on the thickness of titanium oxide layers at the grain boundaries (6): *i.e.*

$$\rho = Ae^{\alpha x} \quad [2]$$

where x is the width of the barrier. It is assumed here, that, since the thickness of the titanium layer is very small, diffusion of oxygen through grain boundaries to the substrate occurs fast especially at higher temperatures. Formation of titanium oxides, while occurring readily at temperatures above 700°C, at lower temperatures occurs much slower and at 150°C, even after 750 hr of exposure, no change in sign of temperature coefficient was observed. At temperatures below 400°C formation of titanium oxides and not diffusion of oxygen is, therefore, a rate-limiting process in the widening of the oxide layer at grain boundaries. It can be written, therefore, that $x = ct$, where c is a constant and t is the time of exposure counted from the moment at which the observed exponential dependence of resistance commences. By substituting x into [2] an exponential dependence of resistance on the time of exposure is obtained

$$\rho = Ae^{\alpha t} \quad [3]$$

The larger rate of increase of resistance, observed in the humid argon atmosphere at temperature 300°C (specimen No. 1), as compared with the dry argon atmosphere at 325°C (specimen No. 3, Fig. 1), seems to be related to the supply of additional oxygen derived from the water vapor. In the experiments with very high purity argon the amount of oxygen in the test was small, and during exposure the rise of electrical resistance was slow (specimen No. 3 and 4, Fig. 1). The introduction of additional oxygen produced a sharp increase of resistance (Fig. 2). In the tests in a highly oxidizing atmosphere humidity has no effect on the rate of increase of resistance (Fig. 7). All these observations indicate that the increase of resistance is caused by the oxidation of the titanium and water vapor is only one of the factors, probably an additional source of oxygen, in a test at temperature 300°C and in the atmosphere deficient in oxygen. Specimens of 7200Å thickness behave in the same manner as thinner specimens of 750Å thickness except that a longer time of exposure is needed for the process of oxidation. After about 45 hr of exposure at 400°C, specimen No. 18 of 7250Å thickness exhibited a negative temperature coefficient (Fig. 6). The ratio $(R_T - R_r)/R_o$ was -22.62 (Table II).

The exact composition of titanium oxides in the layer at the grain boundary was not investigated.

Conclusions

Exposure of titanium thin films, at temperatures above 300°C, to argon atmospheres containing oxygen results in the formation of titanium oxides at grain

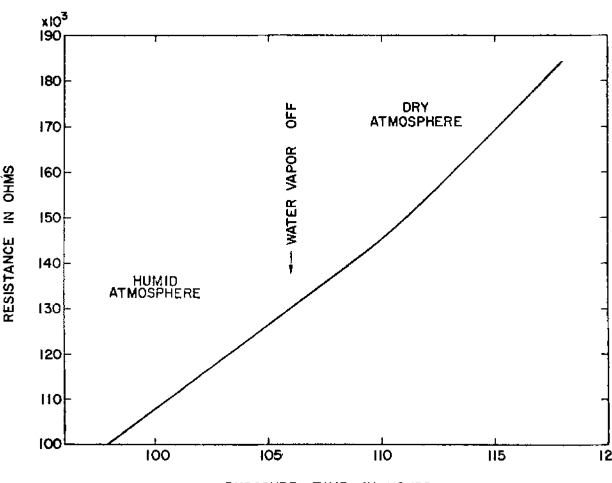

Fig. 7. Specimen No. 12 was tested at 365°C in highly oxidizing atmosphere with water vapor pressure 200 Torr. After 106 hr of exposure the supply of water vapor was cut off from the atmosphere.

boundaries and the formation of films which exhibit a negative temperature coefficient of resistance. Oxidation of specimens exposed to high purity argon proceeds very slowly, but addition of water vapor to the high purity argon accelerates the oxidation process. It is proposed that at temperatures above 300°C, oxidation of titanium along grain boundaries occurs, causing an increase in resistivity. After a nearly linear increase in resisitivity an acceleration in the rate of resistance occurs due to the formation of a network of semiconductive titanium oxides along grain boundaries. This creates a tunneling effect with an exponential dependence of resistance on both temperature and also on the width of the titanium oxides layer, which in turn depends linearly on the time of exposure. It is assumed here that the rate-determining process is the formation of titanium oxides.

At temperatures below 300°C, oxidation does not penetrate through the whole cross section of the specimens. The resistance initially was increasing but became, after some time of exposure, constant. However, the film as a whole does not change to a semiconductor with a negative temperature coefficient.

An Anodic Process for Forming Planar Interconnection Metallization for Multilevel LSI

G. C. Schwartz and V. Platter

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Anodic processing has been extended to aluminum alloy metallurgy. A procedure for forming completely planar interconnection metallization has been described. The factors which control line profile and the electrical isolation of closely spaced conductors have been investigated, and the conclusions used to define the anodizing conditions. The planar structure and the increased cross-sectional area of the conductor which result from the use of this process make increased circuit density possible.

Large scale integration (LSI), with its high circuit density, has made the use of multilevel interconnection metallization a necessity. Conventionally, the interconnection pattern is formed by subtractive etching; the insulating layer may be either CVD SiO_2 or sputtered SiO_2. The resultant two-level structure is shown schematically in Fig. 1(a); the topography worsens as the number of levels increases. Photolithography becomes more difficult and the consequences of inadequate coverage of the metal edges by the insulator result in serious reliability problems. Tapering the metal edge has been suggested for improved coverage (1), but this is done at the expense of metal cross-sectional area which becomes increasingly important as the width of the conductor is decreased to increase circuit density. It is possible to compensate for the reduction of metal cross-sectional area by increasing initial line widths, but this decreases the possible circuit density. The SiO_2 can be deposited under high resputtering conditions which eliminates cusping (2), thus improving edge coverage, but this requires long sputtering runs. However, neither of these measures eliminates the unwieldy topography due to the etched metal. Earlier workers (3, 4) have shown that it is possible to eliminate subtractive etching for aluminum interconnection metallization systems; by anodic conversion of the unwanted metal to an insulating film of aluminum oxide, a substantial reduction in step height has been achieved, as indicated in Fig. 1(b).

This paper describes a process by which a completely planar structure can be made. Since the interconnec-

tion metallurgy is not necessarily pure aluminum (copper may be added to aluminum to improve its electromigration resistance and small amounts of silicon are added to prevent junction penetration) we have extended the application of anodic planarization to aluminum alloys.

Anodization of Aluminum Alloys

The addition of copper and silicon to aluminum alters the anodizing process and the properties of the anodic oxide. For example, the anodizing efficiency decreases as the concentration of the alloying element increases (5).

Copper dissolves in the electrolytes used to form both barrier layer and porous anodic oxides. Consequently, it is not possible to form an impervious barrier layer on an aluminum-copper (AlCu) film. And it is not unexpected that the porous anodic oxide formed from an AlCu film contains voids superimposed upon the fine, fairly regular pore structure; this is seen in the scanning electron micrographs in Fig. 2(a) and (b). Therefore a composite structure is used for anodic planarization of aluminum alloy metallurgy: the bulk of the metal is the appropriate alloy, the top layer is pure aluminum. We refer to such a film as Al/AlCu or Al/AlCuSi. The porous anodic oxide formed from an Al/AlCu film is shown in Fig. 2(c).

Approaches to Planarization

In order to compensate for the expansion which usually accompanies the conversion to anodic oxide, one approach might be to etch a suitable fraction of the metal to be anodized before anodization; another, to dissolve some of the anodic oxide formed. The former requires precise control of the etching process and leads, in any event, to undesirable surface roughness; the latter is impossible, since the time it takes to dissolve a porous anodic oxide film is independent of its thickness (6).

It is known that the thickness of porous anodic oxide formed from a given thickness of aluminum decreases with decreasing current density and increasing temperature; this is true for AlCu as well.[1] Therefore it is possible to find anodizing conditions such that the thickness of the oxide formed will be equal to the thickness of the metal converted. However, it will be shown that arbitrary adjustment of current density and elevated temperatures are not satisfactory means for realizing a planar structure.

The anodization of aluminum is 100% efficient under all conditions; therefore it is simple to anodize a precisely controlled thickness of aluminum. There is an etchant for anodic oxide which does not attack aluminum; it contains 35 ml/liter 85% H_3PO_4 and 20 g/liter CrO_3 and is used at 80°C and is referred to in this paper as P-C etch. Thus it is possible to reduce the aluminum thickness, in the areas in which complete conversion to aluminum oxide will occur ultimately, with precision and without surface roughening. It can be seen that the choice of this method of planarization makes the use of the composite film (Al/AlCu or Al/AlCuSi) necessary.

Experimental

The anodization cell is shown in Fig. 3. It provides electrical contact to the bare silicon side of the wafer; *i.e.*, the bias is applied to the metal through the contact holes to silicon. The electrolyte is confined to the metallized top surface; the area exposed to the electro-

lyte is defined by the O-ring which seals the electrolyte vessel against the wafer. The cathode is a platinum disk slightly larger in diameter than the O-ring. The electrolyte is neither stirred nor kept at constant temperature; the temperature rise during the longest anodization is only 0.5°C. The electrolyte for porous oxide formation is an 8% solution of oxalic acid in water. Oxalic acid is used because it is compatible

with photoresist and is decomposed when the anodized film is dried. Also, at the appropriate current density, the voltage is suitable for device fabrication. Barrier layer is formed in a 30% solution of ammonium borate in ethylene glycol.

A constant current power supply is used. When a two-current mode of anodization is used, there is a control circuit which automatically reduces the current from its initial value to a preset value after any predetermined time. There is another control circuit for automatic control of decay time. At the completion of anodization, the rising voltage is sensed and when it reaches a predetermined value, that voltage is maintained, as the current decays, for a preset length of time. At the end of the decay period, the anodization is stopped automatically and a buzzer is sounded to summon the operator to empty the cell.

Current and voltage are recorded on a strip chart throughout the anodization.

Process Description

The process is outlined, with the aid of diagrams, in Fig. 4.

Discussion.—To preserve the greatest possible thickness of metal in the areas in which the interlevel metal connection is to be made (*i.e.*, the via areas) such regions should not be anodized (4). However, we have observed that the adhesion of photoresist to an aluminum surface during anodization is too weak to prevent appreciable lateral anodization during porous oxide formation. Although the anodization time in step 6 is relatively short, the via diameter is quite small ($\sim 5\mu$). Therefore a thin barrier layer is formed in the via areas to prevent subsequent porous oxide growth (3). The barrier layer is formed at low current density (1 mA/cm^2 is a typical value) and when the desired voltage is reached, the anodization is stopped since both high current density and prolonged maintenance of the film at constant voltage are reported to result in pore formation (7).

The initial anodization (step 2) improves resist adhesion during barrier layer growth but it is not essential.[2]

An alternate approach could be the formation of a somewhat thicker layer in step 2 (protection against porous oxide growth requires this), the use of the reverse mask in step 3, followed directly by step 6. While this eliminates one resist removal step, it does

[2] When barrier layer is grown within a resist mask to about 100V, the resist breaks down; providing a porous oxide underlay for the resist does not increase the voltage to which a barrier layer can be grown before resist breakdown.

not eliminate a masking operation. More important, the structure of the via hole is better when the procedure given in Fig. 6 is followed, particularly if the mask used in step 3 protects an area slightly larger than that of the final via hole.

Photoresist is stripped in a dry asher because the usual chemical strippers (*e.g.*, J-100) etch anodic oxide; there is also the risk of possible binding of some of the components of such strippers to the walls of the pores.

Step 6 is carried out at constant current since a known quantity of charge must be passed to anodize a given amount of aluminum. The area of aluminum to be anodized can be determined by measuring the rate of voltage rise during barrier layer formation at constant current since the rate is approximately proportional to current density (8). The current density used must be such that the voltage does not approach the final voltage in barrier layer formation in step 4 to insure that no further oxide growth occurs in the via areas.

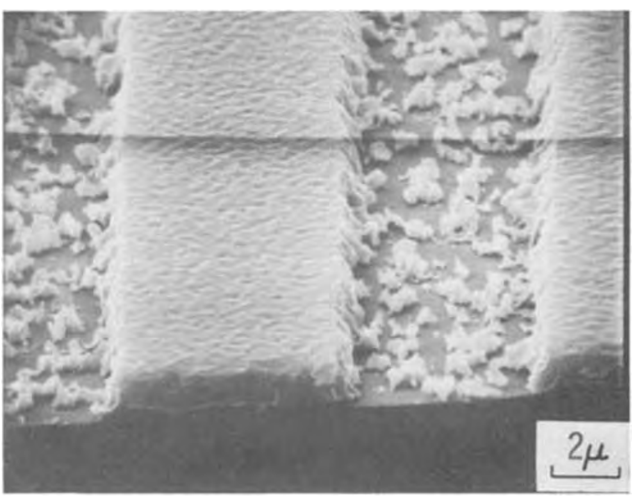
When the bulk of the metal has been converted to anodic oxide, *i.e.*, when the anodization voltage rises abruptly to its limiting value and the current decreases exponentially, closely spaced conductors are still shorted. The shorts are due to residual metal which clings to the edges of the lands and forms bridges between them. Only by continuing to supply current to the lands via the contact holes to the silicon can this residual metal be converted to an insulator. The interval during which this continually decreasing current is supplied to the lands we call the decay period. Residual metal within the isolation oxide, at some distance from the lands, is unaffected during the decay period. It cannot be emphasized too strongly that such residual particles do not form a conducting layer, they are merely a cosmetic defect. Indeed, after a sufficient decay period, leakage between adjacent conductors is small. A test structure was designed so that it could be isolated from silicon after completion of the anodic processing. It consists of pairs of lines 9×10^{-2} cm long separated by 3, 6, and 15μ spaces. For the pairs which are 3μ apart, the leakage current at 10V is 10-20 picoA. One hundred chips, each containing one isolated test structure, were mounted on headers for stress testing under bias at 85°C and 85%R.H. The pairs of stripes separated by 6μ were biased at 20V. After 2000 hr, when the test was terminated, there had been no increase in leakage current on any chip, some of which had not been protected by sputtered SiO_2.

During decay, the voltage must be limited to about 50V. R. C. Turnbull[3] has shown that if the voltage is excessive, ridges are formed at the interface between the conducting stripe and the anodic oxide which abuts it.

The decay process may be monitored: the anodization is stopped, the wafer removed from the cell, rinsed, dried, then examined in the infrared microscope; if further decay is required the wafer is replaced in the cell and the bias reapplied. Infrared micrographs taken during a decay period are shown in Fig. 5. We have found that ordinary optical micrographs can be misleading, particularly when the anodic oxide is very thick.

The conversion of the residual metal clinging to the lands as well as the nonconversion of totally isolated residue during decay is seen very clearly in the scanning electron micrograph in Fig. 6. For examination in the scanning electron microscope, the anodic oxide must be removed in P-C etch to make the metal particles visible. In Fig. 7 scanning electron micrographs illustrate the efficacy of a fixed decay period in isolating pairs of lands with different spac-

[3] R. C. Turnbull, this laboratory, private communication.



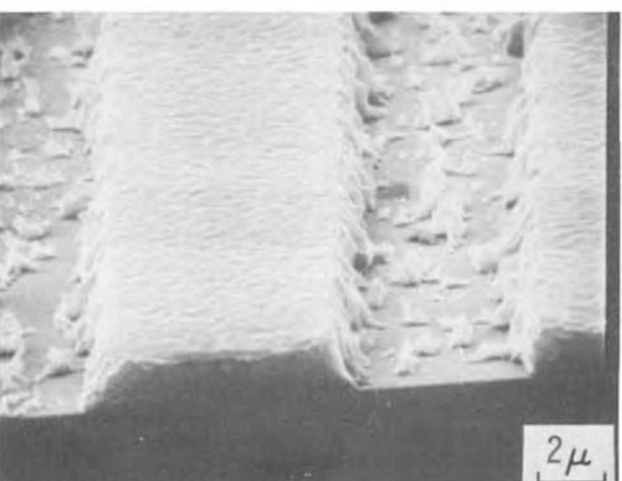


Fig. 8. Scanning electron micrograph showing the effect of metal thickness; P-C etched: (a, above left) 9000Å Al; isolation anodization 2.25 mA/cm^2; decay period 3.5 min. (b, above right) 12,900Å Al; isolation anodization 2.25 mA/cm^2; decay period 21 min. (c, left) 18,500Å Al; isolation anodization 2.25 mA/cm^2; decay period 61 min.

ings, while Fig. 8 shows that the thickness of metal which must be converted to isolation anodic oxide is an important factor in determining the length of the decay period.

Now it is clear why using elevated temperatures to reduce the ratio of anodic oxide formed to metal converted is not practical. The decay period has been shown to be necessary. If during the decay period the temperature were elevated, pore widening and pore shortening would proceed at an accelerated rate which is undesirable.

