Growth rates.—The thickness of the epitaxial layer was measured by taking photographs of cleaved and stained sample at 640× using a phase contrast microscope. The etchant used is alkaline $K_3Fe(CN)_6$ (11) which delineates abrupt concentration changes in 5-10 sec at room temperature. The precision of this method is equivalent to fringe count methods on angle lapped and stained sample with a resolution of 0.3μ. This was established by direction comparison before adopting the cleave and stain method, which was considered to be faster and easier. Average growth rates were then obtained by dividing layer thickness by growth time. Since two layers were always grown, this yields two measurements. In each sample the very narrow high-doped layer served as a marker permitting an additional independent measurement of growth rate at the time of dopant introduction. The distance of the center of this layer from the surface (0.5-1.5μ) was measured using a capacitance profiler. This distance was divided by the time between dopant injection and termination of growth by withdrawal from the furnace. A small correction amounting to 0.7 min was made to allow for the time of passage of the dopant gas from injec-

tion site to the substrate. In most instances this growth rate established for the last 5-10 min of growth was in good agreement with the average growth rate. Exceptions were noted in cases where the Ga source was significantly depleted and growth rates decreased rapidly.

C-V profiles.—The doping profile of the layers, that is the doping level as a function of distance from the surface of the crystal, was measured by means of a feedback profiler designed by Miller (12). This profiler processes differential capacitance measurements and plots doping level *vs.* distance from the surface. Schottky barrier diodes are formed by depositing 10 and 20 mil Au dots on a step-etched sample. Step etching is accomplished by dipping a sample strip into a stirred mixture of 5:1:1 H_2SO_4:H_2O_2:H_2O at room temperature. Several steps are usually needed to establish a complete profile. Occasionally "punch through" devices were obtained which allowed depletion and hence profiling of the entire active layer. As a check on possible fringe field effects on the capacitance voltage profiles, mesa Schottky diodes were prepared by ion milling through an evaporated 3000Å gold layer and about 1μ of one GaAs epitaxial layer. The mesas were defined with Photoresist. The n^+ layer was located at a depth of 0.4μ, *i.e.*, within the mesa. No difference was seen between the profiles of the n^+ layer as obtained from the planar and the mesa Schottky diodes.

The interpretation of differential capacitance (*C-V*) profiles containing abrupt transitions in impurity concentration requires some care. A distinction must be made between the impurity profile, N(x), and the majority carrier profile, n(x). Electrons in n-type material with large concentration gradients diffuse away from the impurity donor atoms. Balance is restored by drift currents in the resulting field. The situation is similar to that prevailing near a p-n junction. To first order the *C-V* profiler measures the majority carrier profile and all the abrupt features of the underlying impurity profile are washed out. A step function impurity profile is "rounded off" with shoulders extending several Debye lengths to either side of the function (13).

An additional correction must be made for the influence of the electrical measurement (application of d-c bias) on the thermal equilibrium of the majority carriers. Johnson and Panousis (14) have obtained estimates for this effect from computer simulation studies. They showed how the differential capacitance profile, N*(x), differs from the equilibrium majority carrier profile, n(x), and how the deviation depends upon the geometry of measurement. The *C-V* profile of a step function is an S-curve intersecting the vertical branch of the step function at about one-third of its height and reaching full height only after 3-4 Debye lengths. We have synthesized a two-step function impurity distribution from two step functions of opposite sign and approximated the corresponding *C-V* profile from the computer simulation curves, Fig. 2. The asymmetry is due to the experimental geometry: the contact is either on the high- or the low-doped side of the step function. We considered on Fig. 2 two limiting cases. The width of the two-step function is expressed in units of Debye lengths appropriate to the high doping level. If the two-step function is equal to or more than 7 Debye lengths (λ_D) the peak of the *C-V* profile, N^*_{max}, is nearly equal to the impurity doping level, N_{max}. The width at the 0.6 N_{max} level, which is the 2σ level if the profile is approximated by a Gaussian curve, is about $2\lambda_D$ narrower than the width of the impurity distribution. If, on the other hand, the two-step function is only two λ_D wide, the *C-V* profile peak will approach two-thirds of the impurity doping peak while the 2σ width is nearly equal to the true width. This second case is the delta function model intuitively applied to Hi-layers. As we shall see, our Hi-layers are typically 3-5λ_D wide at the 2σ level, or somewhere between the two extremes considered. Their *C-V* profiles are

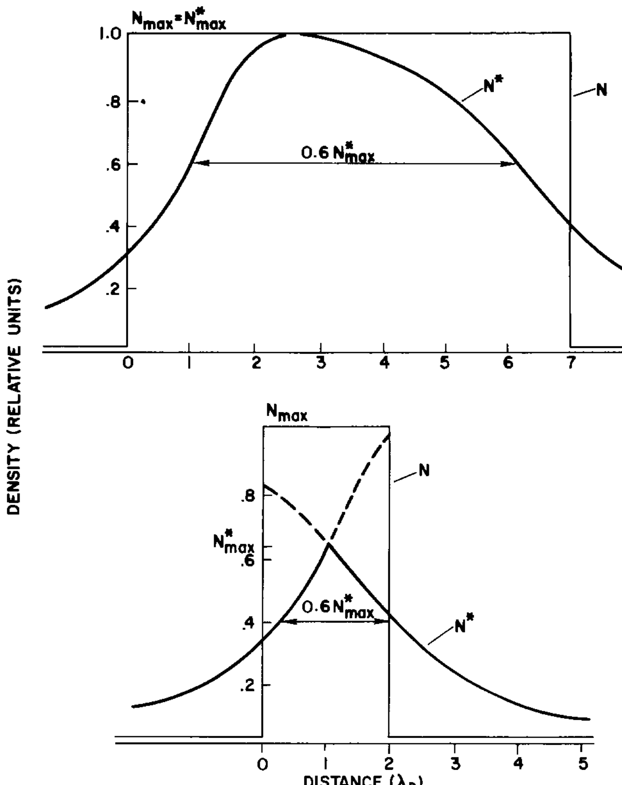

Fig. 2. Simple models of Hi-layer impurity distributions, N(x), and the corresponding *C-V* profile, N*(x). The models were constructed using the computer simulation studies of step functions described by Johnson and Panousis (14).

probably 1-2 Debye lengths narrower than the width of the impurity profile. Although the above considerations are of a qualitative nature only they will be helpful in the discussion of dopant incorporation.

Impurity content of Hi-layers.—We have used two different methods to estimate the amount of impurity in Hi-layers. One method, profile integration, yields the amount of charge per unit surface area by integrating the Miller profile N*(x) over the distance, where N*(x) is significantly above the background. This assumes that N*(x) = n(x), which is a reasonable approximation. According to the Johnson-Panousis analysis N*(x) < n(x) at the edge of a step function profiled from the low doping side, and N*(x) > n(x) if profiled from the high doping side. The deviations are small and in opposite directions and so tend to cancel.

The other method (15) utilizes

$$C = \frac{\Delta Q}{\Delta V} \quad \text{and} \quad \Delta Q = qN(x)dx$$

to obtain

$$Q = q\int_{\Delta x} N(x)dx = \int_{\Delta V} C(V)dV$$

The capacitance as a function of voltage for a typical doping "spike" is shown in Fig. 3. Integration was done numerically or by use of a planimeter. The voltage differential was established by noting the d-c bias on the *C-V* profiler before and after passing the depletion zone through the high-doped region. Alternatively a separate N(V) plot was made using the profiler to define N(V). The agreement between the two methods of estimating impurity content was checked on a uniformly doped layer. For such a layer the gross distortions of the profile associated with abrupt changes in doping level do not exist, and agreement was within ±10%. The same level of precision was observed on 200Å wide n^+ layers.

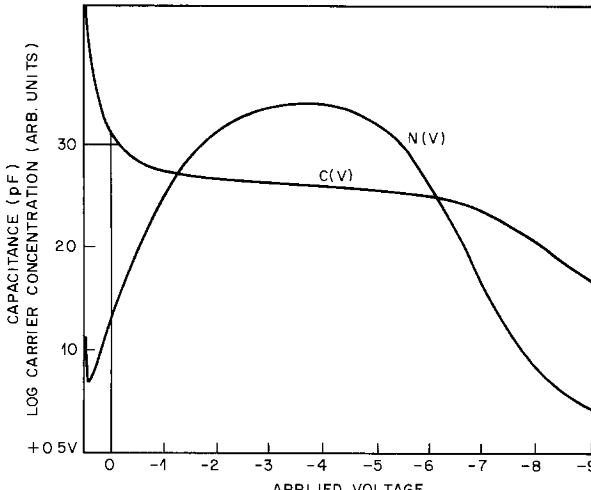

Fig. 3. *C(V)* and *N(V)* profiles of an impurity spike from which the impurity density is obtained by integration.

Results

Profiles.—Typical differential capacitance (*C-V*) profiles of Lo-Hi-Lo structures grown by injection doping are reproduced on Fig. 4 and 5. Often these profiles exhibit a more or less pronounced decrease in apparent doping after the high region. This "dip" we believe to be an artifact of the measurement technique for the following reasons. Empirically, it has been established that the following conditions favor the appearance of dips: (*i*) large amounts of charge in the high-doped layer, (*ii*) low background doping, and (*iii*) small distance from the surface of the crystal.

In Fig. 5 the top profile shows no dip in an experimental profile with a Hi-layer containing an integrated impurity concentration of 0.6×10^{12} cm^{-2}. The second profile shows a pronounced dip for a total impurity concentration of 2×10^{12} cm^{-2} in the Hi-layer. The bottom profile illustrates how the dip dominates the profile if the background doping level falls to 1×10^{15} cm^{-3}. Figure 6 illustrates the effect of distance from the surface of the crystal on the severity of the dip. The test strip was step etched to remove material above

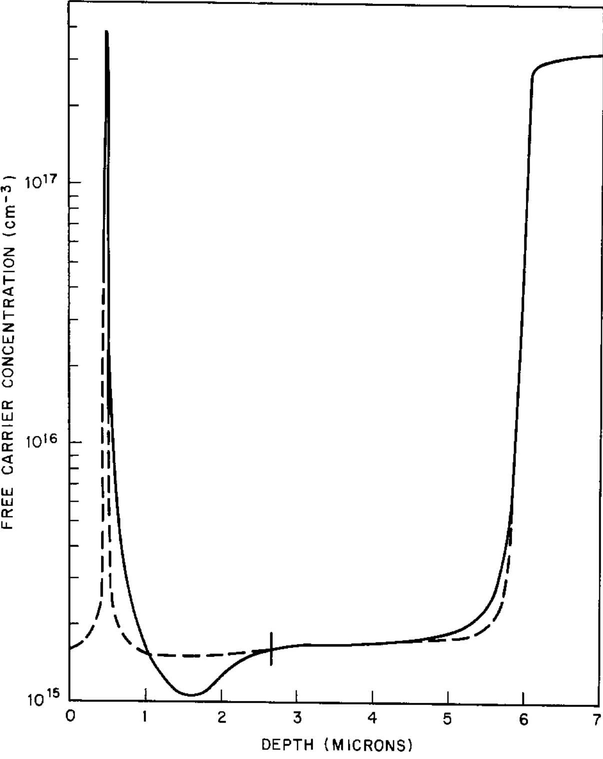

Fig. 4. *C-V* profile of a Lo-Hi-Lo structure (full line). The broken line is believed to be representative of the underlying impurity distribution. The dip in the background doping is probably an artifact; its depth is a function of the position of the spike relative to the surface. The marker at 2.6μ indicates the depth at which the Schottky diode on the unetched surface broke down and where the profile was patched together using a second diode on the taper-etched portion of the test strip.

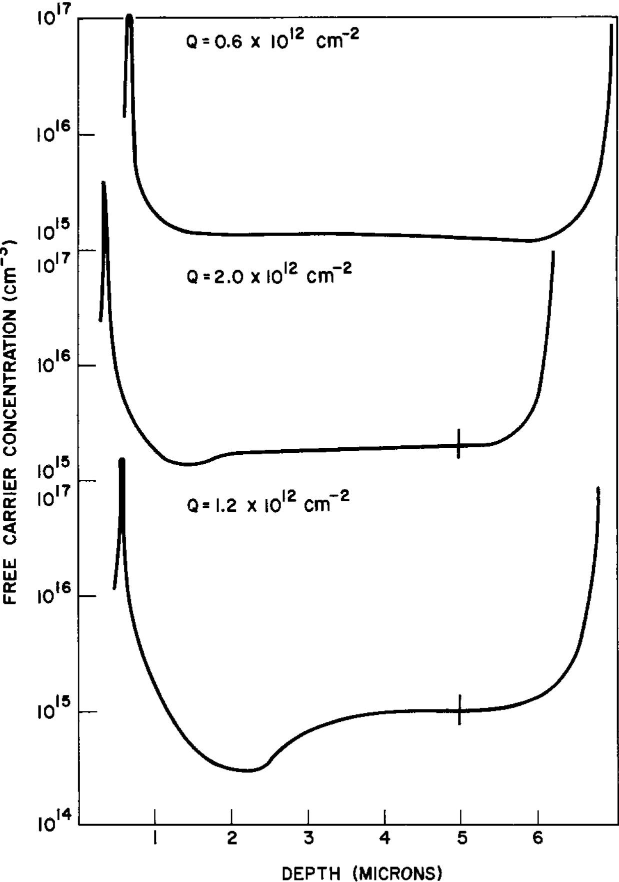

Fig. 5. Three *C-V* profiles of Lo-Hi-Lo structures with varying impurity densities, *Q*, and background doping levels. The profile undershoot or dip near the Hi-layer appears to be a function of both *Q* and background doping level. Breakdown of unetched surface Schottky diodes is indicated by the vertical markers.

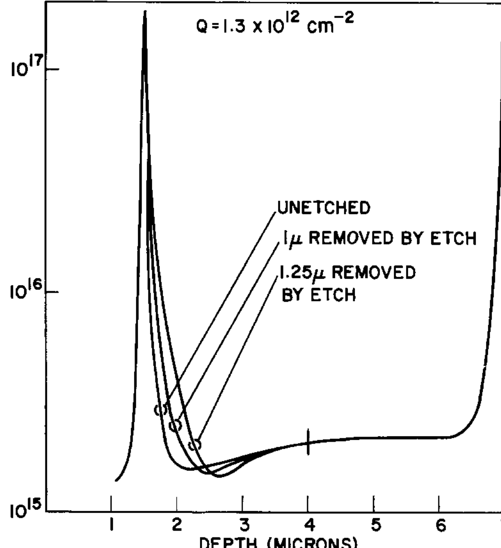

Fig. 6. *C-V* profile of a "deep" Hi-layer as measured with and without step etching. Material above the Hi-layer is removed in two steps. The three profiles obtained show how the dip in the background doping level is intensified with decreasing distance from the surface. Breakdown of the unetched surface Schottky diode is marked at 4μ.

the Hi-layer. As the Hi-layer moves to the surface the dip becomes more pronounced. The accumulated indirect evidence together with the geometrical asymmetry (the dip appears only on the far side of a Hi-layer as seen from the Schottky barrier) supports the view that the dip is a profiling artifact and does not reflect either a sudden drop in a background doping level or an impurity segregation caused by the larger concentration gradient near a Hi-layer.

In Fig. 7 we show a high resolution *C-V* profile of a Hi-layer and compare the thickness at high and low concentration levels with the corresponding Debye lengths which provide a measure of the distortion of the impurity profile. A curve of the form $N^*_{max} \exp(x^2/2\sigma)$ was found to approximate the free carrier concentration reasonably well, except that the decay of the latter is less rapid than the Gaussian below 0.3 N^*_{max}. Identification of the carrier distribution with a Gaussian distribution simplifies the discusson of the Hi-layers by providing a standard measure of the width of Hi-layers. This width will be defined as the width at 0.607 times the peak height, N^*_{max}. The Gaussian approximation should not be used to estimate the impurity content of a Hi-layer. The area under a Gaussian distribution is given by $\sigma N_{max}\sqrt{2\pi}$. This formula was found to underestimate the impurity content by ~40%.

Width of Hi-layers.—The widths of Hi-layers grown under different conditions and annealed for varying times after growth exhibit regularities which indicate that both growth rate and solid-state diffusion after growth must be considered in an analysis. Figure 8 shows the variation of the square of the Hi-layer width (2σ) with growth rate squared. Only Hi-layers with postgrowth anneal times between 4 and 5 min are included. These samples have undergone a minimum of diffusion broadening (having been held at temperature for only 5 min) while still yielding Hi-layers that can

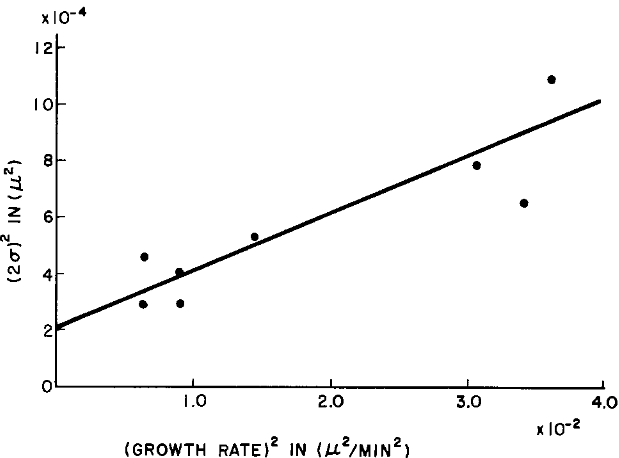

Fig. 8. Correlation between width (2σ) of short term (4-5 min) annealed Hi-layers and epitaxial growth rate. The squares of both variables are plotted for reasons explained in the text.

be fully profiled. A correlation between the width and the growth rate is inferred from the data. If the widths were dominated by diffusion broadening no dependence on growth rate would have been observed. The reason for plotting the squares of the variables are discussed in the following. Diffusion broadening is best studied on structures exposed to long postgrowth anneals. Several deeply buried Hi-layers were grown and evaluated. In addition, one wafer was returned to the furnace and annealed for 16 hr at growth temperature after removal of a test piece. Following the discussion of a model for the growth process we show that the final width of long time annealed structures as well as the diffusion broadening of minimally annealed layers is in accord with the ideal diffusion law.

In the following a simple model for the growth of Hi-layers is developed. Figure 9 is a schematic diagram of the experimental situation during layer growth. The dopant gas is injected into the reactor tube from a small bore quartz tube passing over the Ga source. We disregard any mixing that may occur due to interdiffusion and turbulence between carrier gas and dopant gas during the travel from the injection valve to the injection point in the reactor. After injection the dopant gas cloud travels a distance, *d*, until it passes over the substrate. During this passage it diffuses rapidly and

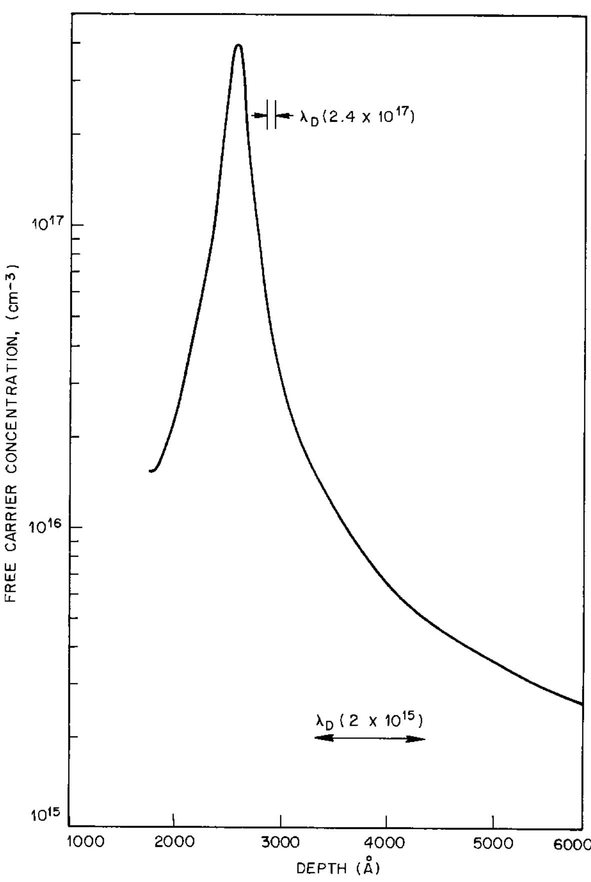

Fig. 7. High resolution *C-V* profile of a Hi-layer. The width of the Hi-layer is compared with the Debye length, λ_D, at background doping level and with the Debye length, at the 2σ level (~ half-height).

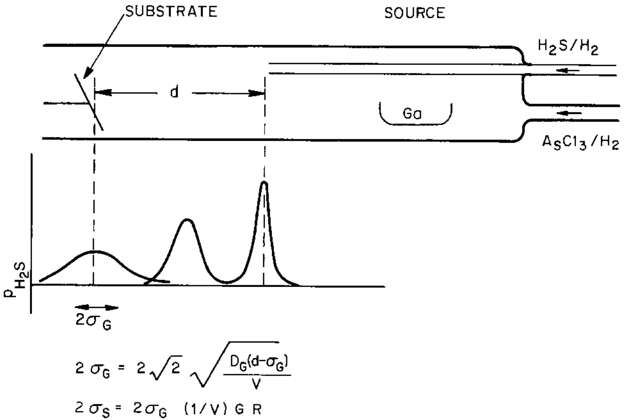

Fig. 9. Diagram of the sulfur injection tube and the sulfur cloud as it travels toward the substrate. The sulfur cloud is modeled by a plane source

$$P_{H_2S}(x,t) = \frac{P_O}{2\sqrt{\pi D_G t}} e^{-\left(\frac{(x-vt)^2}{4D_G t}\right)}$$

where x is the distance from the injection point and t is the time since injection. The original partial pressure, P_O, falls as the cloud spreads by gaseous interdiffusion characterized by a diffusion coefficient D_G.

we will assume that the concentration of dopant in the carrier gas is given by a plane source model

$$C(x,t) = \frac{C_o}{2\sqrt{\pi D_G t}} \exp - \frac{(x - vt)^2}{4D_G t}$$

where x is the distance measured from the injection point, D_G is the gaseous interdiffusion coefficient, and t the time elapsed since the injection.

It is important to take into account the fact that the carrier gas velocity, v, at growth temperatures is much higher than the room temperature velocity obtained by dividing the flow rate by the cross-section area. Due to thermal expansion of the gas volume the velocity increases by a factor given by the ratio of the initial and final temperatures

$$\frac{1050}{300}, \quad \text{or } 3.5$$

The progress of the doping gas cloud is drawn schematically in Fig. 9. When the dopant gas cloud passes over the substrate its width is given by

$$2\sigma_G = 2\sqrt{\frac{2D_G(d - \sigma_G)}{v}} \qquad [1]$$

We assume that the doping level in the growing layer is directly proportional to the dopant gas concentration which results in an impurity concentration profile of width $2\sigma_S$, given by

$$2\sigma_S = \frac{2\sigma_G}{v} \text{ G.R.} \qquad [2]$$

where G.R. is the growth rate. Subsequently, a layer of low-doped material is grown over a time span t_D. Alternately, the grown layer may be annealed without additional growth. During such periods solid-state diffusion of the incorporated impurity will broaden the Hi-layer. The theoretical amount of diffusion broadening can be obtained from the well-known delta function solution of the ideal diffusion equation (16) by simply adding an imaginary prediffusion process in the mathematical model. If the diffusion broadening is denoted by $2\sigma_D$

$$2\sigma_D = 2\sqrt{2D(t + t_o)} - 2\sqrt{2Dt_o}$$

where t_o is the time required to broaden a delta function (in the imaginary prediffusion process) to the width of the initial (as grown) Gaussian distribution and t is the time of the actual diffusion. With the initial width as given by Eq. [2]

$$2\sqrt{2Dt_o} = \frac{2\sigma_G}{v} \text{ G.R.}$$

We find that the total width 2σ of the n+ layer after diffusion broadening is

$$2\sigma = 2\sqrt{2D(t + t_o)} = 2\sqrt{2Dt + \frac{\sigma_G^2}{v^2}(\text{G.R.})^2}$$

which gives us the rationale for plotting the data $(2\sigma)^2$ *vs.* $(\text{G.R.})^2$ as was done on Fig. 8. Extrapolation to zero growth rate yields

$$8Dt = 2 \times 10^{-4}\,\mu^2$$

from which with $t = 240$ sec, we find a value for the diffusion coefficient, $D = 1 \times 10^{-15}$ cm²/sec.

Table II shows pertinent data for a number of representative Hi-layers grown under different conditions and annealed for different lengths of time. The gaseous interdiffusion coefficient was estimated from

$$D_G(1100°\text{K}) = D_G(300°\text{K}) \left(\frac{1100}{300}\right)^{1.5}$$

using $D_G(300°\text{K}) = 0.7$ cm²/sec (17). To obtain agreement for the long term diffusions a diffusion coefficient of 2×10^{-15} cm²/sec was used. This value is intermediate between that obtained by extrapolation of published data (18) to the growth temperature (750°C): 5×10^{-15} cm²/sec, and the value obtained by extrapolation to zero growth rate. With some exceptions for very narrow Hi-layers the agreement between estimate and experiment is within one Debye length. The qualitative considerations of the free carrier diffusion and the distortions of the *C-V* profile discussed earlier may be applicable and explain the tendency of the profile widths to be narrower than the estimated widths. Alternatively, various shortcomings of the model may be responsible for the discrepancies. The assumption of a plane source gaseous dopant is clearly an oversimplification. The dopant gas is injected from a small bore tube (0.4 mm ID) with a nozzle velocity about 10-20 times the carrier gas velocity. It is possible that gas mixing takes place closer to the substrate and is due to turbulence rather than diffusion. A more serious difficulty is the assumption that the solid-state diffusion after growth can be adequately described by a concentration independent diffusion process.

We have found that for steady-state S-doping in GaAs grown by CVD, saturation of free carriers occurs at 4-5 × 10^{18} cm^{-3}. This limit agrees well with that obtained by Mil'vidskii and Pelevin (19) for melt growth of GaAs. According to their data the difference between the total amount of S and the electrically ac-

[a] t_D = time after growth of Hi-layer during which the epitaxial layer was held at 730°-750°C.
[b] Q = total amount of impurity in the Hi-layer (atoms/cm²).
[c] $2\sigma_S$ = width of the impurity distribution at 0.6 × peak doping level prior to solid-state diffusion.

$$= \frac{2\sigma_G}{v} \text{ G.R.}$$

where $2\sigma_G$ = width of sulfur distribution in the carrier gas

$$= 2\sqrt{\frac{2D_G(d - \sigma_G)}{v}}$$

where v = carrier gas velocity at growth temperature, 190 cm/min; D_G = diffusion coefficient in gas phase at 800°C, 5 cm²/sec; and d = distance traveled by dopant between injection site and substrate, 25 cm.
[d] $2\sigma_D$ = diffusion broadening of Hi-layer.
[e] Theoretical width: $2\sigma_S + 2\sigma_D$.
[f] Profile width: width of free carrier distribution as given by *C-V* profiles.
[g] λ_D = Debye length at 0.6 N_{Hi}.

tive S becomes significant when the free carrier concentration exceeds 2×10^{18} cm^{-3}. We conclude from this comparison that for CVD GaAs the component of neutral S will probably also become significant when the free carrier concentration exceeds 2×10^{18} cm^{-3}.

For an impurity density of 2×10^{12} cm^{-2} in a typical n^+ layer this limit is exceeded when $2\sigma < 100$Å. If the layer were narrower than 100Å the initial stage of the diffusion process, lasting until the peak concentration is reduced to 2×10^{18} cm^{-3}, is complicated by the presence of at least two species. The serious discrepancy seen for sample K which is representative of several similar layers, may be due to such an effect.

Sulfur incorporation.—The distribution coefficient for an impurity incorporated into a solid in equilibrium with the gas phase is

$$k = \frac{x_S}{x_G}$$

This is the definition for dilute solutions ($k = x_S/x_L$) given by Thurmond and Struthers (20), where the mole fraction in the liquid (x_L) is replaced by the mole fraction in the gas phase. We shall apply this definition to the case of sulfur-doped GaAs. The mole fraction of the almost completely ionized sulfur in the solid (for low doping levels) is given by

$$x_S = \frac{[S^+]}{N_S} = \frac{[S^+]}{L\dfrac{d}{\text{F.W.}}}$$

where $[S^+]$ is the number of ionized sulfur atoms/cm^3, N_S is the number of available lattice sites, L is Avogadro's number, d is the density of GaAs (5.35 g/cm^3), and F.W. is the formula weight of GaAs (144 g/mole). For the dilute gas we have

$$x_G = \frac{P_{H_2S}}{P_{H_2}}, \therefore k = \frac{[S^+]P_{H_2}}{N_S P_{H_2S}} \qquad [3]$$

Simple estimates using JANAF (21) data show that H_2S is by far the most stable sulfur species at 1100°K with $P_{H_2} = 1$ atm and very low total sulfur concentration. Since we cannot measure the instantaneous sulfur doping level corresponding to an instantaneous sulfur partial pressure we integrate over the time interval, Δt, needed to grow the Hi-layer

$$\int_{\Delta t} k\, dt = \frac{\text{F.W.}\, P_{H_2}}{Ld} \int_{\Delta t} \frac{[S^+]}{P_{H_2S}}\, dt$$

It is known from the diffusion studies of Young and Pearson (18) that the solid solubility of sulfur in GaAs is a linear function of the sulfur vapor density. Depending on the diffusivity of the dopant the equilibrium incorporation behavior may or may not be reflected in the doping level of a crystal grown at finite growth rates. For S-doped GaAs linearity between dopant gas (H_2S) concentrations and doping level was observed by Goldsmith and Oshinsky (22) in the range 4×10^{17}-4×10^{19} cm^{-3} at growth rates comparable to ours.

The first-order doping dependence allows us to integrate over the two sulfur concentrations separately

$$\frac{1}{\Delta t}\int_{\Delta t} k\, dt = k = \frac{\text{F.W.}\, P_{H_2}}{Ld} \frac{\int_{\Delta t} [S^+]\, dt}{\int_{\Delta t} P_{H_2S}\, dt}$$

The upper integral is

$$\int_{\Delta t} [S^+]\, dt = \int_{\Delta t} [S^+] \frac{\partial t}{\partial x}\, dx = \frac{1}{\text{G.R.}} Q$$

where G.R. is the growth rate and Q is the charge density/cm^2 of the Hi-layers. For the gas phase we have

$$\int_{\Delta t} P_{H_2S}\, dt = \frac{RT}{\mathbf{F}} \int_{\Delta t} \frac{F\, P_{H_2S}}{RT}\, dt = \frac{RT}{\mathbf{F}}\, n$$

where n is the total number of moles of hydrogen sulfide injected, R is the gas constant, T the temperature at which the flow rate, F, in the reactor is measured. The distribution coefficient is now given by

$$k = \frac{\text{F.W.}\, P_{H_2}}{RT\, d} \frac{F}{\text{G.R.}} \frac{Q}{N}$$

where we have converted the number of moles of H_2S injected to atoms: $L\, n = N$. If the growth rate, G.R., is expressed in cm/min, and F, the flow rate, in liters/min at room temperature we find for typical experimental growth conditions

$$k = 0.75 \frac{Q/N}{\text{G.R.}} \qquad [4]$$

The amount of H_2S injected during epitaxial growth to produce the high-doped layer of the Lo-Hi-Lo structure can be varied by changes in the pressure, and the concentration of the gas flowing through the injection loop and by changing the volume of the loop. All three parameters have been varied in the course of the study. Additionally the number of injections can be varied to increase the volume. The amount of dopant gas is conveniently measured in moles according to

$$n = \frac{m \cdot V \cdot C \cdot P}{RT}$$

where m is the number of injections, V, C, and P the volume, concentration, and pressure of the injected gas. The gas constant R is 0.082 liter atm/°K and T the room temperature is in °K.

Typically, a volume of 0.7 mliter at a concentration of 300 ppm and 2 atm pressure was injected ($m = 1$) corresponding to $n = 1.7 \times 10^{-8}$ moles and containing 1×10^{16} S atoms. At a growth rate of 0.08 μ/min this amount of H_2S yielded a Hi-layer containing 2×10^{12} cm^{-2}. Inserting these numbers into Eq. [3] gives

$$Q/N = 2 \times 10^{-4}$$
$$k = 20$$

The doping efficiency, Q/N, was found to be independent of the total amount of sulfur injected, N, for a fixed growth rate. For 13 layers grown at rates between 0.65 and 0.75 μ/min the ratio Q/N remained constant with an average value of 2.05×10^{-4} and a standard deviation of 19% as N was varied by a factor of 4. This result supports the assumption discussed earlier that sulfur doping in the 10^{17}-10^{18} cm^{-3} range is linear with H_2S partial pressure.

On Fig. 10 we show similar data obtained for other growth rates. The growth rate was varied intentionally by changing the source and the substrate temperatures and also unintentionally by depletion of the Ga source. Thus for a source temperature of 765°C and substrate temperature of 725°C the growth rates fell from 0.11 to 0.04 μ/min as the source was depleted. The reason for this decrease is presumably that the HCl to GaCl conversion efficiency decreased. By increasing the source temperature to 805°C and by varying the substrate temperature between 750° and 735°C the growth rate could be varied from 0.04 to 0.18 μ/min. The straight line drawn through the combined data on Fig. 11 using least squares fitting has a slope of 1.6 rather than unity as given by Eq. [4]. This implies that the experimentally measured distribution coefficient is not an equilibrium value as required by theory. It is reasonable to propose that the departure is due to kinetic effects. If this is true, then the slowest experimentally realized growth rates would yield the best estimate of k. The lowest value of k obtained in this study is

$$k_{min} = 13$$

A value of k larger than unity does not imply depletion of the gas phase dopant concentration which would invalidate the simple model used to estimate Hi-layer widths. This is readily seen from the experimental

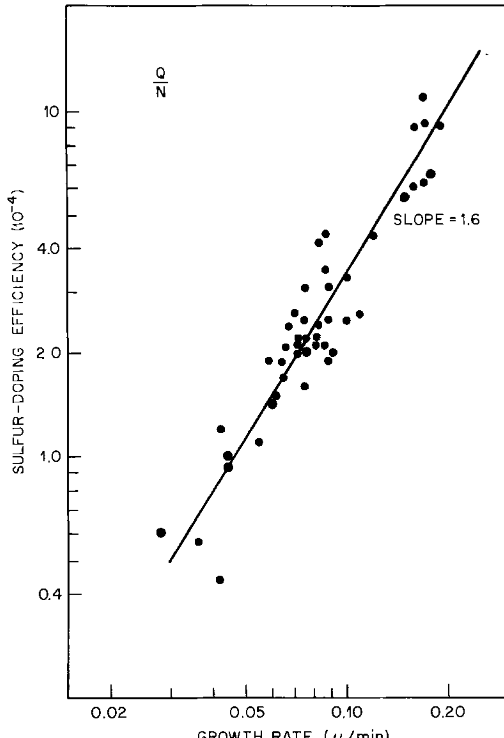

Fig. 10. Sulfur incorporation efficiency Q/N as a function of growth rate. The impurity content of a Hi-layer, Q, is divided by the number of S-atoms, N, injected into the gas stream. The quotient, Q/N, is related to a concentration averaged distribution coefficient k by $k = 0.75\ Q/N\ (\text{G.R.})^{-1}$, Eq. [4].

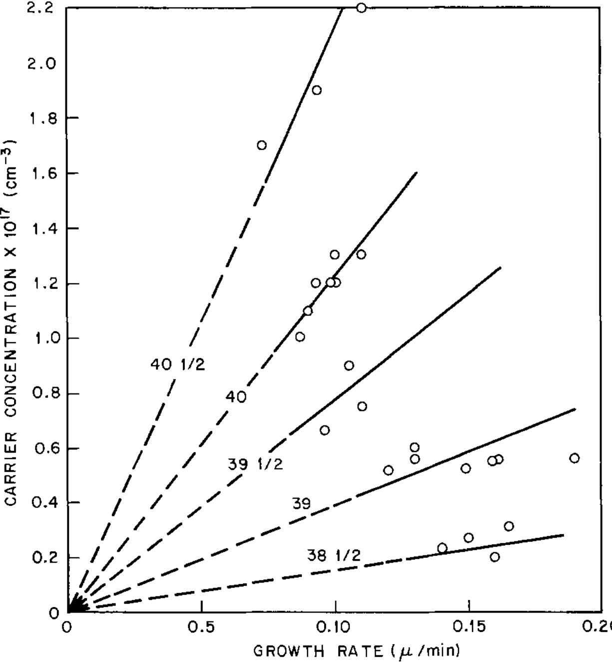

Fig. 11. Free carrier concentration vs. growth rate for steady-state S-doping. The numbers indicate the settings of the variable leak (Granville Phillips) used. Calibration of the leak indicates that leak flow rates increase linearly with the leak settings at a rate of a factor of 5 per integral number in the range covered here.

ratio Q/N, which is of the order 10^{-4}-10^{-3}. The wafer area is 4 cm^2 and there is no wall nucleation near the substrate. Thus at most 2.5% of the injected sulfur is taken up by the solid.

It is realized that the experimental values for the distribution coefficient obtained in this study are probably influenced by factors not recognized specifically, *i.e.*, they are probably system dependent. System dependent data should not be modeled, but summarized as simply as possible, *e.g.*, as a coefficient of linearity. The relatively complex approach taken here is not a model and attempts only to remove the time dependence of the growth process to isolate a coefficient of linearity which may be compared to more conventional steady-state doping coefficients obtained with other crystal growth systems.

The S-doping data given by Goldsmith and Oshinsky (22) can be applied to the formula given in Eq. [3] to yield an experimental distribution coefficient for their system

$$k = 140$$

This value represents an order of magnitude more efficient sulfur incorporation. Among major differences between the two systems compared is the nature of the Ga and As sources. Goldsmith and Oshinsky used $GaCl_3$ and As. The gas flow data and source temperatures given in their report lead to the estimate that the Ga/As ratio in their system was $\sim$1, taking into account that $GaCl_3$ vapor is dimeric. For a typical Ga/$AsCl_3$ system the Ga/As ratio is $\sim$2 (23). In conflict with experimental results, the more As-rich system would be expected to incorporate the As-substituting impurity less efficiently. Another effect is to be expected from the partial pressure of free HCl which must be higher in the $GaCl_3$/As system. However, the range of Si-background doping governed by P_{HCl} is negligible compared with 10^{17}-10^{18} cm^{-3} S-doping levels.

Steady-State S-Doping

The observation that the experimentally determined distribution coefficients vary superlinearly with growth rate suggests that steady-state doping might show growth rate dependence too. For this case the analysis would not involve the time integration required for a transient phenomenon and, therefore, no growth rate dependence would be predicted. But the additional fractional (0.6) growth rate dependence suggested by the data on Fig. 10 may be expected to be reflected in the steady-state case too. Experimentally (10) this is indeed observed. We used the standard method of doping with dilute (1000 ppm) H_2S admitted through a variable leak. Figure 11 shows that doping data for a limited range of growth rates are qualitatively in agreement with the transient doping data. The straight lines drawn through the data points suggest a linear relationship, *i.e.*, larger than the 0.6 power dependence suggested by the transient experiments. However, the data cover too narrow a range to allow discrimination between a 0.6 and a unity power dependence. The scatter is probably due to the difficulty of setting the leak reproducibly to a given opening.

Returning to the definition of k we can calculate the partial pressure of H_2S in equilibrium with a given doping level in the solid, *e.g.*, 2×10^{17} cm^{-3}. With $k = 20$ we obtain

$$P_{H_2S} = \frac{P_{H_2}}{20} \frac{2 \times 10^{17}}{2 \times 10^{22}} = 5 \times 10^{-7} \text{ atm}$$

Thus for steady-state doping using 1000 ppm H_2S with a carrier gas velocity of 0.7 liter/min we find that the leak flow rate of dopant should be 0.35 mliter/min. This estimate agrees well with leak doping experience and with extrapolation of leak flow rates measured at higher leak settings.

The positive growth rate dependence of steady-state S-doping can be compared with the results obtained by Wolfe *et al.* on Sn-doping of GaAs (24). For this system at low growth rates comparable to ours, a negative growth rate dependence was found. For growth rates higher than 0.2 μ/min the dependence changed sign and became first order. The explanation advanced by Wolfe *et al.* was based on the suggestion that higher growth rates lead to increasing roughness of the growing surface, thereby creating more surface area available for dopant adsorption. But since at all growth rates there

Table III. Reproducibility of sulfur doping and n^+-layer width

Note: The standard deviation is here taken with respect to the target, 2.5×10^{12}, rather than the experimental mean of $2.3 + 10^{12}$. Using the latter, σ becomes 0.4×10^{12} or 17%.

is competition between dopant and host atoms for sites, this mechanism seems unlikely to produce the observed effects unless the proportion of surface area of different facets changes with growth rate. If so, the growth rate dependence of the sulfur incorporation would actually be due to an orientation effect. We found no correlation between surface roughness, growth rate, and doping. One layer grown at the rate of 0.04 μ/min had a fish scale pattern with features registering between 500 and 1500Å high on the Talysurf. Another grew at a rate of 0.18 μ/min and exhibited features less than 300Å high.

The observed growth rate dependence of the sulfur incorporation is undesirable as it magnifies the difficulties of doping control. The inherent dependence might be eliminated by changing to a different dopant or by increasing the growth rate. If a dopant were found with a higher distribution coefficient, the basic idea of injection doping would offer better control than was realized with sulfur. Alternatively, a dopant with a negative inherent growth rate dependence should be employed. For such a dopant the two observed growth rate dependences would cancel. The results of Wolfe *et al.* suggest the use of tin which, however, for application in the present system would have to be available in gaseous form (metallorganic).

As a result of the strong growth rate dependence (1.6 power) of the sulfur incorporation the reproducibility of doping was not improved by employing injection doping. Using the manually operated valve in a series of consecutive runs we aimed at a target impurity density of 1.25×10^{12} cm^{-2}. The slice-averaged impurity density ranged from 0.95 to 1.56×10^{12} cm^{-2} with a standard deviation of 0.20×10^{12} cm^{-2}, or 16%. In a similar series of 9 injection doping runs the target of 2.5×10^{12} cm^{-2} was obtained with a standard deviation of 0.45×10^{12} cm^{-2}, or 18%, and a range of 1.7-2.8 $\times 10^{12}$ cm^{-2}, Table III. These results show that improving the control over the amount of dopant added does not solve the problem. An idea of the uniformity across a 1 × 1 in. wafer grown by S-injection may be obtained by referring to Fig. 12. The level of uniformity is comparable to that of wafers produced by conventional steady-state doping. The table also contains data on the reproducibility of the width of the Hi-layers. Additional data on reproducibility and uniformity will be published as a separate report (6). Two useful results have been obtained using injection doping. The minimum practicable width of Hi-layers has been reduced by a factor of five. Using the manually operated variable leak the narrowest Hi-layers achieved were about 700Å wide. With the injection valve Hi-layers only 150Å wide (uncorrected C-V profile) could be reproducibly grown. Although no improvements in the performance of 6-11 GHz devices have been attributable to the reduction in layer width, it is possible that such improvements may be realized for higher frequency devices. This suggestion is based on the fact that higher frequency devices have $x_c \leq 1000$Å and

therefore, layers of widths approaching 1000Å are not feasible for this type of device.

Secondly, the injection doping technique has been useful in demonstrating that doping control is primarily dependent on growth rate control. Future work will have to aim at improvements in the reproducibility of growth rates.

Conclusions

An experimental approach to investigate the reproducibility of growing 100-200Å thin epitaxial layers with a predictable impurity content is described. This system has been utilized to grow Lo-Hi-Lo (modified Read profile) structures for GaAs IMPATT diodes. The dopant system is very flexible, allowing control of the amount of dopant through three easily manipulated variables: pressure, volume, and concentration of the doping gas. The position, width, and impurity density of the Hi-layers could be explained in terms of the experimental conditions and known material parameters. A distribution coefficient of ~20 for S-doping from the gas phase was extracted from the data. A strong growth rate dependence of the total amount of incorporated impurity was observed. It is, in part, due to the transient nature of the doping procedure. In addition there appears to be a positive, inherent growth rate dependence of sulfur incorporation. As a result of the growth rate dependence no improvement in doping control was achieved compared with previously used methods. The value of injection doping lies in the achievement of sufficient precision in the control of amount of dopant added to obtain reliable data on sulfur incorporation. These data justify the conclusion that improved growth rate control will lead to improved doping control.

Reactions Between the Ta-Pt-Ta-Au Metallization and PtSi Ohmic Contacts

H. M. Day,* A. Christou, W. H. Weisenberger, and J. K. Hirvonen

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

The purpose of this work was to determine processing and/or operating limitations of the proposed microwave power transistor metallization scheme consisting of Si/PtSi-Ta-Pt-Ta-Au. Typical Si-PtSi ohmic contacts were processed and metallized along with larger area wafers and annealed at temperatures from 400° to 785°C. Small area contacts were checked for variation of contact resistivity and the large area metallizations were examined by Auger electron spectroscopy (AES), Rutherford backscatter (RBS) analysis, and x-ray diffraction at a 5° glancing angle. Evidence of significant interdiffusion and chemical interaction at 400°C was absent. Above 600°C tantalum was found to react with gold and PtSi to form various compounds. Consumption of silicon from the substrate accompanied the formation of $TaSi_2$ with the formation of PtSi as an intermediate step. These thermochemical reactions with the accompanying diffusions which take place at temperatures in the range sometimes used for device processing could significantly alter device geometry and, therefore, device performance. At normal operating temperatures and temperatures up to 400°C the PtSi-Ta-Pt-Ta-Au system appears to be adequately stable.

Gold has been found to be less susceptible than aluminum to electromigration (1) and metal restructuring effects (2). It is, therefore, a strong candidate for a more reliable metallization system for microwave power transistors. However, due to the lower eutectic temperature of the Au-Si system (377°C) a diffusion barrier between gold and silicon is necessary to prevent alloying and shorting of the device. Several refractory metals have been used for this purpose as well as for better adhesion. In previous work (3, 4) the authors found that a Ta-Pt-Ta sandwich is an effective barrier to the interdiffusion of gold and silicon and provides satisfactory adhesion to the PtSi coated silicon substrate as well as to SiO_2 coated areas.

The reliability of composite contact metallizations is expected to be affected by diffusion controlled processes which take place at the various interfaces. Previous investigations (5-7) have indicated that while providing satisfactory adhesion in most cases the refractory metals tend to form silicides themselves. More recent work (8) indicates that the presence of PtSi between tungsten and silicon actually enhanced the rate of WSi_2 formation. In the case of a Si-PtSi-Al contact a reaction between Al and PtSi was also observed to take place, significantly altering the characteristics of the contact (9).

Thus, an evaluation of tantalum films on PtSi is necessary in order to determine processing and/or operating limitations of the proposed microwave power transistor metallization scheme consisting of Si/PtSi-Ta-Pt-Ta-Au.

The present investigation concentrates upon the stability and contact resistance of the Si/PtSi-Ta-Pt-Ta-Au metallization system in which interfacial reactions and diffusion under extreme conditions can result in the formation of a number of additional compounds such as Ta_5Si_3, $TaSi_2$, TaPt, and TaAu. We report on the interdiffusion of the various constituents of the system, the various compounds actually formed as a function of annealing temperatures up to 785°C, and the variation or stability of the contact resistance at annealing temperatures up to 400°C. niques and procedures used in the formation of small area contacts are presented along with the methods used to obtain compositional data. These methods include Auger electron spectroscopy (AES), Rutherford backscattering (RBS) analysis, and 5° glancing angle x-ray diffraction.

Experimental Techniques

Ohmic contact processing.—The substrate used for ohmic contact processing and evaluation consisted of an n-type single-crystal silicon wafer with localized (oxide window, boron diffused) regions of p-type material of approximately 0.05 ohm-cm resistivity or 180 ohms per square sheet resistance. This resistivity was selected as being typical of the npn L-band microwave power transistor base region. The test pattern consisted of six parallel contacts 125 × 10μ defined by oxide windows spaced 35μ on center within the base area diffusion window. Contacting pads were extended onto the surrounding oxide which was typically 5000Å thick. The contact resistivity was measured according to the method outlined by Terry and Wilson (10).

Platinum silicide was formed in the contact windows by sputter deposition of 600Å of Pt at a substrate temperature of 110°C followed by a 10 min sinter in vacuum at 475°C. The excess Pt was removed by etching in aqua regia or by sputter etching. For many applications, sputter etching produces excessive ion bombardment damage to the surrounding oxide. Platinum silicide exposed to aqua regia is also etched and left with a very roughened texture. To avoid the above problems, the PtSi reaction was driven to completion by further sintering in air at 475°C for 10 min. A layer of SiO_2, grown during sintering effectively masked the PtSi from attack by aqua regia during the removal of the excess platinum (11). The SiO_2 was subsequently removed by etching in buffered hydrofluoric acid before metal deposition.

Thin film deposition.—Layers of Ta, Pt, Ta, and Au were sputter deposited in sequence to thicknesses of approximately 1000, 300, 1000, and 3000Å, respectively, at 200W rf power, 5 μm argon pressure, and 110°-112°C substrate temperature. Conventional photolithographic techniques were used to define the resistivity test pattern in the Au. Using the Au layer as a mask, the top layer of Ta was etched away in a solution of 9 parts saturated KOH (heated in a boiling water bath) and one part H_2O_2, added just before etching (12). The top layer of Ta was removed within 20 to 30 sec, whereupon the Pt layer prevented further etching. Further etching of the Ta was accomplished only after the Pt layer was removed by sputter etching at 100W rf power and 5 μm argon pressure. An alternative to the above procedure is to use low power reactive plasma etching techniques, followed by a chemical etch for the final Ta layer.

Two centimeter diameter wafers of silicon and PtSi coated silicon were metallized simultaneously with the small area contact substrates. The larger wafers were used for compositional analysis and profile studies. The sputtered films were annealed in vacuum at pressures less than 10^{-4} Torr.

Compositional analysis.—Metallization diffusion profiles were obtained by AES (13) analysis as a function of argon ion sputter etching times and by RBS analysis (14, 15). Compositional data after the various heat-treatments were obtained by x-ray diffraction (16).

The AES profiles were made in a Physical Electronics, Model 1300 Auger electron spectrometer. Multiplexing and a peak-to-peak detection capability were used permitting variations in Auger signal amplitudes to be read out directly while sputter etching. The AES data were taken with a 50 μA beam current at a 3 kV beam voltage. A 2 kV, 30 mA argon ion beam was used for sputter etching. The AES depth-composition profiles are normalized so that the amplitude of the Auger signal for each element is compared to the signal amplitude obtained for 100% surface coverage by that element. The normalized peak amplitude corresponds to the per cent coverage of a particular element assuming that the signal is unaffected by the presence of other elements or compounds on the surface. However, ion bombardment during sputter etching is known to produce chemical and topographical changes (13). Therefore, the correspondence of the depth composition profile to actual atomic per cent distribution of the elements in the samples can only be approximately determined. Robinson and Jarvis (17) have estimated that, at a given depth, in the specific case of a gold metallization on gallium arsenide, the per cent composition for any of the constituents is correct to within 15%.

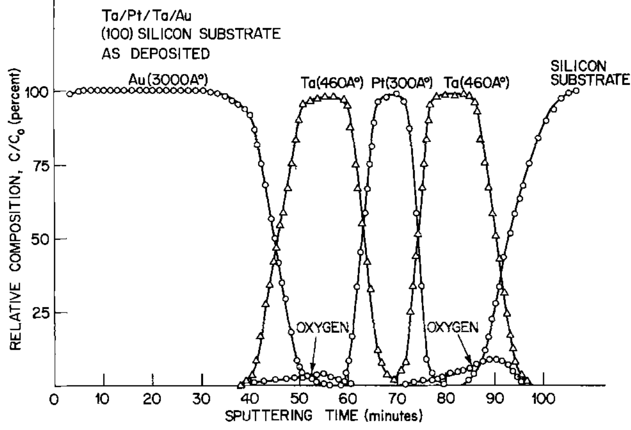
With RBS analysis (18) $^4He^+$ ions which penetrate the sample are backscattered from within the sample to give information on interdiffusion without the conventional sectioning by sputter etching during AES profile analysis. RBS analysis in this case was performed on the metallization specimens Si-PtSi and Si-PtSi-Ta-Pt after a sequence of annealing treatments up to 785°C. These measurements were performed using a 2.0 or 4.0 MeV $^4He^+$ beam from the NRL 5 MV Van de Graaff accelerator. The backscattered ions were detected at an angle of 165° in a silicon surface barrier detector with a system resolution of approximately 12 keV FWHM.

Results and Discussion

Preanneal film structure and contact resistivity.—The grain size of the sputter deposited tantalum and gold films measured by electron diffraction was 100-300 and 300-600Å, respectively. Likewise, the grain size of the platinum film was 200-400Å. The gold was strongly (111) textured while the tantalum and platinum did not show any observable texture. The electrical resistivity of the gold films after deposition was measured to be 1.25 times the bulk resistivity. The sputtered tantalum films had a resistivity of 2.1 times that of bulk tantalum. The tantalum films were deposited as β-Ta as verified by electron diffraction examination (19).

The contact resistivity before annealing was found to be typically less than 8 μohm-cm² and did not vary with annealing temperatures up to 400°C for 24 hr. As a result of the particular measurement technique used, this value contains a component of resistance due to nonuniform fields and, therefore, represents an upper limit. In comparison, an average value computed from the Terry and Wilson data (10) for PtSi contacts on approximately equal resistivity material was 110 μohm-cm². This is an average of contact resistivity values for Al, Mo, Ni, Cr, and Ti on PtSi with a substrate resistivity of 0.04 ohm-cm. However, the PtSi-Al contact resistivity was consistently an order of magnitude below the average value. A value of approximately 15 μohm-cm² for a PtSi-W contact on p-type material doped to $2 \times 10^{19}/cm^3$ (or 0.05 ohm-cm) was obtained by Sinha (7).

Metallurgical stability.—Figure 1 compares the Auger depth-composition profiles of the Ta-Pt-Ta-Au metallizations on silicon substrates as-deposited and after annealing at 550°C and 10^{-7} Torr. The fact that the interfaces in general appear slightly diffused initially may be attributed to differential sputtering (17). After annealing at 550°C interdiffusion is evident by a slight decrease in the slope of each peak with extensive tailing at each interface. Tantalum has diffused completely through the thin platinum layer while gold has not completely penetrated the thicker tantalum layer. A comparison of the RBS spectra of the Si-PtSi-Ta-Pt metallization taken on samples as-deposited and after being annealed at 785°C is shown in Fig. 2. The verticle arrows indicate the energy of the backscattered $^4He^+$ ions which would be obtained for a particular species if it were on the outer surface. The width of a peak is a measure of the thickness of that particular layer, while the slope of the edge of a particular peak after taking energy straggling into account is a measure of the diffusion at that particular



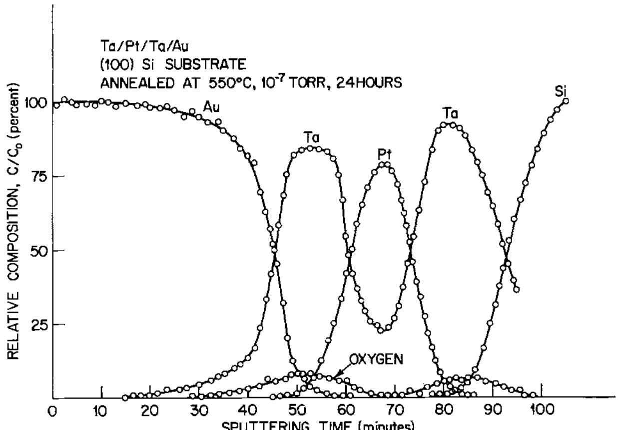


Fig. 1. Ta-Pt-Ta-Au metallization on (100) silicon substrate; as-deposited and as annealed at 550°C, 10^{-7} Torr for 24 hr.

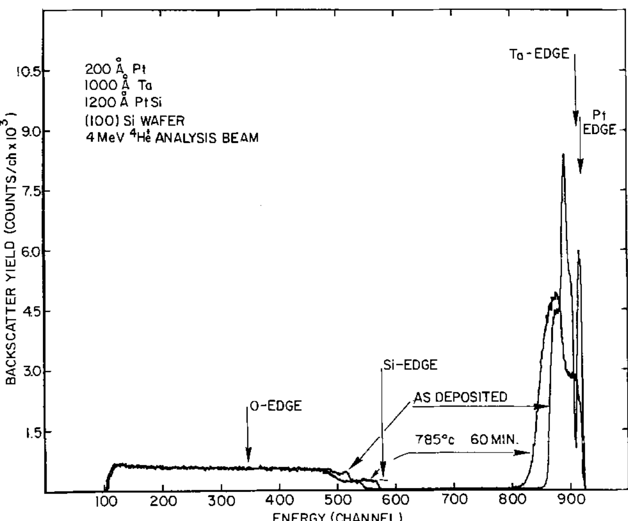

Fig. 2. RBS spectra of a PtSi-Ta-Pt metallization on (100) Si wafer; as-deposited and after annealing at 785°C for 60 min.

interface. The increase in signal at the silicon edge and the decrease in the low energy edge of the Ta-Pt mixture after annealing at 785°C indicates that considerable intermixing and movement of the Si-PtSi interface has taken place with silicon penetrating to the outer surface. This is further corroborated by Auger spectra of identical specimens shown in Fig. 3 along with the spectrum of another specimen annealed at 550°C. The spectrum of the 550°C specimen shows significantly less interdiffusion or reaction of Pt-Ta as compared to the spectrum of the 785°C specimen. The latter clearly indicates that $TaSi_2$ has formed while the PtSi layer between the $TaSi_2$ and the silicon substrate remains essentially unchanged. Similar spectra (Fig. 1) of the Ta-Pt-Ta system directly on silicon likewise show less interdiffusion or reaction of Ta and Si when annealed at 550°C. Finally, x-ray diffraction data on three Si-PtSi-Ta-Pt specimens (the control and specimens annealed at 600° and 785°C) are shown in Fig. 4. After annealing at 600°C, tantalum-rich silicides are predominant though the Auger spectra showed little interdiffusion at 550°C. After annealing at 785°C the x-ray spectra, in agreement with the Auger spectra, show that $TaSi_2$ is dominant with the (112) PtSi line increasing in intensity.

The reaction of tantalum with PtSi in this case is exactly analogous to the reaction of tungsten with PtSi to form the more stable WSi_2 as observed by Sinha (6). Similar observations have been made for other refractory metals according to reports by Tu and Mayer (18). In the case of the Si-PtSi-Ta reaction, movement of the Si-PtSi interface at temperatures above approximately 600°C takes place by a complex

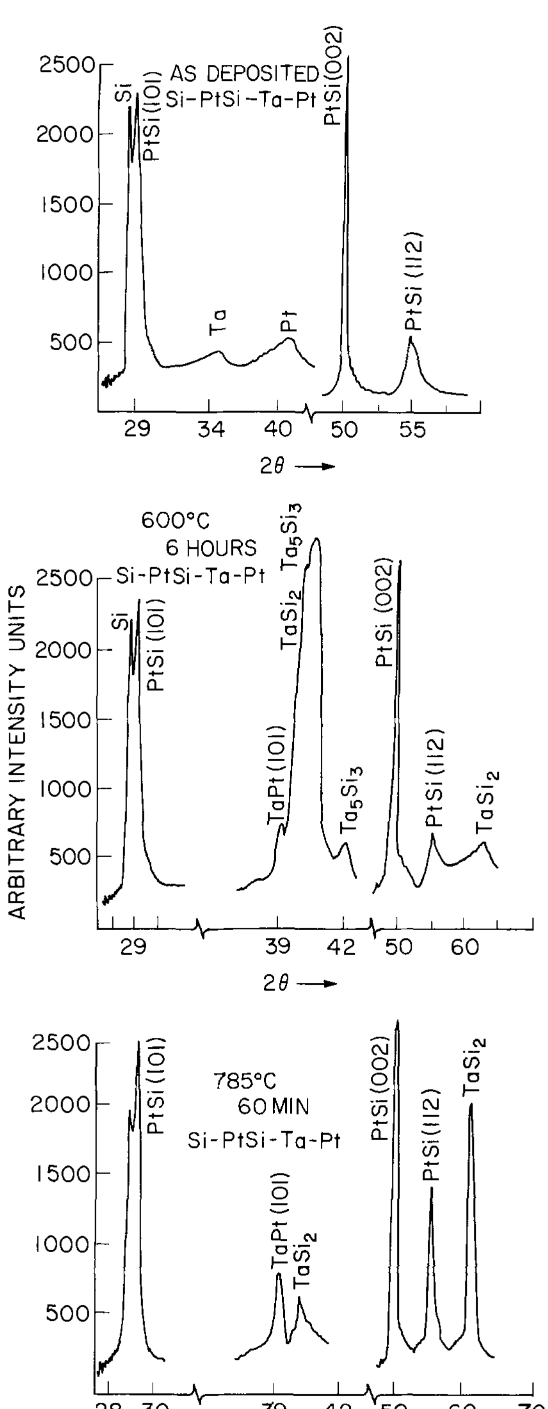

Fig. 4. X-ray diffraction spectra of the PtSi-Ta-Pt metallization on (100) Si wafer; as-deposited and after annealing at 600°C for 6 hr and 785°C for 60 min.

reaction (between PtSi and tantalum) in which silicon is the diffusing species. Thus, from a combination of the data it can be inferred that at excessively high temperatures tantalum displaces silicon from PtSi to form the various tantalum silicides until the most stable one, $TaSi_2$, is formed. As platinum is displaced it is free to react further with the silicon substrate to form more platinum silicide. During and upon completion of these reactions, silicon diffuses through the resulting films or layers at a rate which depends on the temperature and the particular layer.

Conclusions

Reactions between silicon substrates and a stabilized tantalum gold metallization with and without an intervening PtSi layer have been studied as a function of annealing temperatures up to 785°C. A complex reaction between PtSi and tantalum results in the formation of $TaSi_2$ at excessively high temperatures resulting further in the uptake or consumption of silicon of the substrate at the higher temperatures. The contact resistance of small area PtSi ohmic contacts with geometries representative of microwave power transistors overlaid with the Ta-Pt-Ta-Au system remained constant during anneals up to 400°C for 24 hr. This indicates that thermochemical reactions and diffusion observed to take place at higher temperatures are probably not significant at normal operating temperatures but could be significant at some processing temperatures.

In view of the fact that enhanced reactions take place in this system at elevated temperatures, additional work should be done in order to completely characterize the system. The energies of formation of the compounds Ta_5Si_3 and $TaSi_2$ should be determined along with those of the intermetallic compounds TaPt, Ta_2Pt, and TaAu.

Manuscript submitted Sept. 30, 1974; revised manuscript received Jan. 2, 1975. This Paper 75 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

The Characterization of GaAs Surfaces

David R. Wood and D. Vernon Morgan

Electrical and Electronic Engineering, The University of Leeds, Leeds LS2 9JT, England

ABSTRACT

In this paper, we discuss the preparation of GaAs crystal surfaces by mechanical and chemical techniques. A comparative study of the surface in the course of consecutive polishing by various chemical etchants is made. The surface is assessed qualitatively by microscopy and quantitatively by the Rutherford backscattering/channelling technique. The concentration of gallium and arsenic at the surface is reported, and it is found that the surface is generally arsenic rich, the excess depending on the chemical polish used. Low concentrations of surface impurities (*e.g.*, Te $\gtrsim 2.10^{13}$ atoms cm^{-2}) are measured and the variation monitored between the chemical polishing stages. No systematic behavior in the variation of impurity concentrations is observed.

The advent of GaAs as a new material for fabricating semiconductor devices has demanded a new technology different from that used for silicon devices. An important part of this technology is the fabrication of electrical contacts to the completed device. Transferred electron devices, for example, are thought to require two low resistance ohmic contacts whereas Barritt diodes need high quality Schottky barriers. A prerequisite for fabricating reproducible electrical contacts, is the development of analytical techniques to study the semiconductor surface prior to the deposition of the metal contacts. In this way it should be possible to relate any variations in the electrical behavior of the contact to the physical nature of the crystal surface. In this paper, we consider the physical characteristics of GaAs surfaces resulting from a wide variety of surface preparations.

The techniques which we used to study GaAs surfaces fall into two groups, qualitative and quantitative. In the first group we have the techniques of optical and scanning electron microscopy which give information about the topography of the surface. However, microscopy when combined with surface decoration techniques can yield quantitative information on the dislocation density and hence the surface damage present. Optical interferometry was also used to investigate surface irregularities. The second group comprises the technique of Rutherford scattering and channelling. This technique is now well established as a versatile tool suitable for lattice site location (1), thin film analysis (2), impurity detection (3), and more recently for surface studies (4). The latter technique has been described in detail in an earlier paper (5).

Surface Preparation

For the majority of the work described in this paper, the material used was Czochralski grown, Te-doped n-type gallium arsenide. The samples were approximately 8×8 mm^2 in area, and in order to obtain the best channelling results, the (110) orientation was used. The surface preparation consists of two stages; (*i*) mechanical lapping/polishing to obtain a flat smooth surface and (*ii*) a chemical polish to remove the surface damage left by the mechanical polish.

The mechanical preparation was carried out in two stages, mechanical lapping followed by vibratory polishing, (Table I). First, the samples were lapped with diamond abrasive to remove the gross damage and produce an optically flat surface. In order to minimize damage, two grades of abrasive were used; 1.0-5.0 μm grit followed by 0.5-2.0 μm grit. After washing in trichloroethylene to remove contamination due to the abrasive, the samples were vibratory polished (6). Four samples were polished simultaneously in the polisher bowl in order to encourage the samples to spin around and hence reduce directional polishing. The abrasive was alumina dispersed in water and again two grit sizes were used, 1.0 followed by 0.05 μm.

The samples were then cleaned using "Analar" grade organic solvents in an ultrasonic bath. Particular attention was paid to this cleaning procedure since the presence of grease, dirt, or any impurity can drastically affect any subsequent chemical etching (11). The chemical etchants examined in this paper are described in Table II and were chosen because of their extensive use in the preparation of GaAs crystals. Most of the work concentrated on the first four, polishes A-D, since these are the ones most commonly used.

Polish E was included so that our results could be compared with those of Hvalgård *et al.* (3) who used Rutherford backscattering to study changes in surface impurity concentration on GaAs caused by chemical etching.

The mechanical/chemical etching procedure, used with polish D, was carried out on an apparatus similar to that described by Dyment and Rozgonyi (12). Here, the sample was mounted onto the bottom of a small stainless steel holder which was then placed on the turn table which was covered with a microcloth. The microcloth was initially soaked in 0.1% bromine-methanol and then while the table rotated at 60 rpm fresh

Table I

Initial preparation	Thickness removed, μm	Removed rate, μm/min	Comments
Mechanical lapping			Damaged caused by abrasive and especially loose material. Optically flat surface.
1-5 μm	9.0	0.6	
0.5-2 μm	2.5	0.06	
Vibratory polishing			Smooth featureless surface with rounding of sample edges.
1.0 μm	16.0	0.04	
0.05 μm	4.0	0.01	

Table II

Etchant	Composition*	Rate,** μm/min	Comments and references
Polish A	$HF:HNO_3:H_2O$ 1:3:2	24	Polish, fast reaction producing rough surface. (7)
Polish B	$Br_2:CH_3OH$ 4:100	9	Polish (8)
Polish C	$H_2SO_4:H_2O_2:H_2O$ 3:1:1	20	Polish, controllable reaction. (9)
Polish D	$Br_2:CH_3OH$ 0.1:100	0.3	Chemical/mechanical polish. (8)
Polish E	$HF:HNO_3:H_2O$ 1:9:5	—	Polish, very fast reaction producing rough surface. (3)

* Reagent assays: HF(40%), HNO_3(63%), H_2SO_4(98%), H_2O_2(40%).
** Measured on (110) Te-doped GaAs.

Key words: gallium arsenide polishing, Rutherford backscattering/channelling.

etchant was dripped onto the cloth at about 15 ml/min. In every case, the etchant was freshly made up from Analar grade reagents which were mixed together in the same order. The polishing was carried out under normal illumination with slight agitation and at room temperature. The etchants had been previously calibrated for similar material, so that the thickness of material removed by the etchants was known to within $\pm$ 1 μm.

Results and Discussion

Mechanical polishing.—After lapping with the 1-5 μm diamond grit, there are numerous straight shallow scratches across the surface caused by the abrasive. More serious is the presence of jagged and deeper scratches and areas of damage caused by material chipped from the sample edges scoring the surface. The use of interference microscopy (λ = 547 nm) confirms that the surface is optically flat. When a further 4 μm is removed by the 0.5-2.0 μm abrasive, there is a marked improvement in the condition of the surface. Some scratches from the abrasive are present but in general these are less than 2μ deep. In addition, some of the severe damage of the previous lapping remains.

After vibratory polishing in 1.0 μm alumina, no linear damage from the lapping process is visible, although there are some curved scratches caused by this polishing. In contrast with the even polishing produced by the planetary motion of the previous lapping, a tendency for directional polishing is seen. This is caused by the shape of the sample having a preferred orientation to the direction of travel as it moves across the microcloth.

Furthermore, since the holder is not rigidly held parallel to the plane of the abrasive surface during polishing, the surface becomes less flat especially near the edges. It should be noted that, although the abrasive particles used in this vibratory polish are similar in size to those used in the previous lapping stage, the rate of removal and, hence, the depth of damage, is considerably less. After the final mechanical polish with 0.05 μm abrasive, the crystal surface is very smooth. This is confirmed by optical and scanning electron microscopy, which reveals no visible surface damage. Interferometry patterns show a slight degradation in flatness, with a variation of 1% across the surface.

Consider now the results obtained by the Rutherford scattering/channelling technique. A typical energy spectrum is illustrated in Fig. 1(a) which shows the scattering yield as a function of the energy of the backscattered alpha particles. The energy axis can be converted into either a mass scale or a depth scale (5, 13). The depth resolution for the experimental configuration used is also shown in Fig. 1(a).

This energy spectrum is obtained when a 2.2 MeV beam of alpha particles is scattered through 135° from a (110) GaAs crystal which has been vibratory polished. The inset shows the surface peak after the random line-shape background correction (5) (shown as a dotted line in the figure). This correction procedure is used throughout the results presented in this paper. For a good quality crystal, two surface peaks are observed corresponding to the Ga and As sublattices. However, because of the surface damage resulting from the vibratory polishing, two peaks cannot be resolved. This is a result of multiple scattering by unscreened Ga and As atoms in the thick disordered layer which causes the two surface peaks to overlap. From the area, A, under this surface peak, the total concentration of atoms, N_T, is calculated using the expression

$$N_T = \frac{t}{l} \cdot N_{(110)} \quad [1]$$

In this expression, l is the monolayer separation; $N_{(110)} = 1.77 \cdot 10^{15}$ atoms $\cdot$ cm^{-2} is the concentration of atoms in one monolayer of GaAs(110); and t is the disordered layer thickness obtained from [Eq. 7, Ref. (5)]

$$t = \frac{A}{Y[k^2 S(E_0) - S(E_1)/\cos\theta]} \quad [2]$$

where Y is the random yield; k^2 is the kinematic factor; $S(E_0)$ and $S(E_1)$ are the stopping powers of the ion in GaAs at the energies E_0 and E_1, respectively; and θ is the scattering angle. For the vibratory polished surface shown in Fig. 1(a), N_T = (3.51 $\pm$ 0.5)10^{16} atoms $\cdot$ cm^{-2}. By comparing N_T with $N_{(110)}$, the extent of the surface disorder can be assessed.

An alternative qualitative measure of the perfection of the crystal at the surface is the minimum yield, χ_{min}, where

$$\chi_{min} = \frac{\text{Aligned Yield}}{\text{Random Yield}} \quad [3]$$

measured just behind the surface peak [*i.e.*, at X in Fig. 1(a)]. For a high quality damage free crystal, at room temperature $\chi_{min} \simeq 0.03$ while for the vibratory polished crystal $\chi_{min} = 0.13$, indicating that there is a large amount of damage present at the surface.

The peak beyond the leading edge of the host spectrum corresponds to the impurity tellurium. By comparing the area of this impurity peak, with the yield from the host crystal the concentration is calculated to be (3.4 $\pm$ 0.5)10^{14} atoms $\cdot$ cm^{-2}. Although it is convenient to express impurity concentrations as (atoms $\cdot$ cm^{-2}), it must be remembered that this is the total concentration of unscreened impurity atoms

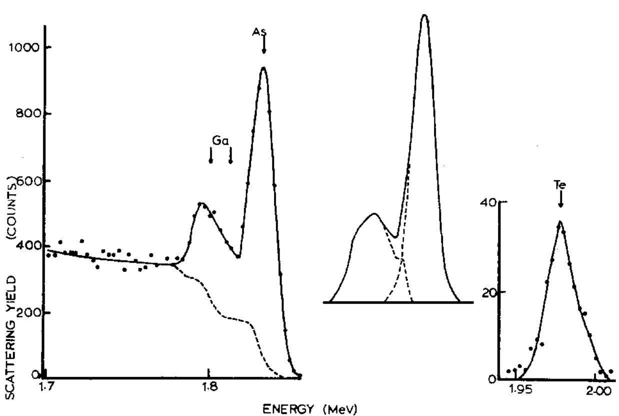

Fig. 1. The energy spectra for 2.2 MeV alpha particles scattered through 135° by (110) GaAs. (a, left) For the surface vibratory polished in 0.05 μm alumina. The inset shows the surface peaks after the removal of the background (broken line). Also shown in (a) is the detection resolution and at X, the position of the measurement of χ_{min}. (b, right) The same crystal after 10 μm has been removed by polish A. The reduction in damage enables the contributions to the surface peak of the Ga and As atoms to be separated as shown by the dashed line in the inset. In (a) and (b), small peaks produced by surface tellurium are seen beyond the leading edge of the host spectra.

distributed throughout the whole of the disordered layer.

Chemical polishing.—The effect of subsequent chemical polishing is illustrated in Fig. 2. There is a loss of surface flatness as polishing continues due to a variation in the rate of attack over the crystal surface. The nature of the surface also varies with the actual etchant used and the crystal face being polished, *e.g.*, the production of etch pits on the (111) Ga face of GaAs by the bromine-methanol etchant (7). After the first etch, which removes 5 μm, the surface becomes uneven, and as further polishing is carried out, this irregularity increases. In the worst case, polish A, the surface is covered with hillocks. In Fig. 2, we show typical areas of the sample surfaces after the removal of 20 μm by the various etchants. The rough surface produced by polish A is caused by the adhesion of gas bubbles which passivate varying areas on the surface. The optical micrograph shows that after the removal of all the damage (*i.e.* $\gtrsim$ 10 μm of material), polish A produces no preferential etch pits.

Similar changes in appearance are observed for polishes B and C, although both these etchants produce smoother surfaces than polish A. Before using polish C, it is important to ensure that the surface is completely scratch free, since any areas of localized damage are attacked preferentially, and are not removed by the etchants. It was because of the degradation in surface flatness that the mechanical/chemical technique was developed. In Fig. 2(d), we illustrate the improvement in flatness obtained by this procedure. Furthermore, the surface retains its flatness even after a short "free" etch in polish B, necessary to ensure a damage free surface.

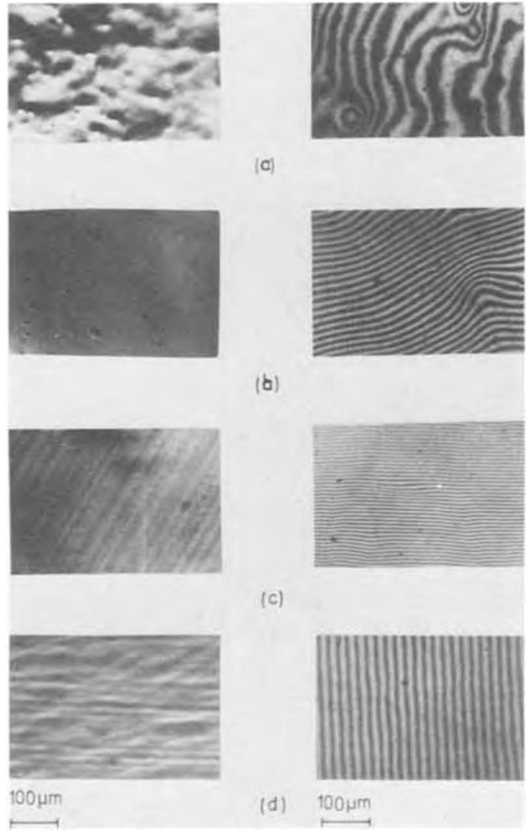

Fig. 2. Optical micrographs (left) and interference micrographs (right) of n-type (110) GaAs. The photographs show typical random areas of the surface after removal of 20 μm by (a) polish A, (b) polish B, (c) polish C, and (d) polish D. (λ = 547 nm for the interference pictures).

With the removal of 5 μm of damaged material, the Ga and As surface peaks of the Rutherford scattering spectrum, are resolved. From the areas of these individual Ga and As peaks, we can calculate the absolute concentration of unscreened Ga and As and hence the surface stoichiometry (5). In this case the values obtained are $N_{As} = (1.2 \pm 0.2) \cdot 10^{16}$ atoms cm^{-2}, $N_{Ga} = (7.3 \pm 0.1) \cdot 10^{15}$ atoms cm^{-2} and hence $N_{As}/N_{Ga} = 1.7$. It should be noted that this ratio is for the surface region only ($\sim$ 4 nm) and that any departure from bulk stoichiometry is caused entirely by the selective action of the chemical etchant. The removal of 5 μm of damaged material also produces a corresponding decrease in χ_{min} to $\sim$0.057. A tellurium surface impurity peak is visible again but in this case it corresponds to a concentration of $(7.4 \pm 1.0) \cdot 10^{12}$ atoms cm^{-2}.

When a further 5 μm of material is removed, χ_{min} decreases to 0.030 and the surface peaks are more clearly resolved [Fig. 1(b)], and their separation depends only on the resolution of the detector. Etching of the crystal by polish A is continued in stages until a total of 60 μm is removed. Two energy spectra from the final surface are taken with beam energies of 2.2 and 4.0 MeV. The results from the 4.0 MeV analysis are more accurate (5) and are used as a check on the 2.2 MeV results.[1]

Similar measurements are made on identical material but with the crystals etched in polishes B and C, until a total of 45 and 30 μm, respectively, had been removed. A summary of the results obtained at the various stages of chemical treatment is given in Table III. The variation of χ_{min} with thickness removed is similar for all three polishes and illustrates that in order to obtain a damage-free surface it is necessary to remove > 10 μm of GaAs. Although the theoretical value of χ_{min} is 0.01 for a perfect crystal surface, this ignores the effect of oxides and hydrocarbons on the surface so that χ_{min} $\sim$0.03 (with a liquid nitrogen cold shield) is typical of a good quality crystal surface (14). The ratio, χ_{min}, is extremely sensitive to disorder and Table III shows that although N_T for the vibratory polished surface indicates a disordered surface of only $\sim$9 nm, the crystal structure immediately below the surface is badly strained and $\sim$10 μm has to be removed before a damage free crystal is obtained. This is confirmed by the use of the Abrahams and Buiocchi dislocation etch (10) which reveals a steady dislocation density of $\sim$10^4 cm^{-2} for all the surfaces after 10 μm has been removed.

In Table III, we see that, initially, the total concentration of unscreened atoms, constituting the disordered surface region, N_T, shows the same variation as χ_{min}. However. after 10 μm is removed, N_T depends

[1] All the results presented in this paper were obtained with an incident energy of 2.2 MeV which is the limit of the Aarhus and Salford Van de Graaff accelerators.

Table III

	Polishing solution	Thickness removed by polishing solution (μm) 0	5	10	20	45

* After 30 μm has been removed by polish C.

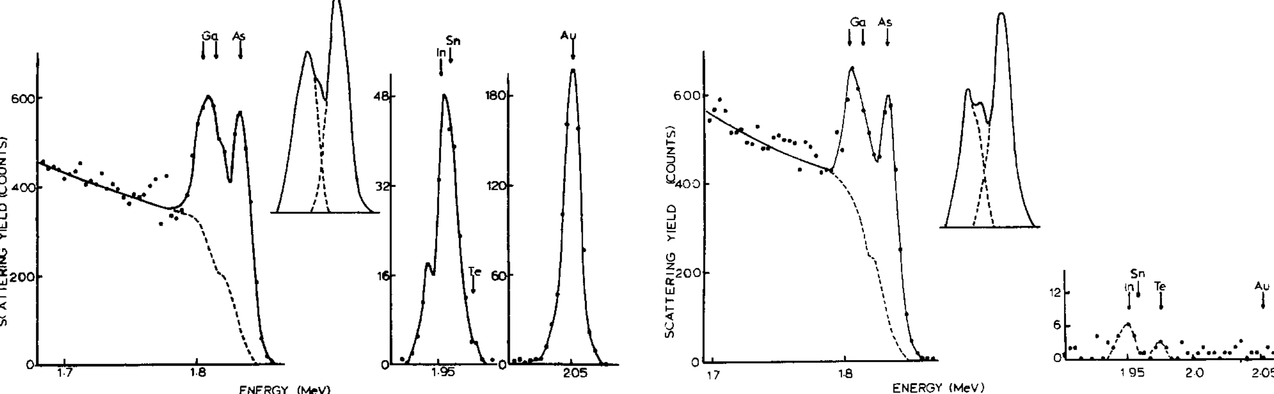

Fig. 3. The energy spectra for 2.2 MeV alpha particles scattered through 135° by (110) GaAs. (a, left) After the removal of 10 μm by polish D and (b, right) the same sample after a further 2 μm has been removed by polish B. The insets show the surface peaks after the background correction. In (b), the impurity symbols are used to indicate where the peaks would occur if those impurities were detectable.

only on the chemical nature of the surface produced by the etchant and is the result of natural oxides and other impurities at the surface.[2] The values of N_{As} and N_{Ga}, and their ratio (Table III) are closely dependent on the actual etchant used. All the etchants produce arsenic-rich surfaces and the excess arsenic varies with polish as

$$[N_{As}/N_{Ga}]_A > [N_{As}/N_{Ga}]_C > [N_{As}/N_{Ga}]_{B(\text{or } D)} \quad [4]$$

In order to investigate the consistency of the ratio (N_{As}/N_{Ga}) across the surface of a sample, three energy spectra were taken from different positions on the same surface for samples in polishes A and B. For both of these polishes, there is no variation in stoichiometry within experimental error. However, this does not rule out microscopic variations since these results are averaged over the area of the analyzing beam (*i.e.*, 1.0 mm^2).

The variation of the main surface impurities with etching is presented in Table III. The amount of Te present on the surface at all stages is larger than would correspond to the bulk doping, 8×10^{10} atoms cm^{-2} monolayer^{-1}. Furthermore, although there are large variations, the concentration of Te is generally larger for polish A than for polish B with the effects of polish C somewhere in between. We also note the presence of impurities deposited from the etchant such as bromine and gold from polishes B and D (Fig. 3) and occasionally zinc from polish C. In Fig. 3(a), the energy spectrum for the sample prepared by the removal of 10 μm by polish D is shown. This energy spectrum has two interesting features:

(*i*). The large impurity peak corresponding to In or Sn on the surface. The samples used to obtain the results presented here were cleaved from the same (110), GaAs wafer, and the presence of small concentrations ($\sim 10^{13}$ atoms cm^{-2}) of Sn or In is occasionally observed in all of them. However, the large concentration, $(2.0 \pm 0.2) \cdot 10^{14}$ atoms cm^{-2}, seen here appears to be a direct result of the dilute solution (0.1%) of bromine in methanol used to prepare this crystal.

(*ii*) The large gold peak corresponding to $(1.9 \pm 0.2) \cdot 10^{14}$ atoms cm^{-2}. Small concentrations ($\sim 2 \cdot 10^{12}$ atoms cm^{-2}) of gold have been observed (4) occasionally after using polish B and are thought to arise from the organic solvent, methanol. Thus, the large gold peak present after the etch in polish D is consistent with the large volume of methanol used during the polishing. However, after a short free etch in polish B to ensure a damage free surface [Fig. 3(b)], no gold peak is observed indicating that the bromine concentration is also important in determining the gold impurity concentration. This second chemical polish also reduces the Sn or In concentration to $(2.3 \pm 1.0) \cdot 10^{13}$ atoms cm^{-2}. (Because of the poor statistics of the impurity counts, dashed lines are used to position the peaks.) The effect of polish D on the host lattice of Ga and As, is similar to that of polish B and the above qualitative remarks concerning polish B apply equally to polish D.

It is clear from these results, that it is impossible to make exact predictions about the behavior of a dopant impurity in a particular etchant with time. The tellurium concentration shows no consistent behavior with etching time but varies randomly with consecutive etches. This is in contrast with the results of Hvalgård *et al.* (3) who observed, with polish E, a definite increase in dopant concentration with time. Now polish A acts very rapidly removing 0.4 μm sec^{-1} and leaves a rough finish (see Fig. 2). For these reasons, attempts were made to produce a more controllable etchant and at the same time repeat the work of Hvalgård *et al.* Thus, the ratios of $HF:HNO_3:H_2O$ listed in Table IV, together with their effects, were investigated. The main problem with polish A, is the release of a gas which together with the fast rate of attack produces a rough finished surface. The 1:3:5 etchant is slow and controllable but produces a poor dull surface covered with a white reaction product. As the nitric acid concentration is increased, the reaction rate increases correspondingly and produces a finished surface similar to that of polish A. The final etchant, polish E, is even less controllable than polish A and produces a rougher surface. As seen in Table IV, the Te concentration at the surface actually decreases with the consecutive polishes. These results conform to the unpredictable nature of chemical polishing discussed above.

The effect of the chemical etchants on other crystal planes and with different impurity dopants was investigated. In particular results were obtained for the (111)Ga and the $(\bar{1}\bar{1}\bar{1})$As faces etched in polishes A, B, and C. From these we conclude that there are no measurable differences between the two faces. There are two reasons for this result: (*i*) The surface peaks are produced by unscreened atoms, and there are equal Ga and As atoms visible to the analyzing beam even for a perfect (111) or $(\bar{1}\bar{1}\bar{1})$ crystal surface. (*ii*) The

Table IV

Etchant composition $HF:HNO_3:H_2O$	N_{As}/N_{Ga}	$N_T \times 10^{16}$ atoms · cm^{-2}	N_{Te}, $\times 10^{14}$ atoms · cm^{-2}	Polishing time, sec
1:3:5	3.3	2.92	1.5	40
1:6:5	3.4	2.16	7.1	40
1:9:5	1.4	2.05	1.3	15
1:9:5	1.1	7.15	0.54	30

[2] Because of the dependence of the collision cross section for Rutherford scattering on the (atomic number) (2) and the large background from the GaAs, it is not possible to detect small concentrations of the light elements, especially carbon and oxygen that are known to be there from Auger electron spectroscopy measurements (15).

rearrangement of the surface atoms caused by oxidation and absorption of impurities results in a loss of the original Ga and As surface structure. The results obtained are consistent with those obtained for the (110) planes, *i.e.*, arsenic-rich surfaces were produced in all cases, and the degree of nonstoichiometry increased in the order B, C, A.

The effect of using material with different doping species was examined by studying the surfaces of Zn-doped (p-type) and semi-insulating Cr-doped material. These results are in agreement with those from the n-type material. The p-type GaAs has arsenic rich surfaces, $N_{As}/N_{Ga} = 1.23$ and 2.53 after 30 and 90 sec in polish A, respectively.

However, because the Zn is lighter than the host material, it is much more difficult to detect than a heavier dopant such as Te and, in fact, none is detected (indicating an upper limit of $\sim 5 \cdot 10^{14}$ zinc atoms $\cdot$ cm^{-2}). Similarly, no chromium impurity peak is observed for the semi-insulating case. However, the familiar excess arsenic surfaces are produced by both etchants, the values being $N_{As}/N_{Ga} = 2.3$ and 1.1 and $N_{As} = 9.9 \cdot 10^{15}$ and $5.3 \cdot 10^{15}$ atoms $\cdot$ cm^{-2} for polish A and polish B, respectively. For all these etchants, there is no measurable difference in etch rate for the different materials, and it is probable that the reactions are diffusion limited with photogeneration providing sufficient carriers for the reaction (11).

Conclusions

In this paper, we have tried to characterize the quality and the chemical state of the surface of GaAs. We have shown that great care must be exercised during the mechanical handling of the material, in order to minimize the extent of damage at the crystal surface. For the procedure described above, at least 10 μm of material had to be removed chemically in order to ensure a damage free surface.

The chemically prepared surface was investigated qualitatively using microscopy techniques and quantitatively using the Rutherford backscattering/channelling technique for a variety of chemical etchants. It was found that the surface consisted of a disordered layer of GaAs $\sim$ 3 nm thick and that its stoichiometry could vary appreciably from the equality of the bulk. Absolute measurements of the concentrations of gallium and arsenic showed that the surface was always arsenic rich, the degree of nonstoichiometry increasing in the order polish B (polish D), polish C, and polish A. In all cases, the impurity dopant tellurium accumulated at the surface although no predictable behavior with etching time was observed.

Acknowledgments

We wish to thank our colleagues Dr. E. Bøgh (Aarhus), Professor G. Dearnaley (A.E.R.E., Harwell), Professor G. Carter (Salford) for the use of their Van de Graaff accelerators; Drs. J. Whitton (Chalk River), D. Colliver (R.R.E. Malvern), and M. J. Howes (Leeds) for many useful discussions. We also wish to thank Dr. T. Gallon and Mr. D. Smith (York) for assistance with the Auger measurements made at their laboratory. The work was supported by the S.R.C. who provided finance for accelerator time; N.A.T.O. and C.V.D. who awarded research grants. Finally, one of us (D.R.W.) would like to thank the S.R.C. for the award of a studentship.

Thermochemical Analyses and Optimum Conditions for Vapor Epitaxy of $GaAs_{1-x}P_x$ $(0.7 < x < 0.9)$

Tao Yuan Wu*,[1]

Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The gas-solid relationships for the vapor phase epitaxy of $GaAs_{1-x}P_x$ $(0.7 < x < 0.9)$ at a temperature of 840°C have been established. The $GaCl$-AsH_3-PH_3-H_2 process and <100> oriented GaP substrates were employed. Experimental data were obtained and then a semiempirical calculation was carried out to give accurate relationships between gas concentrations and solid composition. Furthermore, effects of vapor pressures on surface morphology have been investigated and certain optimum conditions were determined. Such conclusions, together with the above relationships, have been used to determine optimum flow rates for specific growth compositions.

In recent years, the observation of efficient radiative processes in indirect-gap $GaAs_{1-x}P_x$ due to nitrogen isoelectronic traps (1-3) has made such materials attractive for use in amber and yellow light-emitting diodes. Compositions with GaP content between 70 and 90% are of particular interest. However, accurate and detailed relationships between the input gas concentrations and the resulting crystal composition for the vapor epitaxy process, as well as the optimum growth conditions, have not been available in the literature. Previous papers (4-6) by the author have reported such relationships and conditions in the composition range of $0.3 < x < 0.5$, which is particularly important for applications in red emission, microwave switching (7), high speed current limiting (8), and superlattice structures (9). The present report extends such results to the composition range of $0.7 < x < 0.9$.

Experimental

Figure 1 shows a schematic diagram of the epitaxial reactor, together with the temperature profile. The apparatus is the same as that used previously in this study for $0.3 < x < 0.5$ (4), except that GaP was used as the substrate, and higher temperatures were used in the reactor. A total flow rate of 1000 ml/min was always maintained during the growth process. Similar designs have been adopted by other people (10-12). Preliminary experiments here established that such conditions yielded good growth for $0.7 < x < 0.9$.

The experimental procedure described in (4) was also used here except that GaP was grown initially, and the taper layer was produced by increasing AsH_3 flow and decreasing PH_3 flow. Under such growth conditions, the input HCl is almost completely converted into GaCl and no deposition occurs upstream of the substrates. This allows one to accurately relate the input flow rates to the gas concentrations in the substrate region. The input flow rates were varied from run to run to determine the effect of the growth atmosphere and the gas-solid relationships.

The same effects of the growth atmosphere observed previously for $0.3 < x < 0.5$ were found to be true in the present case. The gas-solid relationships were determined by measuring the flow rates with precision flowmeters and the crystal composition with electron microprobe analysis.

The results are listed in Table I as a function of the input flow rate ratios, $f°_{HCl}/f°_{H_2}$, $f°_{AsH_3}/f°_{H_2}$, and $f°_{PH_3}/f°_{H_2}$. All these data were found to be reproducible. It was estimated that x_o is accurate to ±0.01 and various flow rate ratios to be within ±5%.

Semiempirical Calculations

The same model used for $0.3 < x < 0.5$ (4) was adopted in the present case. With this model, one can calculate the crystal composition together with all the partial pressures at any given incoming gas concentrations, once all the equilibrium constants and the interaction parameter are evaluated.

Using Kirwan's results (13), all the equilibrium constants were evaluated, and are given in Table II, at the

temperature of interest here, 840°C. Also given in the table is the interaction parameter, which was evaluated by fitting some of the measured data in Table I into the above equations with the above constants. Finally, a computer calculation based on all the equations and constants was carried out and the following results for the crystal composition as a function of the input flow rates were obtained.

Results and Discussions

Figures 2 and 3 give the calculated x as a function of $f°_{PH_3}/f°_{AsH_3}$, $f°_{AsH_3}/f°_{H_2}$, and $f°_{HCl}/f°_{H_2}$, together with the measured data. The solid lines are calculated results. They agree with all the experimental data to a precision in x of ± 0.02. Based on these two figures, the flow relationships to achieve $x = 0.85$ at 840°C were obtained as is shown in Fig. 4. Similar figures can be plotted for any other $0.7 < x < 0.9$. Although wide ranges of flow rates can be used to achieve a specific x, only one set of flow rates will yield optimum crystal morphology.

As mentioned above, the optimum flow rate condition obtained previously for $0.3 < x < 0.5$ (5, 6) was found to be valid in the present case, *i.e.*, $f°_{HCl}/f°_{H_2} = (f°_{PH_3} + f°_{AsH_3})/f°_{H_2} = 0.02$. This means the growth atmosphere must be stoichiometric. If it is rich in Ga, pyramids were developed; if rich in P+As, pits were always observed. A model has been proposed to explain such behavior in this study (5). Now, applying such a condition to Fig. 4, one can obtain an optimum flow rate condition to grow $x = 0.85$ at 840°C, namely, $f°_{HCl}/f°_{H_2} = 0.02$, $f°_{AsH_3}/f°_{H_2} = 0.005$, and $f°_{PH_3}/f°_{H_2} = 0.015$. Similar conditions, of course, can be obtained for other values of x.

In a previous paper (4), the author explained the variation in x due to $f°_{HCl}/f°_{H_2}$ or $f°_{AsH_3}/f°_{H_2}$, while

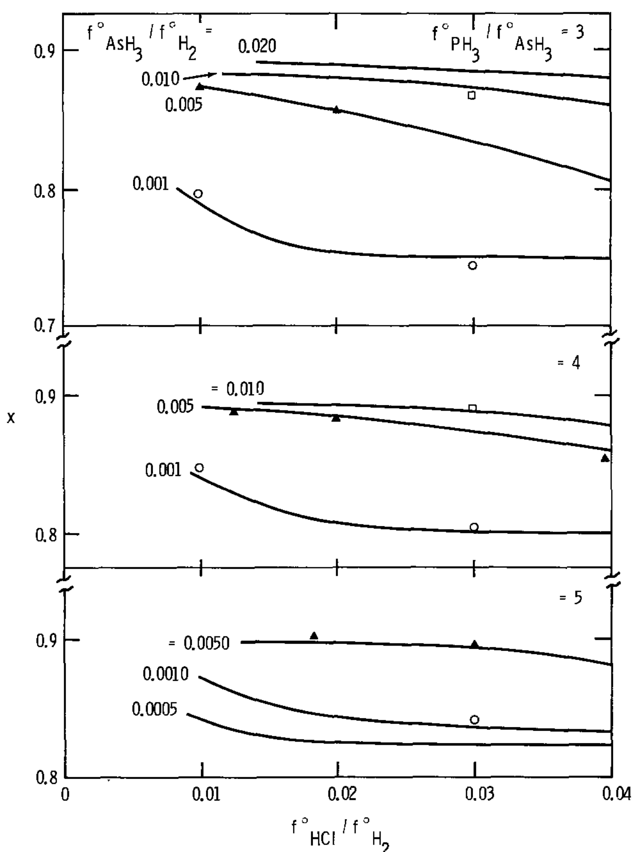

Fig. 3. Crystal composition x as a function of input flow rate ratios $f°_{HCl}/f°_{H_2}$, $f°_{AsH_3}/f°_{H_2}$, and $f°_{PH_3}/f°_{AsH_3}$ (= 3, 4, and 5) at a growth temperature of 840°C. Solid lines are calculated results. The values of $f°_{AsH_3}/f°_{H_2}$ for various measured data are: 0.001 (○), 0.005 (▲), and 0.010 (□).

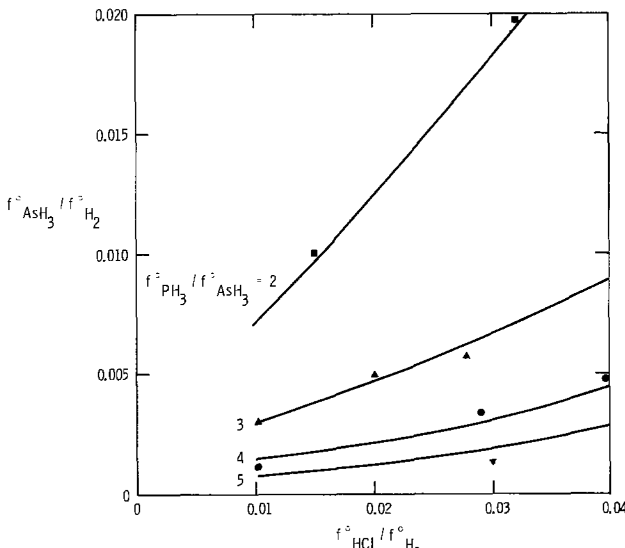

Fig. 4. Input flow rate ratio $f°_{AsH_3}/f°_{H_2}$ required to achieve $x = 0.85 \pm 0.02$ with various fixed $f°_{HCl}/f°_{H_2}$ and $f°_{PH_3}/f°_{AsH_3}$ at 840°C. All the lines are calculated results. The values of $f°_{PH_3}/f°_{AsH_3}$ for various measured data are: 2 (■), 3 (▲), 4 (●), and 5 (▼).

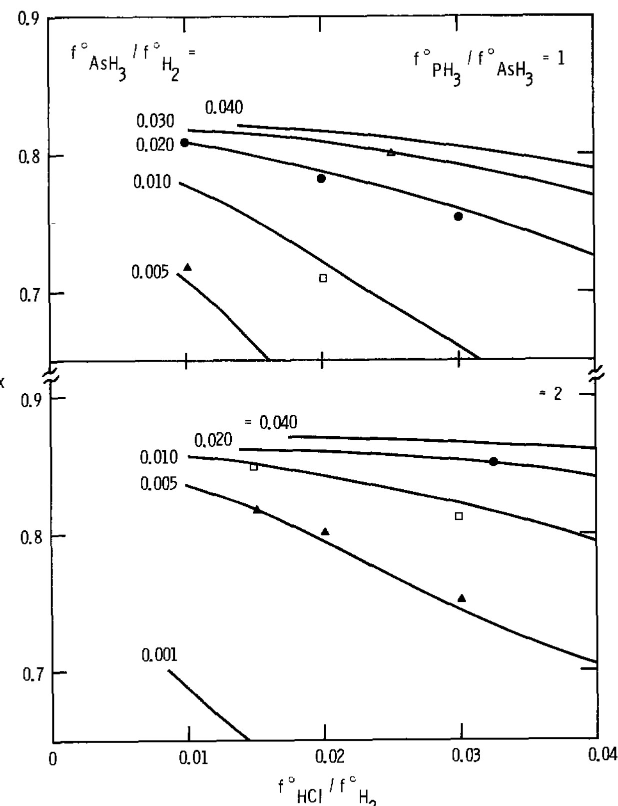

Fig. 2. Crystal composition x as a function of input flow rate ratios $f°_{HCl}/f°_{H_2}$, $f°_{AsH_3}/f°_{H_2}$, and $f°_{PH_3}/f°_{AsH_3}$ (= 1 and 2) at a growth temperature of 840°C. Solid lines are calculated results. The values of $f°_{AsH_3}/f°_{H_2}$ for various measured data are: 0.005 (▲), 0.010 (□), 0.020 (●), and 0.030 (△).

keeping the other two flow rate ratios constant, in terms of the combined effects of pressure and reactivities. Such an explanation is also valid in the present case. Furthermore, the same argument can be used to explain the increase in x and decrease in $|dx/d(f^\circ_{HCl}/f^\circ_{H_2})|$ as $f^\circ_{PH_3}/f^\circ_{AsH_3}$ increases, while keeping $f^\circ_{HCl}/f^\circ_{H_2}$ and $f^\circ_{AsH_3}/f^\circ_{H_2}$ constant in the range of interest here.

The semiempirical approach used here has been found to be a good technique to determine accurate phase relationships in a relatively simple way (4, 14). The present results further confirm such observations. Since the objective here is to establish accurate and practical gas-solid relationships rather than a theoretical model, the empirical adjustment is necessary. Shaw (12, 13) has reported, after all, that kinetic effects cannot be ignored in actual cases.

In conclusion, accurate relationships between input flow rate conditions and the grown crystal composition have been obtained for $0.7 < x < 0.9$ at a satisfactory growth temperature of 840°C. In addition, flow rate conditions which yield optimum growth morphology have also been determined. Such relationships and conditions can be applied to any systems satisfying the present, practical design criteria.

ABSTRACT

High-resistivity epitaxial layers with carrier concentrations of the order of 10^{12}-10^{13} atoms/cm^3 have been reproducibly grown on heavily Sb- or B-doped substrates. The epitaxial layers so obtained have been used to observe the behavior of impurities during epitaxial growth. When the epitaxial growth is performed using an as-grown surface as the substrate, an abnormal peak in the impurity distribution appears near the substrate-epitaxial interface. The resistivity of the layers is found to increase by heat-treatment in a hydrogen atmosphere, which is probably due to the effect of defects. Similar epitaxial layers have also been obtained by pyrolysis of SiH_4 and the carrier concentrations of these layers are found to have a considerably larger temperature dependence than the layers from $SiCl_4$. It has been established that the carrier concentration of the epitaxial layer is a function of the contamination from the substrate and the experimental apparatus. However, from the results of the present investigation, it appears that the impurities adsorbed on the substrate surface and defects introduced during epitaxial growth also play a role in determining the impurity distribution of such a high-purity epitaxial layer.

High power silicon devices and high frequency silicon devices have required high-purity epitaxial layers deposited on heavily doped substrates. The method for the vapor growth of silicon epitaxial layers by hydrogen reduction of $SiCl_4$ and pyrolysis of SiH_4 has been the subject of many studies. Some phenomena relating to the behavior of impurities such as the autodoping process, have been reported only for epitaxial layers containing carrier concentrations higher than 10^{14}-10^{15} atoms/cm^3 (1-10).

In the present investigation, reproducible, highly pure epitaxial layers with carrier concentrations as low as 10^{12}-10^{13} atoms/cm^3 have been grown successfully on heavily Sb-doped substrates, and the use of these epitaxial layers has been instrumental to a better understanding of impurity behavior during epitaxial growth. This paper deals mainly with abnormal impurity profiles observed at the interface between the high-resistivity layers. The difference between the temperature dependences of the impurity distribution by hydrogen reduction of $SiCl_4$ and pyrolysis of SiH_4 is also briefly discussed.

Experimental

The epitaxial growth was carried out by means of hydrogen reduction of $SiCl_4$ and pyrolysis of SiH_4 in a conventional horizontal reactor. In fabricating the epitaxial deposition system, however, scrupulous precautions were taken to minimize background contamination, and the susceptor was made of high-purity quartz. Commercially available nondoped $SiCl_4$ was used without further purification.

Silicon substrate wafers were prepared by either the floating zone or Czochralski techniques and doped with impurities such as P, As, Sb, or B in the concentration range of 10^{13}-10^{19} atoms/cm^3. The wafer orientation was (111). Dislocation densities of wafers were in the range of 0-10^4 cm^{-2}. The substrates were mechanically or chemically mirror polished and cleaned by the usual semiconductor process before loading into the reactor.

Normally, the growth conditions were as follows: The growth temperature was 1200° ± 5°C in resistance heating; the ratio of mole fraction $SiCl_4/H_2$, 0.01-0.015; the gas flow rate in the reactor, 5-10 cm/sec; the growth rate, in the range of 0.2-1.5 μ/min; and HBr vapor etching was performed at the same temperature as the growth temperature just before the epitaxial growth.

Impurity profiles of the epitaxial layers were calculated from capacitance measurements of mesa diodes formed on the grown surface by shallow diffusion of B or P at 1000°C for 10 min. Surface carrier concentrations after the diffusion were 10^{19}-10^{20} atoms/cm^3, and the junction depth was about 0.3μ. The thickness of the epitaxial layer was determined from the size of stacking faults on the as-grown surface. The error in the measurements was less than 0.5μ.

The conduction types of the epitaxial layers were detected by hot probe methods and *I-V* characteristics of the diodes made after B or P diffusion. In the case of p^- substrates, Hall effect measurements were made to determine the carrier concentration and conductivity of the epitaxial layers.

Results and Discussion

The epitaxial layers deposited on various substrates.—The conduction types and the carrier concentrations of the epitaxial layers on various substrates by resistance heating are listed in Table I. Using high-resistivity n^- (P-doped) or p^- (B-doped) substrates with carrier concentrations less than 10^{14} atoms/cm^3, the epitaxial layers are always of the n-

* Determined by Hall effect measurements.

type in conductivity and are less than 10^{13} atoms/cm³ in carrier concentration. From this, it is obvious that the obtained high resistivity is not caused by the contamination of p-type impurities. In the Hall effect measurements from liquid nitrogen temperature to room temperature, no deep impurity levels were observed.

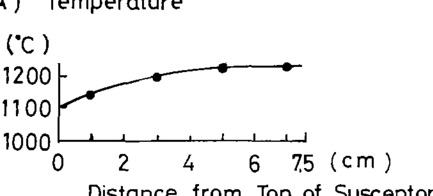
As can be seen from Table I, carrier concentrations in the range of 10^{12}-10^{13} atoms/cm³ were reproducibly obtained on heavily Sb-doped substrates. However, in the case of P- and As-doped substrates, the concentrations in the layers were higher.

In general, the carrier concentration and the conduction type depend strongly on the characteristics of the substrate impurity and are significantly affected by the back surface of the substrate (6-8). It must be noted that the effect of the substrate on the epitaxial layer can be clearly seen only if the intrinsic system contamination is low. Since the concentration in the epitaxial layer due to the deposition system has been as low as 10^{12} atoms/cm³, the influence of the substrate would be detectable with high sensitivity. It is well known that in a multislice system the epitaxial layer concentration far from the interface, or the impurity doping level as it is generally termed, of samples which are placed downstream on the susceptor is much higher than that of samples placed upstream (8). This effect has also been ascertained and and is discussed below.

The n^- (P-doped, 300 ohm-cm) substrates and the n^+ (0.01 ohm-cm) substrates were alternately placed on the susceptor along the gas stream. The epitaxial growth was performed without vapor etching. These results are shown in Fig. 2 and 3 for Sb-doped n^+ substrates, and in Fig. 4 for As-doped n^+ substrates. Figure 1 illustrates the experimental conditions presented in Fig. 2 and 3. In Fig. 2 and 3, the horizontal axis is the growing time. In Fig. 4, curves (a) and (b) are the impurity profiles when only a single n^- (P-doped) substrate and a single n^+ (As-doped) substrate, respectively, were used at position 1.

It should be noticed that the growth rate is a function of the position and decreases in the downstream portion of a reactor (11, 12). However, the increase of the carrier concentration of the epitaxial layer in the downstream portion cannot be explained by the decrease of the growth rate. This is because the carrier concentration of the layer deposited only on the n^- substrate was in the order of 10^{12} atoms/cm³ for growth rates in the range 0.2-1.5 μ/min as depicted in Table I.

From these experiments, it was confirmed that the transfer ratio of Sb is very small in comparison with that of P and As (8, 13), and that the autodoping effect is more pronounced in the case of As and P than Sb (7, 8). It is generally believed that the impurities are evaporated out of the n^+ substrates, and are transferred along the gas stream to make the gas impurity-rich in the downstream portion. Cave *et al.* (8) have reported that the increase in downstream doping is caused by the reaction of the quartz with silicon which



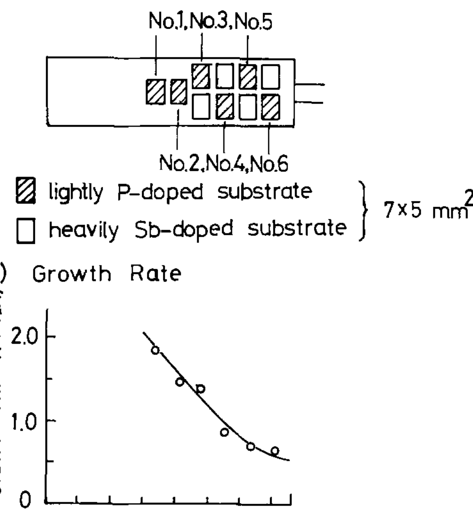


Fig. 1. The experimental conditions. Before the epitaxial growth, heat-treatment at the growth temperature was performed for 20 min. Growth time 40 min.

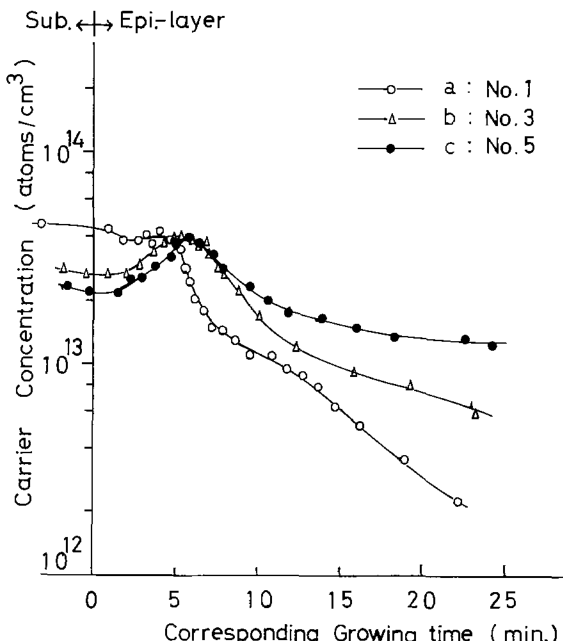

Fig. 2. The impurity profile of the epitaxial layers deposited on the n^- substrates in the experimental conditions presented in Fig. 1. (a) No. 1, (b) No. 3, (c) No. 5.

liberates the substrate dopant. On the other hand, Shepherd (4) proposed an autodoping model based on impurity liberation from the back surface. However, this model is not adequate when the growth rate is a function of the position for a large substrate.

It appears that the impurity liberated out of the back surface of the substrate by means of the etch back mechanism and etching reaction with HCl is a dominant factor in the present high-purity epitaxial growth. Hence, a model based on a detailed analysis of

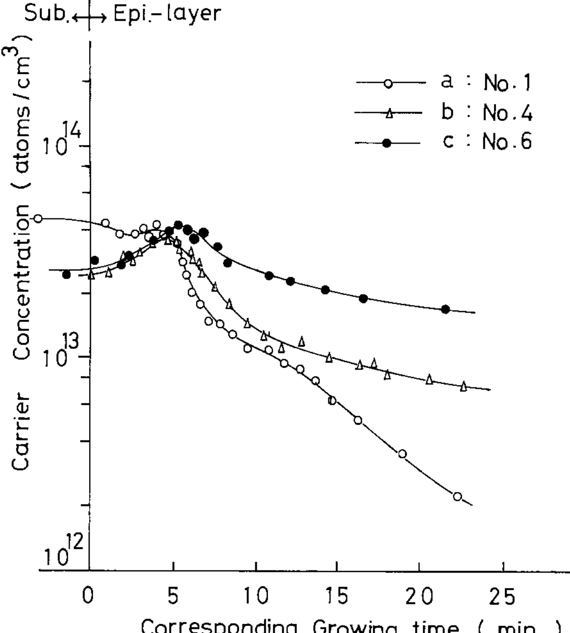

Fig. 3. The impurity profile of the epitaxial layers deposited on the n^- substrates in the experimental conditions presented in Fig. 1. (a) No. 1, (b) No. 4, (c) No. 6.

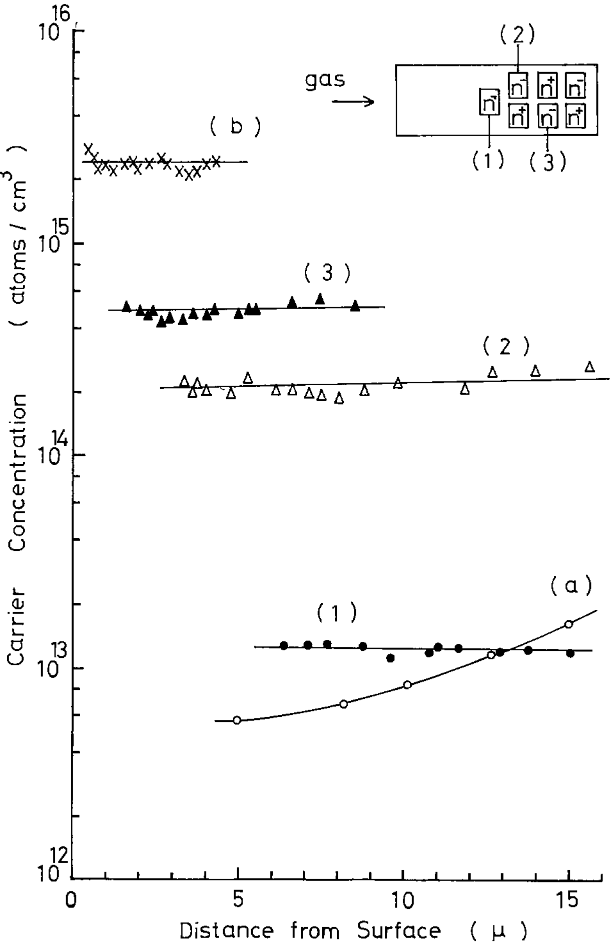

Fig. 4. The impurity profile of the epitaxial layers. Curves 1, 2, and 3 represent the carrier concentrations corresponding to the experimental conditions shown in Fig. 1, but n^+ substrates are As-doped (0.01 ohm-cm). (a) and (b) are the carrier concentrations when the growth was performed individually using the n^- (P-doped, 300 ohm-cm) substrate and the n^+ (As-doped, 0.01 ohm-cm) substrate, respectively.

the gas composition in the reactor is necessary to fully explain the impurity liberation from the substrate.

Abnormal impurity distribution phenomena.—In investigation of the mechanism of the impurity distribution and the autodoping phenomena during the epitaxial growth using the high-purity epitaxial growth technique, an abnormal impurity distribution has been observed at or near the interface between the high-purity epitaxial layers. To specifically understand the origin of this abnormal impurity distribution, the following experiments were performed.

After the epitaxial growth of the high-resistivity layer from the n^+ (Sb-doped, 0.01 ohm-cm, 10^4 cm^{-2} in dislocation density) substrate (it is called hereafter the first epitaxial layer), the sample is taken out of the reactor and exposed to the atmosphere for a varying time in the as-grown surface condition, loaded into the reactor again, and the epitaxial growth is performed under the same growing conditions without prevapor etching (this layer is called hereafter the second epitaxial layer). In this case an abnormal peak of the carrier concentration can always be observed at or near the interface between the first epitaxial layer and the second epitaxial layer. The peak value of the abnormal impurity profile is in the range of 10^{13}-10^{15} atoms/cm^3. A typical impurity profile thus obtained is shown in Fig. 5.

The phenomenon does not depend on the growth conditions such as the mole fraction $SiCl_4/H_2$, the flow rate, and growth rate. The abnormal impurity distribution can be observed to have the same order of the carrier concentration even on the n^- (P-doped) substrates with a carrier concentration of 10^{13} atoms/cm^3 and a dislocation density of 10^4 cm^{-2}. Moreover, there is no significant difference in the peak value of the abnormal impurity profile between the n^- substrates with and without dislocations as shown in Fig. 6.

The peak is not observed when light chemical etching is applied to remove the surface layer of the first epitaxial layer before the second growth. The absence

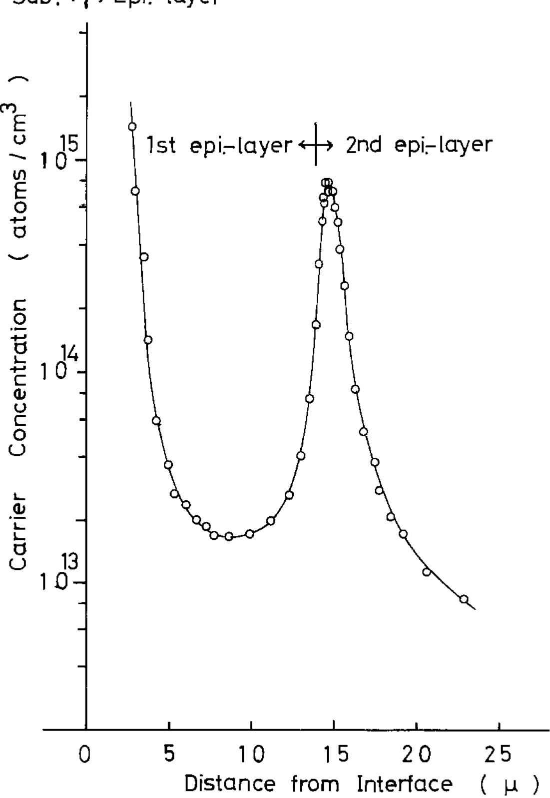

Fig. 5. The impurity distribution of the epitaxial layer deposited on the n^+ (Sb-doped) substrate. After the first epitaxial growth, the sample was exposed to the atmosphere for 24 hr. The first epitaxial layer is deposited to a thickness of 14.8μ for 20 min, and the second epitaxial layer to 18.2μ for 30 min.

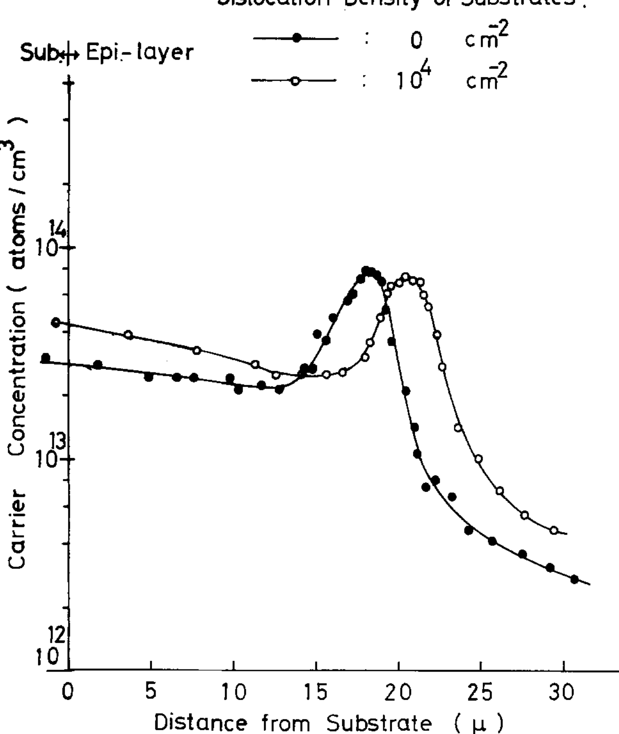

Fig. 6. The impurity profile of the epitaxial layer deposited on the n^- substrate of dislocation density 10^4 cm^{-2} and zero. The first growth for 20 min and the second for 20 min. Growth rate ca. 0.8 μ/min. After the first epitaxial growth, the samples were exposed to the atmosphere for 24 hr.

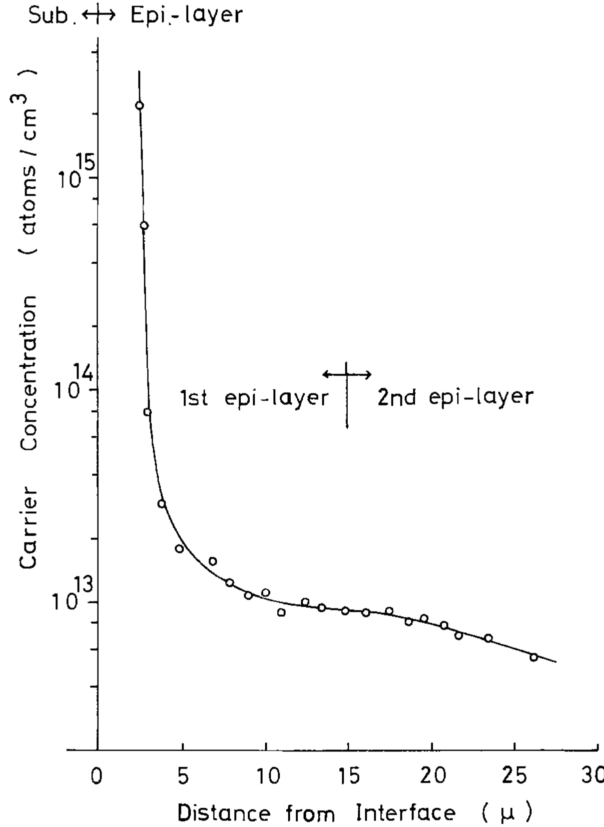

Fig. 7. The impurity profile of the epitaxial layer deposited on the n^+ substrate (Sb-doped, 0.01 ohm-cm). After the epitaxial growth was suspended, the sample was not exposed to the atmosphere and the second epitaxial growth was started. Growth rate 0.75 μ/min. Total growth time 40 min.

of the peak is also observed when vapor etching is performed before the second growth in the case of a n^- substrate. Further, the peak is not present when a n^- substrate exposed to the atmosphere is used for epitaxial growth.

The phenomenon is not due to the transient behavior at the initial stages of the second epitaxial growth. To ascertain this, the following experiment was performed. First, after the first epitaxial layer is deposited on the n^+ (Sb-doped) substrate, the sample is kept in the low temperature region of the reactor for about 10 min, the second epitaxial growth is performed. In this case, the abnormal peak of the impurity distribution cannot be observed as shown in Fig. 7.

From these observations, the abnormal impurity distribution is caused by the interaction between the as-grown surface and the atmosphere. The abnormal peak is not related to the dislocation density of the substrate, but it seems to appear depending on the surface conditions of the first epitaxial layer, such as the existence of defects on the surface.

By heat-treating in a hydrogen atmosphere at the same temperature as the growth temperature, a variation of the carrier concentration of the high-resistivity layer occurs in the n^+ (Sb-doped) substrate as shown in Fig. 8. The deviation of the impurity profile near the interface by heat-treatment can be explained by the normal diffusion of impurity from the substrate. On the other hand, the variation of the impurity doping level cannot be explained by such a diffusion process. Further, a similar variation is also observed for the epitaxial layer deposited on a n^- substrate. From these results, the variation of this type seems to be caused mainly by defects involved in the layer and activated by heat-treatment.

It is very likely that the as-grown surface of the epitaxial layer is activated and exists in an unstable condition, because the surface is extremely clean and appears to have many steps and kinks. Therefore, during its exposure to the atmosphere, impurities, oxides, and other contaminants would be adsorbed on the

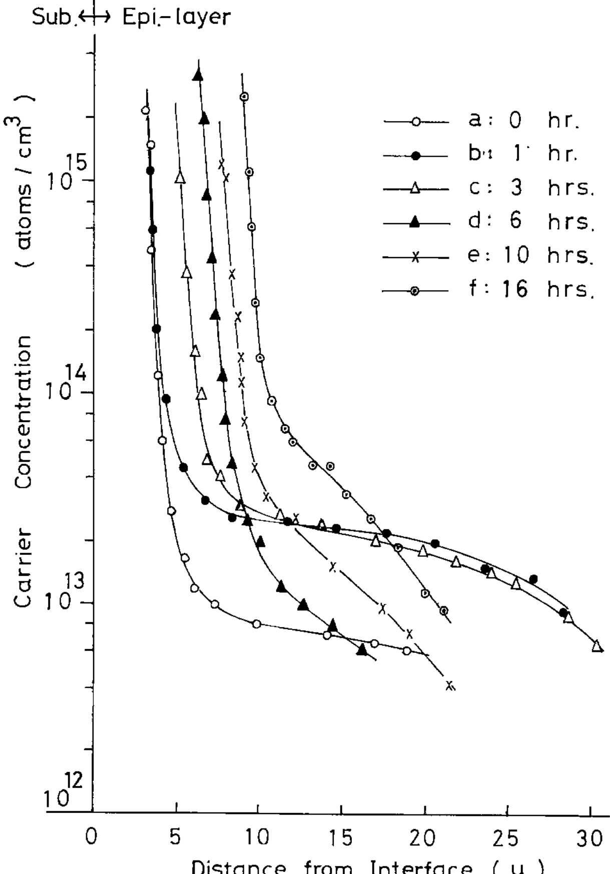

Fig. 8. The variation of the impurity profile by the heat-treatment at 1200°C in hydrogen atmosphere. Epitaxial layers, about 35μ. Growth time 30 min. (a) The sample without heat-treatment. Heat-treating times: (b) 1 hr, (c) 3 hr, (d) 6 hr, (e) 10 hr, (f) 16 hr.

active as-grown surface. These adsorbents are expected to induce defects at the interface between the first and second epitaxial layers and consequently to increase n-type carrier concentrations. However, the mechanism remains unresolved.

Temperature dependence of impurity distribution.—In these experiments, the same rf heated deposition system was used to obtain the epitaxial layers from $SiCl_4$ and SiH_4. The susceptor was a heavily Sb-doped silicon which was coated sufficiently with the high-purity epitaxial layer grown by the hydrogen reduction of $SiCl_4$.

The impurity profiles of high-resistivity layers, grown at 1200°, 1100°, and 1000°C by the hydrogen reduction of $SiCl_4$, are shown in Fig. 9. No significant difference between the impurity doping levels can be observed for the different growth temperatures for a substrate size of 1 × 1 cm. But, for a relatively large substrate, the carrier concentration grown at 1000°C is about one order lower than that grown at 1200°C (3, 5).

Experiments were also performed by the pyrolysis of SiH_4 to compare with the results from $SiCl_4$ on small substrates. The temperature dependence of impurity doping levels is observed clearly as shown in Fig. 10. To ascertain this, the epitaxial growth is performed in steps at different temperatures (1200°, 1100°, 1000°C) on the small substrate. The experimental conditions of the growth temperature and the growing time and results are shown in Fig. 11, from which it is evident that the impurity doping level decreases with increasing temperature as in the case of Fig. 10, and that the temperature dependence cannot be explained in terms of outdiffusion of the impurity of the substrate.

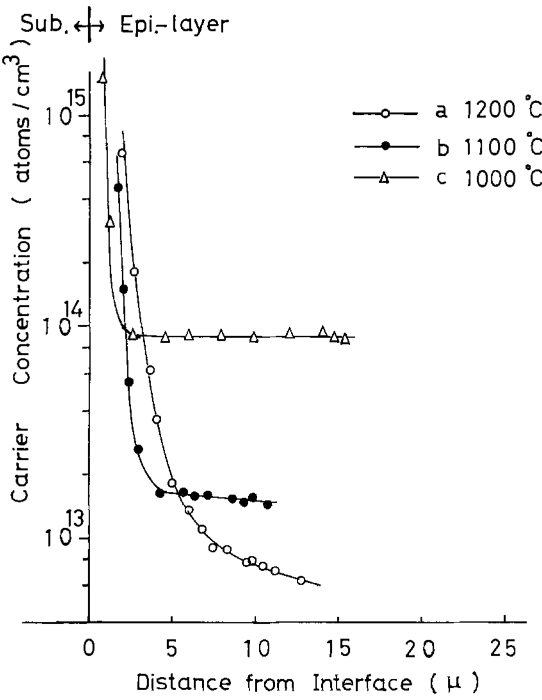

Fig. 10. The temperature dependence of impurity distribution of the epitaxial layer by the pyrolysis of SiH_4 in rf heating. The growth temperature is the same as that in Fig. 10. Growth rates *ca.* 0.34 μ/min.

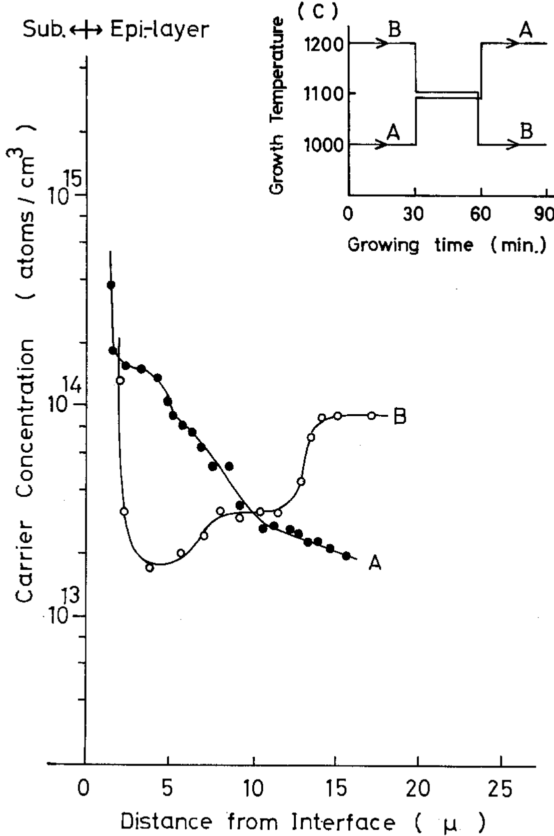

Fig. 11. Growth temperature *vs.* growing time and carrier concentrations as a function of distance from the interface.

These results show the epitaxial layer grown by the pyrolysis of SiH_4 seems to be independent of the surface condition of the pregrown layer or the substrate, and is influenced by defects introduced during the epitaxial growth, or by the growth mechanism where obviously no chlorine can be present (14-16). In the case of the hydrogen reduction of $SiCl_4$, the incorpora-

tion of the dopant in the epitaxial layer of the small substrate does not change with temperature. Further, the number of defects in the epitaxial layer and the surface morphology influencing the carrier concentration, if present, would not vary significantly with temperature.

Conclusions

In the epitaxial growth of high-resistivity layers (10^{12}-10^{13} atoms/cm^3 concentration) it has been found that the intrinsic impurities in the deposition system are n-type and give rise to a concentration of about 10^{12} atoms/cm^3 in the epitaxial layers. An abnormal peak in the impurity distribution is found to appear when the active as-grown surface exposed to the atmosphere is used as the substrate.

The carrier concentration of high-resistivity epitaxial layers obtained varies within the range of 10^{13} atoms/cm^3 by heat-treatment at 1200°C in a hydrogen atmosphere. The epitaxial layer concentration obtained by the hydrogen reduction of $SiCl_4$ does not depend on the growth temperature for a small substrate, but that obtained from SiH_4 strongly depends on the temperature.

It has been considered that defects involved in such a high-purity epitaxial layer influencing the carrier concentration originate from defects to be induced by materials adsorbed on the active silicon surface.

Acknowledgment

The authors wish to thank Mr. S. Tagami for carrying out the pyrolysis of SiH_4.

Diffusion Gettering of Au and Cu in Silicon

R. L. Meek,* T. E. Seidel, and A. G. Cullis*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The gettering of Au and Cu by phosphorus diffused from PBr_3 and $POCl_3$ sources and by boron diffused from a BBr_3 source has been studied. Samples were intentionally contaminated with moderate to large amounts of Au and Cu to obtain impurity levels above the background level, then gettered and finally examined by ion backscattering. The solubilities of Au and Cu were experimentally measured for phosphorus diffusions at various temperatures. The gettering, using either phosphorus source, was found to take place in the silicon and not in the source glass and the Cu and Au atoms were on lattice sites. Differences in the shapes of the profiles of gettered Au for $POCl_3$ and PBr_3 diffused sources were found and these are discussed in terms of vacancy enhancement effects. In general, phosphorus diffusion gettering appears to operate by solubility enhancement and ion pairing of substitutional metal acceptors. Boron diffusion gettering is less effective than phosphorus, a result which is consistent with solubility calculations and physical arguments. When the solubility is exceeded new phases are formed. The formation of precipitates for boron diffusions has been studied by electron microscopy.

Recent studies of diffusion (1, 2) and ion damage (1, 3) gettering have greatly increased our understanding of gettering. However, when the recent diffusion results are compared with older studies (4-6) many unanswered questions remain. For example, recently it was shown by the use of backscattering that phosphorus (PBr_3) diffusion gettering of Au takes place entirely in the phosphorus-diffused layer (1) (900°-1100°C), while Lambert and Reese (5) reported a nonnegligible fraction of the gettered Au to be in the diffusion-source glass. Hence the conditions under which a significant amount of Au will be in the glass appears to be an open question. In this paper we show that the gettering takes place in the silicon for PBr_3, $POCl_3$, as well as BBr_3 diffusions, all of which have different glass compositions. In all our samples, the Au impurity content of the glass is, at most, a few per cent of that of the silicon and, as shown with control samples, this can always be attributed to furnace contamination.

Another question concerns the nature of the gettering mechanism. Recently it was shown that Cu and Au were gettered onto substitutional sites by phosphorus diffusion, while these impurities were gettered onto nonsubstitutional sites by boron diffusion (1). This pointed to an association mechanism: namely that Cu and Au, which are acceptors on substitutional sites, are paired with phosphorus donors (1, 2). However, in the case of boron diffusion, which produces a high density of acceptors, the solubility of Cu and Au donors would

* Electrochemical Society Active Member.

Key words: gettering, diffusion, solubility enhancement, ion pairing, ion scattering.

be enhanced so that Cu and Au would be on nonsubstitutional sites. This complementary behavior involving Cu and Au on substitutional sites under a diffused donor profile and on nonsubstitutional sites under a diffused acceptor profile was experimentally verified (1). These results gave a qualitative understanding and formed the basis for detailed solubility calculations (2). More experimental results are reported here which supplement the earlier work (1, 7). The principal concern is to obtain meaningful experimental values for the saturated solubility of Au and Cu by phosphorus diffusions. Solubilities of Cu and Au in P- or B-doped silicon have previously been studied, mainly for low P and B concentrations (8, 9). In the present work, the impurity content in the samples is progressively increased until precipitation is observed in the gettering layer. The procedure for this is described in the experimental section on determination of solubility limit below. Our earlier work (1) used only a fixed impurity content.

Another question regarding the mechanism is the role of vacancies in the gettering process. Differences in the Au profile under $POCl_3$ and PBr_3 diffusions have been observed in this study. The peak concentration of Au is buried for $POCl_3$ diffusion and is at the surface for PBr_3 diffusion. This result is interpreted in terms of a vacancy assisted gettering for the $POCl_3$ process. The PBr_3 and $POCl_3$ diffusion processes have different gas flow conditions. Hence the different physical effects observed and reported here are not necessarily due to the different chemical species in the bubbler. Our early work (1, 3) was done with PBr_3 sources, and we found a qualitatively different dislocation structure with TEM than that found by Dash and Joshi (10), who used a $POCl_3$ source. This led us to suspect that PBr_3 and $POCl_3$ diffusions result in different dislocation configurations and to make comparisons of gettering behavior.

The solubility calculations (2) for Au and Cu in the case of boron diffusion led to the conclusion that if interstitial donor Au and Cu were ion paired to the boron atoms then the Au and Cu would be very well gettered, which is contrary to experience and leads to a several order of magnitude discrepancy with existing solubility data. This led to physical arguments for the absence of ion pairing between interstitial Au and Cu and substitutional boron (2). The experiments presented here show that boron diffusion getters Au by the formation of precipitates at moderate to heavy Au contamination levels. It may well be that dislocations extract Cu and Au into their cores thereby promoting the formation of small precipitates (11). These precipitates are not found for more dilute Au contamination levels. Transmission and scanning electron microscopy were used to study the precipitates in the boron-diffused layers.

Experimental

Sample preparation.—Sample wafers, approximately 10 mils thick, were prepared from 10 ohm-cm, <111>, n-type, low dislocation silicon. One side of the sample was covered by evaporation of 1000Å of Au or Cu, equilibrated with the metal at temperatures typically ~ 1100°C in a nitrogen ambient and quenched to ~ 100°C in ~ 3 sec. The wafers were lapped and etched so that ~ 1 mil of each surface was removed. It has been shown that this is more than sufficient to remove metal pile-up at the surface and that all surface damage is removed. The samples were diffusion gettered and examined by Rutherford backscattering.

Backscattering.—Rutherford backscattering of 1.8-2.0 MeV He ions, which has been reviewed by others in detail elsewhere (12, 13), was used to determine the number, distribution, and lattice location of the gettered impurities. The details of the technique as utilized in this laboratory may be found in Ref. (7) and (14); here we only give a brief summary. The energy of the backscattered ion identifies the mass of the atom from which it is scattered, and the number of backscattered ions determines the number of scattering atoms. For scattering from target atoms of a given mass, the scattered ion energy scale may be converted to a substrate depth scale through knowledge of the kinematics and the stopping power. The channeling effect is used to determine impurity atom lattice location (13).

Electron microscopy and x-ray microanalysis.—Certain samples were examined in the scanning electron microscope (SEM) and, in addition, x-rays excited by the electron beam were monitored using an energy dispersive spectrometer to provide elemental analyses. Furthermore, samples were thinned from the side opposite the diffused layer of interest (3) so that the region adjacent to the diffusion gettered surface could be examined using the transmission electron microscope (TEM).

Determination of solubility limit.—We have calculated the solubility of Cu and Au in silicon for heavy dopings and high temperatures taking into account solubility enhancement (Fermi level effect) and pairing of metal and dopant ions (2). It is possible to obtain concentrations of impurities in excess of the solubility limit by sample preparation with infinite sources. For this reason an effort has been made to carry out experiments with both "limited" and "infinite" sources of impurities. Quantitative effects are rather difficult to assess unless some intentional contamination is introduced. The background Au and Cu levels can vary by a factor of ten, but with added Au and Cu the total impurity levels can always be controlled at a level which is well above the background variations (1). Hence the generic study of PBr_3 and $POCl_3$ diffusions and solubility is best carried out using moderate impurity levels.

The metal-Si-dopant ternary phase diagram is doubtless very complex. A qualitative cross section, for constant Si/P ratio, for the M-P-Si system might appear as in Fig. 1. In region 1 one has the metal in solution in phosphorus-doped silicon. Line a-b represents the metal solubility and line c-d a new phase, which, as we will show, is generally a metal-dopant compound or the metal itself which precipitates out of solid solution. In zone 2, then, one has a two-phase equilibrium. For comparison with the above-mentioned calculations (2), it is necessary to determine the point B along A-B-C. This is done experimentally by providing various amounts of metal in the wafer, by equilibrating at different temperatures, and then gettering at the same temperature and for the same time, and by eventually going to an "infinite" source of metal.

Infinite source samples are prepared by providing a diffused layer in an uncontaminated sample, evaporating metal onto the opposite side, and diffusing the metal across the wafer to the diffused layer (15). The occurrence of new phases is determined by backscattering, SEM and TEM. In this way we obtain an estimate of the point B on the phase diagram for comparison to the calculated values.

Results

PBr_3 diffusion.—Figure 2 is a typical backscattered ion spectrum obtained from a Au-equilibrated and PBr_3-gettered sample. The phosphosilicate glass remained on the sample during measurement. Note that most (~90%) of the Au is found in the phosphorus-diffused silicon layer. In fact, simultaneous phosphorus diffusion of a control sample, containing no Au, yielded the same amount of Au in the glass (see Fig. 2) so it is clear that the Au in the glass came from furnace contamination. Generally, when precautions were taken to preserve furnace cleanliness, no Au (or Cu) was detected in the glass on either intentionally contaminated or control samples. The detection limit was $\sim 10^{13}$ cm^{-2} for Cu and $\sim 10^{12}$ cm^{-2} for Au (14).

Figure 3 shows random <110> axial channeled spectra for a similar sample after the glass had been removed. The large reduction in yield in the channeling direction shows essentially all of the Au (~90%) to be substitutional. Similar results are obtained for Cu in agreement with earlier results (1). Also, it is apparent that the Au profile is at its maximum at the surface and decreases with increasing depth into the silicon as the phosphorus concentration decreases.

Figures 4 and 5 are detailed angular scans across the <110> axis for gettered Au and Cu, respectively. The energy windows were set so that counts from the metal or Si from 200 to 3000Å below the surface were accepted. This eliminates counts corresponding to metal or Si at the surface so that the results are representative of the diffused layer in the silicon. For undiffused silicon we typically find that the silicon minimum yield is 0.03 and the channeling angle $2\psi_{1/2}$(Si) is 1.0 degrees. Here we see that the silicon minimum yield is ~0.05 and that $2\psi_{1/2}$(Si) is ~0.8 degrees. This indicates the presence of a small amount of lattice disorder or strain. The channeling angle for the metal atoms is approximately equal to that for silicon, the minimum yield is somewhat greater and no structure is observed in the angular scan. From Fig. 4 the Au is found to be 90% substitutional and from Fig. 5 the Cu is found to be 80% substitutional for these particular samples. In general, substitutional fractions of from 75 to 100% are observed. In summary, most of the Au and Cu atoms reside on substitutional sites, a result that is accounted for by enhanced solubility and ion pairing considerations (2). The fact that ~20% of the atoms are not substitutional suggests an occasional clustering of impurities or the formation of small precipitates. The solubility at saturation is essentially the maximum value that appears substitutionally (2). The nonsubstitutional component is further discussed below.

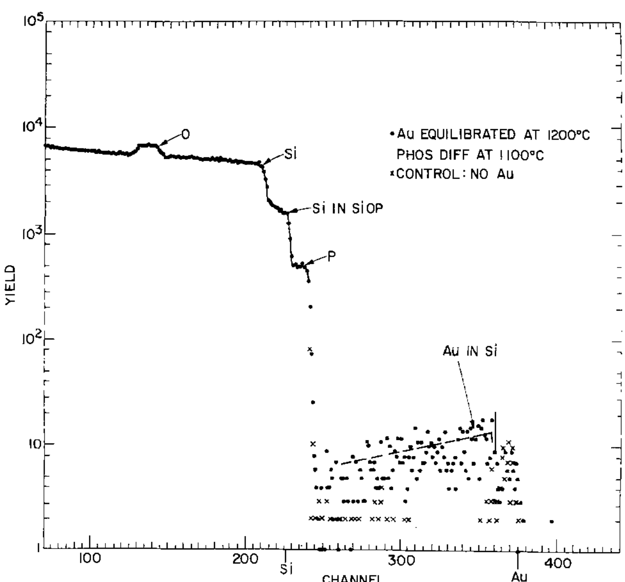

Fig. 2. Typical backscattered ion spectrum (scattered ion yield as counts per channel vs. scattered ion energy as channel number) from a phosphorus-gettered, Au-contaminated sample. Diffusion source glass is on.

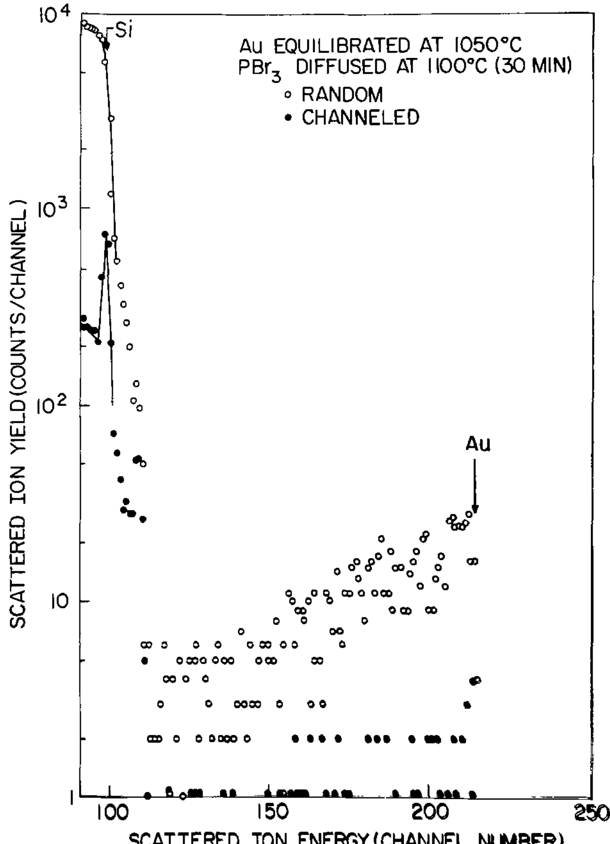

Fig. 3. Backscattered ion spectrum for phosphorus-gettered, Au-contaminated sample with glass removed. The arrows labeled Si and Au denote the scattered ion energies for scattering from Si and Au at the sample surface.

Figure 6 illustrates the result of increasing the diffusion time. For 900°C, 30 min diffusion and this Au equilibration level, not all the Au is gettered (4), so we expect that increasing the diffusion time will cause more gettering of the Au. Figure 6 shows that increasing the gettering time by a factor of four does not change the Au concentration at the surface but does increase the depth of the gold profile by a factor of two in agreement with the factor of two increase in phosphorus diffusion length. The lack of change in the peak Au concentration indicates near saturation of the profile with Au. The total amount of Au gettered is, of course, a factor of two greater for the 2 hr than for the ½ hr diffusion.

Figures 7 and 8 for Au and Cu respectively, show the result of increasing the contamination level by raising the metal equilibration temperature in the case of 1000°C, 30 min P diffusion. In each case, metal is gettered from the sample and it remains mainly substitutional in the diffused layer. There is no evidence of the appearance of a second phase. The increased Au concentration for the higher equilibration temperature suggests the higher Au concentration is closer to saturation, while the constant Cu concentration suggests that saturation has been reached. At the surface, for the higher temperature equilibration, the Au concentration is 10^{19} cm^{-3} and the copper concentration is $5(10)^{20}$ cm^{-3}.

Figure 9 shows the quite different result when an "infinite" source of Cu is provided. The annealing time was 30 min. During this time, Cu atoms are diffused from a 1000Å thick evaporated Cu film across the sample to the already phosphorus diffused layer. Clearly the copper concentration at and near the surface has increased significantly and is found to be completely off

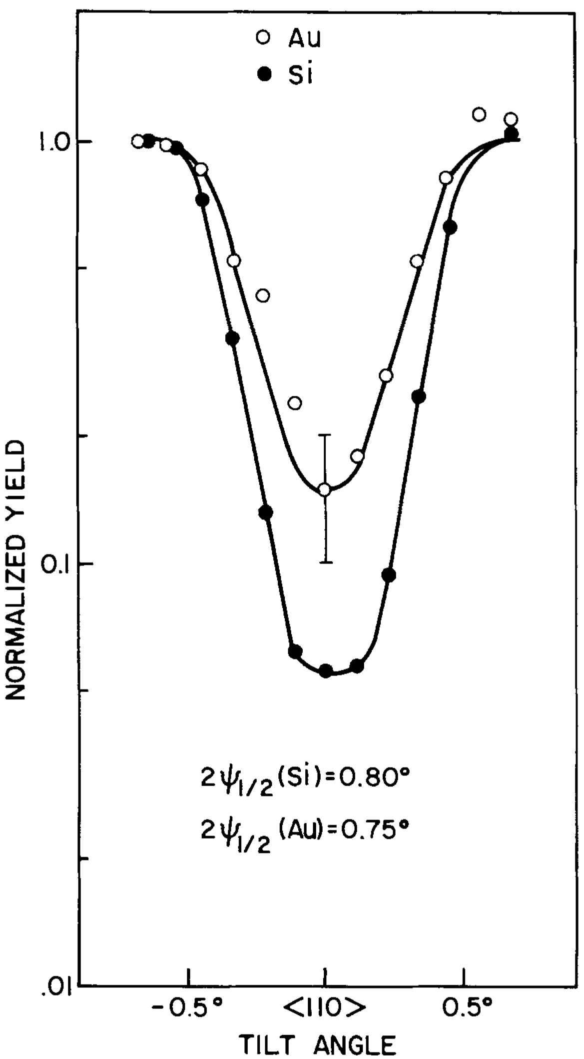

Fig. 4. Angular scan across <110> axis for a Au-contaminated (1200°C), phosphorus-gettered (PBr_3, 1000°C, 30 min) sample.

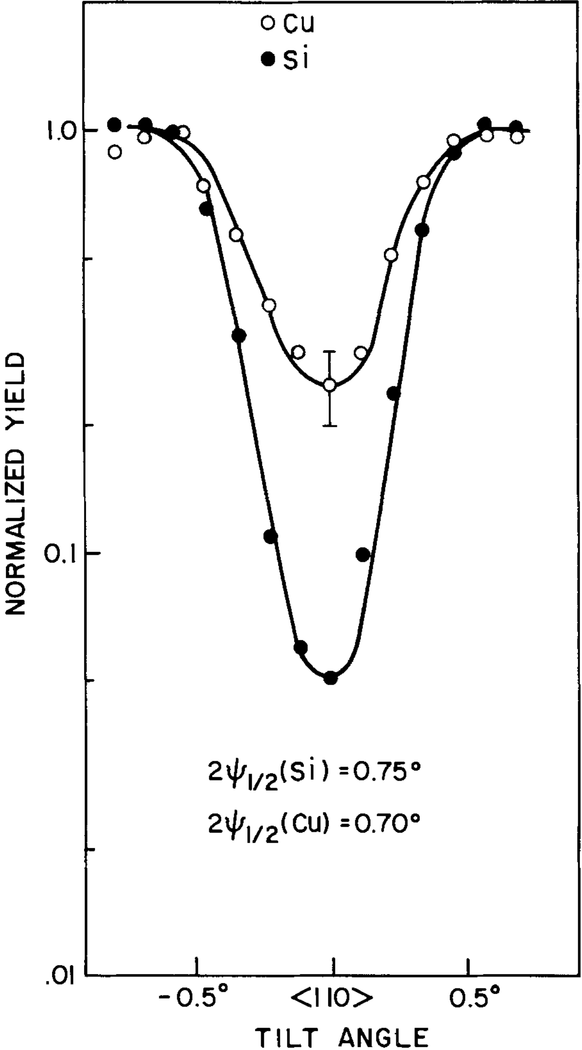

Fig. 5. Angular scan across <110> axis for a Cu-contaminated (1200°C), phosphorus-gettered (PBr_3, 1000°C, 30 min) sample.

lattice sites. Furthermore, at and near the surface the phosphorus is also completely off lattice sites, and it is possible that a second phase has precipitated. Comparing off lattice site phosphorus and Cu indicates that there is an over-all Cu to P ratio of approximately 2:3 and a volume concentration of $\sim 10^{21}$ cm^{-3}. Note that much of the Cu is substitutional at a depth ~0.4-0.5μ (corresponding to channel 120-140). The phase Au_2P_3 is found (16) when the Au solubility is exceeded in heavily P doped silicon.

$POCl_3$ diffusion.—$POCl_3$ diffusions yield silicon lattice defects which are significantly different, as determined by both backscattering and by TEM, from those associated with PBr_3 diffusions. (As noted above, the flow rates are different as well as the phosphorus sources.) Briefly, when examined using the TEM, PBr_3 diffusions produce only relatively few very small dislocation loops, whereas the $POCl_3$ diffusions produce larger loops together with a more deep and dense network of dislocations. In backscattering, the aligned ion beam is dechanneled at a greater rate in passing through a $POCl_3$ diffused zone than in passing through a PBr_3 diffused one.

Figure 10 shows a typical spectrum from a Au-contaminated sample gettered by $POCl_3$ diffusion. Comparison to Fig. 3 shows that the shape of the Au distribution in the diffused layer is considerably different from that obtained after a PBr_3 diffusion. That this is, in fact, an Au distribution has been confirmed by etching off ~ 500Å of silicon and redetermining the spectrum. We emphasize, however, that the Au is almost all (in this case 95%) substitutional. Different parts of the same Au-equilibrated sample have been PBr_3 and $POCl_3$ diffused. The observed Au profiles are shown in Fig. 11. The curves are the predictions of theoretical calculations (2) to which we shall return in the next section. The total amount of Au gettered by PBr_3 and $POCl_3$ is the same within experimental error.

BBr_3 diffusions.—It is a rather general observation that boron diffusion provides a relatively poor gettering system. We have attempted to explain (2) this in terms of the enhanced solubility and ion pairing theory of metal solubility. Essentially, the argument relies upon configurational and vibrational entropy effects which indicate that ion pairing of interstitial metal donors and substitutional acceptors is not important at these temperatures and doping levels, so that the total metal solubility in a heavily doped p-type region is much less than that in a similar n-type region.

Figure 12 is a typical spectrum obtained when a Au-contaminated wafer is boron diffused. The only gold detected is a surface peak. Similar surface peaks are often obtained when an Au-contaminated sample is prepared in the usual manner and then annealed, but not gettered. This is simply another type of control, see *e.g.*, Fig. 4 of Ref. (1). Similar results are obtained for Cu. Again, it should be mentioned that boron glasses are impurity free if the furnace is not contaminated.

If the metal contamination level is increased by raising the initial equilibration temperature, the experimental observations change in a characteristic manner, as shown in Fig. 13 for Au. Now a large amount of Au is present and <110> and <111> axial channeled spectra show the same yield from Au atoms as does the

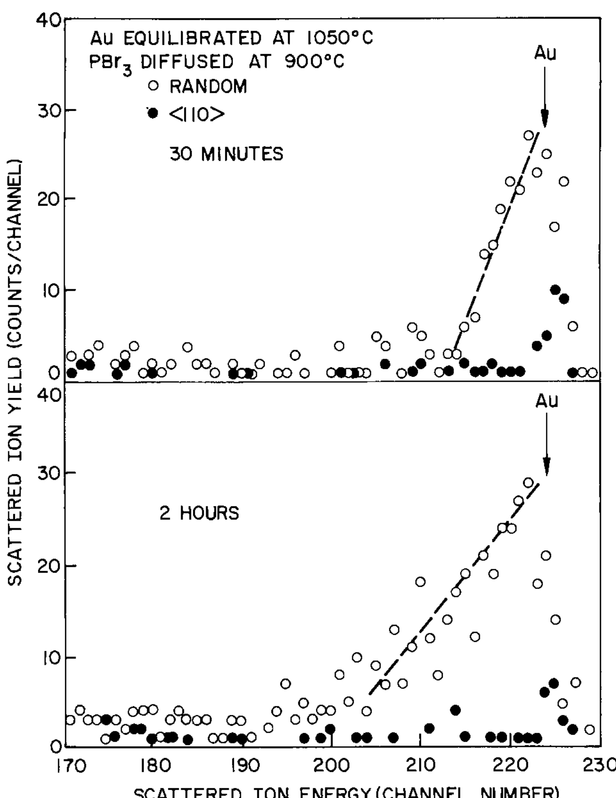

Fig. 6. Au spectra from Au-equilibrated, phosphorus-diffused samples at 900°C.

random spectrum, showing that the Au is distinctly off matrix lattice sites. Figure 14 is an angular scan across the <110> axis. Note that for silicon the minimum yield and channeling angle are those of undiffused silicon; thus any precipitates formed do not appear to introduce significant strain or disorder into the silicon matrix. For scattering from Au, no structure is apparent in the angular scan for the <110> or <111> axes. (The <111> scan is not shown.) This latter observation suggests the presence of precipitates rather than interstitial metal atoms because of the absence of any flux-peaking effects.

We have used the boron (p, α) nuclear resonance (17) in an attempt to detect differences in, on, and off lattice site boron fraction for layers which either did or did not contain precipitates. However, 15 $\pm$ 5% of the boron is found off lattice sites in all cases, including a boron diffused, uncontaminated sample.

Electron microscopy.—In order to resolve this problem, the surfaces of boron-diffused samples were examined using the SEM. The sample which had been equilibrated with Au at the highest temperature was observed to have many precipitate-like islands distributed over its surface. These varied in size over a range, the largest being present in number densities of $\sim 10^6$ cm^{-2} and often having triangular shapes with edge dimensions of $\sim$ 5000Å (Fig. 15a). Correlation of images with crystallographically oriented electron channeling contours showed that the edges of such features were sometimes aligned near <110> type matrix directions. Furthermore, the triangular islands were often located in shallow depressions in the matrix surface.

In order to determine whether the islands contained an impurity element they were subjected to electron probe x-ray microanalysis. Selected regions of the specimen surface were scanned with a 3000Å $\times$ 3000Å electron raster and the x-rays produced showed that the islands alone contained substantial quantities of Au. To confirm that the Au impurity was contained within the island structures, scanning x-ray images were generated using only x-ray photons which contributed to one of the Au x-ray peaks (2.14 keV). Such an image is given in Fig. 15b, which shows the same specimen area as the electron image of Fig. 15a, and it is clearly seen that Au-produced x-rays have emanated from the regularly shaped island. Photon counts regis-

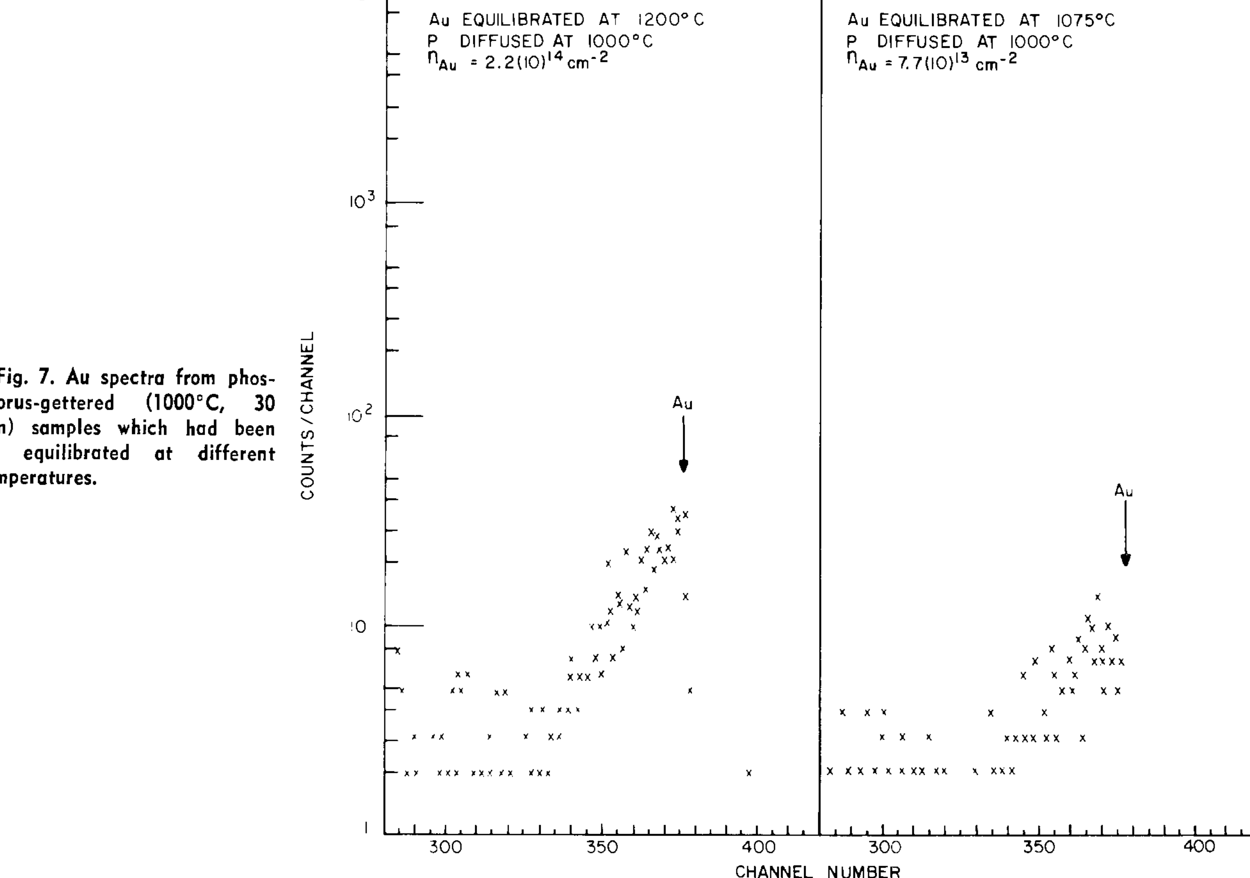

Fig. 7. Au spectra from phosphorus-gettered (1000°C, 30 min) samples which had been Au equilibrated at different temperatures.

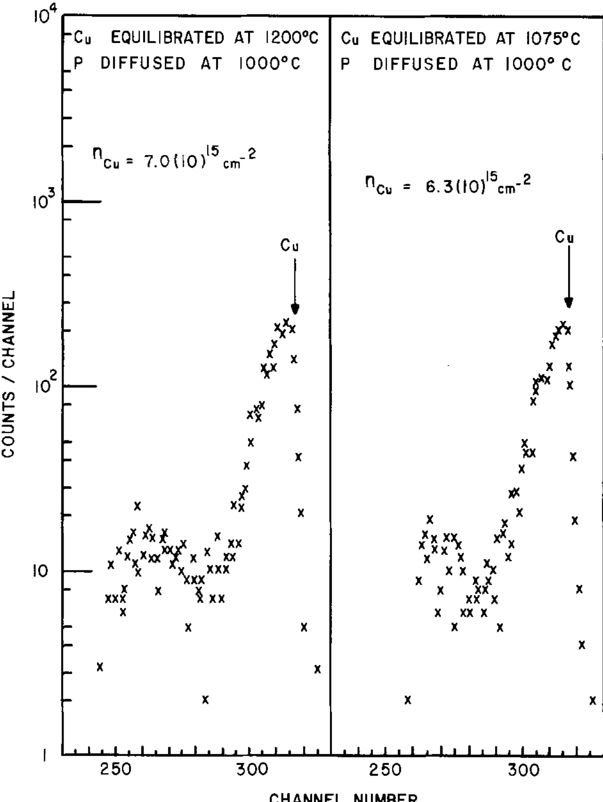

Fig. 8. Cu spectra from phosphorus-gettered (PBr_3, 1000°C, 30 min) samples which had been Cu equilibrated at different temperatures.

tered from the surrounding matrix were contributions from the random x-ray background and do not indicate the presence of a detectable Au concentration. A typical impurity x-ray spectrum is given in Fig. 16 where it will be seen that the Au peak at 2.14 keV has an amplitude ~ 25% of that of the matrix Si peak at 1.74 keV.

The Au-containing precipitates described above were also studied using the TEM. A typical island is shown in Fig. 17, and the depression in which it is situated is clearly evident. Such islands were composed of a well-defined precipitate phase, and by analysis of transmission electron diffraction patterns containing precipitate Bragg reflections it has been found that the phase was elemental Au (18). The islands did not appear to have a unique orientation relationship with the Si matrix and they often showed evidence for the presence of internal defect structures. The linear features within the precipitate of Fig. 17 may be dislocations or microtwin lamellae.

For comparison with the above observations, the surfaces of other boron-diffused Si samples which had originally contained the lower Au impurity concentrations were also studied. In such cases, no Au-containing precipitates were found to be present and Au impurity levels were below the limit of detection. It should also be noted that the presence of the boron diffused layer is apparently necessary for formation of the precipitates, since an Au contaminated sample which was annealed but not diffused, did not yield precipitates.

Concluding Discussion

Our results clearly show that metal impurities are gettered into the diffused layer in the Si, not into the diffusion source glass. This result is contrary to some previous results (5, 6), but we emphasize that the backscattering measurement plus the use of control samples gives a clearly unambiguous result. Others (19, 20) have arrived at similar conclusions, using somewhat different experimental methods, but there still exists considerable confusion in the literature (21).

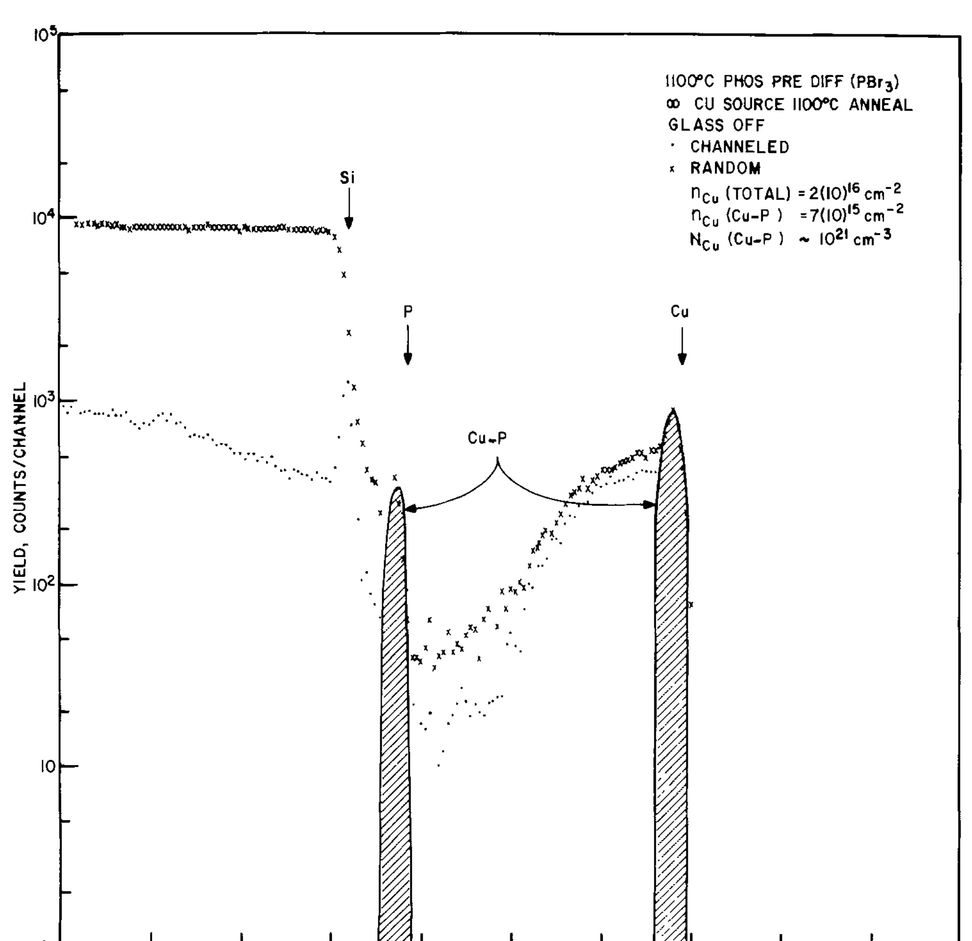

Fig. 9. Spectra from "infinite" Cu source sample (30 min anneal).

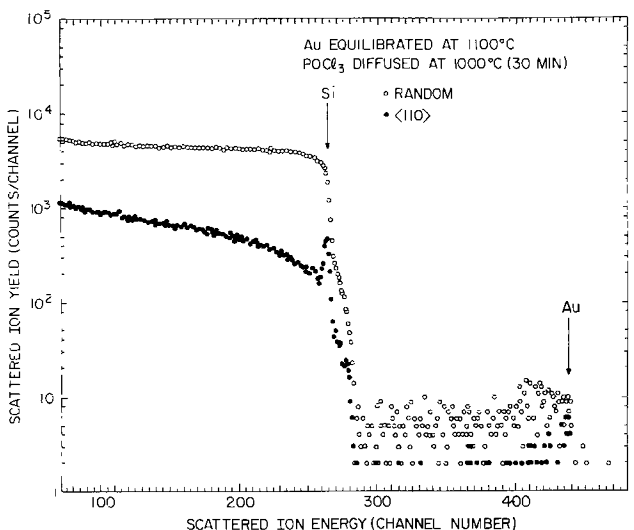

Fig. 10. Spectra from $POCl_3$-diffused, Au-contaminated sample

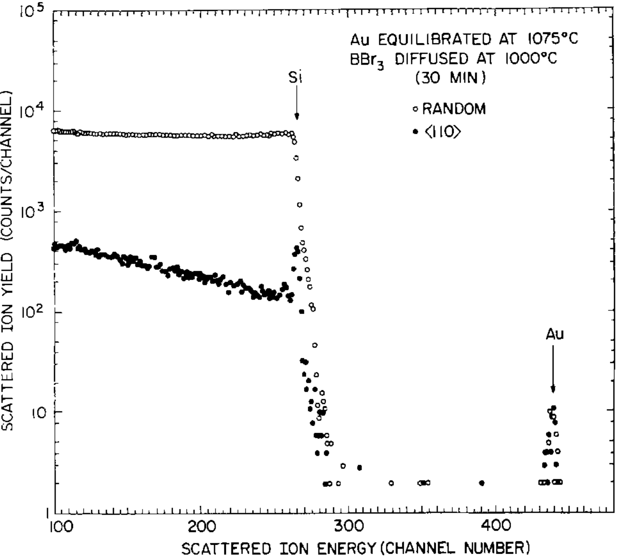

Fig. 12. Spectra from B-diffused sample, originally Au equilibrated at 1075°C.

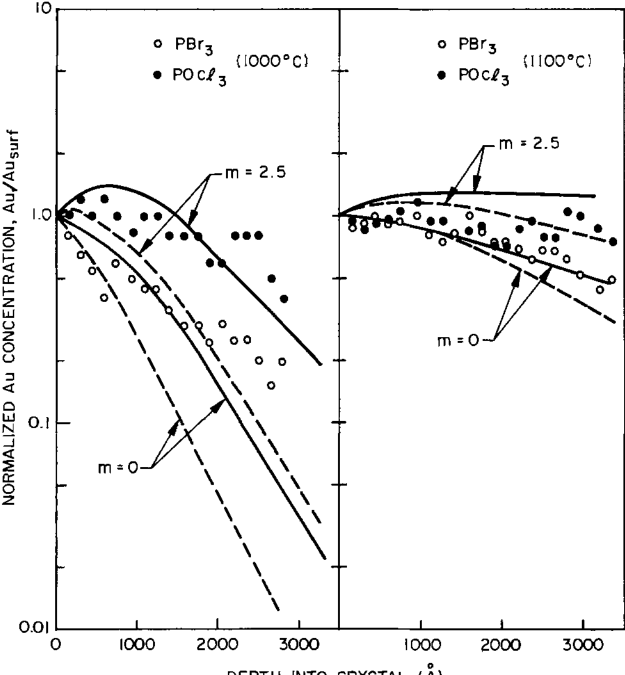

Fig. 11. Au concentration profiles from different parts of the same sample which were PBr_3- and $POCl_3$-diffused (30 min diffusion, 1000° and 1100°C). Samples originally equilibrated with Au at 1200°C.

For phosphorus diffused layers, the gettered metal atoms are found to be on lattice sites. In general, Cu and Au can exist in silicon as a substitutional acceptor and as an interstitial donor [see Ref. (2) and references quoted therein]. We propose that the gettering mechanism for P diffusion is solubility enhancement and ion pairing (22) of the substitutional metal acceptor. This is especially convincing for the case of Cu, where at 1000°C the intrinsic interstitial solubility is $\sim 10^{17}$ cm^{-3} and the intrinsic substitutional solubility is $\sim 10^{13}$ cm^{-3}, but yet one finds up to $5(10)^{20}$ cm^{-3} Cu on substitutional sites in heavily doped n layers. The experiments [see also Ref. (1)] show 75-100% substitutional character while the calculations (2) predict 100% substitutional at the highest P concentrations. However, we note that as the sample is cooled from the diffusion temperature, it becomes supersaturated at some lower temperature, so that some of the dissolved metal may be able to redistribute slightly or cluster to appear off lattice sites.

$POCl_3$ diffusion yields a somewhat different Au or Cu profile than does PBr_3 diffusion (see Fig. 11). Although the dislocation structure is more closely spaced and extends deeper into the matrix for the $POCl_3$ diffusion, the fact that the impurity is still essentially all substitutional throughout the diffused layer implies that the impurity atoms are not directly associated with the dislocation network.

Rather, we postulate that the $POCl_3$ result is caused by vacancy enhancement due to the climbing dislocation network as proposed by Hu and Yeh (23) for an explanation of the emitter push effect. In Fig. 11 the calculated curves are: $m = 0$, no vacancy enhancement; $m = 2.5$, vacancy enhancement predicted by the quasistatic approximation to Hu and Yeh's (23) theory. The solid and dashed lines are for two different values of the activity coefficient for electrons [see Ref. (2)]. The data for PBr_3 diffusions [and other data in Ref. (2)] indicate little or no vacancy enhancement. For $POCl_3$ diffusions, however, the Au profile is much flatter, and in fact peaks at a significant distance from the surface in fairly good agreement with the vacancy enhancement predictions.

In the linearized approximation (2) to Hu and Yeh's (23) quasi-steady-state theory, the vacancy enhancement is given by

Table I. Solubility of Cu and Au in heavily doped Si

Dopant	Temperature (°C)	Dopant surface concentration (cm^{-3})	Cu solubility (cm^{-3}) Exp.	Cu solubility (cm^{-3}) Theory	Au solubility (cm^{-3}) Exp.	Au solubility (cm^{-3}) Theory
P	900	$6(10)^{20}$	$2.5 \pm 1(10)^{20}$	$2 \pm 0.5(10)^{20}$	$9 \pm 3(10)^{18}$	$5 \pm 2(10)^{18}$
P	1000	$1.1(10)^{21}$	$5 \pm 2(10)^{20}$	$5 \pm 2(10)^{20}$	$1.5 \pm 0.5(10)^{19}$	$3 \pm 2(10)^{19}$
B	1000	$4(10)^{20}$	$\lesssim 10^{19}$	$9 \pm 3(10)^{18}$	$\lesssim 10^{15}$	$7.5 \pm 2.5(10)^{16}$

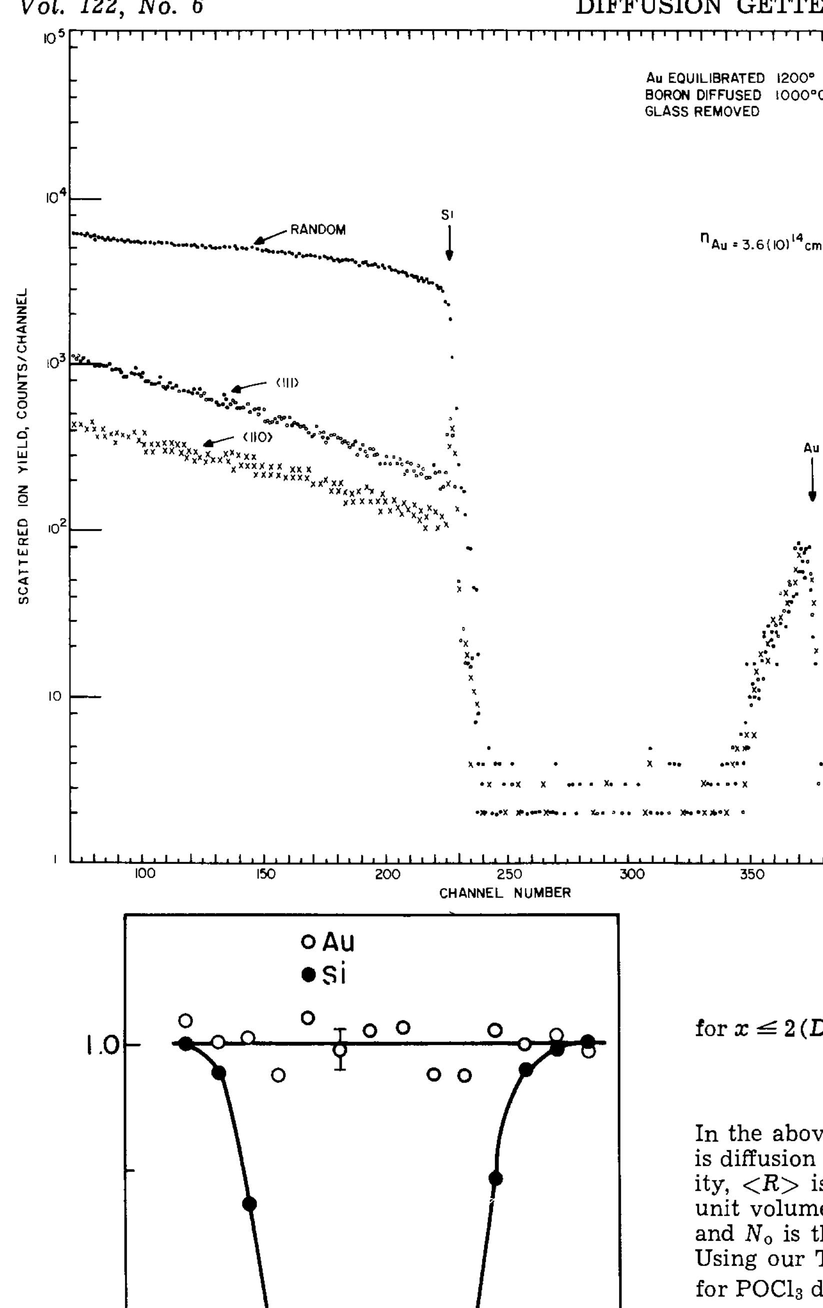

Fig. 13. Spectra from B-diffused sample (30 min), originally Au equilibrated at 1200°C.

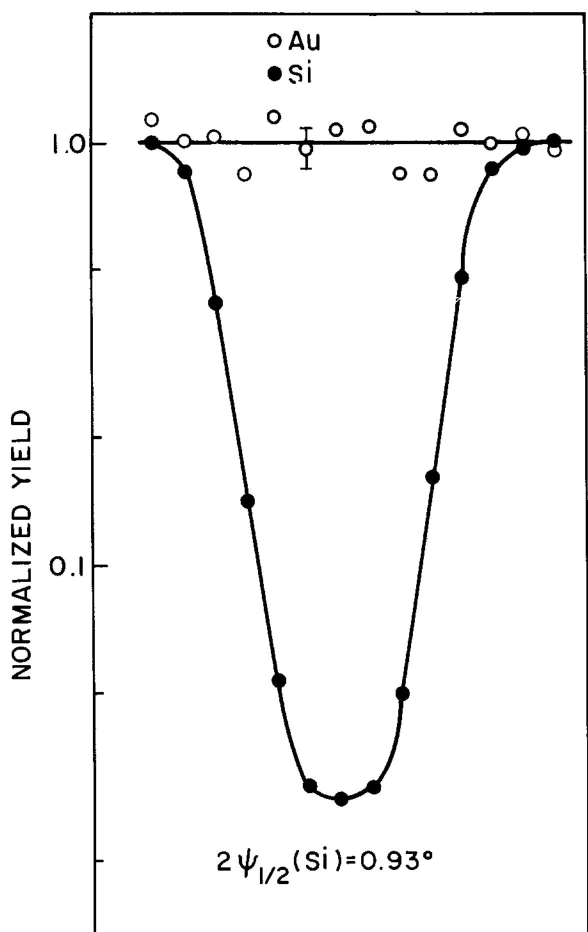

Fig. 14. Angular scan across <110> axis for sample from Fig. 13.

$$\frac{V}{V_{eq}} = 1 + mx/(Dt)^{1/2}$$

for $x \leq 2(Dt)^{1/2}$, where

$$m = 2\langle R\rangle tD/N_0D^*$$

In the above formulas, x is distance into the crystal, t is diffusion time, D is the effective phosphorus diffusivity, $\langle R\rangle$ is the mean rate of vacancy generation per unit volume, D^* is the intrinsic silicon self-diffusivity, and N_0 is the number of lattice sites per unit volume. Using our TEM results to estimate $\langle R\rangle$, we find that for $POCl_3$ diffusions $m \sim 1$ and for PBr_3 diffusions $m \lesssim 0.1$. Thus theory and experiment are in agreement with the hypothesis that vacancy enhancement is significant for $POCl_3$ but not for PBr_3 diffusions. However, it should also be pointed out that the shape of the P profile itself may be quite different for the two diffusion sources.

Our estimates of the saturation solubilities are given in Table I. We compare theory and experiment near the surface where the dopant should be at its solubility limit (24) and where vacancy enhancement should not be significant (23). Detailed examination of the leading edge of the Si spectrum shows a small shoulder corresponding to scattering from ^{31}P at the surface which is separated from the 3.12% abundant ^{30}Si isotope by about 20 keV. The magnitude of this shoulder indicates that assuming the surface phosphorus concentration to be equal to the solubility is reasonable, and the channeled spectrum indicates that $\sim$ 10% of the phosphorus atoms are off lattice sites at the surface. Similarly, the boron (p, α) nuclear resonance experiment indicates that it is reasonable to take the boron surface concentration to be equal to the boron solubility. In Table I, the range of experimental values is due to the fact that we cannot determine that we have passed point B on Fig. 1 until a detectable amount of the new phase has formed. The range of theoretical values is due to the range of possible electron activity coefficients (2). The agreement between theory and experiment is within the uncertainty in either value.

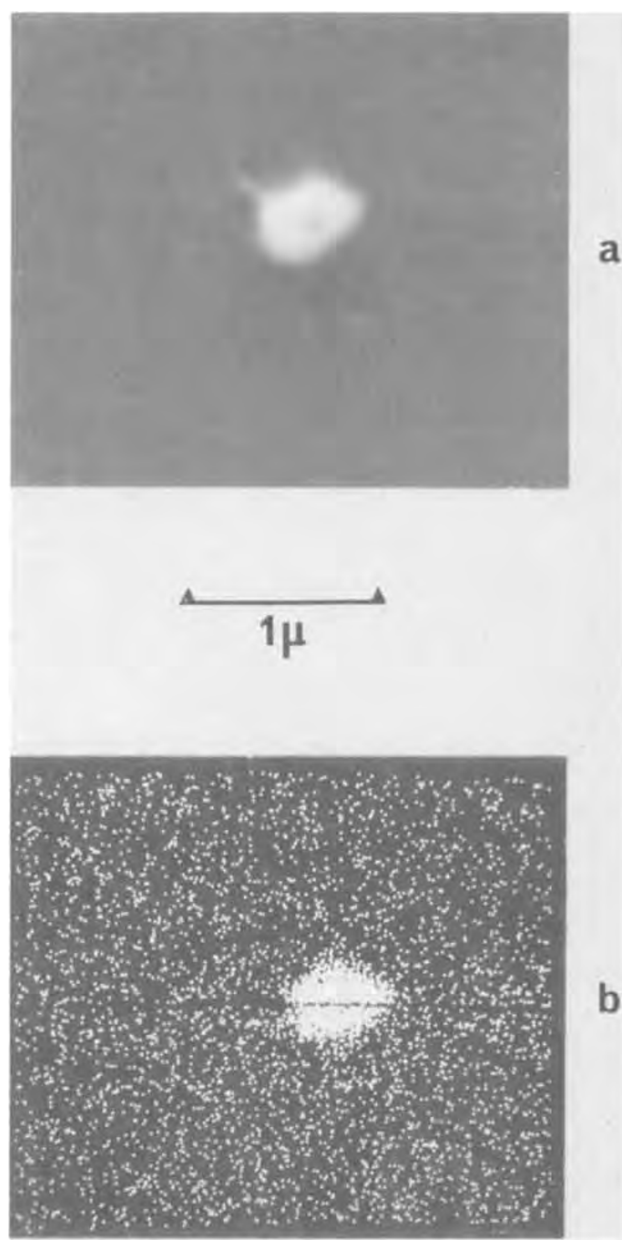

Fig. 15. (a) Scanning electron micrograph of partially truncated triangular island in boron diffused sample. (b) Scanning x-ray micrograph obtained using photons with energies near to 2.14 keV. Same specimen area as shown in part (a).

In the case of B diffusion, except for a surface peak already discussed, the gettered Cu or Au is at or near the detection limit until the solubility limit has been exceeded, and a new phase precipitates. We conclude, therefore, that the solubility is less than or nearly equal to the detection sensitivity of our measurements which is $\sim 10^{18}$ cm^{-3} for Au and $\sim (10)^{19}$ cm^{-3} for Cu. Again this conclusion is in agreement with solubility calculations (2).

Acknowledgments

We would like to thank J. M. Poate for his participation in the early angular scan experiments, W. M. Augustyniak for his invaluable assistance in the (p, α) resonance experiment, and F. L. Worthing for his capable sample preparation.

APPENDIX

The equilibrium solubilities for Cu and Au in silicon have been calculated for high temperatures (900°-1100°C) and heavy dopings (10^{19}-10^{21}/cm^3). For strongly n-type material a large solubility enhancement is calculated (about 10^3 times the intrinsic solubility) due to ion pairing of substitutional metal acceptors with substitutional donors. The equilibrium pairing is described by

$$MD = K_{\text{pair}} M^s D^+ \qquad \text{[A-1]}$$

where MD is the metal-donor pair density, M^s is the substitutional concentration of the metal in the presence of donors, D^+ is the ionized donor concentration. M^s is given by $M^s = M_i^s \gamma_e n/n_i$ where M_i^s is for the undoped-intrinsic case, γ_e is the activity coefficient depending on doping degeneracy, n the free electron concentration, and n_i the intrinsic electron concentration.

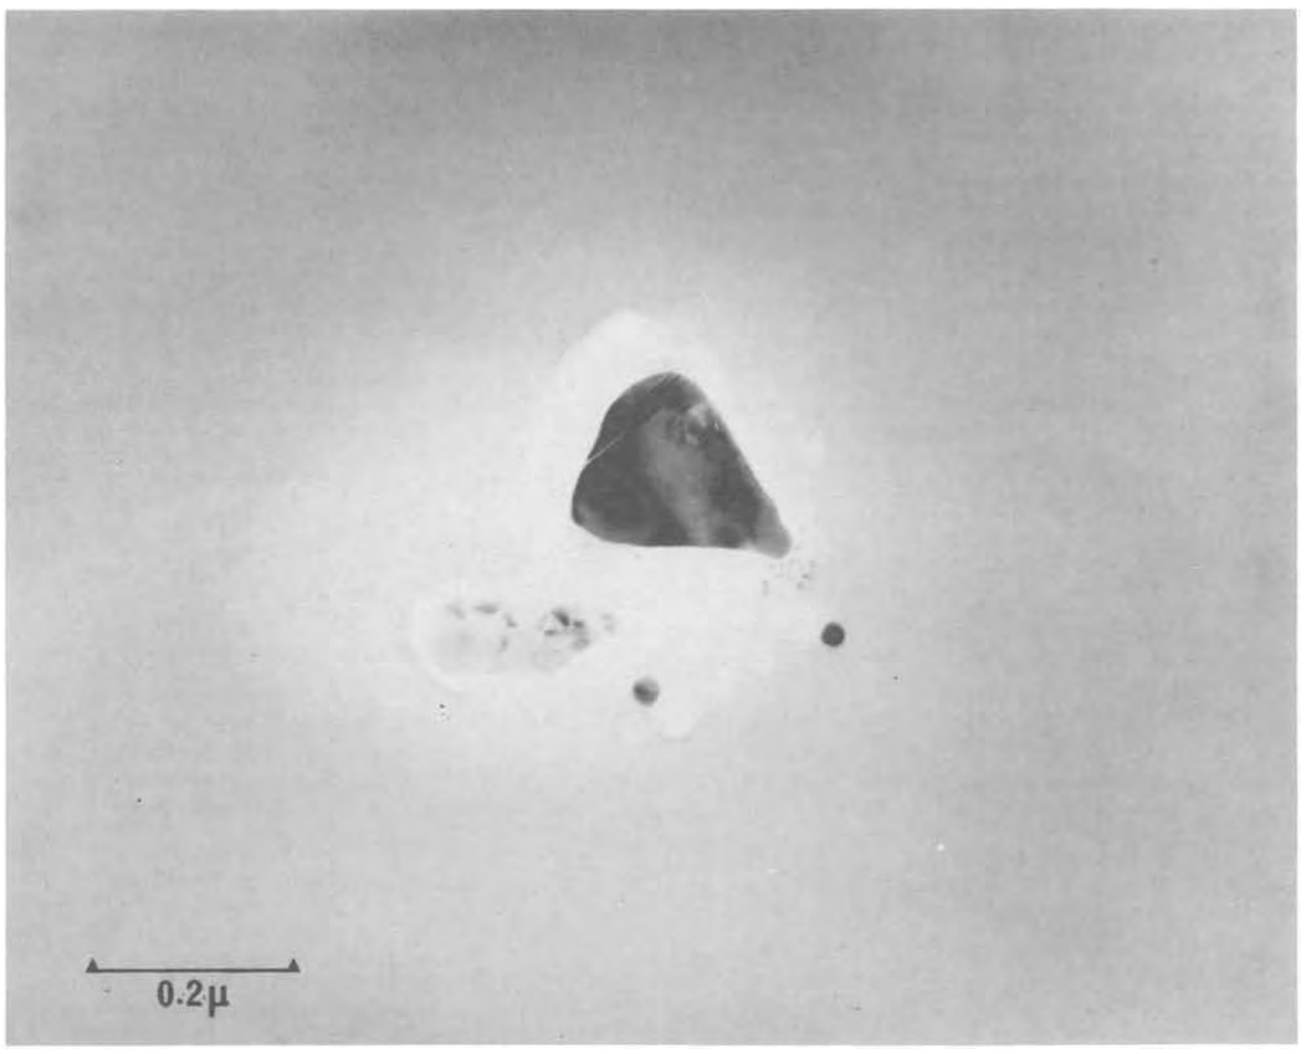

Fig. 17. Transmission electron micrograph (bright-field) showing geometrically shaped precipitate island situated in matrix surface depression.

The pairing constant is estimated from Coulomb considerations (25, 26)

$$K_{\text{pair}} = (Z/N) \exp(nq^2/\epsilon akT) \qquad \text{[A-2]}$$

where (Z/N) is the ratio of nearest neighbor sites to the atom lattice site density and n is the charge on the substitutional metal atom, ϵ is the bulk dielectric constant, and a is the nearest neighbor distance of the pair. Typically the coulomb energy is 0.4 eV ($n = 1$) so for multiply charged acceptors like Cu ($n = 3$) the coulomb energy is ~ 1.2 eV and the pairing constant is $\sim 10^4$ more than for Au with phosphorus donors. Hence the pairing model predicts that the gettering is more thermally stable for Cu than for Au.

When considering the pairing probability for interstitial donors (metal) and substitutional acceptors such as boron, the influence of the changed vibrational frequencies and configurational possibilities on entropy must be taken into account. The effect is to decrease the pairing constant. This argument has been used to explain the relatively weak solubility enhancement of metal donors under boron diffused layers.

Rotating Scan for Ion Implantation

G. I. Robertson

Western Electric Company, Engineering Research Center, Princeton, New Jersey 08540

ABSTRACT

With the development of 1-2 mA beam current ion sources, production implantation systems became limited by scanning techniques. In particular, high beam currents could not be used efficiently for low and moderate dose implants. To overcome this deficiency, a multiwafer rotating mechanical scan technique was developed. Combining the high speed advantage of low current electrical scan and the high current capability of mechanical scan, the rotating scan technique can achieve implantation times of less than 1 sec per 2 in. wafer at full beam current with better than 99% uniformity.

The rotating mechanical scan described in this paper is a mechanism that permits the implant time of high current ion implantation machines to be reduced by up to two orders of magnitude. Although ion sources can produce over 1 mA of analyzed beam, the scanning system often limits the usable current, especially for low or medium dose implants. A production implantation system must make full use of the available beam current: a reduced beam current directly affects the throughput of the system, thereby increasing the cost of the implant. Rotating mechanical scan enables a wide range of ion doses to be implanted using the full available beam current.

The two principal methods of uniformly implanting an ion beam into a wafer are electrical scanning of the beam and mechanical scanning of the wafer through the beam. Electrical scanning has been in general use since the start of ion implantation technology as it is simple and effective. However, with the advent of analyzed beam currents of 1-2 mA, space charge spreading in the drift space between the deflection plates and target increase the beam to unacceptable dimensions. The beam diameter must be kept small to avoid large overscan losses, and this limits the usable current to a few hundred microamperes. Mechanical scanning techniques overcome this disadvantage. Since the beam is stationary, a shorter machine is possible, minimizing space charge effects at high currents. Moreover, there are additional advantages to mechanical scanning. By moving the wafer parallel to its surface, the angle of the beam with respect to the crystalline lattice remains constant, so there is no channeling nonuniformity across the wafer. Also, neutralized particles are scanned with ions, thus avoiding a hot spot, but instead causing a small dose measuring error. Finally, mechanical scan is conducive to batch implantation and the number of wafers handled in one batch is limited only by the mechanical requirements of the target chamber.

Conventional X-Y mechanical scanning systems suffer from one disadvantage which has outweighed all their advantages in most cases; they are slow. To achieve the required uniformity of implant, many overlapping scans must be made. Taking the Harwell-Lintott X-Y mechanical scan as an example, the minimum time required to implant at 1% uniformity is about 1 min per wafer (1). The X-Y mechanical scan is thus only efficient when the implant time is 1 min or more per wafer: that is, at high doses or low beam currents. In other cases the system is scan limited.

Key words: beams, semiconductors, scanning, production.

There have been several attempts to combine electrical and mechanical scans into a system in which the fast axis is scanned electrically and the slow axis mechanically (2). This technique permits large batches to be implanted and improves the throughput over a purely electrical scan system. The principle disadvantage of electrical scan remains however, so hybrid scan is classified with electrical scan for the purpose of this paper.

Considering the relative limitations of the two types of scan, it is apparent that the single advantage of electrical scan is the ability to scan the beam rapidly. This is not possible in the case of X-Y mechanical scanning because of inertia.

The rotating mechanical scan described in this paper is not limited by inertia, so rapid scanning is possible. The uniformity limited minimum implant time is about 1 sec per wafer, depending on dose, and high beam currents may be used. The rapid throughput of rotating scan makes it a suitable technique for high capacity production line machines.

Concept of Rotating Scan

The wafers to be implanted are mounted on a disk which is rotated about an axis parallel to the ion beam at approximately 1000 rpm, providing the first direction, or rapid scan. Typically the disk is 50 cm diameter, and holds 50-60 wafers. The disk is slightly dished, which holds the wafers in position centrifugally thereby avoiding hold-down clips. The second direction of scan is provided by translating the entire rotating disk back and forth in the plane of the disk and perpendicular to the beam as is depicted in Fig. 1. The speed of the fast scan is about two orders of magnitude higher than is possible with an X-Y mechanical scan, so the minimum implant time is similarly reduced.

The dose uniformity is controlled only by the lateral translation velocity of the disk. This velocity must vary inversely with the radial position of the beam on the disk, and directly with the beam current, as is shown below.

Comparison of Rotary and X-Y Scans

The uniformity of a mechanical scan system is determined largely by the step size y of the slow speed scan. If the beam is assumed to have a pillbox intensity profile for the present purpose, and its width in the direction of the slow scan is a, then the uniformity

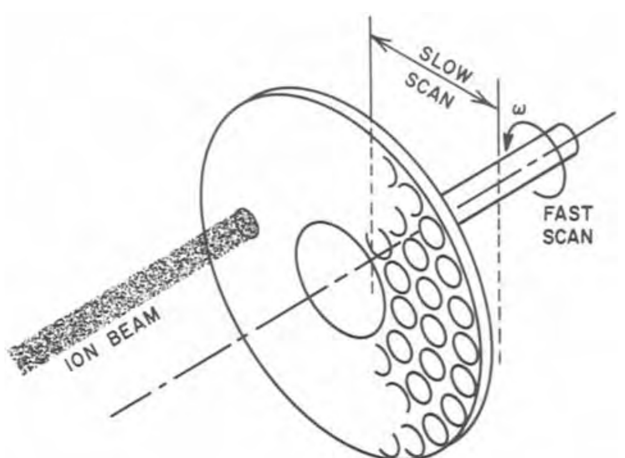

Fig. 1. Fast and slow scan motions of the rotating scan target

may be written as

$$\pm\frac{\Delta D}{D}=\frac{y}{2na} \quad [1]$$

where D represents the dose, y is the increment in the slow scan direction, and n is the number of passes made for one implant. This is a crude representation of the uniformity and assumes the worst case when the beam is extinguished during a constant speed scan. In practice, the speed of the scan may be made dependent on the beam current as will be shown later, but Eq. [1] is suitable for the present comparison.

The maximum speed at which the slow scan may be incremented is determined by the time taken for a fast scan. The minimum time for a complete pass of the wafer holder is then

$$t_{\min}=\frac{Y}{y}\cdot\frac{X}{V_x} \quad [2]$$

where X and Y are the dimensions of the plate in the fast and slow scan directions respectively, and V_x is the maximum x-velocity. Combining [1] and [2] gives

$$t_{\min}=\frac{XY}{V_x\cdot 2na\dfrac{\Delta D}{D}} \quad [3]$$

If there are N wafers on the holder the minimum implant time per wafer $t'_{\min}$ is

$$t'_{\min}=\frac{XY}{V_x\cdot 2na\dfrac{\Delta D}{D}N} \quad [4]$$

But since N is roughly proportional to the wafer holder area XY

$$t'_{\min}\propto\frac{1}{V_x} \quad [5]$$

for a given uniformity.

If the velocity limited implantation time for a required uniformity occurs at a high beam current and dose, then the only way to achieve lower doses is to lower the beam current.

In Fig. 2 the relationship between dose, implantation time, and beam current is plotted. The diagonal lines are lines of constant scanned beam current, and are common to all scanning methods. For reference, the maximum practical beam current for electrical scanning is shown as the solid diagonal line at 200 μA. This limit is appropriate for present day implantation equipment.

The Harwell-Lintott system is again taken as the example of a typical X-Y scan. For a ±1% uniformity using a beam 1 in. high, the minimum implant time is 50 sec/2 in. wafer. This is shown as the upper solid line in Fig. 2. In contrast, for the same uniformity and

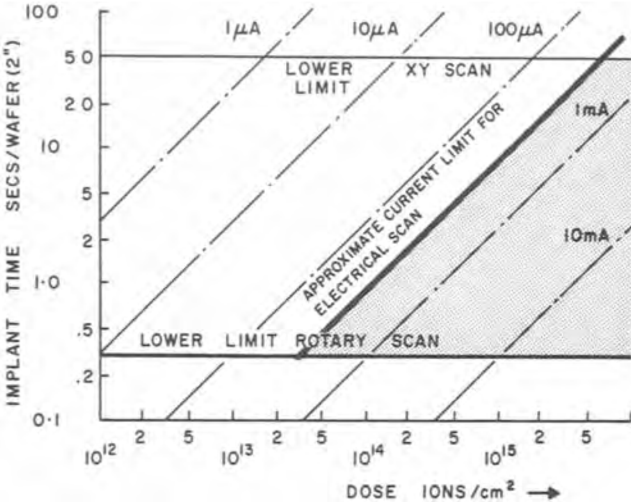

Fig. 2. Implant time for 1% uniformity as a function of ion dose. The limits for the three scan methods are shown.

beam size, the minimum implant time for a rotating scan of the type described is 0.3 sec/2 in. wafer, due solely to the increased velocity V_x of the fast scan (Eq. [5]). This limit is shown as the lower solid line in Fig. 2. The shaded area enclosed by these three solid lines is that region particularly suited to rotating mechanical scan. It can be seen that it includes doses of 2.10^{13} ions/cm^2 and over, using ion beams of 200 μA and over.

The principal benefit of rotating scan over X-Y mechanical scan is the ability to use high beam currents efficiently for low or moderate dose implants, as well as for high dose implants. There are two other benefits of lesser importance. Firstly, the current loss due to overscan is reduced. The ion beam should be overscanned by at least one radius in each direction to assure edge uniformity. In the case of a typical X-Y scan, the loss is approximately 15%. With rotating scan, overscan occurs only in the radial direction and many more wafers are implanted in each batch, so a typical overscan loss is 5%. Secondly, the average power applied to each wafer by the ion beam is reduced because of the increased batch size. Present machines are capable of beam currents of up to 1 mA at 300 kV acceleration, which represents a beam power of 300W. The instantaneous heating of the surface of the wafer is a complex subject (3), but to first order it is a function of the number of wafers in each batch. To dissipate 300W, the six wafers of the Harwell-Lintott X-Y scan must dissipate an average of 50W each, whereas the 60 wafers on a rotating scan disk need dissipate only 5W each. In this context it should be noted that a pure electrical scanning system cannot put 300W into a single wafer for more than 1 sec or so, although the AI hybrid scan (2) can absorb this power.

Dose Uniformity

The circumferential uniformity of the implanted dose is guaranteed if the rotation of the disk is sufficiently rapid to average out all the beam fluctuations. The possibility of stroboscopic effects can be avoided by rotating the disk at a speed not synchronous with harmonics of the line frequency. Radial uniformity, however, requires a precise control of the radial velocity which must vary as a function of disk position and beam current. The theoretical translational velocity is derived below, first for a small dimension ion beam and then for the general case.

Initially it is assumed that the beam has a small, rectangular cross section $L_1 \times L_2$ as shown in Fig. 3. The center of the disk is R from the beam, and the disk is translating at a velocity $V(t,R)$. The current density of the beam is $j(t)$, so the average current density seen by the annulus that passes through the beam is

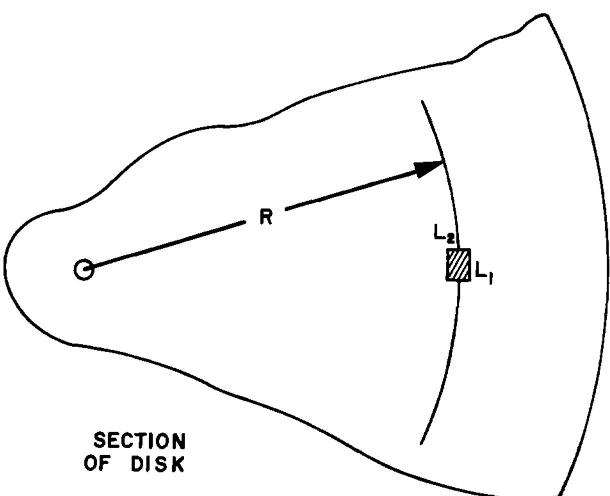

Fig. 3. Section of the target disk showing the small ion beam approximation.

$$\frac{j(t)L_1}{2\pi R} \quad [6]$$

The average current density is received on this annulus for a time $L_2/V(t,R)$ before it has passed through the beam, so the total ion dose D at a point R from the disk center is

$$D = \frac{L_1 L_2 j(t)}{2\pi R q V(t,R)} \quad [7]$$

where q is the ion charge. But $L_1L_2 \cdot j(t)$ is the total beam current $I(t)$. Therefore the dose is

$$D = \frac{I(t)}{2\pi R q V(t,R)} \quad [8]$$

and to achieve a uniform dose over the target disk, the velocity $V(t,R)$ must be

$$V(t,R) = \frac{1}{2\pi D q} \cdot \frac{I(t)}{R} \quad [9]$$

Now consider the case shown in Fig. 4. An ion beam with irregular current distribution is shown divided into n annuli of constant width δr. The total current in each annulus is $I_1, I_2, \ldots, I_n, (t)$. An arc passes through the current weighted average of the ion beam, at radius R from the center of the disk, such that the distance to each annulus of the ion beam is $d_1, d_2, \ldots, d_n$, and $\sum_{j=1}^{n} I_j(t)d_j = 0$.

To determine the total dose implanted, consider the annulus on the disk, at radius R_a, which is just about to enter the ion beam. Assuming that it spends times $\delta t_1, \delta t_2, \ldots, \delta t_n$ in each section of the ion beam, the total dose received by the annulus will be

$$D_a = \frac{1}{q 2\pi R_a \delta r} \sum_{j=1}^{n} I_j(t)\delta t_j \quad [10]$$

We now show that the same translation velocity derived for the small beam case in Eq. [9] will make D_a constant, independent of the radius R_a. From Eq. [9]

$$V(t,R) = \frac{\delta r}{\delta t_j} = \frac{1}{2\pi D q} \cdot \frac{I(t)}{R} \quad [11]$$

But

$$R = R_a + d_j$$

so

$$\delta t_j = \frac{q 2\pi D (R_a + d_j)\,\delta r}{I(t)}$$

Combining with [10]

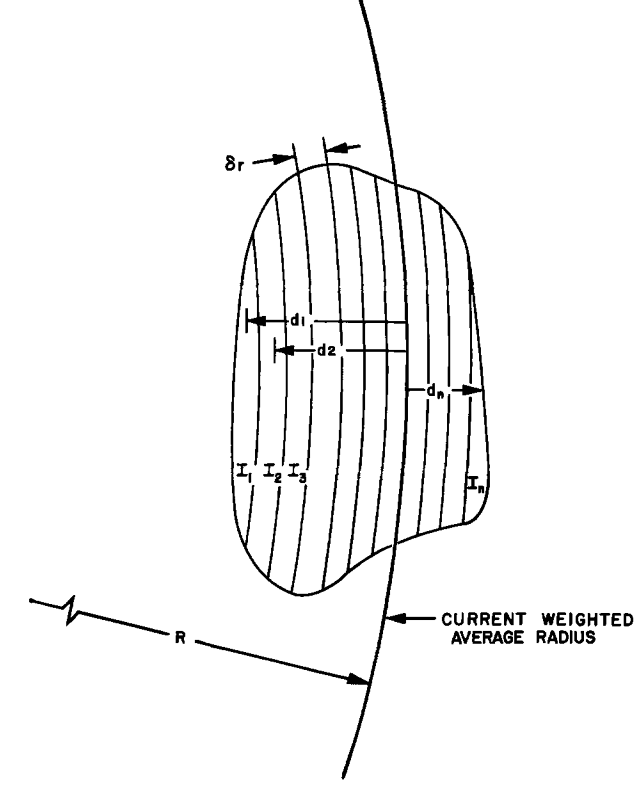

Fig. 4. Diagram of large ion beam divided into n sections

$$D_a = \frac{D}{I(t)R_a} \sum_{j=1}^{n} I_j(t)\,(R_a + d_j)$$

or

$$D_a = \frac{D}{I(t)} \sum_{j=1}^{n} I_j(t)\left(1 + \frac{d_j}{R_a}\right)$$

$$D_a = D\left[1 + \frac{I}{R_a I(t)} \sum_{j=1}^{n} I_j d_j\right] \quad [12]$$

But by definition $\sum_{j=1}^{n} I_j d_j = 0$, so $D_a = D =$ constant.

Thus a finite size beam may be treated as a small beam if its effective radius R is the radius to the weighted current average point.

The above derivation neglects the changing curvature of the annuli, and breaks down if the beam is comparable in size with its radial position R. However, for all reasonable beam sizes and radii, the results are accurate to better than 0.5%.

Control Methods

Equation [9] shows that the lateral translation velocity of the disk should be an inverse function of the distance R between the disk center and beam, and a direct function of the beam current I. The ion dose will then be uniform across the disk. Unfortunately it is not easy to generate an exact drive velocity, and any errors will be accumulated. A more suitable form of the control equation can be derived.

From Eq. [9], V and I may be rewritten

$$\frac{dR}{dt} = \frac{1}{2\pi D q} \frac{\frac{dQ}{dt}}{R} \quad [13]$$

Integrating

$$Q = \pi D q R^2 + C \quad [14]$$

where Q is the total charge received since some time t_0. The constant of integration is found by assuming that $Q = 0$ when the beam is at the starting radius R_0.

Equation [14] is now in a more suitable form for control. The total charge received may conveniently be measured by a current integrator, and the value of R can be found either by using a linear potentiometer attached to the disk carriage, or by counting the steps of a digital stepping motor. Of course, Eq. [14] refers only to a single pass of the disk through the beam. While it is possible to obtain the correct dose in this manner, it is preferable to make several more rapid passes. Travel in the reverse direction is readily accomplished by treating each unit of charge as a negative quantity, instead of a positive quantity.

The control system may be either analog or digital. Each has advantages, and the principles of each are outlined below. In general analog control is simpler to construct, but it is not as flexible as digital control.

Figure 5 shows a block diagram of an analog control system. The ion current is measured by a current integrator, which generates a pulse every time a certain charge is accumulated. The pulses are summed in a counter, which is connected to a d/a converter (dac). The voltage output from the dac is then a measure of the accumulated charge. The required dose per sweep is set on the potentiometer at the output of the dac, and in turn is connected to one input of the servo amplifier.

The second input to the servo amplifier is taken from a precision square-law potentiometer attached to the disk carriage. The servo motor drives the carriage and satisfies Eq. [14] by keeping the two amplifier inputs balanced.

When the limits of the scan are reached, a microswitch triggers a bistable latch. The latch is connected to the count-up/count-down input of the counter, and causes it to change the direction of its count on receipt of each integrator pulse. In this manner, the incoming current causes an increase in the dac output if the motor is to move forward, and a reduction in the dac output if the motor is to move in reverse. The limit switch at one end of the scan also increments a second counter which terminates the implant when the correct number of scans has been completed.

This type of analog control is easy and relatively cheap to construct. Its main disadvantage lies in its accuracy, which is affected by two potentiometers and one digital to analog converter. It is suitable for dose reproducibilities of approximately 2%.

A higher degree of precision may be obtained at the expense of increased complexity by using digital control. The ion beam current is measured using a current integrator as before, but the disk translation is by a stepping, rather than a servo motor. A stepping motor eliminates the requirement for a feedback potentiometer, since the position of the carriage is known at all times by counting the stepping motor pulses. A small computer is programmed to solve Eq. [14] in real time as the integrator pulses are received. A disadvantage of using a stepping motor is that it must either be run slowly, or provision must be made to accelerate and decelerate it at the ends of each sweep.

A significant advantage of a digital system is that the control computer may be used to perform many peripheral tasks. Prior to the implant, the various parameters that determine the dose may be calculated. Printers may be used to provide a log of all implants, and the system can be made self-monitoring to some degree. In a complex system like a high energy implantation machine, there are sequences of events to be followed, and emergency conditions to be recognized and acted upon. All of these are easily implemented once there is a small computer on line.

Conclusion

A rotating mechanical scan is particularly suited to production line equipment, since it combines the high speed of electrical scan with a high current handling capacity. Uniformity limited minimum implant times are about 1 sec per wafer at 1% uniformity.

The prototype system uses digital control with a small computer controlling the implant, although an analog system could also be used. Sixty wafers may be implanted in 1 or 2 min, excluding pumpdown time, so currents as high as 1 mA may be used to implant doses of 1×10^{15} ions/cm^2.

Figure 6 is a histogram of the dose nonuniformity within each batch of 60 wafers, measured using the van der Pauw technique. Each point in the histogram represents the mean dose on one wafer, and the per cent dose deviations have been calculated relative to the average dose of all wafers implanted during a run. The uniformity across the target disk is better than 0.9% (1σ). When different runs are included the absolute dose accuracy and batch to batch reproducibility together are measured as 1.5% (1σ).

Boron Diffusion in Silicon-Concentration and Orientation Dependence, Background Effects, and Profile Estimation

Richard B. Fair*

Bell Laboratories, Reading, Pennsylvania 19603

ABSTRACT

Boron is almost universally used as a p-type dopant in Si devices. Since this dopant is introduced into the Si lattice under a wide range of diffusion conditions, effects are often observed which appear anomalous because the mechanism of B diffusion is not completely understood. Anomalous effects that have been observed include a concentration-dependent diffusion coefficient, orientation-dependent diffusion under oxidizing conditions, and retarded or accelerated diffusion in the presence of n-type impurities. This paper discusses a model of B diffusion which can be used to explain these observed effects. Data and arguments are presented which show that B diffuses via a monovacancy mechanism when the diffusion is performed in a nonoxidizing ambient. A donor-type vacancy is responsible which has a presumed energy level of $\sim E_v + 0.37$ eV as suggested from the quenching experiments of Elstner and Kamprath. High concentration ($>2 \times 10^{19}$ cm^{-3}) B diffusions into Si over a 550°C temperature range in neutral ambients result in profile data that fit a normalized universal curve which is a polynomial approximation to the solution of the diffusion equation with concentration-dependent diffusivity. From this result, useful curves of surface concentration *vs.* resistivity and junction depth are presented.

For high concentration ($>10^{19}$ cm^{-3}) single component diffusions of Group III and V dopants in silicon (Si) it is known that simple complementary error functions and gaussian functions do not correctly describe the resulting diffusion profiles. At lower concentrations ($<10^{19}$ cm^{-3}) the diffusivity is essentially constant, and these simplified analytical expressions can be used. However, at high doping densities or when multiple component diffusions are performed, the diffusion coefficients of these elements in Si exhibit a dependence on the local concentrations of the diffusing species. For the case of boron (B) in Si it has been suggested that the cause of this dependence is either related to plastic deformation and degeneracy of the highly doped Si (1, 2) or to interactions of the B^- ions with positively charged defects (3-6). It is the purpose of this paper to present data and arguments which give support to the model that B generally diffuses by interacting with donor-type monovacancies with an electronic energy level at $\sim E_v + 0.37$ eV. Support for the existence of this level comes from the quenching experiments of Elstner and Kamprath (7) and the thermodynamic arguments of Van Vechten and Thurmond (8). It will be shown that this model predicts the linear dependence of B diffusivity on B concentration, and also explains why the diffusion of B is retarded in a heavily As-doped substrate.

In the first section, data will be presented which describe the concentration-dependence of B diffusivity and the general shape of high concentration B diffusion profiles in Si when diffusions are performed in nonoxidizing ambients. Then it will be shown that the profile data fit a normalized universal curve which is not an exact solution to the diffusion equation. However, an approximate result is used to generate useful curves of surface concentration *vs.* resistivity and junction depth. Following a discussion of the monovacancy diffusion model for B, the diffusion of B in an oxidizing ambient will be discussed.

Experimental Results

Concentration-dependent diffusivity.—In order to obtain information on the concentration-dependence of B diffusivity, Boltzmann-Matano analysis was performed on several B diffusion profiles obtained by Tsai(9) using the differential conductivity method. Tsai's data, which represent BN disk and B_2O_3 box source diffusions into (111) oriented Si in N_2 ambients, were combined with previously reported results (10, 11), and are shown plotted in Fig. 1a and b. In Fig.

* Electrochemical Society Active Member.
Key words: ion implantation, vacancies, cooperative diffusion.

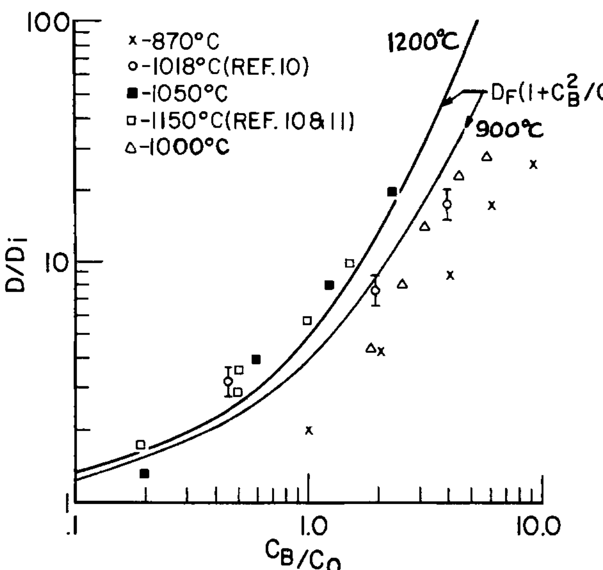

Fig. 1a. Normalized B diffusivity vs. B concentration normalized to Thai's "anomalous diffusion" parameter (1, 2, 11).

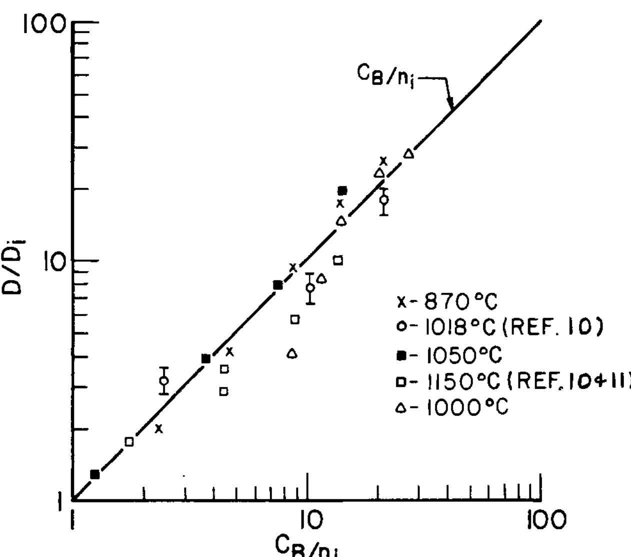

Fig. 1b. Normalized B diffusivity vs. B concentration normalized to the intrinsic electron concentration at the diffusion temperature.

1a normalized diffusivity is plotted *vs.* normalized B concentration, where D_i is the intrinsic diffusivity and C_o is Thai's characteristic concentration parameter (1, 2) which gives the solute density necessary to cause anomalous diffusion to occur. The C_o values used are those corrected values reported by Jain and Van Overstraeten (11), and it is assumed that $p \simeq C_B$, where C_B is the B concentration.

It can be seen that for diffusions performed at temperatures greater than ~1050°C, the data approximately agree with Thai's theoretical curve which is the equation

$$D = D_F(1 + (C_B/C_o)^2) \quad [1]$$

where D_F is a factor that carries the effects of electric-field enhancement and degeneracy. Since Eq. [1] cannot be completely normalized with respect to temperature, two curves are shown, one for 1200° and one for 900°C.

The data obtained from lower temperature diffusion profiles do not agree with Thai's theory. In Fig. 1b these same data are plotted with C_B normalized to n_i (intrinsic electron concentration at the diffusion temperatures). Heavy doping effects on n_i are neglected here, but may be important for large values of C_{SB}. Values of n_i used in Fig. 1b are shown in Fig. 2 along with the D_i *vs.* temperature curve. From Fig. 1b it can be seen that the diffusion data are approximately described by the equation

$$\frac{D}{D_i} = \frac{C_B}{n_i} \quad [2]$$

over the entire temperature range studied. This result agrees with previous observations (3).

Profile shape.—In Fig. 3, B concentration profiles normalized with respect to surface concentration, C_{SB}, and junction depth, x_J, are plotted. All of the diffusions, which had $C_{SB} > 2 \times 10^{19}$ cm^{-3}, were performed in nonoxidizing ambients, and the junction depth was measured at ~0.01 C_{SB} (typically ~10^{18} cm^{-3}). Also shown are the erfc curve and two curves of the general form

$$\frac{C_B}{C_{SB}} = 1 - Y^n, \ 0 \leq Y \leq 1 \quad [3]$$

where

$$Y = Y(x, t, T) \quad [4]$$

The polynomial approximation to the solution of the diffusion equation that describes the arsenic profile shape in Si[12] is also shown. It can be seen that over a 550°C temperature range the high concentration profile data follow neither the erfc curve nor the As profile curve. However, the profile data do follow approximately a universal curve of the form

$$\frac{C_B}{C_{SB}} = 1 - Y^{2/3} \quad [5]$$

In the next section the functional form of Y will be determined for the general Eq. [3] so that an expression for junction depth as a function of C_{SB}, D_i, and t can be determined for $n = 2/3$.

Analysis

Diffusion equation solution.—In order to find the functional form of Y in Eq. [3] for concentration-dependent B diffusion expressed by Eq. [2], Eq [2] and

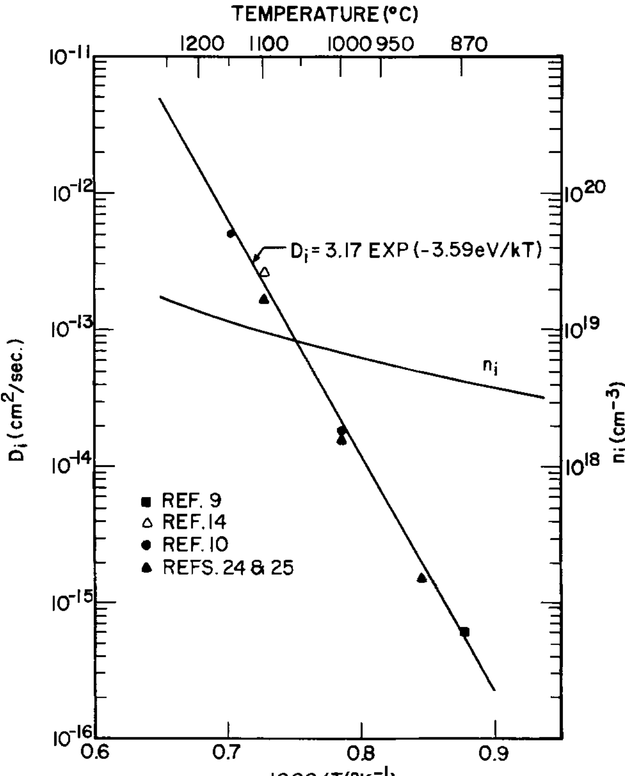

Fig. 2. Intrinsic B diffusivity, D_i and intrinsic electron concentration, n_i vs. temperature.

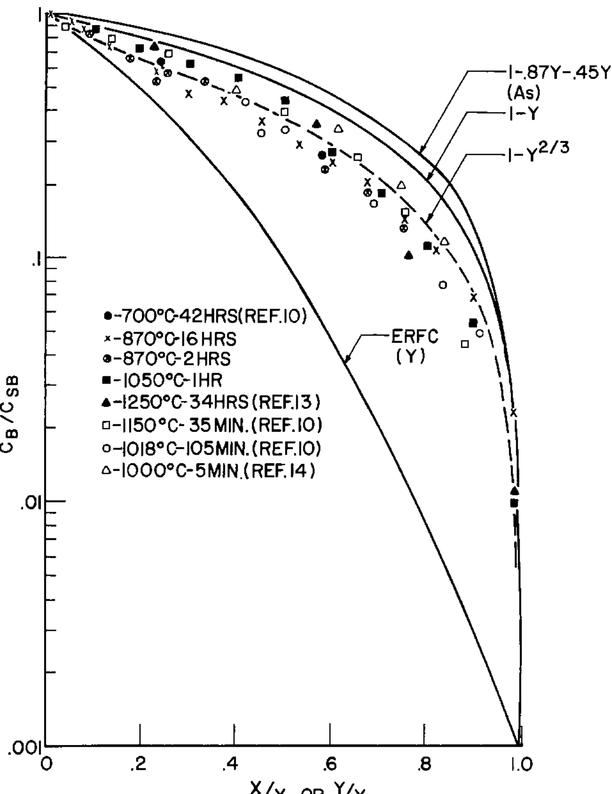

Fig. 3. B diffusion profiles normalized with surface concentration and junction depth. All data have $C_{SB} > 2 \times 10^{19}$ cm^{-3} and x_J is taken at $C_B \simeq 0.01\ C_{SB}$.

[3] will be substituted into the diffusion equation given by

$$\frac{\partial C_B}{\partial t} = D_S \frac{\partial}{\partial x}\left(\frac{C_B}{C_{SB}} \frac{\partial C_B}{\partial x}\right) \quad [6]$$

where

$$D_S = \frac{C_{SB}}{n_i} D_i \quad [7]$$

Thus

$$-\frac{\partial Y}{\partial t} = D_S \left(\frac{\partial Y}{\partial x}\right)^2 Y^{-1} [Y^n(2n-1) + 1 - n] - D_S (1 - Y^n) \frac{\partial^2 Y}{\partial x^2} \quad [8]$$

Since Y is dimensionless it will have the general form (12)

$$Y = \left(\frac{x^2}{K_1 D_S t}\right)^{1/m} \quad [9]$$

where K_1 is a dimensionless constant that must be determined. Substitution of Eq. [9] into Eq. [8] yields

$$Y = \left[\frac{\dfrac{x^2}{2D_S t} + \left(\dfrac{2n}{m} - 1\right)}{\dfrac{4n}{m} - 1}\right]^{\frac{1}{n}} \quad [10]$$

In order for Eq. [10] to have a similar functional form in x and t as Eq. [9], then $n = m$ and

$$Y = \left[\frac{x^2}{6D_S t} + \frac{1}{3}\right]^{\frac{1}{m}} \quad [11]$$

Equation [11] is not a valid form for Y since at the surface ($x = 0$), Y must equal zero according to Eq. [3]. This result indicates that the empirical Eq. [3] (or [5]) with Y defined as it is in Eq. [9] is not an exact solution to the diffusion equation, since no functional form of Y can be derived from it that satisfies all the requirements on Y. However, near the junction as $x \rightarrow x_j$, the first term on the right hand side of Eq. [11] becomes ~10 times larger than the 1/3 term, and Eq. [11] approximates Eq. [9] with $K_1 = 6$. Setting Y = 1, Eq. [11] becomes at the junction

$$x_J = 2.45 \left(\frac{C_{SB} D_i t}{n_i}\right)^{1/2} \quad [12]$$

or

$$\frac{x_J}{2\sqrt{D_i t}} = 1.225 \sqrt{C_{SB}/n_i} \quad [13]$$

Equation [13] is shown plotted in Fig. 4a along with data of normalized surface concentration *vs.* normalized junction depth. All of the data referenced on the figure were taken from measured diffusion profiles (usually obtained by the differential conductivity method), and the junction depths were taken as the distance from the surface at which C_B had fallen to ~10^{18} cm^{-3}. Good agreement between data and the theoretical curve is obtained. These same data are shown plotted in Fig. 4b with C_{SB} normalized to $C_B = 1 \times 10^{18}$ cm^{-3}. By comparing these data with the complementary error function curve plotted in the figure, the significance of neglecting the concentration dependence of B diffusivity can be seen.

Resistivity vs. surface concentration.—The sheet resistance of a diffused layer is given by the equation

$$R_S = \frac{1}{q\bar{\mu}\int_0^{x_J} C_B dx} \quad [14]$$

where $\bar{\mu}$ is the effective bulk carrier mobility (cm²/Vsec). For $C_B > 5 \times 10^{19}$ cm^{-3}, the hole mobility in silicon becomes approximately independent of C_B ($\tilde{\mu} \cong 55$ cm²/Vsec) (15). If it is assumed that $\bar{\mu}$ is essentially that value of μ corresponding to the doping near the surface, and if Eq. [5] is integrated to give

$$Q = \int_0^{x_J} C_B dx = 0.4\ C_{SB} x_J \quad [15]$$

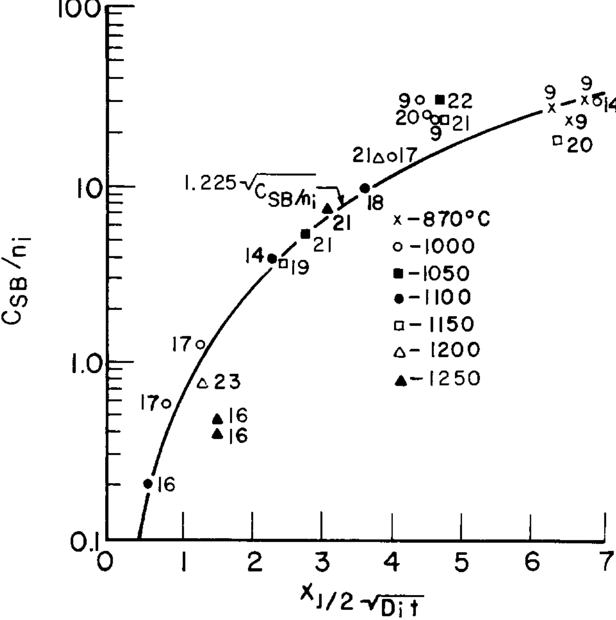

Fig. 4a. B diffusion profile surface doping normalized to n_i vs. normalized junction depth ($x_J \rightarrow C_B \cong 10^{18}$ cm^{-3}). The solid curve is Eq. [13].

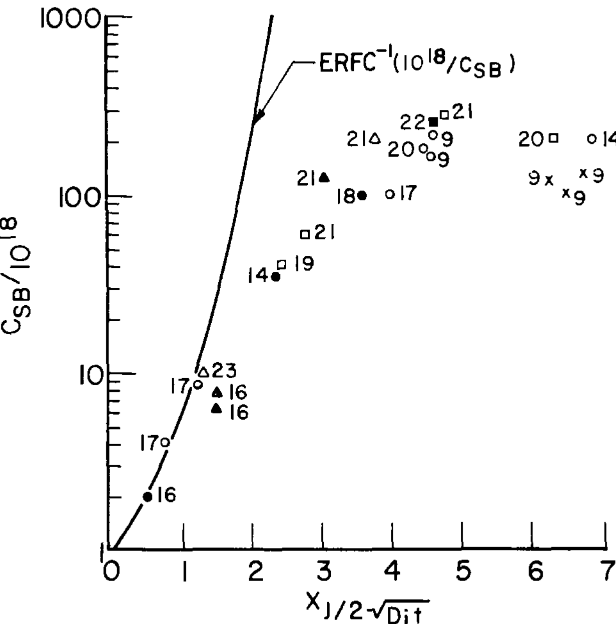

Fig. 4b. B diffusion profile surface doping normalized to $C_B = 10^{18}$ cm^{-3}. The solid curve is an erfc curve.

then Eq. [14] becomes

$$C_{SB} = \frac{2.78 \times 10^{17}}{R_S x_J} \qquad [16]$$

An estimate of the accuracy of Eq. [16] can be obtained by referring to Fig. 5 where $C_{SB}(x_J, R_S)$ data are plotted along with Eq. [16]. All of the data shown fall within 20% of the theoretical curve for $C_{SB} \gtrsim n_i$. Again, x_J corresponds to the distance from the surface at which C_B falls to $\sim 10^{18}$ cm^{-3}.

Discussion

Boron diffusion model.—The linear relationship between the apparent diffusivity of boron in silicon and the boron concentration suggests several possible diffusion mechanisms: the interstitialcy mechanism, the vacancy mechanism, and the divacancy mechanism. In the interstitialcy mode of diffusion, it would be necessary for Si self-interstitials to have a donor level in the lower half of the bandgap. Thus, the donor-type Si interstitial concentration would be enhanced by the Fermi-level lowering effect of the B dopant. It seems plausible that some form of the interstitialcy mode of diffusion will occur when there exists an extrinsic source of interstitial Si atoms (such as during oxidation, see later discussion). However, the donor properties of Si interstitials have not been confirmed, since it has not yet been possible to identify intrinsic interstitials definitely. Recently, Van Vechten (26) has presented experimental and theoretical arguments which show that the enthalpy of formation of the interstitial component of a Frenkel pair is $\approx$8 eV in Si (as compared to 2.8 eV for the vacancy). Thus, the ratio of the concentration of interstitials to vacancies in equilibrium in Si near the melting point would be of the order of 10^{-15} or less.

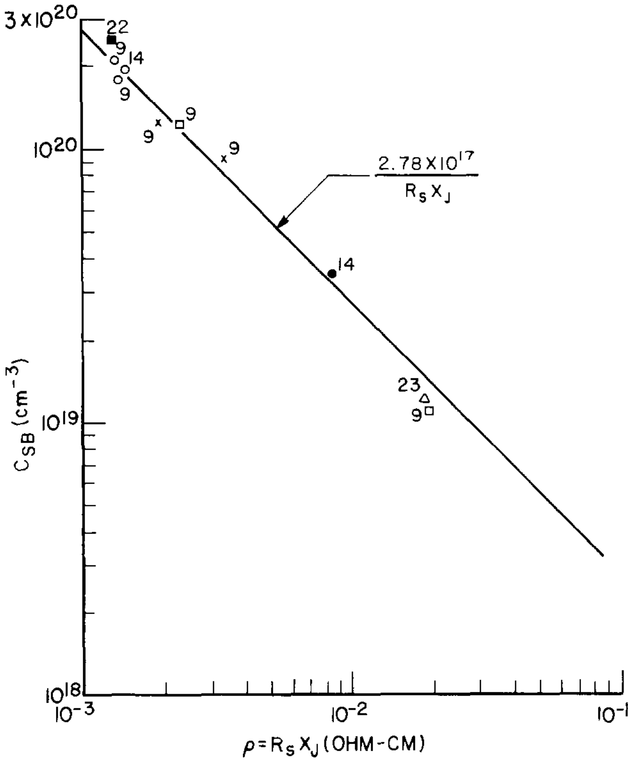

Fig. 5. B surface concentration vs. diffused layer resistivity

With regard to the divacancy mechanism of impurity diffusion discussed by Kendall and DeVries (6), Hu (4) has pointed out that since the monovacancy concentrations are $<10^{16}$ cm^{-3} in Si at high temperatures, thermal equilibrium should favor the formation of monovacancies, and divacancies will dissociate rapidly after their creation. In addition, it is apparent that monovacancies rather than divacancies are involved in the extrinsically created vacancy transients described in the present cooperative diffusion theories (27, 28), since the activation energy of monovacancy migration is much lower than that of divacancies.[1]

Watkins (5) discussed the coulombic interactions between positively charged monovacancies and ionized acceptor-type dopants in Si. Crowder *et al.* (3) showed that a positively charged defect model could be used to explain the diffusion results of B in Si. It is known from the experiments of Elstner and Kamprath (7) that an energy level exists at $E_v + 0.37$ eV associated with donor-type complexes in quenched p-type Si samples. Van Vechten (26) and Thurmond (8) have argued that these complexes will contain vacancies of the dominant charge state that existed at the temperature from which the quenching occurred. While the observed ionization spectrum of the complexes is not necessarily the same as that for the individual vacancies,[2] Van Vechten and Thurmond have shown that by assigning the $E_v + 0.37$ eV level to donor-type vacancies yields reasonable estimates of the entropy and enthalpy of vacancy formation at low temperature.

Assigning the $E_v + 0.37$ eV level to a V^+ vacancy means that above 800°K, V^+ is the dominant charge state of the monovacancy in p-type Si. Consequently, the hypothesis that B^- ions diffuse by interacting with V^+ vacancies becomes very reasonable, and will, therefore, form the basis of the B diffusion model presented here.

The ionization reaction of a neutral vacancy is given by

$$V^{o}_{Si} \leftrightarrows V^{+}_{Si} + e^- \qquad [17]$$

and the equilibrium relation is

$$K_1(T) = \frac{[V^+]}{[V^o]} n \qquad [18]$$

where n is the electron concentration. Evaluating [18] under intrinsic conditions and using the electron-hole mass-action relation gives

[1] For more complete arguments against the formation of divacancies at high temperatures, see Van Vechten [Ref. (26)] and A. Seeger and K. P. Chik, *Phys. Status Solidi*, 29, 455 (1968).

[2] In quenching experiments it is likely that most vacancies have associated with oxygen or other impurities by the time the sample has cooled. However, the effect of association is only to shift the ionization energy of the donor level by a small amount [see H. J. Stein in "Radiation Effects in Semiconductors," J. W. Corbett and G. D. Watkins, Editors, p. 125, Gordon and Breach, London (1971)].

$$\frac{[V^+]}{[V_i^+]} = \frac{p}{n_i} \quad [19]$$

where $[V_i^+]$ is the ionized monovacancy concentration under intrinsic conditions. The diffusing B will be an ionized acceptor and will control the hole concentration, p. If the diffusivity of B in intrinsic Si is D_i and is proportional to the ionized vacancy concentration, then at high B concentrations $[V^+]$ is enhanced and the diffusivity is given by

$$\frac{D}{D_i} = \frac{p}{n_i} \quad [20]$$

which is just Eq. [2]. In a similar manner, if the $[V^+]$ concentration is decreased below $[V_i^+]$ which would occur if B were diffusing in heavily doped n-type Si, then the diffusivity would decrease accordingly. In terms of the Fermi level, E_F, and V^+ energy level, E_{v^+}, Eq. [19] can be written as

$$\frac{[V^+]}{[V_i^+]} = \frac{1 + \exp[(E_{Fi} - E_{v^+})/kT]}{1 + \exp[(E_{v^+} - E_{Fi})/kT]} \cdot \frac{1 + \exp[(E_{v^+} - E_F)/kT]}{1 + \exp[(E_F - E_{v^+})/kT]} \quad [21]$$

where spin-degeneracy factors have been neglected. Equation [21] is shown plotted in Fig. 6 as a function of the Fermi level. Also shown are values of $D/D_i = [V^+]/[V_i^+]$ for several values of donor concentrations with $C_B = 5 \times 10^{19}$ cm^{-3} boron calculated from the curves of Jain and Van Overstraeten (29) in which heavy doping effects on band structure are taken into account. For $E_F < E_{Fi}$ it can be seen that values of $D/D_i > 10$ can be obtained at high B concentration at 1000°C, in agreement with the data of Fig. 1b. For $E_F > E_{Fi}$, values of $D/D_i < 0.1$ are possible.

As an example of a profile calculation using Eq. [21], the results of Crowder *et al.* (3) will be simulated. They implanted B into intrinsic Si and into Si doped with $\approx$ 1-2 $\times$ 10^{20} cm^{-3} As (assumed to be the electrically active As concentration). Both kinds of samples were subsequently diffused at 1000°-1100°C for 30-120 min. The resulting profile data are shown in Fig. 7 for a 40 keV, 1.15 $\times$ 10^{15} cm^{-2} implant (30). It can be seen from Fig. 7 that the B diffusion was retarded in the As-doped sample. This retardation

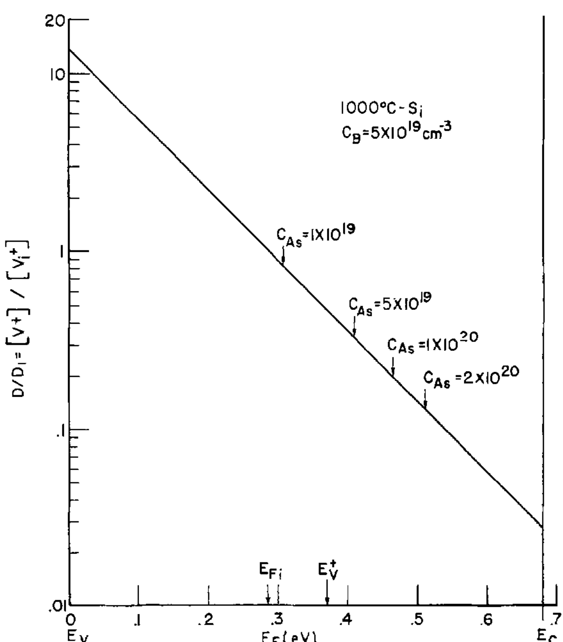

Fig. 6. Normalized concentration of positively charged vacancies vs. Fermi energy.

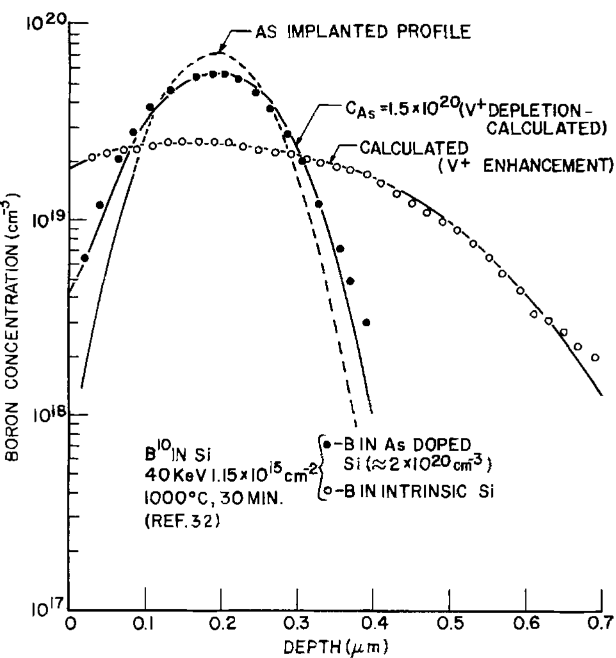

Fig. 7. Calculated B profiles in heavily As-doped Si and in intrinsic Si. The data are from Ziegler *et al.* (30).

cannot be attributed to As-vacancy complexing since a diffusion source for As was not used during the B drive-in (31) (As$^+$-complex equilibrium probably had been established already). Therefore, in order to determine whether the B retardation was due to a depletion of positively charged vacancies as described by Eq. [21], the diffusion equation for B in the presence of As was solved with values of D determined from Fig. 2 and 6. Thus

$$\frac{\partial C_B}{\partial t} = D \frac{\partial}{\partial x}\left[h_1 \frac{\partial C_B}{\partial x}\right] \quad [22]$$

where $\partial C/\partial x$ (As) $\cong$ 0 (uniformly As-doped Si) and h_1 is the field enhancement factor described in Ref. (28). Since no data was published on the as-implanted B profile, the straggle and range were extrapolated from a 50 keV, 1 $\times$ 10^{15} cm^{-2} B implantation profile obtained by Tsai (9) using the secondary ion mass spectrometry technique (SIMS). The parameters used for 40 keV B in Si were R_p = 0.19 μm and ΔR_p = 0.062 μm. Excellent agreement between the calculated and measured profiles resulted with $D = 3.7 \times 10^{-15}$ cm^2/sec, [compares to 2 $\times$ 10^{-15} cm^2/sec as determined by Crowder *et al.* (3)] corresponding to a background As doping of $\approx$ 1.5 $\times$ 10^{20} cm^{-3} (E_F = -0.19 eV). The B redistribution in intrinsic Si was calculated with $D_i = 2.1 \times 10^{-14}$ cm^2/sec, and the concentration dependence of D was accounted for by using Eq. [21] and the calculated local Fermi level. Good agreement with the data also is obtained. Additional data and calculations are published elsewhere in support of the vacancy model (32).

Orientation-dependent diffusion during oxidation.— Up to this point, consideration in this study has been given only to the diffusion of B in nonoxidizing ambients. However, a considerable amount of information has been reported on the enhanced diffusion of B during oxidation and the orientation dependence of this enhancement. Recently, Hu (33) presented a quantitative model of B diffusion during oxidation in which he combined the observations of stacking fault growth and B diffusion characteristics. Briefly, it is known that the rate of growth of stacking faults is dependent upon the crystal orientation of surface planes, and increases in the order (111), (110), and (100). The B

diffusivity is also dependent upon orientation, and increases in the same order.

Sanders and Dobson (34) have pointed out that mass transfer in Si is responsible for oxidation-induced fault growth which could result from the flow of Si self-interstitials from the interface into the Si substrate bulk. Hu's model for the formation of faults is based upon this observation.

In order to correlate enhanced B diffusivity with enhanced Si interstitial density, Hu assumed that B diffused (at least partially) by the interstitialcy mechanism. This observation is consistent with the fact that the Si interstitial prefers to replace Group I, II, and III substitutional impurities (but not Group V substitutional impurities) (35, 36). Thus, one can envisage the oxidation-induced flux of Si interstitials interchanging with B atoms and creating B interstitials which migrate through the lattice until they interact with a vacancy, and then continue to diffuse via a vacancy mechanism. The fact that Si interstitials do not readily replace Group V substitutional impurities (presumably because the enthalpy of Group V interstitial formation is larger) explains why the enhanced diffusion of As (but sometimes P) during oxidation is not observed (37, 38).

Summary and Conclusions

The apparent diffusion coefficient of B in Si increases linearly with ionized B concentration for $C_B > n_i$. Consequently, the erfc impurity distribution function may only be used with confidence when C_{SB} is $\lesssim 10^{19}$ cm^{-3}. When B diffuses into heavily As-doped Si, the diffusion is retarded. In this paper the model invoked to explain these results assumes that in p-type Si the dominant charge state of monovacancies is V^+ at typical diffusion temperatures. The concentration of V^+ increases linearly with ionized boron concentration from $[V_i^+]$, where $[V_i^+]$ is the concentration of V^+ in intrinsic Si. For the situation in which the background n-type doping is greater than the local B concentration, $[V^+]$ decreases as the background doping increases, thus affecting a decrease in the B diffusivity. It should be pointed out that the V^+ depletion effect is a "local" effect, and does not contribute significantly to the "long-range" interactions that have been observed between B and in-diffusing P and As regions in Si. These interactions have been attributed to extrinsic vacancy transients (27, 28).

The diffusivity of B can also be enhanced by Si self-interstitials which are known to replace the substitutional B atoms, making them interstitial B atoms. These B atoms then migrate to a vacancy wherein normal diffusion (monovacancy mechanism) continues until interaction with another Si self-interstitial occurs. Since the concentration of Si interstitials is extremely small under equilibrium conditions, this type of diffusion enhancement will only occur when Si interstitials are extrinsically generated (such as during oxidation). Since during oxidation the concentration of Si interstitials is so much greater in (100) oriented Si than in (111) Si, enhanced B diffusivity and stacking fault growth in (100) Si should be, and are, observed.

Acknowledgments

The author would like to thank Dr. J. C. Tsai for making his B profile data available for this work. Discussions with Dr. L. E. Katz are also gratefully acknowledged.

Manuscript submitted July 19, 1974; revised manuscript received Feb. 16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Bell Laboratories.

Department of Chemistry, University of Surrey, Guildford, Surrey GU2 5XH, England

ABSTRACT

The increasing demand for finely powdered boron carbide together with the rapidly rising cost of this material has stimulated research into alternative methods for its production. When boron trichloride is reacted with methane-hydrogen mixtures in a radio frequency argon plasma, boron carbides of variable B/C ratios are obtained as submicron powders, the product stoichiometry depending on the reactant composition. This reaction has been studied over a range of reactant compositions and flow rates to obtain information about the reaction mechanism involved and the growth of particles from the gas phase. The amount of reaction taking place and the product stoichiometry have been determined as functions of the reactant stoichiometry and flow rate using a factorial experimental design. The products obtained were studied by x-ray diffraction analysis to determine any changes in crystal structure with composition. It was found that the B/C molar ratio of the products varied linearly with the B/C molar ratio of the reactants, was unaffected by the H_2/BCl_3 molar ratio (for $H_2/BCl_3 > 1$) and decreased as the reactant flow rate increased. X-ray diffraction analysis of the products revealed that the lattice parameters of the crystalline material decreased linearly as the carbon content increased up to the composition B_4C. Samples containing excess carbon over the composition B_4C showed the presence of free graphite, while most of the samples with a carbon content of less than 13.6% (corresponding to B_7C) also showed the presence of β-rhombohedral boron, the product obtained in the absence of methane. Line broadening measurements suggest that the crystallite sizes of both the boron carbide and β-rhombohedral boron lie in the 200-300Å range.

Boron carbide has a combination of physical, electrical, mechanical, and nuclear properties which have resulted in its being used in such diverse applications as control rods for nuclear reactors, armor plating, electrodes, and shot-blast nozzles. In most cases the boron carbide is fabricated by being hot-pressed in a mold. The process requires careful control over the particle size range in the powder. Where the maximum density, hardness, and surface finish are important, the use of fine powder ($< 5\ \mu m$) reduces processing costs and improves product quality. Because boron carbide is so hard, its comminution by conventional techniques *e.g.*, ball-milling, is expensive and usually leads to a product contaminated with iron from the grinding process. Figure 1 shows how the cost of commercially available boron carbide varies with particle size.

An rf plasma torch has recently been used in this laboratory to produce pure boron (1, 2) and the technique has now been extended to boron carbide. The results of some early experiments have already been published (3). In this paper we describe further work on the reaction between boron trichloride, methane, and hydrogen and the nature of the product obtained. The reaction, represented by the equation

$$4BCl_3 + CH_4 + 4H_2 \rightarrow B_4C + 12HCl$$

has been studied over a range of reactant compositions and flow rates in order to obtain information about the reaction mechanism and the growth of particles from the gas phase.

The production of boron carbide by reaction of boron trichloride with a hydrocarbon or hydrogen/hydrocarbon mixture is well known. Where the interest has been in the preparation of protective coatings, chemical vapor deposition techniques have been used to produce boron carbide films on a variety of substrates including graphite, tungsten, tantalum, mullite, silica, molybdenum, and boron nitride.

Key words: boron, carbide, plasma, mechanism, structure.

Boron carbide films have been produced by the reaction between boron trichloride and methane on an induction-heated graphite substrate (4) and by the reaction between BCl_3/H_2 (1:1) mixtures containing 2 volume per cent (v/o) toluene (5). The use of $BCl_3/CH_4/H_2$ mixtures has been widely investigated (6-10) and $BBr_3/CH_4/H_2$ mixtures have been used to deposit $B_{13}C_2$ crystals onto a boron nitride substrate (11). Patents have been issued covering the deposition of boron carbide films from BCl_3/C_3H_8 mixtures in an electrical discharge (12), BCl_3/CH_4 mixtures (13) and $BCl_3/CH_4/H_2$ mixtures (14, 15). The preparation of boron carbide powder by reaction of BCl_3/CH_4 mixtures in a hydrogen plasma jet is covered by one patent (16). The product formed is said to have a mean particle diameter of 0.02 μm.

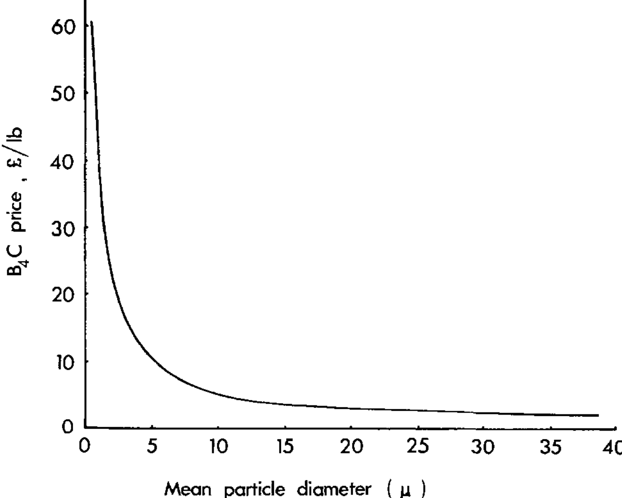

Fig. 1. Boron carbide selling price as a function of particle size (U.K. prices, 1974).

Apparatus and Procedure

A diagram of the apparatus is shown in Fig. 2. The plasma torch consisted of a water-jacketed silica tube 50 mm ID × 70 mm OD × 200 mm long fitted with a tangential inlet at one end for the plasma-forming gas. The torch was sealed to a water-cooled brass tail ring through which reactants were introduced to the plasma tail-flame. The products were passed down a water-cooled brass quench tube 50 mm ID × 1500 mm long and through a glass-fiber bag-filter which retained the boron carbide powder. The waste gases were passed up a scrubbing tower to remove acid by-products before being released to the atmosphere. Power for the plasma was supplied by a Radyne RD 300 0-30 kW rf generator operating at a frequency of 2-5 MHz.

Boron trichloride was produced on site by the interaction of chlorine with commercial grade boron carbide, its purity being determined by IR spectroscopy and observations of its color. The main impurity detected spectroscopically was hydrogen chloride [< 0.5 weight per cent (w/o)]; the absence of any color in the liquid indicated that it was free from iron and lower boron chlorides. Methane (C.P. grade) was supplied by British Oxygen Limited, argon and hydrogen (commercial grades) were supplied by Air Products Limited.

The plasma was initiated in argon but could be run on boron trichloride or argon/boron trichloride mixtures as required. To maintain the maximum coupling efficiency of the generator to the plasma adjustments to the size of the inductance coils were made to match the resistive load of the different plasma gases used. Boron trichloride (bp 12.5°C) was vaporized in a simple coil heat exchanger immersed in a water bath at 80°C before being mixed with the other reactants.

After each run a sample of the product formed was degassed *in vacuo* to remove adsorbed BCl_3 which would otherwise have hydrolyzed on exposure to the atmosphere and contaminated the product with boric acid. The upgraded products were analyzed for total boron, carbon, and water-soluble boric oxide contents. The x-ray diffraction pattern of each sample was determined on a Philips 1050 goniometer using CuK α radiation.