The current density during the isolation anodization influences the size and shape of the residual metal particles, which in turn determines the decay time required to achieve good electrical isolation, and thus ultimately determines the line profile and what may be called the anodization bias. The effect of current density is illustrated in Fig. 9. We have obtained the best line profile when two-thirds of the film is anodized at 3.5 mA/cm^2 and the rest at 1 mA/cm^2. The reduction in cross-sectional area after anodic processing can be substantially less than after standard chemical etching; using the two current density mode described above, the taper of the lines is about 70°. A rough estimate of the increase in cross-sectioanl area which results from this decreased taper can be made, assuming that a land is a trapezoid in cross section. For 5μ wide lands, 1μ thick, there is a 16% increase over conventionally etched lines (45°) and a 22% increase over deliberately tapered lines (30°). For 2.5μ wide lines, 1μ thick, there is a 42% increase over conventionally etched lines, while it is not possible to form usable lands with an exaggerated taper. Yet because the lands are encapsulated in the anodic oxide and the entire structure is planar, there are none of the edge coverage problems associated with insulating lands with such steep sides. In Fig. 10, the reduction in cross-sectional area is illustrated. In this case the proc-

ess was altered somewhat[4] to make it possible to see the final line profile together with the initial mask size which is replicated in the layer of SiO_2 at the top of the land.

Because of the importance of current density in determining line profile, it is apparent that arbitrary adjustment of current density is not a good approach to planarization.

Upon completion of the anodic processing, the wafer is stripped of photoresist and heated for about half an hour at 450°C to drive off the water and decompose the oxalic acid which is bound to the pores.

Anodic oxide is not suitable for interlevel insulation; it has a high dielectric constant and porous anodic oxide does not provide protection of a lower level during anodization of the next level.[5] An additional dielectric layer (sputtered SiO_2) must therefore be deposited. Because of the planarity of the metallization structure, there are no edge coverage requirements; the thickness of the SiO_2 is determined only by the interlevel capacitance requirements and the need to insure a low defect level. The presence of the underlying anodic oxide reduces the hazard of pinholes that may be present in the thinner SiO_2. Because the SiO_2 can be thinner than that required for conventional processing, via holes are easier to etch and the spacing between neighboring holes can be reduced. A typical via hole, etched through the SiO_2 and the barrier layer, is shown in Fig. 11.

The degree of planarity which has been achieved is illustrated in Fig. 12 which shows a scanning electron micrograph of a cross section of a land and the adjacent isolation anodic oxide. Figure 13(a) is a Talystep trace of such a structure. Figure 13(b) shows the Talystep trace of a planar structure which has a ridge between the land and the oxide because (as mentioned earlier) the voltage during decay was too high.

We have observed that the pattern definition (edges, line widths, and spacings) is superior when anodic

[4] The process used to produce this sample is as follows: A very thin layer of SiO_2 is sputtered on the surface of the aluminum. Using standard photoresist processing, the SiO_2 in the regions which are to become the interconnection pattern is protected. The unprotected SiO_2 is etched. Since the SiO_2 is very thin, there is little undercutting and the SiO_2 which remains approximates the dimensions of the mask which defines the interconnection pattern. The anodic processing is performed as usual; *i.e.*, the initial anodization and P-C etch to compensate for the expansion and the isolation anodization and decay. While this variation eliminates some of the steps in the usual process, it involves an extra vacuum step. Under most circumstances the usual procedure is preferable.

[5] It is true that if the upper level were anodized at a voltage considerably lower than that used to anodize the layer beneath, the lower interconnection pattern would not be converted to oxide. However, it has been shown that the current density (and hence, voltage) cannot be changed in an arbitrary fashion if control of line profile is required.

processing is substituted for conventional processing, using the same mask.

The electrical characteristics of both FET and bipolar transistors made by conventional and anodic processing are the same. A two-level device, made using anodic processing is shown in Fig. 14.

Summary

An anodic planarization process which is applicable to aluminum alloy metallurgy has been described. While anodic processing is more complex than conventional subtractive etching, the results justify the use of this technique. It has been shown that a completely planar structure is produced and the advantages of a planar structure have been discussed. The factors which affect the line profile have been discussed and illustrated; it has been shown that, with the proper choice of anodizing conditions, the cross-sectional area of a conductor formed by this technique can be substantially greater than that formed by conventional subtractive etching. Therefore increased circuit density is possible without loss of performance or reliability. The factors which affect electrical isolation have also been discussed and low leakage levels have been obtained. Stress test results show that the residual aluminum is truly a cosmetic defect and is not a reliability hazard. Improved pattern definition is still another dividend of anodic processing.

Electron Penetration and Power Dissipation in Thin Films of Gd_2O_3:Eu

J. S. Prener*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The cathodoluminescent brightness as a function of electron energy was measured for thin films of Gd_2O_3:Eu. Proper account is taken of the power dissipation of the electron beam in the thin Al layers deposited on top of the phosphor films. These Al films were necessary to prevent charging during the measurements. From an analysis of the data we derive the power dissipation of the electron beam in the Gd_2O_3:Eu. We find that the results on power dissipation are in reasonably good agreement with theoretical calculations appearing in the literature.

There have been a number of investigations which have dealt with the problem of electron penetration in solids and the power dissipation of an electron beam as studied by cathodoluminescence. Feldman (1), using thin phosphor films, measured the brightness as a function of electron energy up to 20 keV and determined the electron range-energy relationship for a number of materials. He did not, however, utilize his data in determining the power dissipation of the electrons in the phosphor films. Ehrenberg and King (2) studied optically the luminescence glow profiles produced by a narrow beam of electrons in a number of transparent phosphor crystals. They deduced electron ranges as well as power dissipation from their measurements. The accurate determination of contours of equal brightness from photomicrographs of the cathodoluminescent glow for high Z (average atomic number) materials is extremely difficult for primary electron energies below 30 keV since the total electron penetration depths are only a few microns. Bieringer (3)

* Electrochemical Society Active Member.

again measured the brightness of thin phosphor films as a function of primary electron energies up to 30 keV. He compared his results with a model based on the density of energy dissipation per electron obtained by differentiation of the Thomson-Widdington law and the statistical loss in the number of electrons penetrating to a given depth in the solid. More recently Kingsley and Prener (4) showed that the luminescence efficiency as a function of electron beam power for powder ZnS: Cu phosphors having nonluminescent ZnS coatings of various thicknesses on each particle was compatible with Makhov's (5) formulation for the power dissipation of an electron beam in a solid. The analysis was, however, complicated by the necessity for making geometrical corrections since the phosphor layer was composed of small particles rather than being a continuous film of uniform thickness. A shortcoming of Makhov's formulation was his neglect of backscattered electrons. This can lead to significant errors in calculations of power dissipation for materials of high atomic number (6).

In this paper we analyze the relationship between the cathodoluminescence brightness and the energy of the primary electrons for thin phosphor films. We determine the power dissipation of the electron beam and show that the results are in agreement with theoretical calculations appearing in the literature. As far as we know no such comparison between theory and experimental data for thin phosphor films has been made previously. We measured the cathodoluminescent brightness of thin films of the Gd_2O_3:Eu phosphor as a function of primary electron energies up to 20 keV. Proper account was taken of the power dissipation in the thin Al layers deposited on top of the phosphor films. These Al layers are necessary to prevent charging of the films during the measurements. The results were analyzed and shown to agree reasonably well with theoretical calculations of power dissipation of electrons in solids as given by Spencer (7) and by Kanaya and Okayama (8). Gd_2O_3:Eu is a good choice of material for such studies. The diffusion of generated electrons and holes to the surface of the phosphor and their subsequent radiationless recombination lead to the phenomena of "dead-voltage" and diffusion layer thickness [see, for example, Gergeley (9)]. This greatly complicates the analysis of brightness-voltage data as we shall see later. The dead-voltage of Gd_2O_3: Eu has been found to be about 0.5 kV which is quite small compared to many other phosphors (10). One can estimate from this a diffusion layer thickness of about 0.01μ which is much smaller than the thickness of our phosphor films and could be neglected in the analysis.

Preparation of Gd_2O_3:Eu Phosphor Films by Spinning

The films were deposited on clear, fused quartz (CFQ) substrates which, after cleaning in boiling nitric acid, were prepared for film deposition by immersion for several minutes in a boiling 10% (V/V) solution of K-200 potassium silicate (du Pont) followed by a thorough rinse in distilled water. The silicate treatment was necessary since good continuous films could not otherwise be produced. A typical solution used for spinning consisted of 10g of $Gd_{0.95}Eu_{0.05}Cl_3 \cdot 6H_2O$, 5.7 ml H_2O, and 12.8 ml isopropanol. A few drops of the solution were placed on the substrate and allowed to spread on the surface. The substrate was then spun in a horizontal position, typically at 3000 rpm for about 30 sec until it was dry. It was then annealed for about 5 min in air. Depending on the annealing temperature GdOCl:Eu, Gd_2O_3:Eu, or a mixture of the two phases was obtained. Films of increasing thickness were obtained by repeating, a number of times, the spin-anneal cycle. With some care films of uniform thickness over an area of ½ × ½ in. could be produced as indicated by the interference colors. The films appeared to be thicker near the edges and for the purpose of measurement the outer edges of the films were dissolved in hot 1-1 H_2SO_4 leaving only the uniformly thick central area. The film thickness was determined either by using a Sloan "Dektak" surface profile measuring instrument or chemically. For chemical analysis the oxide films of known area were dissolved in dilute HCl and the total rare earth content determined colorimetrically using sodium alizarinsulfonate (11). The thickness was calculated assuming bulk density.

Film Properties and Cathode-Ray Excitation

In Fig. 1 is shown the thickness of the Gd_2O_3:Eu films as a function of the number of spin-anneal cycles. It is seen that about 0.07μ of film is deposited in each cycle. The emission spectra under 254 nm excitation for films annealed for a few minutes in air at various temperatures are shown in Fig. 2. At 200°C only a weak broad-structured emission is seen indicating poor crystallinity of the film. At 300°-500°C the emission spectrum is characteristic of GdOCl:Eu; at 600°C both GdOCl:Eu and Gd_2O_3Eu spectra appear; and at 700°C only the oxide spectrum remains. The formation of GdOCl as an intermediate in the thermal decomposition of hydrated $GdCl_3$ in air has been well established (12, 13). X-ray diffraction indicated that the films annealed at 700°C and higher consisted of polycrystalline Gd_2O_3.

Gd_2O_3:Eu films of various thicknesses deposited on polished CFQ substrates and overcoated with 800Å of Al were placed in a demountable cathode-ray tube and the radiated power measured as a function of electron energy (at constant current). The results are shown in Fig. 3. The lower portions of the curves are straight lines intercepting the abscissa near 2.5 keV. At some critical energy, depending on the film thickness, the curves deviate downward from a straight line.

Power Dissipation of an Electron Beam

The incident electron beam power density P is equal to the incident current density j multiplied by the in-

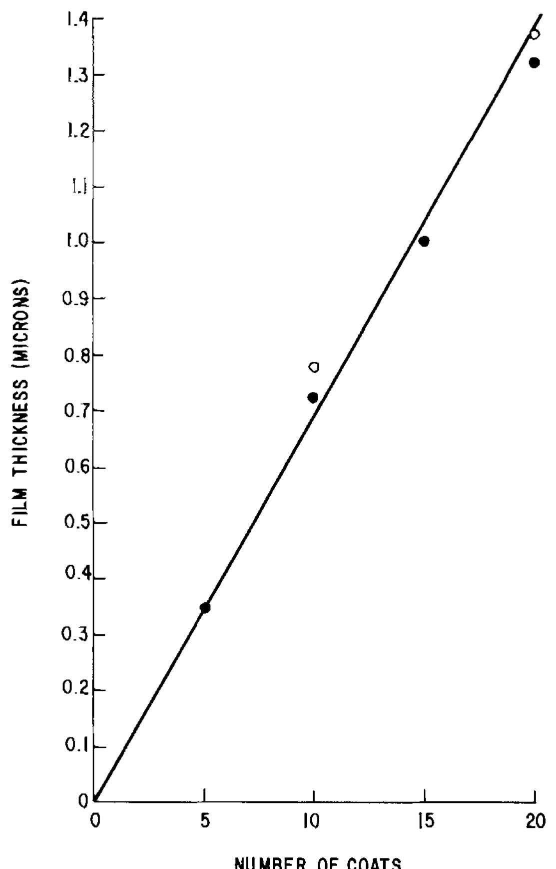

Fig. 1. Gd_2O_3 film thickness as a function of the number of spin-anneal cycles. ●, Thickness using Sloan "Dektak" surface profile measuring instrument; ○, thickness determined by chemical analysis.

Fig. 2. Emission spectra of Gd_2O_3:Eu films under 254 nm excitation. These were annealed at various temperatures. (a) 200°C; (b) 300°, 400°, 500°C; (c) 600°C; (d) 700°C.

cident electron energy E. If $P(x)$ is the mean power density at a depth x in the solid, then the power density lost by the electron beam in traversing a distance x in the solid is

$$\Delta P = P - P(x) - P_b \quad [1]$$

where P_b is the power density contained in the backscattered electrons. The electrons in the solid will be distributed in space, energy, and direction of travel. If R is the mean distance in the solid where the electrons have lost all their initial kinetic energy, then the principle of scaling (2, 14) states that the shapes of the various distributions for a given distance x depend only on x/R, that is, on the fraction of the initial energy which has been lost. The mean values of the electron energy and current density in the solid are, of course, derivable from the various distributions. The quantity R is termed the electron range and there are in the literature a number of different definitions of electron range (15). However, from the scaling principle they should all be proportional to each other. Generally, over not too large an energy span, the range, however defined, has been found to depend on the initial electron energy through the equation

$$R = AE^n \quad [2]$$

where the constants A and n are material parameters (5, 15). Because of the proportionality of the various ranges they should differ only in the factor A.

It has, therefore, been common practice to express the mean values of the electron energy and current density at a depth x in the solid terms of a reduced distance y (3, 5, 8)

$$y = x/R = x/AE^n \quad [3]$$

The value of the reduced distance will vary depending

on the range definition used, but the quantity Ay should be independent of the choice of range. For our purposes we need not be concerned with any particular definition of range, but assume, as others have done, that at a distance x in the solid, the mean energy and current density and hence the mean power density, all of which are functions of E and x, can be written as functions of y. We write

$$\Delta P/P = g(y) \quad [4]$$

$$P^{-1}(d\Delta P/dx) = (dg/dy)/AE^n \quad [5]$$

The shape of the important functions $g(y)$ and dg/dy are shown schematically in Fig. 4b, c. [See, for example, Fig. 10 and 11 of Ref. (8).] Values of y_m and y_c are marked. At $y = y_c$, $dg/dy = 0$. The function $g(y)$ is a constant, $g_c = 1 - P_b/P$ for all $y > y_c$. The quantity y_m is some arbitrarily chosen value of $y < y_c$ and is discussed later.

Power Dissipation in Al Film

As indicated above, in order to prevent charging of our phosphor films they were coated, by evaporation, with 800Å of Al. The geometry of our Al-phosphor film layer is shown in Fig. 4a. The incident monoenergetic electrons have an energy $E(-a)$ and the current density of the beam is $j(-a)$. The electron beam suffers a power loss in passing through the Al layer and the transmitted electrons will be distributed in energy. For a thin, 800Å Al film ($\rho a = 22\ \mu g/cm^2$) at incident energies larger than that required to penetrate the film (*i.e.*, larger than 2.5 keV) the energy distribution of the transmitted electrons becomes sharply peaked so that the mean and most probable energies of the transmitted electrons differ very little from each other (15). Therefore, the electrons transmitted through the Al layer and impinging upon the phosphor layer may still be considered as being essentially monoenergetic with energy $E(0)$ where $E(0) < E(-a)$. At incident energies comparable to those required to penetrate the Al layer, $E(0)$ is the mean energy of the transmitted electrons.

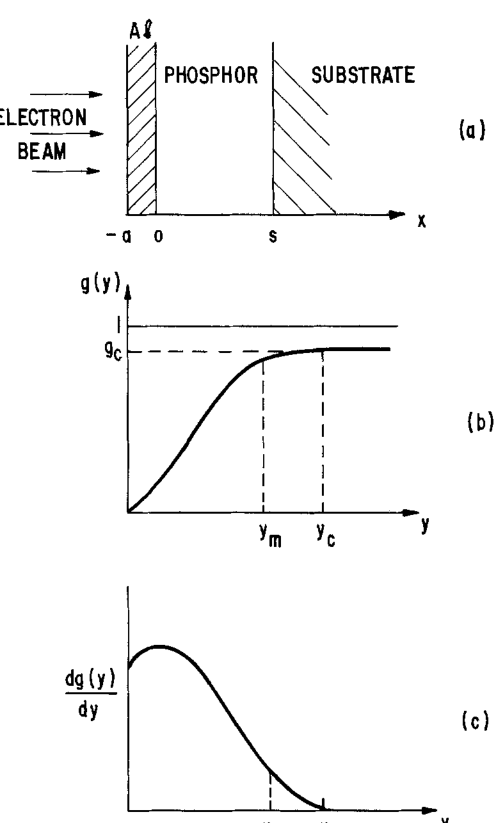

Fig. 4. (a) Geometry of Al-phosphor film; (b) shape of the function $g(y)$ (see text); (c) shape of the function dg/dy (see text).

Table I. Values of the mean energy, the transmission coefficient η_T, and the power density, for unit initial current density, of electrons transmitted through 800Å of Al

$E(-a)$ (keV)	$E(0)$ (keV)	$\eta_T(0)$	$P(0)$
1	0.01	1.0×10^{-14}	1.0×10^{-16}
2	0.44	0.043	0.02
3	1.33	0.448	0.60
4	2.36	0.737	1.74
5	3.42	0.865	2.96
6	4.50	0.925	4.16
7	5.58	0.954	5.32
8	6.64	0.971	6.45
9	7.70	0.980	7.56
10	8.76	0.986	8.64
11	9.81	0.990	9.71
12	10.85	0.992	10.76
13	11.89	0.994	11.82
14	12.93	0.995	12.87
15	13.96	0.996	13.90
16	14.99	0.997	14.95
17	16.02	0.998	15.99
18	17.05	0.998	17.02
19	18.07	0.998	18.03
20	19.09	0.999	19.07

We consider first the energy $E(0)$ and current density $j(0)$ of electrons transmitted through the 800Å Al film. For Al, Makhov (5) finds that the mean energy of the transmitted electrons is given by

$$E(0)/E(-a) = \exp(-0.9\, y_a^{0.9}) \quad [6]$$

When the incident energy $E(-a)$ is measured in keV and the Al film thickness, a, is in angstroms, y_a is given by

$$y_a = a/1.41 \times 10^2 E(-a)^{1.68} \quad [7]$$

Values of $E(0)$ are given in Table I for values of $E(-a)$ from 1 to 20 keV with $a = 800$Å. Makhov also gives for the transmitted current density $j(0)$

$$j(0)/j(-a) = \eta_T = \exp(-y_a^2) \quad [8]$$

Values of η_T are also given in Table I. Finally, the mean power density of the transmitted beam $P(0) = j(0)E(0)$ for unit initial current density is tabulated in the last column of the table. We recall that for values of $E(-a) > 2.5$ keV, the transmitted electrons (*i.e.*, those incident on the phosphor surface) are close to being monoenergetic.

We can replot, in Fig. 5, the experimental curves of Fig. 3, using as the abscissa not $E(-a)$ but $P(0)$. The lower portions of the curves are straight lines whose slopes and intercepts were determined by a least squares analysis (correlation coefficients were 0.999). The intercepts on the abscissa all lie close to the origin indicating a very small diffusion layer thickness for Gd_2O_3:Eu (9). This is in accord with the results of Ludwig and Kingsley (10) who find a dead-voltage of about 0.5 keV for Gd_2O_3:Eu. As indicated earlier in this paper we will neglect the effect of the diffusion layers at the phosphor surfaces. At some critical value of $P(0) = P_c(0)$, depending on the thickness, the curves deviate downward from straight lines.

Analysis of Radiated Power: Beam Power Data

If we consider a phosphor film of thickness s, and if a fraction $\epsilon[x, E(0)]$ of the beam power density dissipated in a thickness dx at depth x generates fluorescence, then the total power density emitted as fluorescence radiation is given by

$$B = \int_0^s \epsilon[x, E(0)](d\Delta P/dx)\,dx = P(0)\int_0^{y_s} \epsilon[y, E(0)]g'(y)\,dy \quad [9]$$

where $y_s = s/AE(0)^n$. We assume no diffusion of the excitation in the phosphor and take $\epsilon[y, E(0)]$ to be a constant ϵ_0. Gergeley (9) treated the problem by including the diffusion of generated secondaries and radiationless recombination at the surface, In order to

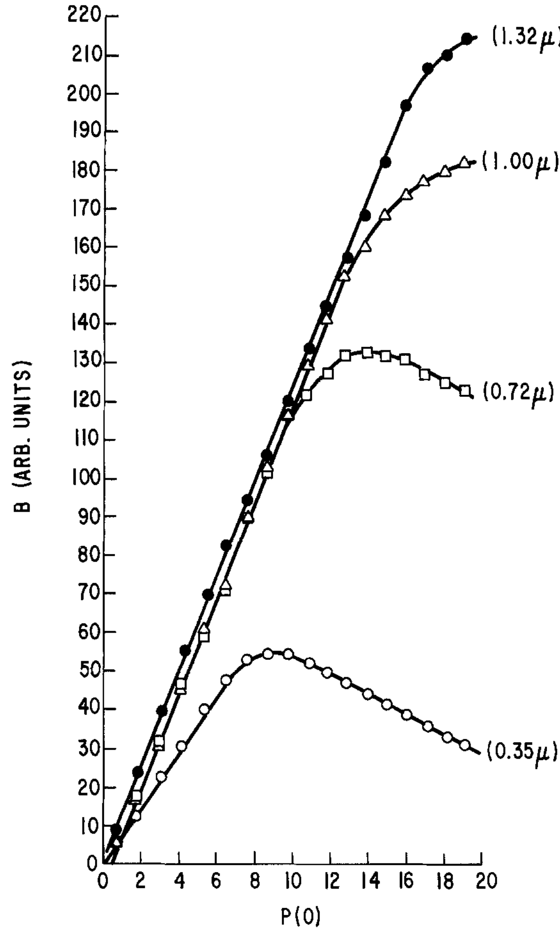

Fig. 5. Radiated power of Gd_2O_3:Eu films overcoated with 800Å of Al as a function of the electron beam power at the phosphor surface.

get a closed form solution to the diffusion equation he assumed a rather simple form for $g(y)$. He let $g(y) = y$ for $0 \leq y \leq 1$ and $g(y) = 1$ for $y \geq 1$. This is, of course, an unreasonable shape for the function and cannot generate the correct shape of $B - P(0)$ curves for $P(0) > P_c(0)$.

With ϵ a constant we get

$$B = P(0)\epsilon_0 g(y_s) \quad [10]$$

For values of $E(0) < (s/Ay_c)^{1/n}$ (*i.e.*, $y_s > y_c$) Eq. [10] yields a linear relation between B and $P(0)$

$$B_l = P(0)\epsilon_0 g_c = \text{constant} \cdot P(0) \quad [11]$$

The critical energy $E_c(0)$ is given by the condition that

$$y_s = y_c$$

$$E_c(0) = (s/Ay_c)^{1/n} \quad [12]$$

For values of $y_s < y_c$, the curves will deviate downward from a straight line. Since preparative conditions and the geometry used in measuring the radiated power might vary from sample to sample (for example, the thinnest film has a slope smaller than the other three samples), it is better to take the ratio of the radiated power values for $P(0) > P_c(0)$ and divide them by the ones obtained by extrapolation of the linear portion of the curves. We get

$$B/B_l = g(y_s)/g_c \quad [13]$$

Range-Energy Relation

The values of $E_c(0)$ obtained from the observed values of $P_c(0)$ for the different film thickness enable us to determine the exponent n in the range-energy relation. Having this value, we can compare our experimental value of B/B_l with the $g(y)$ functions derived from theory.

Table II. Values of $E_m(0)$ for Gd_2O_3:Eu films of various thicknesses

s, μ	ρs, mg/cm²	$E_m(0)$, keV
0.35	0.26	8.1
0.72	0.53	11.9
1.00	0.74	15.8
1.32	0.98	19.0

Since B/B_l, particularly for the thicker samples, has a very small slope near $P_c(0)$, it is difficult to determine with precision the values of $P_c(0)$. We can, however, readily find the value of $P(0)$ at which B/B_l has some arbitrary value less than unity. We have chosen the point at which $B/B_l = 0.9$ and the corresponding values of electron energy and beam power we denote by $E_m(0)$ and $P_m(0)$.

The quantity y_m is defined by

$$y_m = s/AE_m(0)^n \quad [14]$$

so that

$$\log s = n \log E_m(0) + \log (y_m A) \quad [15]$$

In Table II are tabulated the values of $E_m(0)$ obtained from the experimental curves of Fig. 5 and Table I.

In Fig. 6 we plot log ρs against log $E_m(0)$. The slope of the line as determined by a least squares fit (correlation coefficient 0.995) gives $n = 1.53$. With ρs in mg/cm² we find $\rho Ay_m = 0.011$. The value of n agrees very well with the results of Cosslett and Thomas for the extrapolated range (15). They find $n = 1.5$ for a number of elements (Al, Cu, Ag, Au) in the range 5-15 keV. We note that only the product ρAy_m is obtained from the data, the value of y_m being determined by the particular definition of electron range.

We can also compare our data with those obtained by Ehrenberg and King (2) who, as already mentioned, observed microscopically the extent of the luminous zone in single crystals of various phosphors. Their data for CsI ($Z_{avg} = 54$) can be used for comparison. They define an ultimate range, U, as the total length of the luminous zone. In Table III are tabulated Ehrenberg and King's values of ρU after correction, as they suggest, for errors in the optical observations.

The length of the luminous zone at any given value of the electron energy $E(0)$ is the distance in the solid at which $dg/dy = 0$. This distance is given by

$$\rho x_c = \rho Ay_c E(0)^{1.53} \quad [16]$$

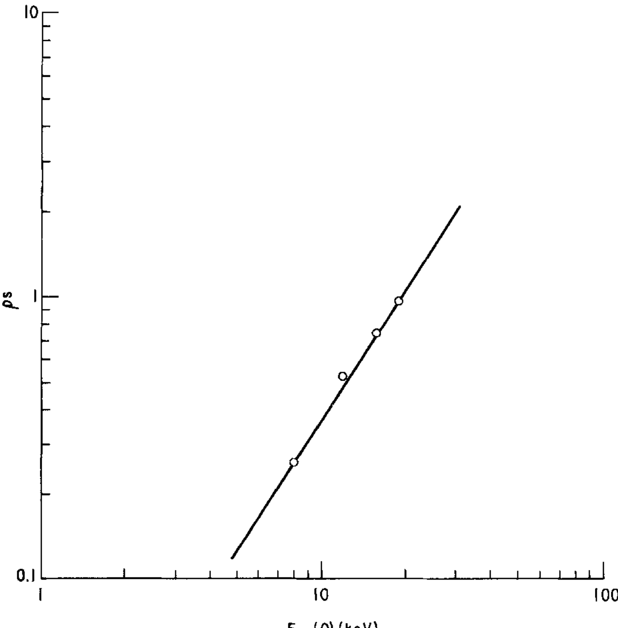

Fig. 6. Log ρs for the four Gd_2O_3:Eu films plotted as a function of log $E_m(0)$.

Table III. Comparison of various electron ranges

$E(0)$	ρU(mg/cm²)[a] (CsI; $Z_{avg} = 54$)	ρx_c(mg/cm²) (Gd_2O_3; $Z_{avg} = 57$)	ρR_{max}(mg/cm²)[b] (Ag; $Z = 47$)
5	0.48	0.18	0.15
10	0.72	0.50	0.42
15	1.06	0.95	0.85
20	1.48	1.47	—
25	1.98	2.07	—

[a] Ref. (2).
[b] Ref. (15).

From our data the quantity $\rho A y_c$ can be determined from

$$\rho A y_c = \rho s / E_c(0)^{1.53} \quad [17]$$

Using the value of $E_c(0) = 6.5$ keV estimated from the data for our thinnest sample, we get $\rho A y_c = 0.015$. Tabulated in Table III are our calculated values of the length of the luminous zone given by

$$\rho x_c = 0.015\, E(0)^{1.53} \quad [18]$$

It can be seen that the results are in close agreement except at the lowest energies. Since our values of x_c should correspond to the maximum range R_{max}, of Cosslett and Thomas (15), we also compare in Table III the two ranges. R_{max} was measured for Ag ($Z = 47$) but the authors reported very little Z dependence in R_{max}. Again the agreement is seen to be reasonably good.

Electron Power Dissipation in Gd_2O_3:Eu

In accord with Eq. [13] when B/B_l is plotted against $\rho s/E(0)^{1.53}$ ($= \rho A y_s$) for the four Gd_2O_3 films, all the data points should fall on a common curve, this curve being the function

$$g(y)/g_c = [\Delta P/P(0)]/[1 - P_b/P(0)] \quad [19]$$

plotted against ρAy. Such a plot of the data is given in Fig. 7 and it is seen that the data do tend to cluster about a single curve. It would have been advantageous to take data for the thicker films at electron energies, $E(-a)$, greater than 20 keV, but we were limited by the capabilities of our demountable cathode-ray tube.

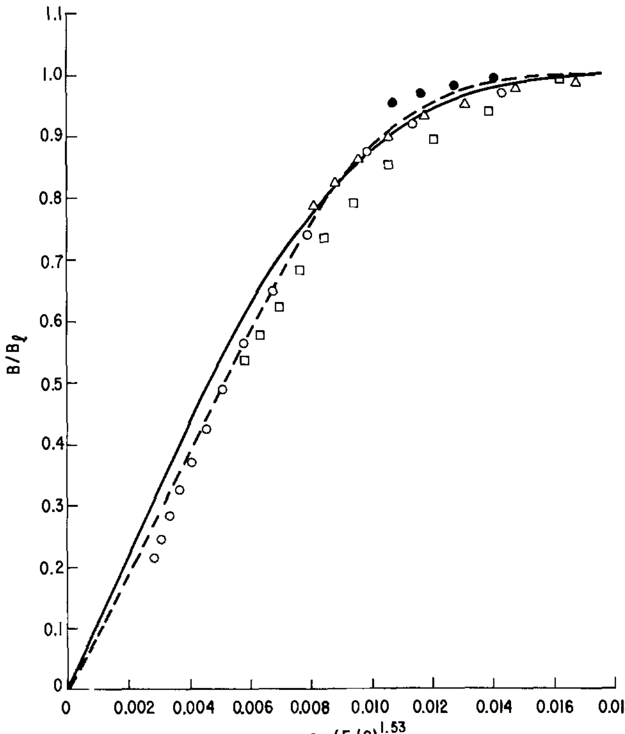

Fig. 7. Observed values of B/B_l plotted against $\rho s/E(0)^{1.53}$ for the four Gd_2O_3:Eu films. Values of ρs in mg/cm² are: ○, 0.26; □, 0.53; △, 0.74; ●, 0.98. The calculated curves $g(y)/g_c$ are from the data of Spencer (7) (———) and Kanaya and Okayama (8) (- - - -).

We can compare our experimentally determined power dissipation with the theoretical calculations of Spencer (7) and of Kanaya and Okayama (8). In our notation, Spencer's tabulated values of $J(y)$ are related to the power loss by

$$J(y) = [d(\Delta P/dx)]/(dE/dr)_{E(0)} \quad [20]$$

where $(dE/dr)_{E(0)}$ is the stopping power for electrons of energy $E(0)$ and r is the distance measured along the path of the electron. From Eq. [5] and [20]

$$dg/dy = J(y) R[E(0)] (dE/dr)_{E(0)}/P(0) \quad [21]$$

Upon integration we get

$$g(y)/g_c = \int_0^y J(y)dy \Big/ \int_0^\infty J(y)dy \quad [22]$$

Since the average atomic number of Gd_2O_3 is 57, we have used Spencer's computed values of $J(y)$ for Sn($Z = 50$) at the lowest electron energy for which calculations were made: $E(0) = 50$ keV. This, of course, requires a rather large extrapolation in energy, but as Spencer points out, the shapes of the $J(y)$ curves change little with electron energy. This is in accord with the assumption that $g(y)$ is independent of energy. In order to compare the experimental data with theory, we must evaluate the constant ρA in the range-energy relation. In the previous section we found that $\rho A y_m = 0.011$ where y_m is the particular value of y for which $g(y)/g_c = 0.9$. From Spencer's data we find that $y_m = 0.34$ so that $\rho A = 0.032$. Spencer's calculated curve of $g(y)/g_c$ *vs.* ρAy is shown by the solid line in Fig. 7. The agreement between theory and experiment is seen to be reasonably good.

Kanaya and Okayama, using the quasi elastic scattering theory of Lindhard *et al.* (16) applied to a semi-infinite medium, give an equation for evaluating $g(y)$ for any Z (Eq. [22] of Ref. (8) where E_A/E_0 is our $g(y)$). From their calculations $y_m = 0.47$ and, therefore, $\rho A = 0.023$. The calculated curve of Kanaya and Okayama is given by the dashed line in Fig. 7. The fit to the experimental points is again seen to be reasonably good.

From the experimental values of B/B_l we can also evaluate the electron beam power dissipation in Gd_2O_3 as a function of depth, ρx, for various initial energies $E(0)$. Since $\rho Ay = \rho x/E(0)^{1.53}$, we can from Fig. 7 determine values of B/B_l for a given E(0) at various values of ρx. Using the data for our thinnest sample we plot in Fig. 8 the values of $B/B_l = [\Delta P/P(0)]/[1 - P_b/P(0)]$ as a function of ρx for electron energies, $E(0)$ of 5, 10, 15, and 20 keV. The arrows at the top of the figure mark the values of ρx for which $B/B_l = 0.9$. These values agree very well with those read from Fig. 6.

Summary

We have shown that brightness-electron energy data for thin films of Gd_2O_3:Eu are in reasonably good agreement with theoretical calculations of the power dissipation of an electron beam in a solid. Account was taken of the power loss of the electron beam in the Al film deposited on top of the phosphor layer. Since the dead-voltage of Gd_2O_3:Eu is about 0.5 keV, the diffusion layer is much smaller than the phosphor thicknesses being studied and was neglected. This made the relationship between the measured phosphor brightness as a function of electron energy and the power dissipation of the electron beam (Eq. [13]) a particularly simple one.