Experimental Results

The reaction between boron trichloride and methane was carried out in the absence of argon and hydrogen by addition of methane to the tail-flame of a boron trichloride plasma. A plasma power of 28 kW with a boron trichloride flow rate of 100 g/min was used throughout this section of the work, with methane being added in amounts giving CH_4/BCl_3 molar ratios of 0.125-0.750. In all cases it was found that the product contained a higher proportion of carbon than indicated by the equation

$$4BCl_3 + 3CH_4 \rightarrow [B_4C_3] + 12HCl$$

the stoichiometry of which predicts a carbon content of 45.4 w/o. Equations of other stoichiometries predict the formation as by-products of either chlorinated hydrocarbons or chloroboranes for products that are boron-rich or carbon-rich respectively relative to $[B_4C_3]$. The gaseous reaction products were analyzed by IR spectroscopy and gas chromatography and found to contain appreciable amounts of hydrogen and dichloroborane, $BHCl_2$, in addition to hydrogen chloride and unreacted boron trichloride. When boron trichloride was reduced with hydrogen alone, *i.e.*, in the absence of methane, dichloroborane was not formed.

In Fig. 3 and 4 the conversions of boron trichloride and methane respectively to solid product are plotted as functions of the reactant composition. It was found that the boron trichloride conversion was proportional

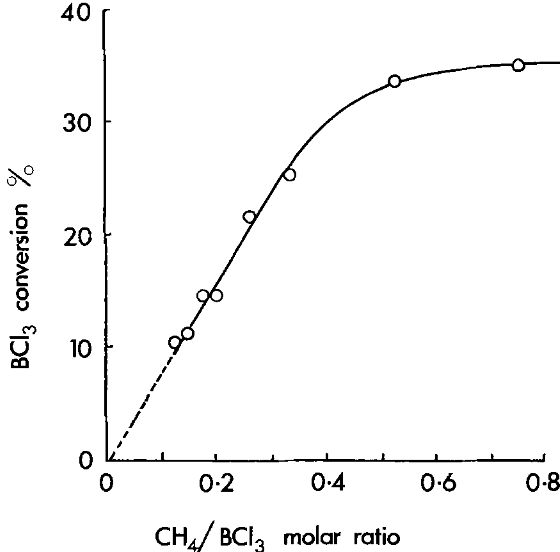

Fig. 3. BCl_3 conversion vs. (CH_4/BCl_3) molar ratio. Reaction carried out in the absence of argon and hydrogen. Plasma power, 28 kW; BCl_3 flow rate, 100 g/min.

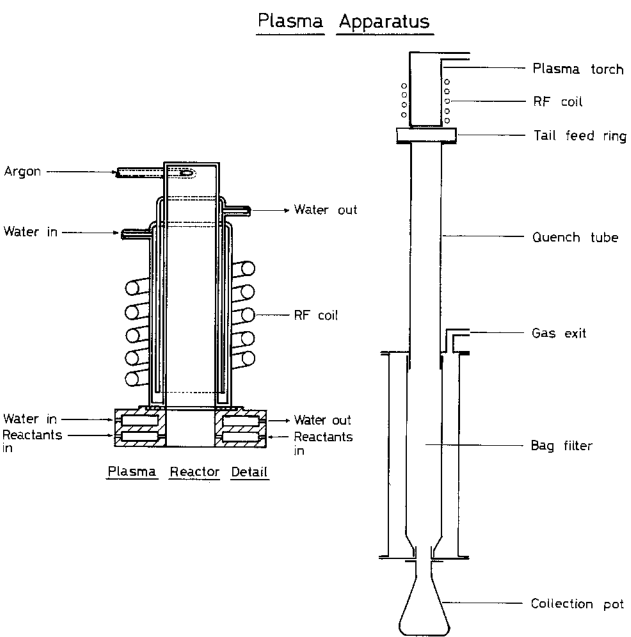

Figure 2

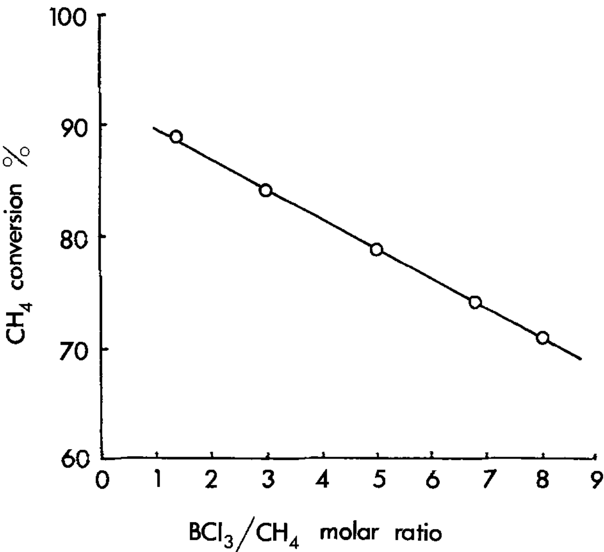

Fig. 4. CH_4 conversion vs. (BCl_3/CH_4) molar ratio. Reaction carried out in the absence of argon and hydrogen. Plasma power 28 kW, BCl_3 flow rate 100 g/min.

to the CH_4/BCl_3 molar ratio for $CH_4/BCl_3 < 0.35$ and tended to a maximum of about 35% at higher methane concentrations. The methane conversion decreased linearly with the BCl_3/CH_4 molar ratio over the range of experimental conditions investigated.

The reduction of boron trichloride by CH_4/H_2 mixtures was carried out under constant reactor conditions by feeding a mixture of the reactants into the tail-flame of a 20 kW argon plasma (argon flow rate 40 liters/min). The effect of varying the composition and throughput of the reactants was investigated by means of a $3 \times 3 \times 6$ factorial experiment in which the three variables and their values were:

BCl_3 flow rate (g/min)	:	20, 60, 100
H_2/BCl_3 molar ratio	:	1, 4, 8
CH_4/BCl_3 molar ratio	:	0, 0.05, 0.063, 0.083, 0.125, 0.25

Thus eighteen different compositions were each reacted at three different flow rates. The upper limit to the CH_4/BCl_3 molar ratio was chosen as that value which yielded a product containing carbon in excess of B_4C; x-ray analysis showed that such products usually contained free graphite.

The product from each run appeared as a light fluffy powder containing small compacted flakes. These flakes broke up readily on passage through a coarse mesh sieve (250 μm aperture) to give a free-flowing powder. The products ranged in color from brown for plasma boron through gray to black for products with a high carbon content. The product was usually found to contain a small amount (1-2 w/o) of boric oxide. This was believed to be due either to hydrolysis of boron trichloride which the upgrading process had failed to remove, or to the presence of air remaining after the apparatus had been flushed with argon before each run. The boron carbides prepared by the reaction of boron trichloride and methane alone also contained boric oxide, indicating that the argon and hydrogen were not sources of oxygen. The amount of boron present as boric oxide was subtracted from the total boron content before calculation of product stoichiometry.

In Fig. 5 the boron-to-carbon ratio in the product, $(B/C)_P$ is shown as a function of the boron-to-carbon ratio of the reactants, $(B/C)_R$. Over the range of experimental conditions investigated, a linear dependence was observed except when the reactant flow rates, BCl_3/H_2 ratios and $(B/C)_R$ ratios were all high. Under these conditions the products contained a substantial excess of carbon over B_4C. Provided hydrogen was present in excess, the $(B/C)_P$ ratio was largely independent of the H_2/BCl_3 ratio. The $(B/C)_P$ ratio increased as the reactant flow rate decreased, *i.e.*, as the residence time increased.

The experimental data on the conversions of boron trichloride and methane to boron carbide show considerable scatter when plotted against reactant composition. This scatter is probably due to inefficient retention of the product by the bag-filter during the early stages of each run. This would cause the calculated conversions of boron trichloride and methane to appear too low. A finer grade of filter tended to block causing premature termination of the run. Significant effects were identified by a Yates analysis of the original data (17). Yates analyses were carried out for the conversions of boron trichloride and methane separately and also the $(B/C)_P$ ratio. The significant effects are listed below in terms of the H_2/BCl_3 ratio (a), the boron trichloride flow rate (*i.e.*, total reactant flow rate) (b) and the CH_4/BCl_3 molar ratio (c), in order of significance:

1. BCl_3 conversion : $-$b, $-$ab, a
2. CH_4 conversion : $-$ab, $-$bc, $-$b
3. $(B/C)_P$: $-$c, a, $-$b

The negative sign indicates that the measured quantity decreases as that factor or interaction increases. Variations in H_2/BCl_3 molar ratio had as much effect on the residence time of the reaction as had variations in total flow rate. This leads to possible ambiguities in interpretation of the results.

In general terms it was found that at high boron trichloride flow rates (100 g/min) the boron trichloride conversion remained approximately constant at about 25% over the whole range of reactant compositions, while the methane conversion decreased both with increasing methane concentration and increasing hydrogen concentrations. At low boron trichloride flow rates (20 g/min), however, the reverse effect occurred with both the boron trichloride and methane conversions increasing as both the methane and hydrogen concentrations increased (Fig. 6).

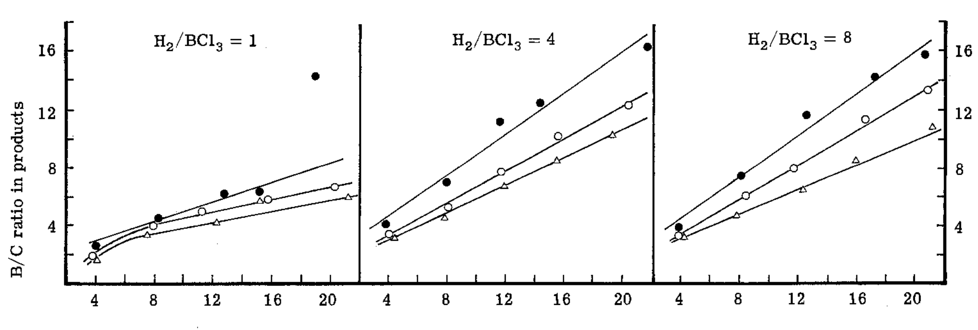
When the flow rates of each reactant composition were varied, it was found that for hydrogen-deficient compositions ($H_2/BCl_3 = 1$) the amount of reaction taking place was approximately independent of the residence time. When the hydrogen was present in excess, the amount of reaction increased with time, the increase becoming more pronounced as both the CH_4/BCl_3 and H_2/BCl_3 ratios increased.

Production rates varied with reaction conditions and no attempt has yet been made to optimize this process for the production of boron carbide. Production rates of about 250 g/hr were achieved during the course of this experimental work.

Crystallographic Results

When boron trichloride is reduced with hydrogen in a thermal rf plasma, β-rhombohedral boron (the high temperature form) is obtained (18, 19). The addition of small amounts of methane to the system yielded a product shown by x-ray diffraction analysis to contain both β-rhombohedral boron and boron carbide (α-rhombohedral boron structure). The presence of β-rhombohedral boron was detected in all samples with carbon contents from 6.2 w/o (the lowest prepared) to 10.9 w/o and in some other samples with carbon contents up to 13.9 w/o. Free graphite was detected in all but one of the samples with carbon contents in excess of 21.5 w/o.

The position of the boron carbide peak corresponding to the (021) reflection was determined as a function of the carbon content of each product (Fig. 7). During



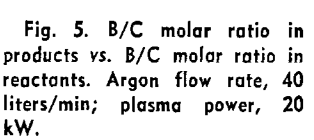


Fig. 5. B/C molar ratio in products vs. B/C molar ratio in reactants. Argon flow rate, 40 liters/min; plasma power, 20 kW.

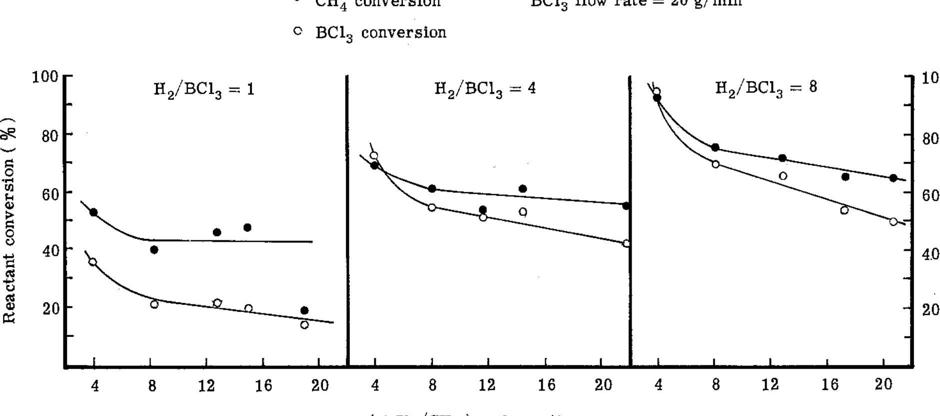

Fig. 6. Reactant conversion vs. (BCl_3/CH_4) molar ratio. Argon flow rate, 40 liters/min; plasma power, 20 kW.

these measurements it was found that, for thick layer samples of each product (~ 1.5 mm), the diffraction peak was distorted and the apparent peak position was too low. This was explained (20) as being due to absorption and multiple reflection of the incident radiation by elements of low atomic number in samples thicker than about 50 μm. The boron carbide peak position was remeasured using thin layer samples obtained by painting a slurry of each product in acetone onto a glass slide. This method led to greatly reduced sensitivity, but produced symmetrical peaks whose position could be measured with an accuracy of ± 0.02° 2θ.

The displacement of the boron carbide peak position in samples with low carbon contents towards higher values of the diffraction angle is consistent with the evidence that these samples also show the presence of free boron. Thus the boron carbide peak in these samples will have arisen from crystallites with a higher carbon content than the sample as a whole.

Line broadening measurements carried out on five samples indicated that the crystallite sizes of both boron carbide and β-rhombohedral boron lay in the range 200-300Å.

Figure 8 shows an electron micrograph of a typical product with the composition B_4C.

Discussion of Plasma Results

At this stage in the work, any mechanism for this reaction would be speculative. A number of interesting features, however, deserve comment.

1. Work on the BCl_3/H_2 reaction (1) has suggested that boron trichloride dissociates completely and reversibly under plasma conditions yielding mainly BCl and chlorine but also BCl_2 and B atoms. Hydrogen, in contrast, is known not to dissociate more than a few per cent in the plasma. Methane is assumed to give $CH_3\cdot$ as a primary product (21) which then combines to give C_2 compounds. These lose hydrogen, and the main product is acetylene formed via $C_2H\cdot$.

2. The thermal dissociation of methane is inhibited by hydrogen (22) and the effect is said to be proportional to $[H]^4$. Presumably it acts by displacing to the left the equilibria involved in the hydrogen loss processes. If the thermal decomposition of methane and the formation of such species as $C_2H\cdot$ were important in the reaction, then addition of hydrogen to the CH_4/BCl_3 reaction mixture should suppress $C_2H\cdot$ formation and hence increase the $(B/C)_P$ ratio. Figure 5 shows that this is qualitatively true at low proportions of hydrogen, although the effect is not as large as one would

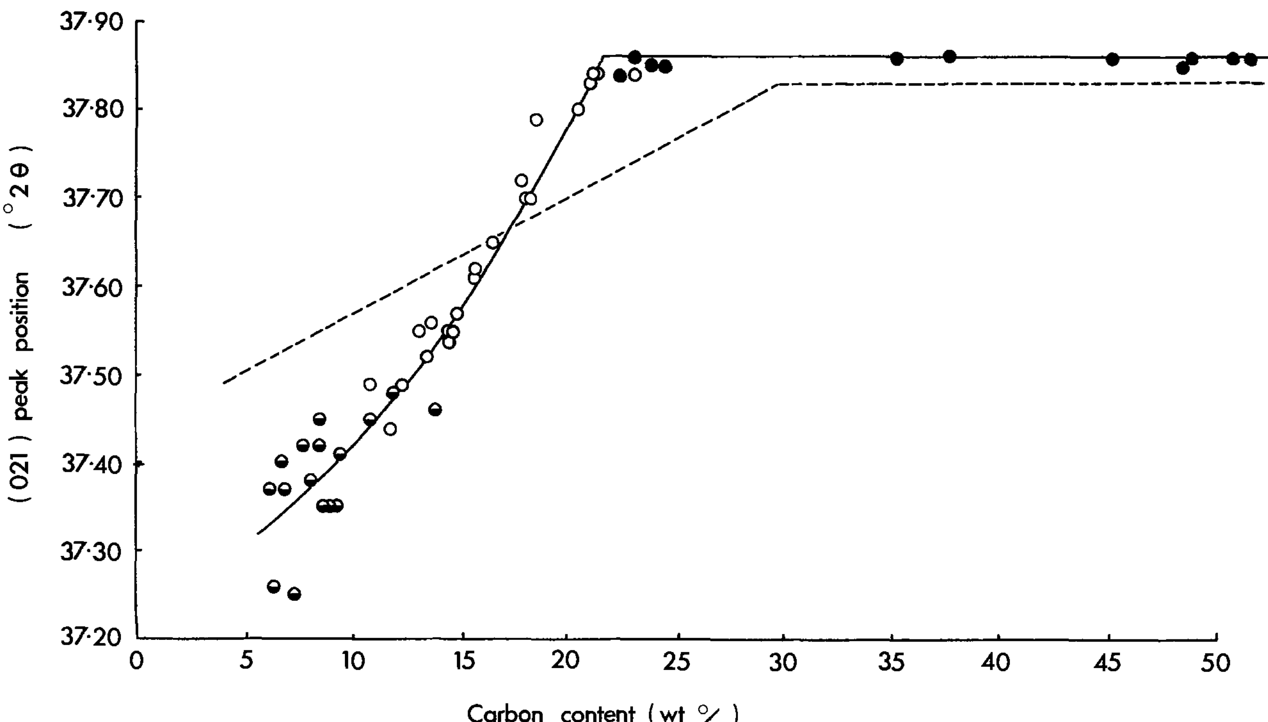

Fig. 7. XRD study of plasma B_4C. 2θ values of the (021) reflection vs. carbon content. ○ Boron carbide, ● boron carbide containing free graphite, ◒ boron carbide containing free boron, - - - Ref. (23).

Fig. 8. Electron micrograph of B_4C. (X40,000).

expect, and that in the presence of excess hydrogen additional hydrogen has virtually no effect. It is possible that removal of $C_2H^{\cdot}$ by a reaction to give a boron carbide might swing the equilibria back to the right, but it is unlikely that this would balance the contrary effect of hydrogen. Examination of the reaction by-products for traces of acetylene etc. should provide a crude test of this.

3. The formation of dichloroborane is difficult to explain simply. The reaction

$$BCl_3 + H_2 \rightarrow BHCl_2 + HCl$$

is attractive but does not explain why dichloroborane is formed in BCl_3/CH_4 plasmas and in $BCl_3/CH_4/H_2$ plasmas but not in BCl_3/H_2 plasmas. As the chlorination of methane would require several steps, it is reasonable to suppose that dichloroborane is formed from a boron compound which already contains two atoms of chlorine, *i.e.*, BCl_3 or BCl_2. Exchange reactions of the type

$$BCl_3 + CH_x \rightarrow BHCl_2 + CH_{x-1}Cl$$

are *prima facie* unlikely and would lead to chlorinated hydrocarbons in the reaction products which we have been unable to detect. However, processes of the type

$$BCl_2 + CH_x \rightarrow BHCl_2 + CH_{x-1}$$

are much more likely. Hamblyn *et al.* (18) considered that BCl_2 was only a minor product of the dissociation of boron trichloride, but this view was based on the intensity of BCl_2 lines in the emission spectrum. The formation of ground-state BCl_2 would have been overlooked by this technique.

4. The greatest conversion of boron trichloride to boron carbide (93%) was obtained at a low boron trichloride flow rate (20 g/min), a high H_2/BCl_3 ratio (8:1), and stoichiometric CH_4/BCl_3 ratio (1:4). In general the amount of reaction taking place increased with residence time except under hydrogen-deficient conditions. In the BCl_3/H_2 work, it appeared that after the boron trichloride has dissociated, the hydrogen acted merely as a scavenger for the chlorine. It is possible that in the present work, hydrogen is again scavenging chlorine and the B, BCl, and BCl_2 fragments are reacting with the CH_x species. The idea is supported by the observation (Fig. 5) that as the residence time of any given reaction mixture increases, so does the $(B/C)_P$ ratio of the product obtained. This implies that an initial boron-carbon compound is formed which subsequently reacts slowly with further boron-containing species. It may well be the reverse of the process by which, when boron carbide is heated, boron evaporates from the lattice.

Discussion of Crystallographic Results

The results of the x-ray work are in qualitative agreement with the results of Glaser, Moskowitz, and Post (23) who found that the lattice constant of the boron carbide unit cell decreased as the carbon content increased. However, the amount of variation was greater than they found, and the limiting carbon content was found to be 21.6 w/o as compared with their figure of 30 w/o. We attribute the discrepancy to differences in experimental technique mentioned in the results section. The change in the d spacing of the lattice corresponded to a change in the b axis from 5.43 to 5.35Å and in the c axis from 12.31 to 12.12Å as the carbon content increased from 6.2 to 21.6 w/o.

The figure of 21.6 w/o is significant because it implies a compound of formula B_4C (carbon content 21.7 w/o). The structure of this compound was originally determined by x-ray diffraction analysis (24, 25) and was reported to consist of B_{12} icosahedra and linear C-C-C chains. It was subsequently shown by nmr investigations (26) that the central atom of the triatomic chain was in fact a boron atom, and two distinct phases have since been identified; $B_{13}C_2$, otherwise $B_{12}(CBC)$ and $B_{12}C_3$, in which one icosahedral boron atom is replaced by a carbon atom to give $B_{11}C(CBC)$. Of these two, $B_{13}C_2$ is the more thermally stable and is the only congruently melting phase.

It has recently been suggested (27) that the phase $B_{11}C(CBC)$ is not formed at temperatures below 1800°C, and possibly below 2500°C, but that a phase of composition $B_{13}C_3$, *i.e.*, $(B_{12}(CBC)C)$, containing one interstitial carbon atom per unit cell is formed instead. This composition has a carbon content of 20.4 w/o, and it was stated that all samples with carbon contents > 21.0 w/o contained free graphite. Our results do not support this conclusion. Figure 7 includes five points obtained from samples containing more than 20.4 w/o carbon (four of them containing more than 21.0 w/o carbon) none of which show the presence of free graphite. The point of intersection between the rising curve and the horizontal line in Fig. 7 represents the point at which the lattice ceases to change. It appears to come at a carbon content of 21.7 w/o corresponding to B_4C, and to move this point to a carbon content of 20.4% would not fit so well with the experimental data. The difference between 21.7 w/o carbon and 20.4 w/o carbon is not large but we feel that the balance of probability in this work favors the more conventional formula B_4C.

I-V Characteristics of PtSi-Si Contacts Made from CVD Platinum

Myron J. Rand*

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

Small amounts of phosphorus codeposit during the chemical vapor deposition of thin-film platinum from $Pt(PF_3)_4$. Because of the possibility that the P may dope a narrow zone of adjacent Si during silicide formation, the room temperature *I-V* characteristics of such PtSi contacts made at 450°-700°C to various Si types were investigated. CVD Pt readily forms PtSi in a few minutes at temperatures as low as 450°C. Contacts to n^+ or p^+ Si made at 450°-700°C are ohmic. Contacts formed at 450°C to lightly doped n-Si are good quality Schottky barrier diodes with a barrier height of 0.84 eV and an "ideality factor" $n = 1.02$. At higher sintering temperatures the reverse current increases, and with sintering at 650°-700°C the contact becomes ohmic. In the case of lightly doped p-Si, PtSi contacts made at 450°C from CVD Pt have an ohmic room-temperature characteristic, as expected. If the silicide is made at 700°C, a p-n junction is created in the p-Si. PtSi contacts made from CVD Pt at 450°C are thus electrically equivalent to those made from sputtered Pt at ~ 600°C. At higher formation temperatures, deviations from expected behavior are observed, all of which are consistent with diffusion of phosphorus from the PtSi into the Si to a depth in the range 10-100Å.

The chemical vapor deposition (CVD) of thin-film platinum by $Pt(PF_3)_4$ pyrolysis was developed to provide a simple and radiation-free Pt deposition for high-reliability PtSi contacts to silicon and for beam-lead metallization (1). It was soon discovered that small amounts of phosphorus codeposit with the platinum, and that this phosphorus is not uniformly distributed in depth but instead concentrates at interfaces (2). Depending on what happens when Pt on Si is heated to form the silicide, the phosphorus, if it has any detectable effect at all, might be either helpful, *e.g.*, in gettering impurities or harmful, *e.g.*, by changing Si doping levels and therefore current-voltage characteristics. It was the purpose of the work reported here to see in at least a preliminary way if there are any restrictions on the use of CVD Pt in contacting Si, or any phenomena different from those seen with sputtered or e-gun Pt.

Some aspects of the interdiffusion of CVD Pt and single-crystal Si have already been reported (2, 3). With the usual Pt thicknesses of 500-1000Å the reaction to PtSi is complete in 10 min at 450°C. The PtSi grain size, as seen by transmission electron microscopy, is about 600Å, or about 900Å if formed at 625°C in 10 min. A low-voltage-sputtered Pt sample diffused at the same time gave PtSi grain sizes about twice these values. The phosphorus profiles have been investigated by sputtering-Auger and ion-probe methods. At present these cannot give accurate quantitative analyses, but the situation is believed to be as shown schematically in Fig. 1. After Pt deposition at 225°C there is a high P concentration in the outer ~ 50Å of the Pt, perhaps ~ 0.1 atom per cent P in the bulk of the film, and a broad peak of 1% or so coincident with the Pt-Si interdiffusion zone. When PtSi is formed,

Key words: chemical vapor deposition, platinum, platinum silicide, contacts to Si, Schottky barrier diodes.

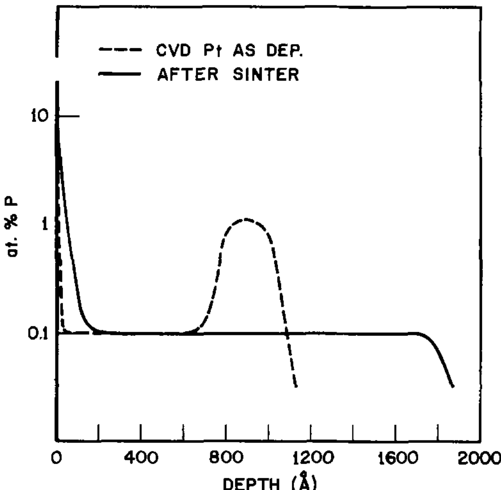

Fig. 1. Phosphorus profiles in 900Å CVD Pt on 4 ohm-cm As-doped <100> Si, as deposited and after sintering to 1800Å PtSi. %P is approximate only. Note that the ordinate scale is logarithmic.

this latter P moves to the outer surface, and no accumulation can then be detected at the PtSi-Si interface.

This behavior would seem to be harmless to the electrical properties of PtSi contacts, but the analytical methods lack both adequate sensitivity and depth resolution to assure that there is no phosphorus doping of the Si. The contacts themselves are the best tool for this. We report here room-temperature current-voltage characteristics and other diagnostic experiments on both Schottky barrier and ohmic PtSi contacts to various Si types where the PtSi was formed from CVD Pt at varying temperatures.

Both conventional and guard-ringed structures were studied. In the latter a diffused diode, *e.g.*, p^+ Si in n-Si, underlies the periphery of the silicide and blocks leakage caused by edge effects such as diffusion spikes, stress concentrations, small radii of curvature, etc. Results using guard rings characterize the best attainable contact interfaces. Those from unguarded contacts have practical usefulness because integrated circuit designers may choose to avoid the extra processing and chip space guard rings require if some leakage can be tolerated.

Experimental

Test arrays were fabricated in 3μ thick epitaxial Si, 2-6 ohm-cm As or B doped, on heavily doped <100> or <111> substrates, in order to minimize series resistance which would mask the contact characteristics. Square windows ranging in size from 0.5 to 20 mils were opened in 6000Å thermal SiO_2. Some windows were enclosed by heavily diffused rings of the opposite type and some left unguarded. (The SiO_2 mask extended to the middle of the guard ring.) In each array a heavily diffused (P or B) ohmic contact was included, and also a heavily diffused contact of opposite conductivity type, to provide a p-n diode. The latter was made in the same diffusion step as the guard rings and thus served as a control for their characteristics. With the processing sequence used, diffusions were $\sim 1\mu$ deep.

Test slices were given a 45 sec dip in 3% HF before loading into the CVD apparatus, but no other cleaning or surface treatment. Platinum was deposited in 1 atm hydrogen at 225°-250°C at 40-80 Å/min to a thickness of 500-800Å. Sintering was done in ultrahigh-purity grade (99.999%) hydrogen (Matheson Gas Products) in a tube furnace, temperatures and times as given. Some samples received an additional air-bake to increase resistance to aqua regia (3). Platinum was stripped in 50% 7:1 HCl:HNO_3 at 85°C; the clearing time was 1-2 min. After 1 min in 3% HF the patterns were metallized with $0.7\text{-}1.0\mu$ filament-evaporated Al, contact pads for the probes being provided some distance removed from the silicide contacts. The Al was not further sintered, since here it serves only to contact PtSi and not to form contacts to Si.

Current-voltage curves were displayed using a Tektronix 576 Curve Tracer, and currents were measured by standard electrometer techniques. The diffused ohmic contact, rather than the back of the slice, was always used as one contact. The result of probing two ohmic contacts was checked in several locations on each slice. In the case of Schottky barrier contacts, the effect of contact dimension was observed by measuring reverse currents of 1, 3, 8, and 20 mil contacts and plotting current *vs.* dimension on a log-log scale. On all occasions the slope of this plot was 2, showing leakage current proportional to contact area. If leakage were occurring chiefly at edges the slope would have been close to unity.

An additional test of ohmic contact integrity was provided by a test pattern devised by Bindell (4), which contains arrays of 600 contacts series-connected alternately by p^+ diffusions and by metallization. A single high-resistance or rectifying contact in the entire chain is easily detected. Statistics are provided by four window sizes and 55 chips per wafer.

One determination was made of the resistivity of the PtSi, a quantity for which most existing reports are estimates only. For this purpose Pt was deposited on a ¼ × ½ in. strip of 50 ohm-cm B-doped <111> Si and sintered at 525°C, 30 min. After sheet-resistance measurement by four-point probe, part of the silicide was wax-masked and the exposed remainder removed by etching in buffered HF, 1 min, followed by 85° aqua regia and then another BHF treatment (3). The step height, after wax removal and Al evaporation, was determined by multiple-beam interferometry, thereby establishing the silicide thickness.

Results

PtSi Resistivity.—A 2000 ± 50Å thick PtSi film gave a sheet resistance of 1.87 ohm/□ or a resistivity of 37 μohm-cm. Using the product of electron density (5) = $1.5 \times 10^{22}/cm^3$, mobility = 13 $cm^2\ V^{-1}\ sec^{-1}$, and electronic charge = 1.60×10^{-19} coulomb, a conductivity of $3.1 \times 10^4\ cm^{-1}\ ohm^{-1}$ may be calculated, or a resistivity of 32 μohm-cm. For single-crystal PtSi a value of 27 μohm-cm has been reported (6).

Ohmic contact.—The work reported here involved examination of several hundred PtSi contacts made from CVD Pt and single-crystal Si at temperatures from 450° to 700°C. No case of failure to silicide was seen. Reaction invariably occurred over the entire window area and produced a smooth, characteristically pearl-gray contact. When two ohmic contacts were probed using the curve tracer the *I-V* curve was linear, on either side of the origin, to current densities beyond 400 A/cm^2. Observed resistances were within less than a factor of 2 of those calculated from a knowledge of the test structure geometry and epitaxial layer resistivity.

Table I gives results of a test employing the arrays of 600 series-connected contacts. Here the CVD Pt

emerges superior to e-gun Pt sintered in identical fashion, and at least the equal of typical Pd_2Si contacts.

Schottky barrier contacts.—Figures 2 and 3 show results of reverse leakage current measurements at 5V, for guard-ringed (Fig. 2) and unguarded (Fig. 3) Schottky barrier contacts. Sinter temperatures, as shown, are in the range 450°-500°C. Most of the data are from 1 to 8 mil square contacts. Different sizes have been normalized by plotting current densities. In these log-normal probability plots, showing the distribution of the results, no data have been arbitrarily discarded. Table II summarizes the conditions and median values of J_{-5V}. Two other numbers included in the table represent the leakage of an ideal theoretical Schottky barrier and the leakage at which the contact becomes of marginal usefulness in circuit design. For this latter criterion a 1 $\mu A/mil^2$ rule of thumb has been chosen.

Table II. Reverse leakage currents of Schottky barrier contacts

Useful, allowing 1 $\mu A/mil^2$					1.5×10^{-1}

* See Ref. (5).

The guard-ringed contacts made at 450°C are very good, approaching within one or two orders of magnitude of ideality. Contacts made at 500°C are about two orders of magnitude more leaky; this is still quite acceptable.

Without guard rings the leakage increases roughly another two orders of magnitude in each case. The 450°C contacts are still safely below the 1 $\mu A/mil^2$ limit but the 500°C contacts are now within one order of magnitude of it.

After measurement, the contacts of run 71 (Fig. 2) including their Al metallization, were baked in air at 325°C for 8 hr. Leakage currents changed less than 10% in all cases, and most decreased.

A representative guard-ringed contact made at 450°C (run 74) has also been characterized by its room-temperature forward-bias characteristic, as shown in Fig. 4. A voltage change of 61 mV changes the current one decade; the 100 A/cm^2 turn-on voltage is 0.56V. These results are in close accord with the prediction of the standard forward-bias diode equation with $T = 300°K$ if ϕ_B, the barrier height, $= 0.843$ eV. ϕ_B is determined most simply by extrapolating to zero voltage to obtain the "saturation" current density

$$J_s = A^{**}T^2 e^{-q\phi_B/kT}$$

where A^{**} is the Richardson constant. Our "ideality parameter"

$$n = \frac{q}{kT}\frac{\partial V_F}{\partial(\ln I_F)}$$

is 1.02. Barrier heights for PtSi:n-Si have been reported (5, 7) in the range 0.83-0.85 eV.

Thus PtSi contacts made by interdiffusing CVD Pt and Si at 450°C are of good quality and have all the expected properties; there is no hint of the presence of electrically active phosphorus. There is no obvious reason for higher leakage in Schottky barrier contacts made at 500°C unless a narrow diffusion zone of more

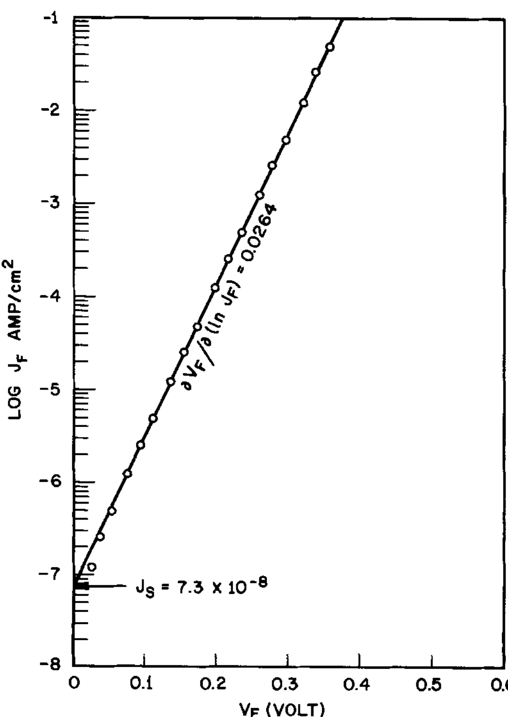

Fig. 4. Room temperature forward-bias characteristic of PtSi:n-Si Schottky barrier contact (run 74).

heavily doped Si has formed at the PtSi-Si interface. If this occurs, sintering at yet higher temperatures should have an even greater effect. This is indeed the case. In the formation range 500°-625°C the contacts become progressively more leaky, and a gamut of soft rectifying characteristics has been seen. Figure 5, showing the *I-V* curve for a contact to 3 ohm-cm n-Si made at 525°C for 60 min, is typical.

Finally, at formation temperatures of 650°-700°C the process reaches its logical conclusion: ohmic contact is made to lightly doped n-Si without a separate n^+ diffusion step. Such a contact, made at 700°C, 10 min, to 5 ohm-cm n-Si, is shown in Fig. 6, along with the conventionally diffused ohmic contact. (A factor of 2 in apparent contact resistance results from difference in contact size and a greater diffusion depth for the n^+ contact, leaving a shorter current path in the epi layer. The change in slope at +1V in curve B is a contribution from the forward current of the guard-ring diode.) An ohmic contact made this way in device processing cuts out one photolithography step and one diffusion step. Requirements for practical use would appear to be that the device be able to tolerate 650°-700°C at this stage, that a larger n^+ area than contact area is not required, and that one cannot make ohmic and Schottky contacts in the same siliciding step.

If the phosphorus in CVD Pt can dope Si, the consequences should be evident in working with p-type material also. With heavily boron-diffused Si the contact characteristic is unaffected (see Table I). It remains so even at 700°C, since in the n-type test slice described in the preceding paragraph the forward current of the diffused p-n diode was normal when contacted with PtSi. If the series structure PtSi/n/p/n had been developed, the *I-V* characteristics would have been those of back-to-back diodes.

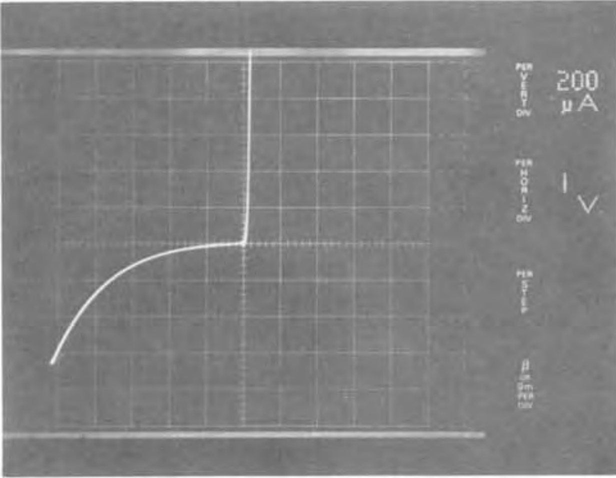

Fig. 5. Soft rectifying contact to 3 ohm-cm n-Si produced by sintering CVD Pt at 525°C, 60 min.

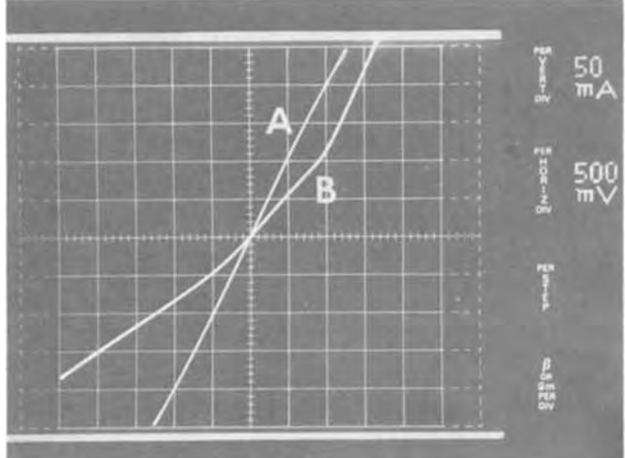

Fig. 6. Ohmic contact to 5 ohm-cm n-Si produced by sintering CVD Pt at 700°C, 10 min (curve B). The diffused (n^+) contacts (curve A) are 50% larger in area than the test contacts. Above +1V there is a contribution from the forward current of the guard-ring diode in curve B.

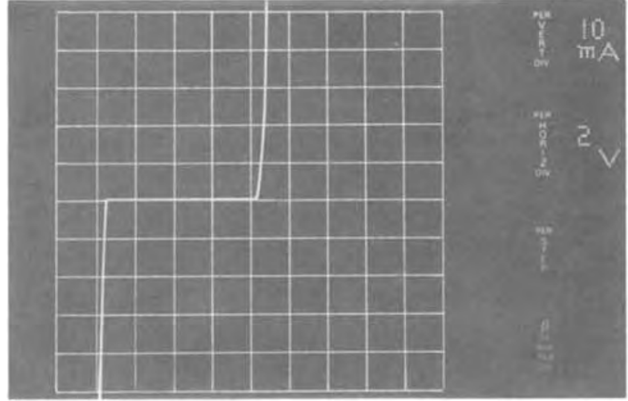

Fig. 7. p-n diode created in 3 ohm-cm p-Si produced by sintering CVD Pt at 700°C, 10 min.

With lightly doped p-Si contacted by PtSi made at 450°C, the room-temperature *I-V* plot appears strictly ohmic, and essentially indistinguishable from that for the p^+ diffused contact. This is what would be expected for PtSi:p-Si, where the barrier height is only 0.25 eV (5). Thus no phosphorus impurity effect is evident, just as in the case of 450°C PtSi:n-Si. Judging by what happens with 700°C PtSi:n-Si, however, there should be more than enough phosphorus diffusion to convert $10^{16}/cm^3$ p-Si and produce an n-type layer at the PtSi-Si interface at this temperature. In other words, a p-n diode could be created in the p-Si. Figure 7 shows a rectifying characteristic for CVD Pt sintered with 3 ohm-cm B-doped Si at 700°C, 10 min. (We have not yet thoroughly analyzed this characteristic.)

Even though we have not been able to detect by analytical techniques $\gtrsim$ 0.1% P in the vicinity of the PtSi-Si interface, all the effects we have described are consistent with phosphorus doping of the Si adjacent to the "interface," wherever that might be. If the high-temperature diffusion constant for phosphorus in single-crystal Si is accepted for ~ 600°C, it may be calculated that in 15 min, movement of the order of 10Å could occur. Of course, the Si near PtSi is highly stressed, and the crystal structure is undoubtedly highly disturbed also. Since 10^{19} B-doped Si was not compensated by the phosphorus, an upper limit of $10^{18}/cm^3$ P can be assigned. It may then be calculated that a p-n junction to 3 ohm-cm p-Si would require of the order of 30Å phosphorus diffusion depth. Thus it appears entirely reasonable that diffusion of phosphorus into lightly doped silicon at > 500°C could be detectable in the *I-V* characteristics of what was intended to be a Schottky barrier contact.

A qualitative summary of the results of using CVD Pt to make PtSi contacts appears in Table III. In brief, with heavily doped Si and sintering at 450°-700°C no electrical anomalies appear. The contacts behave like those from the vacuum-deposited Pt that represents present practice. With light doping, there still is no problem provided a relatively low (~ 450°C) inter-

Table III. PtSi-Si room temperature *I-V* characteristics

diffusion temperature is used. CVD Pt reliably forms PtSi at this temperature. With higher contact formation temperature, changes in the *I-V* characteristics set in; these effects apparently result from phosphorus out-diffusion from the PtSi. At PtSi formation temperature ~ 700°C contact behavior is altered to such a degree that PtSi formation from CVD Pt may be considered as contacting and phosphorus-doping in a single operation.

Effect of Reactant Nitrogen Pressure on the Microstructure and Properties of Reactively Sputtered Silicon Nitride Films

C. J. Mogab, P. M. Petroff,* and T. T. Sheng

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The quality of silicon nitride films deposited by rf reactive sputtering of silicon in a nitrogen discharge is found to be strongly dependent on the discharge nitrogen pressure. For a given substrate to target spacing there is a "critical" sputtering pressure which, if exceeded, results in deposition of films with noticeably inferior properties. The properties of silicon nitride films deposited both above and below this critical pressure are compared. The degradation of film properties accompanying an increase in the nitrogen discharge pressure is correlated with the presence of microvoids (~50Å), revealed by transmission electron microscopy. It is suggested that the microvoids result from a reduction in the reemission of deposited material as the discharge pressure is increased.

Amorphous silicon nitride films have found widespread use in silicon integrated circuit processing, primarily as a junction seal against penetration by undesirable contaminants. Certain processing schemes require that the nitride film be deposited at low temperature ($\lesssim$ 350°C) thus making sputtering a potentially useful deposition technique. In the course of evaluating rf reactively sputtered silicon nitride films for integrated circuit applications we have found that the nitrogen pressure used during sputtering has a pronounced effect on film properties. Hu and Gregor (1) observed a similar effect, although they offered no explanation for it.

This paper describes some of the observed effects and correlates them with changes in film microstructure determined by transmission electron microscopy.

Experimental

Silicon nitride films were formed by the rf reactive sputtering of an 8 in. diameter silicon (99.999%) target in a research grade (<1 ppm total impurities) nitrogen discharge. A Varian sputtering module (Model No. 980-2097) and matching network mounted on an all metal, turbomolecular pumped vacuum chamber were used for deposition. Gas pressure was measured with a capacitance manometer and controlled with a servo-driven leak valve.

Substrates for deposition were Si or thermally oxidized Si wafers which were supported on a grounded, stainless steel, water-cooled anode. Film thickness and refractive index were measured by ellipsometry at 5461Å. In certain cases, film thickness was determined by Talystep measurement on a step created by etching in 7:1 buffered HF (BHF) solution. Infrared spectra were obtained with a Perkin-Elmer Model 621 spectrophotometer. Film stresses were determined by comparing wafer curvature before and after deposition. The curvature was measured by an optically levered laser technique.

Sodium penetration was measured by standard ^{22}Na tracer techniques. This involved deposition of a NaCl film containing ^{22}Na on nitride coated, thermally oxidized silicon wafers followed by annealing at 400°C for 22 hr in forming gas. ^{22}Na profiling was then done by repetitive etching and counting of the coincident 0.51 MeV gamma rays emitted at 180° to each other upon positron decay. BHF was used for etching except near the nitride-oxide interface where refluxed boiling phosphoric acid was employed to selectively etch the

* Electrochemical Society Active Member.
Key words: insulator films, transmission electron microscopy, ion bombardment.

nitride film. Autoradiographs were also made, using fast x-ray film, after various etch steps to reveal the spatial distribution of the remaining ^{22}Na.

Current-voltage and breakdown characteristics were measured using 10, 15, and 25 mil diameter aluminum field plates over nitride films deposited on 0.1 ohm-cm N-type wafers.

The microstructure of the silicon nitride films deposited on SiO_2 and Si substrates was investigated by transmission electron microscopy (TEM). Samples suitable for TEM observations were prepared by chemical etching of the substrate in a standard Si etch solution; the nitride film was protected by a wax coating during the thinning of the substrate. Carbon surface replicas were also made on several films which had been etched in BHF for various times. The thinned specimens and the carbon replicas were examined by TEM with a microscope operated at 200 keV in an attempt to correlate the film etching rate with its microstructure. In addition to the silicon nitride films deposited by sputtering, a few films deposited by chemical vapor deposition (CVD) using SiH_4 and NH_3 at 720°C were examined for comparison purposes.

Results

For a target to substrate spacing of 5 cm, the deposition rate for sputtering in pure N_2 was found to be nearly independent of pressure over the range 2-40 mTorr N_2. The deposition rate increased nearly linearly with power density from 65 Å/min at 1 W/cm² to 215 Å/min at 4.8 W/cm². In addition, the infrared spectra for films deposited within this pressure range were indistinguishable. An example of one such spectrum is shown in Fig. 1 for a 6400Å thick film deposited at 8 mTorr and at a power density of 4.8 W/cm². Figure 1 exhibits the prominent Si-N bands at $\approx$11.5 and 21 μm (2) and is representative of all sputtered films. No additional bands were observed in the range 2.5-50 μm.

In contrast to the relative insensitivity of infrared spectra to N_2 pressure, the BHF etch rate showed a marked dependence on pressure as seen in Fig. 2. These data are similar, although not identical, to those presented by Hu and Gregor (1) for rf reactively sputtered silicon nitride films. Hu and Gregor found an etch rate nearly independent of pressure between $\approx$2-13 mTorr with a sudden steep rise beginning at about 20 mTorr. They also noted that film density decreased by about 7% over the range of deposition pressure from 5 to 30 mTorr. However, they suggested that the increased etch rate could not be attributed solely to a lowering of the film density and proposed that the change might be due to an increase in the content of trapped impurities in the films formed at higher pressure. As will be shown, the increased etch rate and reduced density are both explainable in terms of the marked change in film microstructure which occurs above a certain "critical" deposition pressure whose magnitude depends on the substrate-target spacing.

It will be convenient to refer to films formed at pressures below this critical pressure as "good" films and those formed above it as "bad" films. The dependence of critical pressure on substrate-target spacing is shown in Fig. 3. The dashed line in Fig. 3 cor-

responds to ten mean free paths for N_2 at 100°C. Its significance is discussed later. The critical pressure at a fixed spacing is relatively insensitive to power density although films formed at low power (<2.5 W/cm^2) and just below the critical pressure often exhibit some features of bad films. That is, the demarcation pressure separating good and bad films is somewhat more diffuse than is implied by stating a single value for the critical pressure. In any case, films deposited at 1 mTorr or more in excess of the critical pressure are reproducibly bad. Films deposited by sputtering in mixtures of argon and nitrogen exhibit the same microstructural dependence on total pressure as those deposited in pure N_2. In this case the N_2 content of the mixture must exceed ≈10% in order to produce a nitride film.

It is worthwhile to present some differences in properties between good and bad films before considering their microstructures. Figure 4 indicates the BHF etch behavior of a good film, and shows that the etch rate and refractive index are constant through the film thickness, within the accuracy of the measurements. In contrast, bad films etch at a nonuniform rate and have an apparent refractive index which varies erratically through the film. An example of the results of etching a bad film are given in Table I. Note that the refractive index and thickness as determined by ellipsometry show inconsistencies. The ellipsometric measurements were made after removal of the film from the etchant followed by a DI H_2O rinse and spin drying. Measurement of etch rate and refractive index has proved to be a reasonably sensitive method of distinguishing good and bad films.

Figure 5 illustrates typical *I-V* characteristics for good and bad films. Good films always exhibit linear ln I *vs.* $V^{1/2}$ plots indicative of a Poole-Frenkel conduction mechanism,[1] whereas *I-V* data for bad films

[1] Other conduction mechanisms can yield the same functional dependence of current on voltage. The slope of the straight line in Fig. 5 yields a dielectric constant for silicon nitride films of 4 when the Poole-Frenkel mechanism is assumed.

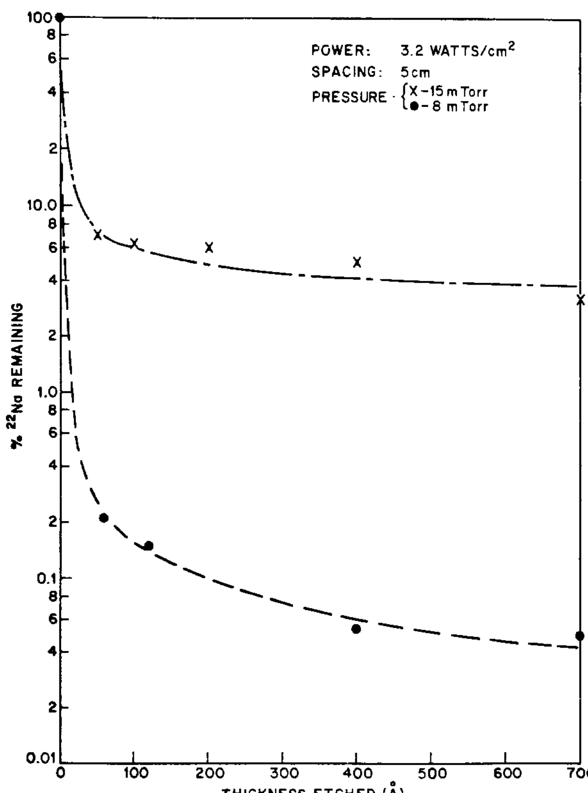

Fig. 6. Penetration profiles for ^{22}Na in good (8 mTorr deposition pressure) and bad (15 mTorr deposition pressure) films following a 22 hr, 400°C drive-in. Both films were 1400Å thick as-deposited.

invariably exhibit curvature when plotted in the same manner. Moreover, bad films break down on the average at approximately half the field needed to cause breakdown in good films.

Figure 6 shows Na penetration profiles for good and bad films following a 400°C, 22 hr anneal. Autoradiographs taken at selected depths indicate that penetration is nearly uniform over the bad film and not just a result of a few large, isolated defects in the film. In contrast, for good films, penetration occurs only at isolated defects (*e.g.,* pinholes).

Stress measurements indicate little or no difference in the stresses in good and bad films deposited at the same power density. For example, films deposited at 3 W/cm^2 exhibit a compressive stress of about 8×10^9 dynes/cm^2 independent of the discharge N_2 pressure.

TEM analysis of the films shows them to be completely amorphous. A phase contrast technique (3) was used to image possible microdefects which might be present in the bad films. A series of electron micrographs of the films taken under "overfocused," "in focus," and "underfocused" conditions indicate the presence of microcavities in the bad films. As shown in Fig. 7, the contrast of the cavities is reversed when imaged in under- or overfocused conditions. No cavity contrast is visible in the "in focus" condition indicating that the strain field of these defects is small. The density and size of the cavities is dependent on the pressure and power of deposition. As seen in Fig. 8, the density of cavities as a function of pressure (at a power density of 2.54 W/cm^2) varies from 0 to $10^{12} \times$ cm^{-2}. The size of the cavities (see Fig. 7) ranges from $\approx$10 to $\approx$50Å. From stereoelectron micrograph pairs the cavities are found to be more numerous at the side of the silicon nitride film close to the substrate. The good films and CVD films imaged with the same contrast technique do not show any cavities.

The etched silicon nitride surfaces are also different for the good and bad films. The TEM micrographs of carbon surface replicas for the bad films show that a very irregular and rough surface develops near the film-substrate interface subsequent to etching (see Fig.

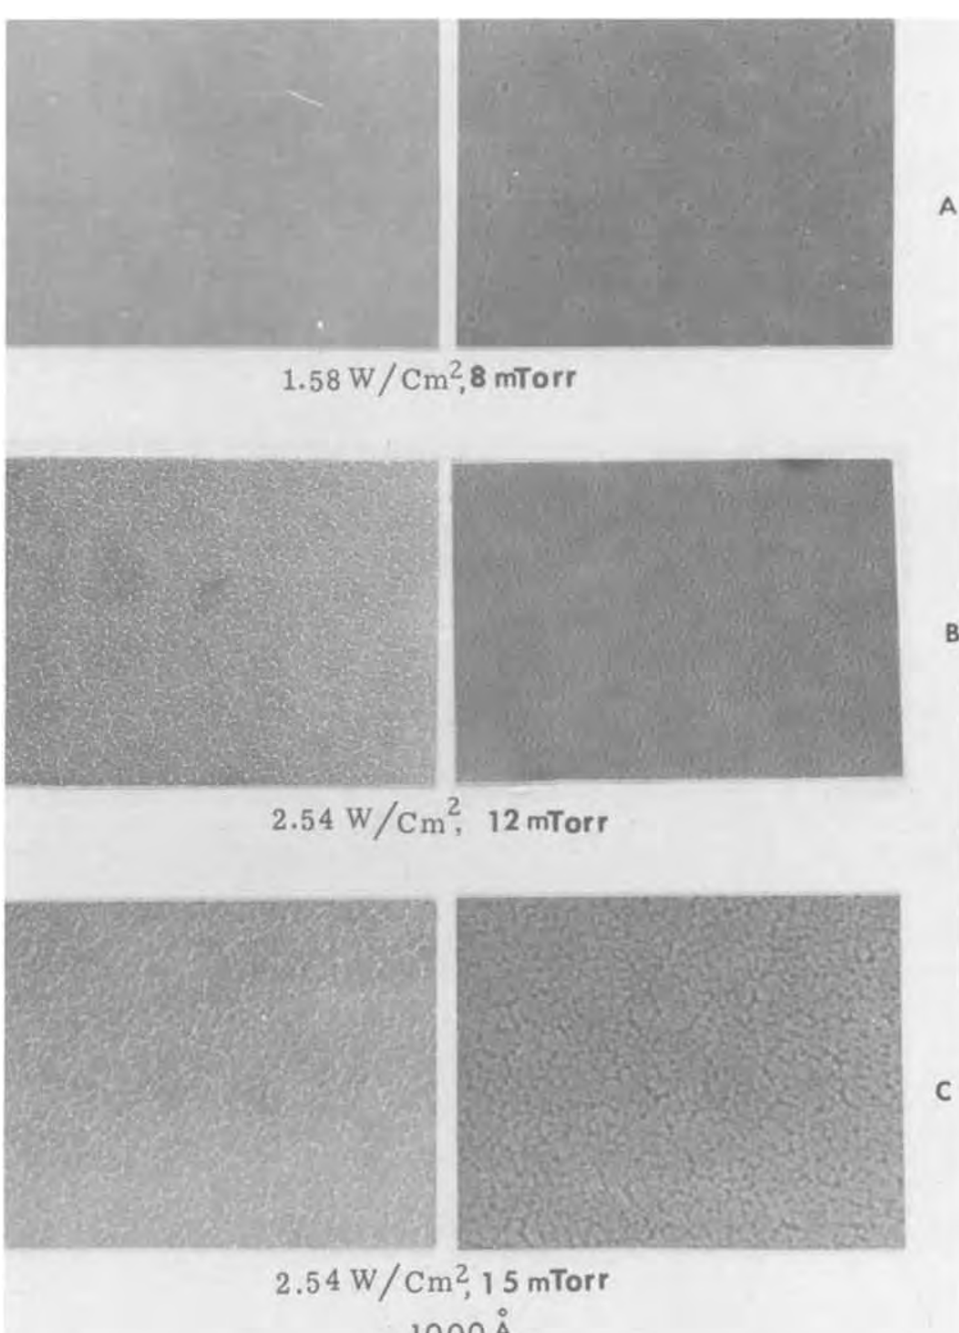

Fig. 7. Bright field transmission electron micrographs of sputtered silicon nitride films deposited under various power and N_2 pressure conditions. The micrographs in the left and right columns correspond, respectively, to underfocused and overfocused imaging conditions.

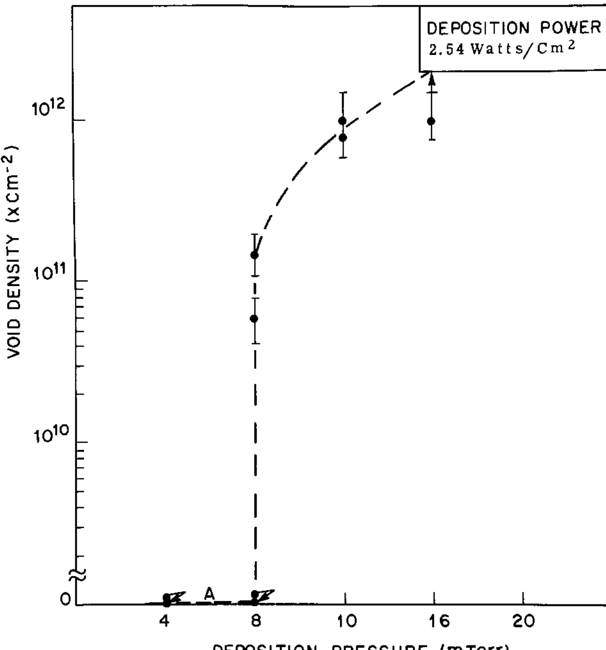

Fig. 8. Void density as a function of deposition pressure for silicon nitride films deposited at 2.54 W/cm^2.

9). The etched surface of a good film is smooth and regular through the entire film thickness, as shown in Fig. 10.

Discussion

The TEM structural analyses strongly suggest that the marked increase in etch rate and sodium penetration in films formed above the critical pressure arises from the large amount of internal surface area associated with the microvoids present in these films. It should be pointed out that good and bad films (of equivalent thickness) are indistinguishable by visual inspection. The microvoids are too small to produce detectable scattering of visible light and thus as-deposited bad films are quite specular and uniform in appearance. Extended etching of bad films generally leads to a less specular, nonuniform appearance due to surface roughening (see Fig. 9), whereas good films remain specular and uniform on etching (Fig. 10). Surface roughening evidently results from penetration of the etchant into the microvoids. The roughened surface and the possibility of trapped etchant or rinse in the voids probably account for the anomalous variation of measured refractive index following step etching (see Table I).

The extent and uniformity of sodium penetration over the entire slice in the case of bad films would indicate that the microvoids are distributed throughout the film and form an interconnected network. As noted before, however, there is evidence from TEM stereo pairs and surface replicas of etched films (see Fig. 9) that the microvoids are more concentrated near the substrate-film interface.[2] In the presence of a void network sodium can migrate by surface diffu-

[2] When pressure is changed in the middle of a run from less than to greater than the critical pressure films containing microvoids result indicating that these defects are not due to some nucleation phenomenon.

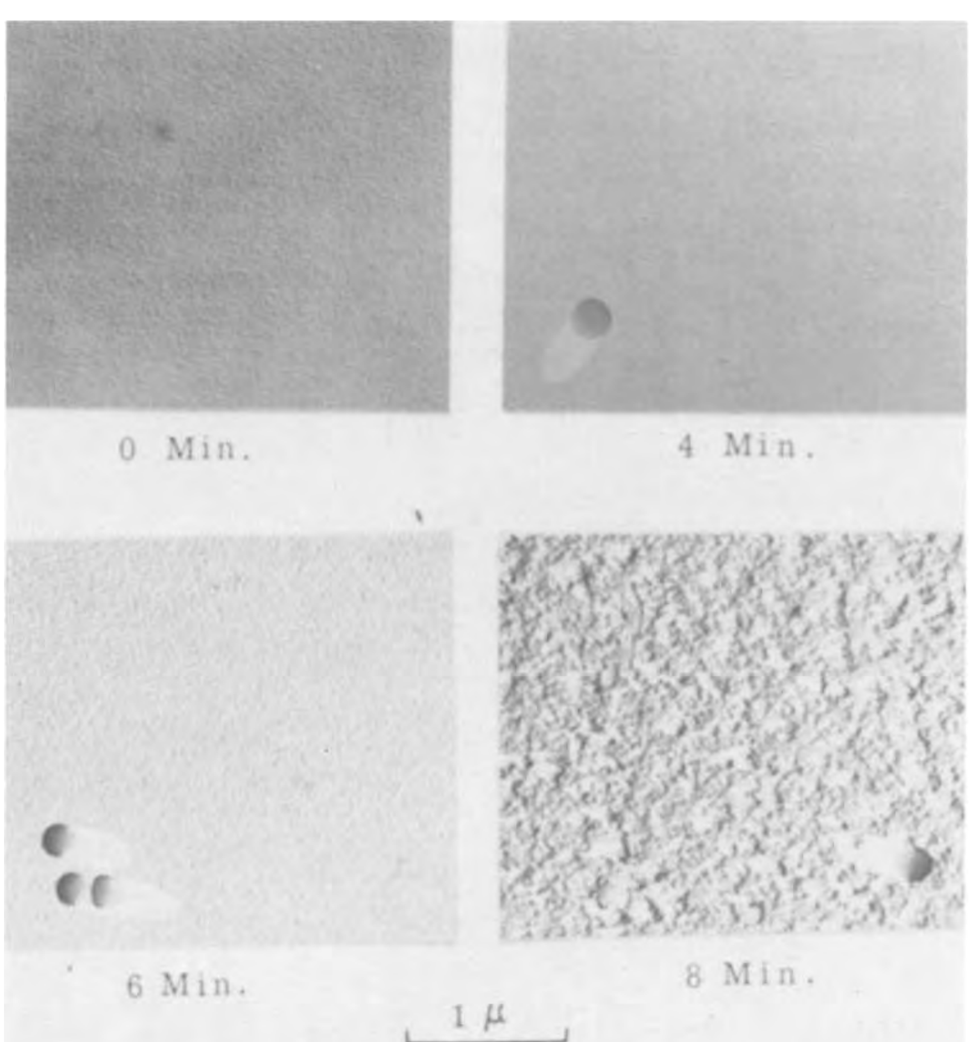

Fig. 9. Transmission electron micrographs of surface carbon replicas of a bad silicon nitride film as a function of increasing etching time.

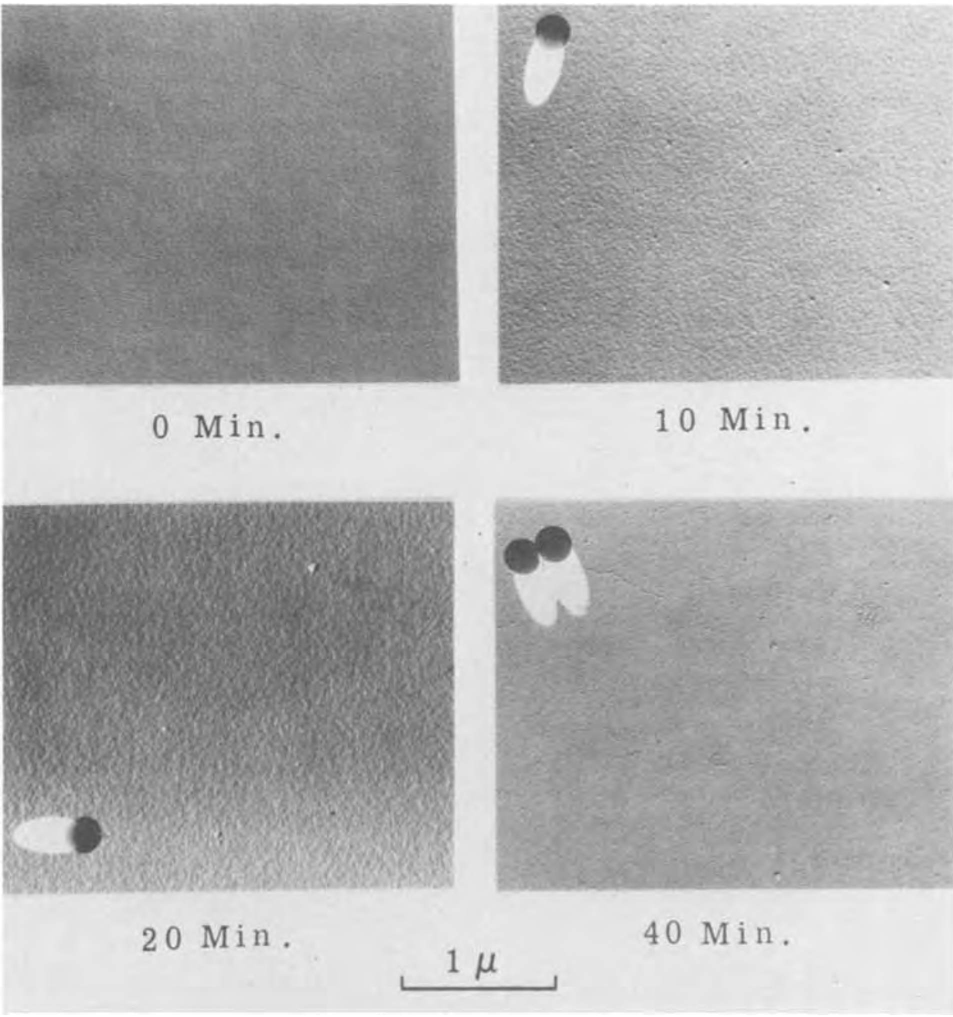

Fig. 10. Transmission electron micrographs of surface replicas of a good silicon nitride film as a function of increasing etching time.

sion which is expected to be considerably faster than diffusion through bulk regions of a dense nitride film. Pinhole-free regions of good films exhibit excellent resistance to the penetration of sodium and are comparable in this respect to high temperature CVD silicon nitride films.

Whereas, the microvoids are clearly responsible for the marked differences between good and bad films, the reason for the existence of the voids is less evident. Possible explanations include impurity effects, change in reaction site, gas trapping, and the effects of energetic particle bombardment on film growth.

Impurity effects should be considered since an increase in pressure which produces the transition from good to bad films can result in an increased impurity content of the film. This can occur as a result of an increased partial pressure of impurity gases introduced with the sputtering gas or because of an increase in discharge-induced heating and outgassing effects. Accordingly, the impurity content of good and bad films was compared, semiquantitatively, by ion scattering and by combining ion milling with Auger spectroscopy. No pronounced differences in impurity content of good *vs.* bad films were found. For both types of films oxygen was the only detectable impurity ($\lesssim 1\%$); the oxygen content was highest at the free surface of the films and decreased rapidly with depth. On the average, bad films had a higher oxygen content than good films but never by more than a factor of two. It seems likely that the enhanced oxygen content of bad films is a result of adsorption, both during and after deposition, within microvoids rather than their cause. This conclusion is supported by the fact that oxynitride films intentionally "doped" with substantial amounts of oxygen do not contain microvoids. Thus, impurity effects do not provide a reasonable explanation for void formation.

Mixtures of argon and nitrogen wherein the nitrogen pressure is held below the critical value but the total pressure is above the critical value also result in microvoids. This observation would seem to rule out any void formation mechanism dependent on a change in reaction site from substrate to cathode as the N_2 pressure is increased. Additional evidence in support of this contention comes from the invariance of deposition rate and film stress as nitrogen pressure is increased. Both of these parameters might reasonably be expected to change if the reaction site shifted within a small range of pressure.

Trapping of the discharge gas in the film can also be considered as a possible mechanism for microvoid generation. Gas entrapment presumably must occur in conjunction with sorption of the gas at or near the surface of a growing film. Molecular nitrogen (N_2) in the ground state, which is the predominant species impinging on the film during growth,[3] is not chemisorbed (4) and thus, cannot be trapped. There are several species in the discharge, however, which presumably bombard the film and can be chemisorbed. In this regard the work of Shahin (5) is of interest. He studied the ions present in the cathode region of a nitrogen discharge and found that N_2^+ and N^+ were the dominant species, with N^+ being formed primarily in the dark space according to $N_2^+ + N_2 \rightarrow N^+ + N + N_2$. Thus, N_2^+, N^+, and N are present in the discharge. Atomic nitrogen impacting the film should be readily chemisorbed. Since the insulating nitride film probably floats at a negative potential with respect to the

[3] According to Winters and Kay (4) the ratio of excited to ground-state species in a typical sputtering discharge is less than 10^{-3}.

plasma during deposition some bombardment by N_2^+ and N^+ must also occur. Either of these species can be sorbed; the N^+ being highly active and the energetic N_2^+ (>8 eV) having a high probability of dissociation upon impact with the film surface (4, 6). Therefore, the sorbed species in every case is atomic nitrogen. It is reasonable to assume that these sorbed atoms are converted to silicon nitride "molecules," *i.e.*, that the reaction between silicon and nitrogen occurs at the substrate via these sorption events (7). Such a highly active sorbate would be unlikely to revert to N_2 and become trapped in the film. There is, of course, the possibility that energetic neutral N_2 molecules are driven into film and trapped as suggested by Cordes (8). [Trapping of energetic Ar in sputtered Ni films has been observed by Winters and Kay (6).] However, this effect should be reduced by an increase in pressure [as is the case for Ar entrapment (6)] and would thus not explain the formation of microvoids at higher pressure. In short, gas entrapment does not seem to afford a viable explanation.

In an attempt to confirm this expectation several samples of good and bad films deposited under identical conditions (5 cm spacing, 3.2 W/cm^2) except for the discharge pressure were analyzed by Rutherford backscattering (9) of 1.8 MeV $^4He^+$ ions. From these measurements one can determine the ratio of silicon to nitrogen atoms at a particular depth in the film, with a depth resolution of the order of 200Å. Films deposited below the critical pressure had a silicon to nitrogen ratio of $\approx$0.6 while those deposited above it had a ratio of $\simeq$0.76. In both cases this ratio was constant with depth into the film. Thus, good films are nitrogen rich (based on a comparison to the compound Si_3N_4) while bad films are more nearly stoichiometric. This result is obviously inconsistent with the hypothesis of gas entrapment being the cause of microvoid formation. Moreover, as already mentioned, films formed in mixtures of argon and nitrogen, such that the nitrogen partial pressure was well below the critical pressure but the total pressure was just above it, still contained microvoids. The probability for trapping argon is much smaller than for nitrogen (4); thus, suggesting again that gas entrapment is not responsible for microvoid formation.

A more plausible mechanism for microvoid generation can be inferred from the functional form of the dependence of critical pressure on substrate-cathode spacing. Figure 3 shows that the critical pressure is raised in inverse proportion to the spacing. An identical relationship exists between the N_2 molecular mean free path and pressure as indicated by the dashed line in Fig. 3. This suggests that the existence of microvoids is related to the extent to which energetic particle (atoms, ions, molecules) bombardment of the growing film is suppressed. For a given substrate-cathode spacing the number of energy dissipative collisions suffered by the average particle (ion, atom, molecule) increases rapidly with pressure so that the energy of the particle at the instant of impact with the growing film is strongly dependent on pressure. The higher the pressure the less the energy, on the average, of the particles bombarding the film. Energetic particle bombardment can lead to densification in at least two ways: (*i*) enhancement of surface mobility of depositing atoms and (*ii*) reemission of weakly bound atoms or clusters which are in unfavorable positions for achieving optimum density. Both of these effects will be attenuated due to scattering collisions as pressure is increased.

Reemission of deposited material has been shown to be necessary for obtaining high quality rf sputtered SiO_2 films (10-12), formed by sputtering of an SiO_2 target. The work on SiO_2 films can be summarized as follows. The reemission coefficient (a measure of the fraction of deposited material reemitted from the film surface during deposition) decreases when either pressure or cathode to substrate spacing is increased (10-11). For a fixed spacing and pressure the reemission coefficient is increased by an increase in negative bias at the surface of the growing film, indicating that energetic positive ion bombardment is a major contributor to reemission. However, reemission can still occur at zero bias due to bombardment by energetic neutrals (11, 12).

Assuming that a high reemission coefficient is necessary to the attainment of defect-free films, one would expect that the onset of microvoid generation would be dependent on power (or cathode self-bias) as well as pressure since the former parameter determines the energy spectrum of excited species in the discharge. This is consistent with our observations. Deposition at lower power (<2.5 W/cm^2) can result in microvoids even at pressures slightly below the critical pressure for higher power deposition. We had also anticipated, on the basis of the reemission model and consideration of the results on sputtering of SiO_2 (10-12), that deposition in the presence of an rf bias on the substrate would lead to high quality, void-free films even at pressures somewhat above the critical pressure. This follows from the fact that use of an rf bias results in a d-c self-bias on the depositing film which is negative with respect to the plasma and should therefore promote positive ion bombardment. To our surprise, the application of rf biases resulting in d-c self-bias values ranging from -150 to -300V yielded films having

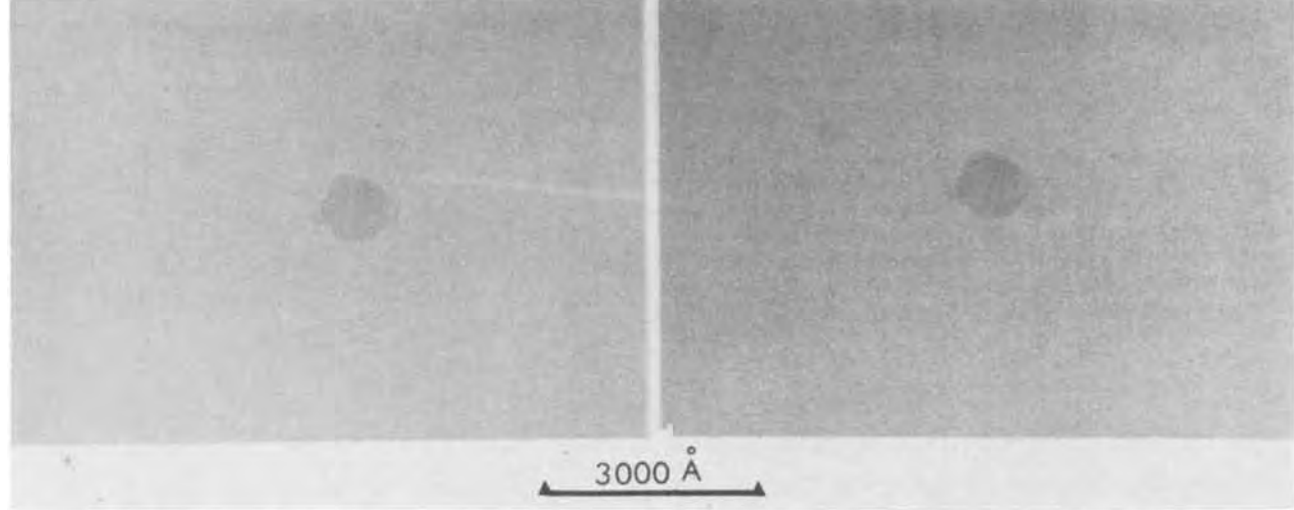

Fig. 11. Transmission electron micrographs of an rf bias sputtered silicon nitride film. The micrographs in A (left) and B (right) correspond, respectively, to underfocused and overfocused imaging conditions.

BHF etch rates from 300-600 Å/min. This was true even at total discharge pressures well below the critical pressure for a given spacing. TEM examination revealed that films formed under rf bias, both above and below the nominal critical pressure, did not contain microvoids. However, as shown in Fig. 11 for a film deposited with a 10% rf bias, the microstructure of these films was different than that for good films formed in the absence of applied bias. In addition, Rutherford backscattering studies revealed that bias-sputtered films were substantially more nitrogen-rich than films deposited without bias. The silicon to nitrogen ratio for rf bias sputtered films was $\approx$0.5. The higher nitrogen content is consistent with an increased positive ion bombardment as expected.

The absence of voids at pressures greater than the critical value in the bias sputtered case is consistent with the reemission model. The change in microstructure and marked increase in etch rate of bias sputtered films suggest that the reaction does, in fact, occur at the substrate and that these parameters may be very sensitive to the film stoichiometry in the nitrogen-rich regime. More work is needed to clarify this.

Conclusions

The microstructure of silicon nitride films deposited on electrically grounded or isolated substrates and formed by rf sputtering of a silicon target in a nitrogen discharge is strongly influenced by the nitrogen pressure. An increase of pressure beyond a certain critical value results in the incorporation of microscopic ($\sim$50Å) void-like defects which can be observed directly by a through-focus TEM technique and which are responsible for marked degradation of film properties. The interdependence of critical pressure and the substrate-target separation has a functional form which suggests that the voids arise from the reduction of energetic particle bombardment of the growing film at higher pressure. This results in a reduction in the mobility of adsorbed atoms or molecules at the surface of the film and/or a decrease in the reemission of condensed material.

Technical Note

The Relative Dielectric Constant of Two Semiconductor Passivation Glasses

Alvin M. Goodman, Kenneth W. Hang, and James M. Breece

RCA Laboratories, Princeton, New Jersey 08540

A variety of glasses is commercially available for hermetically sealing and thereby passivating silicon devices against the effects of hostile ambient environments. The glass is often used in direct contact with the silicon at or near p-n junctions. The operating characteristics of the devices may for this reason depend strongly upon the relative dielectric constant K of the glass. This is particularly true when large reverse bias is applied to the junctions. This note describes the measurement of K for two widely used commercial glasses, Innotech IP760 and IP820.[1] To our knowledge, no previous measurement of K for these glasses has been reported.

Key words: glass properties, silicon-passivation glass, dielectric measurement.

[1] Further information available from Innotech Corporation, Norwalk, Connecticut 06851.

The usual methods of forming layers of this type of glass (1)[1] may, under some conditions of preparation, lead to bubble formation thereby rendering the material unsuitable for a measurement of K. We chose to circumvent this problem by using a long glass fusion time to allow bubble dissipation. This is treated below wherein we describe the preparation of "bubble-free" glass samples and appropriate electrode structures. The electrical measurements and results are also presented.

Sample Preparation

Glass fusion.—The glass samples were prepared by powder fusion of the commercial glass. Due to the high fraction of glass particles in a size range below 2μ, a long fusion time was necessary to remove the small bubbles. A covered platinum + 40% rhodium

crucible of 80 cm^3 capacity was used to fuse the powder in an air ambient for 20 hr at 1200°C. The crucible was then quickly cooled in air to facilitate removal of the solidified glass from the crucible. The IP820 glass was annealed at 650°C for 1 hr and slow-cooled in the furnace. The IP760 glass was annealed at 540°C for 1 hr and slow-cooled in the furnace.

Glass analysis.—By physical property and wet chemical analysis the glasses were found to have the composition shown in Table I.

Shaping and polishing.—A disk (right-circular cylinder) with nominal dimensions of 2.1 cm diameter and 0.1 cm thick was cut from each fused boule. The two large faces of the disk were made flat, parallel, and smooth by polishing with progressively finer abrasive, finishing with 0.5μ diamond paste. The surfaces were flat to better than $\lambda/4$ of the green line of mercury and parallel within 25 sec of arc. A microscopic examination of the disk showed that it was "bubble-free." That is, the bubble volume was less than one part in 10^6 of the volume of the glass.

Electrodes.—Evaporated aluminum was used to produce a "three-electrode system" (2) on the faces of each disk. A single solid layer (unguarded electrode) was used on one side while the pattern on the other side consisted of a center area (guarded electrode) of circular geometry surrounded by an annular layer (guard electrode).

Dimensions.—Multiple observation measurements were carried out to determine the average values and probable errors of the diameter, $2r_1$, of the guarded electrode, the gap, g, between the guarded and guard electrodes, and, t, the thickness of the disk. An optical comparator (Nikon Shadowgraph) was used for the measurements of $2r_1$ and g; a dial-indicator-type mechanical height comparator was used for the t measurements. The accuracy of each comparator was checked against gauge blocks (dimensions certified to 5×10^{-6} in.). The resultant values and their probable errors (3) are given in Table II.

Electrical Measurements and Results

Three terminal grounded-guard capacitance measurements were carried out in the frequency range 10^2-10^6 Hz. Three capacitance bridges were used to cover this range: a General Radio Model 1615A (10^2-10^5 Hz), a Boonton Electronics Model 75C (5×10^3 to 5×10^5 Hz) and a Boonton Electronics Model 75B-S8 (10^6 Hz). All of the measurements were performed with the sample at room temperature. The results are shown for IP760 in Fig. 1 and for IP820 in Fig. 2. The agreement between the results obtained using different bridges is excellent and well within the maximum expected inaccuracy for any data point (0.25%). There is a small but clearly observable decrease in capacitance with increasing frequency for each sample. Within the frequency range measured this decrease is approximately linear with the logarithm of frequency.

Table I. Composition in mole per cent of major constituents of IP760 and IP820

	PbO	SiO_2	B_2O_3	Al_2O_3
IP760	18.3	65.3	14.0	2.4
IP820	23.7	69.8	—	6.5

Table II. The average values and probable errors of the sample dimensions

	$\bar{r}_1$, cm	$\bar{t}$, cm	$\bar{g}$, cm
IP760	0.40495 ± 0.00083	0.09223 ± 0.00004	0.04222 ± 0.00122
IP820	0.40423 ± 0.00094	0.10127 ± 0.00049	0.04353 ± 0.00133

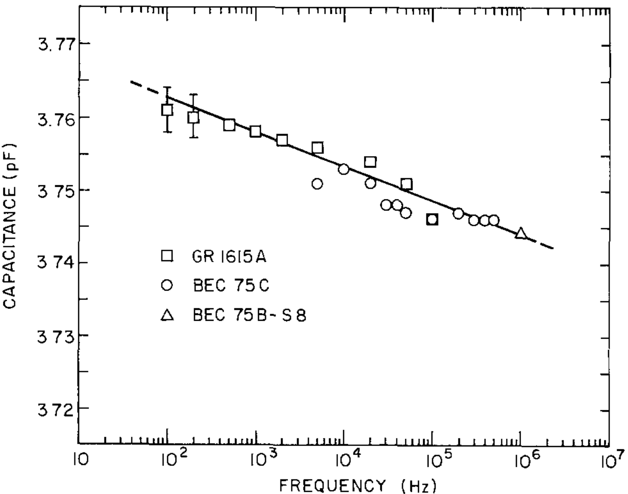

Fig. 1. Capacitance *vs.* frequency of a sample of IP-760 glass using a three-electrode, grounded-guard system. The data symbols indicate the manufacturer and model of the capacitance bridge used for each measurement (see text). The flags on the data points at 100 and 200 Hz indicate the approximate width of the null point determinations; at higher frequencies the null points could be determined within ±0.001 *p*F.

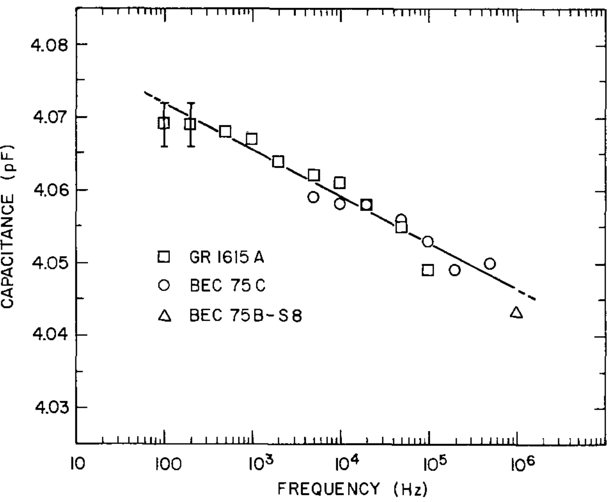

Fig. 2. Capacitance *vs.* frequency of a sample of IP-820 glass using a three-electrode, grounded-guard system. The data symbols indicate the manufacturer and model of the capacitance bridge used for each measurement (see text). The flags on the data points at 100 and 200 Hz indicate the approximate width of the null point determinations; at higher frequencies the null points could be determined within ±0.001 *p*F.

The capacitance C and the relative dielectric constant K are linearly related by the formula

$$K \equiv SC = \frac{t}{\pi r^2 \epsilon_0} C \quad [1]$$

where S is a constant that is determined by the structure (geometry) of the sample and r is the effective radius of the guarded electrode. The value of r is given by (2, 4)

$$r = r_1 + g/2 - \frac{2t}{\pi} \ln \cosh \left(\frac{\pi g}{4t} \right) \quad [2]$$

The value of S and its probable error limits (3) have been computed from the sample dimensions

$$S(\text{IP760}) = (1.859 \pm 0.004) \times 10^{12} \mathbf{F}^{-1}$$
$$S(\text{IP820}) = (2.040 \pm 0.011) \times 10^{12} \mathbf{F}^{-1}$$

Since the capacitance varies with frequency, K is, in fact, not a constant. As a practical matter, however,

we can say that in the range 10^2-10^6 Hz, K(IP760) = 6.98 and K(IP820) = 8.28 within 1%.

Acknowledgment

The assistance of Carl Bjorling with the sample preparation is gratefully acknowledged.

Selective Removal of BP from Si Substrate

M. Takigawa, T. Satoh, and K. Shohno

Department of Electronics, Sophia University, Chiyoda-ku, Tokyo, Japan

Boron monophosphide (BP) can be epitaxially grown on Si substrates by the thermal reaction of B_2H_6 and PH_3 in the presence of H_2 (1-3). The crystallographic orientation of the BP is the same as that of the Si substrate. BP is chemically stable and is not attacked by normal chemical etchants. BP has a forbidden energy gap of 2.0 eV (4) and may be useful as an optoelectronic material. For optoelectronic applications a technique must be found for removing the BP selectively from the Si substrate.

The experimental apparatus for epitaxial growth of BP has been reported in a previous paper (3). A BP thin film of n-type with a thickness of 0.5-5 μm was grown at a substrate temperature of 950°C. The Si (100) substrates used had a thickness of 180 μm and a resistivity of 5-8 ohm-cm (p-type). The BP obtained had an electron concentration of 5×10^{18} cm^{-3} and a Hall mobility of 40-60 cm^2/V-sec. When the thickness of the BP grown on the Si (100) substrate was less than 7 μm, the surface of the BP was as smooth as the Si substrate, and no bending of the wafers could be detected. However, when the thickness of the BP film was more than 7 μm, crack lines along <011> directions in the BP, and bending of the wafers were observed.

After the epitaxial growth of the BP on the Si substrates, the water was spin-coated with liquid photoresist and then baked to drive off the resist solvents. It was then exposed with a standard test mask. The resists used in this experiment were of positive type (AZ 1350) and negative type (KTFR). The mask pattern was oriented to the flat edge of the wafer, which is parallel to a <011> direction. Subsequent developing of the photoresist removed the resist from the unnecessary areas. After a second bake to complete the polymerization of the photoresist, the wafer was ready for electrolytic removal.

The experimental apparatus for removing the BP, shown schematically in Fig. 1, is the same as that used for anodic oxidation of Si wafers. The solution consisted of 4*N* aqueous sodium hydroxide The Si wafer was placed at the anode side, and a platinum plate was used as the cathode. A d-c pulse voltage was repeatedly impressed. The duration of the d-c pulse voltage was adjusted to 1 sec in this experiment. After all the BP was removed from those areas that were free of photoresist, the remaining photoresist was removed in a suitable stripping solution.

When the first voltage pulse of 30-50V was applied, crack lines in the BP film along the edge of the resist were clearly visible with an optical microscope. This is an initial change observed in the BP. After a few more pulses, the BP areas free from resist changed to a yellowish color. At this stage, exposure to ultrasonic vibrations in an organic solvent was found to be the easiest way to remove the BP from the Si substrate. The bare Si surface areas were not oxidized. An example of the process, using a resist of the positive type and one of the negative type is shown in Fig. 2 (a) and (b). Minimum BP line-widths and spacing are 4 μm for AZ 1350 and 2 μm for KTFR. The limiting dimensions are determined by the size limitation of the photoresist.

By repeating the voltage pulse, the BP can also be removed from the Si substrate without the use of ultrasonic agitation. The BP film removed floated on the solution and the bare Si surfaces were anodically oxidized. When a voltage pulse of more than 50V was applied, the BP could be removed from the Si substrate with only one or two pulses.

When a constant d-c voltage was applied, the resist curled up at the edges and eventually came off.

Several alkaline and acid solutions were used, but almost any kind of ionic solution can be used successfully for this purpose. The number of voltage pulse repetitions needed for the complete removal of the BP did not depend on the solution used.

However, the total number of voltage pulse repetitions needed for the complete removal of the BP depended on the thickness of the BP. For a thin BP film (0.5 μm), two or three voltage pulses of 30V were sufficient. On the other hand, for a thick BP film (5

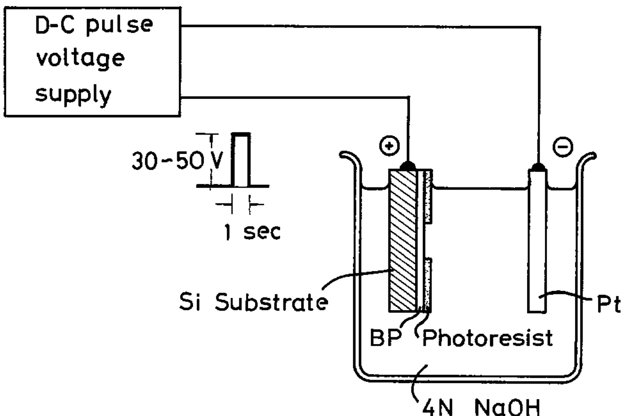

Fig. 1. Schematic diagram of the experimental apparatus for the selective removal of BP from Si substrates by the electrolytic process.

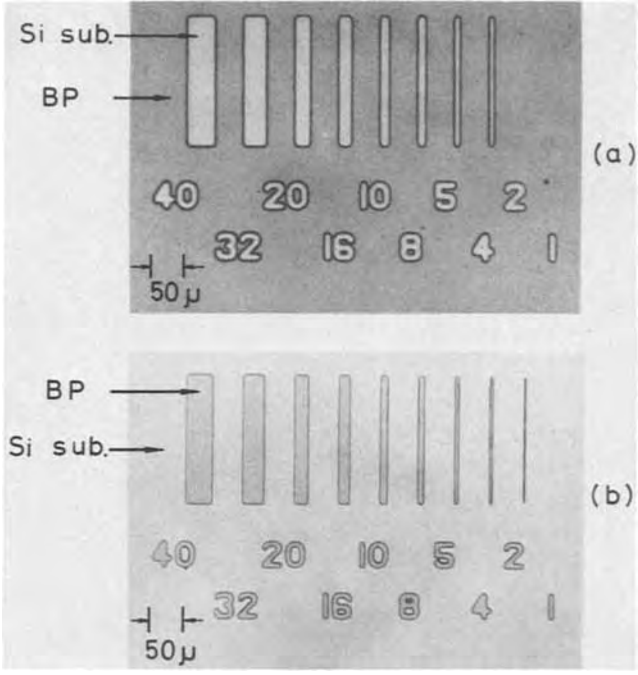

Fig. 2. Microscopic photographs of selectively removed BP by the electrolytic process. (a) BP areas removed using positive type resist (AZ 1350). (b) BP areas remained using negative type resist (KTFR). The thickness of the BP is 0.85 μm.

μm), 7 or 8 pulses of 50V were necessary for complete removal.

The BP films obtained by removal of the Si substrate by chemical etching with HF-HNO_3 solution were smooth and flat. However, the BP films removed electrolytically had many small cracks. This difference can be seen in Fig. 3 (a) and (b). The cracked features of the BP films depend on the conditions of the electrolytic process, mainly on the voltage applied between the cathode and the anode. These differences in the BP films suggest that strong forces are applied to the BP

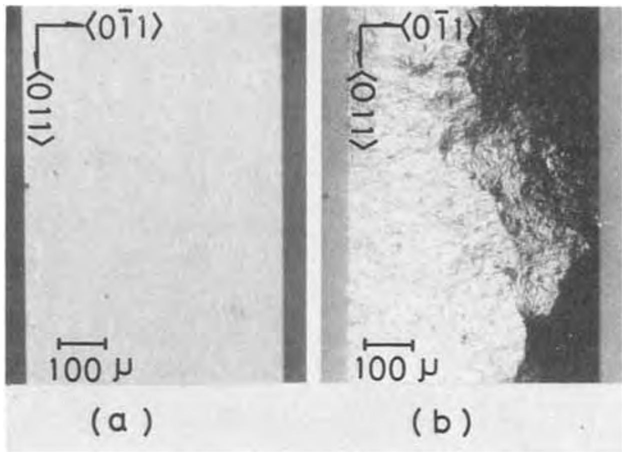

Fig. 3. Microscopic photographs of BP films with thicknesses of 5.0 μm. (a) BP film obtained by chemical etching of the Si substrate. (b) BP film obtained by the electrolytic process; it has many small cracks.

when removed from the Si substrates by the electrolytic process.

Beveling Aluminum in Multilayer Metal Circuitry

T. Agatsuma,* A. Kikuchi, K. Nakada, and A. Tomozawa

Semiconductor and Integrated Circuits Division, Hitachi Limited, Kodaira, Tokyo, Japan

Fabrication of semiconductor multilayer metal IC's and LSI's involves a number of photoengraving steps, and the surface topography becomes increasingly more complex as the processing proceeds. The exact processing conditions and materials used determine the contour of the edge of photolithographically delineated structures. If the device structure involves steep steps, sharp corners, or multilevel metals, improper coverage of the surface topography can lead to a variety of reliability and yield problems.

Two processing techniques have been developed for improving multilayer metallization. The first involves optimizing substrate topography by application of beveling techniques; conventional deposition techniques serve to cover the modified topography. The second involves improvement of the quality of deposited oxide contours, taking advantage of several types of specialized film deposition techniques.

Regarding oxide deposition, effects of rates of gas flow in the system (1), rate of deposition of the oxide, and ratio of oxide/metal layer thickness (2) on oxide contours have been shown to be significant; however, when a thick metal layer is used, its step becomes steep and optimization of its step coverage by oxide will be limited. A technique for producing good oxide coverage over steep metal steps is to deposit phosphosilicate glass (PSG) or borosilicate glass (BSG) at temperatures of 700°C or more (3), or to fuse the glass at a temperature above its softening point (4) which depends on the phosphorus content of the glass. However, applicability of these methods is limited to devices such as Si Gate MOSLSI's, where higher melting point materials are used as gate electrodes or first level conductors.

In the case of two level aluminum metallization, such as bipolar IC's or LSI's, higher temperature deposition or oxide fusion cannot be used. The quality of step coverage by a CVD oxide layer over an aluminum pattern can be almost entirely determined by the contour of the aluminum; hence the importance of beveling the edge of the first level aluminum.

Two approaches to beveling aluminum have been studied. The first is photoresist undercutting (5) which achieves lateral attack at the polymer/aluminum inter-

* Electrochemical Society Active Member.
Key words: multilayer circuit, aluminum, anodic oxidation.

face, using a suitable etchant so as to produce undercutting of the photoresist due to loss of its adhesion during photoetching. However, practical use will be difficult because of lack of reproducibility as a result of the many process parameters involved.

The second is to deposit or form an additional faster etching layer over the aluminum prior to coating with photoresists. In this technique, formation of the upper layer and composition of the etchant become predominant factors in determining bevel angle. The use of phosphosilicate glass (6) or an anodic oxide film (7) have already been presented as means for beveling aluminum. This paper discusses a beveling technique for aluminum using an anodic oxide film of aluminum as a bevel control layer, and discussses the effects of process variables on reproducibility of the results.

Experiments

Silicon dioxide layers were grown on Si slices by thermal oxidation, and the aluminum of 1.0 ~ 1.2μ thickness was evaporated by a resistance-heated filament or electron beam. Subsequently, anodic oxidation of the aluminum was performed in diluted oxalic acid, forming a porous anodic oxide film on the evaporated aluminum.

Anodizing current was observed to rise rapidly just after applying voltage, and then decrease slowly until it was saturated (8). The saturated value of current for anodization of 1.0V and 25°C in 5% oxalic acid was 0.14 mA/cm^2. Oxide film thickness was determined by etching the oxide film selectively in chromic acid and measuring the steps with a talystep. Dividing step height by the time required for anodization, growth rate of the oxide film per unit voltage was estimated as 33 ~ 38 Å/min for 5% oxalic acid at 25°C in the range 0.5 to 3.0V.

Photoresist coating followed a precoating bake of the anodized wafer at 200°C for 20 min in N_2 ambient. Negative-type resists used were OMR81-PL, OMR83, and KTFR. After defining the patterns, the photoetching was performed using a conventional aluminum etchant (H_3PO_4: 76, CH_3COOH: 15, HNO_3: 3, H_2O: 5 by volume) containing a small amount of ammonium fluoride, NH_4F.

To express the degree of bevel or taper angle preferentially, the bevel etch factor was defined in Eq. [1], which is the reciprocal of the usual definition of etch factor. In this way the value of bevel etch factor better expresses the degree of beveling aluminum at its edge during etching

$$\text{Bevel etch factor} = d/t \qquad [1]$$

where t is the thickness of evaporated aluminum and d is the extent of beveling measured from the bottom edge of the aluminum.

Bevel etch factor was measured by a microscope at 400X magnification. When the bevel etch factor is smaller than unity, light reflected from the bevel surface will be scattered and not reach the microscope field of view. In this case the measured bevel etch factor is smaller than its actual value. As a correction for the effect of light in this case, a value of $t/2$ (t is the aluminum thickness in micrometers) must be added to the measured value of bevel etch factor, because the actual value of bevel etch factor measured at zero or near zero was observed equal to $t/2$.

Results and Discussion

Figure 1 shows how the bevel etch factor varies when changing oxide film thickness with anodizing time for a fixed value of anodizing voltage at 1.0V. Etchant used was 3/100 or 4/100; these are the volume ratios of ammonium fluoride to the aluminum etchant. This figure may be roughly divided into two regions on either side of a 1000Å film thickness. When the oxide film is in the range 0-400Å, both the value of bevel etch factor and its variability were extremely large; they both decreased sharply with increasing oxide film thickness, reaching minimum values at a thickness near

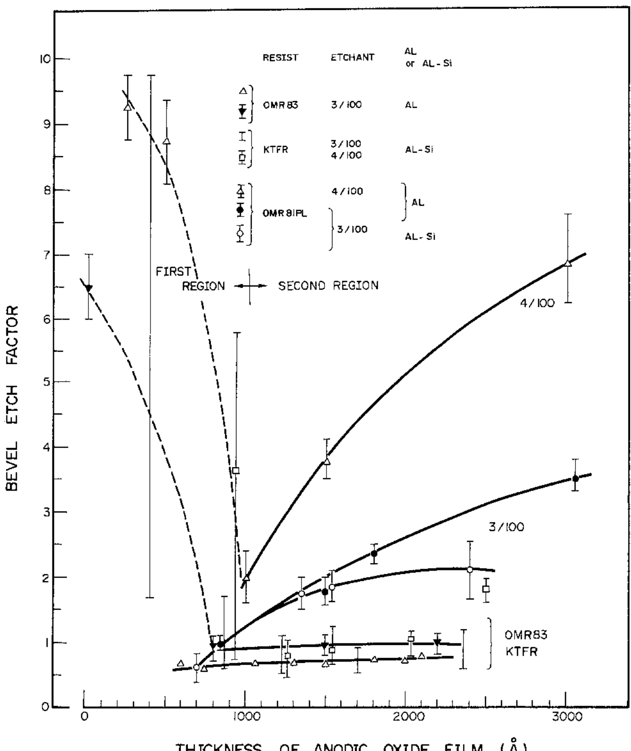

Fig. 1. Variations of bevel etch factor with thickness of anodic oxide film formed at an anodizing voltage of 1.0V. Content of ammonium fluoride in aluminum etchant and types of photoresist are taken as parameters.

1000Å. The first region is defined by a thickness range 0 to near 1000Å, where the bevel etch factor decreased from its initial value to a minimum. Oxide film thickness in the region of the minimum was in the range 500-1000Å, depending on type of resist and composition of the etchant.

The second region, as seen in Fig. 1, defines a range of oxide film thickness in which the bevel etch factor tends to increase gradually from its minimum value; the rate of increase differs with type of resist and composition of the etchant. With OMR81PL resists, the rate of increase in the bevel etch factor with thickness was extremely large, and varies appreciably with composition of the etchant. Bevel etch factor for OMR83 and KTFR resists maintained almost constant values of 0.5 ~1.5 over the range 700-2500Å. The bevel profile of aluminum obtained using the conventional aluminum etchant without forming the anodic oxide film exhibited a near vertical slope at the top edge and curved cylindrically towards the bottom edge. In this case, the value of bevel etch factor was measured at zero or near zero.

Figure 2(a) top shows beveled aluminum patterns for the first and second regions of Fig. 1. In the first region, partial etch undercut is seen to occur, thereby resulting in large values of bevel etch factor. This may be caused by preferential attack at the photoresist/oxide film interface due to loss of adhesion between photoresist and the oxide film during etching. In this region, controlled beveling could not be attained.

A bevel with constant slope was obtained in the second region, as seen in the bottom of Fig. 2(a), and Fig. 2(b), where SiO_2 was deposited to delineate the beveled aluminum surface. Bevel etch factor depends on etch rates of the interface layer which relates to adhesion between photoresist and the oxide film, the oxide film and the aluminum itself. It will be impossible to control etch rates of the interface layer and the oxide film separately. Thus, bevel etch factor is considered to be determined by etch rates of the composite layer consisting of the interface layer and the oxide film, as shown in Fig. 3, and the aluminum.

Fig. 2(a) Beveled aluminum patterns for the first and second regions shown in Fig. 1.

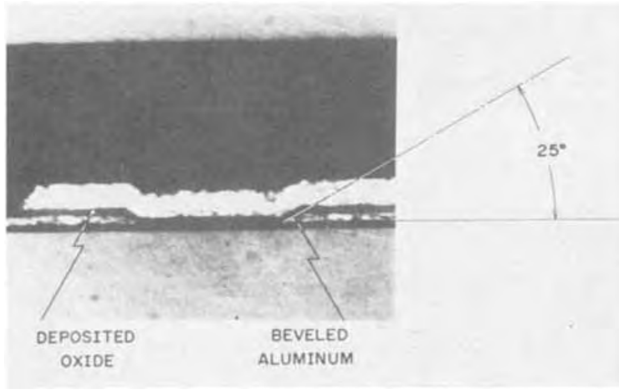

Fig. 2(b). Beveled aluminum for the second region showing a constant slope of $\theta = 25°$ at the beveled surface.

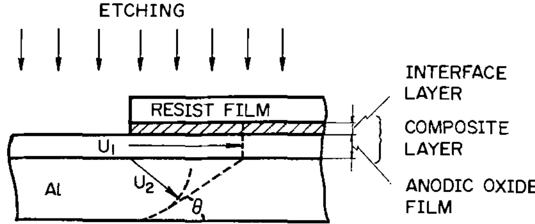

Fig. 3. Schematic illustration of etching for a composite layer consisting of interface layer and anodic oxide film.

Expressing etch rate of the composite layer and the aluminum as U_1 and U_2 respectively, the angle θ of the etched edge slope of aluminum is given by Eq. [2], as shown in Fig. 3

$$\theta = \arc\sin (U_2/U_1) \qquad [2]$$

Here, it is assumed that etch rate of the composite layer is that of lateral attack, and etching in aluminum proceeds isotropically. The cross section in Fig. 2(b) corresponds to the case of $U_1/U_2 = 2 \sim 2.4$, giving $\theta = 30 \sim 25°$ from Eq. [2].

Figure 4 shows how etch rates for OMR81PL resist of the composite layer U_1 and aluminum U_2 change with content of ammonium fluoride in the aluminum etchant; a 1500Å oxide film and an anodizing voltage of 1.0V are used. Etch rate of the aluminum decreased gradually with increasing ammonium fluoride, and became constant at an ammonium fluoride content exceeding 3/100. On the other hand, etch rate of the composite layer is smaller than that of the aluminum when the content of ammonium fluoride is low, and increases with NH_4F content. Etch rate of the composite layer is seen to be identical with that of the aluminum at an NH_4F content of near 1.7/100, where U_1 and U_2 curves in Fig. 4 intersect. Under this condition, bevel etch factor becomes unity for an aluminum thickness of 1.0μ from Eq. [1] because θ becomes 45° by putting $U_2/U_1 = 1$ into Eq. [2]. When the content of ammonium fluoride exceeds 1.7/100, etch rate of the composite layer becomes larger than that of the aluminum. This results in an increase in the bevel etch factor, as shown in the second region for OMR81PL of Fig. 1.

Figure 5 illustrates how the film thickness of OMR81PL resist and its corresponding bevel etch factor vary with oxide film thickness, when exposure time to light was varied from 2 to 16 sec at a constant value of light intensity. Resist film thickness is a slowly decreasing function of oxide film thickness, with exposure time as a parameter. But, its corresponding bevel etch factor shows different behavior in the first and second regions. In the first region, bevel etch factor decreases appreciably with oxide film thickness, and displays a larger value for shorter exposure time corresponding to thin resist film. That is, the value of bevel etch factor is seen to be related to resist film thickness as a function of exposure time. This may indicate that etch rate of the interface layer, which depends on adhesion between photoresist and the oxide film, becomes an influencing factor in determining bevel etch factor.

In the second region bevel etch factor increases with oxide film thickness, although resist film thickness varies according to exposure time and decreased slowly with film thickness as in the first region. This is a re-

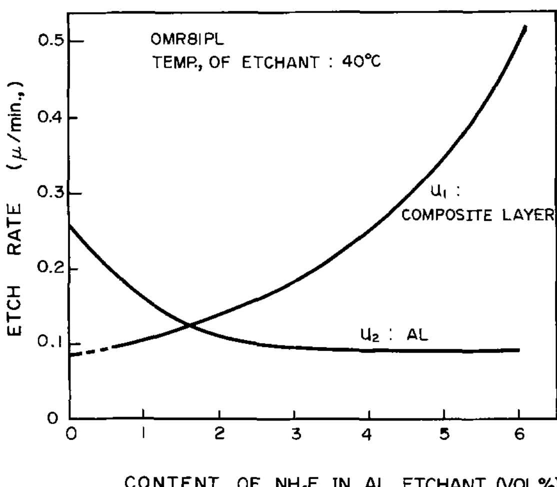

Fig. 4. Changes in etch rate of composite layer U_1 and that of aluminum U_2 with content of ammonium fluoride, OMR81 resist.

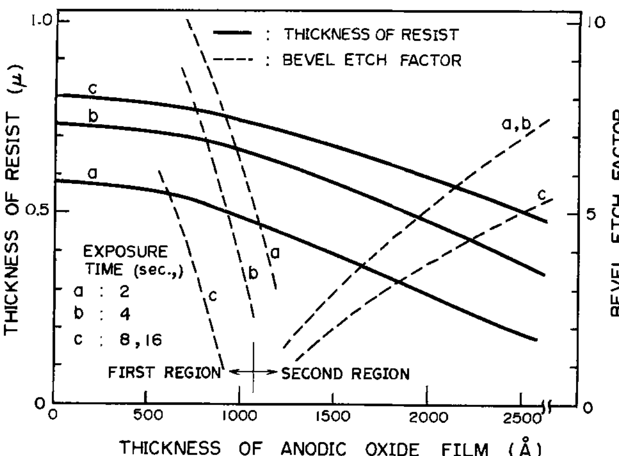

Fig. 5. Variations of film thickness of OMR81PL resist and corresponding bevel etch factor with anodic oxide film thickness. Exposure time to light is taken as a parameter.

verse tendency to that of the first region. Thus, behavior of bevel etch factor in the second region cannot be explained in terms of the etch rate of the interface layer *vs.* the resist film thickness which is controlled by exposure time.

The anodic oxide film consists of a porous layer which grows with anodizing time, and a barrier layer determined by the anodizing voltage (10). Variations of the composite layer structure with oxide film thickness are shown schematically in Fig. 6(a), (b), and (c). When oxide film thickness is far below 1000Å, the porous layer is also so thin that adhesion between photoresist and the oxide film will be poor. This will result in a large value of bevel etch factor as in the first region. At around 1000Å, the porous layer becomes thicker and photoresist adhesion will be enhanced giving a slow etch rate of the interface layer. Thus, etch rate of the composite layer will be determined by the barrier layer with a slow etch rate, resulting in a smaller value of the bevel etch factor.

When oxide film thickness is further increased beyond 1000Å, porous layer thickness will be increased although the barrier layer does not change with oxide film thickness. As a result, the porous layer will exert a predominant influence on etching characteristics, and etch rate of the composite layer will be increased, giving rise to a larger value of bevel etch factor. Thus, as shown in Fig. 1, there appears a minimum value of bevel etch factor at a thickness near 1000Å.

In the case of OMR83 and KTFR resists, as shown in Fig. 1, bevel etch factor in the second region is not largely altered by oxide film thickness. This cannot be explained by the processes as stated above, but differences in chemical composition of photoresist materials may be involved in connection with the anodic oxide structure as illustrated in Fig. 7(a) and (b).

Since the polymetric composition of OMR81PL is natural cisrubber, it is believed that the high polymers such as proteins and similar types are included in the rubber (9). The size of the polymer molecule after polymerization is, therefore, considered to be of the same order of magnitude as the diameter of the pore of the porous layer, ~170Å (10). Thus, the resist may not flow completely into the pores, but covers the pores as seen in Fig. 7(a). Then, the etch rate of the composite layer for OMR81PL will be determined predominantly by the etch rate of the porous layer which increases with oxide layer thickness as stated previously.

In the case of OMR83 and KTFR resists, on the other hand, the polymer molecule will be sufficiently small compared to the pore diameter because these resists are said to be synthetic rubber (9), and the pores will be completely filled with resist as seen in Fig. 7(b), eliminating effects of the porous layer on etch rate. Thus, etch rate of the composite layer asso-

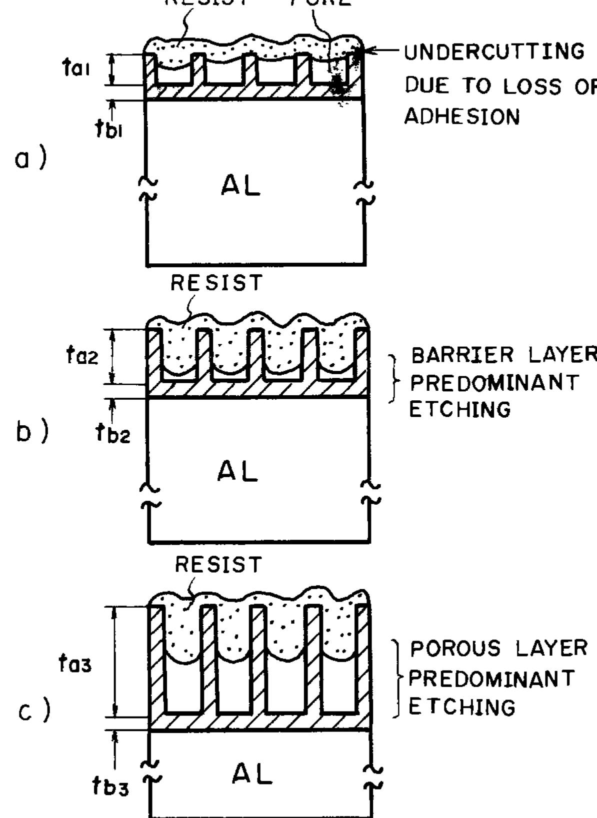

Fig. 6. Schematic illustration of changes in structure of composite layer and its associated etch rate limiting factor with anodic oxide film thickness.

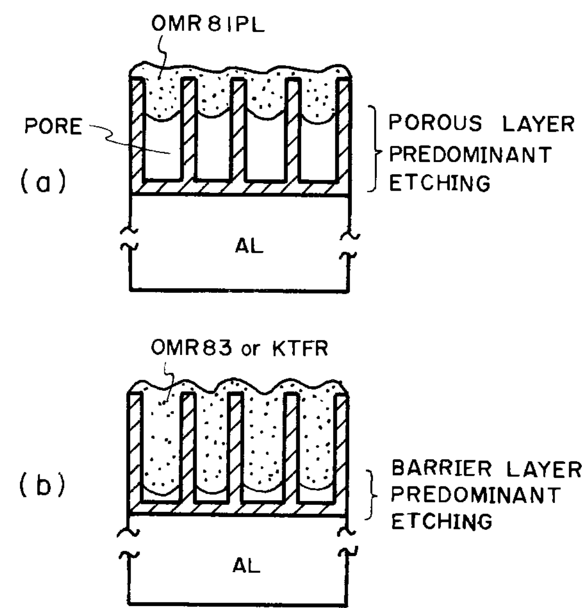

Fig. 7(a), (b). Schematic illustration of difference in etch rate limiting factor of composite layer with OMR81PL and OMR83 resists.

ciated with OMR83 or KTFR resist will not be predominantly influenced by the etch rate of the porous layer, although it increases with oxide film thickness, but by that of the barrier layer determined by the anodizing voltage. This will explain the small dependence of bevel etch factor for OMR83 or KTFR in the second region on the oxide film thickness for an anodizing voltage of 1.0V as shown in Fig. 1. But, when the anodizing voltage becomes lower, it was observed that etch rate of the porous layer, rather than the barrier layer limited over-all etch rate.

Figure 8 shows the variation of bevel etch factor for OMR83 resist when changing the anodizing voltage from 0.5 to 3.0V with oxide film thickness as a parameter. When the anodizing voltage is above 1.0V, the thickness dependence of bevel etch factor and its variation with anodizing voltage are seen to be small. On the other hand, when the anodizing voltage drops below 1.0V, the bevel etch factor increases with decreasing voltage, and its dependence on thickness of the oxide film becomes pronounced particularly for increasing oxide film thickness. When comparing oxide films having the same film thickness but different anodizing voltages, the film anodized at a lower voltage has a larger porous layer thickness than the film produced with a higher anodizing voltage. This may be explained by considering that with decreasing anodizing voltage, etch rate of the porous layer becomes a limiting factor for the composite layer rather than etch rate of the barrier layer.

Summary

Beveling of an aluminum edge for multilayer metal circuitry was performed by forming a porous anodic oxide film on aluminum during conventional photoresist and aluminum etch processing. The aluminum etchant employed contained a small amount of ammonium fluoride. The bevel etch factor was found to vary largely with anodic oxide film thickness, content of ammonium fluoride, and type of photoresist.

Bevel etch factor *vs.* oxide film thickness curves were divided into two regions on either side of a thickness near 1000Å. In the first region, with the oxide thickness in the range 0 to near 1000Å, the value of bevel etch factor and its variation were so large the controlled beveling could not be attained. This may be due to partial undercut at the interface between photoresist and the oxide film. As the oxide film approached 1000Å in thickness, the bevel etch factor declined to a minimum value.

In the second region above 1000Å, the bevel etch factor tended to increase from its minimum value with oxide film thickness; the rate of increase differed with types of resist and composition of etchant. The beveled surface in this region varied linearly at a constant slope determined by etch rate of the composite layer U_1 and that of the aluminum U_2. Etch rates were found to be controlled by the content of ammonium fluoride.

The increase in bevel etch factor with oxide film thickness was observed predominantly for OMR81PL resist. This can be explained by assuming that the limiting factor of etch rate of the composite layer U_1 changes from etch rate of the barrier layer to that of the porous layer with increasing oxide layer thickness at a constant anodizing voltage. For OMR83 and KTFR resists, however, the variation of bevel etch factor with oxide film thickness was not so pronounced. The results were explained by assuming that etch rate of the composite layer may be influenced by its structure, which is determined by the chemical composition of resists and the pore diameter of the anodic oxide film.

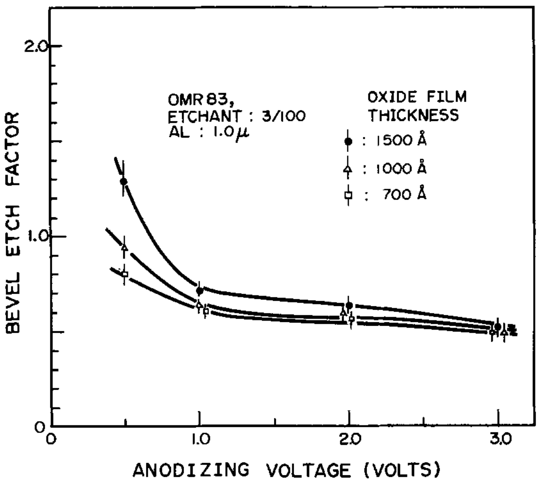

Fig. 8. Variations of bevel etch factor for OMR83 resist with anodizing voltage with anodic oxide film thickness as a parameter.

Adaption of Ion Implantation for Integrated Circuits

S. Prussin*

TRW Semiconductor Division, Lawndale, California 90260

and Anthony M. Fern*

TRW Systems, Lawndale, California 90260

Ion implantation has become established as a useful process for MOS device manufacture. In this use the implantation process determines the positioning of the electrically active atoms. Further processing consists of low temperature annealing whose primary function is to return the implanted atoms to full electrical activity.

For processing bipolar IC's, ion implantation is used primarily as a means of obtaining the uniform and reproducible deposition of electrically active impurity atoms. This is usually followed by high temperature heat-treatments which result in the redistribution of these deposited atoms. Such heat-treatments include the oxidation of the surface silicon as well as the in-diffusion of additional chemical species. The interaction of these heat-treatments with the radiation defects introduced by the prior ion implantation has been shown to result in the generation of stacking faults and dislocation loops capable of affecting device performance (1).

Uniformity of Ion-Implanted Impurity Deposition

The interest in applying ion implantation as a deposition technique in the processing of bipolar integrated circuits stems from two sources, the inherent uniformity obtainable over an entire wafer surface and the reproducibility from wafer to wafer. This uniformity was evaluated by measuring the resistance of identical 10□ resistors for 82 IC's which fitted over a 2 in. diameter wafer. The resistors were generated by implanting a fluence of 2.5×10^{13} p^{31} cm^{-2} at an energy of 100 keV. The background was a p-well similar to that used in CMOS construction. Implantation was carried out at room temperature using commercially available equipment. The coefficient of variation, *i.e.*, the standard deviation divided by the average resistor value was 1.0%. This uniformity is reflected in the uniformity of electrical parameters when ion implantation is used as a processing technique.

Experimental Study

This study was based on a specific IC design which had been successfully produced for several years by a triple diffusion technique for which a detailed performance record was available. The three chemical diffusions begin with an arsine collector deposition and drive. The base is formed by a BN deposition and a two-stage drive, first in wet N_2 and then in dry N_2. A PH_3 emitter diffusion completes the diffusions. Test diodes permitted easy evaluation of all the following pn junctions: the n^-p^- collector-substrate junction, the p^+n^- base collector junction, the n^+p^+ emitter-base junction and the n^+p^- emitter substrate junction.

Experience indicated that the base deposition was the most critical diffusion operation and it was chosen for replacement with an implantation of 1.2×10^{15} B^{11} cm^{-2} at 30 keV. The chemical emitter diffusion and other steps were maintained without change with one exception. Unless special precautions were taken with the base drive, heavy stacking fault concentrations resulted. These were found to correlate with excess leakage in the n^+p^+ junctions.

Ternary Defect Generation

Annealing processes which result in complete return of implanted ions to electrically active substitutional positions usually leave a concentration of microdefects of a size requiring transmission electron microscopy for their individual distinction (2). These have been referred to as secondary defects (3). Initial studies have shown that the thermal oxidation of silicon surfaces containing B atoms implanted at room temperature causes the small extrinsic dislocation loops to expand by several orders of magnitude into dislocation loops large enough to be easily detected by chemical etching and optical microscopy (1). These are referred to as ternary defects.

The combination of wet oxidation for 1 hr at 1100°C with Sirtl etching was found to result in easily discernable ternary defects when applied to ion implanted surfaces. Figures 1 and 2 illustrate the defects found for implantations of 10^{14} and 10^{15} B cm^{-2}. The upper left-hand corner of the illustration was shielded from implantation by the retaining chip which held the silicon wafer in position during the implantation. The ternary defects associated with the 10^{14} B cm^{-2} implantation appear to be an array of individual stacking faults, those associated with the 10^{15} B cm^{-2} implantation contain stacking faults superimposed over a background of fine substructures. This is illustrated in Fig. 3, where the fine substructure appears to consist of short defects, 0.5-1μ in length, grouped in radial arrays. High temperature annealing treatments in dry N_2 were found effective in preventing the generation of ternary defects (1).

Diffusion into Ion Implanted Surfaces

The all-chemically diffused process utilized a BN deposition followed by a two-step drive consisting of 15 min wet N_2 followed by 30 min dry N_2, both at 1140°C. Windows were opened in the oxide and the emitters were indiffused with PH_3. When ion implantation of B was substituted for BN deposition, the test diodes for the n^-p^-, p^+n^-, n^+p^-, and n^+p^+ junctions

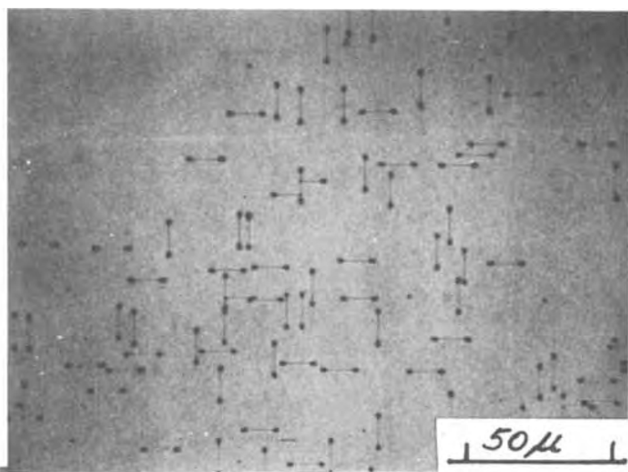

Fig. 1. Ion implant boundary, 10^{14} B cm^{-2}, 30 keV, (100) wet oxidized at 1100°C for 1 hr, Sirtl etched 30 sec. Magnification 405X.

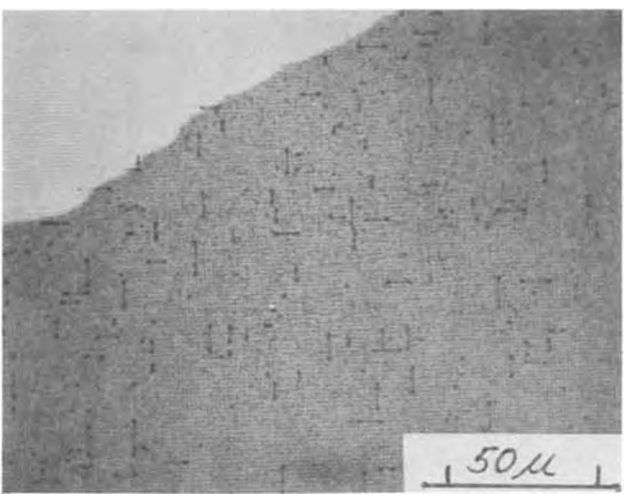

Fig. 2. Ion implant boundary, 10^{15} B cm^{-2}, 30 keV, (100) wet oxidized at 1100°C for 1 hr Sirtl etched 15 sec. Magnification 405X.

were evaluated. Similar characteristics were found for chemically deposited and ion implanted bases except for the n^+p^+ diodes. Here the leakage at reverse bias was much greater for the ion implanted diodes.

To reduce the generation of ternary defects without substantially changing the processing procedure, the base drive was changed from 15 min wet, 30 min dry, to a 15 min dry, 15 min wet, and 15 min dry sequence. The leakage current for three sizes of n^+p^+ test diodes for these two driving conditions is given in Table I. The introduction of a dry N_2 anneal at the beginning of the drive results in a leakage that is kept at, or below, the level associated with the all-chemical process.

Figures 4 and 5 illustrate emitter and base areas subjected to Sirtl etching to bring out defect structures. They represent structures that are identical except for being subject to different annealing cycles. The difference in their electrical properties is described

Table I. Correlation of base drive with leakage

Average leakage current in pA, $V_R = 3V$

Drive treatment	0.1 sq. mils	0.5 sq. mils	2.0 sq. mils
15 min wet N_2 30 min dry N_2 at 1140°C	2.3×10^3	10×10^3	47×10^3
15 min dry N_2 15 min wet N_2 15 min dry N_2 at 1140°C	1.1	2.1	7.0

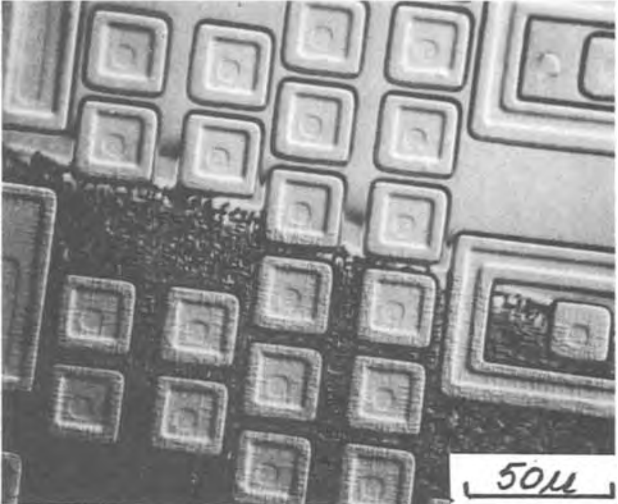

Fig. 4. Ion implant boundary, base deposition 1.2×10^{15} B cm^{-2}, 30 keV, base drive 15 min wet N_2, 30 min dry N_2, both at 1140°C, standard PH_3 emitter, Sirtl etched 15 sec, Nomarski phase contrast. Magnification 476X.

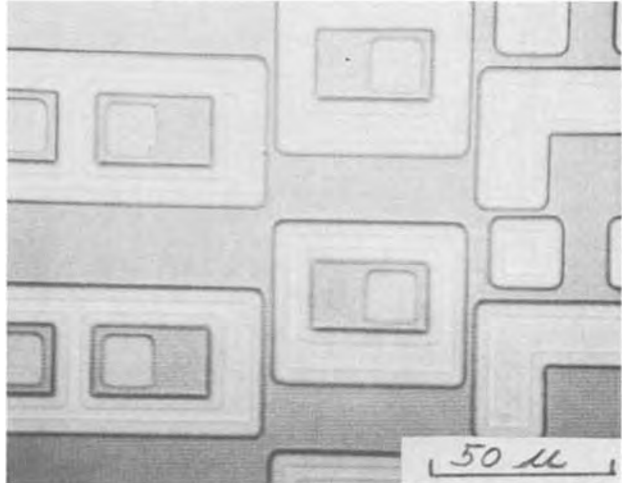

Fig. 5. IC surface, base deposition 1.2×10^{15} B cm^{-2}, 30 keV, base drive 15 min dry N_2, 15 wet N_2, 15 min dry N_2, all at 1140°C, standard PH_3 emitter, Sirtl etched 15 sec. Magnification 405X.

in Table I. The upper area in Fig. 4 was shielded from ion implantation. The darkened cross-hatched areas, characteristic of structural defects appear in the emitter areas only where they are superimposed over the ion implanted base areas. For Fig. 5, where the base drive included an initial anneal in dry N_2, no such structural defects appeared in any of the diffused emitter areas.

The presence of stacking faults and edge dislocations has been associated with soft junctions and emitter-collector pipes in all-chemically diffused npn structures (4, 5). Such pipes were found only under the phosphorus-diffused emitter areas and not in the remainder of the base area. This suggested a model that the pipes are a result of enhanced phosphorus diffusion along crystalline defects (4). The addition of gold increases the junction leakage suggesting that the precipitation of gold or other fast diffusers on the defects passing through the collector-base junction may also play a significant role (5).

Parameter Control Comparison

Table II compares the parameter distribution found for a lot of wafers processed with chemical diffusion

Table II. Parameter control comparison of typical lots
(Approximately 640 devices of each type represented)

Parameter	Average value Chem	Average value Ion	Coefficient of variation % wafer to wafer array 8 wafers within lot Chem	Ion	Average coefficient of variation % within a wafer 80 samples per wafer Chem	Ion

only with the parameter distribution found when an ion-implanted base is substituted for BN deposition. The average electrical parameters for both production techniques were very close with the exception of the V_{SAT} values. This is attributed to the fact that the Q value for the collector deposition was chosen to be substantially less for the case where the base was ion implanted than for the case where the base was chemically deposited. It is noted that the ion-implanted group exhibits significantly greater uniformity over individual wafers and greater reproducibility from lot to lot.

Acknowledgments

The authors thank Dr. Arthur Hochberg and Ralph Miller for their support and useful discussions, and Leonard Braun and Jay Levine for preparing the ion-implanted specimens.

A Nondestructive Method for Examining Compositional and Doping Variations in GaAs-GaAlAs Heterostructure Material Using a Scanning Electron Microscope

R. A. Linnell

Bell Laboratories, Murray Hill, New Jersey 07974

Presently, layer thickness measurements of multilayered GaAs-GaAlAs material are usually made by optically viewing samples that have been mechanically lapped at a shallow angle and etched to reveal the interfaces of thin layers. This technique suffers from two major defects: (*i*) it is inherently destructive and wastes material; and (*ii*) polishing-induced scratches obscure micron-size defects. An alternate method of layer thickness measurement requires cleaving a facet perpendicular to the epitaxial layers, etching to achieve topographic distinction among the layers, and then observing with a scanning electron microscope (SEM). This method also has drawbacks which are often important: (*i*) the etching (partial destruction) of the laser mirror surface makes the method unsuitable for studying a device which is subsequently to be used; (*ii*) cleaving faults, often produced in as-grown wafers, can parallel and be indistinguishable from the etch-revealed layer interfaces; (*iii*) "highlights" and shadows associated with etch-revealed edges can often make the thickness determination of thin layers somewhat uncertain; and (*iv*) some etchants have the effect of producing sloping facets at interfaces so that subsequent viewing with the SEM can misleadingly reveal additional layers (1).

This paper discusses a third method of layer thickness measurement which allows a sample without prior treatment to be measured quickly using the SEM. Since no etching of the cleaved face is required, this technique is appropriate for observations of micron-size defects, for layer thickness or taper determinations, etc., in devices that are to be subsequently used. An acronym which serves as a convenient shorthand notation and which describes our technique is ACABOB (Adjustment of Contrast, Amplifier type, Brightness, Orientation and Beam current). The enhanced contrast in our case is related to signal processing and should be distinguished from what is commonly known (2) as the voltage-contrast technique. In the latter case, contrast at a p-n junction is achieved by applying an external d-c voltage across the specimen; this is unnecessary in our case. It should be noted that scanning electron micrographs somewhat similar to our Fig. 2-4 have appeared in the literature (3) but no discussion of the techniques employed has been given.

Key words: SEM, GaAs, semiconductor, laser, epilayer.

When one attempts to accurately measure the spatial variations in thicknesses of epitaxially grown layers of GaAs-GaAlAs laser material, it is convenient to view these layers in an end-on fashion. If a smooth and clean surface, as would be obtained by properly cleaving this material, is oriented normally to the primary beam, the variations in the image formed by Secondary Electron Emission (SEE) can be attributed entirely to changes in work function caused by changes in impurity doping and material composition of the various layers. Under normal operating conditions, these variations are extremely small compared with the over-all image intensity and meaningful determinations are difficult to make. The purpose of this paper is to describe a technique for greatly enhancing these variations and to illustrate the application of this technique for characterization of epitaxially grown GaAs-GaAlAs laser material.

A major component of the image formed by SEE is noise. Noise can be detected as backscattered electrons (those electrons emerging from deeper regions of the primary beam interaction volume and hence from a larger region of surface area) or as unwanted, self-generated signals in the electron detection and imaging system. Unfortunately, under normal operating conditions the noise fluctuations are often larger than the variations due to the specimen's compositional differences. In an effort to improve the signal-to-noise ratio it has been found that the number of electrons reaching the sample can be increased by decreasing the current in the first condenser lens. This results in an increased primary beam diameter at the sample surface and thus decreases the resolution of SEE. The majority of SEM's presently in use have an absolute resolution of 100Å in the SEE mode. Since the layer thicknesses of interest are usually greater than 0.1μ, we can tolerate some degradation in resolution. In practice we find the improvement in signal-to-noise (which is primarily a function of the beam area) is greater than the loss of resolution (which is primarily a function of the beam diameter), and we can usually find a point at which both parameters are satisfactory. The resulting improvement in the discrimination of intensity variations of the image formed by SEE is still often insufficient to allow easy identification of layer interfaces. Therefore, several additional electronic image processing techniques are employed to maximize these variations.

The image from SEE (or any other mode) is typically amplified, electronically processed, and then displayed on a cathode ray tube (CRT). Since the CRT phosphor has a limited dynamic range, the image produced by SEE must be confined within that range through video image processing. The a-c (contrast) and the d-c (dark level) portions of the video signal can be separately controlled. Small variations in amplitude in an image can be maximized by increasing the contrast until the maximum signal variations are as large as the useful range of the CRT and then by decreasing the dark level until the signal variations fall within that range of the CRT (4). In addition, it has also been suggested (4) that the use of a logarithmic circuit element (γ-control) will reduce the contrast variation when one region of the image has a much greater amplitude than the remainder of the image. Without the γ-control, contrast would be limited by the need to keep the largest amplitude within the range of the CRT. Figure 1 illustrates these techniques.

Figure 1a is a schematic of double heterostructure gallium arsenide laser material and the other figures are single line waveforms of SEE from this material. Figure 1b displays the waveform which would result from the use of the linear video amplifier and the "normal" setting of the dark level for our SEM. The useful range of the CRT is bracketed at the left. The amplitude of the image from SEE for the metal contact is much greater than the amplitude of the image from SEE for GaAs and appears above the useful range of the CRT. Figure 1c shows the result when a logarithmic video amplifier is introduced. The signal from the metal contact is now within the range of the CRT but notice that the contrast differences of the

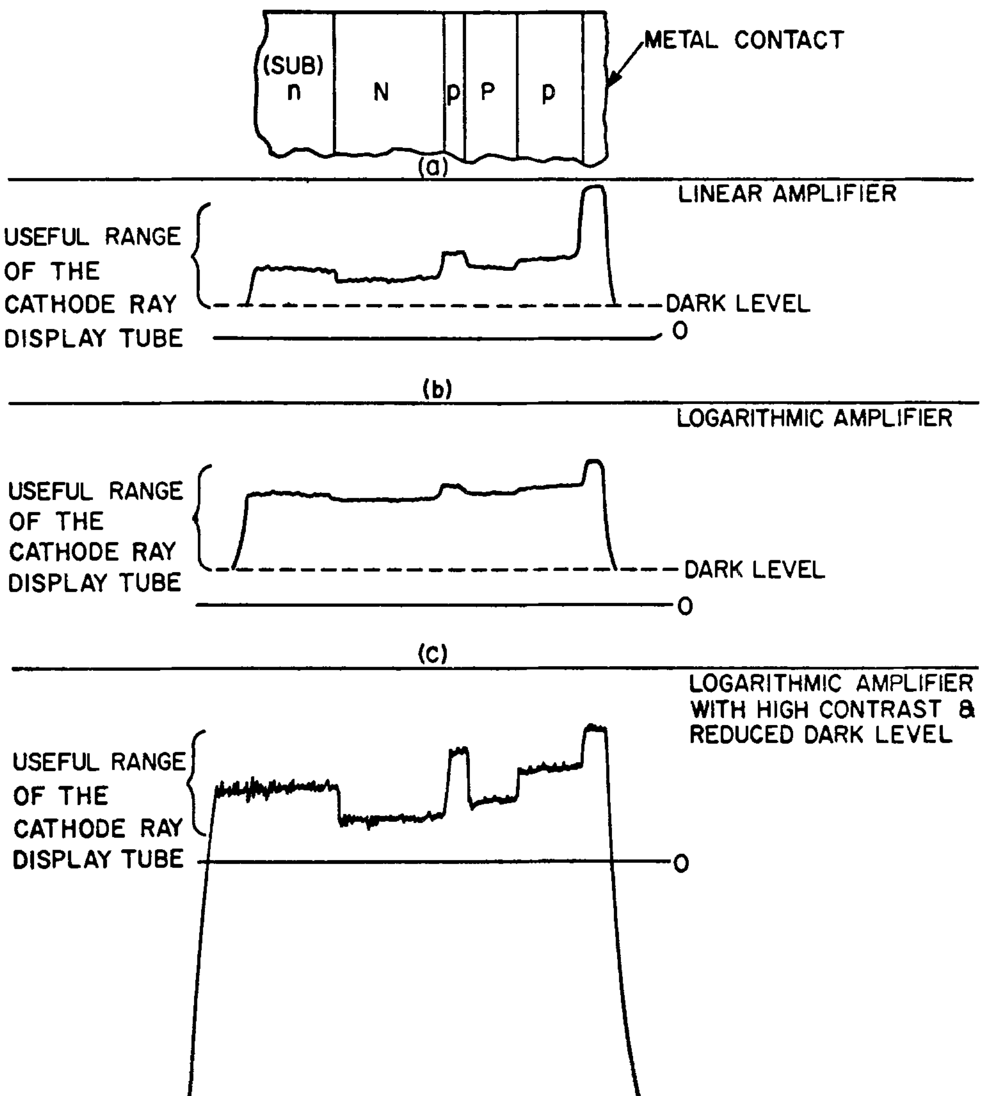

Fig. 1. (a) A schematic of double heterostructure GaAs-GaAlAs laser material with an n-tpye GaAs substrate, an N-type GaAlAs ternary layer, a p-type GaAs active layer, a P-type GaAlAs ternary layer, a p-type GaAs cap layer and a metal contact. (b) A single line scan of secondary electron emission (SEE) of the material in (a). Normal settings of dark level and contrast, and linear amplification are used. (c) Same line scan as (b) with the same settings of dark level and contrast, but using logarithmic amplification. (d) Same line scan as (c) with the dark level reduced and the contrast increased to utilize the maximum dynamic range of the cathode ray display tube.

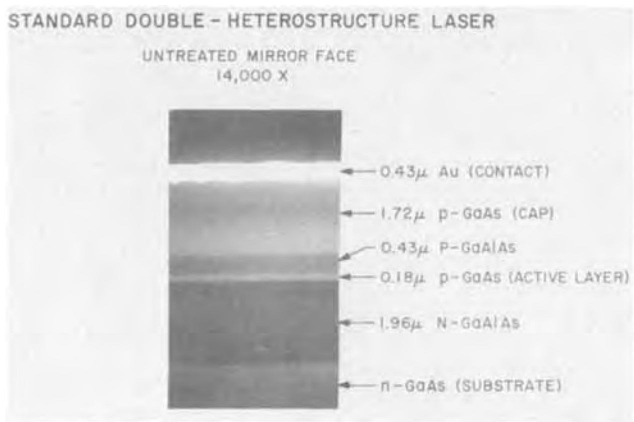

Fig. 2. Scanning electron micrograph of an untreated, cleaved mirror face of a double-heterostructure laser with a metal contact.

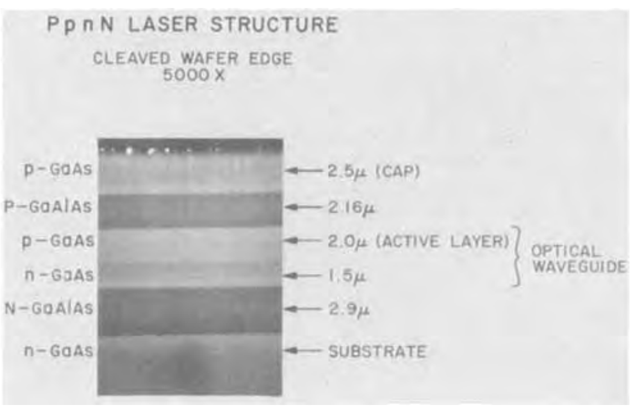

Fig. 3. Scanning electron micrograph of an untreated, cleaved face of a thick optical cavity laser without metallization.

layers have been reduced to a small portion of the useful CRT dynamic range. Figure 1d utilizes the entire dynamic range of the CRT to display information from layer differences. As shown, the contrast has been increased and the dark level decreased to place the signal within the useful range of the CRT. These techniques were employed to make the scanning electron micrograph of a metallized double heterostructure laser (5) shown in Fig. 2.

One further technique proved useful when examining layers of material with no metallization, such as

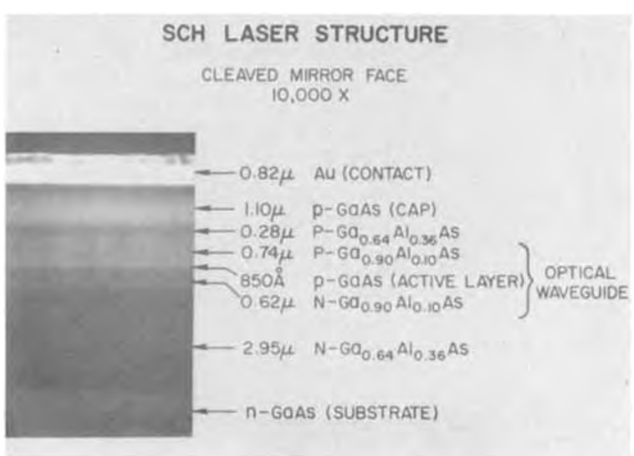

Fig. 4. Scanning electron micrograph of an untreated, cleaved mirror face of a separate confinement heterostructure laser with adjacent ternary layers and a thin active layer.

portions of as-grown wafers. When a primary beam strikes a sharply curving surface such as the edge of a specimen, more secondary electrons are generated. In order to prevent the edge from appearing overly bright and "washing out" the interface between the first two layers, the normal to the sample face is placed at a slight angle with respect to the primary beam axis with the troublesome edge farthest from the detector. This puts the edge in "shadow" and eliminates interfering "highlights". With no metallization, a linear amplifier, rather than a logarithmic amplifier can be employed. Figure 3 illustrates this technique. Shown is a scanning electron micrograph of an unmetallized thick optical cavity laser (6). The bright spots along the edge are dirt particles extending over the cleaved face.

A severe test of the resolution of the ACABOB technique is the separate confinement heterostructure laser (7) shown in Fig. 4. This configuration differs from the double heterostructure configuration in that the GaAs active layer is sandwiched between four GaAlAs layers rather than just two. The two ternary layers on each side have differing aluminum concentrations: the outer layer has 36 atom per cent (a/o) Al; and the inner layer has only 10 a/o Al. In addition, the active layer is only 850Å thick. While all interfaces can be seen, the interfaces between the 10 a/o ternary layers and the active layer are less clear than the interfaces in the first two micrographs. The variance in mea-

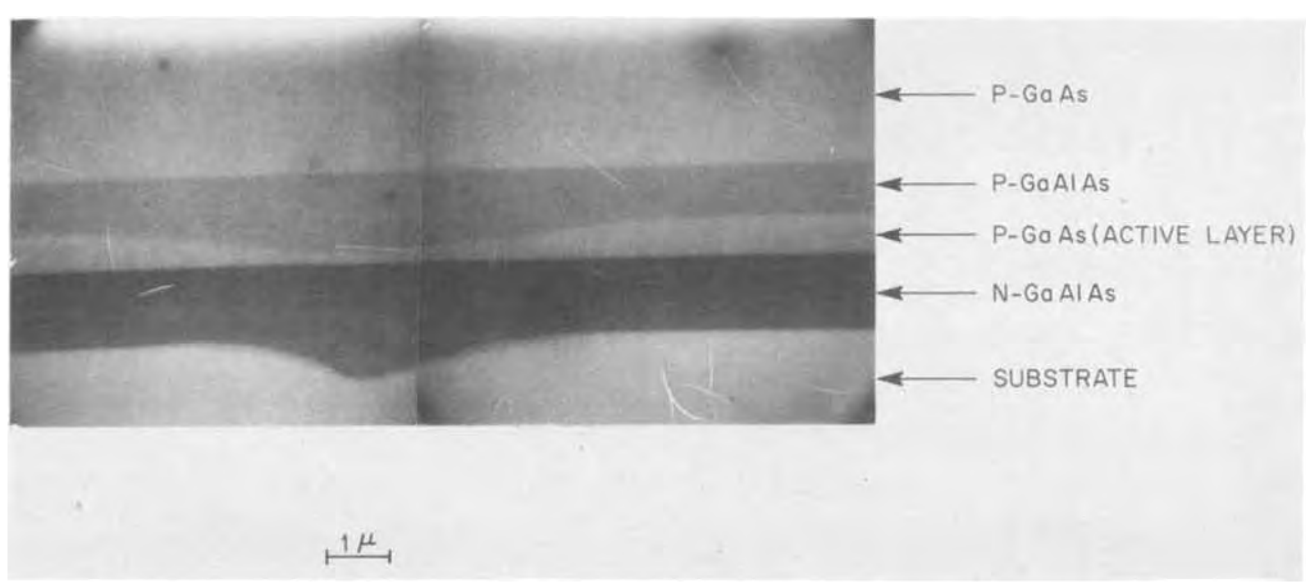

Fig. 5. Scanning electron micrograph of an untreated, cleaved face of double-heterostructure laser material, revealing two defects in the layers.

surements of the thin active layer using this and other micrographs of the same sample is ±250Å, suggesting an ability to detect layers as thin as 500Å.

The ACABOB technique can also be used to examine micron-size defects appearing at the cleaved surface. Figure 5 is a scanning electron micrograph of a DH structure showing defects in the layers which would adversely affect laser operation. These defects are three dimensional, and the cleaved face is a cross section in one plane. It appears that the bottom defect has been cleaved near its diameter, while the upper defect center is either into or out of the paper. The locations of the cleave must be known to properly analyze the nature of the revealed defects. No lapping procedure could reveal defects of this magnitude.

Sample contamination due to the presence of hydrocarbons in the vacuum space of the specimen chamber is inherent in all scanning electron microscopes using a hydrocarbon-based diffusion pump fluid. Such contamination will act as a mask if the sample is subsequently exposed to one of the standard etchants (8). The increase in rate of contamination with increasing primary electron beam current might seem to be a drawback of the ACABOB technique. We do not find this to be the case since the contamination can be removed by cleaning and no evidence of permanent specimen damage can be found.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 121, No. 8, 9, 10, and 12; August, September, October, and December 1974.

Thermodynamics and Kinetics of Pack Aluminide Coating Formation on IN-100

S. R. Levine and R. M. Caves (pp. 1051-1064, Vol. 121, No. 8)

J. M. Trenouth:[1] In the paper under discussion, the authors reported that the variation in coating weights and thicknesses of specimens within a pack was generally small whereas there was more variation in these measurements between packs. It was noted that this latter variation influenced coating composition and microstructure but no satisfactory explanation for its occurrence could be found.

Such behavior has been observed in some of the experimental coating work conducted in this laboratory (and also noted in other coating results reported in the literature). While a number of coating variables such as activator carry-over and pack permeability as well as those mentioned by Levine and Caves in the paper under discussion were considered, it was concluded that, in our coating experiments, the primary variable responsible for such coating variation was pack temperature. In these experiments it was calculated that a 10°C variation in coating temperature would result in a 10% change in coating weight during deposition of a chromium-titanium alloy coating using processing times of 2, 4, or 8 hr at 1300°C. Based on their reported level of temperature control for the box furnace used for coating formation (±15°C) and their subsequently determined temperature dependence of coating formation (a +15°C variation in temperature giving an 18% increase in coating thickness), it is suggested that pack temperature variability may adequately explain the variation in coating weights and thicknesses between packs noted in the paper being discussed.

S. R. Levine and R. M. Caves: We agree that temperature control was primarily responsible for the variability between packs run under the same nominal conditions.

Hall Effect, Schottky Barrier Capacitance, and Photoluminescence Spectra Measurements for GaAs Epitaxial Layer and Their Correlation

T. Katoda and T. Sugano (pp. 1066-1073, Vol. 121, No. 8)

R. Bhat:[2] With regards to the paper under discussion we wish to point out that when the Fermi level goes below the donor level (Fig. 7 of that paper) the donors will be positively ionized but the acceptors will remain neutral. This can be seen from the following expression obtained using detailed balance

$$\frac{Na^-}{Na} = \frac{1}{1 + 2\exp{(E_A - E_F)/kT}}$$

where Na^- is the number of ionized acceptors and Na is the total number of acceptors. Since $(E_A - E_F)$ is positive for the case being considered, it follows that (Na^-/Na) is very small, *i.e.*, most of the acceptors are un-ionized.

[2] Rensselaer Polytechnic Institute, School of Engineering, Troy, New York 12181.

The difference they obtain between the variation of the number of mobile carriers with temperature and the variation of the number of ionized impurities with temperature is probably due to inaccuracies in their theory rather than the presence of impurities which are undetectable by Schottky barrier capacitance and photoluminescence methods.

T. Katoda and T. Sugano: We thank the above author for his discussion of our work. Here we would like to direct his attention to the change of the shape of the distribution function as well as to the shift of the Fermi level with increase of temperature, with regards to the change of ionized acceptor density as shown in Fig. 7 in the paper being discussed.

For example, assuming that the acceptor level is located 0.07 eV above the Fermi level, that is $E_A - E_F = 0.07$ eV at 118°K, where the carrier density of the sample No. 213 begins to increase abruptly as shown in Fig. 5 of the paper under discussion, we find out that electrons trapped at the acceptor level increase by more than a factor of 50 even if the Fermi level goes down by 0.01 eV, *i.e.*, $E_A - E_F = 0.08$ eV, with an increase of temperature to 300°K.

Figure 7, of the paper under present consideration, which shows the shift of Fermi level to a value lower than that of the donor level, rather exaggerates the shift of Fermi level, but the above numerical example indicates that acceptors can be negatively ionized at room temperature even if the Fermi level is below the acceptor level.

Reexamination of Some Aspects of Thermal Oxidation of Silicon

Y. Ota and S. R. Butler (pp 1107-1111, Vol. 121, No. 8)

R. H. Doremus:[3] The authors of the paper under discussion have concluded that "there is no acceptable model for the processes going on at the gas-oxide interface." However, their experiments do not measure processes at the gas-oxide interface, but rather the rate of transport of water through the silica film. A model of molecular diffusion of water through the oxide film[4] can explain their results and those of Deal and Grove.[5] In this model water molecules diffuse through the film to the silicon-oxide interface, where they react to form more oxide

$$2H_2O + Si = SiO_2 + 2H_2 \quad [1]$$

The hydrogen formed in this reaction diffuses rapidly out of the film.

Gas molecules dissolve and diffuse in the open structure of amorphous silica.[6] Molecules as large as krypton and xenon dissolve and diffuse in silica, as well as argon, oxygen, water, and smaller molecules. The diffusion coefficient of water molecules in amorphous silica is about $3(10)^{-9}$ cm^2/sec at 1000°C, so the measured rates of oxidation of silica by water can readily be explained by molecular diffusion of water.

In this model the parabolic rate coefficient B in the paper under discussion should be directly proportional to the water vapor pressure, as found in the above-mentioned work and by Deal and Grove,[5] since the molecular solubility of water is proportional to the gas pressure. There is no conflict with the results of Moulson and Roberts,[7] since they measured the concentration of water that had reacted with the silicon-oxygen lattice to form SiOH groups, not the concentration of molecularly dissolved water. The concentration of reacted water should be proportional to the square root of the water vapor pressure, as found by Moulson and Roberts, because of the reaction

$$H_2O + Si\text{-}O\text{-}Si = 2SiOH \quad [2]$$

The hydrogen formed in reaction [1] diffuses rapidly from the oxide because of the small size of the hydrogen molecule. Addition of external hydrogen pressure does not affect the rate of water diffusion or oxidation because these molecules diffuse independently in the silica lattice.[6] Only if the hydrogen pressure is high enough to suppress reaction [1] and make its rate the controlling step in the oxidation process would one expect to find an influence of hydrogen. Thus the similarity of oxidation rates with and without hydrogen, as found in the paper being discussed, is consistent with the molecular diffusion model.

Y. Ota and S. R. Butler: We are grateful to Doremus for pointing out his molecular diffusion model for H_2O transport in SiO_2.[6] This model is consistent with the linear pressure dependence for the oxidation rate equation coefficient B [5] as he asserts. Further, he supplies a logical rationale for the inapplicability of the data of Moulson and Roberts[7] to the analysis of silicon oxidation rates of Deal and Grove.[5] Doremus also asserts that the diffusion coefficient of 3×10^{-9} cm^2/sec [6] will account for the observed oxidation rates.

However, if we take this value for the concentration of dissolved H_2O, 2.9×10^{-7} moles/cm^3 [6] (which converts to 1.7×10^{17} cm^{-3}) and calculate the coefficient B we obtain $\sim 2 \times 10^{-14}$ cm^2/sec, which is nearly 2 orders of magnitude less than the measured value of Deal and Grove[5] at 1000°C. We cannot therefore agree that the oxidation rates can be "readily" explained by the molecular solution and diffusion model. In addition, if we apply the model of diffusion with chemical reaction which Doremus has proposed for H_2O transport in SiO_2,[6] we obtain a further reduction in the effective diffusion coefficient by two orders of magnitude. We must still conclude that there is no adequate model of the process of silicon oxidation.

The Temperature and Oxygen Pressure Dependence of the Ionic Transference Number of Nonstoichiometric CeO_{2-x}

G. J. VanHandel and R. N. Blumenthal (pp. 1198-1202, Vol. 121, No. 9)

H. L. Tuller[8] and A. S. Nowick:[9] In the paper under discussion VanHandel and Blumenthal reported results for the ionic transference number, t_i, of "pure" CeO_{2-x} as a function of p_{O_2} and temperature. Because these results showed maxima in the plot of t_i *vs.* p_{O_2} at 590° and 702°C, they concluded that electron holes become the dominant charge carriers at high p_{O_2} and low T.

The question of electronic contributions to the conductivity of ceria has become particularly important of late because of interest in ceria doped with lower valent cations (*e.g.*, Ca^{2+} and Y^{3+} ions) as a possible solid oxide-ion electrolyte for application in fuel cells.[10-12] In recent papers,[13,14] the present authors presented results for the system CeO_2:5% Y_2O_3 from

which the electrolytic domain (T-p_{O_2} region for which $t_i \geqq 0.99$) was determined. It was concluded that doped ceria looked particularly attractive as a solid oxide electrolyte at temperatures below 800°C. In such applications it is important that electronic contributions be kept very small. Accordingly, it is essential that all sources of electronic carriers be established in this range of prospective application.

In this discussion, we will demonstrate that the maximum in t_i reported in the paper under discussion which led VanHandel and Blumenthal to propose an electron hole contribution, is inconsistent with electrical conductivity measurements which we have made,[15] and we will attempt to explain the discrepancy.

Since the reported maximum in t_i is a value whose magnitude is ~0.5, and since the mobility of the oxygen-ion vacancies $V^{\cdot\cdot}_O$ is much smaller than that of electrons and holes, it follows that the maximum must occur in the range where $[V^{\cdot\cdot}_O] >> n, p$ and therefore where the vacancies are primarily compensated by impurities (mainly Ca_{Ce}) so that

$$[Ca''_{Ce}] = [V^{\cdot\cdot}_O] \quad [1]$$

In this range, the total conductivity may be expressed the form[16]

$$\sigma_{total} = C_i\mu_i + C_h\mu_h p_{O_2}^{1/4} + C_e\mu_e p_{O_2}^{-1/4} \quad [2]$$

where the μ's are mobilities and the C's are constants, the subscripts i, h, and e referring to ions (*i.e.*, vacancies), holes, and electrons, respectively. The ionic transference number is then

$$t_i = C_i\mu_i/\sigma_{total} \quad [3]$$

since $C_i\mu_i \equiv \sigma_i$ is the ionic conductivity.

One can therefore investigate the question of a hole contribution in this range of p_{O_2} by observing the p_{O_2} dependence of either σ or t_i. If the hole contribution is significant, Eq. [2] predicts a minimum in σ as a function of p_{O_2} while Eq. [3] predicts a maximum in t_i, such as reported in the paper being discussed. On the other hand, if the hole contribution is negligible, σ should decrease with increasing p_{O_2} until a plateau in σ is reached, the magnitude of which is determined by the constant contribution of σ_i. In that case, t_i should increase toward a saturation value close to unity without passing through any maximum.

A dependence of conductivity of the second sort has in fact been observed by the present authors[15] in single crystal CeO_2 at 635°C. Figure 1 shows a plot of σ_{total} (normalized with respect to the constant σ_i term) as a function of p_{O_2} both for the experimentally obtained values at 635°C and for values derived from the t_i data in the work under consideration at 590°C.[17] While the increase in σ_{total} at low p_{O_2} has been widely observed (and is known to be due to the electronic contribution which appears when CeO_2 is reduced to CeO_{2-x}), there is no evidence for the increase in σ_{total} for $p > 10^{-4}$ atm predicted from the data for t_i in VanHandel's and Blumenthal's paper. Rather the conductivity shows a slow decrease toward a p_{O_2}-independent saturation value. Such a discrepancy between the two sets of data would be explained if our sample were substantially less pure than that in the paper being discussed. However, from the absolute conductivity values as well as the analysis published by Blumenthal *et al.*[18] in comparison with an analysis of our own material, it appears that, if anything, the aliovalent cation impurity content of the material in the paper under discussion is slightly higher than that of ours.

[15] H. L. Tuller and A. S. Nowick, To be published.

[16] R. A. Rapp and D. A. Shores, in "Techniques of Metals Research," Vol. 4, Book 2, John Wiley and Sons, Inc., New York (1970).

[17] A correction for the temperature difference would make the rise in the curve of Fig. 1 from the paper under discussion slightly less steep, but nevertheless it would be clearly present.

[18] R. N. Blumenthal, F. S. Brugner, and J. E. Garnier, *This Journal*, 120, 1230 (1973).

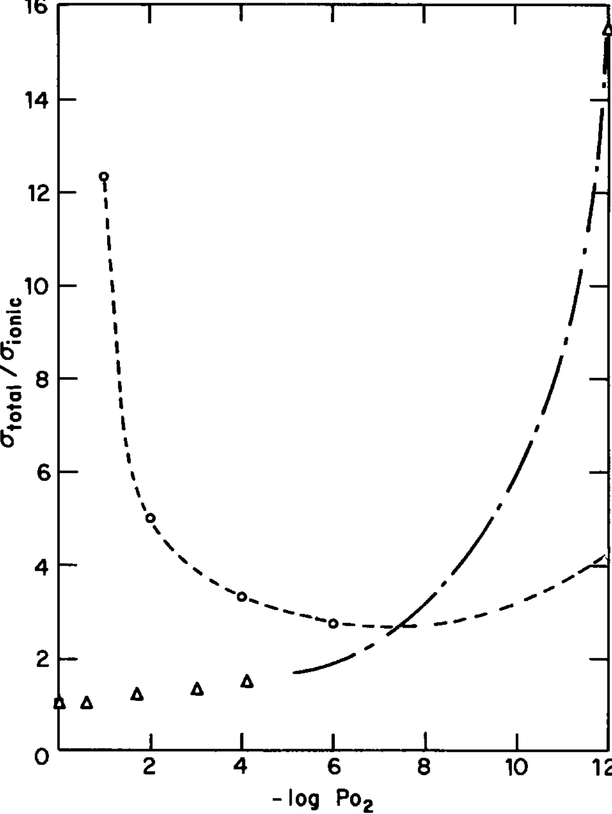

Fig. 1. Isothermal plots of σ_{total}/σ_i vs. log p_{O_2} from direct measurements and as calculated from t_i data in paper under discussion by VanHandel and Blumenthal. ○, Calculated from the work of VanHandel and Blumenthal at 590°C; △, measured by Tuller and Nowick[15] at 635°C.

In seeking the cause of this discrepancy, we wish to note the possibility that the experimental apparatus used in the work being discussed is subject to errors in the determination of t_i due to possible leakage and mixing of gases between the cathodic and anodic chambers. From the equation relating the measured emf of the cell to t_i

$$E_{meas} = (RT/4\mathbf{F})\, t_i \ln(p_{O_2}'/p_{O_2}) \quad [4]$$

it is clear than any unaccounted-for mixing of gases between the two chambers will always result in a calculated value of t_i which is less than the true value. Such leakage would be expected to be a more serious problem at the lower temperatures of this experiment due to a decrease in viscosity of the Pyrex "O"-ring used. This, in addition to possible polarization problems at these lower temperatures, could explain the apparent maxima obtained in the paper being discussed. In fact, preliminary cell measurements in our laboratories, in which a calcia-stabilized zirconia reference electrolyte was employed to avoid the problem of gas leakage, do not indicate the appearance of a maximum in t_i at low temperature and high p_{O_2}.

In summary, it can be said that the suggestion that the electron hole is a significant contributor to the conductivity in the range close to stoichiometry is not supported by the observed partial pressure dependence of the conductivity in this range. Rather, a model involving impurity compensating oxygen vacancies, which give rise primarily to ionic conductivity, appears to be consistent with the results. Such positively charged vacancies also serve to explain the "p-type" thermoelectric power observed in this range.[19] It appears that the decreasing values of t_i at high p_{O_2} and low temperatures reported in the paper under con-

[19] Y. Wilbert, J. J. Oehlig, and A. Duquesnoy, *C.R. Acad. Sci. Paris*, C272, 1960 (1971).

sideration may be explained by the occurrence of gas mixing and/or polarization effects.

G. J. VanHandel and R. N. Blumenthal: In the paper under discussion we reported the results of a study employing an electrochemical cell technique to measure the ionic transference number, t_i, of sintered specimens of "pure" CeO_{2-x} as a function of P_{O_2} and temperature. The results were described in terms of a high and low oxygen pressure region. At high oxygen pressures t_i is controlled by impurities. In this region the electronic conductivity was p-type at lower temperatures and n-type at higher temperatures. No attempt was made to quantitatively analyze the data in this P_{O_2} region, because the electrical conductivity has been reported to be influenced by impurities.[20] In the low oxygen pressure region $t_i \sim 0.05$ when both the electronic and ionic conduction is controlled by the nonstoichiometric defects.

The above comments by Tuller and Nowick suggest that the electron hole conduction in "pure" CeO_{2-x} is negligible. They base their argument on the use of the following expression (*i.e.*, Eq. [2] in the above discussion) for the total electrical conductivity

$$\sigma_{total} = C_i\mu_i + C_h\mu_h P_{O_2}{}^{1/4} + C_e\mu_e P_{O_2}{}^{-1/4} \quad [1]$$

and the P_{O_2} dependence of a single crystal of CeO_2 at 635°C.

It is difficult to compare directly the transference numbers calculated by the above-mentioned authors with the t_i data we obtained using an electrochemical cell technique at high P_{O_2} and low temperatures, because the departure from stoichiometry[21] is small in this region and thus the electrical conductivity is very sensitive to impurities. We have found, for example, the dependence of σ on P_{O_2} is different for sintered CeO_2 specimens prepared from the same grade of CeO_2 powder.

Since we cannot make a direct comparison of the results of these two studies, we will demonstrate some of the problems associated with calculation of ionic transference numbers from Eq. [1] and the P_{O_2} dependence of the electrical conductivity of "pure" CeO_{2-x}.

As an example consider the results of Tuller and Nowick (see their Fig. 1 above) where the plot of $1/t_i$ *vs.* log P_{O_2} would suggest that t_i approaches zero asymptotically with decreasing P_{O_2} below approximately 10^{-12} atm. In contrast to their results, our direct measurements of t_i at low oxygen pressures (in the work being discussed) show that t_i approaches a value of approximately 0.05 over a wide range of oxygen pressures and temperatures and thus the nonstoichiometric defects (*i.e.*, $V^{\cdot\cdot}_o$ and Ce'_{Ce} [21]) control both the ionic and electronic conduction. Using the value of $t_i \simeq 0.05$ an estimate of the diffusion coefficient for doubly ionized oxygen vacancies, $D_{V^{\cdot\cdot}_o} \simeq 3.5 \times 10^{-5}$ cm²/sec, at 1000°C was calculated by combining recently obtained thermodynamic $x = x(P_{O_2},T)$ and conductivity $\sigma = \sigma(P_{O_2},T)$ data with the Nernst-Einstein relation. Within experimental error the result was in good agreement with $D_{V^{\cdot\cdot}_o} \simeq 1.1 \times 10^{-5}$ cm²/sec calculated at 1000°C from the expression for $D_{V^{\cdot\cdot}_o}$ obtained from a recent electrical conductivity study[18] on CaO-doped CeO_2. Information of this type could not be obtained from the analysis used by Tuller and Nowick above. In fact at low oxygen pressures (*i.e.*, $10^{-3} < x < 10^{-2}$) the electronic conductivity is proportional to $P_{O_2}{}^{-1/5}$ and Eq. [1] would not be applicable.[20,21]

At high oxygen pressures Tuller and Nowick report that σ approaches a plateau with increasing P_{O_2} and as shown in Fig. 1 above, $t_i = 1$ at $P_{O_2} = 1$ atm. Thus according to these authors there is no evidence from their study to suggest the presence of any p-type conduction. In contrast to these results of Tuller and Nowick an investigation of ionic transference of CaO-doped CeO_2 [*i.e.*, $t_i = t_i(CaO,P_{O_2},T)$] using an oxygen concentration type cell[22-24] shows that $t_i \simeq 0.9$ (the exact value depending on T, P_{O_2}, and CaO content) at high oxygen pressures (*i.e.*, $1 < P_{O_2} < 10^{-4}$ atm). The absolute value of the t_i measurements has also been confirmed in this laboratory using a novel new method based on a coulometric type titration technique. The $t_i = t_i(CaO,P_{O_2},T)$ data was combined with recently reported electrical conductivity data $\sigma = \sigma(CaO,P_{O_2},T)$[18,22-24] and thermodynamic data $x = x(CaO,P_{O_2},T)$[25] to determine the dependence of the ionic and electronic conductivities on CaO content, oxygen nonstoichiometry, and temperature. The results of this study show that the electronic conductivity at high oxygen pressures (*i.e.*, $1 < P_{O_2} < 10^{-4}$ atm) is much larger in magnitude than would be expected assuming n-type electronic conduction only (*i.e.*, $\sigma_e \propto P_{O_2}{}^{-1/4}$). These observations can be more easily explained by assuming the presence of some p-type conduction. It is interesting to note that σ is essentially independent of P_{O_2} in this oxygen pressure region[18] and thus according to Eq. [1], the calculated value of t_i should be equal to unity. This calculated value of t_i, however, is inconsistent with the above experimentally measured value of t_i.

There may be some question about the presence of some p-type conduction in "pure" CeO_2 at high oxygen pressures because of (*i*) the influence of impurities in the region near stoichiometry and (*ii*) the effect of possible leaks in the Pyrex seal at lower temperatures on the oxygen concentration t_i measurements. However, in CaO-doped CeO_{2-x} there appears to be some evidence for the presence of p-type conduction.

In summary it is the authors' opinion that analysis of the electronic and ionic conduction based only on the dependence of σ on P_{O_2} provides information only about the predominant type of conduction mechanisms. A more reliable determination of the ionic and electronic conductivities requires a combined analysis of data obtained from measurements of t_i, σ, and departures from stoichiometry over a wide range of P_{O_2} and temperature.

A Simplified Method of Measuring Lifetime Using Steady-State Back Illumination of an MOS Capacitor

C. St. L. Rhodes and C. A. T. Salama
(pp. 1219-1222, Vol. 121, No. 9)

W. Zechnall:[26] In the above-cited work the authors reported about a simplified method for determining minority carrier lifetime from the transient response of a back-illuminated MOS capacitor.

If this method is applied for measuring lifetime on thin silicon slices, the measured lifetime values usually are very small and there is but little scatter in their spatial distribution. This result does not agree with results obtained by the frequently used pulsed MOS capacitance method without back illumination. In this case the measured lifetime values usually are

[26] Institut für Theoretische Elektrotechnik, Technische Hochschule Aachen, 51 Aachen, West Germany.

much larger and there is a large scatter in their spatial distribution.[27-29]

In order to understand the reason of this disagreement, a numerical analysis of the transient response of a back-illuminated MOS capacitor on n-type substrate was carried out by solving the following differential equation

$$j_{gen} = q \int_0^{w(t)} \frac{pn - n_i^2}{\tau_{no}(p + n_i) + \tau_{po}(n + n_i)} dx + q \sqrt{\frac{D_p}{\tau_{po}}} (p_w - 2C_1) \quad [1]$$

where

$$C_1 = \frac{p_w \sqrt{\frac{D_p}{\tau_{po}}} \exp\left(\frac{d}{l_d}\right) - g}{2 \sqrt{\frac{D_p}{\tau_{po}}} \cosh\left(\frac{d}{l_d}\right)} \quad [2]$$

j_{gen} is the current flowing normal to the interface of the MOS system, D_p the diffusion coefficient of holes, n and p the concentrations of electrons and holes, $w(t)$ the width of the space charge region, τ_{no} and τ_{po} the low-level lifetimes of electrons and holes, l_d the diffusion length of holes, d the thickness of the silicon slice, g the optical generation rate, and p_w the hole concentration at the edge of the space charge region.

The differential equation consists of a first term which considers thermal carrier generation in the space charge region according to Shockley, Read, and Hall[30,31] and a diffusion term which considers diffusion of carriers optically generated on the back of the specimen. This current component causes the interface charge in the MOS-system to increase much faster than in the case of thermal generation only.

From the numerical solution of this equation we calculated capacitance-time plots for an n-type substrate impurity concentration of 3×10^{15} cm^{-3}, a slice thickness of 0.2 mm, a gate voltage step from 0 to -20V, an oxide thickness of 0.12μ, an optical generation rate of 10^{14} cm^{-2} sec^{-1} and various values of generation lifetime $\tau_{gen} = \tau_{no} + \tau_{po}$. From these theoretical plots we determined lifetime τ_{Ph} by applying Eq. [2], [5], [6], and [7] of the paper under discussion. The result of this evaluation is plotted in our Fig. 1.

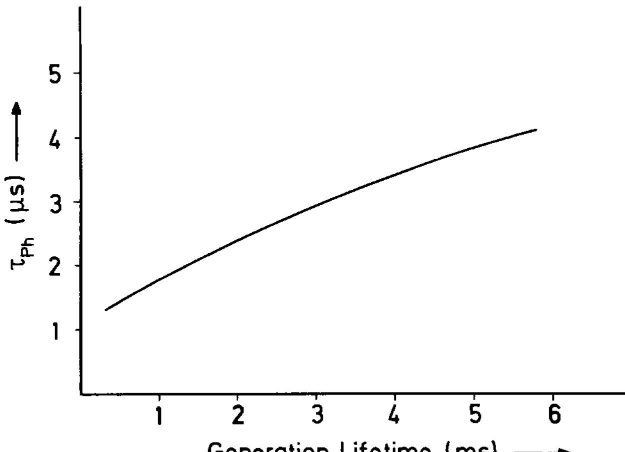

Fig. 1. Lifetime values τ_{Ph} as dependence on generation lifetime.

Firstly, the plot shows that lifetime values τ_{Ph} are much smaller than generation lifetime τ_{gen}. Secondly, a change of generation lifetime does not cause a change of lifetime τ_{Ph} by the same percentage. For instance, a variation of generation lifetime from 5.5×10^{-4} to 5.5×10^{-3} sec only yields a change of lifetime τ_{Ph} from 1.4 to 4.0 μsec. Therefore we can conclude that lifetime values τ_{Ph} are mainly controlled by diffusion of carriers optically generated on the back of the specimen. This effect causes the values τ_{Ph} to be much less dependent on the actual values τ_{no} and τ_{po} of low-level lifetime in the thin silicon slice. Therefore the method described in the paper under discussion cannot be applied for material characterization on thin silicon slices.

C. St. L. Rhodes and C. A. T. Salama: Zechnall's comments on the back illumination method[32] of measuring lifetime imply a misinterpretation on his part of the basic principles underlying the method of measurement. Zechnall claims that the values of lifetime measured using our method are usually very small (and exhibit but little scatter in their spatial distribution) as compared to the measured values using Zerbst's method.[33] Our experimental data,[32] however, indicate that when properly implemented the back illumination method and Zerbst's method yield almost identical values of lifetime. Zerbst's method, as commonly implemented without taking into account the position of the trapping level in the energy gap, yields large values of lifetime particularly if the dominant trap is not at midgap.[32]

Equations [1] and [2] in Zechnall's comments above do not represent the physical situation during proper implementation of the back illumination method.[32] These equations appear (Zechnall, above, has not clarified his boundary conditions) to represent the case of back illumination using short wavelength light which does not significantly penetrate the silicon, thus causing most of the generation to occur at the back surface. For proper implementation of the back illumination method, a red or near infrared, light-emitting diode source must be used to ensure that light penetrates deeply into the silicon. The back illumination method requires that, under steady-state conditions, the diffusion flux be sufficiently large to ensure that the excess carrier density r at the edge of the space charge region in the semiconductor is much larger than the minority carrier density under thermal equilibrium conditions. The back illumination method derives the lifetime from an indirect measurement of the steady-state recombination rate in the space charge region and from a measurement of the excess carrier density in the space charge region. The lifetime is not obtained from measurement of the diffusion parameters of the silicon slice.

Furthermore, the experimental implementation of the back illumination method requires that the device be initially biased in the inversion region. Zechnall's calculations, above, assume an initial bias of 0V; as well as assuming an optical generation rate which is insufficient to meet the requirement on r mentioned above. Thus, his use of Eq. [2], [5], [6], and [7] in our paper under discussion is not justified.

One final comment should be made on the order of magnitude of the generation lifetime quoted by Zechnall. These values appear to be at least one order of magnitude larger than values commonly referred to in the literature[34] for high quality silicon slices.

The Incorporation of Phosphorus in Silicon Epitaxial Layer Growth

J. Bloem, L. J. Gilling, and M. W. M. Graef

(pp. 1354-1357, Vol. 121, No. 10)

S. E. Craig, Jr.:[35] In the paper under discussion J. Bloem *et al.* present informative data on the electrically active phosphorus concentration in silicon deposited from a feed gas mixture of H_2, SiH_4, and PH_3. In addition they present an original and correct concept of how the intrinsic-extrinsic behavior of silicon influences the chemical equilibrium. However, their analysis of the results is misleading because it is based upon an assumption which logically contradicts itself, *i.e.*, "It is assumed, because of the low growth rate which is being used, that equilibrium in the gas phase is attained near the silicon surface, and that the transport effects are of minor importance."

In reality, if equilibrium is obtained at the solid-gas interface, then the rate of reaction must be mass transfer controlled. The logic is that for equilibrium to be obtained, the rates of the various chemical reactions must be extremely fast compared to other possible rate-limiting steps and the only other possible rate-limiting step is mass transfer in the gas phase.

In this experiment, the argument that mass transfer is unimportant because the rate is small cannot be accepted. The true fact is that the rate is small because the feed gas concentrations are very small. Concentration gradients must exist in the gas phase to cause the active species to migrate to the solid where the major deposition reactions occur. Since the feed gas concentrations are so small, it is necessary that the concentration gradients be exceedingly small. Therefore, the rate of reaction must be small even for a mass transfer controlled reaction.

In the work under present consideration the authors also err in the use of this assumption. That is, equilibrium involving phosphorus in the solid phase was not included in the calculations. Rather, it appears that Bloem *et al.* assumed equilibrium between the solid silicon and the gas phase species containing silicon but then assumed that the various phosphorus species in the gas phase were in equilibrium with each other, but not with the phosphorus in the solid phase. [Bloem's *et al.'s* unnumbered chemical equation representing this equilibrium, $P(g) \rightleftarrows P(Si)$, was not included in the equilibrium calculations.] Bloem *et al.* treated the phosphorus as if its rate of incorporation into the solid was limited by some step other than mass transfer control. The only remaining possibility is that the rate of incorporation is limited by some activated chemical step. If this were true we would have an equation of the form

$$J_D = k_{a1}[P] + 2\,k_{a2}[P_2] + k_{a3}[PH_3] + \ldots\ldots$$

where J_D is the flux of dope being incorporated into the solid and the bracketed quantities would represent the chemical activities or partial pressures of the indicated gas phase species as given by the authors' calculations. The various k_a's are reaction velocity constants for the chemical reactions. An equation of this form seems to fit their results until it is noted that these k_a's are strong exponential functions of temperature (*i.e.*, they must fit the Arrhenius equation). Therefore, if this model were correct, the rate of incorporation of dope at 1600°K would be much greater than the rate at 1400°K. Since this is contrary to the experiment we must reject this model. It appears that Bloem *et al.* assigned no rate-limiting step to the incorporation of phosphorus into the solid.

In the following paragraphs, we shall show that gas phase mass transfer controlled kinetics fully explains the results in the paper being discussed provided that the solid-gas equilibrium calculations are complete.

To simplify the analysis, we shall neglect the following minor points: (*i*) the increase in number of gas phase moles caused by the reaction; (*ii*) the change in hydrogen partial pressure caused by the reaction; and (*iii*) differences between the mole ratio and mole fraction of phosphorus in the solid. We shall also neglect differences in the gas phase mass transfer coefficients for the various chemical species. This assumption greatly simplifies the mathematical development and the errors that it causes should be less than ± 20%.

The model we propose consists of three steps. (*i*) Diffusion of the gas phase species from the bulk gas phase to the solid-gas interface. (*ii*) Very rapid kinetics for the inclusion of the silicon and phosphorus into the solid at the solid-gas interface. Step (*iii*) is a direct result of these very rapid reactions. (*iii*) Chemical equilibrium between all gas phase species and the solid at the solid-gas interface.

Bloem has identified the important gas phase species. Each of these species containing phosphorus will diffuse toward the solid-gas surface because of concentration gradients. The total flux of phosphorus toward the surface is

$$-J_P = \frac{\mathcal{D}_1}{RT}\frac{\partial[P]}{\partial z} + \frac{\mathcal{D}_2}{RT}\frac{\partial[PH]}{\partial z} + \frac{\mathcal{D}_3}{RT}\frac{\partial[PH_2]}{\partial z} + \frac{\mathcal{D}_4}{RT}\frac{\partial[PH_3]}{\partial z} + 2\frac{\mathcal{D}_5}{RT}\frac{\partial[P_2]}{\partial z} + 4\frac{\mathcal{D}_6}{RT}\frac{\partial[P_4]}{\partial z}$$

where z is the direction normal to the surface, R is the ideal gas constant, T the absolute temperature, and $\mathcal{D}_i$'s are the gas phase diffusion coefficients. The bracketed quantities are the chemical activities or partial pressures of the indicated species. When all the $\mathcal{D}_i$'s have the same value the equation reduces to

$$J_D = -\frac{\mathcal{D}}{RT}\frac{\partial[D]}{\partial z} \quad [1]$$

where $[D]$ is the pseudo total chemical activity of phosphorus in the gas phase defined by the equation

$$[D] = [P] + [PH] + [PH_2] + [PH_3] + 2[P_2] + 4[P_4] \quad [2]$$

An important consideration concerning Eq. [1] and [2] is that the gas phase chemical reactions given by Bloem *et al.* in their Eq. [1] through [6] in the paper under discussion cannot change the value of $[D]$ and therefore cannot affect the rate of mass transfer in the bulk gas phase. In other words, to a first approximation, it makes no difference whether or not chemical equilibrium is obtained in the bulk gas phase.

The only way $[D]$ can be changed is by adding or removing phosphorus atoms from the gas phase. This is accomplished at the feed point where phosphorus is added and at the solid-gas interface where it is removed.

At the feed, or in the bulk gas phase, the total phosphorus activity is $[D°] = [PH_3°]$. At the solid-gas interface, phosphorus is removed from the gas phase so that the total phosphorus activity is reduced to $[D^*]$. The phosphorus atoms are transported from the feed to the gas-solid interface by flow and by diffusion. The effective gas phase diffusion length is approximately the same for each species. Therefore, Eq. [1] integrates into

$$J_D = k_m([D°] - [D^*]) \quad [3]$$

where k_m is the mass transport coefficient and includes the combined effects of flow, diffusivity, and effective diffusion length.

In all cases, $[D^*]$ is equal to or greater than the value given by chemical equilibrium at the surface.

[35] Department of Chemical Engineering, Arizona State University, Tempe, Arizona, 85281.

For mass transfer controlled kinetics, $[D^*]$ is equal to the equilibrium value. Hereafter, all quantities followed "*" will indicate the value at equilibrium at the solid-gas interface.

A similar treatment[36] gives the flux of silicon as

$$J_{Si} = k_m([Si^\circ] - [Si^*]) \quad [4]$$

The ratio of the flux of phosphorus to the flux of silicon gives the atomic fraction of phosphorus in the solid. For silicon, this is the concentration of phosphorus atoms, $N_p{}^+$, divided by $5(10^{22})$

$$\frac{N_p{}^+}{5(10^{22})} = \frac{[D^\circ] - [D^*]}{[Si^\circ] - [Si^*]} \quad [5]$$

Again we have neglected the minor differences in mass transport coefficients between the various species.

Figure 2 in the paper under discussion shows that the equilibrium activity of silicon in the gas at the solid interface is much smaller than the feed gas activity of silicon, $[Si^\circ]$. Therefore

$$[Si^\circ] - [Si^*] = [Si^\circ] = 2.2(10^{-3})$$

The chemical reaction and equilibrium equations which dictate the value of $[D^*]$ are

$P(ss) \rightleftarrows P$

$$K_1K_7 = [P^*]/(N_p{}^+n) \quad [6]$$

$P(ss) + 1/2\, H_2 \rightleftarrows PH$

$$K_2K_7 = [PH^*]/(N_p{}^+n[H_2]^{1/2}) \quad [7]$$

$P(ss) + H_2 \rightleftarrows PH_2$

$$K_3K_7 = [PH_2{}^*]/(N_p{}^+n[H_2]) \quad [8]$$

$P(ss) + 3/2\, H_2 \rightleftarrows PH_3$

$$K_4K_7 = [PH_3{}^*]/(N_p{}^+n[H_2]^{3/2}) \quad [9]$$

$2P(ss) \rightleftarrows P_2$

$$K_5K_7{}^2 = [P_2{}^*]/(N_p{}^+n)^2 \quad [10]$$

$4P(ss) \rightleftarrows P_4$

$$K_6K_7{}^4 = [P_4{}^*]/(N_p{}^+n)^4 \quad [11]$$

$P^+(ss) + e^- \rightleftarrows P(ss)$

$$K_7 = [P(ss)]/(N_p{}^+n) \quad [12]$$

Electron hole generation in solid silicon

$$k_i = np \quad [13]$$

where P(ss) is neutral phosphorus in solid solution and [P(ss)] is its chemical activity. n, p, and $N_p{}^+$ are the concentrations of electrons, holes, and ionized phosphorus in the solid silicon, respectively.

Equation [12] is necessary because at the reaction temperature essentially all the phosphorus in the solid is ionized. However, the available thermodynamic data for solids pertains only to neutral solid silicon.

The values of the equilibrium constants K_1 through K_6 reported in Table I were computed from the JANAF Tables[37] using a hypothetical standard state of pure, solid red phosphorus at the reaction temperatures. The values of k_i were obtained from Morin's equation.[38]

The total electron concentration within the silicon is equal to that from the ionized phosphorus plus that from the silicon lattice, $n = N_P{}^+ + p$. When this is combined with Eq. [13], the electron concentration is found to be

$$n = (N_p{}^+ + \sqrt{(N_p{}^+)^2 + 4k_i})/2 \quad [14]$$

The solutions to Eq. [14] are plotted in Fig. 1. Three features of these solutions should be noted. First, for $N_p{}^+ < 10^{18}$ the silicon is intrinsic and n is a constant. Next, in this intrinsic range, n increases sharply with temperature. Finally, for $N_p{}^+ > 10^{20}$, the silicon becomes extrinsic and $n = N_p{}^+$. In this region there is no temperature effect upon n.

The value of K_7 is not directly known. However, the $N_p{}^+$ *vs.* $[PH_3{}^\circ]$ data in the work being discussed for the intrinsic region was used in Eq. [2], [4], and [6] through [13] to calculate the values of K_7 for each temperature. This is the only parameter in the analysis that must be determined from the experimental data. Now that it has been determined, it can be used for any other Si-P system.

The equilibrium concentrations shown in Fig. 1 were calculated from Eq. [6] through [14] and the values in Table I. These equilibrium values are far below those calculated by Bloem *et al.* in the paper under consideration because these values include the effect of the phosphorus in the solid. A unique feature of these equilibrium curves is the manner in which they all deflect upward near $N_p = 10^{19}$ cm^{-3}. This is a direct result of the increase in the number of electrons as the silicon shifts toward extrinsic. These additional electrons force all the chemical reactions toward the right. The value of $[D^*]$ computed from Eq. [2] is also included in Fig. 1.

These values of $[D^*]$ were used in Eq. [5] to compute the theoretical $N_p{}^+$ *vs.* $[PH_3{}^\circ]$ curves shown in Fig. 2. At low values of $N_p{}^+$, the silicon is intrinsic, n is a constant, PH_2 and PH_3 are the major gas phase species, and $[D^*]$ is a linear function of $N_p{}^+$. This

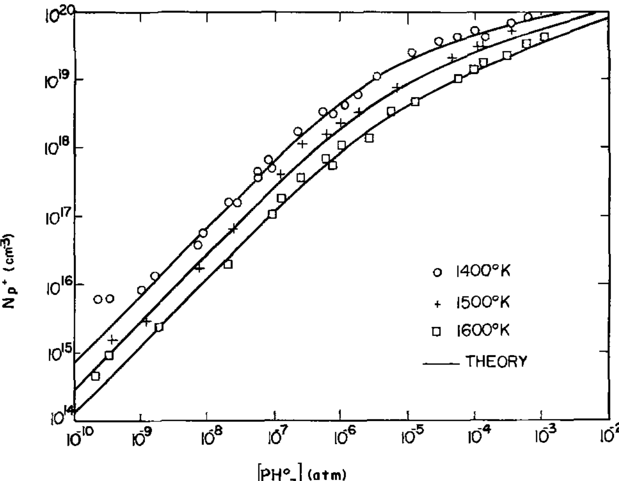

Fig. 2. A comparison of the theoretically and experimentally determined concentration of phosphorus donor centers in silicon as a function of the partial pressure of phosphine in the feed gas. The reaction gas mixture is SiH_4-PH_3-H_2.

led to N_p^+ being directly proportional to [PH_3°]. At very high values of N_p^+, the silicon is extrinsic and n is equal to N_p^+. Also P_2 is the major gas phase species. These two facts cause N_p^+ to be proportional to $[PH_3°]^{1/4}$ at high values.

The decrease in N_p^+ with increasing temperature is caused by two phenomena. First, silicon is more volatile at higher temperatures as shown by the increases in K_1 to K_6 with temperature. Secondly, the concentration of intrinsic electrons increases with temperature. Both of these phenomena cause $[D^*]$ to increase with temperature and this reduces the rate at which phosphorus is transported to the solid-gas interface.

The experimental data from the paper under discussion are also shown on Fig. 2. The excellent fit between theory and data attests to the validity of the theory as well as to the accuracy of the data.

In summation, the data of Bloem *et al.* in the work being discussed not only fit a kinetic model based on gas phase mass transport, but in addition, their data allow the determination of thermodynamic data not previously available.

The analysis presented here is totally general and can be applied to all epitaxial, chemical vapor deposition systems now in use.

J. Bloem, L. J. Giling, and M. W. M. Graef: In the above discussion by Craig three points emerge: (*i*) the model, based on gas-phase diffusion; (*ii*) inclusion of electron concentration and ionized P in the solid; and (*iii*) determination of equilibrium constant for the ionization of P.

As regards point (*i*) the discussion given by Craig above on the incorporation of P in Si is interesting but the suggestion that the amount of P incorporated in the growing Si is mass transfer controlled is not applicable in our case.

Mass transfer control is evidently present for the growth of silicon itself, but not for P. This is shown by the experimental evidence that the concentration of P in the layer is independent of the Si growth rate, as already indicated in Ref. (7) of the original article.

Equation [5] in the above discussion shows that following his assumption of mass transfer control an increase in silicon growth rate (with constant input of PH_3) would give a decrease in the amount of P incorporated in the silicon. This is not the case; the use of much higher growth rates than the one used here firstly gives an increase and later a decrease in the donor concentration. This shows that at low growth rates the transfer of P to the surface is not rate limiting, that only a small part of the P present is incorporated in the growing layer, and that a direct relation exists between the phosphorus concentration in the gas phase and in the solid, described by the equilibrium segregation coefficient.

Concerning point (*ii*) the ionization of P in the solid and the intrinsic or extrinsic origin of electron concentration is adequately covered in the article under discussion and no new points emerge from Craig's analysis above.

It is interesting that in the paper being discussed the gas phase equilibria and the equilibrium in the solid are kept separated, in order to be able to discuss the segregation of P between gas and solid in a subsequent article. This link has been laid by Craig in combining the equilibria in gas and solid by the introduction of a segregation coefficient k_1 in which it is implicitly assumed that the evaporation of P from the silicon matrix is equal to the evaporation of P from a hypothetical solid P source at the same temperature. This, of course, is an oversimplification and an analysis based on the work of Thurmond and Struthers[39] and Weiser[40] using the experimental data then can give more information on the energy of incorporation of P in solid silicon.

As regards point (*iii*), according to Craig, the ionization of P in the solid is the only unknown in the series of equilibria; the equilibrium constant, k_7 in the above discussion, however, is readily calculated.

For the ionization of P

$$P \rightleftharpoons P^+ + e^-$$

$$\frac{1}{k_7} = \frac{[P^+] \cdot n}{[P]} = N_c \exp(-E_D/kT)$$

where N_c is the density of states in the conduction band of silicon, equal to $2(2\pi mkTh^{-2})^{3/2}$ and E_D is the distance of the donor level from the conduction band ($\approx$0.04 eV). The value of $1/k_7$ is of the order of 10^{20}-10^{21} cm^{-3} in the range of temperatures considered.

The real unknown is the segregation coefficient of phosphorus between gas phase and solid, (k_1); knowing the value of k_7, k_1 can then be determined from the experimental data giving information on the incorporation of P in Si as indicated in our comments here on point (*ii*).

It is interesting to note how the use of the simplified value of k_1 leads to such a good correlation between theory and experiment. In the theory of Craig above the difference in input ($p_{PH_3°} = D°$) and the weighted sum of the resulting equilibrium values of the phosphorus components (D^*) has to be great in order to conclude to a mass transfer controlled reaction. As this is not the case ($D° \approx D^*$) the model of Craig converts to the equilibrium model with $D° = D^*$ proposed in the article under discussion.

A New Generation of "Deluxe" Fluorescent Lamps, Combining an Efficacy of 80 Lumens/W or More with a Color Rendering Index of Approximately 85

J. M. P. J. Verstegen, D. Radielović, and L. E. Vrenken
(pp. 1627-1631, Vol. 121, No. 12)

W. A. Thornton:[41] In the tradition of "the mouse that roared," the United States is being invaded by one of her small friends from across the water, who lays claim to a most interesting and unexpected development in practical illuminants. But this development occurred on the home ground of *This Journal*. The prime reference[42] includes the results of a conference in 1966 in New Jersey at which sixty experts witnessed the remarkable properties of the new illuminant. The

[42] W. A. Thornton, *J. Opt. Soc. Am.*, **61**, 1155 (1971).

new fluorescent lamps were demonstrated and discussed in 1972 at the Tulsa conference of the Illuminating Engineering Society,[43] and the general phenomenon was the keynote of the May 1972 Electrochemical Society Meeting in Houston, Texas (luminescence). The essential discovery[42] was that both luminous efficiency and color rendering capability are astonishingly high when the white light is composed predominantly of three very specific colors, near 450, 540, and 610 nm, since called the prime colors; the luminous efficiency-color rendering index, in combination, excels all other possible spectral power distributions.[42] It has become clearer that both characteristics are due to strongly peaked visual response at these three wavelengths.[44]

What the authors of the paper under discussion call the "Koedam-Opstelten principle" is in itself impractical, since lamps of considerably higher color rendering index have long been commercially available. Only when it is shown that efficacy is also high, or that color preference[45] is pronounced, are three-spectral color illuminants recognized to be of profound interest. In regard to color preference, I think that the above authors will find that the new lamps have an appeal far beyond that indicated by the color rendering index. Two-hundred observers preferred daylight-color prime-color lamps well above real daylight itself for illuminating foods,[46] and the standard daylight lamp was much lower still in preference.

Possibly the performance of the new aluminate phosphors will in the long run justify their cost, but at present the performance improvement over more familiar phosphors appears to be marginal. Prior use of blue-emitting Eu^{2+} phosphors, green-emitting Tb^{3+} phosphors, and red-emitting Eu^{3+} phosphors, all in lamps, might well have been referenced.

The proposed new high-efficacy fluorescent lamps,[47] with essentially only blue and yellow emission, certainly do have disastrously poor color rendering. We use these lamps in demonstrations to show how bad color rendering can get without changing the white color of the lamplight. Their commercial promise we consider to be negligible.

Some additional background references dealing with optimization of the spectral power distributions of lamps include Ivey,[47] the Einhorns,[48] and Walter.[49]

J. M. P. J. Verstegen, D. Radielović, and L. E. Vrenken: It is unfortunate if a technical discussion is clouded by arguments of essentially nontechnical nature. We will refrain from that and stay with the paper under discussion.

Dr. Thornton's claim that our three-spectral color lamp has an appeal far beyond that of the color rendering index, is irrelevant as long as the CRI is the unit agreed upon internationally.

Apart from that, his claim has proven to be basically untrue. Comparison of our conventional "deluxe" lamp of 4000 K with the new aluminate lamp, does not result in overwhelming preference for the latter. Comparison of the standard halophosphate 4000 K lamp and the aluminate lamp, however, does but this is to be expected from the higher CRI of the latter.

We were and are unaware of any efficient green-emitting Tb^{3+} phosphor with acceptable lamp performance before our aluminate was developed. However, we referred to the use of (Sr, Eu) chloroapatite [our Ref. (6) in the paper under discussion].

The performance improvement of the aluminates might be marginal in the eyes of a United States citizen, but the 10 lm/W increase over the Haft and Thornton lamp is a respectable gain for a "small friend."

The proposed new high-efficacy fluorescent lamp with 100 lm/W would certainly outgrow Dr. Thornton's demonstration kit and develop into a useful outdoor illuminant.

Low-Rate Cathodic Linear Sweep Voltammetry (LSV) Studies on Anodized Lead

Thomas F. Sharpe*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Low-rate (~ 0.5 mV/sec) cathodic linear sweep voltammetry (LSV) experiments were conducted on preanodized antimonial and nonantimonial lead. The sweeps were supplemented by current-time traces obtained during the short term ($\leqq$ 1 hr) anodic treatment above the $PbO_2/PbSO_4$ reversible potential in H_2SO_4 electrolytes. Despite complications from additional substrate corrosion during the sweeps, semiquantitative observations were possible and the cathodic discharge could be resolved into α- and β-PbO_2 components. A major finding was that antimony in the lead retards the formation of β-PbO_2 in the preliminary anodic treatment. Implications from the results with regard to the behavior of the Pb-acid battery positive plate are briefly discussed.

In view of the fundamental information gained in recent years on the behavior of PbO_2 through the use of linear sweep voltammetry (LSV) (1-3), it would appear that such a technique might be useful for studying the differences in behavior of specific lead alloys used as grids for lead-acid battery positive plates. Although Panesar (4) has reported anodic and cathodic LSV studies on both antimonial and nonantimonial lead, many details concerning the PbO_2 reduction step were not considered. In his studies, anodization was effected by a low-rate (0.5 mV/sec) sweep extending from the potential for hydrogen evolution up to that for oxygen evolution. Under these conditions, the time above the $PbO_2/PbSO_4$ reversible potential was very short and the value of the potential was continuously changing, thereby making it impossible to relate the PbO_2 discharge phenomena to the potential of anodic treatment.

For Panesar's anodic treatment, only one cathodic current peak was resolved that could be ascribed to PbO_2 reduction in the subsequent cathodic scan. It is known, however, that two polymorphs of PbO_2 (α and β) exist, and that each may exhibit a different discharge overpotential (5-7). Depending upon the time and potential of anodic treatment, both polymorphs may be present in the corrosion film (8, 9). From x-ray diffraction, it has been established that β-PbO_2 resides primarily in the outer portion of the film and that α-PbO_2 exists, along with tetragonal PbO (PbO_t) in the inner portion of the film closer to the metal. The latter species are thermodynamically unstable in acid medium, but it is believed that they are formed in a localized high pH environment that is protected from the bulk acid by a $PbSO_4$ layer highly impermeable to H_2SO_4 (10).

In the present work, attempts are made to resolve in greater detail the PbO_2 discharge products using low-rate cathodic LSV following specified conditions of anodization. The sweeps were supplemented by current-time transients that were obtained during the anodization at constant potentials above the $PbO_2/PbSO_4$ reversible potential. It was of particular interest to compare antimonial and nonantimonial lead because of the well-known fact that antimonial grids prolong positive plate cycle life.

Key words: lead electrode, lead dioxide electrode, lead corrosion, lead-acid battery.

Experimental

The alloys chosen for this study were Pb/4.5% Sb and Pb/0.05% Ca. Both alloys contained the same level of concentration of Sn (0.6%) and were essentially free of other alloying constituents; therefore, the difference in behavior between the alloys in this study is ascribed to the effect of antimony. Test electrodes were current collector tabs cut from battery grids and the portion exposed to the electrolyte had a geometric area of 5 cm^2. The test electrodes were wiped with cotton wet with acetone, air-dried, and then given a 1 mA/cm^2 cathodic treatment for 5 min in the test cell prior to anodic treatment. The counterelectrode was sheet lead of 99.99+% purity and the reference electrode was Hg/Hg_2SO_4. The electrolyte was either 1.16 (2.7M) or 1.26 sp gr (4.5M) H_2SO_4 prepared from reagent grade chemical and distilled water. All experiments were conducted at ambient temperature (~25°C).

The $PbO_2/PbSO_4$ reversible potential values in each acid were determined by measuring (with a high-impedance electometer) the steady-state rest potentials of anodic films formed on Pb/Ca alloy for 2 hr at oxygen evolution potentials. These were 1142 ± 5 mV in 1.26 sp gr H_2SO_4 and 1067 ± 5 mV in 1.16 sp gr H_2SO_4.

For the potential sweeps, the 10 turn potentiometer of a commercial potentiostat was driven by an electric motor whose speed could be changed to give the desired linear sweep rate. All currents and potentials were continuously monitored with a strip chart recorder. Following preliminary work, greater sensitivity on the potential scale was achieved by synchronizing the speed of the recorder to the chosen sweep rate so that each major division (2.54 cm) of the strip chart corresponded to 12 mV.

Results and Discussion

Lead preanodized at constant current.—In preliminary work, cathodic potential sweeps were obtained on test electrodes after they were anodized at constant current, and typical results are shown in Fig. 1. The sweeps were started immediately after switching off the current and covered a potential range of about 200 mV on each side of the $PbO_2/PbSO_4$ reversible potential. The cathodic current peaks, just below that potential, correspond to the reduction of PbO_2 to $PbSO_4$. Two peaks were observed; a major peak b and a minor peak b'. For the Pb/Sb alloy the minor peak became well defined after anodization at the higher current.

Just following the reduction of PbO_2, Panesar (4) reported an anodic current peak which he correlated to a cathodic current peak appearing at more negative potentials. From thermodynamic considerations these must be assigned[1] respectively, to the formation and reduction of PbO_t in the interior of the corrosion film. In the present work, a number of anodic current constituents were present in the scans, and it is shown subsequently that these are portions of an anodic current peak that extends throughout much of the PbO_2 discharge potential range. It has been demonstrated (6, 10) that in the vicinity of the $PbO_2/PbSO_4$ reversible potential, oxidation and reduction processes can occur at nearly the same potential. As a result, if the oxidation process gives rise to sufficient anodic current, the net current will exhibit anodic values, even though a reduction (cathodic) reaction (*e.g.*, $PbO_2 \rightarrow PbSO_4$) is occurring. This is believed to account for the rather peculiar voltammetric behavior observed in Fig. 1 and subsequent figures.

[1] See the discussion of Panesar's paper in Ref. (10).

Lead preanodized at constant potential.—To gain greater insight, the shape of the sweeps was followed as a function of preanodization potential in increments at least as small as 50 mV above the $PbO_2/PbSO_4$ reversible value. During potentiostatic control, a continuous current-time (i-t) trace was obtained. The i-t traces for Pb/Ca alloy are similar to those previously reported by Ruetschi and Angstadt (11). Current-time traces at constant potential for Pb/Sb alloys have not been reported previously.

Results for Pb/Ca alloy.—Current-time traces obtained from 1150 to 1400 mV and corresponding selected cathodic sweeps in 1.26 sp gr H_2SO_4 are given in Fig. 2. After the 1 hr potentiostatic treatment, the potentials of the test electrodes were immediately de-

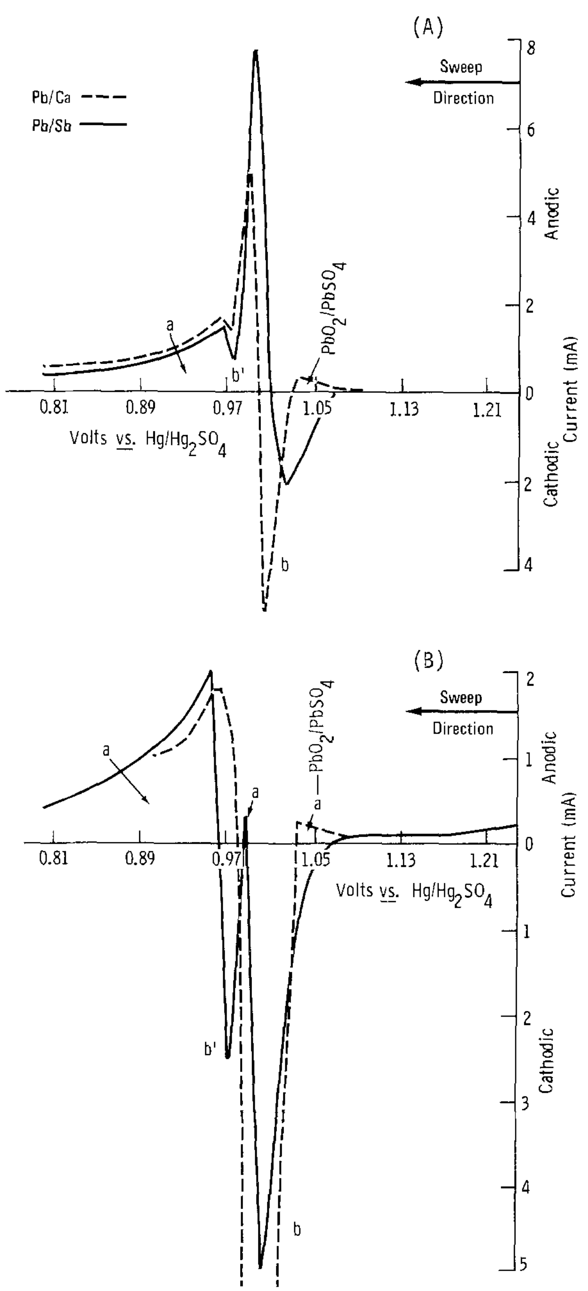

Fig. 1. Cathodic sweeps on Pb electrodes that were preanodized at (A) 5 mA and (B) 25 mA for 3 hr. Electrode area = 5 cm²; H_2SO_4 = 1.16 sp gr; sweep rate = 0.28 mV/sec.

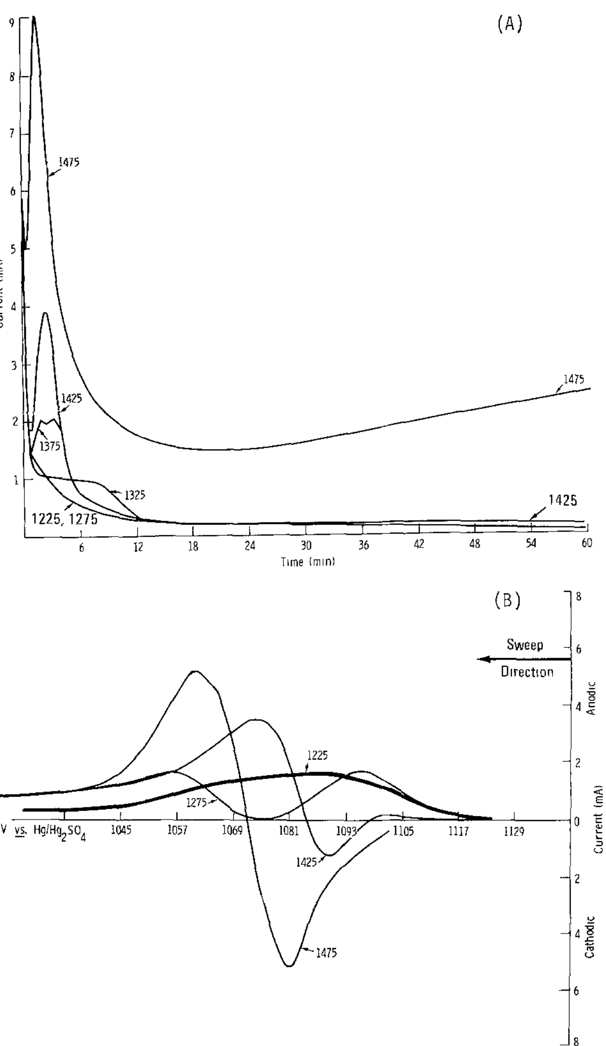

Fig. 2. Current-time curves (A) and subsequent cathodic sweeps (B) for Pb/Ca electrodes in 1.26 sp gr H_2SO_4. Numbers on curves indicate potential of anodic treatment. Electrode area = 5 cm²; sweep rate = 0.42 mV/sec.

creased to the $PbO_2/PbSO_4$ reversible potential, and then the sweeps were started.

Following control at 1225 mV (about 75 mV above $PbO_2/PbSO_4$) the current in the scans was entirely anodic, as emphasized by the heavy line in Fig. 2B. At 1275 mV a current peak in the cathodic direction emerged, indicating the reduction of some tetravalent Pb compound. Up to that potential, the i-t traces indicated only the formation of $PbSO_4$ (11). It is assumed that the tetravalent compound corresponds to α-PbO_2 that formed by the oxidation of PbO_t beneath the partially passivating $PbSO_4$ layer.

After control at successively higher potentials, the onset of the cathodic current peak shifted to higher potentials along the anodic current profile and increased substantially in capacity. This trend is illustrated in greater detail in Fig. 3 after control at 50 mV increments and at a slower sweep rate. The shift and buildup in capacity can be correlated to the buildup of a pronounced peak in the i-t transients (Fig. 2A) that has been ascribed (11) to the oxidation of $PbSO_4$ to β-PbO_2 in the outer part of the corrosion layer. It appears, therefore, that the 1325-1375 mV interval marks the transition at which the cathodic peak in the scans becomes affected primarily by the discharge of β-PbO_2.

At or above 1475 mV, the current increase in the i-t transient, after the first few minutes (Fig. 2A and Fig. 4A) signifies the onset of oxygen evolution and pronounced base metal corrosion. The corresponding sweeps (Fig. 4B) indicate a shoulder emerging on the negative-potential side of the growing β-PbO_2 discharge peak. This is ascribed to the buildup of additional dischargeable α-PbO_2 that is expected to form by the direct oxidation of base metal at these high potentials.

A complicating issue in the cathodic scans is a background anodic current that extends throughout much of the $PbO_2/PbSO_4$ reversible potential region. As a result, net currents are involved and as mentioned above, despite the presence of dischargeable PbO_2, the net current may show an anodic value. This is especially exemplified in Fig. 5 where the effect of increasing time at high potential (1575 mV) is considered. At first, the current is slightly anodic which may be due to the further formation of $PbSO_4$. As the alkalinity beneath the $PbSO_4$ film becomes established (and as the electrode becomes progressively roughened by further anodic treatment), the anodic current would be expected to increase through the further anodic generation of Pb^{2+} to form PbO_t. At the same time, the buildup of PbO_2 also occurs (as confirmed on replicate electrodes by increasing time arrests at the $PbO_2/PbSO_4$ reversible potential after 30 sec anodic treatment) but not in sufficient quantity

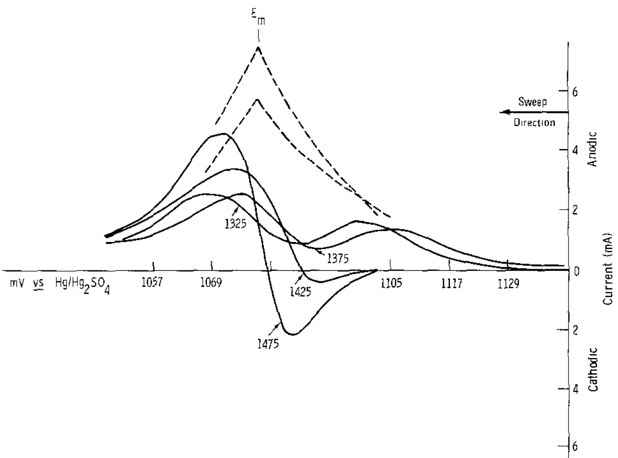

Fig. 3. Cathodic sweeps for Pb/Ca electrodes following 1 hr control at potential values indicated on sweeps. H_2SO_4 = 1.26 sp gr; electrode area = 5 cm^2; sweep rate = 0.21 mV/sec.

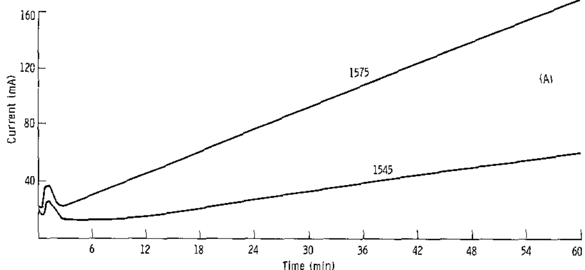

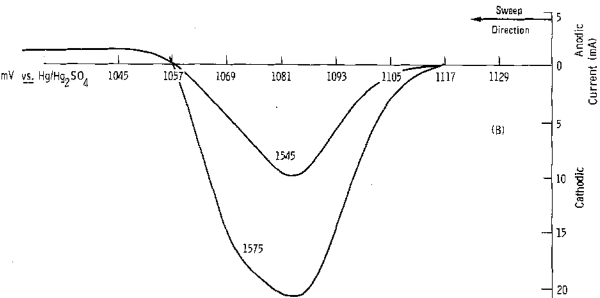

Fig. 4. Current-time curves at 1545 and 1575 mV (A) and subsequent cathodic sweeps (B) for Pb/Ca electrodes in 1.26 sp gr H_2SO_4. Electrode area 5 cm^2; sweep rate 0.42 mV/sec.

to compensate for that effect so the net current increases in the anodic direction. However, as the amount (and therefore the discharge capacity) of the PbO_2 increases, the net current builds in the cathodic direction.

Although the exact anodic current profile is always obscured by dischargeable PbO_2, there is seen in Fig. 5 a tendency toward a peak value at about 1.08V. This is in agreement with results obtained after control at lower potentials, where ascending and descending portions of the anodic current profile are well defined and can be extrapolated (cf., broken lines, Fig. 3). Similar maxima (E_m) have been observed based on steady-state corrosion current (11) and weight loss (12, 13) measurements. Lander (12) established that the E_m (on the Hg/Hg_2SO_4 scale) is a function of acid concentration, and the value interpolated from his data is in good agreement with the present observations.

It is also observed from Fig. 5 that the peak ascribed to β-PbO_2 reduction continues to grow beyond the time observed for $PbSO_4$ oxidation in the i-t curve. X-ray diffraction has indicated (9) that the amount of β-PbO_2 in the corrosion film is substantially larger than that provided by the oxidized $PbSO_4$. This has been ascribed (9) to an ionic current of Pb^{4+} passing through the corrosion film at high potentials to give

additional β-PbO_2 at the solution/corrosion film interface.

Selected i-t transients and subsequent cathodic sweeps obtained in 1.16 sp gr H_2SO_4 are shown in Fig. 6, and the buildup of dischargeable PbO_2 as a function of time at high potentials (1515 mV) are shown in Fig. 7. The discharge occurs ~75 mV below that observed in 1.26 sp gr which is, of course, expected from the difference in $PbO_2/PbSO_4$ rest potential values. The shape of the sweeps, however, is somewhat different, which can be explained primarily on the basis of increased substrate corrosion during the sweeps. A comparison between the sweeps in Fig. 7 and Fig. 5, obtained after the earliest stages of anodization under conditions where the i-t curves can be superimposed, indicates a greater tendency in the more dilute acid toward net currents in the anodic direction. Although this could be the result of a kinetic limitation on the PbO_2 discharge brought about by decreasing the acid strength, such an effect is not expected to be significant at these slow sweep rates. However, by decreasing the bulk concentration of acid, the pH in the interior of the film would be further increased, thereby favoring a greater anodic current flow. This is in agreement with Lander's observation (12) that weight loss at the potential of maximum anodic current increases with decrease in acid concentration.

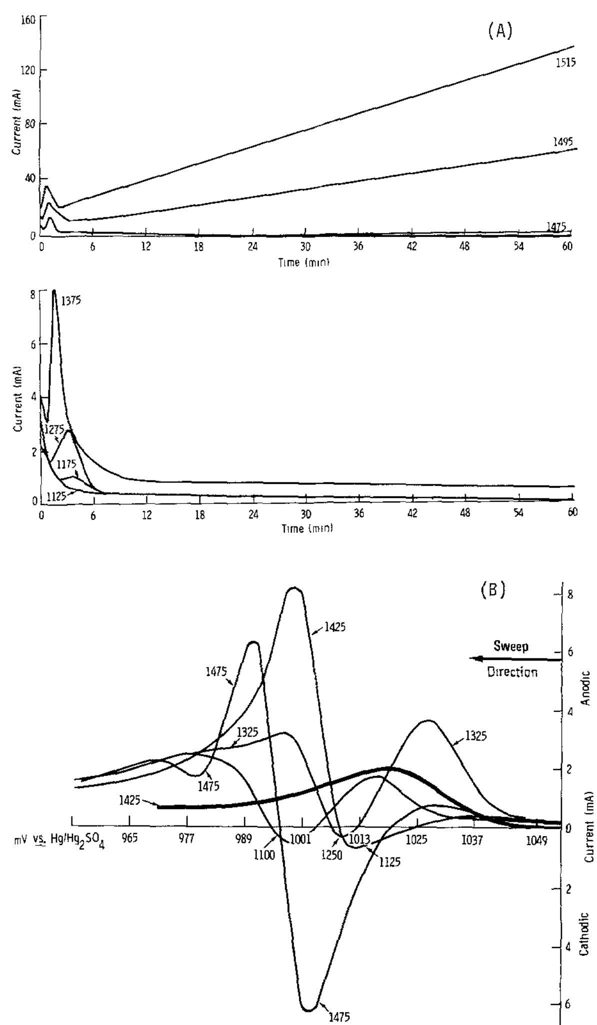

Fig. 6. Current-time curves (A) and subsequent cathodic sweeps (B) for Pb/Ca electrodes in 1.16 sp gr H_2SO_4. Numbers on curves indicate potential of anodic treatment. Electrode area = 5 cm^2; sweep rate = 0.42 mV/sec.

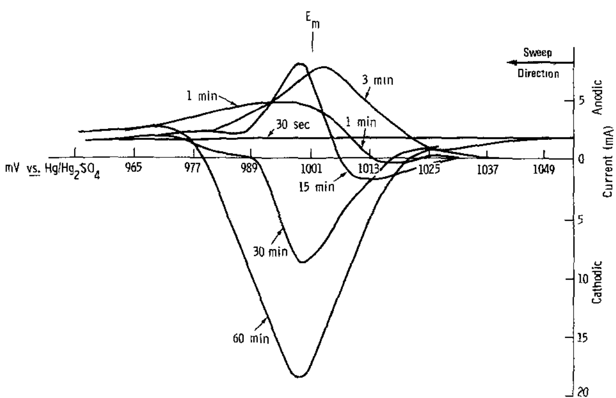

Fig. 7. Cathodic sweeps for Pb/Ca electrodes after control at 1515 mV for various times in 1.16 sp gr H_2SO_4. Electrode area = 5 cm^2; sweep rate = 0.42 mV/sec.

Results for Pb/Sb alloy.—Current-time traces and corresponding cathodic sweeps in 1.26 sp gr H_2SO_4 are shown in Fig. 8. A notable feature is that the current peak for $PbSO_4$ oxidation to β-PbO_2 does not occur below 1375 mV, a significantly higher overvoltage than required to effect that reaction on Pb/Ca alloy. After control at or below that potential, the current is only slightly anodic in the sweeps. Above that potential an anodic current profile develops which gradually becomes masked after control at successively higher potentials by the buildup of two cathodic current peaks. The buildup of the cathodic peaks along the ascending and descending branches of the anodic current profile is also shown in Fig. 9, which gives the effect of anodization time at high potential (1575 mV).

The same experiments were repeated in 1.16 sp gr H_2SO_4, but for brevity only that series showing the effect of time at a high potential (1515 mV) is shown (Fig. 10). As in the case for the Pb/Ca alloy, the difference in sweep profiles as the acid strength is decreased appears to be the result of increased substrate corrosion during the sweeps. From the results in Fig. 9 and 10, a reasonable estimation of the peak

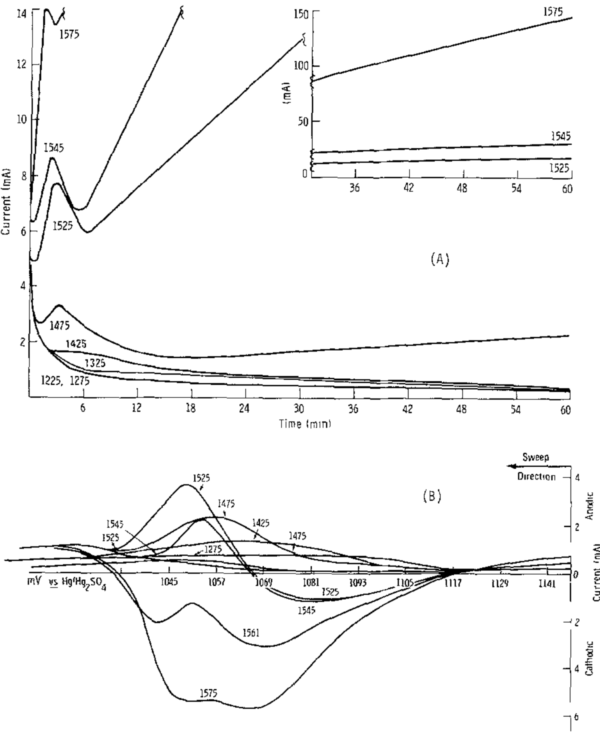

Fig. 8. Current-time curves (A) and subsequent cathodic sweeps (B) for Pb/Sb electrodes in 1.26 sp gr H_2SO_4. Numbers indicate potential of anodic treatment. Electrode area = 5 cm^2; sweep rate = 0.42 mV/sec.

anodic current potentials (E_m's) are 1050 and 990 mV, respectively. These are slightly lower than the corresponding indications on Pb/Ca alloy (1075 and 1003 mV).

The two cathodic discharge peaks emerging after control at high potentials, as well as the peaks observed after constant current anodic treatment (Fig. 1) appear to correspond to the two plateaus observed by Ruetschi (6) during the constant current discharge of Pb/Sb alloy that had been anodized at constant current. In that work, however, an unambiguous assignment of each plateau to a specific PbO_2 polymorph could not be made. By analogy to the results for Pb/Ca alloy in the present work, the peak discharging at the higher potential would be assigned to β-PbO_2. A further indication that this is the correct choice is shown in Fig. 11, where an electrode that was discharged in the course of anodic treatment exhibited a growth of the peak at the higher potential. Such an intermittent discharge would provide additional $PbSO_4$ for oxidation, thereby enhancing the β-PbO_2 discharge peak.

Summary and Conclusions

Cathodic potential sweeps were obtained on an antimonial (Pb/4.5% Sb) and a nonantimonial (Pb/0.05% Ca) alloy after specific conditions of short-term anodization above the PbO_2-$PbSO_4$ reversible potential. The situation is complicated by additional substrate corrosion during the sweeps which gives rise to a substantial background anodic current that extends throughout much of the PbO_2 discharge potential range. As a result, net currents are always obtained, and the sweep profiles may exhibit the extremes shown schematically by the solid lines in Fig. 12. After control near the PbO_2/$PbSO_4$ reversible potential, or at higher potentials for very short periods of time, the current may be entirely anodic (a). It is believed that at the low-sweep rates employed the maximum anodic current in the scans (observed

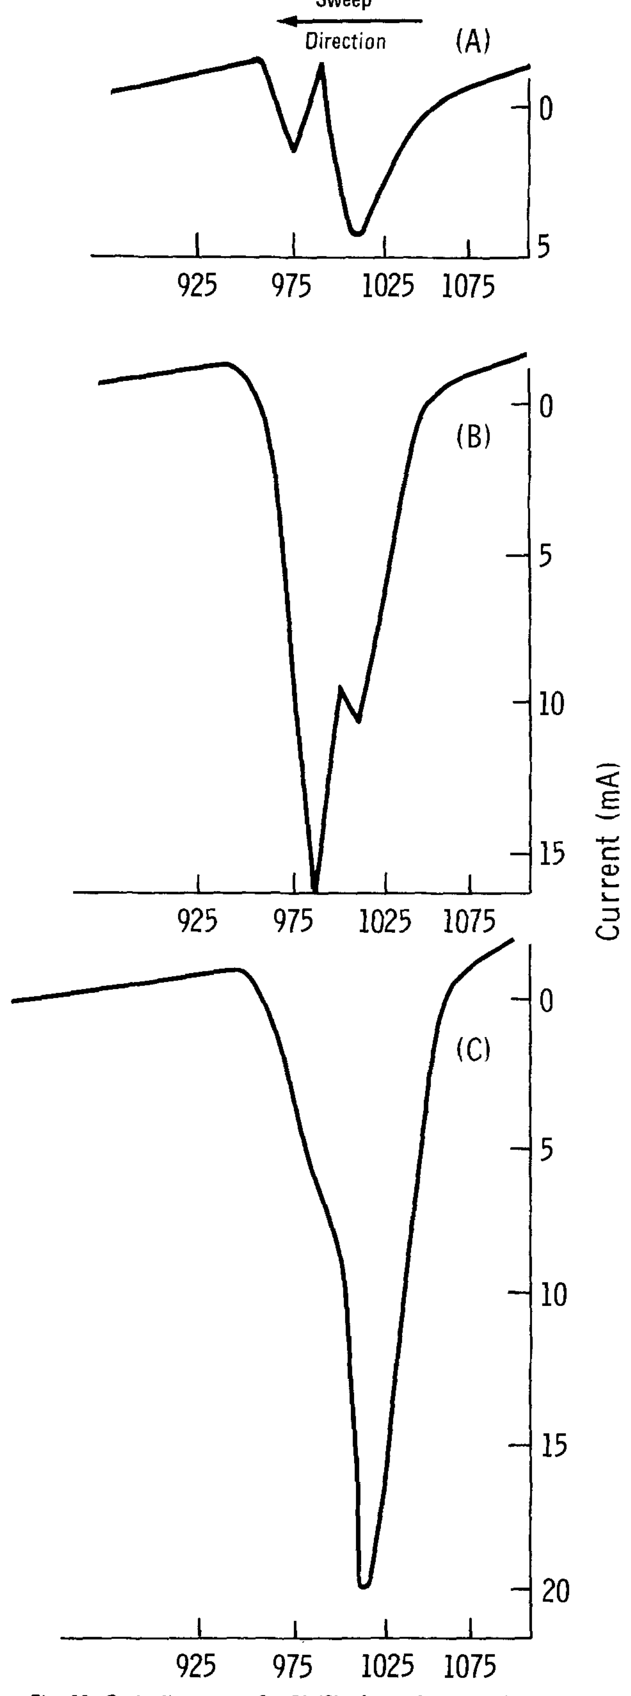

Fig. 11. Cathodic sweeps for Pb/Sb electrodes in 1.16 sp gr H_2SO_4 after control at 1525 mV for (A) 1.5 hr, (B) and (C) 3 hr. In (C), electrode was given intermittent discharge to 925 mV after 1.5 hr. Electrode area = 5 cm^2; sweep rate = 0.28 mV/sec.

prior to the buildup of appreciable discharge product) can be related reasonably well to the potential at which maximum corrosion would occur (E_m) under steady-state conditions near the PbO_2/$PbSO_4$ reversible potential.

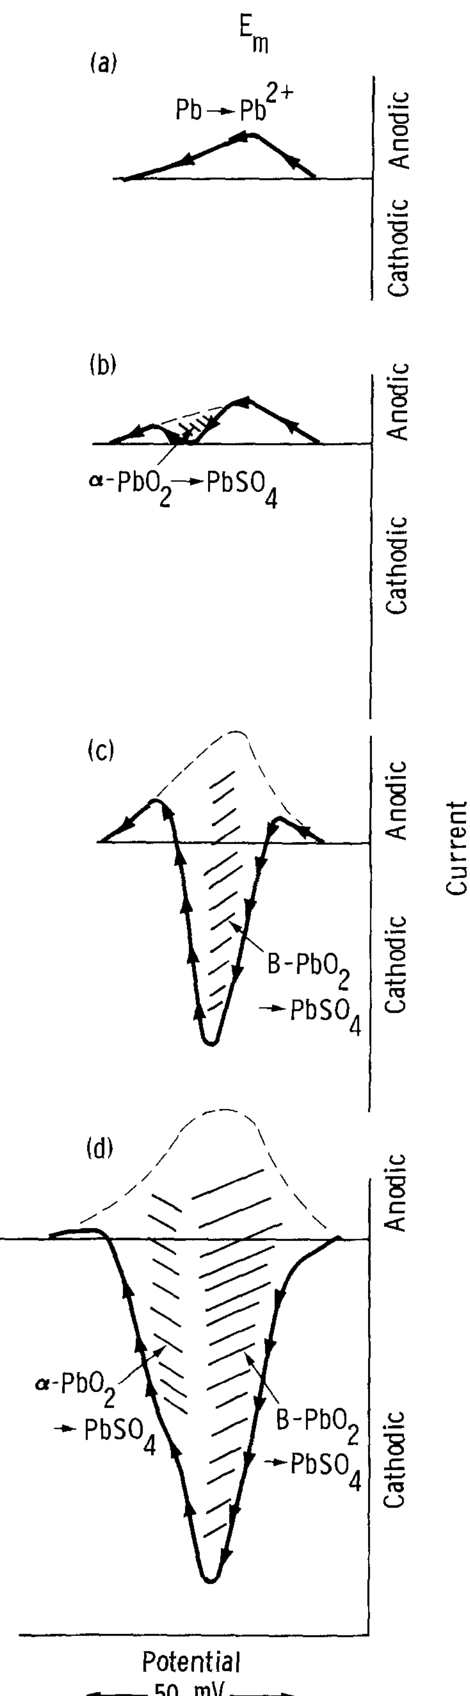

Fig. 12. Schematic showing possible cathodic sweeps for pre-anodized lead (see text).

As dischargeable PbO_2 is built up, the anodic current (broken lines, Fig. 12) may become partially or totally obscured. The sweep profile may then be influenced primarily by the discharge of α-PbO_2 (Fig. 12b), β-PbO_2 (Fig. 12c) or a composite of the two (Fig. 12d). The cathodic current peak intensities depend upon potential and time of anodic treatment and are strongly influenced by antimony in the lead.

Comparisons between nonantimonial and antimonial lead.—For nonantimonial (Pb/Ca) lead, the cathodic sweeps essentially follow the series of profiles in Fig. 12 after anodic control at progressively higher overvoltages. From the i-t curves obtained during the anodic treatment, the conversion of $PbSO_4$ to β-PbO_2 became evident at overvoltages of no more than 175 mV (*vs.* $PbO_2/PbSO_4$).

A striking feature of the Pb/Sb alloy was that substantially higher overvoltages (η = 375 mV) were required before effects due to oxidation of $PbSO_4$ to β-PbO_2 were observed in the i-t curves. A low rate of buildup of β-PbO_2 on antimonial alloy has also been observed by x-ray diffraction following anodic treatment at constant current (14). This may stem from parasitic oxidation of the antimony, occurring preferentially to the oxidation of $PbSO_4$ in the corrosion film. The difficulty in forming PbO_2 on antimonial lead has also been recognized in cathodic protection applications (15).

After control at high potentials (η = 425 mV) the concommitant growth of α- and β-PbO_2 discharge peaks was observed, but the β-PbO_2 discharge peak was substantially lower in capacity than that observed on the nonantimonial lead after comparable anodic treatment.

Antimony in positive plate grids.—Proposals as to why antimony prolongs positive plate cycle life have been based primarily on the observed effects of antimony on morphology and other properties of the PbO_2 active material (16). Antimony has also been shown to affect grid growth (17). An estimation of the importance of the numerous factors involved would indeed be a formidable task. However, it has been generally observed that corrosion films on nonantimonial lead, which, in view of the present work, contain substantial quantities of β-PbO_2, are more powdery and loosely adherent than those found on antimonial lead. The desirable effect from antimony, therefore, may be to inhibit the buildup of excess β-PbO_2 during the formation step, thereby providing a thinner, and presumably more tenacious film on which the active material of the plate can be formed. If this mechanism is operable, then it would appear that other effects that have been observed after formation and cycling would be of a secondary nature.

At the rather modest level of antimony concentration considered here (4.5%), there was also an indication that Sb shifts the E_m to more negative values. Although the trend was marginal, it was in a direction that would extend positive plate cycle life. It may be of interest to examine that trend, as well as the other findings of this study, as a function of antimony concentration in the alloy.

Anodic Passivation by "CdO" Studied by ESR

E. J. Casey* and C. L. Gardner

Defence Research Establishment Ottawa, Ottawa, Ontario, Canada K1A 0Z4

ABSTRACT

The appearance of superoxide O_2^- and ozonide O_3^- ions in strong KOH electrolyte at temperatures 25° to −40°C during the anodic oxidation of cadmium and oxygen evolution has been investigated using the electron spin resonance technique. The fact that O_2^- forms at the higher temperatures and O_3^- predominates at −40°C correlates with the appearance of β-$Cd(OH)_2$ at higher and γ-$Cd(OH)_2$ at lower temperatures, but it is argued that this correlation is coincidental and that it is the character of the surface states of the elusive and dynamic "CdO" underlayer beneath the $Cd(OH)_2$ that determines which paramagnetic species is produced. These new facts and the interpretation are discussed within the framework of the solid state/solution-precipitation mechanism.

In this paper the evidence for a form of cadmium oxide as the instrument of anodic passivation of cadmium in aqueous KOH from 33° to −40°C is reviewed, and some new evidence obtained via ESR is added and interpreted. The mechanism by which the metal ceases to be anodically oxidizable after a period of active oxidation is one important element of the information needed if more efficient utilization of the metal in negative plates of alkaline batteries is to be achieved. Other important elements, such as those related to surface exposed and to pore structure (1), are not reviewed here.

Review of Evidence for CdO as an Intermediate Product

Since 1950, Epelboin (2) has written extensively about the probability of the existence of monovalent intermediates such as Cd^+ resulting from anodic, one-electron charge-transfer steps, especially during electropolishing of metals. The evidence is still equivocal, direct proof still lacking in the case of cadmium. By 1950 Huber (3) and Ershler *et al.* (4) had found CdO by x-ray diffraction of samples taken from the surface of Cd anodized at high potentials. Lake and Casey (5) studied the electrical behavior of cadmium before, during, and after passivation, and inferred that a solid-film intermediate, "CdO," must be a substantial intermediate in the reactions which eventually lead to $Cd(OH)_2$ in KOH and to $CdCO_3$ in K_2CO_3 solutions, and which ultimately causes the passivation.

Many workers have sought CdO, without finding it, in the passivating layer. Falk (6a) found none at room temperature in Sweden (20°C). Sanghi *et al.* (6b) found none at room temperature in India (33°C!). Nor did Croft (6c), nor Thirsk *et al.* (6d). Nor did others (7). The hexagonal platelets of β-$Cd(OH)_2$ are usually identified as the product, either by x-ray diffraction of moist or dry particulate samples, or by electron diffraction of dried, anodically formed, very thin films. However, Breiter and Vedder (8), and later Okinaka and Whitehurst (9a), found the more recently identified (10) needlelike monoclinic γ-$Cd(OH)_2$ as the major product: the former authors during experiments at room temperature and the latter group during experiments at low temperatures. The γ-$Cd(OH)_2$ seems to be more readily reducible to metallic cadmium than is the β-form, especially at low temperatures, during the electrochemical charging reaction (9a). More recently (9b), the needles have been shown by the scanning electron microscope technique at 25° and possibly [note the authors' uncertainty, Ref. (9b)] up to 40°C in porous electrodes.

No attempts were made by the authors of any of the quoted work to freeze-dry, or otherwise to stop any hydrolysis, hydration, or protonation of CdO which could occur after anodic treatment ceases and during manipulation of the wet sample.

Yoshizawa and Takehara (11a), however, did find CdO by x-ray diffraction of samples buried within thick plates. Ohse found it also (11b), and concluded that it formed underneath the $Cd(OH)_2$. The results found by Devanathan *et al.* (11c) suggested to those workers that the CdO and $Cd(OH)_2$ form at the same time. Okinaka (12) also found CdO, following a period of vigorous oxygen evolution in solutions of low KOH concentration [conditions much like Huber's (3)]. Galushko *et al.* (13) recently reported further experimental conditions (low concentration of KOH, mild anodic treatment) under which CdO could accumulate, be identified, and its electrochemical reduction studied.

Indirect evidence also exists that CdO forms as an intermediate. Thus Breiter and Weininger (8b), using triangular voltage sweeps for anodic oxidation and cathodic reduction, found a reduction peak just about where one would expect the polarized Cd/CdO potential on an electrode which had not been heavily passivated anodically; they concluded that CdO was indeed formed and then remained stable long enough to be electrochemically reduced. Okinaka (12) showed that the CdO reduction peak occurs also following anodic oxidation during ring-disk experiments.

On Mechanisms

Throughout the past fifteen years there have been several papers containing discussion of the relative merits of and the role of two proposed mechanisms of the anodic oxidation: (*i*) the "solid-state mechanism"

* Electrochemical Society Active Member.

Key words: CdO, cadmium, anodic passivation, ozonide O_3^-.

(Cd^{++} penetrating an underlayer [CdO? $Cd(OH)_2$?] to the solid/solution interface and reacting with electrolyte there); (*ii*) the "solution-precipitation mechanism" (Cd^{++} ions dissolving directly from Cd metal, as $Cd(OH)_3^-$, perhaps, to precipitate as $Cd(OH)_2$.

Either one offers a good first approximation (6a, 6b) over a narrow range of experimental conditions. Neither, however, can describe polarization data taken on cadmium over a wide range of current density, temperature, and electrolyte composition, both before and after passivation, but especially during passivation. As far as we are aware, only the combined solid-phase/solution-precipitation mechanism (see Fig. 1) has the flexibility needed. Thus an underlayer which is difficult to detect is pictured as being covered by the x-ray-detectable final reaction product: cadmium ions penetrate the nonstoichiometric "CdO," the outer surface of which is continually dissolving (*i.e.*, complexing) and precipitating out again as the final product, $Cd(OH)_2$. At passivation this dynamically self-refurbishing glassy underlayer seals over, dissolves only slowly, and is continuously being replaced.

A mechanism for the escape of the soluble complexes from the "CdO" surface has been proposed (15). It has already been shown that when this part of the process is significantly slowed down by conducting the experiments at −40°, the total anodic film need be only about 6 CdO-layers thick to effect passivation (15). It was early argued [see Fig. 5, Ref. (5b)] that the underlayer must be nonstoichiometric everywhere except at one interior plane: rich in $O^=$ near the CdO/electrolyte interface, rich in Cd^{++} near the Cd/CdO interface; thin and glassy, nonstoichiometric, continuous; of the variable composition so elegantly demonstrated directly by Hoar quite recently on iron-tin using Auger techniques (16).

No direct physical identification of CdO as an intermediate during active oxidation of cadmium or even after passivation of cadmium at low oxygen overpotentials, has been acquired, presumably because it is (*a*) buried beneath the final hydrolysis product, and (*b*) rapidly converted to final product under all but exceptional conditions. The final reaction products may be formed through soluble intermediates such as $Cd(OH)_3^-$ or $Cd(OH)_4^=$ in KOH, $Cd_3(CO_3)_4^=$ in K_2CO_3, or through poorly characterized hydroxy-carbonates in mixed electrolytes (14a and b). The question of what soluble complexes exist in high concentrations of KOH has not been conclusively answered, some evidence favoring $Cd(OH)_3^-$ and other favoring $Cd(OH)_4^=$. Gilman and Sangermano (17a) recently wrestled with this difficulty, as had others earlier (17b, 17c).

Such investigations have elaborated the complexity of the anodic oxidation of cadmium. The search continues for new evidence.

Detection of Anodically formed O_3^- and O_2^-

By the late 1960s, we were applying ESR techniques to the anodic oxidation of cadmium and silver, and to other similar basic problems. It was found (18) that O_3^- and other paramagnetic species such as O_2^-, and $CuO_2^=$, produced anodically on some metals in aqueous KOH, at temperatures well below 0°C, were stable enough to be identified, and that their concentrations could be measured. Concerning cadmium we have reported (18a) that O_2^- is the detectable product of anodic oxidation in aqueous KOH at the higher temperatures (−10° to −20°C), while O_3^- is the observable product at the really low temperatures (down to −40°). Temperature inversion from one species to the other was sought but not observed (18b). The technique has been improved, and O_2^- has been detected in the anolyte during oxygen evolution off Cd even at room temperature, both in this work and elsewhere (18c).

Figure 2 shows the distinctly different spectra of O_2^- and O_3^-. The O_2^- was produced chemically by the decomposition of H_2O_2 in KOH solutions. The O_3^- was produced electrochemically during O_2 evolution on oxidized silver, as before (19). In each case electrolyte samples were quick-frozen in liquid nitrogen and spectra recorded on the frozen samples at 77°K, as described in Ref. (19). Characteristic *g*-values are given for each. The g_z for O_2^- shifts much more with the electrostatic environment to which it is bound than do g_x and g_y. [See Lunsford's Table 2 (20).]

Measurements taken with an electrochemical cell placed directly in the microwave cavity were insensitive, as the cavity was detuned by gas bubbles. After anodic oxidation for ~5 min at ~100 mA/cm² at the temperature shown, samples of electrolyte from near the cadmium anode were withdrawn into thin quartz tubes and quick-frozen in liquid nitrogen. Spectra of

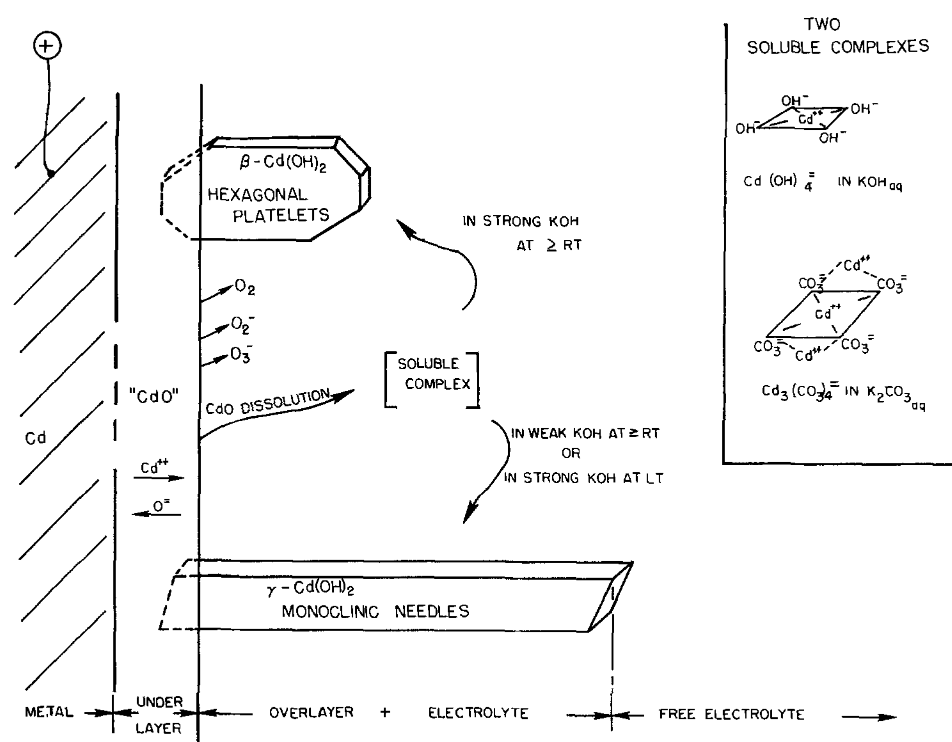

Fig. 1. Schematic indicating solid-state/solution-precipitation mechanism for anodic oxidation of cadmium. After passivation by the underlayer and the onset of oxygen evolution, the radicals O_2^- and O_3^- can be detected in the electrolyte at low temperatures. The underlayer continues to dissolve and be reformed during oxygen evolution. This seems to correlate with radical formation.

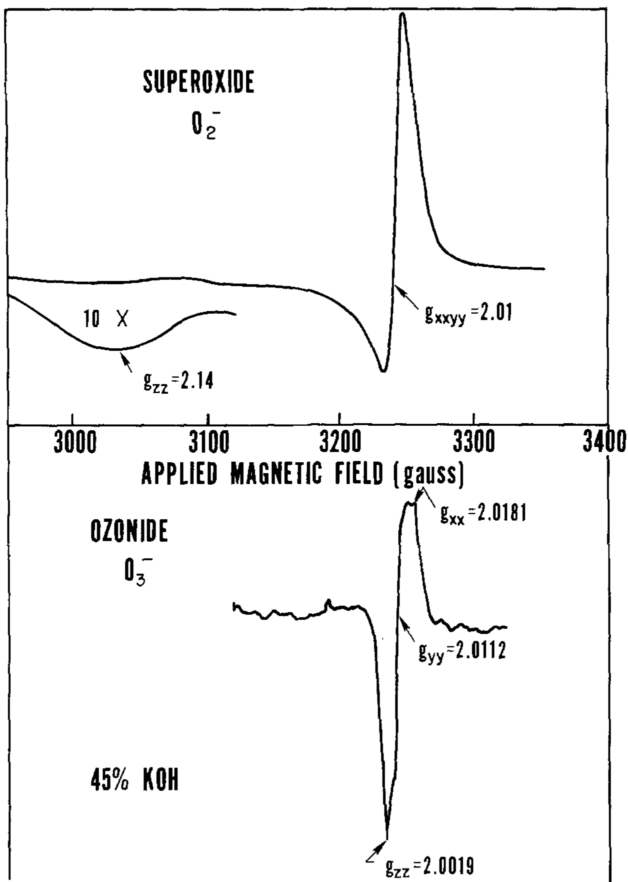

Fig. 2. ESR spectra taken at 77°K of O_2^- and O_3^-. Note distinctly different line shapes as expressed by the g-values. The g_{zz} peak of O_2^- is shown amplified 10× for clarity.

these samples were then taken at 77°K. From Fig. 3 it can be seen that the superoxide ion O_2^- is the main paramagnetic product detected from +25° to −25°C, while at −35° the O_3^- predominates. At −40° in 45% KOH the spectrum is that of O_3^- only, there being no evidence at all for O_2^-. Careful inspection reveals that the absorption by species "X," at $g = 2.00$, which will be discussed below, appears from under that of O_2^- as the spectrum of O_2^- fades out at lower temperatures.

So far no evidence has been obtained with the ESR technique for the anodic formation of free-radical intermediates from Cd except during oxygen evolution, *i.e.*, after passivation. The question of whether any free-radical intermediates which might be formed before and/or during passivation can somehow be detected by this method is still an open one: it will be necessary to find conditions under which the intermediates can desorb into the electrolyte, accumulate there, and then be stable while a sample of the anolyte is being quick-frozen and examined in the ESR cavity. The following discussion, therefore, refers only to the situation after passivation, after completion of the "CdO" underlayer.

Discussion

Of the several metals studied so far cadmium is the only one from which both O_2^- and O_3^- have been detected having been produced during anodic oxygen evolution. From the fact that O_2^- is formed at the higher temperatures investigated and O_3^- at the lower, one can infer that the passivating glassy underlayer is different at different temperatures. Perhaps it is more highly protonated at −10° than at −40°, and the primary product of the discharge of OH_{ads}^-, namely O_{ads}^-, is more weakly bound at −10° than at −40°. The mechanism could change as follows. Since the second discharge event produces O_{ads} in both cases, the O_{ads}^- can rapidly combine with one O_{ads} to evolve O_2^- from the surface of the underlayer at −10°, while at

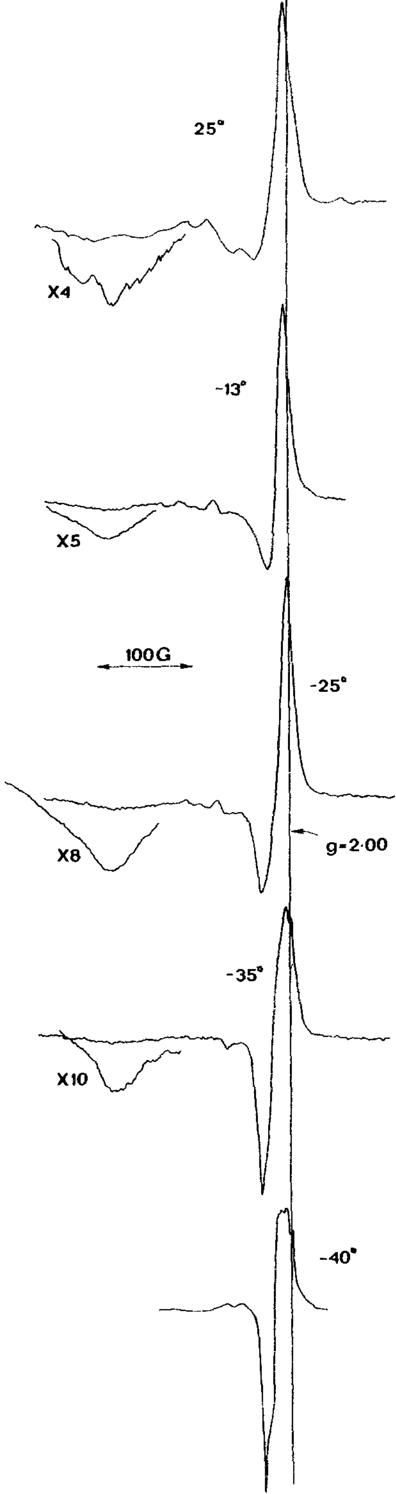

Fig. 3. Spectra of strong KOH anolyte samples extracted in a capillary and quick-frozen to 77°K, following anodic oxygen evolution off cadmium at temperatures shown. Clear spectra of O_2^- for 25° and O_3^- for −40°C. "X" is just perceptible near $g = 2$ at −35° and −40°.

−40° it gets away more slowly and then only by combining with two O_{ads} to evolve O_3^-. In summary, the discharge reactions

$$OH_{ads}^- \rightarrow O_{ads}^- + e + H^+ \quad \text{and} \quad O_{ads}^- \rightarrow O_{ads} + e$$

followed by

$$O_{ads}^- + O_{ads} \rightarrow O_2^- \quad \text{at} \ -10°$$

and

$$O_{ads}^- + 2\ O_{ads} \rightarrow O_3^- \quad \text{at} \ -40°$$

produce the paramagnetic species detected.

These mechanisms seem simpler than those proposed in our earlier work (18, 19), namely

$$2\,OH_{ads} \rightarrow H_2O_2 \rightarrow \tfrac{1}{2}\,O_2 + H_2O$$

$$H_2O_2 + OH^- \rightarrow HO_2^- + H_2O$$

$$HO_2^- + OH \rightarrow O_2^- + H_2O$$

and

$$O_{ads}^- + O_2 \rightarrow O_3^-$$

although there is no experimental reason to favor one over the other at this juncture.

A cautionary note is introduced by the possibility that O_3^- is not observed at the higher temperatures from Cd simply because it decays too fast (in the cadmium-saturated electrolyte) and not that it never was formed in the first place, as we have implied above. This will be a hard point to prove experimentally.

In addition to the oxygen species the elusive species "X," which gives a sharp ESR absorption peak at $g = 2.0023$, is produced as a second anodic reaction product of cadmium [and several other metals (18)] in strong KOH at low temperatures. The nature of species X is still uncertain. Its decay rate varies markedly (minutes to less than seconds) (19). In the case of cadmium oxidation this sharp absorption line (Fig. 2, −35° and −40°) could be due to conduction electrons in colloidal metal which has been undermined during anodic dissolution, a manifestation of the classical "chunk effect" (21). Or, it might be due to complexed electrons arising from oxidation of Cd^+ by electrolyte. Although it is unlikely to be due to Cd^+ itself [whose magnetic parameters (22) are $g = 1.992$ to 2.001, and a large hyperfine splitting for the isotope 114, none for the more abundant isotope 112], it could be due to the electron which has just been ejected from anodically formed Cd^+ and which is temporarily resting in the metal-ion/hydroxyl-ion/water complex, $M(OH)_n^{2-n} \cdot xH_2O$. The analogy with Epelboin's recent work (23) on Be^+ produced anodically in an aprotic solvent elicits further thought along these lines. However, since the absorption peak at 2.0023 is devoid of fine structure, ESR work to date cannot distinguish unambiguously between colloidal metal or complexed electron.

The elements of the solid-phase/solution-precipitation mechanism given in this paper seem able to accommodate the new facts obtained by ESR as well as many seemingly incompatible observations earlier reported. New techniques which can permit *in situ* examination of composition, structure, and electrical properties are still needed, however, as is a quantitative theory which can describe the discontinuities of the passivation process. To delay the onset of passivation during anodic oxidation of the metal remains the primary practical objective of work of this kind.

The ESR results reported in this paper can be considered as relevant to the mechanisms operating at the cadmium electrode of a cadmium-alkali cell which has been driven into cell reversal (*i.e.*, forced discharge) at low temperatures. Attack of cell components by anodically produced free radicals, which are mobile in the electrolyte, can be anticipated.

Behavior of Salicylaldoxime and 8-Hydroxyquinoline at a Copper Electrode

Katsumi Niki,[*,1] **Frank M. Delnick,**[**] **and Norman Hackerman**[†]

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

Effects of salicylaldoxime (SAO) and of 8-hydroxyquinoline (HQ) on the anodic dissolution of copper were studied by using a potentiokinetic polarization method and phase-selective a-c polarography at a rotating copper disk electrode at various *p*H values. At *p*H 1.5, where cupric ions do not precipitate as the chelates of SAO and HQ, the anodic dissolution of copper was retarded slightly by these additives. At *p*H 2.8 and 5.0, where SAO precipitates cupric ions quantitatively, the anodic dissolution of copper was markedly retarded by SAO, especially from the rotating disk electrode. The anodic polarization curves of copper in the SAO solutions were similar to those obtained in the passivation of iron. A thin protective chelate film was formed on the copper electrode. At very positive potentials, the chelate film ruptured and the anodic dissolution of copper started. On the other hand, HQ chemisorbed strongly on the copper electrode from *p*H 2.8-5.0, where HQ also precipitates cupric ions, and the copper dissolution was retarded markedly. The Cu-HQ chelate did not act as a barrier for the copper dissolution in this *p*H range.