Manuscript submitted April 16, 1975; revised manuscript received June 18, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976

Silicon Epitaxial Wafer with Abrupt Interface by Two-Step Epitaxial Growth Technique

T. Ishii, K. Takahashi, A. Kondo, and K. Shirahata

Mitsubishi Electric Corporation, Central Research Laboratories, 80 Nakano, Minamishimizu, Amagasaki, Hyogo 661, Japan

ABSTRACT

A new silicon epitaxial growth technique was developed to respond to the strong demand from higher frequency semiconductor devices. It includes a low temperature epitaxial growth technique by SiH_4 and a newly developed two-step epitaxial growth technique based upon a hydrodynamic analysis of crystal growth from vapor phase considering a stagnant gas layer. Autodoping and autodilution phenomena are both completely suppressed and a controlled abrupt impurity profile can be obtained between two regions of different doping level. Silicon Read Type IMPATT diodes made by this technique demonstrated a remarkable improvement of microwave characteristics over the ones made by the conventional technique, thus verifying the usefulness of this new technique.

A high quality silicon epitaxial wafer with an abrupt interface is required for high frequency, high efficiency, and high reliability operation of semiconductor devices. Such a wafer is especially required for high speed variable capacitors, bipolar IC's, high frequency transistors, and microwave diodes such as IMPATT diodes and PIN diodes. These devices are usually fabricated in a lightly doped epitaxial layer grown on a heavily doped substrate.

When the lightly doped epitaxial layer is formed on the heavily doped substrate, the so-called autodoping phenomenon occurs. It makes a graded impurity profile at the substrate-epitaxial layer interface. The presence of a region of graded impurity profile makes it difficult to design devices accurately because of the discrepancy between actual and apparent epitaxial layer thickness. It also increases an undesirable series and thermal resistance which results in the degradation of operation efficiency and device reliability. The restraint of the autodoping in an early stage of the epitaxial growth is therefore an important industrial problem.

Many papers have been published on this subject. The causes of the autodoping have so far been attributed as follows:

1. Solid-state diffusion of impurities: Impurities in the heavily doped substrate diffuse thermally into the lightly doped epitaxial layer (1).

2. Redeposition of vaporized impurities: Impurities vaporized from the substrate redeposit in the epitaxially growing layer at high concentration *via* gas phase (2, 3).

3. Etching by halides: Impurities etched off by halides and their halide by-products redeposit in the epitaxially growing layer *via* gas phase when silicon halides are used as source materials (4).

4. Acceleration of solid-state diffusion: The diffusion of impurities from the substrate into the epitaxial layer is accelerated by halides (5).

5. Contamination from the surroundings: Undesirable impurities vaporized from a heated susceptor, a reactor tube, and so forth contaminate the epitaxial layer (6, 7).

6. Deviation from ideal, instantaneous injection of dopant gas at the steady-state composition.

Several techniques have been proposed to prevent the autodoping. They are:

1. Low temperature epitaxial growth: The silicon epitaxial growth is carried out at low temperature by use of silane (7, 8) or dichlorosilane (9, 10), by the high-low temperature cycle epitaxial growth method (11), or by the mole fraction coating epitaxial growth method (12).[1]

2. Substrate sealing: The back surface of the substrate is sealed by highly pure polycrystalline silicon, silicon nitride, or silicon dioxide to suppress the vaporization of impurities (6, 7).

3. Susceptor sealing: The susceptor is sealed completely, usually by highly pure polycrystalline silicon to suppress the vaporization of undesirable contaminants (7).

4. Impurities of slow diffusion rate: Impurities of slow diffusion rate, such as antimony, are used as the substrate dopant to suppress a fast solid-state diffusion (3).

5. Silicon deposition without halides (7, 8).

These techniques are available to restrain the autodoping to some extent, but they are sometimes very troublesome industrially, and an essential solution has not so far been obtained. Low temperature epitaxial growth and accurate gas flow control are thought to be essential.

The widely used method for the silicon epitaxial growth is still the reduction of silicon halides, such as $SiCl_4$ or $SiHCl_3$, by hydrogen. This method has merits of a high growth rate, easy handling, and low cost, but it has such demerits as a high growth temperature and an etching reaction by halides.

[1] The quality of an epitaxially grown layer is largely dependent on substrate conditions and it is more serious at low temperature. The mole fraction coating epitaxial method is a technique to obtain a good crystalline epitaxial layer grown at low temperature. It consists of an initial slight epitaxial growth from low mole fraction of a source gas ($SiCl_4$, SiH_4, etc.) in a carrier gas (H_2) and a succeeding normal epitaxial growth from higher mole fraction of source gas.

Key words: epitaxy, autodoping, silane, IMPATT.

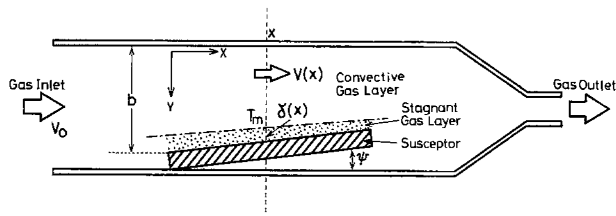

Fig. 1. Schematic cross section of the horizontal silicon epitaxial reactor (14).

Silane has become popular as a silicon source material in place of silicon halides because it does not have these disadvantages. The growth temperature is lowered to around 1000°C, even below 900°C (8, 13) from the common growth temperature of 1200°C in the case of silicon halides, and the etching reaction does not take place.

The gas flow control in the reactor tube is another important factor to restrain the autodoping. We investigated analytically the gas flow in the reactor tube and the autodoping mechanism based upon the stagnant gas layer model by Eversteyn *et al.* (14) and confirmed that the stagnant gas layer on the susceptor was supposed to be an essential reason for the autodoping. We developed a simple but very effective silicon epitaxial growth technique without the autodoping and named it "two-step epitaxial growth technique." The object of this paper is to show that the autodoping can be prevented by low temperature epitaxial growth through the pyrolysis of silane and by the controlled gas flow considering the stagnant gas layer.

We recognized that this new epitaxial growth technique was also available to restrain autodilution phenomenon, an inverse phenomenon which occurs when a highly doped epitaxial layer is formed on a lightly doped substrate.

Autodoping.—According to the stagnant gas layer model (14) or the boundary layer model (15), the gas flow in a horizontal reactor tube splits into two regions, a stagnant gas layer and a convective gas layer. The stagnant gas layer is formed on the heated susceptor by flow resistance and thermal force. The gas flow in it is negligible with respect to the main stream flow. It is so static and stable that a substantial transportation of gas molecules or atoms is performed only by diffusion. Figure 1 shows a schematic cross section of a horizontal reactor tube. Injected gases are carried in the convective gas layer. Molecules of silicon source gas and doping gas diffuse into and through the stagnant gas layer, reach the surface of the substrate, and then decompose to deposit silicon and impurity atoms epitaxially.

According to Eversteyn *et al.* (14), the thickness of the stagnant gas layer is expressed experimentally by

$$\delta(x) = \frac{A}{\sqrt{V_T(x)}} - B \quad [1]$$

where $\delta(x)$ is the thickness of the stagnant gas layer at the distance of x from an entrance edge of the susceptor (cm); $V_T(x)$ is the gas velocity in the convective gas layer at x (cm/sec); and A and B are experimentally determined constants. $V_T(x)$ is expressed by

$$V_T(x) = \left(\frac{b}{b - x\tan\psi}\right)\left(\frac{T_m}{T_o}\right)V_o \quad [2]$$

where b is the maximum distance between the wall of the reactor tube and the susceptor (cm); ψ is the tilted angle of the susceptor; T_m is the temperature of the convective gas layer depending upon the growth temperature and assumed to be constant throughout the convective gas layer (°K); T_o is the temperature at which a diffusion constant of the silicon source is is given (°K); and V_o is the gas velocity of the injected gases at the entrance edge of the susceptor (cm/sec).

The thickness of the stagnant gas layer therefore depends upon the gas velocity and the growth temperature. The faster the gas velocity and the higher the growth temperature, the thinner the stagnant gas layer becomes.

Before the epitaxial growth starts, the heavily doped silicon substrate is exposed to high temperature and thereby vaporizes doped impurities up to high vapor pressure.

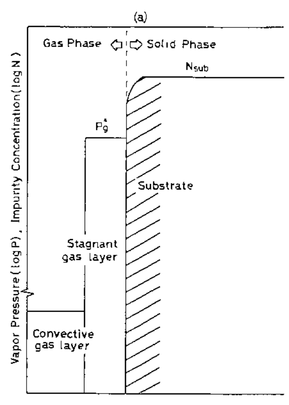
As the stagnant gas layer is stable and static enough, the vaporized impurities stay in the stagnant gas layer without flowing out promptly, and a steady state of the impurity concentration is established in the stagnant gas layer.

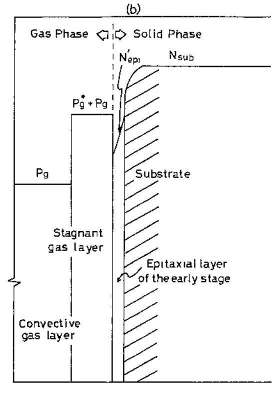
The vapor pressure of gaseous impurities in the stagnant gas layer is related to the impurity concentration of the substrate. The relation is expressed as follows [Fig. 2(a)]

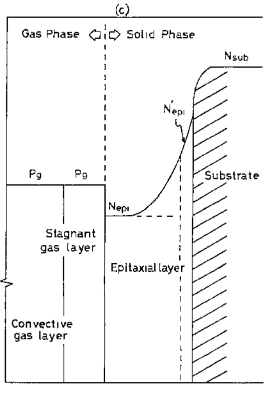
$$N_{sub} \underset{s-g}{=} \eta \cdot k \cdot P_g^{*1/n} \quad [3]$$

where N_{sub} is the impurity concentration of the substrate (atoms/cm^3); P_g^* is the vapor pressure of gaseous impurities in the stagnant gas layer vaporized from the substrate (atm); k is the distribution coefficient between the solid phase and the gas phase; η is a correction factor for the imperfect closing of the system; that is, while all impurity atoms vaporized from the substrate contribute to the gaseous pressure in the stagnant gas layer, some of the gaseous impurity atoms in the stagnant gas layer escape to the convective layer resulting in its imperfect contribution to its gaseous pressure. It depends on the gas velocity, process temperature, reactor dimensions, etc.; and n is an aggregation coefficient depending upon P_g. The gaseous impurities are composed of their various aggregates. The equilibria for arsenic, for instance, between the various aggregates' forms can be represented as (16): $As_4(g) \rightleftharpoons 2As_2(g)$, $As_2(g) \rightleftharpoons 2As(g)$. It depends on the process temperature and total pressure of impurities. Figure 3 shows our experimental result of the relation between the concentration of gaseous arsenic in the injected gases and the concentration of arsenic in the

Fig. 2. Schematic views of relation between vapor pressure of gaseous impurities in the stagnant gas layer and impurity concentration of the epitaxial layer or of the substrate: (a) before the epitaxial growth starts, (b) at a very early stage of the epitaxial growth, (c) after enough growth of the epitaxial layer.







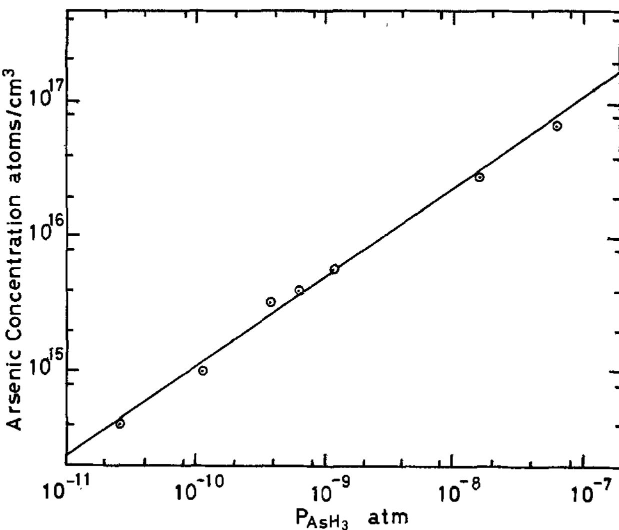


Fig. 3. Variation of arsenic concentration in the epitaxial layer grown at 1050°C with arsine partial pressure.

epitaxial layer after enough growth of the epitaxial layer (17). The subscript s-g means the vaporization from the solid phase (the substrate) to the gas phase (the stagnant gas layer).

When the doping gas of the predetermined vapor pressure P_g is supplied to form the epitaxial layer of the impurity concentration N_{epi}, the total vapor pressure of gaseous impurities in the stagnant gas layer becomes $P_g + P_g{}^*$ at the beginning of the epitaxial growth. In consequence, at a very early stage of the epitaxial growth the impurity concentration in the epitaxial layer N'_{epi} would be as follows [Fig. 2(b)]

$$N'_{epi} = \underset{g-s}{\eta} \cdot k \cdot (P_g{}^* + P_g)^{1/n} \qquad [4]$$

where N'_{epi} is the impurity concentration in the epitaxial layer of the early stage (atoms/cm³) and P_g is the vapor pressure of the doping gas (atm). The subscript g-s means the deposition of impurities from the gas phase (the stagnant gas layer) to the solid phase (the epitaxial layer). As $P_g{}^*$ is much greater than P_g in the case of interest, N'_{epi} becomes much higher than the expected N_{epi}. This means that the epitaxial layer at the beginning is doped more than the predetermined impurity concentration. This is the phenomenon of autodoping.

As the epitaxial growth proceeds, the vapor pressure of impurities vaporized from the substrate decreases and reaches the predetermined pressure P_g of the doping gas. The impurity concentration of the epitaxial layer in this case is expressed as follows [Fig. 2(c)]

$$N_{epi} = \underset{g-s}{\eta} \cdot k \cdot P_g{}^{1/n} \qquad [5]$$

Figure 4 shows a typical impurity profile of the epitaxial layer grown by the conventional epitaxial growth method (18). The impurity concentration of the epitaxial layer N_{SS} is expressed by a sum of the solid-state diffusion of impurities from the substrate and the autodoping

$$N_{SS} = N_{sD} + N_{sA} \qquad [6]$$

where N_{sD} is the term of the solid-state diffusion from the substrate; N_{sA} is the term of the autodoping; and the N_{sD} and the N_{sA} are expressed by

$$N_{sD} = \frac{N_{sub}}{2}\left(1 - \text{erf}\frac{x}{\sqrt{2Dt}}\right) \qquad [7]$$

$$N_{sA} = N_o{}^* \exp(-\phi x) \qquad [8]$$

Here $N_o{}^*$ is the impurity concentration of the epitaxially grown layer at a very early stage, coincides with N'_{epi}, and is expressed from Eq. [4] as follows

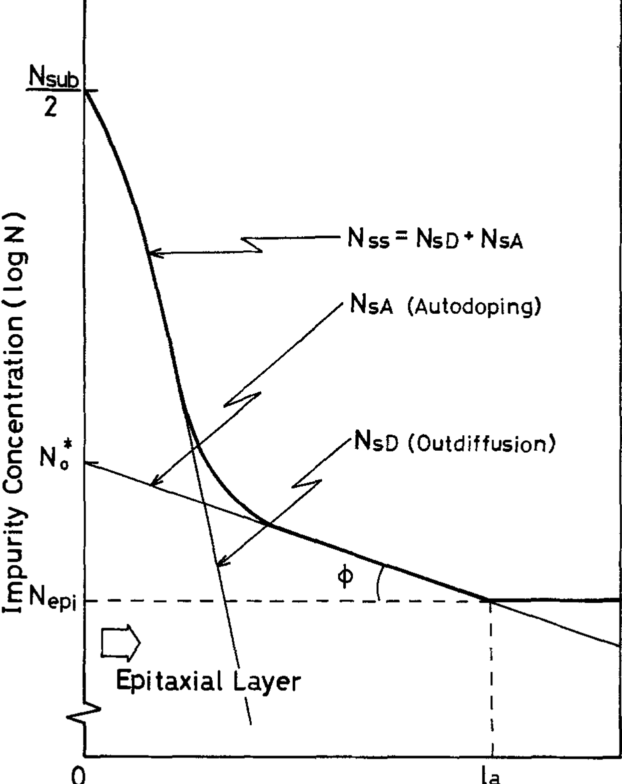

Fig. 4. Typical impurity profile of the epitaxial layer near the substrate grown by the conventional epitaxial growth method (18).

$$N_o{}^* = N'_{epi} = \underset{g-s}{\eta} \cdot k \cdot (P_g{}^* + P_g)^{1/n} \qquad [9]$$

$$N_o{}^* = \underset{g-s}{\eta} \cdot k \cdot P_g{}^{*1/n} \qquad [9a]$$

ϕ is defined as in Fig. 4.

From Eq. [3] and [9a]

$$N_o{}^* = \frac{\underset{g-s}{\eta}}{\underset{s-g}{\eta}} \cdot N_{sub} = \eta \cdot N_{sub} \qquad [10]$$

ϕ and η are determined experimentally and have been reported previously (18, 19).

In order to prevent the autodoping, it will therefore be understood as essential to suppress the vaporization of impurities from the heavily doped substrate at high vapor pressure and to clean up the excess impurities from the stagnant gas layer.

Two-step epitaxial growth technique (20).—Once the surface of the substrate is covered with a thin epitaxial layer, though it is doped excessively, it would effectively suppress the vaporization of impurities at a high vapor pressure from the heavily doped substrate. With the suppression of impurity vaporization, gaseous impurities in the stagnant gas layer decrease their vapor pressure, gradually approaching the predetermined value because some of them are taken into the epitaxially growing layer while others diffuse out into the convective gas layer. Figure 5 shows a schematic relation among the vapor pressure of gaseous impurities in the stagnant gas layer, the impurity concentration in the epitaxial layer, and the thickness of the epitaxial layer as a function of the growth time when the epitaxial growth is carried out conventionally. The lines A, B, and C represent the change of the vapor pressure, impurity concentration, and epitaxial layer thickness, respectively. Until the time t_a, the grown layer is doped excessively. In other words, autodoping is observed in a region within l_a of the substrate-epitaxial layer interface.

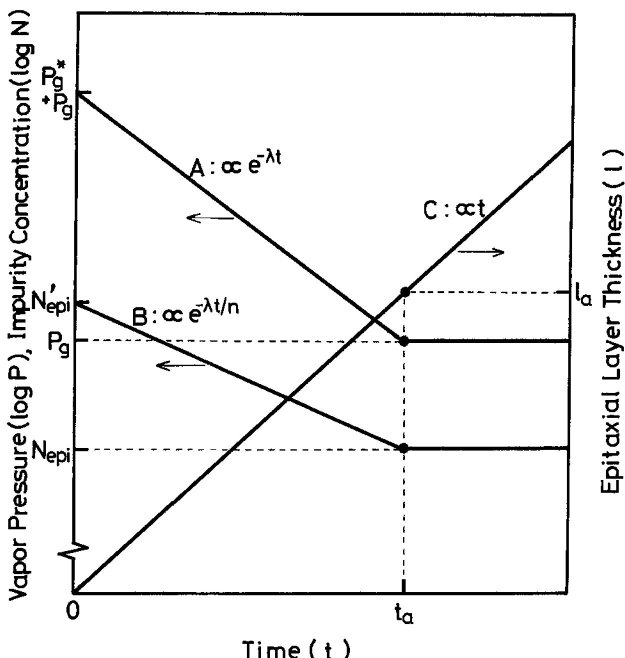

Fig. 5. Qualitative relation among the vapor pressure of impurities in the stagnant gas layer (A), the impurity concentration in the epitaxial layer (B), and the epitaxial layer thickness (C) as a function of time by the conventional epitaxial growth method concerning the autodoping. λ = decreasing coefficient of vapor pressure.

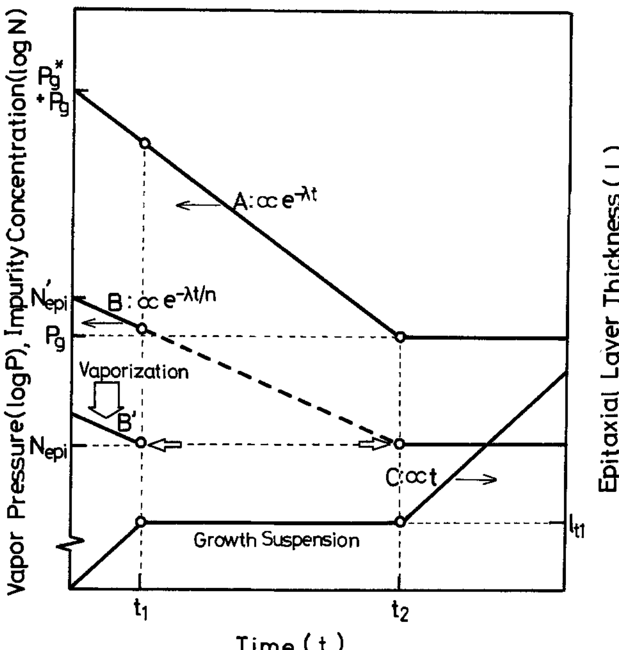

Fig. 6. Qualitative relation among the vapor pressure (A), the impurity concentration (B), and the epitaxial layer thickness (C) as a function of time by the two-step epitaxial growth technique. Between t_1 and t_2, the stagnant gas layer is purified suspending the epitaxial growth.

In the two-step epitaxial growth technique, the epitaxial growth process is divided into two growth steps. The first step is very short with only enough time to cover the substrate surface slightly. The second step is carried out conventionally until getting the required layer thickness. Between the two growth steps, purification of the stagnant gas layer is performed suppressing impurity vaporization from the substrate by the first thin epitaxial layer.

During the purification treatment of the stagnant gas layer, only the carrier gas is supplied; the source gas and the doping gas are stopped. So epitaxial growth does not occur and the vapor pressure of gaseous impurities in the stagnant gas layer decreases gradually. Figure 6 shows the principle of the two-step epitaxial growth technique. The vapor pressure of gaseous impurities changes along line A. At the time t_1, the first growth step is over. Between the time t_1 and t_2, the stagnant gas layer is purified and the vapor pressure of gaseous impurities decreases to reach the predetermined level P_g at the time t_2.

The first epitaxial layer is doped excessively and the impurity concentration is shown by line B at first. During the purification treatment, as impurities vaporize from the surface of the first epitaxial layer and the vaporization rate is much faster than the solid-state diffusion of impurities from the substrate to the epitaxial layer, the impurity concentration in the first epitaxial layer will also fall down to the line B′ at the end of the purification treatment. At the time t_2, the second epitaxial growth starts. Now that the vapor pressure of gaseous impurities in the stagnant gas layer has reached the predetermined level, an epitaxial layer with the expected doping level N_{epi} can be obtained. The intermission of the epitaxial growth during the gas purification treatment shortcuts the autodoped region resulting in the abrupt impurity profile at the substrate interface.

These succeeding steps are carried out at the same temperature, and the supplied gas composition in the first and second epitaxial growth steps is kept the same. These facts make the two-step epitaxial growth technique quite simple and useful industrially in contrast with the so-called high-low temperature cycle epitaxial growth method or mole fraction coating epitaxial growth method.

Experimental Procedure

The silicon epitaxial growth apparatus used in the experiment was the conventional horizontal type and its flow diagram is shown in Fig. 7.

Silicon wafers were supported on a SiC-coated graphite susceptor which was 70 mm wide, 230 mm long, and 15 mm thick with a tilted angle of 2°. The susceptor was heated by a 15 kW, 450 kHz rf generator in a boron-free quartz reactor tube. In Table I, specifications of materials used in the experiments and the important experimental conditions are summarized. Highly purified H_2 was used as the carrier gas and its flow rate was 40 liter/min (26.7 cm/sec). Silane was used as the source material to allow low temperature epitaxial growth without halides. The silane concentration in the supplied gas was principally 0.13% and it set the epitaxial growth rate at 0.35 μm/min. Arsine (AsH_3) and diborane (B_2H_6) were used as n- and p-type doping gases, respectively. AsH_3 and B_2H_6 concentration in the supplied gas was varied from 10^{-11} to 10^{-6} atm according to the doping level. The epitaxial

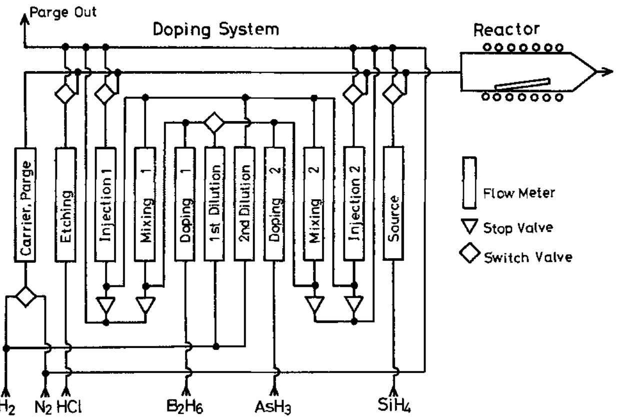

Fig. 7. Construction of the doping system of the silicon epitaxial growth apparatus.

Table 1. Specifications of materials used in the silicon epitaxial growth and the silicon epitaxial growth conditions

Si substrate	n-type		As doped Si (0.005 ohm-cm)
			Sb doped Si (0.015 ohm-cm)
	p-type		B doped Si (0.005 ohm-cm)
Supplied gas	Carrier gas		99.9999% H_2
	Etching gas		100% HCl
	Si source gas		10% SiH_4 (diluted by H_2)
	Doping gas	n-type	50 ppm AsH_3 (diluted by H_2)
		p-type	50 ppm B_2H_6 (diluted by H_2)
Growth condition	Carrier gas flow rate		40 liters/min (26.7 cm/sec)
	Vapor etching	Temperature	1200°C
		Gas composition	$HCl/H_2 = 0.04$
	Si deposition	Temperature	1050°C
		Gas composition	$SiH_2/H_2 = 0.001$-0.002 (0.0013 typical)
			AsH_3/H_2 or $B_2H_6/H_2 = 10^{-11}$-10^{-6}
		Growth rate	0.30-0.45 μm/min (0.35 μm/min typical)
		Doping level	10^{14}-10^{18} cm^{-3}

growth was mainly carried out on As-doped substrate and B-doped substrate at the growth temperature of 1050°C. As arsenic has the highest vapor pressure among commonly used impurities in silicon, autodoping occurs most easily with it. So it would be thought to be most suitable in the investigation of the autodoping phenomenon.

Figure 8 shows a typical temperature-time schedule of the silicon epitaxial growth process by the two-step epitaxial growth technique. Only a vapor etching process by HCl (process I in Fig. 8) was carried out at 1200°C. After the vapor etching, a gas cleaning-up (process II) was performed for enough time to purge etched materials and halides from the stagnant gas layer reducing the process temperature. At the growth temperature of 1050°C, the first epitaxial growth step (process III) provided a very thin epitaxial layer usually less than 0.5 μm, on the substrate surface. In the gas purification step between the first and the second epitaxial growth steps (process IV), excess impurities above the predetermined doping level were purged from the stagnant gas layer suspending the epitaxial growth. The second epitaxial growth step (process V) was carried out conventionally until the expected wafer characteristics were obtained. The duration of the gas purification treatment is very important in the two-step epitaxial growth technique and will be discussed later.

The impurity concentration distribution at the substrate-epitaxial layer interface was determined by capacitance measurement on mesa diodes with a shallow abrupt p-n junction fabricated from the epitaxial wafers.

Experimental Results

Figure 9 shows experimental results related to the cleaning-up effect of the stagnant gas layer contaminated by the HCl vapor etching. The epitaxial wafers A and B were both prepared in the same manner by the conventional epitaxial growth method except for the different cleaning-up time. The stagnant gas layer was cleaned up by 4 min after the HCl etching in sample A and by 16 min in sample B. The results show that a longer cleaning-up treatment is preferable to get an abrupt impurity profile at the substrate interface. This is proof that etched materials and halides stay in the stagnant gas layer without being carried away promptly and have a harmful effect on the abrupt impurity profile. By the conventional epitaxial growth method, a cleaning-up treatment in excess of 20 min was not so effective in improving the impurity profile at the substrate interface. So our sample B shows a technical limitation from the conventional epitaxial growth method.

Figure 10 shows impurity profiles made by three different epitaxial growth processes. Sample A was made by the conventional epitaxial growth method and was grown for 11 min. Samples B and C were both made by the two-step epitaxial growth technique, but the duration of the first epitaxial growth step was different. Namely, it was 1 min long in sample B and was 30 sec long in sample C. The thickness of the first

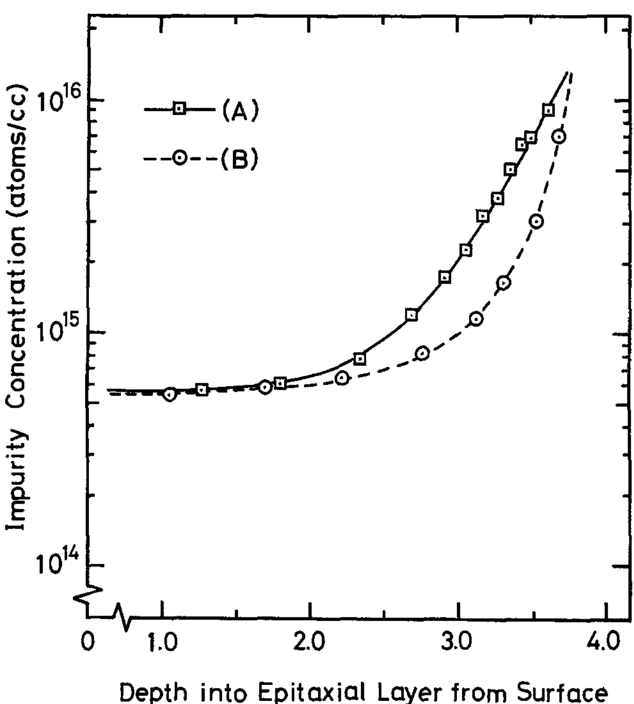

Fig. 9. Dependence of the impurity profile of the silicon epitaxial layer on the gas cleaning-up time after the HCl gas etching. Cleaning up time: (A) = 4 min, (B) = 16 min.

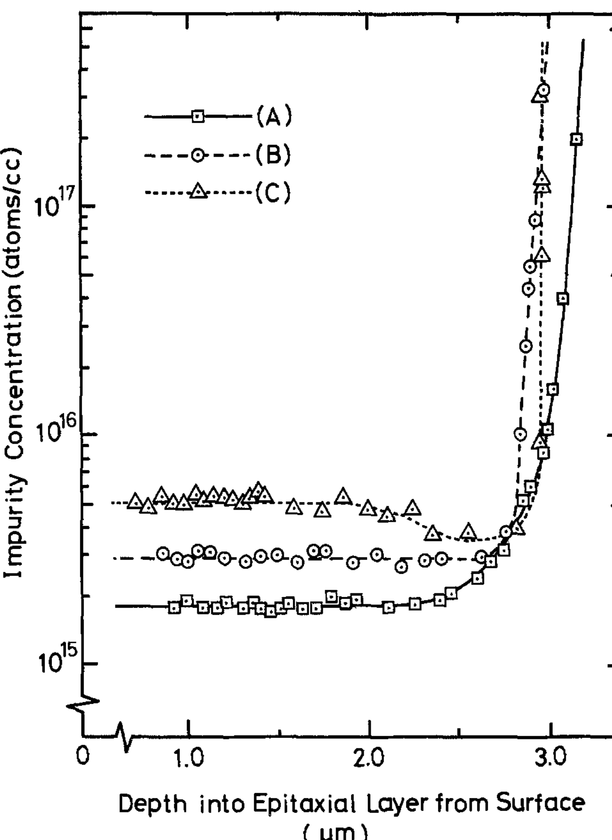

Fig. 10. Impurity profiles of the silicon epitaxial layers grown by the conventional epitaxial growth method (A) and by the two-step epitaxial growth technique (B, C). The first epitaxial layer thickness: (B) = 0.35 μm, (C) = 0.2 μm. The gas purification time: (B), (C) = 16 min.

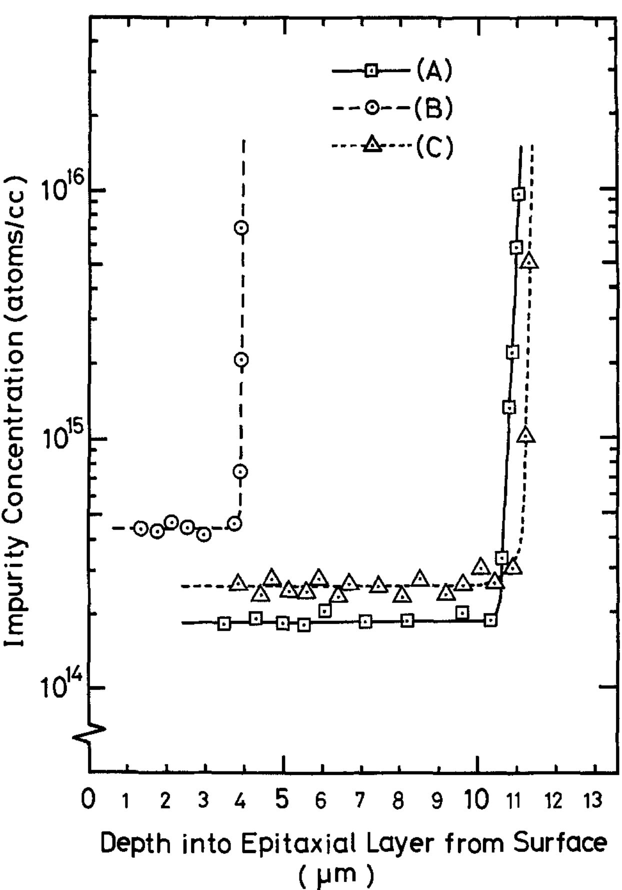

Fig. 11. Impurity profiles of the silicon epitaxial wafers of N on N^+ and P on P^+ structure prepared by the two-step epitaxial growth technique: (A) = N(As) on N^+(As), (B) = N(As) on N^+(Sb), and (C) = P(B) on P^+(B).

epitaxial layer was 0.35 μm in sample B and 0.2 μm in sample C. Other growth conditions were the same, *i.e.*, a 16 min gas purification after the first epitaxial growth, and a 10 min second epitaxial growth. The total epitaxial layer thickness was 4.0 μm in these three samples. Prior to the epitaxial growth, the surface of the substrates was etched by HCl for 5 min, then the gas cleaning-up was performed for 17 min. In sample A the impurity profile was rather gradual at the substrate interface, but it was abrupt enough in sample B or C. For convenience, we estimated the width in order to get a 10^2 increase of impurity concentration from the epitaxial layer with the predetermined impurity concentration to the substrate as an impurity gradient at the substrate interface. The impurity gradient was more than 1 μm in sample A, but it was 0.3 μm in sample B and less than 0.1 μm in sample C. The improved quantity of 0.3 μm or 0.1 μm is comparable to the theoretical solid-state diffusion of arsenic from the substrate. In spite of the high vapor pressure of As, the autodoping was completely suppressed in samples B and C. A slight dip in the impurity profile at the substrate interface observed in sample C will be discussed later.