Numerous studies have been made to elucidate the mechanism of corrosion inhibition by organic substances. Inhibitors of the first class are physically adsorbed on the metal surfaces. This adsorption is nonspecific and reversible. On the other hand, for inhibitors of the second class the adsorption is chemical in nature and is specific to the metal. For instance, as a general rule, organic inhibitors are more effective with ferrous metals than with nonferrous metals. It can be predicted that for a given inhibitor the order of increasing effectiveness is likely to be: Zn < Cu < Ni <Fe. It is interesting, also, that the series cited above is a familiar one in terms of the stability of chelate complexes.

Hayakawa and Ida (1) estimated the stability constants for a series of hydroxyazo compounds of aluminum and they suggested that inhibition of aluminum corrosion in alkaline solutions by these compounds should be increasingly effective with increasing stability of the complex. These chelating agents were considered to form protective films of aluminum chelates on the aluminum surface.

Benzotriazole forms a water-insoluble precipitate with both cuprous and cupric ions and has been used as an efficient corrosion inhibitor for copper in a wide variety of environments (2-7). Cotton (2-4) concluded that benzotriazole inhibits the corrosion of copper by forming a Cu(I)-benzotriazole compound on the copper surface. Poling (8) showed from infrared reflectance spectra that the protective film was highly inert Cu(I)-benzotriazole complex polymer.[2] Wall and Davis (9) suggested that benzotriazole reacts to form an invisible insoluble chelate on the copper surface. On the other hand, Mansfeld *et al.* (7) suggested, on the basis of ellipsometric studies, that benzotriazole is chemisorbed on the copper surface.

Ushenina and Klyuchnikov (10) studied the influence of various chelating agents on the corrosion rates of iron, cobalt, zinc, and copper. Both benzotriazole and 8-hydroxyquinoline retarded the corrosion of copper considerably in ammoniacal buffer. Inhibitor efficiencies of these chelating agents were 90.2 and 44.3%, respectively. On the other hand, the inhibitor efficiency of salicyladoxime in ammoniacal buffer was only 6.2%. They stated that when the chelate is formed directly on the surface as a compact film having good adhesion to the metal (discharge and nucleation mechanism), it retards corrosion. When the chelate is formed in the bulk of the solution and is then deposited (dissolution-precipitation mechanism), the film has only a slight retarding effect on corrosion.

In the present work we have investigated the anodic dissolution of copper in the presence of salicylaldoxime (SAO) and 8-hydroxyquinoline (HQ). Cu^{2+} is precipitated quantitatively by SAO at *p*H values higher than 2.6 (12), and by HQ at *p*H values between 5.3 and 14.5 (incomplete precipitation begins at *p*H 3.5) (11), according to the following reactions:

Cu^{2+} + 2 SAO → Cu(SAO)$_2$ chelate

Cu^{2+} + 2 HQ → Cu(HQ)$_2$ chelate

Solutions of *p*H 1.5, 2.8, and 5.0 were chosen so that the relation between the stability and/or solubility of the chelates and the inhibition efficiency could be studied.

Experimental

All chemicals except SAO (Eastman) were analytical grade and were used without further purification. All solutions were prepared using doubly distilled water (deionized and then distilled). The composition of the buffer solutions was as follows: *p*H 1.5, 0.05M H_2SO_4; *p*H 2.8, 0.2M monochloroacetic acid, 0.1M NaOH; and, *p*H 5.0, 0.1M sodium acetate, 0.033M acetic acid.

The ionic strength of these solutions was adjusted to 0.5 by the addition of sodium sulfate. All solutions were deaerated using purified nitrogen. A single-crystal copper rod (6.0 mm in diameter) with the

[2] Benzotriazole (BTA) forms a water-insoluble stoichiometric compound Cu(I) (BTA) with cuprous ions, whereas it precipitates a nonstoichiometric Cu(II) $(BTA)_x$ (x = 1.4-2.0) with cupric ions.

(100) plane as the electrode surface was sheathed in a Teflon cylinder. The electrode surface was polished mechanically with No. 600 emery paper and then electropolished in concentrated phosphoric acid. After washing with distilled water, the electrode was attached to a Beckman rotating electrode assembly with variable drive. A potentiostat with a linear-sweep voltage source (constructed locally with Teledyne-Philbrick operational amplifiers) was used. The phase-selective a-c polarograph was built according to the circuit given by Matsuda *et al.* (13). Unless otherwise stated, all polarization curves were obtained potentiokinetically with a sweep rate of 50 mV/min, after polarizing the rotating copper electrode to a predetermined potential in the region of hydrogen evolution. All measurements were carried out at 25° ± 1°C, and potentials were measured against a saturated calomel electrode.

Results

pH 1.5.—The polarization curves for the rotating copper disk electrode in the solutions of pH 1.5 containing the chelating agents are shown in Fig. 1a and 1b. Both SAO and HQ retarded the dissolution rate of copper. The Tafel slope for the copper dissolution was not altered by the addition of either SAO or HQ. The polarization curve shifted to more cathodic potentials with an increase in the rate of rotation. At high anodic polarizations the current tends to be diffusion controlled, as reported by Leckie (14). The effect of additives on the polarization of copper at high anodic polarization was significantly decreased but did not disappear. However, the effect of rotation disappeared.

Salicylaldoxime.—The polarization curves in the presence of SAO at pH 2.8 are shown in Fig. 2a and

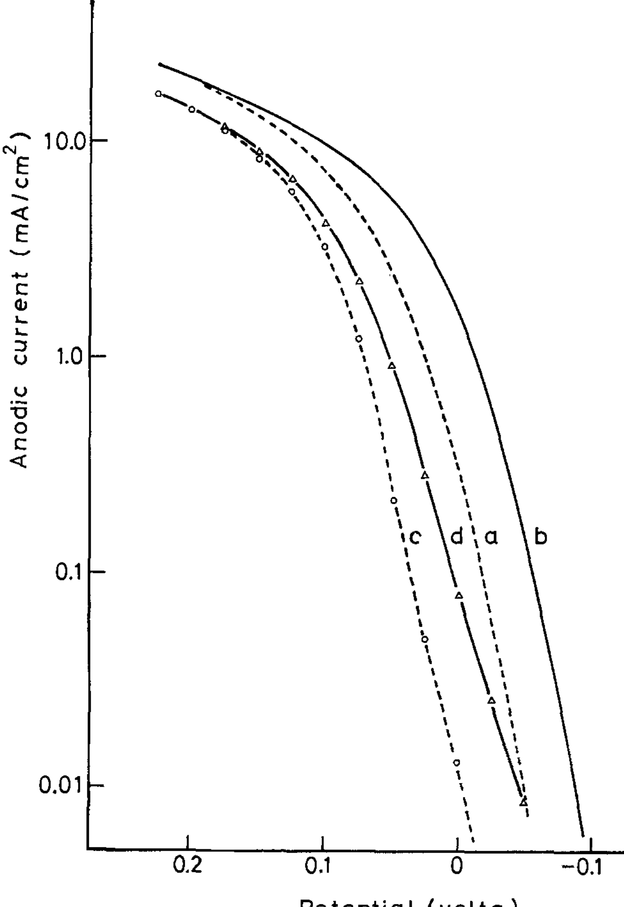

Fig. 1a. Tafel plots in SAO solution at pH 1.5. In the base solution with stationary disk electrode (SDE) (curve a), and with rotating disk electrode (6000 rpm) (RDE) (curve b). In 5.0 mM SAO solution with SDE (curve c), and with RDE (6000 rpm) (curve d).

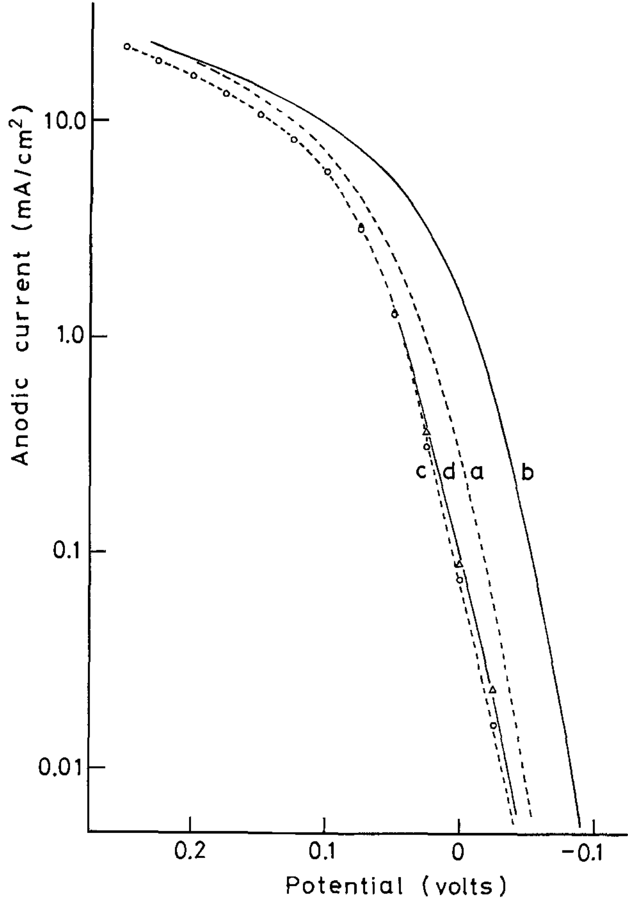

Fig. 1b. Tafel plots in HQ solution at pH 1.5. In the base solution with SDE (curve a), and with RDE (6000 rpm) (curve b). In 5.0 mM HQ solution with SDE (curve c), and with RDE (6000 rpm) (curve d).

2b: A current maximum and minimum were observed, followed by a current increase at more anodic potentials. The polarization curves shifted slightly toward cathodic potentials as the rate of rotation was increased at lower current densities (in the potential region of the current peak). The peak current was higher and the peak potential more anodic at the lower concentration of SAO and lower rotation rate. The current in the passive region which followed the current peak decreased with increasing concentration of SAO. At higher anodic polarizations (trans-passive potential, region), a white precipitate of $Cu(SAO)_2$ was seen to fall from the stationary disk electrode. The curves corresponding to increasing and decreasing polarization did not coincide. The current at decreasing polarization was higher than that observed during increasing polarization in the passive region and the current peak was not observed, as shown in Fig. 2a.

In the steady-state potentiostatic polarization curves from cathodic to anodic direction, the current peak was not observed.

In the acetate buffer solution at pH 5.0 (Fig. 3a and b), the effect of SAO on the copper dissolution was qualitatively similar to that at lower pH values, but was more pronounced. The current peak occurred at about —0.05V, which is more cathodic than at pH 2.8. The current peak was also observed with the stationary electrode when the concentration of SAO was more than 10 mM at pH 5.0 and 20 mM at pH 2.8, respectively. The polarization curves in the trans-passive region were not influenced significantly by the rotation rate (600-6000 rpm) (Fig. 3a), and depended slightly on the concentration of SAO (Fig. 3b); the electrode surface showed local corrosion on a shiny background after polarization in this region. However, it remained shiny when the anodic

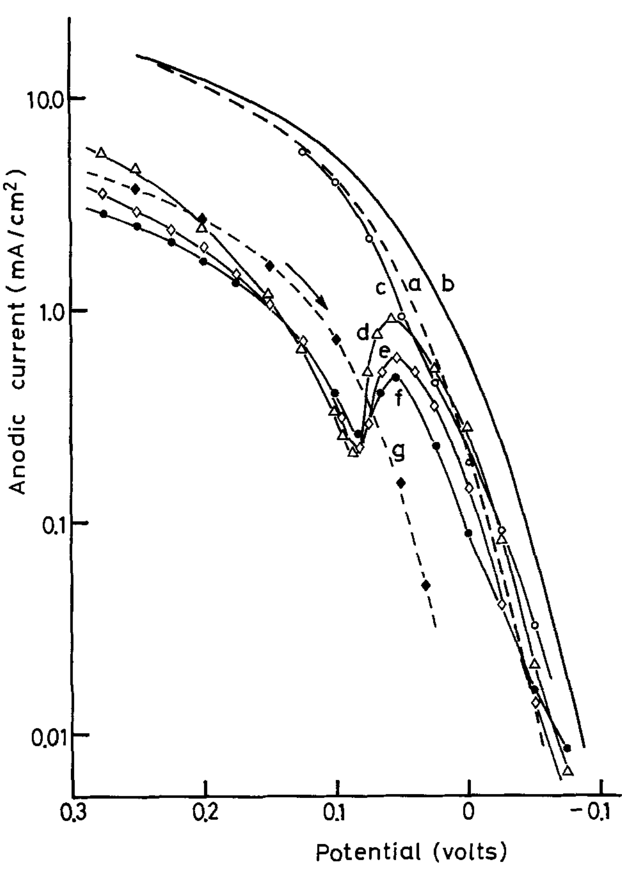

Fig. 2a. Tafel plots in 5 mM SAO solution at pH 2.8 with various rotation rates. In the base solution with SDE (curve a), and RDE (6000 rpm) (curve b). In 5 mM SAO solution with SDE (curve c), 600 rpm (curve d), 1200 rpm (curve e), 3000 rpm (curve f), and with RDE (1200 rpm) polarized from anodic to cathodic direction (curve g).

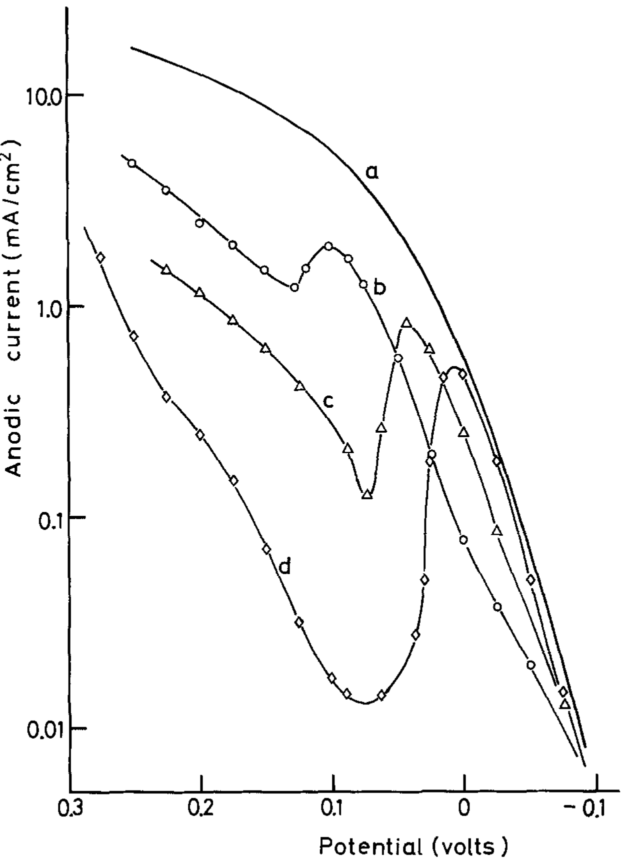

Fig. 2b. Tafel plots in SAO solutions at pH 2.8 with RDE (3000 rpm). In the base solution (curve a), 2.5 mM SAO (curve b), 5.0 mM SAO (curve c), and 10 mM SAO (curve d).

polarization was stopped at potentials more cathodic than the second increase in current rise.

Cyclic voltammetry at the copper electrode in the SAO solution (Fig. 4) showed that the surface film formation was irreversible. The chelate film was partially reduced at potentials more cathodic than about -0.6V. Successive anodic sweeps started from potentials more cathodic than -0.6V gave a larger anodic current peak at -0.1V; the chelate film formed during the anodic process was almost completely reduced at -1.0V.

The total amount of electrical charge involved in the Cu-SAO chelate film formation in the potential region of the current peak depended on the pH of the solution, the concentration of SAO, and the rate of rotation of the electrode (Table I). With increase in the rotation rate, the amount of electrical charge involved in the chelate film formation decreased slightly.

The impedance of the copper electrode in the presence of SAO at pH 5.0 was measured by using the phase-selective a-c polarograph and was represented

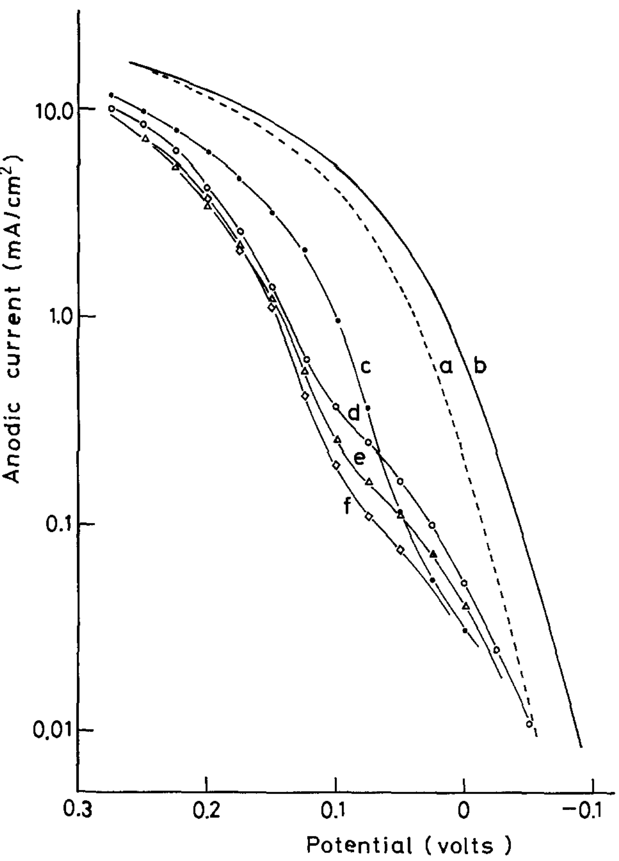

Fig. 6. Tafel plots in 5 mM HQ solution at pH 2.8 with various rotation rates. In the base solution with SDE (curve a) and with RDE (6000 rpm) (curve b). In 5.0 mM HQ solution with SDE (curve c), 600 rpm (curve d), 1200 rpm (curve e) and 3000 rpm (curve f).

as a series combined of a capacitance, C_s, and a resistance, R_s (Fig. 5). In the double layer region, C_s decreased markedly on addition of SAO. On the other hand, R_s remained constant regardless of the concentration of SAO. In the region of the d-c peak, C_s increased slightly, and then decreased to a very small value in the passive region, whereas R_s increased steeply to a very large value.

8-Hydroxyquinoline.—In a solution of 5.0 mM HQ at pH 2.8 (Fig. 6), the dissolution rate increased monotonically as the potential became more anodic, and no current peak was observed. With the rotating disk electrode, a shoulder was observed in the anodic polarization curves at about 2×10^{-4} A/cm². At current densities smaller than 2×10^{-4} A/cm², the polarization curve shifted slightly to the more cathodic region and above this current density it shifted toward the anodic side on rotating the electrode. The effect of rotation rate on the polarization curve was small in a 5 mM HQ solution at pH 5.0 (Fig. 7). With an increase in the rotation rate the polarization curve shifted slightly to more anodic potentials.

Figure 8 shows C_s and R_s for the copper electrode in a 5 mM HQ solution (pH 5). HQ depressed C_s markedly in the double layer region as in the case of the SAO solution and C_s showed a considerable increase

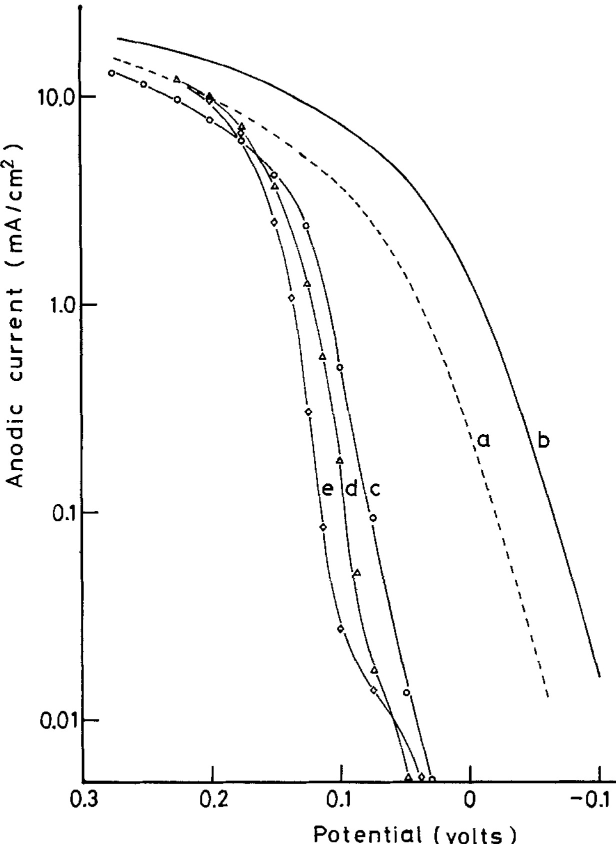

Fig. 7. Tafel plots at pH 5.0 in the presence of HQ. In the base solution with SDE (curve a) and with RDE (6000 rpm) (curve b). In 5.0 mM HQ solution with SDE (curve c), 3000 rpm (curve d), and 6000 rpm (curve e).

in the potential region where the d.c. started to increase.

Discussion

At pH 1.5.—About one-half of SAO and most of HQ molecules are protonated in the solution at pH 1.5 (15, 16). According to earlier work (17, 18), SAO would therefore be expected to be a better corrosion inhibitor. If we assume that the deceleration of the copper dissolution is only due to a blocking effect and that the surface coverage is independent of the electrode potential, the Tafel slope should not be affected by organic additives because the mass transport to or from the electrode is not disturbed by the additives (19). The shift of the Tafel plots with rotation in the absence of SAO was comparable with that in the presence of SAO; this suggests that the adsorption of SAO did not disturb the diffusion of products from the electrode. Capacity measurements indicated that the potential dependence of the SAO adsorption was very small in this potential region. Although the solubility of HQ is smaller than that of SAO at pH 1.5, the inhibitor efficiency of SAO was slightly better than that of HQ. The adsorption of SAO on the copper electrode is probably chemical in nature.

Salicylaldoxime.—In the pH range where Cu^{++} precipitates as a chelate with SAO, the polarization curves are similar in shape to those observed for the passivation of iron. In this case, however, the current peak corresponds to the faradaic process for the formation of an insoluble Cu-SAO chelate film at the electrode surface. After the copper electrode surface was covered by the insoluble film the dissolution of copper was completely inhibited. The protective film of Cu-SAO chelate may be very similar to that formed by benzotriazole which reacts at the copper surface to form benzotriazole complexes. Poling (8) identified these complexes as a near stoichiometric Cu(I)-benzotriazole polymer. With increasing anodic polarization beyond the potential of the current peak, the anodic current reached a minimum (which corresponds to the passivation region of iron) and then started to increase again. The current increase in the transpassive potential region was caused by a rupture of the protective chelate film. This is evidenced by a visible localized corrosion of the copper surface.

Hysteresis of the polarization curve also suggests chelate film formation and rupture of the film at very anodic potentials, as in the case of passivation of iron.

In the pH range where SAO precipitates Cu^{2+} as Cu-SAO chelate, the formation of Cu-SAO chelate at the copper electrode is thermodynamically more favorable than the dissolution of copper as Cu^{2+}. At pH 2.8, however, the rate of chelate film formation at the copper electrode is slow, and the SAO film chemisorbed on the copper electrode, suggested by the data of Fig. 5, inhibited the dissolution of copper. With increase in the electrode potential, the faradaic process took place for the formation of Cu-SAO chelate as a first step. The chelate film formation is probably due to the reaction between the chemisorbed SAO and copper at the copper electrode surface. This mechanism was supported by the fact that the effect of rotation of the electrode on the polarization curves was insignificant at lower current densities. The mass transport of SAO to the electrode surface was so slow with the stationary electrode that the dissolution of copper as Cu^{2+} became predominant at higher current densities and the effect of SAO disappeared at very positive potentials.

With the rotating disk electrode the mass transport of SAO to the electrode was sufficient to form the chelate film on the electrode and the chelate film formation was a predominant reaction at the copper electrode in the current peak region. With increase in the rotation rate of the electrode the mass transport of SAO to the electrode was enhanced and the height of the current peak became smaller because the dissolution of copper was completely inhibited and the peak potential shifted cathodically. This behavior was very similar to the dependency of the polarization curves on the concentration of SAO as shown in Fig. 2b.

At pH 5.0, SAO also accelerates the faradaic process for formation of the chelate film on the electrode in the potential region of the current peak. The polarization curves shifted toward the cathodic region with increase in pH values of the solution. This is due to the formation of a more stable chelate film at pH 5.0 than that at pH 2.8.

The anodic process for the chelate film formation on the copper electrode in the presence of SAO can be considered to be due to: (*i*) the chelate film formation taking place at the electrode covered by the chemisorbed SAO, θ_{ad} $(1 - \theta_{film})$, where θ_{ad} is the fraction of the electrode surface covered by the chemisorbed SAO and θ_{film} is the fraction of the electrode surface covered by the chelate film; $Cu + 2(SAO)_{ad} \rightarrow Cu(SAO)_2$, and (*ii*) copper dissolution taking place at the uncovered electrode surface and Cu^{2+} formed by the anodic process reacting with SAO in the diffusion layer at the electrode interface and this Cu-chelate diffusing away from the electrode.

The mathematical solution of this process was very complicated and hence impractical for the analysis of the experimental data.

We made the further simplification that the electrode surface covered by the chemisorbed SAO was considered to be appreciably high on the basis of the differential capacity measurements so that the dissolution of copper as Cu^{2+} from the uncovered surface was ignored. The fraction of the electrode surface covered by SAO, θ_{ad}, was assumed to be a constant because the peak currents shown in Fig. 3a were far less than the flux of the limiting diffusion of SAO to the electrode surface under the present condition. The current-potential relation in the potentiokinetic measurement can be easily calculated by using Eq. [1] and [2]

$$i = 2\mathbf{F}k\,\theta_{ad}^2(1 - \theta_{film})\exp(2\beta\mathbf{F}E/RT) \quad [1]$$

$$i = Sd\theta_{film}/dt \quad [2]$$

$$E = E_i + vt \quad [3]$$

where i (A/cm²) is the faradaic current for the chelate film formation; k the rate constant for the chelate formation at $E = 0$, β the anodic transfer coefficient; θ_{film} and θ_{ad} (%) the fraction of the electrode surface covered by the chelate film and chemisorbed SAO, respectively; S (coulombs/cm²) the amount charge required to cover the electrode surface by the chelate film; v (V/sec) the scan rate, and t (sec) time. A solution of Eq. [1] is easily obtained as follows: (*i*) Substitute i and E into Eq. [1], and then integrate Eq. [1] to get θ_{film} as a function of time. (*ii*) Substitute $\theta_{film}(t)$ into Eq. [1] and then set its time derivative equal to zero to get t_{max}, the time required to reach the current peak potential from $E = E_i$.

One can obtain

$$t_{max} = \underline{\overline{K}}_1 - \underline{\overline{K}}_2 \ln \theta_{ad} \quad [4]$$

where

$$\underline{\overline{K}}_1 = \frac{RT}{2\beta\mathbf{F}v}\ln\left(\frac{S\beta v}{RTk}\right) - \frac{Ei}{v}$$

and

$$\underline{\overline{K}}_2 = RT/\beta\mathbf{F}v$$

Then one can easily obtain the peak current

$$i_{max} = \ln(2\beta\mathbf{F}v/RT) - 1 + (RTk\theta_{ad}^2/S\beta v)$$
$$\times \exp(2\beta\mathbf{F}E_i/RT) = \underline{\overline{K}}_3 + \underline{\overline{K}}_4\,\theta_{ad}^2 \quad [5]$$

The peak potential shifts linearly toward cathodic values with log θ_{ad} and the peak height increases linearly with θ_{ad}^2.

The shift of the peak potential with respect to the SAO concentration is shown in Fig. 9. Since θ_{ad} is a function of concentration of SAO, the steeper the slope of plots, the stronger is the adsorption of SAO on the copper electrode. Qualitatively, the adsorption of SAO onto the copper electrode becomes stronger with increasing pH of the solution. Similar behavior was observed with EDTA, adsorbed on a mercury electrode (20).

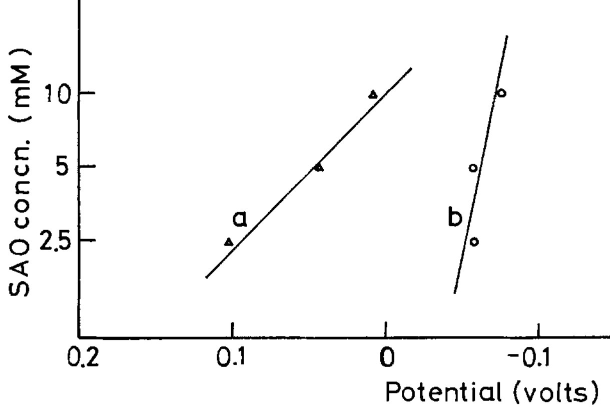

Fig. 9. Shift of peak potential with the concentration of SAO at pH 2.8 (curve a) and pH 5.0 (curve b).

The marked decrease in the capacitive component, C_s, of the copper electrode in the presence of SAO (Fig. 5) suggested that SAO adsorbed strongly on the electrode in the pH range where the Cu-SAO chelate is stable. In the current peak region of the above condition, the capacitive component became very small and the resistive component reached several thousands ohms. These changes strongly suggested the chelate film formation on the electrode surface. With the stationary disk electrode in the 5 mM SAO solution at pH 5.0, both C_s and R_s started to increase from the values in the double layer region at about +0.05V which is 75 mV more anodic than those in the base solution. This is probably due to the dissolution of copper as Cu^{2+} because of the insufficient supply of SAO onto the electrode to form a compact chelate film.

If we assume that the chelate film is formed through the dissolution-precipitation mechanism (21) the peak current in the cyclic voltammogram with a rotating disk electrode should increase with increasing rotation rate such as in the passive film formation on copper (22). In the present case, however, the peak current decreased with an increase in the rotation rate. This behavior indicates a discharge-nucleation mechanism for the formation of the Cu-SAO chelate on the copper electrode (21).

Assuming the density to be 2 g/cm³, the thickness of the surface film calculated from the amount of charge required for its formation ranged from 100Å, in 20 mM SAO solution at pH 5.0, to 1000Å, in 5.0 mM SAO solution at pH 5.0. These thicknesses are comparable with those reported by Poling (8) for the Cu-benzotriazole film on copper electrode.

8-Hydroxyquinoline.—In the HQ solution at pH 2.8, a shoulder was observed in the polarization curves with the rotating disk electrode (Fig. 6). The cathodic shift of the polarization curve at lower current densities (2×10^{-4} A/cm²) would be explained from the analogy of the copper electrode in the HQ solution to that in the SAO solution. The effect of HQ in the pH 5.0 solution is more pronounced than that in the pH 2.8 solution and the polarization curves were not influenced by the rotation rate (Fig. 7).

A strong adsorption of HQ on the copper electrode in the pH range where HQ precipitates cupric ions was evidenced by the capacitance curve in the double layer region (Fig. 8). Both capacitive and resistive components of the copper electrode in the pH 5.0 solution remained at almost the same value up to about +0.1V which corresponded to the potential at which the anodic dissolution of copper started. No decrease of the capacitive component was observed in the HQ solution. This result suggests that the inhibition of copper dissolution by HQ is not due to the chelate film on the

electrode but mainly to the chemisorbed film. This mechanism is also supported by the evidence that the rotation rate did not show any significant influence on the anodic polarization curves. The formation of a Cu-HQ chelate film on the electrode was evidenced by the result that the decreasing polarization curve (from anodic to cathodic) was higher than that of the increasing ones. However, the adhesion of the film on the electrode was not so strong as to decrease the capacitive component of the electrode, in contrast to the case of the SAO solution.

Conclusion

It was shown that the adsorption of both SAO and HQ on the copper electrode became stronger with increase in pH of the solution. This tendency is parallel to the stability of the copper chelates of SAO and HQ. In the pH range where SAO and HQ precipitate cupric ions as a chelate, the adsorbability of these chelating agents increased markedly and the anodic dissolution rate of copper was retarded to a considerable extent. In the SAO solutions the anodic polarization curves of copper were similar in shape to those for the passivation of iron. The Cu-SAO chelate film was formed in the active-to-passive transition region and the copper electrode became passive after the surface was covered by the chelate film. In the HQ solutions, on the other hand, the chemisorbed film retarded the dissolution of copper. The Cu-HQ chelate did not adhere to the copper electrode.

The Mechanism of Metallic Chromium Electrodeposition in the Cathodic Dichromate Treatment of Tinplate

Ph. Aubrun and P. Rocquet

Centre de Recherches du Fer Blanc, B. P. 135, 57100 Thionville, France

ABSTRACT

The passivation film deposited on tinplate by a cathodic treatment in a dichromate solution partly consists of metallic chromium. In order to clarify this rather surprising electrodeposition of metallic chromium, the successive reactions taking place were characterized. As a consequence, it is explained why the metallic chromium electrodeposition is made possible, and for what reason the deposit is of limited amount. The role played by the high hydrogen overvoltage on tin is emphasized.

At the end of its manufacturing process, electrolyte tinplate is subjected to a passivation treatment which improves its properties. Generally, this treatment consists of making the strip cathodic in a low-acid, sodium dichromate solution (CDC treatment). Tinplate is thus coated with a thin film containing metallic chromium (1, 2). This has been established by means of anodic dissolutions of the film, part of which involves six electrons per atom-gram of chromium. One cannot fail to be surprised by the following two items: First, how

Key words: tinplate passivation films, mechanism of chromium electrodeposition.

Table I. Conditions of metallic chromium deposition

	CDC treatment	Conventional chromium plating
Electrolyte: concentration	0.09M $Na_2Cr_2O_7 \cdot 2H_2O$	0.5M CrO_3
Acidity	pH 3-8	pH 1
Catalyzer	None	Yes
Current density	1 A/dm²	20 A/dm²

can metallic chromium be deposited under conditions so different from those under which this metal is generally deposited (Table I)? Second, why does the amount of metallic chromium obtained through tinplate CDC treatment rapidly reach a limit, dependent on the experimental factors, whereas it increases proportionally to the time with conventional chromium plating of iron (Fig. 1)?

A good understanding of the mechanism of metallic chromium electrodeposition during CDC treatment is required to explain these two facts. This is the subject of the first part of the present paper; then the two characteristics of this electrodeposition are explained in the last parts.

Successive Steps Leading to the Metallic Chromium Electrodeposition during CDC Treatment

In the case of conventional chromium plating of iron, the potentiokinetic cathodic polarization curve indicates the reaching of successive reactions (3). Prior to metallic chromium deposition, the building up of two films of chromium oxides and hydrogen evolution are noted (Fig. 2). It is noteworthy that if one substitutes the conventional chromium electrolyte with a dilute sodium dichromate solution, the successive waves of Fig. 2 disappear; at the same time, there is no metallic chromium electrodeposition.

Now, if we plot a curve of the same type, but relating to a tin electrode and a dilute sodium dichromate solution, we note (Fig. 3) the same features as those shown in Fig. 2, but only if we have used rolled tin or hot-dipped tinplate, cathodically cleaned in a Na_2CO_3 aqueous solution (5 g/liter). Under the same conditions, peak II does not appear with electrolytic tinplate as flow-melted, although we still notice the final deposition of metallic chromium. This particular behavior of electrolytic tinplate is probably due to an absorption of phenolsulfonic acid in the tin coating, as revealed by experiments which are not reported in this paper.

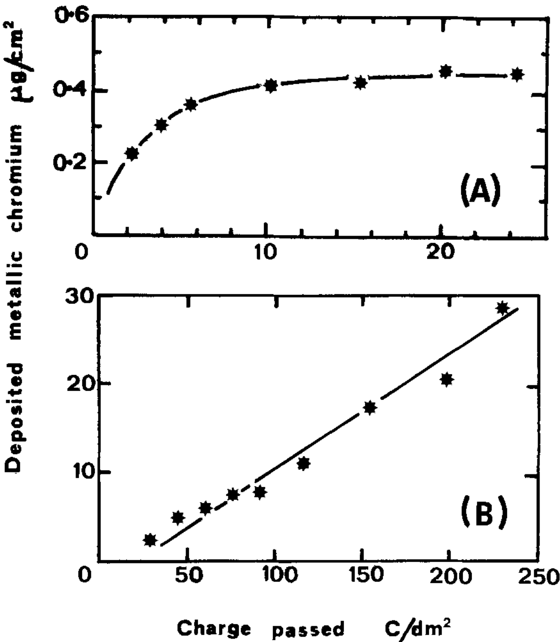

Fig. 1. Comparison between the rates of metallic chromium electrodeposition in the CDC treatment (A) and the conventional chromium plating of iron (B). (A) Cathode of electrolytic tinplate flow-melted and alkaline-cleaned. $Na_2Cr_2O_7 \cdot 2H_2O$ 25 g/liter (0.083M); pH 5.1; temperature 47°-49°C; 2 A/dm². (B) Cathode of mild steel cold-rolled, annealed, and alkaline-cleaned. CrO_3 50 g/liter (0.5M); H_2SO_4 0.5 g/liter; 20 A/dm².

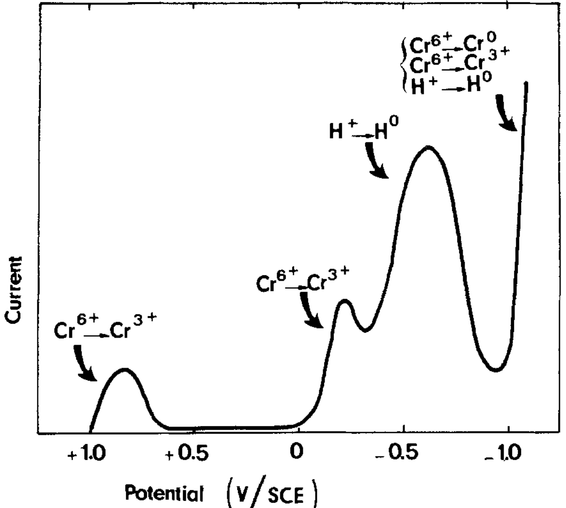

Fig. 2. Cathodic polarization curve of iron in a chromium plating bath (CrO_3-H_2SO_4) plotted potentiokinetically. Published by A. T. Vagramyan and D. N. Usachev, *Zhur. Fiz. Khim.*, **32**, 1900 (1958); after (3).

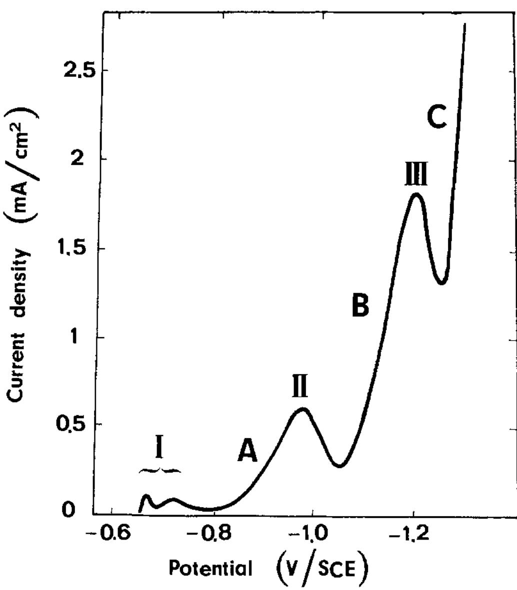

Fig. 3. Cathodic polarization curve plotted potentiokinetically with pure tin in an aqueous solution of $Na_2Cr_2O_7 \cdot 2H_2O$, 0.085M; pH 5.2; temperature 55°C; sweep rate 6 V/hr. Curve shape remains unchanged in the range of: $Na_2Cr_2O_7 \cdot 2H_2O$, 0.02-0.25M; temperature 25°-70°C; sweep rate 0.166-60 V/hr.

Comparison between Fig. 2 and 3 provides information on the studied mechanism. Thus, peak I (or the group of peaks I) would correspond to the building up of a primary chromium oxide film after the reduction of the tin oxides, peak II to the building up of a secondary chromium oxide film which changes at peak III. The final slope C results from a visible hydrogen evolution and from a chromium deposit under the metallic and oxide forms as indicated by chemical analysis.

The above propositions were investigated by repetitive potentiokinetic oxidation and reduction to specific potentials.

Electrochemical oxidations and reductions which do not reach the A slope (Fig. 3) show how the shape of

the group of peaks I depends on the potential of the oxidation taking place prior to the reduction. When this oxidation potential is increased, the group first consists of a single peak I, to which a second peak with a more cathodic potential is added, then again a single peak but with an even more cathodic potential (Fig. 4). Additional experiments (4) allow us to assign the reductions of Sn(II), Sn(IV), and SnOx (1) to these successive peaks. Prior to peak I, the electrode was already coated with chromium due to immersion in the electrolyte, as a subsequent oxidation (around + 0.8 V/SCE) reveals the peak where oxidation of metallic chromium and chromium oxide generally takes place (4-6). Chemical analysis (1) allows us to specify that only chromium oxide is present. However, it is to be noted that tin oxide reduction at peak I increases this deposit of chromium oxide (which will be qualified as primary) as it raises the height of the oxidation peak which is located at + 0.8 V/SCE.

Peak II very likely corresponds to a film of chromium oxide as, after the dissolution of the primary chromium oxide through electrochemical oxidation at + 0.8 V/SCE, a tin polarization up to the A slope is sufficient to recover subsequently an oxidation peak at + 0.8 V/SCE (Fig. 5). Therefore, this new film will be called "secondary." The reaction which originates it is apparently reversible as indicated in Fig. 6. It is thought that chromium oxide may have valency III in the secondary film.

As long as the cathodic scanning end remains in the B slope, the secondary film of chromium oxide retains its solubility and the originating reaction retains its reversibility (Fig. 7). As soon as the maximum of peak III has been passed, peak II disappears whatever the scanning direction may be. This disappearance is progressive as long as the cathodic end remains between

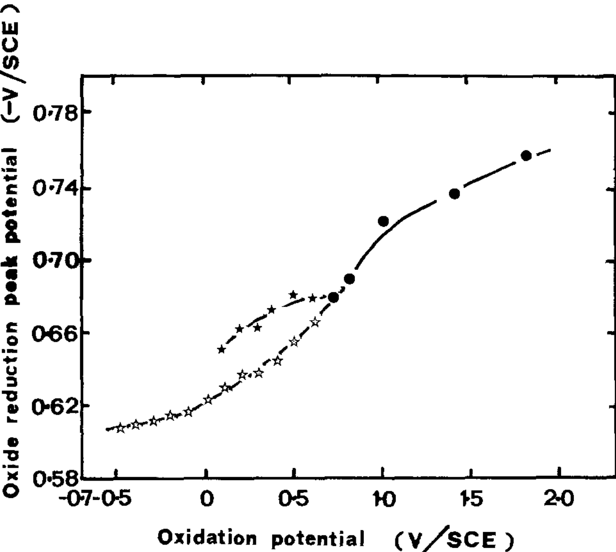

Fig. 4. Reduction potential(s) of tin oxide(s) vs. potential of oxidation done before. ☆☆☆ SnO; ★★★ SnO_2; ●●● what we have called SnO_x (1). Solution of $Na_2Cr_2O_7 \cdot 2H_2O$, 0.085M deaerated by nitrogen bubbling; pH 5.2; temperature 55°C; sweep rate 6 V/hr.

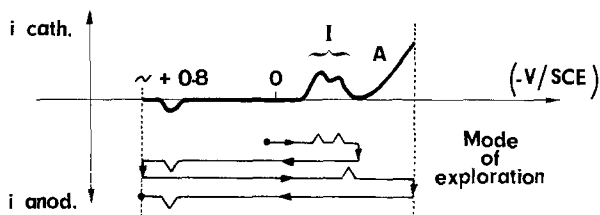

Fig. 5. Repetitive potentiokinetic oxidation and reduction to specific potentials. See text.

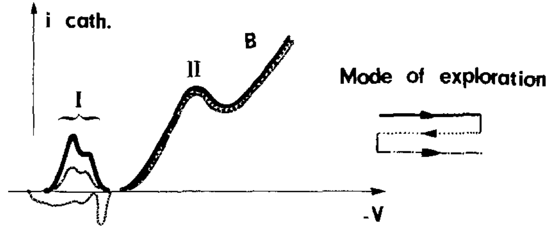

Fig. 7. Repetitive potentiokinetic oxidation and reduction to specific potentials. See text.

peak III and the valley which separates it from the C slope (Fig. 8); it occurs suddenly when the cathodic end is in the C slope (Fig. 9). Peak III corresponds to a change in chromium oxide film, but not to its destruction: in fact, oxidation of the sample at + 0.8 V/SCE is sufficient to obtain the peak of chromium oxidation (Fig. 9) and to regenerate the electrode as a subsequent reduction will reveal the peak II again. (In order to avoid any possible interference of the primary chromium oxide film, the sample was oxidized at + 0.8 V/SCE prior to the first scanning in the cathodic direction of Fig. 8.)

As previously indicated, deposits of metallic chromium and of trivalent chromium oxide build up and a hydrogen evolution occurs in the C slope. It is noteworthy that we regenerate the electrode which reaches the C slope through a simple oxidation at + 0.8 V/SCE: a subsequent cathodic polarization restores peaks I, II, and III (Fig. 10).

The reaction sequence of tin CDC treatment is reminiscent of the one of conventional chromium plating of iron. Using tin, we have pointed out the successive

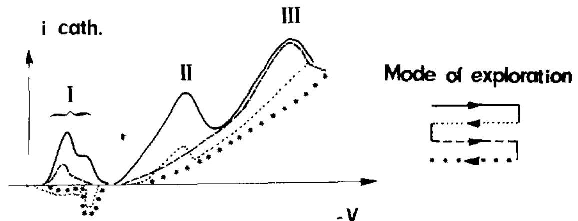

Fig. 8. Repetitive potentiokinetic oxidation and reduction to specific potentials. See text.

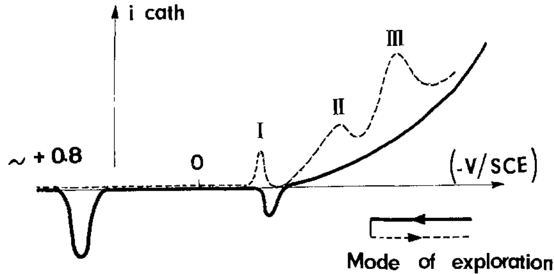

Fig. 10. Repetitive potentiokinetic oxidation and reduction. See text. The start point is in the slope C.

steps: (*i*) building up of a chromium oxide primary film; (*ii*) reduction of tin oxides and strengthening of the primary film; (*iii*) building up of a secondary film of chromium oxide; (*iv*) alteration of this film at the time of a hydrogen evolution; and (*v*) hydrogen evolution, deposition of metallic chromium and chromium oxide.

Limited Amount of Metallic Chromium Deposition

As stated above, the amount of metallic chromium deposited through CDC treatment reaches a limit (4, 8) (see first diagram of Fig. 1).

It has been shown that this limited amount can be deposited at several times as long as the surface film is not damaged by water rinsing. This is clearly reflected in a galvanokinetic cathodic polarization experiment (Fig. 11, in which the various features of Fig. 3 are easily traced), the results of which are shown in Table II.

This limited amount of metallic chromium which may be deposited depends on experimental factors (8) (temperature, acidity, foreign ion content of the electrolyte) which also alter the magnitude of peaks II and III on the potentiokinetic curve of the cathodic polarization. Comparison of the effects of these factors on the limited metallic chromium deposition and on the polarization curve (Table III) shows that an intensification of peaks II and III increases the limited amount of metallic chromium. We can say that the limited amount of metallic chromium is directly dependent on the amount of chromium oxide of the secondary film (and possibly the primary film) which is modified by the reaction of peak III.

Consequently, the maximum amount of metallic chromium to be deposited is determined when the electrode reaches the C slope.

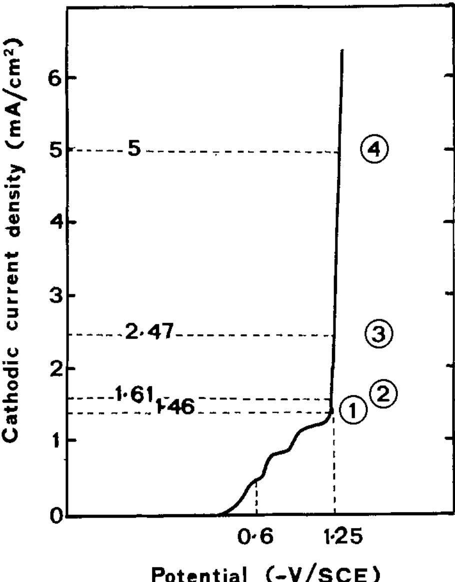

Fig. 11. Cathodic polarization curve plotted galvanokinetically. Pure tin. $Na_2Cr_2O_7 \cdot 2H_2O$, 0.085M; pH 5.2; temperature 55°C; sweep rate 0.25 A/cm^2/mn. Encircled numbers refer to the text and to Table II.

Let us now consider the shape of the C slope when increasing amounts of metallic chromium are deposited through CDC treatment on a tin electrode. Figure 12 shows that it rises progressively, moves toward less cathodic potentials, and finally stabilizes. This matches the cathodic polarization curve of a chromium electrode dipped in this dichromate electrolyte.

To conclude, metallic chromium which is deposited on tin during CDC treatment originates from the film or films of chromium oxides built up during the previous steps and its amount is limited. After deposition, the electrode changes and becomes a chromium electrode.

Reason for Metallic Chromium Deposition during CDC Treatment

We have shown in the previous part that dichromate solution is unable to continue the metallic chromium deposition once the electrode becomes a chromium electrode. We can therefore assume that this deposition is due to the nature of the tin electrode.

Table II. Possibility for a two-step deposition of the limited amount of metallic chromium

Cathode reduction up to[a] →	Metallic chromium level[b]	Cathodic reduction up to [a] +	Water rinsing +	Cathodic reduction up to[a] →	Metallic chromium level[b]
1	0.23	1	No	4	2.7
1	0.23	1	Yes	4	1.6
2	0.29	2	No	4	2.4
3	1.31	3	No	4	2.6
4	2.5	4	No	4	2.5

Table III.

Factor	Influence on the peaks of the polarization curve	Influence on the maximum amount of metallic chromium deposited during full-scale or laboratory passivation trials
Dichromate concentration	None between 13 and 74 g/liter $Na_2Cr_2O_7 \cdot 2H_2O$	None
pH increase	Reduces peaks II and III	Decrease
Rise in temperature	Intensifies peaks II and III	Increase
Additions of Cl^- or SO_4^{2-}	At high content levels, lightly reduce peaks II and III	Not obvious at low industrial contents
Phosphate addition	Little effect on peak II, but lessens peak III	Delays the deposition
Increase of the amount of tin oxide	Little influence on peaks II and III from which peak I element has been subtracted	Negligible if any

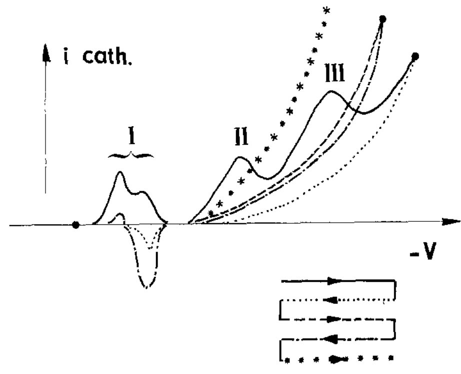

Fig. 12. Repetitive potentiokinetic oxidation and reduction. See text. *** refers to the cathodic polarization curve plotted in the same conditions but with a metallic chromium electrode.

As one of the properties of tin is a very high hydrogen overvoltage, which is not true for metallic chromium, we may ask ourselves if this is actually the determinative factor.

In order to answer this question, we have studied the potentiokinetic curve of cathodic polarization of some other common metals. Lead is the only metal to present the same peaks as those of tin (Fig. 13). The other metals (platinum, iron, copper, nickel, cadmium, chromium, silver, and zinc) present normal curve sections. Among the metals investigated, tin and lead are the only two to possess the higher hydrogen overvoltage in their final curve sections.

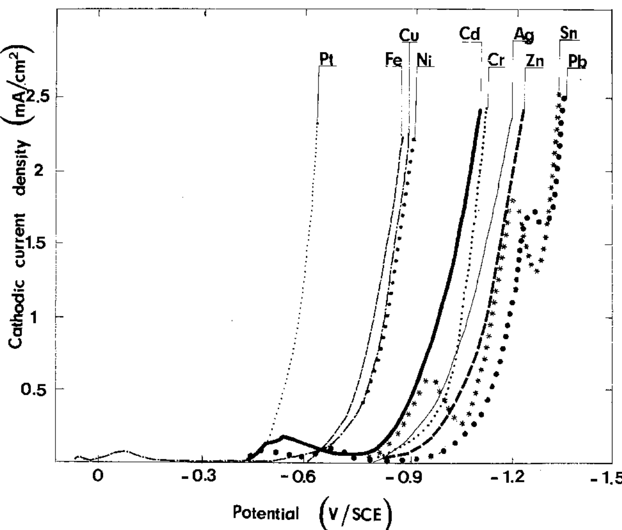

Fig. 13. Cathodic polarization curves plotted potentiokinetically with many metals; $Na_2Cr_2O_7 \cdot 2H_2O$, 0.085M; pH 5.2; temperature 55°C; sweep rate 6 V/hr.

As a result, CDC treatment deposits metallic chromium due to the high hydrogen overvoltage on tin. We are thus in compliance with the result given in the last part: Deposition is only possible when tin is not coated with a metallic chromium film, the thickness of which has therefore to be very uniform.

Conclusions

The points developed in this report allow us to state that:

1. CDC treatment includes the following successive reactions: (*i*) building up of a chromium oxide primary film; (*ii*) reduction of tin oxides and strengthening of the primary film; (*iii*) building up of a chromium oxide secondary film; (*iv*) alteration of this film (or films) at the time of hydrogen evolution; and (*v*) hydrogen evolution, deposition of metallic chromium and chromium oxide.
2. Metallic chromium deposition, under conditions very different compared with those of conventional chromium plating of iron, is made possible by the high overvoltage of hydrogen on tin.
3. Metallic chromium deposition stops when the electrode changes to become a metallic chromium electrode. The amount which can be deposited is limited by the amount of chromium oxide which has built up during the previous steps: It is therefore dependent on the experimental conditions.

On the Structure and Electrical Properties of Electroless Ni-B Films

N. Hedgecock, P. Tung, and M. Schlesinger*

Department of Physics, University of Windsor, Windsor, Ontario, Canada N9B 3P4

ABSTRACT

An electron microscope study and measurements of electrical resistivity have been performed on electrolessly deposited Ni-B thin films. In contrast to Ni-P films, the islands of Ni-B films show a marked internal structure. Ni-B films have higher electrical resistivity than equally thick Ni-P films.

Electroless deposition of the nickel-boron system is possible using either alkali borohydrides or amine boranes as reducing agents. A survey of early work has been given by Goldie (1). More recent studies have been made by Fléchon *et al.* (2-4), Petrov *et al.* (5), and Gorbunova *et al.* (6, 7).

The as-deposited state of both Ni-P and Ni-B is highly disordered, and metastable in that heat-treatment irreversibly induces a state of higher crystallinity. In both systems, the initial state is a solid solution of phosphorus (8) or boron (4, 6) in nickel. For the deposits studied in this work the phosphorus and boron contents were about 20 and 25 per cent atomic, respectively.

Heat-treatment of Ni-P above 325°C produces two components, fcc nickel and tetragonal Ni_3P. The latter in bulk form has an electrical conductivity close to that of nickel, and indeed has an electronic band structure remarkably similar to that of nickel (9).

X-ray and thermal studies of Ni-B (3-7) have revealed analogous formation of nickel borides after annealing in vacuum. The formation of Ni_3B occurs around 300°C, accompanied by an abrupt change in electrical properties (3, 4). Above 400°C, Ni_2B and possibly other borides are formed.

* Electrochemical Society Active Member.

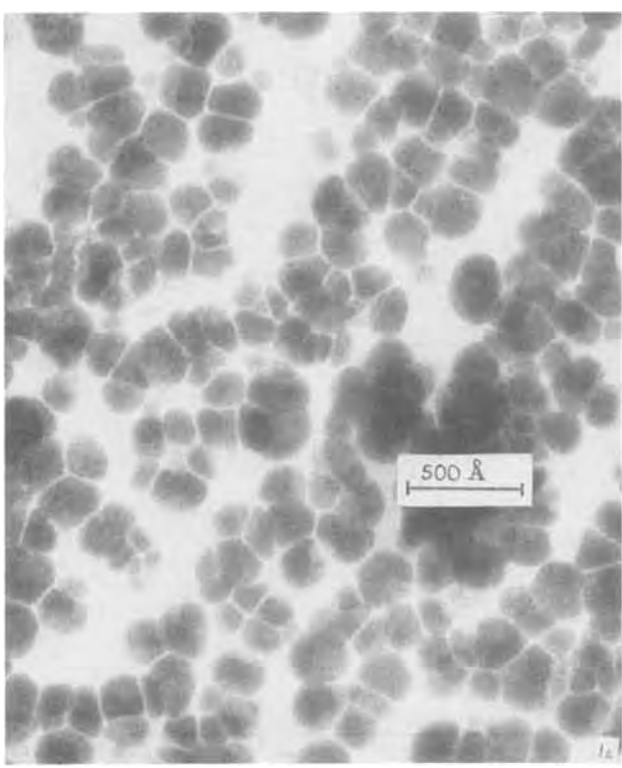
Key words: electroless, thin film, nickel-boron.

The present work describes further studies of electroless Ni-B films, involving electron microscopy and measurements of electrical resistivity. Results are presented for both freshly deposited and heat-treated films prepared under different conditions. Some results are also compared with those obtained from our earlier work on the nickel-phosphorus system (8).

Experimental

Electron microscopy.—A Hitachi HU-12 electron microscope operated at 100 kV was employed for obtaining transmission micrographs and selected area diffraction patterns. An aluminum foil standard was used to calibrate measurements of diffraction patterns. In many cases, the diffraction rings obtained were broad, indicating small crystallite size, and limiting the accuracy of measurement to about 1%.

The Ni-B films were grown on glass microscope slides coated with Formvar (4g polyvinyl formal in 1 liter ethylene dichloride). The Formvar layer was subsequently floated off in distilled water, and samples were deposited on copper grids for insertion into the microscope.



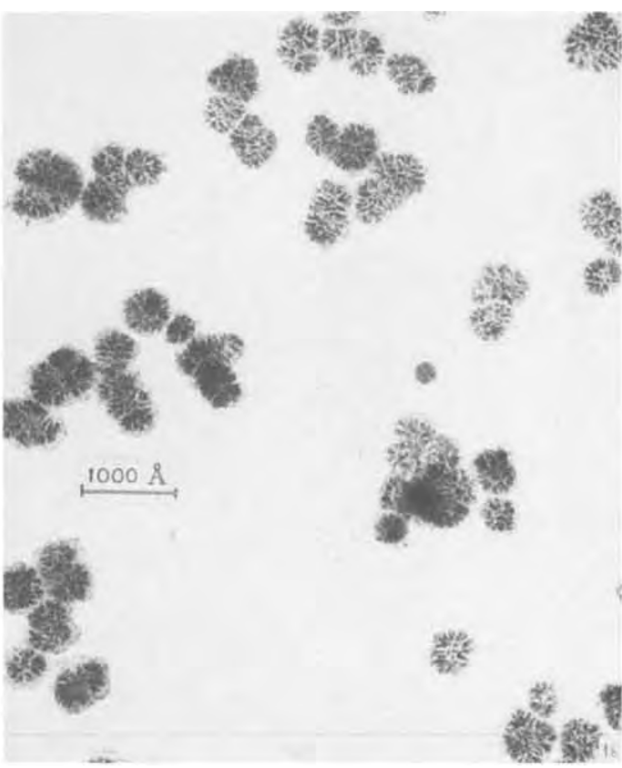


Fig 1. Transmission electron micrographs of thin films of (a, left) Ni-P deposited at room temperature from acidic (pH = 5.3) solution, (b, right) Ni-B deposited at 60°C using conventional $SnCl_2$/HCl sensitizer.

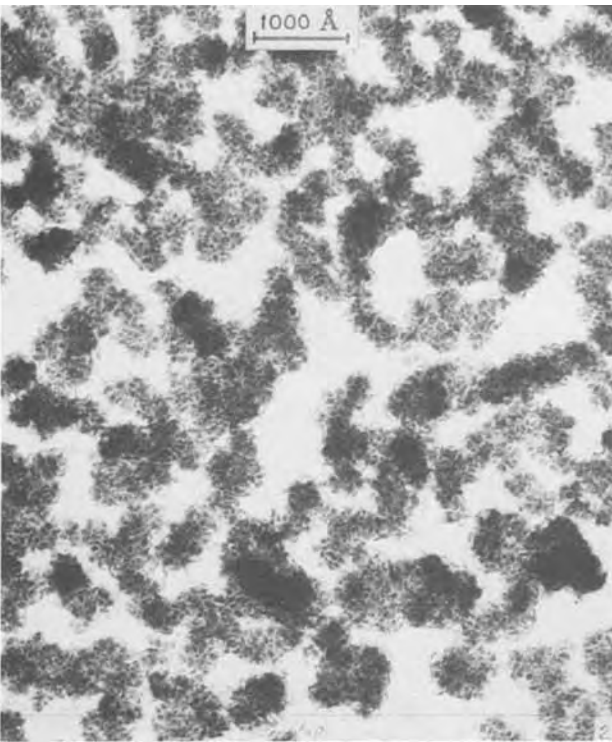

Fig. 2. Transmission electron micrograph of a thin film of Ni-B deposited at 60°C using improved ($SnCl_2$/HCl with additional aged $SnCl_4$) sensitizer.

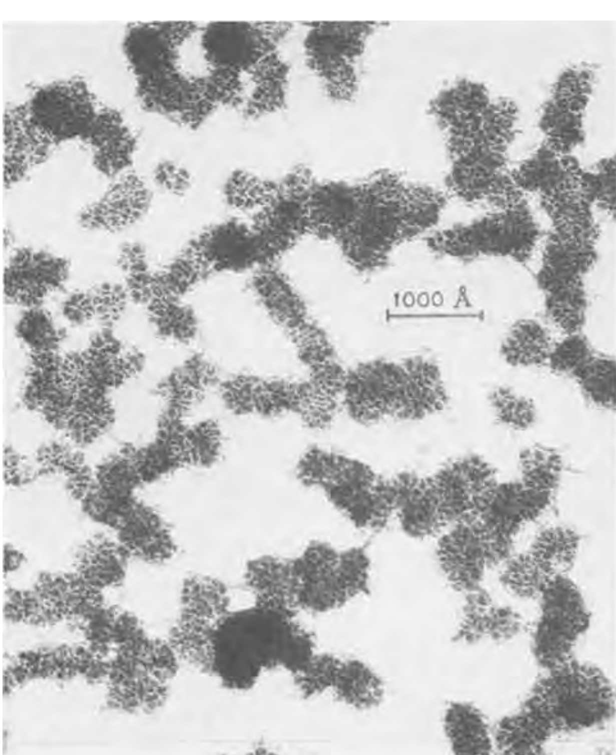
Three different sensitizers were employed in preparing the substrates for deposition: fresh $SnCl_2$/HCl with and without additional aged $SnCl_4$, and aged (4-6 days) $SnCl_2$/HCl. All were used in conjunction with the usual $PdCl_2$/HCl activator. The properties of these solutions have been investigated previously (10) and (11). The metallizing bath was that given as "B" by Gorbunova *et al.* (7). It employs borohydride as the reducing agent, has a pH of 14, and contains no stabilizer. This solution was maintained at 60°C; deposition times ranged from 40 sec for the thin samples prepared for electron microscopy to 100 sec for the thickest samples used in the electrical measurements.

Samples were examined in the electron microscope before and after heat-treatment at 400°C. The heating was carried out in an evacuated glass tube which was flushed with dry nitrogen prior to evacuation. The pressure in the tube during heating was about 10^{-5} Torr. The heating sequence was as follows: 45 min heating from room temperature to 400°C; 45 min at 400°C; 45 min cooling back to room temperature.

Electrical resistivity.—The four-probe method of van de Pauw (12) was used to determine the resistivity of films of various thicknesses. For these measurements, deposition was made directly onto microscope slide glasses. Circular samples of 1 in. diameter were subsequently made by placing the deposited glasses in a Teflon mask, and etching away the unwanted Ni-B with a solution of HCl and HNO_3. Spring-loaded stainless steel contacts were located symmetrically on the periphery of the circular samples for the measurements. The resistivity was determined both before and after the same heat-treatment as described above. The current in the samples was restricted to 100 μA during the measurements. For comparison, similar samples of Ni-P films of various thicknesses were made and their resistivity measured before and after the heat-treatment. For both Ni-B and Ni-P samples, the improved sensitizer was used. Film thicknesses were determined using the Tolansky interferometric method.

Results and Discussion

Electron microscopy.—Electron micrographs reveal both similarities and differences between Ni-P and Ni-B deposits. Figure 1 shows (a) Ni-P deposited at room temperature from acidic (pH = 5.3) solution and (b) Ni-B deposited at 60°C using conventional sensitizer. In both cases the deposit is composed of islands, typical of the initial stage of thin film growth in general. Moreover the islands are circular in shape and of rather uniform size. For Ni-P, these islands resemble liquid drops and have no discernible internal features. In contrast, the Ni-B islands usually show a characteristic "flowerlike" internal structure. The diffraction



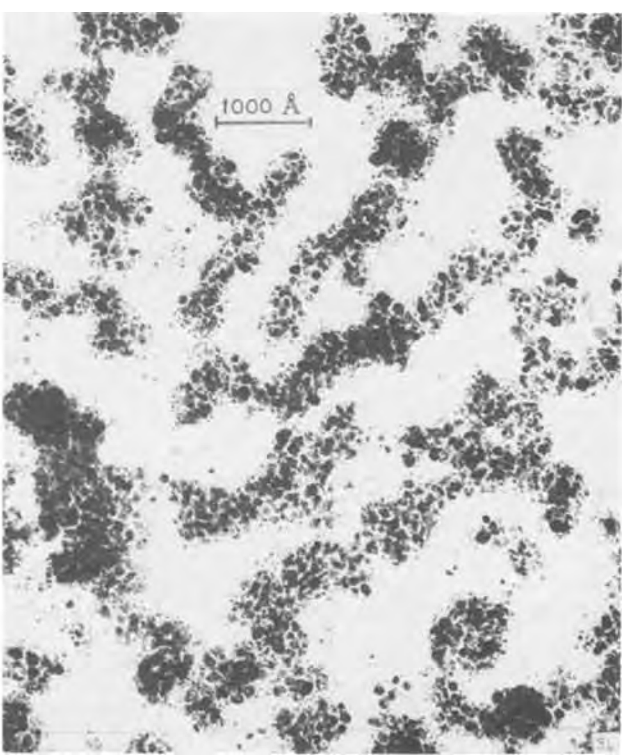


Fig. 3. Transmission electron micrographs of a thin film of Ni-B (a, left) freshly deposited (b, right) after heat-treatment at 400°C

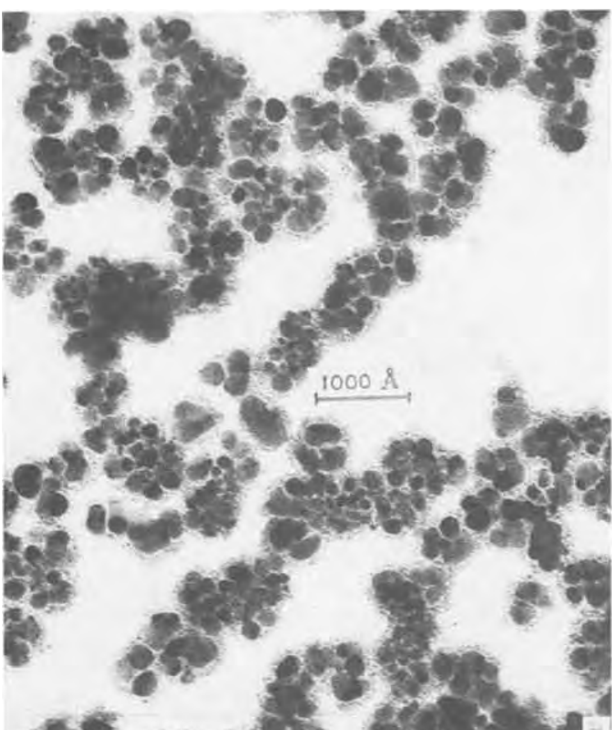

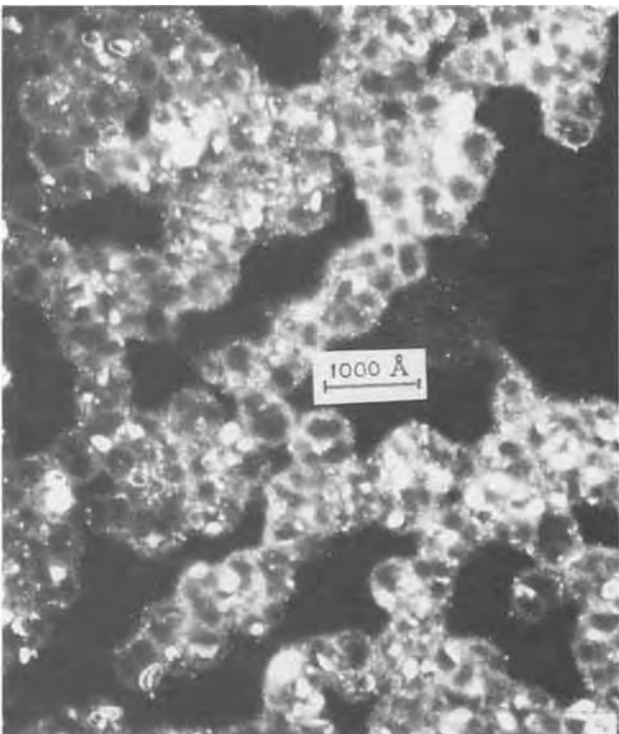

Fig. 4. Transmission electron micrograph of a thin film of Ni-B after heat-treatment at 400°C in (a, left) bright field mode (b, right) dark field (111) mode.

patterns obtained in the two cases are indistinguishable; they consist of a few very broad rings, characteristic of liquidlike or fine polycrystalline structures having essentially no long-range order.

A typical result obtained with improved sensitizer is shown in Fig. 2. The higher island density and uniformity of the deposit is evident, as is the tendency of the islands to join in clusters (10). The diffraction pattern obtained in this case shows sharper rings, some of which can be identified with a face-centered cubic structure.

The result of heat-treatment of Ni-B is a deposit consisting of small crystals. Diffraction patterns reveal clearly fcc structure with a lattice constant matching that of bulk nickel within our experimental error. No conclusive evidence for the presence of Ni_3B was found. This is presumably due to the fact that the diffraction intensity of the fcc nickel component is much greater than that of the small amount of boride formed in our annealing procedure. Electron diffraction studies of heat-treated Ni-P only revealed Ni_3P after annealing above 500°C (13), although the phosphide starts to form at 325°C. Figure 3 shows (a) freshly deposited Ni-B and (b) the same sample after heat-treatment. It appears that the cells within the islands have been replaced by crystallites of approximately the same size (typically 50Å) as the original cells. This trend has been seen in many other samples. Dark field microscopy shows even more clearly the presence of crystals ranging in size from 30 to 300Å. This can be readily seen by comparison of the bright and dark field micrographs shown in Fig. 4.

Electrical resistivity.—The results of measurements of the electrical resistivity of Ni-B and Ni-P films of various thicknesses are shown in Fig. 5. They are in general agreement with previous work on Ni-B (4) and Ni-P (14). The following observations can be made: (*i*) Within each system, the effect of heat-treatment appears to be a shift in resistivity which roughly preserves the shape of a curve drawn through the experimental points. This shift amounts to about 2 orders of magnitude for Ni-B over the thickness range studied, and 3-4 orders of magnitude for Ni-P. For thicknesses greater than 600Å, the resistivity of a Ni-B film is about one order of magnitude greater than that of an equally thick Ni-P film. (*ii*) The transition from continuous films, indicated by the sharp rise in resistivity with decreasing thickness, occurs at about 500Å for Ni-B compared with about 250Å for Ni-P (14). The island size is comparable in the two systems under the same sensitization conditions, and it seems therefore likely that this effect is attributable to the internal structure of the Ni-B islands. If the islands are fragmented into cells, then a larger number of contacts between cells would be required to produce a drop in resistivity.

Catalytic Decomposition of Nitric Oxide on Zirconia by Electrolytic Removal of Oxygen

S. Pancharatnam, R. A. Huggins,* and D. M. Mason

Department of Chemical Engineering and Department of Material Sciences, Stanford University, Stanford, California 94305

ABSTRACT

Zirconia stabilized with 8 mole per cent of scandia has a very high oxygen ion conductivity and can "pump" oxygen from oxygen-bearing gases thus decomposing them. In this study the rate of decomposition of the air-pollutant species, nitric oxide, to harmless species (via the reaction: $2NO \rightarrow N_2 + O_2$) was found to be markedly catalyzed when a potential above 1V was applied across a zirconia disk coated with either a porous platinum or porous gold electrode. It is known that platinum can both form oxides and catalyze the decomposition of NO; whereas, gold does neither. The catalytic decomposition of NO on platinum metal is inhibited by O_2, such behavior being attributed to preferential chemisorption of O_2 over NO as well as the possible formation of an inhibiting platinum oxide surface. The original rationale for this investigation was the possibility that the decomposition of NO might be enhanced if O_2 were electrolytically "pumped" away from a platinum electrode deposited on zirconia, keeping the platinum oxygen-free. However it was not anticipated that at high potentials dissociation rates a thousandfold that on nonporous platinum electrodes occur in the presence of either a platinum or gold porous electrode. No reactivity at all was observed on a nonporous gold electrode. These results suggest that catalysis occurs mainly on a surface other than the platinum or gold, namely, on the zirconia surface itself. It is proposed that F-centers on the zirconia surface formed by the applied potential are primarily responsible for the observed enhanced catalysis.

A number of studies (1-4) have shown that the catalytic decomposition of nitric oxide (NO) on platinum is markedly inhibited by oxygen. This behavior has been attributed to preferential chemisorption of O_2 over NO as well as possible formation of a surface oxide (3, 4). Recent development of solid oxide electrolytes possessing high oxygen ion mobility and relatively low electronic conductivity has made it possible to "pump" oxygen at very low concentrations ($<10^{-20}$ atm) by the application of an electrical potential. Therefore it was suggested and tested in a preliminary measurement (5), that by using platinum as the electrode material deposited on stabilized zirconia, O_2 might be removed electrochemically from the Pt surface leading to substantial enhancement of the rate of NO decomposition. The purpose of this paper is to present the results of more extensive experiments (6, 7) confirming the pumping of oxygen from NO along with some postulated reaction mechanisms. The wealth of information concerning the preparation, properties, and applications of solid electrolytes has been reviewed in numerous places (8, 9). Although the zirconia pump has been previously employed for the decomposition of oxygen-bearing gaseous compounds such as CO, CO_2, and H_2O (11-13) it is believed that the present application relating to the enhancement of the catalytic activity of the zirconia itself by imposing an electrical potential and forming F-centers as active sites has not been reported.

Experimental Procedures

The apparatus used consisted of a high vacuum source (10^{-6} Torr) for purification of NO by distil-

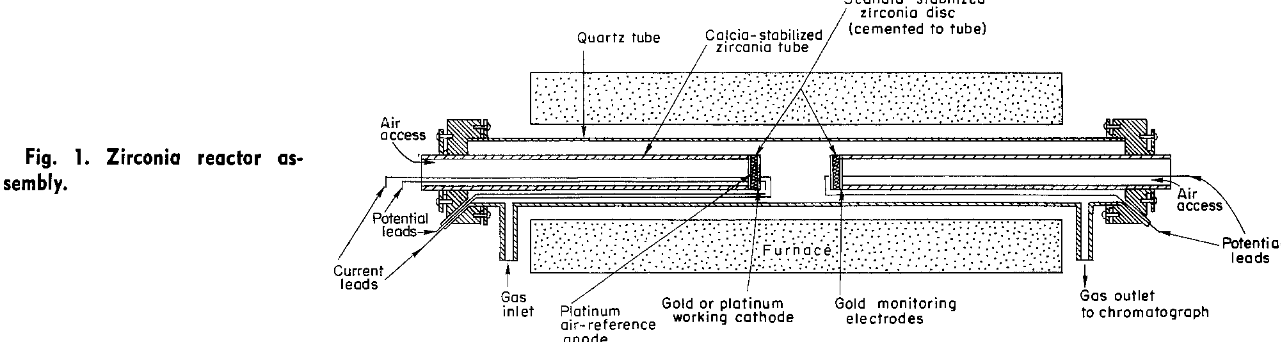

Fig. 1. Zirconia reactor assembly.

lation with subsequent condensation and storage. The reactor-gas distribution system contained a gas-phase chromatograph for analyzing the product nitrogen formed by the decomposition of NO and details of design of this system are given elsewhere (7). The chromatograph used was a single column Varian Model A90-P3 with a thermal conductivity detector. The column was made of 1/4 in. OD × 8 ft long stainless steel tubing hand-packed with 60-80 mesh Linde molecular sieve 13×. The column was preactivated at 250°C for 5 min with a rapid purge of helium at a flow rate of 120 ml/min and the optimal operating conditions were found to be as follows: the carrier gas helium was introduced at a flow rate of 30 ml/min while the reference flow rate was 6 ml/min; the filament current was maintained at 180 mA; the volume of samples was 0.75 ml; the temperatures of the distillation column, injector, and detector were 75°, 55°, and 100°C, respectively. A resolution of 50 ppm N_2 in 100% NO was possible, which set the lower acceptable limit on the conversion of NO, *viz.*, 0.01% for pure NO and 1% for a mixture of 1% NO in helium.

The experimental observations consisted of measuring current-voltage characteristics at 600°-800°C for various concentrations of NO in the feed and for various gas flow rates. All electrical measurements were made on a Fluke 8200A digital voltmeter with an input impedance of 10^{14} ohm.

The reactor assembly is shown in Fig. 1. The working electrode consisted of a zirconia disk electrolyte with either platinum or gold deposited as electrode material. The monitor electrode system consisted of another zirconia disk with gold electrodes for measuring oxygen formed at the working electrode. The disks consisted of 8 mole per cent (m/o) scandia-stabilized zirconia of dimensions: 1 mm thick × 12 mm diameter with a superficial area of 0.713 cm^2. The disk was cemented to one end of a calcia-stabilized zirconia supporting tube of dimensions 12.5 mm OD × 300 mm long. This disk construction permitted easy application of electrode materials and facilitated inspection and characterization of the surface morphology by photomicrography prior to and after the experimental runs. Also by approaching the conditions of a continuous-flow differential reactor with uniform accessibility of reactants to the surface with negligible resistance to gas-phase mass transport, this disk-configuration allowed unambiguous chemical rate data to be obtained directly. In a practical system however such a configuration consisting of a series of ring-shaped electrode-electrolyte cells deposited on the outside of a porous zirconia tube with electrical interconnectors might more appropriately be employed. This design has been used for solid-state fuel cells for "burning" coal gases (14). Simplified kinetics and diffusion models for such tubular reactor systems under both laminar and turbulent flow regimes are available (7).

The extent of decomposition of NO on the cathode surface was determined coulometrically as well as by measuring the concentration of N_2 in the exit gas by chromatographic techniques. The polarization studies were restricted to currents less than 50 mA/cm^2 and overpotentials less than 2V to avoid irreversible electrolysis of the zirconia. The influence on the over-all current-voltage characteristics of rate processes at the anode, with air being used as the reference oxygen-bearing gas, was negligible under the conditions of these experiments (7, 11).

Results

Nonporous platinum film cathode.—The cathodic polarization behavior for a 0.4 μm thick nonporous sputtered platinum film electrode is shown in Fig. 2 for 700°C where current *vs.* overpotential, (E-$E°$), is plotted. ($E°$ is the open-circuit voltage, E the closed-circuit voltage.) The behavior at 600° and 800°C was qualitatively similar and complete experimental data are presented elsewhere (7). The straight thin line through the origin represents the measured ohmic cell resistance of 11 ohms at an alternating current frequency of 1000 Hz.

The current is simply related to the reaction rate by the relationship

$$I = 2A\rho\mathbf{F}r \qquad [1]$$

where A = superficial electrode area, ρ = roughness

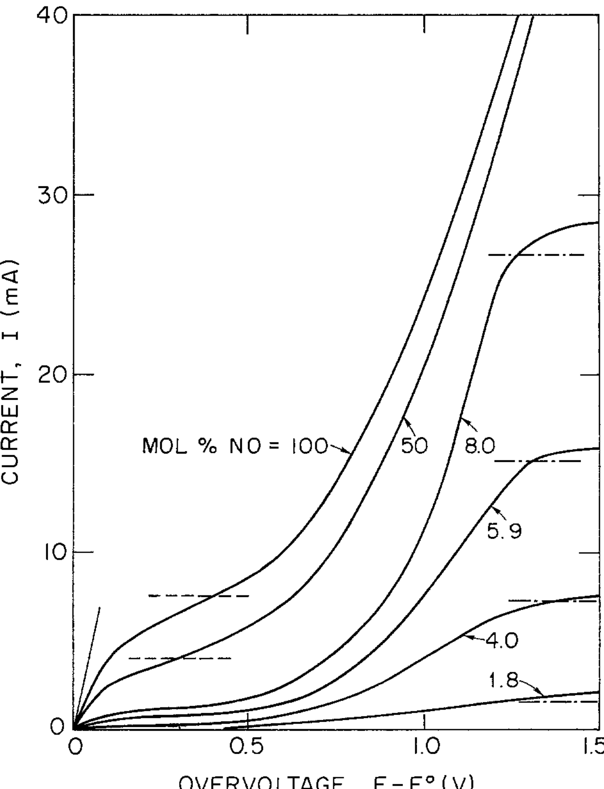

Fig. 2. NO decomposition on zirconia with a nonporous platinum cathode at 700°C. ———— 100 Hz (a.c.), - - - - current equivalent based on nitrogen produced at open circuit, —·—·—· current equivalent based on maximum constant nitrogen produced at overvoltages greater than 1.5V.

factor, and $\mathbf{F}$ = Faraday's constant. The number two is the equivalence for oxygen ion formation. The reaction rate (r) is given in mols NO/sec-cm².

Two sets of horizontal lines intersecting the curves have been included in Fig. 2. The left-hand set of lines intersecting the curves near the point of inflection represents the current calculated from Eq. [1] from the chromatographically measured rate of nitrogen produced by NO decomposition at open circuit. The right-hand set of horizontal lines represents the current equivalent to the observed rate of N_2 generated for overpotentials around 1.5V. It should be noted that these latter lines are below the plateaus of current observed in Fig. 2. It is evident that there are two reaction-rate limiting processes represented by the two sets of lines. The limiting current at the lower overpotentials and high NO concentration was generally ill-defined resulting in a point of inflection, though definite plateaus occurred at lower NO concentrations. Plateaus at the higher overpotentials are evident for all concentrations. The fractional conversion of NO was generally less than 1% and the influence of gas flow rate (50-100 ml/min) on the I *vs.* E-$E°$ behavior was inappreciable, demonstrating that the process is not affected by gas phase mass-transfer rates. The O_2 concentration measured by the downstream gold electrodes varied between 10^{-3}-10^{-4} atm at zero current and 10^{-5}-10^{-6} atm at potentials greater than 1V.

The relationship between the measured N_2 production rate and the measured electrical current (or its equivalent in terms of O_2 pumped) calculated from Eq. [1] for the data in Fig. 2 is shown in Fig. 3, which is typical of all runs. The line of unit slope represents the equivalence, in accordance with Eq. [1] between coulombs passing through the electrolyte and O_2 (or N_2) produced at the surface. The deviations to the left of this line which can be seen at low currents (and potentials) and high NO concentrations indicate a condition where not all of the O_2 formed by the decomposition of NO is electrochemically removed. The rate of production of O_2 (or N_2) rises slightly in approaching the equivalence line. This behavior is depicted in a different fashion by the left-hand set of horizontal lines in Fig. 2.

The deviations to the right of the equivalence line in Fig. 3 occur at the lower NO concentrations with high currents (and potentials). This behavior is probably due to the contribution of a measurable amount of electronic current added to the O_2-pumping current. In Fig. 2 this behavior is seen in the deviation of the right-hand set of horizontal lines from the plateaus. These lines represent a process limited by the maximum inherent rate of reaction of NO decomposition on oxygen-free platinum. These two current limiting phenomena will now be further analyzed.

Behavior at low overpotentials.—Since the low voltage saturation current shows a good correlation with the rate of NO decomposition at zero potential (and current), the rate has been plotted in Fig. 4 *vs.* the concentration of NO in the feed. Owing to the insensitivity of the chromatographic analysis of N_2, the rate of decomposition could be precisely determined only for NO concentrations of the order of 10 m/o or greater. The straight lines drawn through the origin in Fig. 4 represent the reaction rate calculated from the rate expression given in (3) with $P_{O_2} \rightarrow 0$

$$r_I = \frac{k[\text{NO}]}{1 + KP_{O_2}} \qquad [2]$$

where

$$k = 8.1 \exp\left(\frac{-17{,}100}{RT}\right) \text{cm sec}^{-1} \qquad [2a]$$

and

$$K = 13.9 \exp\left(\frac{6600}{RT}\right) \text{atm}^{-1} \qquad [2b]$$

The points represent the open-circuit decomposition rates determined by the chromatographic measured rate of formation of N_2.

Because of the small superficial area of the disk electrodes it was impossible to determine the surface area by any conventional means such as BET adsorption measurements. Thus the NO rate data from (3) with known surface areas were used for the oxygen saturated electrodes in this study. The surface roughness factor (ρ) for the present data was used as an adjustable parameter to give agreement with (3) and a value of $\rho \cong 3$ fits the data well.

Behavior at high overvoltages.—The high overvoltage limiting current plateaus displayed in Fig. 2 are represented on a log-log scale in Fig. 5 where limiting current, I_l is plotted *vs.* NO concentration in the exit gas which was approximately equal to that in feed gas owing to the low conversions that occurred. The data are well approximated by straight lines of slope 2 which indicates that the rate-determining step has a second order dependence on NO. Except for the deviations from this behavior at high concentrations of NO, a rate expression of the form

$$r_{II} = k_2[NO]^2 \quad [3]$$

may be used. An Arrhenius plot of log k_2 *vs.* $1/T$ shown in Fig. 6 yields the following expression for k_2

$$k_2\left(\frac{cm^4}{mol/sec}\right) = 5.05 \times 10^8 \exp\left(\frac{-17,000}{RT}\right) \quad [4]$$

Since diffusion of oxygen through platinum has been shown to have an activation energy of 35-60 kcal/mol (14), the low activation energy for k_2 rules out a diffusion-controlling mechanism. It will be shown subsequently that the high voltage behavior corresponds to the dissociation of NO on oxygen-free platinum.

Porous platinum electrodes.—The cathodic current overvoltage characteristics shown in Fig. 7 were typical for temperatures of 700°C and greater. The limiting current shown as the left-hand set of horizontal dashed lines are equivalent to the open current N_2 production rate. As was the case of the nonporous film electrode data (Fig. 2), the low-potential current saturation is again noticeable either as points of inflection at high NO concentrations or as plateaus at low NO concentrations. However (as seen by comparing Fig. 2 and 7) in contrast with the case of the nonporous platinum electrode, the current at high overvoltages increases continuously with increasing overvoltage and merges with the electronic transport curve I_e without exhibiting a plateau. From the measured rate of N_2 generation, the current equivalents for high overpotentials are shown in the right-hand set of horizontal lines in Fig. 7. The striking feature of the porous electrode is the extremely low concentration of NO in the feed gas at which extremely high decomposition rates have been observed. The effect of gas flow rate (80-100 ml/min) evidenced in Fig. 7 is predominantly due to the high rates of decomposition and high conversions of NO ranging from 40-70%. It is believed that under these conditions the cathode no longer behaves as a differential reactor and also mass transfer in the gas phase may be influencing the process, resulting in the observed increase in current with increasing flow rate.

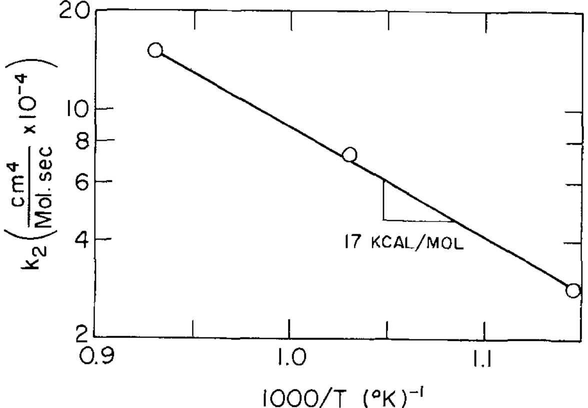

Fig. 6. Second order NO decomposition rate coefficient on zirconia with nonporous Pt electrode *vs.* $1/T$. (Roughness factor ≅ 3.)

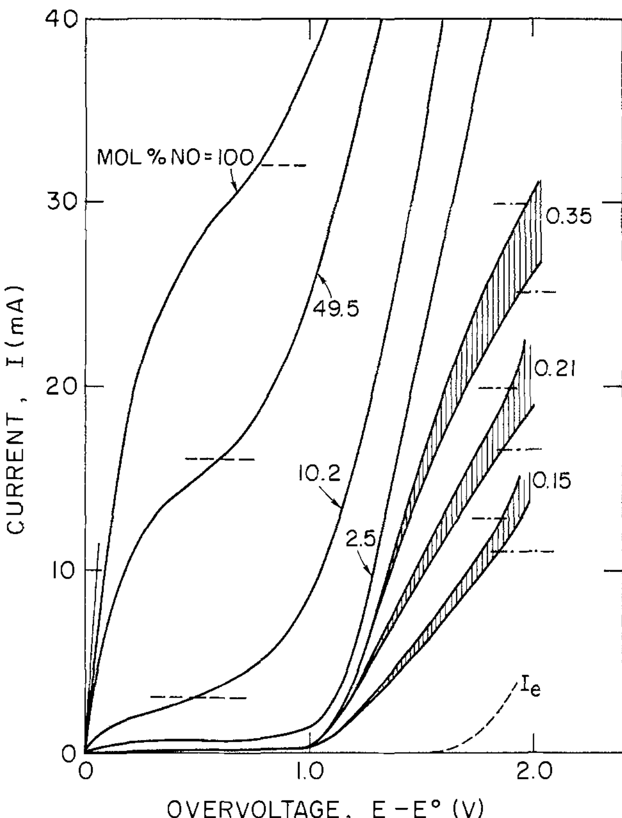

Fig. 7. NO decomposition on zirconia coated with porous platinum at 800°C. (Shaded area represents influence of flow rate, 80-100 ml/min.) ——— (1000 Hz a.c.), - - - - - - current equivalent based on nitrogen produced at open circuit, —·—·— current equivalent based on nitrogen produced at high overvoltages.

Porous Pt electrode at low overpotentials.—The low potential limiting behavior was analyzed by comparing the zero-current rate of decomposition of NO with the rate expression given in Eq. [2]. As in the case of nonporous Pt, the agreement was found to be satisfactory when a roughness factor of about 6 was employed.

Porous Pt electrode at high potentials.—A plot of the equivalent high potential limiting current *vs.* concentration of NO in exit gas is shown in Fig. 8. Despite the scatter in the data, a first order dependence of I_l on [NO] is indicated over the experimental range of NO concentrations. The corresponding value of the first order rate constant k_1 has been shown in Fig. 9 as a function of $1/T$ which gives an approximate expression for k_1

$$k_1(\text{cm sec}^{-1}) \simeq 4.7 \times 10^5 \exp\left(\frac{-25,500}{RT}\right) \quad [5]$$

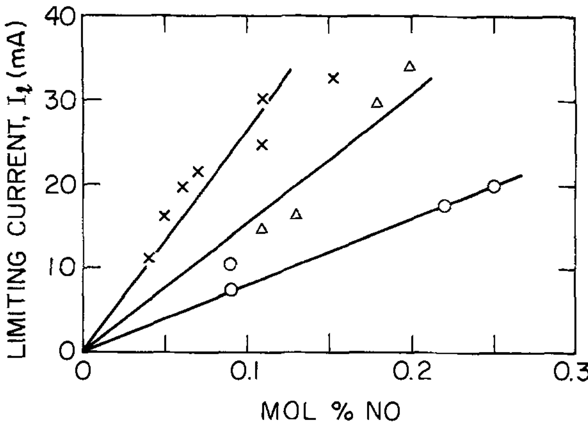

Fig. 8. Limiting current equivalent to maximum N_2 produced on zirconia with porous platinum electrode at high overvoltages (> 1.5V). ○, 700°C; △, 750°C; ×, 800°C.

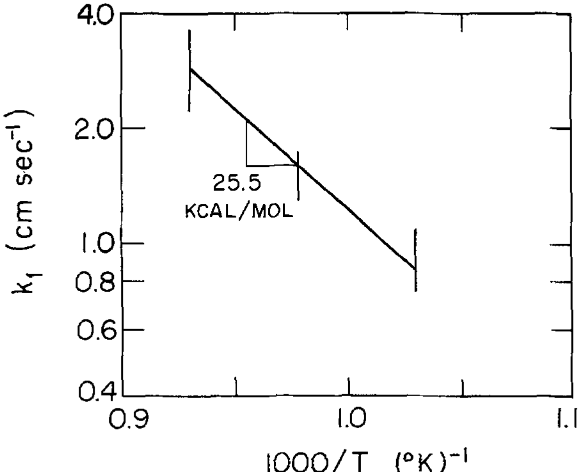

Fig. 9. k_1, first order NO decomposition rate coefficient on zirconia with porous platinum electrode vs. $1/T$ (roughness factor ≅ 6).

The experimental difficulties associated with the relatively high rates of reaction and poor sensitivity of chromatographic analysis for low concentrations of NO and N_2 have resulted in a rather small operating range of temperatures and NO concentration.

Nonporous and porous gold electrodes.—The cathodic behavior of porous gold at 800°C is shown in Fig. 10. No limiting current or limiting decomposition rates were observed in the whole range of overpotentials investigated. The current was found to be essentially ionic over the range shown and decomposition of NO at open circuit was negligible, indicating neither the gold nor zirconia is catalytic. No ionic current or NO decomposition was observed at any potential for a nonporous gold electrode, confirming the noncatalytic nature of gold with respect to NO decomposition. Appreciable ionic current was, however, obtained when the originally nonporous electrode surface was scored to expose the zirconia, thus strongly supporting the hypothesis that an enhanced catalytic decomposition of NO occurs on the zirconia surface itself.

Discussion of Results

NO decomposition on nonporous Pt.—It is speculated that the high potential limiting process represents the decomposition of NO on a clean platinum surface, uncontaminated with oxygen, obeying the following Rideal-Eiley mechanism found to apply to nonelectrochemical catalysis (4)

$$NO + (*) \rightleftarrows (NO - *) \quad [6a]$$

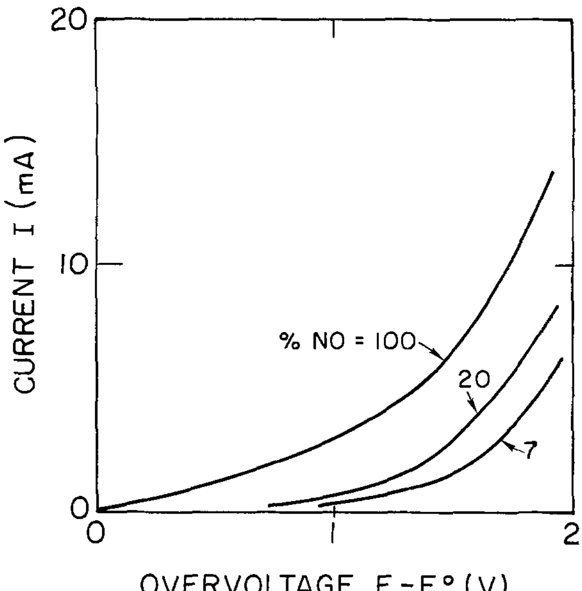

Fig. 10. NO decomposition on zirconia with a porous gold electrode. (Flow rates varied between 40 and 80 ml/min.)

$$NO + (NO - *) \rightarrow --- N_2 + O_2 \quad [6b]$$

$$O_2 + 2(*) \rightleftarrows 2(O - *) \quad [6c]$$

where (*) denotes an adsorption site on the Pt surface and (NO − *) and (O − *) represent respective species adsorbed on a site. Steps [6a] and [6c] are assumed to be at equilibrium and step [6b] is rate determining. The exact nature of all the processes involved in step [6b] cannot be determined from these experiments, but some speculation will be subsequently made. The rate expression for the above reaction scheme with a constant number of total sites [* + (NO − *) + (O − *)] is

$$r_{II} = \frac{k_2[NO]^2}{1 + K_1[NO] + K_2[O_2]^{1/2}} \quad [7]$$

Equation [7] reduces to Eq. [3] for low fractional coverage of active sites by NO, *i.e.*, (K_1[NO] << 1) and for $[O_2] \rightarrow 0$.

The rates of decomposition of NO on Pt observed by various techniques are compared in Fig. 11 in terms of "turnover number," (molecules of NO reacting per surface site per second) based on a nominal value of 10^{15} sites/cm^2. For comparison with Ref. (3) the data of various batch studies have been extrapolated to 48 Torr using first order kinetics. This assumption is reasonable because at the high concentrations of NO actually used in the batch studies (400-2000 Torr) first order kinetics were closely obeyed (*e.g.*, 1 << K_1[NO] in Eq. [7]). Two sets of results were reported in Ref. (3); the lower rates (curve 6 with rate expression Eq. [2]) were observed when O_2 was fed along with NO, and the higher rates (curve 7) correspond to O_2-free gas feeds, but with 0.1-0.3% O_2 generated by the decomposition of NO. Both of these rates had been extrapolated to zero O_2 concentration. The following mechanism was proposed in Ref. (3) for the case of O_2-free gas feeds

$$NO + (*) \rightleftarrows (NO - *) \quad [8a]$$

$$NO + (NO - *) \rightarrow N_2O + (O - *) \quad [8b]$$

$$N_2O + (*) \rightarrow N_2 + (O - *) \quad [8c]$$

$$2(O - *) \rightleftarrows O_2 + 2(*) \quad [8d]$$

Steps [8a] and [8d] were assumed to be in equilibrium; step [8b] was assumed to be rate determining. For total sites equal to [* + (NO − *) + (O − *)] this mechanism leads to a rate expression identical to

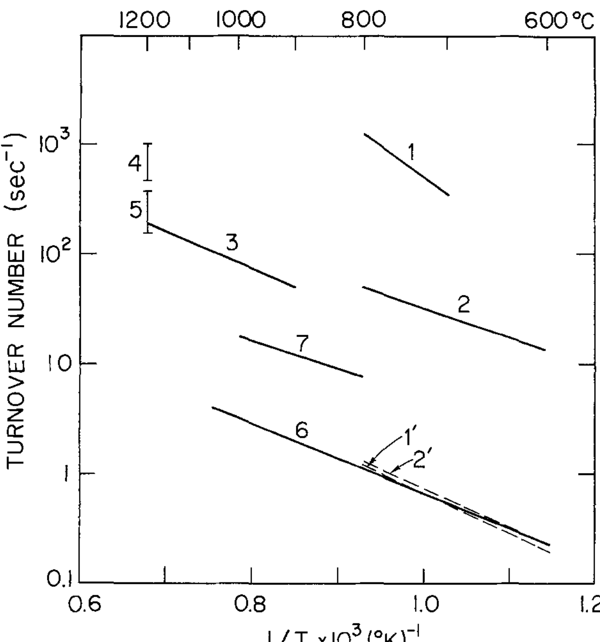

Fig. 11. Summary of data on turnover for NO decomposition on platinum at 48 Torr. 1', porous Pt, open circuit; 2', nonporous Pt, open circuit. Curve 1, porous Pt maximum rate of N_2 formation corresponding to clean platinum and F-center catalysis. Curve 2, nonporous Pt maximum rate N_2 formation corresponding to clean platinum surface. Curve 3, heated Pt wire [Ref. (4)]. Curve 4, heated Pt wire [Ref. (2)]. Curve 5, Heated Pt wire [Ref. (1)]. Curve 6, [Ref. (3)] Pt foil with O_2 in feed extrapolated to zero (O_2). Curve 7, [Ref. (3)] Pt foil without O_2 in feed extrapolated to zero (O_2).

Eq. [7]. If the assumption is made that (NO – *), (O – *) >> (*) or the total sites are equal to (NO – *) + (O – *), the resulting rate expression is

$$r_{II} = \frac{k[NO]}{1 + K[O_2]^{1/2}/[NO]} \quad [9]$$

For (O_2) → 0 this rate expression leads to first order kinetics with respect to NO. The agreement between the results of electrochemical studies with Pt and the various batch studies is quite good. The lower rates observed in the study of Ref. (3) even for O_2-free gas feeds may be attributed to appreciable coverage of the active sites by oxygen owing to the relatively large conversion of NO to O_2 in the region of the catalyst. This hypothesis is supported by the reported nature of chemisorption of O_2 on Pt (16-18).

NO decomposition with porous Pt.—The high rate of decomposition of NO observed at high overpotential which characterizes porous Pt leads one to believe that an entirely different mechanism of NO decomposition occurs than in the case of nonporous Pt.

The decomposition of NO on metal oxides has been studied extensively (3) and a catalytic sequence of five steps with similarity to Eq. [8a]-[8d] for oxygen free feed can be speculated

$$NO + (*) \rightleftarrows (NO - *) \quad [10a]$$

$$NO + (NO - *) \rightarrow N_2O + (O - *) \quad [10b]$$

$$N_2O \rightarrow N_2 + O_a \quad [10c]$$

$$(O - *) + O_a \rightleftarrows O_2 + (*) \quad [10d]$$

$$2\, O_a \rightarrow O_2 \quad [10e]$$

where O_a represents a mobile surface-O atom. The rate expression found experimentally was unimolecular in NO, identical to Eq. [2], which may be obtained from the above reaction sequence along with the assumptions that: step [10a] is irreversible; step [10d] is in quasi-equilibrium; the concentration of mobile oxygen O_a is constant; and [*], [O – *] >> [NO – *], or the total site concentration equals [*] + [O – *]. The activation energy for k (Eq. [2]) ranged from 20 to 30 kcal/mol with a value of 28 kcal/mol being reported for pure zirconia, which was also reported by Fraser and Daniels (18). From the dissociation energies of NO (151 kcal/mol) and NO^- (112 kcal/mol) it was argued (3) that the active site (*) is probably an oxygen ion vacancy with at least one trapped electron, *i.e.*, an "F-center."

Taking into consideration the injection of electrons from the cathode and transport of vacancies from the anode, the following modified electrocatalytic sequence is proposed

$$V_{O}^{\cdot\cdot}(s) + 2e'(\text{cathode}) \rightleftarrows V_{O}x \ (\text{F-center}) \quad [11a]$$

$$NO + V_{O}x \rightarrow N + O_{O}x \quad [11b]$$

$$NO + N - O_{O}x \rightarrow N_2O + O_{O}x^{(s)} \quad [11c]$$

$$N_2O + V_{O}x \rightarrow N_2 + O_{O}x^{(s)} \quad [11d]$$

$$O_{O}x^{(s)} + V_{O}^{\cdot\cdot(b)} \underset{\text{anode}}{\overset{\text{from}}{\rightleftarrows}} V_{O}^{\cdot\cdot(s)} + O_{O}x^{(b)} \quad [11e]$$

where $V_{O}^{\cdot\cdot}$ = a vacant oxygen ion; e' = an electron; $V_{O}x$ = an oxygen ion vacancy with two trapped electrons; $O_{O}x$ = a normal oxygen ion; and the superscripts (s) and (b) denote lattice positions in the surface and in the bulk of the electrolyte, respectively. Under the influence of an impressed potential, the exchange step [11e] would be driven toward the right, thus leading to an acceleration of the steps [11c] and [11d]. Hence as in the case of a nonelectrochemical reaction, step [11b] would be the rate-determining step for the over-all decomposition. Assuming a high concentration of F-centers sustained by an applied potential, the surface average concentration of (NO) and (O) may be neglected with total sites equal to $V_{O}x$ and the following rate expression resulting

$$r_{III} = k'[V_{O}x][NO] = k''[NO] \quad [12]$$

The rate is proportional to the surface concentration of F-centers which would increase with increasing cathodic applied overpotential. From Eq. [1] and [12] one would expect a continuous increase of current with overpotential until all of the NO in the feed has been decomposed. In reality migration of electrons and F-centers to the anode can occur before this limit is reached and thus set an apparent upper limit on the value of k''. The activation energy for k'' observed in the current experiments (25.5 ± 5 kcal/mol) shows a fair agreement with that found in (3) supporting the belief that the nature of active sites and the rate-controlling step are probably the same in both the studies.

An interesting study of the nonstationary state behavior of metal oxides was made in (3). In the absence of oxygen presaturation, initial decomposition rates 6-10 times greater than the steady-state values were reported. This behavior was explained by postulating higher concentration of F-centers generated on the surface when the catalyst was flushed with pure helium. In other words a partially reduced surface seems to result at very low concentration of O_2 in the gas. The turnover numbers (Fig. 12) reported in (3) for zirconia at 400-1000°C seem to be lower than the values in the current study by 6-8 orders of magnitude. The reaction rates observed in the electrochemical experiments can be satisfactorily explained by assuming that only 1% of the surface sites have been converted to F-centers and the sticking probability for the adsorption of NO on an F-center is about 0.01. Association of catalytic activity with surface defects has been confirmed in recent studies on ZnO (20) and d-band perovskites (21). The hypothesis that the surface of zirconia can be made active to NO decomposition by applying an electrical potential is also confirmed quali-

tatively by the studies on a gold cathode. The results of the gold experiments, however, could not directly be compared quantitatively with those on porous Pt because of the lack of identical electrode morphology and due to the catalytic action of Pt which dominates the current-potential behavior at high NO concentrations and low potentials.

Conclusion

Decomposition of NO on nonporous Pt with electrolytic removal of O_2 reinforces the previous observation that the presence of O_2 not only inhibits the decomposition of NO but also alters the kinetic behavior. A second order rate mechanism observed in the present study is in agreement with the previous findings from batch as well as continuous flow experiments.

The feasibility of altering the catalytic activity by controlling the oxygen concentration has been established in another way. The tremendous enhancement of the rate of NO decomposition in the case of either porous platinum or gold demonstrates a convenient and powerful technique of reducing oxygen bearing species, *viz.*, the injection of F-centers on the surface of the electrolyte at sufficiently high overpotentials. This mechanism is supported by the following facts: (*i*) catalytic enhancement for zirconia covered with a nonporous layer of platinum is that typical for pure platinum in a nonelectrolytic system and (*ii*) with nonporous gold electrodes no decomposition occurs at all, typical of gold in a nonelectrolytic system. From these observations it may be concluded that any nonnoble metal porous electrode could be chosen for dissociating NO on zirconia in the presence of F-centers.

A summary of the general behavior of the zirconia electrochemical system is as follows:

1. For low potentials (0-0.5V) the rate of decomposition of NO with both porous and nonporous platinum electrodes is found to be first order with respect to NO consistent with the reported rate data for "O_2-saturated" platinum metal catalysts.
2. For nonporous Pt films the limiting current at higher potentials (1.3-1.6V) corresponds to the second order rate of decomposition of NO mixtures containing 5-10 m/o NO reported for O_2-free platinum. These rates are about fiftyfold higher than on oxygen saturated platinum surfaces.
3. On either porous platinum or porous gold surfaces, at potentials around 1.5V, first order rates of the order of a thousandfold that in case 1. are obtained, owing to the presence of highly catalytic F-centers on the zirconia surface.

Remaining to be studied systematically is the porous electrode configuration with carefully controlled electrode morphology and surface areas. Also to permit unambiguous kinetics data the disk electrode system should be redesigned so that reactant gases strike the electrode surface head-on, thus increasing mass-transfer rates and insuring at high reaction rates that the reactor behaves differentially with uniform accessibility to reactant species.

Electrochemical and Spectroscopic Properties of Cation Radicals

III. Reaction Pathways of Carbazolium Radical Ions

James F. Ambrose,*,[1] Lawrence L. Carpenter,[2] and Robert F. Nelson

Department of Chemistry, University of Georgia, Athens, Georgia 30602

ABSTRACT

Previous work had elucidated the anodic oxidation pathways of carbazole and several N-substituted derivatives. These studies have now been extended to seventy-six ring-substituted carbazoles using electrochemical and spectroscopic techniques to study the reactivity of the various substituted carbazole cation radicals. Generally, it was found that 3, 6, and 9 (N) positions are extremely reactive; if these sites are not blocked by inert substituents the cation radicals generated by electrolytic oxidation react rapidly via coupling-deprotonation. In some cases, substituents are eliminated from the 3 and 6 positions in the cation radicals followed by coupling to form substituted bicarbazyls. In other cases, relatively stable cation radicals were obtained and their EPR and visible absorption spectra were recorded. It was found that the reactivities of substituted carbazole cation radicals are considerably greater than those of analogous di- and triphenylaminium ions due to the planarity of the carbazole aromatic rings.

Carbazole, a relatively unimportant molecule in the past, is of considerable interest at present due to the uses of substituted carbazoles in polymerization studies and as inhibitors of zoxazolamine-induced paralysis (1). In addition, polycyclic carbazoles have been established as carcinogenic agents by a number of workers (2-4) and methyl-substituted carbazoles have been isolated from cigarette smoke (5, 6). Since the carcinogenic activity of these molecules may be associated with their redox properties, and considering that present and future studies may verify the presence of other substituted carbazoles in our environment, it was deemed desirable to carry out a broad survey of the anodic oxidation pathways of a number of variously substituted carbazoles. Due to solubility problems, these studies were limited to nonaqueous media, namely acetonitrile. This work is also designed to serve as a basis for investigating the oxidation behavior of simple and biologically important indoles. Preliminary work has shown that indole and its derivatives are extremely reactive upon anodic oxidation, so it was hoped that a good deal of background knowledge could be obtained from studies of the less reactive carbazoles. Due to the large number of compounds involved, substitution patterns as well as substituent effects upon the reaction pathways of the carbazole cation radicals were generally elucidated; however, several compounds have been incompletely characterized and so full disclosure must await further, more detailed investigations. Because of this survey nature, considerable license has been taken with regard to speculation on the mechanisms and products involved; on-going studies will hopefully refute or verify these speculations but in any case it is felt that the ideas forwarded are at least plausible and often likely.

Previous work had established that carbazole, upon anodic oxidation, forms a very unstable cation radical that reacts via coupling-deprotonation to 9,9'- and 3,3'-bicarbazyls;[3] higher polymers were thought to form upon prolonged electrolysis (8). When alkyl or phenyl groups were placed on the carbazole nitrogen only the corresponding 3,3'-bicarbazyls formed, in quantitative yields, and they appeared to be quite stable under electrolytic conditions. These findings were in agreement with previous work on the chemical oxidations of carbazole and its derivatives (8-13).

There is a paucity of data available in the literature on the chemical oxidation pathways of ring-substituted carbazoles; however, chemical substitution reactions indicate that the active ring sites are the two positions *para* to the nitrogen (3 and 6) and, to a lesser extent, those *ortho* to it (1 and 8). It was anticipated that by blocking the 3, 6, and 9 positions relatively stable cation radicals would be formed; these could then be studied using EPR as a probe to elucidate the electron distribution in the cation radicals. It was found that the carbazole nucleus is so reactive, in fact, that upon oxidation normally inert substituents undergo unusual decomposition reactions in several cases. Some success was achieved in the EPR and visible absorption spectral studies of the primary cation radicals, however, and the preliminary results are reported herein, along with the electrochemical data on these interesting and sometimes piquant molecules.

Experimental

All of the electrochemical studies were carried out in acetonitrile (MeCN) using tetraethylammonium perchlorate (TEAP) as supporting electrolyte. Purifications of these materials, as well as the general instrumentation employed, have been previously described (7).

Throughout this paper radical stabilities are cited as half-lives; these are estimates from cyclic voltammograms taking into account voltage sweep rates and cathodic to anodic peak current ratios. The uncertainty in the values is estimated at ± 10-20%.

Rotating disk studies were performed with a 10,000 rpm Motomatic E-550 motor and E-550M master control unit using the rotoamperometric technique for rapid data collection (14). Evaluation of coupling rate constants were carried out at low concentrations (10^{-4} to 10^{-5} *F*), so all rotoamperograms were corrected for background currents. A previously published working curve was employed for the determination of numerical values for the coupling rate constants (15).

Electrochemical *n* values were obtained using a Wenking 61RH potentiostat and a digital coulometry assembly employing two counters, one for gating, and one for totalizing (16). The gating counter was found

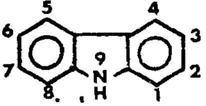
Key words: carbazole, anodic oxidation, electrosynthesis, cation radicals.

[3] We are employing the traditional carbazole nomenclature where the nitrogen is numbered "9" as opposed to the standard heterocyclic numbering where N is "1". The ring carbons are numbered clockwise, with the bridge-head carbons omitted.



to be very useful for following the course of the decaying electrolysis current; chemical complications in the electrochemical processes were immediately apparent using this sensitive technique. Most of the n-value determinations were carried out at parent concentrations of 10^{-3} to 10^{-5} F. At these levels the electrolyses were found to be extremely sensitive to impurities in the MeCN and TEAP. Therefore, both solvent and supporting electrolyte were freshly prepared before coulometry experiments. If these precautions were not taken, n values that were found to be about 2.0 under proper conditions varied up to values as high as 5 to 7 and even then low steady-state currents were often obtained.

Preparative electrolyses.—Preparative electrolyses were effected using a home-built potentiostat designed to deliver ± 70V, ± 3A. Typically, 100 mg of the carbazole derivative was dissolved in 150 ml MeCN/0.1F TEAP and exhaustively electrolyzed at a large platinum gauze at a potential 200 mV past the anodic peak current voltage. The reference electrode was a SCE and the auxiliary was a carbon rod contained within a porous ceramic cup. The solution was then rereduced at −0.7V to convert any products to the neutral form and reduce off protons liberated in the coupling reactions. Electrolysis solutions were then taken to dryness by evaporation of the solvent (ambient conditions) and the residue was partitioned with benzene/hot water mixtures. The benzene layer was concentrated by evaporation and chromatographed on Woelm neutral alumina. The products were then recrystallized from the appropriate solvent mixture.

Electrolyses were carried out on compounds from each major group where radical reaction pathways were detected. For the 3- and 3,6-disubstituted carbazoles intractable mixtures were obtained following electrolysis in unbuffered MeCN, but in the presence of the organic base 2,4,6-trimethylpyridine good yields of the corresponding N,N'-coupled products could be isolated. Pertinent data are given below for the various classes of compounds.

3-Methylcarbazole.—100 mg was oxidized in the presence of 2,4,6-trimethylpyridine (threefold molar excess) at 1.3V to 3,3'-dimethyl-9,9'-bicarbazyl (87% yield), recrystallized from benzene/EtOH as off-white crystals, mp 176°-178°. Calculated for $C_{26}H_{20}N_2$: C, 86.7; H, 5.55; N, 7.78. Found: C, 86.5; H, 5.62; N, 7.74.

3-Fluoro-N-Ethylcarbazole.—100 mg was oxidized in MeCN/0.1F TEAP at 1.4V to 3,3'-difluoro-N,N'-diethyl-6,6'-bicarbazyl (86% yield), recrystallized from benzene/EtOH as pale yellow flakes, mp 201°-203°. Calculated for $C_{28}H_{22}N_2F$: C, 79.2; H, 5.24; N, 6.60. Found: C, 79.2; H, 5.26; N, 6.63.

3,6-Dibromocarbazole.—100 mg was oxidized in the presence of a threefold molar excess of 2,4,6-trimethylpyridine in MeCN/TEAP at 1.5V to 3,3',6,6'-tetrabromo-N,N'-bicarbazyl (93% yield), recrystallized from benzene/EtOH as small white cubes, mp 248°-250° [Ref. (9) 248°-250°].

N-(p-Methoxyphenyl)carbazole.—100 mg was oxidized in MeCN/TEAP at 1.4V to N,N'-bis (p-methoxyphenyl)-3,3'-bicarbazyl (88% yield), recrystallized from benzene/hexane as a cream colored amorphous solid, mp > 275°. Calculated for $C_{38}H_{28}N_2O_2$: C, 83.7; H, 5.17; N, 5.14. Found: C, 83.5; H, 5.15; N, 5.09.

N-(p-nitrophenyl)carbazole.—100 mg was oxidized in MeCN/TEAP at 1.6V to N,N'-bis (p-nitrophenyl)-3,3'-bicarbazyl (72% yield), recrystallized from benzene/hexane as a yellow amorphous solid, mp 240°-245° (decomp.). Calculated for $C_{36}H_{22}N_4O_4$: C, 75.2; H, 3.86; N, 9.74. Found: C, 75.3; H, 3.82; N, 9.77.

Preparation and characterization of carbazole derivatives.—Many of the compounds studied have been previously reported in the literature. These synthetic routes were followed with some modifications in work-ups; structures were verified by comparison of melting points with literature values, where possible, and by spectroscopic data in all cases. New compounds were verified by their CHN analyses.

Infrared spectra, obtained on a Perkin-Elmer 621 spectrometer, proved very useful in structure and purity determinations. Carbazoles substituted at the nitrogen atom do not show the strong N-H stretching peak at about 3400 cm^{-1} present in carbazole and its ring-substituted derivatives. The disappearance of this peak was used to chart the progress of Ullmann reactions when a carbazole was reacted with a *para*-substituted iodobenzene to produce substituted N-phenylcarbazoles. Carbazoles with either one or both rings unsubstituted show two strong out-of-plane bending (*ortho*-disubstituted ring) peaks at about 725 and 750 cm^{-1}; these peaks were used to ascertain the completeness of 3,6-disubstitution reactions. N-phenylcarbazole, N-p-biphenylcarbazole, and ring-substituted N-phenylcarbazoles show a weak out-of-plane bending (monosubstituted ring) peak at 760 cm^{-1}. If the compound has an unsubstituted carbazole ring the 760 cm^{-1} peak will appear as a shoulder on the 750 cm^{-1} peak. The *para*-substituted N-phenylcarbazoles show a strong out-of-plane bending (*para*-disubstituted ring) peak between 825 and 850 cm^{-1}, the position depending upon the electron-donating ability of the *para*-substituent. A rough Hammett-type correlation was obtained whereby the peak frequency was found to shift to lower values with increasing electron-donating ability. Carbazoles substituted at the 3-position show a strong out-of-plane bending peak around 810 cm^{-1} and a medium intensity peak between 840 and 905 cm^{-1}, both indicative of a 1,2,4-trisubstituted aryl ring.

The position of this latter peak was found to depend upon the electron-donating effect of the substituent in much the same way as does the 725-750 cm^{-1} peak found in *para*-substituted N-phenylcarbazoles.

Carbazoles disubstituted at the 3 and 6 positions also show both the 1,2,4-trisubstitution peaks but the medium intensity peak is usually 5-15 cm^{-1} lower than in the corresponding 3-substituted carbazoles. The fact that this lowering occurs for substituents such as NH_2 and NMe_2 is reasonable but why it also is observed with electron-withdrawing groups is not understood at present. This latter peak was found to be well suited for determining the extent of synthetic reactions such as halogenations and acylations where both 3- and 3,6-substituted products could be formed. For mixtures, two peaks are readily discernable.

The purity and structure of some of the 3,6-disubstituted N-ethyl- and N-phenylcarbazoles were confirmed by nmr spectroscopy using a Perkin-Elmer R20 spectrometer; an ABX splitting pattern in the aromatic region is readily observed. Many others could not be analyzed via nmr due to either limited solubility or spectral complexity.

Column chromatography using benzene, hexane, or heptane as the solvent and either basic or neutral alumina (Woelm) as the support was invaluable in purification of all but the carboxyl-substituted carbazoles. Also, the 3,6-dinitro-substituted carbazoles were chromatographed with acetone or nitrobenzene on neutral alumina.

The carbazole-3-carboxylic acids were purified by sublimation and the carbazole-3,6-dicarboxylic acids by repeated formation of the salt in aqueous base and reprecipitation of the free acid with strongly acidic solutions.

In halogenation and acylation reactions, separation of the mono- and di-substituted products was often a problem. In these cases, recrystallization from refrigerated methanol solutions was used to separate the mixtures. In the cold solutions the disubstituted carbazoles precipitated first and were collected before crystallization of the monosubstituted derivatives began.

Brief descriptions of the compound preparations are given below. Although some of it is repetitive of litera-

ture methods, modifications in work-up were effected in every case.

3-Substituted carbazoles.—3-Aminocarbazole was obtained from Aldrich Chemical Company and was purified by recrystallization three times from ethanol, mp 255°-258° [Ref. (17) 254°]. Methylation with trimethylphosphate gave 3-dimethylaminocarbazole, which was recrystallized twice from heptane, mp 114°-115° [Ref. (18) 114°-116°]. Diazotization of the hydrochloride salt of 3-aminocarbazole, followed by treatment with sodium tetrafluoborate, heating in xylene and extraction with benzene gave 3-fluorocarbazole. The crude material was chromatographed on neutral alumina and recrystallized twice from benzene/hexane, mp 208°-209° [Ref. (19) 202°-203°]. 3-Chlorocarbazole was prepared by treating carbazole with an equimolar amount of sulfuryl chloride in chloroform, followed by chromatography with benzene on basic alumina. Two recrystallizations from cold methanol and one from ethanol (charcoal) yielded the product, mp 197°-198° [Ref. (20) 196°-197°]. 3-Bromocarbazole was prepared by reacting carbazole with an equimolar amount of N-bromosuccinimide in carbon tetrachloride containing a small amount of benzoyl peroxide. Chromatography with benzene on basic alumina, followed by two recrystallizations from cold methanol and one from ethanol (charcoal) yielded white flakes, mp 195°-197° [Ref. (21) 194°-196°]. Heating of 3-bromocarbazole with cuprous cyanide in pyridine at 215°-225° for 24 hr produced a solid reaction mass which was chromatographed twice with benzene on basic alumina; recrystallization from ethanol/heptane yielded 3-cyanocarbazole, mp 183°-184° [Ref. (22) 184°-185°]. Treatment of carbazole with an equimolar iodide-iodate solution (23) yielded 3-iodocarbazole, which was purified by chromatography on basic alumina with benzene and two recrystallizations from cold methanol and one from ethanol (charcoal) to yield the product, mp 195°-196° [Ref. (23) 192°-194°]. 3-Nitrocarbazole was prepared by nitration of N-nitrosocarbazole and subsequent removal of the nitroso group (24). Chromatography with benzene on neutral alumina and recrystallization from benzene yielded a yellow powder, mp 213°-214° [Ref. (21) 212°-213°]. 3-Methylcarbazole was synthesized by formylation of carbazole followed by a Wolff-Kishner reduction (25); the product was chromatographed twice on neutral alumina with benzene and recrystallized from methanol, mp 205°-207° [Ref. (26) 206°-207°]. N-Benzoylcarbazole was obtained commercially and converted to 3-benzoylcarbazole by a Fries rearrangement, mp 206° [Ref. (27) 206°].

3-Substituted-N-ethylcarbazoles. — 3-Nitro-N-ethylcarbazole and 3-amino-N-ethylcarbazole were donated by Southern Dyestuffs Company and were purified by chromatography with benzene on basic alumina. Recrystallizations from benzene/ethanol yielded the products, mp 128°-129° [Ref. (28) 128°] and 111°-112° [Ref. (28) 113°-114°], respectively. Methylation analogous to that for 3-aminocarbazole yielded 3-dimethylamino-N-ethylcarbazole, which was recrystallized once from heptane, mp 62°. Calculated for $C_{16}H_{18}N_2$: C, 80.7; H, 7.60; N, 11.7. Found: C, 80.8; H, 7.67; N, 11.7. Acetylation of the amino derivative yielded, after recrystallization from ethanol, 3-acetamido-N-ethylcarbazole, mp 194°-196° [Ref. (29) 203°-204°]. Diazotization of the 3-amino-N-ethylcarbazole hydrochloride salt and work-up similar to that for 3-fluorocarbazole yielded 3-fluoro-N-ethylcarbazole, which was chromatographed on basic alumina to yield a colorless oil which solidified after several months' standing, mp 44°-48°. Calculated for $C_{14}H_{12}NF$: C, 78.9; H, 5.67; N, 6.57. Found: C, 79.2; H, 5.63; N, 6.52. 3-Formyl-N-ethylcarbazole was obtained from Aldrich Chemical Company and purified by benzene chromatography on basic alumina followed by recrystallization from benzene/hexane, mp 88°-89° [Ref. (30) 92°-93°]. Wolff-Kishner reduction (25) and two recrystallizations from methanol yielded 3-methyl-N-ethylcarbazole, mp 43°-44° [Ref. (25) 45°]. Methods similar to those described for the 3-substituted carbazoles were employed to obtain 3-chloro-N-ethylcarbazole, mp 66°-67° from cold methanol [Ref. (31) 81°-82°]; 3-bromo-N-ethylcarbazole, mp 78°-80° from ethanol [Ref. (30) 81°-82°]; 3-iodo-N-ethylcarbazole, mp 78°-80° from methanol [Ref. (30) 82°-83°]. Treatment of the bromo derivative with cuprous cyanide in pyridine produced 3-cyano-N-ethylcarbazole which was purified in the same fashion as the 3-cyanocarbazole to yield the product mp 113°-115° from benzene/hexane. Calculated for $C_{15}H_{12}N_2$: C, 81.8; H, 5.49; N, 12.7. Found: C, 81.8; H, 5.55; N, 12.7. 3-Acetyl-N-ethylcarbazole was prepared by Friedel-Crafts acylation of N-ethylcarbazole; the product was recrystallized twice from ethanol, mp 112°-114° [Ref. (31) 115°]. Similarly, 3-benzoyl-N-ethylcarbazole was synthesized from N-ethylcarbazole and benzoyl chloride and chromatographed with benzene on basic alumina, followed by recrystallization twice from ethanol to yield mp 90°-92°. Calculated for $C_{21}H_{17}NO$: C, 84.3; H, 5.72; N, 4.68. Found: C, 84.2; H, 5.72; N, 4.59. The N-ethylcarbazole-3-carboxylic acid was prepared by lithiation of the 3-bromo derivative followed by addition of CO_2 to yield the product, mp 232°-234° [Ref. (32) 224°-226°]. Esterification of the latter product with ethanol gave ethyl-N-ethylcarbazole-3-carboxylate, which was purified by benzene chromatography on basic alumina to yield a colorless, viscous oil. Calculated for $C_{17}H_{17}NO_2$: C, 76.4; H, 6.40; N, 5.24. Found: C, 76.3; H, 6.38; N, 5.25.

3,6-Disubstituted carbazoles.—3,6-Dinitrocarbazole was donated by Southern Dyestuffs Company mixed with the 1,6 isomer. They were separated by selective solubilities of the potassium salts (33) followed by chromatography with acetone on neutral alumina and recrystallization from acetone, mp $>$ 350° [Ref. (33) 386°-387°]. 3,6-Dichlorocarbazole, mp 204°-205° from methanol [Ref. (31) 201°-203°], 3,6-dibromocarbazole, mp 211°-212° from methanol [Ref. (9) 211°-213°], and 3,6-diiodocarbazole, mp 205°-206° from methanol [Ref. (9) 204°-206°] were synthesized in manners similar to the monohalogenated derivatives except that two moles of halogenating reagent was used per mole of carbazole. Purification methods were identical. 3,6-Diacetylcarbazole was prepared by Friedel-Crafts acylation and recrystallization twice from ethanol, mp 236°-238° [Ref. (32) 233°]. The 3,6-dicyanocarbazole was synthesized by heating 3,6-dibromocarbazole with an excess of cuprous cyanide in pyridine at 220°-230° for 48 hr. The product was extracted from the hot reaction mass with benzene and chromatographed on neutral alumina; recrystallization was effected from benzene, mp $>$ 300° [Ref. (22) $>$ 360°]. Photolysis of bis (*p*-anisylamine) in cyclohexane at 300 nm for 24 hr yielded 3,6-dimethoxycarbazole. The crude product was purified by benzene chromatography twice on basic alumina followed by recrystallization from benzene/ethanol, mp 175°-177°. Due to the presence of large amounts of unreacted parent, great care must be taken in the chromatographic separation; the carbazole comes off the column after the parent diphenylamine. Calculated for $C_{14}H_{13}NO_2$: C, 74.0; H, 5.94; N, 6.16. Found: C, 74.2, H, 5.89; N, 6.13.

Several *t*-butylated carbazoles were kindly donated by F. A. Neugebauer of the Max-Planck Institute, Heidelberg, Germany, namely the 3,6-di-*t*-butylcarbazole, 1,8-di-*t*-butylcarbazole, 1,3,6-tri-*t*-butylcarbazole, 1,3,8-tri-*t*-butylcarbazole, and 1,3,6,8-tetra-*t*-butylcarbazole.

3,6-Disubstituted-N-ethylcarbazoles.—Treatment of 3-nitro-N-ethylcarbazole with 1.2 equivalents of nitric acid in refluxing acetic acid produced 3,6-dinitro-N-ethylcarbazole as a precipitate. The crude material was chromatographed on neutral alumina with acetone and recrystallized twice from nitrobenzene, mp $>$ 300°. Calculated for $C_{14}H_{11}N_3O_4$: C, 59.0; H, 3.90; N, 14.7. Found: C, 58.8; H, 3.86; N, 14.7. Reduction of this compound with tin/HCl in ethanol, followed by neutralization gave 3,6-diamino-N-ethylcarbazole which was

purified by repeated acid-base recrystallization, mp 188°-189°. This compound air oxidizes very readily and darkens rapidly upon standing. Calculated for $C_{14}H_{15}N_3$: C, 74.6; H, 6.71; N, 18.7. Found: C, 74.5; H, 6.75; N, 18.6. Methylation of the diamino derivative with trimethylphosphate, followed by benzene/basic alumina chromatography (twice) and recrystallization from benzene/heptane yielded 3,6-bis(dimethylamino)-N-ethylcarbazole, mp 120°-122°. Calculated for $C_{18}H_{23}N_3$: C, 76.8; H, 8.23; N, 14.9. Found: C, 76.5; H, 8.27; N, 15.0. Photolysis of N-ethylbis-(*p*-anisyl)amine in cyclohexane at 300 nm for 24 hr, followed by chromatography with benzene on basic alumina and recrystallization from ethanol produced 3,6-dimethoxy-N-ethylcarbazole, mp 178°-180°. Calculated for $C_{16}H_{17}NO_2$: C, 75.3; H, 6.71; N, 5.49. Found: C, 75.1; H, 6.58; N, 5.62. 3,6-Dichloro-N-ethylcarbazole, mp 117°-118° from methanol [Ref. (31) 113°], 3,6-dibromo-N-ethylcarbazole, mp 137°-138° from ethanol [Ref. (31) 136°], 3,6-diiodo-N-ethylcarbazole, mp 152°-153° from ethanol [Ref. (32) 154°], 3,6-dimethyl-N-ethylcarbazole, mp 62°-63° from benzene/heptane [Ref. (25) 67°] and 3,6-diacetyl-N-ethylcarbazole, mp 182°-183° from benzene [Ref. (31) 182°] were all prepared in manners similar to those for the monosubstituted analogs with the exception that the substituting reagents were doubled in concentration (or, in the case of the methyl derivative the substitution reaction was carried out twice). 3,6-Dipropionyl-N-ethylcarbazole was prepared similarly to the diacetyl compound to yield mp 133° [Ref. (31) 132°]. Wolff-Kishner reduction of the diacetyl derivative followed by chromatography with benzene twice on basic alumina generated the 3,6,N-triethylcarbazole. Recrystallization twice from cold methanol yielded the pure product, mp 81°-85° [Ref. (29) oil]. 3,6-Di-*t*-butyl-N-ethylcarbazole was prepared by a Friedel-Crafts alkylation of N-ethylcarbazole with *t*-butylchloride. Chromatography with benzene on basic alumina and recrystallization from benzene/heptane yielded the product, mp 151°-153°. Calculated for $C_{22}H_{29}N$: C, 85.9; H, 9.53; N, 4.55. Found: C, 85.5; H, 9.47; N, 4.56. N-Ethylcarbazole-3,6-dicarboxylic acid was prepared by a hypobromite oxidation of 3,6-diacetyl-N-ethylcarbazole according to the method of Buu-Hoi (29), mp $> 300°$ [Ref. (29) $> 300°$]. Dimethyl-N-ethylcarbazole-3,6-dicarboxylate was synthesized by esterification of the diacid with methanol and was purified by recrystallization twice from methanol/benzene/pet. ether, mp 187°-188° [Ref. (36) 187°]. Treatment of 3,6-dibromo-N-ethylcarbazole with excess cuprous cyanide according to the previously mentioned procedure for cyanations, followed by benzene extraction, chromatography on neutral alumina and recrystallization from benzene gave 3,6-dicyano-N-ethylcarbazole, mp 230°-231°. Calculated for $C_{16}H_{11}N_3$: C, 78.3; H, 4.54; N, 17.1. Found: C, 78.1; H, 4.52; N, 17.1. 3-Acetyl-6-methyl-N-ethylcarbazole and 3-acetyl-6,N-diethylcarbazole were obtained from N. P. Buu-Hoi and were used without further purification.

Substituted N-phenylcarbazoles.—The purification of N-phenylcarbazole has been previously described (7). N-(*p*-nitrophenyl)carbazole was prepared from carbazole and nitrobenzene by the method of de Montmollin (37) and was recrystallized once from toluene and then once from benzene, mp 211°-213° [Ref. (37) 212°]. Reduction of this compound with tin/HCl in ethanol produced N-(*p*-aminophenyl)carbazole, which precipitated out after several hours' refluxing as the hydrochloride salt. The free base can be obtained from the salt by neutralization but it is difficult to purify, apparently forming a matrix with many solvents. Chromatography using benzene on a basic alumina column followed by evaporation of the solvent from the eluent gave an oil [Ref. (38) resin]. After several hours' heating *in vacuo* a brown, glass-like solid was obtained which possessed a large variable melting point range. Methylation of the amino derivative with trimethylphosphate (careful heating required!), followed by chromatography with benzene on basic alumina and recrystallization from benzene/hexane yielded N-(*p*-dimethylaminophenyl)carbazole, mp 213°-215° [Ref. (39) 210°-212°]. Acetylation of the amino derivative gave N-(*p*-acetamidophenyl)carbazole; recrystallization twice from ethanol yielded the desired compound, mp 258°-260° [Ref. (38) 260°]. Several of these N-*para* substituted phenylcarbazoles were obtained using a modified Ullmann reaction in which an appropriately *para*-substituted iodobenzene is allowed to react mole-per-mole with carbazole in the presence of copper powder and potassium carbonate. The mixture is heated for 12-24 hr at about 200° without solvent (the iodobenzenes melt and serve as the solvent; in some cases a few ml of xylene was added to keep the mixture fluid). The hot reaction mixture is extracted with benzene (in which unreacted carbazole is almost totally insoluble), and the benzene solution is chromatographed on basic alumina. The first fraction contains the substituted phenylcarbazole; all were then recrystallized from benzene/hexane or benzene/ethanol. Pertinent data on these compounds, many of which are believed to be new, are given below:

N-(*p*-anisyl)carbazole, from benzene/ethanol, mp 154°-155° [Ref. (40) 149°-150°].

N-(*p*-methylthiophenyl)carbazole, from benzene/ethanol, mp 153°-155°. Calculated for $C_{19}H_{15}NS$: C, 78.9; H, 5.22; N, 4.84. Found: C, 78.7; H, 5.18; N, 4.76.

N-(*p*-biphenyl)carbazole, from benzene/ethanol, mp 225°-227° [Ref. (42) 224°-226°].

N-(*p*-tolyl)carbazole, from benzene/ethanol, mp 106°-108° [Ref. (42) 105°-107°].

N-(*p*-*t*-butylphenyl)carbazole, from benzene/ethanol, mp 191°-192°. Calculated for $C_{22}H_{21}N$: C, 88.2; H, 7.06; N, 4.68. Found: C, 88.2; H, 7.12; N, 4.62.

N-(*p*-fluorophenyl)carbazole, from benzene/ethanol, mp 120°-122°. Calculated for $C_{18}H_{12}NF$: C, 82.7; H, 4.63; N, 5.36. Found: C, 82.6; H, 4.69; N, 5.29.

N-(*p*-chlorophenyl)carbazole, from benzene/ethanol (charcoal), mp 141°-143° [Ref. (37) 146°].

N-(*p*-bromophenyl)carbazole, from benzene/ethanol, mp 142°-143° [Ref. (43) 146°-147°].

N-(*p*-iodophenyl)carbazole, from benzene/ethanol then benzene/hexane, mp 139°-140°. Calculated for $C_{18}H_{12}NI$: C, 58.6; H, 3.28; N, 3.80. Found: C, 59.0; H, 3.30; N, 3.74.

N-(*p*-carbomethoxyphenyl)carbazole, from benzene/ethanol, mp 116°-118°. Calculated for $C_{20}H_{15}NO_2$: C, 79.7; H, 5.01; N, 4.65. Found: C, 79.5; H, 5.03; N, 4.57.

N-(*p*-cyanophenyl)carbazole, from benzene/ethanol, mp 180°-183° [Ref. (37) 165°].

Several other 3,6-disubstituted N-phenylcarbazoles were synthesized by methods similar to the N-ethyl analogs; below the crystallization media and physical data are given for these compounds:

3,6-Di-*t*-butyl-N-phenylcarbazole, from benzene/heptane (twice), mp 144°-146°. Calculated for $C_{26}H_{29}N$: C, 87.8; H, 8.21; N, 3.94. Found: C, 87.7; H, 8.24; N, 3.95.

3,6-Diiodo-N-phenylcarbazole, from heptane (twice), mp 179°-182°. Calculated for $C_{18}H_{11}NI_2$: C, 43.7; H, 2.24; N, 2.83. Found: C, 43.9; H, 2.30; N, 2.79.

3,6-Dibromo-N-phenylcarbazole, from benzene, mp 159°-160°. Calculated for $C_{18}H_{11}NBr_2$: C, 53.9; H, 2.76; N, 3.49. Found: C, 53.9; H, 2.75; N, 3.53.

3,6-Dichloro-N-phenylcarbazole, from benzene/heptane, mp 140°-141°. Calculated for $C_{18}H_{11}Cl_2$: C, 69.2; H, 3.55; N, 4.49. Found: 69.4; H, 3.59; N, 4.43.

3,6-Dichloro-N-(*p*-chlorophenyl)carbazole was prepared via an Ullmann reaction involving 3,6-dichlorocarbazole and *p*-chloroiodobenzene. It was twice chromatographed with benzene on basic alumina and recrystallized from benzene/ethanol, mp 174°-175°. Calculated for $C_{18}H_{10}NCl_3$: C, 62.4; H, 2.91; N, 4.04. Found: C, 62.8; H, 3.02; N, 3.93. Photolysis of tris(*p*-tolyl)amine at 300 nm in cyclohexane for 24 hr, followed by chromatography with benzene on neutral alumina and recrystallization from benzene/heptane yielded 3,6-dimethyl-N-(*p*-tolyl)carbazole, mp 105°-107°. Calculated

for $C_{21}H_{19}N$: C, 88.4; H, 6.71; N, 4.91. Found: C, 88.2; H, 6.72; N, 4.90.

Spectroscopic studies.—Visible absorption spectra were obtained on a Cary 14 spectrometer by external electrolysis of the carbazole solution and immediate transfer to a standard cuvette. Only those carbazoles whose cation radicals were known from electrochemical data to be quite stable were studied in this manner.

The EPR spectra were recorded on a Varian E-3 spectrometer using either external electrolytic generation or by chemical oxidation with iodine/propylene carbonate. Although interpretations are incomplete at present, we are confident that the spectra obtained are those of the primary carbazole cation radicals, based on the stabilities of the compounds as determined by electrochemical methods.

HMO calculations.—HMO calculations were carried out using a simple Hückel program modified for cation radical systems; the heteroatom parameters were those shown below:

carbazole nitrogen: $h_N = 1.0$ $k_{C-N} = 0.8$
(same for N—H or N—Et)

$>C—NR_2$ (R = H, Me)	$h_N = 1.0$	$k_{C-N} = 0.8$
$>C—OMe$	$h_C = 2.0$	$k_{C-C} = 0.8$ (methyl carbon neglected)
$>C—Me$	$h_C = -0.3$	(inductive model, neglecting methyl carbon)
$>C—F$	$h_F = 3.0$	$k_{C-F} = 0.7$
$>C—Cl$	$h_{Cl} = 2.0$	$k_{C-Cl} = 0.4$
$>C—Br$	$h_{Br} = 1.5$	$k_{C-Br} = 0.3$
$>C—C{\equiv}N$	$h_{C\,(cyano)} = 0.0$, $h_N = 1.0$,	$k_{C-C} = 0.9$, $k_{C\equiv N} = 2.0$
$>C—NO_2$	$h_N = 2.2$, $k_{C-N} = 1.2$, $h_O = 1.4$, $k_{N-O} = 1.67$	

The "frontier orbital" approach was employed, in which one assumes that the reactivity of the cation radical is best described by the c^2 coefficients in the highest filled orbital (HFMO).

Results and Discussion

Due to the large number of compounds studied, the electrochemical data are broken down into compound classes according to the mode of substitution. It was found that there are characteristic reaction pathways for the cation radicals in each group but there are also variations and so each substitution group is discussed in some detail.

Since spectral data have only been obtained on those molecules possessing stable radicals all compound classes are considered together in these sections.

Electrochemical Data

Carbazoles and N-substituted derivatives.—Although the electrochemistry of these molecules has been presented in detail previously (7), a brief review at this point will serve as a useful basis for discussing the ring-substituted derivatives.

When carbazole is oxidized in MeCN/TEAP at platinum, the initial step is a (proposed) removal of one electron to form a very unstable cation radical. This cation radical reacts by deprotonation-coupling (the sequence is not known) to form the 9,9'- and 3,3'-bicarbazyls. Both bicarbazyls were chemically synthesized and were thus available for comparison. The 3,3'-bicarbazyl is more easily oxidized than carbazole itself and so the former loses two electrons in two reversible one-electron steps to yield a moderately stable dication with extensive conjugation. The 9,9'-bicarbazyl is only formed initially under cyclic voltammetric conditions and could not be isolated from controlled-potential electrolyses in unbuffered MeCN; the 3,3'-bicarbazyl was isolated in moderate yields. The 9,9'-bicarbazyl was found to form quantitatively, however, when electrolyses were carried out in the presence of an organic base such as pyridine. This fact led to the conclusion that the carbazole cation radical forms the 9,9'-bicarbazyl by diffusing out into solution, followed by deprotonation of the central nitrogen and subsequent coupling of the resultant free radicals in solution before they can diffuse back to the electrode to be further oxidized.

Interestingly, the 9,9'-bicarbazyl was found to oxidize considerably more anodic than carbazole (E_p's of 1.85 and 1.20V, respectively) in a multielectron, irreversible process accompanied by severe filming to form unknown products.

In accordance with this scheme, N-alkyl- and N-phenylcarbazoles were found to form only the corresponding 9,9'-disubstituted-3,3'-bicarbazyls cleanly in quantitative yields. Due to the steric hindrance afforded by the alkyl and phenyl groups no 1,1'- or 3,1'-coupling products were detected.

3-Substituted carbazoles.—The electrochemical data for these compounds are presented in Table I. In general, the electrochemistry of this class is similar to that

Table I. Electrochemical data for 3-substituted carbazoles

No.	R	$E_{p/2}$[a]	$it^{1/2}/C$	n value	Product(s) (% yield), comments
I	R = NH_2	0.47	44	0.99	Irreversible one-electron oxidation, coupled product appears to form
II	NMe_2	0.38	46	0.98	Stable cation radical, second reversible process at $E_{p/2}$ = 1.00V, moderately stable dication, no bicarbazyls appear to form
III	Me	1.12	133	2.6[b]	Bicarbazyl[c] forms in poor yield
IV	F	1.23	132	3.4[b]	Bicarbazyl[c] forms in poor yield
V	Cl	1.27	115-121[d]	3.4[b]	Bicarbazyl[c] forms in poor yield
VI	Br	1.26	107-115[d]	3.2[b]	Bicarbazyl[c] forms in poor yield
VII	I	1.25	102	3.0[b]	Bicarbazyl[c] forms in poor yield
VIII	COPh	1.36	100	2.8[b]	Bicarbazyl[c] forms in poor yield
IX	CN	1.43	106-123[d]	4.0	Bicarbazyl[c] forms in poor yield
X	NO_2	1.51	113-122[d]	4.0	Product(s) unknown

[a] In volts *vs.* SCE, taken from linear scan voltammograms; values shift anodic with increasing scan rate.
[b] Low steady-state currents are observed at these n values; the cut-off point is not uniform for all compounds and so only the trend in the n values is meaningful.
[c] From controlled-potential electrolyses in MeCN/TEAP; in all cases the bicarbazyl is the 3,3'-disubstituted-6,6'-bicarbazyl in yields of 20-40%.
[d] Chronoamperometric value increases with increasing electrolysis time (1-8 sec).

of carbazole itself. Since both the N(9) and 6 sites are open in these molecules one has the possibility for N-N, N-ring, and ring-ring couplings. Cyclic voltammograms show the presence of 6,6'- and N,N'-disubstituted bicarbazyls as in the case of carbazole with the exception of the fluoro derivative, which shows only 6,6'-bicarbazyl formed. However, controlled-potential electrolyses in MeCN/TEAP yield only the 3,3'-disubstituted-6,6'-bicarbazyls in poor yields; this has also been reported for carbazole (7). In addition, when the electrolyses are conducted with 2,4,6-trimethylpyridine added to the solution one obtains only N-N coupling; this is observed on both cyclic voltammograms and in controlled-potential electrolyses. This was also reported for carbazole and seems to point to a general rule that N-N coupling can only occur if the cation radical is deprotonated (7). This is shown graphically in Fig. 1 for 3-methylcarbazole; the curves are not well defined, but it is apparent that addition of the pyridine derivative wipes out formation of the ring-ring coupled product and gives essentially a quantitative yield of the 9,9'-bicarbazyl. In accordance with this, the peak current of the initial oxidation wave on curve B is about half that in curve A and the 3,3'-disubstituted-6,6'-bicarbazyl couple seen on curve A is absent in the presence of the relatively strong pyridine base on curve B. The oxidation process for the substituted 9,9'-bicarbazyl is a multielectron process (7) and so the bicarbazyl wave height on curve B is quite large relative to the primary oxidation wave. Formation of the 9,9'-bicarbazyl was verified by carrying out a preparative-scale electrolysis after which it was isolated in high yield (see Experimental section).

This reactivity pattern was found to be general for all of the 3-substituted carbazoles except for the amino and dimethylamino derivatives and is identical to the scheme presented previously for carbazole itself (7); the R group denotes all the substituents shown in Table I except amino and dimethylamino

[1]

[2]

[3]

The rather high n values observed as one goes to more electron-withdrawing substituents is indicative of significant secondary chemical reactions in these systems. The dimethylamino derivative is completely different in that it has a stable cation radical, as verified by a complicated but well-resolved EPR spectrum (*vide infra*). Further one-electron oxidation to the dication quinonediimine occurs and this couple is also reversible. This is to be anticipated due to the highly conjugated species that can be generated by loss of two electrons

[4]

The dication does react slowly, and the cation radical more slowly still (half-lives of about 30-40 sec and 20-30 min, respectively), but neither appears to form a bicarbazyl in either the 6 or 9(N) positions. This is not surprising, since the charge density at the open 6-ring position is very low in this molecule. Simple HMO calculations show that the 6-position will not be a center of reactivity and thus the 6,6'-bicarbazyl is not likely to form. The reactive site is instead predicted by HMO calculations to be the dimethylamino group and its *ortho* ring carbons and so the reaction pathway may be similar to that for N,N-dimethylaniline, where coupling has been shown to take place through the N-methyl groups and, possibly, the ring positions *ortho* to it (44).

3-Aminocarbazole undergoes a different oxidation pathway in that the first step, also a one-electron process, is irreversible. The cyclic voltammograms and n value of unity suggest formation of a product generated by intermolecular coupling and subsequent oxidation with concomitant protonation of parent material (thus rendering it electroinactive at the parent oxidation potential) according to the general mechanism

$$2C \overset{2e}{\rightleftharpoons} 2C^{\cdot +} \xrightarrow[\text{fast}]{\text{coupling}} C_2 + 2H^+ \quad [5]$$

$$C_2 \overset{2e}{\rightleftharpoons} C_2^{++} \quad [6]$$

$$2C + 2H^+ \rightleftharpoons 2CH^+ \text{ (electroinactive)} \quad [7]$$

Thus, a total of four electrons is taken up and four parent molecules are removed from the system either by electrolysis or protonation. From known reactivities of aniline derivatives and the observed instability of the 3-aminocarbazole cation radical compared to that of the dimethylamino derivative, one would anticipate that the NH_2 group is directly involved in the coupling reaction; however, it is not certain at this time whether N-N or N-ring compounds are being generated.

Considering all the potential active sites, a large number of coupled products are possible. Although the 6-position is open, simple HMO calculations again predict a reactivity pattern characteristic of a substituted aniline, analogous to the dimethylamino derivative; thus, 6,6' coupling is not likely. The numbers shown below are c^2 values[4] for the highest filled orbitals occupied by a single electron for carbazole and 3-aminocarbazole (the picture for the dimethylamino compound would be very close to the latter); one sees that these crude calculations predict a drastic change in reactivity, a change that is qualitatively confirmed by the experimental data

In the 3-amino compound, the charge density is very low in the unsubstituted ring and is largely restricted to the amino group and the ring positions *ortho* and *para* to it. Of all the possible coupled products, the two shown below seem most likely based on these calculations

Studies are now under way to determine the structure(s) of the coupled product(s) derived from both 3-amino- and 3-amino-N-ethylcarbazole.

3-Substituted-N-ethylcarbazoles.—It was anticipated that blocking of the carbazole nitrogen with an ethyl

[4] The c^2 values (squares of atomic orbital coefficients) are roughly proportional to the unpaired electron densities, and it has been empirically observed that the values for each atom taken only from the highest filled orbital, rather than summing the values for all the occupied orbitals, give reliable reactivity patterns for aromatic cation radicals.

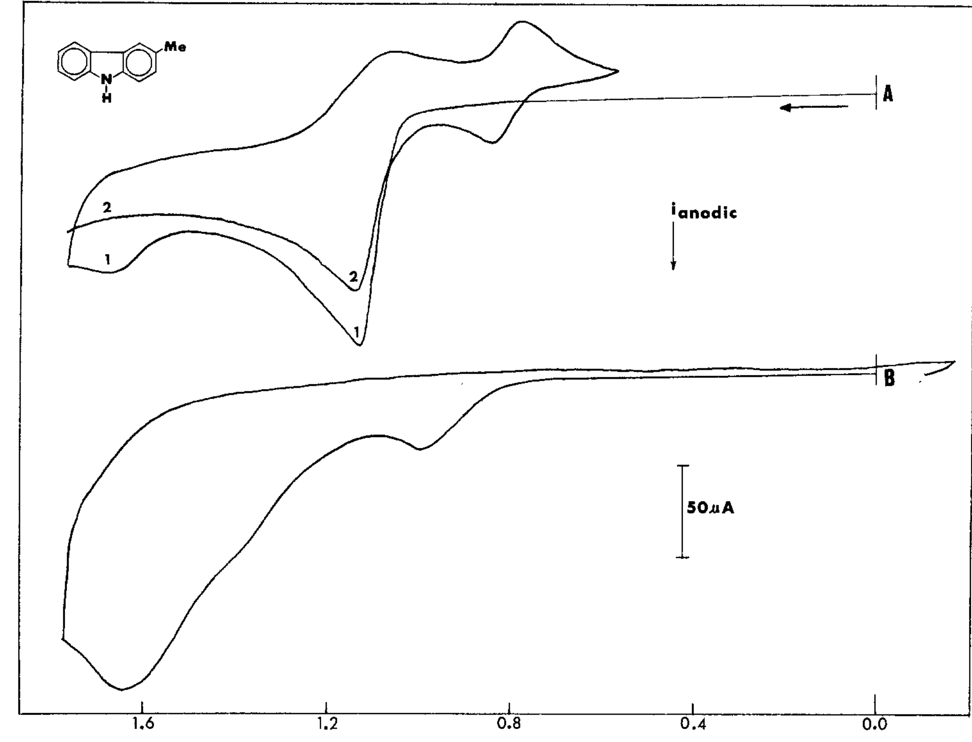


Fig. 1. Curve A: Cyclic voltammogram of $1.2 \times 10^{-3}F$ 3-methylcarbazole in MeCN/TEAP, sweep rate = 150 mV/sec. Curve B: Cyclic voltammogram of the same solution with excess 2,4,6-trimethylpyridine added, sweep rate = 50 mV/sec.

group would render the previous systems somewhat less complicated, in a similar fashion to the previous studies on carbazole and N-ethylcarbazole (7). With the nitrogen blocked, N-N and N-ring coupling cannot occur and one should obtain only the 3,3'-disubstituted-N,N'-diethyl-6,6'-bicarbazyls by bond formation through the only available active site (excluding the amino and dimethylamino derivatives)

R, N, Et —anode→ R, N, Et, N, Et, R [8]

This is observed for most of these compounds, as shown in Table II and Fig. 2. By and large, the bicarbazyls are the major products in these systems, but most of the coupled products are somewhat unstable and react further, particularly in the presence of impurities in the solvent or supporting electrolyte. As for the 3-substituted carbazoles, the n values cited in Table II were taken at parent concentrations of 10^{-3} to $10^{-4}F$ and the amounts of bicarbazyl cited were estimated from peak currents on cyclic voltammograms of exhaustively electrolyzed $10^{-3}F$ solutions. Very good product yields were only obtained at low concentrations and in very pure solvent, so the numbers cited in Table II are probably near the optimum values to be expected. At higher concentrations further reactions ensue in many cases and telomers or other unidentified products are obtained. As with the 3-substituted carbazoles, low steady-state currents were encountered in exhaustive electrolyses, but they were generally quite a bit lower, indicating that the 3-substituted-N-ethylcarbazoles are considerably "cleaner." Cyclic voltammograms of exhaustively electrolyzed solutions suggest that prepara-

XXV	NO_2	1.46	102-110[a]	2.26[b,c]	6,6'-bicarbazyl (50)

[a] Chronoamperometric value increases with increasing electrolysis time (1-8 sec).
[b] Low steady-state currents are observed at these n values; however, they are considerably lower than in the case of the 3-substituted carbazoles (see text).
[c] n value is very sensitive to solvent/supporting electrolyte impurities.
[d] Yields are lower at higher carbazole concentrations.
[e] Current-time curves are distorted due to severe filming.

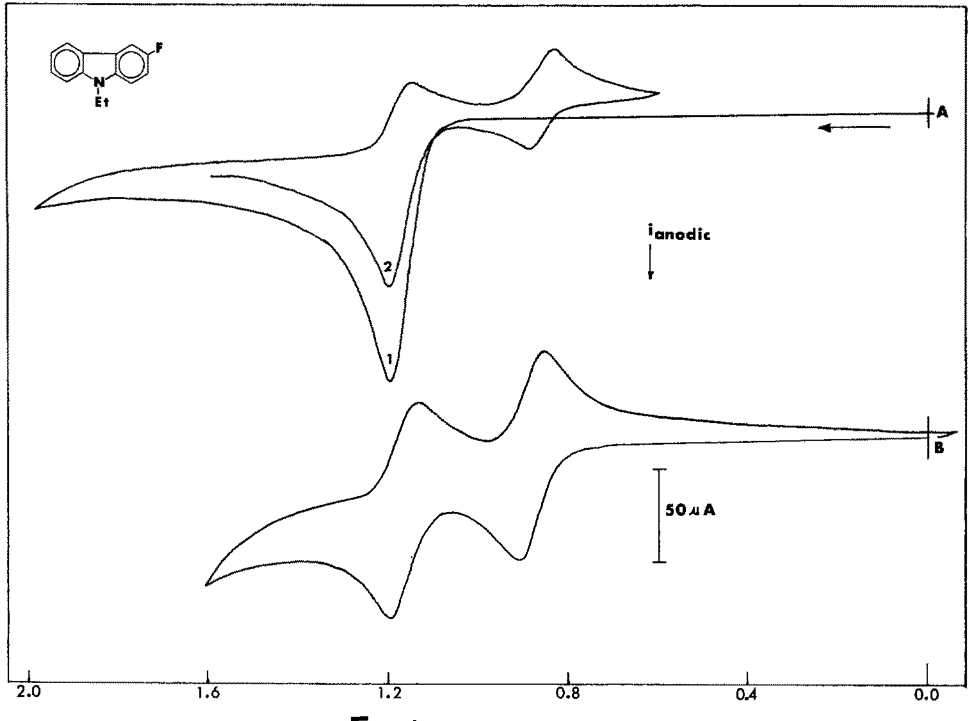

Fig. 2. Curve A: Cyclic voltammogram of $9.6 \times 10^{-4}F$ 3-fluoro-N-ethylcarbazole in MeCN/TEAP, sweep rate = 100 mV/sec. Curve B: Cyclic voltammogram of the same solution following exhaustive electrolysis at 1.4V, sweep rate = 67 mV/sec.

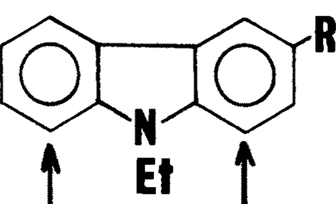
tive studies on these systems would be difficult at best. However, several derivatives can be electrolyzed on a preparative scale (~0.5g) to give moderate yields of bicarbazyls, among them the fluoro, iodo, acetyl, benzoyl, ethylcarboxylate, cyano, and nitro compounds (see Experimental section).

At short electrolysis times, these systems are model two-electron over-all ECE processes and so several attempts were made to measure the coupling rate constants for bicarbazyl formation using rotating disk voltammetry and digital simulation methods (14). In all cases, the coupling rates were too fast to measure, which indicates that a lower limit for the second-order k's would be a value of about 10^8 mole^{-1} sec^{-1}. This is not surprising since the carbazole ring system is planar and thus the charge densities at the 6-positions are quite high for the molecules in this series compared to, say, 4-substituted triphenylamines, which have second-order coupling rate constants ranging from 0.6 to 10^4 mole^{-1} sec^{-1} (45). Thus, the primary reaction pathway of these cation radicals is intermolecular coupling to form the corresponding bicarbazyls; these latter species then further decompose in a variety of secondary follow-up reactions.

In some cases, these secondary reactions following bicarbazyl formation can be speculated upon. The acetamido derivative yielded an appreciable amount of bicarbazyl but also a second product that appears to be a hydrazine-type derivative formed by deacetylation of the acetamido group and coupling through the 3-amino substituents. The methyl derivative also exhibited secondary reactions and cyclic voltammograms of exhaustively electrolyzed solutions indicated that further coupling through the methyl groups might be taking place in a similar fashion to the behavior previously reported for N,N-dimethyl-p-toluidine (46).

In several instances, the bicarbazyls formed were found to be only sparingly soluble and tended to film the electrode severely. In these cases, the product was collected by filtration of the electrolysis solution; the *IR* spectra indicated that these were perchlorate salts, probably of the bicarbazyl dication. This phenomenon was very marked for the aldehyde and carboxylic acid derivatives, although the ethyl ester was relatively uncomplicated and exhibited no filming.

In other cases, the nature of the secondary reactions could not be ascertained but previous chemical oxidation studies have shown that the 1 and 8 ring positions, denoted by arrows below, are active and can be readily substituted in the absence of steric inhibition. These



ring sites could also be susceptible to attack in the bicarbazyls and so further couplings past the latter cannot be ruled out. This is also consistent with the observed fact that the stabilities of the bicarbazyls increase markedly as the carbazole nitrogen is substituted with first ethyl and then phenyl groups (*vide infra*). However, whereas further couplings past the bicarbazyl may be occurring, it should be pointed out that these reactions would never yield an n value greater than two, since the formation of successive telomers introduces increasingly greater possibilities for more conjugated systems generated by removal of electrons, but at the same time involves the consumption of more parent molecules. Thus, the secondary reactions leading to higher n values are more likely degradation of the bicarbazyl skeleton or the attached substituents. If further coupling reactions were involved, they would have to be intramolecular in nature.

Again, different behavior is observed for the amino and dimethylamino derivatives, these being quite similar to the 3-substituted analogs in not undergoing the standard bicarbazyl couplings. The major exception is that the N-ethyl compounds have more stable cation radical and diimine forms; in fact, 3-dimethylamino-N-ethylcarbazole exhibits two nicely reversible redox steps, as shown in Fig. 3. Comparison of the current-voltage curves for compounds I, II, XI, and XII confirms a general characteristic of p-phenylenediamine-type molecules in that protection of the nitrogen with alkyl or phenyl groups lends considerable stability to both the cation radical and diimine species. As with compound II, however, both the cation radical and diimine of compound XII slowly react to form unknown products.

When the 3-amino group is not methylated (No. XI) the cation radical is much less stable, although reversi-

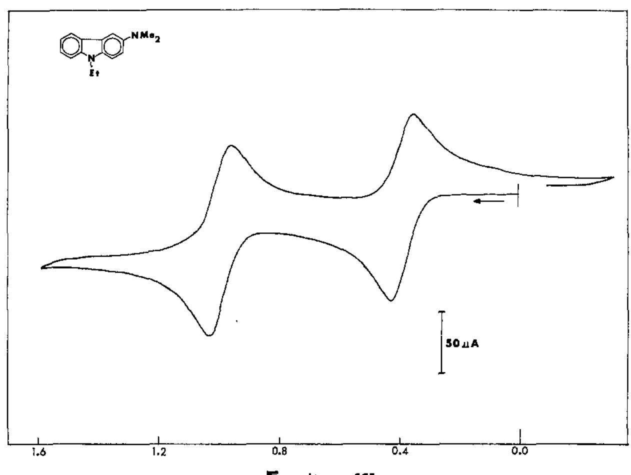


Fig. 3. Cyclic voltammogram of 1.0 × $10^{-3}F$ 3-dimethylamino-N-ethylcarbazole in MeCN/TEAP, sweep rate = 150 mV/sec.

bility can still be observed on both the first and second anodic waves even at sweep rates as low as 200 mV/sec. At sweep rates of about 2 V/sec and above the first process is completely reversible, and a half-life of about 0.5 sec for the primary cation radical can be estimated. As with compound I, however, little is known about the process taking place and the n value of 0.7-0.8 (average value = 0.75), which was obtained repeatedly and appears to be genuine, is quite perplexing. This is, of course, different than for 3-aminocarbazole, which had an n value of unity. It is difficult to propose a mechanism involving 0.75 electrons per molecule with simple coupling as the only pathway. If the oxidized form of the bicarbazyl were to lose one or two protons this would generate n values of 0.80 or 0.67, respectively; it is conceivable that a mixture of these two processes is taking place, but it seems more likely that a completely different mechanistic pathway yet to be considered is operative here.

It is interesting to note that the primary radical of the acetamido derivative, No. XIII, is moderately stable, having a half-life of about 30 sec. As mentioned above, the reaction pathways of this radical are complex but again they are different than for No. XI and XII and are more characteristic of the other derivatives in this series in that an appreciable amount of the 6,6′-bicarbazyl is formed. It appears that the acetamido group is withdrawing electron density from the unsubstituted ring, but not to the extent that the —NH_2 and —NMe_2 groups do; these latter substituents stabilize the primary radicals by markedly decreasing electron density at the reactive 6-position. The result is that for these two compounds the electrochemistry is more characteristic of p-phenylenediamine-type molecules. There is probably also a steric factor for the acetamido derivative in that any coupling reactions involving the 3-substituent will be hindered by the acetyl group.

In all of the other compounds, No. XIV-XXV, simple HMO calculations indicate that the 3-substituents either have little effect on the 6-position electron density or actually increase it (relative to N-ethylcarbazole) making coupling more likely. The result is that in all cases the primary cation radicals are extremely short lived.

Thus, radical stabilities in this series can be interpreted in terms of the electron density at the reactive 6-position. Substituents such as —NH_2,—NMe_2, and —NHCOMe (and presumably —OR and —SR) can accommodate the unpaired electron density in the cation radicals and thus remove electron (and charge) density from the open ring. The others from —Me through —NO_2 do not and in fact enhance coupling at the 6-position.

3,6-Disubstituted carbazoles.—For this series, it is apparent that barring substituent elimination, the only likely coupling sites would be the 1, 8, and 9 (N) positions. Thus, only the 1,1- 1-N, and N-N coupled products should, in principle, be possible

[9]

As with the other systems previously mentioned, the feasibility of these products forming depends upon the status of the carbazole nitrogen (protonated or unprotonated) and the electron densities at the remaining reactive coupling sites. In addition, since all of the above reactions would be expected to be rapid and the carbazole nitrogen and 1 and 8 ring positions are unprotected cation radicals in this series would be predicted to be quite unstable.

Cyclic voltammetric data for these compounds are varied, as is seen in Fig. 4, and the electroanalytical data in Table III further indicate the diverse and generally poorly defined behavior in MeCN/TEAP. Current-voltage and current-time curves for a number of the derivatives in this series were markedly affected by adsorption of either parent material or electrolysis products and cyclic voltammograms run after exhaustive electrolyses were very poorly defined and showed little in the way of discernable products.

Only the methoxy derivative, No. XXVI, shows reversibility at low sweep rates and in fact the cation radical is quite stable, having a half-life ($t_{1/2}$) of several minutes. The primary radicals for the other compounds in this group are quite unstable, having $t_{1/2}$'s of 0.1-1.0 sec, but all of these radicals are much more stable than those of previously mentioned compounds with open 3 or 6 positions, with the exception of the aminocarbazoles. This marked stabilizing effect of methoxy groups has been noted previously (45, 47, 48) and is due to delocalization of charge and electron density out onto the methoxy's, with a resultant decrease at reactive sites in the carbazole nucleus. This is shown below, where electron densities are again represented by c^2 values for the HFMO; with the 3 and 6 positions blocked activity would be expected to shift to the 1, 8, and 9 sites, but as can be seen the latter are considerably deactivated

Of the other functional groups, only the t-butyl is predicted to have a similar effect, but to a much lesser extent. The others actually increase the electron density at the active sites and so further destabilize the primary cation radicals in a regular fashion, the stability decreasing from chloro to nitro.

It is interesting to note that the HMO calculations show an appreciable enhancement in electron density at the 4 and 5 ring carbons *ortho* to the methoxy groups (similar to the 3-aminocarbazole systems) to a point where these positions must be considered as possible coupling sites. Since methoxy is classically an *ortho-para* director this is not totally unexpected, but it will

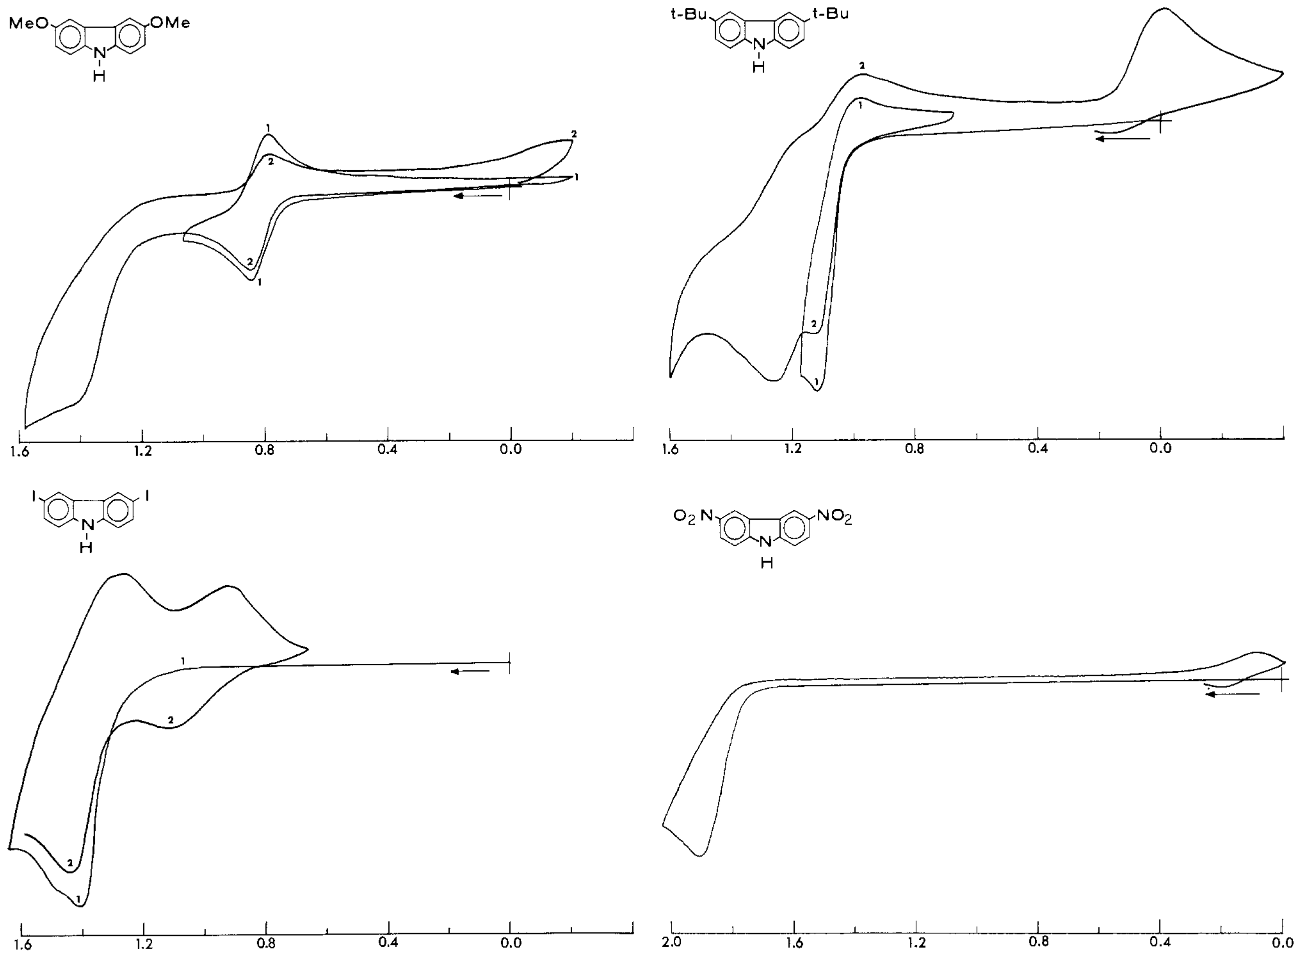

Fig. 4. Cyclic voltammograms of 3,6-disubstituted carbazoles in MeCN/TEAP. Abscissa is in volts vs. SCE and for all curves the solutions were 1.0 × $10^{-3}F$ in the carbazoles and the sweep rate was 150 mV/sec. In some cases, scans are numbered sequentially.

be indeed interesting if further work on the reaction pathways of these molecules verifies the HMO prediction. It is particularly germane, since EPR studies have indicated that the spin density at the 4 and 5 positions is quite low in some substituted carbazoles (*vide infra*) (49).

Little has actually been determined concerning the reactivity routes of No. XXVII-XXXIII in MeCN/TEAP. Some substituent elimination does occur for the halogen derivatives, leading to 6,6′-disubstituted-3,3′-bicarbazyls; this can readily be seen in Fig. 4 for 3,6-diiodocarbazole. The follow-up peaks in the region between 1.0 and 1.4V match perfectly with those for the 6,6′-bicarbazyl formed from 3-iodocarbazole. Of the other derivatives, it has only been determined that the primary cation radicals are very unstable ($t_{1/2} \simeq 1$ sec) and the decay pathways do not appear to involve substituent elimination.

In the presence of 2,4,6-trimethylpyridine, a strong organic base, electrolysis again produces only the substituted 9,9′-bicarbazyls in near quantitative yields. They are easily isolated, since they are in some cases insoluble and can be filtered off following electrolysis; alternatively, they are easily separated from the solvent and supporting electrolyte by column chromatography (see Experimental section). Such electrolyses in basic medium exactly parallel similar chemical work involving permanganate oxidations in acetone of the bromo (9) and *t*-butyl (49) derivatives, and it appears that near quantitative yields of the 9,9′-bicarbazyls

Table III. Electrochemical characteristics of 3,6-disubstituted carbazoles

No.	(3,6-R-carbazole, N-H)	$E_{p/2}$	$it^{1/2}/C$	n value	Product(s) (% yield)
XXVI	R = OMe	0.78	48-53	1.76[d]	Stable cation radical, decomposition pathway unknown

[a] Electrolyses in MeCN/TEAP with added excess 2,4,6-trimethylpyridine.
[b] Data are distorted by strong adsorption of parent material or electrolysis product.
[c] Observed on cyclic voltammograms in MeCN/TEAP, no 2,4,6-trimethylpyridine added. The 3,3′-bicarbazyls are formed by substituent elimination and subsequent coupling.
[d] Current decays rapidly to about $n = 1$ where a low steady-state current ensues, the latter slowly dropping further to near zero.
[e] Primary oxidation wave overlaps substantially with a second wave which is also included in the potential step.

Table IV. Radical stabilities of *t*-butylated carbazoles

No.	Compound	$E_{p/2}$	Radical half-life	Decomposition product
XXVII		1.07	~1 sec	1,1′-bicarbazyl ?
XXXIV		1.17	<<1 sec	3,3′-bicarbazyl
XXXV		1.15	<<1 sec	3,3′-bicarbazyl[a]
XXXVI		1.08	~1 min	1,1′-bicarbazyl ?
XXXVII		1.09	~30 min	?

[a] Verified with an authentic 3,3′-bicarbazyl sample.

from any of the 3,6-disubstituted derivatives can be readily obtained by either chemical or electrochemical means.

In the case of 3,6-di-*t*-butylcarbazole, authentic samples of the corresponding 1,9′- and 9,9′-bicarbazyls were available to aid in product identification. Cyclic voltammetric and optical spectra indicate that these are not the major product(s) in MeCN/TEAP electrolyses, however, and so it appears by a process of elimination that the most likely reaction pathway is ring-ring coupling-deprotonation to form the 1,1′-bicarbazyl.

In the pathways above, it appears that there is a reaction selectivity order that is highly contingent upon the acidity of the solution near the electrode similar to the diphenylamine system previously reported by Cauquis (50). That is, in acid solution, which is the case in unbuffered MeCN after coupling is initiated and protons are released into solution, only C-C coupling occurs, while the presence of a weak base would be expected to promote mixed C-C and C-N coupling. Strong bases in solution then lead exclusively to formation of the N-N coupled products.

The series of *t*-butylated carbazoles shown in Table IV provide further valuable information on the possibilities of various coupling modes and the importance of steric factors in stabilizing the primary cation radicals. It is apparent from the radical stabilities shown that the 3 and 6 positions are far more reactive than the 1, 8, and 9 sites. Steric blocking of the 8 and 9 positions by a 1-*t*-butyl group (No. XXXVI) stabilizes the primary cation radical substantially compared to No. XXVII and introduction of another *t*-butyl substituent on the 8-carbon leads to a very stable cation radical for No. XXXVII. Stabilization through electronic effects would be minimal with *t*-butyl groups and so this is clearly an example of hindering reaction pathways by blocking reactive ring positions with inert functional groups.

The information provided by the molecules in this series is that simple blockage of the highly reactive 3 and 6 carbons does stabilize the primary cation radicals to a substantial degree, but the half-lives are still in the 0.1-1.0 sec region. An exception is the methoxy derivative which stabilizes by a delocalization mechanism similar to that operative for No. I, II and XI-XIII. When a reaction does take place, it appears to occur through the nitrogen in the presence of a strong organic base and through the 1 and 8 ring carbons in unbuffered MeCN; this last assertion is speculative at present. Introduction of blocking groups at these latter sites leads to substantially more stable primary cation radicals.

3,6-Disubstituted-N-ethylcarbazoles.—With the nitrogen alkylated (and the 1 and 8 ring positions thus somewhat sterically hindered) and both the 3 and 6 ring carbons substituted, one might anticipate that the primary cation radicals of such molecules would be quite stable. To some degree this was found to be true and as a result the electrochemistry of this series of molecules is centered about detectably stable cation radicals with $t_{1/2}$ values ranging from about 1 sec up to several days; the electroanalytical data are given in Table V.

Even at that, the lifetimes of these radicals are less than what might have been expected, since previous studies have shown that structurally similar 4,4′-disubstituted-N-alkyldiphenylamines possess very stable primary cation radical species (51, 52). In general, the carbazole radicals are at least two orders of magnitude less stable than the correspondingly substituted diphenylamines; this phenomenon appears to be largely due to the fact that the carbazoles have a very planar pi system whereas the diphenylamine rings are skewed. This leads to marked differences in electron distributions, as shown below for the alkyl derivatives (these calculations do not include the alkyl substituents, all of which are considered equivalent, but their electron densities will be proportional to the ring carbons to which they are attached)

The major change is that electron density in the carbazole system is, relative to the diphenylamine skeleton, distributed more into the aromatic rings and less on the central nitrogen; this assertion has been quantitatively substantiated by EPR data (49). It is normally the case that increased delocalization leads to enhanced cation radical stability, but it appears at first glance that here the opposite is the case, *i.e.*, the more highly delocalized carbazoles are the less stable radicals. The alternate viewpoint however, is that at the same time decreased localization takes place in the carbazoles relative to the diphenylamines at the unreactive central nitrogen with an attendant increase in electron density in the more reactive aromatic rings. Interestingly, the same result can be qualitatively achieved in the HMO calculations by increasing the pi overlap between the central nitrogen and the aromatic rings in the diphenylamine systems by increasing the value for the resonance integrals for the central nitrogen and the adjacent ring carbons. The net effect is to generate a more planar diphenylamine. As expected, electron density is drained away from the central nitrogen into the aromatic rings more and more as the k_{CN} value is increased.

The same effect is seen in a comparison of the calculated orbital energies with the experimentally obtained oxidation potentials. The calculations indicate that the carbazole HOMO's are lower (more positive) in energy than the correspondingly substituted diphenylamines and in accordance with this the oxidation potentials of the carbazoles are consistently more anodic by 0.2-0.3V. This is reasonable if one considers that the carbazoles are more "hydrocarbon-like" than "amine-like" relative to the diphenylamines (because of enhanced delocalization into the aromatic rings) and thus would be more difficult to oxidize.

The net result of all this is that the ring positions in the carbazoles are more reactive, particularly the 3 and 6 carbons, and so even though the rings are heavily substituted and sterically protected radical stability is

Table V. Electrochemical characteristics of 3,6-disubstituted-N-ethylcarbazoles

No.	R_1, R_2 (N-Et carbazole)	$E_{p/2}$	$it^{1/2}/C$	n value	Product(s) (% yield), comments
XXXVIII	$R_1 = R_2 = NH_2$	0.32	47	1.09	Unstable cation radical, structure of coupled product is unknown
XXXIX	NMe_2	0.22	45	1.03	Highly stable cation radical, stable dication formed at $E_{p/2}$ = 0.60V, unstable trication radical generated at $E_{p/2}$ = 1.41V
XL	OMe	0.80	48	1.01[a]	Stable cation radical, unstable dication; mode of decomposition appears to be hydrolysis
XLI	Me	1.04	59-103[b]	2.2[a]	Moderately stable cation radical, decomposition appears to be via coupling through methyl groups
XLII	Et	1.06	119-184[b]	3.1[a]	Unstable cation radical, decomposition appears to be via coupling through ethyl groups
XLIII	t-Bu	1.04	43	1.07[a]	Stable cation radical, slowly decomposes probably via 1,1'-coupling
XLIV	Cl	1.48	53-67[b]	1.3[a]	Moderately stable cation radical, decomposition pathway unknown
XLV	Br	1.40	43-48[b]	1.2[a]	Moderately stable cation radical, decomposition pathway unknown
XLVI	I	1.34	78-88[b]	2.0[a]	Unstable cation radical, eliminates iodine, forms corresponding 3,3'-bicarbazyl (60-70)[c]
XLVII	COMe	1.50	79-136[b]	3.2[a]	Unstable cation radical, some deacetylation occurs to form the corresponding 3,3'-bicarbazyl
XLVIII	COEt	1.50	86-144[b]	3.4[a]	Unstable cation radical, eliminates propionyl group, forms corresponding 3,3'-bicarbazyl
XLIX	COPh	1.49	76-105[b]	2.9[a]	Unstable cation radical, eliminates benzoyl group, forms corresponding 3,3'-bicarbazyl
L	COOMe	1.56	—[c]	—[c]	Unstable cation radical, products unknown
LI	CN	1.74	81-133[b,d]	3.4[a]	Moderately stable cation radical, products unknown
LII	NO_2	1.81	116-211[b,d]	3.8[a,d]	Moderately stable cation radical, products unknown
LIII	R_1 = Me, R_2 = COMe	1.26	124-165	2.7	Unstable cation radical, alkyl coupling predominates, small amount of deacetylation
LIV	R_1 = Et, R_2 = COMe	1.25	166-188	2.9	Unstable cation radical, alkyl coupling predominates, small amount of deacetylation

[a] n value at the onset of low steady-state current.
[b] Taken from t = 1-8 sec; value increases with increasing time.
[c] Primary wave is very obscure, merges with more anodic waves; meaningful data could not be obtained.
[d] Data are affected by proximity to background; residual currents are quite high.

diminished relative to systems such as the diphenylamines. Of course, the cation radicals in this series are enormously more stable than those previously discussed herein, but even so very few could be called truly stable (half-life of 30-60 min). Interestingly, it was generally found that protecting the area around the carbazole nitrogen (with N-alkyl or N-phenyl substitution) shielded the moderately reactive 1- and 8-carbons and led to greatly enhanced activity at the nominally blocked 3 and 6 ring sites; the decay reactions of the less stable radicals in this series were thus found to take place at these latter positions.

In all cases in this series, the initial process involves removal of one electron to generate the cation radical. Of those which are reasonably stable, the dimethylamino derivative, No. XXXIX, is by far the longest lived. Not only is the primary radical stable for days, but the dication quinonediimine also appears to have a negligible decomposition rate. In fact, a third redox process can be observed which is reversible even at moderately low voltage scan rates, as shown in Fig. 5. One readily sees that switching past the first two waves (dotted lines) yields substantial reverse current and a lesser amount is observed on the third anodic wave; however, oscilloscope traces show that this latter process is completely reversible above sweep rates of about 2 V/sec. Chronoamperometric data yield constant $it^{1/2}/C$ quotients for the first two anodic processes (45 and 91, respectively) and coulometric measurements indicate n values of 1.03 past the first wave and 2.05 past the second. This third anodic wave, then, is apparently due to further oxidation of the stable dication and so the reversibility seen at high sweep rates indicates that this molecule has a moderately stable trication radical with $t_{1/2} \simeq 1$ sec. This is an extremely rare species, of which few examples are available (53); it offers the very exciting possibility of matching of spectral data for the cation and and trication radicals of a single species.

The amino derivative exhibits behavior similar to the previously discussed 3-aminocarbazoles except that the electrolysis product is much more in evidence on cyclic voltammograms. Since this same general electrochemical behavior was noted for 3-amino- and 3-amino-N-ethylcarbazole this would imply that the carbazole nitrogen is not implicated and the common reaction pathway, if it is indeed common, is N-N or N-ring coupling involving the amino groups and the 1, 4, 5, or 8 ring carbons. Again, the primary cation radical is short-lived ($t_{1/2} \simeq 1$ sec), but its existence was verified by rapid-sweep cyclic voltammetry.

Of the other derivatives in this series, both the methoxy and t-butyl compounds were found to have stable primary radicals with half-lives of 1 hr or more. The 3,6-dimethoxy-N-ethylcarbazole cation radical is exceptionally stable, probably due to the low charge density at the 1 and 8 ring sites and the blocking action

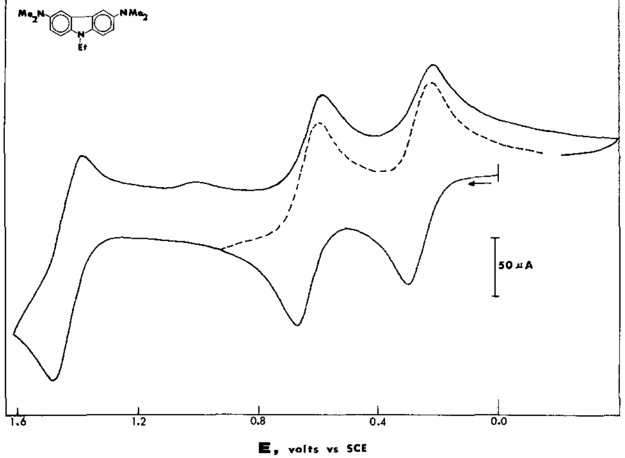

Fig. 5. Cyclic voltammogram of 1.0 × 10^{-3}F 3,6-bis(dimethylamino)-N-ethylcarbazole in MeCN/TEAP, sweep rate = 667 mV/sec.

of the N-ethyl group. The cation radical is oxidized to the dication in a second anodic process at $E_{p/2} = 1.36$V; no reverse current was observed even at a swep rate of 10 V/sec. The dication of this molecule would have

MeO ... OMe (N+, Et)

several resonance forms but the one shown above would be very susceptible to nucleophilic attack by trace amounts of water in the MeCN to generate the corresponding hydroxy derivative, 3-hydroxy-6-methoxy-N-ethylcarbazole. This is suggested by the cyclic voltammetric curves for this compound which are very similar in shape to other aromatic amine systems where a similar hydrolysis mechanism has been shown to occur (54, 55). The primary cation radical probably reacts via this same route, but at a markedly slower rate.

The 3,6-di-t-butyl-N-ethylcarbazole cation radical was also found to be quite stable, but slow decomposition was evident. Reaction probably occurs via 1-1 ring coupling, as was speculated for the t-butylated carbazoles No. XXVII and XXXIV-XXXVII. Nevertheless, a half-life of 30-40 min (stability for this compound, as for many of the others, is dependent upon concentration and solvent purity) ensures that this radical can be easily studied.

The methyl and ethyl derivatives, No. XLI and XLII, have cation radicals that are considerably more reactive than the t-butyl analog and beyond this the ethyl is much less stable than the methyl. This assertion is graphically illustrated in Fig. 6, where cyclic voltammograms for the three alkyl derivatives are shown. The t-butyl curve is seen to be perfectly reversible with no sign of decomposition products (however, holding the potential at the anodic limit for about 1 min and then sweeping back to more cathodic potentials yields a ratio of cathodic to anodic peak currents of about 0.92, indicating that the primary radical is in fact reacting very slowly). The methyl compound also shows considerable reverse current, but a small cathodic wave near -0.2V corresponding to reduction of protons indicates that the cation radical is not exceptionally stable ($t_{1/2} = 1$-2 min); the ethyl curve shows extensive reaction and reversal just past the primary wave (dotted line) shows very limited stability for the cation radical ($t_{1/2} \simeq 0.8$ sec).

These data are consistent with a mechanism whereby the electrogenerated cation radical diffuses away from the electrode surface and a proton is lost from the alkyl carbon alpha to the carbazole skeleton, thus generating a benzylic-type free radical. Coupling of the resulting free radicals out in solution would ensue to generate a bridged bicarbazyl in a fashion similar to that proposed for No. XIV and previously published systems (46, 56). The relative stabilities of the methyl, ethyl and t-butyl compounds are thus explained by ring alkyl proton loss from the cation radical; a proton will eliminate more readily from a secondary carbon (ethyl) than from a primary (methyl) and when no alpha hydrogens are present (t-butyl) elimination cannot occur and enhanced stability is to be anticipated, as well as slow reaction via a different pathway. These relative stabilities are also nicely mirrored in the chronoamperometric data in Table V, which show the t-butyl derivative having a fairly constant one-electron value, and the others having much higher, and rapidly increasing, $it^{1/2}/C$ quotients. The n value data also point up the same disparity. The general mechanism is shown below for No. XLI but would also apply to No. XLII

Me–carbazole(N-Et)–Me $\underset{}{\overset{-\text{le}^-}{\rightleftharpoons}}$ [Me–carbazole(N-Et)–Me]$^{\cdot+}$ (I) [10]

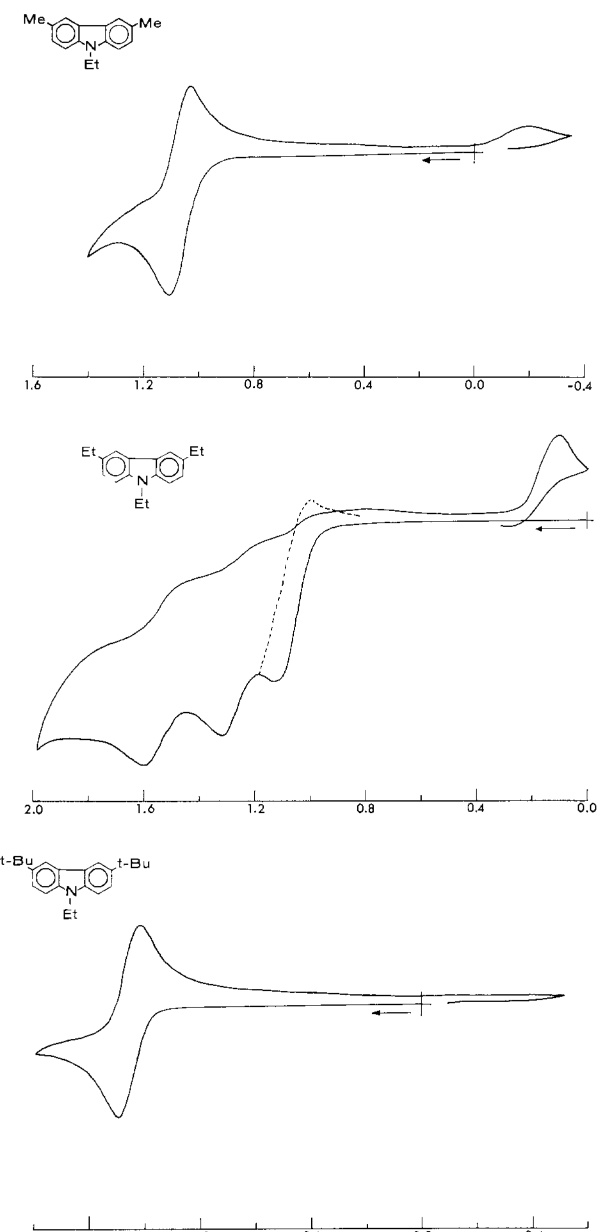

Fig. 6. Cyclic voltammograms of 3,6-dialkyl-N-ethylcarbazoles in MeCN/TEAP. Abscissa is in volts vs. SCE and for all curves the solutions were $1.0 \times 10^{-3}F$ and the sweep rate was 150 mV/sec.

II $\xrightarrow{\text{oxid'n}}$ UNKNOWN PRODUCTS [12]

The halogen derivatives, No. XLIV-XLVI, offer an interesting contrast in that the iodo compound eliminates iodine from the primary cation radical quite rapidly ($t_{1/2} \simeq 0.5$ sec) with subsequent coupling to form 6,6′-diiodo-N,N′-diethyl-3,3′-bicarbazyl, the same compound that is generated by oxidation of 3-iodo-N-ethylcarbazole. The products from electrolysis of the mono- and diiodo-N-ethylcarbazoles were found to be identical by matching of cyclic voltammetric curves and visible absorption spectra run on exhaustively electrolyzed solutions; in both cases the match-up is perfect.

The bromo and chloro analogs (No. XLIV and XLV), however, have reasonably stable primary cation radicals with half-lives of several minutes. In addition, it does not appear in our as yet cursory studies of these

latter two compounds that the radicals decompose by halogen elimination and subsequent coupling; the primary reaction route may instead be some form of ring-ring coupling. This observation is also in marked contrast to the data on the 3,6-dihalocarbazoles, No. XXVIII and XXIX, for which appreciable halogen elimination and subsequent 3,3′-coupling was noted, even though the cation radicals were much less stable than for the N-ethyl analogs and the 1, 8, and 9 positions are less protected.

As a group, No. XLVII-XLIX are characterized by unstable cation radicals which appear to react via elimination and subsequent 3,3′-coupling as the dominant, but not exclusive, pathway. Acetyl and benzoyl group eliminations are indicated by the fact that as with the 3-iodo- and 3,6-diiodo-N-ethylcarbazoles above identical cyclic voltammetric curves and visible absorption spectra were obtained from exhaustively electrolyzed solutions of the mono- and diacetyl-N-ethylcarbazoles (No. XX and XLVII) and the mono- and dibenzoyl-N-ethylcarbazoles. Of the cation radicals here, the acetyl derivative is least stable ($t_{1/2} \simeq 0.6$ sec), followed by the propionyl ($t_{1/2} \simeq 0.9$ sec) and the benzoyl ($t_{1/2} \simeq 1.5$ sec) compounds. The enhanced stability of the latter compound may be due in small part to increased delocalization afforded by the phenyl rings of the benzoyl groups by a mechanism other than direct conjugation, since this cannot be invoked here. This mode of cation radical reaction is quite unique and so we are at present pursuing kinetic and mechanistic studies of this novel pathway.

Little has been determined for No. L, the methyl ester, beyond the facts that the primary cation radical is unstable ($t_{1/2} \simeq 0.5$ sec) but detectable and it appears to react by direct ring coupling rather than by elimination and subsequent 3,3′-coupling; cyclic voltammograms of electrolyzed solutions show no 3,3′-bicarbazyl present.

The carboxylic acid derivative, N-ethylcarbazole-3,6-dicarboxylic acid, was prepared but its electrochemistry could not be investigated due to its complete lack of solubility in MeCN/TEAP.

The nitro and cyano derivatives, No. LII and LI, respectively, were also only lightly studied, but it appears here that ring coupling is the mode of cation radical reaction. In addition, the primary radicals have surprisingly long half-lives; $t_{1/2}$ for the cyano compound is 5-7 sec and that for the nitro derivative is 2-3 sec.

Compounds LIII and LIV offer a fascinating comparison between alkyl coupling and acetyl group elimination as competitive pathways. Cyclic voltammetric data indicate that alkyl coupling is the dominant pathway, with a small amount of acetyl elimination observed. Thus, the radical for No. LIII is considerably more stable ($t_{1/2} \simeq 1$ sec) than for No. LIV ($t_{1/2} \simeq 0.1$ sec) but both are much shorter lived than their dialkyl analogs due to the destabilizing influence of the acetyl group. This is indicative of a fairly drastic change in electron distribution which makes the alkyl groups much more acidic in No. LIII and LIV than in No. XLI and XLII.

Whereas in the previous section we saw that blockage of the highly reactive 3 and 6 ring carbons largely forced the radical reactions to the area around the carbazole nitrogen, the data presented in this section indicate that N-alkyl substitution in many cases shifts the center of reactivity back to the 3 and 6 sites. The primary radicals are much more stable than if either of these positions is open and so in all cases they can be readily detected. These data clearly show that relatively few substituents can be considered "inert" as possible agents for blocking reactive sites in cation radicals. For intrinsic inertness to reactivity and for having the additional property of affecting as little as possible the electron distribution in the molecular skeleton, the *t*-butyl group seems to be most satisfactory, a view previously forwarded by Neugebauer in his EPR spectral work on carbazole derivatives (49).

Substituted N-phenylcarbazoles.—Substitution of a phenyl group on the carbazole nitrogen would be expected to have at least two beneficial effects with regard to radical stability. The phenyl ring extends the pi system of the carbazole skeleton and thus contributes to radical stabilization through enhanced delocalization. In addition, the bulky phenyl group acts as an efficient blocking agent for the 1 and 8 ring sites, more so than an N-alkyl group. On the other hand, the phenyl ring introduces the possibility of another coupling site, namely the phenyl carbon *para* to the carbazole nitrogen. Since these molecules are structurally quite similar to triphenylamines such a reaction is not unlikely, but it was not detected in the previous study on the anodic oxidation of N-phenylcarbazole (7).

With the above stabilizing factors in mind, we might expect that 3,6-disubstituted N-phenylcarbazoles such as No. LXXI-LXXIV should have primary radicals more stable than their N-ethyl analogs, No. XLIII-XLVI. In fact, this was found to be the case, although it is not apparent in the chronoamperometric or *n* value data. The iodo derivatives are probably the easiest to compare, since for these there is rapid reaction via iodine elimination, a reaction contingent upon the electron density at the 3 and 6 ring positions. Whereas the 3,6-diiodo-N-ethylcarbazole cation radical was observed to have a half-life of roughly 0.5 sec, the phenyl analog has $t_{1/2} \simeq 1$ sec. This twofold gain in stability appears to be due to the extended delocalizing influence of the N-phenyl ring.

The other three compounds in this series (No. LXXI-LXXIII) appear to have a common mode of radical reaction that is different from the N-ethyl analogs. All exhibit a quasi-reversible (anodic to cathodic peak separation of about 250 mV) redox couple about 0.2-0.4V less anodic than the primary oxidation waves. It is not altogether unlikely that these radicals may slowly undergo a triphenylamine-type coupling to generate something akin to a tetraphenylbenzidine, as shown below.

R R N N R R

This species would be more easily oxidized than the parent carbazole and the twisted nature of the N-ring-ring-N portion would lead to irreversible redox behavior (57, 58). Further support for this view is afforded by the observation that no such follow-up couple is seen in the current-voltage curves for No. LXXV and LXXVI, compounds in which the *para* position of the N-phenyl group is substituted. In addition, the cation radical for No. LXXV was qualitatively observed to be more stable than that for No. LXXII by about a factor of three.

The major factor mitigating against this mode of reaction is the rather low electron density that would be predicted for the potential coupling site assuming a moderate amount of twisting of the N-phenyl ring due to steric interaction with the 1 and 8 ring protons. HMO calculations show that as the twist angle is increased from a nominal value of about 45° (that assumed for a freely rotating triphenylamine-type system) the electron density at the *para* site on the N-phenyl ring drops dramatically. Unfortunately, we have no data on the twist angles in cation radicals of

this type, but molecular models show that such twisting would be expected to be substantial. Obviously, the question can best be answered by isolation and characterization of the electrolysis product; we are at present attempting to carry this out.

Stabilization through enhanced delocalization is also indicated by the somewhat greater stability of No. LXXVI as compared to No. XLI, N-substituted-3,6-dimethylcarbazoles. Though both radicals appear to react by alkyl coupling through the 3 or 6 methyl groups, the radical half-life of the N-phenyl derivative is 4-5 min, as compared to 1-2 min for the N-ethyl analog. The disparity is seen even more clearly in the chronoamperometry and n value data in Tables V and VI.

Other effects of the N-phenyl group upon the carbazole skeleton were detected in the electrochemcial behavior of No. LV-LXX. These are all N-(p-substituted) phenylcarbazoles with both the 3 and 6 carbabole ring positions open for coupling. Not surprisingly, then, it was found that the 3,3′-coupling mode dominates this series, as can be seen in Table VI; the bicarbazyls are generated in high yields and can be readily isolated following controlled-potential preparative-scale electrolyses (see Experimental section).

Two exceptions to this are the amino and dimethylamino derivatives, No. LV and LVI, whose anodic oxidation pathways are more characteristic of *para*-substituted anilines and N,N-dimethylanilines, respectively. In both cases, the carbazole skeleton functions as a rather inert substituent and HMO calculations show most of the electron density residing in the aminophenyl rings; thus, it is not surprising that 3,3′-coupling is not observed. The electrochemical behavior for these compounds appears to be similar to that discussed previously for carbazole derivatives with an amino or dimethylamino group *para* to the carbazole nitrogen, *i.e.*, the N-(p-dimethylaminophenyl) carbazole shows two reversible one-electron redox processes; the first leads to a stable cation radical and the second to a moderately stable quinonediimine form that slowly decomposes to a product other than a 3,3′-bicarbazyl. The amino derivative has an irreversible one-electron wave (the cation radical was, however, detected by rapid-sweep cyclic voltammetry), and it appears that again some sort of N-ring or N-N (amino nitrogen) coupled product is generated in a fashion similar to the other amino-substituted carbazoles.

Interestingly, if the amino group is deactivated by acetylation (No. LVIII) the redistribution of electron density is such that the radical reacts predominately via the 3,3′-coupling-deprotonation route.

Another exception to the 3,3′-coupling mode is the methylthio derivative, No. LVIX. This compound has a very unstable cation radical that decomposes to an unknown product, probably involving oxidation of the methylthio substituent. As can be seen in Table VI, the over-all process involves a one-electron transfer, but no radical species could be detected using EPR spectroscopy with *intra muros* electrochemical generation.

All of the other compounds in this series undergo an initial one-electron oxidation to generate a very reactive cation radical ($t_{1/2} << 1$ msec); two of these then couple at the 3 positions to yield a N,N′-bis(p-substituted phenyl)-3,3′-bicarbazyl. This species is then oxidized more easily than the corresponding carbazole to a stable dication, so over-all one has a classic two-electron ECE mechanism identical to that previously characterized for *para*-substituted triphenylamines (45). The reaction is quantitative and these systems are extremely "clean," as is seen in Fig. 7 for the t-butyl derivative. On the time scale of chronoamperometry or rotating disk experiments this reaction appears to be quantitative for all the derivatives studied with the exceptions mentioned above. This group thus constitutes an unusual series of organic molecules in that one has a single, quantitative homogeneous chemical reaction following the initial electron transfer process in a classic ECE pathway for a wide variety of substituents.

[c] Estimated from peak currents of cyclic voltammograms run on exhaustively electrolyzed solutions.
[d] Data are distorted by strong filming of the electrode surface.
[e] Cation radicals are very unstable ($t_{1/2} < 1$ msec); 6,6′-disubstituted-N,N′-diphenyl-3,3′-bicarbazyls are formed in all cases.
[f] Drifts slowly to n = 2.

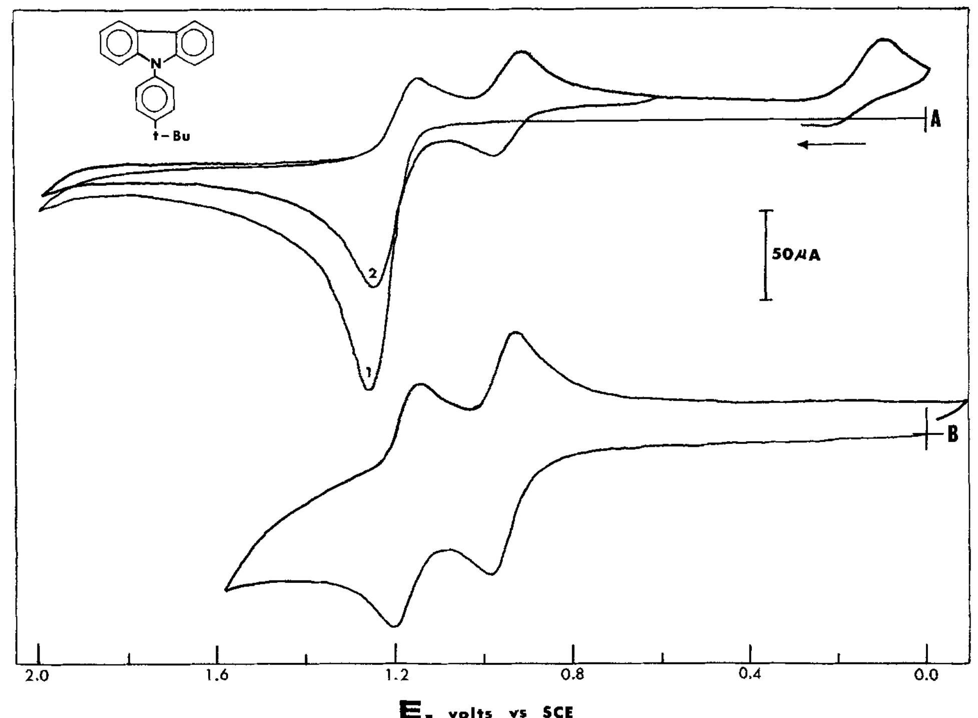

Fig. 7. Curve A: Cyclic voltammogram of 8.0 × $10^{-4}F$ N-(p-t-butylphenyl)carbazole in MeCN/TEAP, sweep rate = 100 mV/sec. Curve B: Cyclic voltammogram of the same solution following exhaustive electrolysis at 1.4V, sweep rate = 67 mV/sec.

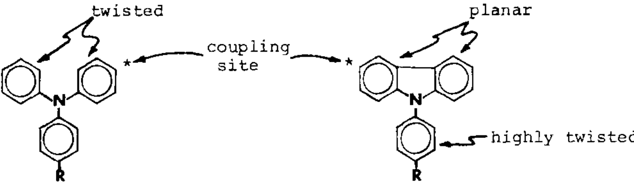
Unfortunately, the rate constants for the coupling reactions are extremely rapid and as such are difficult to measure. However, some preliminary data have been obtained from rotating disk experiments at very low (10^{-4} to $10^{-5}F$) parent concentrations and these numbers are presented in Table VII, along with similar data for a series of correspondingly substituted triphenylamines; these data provide some interesting comparisons concerning the reactivities of organic cation radicals as a function of geometry.

The basic difference between these compounds is that the carbazoles are planar across two rings while the triphenylamines have all three rings at angles to one another. Also, as mentioned, the substituted ring in the carbazole is highly twisted because of steric interaction with the 1 and 8 ring hydrogens



Thus, two effects are to be anticipated, namely that due to the planarity of the carbazole system and the attendant high electron density at the reactive sites (cf. the comparison of diphenylamine and carbazole HMO calculations) the coupling rates will be much faster than for the triphenylamines. Also, there will be a diminished substituent effect on the coupling rate constants for the carbazoles due to the lesser interaction of the substituted rings with the rest of the system. The much enhanced carbazole coupling rate constants can readily be seen even in the rough data in Table VII; greater reactivity for the carbazole systems relative to the corresponding triphenylamines is also predicted by HMO calculations.

Table VII. Comparative electrochemical and kinetic data for triphenylamine and carbazole derivatives

	Triphenylamine $E_{p/2}$, V	k^a	Carbazole $E_{p/2}$, V	k^a
R = OMe	0.76	$6 \pm 2 \times 10^{-1}$	1.19	$7 \pm 4 \times 10^5$
Me	0.87	$9.0 \pm 1.0 \times 10^1$	1.24	$8 \pm 4 \times 10^6$
C_6H_5	0.89	$6.0 \pm 0.6 \times 10^1$	1.24	
H	0.97	$1.2 \pm 0.4 \times 10^3$	1.24	$9 \pm 6 \times 10^7$
Cl	1.02	$6.5 \pm 1.3 \times 10^2$	1.28	
Br	1.02	$1.4 \pm 0.3 \times 10^3$	1.30	
NO_2	1.22	$1.4 \pm 0.4 \times 10^4$	1.36	

[a] Bimolecular coupling rate constant in mol^{-1} sec^{-1}.

The lessened substituent effects cannot be clearly seen in the rate constant data due to their uncertainties, but it is evident in the half-peak potential data; the change in $E_{p/2}$ going from OMe to NO_2 is considerably greater for the triphenylamines (0.46V) than for the carbazoles (0.17V). These data must be tempered with the facts that the triphenylamine values were taken from rotating disk curves and are for reversible processes, *i.e.*, there is no shift in the half-peak potentials with variation of the time gate due to associated homogeneous chemical reactions, whereas the carbazole data were obtained from linear scan voltammograms and the $E_{p/2}$ values are markedly affected by the associated chemical reactions and their attendant peak potential shifts. Still, it is felt that the data are qualitatively valid in indicating a substantial difference in substituent effects for the two series.

Conclusions.—The foregoing data allow us to formulate a series of "selection rules" for the various radical reaction pathways. It appears that in many organic systems there is a series of possible reaction pathways for the electrogenerated cation radicals, one being most favorable with the others then occurring in a given sequence as the molecular structure is changed by introduction of various substituents at different sites. The following selection rules apply to carbazole derivatives:

1. The cation radical of the parent molecule, carbazole, reacts by both 3,3′- and 9,9′-couplings, the former taking place in acidic unbuffered MeCN and the latter dominating in basic solution; the same applies for 3-substituted carbazoles with the exception of the amino and dimethylamino derivatives.

2. Blockage of the 9-nitrogen with alkyl or phenyl groups results in exclusive formation of 3,3′-bicarbazyls; the same holds true if the 3 position is substituted but the 6 carbon left open, as in the 3-substituted-N-ethylcarbazoles, again with the exception of the amino and dimethylamino compounds.

3. Substitution of the 3 and 6 sites with the 9 nitrogen left open results in unstable, but detectable, cation radicals which decompose by substituent elimination (I, Br, Cl) or (presumably) ring-ring coupling (OMe, t-Bu, OAc, CN, NO_2); the systems are poorly behaved. Electrolysis in basic MeCN leads smoothly in all cases to the 9,9'-bicarbazyls. Further substitution of the 1 and 8 ring positions protects the 9 nitrogen and leads to considerably more stable cation radicals.

4. Blockage of the 3, 6, and 9 sites, as in the 3,6-disubstituted-N-ethylcarbazoles, predictably yields quite stable cation radicals (relative to the other series of substituted carbazoles) since all the active coupling positions are substituted. Many of the derivatives react relatively slowly by as yet undetermined ring-ring coupling modes. A number of compounds in this series show unusual reactions through the 3 and 6 substituents such as alkyl coupling (Me, Et) and group elimination (I, COMe, COEt, COPh). Analogous N-phenyl derivatives appear to have more stable cation radicals because of enhanced delocalization and more efficient blockage of the 1 and 8 ring sites; an additional complication, however, is the possibility of coupling through the N-phenyl rings.

5. Compounds with NH_2 or NMe_2 groups (and presumably OR-type substituents) *para* to the carbazole nitrogen behave very much like p-phenylenediamine derivatives. The electron distributions in these compounds are changed so much that they no longer are characteristic of carbazole systems; thus, the cation radicals are quite stable relative to others in the same series and in the cases of the dimethylamino-substituted molecules reasonably stable dication diimines are generated by a second one-electron process. In all cases, the reaction pathways appear to be more representative of aniline-type molecules than of carbazoles.

Spectroscopic Studies

The spectroscopic studies were undertaken in order to obtain information concerning electron distributions in carbazole cation radicals and correlate these data with the chemical reactivities monitored electrochemically. In addition, it was deemed desirable to provide some basic spectral data on these types of radicals since little is available in the literature. It was hoped that optical spectra would provide an idea of the degree of delocalization of the unpaired electron in the cation radicals and the EPR spectra would give a concrete picture of electron distributions from coupling constant data. The data collected thus far, along with those from other sources, are generally consistent with the electrochemical studies in the previous sections.

Optical spectra.—Ledwith first reported optical data on the carbazole and N-methylcarbazole cation radicals (59), which were proposed to arise through charge-transfer interaction with tropylium tetrafluoborate and exhibited absorption maxima at 506 and 520 nm, respectively. N-isopropylcarbazole was also shown to form charge-transfer complexes with a number of acceptors (60), and it was subsequently claimed that the optical spectrum of the N-isopropylcarbazole cation radical had been obtained by electrolytic oxidation in MeCN (61). However, for the latter two studies the data reported correspond quite closely to optical and EPR spectra previously published for similar carbazole systems where assignments were made to oxidized forms of the corresponding 3,3'-bicarbazyls (7, 62), the optical spectra having two broad maxima positioned at roughly 400 and 800 nm. More recently, cation radical optical spectra for carbazole (63) and N-vinylcarbazole (64) have been reported, the former having an absorption maximum of 610 nm, the latter a series of bands ranging from 508-780 nm.

From this array of conflicting data and the electrochemical data in the previous sections of this paper, it is obvious that optical spectra of carbazole and its N-alkyl derivatives must be considered with caution. Although we have not as yet measured rate constants for the decomposition reactions of these radicals, it is clear from the electrochemical studies that their half-lives are, at best, in the microsecond region. As we have seen, though, by proper substitution these radicals can be stabilized and more reliable spectral data should then be obtainable. Thus, Neugebauer has reported λ_{max} values for 1,3,6,8-tetra-t-butylcarbazole cation radical with the primary absorption band being at 925 nm and lesser peaks at 583 and 547 nm (49). We have also obtained spectral data for a numbr of carbazole derivatives and these data, as shown in Table VIII, verify the fact that carbazole cation radicals have primary absorption bands in the 750-850 nm region, with the exception of the dimethylamino derivatives, which have absorption spectra more characteristic of p-substituted-N,N-dimethylanilines (65). It is noteworthy that these primary electronic transitions are at quite long wavelengths compared to other known cation radicals. Such facile transitions are suggestive of a very "loose" pi system in which there is extensive delocalization of the unpaired electron, assuming that these primary bands correspond to a transition of the unpaired electron from the highest filled to the lowest unfilled molecular orbitals.

In addition, these data cast considerable doubt on many of the previously reported λ_{max} values for the carbazole and N-alkylcarbazole cation radicals. From the absorption maxima shown in Table VIII for the series of 3,6-disubstituted-N-ethylcarbazoles, we feel that we can safely predict that the carbazole and N-alkylcarbazole cation radicals will have absorption maxima for the longest wavelength primary electronic transitions in the 750-790 nm region (58). This assertion will be expanded upon and reported in full in the near future.

EPR studies.—The degree of delocalization can be more quantitatively ascertained from EPR coupling constants, since these latter parameters are generally analogous to unpaired electron densities at the various atoms in a cation radical.

We have obtained moderately well-resolved EPR spectra for all of the radicals shown in Table VIII, but interpretations at this time have not been realized. Neugebauer has, however, obtained interpreted EPR spectra for the substituted carbazole radicals shown below (49, 66), and these can be used as indicators of the degree and direction of delocalization in the carbazole nucleus. These molecules are particularly well suited, since the alkyl substituents will not perturb the

Table VIII. Wavelengths of principal absorption bands of carbazole cation radicals

electron distribution greatly relative to the parent carbazole nucleus

$a_N = 6.89G$ $a_{H(NH)} = 8.09G$ $a_N = 6.6G$
$a_{H1} = 3.84G$ $a_{H2} = 0.80G$ $a_{H(NH)} = 7.8G$
$a_{H4} = 0.80G$ $a_{H(CH3)} = 6.57G$ $a_{H1} = 3.4G$

These coupling constants correlate nicely with the qualitative reactivity data determined electrochemically in showing that large spin densities exist at the central nitrogen and the ring positions *ortho* and *para* to it (the 1,3,6,8 sites). Thus, these are shown quantitatively to be the centers of reactivity in these molecules and so the relatively short radical lifetimes encountered are not unexpected with so many active sites.

The rather large coupling constant for the methyl groups in 3,6-dimethylcarbazole is also consistent with the proposal of alkyl coupling through the substituent groups in No. XIV, XLI, and XLII, since the alkyl group deprotonation is contingent upon a high unpaired electron spin density at the benzylic position.

The spectra of the 3-dimethylamino derivatives (No. II and XII) have not been fully interpreted, but it is apparent that the coupling constant pattern is much more like that of *p*-substituted-N,N-dimethylanilines than substituted carbazoles in showing large spin densities on the dimethylamino group and the ring positions *ortho* and *para* to it and virtually none in the unsubstituted ring. Again, this is compatible with the electrochemical data.

Acknowledgments

We are indebted to the Petroleum Research Fund (Grant No. 1039-G3) and the National Science Foundation (Grant No. GP-20606) for financial support of this work. A substantial portion of this study was done at Sacramento State College, and we are grateful for the use of facilities there. Samples of various carbazoles were kindly donated by Southern Dyestuffs Company, Charlotte, North Carolina, Dr. N. P. Buu-Hoi of the Institute for the Chemistry of Natural Substances in Gifsur-Yvette, France, and Dr. Franz Neugebauer of the Max-Planck Institute in Heidelberg, Germany. Technical assistance by Larry Line, Sam Creason, and Kurtz Carpenter proved to be invaluable. Special thanks are also due to Drs. R. N. Adams and D. E. Smith for their support and encouragement.

This work was extracted in part from the M.S. thesis of one of the authors (J.F.A.) at Sacramento State College (1968).

Manuscript submitted Aug. 22, 1974; revised manuscript received March 17, 1975. This was Paper 145, presented at the New York, New York, Meeting of the Society, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by the Petroleum Research Fund.

Electrohydrodimerization Reactions

V. Liquid Ammonia as a Solvent for Reductive Coupling of Diethyl Fumarate, Cinnamonitrile, and Acrylonitrile

Iuliana Vartires,[1] Wayne H. Smith, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Cyclic voltammetric (CV) and controlled potential coulometric investigations of the reduction of several activated olefins in anhydrous liquid ammonia containing either 0.1*M* methyl-tri-n-butylammonium iodide or 0.1*M* potassium iodide as supporting electrolytes are reported. For diethyl fumarate and cinnamonitrile the studies provide evidence for formation of a radical anion, which undergoes dimerization and polymerization reactions, and of dianion formation at more negative potentials. The effect of adding isopropanol and glacial acetic acid was also investigated.

The reduction of activated olefins in aprotic media has been the subject of numerous investigations [see (1, 2) and references therein]. Diactivated olefins (R) react via formation of the radical anion and produce, depending upon the acidity of the medium, hydrodimer (R_2H_2), reduced monomer (RH_2), and polymer. At more negative potentials, where dianion is produced, extensive polymerization apparently occurs, so that the second reduction waves observed in voltammetry are frequently much smaller than the first waves. We have previously shown that anhydrous liquid ammonia is a useful medium for studies of the electroreduction of organic compounds (3, 4) and that stable dianions of benzophenone and nitrobenzene could be prepared in this solvent. This stability of radical anions and dianions in ammonia can be attributed to the low acidity of the solvent, the possibility of preparing highly pure solutions through the use of vacuum line techniques and solvent treatment with sodium, and the fact that these studies are carried out at low temperatures, decreasing the rate of homogeneous chemical reactions following the electron transfer steps. Previous studies of amalgam reductions leading to hydrodimerization in liquid ammonia have also been described (5). In this paper we describe preliminary cyclic voltammetric and coulometric experiments on the reduction of several activated olefins in liquid ammonia; the structures of the substances studied are shown below

$$R_1(H)C{=}C(H)R_2$$

Diethyl fumarate (DEF) $R_1 = R_2 = -C(=O)-O-CH_2CH_3$

Cinnamonitrile (CN) $R_1 = -C_6H_5 \quad R_2 = -CN$

Acrylonitrile $R_1 = H \quad R_2 = -CN$

Key words: cyclic voltammetry, coulometry, electrochemical dimerizations, organic electrochemistry.

Experimental

General experimental techniques were the same as those reported previously (2-4); a detailed description is available (6). The four-compartment cell, containing separate chambers for the working, reference, and auxiliary electrodes, and an intermediate chamber between the working and auxiliary compartments was employed. A gold working microelectrode, polished with AB ALPHA polishing alumina (Buehler Limited, Evanston, Illinois) before each experiment, was employed in cyclic voltammetric experiments and a 3 cm by 8 cm platinum electrode was used in coulometry. A silver wire (Ag. R.E.) isolated in a separate compartment closed with a sintered-glass disk was used as reference electrode. All experiments were carried out with a Princeton Applied Research Corporation Model 170 electrochemistry system using positive feedback resistance compensation. All experiments were conducted on a high vacuum line (10^{-5} Torr) at $-43°C$.

Results and Discussion

Diethyl fumarate.—The cyclic voltammetric (CV) reduction of DEF in DMF solution shows a fairly reversible first reduction wave at fast scan rates and has been characterized by reversible reduction to the radical anion followed by a coupling reaction (2). The second reduction wave is very small or even characterized by a current decrease in polarography or RDE voltammetry, which has been ascribed to production of the dianion which initiates a rapid polymerization reaction removing parent from the vicinity of the electrode. In liquid ammonia, the CV reduction occurs in two reversible waves at fast scan rates (Fig. 1a) with the reversal wave heights decreasing at slower scan rates (Fig. 1b) indicating decomposition reactions of the electrogenerated species. Typical data for CV experiments for DEF are shown in Table I. The theory of CV for electrode reactions with following dimerization reactions has been presented (7, 8); application of this theory in estimating the rate constant for the dimerization step from the variation of i_{pa}/i_{pc} for the first reduction wave yields a value of about 0.1 M^{-1} sec^{-1}.

[a] Solution contained indicated supporting electrolyte in anhydrous liquid ammonia.
[b] *vs.* Ag-wire reference electrode.
[c] Second reduction wave and reversal waves were to ill-defined for precise current measurements.

The addition of alkali metal ions has been shown to increase the rate of the coupling reaction in DMF, probably by formation of ion pairs with the radical anions (2). The CV reduction of DEF is similarly affected by the addition of KI in liquid ammonia (Fig. 1c), although the kinetics of the reactions were not studied in this case. The addition of a threefold excess of a proton donor, either the weak acid, isopropanol (i-PrOH), or the strong acid, acetic acid (HOAc) to the DEF/MTBAI/NH_3 system has essentially no effect on the first reduction wave, but decreases the reversal current of the second wave and shifts the second wave to more positive potentials. The extent of the shift increases linearly with the log of the proton donor concentration; for acetic acid $\Delta E_p/\Delta \log[\text{HOAc}] = 39$ mV; and for i-PrOH, $\Delta E_p/\Delta \log[\text{i-PrOH}] = 57$ mV. These results suggest that protonation of the radical anion species does not occur, even with the strong acid HOAc, while the dianion reacts with acid. This scheme is reminiscent of that found with benzophenone (3), and the CV reaction order treatment of Savéant and Vianello (8) probably applies here as well. From the limiting slopes of the peak shift with log proton donor concentration we find a reaction order of dianion (m) and proton donor (m_Z) of 0.5 and 1.9, respectively, for i-PrOH and 0.4 and 1.2 for HOAc. This half-order dependence on dianion is the same as that observed for benzophenone dianion and probably indicates kinetic complications in the electron transfer reaction or interferences due to the dianion polymerization reaction.

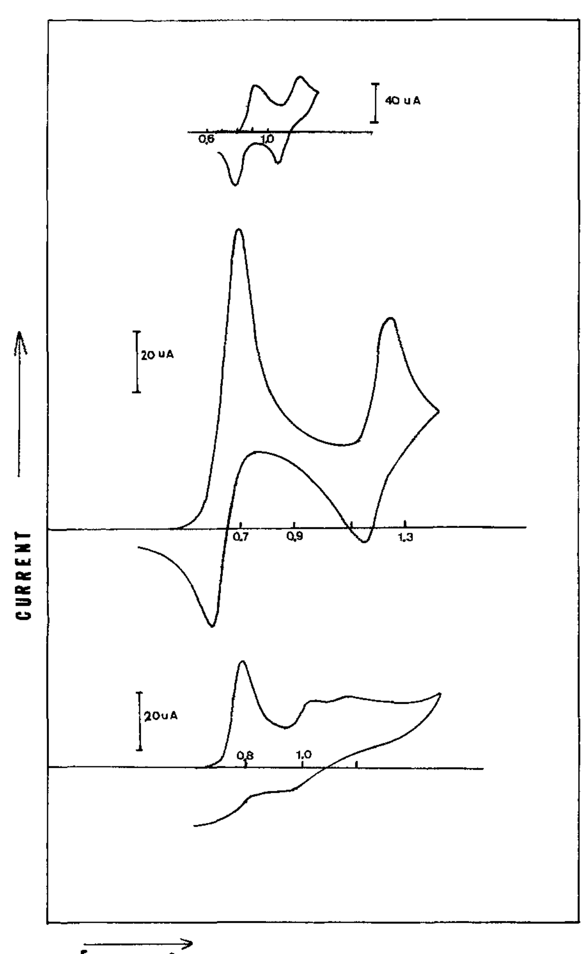

Fig. 1. Cyclic voltammograms of diethyl fumarate in liquid ammonia: (a) 1.75 mM DEF, 0.1*M* MTBAI, $v = 20$ V/sec; (b) 3 mM DEF, 0.1*M* MTBAI, $v = 0.2$ V/sec; (c) 3.5 mM DEF, 0.1*M* KI, $v = 0.2$ V/sec.

Controlled potential coulometry of DEF in the presence of either MTBAI or KI as supporting electrolyte (Table II) at potentials beyond the first reduction peak show n_{app} values less than one, even in the presence of proton donor. This result suggests, as do the similarly low values of n_{app} in DMF, that a slow polymerization reaction of the radical anion occurs on the coulometric time scale. CV experiments after coulo-

Table II. Controlled potential coulometry results

Compound	Concentration (mM)	Conditions	n_{app}
DEF	4.3	0.1*M* MTBAI	0.6
	10	0.1*M* MTBAI	0.5
	20	0.1*M* MTBAI + 40 mM i-PrOH	0.5
DEF	7	0.1*M* KI	0.4
DEF	3	0.1*M* KI + 14 mM HOAc	0.5
CN	10.4	0.1*M* MTBAI	0.16
	13.6	0.1*M* MTBAI	0.04
CN	20	0.1*M* MTBAI + 40 mM i-PrOH	0.27
AN	3	0.1*M* MTBAI	0.05
	14	0.1*M* MTBAI	0.17
AN	10	0.1*M* KI + 10 mM i-PrOH	0.96
AN	20	0.1*M* KI + 20 mM i-PrOH	0.88
AN	20	0.1*M* KI + 10 mM HOAc	2

metric reduction showed no reduction or oxidation peaks.

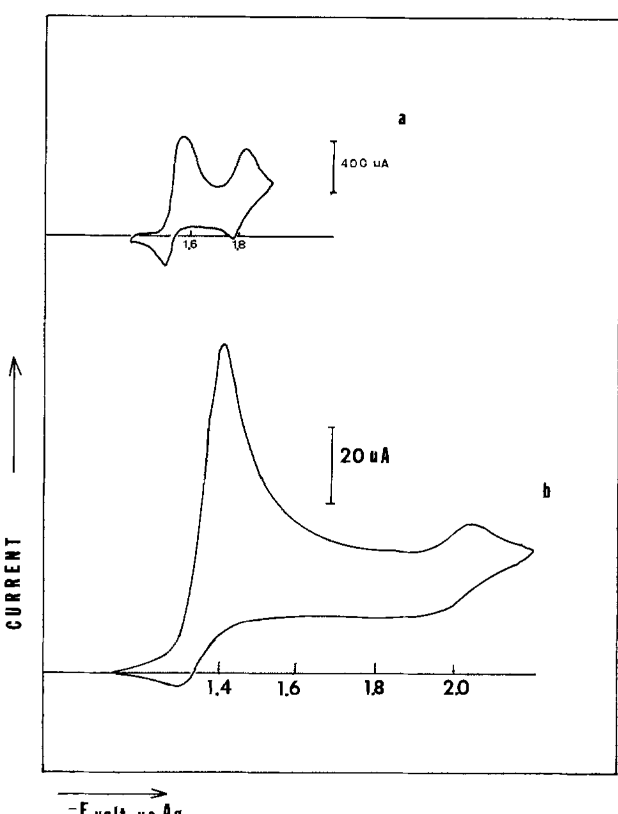

Fig. 2. Cyclic voltammograms of 3.2 mM cinnamonitrile in liquid ammonia containing 0.1M MTBAI with a v of (a) 20 and (b) 0.2 V/sec.

Cinnamonitrile.—The CV reduction of CN at high scan rates (Fig. 2) also shows two reduction waves with appreciable anodic currents on reversal. Typical CV data for CN are shown in Table III. At slower scan rates the second reduction peak decreases in size and the reversal currents decrease. For CN, as opposed to DEF, the value of $i_p/v^{1/2}C$ decreases significantly with increasing concentration of CN, suggesting that the polymerization reaction of the radical anion is important, even on the CV time scale. Treatment of the i_{pa}/i_{pc} data for the first reduction wave, assuming a following coupling reaction of the radical anion, yields a dimerization rate constant of about 5.7 M^{-1} sec^{-1}. The CV behavior in the presence of proton donor resembles that of DEF: the first wave is unaffected by additions of i-PrOH or HOAc, while the second wave is shifted to more positive potentials. The limiting E_p *vs.* log proton donor concentration plots for the second wave yield reaction orders m and m_Z of 0.4 and 2, respectively, for i-PrOH and 0.7 and 1 for HOAc. Controlled potential coulometry of CN (Table II) in the absence of proton donor or with i-PrOH showed very low n_{app} values suggesting abundant polymerization.

Acrylonitrile.—The CV reduction of AN at all scan rates up to 20 V/sec in both MTBAI and KI electrolytes occurs in a single irreversible wave (Fig. 3); typical CV data are shown in Table IV. The very low $i_p/v^{1/2}C$ values observed with MTBAI as electrolyte are evidence of a very rapid polymerization of AN, as is also observed in aprotic solvents in the absence of proton donor. In the KI electrolyte however the $i_p/v^{1/2}C$ values are larger and closer to those of DEF and CN. Controlled potential coulometric reduction of AN (Table II) also shows evidence of polymerization in MTBAI. In a KI + i-PrOH medium, however, n_{app} values close to one are obtained, suggesting significant formation of the hydrodimer product. Product analysis

of these solutions by gas chromatography was attempted, but unambiguous analyses were not obtained. The addition of HOAc yields n_{app} values near 2, probably signalling the production of some of the two-electron protonated product, propionitrile, in the presence of strong acid.

The preliminary results show the formation of radical anions and dianions of the diactivated olefins DEF and CN and suggest that with the addition of suitable amounts of proton donor, hydrodimerization reactions can be carried out in liquid ammonia. After this paper was submitted, a communication by Chiba *et al.* (9) appeared, in which the electrolytic reduction of acrylonitrile in liquid ammonia containing ammonium perchlorate as supporting electrolyte at a mercury cathode was described. These authors found a high yield of adiponitrile with some formation of propionitrile under these conditions with constant current electrolysis.

ABSTRACT

Electrochemical oxidation of iminobibenzyl and several related compounds has been investigated in acetonitrile. The mechanism of the oxidation is best described by an ECE process with coupling of the product of an initial one-electron oxidation in a subsequent but very fast reaction to form a dimeric compound that is further oxidized by an over-all two-electron process at potentials more negative than those required for oxidation of the parent compounds. The electrochemistry of these compounds is complicated by the release of protons during the oxidation which protonate the starting materials and the neutral dimerized products rendering them electrochemically inactive. Differences in the electrochemistries of the various coupled products are discussed in terms of structural variations.

In recent years considerable effort has been expended in elucidating the mechanisms of electrolytic oxidation of heterocyclic nitrogen and amine compounds as well as other nitrogen containing species. [See Ref. (1) and (2) for reviews of the work in this area.] One of the prominent characteristics of aromatic amines is oxidative coupling to form a variety of dimerized derivatives of the original parent compounds. Certain heterocyclic nitrogen compounds such as carbazole which may be considered as being derived from diphenylamine also undergo a similar coupling process on oxidation (3).

The present investigation was initially undertaken to compare the electrochemistry of imipramine hydrochloride, a widely prescribed antidepressant drug, with the electrochemical behavior of the structurally similar but physiologically less active iminobibenzyl and 5-methyliminobibenzyl. We also felt it worthwhile to compare the electrochemistry of these compounds with that of the related carbazoles (I) whose primary structural difference with the above compounds is the nature of the biphenyl linkage.

The homogeneous oxidation of most of the present compounds along with a number of carbazoles with chemical oxidants (*e.g.*, 2,3-dichloro-5,6-dicyano-p-benzoquinone) has shown recently (4) that all of the compounds undergo oxidative coupling with ultimate formation of the cation radical salt of the coupled product. The electrochemical coupling of the carbazoles has been previously investigated by Ambrose and Nelson (3) who showed that the neutral coupled products can be oxidized to corresponding cation radicals and dications at potentials negative of those for the oxidation of the parent compounds. The electrochemical behavior of the carbazoles was consistent with an ECE mechanism with oxidative peak heights of the potential sweep voltammograms being twice those expected for a 1-electron process (3). Controlled potential electrolysis also gave an n value of 2. Ambrose and Nelson (3) proposed the following mechanism for the oxidative coupling of the carbazoles (3).

$$RH - e \leftrightarrows RH^{+\cdot} \quad [1]$$

$$2RH^{+\cdot} \xrightarrow{k_1} R_2 + 2H^+ \quad [2]$$

$$R_2 - e \leftrightarrows R_2^{+\cdot} \quad [3]$$

$$R_2^{+\cdot} - e \leftrightarrows R_2^{2+} \quad [4]$$

* Electrochemical Society Active Member.

Key words: cyclic voltammetry, coulometry, oxidative coupling, imipramine, 5-methyliminostilbene.

The chemical reaction in Eq. [2] is undoubtedly very rapid, since under no circumstances was it possible to observe the reduction of the radical cation of the oxidized parent ($RH^{+\cdot}$). In neither study (3, 4) were the investigators able to determine if the protons are lost before or after coupling.

We report here the electrochemical oxidation of iminobibenzyl (**II**), 5-methyliminobibenzyl (**III**), imipramine·$HClO_4$ (**IV**) and 5-methyliminostilbene (**V**), and the electrochemical behavior of the products of the oxidation

Experimental

The preparation of the compounds used in this study has been described (4). Tetrabutylammonium perchlorate (TBAP), the supporting electrolyte in all experiments, was of polarographic grade and purchased from Southwestern Analytical Chemicals. The TBAP which is contaminated with water was dried under vacuum at about 100°C for 24 hr. All other chemicals were of reagent grade quality and used without further purification.

Acetonitrile used as the solvent in these experiments was prepared from spectrograde acetonitrile by vacuum distillation from P_2O_5 at room temperature. The distillation was repeated at least three times with periodic freeze-pump-thawing to remove air.

Table I. $i_p/Cv^{1/2}$ ratios and oxidation and reduction peak potentials for parent and product of the oxidation of parent

Compound	$i_p/Cv^{1/2}$ [a] Parent	E_p ox[b] Parent	E_p ox[b] Product	E_p red[b] Product
Carbazole[3]		+0.86	0.86, 0.56	0.8, 0.5
Iminobibenzyl	17.9	+0.48	0.42, 0.24	0.36, 0.18
5-Methyliminobibenzyl	18.3	+0.61	0.48	0.40
Imipramine $HClO_4$[c]	17.7	+0.75	0.61	0.55
5-Methyliminostilbene	17.9	+0.58	−0.27	−0.30
10-Methylphenothiazene[d]	16.1			

[a] i_p in μA, C in mM, v in V/sec. Within experimental error the $i_p/Cv^{1/2}$ values were independent of sweep rate between 0.2 and 10 V/sec.
[b] Sweep rate = 0.2 V/sec. E_p *vs.* Ag/0.1M $AgNO_3$.
[c] Imipramine hydrochloride was converted to the perchlorate by passing an aqueous solution through an anion exchange column in the perchlorate form and freeze drying the eluent.
[d] A standard one-electron oxidant of similar geometric size to the compounds under investigation. Due to the similarity in size the diffusion coefficients should be nearly the same for all compounds.

The cell used in this study for coulometric and electrochemical characterizations was of conventional design (5). The working electrode for coulometry was a platinum gauze. The working electrode for cyclic voltammetry was a small platinum disk electrode sealed in glass (~0.013 cm^2) and was polished before each use with 0.5μ alumina polishing powder. The auxiliary electrode was a platinum wire and the reference electrode a silver wire which for certain experiments was in contact with a solution of 0.1M $AgNO_3$ in acetonitrile; the potential of this electrode was +0.333V *vs.* an aqueous SCE. All potentials are reported *vs.* this Ag/Ag^+ electrode.

All electrochemical experiments were carried out under an inert helium atmosphere in a Vacuum/Atmospheres Corporation (Hawthorne, California) dry box. A PAR Model 170 electrochemical system (Princeton Applied Research Corporation, Princeton, New Jersey) was used for the electrochemical experiments.

Infrared measurements were made with a Beckman Model IR5A spectrophotometer (KBr pellets). Mass spectra were obtained on a Bell & Howell Model 21-491 low resolution mass spectrometer.

Results

Iminobibenzyl.—At a voltammetric sweep rate of 0.2 V/sec iminobibenzyl shows an oxidation wave with E_{pa} at +0.48V *vs.* the Ag/0.1M Ag^+ electrode. The height of this peak corresponded to that for a one-electron process by calibration against the peak height for the known one-electron oxidation of 10-methylphenothiazene (Table I). This result contrasts with the two-electron peak height previously observed for the carbazoles (3). On sweep reversal two reduction peaks were observed with E_{pc}'s at +0.36 and +0.18V (Fig. 1). Upon repeated cycling two new oxidation peaks were evident at +0.42 and +0.24V. The peak potentials for iminobibenzyl and the other compounds in this study are summarized in Table I.

Table II. Coulometric n_{app} values for parent compounds and the products of a controlled potential oxidation of the parent compounds

Compound[a]	n_{app} ox Parent	n_{app} red Product	n_{app} ox of red product	n_{app} red of H^+
Iminobibenzyl	2.02	0.96	0.94	0.95
5-Methyliminobibenzyl[b]	1.0	0.5	0.5	0.5
	2.2	0.93	0.9	0.98
Imipramine $HClO_4$	0.92	0.45	0.44	1.5
5-Methyliminostilbene	0.95	0.45	0.43	0.47

[a] The concentration of compound ~1 mM in all coulometric experiments.
[b] The two values listed correspond to the two breaks observed in the Q-t curve.

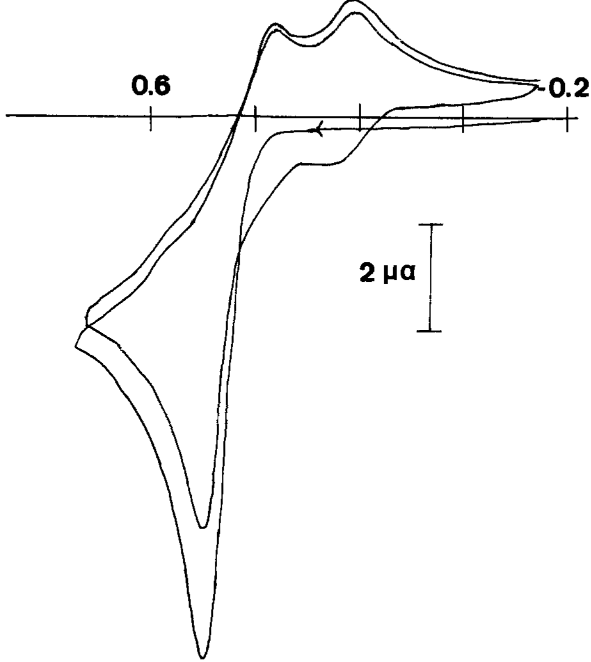

Fig. 1. Cyclic voltammogram of 1.25 mM iminobibenzyl. Conditions: sweep rate = 0.2 V/sec; 0.1M TBAP supporting electrolyte; X-axis is E, V, *vs.* Ag/0.1M Ag^+ reference electrode.

Controlled potential electrolysis at +0.85V gave an n_{app} value of 2 (where n_{app} represents the coulombs of electricity per mole of electroactive compound) (Table II) which is twice the value indicated by the voltammetry results. The oxidized solution had an intense blue color. Cyclic voltammetry of the solution following oxidation showed a redox couple centered at about +0.5V (Fig. 2) and a hydrogen ion reduction wave commencing at about −0.5V. Controlled potential coulometry of this solution indicated that the product of the initial oxidation could be reduced (at E = +0.2V) and then reoxidized again (at E = +0.85V) with an n_{app} = 1. Controlled potential reduction at −1.3V (following the oxidation at +0.85V) showed the release of one H^+ per parent molecule oxidized (*i.e.*, n_{app} = 1.0) during the initial oxidation at +0.85V. After the reduction of the protons only the two redox couples observed after repeated cycling of a solution of unoxidized parent were present (Fig. 3). There was no evidence of any

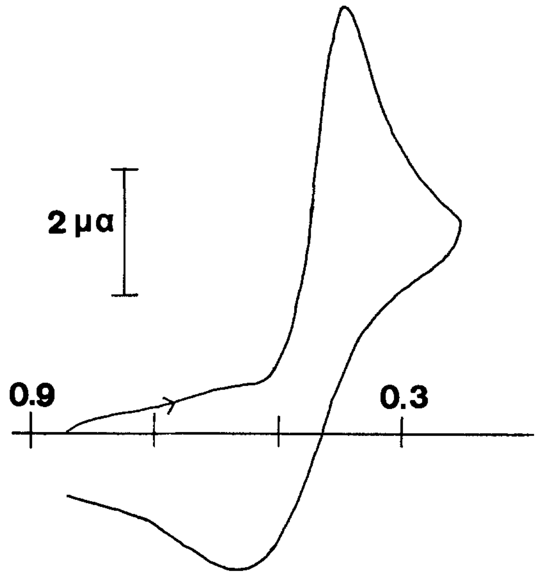

Fig. 2. Cyclic voltammogram of 1.25 mM iminobibenzyl after oxidative electrolysis at +0.85V. Conditions: Same as Fig. 1.

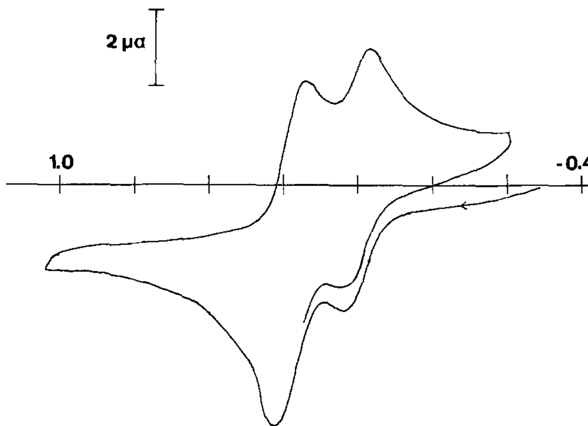

Fig. 3. Cyclic voltammogram of 1.25 mM iminobibenzyl following electrolysis at +0.85 and at −1.3V. Conditions: Same as Fig. 1.

remaining parent or the couple observed at +0.5V following the initial oxidation at +0.85V. The separation between E_{pa} and E_{pc} for each couple was 60 mV and indicates that each couple corresponds to a one-electron process. Coulometry demonstrated that a total of one electron was necessary to oxidize and then reduce both couples. In the absence of protons the product of the oxidation of parent at +0.85V behaved electrochemically in an entirely analogous manner to the carbazole products where two one-electron couples were also seen. In fact, except for the anomalous voltammetric peak height observed for the parent and the electrochemical behavior of the product of the oxidation of iminobibenzyl in the presence of protons, the electrochemistry is similar to that for the carbazoles. It seems likely therefore that a similar mechanism is operative in the case of iminobibenzyl with ultimate formation of a product (**VI**) which, by analogy with homogenous studies (4), probably arises by coupling at the 2-position

VI

The rate of the coupling reaction is fast because no evidence was obtained for reduction of the parent radical cation during the voltammetry experiments.

In order to confirm that **VI** is indeed the major product of the oxidation at +0.85V, an attempt was made to isolate the neutral analog of **VI** prepared by a controlled potential reduction of a solution of **VI**. At the relatively high solution concentrations necessary to isolate a reasonable quantity of material (≧ 20 mM), the electrochemistry of iminobibenzyl was not as clean as observed at lower concentrations (~ 1 mM). This is probably because of precipitation of the electrolysis products onto the working electrode. At these concentrations it was not possible to carry the oxidations or reductions to theoretical completion before the electrolysis currents decayed to very small values. The solutions that resulted upon reduction of an oxidized solution of iminobibenzyl contained significant quantities of unreduced material as indicated by an intense bluish-green color. Removing the acetonitrile solvent after reduction on a vacuum line followed by dissolution of the solid in benzene to separate the neutral from most of the charged products and extraction of the benzene solution with water to remove most of the remaining charged species resulted on freeze-drying in a brown solid with a slight violet tinge. Infrared spectra of this material showed a strong absorption at 805 cm^{-1}. This is the same absorption expected for the iminobibenzyl dimer with coupling at the 2-position (4). The parent peak of a mass spectrum of this compound occurred at a molecular weight of 388 the same as the bibenzyl dimer. The mass spectrum also indicated the presence of minor amounts of higher molecular weight materials.

Possible complications due to the presence of H^+ that may explain the anomalous behavior of the coupled product and one electron peak height of the parent will be discussed later.

5-Methyliminobibenzyl.—Investigations of the homogeneous oxidation of 5-methyliminobibenzyl have demonstrated a similar coupling process as was found for iminobibenzyl with coupling also taking place at the 2-position (4). In view of this and the strong supporting evidence presented above demonstrating that the homogeneous and electrochemical oxidations of iminobibenzyl result in the same reaction product, it is assumed that the product of the electrolytic oxidation of 5-methyliminobibenzyl is structurally similar to **VI**.

5-Methyliminobibenzyl also had a voltammetric peak height on oxidation the same as that expected for a 1-electron process (See Table I). On sweep reversal, a reduction peak approximately one-half the height of the oxidation peak was observed (Fig. 4). The ratio of the two peak heights was independent of sweep rate up to 10 V/sec. At a sweep rate of 0.2 V/sec E_{pa} and E_{pc} were 0.61 and 0.40V, respectively. If cycling was continued, a new oxidation peak develops at about +0.48V.

A number of controlled potential electrolysis experiments were performed with 5-methyliminobibenzyl. *Q-t* curves for electrolysis at +0.8V showed a sharp break at an n_{app} value of 1. The oxidized solutions were an intense blue color. The slope of the *Q-t* curves after this break was small but definitely larger than the slope usually found after complete electrolysis. On continuing the electrolysis, another break in the *Q-t* curves was observed at an n_{app} value of 2-2.2. If the electrolysis was stopped after the first break ($n = 1$) and a cyclic voltammogram obtained, a redox couple was seen centered at +0.44V (Fig. 5). There was no evidence for the original peak at +0.61V. When the scan was continued to negative enough potentials, a number of irreversible and distorted peaks corresponding to proton reduction was seen between −0.3 and −1.2V. When the electrolysis was continued until $n_{app} = 2$, cyclic voltammetry (with the initial potential at the potential of the electrolysis) showed only the reduction peak at +0.4V. There were no oxidation peaks at +0.48 or 0.61V. Stopping the electrolysis at +0.8V at any stage and electrolyzing at

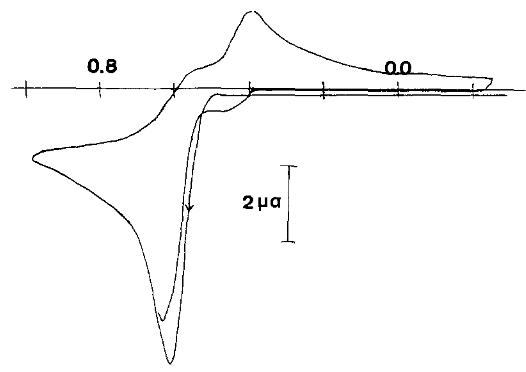

Fig. 4. Cyclic voltammogram of 0.85 mM 5-methyliminobibenzyl. Conditions: Same as in Fig. 1.

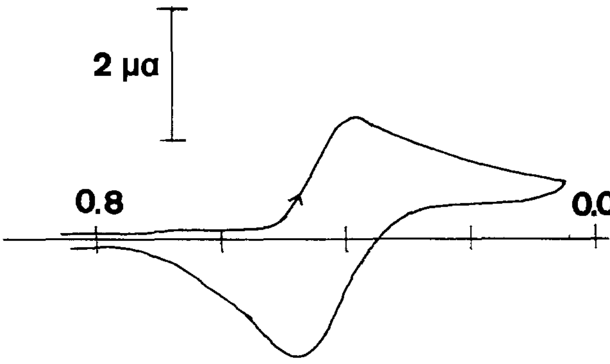

Fig. 5. Cyclic voltammogram of 0.85 mM 5-methyliminobibenzyl after one electron of electrolysis at +0.8V. After two electrons of electrolysis the oxidation peak is not observed. Conditions: Same as in Fig. 1.

+0.2V always resulted in half of the number of coulombs for reduction as had been passed during oxidation at +0.8V. The number of electrons obtained in reduction at −1.3V after electrolysis at +0.2V was the same as the number that had been obtained at +0.2V. Cyclic voltammetry following this reduction at −1.3V showed oxidation waves at +0.48 and +0.61V (Fig. 6), unless a complete electrolysis had been carried out at +0.8V ($n_{app} = 2$) at which time the +0.61V peak was absent.

A mechanism consistent with the above results is

$$RH - e \rightleftarrows \overset{+}{RH}\cdot \quad [5]$$

$$2\overset{+}{RH}\cdot + 2RH \rightarrow R_2 + 2RH_2^+ \quad [6]$$

$$R_2 - e \rightleftarrows \overset{+}{R_2}\cdot - e \leftrightarrows R_2^{+2} \quad [7]$$

$$RH_2^+ \overset{K_1}{\rightleftarrows} RH + H^+ \quad [8]$$

$$R_2 + H^+ \overset{K_2}{\rightleftarrows} R_2H^+ \quad [9]$$

and/or

$$R_2 + 2H^+ \overset{K_2'}{\rightleftarrows} R_2H_2^{+2} \quad [10]$$

Equation [6] above implies no mechanistic interpretation since it cannot be ascertained whether coupling occurs before or after loss of a proton from the cation radical. The proposed mechanism is the same as that for carbazole except for the protonations of the neutral parent and coupled product. The chemical reactions in Eq. [6] are undoubtedly very rapid as demonstrated by the absence of a reverse reduction peak accompanying the oxidation peak at +0.61V. The reduction peak at +0.40V and the oxidation peak at +0.48V correspond to the redox processes of Eq. [7]. Both redox processes occur at similar potentials since only one peak is observed. The apparent total one-electron oxidation of the 5-methyl parent plus coupled product; whereas two would be expected by analogy to carbazole, comes about because of the protonation of the parent molecule in Eq. [6] which renders the parent molecule electrochemically inactive. By the time half the parent has become oxidized the remaining parent is protonated. The small residual slope of the Q-t curves after one electron of oxidation is due to the oxidation of the small amount of parent that can remain in equilibrium with protons and protonated parent, Eq. [8]. If the resulting dication is now reduced, the neutral dimer itself can be protonated and rendered inactive to oxidation, Eq. [9]. This mechanism is consistent with the fact that 5-methyliminobibenzyl is a stronger base than the related carbazoles (*vide infra*) where protonation of parent introduced no complications.

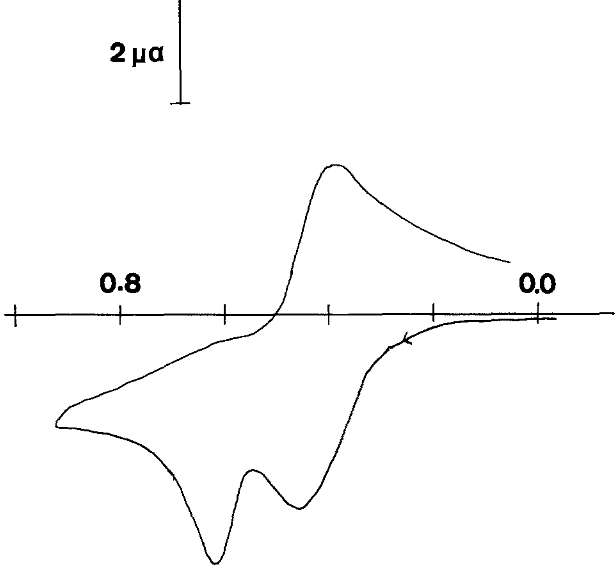

Fig. 6. Cyclic voltammogram of 0.85 mM 5-methyliminobibenzyl after one electron of electrolysis at +0.8V followed by electrolysis at −1.3V. After two electrons of electrolysis, the oxidation peak at 0.61V is not observed. Conditions: Same as in Fig. 1.