Impurity profiles of three different epitaxial wafers are compared in Fig. 11. Arsenic-doped epitaxial layers were grown on As- and Sb-doped substrates in samples A and B, respectively, and a boron-doped epitaxial layer was grown on a B-doped substrate in sample C. Those were all prepared by the two-step epitaxial growth technique and the duration of the gas purification treatment after the first epitaxial growth was properly chosen. As antimony has the lowest vapor pressure and also the lowest diffusion rate in commonly used n-type impurities, the autodoping is minimized. But by use of the two-step epitaxial growth technique, an abrupt impurity profile without autodoping can be obtained even in the epitaxial growth on an As- or B-doped substrate as well as an Sb-doped substrate.

Application of the Two-Step Epitaxial Growth Technique

Restraint of autodilution (20).—Occasionally, the successive formation of a highly doped epitaxial layer on a lightly doped substrate or on a lightly doped epitaxial layer is required. In this case, just the opposite phenomenon from autodoping occurs in the early stage of the epitaxial growth; namely, the impurity concentration of the epitaxial layer is considerably lower than the predetermined beginning doping level. We call this phenomenon autodilution.

Before the epitaxial growth starts, the gaseous impurities in the stagnant gas layer practically equilibrate with the impurities in the lightly doped substrate or proceeding epitaxial layer. The vapor pressure $P_g{}^*$ in this case is lower than the P_g necessary to obtain the predetermined doping level $N_{epi}(P_g{}^* < P_g)$. When the source gas and the doping gas of appropriate composition are supplied to form the epitaxial layer of the predetermined doping level, the vapor pressure of the gaseous impurities in the stagnant gas layer does not respond quickly. According to the schematic illustration in Fig. 12, the vapor pressure increases gradually along line A and reaches the predetermined value P_g at the time t_d. Corresponding to this, the impurity concentration in the epitaxial layer changes along line B and the intended doping level is attained at t_d. Before that, the epitaxial layer of the thickness l_d has already grown and, therefore, the impurity profile becomes sluggish in this region.

Here we transform the two-step epitaxial growth technique a little and apply it to restrain the autodilution. At least until the time t_d in Fig. 12 is reached, the epitaxial growth is suspended by stopping the

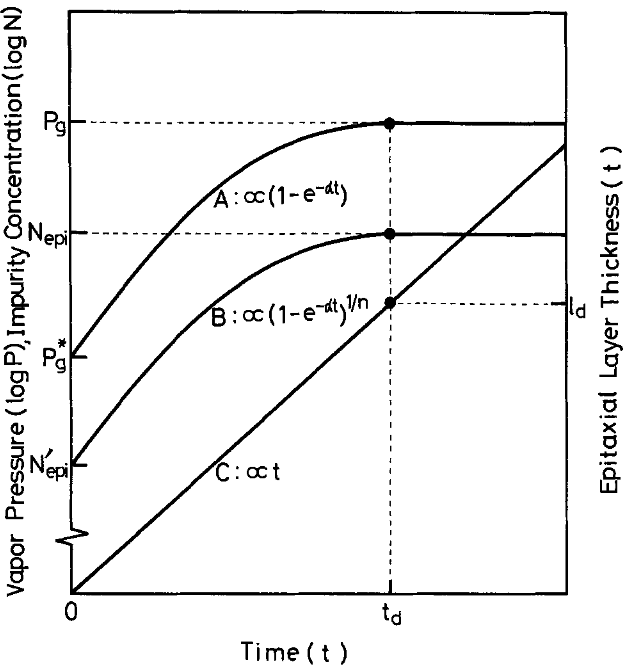

Fig. 12. Qualitative relation among the vapor pressure of impurities (A), the impurity concentration (B), and the epitaxial layer thickness (C) as a function of time concerning the autodilution. α = increasing coefficient of vapor pressure.

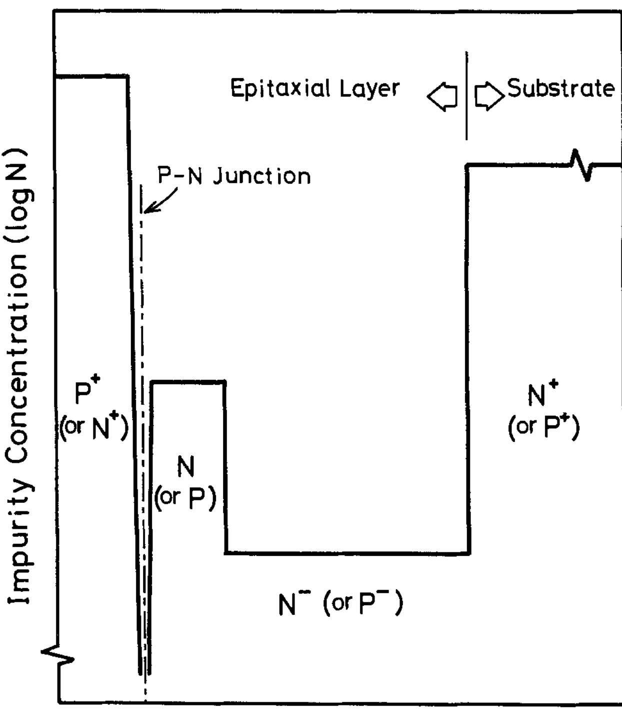

Fig. 13. Schematic hyperabrupt impurity profile of the Read Type IMPATT diode (21).

source gas (SiH_4). As the carrier gas and the doping gas are supplied continuously in this period, the vapor pressure of impurities in the stagnant gas layer is raised to the predetermined level P_g. The epitaxial growth starts only after the vapor pressure has reached P_g. The intermission of the epitaxial growth shortcuts the autodiluted region resulting in the abrupt impurity profile at the interface.

Hyperabrupt impurity profile.—Some microwave semiconductor devices, Read Type IMPATT diodes for example, require hyperabrupt impurity profiles such as P^+NN^- on N^+ or N^+PP^- on P^+ illustrated schematically in Fig. 13 (21). Such impurity profiles can be formed first by the epitaxial growth of a lightly doped layer (N^- or P^-) on a heavily doped substrate (N^+ or P^+), then by the succeeding epitaxial growth of a highly doped layer (N or P) on the lightly doped epitaxial layer, and finally by the succeeding epitaxial growth or diffusion of a heavily doped layer (P^+ or N^+). The autodoping and the autodilution may occur at the N^+N^- (or P^+P^-) and N^-N (or P^-P) interface, respectively.

Figure 14 shows the impurity profile of silicon epitaxial wafers with a hyperabrupt $P^+NN^-N^+$ structure prepared for the Read Type IMPATT diodes of K band use (20,22). Sample A was made by the conventional epitaxial growth method and sample B was made by the two-step epitaxial growth technique. The two-step epitaxial growth technique was used twice in sample B to prevent autodoping at the N^+N^- interface and to prevent autodilution at the N^-N interface. Both samples were made by the same wafer parameters; namely, a 1×10^{15} cm^{-3} As-doped epitaxial layer (N^- layer) was first grown on a 3×10^{19} cm^{-3} As-doped substrate (N^+ substrate) and then a 1×10^{17} cm^{-3} As-doped epitaxial layer (N layer) was grown successively. A P^+ region was formed by boron diffusion at a high surface concentration from the surface of the N epitaxial layer.

In sample A, the autodoping occurred at the N^+N^- interface. As a result, the impurity concentration in the N^- layer became higher than the expected doping level. In sample B, on the other hand, the impurity profile at the N^+N^- interface was abrupt enough and the predetermined doping level was attained.

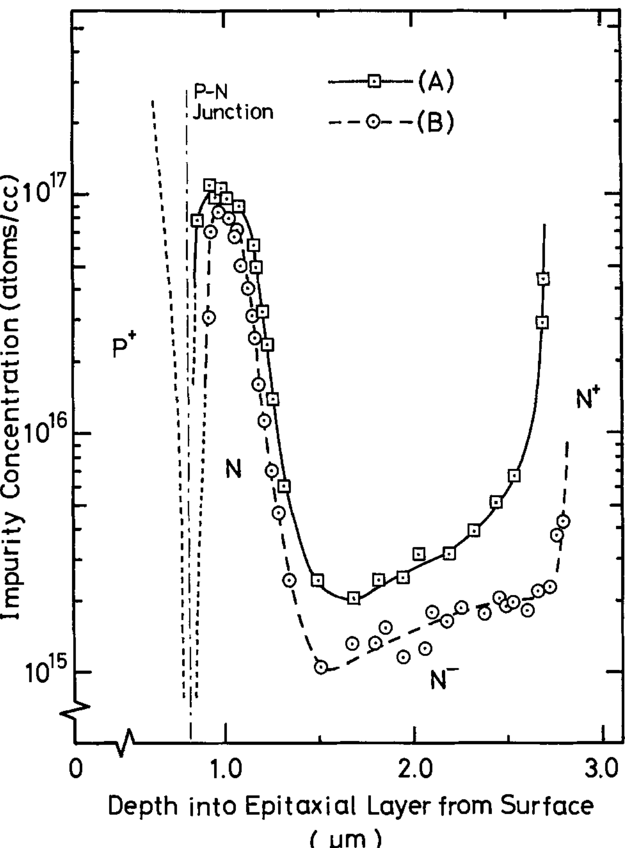

Fig. 14. Hyperabrupt impurity profiles of silicon epitaxial wafers for K band Read Type IMPATT diodes grown by the conventional epitaxial growth method (A) and by the two-step epitaxial growth technique (B).

The transition from N^- to N layer became steeper in sample B than in sample A. The Read Type IMPATT diode requires a narrow avalanche region for high efficiency and wide band operation and the narrow avalanche region corresponds to the abruptness of the

impurity profile at the N-N interface. The improvement of the impurity profile at the N-N interface in sample B narrows the avalanche region and therefore increases the operation efficiency of the Read Type IMPATT diodes. Figure 15 shows the comparison of typical operation characteristics of the Read Type IMPATT diodes. Diodes A and B were fabricated from the epitaxial wafers A and B as shown in Fig. 14, respectively. The CW output power and the operation efficiency were improved by 50% through the improvement of the avalanche region width.

Discussion

In the two-step epitaxial growth technique, the duration of the gas purification treatment after the first epitaxial growth is especially important. It depends upon the process temperature, the gas velocity, the thickness of the first epitaxial layer, and the impurity concentration of the second epitaxial layer. A higher temperature and a faster gas velocity make the stagnant gas layer thinner. The higher temperature also accelerates the vaporization of impurities from the first epitaxial layer and accelerates the diffusion of gaseous impurities in the stagnant gas layer. So the higher the process temperature and the faster the gas velocity become, the shorter the duration of purification treatment becomes. A thicker first epitaxial layer and a higher impurity concentration of the second epitaxial layer also shorten the duration.

An insufficient purification treatment accentuates the autodoped region and makes the impurity profile gradual at the substrate interface. An extreme purification treatment excessively lowers the impurity concentration at the surface of the first epitaxial layer by overvaporization. It also lowers the vapor pressure of gaseous impurities in the stagnant gas layer below the predetermined doping level. The shortage of impurities at the beginning of the second epitaxial growth results in a dip of the impurity profile at the substrate interface. Sample C in Fig. 10 is an example of this.

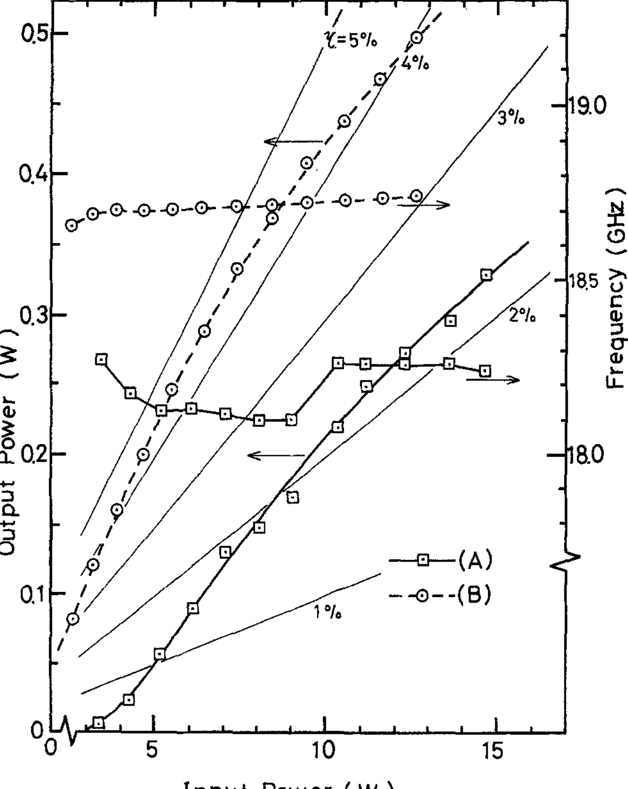

Fig. 15. Comparison of the oscillation characteristics of Read Type IMPATT diodes fabricated from silicon epitaxial wafers prepared by the conventional epitaxial growth method (A) and by the two-step epitaxial growth technique (B).

The slight dip means that the gas purification treatment was performed a little more than the appropriate duration required for the thickness of the first epitaxial layer and the impurity concentration of the second epitaxial layer.

The duration of the gas purification treatment is now determined experimentally, but it should be determined accurately by a rigid hydrodynamic analysis considering the diffusion of gaseous impurities in the stagnant gas layer and the vaporization of impurities from the wafer surface. The analysis is so complicated that a computer simulation is required.

The duration, however, can be roughly estimated by the following method. Referring again to Fig. 4, when the epitaxial layer of l_a thick has grown, the vapor pressure of gaseous impurities in the stagnant gas layer becomes P_g from the initial $P_g + P_g^*$ and the doped impurity concentration in the epitaxial layer N_{ss} becomes the predetermined value N_{epi}. The ratio of impurities being taken into the first epitaxial layer to gaseous impurities diffusing out into the convective gas layer is negligibly small during the gas purification treatment. The gas purification treatment should, therefore, be performed at least for the time necessary to get the epitaxial layer of l_a thick. That is, duration time $= l_a(\mu m)$/growth rate (μm/min). For our samples in Fig. 9, the autodoped region is about 2 μm for the epitaxial layer of doping level of about 6×10^{14} cm^{-3} grown by conventional technique. So in this case, the appropriate duration of heat-treatment is 2 μm/0.35 μm/min = 5.7 min. As for sample C in Fig. 10, the duration of heat-treatment was 16 min as already mentioned, and the slight dip in the doping level at substrate-epitaxial layer interface is quite reasonable for excess heat-treatment.

Conclusion

A silicon epitaxial wafer in which the impurity concentration and profile are rigidly controlled is required for microwave semiconductor devices. The low temperature epitaxial growth by SiH_4 and the newly developed two-step epitaxial growth technique based upon a controlled gas flow in the reactor tube make it possible to eliminate the autodoping and the autodilution phenomena. It has been confirmed by the two-step epitaxial growth technique that the epitaxial growth mechanism based upon the stagnant gas layer model is quite reasonable. The behavior of impurities in the stagnant gas layer is the essential phenomenon in autodoping and autodilution. The usefulness of the silicon epitaxial wafers with controlled abrupt impurity profile between two regions of different impurity concentration was proven concretely by the improved operation characteristics of Read Type IMPATT diodes. The problem left to be solved is the theoretical determination of the most appropriate duration of the gas purification treatment for attaining the best impurity profile at the substrate interface.

Studies of the Push-Out Effect in Silicon

I. Comparison of Sequential Boron-Phosphorus and Gallium-Phosphorus Diffusions

Christopher L. Jones and Arthur F. W. Willoughby

Engineering Materials Laboratories, The University, Southampton, S09 5NH, England

ABSTRACT

The push-out effect in silicon has been investigated by comparing the effect of similar phosphorus emitter diffusions on previously diffused boron and gallium base diffusions, using junction depth and electrical measurements. The closely similar behavior of the two base dopants suggests that both diffuse by the same mechanism in silicon, despite their different covalent radii. For both dopants the amount of push-out increases with emitter diffusion time for constant base diffusion and emitter surface concentration, and decreases as base depth increases for constant emitter diffusion and base surface concentration, and it is concluded that push-out occurs during the emitter diffusion rather than during cooling. The results are discussed with reference to an approximate theory, and agreement between experiment and this theory strongly suggests that push-out is due to a uniform enhancement of the base diffusivity throughout the emitter diffusion period. This study, using junction depth and electrical profiling techniques only, is the first part of this investigation, the second of which will report results of a radiotracer study of push-out.