In an attempt to verify the role of protons, several experiments were carried out in the presence of the nucleophile pyridine in the hope of scavenging protons. When a large excess of pyridine was present (>10:1), cyclic voltammograms indicated that two electrons were transferred. Controlled potential electrolysis, however, showed that eventually in excess of four electrons were transferred. Pyridine apparently attacks the dication dimer forming a species that is oxidized further. The rate of the attack cannot be too rapid or else the voltammetry and electrolysis would have indicated the same number of electrons. Cyclic voltammetry showed no evidence of the couple at +0.44 following an oxidation with a large excess of pyridine. Also, the solution did not attain the intense blue color found after electrolysis performed without pyridine. If the electrolysis was carried out until the first break in the Q-t curves with a somewhat less than stoichiometric amount of pyridine followed by a reductive electrolysis at +0.2, the yield of the neutral dimerized product was 30% greater than was found in the absence of pyridine (n_{app} = 0.65 *vs.* 0.5, the time of the oxidative electrolysis was about the same). Some proton scavenging is apparently taking place. Interestingly, pyridine acted only as a proton scavenger in the electrolysis of carbazoles (3).

Experiments were also performed with added acid. According to the proposed mechanism, the acid should protonate the parent and no oxidation should be observed. Addition of equivalent amounts of acetic acid resulted in no change in the electrochemical behavior. However, when acetic acid was in large excess (100:1), the peak height of the +0.61V oxidation was somewhat diminished. At these concentrations of acetic acid a new smaller peak approximately 100 mV positive of the main oxidation appeared. With equivalent amounts of H_2SO_4, the +0.61V peak was absent and the new peak at ∼ +0.7V attained its maximum development, about one-third the peak height of the original oxidation. Further addition of H_2SO_4 resulted in the disappearance of this peak also. The results suggest that acetic acid is too weak an acid to protonate the 5-methyliminobibenzyl parent. Blank experiments where only supporting electrolyte and acid were present showed oxidative currents in the region of the peak observed above at +0.7V. These currents are probably due to added impurities such as water which undergoes a pH dependent oxidation in this region.

Imipramine · $HClO_4$.—A number of electrochemical experiments were also performed on the $HClO_4$ salt of

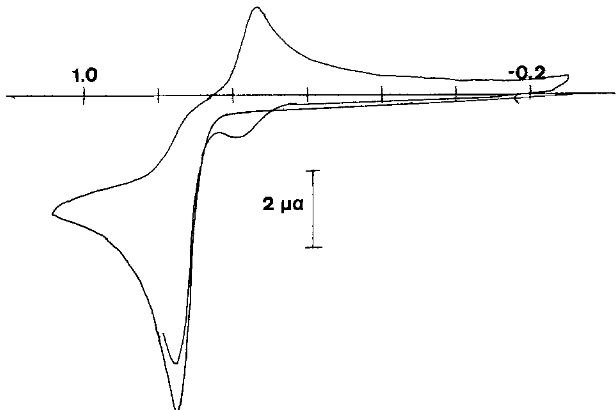

Fig. 7. Cyclic voltammogram of 1.0 mM imipramine $HClO_4$. Conditions: Same as in Fig. 1.

imipramine. After reduction of the proton of the tertiary amine group, the tertiary amine probably serves as a base for scavenging protons. The electrochemistry of the protonated imipramine was in all ways similar to 5-methyliminobibenzyl. An apparent one-electron oxidation was observed at +0.75V and an apparent one-half electron reduction at +0.55V (Fig. 7). These ratios and numbers were confirmed with controlled potential oxidations and reductions. Reduction of the amine proton (−1.2V) apparently activated the amine group which was oxidized before 0.75V. Controlled potential electrolysis at +0.9V indicated that considerably more than two electrons were necessary for complete oxidation. The mechanism, however, appeared to be complicated and was not pursued further.

5-Methyliminostilbene.—Homogeneous oxidations of 5-methyliminostilbene (4) have shown that the coupling process may be more complicated than with the related bibenzyl compounds. A possibility of coupling at both the 2 and 10 positions was postulated (4). Electrochemical oxidation might then be expected to result in a more complex product distribution than was observed with the above compounds.

Cyclic voltammograms of 5-methyliminostilbene were characterized by two oxidation peaks at +0.58 and +1.0V at 0.2 V/sec (Fig. 8). The height of the 0.58V peak corresponded to 1 electron (Table I). The peak at +1.0V was more rounded and corresponded to about 0.2 electrons. On sweep reversal a new redox couple was observed at −0.28V (peak separation = 30 mV). There was no evidence for reduction of the oxidized parent (radical cation). Coulometry at +0.7V resulted in an initial n_{app} = 1. The oxidized solution (with a yellow color) had a reduction peak at −0.30 and an accompanying oxidation peak at −0.27 (Fig. 9). No evidence was seen of the original oxidation peaks at +0.58 and +1.0V suggesting that the +1.0V peak may be oxidation of the parent or a species formed at +0.58V. Close inspection of the region around −0.28V showed evidence of another redox couple at somewhat more positive potentials suggesting that at least two products may result from the oxidation at +0.7V. Controlled potential reductions and oxidations of the couples in the −0.28V region showed that one-half the number of electrons are required as are initially consumed at +0.7V. Reduction of protons at −1.3 suggest that one proton is liberated per parent molecule oxidized. Reduction of protons results in the reappearance of the +0.58 and +1.0V peaks (Fig. 10) which are about one-half of their original height. The mechanism of oxidative coupling of 5-methyliminostilbene at +0.7V appears similar to 5-methyliminobibenzyl except more coupling positions are available.

An apparent change in mechanism occurs when the oxidation is performed at a potential positive of the +1.0V peak. Performing such an electrolysis resulted in an n_{app} of about 1.85 and the product distribution appears to be much more complicated. The resulting products are reduced with one-half of the number of electrons required for the oxidation. Electrolysis at −1.3V requires the same number of electrons as required for reduction of the products of the oxidation.

Discussion

The general oxidative behavior of all of the above compounds is probably similar. The likely initial step in the oxidation is the formation of a cation radical of the parent compound. In a very fast follow-up reaction the cation radicals couple at the 2-position (except possibly for iminostilbene where more coupling modes are possible) with the loss of one proton per parent. The proposed mechanism now deviates from the carbazole mechanism in that the parent and neutral coupled product may be protonated by the protons released during coupling and become electrochemically inactivated. A similar inactivation by released protons has been proposed for the anodic oxidation of N-alkylanilines (6).

Differences in electrochemical behavior between the compounds may in part be explained by differences in basicity of the parents. A relatively minor decrease in basicity of iminobibenzyl as compared to 5-methyliminobibenzyl would probably not increase the concentration of unprotonated parent that can remain in equilibrium with protons enough to have an easily measurable effect on the height of the oxidation wave. Because of the difference in time scale between potential sweep and coulometric experiments, this relatively small increase in unprotonated parent could have a significant effect on the shape of the *Q-t* curve. What might be expected would be a more drawn out *Q-t* curve with a less well-defined break. This is in fact the case with iminobibenzyl and supports the contention that iminobibenzyl is less basic than the 5-methyl analogue. Protonation of the neutral iminobibenzyl dimer might well be responsible for the merging and shifting of the two product couples observed in cyclic

voltammetry of the parent compound as indicated by the reappearance of these couples upon reduction of protons.

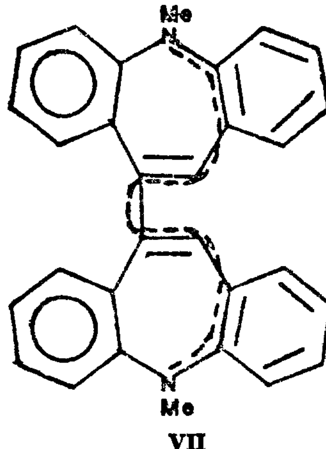
The difference in basicities between the present compounds and the carbazoles can be explained in terms of structural considerations. The planar structure of the carbazoles permits the interaction of the lone pair of electrons on the nitrogen with the pi-electrons of the benzene rings making the lone pair less nucleophilic and very much less basic. X-ray structures of iminobibenzyl-type compounds of interest in this study have not been obtained. However, x-ray studies of related compounds (7) and other considerations (8) indicate that the ethylene bridge of iminobibenzyl, 5-methyliminobibenzyl, and imipramine prevents easy attainment of a planar structure thus making the nitrogen lone pair more available. Although some increase in planarity is expected for 5-methyliminostilbene due to the unsaturated nature of the ethylene linkage, consideration of molecular models indicates that this bridge is highly strained and some rotation out of the plane is expected with a subsequent increase in basicity as compared to carbazole.

The subtle variation in basicities among the studied compounds is not as easily explained. The greater basicities of the N-substituted iminobibenzyls may partly result from the electron-donating properties of the aliphatic substituents on the nitrogens. Comparisons of the changes in basicity that result from substituting an aliphatic chain for hydrogen in a variety of amine compounds [*e.g.*, pK_a's for anilinium and N,N-dimethylanilinium are 4.63 and 5.15, respectively (9)] indicate that the effect may not be large.[1] However, it may be that only small effects are necessary to explain the observed differences. An attractive aspect of this explanation is that it may explain why 5-methyliminostilbene is apparently a stronger base than iminobibenzyl even though it should be more planar. Arguments are presented below that suggest that iminobibenzyl is more planar, and therefore less basic, than 5-methyliminobibenzyl, perhaps because of some nonbonding interaction between the nitrogen methyl group and the benzene rings (9). Steric hindrance around the nitrogen atom of iminobibenzyl is well established from N-alkylation studies (10). Several attempts were made at determining the pK_a's for these compounds by titration of the base-forms in acetonitrile with perchloric acid (made anhydrous by addition of an excess of acetic anhydride). However, the basicity of these compounds (less than that of acetate ion) was too small to show glass electrode responses larger than the drifts we observed for this electrode in changing from one calibration solution to another (up to 100 mV). Moreover, to account quantitatively for the differences in these compounds, differences in the acidity of the very unstable radical cations would also have to be considered.

[1] Most pK_a's determined are for aqueous solutions where as pK_a's for nonaqueous solvents would be more appropriate. For certain nonaqueous solvents such as acetonitrile pK_a's and the differences between pK_a's may well be much larger than found in aqueous systems.

Differences in planarity should also have some effect on the redox potentials of these compounds. Unfortunately, the irreversible nature of the following chemical reaction prevents using peak potentials as a reliable guide as to the ease of oxidation of the parent compounds although where known the differences in potentials correlate with the differences in ionization potentials (11). For the most part the redox processes of the coupled products are reversible or nearly so. Inspection of Table I shows that no real trend exists for the redox potentials of the coupled products, and it is likely that a number of effects such as the relative stabilization of reduced and oxidized forms by delocalization and conformational effects may play important roles. Related substituent effects are apparent in the anodic oxidation of N-akyl anilines (6).

Deserving special note, though, is the unusual ease with which the 5-methyliminostilbene dimer may be oxidized. A reasonable explanation is that the major product of the 5-methyliminostilbene oxidation is a dimer coupled at the 10-position rather than the 2-position as is the case for the other compounds. A structure **VII** reminiscent of a



diamiminobutadiene results (dotted line outlines the butadiene backbone). Compounds such as this are known to be exceedingly easy to oxidize (12). One might also consider **VII** to be related to the dihydro forms of bipyridylium dications which are very easily oxidized (13). **VII** cannot be isolated in the presence of atmospheric oxygen because of its low oxidation potential. Attempts at isolating the dication salt of **VII** after bulk electrolysis were unsuccessful.

If the parent molecules are sufficiently nonplanar, the two parent moieties of the dimers are effectively electronically decoupled. Removing an electron results in most of the positive charge residing on one of the parent moieties. Removing the second electron should then not be much more difficult than the first. The oxidation peaks for the two processes would then appear close together. This appears to be the case for 5-methyliminobibenzyl and imipramine. The two oxidation peaks observed for iminobibenzyl suggests on the basis of the above argument that iminobibenzyl is more planar than the 5-methyl analogue.

Since the coupled 5-methyliminostilbene also has only one oxidation peak, one might be tempted to suggest that a reaction scheme analogous to that of 5-methyliminobibenzyl was occurring. However, the peak separation between the oxidation is 30 mV and it is, therefore, not possible to ascertain whether these peaks correspond to two 1-electron processes occurring at the same potential or one 2-electron process.

A nuance of the 300 mV separation between the two oxidations of bicarbazoles is that any neutral bicarbazole formed as a transient in the oxidation of carbazole can react with dication to yield the radical cation. A measurable ESR signal might be expected during electrolysis. Such an ESR signal was observed for carbazole (3). The closeness of the two oxidations for the dimeric 5-methyliminobibenzyl make the driving force for such a reaction sequence much smaller. Accordingly, the probability of producing a sufficient number of free radicals to observe during an electrolysis in an ESR cavity is much less. In line with this reasoning, an *in situ* electrolysis of 5-methyliminobibenzyl in an ESR (14) cavity resulted in no ESR signal.

ABSTRACT

Emf measurements have been made on cells with CdI_2-Cd_2I_2 mixed-valence electrolytes (*a*) to establish structural and thermodynamic properties for molten Au-Cd alloys and (*b*) to study the source and behavior of some unexpected voltages associated with bare W electrodes dipping into these electrolytes. Changes with temperature and composition of the partial molal entropies, enthalpies, and free energies of the Cd component in the Au-Cd melts point out the existence of premonitory changes a few degrees above the liquidus as well as of liquid structural changes far from the liquidus; these changes correlate with earlier studies by vapor pressure and by electrical conductivity in the Au-Cd system at higher temperatures. $n = 1.87 + 0.001(773T)$ is used to evaluate the effective valence for these electrolytes when saturated with Cd; this n appears in calculation of $\Delta\overline{F} = -n\mathbf{F}\epsilon$. Apparently the mixed-valence electrolyte, plus probable oxide impurities, reacts with the bare electrode (in this case W) surfaces by direct chemical action to form surface films which protect the metal below against direct chemical attack. These films are in equilibrium with the electrolytes. When, however, electrochemical attack is permitted, as when an emf measurement is made, then the underlying metal becomes subject to attack and another reactant enters the reaction. This effect leads to anomalous voltages in electrodes which are normally considered to be inert in molten salts, *e.g.*, W, Mo, and graphite. If these sources of voltage are recognized, then proper determinations of activities and phase boundaries can be made; some earlier measurements of this type which neglected these voltages, however, must be re-evaluated. Application of these proper techniques to the Cd-CdI_2 system is made.

In aqueous systems the usual "inert" electrodes are platinum, gold, silver, etc. These electrodes are unsatisfactory in many molten salt systems, however, because of their tendency to form alloys with many metals. Attack can occur either by direct contact with these metals or by secondary reaction with the products formed by dissolution of the metals in their molten salts. Thus platinum dipping into pure molten CdI_2 is stable, but if the CdI_2 is in contact with a molten Cd phase below, then the platinum is attacked by the CdI_2-Cd_2I_2 mixture formed by the dissolution of Cd in CdI_2, and a Pt-Cd alloy is formed.

In order to avoid alloying attack in molten salt systems it is customary to turn to "inert" electrodes, *i.e.*, tungsten, molybdenum, graphite, etc. It is the thesis of this paper that such electrodes are often not inert and that a number of apparent thermodynamic conflicts in the literature can be resolved if this fact is recognized. As corollary we offer a thermodynamically acceptable interpretation of these anomalies and of the electrode behavior.

[2] Present address: CNC-2, LASL, Los Alamos, New Mexico 87544.
Key words: mixed valence electrolytes, alloy activities, surface reactions.

To study this problem we have used cells of the types

$$\text{W, Cd}/\text{CdI}_{2(\text{Cd satd})}/\text{W} \quad [1]$$

$$\text{W, Cd-Au}/\text{CdI}_{2(\text{Cd-Au satd})}/\text{W} \quad [2]$$

$$\text{W, Cd}/\text{CdI}_{2(\text{Cd satd})}//\text{CdI}_{2(\text{Cd unsatd})}/\text{W} \quad [3]$$

$$\text{W, Cd-Au}/\text{CdI}_{2(\text{Cd-Au satd})}//\text{CdI}_{2(\text{Cd-Au unsatd})}/\text{W} \quad [4]$$

Here all phases are molten except W, and one must recognize that the shiny, cleaned W will be coated with traces of oxides. These cells have been studied as functions of composition, temperature, and time.

In addition usual [*e.g.*, Ref. (1-3)] stirred H-cell measurements were made between molten Cd and molten Cd-Au alloy. There the cell is represented exactly as

$$\text{W, Cd-Au}/\text{CdI}_{2(\text{Cd-Au satd})}//\text{CdI}_{2(\text{Cd satd})}/\text{Cd, W} \quad [5a]$$

but it can be represented to a close approximation by

$$\text{W, Cd-Au}/\text{CdI}_{2(\text{Cd satd})}/\text{Cd, W} \quad [5b]$$

as long as the Cd activity in Cd-Au is close to unity, thus making the CdI_2/Cd_2I_2 ratio essentially identical at both electrodes, as set by the equilibrium constant

$$K = (a_{Cd_2I_2})/(a_{CdI_2})(a_{Cd}) \quad [6]$$

Experimental Chemicals, Apparatus, and Operations

Emf cells.—Two modifications of the usual stirred H-cells mentioned above were used. These cells allow for composition changes *in situ* by additions of preweighed solids in the sidearms, for stirring and long equilibrations to assure that phases are homogeneous and at equilibrium, and for initial cleanup operations such as the vacuum melting of CdI_2 before it is melted and poured or vaporized into the H-cell portion of the system. Temperatures are very uniform (to < 0.01°K) because of the heat distribution and heat ballast from nesting copper cylinders.

Type I.—This version differs from the usual stirred H-cell only in that a second W lead in each cell leg is mounted on the stirrer so as to be exposed bare to the electrolyte. As is customary the exposed portion of the other lead was completely immersed in molten cadmium or alloy. (See Fig. 1.)

This cell type was used for almost all the data presented here.

Type II.—In this modification the bottoms of the H-cell legs were joined so that a single alloy touched the electrolyte in both legs. The electrolyte in each leg was essentially independent of that in the other, and stirring one side did not agitate the other. (See Fig. 2.)

Two types of electrodes dipped into the electrolyte, namely (*a*) large current collectors made by wrapping ~100 cm of 10 mil W wire around each stirrer but not touching the alloy, and (*b*) small potential sensors exposing ~3 cm of 10 mil rod to the CdI_2, there being two of these in each cell leg.

Chemicals and their purification.—Commercial cadmium of purity reported as 99.999% was melted in vacuum and washed with boiling, molten CdI_2. Reagent grade CdI_2 was sometimes (cell type II) melted under vacuum and washed with molten Cd. Later this material or new reagent grade CdI_2 (cell type I) was loaded into the sidearm of the cell and remelted repeatedly under vacuum, the final melting being used to introduce the salt into the cell legs. Commercial argon was condensed at liquid nitrogen temperatures, flash frozen by evacuation to flush out the more volatile impurities, then gently warmed and distilled into the cells at ~0.5 atm.

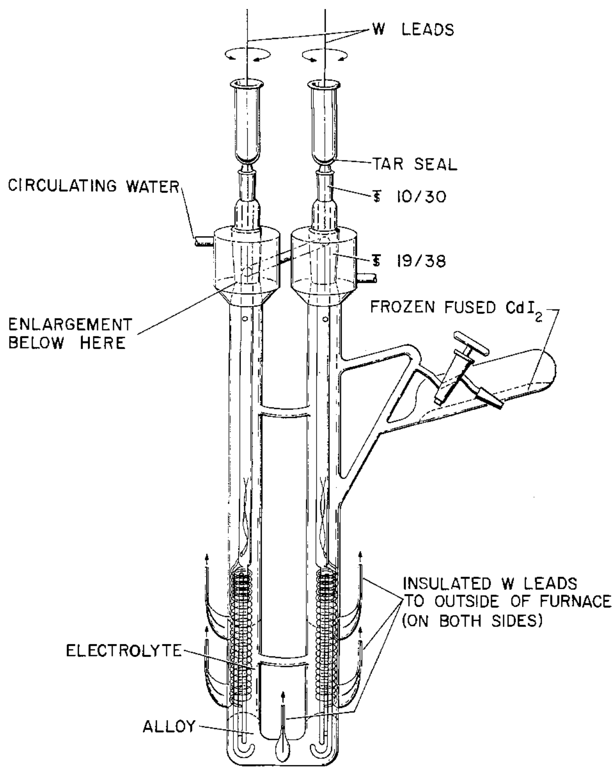

Fig. 2. Multiple electrode cell for checking reproducibility of bare electrode emf's (reaction [2]) with time, with stirring, with composition, and with different sources of tungsten having different levels of initial oxidation on their surfaces.

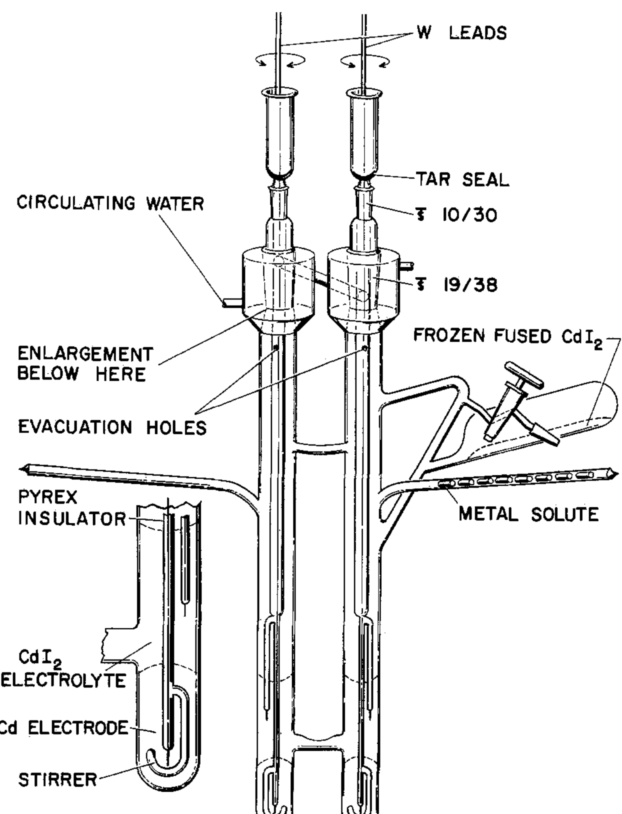

Fig. 1. Stirred H-cell for studying various usual reactions (*e.g.*, reaction [5a]) as well as the bare electrode reactions (*e.g.*, reactions [1]-[4]). Sometimes the metal solute sidearm included a standard taper joint which could be turned to make sequential solute additions more easily as they were needed. Only the lower sections of the legs are involved in the emf measurements; the upper portions are outside the furnace and are used during loading. This is the type I cell design.

For cells of type I the electrodes were cleaned by a-c electrolysis in NaOH solution, then were water washed and dried by touching tissue. With cells of type II the working electrodes on the stirrers were made from commercially cleaned and still shiny 10 mil W wire. Additional potential sensors were made from a different commercial tungsten; these electrodes were oxidized to a dark color during a Pyrex anneal and were not cleaned further. The electrodes represent two commercial sources and two levels of preliminary oxidation of the W surface.

Gases adsorbed on the Pyrex or chemicals were removed by evacuation at 10^{-5}-10^{-6} Torr while the system was in the furnace, and then the purified argon was added.

Electrical equipment.—Usual measurements with potentiometers having no connection to house current were employed (Wenner, K-2, etc.). Pt/Pt-10% Rh thermocouples were used.

For further discussion of these various techniques, see our earlier papers, *e.g.*, Ref. (1-3).

Cell operation.—Consistent with earlier observations (1), cadmium solutions required much stirring before equilibrium was reached, as compared with Sn-$SnCl_2$ solutions [*e.g.*, (2)]. When a cell could be stirred with almost negligible effect on the voltage, and when it also returned in a few minutes to the original voltage, the system was accepted as being at equilibrium. (As must always be faced, a system can often be in equilibrium with regard to one type of reaction while it is

far off of equilibrium with regard to other reactions.) The equilibrium condition was achieved in about 2 hr after adding Cd to the CdI_2 electrolyte, if stirring had been frequent. For gold additions, equilibrium was achieved in 4 hr or more, and further stirring or long standing did not alter the emf except at the highest temperatures studied, where a small amount of Cd evaporated. For temperature changes at a single composition, some measurements were taken about one-half hour apart, but most were taken more quickly.

Solubility measurements.—The cell that had been used for the study of Au-Cd alloys was held in the furnace at 773°K with sufficient stirring to ensure that equilibrium had been achieved. The cell was then taken out of the furnace at 773°K and cooled rapidly, consistent with a technique that had been used earlier (1). The cadmium that had dissolved into the electrolyte over the reference electrode was determined by breaking open the cell, washing away the electrolyte, and establishing the weight loss of the cadmium electrode.

Results, Methods of Calculation, and Conclusions

The significant figures carried reflect the differences between compositions which can be identified. The absolute compositions vary slightly because of the dissolution of some Cd into CdI_2 to form the equilibrium concentration of Cd_2I_2 which is unstable as the pure condensed phase but can be present in solution in the salt melt.

The effect of this solubility on n in $\Delta\bar{F} = -n\mathbf{F}\epsilon$ must be considered in the evaluation of thermodynamic properties from the emf data. (Contrary to popular assumption, the value of n is seldom whole-numbered for molten salt systems, and the effect of solubility equilibria such as for Eq. [6] must be considered even if an inert carrier solvent such as LiCl-KCl is being used.) For CdI_2 at 773°K the value of n has been recently determined by three independent experimental checks. First, and most directly, Houseman and Elliott (1) have shown that the value of the apparent n is markedly dependent on the charging rate, and Houseman (4) has carried out very slow conduction experiments which can be extrapolated to zero current. His value of effective n, reflecting both the concentrations and mobilities of the Cd_2^{++} and Cd^{++} species, is 1.87. Second, $n = 1.87$ is what agrees with the vapor pressure measurements for several systems as reported by Conant and Elliott (5). Third, $n = 1.87$ is what brings a number of dilute solutions into asymptotic approach to Raoult's law when activities are calculated from emf's, as shown by Conant (6), by Houseman and Conant (7), and by Conant and Elliott (5).

Because Houseman (4) has shown that the mobilities of Cd^{++} and Cd_2^{++} are nearly the same and that the solubility measurements by Topol and Landis (8) and by us here can be used for predicting n at 773°K, we will use the temperature dependence of solubility from Topol and Landis and will assume that equal mobilities continue to other temperatures in order to make our calculations of thermodynamic properties. These solubility values from Topol and Landis also agree with our solubility measurements at 713°K, as is discussed later.

By using the assumption and solubilities just discussed, we get the calculation of n by the equation

$$n = 1.87 + 0.001(773T) \qquad [7]$$

(Although solubilities often follow a logarithmic dependence on T, Topol and Landis's values do not appear to require this form.)

To understand the calculations using Eq. [7], recognize that Topol and Landis's solubility of Cd at 773°K is 0.065 mole fraction, leading to 0.065 of the Cd having zero valence and 0.935 having a valence of 2. Our value for this solubility is 0.063 in this present paper. Doubling the 0.935 (or 0.937) leads to a value of $n =$ 1.87. This calculation is independent of what species form as long as mobilities of the species and their charges are equal.

Results with Cell Type I

Measurements using cells as in Fig. 1 were made on two types of emf's: (a) between the cadmium reference electrode and the alloy whose composition could be varied, and (b) between cadmium or alloy and bare electrodes made of tungsten which dipped into molten CdI_2, the CdI_2 being partially or completely saturated with Cd. As will be developed, the former were of "thermodynamically" expected form, but the latter did not conform to usual expectations.

Metal vs. alloy studies.—The experimental emf values at 4 mole fractions of the solvent taken over a temperature range of 50°K are represented in Fig. 3-6.

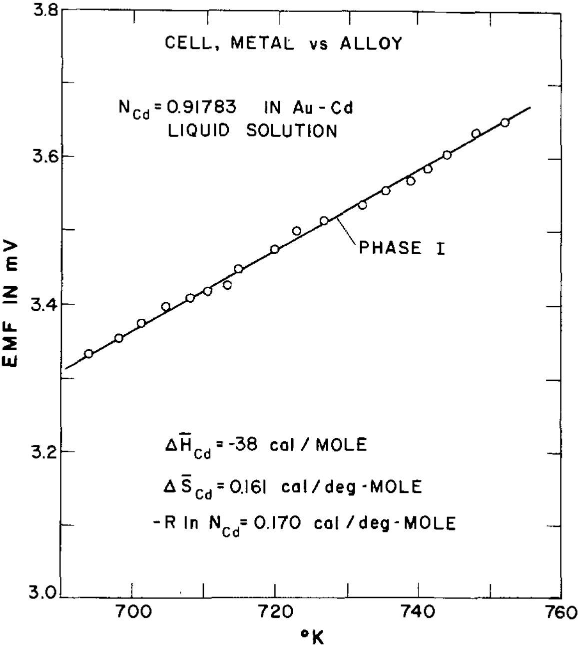

Fig. 3. Reaction [5a] for Cd vs. Au-Cd at $N_{Cd} = 0.91783$. No phase boundary for liquid Au-Cd solution is detected over the temperature range studied.

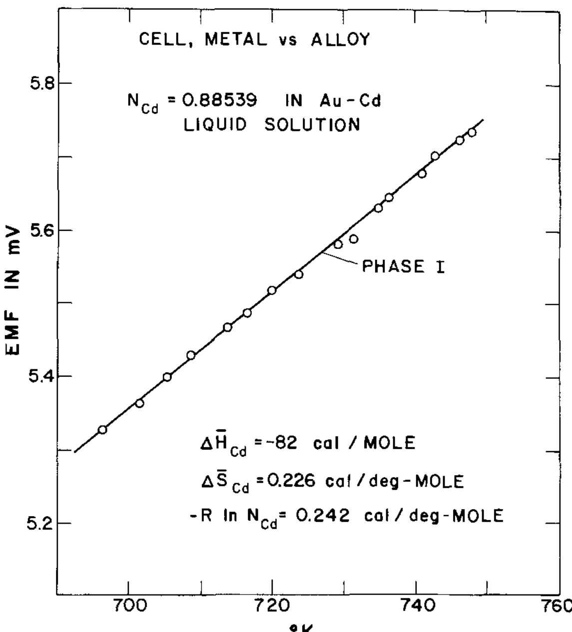

Fig. 4. Reaction [5a] for Cd vs. Au-Cd at $N_{Cd} = 0.88539$. No phase boundary for liquid Au-Cd solution is detected over the temperature range studied.

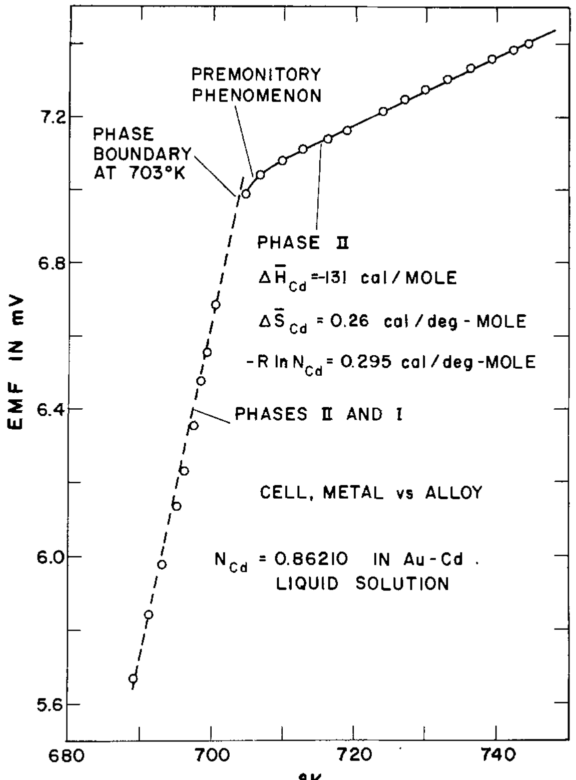

Fig. 5. Reaction [5a] for Cd vs. Au-Cd at $N_{Cd} = 0.86210$. The liquidus is detected at 703°K, and premonitory phenomen are detected about 4°K before the liquidus temperature is reached.

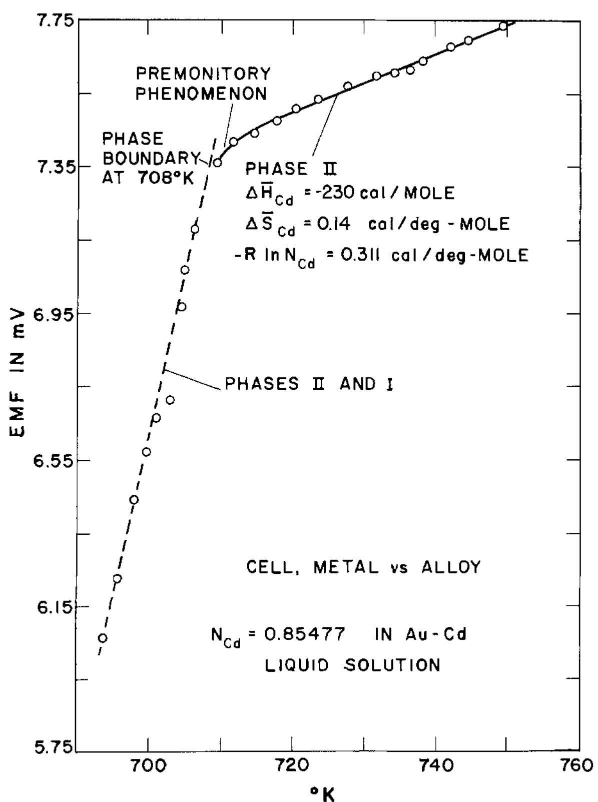

Fig. 6. Reaction [5a] for Cd vs. Au-Cd at $N_{Cd} = 0.85477$. The liquidus is detected at 708°K, and premonitory phenomena are detected for perhaps 4°K before the liquidus temperature is reached.

Pure single-phase region is observed at $N_{Cd} = 0.91783$ and 0.88539 (Fig. 3 and 4), but for $N_{Cd} = 0.86210$ and 0.85477 (Fig. 5 and 6) there are phase changes as indicated by the slope shift in the emf-temperature data. In the transition region between pure single-phase region linearity and the two-phase region linearity there is in each case a transition region labeled "premonitory phenomena."

The thermodynamic quantities listed have been calculated using Eq. [7], but we have neglected the small changes of alloy composition as the solubility of Cd in CdI_2 changes with temperature.

Note that with correction of n off the usually accepted 2, the partial molal entropy of the Cd falls close to the ideal random solution value for the three higher concentrations. If n were accepted as 2, the apparent partial molal entropies would be about 50% larger than the ideal values.

Figure 7 and Table I give the variation of emf and activity with composition for a single temperature using $n = 1.93$ corresponding to the equation above. Table I indicates both the added alloy composition and the corrected composition due to Cd_2I_2 formation in the iodide.

Conclusions from the Cd vs. Au-Cd emf studies.—The liquidus is detected at two compositions (Fig. 5 and 6) and occurs at temperatures consistent with the accepted phase diagram (9).

Premonitory phenomena (depressions of the cell voltage) are observed slightly above the liquidus at these same compositions. In further support of this view, premonitory phenomena near phase boundaries (including the liquidus) have already been detected in this same system by vapor pressure-composition studies at constant, but higher, temperature (939°K) using an isopiestic balance (10).

Note that these premonitory phenomena show smaller voltages than extrapolation would predict. Of course, the total activity must drop for any such reaction to occur, so we conclude that the necessary component activity decrease and phase stabilization must occur for the nonvolatile component. This kind of activity behavior is not uncommon: For example, the

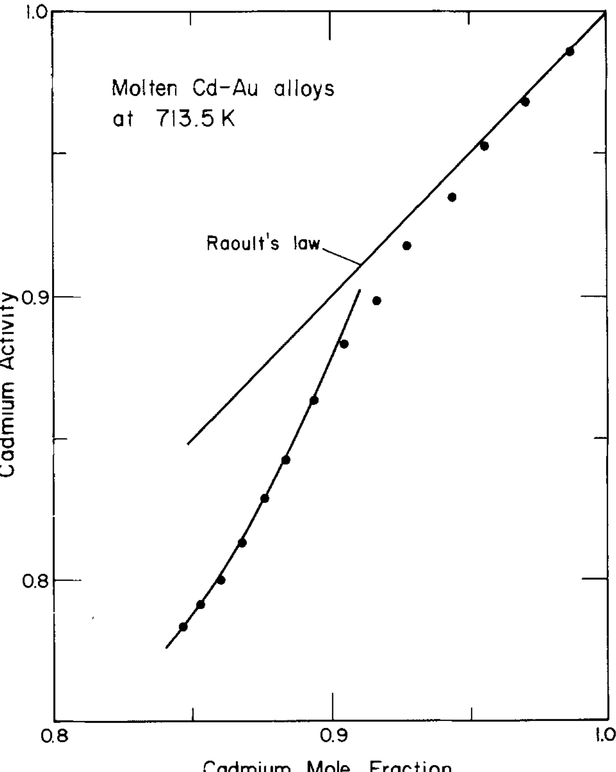

Fig. 7. Cadmium activity-mole fraction relations from emf's (reaction [5a]) for various molten Au-Cd alloys at 713.5°K. At least one liquid alloy structural change is probable at ~0.9 mole fraction of Cd, consistent with a change detected earlier at this composition by vapor pressure at 939°K.

[a] The amount of Cd added was 29.2264g.
[b] Assumed solubility of Cd in CdI_2 from present investigation (same as Topol's and Landis's data): 713°K, N_{Cd} = 0.0348.
[c] Corrections have been added to the observed emf to give the listed readings. This correction, 0.0240 mV, was measured when no solute had been added to either cell leg. Those emf readings were taken after sufficient stirring and did not change after further stirring or long standing.
[d] Calculated for 1.93 electrons involved per cadmium atom transferred.

solid $CeCd_{\sim 4.5}$ microphases showed metastable extensions which include many examples of both too high and too low Cd component activity before the transformation took place (11).

The change of activity-composition behavior at $N_{Cd} \approx 0.9$ shown in Fig. 7 was noted also at higher temperatures in the earlier vapor pressure studies (10). Likewise, comparing Fig. 3-5 *vs.* 6, there is a sharp decrease of the $\Delta\bar{S}_{Cd}$ from that for ideal solutions as we pass from 0.86210 to 0.85477 mole fraction of Cd. It seems likely that this change of entropy behavior corresponds with the liquid-liquid transformation at 0.8620-0.8625 shown at 939°K in the isopiestic balance studies just mentioned.

Metal or alloy vs. bare electrode studies using cell type I and CdI_2-Cd_2I_2 electrolytes.—In the development of the stirred H-cell design (1, 2) it became clear that, if the W or Mo current leads to metal and alloys were not insulated as they passed through the electrolyte, then the cell behavior would be erratic in the μV range. It was important sometime to learn the causes and implications of this behavior.

Preliminary studies (to be presented in part later under the heading cell type II) had indicated that W, Mo, and graphite all showed persistent voltages in the millivolt range when bare electrodes dipping in CdI_2 were compared against Cd or Au-Cd in contact with the bottom of the electrolyte. Furthermore, use of cell type I with Mo or W electrodes in $SnCl_2$-based electrolytes *vs.* Au-Sn molten alloy shows similar behavior. [This latter work was carried out along with the Au-Sn alloy liquid structure work (3) but was not included in the publication of that already complex paper.]

For the present studies measurements were made on both saturated and unsaturated solutions of Cd in CdI_2 (*i.e.*, CdI_2-Cd_2I_2 solutions).

Unsaturated solutions.—Cells as in Fig. 1 were operated with initially no liquid Cd phase on the right side and with small solid Cd pieces in the sidearm. The emf-temperature relationships for reaction [4], *i.e.*

$$W, Cd/CdI_2\text{-}Cd_{(satd)}//CdI_2\text{-}Cd_{(unsatd)}/W$$

at unsaturated solution compositions are plotted in Fig. 8-11. The compositions, N_{Cd} = 0.0143 and 0.0348, do achieve saturation at the lower temperatures, however.

For the first few days the solutions in one leg of the H-cell were not allowed to become saturated. First, limited Cd was added to the CdI_2 to partially saturate it, and the solution was stirred periodically for a day while composition and temperature equilibrium was being achieved.

The next day more Cd was added and the solution was stirred periodically for 4 hr. Then the stirring was stopped, and the system was cooled slowly. The emf changes were systematic (Fig. 8) with the two electrodes agreeing to about 1 mV. The system was then reheated and again slowly cooled, this time over a two day period with cooling by increments rather than steadily (Fig. 9). By this time the two electrodes agreed within ~0.2 mV. A further heating and cooling cycle is shown on Fig. 10.

Because we do not know how to handle the mixed n values (the CdI_2/Cd_2I_2 ratios are different in the two cell legs), we have calculated apparent values of $\Delta\bar{H}_{Cd}$ and $\Delta\bar{S}_{Cd}$ as shown on Fig. 9 by using $n = 2$.

Although the solutions followed a single relationship during a heating or a cooling half-cycle, there were slower over-all changes in the apparent values of both the magnitude of the emf and of the slope of the emf-temperature relationships. The magnitudes of the emf values did not appear to be approaching zero, however. Considering the emf at 740°K, the emf dropped from 82.5 mV on the second day, to 64 on the third day, to 56 on the fifth day, to 55 on the sixth day. Likewise, the corresponding apparent $\Delta\bar{S}_{Cd}$ fell from 25 to 18 eu to 15 eu and remained 15 eu. After the initial changes, the major changes of emf and slope seemed to be associated with hysteresis following electrolyte phase changes such as freezing. (Does the electrode surface crack and strain?) For example, in Fig. 9 the freezing of CdI_2 is detected in the initial cooling, but the emf's are lowered for the higher temperatures as well (Fig. 10 *vs.* Fig. 9).

Comparing Fig. 10 and 11 will show the influence of electrolyte composition upon the emf. Likewise, these data pick off the Cd-CdI_2 phase boundary both on cooling and on heating. Finally, they show that shorting the two "inert" electrodes together allows an

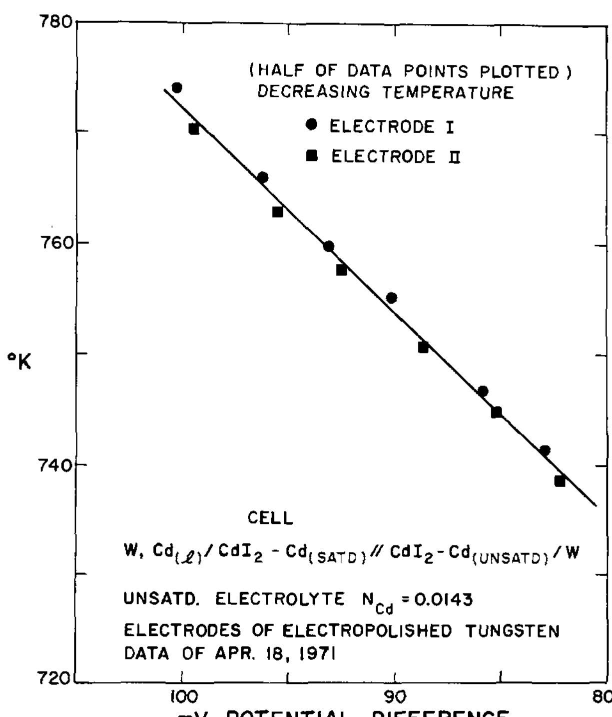

Fig. 8. Studies of the emf between a cadmium electrode in one leg of an H-cell and tungsten electrodes in an unsaturated Cd-CdI_2 solution in the other leg. (Electrode I was high in the solution and electrode II was low.)

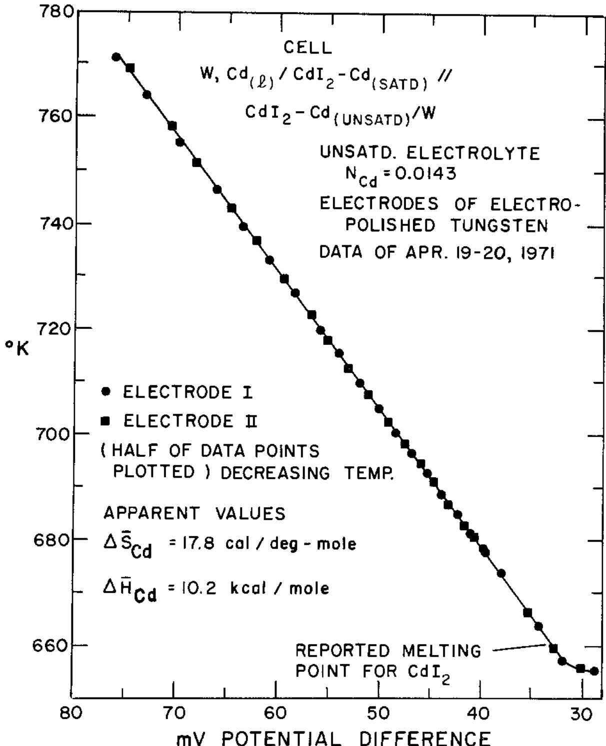

Fig. 9. Two-day cooling of the cell in Fig. 8. Cooling was not continuous. $\Delta \bar{H}_{Cd}$ and $\Delta \bar{S}_{Cd}$ calculated with $n = 2$, i.e., no correction for Cd_2^{++} was made here. See text.

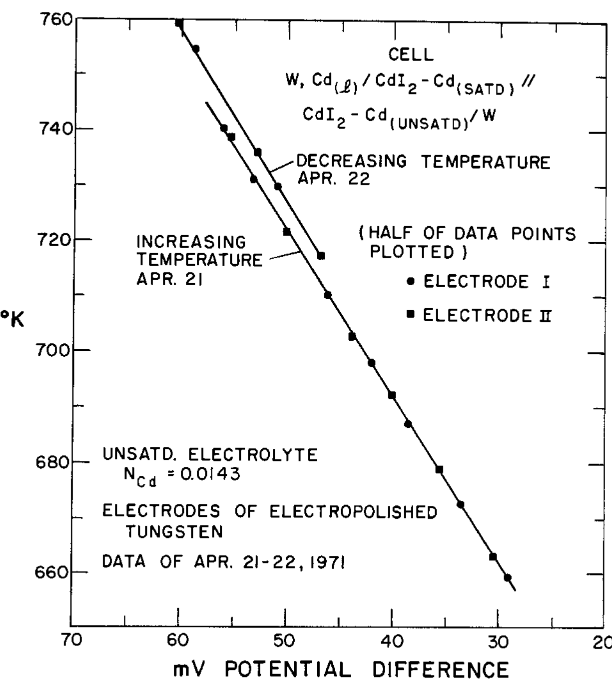

Fig. 10. Cell behavior for the cell in Fig. 8 and 9 as shown 3 and 4 days after freezing then remelting the electrolyte.

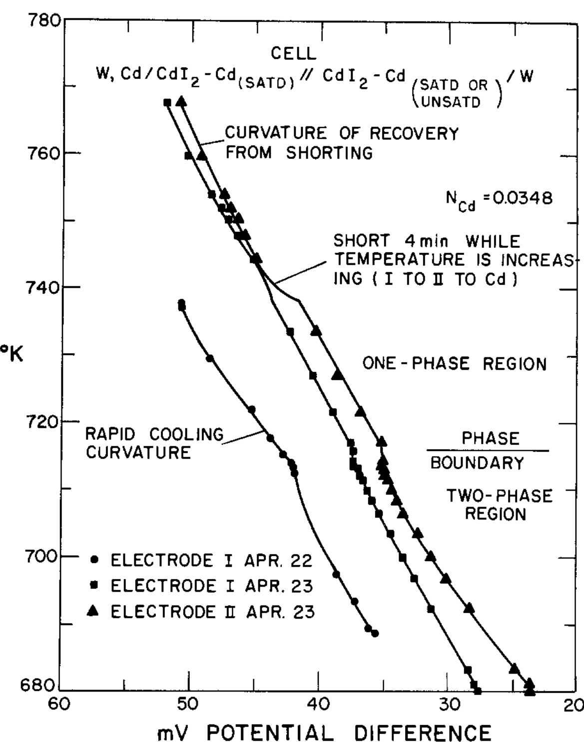

Fig. 11. Saturated and unsaturated electrolyte and effects of electrochemical drain at $N_{Cd \text{ in } CdI_2} = 0.0348$ on the emf of bare tungsten electrodes.

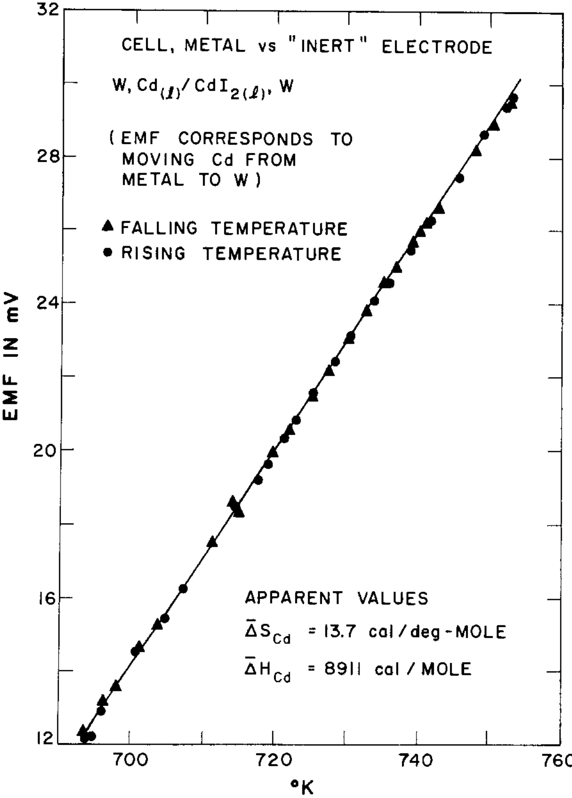

Fig. 12. The effect of temperature on the bare tungsten electrode emf in CdI_2 solutions saturated with Cd. The CdI_2 and Cd phases in contact were stirred intermittently during heating and cooling stages. Heating and cooling stages were separated by 3 days.

electrochemical drain which does change the electrode behavior temporarily.

Saturated solutions.—These measurements refer to the potentials observed in comparing a molten Cd reference electrode with a bare tungsten electrode dipping into molten CdI_2-Cd_2I_2 solution. The Cd_2I_2 concentration is set by equilibration with either molten Cd or molten Au-Cd.

Figure 12 shows tests of reaction [1]. Physically, referring to Fig. 1, the reference Cd was in the left leg and the bare electrodes were over a second Cd melt in the right side. Later, gold would be added to the right-side melt to give the data in Fig. 13, again with reference to the same Cd in the left side.

With regard to Fig. 12 note that the heating and cooling half-cycles gave the same results even though the half-cycles were separated by three days. Similar

temperature coefficients of emf are shown by the W *vs.* Cd couples where Au-Cd alloys supplied the Cd_2I_2 to the electrolyte in the W region (Fig. 13).

These voltages were stable, reproducible, and (according to usual expectation) very large. The changes of voltage with alloy composition (~3 mV on Fig. 13) were smaller than would have been expected from the changes of alloy activity (~7.5 mV on Fig. 6) and the temperature coefficients were different. Part of the difference in temperature coefficient is a consequence of carrying out the measurements for Fig. 13 without stirring; the metal-electrolyte and the alloy-electrolyte interfaces adapt quickly to the changing n but the electrolyte CdI_2-Cd_2I_2 mixture in the bulk of that phase readily supersaturates relative to metallic Cd. There are further differences, however, because the line for $N_{Cd} = 0.85477$ as the saturating solution does not follow the other trends of voltage. (Remember that the $\Delta\bar{S}_{Cd}$ at $N_{Cd} = 0.85477$ was also anomalous, Fig. 6.)

Apparently traces of impurity (probably CdO) do influence the voltage significantly, since the long-term stability was not achieved until after the cell had been at temperature with much stirring for a month. A few milligrams of material had then vaporized to form a brown condensate ring. (This could, for example, have been volatile tungsten oxyiodides whose vaporization removed $O^{=}$ from the electrolyte solution.)

In this case the effect of stirring was not large. The data for Fig. 12 were taken with stirring during heating and cooling while the alloy solutions were stirred extensively at the highest temperature before cooling but not during the cooling.

Conclusions from the unsaturated and saturated solution studies using type I cells.—These emf's are real, large, and roughly reproducible. They satisfy many usual tests of equilibrium. They vary with composition. They react to phase changes. They vary reproducibly with temperature during tests over several hours. They react to and recover from drains and imposed voltages.

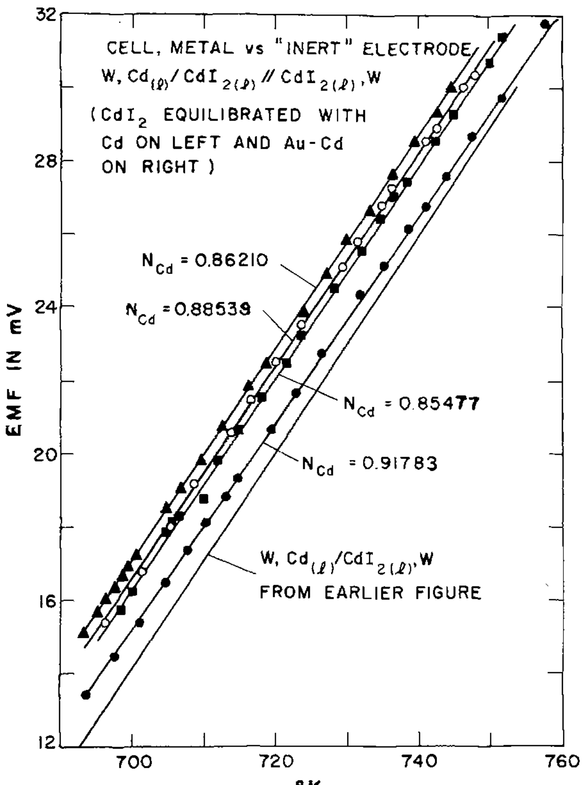

Fig. 13. The effects of temperature and composition on the emf of cells in which bare tungsten electrodes dip into CdI_2 equilibrated with Cd-Au alloys of various compositions.

Considering that (for Henry's law solutions) 30 mV would correspond to about one-fourth of the saturation concentration at these temperatures, it would be most difficult to write the voltages off as due to reproducible partial saturation of the CdI_2 by Cd. Furthermore, the electrolyte phase is at least nearly homogeneous as shown by comparison between different electrodes in different parts of the electrolyte. This homogeneity is much more strongly emphasized by results from the type II cells to be discussed later. Finally, including information from our unpublished work, different electrode materials do show different voltages in the same electrolyte solutions. Another aspect of this difference in behavior is discussed later during analysis of published phase diagrams and solution activity studies.

Likewise, these voltages cannot be written off as the "stray voltages which always occur when one dips metal into electrolyte." Here there is several per cent of Cd_2I_2 so that the activity of Cd as set by metal or alloy is well buffered even though metallic Cd is, of course, not an electrolyte species. This is not a case where a tiny concentration of a species varies tremendously during any attempt to measure it.

It is our interpretation that W (and at least most other potentially useful solid electrodes for these molten salt systems) will form a protective film (probably oxide) over the metal surface. The surface comes into equilibrium fairly rapidly with the electrolyte, and it reacts to changes in the electrolyte activity. Thus the chemical equilibria available involve electrolyte and surface.

But the electrochemical equilibrium permits attack on the base W because the surface passes ions and the metal passes electrons. Thus it can reflect very different reactions from those which have come into equilibrium during the long purely chemical equilibration.

Because unit activities of the base W and the surface film are not involved, we see no way to predict the magnitudes of the emf effects superimposed on the usually expected voltages.

Solubility of Cd in CdI_2.—The cell which had been used for the unsaturated electrolyte studies was broken open after cooling rapidly from 773°K. The remaining metallic Cd was found to contain 2.07055g less than initially had been added, the loss being due to saturating 100g of CdI_2. The corresponding solubility of Cd in CdI_2 at 773°K is 0.063 mole fraction.

The solubility from the temperature coefficient of emf (Fig. 11) is 0.0348 at 713°K.

Both of these solubilities are completely in agreement with Topol's and Landis's results (8).

Results with Cell Type II

This cell design is shown in Fig. 2. The cell was (*a*) loaded with 78.361g Cd, 18.573g Au, 183.5g CdI_2, and ~0.5 atm Ar, (*b*) heated at 773°K for nearly 3 months, (*c*) stirred occasionally, (*d*) electrically drained periodically, and (*e*) monitored for open circuit at six tungsten *vs.* alloy couples.

The results of the emf measurements are indicated on Fig. 14. The following observations should be made.

1. The plots are offset on the ordinate to avoid overlap.
2. On any particular day all six W *vs.* Au-Cd couples showed nearly the same voltage.
3. The stirrer voltages (electrodes made from W wire) were consistently slightly larger, by 1-2 mV, than those of the potential sensors (made from W rod).
4. All voltages increased together with time. Apparently this change was associated with the change of alloy composition resulting from slow evaporation of Cd to cooler portions of the cell. Melting the evaporated Cd (~10% of the Cd) back into the alloy decreased the voltage.
5. Electrically shorting the large stirrer leads together and to the alloy caused the voltage to drop.

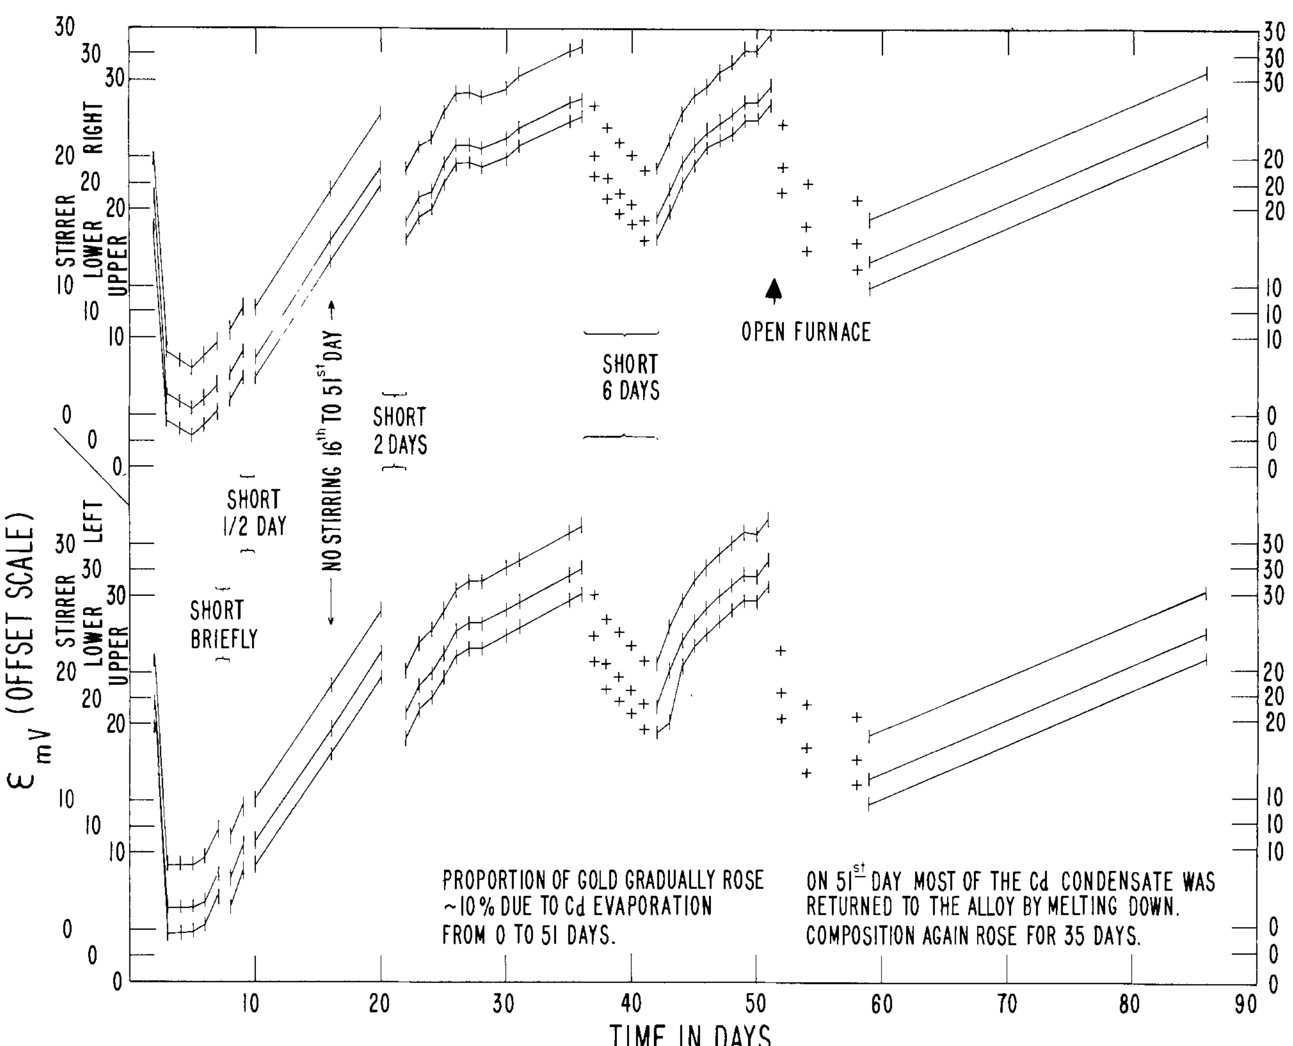

Fig. 14. Offset-scale plots for the open-circuit voltages of W vs. Cd-Au couples (reaction [2]) in a type II cell. Six electrodes vs. Cd-Au are represented as identified beside the ordinate: three in left leg, three in right; upper and lower are potential sensors; indicated shorting is via outside connections between the stirrer electrodes and the alloy. See text.

The potential sensors followed the drained electrodes.

6. Reaction of the alloy with the electrolyte appeared to create nearly identical conditions in the two electrolyte regions.

7. Reaction of the electrolyte with the oxidized potential sensors and with the unoxidized current collectors on the stirrers yielded nearly equivalent behavior in both (except for the 1-2 mV difference which we associate with compositional and strain differences between W wire and rod).

Conclusions from the type II cell measurements.— With adequate stirring and equilibration time, the metal or alloy sets the Cd_2I_2 concentration in the electrolyte following K in reaction [6]. The chemical reaction of the electrolyte with the electrode surfaces sets the surface activities. The electrochemical reaction can involve the base metal, not just its surface coat, and can be very different from the feasible purely chemical reactions. This difference can lead to anomalous voltages in what have been treated as inert electrodes in molten salts.

See also the conclusions regarding type I cells given earlier and the applications to published data to follow.

Applications of These Conclusions to Published Data

We have long believed that a major source of irreproducibility and scatter in the published data for molten salt emf cells lies with improper equilibration with the electrolyte and with failure to insulate the "inert" leads which pass through the electrolyte. These present measurements strongly support that belief.

A number of papers have been published in which the activities of dissolved species have supposedly been determined by measuring the voltages of bare W, Mo, or graphite "inert" electrodes dipping into unsaturated solutions as compared with saturated solutions. In principle these are cells with provision to carry out reactions like reaction [3], but many systems can be used. In physical design the cells can look much like cell type I.

As noted in this present paper, one can determine solubilities and activities as long as he corrects for the residual "inert" electrode voltage some way, *e.g.*, note the correct determination of the solubility of Cd in CdI_2 at 713°K by the change of emf-temperature pattern in Fig. 11. However, one would be incorrect to assume that zero voltage difference between bare electrode and reference metal gave the saturation composition.

Figures 15 and 16 show data where people have neglected the bare electrode voltage. In Fig. 15 Mashovets and Poddymov (12) and Crawford and Tomlinson (13) have attempted to establish the activity of Cd in $CdCl_2$ solutions by calculation from the emf's of bare Mo, W, or graphite *vs.* molten Cd, assuming the electrodes are inert. These voltages differ by as much as 5 mV, corresponding to a 15% difference in apparent activity. In Fig. 16 we see the Cd-$CdCl_2$ liquidus as established by standard techniques and as "established" by extrapolating to zero voltage by Mashovets and Poddymov.

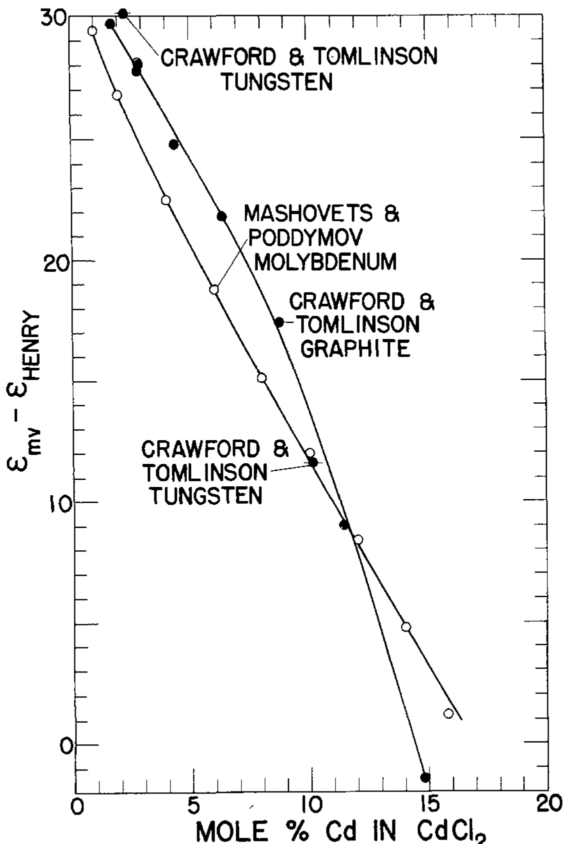

Fig. 15. Cd-$CdCl_2$ activity studies by emf using "inert" graphite, molybdenum, and tungsten electrodes at 873°K.

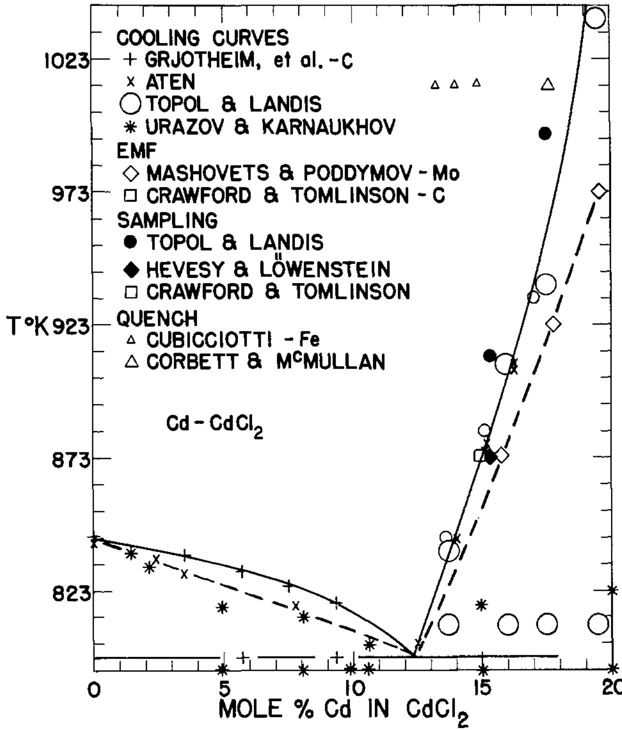

Fig. 16. Cd-$CdCl_2$ phase diagram measurements by different techniques with use of electrical conductors indicated. Hedger and Terry data are indicated by small circles.

Melting, Freezing, and Premonitory Phenomena

Both here in emf and earlier in vapor pressures (10), there has been evidence of unexpected variations of activity with composition near phase boundaries for molten Au-Cd alloys. Similar phenomena have often been reported in sensitive properties such as changes of viscosity with temperature; thus the phenomena are detectable whether the phase boundary is approached with changing composition or with changing temperature.

Changes in property near a phase boundary are often called "premonitory phenomena," and we accept the term even though our measurements indicate that these deviations in the trends of properties reflect the true, equilibrium condition rather than some phenomenon akin to prescience. For molten alloys in this case, but also apparently for other kinds of solutions, *e.g.*, molten salts, when a composition is close to the phase boundary there can sometimes exist significant quantities of atoms in atomic groupings which are similar to the atomic groupings which will be met when the adjacent phase becomes stable. These structures exist primarily because a large entropy of mixing overcomes an unfavorable enthalpy, thus they are often inherently dilute, but the fact of their existence indicates the solution free energy is decreased by their formation. In the case of metallic bonds in alloys, the shift of expected activities is particularly sharp; this sharpness reflects the fact that impurities weaken the metallic bond, and the new structures look like impurities to the resonance in the existing "metallic lattice."

Melting and freezing.—Premonitory phenomena and clustering similar to those we observe have been examined for pertinence to the relationship of solids to liquids, *e.g.*, (14) and (15). This relationship has been subject to controversy. For example, Borelius (16) argues with experimental support that a continuous (but physically unattainable) curve joins the properties of a liquid metal to those of its solid, Danilov and Neimark [see Neimark in Ref. (17)] show x-ray correlations between solid and liquid mercury, and Saxton and Sherby (18) demonstrate good correlation between solid and liquid properties. Turnbull (19) presents the thermodynamic argument that melting occurs because of the crossing of the free energy-temperature curves, which for the solid and liquid, are "quite independent" of each other. He concludes that, "Therefore there should be no unusual changes in the properties of either the liquid or the crystal when they pass from their stable to their metastable condition." Also supercooling is sometimes used to conclude that the melting-freezing phenomena involve changes only in the solid, since the liquid may be unchanged at the melting point while the solid always does change. Assigning all the pretransformation effects to the solid leads to a further theoretical concern about the sharpness of the melting point and the absence of rapid changes in the solid properties close to the melting point as calculated by melting models related to that of Lennard-Jones and Devonshire.

In our view prenuclei similar to those discussed in the previous section would be important to certain solid-liquid equilibria. Where the solid and liquid structures were very different, there would be two possible liquid structures at the melting point: (*i*) One form would be a simple continuation of the usual liquid properties to lower temperatures; this structure would be metastable (though otherwise showing equilibrium behavior), supercoolable, and unable to exist in equilibrium with the solid. (*ii*) The second and stable liquid form would contain the solid precursors (prenuclei) at an equilibrium concentration. It is this latter form that might pass along a continuous but hypothetical curve relating solid and liquid properties as Borelius proposes. Stabilizing the liquid by the presence of prenuclei would remove part of the temperature region in which the solid was stable and would reduce the opportunity to observe premelting phenomena in such a system.

Once a prenucleus happened to form it would presumably act as a template for the formation of the equilibrium concentration of prenuclei. This is indicated in our systems by the absence of vapor pressure results intermediate between those for the presence or

absence of prenuclei, even in the prenuclei region the results are reproducible. Likewise, our second phases apparently form without difficulty once their equilibrium concentration has exceeded their solubility in the liquid, as indicated by the absence of metastable extensions (supersaturation) into two-phase regions by solutions containing prenuclei.

The pertinence of this work to the freezing of pure substances seems to be as follows: If the usual solid and liquid structures are rather different as emphasized by Turnbull, then the solid and liquid cannot be in equilibrium until the liquid becomes saturated with prenuclei. The freezing point is that point where the cooling liquid becomes saturated with prenuclei, *i.e.*, where the equilibrium concentration or size of prenuclei becomes greater than the liquid can hold in solution. In this view the deviation in properties between the supercoolable and nonsupercoolable liquids occurs not at the freezing point but rather at some higher temperature.

If the solid and liquid metal structures are very simply related as emphasized by Borelius, then any supercooling would seem to result largely from the metallic resonance energy which would have to be overcome in the region where the solid first formed in the liquid phase. In this case there would be no particular reason to expect that a significant concentration of prenuclei would exist in the liquid at equilibrium with the solid.

Sodium Phosphate Solubility and Phase Relations Basis for Invariant Point Chemistry Control

A. J. Panson, G. Economy, Chia-tsun Liu,
T. S. Bulischeck, and W. T. Lindsay, Jr.*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

A study of sodium phosphate solubility and phase relations was made in the temperature region of 300°C. A sharp retrograde temperature dependence of solubility was observed for disodium phosphate solutions. Solubility at constant temperature is strongly dependent on the composition of the solution. A low-Na/PO_4-ratio solid precipitates incongruently from solutions that have Na/PO_4 ratios from 2.13 to 1.6. A high-ratio solid phase precipitates incongruently from solutions with Na/PO_4 above 2.13, which corresponds to an invariant or "drying-up" point in the system. Both solid phases have a range of variable composition, indicating that they are solid solutions. The effects of concentration and dry-up in localized zones are discussed in terms of this new information. The work shows that chemistry variations can be controlled by maintaining solution composition above the invariant point in the phase diagram.

Sodium phosphate has been used in boiler applications to serve as a pH buffer for corrosion control and for prevention of scale by precipitation of hardness ions. Phosphate concentrations in the bulk solution usually are maintained at low levels, for example in the range of 10^{-4} M or about 10 ppm or less. However, boiling in regions of restricted flow can lead to concentration and precipitation of sodium phosphate salts. Thus, it is important to know the composition and concentration of the saturated solutions that can be produced and the effects of salt precipitation on the composition of saturated solutions as dry-up progresses.

The work of Ravich and Shcherbakova (1) has provided key information on solubility and phase relations of sodium phosphate salts in the 300°C region. These workers determined that, at 300°C, trisodium phosphate solutions show retrograde solubility, and solutions of Na/PO_4 mole ratio 2.85 precipitate a congruent solid solution phase, while solutions of greater than 2.85 mole ratio precipitate a solid solution phase of lower mole ratio. Thus, an increase in solution mole ratio results when precipitation occurs. Significantly, solutions of mole ratio greater than 3 can be produced in this manner so that a "free caustic" condition which may be detrimental to boiler materials can be produced. The work of Ravich and Shcherbakova thus provided a basis for controlling chemistry variations on precipitation to prevent formation of "free caustic." By maintaining boiler water solutions at a mole ratio less than the congruent ratio of 2.85, formation of high mole ratio solutions can be prevented. Precipitation from solutions of mole ratio less than the congruent ratio, 2.85, leads to a decrease in solution mole ratio since a solid solution of higher mole ratio precipitates. This operating strategy for sodium phosphate solutions is known as congruent control (2).

The work described in this paper was undertaken to provide more complete information on solubility and phase relations of sodium phosphate solutions.

This work has investigated solubility and phase relations in the system Na_2O-P_2O_5-H_2O at Na/PO_4 molar ratios primarily from 1.6 to 2.4 at 300°C (572°F). Some additional data have been obtained at 275°C and 324°C, and also at some compositions of higher molar ratios.

Experimental

The experiments were carried out in two-liter autoclaves of stainless steel (A.I.S.I. Type 316) and Inconel Alloy 600 fitted with internal sampling tubes and filters. Three different experimental procedures were followed in obtaining the solubility results: nonisothermal procedures with slow, steady heating and continuous sampling of the autoclave contents; isothermal experiments with saturation approached from below by increasing the temperature, followed by equilibration for periods ranging from hours to many days; and experiments in which saturation was approached by evaporation at approximately isothermal conditions. Samples of solution were periodically removed from the autoclaves and analyzed by potentiometric acid-base titrations. The results from all three methods were essentially in agreement within experimental error.

The compositions of solids precipitated from the saturated solutions were calculated from differences between successive solution samples. In some instances it was possible to recover solids from the vessels for direct determination of sodium-to-phosphate ratios and comparison with calculated compositions. The agreement was satisfactory.

Results

Disodium phosphate solubility.—The solubility of Na_2HPO_4 hydrates has been shown to increase with temperature (3, 4). Above the 95°C temperature for transition from the dihydrate to anhydrous Na_2HPO_4, the solubility appears to be nearly independent of temperature up to about 240°C. The results of our work show that the solubility becomes sharply retrograde above 240°C. Figure 1 shows this information in the form of a binary melting point phase diagram. The diagram suggests that a new solid is the stable saturating phase above 220°C at pressures close to the vapor pressure of the saturated solution.

We have found that the solids which precipitate from disodium phosphate solutions are incongruent as evidenced by our observation of a decrease in solution Na/PO_4 mole ratio on precipitation. Thus, the solids precipitating from solution have Na/PO_4 mole ratios greater than 2. At 300°C, the precipitating solid phase has a mole ratio of 2.1.

The solubility of disodium phosphate solutions shown in Fig. 1 was obtained by slowly heating under-

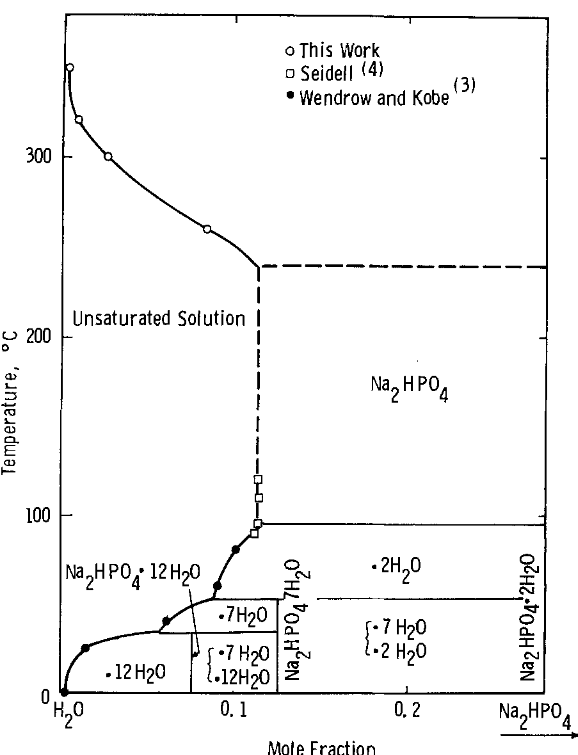

Fig. 1. Solubility of Na_2HPO_4 vs. temperature

saturated solutions in a Type 316 stainless steel autoclave and determining the temperature at which precipitation first occurred. Solution samples were withdrawn at temperatures by means of an internal sampling tube. The samples were conveniently checked for onset of precipitation by measuring their room temperature conductivity. Figure 2 presents these data. The solution compositions were determined by a potentiometric acid base titration. Tables I and II present the data of two experiments which show how the solution composition of disodium phosphate solutions proceed to lower mole ratio as precipitation proceeds on heating to higher temperatures. Mole ratios as low as 1.6 were obtained.

Retrograde solubility and formation of low ratio solutions on precipitation from disodium phosphate solutions were not anticipated and were considered to be undesirable in the steam generator since corrosive reactions could result from the changed composition of the solutions.

Invariant point determination.—Application of the phase rule provided a means to avoid solution composition changes on precipitation. We anticipated that if the disodium phosphate solubility curve intersection with the trisodium phosphate solubility curve could be found then, at the point of intersection, two solid phases would be present, and the three component system, Na_2O, P_2O_5, H_2O, would be invariant. On evaporation, precipitation then would proceed with no solution composition changes as long as the two equilibrium solid phases were present.

A conceptual idea of the ternary phase diagram is provided in Fig. 3, which shows a solution invariant composition at the intersection of two solubility curves and a congruent composition. On this diagram, a solution of composition to the left of the congruent composition but to the right of the invariant composition will precipitate higher ratio solids and proceed in composition toward the invariant ratio at which point a second solid will precipitate and the system will be invariant.

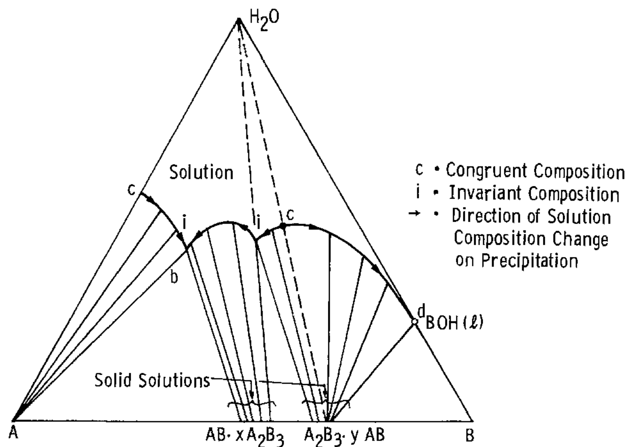

Fig. 3. Isothermal solubility diagram illustrating series of solid solutions between two compounds.

The solution composition is fixed and the over-all composition of the precipitating solid solutions will lie in the range covered in the gap between the two solids or in compositions between the solid solution composition limits. The final over-all composition depends on the initial solution composition.

A series of isothermal solubility determinations were made and the results are presented in Table III. The composition of the precipitating solids was determined by a mass balance and also, in some cases, by direct analysis of the solids as a check. Good agreement was found as shown in Table IV.

Figure 4 shows a plot of solution compositions in equilibrium with the various solid compositions formed at 300°C. The horizontal center section of the curve indicates that two solid phases coexist along with a solution of invariant composition at Na/PO_4 approximately 2.13. The other segments of the curve show variable composition for both solid and solution, indicating that the solids are solid solution phases. An upper congruent composition of 2.85 Na/PO_4 is indicated by the intersection with the dashed line. A lower congruent composition appears to occur at 1.6 Na/PO_4.

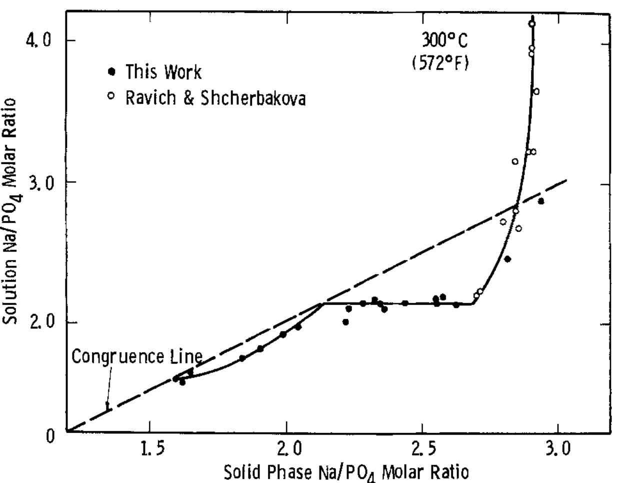

Fig. 4. Phase relationship in sodium phosphate precipitation equilibrium at 300°C.

Solubility is plotted as a function of solution mole ratio and temperature in Fig. 5. The curves were drawn as an intersection of two solubility curves as indicated by the plateau or two-phase region in the phase relation plot. The intersection is the invariant point at which two solid phases precipitate. On both Fig. 4 and 5, the data of Ravich and Shcherbakova are seen to be consistent with this extension of their work to lower Na/PO_4 ratios.

A test of the invariant point could now be made by heating undersaturated solutions of composition greater than the invariant ratio to cause them to precipitate and proceed to the invariant composition. Table V shows the results of experiments in which solutions of initial ratio greater than the invariant ratio were heated to cause precipitation. No further compositional decrease was observed after an initial decrease to the invariant ratio. The result is in strong contrast to the behavior of disodium phosphate solutions in the experiments described earlier in which a significant ratio decrease below 2 was observed. These solutions were initially at a composition lower than the invariant ratio so that they proceeded to decrease in ratio on precipitation moving towards some lower invariant ratio.

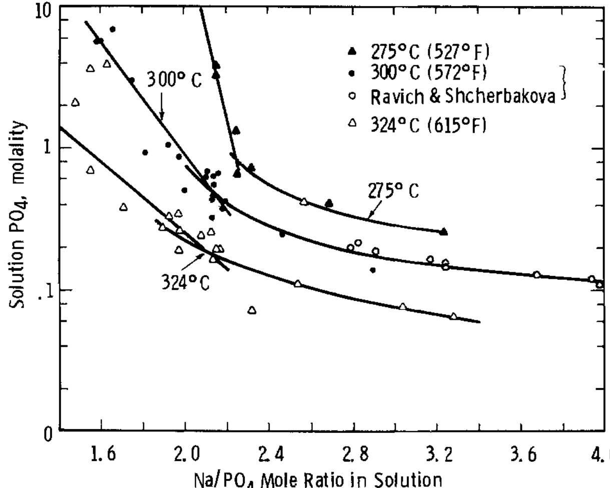

Fig. 5. Solubility of sodium phosphate solutions as a function of Na/PO_4 solution mole ratio.

Table V. Solution composition variation on precipitation of solids from solution initially close to and above invariant point

	Temperature range (°F)	Percent depletion of dissolved salt by precipitation	Solution Na/PO_4 ratio
A.	<541	0	2.31
	570-582	18	2.22
	591-605	45	2.15
	608-625	63	2.20
	633-653	76	2.18
	657-664	85	2.21
B.	<532	0	2.21
	570-590	14	2.17
	595-607	29	2.16
	612-627	56	2.15
	630-640	75	2.14
	649-667	89	2.14
C.	<467	0	2.19
	478-518	1	2.18
	575-587	16	2.15
	593-594	36	2.13
	610-614	49	2.14
	628-636	65	2.13
	636-659	82	2.11

Thus, solution mole ratio decrease below 2 in an acid direction on precipitation can be prevented by using solutions of mole ratio above the invariant ratio.

Discussion

In this work, we have found that disodium phosphate solutions have a sharply retrograde solubility above 240°C. Incongruent solids of higher mole ratio than 2 precipitate so that precipitation causes the solution mole ratio to proceed to lower or more acid values. An invariant composition of 2.13 at 300°C was found. The solubility increases sharply with decreasing mole ratio from the invariant point of 2.13 to 1.6.

These results provide a rational basis for controlling the composition of sodium phosphate solutions in boilers. As previously recognized by Marcy and Halstead (2), the Na/PO_4 ratio should be maintained below the upper congruent composition to avoid excessive alkalinity caused by incongruent precipitation during evaporative concentration. This work indicates that the Na/PO_4 ratio should also be maintained above the invariant composition to avoid composition shifts toward the lower ratio compositions of very high solubility as evaporative concentration and dry-up proceed.

Chemisorption on Powdery Indium Amalgams: Catalysis of the Oxygen Reduction

R. Barrue* and J. F. Rialland

Laboratoire de Génie Electrique (LGEP-LCIE), 92260 Fontenay-Aux-Roses, France

ABSTRACT

A number of works have described the catalytic properties of powdery indium amalgams in the electrochemical reduction of oxygen in basic media. X-ray diffraction studies of these powders exhibit that their surface mainly consists of the three following compounds: $In(OH)_3$, InOOH, and In_2O_3. The chemisorption isotherms, determined in the pressure range 0-1.5 atm, show that only In_2O_3 can take a predominant part in the catalytic properties of the powdery amalgams. Electrochemical measurements of oxygen cathodic reduction in aqueous basic solutions corroborate the previous result.

Indium amalgams are liquid at room temperature for indium concentrations lower than 69 atomic per cent (a/o). These liquid alloys may yield a powdery material through strong mechanical shaking under atmosphere. This phenomenon seems to be attributed to a superficial enrichment in indium and an adsorption of gases. X-ray diffraction studies have led us to suggest a grain model which consists in a liquid core surrounded with a quasi solid superficial layer (1).

A number of works (1-3) have described the catalytic properties of those powdery amalgams in the electrochemical reduction of oxygen in basic media. X-ray analyses have established that the superficial layer of grains mainly consists of the three following compounds: indium oxide (In_2O_3), indium oxyhydrate (InOOH), and indium hydroxide ($In(OH)_3$).

In this paper, our purpose is to specify if the catalytic properties of the powdery indium amalgams may be specifically attributed to one of those three compounds.

Oxygen Chemisorption Isotherms

In heterogeneous catalysis, the adsorption of the reactive compounds is the first step of the catalytic process. This fact led us to determine the oxygen chemisorption isotherms on the powdery amalgams and on the three above-mentioned compounds. The isotherms have been plotted for usual pressures in heterogeneous catalysis and at room temperature.

Key words: chemisorption, catalysis, indium amalgams, indium oxide.

Experimental

The powdery amalgam samples were obtained from a liquid alloy of 16 a/o In through mechanical shaking under atmosphere (1). Indium oxide and indium hydroxide were made and then analyzed by means of x-ray diffraction, in our laboratory. For InOOH, an ultrapure product (Ventron U.S.A.) was used. The powdery samples consisted of particles of about 50 μm diameter. Oxygen and nitrogen were high purity gases ($O_2 \geqq 99.995\%$; $N_2 \geqq 99.998\%$).

The diagram of the apparatus is shown in Fig. 1. The volume of the cell is about 500 cm^3. In a first step, a 10g sample was put in the cell. After a 48 hr long desorption in a high vacuum (10^{-6} Torr), a mixture of oxygen and nitrogen (an unchemisorbed gas) was introduced into the cell. The number of moles for each of the two gases contained in the cell was determined by means of the gas-chromatography analysis of a 1 cm^3 gaseous sample. The change of the partial pressures of the two gases as a function of time was obtained in the same way.

As an example, Fig. 2 shows the superposition of two chromatograms obtained at the start (s) and the end (e) of adsorption on a powdery amalgam sample. The first peak is the one of oxygen, and the second peak is the one of nitrogen. The numbers of moles for each gas are in ratio to the corresponding peak areas. The examination of the chromatograms shows that the N_2 peak is unchanged, while the O_2 peak area is strongly reduced, exhibiting a large adsorption of this gas.

Results

No adsorption on $In(OH)_3$ and InOOH could be detected, while oxygen adsorption on In_2O_3 and on the powdered amalgam was measurable by the experimental method.

The specific surface areas were determined from the BET transforms (4) of the nitrogen physical adsorption isotherms at 77°K. The values deduced from these measures are: 115 m^2/g for the powdery amalgam and 74 m^2/g for In_2O_3.

The times for establishing the adsorption-desorption equilibrium were relatively long. The time constants were related mainly to diffusion phenomena through the powdery material. Thus in order to quicken the rate of reaction, the powdery samples were shaken by using a magnetic device. With this agitation, the equilibrium was reached after about 7 days for the powdery indium amalgam and after about 15 days for In_2O_3. In Fig. 3 the amounts of adsorbed oxygen are plotted *vs.* time for the two adsorbents.

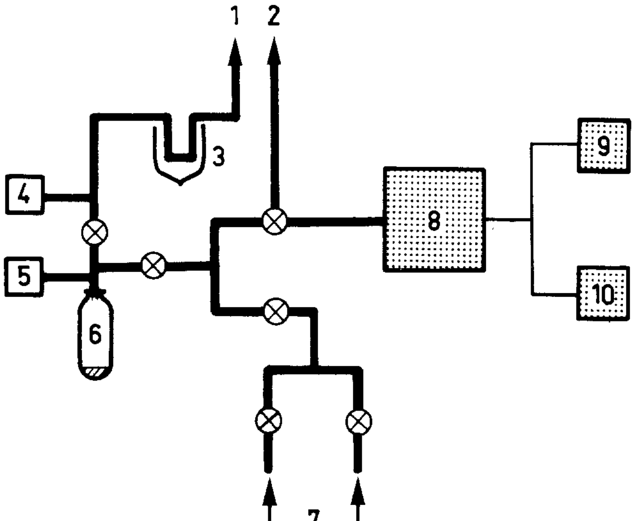

Fig. 1. Apparatus for chemisorption isotherms measurements. 1, To high vacuum; 2, to vacuum; 3, trap; 4, vacuum gauge; 5, pressure gauge; 6, adsorption cell; 7, gas supplies; 8, chromatograph; 9, recorder; 10, digital integrator.

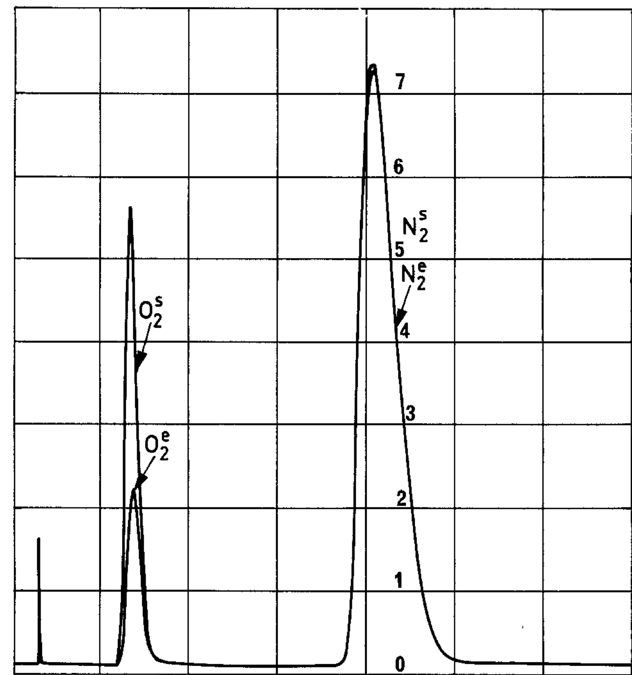

Fig. 2. Superposition of chromatograms. Adsorbent: powdery indium amalgams. Lasting of adsorption: 5 days; $T = 25°C$. $P_{O_2}{}^s = 0.2$ atm; s = start; e = end.

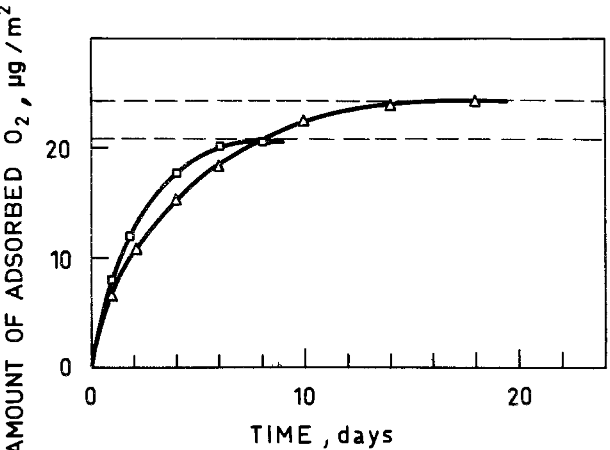

Fig. 3. Kinetics of oxygen adsorption referred to unit surface area. Temperature: $T = 25°C$. Initial pressure: $P_{O_2}{}^s = 0.5$ atm. Square, on powdery amalgams; triangle, on indium oxide

The isotherms are plotted in Fig. 4. For the two curves, a saturation quickly occurs in terms of pressure. For oxygen partial pressures over 1 atm, the powdery amalgam isotherm increases again; in addition, the adsorbed oxygen could not be desorbed fully by the usual ways. This behavior may be attributed to the existence of a secondary chemical reaction, as in the oxidation of a metallic phase (mercury or indium).

Oxygen Reduction on an Indium Oxide Electrode

The catalytic effect of indium oxide in the electrochemical reduction of oxygen in basic media has been specified by electrochemical measurements.

Experimental

Gas porous electrodes were made with indium oxide. Two grams of indium oxide and 2g of powdered metallic indium were mixed and compressed in a cylindrical matrix. The binding material was sintered at 150°C for 24 hr. The powdered indium was included to ensure good cohesion and good electrical conductivity in the sintered material. The area of the electrode was about 1.5 cm^2. Electrolyte was an aqueous solution of sodium hydroxide (1M NaOH); the temperature was 25°C. The

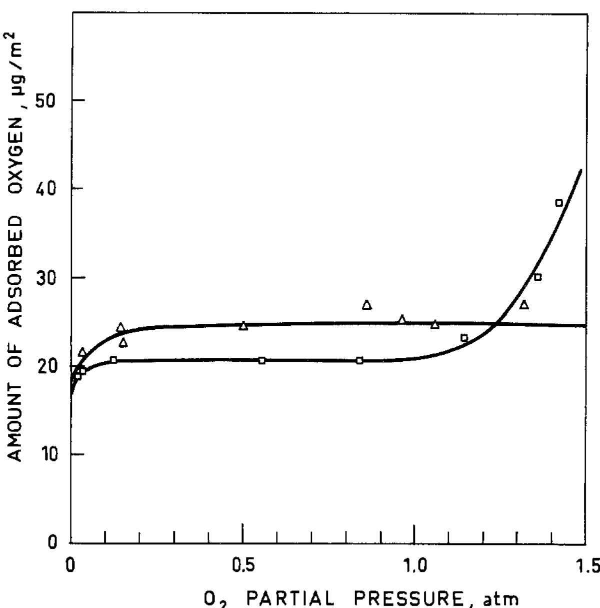

Fig. 4. Oxygen chemisorption isotherms referred to unit surface area. Temperature: $T = 25°C$. Square, on powdery amalgams; triangle, on indium oxide.

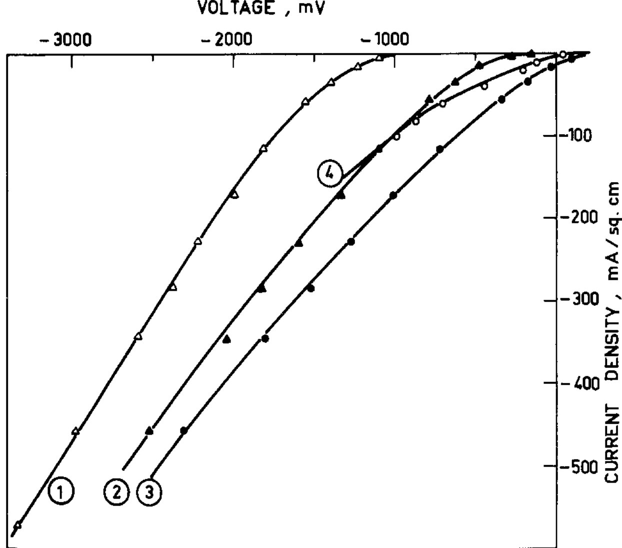

Fig. 5. Effect of O_2 pressure on polarization curves. 1, In_2O_3-O_2 pressure = 0; 2, In_2O_3-O_2 pressure = 1 atm; 3, In_2O_3-O_2 pressure = 2 atm; 4, powdery indium amalgams-O_2 pressure = 2 atm. Temperature: $T = 25°C$. Electrolyte: 1M NaOH. Reference: Hg/HgO · 1M NaOH.

cathodic potentials were recorded *vs.* the Hg/HgO potential.

Results

Three reactions were possible

$$2\,H_2O + O_2 + 4e \rightarrow 4\,OH^- \quad [1]$$

$$3\,H_2O + In_2O_3 + 6e \rightarrow 2\,In + 6\,OH^- \quad [2]$$

$$2\,H_2O + 2e \rightarrow 2\,OH^- + H_2 \quad [3]$$

Only reaction [1] was associated with the catalytic process. This reaction occurred with the reduction of oxide to metal (reaction [2]). In the studied current density range, reaction [3] was so slow that the current corresponding with the H_2-release was negligible.

The current density potential curves are plotted for different pressures of oxygen in Fig. 5. The curves are typical of electrodes for which the oxide capacity is 4160 coulombs (2g of In_2O_3). Curve 1 is associated with the reduction of oxide. The differences between this curve and curves 2 and 3 show the effect of oxygen. Curve 4 was obtained with a powdered amalgam electrode studied under the same conditions (1).

Because of its slowness, the chemisorption of oxygen is probably the limiting step of reaction [1]. In Fig. 3, the maximum rate of adsorption is given by the slope at origin; this rate is too slow to explain the effect of oxygen in the electrochemical measurements. In fact, the time constants determined in chemisorption were mainly due to diffusion through the pores of the powdery bulk. In the electrochemical measurements there is forced convection of oxygen and thus an increase in adsorption rate. Thus the rate of adsorption cannot be determined from the curves of Fig. 3.

Conclusion

Oxygen chemisorption on $In(OH)_3$ and InOOH cannot be detected by our experimental method. With regard to In_2O_3 and to the powdery indium amalgams, the amounts of adsorbed oxygen are about the same order of magnitude.

The electrochemical experiments exhibit the catalytic effect of In_2O_3 in oxygen reduction in basic media. The measured cathodic potentials are comparable with those obtained for a powdery indium amalgam electrode.

These results lead us to attribute the catalytic properties of the powdery amalgams to the presence of In_2O_3 in the surface layer of the individual grains.

At the present time, investigations on the powdery indium amalgams are being made to differentiate the kinetics of In_2O_3 reduction from that of catalytic oxygen reduction.

Undervoltage Deposition of Alkali Metal at Carbon Electrodes in the LiCl-KCl Eutectic Melt

S. D. James*

Electrochemistry Division, Naval Surface Weapons Center, White Oak, Maryland 20910

ABSTRACT

Voltammograms and charge-discharge curves are presented for carbon electrodes of varying graphitic crystallinity in LiCl-KCl eutectic melt at 703°K (430°C). For rods of glassy carbon, graphite, and pyrolytic graphite there is a very marked cathodic depolarization below about −2.5V *vs.* a chlorine electrode. Chemical analysis of the cathodized carbons shows that this depolarization is caused by undervoltage deposition of alkali metal. The deposited metal normally consists entirely of Li but in two cases, during potentiostatic cathodizing, significant amounts of K were codeposited. Cathodized graphite rods disintegrate before reaching the Li potential but glassy carbon rods do not and can survive about 25 charge-discharge cycles before breaking up. The uninflected charging curves obtained for glassy carbon and graphite give no indication of distinct transitions between Li intercalation compounds of different stages. However, the relatively low Li contents of cathodized carbons, their x-ray diffraction patterns and the absence of acetylene in their reaction with water all favor the presence of intercalation compounds rather than a carbide. Lithium contents of glassy carbon rods cathodized toward the Li potential range up to about 7 weight per cent compared with 8.9% for C_6Li, the richest intercalation compound and 37% for Li_2C_2. Even quite brief exposures of carbon electrodes in this melt to potentials below −2.5V have lasting effects on electrode behavior; carbon loses its melt-repellency and the electrode suffers a 1-2V lowering of its open-circuit voltage.

Unexpectedly high cathodic currents were noticed when carbon electrodes were driven below −2.5V *vs.* the chlorine electrode in LiCl-KCl melt at 703°K (430°C). This surprised us since it occurred more than a volt above the equilibrium potential of lithium in this melt, *viz.*, −3.65V *vs.* the chlorine electrode (1). Since a literature search failed to unearth any explanation of this anomaly we made tests to elucidate its cause. The present paper describes these tests and the conclusions arrived at.

Experimental

Equipment.—The LiCl-KCl eutectic melt volume was 376 cm^3, occupying a 115 mm depth in a 210 mm tall, 70 mm diameter Pyrex test tube. This inner test tube rested inside a 360 mm tall, 76 mm diameter, flange-topped Pyrex pot (flange assemblies were of 3 in. Conical Pipe System from the Corning Glass Company). A flanged Pyrex lid with Teflon O-ring gasket was bolted onto the pot. This lid has six short vertical glass tubes acting as ports through which a thermocouple, a 4 mm Pyrex gas-bubbling tube and various electrodes can be fed down into the melt. Sliding seals at these ports were made using modified Teflon Tube Fittings (Beckman Instrument Incorporated). A cylindrical electric furnace was used; its temperature was controlled to ±1°K (1°C) by Versatherm Model 2157 (Cole Palmer Instrument Incorporated). A Chromel-Alumel thermocouple inside a 6 mm Pyrex tube thermowell dipped into the melt. At 703°K the 110 mm deep, normally unstirred melt was 1°K hotter at the top than at the bottom.

The Tacussel fast-rise potentiostat PIT20-2X (plus GSTP2 function generator) was used in the potentiostatic or galvanostatic mode giving rise to linear scan voltammograms and constant current charge-discharge curves, respectively. The voltammograms were displayed on a Tektronix X-Y oscilloscope model 561A with two, 2A63 differential amplifier plug-ins. The two inputs of the Y-plate plug-in were connected across a standard resistor (normally one ohm) in the counter-electrode lead, thus registering cell current. The other plug-in received the controlled voltage sweep (test electrode *vs.* reference) from a jack on the potentiostat. The voltammograms were photographed. In the constant current mode, the voltage-time curves were recorded on a strip chart recorder (Varian G-11A with B1 input chassis).

Materials.—Lithium chloride and potassium chloride powders were ACS certified reagents from Fisher Scientific Company. Chlorine gas (used both in the reference electrodes and for dehydrating the melt) was Electronic Grade, 99.98% pure, from Precision Gas Products, Rahway, New Jersey. The usual cell atmosphere was high purity argon (water pumped, 99.996%), passed through a drying train of Drierite (anhydrous calcium sulfate). Three types of carbon rods were used as electrode materials. Glassy carbon rods, 1.5 or 3 mm in diameter (grade V25-99.99% carbon) were obtained from the Carbone Company, of Boonton, New Jersey. Synthetic graphite rods of spectroscopic purity (99.999% carbon) came from Ultra Carbon Corporation, Bay City, Michigan. Both ⅛ in. (3.0 mm) and ¼ in. (6.1 mm) diameter rods were used. In one experiment, graphite rods, 254 × 6.3 mm, covered with a 0.1 mm thick coating of pyrolytic graphite were used. The graphite orientation is said to be such that the a-b planes are parallel to the coated surface at all points. These rods, designated EC-2, were bought from the General Electric Company, Detroit, Michigan.

Electrodes.—Working electrodes of glassy carbon used in getting the cyclic voltammetry data of Fig. 2 are illustrated in Fig. 1A. These were made as follows. Firstly a 25 mm length of 1.5 mm diameter glassy carbon rod was carbon-cemented 6 mm deep into the end of a 3 × 600 mm spectroscopic graphite rod. The composite rod was then sealed into a Pyrex tube and sawn off at 45°. This angular cut allows any chlorine bubbles, anodically formed during use, to escape from the electrode. A final polish was given to the Pyrex-carbon sawn surface on a 180 grit diamond-coated wheel. The geometric area of the exposed glassy carbon ellipse was 2.43 mm^2. The Carbone Company's

* Electrochemical Society Active Member.

Key words: molten salts, carbon electrodes, intercalation compounds, cathode depolarization, high temperature electrochemistry.

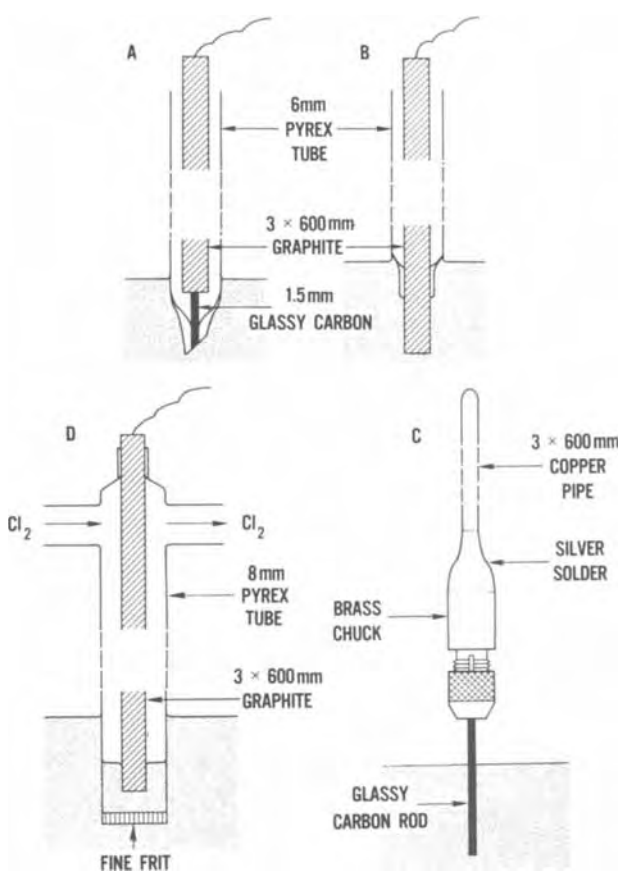

Fig. 1. Types of carbon electrode used: (A) working electrode of glassy carbon sealed in Pyrex, (B) working or counterelectrode of graphite sealed through Pyrex, (C) working electrode of glassy carbon held in chuck, (D) chlorine reference electrode.

glassy carbon has a thermal expansion coefficient of 3.2 μm/m.K at 373°K. This is almost as big as that of the Pyrex glass (3.3 for Corning 7740) and thus the carbon-Pyrex seal of Fig. 1A has little or no tendency to leak. In the early experiments it was noticed that the Pyrex tips of working electrodes like those of Fig. 1A and B cracked and admitted melt after prolonged cathodic polarization (even at potentials well positive of the Li/Li^+ equilibrium). It became apparent later that this was caused by swelling of the carbon tip due to its absorption of alkali metal deposited at undervoltage. In subsequent work designed to examine this undervoltage deposition, the Pyrex envelopes were dispensed with and the bare carbon was dipped directly into the melt. A graphite working electrode used in the initial cyclic voltammetry is shown in Fig. 1B. The end of a 3 mm diameter graphite rod (Ultra's U7, a high density grade, 1.90 g/cm^3) protruded 20 mm from the sealed Pyrex tube. The geometric area of exposed graphite was 2.0 cm^2. Electrode (C) of Fig. 1 was used when we wished to weigh the carbon before and after cathodic treatment. The carbon rod was gripped in a brass chuck (taken from an electrical test prod). The only carbon material studied in this way was glassy carbon. Rods 1.5 mm in diameter slipped easily into the chuck whereas 3 mm rods had to be tapered by filing.

The counterelectrode was a 6 $\times$ 600 mm graphite rod (Ultra, U7) dipping about 75 mm undermelt. When acting as a cathode in pure LiCl-KCl melt, graphite absorbs alkali metal plated onto it. In the anodic mode it reoxidizes this absorbed metal and/or gasses chlorine. None of these reactions significantly contaminates the melt. A graphite rod of these wetted dimensions can absorb at least 1500 coulombs of cathodic charge before there is any danger of its disintegrating under the stress of the absorbed alkali metal (see below)

The chlorine electrode was used as reference. It is illustrated in Fig. 1D. Ultra Carbon's U120 grade of spectroscopic graphite rod was normally used as the electrode substrate although other grades of pure graphite worked just as well. The chlorine flows by the carbon and over the melt rather than through the carbon and into the melt as is more customary (2). This flow-by electrode has the advantage of relative ease of construction and safety from the danger of the melt sucking back and freezing. It takes about 10-15 hr of chlorine flow to equilibrate the electrodes to within 1 mV of the reversible chlorine potential. We always used a pair of reference electrodes, regularly monitoring their interelectrode or bias potential. After the initial equilibration period the bias potential never exceeded 1 mV during weeks of continuous use. All quoted potentials are *vs.* this chlorine electrode.

Melt purification.—A charge of LiCl-KCl salt powders (mixed in the eutectic proportion) was outgassed at 2.66-6.65 $N \cdot m^{-2}$ (20-50μ Hg) while being heated up to about 703°K (430°C). On melting, a brisk evolution of water vapor commenced and continued for 30-45 min. Residual water was then removed by bubbling chlorine through the melt for 60 min (3). It was then freed from platable impurities by preelectrolysis at an auxiliary aluminum cathode (*vs.* a graphite anode). The cathode was 80 cm^2 in area and held at -2.95V to the chlorine electrode. Preelectrolysis was continued for 24 hr although the residual current density (at the cathode) fell to a steady value of 10 μA/cm^2 after 4 hr. The Al cathode which had become dark gray was withdrawn from the melt at the end of the preelectrolysis.

X-ray examination of cathodized carbons.—After cathodizing in the melt at constant current down to the lithium potential (-3.65V *vs.* the chlorine electrode), several different types of 3 mm carbon rod were x-rayed to see if any structural change had occurred. After filing free from adherent solidified melt the rods were laid in a Lucite x-ray sample holder and filed half round so as to expose a 10 mm $\times$ 22 mm expanse of flat carbon surface. This was all done in an argon-filled glove bag. Then each holder was securely enveloped with one layer of cellulose acetate transparent adhesive tape (Magic Tape 3M Company) and placed in its own, argon filled, screw-cap bottle. The x-ray diffraction pattern was recorded in air without removing the tape, immediately after taking the holder from its bottle. The Standard Phillips x-ray powder diffractometer was used employing CuK_α radiation.

Chemical analysis of cathodized carbons.—Cathodized carbon rods were ground up and extracted with water which was then analyzed for Li^+, K^+, Cl^-, and OH^-. The rods were first freed from solidified melt by a quick rinse with a jet of distilled water then dried, crushed in a press and ground in a mortar. The powders were then weighed; weights varied between 0.2 and 0.8g. After 4 hr of refluxing with distilled water, the extracts were filtered and analyzed for Li^+ and K^+ by atomic absorption spectroscopy and for Cl^- and OH^- by conventional titrimetry. In some cases, second extractions were done on the powder. The second extracts contained the sought ions at no more than background levels. In spite of this apparently complete removal of alkali metal, flame tests showed that most of the extracted carbons still contained appreciable amounts of Li. Hence the extracted powders were ashed to constant weight in silica crucibles at 1023°K (750°C) then digested in water which was analyzed to determine the residual alkali metal.

Results and Discussion

Voltammograms.—Figure 2 shows current-voltage curves obtained at a glassy carbon electrode of Fig. 1A

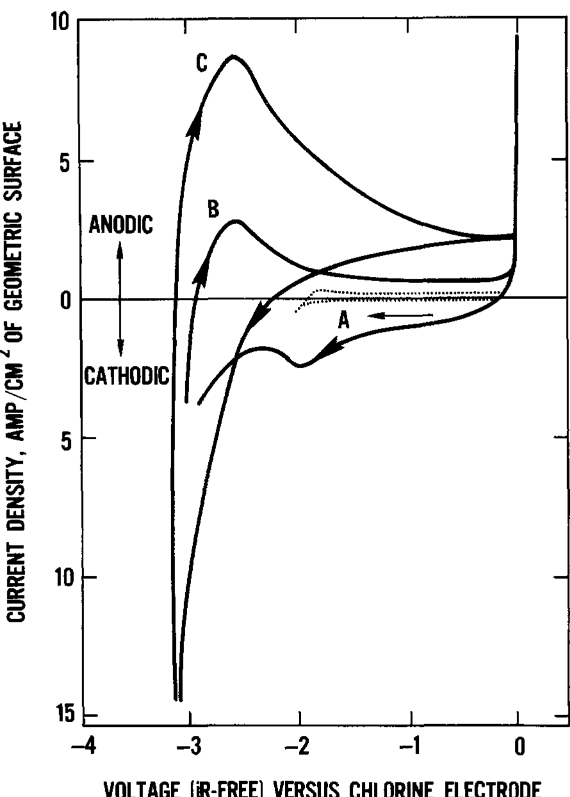

Fig. 2. Voltammograms at glassy carbon in LiCl-KCl at 430°C as a function of the range of applied voltage. Sweep cycle time was 0.2 sec.

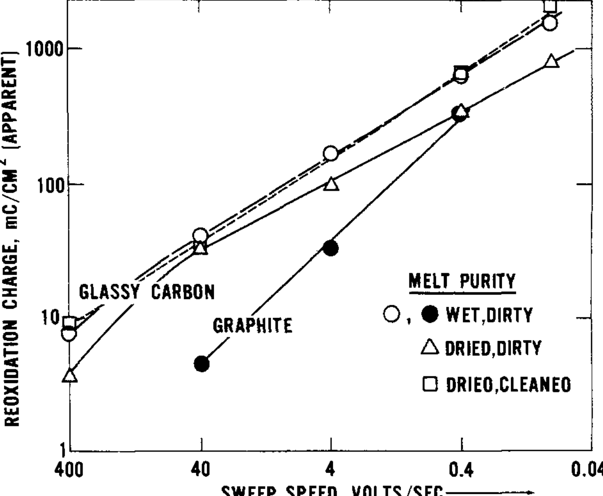

Fig. 3. Coulombic charge of anodic peaks in voltammograms at carbon electrodes. Applied voltage range: −3.5 to +0.5V, vs. chlorine electrode. LiCl-KCl at 430°C.

type construction. The geometric area of the carbon ellipse was 0.0243 cm², and the electrode was dipping in a purified melt at 703°K (430°C). Basically similar curves were obtained using a 2.0 cm² graphite electrode (Fig. 1B type). The curves of Fig. 2 are the reproducible ones obtained after a train of five or more voltage triangles had been applied to the working electrode. The nominal voltage range of these triangles were: Curve A, −2.0 to 0.0V; B, −3.5 to +0.5V; C, −4.0 to 0.0V *vs.* the chlorine electrode. However, after correction for substantial *iR* drops the actual limits of voltage excursion were −3.2 and 0.0V. In the low amplitude sweeps of curve A the trace differs little from expected, except perhaps at −2V where cathodic current is starting followed by a small anodic peak after sweep reversal. These effects are much more marked in B which also has a pronounced cathodic peak at −2.1V. This latter peak is presumably due to reduction of chlorine generated at positive voltages since it vanishes if the positive excursion of applied voltage is restricted to 0.0V. In curve C the cathodic depolarization below −2.5V is very striking. Extremely large cathodic current densities are found and a big anodic peak appears after voltage sweep reversal as species produced in the cathodic sweep are reoxidized.

These results were unexpected; we did not look for significant cathodic current till below about −3.65V, the lithium potential in this melt (1). Such big cathodic currents (10 A/cm², at 0.7V above the Li potential) cannot arise from impurities at the level normally found in reagent grade salts. This is confirmed by the independence of the effect on the degree of melt purification employed. So it seems that carbon electrodes are far from inert in this metal. The rest of this paper shows that carbon rods of diverse types will, between −2.5 and −3.6V, absorb at undervoltage, large quantities of alkali metal (mainly Li). Due to a compound formation between carbon and deposited metal (probably a laminar or intercalation compound) deposition is energetically assisted, *i.e.*, occurs at undervoltage.

Figure 3 shows the electrical charge used to reoxidize the material plated out at undervoltage. The coulombic content of the anodic peaks in curves such as those of Fig. 2 is plotted against the voltage sweep rate. The glassy carbon was a Fig. 1A type and the graphite electrode a 1B type. There is no correlation of reoxidation charges with melt purity which, together with the very high values of the cathodic currents in Fig. 2 shows that these currents do not correspond to reduction of impurities in the melt. Thus these currents must arise from the cathodic reduction of the lithium or potassium cations. The deposited metal is obviously quitting the interface as fast as it is formed there, otherwise the cathode voltage would fall immediately to the potential range of Li or K deposition (<−3.6V). Thus the alkali metal is either soaking rapidly into the carbon rods or dissolving rapidly in the melt. Since an iron rod under the same conditions cannot sustain even 8 mA/cm² cathodic current without plunging at once to the Li potential (see Fig. 4) it seems the carbon must be soaking up the alkali metal in some way. Undervoltage deposition of a metallic monolayer on various substrates is well known in aqueous solution (4) and even recently in fused salts (5). However, the charges of Fig. 3 at slow sweeps correspond to many thousands of monolayers. Thus undervoltage deposition of a single superficial monolayer cannot explain our data. The alkali metal must be continuously soaking into the carbon. The slower the voltage sweep speed, the more time is available in the anodic sweep to reoxidize this metal as it diffuses back to the melt interface; hence the larger is the reoxidation charge.

Charge-discharge curves.—Figure 4 shows first-cycle charge-discharge curves at a 1.5 mm diameter rod of glassy carbon. The 76 mm long rod was carbon-cemented into the end of a 600 mm long, ¼ in. diameter graphite rod, serving as support and electrical lead. The glassy carbon protruded 70 mm from the graphite and dipped 25 mm undermelt such that its wetted area was 1.2 cm². On switching on cathodic current at A, carbon voltage falls sharply to about −2.7V then more gradually, leveling off when the wetted carbon whitens with a coating of tiny white Li droplets. On current reversal at B, the discharge curve after a small step due to *iR* drop, more or less mirrors the charging curve except that (*i*) the discharge time to chlorine evolution, τ_a, is only about 0.9 of the charging time, τ_c, (*ii*) on switching off the anodic current at C, carbon voltage falls almost to −3V, two volts lower than the original value of about −1V, the usual voltage of untreated carbon in these melts. The

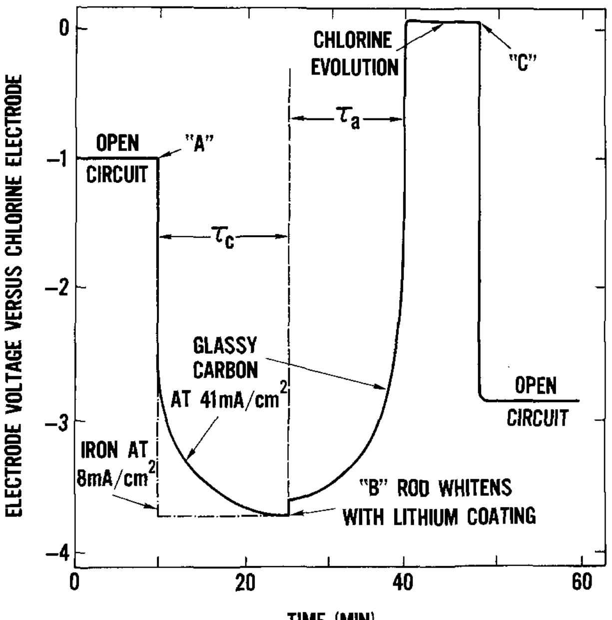

Fig. 4. Charge-discharge curves for 1.5 mm glassy carbon rod in LiCl-KCl at 430°C. Current switched on cathodically at A, reversed at B, and switched off at C.

dot-dash-dot curve depicts the behavior of a pure iron rod cathodized at 8 mA/cm^2; it was driven to the Li potential in less than 3 sec. This shows that the depolarization exhibited by carbon arises on the carbon side rather than the melt side of the interface.

The data of Fig. 4 parallel those of Fig. 2 but they go further, showing the effects to be large ones rather than merely a transitory depolarization. Large amounts of charge are passing at undervoltage. Chemical analysis of various cathodized rods showed this charge to be wholly in the form of deposited Li absorbed in the carbon, to the extent of about 5 weight per cent (w/o) Li. The rod whose first charge-discharge cycle is illustrated in Fig. 4 was subjected to 24 additional similar cycles at four successively higher current densities (43, 83, 143, and 286 mA/cm^2). It was found that the coulombic charges Q_c and Q_a corresponding to times τ_c and τ_a had no significant dependence on current density. Neither did the ratio Q_c/Q_a which remained at an average value of 0.90 $\pm$ 0.015. The first observation shows that Li permeates the glassy carbon structure quite easily. If this were not so, high current densities would soon effect, in the skin of the carbon rod, such Li enrichment on charge and Li depletion on discharge as to polarize the electrode quickly to the Li and Cl_2 potentials, respectively. The Q's would then depend sharply on current density which was not observed. The fact that Q_a/Q_c = 0.90 suggests either a low current efficiency for Li deposition or that some of the absorbed Li is bound too tightly to be reoxidized anodically. The lack of variation of Q_a/Q_c with current density favors the latter explanation.

Graphite rods gave very similar charging curves to that of Fig. 4. However, with graphite rods the charging curves could not be completed to the Li potential as the rods broke prior to this point. Sometimes they snapped cleanly at the melt meniscus but more often, towards the end of the charge, fine carbon powder began to fall from the meniscus area of the rod which soon necked down till the wetted part of the rod fell off. Presumably this is caused by high stresses arising at the demarcation between wetted carbon swollen with absorbed Li and relatively unaffected material above the meniscus. A few experiments with graphite rods coated with a 0.1 mm thick layer of pyrolytic graphite also gave charging curves similarly shaped to that of Fig. 4. According to the manufacturer, the graphitic planes in the pyrolytic graphite coating were parallel to the coated substrate at all points. Thus either the Li atoms can permeate freely through the carbon hexagons of the pyrolytic coating or this coating is highly imperfect. We suspect the latter since Li, atomic radius 0.153 nm (1.53Å) would be grossly deformed in passing through a carbon hexagon (inner radius 0.071 nm). On the other hand, in intercalation compounds, the alkali metal atoms are believed to be substantially ionized (6). In this case the Li^+ ionic radius of 0.068 nm, would permit it to pass through the sheets.

A series of well-defined Li graphite intercalation compounds has been made in other laboratories by reacting Li directly with crystals of natural graphite (6). These are: C_xLi where x = 72, 36, 18, 12, 8, or 6. None of our charge-discharge curves ever showed any arrests in voltage corresponding to the formation of compounds successively richer in Li. Arrests would have been seen in the charging curve of Fig. 4 after about 2.5, 5, and 10 min corresponding to compounds with x = 72, 36, and 18. On the contrary, the smooth curves of Fig. 4 suggest a continuous spectrum of interaction energies of Li with the carbon structure. Perhaps this difference is related to the relatively amorphous structure of glassy carbon and synthetic graphite used in this work as opposed to natural graphite which is much more highly crystalline.

Figure 5 shows data for five separate glassy carbon rods cathodized at different constant current densities between 9 and 144 mA/cm^2. The rods were 76 $\times$ 1.5 mm, held in a chuck as in Fig. 1C and dipped 60 mm undermelt. The original charging curves were replotted as voltage *vs.* amount of charge passed, to aid their comparison. The results show there is a small but significant concentration polarization effect. At the same stage of charge there is a 0.1V spread in voltage according to the charging rate. Thus at the higher current density there is a perceptible backup of the permeating Li. The curves merge close to the Li potential as all the rods approach saturation with Li.

Composition of cathodized carbon rods.—Glassy carbon.—Figure 6 shows the Li uptake of glassy carbon rods (determined by chemical analysis) as a function of potential. Seven, 3 mm rods, supported in chucks as in Fig. 1C were held for 60 min at various constant potentials. They were then removed from the melt and analyzed chemically for Li and K. Their Li contents rise smoothly with falling voltage with a sharp rise close to the reversible Li potential (though ostensibly from the same batch, the rod with the anomalously high Li content at -3.0V was also anomalously hard; it was very difficult filing its end tapered to enter the chuck). No study was made of Li uptake *vs.* time at constant potential so it is not certain that the data points of Fig. 6 represent true equilibrium values. However, in getting the constant current

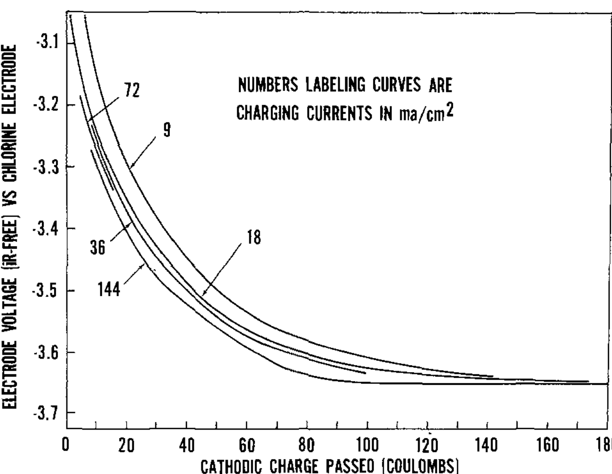

Fig. 5. Voltage *vs.* amount of charge passed for glassy carbon rods cathodized at various rates in LiCl-KCl at 430°C.

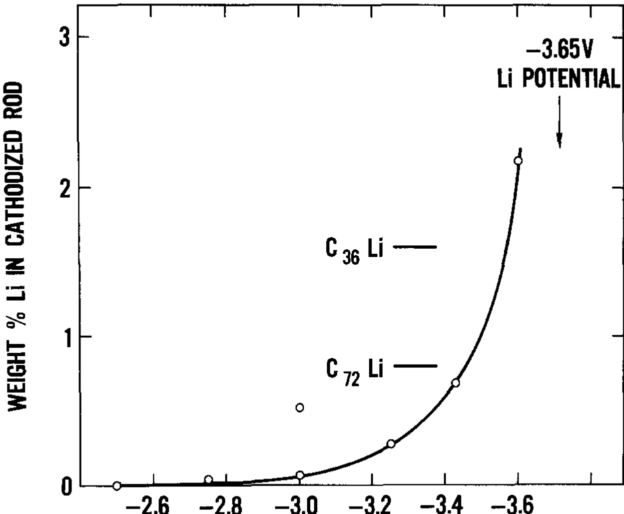

Fig. 6. Lithium uptake of glassy carbon rods as a function of potential in LiCl-KCl at 430°C. A separate rod was held at each potential for 60 min then removed from melt for Li determination by chemical analysis.

charging data of Fig. 7 we found that 1.5 mm diameter rods could be charged up to 3.6 w/o Li in only 8 min. Thus it is unlikely that the curve of Fig. 6 would be significantly altered by longer potentiostating. The smooth curve of Fig. 6 agrees with the smooth charging curves of Fig. 4 and 5. They both indicate continuous rise in Li content with falling voltage; there are no arrests in voltage as might occur during the transformation of one layer-compound to another richer in Li, *e.g.*, $C_{12}Li$ to C_8Li. This contrasts with the preparation of layer compounds from single-crystal graphite. Here at 673°-773°K (400°-500°C), steps were obtained in curves of composition *vs.* alkali metal vapor pressure for both K and Cs (6, 7). The uninflected voltage-composition curves of the present work are probably associated with the relatively

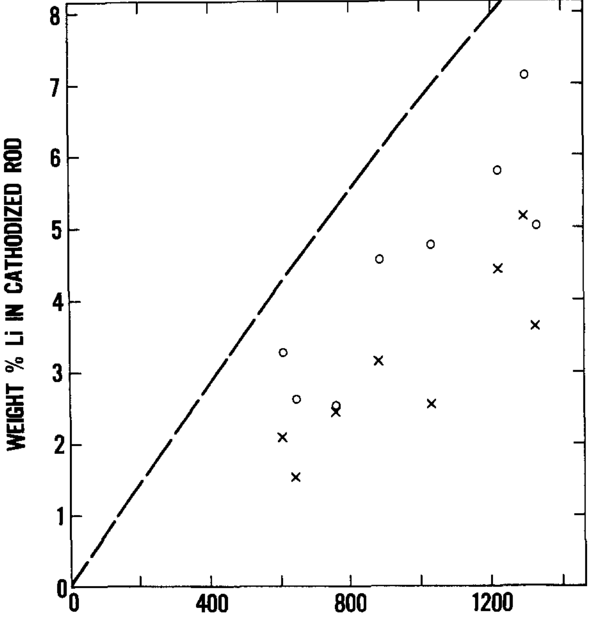

Fig. 7. Lithium uptake of glassy carbon rods cathodized at constant current toward the Li potential (LiCl-KCl, 430°C). Broken line: Assumes carbon absorbs Li, equivalent to the total charge passed. Circles: Observed per cent gain in weight. Crosses: Li contents from chemical analysis.

amorphous nature of the glassy carbon used. This agrees with the work of Herold *et al.* (8, 9). Using the same source and grade of glassy carbon as the present work (V25 from Carbone Company) they got uninflected isotherms for the absorption of K vapor at 873°K (600°C). Their richest material was 25.8 w/o K (C_8K contains 29.0 w/o K). They considered this material to be, at least partially, an intercalation compound. This work of Herold and a brief note by Halpin (10) seem to be the only published data on the action of alkali metals on glassy carbon and is restricted to potassium. Recently (11) steps were obtained in constant-current charging curves using cathodes of synthetic graphite foil. In these room-temperature experiments, Li, K, and NMe_4 were cathodically impregnated into the graphite from salt solutions in dimethyl sulfoxide. It would seem thus that high crystallinity of the carbon and low temperature of impregnation favor the observation of steps in charging curves.

In the intermediate potential range of Fig. 6, significant amounts of K were found in the glassy carbon. For the rod at −3.0V, anomalously rich in Li, K/(K + Li) was 0.39 mole fraction and at −3.25V the fraction was 0.16. No chloride was found in these rods so all their K came by electrodeposition rather than by uptake of melt. These two rods were the only cases in this work where K was found to be codeposited at undervoltage with Li. It is not clear why K deposition was restricted to this intermediate range of potential. At inert iron cathodes in LiCl-KCl eutectic, highly pure Li with less than 0.1%, K is deposited (12).

Figure 7 shows the Li uptake of eight glassy carbon rods cathodized at constant current toward the Li potential. The experimental setup was the same as in the constant potential work. The rods were 76 mm long, 1.5 mm diameter and dipped 60 mm undermelt. No K^+ or Cl^- were found in the extracts of these rods and within experimental error the extracts contained Li^+ and OH^- in equivalent amounts. Thus Li deposition was solely responsible for the observed depolarization in the charging curves, and no melt is absorbed by glassy carbon rods. In spite of the scatter of the data it can be seen that the rods absorb Li proportional to the cathodic charge passed. In Fig. 7 the Li contents determined by chemical analysis (X) are almost all higher than the −3.6V value of Fig. 7. This is consistent with the open-circuit voltages of the rods at the end of charging; these varied from −3.630 to −3.654V. The Li contents of Fig. 7 range up to about 7 w/o. These relatively low values plus the absence of acetylene on reacting cathodized carbons with water show no carbide is present (lithium carbide has 37 w/o Li). The observed Li contents tally much better with those of intercalation compounds, the richest of which, C_6Li, has 8.9% Li.

In Fig. 7 it is clear that Li contents obtained by chemically analyzing the carbon rods are systematically less than those derived from weight gains, which in turn are consistently below those calculated from the total cathodic charge passing. The analytical figures average 0.69 ± 0.09 of those from weight gain which themselves average 0.67 ± 0.10 of the calculated values. During the electrolyses, the melt was pale yellow from dissolved chlorine formed at the graphite counterelectrode. However, calculation based on chlorine's solubility and diffusivity in the melt (13) shows that, even in chlorine-saturated melt, the limiting current for chlorine reduction should be below 1 mA/cm^2. Parallel reduction of chlorine can thus not account for the discrepancies of Fig. 7 as these data were secured at 9-144 mA/cm^2. Furthermore, there was no correlation at all between current density and the magnitude of deviation of measured values below the broken line. Thus at this time we have no explanation for these deviations. More work is also needed to elucidate the systematically lower measured Li contents from chemical analysis as opposed to weight gain.

Graphite.—Much less work was done with graphite rods because charging curves could not be completed to the Li potential before the rods disintegrated at the melt meniscus level. Also, at these highly negative potentials, graphite rods wicked up significant amounts of the melt. This effect precluded determining weight gains and confused the results of chemical analysis by introducing into the graphite an unknown proportion of Li^+ and K^+ from the melt. Two grades of synthetic graphite were used, U7 and UF4S from Ultra Carbon Company, having densities of 1.90 and 1.76 g/cm^3, respectively. The glassy carbon used, at 1.50 g/cm^3 was more porous than both graphites. Nevertheless glassy carbon approaches Pyrex glass in its resistance to gas flow while graphite is typically 5-10 orders of magnitude more permeable. Apparently glassy carbon's pore system is largely blind and inaccessible to the melt whereas graphite's is open and interconnected (13). Thus it is understandable that no chloride was found in any cathodized glassy carbon while significant amounts were found in each cathodized graphite rod. The wicking up of this melt into porous carbon at negative potentials was previously observed and utilized by Adams (15) with activated carbon.

Six 3 mm diameter graphite rods were cathodized to breakage in LiCl-KCl at 703°K (430°C). They averaged 590 ± 290 coulombs/g of carbon at the breaking point (glassy carbon rods were routinely charged without breaking to 1200 coulombs/g of carbon where Li droplets covered the carbon surface). Aqueous extracts of the cathodized graphite rods contained mainly Li^+ and OH^- with lesser amounts of K^+ and Cl^-. Extracts with higher K^+ contents had proportionately more Cl^-. This indicates that potassium was entering the rods via absorbed melt rather than by electrodeposition. So it seems that, with graphite also, the observed depolarizations are basically due to undervoltage deposition of Li. From the OH^- content of the most highly charged rod we derive a Li content of 4.1 w/o. This is in line with the Li contents of Fig. 7 for glassy carbon. Thus the limited amount of data secured using graphite indicates its behavior to be basically similar to that of glassy carbon with the added complication of uptake of melt into the more permeable graphite.

X-ray analysis of cathodized carbons.—Figures 8 and 9 compare the x-ray diagrams of carbon rods before and after cathodizing toward the Li potential in the melt at 700°K (427°C). Figure 8 refers to a 3 mm diameter glassy carbon rod whose Li content by chemical analysis was 4.4 w/o. Figure 9 refers to the 3 mm graphite rod which was analyzed as

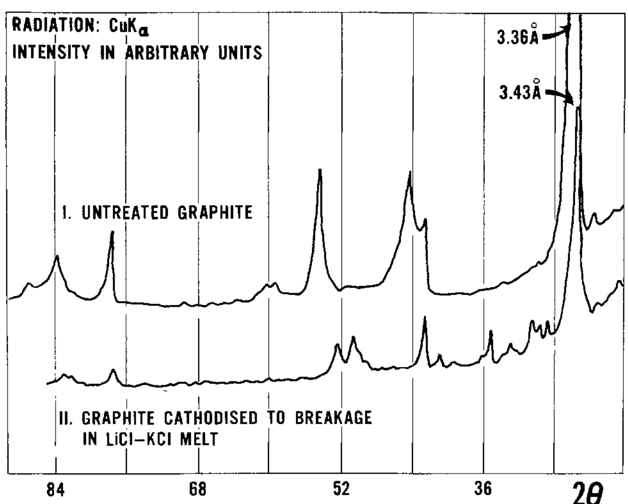

Fig. 8. X-ray diffractograms for glassy carbon rods before and after undervoltage deposition of Li in LiCl-KCl at 430°C.

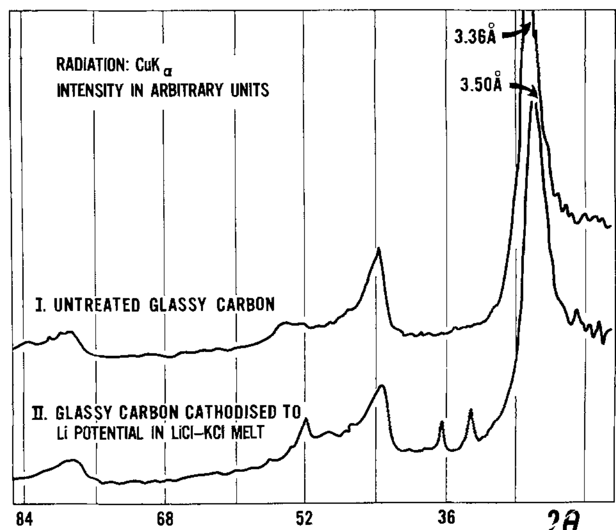

Fig. 9. X-ray diffractograms for synthetic graphite rods before and after undervoltage deposition of Li in LiCl-KCl at 430°C. (Graphite: Grade U7 from Ultra Carbon Company.)

4.1 w/o Li. The x-ray lines of glassy carbon are fewer and broader than those of graphite. This reflects the more disordered, amorphous structure of glassy carbon (14). For both types of carbon, electrolysis effected marked changes in the x-ray patterns; new lines appeared and old ones vanished or weakened. Although the data are not accurate enough to determine a- and c-spacings it is clear that the structure of the cathodized carbons is still basically graphitic. The intense reflection corresponding to the graphite hexagonal sheets is still present though the interplane distance has slightly expanded from the original 0.336 nm (3.36Å) to 0.343 nm for graphite and 0.350 nm for glassy carbon. No lines corresponding to potassium graphite or to lithium or potassium carbides are present. Thus the x-ray data are consistent with the formation of Li intercalation compounds.

Some implications of undervoltage deposition of alkali metal for the use of carbon electrodes.—Considering the very marked depolarizing effect that undervoltage deposition causes (Fig. 2 and 4) and the common use of carbon electrodes in alkali halide melts it is surprising that the phenomenon has not previously been studied. The most that is apparent in the literature is some fleeting references to the effect *e.g.*, by Laitinen (1) at synthetic graphite in LiCl-KCl at 723°K (450°C), by Mamantov (16) for pyrolytic graphite in LiF-NaF-KF at 773°K (500°C), and by Thonstad (17) for Na deposition in pyrolytic graphite from cryolite-alumina melts at 1283°K (1010°C). It is virtually certain that undervoltage deposition of alkali metal vitiated the early measurements by Neumann of decomposition voltages of metal halides between graphite electrodes (18). For fused chlorides of Li, Na, K, and Ca at 1073°K (800°C), his values were 0.77, 0.59, 0.44, and 0.51V, respectively, less than those derived from modern thermochemical data (19). This was certainly due to some form of compound formation (alkali metal carbide or intercalation compound) at the graphite cathode.

In the present work it was found that carbon electrodes exposed to undervoltage Li deposition suffered a lasting negative bias to their open-circuit voltages which could be very misleading in their subsequent use as indicator electrodes. In one case, glassy carbon and graphite rods, after cycling for an hour between −3.1 and 0.0V, *vs.* chlorine electrode, were left overnight in Ar-saturated melt. When the melt was then saturated with chlorine for an hour, the carbon voltages varied erratically between −1.1 and −2.6V and showed no sign of approaching the chlorine potential. Unelectrolyzed carbons are normally within 10 mV of the chlorine potential by this time. Thus a

worker unaware of the easy entry of Li into carbon below about −2.5V could seriously contaminate his carbon electrode without realizing it during even a brief excursion to negative potentials (such as when obtaining a background voltammogram of his melt). The electrode would then be unable for some time to function as an inert, indicator electrode.

Carbon is not normally wetted by purified chloride melts (20). However, lithiation of the carbon causes it to effectively contact the melt. This was shown in the present work where no chloride was found in graphite rods soaked in the melt for hours at open circuit whereas significant amounts had penetrated the rods after relatively brief contact at potentials close to the reversible Li value. This wetting effect was used by Adams (15) to flood activated carbon with fused LiCl-KCl and create a high-area carbon electrode. He did it by cycling the carbon between 0 and −3V *vs.* chlorine electrode. The resultant wetting was stable even during prolonged exposure of the carbon to voltages well above −2V. This emphasizes again the important and lasting effects on the carbon-melt interface of quite brief exposure to negative potentials. While vital to the operation of a high-area electrode, the stable wetting induced by lithiation would be of course fatal to the performance of a porous carbon gas-cathode. Flooding of the porous carbon by melt causes severe cathode polarization.

The lasting effects of lithiation at potentials where Li is thermodynamically quite unstable may be due to the presence of a Li residue compound. Graphite intercalation compounds on extraction or evacuation are known to retain tenaciously a minor proportion of their adduct molecules forming the so-called residue compounds (21). There is evidence that this residual adduct is tightly bound at lattice imperfections as distinct from normal adduct which can move freely between the graphite sheets.

In recent years, undervoltage deposition of Li has been reported from organic solvents into a variety of metals at room temperature, *e.g.*, Sn, Pb, Al, Au, Zn, Cd (22), and Pt (22, 23). Intermetallic Li compounds were formed. No such undervoltage deposition of the other alkali metals or of alkyl ammonium was obtained. In the paper mentioned earlier (11), Li, K, and tetramethylammonium were impregnated at undervoltage into graphite foil cathodes from dimethyl sulfoxide solutions at room temperature. Intercalation compounds resulted. However, cathodizing glassy carbon resulted in immediate deposition of free alkali metal at this relatively impermeable material. In these room temperature studies undervoltage deposition currents were limited to about 1 mA/cm^2 by the relative slowness of solid-state diffusion at this temperature. At the higher temperature of the present molten salt study much higher (hundreds of milliamperes per square centimeter) undervoltage currents were possible.

Mass Transfer to an Eccentric Rotating Disk Electrode

Charles M. Mohr, Jr.* and John Newman**

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The mass transfer rate to a rotating disk electrode rotated about an off-center axis is calculated for eccentricities of from zero to 5 electrode radii. An asymptotic form for the transfer rate valid for large eccentricities is also derived and compared to two previous analyses. It is found that mass transfer is not affected until a critical eccentricity is reached and that the asymptotic expression provides a good approximation to the rate of mass transfer even at moderately small eccentricities. The analysis is supported by experimental data on the deposition of copper on several electrodes of eccentricities between 0.66 and 3.94.

When the active portion of a rotating disk electrode is offset from the axis of rotation, the Levich formula (1) for the mass transfer rate may no longer be applicable. Riddiford (2) implies that exact centering of the active portion is an important design consideration for such electrodes but does not estimate the change in mass transfer rate due to an eccentricity. More recently Chin and Litt (3) have treated the effect of large eccentricities, where the small active portion is located at least several diameters from the center of rotation. Also, Bardin and Dikusar (4) have attempted an analysis for moderate eccentricities (offsets slightly greater than the electrode radius).

Both of these works are limited in their applicability. Chin's paper is nearly correct for large eccentricities but is inappropriate for only slightly off-center electrodes. Bardin and Dikusar erred seriously in their simplifying assumptions, and their conclusions are incorrect for all eccentricities.

We hope to provide here a more rigorous formulation of the problem and, particularly, to describe the behavior at small eccentricities where the easily developed asymptotic form (for large eccentricities) is not applicable. The small eccentricity behavior should be found useful in assessing error limits due to machining tolerances in the manufacture of rotating disk electrodes. Attention is given to large eccentricities for the purpose of completeness only. It seems unlikely that disk electrodes would be operated in this fashion since the imbalance could be dangerous at high rotation rates.

A little contemplation suggests that the mass transfer rate is strictly constant until an eccentricity is reached where a fluid trajectory can spiral off the disk electrode and then back onto it. We have sought the value of the eccentricity at this limit as well as the behavior of the mass transfer rate for somewhat larger eccentricities.

Theory

The laminar flow pattern near a rotating disk has been described by Von Kármán with later improvement (in numerical constants) by Cochran (5). Basically, a fluid particle drawn toward the disk near its center spirals outward while approaching the disk and eventually leaves the region of interest. For Schmidt numbers typical of electrolytic solutions, the diffusion layer is very near the disk, and the radial and tangential velocities of the fluid relative to the disk may be adequately expressed as linear functions of the distance from the disk. Cochran found that these velocities are

$$v_r = 0.510r(\omega^3/\nu)^{1/2}z$$
$$v_\theta - r\omega = -0.616r(\omega^3/\nu)^{1/2}z \qquad [1]$$

where ν is the kinematic viscosity of the solution and ω is the rotation speed ($\sec^{-1}$).

A fluid particle near the disk will be tracing a path $r(\theta)$, relative to the disk, described by

$$\frac{1}{r}\frac{dr}{d\theta} = \frac{v_r}{v_\theta - r\omega} = -0.828 \qquad [2]$$

Note that this is independent of either r or z within the range of validity of the linear approximations in Eq. [1]. Thus the path followed by any fluid particle near the disk is such that its direction of travel is at an angle α to a ray drawn from the center of rotation (see Fig. 1) and

$$\alpha = \cot^{-1}(0.828) = 50.38^\circ \qquad [3]$$

Equation [2] can be integrated to yield the equation for the trajectory passing through the point (r_1, θ_1)

$$r = r_1 \exp[(\theta_1 - \theta)\cot\alpha] \qquad [4]$$

On the other hand, a point on the edge of the electrode is given by

$$r = r_0\sqrt{\epsilon^2 + 1 - 2\epsilon\cos\theta'} \qquad [5]$$

The condition of uniform accessibility, that is, uniform rate of mass transfer, will be maintained for nonzero eccentricities as long as fluid particles spiraling off the electrode never return to or pass over the electrode again. Fluid begins to return to the electrode for an eccentricity at which a trajectory first becomes tangent to the edge of the electrode. Tangency is given by $\alpha = \beta$, where β is the angle

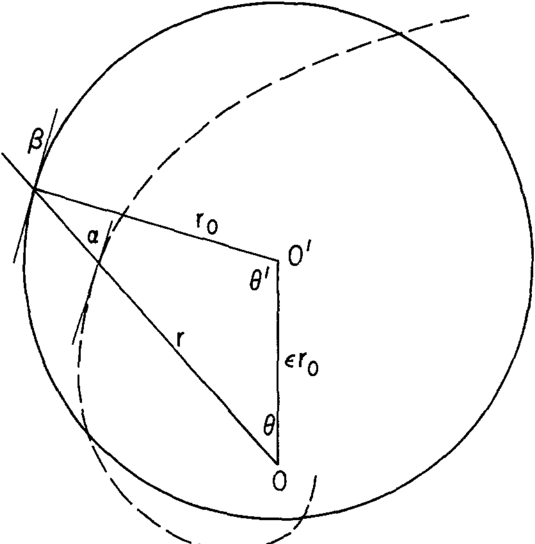

Fig. 1. Nomenclature for offset disk electrode

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: convective diffusion, diffusion coefficient measurement.

between the edge of the disk and the ray drawn from the center of rotation.

Geometrical considerations then lead to the relation

$$\alpha = \beta = \theta + \theta' - \frac{\pi}{2} \quad [6]$$

for a tangent point on the edge. Since the relationship between θ and θ' is

$$\theta = \tan^{-1}\left(\frac{\sin\theta'}{\epsilon - \cos\theta'}\right) \quad [7]$$

the condition for a tangent point reduces to

$$\theta' = \alpha + \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right) \quad [8]$$

after rearrangement using trignometric identities. This equation shows that no point of tangency exists for $\epsilon < \cos\alpha$. Thus, the critical eccentricity we seek is

$$\epsilon_c = \cos\alpha = 0.6377 \quad [9]$$

For $\epsilon > \cos\alpha$, Eq. [8] gives two tangent points

$$\theta'_{t1} = \alpha - \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right)$$

and

$$\theta'_{t2} = \alpha + \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right) \quad [10]$$

where the principal branch of $\cos^{-1}$ is now to be used.

As $\epsilon \rightarrow 1.0$, it eventually becomes possible for the same trajectory to spiral off the disk, return, spiral off again, and then return once more. Since in this analysis we will not attempt to treat this case, we must determine at what eccentricity this effect begins. At the onset of this behavior, the critical trajectory is one that is tangent to the disk at two points, (r_1, θ'_{t1}) and (r_2, θ'_{t2}), as shown in Fig. 2. To determine the eccentricity at which this occurs, we begin with 5 equations in 5 unknowns $(r_1, r_2, \theta'_{t1}, \theta'_{t2}, \epsilon)$. Equation [10] gives two relations for the angles at the tangent points. Equation [5] gives two relations for points on the edge of the electrode. Since the two points must be on the same spiral, Eq. [4] can be written

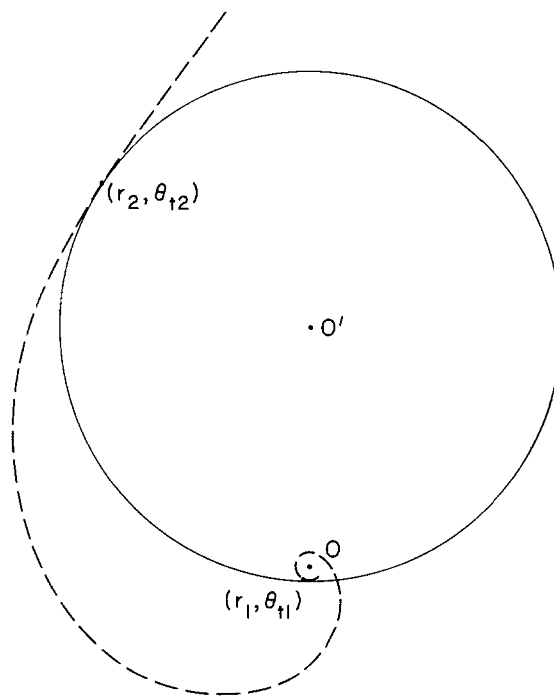

Fig. 2. Trajectory for eccentricity at which analysis fails

$$r_2 = r_1 \exp\left\{\left[\tan^{-1}\left(\frac{\sin\theta'_{t1}}{\epsilon - \cos\theta'_{t1}}\right) - \tan^{-1}\left(\frac{\sin\theta'_{t2}}{\epsilon - \cos\theta'_{t2}}\right) + 2\pi\right]\cot\alpha\right\} \quad [11]$$

where 2π appears since the trajectory completes a full spiral before the second tangent point is reached. These 5 equations can be reduced to one equation in ϵ

$$\epsilon^2 + 1 - 2\epsilon\cos\left[\alpha + \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right)\right] = \left\{\epsilon^2 + 1 - 2\epsilon\cos\left[\alpha - \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right)\right]\right\} \exp\left\{\left[\pi + \cos^{-1}\left(\frac{\cos\alpha}{\epsilon}\right)\right] 4\cot\alpha\right\} \quad [12]$$

which has two solutions

$$\epsilon_1 = 0.998476$$
$$\epsilon_2 = 1.001523 \quad [13]$$

The second solution is significant for calculations with $\epsilon > 1$, since it gives the eccentricity at which fluid begins to pass over the disk only once. Eccentricities between these two critical values will not be treated in this analysis.

The mass transfer rate to the electrode may now be determined. It should be noted that for eccentricities $0.9985 > \epsilon > 0.6377$, some of the fluid experiences a situation similar to what would occur in a ring-disk system. That is, it spirals off the electrode, passes over an insulating surface, and then spirals over an active surface once more, after which it leaves the region of interest. It seems then that we may calculate the mass transfer rate for fluid following such a trajectory by determining the radii (r_1, r_2, r_3) at which this fluid (*i*) leaves the electrode initially, (*ii*) returns to the electrode, and (*iii*) leaves the electrode for the last time, and then use the appropriate formula (6, 7) for mass transfer to a ring-disk electrode which is operated at the limiting current for the same reaction on both the ring and disk. Similarly, for $\epsilon > 1.0015$ one could determine the radii at which a trajectory enters and leaves the electrode surface and use Levich's formula (1) for mass transfer to a ring electrode, with inner and outer dimensions identical to these, to determine the transfer rate along that trajectory. Since each trajectory would have a different ring-disk (or ring only, for $\epsilon > 1.0015$) analogue, it would be necessary to section the surface of the electrode into thin strips following the trajectories (shaded on Fig. 3) and determine, via the above method, the transfer rate to each. In the following discussion, details are presented only for the case $\epsilon > 1.0015$, which can be compared easily to previous treatments. The analysis for $0.6377 < \epsilon < 0.9985$ is similar except that the more complicated expression for mass transfer to a ring-disk system must be substituted for Levich's equation for transfer to a ring electrode only.

For a ring electrode with the active portion between r_1 and r_2, the Levich formula for mass transfer to a segment of width $d\theta$ is

$$dj = \frac{(r_2^3 - r_1^3)^{2/3}}{\sqrt{\nu/\omega}} \frac{\mathcal{D}c_\infty}{2\Gamma(4/3)} \left(\frac{0.510\nu}{3\mathcal{D}}\right)^{1/3} d\theta \quad [14]$$

The total mass transfer to the disk will be given by this equation integrated between the two tangent points θ_{t1} and θ_{t2}. Upon changing the independent variable from θ to θ' and dividing by the rate of mass transfer to a centered disk electrode of equal area (j_{disk}), we find

$$j/j_{disk} = \frac{1}{2\pi}\int_{\theta'_{t1}}^{\theta'_{t2}} \left(\frac{r_2^3}{r_1^3} - 1\right)^{2/3} \left[\epsilon\frac{\cos(\theta' - \alpha)}{\cos\alpha} - 1\right] d\theta' \quad [15]$$

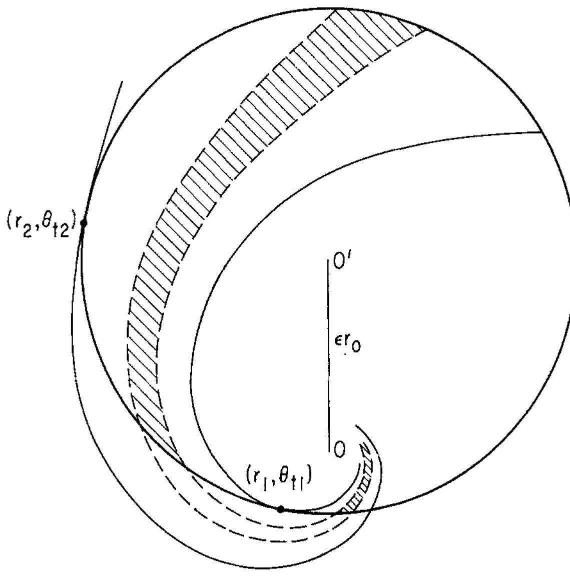

Fig. 3. Partitioning scheme for ring-disk analogy ($\epsilon < 1$)

Given θ'_1, the quantity r_2/r_1 can be determined by simultaneous solution of Eq. [4] and [5]. This must be done numerically due to the complexity of these equations. As a test of this numerical procedure, one can verify the identity

$$2\pi = \int_{\theta'_{t1}}^{\theta'_{t2}} \left(\frac{r_2^2}{r_1^2} - 1 \right) \left[\epsilon \frac{\cos(\theta' - \alpha)}{\cos \alpha} - 1 \right] d\theta' \quad [16]$$

which results from calculating the area of the electrode.

The asymptotic behavior as $\epsilon \to \infty$ is of some interest since it shows clearly the differences between this analysis and those of Chin and Litt and Bardin and Dikusar. As $\epsilon \to \infty$

$$\frac{r_1}{r_0} \to \epsilon - \cos \theta'$$

$$\frac{r_2}{r_0} \to \epsilon + \cos(\theta' - 2\alpha)$$

$$\theta'_{t1} \to \alpha - \frac{\pi}{2}$$

$$\theta'_{t2} \to \alpha + \frac{\pi}{2} \quad [17]$$

and with $x = \sin(\theta' - \alpha)$, Eq. [15] becomes

$$j/j_{\text{disk}} \to \frac{1}{\pi} \left(\frac{36\epsilon}{\cos \alpha} \right)^{1/3} \int_0^1 (1 - x^2)^{1/3} dx$$

$$= \frac{1}{\sqrt{\pi}} \left(\frac{9\epsilon}{2 \cos \alpha} \right)^{1/3} \frac{\Gamma(4/3)}{\Gamma(11/6)} = 1.027\, \epsilon^{1/3} \quad [18]$$

correct to the largest order in ϵ. The method of Bardin and Dikusar leads to

$$j/j_{\text{disk}} \to \frac{1}{\sqrt{\pi}} \left(\frac{9\epsilon}{2} \right)^{1/3} \frac{\Gamma(4/3)}{\Gamma(11/6)} = 0.884\, \epsilon^{1/3} \quad [19]$$

while Chin and Litt obtained an expression equivalent to

$$j/j_{\text{disk}} \to \frac{3}{2\pi^{1/6}} \left(\frac{\epsilon}{3 \cos \alpha} \right)^{1/3} = 0.998 \epsilon^{1/3} \quad [20]$$

The differences arise from different schemes for segmenting the electrode before applying the ring analogy. Bardin and Dikusar took the streamlines to be radially outward from the center of rotation (Fig. 4). Chin and Litt approximate the circular electrode by a square of equal area, but with the proper angle given to the spiral streamlines. Thus we conclude that the shape approximation used by Chin and Litt introduces less than a 3% error in the asymptotic transfer rate, but the neglect of the fluid trajectory by Bardin and Dikusar yields a 14% error.

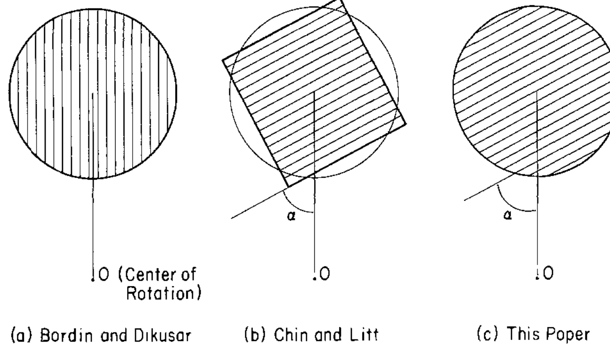

Fig. 4. Comparison of partitioning schemes ($\epsilon > 1$)

Experimental Technique

The mass transfer rates for centered and eccentric electrodes were determined for electrodeposition of copper onto copper electrodes. The solution used was 0.008M $CuSO_4$ in 1.5M H_2SO_4. The rotating disk electrodes were fabricated from Plexiglas, drilled and fitted with short sections of 0.25 in. copper rod. The over-all diameters of the disks were 1.5 in., except for the electrode with an eccentricity of 3.94, for which a 2.0 in. disk was used. The electrodes were polished with emery paper and then wet crocus cloth prior to use. Limiting current curves were recorded at three rotation speeds, 405, 510, and 1590 rpm, at room temperature (22°C) for electrodes of eccentricities 0.00, 0.66, 0.88, 2.13, 2.94, and 3.94. The ratios j/j_{disk} were then calculated for each electrode and rotation speed by dividing the total current to the eccentric disk by that to the centered electrode at the same rotation speed. To minimize the effect of temperature variations, the centered electrode was used for every third run, and these results used to calculate the transfer ratios for the noncentered electrodes used in the immediately preceding and following runs.

Results

The experimental results are given in Fig. 5 along with the numerical results, the large eccentricity asymptote Eq. [18]), and the analytical and experimental results of Bardin and Dikusar. The data emphasize the importance of sectioning the electrodes along streamlines in order to use the Levich equation for ring electrodes to predict the mass transfer rate. Our data disagree significantly with those of Bardin and Dikusar, due, perhaps, to their use of quite small electrodes (~ 1 mm in diameter). This small size might make accurate determination of the eccentricity difficult and would tend to emphasize edge effects. The data gathered by Chin and Litt support this analysis also, since they correlated well with their theoretical analysis, which differs from the present analysis by only 3% at the large eccentricities at which their experimental work was conducted ($\epsilon > 9$).

Although, as previously noted, this analysis fails in a limited region about $\epsilon = 1$, the curves for the results for $\epsilon < 1$ and $\epsilon > 1$ can be joined with no apparent discontinuity at $\epsilon = 1$, as shown on Fig. 5.

The close agreement between the numerical and asymptotic (analytic) results is somewhat surprising in view of the fact that curvature of the trajectories was ignored in the asymptotic analysis and becomes pronounced as ϵ becomes small. It appears that the formula

$$\frac{j}{j_{\text{disk}}} = 1.027 \epsilon^{1/3} + 0.044 \epsilon^{-5/3} \quad [21]$$

will be accurate to within 1.0% for $\epsilon > 0.8$. The ex-

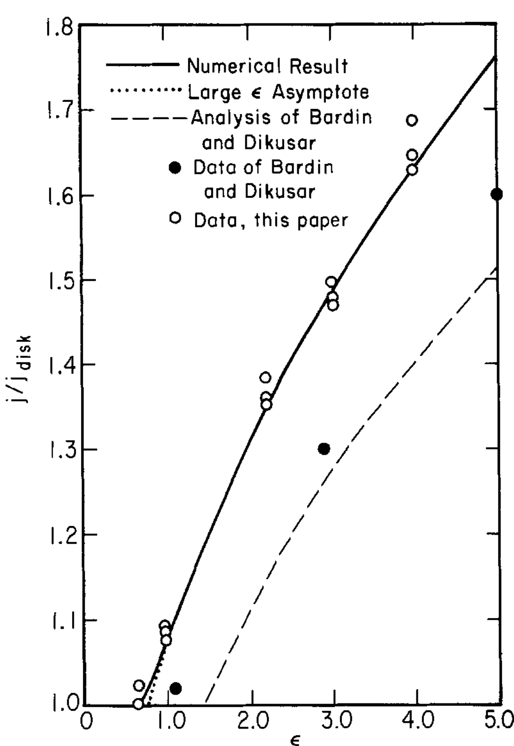

Fig. 5. Mass transfer ratio j/j_{disk} vs. eccentricity for an off-center rotating disk electrode.

ponent −5/3 is justified by an extension of the asymptotic analysis.

An Electrochemical Study of Undercutting during Etching of Duplex Metal Films

J. J. Kelly and C. H. de Minjer

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

For various technological applications patterns are chemically etched in metal films partly covered with a nobler metal. As a result of the bimetallic contact, accelerated etching may occur, giving rise to considerable undercutting. From electrochemical considerations it was expected that the use of certain chemical polishing solutions would significantly reduce the degree of such undercutting. This was verified by studying the electrochemical properties of various polishing and nonpolishing etching agents. Suitable solutions were developed for the etching of Al, Mo, and Ni-P. These etching agents, when used to etch metal films partly covered by nobler metals, gave markedly less undercutting than nonpolishing etching agents.

In various technologies it is often necessary to etch fine patterns in metal films. Important factors determining the choice of a chemical etching agent are generally the etching rate, the degree of undercutting, the chemical aggressiveness of the solution to other materials present, and the definition of the etched patterns. One particular problem arises with duplex systems when patterns have to be etched in metal films partly covered by a nobler metal. Because of galvanic action arising from the bimetallic contact, accelerated etching may occur, causing considerable undercutting at the interface between the two metals. This paper describes an electrochemical study of such undercutting and suggests how the effect may be avoided by a suitable choice of etching agent.

The increase in the rate of dissolution of a metal due to contact with a nobler metal may be explained by considering the partial polarization curves for the

Key words: aluminum, chemical polishing, duplex metal films, electropolishing, etching of metals.

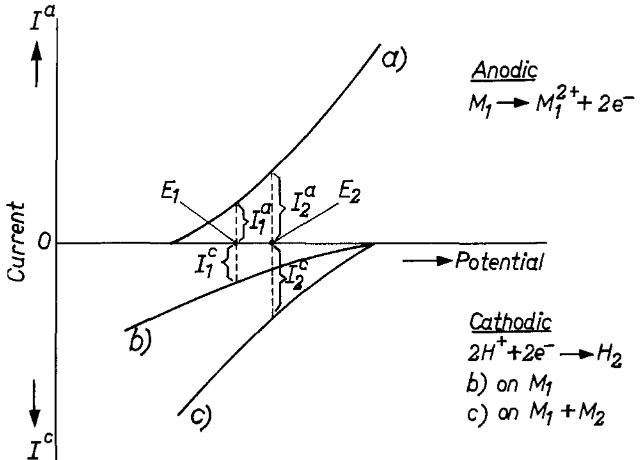

Fig. 1. Partial polarization curves for dissolution of metal M_1 in a nonpolishing solution.

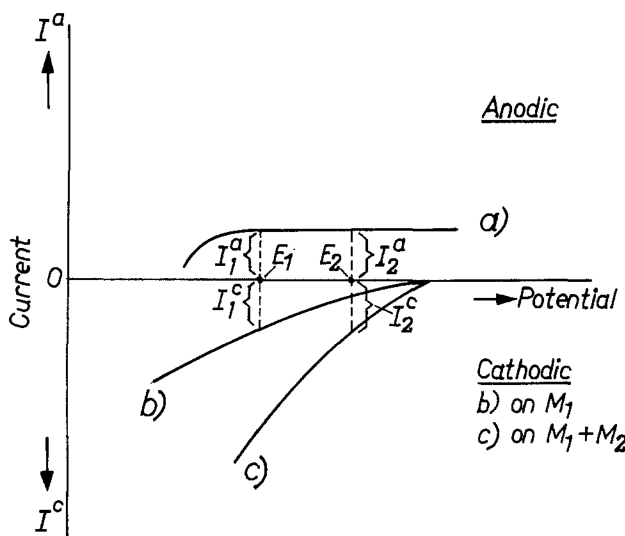

Fig. 2. Partial polarization curves for dissolution of metal M_1 in a polishing solution.

process (1). An example is shown in Fig. 1 for a metal M_1, of a given area, dissolving in acidic solution. Curves (a) and (b) are the partial anodic and cathodic polarization curves for metal dissolution and hydrogen evolution, respectively. Under open-circuit conditions (no external current) M_1 dissolves at a rest potential E_1 ($I_1^a = I_1^c$) and at a rate given by I_1^a. When M_1 is connected to a second metal M_2, which does not dissolve in the potential region shown, only hydrogen evolution will occur at M_2 and the cathodic polarization curve for $M_1 + M_2$ may be represented by curve (c). The increase in the cathodic current depends, among other factors, on the area of M_2. With this combined system, the rest potential is shifted to a more positive value $E_2(I_2^a = I_2^c)$. It is obvious that, with no external current, M_1 dissolves more rapidly when connected to M_2 ($I_2^a > I_1^a$). When the cathode area is further increased by increasing the area of M_2, then M_1 should dissolve even more rapidly.

It seemed to us that such accelerated etching might be prevented by choosing a solution for which the anodic partial current does not increase as a function of potential in a suitable potential range. Electropolishing solutions generally give such current-potential characteristics (2, 3) and a typical polarization curve for such a system is shown in Fig. 2, curve (a). At lower potentials the current increases with increasing potential and etching of the metal is observed. At higher potentials a "polishing" film, consisting of either a viscous layer or an oxide or salt film, is present on the metal. No increase in current is obtained despite an appreciable increase in potential and, as a rule, polishing is observed in this range. When an oxidizing agent with a cathodic polarization, curve (b) as shown in Fig. 2, is added to the electropolishing solution, the metal M_1 is "chemically polished" at an open-circuit potential E_1 and at a rate given by I_1^a. Enlarging the cathodic surface by combining M_1 with a noble metal M_2 leads to an increase in the cathodic current at a given potential (curve c, Fig. 2). Despite the fact that the rest potential increases to E_2 the rate of dissolution of the metal should remain the same ($I_1^a = I_2^a$). When such a solution is used as an etching agent for M_1, the etching rate should not be affected by the presence of a noble metal. The purpose of this work was to determine experimentally if this assumption was correct and in this way to develop suitable etching agents for bimetallic systems.

Our investigations were directed mainly to the study of etching agents for Al and, to a lesser extent, for Mo and Ni-P.

Experimental

Electrode materials.—Aluminum metal (99.99%) was supplied by Rebag (Grevenbroich, West Germany) in the form of 8 mm thick plate and molybdenum (99.9%) by Philips N.V. (Maarheeze, Netherlands) as cylindrical rods with a diameter of 6 mm. Nickel-phosphorus electrodes, containing approximately 10% P by weight, were made by electroless deposition of a 100 μm thick layer onto Ni strips.

The electrodes for the polarization measurements were first mechanically machined and, after cleaning, were electropolished in the same solutions as used for the electrochemical experiments (Table I). Since current-voltage curves were measured in electropolishing solutions, generally under polishing conditions, essentially no roughening of the electrode surface occurred. The metal disks for the chemical dissolution experi-

Table I. Solutions used for etching metal films

Metal	Electropolishing solution	Corresponding chemical polishing solution	Nonpolishing Solution
Al	(*i*) 75g Na_2CO_3 35g $Na_3PO_4 \cdot 12H_2O$ 0.5 liter H_2O	75g Na_2CO_3 35g $Na_3PO_4 \cdot 12H_2O$ 16g $K_3Fe(CN)_6$ 0.5 liter H_2O	0.25M NaOH
Al	(*ii*) 40 ml H_3PO_4 (85%) 40 ml CH_3COOH (100%) 20 ml H_2O	40 ml H_3PO_4 (85%) 40 ml CH_3COOH (100%) 10 ml HNO_3 (65%) 10 ml H_2O	
Mo	50 ml H_3PO_4 (85%) 50 ml H_2O	50 ml H_3PO_4 (85%) 30 ml HNO_3 (65%) 20 ml H_2O	22% (wt) $Ce(NH_4)_2(NO_3)_6$ in 1% HNO_3
Ni-P	90 ml H_3PO_4 (85%) 10 ml H_2O	(*i*) 90 ml H_3PO_4 (85%) 10 ml HNO_3 (65%) (*ii*) 30 ml H_2SO_4 (85%) 15 ml HNO_3 (65%) 4 ml HCl (37%) 1 ml H_2O	50 ml HNO_3 (65%) 50 ml H_2O

ments were either chemically or electrolytically polished, prior to use.

Metal films.—For the etching experiments metal films were prepared on glass microscope slides (18 × 18 × 0.12 mm³). Aluminum films (0.4 μm thick) were made by evaporation, Mo films (0.03 μm thick) by sputtering, and Ni-P films (10% P) (0.3 μm thick) by electroless deposition. The metal films were then partly covered either with photoresist or noble metal patterns containing details of 5 μm and greater.

The Al was provided with a noble metal pattern by first sputter-etching the metal surface to remove the oxide film and then depositing a 0.1 μm Pt film on the clean Al in the same apparatus. Through the windows of a resist pattern a 2 μm thick Au film was electrodeposited on the Pt. After removal of the resist, the thin Pt film, not protected by the thick Au film, was removed by sputter-etching.

In a similar manner a thin Au film was sputtered onto the clean Mo film and a thicker Au film was electrodeposited through the windows of a photoresist pattern. After removal of the resist the thin Au film was chemically etched to expose the underlying Mo. The Ni-P films were also provided with a Au pattern by electrodeposition.

In all cases the area of the exposed metal film was kept small compared to the area covered by resist or noble metal.

Composition of etching solutions.—Table I gives a list of the solutions used for the electrochemical and chemical etching experiments with the different metals. All chemicals used in this work were of reagent grade.

Determination of dissolved Al.—Etching rates were measured by removing 1 ml samples from the etching solution at regular intervals and determining the concentration of dissolved Al spectrophotometrically using 8-hydroxyquinoline (4).

Measurements of the polarization curves.—Polarization curves were recorded at a scanning rate of 95 mV/min using a Wenking 61 TR potentiostat and a Philips PM 8100 recorder. Because both the dissolution of metals in a potential-independent current region and the electrolytic reduction of various oxidizing agents may be diffusion controlled, we used rotating disk electrodes (RDE) for the Al study. The metal electrode (Al or Pt) in the form of a cylinder with a face area of 1 cm², was imbedded in a Teflon shaft, which was driven by a motor with an electronically regulated feedback system.

The cell consisted of a Pyrex vessel coated with a conducting tin oxide layer which acted as a heating element. The reference standard calomel electrode (SCE) was placed in a sidearm which was connected to the bottom of the main cell via an inlet fitted with a capillary extending to just below the center of the rotating disk. The counterelectrode was a Pt ring set at the bottom of the capillary inlet. For certain experiments a large area Pt strip was placed against the inner wall of the cell and connected to the rotating electrode via the mercury contact.

For experiments with Mo and Ni-P, only a stationary test electrode in the form of a flat metal strip was used with a Pt strip as counterelectrode. The SCE reference was placed in a second vessel containing the same solution and was connected to the test electrode in the working cell via a salt bridge and a Luggin capillary. The solutions were not stirred in this case.

All potentials quoted either in the text or in the figures of this paper are values with respect to SCE.

Results and Discussion

Aluminum

Numerous electropolishing agents for Al are described in the literature (2, 3). From the various solutions investigated by us, current-potential measurements indicated that two of these, an alkaline and an acidic solution, had electrochemical properties suitable for our purposes.

Alkaline polishing solution.—Anodic polarization measurements.—The current-potential characteristics of a 1 cm² Al RDE at 24°C in an electropolishing solution containing Na_2CO_3 and Na_3PO_4 (cf. Table I) are shown in Fig. 3, curve (a). For potentials greater than −0.8V the anodic current is constant. In this potential range 3 faradays are required to dissolve 1 mole of Al in agreement with Faraday's law. No cathodic reaction occurs in this region. At potentials below −0.8V hydrogen is cathodically evolved at the Al electrode. The current voltage curves were reproducible to within approximately 5% for the scan rate shown. The difference between the limiting anodic current density measured potentiostatically and during scanning at 95 mV/min was <10%.

The partial current for Al dissolution was calculated from the dissolution rate of the metal and is shown in Fig. 3, curve b. The difference between this partial current and the total current (curve a) at lower potentials is due to the cathodic reaction-hydrogen evolution.

The effect of a stationary 15 cm² Pt electrode in contact with the 1 cm² Al rotating electrode in the same solution at the same temperature and rotation rate is shown in Fig. 3, curve (c). The differences between the polarization curves (c) for Al + Pt and (a) for Al alone are due to a lower hydrogen overvoltage on Pt than on Al and to oxygen evolution at the Pt electrode as is shown in curve (d), the polarization curve for the Pt strip alone. It is obvious from Fig. 3 that a relatively wide potential region exists in which the anodic current of Al is not affected by the presence of the noble metal.

A plot of the limiting anodic current density as a function of the square root of the rotation rate gave a straight line. This indicates, that for the rotation range 100-1000 rpm, the reaction is diffusion controlled (5). The line did not pass through the origin (intercept 4 mA/cm²).

Anodic current-potential measurements performed at temperatures between 25° and 60°C and at the same rotation rate showed in each case a well-defined constant current region. The activation energy for the electropolishing process, calculated from the limiting current densities, was 9.8 ± 0.2 kcal/mole, a value which is in good agreement with that reported by Gabe (6) for a similar Brytal-type bath. This is higher than values reported for reactions in other diffusion-controlled electrochemical systems (5, 7, 8) (≤4 kcal/mole). In the case of electropolishing a highly viscous film and/or an oxide layer may be

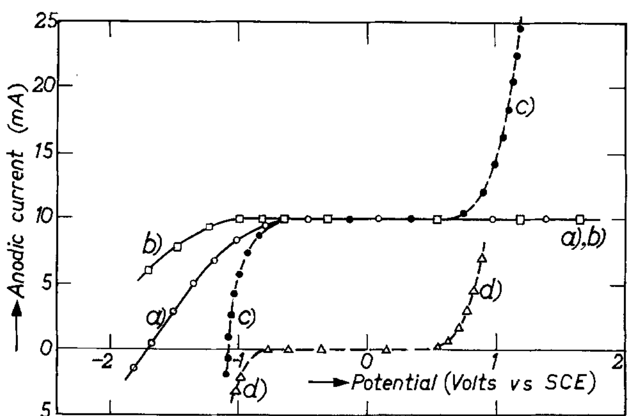

Fig. 3. Polarization curves measured in PO_4^{3-}/CO_3^{2-} solution at 24°C. Curves (a), (c), and (d) are curves recorded using: (a) 1 cm² Al RDE, 550 rpm; (c) 1 cm² Al RDE + 15 cm² stationary Pt electrode; (d) 15 cm² stationary Pt electrode. Curve (b) is the partial anodic curve for case (a) calculated from Al dissolution rates.

present on the electrode and this may be responsible for the higher activation energy.

For comparison we also measured the polarization curve for an Al RDE in a nonpolishing solution, 0.25M NaOH. In this case the anodic current density increased significantly with increasing potential.

Chemical dissolution of Al.—As an oxidizing agent for the alkaline electropolishing solution we chose $K_3Fe(CN)_6$ (0.092M). The solution shown in Table I had a pH of 12.6. The ferricyanide/ferrocyanide system in 0.01M NaOH has a standard potential of +0.22V (9) which is in the region of constant anodic current of Fig. 3.

Curve (a) of Fig. 4 shows the amount of Al chemically dissolved as a function of time at 24°C and 550 rpm for a 1 cm^2 Al RDE (circles) and for the same disk connected to a stationary Pt strip (15 cm^2) in the same solution (squares). No increase in the Al dissolution rate due to the noble metal was observed. If the rate of Al dissolution is expressed as current density, then this value agrees well with the limiting anodic current density observed in Fig. 3.

Results are also shown in Fig. 4 for chemical dissolution of Al at 36°C (curve b) and at 48°C (curve c). For Al alone (circles) the current densities calculated from these rates are lower than those expected from the corresponding limiting anodic current densities. This effect will result when the cathodic process, the reduction of ferricyanide, is rate determining at the rest potential. When the Al disk was in contact with a large area Pt strip (squares), an increase in the rate of chemical dissolution was observed at these temperatures. In this case the measured chemical dissolution rates agreed with the values calculated from the limiting anodic current densities. This must mean that the anodic process is rate determining.

Cathodic polarization measurements.—In order to check the above explanation, polarization curves for the ferricyanide reduction in the PO_4^{3-}/CO_3^{2-} solution were measured. Figure 5 shows such a curve for a Pt RDE at 24°C and 550 rpm. A well-defined diffusion-controlled cathodic current density (i_l^c) was observed. The limiting current density was directly proportional to the $Fe(CN)_6^{3-}$ concentration as can be seen in Fig. 5 and to the square root of the rotation rate (5, 8).

The cathodic limiting current was determined as a function of temperature between 20° and 60°C and an activation energy of 3.9 kcal/mole was calculated from these results. This is in the region expected for a process controlled by laminar flow (5, 7, 8).

The anodic limiting current density for Al dissolution (curve a) and the cathodic limiting current density for the reduction of ferricyanide (curve b) are plotted as a function of temperature in Fig. 6. The measured chemical dissolution rates of Al, expressed as current densities, are also plotted in Fig. 6, circles for Al alone and crosses for Al in contact with a 15 cm^2 Pt strip. It is clear that for the case of Al alone at temperatures below 32°C, the limiting anodic current density is less than the cathodic ($i_l^a < i_l^c$) and in this range the chemical dissolution rate expected from i_l^a is obtained. For temperatures above 32°C, $i_l^c < i_l^a$ and the dissolution rate for Al alone is determined by the magnitude of i_l^c. Hence the circles fall on the cathodic line (curve b). Contacting the Al with Pt leads to an increase in cathodic current, therefore $Fe(CN)_6^{3-}$ reduction is no longer rate determining and the crosses fall on the anodic curve. The chemical etching results shown in Fig. 4 can be explained in this way, using the partial polarization results.

It is obvious from the electrochemical results shown in Fig. 6 that the etching of bimetallic systems without the risk of undercutting in the $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ solution (Table I) is only guaranteed at or below 32°C, *i.e.*, where the etching rates of both Al alone and of Al in contact with Pt are under anodic control. For temperatures above 32°C the etch-

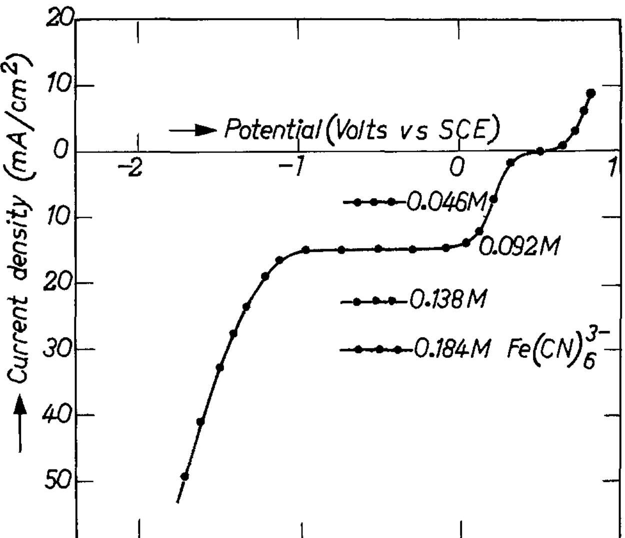

Fig. 5. Cathodic polarization curve for a 1 cm^2 Pt RDE in $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ (0.092M) solution, 550 rpm, 24°C. Limiting current densities are also shown for other concentrations.

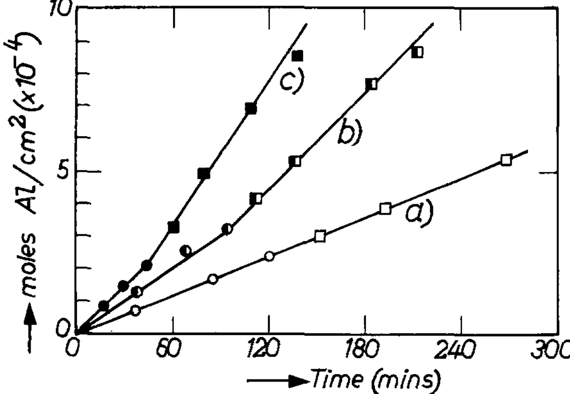

Fig. 4. Chemical dissolution of Al as a function of time for an Al RDE alone (circles) and in contact with a 15 cm^2 Pt strip (squares) in $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ solution, 550 rpm at (a) 24°C, (b) 36°C, and (c) 48°C.

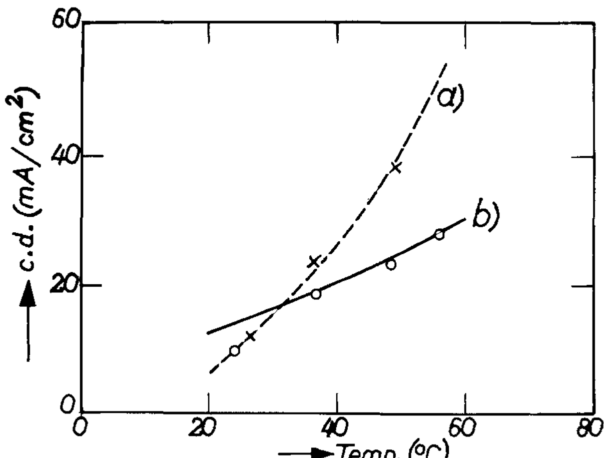

Fig. 6. Summary of electrochemical and chemical results: anodic (curve a) and cathodic (curve b) limiting current densities are plotted as a function of temperature; chemical dissolution rates of Al alone and of Al in contact with Pt are given by circles and crosses, respectively.

ant can be modified by increasing the ferricyanide concentration sufficiently (see Fig. 5) so that the etching is no longer under cathodic control.

Rest potential of Al.—The value of the rest potential of Al measured in the $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ solution was −1.05V. From the partial anodic Al curve measured in PO_4^{3-}/CO_3^{2-} solution (Fig. 3, curve b) and the cathodic curve measured on Pt in the $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ solution (Fig. 5) a much higher value of the rest potential (+0.16V) was expected, *i.e.,* 1.2V higher. The cathodic polarization curve for Al in aqueous $Fe(CN)_6^{3-}$ solution, with no PO_4^{3-}/CO_3^{2-} present, showed that ferricyanide was reduced only at potentials much more cathodic (>1V) than on Pt. This was also found to be the case for cathodic reduction of $Fe(CN)_6^{3-}$ in PO_4^{3-}/CO_3^{2-} solution. This considerable shift in the cathodic curve for Al with respect to that for Pt explains the discrepancy between measured and predicted values of rest potential. The value of the limiting cathodic current density was the same for both metals.

Petrocelli has reported similar effects for Al using $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ in NaOH solution (10) and Ce^{4+}/Ce^{3+} in H_2SO_4 solution (1). He suggests (1, 11) that a coherent oxide film, the thickness of which increases with increasing potential, exists on Al even at cathodic potentials. He attributes the shift in the cathodic reduction curves to the fact that Al ions may diffuse or migrate through the oxide film while electrons may only pass through by quantum mechanical tunneling.

Acidic polishing solution.—The acidic polishing solution was not as extensively studied as the alkaline solution. However the same general features were also observed in this case.

The anodic current-potential curve, measured using an Al RDE (1 cm^2) at 25°C in a solution containing H_3PO_4 and CH_3COOH (Table I), was similar in form to that found for the alkaline solution. At a rotation rate of 500 rpm, a rest potential of −0.9V and a limiting anodic current density of 3 mA/cm^2 were observed. The limiting current density depended on the rotation rate. Over a broad potential range (+0.2 to +0.8V) the anodic polarization curve was essentially unaffected by contacting the Al electrode with a large area Pt strip.

Nitric acid (Table I) was a suitable oxidizing agent for this system. During chemical dissolution of Al in this solution a rest potential in the required plateau region was observed. The cathodic current was not a limiting factor for the Al dissolution rate at 25°C.

Application of polishing solutions for Al etching.—In order to test the applicability of these chemical polishing solutions as etching agents, Al films were etched through the windows of a photoresist or a noble metal pattern. Because it was more convenient to electrodeposit thick layers of gold instead of platinum, we used gold for the upper noble metal layer in these experiments. The electrochemical behavior of gold in these solutions was the same as that of platinum. During etching the solutions were stirred. The degree of undercutting was studied by observing the etched film through the glass substrate using a microscope.

Etching Al/resist films with the $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ and $H_3PO_4/CH_3COOH/HNO_3$ solutions gave results similar to those obtained with 0.25M NaOH, *i.e.,* a controlled etching rate, good definition, and negligible undercutting.

The etching rate of Al in 0.25M NaOH for the Al/noble metal films was much greater than for the corresponding Al/resist films. In Table II the times required to etch the two types of film are given. An increase in etching rate by a factor of 7 was observed. Figure 7a shows the results of 3 min etching of an Al film partly covered with Pt + Au. Considerable undercutting (~10 μm) has occurred at the

Table II. Etching of Al films

Solution	Film	Etching time (min)
0.25M NaOH	Al/resist	7 ± 2
	Al/Pt + Au	1 ± 0.5
$PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$	Al/resist	3 ± 1
	Al/Pt + Au	3 ± 1
$H_3PO_4/CH_3COOH/HNO_3$	Al/resist	12 ± 3
	Al/Pt + Au	11 ± 2

Al/Pt + Au interface. For comparison a photograph of an Al/resist interface is also included (Fig. 7b) in which the Al film has been etched for 7 min under the same conditions. Only slight undercutting was observed.

The Al tracks, not covered by either noble metal or resist, were approximately 200 μm wide. In the NaOH solution, etching of the Al covered by noble metal was considerably accelerated both at the contact area (Fig. 7a) and in the narrow tracks (Table II). In general the effect of the noble metal in such solutions will always be greater near the bimetallic contact. Although the resistances of the metals are low and the metals have the same potential, the resistance of the solution is higher and the current density will therefore decrease with increasing distance from the contact area. Besides this, complications may also arise due to inadequate refreshing of the etching electrolyte in narrow slits, local excessive stirring, or the formation of islands in the etching metal.

The data given in Table II show that no appreciable difference in etching time was found for the Al/resist and Al/Pt + Au films using the two polishing solutions. Figure 7c shows the results of 4 min etching of the Al/Pt + Au film in the alkaline polishing solution. Very little undercutting was observed. A similar result was also found for the acidic solution.

A higher etching rate in the alkaline solution can be obtained by either increasing the temperature and/or replacing Na_2CO_3 by NaOH with equally favorable results. In both cases the $Fe(CN)_6^{3-}$ concentration must be increased to prevent the cathodic reaction from becoming rate determining.

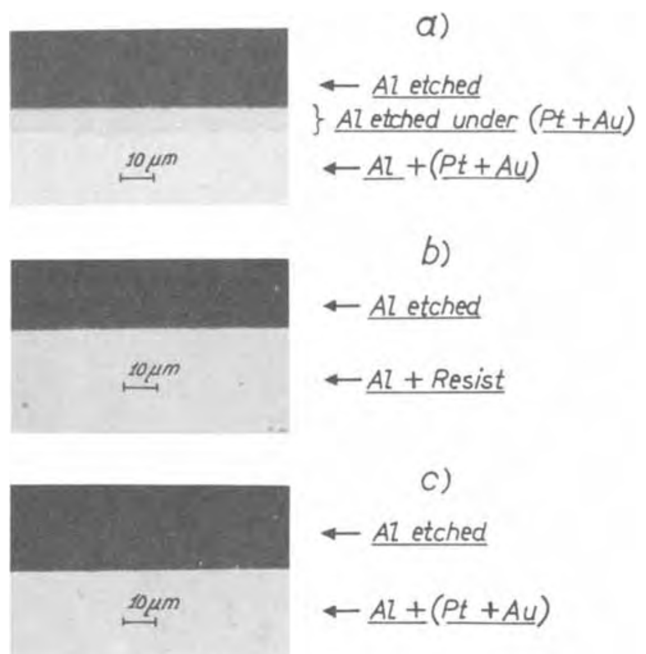

Fig. 7. Undercutting in Al films: (a) Al/(Pt + Au) film etched 3 min in 0.25M NaOH; (b) Al/resist film etched 7 min in 0.25M NaOH; (c) Al/(Pt + Au) film etched 4 min in $PO_4^{3-}/CO_3^{2-}/Fe(CN)_6^{3-}$ solution.

Molybdenum

For etching Mo a solution of $Ce(NH_4)_2(NO_3)_6$ in HNO_3 is often used (Table I). With no noble metal present, this solution etches Mo at a rate of approximately 0.1 μm/min. Thus a 0.03 μm Mo film partly covered by a photoresist film could be etched in 20-30 sec without significant undercutting. When the Mo film was etched through the windows of a gold pattern for 15 sec using the same solution, enormous undercutting (80 μm) was found (Fig. 8a). The etching rate of Mo under Au was more than three orders of magnitude greater than that of Mo under resist.

The polarization curve measured using a stationary Mo electrode in the same solution showed that the anodic current rose very steeply for very slight increases in potential. The corresponding curve for a stationary Pt electrode in this solution showed a limiting cathodic current due to reduction of Ce^{4+}, which in this case determined the etching rate. The fact that the anodic current rises so rapidly means that very large acceleration factors in etching rate are possible when the cathode area is large relative to the exposed Mo area.

Molybdenum may be electropolished in H_3PO_4 solution (2) (Table I). The polarization curve shows a wide potential region above +0.6V with an essentially constant anodic current. Nitric acid is a suitable oxidizing agent giving a rest potential of approximately +0.8V. This chemical polishing etching agent gave very little undercutting (Fig. 8b), as expected from the electrochemical results.

Nickel-Phosphorus

An etching agent often used for Ni-P films is a diluted HNO_3 solution (Table I). The anodic polarization curve of Ni-P in this solution does not show a constant current region and accordingly the etching of Ni-P under a gold pattern with this solution gives rise to undercutting.

We did not succeed in finding an electropolishing solution for Ni-P. Various solutions which are used to electropolish pure Ni (2, 3) did not give favorable results with Ni-P. Our earlier experiments had shown that the anodic behavior of Ni-P is quite different from that of pure Ni. As an example Ni tends to passivate in H_2SO_4 solutions while Ni-P does not.

Although no polishing effect was observed a concentrated H_3PO_4 solution (Table I) gave polarization curves for Ni-P in which the anodic current did not increase appreciably between 0.8 and 1.7V.

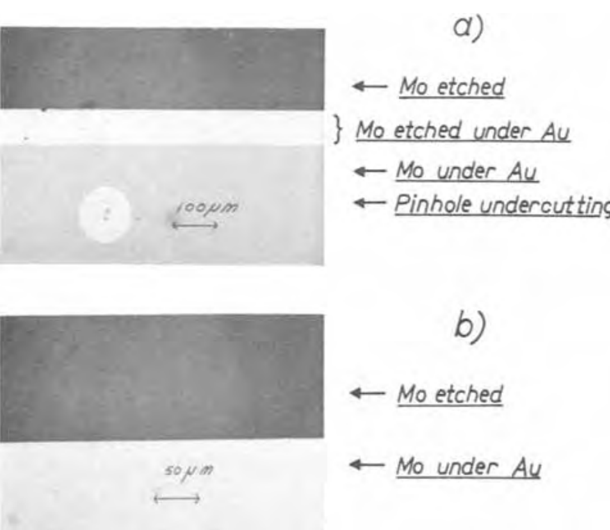

Fig. 8. Undercutting in Mo films: Mo/Au film etched using (a) $Ce(NH_4)_2(NO_3)_6/HNO_3$ solution, 15 sec, and (b) H_3PO_4/HNO_3 solution, 15 sec. In photo (a) the result of etching of the Mo at a pinhole in the Au is also shown.

Nitric acid was used as the oxidizing agent and the rest potential of Ni-P in this solution was 0.85V. Much less undercutting of Ni-P/Au films was observed with this solution than with the diluted HNO_3 solution. A solution containing HCl, HNO_3, H_2SO_4, and H_2O (Table I), which is widely used to etch Ni-P films in the presence of Cu, also gives rise to very little undercutting.

Summary

The aim of this work was to investigate whether it was possible from electrochemical considerations to develop etching agents with the property that the rate of dissolution of the metal in the solution remains unaffected by contact of the metal with a nobler metal. The procedure for a given metal was to choose a solution having a suitable potential range in which the anodic current is constant and to add an oxidizing agent with a standard potential in this range. Electropolishing solutions usually fulfill the requirement of a constant current range and addition of an oxidizing agent to such a solution gives a chemical polishing solution.

As electropolishing agent for Al, a Na_3PO_4/Na_2CO_3 solution was investigated. To obtain a corresponding chemical polishing solution, $K_3Fe(CN)_6$ was added as oxidizing agent. Various aspects of the anodic and cathodic polarization curves for Al in these polishing solutions were studied, *e.g.*, dependence of the limiting current density on temperature, concentration, and rotation rate. The rates of dissolution of an Al rotating disk alone and in contact with a Pt strip were measured in the chemical polishing solution. As expected from the electrochemical results no increase in the dissolution rate of Al at 24°C due to the presence of the nobler metal was observed. This etching solution gave very little undercutting of Al films partly covered by a Pt + Au film, whereas considerable undercutting was found with a nonpolishing solution.

An acidic polishing solution for Al gave equally favorable results.

Suitable etching agents for duplex metal systems with Mo or Ni-P films, in combination with Au films, were also found.

These results confirm the hypothesis that certain chemical polishing solutions, when used to etch metals in the presence of nobler metals, give much less undercutting than nonpolishing solutions.

Technical Note

Electrochemical Determination of Porosity in Nickel Electroplates on a Uranium Alloy

L. J. Weirick*

Metallurgy and Electroplating Division 8312, Sandia Laboratories, Livermore, California 94550

Typical chemical and electrographic test procedures for the determination of porosity in electroplates are usually destructive in nature and not generally applicable to process control procedures. Electrochemical techniques are preferable because they offer good sensitivity and rapid analysis and are relatively nondestructive. A quality control technique having these characteristics was needed to determine the porosity in nickel electroplates on a uranium-3/4 weight per cent titanium alloy.

Mansfeld (1) has derived general expressions for the corrosion potential ϕ_g of galvanic couples in terms of the anodic and cathodic areas. For the case of Tafel behavior or activation control, his expression is

$$\phi_g = \frac{b_a\phi_o^C + b_c\phi_o^A}{b_a + b_c} + \frac{b_a b_c}{b_a + b_c}\log\frac{i_o^C A^C}{i_o^A A^A} \quad [1]$$

If the influence of area variations is investigated while all other parameters are held constant and the cathodic and anodic area fractions (A_A, A_C) are introduced, Eq. [1] can be written in the form

$$\phi_g = k + \frac{b_c b_a}{b_a + b_c}\log\frac{A_C}{A_A} \quad [2]$$

For base metal specimens coated with noble metal electroplates of moderate to low porosity, $A_C >> A_A$. In this case, A_C approaches unity, (log A_C) approaches zero, and Eq. [2] can be reduced to the form

$$\phi_g = k - \frac{b_a b_c}{b_a + b_c}\log A_A \quad [3]$$

Starting from a general expression by Stern (2) Morrissey (3) derived an equation identical to Eq. [3], for the case of only one metal undergoing corrosion in a binary galvanic couple controlled by activation polarization.

For a second case, Mansfeld (1) assumed that the corrosion rate of metal A is controlled by the diffusion rate of the oxidizer to the surface of metal A and that metal C is acting only as an oxygen electrode. In this case, after following arguments and simplifications similar to those used for the previous case, the expression for the corrosion potential is

$$\phi_g = \phi^A - b_a \log A_A \quad [4]$$

In summary, Eq. [3] and [4] are both linear in form, and a plot of corrosion potential *vs.* log A_A will yield a linear trace in either case. If the cathodic and anodic reactions are activation-controlled, the slope will be $(b_a b_c/b_a + b_c)$; if the cathodic reaction is diffusion-controlled, the slope will be b_a.

Key words: galvanic couples, corrosion potentials, U-¾ Ti.

Luborsky, Breiter, and Drummond (4) investigated gold-copper couples in ammonium chloride solutions. They found that these couples were under activation control in 0.1M NH_4Cl, but under cathodic diffusion control in 1.0M NH_4Cl. Morrissey (3) also studied gold-copper couples in ammonium chloride solutions and found them to be activation-controlled in 0.1M NH_4Cl. He established techniques for determining calibration curves of corrosion potentials as a function of base metal area fraction of galvanically connected noble-base couples. These techniques were applied in the present study, the purpose of which was to determine the amount of porosity in nickel electroplates on a uranium alloy.

Experimental

Experiments were undertaken to determine the change in corrosion potential as a function of uranium alloy area fraction in galvanically connected nickel-uranium alloy couples. Figure 1 is a schematic of the experimental arrangement. Electroplated nickel sheet (stripped from a steel mandrel) was cut to form a 7.62 cm (3 in.) square having a geometric gross surface area of 116.13 cm² (18 in.²). This square was used as the standard nickel specimen in all subsequent determinations and was suspended in the electrolyte by means of a platinum wire (the platinum wire caused no secondary effects in this particular arrangement).

For uranium alloy area fractions above 1%, coupons of uranium alloy were cut from a 25 mil sheet to the dimensions necessary to obtain the desired sur-

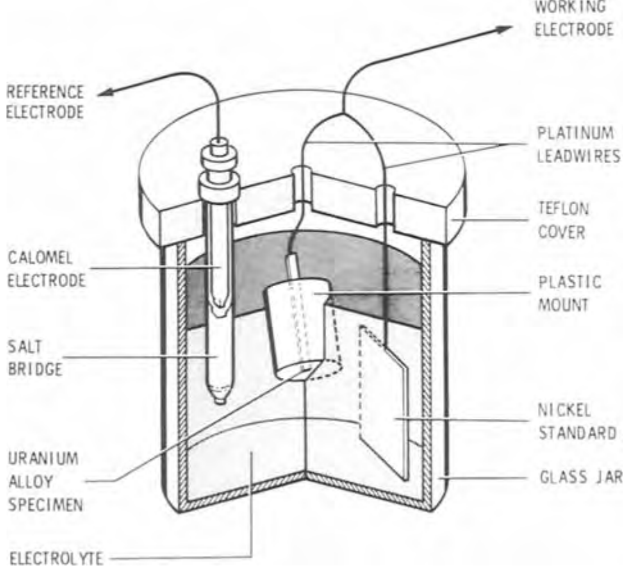

Fig. 1. Schematic of electrochemical cell

face areas. These coupons were spot-welded to platinum wires for suspension in the electrolyte. For area fractions below 1%, wires of rectangular cross section were cut from the alloy sheet and mounted in plastic with the ends of the wires exposed. After these mounts had been polished, the cross-sectional area of the alloy was determined and the area fraction ratios were calculated. The potted wires were electrically connected on the back side of the mount to leads above the electrolyte surface.

A saturated calomel electrode (SCE) was used as the reference electrode. A 0.1M KCl solution was chosen as the electrolyte for the initial calibration curve determination. Subsequent curves were generated based on other concentrations of KCl and a 0.1M solution of KBr. Electrolytes of nitric, sulfuric, acetic, and oxalic acids and sodium carbonate, oxalate, and thiocyanate were also tried.

Corrosion potentials of uranium alloy specimens electroplated with various thicknesses of nickel were measured, and the area fraction of exposed alloy was determined from the calibration curves.

Results and Discussion

Plots of measured corrosion potential (*vs.* SCE) as a function of area fraction A_A of uranium alloy for nickel-uranium alloy couples in KCl solutions are shown in Fig. 2. Deviations from linearity can be observed in Fig. 2 at large values of area fraction A_A. This is in accordance with Eq. [2], for then log A_C can no longer be considered negligible. It can also be seen that the corrosion potential for a given area fraction becomes more positive in more dilute solutions, a point further expanded in the following. In addition, the slopes of the calibration curves in Fig. 2 decreased when the solutions were more dilute. As outlined previously, the analysis by Mansfeld suggests that the couple is under activation control if the slope is equal to $b_a b_c / b_a + b_c$ and under diffusion control if the slope is equal to b_a. From Fig. 2, the slopes are approximately 90, 60, and 40 mV for 10^{-1}, 10^{-2}, and 10^{-3} KCl, respectively.

In order to compare these values for the slopes to the values calculated from the Tafel constants, thus determining whether the corrosion reaction was under activation or diffusion control, anodic and cathodic polarization curves were made for each solution, as shown in Fig. 3. However, the uranium alloy undergoes severe pitting in these KCl solutions, as indicated by the significant upturn in the anodic polarization curves. It was also observed that the pitting became more severe with increased chloride concentration. Thus the anodic polarization curves and the anodic Tafel slopes are significantly affected by, and perhaps determined by, this pitting reaction. The use of these anodic Tafel slopes to compare with the slopes of the calibration curves to determine whether the corrosion reaction is activation or diffusion controlled is thus not correct. However, indications of the type of control can be gotten from the intersections of the anodic and cathodic polarization curves in Fig. 3. These intersections occur in the diffusion-controlled region for all three electrolyte concentrations. The intersection for the most concentrated solution, however, is close to an activation-controlled region, that is, the discharge of water. Thus the resulting experimentally determined slopes are most likely a combination of both activation and diffusion control, with diffusion control the more dominate at dilute concentrations. The change in the slope of the calibration curves with concentration may be simply a reflection of a change in pitting severity with concentration.

Figure 3 also shows why the galvanic corrosion potential becomes more cathodic in more dilute solutions for a given area fraction. This is shown by the more positive values of potential at the intersection of the polarization curves (corrosion potential) for more dilute solutions.

Figure 4 is a plot of measured corrosion potential (*vs.* SCE) as a function of area fraction of uranium alloy in 0.1M KBr solution. It is observed that the corrosion potential for a given area fraction is smaller in this solution than it was in the comparable 0.1M KCl solution. Since the bromide ion Br^- is known to be less aggressive towards uranium alloys than the chloride ion Cl^-, this result is consistent with previous studies (5). The slope of the calibration curve measured in 0.1M KBr is very steep; in fact, steeper than that measured in 10^{-3}M KCl solution. Therefore, if this solution were used in process control to monitor porosity in nickel electroplates, the measurement would be less accurate than if the 0.1M KCl solution were used.

Solutions of 0.1M concentrations of nitric, sulfuric, acetic, and oxalic acids were tried as electrolytes to determine analogous calibration curves. In spite of

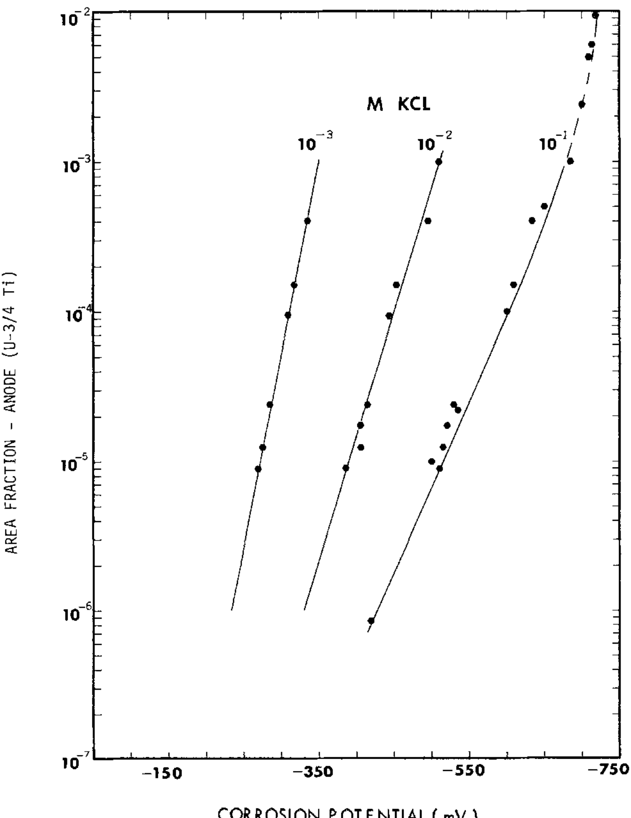

Fig. 2. Corrosion potential as a function of uranium alloy area fraction in potassium chloride.

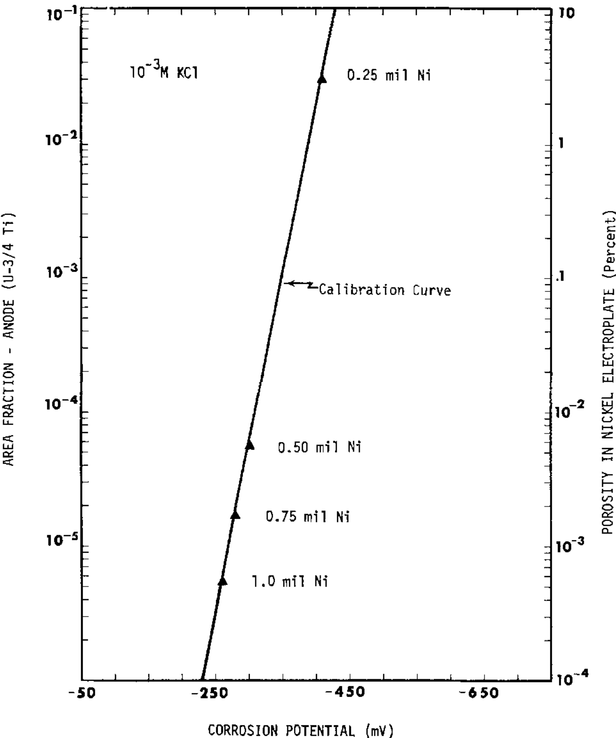

Fig. 5. Amount of porosity in nickel electroplates on a uranium alloy as a function of nickel thickness.

reported ability of these acids to dissolve uranium (6), the corrosion potential did not change with varying area fractions. The apparent reason for this was that the exchange current density of nickel was high relative to the exchange current density of uranium in these solutions. Thus, as outlined by Mansfeld (7) in his case of an active metal imperfectly coated by a noble metal, when the ratio of the exchange current densities of the substrate to the coating is small, the reaction kinetics of the coating, and not the area relationships of the couple, fix the potential of the system.

Solutions of 0.1M concentrations of sodium carbonate, oxalate, and thiocyanate were also tried as possible electrolyte candidates. However, in oxalate and carbonate solutions, insoluble compounds which suppressed the corrosion reactions were formed. Only the thiocyanate ion produced any change in corrosion potential with varying area fractions of cathode, and these changes were very small.

The utility of this electrochemical technique for determining the amount of porosity in nickel electroplates on the uranium alloy was demonstrated in further experiments. Four coupons of U-3/4 Ti of dimensions 1.9 × 2.5 × 0.32 cm (3/4 × 1 × 1/8 in.) were electroplated with nickel in a nickel sulfamate bath to thicknesses of 0.25, 0.50, 0.75, and 1.0 mil, respectively. Platinum wires were spot-welded to the specimens for electrical connection. The measured corrosion potentials of the four specimens as compared to the calibration curve generated in 10^{-3} M KCl solution are shown in Fig. 5. Progressive reductions in porosity with increasing plating thickness were observed. The total surface area of exposed uranium alloy in the specimen plated with 1 mil of nickel was extremely low, *i.e.*, porosity below 10^{-3}%.

Summary

This study has shown that for uranium alloy specimens galvanically coupled to a nickel sheet in KCl electrolytes, the corrosion potential varies linearly with the logarithm of the exposed area fraction of uranium alloy according to expressions derived by Mansfeld (1, 7). It was possible to calibrate the technique so that the exposed base metal area fractions of uranium alloy specimens plated with nickel could be estimated to a reasonable approximation. This technique is relatively nondestructive and offers the advantages of simplicity and high sensitivity, particularly at low porosities.

The Effects of Lead on the Hot Corrosion of Nickel-Base Alloys

D. Chatterji,* D. W. McKee, G. Romeo,* and H. S. Spacil*

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

ABSTRACT

Lead is often found as a trace impurity in fuels used in gas turbines. In addition, lead salts may form on hot superalloy parts during turbine operation in contaminated urban environments. An experimental and thermodynamic study of Na_2SO_4-induced hot corrosion of nickel-base alloys at 900°C, in the presence of small concentrations of lead salts, has shown that these contaminants can be very deleterious to alloy corrosion resistance. PbO reduces the corrosion resistance of Ni-Cr and Ni-Al alloys by complexing normally protective scale to form $PbCrO_4$ and $PbO \cdot Al_2O_3$ which are soluble in the sulfate melt. PbO is a more aggressive contaminant than $PbSO_4$, and PbO concentrations of 1 mole per cent in the salt condensate can result in catastrophic corrosion rates with Ni-Cr alloys.

Accelerated corrosion of high temperature superalloys in the presence of ingested sodium salts and residual sulfur is a problem of major concern in marine and industrial gas turbines and is the subject of an extensive literature (1). The increased use of crude oil and residual fuels in these applications has led to the recognition that severe corrosion effects can also be induced by traces of metallic impurities present in these low grade fuels. In particular, the deleterious effects of vanadium have been well documented (2). Lead impurities may arise from various sources. Industrial gas turbines may ingest particulate lead compounds during operation in contaminated urban atmospheres. Occasionally contamination of turbine fuels with lead tetraethyl from gasoline residues may occur in tankers and storage vessels. Lead compounds have been detected occasionally in crude oils in concentrations up to 2 ppm (3). However, in spite of these considerations, the effects of lead compounds on the hot corrosion behavior of superalloys have not been previously reported.

Thermodynamic calculations have shown (4) that a level of 1-2 ppm of lead in the fuel can be expected to produce a salt condensate containing up to 1 mole per cent (m/o) PbO + $PbSO_4$ in Na_2SO_4 at temperatures in the hot corrosion range of 850°C and above. Deposits on gas turbine blades formed during operation with aviation fuel containing lead have indeed been found to contain PbO (5), although the effects of lead on hot corrosion rates have not been studied. There are, however, reports that lead deposits on Ni-Cr-Fe alloy manifolds and afterburners in gasoline engines are associated with accelerated corrosion (6, 7).

This paper describes the results of an experimental investigation into the effects of low concentrations of lead salts on the Na_2SO_4-induced hot corrosion of nickel-base alloys and an attempt to interpret the observed effects from an equilibrium thermodynamic standpoint.

Experimental

Binary Ni-Cr and Ni-Al alloys used in the corrosion experiments were prepared by induction melting and casting in argon. From bars of 1-in. round stock, rectangular coupons of dimensions 5/8 × 1/4 × 1/16 in. were cut and polished through 600-grit silicon carbide paper. The nominal and actual compositions of the alloy specimens are listed in Table I.

Salts used in the crucible experiments were anhydrous sodium sulfate (Mallinckrodt Analytical Reagent), lead oxide (Matheson, Coleman and Bell Reagent PbO), and lead sulfate (Fisher Certified Reagent).

Polished coupons of the alloys were placed in glazed porcelain crucibles containing 1g quantities of the powdered salt mixtures which had previously been ground in an agate mortar and blended in a Fisher Minimill. On heating the crucible and contents to 900°C, the salt melted and wetted the alloy coupon to form a thin liquid layer with the excess salt forming a pool at the bottom of the crucible. Weight changes of the crucibles and contents were measured thermogravimetrically in the Chevenard balance described previously (8). Corrosion experiments were carried out isothermally at 900°C in both air and a 0.1% SO_2-76% O_2-balance N_2 gas mixture, using a constant gas flow rate of 250 ml/min. Postexperimental examination of the corroded alloy specimens by means of conventional metallographic and electron microprobe techniques showed that the attack was generally fairly uniform throughout the length of the specimen and

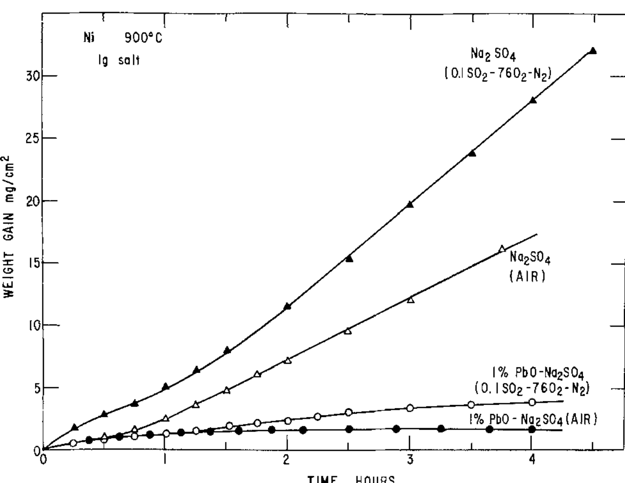

Fig. 1. Effect of 1 m/o PbO on the Na_2SO_4-induced corrosion of nickel at 900°C. Weight changes vs. time in air and 0.1% SO_2-76% O_2-N_2 atmospheres.

therefore the total sample geometrical area was used to compute kinetic data. A blank experiment carried out in the absence of an alloy sample showed that the crucible gained less than 0.04 mg/cm² of internal surface after exposure to a melt of 1% PbO-Na_2SO_4 for 6 hr at 900°C. Weight changes resulting from attack on the crucible were therefore considered to be negligible under the conditions of the experiments.

Results

Nickel.—Thermogravimetric data for the corrosion of pure nickel specimens by Na_2SO_4 alone and by 1 m/o PbO-Na_2SO_4 mixtures in atmospheres of air and 0.1% SO_2-76% O_2-balance N_2, are presented in Fig. 1. These experiments were all carried out at 900°C, using polished nickel coupons partially immersed in 1g of the powdered salt. In Fig. 1, weight gains of the crucibles and contents are plotted as functions of time, the extent of corrosion being computed as weight gain in milligrams per square centimeter of total alloy surface.

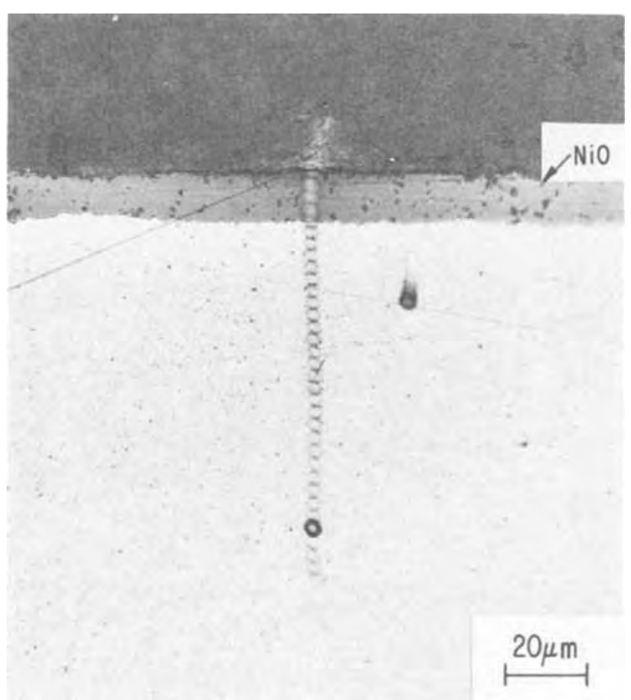
Corrosion of nickel by Na_2SO_4 alone took place at a rapid rate at 900°C in both gaseous atmospheres, weight gains being essentially linear with time for the duration of the experiments. The rate of attack in the 0.1% SO_2-76% O_2-N_2 environment was substantially greater than that in air, although in both cases the extent of the corrosion could be characterized as catastrophic,[1] with weight gains that exceeded 20 mg/cm² after a 5 hr exposure to the salt melt. By contrast, the experiments carried out with an initial 1% PbO-Na_2SO_4 salt mixture resulted in sharply reduced rates of corrosion, with weight gains of less than 4 mg/cm² during the 5 hr runs. Although weight increases were again larger in the SO_2-containing atmosphere than in air, in both cases corrosion of the nickel specimens was minimal in the presence of the lead salt.

Postexperimental metallographic examination of the metal coupons showed marked differences in the morphology of the corrosion layers produced in the presence and absence of the lead additive. As shown in Fig. 2(a), corrosion experiments with the PbO-Na_2SO_4 salt mixture produced a protective oxide layer on the surface of the nickel, with no evidence of subscale sulfide formation. Electron microprobe examination of this sample, shown by the traverse in Fig. 2(b), indicated that the scale was dense NiO, the concentration of Pb being too low to be detectable. Corrosion of nickel by Na_2SO_4 alone produced a thick porous scale, shown in section in Fig. 3. In this case, x-ray images of Ni and S for an area at the base of the scale (Fig. 4) indicated that finely divided sulfides were distributed in a band beneath the outer oxide layer.

Additional experiments carried out with nickel specimens immersed in salt mixtures of composition 1 m/o $PbSO_4$-Na_2SO_4 gave the same rapid weight gains and catastrophic corrosion rates as found with pure Na_2SO_4, indicating that the inhibitory effect observed with PbO is not a general effect associated with the presence of lead salts. No appreciable corrosion of nickel was observed with $PbSO_4$ alone at 900°C.

Nickel-chromium alloys.—The most significant result found with binary Ni-Cr alloys was that the presence of PbO in the salt condensate caused a considerable

[1] Hot corrosion rates are generally regarded as "catastrophic" when they amount to 1-2 orders of magnitude greater than for normal oxidation (9).



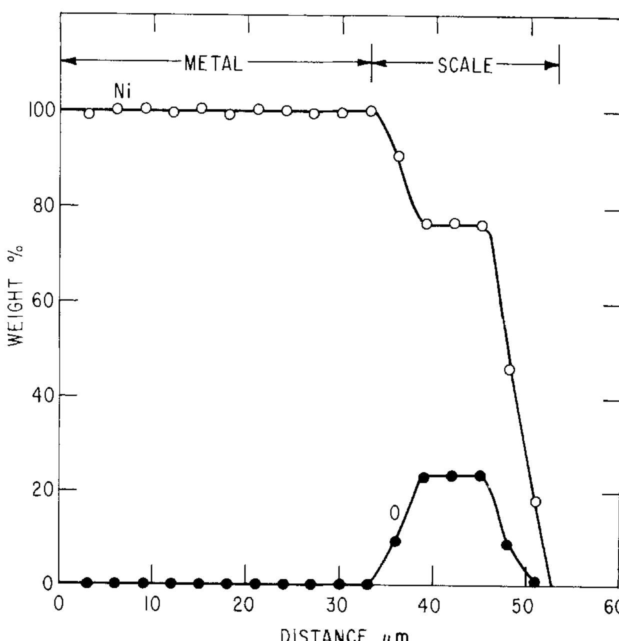


Fig. 2. Transverse section through Ni sample after 6 hr exposure to 1 m/o PbO-Na_2SO_4 at 900°C in air. (a, left) Optical micrograph showing uniform NiO scale. (b, right) Microprobe traverse along electron beam trace shown in (a).

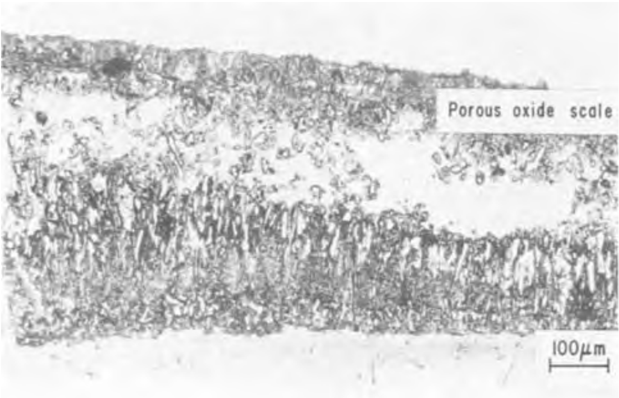

Fig. 3. Section of Ni sample after 5 hr exposure to 1g Na_2SO_4 at 900°C in 0.1% SO_2-76% O_2-N_2 atmosphere.

increase in the rate of Na_2SO_4-induced hot corrosion at 900°C. The magnitude of the effect, however, depended to a large extent on the chromium content of the alloy.

Typical thermogravimetric results for Ni-15 Cr specimens are summarized in Fig. 5, which shows weight gain data obtained in crucible experiments with Na_2SO_4 and 1 m/o PbO-Na_2SO_4 salt mixtures in both air and 0.1% SO_2-76% O_2-N_2 atmospheres. When coupons of Ni-15 Cr were immersed in pure Na_2SO_4 and heated in flowing air at 900°C, a very small weight gain was observed (<0.5 mg/cm^2) over a period of 5 hr and corrosion was very slight as the result of the formation of a protective Cr_2O_3 scale. Addition of 1 m/o PbO to the initial salt, however, resulted in a marked increase in corrosion rate and the specimen weight continued to increase during the course of the experiment. As with nickel, the corrosion rate in the PbO-Na_2SO_4 experiments was still further increased when 0.1% SO_2 was present in the ambient atmosphere, as shown in Fig. 5.

Metallographic examination of the corrosion layers produced on this alloy by the PbO-Na_2SO_4 salt melt showed (Fig. 6) a thick nonuniform Cr_2O_3 surface layer and dispersed chromium sulfide globules at depths of 40-50 μm into the bulk alloy, which are not clearly visible in the micrograph. This morphology is characteristic of sulfidation under conditions of high sulfur potential (8).

The results of an experiment on the interaction of Ni-15 Cr alloy with $PbSO_4$ alone are shown in Fig. 7. In this case the alloy specimen was partially immersed in 1g of the powdered salt and heated at 900°C in the 0.1% SO_2-76% O_2-N_2 gas mixture for a period of 5 hr. A moderate (3 mg/cm^2) weight gain was observed during this period and metallographic examination of a section of the specimen at the end of the experiment showed localized areas where sulfide particles had formed beneath the surface oxide scale. Although the extent of corrosion was greater with $PbSO_4$ than with Na_2SO_4 alone, the attack was much less intense and less uniform than with the 1% PbO-Na_2SO_4 salt mixture under the same conditions. As $PbSO_4$ is solid at 900°C, a direct comparison of corrosion rates is not possible.

A series of experiments was carried out with Ni-50 Cr alloy coupons, immersed in PbO-Na_2SO_4 mixtures of various compositions and heated at 900°C in the 0.1% SO_2-76% O_2-N_2 gas mixture. This alloy is very resistant to both oxidation and Na_2SO_4-induced hot corrosion and weight changes in pure Na_2SO_4 amounted to less than 1 mg/cm^2 in a 5 hr period at 900°C. However, as shown in Fig. 8, immersion in a 1 m/o PbO-Na_2SO_4 mixture resulted in an initial rapid weight change, which amounted to 3.6 mg/cm^2 in the first hour of the experiment. The corrosion rate then diminished as the lead concentration in the salt melt

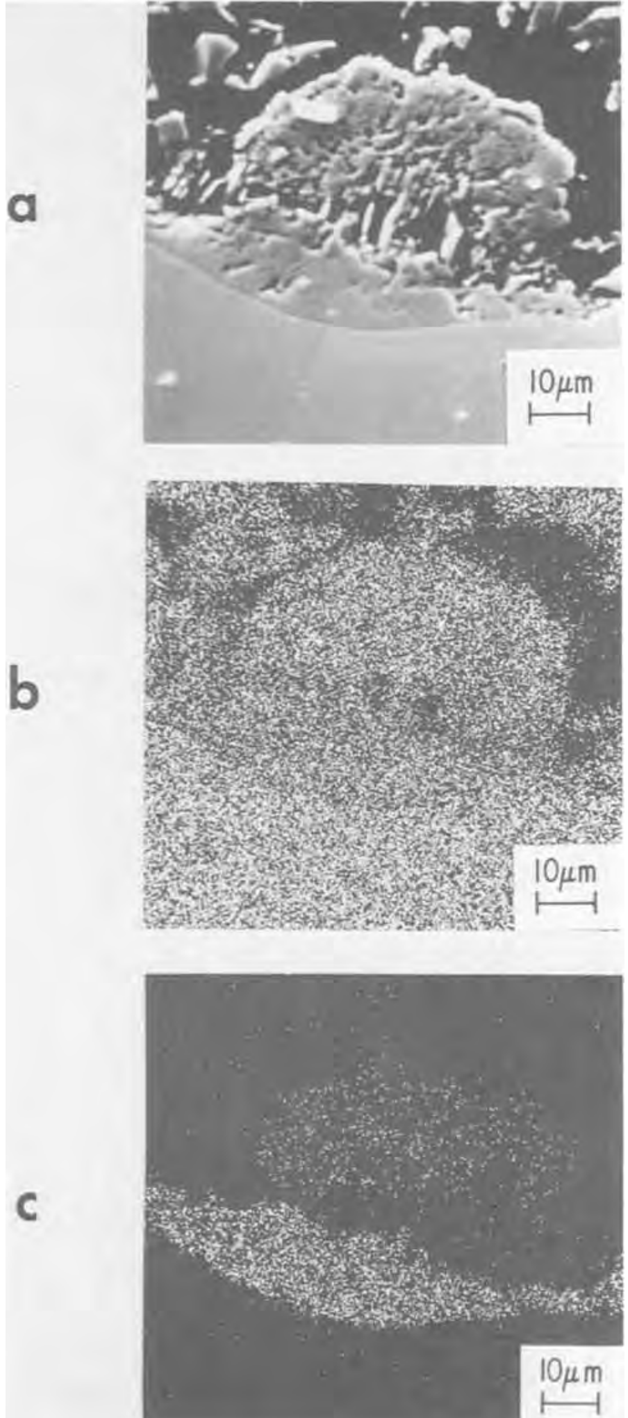

Fig. 4. X-ray images of base of corrosion layer on Ni following 5 hr exposure to 1g Na_2SO_4 at 900°C. (a) Back-scattered image, (b) $Ni_{K\alpha}$ scan, (c) $S_{K\alpha}$ scan.

became depleted. The Nomarski interference contrast micrograph of the corrosion layer on this specimen, shown in Fig. 9, revealed a thick Cr_2O_3 scale on the surface, particles of chromium sulfide in the subscale region, and a zone about 20 μm thick near the surface which has become depleted in the chromium-rich eutectic, which is visible as irregular inclusions in the bulk alloy. As shown in Fig. 8, increasing initial PbO concentrations in the salt mixture resulted in marked increases in the corrosion rate of the Ni-50 Cr alloy, initial weight gains amounting to 5 and 10 mg/cm^2-hr for initial 5 and 10% PbO-Na_2SO_4 salt compositions, respectively. (The morphology of the corrosion layer following exposure to the 5% PbO-Na_2SO_4 mixture is shown in Fig. 10. Penetration of sulfides into the bulk

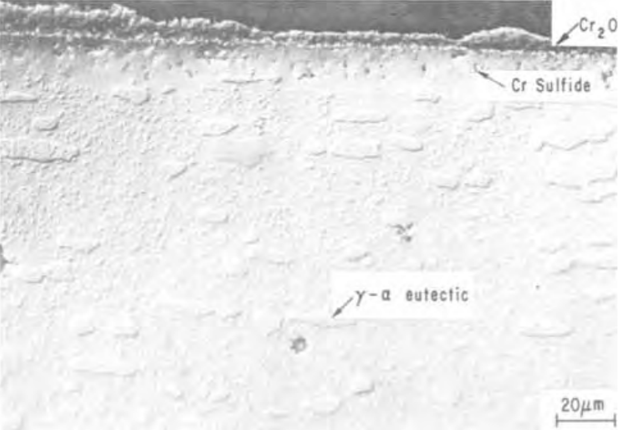

Fig. 9. Section of Ni-50 Cr sample showing corrosion morphology following exposure to 1 m/o PbO-Na_2SO_4 for 6 hr at 900°C in 0.1% SO_2-76% O_2-N_2 atmosphere.

alloy is obviously more marked than in the experiment with 1% PbO-Na_2SO_4.) In each case the salt residue at the end of the experiment was colored bright yellow, which chemical analysis showed to be due to the presence of chromate. For example, analysis of the residue from the experiment with 5 m/o PbO-Na_2SO_4 gave a $CrO_4^{=}$ concentration of 0.22 and 2.17 weight per cent (w/o) in the case of the run with 10 m/o PbO-Na_2SO_4 initially. With Na_2SO_4 alone in contact with the Ni-50 Cr alloy, the concentration of residual chromate after the 5 hr experiment at 900°C was 0.098 w/o. Apparently the effect of PbO in the salt was to promote the formation of chromate as a result of the reaction

$$PbO + 1/2\ Cr_2O_3 + 3/4\ O_2 \rightarrow PbCrO_4$$

A combined TGA-DTA experiment with a 2:1 molar mixture of PbO and Cr_2O_3 heated at a rate of 10°C/min in an atmosphere of flowing O_2 showed that this reaction began to occur at 400°C and was virtually complete at 750°C.

With the Ni-Cr binary alloys the corrosion rates were greatest during the first hour of the experiments, hence the measured weight gains for the initial 1 hr of exposure could be used as a basis for qualitative comparison of the corrosion behavior of the different alloy compositions. Figure 11 shows initial corrosion rates for the Ni-Cr alloy series computed in this manner; these are expressed in arbitrary units because the kinetics in general did not follow established rate laws. Postexperimental metallographic observations of the extent of corrosion confirmed the general trends shown in Fig. 11. The lower curve shows that the rate of corrosion by Na_2SO_4 alone decreased rapidly as chromium was added to nickel and became very low for Cr contents of 15 w/o or more, due to the formation of a protective Cr_2O_3 scale. By contrast, corrosion rates in the 1% PbO-Na_2SO_4 melt were low for pure nickel but increased rapidly as the Cr content of the alloy was increased and became very rapid for alloys containing 10-15 w/o Cr. In these cases, complexing of the surface Cr_2O_3 by the lead component of the salt melt produced a porous unprotected Cr-depleted matrix which was readily attacked by the Na_2SO_4 melt. Further increases in chromium content resulted in some decrease in the rate of corrosion because of the high residual content of Cr in the alloy matrix even after removal of the surface layer by lead complexing. However, even alloys containing 50 w/o Cr were more

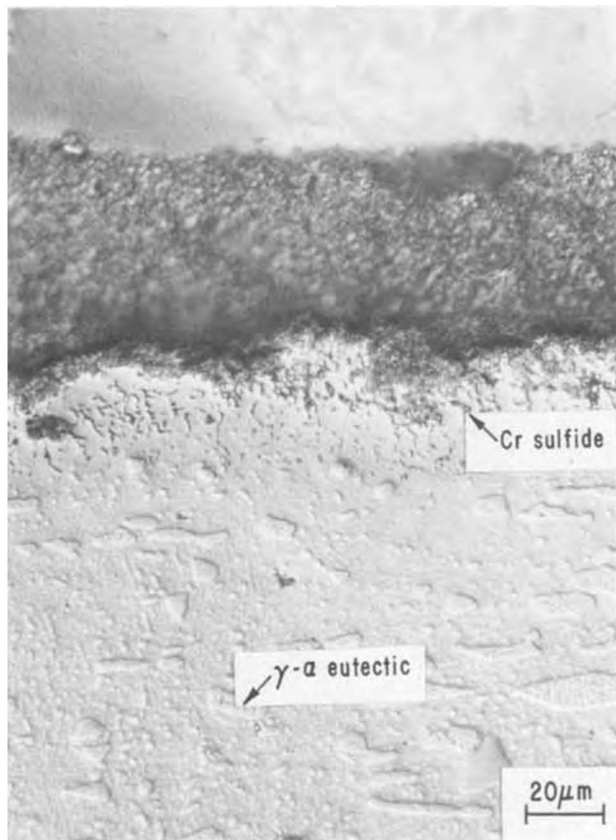

Fig. 10. Section of Ni-50 Cr sample showing corrosion morphology following exposure to 5 m/o $PbO-Na_2SO_4$ for 5 hr at 900°C in 0.1% SO_2-76% O_2-N_2 atmosphere.

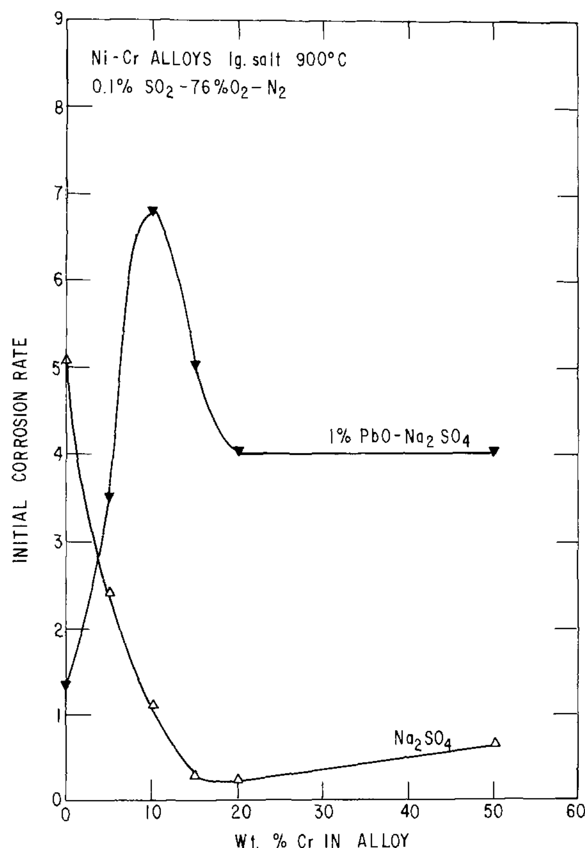

Fig. 11. Effect of PbO on initial corrosion rates of Ni-Cr alloys by Na_2SO_4. Corrosion rates after 1 hr (in arbitrary units) at 900°C in Na_2SO_4 and 1 m/o $PbO-Na_2SO_4$ as a function of Cr content.

readily attacked in the presence of PbO than by Na_2SO_4 alone. Typical catastrophic attack by $PbO-Na_2SO_4$ on Ni-Cr alloys in the intermediate Cr range is illustrated in Fig. 12 which shows the corrosion layer produced on a Ni-10 Cr specimen following exposure to 1% $PbO-Na_2SO_4$ for 5 hr at 900°C. The surface of the alloy is extensively degraded to form a porous oxide layer and widespread chromium sulfide globules within the alloy interior.

At higher chromium concentrations corrosion in the presence of PbO was less catastrophic, although sulfide particles were formed at considerable depths beneath the surface scale. Figure 13 shows a section of the corrosion layer formed on a Ni-20 Cr specimen after the same treatment as that described above. The extent of attack may be compared with that shown in

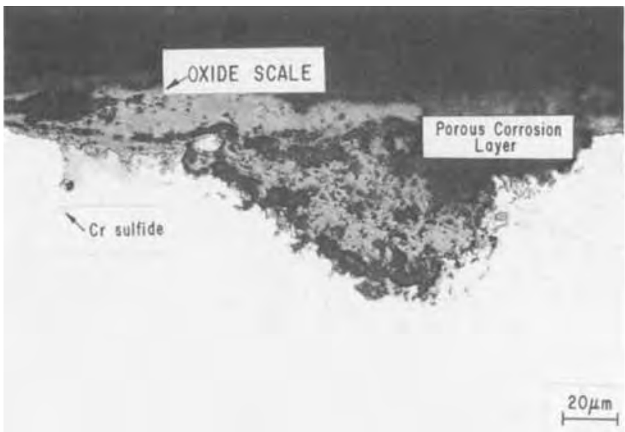

Fig. 12. Section of Ni-10 Cr sample following exposure to 1 m/o $PbO-Na_2SO_4$ for 5 hr at 900°C in 0.1% SO_2-76% O_2-N_2 atmosphere. Total salt concentration = 1g.

Fig. 13. Section of Ni-20 Cr sample following exposure to 1 m/o $PbO-Na_2SO_4$ for 5 hr at 900°C in 0.1% SO_2-76% O_2-N_2. Total salt concentration = 1g.

Fig. 6 for a Ni-15 Cr alloy and in Fig. 9 for a Ni-50 Cr alloy.

Nickel-aluminum alloys.—A series of crucible experiments was carried out with Ni-Al alloy specimens, of composition 5-30 w/o Al, which were partially immersed in 1g quantities of Na_2SO_4 and 1 m/o PbO-Na_2SO_4 salt mixtures and heated at 900°C in the 0.1% SO_2-76% O_2-N_2 gas mixture. Under these conditions, alloys with aluminum concentrations in the range 5-20 w/o were vigorously attacked by Na_2SO_4 alone, the corrosion becoming catastrophic at an alloy composition of Ni-13 Al (Ni_3Al). Alloy coupons of this composition were reduced to a gray porous mass after exposure to the molten salt for a period of only 2 hr (10). The presence of PbO exerted very little influence on the very high corrosion rates of these alloys. By contrast, an alloy of composition Ni-30 Al (the β-NiAl phase) was very resistant to corrosion by excess Na_2SO_4 because of the formation of a protective Al_2O_3 scale and gained only 0.5 mg/cm^2 during 4 hr contact with molten Na_2SO_4 at 900°C, as shown by the lower curve in Fig. 14. Addition of 1% PbO to the initial salt mixture resulted in a marked increase in the extent of corrosion of this alloy which gained weight in an almost linear manner during the course of the run, as shown by the upper curve of Fig. 14. Although the magnitude of the enhanced corrosion induced by the PbO was much less than with the Ni-Cr alloys, metallographic examination of the corroded specimen (Fig. 15) showed that a protective oxide scale was not formed in the presence of PbO, the thick corrosion layer showing a porous structure of finely dispersed particles identified by electron microprobe analysis as oxides and sulfides. Similar enhanced corrosion rates and morphology were found with a salt mixture of composition 1 m/o $PbSO_4$-Na_2SO_4. An experiment in which a coupon of Ni-30 Al was immersed in 1g of powdered $PbSO_4$ and heated in the SO_2-O_2-N_2 mixture for 5 hr at 900°C resulted in localized attack of the alloy coupon at points of contact with the salt particles. Thick porous oxides were formed in these regions, as shown in Fig. 16, in which networks of oxide particles could be identified.

Discussion

As far as oxidation behavior is concerned, the alloys selected for the present study can be broadly classified as belonging to the following groups: (*a*) NiO formers (*e.g.*, pure Ni), (*b*) Cr_2O_3 formers (*e.g.*, Ni-50 Cr), (*c*) Al_2O_3 formers (*e.g.*, Ni-30 Al), and (*d*) mixed oxide formers (*e.g.*, Ni-15 Cr, Ni-5 Al). Unlike the first three classes of alloys where only one type of oxide is observed at steady state, the mixed oxide forming alloys may exhibit a complex, multiphase external scale plus extensive internal oxidation. For example, depending on temperature and time of oxidation and grain size, Ni-15 Cr can form a duplex NiO scale with a Cr_2O_3 subscale, a scale composed entirely of Cr_2O_3 only, or a scale containing islands of Cr_2O_3 or spinel surrounded by NiO (11-14).

Since the selected alloys depend mainly on NiO, Cr_2O_3, or Al_2O_3 for protection in salt-free oxidizing environments, an understanding of the thermodynamic reactivity of these oxides to salt environments becomes essential in interpreting the salt-induced hot corrosion behavior of these alloys. Thermochemical stability diagrams (1, 15-18) are very helpful in identifying and predicting the products formed in reactions involving gases and condensed phases. Reactions likely to occur between Na_2SO_4 and oxide scales are, therefore, best discussed in terms of isothermal Na-S-O-M (M = Ni, Cr, or Al) stability diagrams (16) (Fig. 17a-d[2]). The solid lines in these diagrams outline the stability limits of individual condensed phases and represent equilibria between two coexisting compounds at unit activities and the gas phase. The shaded regions outline the stability limits of individual Na_2SO_4/metal oxide reaction products, *e.g.*, $NaNiO_2$ Na_2CrO_4, and $NaAlO_2$.

It should be emphasized that the phase boundaries shown in Fig. 17a-d were calculated assuming unit activity for all condensed phases and neglecting mutual solubility among them. In reality, however, all these compounds exist over a range of stoichiometry and show finite mutual solubilities. Thus, for example, Na_2SO_4 has a finite Na_2O activity that is determined by the experimental variables, *i.e.*, temperature, pressure, and oxygen and sulfur potentials in the gas phase.

Point A in Fig. 17 refers to the gas phase composition utilized in most of our experiments, viz., 0.1% SO_2-76% O_2-N_2. Calculations by Spacil (16) indicate that this composition closely simulates, at least as far

[2] Note that the diagrams shown in Fig. 17 are for 1200°K whereas our experiments were done at 1173°K (900°C). This temperature difference does not affect our discussions to any significant extent.

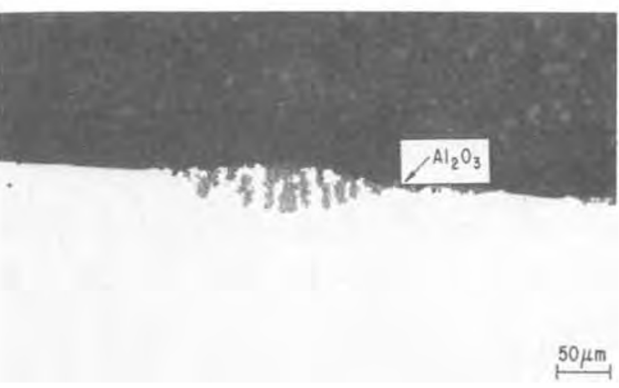

Fig. 16. Section of Ni-30 Al coupon after 5 hr immersion in 1g $PbSO_4$ at 900°C in 0.1% SO_2-76% O_2-N_2 atmosphere.

as oxygen and sulfur potentials are concerned, the nominal conditions prevailing in the first stage of a gas turbine operating at an average pressure of 5 atm with typical air/fuel ratios. The Na_2O activity in a Na_2SO_4 melt equilibriated in this environment can be calculated as follows

$$Na_2O(soln) + 1/2\,S_2(g) + 3/2\,O_2(g) = Na_2SO_4(l) \quad [1]$$

$$K_1 = \frac{a(Na_2SO_4)}{a(Na_2O)P_{S_2}^{1/2}\cdot P_{O_2}^{3/2}} = 1/[a(Na_2O)\cdot P_{S_2}^{1/2}P_{O_2}^{3/2}]$$

$$\Delta G°_1 = -RT \ln K_1$$

$$= RT\,[\ln a(Na_2O) + \ln P_{S_2}^{1/2} + 3 \ln P_{O_2}^{1/2}]$$

$$= RT \ln a(Na_2O) + \mu_S + 3\mu_o$$

$$\ln a(Na_2O) = [\Delta G°_1 - \mu_S - 3\mu_o]/(RT)$$

For 1200°K and $\mu_S = -81.4$ kcal/mole, $\mu_o = -0.33$ kcal/mole (point A in Fig. 17), $\Delta G°_1 = -155.5$ kcal/mole, and $a(Na_2O) \simeq 4.8 \times 10^{-14}$. The "reactivity" of such a melt to NiO, Cr_2O_3, and Al_2O_3 scales can be estimated from considerations of the following type

$$2Na_2O(soln) + Cr_2O_3(s) + 3/2\,O_2(g) = 2Na_2CrO_4(soln) \quad [2]$$

$$K_2 = \frac{a^2(Na_2CrO_4)}{a(Cr_2O_3)\cdot a^2(Na_2O)\cdot P_{O_2}^{3/2}} = \frac{a^2(Na_2CrO_4)}{a^2(Na_2O)\cdot P_{O_2}^{3/2}}$$

$$\ln a(Na_2CrO_4) = [2RT \ln a(Na_2O) + 3\mu_o - \Delta G°_2]/(2RT)$$

$$a(Na_2CrO_4) = 9.7 \times 10^{-5}$$

Results of similar calculations for Al_2O_3 and NiO are summarized in Table II.

Table II. Expected activity of Na-M-O reaction products, i, dissolved in Na_2SO_4 equilibrated with a 0.1% SO_2-76% O_2-balance N_2 atmosphere at 1200°K ($\mu_S = -81.4$ kcal, $\mu_o = 0.33$ kcal)

Oxide	$\Delta G°$ [(a)]	i	a_i	% i [(b)]
Cr_2O_3	−103,600	Na_2CrO_4	9.7×10^{-5}	0.0097
Al_2O_3	−42,900	$NaAlO_2$	1.8×10^{-3}	0.18
NiO	−19,900	$NaNiO_2$	1.3×10^{-5}	0.0013

[(a)] Refers to net $\Delta G°$ for dissolution reactions similar to reaction [2].
[(b)] Assuming % i = 100 $N_i \simeq$ 100 a_i.

It is obvious from Table II that among the oxides considered, only Al_2O_3 may be complexed to an appreciable extent by Na_2SO_4; Cr_2O_3 and NiO are expected to dissolve in Na_2SO_4 only to limited extents. Some caution must be exercised, however, in directly extending this conclusion about the relative thermodynamic reactivities of these oxides to the actual corrosion behavior of the alloys. The above analysis does not take into account kinetic, morphological, and other nonthermodynamic features of the corrosion phenomenon, and allows calculation of upper limits of activity provided all other factors are favorable. Sometimes the kinetics are slow, as in the case of Na_2SO_4 attack of Ni-30 Al (Fig. 14), and the actual corrosion rate is less than that expected from thermodynamic reasonings alone. In some cases, the morphology of the oxide is such that a number of side processes may occur and confuse the over-all picture. Thus, the scale forming on Ni, for example, is not very dense and cannot effectively isolate the alloy from the salt. The extent of corrosion as measured by weight change is consequently quite high (Fig. 1) although NiO is relatively inert under the experimental condition employed. Considerations of oxide stability in Na_2SO_4, therefore, may play an important role in understanding the corrosion behavior of an alloy but must be supplemented by kinetic and morphological information on the system. Before proceeding to a detailed discussion of corrosion features of the various alloys, an attempt will be made to compare the corrosive capabilities of $PbSO_4$ as well as 1 m/o PbO-Na_2SO_4 following the thermodynamic framework presented earlier.

Figure 18 is a composite diagram showing the stability limits of relevant compounds in the Pb-S-O system at 1200°K as well as the products likely to be formed in presence of Cr_2O_3 and Al_2O_3. Considerable controversy exits in the literature on the thermochemistry of the Pb-S-O system (19-21). Figure 18 is based on the data that are in the authors' opinion, most acceptable. These are listed in Table III. Thermodynamic data for $PbCrO_4$ are available (22) but the same cannot be said for $PbO\cdot Al_2O_3$ (23). In view of what is known about double oxides like $PbO\cdot WO_3$, $PbO\cdot MoO_3$,

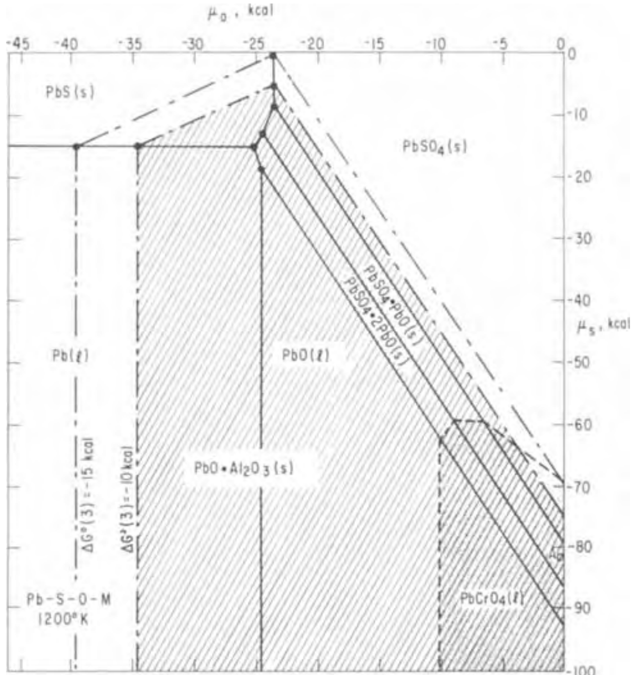

Fig. 18. Stability diagram for Pb-S-O-M system showing the regions of $PbCrO_4$ and $PbO \cdot Al_2O_3$ stability. Effect of assuming different $\Delta G°$ values for the reaction $PbO + Al_2O_3 = PbO \cdot Al_2O_3$ is indicated by dash-dot lines.

and the numerous spinels that form exclusively through condensed phase reactions, it is unlikely that $\Delta G°$ for the reaction

$$PbO(l) + Al_2O_3(s) = PbO \cdot Al_2O_3(s) \quad [3]$$

will be more negative than -10 kcal. The boundaries of the $PbO \cdot Al_2O_3$ stability region in Fig. 18 were calculated using the reasonable value of $\Delta G°$ ($PbO \cdot Al_2O_3$) of -343 kcal. Figure 18 also shows how the stability region for $PbO \cdot Al_2O_3$ would look if a value of -15 kcal were chosen for $\Delta G°_3$, *i.e.*, -348 kcal for $\Delta G°$ ($PbO \cdot Al_2O_3$). It is clear that in going from $\Delta G°_3 = -10$ to -15 kcal, only the over-all size of the stability region has increased; no major changes have occurred in the features of the diagram.

As no Pb-Ni-O compound apparently exists, the reactivity of NiO to $PbSO_4$ or PbO cannot be discussed in terms of a complexing capability of the lead salt. The behavior of NiO formers in the presence of lead salts can nevertheless be rationalized if all the chemical and physical processes occurring in the vicinity of the alloy surface are taken into consideration. Discussion of actual corrosion processes for the individual alloys will appear later in this section.

As before, point A on the stability diagram of the Pb-S-O-M system (Fig. 18) indicates the composition of the SO_2-O_2-N_2 gas phase used in the present experiments. The Pb-S-O phase that is stable in this environment is of the type $PbSO_4 \cdot nPbO$ (most likely $PbSO_4 \cdot PbO$). In other words, irrespective of whether PbO or $PbSO_4$ is used at the beginning of an experiment, the phase likely to be found at equilibrium is Pb-oxysulfate. It is obvious from Fig. 18 that both Cr_2O_3 and Al_2O_3 are unstable in the presence of $PbSO_4 \cdot nPbO$ and will react to form $PbCrO_4$ and $PbO \cdot Al_2O_3$, respectively. That $PbCrO_4$ is the only reaction product that is liquid under these conditions should be noted at this point. Since formation of liquid phases is usually detrimental to the corrosion resistance of an alloy, Cr_2O_3 formers are more likely to be attacked by a $PbSO_4$/PbO environment than Al_2O_3 formers.

Since the presence of a pure $PbSO_4$/PbO type condensate in actual turbine practice is ruled out, the behavior of the protective oxides in a Na_2SO_4 melt containing minor amounts of Pb compounds must be considered. Spacil (4), has carried out a preliminary thermochemical analysis of the most likely reactions in a turbine burning Pb-contaminated fuels, and has concluded that the combined $PbSO_4$ plus PbO content in a typical Na_2SO_4-base condensate is not likely to exceed 1 m/o. Preliminary experiments showed that 1% PbO-Na_2SO_4 melt was more corrosive than 1% $PbSO_4$-Na_2SO_4. All subsequent work involved 1% PbO-Na_2SO_4 as the corrosive medium. It is believed that the results obtained provide an assessment of the effects of Pb contamination on hot corrosion that is somewhat overpessimistic but nevertheless realistic.

A quantitative estimation of the reactivity of Cr_2O_3 and Al_2O_3 to the PbO-Na_2SO_4 melt is a rather difficult task. The system, in either case, contains as many as five components (Na, S, O, Pb, M) and involves multiphase equilibria. Calculation of activities of individual reactive species in the melt therefore becomes a formidable problem. A simple approach may nevertheless provide qualitative information on the effect of PbO contamination on the complexing of protective scales.

Addition of 1% PbO to Na_2SO_4 is likely to produce a homogeneous melt free from second phases. The presence of PbO may or may not affect the activity of Na_2O in the melt; in view of the fact that no Na-Pb-O compound is known, it is unlikely that PbO will substantially affect the 10^{-14} value of $a(Na_2O)$ in the melt. The initial activity of PbO may be approximately equated to the concentration of PbO on the melt; *i.e.*, initial $a(PbO) \simeq N(PbO) \simeq 10^{-2}$. Although such an assumption is obviously speculative, as will be shown later, the qualitative conclusions to be derived here would remain unchanged even if $a(PbO)$ were as low as 10^{-4}, *i.e.*, even if substantial Na-Pb-O-S interactions took place. In any event, $a(PbO) >> a(Na_2O)$ and PbO is expected to be the most corrosive species in the melt. Exposure of Cr_2O_3 and Al_2O_3 to the PbO-Na_2SO_4 melt should then promote the following reactions

$$2PbO(soln) + Cr_2O_3(s) + 3/2\, O_2(g) = 2PbCrO_4(soln) \quad [4]$$

$$PbO(soln) + Al_2O_3(s) = PbO \cdot Al_2O_3(soln) \quad [5]$$

For these reactions, the activities of the complex compounds are related to $a(PbO)$ through the following relations (valid for 1200°K)

$$a(PbCrO_4) = (587) \cdot a(PbO)$$

$$a(PbO \cdot Al_2O_3) = (66) \cdot a(PbO)$$

These relationships over a broad activity range are graphically illustrated in Fig. 19. It is obvious from this figure that even for $a(PbO)$ in the range of 10^{-4}-10^{-5}, $a(PbCrO_4)$ and $a(PbO \cdot Al_2O_3)$ would reach values as high as 10^{-2}. In pure Na_2SO_4, on the other hand, the equilibrium activities of Na-chromate and Na-aluminate are only about 10^{-5} and 10^{-3}, respectively (Table II). The 1% PbO-Na_2SO_4 melt is, therefore, expected to complex Cr_2O_3 and Al_2O_3 to a greater extent than Na_2SO_4 alone.[3]

The above conclusion could also have been reached from an analysis of the type presented by Goebel, Pettit, and Goward (17, 18). In terms of their model, addition of PbO to Na_2SO_4 should increase oxide ion activity, $a(O^=)$, in the melt. This increase should in turn cause an increased fluxing (*i.e.*, increased aluminate and chromate ion concentrations) of the protective scales

$$Al_2O_3(s) + O^= = 2AlO_2^- \quad [6]$$

[3] Compounds of the type $PbCrO_4$-PbO are known to be volatile (24). Rapid volatilization of reaction products may occur for Cr_2O_3-forming alloys in PbO-Na_2SO_4 melts leading to a further increase in corrosion. Although such vaporization processes might have influenced the observed weight gains in the corrosion experiments, corrections for such losses could not be applied owing to the lack of volatilization data for the complexes involved. In any case this effect will not invalidate the basic conclusions reached in this study.

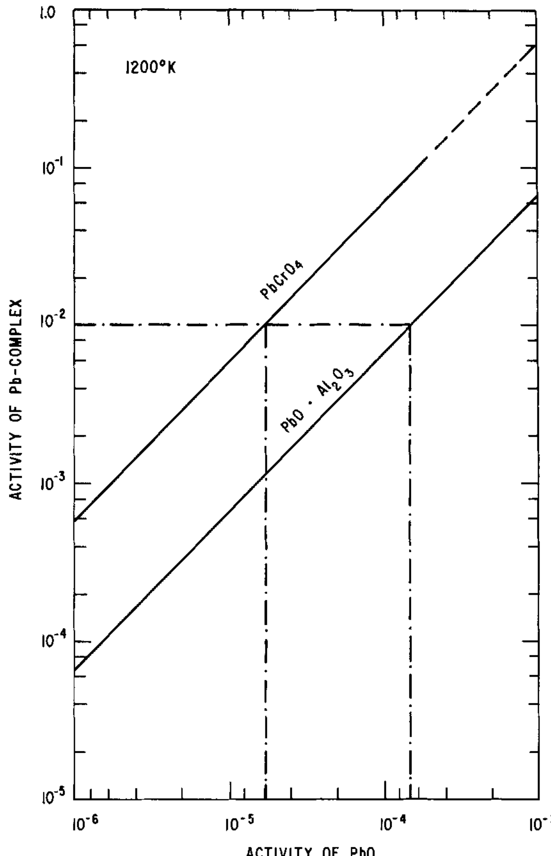

Fig. 19. Equilibrium Pb-chromate and Pb-aluminate activity in Na_2SO_4-PbO for different a(PbO) values.

$$Cr_2O_3(s) + 3/2\,O_2(g) + 2\,O^= = 2CrO_4^= \quad [7]$$

The situation in the presence of PbO then roughly corresponds to that referred to by Goebel *et al.* as "accelerated corrosion due to basic fluxing."

Although the model proposed by Goebel and coworkers explains the effect of PbO on the corrosion of Cr_2O_3 and Al_2O_3, problems appear when NiO reactivity is considered. According to their fluxing model, increased $O^=$ ion activity should lead to increased NiO dissolution through nickelate ion formation

$$NiO(s) + O^= = NiO_2^= \quad [8]$$

$$NiO(s) + 1/4\,O_2(g) + 1/2\,O^= = NiO_2^- \quad [9]$$

PbO should therefore induce accelerated corrosion of Ni. The present experiments (Fig. 1) indicate, however, that PbO causes a dramatic reduction in the hot corrosion of Ni. The complexing model, on the other hand, does not predict what the effect of PbO would be on corrosion of Ni. This dilemma demonstrates clearly that processes in addition to simple fluxing or complexing may become important in particular alloy systems. The physical and chemical processes which may occur simultaneously or concurrently in the immediate vicinity of the individual alloy surfaces will now be examined in some detail.

Nickel.—In view of the work done by Goebel and Pettit (17) and the kinetic and morphological results obtained during the present work, the important stages involved in the hot corrosion of Ni in pure Na_2SO_4 can be said to have been identified. When a specimen embedded in Na_2SO_4 is heated to the experimental temperature of 900°C, the salt melts almost instantaneously and screens the specimen from direct contact with oxygen in the gas phase. Consequently, the metal oxidizes by consuming oxygen from the melt in its immediate vicinity. This locally raises the sulfur potential to such high levels that liquid Ni-S phases begin to form at (or immediately underneath) the metal surface. Occurrence of these two concurrent reactions and formation of a solid-liquid phase mixture results in the development of a porous nonprotective scale that does not prevent further Na_2SO_4 infiltration. In the presence of excess Na_2SO_4 (as in our experiments but not in Pettit's), the sequence of oxidation-sulfidation can repeat many times and accelerate the corrosion process. Figure 20(a) schematically outlines this model.

It seems likely that the presence of 1% PbO in Na_2SO_4 alters the corrosion mechanism for Ni in the following way. Following melting of the salt mixture and the formation of homogeneous solution, Ni oxidizes by reducing PbO

$$Ni(s) + PbO(soln) = NiO(s) + Pb(l) \quad [10]$$

A large thermodynamic driving force exists for this reaction

$$\Delta G = \Delta G^\circ + RT\ln a(PbO)$$
$$= -7600 + RT\ln a(PbO)$$
$$< -7600\ \text{cal}$$

Since the oxygen needed for NiO formation is obtained from PbO in the melt, the stoichiometry of Na_2SO_4 (and the sulfur potential in it) remains virtually unchanged, and no sulfides can form. In the absence of sulfide formation, dense protective NiO scale can develop over the metal. The scale formed over Ni exposed to the 1% PbO-Na_2SO_4 melt (Fig. 2) is identical in appearance to the scale observed in ordinary oxidation in a salt-free environment [Fig. 3a in Ref. (17)]. Figure 20(b) schematically summarizes the processes responsible for the development of dense sulfide-free NiO scale on Ni in the 1% PbO-Na_2SO_4 melt.

Nickel-chromium alloys.—Corrosion processes occurring in Ni-Cr alloys are more complex than in Ni because the nature of the scale on these alloys depends on alloy composition, grain size, the surface condition, and time and temperature of oxidation (11-14). All Ni-Cr alloys pass through an initial transition stage during which nuclei of NiO and Cr_2O_3 form on the surface, the amounts of each mainly depending on

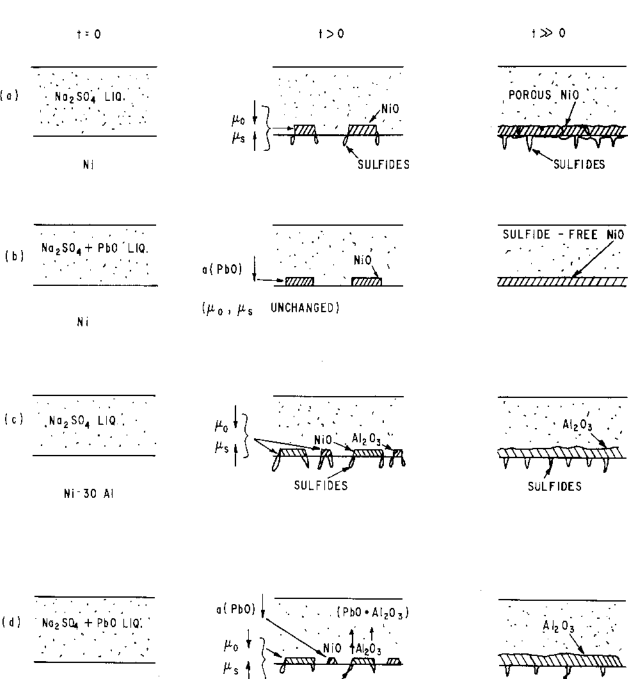

Fig. 20. Schematic summary of proposed reactions responsible for development of steady-state corrosion morphologies in (a) Ni in Na_2SO_4, (b) Ni in Na_2SO_4 + 1% PbO, (c) Ni-30 Al in Na_2SO_4, and (d) Ni-30 Al in Na_2SO_4 + 1% PbO.

the alloy composition (12). For alloys such as Ni-5 Cr, NiO rapidly covers the surface isolating and encapsulating the initially formed Cr_2O_3 particles. Some internal oxidation of Cr may also occur. Ni-Cr alloys containing 20% or more Cr, on the other hand, form Cr_2O_3 and NiO initially, the former process is more rapid however, so that the steady-state scale is essentially pure Cr_2O_3. For alloys in the 10-15% Cr range, experimental and microstructural variables determine whether a duplex NiO scale will form over a Cr_2O_3 subscale, or a Cr_2O_3 scale will cover the entire surface, or an intermediate, mixed mode of oxidation will ensue (11, 12, 14). Since earlier discussion has established that Cr_2O_3 is susceptible to complexing by PbO, the extent of corrosion in Ni-Cr alloys is expected to be a function of Cr-concentration in the alloy. Figure 11 shows that indeed such a functional relationship exists. The presence of a peak in the initial corrosion rate at about 10-15% Cr indicates that simultaneous NiO and Cr_2O_3 formation on an alloy (*i.e.*, a mixed mode of oxidation) makes it particularly vulnerable to PbO attack. It is interesting to note that attack by Na_2SO_4 alone monotonically decreases with increasing Cr-content and does not show any peak throughout the entire composition range.

Figure 21(a) schematically outlines the important stages in the morphological development of a reasonably dense NiO scale over Ni-5 Cr in pure Na_2SO_4. Corrosion processes occurring here are not very different from those occurring in pure Ni [Fig. 20(a)] except that solid Cr-sulfides form in Ni-5 Cr instead of liquid Ni-sulfides. Prevention of liquid sulfide formation helps in forming a dense scale over Ni-5 Cr and in reducing the corrosion rate in Na_2SO_4 (Fig. 11).

Figure 21(b) schematically summarizes the processes occurring on Ni-5 Cr in 1% PbO-Na_2SO_4. The processes are similar to those occurring on Ni-5 Cr in Na_2SO_4 alone except that the initially formed Cr_2O_3 is complexed away by PbO to form liquid (and possibly volatile) (24) $PbCrO_4$. Formation of liquid or volatile reaction products tends to make the NiO scale developing on Ni-5 Cr porous, at least until no more Cr_2O_3 forms. These factors together are responsible for increasing the initial PbO-Na_2SO_4 corrosion rate of Ni when 5% Cr is added to it.

Unlike Ni-5 Cr where NiO is the sole constituent of the steady-state scale, both NiO and Cr_2O_3 may persist at steady state on Ni-Cr alloys containing 10-15% Cr. NiO is generally seen to cover grains and forms the matrix, and Cr_2O_3 is found at sites where grain boundaries meet the external surface (11). Often Cr_2O_3 islands link up to form chainlike paths in the NiO matrix (11-13). Sometimes NiO and Cr_2O_3 react to form spinels within the scale, or a Cr_2O_3 subscale develops under a duplex NiO scale (13, 14). In any event, the presence of large amounts of Cr_2O_3 on Ni-(10-15%) Cr alloys makes them susceptible to PbO complexing for longer periods than with Ni-5 Cr. Removal of Cr from the alloy through Cr_2O_3 complexing as well as Cr-sulfide formation cause the Cr concentration at the scale alloy/interface to drop gradually. Ni-15 Cr and Ni-10 Cr, however, cannot sustain severe Cr depletion without becoming a virtual NiO former. After a finite time, therefore, these alloys begin to behave like Ni-5 Cr. But the scale developing at this late stage is not very protective because of all the surface irregularities already introduced by processes such as sulfidation and complexing. Figure 21(c) shows schematically how the scale may develop on Ni-15 Cr in 1% PbO-Na_2SO_4. Ni-15 Cr in pure Na_2SO_4 will show a dense thin protective layer of Cr_2O_3 plus some internal sulfide particles because Cr_2O_3 does not dissolve appreciably in Pb-free Na_2SO_4 (Table II).

Ni-50 Cr withstands Na_2SO_4 attack very well (Fig. 8) because it is a strong Cr_2O_3 former. For the same reason, however, it is expected to be susceptible to attack by the PbO-Na_2SO_4 melt. However, Cr_2O_3 is the sole constituent of the scale in this case and the protective scale develops quite rapidly. Subsequent complexing of Cr_2O_3 must then proceed solely through dissolution at the scale/melt interface. This is quite unlike the irregular dissolution behavior occurring in the NiO/Cr_2O_3 scale over Ni-15 Cr where porous scales are easy to form. Thus although Ni-50 Cr undergoes accelerated attack in 1% PbO-Na_2SO_4 in comparison to Na_2SO_4 alone (Fig. 11), the attack is not as severe as for Ni-15 Cr.

As discussed in the case of Ni-15 Cr, removal of Cr through sulfide and complex formation reduces the Cr-concentration at the scale/alloy interface in Ni-50 Cr. This appears as a band free from α-Cr particles in Fig. 9 and 10. In the case of Ni-50 Cr, however, the alloy is so rich in Cr initially that the Cr depletion cannot reduce it to a NiO former. In Na_2SO_4 alone, the processes are identical to those shown in Fig. 21(d) for Ni-50 Cr in 1% PbO-Na_2SO_4, except that no $PbCrO_4$ forms in pure Na_2SO_4 and the corrosion is lower in magnitude.

An examination of the kinetic curve for Ni-50 Cr corrosion in 1% PbO-Na_2SO_4 (Fig. 8) reveals that the alloy undergoes a relatively rapid corrosion initially, but the corrosion rate becomes negligible within a short time. This suggests that the melt becomes fully complexed and loses its potency quite quickly. This is not surprising in view of the facts that the alloy is very rich in Cr and the melt initially contains only 1% PbO. The series of experiments with 5 and 10% PbO in Na_2SO_4 (Fig. 8) showed that with larger amounts of PbO added to the melt, longer times were necessary for melt saturation and assumption of "steady-state" corrosion. In fact, for the 10% PbO melt, steady state was not reached during the course of the 4 hr experiment. That the amount of Cr depletion and over-all corrosion of the alloy also increases with increasing PbO content of the melt is clear from Fig. 9 and 10.

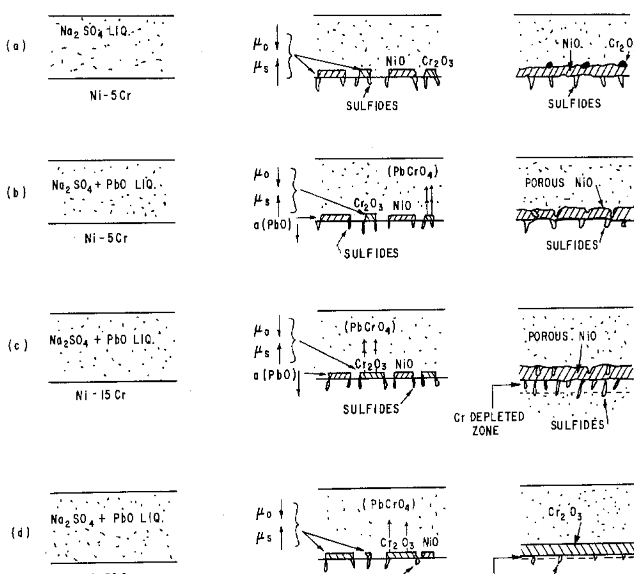

Fig. 21. Schematic summary of proposed reactions responsible for development of steady-state corrosion morphologies in (a) Ni-5 Cr in Na_2SO_4, (b) Ni-5 Cr in Na_2SO_4 + 1% PbO, (c) Ni-15 Cr in Na_2SO_4 + 1% PbO, and (d) Ni-50 Cr in Na_2SO_4 + 1% PbO.

Nickel-aluminum alloys.—Ni-30 (β-NiAl) is the only Ni-Al alloy studied in depth in the present investigations. Alloys containing lower amounts of Al generally contained the γ-Ni_3Al phase as well and were catastrophically attacked even in pure Na_2SO_4. Experiments involving these alloys and Na_2SO_4-PbO melts were, therefore, not attempted.

Figure 14 shows that PbO in the melt increases the hot corrosion of Ni-30 Al but not as significantly as in

the case of Ni-Cr alloys (Fig. 5). (Note that the vertical scale in Fig. 14 is expanded by a factor of two from that in Fig. 5.) This observation is in general agreement with the thermochemical analysis presented earlier (Fig. 19). Kinetic factors may also be responsible for the relatively small effect of PbO in increasing corrosion of Ni-30 Al. For example, unlike $PbCrO_4$ which forms a liquid at 900°C, $PbO \cdot Al_2O_3$ may first appear as a solid and then dissolve in the melt at this temperature. Processes such as these are likely to place kinetic restriction on a system.

Figure 20(c) and (d) attempt to describe schematically how the corrosion morphology may develop in Ni-30 Al exposed to Na_2SO_4 and 1% PbO-Na_2SO_4, respectively. Ni-30 Al is a strong Al_2O_3 former and the sequence of reactions occurring in Ni-30 Al in PbO-Na_2SO_4 [Fig. 20(d)] is analogous to that occurring in Ni-50 Cr [Fig. 21(d)] except for the obvious difference that Ni-50 Cr forms Cr_2O_3 on the surface. Both Ni-30 Al and Ni-50 Cr are very rich in the protective element, and the scale can continue to reform in both cases despite partial dissolution in the melt.

Before concluding the discussion, some incidental observations made during this study need to be examined briefly. One of these involves the effect of SO_2 in the environment and the other involves the relative complexing abilities of $PbSO_4$ and PbO. Corrosion experiments in SO_2-O_2-N_2 environments always produced more extensive material degradation (Fig. 1 and 5, for example) than in air. No simple explanation can be offered for this observation. If PbO complexing of oxide scales was the only reaction determining the extent of corrosion, air should have been the more aggressive environment for the equilibrium a(PbO) would be higher under those conditions. Obviously the answer to this apparent contradiction must lie in the side reactions accompanying the complexing processes. One such reaction is the stabilization of PbO to Pb-oxysulfate in presence of SO_2

$$2PbO(soln) + SO_2(g) + \underline{O}(soln) = PbSO_4 \cdot PbO(s) \quad [11]$$

This reaction would consume $\underline{O}$ from the melt, increase the sulfur potential locally, and thereby enhance over-all corrosion rates. In air, on the other hand, the extent of PbO stabilization is much less, and the net effect on Na_2SO_4 stoichiometry and over-all corrosion rates, etc., should be minimal. This line of reasoning appears to explain the experimental observation but is admittedly speculative at this stage.

No apparent contradiction arises in comparing experimental observations with thermochemical arguments as far as the relative complexing capabilities of Na_2SO_4-PbO and Na_2SO_4-$PbSO_4$ melts are concerned. If the thermochemical analysis leading to Fig. 19 were repeated with $PbSO_4$ replacing PbO in the proper manner, the calculated activities of $PbCrO_4$ and $PbO \cdot Al_2O_3$ would be found to be smaller than those already derived ($<10^{-3}$-10^{-2}). This relatively low amount of corrosion observed in $PbSO_4$-Na_2SO_4 is therefore not difficult to understand. Moreover, reactions of type [11] are not expected to be important in the $PbSO_4$-Na_2SO_2 environment, and less amounts of sulfides are likely to form.

A few experiments were conducted in the course of the present work to determine the reactivity of Ni-Cr and Ni-Al alloys to $PbSO_4$ alone. Figure 7 shows the kinetics of $PbSO_4$-induced corrosion of Ni-15 Cr. A comparison with the data in Fig. 5 shows pure $PbSO_4$ to be more aggressive than pure Na_2SO_4 but less so than PbO-Na_2SO_4 (or $PbSO_4$-Na_2SO_4). Moreover, the corrosion morphology in pure $PbSO_4$ is quite irregular and is characterized by random localized attack. These features are probably due to the fact that pure $PbSO_4$ is solid at the experimental temperature whereas Na_2SO_4 and Na_2SO_4-base mixtures are liquid. As far as Al_2O_3 formers are concerned, the net corrosion in $PbSO_4$ was somewhat more than in Na_2SO_4, and the attack was again localized. Figure 16 shows the morphological features of this localized corrosion. It is interesting to note that $PbCrO_4$ is liquid at 900°C but $PbO \cdot Al_2O_3$ is solid. This fact may be partially responsible for the fact that Cr_2O_3 formers are generally more susceptible to pure $PbSO_4$ attack than Al_2O_3 formers.

Conclusions

1. Addition of 1 m/o PbO to the salt melt reduces sharply the rate of corrosion of pure nickel by Na_2SO_4 at 900°C.

2. With Ni-Cr alloys a large increase in the rate of Na_2SO_4 hot corrosion at 900°C results from addition of 1% PbO to the salt melt.

3. This effect, which is due to the formation of $PbCrO_4$ which is soluble in the molten Na_2SO_4, becomes more significant with increasing Cr content of the alloy and results in catastrophic corrosion rates with alloys containing 10-15% Cr.

4. The Na_2SO_4-induced hot corrosion of Ni-30 Al is also enhanced by the addition of PbO to the salt, probably as a result of the formation of the soluble complex $PbO \cdot Al_2O_3$, although the effect is less dramatic than with Ni-Cr alloys.

5. PbO is a more deleterious condensate than $PbSO_4$, although both are likely to form together during turbine operation with lead-contaminated fuels.

6. In general, hot corrosion rates are higher in a simulated turbine environment (0.1% SO_2-76% O_2-N_2) than in air.

Efficiency of Dy^{3+}-Activated Phosphors

J. L. Sommerdijk and A. Bril

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The quantum efficiency of Dy^{3+}-activated phosphors is reasonably high in lattices where a low activator concentration (< 1%) is already sufficient for effective energy transfer from the lattice to the activator ions. When more activator is needed for effective energy transfer, the quantum efficiency is limited due to concentration quenching of the Dy^{3+} emission. The results are compared with those of corresponding Eu^{3+}- and Tb^{3+}-activated phosphors.

The luminescence of Dy^{3+} is well known (1-9). Emission spectra of Dy^{3+} usually consist of narrow lines in the regions 470-500 and 570-600 nm together with some weak lines at longer wavelengths. Due to the location of the strong lines it is possible to get a near-white emission if the intensities of these lines in the two regions are of the same order. Its luminescence has therefore become of some interest in view of its possible application in low- and high-pressure mercury vapor discharge lamps (6, 7, 9). The Dy^{3+} ions cannot be excited effectively by these discharges which emit mainly at $\lambda > 250$ nm (corresponding to the wave number region $\kappa < 40.000$ cm^{-1}). The lowest charge transfer level of Dy^{3+} in oxides is situated at energies corresponding to $\kappa > 50.000$ cm^{-1} (10) and the same applies to the lowest 5d level of Dy^{3+} (11). Excitation of Dy^{3+} can therefore occur only by 4f-4f transitions. These have a relatively low oscillator strength ($\simeq 10^{-6}$) since they are in first order forbidden by the parity selection rule (12). The radiation of mercury discharges is therefore only weakly absorbed by the Dy^{3+} ions.

The problem of low absorption can be circumvented sometimes by using Dy^{3+}-activated phosphors in which the lattice strongly absorbs the mercury radiation and can transfer the absorbed energy to the Dy^{3+} ions. Some examples of such phosphors reported in the literature are: YVO_4-Dy (2, 5, 7-9), Y_2WO_6-Dy (4), and Ga_2O_3-Dy (6). To our knowledge, the efficiency of these and other Dy^{3+}-activated phosphors has not yet been systematically studied, as has been done, for example, for Eu^{3+}- and Tb^{3+}-activated phosphors (13, 14). It seemed, therefore, interesting to determine the quantum efficiencies of a number of Dy^{3+}-activated phosphors. In this paper we discuss the efficiencies of the lattice emission and that of the Dy^{3+} emission for various lattices and as a function of the Dy^{3+} concentration. We will compare our results with those reported in the literature (2, 4, 13-17) for corresponding Eu^{3+}- and Tb^{3+}-activated phosphors.

Key words: quantum efficiency, luminescence energy transfer, fluorescence energy transfer, rare earths fluorescence.

Experimental

Samples were prepared by the usual techniques as described, for example, in Ref. (2, 4, 13-17). Reaction products were checked by analysis of x-ray powder diagrams (Cu Kα radiation). Quantum efficiencies of the Dy^{3+}-activated phosphors were measured by comparison with the standard phosphors issued by the National Bureau of Standards as described in Ref. (18, 19). As excitation source, a high-pressure mercury discharge lamp with a $Cl_2/NiSO_4$/UG5 filter combination was used, emitting mainly in the 250-270 nm region. In view of the dependence on the sample preparation (the output of the samples was not optimized) and because of the limited accuracy of the optical measurements, only approximate values are given for the quantum efficiencies. All measurements were performed at room temperature.

Results and Discussion

Table I contains the results for Dy^{3+}-activated $YNbO_4$, $LaNbO_4$, and $CeMgAl_{11}O_{19}$. In all cases the quantum efficiency of the Dy^{3+} emission is limited, both for low and high Dy^{3+} concentrations. This can be explained in the following way. For these phosphors, a large amount of Dy^{3+} is needed in order to have efficient energy transfer from the lattice to the Dy^{3+} ions. It is known that energy transfer through these lattices is not efficient (16, 20). For the niobates this is due to the poor overlap between the NbO_4^{3-} emission and absorption bands (20). For $CeMgAl_{11}O_{19}$ the overlap between the Ce^{3+} emission and absorption

Table I. Quantum efficiencies (q) of lattice emission and Dy^{3+} emission under 250-270 nm excitation of Dy^{3+}-activated $YNbO_4$, $LaNbO_4$, and $CeMgAl_{11}O_{19}$

band is also small (16) and furthermore the shortest Ce^{3+}-Ce^{3+} distance is rather large (5.6Å). Since the energy transfer through the lattices is not effective, the transfer from excited lattice centers (NbO_4^{3-}, Ce^{3+}) to Dy^{3+} ions can occur only directly. The probability of this transfer decreases very strongly with increasing distance (21), so that this transfer in effect is restricted to short distances. This implies that a high Dy^{3+} concentration (> 10%) is needed for complete transfer from lattice to Dy^{3+}. The required Dy^{3+} concentration is so high that considerable quenching of the Dy^{3+} emission occurs. This concentration quenching is due to mutual Dy^{3+}-Dy^{3+} interactions (22) and starts generally at a concentration of a few atomic per cent. In conclusion, the quantum efficiency is limited at low Dy^{3+} concentrations by the ineffective energy transfer to Dy^{3+} and at high Dy^{3+} concentrations by the concentration quenching of the Dy^{3+} emission.

Table II contains the results for Dy^{3+}-activated Y_2WO_6, Lu_2WO_6, $CePO_4$, and $CaWO_4$. In these phosphors, the probability of energy transfer through the lattice is somewhat higher than for the phosphors of Table I. This is mainly due to the stronger energy overlap of the lattice absorption and emission bands. In Ref. (23) the transfer probability in Y_2WO_6 has been compared quantitatively with that in $YNbO_4$. It appeared that the average transfer distance through the lattice is twice as great for the tungstate as for the niobate. This explains why quenching of the lattice emission by Dy^{3+} occurs more effectively (*i.e.*, with less Dy^{3+}) in Y_2WO_6 than in $YNbO_4$. Similar arguments have been used in Ref. (23) to explain the difference between $YNbO_4$-Eu and Y_2WO_6-Eu. The compound Lu_2WO_6 has the same crystal structure and about the same luminescence properties as Y_2WO_6 (24). The situation of Lu_2WO_6-Dy will therefore resemble that of Y_2WO_6-Dy. Also in $CePO_4$ energy transfer through the lattice occurs. This can be derived from the concentration quenching of the Ce^{3+} emission

[a] Charge compensation with Na^+ according to 2 Ca^{2+} → Na^+ + Dy^{3+}.

observed for $La_{1-x}Ce_xPO_4$ (17). This quenching is due to energy transfer from one Ce^{3+} ion to another until an energy sink is reached (17, 21). The efficiency of the Ce^{3+}-Ce^{3+} transfer is only moderate, however, since the maximum quantum efficiency of $CePO_4$ is still 40% (17). This explains why still some 5-10% Dy^{3+} is necessary for complete quenching of the Ce^{3+} emission of $CePO_4$. Moderate energy transfer through the $CaWO_4$ lattice has been demonstrated in Ref. (25) where the phosphor $CaWO_4$-Sm was studied. Similarly, complete quenching of the $CaWO_4$ emission occurs at a Dy^{3+} concentration of about 5-10%. Since the amount of Dy^{3+} required for complete transfer from the lattice is lower than for the phosphors of Table I, the effect of concentration quenching of the Dy^{3+} emission is less detrimental. As a result somewhat higher quantum efficiencies can be obtained.

Table III contains the results for Dy^{3+}-activated Ga_2O_3 and YVO_4. Here a small Dy^{3+} content (< 1%) is already sufficient for effective transfer from the lattice to Dy^{3+}. We found that only a little amount of Dy^{3+} can be dissolved into Ga_2O_3. Efforts to dissolve more than 1% Dy^{3+} into Ga_2O_3 were not successful. Instead a second phase occurred which on analysis of the x-ray diffraction diagrams was found to have the composition $Dy_3Ga_5O_{12}$. This phase had the garnet structure with cubic cell parameter a = 12.35Å and it was nonluminescent. In Ref. (6) it was reported that the optimum Dy^{3+} concentration for Ga_2O_3-Dy was 5-10%. In our opinion, the actual Dy^{3+} concentration in the luminescent phase is much lower (< 1%). The x-ray diffraction diagrams of our samples doped with 5-10% Dy^{3+} indicated that nearly all the Dy^{3+} went into the nonluminescent $Dy_3Ga_5O_{12}$ phase. In spite of the slight solubility of Dy^{3+} in Ga_2O_3, the energy transfer from Ga_2O_3 to Dy^{3+} is nearly complete. This implies that this transfer is very efficient. In YVO_4 effective energy transfer occurs through the lattice (23). As a result the Dy^{3+} centers can be easily reached, *cf.* Ref. (2, 7), the lattice emission being completely quenched at a Dy^{3+} concentration as low as 0.3%. The required amount of Dy^{3+} is so low that concentration quenching of the Dy^{3+} emission is not yet important. As in other Dy^{3+}-activated phosphors, concentration quenching of YVO_4-Dy sets in at about 1% Dy (Table III). By choosing the appropriate Dy^{3+} concentration (< 1%), the efficiency of this type of phosphors is therefore not limited by the effect of concentration quenching, so that reasonably high efficiencies can be obtained.

It is interesting to compare the efficiencies of the Dy^{3+}-activated phosphors with those of the corresponding Eu^{3+}- and Tb^{3+}-activated phosphors. Table IV compares the maximum quantum efficiencies under 250-270 nm excitation of some phosphors. The data for the Eu^{3+}- and Tb^{3+}-activated phosphors have been taken partly from the literature (4, 14-17). Usually, lattices giving strong rare earth emissions when activated with Eu^{3+}, do not do so when activated with Tb^{3+}. Examples of this are $YNbO_4$, Y_2WO_6, and YVO_4 (4, 14, 15). This has been ascribed to formation of Tb^{4+}-containing complexes, which is favored in these lattices and which causes radiationless relaxation to the ground state before Tb^{3+} emission can take place

Table III. Values of q (cf. Table I) for Dy^{3+}-activated Ga_2O_3 and YVO_4

Composition	q, % Lattice emission	Dy^{+3} emission
Ga_2O_3	40	—
Ga_2O_3-<1% Dy	4	30
YVO_4	5	—
YVO_4-0.1% Dy	3	40
0.3	<1	60
0.5	<1	65
1.0	<1	65
2	<1	60
4	<1	50
5	<1	40

Table IV. Comparison between the maximum quantum efficiencies (q_m) of the rare earth emission under 250-270 nm excitation of Eu^{3+}-, Tb^{3+}-, and Dy^{3+}-activated lattices

Lattice	q_m, %		
	Eu^{3+} emission	Tb^{3+} emission	Dy^{3+} emission
$YNbO_4$	30	<5	15
$CeMgAl_{11}O_{19}$	<5	65	15
Y_2WO_6	40	<5	20
$CePO_4$	<5	40	15
Ga_2O_3	<5	<5	30
YVO_4	70	<5	65

(14, 20). Such a quenching process does not occur for the Eu^{3+}-activated phosphors since the fourth ionization potential of Eu is much higher than that of Tb. On the other hand, the compounds $CeMgAl_{11}O_{19}$-Tb and $CePO_4$-Tb show strong Tb^{3+} emission (16,17), whereas the Eu^{3+} emission of $CeMgAl_{11}O_{19}$-Eu and $CePO_4$-Eu is very weak (16, 17). The low efficiencies of Eu^{3+}-activated Ce^{3+} compounds have been ascribed to formation of Ce^{4+}-Eu^{2+} containing complexes causing radiationless losses instead of Eu^{3+} emission. This type of quenching does not occur for Tb^{3+}, since this ion has no tendency to become divalent.

Let us now consider the Dy^{3+}-activated phosphors. The tendency of Dy^{3+} to become tetravalent is much less than that of Tb^{3+}, and its tendency to become divalent is much less than that of Eu^{3+}. We can therefore expect that the formation of the type of killer complexes as formed with Tb^{4+} and Eu^{2+} is much less pronounced in the case of Dy^{3+}. In agreement with this, in none of the lattices studied was the efficiency of the Dy^{3+} emission very low. Dy^{3+} is at least the second best of the three activators due to the low efficiency of either the Eu^{3+} emission ($CeMgAl_{11}O_{19}$, $CePO_4$) or the Tb^{3+} emission ($YNbO_4$, Y_2WO_6, YVO_4) or of both (Ga_2O_3). On the other hand, the efficiency of the Dy^{3+} emission is limited in those phosphors where the required amount of Dy^{3+} is so high that considerable concentration quenching occurs (Tables I and II). For the Eu^{3+} and Tb^{3+} activated phosphors, concentration quenching usually occurs at much higher activator concentrations (26). This explains why the maximum efficiencies of $YNbO_4$-Eu, $CeMgAl_{11}O_{19}$-Tb, Y_2WO_6-Eu, and $CePO_4$-Tb are considerably higher than those of the corresponding Dy^{3+}-activated phosphors. For YVO_4-Dy and Ga_2O_3-Dy, the Dy^{3+} concentration can be held low enough to ensure that concentration quenching practically does not limit the efficiency. Correspondingly, the efficiency of YVO_4-Dy is quite comparable to that of YVO_4-Eu. The optimum Dy^{3+} concentration of YVO_4-Dy ($\simeq$ 0.5%) is considerably lower than that of Eu^{3+} in YVO_4-Eu which amounts to 3-10% (2). This suggests that the transfer from the YVO_4 lattice occurs even more effectively to Dy^{3+} than to Eu^{3+}. Finally there remains Ga_2O_3-Dy which shows Dy^{3+} emission of medium efficiency ($\simeq$ 30%). On the contrary, neither Ga_2O_3-Eu nor Ga_2O_3-Tb showed any rare earth emission. At the moment we can offer no satisfactory explanation for the exceptional behavior of Ga_2O_3-Dy. The luminescence mechanism of Ga_2O_3 itself is not known but is probably significantly different from that of the other lattices under consideration (27). It has been indicated that the properties of Ga_2O_3 are similar to those of ZnS-type phosphors (27). Probably the Dy^{3+} luminescence of Ga_2O_3-Dy resembles that of rare earth activated ZnS which has been studied by various authors (28).

Acknowledgments

The authors are indebted to Miss R. B. Engelen for the optical measurements and to Mrs. F. M. J. H. Hoex-Strik for the preparation of part of the samples.

Electrochemichromic Systems for Display Applications

I. F. Chang,* B. L. Gilbert, and T. I. Sun

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Several electrochemical systems exhibit an intense color change when an electrochemical reaction is induced by an applied electrical field or current. The electrochemical and electro-optical properties of several such systems have been investigated. These systems are termed electrochemichromic and they can be classified into the following categories: (*i*) simple redox reaction; (*ii*) redox reaction coupled with an independent chemical reaction, resulting in variable color persistence; (*iii*) redox reaction coupled with a chemical reaction producing an insoluble colored species; (*iv*) redox reaction wherein a solid film deposited on one electrode is reduced and exhibits an intense color change. Analytical models which can describe the electrochemichromic behavior are presented for the different categories.

The spectrum of information display is very broad and fast growing. Functionally, display devices range from a simple status indicator, such as a traffic light, to a complex alphanumeric and graphic information presentation, such as a computer display with graphic and interactive capability. Physically, they vary from small electronic wrist watch displays for personal use to large screen displays for mass entertainment. Display devices are still finding new applications in the areas of automotive electronics, medical diagnosis, supermarket and department store retailing, banking terminals, etc. Not surprisingly, established display technologies cannot cope with the growth in applications, and certainly no single technology can serve all display needs and requirements. Thus new display technologies are constantly being pursued. For instance, liquid crystal displays, d-c plasma panels, and light emitting diodes have already made their entry in the low end (small number of characters) display market and there is some hint that plasma displays may very well penetrate some of the CRT strongholds in the near future (1).

Very recently, several new display devices have been introduced which are based on electrochemistry or some electrochemical effects (2-5). One such device is designated an electrophoretic (EP) display, indicating the phenomenon involved (2). The others, termed electrochromic (EC) [more properly electrochemichromic (ECC)[1]] (3), electrochemiluminescent (ECL) (4), and fluorescence quenching (FQ) displays (5) are related to electrochemical redox reactions. The electrophoretic display employs a dye suspension which changes color as a result of electrophoretic migration of dye particles. The electrochemichromic effect is the direct result of a color change induced by an electrochemical redox reaction taking place at or near an electrode. Electrochemiluminescence is produced by a recombination of two species reduced and oxidized at a cathode or an anode, respectively, in a chemical solution. Fluorescence quenching occurs when a fluorescent ion or molecule is reduced or oxidized at an electrode to a nonfluorescent species. The latter two devices are active displays, that is, light is generated by the display medium whereas the former two are passive devices which modulate the reflected or transmitted ambient light. The EP display device has a very poor threshold characteristic, which would inhibit multiplexing, and requires high operating voltages (75-100V). Comparing the other three redox systems, all have low threshold voltages (0.5-2V) and generally similar electrical behavior. However, the ECC display devices are more attractive because they have fewer chemical system constraints, simpler device operation, and better performance in terms of memory capability and high contrast under bright ambient. Therefore, it is technologically important to make a thorough investigation of various ECC systems, their electrochemical, electrical and electro-optical properties. It is also scientifically interesting to study their physical mechanisms, with the hope that such study can lead to an evaluation of the potential in display applications for ECC systems.

This paper presents a study of several ECC systems with display applications in mind. The systems which are described below in the section on electrochemichromic systems show a relatively efficient electrochemichromic effect. They are categorized into different types according to the electrochemistry involved. Their general characteristics are also presented. In the section on electrochemical and electro-optical properties of ECC systems, we describe the experimental investigation of the electrochemical, electrical, and electro-optical properties of these systems. Polarographic, voltammetric, and electrospectroscopic data are presented. In order to gain a better understanding of the ECC effect, we have devised some analytical models for describing various types of ECC systems. This is detailed in the section on the analytical model for electrochemichromic behavior. Although a different model is derived for each type of ECC system, the ECC response of all systems can be expressed in terms of a common function which represents an optimal ECC response and which, therefore, can be used to assess the ultimate potential of ECC systems for display application. The final section contains such an assessment, as well as a comparison of advantages and disadvantages, for different types of ECC systems.

Electrochemichromic Systems

Electrochromism, in the terminology of display technology, is broadly defined as the production of a color absorption band in a display medium by an applied electric field or current. A number of solid and liquid materials exhibit an EC effect, although the physical mechanisms involved may be different. For example, there are two mechanisms in solids that can lead to electrochromism, the well-known color center absorption due to trapping of an electron in an anion vacancy site in alkali halides (6) or other wide bandgap materials (7-9), and the absorption induced by charge transfer among impurity centers in insulators (10).

On the other hand, there are certain electrochemical effects (3, 11-13) occurring in liquids which also show a relatively efficient EC effect. The color change in these systems can be due to one of three different mechanisms: The first is electroplating, either of metals (12) or of nonmetallic elements (13). The sec-

* Electrochemical Society Active Member.
Key words: electrochromic, electrochemical, display, redox, electrochemichromic.
[1] Electrochromism is more broadly defined and also covers some solid-state phenomena such as color centers induced by an applied electrical field in an inorganic solid. For electrochemical electrochromic systems we propose the nomenclature electrochemichromic.

ond is based on a pH indicator effect, *i.e.*, when the pH value near an electrode is changed by an electrochemical reaction, certain chemicals in an aqueous solution may either change color or fluoresce (11). A third mechanism depends upon the fact that an ion or molecule can be reduced or oxidized at an electrode, changing to a color absorbing species. The important point is that all these effects are governed by the basic electrochemical redox reaction. Thus, we designate all these liquids ECC systems.

The experimental ECC systems investigated here are, by definition, all based on an electrochemical redox reaction; however, some of these systems couple a chemical reaction with the redox reaction, or they involve a solid film in the redox reaction. Therefore, we may classify them into different types as follows:

Type I. Simple redox reaction. Ions or molecules in solution may be either reduced at the cathode or oxidized at the anode to become color absorbing species.

Type II. Redox reaction coupled with an independent chemical reaction, resulting in variable persistence. The chemical reaction controls the rate of reversal of the colored species back to its uncolored state.

Type III. Redox reaction coupled with a chemical reaction producing an insoluble colored species. The insoluble species exhibits excellent persistence and can only be erased electrochemically.

Type IV. Redox reaction in which a solid film deposited on one electrode is reduced and exhibits an intense color change. The color formation is confined to the solid film.

The experimental systems in the present work are listed in Table I according to the above classification. Abbreviations for these systems are listed in the last column and shall be used throughout the paper. All systems are aqueous, although some can be dissolved in a nonaqueous solvent such as dimethyl formamide. Generally the nonaqueous solutions show a relatively weak ECC sensitivity limited by solubility. The electrochemical reactions for these four different types can be described by the following formulas:

Type I. $A \pm ne \rightarrow B$ (colored species)

Type II. $A \pm ne \rightarrow B$ (colored species); $B + Z \rightarrow A + Z'$, $Z' \mp me \rightarrow Z$. The example listed in Table I is $A = PTA$, $Z = H_2O_2 + 2H^+$, $B + n/2\ (H_2O_2 + 2H^+) \rightarrow A + nH_2O$, $nH_2O - ne \rightarrow n/2\ (H_2O_2 + 2H^+)$. By varying the concentration of Z, the persistence of the color absorbing species can be controlled.

Type III. $A \pm ne \rightarrow B$; $B + C \rightarrow BC \downarrow$ where BC is an insoluble compound. The example listed in Table I is $A = HV^{++}$ (diheptyl viologen ion), $B = HV^+$ (one-electron reduction), $C = Br^-$ (bromine ion). In this case, the electrochemical reaction, $HV^{++} \pm e \rightarrow HV^+$, may very well contain another reaction as suggested by Schoot *et al.* (3), $HV^{++} + 2e \rightarrow HV$, $HV^{++} + HV \rightarrow 2HV^+$. However, so long as the reactions are fast, this series of reactions may be viewed as one step.

Type IV. $mWO_3 + 2nH^+ + 2ne \rightarrow W_mO_{3m-n}$ (blue color) $+ nH_2O$ where W_mO_{3m-n} signifies that the ratio of oxygen *vs.* tungsten is reduced to allow color centers to be created. A similar equation applies to MoO_3 films.

Electrochemical and Electro-Optical Properties of ECC Systems

The general characteristics of an ECC system are outlined in Appendix I where we compare them with those of ECL, FQ, and EP systems. In this section we present electrochemical, electrical, and electro-optical properties of each type of ECC system. Polarography and cyclic voltammetry were used to investigate their threshold behavior. Electrospectroscopy was employed to obtain their ECC sensitivity and efficiency. These are the most significant performance parameters of an ECC display device.

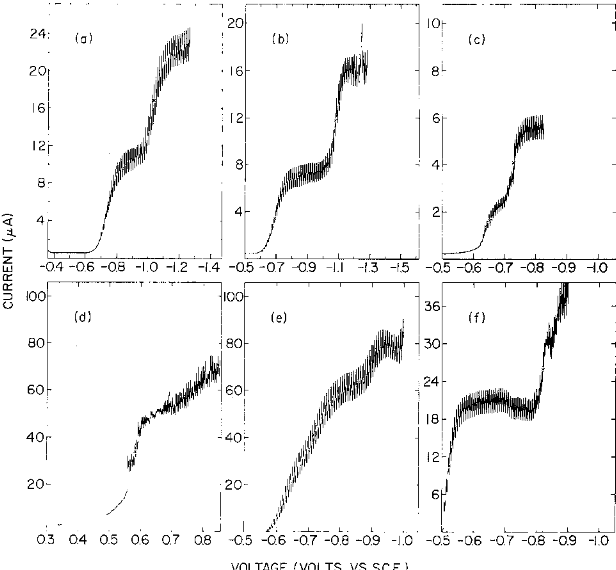

Fig. 1. Polarograph of ECC aqueous systems (a) DPDHC, 50 mg/100 cm^3, pH 3.1, $E_{1/2} = -0.75, -1.05$V; (b) MVDC, 50 mg/100 cm^3, pH 5.3, $E_{1/2} = -0.68, -1.07$V; (c) HVDB, 60 mg/100 cm^3, pH 5.5, $E_{1/2} = -0.65, -0.725$V; (d) OTOL, 50 mg/100 cm^3, pH 2.1, $E_{1/2} = +0.58$V; (e) PTA, $Na_2WO_4 \cdot 2H_2O$ 3 g/100 cm^3, $ClCh_2COOH$ 2 g/100 cm^3, pH 3.1, cathodic wave; (f) HVDB-KBr, 0.02M HVDB, 0.02M KBr.

Polarography.—A Sargent polarograph Model 21 was used to measure the polarographs of each ECC system. The results are shown in Fig. 1(a-f). One notes that the viologen family [Fig. 1(a-c)] all show two cathodic waves, (indicating a two-electron reduction process). The DPDHC, MVDC, and HVDB have their first half-wave potentials at −0.75, −0.68, and −0.65V and second half-wave potentials at −1.05, −1.075, and −0.725V, respectively. [All potentials are given with respect to a saturated calomel electrode (SCE).] The OTOL system with pH value of 2.1 [Fig. 1(d)] shows only one clear anodic wave (one-electron oxidation) with half-wave potential about 0.58V (*vs.* SCE). The polarograph for the PTA system [Fig. 1(e)] is rather poorly defined. There seems to be another wave at lower potential; however, this is not observed in cyclic voltammetry measurement. One does not see a clear one-electron reduction. This suggests that one may have more than one type of polytungsten anion in the solution. When H_2O_2 is added to the solution no significant change in polarographic behavior is observed. Figure 1f shows the polarograph of HVDB when KBr is added as an electrolyte. The half-wave potentials are shifted to −0.52 and −0.8V (*vs.* SCE).

Cyclic voltammetry.—Cyclic voltammetry measurements were performed using a circuit configuration de-

Table I. Electrochemichromic systems

Type	Sample	Formula	Electrolyte	Abbreviation
I	Polytungsten anion	$Na_2WO_4 + ClCH_3COOH$	—	PTA
	44' Dipyridinium dihydrochloride	$N_2C_{10}H_{10}Cl_2$	KCL	DPDHC
	Dimethyl viologen dichloride	$N_2C_{12}H_{14}Cl_2$	KCL	MVDC
	O'Tolidine	$[N_2C_{14}H_{18}]$	KCL	OTOL
II	PTA + H_2O_2	$Na_2WO_4 + ClCH_3COOH + H_2O_2$	—	PTA2
III	Diheptyl viologen dibromide	$N_2C_{24}H_{38}Br_2$	KBr or tetramethyl ammonium bromide	HVDB-KBr
IV	Tungsten trioxide	WO_3	H_2SO_4	WO_3

scribed by Schwarz and Shain (14). A low frequency (0.01 Hz) triangular wave was used in all measurements. The results are shown in Fig. 2(a-f) and Fig. 3(a-f), where the working electrodes were gold and a transparent conductor (tin-oxide-coated glass[2]), respectively. In these measurements high concentrations of ECC materials and electrolyte were used. This tends to wash out the distinction between successive electron reductions. However, we were interested in the current-voltage behavior with solution impedance levels more appropriate to real device operating conditions.

One notes that in Fig. 2(a-c) (data for the viologen family) one cannot distinguish the first electron reduction and the second electron reduction; however, the two reduction steps are more noticeable in Fig. 3(a-c) for the tin oxide electrode cases. Since these scans were taken at high current level with a rate about 80 mV/sec, it might be expected that the two-electron reductions would not be as clearly distinguished in these scans as they were in the polarographs. On the other hand, for the PTA sample, the reduction with the gold electrode [Fig. 2(e)] shows more structure in the I-V scan than is the case with the tin oxide electrode [Fig. 3(e)]. In fact, Fig. 2(e) shows distinctively two reduction steps which are not apparent in the polarograph shown in Fig. 1(e). The half-wave potentials for these reductions may be approximately assigned as −0.37 and −0.6V with respect to SCE potential. Figures 2(d) and 3(d) are the voltammetry curves for OTOL. In both cases, for gold and tin oxide electrodes, the oxidation step is clearly exhibited, the half-wave potential being about +0.6V (*vs.* SCE), which is in close agreement with the value from the polarograph (+0.58V *vs.* SCE). However, one should point out that Kuwana and Strojek (15) have also observed one oxidation wave in their cyclic voltammetric trace in a pH 2.0 solution but observed two oxidation waves in a solution of pH 4.0. This is consistent with results presented in Fig. 2(e) and 3(e) where the pH value is about 2. One recalls that when electrolyte (KBr) is added to the HVDB solution, the polarograms obtained show significant shifts of half-wave potentials; this is not observed in the cyclic voltammetric curves [comparing Fig. 2(f) and 3(f) with Fig. 2(c) and 3(c)]. The high currents employed in the cyclic voltammetry may have masked these shifts.

Electrospectroscopy.—Color and contrast are two important parameters for a display medium. Spectroscopic data for an ECC system in the colored state and noncolored state would be very useful for performance evaluation. Unfortunately, for most of the ECC systems discussed here, there is no spectroscopic data available; therefore, it was necessary to carry out such characterizations. However, in performing absorption measurements, one problem is encountered in the Type 1 and Type 2 samples. The problem is that the colored species electrochemically induced at the electrode tends to diffuse away from it. Due to this diffusion, a nonuniform optical density distribution and a short color persistence result. The reduced (or oxidized) absorbing ion species when meeting an oxidizing (or reducing) ion in the bulk solution will be restored to the uncolored original ion species. Because of this difficulty, among all ECC systems of Type 1 and Type 2 we have measured only the electrochemically induced absorption of the PTA system. Type 3 and Type 4 ECC systems can be measured relatively more easily.

A special optical cell was constructed for the absorption measurement. The cell is O-ring sealed with two windows, either of which can be a transparent electrode serving as a cathode, or working electrode. In the case of measurements of a WO_3 film, the film is deposited on one of the windows. The central vertical port is for a reference electrode such as a SCE. A tilted port next to the central port is for the counterelectrode, which was generally a gold wire. In this cell, one can use either a potentiostatic drive (three electrodes) or a two terminal drive to induce the electrochemical reaction. One also notes that two other side ports are provided for nitrogen flushing, to minimize the oxygen content in the cell.

The three terminal drive is more advantageous than the two terminal drive since it allows a convenient erasure procedure. However, one important fact should be pointed out here: When a colored layer is induced electrochemically on one electrode, an emf is also built up at that electrode. This emf tends to supply through the circuit a reverse current which reverses the redox reaction and erases the color layer. This is especially critical in a three terminal potentiostatic drive circuit, since the back-emf is amplified by the operational amplifier. One remedy for this situation is to use a high off-impedance ($\sim 10^{10}$ ohms) FET switch in the drive circuit, so that the reverse current may be minimized.

The absorption spectrum of the reduced PTA ions is shown in Fig. 4. This is derived from many repeated measurements. One notes a broad absorption band peaked at 710 nm. Considerable asymmetry suggests that a secondary absorption in the infrared around 1000-1200 nm is perhaps superimposed on the main absorption. The resulting color for the reduced PTA ions is a deep blue.

[2] Corning Glass Works.

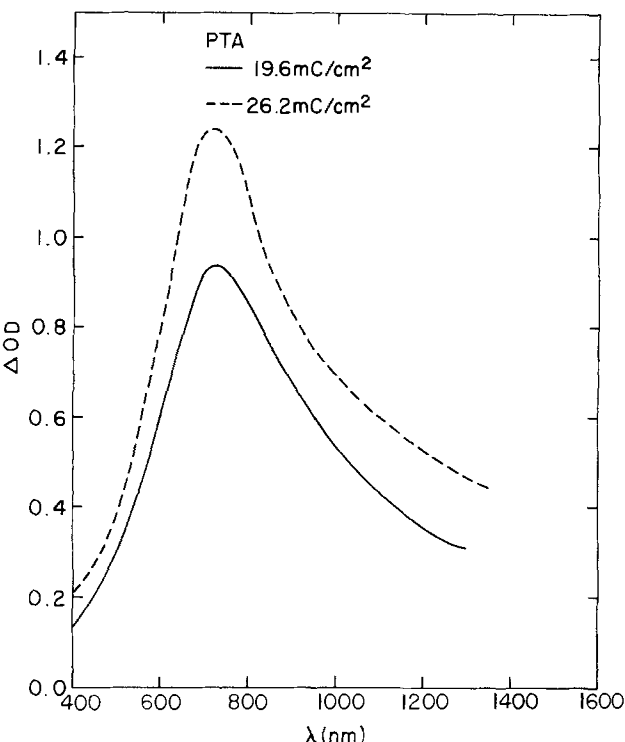

Fig. 4. Absorption spectrum for PTA

The absorption spectra for Type III and Type IV ECC systems are more reliable since there is no color drifting or diffusion in the bulk solution. Figure 5 shows the induced absorption for the HVDB-KBr system. The spectrum exhibits two absorption bands peaked around 515 and 550 nm. The reduced layer has a deep purple color. The induced absorption for a solid WO_3 film is shown in Fig. 6. A very broad absorption band centered around 980 nm is observed. The re-

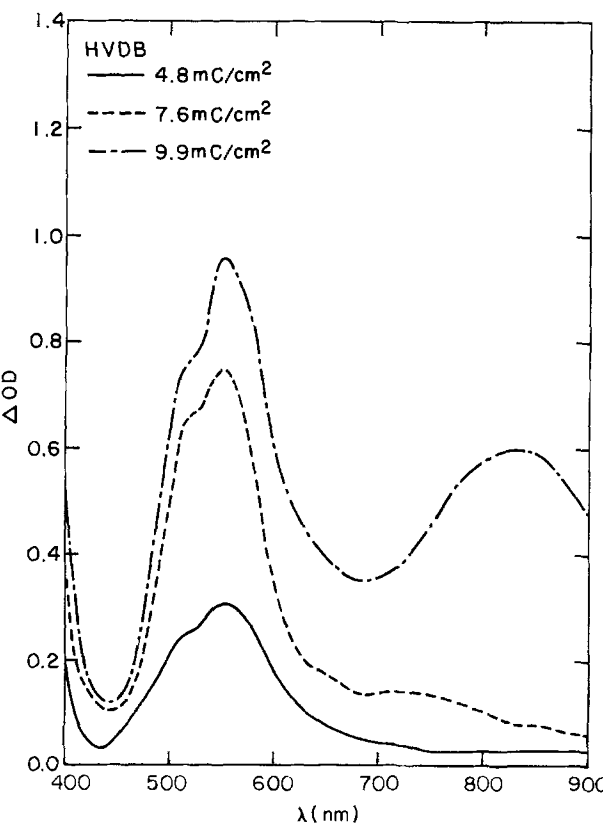

Fig. 5. Absorption spectrum for heptyl viologen bromide

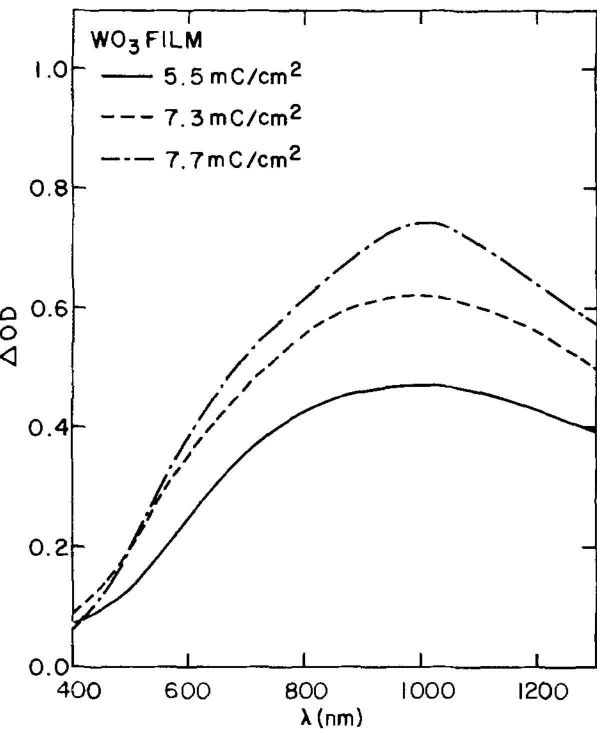

Fig. 6. Absorption spectrum for W_mO_{3m-n}

duced WO_3 also exhibits a deep blue color. In all cases (Fig. 4-6), the induced optical density is proportional to the applied charge density.

Analytical Model for Electrochemichromic Behavior

In order to assess the feasibility and ultimate potential of an ECC system for display device application, it is desirable to derive an analytical model for the ECC effect. The model should consider all first order physical mechanisms involved in the ECC effect and as a consequence should identify the physical parameters relevant to ECC behavior.

In analyzing the ECC effect, one finds that there are two major factors governing the ECC behavior, the electrochemical reaction and diffusion. Other mechanisms such as convection and ion migration can be neglected or minimized in a practical ECC solution. The first mechanism, the electrochemical redox reaction, can be characterized by two constants, the forward and backward reaction rates K_f and K_b (16). The second mechanism is the diffusion process which is characterized by the diffusion equation. The solution of the diffusion equation is governed by the boundary and initial conditions of the oxidant or reductant concentration, $C(x, y, z, t)$. The electrochemical reaction is coupled to the diffusion mechanism through the boundary conditions.

The complete solution to a three-dimensional diffusion equation is very complicated unless some simplifying approximations are made to the problem. Before we proceed to derive models for each different type of ECC system, the following assumptions are made: The first assumption is that the liquid solution is of large volume and is bounded by parallel plane electrodes having a separation much greater than a diffusion length for any species involved. The assumption is a realistic one for a typical experimental cell, although it is certainly possible to make practical cells which violate it. With this assumption one can describe the problem by a one-dimensional diffusion equation. Furthermore, one may consider that the liquid solution extends to infinity relative to the electrode under consideration, thus implying $C(x = \infty, y, z, t) = $ constant as one boundary condition. The second assumption which we make initially is that the speed of the ECC effect is not limited by the electrochemical reaction;

that is, one deals only with fast electrochemical reactions. Again, this assumption is a reasonable one, since for display application one naturally searches for an ECC with a fast reaction rate. Furthermore, in display device operation a sufficiently high voltage is always applied to the device [for instance, one may use $E = 2E_o$ or $3E_o$ in half-select or three-to-one matrix address schemes (17)] such that a fast reaction occurs. For such an operating condition, the most significant limiting mechanism governing the ECC behavior would be the diffusion process. Thus, the analytical model describing ECC systems of practical interest is just a linear diffusion model with appropriate boundary conditions. Analytical models for the four types of ECC systems are presented below.

Type I ECC systems.—Based on the initial and boundary conditions given in Appendix II, the functions C_O and C_R can be determined by the use of Laplace transforms with the result

$$C_O(x,t) = C^O[hS + \mathrm{erf}(x/2\,D_O^{1/2}t^{1/2})]/(1+hS) \quad [1]$$

$$C_R(x,t) = C^O[h\,\mathrm{erfc}(x/2\,D_R^{1/2}t^{1/2})]/(1+hS) \quad [2]$$

where C^O, D_O, D_R, and S are defined in Appendix II, $h = (D_O/D_R)^{1/2}$, erf and erfc are error function and complementary error function, respectively. The current flowing through the cell is given by

$$i = n\mathbf{F}AD_O \left.\frac{\partial C_O}{\partial x}\right|_{x=0} = i_a/(1+hS) \quad [3]$$

where **F** is Faraday's constant, A is the electrode area, and n is the number of electrons involved in the reduction. i_a is the limiting current when the electrochemical reaction rate is so high that the concentration of oxidant at the electrode surface is zero, *i.e.*

$$i_a = i(S=0) = n\mathbf{F}A\,D_O^{1/2}C^O\pi^{-1/2}t^{-1/2} \quad [4]$$

The optical density change induced by the electrochemical reaction is proportional to the density of the colored species produced, which in turn is proportional to the charge supplied by the electrode. Thus, we have

$$OD = \frac{a}{2.3}\int_0^\infty C_R\,dx = \frac{a}{2.3}\,\frac{\int_0^t i\,dt}{n\mathbf{F}A} = OD_a/(1+hS) \quad [5]$$

where a is the absorptivity in terms of liters/M cm, and the numerical factor 1/2.3 implies that the contrast ratio for a given optical density is 10^{OD} rather than e^{OD}, and

$$OD_a = OD(S=0) = \frac{2}{2.3}\,aD_O^{1/2}C^O\pi^{-1/2}t^{1/2} \quad [6]$$

Again the significance of $S = 0$ is that the reaction is very fast due to either K_f being very large or $E << E_o$. Under this condition, $C_O(0,t) = 0$, $C_R(0,t) = hC^O$, $i = i_a$, and $OD = OD_a$. This is the optimal condition for the ECC effect in Type I systems.

Type II ECC systems.—In this type of system, a catalytic chemical reaction is coupled with the electrochemical redox reaction. Therefore we have two coupled diffusion equations

$$\frac{\partial C_A}{\partial t} = D_A\frac{\partial^2 C_A}{\partial x^2} + kC_zC_B$$

$$\frac{\partial C_B}{\partial t} = D_B\frac{\partial^2 C_B}{\partial x^2} - kC_zC_B \quad [7]$$

where k is the rate of the catalytic chemical reaction and C_z is the concentration of the catalyst. The problem can be simplified considerably if we assume that C_z is constant throughout the solution cell at all times and the diffusion constants D_A and D_B are equal, say D. Applying the same boundary conditions given by Eq. [A-2]-[A-4] and setting $S = 0$ [*i.e.*, $C_A(0,t) = 0$], one obtains the following solutions

$$C_B(x,t) = \frac{1}{2}\,e^{-x/(D\tau)^{1/2}}\,\mathrm{erfc}[x/2(Dt)^{1/2} - (t/\tau)^{1/2}] + \frac{1}{2}\,e^{x/(D\tau)^{1/2}}\,\mathrm{erfc}[x/2(Dt)^{1/2} + (t/\tau)^{1/2}] \quad [8]$$

$$OD = \frac{a}{2.3}\int_0^\infty C_B\,dx = \frac{a}{2.3}\,C_A^O\sqrt{D\tau}\,\mathrm{erf}[(t/\tau)^{1/2}] = OD_a\left[1 - \frac{1}{3}(t/\tau) + \frac{1}{5\cdot 2!}(t/\tau)^2\ldots\ldots\right] \quad [9]$$

$$i = n\mathbf{F}A\,D^{1/2}C_A^O\{(1/\tau)^{1/2}\,\mathrm{erf}[(t/\tau)^{1/2}] + (\pi t)^{-1/2}\exp(-t/\tau)\} \quad [10]$$

where $\tau = 1/kC_z$ is the oxidizing time constant. The more oxidizing agent is added, the smaller the time constant. As $kC_z \to 0$, $\tau \to \infty$ (*i.e.*, no oxidizing agent added), $i \to i_a$ and $OD \to OD_a$. Equations [9] and [10] indicate that the ECC response is reduced from the optimal response due to the catalytic action. The reduction is directly related to the chemical reaction rate and the concentration of catalyst.

Type III ECC systems.—For this type of system, modeling of its ECC response is more complicated. It is particularly so if one considers all possible intermediate reactions involving both one-electron and two-electron reductions as well as the final chemical reaction. However, based on the assumption that we are only dealing with fast reactions, *i.e.*, if both electrochemical and chemical reaction rates are high, then the ECC response of such a system may still be regarded as diffusion limited. The system would then be equivalent to the straightforward electrolytic deposition of an insoluble substance on an electrode. This is certainly a reasonable assumption for the HVDB-KBr system which exhibits very fast reactions.

The corresponding boundary conditions for this case are similar to those of the Type I ECC system, but they are complicated by the fact that the activity of the deposit, f_RC_R, is not known until the electrode is completely covered with at least one monolayer of deposit at which point it becomes equal to one. In view of the fact that the ECC system under consideration is a fast one, we neglect the initial uncertainty of the activity of the oxidant and assume that it is equal to one throughout the ECC response. The error introduced by this approximation is very small, and it applies only to the very early stage of the ECC reaction. With this approximation, the boundary condition of oxidant concentration at the electrode becomes

$$C_O(0,t) = S' = \frac{1}{f_O}\exp[n\mathbf{F}(E - E_o)/RT] \quad [11]$$

The solution for this problem is then

$$C_O(x,t) = S' + (C^O - S')\,\mathrm{erf}(x/2\,D_O^{1/2}t^{1/2}) \quad [12]$$

$$i = n\mathbf{F}A\,D_O\left.\frac{\partial C}{\partial x}\right|_{x=0} = i_a(1 - S'/C^O) \quad [13]$$

$$OD = OD_a\,(1 - S'/C^O) \quad [14]$$

However, in Eq. [14], OD_a should be expressed as

$$OD_a = \alpha'\frac{\int i\,dt}{A} = 2\,\alpha' n\mathbf{F}\,C^O D_O^{1/2}\pi^{-1/2}t^{1/2} \quad [15]$$

where $\alpha' = a/2.3n\mathbf{F}$ with units of $(\text{coulomb/cm}^2)^{-1}$. In this case the absorbing species is insoluble in solution; thus, its absorptivity should be defined in terms of ion charge density rather than molar concentration. One should point out that the current and the optical den-

sity functions are both related to their optimal value by a common factor $(1 - S'/C^0)$.

Type IV ECC system.—The electrochemical reaction of this system is not the same as for the above redox reactions involving soluble species. The Type IV system is rather unique in the sense that it is the thin solid film ($\sim$ 0.2-1 μm thick) deposited on the electrode which undergoes a redox reaction. Since the film is an oxide, the reduction is facilitated by the presence of protons. This is borne out by the fact that the redox takes place easily in acidic solution. In fact, the electrochromic sensitivity is proportional to the concentration of hydrogen ions in the solution. Furthermore, we have performed cyclic voltammetry measurements on a WO_3-H_2SO_4 system. The result is shown in Fig. 7 and indicates that the reduction does occur (blue color appears) near the hydrogen redox potential. This seems to support the hypothesis that the over-all electrochemical reaction is of the form

$$mWO_3 + 2nH^+ + 2ne \rightarrow W_mO_{3m-n} \text{ (blue)} + nH_2O$$

Although the involvement of protons is certain, exactly what occurs at the electrode or inside the oxide is not clear at all. One may speculate on several possible mechanisms. One possibility is that H^+ ions are reduced at the solid film surface (since WO_3 or MoO_3 films are semi-insulating and in fact become more conducting when reduced to colored film) becoming hydrogen atoms which then diffuse into the film and reduce it. The solid film is very likely porous which would promote the diffusion of the reduction product, H_2O, out to the solution. A second possibility is that H^+ ions diffuse into the film toward the electrode, an electrochemical reduction takes place within the film, and a chemical reduction reaction follows thereafter. A third possibility is that the oxide film is reduced by receiving electrons from the electrode, and oxygen ions diffuse out of the film to combine with hydrogen ions, which diffuse toward the electrode through the solution. No matter which mechanism prevails, the over-all electrochemical reaction seems to be the one given above.

Although we do not have evidence to support any one of the above described mechanisms, it is clear that in any case the diffusion of H^+ ions in the solution is a possible speed limiting mechanism in that the supply of H^+ ions to the electrode may govern. If one assumes that the electrochemical or chemical reaction taking place in the solid film is fast, then the analytical model for this case is just a diffusion-limited electrochemical reaction of H^+. Since H^+ ions are reduced and combined with oxygen to form water which has an activity of 1, the boundary condition for this problem is the same as that for the HVDB-KBr system, as given by Eq. [A-2], [11], and [A-4]. Thus, the solutions given in Eq. [12], [13], and [14] apply here for the Type IV ECC system. In fact, electrical measurements made on the reduction of WO_3 films (18) indicate that the current is indeed a function of $t^{-1/2}$. This certainly supports the validity of this model.

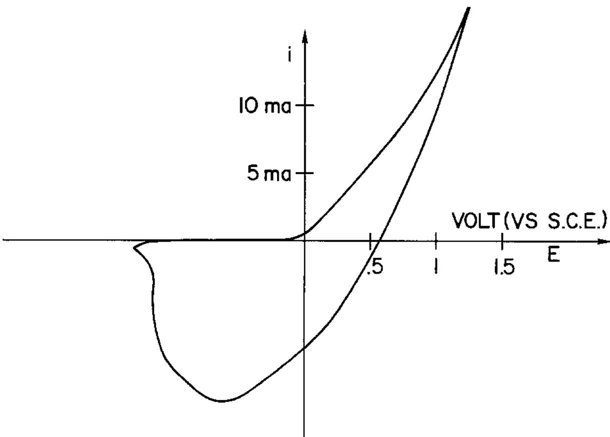

Fig. 7. Cyclic voltammetry measurement of tungsten trioxide film in sulfuric acid (0.3M).

Comparison with experimental data.—Current response, $i(t)$, and electro-optical response, $OD(t)$, of several ECC systems which belong to the four types discussed here have been performed and presented elsewhere (18). The experimental results (18) indicate that for Type I, III, and IV ECC systems, the current response is indeed a function of $t^{-1/2}$ and the optical density a function of $t^{1/2}$. This evidence certainly supports the validity of analytical models presented here. For Type II systems, the model is only confirmed for long persistence systems (*i.e.*, $\tau > 1$ sec). For systems having smaller τ (more oxidizing agent), more experimental work is required to confirm the validity of Eq. [9] and [10].

Discussion and Summary

The systems evaluated here are certainly only a small representation of all possible organic and inorganic ECC systems. The Table I ECC systems are the simplest from an electrochemical point of view. However, for display device applications, they are not practical due to the fact that the induced color species, being soluble, can diffuse or drift away from the electrode, thus causing smearing of an image. There are some possible remedies (19), such as using a gel (or semisolid) electrolyte, but such an approach appears to slow down the ECC response. The second type of ECC system eliminates the color drift problem by providing conversion back to the uncolored species. This feature is acceptable in a display device application where the information can be periodically refreshed. A refresh rate can be selected according to the type and amount of oxidizing chemical used. However, in this type of system, the ECC efficiency is reduced. This effect has been experimentally demonstrated with the PTA-H_2O_2 system (18). As one notes from Eq. [9], unless the oxidizing time constant τ is made much longer than the addressing time (or turn-on time) t, the optical density change is reduced from its optimal value. This condition (*i.e.*, $\tau >> t$) would normally prevail for a multiline matrix display, since it is desirable in that case to select τ to be approximately equal to the refresh cycle time or frame time T.

The third type of ECC system has the advantage of having "memory" capability, since the colored layer is insoluble in the solution. It can only be removed electrochemically. However, because of the presence of this layer there is a back-emf associated with it. This back-emf tends to supply a reverse current through the system if a current path is provided. This leakage current makes matrix addressing complicated (18). However, if all leakage paths are eliminated, the insoluble layer tends to persist indefinitely. This feature offers the potential of saving power in certain applications such as displays for electronic calculators or electronic watches.

The ECC system of the fourth type, namely, a solid ECC film, has similar characteristics to those of Type III. However, the solid film allows the possibility of having such a film deposited on only one electrode, thereby producing an asymmetry not present in the other cases. Figure 8 shows an experimental device arranged in such a manner. When a negative voltage is applied to an electrode coated with an electrochromic solid film, an image is produced (as shown in Fig. 8); and upon reversal of the applied potential, the colored layer is erased without creating a similar colored layer at the opposite electrode. For the other categories of ECC systems an opaque or blocking medium may be required to shield the unwanted coloration created at the opposite electrode by the erasure voltage.

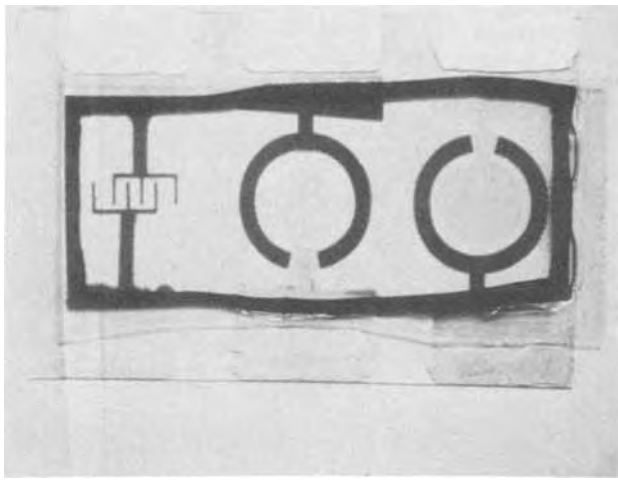

Fig. 8. A display image written on an experimental device containing WO_3-H_2SO_4 gel material.

We have argued that most ECC systems can be described by a diffusion model with appropriate boundary conditions. Solutions for each type of system are all related to an optimal ECC response function OD_a, given by Eq. [6]. One can use this optimal response function to assess the potential of ECC systems for display device applications. If one expresses OD_a as a function of addressing time (turn-on time) in a log-log plot one obtains a straight line with a slope of 1/2. Since OD_a is proportional to the concentration C^O, the absorptivity α or α' and the square root of diffusion constant D, the straight line moves up and down according to the values of these constants. Figure 9 shows a plot for a typical set of constants, $C = 0.1$ M/l, $D = 5 \times 10^{-6}$ cm²/sec, $\alpha = 5 \times 10^4$ liters/M cm. In a transmission mode, one would require a turn-on time ~ 30 msec to obtain an optical density change of 1 (10 to 1 contrast), whereas in a reflection mode (where the light passes through the absorption path twice), a turn-on time ~ 9 msec would be required for $OD = 0.5$ (10 to 1 contrast). Of course, the above example illustrates the ECC response of a typical system under optimal conditions. In practice, Eq. [A-7], [14], or [5] should be used to assess a particular system. ECC device characteristics measured on various ECC systems (18) do in fact indicate that the analytical models are valid and applicable in assessing their performance.

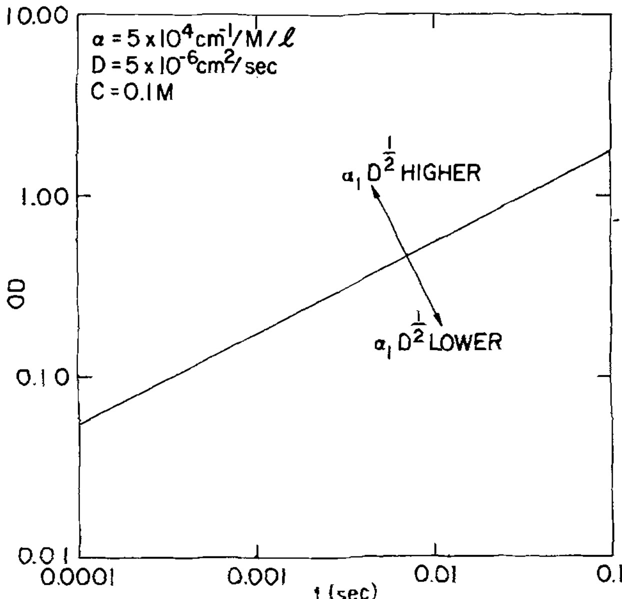

Fig. 9. Induced optical density change of a typical ECC system as a function of addressing time.

Another important question related to ECC device application is their operating life. Although, most examples discussed here were not given a life test, it is worthwhile pointing out that Schoot *et al.* (3) have demonstrated a 10^5 write-erase cycle with the HVDB-KBr system.

In summary, several ECC systems have been evaluated. They are classified into different categories according to the electrochemical reactions involved. The electrochemical, electrical, and electro-optical properties of these systems have been examined and compared. Analytical models which describe the ECC behavior have been derived for the various system types. Based on these models, a performance assessment of the ECC effect can be made. A typical efficient ECC system should have response time in the order of 10-100 msec for contrast of 10 to 1. This response, combined with characteristics such as low threshold voltage, memory capability, and wide viewing angle makes the ECC a strong candidate for direct-addressed segmented displays and small matrix-addressed displays.

APPENDIX II

Initial and Boundary Conditions for Electrochemichromic Effect

The analytical models presented in this paper are given for a reduction process, thus, the initial conditions are

$$C_O(x, 0) = C^O$$
$$C_R(x, 0) = 0 \quad [A\text{-}1]$$

where subscript (or superscript) O and R signify oxidant and reductant, respectively. Equation [A-1] specifies that the ECC solution initially contains only oxidant having a constant concentration C^O throughout the cell. In the case of oxidation reactions one simply interchanges subscript (or superscript) O to R and vice versa in all derivations.

Using the semi-infinite solutions approximation, the boundary conditions are

$$C_O(\infty, t) = C^O, C_R(\infty, t) = 0 \quad [A\text{-}2]$$

$$C_O(0, t)/C_R(0, t) = S = (f_R/f_O)\exp(n\mathbf{F}(E - E_o)/RT) \quad [A\text{-}3]$$

and

$$D_O \frac{\partial C_O}{\partial x}\bigg|_{x=0} + D_R \frac{\partial C_R}{\partial x}\bigg|_{x=0} = 0 \quad [A-4]$$

Equation [A-3] essentially is the Nernst equation which describes the equilibrium situation at the electrode. f_R and f_O are activity coefficients of reductant and oxidant which may be assumed to be equal for the most redox pairs. The third equation indicates that the incoming flux of oxidant to the electrode is equal to the outgoing flux of reductant. D_O and D_R are diffusion constants, for the oxidant and reductant, respectively.

The above description is based on one fundamental assumption, specifically that the electrochemical reaction rate is fast. It is therefore interesting to see what results if this assumption is removed. Most importantly, one requires a different boundary condition at the cathode

$$D_O \frac{\partial C_O}{\partial x}\bigg|_{x=0} = K_f C_O(0, t) - K_b C_R(0, t) \quad [A-5]$$

With this boundary condition, along with that given by Eq. [A-2] and [A-4], the solutions for the current flowing through the cell and the optical density induced are

$$i = nFAC^O K_f \exp(Q^2 t) \operatorname{erfc}(Q t^{1/2}) \quad [A-6]$$

$$OD = \frac{1}{2.3} (\alpha C^O K_f / Q^2) [\exp(Q^2 t) \operatorname{erfc}(Q t^{1/2}) + 2Q(t/\pi)^{1/2} - 1] \quad [A-7]$$

where $Q = K_f/D_O^{1/2} + K_b D_R^{1/2}$. Since one deals with a reduction when the applied potential $E << E_o$, we should have $Q = K_f/D_O^{1/2}$ substituted in Eq. [A-6] and [A-7]. These solutions apply to slow ECC systems. They approach the results for diffusion-limited current i_a and optimal optical density change OD_a if $Qt^{1/2}$ is large, for instance greater than 5.

On the Correction to be Applied to the Thickness of an Epitaxial Layer Measured with Infrared Multiple Interference

P. J. Severin and F. C. Eversteyn

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The extreme values of k plotted against the order of the extrema yield a straight line characterized by a slope d_s and an intercept $\delta_o/2\pi$. The thickness d_m of the deposited layer can be measured with a method described by Eversteyn and van den Heuvel. It turns out that $d_s - d_m$ depends linearly on $\delta_o/2\pi$, the relations being different for N^+ and N^{++}, but further independent of substrate resistivity or thickness. After calibration for a particular growth process the thickness can be determined with d_m as a standard reference from a conventional infrared multiple interference spectrum.

The thickness of a silicon layer grown epitaxially on a conductive substrate of resistivity ρ is an important parameter for integrated circuit technology. In this note fairly conclusive experimental evidence is presented for the validity of the method of interpreting infrared multiple interference spectra described earlier and practiced in this laboratory for several years. The introduction of a new experimentally accessible standard reference allows us now to also discuss the accuracy of the method.

It is well known that the wavenumber k of an extremum depends on the order l by the relation

Key words: silicon, epitaxial film thickness, infrared spectrophotometer, metallurgical film thickness.

$$2ndk = l - \frac{1}{2} + \frac{\delta(k, \rho)}{2\pi} \quad [1]$$

where n and d are the refractive index and the thickness of the layer, respectively. The phase shift $\delta(k, \rho)$ can be calculated from the optical parameters of the layer and the substrate. Over a limited wavenumber range, $\delta(k, \rho)$ may be approximated by a linear relationship

$$\frac{\delta}{2\pi} = \frac{\delta_o}{2\pi} - 2nk\Delta d \quad [2]$$

which yields, with Eq. [1] and after writing $d_s = d + \Delta d$

$$2nd_s k = l - \frac{1}{2} + \frac{\delta_o}{2\pi} \quad [3]$$

It has been shown earlier (1) that when k is plotted *vs.* l, a straight line is obtained from which the slope d_s and the intercept $\delta_o/2\pi$ can be easily determined. In a second paper (2) this formal solution, Eq. [2], has been suggested without actually specifying any experimental values of Δd and $\delta_o/2\pi$. In the absence of a well-defined and experimentally accessible reference for the thickness of an epitaxial layer, there was no point in discussing Δd and the accuracy of the infrared multiple interference method.

However, recently Eversteyn and van den Heuvel (3) outlined a method of thickness measurement particularly suited for epitaxial layers. It is based on the use of the metallurgical thickness d_m, measured with a Taylor Hobson Talystep as a standard reference. It was found that d_m is related to the thickness $d_{m(poly)}$ of polycrystalline silicon deposited simultaneously on an adjacent Si_3N_4 layer and measured in the same way, with accuracy to the second decimal, by

$$d_{m(poly)} = d_m + 0.10\ \mu m \quad [4a]$$

and that the same layer measured with infrared interference and interpreted as described above (1, 2) yields the same thickness also within 0.01 μm

$$d_{s(poly)} = d_{m(poly)} \quad [4b]$$

In this paper, the thickness d_s and the constant phase shift $\delta_o/2\pi$ are shown to be correlated to this metallurgical thickness d_m. The experimental data are presented in the next section and possible interpretations are also discussed in this paper. In the last section the conclusions and recommendations are summarized.

Experimental Results

A large number of epitaxial layers was grown in SiH_4 at 1050°C corrected temperature, undoped, on Sb-doped N^+ substrates and As-doped N^{++} substrates. By plotting k *vs.* l the thickness d_s and the constant phase shift $\delta_o/2\pi$ are determined as in Eq. [3]. When d_m, as measured on an adjacent polycrystalline layer, is plotted against the thickness d_s, the latter does not present the appearance of a reliable parameter. However, when the difference $d_s - d_m$ is plotted against $\delta_o/2\pi$, the parameters show correlation. In Fig. 1 the N^{++} substrate data (1.3-2 mohm-cm) turn out to be clearly separated from the N^+ substrate data (8-15 mohm-cm). The experimental data show no systematic dependence when they are labeled with the appropriate substrate resistivity or thickness values.

For N^+ substrates, $d_s - d_m$ assumes any value between 0 and 0.6 μm correlated linearly with a value of $\delta_o/2\pi$ between 0 and 0.3, satisfying

$$d_s - d_m = 2\frac{\delta_o}{2\pi}\ \mu m \quad [5a]$$

From Fig. 1 it is also clear that the N^{++} substrate data show a greater phase shift than any N^+ substrate does roughly satisfying

$$d_s - d_m = 2\frac{\delta_o}{2\pi} - 0.45\ \mu m \quad [5b]$$

The linear relationships are obeyed with a precision of about 0.05 μm which amounts to about 1% for 5 μm thick epitaxial layers. This error is due in the first place to the lack of precision in measuring k of the extrema for the epitaxial layer to determine d_s with Eq. [3], and for the polycrystalline layer to determine d_m with Eq. [4a] and [4b]. The error in the wavenumber depends slightly on the range but amounts to about $5 \cdot 10^{-3}$ with the instrument used.[1] Secondly, the refractive index n of silicon has been assumed, as usual, to be 3.42. Recently Villa (4) published measurement results, for which $2 \cdot 10^{-4}$ accuracy is claimed, in the range from 1.3 to 11 μm yielding 3.4371 and 3.4176 for the refractive index of two samples of silicon of nonspecified resistivity at 11 μm. Thereupon, the refractive index was measured in the range from 8 to 25 μm by multiple interference between the polished sides of an 8 ohm-cm, n-type silicon slice. It was found that the slope of the line k *vs.* l is constant with a precision of $4 \cdot 10^{-3}$. The thickness of the slice was measured with a precision of $2 \cdot 10^{-3}$ and thus the refractive index was determined to be 3.4135 $\pm$ 0.0042 which is equal to 3.42, well within the relevant accuracy and precision of $5 \cdot 10^{-3}$ for k.

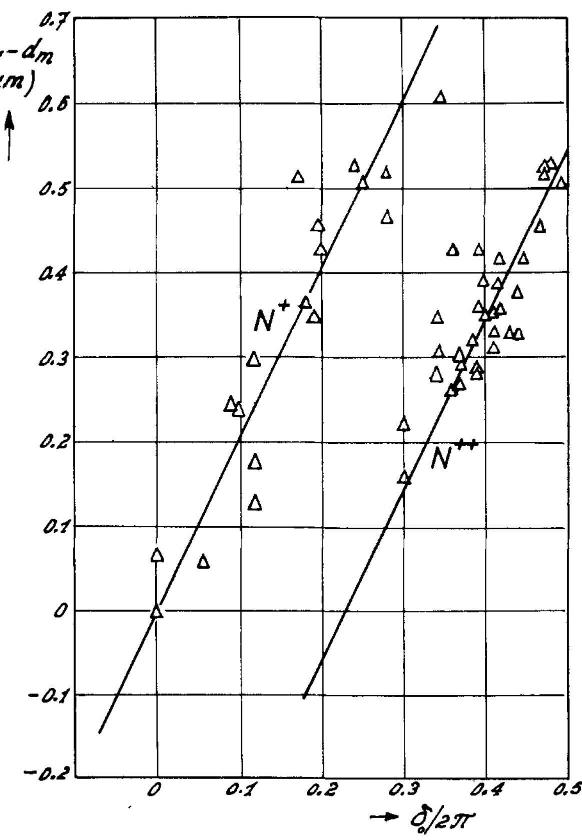

Fig. 1. The difference $d_s - d_m$ depends on the measured constant phase shift $\delta_o/2\pi$. The N^+ and N^{++} data are well separated and the lines are drawn according to Eq. [5a] and [5b].

Interpretation

A classical derivation of the dependence of the phase shift δ on the wavenumber k and the substrate resistivity ρ has been given by Schumann *et al.* (5, 6). It was based on a model with an abrupt junction for dopant atoms and charge carriers with bulk material properties on both sides of the interface. The values of Δd and $\delta_o/2\pi$ have been cursorily calculated from linear approximations to these curves, $\delta(k, \rho)$, over a limited wavenumber range (400-1200 cm^{-1}) and expediently plotted in Fig. 2. This is clearly different from Fig. 1.

For N^+ substrates, the range covered in $d_s - d_m$ and in $\delta_o/2\pi$ is larger than allowed by Fig. 2, where the classical substrate electron dispersion acts as the only cause of $\delta(k, \rho)$. Although it is difficult to speculate about this departure, it may be surmised that the particular state of this interface causes an additional and partly nonreproducible δ-dependence on k, for instance because the interface is not as strain-free as assumed.

The N^{++} substrate data are more concentrated around the values expected from Fig. 2

$$\delta_o/2\pi = 0.45 \text{ and } d_s - d_m = 0.35\ \mu m$$

[1] Spectrophotometer, Model Epi-G3, Hitachi Ltd., Tokyo, Japan.

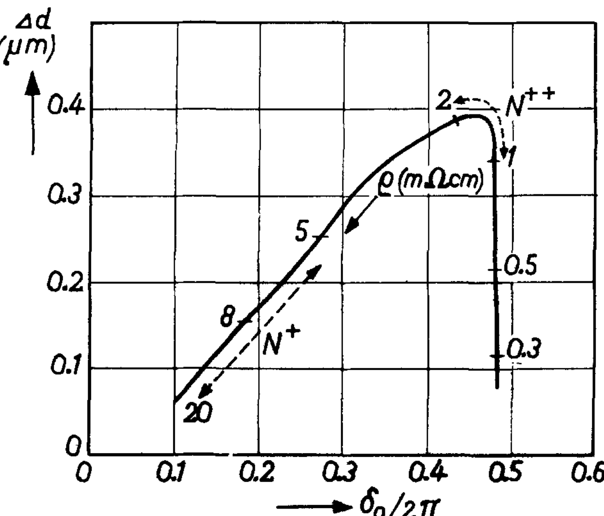

Fig. 2. The correction Δd and the constant phase shift $\delta_0/2\pi$ with the substrate resistivity ρ as a parameter, derived from Schumann's curve. The sections labeled N^+ and N^{++} cover the ranges studied.

Apparently here the phase shift is determined by the substrate resistivity more than by anything else.

It is worth stressing that there is no underlying theory to Eq. [5a] and [5b], but it is the authors' feeling that the nature of the interface conditioned by the growth parameters plays a vital role. This implies that for a range of growth conditions and substrate dopant levels relations similar to Eq. [5a] and [5b] have to be measured. Then the accuracy of the infrared multiple interference method can be established. It is important to note that, from the absence of any correlation between $\delta_0/2\pi$ and d_s or d_m, it follows that out-diffusion of substrate dopant atoms can be ruled out as a determining factor.

Summary and Conclusion

The procedure recommended (7) by the ASTM for determining the thickness of an epitaxial layer is based on the model of an abrupt interface. This definition of the thickness is used in the expression which describes the extreme values of k and in the correction formula used for $\delta(k, \rho)$. In fact, the result is defined by the procedure and cannot be verified otherwise. The precision is determined by the error with which the extreme values of k are reproduced by the instrument and can be read from the spectrum. Accuracy is not claimed.

The procedure described in this paper envisages the production of precise and accurate numerical values of the thickness of the deposited layer by properly interpreting the infrared multiple interference spectrum. In the first place, the experimental observation (1, 2) has been used that, within the attainable precision, a plot of k vs. l yields a straight line characterized by the slope d_s and the intercept $\delta_0/2\pi$. Because it is physically clear that the phase shift at the interface must show dispersion and decrease with increasing k, this can only be combined by employing a linear approximation to $\delta(k)$ over a small range of k. In the second place, the experimentally verified procedure has been used, outlined by Eversteyn and van den Heuvel (3), by which the thickness d_m of the deposited layer is measured. It has been shown above that d_m can be found from d_s by subtracting an amount Δd linearly related to $\delta_0/2\pi$. The parameters of this linear relation probably depend on the growth conditions of the epitaxial layer. There is no dependence on the thickness.

It has been found experimentally that the correction Δd to be applied to the measured thickness d_s is different for N^+ and N^{++} substrates, but does not show any dependence on substrate resistivity beyond that. Therefore, any correction procedure based on the substrate resistivity as a criterion for $\delta(k)$ is unsound.

Penetration of Gold and Platinum Through Phosphorus-Doped N^+ Layers in Silicon

W. Mielke

AEG-Telefunken Forschungsinstitut, Frankfurt am Main, Germany

ABSTRACT

The penetration of gold and platinum through phosphorus-doped n^+ layers in silicon was studied by diode recovery measurements and by four-point measurements together with neutron activation analysis. A sudden breakthrough of gold in a small temperature range for a given n^+ layer and diffusion time is quantitatively observed for gold, while no important inhibition for platinum could be detected. Therefore platinum is proposed as an advantageous substitute for gold in silicon semiconductor device technology. The penetration of gold may be explained by compound formation of Au_2P_3 being in chemical equilibrium with gold and phosphorus in silicon.

Gold and platinum are widely used as contact materials and recombination centers in silicon semiconductor device technology. While gold is well known to control minority carrier lifetime it was only recently realized by Bailey and Mills (1, 2) that platinum possesses similar properties. In 1962, Cicconella, Forster, and Rulison (3) took into consideration a replacement of gold by platinum for providing a controlled reduction of minority carrier lifetime. Further properties of platinum in silicon were published by Carchano and Jund (4), Conti and Panchieri (5), and Charlot and Vapaille (6), while the properties of gold in silicon were reviewed by Bullis (7) in 1966. A general review about properties of deep impurities in silicon was presented by Schibli and Milnes (8, 9).

An intricate problem with gold in silicon is its affinity to phosphorus-doped n^+ layers. This property is positively used in gettering processes (10), while its negative aspects are manifested in its uncontrolled influence on the fabrication of fast switching devices (11). Indiffused gold profiles in phosphorus-doped n^+ layers in silicon were studied by Wilcox, La Chapelle, and Forbes (12) with radiotracer experiments. They stated that these layers greatly slow down gold diffusion and as a possible explanation offered a compound formation (Au_2P_3) between gold and phosphorus. Quantitative results for an enhanced solubility of gold in uniformly heavily doped silicon were presented by Cagnina (13) who emphasized that a solubility enhancement according to the Shockley-Moll model is much too small to explain his data and therefore again cited a possible compound formation.

To give a further insight into this technologically important problem the penetration of gold through phosphorus-doped n^+ layers has been studied and compared with the behavior of platinum.

Experimental Procedure

Silicon float-zone prepared, <111>-oriented single crystals were used as a starting material. Their further data were: 20 mm diameter, 10^{15} cm^{-3} boron doping, 10^4 cm^{-2} Sirtl etch pit density, and 230 μsec photoconductive decay minority carrier lifetime. Neutron activation analysis showed a gold concentration of 0.5-$3.0 \cdot 10^{10}$ cm^{-3} measured with a specimen of 250 mg Si. Platinum concentration was below the detection limit of $5 \cdot 10^{13}$ cm^{-3}.

A phosphorus indiffusion was then performed using an open tube configuration with a P_2O_5 source at 250°C and clean dry nitrogen as a carrier gas. Mirror etched slices of 500 μm thickness were treated for 2 hr at 1180°C with a subsequent cooling rate of 70°C/hr to 700°C. This diffusion step produced n^+ layers with a phosphorus glass layer thickness of 0.5 μm (2.4 g/cm^3), a sheet resistance of 1 ohm/square, and a junction depth of 10 μm. The phosphorus glass layer was removed. Net donor surface concentration was checked by successive four-point measurements to be $5 \cdot 10^{20}$ cm^{-3}. No significant change in resistivity and etch pit density of the base material was observed. Gold concentration in the base material was measured to be 0.8-$9.0 \cdot 10^{10}$ cm^{-3} using 80 mg Si. Again no platinum was detectable. For a further evaluation of the phosphorus diffusion step, n^+p junctions 1.0 mm in diameter were produced by spraying 13 piceine varnish dots through a metal mask onto the n^+p slice, drying and melting the dots, and subsequently etching n^+p junctions to a depth of 20 μm and cleaning off the piceine dots. The thickness of the n^+p configuration was then 465 μm, because one n^+p side of the original 500 μm n^+pn^+ slice has been lapped away. Simple, adequate recombination contacts were applied by rubbing a gallium-wetted aluminum rod onto the silicon. Reverse currents were taken at 23°C and 1.0V and found to be from 1 to $8 \cdot 10^{-9}$A. Minority carrier lifetime was evaluated by diode recovery measurements. In this method a diode is switched from constant forward to constant reverse current and the delay time of the forward voltage to reach zero, the storage time, is measured and converted to minority carrier lifetime according to graphs for p^+n diodes with an arbitrary base width given by Grove and Sah (14). It is assumed that the p^+n graphs are aproximately the same for n^+p diodes. Diode recovery measurements were performed at low injection levels by using forward currents from 1.0 to 20 mA (reverse currents from 0.1 to 2.0 mA), paying attention to junction capacitance and neglecting surface recombination velocity. Minority carrier lifetimes ranged from 6 to 15 μsec. The diodes showed sharp reverse characteristics and breakdown voltages about 200V were observed.

On manufactured n^+pn^+ and pn^+ structures gold was evaporated or platinum sputtered to a thickness of 0.1 μm, checked by weight. This resulted in Au n^+pn^+, Au pn^+, Pt n^+pn^+, and Pt pn^+ structures. During this step the slice temperature remained below 300°C. Subsequently a number of heat-treatments, gold diffusions, and platinum diffusions were performed varying the parameter time from 10 sec to 6 hr, temperature from 800° to 1100°C, and junction depth from 4 to 10 μm. It should be noted that heat-treatments, gold diffusions, and platinum diffusions each had their own quartz tube and were all performed with an open tube configuration using dry clean nitrogen as a flow gas and a one tube diffusion furnace without ceramic protection tube. The slices were quickly put into or pulled from the constant temperature zone of the furnace, n^+pn^+ and pn^+ specimens were treated to-

Key words: diode recovery measurements, four-point measurements, neutron activation analysis.

gether. The treated slices were subjected to the same electrical measurements as before the heat-treatments, gold or platinum diffusions.

For neutron activation analysis a disk of 400 μm thickness and 10 mm diameter was symmetrically prepared out of the p zone by lapping, etching, and ultrasonically drilling. It should be emphasized that the same slice was evaluated by neutron activation analysis which has undergone the given electrical examinations.

Neutron activation analysis was performed by exposing the specimens to a thermal neutron flux of 10^{13} cm^{-2}-sec^{-1} for 10 days. The specimens were then shortly etched with the following mixture: 25% fuming nitric acid, 10% hydrofluoric acid of 40%, 45% acetic acid, 20% nitric acid of 60%. The mixture was doped with inactive gold and platinum and the specimens were then checked in a multichannel counter to examine their cleanliness. After weighing they were dissolved in inactively doped etch, the solution cooked to dryness. The remaining gold and platinum were taken up with aqua regia and measured against a standard in a multichannel counter. Gold revealed by the 411 keV γ-radiation of Au 198 with a half-life of 65 hr while platinum gave a 158 and 208 keV γ-radiation of Au 199 with a half-life of 76 hr. It should be noted that platinum was roughly a factor 1000 less detectable than gold. The reached sensitivities were: $5 \cdot 10^{10}$ cm^{-3} gold concentration and $5 \cdot 10^{13}$ cm^{-3} platinum concentration with 50 mg of silicon and a measuring time of 10 min.

Experimental Results and Discussion

Results are given by drawing minority carrier lifetime τ, specific resistivity ρ, gold concentration C_{Au}, and platinum concentration C_{Pt} of the p region from n^+pn^+ (○, ●, ⊖) or pn^+ structured specimen (□, ■, ⊟) *vs.* heat-treatment or diffusion time t, four-point conductance $1/R$ of the n^+ layer or temperature T of the heat-treatment diffusions.

For each chosen set of parameters in a diffusion experiment a heat-treatment as a control experiment was performed to check whether the observed changes in experimental data were mainly due to the intentioned gold or platinum doping. In heat-treated slices no platinum could be detected. It should be noted that the presented results are not corrected for their control values. Slices supplied with gold or platinum were weighed before and after diffusion to check constancy of these metals. A qualitative difference was observed with the "gold slices," *e.g.*, at 1000°C, 1 hr, the alloy at the p side of an Au pn^+ slice showed a "gold-like glimmering" while this could not be observed with Au n^+pn^+ slices, the gold has "disappeared" into the n^+ layer. Through phosphorus glass layers no penetration of gold during diffusion runs of 1 hr from 800° to 1000°C was observed. After diffusion the gold could be wiped off simply. No such experiments were performed with platinum.

According to Fig. 1 heat-treated n^+pn^+ structures exhibited lower gold concentrations than pn^+ structures, in accordance minority carrier lifetime was higher in n^+pn^+ structures. For gold diffusion a breakthrough of gold was observed, except for the 10 sec point for which the n^+pn^+ structure showed roughly a gold concentration three orders of magnitude lower than for the pn^+ structure. The increase of gold concentration with time is well known to be due to a "vacancy controlled" diffusion mechanism of gold in silicon (7, 15, 16). Furthermore it is well known that there is a steep increase of resistivity when the gold concentration reaches the boron concentration (10^{15} cm^{-3}) (7).

It should be noted that, because of the influence of junction capacitance of the diodes 1 mm in diameter, minority carrier lifetime could only be measured down to 0.1 μsec.

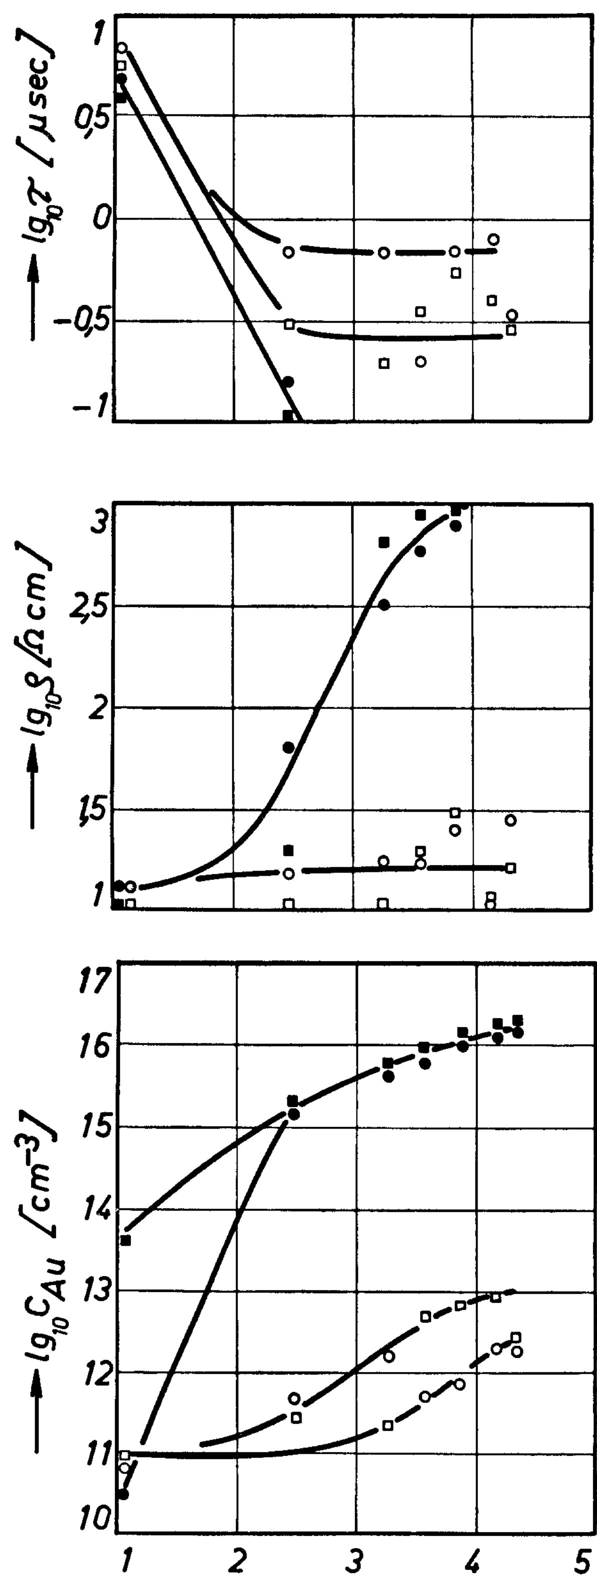

Fig. 1. Heat-treatments (○, □) and gold diffusions (●, ■) at 1100°C; junction depth, 10 μm. Circles and squares represent n^+pn^+ and pn^+ samples, respectively.

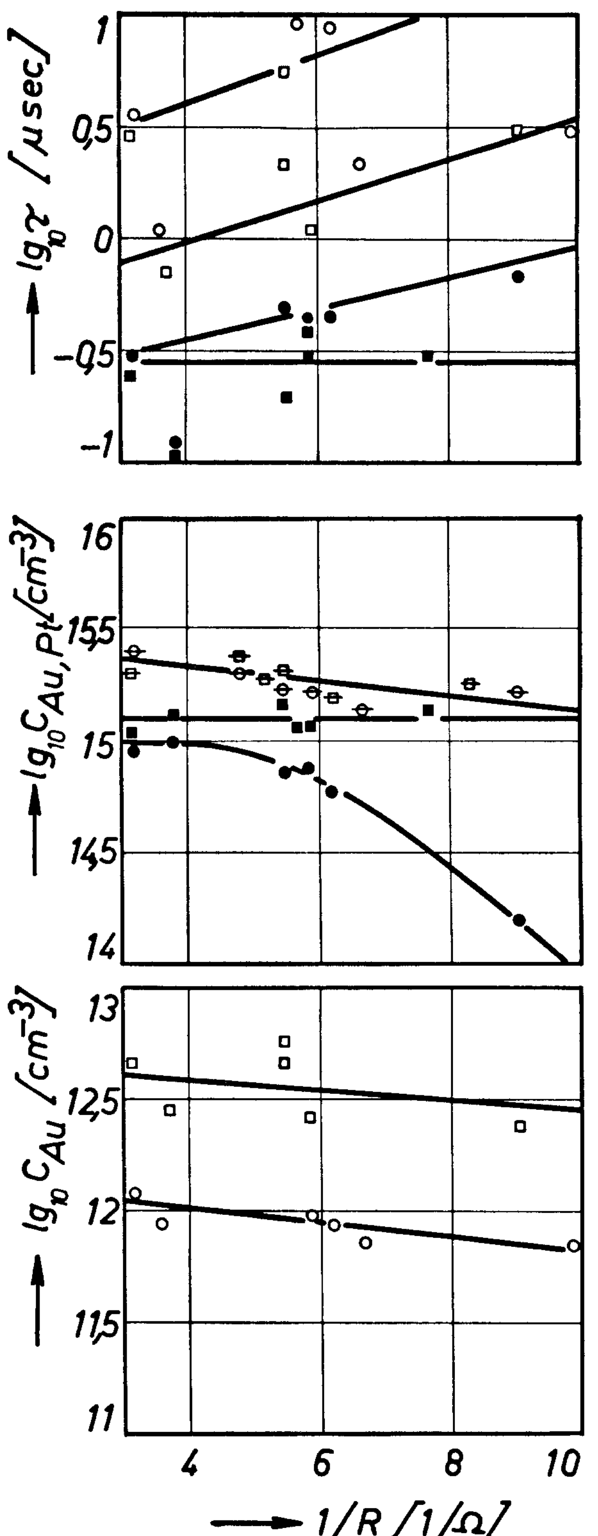
In order to check the validity of the given gold concentration values, profiles of the central disks were taken with the 30 min and 6 hr gold-diffused slices by one side etching thereby dividing the disk 400 μm thick into 7 portions: 3 × 30 + 220 + 3 × 30 μm. For the 30 min pn^+ slice an increase from 3 over a central value 5-7 × 10^{15} cm^{-3} gold concentration was measured with the high value at the p side where gold



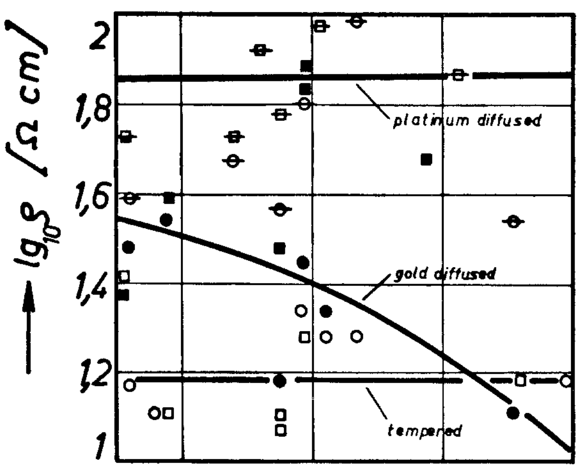


Fig. 2. Heat-treatment (○, □), gold diffusions (●, ■), and platinum diffusions (⊖, ⊟) at 1000°C for 1 hr.

had been evaporated while, for the 6 hr n^+pn^+ and pn^+ slices, concave profiles were measured with a 30% rise at the edges (17). Therefore the given gold concentration values which were averaged for the whole central disk seem to be reasonable.

According to Fig. 2 various n^+ layer thicknesses which were obtained by modifying phosphorus diffusion times are given by their four-point conductance $1/R$ because these values are roughly proportional to the number of electrically active phosphorus atoms per cm^2. A rough proportionality was checked for the $1/R$ values against the square root of phosphorus diffusion times. Lifetimes τ for platinum-diffused specimens were too low to be measured. It is interesting to note the decreasing gold content of gold-diffused n^+pn^+ slices with increasing $1/R$ (18). The scattering in specific resistivity ρ may be due to variations in the resistivity of the starting material. Profile checks were taken for two n^+pn^+ and one pn^+ platinum-diffused slices leading to a decrease of roughly a factor 2 from the "platinum sputtered side" to the other side of the central disk.

According to Fig. 3 the gold concentration of n^+pn^+ slices steeply increased around 965°C; this temperature being the breakthrough temperature for gold through this n^+pn^+ specimen for a 1 hr diffusion.

According to Fig. 4 no differences between n^+pn^+ and pn^+ structures diffused with platinum could be observed.

As mentioned earlier in this paper, Wilcox, La Chapelle, and Forbes (12) and Cagnina (13) in order to explain their results with the behavior of gold in

Fig. 3. Gold diffusions (●, ■) for 1 hr; junction depth, 10 μm

highly phosphorus-doped silicon assumed a compound formation of Au_2P_3, which of course is the most stable compound in the gold-phosphorus system (19), while in the gold-silicon system there is no compound formation (19). For platinum there is a stable compound PtP_2 in the platinum-phosphorus system (20), but the same is true for the platinum-silicon system with Pt_2Si and PtSi (20). Using compound formation as a hypothetical assumption the given experimental arrangement would be describable as a reactive diffusion through thin layers as treated by Sah, Sello, and Tremere (21) for explaining masking properties of silicon dioxide films against phosphorus diffusion.

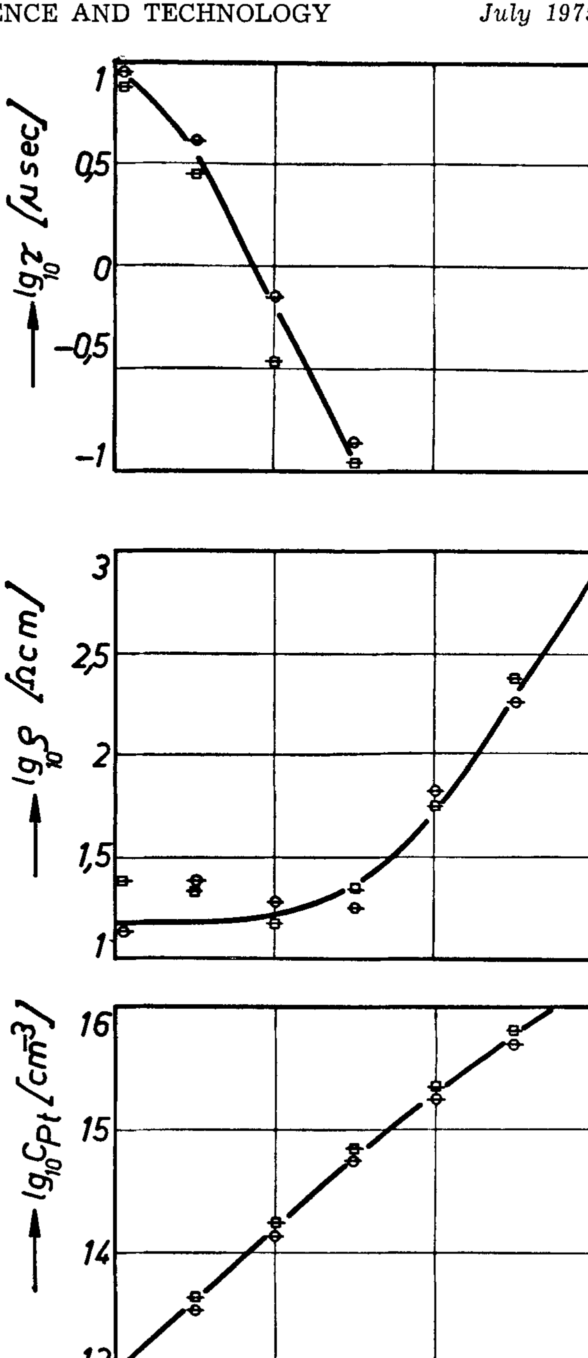

Fig. 4. Platinum diffusions (-⊖-, -⊟-) for 1 hr; junction depth, 10 μm.

However while Au_2P_3 precipitates could be observed in gold-diffused silicon wafers (22), a similar observation of PtP_2 is not known. Together with the results of the given experiments which show no occurrence of masking or gettering of platinum by phosphorus-doped n^+ layers in silicon (Fig. 4) one may suggest that, in spite of the existence of a stable platinum-phosphorus compound PtP_2, such a compound formation does not occur in phosphorus-doped silicon.

The breakthrough according to Fig. 3 may well occur, if the amount of gold in the n^+ layer reaches the amount of phosphorus, so that no further compound formation is possible.

Considering the actual experimental procedure a 0.1 μm thick gold layer was evaporated onto the specimen which corresponds to approximately 6×10^{17} gold atoms per cm^2. Treated with temperature a gold-silicon alloy, 0.1-0.2 μm thick according to temperature, was formed. The junction depth was 10 μm with a surface concentration of 4×10^{20} cm^{-3} which roughly yields 10^{17} phosphorus atoms per cm^2, indicating that a saturation of all phosphorus atoms is indeed possible.

Conclusion

In order to avoid the affinity of gold to phosphorus n^+ layers in silicon, platinum can be used as an advantageous substitute (23).

The measured penetration of gold through these layers may be explained by assuming a compound formation of Au_2P_3, so that gold only can penetrate if all phosphorus has been saturated.

Acknowledgments

The author wishes to thank Dr. M. Reese, H. Pilz, and B. Struck, for devising and performing neutron activation analysis. Misses D. Löchel and G. Kehm prepared the samples while U. Gözinger from AEG-Telefunken, Heilbronn, provided the platinum sputtering. Drs. G. Köhl (†), H. Schlangenotto, K. Roy, and J. Hesse gave valuable comments.

Developer Characteristics of Poly-(Methyl Methacrylate) Electron Resist

James S. Greeneich*

Electronics Department, General Motors Research Laboratories, Warren, Michigan 48090

ABSTRACT

We report on the solubility characteristics of poly-(methyl methacrylate) electron-resist for developer combinations of methyl isobutyl ketone (MIBK) and isopropyl alcohol (IPA). The solubility rate is determined in terms of the fragmented molecular weight which is a function of original molecular weight and the energy absorbed by the polymer in degrading to a lower molecular weight. An empirical formula for the solubility rate is $R = [R_o + \beta/M_f^{\alpha}]e^{-E_a/kT}$, where M_f is the fragmented molecular weight, R_o, β, and α are constants characteristic of a given developer. The temperature dependence is characterized by an activation energy, E_a, for a given developer. The solubility kinetics are discussed showing a rate limited process for most developer conditions. From the solubility rate and the characteristic energy absorption in the resist, the development time and contrast are defined and calculated for a variety of exposure parameters including beam energy, resist thickness, developer, developer temperature, and original molecular weight. Compared to the standard developer, 1:3 MIBK:IPA, an improved sensitivity of 10-50 times is obtained using MIBK at the expense of increased development time. For a given contrast level the development time is greatly reduced by increasing the developer temperature. A lower original molecular weight also reduces the required development time.

Electron-beam and x-ray lithography are important new technologies for fabricating semiconductor devices and circuits with submicron dimensions. The most widely used resist medium is the positive acting poly-(methyl methacrylate), PMMA (1). In addition to a resolution requirement, the performance of the resist is measured in terms of its sensitivity to the incident radiation. Typically the sensitivity is expressed in terms of the required incident charge per unit area to produce the desired resist pattern of the desired thickness. The final resist thickness is important in terms of the suitability of the resist as an etching mask and for the metal lift-off technique (1) for positive resists.

Using the standard developer, 1:3 methyl isobutyl ketone (MIBK):isopropyl alcohol (IPA), the reported sensitivity of PMMA is in the range 5×10^{-5} to 5×10^{-4} C/cm^2. The range in reported sensitivities is primarily due to varying exposure conditions such as beam energy, resist thickness, type of substrate, and geometry of the irradiated pattern (2, 3). For this solvent the development is nearly time independent. Consequently, the sensitivity has been expressed in terms of a critical absorbed energy density (3) which is independent of the exposure parameters. This model is not adequate for time-dependent developer systems described in this paper.

What is the influence of the developer solvent and temperature on the sensitivity and development time for positive electron-beam resists? In the case of PMMA this is an important question since its sensitivity is considered low and improving its sensitivity through the development process is important. Ethyl and methyl alcohol are also used as developers for PMMA with approximately the same sensitivity as the standard developer (4). Hatzakis and Broers (5) report the use of MIBK as a time-dependent developer with increased sensitivity, but the original resist thickness was rapidly reduced. Ting (6) reported on the MIBK developer in terms of a solubility rate as a function of an "effective" charge and Greeneich (7) has shown that high contrast exposures can be made using MIBK if a very high molecular weight polymer is used.

We report a method for evaluating the sensitivity of positive electron resists in which the solubility rate is expressed in terms of the basic quantity which changes during electron radiation, namely the fragmented molecular weight. From the solubility rate the required development time and resulting contrast are defined and evaluated for many of the parameters affecting resist sensitivity.

We report on the solubility of PMMA in several developer combinations of MIBK and IPA at several temperatures. We report an empirical relationship between developer solubility rate and the fragmented molecular weight of the form $R = (R_o + \beta/M_f^{\alpha})e^{-E_o/kT}$, where R_o, β, and α are constants and E_a is an activation energy. An improved sensitivity compared to the standard developer of from 10 to 50 times is obtained by using different developers.

The kinetics of the solubility process is found to be adequately described by a rate-limited process for most developer conditions. At high temperatures it is found that the standard developer has nonlinear solubility properties.

Relationship Between Fragmented Molecular Weight and Exposure Parameters

A positive electron resist is characterized by a reduction of molecular weight owing to chain scission of the original molecules. Since polymers with different molecular weights have different solubility characteristics in a given solvent, the resist developer is required to distinguish between the fragmented molecular weight, M_f, and the original molecular weight, M_n.

The relationship between M_f and M_n and the exposure parameters is expressed in terms of the absorbed energy density, ϵ, as (7, 8)

$$M_f = \frac{M_n}{1 + \dfrac{g\epsilon M_n}{\rho A_o}} \quad [1]$$

where ρ is the resist density, A_o is Avogadro's number, and g is an efficiency factor proportional to the radiation chemical yield. For PMMA we take g to be 1.9×10^{-2} events/eV (9). It should be noted that [1] only applies as long as the resist degrades during electron bombardment. In the case of PMMA cross-linking events dominate at high doses of electron-beam radiation (1, 2).

Key words: electron-beam lithography, electron-resist developers, contrast function, energy dissipation in resists.

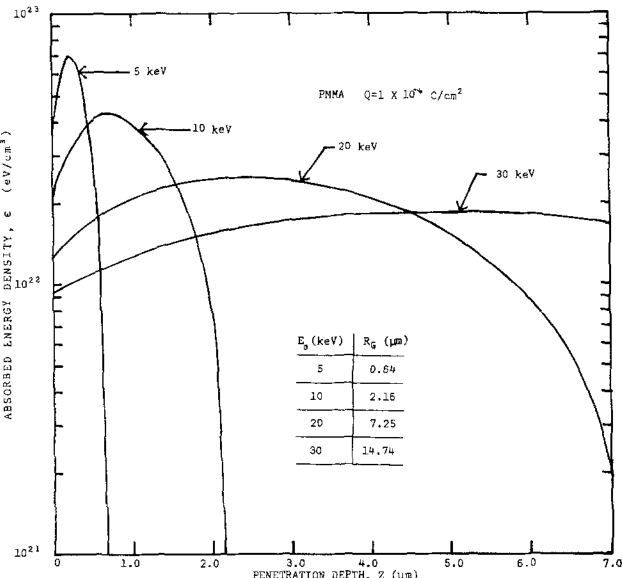

Fig. 1. Energy dissipation per unit volume for area exposures as a function of penetration depth for various incident energies. The table gives the Grun range (Eq. [4]).

The absorbed energy density is in general a complicated function of position within the resist film; the exact dependence being a function of the exposure parameters such as beam energy, resist thickness, type of substrate, and geometry of the irradiated pattern (2, 3). In the case of an area exposure on a low atomic number substrate such as silicon, ϵ is given by the depth-dose function (10) in terms of the depth, z, in the resist and the incident energy, E_o. Specifically

$$\epsilon = \frac{Q}{q}\frac{E_o}{R_G}\lambda(f) \quad [2]$$

where

$$\lambda(f) = 0.74 + 4.7f - 8.9f^2 + 3.5f^3 \quad [3]$$

In [2], Q is the incident charge per unit area, q is the electronic charge, $f = z/R_G$, where R_G is the Grun range given by

$$R_G = \frac{4.6 \times 10^{-6}}{\rho} E_o^{1.75} \quad [4]$$

when E_o is in units of keV. The absorbed energy density in PMMA for an incident dose of 10^{-4} C/cm^2 is shown in Fig. 1 for several beam energies. Two important points are illustrated in Fig. 1. There is a range, R_G, (tabulated in Fig. 1) beyond which ϵ is small; consequently the resist thickness must be equal to or less than R_G. For the higher beam energies and thin resist films (<3000Å), ϵ is approximately uniform and consequently, from Eq. [1], M_f is nearly independent of depth.

Experimental Results

Various molecular weight samples of PMMA were dissolved in trichlorethylene and spin coated onto silicon wafers, resulting in a typical resist thickness of ~3000Å. The nature of the carrier solvent used in coating the resist and the pre-exposure baking play a role in the solubility characteristics of the resist. For example, Fig. 2 shows the resist thickness *vs.* time in the solvent MIBK for various prebaking conditions where MIBK and trichloroethylene were used as carrier solvents. After ~4 min in MIBK the trichlorethylene sample dissolves at about the same rate as the well-baked MIBK sample.

Similarly the solubility rate of degraded PMMA is influenced by remaining carrier solvent; we have observed ~2 times less Q is required for samples developed in the standard developer when MIBK remains. All samples used in this study were coated with trichlorethylene as the carrier solvent and baked for ≳90 min at 160°C.

Typical areas of 10^{-3} cm^2 were irradiated with 20 keV electrons using a Cambridge S4-10 scanning electron microscope (SEM) equipped with a beam blanking unit. The incident dose was varied by changing the frame scan time. Some variation in exposure was observed depending on whether or not the beam is

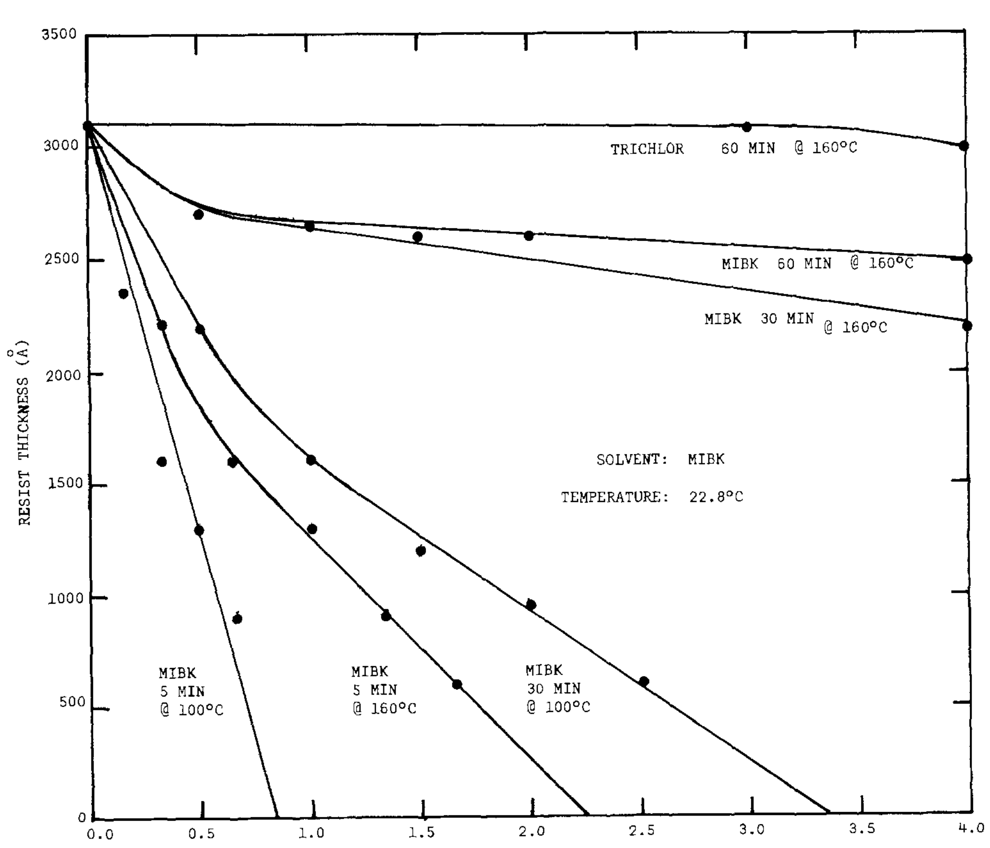

Fig. 2. The influence of the resist carrier solvent on solubility in MIBK for the indicated prebake conditions.

blanked during flyback; all results reported here are for the condition with beam blanking on.

After irradiation the samples were immersed in the developer solvent, which was not agitated. Periodically the samples were removed and the resist thickness determined by the interference color of the irradiated area. Ellipsometer measurements on nonirradiated samples established the refractive index to be 1.48 ± 0.02 and the accuracy of the interference method to be ±150Å. Only a slight increase in refractive index (≤0.04) was observed as a result of solvent migration into the film during prolonged soaking (30 min) in the developer solvents; this did not affect the measured solubility rates.

Several solvents were tested as developers; these consisted of MIBK, 1:1 MIBK:IPA and 1:3 MIBK:IPA. The temperature dependence of MIBK and 1:3 MIBK:IPA was also investigated.

Two different types of behavior were observed. Figures 3 and 4 show the results for 1:1 MIBK:IPA at

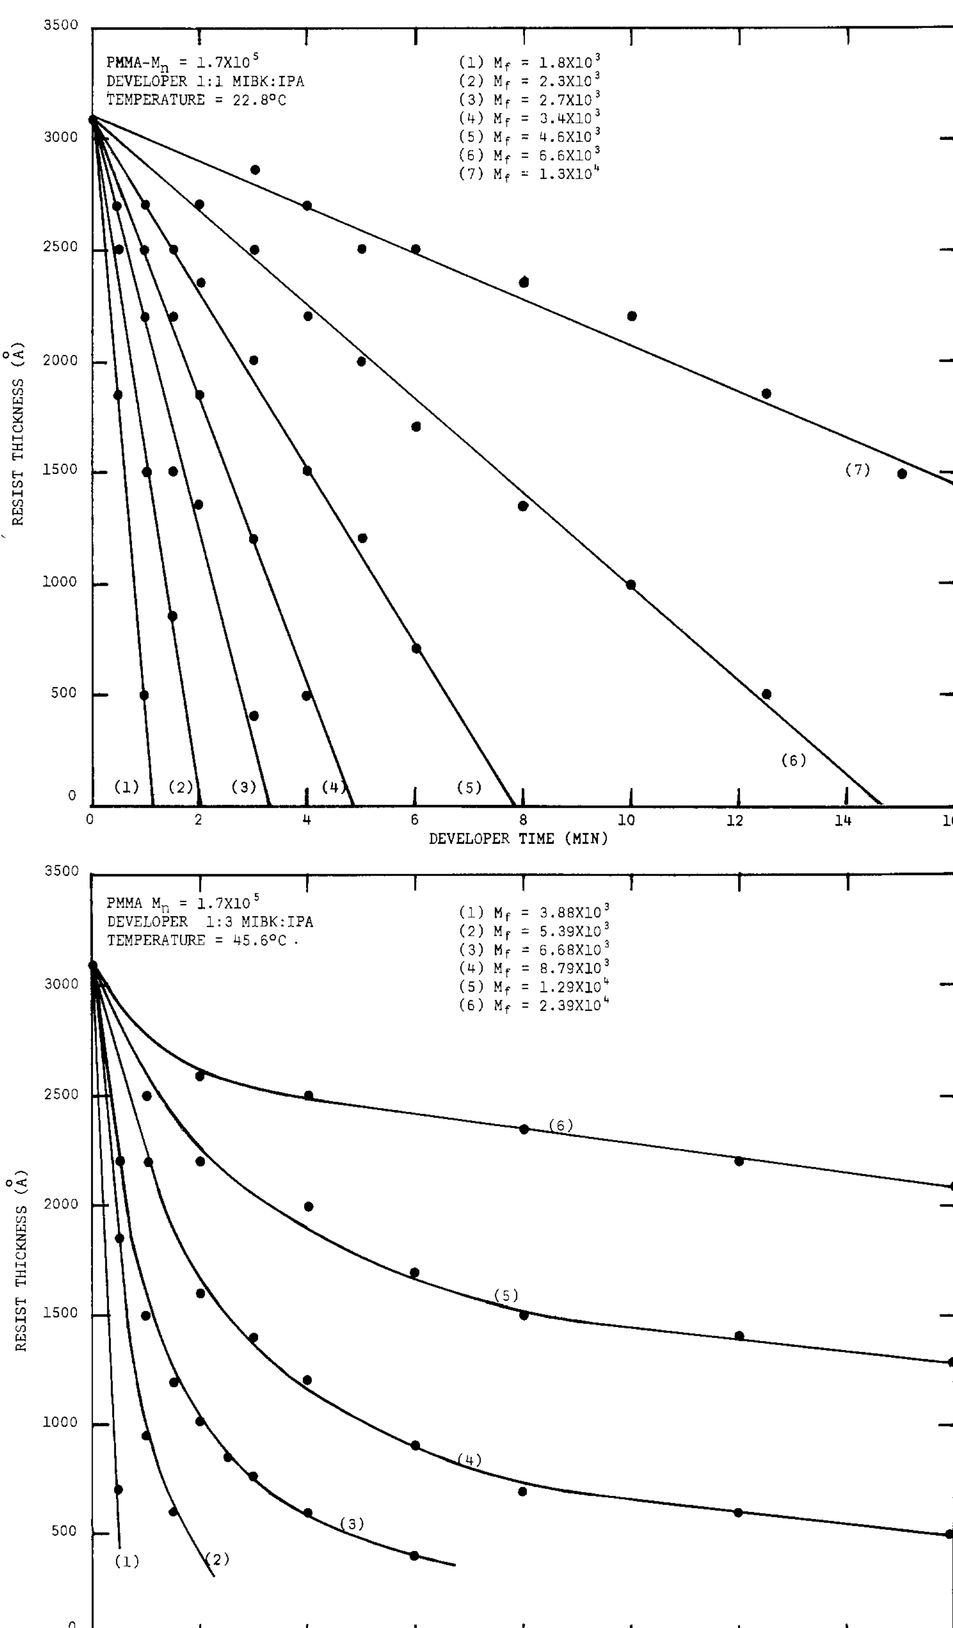

Fig. 3. A typical experimental result characteristic of a rate-limited process relating resist thickness as a function of developer time for various fragmented molecular weights.

Fig. 4. Experimental results for 1:3 MIBK:IPA at 45.6°C showing the nonlinearity in the solubility rate.

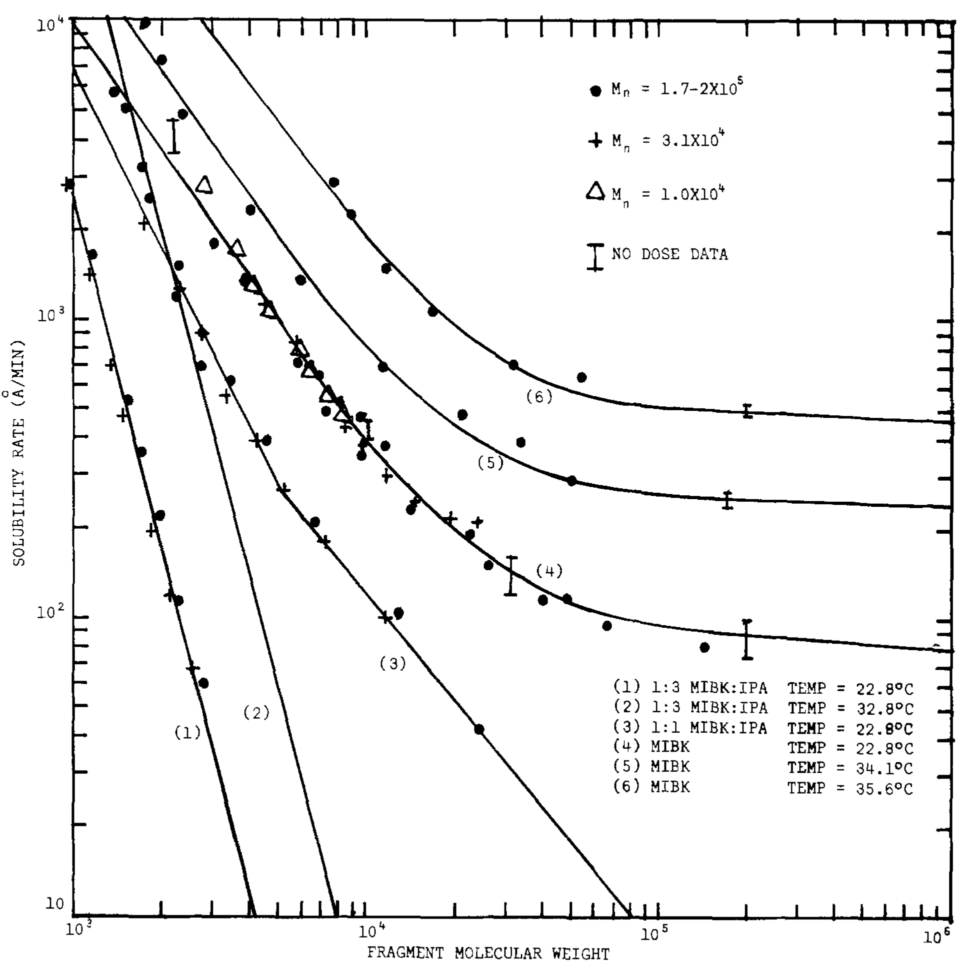

Fig. 5. The solubility rate vs. fragmented molecular weight for three different developers and for various temperatures. Data is for original molecular weights between 10^4 and 2×10^5.

22.8°C and 1:3 MIBK:IPA at 45.6°C, respectively. Figure 3 is typical of most of the developer conditions studied and is indicative of a reaction rate process while the result shown in Fig. 4 is representative of a more complicated kinetics problem. The kinetics of the solubility process is discussed in more detail in a later section.

Solubility Rate

According to [1] the results of electron radiation on positive electron resists is expressed in terms of the fragmented molecular weight. Previously (7) we showed that the solubility rate for MIBK, defined as the slope of the thickness-developer time curve, is a function of fragment molecular weight as given by [1]. This result also applies to the other developer solvents reported here. In Fig. 5 we show the solubility rate *vs.* M_f for original molecular weights between 10^4 and 2×10^5 for the indicated developer conditions. In each case the solubility characteristics are of the rate limited type.

An empirical formula of the form

$$R = R_o + \frac{\beta}{M_f^{\alpha}} \qquad [5]$$

was fitted to the experimental data and is shown by the solid lines in Fig. 5. In Table I the values of R_o, β, and α are given for R in angstroms per minute.

Kinetics of the Solubility Process

In this section we consider the two types of solubility characteristics illustrated in Fig. 3 and 4. We do not consider any solvent to remain in the polymer film although the increased solubility rate when solvent remains is expected on the basis of increased availability of the solvent at the plane of polymer-solvent interaction.

Ueberreiter has reviewed the solution process for polymers (11). According to the model a gel-like skin is formed between the pure solvent and the pure polymer after a short induction period.[1] For this model the solubility rate is given by

$$R = \frac{dz}{dt} = \frac{\overline{D}}{d} \qquad [6]$$

where $\overline{D}$ is a mutual diffusion coefficient of the polymer-solvent system and d is the skin thickness. Consequently, this model describes the linear decrease in resist thickness typical of most of the developer conditions reported.

According to the rate limited process the temperature dependent rate, R_T, is given in terms of an activation energy, E_a, as

[1] We have observed such an induction period for MIBK for very high molecular weight materials.

Table I. Parameters are tabulated for the solubility rate for various combinations of MIBK and IPA at several temperatures

Solvent	Temperature	R_o	β	α	Mol wt range
1:3 MIBK:IPA	22.8°C	0.0	9.332×10^{14}	3.86	—
1:3 MIBK:IPA	32.8°C	0.0	1.046×10^{16}	3.86	—
1:1 MIBK:IPA	22.8°C	0.0	6.700×10^{9}	2.00	$\leq 5 \times 10^3$
1:1 MIBK:IPA	22.8°C	0.0	6.645×10^{6}	1.188	$> 5 \times 10^3$
MIBK	22.8°C	84.0	3.140×10^{8}	1.50	—
MIBK	34.1°C	241.9	5.669×10^{8}	1.50	—
MIBK	35.6°C	464.0	1.435×10^{9}	1.50	—

$$R_T = Re^{-E_a/kT} \qquad [7]$$

where the functional dependence of R on M_f is given by [5]. Figure 6 shows a plot of ln R vs. $1/kT$ for MIBK for the indicated molecular weights. For the highest molecular weights, 2×10^5, the straight line fit is excellent with an activation energy of 1.04 eV. For lower molecular weights the fit is somewhat worse.

The solubility rate of a polymer is determined by two factors: (i) the kinetic suitability of the solvent which determines $\overline{D}$, and (ii) the thermodynamic suitability of the polymer-solvent system is found in d which acts as a resistance to the penetrating solvent (11). In choosing a developer for positive electron resists, thermodynamic arguments are often used as commonly expressed in terms of a solubility parameter and an associated hydrogen bonding index (4, 12). For PMMA the result is a combination of a poor solvent (IPA) and a borderline solvent (MIBK). Many other solvent combinations with desirable thermodynamic properties are possible; a developer with a higher solubility rate results for solvents with high values of $\overline{D}$, and among molecules of similar chemical composition the rate depends mainly on the size of the molecule (11). This is an area for continued investigation.

As we show later it is desirable for the parameter α in [5] to be as large as possible for high contrast exposures. The temperature dependence of the developer 1:3 MIBK:IPA was investigated in hopes of increasing its solubility rate while maintaining its large value of α. Unfortunately, the solubility rate is nonlinear for temperatures $\gtrsim$32.8°C; a typical result is shown in Fig. 4. This nonlinear time dependence is not well understood. Initially the solubility rate behaves in a manner consistent with lower temperature data. This is evidenced by an activation energy of 2.43 eV as shown in Fig. 7 where ln R vs. $1/kT$ is plotted. In Fig. 7 the initial solubility rate

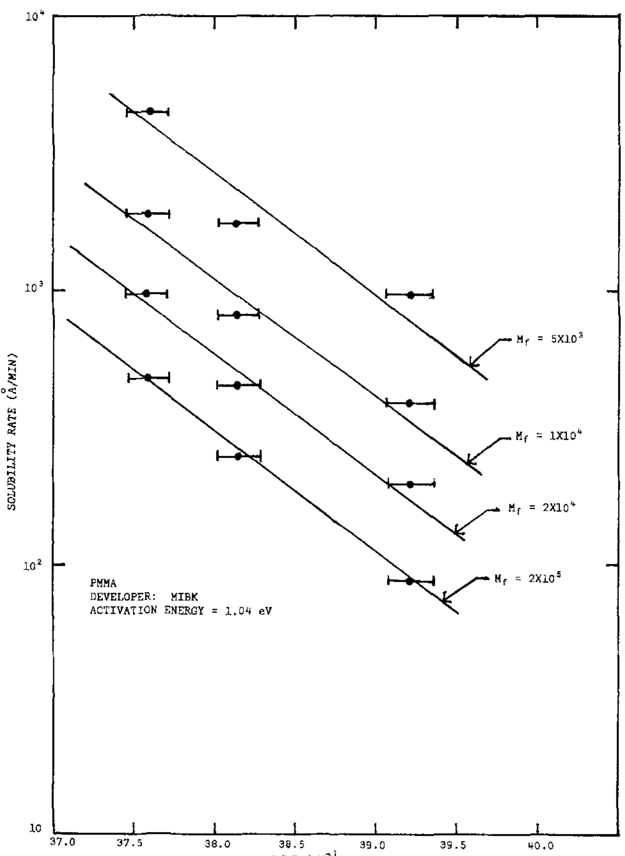

Fig. 6. Developer activation energy for MIBK

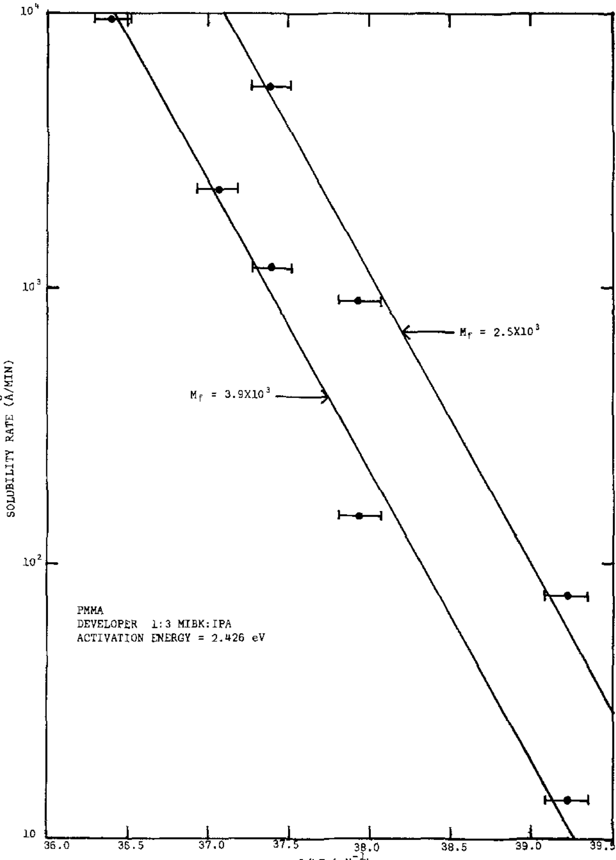

Fig. 7. Developer activation energy for 1:3 MIBK:IPA

was used for the higher temperature data. The higher activation energy of the standard developer compared to MIBK is perhaps indicative of the relatively poor thermodynamic solubility of the standard developer. From Fig. 4 it is apparent that the solubility rate saturates at a level independent of molecular weight. This behavior is found in the temperature range investigated, 37.2°-54.4°C. The temperature dependence for the saturated solubility rate is difficult to determine; however, from the limited data available it appears to be nearly independent of temperature and molecular weight. This is perhaps indicative of a diffusion mechanism in which the transport across the boundary layer is the rate-limiting step.

Development Time and Contrast

In choosing a developer solvent and the electron-beam exposure parameters, a variety of objectives may be sought. For example, one may wish to obtain the highest resolution, minimize the incident charge per unit area, or minimize the developer time. There is a trade-off between these objectives. For the purposes of this section we will be concerned with area exposures and assume that the principal objective is to minimize the incident charge. As a secondary goal, the developer time should be minimized. The influence of developers on spatial resolution will be reported elsewhere (13).

To evaluate the relative merits of various exposure conditions we compute the developer time, τ, at a given temperature as

$$\tau = \int_0^{T_0} \frac{dz}{\left(R_0 + \frac{\beta}{M_f^{\alpha}}\right)} \qquad [8]$$

where T_0 is the original resist thickness and the dependence of the solubility rate on z is found from [1]-[4]. For positive resists complete development to the resist-substrate interface is required. Consequently, the contrast, Γ, is found as (7)

$$\Gamma = 1 - \left(R_o + \frac{\beta}{M_n^{\alpha}} \right) \frac{\tau}{T_o} \quad [9]$$

where M_n is the original molecular weight.

In the following we examine the influence of developer solvent, developer temperature, beam energy, resist thickness, and original molecular weight on the contrast and development time. We previously established (7) that for a given contrast level a larger M_n reduces the required Q at the expense of increased developer time.

Consider 5000Å of resist, molecular weight of 2×10^5, subjected to 20 keV electrons. The required development time and contrast are shown in Fig. 8 and 9 as a function of Q for MIBK, 1:1 MIBK:IPA and 1:3 MIBK:IPA at 22.8°C and also MIBK at 35.6°C. The constrast for the 1:3 MIBK:IPA developer is taken as unity owing to the extremely small removal rate for the original molecular weight. According to [9] Γ should be independent of temperature; however, owing to the slight deviation from $\exp(-E_a/kT)$ in the experimental data, Γ varies slightly with temperature for MIBK as shown in Fig. 9.

It is apparent that a wide range of contrasts and developer times are obtained for the various developer conditions. For example, accepting a 50% contrast (2500Å of resist remains), the required charge can be reduced by over an order of magnitude compared to the standard developer by using other developers. A penalty is paid in developer time. For example, the developer time for $\Gamma = 0.5$ for 1:1 MIBK:IPA would be 750 min, hardly a usable developer. More reasonable developer times are obtained for $\Gamma = 0.5$ for MIBK: 29 min at 22.8°C and 5.3 min at 35.6°C.

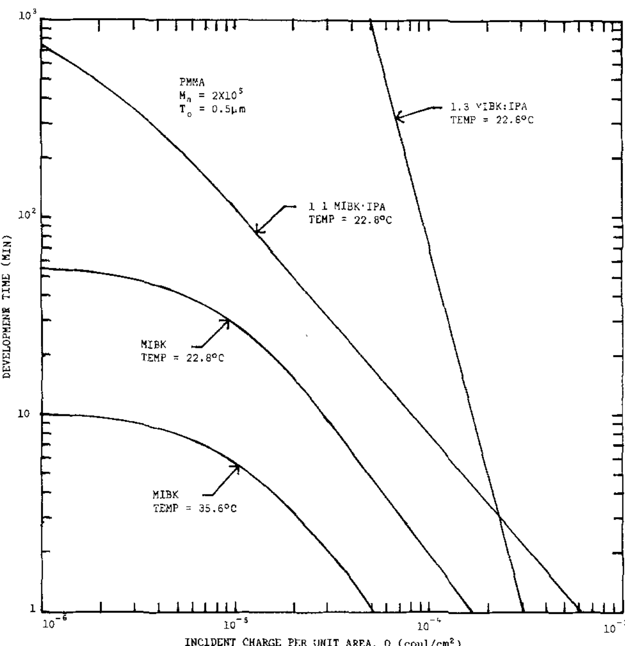

Fig. 8. The dependence of developer time on Q

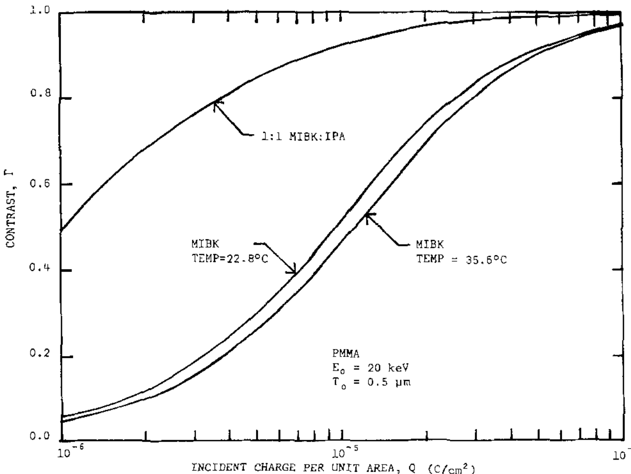

Fig. 9. The contrast as a function of Q

According to Fig. 1, for a given Q a lower beam energy results in a higher ϵ. This results in a smaller fragmented molecular weight and, hence, an increased solubility rate. The influence of beam energy on Γ is shown in Fig. 10 for E_o between 10 and 30 keV. The development time (upper time axis) for a given Γ is shown as the dotted line; it is the same for each of these energies except for very small Γ.

For a given resist thickness there is a lower useful limit on the incident energy; the range R_G [4] defines the thickness and hence energy beyond which the energy absorption is negligible. For positive resists, narrow linewidths are easily obtained at higher incident energies (3) and consequently reducing the beam energy to increase energy absorption may not always be compatible with the desired resolution. Another practical aspect is, for a given SEM beam diameter a decrease in beam energy decreases the beam current, I_B. This decrease is approximately first order in beam energy. Since the increase in ϵ is also first order in energy, then as the beam energy is decreased the required resist exposure time per unit area, Q/I_B, would remain constant independent of energy. Scaling the results in Fig. 10 by the ratio of beam energies confirms this conclusion.

In using a developer such as MIBK which slowly removes high molecular weight PMMA, some reduction in the required Q is achieved by using thicker resist films and taking advantage of the increased ϵ with increasing penetration depth. In this situation the remaining resist thickness, T_r, is specified. In Fig. 11 the required Q is plotted as a function of T_o for two values of T_r (solid lines) for $E_o = 10$ keV, $M_n = 2 \times 10^5$ and MIBK at 22.8°C. The right-hand axis gives the required development time and is plotted *vs.* T_o (dashed lines). Certainly a reduction in original Q is obtained as T_o increases at the expense of increased developer time. Two values of T_o might be considered as optimum. One is the thickness at which the peak in the energy dissipation occurs (0.76 μm at 10 keV) and the other is the thickness at which the energy dissipation equals that at the surface (1.6 μm at 10 keV). The former is preferred if narrow linewidths are required.

Given a desired T_r and choosing E_o and T_o, the development time is reduced by increasing the devel-

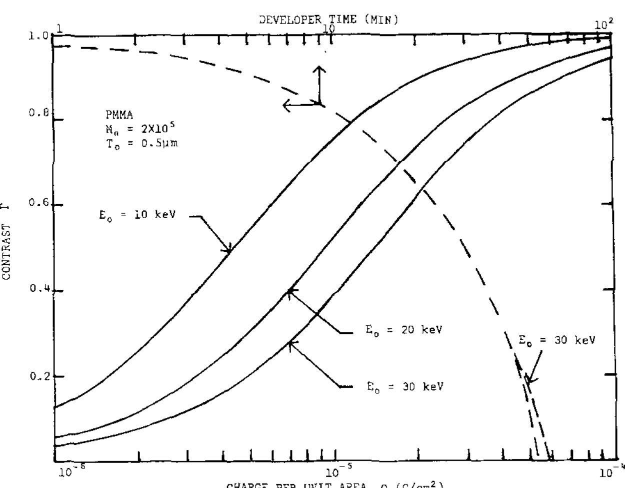

Fig. 10. Influence of beam energy on contrast. The dashed line gives the development time (upper time axis) for a given contrast level.

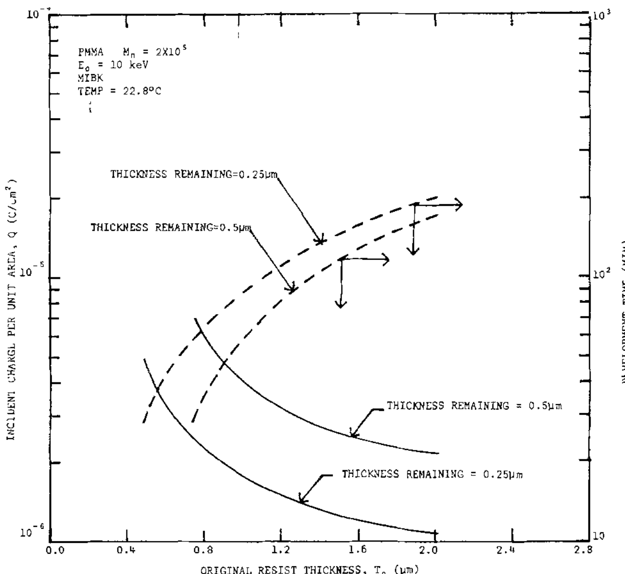

Fig. 11. The required charge per unit area as a function of the original resist thickness (solid lines) resulting in the two final resist thicknesses indicated. The corresponding development time (right axis) is shown as a function of Q by the dashed lines and indicated by the arrows.

oper temperature and/or reducing the original molecular weight. This is illustrated in Table II for $T_r = 0.25$ μm $E_o = 10$ keV, and $T_o = 0.76$ μm. The developer is MIBK at two temperatures, 22.8° and 35.6°C. Also given in Table II is the required incident charge to yield the desired resist thickness. For this situation the required incident dose is reduced by a factor of ~50 compared to the standard developer at 22.8°C.

Conclusions

The following results and conclusions are made for the combinations of MIBK and IPA used as developers for PMMA in this study.

1. A technique for predicting developer characteristics for positive electron resists has been developed in which the solubility rate is determined as a function of fragmented molecular weight.

2. An empirical formula for the solubility rate of the form $R = (R_o + \beta/M_f^{\alpha})e^{-E_a/kT}$ is found with the constants R_o, β, and α dependent upon the developer solvent. Activation energies, E_a, for MIBK and 1:3 MIBK:IPA are found to be 1.04 and 2.43 eV, respectively.

3. The contrast and development times are functions of developer, developer temperature, beam energy, resist thickness, and original molecular weight.

4. An improved sensitivity compared to the standard developer for PMMA of from 10 to 50 times is obtained by using different developers and temperatures.

5. The solubility kinetics of PMMA is characterized by a rate-limited process for most developer conditions. At high temperatures 1:3 MIBK:IPA shows a combination of a rate-limited process and a diffusion process.

Table II. The influence of original molecular weight and developer temperature on development time is tabulated. Also shown is the required minimum Q to yield the final resist thickness, 0.25 μm.

Original molecular weight	MIBK Development time (min) Temp = 22.8°C	Temp = 35.6°C	Required charge per unit area (μC/cm²) Temp = 22.8°C	Temp = 35.6°C
2.5×10^4	30.6	6.1	2.6	2.9
5.0×10^4	44.6	8.6	2.3	2.6
7.5×10^4	50.4	9.5	2.3	2.6
1.0×10^5	54.3	10.0	2.3	2.7
1.5×10^5	57.0	10.4	2.4	2.8
2.0×10^5	58.3	10.6	2.5	2.8

Cross-Slip Dislocations and Their Multiplication in (001)-Oriented Silicon Wafers

Junji Matsui

Nippon Electric Company, Limited, Central Research Laboratories, Kawasaki, 211 Japan

ABSTRACT

Dislocations consisting of a pair of half-loops are found to be characteristic of (001)-oriented silicon wafers, and they are also found to develop and multiply by a combination of cross-slipping of screw segments and their interaction with wafer surfaces. They originate from internal sources which seem to be precipitates formed during course of thermal oxidation.

Recently, silicon single crystals free from dislocations have been available for device fabrications. As is well known, however, several types of defects are often generated in dislocation-free silicon wafers during various device fabrication processes such as thermal oxidation, impurity diffusion, or application of an epitaxial layer. It has been reported that, from the device fabrication point of view, generation of these defects makes it less significant to use a dislocation-free crystal as a starting material. Among those defects, dislocations are especially harmful to the characteristics of fabricated devices, such as leakage current of diodes, whether they are complete dislocations with a Burgers vector of $a/2<110>$ type or partial dislocations with that of either $a/6<211>$ or $a/3<111>$ type. Therefore, it becomes important to know mechanisms in which the dislocations of any type form and multiply in silicon crystals. Several mechanisms of the dislocation formation and multiplication in (111)-oriented silicon wafers have been proposed by many investigators (1-12). Sources of the dislocations have been associated with precipitates (1, 3-4), ruptures at wafer edges (2, 5-6), scratches (7-10), surface irregularities (1-2, 11), and some other defects (12).

It has also been reported that dislocation-free silicon wafers subjected to heat-treatments often reveal a number of circular stacking faults (13-14) and prismatic dislocation loops (14-16) either in the (111)- or (001)-oriented wafers. Particularly when float-zoned, dislocation-free silicon wafers containing grown-in defects along swirls were thermally oxidized, a number of circular stacking faults were also preferentially generated along swirls. On reheating to the subsequent oxidation, hexagonal half-loops of complete dislocation were found to be formed in addition to the stacking faults (17). The nature and structure of the circular stacking faults have been investigated previously (13) but not in detail for the hexagonal half-loops. Structure and dislocation velocities of similar half-loops in the case of (111)-oriented wafers have been determined by Patel and Freeland (8) and George *et al.* (10, 18) from the experimental results of intentional load application to the materials.

This paper describes detail features of the hexagonal half-loops and discusses the multiplication mechanism which may be characteristic of (001)-oriented wafers, from the observation of the dislocations by means of x-ray diffraction topography.

Experimental

Specimens used were (001)-oriented, n-type silicon wafers with a resistivity of about 10 ohm-cm, cut from a float-zoned, dislocation-free crystal rod with a diameter of about 30 mm. Some swirl patterns could be made visible by suitable etching on surfaces of the specimen wafers. They were thinned to about 200 μm by mechanical and chemical methods. Two sequential thermal oxidations were employed. First thermal oxidation for the generation of circular stacking faults along swirls was carried out at 1200°C for 22 hr in a dry oxygen atmosphere. A rapid cooling from the first oxidation was made by extracting the specimens from the center of a furnace to the edge of a quartz tube in less than 20 sec. Second thermal oxidation was carried out in such a manner that the specimens were inserted into the furnace from room temperature to around 600°C very rapidly and then moved to the center of the high temperature zone in about 20 sec and kept there at 1200°C for 3 hr in a wet oxygen atmosphere, which gave rise to the generation of prismatic dislocation loops or hexagonal half-loops. Formation of both the stacking faults and hexagonal half-loops described in this report did not appear to be essentially dependent on whether the oxygen is dry or wet.

In order to observe configurations of both the defects and to determine their Burgers vectors, x-ray diffraction topographs were taken after each oxidation using $MoK\alpha_1$ radiation. All the topographs were recorded on Fuji nuclear plates, ET-7B type, 50 or 100 μm thick emulsion.

Results

Figure 1 shows a topograph of a part of a wafer taken after the second thermal oxidation. Some contrasted ellipses designated as S have been found to correspond to circular stacking faults, each of them surrounded by a partial dislocation loop with a Burgers vector of $a/3<111>$ Frank sessile type (13-14). These faulted loops were found to be formed in one of {111} planes during the course of the first thermal oxidation.

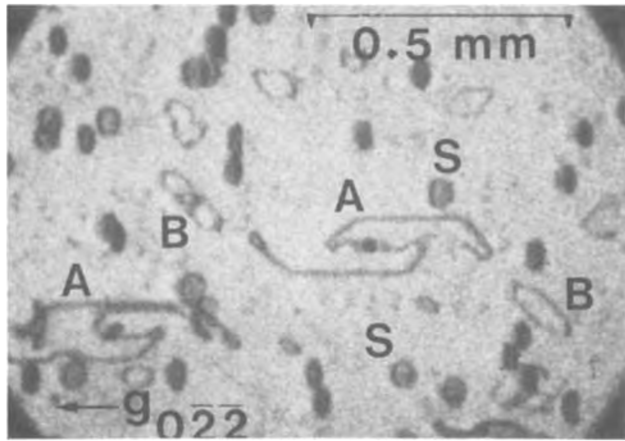

Fig. 1. Topograph of a specimen taken after double thermal oxidation. Besides a number of circular stacking faults, designated as S, which are generated after, a first thermal oxidation, several dislocations consisting of a pair of half-loops are observed. The Burgers vectors of the dislocations A and B are parallel and inclined to the wafer surface, respectively.

Key words: dislocation multiplication, cross-slip, x-ray topography.

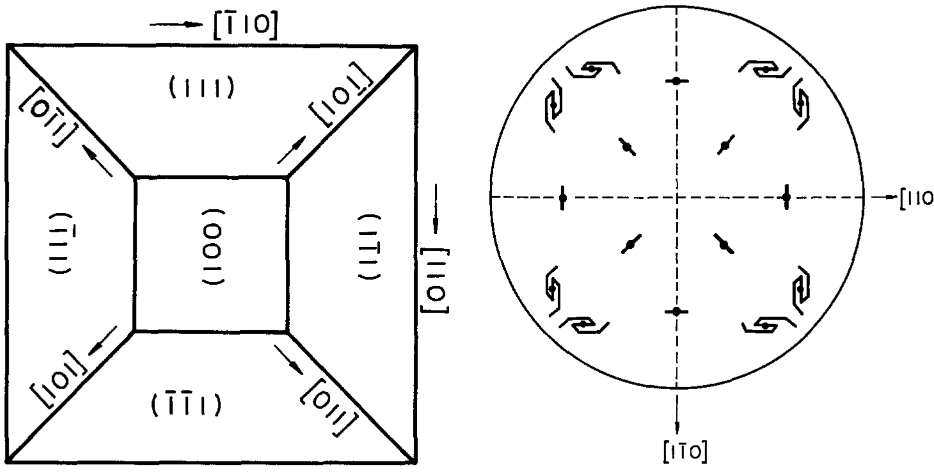

Fig. 2. a (left), Orientations of dislocation lines and glide planes. b (right), Illustration showing a rough distribution and configuration difference of dislocations in a single wafer.

At the conclusion of the second thermal oxidation, other kinds of dislocations in addition to the above circular stacking faults are seen, designated as A and B in Fig. 1. From observation of stereotopographs and topographs reflected from various planes, it is found that the dislocations A in Fig. 1 are lying in two sets of {111} planes inclined at the same angle of 54°44′ to the (001) surface plane, and that they have Burgers vectors of $a/2<110>$ type parallel to the surface and consist of 60° and screw segments with <110> orientation.

Figure 2 presents a schematical rough distribution and configuration difference of dislocations in a single wafer. Pairs of half-loops are mostly symmetrical in shape with respect to two equivalent {1$\bar{1}$0} planes normal to the (001) surface. These dislocations appear to be located in the vicinity of the surfaces, and dislocations close to the upper and lower surfaces give a similar feature on a projected topograph, which may be due to the effect of external stresses during heat-treatments, as will be discussed later in detail.

A typical configuration of the dislocation on a certain stage of development as seen in Fig. 1 is schematically shown in Fig. 3 judged from stereotopographic observation. Since the Burgers vector of this dislocation is parallel to the [110] direction, segment a (Fig. 3) emerging at the surface is a 60° dislocation with the [$\bar{1}$01] orientation, segment b a screw dislocation parallel to the surface, segment c a 60° dislocation with the [011] orientation, and segment d again a screw dislocation. [Hereafter, these will be abbreviated, respectively, as segments a(M, [$\bar{1}$01]), b(S, [110]), c(M, [011]), and d(S, [110]).] Thus, segments a, b, c, and d are lying in the inclined (1$\bar{1}$1) plane, while segments l(S, [110]), m(M, [0$\bar{1}$1]), n(S, [110]), and o(M, [101]) are in the ($\bar{1}$11) plane. Segments e(M, [0$\bar{1}$1]), f(S, [110]), and g(M, [101]) are parallel to segments m, n, and o, respectively, and segments i(M, [$\bar{1}$01]), j(S, [110]), and k(M, [011]) are parallel to segments a, b, and c, respectively. As this feature has not been observed in (111)-oriented wafers (8, 10), the dislocation configuration mentioned above seems to be characteristic of (001)-oriented wafers due to crystallographic orientation of the {111} glide planes, *i.e.*, a pair of inclined {111} planes, as (1$\bar{1}$1) and ($\bar{1}$11) planes in this case, which always lie symmetrically and intersect at a line parallel to the (001) surface.

Besides the fact that the dislocations, as well as the stacking faults, appear preferentially along swirls in oxidized dislocation-free crystals, it is observed that the dislocations consisting of half-loops show dark contrast of a nucleation source lying mostly along a screw segment (as segment h in Fig. 3) which connects two half-loops lying in the different {111} planes. These facts may suggest that the dislocations originate from some clustered defects such as precipitates of oxygen atoms (1, 3, 19), which seem to nucleate during the course of the first thermal oxidation at the grown-in defects usually located along swirls in float-zoned, dislocation-free silicon crystals (20-21). Although the precipitate particles can be expected to nucleate not only near the wafer surfaces but also in the bulk, growth of the dislocation loops around the precipitates may be more intensive near the oxidizing surfaces than in the interior, as will be discussed later.

Discussion

Formation mechanism of dislocations.—It has been reported that oxidized, Czochralski-pulled, dislocation-free silicon crystals reveal both stacking faults surrounded by a Frank partial dislocation and prismatic

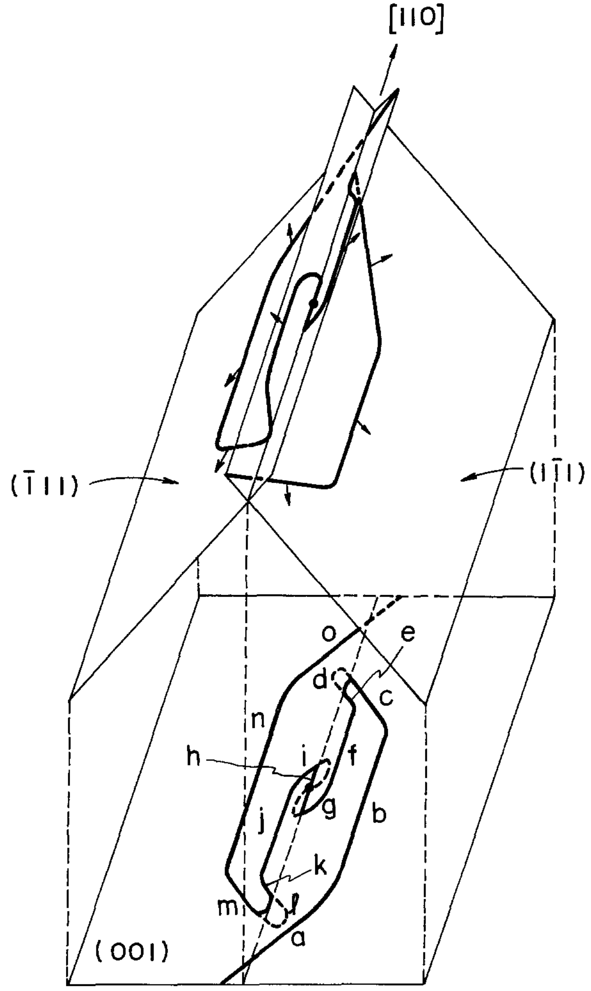

Fig. 3. Spatial illustration of a dislocation lying in two different {111} planes with its projection onto (001) plane.

dislocation loops consisting of $a/2<110>$ type complete dislocations (14-15). In case of float-zoned, dislocation-free crystals containing such grown-in defects along swirls as in the present experiment, however, extrinsic stacking faults surrounded by a Frank partial dislocation loop, *i.e.*, faulted loops, rather than prismatic dislocation loops, are believed to be preferably generated after the first thermal oxidation. But, the fact that the density of the circular stacking faults in a singly oxidized wafer is always lower than that of the grown-in defects which can be seen by etching before oxidation seems to indicate that not all of the grown-in defects turn out to be nuclei of the extrinsic stacking faults. It can be expected, therefore, that the rest of the grown-in defects may provide requisite sites for the aggregates of oxygen atoms which are pre-existent in the specimen or also induced from the surfaces.

On rapid cooling after a first high temperature oxidation, considerably large thermal strains will arise around the precipitate particles since the precipitate particles, probably SiO_2, form with larger specific volume than the silicon. It is speculated, therefore, that small prismatic loops of complete dislocation start to develop at the precipitate surfaces at the beginning of a second thermal oxidation so that the strains may be accommodated. Once the dislocation loops are formed, they will become more active emission sources of vacancies than are the stacking faults during a second thermal oxidation. These ideas seem to be supported by a previous report (22) describing the fact that circular stacking faults failed to be formed in dislocated crystals or in the vicinity of complete dislocations in low-dislocation-density crystals, and also by the fact that additional stacking faults were not observed at all after a second thermal oxidation while a number of prismatic dislocation loops and hexagonal half-loops were.

From the above consideration, the prismatic dislocation loops would be expected to be of interstitial type rather than of vacancy type and thus, as are the extrinsic stacking faults, the dislocation loops would be bulged by dislocation climb resulting from vacancy emission from the dislocation lines to the surfaces where the vacancies are consumed under oxidation conditions (23). Expansion of the loops should take place more markedly in the region close to the oxidizing surfaces for the above mechanism to be important, in order to be consistent with the present experimental result that the nucleation sources lying along the connecting screw segments are located at depths of less than 40 μm below the surfaces, which are known from the observation of the topographs.

Figures 4(a-f) reveal various configurations of the dislocations and indicate that they are on different stages of development and of multiplication probably due to the difference of magnitude of thermal stresses exerted on them during a second thermal oxidation. From the observation of those dislocations, development processes can be derived as schematically illustrated in Fig. 5 which presents successive views of dis-

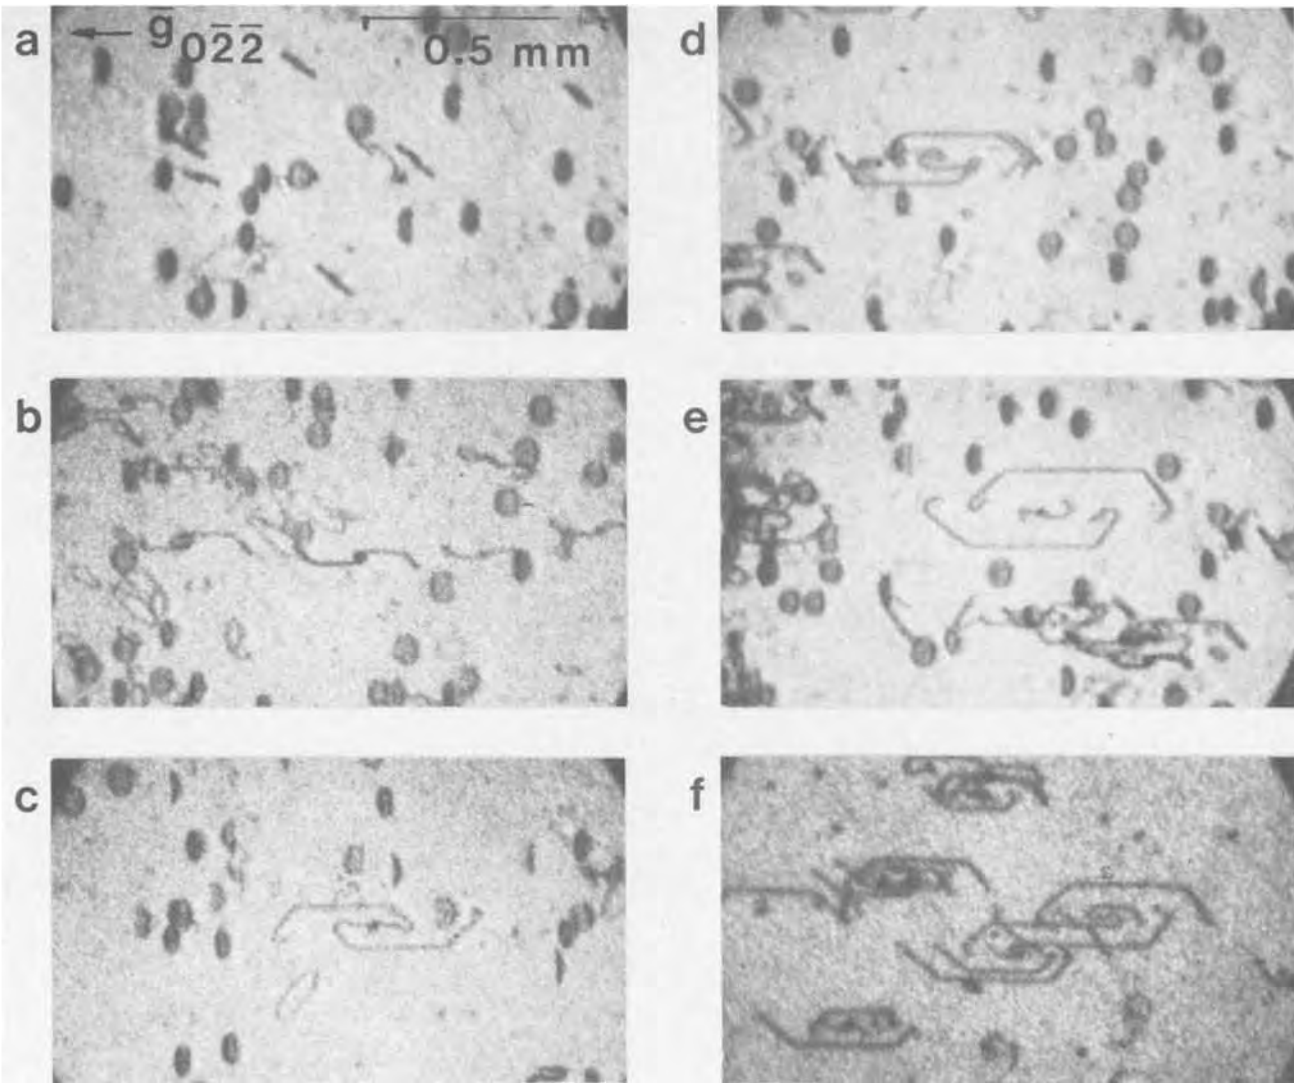

Fig. 4. Topographs showing various configurations of the dislocation half-loops. They seem to correspond to different stages of development.

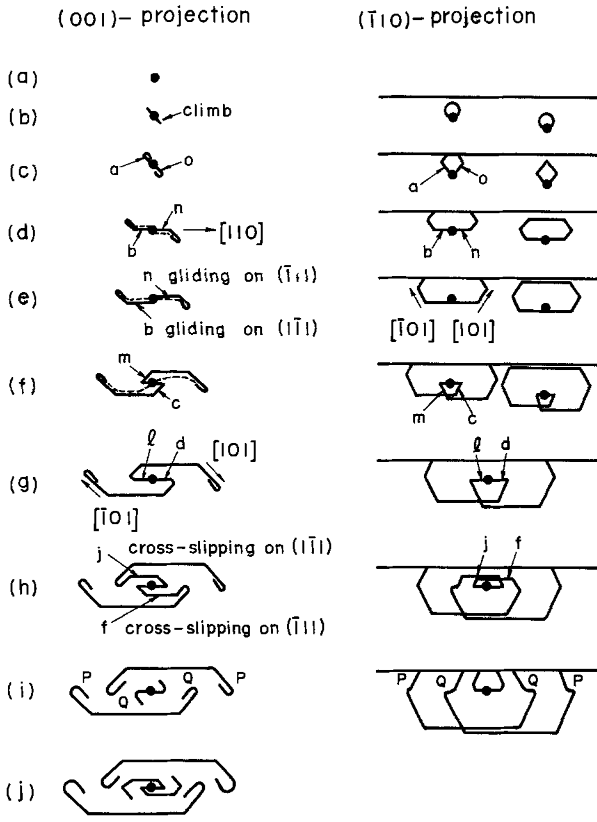

Fig. 5. Schematical illustrations showing successive views of development and multiplication processes as projections onto the (001) and (1̄10) planes. Designations to the dislocation segments correspond respectively to those in Fig. 3.

location shapes projected onto the (001) and (1̄10) planes. The dislocation half-loops shown in Fig. 4(a-f) would thus be expected to form by a combination of expansion of prismatic loops and their subjection to thermal stresses, as follows.

At the first stage, small prismatic loops of interstitial type attached to the precipitates may be emitted in order to lower strain energy increased around the precipitates. Both ends of a single dislocation line would be connected to the surface of a single precipitate. Vacancy emission may be more accelerated at the side close to the surface than the side further from the surface, as shown in Fig. 5b. Incipient alignment of the dislocation line of the climbing dislocation may not be in a particular direction because of high density of jogs on the line. However, <110> alignments would be preserved after considerable expansion of the dislocation loops since hexagonal prismatic loops consisting of straight, <110>-oriented segments have been observed so far in heat-treated silicon crystals (11, 14-15, 18). Therefore, it can be expected that, as shown in the left side of the (1̄10)-projections in Fig. 5(b and c), once a part of the dislocation loop line gets to a wafer surface, it is cut there and resolved into two dislocation lines which connect the precipitate surface and the wafer surface, and which will make a projection onto the (001) plane as is shown in Fig. 5(b and c) consistent with the actual feature of dislocations seen in Fig. 4a. Under the influence of thermal stresses which the specimen undergoes during a second thermal oxidation, each <110>-aligned segment of the prismatic dislocation loops lying in one of the inclined {111} planes would glide in the direction parallel to the Burgers vector. Since the Burgers vectors are $a/2$ <110> type parallel to the surface as already mentioned, the two <110> segments, *e.g.*, segment a(M, [1̄01]) in the (11̄1) plane and segment o(M, [101]) in the (1̄11) plane, as shown in Fig. 5d, glide inevitably in opposite directions from each other with respect to the precipitate, the phenomenon being related to the sense of resolved shear stress in each of the {111} planes. When the specimen is subjected to the thermal stress τ_1 in the [110] direction as shown in the upper part of Fig. 6, resolved shear stresses in the (11̄1) and (1̄11) planes are of such senses as seen in the right-hand part of Fig. 6, where ⊙ and ⊗ mean directions in which the stresses drive the material normally above and below the sheet, respectively. It is apparent that another shear stress τ_2 does not play a role for the movement of the present dislocations because of a null Schmid factor for either the [110]/(1̄11) or [110]/

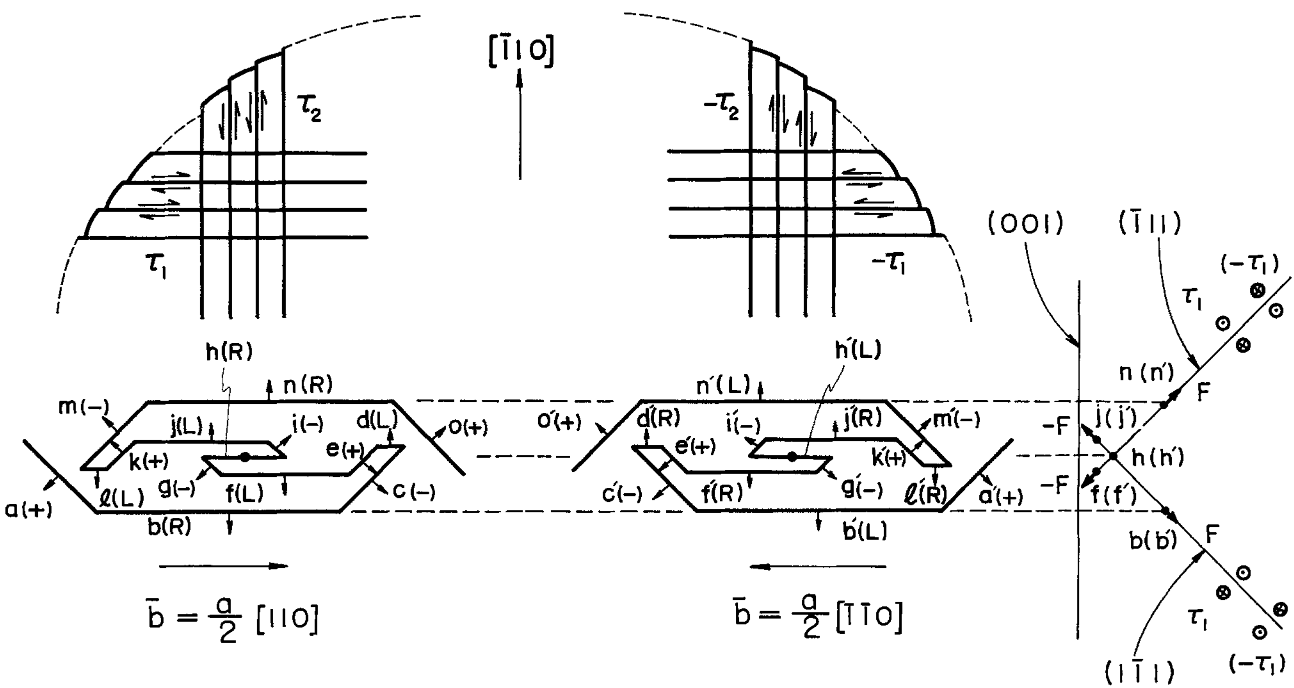

Fig. 6. Movement of each segment of half-loops under the influence of resolved shear stresses exerted parallel to the [110] directions. A 60° segment with the sign (+) has an extra half-plane above the glide plane whereas that with the sign (−) below the glide plane. A screw segment as noted by R in parentheses is of a right-hand screw character whereas that indicated by L is of a left-hand one.

$(1\bar{1}1)$ slip system. Supposing that extra half-planes which terminate at the lines of segments a and o exist above $(1\bar{1}1)$ and $(\bar{1}11)$ planes, respectively [hereafter, segment r of 60° dislocation having an extra half-plane above the glide plane (on the side of the (001) surface) will be written as segment r(+, M, <110>) while that below the glide plane (on the side of the $(00\bar{1})$ surface as segment r(−, M, <110>)], the a(+, M, $[\bar{1}01]$) segment on the $(1\bar{1}1)$ plane should glide in the $[\bar{1}\bar{1}0]$ direction (to the left) and the o(+, M, [101]) segment on the $(\bar{1}11)$ plane should glide in the [110] direction (to the right), under the resolved shear stresses mentioned above. This process must leave a screw segment which connects segments a and o. This screw segment is regarded as made of two parts, *i.e.*, segments b and n on both sides of the precipitate, as shown by the solid lines in Fig. 5d. From the above consideration, the screw segments should be right-hand screw dislocations [hereafter, segment r of this type will be written as segment r(R, S, <110>), while that of left-hand screw type as segment r(L, S, <110>)]. Apparently, both the b(R, S, [110]) segment in the $(1\bar{1}1)$ plane and the n(R, S, [110]) segment in the $(\bar{1}11)$ plane exert motive forces, *F*, normal to the segment lines in each of the {111} planes also due to the resolved shear stresses and, as a result, each of the screw segments glides independently deeper into the wafer thickness in one of these planes. Dislocation configuration as seen in Fig. 5e and actually as shown in Fig. 4b can be thus obtained, and furthermore, formation of the other two 60° dislocations as in segments c(−, M, [011]) and m(−, M, $[0\bar{1}1]$) shown in Fig. 5f and of two screw dislocations as in segments d(L, S, [110]) and l(L, S, [110]) in Fig. 5g takes place. These segments move in such a way that each half-loop expands continuously in each glide plane, and the resulting feature is such a one as seen in Fig. 4c.

Another formation process of the dislocation shown in Fig. 5g may be possible in which the glide motions mentioned above precede arrival of a part of the dislocation line at the surface. The dislocations having not yet reached the surface are shown by the dashed lines in Fig. 5(c-f) in addition to the solid lines and are also shown in the right side of the $(\bar{1}10)$-projections. Dislocation features as seen in Fig. 7(a and b) appear to correspond to this case. By either development process, the dislocation configuration as shown in Fig. 5g can be explained. At this time, the most part of segments d and l in Fig. 5g exert motive forces, -*F*, whose sense is opposite to those on segments n and b as shown in Fig. 6. Therefore, they cross-slip on the $(\bar{1}11)$ and $(1\bar{1}1)$ planes, respectively, turning themselves into f(L, S, [110]) and j(L, S, [110]) segments connected to a pair of the other 60° dislocations, *i.e.*, e(+, M, $[0\bar{1}1]$) and g(−, M, [101]) segments for segment f and k(+, M, [011]) and i(−, M, $[\bar{1}01]$) segments for segment j as shown in Fig. 5h and also actually seen in Fig. 1 and 4d. When segments f and j reach an oxidizing surface again, then these segments disappear and only 60° segments are left, being emergent at the surface as shown in Fig. 4e and 5i. Thus, the dislocation becomes the one that consists of two half-loops and also of one inside dislocation which is of mostly screw character and suspended at the surface. The latter is ready to give off another pair of half-loops by going through the same process all over again, since it is also a right-hand screw segment as are segments b and n. Accordingly, whenever left-hand screw segments cross-slip and emerge from the surface and hence annihilate there, dislocation multiplication takes place and in turn, formation of pairs of multifold half-loops occurs as shown in Fig. 4f and 5j.

It should be noted that part of the 60° segments on both of the ends of each half-loop seem to, at their

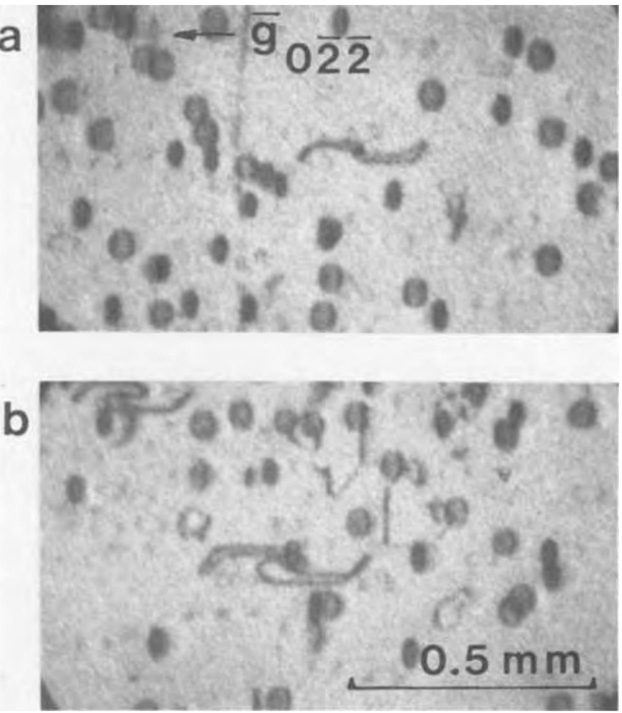

Fig. 7. Dislocations expanding by glide in the direction parallel to the surface before a part of each dislocation line arrives and annihilates at the surface. (a), Early and (b), later stages of development.

emerging points, depart from the initial glide planes since they are not in rectilinear alignments but are revealed in the shape of a hook on the projected topographs, as shown in Fig. 1 and 4e. In fact, stereotopographs give a nonplanar configuration of the dislocations at both the emerging points of each half-loop. George *et al.* (10) have reported that similar bends of the emergent segments observed in (111)-oriented wafers are caused by the cross-slip of screw segments. In the present case of the (001)-oriented wafers, however, this mechanism does not seem to hold since the emergent segments themselves are not screw but 60° dislocations. Apparently one of the bends in a single half-loop, connected to segment a or o as at P in Fig. 5i, is generated in an early stage of development, as already mentioned. The other bend, Q, is made of a 60° segment such as segment e or k, as a result of the disappearance of the cross-slipped screw segment such as f or j segment. After all, it is evident that formation of the two bends takes place due to interaction of the dislocations of screw character with the specimen surface.

The symmetry of the dislocation configuration illustrated in Fig. 2b seems quite reasonable since, as shown in Fig. 6, thermal shear stresses, felt by the dislocations in the opposite sides of the wafer with respect to the (110) plane normal to the stress direction, are in the opposite directions from each other and thus, screw segments of both the dislocations, *e.g.*, segments b(R, S, [110]) and b′(L, S, [110]), are also of opposite senses, whereas the same development mechanism may preside over both the dislocations.

Another type of dislocation.—Another type of dislocation is observed to coexist with the dislocations described above, as marked by B in Fig. 1 and also as shown in Fig. 8, the former having the shape of a full hexagon, whether regular or partly perturbed, and the latter lacking some segments. Each hexagon on the topograph projected onto the (001) plane usually consists of four <110> segments and two <100> segments. Stereotopographs show that they are also lying in two sets of adjacent {111} planes, as schematically shown

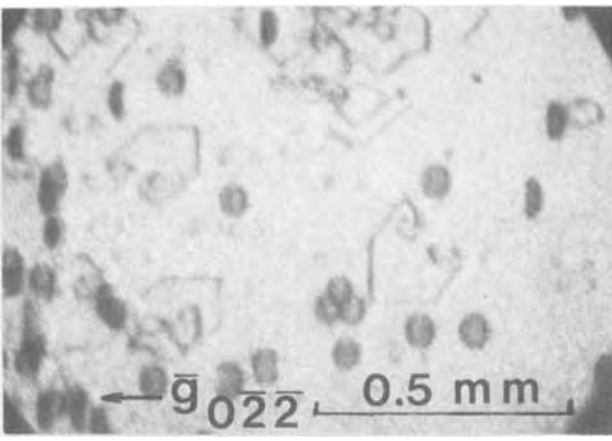

Fig. 8. Another type of dislocation of which Burgers vector is inclined to the wafer surface.

in Fig. 9. They are found to have a Burgers vector of $a/2<110>$ inclined to the surface, and are also found to be prismatic dislocations which contain a pair of screw segments of opposite senses, *e.g.*, as shown in Fig. 9, segments u(M, [110]) and v(S, [011]) are in the $(1\bar{1}1)$ plane, and segments x(M, $[\bar{1}10]$) and y(S, [011]) are in the $(\bar{1}\bar{1}1)$ plane, while segments w(M, $[\bar{1}10]$) and z(M, [110]) are in the $(\bar{1}\bar{1}1)$ and $(1\bar{1}1)$ planes, respectively, parallel to the x and u segments.

This type of dislocation is thought to develop through such processes as are schematically shown in Fig. 10. First, as well as the previous dislocations, sources of the dislocations are probably precipitates, although they are located at larger distances from the surface than those in the previous case. Then, round dislocation loops would be emitted from the precipitates by climb, since these loops seem to lie in planes

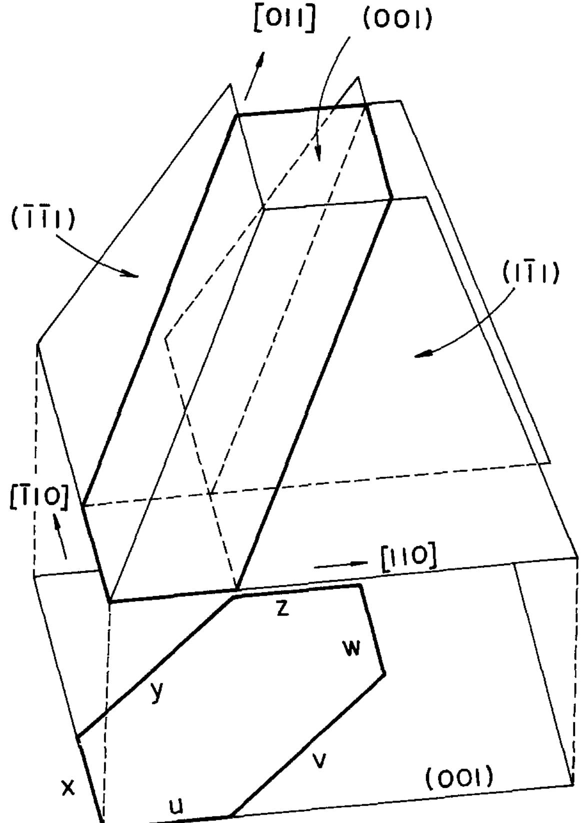

Fig. 9. Spatial illustration of a dislocation with an inclined Burgers vector as B in Fig. 1 and in Fig. 8, with its projection onto (001) plane.

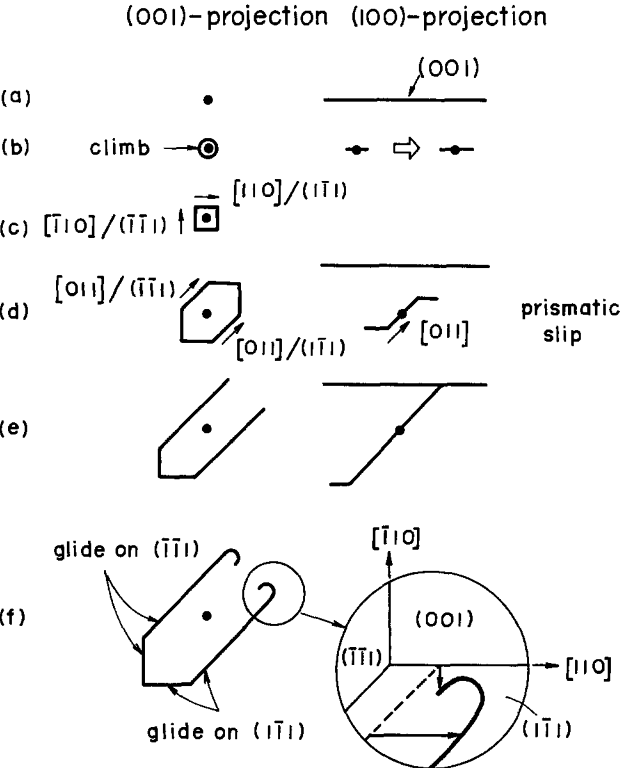

Fig. 10. Development processes of the dislocation with an inclined Burgers vector.

parallel to the (001) surface and no preference of the vacancy emission along the loop line is expected. The loops would turn to the ones with several $<110>$-aligned segments, as shown in Fig. 10c. When the crystal region containing the loops is affected by a resolved shear stress, two halves of each loop with the Burgers vector parallel to the stress might glide in opposite directions, and hence the dislocations would have shapes as shown in Fig. 9 and 10d. The dislocation feature is similar to the previous dislocation shown in the right side of the $(\bar{1}10)$-projection in Fig. 5d except for orientation of the screw segments. Once one of the halves arrives and annihilates at a surface, only four segments are left. This four-segmented dislocation could also be obtained by a mechanism in which two segments with $<110>$ orientation parallel to the surface originate at the surface due to surface irregularities and glide into the material leaving a pair of screw segments behind them. The fact that, by Sirtl-etching, the dislocations made of full hexagon or of four segments sometimes reveal an unidentified dot nearly at their center and sometimes not, seems to suggest the difference of nucleation sources, *i.e.*, the precipitates or surface irregularities.

Additionally, two emergent screw segments of opposite senses often bend toward the inside on a topograph as seen in Fig. 8. The phenomenon is thought, in contrast with the previous dislocations, to be due to cross-slips of the emergent screw segments themselves, similar to the case observed by George *et al.* (10) in addition to the pinning effect of the surface; *e.g.*, as shown in Fig. 10f, a part of the screw segment v would move in the [110] direction on the $(1\bar{1}1)$ plane, slower near the surface than at the inner part, and also could cross-slip in the $[1\bar{1}0]$ direction on the adjacent $(\bar{1}\bar{1}1)$ plane. As has been reported (10), this cross-slipping part can be a new source of another mobile dislocation. Thus, dislocation multiplication may occur also in the case of the present dislocations.

Conclusion

(001)-oriented silicon wafers subjected to two sequential thermal oxidations are found to reveal char-

acteristic dislocation configurations. These dislocations originate from the precipitates nucleated at some grown-in defects in dislocation-free silicon crystals on rapid cooling from a first thermal oxidation. Via small prismatic dislocation loops generated through climb, and under the influence of thermal stresses exerted during the course of a second thermal oxidation, the dislocations can develop and multiply giving off successively pairs of half-loops lying in two sets of symmetrically inclined {111} planes. Another type of dislocation lying in the adjacent {111} planes is also observed.

Diffusion of Cobalt out of Cobalt-Hardened Gold Measured with Auger Electron Spectroscopy

Harland G. Tompkins

Bell Laboratories, Incorporated, Columbus, Ohio 43213

ABSTRACT

The diffusion of cobalt out of a gold layer is considered. The theory is discussed to relate measured quantities to diffusion coefficients. Measurements were taken and appropriate calculations made to obtain values for the coefficients at 100° and 150°C. Arrhenius plot extrapolations are then made to obtain approximate values at ambient temperatures.

Electroplated gold is a material often used in electrical contacts because of its excellent noncorrosive properties. Because pure gold is reasonably soft it is often modified by adding a small amount of cobalt as a hardening agent to reduce its sticking tendency. Cobalt does not have the noncorrosive properties of gold, however, and if a significant amount of the cobalt were to diffuse to the surface and become oxidized, the electrical contact properties would be significantly impaired. The purpose of this work is to study the diffusion of cobalt out of a gold matrix. The theory is developed for a simple model. Measurements of surface cobalt are described and diffusion coefficients (at slightly elevated temperatures) calculated. An Arrhenius plot is made which shows extrapolated diffusion coefficients down to ambient temperatures.

Key words: cobalt, gold, diffusion, Auger electron spectroscopy.

Theory

In setting up the appropriate boundary value problem, we make the following simplifying assumptions: (*i*) Except for the cobalt content, the gold layer is homogeneous throughout. (*ii*) The diffusion coefficient for cobalt in gold is independent of the concentration of cobalt within the ranges studied. (*iii*) The cobalt does not diffuse into the underlying material (*i.e.*, into Cu or Ni). (*iv*) Cobalt which arrives at the outside surface of the gold is immediately oxidized. Formally, we say that a sink exists at the surface for the cobalt.

A few comments are in order about the appropriateness of the initial assumptions to real world conditions. This study concentrates on temperatures near ambient, gold thicknesses large enough to avoid porosity, and times of the order of 40 years or less. For these conditions we shall find that significant transfer of cobalt

occurs only near the surface of the gold and the system could have been treated as if the gold were a semi-infinite slab. We shall, however, consider a finite gold thickness, both for convenience and also to show when the diffusion process is affected by the finiteness of the gold. This information is particularly needed in the area of (possibly incorrect) accelerated aging of corrosion processes. With the semi-infinite idea in mind, the real world boundary condition at the back side of the gold is irrelevant and is chosen for mathematical convenience. The assumption of a sink at the outer surface involves assuming that the chemical and transport processes of oxidation in the film occur much faster than the transport phenomena in the gold. For an oxide with thickness of 60Å or less and gold with cobalt concentrations of tenths of a per cent, this seems reasonable.

We shall use the standard textbook approach (1, 2) in setting up and solving the boundary value problem. Let us make the following definitions. Time (in seconds) will be denoted as t. Distance (in centimeters) normal to the surface will be denoted as x (we will discuss later where the origin is to be chosen). The atomic concentration of cobalt will be denoted as c, and in fact $c = c(x)$, with the uniform concentration at time zero as c_i. The thickness of the gold layer will be taken as $h/2$ (the reason for the half will become obvious later).

The differential equation which is obeyed by the cobalt in the gold layer is

$$\frac{dc}{dt} = D\frac{d^2c}{dx^2} \qquad [1]$$

where D is the diffusion coefficient (assumed to be independent of concentration).

The actual boundary conditions which seem reasonable are that the concentration is uniform at time zero, that the concentration of free cobalt at the outside surface of the gold is zero (*i.e.*, the sink effect), and that the slope of the concentration at the inside gold surface is zero. The boundary value problem is simpler to solve, but equally applicable, if we consider the actual situation plus its mirror image. This is shown in Fig. 1 along with the appropriate mathematical boundary conditions necessary to represent the real world boundary conditions.

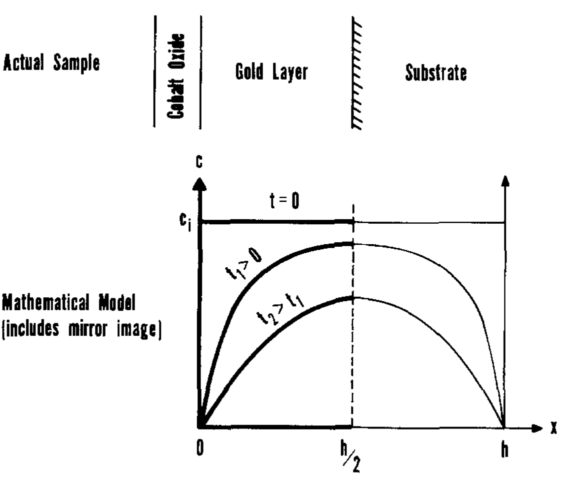

Fig. 1. Boundary value problem and boundary conditions, actual and mathematical.

The solution, expressed as an infinite sum is

$$c = \frac{4c_i}{\pi}\sum_{n=0}^{\infty}\frac{1}{2n+1}\sin\frac{(2n+1)\pi x}{h}\exp\left[-(2n+1)^2\pi^2\frac{Dt}{h^2}\right] \qquad [2]$$

which has the form shown on Fig. 1.

The integral

$$\int_0^{h/2} c(x)\,dx = \frac{1}{2}\int_0^h c(x)\,dx \qquad [3]$$

gives the total content of cobalt in the gold layer at any time, t. The quotient

$$\text{quotient} = \frac{\frac{1}{2}\int_0^h c(x)\,dx}{\frac{1}{2}\int_0^h c_i\,dx} = \frac{1}{c_i h}\int_0^h c(x)\,dx \qquad [4]$$

gives the fraction of the original amount of cobalt remaining in the gold layer. It is clear that this fraction is the same whether we consider x from 0 to $h/2$ or from 0 to h. Let us denote the fraction of the cobalt which has been removed as F. Therefore

$$F = 1.0 - \frac{1}{c_i h}\int_0^h c(x)\,dx \qquad [5]$$

performing this integration we get

$$F = 1.0 - \frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\left[-(2n+1)^2\pi^2\frac{Dt}{h^2}\right] \qquad [6]$$

The reason for concerning ourselves with the cobalt which has been removed is that this is the cobalt which appears at the surface as an oxide and can be easily measured. The reason for considering the fraction, F, is that the fraction of material removed from one-half of the hypothetical system is the same as the fraction removed from the entire hypothetical system, hence the real world problem can be considered with the mathematical boundary value problem which we have set up (and shown in Fig. 1).

The infinite sum, in Eq. [6], is a function of the variables D, t, and h, and in fact these always appear as Dt/h^2.

The infinite sum itself is not very illustrative of how these variables affect F. We can, however, with a simple Fortran program, solve for F, for various values of Dt/h^2, and plot the result. This is shown in Fig. 2.

Crank (2) indicates that for small times an error function-type expression is applicable and if, in fact, the quantity Dt/h^2 is quite small the approximation

$$F = \frac{4}{\sqrt{\pi}}\sqrt{\frac{Dt}{h^2}} = 2.26\sqrt{\frac{Dt}{h^2}} \qquad [7]$$

is valid. This expression is also plotted in Fig. 2. Above $F = 0.6$ or $Dt/h^2 = 0.07$, the curve deviates significantly from the approximation.

The above expression provides some interesting insight in the following way. It is not clear at first thought, whether using a thicker gold layer (with the same cobalt concentration) will give a thicker cobalt oxide film or not. More total cobalt is available, but it has further to travel to arrive at the surface. Equation [7] shows that, in fact, the film growth will be the same, regardless of the thickness of the gold layer in the early stages. This can be seen by rearranging Eq. [7] as follows

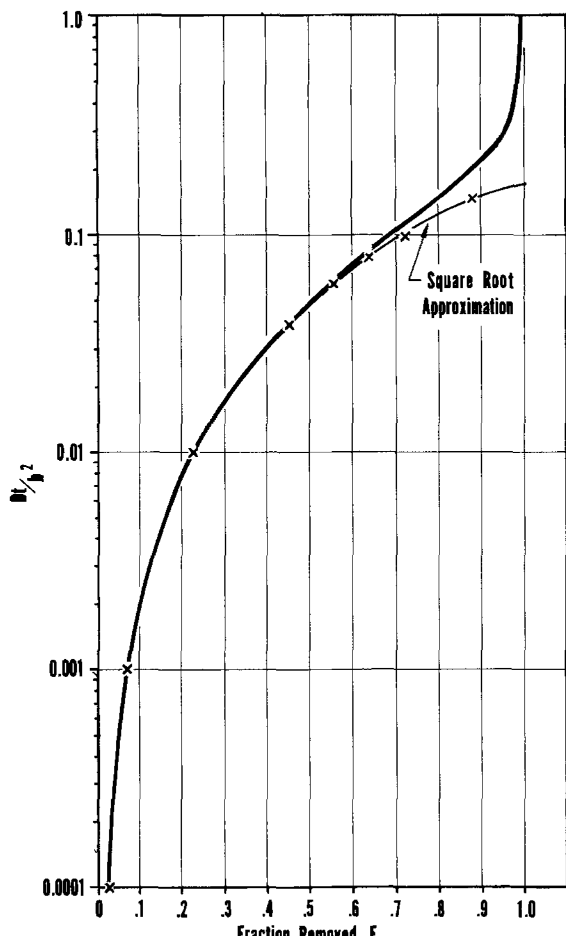

Fig. 2. Fraction of cobalt which has been removed from the gold film plotted *vs.* Dt/h^2.

$$Fh = 2.26\sqrt{Dt}$$

The amount of cobalt in the oxide film is simply the fraction removed times the original amount or

$$\text{amount} = F \cdot h \cdot (\text{area}) \cdot c_i$$

$$= 2.26\sqrt{Dt} \cdot (\text{area}) \cdot c_i$$

and hence is independent of thickness.

This is to say that until the fraction removed approaches 0.6, the thickness of the cobalt oxide film is independent of the gold layer thickness. It is very dependent, however, on the original concentration of cobalt in the gold. The dependence is one-to-one in that twice as much cobalt gives a film twice as thick.

Applying the theory, then, consists of measuring F, t, and h and calculating D, and then, by using values of D obtained, predicting values of F for other values of t and h (and as shown below, for different temperatures).

The diffusion coefficient is generally accepted to be a function of temperature and is usually represented with the Arrhenius equation

$$D = D_0 e^{-Q/RT}$$

where T is in degrees Kelvin, R is the gas constant, Q is the activation energy for diffusion, and D_0 is the preexponential factor. Data are then taken at elevated temperatures, and, using an Arrhenius plot, the values of D for lower temperatures are obtained by extrapolation using the obtained values. Calculations can then be made for F at the lower temperatures as a function of t and h. These extrapolations are based on one rather limiting assumption, *i.e.*, that the mechanism of diffusion is the same for the measured values and the extrapolated values. Serious problems can arise when the diffusion mechanism changes (3). Accordingly, the extrapolation is more likely to be acceptable if the measured values are obtained at temperatures reasonably near the temperature for the extrapolated values.

Experimental Methods

The samples used were electroplated gold films which contained 0.26% (by weight) cobalt as a hardening agent. Some of the films were plated directly on the OFHC copper substrate, and some of the samples had a nickel underplate between the gold and the copper. Results were independent of which material was immediately under the gold. The gold thickness was determined by photomicrography. All except two of the samples had 3.3 μm of gold. Two samples had 50.8 μm of gold. The cobalt content was measured by atomic absorption. The samples were coupons approximately 4 cm^2 $\times$ 0.3 cm. These were heated in air at 150° and at 100°C for extended periods of time in ovens. Temperatures were controlled to within $\pm$ 1°C. At appropriate times, the coupons were removed from the ovens and small sections were cut out of the larger coupons. These smaller (1 $\times$ 0.5 cm) pieces were then analyzed for cobalt.

The cobalt analysis was made using Auger electron spectroscopy (4, 5) along with argon ion bombardment to obtain a depth profile of the cobalt along with other elements. A commercial instrument purchased from Physical Electronics Industries was used. Sputtering and Auger analysis are done simultaneously and a plot of peak-to-peak height *vs.* sputtering time can be obtained for up to six elements. Sputtering rate was obtained by prior calibration of the sputtering parameters for gold. Sputtering rate for cobalt oxide is assumed to be that of cobalt which in turn is taken to be one-half that of gold (6).

The thickness is measured as described above and combined with the calculated value of oxide thickness if all the cobalt were oxidized to give the fraction of the cobalt removed, or F. The stoichiometry of the oxide was not measured, but it was assumed to be CoO. When density and molecular weight are taken into account, the results are within 10% for either CoO

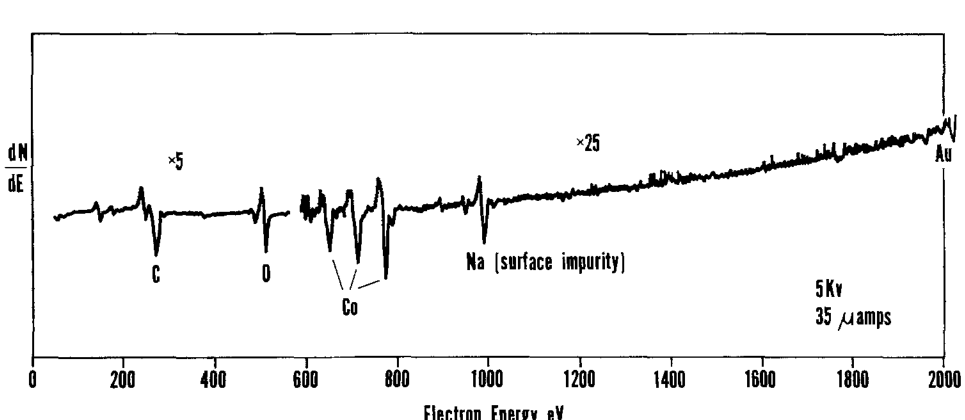

Fig. 3. Typical Auger spectrum taken before sputtering. Sample had been heated at 100°C for 6060 hr.

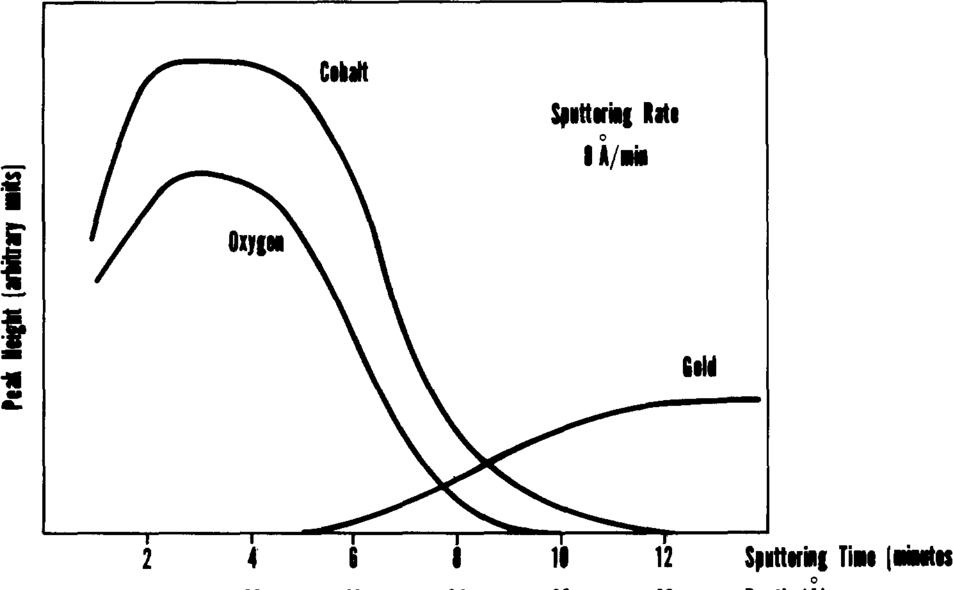

Fig. 4. Typical profile of the top few hundred angstroms. Sample had been heated at 150°C for 2927 hr.

or Co_3O_4 which are the two possibilities (7). For simplicity, then we assume CoO.

Results

Profiles were obtained for samples heated at 150°C for 2927 hr and samples heated at 100°C for 6060 hr. A typical Auger spectrum is shown in Fig. 3 and a typical profile is shown in Fig. 4.

The reason for the initial rise in the cobalt and oxygen signal is that a small layer of carbon (which typically exists on any sample which has been exposed to the atmosphere for any significant length of time) is being removed, thus, uncovering the underlying material.

The oxygen signal follows the cobalt rather closely which tends to indicate that this cobalt is in the oxide form. The gold signal goes from zero in the oxide to its bulk value after the oxide has been sputtered away. The model is, then, that the cobalt at the surface becomes oxidized leaving a lower free cobalt concentration, the cobalt in the bulk diffuses out and in turn is oxidized. The resulting structure is a cobalt oxide film on top of the gold.

Let us take the thickness where the peak height crosses the center point, half-way between maximum and zero, as the thickness of the cobalt oxide. Table I gives the values of time, temperature, thickness, and the corresponding value of diffusion coefficient obtained using methods discussed in the section on Theory.

One immediate observation is that the samples with 50.8 μm of gold give cobalt oxide films which are not significantly different in thickness from the films formed on the 3.3 μm samples. This tends to substantiate the theoretical conclusion that the amount of film formed should be independent of gold thickness.

Table I. Thickness of cobalt oxide and diffusion coefficients for various times and temperatures

Temperature, °C	Time, hr	Thickness, A	D, cm²/sec
150	2927	53	2.0×10^{-16}
150	2927	58	2.28×10^{-16}
150*	2927	64	2.95×10^{-16}
100	6060	7.0	1.85×10^{-18}
100	6060	11.0	4.2×10^{-18}
100	6060	9.6	3.2×10^{-18}
100*	7156	11.4	3.82×10^{-18}

* Gold thickness is 50.8 μm for these samples. Others are all 3.3 μm.

The main thrusts of this work are the description of how Auger spectroscopy can be used for diffusion measurements (along with the necessary diffusion theory) and the reporting of diffusion coefficients at reasonably low temperatures (100° and 150°C). A secondary benefit obtained is that these values of the diffusion coefficient can be plotted on an Arrhenius plot to obtain an activation energy for diffusion and to make rough estimates of diffusion coefficients at even lower temperatures.

Extrapolation beyond measured data is risky, at best, and the choice of the method used for the extrapolation is up to the extrapolator. The author has used a least squares fit along with the 95% confidence limits

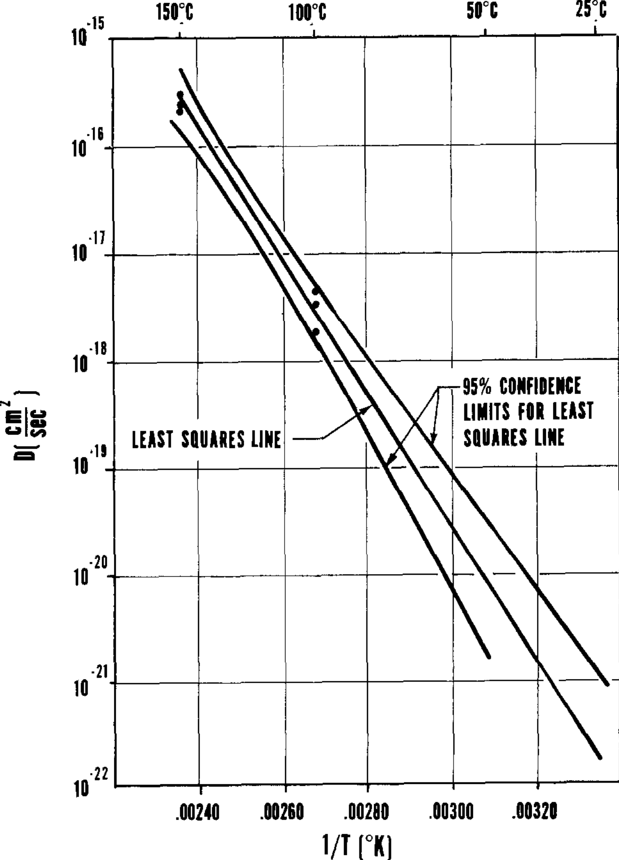

Fig. 5. Arrhenius plot of diffusion coefficient, *D* vs. 1/*T*

of the least squares line. This is shown in Fig. 5. The activation energy for diffusion, Q, obtained from the least squares line is

$$Q = 28 \pm 6 \text{ kcal/mole}$$

Another point of interest is that the square root relation

$$F = 2.26 \sqrt{\frac{Dt}{h^2}}$$

holds for most systems of interest for this model. For gold thicknesses of 3.3 μm and temperature of 50°C (along with the corresponding diffusion coefficient $D = 10^{-19}$) the time corresponding to $F = 0.6$ is of the order of 10^4 years. If we use smaller thicknesses where the fraction might be appreciable, other transport mechanisms, *e.g.*, porosity, would prevail and the model proposed here would not be applicable.

Summary

We have considered the diffusion of cobalt out of a gold layer. The theory is discussed first to relate measured quantities to diffusion coefficients. Measurements were taken and the appropriate calculations made to obtain values for the diffusion coefficients at different temperatures. Arrhenius plot extrapolations were then made to obtain rough values for the coefficients at lower temperatures.

Acknowledgments

The author would like to acknowledge Dr. Morton Antler for preparation and aging of the samples, Dr. M. R. Pinnel for useful discussion, and J. A. Smiley for assistance in taking the Auger spectra.

Multilayer Metallization with Planar Interconnect Structure Utilizing CVD Al_2O_3 Film

H. Mutoh,* Y. Mizokami,* H. Matsui, S. Hagiwara, and M. Ino

OKI Electric Industry Company, Limited, Hachioji, Tokyo, Japan

ABSTRACT

A new, multilayer metallization system has been developed for the purpose of fabricating a planar interconnect structure. This system comprises two levels of metal interconnection, and the first-level metal layer is buried in a low temperature CVD Al_2O_3 film pyrolytically deposited by $Al(i\text{-}C_3H_7O)_3$ at 420°C. The metal chosen for both layers is aluminum, and the insulator is phosphosilicate glass. In the metal processing, a self-aligned photolithographic technique is applied in which positive photoresist AZ-1350 plays an important role in forming the first-level Al layer and the Al_2O_3 film.

The recent development of large scale integration (LSI) of microcircuits has required the use of more than one level of metallization in order to achieve high packing density. In conventional multilevel structures, each metal layer is separated from the next by an insulating oxide, and there are many steps at metal edges which result in limiting the reliability and yield. In the fabrication of multilevel structures, it is highly desirable to provide a planar interconnect structure.

Recently, so-called "no step" metallizations appear to be possible by the use of anodically formed Al_2O_3 or polyimid (1, 2).

This paper describes a new multilayer metallization system in which a first-level metal layer is buried in chemically vapor deposited Al_2O_3 for the purpose of fabricating the planar interconnect structure.

Structure and Manufacturing Process

The schematic cross section of a two-level structure fabricated by this new method is shown in Fig. 1(a), in comparison with a conventional structure using a phosphosilicate glass (PSG) film as the insulating layer in Fig. 1(b). It was found that planarity of surface in the new structure is achieved with the first-level metal layer buried in Al_2O_3.

The metal process steps used in the fabrication of this new planar interconnect structure are shown in Fig. 2. After the diffusion processes are finished, an Al_2O_3 film is deposited on the wafer by pyrolysis of aluminum triisopropoxide $Al(i\text{-}C_3H_7O)_3$ (3-5) as shown in step (A). This CVD Al_2O_3 film can be deposited at a relatively low temperature of about 400°C so that the characteristics of the devices do not deteriorate. The required film patterns are prepared by photomasking with positive photoresist (AZ-1350) and etching in hot phosphoric acid as shown in steps (B) and (C). The Al_2O_3 film can be very quickly etched by phosphoric acid, which makes it possible to perform the etching process with negligible etching of the other oxide film underneath the etched Al_2O_3 film to form selectively desired patterns.

Next, without removing the photoresist, we evaporate aluminum onto the wafer up to the equivalent thickness of the Al_2O_3 film as shown in step (D).

* Electrochemical Society Active Member.

Key words: aluminum oxide film, planar interconnection, lift off, positive photoresist.

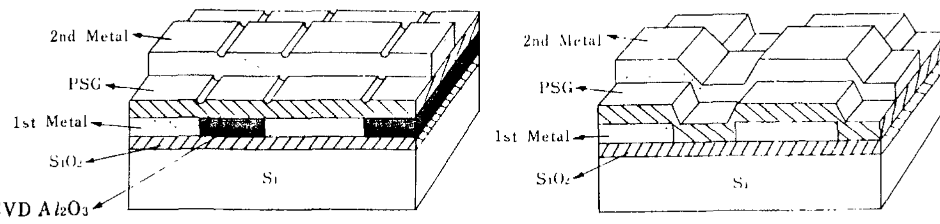

Fig. 1. Schematic cross section of two-level structure. (a, left) Structure made by new method, (b, right) structure made by conventional method.

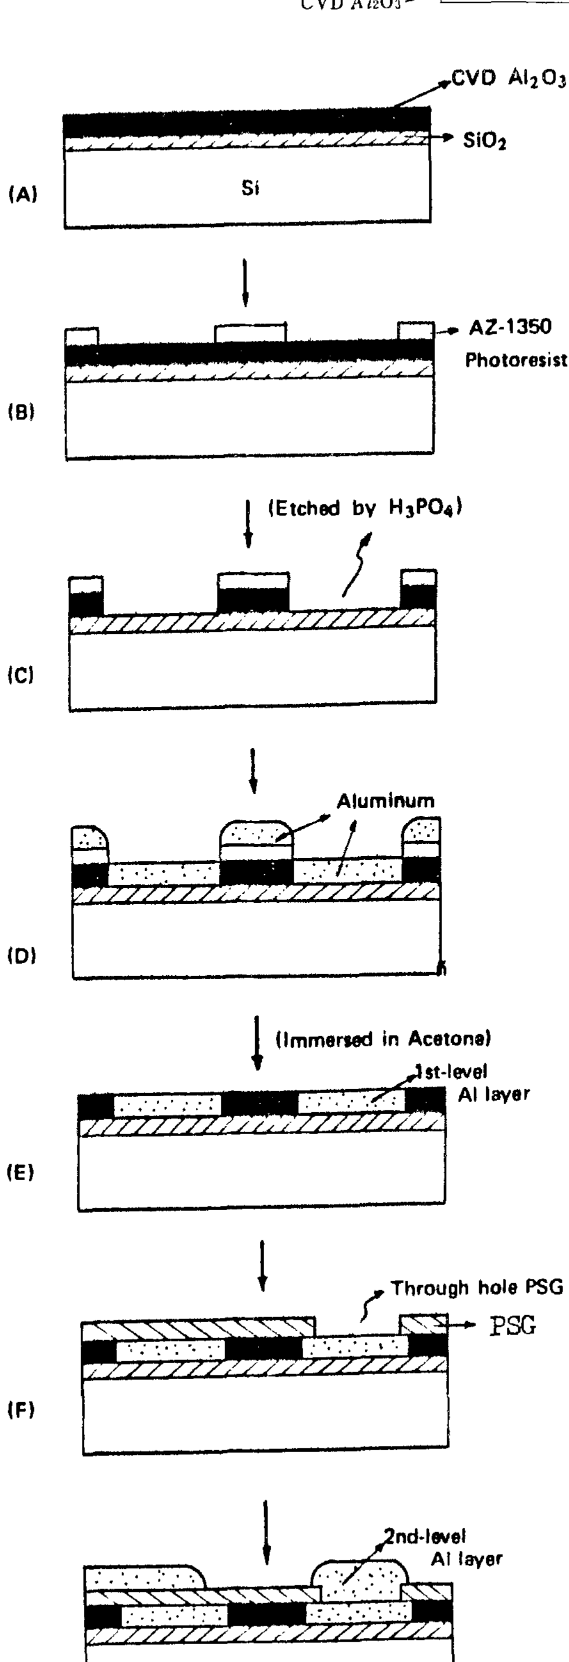

Fig. 2. Manufacturing process

When the wafer is immersed into a solution such as acetone or concentrated sulfuric acid, the AZ-1350 photoresist is dissolved in the solution and the aluminum on the resist is removed. As a result of this operation, the remaining aluminum in spaces between Al_2O_3 areas forms the first-level Al layer as shown in step (E). As mentioned, a self-aligned photolithographic technique is used in this new metallization process; *i.e.,* AZ-1350 photoresist which has been used for formation of the Al_2O_3 areas is also utilized in forming the first-level Al layer.

Additional insulator and second-level Al layer processes are the same as for conventional metal interconnection as shown in steps (F) and (G).

The insulator used in this structure is phosphosilicate glass deposited by a chemical vapor deposition technique, the insulator "through-holes" are patterned by a photoengraving technique, and the second-level Al layer is finally formed. When etching through-holes, a "plasma etching technique" is employed in our process in order to protect the first-level Al layer from corrosion by electrochemical reaction in buffered HF liquid. The specific contact resistance between the first and second-level Al layers through the through-holes was observed to be 4-5 $\times 10^{-8}$ ohm-cm^2.

Properties of CVD Al_2O_3 Film and Effects on Devices

Properties.—Formation of Al_2O_3 films.—The deposition apparatus consists essentially of a bell jar covering a rotating hot plate. A schematic of the apparatus for the deposition of Al_2O_3 film is shown in Fig. 3. Dry nitrogen gas passes through the aluminum triisopropoxide [$Al(i\text{-}C_3H_7O)_3$] vaporizer at a constant temperature of 170°C (vapor pressure = 50 mm Hg), and the organic compound vapor is mixed with more nitrogen gas and transported to the hot plate in the bell jar, where the mixture pyrolizes to form Al_2O_3. We usually deposit at 420°C in our process, when the growth rate is typically 200 Å/min. If deposition is performed in the presence of additional oxygen, the growth rate will increase.

Dielectric breakdown strength measurements.—Some dielectric breakdown strength measurements of this CVD Al_2O_3 film were made using an Al-Al_2O_3-Si structure. The results are shown in Fig. 4. The dielectric breakdown strength of films deposited at 420°C was approximately 4 $\times 10^6$ V/cm, which is about half the breakdown strength of a thermal SiO_2 film.

Cracking.—In our experiments, we observed cracks developing if thick Al_2O_3 was deposited, or if the film was deposited in the presence of additional oxygen.

In our deposition process, however, we form the film under oxygen-free conditions, so no cracks occur for film thicknesses up to 15,000Å.

Film etch rate.—This CVD Al_2O_3 film is highly soluble in phosphoric acid, especially at high temperature.

The etch rate of Al_2O_3 film in phosphoric acid is shown in Fig. 5, in comparison with that of a thermal SiO_2 film containing P_2O_5. The etch rate for the Al_2O_3 film is approximately 4000 times that of the SiO_2 film.

As an example, the etch rate for the Al_2O_3 films prepared at 420°C was typically 4000 Å/min in 85% H_3PO_4 at 70°C, whereas that of the thermal SiO_2 film containing P_2O_5 was as low as 50 Å/hr. This considerable difference between the etch rates for Al_2O_3 and SiO_2 films makes it possible to delineate selectively buried Al_2O_3 films.

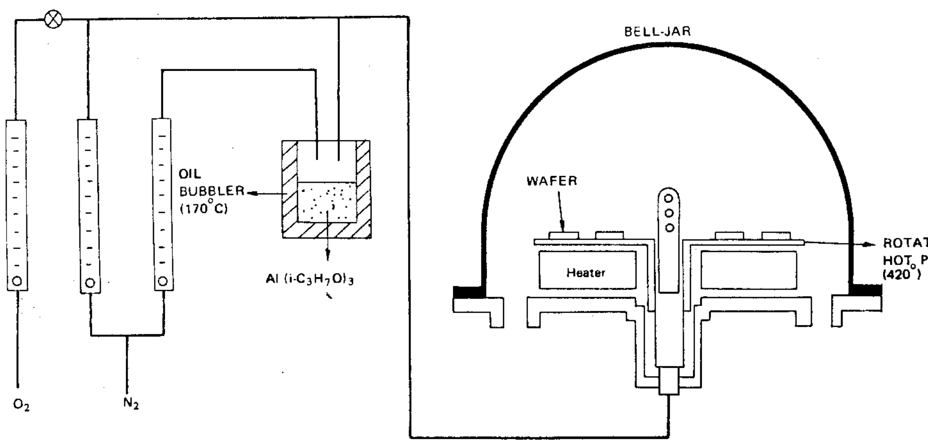

Fig. 3. Schematic of vapor deposition system for preparing Al_2O_3 film.

Effects of Al_2O_3 film on devices.—Since the CVD Al_2O_3 film is formed at a relatively low temperature of 400°-500°C, it may show several electrical properties different from high temperature formed Al_2O_3 films, especially exhibiting bad interface properties with silicon. For example, it is known from the C-V behavior that Al-Al_2O_3-Si (MAS) structures show unstable characteristics because of the presence of mobile electrons in the Al_2O_3 film and charge transfer at the gate electrodes (3, 4). In the new metallization system, however, the presence of the SiO_2 film between the Si and Al_2O_3 eliminates such effects associated with charge transfer at the Si-SiO_2 interface. The flatband surface-state charge density (N_{FB}) characteristics of Al-Al_2O_3-SiO_2-Si structures are shown in Fig. 6, where N_{FB} is plotted as a function of the Al_2O_3 and SiO_2 film thicknesses. It is noted that the thicker the SiO_2 film becomes, the less pronounced the tendency of the Al_2O_3 film to make the surface of the Si more positive.

When this structure is applied to such devices as bipolar IC's, inversion of the collector conductivity may occur. The resistivity of the collector region, however, is usually as high as about 1 ohm-cm, and the thickness of the SiO_2 film is as high as about 7000Å, so we consider it to be free from the influence of Al_2O_3. In this metal process, the Al_2O_3 film is deposited after a contact photolithographic step. Therefore, an insulating layer may be formed on the exposed silicon in the bell jar, which would make it difficult to establish good ohmic contact or to form a Schottky barrier diode. This problem can be overcome by dipping the wafer in a buffered HF liquid just before the Al evaporation step.

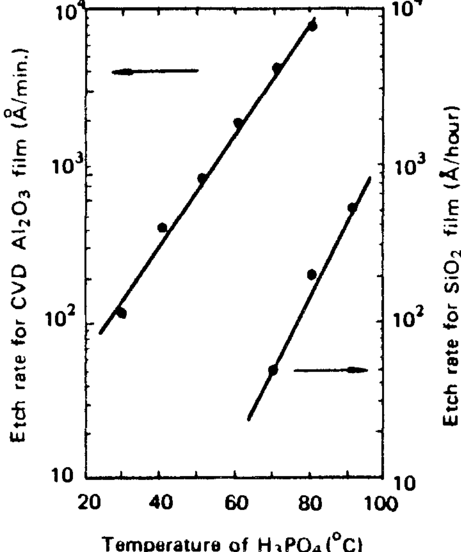

Fig. 5. Comparison of etch rates for CVD Al_2O_3 film and SiO_2 film.

Reliability

Continuity of second-level Al layer.—Observation by SEM and angle-lapping.—Scanning electron microscopy and angle-lapping were used to examine the features of crossovers of leads in new and conventional structures as shown in Fig. 7. Photograph (A) and (C) show the cross section of a chip made by the new method. The thickness of the first-level Al layer is 6500Å, the same as that of the Al_2O_3 film, the interlayer phosphosilicate glass 8000Å, and the second-level Al layer 12,000Å. On the other hand, photograph (B) and (D) show the cross section of another chip made by a conventional method under the same conditions. These photographs indicate that the new structure is very beneficial in realizing surface planarity, whereas

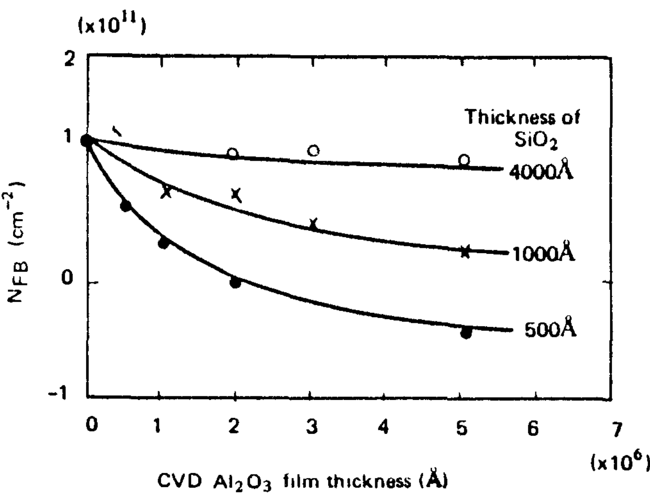

Fig. 6. Characteristics of N_{FB} in Al-Al_2O_3-SiO_2-Si structures

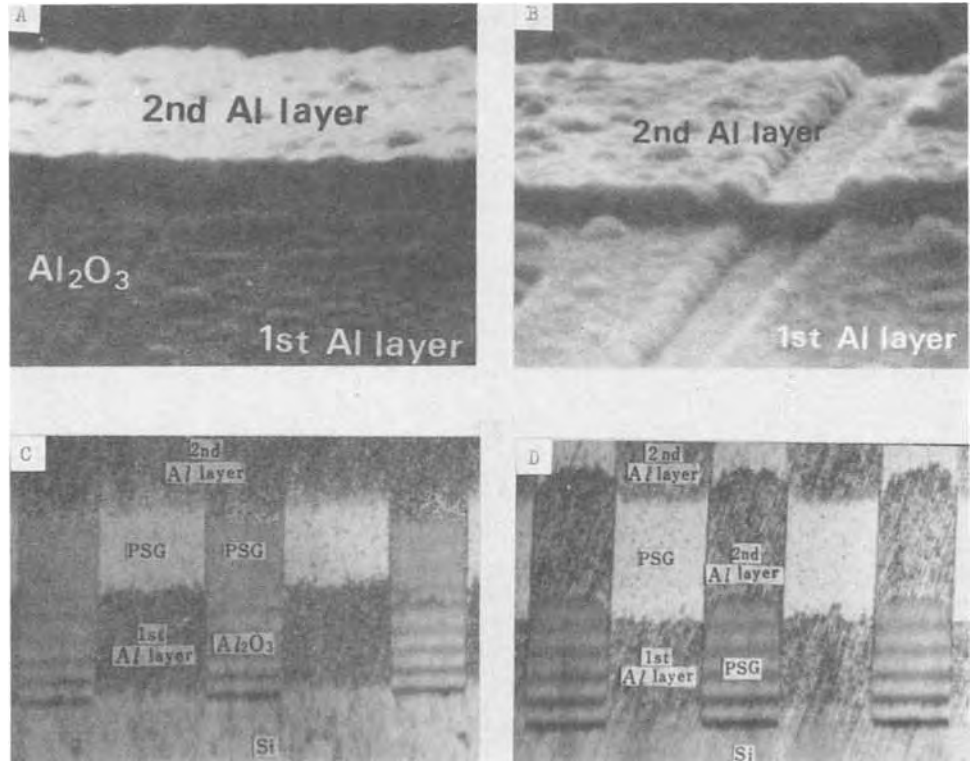

Fig. 7. Scanning electron micrographs (A and B) of crossover and optical photographs (C and D) of angle-lapped surface. A and C, structure made by new method; B and D, structure made by conventional method.

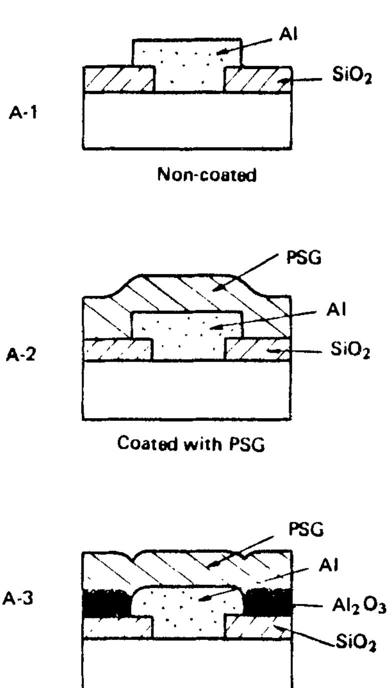
the second-level Al layer of the conventional structure is apt to be cut at the step.

Opens in second Al layer.—The continuity of the second Al layer for several different thicknesses of the first Al layer was checked.

Test patterns were fabricated in which the first Al layers of 20 μm width were 3000, 4500, 7000, and 10,000Å thick, and the second Al layers of 20 μm width were maintained 12,000Å thick. There were the same number of chips for each structure and each chip had 800 crossover points.

The contrast between the number of opens in the second Al layers for the new and conventional structures is presented in Table I. These data show that as long as the thickness of the first Al layer is less than 4500Å, there are no opens for both the new and conventional structures. But when the first Al layer is up to 10,000Å in thickness, the new structure eliminates failures resulting from opens of the second Al layer.

Mean time to failure of the first and second Al layers. —*First Al layer.*—It has been observed that electromigration in aluminum is produced by high current



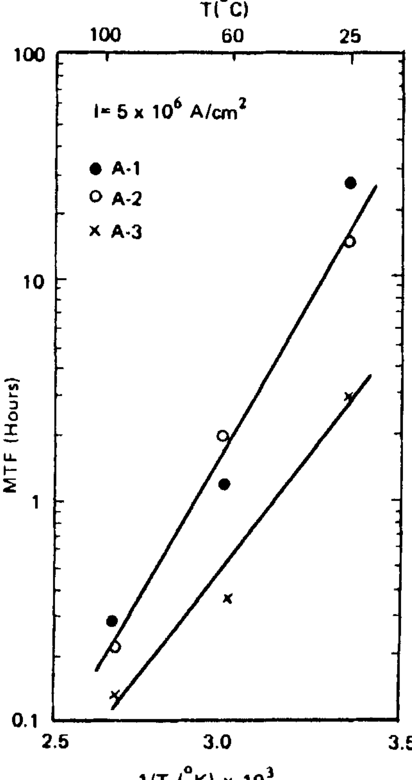


Fig. 8. Mean time to failure *vs.* temperature of first Al layer for three types of test structure. (a, left) Test structures, (b, right) MTF *vs.* temperature.

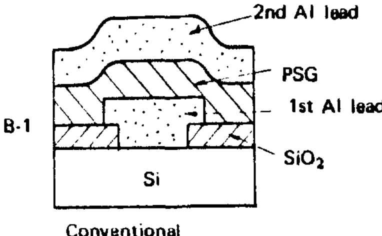
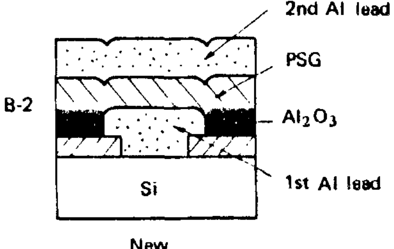
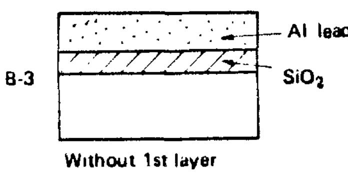
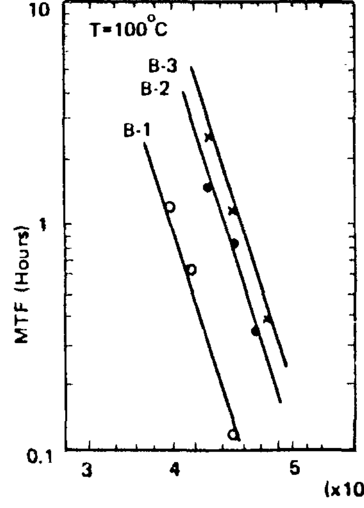






(a) Test structures



(b) MTF vs. current density

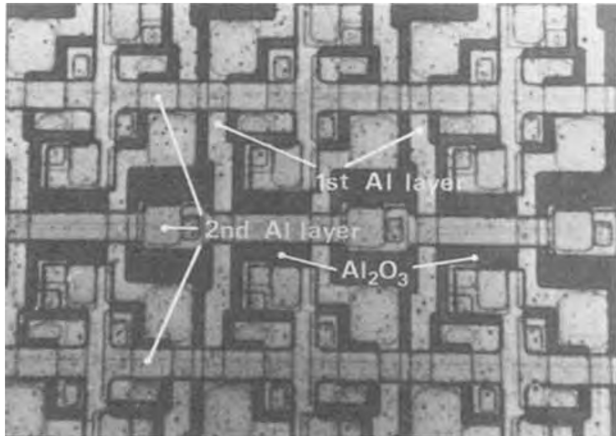

Fig. 10. Two-level LSI pattern using CVD Al_2O_3

densities, which decrease the mean time to failure (MTF) (6). The MTF can be increased by coating the aluminum layer. In the new metal structure, as the first Al layer is coated with Al_2O_3 and PSG films, the MTF is expected to be greater than that of a noncoated Al layer.

Experiments were carried out to evaluate the effects on the MTF of coated first Al layers. In order to compare the MTF of the new structure with others, three types of test structures A-1, A-2, and A-3 were fabricated as shown in Fig. 8(a) where the first Al layer of A-1 is noncoated, that of A-2 is completely coated with PSG, and that of A-3 is coated with Al_2O_3 and PSG. Test strips 20 μm in width and 3000Å in thickness were subjected to a current density of 5 × 10^6 A/cm^2 at 25°, 60°, and 100°C. Aluminum was evaporated at a rate of 40 Å/sec using electron beam evaporation.

Table I. Number of opens in second Al layer

Thickness of first Al layer, A	New structure	Conventional structure
3,000	0/50	0/50
4,500	0/50	0/50
7,000	0/50	23/50
10,000	0/50	50/50

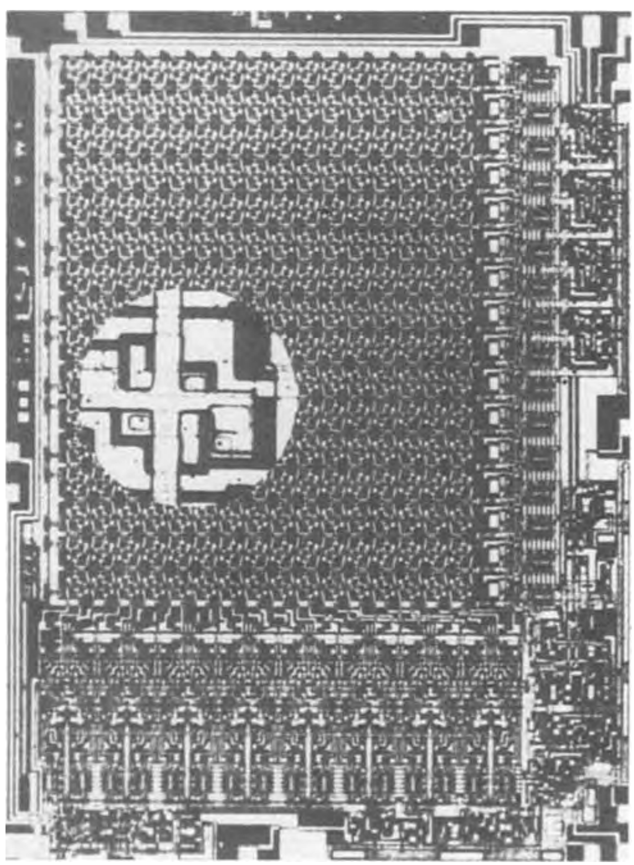

Fig. 11. 256 bit bipolar RAM chip with planar interconnect structure utilizing CVD Al_2O_3.

Data for each structure of MTF *vs.* temperature is presented in Fig. 8(b). We can see that both the new and conventional structures have almost equal MTF, which is greater than that of the noncoated structure.

Second Al layer.—Similarly, experiments were carried out to evaluate the MTF of the second Al layers. Test strips 15 μm in width and 12,000Å in thickness were subjected to a temperature of 100°C at various current densities. In order to compare the MTF of the new structure with others, three types of test structures B-1, B-2, and B-3 were fabricated as shown in Fig. 9(a), where B-1 is a conventional structure, B-2 is the new structure, and B-3 is a test structure without a first Al layer.

Data for each structure of the MTF *vs.* current density is presented in Fig. 9(b). The thickness of the first Al layer is 3000Å, and that of the PSG film is 8000Å. It is noticed that the MTF for the new structure is about five times greater than that of the conventional structure.

Applications

This new planar interconnection technique can be applied to fabricate various LSI chips.

Figure 10 shows an example of a two-level LSI pattern utilizing this technique, and a photograph of a 256 bit bipolar RAM chip fabricated using this new structure is shown in Fig. 11.

Conclusions

A new planar metallization technique has been described for fabricating a two-level structure utilizing CVD Al_2O_3.

It has been shown that a planar interconnect structure can be fabricated using low temperature CVD Al_2O_3 as an insulator between areas of the first-level Al layer, a self-aligned photolithographic technique can be applied in which positive photoresist AZ plays an important role in forming the first-level Al layer and the Al_2O_3 film, and the process for forming the CVD Al_2O_3 film is simple and economical.

This new structure should provide a useful method for establishing a new approach to LSI multilayer structures.

Determination of Excess Zn in ZnO

The Phase Boundary Zn-Zn_{1+x}O

K. I. Hagemark and P. E. Toren

3M Central Research Laboratories, St. Paul, Minnesota 55101

ABSTRACT

The excess Zn of Zn-doped ZnO has been determined using two different methods. An electrochemical method was used as a direct method. Hall effect measurements at 77°-300°K were used as an indirect method. The agreement between the results from the two methods is good. The Zn-Zn_{1+x}O phase boundary is given in the range 700°-1100°C as $\log x_{Zn}$ (ppma) $= -4700/T + 5.6$.

Excess Zn accounts for the n-type character of ZnO. Small changes in the stoichiometric composition have a drastic effect on the physical and chemical properties. However, the Zn concentration level is less than 100 ppm and thus difficult to determine by conventional analytical techniques. Some chemical analytical methods have been reported previously (1-4).

In this paper we discuss the use of two methods, an electrochemical method as a direct chemical method and Hall effect measurements as an indirect method. ZnO single crystals have been equilibrated at 700°-1100°C in Zn vapors from Zn metal kept at the same temperature as ZnO and rapidly quenched to room temperature. As a result Zn-saturated ZnO crystals were obtained. After the Hall effect measurements at 77°-300°K, the crystals were analyzed by an electrochemical technique similar to the one developed by Engell (3). The agreement between the methods is good.

Key words: zinc oxide, coulometry, Hall effect.

Experimental

Crystals.—3M vapor phase grown ZnO crystals were used. Emission spectrometric and mass spectrographic analyses showed no major impurities above 1 ppma (atomic) (4.2×10^{16} atoms-cm^{-3}) except for Si (10-20 ppma). The crystals were cut into bars of typical size $2 \times 2 \times 15$ mm. Excess Zn was introduced into the ZnO crystals by heating the crystals in sealed silica ampuls in saturated vapor of Zn. Doping runs were performed at 700°, 800°, 900°, 1000°, and 1100°C for a length of 2 weeks at the lower temperatures to 2 days at the higher temperatures. After the heat-treatments the crystals were rapidly cooled to room

temperature. A hot concentrated H_3PO_4 etch was used to remove about 50μ from the surface.

Electrical measurements.—A conventional Hall method was used. Details of the method and apparatus are given elsewhere (5).

Electrochemical techniques.—Electrochemical measurements were carried out in a 3-compartment cell with fritted glass disks separating the compartments. The working electrode compartment contained a mercury pool which formed the electrical contact between the external circuit and the ZnO crystal which was floated on it. A platinum counterelectrode and a saturated calomel reference electrode (SCE) were placed in the other two cell compartments.

A Wenking potentiostat was used to maintain the ZnO crystal at a constant potential *vs.* the reference electrode.

Electrolysis current was integrated by a simple analog integrator, built in-house using "μA 741" integrated circuit operational amplifiers and a high quality 10 μF integrating capacitor.

Experimental measurements were carried out by filling the cell compartments with 1.8M H_2SO_4 electrolyte solution, connecting the electrodes (with the mercury pool as the working electrode), and applying the desired working electrode potential while bubbling nitrogen through the stirred solution to remove dissolved oxygen. When the background current at the preset potential (usually −0.2V *vs.* SCE) had decreased to its minimum level (less than 0.01 mA) a weighed crystal of ZnO was dropped into the cell and floated on the mercury pool. The current resulting from the oxidation of Zn° as the ZnO dissolved in the acid electrolyte was integrated and the result used to calculate the equivalents of oxidizable material present in the ZnO crystal. Most of the measurements were made at 40°-50°C to increase the dissolution rate of the ZnO and thus minimize the background current correction.

Results and Discussion

Electrical transport properties.—The electrical resistivity ρ, the carrier concentration n, and Hall mobility μ_H have been measured in the range 77°-300°K. Only the results at 300° and 100°K are given in Table I.

The concentration of excess Zn can be calculated from (*i*) the relationship of the carrier concentration *vs.* the temperature and (*ii*) the Hall mobility at lower temperatures where defect scattering is important.