Diffusion is one of the most important processes in the manufacture of silicon bipolar transistors; yet diffusion mechanisms in silicon are still not well understood. Anomalous diffusion effects have been discussed in a review paper by one of the authors (1) and, more recently, by Hu (2). One of the most important effects is the push-out or emitter-dip effect which is the depression of a base-collector junction beneath a localized emitter diffusion. Since the original observation of this effect by Miller (3) it has become clear that push-out introduces considerable problems in the manufacture of microwave n-p-n transistors using phosphorus-diffused emitters. These problems arise chiefly because narrow base widths are difficult to achieve and control of the base doping level is poor. The influence of various process parameters (*e.g.*, diffusion time, temperature, and surface concentration of the emitter; initial depth and surface concentration of the base) on the amount of push-out have not been definitely established and virtually no information is available concerning the base doping profile shape and how it changes with these parameters.

Most of the information about push-out has been obtained by the traditional method of junction depth measurement (4-8), but in order to understand the diffusion processes much more information is required and this can only be obtained by determining the impurity profiles of the base and emitter through a complete transistor structure. Electrical profiling techniques, although useful, cannot give any information about the base profile within the emitter (5, 9, 10) and therefore a new approach has been adopted by the present authors, that is the radiotracer profiling of the complete base diffusion within and beyond the emitter, preliminary results of which were reported in Ref. (11). Unfortunately, boron does not have a radioisotope of sufficiently long half-life (^{8}B and ^{12}B half-lives are <1 sec) so the conventional boron base was replaced by gallium.

There is very little published information regarding gallium push-out (3, 12) so a necessary first step was to compare boron and gallium push-out by junction depth measurements. This comparison offers the interesting possibility of examining whether or not boron and gallium diffuse by the same mechanism, information which could be of great importance in resolving the current controversy on the diffusion mechanism of the Group III impurities in silicon [Seeger and Chik (13), Hu (2), Kendall and DeVries (14)]. These experiments were aimed also at obtaining more information on how the magnitude of push-out is affected by various parameters of the diffusions used. The results

Key words: diffusion, enhancement, emitter-push, junction depth, transistor.

of this work are described below and analyzed with reference to an approximate theoretical expression for the amount of push-out. A simple approach to estimating push-out in practical cases is also presented.

Further results and analysis of the radiotracer gallium profiling will be given in the second paper (which will be referred to as Part II) together with a discussion of possible causes of push-out in the light of the new evidence.

Experimental Techniques

Material.—All the silicon used was n-type, 1 ohm-cm. in (111) oriented wafer form, chemically polished on one side. Wafers were cleaned by boiling three times in 1-1-1 trichloroethane followed by a 15 min soak in a freshly prepared H_2SO_4/H_2O_2, 1/1 mixture. They were then washed five times in deionized water and blown dry in dry N_2.

Boron base diffusion.—A two-step boron diffusion was employed consisting of a deposition from BBr_3 for 40 min at 960°C after which the boron glass was removed and the boron layer driven-in at 1200° ± 1°C under oxidizing conditions for times in the range 18 to 30 min depending on the depth required.

Gallium base diffusion.—Gallium was diffused in an open tube system using Ga_2O_3 source powder over which was passed a mixture of H_2 and N_2 gases (15). Before entering the furnace the gas mixture passed through a temperature-regulated water bubbler in order to control the amount of water vapor in the gas stream. A diagram of the apparatus is given in Fig. 1. The source temperature was 1000°C and silicon sample temperature was 1100° ± 2°C. Diffusion times ranged from 15 to 180 min depending on the depth required. A thin oxide is formed during the diffusion which can be used for masking subsequent emitter diffusions.

Phosphorus emitter diffusions.—Phosphorus diffusions at 1050° ± 1°C from a $POCl_3$ source were used to form the emitter under the same conditions for both boron and gallium bases. The $POCl_3$ was held at 0°C by crushed ice, and an O_2/N_2 mixture was bubbled through and into the furnace. The amount of dopant introduced was sufficient for the phosphorus concentration in the silicon to reach the solid solubility limit. Once the gas flow rates and the $POCl_3$ bubbler were set up conditions in the furnace tube were allowed to stabilize for 30 min before the silicon samples were introduced. A light weight furnace boat was used to keep wafer warm up time to a minimum and all samples were cooled rapidly following the diffusion.

Junction depth measurements.—P-N junctions were revealed by making a cylindrical groove in the silicon surface and staining the exposed p-type layers with an HF/HNO_3 stain made by adding about one drop of conc HNO_3 to 25 ml of 48% HF. The specimen was illuminated during staining. A photograph showing a stained transistor-type structure is given in Fig. 2(a). The junction depths shown diagrammatically in Fig. 2(b) were measured on the stained groove by sodium light interferometry.

Resistivity profiling.—The layer removal, sheet resistance measurement technique was used to obtain "electrical" profiles of the diffused layers. Sheet resistance was measured by a four-point probe having low tip pressure (60g) to avoid surface damage. Layers of silicon were removed either by a slow HF/HNO_3 etch or anodization followed by an HF etch. The thickness of silicon removed was determined from the oxide color (previously calibrated) when anodization was employed and by interference measurement of step heights when slow etching was used (steps were formed by masking part of the wafer during etching). The sheet resistance *vs.* depth data were converted to concentration *vs.* depth profiles by the method of Evans and Donovan (16) and using Irvin's (17) curves to convert resistivity to concentration. For profiling the emitter plus pushed-out base, and the nonpushed-out base the masking pattern shown in Fig. 3 was used. In this way the oxide formed during the base diffusion was used to prevent phosphorus in-diffusion in certain areas. The central striped area C (Fig. 3) allowed measurements of junction depths and push-out by grooving and staining, area A was used for resistivity profiling of the nonpushed-out base, while area B was used to profile the emitter and pushed-out base.

Results

Push-out of boron by phosphorus emitter diffusion.—A typical impurity profile through a transistor-type structure obtained by the resistivity method is shown in Fig. 4. The limitations of electrical profiling when investigating sequential diffusion processes are well illustrated in this example. These limitations are: (*i*) No information can be obtained about the boron profile within the emitter because the electrical properties in this region are completely dominated by the emitter dopant. (*ii*) Electrical profiling cannot give the true impurity concentration when compensation is heavy as in the vicinity of the emitter/base junction. For this reason the pushed-out base will always appear to have

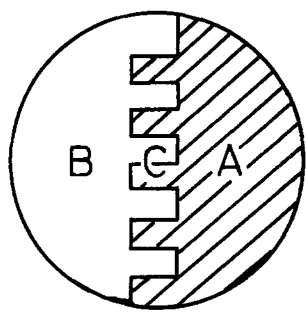

Fig. 3. Diagram showing masking pattern. Oxide is left behind in shaded areas after masking and etching. "A" is used for profiling the nonpushed-out base; "B" for profiling the emitter and pushed-out base; "C" for junction depth measurements by staining.

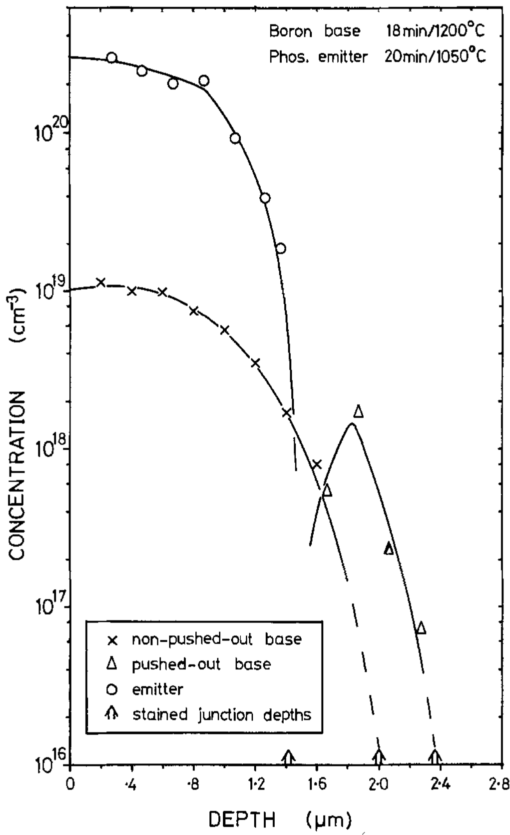

Fig. 4. A typical "electrical" impurity profile

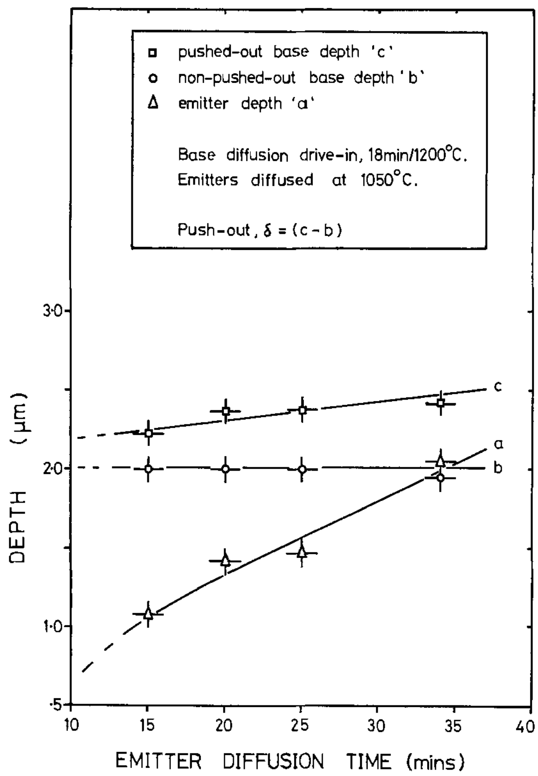

Fig. 5. Boron push-out vs. t_e

a concentration peak even when the true boron profile is not peaked. (*iii*) It is necessary to assume that Irvin's (17) curves can be applied to convert resistivity to impurity concentration but this may lead to error, particularly when the impurity concentration is high ($> 10^{20}$ atoms cm^{-3}).

Clearly the full base profiles to be described in Part II can provide much more information than is obtainable from electrical measurements [see also Ref. (11)].

To examine the effect of varying the emitter diffusion time, t_e, a series of four samples were given the same base diffusion but different emitter diffusion times. Electrical profiling of these samples showed: (*i*) that the emitter and nonpushed-out base surface concentrations had been kept constant as required; (*ii*) that the amount of push-out, $\delta [= c - b$, see Fig. 2(b)], increased as t_e increased; and (*iii*) that the peak in the net p-type carrier concentration decreased as t_e increased. The junction depths were also measured by staining and are shown in Fig. 5. It can be seen from the figure that the nonpushed-out base depth was practically invariant as would be expected if the boron diffuses at its normal rate. (The 18 min/1200°C base drive-in diffusion is equivalent to 510 min at 1050°C and so the extra 15 to 35 min at 1050°C for the emitter should not noticeably deepen the base outside the emitter region.) Push-out, δ, is seen to increase with t_e. A straight line represents c *vs* t_e quite well and when extrapolated predicts almost zero push-out for $t_e = 0$.

The approximately linear increase of δ with t_e found here agrees with the recent results of Nakamura *et al.* (7) but is contrary to the early work on push-out by Gereth *et al.* (5). These last named authors apparently found no correlation of δ with t_e and suggested that push-out occurs during cooling following the emitter diffusion. Their cooling rate experiment is poorly designed, however, since no account was taken of the extra diffusion during the slow, 3°C/min, cool. This point has also been raised by Nakamura *et al.* (7) who could find no dependence on cooling rate themselves when they varied the cooling time from 1 to 180 sec following a 20 min/900°C phosphorus diffusion.

A linear increase of δ with t_e was predicted by Hu and Yeh (6) in their theoretical treatment of the push-out of an initially Gaussian base. The only assumptions they used to reach this result were that the base impurity diffusivity is uniformly enhanced throughout the emitter diffusion period and that the degree of enhancement is determined by the emitter diffusion and is independent of base diffusion parameters. The results of Fig. 5 can be used to estimate the magnitude, χ, of this enhancement following the method of Lee (8). Assuming both the pushed-out and nonpushed-out base profiles are Gaussian in shape and diffusion enhancement is constant throughout t_e, then

$$N_s = \frac{Q_b}{\sqrt{\pi D_b (t_e + t_b)}} \exp\left\{-\frac{b^2}{4D_b(t_b + t_e)}\right\}$$

for the nonpushed-out base and

$$N_s = \frac{Q_b}{\sqrt{\pi D_b (t_b + \chi t_e)}} \exp\left\{-\frac{c^2}{4D_b(t_b + \chi t_e)}\right\}$$

for the pushed-out base, where χ = enhancement factor; N_s = substrate doping concentration; t_e = emitter diffusion time; t_b = base diffusion time corrected to the equivalent at the emitter diffusion temperature; b = nonpushed-out base depth and c = pushed-out base depth, see Fig. 2(b); D_b = unenhanced base diffusivity at emitter diffusion temperature; and Q_b = base dopant atoms per cm^2, considered constant.

Combining the two equations given above yields

$$\frac{t_b + \chi t_e}{t_b + t_e} = \exp\left\{\frac{1}{2D_b}\left[\frac{b^2}{t_b + t_e} - \frac{c^2}{t_b + \chi t_e}\right]\right\} \quad [1]$$

Since the left-hand side of Eq. [1] is close to unity a good approximation for χ can be obtained from

$$\frac{b^2}{t_b + t_e} = \frac{c^2}{t_b + \chi t_e} \quad [2]$$

Table I gives the values of χ found using Eq. [2] which all lie in the range 9½-12 and there is apparently no systematic dependence of χ on t_e.

Push-out of gallium by phosphorus emitter diffusion.—The shape of the gallium base profile prior to the emitter diffusion can be seen in Fig. 6. The set of three profiles was obtained by varying the ratio of H_2 to N_2 in the gas stream and shows clearly that the gallium concentration can be readily controlled in this system. The profiles are not complementary error functions but show a drop in concentration at the surface. An erfc can be fitted to part of the profile (see Fig. 6) yielding a diffusivity of 1.67×10^{-13} cm² sec⁻¹. In these diffusions the H_2 supply was turned off for about 1 min before removal of the sample but by reducing this flushing period the drop in concentration at the surface could be greatly reduced as shown in Fig. 7. This suggests that some out-diffusion is occurring during the flushing period and indeed Grove *et al.* (18) have shown that gallium out-diffuses very rapidly from oxidized silicon because diffusion through the oxide is so fast. The surface drop may also be due in part to compensation or electrical inactivity of the gallium as found by Okamura (19) for concentrations above 10^{18} cm^{-3}.

The effect of emitter diffusion time, t_e, on the amount of gallium push-out was investigated as follows. A silicon wafer was gallium diffused for 120 min and cut into five pieces. The thin oxide grown during diffusion was etched into narrow stripes so that some areas of each piece were masked against phosphorus diffusion. Each piece was then phosphorus diffused at 1050°C for a different time and the junctions measured by grooving and staining. Figure 8 plots the depth of each junction [*a*, *b*, *c*, of Fig. 2(b)] as a function of emitter diffusion time, t_e. It can be seen from the figure that gallium push-out ($c - b$) increases with t_e as for boron. A straight line represents c *vs.* t_e well and when extrapolated predicts zero push-out for $t_e = 0$.

Table II. Enhancement factors for gallium base. Emitter diffused at 1050°C

t_e, min	χ
3.5	16
8	17
12	21
16	15
24	17

The enhancement factors, χ, calculated using Eq. [2] are given in Table II. There is no systematic variation of χ with t_e for these gallium results nor for the boron results described above, but χ ranges from 15 to 21 for gallium as opposed to 9½-12 for boron. This apparent difference is discussed further at the end of this section.

The effect of varying the initial base depth, x_j, on the push-out of gallium was also investigated. Five pieces of silicon were gallium diffused for different times but under otherwise similar conditions to give layers of different depths (x_j) but equal surface concentration. All were then given the same phosphorus diffusion of 8 min at 1050°C, and their junction depths measured. Figure 9 shows push-out, $(c - b)$, plotted against x_j. It can be seen that push-out decreases as x_j increases in agreement with Nakamura *et al.'s* (7) and Lee's (8) results for boron. Lee's results are plotted in Fig. 9 for comparison (but note that his emitter conditions were not identical to those used for the gallium base experiment) and a further boron point has been obtained by extrapolating the results of Fig. 5 to $t_e = 8$ min (*i.e.*, emitter conditions identical to the gallium base experiment). The inverse relationship predicted by Hu and Yeh (6) assuming uniform enhancement throughout t_e and Gaussian base profiles is indicated by the dashed line in Fig. 9. An inverse relationship is also expected if the initial base is erfc (7).

The results described so far show that gallium behaves qualitatively exactly the same as boron but the χ values for gallium are higher than for boron for the same emitter diffusion. To test whether this discrepancy is real or whether it arises because the equation used to calculate χ (Eq. [2]) is derived assuming a Gaussian initial base profile, whereas the gallium base is initially erfc (apart from a drop in concentration at the surface), a further experiment was carried out. A gallium diffusion was performed in two parts: (*i*) 6 min at 1100°C with gallium depositing (H_2 on), (*ii*) 24 min drive-in in N_2 also at 1100°C. This schedule is similar to the two-step boron process and should produce a more Gaussian base profile. The emitter was then diffused and the junction depths measured. The enhancement factor was calculated to be 12 which is comparable to the results for boron, and this indicates that there is no real discrepancy between the gallium and boron results.