Carrier concentration analysis.—From semiconduction statistics (6) the concentration of donors N_D and acceptors N_A can be calculated. A more detailed discussion of Zn-doped ZnO is given in Ref. (5) and (7). We have assumed that excess zinc is incorporated into ZnO lattice as hydrogen-type shallow donors. The results of the calculations are given in Table I. We are assuming the excess Zn, x_{Zn}, is simply given by

$$x_{Zn} = N_D - N_A \qquad [1]$$

The ZnO crystal contains 4.21×10^{22} Zn atoms-cm^{-3}. Thus 1 ppma corresponds to 4.21×10^{16} atoms-cm^{-3}.

Hall mobility analysis.—The total mobility μ can be assumed to be expressed as

$$\frac{1}{\mu} = \frac{1}{\mu_L} + \frac{1}{\mu_I} + \frac{1}{\mu_N} \qquad [2]$$

where the lattice mobility $\mu_L = 2.0 \times 10^3$ cm^2-V^{-1}-sec^{-1} at 100°K (9); μ_I is the ionized defect scattering mobility and μ_N is the neutral defect scattering mobility. The expressions for μ_I and μ_N are given in previous papers (5, 8).

The concentration of excess Zn can be estimated by calculating the concentration of ionized centers N_I and of neutral centers N_N. We will only consider the data at 100°K. Since we are dealing with strongly n-type ZnO we are assuming a low concentration of acceptors. Thus

$$N_I \approx n(100^{\circ}K)$$

where n is the carrier concentration at 100°K. By knowing N_I and n, μ_I can be calculated [from Ref. (5)]. The value for μ_N can then be found from Eq. [2]. The concentration of neutral centers is then (5)

$$N_N = \frac{5.39 \times 10^{20}}{\mu_N} \ (cm^{-3})$$

and the concentration of excess Zn is

$$x_{Zn} \approx n(100^{\circ}K) + N_N$$

The results of the calculations, given in Table I, compare favorably with the results from the carrier concentration analysis.

Electrochemical measurements.—The electrochemical method reported here is similar to Engell's in that both methods involve the measurement of electrochemical oxidation of zinc occurring simultaneously with the chemical dissolution of zinc oxide. Engell calculated the oxidation rate corresponding to a measured steady-state oxidation current, and compared it to the total dissolution rate of the oxide electrode. Our procedure, based on integration of the electrochemical current, is not limited to steady-state currents or electrodes of constant surface area.

Both procedures are based on two assumptions concerning the behavior of the ZnO crystal in the cell: (*i*) that the electrochemical oxidation of Zn° is much more rapid than the chemical solution of metallic zinc in dilute sulfuric acid, and (*ii*) that Zn° is the only oxidizable material present in the ZnO crystal. The first assumption was checked by adding small particles of metallic zinc to the cell in place of ZnO crystals. The integrated current corresponded to greater than 95% of that predicted by Faraday's law. The second assumption rested on the spectroscopic evidence that no metal other than zinc was present in the crystals.

The factors limiting measurement accuracy were the background current and possible integrator drift during the course of the measurement. The effect of both of these factors was minimized by carrying out the measurements at 40°-50°C instead of at room temperature. The higher temperature decreased the time required to dissolve a ZnO crystal from several hours to about 40 min.

Atomic ppm Zn was calculated from

$$\text{ppma} = \frac{(\text{coulombs})(81.38)(10^6)}{(\text{mg ZnO})(96.5)(2)}$$

Table I. Results

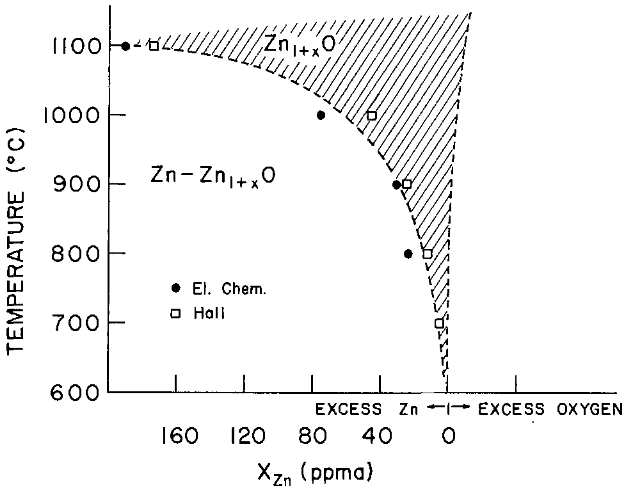

Fig. 1. A portion of the phase diagram $Zn\text{-}Zn_{1+x}O$ is shown. The excess Zn boundary has been determined. ● represents the electrochemical data and □ represents results from the Hall effect analysis. The excess oxygen boundary is suggested only.

Results of these measurements are summarized in the last column of Table I.

The phase boundary $Zn\text{-}Zn_{1+x}O$.—The values for x_{Zn} in Table I represent the phase boundary $Zn\text{-}Zn_{1+x}O$ (the maximum solubility of Zn in $Zn_{1+x}O$). A portion of the phase diagram $Zn\text{-}Zn_{1+x}O$ is shown in Fig. 1. The excess oxygen limit of $Zn_{1+x}O$ is probably very close to stoichiometric ZnO (p-type ZnO has not yet been observed).

The phase boundary is also shown in Fig. 2 as log x_{Zn} *vs.* $1/T$ and may be represented as

$$\log x_{Zn} = -\frac{4700}{T} + 5.6$$

This corresponds to average values of the heat of solution $\Delta H = 22$ kcal/mole and entropy of solution $\Delta S = 26$ eu in the temperature range 700°-1100°C of Zn saturated ZnO.

The Preparation and Properties of Aluminum Nitride Films

T. L. Chu* and R. W. Kelm, Jr.*

Institute of Technology, Southern Methodist University, Dallas, Texas 75275

ABSTRACT

Aluminum nitride films have been deposited on silicon substrates at 800°-1200°C by the pyrolysis of an aluminum trichloride-ammonia complex, $AlCl_3 \cdot 3NH_3$, in a gas flow system. The deposit was transparent, tightly adherent to the substrate, and was confirmed to be aluminum nitride by x-ray and electron diffraction techniques. The deposited aluminum nitride films were found to be polycrystalline with the crystallite size increasing with increasing temperature of deposition. Other properties of aluminum nitride films relevant to device applications, including density, refractive index, dissolution rate, dielectric constant, and masking ability, have been determined. These properties indicate that aluminum nitride films have potential as a dielectric in electronic devices.

Aluminum nitride is a refractory, large energy gap material [sublimation temperature 2400°C (1), energy gap 5.9-6.2 eV (2, 3)] and has chemical, physical, and electrical properties suitable for several applications in electronic devices. For example, its large energy gap, good thermal stability [equilibrium vapor pressure of nitrogen at 1500°C: 0.05 Torr (4)], and chemical inertness [stable in air at temperatures up to 700°C (5)] suggest that aluminum nitride is a good dielectric for active and passive components in semiconductor devices. Aluminum nitride, being a piezoelectric material with a high acoustic velocity, is also well suited for the fabrication of surface wave acoustic devices.

Aluminum nitride has been prepared by several techniques, such as the direct combination of the elements and chemical reactions of gaseous aluminum and nitrogen-containing compounds on substrate surfaces. The direct combination technique requires temperatures in excess of 1500°C (2, 5, 6) and is not suitable for device applications. On the other hand, aluminum nitride films have been deposited on the surfaces of refractory metals, insulators, and semiconductors at considerably lower temperatures by the reaction of aluminum trichloride with ammonia (1, 3, 7-12) and the reaction of trimethylaluminum with ammonia (13). Aluminum nitride films up to 5 μm in thickness have also been deposited on metallic substrates by diode reactive sputtering, and the dielectric properties of sputtered aluminum nitride films were found to be superior to those of bulk polycrystalline material (14). The chemical deposition technique appears to be more compatible with the current device technology; however, the utilization of aluminum nitride in semiconductor devices has not been explored.

In this work, aluminum nitride films have been deposited on single crystal silicon substrates by the pyrolysis of an aluminum trichloride-ammonia complex in a gas flow system. The properties of the deposited films, such as structure, composition, density, refractive index, dissolution rate, dielectric constant, masking ability, etc., have been determined. The experimental methods and results are discussed in this paper.

Preparation of Aluminum Nitride Films

The ammonolysis of aluminum trichloride is commonly used for the deposition of aluminum nitride films. Because of the hygroscopic nature of aluminum trichloride, an aluminum trichloride-ammonia complex was used as the starting material. The complex was prepared by saturating reagent grade anhydrous aluminum trichloride in a fused silica reaction tube with anhydrous ammonia at room temperature. The resulting mass was heated at 350°C in an ammonia flow, and the complex sublimed yielding a white crystalline powder. The composition of the complex, determined by dissolving a weighed amount of the specimen in a known volume of 0.1*N* hydrochloric acid and titrating the excess acid with 0.1*N* sodium hydroxide, was $AlCl_3 \cdot 3NH_3$. This complex is considerably more stable in the laboratory ambient than aluminum trichloride. Its vapor pressure was determined from the extent of vaporization in a sealed silica tube after heating at a predetermined temperature for 24 hr. The vapor pressure data in the temperature range 500°-800°K are shown in Fig. 1; the complex has sufficient vapor pressure at temperatures below 300°C for utilization in the deposition of aluminum nitride. The heat of vaporization of the complex calculated from the slope of this plot was 11.8 ± 0.2 kcal/mole.

Key words: aluminum nitride, chemical deposition, electronic devices, silicon.

The deposition of aluminum nitride by the pyrolysis of the aluminum trichloride-ammonia complex in a gas flow system was carried out using an apparatus shown schematically in Fig. 2. The diluent gases used in the deposition process were commercial hydrogen purified by diffusion through a palladium-silver alloy and Matheson anhydrous ammonia of better than 99.99% purity. The reaction tube was made of clear fused silica, 55 mm ID and 3 ft long. A fused silica boat containing the aluminum trichloride-ammonia complex was maintained at 250°C by using an external resistance heater, and hydrogen or a 6:1 hydrogen-ammonia mixture at a flow rate of 30 liters/min was used to carry the complex to the substrate surface. The silicon substrates with main faces of {111} orientation were n-type, 5-20 ohm-cm resistivity, and were mechanically polished and chemically etched in the usual manner. They were supported on a silicon carbide-coated graphite susceptor, and the susceptor was heated externally by an rf generator. Prior to the deposition of aluminum nitride, the substrates were heated at 1150°C in hydrogen for ½ hr to remove the oxide on the surface. In some experiments, the substrate surfaces were etched *in situ* at 1170°C with a hydrogen-hydrogen chloride mixture containing 2% hydrogen chloride. The deposition of aluminum nitride was carried out at substrate temperatures in the range of 800°-1200°C, and the deposition time was usually 15-45 min. The thickness of aluminum nitride films on silicon substrates was determined by removing part of the film and measuring the height of the step generated with a Sloan Dektak and Graphic Chart Recorder.

Under the conditions described above, the deposited films are transparent and tightly adherent to the substrate. The average deposition rates in the temperature range 800°-1200°C are shown in Fig. 3. The deposition rate decreased with increasing temperature from 160 Å/min at 800°C to 120 Å/min at 900°C and 90 Å/min at 1000°C. This decrease of deposition rate is due presumably to the increased contribution of gas phase nucleation at high temperatures. The gas phase nucleation becomes more pronounced at higher concentrations of the aluminum trichloride-ammonia complex in the reactant mixture. For example, films deposited at a rate of 750 Å/min at 900°C had a cloudy appearance as a result of the enhanced gas phase nucleation.

The films deposited in the temperature range 800°-1100°C were analyzed by the x-ray diffraction technique. Silicon substrates were removed from the specimens by etching with a nitric acid-hydrofluoric acid mixture, and the resulting material was pulverized and examined by the Debye-Scherrer technique using nickel-filtered CuKα radiation. The diffraction patterns were identical with those reported for aluminum nitride (15), thus confirming that the deposited films were aluminum nitride.

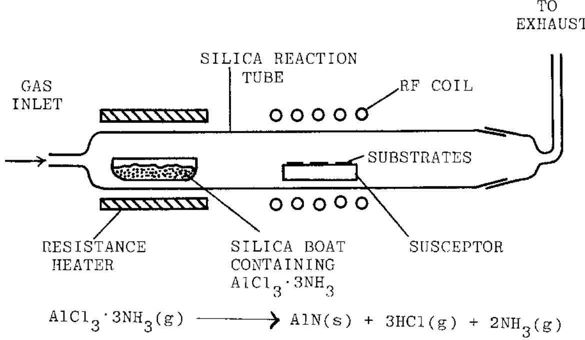

Fig. 2. Schematic of the apparatus used for the deposition of aluminum nitride films.

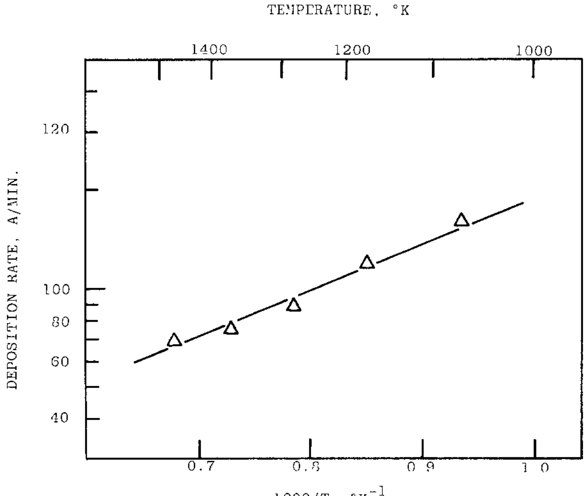

Fig. 3. Average deposition rate of aluminum nitride films as a function of temperature.

Properties of Aluminum Nitride Films

Structure.—Aluminum nitride films deposited on silicon substrates under proper conditions were uniform, transparent, and highly adherent to the substrate. They showed no structural features when examined with an optical microscope. Several films were investigated by transmission electron microscopy using a Hitachi Model 11BU electron microscope after removing the substrates with a nitric acid-hydrofluoric acid mixture. Figure 4 shows the micrographs of aluminum nitride films deposited in the temperature range 800°-1100°C. All films were polycrystalline, and the average linear dimensions of the crystallites increased with increasing deposition temperature. Typical dimensions of crystallites were 100, 200, 600, 1100, and 2200Å in films deposited at 800°, 900°, 1000°, 1100°, and 1200°C, respectively. This increase in crystallite size with temperature is to be expected. The diffraction patterns of aluminum nitride films deposited at various temperatures are shown in Fig. 5. The d-spacings measured from these patterns further confirm that all films are aluminum nitride. Figure 5

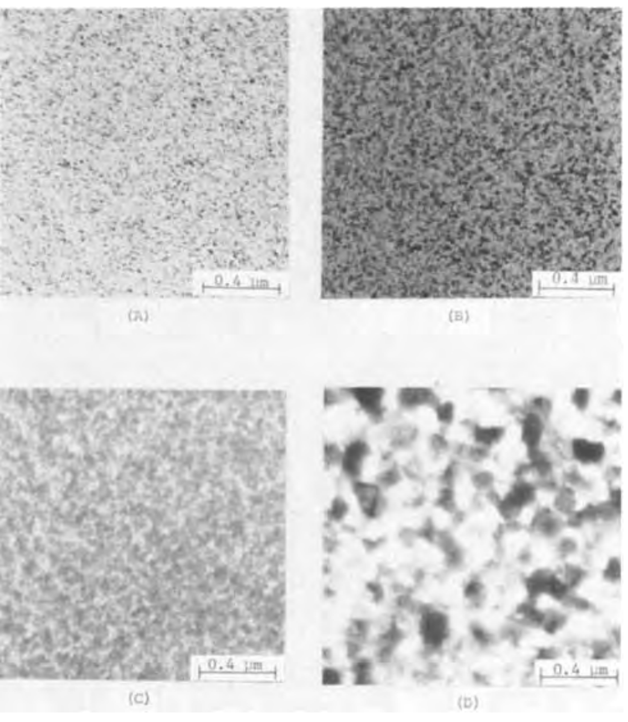

Fig. 4. Transmission electron micrographs of aluminum nitride films deposited at (A) 800°C, (B) 900°C, (C) 1000°C, and (D) 1100°C.

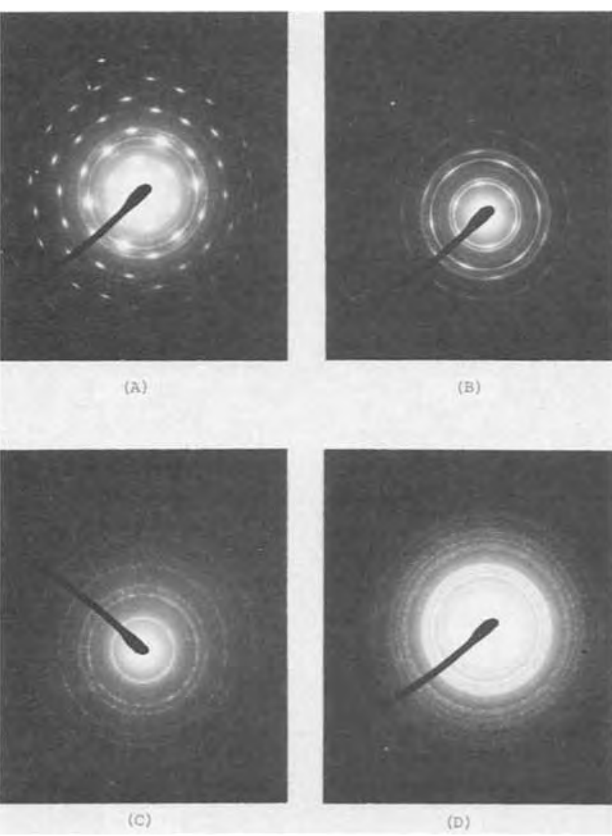

Fig. 5. Electron diffraction patterns of aluminum nitride films deposited at (A) 800°C, (B) 900°C, (C) 1100°C. and (D) 1200°C.

indicates that aluminum nitride films deposited at temperatures above 1000°K are polycrystalline and that preferred orientations are increasingly apparent with decreasing temperature of deposition. The single crystallinity of the substrates appears to have little or no effect on the structural properties of aluminum nitride since aluminum nitride films deposited on the surface of silicon dioxide were essentially the same as those on silicon substrates.

Density, refractive index, and optical absorption.— The density of aluminum nitride films deposited at various temperatures was determined by the floating equilibrium technique using a mixture of 1-bromo 2-iodo benzene and methylene iodide. The temperature of deposition was found to affect only slightly the density of aluminum nitride. Aluminum nitride films deposited at 800°, 900°, 1000°, and 1100°C have densities of 3.15, 3.18, 3.18, and 3.20 ± 0.01 g/cm^3, respectively, as compared with a reported value of 3.13 g/cm^3 (12) and the theoretical density of 3.26 g/cm^3.

The refractive index of aluminum nitride films deposited in the temperature range 800°-1200°C was determined by the Becke line method to be 1.991 ± 0.003, irrespective of the deposition temperature. A few samples were also measured by the ellipsometric technique; the results, though not as reproducible, were usually in good agreement with those by the Becke line method. However, refractive indices as high as 2.17 ± 0.05 have been reported for single crystalline aluminum nitride prepared by the direct reaction of aluminum with nitrogen (16).

The optical absorption spectra of aluminum nitride films deposited under various conditions were taken on a Beckman Model DK-2 spectrophotometer at room temperature. Typical results are shown in Fig. 6, where the thickness of the aluminum nitride film was 18 μm for curve A and 13 μm for curve B. The fundamental absorption edge for all specimens measured was found to be 5.9 ± 0.2 eV, in agreement with that observed by others (2). However, the films deposited at very high rates, 700 Å/min or higher irrespective of deposition temperature, exhibited an additional absorption band in the 3.0 to 3.2 μm region (curve A) while those deposited at low rates, 300 Å/min or lower, showed no absorption in this region (curve B). The absorption in the 3.0-3.2 μm region is presumably due to the N-H or Al-Cl bonds in aluminum nitride films deposited at high rates. As stated previously, the gas phase nucleation becomes pronounced at high deposition rates. The decomposition of the aluminum trichloride-ammonia complex in the gas phase may not proceed to completion, and the deposited material contained N-H or Al-Cl bonds. Thus, the use of low deposition rates is essential for obtaining good quality aluminum nitride films.

Dissolution behavior.—The deposited aluminum nitride films are soluble in phosphoric acid and sodium hydroxide solutions. To determine the dissolute rate of aluminum nitride films, a portion of the specimen was covered with Apiezon Q wax or photoresist, and the specimen was immersed in the etchant with constant agitation for various lengths of time. The dissolution rate was then determined by removing the protective coating and measuring the difference in the step heights using the Dektak system.

The dissolution rate of aluminum nitride films, deposited in the temperature range 800°-1200°C, in a 10% sodium hydroxide solution was determined in the

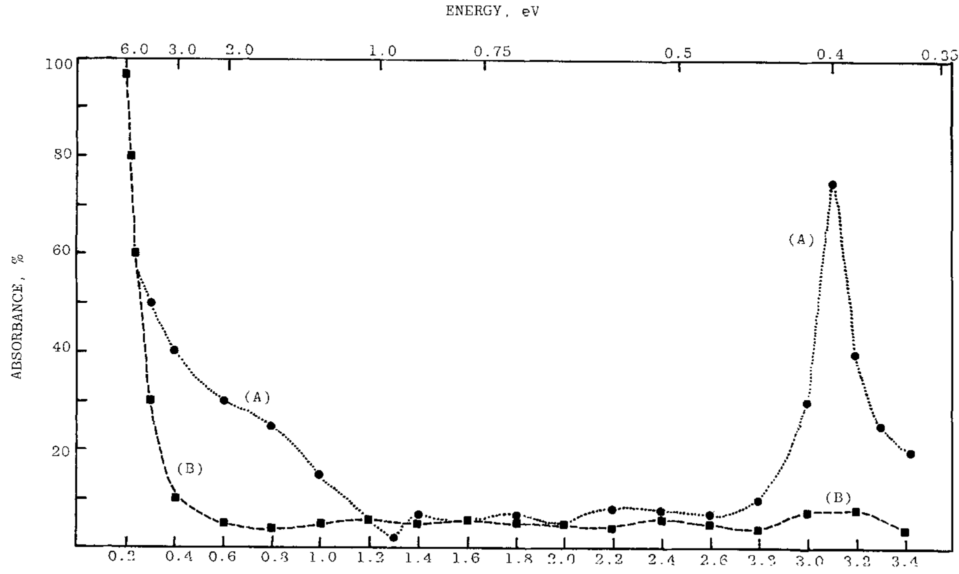

Fig. 6. Optical absorption spectra of aluminum nitride films deposited at a rate of about 700 Å/min (A) and at a rate of about 300 Å/min (B).

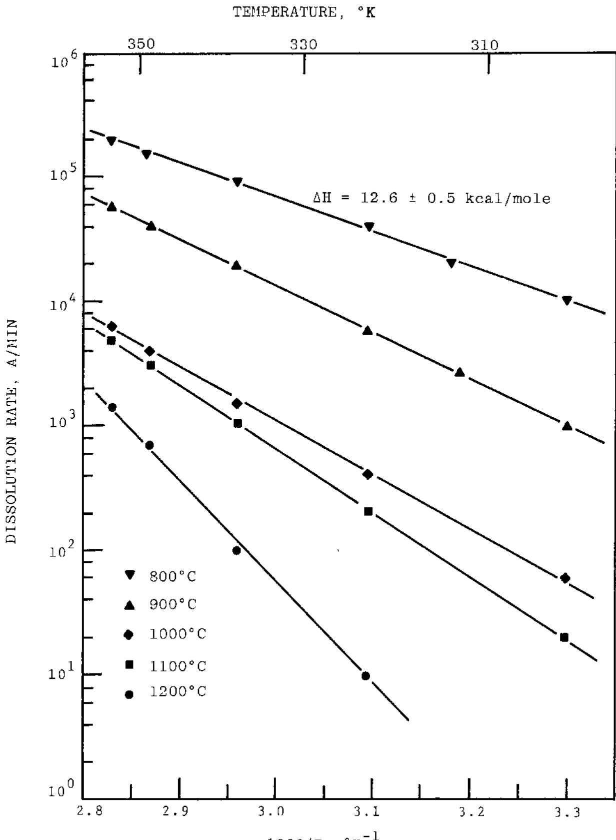

Fig. 7. Dissolution rate of aluminum nitride films, deposited in the temperature range 800°-1200°C, in 10% sodium hydroxide solution.

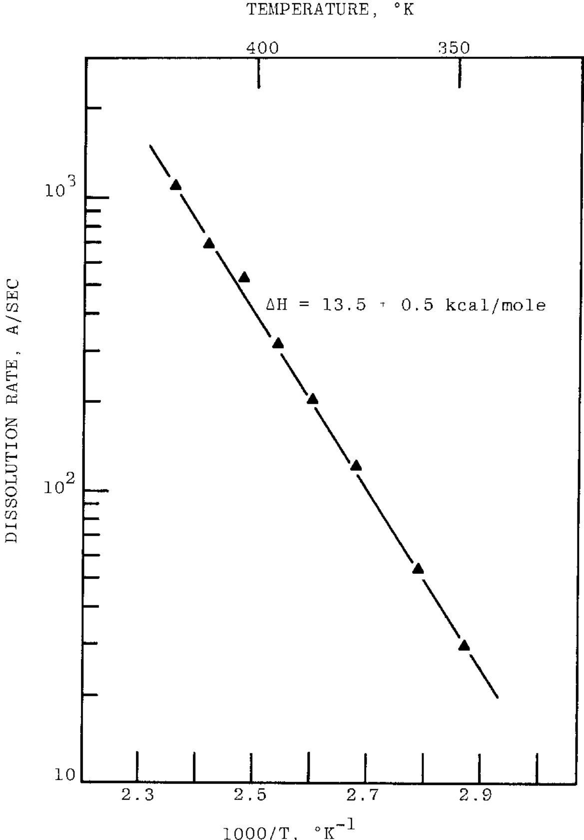

Fig. 8. Dissolution rate of aluminum nitride films deposited at 900°C in 85% phosphoric acid.

temperature range 30°-80°C. The results are shown in Fig. 7. At a given temperature, the dissolution rate of aluminum nitride films decreased with increasing deposition temperature, due presumably to the larger crystallites of aluminum nitride deposited at higher temperatures. Also, the dissolution rate of aluminum nitride films deposited at low temperatures was found to remain the same after annealing at higher temperatures, indicating negligible grain growth. The activation energy of dissolution for aluminum nitride films deposited at 800°C was found to be 12.6 ± 0.5 kcal/mole. The activation energy also increased with increasing deposition temperature. The relatively large activation energy indicates that the dissolution of aluminum nitride films is a surface-reaction controlled process.

The dissolution rate of aluminum nitride films deposited at 900°C was also determined using an 85% phosphoric acid solution. At temperatures up to 50°C, the dissolution rate of aluminum nitride was negligible. Figure 8 shows the dissolution rate in the temperature range 75°-150°C, and the activation energy of this dissolution was found to be 13.5 ± 0.5 kcal/mole, similar to the use of sodium hydroxide solution as an etchant.

Both sodium hydroxide and phosphoric acid solutions used in this work were found to produce clean and structureless surfaces, similar in appearance to the as-grown aluminum nitride films, when examined with an optical microscope.

Masking ability.—To explore the usefulness of aluminum nitride in silicon devices, its capabilities and limitations as masks against the diffusion of boron, phosphorus, aluminum, and gallium into silicon were investigated. Aluminum nitride films of 1000-1700Å thickness, deposited on silicon substrates at 900°C were used in the diffusion experiments. The substrates were n-type, 5-10 ohm-cm resistivity for the diffusion of boron, aluminum, and gallium, and were p-type, 10-20 ohm-cm for the diffusion of phosphorus. The aluminum nitride film was removed completely from circular areas (usually 500 μm diameter) of the specimen by photolithographic techniques using sodium hydroxide or phosphoric acid as an etchant. Sharp, well-defined edges were obtained with virtually no undercutting.

The boron diffusion was carried out by depositing boron oxide glass on the specimen surface at 970°C for 40 min from a boron nitride source followed by redistribution at 1300°C for 1 hr. In the phosphorus diffusion process, phosphorus oxide glass was deposited on the specimen surface at 1000°C for 30 min using phosphorus oxytrichloride as the source, and the redistribution was carried out at 1150°C for 1.5 hr. After the diffusion process, an unmasked region of the specimen was angle-lapped, and the aluminum nitride mask was removed by etching. The resistivity profile on the masked and unmasked regions of the main face and on the beveled surface was measured by the spreading resistance technique (17). The results for the boron diffusion into n-type silicon and the phosphorus diffusion into p-type silicon are shown in Fig. 9. The silicon under the aluminum nitride film was found to have the same conductivity type with essentially no change in resistivity, while p-n junctions were formed in unmasked regions. Thus, aluminum nitride films are successful for masking the diffusion of boron and phosphorus under the conditions used here.

Subsequent to the boron and phosphorus diffusion process, the dissolution rate of the aluminum nitride masks in a 10% sodium hydroxide solution was measured. Aluminum nitride films with boron oxide or phosphorous oxide coatings showed no measurable change in dissolution rate or appearance after heating at 1150°C for 1.5 hr, indicating the inertness of aluminum nitride toward the dopant oxide. However, when the heat-treatment was carried out at 1250°-1300°C after the deposition of boron oxide, the dissolution rate of the nitride films decreased appreciably, indi-

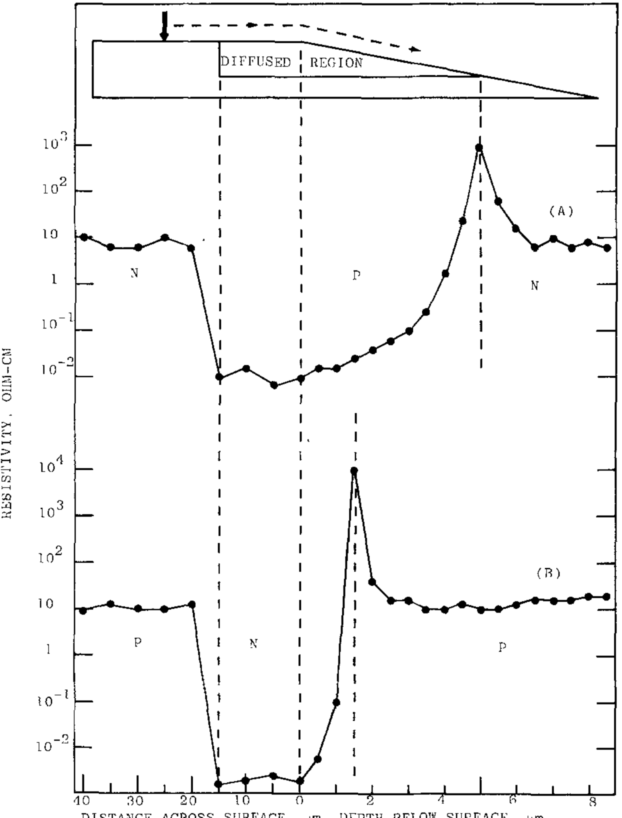

Fig. 9. Resistivity profiles in n-type (A) and p-type (B) silicon specimens after diffusion using aluminum nitride as a diffusion mask.

cating a reaction between aluminum nitride and boron oxide.

The aluminum and gallium diffusions were carried out at 1150°C for 1.5 hr in sealed fused silica tubes using the element as the source material. Aluminum nitride films failed to mask the diffusion of dopant in both cases. This is due presumably to the penetration of aluminum and gallium vapor through the grain boundaries in finely polycrystalline aluminum nitride films at high temperatures.

Dielectric properties.—The dielectric properties of aluminum nitride films were measured at room temperature using aluminum-aluminum nitride-silicon structures. Aluminum contacts of 2.5×10^{-2} cm diameter were deposited on aluminum nitride, and ohmic contacts were applied to the back surface of silicon substrates by electroless plating (18).

The dielectric strength of aluminum nitride films deposited in temperature range 800°-1000°C on low resistivity silicon substrates was measured at room temperature using d.c. and 400 kHz. The average dielectric strength of aluminum nitride was found to be 1.5×10^7 V/cm for films of 300-400Å thickness, independent of deposition temperature; it decreased to the apparent bulk value of approximately 10^7 V/cm for film thicknesses greater than about 1000Å. Aluminum nitride films deposited at 1100°C or above were found to have lower dielectric strength than those deposited at 800°-1000°C, due presumably to the inclusions in the films of the products of volume reaction where the decomposition of the aluminum trichloride-ammonia complex was not complete. The d-c dielectric strength of aluminum nitride films of 2000Å thickness prepared at 800°-1000°C was also measured at higher temperatures and was found to be approximately 10^7 V/cm at 30°C, 5×10^6 V/cm at 100°C, 2.5×10^6 V/cm at 200°C, 1.5×10^6 V/cm at 250°C, and 10^6 V/cm at 300°C.

Capacitance measurements were made on aluminum-aluminum nitride-silicon structures using a Boonton 75C Direct Capacitance Bridge operated at frequencies up to 0.5 MHz. The insulator capacitance was used to obtain the dielectric constant value. The dielectric constant of aluminum nitride films prepared at 800°, 900°, and 1000°C was found to be 11.5 ± 0.2, and that prepared at 1100°C was considerably lower, usually 8.1 ± 0.3, as compared with 9.14 reported for the low-frequency dielectric constant of single crystalline aluminum nitride (19). Also, the dielectric constant of an aluminum nitride film prepared at 800°C was found to remain unchanged after heating at 1100°C in hydrogen for 1 hr, again indicating the structural stability of aluminum nitride. The dielectric constant of all aluminum nitride films prepared in the temperature range 800°-1100°C was found to be independent of frequency and temperature in the ranges 5-500 kHz and 100°-500°K, respectively.

It should be mentioned that the properties of aluminum nitride films discussed above are independent of the nature of the carrier gas, hydrogen or 6:1 hydrogen-ammonia mixture, used in the deposition process.

Summary and Conclusions

Aluminum nitride films have been deposited on silicon substrates at 800°-1200°C in a gas flow system by the thermal decomposition of an aluminum trichloride-ammonia complex, $AlCl_3 \cdot 3NH_3$. This complex was prepared by saturating aluminum trichloride with ammonia and purified by sublimation. The deposit was transparent, tightly adherent to the substrate and was verified by x-ray and electron diffraction techniques to be aluminum nitride. Transmission electron microscopy indicated that all aluminum nitride films were polycrystalline; the crystallite size increased with increasing temperature of deposition, and the preferred orientations became more apparent at lower deposition temperatures.

At deposition temperatures in the range of 800°-1000°C, the average density, refractive index, dielectric strength, and dielectric constant of aluminum nitride were found to be 3.18 g/cm^3, 1.99, 10^7 V/cm, and 11.5, respectively. Aluminum nitride films are soluble in sodium hydroxide and phosphoric acid solutions, and the standard photolithographic technique can be readily applied. Aluminum nitride films were found to be capable of masking against the diffusion of boron and phosphorus into silicon from the oxide sources. These properties indicate that aluminum nitride films have great potential as a dielectric in solid-state devices.

Technical Notes

Vapor Deposition of Sulfur-Doped GaAs Layers

K. H. Bachem*,[1] and H. Bruch

Institut for Semiconductor Electronics/Sonderforschungsbereich 56 "Festkörperelektronik," Technical University Aachen, Germany

Sulfur is a commonly used dopant in the vapor growth of n-type GaAs epitaxial layers (1-7). The most straightforward approach is to use H_2S as a vapor dopant. This gas can be purchased diluted with hydrogen and bled into the deposition system using a variable leak. However, it appears to be difficult to obtain well-defined and reproducible dopant concentrations due to irreversible changes of the leak rates. Experiments have shown that the variable leaks (Varian, Leybold) commonly used in vacuum systems are calibratable only to within an order of magnitude. Another alternative, the stepwise dilution of the doping gas by using fine metering valves and ball flowmeters requires an extensive apparatus and time-consuming calibration also. These problems are most likely responsible for the large discrepancies in the literature data regarding the relationship between the H_2S concentration in the gas phase and the donor concentration in the epitaxial film (5, 6).

Other workers have used solid sulfur as a primary source (2, 7). The element can be vaporized into the reactor either directly or via an H_2S generator. A drawback of this method results from the difficulties in evaporating sulfur powder or grains with a well-defined vapor pressure. Both the evaporating surface area and the crystalline form and hence the vapor pressure of the sulfur may change during heat-treatment.

In the present investigation we have attempted to find improved sulfur doping methods and to clarify the discrepancies referred to above. This was accomplished by using a capillary for the controlled injection of H_2S or by adding a liquid sulfur compound to the $AsCl_3$ bubbler in the deposition system.

The H_2S doping experiments were carried out in a standard apparatus (8) for the $Ga/AsCl_3/H_2$ process (9). Well-defined concentrations of H_2S were added to the gas stream by controlling, via a reducing valve, the input pressure to a capillary tube of ≈ 150 μm diameter and 6 cm length used for injecting the doping gas into the hydrogen carrier. The system was calibrated by determining the time required to pass a defined amount of gas through the capillary at a given input pressure. The doping gas was a mixture of H_2S (985 ppm) in H_2, bottled in a steel cylinder.

Key words: GaAs, epitaxy, sulfur doping, gas phase deposition.

For the second approach S_2Cl_2 was selected as a liquid sulfur dopant source. This compound appears to fulfill the main requirements for use in this application: (*i*) It can be obtained in a relatively pure form. (*ii*) It will decompose at the deposition temperature. (*iii*) In the working temperature range of the $AsCl_3$ source (15°-25°C) its vapor pressure is such that expitaxial layers in the 10^{16}-10^{17} cm^{-3} doping range can be obtained.

The data in Fig. 1 show that the partial pressures of $AsCl_3$ (10) and S_2Cl_2 (11) are equal within approximately 10% around room temperature. Making the likely assumption that the two liquids form an ideal mixture, the ratio of their partial pressures in the vapor phase will be nearly the same as the ratio of their concentrations in the $AsCl_3$-bubbler.

For the S_2Cl_2 doping experiments a reactor was used with two Ga source tubes side by side, each connected to a bubbler, one for $AsCl_3$, the other for the $AsCl_3$-S_2Cl_2 mixture (Fig. 2). In the deposition zone the dopant concentration can be varied either by varying the proportion of the gas streams through the two bubblers or by changing the amount of S_2Cl_2 in the $AsCl_3$ bubbler. The results indicate that after saturation of the Ga source with As along with formation of a GaAs crust (12) a constant sulfur pressure is obtained in the system, and steady-state conditions can be expected during expitaxial growth.

The following starting materials were used: chromium-doped GaAs substrates (ρ = 10^7-10^8 ohm-cm, Monsanto) orientated 2° off {100} towards {110}, gallium (99.9999% Johnson Matthey), $AsCl_3$ (Suprapur, Merck), S_2Cl_2 (99%, Riedel-de Hean) redistilled, H_2S (985 ppm in H_2, Matheson). The hydrogen was purified in a Pd-diffuser.

The experimental results in Table I demonstrate the behavior of the deposition system using S_2Cl_2. The epitaxial layers were grown in the listed succession, at a deposition temperature of 740°C, a flow rate of 200 ml/min (tube diameters: source tube 25 mm, substrate tube 55 mm), and an $AsCl_3$-partial pressure of $9.9 \cdot 10^{-3}$ atm. The deposition time was 1 hr. An amount of 5 μl of S_2Cl_2 was added to 100 ml of $AsCl_3$, giving a doping level of $3.4 \cdot 10^{16}$ cm^{-3} determined by Hall effect measurements. By transferring the Ga source into the second source tube connected to the bubbler containing only $AsCl_3$ a doping level of $2.3 \cdot 10^{15}$ cm^{-3} was reached under the same growth con-

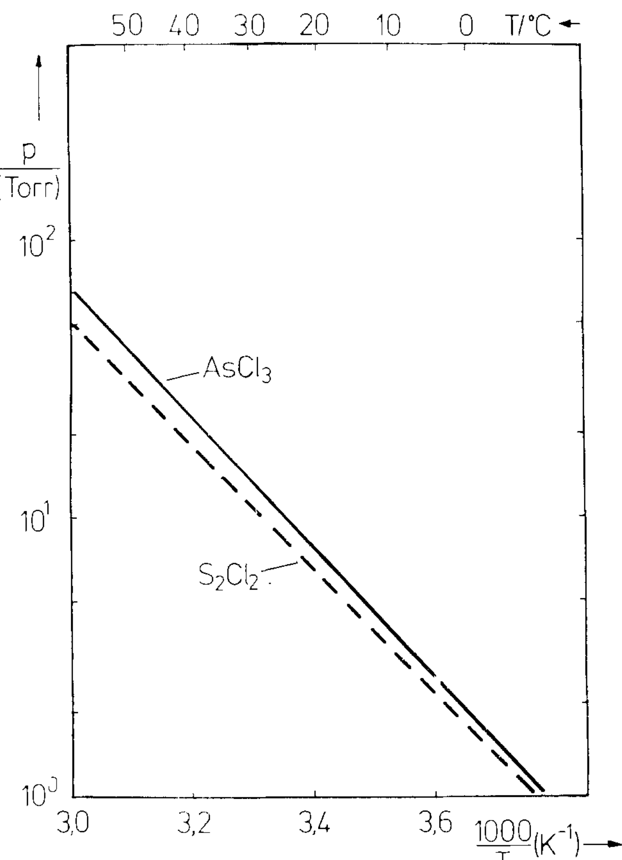

Fig. 1. Partial pressure of $AsCl_3$ and S_2Cl_2 vs. reciprocal temperature [after (9) and (10)].

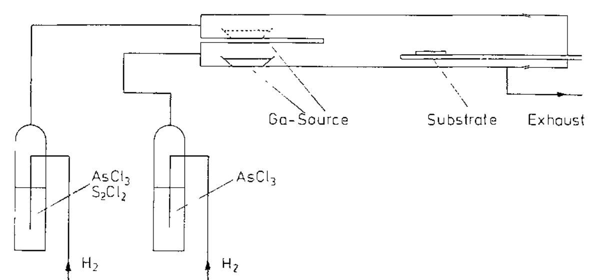

Fig. 2. Schematic diagram of the epitaxial deposition system

ditions. This value is in good agreement with the results obtained for undoped epitaxial layers grown earlier in the same reactor with identical starting material, where as an example a carrier concentration of $1.9 \cdot 10^{15}$ was obtained with an $AsCl_3$ pressure of $11.1 \cdot 10^{-3}$ atm. For the next runs the Ga source was returned to the source tube with the dopant gas stream. Carrier concentrations of $3.1 \cdot 10^{16}$ cm^{-3} and $3.05 \cdot 10^{16}$ were obtained in successive runs. Knight *et al.* (4) found that the apparatus does not exhibit a memory effect when H_2S is injected into the reactor after the Ga source. Our results show that a memory effect is even absent when the entire system

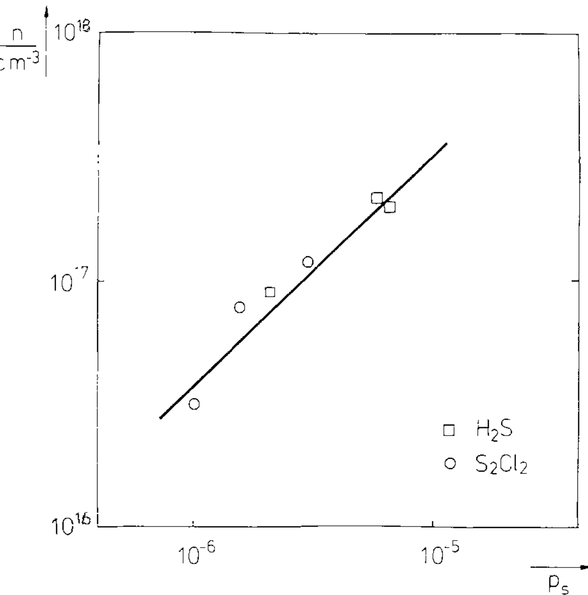

Fig. 3. Carrier concentration vs. partial pressure of sulfur in the gas phase for the H_2S and S_2Cl_2 systems.

including the Ga source has been exposed to sulfur vapor in a previous experiment. Tripling the amount of S_2Cl_2 in the bubbler leads to a roughly comparable increase in the carrier concentration. An intermediate value of $7.8 \cdot 10^{16}$ cm^{-3} was reached by mixing both gas streams with each having a flow rate of 100 ml/min.

Figure 3 compares the carrier concentration obtained for various sulfur pressures in the gas phase both for the H_2S and the S_2Cl_2 systems. Notice first the good agreement between the data for both systems. Of course, such agreement should be expected since at the deposition temperature the composition of the gas phase will be identical in both cases. These results show the proportionality between sulfur pressure and electron density. In calculating the gas phase pressure it was assumed that the system $AsCl_3$-S_2Cl_2 behaves as an ideal solution. Under the assumption that all sulfur incorporated into the films is electrically active it also appears that a relationship analogous to Henry's law exists between sulfur pressure and sulfur concentration in the GaAs. Such behavior was also reported by Rai-Choudhury (13). Of course, it should be realized that the "Henry's law constant" (Table II) derived in this case is not obtained under equilibrium conditions with respect to the GaAs deposition.

Acknowledgment

The authors are indebted to Mr. Schiffers, Institute of Inorganic Chemistry of the Technical University Aachen, for redistilling our S_2Cl_2 dopant material. They would also like to thank Prof. P. Balk for his interest in this project.

Postirradiation Alkali Migration

William Primak

Argonne National Laboratory, Argonne, Illinois 60439

During the course of his ion bombardment studies, Hines noted that the ion charge required to alter the refractive index of glass was greater than that required to alter the refractive index of quartz. He suspected the composition of the glass was altered by selective sputtering (1). Evidence for the migration of alkali ions during electron and ion bombardment appears in the temporal changes occurring during electron and ion probe microanalysis (2). The writer noted that areas of a lithium niobate surface which had been subjected to ion bombardment became decorated with droplets, and from these droplets (over a period of weeks) small crystals formed. They were identified as $LiOH \cdot H_2O$. The decoration could be washed off and would appear again over a period of weeks, repeatedly, evidence of a continuing migration of lithium to the surface (3). Now a number of commercial optical glasses have been subjected to ion bombardment, and the decoration phenomenon has been observed for some of them.

The glasses which were studied were a variety of commercial optical glasses, crown (C-1), borosilicate crown (BSC-2), telescope flint (TF), light barium crown (LBC-1), barium crown (BAK-5), light flint (LF-2), and dense flint (DF). Small areas of polished plates were subjected to ion bombardment with 140 keV D^+ ions for the following accumulated incident charge: 0.018, 0.036, 0.072, 0.108, 0.144, and 0.18 coulombs/cm^2, respectively. Decoration with droplets following ion bombardment during the summer (relative humidity in the laboratory varied between 40 and 60%, temperature controlled to within a degree of 24°C) was most severe on C-1, TF, LF-2, and DF. It was less severe on the barium crowns and was not seen on BSC-2. Decoration reappeared following washing, the time required to obtain droplets easily observed at 50-100X magnification being several days or weeks. Several months later, when the relative humidity had dropped to 20-40% with occasional days at 60%, the specimens were reexamined, and little mounds of solid were seen on the C-1 and TF glasses. Liquid droplets and some solid material were seen on the most highly bombarded areas of the LF-2 and DF glasses. The solid material can form exotic patterns. Probably these are caused by the crystallization rather than being related to structures formed by the ion bombardment. Examples of the decoration are shown in Fig. 1.

Key words: ion bombardment, glass, decoration, electrical leakage.

Water permitted to flow over the specimens will wet the bombarded areas more readily than the surrounding glass surface; and the water will cling to the bombarded areas, but not to the unbombarded areas. Such water adhesion has been interpreted as an indication of cleanliness of the glass surface. It is now seen to have quite a different cause: the bombarded areas have become hygroscopic because of the alkali migration.

The liquid droplets are probably alkali hydroxide solutions, and the deposits which develop are probably largely alkali carbonate. In the ion microprobe work (2), electric charge appeared to facilitate the migration of alkali ions in the solid, for the effects were reduced significantly by flooding the surface with electrons during bombardment or by using neutral atoms instead of ions. Although long-term storage of charge does occur in some materials, it probably did not (in the conventional sense) occur in these glasses which were covered with a solution film and which were washed with water. The freeing of the alkali ions is therefore attributed to a chemical change (such as the change in the valency of another ion or the substitution of some kind of center for the ion) or a structural change. It may be noted that the severity of the decoration effect for these glasses accords with their usually accepted chemical durability (3). Thus the factors which are involved in the chemical attack of glass by water and aqueous solutions (4) are involved in the transport of the alkali ions to the surface, which thus becomes a secondary process following the initial alteration of the glass by the ion bombardment.

When decoration of ion-bombarded lithium niobate was observed, it was the first example of the phenomenon seen in this laboratory. The appearance of liquid droplets could not be accounted for on the basis of the vapor pressure depression caused by lithium hydroxide, because the relative humidity in the laboratory was too low, and the possibility of an electrical effect associated with the charge of a strained piezoelectric material was considered. Now it has been found that irradiation can destroy the piezoelectric effect in lithium niobate. This may serve both to explain the reason why some highly bombarded surfaces showed a lesser decoration effect and to lend support to the hypothesis of an electrical effect. Such an effect is not necessary in the case of these glasses because they contain sodium, and sodium hydroxide is sufficiently more soluble than lithium hydroxide that liquid droplets could form at relative humidities occurring in

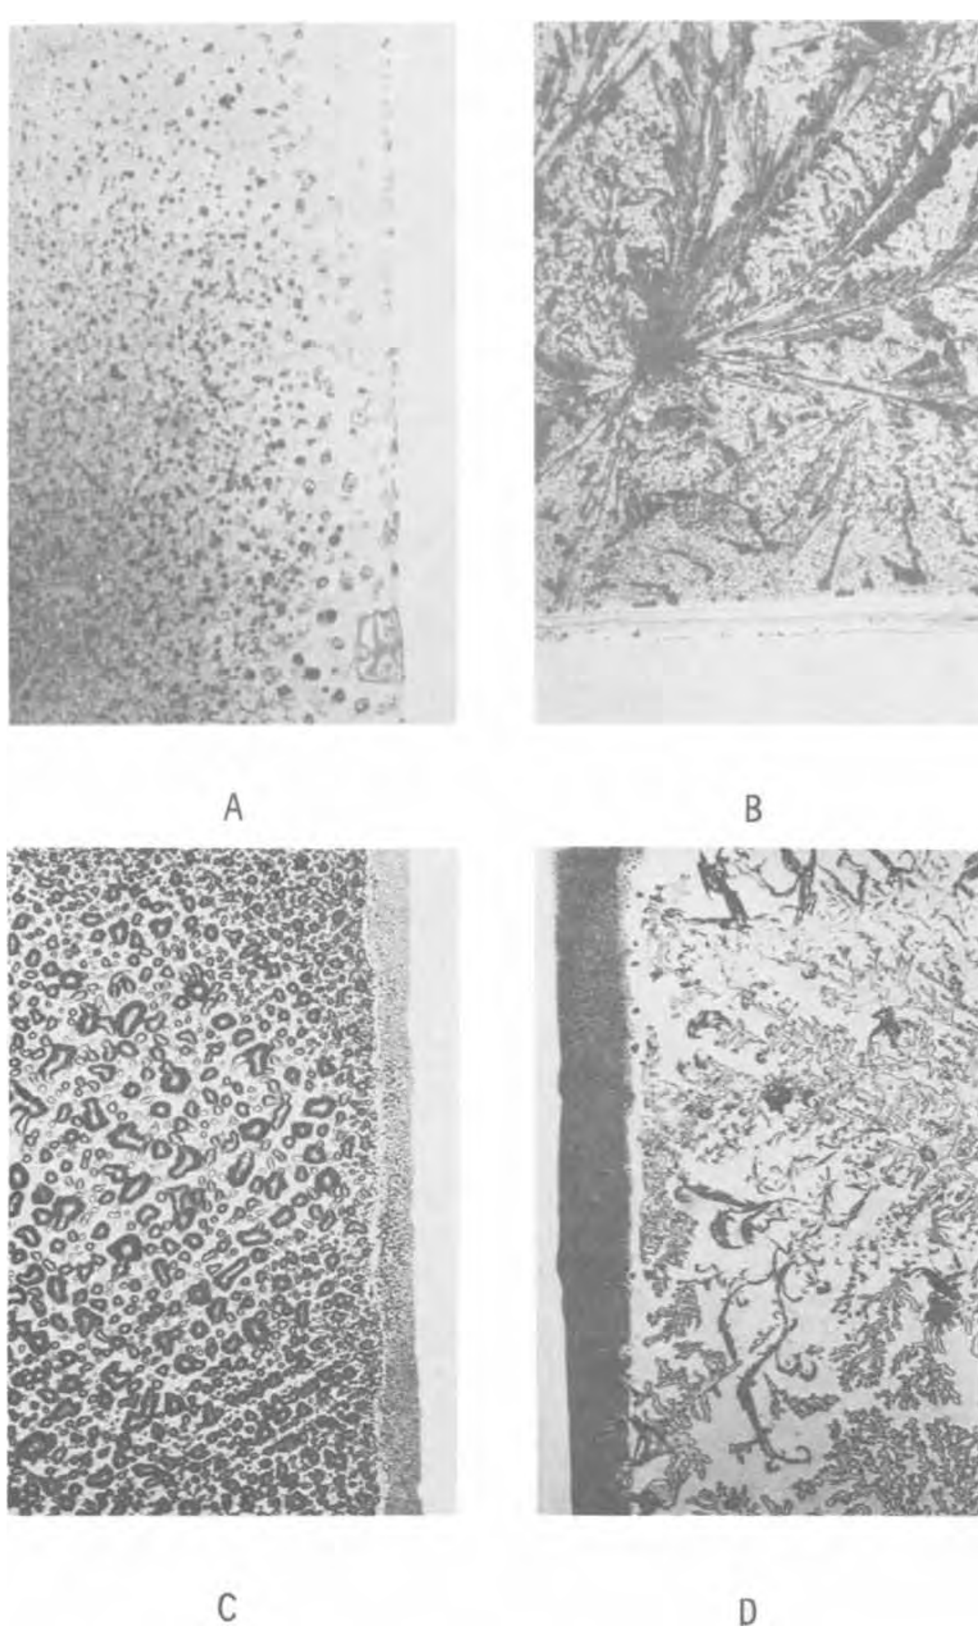

Fig. 1. Decoration of ion bombarded glass caused by water vapor condensation. The specimen areas shown are 0.75 × 1.08 mm. The "penumbral zones" are caused by lack of registry of masking arrangements. All of the decoration begins as liquid droplets. The crystallization depends on the relative humidity, length of storage, the particular glass, and the dose. All of these examples were seen following 140 keV deuteron bombardment (and may have been washed with water) for the following doses: A, C-1 glass, 0.018 coulombs/cm^2; B, C-1 glass, 0.108 coulombs/cm^2; C, TF glass, 0.036 coulombs/cm^2; D, TF glass, 0.108 coulombs/cm^2.

our laboratory. However, the new observations raise the question whether surface impurities may be involved in some of the phenomena observed in the decoration of the lithium niobate. To this end it may be profitable to explore the system LiOH-NaCl-H_2O, and this is planned.

It had been customary to subject glass surfaces intended for coating to ion bombardment. The effect of alkali migration on the film should be considered.

Electrical leakage in ceramic electrical insulation used in radiation environments is a notorious problem. The problems arising from the formation of nitrates in such environments was pointed out many years ago (6). Now effects caused by the alkali migration in these environments should be considered.

The alkali migration may contribute to the difficulties of evacuating glass vacuum systems and to the deterioration of glass structures subjected to bombardment or located in radiation fields.

Cathodes for Seawater Activated Cells

Nehemiah Margalit*

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

Temperature-humidity tests and discharge in an experimental cell were used to evaluate new cathode materials for magnesium seawater activated cells. Of the materials tested AgCl, Hg_2Cl_2, and CuI,S mixes were found promising. Mg/AgCl,Hg_2Cl_2 cells performed almost as well as Mg/AgCl cells due to an apparent intracathode reaction. The Mg/CuI,S system exhibited a lower operating voltage and will require further work for full evaluation.

The need to reduce silver content and loss associated with conventional Mg/AgCl seawater activated batteries has prompted searches for substitute cathodes. This search was directed towards the "silver group" of the classical qualitative analysis procedure (1) and copper(I) halide-sulfur mixes previously investigated by Reutschi *et al.* (2) for weather balloon applications.

Of the "silver group", aside from AgCl, $PbCl_2$ was found promising by other investigators (3); however, the use of Hg_2Cl_2 was hampered by the need to contain the discharge product, liquid mercury. Addition of silver powder for mercury amalgamation, as in the Ruben mercury(II) oxide electrode (4) has resulted in a low energy density cathode. Therefore a new method for making Hg_2Cl_2 electrodes was required.

Of the copper(I) halides, the bromide and the iodide exhibit low solubilities (5); thus their mixes with sulfur were evaluated as candidates for cathode material.

Preliminary Temperature Humidity Tests

In preliminary tests, copper(I) halide-sulfur mixes of the chloride (control), bromide and iodide were made and pelletized using the method described by Honer (6). The formulations for these mixes are shown in Table I.

Hg_2Cl_2 pellets were made using AgCl as an active binder. The AgCl active material-binder was precipitated, using reagent grade hydrochloric acid, from an aqueous solution of $AgNO_3$ (Fisher) in which Hg_2Cl_2 powder (Fisher) was suspended by stirring with a Teflon-coated magnetic stirring bar. The resultant white powder was collected by filtration, washed three times with deionized water and dried under vacuum. An analysis of the powder showed a 3-7 weight ratio of silver to mercury. X-ray data indicated only pure crystals of AgCl and Hg_2Cl_2 in the final product. This white product was pressed into pellets which turned yellow upon exposure to light.

Freshly made pellets were discharged in a weather balloon type cell using magnesium AZ31B as the anode and a 1% NaCl solution as the electrolyte. In this cell the electrodes were separated by a nonwoven cellulosic mat and contact to active materials was made through carbonized steel sheets. At the same time, identical pellets were subjected to ten 24 hr cycles of a high temperature, high humidity test. During each cycle the pellets underwent a steady temperature rise from 38° to 50°C for 2 hr followed by a rest of 6 hr at 50°C and a gradual temperature drop to 38°C lasting 16 hr. The relative humidity was kept above 95% throughout this test.

* Electrochemical Society Active Member.

Key words: seawater activated cell, magnesium anode, AgCl, Hg_2Cl_2-cathode, CuI,S-cathode.

Results

Only AgCl, Hg_2Cl_2, and CuI,S pellets passed the temperature, humidity test unchanged. CuBr,S pellets were covered with green droplets which dried to green crystalline spots, whereas CuCl,S pellets disintegrated.

When discharged after temperature, humidity testing, as shown in Table II, both AgCl,Hg_2Cl_2 and CuI,S cathodes exhibited behavior similar to fresh pellets, while CuBr,S cathodes gave unreliable results.

As seen in Table II, the AgCl,Hg_2Cl_2 cathodes exhibited 90% coulombic efficiency based on both chlo-

rides. Furthermore, only one discharge plateau was observed with Mg/AgCl,Hg_2Cl_2 cells at a voltage close to that of Mg/AgCl control cells. Therefore the investigation of the discharge behavior of CuI,S and AgCl,Hg_2Cl_2 cathodes was extended by using simulated seawater as the electrolytic solution, and varying the ratio of the components in the AgCl,Hg_2Cl_2 cathode.

Experimental "Seawater Cell" Tests

Two series of AgCl,Hg_2Cl_2 cathode materials containing varying amounts of silver and mercury were prepared. One, the P (precipitated AgCl) series was prepared by the above-mentioned method, whereas the CP series was prepared by coprecipitation of both chlorides from an aqueous solution of their nitrates using hydrochloric acid. The amounts of starting materials are presented in Table III.

The composition of these materials was designed to produce discharge products of different silver mercury ratios starting with the γ phase (P-30) and ending with P-10 and CP-10 dilute amalgams (7).

Mixes of AgCl,Hg_2Cl_2 and CuI,S (Table I) were pressed at about 1000 kg into pellets 1.9 cm in diameter and 0.11 cm thick and tested in a laboratory version of a seawater activated cell (Fig. 1), using simulated seawater (ASTM D1191-52, solution 2). Cells were placed in a perforated Plexiglas holder, inside a 400 ml beaker, to allow free circulation of the electrolytic solution. The solution temperature did not increase more than 1°C above room temperature throughout discharge.

Results

CuI,S.—Tests with CuI,S cathodes showed (Fig. 2) that at an average current density of 13 mA/cm² of cathode, in this test cell, the coulombic efficiency decreased to 66%. This apparent decrease of coulombic efficiency was traced to loss of active material due to shedding during discharge.

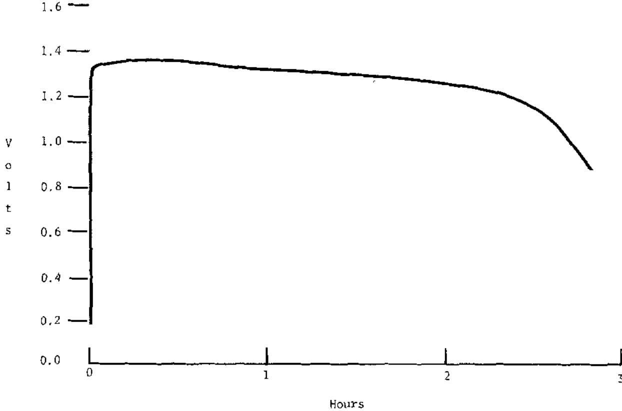

Fig. 2. Discharge behavior of the Mg(AZ61)/"seawater"/CuI,S experimental cell under a 32 ohm load at ambient temperature and pressure.

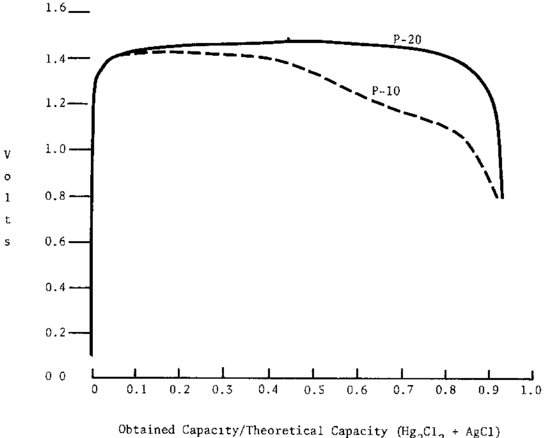

Fig. 3. Discharge behavior of Mg(AZ61)/"seawater"/Hg_2Cl_2, AgCl (precipitated binder) experimental cells under a 32 ohm load at ambient temperature and pressure. P-20 cathode composition, 78% Hg_2Cl_2, 22% AgCl; P-10 cathode composition, 88.8% Hg_2Cl_2, 11.2% AgCl.

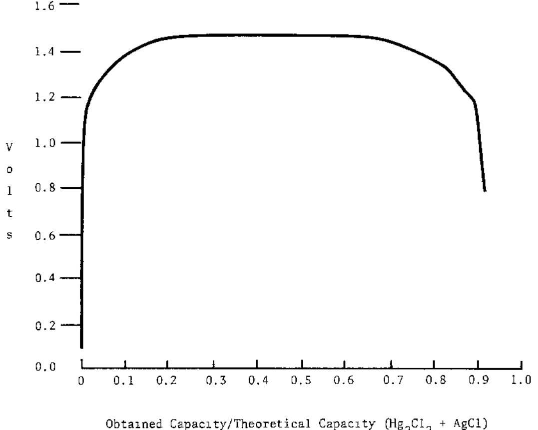

Fig. 4. Discharge behavior of the Mg(AZ61)/"seawater"/88.8% Hg_2Cl_2, 11.2% AgCl (coprecipitated) experimental cell under a 32 ohm load at ambient temperature and pressure.

AgCl,Hg_2Cl_2.—Two typical discharge curves were obtained with AgCl,Hg_2Cl_2 active materials (Fig. 3). The first shows a fast rise followed by a single discharge plateau and a sharp knee, typical of CP-15 and silver-rich P cathodes. However, silver-poor cathodes of the P series such as P-10 gave a two-step discharge. A much shorter second plateau occurred with CP-10 electrodes (Fig. 4). A summary of discharge data for such cells is presented in Table IV.

Discussion

In general, the discharge behavior of the Mg/AgCl,Hg_2Cl_2 cells was almost identical to that of Mg/AgCl ones. The major exceptions were cells whose cathode consisted of a P-type silver-poor electrode, such as P-10. The virtual nonexistence of the second plateau when CP-10 electrodes were utilized and the superior performance of CP-15 over P-20 cathodes indicate that intimate mixing of the electrode components improves cell performance. This behavior suggests that several processes take place simultaneously at the cathode. These postulated processes are

$$AgCl + e^- \rightarrow Ag + .Cl^- \quad [E_o = 0.222V\ (8)] \quad [1]$$

$$Hg_2Cl_2 + 2e^- \rightarrow 2Hg + 2Cl^- \quad [E_o = 0.268V\ (8)] \quad [2]$$

$$Hg_2Cl_2 + 2Ag \rightarrow 2AgCl + 2Hg \quad (E_o = 0.046V) \quad [3]$$

$$Hg + Ag \rightarrow \text{silver-mercury intermetallic compounds and amalgams} \quad [4]$$

The major electrochemical reaction, silver chloride reduction, is responsible for the high operating voltage of the cell. However, some contribution from Hg_2Cl_2, especially with low silver content electrodes, is observed and both P-10 and CP-10 electrodes which show a second discharge plateau at 1.1V. Simultaneously, an intraelectrode reduction of mercury(I) chloride by silver, reaction [3], is replenishing the silver chloride, thus controlling the relative quantities of active materials within the electrode, hence determining the discharge voltage of the cell (9). Considering the operating current densities. such a rapid intracathode reaction must proceed either through a corrosion-like mechanism (10) or direct contact between the reacting species. Either way, the rate determining step will be mass transport dependent, hence the increase in cell performance with the increase in the physical proximity of the mix components in the active material.

The effect of the process described in Eq. 4 on the instantaneous silver activity, and thereby on the overall cathode behavior, is not clear. It was observed, especially with low silver content electrodes, that free mercury droplets required at least 24 hr to be absorbed into the discharged pellet. If this behavior is indicative of the rate of this process, then the change in silver activity, at least beyond the γ phase, is slow, thus allowing the intraelectrode reaction (reaction [3]) to proceed more efficiently.

The similarity between the AgCl,Hg_2Cl_2 and the AgCl cathodes extends beyond discharge voltage. The reduced mercury, like reduced silver, occupies slightly more than half the volume of the original chloride, and reaction [4] will further reduce the volume of the discharge product; hence solid, nonporous electrodes can be used in both cases. A final comparison between AgCl,Hg_2Cl_2 mixes and AgCl in terms of calculated volumetric capacity densities based on the known densities of AgCl and Hg_2Cl_2 (5), and assuming nonporous cathodes is presented in Table V.

Conclusions

AgCl,Hg_2Cl_2 cathode materials were found highly efficient and suitable for replacing AgCl cathodes with minimal changes in present cell design. Indeed, the AgCl,Hg_2Cl_2 cathode could be regarded as a highly efficient Ag/AgCl electrode in which the expensive active material, present in a small quantity, is regenerated by the reaction of the discharge product with Hg_2Cl_2.

Table IV. Performance of experimental Mg/seawater/AgCl,Hg_2Cl_2 cells

Active material	Average voltage	Current density mA/cm² of cathode	Coulombic efficiency (%)
P-30	1.40	15.3	97
P-25	1.38	15.0	97
P-20	1.41	15.5	93
CP-15	1.39	15.3	94
P-10	1.29	14.1	84
CP-10	1.38	15.0	90
AgCl (control)	1.39	15.2	99

Table V. Calculated maxima of capacity-volume ratios* for AgCl, Hg_2Cl_2 cathodes

Per cent AgCl in active material	A-hr/DM³ of active material	(A-hr/DM³ active material / A-hr/DM³ AgCl) × 100
100.0	1040	100.0
32.6	900	86.5
27.3	886	85.3
22.0	873	83.9
16.6	859	82.6
11.1	849	81.2

* Based on the known densities of AgCl and Hg_2Cl_2 (5) and assuming solid, nonporous electrodes.

The Mg/CuI,S system exhibited lower operating voltages and would require further improvement of cathode formulation and/or cell design in order to reduce the loss of coulombic efficiency due to shedding of active material during discharge. However, no silver is required for the operation of this system.

Both CuI,S and $AgCl,Hg_2Cl_2$ mixes could serve as cathode materials in magnesium water activated cells.

Electrocatalytic Activity of Metals and Alloys Electrodeposited on Foreign Substrates

I. Some Aspects of Oxygen Reduction on Electrodeposited Silver Films on Pyrolytic Graphite

Ikram Morcos*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

Oxygen reduction has been studied in alkaline medium on both bulk silver electrodes and electrodes prepared by the electrodeposition of a silver film on pyrolytic graphite, platinum, and silver substrates. The rotating disk technique was used throughout the work and the current potential data were obtained by slow scanning voltammetry. The effect of the starting potential and some surface pretreatments were also examined. The experimental results indicate that a silver surface electrodeposited on a foreign substrate is more catalytically active toward O_2 reduction than either bulk silver or silver electrodeposited on a silver substrate. A silver surface which has been electrochemically oxidized and subsequently reduced is more catalytically active than a surface which has been only subjected to the reducing potential. It appears that these variations in electrocatalytic activity are caused by variations in both surface area as well as the reversibility of adsorbed oxygen.

The electrocatalytic properties of electrodeposited metallic films on foreign substrates are important for both its fundamental and applied aspects. The cost of a catalyst in the form of an electrodeposited metal film on a substrate such as graphite could be less than one made of the corresponding bulk metal. The method of electrodeposition provides a better control on the reproducibility (*e.g.*, on such properties as surface area, grain size, and impurities) of the metal surface and that may contribute to the obtainment of more reliable kinetic data. Moreover the topographical and metallurgical analysis of thin metal films can be more easily carried out by a variety of optical and spectroscopic techniques.

In the present paper some aspects of O_2 reduction on electrodeposited silver films on pyrolytic graphite and platinum substrates will be compared to the corresponding phenomena observed on bulk silver and electrodeposited silver on bulk silver electrodes.

Experimental Procedure

The electrochemical reduction of oxygen was studied using a Teflon cell and electrode assembly as described in a previous work (1). The solution was 0.1*N* KOH prepared from A. R. quality potassium hydroxide and triply distilled water twice from a permanganate solution. The reference electrode was an Hg/HgO, 1.0*N*

* Electrochemical Society Active Member.

Key words: rotating disk electrode, electrocatalytic activity and nucleation of metals on pyrolytic graphite, oxygen reduction on silver, surface active area of electrodeposited silver on pyrolytic graphite, adsorption of oxygen on electrodeposited silver on pyrolytic graphite.

KOH. The rotating disk technique was applied throughout the work to control mass transfer of oxygen. Current-potential plots were obtained by slow scanning voltammetry, using a Tacusel function generator, a Wenking potentiostat, and a Honeywell X-Y recorder.

The bulk silver electrode consisted of a disk of 0.785 cm^2 area. Prior to the study the electrode was mechanically polished with 0.3μ alumina powder on a felt wheel followed by cleaning in carbon tetrachloride, isopropyl alcohol, and triply distilled water. Other electrodes were prepared by electrodepositing silver from silver cyanide solution on pyrolytic graphite, platinum, and silver substrates. The areas of these electrodes were 0.338, 0.502, and 0.785 cm^2. Except where otherwise noted, the latter three electrodes were used after cleaning in triply distilled water without any further pretreatment.

Some surface area study was attempted using the capacity method. The potential dependence of the differential capacity was measured at 1000 Hz and using other experimental details as those described by Randin and Yeager (2). Topographical examination of silver deposits on pyrolytic graphite was carried out by the scanning electron microscope. For this, the deposited sample was bombarded with an electron beam of 20 kV.

Results and Discussion

The dependence of the cathodic current on potential in the range 0 to −1.0V and on rotation rate for O_2 reduction in oxygen-saturated 0.1*N* KOH on bulk silver electrode and on electrodeposited silver on silver substrate is given in Fig. 1 and 2. The corresponding plots obtained on silver electrodeposited on pyrolytic graphite and platinum substrates are given in Fig. 3 and 4. In Fig. 5 is shown the corresponding plots obtained on silver electrodeposited on pyrolytic graphite electrode which has been mechanically polished after the deposit was prepared. Figures 6 and 7 show similar plots obtained on mechanically polished bulk silver and silver electrodeposited on pyrolytic graphite electrodes which have been prior to the experiment (in both cases) immersed in dilute HNO_3 for about 5 sec.

Figures 8-10 show the dependence of the cathodic current on potential in the range 0.5 to −1.0V and on rotation rate in oxygen-saturated 0.1*N* KOH solution on bulk silver electrode, silver electrodeposited on pyrolytic graphite, and on platinum substrates, respectively.

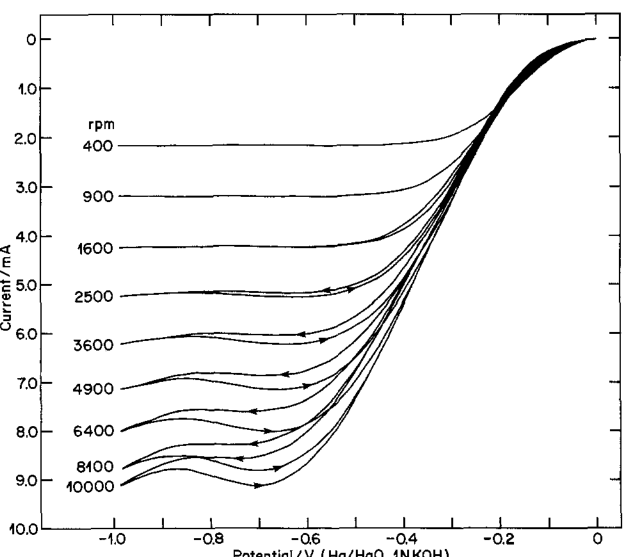

Fig. 1. Reduction of O_2 on bulk silver electrode at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.786 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

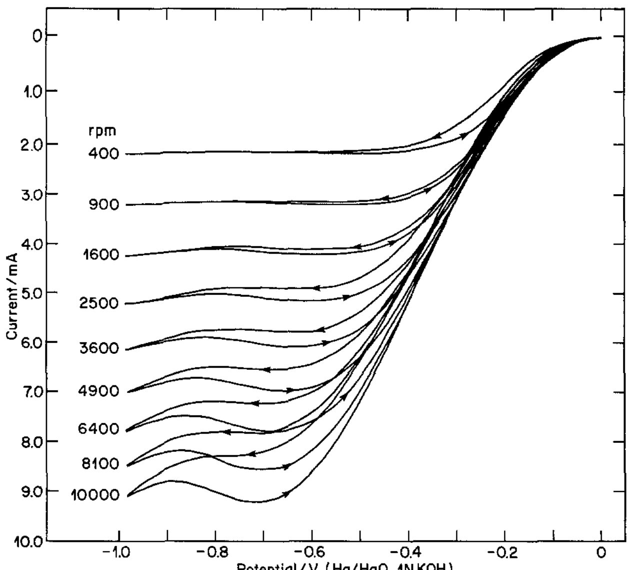

Fig. 2. Reduction of O_2 on electrodeposited silver on bulk silver at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.786 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

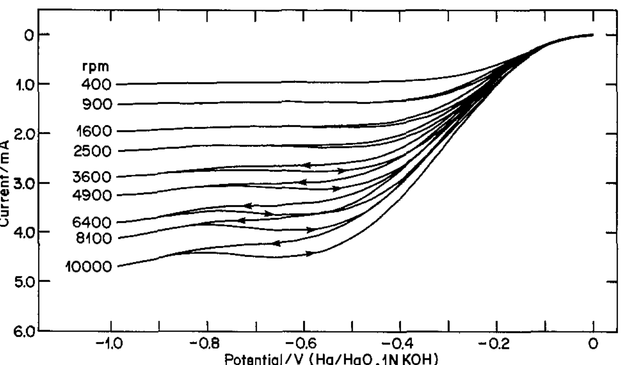

Fig. 3. Reduction of O_2 on electrodeposited silver on pyrolytic graphite substrate at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.338 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

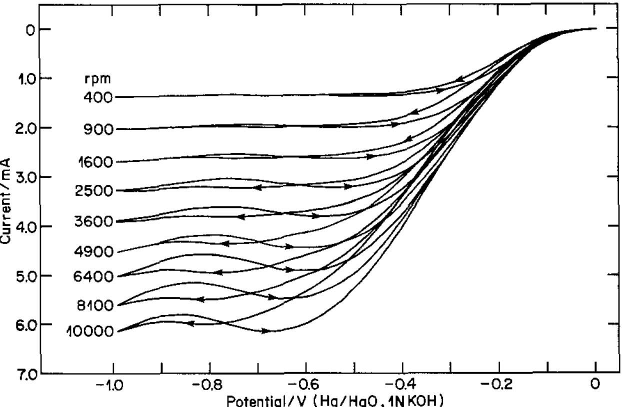

Fig. 4. Reduction of O_2 on electrodeposited silver on platinum substrate at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.502 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

In all the experiments reported in Fig. 1-10 a voltage scan rate of 1 V/min was used and the first potential scan was always started from the most anodic potential. The current-potential plots were independent of scan rate from 0.1-1 V/min. No faster scan rates than 1 V/min was attempted. The direction of the voltage sweeps are indicated by the arrows. Figure

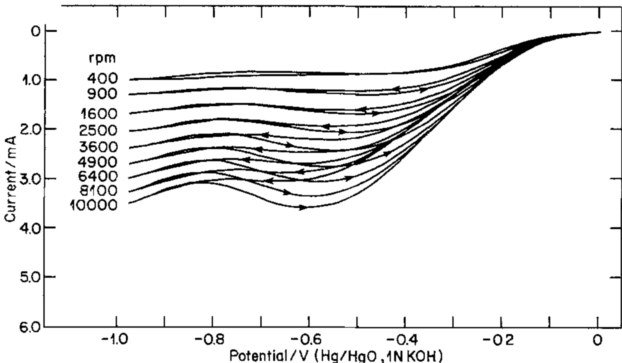

Fig. 5. Effect of mechanical polishing on reduction of O_2 on electrodeposited silver on pyrolytic graphite substrate at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.338 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

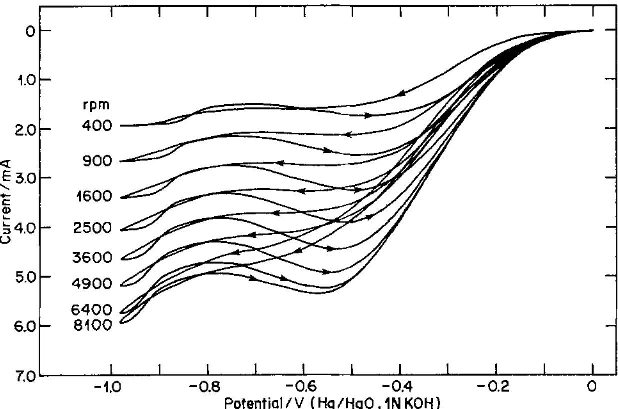

Fig. 6. Effect of pretreatment with dilute HNO_3 on reduction of O_2 on bulk silver electrode at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.786 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

11 shows the dependence of the current on potential in helium-saturated 0.1*N* KOH on bulk silver electrode for potential scans starting at both 0 and 0.5V, respectively. Figure 12 shows the corresponding curves obtained on silver electrodeposited on pyrolytic graphite. The current in both Fig. 11 and 12 exhibits no dependence on rotation rate.

The dependence of the cathodic limiting current/square centimeter on the square root of the rotation rate for the different experimental data of Fig. 1-10 is shown in Fig. 13-16. The latter figures were plotted after correction for the corresponding residual current observed in Fig. 11 and 12. Whenever hysteresis exists between the cathodic and anodic potential scans, the value of the limiting current used is that corresponding to the anodic scan. Figure 13 also shows (the top curve) the theoretically calculated Levich plot for a 4-electron process oxygen reduction using the equation (3)

$$i_d = B\sqrt{\omega} \quad [1]$$

where i_d is the mass-transfer limiting current in mA, ω is the rotation rate in rev/min, and B is given by Newman (4) as

$$B = 10^3(2\pi/60)^{1/2} \frac{n\mathbf{F}AC\nu^{1/2}\ (0.621\ \mathrm{Sc}^{-2/3})}{1 + 0.298\ \mathrm{Sc}^{-1/3} + 0.145\ \mathrm{Sc}^{-2/3}} \quad [2]$$

where ν is the kinematic viscosity, D is the diffusion coefficient of oxygen (moles/cm^3), n is the number of electrons transferred per mole of O_2, $\mathbf{F}$ is the faraday, A is the disk electrode area (cm^2), c is the bulk concentration of O_2 (moles/cm^3), $\mathrm{Sc} = \nu/D$ is the Schmidt number. Using values of 1.22×10^{-6} mM and 1.9×10^{-5} cm^2/sec for the solubility and diffusion coefficient of oxygen in 0.1*N* KOH at 25°C reported in Ref. (5-6) a value of $B = 0.142$ was calculated for $n = 4$ and electrode surface area of 1 cm^2.

The following are some important observations from Fig. 1-15.

1. The dependence of the cathodic current density on rotation rate (Fig. 1-10) starts at a relatively small overpotential. Consequently the study of the kinetics of oxygen reduction on silver cathodes in the absence of a forced control of mass transfer will be restricted to a small potential region near the open-circuit value and therefore will be of limited use. In view of this, caution must be considered in analyzing kinetics data obtained over a relatively large potential region of few hundreds millivolts without the use of the rotating disk electrode.

2. The relative magnitude of the limiting current as compared to theoretically predicted values on the basis of the Levich equation (Fig. 13-16) depends on the rotation rate, the form of silver electrode used, the starting potential of the sweep, and electrode pretreatment.

With silver electrodeposited on pyrolytic graphite Levich plots are linear (throughout the range of rotation used) even in cases where the limiting current is slightly less (see Fig. 13) than that theoretically predicted. Deviation from linearity at higher rotation rates is very evident (Fig. 13) in the case of bulk silver and electrodeposited silver on silver substrate electrodes. Slight deviation from linearity is observed in the case of silver electrodeposited on platinum substrate electrodes.

When the starting potential is 0.5 instead of 0V, all the limiting currents (Fig. 14) shift to higher values

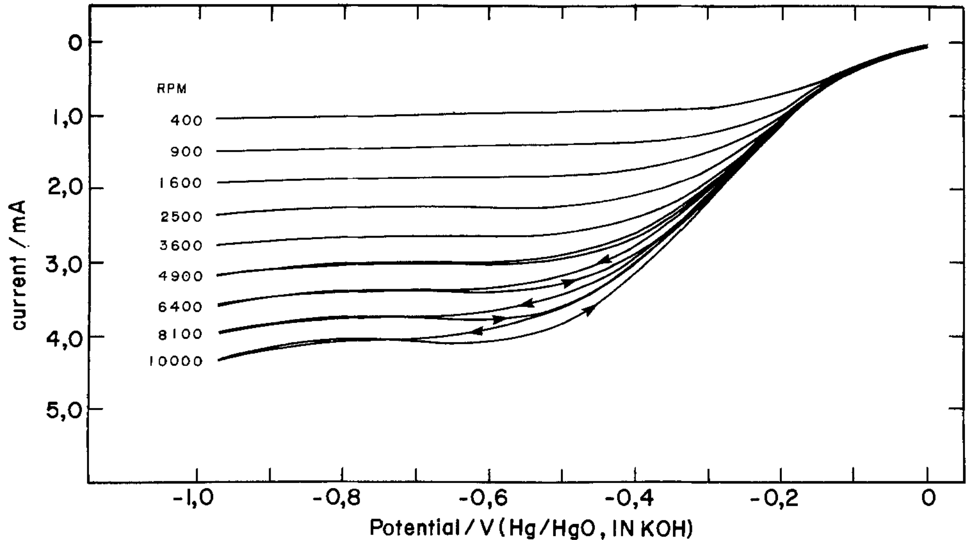

Fig. 7. Effect of pretreatment with dilute HNO_3 on reduction of O_2 on electrodeposited silver on pyrolytic graphite at different rotation rates in O_2-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.338 cm^2, and potential scan from 0 to −1.0V at a rate of 1 V/min.

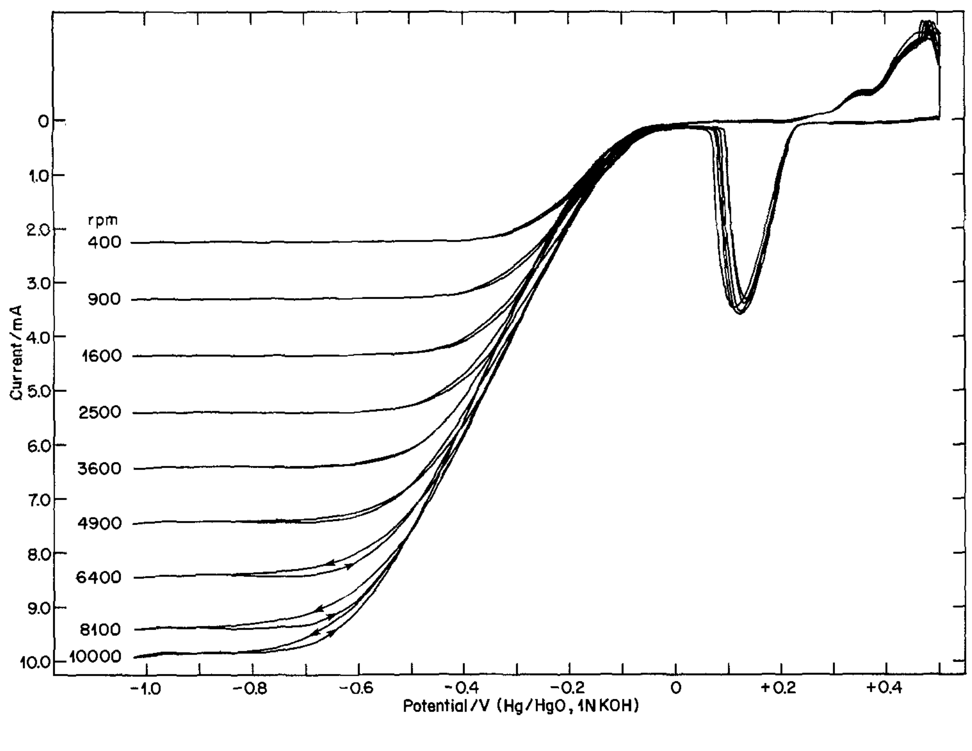

Fig. 8. Reduction of O_2 on bulk silver electrode at different rotation rates in O_2-saturated 0.1N KOH. Temperature 25°C, electrode area 0.786 cm^2, and potential scan from 0.5 to −1.0V at a rate of 1 V/min.

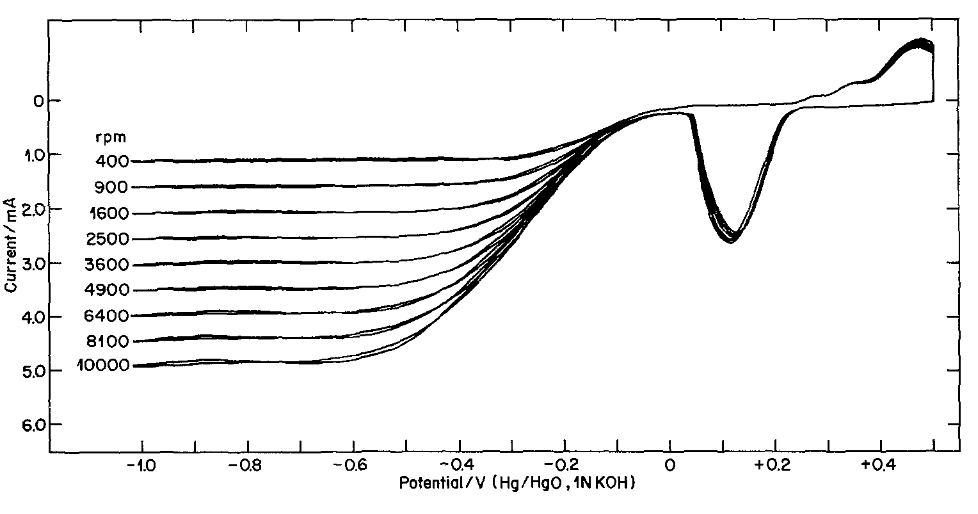

Fig. 9. Reduction of O_2 on electrodeposited silver on pyrolytic graphite at different rotation rates in O_2-saturated 0.1N KOH. Temperature 25°C, electrode area 0.338 cm^2, and potential scan from 0.5 to −1.0V at a rate of 1 V/min.

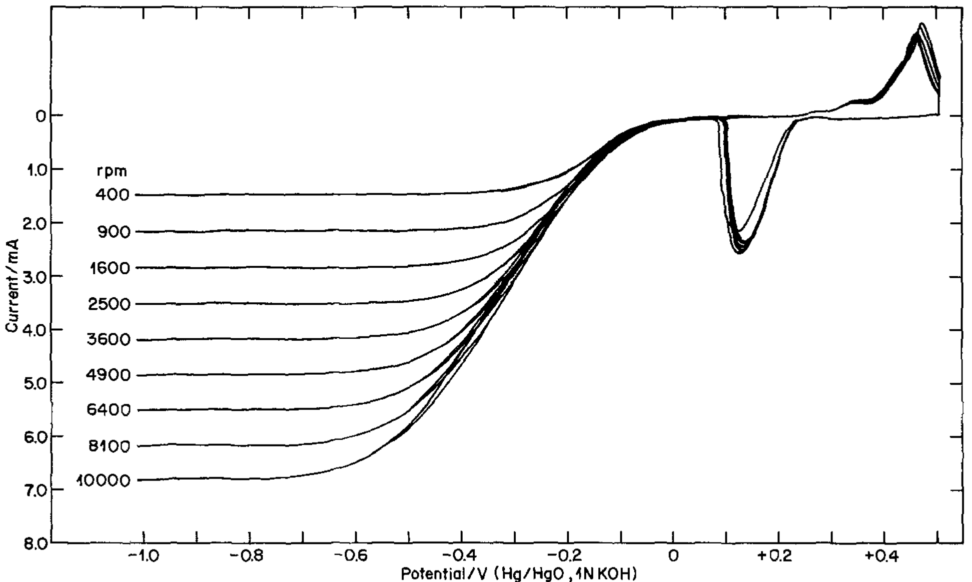

Fig. 10. Reduction of O_2 on electrodeposited silver on platinum substrate at different rotation rates in O_2-saturated 0.1N KOH. Temperature 25°C, electrode area 0.502 cm^2, and potential scan from 0.5 to −1.0V at a rate of 1 V/min.

(higher electrocatalytic activity) and generally approach the mass-transfer limiting currents. In the case of silver electrodeposited on pyrolytic graphite the limiting current coincides with the theoretical plot (Fig. 14). With bulk silver electrodes however slight deviation from linearity is still observed (Fig. 14).

The electrocatalytic activity and limiting current are strongly influenced by electrode pretreatment pro-

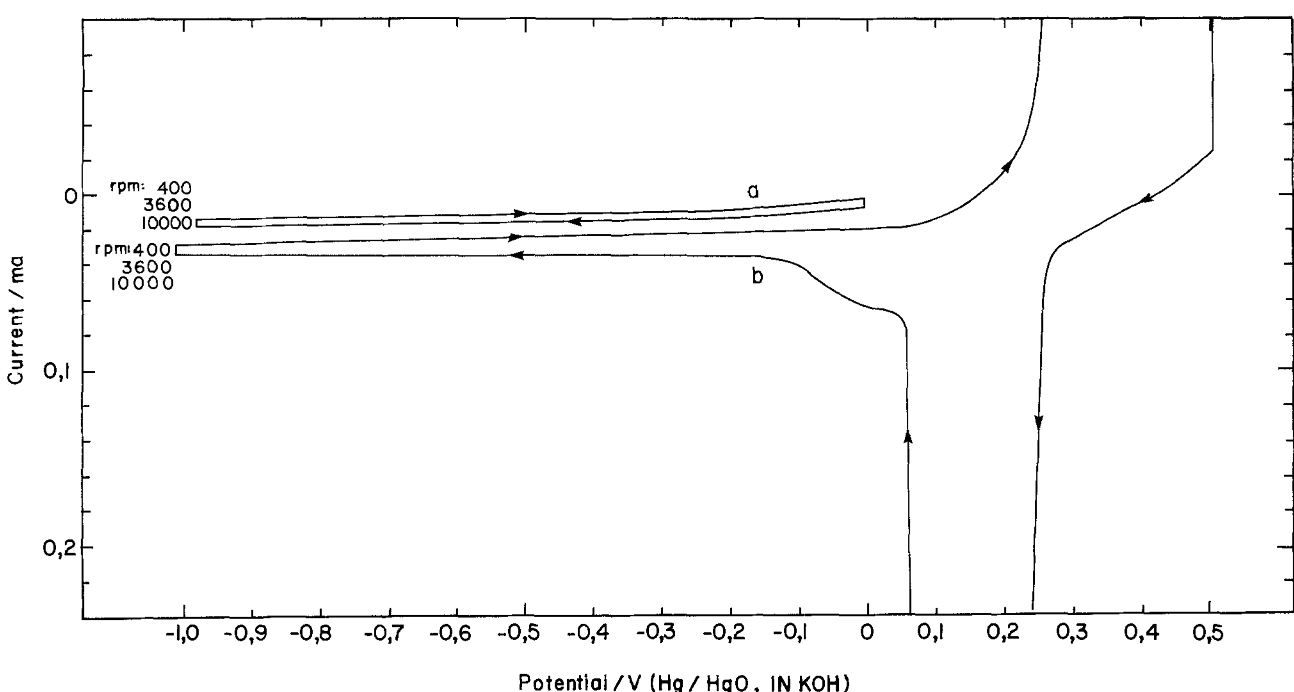

Fig. 11. Current-potential plots on bulk silver electrode at different rotation rates in He-saturated 0.1*N* KOH. Temperature 25°C, electrode area 0.786 cm², and potential scan: curve a, from 0 to —1.0V, and curve b, from 0.5 to —1.0V at a rate of 1 V/min.

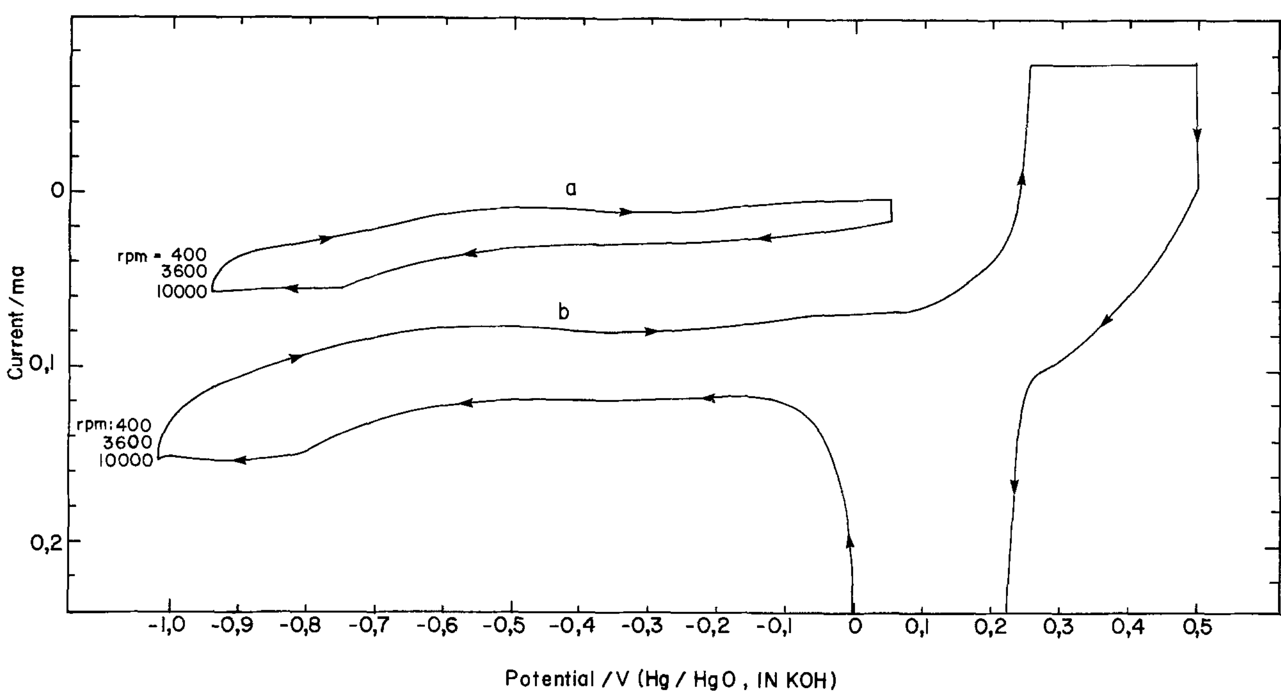

Fig. 12. Current-potential plots on silver electrodeposited on pyrolytic graphite at different rotation rates in He-saturated 0.1*N* KOH. Temperature 25°C. electrode area 0.338 cm², and potential scan: curve a, from 0 to —1.0V, and curve b, from 0.5 to —1.0V at a rate of 1 V/min.

vided that the starting potential used is 0 and not 0.5V. A drastic reduction in the cathodic current of a bulk silver electrode is observed (Fig. 15) when the electrode prior to the experiment is immersed for 5 sec in dilute HNO_3. The limiting currents after such treatment approach those corresponding to a 2-electron reduction process. H_2O_2 was detected in the cell after the experiment of Fig. 6 and its concentration was found to be $1 \times 10^{-5}N$. A far less reduction in the current is observed (Fig. 16) when the same treatment is applied to a silver surface electrodeposited on pyrolytic graphite. A stronger reduction in the limiting current of the latter surface is observed (Fig. 16), when the surface, prior to the experiment, is mechanically polished with alumina powder or even a filter paper.

3. The limiting currents in the case of silver electrodeposited on pyrolytic graphite or platinum substrates start at more positive potentials as compared to the limiting currents on bulk silver or electrodeposited silver on silver substrate (Fig. 1-10).

4. The increase in rotation rate, results, for the same silver surface, in a significant shift into more cathodic potentials of the limiting current. The only exception for this observation is the case in which the bulk silver electrode is immersed prior to the experiment in dilute HNO_3. In the latter case only slight shift is observed.

5. Hysteresis between the anodically and cathodically increasing potential scans is much more significant in curves where the starting potential is 0V than

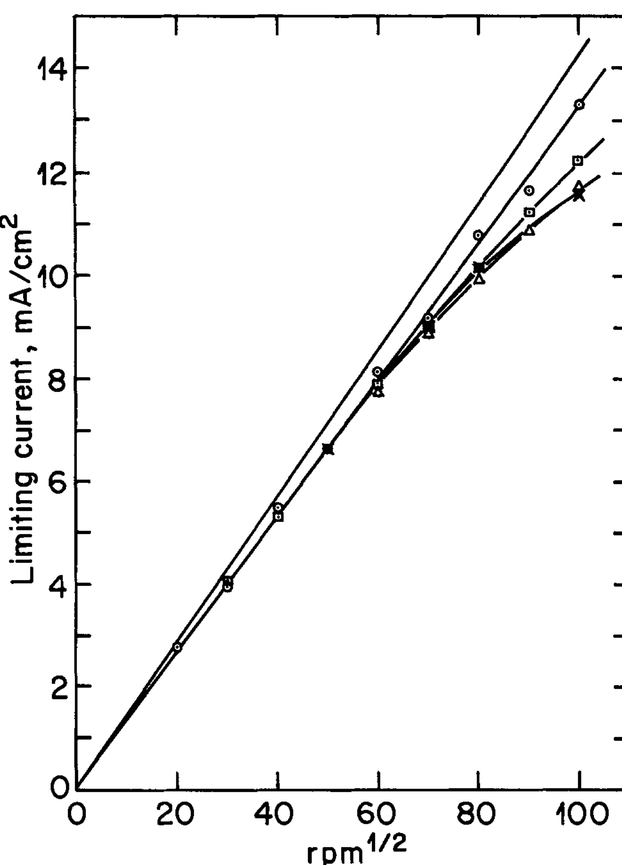

Fig. 13. Dependence of the limiting current/cm^2 on the square root of rotation rate at different silver surfaces. — Theoretical plot calculated by Eq. [1]; ⊙, data of Fig. 3 obtained on electrodeposited silver on pyrolytic graphite substrate potential scan from 0 to −1.0V; ⊡, data of Fig. 4 obtained on electrodeposited silver on platinum substrate, potential scan from 0 to −1.0V; ⚠, data of Fig. 1 on bulk silver, potential scan from 0 to −1.0V; x, data of Fig. 2 obtained on electrodeposited silver on bulk silver, potential scan from 0 to −1.0V.

[1] and data of Fig. 9 obtained on electrodeposited silver on pyrolytic graphite substrate, potential scan from 0.5 to −1.0V; +, data of Fig. 10 obtained on silver electrodeposited on platinum substrate, potential scan from 0.5 to −1.0V; x, data of Fig. 8 obtained on bulk silver electrode, potential scan from 0.5 to −1.0V.

when it is 0.5V (Fig. 1-10). Whenever hysteresis exists it increases with the increase in rotation rate. Hysteresis is generally higher with silver surfaces which have been prior to the experiment immersed in dilute HNO_3 or mechanically polished than with those surfaces which have not been subjected to such treatments.

The experimental results indicate that the total number of electrons transferred in the over-all reduction of O_2 on silver cathodes ranges between a value which is slightly above 2 electrons in the case of bulk silver electrodes (with a potential scan starting at 0V) pretreated in dilute nitric acid to 4 electrons in the case of silver electrodeposited on pyrolytic graphite with a potential scan starting at 0.5V. Such wide variation in the electrocatalytic activity of silver cathodes as a function of surface pretreatments is consistent with previously reported work (7-12). Also on the basis of previous work (13) it is known that oxygen reduction on silver may follow one or more of two routes. In one route oxygen is first reduced to peroxide

$$O_2 + H_2O + 2e \rightarrow HO_2^- + OH^-$$

The resultant peroxide ion may be further reduced electrochemically or catalytically decomposed as shown by

$$HO_2^- + H_2O + 2e^- \rightarrow 3\,OH^-$$
$$HO_2^- \rightarrow O_2 + 2\,OH^-$$

If oxides are present, they may be reduced by the peroxide intermediate as shown by

$$HO_2^- + Ag_2O = 2Ag + OH^- + O_2$$

Also some of the peroxide may be removed into the bulk of the solution. In the second route oxygen is dissociatively adsorbed and the adsorbed oxygen atoms are directly reduced to hydroxide

$$O_{ads} + 2e + H_2O \rightarrow 2\,OH^-$$

A limiting current that corresponds to 2 electrons or slightly more than 2 electrons, as observed in the case of bulk silver electrodes pretreated in dilute HNO_3 and with a 0V starting potential, indicates that O_2 reduction occurs mostly via the peroxide route. It also indicates that the electrode surface is a poor catalyst for peroxide decomposition. The removal of formed peroxide into the bulk of the solution (as detected by chemical analysis) considerably reduces the amount of peroxide available for further electrochemical reduction. The pretreatment in dilute HNO_3 must result in the formation of an oxide or chemisorbed O_2 layer which is not easily reduced when the potential is scanned in the region of O_2 reduction. The formation of such a layer decreases the electrocatalytic activity of the electrode surface both by preventing the dissociative adsorption of O_2 as well as by reducing the catalytic activity for peroxide decomposition. This observation is consistent with the results of Palous and Buvet (8) and of Mazitov *et al.* (9) who observed two waves for O_2 reduction on silver electrodes preheated in oxygen. The fact that pretreatment in dilute HNO_3 causes by contrast very little reduction in the electrocatalytic activity of silver electrodeposited on pyrolytic graphite suggests that any formed oxide or chemisorbed O_2 layer is more easily removed when the potential is scanned in the region of O_2 reduction. That probably means that O_2 adsorbs more reversibly on a silver surface electrodeposited on pyrolytic graphite than on a bulk silver electrode.

A limiting current that corresponds to 4 electrons as observed in the case of silver electrodeposited on pyrolytic graphite and with a 0.5V starting potential, may result from a reduction of oxygen via either route 1, route 2, or both routes. In case route 1 is followed either partially or completely, a 4-electron reduction limiting current can only mean that the reaction leading to peroxide formation is coupled with a second-order heterogeneous catalytic reaction with a rate constant for the catalytic reaction tending to infinity (14). If the latter condition is not satisfied, then a 4-electron limiting current may only result from the direct reduction of dissociatively adsorbed oxygen into hydroxide. This point cannot be settled however without the use of the rotating disk-ring electrode. Zhutaeva and co-workers (13) used the latter electrode and showed that in the case of a mechanically polished bulk silver electrode the relative fraction of the current going via the intermediate formation of H_2O_2 is at most 10% in the potential region between 0.7 and −0.2 (*vs.* H_2). At potentials more positive than 0.7 the proportion of H_2O_2 production increases and reaches 40% at 0.8V. On the basis of these results it may be concluded that the 4- and near 4-electron limiting currents observed in the present work must result mostly from the reduction of dissociatively adsorbed oxygen. The occurrence of the later reaction must be associated with the shift in potential as a function of rotation rate observed in Fig. 1-10. In Fig. 6 this shift is very slight because the 4-electron reduction of dissociatively adsorbed O_2 is largely absent.

The observed increase in the electrocatalytic activity when the silver surface is prepared by electrodepositing Ag on either graphite or platinum most probably results from the effect of electrochemical three-dimensional nucleation (associated with the electrodeposition of silver from silver cyanide on a foreign substrate such as graphite or platinum) in increasing the electrocatalytically active area of the silver surface. Other alternative explanations would be that impurities left on bulk silver surface from polishing with an alumina powder has a poisoning effect on such active area or that the difference between the residual current due to reduction of silver oxide species in both cases results in the observed difference in limiting current. In view of the fact that a silver surface prepared by electrodepositing silver on a bulk silver electrode exhibits the same electrocatalytic activity (Fig. 13) as that of bulk silver, the former objection is ruled out. Figures 11 and 12 also show that in helium-saturated solutions and with a 0V starting potential, the magnitude of the currents as well as the difference between the current-potential characteristics of both bulk silver and electrodeposited silver on graphite, are too insignificant to influence the currents in Fig. 1-4.

If three dimensional electrochemical nucleation of silver on a foreign substrate results in the observed higher electrocatalytic activity, one would anticipate that the nucleation mechanism of silver from silver cyanide on a foreign substrate (such as graphite or platinum) would be considerably different from the corresponding nucleation mechanism on the same silver substrate. Figure 17 shows that the electrodeposition of silver from silver cyanide on either pyrolytic graphite or platinum is accompanied with a very high nucleation overpotential.[1] In contrast the electrodeposition of silver on a silver substrate occurs without any such nucleation overpotential. The high nucleation overpotential in the case of graphite and platinum substrates results from the high energy barrier associated with nucleation. Silver cannot form mixed crystals with such foreign substrates and therefore can only condense on its surface and forms a granular

[1] For further information on the correlation between potential-time plots of Fig. 17 and nucleation overpotential, see Ref. (15).

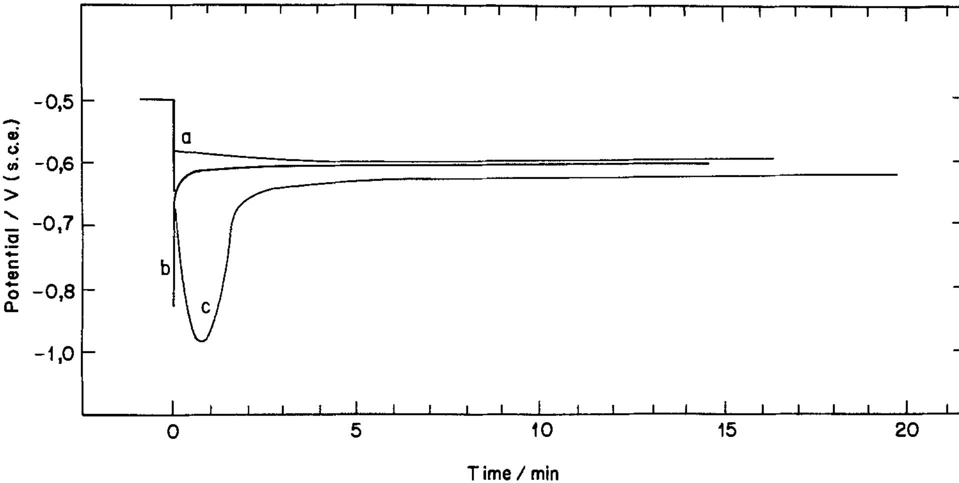

Fig. 17. Potential-time relationships at 0.3 mA/cm² for the electrodeposition of silver from silver cyanide on different substrates: (a) silver substrate; (b) platinum substrate; (c) pyrolytic graphite substrate.

deposit. The fact that such a granularly shaped deposit actually forms is seen in the scanning electron micrograph (Fig. 18) of a silver deposit obtained by electrodepositing silver on pyrolytic graphite from silver cyanide solution at a current density of 3 mA/cm² for 12 min.

The slightly higher electrocatalytic activity of silver electrodeposited on a pyrolytic graphite substrate as compared to that electrodeposited on a platinum substrate may be attributed to the formation of a higher number of nuclei/square centimeter in the former case. The higher number of nuclei is expected on the basis of the much higher nucleation time (see Fig. 17) observed with the graphite substrate.

In order to find out whether electrodeposited silver on pyrolytic graphite has a higher ratio of true/apparent surface area as compared to bulk silver electrodes, the potential dependence of the differential capacity for both surfaces was measured in 0.1*N* KOH. Figure 19 shows that the differential capacity in the potential region of O_2 reduction is about 3½ times larger with electrodeposited silver on graphite than with bulk silver electrodes.

The effect of the variation in true surface area (due to the change in the form of silver surface) on the experimental result can be quantitatively described as follows. The relationship between the observed limiting current, i_L, mass-transfer limiting current, i_d, and pure first-order kinetically controlled limiting current, i_K, is given (16) by

$$\frac{1}{i_L} = \frac{1}{i_K} + \frac{1}{i_D} = \frac{1}{i_K} + \frac{1}{B\sqrt{\omega}} \qquad [3]$$

and a linear $1/i_L$ *vs.* $1/\sqrt{\omega}$ plot indicates that the reaction is first order. Now if the experimentally observed limiting current is equal to the mass transfer limiting current, the plot $1/i_L$ *vs.* $1/\sqrt{\omega}$ passes through the origin as shown in Fig. 20 for the case of O_2 reduction on an electrodeposited silver on pyrolytic graphite. But if $i_d \neq i_L$ as for the case of O_2 reduction on bulk silver or electrodeposited silver on silver substrate, the corresponding plot of Fig. 20 intercepts the Y axis at a value of $1/i_K$ or $i_K \simeq 100$ mA/cm². But from

Fig. 18. Scanning electron micrograph of silver deposit obtained at current density of 3.0 mA/cm² and 12 min. Magnification 1500X.

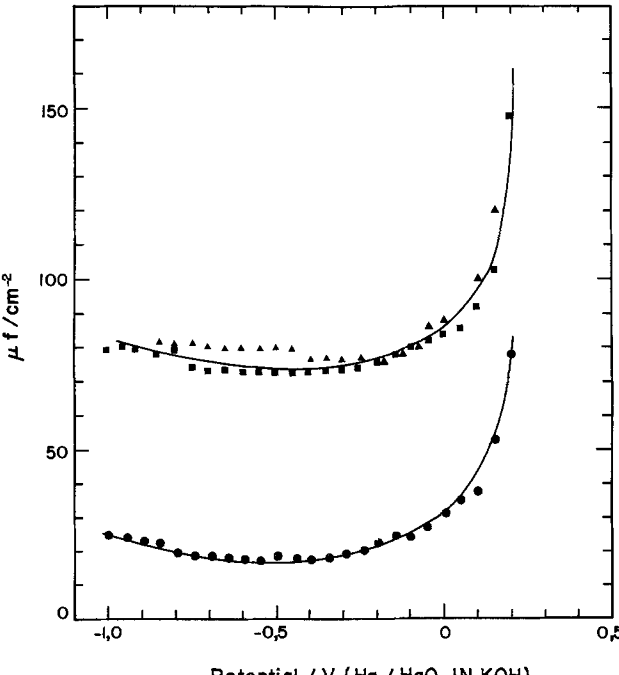

Fig. 19. Differential capacity *vs.* potential plots in helium-saturated 0.1*N* KOH at 1000 Hz. ▲ and ■, Same experiment on silver electrodeposited on pyrolytic graphite; ●, on bulk silver electrode.

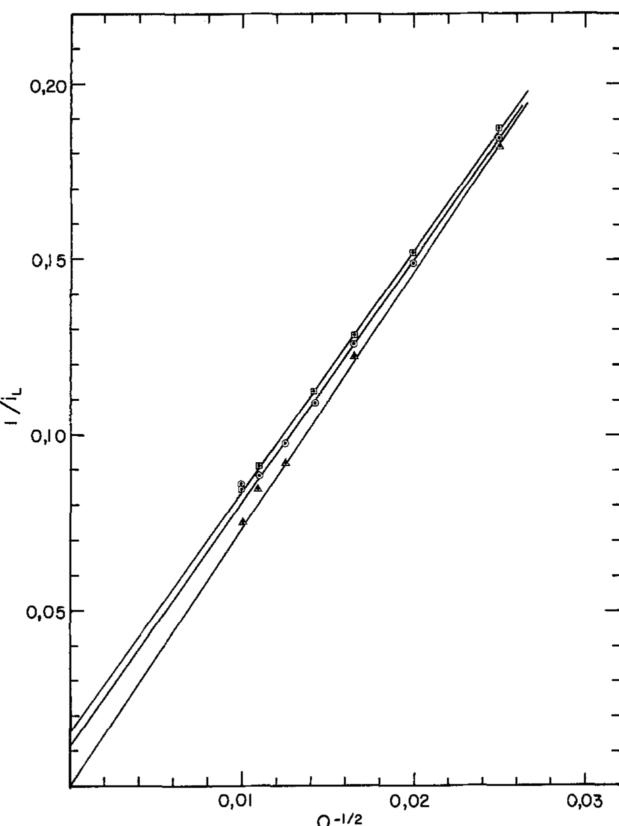

Fig. 20. Dependence of $1/i_L$ on $\Omega^{-1/2}$ for the data of Fig. 1, 2, and 3. ⊡, Electrodeposited silver on silver substrate; ○, bulk silver; △, electrodeposited silver on pyrolytic graphite.

Eq. [3] one obtains

$$i_L = \frac{i_d i_K}{i_d + i_K} \quad [4]$$

Since the value of i_d (10-15 mA/cm^2) at higher rotations is not negligible compared to 100 mA/cm^2, i_L will be under mixed mass-transfer and kinetic control and a plot of i_L *vs.* $\Omega^{1/2}$ will deviate from linearity as observed in Fig. 13. If it is assumed that the increase in electrocatalytic activity of the electrodeposited silver on pyrolytic graphite is proportional (17) to the increase in true surface area, i_K, for the latter surface is found to be $\simeq$ 350 mA/cm^2. Since this value is much greater than the mass-transfer limiting current, Eq. [4] shows that the observed limiting current will be equal to i_d. The fact that a plot of i_L *vs.* $\Omega^{1/2}$ of Fig. 13, although linear, exhibits i_L values that are slightly less than those predicted on the basis of pure mass-transfer control probably results from the removal at higher rotation rates of some of the peroxide intermediate into the solution bulk.

Several objections could be raised against the preceding quantitative treatment; first there is no concrete proof that the increase in the electrocatalytic activity is directly proportional to the increase in true surface area. Second, it could be argued that Eq. [3] is only applicable for an electrode reaction that is determined both by electrode kinetics and by mass transfer (18) and not for the case of mixed control by a chemical reaction (which may be the case in the present work) and mass transfer. Third as shown by McIntyre (19) and Riddiford (16) it is possible for there to be intercepts in the plot of the reciprocal of the transfer limiting current *vs.* $\omega^{-1/2}$. But regardless of the validity or not of Eq. [3] for the present treatment, the conclusion would still be that silver electrodeposited on such foreign substrates as graphite and platinum exhibits higher electrocatalytic activity and therefore higher kinetically controlled limiting current as compared to bulk silver electrodes.

The strong decrease in the electrocatalytic activity observed when the electrodeposited silver on pyrolytic graphite electrode is mechanically polished must in view of the preceding discussion result from a decrease in active surface area. The dependence of hysteresis on the type of silver surface and rotation rate can be also easily interpreted in the light of the same discussion. A mass-transfer limiting current is a property of a certain species (O_2 in this case) in the electrolyte and therefore its magnitude should not depend on the variation of surface properties. In contrast a kinetically or chemically controlled limiting current may be influenced by the variation in surface properties and therefore would be expected to be less reproducible and to exhibit more hysteresis. Consequently, at lower rotation rates, where the limiting currents are mass-transfer controlled, no hysteresis is observed, and at higher rotation rates where the currents are under kinetic or chemical control hysteresis appears.

The higher electrocatalytic activity and far less hysteresis generally observed when the potential scan is started at 0.5V must be also related to the increase in the number of active surface sites as a result of surface oxidation and subsequent surface reduction. The oxidation and reduction processes are indicated by the two anodic and one cathodic peaks which are observed at about 0.45, 0.33, and 0.15V, respectively. These correspond to the formation of Ag_2O, AgOH, and silver surface, respectively (20).

On the basis of electron microscopic examination Stonehart (20) claims that the area of a smooth silver surface increases by more than 100× after one single potentiodynamic scan involving the previously mentioned oxidation and reduction processes. Differential capacity measurement by the present author has shown however that the increase in the surface area of a bulk silver electrode after one single potentiodynamic scan is only of the order of 3-4×. But even if the increase in surface area of the bulk silver electrode is only 3-4× one would have expected that with a starting potential scan of 0.5V the limiting current/square centimeter would reach as in the case of electrodeposited silver on graphite, the mass-transfer limiting value. The fact that the limiting current on bulk silver deviates from such value (Fig. 14) at 10,000 rpm suggests a lower frequency of active sites as compared to its frequency on the electrodeposited silver on graphite substrate. Figures 11 and 12 actually indicate that the amount of chemisorbed O_2 and/or Ag oxides reduced in He-saturated solutions and with a scan started at 0.5V, is about 8× larger[2] in the case of electrodeposited silver on graphite. This is consistent with the previously made conclusion that the adsorption of O_2 is probably more reversible on silver electrodeposited on graphite than on bulk silver electrodes. This higher reversibility is also consistent with the observation that the limiting currents in the case of electrodeposited silver on graphite start at more positive potentials as compared to the limiting currents on bulk silver or electrodeposited silver on silver substrates (Fig. 1-10). The fact that this shift in potential is related to the reversibility of O_2 adsorption rather than to a mere increase in surface area is supported by the observation that the magnitude of the shift in potential which is associated with the increase in rotation rate is not reduced when the surface area is presumably increased by the oxidation and subsequent reduction of the silver surface (compare Fig. 1-3 with Fig. 8-10).

A detailed analysis of the mechanism of O_2 reduction on the different types of silver electrodes is too complex and will require further experimental work including the use of the rotating disk-ring electrode. On the basis of the present data some general conclusions are possible.

[2] After converting the currents of Fig. 11 and 12 into current densities.

It can be shown (1) that for a cathodic electrochemical reaction which is partially controlled by charge transfer and partially by mass transfer and in which the limiting current, i_L, is caused by either mass-transfer control or a potential insensitive chemical step, or both, with first-order kinetics with respect to the diffusing reactant, the following equation may be used

$$\eta = -\frac{RT}{\alpha \mathbf{F}}\left[\ln\frac{i}{i_L - i} - \ln\frac{(i_o)}{-i_L}\right] \quad [5]$$

where η is the overpotential and i_o the exchange current of the rate-determining step. The validity of Eq. [5] also requires that i_L is the product of the total diffusing reactant. Figure 21 shows that the plots of log $[i/(i_L - i)]$ *vs.* the potential at different rotation rates for the data of Fig. 9 are linear with a Tafel slope that increases slightly with the increase in rotation rate. This suggests (*i*) that the same O_2 reduction mechanism takes place at the same O_2 concentration, and (*ii*) that a continuous change in the mechanism occurs as the concentration of O_2 reaching the surface is increased. At 400 rpm the Tafel slope is $\simeq$ 0.12 V/decade. In accordance with previously attempted analysis (1, 12) of O_2 reduction metchanisms on silver as well as other electrodes a Tafel slope of 0.120 V/decade suggest that the rate-determining step is

$$O_2 + e^- \rightarrow (O_2^-)_{ads}$$

assuming that α is equal to ½ and that Langmuir conditions of adsorption prevail.

An increase in the value of the Tafel slope with the increase in rotation rate probably reflects the continuous increase in the contribution of the irreversible dissociative O_2 adsorption step which is known to become more dominant with the increase in current density. Figure 22 shows that similar log $[i/(i_L - i)]$ *vs.* potential plots are obtained from the data of Fig. 8 on bulk silver electrode. It is observed however that the increase in the value of the Tafel slope with the increase in rotation rate is larger, probably because of the higher irreversibility of O_2 adsorption.

On the Nature of Electrochemical Reactions at a Crack Tip during Hydrogen Charging of a Metal

B. G. Ateya*[,1] **and H. W. Pickering***

ABSTRACT

The electrochemical conditions within cracks in metals undergoing cathodic hydrogen charging in acid solutions are analyzed. The gradients of the electrical potential and concentrations of the various ionic species and the current distribution are calculated for a model crack. The actual potential profiles were measured in slots in Fe, Ni, and Cu samples during hydrogen charging using an electrical potential probe. The measured potential drop in the electrolyte in the slots of all three metals is often very large, *e.g.*, 0.5V. This is about an order of magnitude larger than that calculated, and is in general at odds with the usually implicit assumption that the electrode potential is not an important variable within a growing crack. The reason for this discrepancy is shown to be the large potential variation caused by the presence of trapped hydrogen gas bubbles in the slot.

The measured electrode potentials in the slot during cathodic hydrogen charging are in the region of metal dissolution in the case of the two base metals, Fe and Ni. On the other hand, the outer surface of these metals is under perfect cathodic protection for the typical impressed cathodic currents of 5 or 10 mA cm^{-2}. Subsequent tests of electrolyte samples taken from within slots while the current was flowing, indeed, showed the presence of relatively large amounts of iron and nickel ions indicating that anodic dissolution of iron and nickel occurs within the slots, though not at the outer surface during cathodic hydrogen charging. Analysis of the solution at the outer surface of the slot under conditions of impressed current showed the absence of significant concentrations of metal ions.

It has long been recognized that the concentrations of the ionic species within probes and cracks in an electrode are always different from those at the outer surface, *e.g.*, see the review paper by Szklarska-Smialowska (1). Some measure of these composition changes within pits have been obtained in a few cases (2-5). The electrode potential is another parameter that is known to vary as a function of position in a cavity (6-11), although the fact that the potential change can be quite large is not generally recognized.

There is also the possibility of additional or alternative electrochemical and/or chemical reactions in the cavity or crack. Pickering and Frankenthal (9) observed hydrogen evolution from inside pits in iron samples during strong anodic polarization; the electrode potential at the outer surface was >0.8V SHE. At this potential hydrogen evolution from the outer surface is not thermodynamically possible and was not observed. It was found that the electrode potential inside the pit, on the other hand, was so base as to allow hydrogen evolution. These measured large potential drops were attributed to constrictions caused by trapped hydrogen gas bubbles.

More recently Beck (11) has obtained a similar result. He found hydrogen evolving from pits in titanium while the sample was anodically polarized at large noble potentials. The generation of hydrogen in this case would again seemingly require that at some location within the pit the electrode potential is in the region of hydrogen evolution.

A corresponding situation exists for cathodic polarization, although it has attracted little if any attention. For this case, in particular, one wishes to answer the question: Does metal dissolution occur at the bottom of cracks in samples being cathodically charged with hydrogen? This is important with regard to the question of crack propagation under corrosion conditions and during cathodic protection practices. Recent results show that metal dissolution does occur within pores and cracks for Fe-10Pt (12) and iron (13) samples during aggressive hydrogen charging.

The purpose of the present paper is to determine the electrochemical conditions and the ongoing electrode reactions within cracks in metals during cathodic charging. A model is proposed for the combined effect of ohmic, mass transfer, and concentration polarizations

Key words: cathodic protection, current distribution, iron, nickel, copper.

on the current, concentration, and potential profiles inside the crack. The approach taken here is similar to that developed by Wagner (14) in electroplating. Related models and calculations for different conditions have appeared in the porous electrode literature (15-17). Experimental results are presented to test the validity of the proposed model.

Theoretical

Model, assumptions, and solution.—The model of a crack considered here is that of a narrow, deep slot whose outer surface is maintained at a large negative potential so that the only reaction taking place at the outer surface is hydrogen evolution. The cross section of the slot is a rectangle of dimensions a and b, and its depth is L such that $a << L$ and $a << b$, Fig. 1, in which case the reaction can be considered to occur only on the outer surface and on the side walls. A more precise condition for validity of the equations is $X >> a$ where X is the characteristic distance defined later. It is assumed that mass transfer in the electrolyte takes place by molecular diffusion and ionic migration according to the Nernst-Einstein relation. The electrolyte is a simple acid, HY, which completely dissociates to give monovalent ions.

Performing a mass balance on an element dx, Fig. 1, under steady-state conditions, one has for the fluxes, j, of the H^+ and Y^- ions in the direction of the interior of the slot

$$j_{H^+} = -D_{H^+}\left(\frac{dc_{H^+}}{dx} + c_{H^+}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx}\right) = \frac{i}{\mathbf{F}} \quad [1]$$

$$j_{Y^-} = -D_{Y^-}\left(\frac{dc_{Y^-}}{dx} - c_{Y^-}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx}\right) = 0 \quad [2]$$

in which D is the diffusivity and c is the concentration of the indicated species, ϕ is the local electrical potential in the electrolyte in the crack with respect to the potential at the opening where $\phi = 0$ by definition, i is the local current density of cathodic hydrogen evolution, T is the absolute temperature, $\mathbf{F}$ is the Faraday constant, and R is the gas constant. Since Y^- ions are neither produced nor consumed, the right-hand side of Eq. [2] equals zero.

The electroneutrality equation is

$$c_{H^+} = c_{Y^-} = c \quad [3]$$

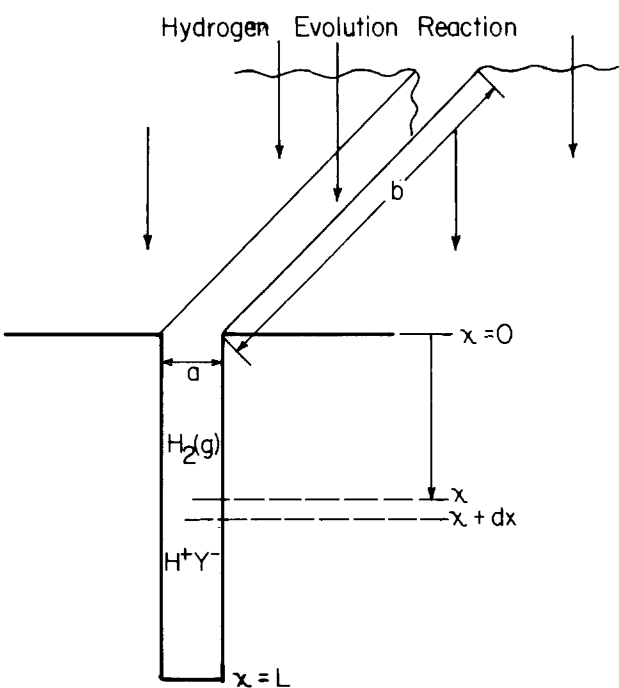

Fig. 1. Model of crack

The boundary condition at $x = 0$ for a bulk acid concentration of c_o is

$$x = 0:\ c_{H^+} = c_{Y^-} = c_o \text{ and } \phi \equiv 0 \quad [4]$$

A boundary condition at $x = L$ is formulated below in Eq. [12]. Equations [1]-[4] are then used to find ϕ, c, and i as functions of x, c_o, a and the local current density, i_s, at the outer surface, $x = 0$, far from the slot.

Rearranging, integrating Eq. [2], and using Eq. [3] and [4] yields

$$c = c_o \exp\left(\frac{\mathbf{F}\phi}{RT}\right) \quad [5]$$

Note that $c(x > 0) < c_o$ since $\phi(x > 0)$ is negative in view of the current flow direction. Modifying Eq. [5] by Eq. [3] and substituting in Eq. [1] gives

$$j_{H^+} = -2D_{H^+}c_o \exp\left(\frac{\mathbf{F}\phi}{RT}\right) \cdot \frac{\mathbf{F}}{RT}\frac{d\phi}{dx} \quad [6]$$

Let us consider a mass balance for the volume element $(ab)dx$. Equation [1] gives

$$(ab)\,dj_{H^+} = -(2bi/\mathbf{F})\,dx \quad [7]$$

with $(2b)dx$ the lateral area of the element if $b >> a$. Note that ab is the electrolyte cross-sectional area available for diffusion and migration of ions. If any gas bubbles accumulate in the slot this area effectively decreases. The local current density at distance x is (18)

$$i = i_s\left(\frac{c}{c_o}\right)^{\beta} \exp\left(\frac{\beta\mathbf{F}\phi}{RT}\right) \quad [8]$$

in which β is the transfer coefficient of the hydrogen evolution reaction. The value of i_s is given by the Tafel relation

$$i_s = i_o \exp\left(\frac{\beta\mathbf{F}\eta}{RT}\right) \quad [9]$$

in which i_o is the exchange current density at the bulk concentration of H^+ ions and η is the polarization at $x = 0$.

Introducing the auxiliary variable

$$\mu = \exp(\mathbf{F}\phi/RT) \quad [10]$$

and substituting Eq. [10] in Eq. [6] gives

$$j_{H^+} = -2D_{H^+}c_o d\mu/dx \quad [6a]$$

and substituting Eq. [5] in Eq. [8], using Eq. [10] and taking $\beta = 1/2$ gives

$$i = i_s\mu \quad [8a]$$

Substituting with Eq. [6a] and [8a] in Eq. [7] gives

$$d^2\mu/dx^2 = (1/X^2)\mu \quad [11]$$

in which the characteristic length X is

$$X = (D_{H^+}c_o\mathbf{F}a/i_s)^{1/2} \quad [11a]$$

X is an important parameter because it contains all the necessary parameters of the system, *i.e.*, the bulk concentration c_o, the mass transfer constant D_{H^+}, the charging current i_s, and the important geometric property of the crack, a. Note that X is independent of the length L. For $X >> a$ the use of one-dimensional transport equations in the x-direction is a valid approximation (14).

In terms of the new variable Eq. [4] becomes

$$x = 0 \qquad \mu = 1 \quad [4a]$$

The boundary condition at $x = L$ in terms of μ can be obtained by equating Eq. [6a] and [8a] after dividing Eq. [8a] by $\mathbf{F}$, and then substituting Eq. [11a], since the current at the bottom of the slot is supported by the flux of H^+ ions at $x = L$. Thus

$$(d\mu/dx)_{x=L} = -(a/2X^2)\mu_L \quad [12]$$

The solution to the problem is obtained by solving Eq. [11] using Eq. [4a] and [12] as boundary conditions. Substituting by the equality

$$\frac{d^2\mu}{dx^2} = \frac{1}{2}\frac{d}{d\mu}\left(\frac{d\mu}{dx}\right)^2 \quad [13]$$

in Eq. [11], rearranging, and integrating with Eq. [12] as a boundary condition, one obtains

$$\left(\frac{d\mu}{dx}\right) = -\left(\frac{1}{X}\right)\left[\mu^2 - \mu_L^2\left(1 - \frac{a^2}{4X^2}\right)\right]^{1/2} \quad [14]$$

The negative root is taken in Eq. [14] because μ decreases as x increases. Since the treatment is realistic only if $a << X$, it follows that $a^2/4X^2 << 1$ and the factor of μ_L in Eq. [14] can be set equal to unity as an approximation. Thus

$$\frac{d\mu}{dx} \simeq -\frac{1}{X}(\mu^2 - \mu_L^2)^{1/2} \quad [14a]$$

Integration of Eq. [14a] for $\mu = 1$ at $x = 0$ as a boundary condition yields

$$\mu = \frac{\cosh\ [(L-x)/X]}{\cosh\ [L/X]} \quad [15]$$

The validity of this solution can readily be checked upon substitution in Eq. [14a].

If the argument z of the cosh function is much greater than unity, one may use the approximation

$$\cosh z \simeq ½ \exp z \text{ if } z >> 1$$

Then it follows from Eq. [15] that

$$\mu_L = \frac{1}{\cosh\ (L/X)} \simeq 2\exp\left(-\frac{L}{X}\right) \text{if } L >> X \quad [16]$$

From Eq. [10] and [15] the potential in the electrolyte as a function of distance into the slot is given as

$$\phi = \frac{RT}{\mathbf{F}}\ln\frac{\cosh\ [(L-x)/X]}{\cosh\ [L/X]} \quad [17]$$

The concentration and the current distribution are obtained by substituting Eq. [17] in Eq. [5] and Eq. [15] in Eq. [8a], to yield, respectively

$$c = c_0\frac{\cosh\ [(L-x)/X]}{\cosh\ [L/X]} \quad [18]$$

$$i = i_s\frac{\cosh\ [(L-x)/X]}{\cosh\ [L/X]} \quad [19]$$

Equation [17] may be used to estimate the depth (using also Eq. [28]) at which the potential ϕ (in the electrolyte) assumes a sufficiently high negative value for anodic dissolution of the metal. Similarly, Eq. [18] and [19] may be used to estimate the depth at which depletion of H^+ and decrease in the hydrogen evolution rate became significant.

The potential, concentration, and current density at the bottom of the slot are obtained by substituting $x = L$ in Eq. [17]-[19]. Thus

$$\phi(x = L) = -\frac{RT}{\mathbf{F}}\left(\frac{L}{X} - \ln 2\right) \quad \text{if } L >> X \quad [20]$$

$$c(x = L) = 2c_0\exp\left(-\frac{L}{X}\right) \quad \text{if } L >> X \quad [21]$$

and

$$i(x = L) = 2i_s\exp\left(-\frac{L}{X}\right) \quad \text{if } L >> X \quad [22]$$

If $(L - x) >> X$, Eq. [17] reduces to the linear relation

$$\phi \simeq -\frac{RT}{\mathbf{F}}\cdot\frac{x}{X} \quad \text{if } (L-x) >> X \quad [23]$$

and Eq. [18] and [19] reduce to

$$c \simeq c_0 \exp(-x/X) \text{ if } (L-x) >> X \quad [24]$$

$$i \simeq i_s \exp(-x/X) \text{ if } (L-x) >> X \quad [25]$$

From Eq. [6a], [10], and [14] one may calculate the relation between the current density i_n in the slot normal to the outer surface and the local potential ϕ

$$i_n = j_{H^+}\mathbf{F} = \frac{2D_{H^+}c_0\mathbf{F}}{X}\left[\exp\left(\frac{2\mathbf{F}\phi}{RT}\right) - \exp\left(\frac{2\mathbf{F}\phi_L}{RT}\right)\left(1 - \frac{a^2}{4X^2}\right)\right]^{1/2} \quad [26]$$

where ϕ_L is the potential at the bottom of the slot. For the entrance of the slot ($x = 0$, $\phi = 0$), one obtains as an approximation

$$i_n(x = 0) \simeq \frac{2D_{H^+}c_0\mathbf{F}}{X} \quad \text{if } -\phi_L >> \frac{RT}{\mathbf{F}} \quad [26a]$$

Substituting Eq. [11a] and [9] with $\beta = ½$, one obtains

$$i_n(x = 0) = 2\left(\frac{D_{H^+}c_0\mathbf{F}i_s}{a}\right)^{1/2} = 2\left(\frac{D_{H^+}c_0\mathbf{F}i_0}{a}\right)^{1/2}\exp\left(\frac{\mathbf{F}\eta}{4RT}\right) \quad [27]$$

This is a Tafel equation with a slope of twice the normal value and an apparent exchange current density of $2(D_{H^+}c_0\mathbf{F}i_0/a)^{1/2}$. The appearance of a double Tafel slope is common in porous electrode work (16, 17). This is attributed to both ohmic and mass transfer effects.

The results of the calculations are plotted in Fig. 2-5 for a slot of depth $L = 1$ cm and a diffusivity of H^+ ion at 25°C of $D_{H^+} = 10^{-4}$ cm² sec^{-1} (19). Figure 2 shows the concentration of both H^+ and Y^- as a function of x and i_s for a slot width $a = 0.05$ cm. With increasing distance into the slot, the concentration of H^+ decreases as it is consumed by the electrode reaction at the walls. Under the existing potential gradient, c_{Y^-} decreases as x increases such that at any distance $c_{H^+} = c_{Y^-}$ as required by electroneutrality. Actually, c_{Y^-} may fall off less rapidly with increasing distance

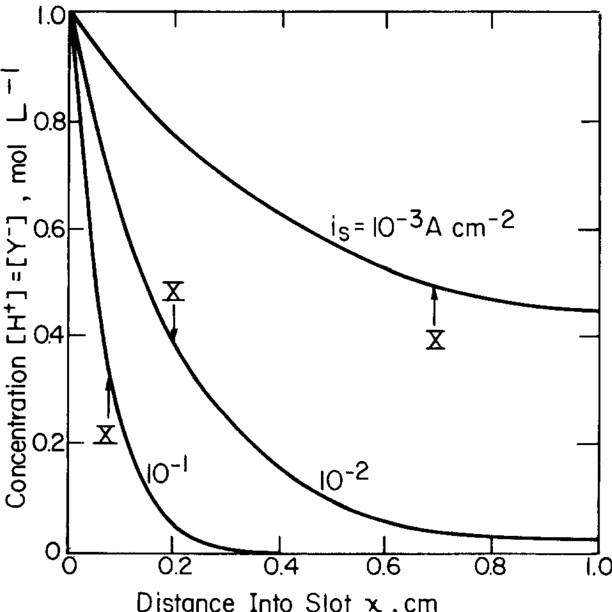

Fig. 2. Calculated concentration profiles of H^+ and Y^- ions in a slot of depth $L = 1$ cm and width $a = 0.05$ cm for three rates of cathodic hydrogen evolution at the surface, $x = 0$. See text for definition of the characteristic distance X.

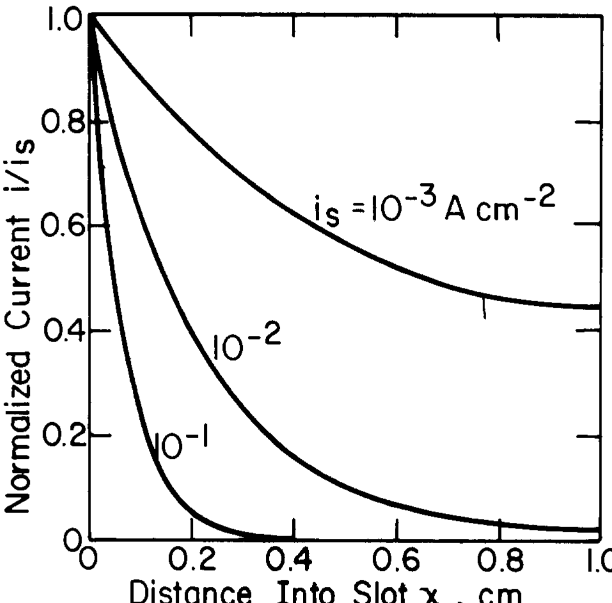

Fig. 3. Ratio of the calculated current density to the charging current density *vs.* distance into the slot for the same conditions as in Fig. 2.

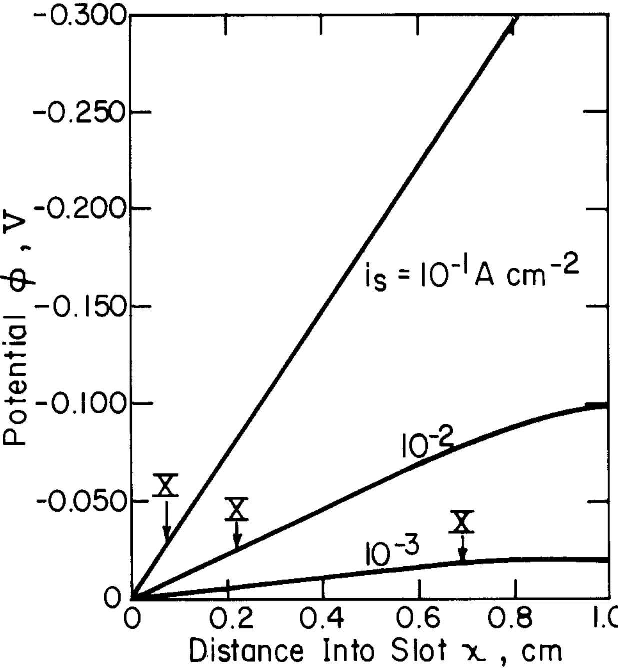

Fig. 4. Calculated profiles of the electrical potential in the electrolyte in a slot with respect to the potential at the opening where $\phi \equiv 0$ for same conditions as in Fig. 2.

if anodic dissolution occurs near the crack tip to form metal ions, the presence of which was not considered in this model. It is shown later that metal dissolution does actually occur inside cracklike slots for the base metals, iron and nickel. It is also seen from Fig. 2 that as i_s increases, the H^+ (and Y^-) concentration profile becomes steeper.

The current distribution was found to behave similarly, Fig. 3. It decreases sharply with increasing distance into the slot, in agreement with an earlier analysis by Wagner (14). The distance into the slot at which the rate of hydrogen evolution becomes negligible decreases with increasing i_s, in agreement with established rules (20, 14) which state that the "throwing power" decreases with increasing current density.

Figure 4 shows that the electrical potential, ϕ, becomes more negative with increasing distance into the

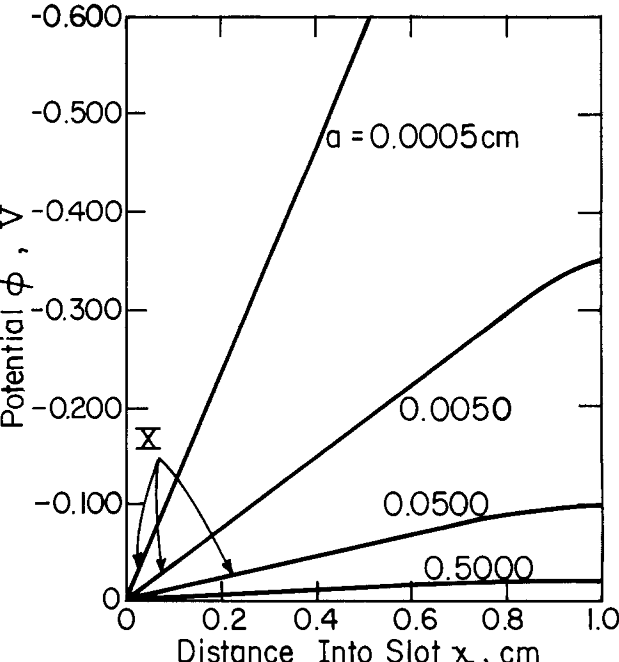

Fig. 5. Effect of crack width "*a*" on the electrical potential profile inside a crack of depth $L = 1$ cm at a constant hydrogen charging rate at the electrode surface of $i_s = 0.01$ A cm^{-2}.

slot ($a = 0.05$ cm). The magnitude of ϕ is seen to increase with increasing i_s and x. In the presence of metal ions (which may be produced by dissolution of the metal at the bottom of the slots) the electrolyte conductivity may be higher and accordingly the magnitude of ϕ lower.[2]

Figure 5 shows for $i_s = 10^{-2}$ A cm^{-2} the important effect of slot width, a, on the potential profiles inside the slot. As the slot width decreases ϕ changes more sharply with distance into the slot. Correspondingly larger variations in current and concentration also occur as the slot width decreases. This is a particularly noteworthy feature of this model since cracks usually are very narrow, and since the effect of crack width on concentration and potential profiles is not generally recognized. The bulk electrolyte concentration has the same effect on the various profiles as the slot width since it is the product $c_0 a$ which influences the value of X, see Eq. [11a]. It follows that as the bulk concentration of the acid decreases (hence its conductivity decreases) the potential drop over a certain distance increases.

The potential ϕ involves an ohmic potential drop inside the slot and the contribution of a diffusion potential as well. The *IR* drop in the metal is negligible. Thus ϕ is equal to the difference of the electrode potentials E at $x = 0$ and $x > 0$, *i.e.*

$$\phi = E(x = 0) - E(x) \qquad [28]$$

Thus, a more negative value of ϕ in the electrolyte corresponds to a more positive (noble) local electrode potential of the metal with respect to the solution, as pointed out previously by Wagner (14).

The results in Fig. 2 are reliable for $i_s = 10^{-3}$ and 10^{-2} A cm^{-2}, but of only marginal value for $i_s = 10^{-1}$ A cm^{-2} for which $X = 0.07$ cm is not much larger than the slot width. The validity range of the equations increases as the slot width decreases, *e.g.*, $X >> a$ for all except the bottom curve in Fig. 5. Nevertheless, they apply quantitatively only at $x >> X$ in view of appreciable three-dimensional transport at the slot opening. However, even precisely calculated current and concentration distributions have limited practical application since experimental data are often obtained

[2] It is shown later that the increase in resistance due to constrictions (gas) in the electrolyte path far outweighs the increase in conductivity due to anodically formed metal ions.

from laboratory experiments or industrial practice for which conditions in the crack differ from those in the idealized model, *e.g.*, the accumulation of gas to form a constriction, and the occurrences of additional chemical and electrochemical reactions. Gas accumulation is likely in cracks with a corresponding increase in the effective electrolyte resistance as shown previously by Pickering and Frankenthal (9). The consequence of such constrictions in the present study would be steeper gradients of H^+, Y^-, i, and ϕ than in Fig. 2-4, and a more noble local electrode potential at the slot bottom, $E_{x=L}$, according to Eq. [28]. It is shown later that gas accumulation and larger-than-expected negative ϕ values occur in cracklike slots during hydrogen charging, and that anodic dissolution occurs in slots of base metals.

In summary, substantial changes in electrochemical conditions within pores or cracks during cathodic hydrogen charging are expected. This, in turn, means that the nature and the rates of the electrochemical reactions occurring inside the pores may be quite different from those at the outer surface. For example, at high hydrogen charging rates the electrode potential at the outer surface of iron in 1*N* H_2SO_4 may be sufficiently negative such that no significant iron dissolution occurs. Nevertheless, at some distance into a pore or crack iron dissolution may occur because the electrode potential is more positive. This shift of electrode potential is illustrated in Fig. 6 using the partial polarization curves according to Wagner and Traud (21).

Iron dissolution inside the pore or crack is also favored by the higher *p*H (Fig. 2). It is recognized now that the anodic current density of iron dissolution at a given potential increases with increasing *p*H (22-27). Thus, dissolution of iron inside a pore is favored, not only by the shift of the potential to more noble values with respect to the potential at the outer surface, but also by a decreasing hydrogen ion concentration inside the pore.

Experimental

General procedure.—An experimental system was set up to test the above hypothesis and conclusions. Cracklike slots, (see Fig. 1), were cut in the middle of cubes of Ferrovac E Fe, electrolytic Ni, and 99.999+ Cu ($a \simeq$ 0.5-1.5 mm, $b \simeq$ 1.2 cm, $L \simeq$ 1.2 cm). The cutting procedure differed for the metals, with the result that the surfaces of the slot in the iron sample were smooth in comparison to those for the Ni and Cu samples. In order to shield the outer (except the top) surfaces from the electrolyte the sample was tight-fitted into a Teflon mount such that only the horizontal outer top and inner (slot) surfaces were accessible to the electrolyte. Electrical contact to the sample was made through a thin platinum wire attached to one side of the electrode before it was fitted inside the Teflon mount. The platinum wire was shielded from the electrolyte with an Alphex shrinkable tubing, the diameter of which decreases considerably on gentle heating.

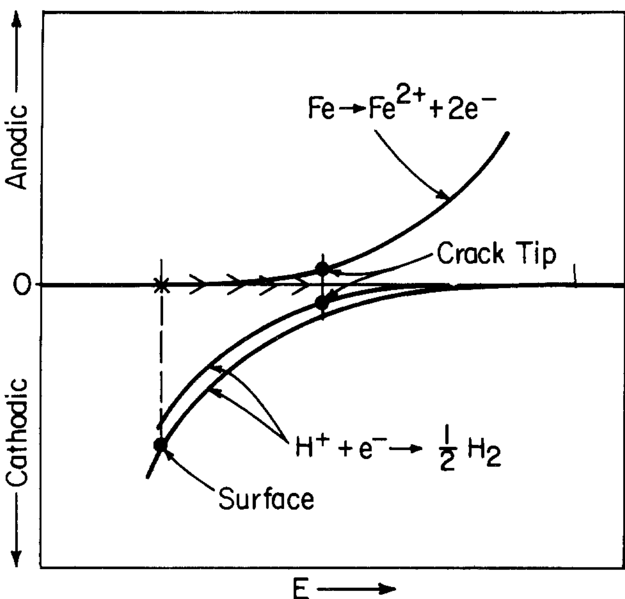

Fig. 6. Schematic partial polarization curves illustrating the shift of the local electrode potential *E* from the region of solely hydrogen evolution at the outer surface to the mixed potential region of iron dissolution and hydrogen evolution at the bottom of the crack.

This assembly was then put into a large volume of electrolyte (about 1.5 liter). The electrolytes used were 1M $HClO_4$ and a sodium acetate-acetic acid buffer, *p*H $\simeq$ 5 (0.5M each). All tests were made at room temperature. Electrode potentials are reported with respect to the standard hydrogen electrode (SHE).

A constant cathodic current was impressed on the sample. After a steady potential was obtained the potential of the metal with respect to the solution at the outer surface ($E_{x=0}$) and at various positions inside the slot (E_x) was measured using a Hg/Hg_2SO_4 (0.1*N* H_2SO_4) reference electrode and a fine Luggin capillary (diameter $<$ 0.01 cm) (9). In order to avoid probe-induced ϕ values the probe diameter was 5-10 times smaller than the slot width, values at the slot bottom were obtained with the probe backed off the bottom, and a technique for detecting gas accumulation within the probe was developed. For these conditions the potential variation in the electrolyte ϕ between two positions of the Luggin capillary is the difference in the measured electrode potentials, Eq. [28].

A second procedure was also used which allowed direct measurement of the variation in potential ϕ inside the slot. In this arrangement two reference electrodes were used, one with Luggin capillary positioned at $x = 0$ and the other with a (adjustable) Luggin capillary at distance x into the slot. The two reference electrodes were connected to a high impedance voltmeter. The measured potential was the magnitude of ϕ over the distance x.

The position of the capillary inside the slot was adjusted and the distance measured using a micromanipulator. The counterelectrode was a spectrographically pure porous graphite rod positioned about 10 cm away from the iron sample to insure a uniform current distribution on the exposed outer (top) surface of the metal.

After reaching steady state and while the current was flowing, the solution inside the slot was extracted using a fine capillary glass tube and a simple suction mechanism. Qualitative tests for iron were done using the Standard Orthophenanthroline color procedure (28). Quantitative tests for Fe^{2+}, Cu^{2+}, and Ni^{2+} ions were made using atomic absorption spectrometry.

Electrode potential values and gas bubbles.—The measured potential variation ϕ inside a slot of $a = 0.05$ cm width in a Ferrovac E iron sample is shown in Fig. 7. The charging current density (comparable to i_s in the model) was 5.2 mA cm^{-2} cathodic and the electrolyte was acetate-acetic acid buffer, *p*H $\simeq$ 5. Although this *p*H is different than that used in the model, it is not an important consideration for reasons to be discussed; its choice was based on experimental considerations. Electrolytes which fit the model were used for the Ni and Cu samples.

It is seen from Fig. 7 that there is a significant difference between the measured potential at the outer surface and that at the bottom of the slot. The measured electrode potential at the outer surface was approximately $E_{x=0} \simeq -$ 0.9V SHE and that at the bottom was $E_{x \simeq L} \simeq -$ 0.5V. Since the ferrous ion concentration in the bulk electrolyte is extremely low, one may use the standard single electrode potential of iron minus 0.2V ($E = -$ 0.64V) as the limiting condition for virtually complete cathodic protection (29, 30). Hence, the outer iron surface was cathodically pro-

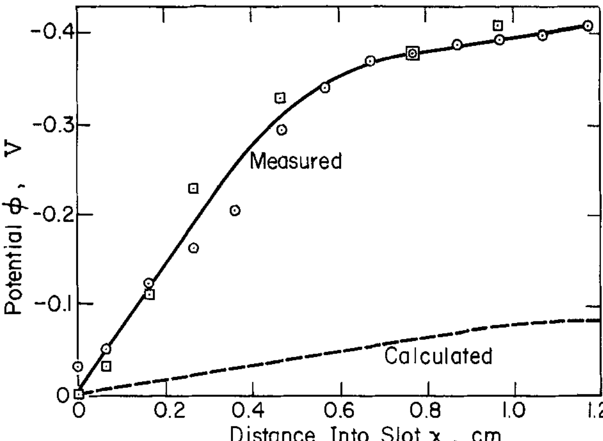

Fig. 7. The ϕ profile from the measured electrode potentials as a function of distance x into the slot in the iron sample exposed to the acetate-acetic acid solution for $i_s = 5.2$ mA cm^{-2} and $a = 0.05$ cm. Points are for a traverse of the Luggin probe into (○) and out of (□) the slot. Total time of traverse was 25 min. The calculated ϕ profile (Eq. [19]) is shown for comparison; $X = 0.3$ cm.

tected well into the stable iron region. The electrode potential at the bottom corresponds to appreciable equilibrium concentrations of Fe^{2+} ions (see Appendix) and as such is a mixed potential value established by the iron and hydrogen reactions.

A second series of measurements made 3 hr later showed nearly the same potential variation within the slot as in Fig. 7, *viz.*, $\phi_{x \simeq L} \simeq -0.34$V. In a third series of measurements the potential variation in the electrolyte within the slot was measured directly using the alternative circuit and gave $\phi_{x \simeq L} \simeq -0.33$V, in good agreement with the above value.

Figure 8 shows the measured ϕ values inside a slot 0.15 cm wide and 1.4 cm deep in a Ni sample. The charging solution was 1M $HClO_4$ and the current density was 10 mA cm^{-2} cathodic. It is seen that part way inside the slot ϕ increases sharply. This behavior was very reproducible in all cases when a gas bubble was seen to occupy the bottom portion of the slot. The measured electrode potential at the opening of the slot

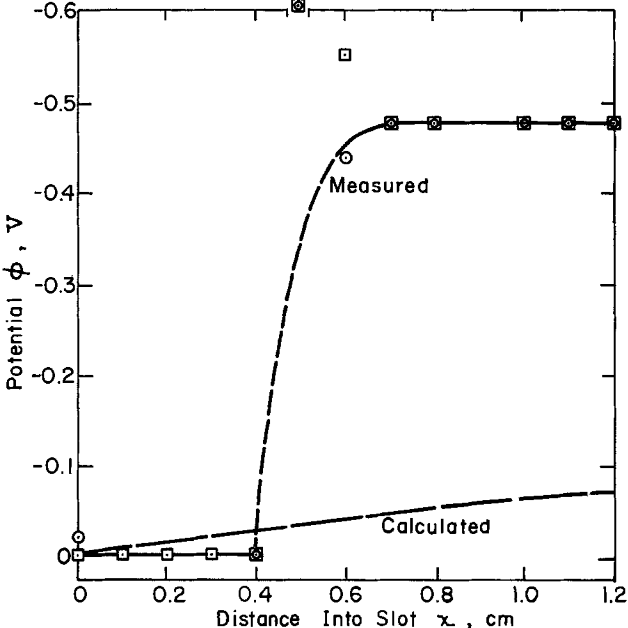

Fig. 8. The experimental and calculated ϕ profiles for a nickel sample in 1M $HClO_4$ for $i_s = 10$ mA cm^{-2} and $a = 0.15$ cm; $X = 0.4$ cm.

was $E_{x=0} \simeq -0.6$ to -0.7V, a value which is too negative for anodic dissolution of Ni ($E^\circ - 0.2$V $= -0.45$V). However, the electrode potential in the deeper portion of the slot, being 0.4-0.5V more noble at $E_{x>L/2} \simeq -0.2$V is in the region of Ni dissolution. Some difficulty was encountered in the measurements, which may explain the scatter of values of ϕ about halfway into the slot (Fig. 8). The sharp increase in ϕ is attributable to the presence of a large gas bubble in the slot.

The large width of the slot in the nickel sample enabled information to be obtained on the nature of gas bubble formation and evolution within the slot. It was seen that accumulation of the gas occurred to give a large bubble which occupied most, if not all, of the cross section about halfway down the slot. Intermittently, a smaller bubble (though much larger in size than those evolving off the outer surface) evolved from the slot as if coming from the accumulated hydrogen gas "stuck" in the slot. Since only the small area at the edges of the slot were material other than iron (Teflon), the accumulation of gas occurs primarily, if not entirely, on the iron walls of the slot.

Data for the Cu sample were obtained for a charging current of 10 mA cm^{-2} in 1M $HClO_4$. The slot was 0.5 mm wide and 1 cm deep. The measured electrode potential at the outer surface was $E_{x=0} \simeq -0.7$V, a value which is well below that required for anodic dissolution of copper since $E^\circ - 0.2$V $= 0.14$V. The measured electrode potential inside the slot was erratic and oscillating very quickly. During the first traverse of the probe to the slot bottom a relatively small potential variation, $\phi_{x=L} = -0.10$ to -0.15V, was measured. At a later time, a larger increase in potential, $\phi_{x=L} \simeq 0.50$V, was noted. Gas accumulation was observed within the slot during the experiment.

Results with the Cu sample differed in an important way from those for iron and nickel. The potential variation, $\phi_{x=L} \simeq -0.50$V, though large was not enough to shift the electrode potential into the region of copper dissolution. The most noble potential reached was $E_{x \simeq L} \simeq -0.2$V which is well below the limiting value of $E = 0.14$V.

The measured potential data for the Fe, Ni, and Cu samples are summarized in Table I. Values listed for the slot bottom were the most noble ones measured for each sample, and in most cases could be associated with accumulated gas which was lodged in the slot.

Metal ion concentrations.—Tests for increased metal ion concentrations within slots of the samples were done on solution periodically extracted from the slots. The amount of solution extracted was several times larger than the volume of the slot, a relatively large volume of liquid being required for the analysis (about 0.5 cm^3). Thus, average values heavily weighed toward the bulk concentrations were obtained. Consequently, in those cases in which departures from the bulk concentrations were observed, the measured concentrations were only small fractions of the true concentrations at $x = L$. Contributing to this averaging effect is the fact that the greatest departure occurs in only a small fraction of the slot volume (slot bottom or the region of a trapped gas bubble) where the electrical potential in the solution differs most from that in solution at the outer surface. For these reasons the

Table I. The largest measured potential variations (ϕ) in slots of Fe, Ni, and Cu samples and the corresponding (approximate) electrode potential at the bottom and at the opening of the slots

Metal	$\phi_{x \simeq L}$, V	$E_{x \simeq L}$, V SHE	$E_{x \simeq 0}$, V SHE
Fe	−0.4	−0.5	−0.9
Ni	−0.5	−0.2	−0.7 (approx)
Cu	−0.5	−0.2	−0.7

greatest concentration in the slot is estimated to be up to 100 times the difference in concentration of the measured bulk and slot values. The measured slot and bulk concentrations for Fe, Ni, and Cu specimens and the estimated limiting concentrations are shown in Table II.

Solution extracted from the slot of an iron sample ($a = 0.05$ cm) during cathodic charging at a rate of 5.2 mA cm^{-2} ($\phi_{x=L} = -0.36$V) showed an iron content of 50 ppm and gave a definite color in the orthophenanthroline test. Solution extracted at the same time from the bulk solution showed about 2 ppm Fe (as did the stock solution) and gave a barely detectable orthophenanthroline color. This was found to be reproducible on a daily basis for a period of 10 days of continuous hydrogen charging.

A similar result was obtained for a Ni sample. Quantitative analysis of electrolyte extracted from the slot during cathodic charging at 10 mA cm^{-2} showed 15 ppm of Ni^{2+} as compared to a negligible quantity in the bulk solution.

The results for the Cu specimens were quite different. The measured Cu^{2+} ion concentration in the slot was much lower than for iron and nickel.

One may calculate the lowest (most negative) electrode potential which will support the concentrations of metal ions shown in Table II. Using concentrations in place of activities in the Nernst equation one obtains $E = -0.53$ and -0.47V (SHE) for 50 and 5000 ppm iron, respectively; $E = -0.36$ and -0.30V for 15 and 1000 ppm nickel, respectively, and $E = 0.20$V for 1 ppm copper. In the case of iron and nickel the measured electrode potentials at the slot bottom (Table I) are more noble than these values, indicating that the measured metal ion concentrations in the slot are stable. The 1 ppm copper level in the slot is not stable at the measured $E_{x=L} = -0.2$V, and indicates that either more positive electrode potentials exist in the slot[3] or transport of Cu^{2+} in the electrolyte becomes a factor at these low concentrations. It may also be noted in this regard that the concentration of Cu^{2+} may be somewhat higher in the slot than in the bulk solution (where <1 ppm was measured) in view of the prevailing potential gradient within the solution.

Discussion

Comparison of the experimental results with the model.—The calculated ϕ potential from Eq. [17] is compared to the measured electrode potential for an iron sample in Fig. 7. It is clear that, although the direction of the potential change for calculated and measured values agree, the actual potential change is very much greater (order of magnitude) than that calculated. The disparity is much greater than that due to the use of a $pH = 5$ rather than a $pH = 0$ solution as called for in the model. Similar comparisons exist for Ni (Fig. 8) and Cu; in these cases the pH of the aqueous solutions fit the model. Large trapped gas bubbles were identified within the slot during the potential measurements, and are the most obvious reason for the deviation. Their presence would reduce the available cross section for current flow in the electrolyte, *i.e.*, comparable to a local reduction in the slot width a, Fig. 5 For a given current, the actual potential variation ϕ in the constricted (high resistance) region is necessarily larger than in the absence of the constriction. Hence, the measured ϕ is larger than that calculated, and in turn, so is the change in electrode potential per unit distance into the slot according to Eq. [28].

The present model and equations do correctly predict the signs of the gradients of the ionic species and of the electrical potential, and consequently are helpful in explaining and predicting the occurrence of electrochemical reactions inside a cavity when, as usual, only the electrochemical conditions at the outer surface are known. Furthermore, the solutions could apply in a quantitative sense to cracking situations in which constrictions are absent.

Role of gas bubbles and crack width.—Are constrictions likely in real cracks? Are they necessary for the attainment of large potential variations in real cracks? Since real cracks are usually much narrower than the slots used in this investigation, and since for all known conditions the vast majority of reduced H^+ ions becomes hydrogen gas, it seems likely that hydrogen gas will accumulate in real cracks. As to the second question, Fig. 5 shows that the gas may not be necessary for the attainment of large potential variations in the case of real cracks which are very narrow (small a). Recall that results in Fig. 5, which show the effect of slot width on the magnitude of the potential variation in the electrolyte, were obtained from a model which does not include constrictions. Hence, for a crack of 5 μm width ($a = 0.0005$ cm) and an impressed cathodic current of 0.01 A cm^{-2}, a potential variation of 0.5V exists over a distance of only 0.4 cm, *i.e.*, $\phi_{x=0.4\text{ cm}} \simeq -0.5$V. From these data it is clear that crack width also plays an important role in determining which reactions occur at the crack tip.

What is the upper limit of the electrode potential in a crack? The answer to this question for cathodic polarization (meaning a net cathodic current) is the reversible potential of the cathodic reaction. One has the basic condition that a net cathodic current (current flow into the slot) is required in the slot for ϕ to be negative. The more noble the electrode potential, the smaller is the rate of the cathodic reaction (hydrogen evolution) in accord with the general polarization behavior for a cathodic reaction. Since the rate goes to zero at the reversible potential of the hydrogen reaction, the local electrode potential in the slot can increase only to the point of approaching this value. Furthermore, if anodic reactions occur in the slot, a net zero current would occur at a more negative electrode potential than the local reversible hydrogen potential, and this "mixed" potential would then be the upper limit.

The experimental data are consistent with this concept of a limiting potential in the slot which is dictated by the cathodic (hydrogen) reaction. For the three metals investigated the most noble potentials measured were all negative of SHE. For two of the metals (Fe and Ni) whose anodic polarization behavior overlaps the cathodic polarization behavior of the hydrogen reaction, the measured electrode potential at the bottom of the slot may have been a mixed potential established by the metal and hydrogen reactions, in accord with the finding that Fe and Ni concentrations were significantly higher in the slots. In the case of Cu, anodic dissolution could not be expected (and was not observed) since the electrode potential at the bottom of the slot never attained a value near the dissolution potential. In this case, the measured electrode potential may have approached the reversible potential of the hydrogen evolution reaction at $x \simeq L$. A similar limiting potential criterion applies in the case of anodic polarization, and the available experimental data (6, 9) are consistent with such.

[3] This is due to the possible occurrence of oxygen reduction, in addition to H^+ ion reduction, in which case the limiting electrode potential also is a more positive value.

Table II. The measured concentrations of Fe^{2+}, Ni^{2+}, and Cu^{2+} ions in samples of electrolyte extracted from within the "slot" and from the bulk solution are listed. From these data an estimated concentration at the slot bottom was obtained as described in the text.

Metal	Bulk $[M^{2+}]$ (ppm)	"Slot" $[M^{2+}]$ (ppm)	Estimated $[M^{2+}]$ @ $x = L$ (ppm)
Fe	2	50	$\lesssim 5000$ ($\lesssim 0.1$M)
Ni	0.2	15	$\lesssim 1000$
Cu	—	1	—

From a practical point of view it is an important finding that the local electrode potential in the slot may shift by much larger amounts than previously assumed. This means that the likelihood of additional electrochemical reactions occurring in a crack is substantially increased. In particular, the noble E_x values measured and the detection of substantial amounts of iron and nickel ions in the slot during cathodic polarization indicate that in the case of the base metals and base-metal alloys, metal dissolution within cracks, crevices, etc. has to be taken into account in applying protection methods, as well as in mechanistic analyses of crack propagation.

Conclusions

The most significant experimental results of this investigation of cathodic charging of metals are (*i*) that the electrode potential measured at the bottom of cracklike slots in iron, nickel, and copper are about 0.5V more noble than at the outer surface, and (*ii*) that relatively large concentrations of metal ions were detected at the bottom of slots in the iron and nickel samples.

It is concluded that metal dissolution occurs in the slots, though not at the outer surface, in iron and nickel samples during cathodic hydrogen charging. In the case of copper, no metal dissolves at the external surface or at the bottom of the slot, in accord with its positive standard potential. Since these results are a consequence of mass and charge transfer conditions in the electrolyte and depend on the metal only as to its nobility, metal dissolution in slots or cracks during cathodic hydrogen charging or during cathodic protection should be considered a possibility for all base metals and their alloys, including the vast majority of commercial alloys.

Based on a simple model, the electrode potential, ionic concentration, and current distributions within cracks undergoing cathodic hydrogen charging in acid solutions were analyzed. The calculated solutions of the model show that (*i*) the concentrations of both ionic species, H^+ and Y^-, decrease with increasing distance into the slot, and that both gradients become sharper as the charging current is increased or the slot width decreased (Eq. [18] and [11a], and Fig. 2); (*ii*) the current distribution on the walls of the crack is nonuniform and becomes even less uniform as the hydrogen charging rate increases or as the slot becomes narrower (Eq. [19] and [11a], and Fig. 3); (*iii*) the electrical potential ϕ in the solution decreases with increasing distance into the slot, and the ϕ gradient becomes sharper with increasing rate of hydrogen evolution and with decreasing width of the slot (Eq. [17] and [11a], and Fig. 4 and 5); and (*iv*) the local electrode potential E_x increases in the noble direction with increasing x (Eq. [28] and at some distance into the slot may cause metal dissolution (Fig. 6) as was indicated for iron and nickel.

The very large measured change in ϕ in the slots of Fe, Ni, and Cu samples showed that the model greatly underestimated the electrical potential change, and hence, the local electrode potential in the slot. This is not surprising since hydrogen gas was regularly observed to partially fill the slots, in which case the experimental conditions clearly departed from those stipulated in the model. The gas has the effect of restricting current flow and mass and charge transport. It follows that a new model should include accumulation of gas in the slot or a comparable reduced cross-section effect. The present model, therefore, is a limiting one. The presence of gas constrictions does not invalidate the above-mentioned conclusions of the model.

APPENDIX

A check on the estimated Fe^{2+} concentrations shown in Table II can be made by assuming that the metal ion concentrations were in local equilibrium with the metal. For an electrode potential at the slot bottom of $E_{x=L} \simeq -0.5V$ (SHE), the Nernst equation gives a value of about 600 ppm Fe^{2+} ions (activity coefficient $= 1$) at $x = L$, which is midway between the measured and estimated values (Table II). A similar calculation is not realistic for the Ni sample since Ni is appreciably polarized at $E_{x=L} \simeq -0.2V$ in aqueous electrolytes.

Retentivities of Anodic Oxide Coatings on Aluminum Containing Electrodeposited Cobalt, Nickel, and Cobalt-Nickel

Satoshi Kawai

The Pilot Pen Company, Limited, Hiratsuka-Works, Kanagawa, Japan

ABSTRACT

Cobalt, nickel, and cobalt-nickel alloy were electrodeposited into the micropores of anodic oxide films on aluminum obtained in a sulfuric acid bath. The deposits in the micropores were separated from the oxide films and were observed as needlelike crystals about 100Å in diameter. The metallic deposits were quite dense at the bottom of the micropores and then gradually grew to the surface. Finally the deposits form layers distributed uniformly parallel to the surface. The density of residual magnetizations in cobalt and nickel deposits increase to about 1700 and 600G, respectively, when the outer layers are lapped down to a few microns in thickness. The films can be used as magnetic recording disks.

In the previous paper, it has been reported by the present author and his collaborator that the anodic oxide films of aluminum obtained from various electrolytic baths in which cobalt and Co-Ni alloy were electrodeposited showed characteristic magnetic anisotropies (1). These properties have been considered to be caused by the regular formation of micropores perpendicular to the substrate and the crystal orientation of metallic deposits in them. The coercivities of the films (about 500-1100 oe) showed rather higher values and the retentivities (about 1000G) indicated lower values compared to conventional magnetic thin films.

In the study of electrolytic coloring process of aluminum, Lichtenberger-Bajza *et al.* deposited copper crystals in the micropores by a-c electrolysis and observed with an electron microprobe analyzer that the metallic copper was deposited near the bottom of the pores (2). Sandera separated the deposits from the anodic oxide films which were pigmentated in the baths contained metal salts and found under an electron microscope and by the diffraction method that the metal deposits such as gold and silver crystallized as very fine fibrous structures in the micropores (3).

Meanwhile, in the study of a magnetic recording system, Iwasaki presented an empirical equation concerning the relationship between the half-pulse width (W_{50}) of output and the magnetic property of thin films as follows

$$W_{50} \propto (\delta \cdot Br/Hc)^{0.5}$$

and he elucidated that the high bit density magnetic recording can be obtained by decreasing the value of W_{50} (4). Therefore, δ (film thickness) has to be thinner and Hc (coercivity) to be larger while Br (residual magnetization) should be maintained at the same strength.

In the present paper, for the purpose of maximizing the recording performance of the magnetic oxide films, the author has studied the structures and remanences of electrodeposited metals in the oxide films.

Key words: anodic oxide film, electron microprobe analyzer, saturation magnetization moment.

Experimental Procedures

Rolled aluminum sheets, 99.99% in purity, 0.5 × 50 × 100 mm³ in size, were used as substrates. For the measurement with a magnetometer, the surfaces of the specimens were previously machined with a lathe to a surface roughness of about 1 μm.

First, aluminum sheets were anodized in a sulfuric acid bath and then electrolyzed between a carbon electrode with a.c. in various metal sulfate solutions as shown in Table I. Cobalt, nickel, and cobalt-nickel alloy were deposited in the micropores of oxide films as reported in the first paper (1).

In order to observe the electrodeposited crystals under an electron microscope, the specimens were immersed in 3% mercuric chloride solutions for a few hours at room temperature to separate the oxide films from the substrates, and the stripped films containing magnetic metals were dissolved in 5% NaOH solutions at 50°C for several minutes. Then, the extracted crystals were washed thoroughly with clean water and transferred to collodion films to keep the deposits as they were.

By using an electron microprobe, an x-ray microanalysis was performed. The specimens were buried in polyester resins and the cross sections of films were polished to flat surfaces. The measuring conditions were as follows; diameter of emission electron beam, 2 μm; scanning rate, 10 μm/min; acceleration voltage,

Table I. Bath compositions

Procedures	Remarks
Degreasing	5%—NaOH, 60°C, 2 min
Desmut	5%—HNO_3, 23°C, 1 min
Anodizing	15%—H_2SO_4, 0.1%—Al, 1.3 A/dm², 20°C, 40-50 min
Electrodeposition	
Co	5%—$CoSO_4 \cdot 7H_2O$, 2%—H_3BO_3, 0.2%—glycerine, 15V (50 Hz), 20°C, pH 6.0, 40-150 min
Ni	5%—$NiSO_4 \cdot 7H_2O$, 2%—H_3BO_3, 0.2%—glycerine, 15V (50 Hz), 20°C, pH 6.0, 15-120 min
Co-Ni	3%—$CoSO_4 \cdot 7H_2O$, 7%—$NiSO_4 \cdot 7H_2O$, 2%—H_3BO_3, 0.2%—glycerine, 15V (50 Hz), 30°C, pH 6.0, 20-120 min

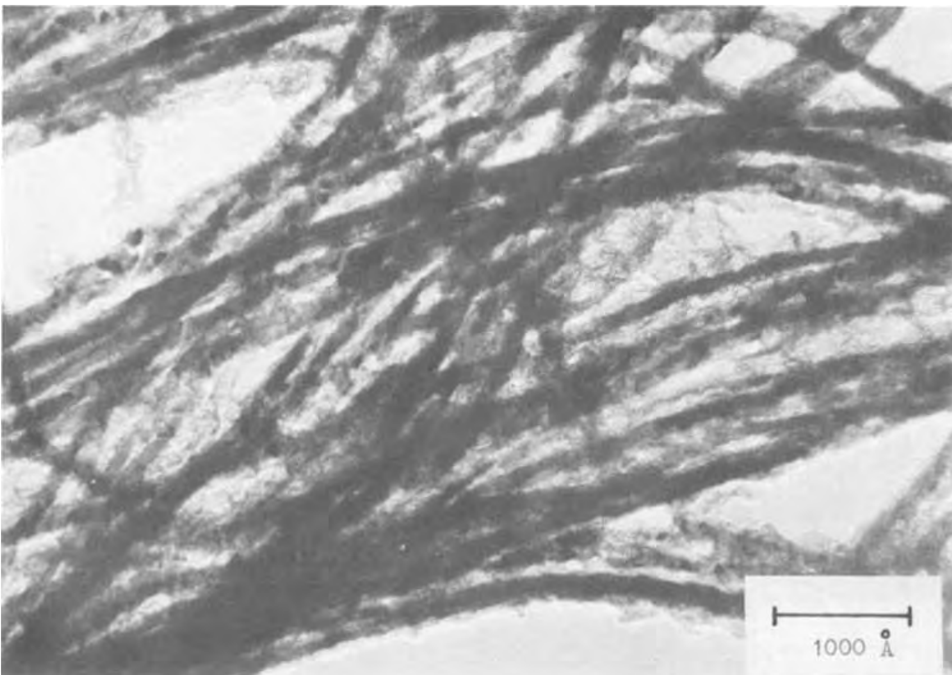

Fig. 1. Electron micrograph of nickel deposits extracted from anodic oxide film.

25 kV; absorbed electron current, 0.18 μA. The electron beam scanned the cross-sectional area from the outer surface of the oxide to the aluminum substrate. X-ray intensities due to ferromagnetic and aluminum metals at each position of film were continuously described with an X-Y recorder. In addition, the same specimens were also observed with a scanning electron microprobe image.

The total amount of cobalt and nickel deposits in the oxide films were determined by an atomic absorption spectroscopy. The specimens, 20 × 20 mm^2 in size, were immersed in 5% NaOH solutions at 50°C to dissolve the films from the substrates. Then the undissolved aluminum metals were washed and removed from the solutions. The caustic solutions which contained the metal deposits were dissolved in hydrochloric acid solutions and subjected to quantitative analyses.

With a lapping machine, the surfaces of the oxide films were abraded with aluminum oxide powder with a diameter of about 0.1 μm. And with this procedure, the surface roughness of the films could be maintained at 0.05 μm while the flatness was about 0.1 μm in a 20 mm length. The thickness of the oxide films was reduced gradually by this polishing and finally reached a value of about 2 μm. At each step in decreasing the thickness, the strength of magnetization was measured by the sample vibrating magnetometer as described in the previous paper (1).

Hysteresis loops were measured by the sample vibrating magnetometer in which 80 Hz vibration is applied to the specimen by a quartz oscillator. By using this method, the magnetic moment in the direction of vibration can be determined with high sensitivity. The specimens in the form of a disk, 6 mm in diameter, were inset on a quartz holder, and hysteresis curves were measured with an X-Y recorder under 5 kOe of magnetic field.

Experimental Results

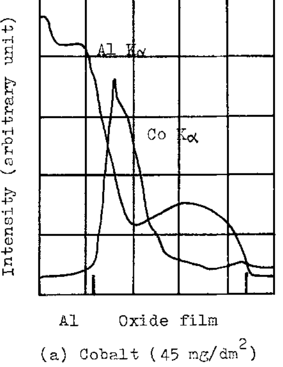
The deposited crystal extracted from the oxide films showed needlelike structure, and the typical crystalline form of the nickel deposits is shown in Fig. 1.

Figure 2 (a) and (b) show the results of the cobalt deposits in the cross section of the oxide films as determined by the electron microprobe analysis. Samples (a) and (b) differ in the amount of cobalt deposits with different electrolysis time. Separate distributions for cobalt and aluminum were observed as a function of thickness. The Al Kα lines had two different intensities. The area showing the lower intensities indicated the anodic oxide film sections, because of the lower aluminum content in the oxide. In specimen (a), the x-ray intensity of Co Kα was relatively high near the bottom of the micropores, but very low in the vicinity of the surface of the oxide film. On the other hand, the Co Kα line of specimen (b) was nearly uniform from the bottom of the micropores to the outer surface of the oxide.

With the scanning electron microscope, the same sections of the oxide films were observed. Simultaneously the scanning x-ray images of aluminum and cobalt at the identical positions are indicated as shown in Fig. 3 of which the (a) and (b) portions are different in the amount of cobalt deposits, respectively. The thickness of the oxide layers observed under the electron microscope correlated well with the layers examined by the x-ray images of aluminum which were discerned clearly by the spot distributions. The spot density of cobalt deposits were found to be very homogeneous and the layer became thicker with increasing cobalt deposits. The same tendencies for cobalt were also recognized in the case of nickel and Co-Ni alloy.

Figure 4 indicates the amount of precipitated metals of cobalt and nickel which varied with the duration time of electrolysis. The deposition rate in each case decreased as the electrolysis time became longer.

The saturation magnetization moments calculated with the amount of deposited cobalt and nickel increased linearly and showed approximately equal



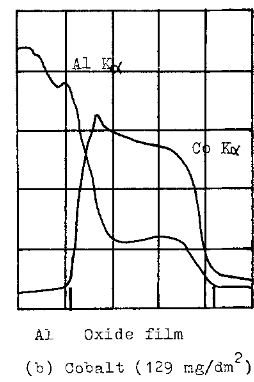


Fig. 2. Line profiles of Co and Al in cross section of oxide films

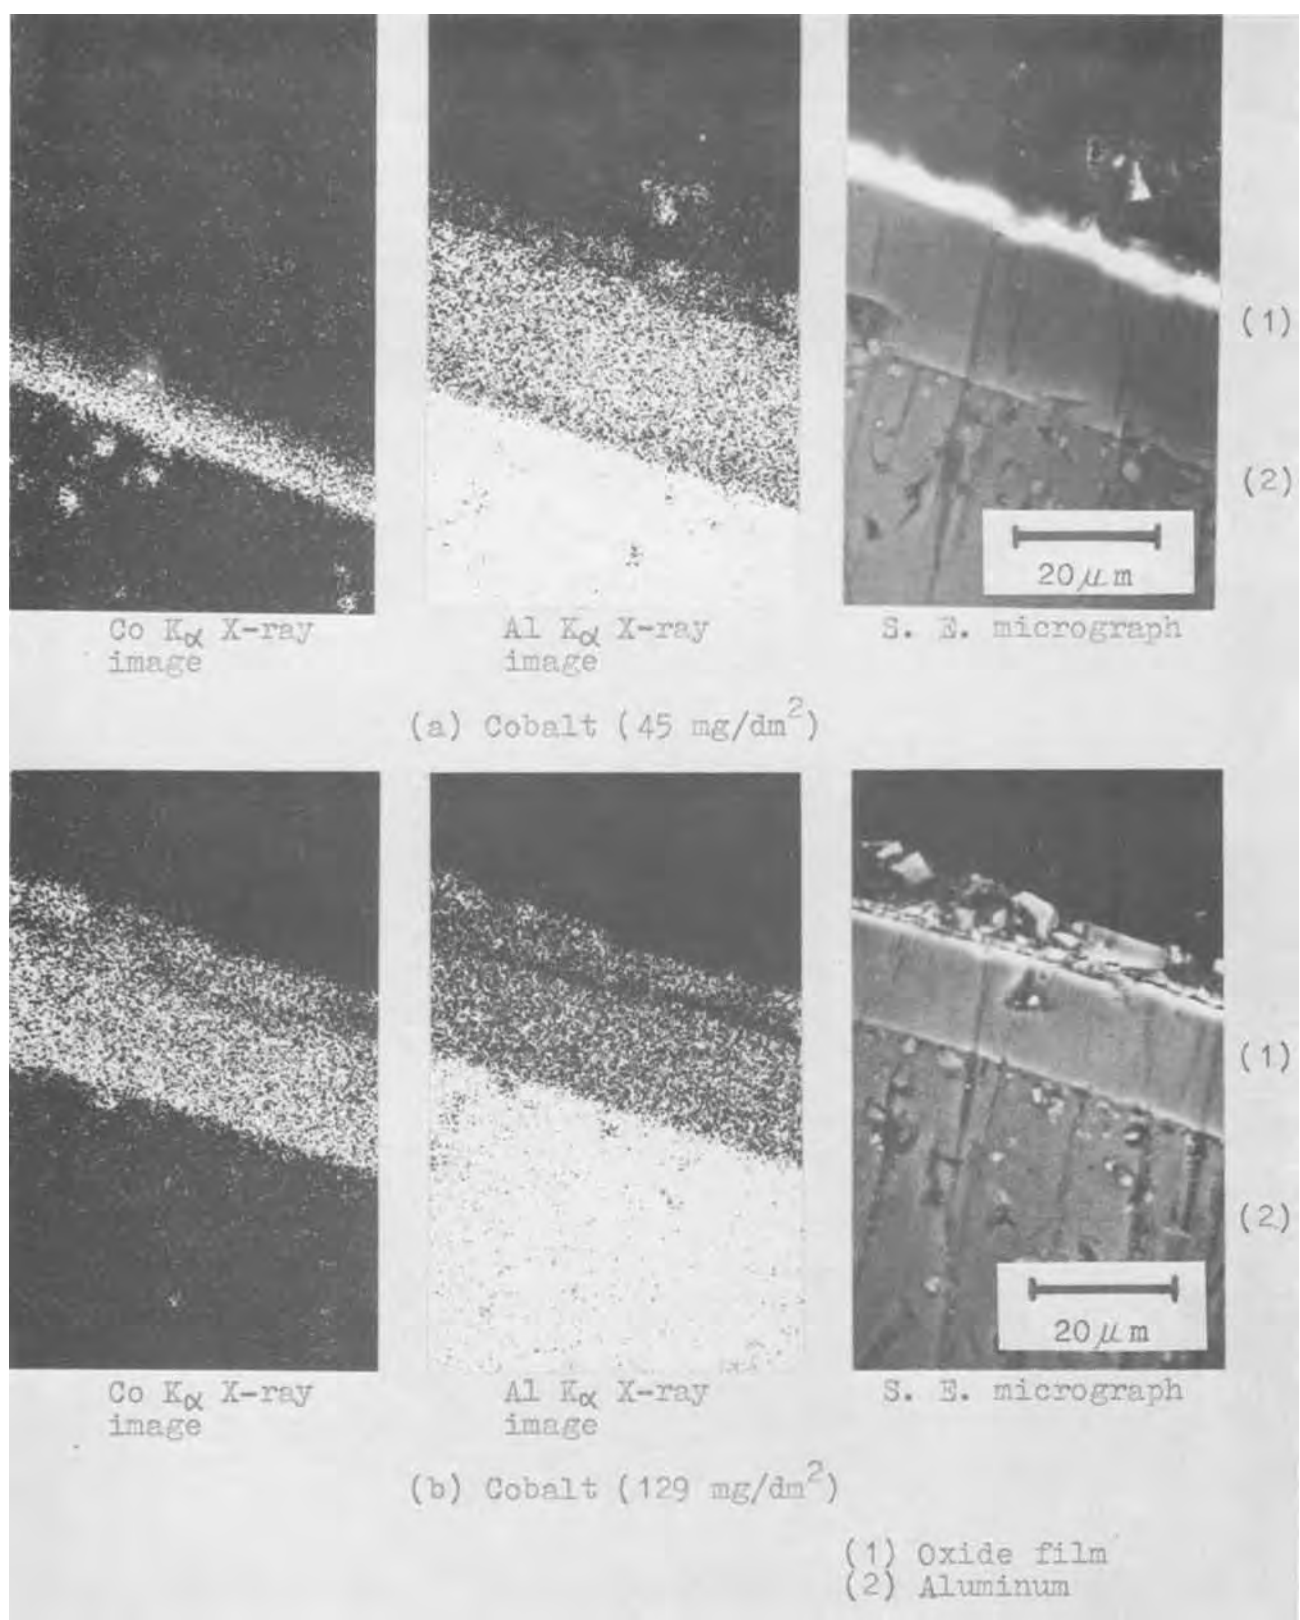

Fig. 3. Scanning electron and x-ray micrograph on the cross section of oxide films

strengths of pure bulk cobalt and nickel (σ_s) as shown in Fig. 5. From the hysteresis loops obtained by the magnetometer, it was found that the density of residual magnetization of films increased by degrees with decreasing film thickness and reached a definite value when the thickness was reduced to about 2 μm by polishing as shown in Fig. 6.

No particular changes in the other magnetic properties were observed on the oxide films thinned by mechanical treatments. The coercivities of cobalt and nickel deposits remained at about 1100 and 750 Oe, and the squareness ratios measured about 70 and 95%, respectively.

Crystal Structures of Deposits

The deposits in the micropores formed fibrous structures about 100Å in diameter which coincides well with the diameter of micropores anodized in a sulfuric acid bath. Each fibrous deposit consists of fine

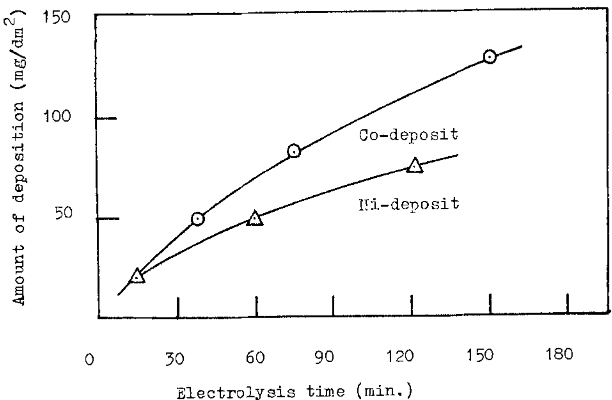

Fig. 4. Relationship between amount of deposits and electrolysis times.

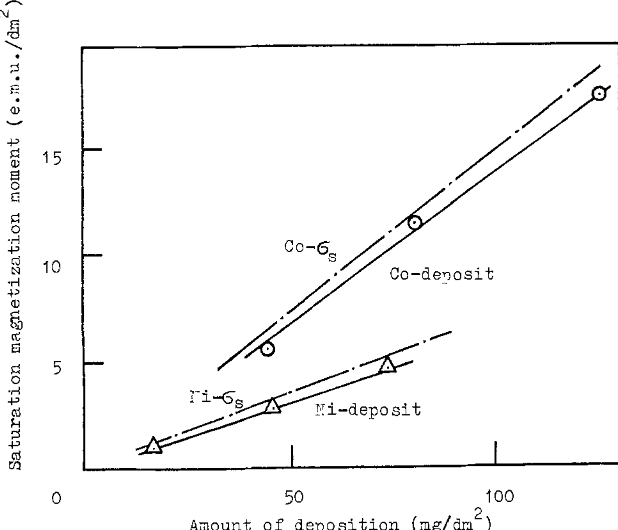

Fig. 5. Relationship between amount of deposits and saturation magnetization moments.

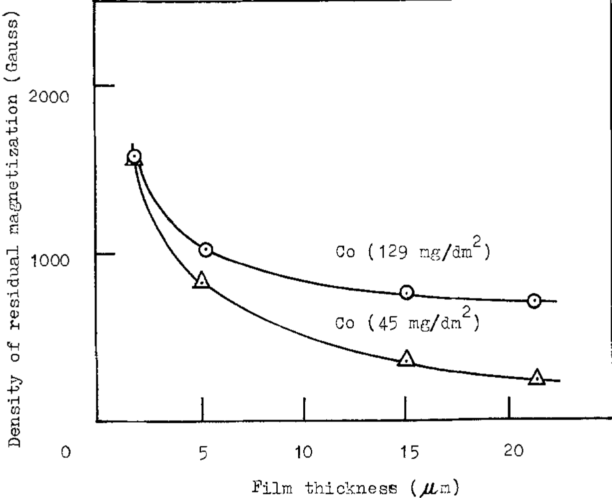

Fig. 6. Relationship between density of residual magnetizations and film thickness.

segmented crystals which are considered to show a spontaneous magnetization.

Although the length of deposits could not be measured exactly, the metals formed in cobalt and nickel depositions were relatively long fibers, while the Co-Ni alloy deposits were somewhat shorter in length. These deposits may be caused by the crystal orientations in the micropores and form either a columnar or lamellar structure.

The deposits distributed uniformly in the micropores and were arranged regularly at intervals parallel to the surface. And the initial high current density of electrolysis has the effect of a heavy deposition of the metals at the bottom of the micropores, while the subsequent decreasing current density is attributed to decreasing metal deposition along the length of the micropores.

Retentivities of Deposits

When the thickness of oxide films containing cobalt and nickel were scraped from the surface within about 15-2 μm by using the lapping machine, the density of residual magnetizations increased and reached about 1700 and 600G, and the density of saturation remanences attained about 2400 and 630G, respectively.

Then, the saturation magnetization moments of the oxide films electrodeposited with cobalt and nickel are calculated to be about 136 and 54 emu/g. Whereas, in the case of pure bulk metals of cobalt and nickel, the same moments were reported at 161 and 54 emu/g (20°C), respectively (5). These values are almost equal to the former values.

According to Keller *et al.* (6) the pore volume of micropores to the whole film layer anodized in sulfuric acid bath under the same conditions of the present experiments has been revealed as about 10%. As the density of saturation magnetizations can be reckoned to be about 18,000 and 6,000G in each metal by referring to the specific gravity, the strength of remanences of these metals were found to be about 13 and 11% of those values in bulk metals. It may be noted that the micropores of anodic oxide films are fully packed with the metallic deposits by a-c electrolysis.

The thinned oxide films show not only the stronger remanences than the part of outer layers of the oxide films, but also can easily provide the very flat surface by mechanical polishings. It is considered that there are possible applications for magnetic recording disks.

Acknowledgments

Kinetics of Decomposition of Silane (Diluted in Argon) in a Low Pressure Glow Discharge

G. Nolet

Laboratoire de Physique et Electronique de l'Etat Solide, Université Catholique de Louvain, Institut d'Electricité, Bâtiment Maxwell, 1348 Louvain-la-Neuve, Belgium

ABSTRACT

The high temperature electrons in a plasma are able to excite as well as to ionize neutral atoms and molecules. At sufficiently low pressures, the inelastic collisions between electrons and molecules are generally considered to be the most effective mechanism for molecular dissociation in the positive column of a glow discharge. It is therefore expected to obtain, at constant current density, a first-order reaction with respect to the molar fraction of the reagent, if all other reactions are negligible. In the case of silane diluted in argon investigated in this work, the first-order rate equation $\ln X_{SiH_4} = -kt$ is not observed; in this equation k is the first-order rate constant, t the gas transit time in the discharge, and X_{SiH_4} the mole fraction of silane at time t. The k value increases with time during decomposition. This is attributed to an increase of the electronic temperature of the gaseous mixture during its transformation.

A bibliographical analysis of the achieved researches on electric discharge chemistry shows that very often one is mainly concerned with the aspects of empiricism and reactor stability (1, 2). Some attempts to explain the chemical reaction mechanisms and to establish a general theory were not successful because the investigated systems were too complex. On the other hand, the physical aspects of the electric discharges are not simple and have a large influence on the behavior of the chemical reactions.

Therefore, it is necessary (*i*) to study the influence of the physical parameters of the electric discharge on the total kinetics of an irreversible gaseous decomposition; (*ii*) to work at low pressure and low current density in order to dissociate the thermal and electric phenomena; (*iii*) to use low pressures in order to limit the number of parallel reactions; (*iv*) to work with the best known discharges, often studied in an inert medium (rare gases); (*v*) to study the total kinetics of gases with a simple chemical dissociation mechanism (irreversible decomposition, few synthesis products in low concentration, etc. If the kinetics may be overcome under the previous conditions, it will be possible to investigate more complicated systems (with side reactions, opposing reactions, etc.).

The purpose of this work it not to explain the decomposition mechanisms of a gas, but to examine the influences of the physical parameters of the discharge on the kinetics of gaseous decomposition. This paper only presents the experimental results on the silane kinetics.

Choice of the Experimental Conditions

Gases.—Silane, SiH_4, has a simple structure and irreversibly decomposes to form an amorphous thin film on the walls of the reactor (3); the only gaseous reaction products found in our electric discharges are hydrogen with traces of disilane, Si_2H_6. Furthermore, silane diluted in an inert gas is widely used in microelectronic device technology and, more precisely, in its reactive plasma applications (3) for deposition of thin films on silicon substrates. These applications make use of an rf induced discharge, which is quite ideal since it limits the plasma extension to the neighborhood of the substrate and avoids the contamination of the thin films by internal electrodes. Diluted silane was chosen to obtain a small impact of the reaction on the reactant volume. The silane gas is prediluted in argon (10% SiH_4-90% Ar; Air Products) and it is always injected at the same concentration in a "plug-flow" tubular reactor which obviously the glow discharge tube is.

Electric discharge.—For microelectronics purposes diluted silane is injected in a rf discharge. However for our study this kind of discharge must be discarded for several reasons: (*i*) The power transmitted to the gas by the rf generator cannot be estimated with sufficient accuracy (4). (*ii*) Numerous problems, depending on the high frequency, are related to the measurement of parameters, such as electric field and electronic temperature. (*iii*) The theoretical value of the electronic temperature is a function of the tube radius, R, the gas nature and its pressure, P (as in the case of a d-c glow discharge), but also of the frequency and the electric field. The calculation of the electronic temperature becomes quite difficult when a gas mixture is present. (*iv*) It is difficult to obtain a large and homogeneous reaction zone. Furthermore, since rf and d-c discharges have similar properties (5), we decided to use the low pressure ($0.1 < P < 3$ Torr) d-c glow discharge because its physical properties are relatively well known and easily measurable (6).

Apparatus

Since silane and its derivatives decompose very rapidly in the presence of oxygen, a rapid and direct analysis of the gaseous mixture composition must be done (dynamic flow system). Mass spectrometry was chosen as the analytical technique. The measurement of the silane concentration is achieved on the preselected mass 30 of the SiH_2^+ ion which is the most characteristic for silane (7, 8). The apparatus is composed of four parts (Fig. 1).

Two low pressure rooms.—In the first one, 1, in Fig. 1, (glass tube of 3m length; internal diameter of the tube 13.4 mm; mean pressure 0.1 Torr) the decomposition of silane by the glow discharge occurs. In the second one, 8, (stainless steel tube; mean pressure 10^{-5} Torr) the gas analysis is achieved by the mass spectrometer, 9.

The differential pressure existing between the discharge tube, 1, and the analysis room, 8, is obtained by means of a diffusion pump, 3, coupled to a rotative pump, 2'. This allows a small fraction of the gas flowing along the discharge tube to be continuously extracted through a microleak, 15. The pressure gauges, 6, 6', and, 6", are, respectively, of the Pirani, Penning, and McLeod type.

Key words: electric discharge, electronic temperature, plasma chemistry.

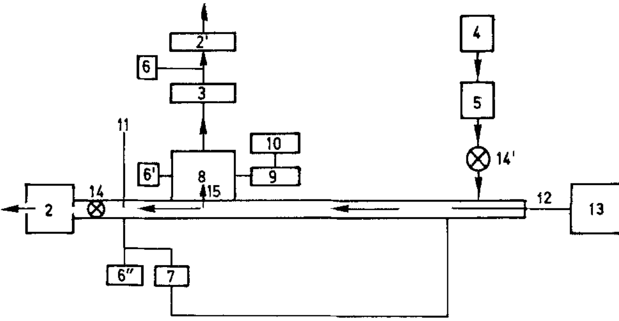

Fig. 1. Schematic diagram of the apparatus. The arrows show the directions of the gas flow. 1, Discharge tube; 2 and 2', primary pumps; 3, diffusion pump; 4, premixed gases; 5, flowmeter; 6, 6', and 6'', pressure gauges; 7, U-tube for $\Delta P/\Delta x$ measure; 8, analysis room; 9, mass spectrometer; 10, control console; 11, fixed cathode; 12, anode; 13, high voltage source; 14 and 14', taps; 15, microleak.

Gas flow system.—Before the injection of the premixed gases, 4, in the discharge tube, 1, the flow rate must be measured at atmospheric pressure, 5. Then the gases cross all the tube, 1, and are extracted by a rotative pump, 2. The taps, 14 and 14', allow the regulation, respectively, of the pressure and of the gas flow rate. The pressure gradient in the discharge tube is measured with a "U" gauge, 7.

Electric system.—A stabilized d-c high voltage source, 13, (V_{max} = 10,000V; I_{max} = 150 mA) creates an electric discharge between the grooving anode (high voltage, 12) and the fixed cathode (grounded, 11).

Gas analysis system.—At the exit side of the discharge tube, near the cathode, a VEECO GA 4R gas analyzer, 9 (with a regulation system, 10), is coupled to the gas analysis room, 8.

Experimental Results

The study of the decomposition of light hydrocarbons under electric discharge conditions has shown that the first-order rate law is well obeyed (9); a typical experimental result is shown in Fig. 2. We shall use the same presentation for our results in order to allow a better comparison. Hence, to plot the typical concentration *vs.* time graphs, we must first determine the transit time of the gas in the discharge.

Determination of the gas transit time, t.—The gas flow rate in the discharge tube involves the existence of a pressure gradient all along the tube. Since the tube area is constant and since the transformation of the highly diluted gas only gives a small volume variation, the pressure gradient along the tube must be constant

$$P_x = P_o + ax \qquad a = \Delta P/\Delta x$$

where a is the pressure gradient (Torr/cm); P_o, the pressure (Torr) at the reference point located at the microleak (15 in Fig. 1); P_x, the pressure (Torr) at the anode; and x, the tube length between the reference point and the anode (12 in Fig. 1).

The gas flow being laminar, the following gas flow rate relation holds

$$v = dx/dt = 760\, D_o\, T/S\, T_o(P_o + ax)$$

where D_o is the NPT flow rate (cm^3/sec); T, the gaseous temperature in the plasma (°K); T_o, the reference temperature (298°K); and S, the tube area.

The transit time expression may then be written as

$$t = ST_o(P_o + ax/2)\, x/760\, D_oT \qquad [1]$$

By moving the anode, different x values may be obtained. Relation [1] is only valid for inert gases for reactions without volume variation. For highly diluted gases we may, as a first approximation, consider flow variation with x (or t) as negligible. For all other cases the constant flow rate D_o must be replaced by a position dependent flow rate D_x.

In practice for the study investigated on 10% SiH_4 in Ar, the simple equation, Eq. [1], may be used. On the other hand, a kinetic study of the silane decomposition can only be done at low current levels ($I < 5$ mA); this implies a small variation of the gas temperature with respect to the reference temperature, T_o. In general the correction term T_o/T is greater than 0.95.

Results on the kinetics.—To compare our results on diluted silane (typical examples are given in Fig. 3 and 4) with those of Loix (9) on hydrocarbons (Fig. 2), we have plotted graphs of ln X *vs.* t. Curves for different experimental conditions (the pressure was changed from 0.3 to 2.5 Torr and the current from 0.2 to 6 mA) all have the same shape.

The difference between the kinetics of the decomposition of a pure hydrocarbon and of a diluted silane gas is attributed to a difference in experimental conditions (initial concentration and current density).

For silane the rate constant always increases with time under constant pressure and current conditions.

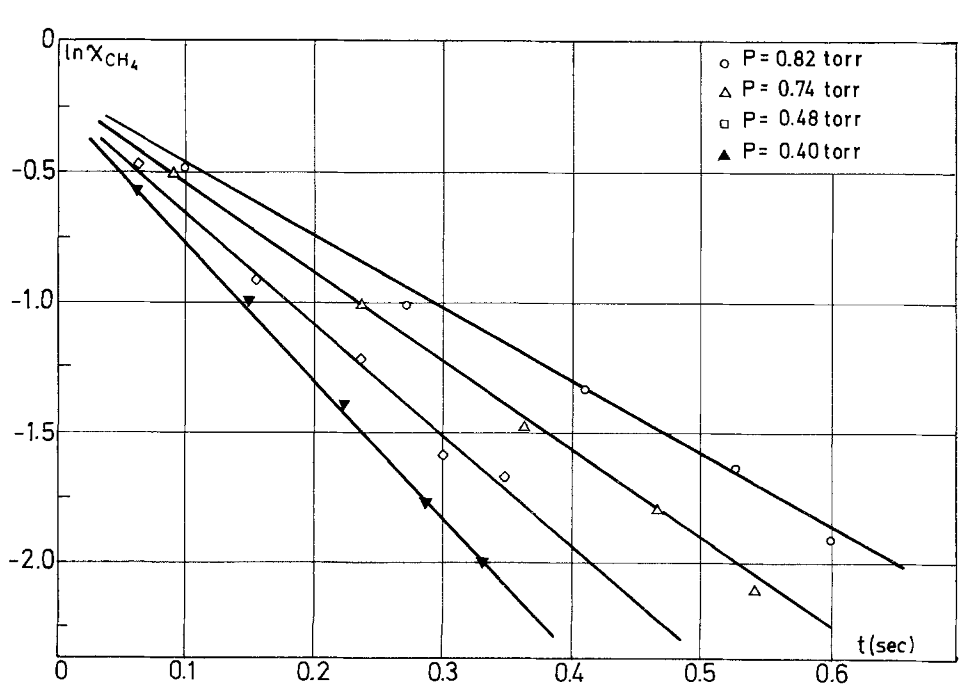

Fig. 2. Kinetics of methane decomposition. Experimental results (I = 50 mA).

Table I. Determination of the experimental rate constants k_o and k_t in function of discharge current and pressure

P (Torr)	I (mA) 0.20	0.50	0.75	1.0	1.5	2.0	3.0	4.0	6.0
	Rate constant k_o (sec^{-1})								
0.30		0.77	2.3	4.5	5.4	8.2	14.1	19.6	33.1
0.60			1.7	3.0	4.6				
0.75		0.70	1.5	2.1	3.4	5.1	7.6	10.6	
1.0		0.87	1.9	2.9	4.4	6.1	9.5	14.5	
1.5		0.80	1.9	2.7	3.8	5.5	7.9		
2.5	0.22	0.70		2.3	(4)	(6.4)			
	Rate constant k_t (sec^{-1})								
0.30				10.9	16.0	21.8	29.8	41.0	63.2
0.60			7.0	9.2	13.0				
0.75				7.6	11.8	15.8	20.1	28.3	
1.0			4.8	7.1	10.3	15.0	21.0	26.6	
1.5			5.3	7.2	10.7	13.4	17.0		
2.5						12.7			

Table I presents, for each kinetic curve, the values of the following rate constants: k_o (rate constant for $t = 0$, or $X°_{SiH_4} = 0.1$) and k_t (rate constant for a large t, or $X_{SiH_4} < 0.01$). The values were obtained from the slope of the curves at the two points under consideration; the accuracy is relatively poor (10-20% error).

For all cases, the rate constant for a nearly complete silane transformation is greater than two times the initial rate constant at $t = 0$; such a variation may not be attributed to the experimental errors.

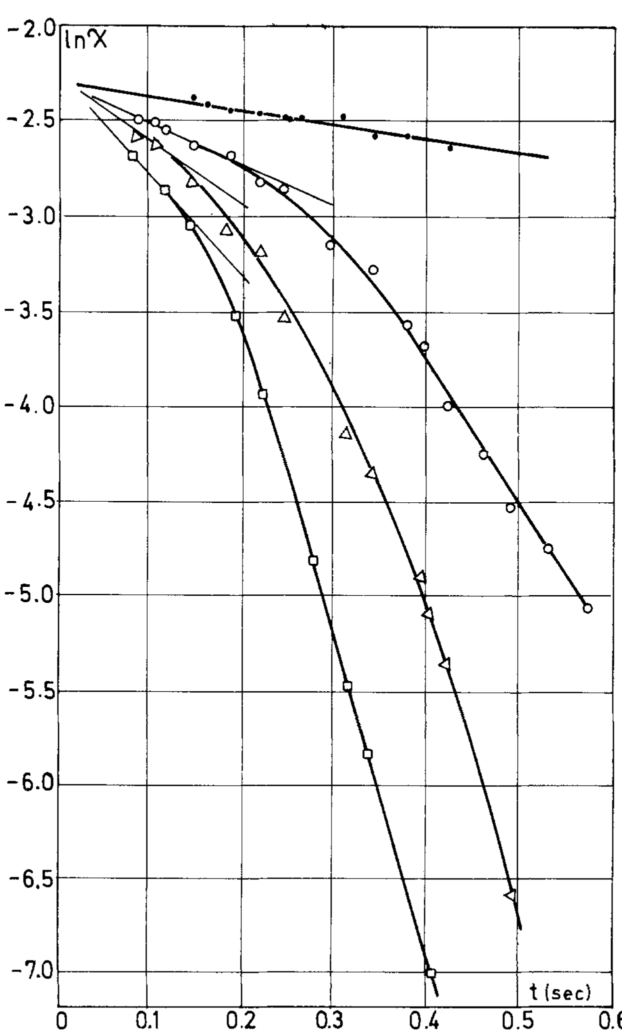

Fig. 3. Kinetics of silane decomposition. Experimental results ($p = 0.75$ Torr); ●, $I = 0.5$ mA; ○, $I = 1.0$ mA; △, $I = 1.5$ mA; □, $I = 2.0$ mA.

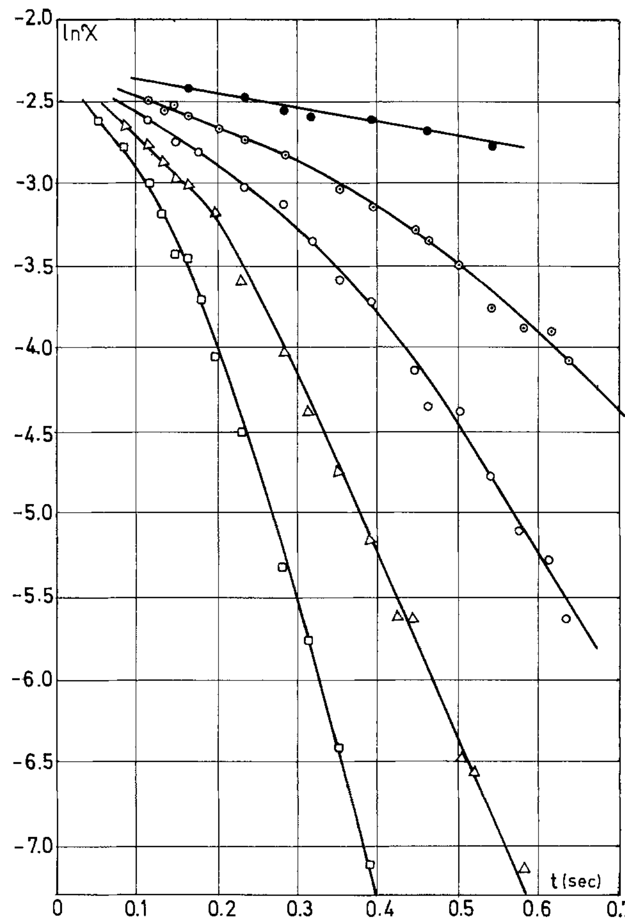

Fig. 4. Kinetics of silane decomposition. Experimental results ($P = 1.0$ Torr). ●, $I = 0.5$ mA; ⊙, $I = 0.75$ mA; ○, $I = 1.0$ mA; △, $I = 1.5$ mA; □, $I = 2.0$ mA.

Before examining these results, a theoretical approach of the phenomena must be pursued.

Theoretical Considerations

Hypothesis.—It is accepted that the electron molecule collisions form the initial step of the chemical transformation in the positive column of the low pressure glow discharge. A modification of the discharge parameters and particularly of the electron energy may then explain the particular shape of the experimental curves ln X_{SiH_4} as a function of t; the electron energy (or electronic temperature) would increase during the silane transformation.

Indeed, at low pressure ($P \simeq 0.1$ Torr), the electronic temperature T_e is much larger than the gas temperature T_g ($T_e > 15{,}000$°K; $T_g < 350$°K) whereas both temperatures are approximatively equal ($T_e \simeq T_g \simeq 4000$°K) at high pressure ($P > 10^2$ Torr). The gas temperature is quite insensitive to a variation of the gas mixture composition; furthermore, since low current densities are used, the gas temperature will remain near the reference temperature.

On the other hand it is known that the electronic temperature, T_e, is a function of the gas under consideration, of its ionization potential, V_i, and the pressure, P, in the tube of radius, R. The theoretical expression of the electronic temperature, in the case of a pure and inert gas, has been derived by Von Engel, following the extension of Schottky's diffusion theory (10)

$$(eV_i/kT_e)^{-1/2} \cdot \exp(+eV_i/kT_e) = 1.17 \times 10^7 \, c_i^2 P^2 R^2 \quad [2]$$

c_i being a constant for the gas i. One can find in the literature numerous examples of the sensitivity of the electronic temperature on the gas type used in the discharge (6, 11, 12). Figure 5 shows that pure inert gases

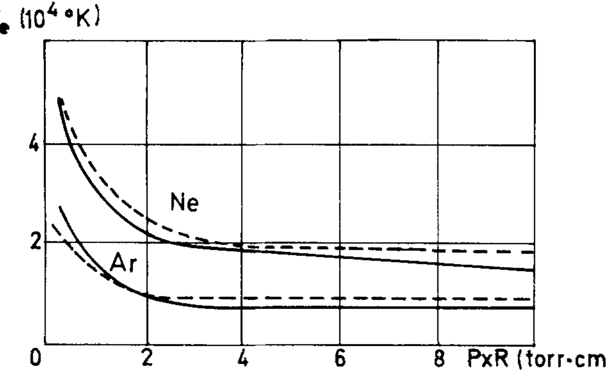

Fig. 5. Dependence of electronic temperature on *PR*. ———, Measured; - - -, calculated (13).

have a distinct electronic temperature for identical experimental conditions (13).

The total kinetics may however be affected by other possible reactions occurring in the plasma: electron-ion, radical-molecule, ion-molecule, radical-radical reactions; the wall effect on these reactions is not negligible (14).

For relatively high pressures ($P > 10$ Torr), the total kinetics of an irreversible gaseous decomposition necessarily implies the intervention of phenomena which may be neglected in the low pressure glow discharge: (*i*) trimolecular collisions; (*ii*) excitation of rare gas atoms on metastable levels; (*iii*) electron-molecule association [considered in the case of the CO_2 laser (15)]; and (*iv*) modification of the electron energy distribution function when the electron energy is used to excite levels of the vibration spectrum rather than of the electronic spectrum (16) (most frequent case when $P > 10$ Torr).

These miscellaneous effects are considered as negligible when a low pressure exists, because the electron energy is almost used for electronic excitation of the molecules which then dissociate into atoms and (or) radicals (16, 17). The electron-molecule collisions imply the intervention of the electron energy in the efficiency of the molecular dissociation; this fact can explain the evolution of the rate constants.

Kinetics of diluted silane.—Indeed, admitting that the reaction initiating step is due to the inelastic electron-molecule collision, one concludes that the electron must at last possess the necessary energy to excite the molecule on its first electronic level; one has to know the pattern of the electron energy distribution function. Among the two types of distribution generally used in the electric discharge field, the Maxwell-Boltzmann and the Druyvenstein-Penning functions, the Maxwell function must be used when the electrons transmit their energy essentially by inelastic collisions (16, 17).

The frequency of efficient collisions between silane molecules and electrons is given by

$$-dn_{SiH_4}/dt = \bar{\sigma}_e \bar{v}_e n_e^* n_{SiH_4} \quad [3]$$

where n_{SiH_4} and n_e^* are, respectively, the silane and efficient electron concentration; $\bar{v}_e$, the mean electron speed (cm/sec); and $\bar{\sigma}_e$, the mean collision cross section.

A more practical form is obtained when using the molar fraction of silane, X_{SiH_4}

$$-dX_{SiH_4}/dt = \bar{\sigma}_e \bar{v}_e n_e^* X_{SiH_4} \quad [4]$$

If the Maxwell-Boltzmann function is used, one obtains

$$dX_{SiH_4}/dt = \bar{\sigma}_e \bar{v}_e n_e X_{SiH_4} \exp(-eV_*/RT_e) \quad [5]$$

where V_* is the excitation potential of the silane molecule on its first electronic level. The current density is $J = n_e e v_d$ and the electron drift velocity, v_d, is proportional to the electron thermal velocity, v_e (18)

$$-dX_{SiH_4}/dt = \alpha \cdot \bar{\sigma}_e J X_{SiH_4} \exp(-eV_*/RT_e) \quad [6]$$

where α is a constant; the rate constant k takes the form

$$k = \alpha \cdot \bar{\sigma}_e J \exp(-eV_*/RT_e) \quad [7]$$

The preexponential term $A = \alpha \cdot \bar{\sigma}_e \cdot J$ is independent of the pressure, P, and of the electronic temperature, T_e, for the usual conditions existing in the positive column. On the other hand, the exponential term only depends on the electronic temperature, which is function of the pressure, P, of the gas, the tube radius, R, the current density, J, and the composition of the gaseous mixture.

Some Qualitative Verifications of the Theory

Constant pressure and current.—The particular shape of the curves of Fig. 3 and 4 may be attributed to the change of the discharge parameters when the gas mixture composition is modified during the decomposition of silane. We consider the shape of the kinetic curves as essentially determined by a modification of the electronic temperature as a function of the gaseous composition. Indeed, at the start ($t = 0$) one has an argon-silane mixture, but when t becomes large the argon-silane-hydrogen mixture tends more and more to the pure argon-hydrogen mixture.

If T_{eo} and T_{et} are the electronic temperatures of the $Ar\text{-}SiH_4$ and $Ar\text{-}H_2$ mixtures, respectively, Eq. [7] may be written as

$$k_o = A \exp(-eV_*/RT_{eo}) \quad [7']$$

$$k_t = A \exp(-eV_*/RT_{et}) \quad [7'']$$

where k_o and k_t are the rate constants for the extreme compositions of the gaseous mixture (Table I).

Figures 3 and 4 are related to a first-order reaction, if $T_{et} > T_{eo}$. Further research is necessary to confirm this condition, both theoretically and experimentally.

Constant current.—Following Von Engel's law (Eq. [2]), any pressure increase reduces the electronic temperature (Fig. 6). If only the pressure is changed, the resulting change in electronic temperature will strongly affect the k_o and k_t values, as seen in Eq. [7'] and [7'']. This is effectively observed in our experiments (Fig. 7).

Constant pressure.—For our experiments at constant pressure, the kinetics are almost entirely determined by the current effect. Figure 8 shows some results, in agreement with Eq. [7]. If the electronic temperature, T_e, remains constant, one should expect a linear relationship between k_t (or k_o) *vs.* J. Hence the observed deviation from linearity must be attributed to the variation of T_e with current. As the observed deviation is not too strong, a weak variation of T_e *vs.* J is suspected.

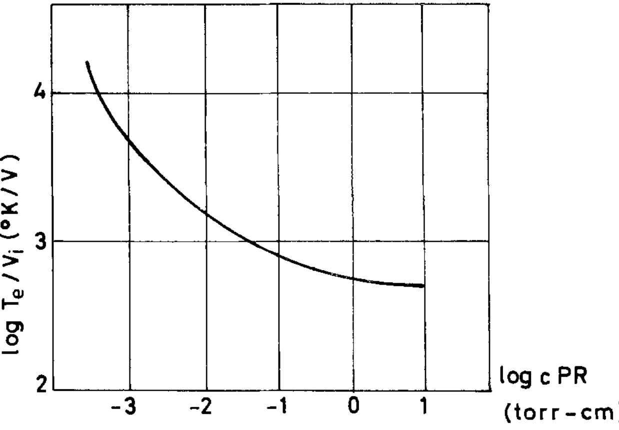

Fig. 6. T_e/V_i as function of *cPR*, plotted from Eq. [3]

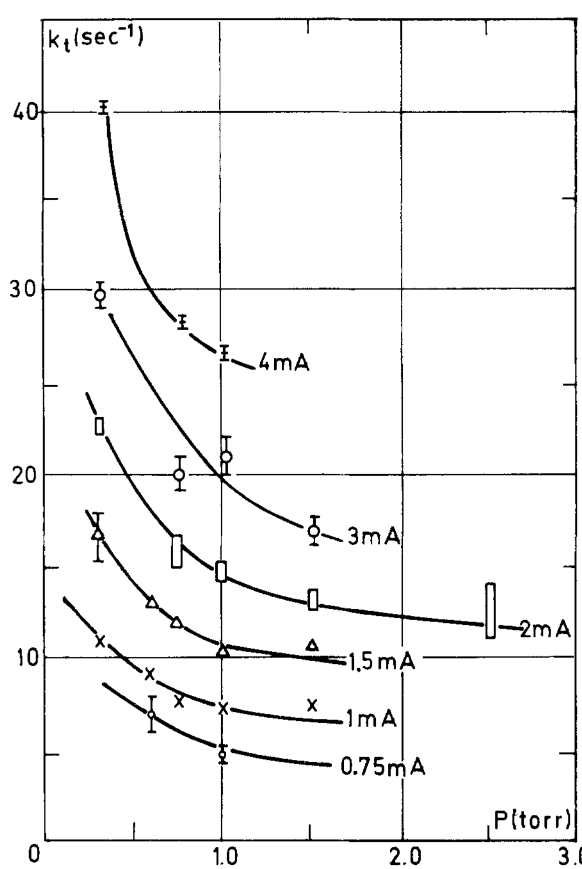

Fig. 7. Effect of the pressure of the k_t rate constants

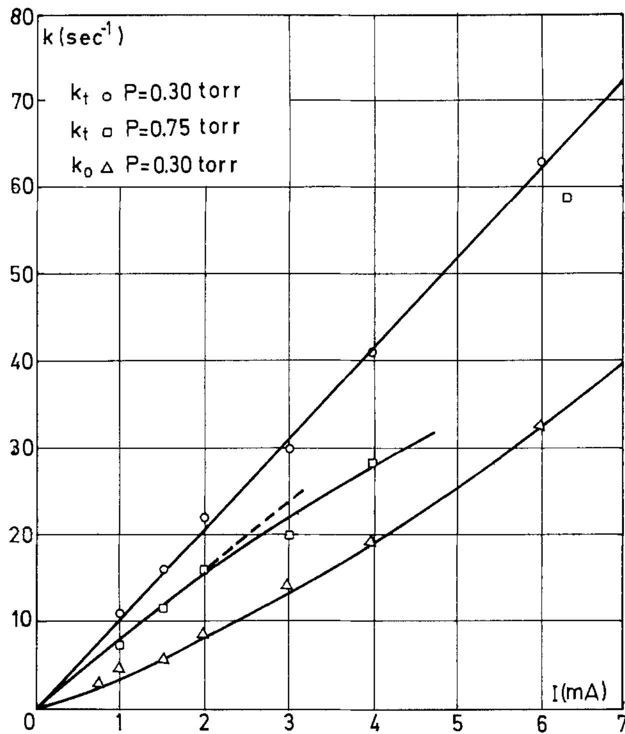

Fig. 8. Effect of current on rate constants. Experimental results

The last fact remains to be confirmed by further experiments on the electronic temperature.

Conclusions

The shape of the kinetic curves for silane diluted in argon is related to a simple first-order rate equation, if a variation of the electronic temperature during the decomposition of silane is accepted. Experimental evidence of the validity of the rate equation is found by varying pressure and current parameters.

A Novel Electrochemical Cell Employing a Rotating Bipolar Electrode

P. R. Nadebaum and T. Z. Fahidy

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

An overview of a recent study of a rotating bipolar cylindrical electrode (RBE) cell is presented. The central rotating electrode in this cell is surrounded by axially located wiper blades which form 2 (bipolar) or 3 (tripolar) compartments. An outer electrode governs in each compartment the central electrode potential, and conditions similar to potential and current pulsing can be obtained. The rotating electrode surface can be maintained in the state of continuous activation and the cell is well suited for refining, concentrating, and removal of impurities from electrolyte solutions.

It is well known (1-20) that the rate of oxidation of many fuels [*e.g.*, H_2, C_2H_4, CH_3OH, HCOOH, and $(COOH)_2$] at a Pt electrode decreases with time and can be increased momentarily by a current or potential pulse. This increase in the rate of reaction can be caused by various factors, such as removal of adsorbed impurities and of partially oxidized substances from the electrode surface and removal of surface oxide layers. Many other electrode reactions can be significantly affected by voltage and current pulsing. It has been reported, for example, that pulsing can be used to control the product spectrum of electrolysis (21-29), to prevent passivation and improve the quality of deposits in the electrodeposition of metals and alloys (30-35), to avoid fouling of electrodes by alkaline earth salts during the electrochemical sterilization of sewage (36-39), and to prevent passivation during the electrochemical production of acrolein (40).

While the results of these studies have been interesting, there has been little or no commercial application of current and voltage pulsing because of the practical difficulty of controlling and varying the large amounts of current (>1000A) required by an industrial scale process.

An alternative approach to pulsing is to vary the electrode potential by mechanically moving the electrode through different potential regions, rather than by directly varying the applied potential (41). In this manner steady currents and potentials can be employed while still achieving the effects of potential or current pulsing.

One relatively simple way in which this can be done is to use a "rotating bipolar electrode" as shown in Fig. 1. The cell in its simplest form involves three main electrodes: a central rotating bipolar electrode and two counterelectrodes separated by an insulating barrier. As the center electrode rotates, its surface passes through a potential region determined first by V_{S1} and then by V_{S2}. Depending on the relative potentials of V_{S1}, V_{S2}, and V_M, the center electrode can first form either an anode or cathode in one compartment, and then either an anode or cathode in the other compartment. In this way an effect similar to "continuous" voltage or current pulsing is achieved. This method of performing the pulsing has an additional advantage, namely, that the products of the reaction can be separated from the products of the pulse treatment, thus avoiding some of the problems involved with the recombination of the products.

There have been many types of electrolytic reactors described in the literature which employ either stationary bipolar electrodes, rotating monopolar electrodes, or some sort of a "wiper" arrangement; however, a search of the literature (summarized in Table I) indicates only one cell employing the rotating bipolar electrode principle. This cell, recently designed

Key words: continuous activation, voltage pulsing, cost, mass transfer, refining.

by Benner (42), consists of two side-by-side cylindrical rotating electrodes, and was created for the purpose of removing ions from solution. No further details are available to the authors at this time. There appears to be no mention in the literature of the use of a rotating bipolar electrode cell to achieve the conditions of voltage or current pulsing, other than a publication arising from some of the preliminary experimental results obtained in this work (41).

In this paper we summarize the operation and performance of two rotating bipolar electrode (denoted as RBE) cells, and provide an overview of recent work (112) carried out with these cells. For the purposes of discussion, we have selected only the most important experimental results; other results and a more detailed discussion can be found elsewhere (112) and will be available in further papers providing details on specific areas of the study.

Design and Construction of the Laboratory RBE Cells

Two RBE cells were constructed during the course of this work. The first cell to be constructed had two compartments (a "bipolar" cell), while the second cell, of considerably more sophisticated design, had three compartments (a "tripolar" cell).

In order to provide for rigorous cleaning of the cell and to avoid contamination of the electrolyte by traces of impurities, the cell bodies and fixtures were constructed entirely out of glass and Teflon. The electrodes were platinum (99.9%, Engelhard). While the use of Pt was desired by the reaction systems to be studied, it had the added advantage of being resistant to the corrosive effects of potential cycling. Because of the great cost of Pt, however, it was necessary to minimize the amount used and this considerably complicated the design of the rotating electrode. In its simplest form this electrode could merely be a solid, cylindrical rod.

The outer electrodes surrounding the center electrode were symmetric, forming compartments of equal size, and the interelectrode spacing was quite generous to permit insertion of reference electrodes and to allow inspection of the electrolyte flow patterns.

Bipolar and tripolar cells.—The principle and details of construction of the simple bipolar cells are shown in Fig. 1. The cell consisted of a glass outer body sandwiched between two Teflon plates. It was found that although the wiper blade design efficiently removed the electrolyte boundary layer at the electrode surface, considerable difficulty was experienced in obtaining a low level of current leakage between the compartments. For this reason the simple cell was not used extensively in actual bipolar operation. It was found to be suitable, however, to determine the mass transfer characteristics of such cells, a situation where current leakage is not important.

The principle of the more sophisticated tripolar cell is shown in Fig. 2 and 3. The cell body consisted of a Teflon cylinder supported by a steel sheath, properly sealed between the cylinder and the Teflon base plate and provided with inlet and outlet tubes. The central rotating electrode was a relatively large platinum cylinder fabricated from a 0.05 cm thick uniform Pt foil and was supported on a solid Teflon cylinder. The dimensions of the assembled electrode were: 12.50 cm in length, 3.176 ± 0.0075 cm in diameter, and 145.8 cm^2 in area. The estimated resistance of the electrode to the current flow was about 37 μohms. In order to avoid wear at the bottom Teflon-Teflon bearing surfaces, the electrode was located and supported by a top bearing so that a clearance of about 0.01 cm was maintained. Gas (O_2, N_2, or Ar as desired) was passed through the bottom bearing, thus obviating a continuous electrolyte film under the electrode and reducing current leakage. The design of the insulating barriers or wiper blades was critical, and their construction represents a compromise between flexibility (*i.e.*, uniform wiping action) and a minimum current leakage.

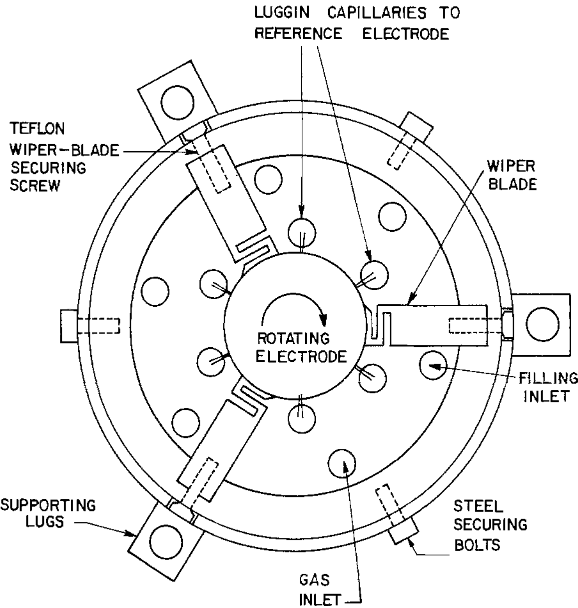

Fig. 2. Rotating tripolar electrode cell; top, inside view

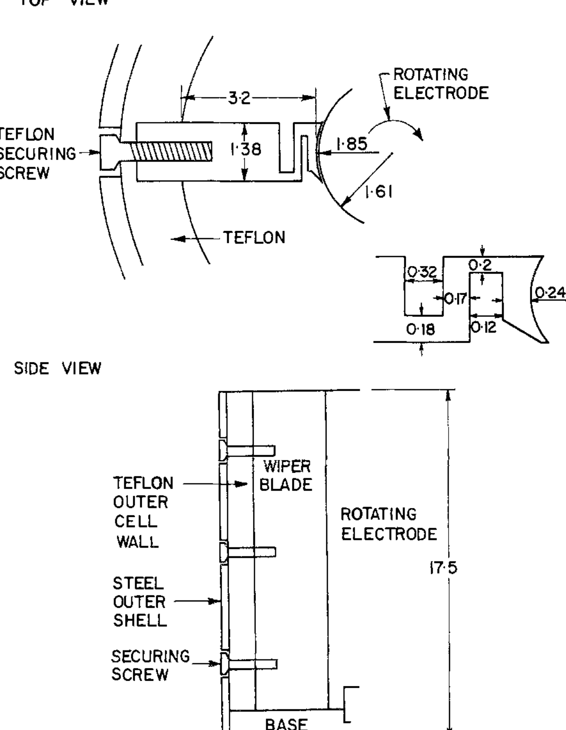

Fig. 3. Rotating tripolar electrode cell: wiper blade design (all dimensions in cm).

Amongst many configurations considered, the design shown in Fig. 3 was found the most satisfactory. Several points may be noted. The wiper blades are relatively thick in cross section, and the bearing surfaces are machined to a slightly smaller radius than the rotating cylinder, thus providing a good wiping action. The leading edge of each wiper blade is quite sharp and the electrolyte as it is removed from the electrode surface tends to further press the wiper blade onto the surface and improve the sealing action. The seal between the wiper blades and the outer cell body was simply achieved by machining a slot in the outer wall and pressing the wiper blades into it. The wiper blades were, in addition, secured by Teflon screws passing through the outer wall of the cell. The seal between the wiper blades and the cell bottom plate was achieved by pulling the blades hard down onto the bot-

tom plate by a Teflon screw inserted through the bottom plate into each wiper blade. The most significant feature is the slots machined into the wiper blade near the curved sealing surface. This arrangement is simple, easily constructed, and accurate machining is not necessary. Furthermore, considerable misalignment of the wiper blades could easily be accommodated without sacrificing the efficiency of the wiping action. The pressure exerted by the wiper blades on the central cylinder could easily be controlled by varying the dimensions of the slots. This design affords a relatively flexible sealing surface which can closely adapt itself to the contours of the electrode surface, even at quite high electrode rotation rates. Under these circumstances, an average gap size of less than 0.0015 cm was maintained; for an electrolyte of specific conductance of 0.01 Scm^{-1}, the minimum gap resistance was about 8000 ohms. For potential drops of 1V or less the magnitude of leakage current density was 1 $\mu A/cm^2$ (based on the true surface area in the working compartment). The wear of the sealing surface was found to be negligible.

The temperature of the electrolyte was regulated by glass cooling coils which passed cold water through the top cell cover and dipped into the electrolyte in each compartment. Cooling was found to be adequate even at high power densities (50W/compartment), and the cell temperature was maintained without difficulty at 297° ± 1°K.

Gas was bubbled through the electrolyte via gas inlet tubes in each compartment. The inlet tubes consisted of a standard ground glass joint containing a fine porous frit fused into the end of the joint. This permitted a fine dispersion of the gas into the electrolyte. The three gas inlet tubes were fed via a single gas line, and the flow rate into each compartment was not individually adjusted. The gas flow rate was measured by the pressure drop across a small orifice plate.

Filling and emptying each compartment was accomplished via tubes let into the base of the cell, which were then connected via a stopcock to large funnels, or drain pipes.

Two Luggin capillaries were used in each compartment, and these were both connected to a single reference electrode chamber; in this manner an average solution potential was obtained. The location of the Luggin capillaries is shown in Fig. 2. The clearance between the capillaries and the rotating electrode was about 1 mm in order to eliminate the possibility of scratching the electrode surface should the electrode position vary slightly. The reference electrode chamber for each compartment was isolated from the cell electrolyte by a large diameter ground glass stopcock; the electrolyte film around the stopcock, while in the closed position, was of sufficiently low resistance for accurate potential measurement. This arrangement minimized the possible contamination of the electrolyte by the reference electrode solution.

In acid electrolyte reference electrodes of the type (Pt)$Hg,HgSO_4/H_2SO_4$ (1.0 mol/dm^3) were used, and in alkaline solution a saturated calomel reference electrode was used. The reference potential was corrected for liquid junction potentials by measuring the potential of the reference electrode with respect to the potential of a reversible hydrogen electrode in the same solution. Potentials are reported with respect to RHE. At higher current densities correction for errors arising from the ohmic drop in the electrolyte was accomplished by the voltage interrupt methods (113-116). Current densities are reported with respect to the true surface area exposed in each compartment. The cell was cleaned by alternatively rinsing and allowing to stand with alcoholic KOH, dilute HNO_3, deionized water (approximately 10^{-6}-10^{-7} S/cm specific conductance), and the desired electrolyte (prepared with reagent grade chemicals and 10^{-7} S/cm conductivity water).

While in some applications one power supply would be used (*i.e.*, the central electrode would be floating with respect to the other electrodes), in this study a separate power supply was used for each compartment and conventional circuits employing operational amplifiers were used to control large power supplies [for a list of specific instruments employed for generating potential step and triangular waveforms, recording and stabilizing devices, etc., consult Ref. (112)]. The rise times of these potentiostats were in the range of 10^{-5}-10^{-4} sec.

Rate of Mass Transfer at a Rotating Cylindrical Electrode with Wiper Blades

While the primary purpose of the wiper blades is to insulate one cell compartment from another, they also serve to significantly increase the rate of mass transfer to the electrode surface. Spencer *et al.* (101), for example, have used wiper blades to remove the diffusion layer on a rotating cylindrical electrode. They report large increases in the current efficiency of producing sodium dithionite from sodium bisulfite [c.f. (117)].

At the present time there seems to be no available theory which can predict the mass transfer rates expected at a rotating wiped electrode, although the case of concentric rotating cylinders without wiper blades has been treated in some detail (118-121). There is apparently no quantitative indication in the literature concerning the enhancement of mass transfer via wiper blades.

The mass transfer effects were studied in two cases: (*a*) the reduction of ferricyanide ions and (*b*) the reduction of oxygen, employing the rotating electrode as cathode. In the former reaction, the net change in composition is zero (the anode reaction is exactly the opposite of the cathode reaction) and at the low *p*H employed the chemical decomposition of the ferricyanide ions, whose concentration was determined by iodometric titration, is negligible. In the reduction of oxygen experiments, oxygen was bubbled rapidly through the cell before each measurement while the electrode potential was kept at 1.2V under no current load. Thus, the electrolyte was saturated with O_2 and the electrode was covered with oxide, thereby minimizing the side reaction producing H_2O_2. After these preliminaries, the electrode potential was quickly set to the value of interest and the measurements of current were begun. At each rotation rate typical polarization curves were obtained and the limiting current flows were determined. The results are summarized in Fig. 4 where the solid lines denote theoretical relationships between the limiting current density and electrode rotation rates, computed from the dimensionless relationship

$$Nu_R = \frac{2}{\pi}(1 - C)\sqrt{\frac{w}{1 - wd/2\pi R} Re_R Sc} \quad [1]$$

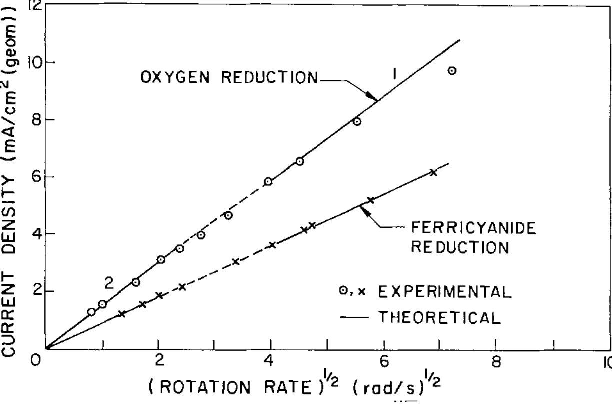

Fig. 4. Comparison of theory and experimental results in the mass transfer study.

Here, w and d represent the number and thickness of the wiper blades, respectively, R is the radius of the rotating electrode, and Re_R, Nu_R, and Sc are the Reynolds, Nusselt, and Schmidt numbers defined as follows

$$Re_R = 2\Omega R^2/\nu$$
$$Nu_R = 2\bar{i}_L R/(z\mathbf{F}Dc_b)$$
$$Sc = \nu/D$$

As usual, ν is the kinematic viscosity of the solution, D is the diffusion coefficient, c_b is the bulk activity of the reacting species, Ω is the angular rotation rate (rad/sec) of the electrode, z is the number of electrons transferred in the electrode reaction, and $\bar{i}_L$ is the average limiting current density over the electrode surface. The term C represents a correction for the effects of convection arising from the rotation of the electrode. In general, this term is small for large Sc (less than 5% for Sc greater than 200) and acts to decrease the rate of mass transfer. This decrease occurs because convection arising through electrode rotation tends to transport fluid of lower concentration into regions of higher concentration near the electrode surface (112). The ranges of pertinent parameters are as follows: $392 \leq Sc \leq 1237$; $0.6 \leq \Omega$, rad/sec ≤ 52; $824 \leq Re_R \leq 71{,}300$; $0.181 \leq k_L \cdot 10^4$, cm/sec ≤ 145; $2.9 \leq Nu_R \leq 6850$ (k_L denotes the mass transfer coefficient). The results indicate that flow is essentially laminar at this set of experimental conditions, although the presence of relatively slow Taylor vortices was experimentally observed. This aspect and details of the rather involved mathematical analysis, including expressions for local mass transfer rates at the electrode surface, are presented elsewhere (122). As shown in Fig. 4, the rather good agreement between theory and experimental findings renders Eq. [1] a reliable design equation for a rotating cylindrical wiped electrode system, if the following conditions are met: the temperature, pressure, and density of the fluid are constant; there is no chemical reaction; there is a relatively high concentration of supporting electrolyte; the Sc number is high (> 200); there is no axial electrolyte flow; bubble formation (gas evolution) at the electrode surface is negligible; the rate of reaction is determined solely by the rate at which the reactants are transported to the electrode surface; and removal of the diffusion layer by the wiper blades is complete.

"Continuous" Activation via Impurity Stripping

It is well known that many reactions occurring at platinum electrodes are susceptible to poisoning by traces of impurities and that often this poisoning effect can be overcome (*i.e.*, the electrode surface can be "activated") by potential cycling or by an appropriate prepolarization treatment (11, 123-143). One such electrode reaction, occurring at Pt electrodes, which is particularly susceptible to poisoning is the reduction of oxygen (144-147). Impurities known to inhibit the rate of this reaction include, for example: various cations [*e.g.*, Ag^+, Cd^{2+}, Tl^+, Ba^{2+}, Sr^{2+}, Ca^{2+} (148-151)], anions [*e.g.*, halide and sulfate ions (11, 133, 146, 150, 152-156)], and organic impurities (146, 157, 158). Tindall, Cadle, and Bruckenstein (151) have shown that in the presence of Cu^{++} ions, inhibition occurs through the deposition of submonolayer Cu films. These films are deposited at very low Cu^{++} concentrations (<1 ppm) and at "underpotentials," *i.e.*, at potentials more anodic then the reversible potential, in the potential range $E_{rev} < E < 0.8$V (159, 160). This apparent violation of thermodynamics has been clarified by demonstrating (161) that if copper atoms absorbed on an inert surface are more stable than those in the copper lattice, such depositions are feasible from energy considerations.

The experiments were carried out in the tripolar cell, operated in a fashion similar to the general procedure described in the previous section, except for the flowing electrolyte (dilute aqueous solutions of $CuSO_4$) and preparation of the active surface: prepolarization at 1.4V for 15 sec, and 0.0V for 0.5 sec. This treatment serves to strip off any Cu deposited on the electrode surface and also to reduce surface oxides during the anodic treatment. The rate of inhibition of the oxygen reduction current is determined by the diffusion-limited rate of copper deposition and is quite rapid.

The typical rate of poisoning of an "active" electrode surface observed in a relatively concentrated Cu^{++} solution is shown in Fig. 5, which also shows the steady-state uninhibited oxygen reduction current observed in the absence of Cu^{++}. The ability of a RBE to achieve "continuous" activation of the electrode surface in the same solution is shown by the following. The potential of the inner electrode was maintained at a sufficiently anodic potential in compartment 1 to strip off the Cu film (0.85-1.2V), and in compartments 2 and 3 it was maintained independently at the desired reduction potential (0.2V). As the electrode surface passes out of compartment 1 into compartment 2, there is an initial additional current flow arising from the reduction of surface oxides and double layer charging. In compartment 3, however, the measured current corresponds almost entirely to the oxygen reduction current, and the steady-state current thus obtained may be compared in Fig. 5 with the steady-state current in the absence of Cu^{++}. It can be seen from these results that the electrode can operate at high activity under conditions where ordinarily almost complete passivation would occur. Similar behavior is observed (112) at other reduction potentials (0.0-0.7V) and Cu^{++} concentrations (10^{-5}-10^{-2} mol/dm^3).

"Continuous" Activation by Decreasing the Thickness of the Surface Oxide Film

In some cases an apparent "activation" of the electrode surface is obtained in the absence of impurities.

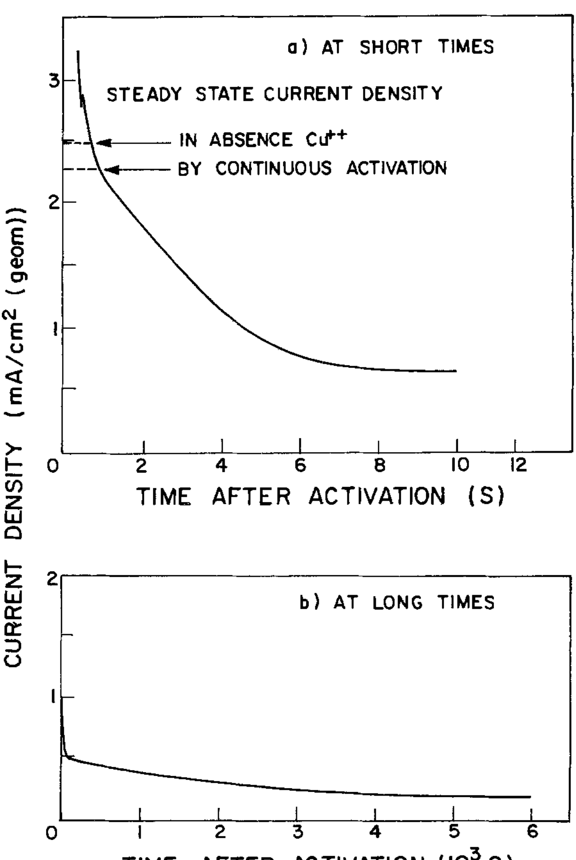

Fig. 5. Decay of oxygen reduction current density following activation in presence of Cu^{++}, compared with steady-state continuous activation. 10^{-3} mol/dm^3 Cu^{++} + 0.05 mol/dm^3 H_2SO_4; Ω = 0.78 rad/sec, electrode roughness factor = 3.63. Electrode potential 0.2V RHE.

This can be seen, for example, in the large increases in the rate of oxygen evolution immediately following a cathode potential pulse at Pt (162-167) and other metals [*e.g.*, Ni, Co, Fe, Au (168-175)], and for other reactions [*e.g.*, the oxidation of CO, the reduction of Cl_2 (163), and the reduction of oxygen (176-186)]. Afonshin, Tyurin, Volodin, and co-workers (162, 186-188) and Schultze and Vetter (163-167) have studied the oxygen evolution reaction at Pt electrodes in detail, and have clearly established that the rate of oxygen evolution is directly dependent on the thickness and nature of the surface oxide film. Thus, the rate of oxygen evolution can be increased temporarily by an appropriate cathodic treatment which serves to reduce the oxide thickness. Although much of the oxide film is quickly reestablished at the anodic potentials necessary for oxygen evolution, the growth is logarithmic with time (166, 189, 190) and the rate of oxygen evolution is significantly higher than its steady-state rate even as long as 60 sec after activation. A steady-state oxide thickness is not reached until very long times have passed (> 1000 sec).

Utilizing these ideas, the ability of a RBE to effect large increases in the rate of oxygen evolution by controlling the thickness of the surface oxide layer was investigated. Oxygen was liberated at the platinum anode from a 3.5 mol/dm^3 aqueous H_2SO_4 solution; first, the cell was operated in a conventional monopolar manner, with the outer electrodes connected together and the inner electrode rotating at the speed of 1 revolution per 8 sec. A 0.3V cathodic potential was first applied to the rotating electrode for 15 sec to strip off the surface oxide film, and the potential was then raised to a working oxidation potential within the 1.4-2.1V range. The results obtained have been summarized in Fig. 6, where the current density (CD) arising from oxygen evolution and oxide formation 4, 60, and 1000 sec after a cathodic pretreatment of 15 sec at 0.3V is shown. It can be seen that the "activation" of the electrode is considerable and CD's are greater than the steady-state CD's (*i.e.*, the CD's at times > 1000 sec) by more than one order of magnitude. These unsteady-state CD's can be compared with the steady-state CD's obtained at a RBE. The latter results were obtained with the potential of the rotating electrode in compartment 1 maintained at 0.3V, and independently at the desired potential E in compartments 2 and 3. As before, the CD's in compartment 3 are reported, since they can be expected to be relatively free from contributions from oxide formation and double layer charging (these processes will take place in compartment 2). The electrode rotation rate employed was 0.78 rad/sec (about 1 revolution every 8 sec) and was selected so that the exposure of the electrode surface in compartment 3 occurs approximately 4 sec after exiting from the treatment compartment. It can be seen that the use of a RBE has effected large increases (more than 1 order of magnitude) in the steady-state CD, and corresponds quite well with the unsteady-state CD observed at 4 sec after cathodic activation. Further experiments showed that the steady-state CD's achieved with the RBE increase with electrode rotation rate and are higher in compartment 2 (which immediately follows the treatment compartment).

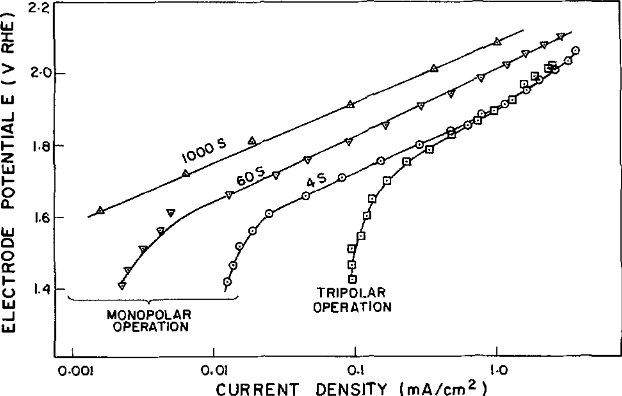

Fig. 6. Oxygen evolution current density vs. potential: tripolar operation compared with conventional (monopolar) operation. 3.5 mol/dm^3 H_2SO_4; $\Omega = 0.78$ rad/sec; roughness factor = 4.28; potentials corrected for ohmic drop. Tripolar operation: steady-state CD in compartment 3, $E_1 = 0.3V$, $E_2 = E_3 = E$. Monopolar operation: CD in compartment 3 at 4, 60, and 1000 sec after activation, $E_1 = E_2 = E_3 = E$.

Two points can be noted regarding these results. Firstly, the enhanced CD's at lower potentials (1.4-1.7V) arise through current leakage from compartment 3 to compartment 1 and do not represent a useful increase in the oxygen evolution reaction. Leaving the results uncorrected in this form helps to portray the typical deviations which might be expected through this effect. Secondly, as further experiments have confirmed, the major portion of the observed current increase arises through an increase in the rate of oxygen evolution rather than simply through oxide film growth; at 1.8V, for example, the contribution of the oxide film growth to current was found to be less than 10%. This agrees generally with the work of Schultze (163), who has studied the relationships governing the relative portions of the total CD due to oxygen evolution and oxide film growth in some detail.

Control of the Relative Rate of Competing Electrode Reactions

Under particular conditions of voltage and current pulsing the product spectrum of some electrode reactions can be altered, *e.g.*, in the electrolysis of aqueous acetate solutions (21-29). Normal steady-state electrolysis at potentials greater than 2.1V yields largely ethane via the Kolbe dimerization reaction

$$2CH_3COO^- \rightarrow C_2H_6 + 2CO_2 + 2e^- \quad [I]$$

Under current pulsing conditions (23), and to a lesser extent under voltage pulsing conditions (26), the yield of ethane decreases. At moderate frequencies (1-100 Hz) oxygen is evolved

$$2H_2O \rightarrow O_2 + 3H^+ + 4e^- \quad [II]$$

and at higher frequencies (> 1000 Hz) acetate ions begin to be completely oxidized to CO_2

$$CH_3COO^- + 2H_2O \rightarrow 2CO_2 + 7H^+ + 8e^- \quad [III]$$

It is pertinent to note that during steady-state electrolysis of acetate solutions, the complete oxidation of acetate ions occurs at low potentials ($0.4 < E < 0.8V$), and at intermediate potentials ($1.5 < E < 2.1 \sim 1V$) oxygen is evolved (191).

A RBE can be used to obtain similar changes in the product spectrum if the electrode rotation rate is fast enough to correspond to the pulsing frequencies at which such changes occur. In order to study this application of the electrode, a 1 mol dm^{-3} CH_3COOK + 2 mol dm^{-3} CH_3COOK aqueous electrolyte mixture (pH buffered strongly at 5.5) was electrolyzed in the cell where the outer electrodes of compartments 1 and 2 were connected together. A constant current was applied to the compartments (the resulting CD was 2.82 mA/cm^2, with a sign such that reduction occurred at the center electrode). Compartments 1 and 2 formed the "treatment" compartment. In compartment 3 a constant current corresponding to a CD of 27.4 mA/cm^2 was applied. The center electrode was rotated at 14.6 rad/sec (140 rpm), and Ar was bubbled through each cell compartment at 4 cm^3/sec. After 10 min of operation, the outlet gas from compartment 3 was sampled. The electrode rotation was then stopped, and the CD in compartment 3 was reduced by an amount equal to twice the treatment compartment CD (becoming 21.8 mA/cm^2). The CD in the treatment compartment 3 was again sampled.

The analysis of the anodic outlet gases is summarized in Table II. It can be seen that under conventional, steady-state electrolysis (with the electrode stationary), the Kolbe dimerization reaction proceeds with high efficiency, and the product gases consist mainly of C_2H_6, CO_2, with very little O_2. Under simulated current pulsing conditions (while the electrode is rotating), however, the product spectrum changes considerably: evolution of ethane via Kolbe dimerization is almost completely nonexistent, instead of which the evolution of oxygen and other processes which yield CO_2 are observed. These results clearly illustrate that for some electrode reactions the relative yield of the various reaction products can be significantly altered using a RBE. This selectivity effect is manifest by the fact that at lower electrode potentials oxygen evolution proceeds in preference to the Kolbe dimerization, although only at low rates. Furthermore, the rate of oxygen evolution is greatly increased at short times, as demonstrated above, after a decrease in the thickness of the oxide layer on the electrode surface. Thus, under bipolar operation, the high CD's can be achieved by oxygen evolution taking place at relatively low electrode potentials, and at these lower potentials the Kolbe reaction does not proceed at a significant rate relative to the enhanced rate of oxygen evolution. The relative rate of the various electrode reactions is most likely determined by the thickness of the oxide film of the electrode. This is also very likely the cause of the increase in the complete oxidation reaction at shorter pulse times reported in the literature (21), since it is well known that complete oxidation takes place under conditions of very low oxide coverage and is inhibited by the formation of the oxide film (192) The additional observation that the changes in selectivity are greater during constant current operation (23) than constant potential operation (21) is also consistent with this view of the mechanism. In previous discussions of the unsteady-state nature of the Kolbe reaction [*e.g.*, by Fleischmann *et al.* (21, 25, 27), Hickling and Wilkins (23), Vijh and Conway (193), and Nadebaum and Fahidy (28)], the particular importance of the oxide film thickness has not been adequately taken into account, and a new appraisal of the factors involved in the kinetics of the Kolbe dimerization reaction is required.

Concentration and Refining of Metals and Other Substances

In using a RBE to achieve activation via stripping of adsorbed impurities, it is apparent that when the impurity is, *e.g.*, copper, the process involves deposition of Cu on the rotating electrode surface in one compartment and stripping in another. Thus, a net transfer of copper from one compartment to another takes place and a "concentrating" effect is observed. This process was also studied in some detail and the findings (194) are summarized in Fig. 7, showing cupric ion concentration in each compartment. It can be seen that, commencing with about 0.85×10^{-3} mol/dm³ Cu(II) in all cell compartments, after several hours of operation almost all of the copper ions has been transferred to compartment 1. After about 20,000 sec, *e.g.*, the concentration in compartments 1, 2, and 3 are 2.15×10^{-3}, 1.1×10^{-4}, and 8.5×10^{-6} mol dm³, respectively. This process can be analyzed by carrying out a simple mass balance on the ith, cathodic compartment of a multicompartment cell

rate of removal = rate of deposition
+ rate of leakage via electrode gap

At short times, the rate of decomposition is approximately linear, hence

$$-\frac{dc_i}{dt} = \frac{r_o}{c_o} c_i + \frac{L_e R \Omega g}{2V_{compt}} (c_i - c_{i-1}) \quad [2]$$

From this equation the maximum attainable ratio of the concentrations in adjacent compartments is given by

$$\frac{c_{i-1}}{c_i} = 1 + \frac{2(r_o/c_o) \cdot V_{compt}}{L_e \cdot R \cdot \Omega \cdot g} \quad [3]$$

$$\simeq 1 + 4\pi \left(\frac{r_o/c_o}{w \cdot \Omega}\right)\left(\frac{G}{g}\right) \quad [4]$$

In these equations c_i = bulk copper concentration at time t in the ith compartment (mol/dm³), c_o = initial bulk copper concentration (mol/dm³), r_o = rate of deposition when $c_i = c_o$ (mol/dm³·sec), L_e = depth of the electrolyte in the compartment (m), V_{compt} = volume of electrolyte in the compartment (dm³), g = effective gap between the inner rotating electrode and the stationary wiper blade, G = annular gap between the inner and outer electrodes. These expressions indicate the following: (*I*) The rate of removal of Cu^{++} increases with deposition rate (r_o). Thus, if the deposition rate is mass transfer controlled, increasing the rotation rate (Eq. [1]) or agitating the electrolyte will increase the rate of transfer. (*II*) The maximum attainable concentration ratio can be increased by decreasing the leakage gap at the wiper blades, or by increasing the volume of the cell compartment (*e.g.*, by increasing the gap between the inner and outer electrodes). (*III*) Multicompartment cells can sustain much greater concentration ratios than a simple two-compartment cell.

Similar concentration-time curves were obtained over a wide concentration range (10^{-5}-10^{-2} mol/dm³ Cu^{++}). It was also found that the stripping process in compartment 1 can be effected chemically. Thus, in the

Table II. Change in the product distribution of an electrochemical reaction with a rotating bipolar electrode cell

Electrolyte: 1 mol/dm³ CH_3COOH + 2 mol/dm³ CH_3COOK

Operating conditions	Current efficiency* of production of anodic gases† (via chromatographic analysis)			
	O_2	C_2H_6	CO_2 (other than formed during C_2H_6 production)	CO_2 (total)
Simulated current pulsing (electrode rotating at 14.6 rad/sec)	25.0	4.0	19.9	27.9
Conventional constant current (electrode stationary)	0.7	94.7	2.9	192.4
Equivalent*	2	1	1	1

* Current efficiencies were calculated with respect to the percentage of hydrogen in the product gas

$$\text{current efficiency} = \frac{100\,(\%\text{ product})\,(\text{equivalent})}{(\%\text{ hydrogen})}, \%$$

† Qualitative determination of CH_4 and CO indicated the presence of very small amounts of these constituents.

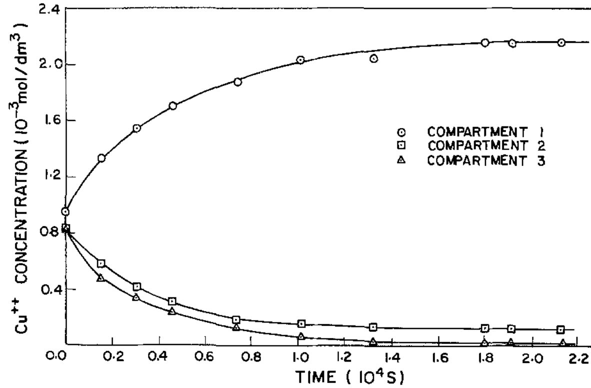

Fig. 7. Copper concentration vs. time in individual compartments under tripolar operation. ~10^{-3} mol/dm³ Cu^{++} (initial) + 0.05 mol/dm³ H_2SO_4; Ω = 0.73 rad/sec; oxygen flow rate 4.6 cm³/sec; $E_2 = E_3$ = 0.2V; compartment 3 short-circuited.

case of Cu, bubbling oxygen through the solution at open circuit rapidly strips deposited copper from the electrode surface. A more rapid stripping action can be achieved by short-circuiting the electrodes of the stripping compartment, the outer electrodes thus providing additional area for oxygen reduction. As explained in a previous section, the deposition process involves the formation of submonolayer films and can take place at potentials more anodic than the reversible potential.

Concluding Remarks

In this paper the concept, operation modes, and some applications of a rotating bipolar cell were described. Much more work remains to be done: at present reaction systems of importance in fuel-cell technology are being studied, and an investigation with respect to electrode materials other than platinum will soon begin.

While it is somewhat premature to draw definite conclusions on technological applicability, the RBE cell may become an attractive means of carrying out certain electrochemical reactions. The economics involved in the design and construction of an industrial cell will be the subject of a future publication by the authors.

ABSTRACT

Experimental results are presented for the anodic oxidation of ferrous iron in dilute ferrous sulfate-sulfuric acid solutions. A conductive fixed-bed, flow-through, electrochemical reactor in which electric current flow is parallel to the direction of electrolytic solution flow was used. Steady-state anodic polarization curves were obtained at seven different flow rates, ranging from 1.5 to 10 ml/min in a cell of 81.1 cm^2 cross section. Input ferrous iron concentrations were 725 μg/ml in an acid mine water simulant containing 1430 μg/ml of sulfuric acid. Conversion efficiency for ferrous to ferric iron exceeded 99.9% at the lower flow rates. Design equations have been developed which predict performance of the system. Measured limiting currents exceed theoretical values by 6-14%. A preliminary cost analysis for a million gallons per day acid mine water treatment plant for oxidizing ferrous to ferric iron using parallel current-electrolytic solution flows predicts 7.5¢ per thousand gallons of which 4.6¢ per thousand gallons is assigned to capital costs. An additional 22.3¢ per thousand gallons must be added for following limestone treatment and precipitation of the ferric iron.

A serious industrial water pollution problem associated with coal mining operations results from the oxidation of iron pyrite in coal by exposure to air and water. This results in the formation of a dilute solution of ferrous sulfate and sulfuric acid, each product concentration varying typically from several hundred to several thousand micrograms/milliliter (acid mine water). To avoid pollution, this effluent must be neutralized and freed of iron before discharge into receiving waters.

A number of processes have been investigated for acid mine water treatment, including ion exchange, reverse osmosis, freezing, foaming, microbiological oxidation-limestone neutralization, ozone oxidation-limestone neutralization, and combination limestone-lime neutralization with aeration. Except for special circumstances, poor efficiencies, adverse economics, or both appear to rule out present use of most of these approaches. The principal treatment now in use commercially is the lime neutralization with aeration process.

An alternate approach is to preoxidize the ferrous ion electrolytically with subsequent iron precipitation and acid neutralization effected by addition of ground limestone. Certain economic advantages are claimed for this approach over the lime neutralization with

Key words: ferrous oxidation, flow-through electrodes, water treatment.

aeration process (1-3). These previous studies report on processes in which electrolytic preoxidation was carried out in a conductive packed bed, flow-through reactor with current flow perpendicular to the direction of electrolytic solution flow. Maximum conversion efficiency for ferrous to ferric iron electro-oxidation of about 73% was achieved in the bench-scale reactor used. A rather complete mathematical analysis for that cell geometry has been presented by Alkire and Ng (4).

In the present work, a packed bed, flow-through reactor with powdered graphite filler was used with current flow parallel to the direction of electrolytic solution flow. Design and operation of this reactor, shown schematically in Fig. 1, is similar to that described by Bennion and Newman (5) and further tested by Wenger (6) and by Yip (7). The iron oxidation cell consists essentially of the anode half of the Bennion-Newman cell with a stainless steel cathode. Electrolytic solution was gravity-flowed through the cell, downward through the cathode screen, through a thick, porous anode, and then discharged through a micrometer control valve.

Design Principles

In order to achieve maximum utilization of the reactor volume, all or most of the volume must be involved in converting ferrous to ferric ions. The object is to maximize the average conversion rate per unit volume for the whole reactor and maintain product quality while minimizing the cost of the reactor and associated operating costs. The principal operating costs are electrical energy, pumping to overcome pressure drop across the cell, and associated labor and maintenance costs. Various geometries can be considered. However, this discussion is limited to the geometric cell configuration shown in Fig. 1 in which solution flow is parallel to electrical current flow and the counterelectrode is upstream of the working electrode. For this configuration, it has been shown (5, 6) that the pumping costs are very small. The details of labor costs are beyond the scope of this study. In the following calculations it is assumed that the system is capital intensive and that the primary objective is to achieve maximum conversion rates per unit volume. The effects of electrical energy costs on the design can be considered later. The basic principles used here are very similar to those presented earlier for a copper system (5).

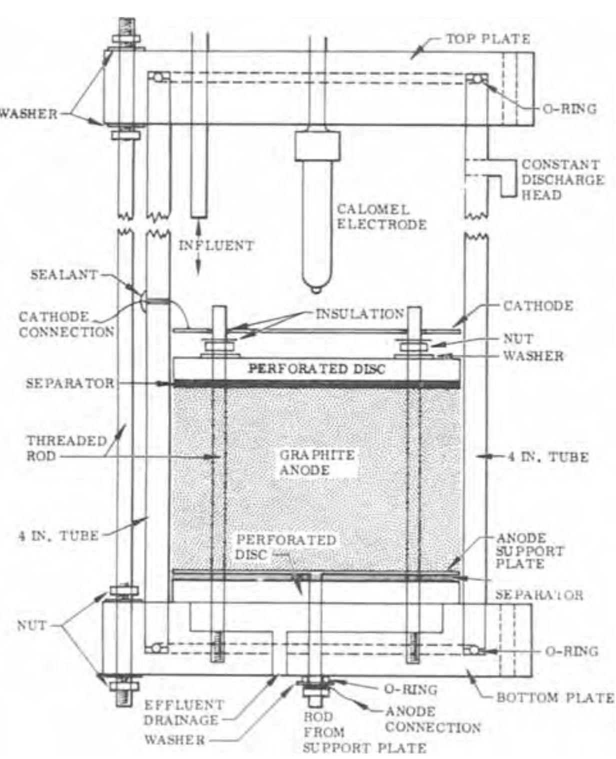

Fig. 1. Four-inch, flow-through electrolytic reactor

As fluid flows through the porous electrode, ferrous ions are transported from the bulk solution to the electrode surface and react to form ferric ions. The larger the electrode surface area per unit volume, a, the greater will be the reaction rate. It is assumed there is an excess of supporting electrolyte and that ferrous ions are transferred from bulk solution within the pores to the electrode surface by diffusion only. Thus the rate of reaction of the ferrous ions per unit area is proportional to the concentration difference between the bulk, c_b, and the surface, c_s. It is convenient to express the surface reaction rate in terms of the local transfer current density, j. Based on Faraday's law, the volumetric reaction rate, R, can be written as follows

$$R = \frac{aj}{\mathbf{F}} = ak_m (c_b - c_s) \qquad [1]$$

k_m is the effective mass transfer coefficient. In order to maximize R, c_s must go to zero. This condition is achieved by applying a sufficiently large electrical potential driving force. The driving force must not be so large as to create excessive oxygen evolution.

Oxygen bubbles trapped in the packed bed will cause channeling and reduce the effective value of ak_m. The parameter combination ak_m is determined experimentally from the limiting current for ferrous to ferric conversion prior to O_2 evolution. Electrolytically evolved oxygen or other oxidant diffusing into the bulk of a pore and oxidizing ferrous iron in the pore leads to values of j larger than predicted by Eq. [1] based on ferrous diffusion only. This latter effect will be dominant in early stages of oxygen evolution, but, as oxygen bubbles continue to plug the bed more and more, the effects of oxygen evolution can decrease over-all performance.

A material balance on the ferric ion yields the concentration distributed within the flow-through porous electrode

$$v \frac{dc_b}{dy} = -R = -ak_m c_b \qquad [2]$$

The symbols are defined at the end of the paper. The variation of the potential driving force is described by Ohm's law and the conservation of charge

$$i = \kappa \frac{d\phi}{dy} \qquad [3]$$

$$aj = \frac{di}{dy} \qquad [4]$$

i is the superficial or observed current density and κ is an effective, electrolytic conductance in the porous bed.

The boundary conditions are

$$c_b = c_o \text{ at } y = 0 \qquad [5]$$

$$i = 0 \text{ at } y = L \qquad [6]$$

$$\phi = 0 \text{ at } y = L \qquad [7]$$

$$c_b = c_L \text{ at } y = L \qquad [8]$$

The final condition is not really a boundary condition, but more of a design criterion. Given c_L, the optimum electrode thickness, L, and flow rate, v, can be determined. The solution to these equations is

$$c_b = c_o \exp(-\alpha y) \qquad [9]$$

$$i = Fvc_o [\exp(-\alpha y) - c_L/c_o] \qquad [10]$$

$$\Delta\phi = \beta[\exp(-\alpha y) - 1 + \alpha y c_L/c_o] \qquad [11]$$

where

$$\alpha = ak_m/v \qquad [12]$$

$$\beta = Fv^2c_o/ak_m\kappa \quad [13]$$

As a first approximation, the cost of a processing plant will depend on the volume or weight of cells required to process a given feed flow rate of acid mine waters to be treated. The volume of cells is just the area, A, times the thickness, L. The area, A, is the feed flow rate, F, in cm^3/sec divided by the maximum allowable feed velocity through the cell, v

$$A = F/v \quad [14]$$

The larger the velocity v, the smaller A, and the lower the capital cost. Typically k_m depends on the velocity through the bed and the bed geometry expressed through the area per unit volume, a, and the particle shape factor, ψ. A correlation suggested by Bird *et al.* (8) has been used

$$\frac{k_m}{aD} = 0.91 \frac{\rho v^{0.49}}{a\mu\psi} \psi^2 Sc^{1/3} \quad [15]$$

Given c_o, c_b^L, a, $\Delta\phi$, and κ, Eq. [9], [11], and [15] can be solved for v, L, and κ_m. Equation [15] assumes no channeling. If there is channeling, one must use an effective a which may be much smaller than the geometric a based on particle size alone. The larger the magnitude of $\Delta\phi$, the larger will be v. L also increases with $\Delta\phi$, but the gain in v more than offsets any increased size associated with the larger L. The larger the magnitude of $\Delta\phi$, the greater the rate of oxygen evolution. A value of about -1.7V appeared optimum for the experiments reported on here. For higher magnitude $\Delta\phi$, the oxygen which formed caused channeling which reduced the effective value of a and thus v_{max} decreased with further increase in magnitude of $\Delta\phi$. The optimum value of $\Delta\phi$ could vary considerably with local operating conditions.

The effective electrolytic conductivity in the porous electrode, κ, was estimated using the Bruggemann equation (9, 10)

$$\kappa = \kappa_0\epsilon^{1.5} \quad [16]$$

where κ_0 is the bulk electrolytic solution conductivity and ϵ is the porosity of the electrode.

Given c_o, c_b^L, L, v, and κ from experimental observations, it is possible to calculate effective values of $\Delta\phi$, a, and k_m. If the effective a is much smaller than a calculated from the geometric area of the packing material, it implies there is channeling of the flow through the bed. It was not possible to measure $\Delta\phi$ directly. However, by placing a reference electrode in the effluent stream and measuring its potential relative to the anode, one measures a potential V_p. This V_p is essentially $\Delta\phi$ plus any electronic resistance losses in the matrix, surface overpotential at the front of the electrode, local concentration overpotential at the front of the electrode, and possibly a constant term which depends on the particular reference electrode selected. These local effects in comparing V_p and $\Delta\phi$ have been discussed by Wenger (6). It seems sufficient to state here that V_p is related to $\Delta\phi$. The larger V_p, the larger the magnitude of $\Delta\phi$ and the greater the tendency for oxygen evolution.

In experimental runs, current is increased by increasing the cell voltage, V_f, and measuring V_p. When limiting current is reached throughout the cell, c_s everywhere very much less than c_b, further increases in the cell voltage increase V_p, but the current no longer changes. The length of the I *vs.* V_p plateau is a measure of the excess capacity of the cell. As v is increased, the length of the limiting current plateau decreases. When the plateau just disappears with increasing v, the maximum velocity is assumed to have been established experimentally, see Fig. 2 and 3. For a given set of input and output conditions, the larger the value of the effective a, the larger will be the maximum v. Thus the importance should be clear of minimizing channeling and realizing an effective a as close to the geometric or true a as possible.

Experimental

Cell construction.—The experimental reactor is shown in Fig. 1. It is constructed of Plexiglas tubing, 4 in. ID, with two end plates consisting of Plexiglas disks fitted with O-rings to close off both ends of the tube. Sealing is effected by compression of six external, threaded, steel rods located peripherally on the end plates at 60 degree intervals. The graphite bed is contained between two Plexiglas support plates containing 72 ¼-in. and 18 ⅜-in. perforations spaced in a geometrical pattern to give a uniform flow rate and still maintain structural strength. These support plates are compressed by means of six internal stainless steel threaded rods. Cloth separators, placed below the top perforated support plate and below the perforated anode support plate, prevent graphite particles from washing out of the bed by the electrolytic solution flow. The graphite used in the bed was Stackpole Carbon Company, Grade 6026 graphite, sized to $-100 + 150$ mesh.

Electrical circuit.—Circuitry was similar to that used by Bennion and Newman (5). Influent and effluent were monitored continuously for pH and conductance. Anode potential was measured *vs.* saturated calomel reference electrodes located above the cathode (V_f) and below the anode (V_p) in the effluent stream. Conductance was measured with Beckman flow-through conductivity cells (cell constant 0.5 cm^{-1}). Anode potential, cell voltage, and pH were measured with an Orion Model 601, digital pH meter; cell resistance was measured with a General Radio tube 1650-A impedance bridge. Power was supplied to the cell from a Gerhard Bark, Wenking potentiostat in which the impressed current is regulated at a constant potential between anode and a calomel reference electrode placed above the cathode (V_f).

Flow control.—Flow of effluent being discharged was controlled with a Nulcear Products Company micrometer valve. Influent flow rate was adjusted always to exceed that of the effluent, the overflow being discharged through an outlet located near the top of the reactor in order to maintain a constant head of electrolytic solution on the micrometer valve exit port. This was necessary in order to minimize fluctuations in flow rate over 24 hr periods. Flow rates were determined using graduated cylinders to collect known volume of effluent over measured time intervals.

Electrolyte concentrations.—The electrolytic solution was an acid mine water simulant, 725 μg/ml in ferrous iron (as ferrous sulfate heptahydrate) and 1430 μg/ml in H_2SO_4. Solutions were made up from deionized water and reagent grade (J. T. Baker) chemicals. The pH of the influent electrolyte ranged from 1.9 to 2.1 with a mean conductivity of 0.065 mho/cm. Influent temperature varied between 22° and 26°C.

After reaching a steady state for V_p at each V_f setting for a given flow rate, the effluent was analyzed for the ferrous and total iron concentration. Analysis was made spectrophotometrically, using a Beckman Model D2 spectrophotometer. Either 1-10 phenanthroline or α-α' bipyridyl procedures were followed (11), depending on the ferrous iron concentration.

For solutions containing less than 10 μg/ml of ferrous iron, two parts (by volume) of the sample were diluted by addition of one part of saturated potassium fluoride solution to complex ferric ions, thereby inhibiting formation of the colored ferric complex. An additional one part of α-α' bipyridyl solution (2% in 6*N* HCl) was then added to form the yellow ferrous complex which was determined spectrophotometrically at 415 mμ. For solution containing more than 10 μg/ml ferrous iron, the sample was suitably diluted to give 0-3 μg/ml, and the red 1-10 phenanthroline ferrous complex was determined at 515 mμ. Total iron was determined by using a 500× dilution treated with solid hydroxylamine hydrochloride to reduce ferric to fer-

rous iron, followed by spectrophotometric determination of the red O-phenanthroline complex.

Above 20 μg/ml, accuracy of the analytical determinations was about 7%; at the lower limit of the measurements near 1 μg/ml, the accuracy was 10%.

Materials compatibility.—It was found necessary to thickly gold plate 316 stainless steel anode support plate and the six internal tie rods, washers, and nuts. All other metal exposed to the electrolyte was unplated 316 stainless steel. The cell body was Plexiglas. Separators were cut from Webril material, a nonwoven Dacron cloth.

Results

Figures 2 and 3 show the family of anodic polarization curves (I *vs.* V_p) at seven flow rates ranging from 1.5 to 10 ml/min, or 3.1×10^{-4} to 2.1×10^{-3} cm/sec. These results were obtained under steady-state conditions with an electrolytic solution of acid mine water simulant containing from 705 to 725 μg/ml ferrous iron. Runs were made at constant flow rate. Variations in flow rate of up to 10%, in some cases, occurred due mainly to temperature variations occurring overnight with consequent viscosity changes in the solution. Flow rates for each point have been normalized to the value shown for each curve and the corresponding current values corrected accordingly. From 4 to 24 hr are required to reach a true steady state for each point on the curve after each change in the control potential V_f. Superficial residence time is of the order of 8 hr. It normally takes about three superficial residence times to achieve a steady state. This point is discussed in greater detail by Bennion and Newman (5) in their work on copper deposition. Shapes of the curves are typical (at flow rates up to 6.85 ml/min) for an electrode process approaching and then establishing a limit current. A reasonably identifiable plateau is established before the rapid rise due to oxygen evolution occurs.

Analysis of the effluent stream for ferrous and total iron concentrations was carried out for each run. Coulombic conversion efficiencies of over 99.9% were obtained at the lower flow rates. Effluent ferrous iron concentration is given in micrograms/milliliter beside each datum point. Effluent total iron concentration was lowered from that of the influent by electrodeposition of some metallic iron at the cathode.

Discussion

Current increment.—Table I is a summary of steady-state, limiting current operation at various flow rates. Comparing the calculated current based on Eq. [10] and the observed current shows the observed current to be consistently 10-12 mA higher. This effect is also shown by comparing the dashed lines and plateau positions in Fig. 2 and 3. One possible explanation of this difference is that hydrogen produced at the cathode and dissolved in the electrolyte is oxidized in the bed to give the observed increment of current. It is difficult to account for more than half this difference, however, assuming the solution is saturated (not supersaturated) with hydrogen at a solubility concentration of 1.34 ppm. An experiment was conducted at 1.50 cm³/min to test this concept using a Nafion XR-475 ion exchange membrane to separate the dissolved hydrogen formed at the cathode from the anode bed. No decrease in limiting current was observed. This experiment supports the view that the anomalous current increment is not due to electro-oxidation of hydrogen.

Another point mitigating against the concept of oxidation of dissolved hydrogen is that the incremental current observed should increase with increasing flow rate for any dissolved species being oxidized. This does not occur; the incremental current remains essentially constant at about 10-12 mA.

Another explanation of the anomalously high observed limiting current and the relatively constant value of the current increment at increasing flow rates is that the incremental current is due to the anodic oxidation of the graphite surface. Since the oxidation product may be a solid and remain on the surface of

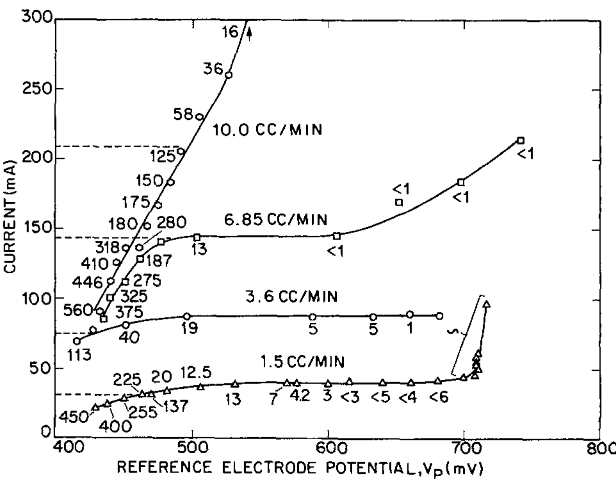

Fig. 2. Polarization curves for porous, flow-through anode. 81.1 cm² cross section, 7.4 cm length, $\kappa_{in} = 6.5 \times 10^{-3}$ mho/cm, $\kappa_{out} = 5.3 \times 10^{-3}$ mho/cm, $Fe^{++}{}_{in} = 725$ ppm, $Fe^{++}{}_{out}$ noted by numbers next to experimental points. Average total iron out = 705 ppm. Flow rate noted beside each curve. - - - - shows calculated limiting currents.

the graphite, no dissolved species would be involved, and hence no increase in incremental current with flow rate would occur. A recent study (12) has shown that hydroquinone-like groups on a graphite surface are anodically oxidized to quinone-like groups. These quinone-like surface species could eventually react with the ferrous ions to establish a steady-state condition. Other observations favoring this point are that the bed appeared to improve with age, and that a yellow colloidal layer appeared above the packed graphite bed when the reactor was back flushed after running above oxygen evolution potentials for a prolonged period. Quinoidal compounds are usually colored.

If carbon is reacting, eventually the carbon bed will be destroyed. Over a three month period of operation, the graphite bed used in these experiments showed no noticeable deterioration. If impurities in the graphite are involved, eventually they would be used up and the excess current would no longer be observed. If the impurity level is estimated at 5% of the graphite by weight and to have an effective equivalent weight of 50, a graphite bed of 700g would contain 0.7g equivalents of impurities. Assuming operation for 20 days at 10 mA excess current implies consumption of only 0.18g equivalents in some Faradaic reaction other than ferrous iron oxidation. (This calculation is only good to about an order of magnitude.) Hence, it is concluded that for the length of time involved, impurities could have been reacting or possibly graphite breakdown would not have been extensive enough to be noticed.

Another more obvious explanation for the excess current is oxygen evolution. If bubbles of oxygen form, they are expected to plug the porous electrode flow channels and cause electrolyte channeling, which should result in poor iron oxidation rates. Since observed oxidation rates were high, it could be that oxygen did not nucleate, but reacted with ferrous iron as fast as it formed at the graphite surface. It is known that the uncatalyzed reaction of molecular oxygen with ferrous iron is a slow reaction (13). However, this reaction is catalyzed by activated carbon (14). Hence, the rapid oxidation of ferrous iron by the active oxygen forming in the bulk of the electrode pores cannot be ruled out.

A difficulty with both the quinone and oxygen evolution explanations for the anomalous limiting current increment is that the anomaly is observed at potentials below those required for either oxygen evolution or surface quinone formation.

It seems improbable that peroxide, formed by partial oxidation from water, could be the active intermediary, since at pH 2 the oxidation of ferrous iron by hydrogen peroxide is incomplete unless a large excess of peroxide is present.

The experimental results presented here are not sufficient to determine the precise secondary reaction or reactions taking place. However, the results do indicate that electrochemical oxidation of ferrous ions is feasible and that the proposed design equations and procedures work and yield conservative design conditions. The unaccounted for side reactions apparently do not hinder operation so far as has been determined to date. Their possible beneficial effects should not be counted upon until more is known about them and under what conditions they occur.

Conversion efficiency.—As shown in Fig. 2, conversion efficiency of ferrous to ferric iron is over 97% at the highest flow rate (10 cm^3/min), the last point indicated on the curve. This high conversion efficiency is achieved even though no limiting current is established at this high flow rate. Normally one would expect a relatively low conversion efficiency under these conditions, since ferrous iron flows through the bed faster than it can diffuse to the anodic surfaces and be oxidized. Surface quinone formation at the anode, as discussed above, could serve as a solid redox couple and catalyze the oxidation of ferrous ion, especially if it were partially soluble in the electrolyte. In effect, it would increase the effective mass transport coefficient of ferrous ion by rapidly oxidizing it within the pores of the graphite anode surface.

Cost analysis.—Using actual data at a cell flow rate of 8.14 cm^3/min, feed of 725 μg Fe^{++}/ml, feed conductivity of 0.005 mho/cm, effluent concentration of 6 μg Fe^{++}/ml, bed length of 7.4 cm, and a bed shape factor of 0.86 yields an effective surface area per unit volume for the bed of 12.3 cm^{-1} and an allowable resistance loss through the bed of 1.768V. The effective surface area is quite low compared to an estimated geometric specific surface area of over 100 cm^{-1}. By optimizing the packing material to get more uniform size distribution, the specific surface can probably be increased substantially, possibly to between 26 and 50 cm^{-1}. For design estimates here, specific area of 14 cm^{-1} and 1.7V resistance potential drop across the packed bed will be used. In order to compare costs with previous estimates (3), feed of 500 μg Fe^{++}/ml and effluent with 95% conversion[1] (25 μg Fe^{++}/ml) will be used as the design basis. These conditions imply an optimum bed length of 4.8 cm and a flow velocity of 2.7×10^{-3} cm/sec or 57 gal/day·ft^2. To take advantage of any soluble oxidant or dissolved oxygen production in the cell, the cell should be made a little longer than 4.8 cm, possibly up to 7 cm.

To handle one million gallons per day, the above cell design implies that 17,544 ft^2 of cell area will be needed. If the cells are coated concrete slabs and walls with a packed bed on top, a separator, a cathode, the concrete container filled with electrolytic solution, and a hood to collect the hydrogen, the construction cost is assumed to be similar to that of a concrete slab warehouse for which the construction cost is estimated (15) as \$9.50/ft^2. Detailed cost estimating procedures for copper removing flow-through electrodes yield \$4 to \$15/ft^2, depending on design details and cost bases. It seems reasonable to assume a cost of \$10/ft^2 for a large-scale reactor of this type.

At \$10/ft^2, the cost of a one million gallon per day reactor will be \$175,440. For purposes of comparison, straight line depreciation over ten years with no interest charges is assumed. This gives a fixed cost of \$17,-544 per annum or 4.8¢ per thousand gallons of acid mine water treated. For cell voltage of 3V, it requires 2.73 kW-hr to treat one thousand gallons of feed assuming 100% current efficiency for the $Fe^{++} \rightarrow Fe^{+++} + e^-$ reaction. If power costs 1¢/kW-hr, energy costs will be 2.7¢ per thousand gallons of feed. Other costs for limestone precipitation have been estimated (3) to be 22.3¢ per thousand gallons based on 500 μg Fe^{++}/ml and 1000 μg/ml total acidity. This implies a total treatment cost of 29.8¢ per thousand gallons. This cost figure compares to 36¢ per thousand gallons for the Tyco Laboratories estimate (3). A credit of 6¢ per thousand gallons for salable hydrogen gas produced is deductible from each of these figures for comparison with non-electrolytic processes. Sludge handling costs are not included in these estimates.

Cost estimates of this type are of necessity approximate. They should be useful for preliminary comparisons and to illustrate how the costs are capital intensive at today's energy costs. By achieving higher flow rates per unit geometric area and/or lower cost per unit geometric area of the electrode, more favorable economic situations should be possible. In particular, larger values of the effective specific surface area, *a*, should allow for higher flow rates. This might be achieved by minimizing channeling of electrolytic solution flow through the bed and increasing the actual specific surface area within the bed.

Other applications.—This use of flow-through, porous electrode reactors should be applicable to the anodic oxidation of cyanide ions from dilute solutions

[1] This is reported to be (3) the lowest conversion efficiency for Fe^{++} that will allow complete precipitation of iron by addition of limestone.

such as plating rinse waters for cyanide concentrations up to several hundred parts/million. It should also be applicable to the reduction of chromate to chromic ions in plating bath rinse waters from acid chromium plating baths. In addition it should be possible to cathodically strip gold, silver, copper, and nickel from plating bath rinse waters. The details for metal recovery are discussed elsewhere (5, 6, 16). By using a combination of cyanide destruction and ion recovery, it may be possible to clean rinse waters for reuse.

Investigation of the Reaction Between Liquid Lithium and Lithium Chloride-Potassium Chloride Melts

Randall N. Seefurth* and Ram A. Sharma*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The fumes over lithium chloride-potassium chloride melts containing lithium were determined to be potassium vapors resulting from the exchange reaction between the lithium and the potassium chloride in the melt. The rate of this reaction was measured by using a simple electrochemical half-cell containing two lithium electrodes. The amount of unreacted lithium was determined at any desired time by transporting it electrochemically between the electrodes. The reaction rate was determined at various current densities up to 3000 A/m^2 over a temperature range of 648°-773°K; it was found to be independent of current density, potassium chloride concentration in the melt, and electrode-melt interfacial area. The activation energy was found to be 111 kJ/mol of lithium, which is nearly equal to the heat of potassium vaporization (115 kJ/mol) from the melt. Since the activation energy is about equal to the heat of potassium vaporization, the rate of the reaction of lithium with potassium chloride is considered to be controlled by the rate of potassium vaporization from the melt.

In the course of Li-S cell studies in a helium atmosphere, fumes of varying intensity were observed when lithium metal, held in a stainless steel matrix, was dipped into the molten LiCl-KCl electrolyte at 673°K. The fumes, which became more pronounced as the temperature was increased, were reddish-brown and gave a grayish-purple to violet deposit on condensation. When the condensate was smeared, it appeared to be very soft and had a metallic luster.

The metallic lithium which dissolves in LiCl-KCl melts should not be the source of the fumes, as no fumes have been observed over Li-LiCl solutions at about 923°K. The partial vapor pressure of lithium is expected to be lowered by dissolution in these melts if the solution is similar in behavior to that of alkaline earth metals in their respective chlorides. The partial vapor pressures of the alkaline earth metal in their respective chlorides have been observed to be lowered (1).

Hammer *et al.* (2) calculated the standard decomposition potentials of the alkali halides and indicated that the LiCl-KCl melt can be used as an electrolyte in galvanic cells with lithium anodes. The LiCl-KCl melt is used as an electrolyte in the electrolytic production of lithium metal (3). But both of these sources did not give any information as to what extent the lithium reacts with the potassium chloride under the existing conditions. The reaction of lithium with potassium chloride at cell operating temperatures (~673°K) may proceed to the extent where the activity of the potassium may be high enough to give appreciable vapors, and consequently may be the source of the fumes seen in the lithium-sulfur studies. Some indication of potassium vaporization at higher temperatures (above 773°K) from a LiCl-KCl melt in contact with lithium may be obtained from the emf work of Foster *et al.* (4) where they observed potassium condensate on the cooler sections of the electrode leads of cells with Li anodes, Li-Bi cathodes, and LiCl-KCl electrolyte. Therefore, a systematic investigation was undertaken to identify the volatile product and the sources of its formation and to determine its rate of formation and the rate-controlling step.

Experimental

Materials.—Lithium metal of 99.97% purity and a compressed nickel-fiber sheet of 80% porosity with an average pore size of 40 μm (pore range ≃20-60 μm) were used to make the test electrodes.

Lithium chloride of 99.6% purity and potassium chloride of 99.9% purity were used in preparing the eutectic mixture. The eutectic mixture was purified by bubbling chlorine through the melt at about 723°K for 2 hr and subsequently scavenging the chlorine by bubbling helium for about 1 hr. The exact purity level of the prepared electrolyte was not determined. However, lithium cycling tests yielded a mean current efficiency of 97 ±5% which was taken to indicate no gross amount of impurities. In addition, the low electronic conductivity, 8×10^{-3} ohm^{-1}cm^{-1} at 723°K (5) is not expected to have any influence on the measurements. This may also be observed from the current efficiency.

Electrode preparation.—The lithium electrodes were prepared by cutting rectangular pieces, 13 × 25 mm each, from the 1.6 mm thick nickel-fiber sheet. A 1.5 mm hole was drilled through each of the matrices near the narrow edge (Fig. 1). A 1.5 mm diameter by 450 mm long rod of 304 stainless steel was then inserted through the hole, bent to form a hook, and then arc welded to provide an intimate contact with the nickel-fiber matrix. This rod served as the electrical lead during testing. The matrices were hydrogen-fired at 1100°C for 2 hr to remove oxides from their surfaces before use.

The electrode matrices were loaded by immersing them in a molten pool of lithium at approximately 973°K. After loading, the counterelectrode was electrolytically stripped of its lithium in a separate cell.

Apparatus.—The furnace was a clamshell heater, 150 mm long and 75 mm ID, insulated with firebricks. This simple furnace was convenient to use in the dry box. The furnace temperature was controlled with a proportional-band temperature controller. A millivolt potentiometer and a Chromel-Alumel thermocouple were used for temperature measurements. The electrical instruments included a d-c power supply, together with the necessary logic and switching circuitry to cycle the cell automatically according to a preset charge-discharge program, and a dual channel recorder for measuring cell potential and current.

A bell-shaped condenser made from 304 stainless steel, large enough to cover the clamshell heater, was used for the condensation of the fumes. The condenser had a central tube to allow the hot gases to escape. A tray inside the condenser, which was attached at the

* Electrochemical Society Active Member.

Key words: lithium electrode, molten salt electrolyte, lithium chloride-potassium chloride, exchange reaction, potassium vaporization.

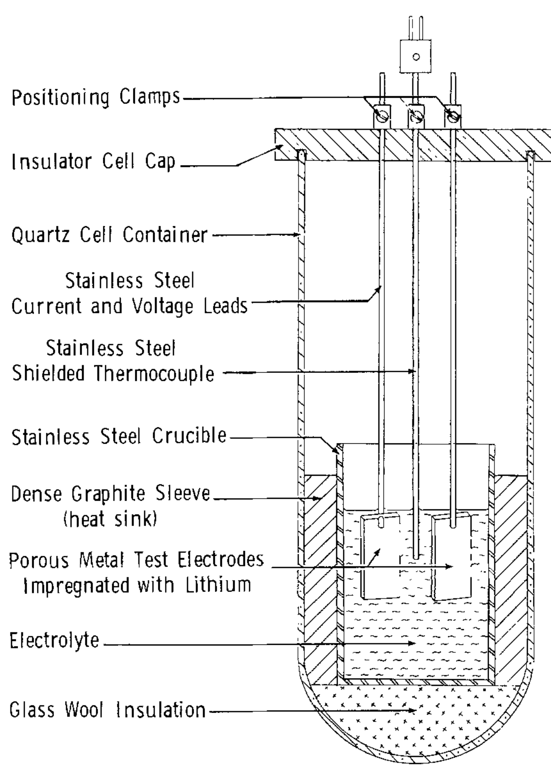

Fig. 1. Lithium electrode test cell

bottom end of the central tube for collecting the condensate, also served as a baffle.

The cell used for cycling the lithium between the two electrodes is shown in Fig. 1. It consisted of a quartz enclosure (70 mm diam, 300 mm deep) fitted with a cap which served to position the two electrodes and a thermocouple. A 304 stainless steel cup (50 mm diam, 100 mm deep) was used to hold the electrolyte.

Procedure.—About 50g of purified LiCl-KCl eutectic was placed into a hydrogen-fired stainless steel container, 100 mm long and 50 mm ID inside a helium-atmosphere dry box. The container with the eutectic was placed inside the furnace and heated to 673°K. While the melt was maintained at this temperature, lithium metal was slowly added. After about 15 min, reddish-brown fumes were observed to be coming from the melt. (These fumes were similar in appearance to cigarette smoke.) The condenser was positioned above the melt container to condense the fumes. After a week, the condensate was scraped from the condenser and sent for chemical analysis.

To determine the rate of product volatilization, the test cell (Fig. 1) was assembled inside the dry box holding the electrodes above the solid electrolyte (usually 200g). The cell was placed inside the furnace, heated to the desired temperature, and the electrodes were lowered into the molten electrolyte. The immersion depth was kept at a minimum so that the electrode leads would not contribute appreciably to the electrode areas. After thermal equilibrium was reached, the testing was accomplished by continuously cycling the cells at varying current densities with the aid of the automatic cycling device. The usual test consisted of discharging the working electrode at constant current until an increase in voltage (5-10 mV at 0.1A) indicated that the lithium was depleted from the electrode. After a short recovery time (300 sec), the current was reversed and the lithium was recharged onto the working electrode until a similar voltage increase again indicated the complete transfer of lithium. The cycling was continued in this manner for several hours to determine the loss in lithium capacity as a function of time under the test conditions. In addition, visual inspection of the electrodes was made periodically to determine the wetting characteristics and the general appearance of the deposited lithium. These determinations were made at various temperatures and current densities.

Results and Discussion

Identification of the volatile product and the source of its formation.—The condensate that was obtained from over the Li-LiCl-KCl melt was gray. It appeared to be very soft when rubbed with a stainless steel spatula. The chemical analysis of this condensate gave >99.0% potassium and 0.1% lithium. This indicates that potassium vapors may have been the source of the fumes seen during lithium-sulfur cell studies. As stated earlier, potassium vapor formation has also been reported by Foster *et al.* (4) during their emf measurements of cells with Li anodes, Li-Bi cathodes, and LiCl-KCl electrolyte above 773°K. Another recent work has also reported vaporization of potassium from Li-LiCl-KCl solutions at 400°C (6). Together, these findings indicate the possibility of the following reaction

$$\mathrm{KCl(melt)} + \mathrm{Li(l)} = \mathrm{LiCl(melt)} + \mathrm{K(melt)} \quad [1]$$

The standard free energy changes, ΔG°, calculated at various temperatures, from the data given in the JANAF compilation (7), are given in Table I. The value of ΔG° varies from 18.8-16.1 kJ/mol of lithium (4490-3855 cal/mol of lithium) in the temperature range 627°-823°K. The activity of potassium may be calculated from the equilibrium constant

$$K = \frac{a_{\mathrm{LiCl}}\, a_{\mathrm{K}}}{a_{\mathrm{KCl}}\, a_{\mathrm{Li}}} \quad [2]$$

where a is the activity of the designated component.

The values of K at various temperatures were calculated from the relation

$$K = e^{-\Delta G^\circ/RT} \quad [3]$$

Table I. Standard free energy change, ΔG°, equilibrium constant, K, and activities a, of the components for the reaction $\mathrm{KCl(s)} + \mathrm{Li(l)} = \mathrm{LiCl(s)} + \mathrm{K(l)}$, and partial vapor pressures of K, P_K

and are given in Table I. The activity of LiCl in LiCl-KCl melts with respect to pure solid LiCl were calculated in the usual way using the open-circuit potentials for LiCl-KCl melts reported by Anthony *et al.* (8). The relation reported by Bradley and Sharma (9)

$$E^\circ = 4.184\text{-}7.96 \times 10^{-4}T \pm 0.010\text{V} \quad (600^\circ\text{-}881^\circ\text{K}) \quad [4]$$

was used for those of pure LiCl. The activities of KCl with respect to pure solid KCl were calculated using the Gibbs-Duhem relation. These activities are given in Table I. The activities of K at various temperatures were calculated by Eq. [2] at unit activity of Li using the values of K, a_{LiCl}, and a_{KCl} given in Table I. Pure lithium at unit activity will be present under the conditions of the calculations as potassium is not appreciably soluble in lithium (10). The calculated potassium activities also given in Table I are less than unity in each case, indicating that under these conditions potassium will be present only in solution in the eutectic melt. The vapor pressures of potassium (mm Hg) can be calculated using the equation (11)

$$\log P_K = -4770/T - 1.37 \log T + 11.58 \quad [5]$$

The partial vapor pressures of potassium, P_K, over the melt of Li and LiCl-KCl eutectic electrolyte, were calculated from the activity of potassium and its vapor pressure at various temperatures, and are given in Table I. The partial vapor pressure of potassium is quite appreciable at these temperatures. Therefore, reaction [1] appears to occur forming K which vaporizes giving fumes over the LiCl-KCl melt. The enthalpy change of the reaction is 27.2 kJ/mol of lithium (6.5 kcal/mol of lithium) and the entropy change is 64.4 J/K per mol of lithium (15.4 cal/deg per mol of lithium) at these temperatures. So the reaction appears to occur due to the change in entropy.

Rate of the reaction at various current densities and temperatures.—Twelve cells were assembled to generate the data. The matrices made from nickel fiber retained lithium metal better than other metal-fiber matrices tested. A fully loaded matrix had a capacity of 2.5 kC of lithium. Results of typical tests in terms of lithium electrode capacity *vs.* elapsed time are presented in Fig. 2 and 3.[1] The results at various current densities are given in Fig. 4, whereas the results at various temperatures are shown in Fig. 5. Figure 6 presents the rates of lithium loss obtained from Fig. 5 plotted against temperature reciprocals.

The data were obtained after the electrolyte had been in contact with lithium for more than 300 ksec in order to ensure saturation. Similar melts, such as molten magnesium chloride, have been observed to be saturated with magnesium within 5.5 ksec (12) and molten calcium chloride with calcium within 10 ksec (13).

The data in Fig. 2 also indicate electrolyte saturation with lithium before the measurements were made. In this case, the electrolyte had been in contact with lithium for 30 ksec, then the lithium loss rate was measured at 500°C before and after an interval of 340 ksec at 400°C. The lithium loss rates before and after the interval were the same. This observation indicates that the electrolyte had been saturated with lithium within 30 ksec and remained so during the measurements.

Lithium loss by droplet formation can also be discounted from the data in Fig. 2. As may be observed from the plots in this figure, the lithium loss rate with time remains constant at 500°C, then decreases with change in temperature to 400°C, and regains its original value when the temperature was raised to 500°C. This regularity in loss rate with temperature is most unlikely if droplet formation is occurring. However, under certain conditions, especially at lower temperatures (~400°C), lithium loss has been observed by droplet formation. In these experiments, the lithium loss with time was observed to be erratic. The loss increased in an erratic manner with increase in current density, *i.e.*, droplet formation appeared to increase with increase in current density. The droplets in the electrolyte could also be seen visually. The present

[1] The curves shown in these and subsequent figures in the text are a least squares fit to the data. For clarity, the individual data points were not included in Fig. 4.

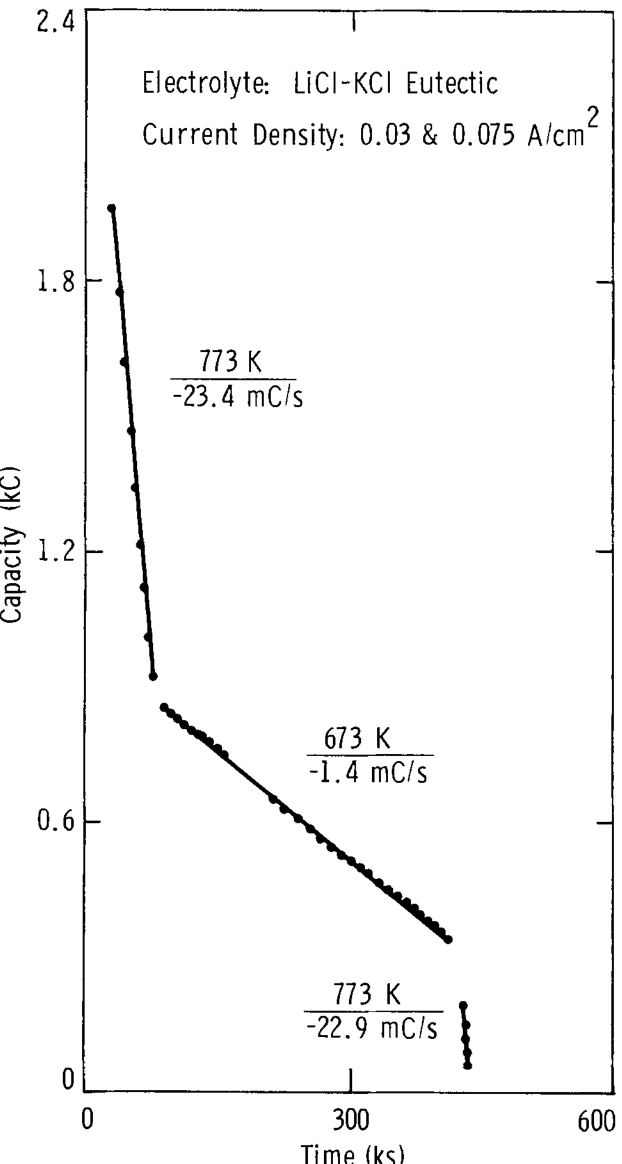

Fig. 2. Lithium content of electrode vs. elapsed time

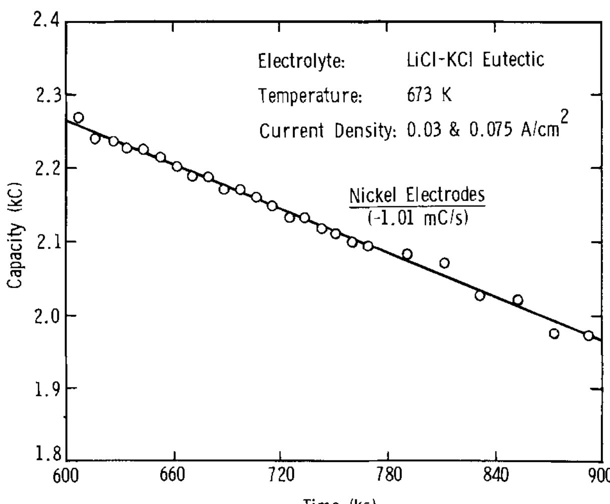

Fig. 3. Lithium content of electrode vs. elapsed time

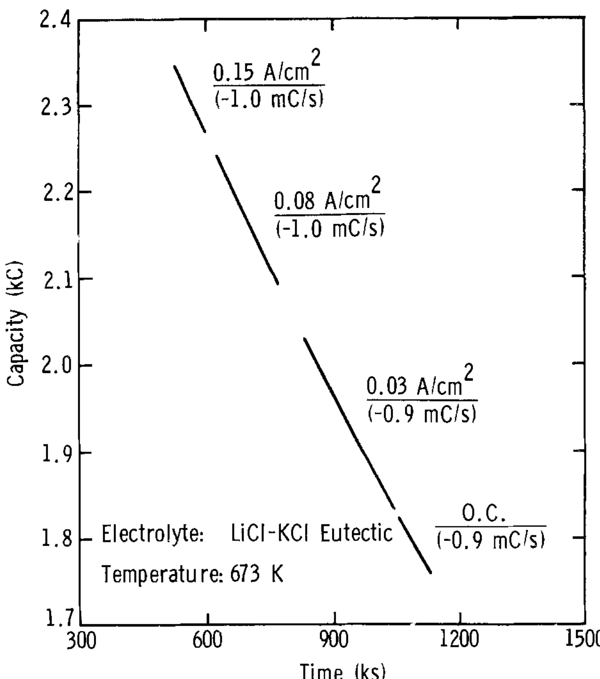

Fig. 4. Lithium content vs. elapsed time at various current densities.

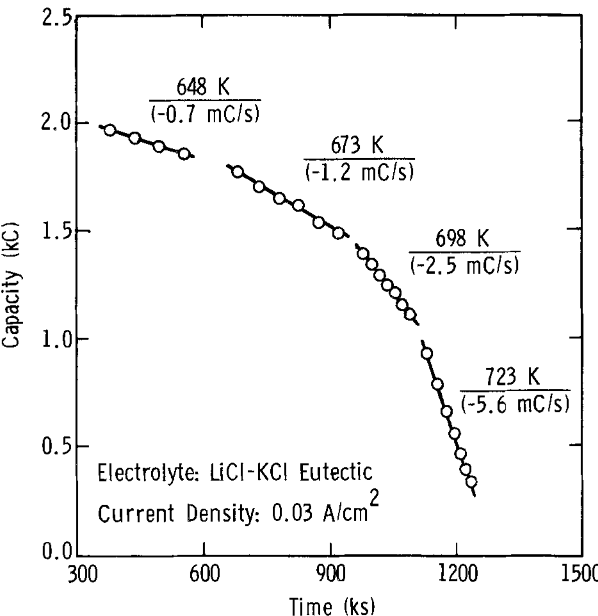

Fig. 5. Lithium content vs. elapsed time at different temperatures.

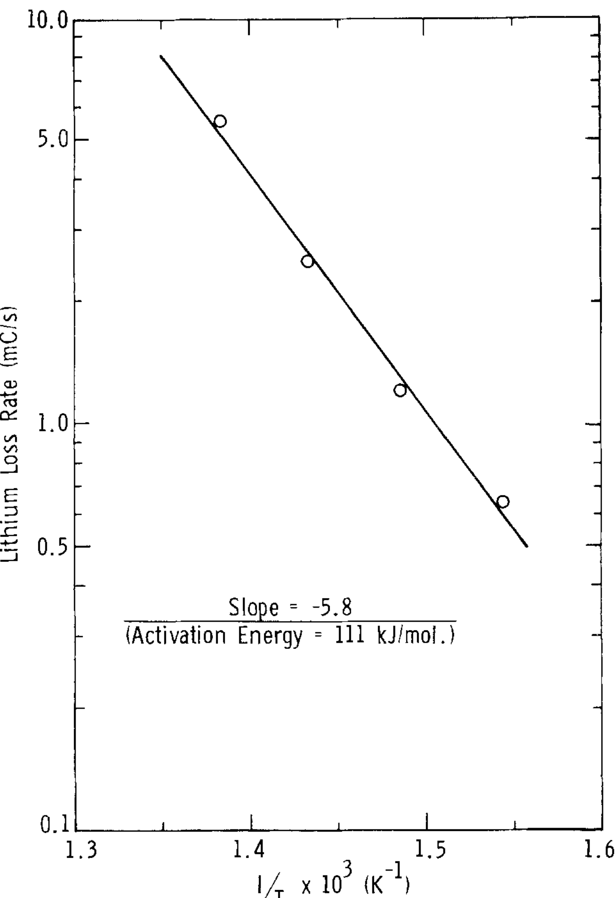

Fig. 6. Effect of temperature on lithium loss rates

data are from experiments where the lithium loss with time was linear (Fig. 2 and 3). It remained constant with change in current density from 0 to 1500 mA (Fig. 4) and no lithium droplets were observed in the electrolyte.

Figures 2-5 show the lithium loss rate to be independent of the change in concentration of lithium chloride [+1.0 weight per cent (w/o) maximum] and potassium chloride (−1.0 w/o maximum) which occurred during the period of the experiments. It also is not affected by the possible lithium chloride and potassium chloride concentration gradients which could occur with current density variations (Fig. 4).

The rate of lithium loss increases exponentially with decreasing reciprocal temperature and follows an Arrhenius relationship as may be seen in Fig. 6. The activation energy calculated from this plot is 111 kJ/mol of lithium. This is nearly equal to the heat of vaporization of potassium (115 kJ/mol of potassium) which was calculated from the equilibrium potassium vapor pressures over the lithium chloride-potassium chloride melts at various temperatures given in Table I.

Determination of the rate-controlling step.—In the homogeneous Li-K-LiCl-KCl melt, the number of K molecules reaching a unit surface in unit time may be taken to be

$$n_K/2\, V_x \qquad [6]$$

where n_K is the number of potassium molecules per cubic centimeter and V_x is the velocity component perpendicular to the surface.

The term ½ implies that only one-half of the potassium molecules are moving toward the surface and the other half are moving in the opposite direction.

The number of molecules in a velocity interval between V_x and $V_x + dV_x$ can be obtained from the Maxwell distribution (14-17) as

$$dn_{V_x} = n_K/2 \sqrt{\frac{M}{2\pi RT}}\, e^{-MV_x^2/2RT}\, dV_x \qquad [7]$$

where M is the molecular weight, R is the gas constant, and T is the temperature in degrees K.

The number of molecules reaching the surface in unit time within this velocity interval is given by

$$dn_K' = V_x\, n_K/2 \sqrt{\frac{M}{2\pi RT}}\, e^{-MV_x^2/2RT}\, dV_x \qquad [8]$$

Now all of the molecules having a velocity less than a certain limiting value, V_L, will be pulled back by the attractive forces of the other molecules in the interior. Only those molecules which have velocities greater than V_L can pass through this zone of attraction and escape as vapors. The number of these molecules can be determined by integrating the above equation be-

tween $V_x = V_L$ and $V_x = \infty$ and so

$$n_K' = n_K/2 \int_{V_L}^{\infty} \sqrt{\frac{M}{2\pi RT}}\, e^{-MV_x/2RT}\, V_x dV_x \quad [9]$$

Upon integration

$$n_K' = n_K/2\, C\, e^{-MV_L/2RT} \quad [10]$$

where C is a constant equal to $\sqrt{Rt/2\pi M}$.

The expression $MV_L^2/2$ represents the kinetic energy of one mole of potassium atoms moving with the limiting velocity, V_L, and which are just capable of escaping into the gas sphere. According to the law of conservation of energy, this amount of energy must be equal to the work performed against the attractive forces of the atoms in the interior, *i.e.*, it is equal to the work of vaporization of potassium from the melt. The work of vaporization can be taken equal to the heat of vaporization, ΔH_V, which gives $MV_L^2/2 = \Delta H_V$. Therefore

$$n_K' = n_K/2\, C\, e^{-\Delta H_V/RT} \quad [11]$$

a relation which shows the activation energy equal to the heat of vaporization of potassium.

In a general way, the Li losses in Li-LiCl-KCl melts may be considered to occur in the following steps: (*i*) contact of lithium with potassium chloride either through solution or by transport of potassium chloride to the lithium-electrolyte interface, (*ii*) Li(l) + KCl (melt) = LiCl (melt) + K (melt) reaction, (*iii*) transport of lithium chloride and potassium away from the reaction zone, and (*iv*) evaporation of potassium by the reaction: K (solution) $\leftrightarrows$ K (vapors).

As was observed earlier, the activation energy calculated from the rate of lithium loss *vs.* temperature has been found equal to the heat of vaporization of K from Li-K-LiCl-KCl melts. The heat of vaporization of potassium was calculated from the equilibrium partial vapor pressures of potassium over these melts at different temperatures. Since the activation energy is equal to the heat of vaporization under these conditions, the rate-controlling step appears to be the potassium vaporization reaction. This also implies that the electrolyte has equilibrium concentrations of potassium and lithium.

Silver/Silver Chloride Electrode: Charging of a Porous Structure

S. Szpak and A. Nedoluha

Electronic Materials Sciences Division, Naval Electronics Laboratory Center, San Diego, California 92152

and T. Katan*

Materials and Structures, Lockheed Palo Alto Research Laboratory, Palo Alto, California 94304

ABSTRACT

Reaction profiles for the charging of porous silver electrodes in 1N KCl are investigated. The effects of changes in the rate-determining step on the reaction profile are calculated and compared with experiment for galvanostatically held superficial current densities of 2-25 mA/cm^2 for 2-8 hr. Interpretations are given for the experimentally determined distributions of anodically formed silver chloride and for the morphology of the silver chloride deposits as observed with the scanning electron microscope as a function of distance into the porous structure.

In recent years several approaches to battery electrode modeling have been proposed. Perhaps the best known and most comprehensive one is that of Bennion and co-workers (1, 2) which is based on the solution of a set of coupled partial differential equations representing the various applicable laws of transport and conservation. An effective computer program is available so that, in principle, the reaction profile can be constructed once the details of the reaction mechanism and transport processes within the porous structure have been established (3). In practice, the difficulty in electrode modeling arises from a lack of sufficiently detailed information concerning the nature of the controlling elementary processes and their dependence on the degree of electrode discharge. Nevertheless, some success has been reported in a comparison of the experimental data of Bro and Kang (4), with the computer simulated behavior using the solution-diffusion model (3).

Experimental efforts in studying the time-dependent evolution of reaction profiles, which are of interest in battery technology, involve the determination of pertinent factors from the analysis of the degree of conversion as a function of distance at externally controlled discharge conditions, *e.g.*, potentiostatic, galvanostatic, or an otherwise programmed discharge mode. In general, it is not possible to assign a reaction path on the basis of a chemical analysis of the reaction products as a function of distance alone. Thus, in addition to the usual analytical procedures, Katan (5) and Katan *et al.* (6, 7) studied surface morphology after charge and discharge in an attempt to obtain data necessary for modeling the sparingly soluble reactant-conductive matrix system. In an extension of this approach, Bennion *et al.* (8) selected a different geometry to simulate the electrode behavior and employed x-ray element scanning analyses combined with scanning electron microscopy to arrive at the nature of the controlling elementary process.

While electrode modeling can be used to predict electrode behavior and to show very clearly the effects of various elementary processes, modeling per se cannot be used to predict the elementary processes. It is the purpose of this communication to illustrate how a gain into describing the working of battery electrodes can be achieved using a more restrictive model for which analytical solutions can be given. In particular, we shall consider the situation where the rate determining step changes during the course of electrode discharge.

* Electrochemical Society Active Member.

Key words: silver chloride, porous electrode, charge distribution, current distribution, reaction profile.

This model is less restrictive than that of Winsel (9) where the reaction path is invariant with time, but certainly is more restrictive than that of Bennion and co-workers (1, 2). The silver/silver chloride electrode will be used here to demonstrate essential features of this model.

Equivalent Circuit Concept

Elementary model of porous electrode.—An extensive review of the equivalent electric circuit concept was given by de Levie (10). The reaction density profile for a one-dimensional porous electrode of length l, and subject to a galvanostatic mode of operation, *i.e.*, for boundary conditions given by

$$i(o, t) = i_o, i(l, t) = 0 \quad [1]$$

is as follows

$$j(x) = \kappa_1 i_o \frac{\cosh[\kappa_1(l - x)]}{\sinh(\kappa_1 l)} \quad [2]$$

The transfer (faradaic) current density is given by Eq. [3]

$$j = -\frac{\partial i}{\partial x} \quad [3]$$

The dimensionless parameter $\kappa_1 = (R_1/Z_1)^{1/2}$, is the square root of the ratio of solution resistance to electrode reaction impedance, both per unit length and unit cross section of the porous electrode.

Equation [2] exhibits an exponential behavior; for $j(x) > 0$, the slope $j'(x)$ is negative and its magnitude decreases with an increase in distance. The rate at which $j(x)$ bends away from the x axis depends on the numerical value of κ_1. Thus, Winsel (9) refers to κ_1 as the reduced pore length, Bro and Kang (4) prefer the name of electrochemical Thiele parameter. Other terms, such as electrode effectiveness factor and depth of penetration, are also associated with it. A formulation by Nanis (11) is especially useful because it reflects the importance of electrode structure as well as the electrochemical process. Regardless of the manner in which this number has been introduced, its use is limited to electrodes under a steady-state regime.

Unfortunately, a true steady-state operation cannot be realized in the course of battery discharge, because the supply of reactant is continually diminishing. Corresponding structural changes occur, and when all active material is used up, the electrode ceases to function. The time-dependent reaction profile is thus related to the material used up, or, alternatively, to the material still present. It is not surprising, therefore, that the experimentally determined Thiele parameter

has been found to vary with the electrode discharge (4, 12).

Porous electrode with change of reaction path.—An electrochemical process, as a rule, consists of a series of consecutive elementary processes. Consequently, there exists a relation

$$Z(x,t) = \Sigma_k Z_k(x,t) \quad [4]$$

as can be inferred from Van Rysselberghe's analysis of the complex reaction path (13), as indicated by de Levie (10), and as explicitly derived by Dunning (3) for the "solution-diffusion" model.

Usually one elementary process dominates the overall reaction path, so that the right side of Eq. [4] contains essentially one term. If, in the course of electrode reaction a change in the rate determining step (rds) takes place, only the numerical value of Z is affected, that is to say, again only one term dominates expression [4]. A typical example is the reduction of thin films of silver chloride partially covering the silver substrate. It was recently shown that, as the individual patches of silver chloride become smaller, a change in the rds from chloride diffusion to silver chloride dissolution occurs (6). If this process is allowed to occur within the confinements of a porous structure, a change in the rds is likely because of the wide variety of local conditions caused by the distribution in transfer current density and the decreased accessibility of electrolyte which effectuates a change in local concentrations.

Consider an electroactive substance uniformly dispersed within the conductive matrix. Assume that the reaction path is initially governed by one elementary process throughout the electrode thickness. The reaction density profile is described by Eq. [2], with R_1 and Z_1 associated with the assumed reaction path. Due to the nonlinear reaction profile, the amount of the active material used up varies with distance. Assume further that, when the amount of active material initially present is reduced to an *a priori* specified level, another reaction path begins to operate. The reaction density profile given by Eq. [2] then no longer applies.

The graphical representation of a change in the rds within the porous electrode is shown in Fig. 1. The change from one mechanism to another has occurred at $x = x_c$. To the right, *i.e.*, for $x_c < x \leq l$, the initial reaction path operates, while for $0 \leq x < x_c$, another process dominates the electrode discharge.

Obviously, the location at which the change in controlling reaction takes place is determined by the extent of the electrode discharge or charge. It follows that the rational description of electrode operation requires specification of three time intervals, namely, the time before the second mode of electrode operation is initiated, the time during which the first and second modes operate simultaneously, each with its own rds, and the time after the first mode of operation has completely disappeared. The determination of these time intervals, the corresponding reaction profiles, and the velocity at which the plane of change in the rds propagates through the porous structure can be used to constitute the basis for electrode evaluation. The plane at which the change in the rds occurs will henceforth be referred to as the mode interface.

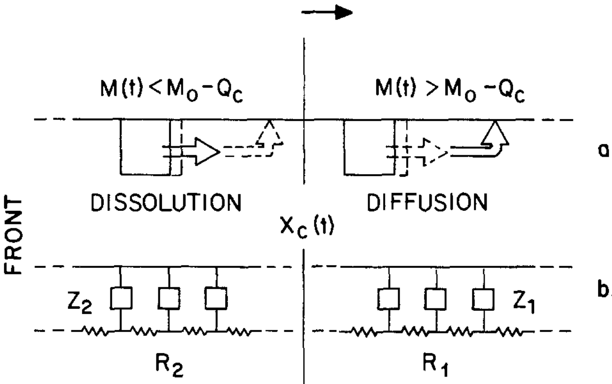

Fig. 1. Schematic representation of a segment of porous electrode. Upper: change in reaction path at $x = x_c\ (t)$; initial reaction path at $x > x_c\ (t)$, newly created path at $x < x_c\ (t)$. Lower: electric circuit analogue, subscript 1 initial path, 2 reaction path after $Q > Q_c$.

Analytical Formulation

Basic concepts.—Consider a small section of an equivalent electric circuit analogue, shown in Fig. 1(b). The current density, $i(x,t)$, and the electrostatic potential in the solution phase relative to the metal matrix, $u(x,t)$, are related by Eq. [5] and [6]

$$\frac{\partial u}{\partial x} = -Ri \quad [5]$$

$$\frac{\partial i}{\partial x} = -\frac{u}{Z} \quad [6]$$

The degree of electrode discharge or charge at point, x, and time, t, is given by Eq. [7]

$$M(x,t) = M_o - \alpha Q(x,t) \quad [7]$$

Here, M_0 is the initial amount of electroactive material uniformly distributed within the porous structure, α is a proportionality constant, and $Q(x,t)$ is the transferred charge. If the discharge process is initiated at $t = 0$, the charge transferred at time t is given by Eq. [8]

$$Q(x,t) = \int_0^t j(x,t')dt' \quad [8]$$

We consider $Q(x,t)$ to be always positive and express it in Asec/cm^3. When the amount of charge transferred exceeds an *a priori* given amount, that is, when $Q(x,t) > Q_c$, a new reaction path becomes operative, characterized by R_2 and Z_2, as illustrated in Fig. 1(a). Thus, the introduction of R_1, Z_1, R_2 and Z_2, identifies two regions within the electrode structure. The region to the left, *i.e.*, for $0 \leq x < x_c$, will be designated as region 2, while the region to the right of the dividing plane at $x = x_c$, will be referred to as region 1.

With the adapted nomenclature, we identify $x_c(t)$ as the position where a change in the rds takes place, for example, from diffusion to dissolution controlled, as illustrated in Fig. 1. All relevant quantities pertaining to position $x_c(t)$ will be denoted by subscript c. The quantities of interest in the present communication are: Q_c, the amount of charge transferred, or extent of electrochemical reaction necessary to initiate the change in the rds; $t_c(x)$, the time at which the mode interface arrives at an *a priori* selected position x; $v_c(x)$, the velocity at which the mode interface penetrates the porous structure.

The extent of the electrochemical conversion is defined by Eq. [8]; the critical time $t_c(x)$ is the inverse of $x_c(t)$. For j bounded, it follows from Eq. [8] that a critical time, $t_c(0)$, exists such that all of the electrode belongs to region 1 for $t \leq t_c(0)$. Within this time period the electrode operates under one mode, that is to say, the same reaction path operates throughout the electrode structure. As discharge of the electrode is carried beyond time $t_c(0)$, the mode interface begins to penetrate into the porous structure, reaching the electrode's backside at time $t_c(l)$. Thus, at a time greater than $t_c(0)$ but less than $t_c(l)$, the electrode operates under two modes, with the change of the rds occurring at position $x_c(t)$.

At times greater than $t_c(l)$, the reaction profile is once again controlled by a single mode, *i.e.*, by the new reaction path which supplanted the original one.

The physical significance of $x_c(t)$, and of the charge transferred, Q_c, is clear; practical utilization, however, requires a knowledge of the dependence of these quantities on the nature of electrochemical reaction and the

electrode's structure, and information is needed on changes in these dependences which occur during the course of reaction. Specifically, we need the reaction profile at any time, t, the rate of penetration of the mode interface, and the amount of charge transferred. The depth of penetration of the mode interface and the rate of penetration are experimentally accessible (12) without electrode destruction. The reaction profile, on the other hand, is usually not accessible to direct measurement; it is inferred from the changes in chemical composition as a function of time and position. If the reaction profile is known and the model is given, one can compute the corresponding charge transferred; conversely, from experimental information on the extent of the electrode reaction as a function of position and time, the reaction profile can be reconstructed.

Determination of critical time, $t_c(0)$.—From the initiation of electrode discharge at $t = 0$ to the time $t_c(0)$, the reaction profile is given by Eq. [2]. The local rate of electrode reaction, $j(x)$, during this period is taken to be independent of time until charge Q_c is accumulated, which is an approximation. Hence, it follows from Eq. [8] that

$$Q(x, t) = j(x) \cdot t \quad [9]$$

which, together with Eq. [2], results in

$$t_c(0) = \frac{Q_c}{\kappa_1 i_o} \tanh(\kappa_1 l) \quad [10]$$

Evidently, the time necessary for the initiation of a new reaction path is determined by the electrode thickness as well as the initial reaction path. The critical time can be experimentally controlled by the total discharge current density, i_o in Eq. [10].

Transfer current density profile, $j(x, t)$.—The transfer current density distribution representing the reaction rate profile prior to initiation of the new reaction path is given by Eq. [2]. A similar expression applies also at times greater than $t_c(l)$, except that R_1 and Z_1 are replaced by R_2 and Z_2, denoting the new reaction mechanism.

In this section we will calculate the discharge profiles when the electrode operates with a change of reaction mechanism, that is, discharge profiles for $t_c(0) < t < t_c(l)$. The general form for the solution of Eq. [5] and [6] is given by Eq. [11] and [12]

$$i = Ae^{\kappa_2 x} + Be^{-\kappa_2 x} \text{ for } 0 \leq x < x_c \quad [11]$$

$$i = Ce^{\kappa_1 x} + De^{-\kappa_1 x} \text{ for } x_c < x \leq l \quad [12]$$

Coefficients A, B, C, and D are evaluated using the boundary conditions in Eq. [1] for the galvanostatic discharge together with the condition of continuity for current, i, and potential, u, at $x = x_c(t)$. After some manipulations, we obtain the coefficients as follows

$$A = -i_o e^{-\kappa_2 x_c} M^{(-)}/2N \quad [13a]$$

$$B = i_o e^{\kappa_2 x_c} M^{(+)}/2N \quad [13b]$$

$$C = -i_o \zeta_2 e^{-\kappa_1 l}/2N \quad [13c]$$

$$D = i_o \zeta_2 e^{\kappa_1 l}/2N \quad [13d]$$

where

$$M^{(\pm)} = \zeta_1 \cosh[\kappa_1(l - x_c)] \pm \zeta_2 \sinh[\kappa_1(l - x_c)] \quad [14]$$

$$N = \zeta_1 \sinh(\kappa_2 x_c) \cosh[\kappa_1(l - x_c)] + \zeta_2 \cosh(\kappa_2 x_c) \sinh[\kappa_1(l - x_c)] \quad [15]$$

and

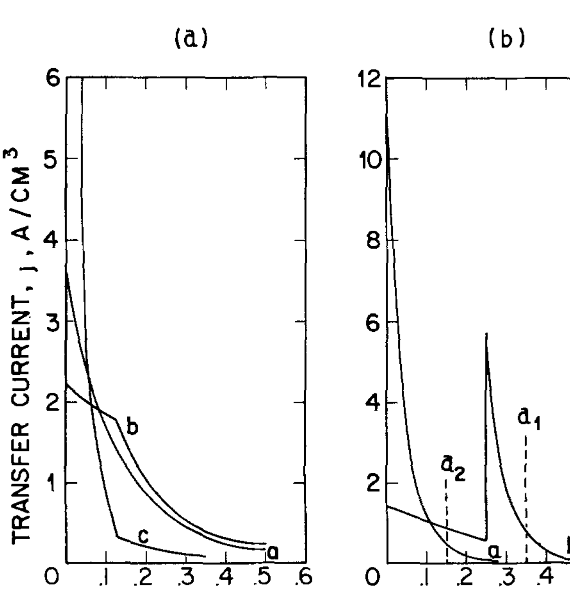
$$\zeta_k = (R_k Z_k)^{1/2} \text{ with } k = 1,2$$

Appropriate substitutions of Eq. [13]-[15] into Eq. [11] and [12], followed by differentiation with respect to distance, yield corresponding local current transfer densities

$$j(x) = \frac{\kappa_2 i_o}{N} \{\zeta_1 \cosh[\kappa_1(l - x_c)] \cosh[\kappa_2(x_c - x)] + \zeta_2 \sinh[\kappa_1(l - x_c)] \sinh[\kappa_2(x_c - x)]\} \quad \text{for } 0 \leq x < x_c \quad [16]$$

$$j(x) = \frac{\kappa_1 \zeta_2 i_o}{N} \cosh[\kappa_1(l - x)] \quad \text{for } x_c < x \leq l \quad [17]$$

Typical current density profiles associated with the change in the reaction path are shown in Fig. 2(a), 2(b), and 2(c). They were computed for a selected set of parameters R_1, R_2, Z_1, and Z_2 to demonstrate the various types of transfer current density profiles that may arise in the course of electrode discharge or charge. For example, by changing values of R_1, R_2, Z_1, and Z_2 two kinds of interferences affecting the evolution of reaction profile can be surmised with the derived equations, and they are designated as choking or blockage of the first and second kind. Specifically, Fig. 2(a), curve c, demonstrates the effect of choking of the first kind where the principal reaction zone, *i.e.*, that portion of the electrode that carries the bulk of the transfer current, is shifted towards the front of the porous structure. This behavior is associated with an increase in electrolyte resistance, R_2, either due to depletion by reactive consumption or because of formation of a voluminous precipitate suspended in the



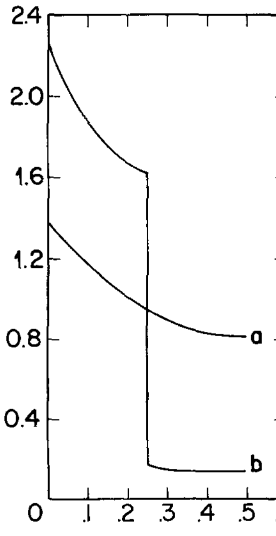


Fig. 2. Transfer current density profiles (from Eq. [16] and [17]) for selected set of parameters: R, Z, and x_c. All curves for $i_o = 5$ mA cm^{-2} and $l = 0.5$ cm. Note that at $x_c = 0$ only R_1 and Z_1 operate and R_2 and Z_2 are nonexistent while for $x_c > 0$ both R_1, Z_1 and R_2, Z_2 are operative. (a) $R_1 = 5$, $Z_1 = Z_2 = 10^{-1}$. Curve a, $x_c = 0$; curve b, $R_2 = 1$, $x_c = 0.125$; curve c: $R_2 = 50$, $x_c = 0.125$. (b) $R_1 = 5$, $R_2 = 1$, $Z_1 = 10^{-2}$, and $Z_2 = 10^{-1}$. Curve a, $x_c = 0$; curve b, $x_c = 0.25$ cm. (c) $R_1 = R_2 = 5$, $Z_1 = 1$, $Z_2 = 0.1$, $x_c = 0.25$ cm. Curve a, $x_c = 0$; curve b, $x_c = 0.25$ cm.

electrolyte. Another type of choking, called that of the second kind, results in an opposite behavior when Z_2 is large, Fig. 2(b), curve b; the principal reaction zone is then shifted into the electrode interior.

Figure 2(c), curve b, illustrates another set of circumstances that may arise when Z_2 is small, *i.e.*, when the electrode reaction becomes faster as more electroactive substance has been converted. In practice, this may occur with complexing of the reaction product.

In our model the transfer current density profile consists of two regions, with a discontinuity at $x = x_c(t)$. By definition

$$\Delta j_c = \lim_{\epsilon \to 0} \{ j[x_c(t) + \epsilon, t] - j[x_c(t) - \epsilon, t] \}, \; \epsilon > 0$$

hence, it follows from Eq. [16] and [17] that

$$\Delta j_c = (Z_2 - Z_1) \frac{i_0 \kappa_2 \kappa_1}{N[x_c(t)]} \cosh [\kappa_1 (l - x_c(t))] \quad [18]$$

Sharp discontinuities as shown in Fig. 2 would be smoothed in real electrodes where the change in rate determining step occurs over a finite length. The magnitude of the discontinuity depends on both reaction paths and becomes smaller as the mode interface penetrates deeper into the electrode structure.

Rate of penetration of mode interface, $v_c(x)$.—The determination of the velocity at which the $x_c(t)$ plane penetrates the electrode structure can be used as a tool in the examination of simple models (12) of electrode discharge.

The charge transferred at any point within region 1 is specified by substitution of Eq. [17] into Eq. [8]

$$Q(x,t) = \kappa_1 \zeta_2 i_0 \cosh [\kappa_1 (l - x)] \int_0^t \frac{dt'}{N[x_c(t')]} \quad [19]$$

but, at $x = x_c(t)$, $Q(x,t) = Q_c$, which is a constant, thus Eq. [19] is an integral equation for $x_c(t)$

$$\int_0^t \frac{dt'}{N[x_c(t')]} = \frac{Q_c}{\kappa_1 \zeta_2 i_0} \operatorname{sech} [\kappa_1 (l - x_c(t))] \quad [20]$$

Upon differentiation of Eq. [20] with respect to t, an expression for the rate of penetration of the mode interface into the porous structure, $v_c(x_c(t)) = dx_c/dt$, can be written as follows

$$v_c(x) = \frac{i_0}{Q_c} \coth [\kappa_1 (l - x)] \left\{ \frac{\zeta_1}{\zeta_2} \sinh [\kappa_2 x] + \cosh [\kappa_2 x] \tanh [\kappa_1 (l - x)] \right\}^{-1} \quad [21]$$

The functional dependence of v_c on the depth of penetration x_c for a selected group of parameters characteristics of the new reaction path, R_2 and Z_2, is shown in Fig. 3. It is seen that, immediately after the initiation of a new reaction path, the velocity of propagation of the mode interface is calculated by taking the limit of Eq. [21]

$$v_c(0) = \frac{i_0}{Q_c} \coth^2 [\kappa_1 l] \quad [22]$$

The velocity, v_c, is thus independent of the kinetics of the newly formed reaction.

For penetration of the mode interface to some distance, x_c, which is small enough ($\kappa_2 x_c << 1$) so that $\sinh \kappa_2 x_c \approx \kappa_2 x_c$, another simplified relationship can be derived

$$v_c(x) = \frac{i_0}{Q_c} \coth [\kappa_1 (l - x)] \left\{ \frac{\zeta_1}{Z_2} x + \tanh [\kappa_1 (l - x)] \right\}^{-1} \quad [23]$$

The rate of penetration is dependent on the reaction

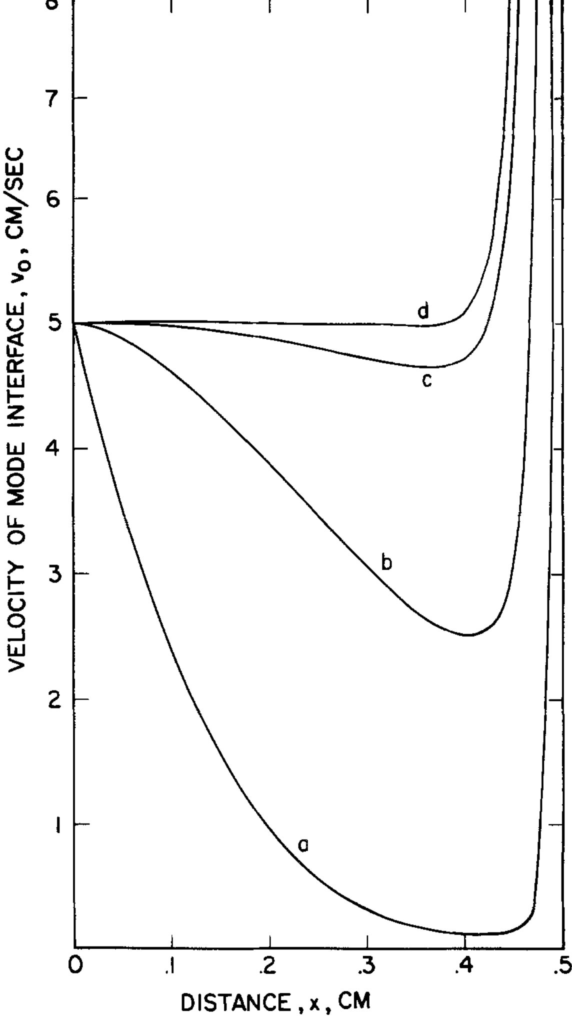

Fig. 3. Rate of penetration of the mode interface, $x = x_c$, into the electrode structure as function of reaction impedance. Curve a, $Z_1 = 10^{-2}$, $Z_2 = 5 \times 10^{-2}$; curve b, $Z_1 = 10^{-2}$, $Z_2 = 5 \times 10^{-1}$; curve c, $Z_1 = 10^{-2}$, $Z_2 = 5$; curve d, $Z_1 = 10^{-2}$, $Z_2 = \infty$; $R_1 = R_2 = 5$.

impedance of the new reaction path. Hence, the larger the value of Z_2, the faster the rate of penetration. As Z_2 becomes infinite, as in the case treated by Winsel (9), Eq. [23] becomes the following

$$v_c = \frac{i_0}{Q_c} \coth^2 [\kappa_1 (l - x_c)] \quad [24]$$

Equation [24] no longer exhibits a minimum in the rate of penetration, as indicated in Fig. 3, *e.g.*, curve d.

Charge transfer.—Direct determination of the transfer current density profile in the course of battery electrode operation has not been demonstrated experimentally thus far, although earlier work by Euler (14) has dealt with simulated behavior. Verification of any proposed or assumed mechanism is usually sought via chemical analysis of the electrode interior. Such an approach essentially involves a comparison of the time integral $\int_0^t j(x,t')dt'$, calculated for an assumed model with the results of chemical analysis. In what follows, we will derive analytical expressions for the charge transferred, *i.e.*, for the extent of reaction, valid for the considered mechanism of two reaction paths operating within the electrode structure at various degrees of electrode discharge.

Consider again Fig. 2(b) and select positions within the porous structure as indicated, *e.g.*, $x = a_1$ and $x = a_2$. Transfer current densities at these locations are given by Eq. [2], [16], and [17] with the extent of reaction obtained from appropriate substitutions into

Eq. [8]. The integration indicated by Eq. [8] extends over distinct time intervals reflecting the occurrence of significant events within the electrode structure, that is, based on the position where the change in the rds takes place.

The first time interval, characteristic of the assumed model, is the time before the onset of the new reaction path. This time has been denoted by $t_c(0)$. The integration indicated by Eq. [8] is particularly simple because the reaction profile is time independent. Hence, by Eq. [9]

$$Q(a_1,t) = i_o\kappa_1 \frac{\cosh[\kappa_1(l-a_1)]}{\sinh(\kappa_1 l)} t \qquad [25]$$

which, at $t = t_c(0)$, by Eq. [10] becomes

$$Q[a_1,t_c(0)] = Q_c \frac{\cosh[\kappa_1(l-a_1)]}{\cosh(\kappa_1 l)} \qquad [26]$$

As the reaction is carried on beyond the critical time, $t_c(0)$, *i.e.*, after the new reaction path is well established, two regions are distinguished. The first region covers depths greater than the position where the change in the rds has taken place, *i.e.*, where $x_c(t) < a_1 \leq l$. The second region is concerned with the locations to the left of $x_c(t)$, *i.e.*, for depths less than determined by the location of the mode interface, that is to say, when $0 \leq a_2 < x_c(t)$.

The charge transferred at any point within region 1 is less than Q_c and is given by Eq. [19]. At $x = a_1$ together with Eq. [20], this yields

$$Q(a_1,t) = Q_c \frac{\cosh[\kappa_1(l-a_1)]}{\cosh[\kappa_1(l-x_c(t))]} \qquad [27]$$

It is seen that the charge transferred depends on the position $x_c(t)$ and only indirectly on the newly generated reaction path.

The calculation of charge transfer in region 2 is performed somewhat differently. The charge accumulated must exceed Q_c (by definition), thus the time integral, Eq. [8], may be split as follows

$$Q(a_2,t) = Q_c + \int_{t_c(a_2)}^{t} j(a_2,t')dt' \qquad [28]$$

Here, it is convenient to change the integration variable through the use of the expression $v_c(x) = dx_c/dt$, and obtain

$$Q(a_2,t) = Q_c + \int_{a_2}^{x_c(t)} \frac{j[a_2,t_c(x')]}{v_c(x')} dx' \qquad [29]$$

The $j(a_2,t_c(x'))$ and $v_c(x')$, needed in Eq. [29], are given by Eq. [16] and [21], respectively. Upon substitution we obtain

$$Q(a_2,t) = Q_c\left\{1 + \kappa_2 \int_{a_2}^{x_c(t)} \tanh[\kappa_1(l-x')] \left\{\frac{\zeta_1}{\zeta_2}\cosh[\kappa_2(x'-a_2)] + \tanh[\kappa_1(l-x')]\sinh[\kappa_2(x'-a_2)]\right\} dx'\right\} \qquad [30]$$

At times greater than $t_c(l)$, the electrode once again operates in a single mode of discharge or charge. The expression for the charge transferred is

$$Q(a_2,t) = Q[a_2,t_c(l)] + i_o\kappa_2 \frac{\cosh[\kappa_2(l-a_2)]}{\sinh[\kappa_2 l]} \cdot [t - t_c(l)] \qquad [31]$$

Figure 4 summarizes the behavior of the porous electrode operating with the change in the reaction path when the charge transferred exceeded a given value, Q_c. In particular, curve a is a plot of Eq. [26] at $t = t_c(0)$, *i.e.*, for $x_c = 0$. Curve b illustrates the Q-x relationship at times $t_c(0) < t < t_c(l)$, when the electrode experiences a change in the rds at $0 < x_c(t) < l$. The curve denoted by b′, represents the Q-x relationship for the same electrode mechanism, but at some later time. It is seen that the curves are displaced to the right, but are otherwise very similar. The relevant equations are: Eq. [27] for the lower part and Eq. [30] for the upper part. The rate at which the displacement penetrates the electrode structure is, of course, the velocity given by Eq. [21]. Finally, curve c illustrates the behavior at time $t \geq t_c(l)$, *i.e.*, when the electrode once again operates in a single mode.

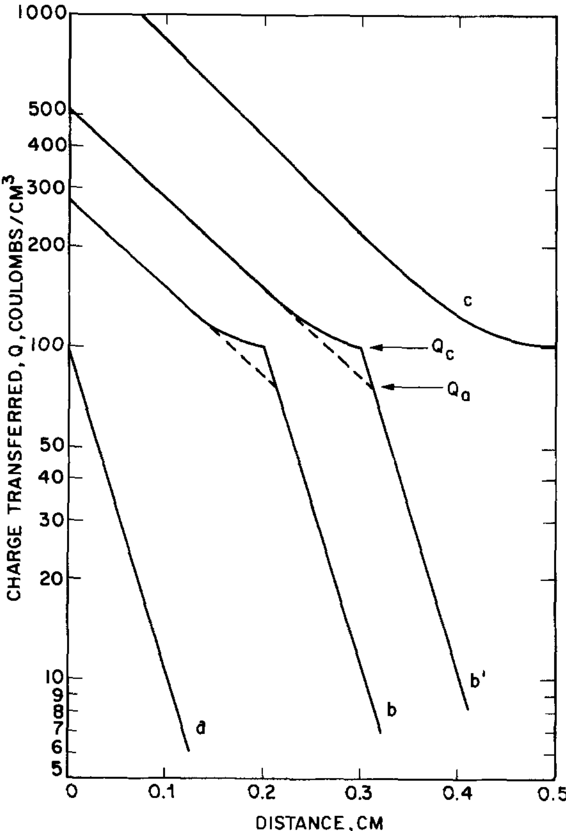

Fig. 4. Reaction product distribution at various time or electrode operation. Curve a, for $t = t_c(0)$; curve b and b′, for $t_c(0) < t < t_c(l)$; curve c, for $t = t_c(l)$. Arbitrarily selected parameters: $i_o = 0.25$ mAcm^{-2}, $Q_c = 100.0$; $R_1 = 5.0$, $R_2 = 5.0$; $Z_1 = 10^{-1}$, $Z_2 = 10^{-2}$.

Comparison with Experiment

Before we proceed with the interpretation of experimental results, it is necessary to review briefly the applied experimental procedures and relate them to the basic assumptions underlying the theoretical development.

The details of the experimental arrangement, including the construction and geometry of the porous electrode employed, were given elsewhere (5, 6). Here, we restrict remarks on experimental procedure to the fact that the porous electrode was constructed by confining loosely packed silver spheres in a glass cylinder and resting the spheres on a silver backing-plate. Such packing assured good electrical conductivity in the electrode matrix, satisfying the assumption of negligibly small ohmic resistance of the matrix in the formulation of the fundamental differential equations, Eq. [5] and [6]. Direct measurements showed that the specific resistance is about 1 ohm-cm at the beginning of the charging process, which is indeed negligible when compared with the ohmic resistance of the electrolyte occupying the voids of the porous structure.

For convenience, quantities useful in the interpretation of experimental results pertaining to the porous

Table I. Summary of relevant parameters of porous electrode

Sphere diameter	$(37.2 \pm 4) \times 10^{-4}$ cm
Weight of Ag per unit	0.49g

Equivalents of Cl^- ions per unit	2.90 coulombs
Electrolyte	1*N* KCl
Cross-section area	1.56 cm^2
Unit thickness	0.05 cm

electrode used in this investigation, are given in Table I.

The Q-x curves.—Data first obtained by Katan (5) were plotted in Fig. 5 as the logarithm of the charge transferred, log Q, *vs.* the position within the porous structure, x. The charging current, i_o, and the charging time, t, were used as parameters. The charge transferred, Q, was determined from the amount of silver chloride found within the experimental unit volume. Atomic absorption spectrometry was the analytical technique employed.

Qualitatively, the predicted behavior is evidenced by displacement of the Q-x curves with change in the charging current, a corollary of Eq. [21] which relates the velocity of penetration of the change in the rds to the charging current. Similar displacement was recorded when the electrode was charged at constant current for various periods of time. Disregarding the first 0.3 cm, further qualitative agreement is found in the invariance of slopes with the degree of conversion.

Quantitatively, the dotted lines shown in Fig. 5 are the constructed Q-x curves, Eq. [27] and [30], obtained by using R's and Z's determined from the experimental data shown by the solid line and under the assumption that $Q_c = 1$ coulomb/experimental unit. The bases for this selection of Q_c and details of the calculations are given in subsequent sections.

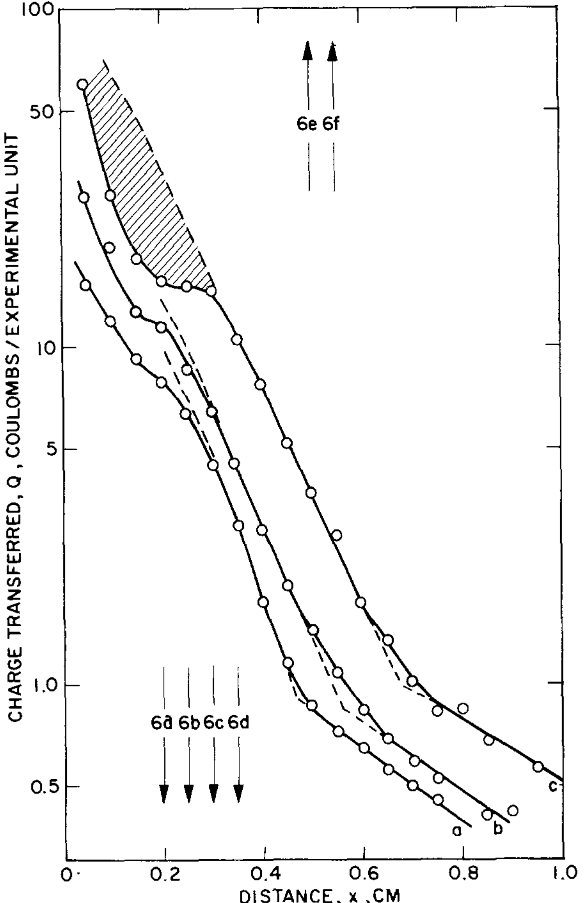

Fig. 5. A plot of experimental data of Q vs. x as a function of charging current i_o. Curves a, b, and c for i_o = 5, 8, and 25 mA cm^{-2}, respectively. Arrows indicate positions of segments examined by SEM (see Fig. 6).

Microscopic examination.—In order to determine causes for the aforementioned presence of an additional break in the Q-x curves, located at approximately $x = 0.3$ cm and independent of the applied charging current, i_o, microscopic examinations of the electrode's interior were undertaken. Representative photographs, showing elements of electrode surface at depths indicated (alongside curve b), Fig. 5, are assembled in Fig. 6(a)-6(f).

As one would expect, the electrode surface close to the bulk electrolyte is heavily converted to silver chloride. Nevertheless, the points of contact between the spheres are seen to be preserved, remaining uncoated, so that good electrical conductivity is maintained. The characteristic feature of the front portion of the electrode is the appearance of a sludge-like, enveloping deposit, resembling in fact, a dried clay. It is noteworthy that the sludge-like deposit is evident until we approach the critical distance, $x = 0.30$ cm, and then it abruptly disappears to be replaced by crystallites. The density of the crystallized conversion product decreases with the electrode depth.

This examination suggests that the porous structure in the proximity of the bulk electrolyte is engaged in processes which are different than those predominant at greater depths.

Origin of the first break in the Q-x curves, a qualitative analysis.—A qualitative analysis based on microscopic examinations (Fig. 6) and experimental Q-x curves (Fig. 5) is given in this section to indicate our interpretation for the origin of the first break. It is seen in Fig. 5, curve b, that the number of coulombs passed through the first experimental unit is approximately 28.0, a number which exceeds by a factor of 10 the initially available chloride ion content. A similar estimate for $x = 0.3$ cm shows that twice as much chloride was used in that segment as was initially present in the pores during the 4 hr of electrode charging at $i_o = 8.0$ mA cm^{-2}. Consequently, chloride must be supplied from the bulk electrolyte. An order of magnitude calculation shows that the necessary chloride could have been supplied by diffusional transport alone and that local chloride concentrations in the pores would be quite low. Significant changes would occur in electrolytic conductivity during the course of electrode charging and some pore blockage takes place (see Fig. 6). Increase in electrolytic resistivity would shift the reaction toward the electrode-bulk electrolyte interface, promoting localized surface coverage. Increase in surface coverage by a nonconductive film, however, would tend to force the transfer current deeper into the electrode structure, thus shifting the region of low chloride content to greater depths. Further shifts are essentially determined by respective interactions of transport and reaction impedances.

This situation is shown in Fig. 7. For $x < a$, the reactive surface within the experimental volume is approaching a condition of full coverage and surface blockage with silver chloride. This forces the transfer current deeper into the electrode structure. Eventually the highest rate of conversion and, consequently, the lowest concentration of available chloride occurs at $x = b$. Although chloride transport will originate at both sides of $x = b$, chloride influx will be principally from the bulk electrolyte. Diffusing potassium chloride then comes into contact with deposited silver chloride to form a complex, $AgCl_n^{-(n-1)}$. The complex ions will diffuse along the path indicated in Fig. 7. The complex ions diffusing toward the bulk electrolyte are irretrievably lost and are most likely deposited on the counterelectrode. Those ions that diffuse inward will encounter a region deficient in chloride, thus favoring nucleation and crystal growth of AgCl from the liquid phase. This disappearance of the diffusing complex ions sharpens the diffusion front of diffusing $AgCl_n^{-(n-1)}$,

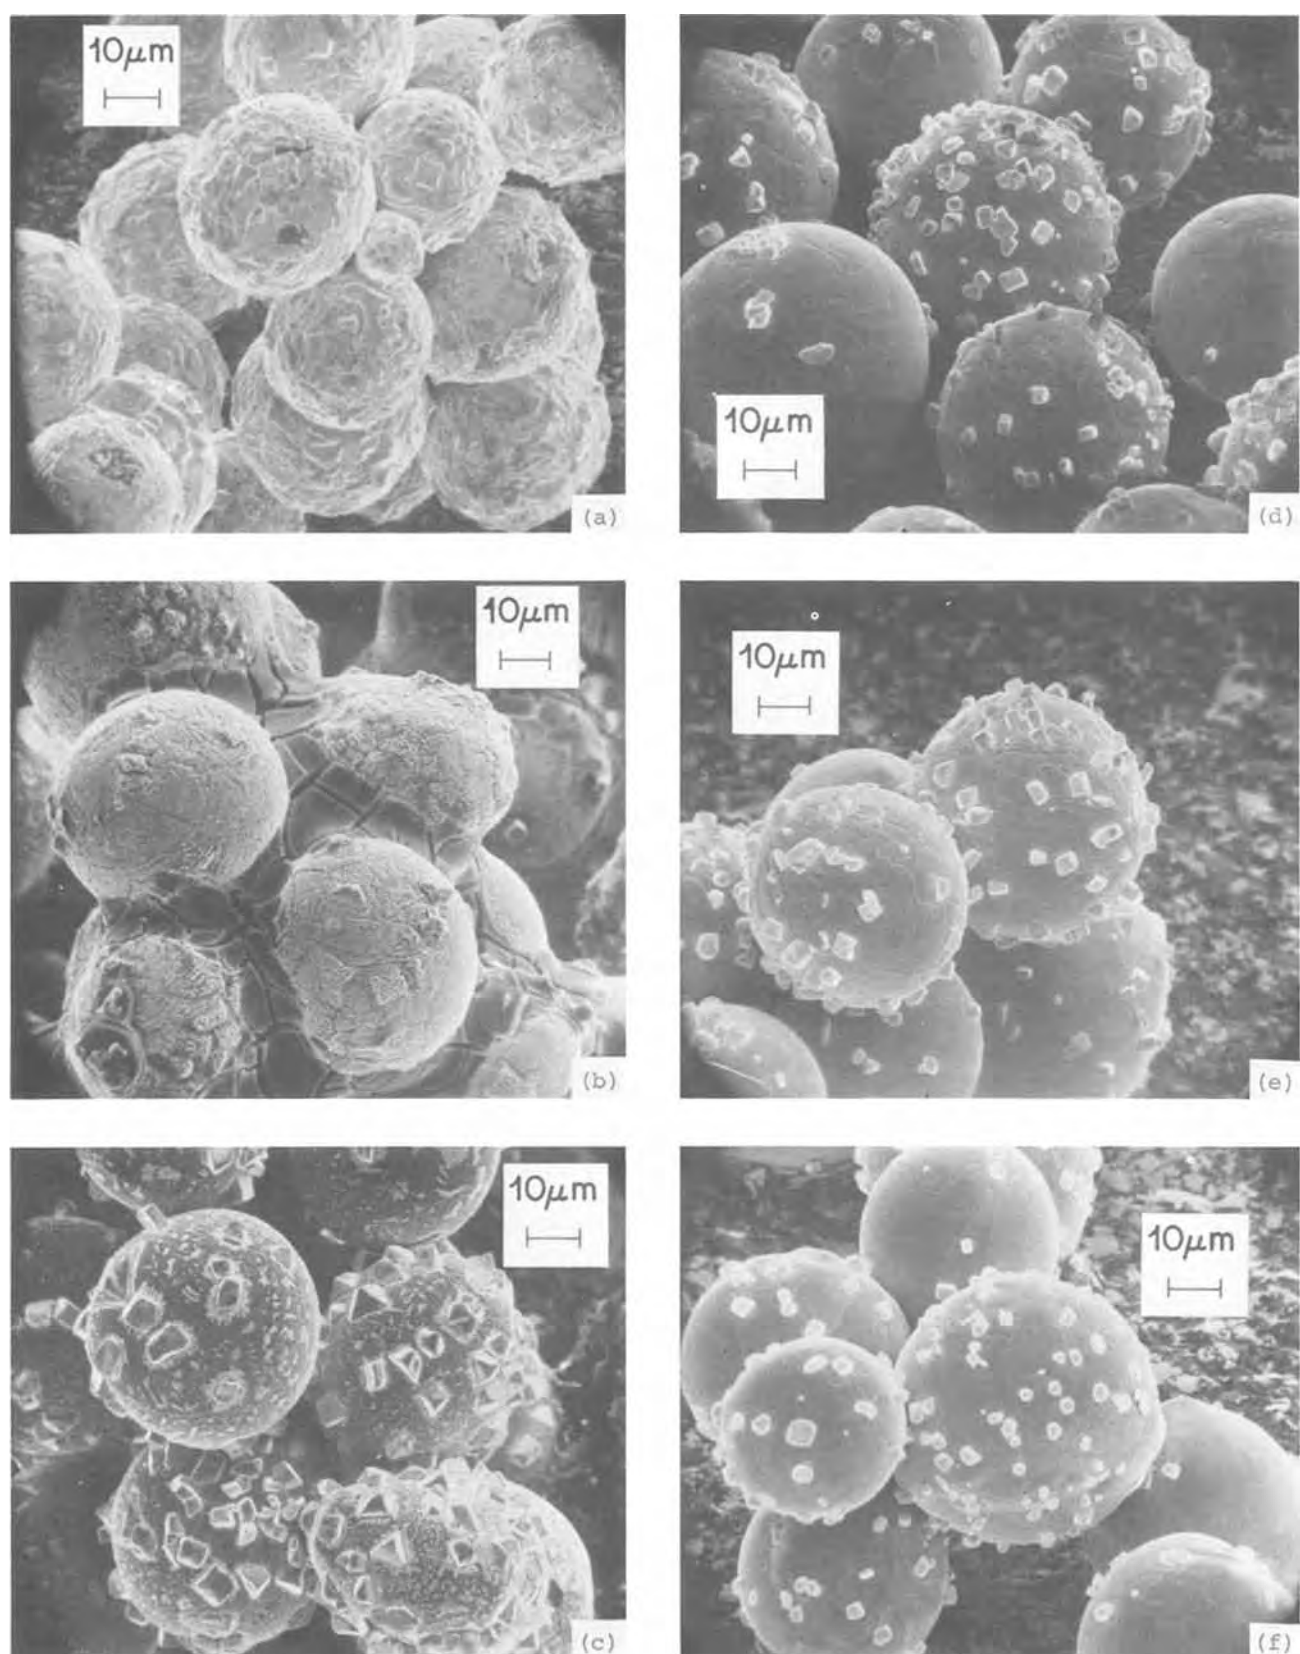

Fig. 6. Surface morphology at various depths indicated in Fig. 5

i.e., increases the concentration gradient, so that there is a rapid termination in diffusing $AgCl_n^{-(n-1)}$ species, and can account for the observed abrupt change in surface morphology at $x = 0.3$ cm [Fig. 6(c)]. Precipitation of AgCl from complex ions releases chloride ions, which further modifies diffusional transport.

Results tabulated in Table II are in qualitative agreement with the processes shown in Fig. 7. The last column of Table II lists the differences in the number of coulombs supplied by the external circuit and that calculated on the basis of chemical analysis. This difference depends on the charging time for a constant charging current and on charging current for a constant charging time in a manner consistent with the loss of silver ions by the mechanism illustrated in Fig. 7. It is known that the electrochemical conversion of silver to silver chloride is 100% efficient, and the differences therefore are attributed to subsequent dis-

Table II. Faradaic losses upon charging*

solution and transport out of the porous structure. For current densities less than 10 mA cm^{-2} and times less than 20 min, faradaic efficiencies of 100% were always maintained in the 1N KCl. In fact, from Table II it is seen that the longer the charging time, the greater the loss. It is noteworthy that the number of coulombs calculated from the extension of the slope shown in Fig. 5, from the shaded area, corresponds to within 10% to the differences tabulated in Table II. This may be considered as evidence for the correctness of the general assumptions.

Quantitative aspects of electrode charging.—This section is devoted to the quantitative analysis of the experimental curves (solid lines) and calculated values (dotted lines) shown in Fig. 5. For this analysis we require, as was shown in previous sections, the specification of transport and reaction impedances, R_1, R_2, Z_1, and Z_2, and the value of charge transferred, Q_c, associated with the change in reaction path. Of these quantities only one, R_1, can be estimated because the initial concentration of electrolyte is known. In the present work, $R_1 = 14.0$ ohm-cm is used. The other impedances are determined from a selection of four points taken from the Q-x curve and from the estimated value of Q_c.

The estimate of the critical charge, Q_c, is not a straightforward procedure. In a semilogarithmic plot of Q *vs.* x, the transferred charge at a sufficient distance above and below x_c is in good approximation represented by straight lines. One might attempt to obtain Q_c as the intersection of the extensions of these straight lines, but this is justified under special conditions only. In region 2, *i.e.*, for $0 \leqq x < x_c(t)$, the transferred charge $Q(x, t)$ is given by Eq. [30]; in region 1, *i.e.*, for $x_c(t) < x \leqq l$, the transferred charge obeys Eq. [27]. For convenience and without committing a serious error, we assume $l \to \infty$ which reduces Eq. [30] to

$$Q_2(x, t) = Q_c + \kappa_2 Q_c \int_x^{x_c(t)} \left\{ \frac{\zeta_1}{\zeta_2} \cosh[\kappa_2(x' - x)] + \sinh[\kappa_2(x' - x)] \right\} dx' \quad [32]$$

and Eq. [27] to

$$Q_1(x, t) = Q_c e^{\kappa_1[x_c(t) - x]} \quad [33]$$

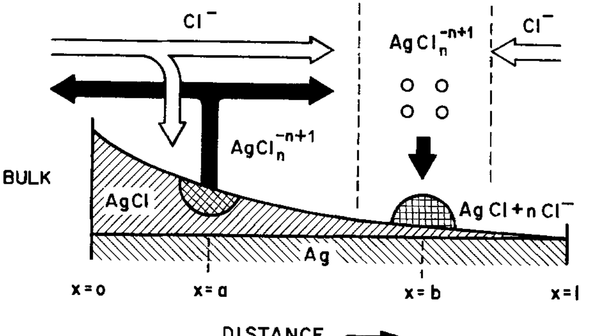

Fig. 7. Schematic representation of nonelectrochemical processes within the porous structure.

Upon integration, Eq. [32] yields

$$Q_2(x, t) = Q_c + Q_c \left\{ \frac{\zeta_1}{\zeta_2} \sinh[\kappa_2(x' - x)] + \cosh[\kappa_2(x' - x)] \right\} \Bigg|_x^{x_c(t)} \quad [34]$$

For $\kappa_2[x_c(t) - x] >> 1$, Eq. [34] takes the form

$$Q_2(x, t) = \frac{1}{2} Q_c \left(\frac{\zeta_1}{\zeta_2} + 1 \right) e^{\kappa_2[x_c(t) - x]} \quad [35]$$

The asymptotic expressions [33] and [35] intersect at a point x_a with a corresponding charge $Q_1(x_a, t) = Q_2(x_a, t) = Q_a$. We shall designate Q_a as the asymptotic charge. By equating Eq. [33] and [35], we obtain

$$x_c(t) - x_a = \frac{1}{\kappa_1 - \kappa_2} \ln \left[\frac{1}{2} \left(\frac{\zeta_1}{\zeta_2} + 1 \right) \right] \quad [36]$$

Upon substitution of Eq. [36] into Eq. [33], an expression for the relationship between the asymptotic charge Q_a and the critical charge, Q_c, is obtained, namely

$$Q_a = Q_c \left[\frac{1}{2} \left(\frac{\zeta_1}{\zeta_2} + 1 \right) \right]^{\frac{\kappa_1}{\kappa_1 - \kappa_2}} \quad [37]$$

Hence, for finite κ_1 and κ_2, the asymptotic charge Q_a will agree with Q_c only if $R_1 Z_1 = R_2 Z_2$.

Evidently, the information contained in the asymptotics of the Q-x curves is insufficient for an unambiguous determination of the critical charge. For this reason, a trial and error procedure was devised, consisting of a selection of "nearly" correct value for Q_c, taken in the vicinity of Q_a (see Fig. 5).

In this investigation the fo lowing procedure was adapted: Select an arbitrary value for Q_c in the vicinity of Q_a (charge transfer density from the intercept) and compute the associated electrode parameters, R_2, Z_1 and Z_2; the R_1 is known from the concentration of the dissolved salt. The calculated values are assembled in Table III.

On purely physical grounds we reject those Q_c's which yield R_2 less than R_1 since otherwise we would accept an increase in salt concentration (here potassium chloride) while none can be produced as a result of electrochemical reaction. Also, we reject those Q_c's that yield values higher than 50 ohm-cm. This is equivalent to the statement that the concentration of potassium chloride in region 2 cannot be less than 0.3N. This appears to be a reasonable value in view of the diffusional processes summarized in Fig. 7. On this basis alone, a value $0.88 < Q_c < 1.0$ coulomb/exp unit was selected. Further decision is made by inspecting the last column of Table III where the Z_2 values are tabulated. Since the reaction impedance is assumed to be independent of the charging current, we seek such Q_c that the Z_2 values for both charging currents agree. $Q_c = 0.94$ coulomb/exp unit was selected.

The experimental evaluation of constants: R_1, R_2, Z_1, Z_2, and Q_c are sufficient to describe the electrode be-

i_o	Q_c	x_c	κ_1	κ_2	ζ_1/ζ_2	R_1	Z_1	R_2	Z_2
5.0 × 10^{-3}	0.75	0.54	3.11	10.72	0.071	13.99	1.44	676	5.98
	0.80	0.518	3.10	10.76	0.24	13.99	1.45	199	1.72
	0.88	0.48	3.10	10.65	0.61	13.99	1.45	78	0.69
	0.92	0.46	3.10	10.41	0.88	13.99	1.45	53.3	0.49
	0.98	0.45	3.10	9.50	1.51	13.99	1.45	28.2	0.31
8.0 × 10^{-3}	0.80	0.59	3.31	8.48	0.532	13.99	1.27	67.3	0.93
	0.84	0.57	3.31	8.45	0.66	13.99	1.27	53.4	0.75
	0.88	0.56	3.31	8.42	0.80	13.99	1.27	44.13	0.62
	0.94	0.54	3.31	8.33	1.06	13.99	1.27	33.14	0.47
	1.00	0.52	3.31	8.17	1.35	13.99	1.27	25.58	0.38
	1.20	0.46	3.31	5.72	4.05	13.99	1.27	5.95	0.181

havior. An additional check on correctness of the reported constants can be obtained by comparing the experimentally located $x_c(t)$ with that calculated for a given current density of the charging process.

Upon integration of Eq. [21], we obtain the information sought, *i.e.*, the time necessary for the change in the reaction mechanism to occur at the position $x_c(t)$, namely

$$t_c(x) = t_c(0) + \frac{Q_c}{i_o}\int_o^x \tanh[\kappa_1(l-x')]\left\{\frac{\zeta_1}{\zeta_2}\sinh[\kappa_2 x'] + \cosh[\kappa_2 x']\tanh[\kappa_1(l-x')]\right\}dx' \quad [38]$$

Note that the Q_c needed in Eq. [38] must be given in coulombs/cm^3 whereas the values tabulated in Table III used for the determination of electrode process parameters were given per volume of experimental unit, *i.e.*, 0.078 cm^3. When the value $Q_c = 0.94/0.078 = 12.05$ coulombs/cm^3, was employed and the integral in Eq. [38] evaluated, $t_c(0.54) = 15{,}700$ sec was obtained. This value compares rather well with the experimental charging time of 14,400 sec. The agreement between the experimental value and the calculated value is within 10%.

Reconstructed j(x) curves.—The theoretical transfer current density profile for $R_1 = 14.0$ ohm-cm, $R_2 = 33.14$ ohm-cm, $Z_1 = 1.27$ ohm-cm^3, $Z_2 = 0.47$ ohm-cm^3, and $i_o = 8 \times 10^{-3}$ as a function of position $x_c(t)$ is plotted in Fig. 8. These parameters are based on the data of Fig. 5.

It is seen that for the first 8.0 min [$t_c(0) = 452$ sec] the electrode operated with a single reaction path. The current density was exponential within $0 < x < 0.6$ cm and starts to flatten out for $x > 0.6$ cm. As the new reaction path was established and the electrode operated with a change in the reaction mechanism, most of the current was shifted toward the bulk electrolyte side of the porous structure. Upon initiation of the change in the rds, the contribution in region 1 became insignificant, being less as region 2 was expanding. The velocity of penetration also became less. These two observations are consistent with the surface morphology shown in Fig. 6.

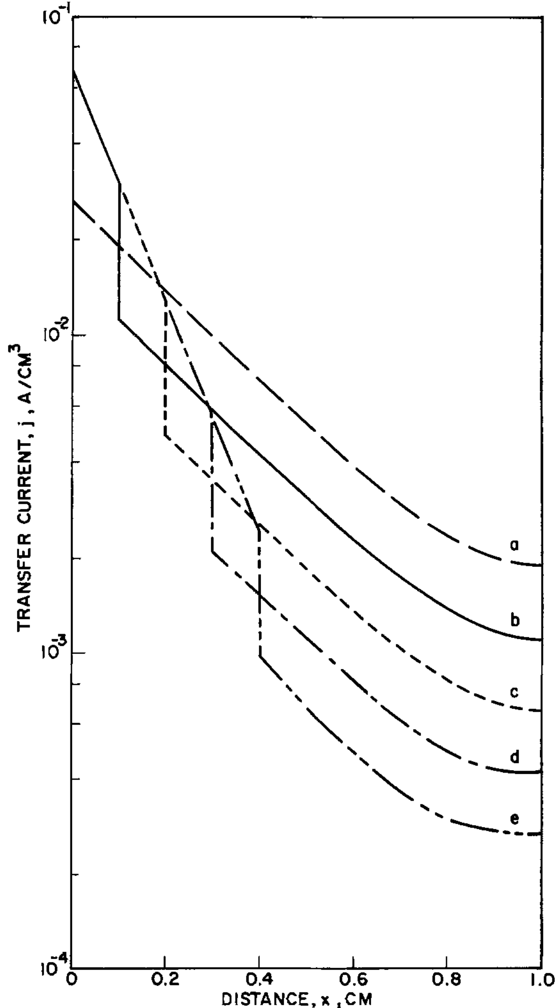

Fig. 8. Reconstructed $j(x)$ curves for the charging of silver/silver chloride system. $R_1 = 13$ ohm-cm, $R_2 = 33.1$ ohm-cm, $Z_1 = 1.27$ ohm-cm^3, $Z_2 = 0.47$ ohm-cm^3, $i_o = 8.0$ mA/cm^2

One would expect on the basis of reconstructed curves very little difference in surface coverage at depths greater than 0.45 cm. Inspection of Fig. 6(d)-6(f) confirms this and indicates that the observed surface coverage in this region was completed within the first 8 min, *i.e.*, before the new reaction path became operative. Within this time the difference between the current densities is relatively small, $j(0.45) = 6 \times 10^{-2}$ Acm^{-2}, $j(0.9) = 2 \times 10^{-2}$ Acm^{-2}. It is also seen that irrespective of the location of x_c, most of the current is concentrated near the bulk electrolyte. The small changes in Z_2 are not associated with the surface coverage, but rather they are due to the difference in concentration of Cl^- ions.

The reconstructed $j(x)$ curves shown in Fig. 8 do not prove but are consistent with the surface morphology exhibited in Fig. 6. It is seen that at depths $x > 0.45$ cm the extent of surface coverage is almost uniform and is developed in the first 8 min, *i.e.*, before the new reaction path was established. When the new mechanism became operative, the reaction profile was shifted toward the bulk electrolyte, which for the galvanostatic case, reduced the transfer current density from $j(0.9) = 2 \times 10^{-3}$ to 0.7 mA/cm^3 when the rds reaction front advanced to $x_c = 0.4$ cm. Before the change in the rds, the transfer current density was more uniformly distributed throughout the porous structure. For example, when $x_c = 0$, $j(0.4) = 60$ mAcm^{-3} and $j(0.9) = 20$ mA/cm^3.

Summary

An analytical method has been formulated to describe the transfer current density in a porous electrode as function of position and time. The mathematical model assumes the electrode mechanism to depend on the amount of the locally transferred charge and accounts for a change in the rate determining step. Application to the silver-silver chloride system and comparison with experiment shows that the depletion of chloride ions initially present in the porous structure is primarily responsible for the location and depth of the principal reaction zone. The performance characteristics of the electrode is further affected by the dissolution of silver chloride and subsequent transport of complex ions. These conclusions were corroborated by examination of the surface morphology.

LIST OF SYMBOLS

a	a constant, defined in text
i	current density (also current in external circuit) in electrolyte, Acm^{-2}
j	$-\partial i/\partial x$, transfer current (faradaic) density, Acm^{-3}
k	running index ($k = 1, 2, \ldots$)
l	electrode thickness, cm

M amount of electroactive material, gcm^{-3}
$M^{(\pm)}$ a function of x_c, defined by Eq. [14]
N a function of x_c, defined by Eq. [15]
Q charge transferred, Asec/cm^3
R ohmic resistance, ohm-cm
t time, sec
u potential, V
v velocity of penetration of rds change, cm/sec
Z reaction impedance, ohm-cm^3
x distance, cm

Greek Symbols

α a proportionality constant, g/Asec
ϵ a small number
κ_k $(R/Z_k)^{1/2}$, dimensionless parameter
ζ_k $(R_kZ_k)^{1/2}$, resistance, ohm-cm^2

Subscripts

c, a, o defined in text

ABSTRACT

An electrode for monitoring the time-dependent distribution of transfer current density in porous electrodes is developed. When applied to the Ag/AgCl system, predicted behavior is obtained, showing interaction of resistances manifested within the pores and on the pore walls. Good correlation is found of the developed experimental electrode to a porous structure similar to those of practical interest.

The aim of porous electrode modeling has been to provide design criteria for electrochemical devices which can operate according to prescribed modes. For realistic representation, this modeling must be based on analyses of actual elementary processes occurring within confines of the porous structure. Principal elements of the analyses are then local and bulk transport, and charge transfer kinetics. Variation in driving force naturally occurs as a function of distance and morphological change for any given mode of operation.

Theoretical aspects of electrode modeling have advanced to a high degree of sophistication. From the simple picture presented by Daniel'-Bek (1) in 1948, that of fixed geometry and invariant reaction kinetics, complex models have evolved. Models now contain such considerations as the effect of surface morphology and the change in pore geometry upon passage of charge as well as the change in transport behavior. Detailed reviews of progress, both historical and conceptual, can be found in numerous publications (2-4). Little progress can be claimed, however, for experimental verification of these models, at least as they apply to battery technology.

* Electrochemical Society Active Member.

Key words: silver chloride, charge distribution, current distribution, segmented electrode.

It is the purpose of this communication to describe an experimental technique, based on a concept of the segmented electrode, for the study of time-dependent behavior of battery electrodes. In particular, it is shown that a simple geometrical arrangement, such as a slotted pore, can represent the behavior of a geometrically more complex porous structure.

Elements of Experimental Modeling

Before presenting details of the segmented electrode, some of the relevant techniques used in the experimental study of battery electrodes are summarized.

Distribution functions.—One of the most important distribution functions relevant to battery electrode modeling is the time-dependent, spatial distribution of transfer current density $j(x,t)$. Unfortunately, under normal conditions, this distribution is not accessible to direct measurement without some modification of the electrode structure. This modification may involve prior electrode slicing into segments and reassembly with interspaced separators (5, 6). The introduction of separators, however, can seriously distort the distribution, especially in cases where transport processes are participating.

The second, equally important distribution function, is the time-dependent overpotential-distance relationship, $\eta(x,t)$. Again, this is not accessible to direct measurement. Insertion of Luggin capillaries into the porous structure (7) not only changes local geometry but it interferes with local flow of current.

Because of these considerations, experimental reconstructions of reaction profiles have typically involved determinations of the amount of charge transferred across the metal-electrolyte interface at selected times and locations. In practice, this requires slicing of the electrode after a given charge or discharge and analyses for the reactant or product in each slice (6, 7). Recently, x-ray element scanning was introduced to provide point-by-point analysis of the extent of reaction in a single pore arrangement (8). Useful but less detailed information was also obtained by slow cycling of the electrode combined with cell power output measurements (9); the thickness of the reaction layer and its position within the electrode structure as a function of electrode discharge was determined.

Experimental reconstruction of reaction profile.—The reconstruction of reaction profile, based on analyses of amounts of charge transferred as a function of position and time, requires a considerable effort: The function $j(x,t)$ is reconstructed from the relationship

$$i(t)t' = \int_0^l \int_0^{t'} j(x,t)\,dx dt \qquad [1]$$

where $i(t)$ is the impressed current in the external circuit, t' is the duration of the experiment, and l is the electrode thickness. For the frequently used galvanostatic mode of discharge the current in the external circuit is kept constant, $i(t) = i_o$.

Upon completion of the experiment, at $t = t'$, the electrode is divided into a number of segments, usually 0.05 cm in thickness (10, 11) and they are analyzed for the amount of charge transferred. In terms of Eq. [1], it is assumed that $j(x,t)$ is a continuous function within the rectangle bounded by the lines $x = 0$, $x = l$, $t = 0$, and $t = t'$, so that the order of integration is immaterial. By sectioning the electrode into k equal parts, so that $l = k\lambda$, Eq. [1] can be written as follows

$$i_o t' = \int_0^{t'} \left\{ \int_0^{\lambda} j(x,t)\,dx + \int_{\lambda}^{2\lambda} j(x,t)dx + \dots \int_{(k-1)\lambda}^{k\lambda} j(x,t)\,dx \right\} dt \qquad [2]$$

Application of the mean value theorem to the integrals in the brackets yields Eq. [3]

$$i_o t' = \int_0^{t'} \left\{ \lambda \sum_0^k j(\bar{x}_k, t) \right\} dt \qquad [3]$$

The time evolution of reaction profile requires a similar expansion of the time integral in Eq. [3], thus

$$i_o t' = \lambda\tau \sum_0^k \sum_0^m j(\bar{x}_k, \bar{t}_m) \qquad [4]$$

where $t' = m\tau$, and $\bar{x}_k$ and $\bar{t}_m$ denote points at which j is evaluated.

Equations [3] and [4] form the basis for the experimental determination of the time evolution of reaction profile utilizing chemical analyses of the electrode interior. The frequently cited Bro and Kang (12) data, for example, were obtained for time intervals of hours rather than minutes, and consequently some of the details of the time evolution of the reaction profile could be lost.

Experimental models of porous electrodes.—A necessary condition for substitute arrangements of electrodes used to simulate behavior of practical porous electrodes is that they must reflect essential features of the real structure.

An approach that gained popularity in recent years has evolved from the concept of the "inverted pore" used to simulate behavior of the gas-diffusion electrode (13). The geometrical analog of this concept for flooded electrodes would be a thin film of electrolyte immobilized between a metal electrode and an inert surface. In practice, a drop of electrolyte can be placed on a smooth metal surface and a flat glass plate may be placed over this drop at a distance of several tens of microns, forcing excess electrolyte away (8, 14). The physical dimensions of concern to electrode modeling, such as electrode film thickness and electrode length, are experimentally controlled variables.

Such an arrangement can be useful in providing information necessary for electrode modeling. Whether or not it directly simulates the behavior of practical porous electrodes should be assessed by comparisons with geometrically realistic structures, such as a packing of metallic spheres of uniform diameter (11). Further, direct measurements of $j(x,t)$ are possible, if the electrode is sectioned and measurements made in a manner free from objections attributed to placement of separators, *i.e.*, if the electrode-separator geometry is clearly defined.

Experimental

The concept of a segmented electrode as an experimental tool for the study of $j(x,t)$ dependence is not new (5, 15). The rather infrequent use of this technique is attributed to difficulties in assembly and questionable validity in interpretation of results. Some of the difficulties can be eliminated by taking advantage of technology developed for the microelectronics industry. Reference is made to techniques of photographic transfer of a pattern and vapor phase deposition of metal films, which greatly enhance reproducibility and accuracy of fabricated microstructures (16, 17). Very small, detailed analogs of electrode structure can be repeatedly prepared on a variety of substrates by using these techniques.

Cell design and principles of measurements.—The prerequisite for direct measurements of space-time distributions of transfer current, $j(x,t)$, is to isolate thin segments of the electrode structure and to provide each segment with a separate current take-off lead. This should be done so that the sectioning will not appreciably change the structure and elementary processes that comprise the over-all reaction path. Also, provisions must be made to assure the monitoring of current in each segment without altering the original $j(x,t)$ distribution. The arrangement shown in Fig. 1 was adopted.

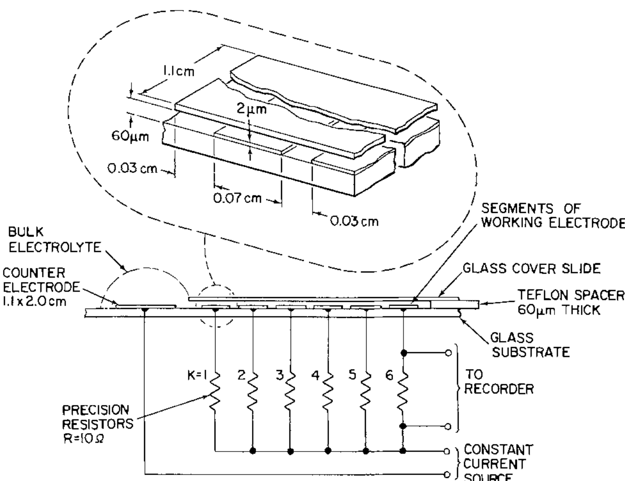

Fig. 1. Schematic representation of the segmented electrode concept. Upper part shows a small section of the segmented electrode showing dimensions.

The silver working electrode consisted of six segments which were vapor deposited onto a glass microscope slide and which had connecting electrical leads insulated by Teflon tape as shown in Fig. 1 and 2. The counterelectrode was similarly formed. As illustrated, the pore structure was simulated by placing and aligning a microscope cover slide onto a drop of electrolyte so that the slide rested on the Teflon tape and was parallel with the segments and slide. The cover slide extended beyond the first segment by approximately 0.03 cm, the distance of separation between the individual segments. Bulk electrolyte protruded around the counterelectrode as shown. The counterelectrode was made large, 1.1 $\times$ 2 cm, compared with the working electrode, 0.07 $\times$ 1.1 cm per segment, and was separated by a distance of 1.0 cm from the counterelectrode.

To measure the $j(x,t)$ distribution, the current in each segment, $j_k(t)$, was obtained by measuring the potential drops across $R_k = 10$ ohm resistors in series with the segments. The resistors deviated by less than 0.005 ohm from their rated values. The measured currents never exceeded 0.6 $\times$ 10^{-3}A, so that the effect on current density by the presence of resistors was quite small, at worst less than 6 mV in reaction overpotential.

Electrode fabrication and assembly.—Silver, deposited from vapor on a glass substrate, constituted the main element of the experimental arrangement. Fabrication of the silver pattern was accomplished in two steps: First, a thin platinum film was deposited onto the masked glass microscope slide, and then, silver was deposited with the mask in place in multiple layers to assure thicknesses sufficient to withstand charge and discharge modes. Vapor deposition was carried out at pressures of *ca.* 5 $\times$ 10^{-5} Torr on slides which were preheated by maintaining filament temperature just below the melting point of the deposited metal for *ca.* 15 min. The mask was prepared from magnetic stainless steel foil and fastened magnetically to the slide.

Prior to the vapor deposition, the Corning No. 2947 microscope slides were roughened with No. 4/0 emery polishing paper and then thoroughly washed in acetone, water, boiling potassium permanganate solution, hydrochloric acid solution, and deionized water, respectively. They were then ultrasonically cleaned in conductivity water, oven dried, and stored in a desiccator.

After vapor deposition, the areas of the working electrode, counterelectrode, and pore thickness were defined by affixing a U-shaped piece of Teflon tape, 60 μm thick, as shown in Fig. 2. The slide could then be placed in a holder for electrical connections, and the electrolyte and cover glass could be attached as required.

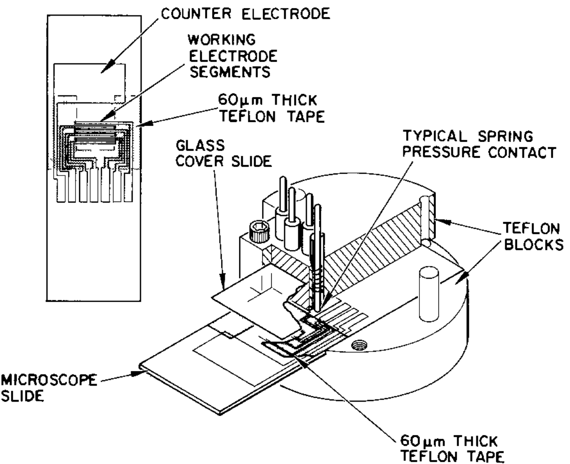

Fig. 2. Experimental cell assembly. Lower right: details of holder construction, electrical connections, and positioning of segmented electrode. Upper left: construction of segmented electrode showing vapor deposited silver on a glass substrate. The shaded area is a U-shaped Teflon tape, 60 μm thick.

The electrode holder was constructed of Teflon and consisted of two parts: The lower part was provided with a groove and a locating pin to position the microslide. In addition, there were two more pins to guide the location of the upper part which contained seven pressure loaded contacts to connect the individual segments and counterelectrode to the galvanostat and to the instrumentation for recording currents $j_k(t)$.

Electrode preparation for the j(x,t) measurements.—Two sets of measurements of transfer current distributions are discussed: those associated with electrode discharge and those associated with electrode charging. Each set requires different preconditioning of the electrode surface.

Preconditioning for the discharge curves was as follows: Each segment of the electrode assembly was individually charged in 1*N* KCl solution and received 0.25 A-sec/cm^2, which corresponds to about 22% surface coverage by a film of AgCl (18). Unless otherwise noted, each segment was charged for 4 min at 80 $\times$ 10^{-6}A in 1*N* KCl solution. The resulting error in Q_k ($k = 1, 2, \ldots, 6$) was determined by discharging each segment galvanostatically while observing the polarization, and it never exceeded 1.5%. Q_k increased in accordance with charging sequence, indicating charge loss by dissolution. To attain better uniformity, the charging sequence was specified, namely, segments 1, 3, 5, 6, 4, and 2, respectively.

After preconditioning, the cover glass was placed as shown in Fig. 1 to construct the single pore assembly. The pore discharge was carried out at preselected currents, in the range of 80-600 μA.

A somewhat different procedure was followed in order to prepare the single pore electrode for studying the charging process. It was found that conversion of freshly deposited silver to silver chloride by an anodic current at 80 $\times$ 10^{-6}A for 2 min, followed by a cathodic current also at 80 $\times$ 10^{-6}A, for 3 min, yielded reproducible results. Following the surface conditioning, the segmented electrode was thoroughly washed in triply distilled water and with electrolyte used in the experimental run.

Failure modes.—The most common cause of failure was severance of the deposited silver film due to "overcharging," *i.e.*, after complete conversion to silver chloride occurred at some location. This type of failure was eliminated by using thicker films of platinum to assure electrical conduction or, alternatively, by limiting the level of charging.

A second type of failure was associated with the current take-off arrangement. Electrolyte would occasionally seep to the location where the pressure loaded contacts pressed against the deposited silver leads, and the dissimilar metal contact would then modify the measured currents. This was prevented by placing a thin film of Apiezon grease only at the pressure loaded contacts to act as a barrier.

Results and Discussion

Experimental results and their interpretation are presented here separately for the discharge process, AgCl → Ag, and for the charging process, Ag → AgCl. In both processes, the effects of varying impressed current, i_o, and concentration of KCl are given. Finally, comparisons are made of the time evolution of reaction profile for a simulated segmented pore with that of a porous electrode comprised of packed spheres, all of the same diameter.

The Discharge Process: AgCl → Ag

A summary of the time evolution of reaction profiles is given in Fig. 3, 4, and 5, for 0.1, 1, and 2*N* KCl solutions, respectively, and for a range of discharge currents, 80-300 μA.

Effect of discharge current, i_o.—For the applied discharge currents, i_o, j_k *vs.* t curves were observed to be

quite similar. In fact, when reduced currents, j^*, where $j^* = j_k/i_o$, and reduced time, t^*, where $t^* = t/t_o$, were employed, all data could be presented by a single plot, as shown in Fig. 3-5. Here, t_o refers to the time necessary for complete discharge of the initial charge, Q_o, by the discharge current, i_o.

Such behavior implies that the over-all discharge path is independent of discharge current, at least

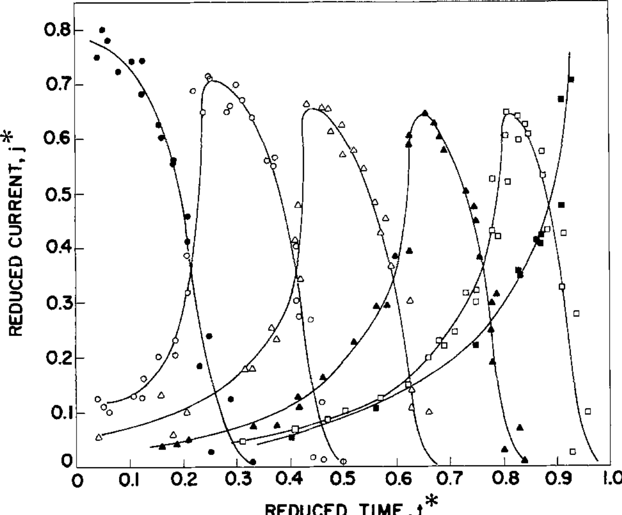

Fig. 3. Time evolution of discharge profiles in 0.1N KCl. Range of discharge currents: 80 to 300 μA.

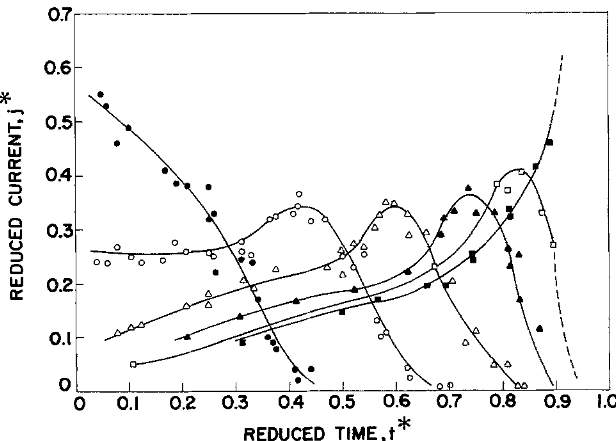

Fig. 5. Time evolution of discharge profiles in 2N KCl. Range of discharge currents: 80 to 300 μA.

within the range of 80-300 μA which is equivalent to superficial current densities of 12.1-45.4 mA/cm^2.[1]

With the exception of the first and last segment, partial transfer currents, $j_k(t)$, always increased with time, reached a maximum, and then decreased monotonically to zero, Fig. 3-5. Evidently, the nature of local change in discharge for each segment is similar, and this behavior does not clearly indicate that a change in the mechanism of electrochemical reaction has occurred, as could be concluded from j/t relationships established for various degrees of surface coverage (18). It can be assumed that measurements with the present design of the segmented electrode are insensitive to the relatively small changes in current-potential dependence which have been found to occur with varying state of charge. Better resolution may be anticipated for finer division by the segments.

Effect of concentration, c_o.—Examination of Fig. 3-5 reveals also the effects of electrolyte concentration. It is seen that, as the concentration of KCl is increased, the transfer current is distributed more uniformly while the similarity of the currents is retained in each segment. For the more concentrated solutions, the decrease in ohmic resistance of electrolyte within the pore enables a more uniform participation of each segment in the over-all discharge current.

For the more dilute solution, *e.g.*, 0.1N KCl, as the reaction proceeds deeper into the electrode structure, the maximum transfer current remains essentially the same with increase in segment number, k. However, in 1 and 2N electrolytes, we notice that the maximum transfer current decreases and then increases again, as the electrode discharge is nearing its completion. It is noteworthy that the increase in current maximum begins earlier for higher concentrations of KCl. This effect of the electrolyte concentration on the time evolution of transfer current during e ectrode discharge can be interpreted in terms of a moving reaction layer.

Concept of reaction layer.—The concept of a reaction layer is well established in many branches of chemistry and chemical engineering (19-21). It is also one of the first concepts that guided the early discussions of porous electrode behavior (22, 23). The reaction layer thickness thus has been defined in many ways. Here, we define the reaction layer thickness as the distance along the x-coordinate which yields the area of the triangle OAB equal to the area under the $j(x,t)$ curve, placed in a manner as to retain the initial slope, as shown in Fig. 6a. The initial portion of the $j(x)$ *vs.* x curves for concentrations and currents investigated ex-

[1] Superficial current density is defined here as i_o/A, where A = 6.6 × 10^{-3} cm^2, the cross-sectional area of the pore, cf. Fig. 1.

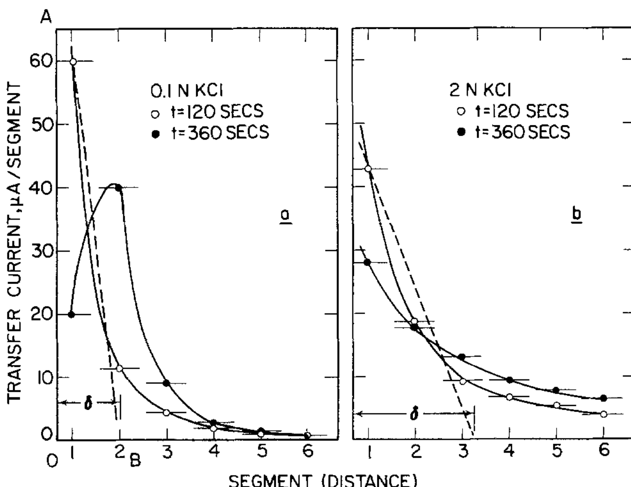

Fig. 6. Initial evolution of reaction profile on discharge and a graphical determination of reaction layer thickness: a, in 0.1N KCl; b, in 2N KCl. Discharge current, i_o = 80 μA; δ is defined as the reaction layer thickness.

hibit exponential behavior as shown in Fig. 6. The transfer current falls off rapidly with the distance, in accordance with an expression of the form

$$j(x) = A \cosh [\kappa(l - x)] \quad [5]$$

where $A = ki_o/\sinh(\kappa l)$ is a constant for a given set of experimental conditions and electrode dimensions.

The thickness of the reaction layer, $\delta(c_o)$, can be determined directly from Fig. 6a and b. We note that the thickness depends strongly on electrolyte concentration, since in both cases the discharge current was the same, namely, $i_o = 80 \times 10^{-6}$A. Accordingly, we find $0.07 < \delta(0.1) < 0.14$ cm and $0.14 < \delta(2) < 0.21$ cm in 0.1 and $2N$ KCl solutions, respectively.

Application of the reaction layer concept.—Before applying the reaction layer concept to the interpretation of results summarized in Fig. 3-5, and introducing additional supporting experimental evidence, the following is noted: The transfer currents, j_k, are expressed here as currents rather than current densities and represent the integrated values of local currents over the segment's area. Time is accurately known; partial currents were recorded every 20 sec. Also, the initial charge deposited on the individual segments, $Q_k = 19.2$ mA-sec/segment, was maintained constant, independent of the running index, k.

In our previous communication (11) we discussed the behavior of a porous electrode operating with a change in reaction path when a predetermined conversion has taken place. We derived the $j(x,t)$ dependence when the reaction path characterized by electrolyte resistance, R_1, and the reaction impedance, Z_1, changed to other values designated by R_2 and Z_2. It was shown that an electrode operating under this restriction is adequately described by the position of the mode interface, x_c, and the velocity, v_c, at which the mode interface penetrates the electrode structure ($v_c = dx_c/dt$).

To simplify the discussion, we consider the electrode discharge as a special case, namely, no reaction occurs in region 2. That is, we assume $Z_2 = \infty$, within region $0 \leqq x < x_c$. For finite R_2 and $Z_2 = \infty$, it follows that $\kappa_2 = 0$ and $\zeta_2 = \infty$, where $\kappa_2 = (R_2/Z_2)^{1/2}$ and $\zeta_2 = (R_2Z_2)^{1/2}$. Under these conditions the developed equations of Ref. (11) are reduced as follows

$$j(x) = 0 \quad \text{for} \quad 0 \leqq x < x_c \quad [6]$$

and

$$j(x) = ki_o \cosh[\kappa(l - x)]/\sinh[\kappa(l - x)] \quad \text{for} \quad x_c < x \leqq l \quad [7]$$

Equations [6] and [7] are identical with those derived by Winsel (22) and represent the exponential distribution within the region where discharge is taking place. Similarly, the velocity of penetration can be obtained

$$v_c = (i_o/Q_o)/\coth^2[\kappa(l - x_c)] \quad [8]$$

It is advantageous to examine the time evolution of discharge profiles in terms of the moving reaction layer concept. Consider Fig. 6a: Two minutes after initiation of the discharge reaction, most of the current is located in the first segment, with only a small fraction in the second and third segments. Four minutes later, most of the current is found in the second segment with only minor increase in the third segment and almost none at greater electrode depths. Bearing in mind that the recorded current in any segment is the integrated current over the segment area, we conclude that for the one-dimensional case, the original current (local current) distribution, given by Eq. [7], is retained, but its zero point, x_c, is shifted into the electrode interior. It indicates that

$$\int_{x_c}^{0.07} j(x)_t dx < \int_{0.07}^{0.14} j(x)_t dx \quad [9]$$

that is, an increase in the current recorded in the second segment is due to the decrease in the active area of the first segment rather than in the value of local transfer current density, $j(x)$, in the first segment.

The time necessary for a similar development in $2N$ solution of potassium chloride is longer than 6 min after the initiation of the electrode discharge. It is seen that the exponential character is retained. This is a consequence of thicker reaction layer, since both electrodes contained initially the same amount of charge, $Q_o = 19.2$ mA-sec, and were discharged with the same current, $i_o = 80 \times 10^{-6}$A. Using the same concept, we can interpret the (j/i_o) *vs.* (t/t_o) curves shown in Fig. 3-5.

Consider Fig. 3: It depicts the time evolution of the discharge profile in $0.1N$ KCl. The existence of the j_k max, in all segments except the first and the last one, has just been discussed, Eq. [9]. The sharpness and lack of overlap of the curves of the reduced current implies the presence of a reaction layer on the order of the segment thickness with a layer thickness unaffected by the degree of electrode discharge, *i.e.*, by the position of mode interface, x_c. The independence of the j_k max of the running index, k, *i.e.*, of the position of x_c, suggests further the validity of Eq. [8], and, therefore also, of Eq. [10]

$$\Delta j_c = j(x_c) = \kappa i_o \coth[\kappa(l - x_c)] \quad [10]$$

These equations are independent of x_c, as long as $\coth[\kappa(l - x_c)] \approx 1$, *i.e.*, as long as $[\kappa(l - x_c)] \geqq 3$. The sharp increase in the transfer current as the discharge process is nearly completed may also be noted. This implies that δ becomes greater than the remaining electrode depth of the active portion.

The form of the (j/i_o) *vs.* (t/t_o) plot is preserved as the chloride concentration is increased. Disregarding the initial contraction of the reaction layer (decrease in j_2), the situation is similar. Since the reaction layer is thicker due to decrease in ohmic resistance of the electrolyte, the j_k max are less, the penetration of the reaction layer is somewhat slower, as indicated by the position of j_k max on the reduced time scale, except when the reaction layer just entered the last segment.

The effect of the reaction layer thickness on details of the discharge profile is also demonstrated in Fig. 5. Here, the j_k max are less than those observed in $1N$ KCl; this is consistent with the increase in the layer's thickness. Also, the penetration rate is less at the beginning of the discharge process, and increases toward the end of the discharge. The increase in the rate of penetration occurred at an earlier time than in $1N$ KCl, and this is also consistent with the increase in the reaction layer thickness.

The degree of a segment's discharge at the time of j_k max is given in Table I. It is seen that the amount of material used up before the event of j_k max is hardly dependent on the discharge current, i_o, but is affected by the position; more material is used up for greater depth. This observation is again consistent with the concept of moving reaction layer.

It has been indicated that the reaction layer thickness is a strong function of electrolyte concentration. However, it did not change with the progress of elec-

Table I. Surface coverage and reactant charge content at j_k max in $1N$ KCl

i_o	$Q(2)$	$\theta(2)$	$Q(3)$	$\theta(3)$	$Q(4)$	$\theta(4)$	$Q(5)$	$\theta(5)$
80×10^{-3}	5.6	0.291	5.0	0.260	4.4	0.229	4.0	0.208
100×10^{-3}	7.8	0.406	5.4	0.285	4.21	0.219	3.6	0.187
120×10^{-3}	6.8	0.354	5.9	0.307	4.83	0.251	3.4	0.177
160×10^{-3}	7.2	0.375	6.01	0.313	5.2	0.270	4.1	0.213

Values computed from formula:

$$\theta = \frac{19.2 \times 10^{-3} - Q(k,t)}{19.2 \times 10^{-3}}$$

where $Q(k,0) = 19.2 \times 10^{-3}$ A-sec/segment, $Q(k,t) = 19.2 \times 10^{-3} - Q$ (transferred), Q (transferred) by integration under the $j(x,t)$ curves.

trode discharge, which should be particularly evident in $0.1N$ solution. A complete discharge of a segment, initially containing 19.2 mA-sec/segment will add, upon discharge, 15.25 mg Cl^-/cm^3. To assure electroneutrality, a corresponding amount of potassium ions must be brought from the bulk. Transport processes must obviously participate. However, their effect on the local current density distribution, on the thickness of the reaction layer, will be relatively unimportant, because the changes in concentration due to the transport phenomena will be restricted to regions toward the pore mouth. Therefore, although the concentration of potassium chloride has increased to about $0.4N$ solution, no effects of change in δ (c_o) were noted. The same observations can be made for 1 and $2N$ solutions.

Similar evolution of a discharge profile was reported for another sparingly soluble reactant-conductive matrix system (24).

The Charging Process: Ag → AgCl

The charging process considered here took place within the geometrical constraints of a porous structure and differs from the discharge process in that chloride ions are used up. Thus, diffusional processes and, in general, transport processes of Cl^- are directed into the porous structure rather than into the bulk electrolyte. This fact alone would imply the possibility of an effect of concentration changes in the porous structure on the time evolution of reaction profile which was not noted in the course of electrode discharge.

We present the experimental data in somewhat different manner, namely, we start the discussion with the presentation of the evolution of reaction profile in $2N$ KCl.

Evolution of reaction profile on charging.—Significant events which occurred during the evolution of the transfer current during charging in $2N$ solution are inferred from the experimental distribution shown in Fig. 7. Shortly after the initiation of charging, at $t = 2$ min, a typical distribution was recorded. At some later time, the exponential distribution degenerated into one exhibiting a minimum and a maximum. Taking into consideration that the recorded currents are in fact integrated values, we may visualize the "degenerated" curves as composed of two exponential branches with the discontinuity, as shown in Fig. 7 by a broken line. As the charging process is being carried out, the discontinuity penetrates into the electrode structure. After 11 min of electrode charging, the discontinuity has reached the fourth segment of the experimental analog. As the charging process was carried out further, a leveling in the distribution was observed. This was interpreted as a disappearance of the upper branch of the distribution curve, at $t = 23$ min. Such profile evolution is in agreement with the predicted behavior for the case of a change in the rds in the course of electrode operation (11).

To seek further confirmation, a plot of log Q *vs.* the distance has been prepared, Fig. 8. The charge transferred, or extent of reaction, in each segment was determined by mechanical integration of the experimentally recorded j-t curves. The similarity of this plot and one based on theoretical calculations and reported previously (11), is evident.

The critical charge accumulation, *i.e.*, the critical extent of reaction, associated with the change in the reaction path, corresponds to about 14% of surface coverage, cf. Fig. 8. It follows from the evidence presented in Fig. 7 and 8 that the change in reaction mechanism is due to inhibition of charge transfer, rather than to an increase in the ohmic resistance of the electrolyte in the electrode pore.

The change in the reaction path appears to be independent of the charging current within the range of

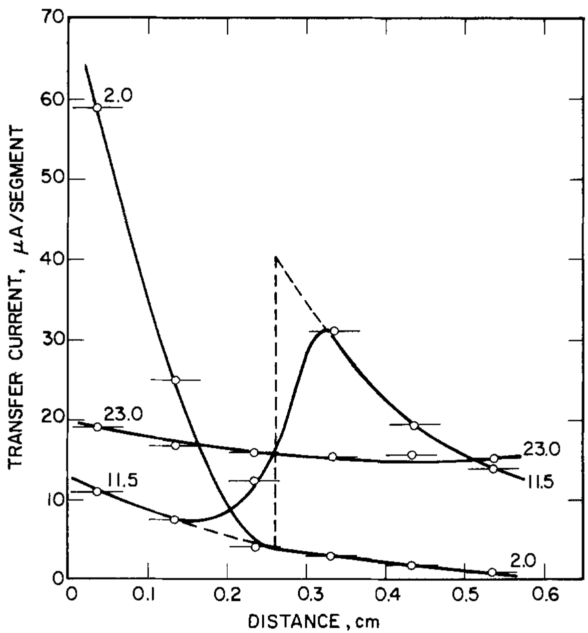

Fig. 7. Evolution of reaction profile on charging in $2N$ KCl. Time in minutes indicated along corresponding curves.

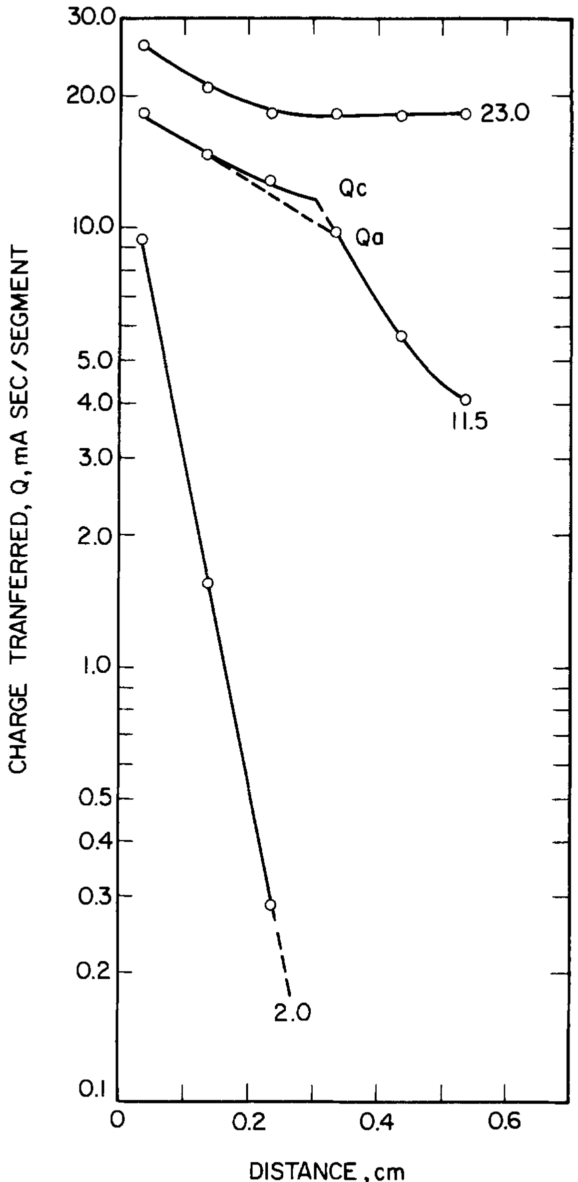

Fig. 8. Charge transferred as a function of distance at $t = 2.0$, 11.5, and 23 min; critical and asymptotic charges, Q_c and Q_a, are indicated [cf. Ref. (11)].

$80\text{-}200 \times 10^{-6}$A. This range was essentially imposed by the limited speed of sampling and recording of the j-t curves. No significant changes in the curves were noted at currents as high as 600×10^{-6}A

The experimental evidence is wholly consistent with the concept of a change in reaction path due to a change in electrochemical mechanism, rather than to an increase in solution resistance. Disregarding the transport from bulk electrolyte, the change in chloride ion concentration did not exceed 12%.

Theoretical analysis (11) has shown that the time evolution of the reaction profile, associated with the increase in interfacial impedance is characterized by the position dependent rate of penetration of the mode interface which, in turn, is associated with the numerical value of the discontinuity at x_c [cf. Eq. [18], Ref. (11)]. Examination of Fig. 8 indicates an increase of about one order of magnitude of the interfacial impedance, after approximately 14% of the available surface has been covered by silver chloride (18).

A plot of (j/i_o) *vs.* t^*, where t^* is the reduced time and is calculated according to the formula $t^* = t/t(l)$, is shown in Fig. 9. Here, $t(l)$ is the time of charge to obtain complete surface coverage (18). Because of the finite dimensions of the segment employed, an error in the dimensionless time $t(l)$ is introduced when complete coverage is judged by the motion of the reaction profile. However, this error appears to be insignificant in view of the correlation obtained for the various charging currents, Fig. 9.

Effect of changing ohmic resistance on the evolution of transfer current distribution.—The effect of a change in solution resistance on the evolution of the reaction profile is of special interest to electrode design. In most systems, especially those containing no supporting electrolyte and having a small ratio of volume to surface engaged in charge transfer, large changes in composition may develop because of an electrochemical process. Chemical changes, in turn, give rise to transport processes and promote the development of interactions between the charge transfer and other processes. The development of this progressive interaction is illustrated in Fig. 10a, b, and c, where the j-t curves for the segmented electrode operation in 1N KCl are shown. Charging currents of 200, 300, and 400 μA were used.

Consider Fig. 10a, where for the purpose of clarity in illustration, currents in the first three segments only are shown. The j-t curves are essentially similar to those obtained in 2N KCl solutions. It is seen that, if a j-x plot were constructed at $t = 2.5$ min, or greater, it would be analogous to the one shown in Fig. 7. Thus, we can reasonably conclude that choking (blockage) of the second kind dominates the transfer current evolution under those circumstances, *i.e.*, the reaction resistance increases; choking of the first kind has been defined as the shift of current profile toward the electrolyte side caused by an increase in solution resistivity (11).

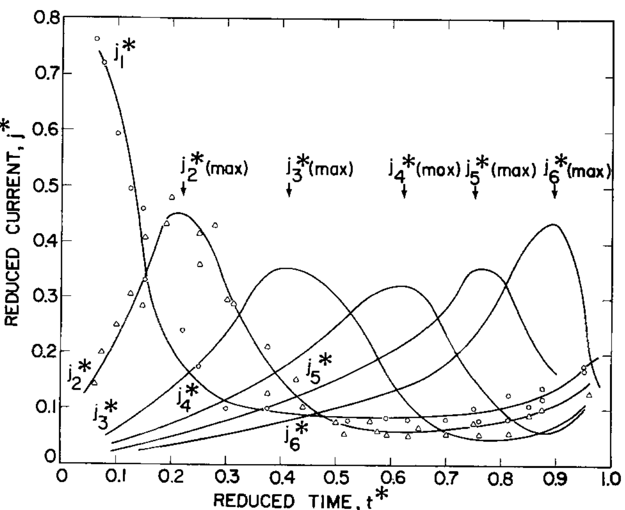

Fig. 9. Time evolution of reaction profile on charging in 2N KCl; charging currents: i_o = 80-600 μA.

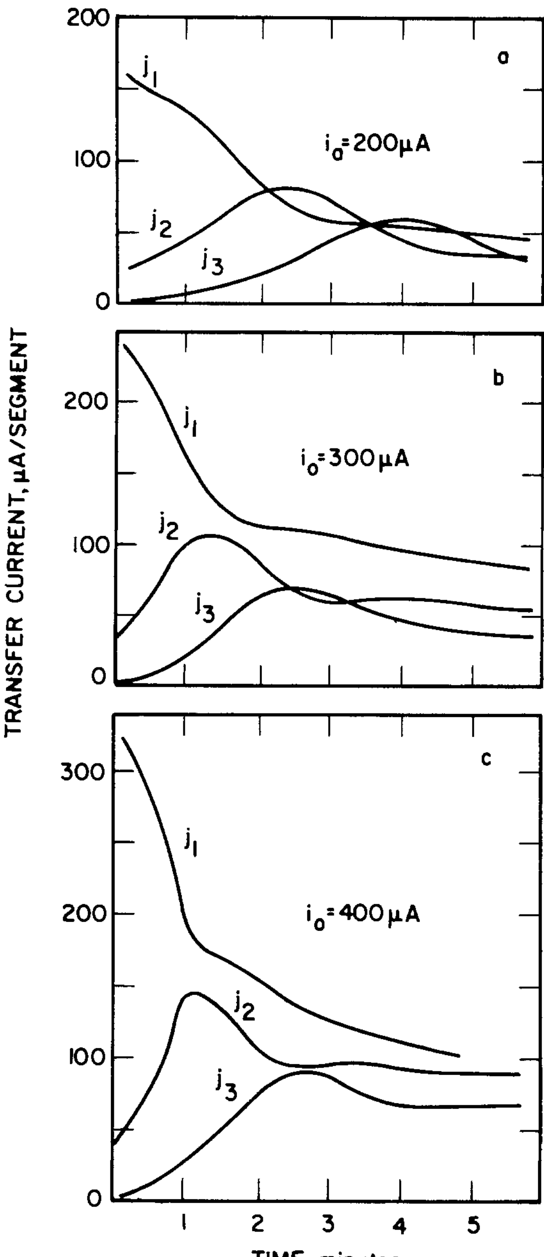

Fig. 10. Time evolution of reaction profile on charging in 1N KCl; charging currents: a, i_o = 200 μA; b, i_o = 300 μA; c, i_o = 400 μA.

As the charging current was increased to 300 μA, Fig. 10b, we noted a shift in the transfer current toward the front of the electrode. The current recorded in the first segment was never less than in the second, third, etc. That is, the transfer current distribution "opened up." It is also seen that, at times greater than 2.5 min, the transfer current in the third segment exceeded that in the second. This can be interpreted as an evidence that choking of the second kind still operates, but at greater depths only. As the charging current was increased further, *i.e.*, to 400 μA, the transfer current distribution was further modified in a sense of further "opening up"; at no time were we able to find $j_{k+1} > j_k$. The j-x curve was no longer exponential, except at the beginning of the charging process. Maxima and minima in the distribution curves are expected instead.

The effect of solution resistance on the development of reaction profile is even more dramatically demon-

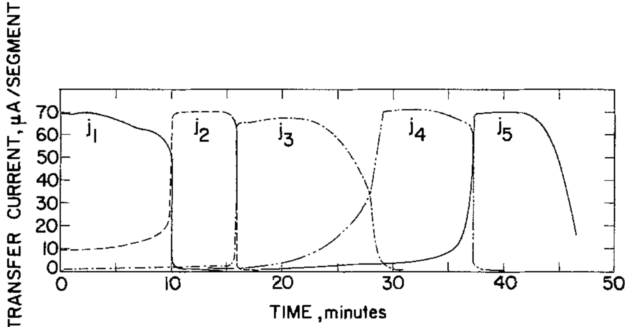

Fig. 11. Time evolution of reaction profile in charging in 0.1N KCl; charging current, i_o = 80 μA.

strated in Fig. 11. It is seen that in 0.1N KCl, the transfer current was almost entirely located in the first segment, with only a small fraction found in the second, and practically none passed through the third. Thus, the reaction was limited to the first two segments: in the concept of reaction layer, $\delta(0.1) < 0.14$ cm. When approximately 40 mA-sec has passed through the first segment, there was a rapid termination of reaction in the first segment and a rapid increase in the second. However, no increase in the transfer current in the third segment was noted. Reaction entered the third segment after approximately 36 mA-sec has been accumulated in the second, again after an abrupt termination. In terms of the reaction layer concept, the reaction layer became less thick, $\delta(c) < 0.07$ cm.

At later times, *i.e.*, after the reaction entered the third segment, the reaction layer increased in size to the same thickness as at the beginning; the participation of the fourth segment was observed. Again, when approximately 40 mA-sec were accumulated in the third segment, the reaction layer penetrated further. The reaction layer thickness again became less than before.

This behavior appears to be consistent with the motion of a layer, provided that its thickness varies with position. On the basis of the progressive evolution of the transfer current distribution illustrated in Fig. 10a, b, and c, the changing thickness of the reaction layer demonstrated in Fig. 11, should be associated with the interaction between the charge transfer reaction and the transport of reactant.

Effect of Electrode Structure on Evolution of Reaction Profile

The segmented electrode concept provided direct experimental support to the fact that an electrode process operating with a change in electrode mechanism in the interior of porous electrode can be found and shows an excellent qualitative agreement with predicted behavior (11). From a point of view of electrode design, it is more relevant if the segmented electrode concept could be used as a tool in an experimental approach to electrode modeling. In what follows, we shall compare the evolution of reaction profile in a structure generated by loosely compacted spheres of uniform diameter, with those derived from Fig. 10b.

The reaction profiles given in Fig. 12 are based on atomic absorption spectrometric analyses of silver chloride produced on galvanostatic charging of sphere bed electrodes and reconstructed using Eq. [3] and [4]. The sphere bed electrodes were charged at constant current density of 50 mA/cm² for periods of ½, 1+½, 2+½, etc., min. The experimental technique was outlined previously (18). The time evolution profile in the segmented electrode constructed from data given in Fig. 10b is also shown in Fig. 12.

The similarity in the transfer current evolution is quite evident. In both cases, the initial distribution was exponential with well-defined depth of penetration. As the charging was continued, the usual advancement in the penetration was observed: the distribution was less steep and the exponential character was retained.

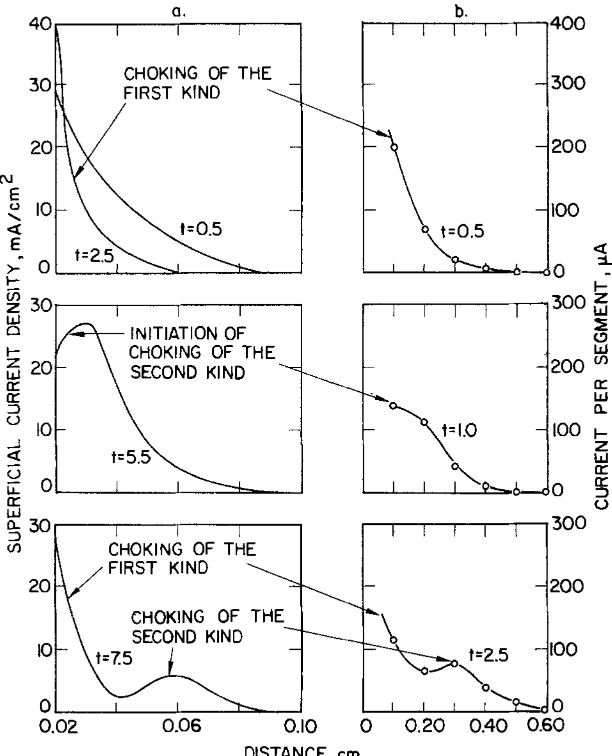

Fig. 12. Comparison of experimentally obtained reaction profile evolutions in 1N KCl. a, Sphere bed electrode, with i_o = 50 mA/cm²; b, segmented electrode, with i_o = 300 μA.

Shortly thereafter, at about 2.5 min of charging, the shift toward the pore mouth in the distribution was noted; that is, choking of the first kind was observed. The origin of this choking, *i.e.*, whether due to the increase in solution resistance due to reactant exhaustion or the onset of voluminous precipitation, cannot be ascertained without independent examination such as electron scan microscopy. Somewhat later, at 5.5 min of charging, choking of the second kind was observed. A noticeable decrease in the current density in the proximity of electrode-electrolyte interface developed. Again, at a later time, at 7.5 min, we observe the formation of a maximum and a minimum in the distribution curve, *i.e.*, the development of reaction profile characteristic of one associated with penetration of choking of the second kind.

The lack of coincidence in time, for the evolution of reaction profiles in the two electrodes can be attributed to differences in detailed structure of the electrodes. The over-all agreement, however, corroborates the usefulness of segmented electrodes as used here in interpreting behavior of more complex geometrical structures.

Conclusions

A segmented, single pore electrode may be prepared to show experimentally the manifestations of reaction regions during the course of charge or discharge for the Ag/AgCl system in aqueous KCl electrolyte. Evolution of the reaction profile and change in the rate determining process could be detected and followed. Further, changes in the distribution of transfer current with varying electrolyte concentration, 0.1, 1.0, and 2.0N KCl, could be distinguished, and a distinction was made from the reaction profiles between choking of the first and second kinds.

In comparison with another, multipore electrode, correspondence between the response of the segmented, single-pore analog and a geometrically three-dimensional porous electrode with interconnected pores were found. In view of insight gained from these studies and practical applications for battery electrodes, important future use of the described technique is anticipated.

Electrochemical Studies on Single Crystalline CuCl Solid Electrolyte

A. V. Joshi*,[1] and J. Bruce Wagner, Jr.*

Department of Materials Science and Materials Research Center, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The d-c polarization technique, relaxation technique, and the charge transfer technique have been applied to cuprous chloride single crystals for the determinations of electronic conductivity, mobility of electronic carriers, and the double layer capacitance at CuCl/graphite interface. A method to separate the electronic charge transfer is presented. It has been shown that the redistribution of electronic carriers within the solid electrolyte in which the concentrations of electronic carriers exponentially increase with the applied potential may make a significant contribution to transient measurements involving a polarization cell. Further, ideal polarization kinetics were observed for the CuCl/graphite interface in the temperature range of 200°-300°C, because the electronic charge transfer was made negligible by selecting the proper parameters such as thickness of the electrolyte and the magnitude of the applied potential step $\Delta E(E_1\text{-}E_2)$ as well as the values of the applied potentials, E_1 and E_2, on the polarization cell.

In two previous papers (1, 2) electrochemical measurements on CuCl single crystals were described. However, the experimental details and some of the data could not be presented due to the limitations of space. The purpose of the present paper is to supplement and to review the available information on the electrochemical properties of cuprous chloride.

Very little is known about the transport properties of cuprous halides compared to silver halides. In contrast to AgCl or AgBr, cuprous chloride is a p-type conductor (3) when equilibrated with its parent metal, copper. The present study mainly uses a d-c polarization cell of the type, M|MX| inert electrode, to determine the following properties of single crystalline

* Electrochemical Society Active Member.
[1] Present address: P. R. Mallory & Company, Inc., Burlington, Massachusetts 01803.
Key words: electrical conductivity, transport numbers, double layer capacitance.

cuprous chloride: (*i*) electronic conductivity, (*ii*) drift mobility and concentrations of electronic carriers, and (*iii*) double layer capacitance at CuCl|graphite interface.

Essentially, three electrochemical techniques are used in the present study. These are: (*a*) the polarization technique (4), (*b*) the relaxation technique (5), and (*c*) the charge transfer technique (6, 7). In what follows, the theory of each type of experiment and the experimental results are discussed.

Theory

D-C polarization study.—These measurements are essentially steady-state measurements. A conductivity cell of the type

$$\mathrm{Cu|CuCl|graphite} \quad [I]$$

where a sample of cuprous chloride is sandwiched between a reversible electrode, copper, and a blocking electrode, graphite, is used as a d-c polarization cell; a positive d-c potential (much below the decomposition potential of cell) is applied to the right-hand electrode. Wagner (4) showed that the total electronic current, I_T, passing through a cell under steady-state conditions is given by

$$I_T = RTA/L\mathbf{F}\{\sigma_{\ominus}^{\circ}[1 - \exp(-E\mathbf{F}/RT)] + \sigma_{\oplus}^{\circ}[\exp(+E\mathbf{F}/RT) - 1]\} \quad [1]$$

where I_T = total current due to excess electrons and electron holes at steady state, A = cross-sectional area of the interface between graphite and the CuX, L = thickness of the sample, $\mathbf{F}$ = Faraday's constant, $\sigma_{\ominus}^{\circ}$ = electronic conductivity due to excess electrons in CuX coexisting with copper, $\sigma_{\oplus}^{\circ}$ = electronic conductivity due to excess electron holes in CuX coexisting with copper. The other symbols have their usual meaning. If $\sigma_{\oplus}^{\circ} >> \sigma_{\ominus}^{\circ}$, then the current due to electron holes, $I_{\oplus}$, becomes

$$I_{\oplus} = RTA/L\mathbf{F}\{\sigma_{\oplus}^{\circ}[\exp(E\mathbf{F}/RT) - 1]\} \quad [2]$$

and when $E >> RT/\mathbf{F}$, Eq. [2] can be written as

$$I_{\oplus} = RTA/L\mathbf{F}\{\sigma_{\oplus}^{\circ}\exp(E\mathbf{F}/RT)\} \quad [3]$$

Equation [3] is very useful in determining the electronic hole conductivity of CuCl equilibrated with copper from a plot of the log of current *vs.* the applied potential, E.

Relaxation study.—Weiss (5) suggested the relaxation technique to measure the drift mobility of electronic carriers in crystals of AgBr. AgBr is an n-type conductor when equilibrated with its parent metal Ag. The theory can be extended for p-type conductor (*e.g.*, the cuprous halides) as follows.

Consider a typical cell of type [I]. On applying a voltage below decomposition potential of CuCl to cell [I] with the positive pole on the graphite side, the activity of copper at the blocking electrode (*e.g.*, graphite) interface is given by

$$a_{\mathrm{Cu}} = \exp(-E\mathbf{F}/RT) \quad [4]$$

Since cuprous halides of ideal composition exhibit mostly cationic conduction and there are substantial concentrations of interstitial cations and cation vacancies, small changes in stoichiometry do not affect the chemical potential of cations but do affect that of electrons or electron holes which are present in concentrations several orders of magnitude less than that of the lattice defects. The concentrations of excess electrons and electron holes at the blocking electrode interface are given by

$$C_{\ominus} = C_{\ominus}^{\circ}[\exp(-E\mathbf{F}/RT)]$$
$$C_{\oplus} = C_{\oplus}^{\circ}[\exp(E\mathbf{F}/RT)] \quad [5]$$

where E is applied potential and $C_{\ominus}^{\circ}$ and $C_{\oplus}^{\circ}$ are the concentrations of electrons and electron holes, respectively, at the Cu-CuX interface.

When the applied potential is removed from cell [I], the concentration of electron holes at the CuX/graphite interface will decrease with time. The open-circuit potential as a function of time $\Delta V(t)$ is given by

$$\Delta V(t) = [RT/\mathbf{F}]\ln[C_{\oplus}(t)/C_{\oplus}^{\circ}] \quad [6]$$

where $\Delta V(t)$ = measured open-circuit potential difference across cell [I] as a function of time, and $C_{\oplus}(t)$ = time dependent electron hole concentration at the CuX/graphite interface.

In ionic compounds where the electronic species are minority defects, it can be shown that the effective diffusion coefficient represents the diffusion coefficient of majority electronic carriers (8). This effective diffusion coefficient in cuprous halides represents the diffusion coefficient of electron holes under the conditions where ionic conduction prevails. Fick's second law may be applied to this case where there is a concentration gradient across the sample. The concentration gradient in the sample of length L is constant, *i.e.*, a linear change in concentration is assumed. Thus

$$C_{\oplus}(x) = C_{\oplus}^{\circ} + \frac{x}{L}[C_{\oplus}(x = L) - C_{\oplus}^{\circ}] \quad \text{for } t = 0 \quad 0 \leq x \leq L \quad [7]$$

where $C_{\oplus}(x)$ = concentration of electron holes at a distance x from the Cu/CuX interface. Also

$$\left(\frac{\partial C}{\partial x}\right)_{x=L} = 0 \quad \text{for} \quad t = 0 \quad [8]$$

With these boundary conditions, the solution to Fick's second law is given by (9)

$$\frac{C_{\oplus}(x,t) - C_{\oplus}^{\circ}}{C_{\oplus}(t = 0) - C_{\oplus}^{\circ}} = \frac{4}{\pi^2}\sum_{\nu=0}^{\infty}\frac{(-1)^{\nu}}{(2\nu + 1)^2} \sin\left[\frac{\pi x(2\nu + 1)}{2L}\right]\cdot\exp\left[-\frac{\pi^2(2\nu + 1)^2 D_{\oplus}t}{4L^2}\right] \quad [9]$$

$$\simeq \frac{4}{\pi^2}\exp\left[-\frac{\pi^2 D_{\oplus}t}{4L^2}\right] \quad [10]$$

where $D_{\oplus}$ denotes the effective diffusion coefficient of electron holes.

Substituting Eq. [5] and [6] in Eq. [10] yields

$$D_{\oplus}t = -\frac{4L^2}{\pi^2}\ln\left\{\frac{\pi^2}{4}\frac{\exp\left(\frac{\Delta V(t)\mathbf{F}}{RT}\right) - 1}{\exp(E\mathbf{F}/RT) - 1}\right\} \quad [11]$$

For $\Delta V(t)\mathbf{F} >> RT$, Eq. [11] becomes

$$D_{\oplus}t = -\frac{4L^2}{\pi^2}\left[\frac{\Delta V(t)}{RT}\mathbf{F} - \left(\frac{E\mathbf{F}}{RT}\right) + \ln\left(\frac{\pi^2}{4}\right)\right] \quad [12]$$

Thus the slope of a plot of $\Delta V(t)$ *vs.* time will yield the value of $D_{\oplus}$.

In the case of an n-type conductor such as AgBr, electrons are the majority carriers when the crystal is equilibrated with silver. In that case the concentrations of electrons are substituted in Eq. [10] instead of electron holes. The expression for $\tilde{D}_{\ominus}$ will be

$$D_{\ominus}t = -\frac{4L^2}{\pi^2}\ln\left[\frac{\pi^2}{8}\cdot\frac{1 - \exp[-\mathbf{F}\Delta V(t)/RT]}{1 - \exp[-E\mathbf{F}/RT]}\right] \quad [13]$$

Charge transfer study.—Raleigh (6) suggested the charge transfer method in order to separate the double layer charge transfer from the bulk electronic charge transfer for the case of AgBr. The theory can be extended to p-type conductors (*e.g.*, cuprous halides) as follows.

When a steady-state bias voltage, E_1, on the polarized cell [I] is changed from E_1 to E_2 ($E_2 > E_1$), charge transfer occurs by three processes. These are: (*i*) the charging or discharging, as the case may be, of a double layer capacitor at the inert electrode-solid electrolyte interface, (*ii*) the redistribution of electronic carriers within solid electrolyte, and (*iii*) diffusion of copper or other impurities into the graphite electrode until the graphite electrode becomes equilibrated with the new activity of copper at the CuCl | graphite interface.

The third process can be neglected for the present case. This is accomplished experimentally by choosing an inert electrode (graphite) which exhibits virtually no solid solubility for copper or chlorine at temperatures of the investigations. We now derive the expression for the charge transfer due to the second process, namely, the distribution of electronic carriers. Consider the typical cell

$$\text{Cu} \mid \text{CuCl} \mid \text{graphite} \quad [I]$$

in which CuCl exhibits electron hole conduction. The total number of electron holes, $N_{\oplus}$, when the cell is polarized with potential E_1 is given by (6)

$$N_{\oplus} = \frac{1}{2} AL \left[C_{\oplus}{}^{o} + C_{\oplus}(o)\right] \quad [14]$$

where A = area of the interface CuCl/graphite, L = length of the CuCl sample, $C_{\oplus}{}^{o}$ = concentration of electron holes at the Cu/CuCl interface, and $C_{\oplus}(o)$ = concentration of electron holes at the CuCl/graphite interface.

$$N_{\oplus} = \frac{1}{2} AL\, C_{\oplus}{}^{o} \left[\exp(E_1\mathbf{F}/RT) + 1\right] \quad [15]$$

Now if the potential is changed to some other value, E_2, then the total number of electron holes, $N_{\oplus}'$, at this new potential is given by

$$N_{\oplus}' = \frac{1}{2} AL\, C_{\oplus}{}^{o} \left[\exp(E_2\mathbf{F}/RT) + 1\right] \quad [16]$$

Thus, the total amount of electronic charge transfer involved in the polarizing potential step ($E_2 - E_1$) is given by

$$Q_e = \frac{1}{2} e\, AL\, C_{\oplus}{}^{o} \left[\exp(E_2\mathbf{F}/RT) - \exp(E_1\mathbf{F}/RT)\right] \quad [17]$$

where e is the electronic charge.

The total charge transfer, Q_T, in response to the potential step, ($E_2 - E_1$), involves double layer recharging, Q_{dl}, as well as electronic charge transfer, Q_e (neglecting diffusion charge transfer into the inert electrode). Therefore, we can write

$$\begin{aligned} Q_T &= Q_e + Q_{dl} \\ &= \frac{1}{2} e\, AL\, C_{\oplus}{}^{o} \left\{\exp(E_2\mathbf{F}/RT) - \exp(E_1\mathbf{F}/RT)\right\} \\ &\quad + A\, C_{dl} \left[E_2 - E_1\right] \end{aligned} \quad [18]$$

where C_{dl} = double layer capacitance at the CuCl/graphite interface. For the case of AgBr, which exhibits electron conduction when equilibrated with silver as in the cell Ag|AgBr|graphite, the electronic charge transfer is given by

$$Q_e = \frac{1}{2} eAL\, C_{\ominus}{}^{o} \left[\exp(-E_1\mathbf{F}/RT) - \exp(-E_2\mathbf{F}/RT)\right] \quad [19]$$

where $C_{\ominus}{}^{o}$ is the electron concentration at the Ag|AgBr interface.

In order to separate the contribution of Q_e and Q_{dl}, Eq. [18] is very useful. Consider a double cell, as shown in Fig. 1, involving two identical specimens of cuprous chloride solid electrolyte differing only in specimen length. One sample is of length L_1 and the other of L_2, ($L_1 > L_2$). If a potential step, E_1 to E_2, is applied to such a cell, the contribution Q_{dl} may be separated from Q_e because if Q_{dl} is the same for each of the two samples, then for a sample of length, ($L_1 - L_2$), one has

$$Q_e = \frac{1}{2} eA(L_1 - L_2) C_{\oplus}{}^{o} \left[\exp(E_2\mathbf{F}/RT) - \exp(E_1\mathbf{F}/RT)\right] \quad [20]$$

for a p-type conductor and a similar expression for an n-type conductor. Moreover, by subtracting the value of Q_e for a sample of length L_1 (or L_2) from the total charge transfer, Q_T for a single cell, then the value of Q_{dl} and hence the double layer capacitance may be obtained. Experimentally it is convenient to use $E_2 >> E_1$, whereupon the first exponential term in Eq. [20] is much larger than the second so that

$$\ln Q_e = \ln \left\{ \frac{1}{2} eA(L_1 - L_2) C_{\oplus}{}^{o} \right\} + E_2\mathbf{F}/RT \quad [21]$$

and the resulting slope yields a value of $\mathbf{F}/RT$ if the experiment is in accord with theory. The intercept yields the value of $C_{\oplus}{}^{o}$.

If the value of the specific electronic hole conductivity, $\sigma_{\oplus}{}^{o}$, has been obtained from the steady-state, d-c polarization measurements, then the mobility, $\mu_{\oplus}$, may be obtained using

$$\mu_{\oplus} = \frac{\sigma_{\oplus}{}^{o}}{C_{\oplus}{}^{o} \cdot e} \quad [22]$$

Determination of electron hole mobility by current-time analysis.—The charge transfer technique described previously, basically involves measurement of current as a function of time for a fixed potential step. In a cell of type [I], if the electronic charge transfer is predominant over the capacitive charge transfer for a fixed potential step, then a current-time relationship can be derived in order to determine the electronic carrier mobility in a solid electrolyte as follows.

Consider cell [I] of length L subjected to some potential E_1. If the electron hole concentration at Cu|CuCl interface is denoted by $C_{\oplus}{}^{o}$ then the concentration of electron holes at CuCl|graphite interface under the potential E_1 is given by

$$C_{\oplus} = C_{\oplus}{}^{o} \exp(E_1\mathbf{F}/RT) \quad [23]$$

Under this steady-state condition, the electron hole concentration at any distance x from the blocking elec-

trode interface where $x = 0$ can be expressed as

$$C_\oplus(x,0) = C_\oplus{}^o \exp(E_1\mathbf{F}/RT) - \frac{x}{L}[C_\oplus{}^o \exp(E_1\mathbf{F}/RT) - C_\oplus{}^o] \quad [24]$$

This is the initial condition.

When the applied potential on the cell is changed from E_1 to E_2, the concentration of electron holes at blocking electrode interface changes to a value of $C_\oplus{}^o \exp(E_2\mathbf{F}/RT)$. For the present experimental conditions this process occurs in 1 or 2 sec. Therefore, the following boundary condition holds

$$C_\oplus(0,t) = C_\oplus{}^o \exp(E_2\mathbf{F}/RT) \quad \text{at} \quad x = 0 \quad t > 0 \quad [25]$$

When the new potential fixes the concentration of electron holes at the blocking electrode interface ($x = 0$), diffusion of electron holes will occur in the solid electrolyte until the steady-state electron hole current passes through the sample. The solution of Fick's second law with the above mentioned initial and boundary conditions is given by

$$C_\oplus(x,t) = \left\{ C_\oplus{}^o \exp(E_2\mathbf{F}/RT)\,\text{erfc}\,\frac{x}{2\sqrt{D_\oplus t}} + C_\oplus{}^o \exp(E_1\mathbf{F}/RT)\,\text{erf}\,\frac{x}{2\sqrt{D_\oplus t}} - [C_\oplus{}^o \exp E_1\mathbf{F}/RT - C_\oplus{}^o]\,x/L \right\} \quad [26]$$

The above solution is for the semi-infinite rod and is valid for early times ($\simeq$100 to 200 sec in the present case).

Differentiation of Eq. [26] with respect to x can be written as

$$\left.\frac{\partial C_\oplus}{\partial x}\right|_{x=0} = \left\{ -\frac{C_\oplus{}^o \exp(E_2\mathbf{F}/RT)}{\sqrt{\pi D_\oplus t}} + \frac{C_\oplus{}^o \exp(E_1\mathbf{F}/RT)}{\sqrt{\pi D_\oplus t}} - \frac{1}{L}[C_\oplus{}^o \exp(E_1\mathbf{F}/RT) - C_\oplus{}^o] \right\} \quad [27]$$

The flux is given by

$$J = -D\left.\frac{\partial C_\oplus}{\partial x}\right|_{x=0} \quad [28]$$

Therefore, the current due to electron holes is given by

$$I_\oplus(t) = -(eAD_\oplus)\left(\left.\frac{\partial C_\oplus}{\partial x}\right|_{x=0}\right) \quad [29]$$

$$= \left(\frac{eAD_\oplus}{\sqrt{\pi D_\oplus t}}\right) C_\oplus{}^o [\exp(E_2\mathbf{F}/RT) - \exp(E_1\mathbf{F}/RT)] + [eAD_\oplus C_\oplus{}^o/L][\exp(E_1\mathbf{F}/RT) - 1] \quad [30]$$

Substituting $D_\oplus = \mu_\oplus RT/\mathbf{F}$ and $\sigma_\oplus{}^o = C_\oplus{}^o \cdot e\mu_\oplus$ in the above expression, we get

$$I_\oplus(t) = \frac{L}{\sqrt{\pi D_\oplus t}}[I_\oplus(E_2) - I_\oplus(E_1)] + I_\oplus(E_1) \quad [31]$$

where

$$I_\oplus(E_2) = (RTA/L\mathbf{F})\,\sigma_\oplus{}^o[\exp(E_2\mathbf{F}/RT) - 1]$$

and

$$I_\oplus(E_1) = (RTA/L\mathbf{F})\,\sigma_\oplus{}^o[\exp(E_1\mathbf{F}/RT) - 1]$$

Experimental

Cuprous chloride crystallizes in the zinc blende lattice up to 407°C and in a wurtzite (hexagonal) lattice from 407°C to its melting point at 422°C. Crystals grown at temperatures below 407°C can crystallize directly in the zinc blende phase and exhibit no strains (10). The single crystals provided to us were grown by the same technique using fluxes to suppress the melting point below 407°C.

Preparation of pellets.—For the measurements of electronic conductivity, electronic mobility, and double layer capacitance, the double cell arrangement as shown in Fig. 1 was used. For this type of arrangement two specimens of single crystalline CuCl with different lengths were used. The pellets were cut from one long cylinder of CuCl (9 mm diam) by using a diamond wire saw. The pellets were then polished mechanically on polishing wheels saturated with abrasives in an acetone solution. After polishing these cylinders were washed successively in acetone, dilute HCl, and acetone. The pellets were then ready for the experimental use. The mass spectrographic analysis for the cuprous chloride is given in Table I. For the reversible copper electrode 99.999% pure copper rod (obtained from American Smelting and Refining Company) was used. For the nonreversible graphite electrode, pyrolytic graphite (obtained from the Union Carbide Company) was used. The pellets of copper and pyrolytic graphite electrodes were also given the same surface treatment as the cuprous chloride pellets. All measurements were carried out in the double cell as shown in Fig. 1.

Apparatus.—The prepared samples of cuprous chloride, copper, and pyrolytic graphite were mounted in a polarization double cell as shown in Fig. 1. The contact was insured by applying slight pressure with springs attached to the plunger P. At temperatures near their melting points, most solid electrolytes tend to soften. Because of this, annealing to a bulk metal electrode under light spring pressure resulted in an excellent interface contact. The electronic conductivity measurements, the drift mobility of electronic carriers by the relaxation technique, the charge transfer technique, and the total conductivity measurements were carried out on the same double cell under a purified Linde argon atmosphere. Purification of the argon was carried out by passing the gas over heated copper turnings (99.999% pure) at approximately 500°C. The gas was then passed through the tubes of Linde molecular sieves and silica gel. A Marshall resistance furnace was used in a horizontal position. The temperatures were controlled to ±1°C by a Leeds and Northrup Electromax controller using Chromel-Alumel thermocouples. A copper tube heat sink was fitted around the cells with a controlled thermocouple within the core of the tube. Shielded wires were used to connect with the digital voltmeters. Various stable d-c potentials were

applied via a Keithley 260 nanovolt source. For the measurement of charge transfer the voltage steps were applied on the two samples. The circuitry for applying voltage steps was similar to that used by Raleigh (15) and is shown in Fig. 2. The cell current in response to such a step is monitored across a resistor using a Tektronix Model 564A storage oscilloscope for initial short times and Doric Digital microvoltmeter for longer times. The Doric digital micrometer is a six range instrument with a digital read out and microvolt sensitivity. The maximum reading rate of this instrument is about 2 readings per second. The readings were recorded by the Datatotal digital printout. The applied voltage on the cell was measured by the other similar Doric digital voltmeter. The total charge transfer was determined by measuring the area under the plot of the transient current *vs.* time. For the relaxation measurements the open-circuit potentials were recorded every 1 sec by the Datatotal printer. The total conductivity measurements were done on the same cells as used for the previous measurements of electronic conductivity, mobility, etc. These measurements were carried out after all the other measurements were completed. A General Radio Bridge (1650A) was used to measure the total electrical conductivity. Before making these measurements some copper was deposited on the graphite electrode by applying positive potential on the copper electrode.

Results and Discussion

Measurement of ionic and electronic conductivity of CuCl.—Current voltage characteristics were measured on the cuprous chloride single crystal mounted between copper and graphite electrode. Equation [3] predicts that logarithm of hole current ($\log I_{\oplus}$) *vs.* applied voltage (E) should yield a straight line plot, the intercept of which would yield the value of the specific hole conductivity of cuprous chloride equilibrated with copper. Vander Meulen and Kröger (11) reported that for heavily doped samples of silver chloride, there is an additional current flow which is due to surface leakage. In the present experiments, the data were analyzed by plotting I *vs.* exp ($E\mathbf{F}/RT$) or by $\log I$ *vs.* E. The slopes of $\log I$ *vs.* E plots were found to be close to the theoretically predicted slope of $\mathbf{F}/RT$. The average ratio of theoretical to experimental slope of $\log I$ *vs.* E plot was found to be 1.01. This suggests that there was no appreciable surface leakage in the cell [see Ref. (11)].

The hole conductivity in cuprous chloride can be due to the excess chlorine as follows

$$\frac{1}{2}Cl_2 \rightleftarrows Cl_{Cl} + V'_{Cu} + \oplus \quad [32]$$

where Cl_{Cl} represents a chlorine ion on chlorine site and V'_{Cu} represents the singly ionized cation vacancy. Since the degree of cationic disorder in cuprous chloride is large compared to its range of stoichiometry, the cationic vacancy concentration is independent of chlorine pressure. Thus, the mas action law applied to Eq. [32] yields

$$[V'_{Cu}]\,[\oplus]/p_{Cl_2}^{1/2} = K \quad [33]$$

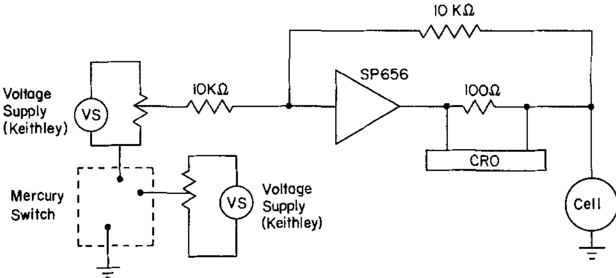

Fig. 2. Circuit diagram for application of stable d-c potential steps to the cell.

From the previous argument

$$[V'_{Cu}] = K_1 = \text{constant} \quad [34]$$

$$\therefore [\oplus] \propto p_{Cl_2}^{1/2} \quad [35]$$

Thus one can see that hole conductivity varies as the square root of chlorine pressure. The observation that slopes of $\log I$ *vs.* E plots are close to the value of ($\mathbf{F}/RT$) at all temperatures of the present investigation is in agreement with the prediction that the electronic conductivity of cuprous chloride is proportional to the square root of the partial pressure of chlorine.

A typical plot of I *vs.* $E\mathbf{F}/RT$ at a particular temperature (383°C) for the case of single crystalline cuprous chloride is shown in Fig. 3. The electronic conductivity was calculated from the value of the slope of the I *vs.* exp ($E\mathbf{F}/RT$) plot. The geometric factor, $L/A \equiv G$, was determined by making a series of a-c measurements and is discussed later. The electronic conductivity values were then plotted against temperature as $\log \sigma_{\oplus}^{o}$ *vs.* $1/T$. The plot of $\log \sigma_{\oplus}^{o}$ *vs.* $1/T$ for two different samples is shown in Fig. 4. The electronic conductivity values were determined in the temperature range of 100°-400°C. The dependence of electronic conductivity on $1/T$ for single crystalline cuprous chloride can be expressed as

$$\sigma_{\oplus}^{o} = 78 \exp\left\{\frac{-24{,}900 \pm 300}{RT}\right\} \quad [36]$$

Following the polarization measurements, the same cells were used to measure the total conductivity of cuprous chloride single crystals by an a-c technique. Previous a-c measurements on cuprous chloride were made by Wagner and Wagner (3) on pressed pellets and by Hsueh and Christy (12) on single crystals. The present measurements were intended to check our

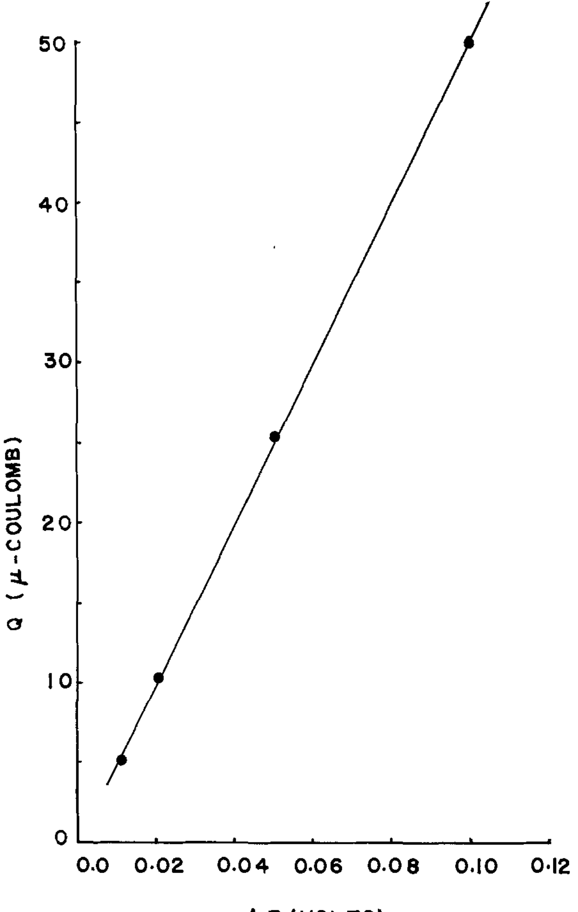

Fig. 3. Typical plot of current *vs.* exp *(EF/RT)* for the case of CuCl at temperature of 383°C.

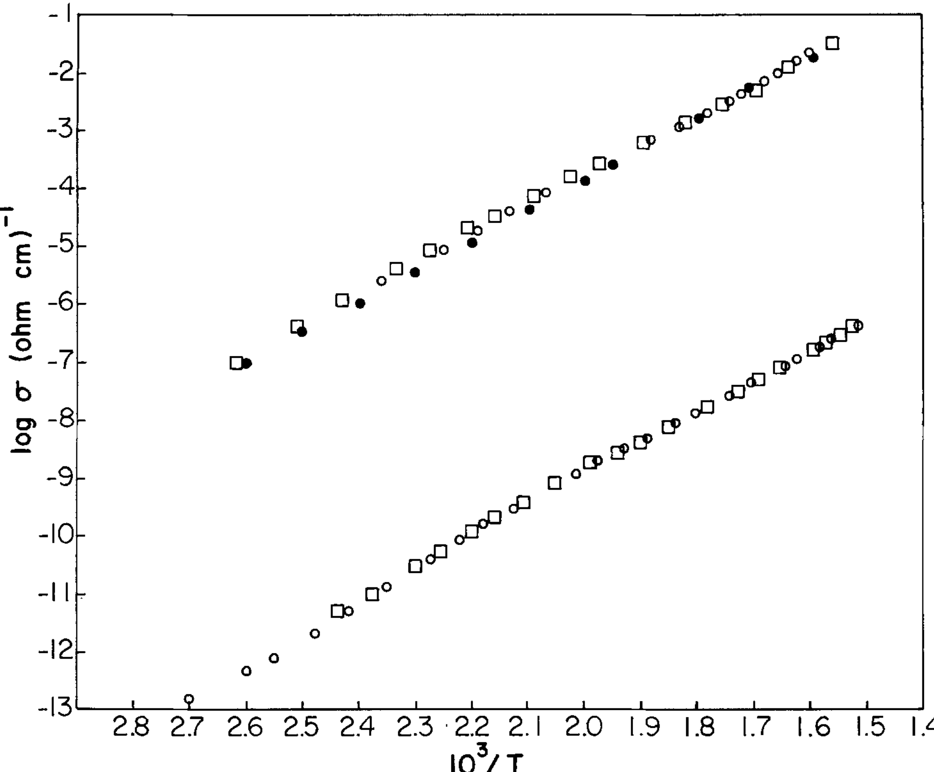

Fig. 4. Logarithm of electron hole conductivity equilibrated with copper log ($\sigma_{\oplus}°$) vs. 1/T for single crystal of CuCl. □, Run 300 series; ○, run 200 series; ●, as obtained by Hseuh and Christy (12) and by Wagner and Wagner (3).

measurements and also to determine the geometric factor $G = L/A$.

In the present study prior to carrying out a-c measurements, a positive current was passed through the copper electrode in order to plate some copper onto the graphite electrode. This arrangement would then be equivalent to sandwiching the cuprous chloride sample between two reversible copper electrodes as was used by Wagner and Wagner (3) and by Hsueh and Christy (12). The resistance of the sample was measured with a-c method using a General Radio Type 1650 A impedance bridge at 1000 Hz. The measurements were carried out on two different samples and the data were compared to previous measurements. The present measurements were in good agreement with the data reported previously (3, 12). These measurements also determined the geometric factor G. If R is the measured resistance of the crystal used and σ is the specific conductivity then $G = R\sigma$.

The conductivity results are summarized in Fig. 4. It can be seen that cuprous chloride is predominantly an ionic conductor throughout the temperature range investigated. Tubandt and Bandowin (13) in the 1930s reported that cuprous chloride becomes predominantly an electronic conductor below 200°C. Recently Maidanovskaya *et al.* (14) reported that cuprous chloride does not exhibit predominantly ionic conduction until the melting point temperature is obtained. The transference numbers of the electronic species in CuCl reported by Tubandt and Bandowin and by Maidanovskaya *et al.* are shown in Fig. 5. Their results are in disagreement with each other and also are in disagreement with present results. The present authors suggest that the probable cause for the discrepancies was due to oxygen, either dissolved or as a second phase, in their samples and that pure CuCl is predominantly an ionic conductor.

Measurement of drift mobility and the concentration of electronic carriers in cuprous chloride equilibrated with copper by the charge transfer technique.—As mentioned above, the electronic charge transfer and double layer capacitive charge transfer in a polarized cell [I] can be separated by the so called charge transfer technique. The charge transfer values were measured on two identical polarized cells of type [I] differing only in sample length. These values are measured by applying a fixed potential step on both cells at a given temperature. The concentration of electron holes at the Cu/CuCl interface, $C_{\oplus}°$, is determined using Eq. [23]. The total charge transfer values for each sample and the calculated values of concentration of electron holes at the reversible electrode ($C_{\oplus}°$) for CuCl are shown in Table II. The values shown are the average values obtained at each temperature. A deviation of ± 3% was observed between successive runs. It can be seen from these measurements that double layer charge transfer at CuCl/graphite interface is negligible compared to the electronic charge transfer for samples longer than 1 cm in the temperature range of 300°-400°C. Therefore, Eq. [21] can be used to test the theory. For this case, charge transfer values on the

longer sample (1.672 cm) were measured as a function of E_2. The lower value of applied potential (E_1) was always maintained at a value such that exp ($E_2\mathbf{F}/RT$) >> exp ($E_1\mathbf{F}/RT$). Figure 6 shows the plot of logarithm of total charge transfer *vs.* E_2 for the longer sample (1.672 cm) of CuCl at 353°C. The plot of log Q_T ($\cong$ log Q_E) *vs.* E_2 yielded a slope which was essentially equal to the theoretical slope of $\mathbf{F}/RT$ between 300° and 400°C. This is a very good proof for the argument that the electronic charge transfer in polarized cells of type [I] is predominant over other processes under the conditions as described earlier. The values of concentrations of electrons ($C_{\oplus}^{o}$) as calculated from Table II or from Fig. 6 were in good agreement with each other. Figure 7 shows the plot of log $C_{\oplus}^{o}$ *vs.* $1/T$ for cuprous chloride equilibrated with copper. The plot shows a very good linear dependence of log $C_{\oplus}^{o}$ on $1/T$. This dependence can be expressed as

$$C_{\oplus}^{o} = 1.04 \cdot 10^{24} \exp(-31{,}000 \pm 500/RT)\ (\text{No./cm}^3) \quad [37]$$

where 31 kcal/mole is the value for the heat of solution of chlorine in CuCl.

The electron hole mobility was determined by using the values of concentrations of electron holes determined by charge transfer technique. The electron hole mobility is given by Eq. [22].

The values of electron hole conductivity, mobility and the concentrations at various temperature for CuCl equilibrated with copper are tabulated in Table III. Figure 8 shows the plot of log $\mu_{\oplus}$ *vs.* log T for CuCl

Table III. Values of electronic conductivity, concentration, and mobility at various temperatures for cuprous chloride

$\sigma_{\oplus}^{\circ}$, ohm-cm	$C_{\oplus}^{\circ}$, No./cm³	$\mu_{\oplus}$, cm²/sec-V	Temperature, °K
4 × 10⁻⁷	5.60 × 10¹³	4.46 × 10⁻²	655
3.09 × 10⁻⁷	4.03 × 10¹³	4.79 × 10⁻²	646
2.17 × 10⁻⁷	2.7 × 10¹³	5.0 × 10⁻²	634.5
1.64 × 10⁻⁷	1.93 × 10¹³	5.32 × 10⁻²	626
1.16 × 10⁻⁷	1.30 × 10¹³	5.62 × 10⁻²	615
8.6 × 10⁻⁸	8.8 × 10¹²	6.1 × 10⁻²	605
5.1 × 10⁻⁸	4.1 × 10¹²	7.77 × 10⁻²	590.5
3.31 × 10⁻⁸	2.5 × 10¹²	8.27 × 10⁻²	578
1.69 × 10⁻⁸	1.05 × 10¹²	1.05 × 10⁻¹	561

in the temperature range of 300°-400°C. The dependence of mobility on temperature can be expressed as

$$\mu_{\oplus} \propto T^{-5.6 \pm 0.2} \quad [38]$$

Raleigh (15, 19) reports a similar dependence of electron hole mobility on the temperature in the case of AgBr.

Measurement of drift mobility of electronic carriers by the relaxation technique.—The relaxation technique as suggested by Weiss (5) for the case of AgBr could be applied for the case of CuCl since it was found that the electronic charge transfer predominates over other processes for samples longer than 1 cm and in the temperature range of 300°-400°C. A typical plot of $\Delta V(t)$ *vs.* time for CuCl is shown in Fig. 9. Equation [12] was

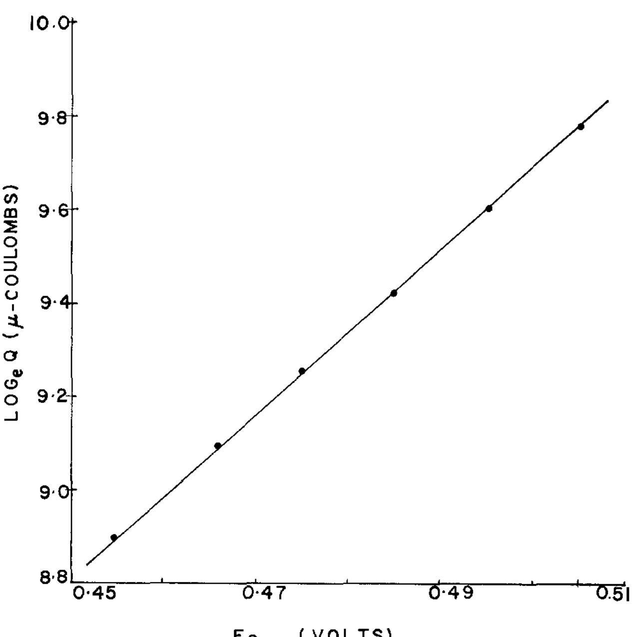

Fig. 6. Plot of logarithm of total charge transfer *vs.* final potential E_2 for CuCl where exp E_2F/RT >> exp E_1F/RT and double layer charge transfer is negligible compared to the total charge transfer.

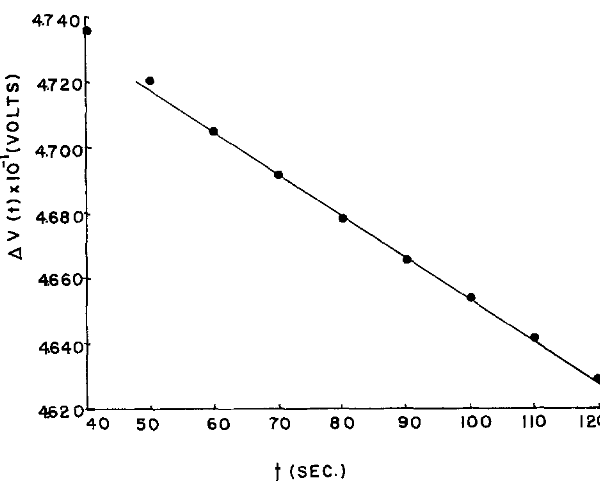

Fig. 9. Typical plot of $\Delta V(t)$ vs. time for the case of cuprous chloride at temperature of 646°K.

used to determine the diffusion coefficient of electron holes from the knowledge of the slopes of $\Delta V(t)$ vs. time plots. The mobility was then calculated by using Nernst-Einstein relation

$$D_\oplus = \mu_\oplus \frac{RT}{\mathbf{F}} \qquad [39]$$

These values are shown in Fig. 8.

Determination of electron hole mobility by current-time analysis.—The charge transfer measurements described earlier involve the measurement of transient currents as a function of time for a fixed potential step. The present authors derived the relationship between the transient current and time under the condition that the charge transfer due to electronic carriers is predominant over the other process. This relationship is given by Eq. [31].

Plots of the transient current, $I(t)$, *vs.* $1/\sqrt{t}$ for the case of CuCl (1.672 cm) at various temperatures are shown in Fig. 10. The magnitudes of the potential steps are shown in Table I. The diffusion coefficients of electron holes were calculated using the slopes of $I(t)$ *vs.* $1/\sqrt{t}$ plots at various temperatures using Eq.

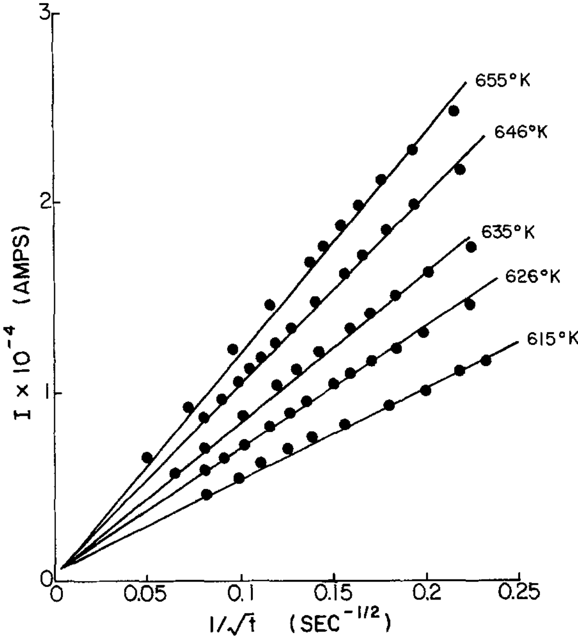

Fig. 10. Plot of current I vs. $1/\sqrt{t}$ for the case of CuCl when the potential on the polarized cell changed from E_1 to E_2. The slope of plot changes according to the temperature as can be seen from the figure.

[31]. The mobility is then calculated by using Nernst-Einstein relation (Eq. [39]). Equation [31] suggests that the intercept of $I(t)$ *vs.* $1/\sqrt{t}$ plot should yield a value of $I_\oplus(E_1)$, if the measurements are in accord with the theory. The values of the intercept for $I(t)$ *vs.* $1/\sqrt{t}$ plot for CuCl were indeed close to the values of $I_\oplus(E_1)$ for temperatures between 340° and 400°C. The mobility values obtained by this analysis are plotted in Fig. 8. It can be seen that these values agree with the values obtained by charge transfer method.

Measurement of double layer capacitance at CuCl | graphite interface at lower temperatures.—Raleigh (15, 19) made various measurements on AgBr to determine the double layer capacitance of the AgBr | inert electrode interface. For the measurement of double layer capacitance at the AgBr | graphite interface, the voltage steps were applied to the polarization cell Ag | AgBr | graphite and transient currents in response to such voltage steps were recorded as a function of time. All the charge transfer involved in the above process was due to the double layer capacitive charging. The electronic charge transfer was negligible as has been shown by Raleigh (6). In Raleigh's experiment the plots of log I *vs.* time were linear at longer times. For initial times they were not linear. The reason for this was attributed by Raleigh to the nonlinear effect in chemical double layer capacitance. The present authors (20) attributed such nonlinearity to the electronic charge transfer at early times. Hull and Pilla (21) also studied the AgI | graphite and the AgI | platinum interfaces at room temperature. They reported pure double layer behavior of such interfaces.

For the case of cuprous chloride at temperatures greater than 350°C the plots of log I *vs.* time were not linear. The reason for this was that the electronic charge transfer contributed significantly, although a small voltage step was applied to the cell. The electronic charge transfer is dependent upon the length of the specimen, the magnitude of the voltage step, and the concentration of electron holes at the reversible electrode. It was therefore decided to work at lower temperatures with very thin samples. A sample of length 0.085 cm was used for the measurements. Various small voltage steps of about 20 mV were applied in the voltage range of 200-450 mV. On the lower side of this voltage range, the plots of log I *vs.* time were

linear for times greater than 30 msec. On the other hand, at the higher side of this voltage range, *i.e.*, between 400 and 450 mV, the plots of log I *vs.* time were not linear. Figure 11 shows this difference. The dotted curve in Fig. 11 represents the characteristics for the voltage step of 0.4287 → 0.4489. This is due to the contribution from the electronic charge transfer. The calculation of electronic charge transfer can be carried out by using Eq. [17]. The concentration of electron holes equilibrated with copper at 264°C can be obtained by extrapolating our high temperature data (see Fig. 7). The calculation shows that the electronic charge transfer due to potential steps of 0.2476 → 0.2677V, 0.2678 → 0.2879V, and 0.2878 → 0.3089V at 242°C amounts to less than 5% of the total charge transfer. However, the electronic charge transfer due to a potential step of 0.4287 → 0.4489 constitutes about 50% of the total charge transfer. This is the reason for the nonlinearity of dotted curve in Fig. 11. Figure 12 shows plots of log I *vs.* time for two temperatures. It was found that for the three temperatures investigated, the double layer capacitance of the CuCl | graphite interface remained constant as has been observed by Raleigh for the case of the AgBr | graphite interface. The double layer capacitance was determined by the slope of log I *vs.* time plot. The current and time relation is given by

$$I = I_0 \exp(-t/R\,C_{dl}) \qquad [41]$$

where R = resistance of electrolyte and C_{dl} = double layer capacitance at the CuCl | inert electrode interface. The average value of the double layer capacitance was found to be 729 ± 60 μF/cm^2. Figure 13 shows the plot of the total charge transfer *vs.* the magnitude of voltage steps. Care has been taken not to exceed the electronic transfer more than 5% of the total charge transfer.

The linear relation between total charge transfer and the magnitude of voltage steps suggests that the double layer charge transfer is predominant over electronic charge transfer for this thin sample.

General comments on the above measurements.—We have discussed, in general, three methods of obtaining mobility of electronic carriers in cuprous chloride. These methods are applicable to any mixed conductor

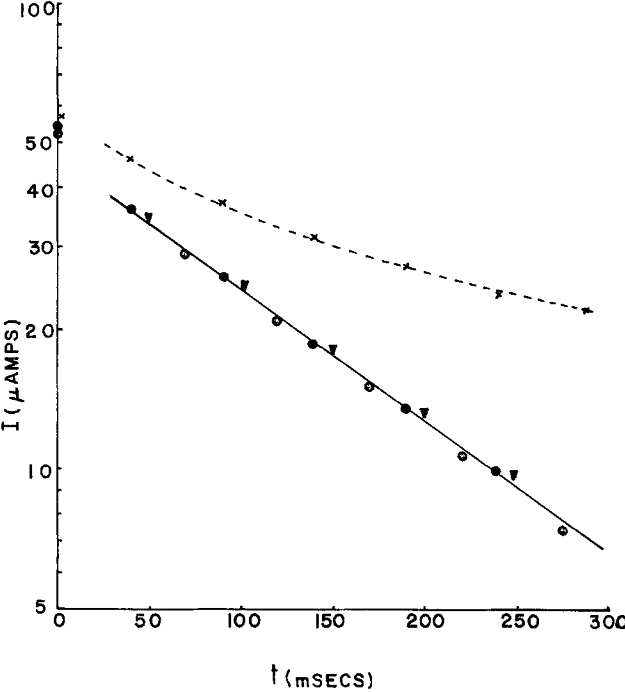

Fig. 11. Plot of log I *vs.* time for the case of thin sample of cuprous chloride for various applied voltage steps at a temperature of 242°C. ●, 0.2476-0.2677V; ○, 0.2678-0.2879V; ▼, 0.2878-0.3080V; ×, 0.4287-0.4489V.

MX in which the electronic charge transfer can be made predominant with respect to other processes. This can be easily achieved in a polarized cell, if the concentration of electronic carriers exponentially increases with the applied potential. In such a case, the

electronic charge transfer can be made predominant over the other processes by using a longer sample and also by using a large potential step.

Among the three techniques used in this study, we found the charge transfer technique was the most reliable. In the other two methods the effect of other interface processes (*e.g.*, diffusion of copper in an inert electrode and double layer capacitance) if present, could interfere with the determination of electron hole diffusivity. This problem is entirely eliminated in our use of the charge transfer technique since the technique eliminates the effects due to interfaces by carrying out the measurements on two samples of different lengths. These measurements also indicate that the requirement that the transference number by virtually unity is not a sufficient condition for an electrolyte to be used for a galvanic cell for the various thermodynamic measurements as has been described by Wagner (2) and Joshi (7).

The exponential increase of concentrations of electron holes with the applied voltage at the blocking electrode interface can be the limiting factor in the use of the electrolyte for electrochemical diffusion measurements of the elemental component of an electrolyte into an inert electrode. Recently Goldman and Wagner (22) have successfully used a cell Cu | CuCl | Au to measure the diffusion of Cu in Au. These workers insured that the electron hole current contribution to the total transient current was negligible. This was achieved by using a very thin sample of CuCl and by using temperatures higher than 350°C. Thus, in the measurements involving transient currents, one should be aware of the transient electronic current resulting from the redistribution of electronic carriers in response to the new potential. The electronic current is especially important in ionic conductors where the concentration of electronic carriers exponentially increases with the applied potential.

Summary and Conclusions

The measurements of conductivity, mobility, and concentrations of electron holes were carried out on single crystals of cuprous chloride. The half-power dependence of electron hole conductivity on chlorine pressure was indirectly verified in the temperature range of 100°-400°C. Further it was found that cuprous chloride is predominantly an ionic conductor throughout the above temperature range. The concentrations and mobility of electron holes in cuprous chloride was determined by three methods; namely, charge transfer, relaxation, and I *vs.* $1/\sqrt{t}$ analysis. The mobility values obtained by the above three methods are in excellent agreement with each other in the temperature range of 300°-400°C. The double layer capacitance of CuCl | graphite interface was also measured at lower temperatures (200°-300°C). Ideal polarization behavior was observed for this interface.

Acknowledgments

The authors wish to thank Professor C. Wagner, Professor John Patterson, and Dr. D. O. Raleigh for helpful discussions during this work. The authors are also grateful to Dr. Okabe of Shizuoka University (Japan) for a gift of cuprous chloride single crystals. This work was supported by contract DAHC 15 67 C 0213 from the Advanced Research Projects Agency through the Materials Research Center of Northwestern University.

Manuscript submitted Sept. 26, 1974; revised manuscript received Feb. 27, 1975.

Any discusssion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Technical Notes

Electrochemical Oxidation of *tert*-Butylamine to 2,2′-Azoisobutane

A. U. Blackham,* Solim Kwak, and J. L. Palmer

Departments of Chemistry and Chemical Engineering, Brigham Young University, Provo, Utah 84602

The electrochemical oxidation of primary aliphatic amines in aqueous solution is complicated by the closeness of the oxidation potentials of the amine and the solvent water. Barnes and Mann (1) have studied the electrochemical oxidation of several primary amines at a platinum anode in acetonitrile to avoid this interference by the solvent. Two reaction paths were postulated to account for the products observed. Most of the amines studied followed both reaction paths simultaneously. However, *tert*-butylamine followed only one path. In one of the steps of this path a carbonium ion was generated

$$RNH_2 \xrightarrow{-e} \dot{R}NH_2^+ \rightarrow R^+ + \dot{N}H_2$$

Accordingly, the reaction products observed were *tert*-butyl alcohol and isobutylene.

We report in this note an electrochemical oxidation of *tert*-butylamine in sharp contrast to the above reaction as the concentration of the *tert*-butylamine is drastically changed. The major anodic product from a concentrated solution in which *tert*-butylamine is essentially the solvent as well as the reactant is azo-*tert*-butane (2,2′-azoisobutane)

$$2t-BuNH_2 \xrightarrow[-4H^+]{-4e} t-Bu-N{=}N-t-Bu$$

Our initial concern in this study was the development of a satisfactory synthesis of azo-*tert*-butane. A few preliminary electrolyses were run in a small H-cell. The progress of the reaction was determined by gas chromatographic detection of the products soluble in 2,2,4-trimethylpentane. In dilute aqueous solutions of *tert*-butylamine with both platinum and graphite anodes only traces of azo-*tert*-butane were detected. As the concentration of *tert*-butylamine in the electrolyte was increased, more azo-*tert*-butane was observed. Also, azoxy-*tert*-butane and nitroso-*tert*-butane were detected. These trends suggested a high concentration of *tert*-butylamine would favor the synthesis of azo-*tert*-butane. Accordingly, a large scale preparative cell was constructed. The following experimental details are for a run made in this cell.

Experimental

Preparative cell.—The anodes were cut from a block of graphite. Each had the dimensions 0.60 × 7.0 × 25.0 cm with a small tab at the top for contact with a copper rod. The cathodes were cut from a sheet of stainless steel. Each had the same length and width as the anodes and with a similar tab. An alternating array of 22 anodes and 23 cathodes were placed in a box 10 × 36 × 36 cm constructed from acrylic plastic. Spacers between the electrodes permitted a distance of 0.5-0.7 cm between the anodic and cathodic surfaces. The evolution of hydrogen provided a stirring action to the electrolyte. This cell design was based on the assumption that the hydrogen gas liberated at the cathode and the azo-*tert*-butane formed at the anode would not react further at opposite electrodes.

Synthesis.—The electrolytic solution was prepared by mixing 2500g *tert*-butylamine, 366g water, and 34g $NaClO_4 \cdot 6H_2O$. Therefore this was an 86% *tert*-butylamine solution. This solution which measured about 4 liters was placed in the cell and electrolyzed at 3.0V. A current of about 2.0A flowed through the cell until 23.0f of charge had passed. The calculated current density for an 80% immersion of the electrodes was 0.33 mA/cm^2. The reaction mixture was diluted with water resulting in two phases. The upper organic phase was distilled yielding 423g of azo-*tert*-butane and 50g of azoxy-*tert*-butane. Of the charge that passed through the cell 41% accounted for the azo compound and 5% for the azoxy compound. About 20g of a white crystalline solid was recovered from the diluted reaction mixture. This was later characterized as di-*tert*-butylurea. The progress of the reaction was periodically determined by gas chromatography. A 2 ml sample of the reaction mixture was mixed with 2 ml of 2,2,5-trimethylhexane and 10 ml water. The gas chromatograms of the hydrocarbon phase had large peaks for the azo and azoxy compounds. Other compounds shown to be present in smaller amounts were isobutylene, isobutane, and nitroso-*tert*-butane. The gaseous product from the reaction contained hydrogen, isobutylene, isobutane, nitrogen, and oxygen. However, the gaseous products were not analyzed accurately and periodically to establish complete material and charge balances. The aqueous phase from the reaction product contained unreacted *tert*-butylamine.

Characterization of products.—Azo-*tert*-butane[1] was distilled at 105°C at 650 Torr (lit. value 109-110 at 760) (2, 3). The NMR spectrum gave a singlet at 1.13 δ. Azoxy-*tert*-butane[1] was distilled at 141°C at 650 Torr. The NMR spectrum gave two singlets at 1.27 and 1.47 δ (lit. values 1.28 and 1.48) (4). The nitroso-*tert*-butane was characterized by its NMR spectrum from gas chromatographic collection in carbon tetrachloride. The solution was blue. The NMR spectrum gave a singlet at 1.24 δ (lit. value 1.25 δ) (4).

The di-*tert*-butylurea was easily sublimed and a mass spectrum was taken of a pure sample. The mass spectrum gave a parent peak at 172 amu with major fragments at 100 (t-$BuNH\overset{+}{C}O$), 72 (t-$Bu\overset{+}{N}H$), 56 ($C_4\overset{+}{H_8}$), and 15 ($\overset{+}{C}H_3$). Some infrared spectral assignments were a NH peak at 3352 cm^{-1}, a CH absorption for *tert*-butyl group at 1388-1319, and a carbonyl absorption at 1630 cm^{-1}. The NMR spectrum (run with

* Electrochemical Society Active Member.

Key words: amine oxidation, electrochemical synthesis, azoalkane, nitrene.

[1] Azo-*tert*-butane and azoxy-*tert*-butane are available from Fairfield Chemical Company, Blythewood, South Carolina 29016.

chloroform as the solvent) gave two peaks at 1.29 and 1.44 δ in a ratio of 9:1. The melting point in a sealed tube was 258°-260°C (lit. value 245°C) (5). In an open capillary tube vigorous sublimation was observed at 242°-250°C.

Discussion

We are considering two possible reaction pathways for this electrolytic oxidation of *tert*-butylamine. The first step may involve a one-electron loss leading to the formation of a free radical, t-Bu$\dot{N}$H, or a two-electron loss leading to the formation of a nitrene, t-BuN. The reaction products isolated can be explained by both intermediates. However, di-*tert*-butylhydrazine which would be expected from the dimerization of t-Bu$\dot{N}$H was not found as a reaction product.

This electrochemical synthesis offers some advantages over chemical oxidations of *tert*-butylamine. Farenhorst and Kooyman (3) prepared the N-chloro-*tert*-butylamine and reacted it with silver oxide to obtain a 5% yield of azo-*tert*-butane. Stevens (6) oxidized *tert*-butylamine with IF_5 to obtain a 48% yield. Stowell (7) reacted N,N'-di-*tert*-butylsulfamide with NaOCl to obtain an 84% yield.

Compared with these chemical methods, the electrochemical synthesis of azo-*tert*-butane can be conducted with cheaper reactants and reagents and with a higher or comparable percentage conversion.

Further work is in progress to establish complete material and charge balances; to determine yields as a function of current density and concentration; and to determine the number of electrons in the first electrochemical step.

Comparison of Some Solutions for the Warburg Impedance of a Rotating Disk Electrode

E. Levart and D. Schuhmann

Laboratoire d'Électrolyse du Centre National de la Recherche Scientifique, 92190 Bellevue, France

Homsy and Newman (1) have recently given the following solution for the Warburg impedance of a rotating disk electrode, valid only for high frequencies and large Schmidt numbers

$$\theta'(0) = -\sqrt{jK} + 3j/4K + 0(K^{-5/2}) \qquad [1]$$

In this equation (Eq. [12] in their paper), K represents a dimensionless frequency and $\theta'(0)$ is the derivative of a complex dimensionless time-varying concentration on the disk surface.

Using the corresponding expressions obtained for $\mathrm{Re}[1/\theta'(0)]$ and $\mathrm{Im}[1/\theta'(0)]$, these authors have evaluated the real and imaginary parts of the Warburg impedance. The error between their results and the exact solution does not exceed 2% for $K = 10$, which evidently offers an improvement over the Nernst stagnant diffusion-layer approximation in the region of intermediate to large K.

Meanwhile, we have published a general method for evaluation of the concentration impedance for a rotating disk electrode (2) which includes the problem above as a particular case. Our asymptotic solution, valid for high frequencies and any finite value of the Schmidt number involved in electrochemistry, was given in the following form

$$M^\circ(\tau,\sigma) = a^{-1/3}\,\tau[u^{-1/2} - \tfrac{1}{4}u^{-2} + 0.3\tau u^{-5/2} + 0(u^{-3})] \qquad [2]$$

where $\tau = \mathrm{Sc}^{-1/3}$ and $u = \chi + j\sigma$. The dimensionless complex variable, u, is related to the frequency by $\sigma = \omega/\Omega\tau a^{2/3}$ and to the rate constant k of the chemical reaction following or preceding charge transfer by $\chi = k/\Omega\tau a^{2/3}$ (for a first-order reaction, $k = \vec{k} + \overleftarrow{k}$). $M^\circ(\tau,\sigma)$, a dimensionless concentration impedance, is the value of a very general transfer function $M(z,\tau,\sigma)$ at the surface of the disk. M, which may be considered as the inverse of the Nusselt (Sherwood) function (3), is proportional to the local variations in the concentration.

For the case of the pure Warburg impedance without chemical complications, Eq. [2] may be written for very large Schmidt numbers as follows

$$M^\circ(\tau,\sigma) = a^{-1/3}\,\tau[(j\sigma)^{-1/2} - \tfrac{1}{4}(j\sigma)^{-2} + 0(\sigma^{-7/2})] \qquad [3]$$

Since Eq. [3] is not usable for $\tau = 0$, we divide by $M^\circ(\tau,0) = (3/a)^{1/3}\Gamma(4/3)\tau$, obtaining

$$\Phi^\circ = M^\circ(\tau,\sigma)/M^\circ(\tau,0) = [(j\sigma)^{-1/2} - \tfrac{1}{4}(j\sigma)^{-2} + 0(\sigma^{-7/2})]/3^{1/3}\Gamma(4/3) \qquad [4]$$

If we replace σ and Φ° in Eq. [4] by their respective equivalents $K/3^{2/3}$ and $1/\theta'(0)\Gamma(4/3)$, we get the following equation

$$1/\theta'(0) = (jK)^{-1/2} + 3/4K^2 + 0(K^{-7/2}) \qquad [5]$$

which is more advantageous than Eq. [1].

First of all, the expressions for the real and imaginary parts of the Warburg impedance derived from Eq. [5]

$$\mathrm{Re}[1/\theta'(0)] = 1/\sqrt{2K} + 3/4K^2 \qquad [6]$$

and

$$\mathrm{Im}[1/\theta'(0)] = -1/\sqrt{2K} \qquad [7]$$

Key words: Warburg impedance, rotating disk electrode, asymptotic approximation, dimensionless quantity, complex plane graphical representation.

are simpler than the corresponding formulas of Homsy and Newman, (Ref. (1), Eq. [13] and [14]). Of course, the contrary may be said about the corresponding expressions for the Warburg admittance.

The important point is that the results obtained using Eq. [6] and [7] agree much better with the numerical exact solution than do the results from Homsy and Newman's equations. As a matter of fact, our error does not exceed 0.2% for $K = 10$, which is one order of magnitude better than the 2% stated by these authors. The same error of 2% which they have for $K \approx 10$, we get for $K \approx 5$. Table I summarizes these results.

We have found that by continuing the (nonconvergent) series expansion of Homsy and Newman we obtain the same result as on inverting our continued expansion. Thus the lower error of our expression (limited, as is that of Homsy and Newman, to the two first terms) results from the smaller contribution of the truncated terms.

We wish to take this opportunity to add a word of caution concerning the graphical representation of such results in the complex plane. Such a representation, frequently used, can be misleading if the corresponding frequencies are not indicated on the graph. For example, looking only at Fig. 1 of Ref. (1), we may think that the proposed asymptotic solution agrees with the exact solution over the entire region where both curves are superimposed, that is, up to $K \approx 4$. In view of their accompanying numerical data, this is evidently not the case. We believe that for this purpose it is more convenient to represent separately the real and imaginary parts of the reduced impedance *vs.* the reduced frequency, as we show here on Fig. 1. The data calculated by Homsy and Newman and those from our asymptotic solution are compared with the exact solution (continuous curves). The black dots represent the results obtained by another approximation, valid only for low and intermediate frequencies, which we had proposed in the paper quoted above (2). These last data were calculated by dividing the values of $\text{Re}(\lambda^\circ_1)$ and $\text{Im}(\lambda^\circ_1)$, published in Table 3 of that paper, by $(3/a)^{1/3} = 1.8049$. They agree perfectly with the exact solution over the entire region of frequencies from $K = 0$ to $K = 30$ at least.

SYMBOLS

Generally used:

a	0.510233
j	$\sqrt{-1}$
Re, Im	real and imaginary parts of a complex quantity
k	chemical-reaction rate constant, sec^{-1}
ω	angular frequency (pulsatance) of alternating current, rad/sec
Ω	rotation speed of disk, rad/sec
Sc	Schmidt number

Used by Homsy and Newman (all are dimensionless):

θ	complex time-varying concentration
$1/\theta'(0)$	Warburg impedance
K	frequency

Used by Levart and Schuhmann (all are dimensionless):

M°	concentration impedance
u	complex variable related to χ and σ
Φ°	Warburg impedance
λ°_1	first coefficient in the series expansion of M° in powers of τ
σ	frequency
τ	$\text{Sc}^{-1/3}$
χ	reaction rate constant

Brief Communication

Note on the Stability of Impregnated Paper Separators

Barbara A. Campbell and J. R. Dafler*

ESB Incorporated, Yardley, Pennsylvania 19067

Impregnated paper separators, made by typical paper-forming techniques, then impregnated with thermosetting resins, are widely used in automotive battery technology. They possess distinct cost advantages compared with microporous rubber or sintered polymer separators. They are adequate for shallow cycling use typical of automotive storage batteries. They tend to fail after a few hundred cycles when discharged at 5 and 10 hr rates. The mechanism of failure is not clearly defined but related to physical and chemical stability.

Our investigation of stability is based on x-ray diffraction measurements of the crystalline cellulose present in the separator matrix. Hermans and Weidinger have explored the question of crystallinity and recrystallization in a series of papers (1-3). The question on order or crystallinity of cellulose has been discussed at some length (4-6). For the purposes of this study the term crystallinity serves well.

We have not used the same technique but have concentrated on direct x-ray comparisons of the crystalline material in unimpregnated paper, finished, and used separators. Using typical diffractometer techniques and postsample monochromated Cu-radiation ($\lambda = 1.543\text{Å}$), we obtained patterns very similar to those Hermans and Weidinger (1) obtained with a microcamera and a carefully compressed plug of sample. As in the case of Hermans and Weidinger, all samples tested gave diffuse peaks in the region 8-15° 2θ, and a much taller, less diffuse peak in the neighborhood of 22° 2θ. All samples tested were derived from the same source of α-cellulose.

Experimental

A large bundle of impregnated paper separators was selected and cut in quarters, the samples then shuffled and divided into groups for storage in sulfuric acid. About 50 such chips were stored at 125°F in sulfuric acid of three concentrations. In addition, one acid medium was saturated with $PbSO_4$. The acid concentrations were defined by the following specific gravities; 1.260, 1.280, and 1.325. Samples were taken from acid storage at intervals and examined by x-ray diffraction.

A number of automotive batteries were fabricated and put on cycle testing. The testing (SAE Schedule K) consisted of discharging for 1 hr at 20A followed by charging at 5A for 5 hr. Separators were taken at 5 and 9 week intervals and washed thoroughly in cold water to free the surfaces of Pb-salt accumulations. After drying the samples, representative chips were taken for x-ray analysis. All sets of x-ray diffraction scans were made with a "blank" chip of the basic α-cellulose used in the paper matrix. This was done to allow normalization of diffractometer intensities to a standard value. A Philips Electronics Mark II x-ray diffractometer was used to obtain x-ray intensity data. The analyses were done at Cu-target parameters of 35 kVA and 15 mA x-ray current. Figure 1 indicates typical diffractometer traces for unimpregnated paper, virgin separators, and separators stored 3690 hr in 1.280 specific gravity H_2SO_4. Counts and relative intensities were also normalized with respect to density of the cellulose compacts.

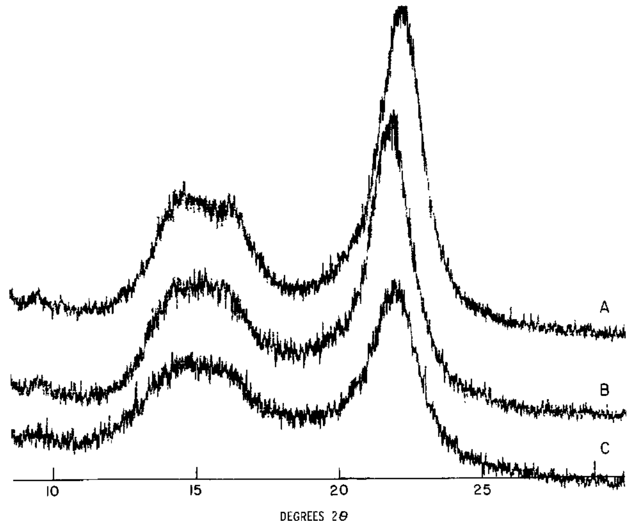

Fig. 1. X-ray diffraction traces. A, Scan of α-cellulose raw material; B, unused separator; C, separator after storage in 1.280 specific gravity H_2SO_4 at 125°F for 3690 hr. All scans were done at the same x-ray field strength and tube current.

Discussion

Hermans and Weidinger and others compared integrated intensity measurements to arrive at a measure of cellulose crystallinity. In this work, the integrated value of the major crystalline peaks are compared with those obtained with samples of unimpregnated paper. The measurement was made by establishing an arbitrary baseline on the line between intensities at 8 and 30°. The integrated areas, A_x, are then compared to those of the untreated source of α-cellulose, A_{std}, then corrected for density. Table I shows data from separators stored in 1.280 H_2SO_4, 1.325 H_2SO_4, and separators taken from batteries cycled for 5 and 9 weeks.

Table I. Crystallinity index: paper separators A_x/A_{std}

Specific gravity	Acid storage Hours at 125°F			Cycled battery samples Weeks cycled at 125°F	
	0	1360	3690	5 (140 cycles)	9 (252 cycles)
1.280	0.59	0.55	0.42		
1.325	0.59	0.48	0.42	0.063	0.080

Work in this study shows that impregnated paper separators possess excellent long-term resistance to attack by H_2SO_4 at specific gravities much higher than those encountered in automotive batteries. The basic α-cellulose structure, measured by an index of crystallinity, is not severely attacked during static storage. During cycling, however, the index of crystallinity decreases very rapidly. Work started here suggests this

* Electrochemical Society Active Member.
Key words: cellulose, crystallinity, x-ray diffraction, lead-acid separators.

Table II. Crystallinity index: separators stored in 1.260 H_2SO_4 saturated with $PbSO_4$

Hours at 125°F	A_x/A_{std}
0	0.55
1360	0.39
2400	0.29

may be due to physical damage. Uncycled separator pieces, stored at 125°F in 1.260 H_2SO_4 saturated in $PbSO_4$, suffer a similar decrease in crystallinity over similar storage periods. The data are summarized in Table II. It is indicated that the dynamic processes of solution/dissolution of the $PbSO_4$ imbibed in the fiber matrix may stress the fiber matrix to a sufficient extent to damage the basic material, lowering the crystallinity index.

The greater resistance to degradation in 1.325 H_2SO_4 compared to the losses of crystallinity in 1.260 acid plus $PbSO_4$ support this argument. In cycling, the dynamic processes of solution/dissolution degrade the cellulose matrix to a greater degree over shorter periods of time.

Independent microscopic examination of cycled separators found frequent examples of brittle fracture of the fibers. In cycled separators, in which considerable amounts of Pb-salts are imbibed and trapped in the fiber matrix, considerable physical damage to the cellulose is expected. Shedding and shape change of electrodes deposit salts and stress the cellulose in a significant way.

Absolute X-Ray Efficiencies of Some Phosphors

J. A. de Poorter and A. Bril

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

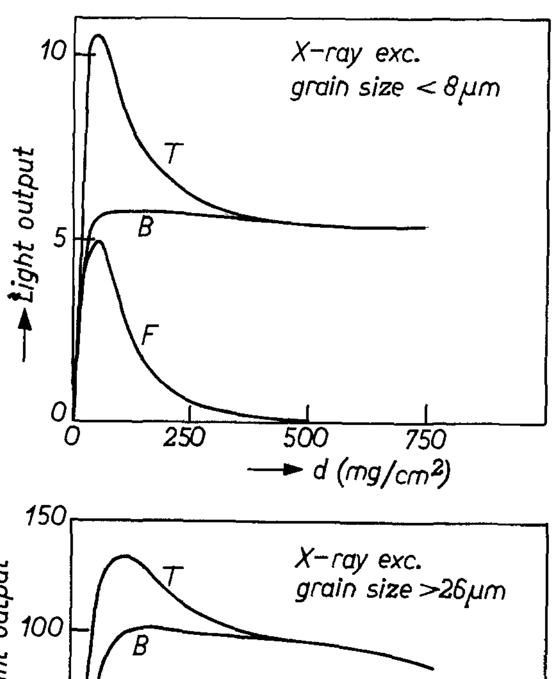
Efficiencies of various powder phosphors under x-ray excitation are determined. Thin layers are used to minimize the loss in light output due to scattering and absorption of the emitted luminescence. The luminescence of the layer is measured with the aid of a calibrated photomultiplier. The absorbed x-ray radiation is measured with a scintillation crystal. The efficiencies found are of the order of the cathode-ray efficiencies; calcium tungstate has the largest deviation.

A review of published data (1-5) on the efficiencies of phosphors with x-ray excitation is given in the paper of Ludwig (6). The author reports efficiencies of powder phosphor layers irradiated with x-rays generated by radioisotopes with energies between 27 and 122 keV. The light output was measured as a function of the weight per square centimeter of the layer while the x-ray absorption was calculated with the aid of tables published by Storm and Israel (7).

As is well known, the light output of a phosphor screen used as a front screen is often different from the light output when used as a back screen. (Front screen output means the output at the nonirradiated side; back screen that at the irradiated side). This difference in light output is due to absorption of the luminescent radiation in the layer. The path length of this radiation is much longer than the real thickness of the layer (the latter is generally more than 100 μm) because of scattering of the luminescent radiation by the phosphor grains. With the aid of the formulas of Hamaker (8) and Klasens (2) the measured light output can be corrected for the loss. This was done by Ludwig, who found a reasonable agreement between cathode-ray efficiencies and the corrected x-ray efficiencies of the phosphors considered. However, the disadvantage of this method is that very large corrections are generally necessary, the real efficiency being 3 to 6 times higher than the values measured. Sometimes the difference is even greater. The marked influence of the scattering is demonstrated in Fig. 1, where the output curves are given for the small grain size fraction (< 8 μm) and the large grain size fraction (> 26 μm) of CsI-Na powder layers as a function of powder weight. We determined these curves experimentally; the spectral power distribution of the exciting x-ray source is given in Fig. 2. The optimum front screen output of the small grain size fraction is very small compared with that of the large grain size fraction due to the stronger scattering (*i.e.*, more absorption) as a consequence of the smaller grain size.

This is contrary to the case of cathode-ray excitation of, *e.g.*, 20 keV, where the correction required for front screen output is only small [generally 10% or less, see Bril and Klasens (9)], due to the fact that the penetration depth of fast electrons is only a few micrometers. Therefore thin layers can be used in that case for maximum absorption of the cathode rays. In order to obtain a negligible correction for the light output with x-ray excitation we used thin layers in the latter case too.

The absorption of the x-rays in the layer was also measured, because the values given in the tables are



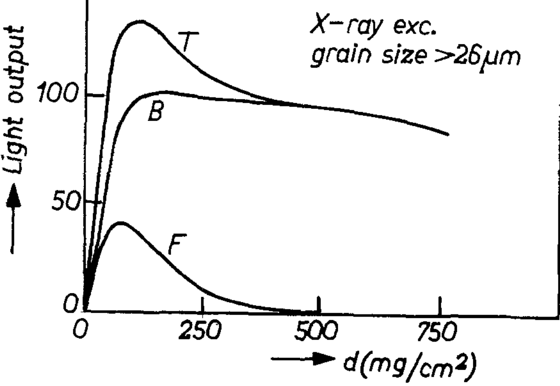


Fig. 1. Front screen (F), back screen (B), and total light output (T) as a function of layer thickness for a sample of CsI-Na. (a) Grain size < 8 μm, (b) grain size > 26 μm.

Key words: luminescence, fluorescence, x-ray excitation, radiant efficiencies.

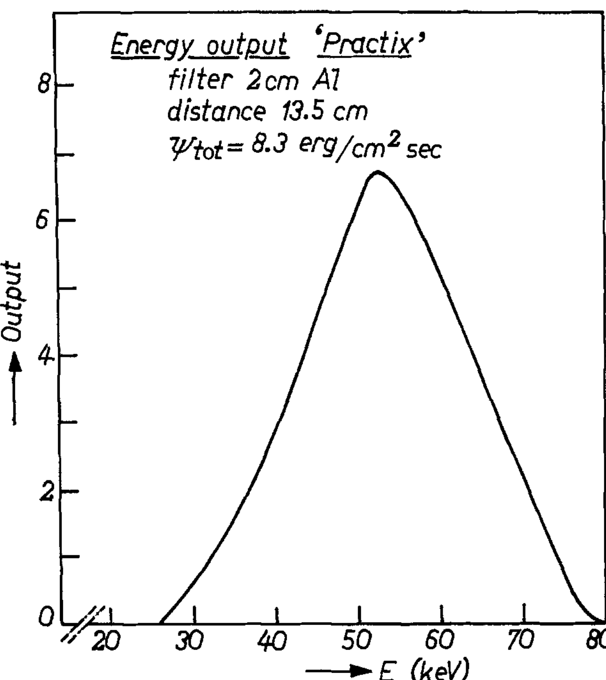

Fig. 2. The spectral power distribution of the x-rays emitted by the "Practix" x-ray tube, filtered by 2 cm Al.

not quite valid for use in the case of x-ray luminescence for reasons explained in the last section.

Experimental

The x-ray source used was a Philips "Practix" tube, operated at a voltage of 75 kV and a tube current of 1 mA. An aluminum filter with a thickness of 2 cm was placed in front of the tube to make the spectral bandwidth narrower. The spectral power distribution and absolute output of the combination was measured in our laboratory by Van der Linden and De Wijk (10) with the aid of a scintillation spectrometer in which a NaI crystal with photomultiplier was employed as a detector. The spectral power distribution is shown in Fig. 2. We chose the thickness of the phosphor layer as equivalent to a screen weight of 25 mg/cm². The layer was applied between two quartz plates. From Hamaker's formulas it was calculated that the loss in light output due to scattering in such thin layers is only a few per cent for a wide range of x-ray absorption coefficients.

A schematic drawing of the setup used for measuring the luminescence output of the phosphors is shown in

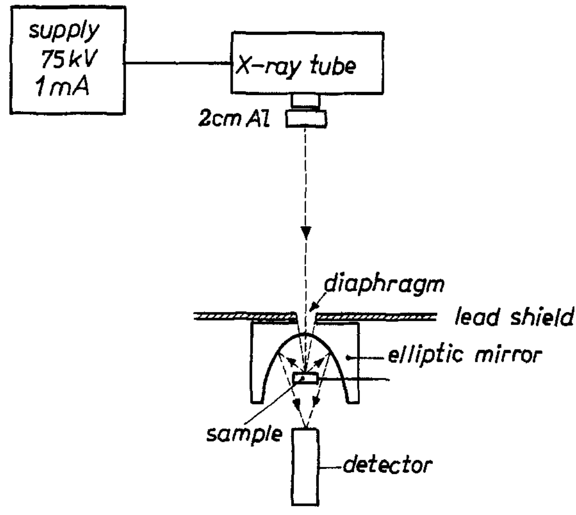

Fig. 3. Schematic diagram of the light output measurement

Fig. 3. The x-ray beam falls on the phosphor layer through a lead diaphragm producing an irradiated area of 1 cm diameter on the sample. Just below the sample a blackened lead shield is placed to prevent x-rays from reaching the photomultiplier and to absorb the luminescence emitted from the front side of the layer. The total back screen emission is collected by a 2π-geometry elliptic mirror (11) and focused onto the detector. The light transmission of the system is calibrated by first directing a light beam via a magnesium oxide screen toward the photomultiplier. Then the MgO screen is taken away, so that the light beam falls directly onto the detector. The transmission of the elliptic mirror system was found in this way to be 63%. The spectral and absolute response of the photomultiplier we used was measured with the aid of a Philips 150 uv photocell calibrated by the National Physical Laboratory in Teddington (Great Britain).

The x-ray absorption coefficients were both calculated and measured. The measurement was carried out in the following way (see Fig. 4). The x-rays transmitted by the phosphor layer are converted into visible radiation by a plaque of CsI-Tl which covers the window of a photomultiplier. The latter collects the generated visible radiation. In order to obtain a more accurate value of the absorption, thicker layers are used in this case than for the luminescence measurements. To obtain the x-ray absorption coefficient two measurements are carried out: (*i*) The transmission of the x-rays is measured with the sample placed at a large distance from the detector (Fig. 4a). (*ii*) The transmission of the x-rays is measured when the sample is placed on the detector (Fig. 4b). In the latter case nearly half of the escaping x-ray fluorescence also reaches the detector. From these two measurements the mass absorption coefficients can be calculated: $(\mu/\rho)_F$ when the escaping parts of the x-ray fluorescence is taken into account and $(\mu/\rho)_{NF}$ when the x-ray fluorescence is not considered (see next section). The x-ray absorption coefficient is denoted by μ, the density by ρ.

Gd_2O_2S-Tb	8.08	7.7	4.14	5.7	50.2

Results and Discussion

We compare the measured absorption coefficients with those calculated from the extensive tables published by Storm and Israel (7). From the coefficients given in these tables $(\mu/\rho)_{tot,a}$ refers to the absorption determined by the difference of the incident monochromatic x-radiation and the transmitted x-radiation of the same wavelength. The coefficient $(\mu/\rho)_{tot,en}$ also accounts for the escape of the emitted x-ray fluorescence of longer wavelengths than that of the incident x-rays. In practice however, only part of the x-ray fluorescence is absorbed and gives rise to luminescence. Therefore $(\mu/\rho)_{tot,en}$ does not give the correct absorption for our efficiency measurements; moreover in the table all data refer to the element in consideration while the phosphors are composed of a number of elements. Consequently the absorption of the x-ray fluorescent radiation will be different from that assumed in the table, especially in cases where the K-absorption edges of one or more of the constituent elements of the phosphor lie within the region of the spectral power distribution of the x-rays. Therefore, it is better to use the absorption coefficient $(\mu/\rho)_F$ as defined in the experimental section. From the foregoing it is evident that the measured absorption coefficients $(\mu/\rho)_F$ will have a value between $(\mu/\rho)_{tot,a}$ and $(\mu/\rho)_{tot,en}$. The results of the absorption measurements are given in Table I, together with $(\mu/\rho)_{tot,a}$ and $(\mu/\rho)_{tot,en}$ from Storm and Israel's tables. We see that the measured $(\mu/\rho)_F$ does indeed lie between the calculated $(\mu/\rho)_{tot,a}$ and $(\mu/\rho)_{tot,en}$ within the error of measurement, and that the deviation between $(\mu/\rho)_F$ and $(\mu/\rho)_{tot,en}$ is large in the cases where the K-absorption edges of the phosphor elements play a role, as is expected (*e.g.*, CsI-Tl and La_2O_2S-Tb).

We also see from the table that the calculated absorption coefficient $(\mu/\rho)_{tot,a}$ is in reasonable agreement with the absorption coefficient $(\mu/\rho)_{NF}$ measured with the detector at a large distance, as should be the case. However, these figures $(\mu/\rho)_{NF}$ cannot be used in our experiment because of the reason mentioned above. Table II gives the radiant efficiencies of the phosphors as determined from the measured absorption coefficient $(\mu/\rho)_F$ and the measured light output. Also given in the table are the radiant efficiencies we obtained with cathode-ray excitation [excitation voltage 20 kV; thick layer in a demountable tube, see Ref (9)].

Table II. Radiant efficiencies

Phosphor	X-ray excitation, %	Cathode-ray excitation (20 keV), %
$CaWO_4$, NBS No. 1026	6.5	3
$CaWO_4$, larger grain size	8	3.5
Zn_2SiO_4, NBS No. 1021	11.5	8
ZnS-Ag,NBS No. 1020	17	21
$BaSi_2O_5$-Pb, NBS No. 1032	3.5	4
$BaSi_2O_5$-Pb, own sample	3.5	4
(0.58 Zn, 0.42 Cd) S-Ag (TV-sample)	14.5	21
(0.64 Zn, 0.36 Cd) S-Ag (large grain size)	19	19.5
CsI-Tl	10	9
La_2O_2S-Tb	12.5	11
Gd_2O_2S-Tb	13	11

A reasonable agreement is found for most phosphors when the efficiencies for x-ray and cathode-ray excitation are compared. An exception is $CaWO_4$, which is often used for x-ray screens. We found for x-ray excitation about twice the value for cathode-ray excitation, for which we have no explanation up to now.

Acknowledgments

We are indebted to Prof. Dr. W. J. Oosterkamp for valuable discussions and for the measurement of the spectral power distribution of the x-ray tube carried out in his research group. Acknowledgments are also due to Dr. Ludwig for drawing our attention to the various tables of Storm and Israel, and to the departments of Ir. Schuil, Dr. Wanmaker, and Mr. Snethorst for the preparation of a part of the phosphor samples.

Manuscript submitted Feb. 4, 1975; revised manuscript received April 14, 1975. This was Paper 114 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Resolution of X-Ray Intensifying Screens

A. F. Sklensky,* R. A. Buchanan, T. G. Maple,* and H. N. Bailey

Lockheed Palo Alto Research Laboratory, Palo Alto, California 94304

ABSTRACT

The purpose of this study is to experimentally explore the dependence of the speed and resolution of radiographs on the thickness and phosphor packing density of rare earth oxysulfide intensifying screens. The quantitative dependence of resolution on the following parameters is also discussed: the wavelength of the emitted light, the presence of a reflective backing, the concentration of dye in the binder, and the use of double screens and film *vs.* single screens and film. It is found that a trade-off exists between speed and resolution for variation of screen thickness, the placement of a reflective backing on the screen, and dye in the binder, and the use of double screens and film. The green-emitted light gives a slight, but usually negligible decrease in resolution over blue-emitted light. Increased packing density increases the speed with little or no sacrifice of resolution.

The resolution that an x-ray intensifying screen permits on a radiograph is a key factor in determining radiographic quality. Nevertheless, we have been unable to find any literature treating screen construction technique.