Discussion

The results described above show that gallium is pushed-out in a very similar way to boron by a similar phosphorus emitter diffusion. Both dopants show (*i*) an increase in push-out with increasing emitter diffusion time for constant base diffusion and emitter surface concentration, and (*ii*) a decrease in push-out with increasing initial base depth for constant emitter diffusion and base surface concentration. The straight line representing pushed-out base depth, c, *vs.* t_e has a greater slope for the gallium base (Fig. 8) than for the boron base (Fig. 5) but this is as expected from the push-out *vs.* x_j results since the gallium base depths were shallower than those for boron, and for any particular t_e the shallower base should show the greater amount of push-out. The calculated enhancement factor, χ, is also the same for boron and gallium provided the initial base profile is Gaussian as is assumed in the calculation of χ.

The results also provide some valuable information both on the mechanism of push-out and on the diffusion mechanisms of boron and gallium. As pointed out by Hu (2) and Seeger and Chik (13), the mechanisms of diffusion of the Group III and Group V elements in silicon are still in considerable doubt. Mechanisms suggested for the Group III elements have been the vacancy (2) or interstitialcy (13) mechanisms and in view of this uncertainty it is not clear whether atoms like boron which have smaller covalent radii than the matrix silicon atoms, diffuse by the same mechanism as atoms like gallium, which have larger radii than the matrix atoms. The experiments reported above give direct evidence on the relation between these two elements, as reasoned in the following paragraph.

It is now well established from simultaneous marker layer and push-out studies (20) that push-out is caused by point defects rather than by direct interaction between base and emitter dopants: the main unresolved questions at present are how these point defects are generated and their identity. Most proposed generation mechanisms (6, 21, 22) would generate, however, one species of point defect only and it seems unlikely that even work-hardening generation mechanisms, which

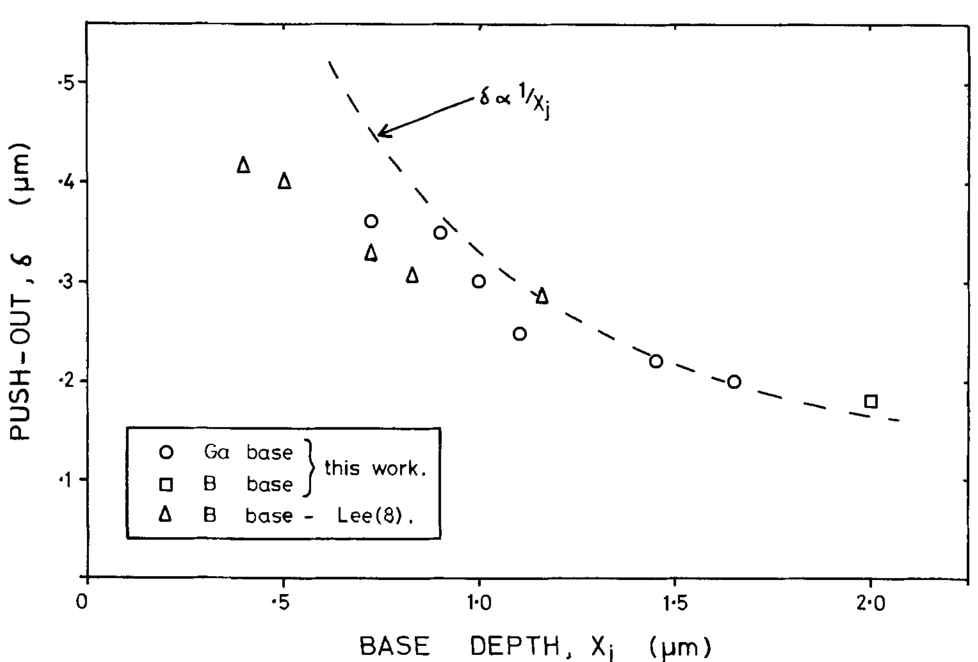

Fig. 9. Push-out vs. initial base depth. Dashed line is δ = constant/x_j, as predicted by Hu and Yeh (6).

might generate both di-vacancies and di-interstitials, would always generate closely similar concentrations of both defect types. It thus follows from the observation in this work that boron and gallium are enhanced to such a closely similar extent that both diffuse by the same mechanism in silicon.

The agreement between experiment and Hu and Yeh's (6) theoretical predictions concerning the effects of t_e and x_j on δ suggest that push-out is due to a diffusion enhancement which is constant throughout the emitter diffusion period. This agreement cannot, however, be used to suggest that the enhancement is constant with depth, as Hu and Yeh assumed for mathematical convenience, for the following reason. The theory of sequential diffusion developed by Hu and Schmidt (23) shows that, when the base diffusion length during the emitter diffusion period is less than the initial base diffusion length, *i.e.*

$$\chi D_b t_e \lesssim D_b t_b \quad [3]$$

the base-collector junction movement is determined principally by the base diffusion coefficient beyond the emitter. In most practical cases of push-out condition [3] is met and the consequences are twofold.

(*a*) The agreement between experiment and theory mentioned above does not imply that χ is constant with depth and that push-out type enhancement is the only interaction between base and emitter dopants. In reality χ may fall off inside the emitter, and the electric field effect, Fermi-level effect, and ion-pairing may affect the base diffusion inside the emitter, but since these are all localized within the emitter they will have negligible influence on δ when condition [3] is satisfied. Agreement between experiment and theory does suggest, however, that χ is constant below the emitter to at least the base/collector junction. This conclusion has now been confirmed by the analysis of radiotracer profiles of pushed-out gallium bases, which will be reported in Part II of this paper.

(*b*) Although diffusion within the emitter region is complex, as will be shown in Part II, the simple theory assuming a uniform enhancement only can still be used to predict the amount of push-out. In other words, for the purposes of calculating δ the existence of the field effect, etc., within the emitter can be ignored.

Since the uniform enhancement model should be useful in predicting amounts of push-out it is worth discussing the theory and its predictions further. Without making any assumptions about the enhancement mechanism, except that χ is independent of t_e, and the base diffusion parameters, Hu and Yeh (6) obtained the following formula for the amount of push-out

$$\delta = \frac{2D_b(\chi - 1)t_e \ln (N_{bo}/N_s)}{\lambda^2 x_j} \quad [4]$$

where D_b = normal base diffusivity at emitter diffusion temperature; N_{bo} = base surface concentration before emitter diffusion; N_s = substrate doping concentration; and λ = a characteristic constant (≈ 0.73).

In deriving this formula Hu and Yeh make the approximation that $\Delta x_j << x_j$, where Δx_j is the increase in base depth as a result of the emitter diffusion. Since Δx_j outside the emitter (nonpushed-out base) is negligible, under the emitter $\Delta x_j \approx \delta$ [see Fig. 2(b)]. In the boron push-out work described above x_j was 2.0 μm and δ had a maximum value of 0.3 μm, while in the gallium push-out *vs.* t_e results x_j was 1.5 μm and δ had a maximum value of 0.6 μm so that the condition $\Delta x_j << x_j$ was barely met in these cases. The Hu and Yeh formula is thus likely to be a poor approximation when push-out becomes large. An alternative approach to the problem which also allows a better approximation for δ when push-out is large is given in the Appendix. The resulting formula for δ is

$$\delta = \frac{2D_b(\chi - 1)t_e \ln (N'_{bo}/N_s)}{b} \left\{ 1 - \frac{2D_b\chi t_e}{b^2} - \frac{2D_b t_b}{b^2} \right\} \quad [5]$$

where N'_{bo} = surface concentration of nonpushed-out base, and t_b = base drive-in time corrected to the equivalent at the emitter diffusion temperature.

Equation [5] is basically the same as Eq. [4] but with the following differences:

(*i*) Equation [5] contains N'_{bo} and b while Eq. [4] contains N_{bo} and x_j. In practice the differences between N'_{bo} and N_{bo}, x_j and b, are negligible because $D_b t_e << D_b t_b$. This has been pointed out above in the section on push-out of boron and was also noted by Hu and Yeh (6).

(*ii*) Equation [4] contains a characteristic constant λ. This is avoided in Eq. [5] by assuming that after drive-in and before the emitter diffusion the base is given by

$$N = N_{bo} \exp (-x^2/4D_b t_b)$$

an assumption which is valid when the diffusion length for the drive-in is much larger than for the deposition step.

(*iii*) Equation [5] contains additional terms in curly brackets. This is the most interesting difference and arises from the different approximation used to obtain Eq. [5], that is $\delta << 2b$ rather than $\delta << b$ (or $\Delta x_j << x_j$) used by Hu and Yeh; in other words Eq. [5] is applicable to larger amounts of push-out. The effect of these additional terms can be seen as follows. Firstly, when the base diffusion and χ are fixed but t_e varies, Eq. [5] can be rewritten as

$$\delta \propto t_e \cdot (m - qt_e)$$

where m and q are constants given by

$$m = 1 - \frac{2D_b t_b}{b^2} \text{ and } q = \frac{2D_b\chi}{b^2}$$

In this case as t_e increases δ will drop below the straight line dependence on t_e predicted by Hu and Yeh and in fact some evidence of this can be seen in the results for boron, Fig. 5. The constants m and q can be estimated from the boron push-out parameters in the experimental section above and it is found, for this case, that $m \approx 1$ and $q = 6 \times 10^{-5}$ sec^{-1}. Then at t_e = 35 min δ is approximately 14% less than predicted by the simple linear relationship.

Secondly, when the emitter diffusion and base surface concentration are fixed but b varies, Eq. [5] can be rewritten as

$$\delta \propto \frac{1}{b}\left(m - \frac{r}{b^2} \right)$$

where r is a constant given by $r = 2D_b\chi t_e$. It can be seen that as b decreases δ drops below the simple inverse relationship as was found for the gallium experimental results (Fig. 9). For example, using the gallium push-out data it turns out that at b = 0.75 μm, δ is approximately 22% less than predicted by the pure inverse relationship.

The analysis above indicates how Eq. [4] can be expected to break down when push-out is severe but because the additional terms of Eq. [5] involve D_b and χ the exact size of the corrections may be uncertain (D_b and χ are not usually known precisely) and therefore the approximation of Eq. [4] is generally more useful. Alternatively Eq. [5] can be used ignoring the bracketed terms. It should also be noted that for large amounts of push-out the assumption that D_b is enhanced uniformly with depth may begin to introduce other errors in δ because condition [3] is not satisfied.

To make the usefulness of the relations $\delta \propto t_e$ (for fixed base diffusion and emitter surface concentration) and $\delta \propto 1/x_j$ (for fixed emitter diffusion and base sur-

face concentration) clearer a graphical method for predicting push-out and base width in practical cases will now be described. First a curve of δ *vs.* x_j is established experimentally for the base surface concentration to be used and a particular emitter diffusion time $t_e = T$; see Fig. 10(a). This is best done with a few experimental points and fitting a curve $\delta = \text{constant}/x_j$ through these points. Next, for the required x_j and using Fig. 10(a), the expected push-out for $t_e = T$ is read off. On a graph of depth *vs.* t_e the points $(x_j + \delta, T)$ and $(x_j, 0)$ are plotted and a straight line drawn through them giving Fig. 10(b). This is the linear relationship between δ and t_e for given x_j. The emitter depth curve is then superimposed on Fig. 10(b) to give Fig. 10(c); the emitter curve is assumed to be independent of base parameters which is reasonable if the emitter profile has a steeply falling front. The push-out and base width for any t_e can now be obtained from Fig. 10(c). Base width *vs.* t_e curves have been calculated in this way for three base depths using the dashed line of Fig. 9 (Ga push-out *vs.* x_j results) together with the emitter depth curve of Fig. 8 (Ga push-out *vs.* t_e results) and are shown in Fig. 11 together with the experimental results for the 1.45 μm deep gallium base. The theory agrees well with experiment. In the figure solid lines end when the base is completely pushed-out, *i.e.,* $a \geqq b$ in Fig. 2(b). It is interesting to note that the base width does not always get narrower as the emitter is diffused deeper.

A final remark regarding the emitter diffusion period should be made. In all the theoretical analysis it is assumed that the whole of the emitter diffusion is at one temperature and that warm up and cool down are instantaneous. In a factory process large numbers of slices diffused together may make the warm up time a considerable fraction of the total emitter diffusion time and in this case the predictions discussed above may be difficult to apply.

Conclusions

(*a*) The push-out of a gallium base is very similar to that of a boron base under identical emitter diffusions, when observed by the junction depth method. This suggests that boron and gallium both diffuse by the same mechanism in silicon, despite their different covalent radii.

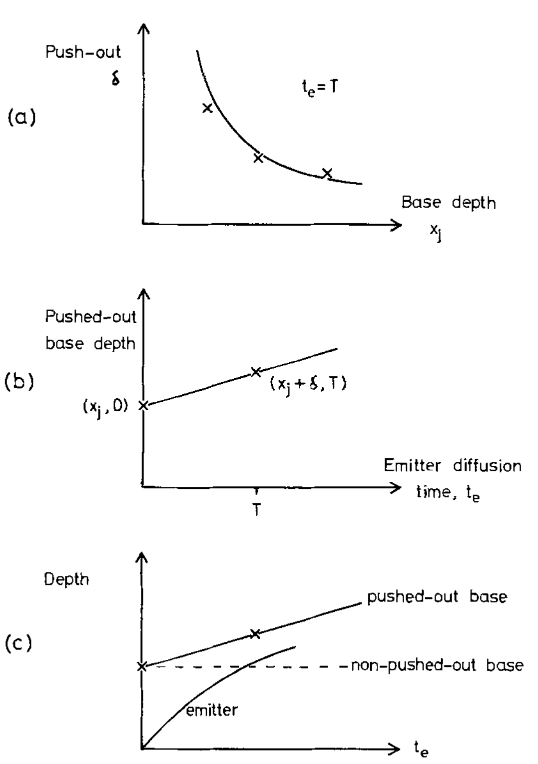

Fig. 10. Graphical method to predict push-out and base-width

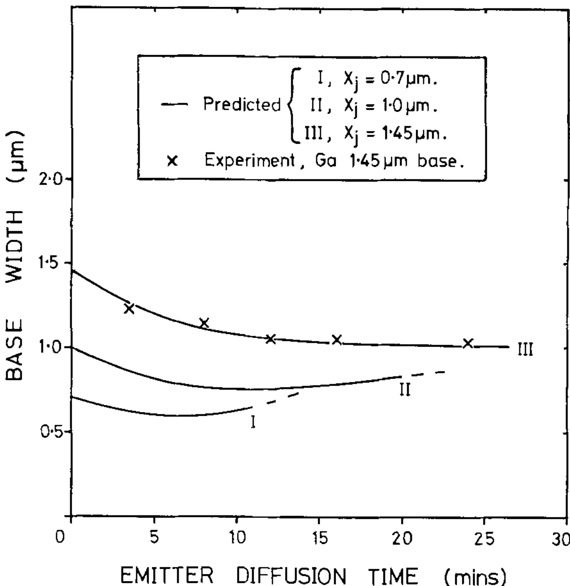

Fig. 11. Base width *vs.* t_e (1050°C emitter diffusion). Solid lines are predicted base widths. Points x are experimental values for the gallium 1.45 μm base.

(*b*) For both dopants push-out, δ, increases practically linearly with emitter diffusion time, t_e, when the base diffusion and emitter surface concentration are fixed. In common with Nakamura *et al.* (7) it is concluded that push-out occurs during the emitter diffusion rather than during cooling following the emitter diffusion.

(*c*) For both dopants δ decreases with increase in x_j, the initial base depth, when the emitter diffusion and base surface concentration are fixed.

(*d*) Push-out and base width can be predicted approximately by making use of conclusions (*b*) and (*c*) together with a few experimentally determined junction depths.

(*e*) Agreement between the experimental results and theory strongly suggests that push-out is due to an enhancement of the base diffusivity throughout the emitter diffusion period; the magnitude of enhancement being controlled by the emitter diffusion conditions.

(*f*) Junction depth measurements cannot tell how the diffusivity enhancement varies with depth except that it is probably constant below the emitter. The only means of determining diffusion processes within the emitter is by obtaining the complete chemical profile of the base as will be shown in Part II.

Acknowledgments

The authors wish to thank the Microelectronics Laboratory of Southampton University for providing phosphorus and boron diffusion facilities, Westinghouse Brake and Signal Company Limited (Chippenham) for advice on gallium diffusion, Mr. J. Keen of R.R.E. Malvern for useful discussions throughout this work, and Professor R. L. Bell for provision of laboratory facilities and discussions. This work has been carried out with the support of Procurement Executive, Ministry of Defense and sponsored by D.C.V.D.

Manuscript received March 24, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

APPENDIX

Approximate Formula for δ

Suppose that before the emitter diffusion the base profile can be described by the Gaussian

$$N(x) = \frac{Q_b}{\sqrt{\pi D_b t_b}} \exp\left\{ -\frac{x^2}{4D_b t_b} \right\} \quad \text{[A-1]}$$