X-ray intensifying screen properties are only one factor in determining quality. Image quality is determined by many factors. First, we have the properties of the subject itself such as x-ray absorption contrast, scattering, and the spatial frequency of the image. Next are the properties of the x-ray source and the geometry involved, such as focal spot size and shape, the film to focal spot distance, and the energies of the x-ray photons. Finally, we have the film characteristics and screen characteristics. Screen characteristics may be broken down into categories, such as technique (single screen and film *vs.* double screen and film), phosphor properties (speed, optical properties, response to x-ray photons of different energies, and the energy of emitted photons), and manufacturing parameters (uniformity, phosphor particle size, the presence or absence of a reflective backing, the optical properties of the binder, the thickness of the screen, and particle packing density).

Of these many factors, our interest is in the effect that an increase in phosphor speed can have on the speed and resolution of a radiographic system. It is self-evident that greater speed in the phosphor permits greater speed in the screen for a given resolution. The purpose of this paper is to show some ways in which greater speed in the phosphor also permits greater resolution for a given speed.

The reason for our interest in the changes in radiographic quality that result from an increase in phosphor speed, is that the oxysulfide phosphors were developed in our laboratory (1-3). We have been exploring the implications of their use in intensifying screens.

Other work in the area of image quality in radiographs has been done by Rao (4-6) and Morgan (7-8). Rao has integrated considerations of film gamma, subject contrast, scattering, quantum mottle and spatial frequency of the subject, and frequency response of the screen-film system, into a single expression for a quantity he calls the image contrast function.

It is shown in this paper that variations in screen manufacturing parameters result in variations in the speed and resolution obtainable with screens. Generally, but not always, a trade-off exists between speed and resolution. The amount of speed that must be traded for increased resolution is greater for some variations in manufacturing techniques than for others. We present here the effect of varying (*i*) the screen thickness, (*ii*) dye concentration in the binder, (*iii*) the use of a diffusely reflecting layer between the phosphor coating and the Mylar substrate, (*iv*) the packing density of the phosphor particles, (*v*) the wavelength of the light emitted by the phosphor, and (*vi*) the use of two screens and double-coated film in place of a single screen and single-coated film.

Experimental Technique

Screens and films used.—Commercially available phosphors from various sources were used in the manufacture of the screens. The rare earth oxysulfide (REOS) materials yttrium oxysulfide (YOS), lanthanum oxysulfide (LOS), and gadolinium oxysulfide (GOS) were the primary materials studied. The particle size within each batch varied from 10 to 20 μm down to a fraction of a micron. In addition, the average particle size in each batch of phosphor varied from about 10 to about 3 μm. Since extensive milling of the powders damages their fluorescent properties and separation is difficult, we did not control particle size and particle size was not studied as a parameter.

Screens were prepared in our laboratory by dispersing the phosphor material in a binder (B48N from Rohm and Haas) and drawing the mixture with a doctor blade. A 10-mil Mylar substrate was used. When a reflective backing was applied, the material used was TiO_2. It was also drawn with a doctor blade. For the dye experiments, Oil Red O was added to the binder. To determine the effects of a greater packing density, a portion of our phosphor was sent to Hyman laboratories where screens were pressed under a force of 725 psi. A density of 4.13 g/cm^3 was achieved, compared to 3.25 g/cm^3 that results from our standard laboratory procedure of simply drawing the screen. The bulk density for GOS is 7.4 g/cm^3.

Four different film types were used. For applications where single-coated film was needed, Kodak SB-54 was used as the blue-sensitive film, and Kodak Type O was used as the green-sensitive film. Du Pont Cronex 4 was the double-coated blue-sensitive film, and an early prototype green-sensitive film from 3M was used for the double-coated green-sensitive film. Where two screens have been used, the back screen is the same thickness as the front screen.

Speed and resolution measurements.—To determine the properties of the screens, a standard tungsten target medical x-ray source was used. Characteristic curves were determined by placing an optical step wedge between the screen and the film. The speed measurements at 90 kV$_p$ were made by placing a 1 in. thick aluminum plate in the beam. A coarse stationary grid (60 lines per inch, 6:1 ratio) was used in these experiments to reduce the scattered radiation level.

* Electrochemical Society Active Member.

Key words: intensifying screen construction, radiography, rare earth oxysulfides.

The speed measurements at 30 kV_p were made without the aluminum plate or the stationary grid.

Most resolution measurements were made with a single screen and single-coated film with the emulsion touching the screen. The screen was placed between the x-ray source and film. All resolution measurements were made at 30 kV_p. A lead bar pattern from Emil Funk (Type 53G) was placed immediately in front of the cassette. The lead grid is 50 μm thick and the bar pattern spatial frequency varies from 0.25 to 10 lp/mm. The film densities behind the grid for each spatial frequency were converted from maximum and minimum densities to maximum and minimum exposures through the characteristic curves previously determined at the same kV_p. We then plotted $(E_{max} - E_{min})/(E_{max} + E_{min})$ *vs.* spatial frequency. In other cases, cross plots are shown of the frequency at which $(E_{max} - E_{min})/(E_{max} + E_{min})$ drops to 0.2.

The effects of noise on resolution are not considered here. Noise in a radiograph has many sources; for example nonuniformities in the screen construction or in the film, film grain, and quantum mottle. The slit height on our densitometer is 2 mm, so all but the lowest spatial frequency noise components are averaged out of our measurements.

The decision to measure the speed at 90 kV_p and resolution at 30 kV_p was somewhat arbitrary. The 90 kV_p, heavily filtered, speed measurement corresponds to typical diagnostic medical procedures. However, the 30 kV_p single-screen technique for measuring the resolution does not. These latter conditions were chosen so that the x-rays would be absorbed far from the film and the light would have a significant distance to scatter through the screen. This maximizes the effect on the resolution of the various parameters being varied. In addition, the contrast from our lead foil resolution grid is greatest at the low kV_p, so we can measure the resolution differences more accurately.

Experimental Results and Discussion

Screen thickness.—Figure 1 shows the changes in speed at 90 kV_p and resolution at 30 kV_p that result from changes in the screen thickness. Measurements were made on both GOS and LOS screens. All the exposures were made with green sensitive film except the frequency response of GOS which was measured with SB-54 film. Speed measurements were made with double screens, the 1 in. aluminum block, and the stationary grid.

The scales that were chosen for presentation of these data were linear in both the spatial frequency and exposure. That is, a factor of 2 increase in exposure time will appear the same on these plots as a factor of 2 increase in resolution. This should be kept in mind while interpreting our results.

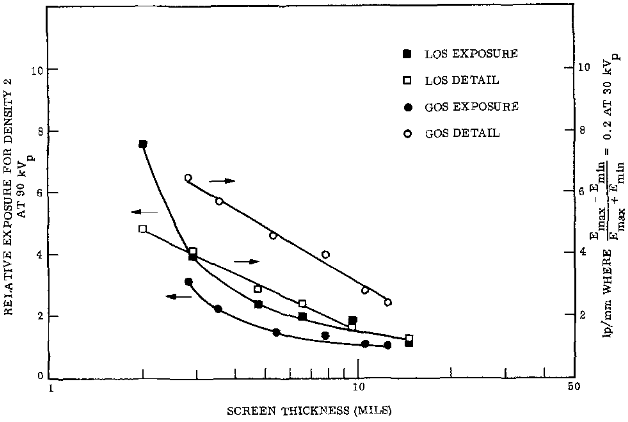

Fig. 1. Speed and resolution as a function of screen thickness. Screens are drawn, have no dye, and no reflective backing. Exposure values measured with double screens, and with green-sensitive, double-coated film. Resolution of LOS was measured with Type 0 film; of GOS with SB-54 film.

For both phosphors, at large thickness values (> 6 mils) the 90 kV_p exposure decreases little with increasing screen thickness, while the 30 kV_p resolution continues to decrease. At small thickness values (below 5 mils) exposure increases rapidly, even on the log scale used, toward the no-screen exposure value. Resolution increases with the same slope as at higher screen thickness values. The difference in resolution between LOS and GOS screens is tentatively ascribed to the difference in particle size between the phosphors. It is not believed to be due to a difference in phosphor properties, such as the x-ray absorption or energy conversion efficiencies.

Resolution changed by about a factor of 3 over the range of thickness values studied, while exposure varied over a factor of 3-6.

Dye concentration.—Figure 2 shows the improvement in resolution that is obtained through the use of dye in the binder. The increased exposure necessary is also shown. Both measurements were made at 30 kV_p.

Most of the light emitted by the LOS is green. GOS emits light in both the green and the blue. The red dye placed in the binder absorbs the light emitted by both phosphors. Since light that is scattered a greater distance from the energy conversion event travels a longer path length than light that is scattered less, the former undergoes greater attenuation and resolution is increased by the inclusion of dye in the binder. However, all the emitted light undergoes attenuation, so the exposure increases with dye concentration also.

For the thick GOS screens, there is a larger increase in resolution at low dye concentrations than at higher dye concentrations. For the thinner LOS screens, the initial improvement in resolution appears to require no increase in exposure. Over the entire range of the measurements for both phosphors, a 25% increase in resolution requires about a 100% increase in exposure. That is, only a relatively small increase in resolution was observed for a large increase in exposure time.

Packing density.—The high packing density screen displayed an increase in the speed at 90 kV_p (Fig. 3) with a negligible decrease in resolution at 30 kV_p (Fig. 4). The 7.2 mil high packing density screen required less exposure than the 12.5 mil drawn screen. The 7.2 mil high packing density screen has the same amount of phosphor per square centimeter as a 9.2 mil drawn screen.

Since we only had one screen available and were unwilling to cut it to obtain two screens for a double-screen, double-film experiment, all the data shown in

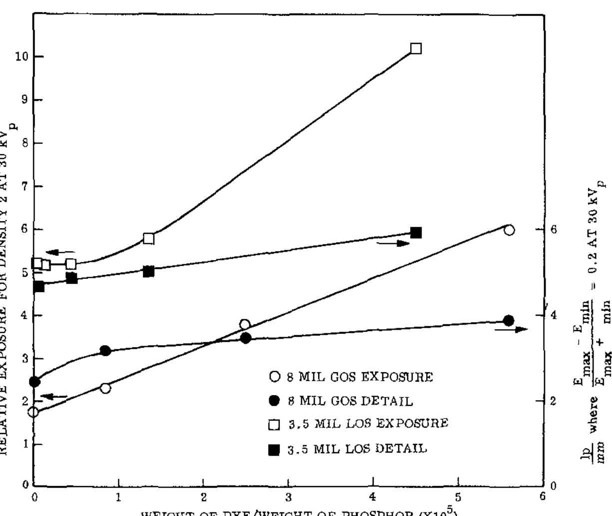

Fig. 2. Speed and resolution as a function of dye concentration. Screens are drawn and have no reflective backing. Exposure and resolution of GOS screens measured with SB-54 film, and of LOS screens with Type 0 film.

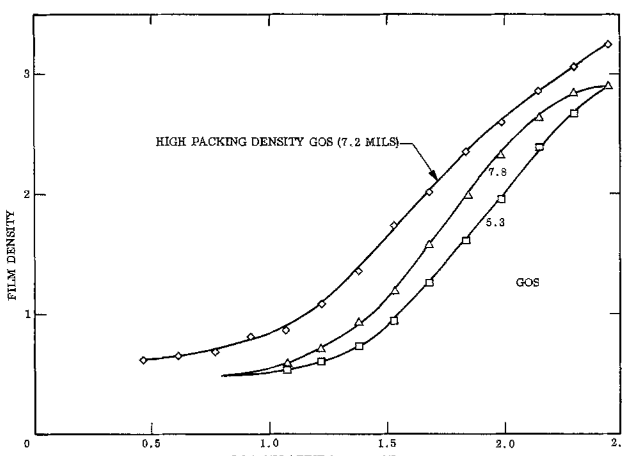

Fig. 3. Comparison of screen speed at 90 kV$_p$ between a high packing density screen and drawn screens. One inch of aluminum and a stationary grid were placed in the x-ray beam. All measurements use single screens and SB-54 film.

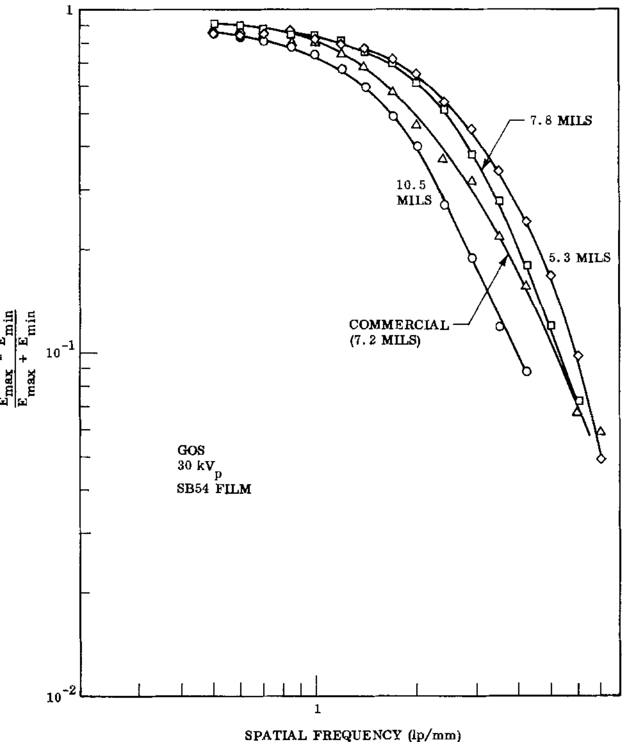

Fig. 4. Comparison of GOS screen resolution at 30 kV$_p$ between a high packing density screen and drawn screens. SB-54 film was used.

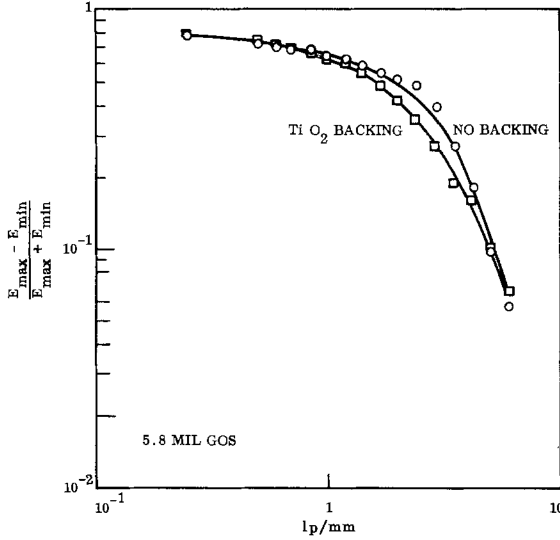

Fig. 5. Resolution of screens with and without a reflective backing. The exposure at 30 kV$_p$ using the screen with the backing was about 70% that used for the screen without the backing. SB-54 film was used.

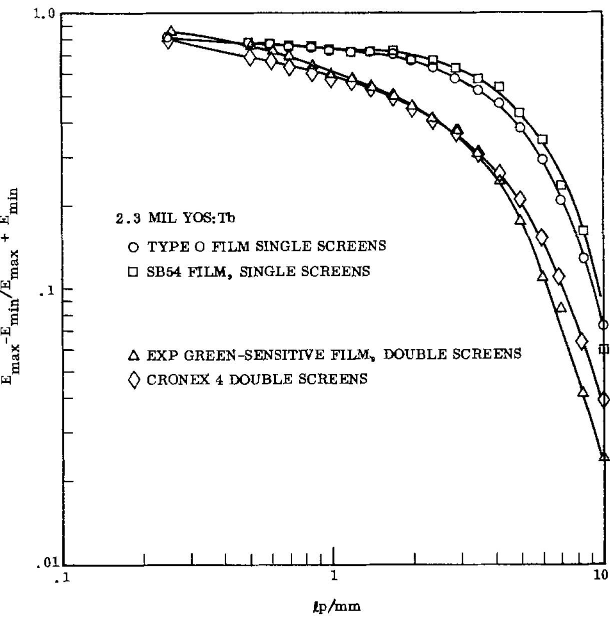

Fig. 6. Resolution of single and double screens, with no reflective backing, using blue-sensitive and green-sensitive film. The double-screen measurements were made with 25 sec exposures and ffd = 98 cm. The SB-54 film was exposed 4.8 sec and the Type 0 for 27 sec at ffd = 47 cm.

the figures were taken with single screens and single-coated film.

Reflective backing.—Figure 5 shows the decrease in resolution at 30 kV$_p$ that occurs when a reflective backing is placed on the screen. Evidently the increased scattering the reflected light undergoes decreases the resolution.

At low spatial frequencies, the two curves are nearly coincident, as would be expected if the SWRF for both is to go to 1 as $f \rightarrow 0$. At high frequency, the two curves join again. About a 30% decrease in exposure time results in about 13% decrease in resolution at the 20% $(E_{max} - E_{min})/(E_{max} + E_{min})$ point.

Wavelength of emitted photons.—Figure 6 shows the resolution of thin YOS screens at 30 kV$_p$ as measured by green-sensitive film and by blue-sensitive film. Green-emitted light is seen to give poorer resolution than blue-emitted light. Since the film sensitivity is broadband the effect is small. However, it does appear to be real. It was observed for both single and double screens, as may be seen in the figure. The experiments were repeated for GOS screens, and similar results were obtained. In addition, $(E_{max} - E_{min})/(E_{max} + E_{min})$ was measured as a function of frequency for the films without screens and their frequency response was found to be the same, within the accuracy of the measurements.

Double screens.—The decrease in resolution at 30 kV$_p$ that results from using double screens and double-coated film is also evident in Fig. 6. The decreased resolution is presumed to be due to spreading of light as it traverses the greater distance through the film base to the emulsion that is not in contact with the screen that emitted the light. At MTF = 0.2 the resolution is decreased by about 30% for double screens and double-sided film relative to single screens and single-sided film. The decrease in exposure necessary is not known, but would not be expected to be greater than 50%.

Conclusions

An empirical study has been presented of six of the many screen parameters that affect resolution, which may be varied at the screen designer's discretion. Most involve a trade-off between speed and resolution. High phosphor packing density, however, appears to increase speed with little or no sacrifice of resolution. The trade-off for green-sensitive film *vs.* blue-sensitive film depends on the phosphor. For $CaWO_4$ and YOS there is no speed advantage for the green-sensitive film (4), and thus, no reason to use it. For GOS and LOS the speed advantage is sufficiently great that the small decrease in resolution is of little consequence. That is, the GOS and LOS phosphor speed with green-sensitive film is sufficiently great that screens made from them can be made faster and with better resolution than screens made from slower phosphors using blue-sensitive film.

The remaining screen parameters require a significant trade-off between exposure and resolution. Qualitatively we can say that a fast, low resolution screen-film system may be given greater resolution by decreasing the screen thickness, or by removing the reflective backing with about the same incremental increase in resolution for a given incremental increase in exposure. Adding dye to the binder requires a significantly larger incremental increase in exposure for an incremental increase in resolution.

Considerable benefit could result from a study that is more analytical than the one presented here. For example, an analytical description of speed and resolution as functions of wavelength of emitted light and particle size could indicate optimal values where experiments are difficult.

Passivation Coatings on Silicon Devices

G. L. Schnable,* W. Kern,* and R. B. Comizzoli*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Passivation coatings are widely used to improve the performance and reliability of silicon devices of various types, ranging from discrete mesa-type diodes and transistors to complex planar silicon integrated circuits, and including both hermetic and plastic-encapsulated devices. This paper reviews the materials and techniques used to apply passivation coatings to completed silicon devices. Principal production techniques used in passivation of silicon devices include thermal oxidation, high-temperature diffusion, high-temperature chemical vapor deposition of Si_3N_4 or Al_2O_3, low-temperature chemical vapor deposition of glasslike SiO_2 or phosphosilicate layers (deposited at approximately 400°C), rf sputtering of SiO_2, mechanical deposition of glass frit layers which are subsequently fused, and application of organic polymer films. The effects of passivation layers on silicon device reliability are discussed, and the interrelationships among the silicon device, the passivation layer or layers used and the final encapsulation are indicated. Pertinent references on passivation and on related topics are cited in the text.

Passivation coatings are widely used to improve the performance and reliability of silicon devices of various types, ranging from discrete mesa-type diodes and transistors to complex planar integrated circuits, and including both hermetic and plastic-encapsulated devices. This paper outlines the materials and techniques used in the semiconductor device industry to achieve silicon device passivation.

Passivation coatings may be classified as primary if they are directly in contact with the single-crystal silicon from which the device is fabricated, and as secondary if they are separated from the silicon by an underlying dielectric layer. The function of the primary passivation layer is to provide good dielectric properties, low surface recombination velocity, controlled immobile charge density, and device stability at elevated temperatures under bias or operating conditions. The functions which are served by the secondary passivation layer are to provide additional stability in various ambients, in both production and use, and to serve as getter, impurity barrier, or mechanical shield.

This paper reviews primary and secondary passivation materials and the techniques used to obtain them, including thermal oxidation, high-temperature diffusion, low-temperature deposition of SiO_2 and binary silicates, deposition of alkali barrier-type layers, and deposition of glass frit or application of preforms followed by fusion. The effect of passivation layers on silicon device reliability is discussed, and the interrelationship among the techniques used for final encapsulation, the passivation layers used, and device reliability is indicated. Emphasis is given to those proc-

esses and materials which have been widely used to fabricate semiconductor devices in production, rather than to processes used only to fabricate exploratory developmental devices. A total of 363 references (listed alphabetically) have been cited to indicate the type of information which has been published on passivation layers and on related topics (1-363).

Thermally Grown Silicon Dioxides

The most commonly used primary passivation material is thermally grown SiO_2, with thickness ranging typically from 0.5 to 1.5 μm. In additon to passivation, two other very important functions of thermal oxides on silicon wafers are to serve as diffusion masks, and to serve as the insulator between the expanded metallization pattern and the underlying silicon in planar devices. Thermally grown oxides are prepared by high-temperature oxidation, at atmospheric pressure, of silicon wafers in atmospheres of dry oxygen, wet oxygen, or steam (11, 70, 114, 259, 72, 226, 348). For surface-sensitive devices, oxidation is frequently followed by one or more annealing steps (heat-treatments) in appropriate nonoxidizing atmospheres to improve the electrical properties of the Si-SiO_2 interface (259, 47, 220, 361, 307).

The cleanliness of the silicon surface is of great practical importance in device processing. Organic and inorganic surface contaminants (159, 149, 150, 137, 199, 152) are frequently introduced during many of the wafer processing steps and must be removed effectively to achieve high-quality oxide layers and interfaces. Decontamination is especially important just prior to heat-treatments and can be carried out by wet chemical methods (159, 124, 213).

The presence of alkali ions in thermally grown SiO_2 can result in device instability (296, 130, 114, 236, 173). Also alkali ions are undesirable because they can lead to devitrification of SiO_2 (202, 224, 212) and are a factor in SiO_2 dielectric breakdown (346, 83, 233). Accordingly, precautions are taken to minimize the level of alkali ion contamination during oxidation, and in some cases subsequent treatments are used to remove alkali ions (206). Whatever the process used, the results achieved are readily monitored by measuring stability of capacitance-voltage curves of metal-oxide-silicon capacitors subjected to bias at an elevated temperature (114, 362, 72, 226) such as 300°C.

In recent years, the technique of oxidation in atmospheres containing a small percentage of HCl (or Cl_2) has been widely used to getter alkali ions, thereby producing thermally grown oxides with very low levels of alkali ion contamination (260, 171, 172, 184, 231, 335, 173). The HCl gettering process, in addition to gettering alkali ions from SiO_2, also removes fast-diffusing interstitial contaminants from silicon, thus increasing bulk lifetime (260, 261, 53) and improving device properties (50, 192).

The thermally grown layer, which is amorphous, may be pure SiO_2, may contain boron if formed by oxidation of a boron-doped region (115), may contain hydroxyl if prepared by wet oxidation (25), or may contain chlorine if prepared using a chlorine-containing oxidizing ambient (211, 52, 334).

A very large body of literature exists concerning thermal oxides on silicon (11, 259, 226, 74, 334) and on the effects of oxidation conditions on the electrical properties and stability of the Si-SiO_2 interface (259, 71, 163, 72-74, 227). This information, to a large extent generated in connection with studies of MOS devices (270-272, 3), is applicable to a wide variety of oxide-passivated silicon devices. Considerable information has also been published on the radiation hardness of various types of SiO_2 (353, 132, 112). Accordingly, SiO_2 primary passivation phenomena will not be treated in detail in this paper. The ambient and temperature during application, or during subsequent fusion or heat-treatment of the secondary passivating layer may, however, modify the electrical properties of the Si-SiO_2 interface, including the mobile and immobile charge density and the fast surface-state density (75, 294, 309, 274, 76, 193, 361, 16). While this is particularly true of high-temperature depositions or heat-treatments (temperatures greater than approximately 800°C), it also occurs to some extent during low-temperature deposition processes [performed at 450°C or lower (274)].

Sequence of Application of Dielectric Layers

Figure 1 shows the sequence of application of passivation layers to various types of silicon devices. Passivation coatings may be applied before or after metallization, depending on the type of device. Some devices contain several different types of passivation layers, each having specific functions.

Table I, II, and III show some of the physical properties of commonly used passivation materials. Single-crystal silicon, thermally grown silicon dioxide, aluminum, and gold are included for comparison purposes.

Considerable information exists on the properties and stability of double dielectric structures such as MNOS memory devices (55, 272, 3, 16, 349). In such structures, the second dielectric layer serves primarily as part of the active device rather than as a secondary passivation layer, and thus is not considered in this paper.

Thermal oxides which have served as high-temperature diffusion masks will have an overlying layer of borosilicate glass and/or phosphosilicate glass. In NPN bipolar transistors and bipolar IC's, the thin layer of phosphosilicate glass (EPSG), formed on the surface of the thermally grown SiO_2 during emitter diffusion, remains on the device and serves as a getter for alkali ions present at that point (164) or introduced during later processing steps. In some processes, a phosphosilicate glass (206) or emitter diffusion layer (phosphorus-doped) (42) is used to getter alkali, and is subsequently removed by etching.

A very thin phosphosilicate layer has also been applied over gate oxides of some MOS transistors and IC's for gettering purposes (17, 266, 91, 141). Typically, this is accomplished at approximately 800°C using a diffusion source such as $POCl_3$. (Gettering of alkali

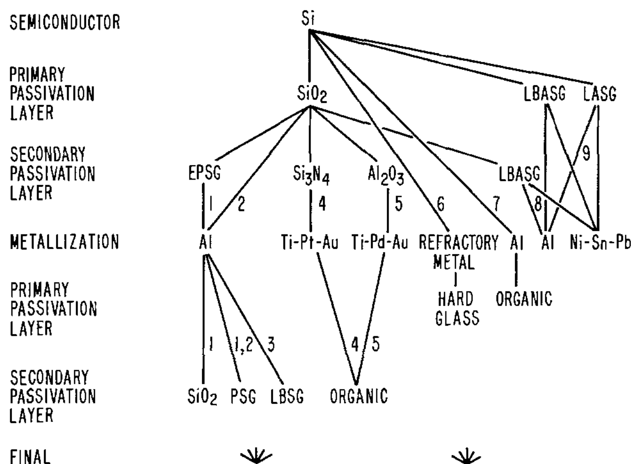

Fig. 1. Sequence of application of passivation layers to various types of silicon devices. Typical devices made by the sequences indicated by numbers are as follows: 1, NPN transistors, digital and linear bipolar IC's; 2, MOS transistors, p-channel MOS IC's, CMOS; 3, face-bonded chips; 4, beam-lead sealed-junction bipolar devices, plastic encapsulated Au-metallized devices; 5, beam-lead sealed-junction MOS IC's; 6, axial-lead diodes; 7, high-power diodes, high-power transistors, thyristors, devices with beveled junction; 8, high-voltage devices, high-voltage power devices; 9, high-voltage devices. Designations for glasses are as follows: EPSG, phosphosilicate glass formed by NPN bipolar transistor emitter diffusion; LASG, lead aluminosilicate glass; LBASG, lead boroaluminosilicate glass; LBSG, lead borosilicate glass; PSG, phosphosilicate glass.

ions from thermally grown SiO_2 by an overlying phosphosilicate layer involves a different mechanism than the high-temperature process of gettering of interstitial impurities such as Au, Cu, Fe, and Ni from Si by phosphosilicate glasses in direct contact with silicon.) Where PSG is used over the gate oxide of MOS devices (under the gate metal), close control of the P-concentration and layer thickness is required to avoid undesirable polarization effects (293, 294, 92, 82).

For MOS and PNP bipolar transistor applications in which an underlying high-temperature phosphosilicate glass is not present, special precautions are taken to insure that deposited films do not contain alkali. For example, deposited Al metal must be alkali-free.

Thermally grown SiO_2 is not used for passivation of some discrete devices, particularly high-voltage devices, because of drift effects and high, immobile charge density. Primary passivation in these devices is achieved by use of a silicate glass or an organic polymer coating. When an organic polymer is applied directly to a silicon surface, it must be recognized that real silicon surfaces contain a native SiO_2 layer (9, 135) on the order of 20Å thick. The exact nature of the processing prior to application of the polymer material and of the polymer itself (135, 190) are significant factors in determining initial device properties, and also device stability.

With both Al- and Au-based metallization systems, the maximum temperature which can be used in processing after metallization is limited by the melting point of the eutectic formed between silicon and the metallization (the Al-Si eutectic temperature is 577°C; the Au-Si eutectic is 370°C) rather than the melting point of the metal itself.

Deposited Thin-Film SiO_2 and Silicates

With IC's and small-signal planar transistors, a secondary passivation coating is applied to completed devices after Al metallization (147, 197, 34, 275, 278, 142). Originally, functions of the deposited layer were to provide resistance to scratching of the metallization pattern during chip handling (142), and to provide immunity to effects of loose conductive particles in hermetic packages. It was subsequently realized that additional benefits could accrue from these coatings. These benefits include reduced effects of ion motion on the surface (273, 275, 280), lower susceptibility to metal corrosion (215, 275), decreased susceptibility of metal stripes to electromigration failure (31, 297, 32, 81), improved stability and reliability of thin-film resistors (144, 342, 234), and alkali-gettering capability in the case of phosphosilicate glasses (PSG). Anodic Al_2O_3 has also been reported to reduce susceptibility of Al metallization to electromigration (180, 77, 178, 263, 81).

Table II. Stress in low-temperature deposited passivation layers. Some of the properties of thermally grown SiO_2 and of Si, Al, and Au are given for comparison purposes.

Material	CTE, ×10^{-6}/°C	Internal stress, dynes/cm^2 (350°-400°C)	Total stress on Si (at 25°C)	Total stress over Al edges (450°C)
CVD SiO_2	0.5	High T* (1-4 × 10^9)	High T* (0.5-2 × 10^9)	Very high T*
Sputtered SiO_2	0.5	Low	C**	T
CVD PSG	0.5	Moderate T	T	High T
Thermal SiO_2	0.5	—	C	—
Si	3.5	—	—	—
Al	26.0	Low	T	—
Au	15.0	—	—	—

* T = tensile.
** C = compressive.

Silicon devices in hermetically sealed packages are susceptible to the effects of loose conducting particles in the package (209, 207, 101) unless the devices are coated with a dielectric. In Al-metallized devices, deposited SiO_2 or PSG is quite effective. In Au-metallized devices, organic coatings are generally used (345, 239) since deposited oxides have low adhesion to gold (63).

Most commonly, chemical vapor deposition (CVD) of SiO_2 on Al-metallized circuits is accomplished at atmospheric pressure at a temperature of approximately 400°C using SiH_4 plus excess O_2 in N_2 as carrier (106, 145, 301, 147, 6, 19, 155, 191, 15, 27, 360, 154); PSG and BSG (borosilicate glass) are deposited using, respectively, PH_3- and B_2H_6-containing mixtures under similar conditions (321, 147, 157, 6, 155, 269, 275, 191, 15, 27, 360, 286, 287, 154). Typically, CVD layers are on the order of 1 μm thick. Tetraethyl orthosilicate (TEOS) has also been used as a source for CVD of SiO_2 (6). CVD SiO_2 layers are in tensile intrinsic stress as deposited (303, 104). Because silicon has a higher coefficient of thermal expansion (CTE) than silicon dioxide, the residual stress in CVD SiO_2 films on Si at room temperature is somewhat lower than the intrinsic stress of films as deposited, but the films are still in considerable tension (175, 19, 302, 303) (see Table II).

Deposited SiO_2 or PSG films, when heated above the deposition temperature, are put in additional tension, particularly in regions over the edges of delineated Al metal films. Accordingly, there is some correlation between the intrinsic tensile stress in deposited films and the temperature increment above deposition temperature which can be attained before cracks begin to form (269, 303).

SiO_2 secondary passivation layers on Si wafers have also been obtained by rf sputtering (251, 61, 188, 99). The sputtering conditions can be adjusted to produce good coverage of topography (188, 339, 161) and to result in low stress (compressive) at room temperature (251, 325). Sputtering processes produce radiation damage in the thermally grown SiO_2 which can adversely affect sensitive devices such as MOS transistors and integrated circuits (251, 188, 58, 187, 205, 318, 204). Most, but not all of the radiation-induced charge can be annealed out by suitable heat-treatments. Techniques which reduce the amount of radiation damage during sputtering have recently been described (58, 187, 205, 318).

Layers of PSG have been widely used because they are in less stress (tensile) than layers of SiO_2 as deposited by CVD (269, 302, 235) and have the ability to getter alkali ions (269). PSG is thus particularly ad-

vantageous for MOS devices, which are more surface sensitive than digital bipolar IC's.

CVD has been more widely used than rf sputtering for depositing layers of SiO_2, PSG, or BSG, because it is faster (see Table I), requires simpler equipment, and, in contrast to rf sputtering, produces no radiation damage in the thermally grown SiO_2.

Deposited SiO_2 or silicate films are sometimes densified by a heat-treatment in a suitable ambient to improve their properties (148, 305, 158). Higher phosphorus contents in the CVD PSG glass reduce intrinsic tensile stress (which tends to cause cracking) (269, 303, 235) and increase the alkali-ion gettering capability of the passivation layer. On the other hand, PSG layers with excessively high phosphorus concentration tend to be hygroscopic and may have poor stability in humid atmospheres (225). These effects can be reduced by depositing a thin SiO_2 layer over the PSG layer (158).

Excessively thin passivation layers tend to contain more pinholes than thicker layers (85) and are less effective in covering topography such as delineated metal lines. Also, any charges which move along the surface of the passivation layer are closer to the Si-SiO_2 interface and thus exert more influence on device characteristics (273). Thicker layers, however, are more likely to contain nodules and are more likely to crack.

The effectiveness of a passivation layer in providing protection against metallization scratches increases with increasing passivation layer thickness (277). It is possible to deposit and delineate crack-free BSG or PSG layers 3 μm thick (157, 158) which afford very good scratch protection. With thicker layers, it is necessary to deposit the layers under conditions in which stress is not excessive. Consideration must also be given to the effects of mismatches in thermal coefficients of expansion. Borosilicate containing 17 mole per cent (m/o) B_2O_3 approximates the linear coefficient of thermal expansion (CTE) of silicon (158). Crack-free layers of BSG over 10 μm in thickness can readily be obtained by CVD at 450°C (157, 158).

Regardless of deposited passivation layer thickness, layers of deposited dielectrics must be applied to properly cleaned wafers under suitable conditions to avoid metal penetration (20) and lateral charge spreading or lateral ion migration effects at the interface between thermally grown SiO_2 and deposited dielectric (273, 118, 280, 39).

There is some reaction of Al metal with SiO_2, BSG, or PSG at relatively low temperatures (289), such as 400°C (277, 232, 253). Thus, an intermediate aluminosilicate film forms during SiO_2 deposition. Subsequent high-temperature processing steps such as chip-to-header eutectic bonding and package sealing, particularly in frit-sealed ceramic packages, which are sealed at temperatures on the order of 500°C (200, 343), can cause additional Al-glass interaction. The Al-SiO_2 reaction tends to be accelerated at localized oxide defects and thus is dependent on oxide quality (51, 232).

Low-temperature deposited films of SiO_2, PSG, and BSG are amorphous. Delineation of deposited SiO_2 and PSG films (to expose bonding pads and open scribe lines) is accomplished using buffered hydrofluoric acid. Delineation of BSG films is preferably performed using unbuffered hydrofluoric acid mixtures because of the higher etch rate (158).

In Si-gate MOS IC's, CVD phosphosilicate is frequently used as the dielectric between polycrystalline silicon and overlying metal; in these devices it also serves as a passivation layer. In some cases the PSG layer is subjected to a heat-treatment at a temperature such as 1000°C to obtain some flow of the PSG (222, 161, 153, 340, 10).

Characterization of Dielectric Films

The characterization of dielectric films used in silicon device passivation is based both on standard chemical, physical, and electrical methods established for surface and thin-film analysis (198, 199, 138, 139) and on methods developed specifically for the analysis of thin dielectric films (341, 137). Special electrical methods include metal-insulator-semiconductor (MIS) measurements of the capacitance-voltage (C-V) relationship before and after bias heat-treatment (116, 296, 259, 362, 72). From these measurements one can calculate the density of electronic states, interface charges, and bulk charges, all of which play important roles in the electrical properties and stability of deposited dielectrics (296, 114, 294, 309, 226). Measurements of the sheet resistivity of a silicon wafer after heat-treatment at temperatures over 1000°C is often used to estimate the composition of a deposited binary oxide film from the resulting doping concentration in the silicon (18, 38, 10). X-ray fluorescence analysis (246, 306, 82), backscattering (186), and Auger electron spectroscopy (292) have been used to determine the composition of deposited dielectric films. Infrared spectroscopy has been used extensively for compositional and structural analysis of deposited SiO_2 (251, 305, 158, 264, 265, 151, 37, 223, 247), PSG (60, 158, 265, 37, 64, 317, 247, 286, 287), and BSG (251, 148, 158, 264, 151, 315, 37, 247, 8, 312) films. Chemical etch rate measurements have also been used to determine film composition and relative density for films as deposited (251, 146, 54, 321, 305, 158, 282, 120, 136, 110, 316) or after densification heat-treatment (321, 305, 158, 156). Moisture absorption and adsorption, and resistance of deposited dielectric films to moisture are important aspects of passivating films and have been examined by various authors (265, 151, 64, 8). Measurements of surface conductivity (46), stress (129, 268, 267, 175, 302, 303, 104, 331), and index of refraction (251, 106, 305, 158) of various deposited dielectrics have been reported. Methods for characterizing localized structural defects in dielectric films have been reviewed recently (153). Coverage of topography by deposited films is important for device reliability (107, 140, 161, 10, 179).

Alkali Barrier Layers

In some high-reliability devices, silicon nitride (Si_3N_4), which serves as both a getter and an effective alkali barrier (322, 65, 100, 41), is applied over the thermally grown SiO_2 prior to metallization. Aluminum oxide (Al_2O_3), which is also an alkali ion barrier (329, 330), has been used in some MOS devices (49, 174, 105). Examples of devices with ion barriers include nitride-passivated bipolar devices (195, 279), beam-lead sealed-junction devices (279, 239), and MNOS devices (262). Silicon nitride can also be deposited over refractory metals (160) such as W and Mo, or over the polycrystalline silicon used in silicon-gate MOS devices. A considerable amount of information has been published on deposition (54, 109, 87, 208, 191, 216, 347, 258) and properties (75, 54, 109, 344, 168, 87, 265, 216, 194, 347, 193) of Si_3N_4, and on device applications (322, 279, 262, 109, 78, 310, 337, 351, 196, 160, 355, 195, 125, 12).

Typically, Si_3N_4 layers are formed by reaction of SiH_4 or of $SiCl_4$ with excess NH_3 at temperatures of 800°-900°C at atmospheric pressure. Layer thicknesses of 0.1-0.2 μm are generally used as alkali barrier layers in bipolar devices. Al_2O_3 is prepared by CVD from $Al_2Cl_6 + H_2 + CO_2$ (328, 329, 86, 326) at approximately 900°C.

Delineation of Si_3N_4 or Al_2O_3 films is performed using hot (180°C) phosphoric acid (336). In MOS devices in which the Si_3N_4 is used under the gate metal, the thickness of the Si_3N_4 is on the order of 0.03-0.05 μm (262, 12). Both thickness and dielectric constant must be closely controlled in this type of MOS application.

Although defect-free silicon nitride layers are effective diffusion barriers, it must be recognized that many

nitride-passivated devices have exposed underlying thermal oxide at each contact cut and at the periphery of the chip. Although procedures exist for sealing the edges with nitride, this is frequently not done because of the additional process complexity and the chip area penalty involved. With unsealed oxide edges, lateral migration of alkali is possible, and has been shown to adversely affect silicon device reliability (208). While the effects of alkali ions on stability of threshold voltage of MOS devices have been the subject of many studies, it has also been clearly established that alkali ions can adversely affect bipolar devices (279, 310, 208, 195, 77).

Fused Glass Layers

Fused glass films are used on various device types. Table III shows the composition and properties of typical fused glasses used in silicon device passivation. Planar, aluminum-metallized IC's have made use of a thin ($\sim$1 μm) fused glass layer applied over metal (68, 69, 323). The high CTE permits only very thin layers, which can be applied by careful sedimentation of fine powder as is described later. Pinholes in the glass film on such devices can lead to metal corrosion (7). Power devices of planar or mesa structure often use fused glass as a direct passivant on the high-voltage junction (169, 126). Various techniques for high-voltage axial-lead diode passivation make use of beads of fused glass powder (79, 80), glass sleeves with metal studs (56, 44), or glass sleeves with glass beads as end seals (67).

The composition of glass used to form fused layers for device passivation depends on the device processing restrictions and designed operating characteristics. Important properties of the starting glass are particle size (in the case of powders), fusion temperature, and melt viscosity. For the fused layer, the important properties are chemical durability, CTE, and dielectric properties, in particular, ionic mobility at intended device operating temperature. Since the CTE increases and chemical durability decreases with decreasing fusion temperature, tradeoffs based on device processing requirements and intended use must be made (214, 354). As an example, low melting glasses used over aluminum can be applied in thicknesses of only a few microns (242).

Because of their good chemical stability, lead oxide-containing glasses are widely used, but the high ionic mobility of the lead ion above about 125°C in some glasses of this type limits device operating temperature (162, 295, 40, 290). For example, lead aluminosilicate glasses (LASG) are used in mesa grooves for thyristor and other high power device passivation (351, 352, 62) where device operating temperature of 125°C is sufficient. The low CTE of such glasses permits the application of thick layers directly on silicon in the grooves (355, 356), and the chemical stability permits contact etching and nickel plating of the device after high-temperature fusion ($\sim$900°C) of the glass powder. The addition of boron oxide (LBASG) (40, 221, 357) permits further decrease of ionic mobility and also of fusion temperature (to about 700°C), rendering the glass suitable for use on higher operating temperature devices (88), such as power transistors. However, CTE is increased (see Table I). ZnO is usually added to such glasses (LAZBSG) to moderate the CTE increase. With boron-containing glass of high fusion temperature ($\geq$900°C), it is not possible to fuse the glass directly on the silicon because of doping effects. An intermediate SiO_2 barrier layer is then necessary. Glasses with ZnO and B_2O_3 as major constituents have higher device operating temperature capability because of reduced ionic mobility (162, 45, 221). In some cases, however, reduced chemical resistance of such glasses limits subsequent processing options.

For scratch and ambient protection over metallization on planar IC's and small-signal transistors, where the glass is applied over the entire wafer, the glass must fuse at a temperature compatible with the metallization. This is an important restriction in the case of Al metallization since, as previously indicated, the Al-Si system forms a eutectic melting at 577°C. Also the low-melting glasses used have a high CTE, and therefore, to avoid cracking, only very thin layers can be used (240, 242, 133, 325, 88, 125).

Depending on thickness desired, the powdered glass may be deposited by several methods. For thin, pinhole-free films on the order of 1 or 2 μm thickness, sedimentation in a centrifuge is suitable. Procedures for dispersing the glass powder in the suspending liquid and choice of liquid(s) are important for obtaining thin, uniform, pinhole-free, and adherent glass films (248, 240, 250, 249) by this technique.

For thicker layers of about 5-25 μm, doctor-blading of a slurry, electrophoretic deposition, spinning on of photoresist-glass mixtures, application of beads of glass powder in a slurry, and silk screening (245) can be used. Doctor-blading requires a step- or groove-type geometry for the selective placement of the glass, and is suited to mesa-type devices. Electrophoretic deposition (123, 313, 217) is used for various power devices, and can be made selective by using insulator films to mask areas where no glass is desired (283-285). Photoresist-glass powder compositions permit removal of unwanted glass before fusion, thus eliminating an etching step (13).

For axial-lead diodes passivated with fused glass powder, a drop of slurry can be formed about the diode and stud lead assembly. In the case of preforms, the glass tubes for axial diodes are fitted over the device and fused into contact. High ambient pressure applied during fusion permits a lowering of fusion temperature (56). Combinations of glass powder as a bonding agent, and preforms as the passivating layer, have also been described (218).

Other glass application techniques include the use of various oxide thin films as a bonding layer between fused glass powder and the silicon surface (241, 244, 251, 243) and the formation of a glass *in situ* by firing of a silicon device with deposited glass-forming oxide powders (134).

The various analytical techniques already noted for grown or deposited layers are also useful for characterizing fused glass materials (247, 153). In addition, differential thermal analysis (102), microhardness testing (331), and particle size analysis (143) of the powder are valuable test methods to assure the attainment of high-quality layers.

Table III. Typical fused glasses. Some of the properties of silicon are given for comparison purposes.

Glass	Composition (% by wt)						Fusion temperature (°C)	CTE (°C)$^{-1}$	Devices	Deposited

Passivation Layers and Silicon Device Reliability

Most of the presently available small-signal planar transistors and integrated circuits are Al-metallized and are passivated with a thin layer of SiO_2 or PSG. The primary purposes of this layer are to provide scratch protection during handling (142), to achieve immunity to shorts caused by loose particles in packages with a cavity, to reduce susceptibility of the Al metallization to corrosion (275), and to meet customer specification requirements. With complex IC's, increased electrical and visual inspection yields frequently more than compensate for the costs of applying and delineating a passivation layer. Glass passivation layers, deposited over the metallization pattern, have also been shown to significantly increase device reliability (197, 97, 276, 125, 185, 324, 127).

Glass passivation is frequently performed on all wafers by the same process, without regard to whether the final product will be commercial or high-reliability, in plastic or in hermetic packages, or will be rated for limited temperature or full temperature operation. Obviously, the thickness and composition of the passivation layer which meet all of these diverse requirements involve some tradeoffs and compromises. Our experimental studies (156) have shown that in a substantial portion of the integrated circuits manufactured in the last several years, the passivation layer contains pinholes, cracks, or a combination of these. A number of publications also confirm this finding (157, 278, 140, 144, 210, 89, 153, 338, 21).

Cracks in passivation layers, when present, frequently occur at and run along topographic steps or along the edges of delineated metal conductors or thin-film resistors (140, 144), and thus cannot be seen by optical microscopy. Pinholes in the dielectric over alloyed metal are generally very difficult to see by optical microscopy because of the rough topography of the recrystallized aluminum. Both cracks and pinholes can be revealed by scanning electron microscopy (SEM), or by subjecting the chip to immersion in an etchant which does not dissolve the dielectric but is capable of dissolving the underlying material (85, 254, 144, 89, 153). After chemical etching to undercut the Al, the actual pinhole in the dielectric is generally visible, by optical microscopy, in the center of the undercut area (153).

Pinholes in the passivating glass can occur for a variety of reasons. They may be present in the passivation layer as deposited (85, 27), may arise during etching to open the bonding pads (because of holes in the photoresist layer), or may be created by the contact printing operation or by impact during chip handling (142).

In a recent study (156), two classes of pinholes were evident in samples of IC's from six manufacturers. The more common class was pinholes in the central regions of aluminum lines. Another type observed was pinholes along the edge of the delineated metal lines (153). The edge pinholes are attributed to inadequate coverage of metal edges by the photoresist and can generally be avoided by the use of thicker photoresist layers or improved photoresist application techniques. Those pinholes which occurred in the central areas of delineated lines are to a large extent believed to be attributable to the presence of hillocks in the aluminum which occur because of recrystallization of the aluminum during the contact alloying step (188, 179, 156). Even if a hillock is completely covered with dielectric during the subsequent step of deposition of the passivation layer, the hillock may not be adequately covered by photoresist, the photoresist may be pushed away from the peak of the hillock during contact printing, or the contact printing step may fracture the dielectric over the hillock. Any of these three conditions, or a combination, will result in a pinhole through the passivation layer, exposing a region of underlying metal. Handling of wafers can result in impact cracks and scratches (142).

Al-metallized IC's are considerably more susceptible to failure due to opens as a result of Al corrosion during operation if the passivation layer contains cracks (235, 358) or pinholes (156) over the metal lines. Defects in passivation layers also increase susceptibility to ionic contaminant effects (156, 111). The requirements for attaining crack-free, pinhole-free passivation layers are very similar to the requirements for a first-layer deposited dielectric in multilevel-metallized integrated circuits. These include minimizing hillocks, low-stress dielectric deposition conditions, good coverage of the edges of delineated metal, and proper photolithographic procedures (303, 278, 104, 161, 103, 153, 340).

Phosphosilicate layers with an excessively high concentration of phosphorus are hygroscopic and have led to aluminum corrosion problems (235, 358, 93, 359). On the other hand, the use of low-phosphorus glass compositions which result in cracks over or along the edges of aluminum metal lines can lead to localized metal corrosion problems (235). The density and structure of phosphosilicate films are factors which influence the optimum phosphorus content (225).

The effectiveness of a passivation layer can be assessed by accelerated techniques in which the devices are exposed to high relative humidities. One commonly used condition is reverse bias or operating life at 85% relative humidity at 85°C. A considerably more severe test is to apply bias to devices which are in a pressure cooker, for example, at 15 psig (121°C).

Moisture plus bias can result in electrochemical corrosion of metal. Electrochemical corrosion normally would be expected to result in open metal lines which have positive (anodic) bias relative to adjacent lines (298, 166); with Al-metallized integrated circuits, corrosion of circuit lines which are cathodic has also been reported (166, 235). Stress-corrosion cracking (30) may be a factor in accelerating cathodic corrosion of Al metallization lines at grain boundaries. Corrosion mechanisms of Al can be chemical as well as electrochemical, and in either case temperature (5), *p*H (252, 170), and presence of chlorides (252, 170) are important factors in determining corrosion rate and corrosion products.

The more costly metallization system Ti-Pt-Au, with Au wire bonds, has been shown to be superior to Al for corrosion resistance (350, 119, 165). With Au metallization systems, electrolytic corrosion can, however, result in formation of dendrites which form shorts between conductors (170, 203, 288, 117).

Device Encapsulation

Final encapsulation of silicon devices may be in hermetically sealed packages (181, 94, 35, 22, 200, 343, 255), in molded plastic packages (181, 22, 4, 165, 113, 189, 23), in cast plastic, or by conformal plastic coating of chips mounted on hybrid substrates (345, 122). The encapsulation process provides the final means for passivation of the device. The device reliability, in terms of both stability of electrical characteristics and susceptibility to catastrophic failure, is a complex function of the device design and processing techniques and materials used, including the metallization, the passivation layer or layers, and the final encapsulation.

Early silicon devices were primarily sealed in hermetic packages. The plastic-encapsulated silicon devices initially offered had reliability limitations (183, 215, 310, 36, 276, 98, 108, 304) which, to a large extent, have now been overcome (24, 95, 98, 165, 113). Plastic encapsulation does permit lower costs, provides mechanically rugged packages, provides freedom from loose particle problems, and permits smaller package size.

Hermetically sealed devices are not totally immune to ionic contamination and moisture effects (20, 209, 140, 319, 332, 239). Ionic contaminants may be inadvertently sealed in the package (319, 320). Also, a percentage of the devices in completed electronic equip-

ment are not actually hermetically sealed (300, 209, 1), either because they escaped hermeticity screening tests, or because the hermetic seal became damaged during device handling or equipment assembly (1). In such cases, a suitable passivation layer can provide some protection against Al corrosion or electrolytic Au migration reactions.

The plastic formulations initially used for molding silicon devices were based on phenolics, epoxies, and silicones (128, 36, 28, 200, 97, 121, 201, 165, 113). In many cases a junction coat (layer of plastic such as an epoxy, silicone varnish, or room-temperature vulcanizing silicone elastomer) was applied prior to molding (84, 97, 121, 311, 165, 2). Plastics can be a source of ions (182, 128, 230, 228, 29, 166, 177, 308) or impurities (183, 230, 135, 298, 176) which adversely affect silicon devices, particularly in moist atmospheres and under bias conditions. In the last several years, a considerable number of process and materials changes has been made to improve the reliability of plastic-encapsulated silicon integrated circuits (96, 24, 95, 98, 165, 113). Most notable of the improvements is the use of novolac epoxy formulations with high glass transition temperatures (165).

Silicones are extensively used for encapsulation of power devices (201, 26) and for beam-lead devices (345, 237). In general, silicones permit high in-process temperatures and higher maximum storage temperatures (201, 257) than epoxy- or phenolic-based encapsulating compounds.

Various test devices and accelerated testing techniques have been developed for evaluating the stability of passivated devices under severe environmental conditions (314, 256, 238, 257). For plastic-encapsulated devices, a moisture-containing ambient constitutes an effective means for accelerating ion migration effects or chemical or galvanic corrosion of the metallization pattern on the chip (182, 28, 237, 33, 7, 90, 256, 121, 29, 238, 229, 291, 236, 257, 189, 23, 166, 176, 177). Moisture is an important factor since surface conductivity of SiO_2 and of other passivation materials increases by several orders of magnitude with increase in relative humidity (131, 46).

In general, passivation techniques provide only partial protection against ambient effects. For example, silicon nitride-passivated devices may be protected against alkali penetration into the underlying SiO_2, but may be influenced by potential buildup at insulator-insulator interfaces or at the ambient-upper dielectric interface. Increased device stability is frequently obtained by specific device construction features which make the device less surface sensitive. Examples include resistive overlays (57), use of diffused channel stoppers (273, 49), field plates (48, 43, 363, 59), ion implanted surfaces (299, 219), and use of beveled junctions (66, 167, 327, 14, 62) in high-voltage devices.

The most reliable silicon devices are those in which device design, wafer processing, metallization, passivation, assembly, encapsulation, and electrical testing are all specified to minimize the incidence of conditions which result in known failure mechanisms, and adequate in-process controls (39) are applied during the entire device fabrication sequence; thus reliability (278, 333, 281, 324, 236, 239) is designed into the product.

Acknowledgments

The authors gratefully acknowledge the contributions of A. W. Fisher and R. D. Vibronek to the experimental results presented in this paper, and the assistance of R. E. Allen and P. L. Pado in preparation of the manuscript. We also thank A. W. Fisher, K. W. Hang, and J. L. Vossen for the helpful discussions and for reviewing the manuscript. We also thank F. P. Jones, S. Merrin, and G. S. Sheldon for bringing several references on fused glass to our attention, and M. H. Woods for supplying several references on double dielectric structures.

This work was in part supported by the Air Force Materials Laboratory, Wright-Patterson Air Force Base, Ohio, under Contract No. F33615-74-C-5146.

Manuscript submitted Nov. 22, 1974; revised manuscript received Feb. 26, 1975. This was Paper 215 presented at the New York, New York, Meeting of the Society, Oct. 13-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by RCA Corporation.

The Nucleation Reaction on Photosensitive TiO_2 Films

J. J. Kelly and J. K. Vondeling

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The nucleation reaction, which occurs when transparent TiO_2 films in contact with palladium ions are exposed to u.v. light, has been investigated. The nuclei, thus formed, may serve as catalytic centers for electroless deposition of various metals. The photographic procedure, which has a high light sensitivity, may be used for the photoselective plating of nonconducting substrates. It has been shown, by electron diffraction and ellipsometry, that metallic palladium is formed on the TiO_2 during exposure. The minimum number of palladium atoms required to initiate electroless metal deposition has been estimated.

Considerable interest exists for systems with which nonconducting substrates can be nucleated and then plated by means of electroless metal deposition. One such system involves a sensitization and activation procedure using stannous chloride and palladium chloride solutions, respectively. It was generally believed that metallic palladium is formed during the nucleation. Recent evidence (1, 2) has shown, however, that this is not always the case. The presence of metallic palladium is therefore not a necessary prerequisite for successful nucleation.

Titanium dioxide, coated from a dispersion as a thin film on various substrates, has been used as a light-sensitive compound for selective nucleation in the fields of printed circuitry (3) and photographic reproduction (4). For the former application the TiO_2 film is dipped in a silver or palladium salt solution, dried, and then exposed image-wise to u.v. light. The nuclei formed in the exposed areas of the film can be developed by electroless deposition to yield a visible metallic image. For photographic reproduction (4) the oxide film is activated in silver nitrate solution after exposure, and the nuclei are developed by silver deposition.

The use of a palladium salt instead of a silver salt as the sensitizing agent presents a more attractive system for electronic applications, since nuclei formed by exposure can be developed, not only with silver, but also with other metals, *e.g.*, copper, nickel, cobalt, and gold (3).

The photocatalytic reaction on TiO_2 has been explained by a number of workers (5-9) in terms of a semiconductor model involving photoexcited electrons and holes. Electrons trapped at surface sites act as reducing centers for metal ions.

Photosensitive TiO_2 films have also been made by pyrolysis of various titanium compounds (10, 11). In this paper we describe an investigation of the photoselective nucleation reaction, occurring on transparent TiO_2 films formed on glass by pyrolysis of titanium acetylacetonate. We considered various techniques for studying the nucleation reaction. The nuclei produced during exposure could not be directly observed by electron microscopy. The amount of product formed by u.v. exposure of dried $PdCl_2$-sensitized films was very small. Radioactive tracer analysis is sufficiently sensitive to study the total amount of palladium on the surface but it does not distinguish between the different forms of palladium, metallic or otherwise, which may be present. In order to increase the amount of reaction product we exposed TiO_2 films in palladium salt solutions and used electron diffraction, optical absorption, spectrophotometric analysis, and ellipsometry to study the product formed.

It has been shown (1, 12) that ellipsometric measurements can be used to detect the presence of very thin films on substrates. A clean substrate is characterized by the ellipsometric parameters Δ and ψ, which are determined by the optical constants (*i.e.*, extinction coefficient and refractive index) of the material. Formation of an adsorbed film on the substrate generally leads to changes, $\delta\Delta$ and $\delta\psi$, in these parameters. The magnitude of these changes depends on the optical constants of the film and on its thickness. For very thin films ($\leq$10Å) $\delta\psi$ is directly proportional to the extinction coefficient (1). This means that a film with low extinction coefficient at the measuring wavelength has an effect in $\delta\Delta$ only, whereas a film with a high extinction coefficient involves changes in both Δ and ψ. Since metallic palladium films have a stronger optical absorption at 632 nm than palladium salts (1) we hoped to be able to use the ellipsometric technique to distinguish between metallic and nonmetallic product and to get a semiquantitative estimate of the film thickness.

In the first part of the paper we describe the photographic properties of the $TiO_2/PdCl_2$ system with special reference to the use of transparent TiO_2 films for photoselective metal deposition. Various techniques were then used to study the nature and the extent of the photonucleation reaction. From the results of these studies an estimate was made of the minimum number of palladium atoms required to initiate electroless deposition.

The mechanism of the primary photocatalytic reaction on these layers has been discussed elsewhere by Möllers *et al.* (9).

Key words: electroless deposition, photosensitivity, nucleation, titanium dioxide.

Table I. Solutions used for image formation on TiO_2 films

Sensitization		
A.	$PdCl_2$ 5.6 × 10^{-3} mol/liter HCl 1.2 × 10^{-1} mol/liter Tensagex DP-24 0.4% (weight) aqueous solution	B. $PdCl_2$ 5.6 × 10^{-3} mol/liter HCl 1.2 × 10^{-1} mol/liter CH_3OH 80% (Vol) H_2O
Development		
Silver	49 ml solution (i) + 1 ml solution (ii)	{ 0.1 mol/liter metol[a] 0.1 mol/liter citric acid } 2.5 mol/liter $AgNO_3$
Copper	42 ml solution (iii) + 8 ml solution (iv)	{ 0.28 mol/liter $CuSO_4 \cdot 5H_2O$ 0.30 mol/liter Na_4 EDTA 0.65 mol/liter NaOH } 35% formaldehyde
Nickel	C. $NiCl_2 \cdot 6H_2O$ 1.3 × 10^{-1} mol/liter $NaH_2PO_2 \cdot H_2O$ 9.4 × 10^{-2} mol/liter NH_2CH_2COOH 4.0 × 10^{-1} mol/liter pH = 3.8, temp. 95°C	D. $NiSO_4 \cdot 6H_2O$ 2.7 × 10^{-2} mol/liter $Na_4P_2O_7 \cdot 10H_2O$ 7.8 × 10^{-2} mol/liter $NaH_2PO_2 \cdot H_2O$ 1.1 × 10^{-1} mol/liter pH = 9.15, temp. 50°C

[a] Metol is methyl-p-aminophenol sulfate.

Experimental

Titanium dioxide films.—Light-sensitive TiO_2 films were prepared on glass by pyrolysis of titanium acetylacetonate (TAA), supplied by Dynamit Nobel (Muhlheim, West Germany) as a 50% solution in isopropanol. For the photographic experiments a mixture containing 20g TAA solution and 80g diacetonealcohol was applied to Pyrex plates by whirl-coating at 1500-3000 rpm. Thin quartz plates lifted from a 12.5% TAA solution in isopropanol were used for the rate experiments. In both cases the layer was pyrolyzed in air at 500°C. The thickness of the resulting TiO_2 film was approximately 50 nm for the whirl-coated and 38 nm for the lifted samples. Electron and x-ray diffraction data for the TiO_2 films on Pyrex indicated the presence of polycrystalline anatase. The films were optically transparent in the visible spectral region but absorbed appreciably at wavelengths below 350 nm.

Rate of the photoreaction.—Kinetic runs were performed at 25°C and virtually constant palladium salt concentrations. The TiO_2 film in contact with the solution in a quartz cuvette was exposed through the quartz substrate to light from a filtered mercury lamp (Philips HPK lamp; $\lambda > 280$ nm). The increase in absorption of the film at wavelengths greater than 500 nm due to product formation could be measured continuously during exposure by means of a Philips 90 AV photocell and filter system. The extent of the photoreaction was measured by dissolving the product film in nitric acid and determining the palladium spectrophotometrically using p-nitrosodimethylaniline (13). For the quantum efficiency measurements monochromatic light from a Bausch and Lomb grating monochromator was used instead of the HPK lamp. The output of the monochromator was calibrated using ferrioxalate actinometry (14).

Ellipsometric measurements.—The ellipsometer and the measuring cell have been described elsewhere (1). The TiO_2 film was mounted rigidly at the center of the cell. The cell was provided with quartz windows and a water-jacket through which water from a thermostat could be circulated to maintain a constant cell temperature (25° ± 0.1°C). A helium-neon laser (λ = 632.8 nm) was used for making the ellipsometric measurements. The angle of incidence was 47°.

A HPK lamp together with a shutter arrangement was used to irradiate both the TiO_2 films in palladium salt solutions and the dried $PdCl_2$-sensitized films.

Results

Photographic image formation on TiO_2 films.—The procedure used for photoselective metal deposition on TiO_2 films consisted of four steps: sensitization, nucleation, fog inhibition, and development.

The TiO_2 film was sensitized by introducing a palladium salt onto its surface. For this purpose the film was lifted from a solution of the metal salt (cf. Table I) at a controlled rate and dried superficially during lifting by warm air or *IR* radiation. Tensagex DP-24, a sodium alkylphenolpolyglycolether sulfate supplied by Labaz Holland N. V. (the Hague, the Netherlands) was used as a wetting agent in the aqueous solution A.

The $PdCl_2$-sensitized TiO_2 film was then exposed through a mask to a high pressure mercury lamp (Philips HPR 125W) or to monochromatic light. In the exposed areas the film became activated due to the formation of nuclei.

In the nonexposed areas, metal ions remained on the surface of the oxide, even after thorough rinsing with water. A radiotracer study using $Pd^{109}Cl_2$ showed that a TiO_2 film sensitized with solution A, contained 0.03 μg Pd/cm^2 (approximately 1.7 × 10^{14} palladium ions/cm^2) after rinsing with water. The presence of palladium salt, in certain cases, caused fogging during development since bivalent palladium could be reduced by the reducing agent of the electroless solution, giving rise to nucleation centers. Solutions containing strong complexing agents for bivalent palladium were effective in drastically reducing the amount of adsorbed metal salt. Satisfactory results were obtained with aminoacetic acid (0.4 mol/liter) and triethanolamine (1.0 mol/liter). Tensagex solution (1-2%) also considerably reduced the amount of palladium salt present on TiO_2 and therefore could be used as an efficient antifogging agent.

The nuclei produced by exposure were developed by electroless deposition of silver, copper, and nickel, with the solutions listed in Table I. Nickel patterns containing 5-10 μm details were made using solutions A and C of Table I.

The photographic sensitivity of the system was measured by exposing the $PdCl_2$-sensitized films to monochromatic light (λ = 300 nm). Values for E_m, the minimum exposure required to initiate electroless deposition, and for D, (= log I_0/I) the density of the developed image after various development times, are given in Table II for Ni and Ag deposition. The sen-

Table II. Photographic sensitivity of TiO_2 films

Nuclei	Development		D[c]	E_m (μJ/cm^2)
Pd (λ = 300 nm)	Ni[a]	1 min	2.1	300-500
	Ni[a]	2 min	4.7	300-500
	Ag[b]	½ min	2.0	100-250
	Ag[b]	1 min	4.3	100-250

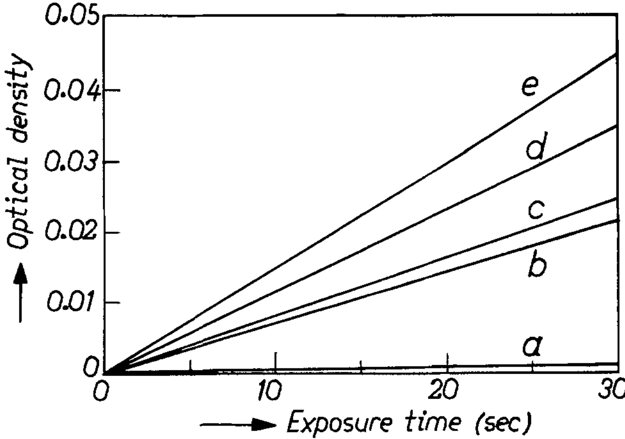

Fig. 2. The effect of certain additives, to a solution containing 5.6×10^{-3} mol/liter $PdCl_2$, 1.2×10^{-1} mol/liter HCl, on the relative rate of palladium deposition. The increase in optical density of the product film is plotted as a function of exposure time for the solution containing (a) no additive, (b) 1-propanol (80% vol), (c) ethanol (80% vol), (d) Tensagex DP-24 (0.4% weight), (e) methanol (80% vol).

sitivity of this $PdCl_2/TiO_2$ system at 300 nm is comparable to that of high resolution silver halide emulsions at 436 nm (15).

Light of wavelengths less than 350 nm was effective in producing developable nuclei on these TiO_2 films. In agreement with the optical absorption spectrum of the films, photographic sensitivity was found to increase as the wavelength decreased from 350 to 290 nm.

Exposure of TiO_2 films in $PdCl_2$ solution.—As a result of u.v. exposure of TiO_2 films in palladium salt solutions a product layer was formed on the surface of the oxide. For all the cases studied, reflection high energy electron diffraction (RHEED) measurements gave the same diffraction pattern, as shown in Fig. 1. This pattern is characteristic of a polycrystalline fcc lattice. The lattice parameters derived from Fig. 1 are given in Table III and are in agreement with the published values for metallic palladium. The oxide film acted as a light-sensitive catalyst for the formation of polycrystalline palladium (9).

The light reaction was followed discontinuously by determining the palladium product spectrophotometrically as a function of exposure time. The same TiO_2 film could be used many times for the photocatalytic reduction without loss of sensitivity. The reaction could also be followed continuously by measuring the increase in absorption of the quartz/TiO_2 film at $\lambda > 500$ nm as a function of exposure time. The optical density of the palladium product film was directly proportional to the amount of metal present on the TiO_2.

The rate of reduction of palladium ions from a solution containing 5.6×10^{-3} mol/liter $PdCl_2$ and 0.12 mol/liter HCl was relatively low (Fig. 2, curve a). Compounds which are known to undergo photocatalytic oxidation on illuminated n-type oxide semiconductors (16-18) gave a considerable increase in the rate of palladium deposition, indicating the importance of the oxidation process. Results are shown in Fig. 2 for additions of methanol, ethanol, and 1-propanol (all 80% by volume). Optimum concentrations of the additives were not determined. We found that Tensagex also markedly increased the rate of formation of palladium on exposed TiO_2 (Fig. 2, curve d).

[a] Values from Swanson and Tatge NBS Circular 539, Vol. 1, 21 (1953).

The quantum efficiency Q, defined as the number of palladium atoms produced per photon, was measured by exposing TiO_2 films to monochromatic light (λ = 300 nm) in the two sensitizing solutions given in Table I. At the light intensities studied ($\leq 3 \times 10^{16}$ photons/cm^2 min), Q was independent of intensity. For the methanolic solution B, Q varied between 0.1 and 0.3, and for solution A values between 0.05 and 0.15 were found. The quantum efficiency for the corresponding $PdCl_2$-HCl solution without additives was at least a factor of 30 lower.

In Fig. 3 the changes in the ellipsometric parameters, Δ and ψ, as a function of exposure time are plotted for a TiO_2 film exposed in a solution containing 1.4×10^{-4} mol/liter $PdCl_2$ and 3.3×10^{-3} mol/liter HCl. For these experiments a diluted $PdCl_2$ solution without additive had to be used because light absorption by the usual sensitizing solutions at the exposure wavelength (~300 nm) was too great. Exposure led to a decrease in Δ and an increase in ψ. For palladium film thickness $\gtrsim$10Å the metal could be determined spectrophotometrically. In this region a linear relationship between film thickness and $\delta\Delta$ was observed. A palladium film with an average thickness of 10Å gave changes in Δ and ψ of approximately 20° and 4.5°, respectively. The magnitude of these changes is consistent with the formation of a metallic film on the oxide (1).

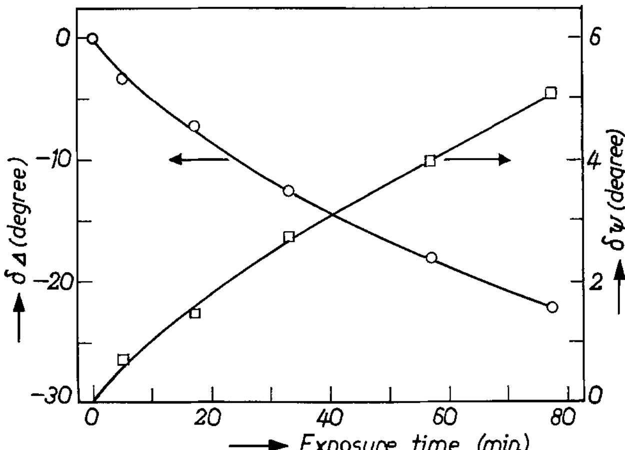

Fig. 3. Changes in the ellipsometric parameters of a TiO_2 film, due to exposure in a solution containing 1.4×10^{-4} mol/liter $PdCl_2$, 3.3×10^{-3} mol/liter HCl, as a function of exposure time.

Exposure of $PdCl_2$-sensitized TiO_2 films.—For the ellipsometric measurements using dried $PdCl_2$-sensitized films, the two sensitizing solutions shown in Table I were used. The TiO_2/glass film was mounted in the cell containing deionized water and the ellipsometric measurements were made. The water was then replaced by a $PdCl_2$-sensitizing solution. After 5 min this solution was removed and the oxide film was rinsed by filling and emptying the cell 5 times with water. The changes in Δ and ψ caused by irreversible adsorption in the dark of palladium species from the sensitizing solution were measured in water.

The cell was then refilled with the same $PdCl_2$ solution for 5 min and, when this solution had been removed, the film was dried using compressed air and exposed in the dried sensitized state to u.v. light. The exposed film was then rinsed 5 times with deionized water and the ellipsometric measurements were again performed with water in the cell.

In both cases adsorption of $PdCl_2$ species in the dark gave only very slight negative changes in ψ as shown in Table IV. Exposure of the dried sensitized films caused substantial changes in both Δ and ψ with Δ decreasing and ψ increasing as a function of exposure time. The direction of the changes in these parameters was the same as found for experiments involving exposure in solution (Fig. 3). These results, especially the considerable increases in ψ, indicated that metallic films are also formed on dried sensitized films.

Activity of nuclei for Ni deposition.—We observed certain anomalies concerning electroless Ni deposition on nuclei formed by exposure of $PdCl_2$-sensitized TiO_2 films. Nuclei obtained using sensitizing solution A could be developed with Ni, Ag, and Cu. However, when sensitizing solution B was used, the nuclei formed during exposure could be developed with Ag or Cu but not with Ni. Aqueous $PdCl_2$/HCl and $Pd(NO_3)_2$/HNO_3 solutions without Tensagex also gave "Ni-inactive" palladium nuclei.

When the TiO_2 film sensitized using solution A was overexposed to u.v. light, the activity of the nuclei for electroless Ni deposition was destroyed. Thus when a sensitized TiO_2 film was exposed at 300 nm at a light intensity of 6×10^{16} photons/cm^2 min, a threshold exposure as reported in Table II was found. However, on increasing the exposure by a factor of 100 at the same intensity the nuclei became inactive for Ni deposition, while remaining active for Ag and Cu deposition.

Discussion

Exposure of TiO_2 films in palladium salt solutions led to the formation of polycrystalline metallic films on the oxide. The presence of metallic nuclei after exposure of dried $PdCl_2$-sensitized films was shown by ellipsometry. It seems likely therefore that the catalytic nuclei for electroless deposition consist of metallic palladium particles. By assuming that the quantum efficiency for the initial stages of exposure of the $PdCl_2$-sensitized TiO_2 film does not differ seriously from the value found experimentally for exposure of TiO_2 in $PdCl_2$ solution, an estimate can be made of the minimum palladium coverage required for electroless deposition. The product of the minimum exposure (Table II) and the quantum efficiency, measured using the same exposure system, gives an indication of the minimum number of atoms required. Results are shown in Table V. If we assume that the palladium is distributed as atoms which each occupy 10Å^2 of the surface, then these values range from 8×10^{-3} of a monolayer for Ag deposition to 3.2×10^{-2} of a monolayer for Ni deposition. This suggests that very low palladium coverages are sufficient to catalyze electroless deposition.

The ellipsometric measurements indicate that this order of magnitude is correct. Thirty seconds exposure of the film sensitized using solution A gave a change in Δ of $-0.8°$ (Table IV). This corresponds to approximately 0.1 of a monolayer. The exposure time required for Ag development with this system was 1 sec. Assuming a linear increase in palladium coverage with exposure time in this range, this is equivalent to a surface coverage of approximately 3×10^{-3} of a monolayer.

Behrndt (19) was able to achieve reproducible surface coverages of from 10^{-3} monolayers upwards of gold and silver on glass and TiO_2 substrates by controlled deposition using a rate-controlled evaporation source, a shutter arrangement, and a quartz crystal oscillator detector system. These films could be developed by Ag deposition. In this way it was possible to specify the number of silver or gold atoms necessary to give Ag development. There is a good similarity between their minimum Au and Ag coverages on TiO_2, given in Table V, and our estimated Pd coverages also shown in the same table. Hamilton and Logel (20) report that for electroless deposition of nickel, from a dimethylamineborane bath, on palladium nuclei evaporated onto amorphous carbon substrates, a coverage of 5×10^{14} atoms/cm^2 is required. Their work suggests that nuclei containing at least 4 palladium atoms are required for Ni deposition.

The results found in the present work do not explain why certain palladium nuclei were not catalytic for deposition of Ni from the solutions used here. The deactivation of "Ni-active" nuclei due to overexposure of the films with u.v. light is also not explained. Chow and co-workers (21) found an analogous effect with nuclei prepared by $SnCl_2$ sensitization, $PdCl_2$ activation of Formvar substrates. Freshly activated substrates were catalytic for Ni and Co deposition. For the activated films they found a diffuse electron diffraction pattern, difficult to attribute to any one symmetry. Recent investigations (1) have shown the absence of metallic palladium on activated glass substrates. Chow *et al.* found that 50 min irradiation of activated films caused the nuclei to become inactive for Ni and Co deposition while remaining active for Cu deposition. They observed an increase in the degree of crystallization of the activated film due to irradiation. They speculate that the increased crystallinity of the palladium may inhibit deposition of Ni and Co, which unlike Cu, give an initial glassy, noncrystalline structure.

Table IV. Changes in the ellipsometric parameters, Δ and ψ, of TiO_2 films as a result of $PdCl_2$ treatments

Solution	Treatment	$\delta\Delta$	$\delta\psi$
$PdCl_2$-sensitizing solution A	Not exposed	−0.22	−0.06
	Exposed ½ min[a]	−0.80	+0.16
	Exposed 1½ min[a]	−1.30	+0.30

Conclusions

As a result of u.v. exposure of transparent TiO_2 films in the presence of various palladium salts, catalytic nuclei are formed. Such nuclei can be developed by electroless deposition of different metals. Electron diffraction and ellipsometric measurements have shown the light reaction product to be polycrystalline metallic palladium. Using the results of quantum efficiency and ellipsometric measurements, the minimum palladium coverages required for electroless Ag and Ni deposition were estimated. The values found ranged from 8×10^{-3} of a monolayer for Ag to 3×10^{-2} of a monolayer for Ni. Two factors contribute to the high photographic sensitivity (100-500 $\mu J/cm^2$) of the $PdCl_2/TiO_2$ film system: the quantum efficiency for the production of metallic palladium is relatively high, while the minimum palladium coverage required for electroless deposition is very low.

ABSTRACT

GaAs epitaxial layers with low electron concentrations were obtained from an alkylgallium and arsine system by use of triethylgallium. The highest Hall mobility of the layer, with an electron concentration of $7.0 \times 10^{13}/cm^3$ at 77°K was 120,000 cm^2/V sec. Carrier concentration and carrier type of the layer could be changed in the range of from 10^{12} to $\sim 10^{16}/cm^3$ by changing the arsine to triethyl gallium mole ratio introduced into a deposition zone. This fact was expected to be due to the amphoteric impurity sharing between the arsenic and the gallium sites of GaAs crystal.

Although the extension of carrier concentration to the lower range resulted from impurity compensation, mobility data of the layers of electron concentrations higher than about $10^{14}/cm^3$ were almost the same as those from the usual $AsCl_3$-Ga-H_2 system. Dominant acceptor impurities observed in the photoluminescence measurements were discussed and were correlated with amphoteric silicon and carbon impurities. This was consistent with the result obtained on the impurities of the layer by mass spectroscopic analysis.

One of the most commonly used techniques for growing high purity GaAs epitaxial layers from vapor phase is one using the $AsCl_3$-Ga-H_2 system (1). Because of extensive efforts for growing high purity GaAs over the past several years (2-8), it is now possible to obtain GaAs with total ionized impurity concentration ($N_D + N_A$) in the $10^{13}/cm^3$ range (4). Although recent reports throw light on the preparation of high purity GaAs (5-8), the $AsCl_3$-Ga-H_2 system is rather complicated and somewhat unstable (9).

A system using alkylgallium and arsine, first reported by Manasevit (10), seems to have some advantage compared with the $AsCl_3$-Ga-H_2 system. This system required only one temperature zone, whose temperature is easily controlled inductively by r.f. power. Crystal growth takes place on the substrate on a heated pedestal in a quartz tube with a cool wall. The system does not contain reactive halogen. This seems to be an important factor to suppress impurity incorporation into the layer from the reactor system.

In spite of extensive experiments on the deposition of the layer by this method (11-15), total impurity ($N_D + N_A$) seems to be higher than $10^{16}/cm^3$ so far. Rai-Chaudhury (12) and Ito *et al.* (15) detected a large quantity of impurities in the layer, such as silicon, carbon, and others by the mass spectroscopic analysis. Shallow active impurities of the layer were examined by the photoluminescence measurement and were expected to be carbon and/or silicon which mainly come from the trimethylgallium source (15). These reports seemed to show that a high purity gallium source, whose silicon and carbon impurities are reduced, should be used to obtain a high purity GaAs layer. Lindeke *et al.* (16) used distilled gallium diethyl chloride as gallium source, but the electron Hall mobility data at 77°K showed that impurity concentration was nearly the same as that from the trimethylgallium source.

In this experiment, high purity triethylgallium (TEG) was used as gallium source in place of trimethylgallium (TMG), in order to reduce carbon contamination. It has been pointed out that decomposition reaction of trimethyl compounds of metallic elements was accompanied with formation of carbide (17), whereas triethyl compound decomposed to pure metal through some alkyl-metal-hydrides and metal-hydride formation steps, in the case of aluminum alkyl compounds (18).

Although no experiment has been reported on gallium-carbide formation by trimethylgallium decomposition, the above experiments on aluminum compounds suggested that less carbide formation (less carbon incorporation) would be expected when TEG was used in place of TMG. Manasevit and Simpson (11) used TEG in their earlier experiment and determined the feasibility of obtaining a signal crystal on a germanium substrate. However few experiments on the electronic properties of a layer from a TEG source have been reported.

In this experiment, an epitaxial layer was deposited on a GaAs substrate by use of TEG and AsH_3. Conduction type conversion, the Hall mobility, compensation ratio, and photoluminescence spectra of the layer are discussed.

Experimental

Expitaxial growth apparatus used in the experiments was a vertical one and almost the same as reported before (15). Gas mixing apparatus was made of a stainless steel tube, joints, and mass flow sensors. Air leak through joint fittings was eliminated as much as possible. Si- and Cr-doped GaAs wafers with (100) face were used as substrates. These were mechanically polished and then etched in a $3H_2SO_4$-H_2O_2-H_2O solution. A quartz bubbler containing TEG was kept at 21°C during the growth. Vapor saturation rate of TEG through the bubbler was found to be over 95% in the experimental condition. Two TEG sources used,[1] TEG-2 and TEG-6, were chemical analysis grade and electronic grade, respectively. AsH_3 diluted to about 1% with a high purity argon,[2] 99.9999%, was used.

[1] TEG sources are commercial products and were supplied by Sumitomo Chemical Company, Limited, Japan.

[2] AsH_3 was made by Phoenix Research Corporation, U.S.A., and was diluted to −1% with argon by Nihon Sanso Company, Limited, Japan.

Key words: crystal growth, chemical vapor deposition, silicon in GaAs, carbon in GaAs, high purity GaAs, GaAs Hall effect, GaAs mobility, GaAs photoluminescence.

Nominal purity of the original AsH_3 was 99.999% and this contained <1 ppm of O_2, N_2, CH_4, and CO_2 as dominant impurities, respectively.

Flow rates of AsH_3 were varied in the ranges from 2×10^{-4} to 3.6×10^{-3} mole/min to a fixed TEG flow rate of 3×10^{-4} mole/min. An additional H_2 flow was added to keep the total gas flow rate constant (3000 cm^3/min).

Deposition temperature was 650°C. AsH_3 flow started when the substrate temperature reached about 500°C, prior to the introduction of TEG into the reactor, in order to prevent substrate decomposition. After the deposition was completed, the AsH_3 flow was continued until the substrate temperature had dropped to 500°C. Growth rate of the layer was about 0.2 μm/min.

For electronic and optical measurements, layers $\geq$10 μm thick were used. Hall measurement of a layer deposited on Cr-doped semi-insulating substrate was carried out in a magnetic field of 6000G. The shell measurements and the C-V measurements using a palladium Schottky barrier gave the same carrier concentrations. Deviation of thickness homogeneity was about 10% throughout the layer with ~5 cm^2 area. Carrier profile measurement using an impurity profile plotter (J.A.C. Electronic Limited, England, Model 366) showed flat profiles, independent of the layer thickness, and no anomaly at the epitaxial-substrate interface was observed.

Photoluminescence measurement of the layer was carried out at near liquid He temperatures by He-Ne laser beam excitation, using nearly the same method reported before (19). Monochrometer resolution was 0.2 meV.

Results and Discussion

Effect of the arsine to triethylgallium mole ratio on carrier concentration.—Figure 1 shows the effect of the AsH_3 to TEG mole ratio ([As]/[Ga] ratio) fed into the reactor during the growth on the carrier concentration for two TEG sources. All data were obtained by changing the AsH_3 flow rate to a fixed TEG flow rate of 3×10^{-4} mole/min. At low [As]/[Ga] ratios, the layers show p-type conduction. Conduction type of the layer was changed from p- to n-type by increasing the [As]/[Ga] ratio. Electron concentration of the layer was increased by further increasing of the [As]/[Ga] ratio. The figure shows some changes in the maximum carrier level and in transition points, where n- to p-type conversion occurred, depending on the TEG source lots, TEG-2 and -6. These were not changed so much, though AsH_3 cylinders were changed. These changes, accompanied with TEG source change, are expected to be due to the difference in residual impurities of the sources. Shift of p- to n-type conversion point is assumed to be due to the fact that there is more column II acceptor in TEG-2 source or more column VI donor impurity in TEG-6 source.

Although there are some few difference in in the result between two sources, as seen in Fig. 1, the main features, where carrier concentration change and p- to n-type conversion occurred by changing the [As]/[Ga] ratio, are the same for the layers from two sources. The same [As]/[Ga] ratio effect, even in the TMG-AsH_3 system, has been observed by Thorsen and Manasevit (14) for a heteroepitaxy case and by Ito *et al.* (5) for a homoepitaxy case. These results seem to show that the [As]/[Ga] ratio is an essential factor in defining the properties of the GaAs layers from the alkylgallium and arsine system.

It has been said that compositional deviation from stoichiometry induces some defects in GaAs, which affect the electronic properties. The direct effects of defects were considered by Blanch *et al.* (20) and others (21-23) in which the conversion of n-type to p-type GaAs by heat-treatment was ascribed to such defects. Also, the effects in the vapor epitaxial growth were considered by Nakagawa and Ikoma (24), Okamoto and Sakata (25), and Ihara *et al.* (26), in which the carrier concentration change was ascribed to the

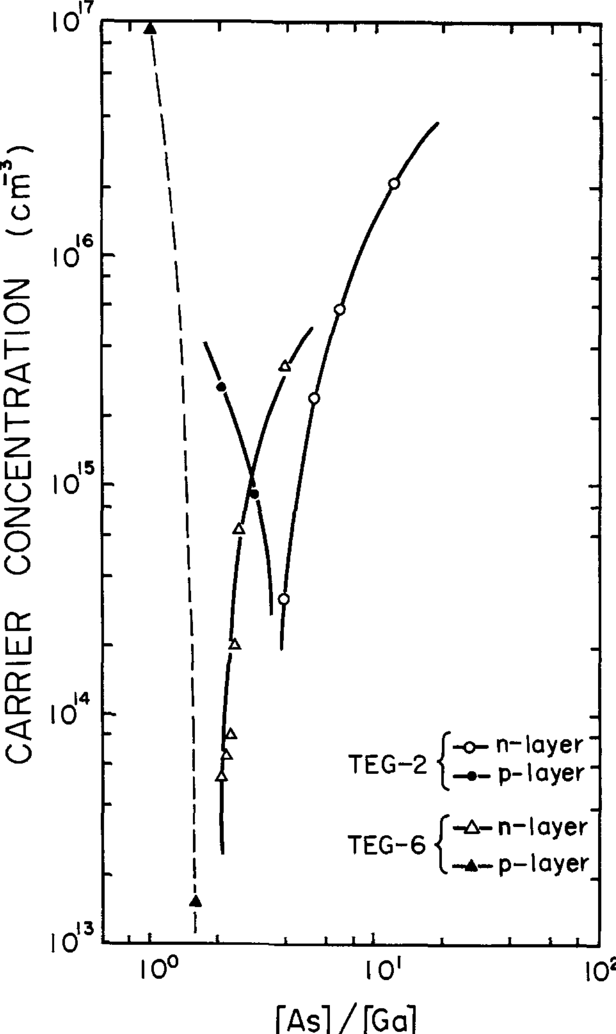

Fig. 1. Effect of the [As]/[Ga] ratio on carrier concentration of the layer. TEG-2 source contained higher silicon impurity than TEG-6.

reaction between the amphoteric impurity and defects. Also, thermodynamic considerations were made by Logan and Hurle (27) for the case without impurity and by Kroger (28) and others (24, 26) for the case with impurity. It is assumed, also, for the alkylgallium and arsine system that the [As]/[Ga] ratio change during the growth affects the stoichiometry which changes properties of the growing GaAs layer.

Thorsen and Manasevit (14) reported that occurrence of p-type layer at a low [As]/[Ga] ratio is ascribed to the arsenic vacancy. But, there have been few experiments reported which show that the arsenic vacancy forms a shallow acceptor. It seems to be difficult to explain the feature, as seen in Fig. 1, from the viewpoint of arsenic vacancy. Ito *et al.* (15) reported that the [As]/[Ga] ratio effect is ascribed to carbon and/or silicon. However they did not identify carbon and silicon, respectively. Detailed experiments are needed in order to explain the [As]/[Ga] ratio effect, as seen in Fig. 1.

Column II element forms a shallow acceptor in GaAs. But, as will be reported in the following section, the layer does not contain column 11 element and main impurities are assumed to be carbon, silicon, and sulfur. The following model, based on the reaction between these column IV impurities and vacancies, seems to explain the [As]/[Ga] ratio effects, as well as the mobility data and the photoluminescence results which will be discussed in the following sections. Since TEG was checked containing 0.5 ppm silicon, column IV elements, such as carbon and silicon in the layer, were thought to come from the TEG sources. Column

IV elements have been thought to be amphoteric impurities, *e.g.*, silicon on gallium site is acceptor and that on arsenic site is donor in GaAs. From a simple thermodynamic consideration, vacant site concentrations of gallium and arsenic are expected to be proportional to $[As]/[Ga]^{-m}$, respectively.[3]

Amphoteric impurities shared from vapor phase to gallium and arsenic sites of the crystal are thought to be proportional to the respective vacant site concentrations. So, it is assumed that, at a low [As]/[Ga] ratio, amphoteric impurities shared to arsenic sites rather than to gallium sites are dominant and the layer becomes p-type. On the contrary, at a high [As]/[Ga] ratio, amphoteric impurities shared to gallium sites are dominant and the layer becomes n-type. This model can explain the reason why, at lower [As]/[Ga] ratios, the layers are p-type and become n-type by increasing the [As]/[Ga] ratio, as seen in Fig. 1.

However in Fig. 1, the p-type layer with the highest carrier concentration of $\sim 10^{17}/cm^3$ from TEG-6 source may come from another origin. At such a low [As]/[Ga] ratio, ~ 1, it was difficult to deposit an epitaxial layer with good quality. In this case, the layer showed poor crystallinity, and some kind of defects should be the origin for the high hole density.

Effects of the [As]/[Ga] ratio on Hall mobility and compensation ratio.—The Hall mobility was measured at room temperature and 77°K. The layers with electron concentration in the range from 5×10^{13} to $8 \times 10^{15}/cm^3$ were obtained by changing the [As]/[Ga] ratio, where AsH_3 flow rate was changed to a fixed TEG flow rate of 3×10^{-4} mole/min. Room temperature Hall mobilities varied in the range from 7400 to 8500 cm^2/V sec for the layers from TEG-6 source and from 6500 to 7800 cm^2/V sec for the layers from TEG-2 source, corresponding to the carrier concentration. These room temperature data are nearly the same as the reported values (8, 29).

Figure 2 shows the correlation between the Hall mobility and the electron concentration at 77°K. Also plotted are curves showing the theoretical 77°K mobility as a function of electron concentration for several fixed compensation ratios (29). Some data plotted in the figure are mobility of the layer with (100) orientation obtained from the $Ga/AsCl_3/H_2$ system (8). Figure 2 shows that mobilities of layers with an electron concentration higher than $\sim 10^{14}/cm^3$ are almost the same as those from the usual $Ga/AsCl_3/H_2$ system.

[3] $m = \frac{1}{2}$. Detailed thermodynamical consideration will be reported in the future.

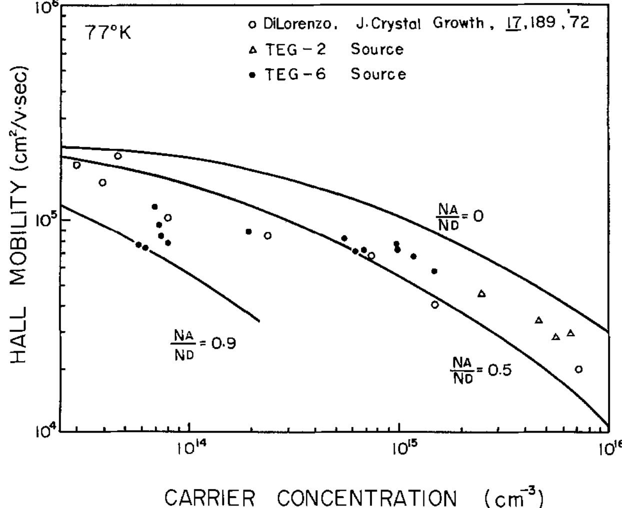

Fig. 2. Variation of 77°K mobility with the carrier concentration ($N_D - N_A$) showing the effects of variable compensation. Carrier concentration of undoped layer was changed by changing the [As]/[Ga] ratio during the growth. Thickness of the layer was in the range from 15 to 30 μm. Symbols △ and ○ represent present work; ● represents DiLorenzo's using the $Ga/AsCl_3/H_2$ system (8); K, compensation ratio calculated by Wolfe *et al.* (30).

Also, this figure shows that layers with a lower electron concentration have a higher compensation ratio and the decrease of electron concentration of the layer is accompanied with an increase in the compensation ratio. This fact is consistent with the result of thermodynamic consideration, in which amphoteric impurities are shared between gallium sites and arsenic sites, according to the [As]/[Ga] ratio. According to the amphoteric impurity share model, the compensation ratio for the n-type region is expected to be proportional to $([As]/[Ga])^{-m}$.[3] This seems to explain the experimental result as shown in Fig. 2, wherein the donor concentration is nearly the same as that of acceptor ($K \doteqdot 1$) in the layer deposited at low [As]/[Ga] ratios and the compensation ratio becomes smaller in the layers deposited at higher [As]/[Ga] ratios.

Photoluminescence experiment.—Shallow acceptor levels of the layer were examined by use of the photoluminescence measurement at low temperatures. Figure 3 shows the photoluminescence spectra of an n-type sample at 10°K. There are five emission peaks near the bandgap in the range from 8180 to 8220Å. Bogardus and Bebb (31) and Rossi *et al.* (32) reported that there are five emission peaks near the bandgap energy in high purity epitaxial GaAs. According to Bogardus and Bebb (31), these are expected to be due to the free exciton (X), the exciton-neutral donor (D°, X), neutral donor-band (D°, h), exciton-ionized donor (D^+, X), and exciton-neutral acceptor (A°, X) recombinations.

It is noted that there are three emission peaks in the range from 8250 to 8450Å.

Figure 4 shows the photoluminescence spectra at 11°K of p- and n-type layers, with different carrier concentrations in the range from 8250 to 8450Å. The spectra of n-type layers consist of three emission lines, indicated as A, B, and C in the figure. Intensities of the emissions are increased in the layers which have lower electron concentrations and are the most intense in the p-type layer. This seems to show that the layer deposited at lower [As]/[Ga] ratios contains many more acceptors. Emission spectra of a p-layer in this range consist of B and C emission. Many workers have pointed out that the photoluminescence spectra of high purity GaAs in this wavelength range have several luminescence peaks involving acceptors (31, 33-35). Recently, Rossi *et al.* (35) identified the origin for the emission line multiplicity in this wavelength region by a photoluminescence experiment under a magnetic field. They identified three emission peaks in the photoluminescence spectra of their high purity n-type GaAs, associated with two shallow acceptors having different binding energies, respectively. Thus, the data indicated that two acceptor levels were present in the sample and that two free-electron neutral-acceptor emissions and two donor-acceptor pair emissions were expected, but two of these emissions were overlapped.

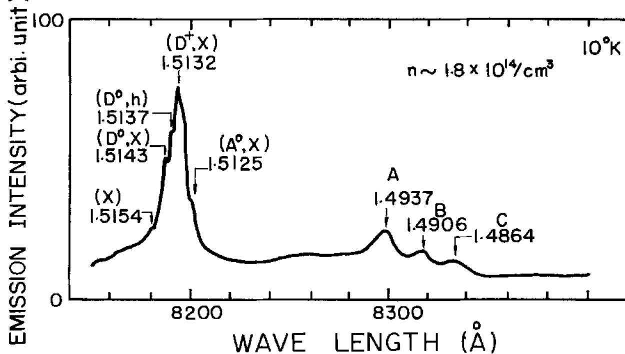

Fig. 3. Photoluminescence spectra from n-type layer at 10°K. Identification of near bandgap emissions, (X), (D°, X), (D°, h), (D^+, X), and (A°, X) follow after Bogardus and Bebb (31).

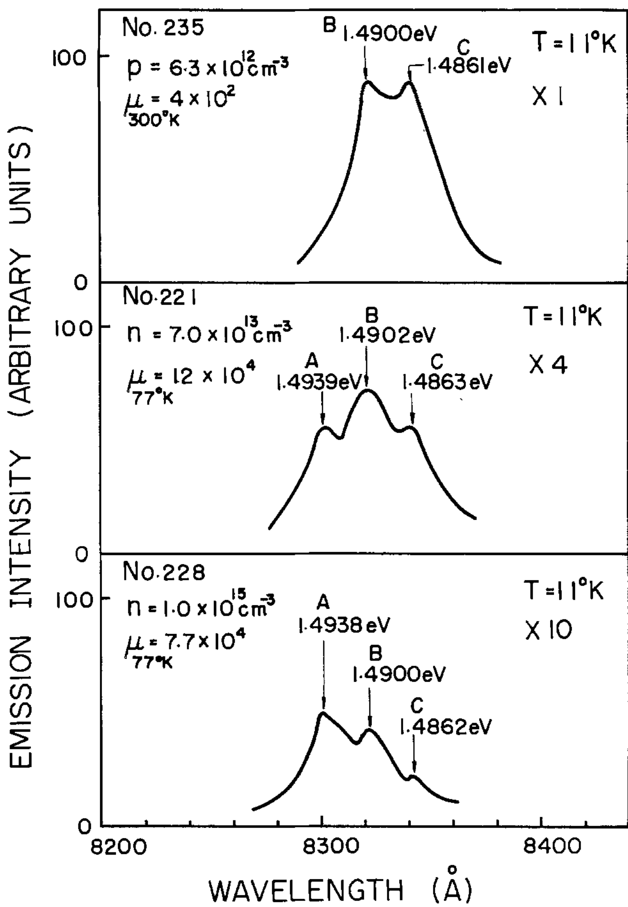

Fig. 4. Photoluminescence spectra of p- and n-layers with different carrier concentration, corresponding to emission peaks A, B, and C in Fig. 3.

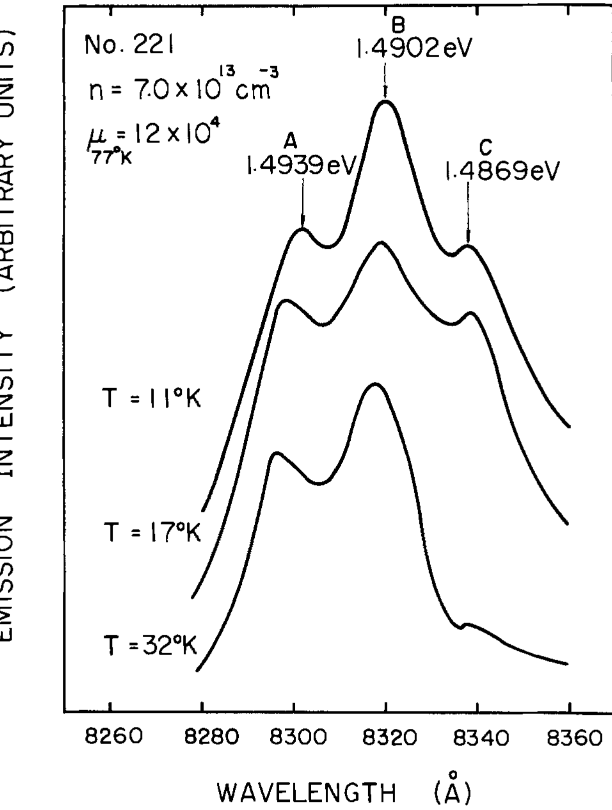

Fig. 5. Variation of photoluminescence showing the increase in intensity of free electron to acceptor recombinations, 1.4939 and 1.4902 eV, with a simultaneous decrease in donor to acceptor pair emission of 1.4869 eV due to increasing temperature.

If the present photoluminescence results were the same as in the above experiments, binding energies of two acceptors are 25.6 and 29.4 meV, respectively, using a bandgap energy of 1.5194 eV (47). This assumption is consistent with the following experiment on temperature dependence of the photoluminescence spectra. Emission peak C of 1.4869 at 11°K was annihilated by increasing temperature, whereas emission peaks A and B shifted toward the higher energy side, but the emission intensities did not change so much, as shown in Fig. 5.

These facts show that emission peaks A and B are due to free electron and to two different acceptor recombinations, respectively, and emission peak C is due to a donor-acceptor pair recombination, being of the same origin of acceptor as emission peak B. It is assumed that an emission due to donor to acceptor pair recombination, being the same acceptor origin as emission A, has not been identified with emission peak B, because of the overlap of this pair emission and the emission peak B.

There have been many reports on the shallow acceptor levels in GaAs. Data are shown in Table I. The acceptor with a binding energy of 25.6 meV in this experiment is assumed to be carbon. However, there are two different results for the acceptor with a binding energy of 29.4 meV. This acceptor is assumed to be either silicon or zinc. Therefore, it cannot be decided, from these reports, whether silicon or zinc is responsible for emission peaks B and C. However, it should be noted that the emission peaks B and C become more intense in n-type layers with lower electron concentrations and become dominant in a p-type layer, as shown in Fig. 4. This fact means that emission peaks B and C are more intense in a layer which is deposited under the low [As]/[Ga] ratios. The layer deposited under the low [As]/[Ga] ratios could be expected to contain higher density of impurity substituting arsenic sites than gallium sites of the crystal.

It is reasonable to think that the impurities substituted on the arsenic sites to form acceptors are the origin for the emissions. Thus, silicon substituted on the arsenic sites is expected to be the acceptor responsible for emission peaks B and C in this sample, rather than zinc. Emission spectra of the p-type layer consist of B and C emissions, in Fig. 1. The C emission was observed to be annihilated at higher temperatures. This seems to show that B emission is due to free electron to silicon acceptor recombination and silicon is a dominant acceptor in the p-type layers.

This expectation was supported by the result of a mass spectroscopic analysis of the layer, as shown in Table II. Carbon, silicon, and sulfur were detected as major impurities, but zinc was not detected within the zinc detection limit of ~ 0.03 ppm. Mass spectroscopic analysis was carried out on the GaAs sample deposited on the lightly sulfur-doped germanium as an electronic

Samples were made by depositing the GaAs layer on sulfur-doped Ge crystal containing C (8 ppm), Si (0.4 ppm), S (0.7 ppm), and Fe 0.5 ppm).

conductive support. The germanium support was found to be containing C(8 ppm), Si(0.4 ppm), S(0.7 ppm), and Fe(0.5 ppm). Analytical data show that the GaAs layer does not contain these impurities exceeding the above values, at least. The carbon contamination (<8 ppm) for the layer from TEG source of less than the 25 ppm for the layer from the TMG source (15) seems to show that TEG is an appropriate source for reducing carbon contamination.

From the amphoteric impurity share model, dominant donor impurities are assumed to be carbon and silicon on gallium sites. Silicon has been thought to form a donor, but no experiment has been reported to show that carbon forms a donor. In order to confirm the existence of a carbon donor, additional experiments, such as carbon doping, are needed. This is a future problem.

Conclusion

High purity epitaxial GaAs has been deposited on GaAs substrate using high purity triethylgallium and arsine as source materials.

The layer carrier type was changed by changing the [As]/[Ga] ratio introduced into the reactor. A higher [As]/[Ga] ratio made the layer more n-type.

Carrier type conversion and carrier concentration change accompanying the [As]/[Ga] ratio change were explained by the sharing of amphoteric impurities between gallium sites and arsenic sites. The Hall mobility data, carrier compensation effect, and photoluminescence results were consistent with the amphoteric impurity sharing model. Dominant impurity active impurities were expected to be carbon and silicon. This agreed with the impurities determined by the mass spectroscopic analysis.

Triethylgallium is a useful source material for growing a high purity epitaxial layer. A higher purity layer would be deposited by eliminating silicon impurity from the source materials.

Electron Hall mobility at room temperature and at 77°K of the layers with an electron concentration higher than $\sim 10^{14}/cm^3$ was nearly the same as those obtained by the usual $Ga\text{-}AsCl_3\text{-}H_2$ system. The highest electron Hall mobility at 77°K was 120,000 cm^2/V sec for the layer with an electron concentration of $7 \times 10^{13}/cm^3$.

Three emission peaks were observed in the wavelength range from 8250 to 8450Å in photoluminescence and were due to two shallow acceptors with binding energies of 25.6 and 29.4 meV, which corresponded to carbon and silicon in the arsenic sites, respectively.

Acknowledgment

The authors are grateful to Dr. S. Asanabe for his encouragement and support.

Grateful acknowledgement is made for helpful discussions on the photoluminescence experiment with Dr. K. Sugibuchi and Mr. H. Iwasaki.

Manuscript submitted Oct. 18, 1974; revised manuscript received April 16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Nippon Electric Company, Limited.

Investigation of Breakdown and Resistivity Striations in High-Voltage Silicon Diodes

A. Mühlbauer, F. Sedlak, and P. Voss

Siemens AG, Bereich Bauelemente, 8 München, F. R. Germany

ABSTRACT

The breakdown behavior of high-voltage diodes prepared from silicon wafers that were cut parallel to the rod axis was observed by means of the infrared breakdown radiation. The breakdown patterns were striated and could be correlated to spreading resistance measurements on a microscopic scale. It could be confirmed experimentally that the breakdown in material with resistivity variations not only depends on the absolute resistivity value at each location, but also to a large extent on the wave form and the period of the variations. Only in diodes in which the microscopic resistivity variations had high amplitudes and a distinct periodicity with wavelengths longer than the extent of the space charge region did individual minima lead to individual clearly separated breakdown lines.

The incorporation of dopants during the growth of silicon crystals from the melt is usually layerlike (1). Microscopic dopant variations are generated in this way along the axis of the rod. They are normally determined by means of a resistivity measurement with high local resolution (1,2).

The effect of these fluctuations on device properties depends to a large degree on their geometrical extent as compared to the dimensions of a single active element of the device. The critical dimension can be given by a lateral dimension or by the extent of a space charge region.

For small-area discrete devices the influence is easily estimated, since in these the resistivity remains virtually constant within one single element. The resistivity variations manifest themselves in variations of the properties from one device to the other. An example is the multidiode vidicon in which the resistivity variations become visible in the dark current display (3).

In the large-area discrete devices used for power applications, *e.g.*, in thyristors and in rectifiers, the period of the variations may be small compared with the lateral dimensions and of the same order or smaller than the extent of the space charge region. Therefore, it is significantly more difficult to estimate the influence of the resistivity variations on the device properties. For example, it is no longer possible to assume a one-to-one relationship between a measured resistivity profile and the breakdown behavior of a p-n junction.

The breakdown of a p-n junction is determined by the field strength at the junction. In homogeneously doped silicon the applied voltage needed to reach the breakdown field strength is proportional to the resistivity, according to Poisson's equation. The breakdown field strength itself varies slightly with resistivity due to the sensitivity of the breakdown to the gradient of the field strength (4).

Cornu and Sittig (5) have investigated theoretically the influence of resistivity variations on the distribution of the electrical field strength for a constant applied voltage. They considered resistivity minima in the shape of a sinusoidal half-wave or of rectangular shape that were arranged perpendicular to the p-n junction. They concluded that as compared with an equivalent one-dimensional resistivity reduction a 10% dip of the resistivity causes hardly any increase in the maximum field strength, if its width is less than the extent of the space charge region.

On the other hand, for a width twice the extent of the space charge region, the increase in field strength reaches 70% of that of the one-dimensional increase. Therefore, in this case breakdown will occur predominantly at the location of the resistivity minimum.

For low-voltage devices and for low current densities there may exist influences on the breakdown behavior other than that of the resistivity, *e.g.*, influences of lattice defects like dislocations, stacking faults, and "swirls." So far we have found no experimental indication that there are any such influences on the high current density breakdown of high-voltage diodes made from dislocation-free silicon of the type investigated in this paper. This was particularly evident when the diodes were manufactured from silicon homogeneously doped by neutron irradiation (6).

The purpose of this paper is to clarify experimentally the correlation between microscopic resistivity variations and the breakdown behavior of high-voltage diodes for devices made from wafers that were cut parallel to the rod axis (lengthwise cuts). In lengthwise cuts the arrangement of the resistivity variations is easier to survey than in normal cuts, *i.e.*, cuts that are perpendicular to the rod axis. While in the first case the dopant layers are arranged perpendicular to the p-n junction across the entire area, the intersection angle varies in the second case (see Fig. 1).

The distribution of the infrared breakdown radiation was observed (7) and the resistivity profile in the same diodes determined by means of spreading resistance (SR) measurements (2).

Key words: spreading resistance measurements, infrared breakdown radiation, breakdown lines, space charge region.

Experimental

The results that are reported were obtained with diodes made from two, dislocation-free, float-zoned silicon rods that were phosphorus-doped. The average resistivity of the first rod (No. 340) was 70 ohm-cm. The macroscopic resistivity variations in this silicon were less than ±10% which is considered quite homogeneous by common standards. Such material is used for the fabrication of power devices. The breakdown voltage of the diodes was higher than 2000V. The second rod (No. 4214B) had a resistivity dip in the center (dopant core). The minimum resistivity was 52 ohm-cm.

The investigated samples were cut from the <111>-oriented silicon rod parallel to the rod axis in a {112} plane. Figure 1 indicates schematically how resistivity striations are distributed inside slices that are cut perpendicular to the rod axis as compared with slices cut parallel to the axis.

Starting from slices approximately 470 μm thick, diodes were fabricated by diffusion as described in Ref. (7). The p-n junction was located 90 μm below the surface. The slices were alloyed onto molybdenum on the p-doped side. The other side was provided with an evaporated grid electrode of aluminum, to make possible the observation of the breakdown radiation. The grid spacing was 3 mm. In one case an arrangement of observation holes, 0.5 mm apart, was used for a p-n-p structure [as in Ref. (7)].

As the first step in the investigation, the distribution of the breakdown radiation emitted from the entire area of each diode was recorded. Then, the aluminum electrode and a layer of the silicon approximately 100 μm wide[1] were removed. The silicon surface was mechanically-chemically polished in preparation for the spreading resistance measurement.

An ASR-100 (Solid-State Measurements) with two probes at a distance of 0.6 mm was used to determine the distribution of the microscopic resistivity variations. The probes were aligned perpendicular to the growth axis. All measurement tracks were parallel to the axis. The distance between steps was 25 μm.

Results

The breakdown radiation emitted from diodes that were cut in the normal fashion perpendicular to the axis from rod No.340 showed a quite regular spiraling pattern (Fig. 2). It thus clearly indicated the presence of periodic resistivity variations.

[1] In lengthwise cut slices, the width of the removed layer is not critical for the result of the measurement, as long as one stays inside the original material. This fact will become evident in the next section.

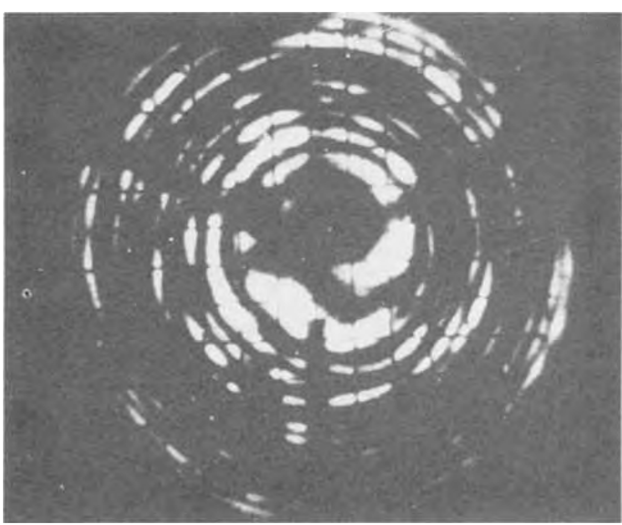

Fig. 2. Breakdown pattern of a normal cut diode from rod No. 340; breakdown current 50A. Grid electrode spacing is 3 mm. The three dark bars separated by 120° are current terminals.

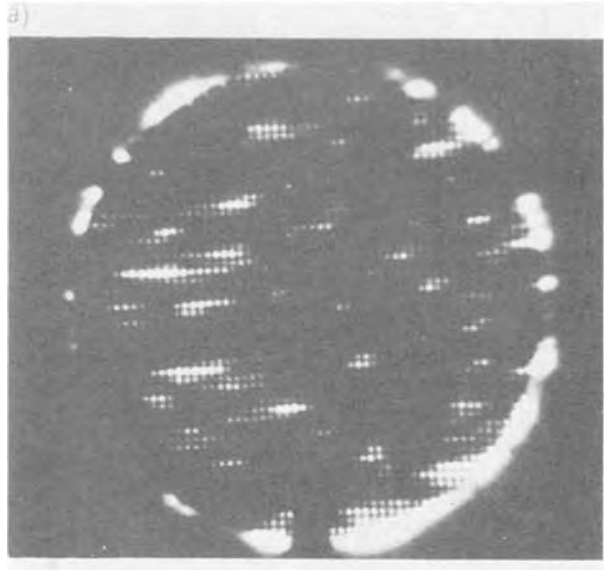
In order to demonstrate that in lengthwise cuts the resistivity distribution virtually does not change perpendicular to the p-n junction over a distance of several hundred microns, we prepared p-n-p structures with the two junctions 300 μm apart. An example of the two breakdown radiation patterns obtained from a p-n-p structure is given in Fig. 3. Only a very close inspection of the patterns reveals that there are actually small differences. Thus, it is justified to compare the breakdown patterns with SR measurements that are taken at some distance from the p-n junction.

Figure 4 shows two examples of diode breakdown patterns. The diameter of the diodes is 33 mm. The slices used for these diodes were cut at position 3.6 and 17.8 mm from the rod axis. The breakdown patterns became more homogeneous at higher current levels. The radiation patterns are clearly striated. The minimum distance between striations is the same (290 μm) as the distance obtained from a striation etch. With larger distance from the rod axis the distribution of the breakdown radiation becomes more homogeneous across the area.

The comparison between breakdown pattern and SR measurement was performed with the diode cut 3.6 mm away from the rod axis (Fig. 4a). The measuring track is indicated in Fig. 5, which is the magnified center section of Fig. 4a, turned 90 degrees. As mentioned above, two SR probes at a distance of 0.6 mm were



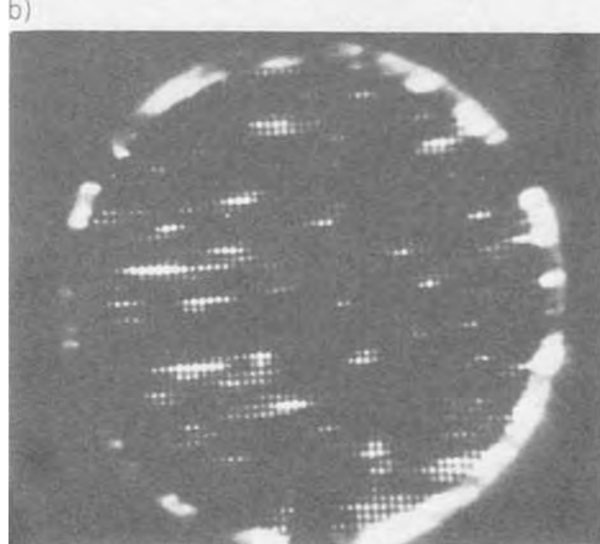


Fig. 3. Breakdown patterns of the two junctions in a p-n-p structure (lengthwise cut); 28 mm diameter of the electrode.

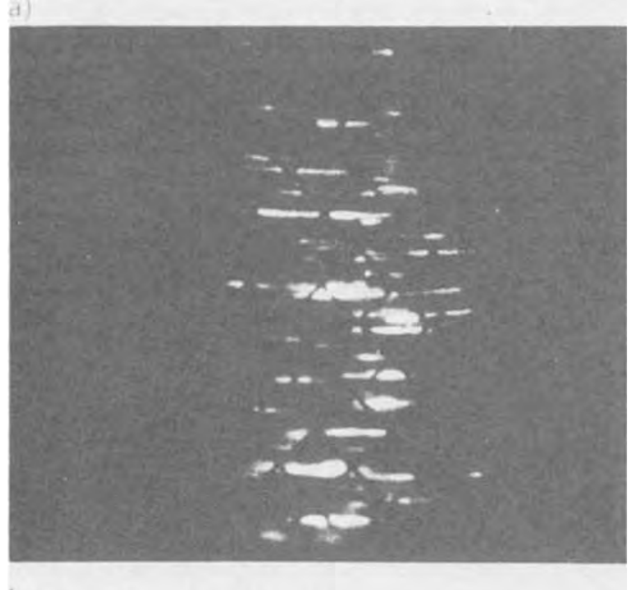

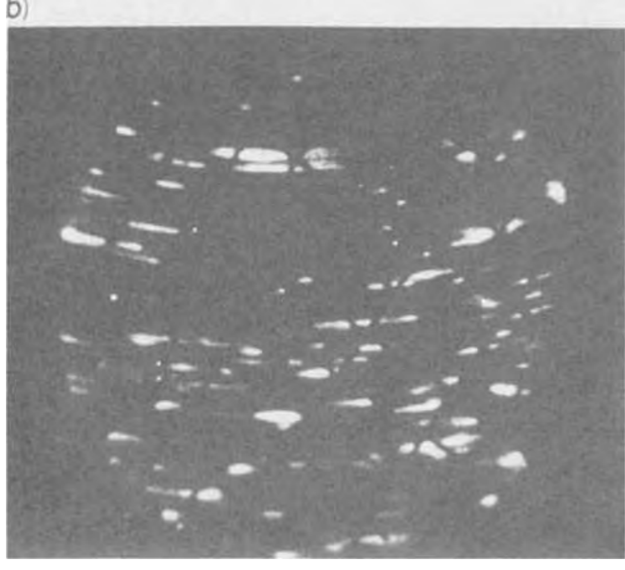

Fig. 4. Breakdown patterns of lengthwise cut diodes at a breakdown current of 7A. The grid electrode spacing is 3 mm. (a) Cut 3.6 mm off the rod axis. (b) Cut 17.8 mm off the rod axis.

used, *i.e.*, the probes were applied to the silicon surface 0.3 mm to both sides of the indicated track. In Fig. 6 the results of the SR measurement and the breakdown pattern magnified to the same scale are arranged adjacently. The spatial resolution of the breakdown pattern in Fig. 5 and 6 is approximately 200 μm.

The SR profile shows a quite regular fluctuation pattern. The amplitudes average to approximately ±20%, the period to 290 μm.

The breakdown patterns in Fig. 4-6 are representative for the breakdown in diodes in which the period of the resistivity variations is longer (290 μm) than the extent of the space region (180 μm), while the width of the individual minima is slightly smaller. The results given in Fig. 7 and 8 are examples for a silicon crystal that shows less regular microscopic resistivity variations with a distance between pronounced minima (125 μm) that is slightly shorter than the extent of the space charge region (140 μm). The etched silicon surface revealed straight striations (facets), also at a distance of approximately 125 μm. The detail of Fig. 8c was taken independently with an optical arrangement with higher resolution. The spatial resolution in Fig. 7 and 8b is approximately 200 μm and better than 100 μm in Fig. 8c.

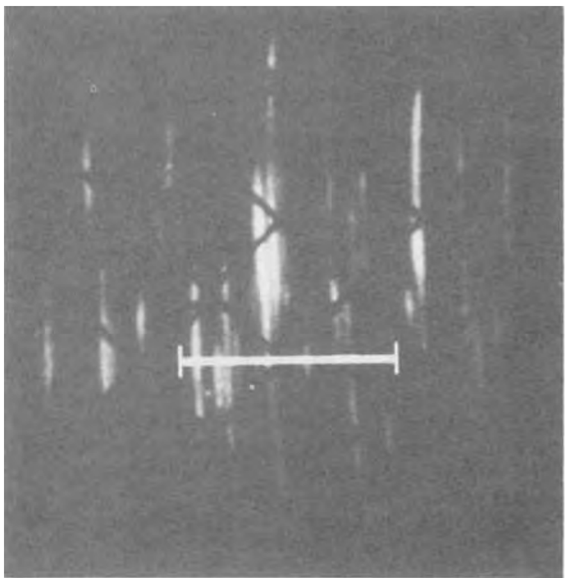

Fig. 5. Breakdown pattern of diode cut 3.6 mm off the axis. Detail from Fig. 4. Indicated is the location of the spreading resistance measurement track.

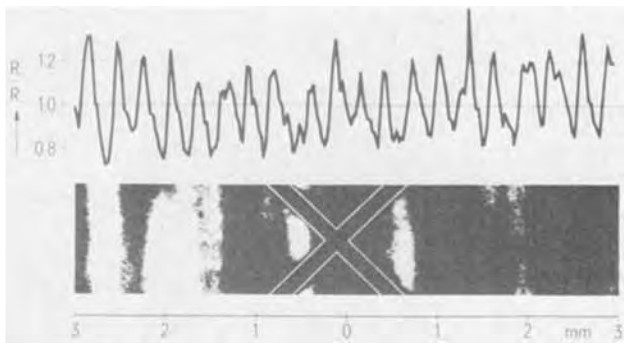

Fig. 6. Correlation between breakdown pattern of diode cut 3.6 mm off the axis with spreading resistance measurement along the track indicated in Fig. 5. Grid electrode outlined.

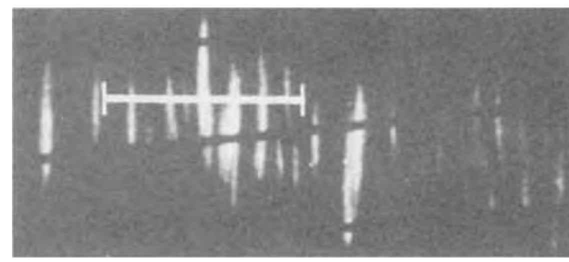

Fig. 7. Breakdown pattern of diode cut 1 mm off the axis from a rod with a central dopant core; breakdown current 2A. Indicated is the location of the spreading resistance measurement track. The grid electrode spacing is 3 mm.

The general appearance of the breakdown pattern in Fig. 7 is similar to that in Fig. 5 (which is of the same scale), only that the breakdown lines are somewhat shorter due to the dopant core. In Fig. 7 the minimum distance between lines is approximately 250 μm. Figure 8a shows the result of the SR measurement along the track indicated in Fig. 7. Figure 8b is a magnified section of Fig. 7.

Discussion

Especially Fig. 4b could be interpreted as indicating that the dopant is very inhomogeneously incorporated in the direction of the rod axis as well as along the slightly curved striations which correspond to the solid-liquid interface during growth. However, since

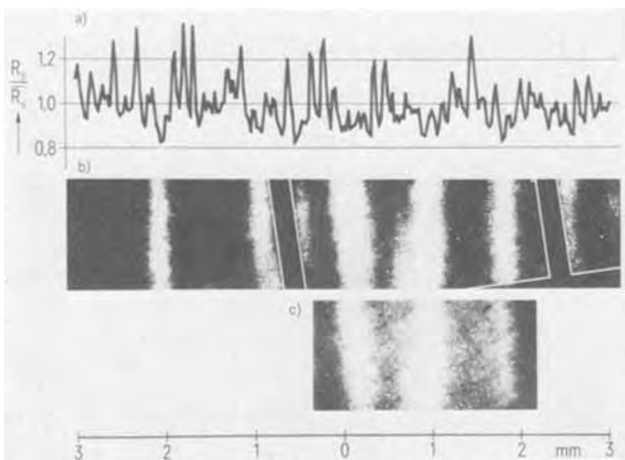

Fig. 8. Correlation between breakdown pattern of Fig. 7 and spreading resistance measurement. (a) SR measurement. (b) Enlarged detail of Fig. 7; optical resolution approximately 200 μm. (c) Detail. Optical resolution better than 100 μm. This photograph is slightly cushion-distorted and has an intensity fall-off toward the edges. The slanted square pattern visible in the photograph originates from the fiber optics in the infrared system.

the breakdown current density rises very sharply once the local breakdown voltage is surpassed, such intensity variations can basically be caused by resistivity fluctuations of only a few per cent.

When one compares the details of the breakdown patterns and the resistivity wave forms in Fig. 6, it becomes evident that all breakdown striations coincide with minima of the resistivity profile, though some of the adjacent lines are only barely separated. For these current and observation conditions there is no breakdown visible for local resistivity minima that lie more than 12% above the absolute minimum.

The intensities of different breakdown lines do not always correspond exactly to the resistivity values of the related minima. This is easily understood in the framework of the calculations of Cornu and Sittig (5): The field distribution is not only determined by the resistivity of the minimum but also by its width and by the resistivity of the surrounding material. Still, for this particular material there is a clear correlation between the resistivity values and the breakdown behavior.

The breakdown patterns in Fig. 7 and 8 are examples for the breakdown in a diode in which the width of some of the individual resistivity minima is markedly smaller than the extent of the space charge region (approximately half).

One could suspect that in Fig. 7 and 8b several of the broad lines are optically not resolved into individual lines due to the lack of optical resolution. However, even the higher resolution of Fig. 8c does not reveal such lines. The juxtaposition of the breakdown pattern and the SR measurement in Fig. 8 indicates that a resolution into narrow lines is not to be expected for the broad line to the left of Fig. 8c, since even the SR measurement shows essentially only a wide macroscopic minimum with little structuring in its bottom. For the broad center line in Fig. 8c the SR measurement shows two distinct narrow minima, *i.e.*, in this broad line a separation into narrower lines is basically possible, but is not observed.

Thus, the experiment shows that for this material the individual variations level out to macroscopic resistivity distributions whose minima lead to breakdown. Wide minima cause a stronger breakdown than narrow ones. When one keeps this in mind it becomes evident that here also the agreement between the breakdown pattern and the SR measurement is quite good.

From these results we can in turn conclude that the SR measurement gives reliable information as far as the form and the relative position of the minima are concerned. However, we cannot determine how accurate the measurement of the absolute resistivity variations might be.[2]

Summary and Conclusion

We were able to observe the breakdown behavior of high-voltage, large area diodes fabricated from silicon slices that were cut parallel to the rod axis. The breakdown patterns were striated similarly to the well-known etched striation patterns. We further attempted to obtain a correlation between the observed breakdown patterns and resistivity fluctuations measured with the spreading resistance technique. It was found that:

1. In silicon of 70 ohm-cm resistivity which contained distinct, regular resistivity fluctuations with periods larger than the extent of the space charge region, the minimum distance between breakdown striations was equal to that between resistivity fluctuations. The breakdown took place at the positions of the microscopic resistivity minima.

2. For faceted silicon of 52 ohm-cm resistivity that showed less pronounced and less regular microscopic resistivity variations with a period slightly smaller than the extent of the space charge region, we also observed a striated breakdown pattern. However, the distance between breakdown striations was at least twice that of the minimum distance between resistivity minima.

The results verified that the individual microscopic resistivity striations in high-voltage diodes do not necessarily lead to equivalent individual breakdown lines. The influence of resistivity variations is leveled as the extent of the space region becomes large as compared with the width of a resistivity minimum. Particularly when the period of the resistivity variations and the extent of the space charge region are of the same order, it may be difficult to deduce the breakdown pattern from a given resistivity profile. For the same reason, a breakdown pattern alone does not give any unequivocal indication as to the microscopic resistivity variations in the bulk material. The observation of the breakdown still has the advantage that it supplies direct information on the device performance over a large area.

[2] Krausse (8) has compared the results of spreading resistance measurements taken with an arrangement of diffused contact areas of defined geometry [nonblocking aluminum-silicon contacts (9)] with standard metal probe measurements taken in different experimental setups. He found that the absolute resistivity variations measured with the standard arrangement may depend on the particular measurement conditions. Aluminum-silicon contacts could not be used in our experiments because they are not suited for the close spacing needed with lengthwise cut material.

Liquid-Phase Epitaxial Growth of ZnTe and $Zn_{1-x}Cd_xTe$

Akihiro Kanamori,[1] Tadahisa Ota,[2] and Kiyoshi Takahashi

Department of Electronics, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo, Japan

ABSTRACT

ZnTe and $Zn_{1-x}Cd_xTe$ crystals were grown on ZnTe substrates by using the liquid-phase epitaxial method in an open system. In, Ga, Sn, and Bi were used as solvents for growing ZnTe, while $Zn_{1-x}Cd_xTe$ with any alloy composition could be grown from both In and Bi solutions. $Zn_{1-x}Cd_xTe$ layers showing n-type conduction could be grown in the composition range $0.6 \leq x \leq 1.0$ from both In and donor-doped Bi solutions. n-$Zn_{1-x}Cd_xTe$/p-ZnTe heterodiodes emitted green light at 77°K in the forward-bias region.

Since ZnTe has a bandgap of 2.26 eV at room temperature, it is potentially a good material for visible light-emitting diodes. However, to prepare n-type ZnTe is very difficult because of self-compensation (1). We have therefore investigated the possibility of using the heteroepitaxy technique for making p-n junction devices with ZnTe.

Liquid-phase epitaxial growth (LPE) is one of the principal methods used to obtain high-quality epitaxial layers of the III-V compounds. The application of this method to the II-VI compounds is difficult because of the high vapor pressure of their constituent elements. However, several authors have used the LPE method to prepare layers of ZnTe on ZnSe (2, 3) and on ZnTe (4), and of CdTe on CdTe (5),

In this study, ZnTe and $Zn_{1-x}Cd_xTe$ epitaxial layers were grown on ZnTe substrates from In, Ga, Bi, or Sn solutions by the LPE method, and their growth properties were examined. Since $Zn_{1-x}Cd_xTe$ crystals containing sufficient CdTe are expected to be amphoteric, their electrical properties have been examined to determine the dependence of amphoteric behavior on the alloy composition and growth conditions. $Zn_{1-x}Cd_xTe$-ZnTe heterodiodes were fabricated, and their electrical and optical properties are briefly described.

Experimental Procedure

The LPE apparatus used here is an open-tube slide system in which a growth solution is brought into contact with a substrate and separated from the substrate after the completion of growth, by moving a graphite solution holder in a hydrogen atmosphere. A diagram of the experimental arrangement is shown in Fig. 1a. The substrates were (111) slices cut from As-doped ZnTe single crystals prepared by the Bridgman method, and they were chemically etched in bromine-methanol solution after mechanical polishing for the epitaxial growth. The solutes for ZnTe and $Zn_{1-x}Cd_xTe$ layers were ZnTe and CdTe + ZnTe, respectively. The ZnTe and CdTe were prepared by the Bridgman method and crushed into small pieces to facilitate dissolution. In, Ga, Bi, and Sn were used as solvents for growing ZnTe layers, and In and Bi for $Zn_{1-x}Cd_xTe$ layers. The ratio of ZnTe to the solvent was determined by the solubility of ZnTe in that solvent (6, 7) at the desired growth temperature. For $Zn_{1-x}Cd_xTe$ crystals, the ratio of CdTe to ZnTe in the growth solution was determined by the desired alloy composition.

The substrate is placed in the depression in the thin graphite plate and is initially covered with the solution holder in order to minimize contamination and thermal etching before it is brought into contact with the solution.

Table I. Conditions for LPE growth of ZnTe and $Zn_{1-x}Cd_xTe$

Grown layer	Solvent	T_M(°C)	v_c(°C/min)
ZnTe	Bi	700-850	1-3
	Sn	650-700	1-3
	Ga	650-750	1-3
	In	600-650	3
$Zn_{1-x}Cd_xTe$	Bi	550-750	1-6
	In	550-650	1-3

A typical temperature program employed for LPE is shown in Fig. 1b. The holding temperatures (T_M) and the cooling rates (v_c) used for each solvent are summarized in Table I. The holding period (t_1) for dissolving the solute was 20-30 min. The solution and the substrate were kept in contact at T_M for 1-3 min, and the solution was separated from the substrate at about 100°C below T_M to terminate growth. The thickness of the grown layers obtained by this program is typically a few micrometers.

Results and Discussion

Epitaxial growth of ZnTe.—High-quality epitaxial layers of ZnTe could be obtained by using any of the four solvents studied. The layers grown from Ga solutions are more reddish in color than those grown from other solvents, possibly because of high Ga doping.

The surfaces of ZnTe epitaxial layers grown from In, Ga, or Sn solutions were flat and mirror-smooth, as shown in Fig. 2a, and the values of T_M and v_c had no significant influence on the properties of the layers. However, the surface condition of the layers grown from Bi solutions was influenced by the cooling rate as illustrated by Fig. 2b and c, where two typical examples are shown for $v_c = 3$ and 1°C/min, respectively.

Though the quality of ZnTe layers did not depend on whether (111)Zn or (111)Te substrates were used, the orientation of the substrate seems to be important in obtaining flat layers like the one shown in Fig. 2a. For example, layers on (110) substrates were granular and rough. Electron diffraction measurements showed that the epitaxy of ZnTe layers on (111) faces is very good. For this orientation, the interface between the ZnTe layer and the substrate was found to be very flat by examining a 5° angle-lapped cross section which was stained with an etchant containing dichromate and $AgNO_3$.

The solvents used here can be dopants in ZnTe, so that ZnTe layers showed various photoluminescence (PL) spectra, especially in the near infrared region, depending on the solvent. The differences are illustrated by Fig. 3, which shows PL spectra obtained from nondoped, Ga-doped, In-doped, and Al-doped ZnTe layers, all grown from Bi solutions. For comparison, the PL spectrum for nondoped bulk ZnTe annealed in an H_2 atmosphere is also shown.

Epitaxial growth of $Zn_{1-x}Cd_xTe$.—$Zn_{1-x}Cd_xTe$ crystals over the entire alloy composition range could be

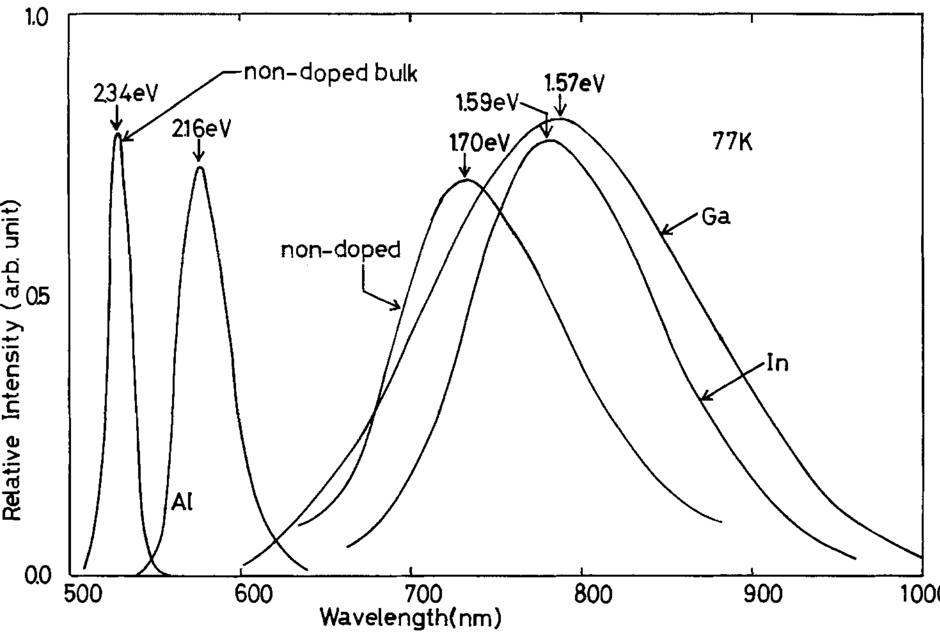

Fig. 3. Photoluminescence spectra at 77°K of ZnTe layers grown from nondoped, Ga-doped, In-doped, and Al-doped Bi solutions.

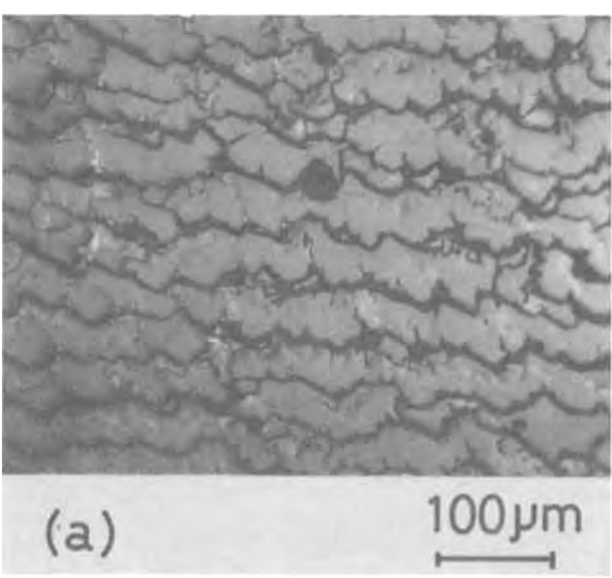
grown from both Bi and In solvents. CdTe and ZnTe were used as solutes. If the constituent elements are used as solutes, because of their high vapor pressures it is very difficult to obtain good epitaxial layers or to control the composition of the mixed crystals. For example, when Cd was used instead of CdTe, the grown layers had a rough surface and a composition close to ZnTe. Moreover, these layers could be grown only on the (111)Te face, but not on (111)Zn face of ZnTe substrates; when CdTe was used, layers could be grown successfully on both faces.

The composition x of the mixed crystals was determined from the results of x-ray diffraction measurements, assuming that Vegard's law is valid (8). Optical transmittance measurements were also used to determine the x-values, where the relationship between bandgap and composition of $Zn_{1-x}Cd_xTe$ crystals obtained by Saito *et al.* (9) was used. No attempt was made to investigate homogeneity with respect to alloy composition in the direction of growth. For compositions close to CdTe, flat layers as shown in Fig. 4a could be obtained from both In and Bi solutions. However, for composition close to ZnTe, flat surfaces could be obtained only from In solution. Mixed crystals with intermediate compositions had rough surfaces as shown in Fig. 4b.

Electron diffraction measurements made on the surface of the $Zn_{1-x}Cd_xTe$ layers yielded patterns like the one shown in Fig. 5, where strong spots and dim Debye-Scherrer rings were observed. The interfaces between the mixed layers and the ZnTe substrates were irregular, as shown in Fig. 6a, and thus inferior to those obtained for ZnTe epitaxial layers. The cleaved and stain-etched cross section of a mixed layer grown from In solution is shown in Fig. 6b. This figure shows that a region of In-doped ZnTe about 30 μm thick adjacent to the interface was formed by diffusion of In into the substrate. Similar diffused regions were observed when growth took place from Al- or In-doped Bi solutions, but not when undoped Bi solutions were used.

In this work the composition of the $Zn_{1-x}Cd_xTe$ layers was controlled by adjusting the concentration of CdTe in the growth solution and by varying the holding temperature T_M. Figure 7 shows the relationship between the layer composition and the CdTe concentration in Bi solutions for values of T_M between 650° and 750°C. The CdTe/Bi ratio is the ratio of moles



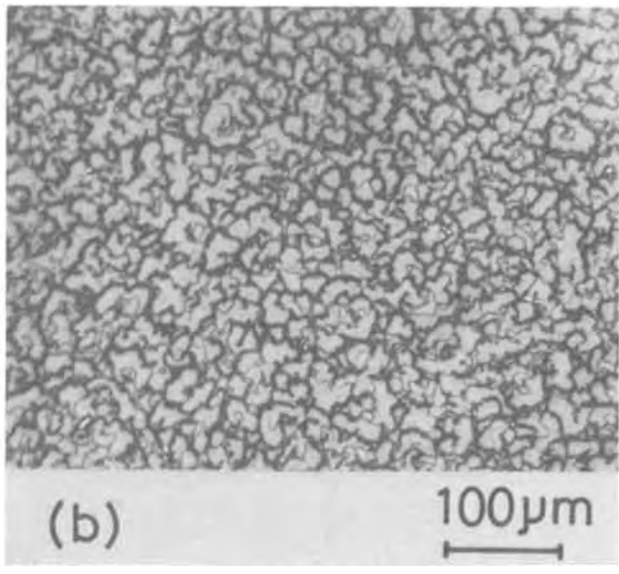


Fig. 4. Photomicrographs of the surfaces of $Zn_{1-x}Cd_xTe$ layers grown on ZnTe (111)Te faces. (a) Composition close to CdTe ($x = 0.89$, $T_M = 650°C$, $v_c = 3°C/min$, Bi solvent); (b) composition close to ZnTe ($x = 0.05$, $T_M = 750°C$, $v_c = 3°C/min$, Bi solvent).

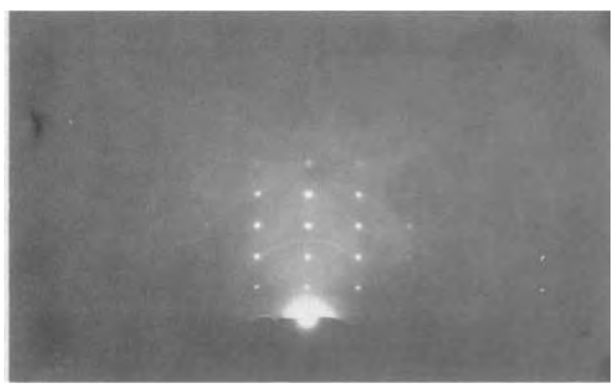

Fig. 5. Electron diffraction pattern of $Zn_{1-x}Cd_xTe$ layer with $x = 0.89$, grown from Bi solution.

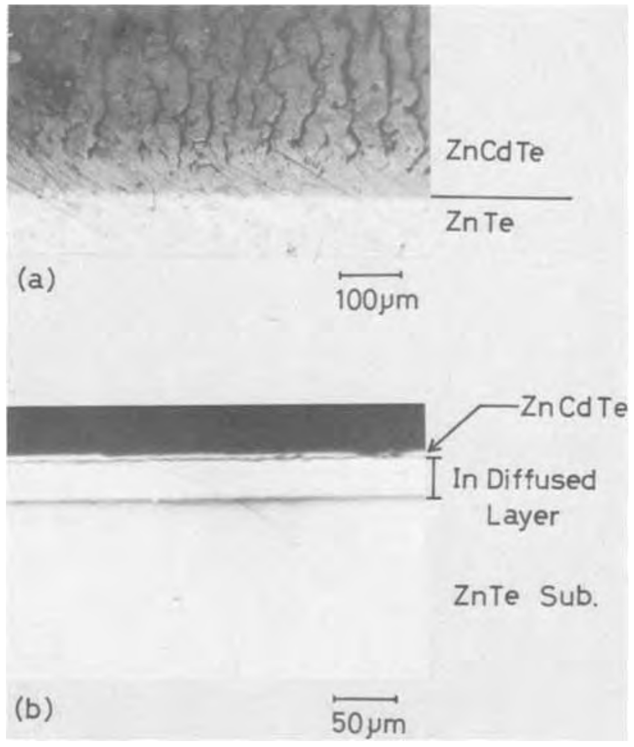

Fig. 6. Typical interfaces between ZnTe substrates and $Zn_{1-x}Cd_xTe$ layers: (a) 5° angle-lapped cross section of a layer with $x = 0.89$ grown from Bi solution, (b) stain-etched cleaved cross section of a layer with $x = 0.80$ grown from In solution.

CdTe to atoms of Bi. This range of temperatures was chosen in order to give sufficient solubility of ZnTe and CdTe in Bi (5, 6). In this range, mixed layers with any desired composition could be obtained by selecting suitable values of T_M and CdTe concentration. The solubilities of ZnTe in Bi are 0.0060, 0.0084, and 0.0120 at 650°, 700°, and 750°C, respectively. These solubilities were obtained by extrapolating Rubenstein's data (6) to the lower temperatures. The ZnTe/Bi ratios used for T_M = 650°, 700°, and 750°C were 0.022, 0.032, and 0.043, respectively. The excess ZnTe was used in order to saturate the solutions. The undissolved ZnTe floated to the top of the solution, so that it did not interfere with epitaxial growth. As an example, the weights of ZnTe, CdTe, and Bi used to form the growth solution for CdTe/Bi = 0.065 and T_M = 700°C were 0.030, 0.070, and 1g, respectively. X-ray diffraction analysis showed that CdTe and Bi do not form any compounds.

The cooling rate v_c also has a strong influence on the composition of the $Zn_{1-x}Cd_xTe$ layers, as shown in Fig. 8. This dependence is presumably due to deviations from equilibrium during the growth process. It appears that only ZnTe is grown on ZnTe substrates under equilibrium conditions (*i.e.*, slow cooling rate).

When In was used as the solvent, mixed crystals with any desired composition could be obtained for T_M = 600°C. At higher growth temperatures, however, it was difficult to obtain mixed crystals with compositions close to CdTe: *e.g.*, only ZnTe could be grown for T_M = 650°C, regardless of the concentration of CdTe in the solution. When a large amount of CdTe was added to a solution at T_M = 650°C, the grown layers became rough due to precipitation of some compound formed between CdTe and In.

In an earlier study (10), it was found that n-type conductivity could be obtained in Al-doped $Zn_{1-x}Cd_xTe$ crystals with $x > 0.3$ which were grown by the Bridgman method in sealed quartz ampuls. In the present work, the conductivity type of the epitaxial layers was determined by Schottky barrier formation or by using the hot probe method. It was very difficult to determine the type without illumination because the layers had high resistivities (10^2-10^5 ohm-cm). Measurements made under illumination showed that n-type conductivity could be obtained in Al- and In-doped layers with $x > 0.6$.

Figure 9 shows the relationship between the composition and dark resistivity of Al- and In-doped layers grown from Bi solutions. It is seen that the resistivity becomes lower with increasing Cd content. The same result was obtained for the layers grown from In solutions. For layers grown from Al- or In-doped Bi solutions, the alloy composition was not influenced by doping when the concentration of dopant was small, though addition of the dopants did influence the flatness of the layers.

$Zn_{1-x}Cd_xTe$-ZnTe heterodiodes.—n-$Zn_{1-x}Cd_xTe$/p-ZnTe heterodiodes were fabricated by making ohmic contacts to the ZnTe substrates and the $Zn_{1-x}Cd_xTe$ layers by electroless plating of Ag and vacuum deposition of In, respectively. The diodes were annealed at 300°C for 5 min to obtain better ohmic contacts to ZnTe.

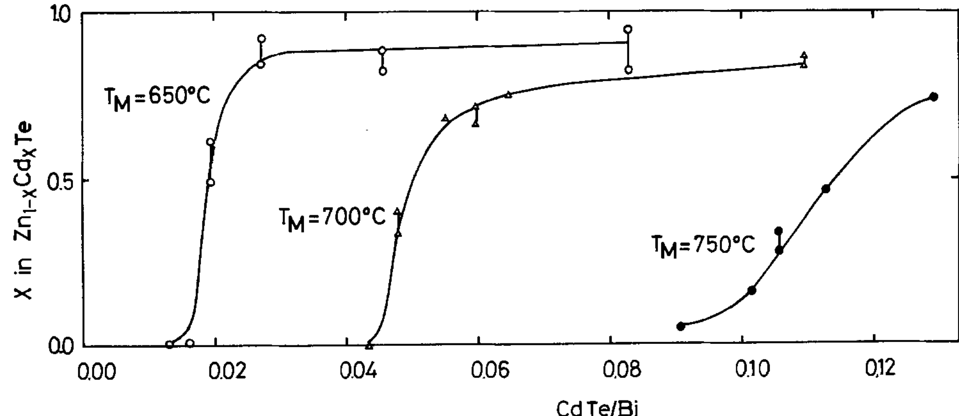

Fig. 7. Relationship between the ratio of moles of CdTe to atoms of Bi in growth solution and composition of epitaxial layers of $Zn_{1-x}Cd_xTe$ for T_M = 650°, 700°, and 750°C with v_c = 3°C/min.

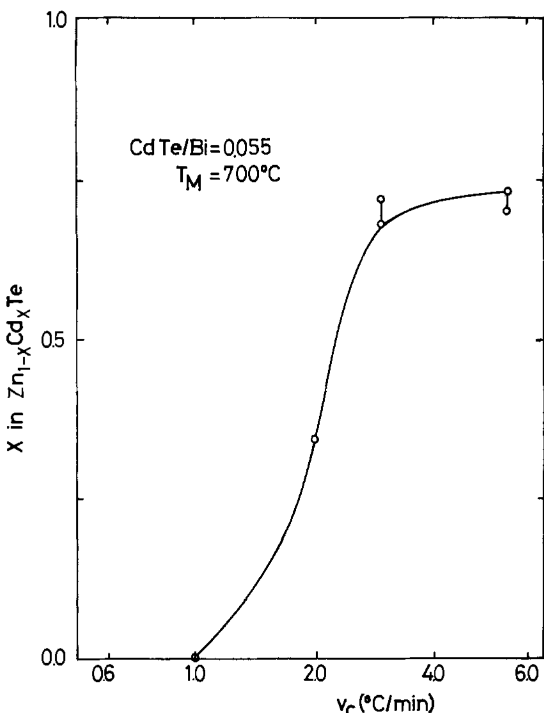

Fig. 8. Relationship between cooling rate v_c (logarithmic scale) and composition of $Zn_{1-x}Cd_xTe$ layers (CdTe/Bi = 0.055, T_M = 700°C).

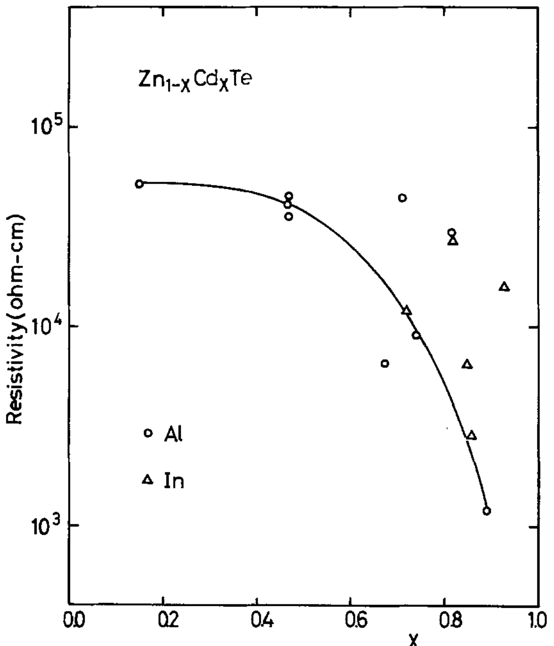

Fig. 9. Relationship between composition x and resistivity of Al- and In-doped $Zn_{1-x}Cd_xTe$ layers grown from Bi solutions.

Figure 10 shows the room-temperature photovoltaic spectra of $Zn_{1-x}Cd_xTe$-ZnTe heterodiodes grown from In solutions for various x-values determined by x-ray diffraction measurements of the lattice constants. The cutoff wavelengths in the long wavelength region agree well with the bandgaps corresponding to the x-values. In the case of $x = 0.13$, the resistivity of the $Zn_{1-x}Cd_xTe$ layer is very high, so that the photovoltage results from the i-p junction.

The current-voltage (I-V) characteristics of the heterodiodes grown from In solutions were dominated by a semi-insulating region which was formed by diffusion of In into the ZnTe substrates. From C-V measurements this semi-insulating region is estimated to be about 30 μm thick, in agreement with the observations on the etched cross section shown in Fig. 6b. The I-V characteristics of the heterodiodes ($x = 0.87$) grown from Al-doped Bi solution could be expressed by $I \propto \exp\ (eV/nkT)$ where $n = 2.7$ at 300°K and $n = 7.5$ at 77°K, as shown in Fig. 11, though a very thin Al-diffused layer ($< 0.25\ \mu$m thick) was formed.

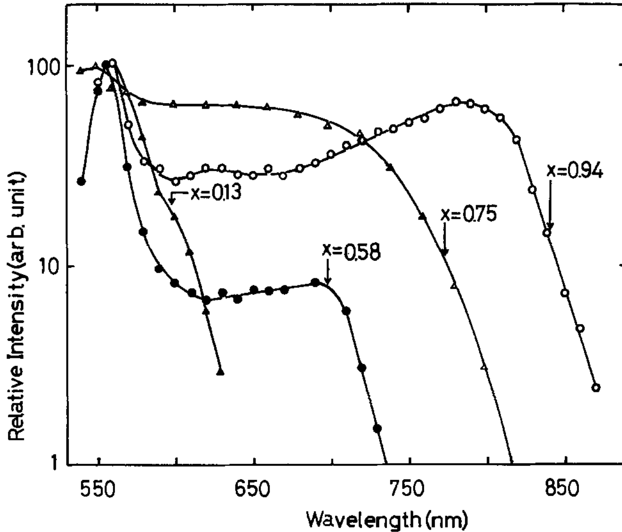

Fig. 10. Photovoltaic spectra at room temperature of $Zn_{1-x}Cd_xTe$-ZnTe heterodiodes with various x-values.

At 77°K, the heterodiodes ($x = 0.87$) prepared from Al-doped layers grown from Bi solutions appeared green under forward bias and red under reverse bias. The emission spectra are shown in Fig. 12. Emission peaks are located at 530, 620, and 720 nm in the forward-bias region and at 620 nm in the reverse-bias region. In the forward-bias region, a shoulder at 550 nm corresponding to yellow emission was also observed, though sometimes it did not appear clearly.

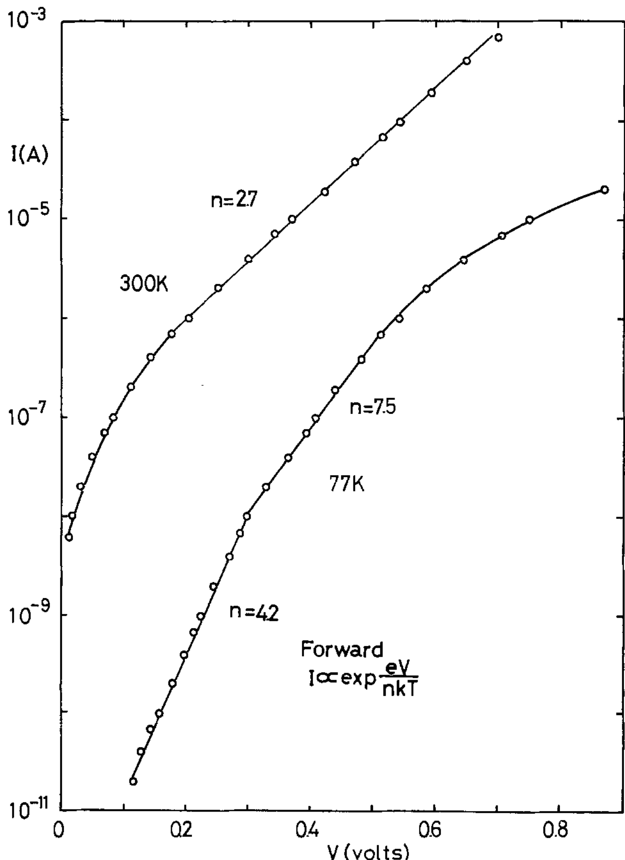

Fig. 11. I-V characteristics in the forward-bias region of $Zn_{0.13}Cd_{0.87}Te$-ZnTe heterodiodes at 300° and 77°K.

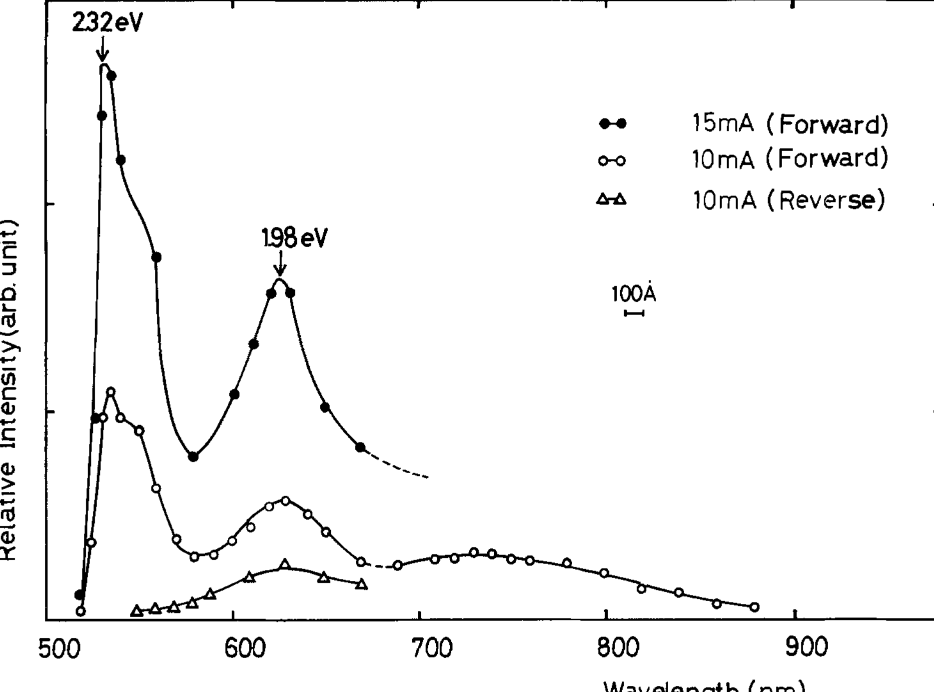

Fig. 12. Electroluminescence spectra at 77°K of Al-doped $Zn_{0.13}Cd_{0.87}Te$-ZnTe heterodiodes (photomultipliers used are R-453 for 500-670 nm and 7102 for 700-900 nm).

This emission is believed to be due to Al-diffusion into ZnTe, because the shoulder was not observed for the heterodiodes prepared from In-doped samples. The green emission at 530 nm is believed to be due to radiative recombination via As acceptor centers. Since this emission was not observed for the heterodiodes prepared from In-doped samples, In centers may act as killer centers for the green emission. The peak at 720 nm may have the same origin as the peak at that wavelength observed in PL spectra of ZnTe layers grown from nondoped Bi solutions (Fig. 3). Though no attempt was made to measure the electroluminescence efficiency, the green emission could be perceived by the naked eye under room light at a forward current of 20 mA.

Summary

ZnTe and $Zn_{1-x}Cd_xTe$ crystals have been grown on ZnTe substrates by the LPE method using various metals as solvents in an open-tube system. High-quality epitaxial layers with flat interfaces were obtained under suitable growth conditions. $Zn_{1-x}Cd_xTe$ layers showing n-type conductivity, but with high resistivities, were obtained in the composition range $0.6 \leq x \leq 1.0$ from both In solutions and donor-doped Bi solutions. Heterodiodes prepared from Al-doped $Zn_{1-x}Cd_xTe$ layers showed green light emission at 77°K under forward bias.

Effect of Nitrogen and Oxygen/Nitrogen Mixtures on Oxide Charges in MOS Structures

D. W. Hess* and B. E. Deal*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The positive fixed charge, Q_{ss}, associated with thermally oxidized silicon, has been investigated as a function of annealing time in nitrogen and oxygen/nitrogen mixtures at 1200°C. The effective density of Q_{ss} was found to increase during long time high temperature treatments in nitrogen, but this increase can be controlled by using O_2/N_2 mixtures in place of nitrogen. The trends in Q_{ss} observed during nitrogen annealing are dependent on the furnace used to do the annealing. A correlation was found to exist between Q_{ss} and interface state generation in the various furnaces, and the dependence of interface state generation on annealing ambient has been investigated. In most cases, an equilibrium Q_{ss} is obtained after a certain annealing time in both nitrogen and oxygen/nitrogen atmospheres. Results obtained from reoxidation of oxides equilibrated in nitrogen suggest that these oxides are more oxygen deficient than those equilibrated in oxygen/nitrogen mixtures.

It is well established that the thermal oxidation of silicon results in a positive fixed charge (designated Q_{ss}) located in the oxide-silicon interface region (1-4). This charge is a function of the SiO_2-Si interface structure and its magnitude depends on the silicon crystal orientation, the oxidation conditions, and subsequent annealing treatments. Q_{ss}, along with other oxide charges, can affect many semiconductor device characteristics, such as MOS threshold voltages, junction breakdown voltages, leakage between devices, and others. Due to the importance of these effects, numerous studies have been carried out to characterize Q_{ss} and to determine its dependence on processing conditions. Such studies have resulted in reasonable control of this oxide charge.

In general, the lowest possible density of Q_{ss} is desirable from a device fabrication standpoint, and this has been attained by using inert gas anneals at temperatures between 900° and 1200°C. Recently, it was recognized that an increase in effective Q_{ss} could result from long time (> 30 min), high temperature (1200°C), inert gas anneals (5, 6). This effect is similar to that observed by Hess and Fowkes (7), where an increase in Q_{ss} resulted from exposure of thermal oxides to a reducing atmosphere at 910°C. Such increases could be due to the breaking of additional Si-O bonds in the somewhat strained oxide interfacial region, and thus a dependence on the silicon surface orientation is expected.

Since no information was available concerning 1200°C nitrogen annealing of thermal SiO_2 films for times greater than 2 hr, and also since the orientation dependence of such anneals had not been determined, this study was initiated to investigate these effects. Also, if the oxygen deficiency or ionized silicon model for this Q_{ss} increase during long time, high temperature, inert gas treatments is correct, subsequent oxidation should eliminate the observed increase. In addition, since Q_{ss} is affected by the amount of oxygen present in the annealing atmosphere, the dependence of Q_{ss} on the oxygen partial pressure was investigated.

Experimental Procedure

The silicon wafers used in this investigation were 4-6 ohm-cm, phosphorus doped, with (100) and (111) orientation. They were cleaned using sulfuric-peroxide, aqua regia, a hydrofluoric acid dip, and several deionized water rinses. Oxidations were carried out at 1200°C in a resistance-heated furnace containing an ultra-high purity Mullite liner and a fused quartz oxidation tube. The samples were oxidized for 39 min and then slow pulled (~2 min) in dry oxygen. This procedure resulted in ~1600Å oxides. The (100) and (111) oxides were then annealed simultaneously in nitrogen or oxygen/nitrogen mixtures at 1200°C in various furnaces. The standard push and pull times were approximately 1 and 2 min, respectively, both in the annealing ambient.

After the anneal, the oxide thicknesses were measured with an Applied Materials (AME-500) ellipsometer. The reproducibility of the oxide thickness over the range investigated was ±4%. The oxides were then stripped from the backs of the wafers. Aluminum dots were evaporated on the front of the wafers through metal masks, and the backs of the slices were coated with aluminum using a cold substrate EB evaporation. The wafers were then annealed for 10 min in dry nitrogen at 500°C, and the MOS capacitors evaluated using the capacitance-voltage technique. In order to separate out any effects due to ionic contamination (Q_o), bias-temperature (*B-T*) stress measurements were made on the MOS capacitors at 300°C, ±5V, for 3 min. Q_o ranged from less than 3×10^{10} cm^{-2} for short (under 4 hr) annealing times to 7×10^{10} cm^{-2} for 16 hr annealing in the various O_2/N_2 mixtures. The fixed charge (Q_{ss}) was calculated from the negatively *B-T* stressed *C-V* curve using the following equation

$$\frac{Q_{ss}}{q} = \frac{(2.13 \times 10^{10})(-V_{FB})}{x_0(\mu)} \text{ charges/cm}^2$$

where the work function difference, ϕ_{MS}, is essentially zero for the n-type silicon. The Q_{ss} values were found to be reproducible to $\pm 3 \times 10^{10}$ cm^{-2}.

The flow meters utilized in this study were calibrated using a Matheson Electronic Mass Flowmeter and a Porter-Vol-U-Meter. The total flow rate was 1 liter/min, which corresponded to a gas velocity of ~1 cm/sec. The oxygen and nitrogen used were from a liquid source and were further dried and filtered by passage through a Matheson Model 451 gas purifier.

Results and Discussion

Effect of N_2 anneal on fixed charge (Q_{ss}).—The variation of the fixed surface state charge (Q_{ss}) with nitrogen annealing time at 1200°C is shown in Fig. 1 and 2 for (100) and (111) silicon surface orientations, respectively. The observed increase in effective Q_{ss} during long time anneals in nitrogen at 1200°C has been reported previously (6) for anneal times up to 2 hr

and (111) silicon surface orientation. It has been proposed (6) that this effect may be related to the breaking of additional Si-Si or Si-O bonds near the Si-SiO_2 interface, which creates additional positive charge in the oxide. The solid line in Fig. 1 represents data obtained from three different furnaces (denoted A, B, and C), while the dotted line represents data obtained from a fourth furnace, D. Similarly, the data presented in Fig. 2 were obtained from the same four furnaces as those in Fig. 1.

The data from furnaces A and B were taken at the various anneal times indicated by the circles in Fig. 1 and 2, while data points for furnaces C and D were taken up to 2 hr of annealing time, and then results obtained for 16 hr of N_2 annealing in both furnaces. The curves were then extrapolated to these 16 hr points (dotted lines). It can be seen from Fig. 1 and 2 that three of the furnaces gave identical (within experimental error) results for (100) samples, while the results of (111) oriented silicon showed three different results for the four furnaces. Particularly interesting is the result obtained in furnaces A and B for (111) samples, where, as for the (100), the effective Q_{ss} increases after one-half hour of nitrogen annealing, but subsequently decreases and reaches a steady state near the original Q_{ss} minimum.

At present, we cannot explain the observed dependence of Q_{ss} on the furnace used to do the annealing, although it should be mentioned that furnace A was the only furnace that utilized a liner. However, the fact that furnace B did not have a liner, yet the results from this furnace agreed within experimental error to those obtained from furnace A, seems to preclude any effect of a liner on the observed Q_{ss}. Also, no differences in mobile ion concentration could be detected among the various furnaces.

In order to determine whether the addition of chlorine to the oxide would affect the value of Q_{ss} obtained during nitrogen annealing, a series of (100) and (111) samples in which chlorine was incorporated during oxidation by passing a small amount of oxygen through a bubbler of trichloroethylene, was prepared at 1100°C. Nitrogen anneals were then performed for times ranging from 15 min to 16 hr in furnace A at 1200°C, and the Q_{ss} values agreed within experimental error to those obtained with nonchlorine oxides in this furnace.

Effect of N_2 anneal on interface states.—In the case of the (111) samples, an interesting correlation existed between the shapes of the *C-V* curves and the value of Q_{ss} obtained in the different furnaces (see Fig. 2). At an annealing time of 7 hr in nitrogen (furnaces A and B), the shape of the *C-V* curve was nearly ideal (Fig. 3), but a relatively large flatband shift was observed. However, as the anneal time was gradually increased from this point, a distortion of the *C-V* curve became apparent as the flatband voltage decreased. This distortion increased rather noticeably as longer anneal times were used (Fig. 3). Even when the flatband (and thus Q_{ss}) reached a constant value (approximately 9 hr), the distortion continued to increase. The distortion is physically similar to that produced by interface states occurring between the intrinsic level and conduction band of silicon as reported by Deal, MacKenna, and Castro (8). However, the present state could not be eliminated by a nitrogen anneal at 500°C with aluminum dots present on the wafer (alneal), suggesting that this is not a normal interface state since it cannot be eliminated by hydrogen produced during the alneal process (9). The (100) samples annealed simultaneously with the (111) showed no evidence of such distortion. (It should be noted that all curves shown in Fig. 3 represent samples which have received an alneal at 500°C.)

Furnace C, which gave an intermediate value of Q_{ss} for the (111) sample ($\sim 3.2 \times 10^{11}$ cm^{-2}) generated the same distortion of the *C-V* curve as furnaces A and B, but the distortion was much less pronounced (Fig. 4). Finally, furnace D, which gave the highest value of Q_{ss} for the (111) and (100) samples, generated no detectable distortion of either the (111) or (100) *C-V* curves. To more specifically indicate the differences in the *C-V* curves of the various samples obtained after nitrogen annealing, a quantity V_{IS}, which represents the "width" of the break in the *C-V* curve in volts and is apparently due to some kind of interface

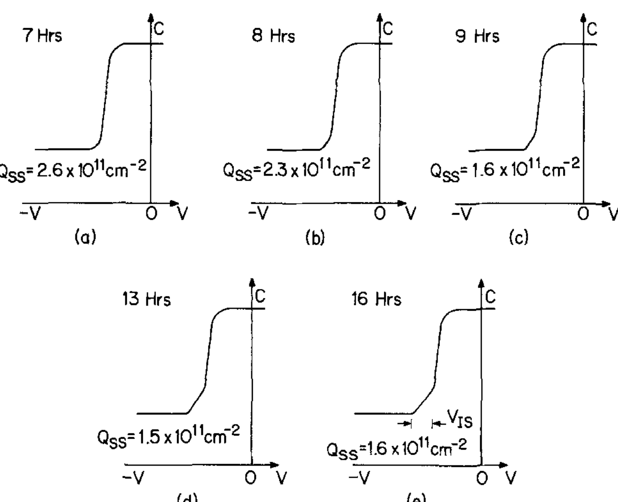

Fig. 3. Effect of nitrogen annealing at 1200°C in furnaces A and B on the shape of the C-V curve for various annealing times. V_{IS} is the magnitude of the "break" observed in the C-V curve in volts. All oxide thicknesses were 1600Å. See Table II.

state, was defined as shown in Fig. 3e. Also, the slopes of the C-V curves obtained after N_2 treatments were measured and compared on the basis of the voltage (V_{slope}) required to go from 0.8 to 0.5 C_{max}. These slopes, along with the V_{IS} values, are given in Table I. The values of V_{slope} indicate that interface states, as measured by distortion of C-V curves, are generated in furnace D, and these states, like those observed in furnaces A, B, and C, are not eliminated by an alneal. These data suggest that the distribution of states in furnace D may be different from the distribution in furnaces A, B, and C. Indeed, preliminary conductance-voltage experiments (10) have shown little difference in interface state densities between samples annealed in furnaces A, B, C, or D. However, while the samples annealed in furnaces A, B, and C showed a rather narrow distribution of states, samples annealed in furnace D showed a relatively broadened distribution.

As with Q_{ss}, we can at present offer no explanation or possible description of the interface states causing the effect reported here. Considering the fact that hydrogen is ineffective in eliminating these states, and also that the results are furnace dependent, an effect such as a heavy metal impurity is suspected. However, reoxidation results that are presented later show that a structural defect in the SiO_2 is also a possibility.

Effect of O_2/N_2 anneals on oxide charges.—Before describing the results of O_2/N_2 mixtures on oxide charges, it should be noted that several selected experiments, utilizing both N_2 and O_2/N_2, were carried out in furnaces A, B, C, and D, and of these, the nitrogen annealing studies described above were the only ones that indicated any dependence on the furnace used.

As stated above, if the ionized silicon or oxygen deficiency model for the Q_{ss} increase during long time, high temperature, inert gas treatments is correct, it should be possible to control this Q_{ss} increase during such anneals if a small amount of oxygen is present during the heat-treatment. The effect on the fixed charge due to treating thermal oxides in various O_2/N_2 mixtures at 1200°C and pulling the samples from the furnaces in the annealing ambient is shown in Fig. 5-8. In these figures, any increase of the oxide thickness during O_2/N_2 treatment was taken into account for the purpose of Q_{ss} calculation.

Figures 5 and 6 show that the initial effect of 2 and 5% O_2/N_2 mixtures is to significantly lower Q_{ss} as in nitrogen up to a time of approximately 2 hr, after which a slight decrease and "leveling off" occurs. As might be expected, an increase in the Q_{ss} minimum is experienced as the oxygen percentage is increased from 2 to 5%. Apparently, at longer anneal times, an equilibrium situation is attained where the increase in Q_{ss} caused by the pure nitrogen treatment is compensated by the oxygen present in the annealing atmosphere. As the oxygen diffuses through the oxide, and a "new interface" begins to form, the Q_{ss} approaches an equilibrium value. This agrees with the data obtained for 10 and 50% mixtures (Fig. 7 and 8) where, after the initial Q_{ss} decrease, an almost immediate equilibrium situation with regard to Q_{ss} is established.

It should be noticed that the times necessary for equilibration decrease with increasing oxygen partial pressure, substantiating the necessity of forming a "new interface" before Q_{ss} can reach a constant value. Figures 5-8 show that for each oxygen partial pressure, the Q_{ss} for (111) oriented silicon is approximately

three to four times that of (100). This is the normally observed orientation dependence (1).

Mention should be made of the pull rate dependence of Q_{ss} experienced during this study. Although slight variations were observed, the pull rate was not found to be critical for the 2, 5, and 10% mixtures, but was quite critical for the 50% mixture. This is in agreement with previous results (1) which showed the difference in Q_{ss} between fast and slow pulling in oxygen. As the percentage of oxygen in the annealing atmosphere increases, the pull rate will determine the final Q_{ss} value for the same O_2/N_2 mixture, where Q_{ss} will increase with increasing pull time. Consideration of the equilibrium Q_{ss} values indicates that up to an oxygen partial pressure of 0.1, the exact amount of oxygen present in the annealing atmosphere is not critical, since the equilibrium values of Q_{ss} are approximately 0.7×10^{11} cm^{-2} and 2.7×10^{11} cm^{-2} for the (100) and (111) wafers, respectively, for 2, 5, and 10% mixtures. Also, it is important to recognize that no distortion of the *C-V* curves such as those shown in Fig. 3 and 4 and tabulated in Table I were observed for any of the O_2/N_2 mixtures investigated.

Effect of O_2 anneals on oxide charges.—It has been postulated that Q_{ss} results from a silicon excess or oxygen deficiency at the Si-SiO_2 interface (1, 7). If this is true, it should be possible to "reoxidize" the present oxides, which have been equilibrated in a deficiency of oxygen and thereby return Q_{ss} to more normal values. Therefore, using (100) and (111) oriented silicon wafers, two sets of oxides were prepared, one of which was equilibrated in 2% O_2/N_2 and the other equilibrated in N_2 only (furnace C) at 1200°C. The oxides were fabricated such that the final oxide thicknesses were the same for all samples (1600 ± 20Å). They were then pushed into the furnace in nitrogen and oxidized in 100% O_2 at 1200°C for times of 1, 2, and 3 min. At the end of these times, some of the samples were slow pulled (2 min) from the furnace in oxygen and some received a 15 min nitrogen anneal prior to being slow pulled from the furnace in nitrogen.

The results of Q_{ss} measurements for the wafers slow pulled in oxygen indicate no difference between samples equilibrated in 2% O_2/N_2 or N_2 alone, and the Q_{ss} values agreed with initially oxidized samples which had been slow pulled in oxygen [$Q_{ss} \simeq 2.5 \times 10^{11}$ cm^{-2} for (100) and 8×10^{11} cm^{-2} for (111)]. The final Q_{ss} values for samples which received a 15 min nitrogen cycle at the end of the reoxidation are given in Table II. It can be seen that after equilibration of the oxides in 2% O_2/N_2, little oxygen is required to compensate for the oxygen deficiency established during equilibration. However, the samples equilibrated in N_2 required substantially more oxygen prior to nitrogen annealing to lower the Q_{ss} significantly.

Similarity of thermal and electrical charge generation.—The increase in Q_{ss} and the simultaneous generation of interface states during 1200°C nitrogen treatments for times greater than 7 hr is quite similar to the effect produced by a negative field applied to MOS capacitor structures at elevated temperatures (1, 11-14). In the latter case, an oxygen vacancy or silicon excess model has been proposed to account for the increase in fixed charge and interface state density (6, 12). Such a model is in agreement with the observed dependence of the generated fixed charge on the initial Q_{ss} density (1). Likewise, the results of the present investigation might be explained by the breaking of additional Si-O bonds, resulting in a higher positive charge, accompanied by an increase in surface-state density. Whereas the negative field at elevated temperatures may break bonds primarily by electrical means, in the present work, as in Ref. (7), the breaking of bonds might be due to thermal energy.

Summary

Using the *C-V* technique, the fixed oxide charge, Q_{ss}, was studied as a function of annealing time in nitrogen and oxygen/nitrogen mixtures at 1200°C. These investigations have shown that after the initial decrease of Q_{ss} due to nitrogen annealing, an increase is observed up to approximately 4-7 hr, possibly resulting from the breaking of additional Si-Si or Si-O bonds at the Si-SiO_2 interface. Longer nitrogen annealing times give scattered results for Q_{ss}, which apparently depend on the oxidation system (furnace) used for the annealing. In most furnaces, these long time nitrogen anneals generate interface states which are observed as

Table II. Reoxidation of oxides equilibrated in 2% O_2/N_2 and N_2 only* at 1200°C

All samples were pushed into the furnace in N_2, oxidized at 1200°C in 100% O_2 for the indicated time, annealed in N_2 for 15 min, and slow pulled (2 min) from the furnace in N_2

Equilibrating atmosphere	Orientation	Equilibrium Q_{ss} (10^{11} cm^{-2})	Oxidation time (min)	Final Q_{ss} (10^{11} cm^{-2})

* The initial N_2 annealing was done for 16 hr in furnace C.

distortions of the C-V curve and cannot be eliminated by a 500°C alneal. A reoxidation of the samples in 100% oxygen, however, does eliminate the distortions. This suggests that the interface states or levels responsible for these distortions may be related to a structural defect in the SiO_2 lattice. No differences in the values of Q_{ss} or interface states were observed between oxides which did or did not contain chlorine (for a given annealing treatment).

After a particular annealing time in oxygen/nitrogen mixtures at 1200°C, Q_{ss} reached an equilibrium value. The fact that the oxidation time necessary to reach equilibrium depended on the oxygen partial pressure, indicated that a "new interface" had to form before Q_{ss} could reach a constant value. Up to a partial pressure of 0.1 this equilibrium value was a rather insensitive function of the oxygen partial pressure. No distortions of the C-V curves such as those generated during nitrogen annealing were observed for any O_2/N_2 mixtures. Also, unlike the nitrogen anneals, all O_2/N_2 mixtures resulted in the normal orientation dependence of Q_{ss} over all times investigated. Reoxidation of samples equilibrated in 2% O_2/N_2 and samples equilibrated in nitrogen suggested, as expected, that there is a difference in oxygen deficiency depending on the oxygen partial pressure of the atmosphere used for equilibration.

Effects of MOS Metallization Geometry and Processing on Mobile Impurities

Arthur J. Learn

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The possible effects on MOS structures of metallization material, method of vacuum deposition, method of electrode delineation, electrode size and geometry, post-metallization heat-treatments, and hydrogen incorporation were investigated. It was found that a minimum in the level of mobile ionic contamination (Q_o) was achieved in a time the order of 15 min for annealing at 500°C in dry nitrogen. The minimum Q_o values were proportional to either the diameter of circular electrodes or the width of rectangular electrodes in the range of 5-30 mil. Results were similar for both aluminum and aluminum-copper-silicon metallization as well as for either shadow masked or photomasked electrodes. The assumed presence of hydrogen, either arising from that produced in the deposition chamber during filament and electron beam evaporation as monitored by residual gas analysis or from hydrogen anneals prior to metallization, resulted in increased Q_o for short anneal times. In interpreting the results, consideration was given mechanisms which would decrease Q_o, such as diffusion of contaminant (probably sodium) to and evaporation from the electrode periphery, and increase Q_o, such as introduction of contaminant and/or aluminum from the electrodes or substitution of protons for contaminant ions at traps.

The importance of minimizing mobile alkali ion contamination (Q_o) in silicon device processing is well recognized (1). Such contamination in silicon dioxide can affect the threshold voltage and stability of MOS devices. Adverse effects on bipolar devices, primarily related to silicon surface inversion and channeling, can also be observed as a consequence of ionic contamination. Many of the processing steps may introduce contamination with one of the more suspect (2) being metallization.

Extensive investigations of the behavior of charges, including Q_o, in oxides have been made (1). Tech-

Key words: mobile impurity monitoring, MOS electrode size effects, hydrogen effects, annealing effects.

niques for minimizing Q_o levels have been developed including gettering by phosphorus (3) or chlorine (4) incorporated in the oxide. In such studies the metallization for the MOS structure is considered to play a passive role, other than serving as an electrode, with the following two exceptions. The annealing of fast surface states in the presence of aluminum is presumed (5) to be a consequence of hydrogen evolution through an aluminum-water vapor reaction. In addition, sintering conditions for the aluminum metallization have been found (6) to affect radiation hardness of MOS structures.

The possibility of the metallization and metallization processing influencing Q_o is more directly examined here. The effects on Q_o of the method of metallization deposition and fabrication into electrodes, electrode size and geometry, temperature treatments, and hydrogen were considered. It was found to be necessary, in interpreting the results, to postulate ionic contamination diffusion to and vaporization from the electrode periphery combined with either activation of contamination in the oxide or introduction of mobile contamination from the electrode. Enhanced mobilization of ionic alkali contamination in the oxide with hydrogen present was also proposed.

Experimental Procedure

The thermal oxidation of silicon wafers of <111> orientation in dry oxygen was performed under clean conditions. The oxide thickness was either 0.1 or 0.2μ. The metal providing contact to the backside of the wafers was deposited after scratching through the oxide. Frequently this metal was deposited and then sintered in dry nitrogen or hydrogen before deposition on the front side of the wafers. Heat-treatment of wafers after front-side metallization was performed in dry nitrogen at 500°C.

Both aluminum and aluminum-alloy metallization of about 1μ thickness were deposited in oil-diffusion-pumped vacuum chambers. Aluminum was deposited by electron beam, tungsten filament, or flash evaporation (7) while only the latter technique was used for aluminum-4% copper-2% silicon deposition. The source material used was always of at least 99.999% purity. The gas composition within the deposition chamber was investigated for each technique. A quadrapole residual gas analyzer attached to the chamber was used for this purpose. Deposition was normally onto wafers heated to temperatures of 300°-350°C. With other conditions held constant, it was found that the increased heating time necessary in order to attain progressively higher wafer temperatures during deposition resulted in increased Q_o. Accordingly, substantially higher temperatures were sometimes used in flash evaporation in order to increase Q_o to readily measurable levels. By the same reasoning, wafers were not heated during flash evaporation when the objective was to gain a measure of Q_o in the prepared oxides. The metal electrodes were formed either by shadow masking during deposition or by subsequent photomasking. The shadow masks were thoroughly cleaned chemically before use. Circular electrodes having nominal diameters of 5, 10, 15, and 30 mil were formed by both techniques. Rectangular electrodes having widths of 6 and 14 mil were prepared by photomasking.

Capacitance measurements at a frequency of 1 MHz were performed on completed capacitors. Room temperature capacitance-voltage traces were obtained for as-formed capacitors and following application of positive or negative bias for 3 min at 300°C. A field of 25 V/μ was used with the electrode negatively biased and 50 V/μ for the positive bias. The samples were rapidly quenched to room temperature following removal of the bias. The values of Q_o/q in charges cm^{-2} were calculated from the usual equation (8)

$$\frac{Q_o}{q} = \frac{2.1 \times 10^{10}}{x_o} \Delta V$$

where x_o is the oxide thickness in μ and ΔV is the voltage shift between the capacitance-voltage characteristics following negative and positive bias-temperature stress. It was determined by this procedure, when clean metallization processes such as cold-substrate flash evaporation were used, that the Q_o levels in the oxide were typically in the low 10^{10} cm^{-2} range for 30 mil diameter electrodes Such measurements also served to establish the cleanliness of the annealing furnace used for all nitrogen anneals.

Results

Effect of anneal time and masking procedure.—Values of Q_o as a function of anneal time at 500°C in nitrogen are shown in Fig. 1 for circular (dot) electrodes of two diameters. The sample was prepared by heated substrate deposition of aluminum-copper-silicon through a shadow mask. A minimum in Q_o is noted for both dot sizes. A longer anneal time was required in order to achieve the minimum for the larger dot.

Results are presented in Fig 2 for a sample similar to that of Fig. 1 except that the dots were formed by photomasking. Two values of Q_o are indicated for the smaller dot at zero anneal time. The larger value was obtained from the initial capacitance-voltage measurement. The second and subsequent measurements on the same dot or other dots of the same size yielded the lower Q_o value. Apparently the bias stress temperature (300°C) was sufficient to alter the contamination for the smaller dots. No such effect was observed with the larger dots but it should be noted that the measurements on such dots were performed last. As was true for the shadow-masked dots, anneals at 500°C resulted in a minimum Q_o. The data are not sufficiently detailed to determine whether or not a longer anneal time was required to minimize Q_o for the larger dots. However, results presented below suggest that this was the case.

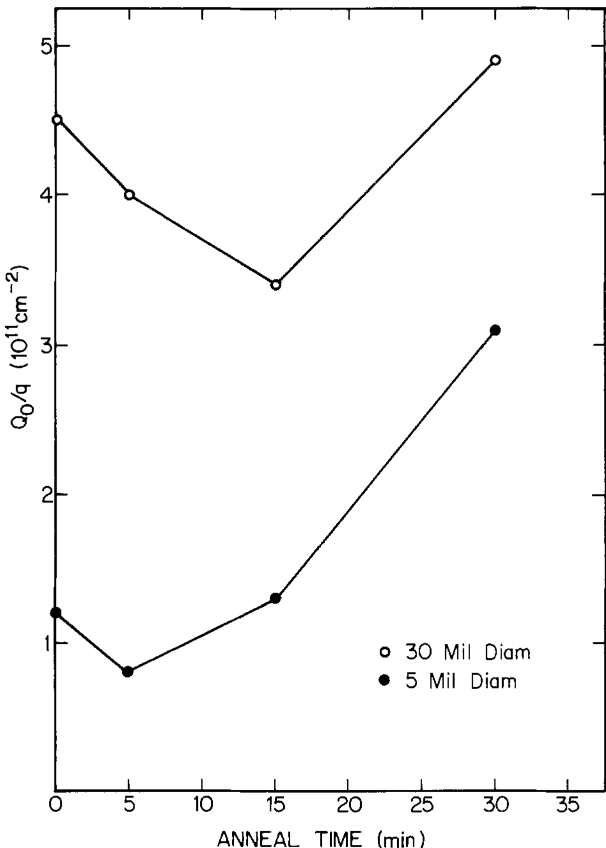

Fig. 1. Dependence of Q_o on the time of annealing in nitrogen at 500°C for a sample with hot-substrate aluminum alloy metallization. Circular electrodes of the nominal dimensions indicated were formed by shadow masking.

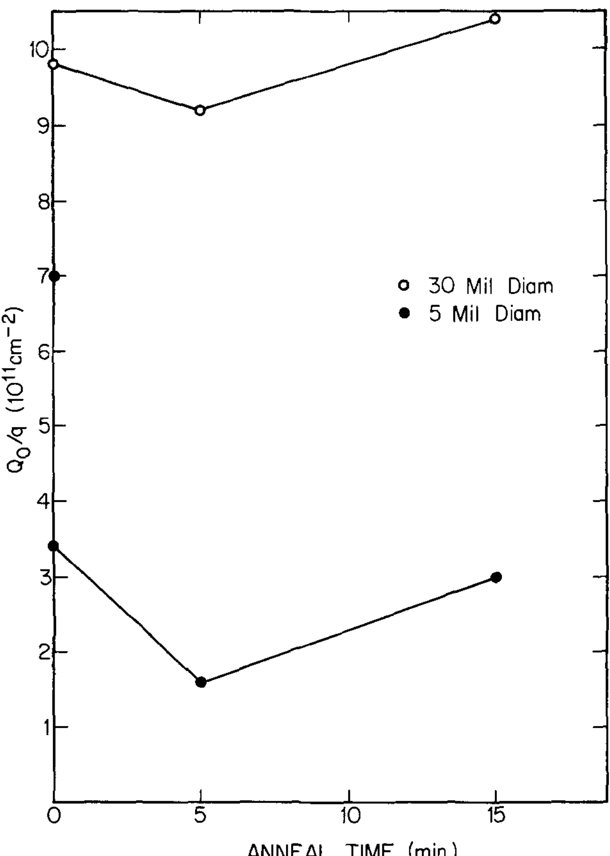

Fig. 2. Dependence of Q_o on the time of annealing in nitrogen at 500°C for a sample with hot-substrate aluminum alloy metallization. Circular electrodes of the nominal dimensions indicated were formed by photomasking.

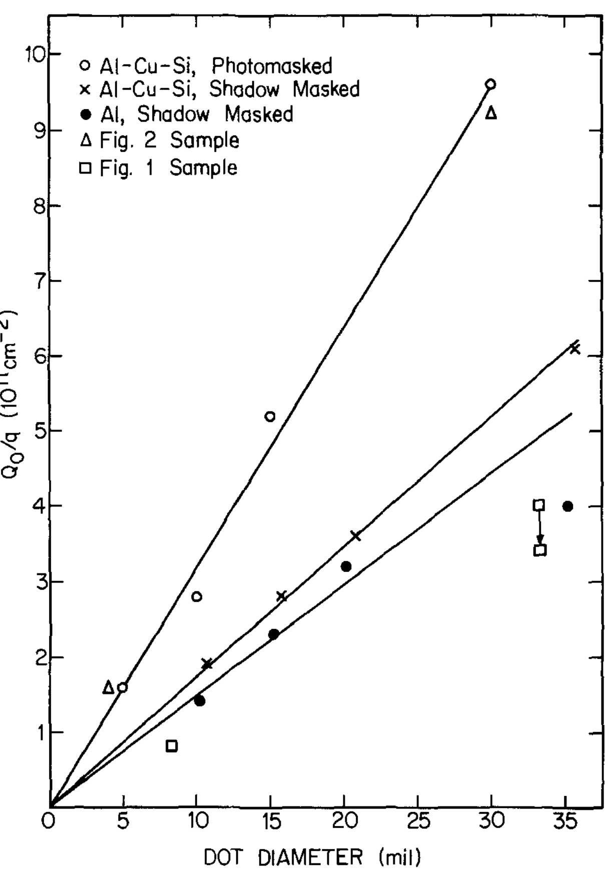

Fig. 3. Dependence of Q_o, obtained after a 5 min anneal at 500°C, on electrode diameter for hot-substrate samples as indicated.

Effect of dot dimensions.—The indication from Fig. 1 and 2 is that the minimum Q_o for smaller dots were reached after approximately 5 min anneals. The attainment of minimum Q_o for larger dots apparently requires somewhat longer anneals but probably the levels reached are not substantially different from Q_o values after 5 min anneals. Accordingly, a 5 min anneal at 500°C was considered to be a useful condition for more complete investigation of the dependence of Q_o on dot size. Values of Q_o after this treatment are plotted as a function of the dot diameter in Fig. 3. Results are shown for aluminum dots formed through a shadow mask and aluminum-copper-silicon dots formed either by shadow masking or photomasking. All of the films were deposited by flash evaporation onto heated wafers. Also included for reference are some of the data of Fig. 1 and 2. The actual dot diameters, as determined from photomicrographs of the dots, were used. In the case of the shadow masked dots the diameters differed substantially from nominal values as a consequence of penumbral effects occurring during deposition.

In all cases, Q_o was found to increase approximately linearly with increasing dot diameter. This was true for both aluminum and the aluminum alloy as well as for both shadow masked and photomasked samples. The two data points shown for the larger dots from the sample of Fig. 1 are the minimum Q_o and the Q_o following a 5 min anneal. While somewhat better fit to a straight line through the origin might be obtained with strict use of minimum Q_o, the basic nature of the curves would remain unchanged.

Effect of hydrogen.—It has been reported (9) that substantial amounts of hydrogen are present in the vacuum chamber during aluminum evaporation from pyrolytic boron nitride which is radiatively heated. The data presented in Fig. 4 show this to be true for tungsten filament and electron beam evaporations as

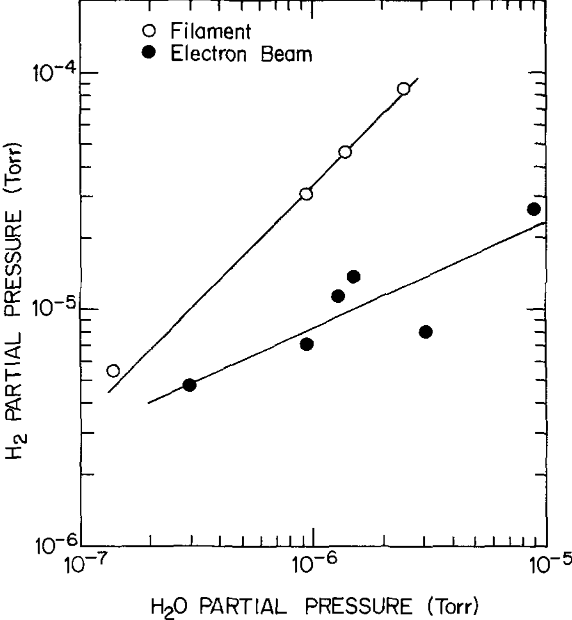

Fig. 4. Partial pressures of H_2 and H_2O in the deposition chamber during filament and electron beam evaporation of aluminum.

well. The partial pressures are averages over the few minute periods of deposition. Prior to melting of the aluminum source material the major gas present was water vapor. Some hydrocarbons were detected both before and during deposition but the concentrations were relatively small. The predominant species of hydrogen observed was H_2 although atomic hydrogen was present in significant concentrations, particularly for filament evaporations. The higher total pressures were obtained by restricting the area of the pumping

line between the vacuum chamber and the diffusion pump. For filament evaporation the data are fitted by a line of unit slope consistent with a constant ratio of H_2 to H_2O partial pressures of approximately 30. The data for electron beam evaporation exhibited considerable scatter. The line shown is a least squares fit. For a typical deposition pressure ($\sim 10^{-5}$ Torr) the ratio of H_2 to H_2O partial pressures is about 10.

The hydrogen presumably is generated through reaction of the aluminum and water vapor. The reaction could occur both on the molten aluminum and on freshly deposited film surfaces. The surface area of the filament was an order of magnitude larger than that of the molten aluminum in the electron gun hearth. The more pronounced H_2 evolution with the filament deposition is an indication then that reaction on molten aluminum is more significant. Some reaction does occur at this surface as evidenced by the buildup of an oxide dross on the electron beam aluminum source material. Further support for such a mechanism is provided by results obtained with flash evaporation. In this case little H_2 was present during deposition. It would be expected that the reaction would be limited with flash evaporation since the molten aluminum is confined in area and remains on the flash bar only for a short period of time. Undoubtedly, reaction also occurs at film surfaces as evidenced by the effect (9) of water vapor on several film properties. It is presumed, however, that the partial pressure of water vapor of importance in this respect is that remaining after reaction with the molten aluminum. It was found, for example, that the properties of filament deposits were much more tolerant of total pressure than electron beam deposits consistent with the lower partial pressure of water vapor in the former case (Fig. 4). A source of hydrogen alternative to that present during deposition may appear when oxides are subjected to heat-treatment in hydrogen prior to metallization.

Values of Q_o for two dot sizes are presented as a function of anneal time at 500°C in Fig. 5 for three samples. The samples were formed by deposition onto unheated wafers using filament evaporation of aluminum (shadow masked), by electron beam deposition of aluminum onto heated wafers (photomasked), or by flash evaporation of aluminum alloy onto heated wafers preannealed in hydrogen (shadow masked). The filament and flash evaporated samples clearly exhibited a maximum in Q_o for short anneal times. For longer anneal times, behavior was similar to that of samples discussed above. For all samples, a longer time is required to achieve minimum Q_o for the larger dots. Meaningful measurements on the electron beam evaporated samples could not be made without an anneal to remove radiation damage (1). It does not appear that the electron beam evaporated sample exhibited maxima for Q_o although the crossover in Q_o values for small and large dots at an anneal time of 15 min may be attributable to the presence of hydrogen. In general, the results were more widely scattered for such samples possibly because of the variability of the hydrogen level generated during deposition.

If the minimum (or near-minimum) values of Q_o are considered, they are in rough proportion to the dot diameter as before. It should be noted that for the filament-evaporated sample the dots were elliptical and the major axis dimension ratio was only about 2.5 for the dots of nominal diameter equal to 30 and 5 mil.

Room temperature drift measurements were performed on samples for which hydrogen was assumed to be present. Some drift was observed but was an order of magnitude smaller than the increases noted in Fig. 5 for short anneal times. Therefore it is probable that the additional Q_o introduced is traceable to alkali ions rather than hydrogen ions.

Effect of electrode geometry.—In addition to circular electrodes, rectangles having widths of 6 or 14 mil and containing at least 5 squares were tested. The electrode material was the aluminum alloy deposited on heated

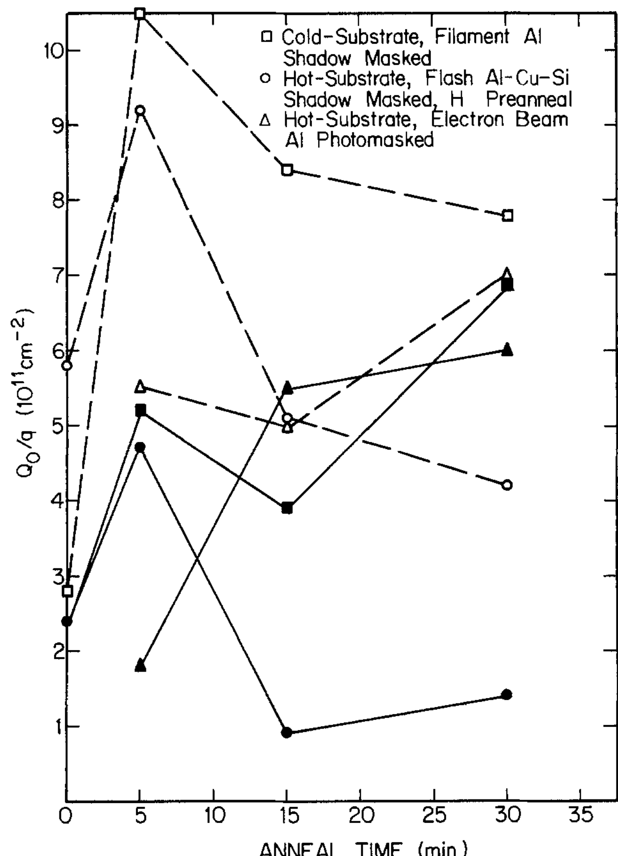

Fig. 5. Dependence of Q_o on the time of annealing in nitrogen at 500°C for samples as indicated. Open symbols denote results for electrodes of nominal 30 mil diameter and solid symbols for nominal 5 mil diameter.

wafers simultaneously with the sample of Fig. 2. The electrodes were delineated by photomasking. Figure 6 illustrates that the general nature of Q_o variation with anneal time was similar to that for dots similarly prepared (Fig. 2). As discussed in connection with Fig. 2, probably the initial values of Q_o/q shown have been reduced from a value of about 9×10^{11} cm^{-2} by the bias stress at 300°C. The minimum values of Q_o are in approximate proportion to the widths and would appear to be about the same as for dots of the same diameter. The anneal time required to reach the minimum Q_o was longer for the wider rectangle, analogous to the case for dots, but was greater than for dots of corresponding diameter.

No systematic dependence of Q_o on rectangle length was observed even though the number of squares examined on a given wafer was 5, 15, and 43 for the wider rectangle and 12, 30, and 100 for the narrower rectangle. A range of Q_o sometimes noted for the different lengths is indicated by the bars in Fig. 6.

Other effects.—For shadow masked samples it was invariably found that the contamination was originally at or very near the metal-silicon dioxide interface. The original capacitance-voltage trace would therefore overlap the trace following negative bias stress (curve A of Fig. 7). The original trace for photomasked samples, such as curve B of Fig. 7, was typically displaced from curve A toward more negative voltages indicating that the ionic contamination was originally located away from the metal-oxide interface. This is presumably a consequence of shorting of the metal to the silicon at the edge of the wafer or at pinholes in the oxide which allows movement of contamination away from the interface. An effect of this type has been categorized (10) as drift XVIII and adds to a previously compiled list of drifts of silicon oxide technology (11).

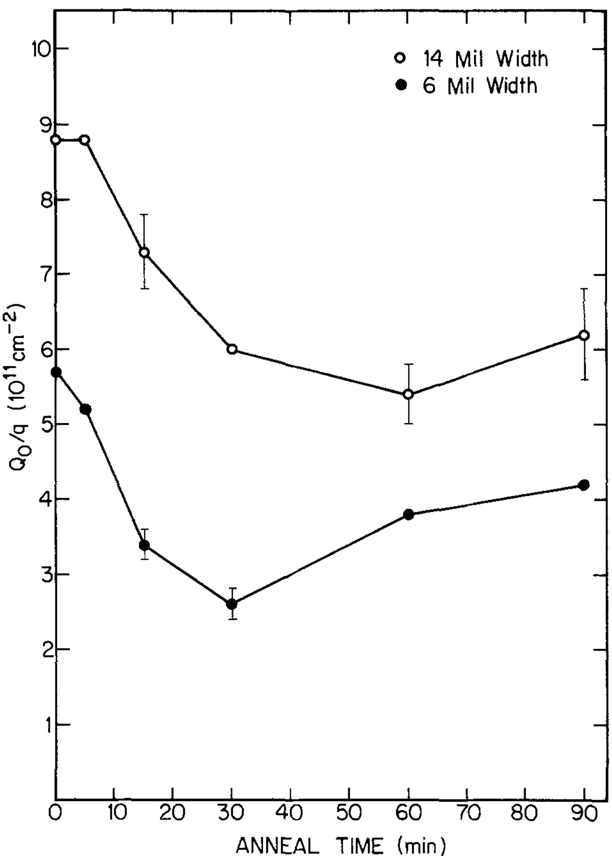

Fig. 6. Dependence of Q_o on the time of annealing in nitrogen at 500°C for samples with hot-substrate aluminum alloy metallization. Rectangular electrodes of the widths indicated were formed by photomasking.

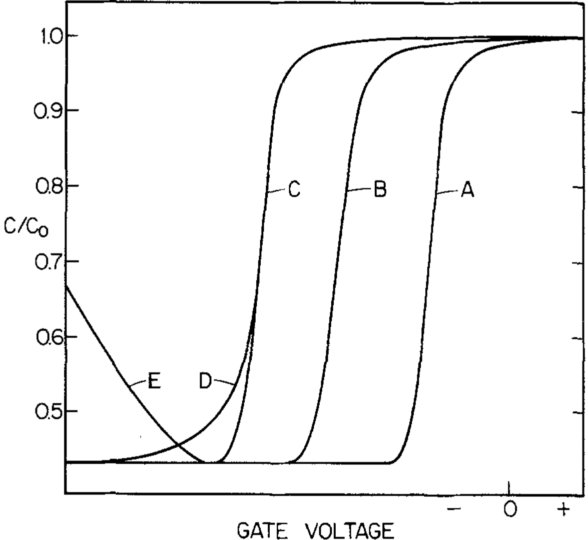

Fig. 7. Capacitance-voltage plots observed under various conditions as discussed in the text.

Annealing at 500°C was found to move the ionic contamination closer to the metal-oxide interface for photomasked samples. For times yielding near-minimum Q_o, the contamination had moved essentially to the interface. Such an effect was more noticeable for the largest dots and the wider rectangles.

The shape of the capacitance-voltage trace was frequently altered in two respects by long anneals. A tail on the trace following positive bias stress, as typified by curve D in Fig. 7, was observed. Again, this was more prevalent for the capacitors with the largest electrode dimensions. Secondly, the trace sometimes returned to higher capacitance values in the inversion region as indicated by curve E in Fig. 7. Such behavior was more common with p-type than with n-type wafers. Apparently defects in the silicon were generated by the anneals which acted as sources of minority carriers.

Discussion

The majority of the effects observed can be explained in terms of the following three postulates:

(*i*) A reduction in ionic contamination level in the oxide under the electrodes as a consequence of heating. A possible mechanism might be diffusion of contaminants to the edge of the electrodes and subsequent vaporization.

(*ii*) Activation of immobilized contamination under short-term heating with hydrogen as a catalyst. This may occur through substitution of protons for sodium ions at trapping sites. An opposite effect in which protons were released from adsorbed water, in the presence of sodium, has been observed (12).

(*iii*) An increase in mobile ionic contamination under prolonged annealing. A release of ionic contamination from the metal or effects associated with diffusion of aluminum into the oxide may produce such a result. As regards the latter, it was noted (6) that the immobilized sodium content near the aluminum-oxide interface increased for more extensive annealing. It is not clear, however, that this would lead to increased Q_o.

The combination of (*i*) and (*iii*) or (*i*), (*ii*), and (*iii*) will obviously reproduce the general features of the curves in Fig. 1 and 2 or Fig. 5, respectively. Also on this basis no fundamental difference would be expected between shadow masked and photomasked electrodes. However, the original (nominally zero anneal time) results for heated wafer, shadow masked samples may actually be appropriate to short anneals That some annealing effect can occur at temperatures of 300°C is apparent from the behavior of Q_o under electrical stress for photomasked samples (Fig. 2).

Consideration of the mechanism mentioned in (*i*) suggests that the effect of heating in reducing Q_o would be more pronounced for smaller dots and narrower rectangles where the circumference to area ratio is larger. This is, of course, the empirical finding. By the same token, in the absence of heating, no dependence of Q_o on electrode size would be anticipated. The initial results for the filament evaporation on unheated wafers in Fig. 5 demonstrate that this is the case. Efforts were made to minimize stress effects at 300°C on Q_o for these measurements by utilizing separate chips from one wafer for the two dot sizes and by performing the positive bias stress first.

A further consequence of (*i*) would be that the time to reduce Q_o to a given level would be larger for larger dots because of the longer diffusion distance required. Again this was observed experimentally. The occurrence of a minimum in Q_o for 30 mil diameter dots after an anneal time t of approximately 15 min implies a diffusion coefficient D of 1.7×10^{-7} cm²/sec if a diffusion length $2\sqrt{Dt}$ of about 10 mil is assumed. Such a value for D would not be considered incompatible with sodium diffusion. For comparison, an extrapolation of data (13) for bulk diffusion of sodium in fused silica to a temperature of 500°C yields a value of approximately 3×10^{-8} cm²/sec. In addition, ready evaporation of sodium would be anticipated since the vapor pressure of sodium at this temperature is about 4 Torr (14). The possibility was also considered that the hydrogen arising from the aluminum-water vapor reaction (5) plays a role when present in the oxide. Diffusion of this species to electrode edges and evaporation therefrom would be expected to reduce Q_o since sodium ions could then be retrapped in the oxide. An increase in Q_o for short term anneals of flash-evaporated metallization, as for the samples of Fig. 5, would be anticipated in such a case. However, an increase of this type was not observed. Apparently the ratio of

circumference to area is also of some significance as regards diffusion since times to reduce Q_o are longer for a rectangular than a circular electrode with width equal to diameter. In such a case the circumference to area ratio for the circle is twice that of the rectangle, assuming a rectangle of length much greater than width. Also, somewhat less uniform contamination under the larger dots or wider rectangles might be expected if diffusion to the dot edge is involved. It was previously noted that a tail on the capacitance-voltage trace, indicative of nonuniform contamination (15), was most prevalent for the capacitors with the larger electrodes.

The logical extension of (*i*) would be that for sufficiently long anneal times Q_o would approach a low value which would be independent of electrode size. This does not occur because of factor (*iii*). The approximately proportionate dependence of minimum Q_o on dot diameter and rectangle width was observed for a wide variety of sample types. This would appear to be more than fortuitous and suggests a possible relationship betwen (*i*) and (*iii*). It is difficult to see, however, that a mechanism involving introduction of aluminum or sodium from the electrode could lead to a size dependence. A convergence of Q_o values for different sizes and shapes, as typically observed for long anneal times, is more consistent with such a mechanism. It should also be noted that no consideration has been given possible effects arising from the aluminum-silicon dioxide reaction. On the basis of one set of reported data (16) about 300Å of silicon dioxide would be reduced to aluminum oxide in 60 min and some consequence might be anticipated. On the other hand no significant reduction of this type is apparent in a later study (6).

Finally, it is probable that for sufficiently large electrodes little or no reduction in Q_o could be effected through heating. The proportionality to size would then saturate. The data in Fig. 2 for the 30 mil diameter dots indicate that this condition may be approached with only slightly larger dimensions than this.

Summary and Conclusions

It was found that the value of Q_o measured on MOS capacitors is dependent on the annealing of the structure and on the electrode size and geometry. A minimum in Q_o is achieved with annealing time, and this minimum value is proportional to either the diameter of circular electrodes or the width of rectangular electrodes. These observations were interpreted to be a consequence of ionic contamination diffusion to and vaporization from the periphery of the electrodes together with eventual introduction of ionic contamination from the electrodes and/or activation of immobilized contamination. The long-term increase in Q_o has evidently been observed previously (10) and was attributed to contamination from the electrodes. The decrease in Q_o with anneal time or electrode dimension has not been noted heretofore. The dependence on size is, of course, the opposite of the normal edge effect where ionic contamination is introduced at the electrode periphery. In addition, substantial evidence was gathered to indicate that active contamination levels can be increased appreciably by annealing when hydrogen is incorporated in the capacitor structure.

The consequences of these findings in connection with semiconductor device fabrication are obvious since several factors may lead to variations in Q_o and therefore induce similar variations in device properties. The results are also of relevance as regards the common use of auxiliary MOS wafers to monitor Q_o at various processing steps (17), in particular metallization. The ideal approach would utilize electrode sizes and shapes closely approximating those on device wafers. In addition, the monitor wafers would experience heat-treatments identical to those of device wafers. Electrode delineation by photomasking rather than shadow masking would also be more in keeping with the processing of device wafers.

Acknowledgments

Bruce Deal and Maija Sklar were the source of many useful conversations and comments. Many of the metallization depositions and Q_o measurements were performed by Ed Dovichi. Pat Kodama was helpful in obtaining materials for evaluation.

The Standard Thermodynamic Functions for the Formation of Electrons and Holes in Ge, Si, GaAs, and GaP

C. D. Thurmond*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The forbidden energy gaps of Ge, Si, GaAs, and GaP have been used to obtain the standard Gibbs energy, enthalpy and entropy of formation of electrons and holes for each semiconductor up to the melting points. The forbidden energy gap is the standard Gibbs energy of formation of electrons and holes and the enthalpy and entropy have been obtained from the energy gap as a function of temperature and familiar thermodynamic relationships. Energy gaps as a function of temperature, available in the literature, have been fit to the semiempirical equation of Varshni and used to extrapolate the energy gaps and thereby the three thermodynamic functions to the melting points. It is well known that the energy gaps, *i.e.*, the Gibbs energies, decrease with increasing temperature but it is not well known that the enthalpy of formation increases with temperature and that it is proportional to the slope of the familiar logarithmic plot of the intrinsic carrier concentration over $T^{3/2}$ *vs.* $1/T$. Examples of the utility of the enthalpy function are given. It is the entropy that leads to the decrease in energy gap with increasing temperature and its magnitude is large near the respective melting points (10-13 cals/deg, *i.e.*, 4 to 5.6×10^{-4} eV/deg) arising from the interactions of electrons and holes with the lattice. The intrinsic carrier concentrations were calculated from the forbidden energy gaps and the average effective masses which were estimated for the higher temperatures.

The forbidden energy gap of a semiconductor is known to be a Gibbs energy, G = H − TS (1-3). It is the Gibbs energy of formation of electrons and holes. More specifically the forbidden energy gap is the standard Gibbs energy of formation of electrons and holes as described by the equilibrium reaction (4)

$$0 \rightleftarrows e^- + e^+ \qquad [1]$$

There is now sufficient information in the literature to permit the forbidden energy gaps of the four principal semiconductors, Ge (5-8), Si (7-9), GaAs(10-12), and GaP (11, 14, 15), to be reasonably estimated at all temperatures from 0°K to the respective melting points. In fact, the forbidden energy gap is known with sufficient accuracy to make possible the estimation of the standard enthalpies and entropies of formation of electrons and holes as functions of temperature. In addition, estimates can be made of the standard heat capacity changes for reaction [1] for these four semiconductors but with a greater degree of uncertainty. After an opening discussion of the forbidden energy gap as a standard Gibbs energy and the thermodynamic relationships giving the standard enthalpy, entropy, and heat capacity from the forbidden energy gap, the measurements of the energy gap are reviewed. These measurements are analyzed with the help of a semiempirical equation due to Varshni (16), which gives the forbidden energy gap as a function of temperature. The standard thermodynamic functions ΔG°, ΔH°, ΔS°, and ΔC_p° are obtained at all temperatures up to the respective melting points by extrapolation of the Varshni equation. An estimate of the uncertainties of these functions is made. The intrinsic carrier concentrations have been calculated from the forbidden energy gap and the average effective mass of electrons and holes, available from reported experiments at lower temperatures but estimated at higher temperatures. In addition, the utility of the standard enthalpy of formation of electrons and holes is illustrated in a discussion of the widely used linear approximation to the forbidden energy gap as a function of temperature and in an alternative explanation of a once anomalous property of the Au energy level in Si.

Thermodynamics

It has been long recognized (1-3, 17) that for a semiconductor the product of the electron concentration, n, and the hole concentration, p, is not a function of concentration when the concentrations are low. This product has been shown by statistical mechanical methods to be proportional to an exponential containing the energy gap (1, 2, 17)

$$np = n_c n_v \exp(-\Delta E_{cv}/kT) \qquad [2]$$

The symbol ΔE_{cv} will be used for the forbidden energy gap as recommended by Phillips (18), who suggests that the symbol E_g be reserved for the average bond energy gap. In the following, the terms forbidden energy gap, minimum energy gap, and energy gap will be equivalent. The two terms, n_c and n_v, are the effective density of states for electrons in the conduction band and holes in the valence band.

Equation [2] has a form similar to that of a chemical equilibrium constant. The equilibrium constant would be the fraction $np/n_c n_v$ and the energy gap, ΔE_{cv}, would be the standard Gibbs energy of formation of electrons and holes. That this is, in fact, true can be shown from the following argument.

The condition to be met for electrons and holes to be at equilibrium at some temperature T and some constant external pressure is that the Gibbs energy (19, 20) of the system be a minimum with respect to a change in the number of electrons or holes. This condition for equilibrium can also be expressed in terms of the chemical potentials of electrons and holes the sum of which must be zero

$$0 = \mu_n + \mu_p \qquad [3]$$

(Equation [3] is the equilibrium condition implied by Eq. [1] for the formation of electrons and holes.)

The chemical potentials of electrons and holes at low concentrations as a function of composition and temperature may be written as follows

$$\mu_n = \mu_n^\circ + kT \ln x_n$$
$$\mu_p = \mu_p^\circ + kT \ln x_p \qquad [4]$$

The standard chemical potentials μ_n° and μ_p° are the values of the respective chemical potentials when the

composition fractions, x_n and x_p, are unity. If the compositions are expressed in terms of concentration ratios, x_n would be n/n° and x_p would be p/p° where n° and p° are the concentrations of electrons and holes, respectively, in the standard states. From Eq. [3] and [4] it follows that

$$np = n^\circ p^\circ \exp\left(-(\mu_n{}^\circ + \mu_p{}^\circ)/kT\right) \quad [5]$$

an equation identical in form to Eq. [2].

The choice of the standard states is based on a statistical and quantum mechanical model of free electrons and free holes in the conduction and valence bands, respectively, of a semiconductor (1). The Fermi level, the electron chemical potential, is referred to the minimum energy of conduction band states, E_c, and therefore $\mu_n{}^\circ = E_c$. The hole chemical potential (the negative of the Fermi level) is referred to the maximum energy of the valence band states, E_v, and therefore $\mu_p{}^\circ$ is $-E_v$. Since the energy gap, ΔE_{cv}, is $E_c - E_v$ it follows that

$$\mu_n{}^\circ + \mu_p{}^\circ = E_c - E_v = \Delta E_{cv} \quad [6]$$

The standard chemical potentials of Eq. [6] are also Gibbs energies since the equilibrium conditions of interest are constant temperature and pressure. Consequently the standard chemical potential sum is the standard Gibbs energy, $\Delta G_{cv}{}^\circ$, for formation of electrons and holes and is also the forbidden energy gap

$$\mu_n{}^\circ + \mu_p{}^\circ = \Delta E_{cv} = \Delta G_{cv}{}^\circ \quad [7]$$

The standard state concentration, n°, is the electron concentration, n_c, which places the Fermi level at the conduction band edge, while the standard state concentration, p°, is the hole concentration, n_v, which places the Fermi level at the valence band edge. The concentration n_c is also the effective density of states in the conduction band and the concentration n_v is also the effective density of states in the valence band (21). They can be obtained from the two equations

$$n_c = 2(2\pi m_n kT/h^2)^{3/2}$$
$$n_v = 2(2\pi m_p kT/h^2)^{3/2} \quad [8]$$

where m_n and m_p are the effective masses of electrons and holes, respectively, and the other symbols have their usual meanings.

Since the forbidden energy gap as a function of temperature is the standard Gibbs energy for formation of electrons and holes as a function of temperature, the standard enthalpy, entropy, and heat capacity of formation of electrons and holes can be calculated from familiar thermodynamic relationships

$$\Delta E_{cv} = \Delta H_{cv} - T\Delta S_{cv} \quad [9]$$

$$d(\Delta E_{cv})/dT = -\Delta S_{cv} \quad [10]$$

$$d(\Delta E_{cv}/T)d(1/T) = \Delta H_{cv} = \Delta E_{cv} - Td(\Delta E_{cv})/dT \quad [11]$$

$$\Delta C_{cv} = d(\Delta H_{cv})/dT = Td(\Delta S_{cv})/dT \quad [12]$$

The superscript $^\circ$ which has been used to designate standard functions has been dropped for the subscript cv. Thus ΔH_{cv}, ΔS_{cv}, and ΔC_{cv} are the standard enthalpy, entropy, and heat capacity of formation of electrons and holes.

Experimental

Ge and Si.—Macfarlane, McLean, Quarrington, and Roberts have measured the forbidden energy gaps of Ge (5-8) and Si (7-9). The absorption coefficient was measured as a function of wavelength and temperature at high optical resolution in the wavelength region of the band edge. Fine structure in the absorption edge permitted identification of four phonon transitions characteristic of these indirect gap semiconductors. Each phonon transition was found to have a component related to an optical transition. The phonon and optical transition energies were obtained by curve fitting. The optical process measured in this way differs from the energy of the forbidden gap by a small amount, the dissociation energy of the exciton. The optical transition measured is the formation energy of an exciton, $\Delta E^f{}_{ex}$, and this energy plus the dissociation energy of the exciton $\Delta E^d{}_{ex}$, is the forbidden energy gap

$$\Delta E_{cv} = \Delta E^f{}_{ex} + \Delta E^d{}_{ex} \quad [13]$$

The exciton dissociation energy in Ge is 2.7 ± 0.2 meV according to McLean (8). A value of 10.0 meV was estimated for the exciton in Si (8) but a more recent measurement by Shaklee and Nahory (22) gives 14.7 ± 0.4 meV.

High resolution measurements of the Si forbidden energy gap as a function of temperature have been reported recently by Bludau, Onton, and Heinke (23). The derivative of the absorption coefficient with respect to wavelength was measured. The energy of formation of the exciton was sharply defined and 140 experimental points between 2° and 300°K were taken on high purity silicon. Thirty points at 10 degree intervals were obtained by quadratic averaging of the measurements. In order to obtain the energy gap, the exciton dissociation energy of 14.7 meV must be added, but in addition, a momentum conserving phonon energy must be subtracted (22) both of which are assumed to be independent of temperature.

The Ge and Si measurements are shown in Fig. 1. The difference between the value of the energy gap at T and its value at 0°K is plotted against T. A characteristic shape is exhibited. The curves drawn in Fig. 1 are obtained from a fit of the measurements to a semiempirical equation suggested by Varshni (16) and will be discussed below. The curves approach 0°K quadratically and at high temperatures approach linearity.

GaAs.—The measurements of Sell and co-workers (12, 13) and of Panish and Casey (11) have been used. Sell, Casey, and Wecht (12) obtained the energy gap at 297°K from reflectivity measurements. Panish and Casey measured the shift in absorption edge at constant absorption coefficient from 297°K to four temperatures up to 973°K. The measured shift added to the value of the energy gap at 297°K is assumed to give the energy gap at the higher temperatures. [Panish and Casey used the 294°K measurement of Sturge (10) to get high temperature values of the energy gap but the more recent reflectivity measurements of Sell, Casey, and Wecht (12) on unstrained GaAs and at higher resolution than used by Sturge are to be preferred.]

The differences between the energy gap at T and 0°K are plotted in Fig. 2 for GaAs.

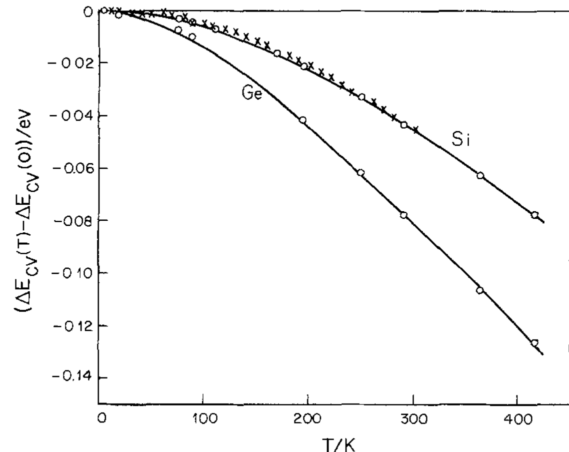

Fig. 1. The difference between the forbidden energy gap at T and 0°K, $\Delta E_{cv}(T) - \Delta E_{cv}(0)$, as a function of temperature for Ge and Si. ○ (Ge), Macfarlane *et al.* (5-8); ○ (Si), same authors (7-9); ×, Bludau, Onton, and Heinke (23); ——— Eq. [14], with the appropriate constants of Table I.

The difference between the forbidden energy gap at T and at 0°K, $\Delta E_{cv}(T) - \Delta E_{cv}(0)$, for GaAs as a function of temperature. ○, Panish and Casey (11); point at 297°K from Sell, Casey, and Wecht (12); $\Delta E_{cv}(0)$ from Sell, Stokowski, Dingle, and DiLorenzo (13) (see Table III); ——— Eq. [14] with the appropriate constants of Tables I and III.

GaP.—Lorenz, Pettit, and Taylor (14) have made absorption measurements up to 868°K. The measurements below 400°K give the energy gap from an analysis of spectral features equivalent to those used for Ge and Si. Between 400° and 868°K, the energy gap shift was estimated from the absorption edge shift at constant absorption coefficient. Panish and Casey (11) have measured the absorption edge shift at constant absorption coefficient from 300° to 1273°K. Figure 3 gives the experimental data as a plot of the energy gap difference between T and 0°K as a function of temperature.

The Evaluation of the Experimental Data

Varshni (16) has proposed a simple equation for the temperature dependence of the energy gap

$$\Delta E_{cv}(T) - \Delta E_{cv}(0) = -\alpha T^2/(T + \beta) \quad [14]$$

Equation [14] is based upon two assumptions; that the energy gap should be proportional to T at high temperatures and proportional to T^2 at low temperatures. The constant β was to be a reasonable approximation to the Debye temperature. The support for the use of the equation comes from the fact that it is a good representation of experiment (11, 16).

The method previously used to evaluate the three constants of Eq. [14] was to plot the energy gap, $\Delta E_{cv}(T)$ *vs.* $T^2/(T + \beta)$ and find the value of β for which a straight line was obtained. The intercept was $\Delta E_{cv}(0)$ and the slope was α. It is found that there is a rather wide range of values of α and β which gives a satisfactory fit to the data. An alternate method of evaluating these two constants will be used here which leads to a direct graphical solution for α and β and an estimate of uncertainties.

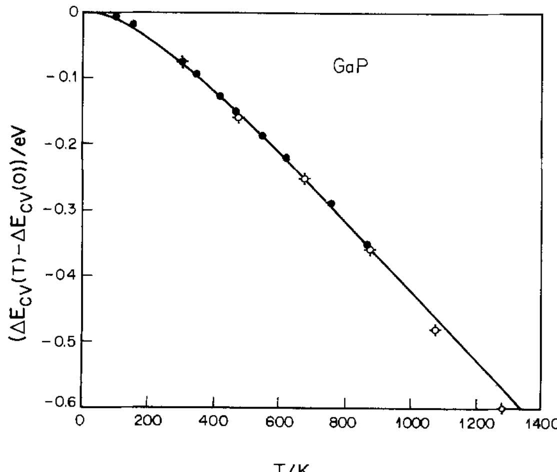

Fig. 3. The difference between the forbidden energy gap at T and at 0°K. $\Delta E_{cv}(T) - \Delta E_{cv}(0)$, for GaP as a function of temperature. ⌖, Panish and Casey (11) and ●, Lorenz, Pettit, and Taylor (14); ——— Varshni Eq. [16], with the appropriate constants of Tables I and III.

The question of the value of the energy gap at 0°K can be dealt with separately since the same value of the exciton dissociation energy applies to all values of the energy gap (Eq. [13]). The constants α and β can be obtained from the difference function, $\Delta E_{cv}(T) - \Delta E_{cv}(0)$, plotted in Fig. 1, 2, and 3. Equation [14] can be rearranged to give

$$T^2/(\Delta E_{cv}(0) - \Delta E_{cv}(T)) = \beta/\alpha + T/\alpha \quad [15]$$

If the experimental data are to fit Varshni's equation, the term on the left of Eq. [15] will depend linearly on temperature.

The measured energy gap differences are plotted according to Eq. [15] in Fig. 4, 5, 6, and 7. The values of α and β obtained and their estimated uncertainties are given in Table I. The values previously used are given for comparison. An uncertainty of 0.5 meV has been estimated for Ge and Si energy gap differences; an uncertainty of 4 meV has been estimated for GaAs and GaP. The uncertainty in α and β was obtained by passing one line of maximum slope through the selected data points and another of minimum slope. The values of α and β obtained from these two lines give

the spread in values which are twice the uncertainties given in Table I.

The curves shown in Fig. 1, 2, and 3 were calculated from Eq. [14] and the constants of Table I. The standard deviations of the experimental points from the calculated curves are given in Table II where they are compared with previous fits to the Varshni equation.

Table I. The coefficients α and β of the Varshni equation [14], $\Delta E_{cv}(T) - \Delta E_{cv}(0) = -\alpha T^2/(T + \beta)$. Comparisons are made with earlier work. The 0°K Debye temperature, $\theta_D(0)$, is also given

	$\alpha/10^{-4}$ eV K^{-1}	β/K	$\theta_D(0)$/K
Ge	4.774 ± 0.30	235 ± 40	374 (24)
	4.561 (16)	210 (16)	
Si	4.730 ± 0.25	636 ± 50	645 (24)
	7.021 (16)	1108 (16)	
GaAs	5.405 ± 0.25	204 ± 45	344 (25)
	5.8 (11)	300 (11)	
GaP	5.771 ± 0.55	372 ± 95	446 (25)
	6.2 (11)	460 (11)	

Table II. The standard deviation of the experimental energy gap difference, $\Delta E_{cv}(T) - \Delta E_{cv}(0)$, from the Varshni equation [14], using the coefficients of Table I. These are compared in the last column with standard deviations calculated using coefficients obtained by others

	Standard deviation/meV	
Ge	1.1	1.3 (16)
Si	0.6 (0.9)[a]	1.2 (16)
GaAs	2.6[b]	2.1 (11)
GaP	2.7[c]	4.0[c] (11)

[a] Measurements of Bludau, Onton and Heinke (23) included.
[b] Sturge (10) measurements not used.
[c] The two points at highest temperatures not included.

It is clear from Fig. 5 that below 250°K, the measurements of Bludau, Onton, and Heinke (23) deviate significantly from the Varshni equation. The low temperature points of Macfarlane *et al.*, (5-9), for Si and for Ge indicate similar deviations. The measurements of Bludau join those of Macfarlane at 250°K and above as can be seen in Fig. 5. The dashed line is equivalent to the fit to the Macfarlane *et al.* data made by Varshni (16).

The GaAs measurements at 297°K and above are satisfactorily represented by Varshni's equation (Fig. 6). No measurements have been used below 297° to fit the Varshni equation but absorption measurements by Sturge (10), photoluminescence measurements by Nathan and Burns (26), and injection luminescence by Sarace *et al.* (27) all below 297°K, give values of the energy gap that can be compared to values calculated from the Varshni equation fit to the temperature measurements above 297°. The energy gap values obtained by Sturge (10) at 90°, 55°, and 21°K agree within +3 meV with the Varshni equation. When Sturge's strain correction is not used and a value of 4.2 meV is used for the exciton dissociation energy, the 185° and 294°K values differ by about +5 meV from the Varshni equation. The energy gap values reported by Nathan and Burns are all higher than the Varshni equation calculations varying from 6.7 meV at 197°K to 3.7 meV at 65°K. The only other point lies at 4.2°K and is in good agreement with the calculated value (−0.5 meV). The experimental emission peaks have been assumed to be from free exciton annihilation, and a value of 4.2 meV has been added for the exciton dissociation energy to obtain the energy gap. Sarace *et al.* (27), have measured the recombination radiation from injected holes into n-type GaAs at 77° and 298°K. Their measures agree within 1 meV of the values of the energy gap calculated from the Varshni equation.

The GaP measurements are fit satisfactorily by the Varshni equation except for the two highest points, one at 1073°, the other at 1273°K. These two points have not been used in obtaining the constants of Eq. [15].

It was suggested by Varshni (16) that the constant α should have a value near that of the Debye temperature, but he found poor agreement among the examples he had. Panish and Casey (11) found better agreement for GaAs than did Varshni and their measurements, with those of Lorenz *et al.* (14), led to reasonable agreement for GaP. Table I includes a value for the Debye temperature evaluated at 0°K, $\theta_D(0)$. The value of β for Si, 636°K, is now in much better agreement with the Debye temperature, 645°K, than the 1108°K found by Varshni. The values of β now fall close to a straight line ($\beta = 1.51\ \theta_D - 324$) revealing the relationship suggested by Varshni.

In order to obtain the value of the energy gap as a function of temperature, the value of the energy gap at 0°K is needed. These are given in Table III along with the exciton dissociation energies used.

The Thermodynamic Functions

It is now proposed to use the Varshni equation to obtain the various thermodynamic functions of inter-

Table III. The forbidden energy gap at 0°K, $\Delta E_{cv}(0)$, and the exciton dissociation energy Δ^{d}_{ex}

	$\Delta E_{cv}(0)$/eV	ΔE^{d}_{ex}/meV
Ge	0.7437 ± 0.001 (9)	2.7 ± 0.4 (9)
Si	1.1700 ± 0.001 (9, 23)	14.7 ± 0.4 (22)
GaAs	1.519 ± 0.001 (13)	4.2 ± 0.2 (28)
GaP	2.338 ± 0.002 (14)	10.0 ± 1.0 (15)

est and to use it at all temperatures up to the melting point. An estimate will be made in a following section of the uncertainties that may be expected in the various functions.

From Eq. [10] and [14] it follows that the entropy of formation of electrons and holes, *i.e.*, the gap entropy, is given by the equation

$$\Delta S_{cv}(T) = \alpha T(T + 2\beta)/(T + \beta)^2 \quad [16]$$

From Eq. [11] it follows that the enthalpy of formation of electrons and holes, *i.e.*, the gap enthalpy, is

$$\Delta H_{cv}(T) = \Delta H_{cv}(0) + \alpha\beta(T/(T + \beta))^2 \quad [17]$$

The thermodynamic functions, Gibbs energy, ΔE_{cv}, the enthalpy, ΔH_{cv}, and the entropy, ΔS_{cv}, are plotted as functions of temperature in Fig. 8, 9, 10, and 11 for each of the four semiconductors of interest.

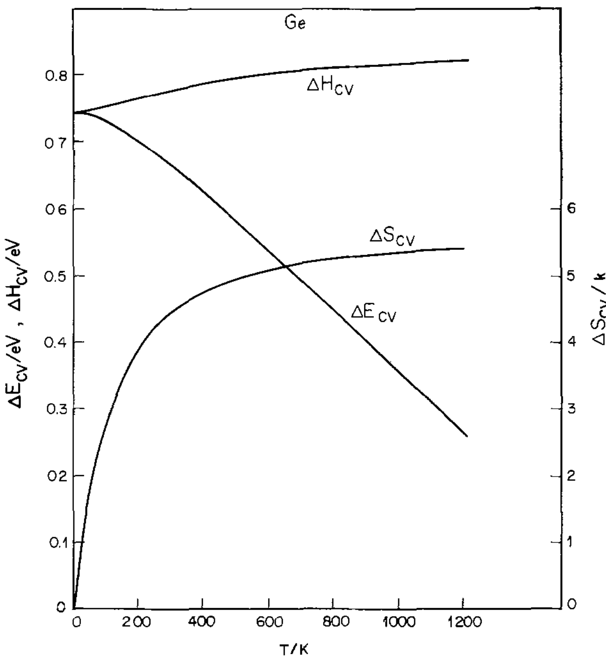

Fig. 8. The Gibbs energy, ΔE_{cv} in eV, the enthalpy, ΔH_{cv} in eV and the entropy, ΔS_{cv} in units of k, as functions of T for Ge.

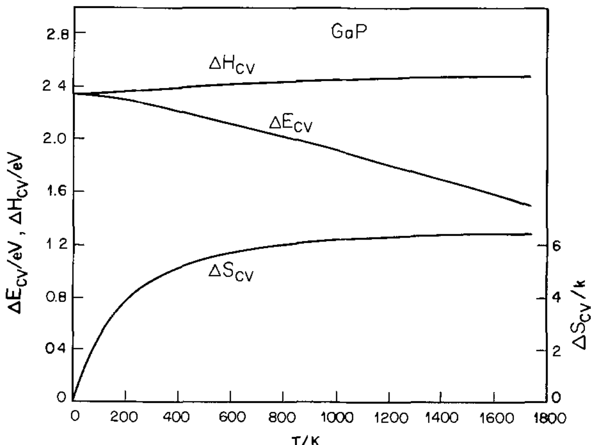

Fig. 9. The Gibbs energy, ΔE_{cv} in eV, the enthalpy, ΔH_{cv} in eV and the entropy, ΔS_{cv} in units of k, as functions of T for Si.

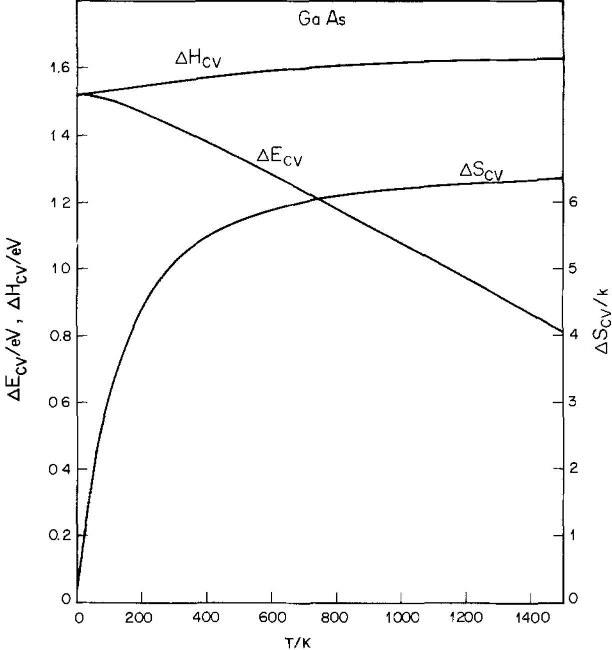

Fig. 10. The Gibbs energy, ΔE_{cv} in eV, the enthalpy, ΔH_{cv} in eV and the entropy, ΔS_{cv} in units of k, as functions of T for GaAs.

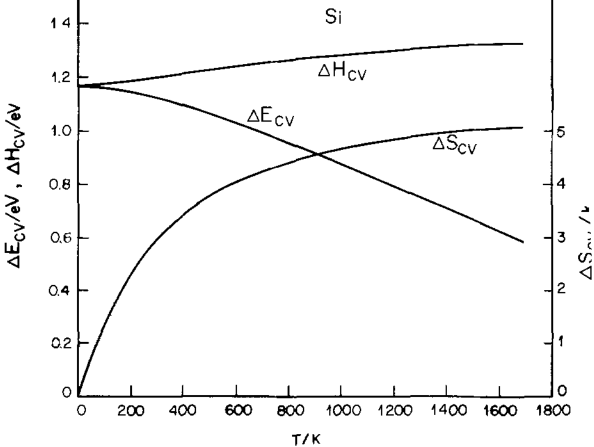

Fig. 11. The Gibbs energy ΔE_{cv} in eV, the enthalpy, ΔH_{cv} in eV and the entropy, ΔS_{cv} in units of k, as functions of T for GaP.

The heat capacity, ΔC_{cv}, can be obtained from Eq. [12] and Eq. [17]

$$\Delta C_{cv} = 2\alpha\beta^2 T/(T + \beta)^3 \quad [18]$$

and is plotted in Fig. 12.

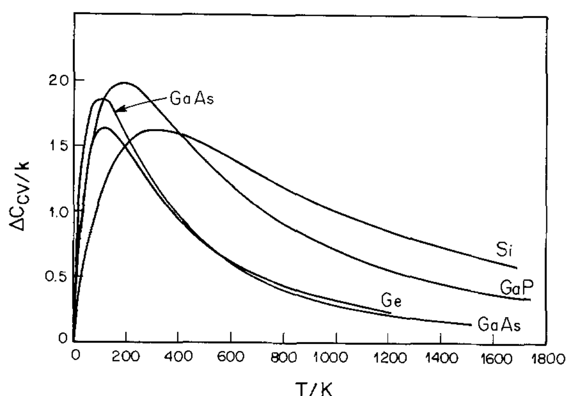

Fig. 12. The heat capacity change, ΔC_{cv} in units of k, for the formation of electrons and holes as a function of T for Ge, Si, GaAs, and GaP.

Discussion

Uncertainties.—An estimate of the uncertainties in the forbidden energy gap and the derived thermodynamic functions can be made based upon the uncertainties in the coefficients α and β of the Varshni equation. Of particular interest are the uncertainties at high temperatures. Table I lists the uncertainties in α and β estimated from Fig. 4-7. The uncertainties in ΔE_{cv}, ΔH_{cv}, ΔS_{cv}, and ΔC_{cv} can be obtained using the α and β uncertainties and Eq. [14], [16], [17], and [18]. Table IV gives the estimated uncertainties for each material at 300°K and at its melting point. At room temperature ΔE_{cv} and ΔH_{cv} are known to within a few tenths per cent; at the melting points, to within 2-7%. The uncertainties in ΔH_{cv} are smaller because it is the larger quantity at the melting point. The entropies are known to a per cent or so at 300°K and 5-8% at the melting points. The heat capacities have the largest uncertainties ranging from 5 to 50%.

The energy gaps of Ge and Si have been measured near the melting points by Glassbrenner and Slack (29). They measured the thermal conductivity of Ge and Si and found that at high temperatures nearly half was determined by the electrons and holes present. From their measurements, they obtained a value of the energy gap of Ge, at its melting point, of 0.26 ± 0.08 eV. The value given in Fig. 8, obtained from the Varshni equation (Eq. [14]) and the constants in Tables I and III, is 0.260 eV with an estimated uncertainty of ±0.018 eV from Table IV. The value given for Si at its melting point by Glassbrenner and Slack (29) was 0.6 ± 0.1 eV. The value given by the extrapolated Varshni equation is 0.591 eV with an estimated uncertainty of 0.018 eV from Table IV. The agreement is well within the estimated uncertainties.

Si below 300°K.—Recent measurements of the energy gap by Bludau, Onton, and Heinke (23), between 0° and 300°K, are in agreement with the measurements of Macfarlane *et al.* (9), between 250° and 300°K. Below 250°K, however, definite departures occur from the values obtained from the Varshni equation (see Fig. 1 and Fig. 5). These departures are relatively small; less than 0.1% for ΔE_{cv} and less than 0.4% for ΔH_{cv} at all temperatures, less than 7% at 300°K for ΔS_{cv} (at 50°K the maximum departure of 25% occurs for ΔS_{cv}) and less than about 30% for ΔC_{cv} at all temperatures below 300°K.

The function used by Bludau *et al.* (23), to represent their measurements in the 0°-190°K temperature range, has a linear term, and as a consequence the calculated value of ΔS_{cv} is not zero at 0°K. The averaged data points given by the authors are consistent, however, with T^2 dependence near 0°K and no linear term is needed.

The intrinsic carrier concentration, n_i.—The concentrations of electrons and holes are equal in a pure semiconductor. From Eq. [2] and [8] the intrinsic concentration is given by

$$n_i = 2(2\pi k/h^2)^{3/2}\langle m\rangle^{3/2}T^{3/2}\exp(-\Delta E_{cv}/2kT) \quad [19]$$

The average density of states effective mass, $\langle m\rangle$, is the geometric mean of the electron and hole density of states effective masses

$$\langle m\rangle = (m_n m_p)^{1/2} \quad [20]$$

Since values of the energy gap have now been either measured or estimated at all temperatures for Ge, Si, GaAs, and GaP, values of n_i can be calculated from Eq. [19] if $\langle m\rangle$ is known as a function of temperature. Casey (30) has used this method to obtain an estimate of n_i to the melting points for GaAs, GaP, and a number of other 3-5 compounds.

Si.—Barber (31) has concluded that the effective masses of electrons and holes in silicon are functions of temperature and from available literature information and his own calculations has obtained values up to 600°K. Values of n_i calculated from Eq. [19] using these effective masses were compared to the Hall measurements of n_i by Morin and Maita (32) and by Putley and Mitchell (33). Best agreement was obtained with the Putley and Mitchell measurements when it was assumed that the exciton dissociation energy was zero.

An alternative approach is to use Eq. [19] to calculate the average effective mass, $\langle m\rangle$, from the measured values of n_i and from ΔE_{cv} obtained from Eq. [14] and the constants given in Tables I and II

$$\Delta E_{cv}(T) = 1.1700\text{-}4.73 \times 10^{-4}(T^2/(T + 636)) \quad [21]$$

The calculated values of $\langle m\rangle$ for Si, given in units of the electron rest mass, are shown in Fig. 13 as a function of temperature. They are to be compared to the $\langle m\rangle$ curve calculated from Eq. [20] using the electron and hole effective masses recommended by Barber (31). The experimental values of n_i were calculated from the equations used by Morin and Maita (32) to fit their data over the temperature range 300°-1200°K

$$n_i = 3.87 \times 10^{16}T^{3/2}\exp(-(0.605 + \Delta\epsilon)/kT) \quad [22]$$

$$\Delta\epsilon = -7.1 \times 10^{-10}(n_i/T)^{1/2}$$

Putley and Mitchell (33) made measurements over the temperature range 370°-500°K, and the data were well represented by the equation

$$n_i = 3.10 \times 10^{16}T^{3/2}\exp(-0.603/kT) \quad [23]$$

It is estimated that the average deviation of the experimental points from the fitting curves in both cases is about 5%.

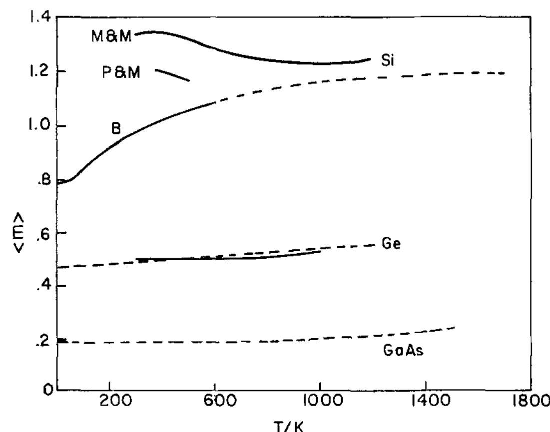

Fig. 13. The density of states average effective mass, $\langle m\rangle$, in units of the electron rest mass, as a function of T. The Si-M&M curve is based upon the n_i measurements of Morin and Maita (32), the Si-P&M curve is based upon the n_i measurement of Putley and Mitchell (33); the Si-B curve is from Barber (31); the dashed extension of the Barber curve is the present estimate of $\langle m\rangle$ to the melting point of Si. The Ge-M&M curve is based upon the n_i measurements of Morin and Maita (34); the straight line is the present estimate of $\langle m\rangle$ from 0°K to the melting point of Ge. The GaAs curve was obtained from Casey (30).

Table IV. The per cent uncertainty in the calculated thermodynamic functions arising from the uncertainty in α and β (Table I) and $\Delta E_{cv}(0)$ (Table III)

Uncertainty, per cent

	T/K	ΔE_{cv}	ΔH_{cv}	ΔS_{cv}	ΔC_{cv}
Ge	300	0.3	0.5	2	15
	1210	7	2	5	35
Si	300	0.1	0.1	0.1	5
	1685	3	1	4	15
GaAs	300	0.3	0.3	0.6	20
	1511	2	1	4	45
GaP	300	0.2	0.2	1	15
	1738	3	2	8	50

Barber pointed out a discrepancy between the early measurements by Morin and Maita and the later measurements by Putley and Mitchell on higher purity silicon. This discrepancy in the measured values of n_i is evident in the two upper curves of Fig. 13 of $<m>$ as a function of temperature. Barber found that the measurements of Putley and Mitchell were in satisfactory agreement with the temperature dependent effective masses he found to represent the best available effective mass measurements. This agreement, however, rested upon the assumption that the exciton dissociation energy was zero. It is now known that for low temperatures the exciton dissociation energy is 14.7 meV (22) and is not expected to be a significant function of temperature. The difference between the Putley and Mitchell curve of Fig. 13 and the Barber curve is due to the exciton dissociation energy of 14.7 meV ignored by Barber.

The high temperature Morin and Maita measurements which should be less sensitive to impurities than the lower temperature data suggest that the average effective mass does not vary much with temperature. We have arbitrarily extrapolated Barber's curve to the melting point of silicon guided to some extent by the high temperature measurements of Morin and Maita.

Ge.—The average effective mass, $<m>$, of electrons and holes in Ge has been calculated from the measurements of n_i by Morin and Maita (34)

$$n_i = 1.76 \times 10^{16} T^{3/2} \exp(-0.785/2kT) \quad [24]$$

and the forbidden energy gap

$$\Delta E_{cv} = 0.7437 - 4.774 \times 10^{-4}(T^2/(T + 235)) \quad [25]$$

The measurements of n_i were made over the temperature range of 300°-1000°K. The calculated values of $<m>$ are plotted in Fig. 13. They show a slow increase with temperature and good agreement with the value of 0.47 near 0°K obtained from an effective mass for the electron of 0.55 and for the hole of 0.40 (35). We have estimated the value of the average effective mass up to the melting point by the straight line shown in Fig. 13. This approximation is expected to be satisfactory at all temperatures not too near 0°K where the average effective mass is expected to approach 0°K with zero slope as shown for Si in the curve given by Barber (31).

GaAs.—No measurements of n_i as a function of temperature have been made. Casey (30) has calculated n_i from the forbidden energy gap and an average effective mass consistent with low temperature measurements and an estimated temperature dependence based upon the GaAs band structure

$$<m> = 0.186\,(1 + 16.67 \exp(-0.36/kT)) \quad [26]$$

$<m>$ is again measured in units of the electron rest mass. Equation [26] is shown in Fig. 13 from 0°K to the melting point of GaAs.

GaP.—The intrinsic carrier concentration, n_i, has not been measured as a function of temperature. Low temperatures effective masses of electrons and holes give a value for $<m>$ of 1.15 which Casey (30) has used to calculate n_i as a function of temperature. The same assumption has been made here.

Values of n_i are shown in Fig. 14 up to the respective melting points. The calculations for GaAs and GaP are nearly identical to those made by Casey (30). We have used the same values of the effective masses and nearly the same values of the forbidden energy gap. At 300°K, n_i calculated by Casey for GaAs and GaP are approximately a factor of 2 larger than given in Fig. 14. At the melting points, Casey calculated a value for GaAs 40% higher than given here and for GaP, about 15% smaller than given in Fig. 14.

Recently, Jain *et al.* (36) have estimated n_i for Si to the melting point. Their value of n_i at 300°K is about

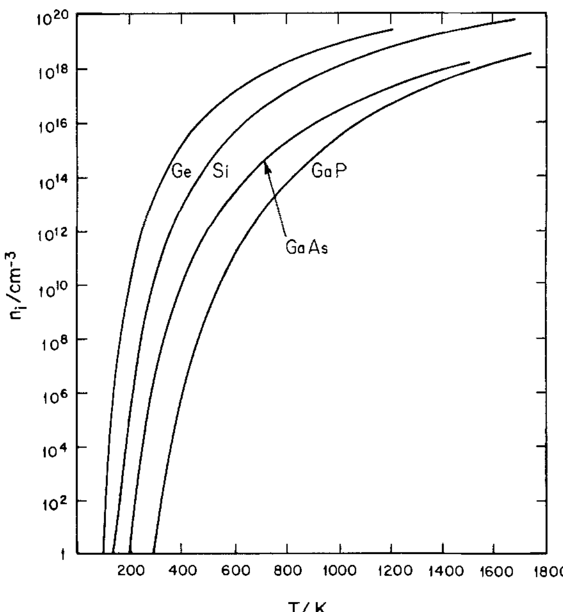

Fig. 14. The intrinsic carrier concentration, n_i in cm^{-3}, as a function of T for Ge, Si, GaAs, and GaP.

25% larger than given here, while at the melting point, n_i is a factor of 1/3 lower than given in Fig. 14.

The assumption that classical statistics can be used to give the electron and hole chemical potentials as a function of composition and temperature (Eq. [4]) receives its severest test at the highest temperatures attainable. The values of n_i calculated using classical statistics rather than Fermi-Dirac statistics are too large at the respective melting points by 10% for Ge, 4% for Si, 2% for GaAs, and 0.2% for GaP. It has been assumed in these calculations that the effective masses of the electron and the hole are the same in each material at its melting point. When room temperature effective mass ratios are used instead, the only significant change is for GaAs, changed from 2% to 4%. It is clear that classical statistics satisfactorily represent n_i for these four semiconductors.

The enthalpy of formation of electrons and holes, ΔH_{cv}.—The temperature dependence of the intrinsic carrier concentrations, n_i, frequently written in the form

$$n_i/T^{3/2} = A \exp(-\Delta E_{cv}/2kT)$$
$$A = 2(2\pi<m>kT/h^2)^{3/2} \quad [27]$$

which follows from Eq. [19]. The assumption is generally made that the average effective mass is independent of T. It was found by Pearson and Bardeen (2) and later confirmed by Morin and Maita (32) that a plot of log $(n_i/T^{3/2})$ *vs.* $1/T$ was a straight line for Si, but the magnitude of the constant A did not agree with theory. Pearson and Bardeen suggested that the inconsistency arose because ΔE_{cv} was temperature dependent. They then assumed a linear dependence and found a reasonable value for the modified preexponential coefficient. The slope of the line was the extrapolated value of the energy gap at 0°K.

In fact, a plot of log $(n_i/T^{3/2})$ *vs.* $1/T$ will, in general, not be a straight line but will be a slowly varying function of T and at any temperature the slope at that temperature gives the enthalpy, ΔH_{cv}. Changes in effective mass with temperature are expected to be sufficiently small to have a negligible effect on the slope. That the slope is the enthalpy, ΔH_{cv}, follows directly from Eq. [27] and the derivative of the exponent with respect to T

$$d(\Delta E_{cv}/T)/d(1/T) = \Delta E_{cv} - T(d\Delta E_{cv}/dt)$$
$$\Delta E_{cv} + T\Delta S_{cv} = \Delta H_{cv} \quad [28]$$

Since ΔH_{cv} is an increasing function of temperature, the slope of the log n_i *vs.* $1/T$ plot should increase with temperature. This effect is clearly shown in the measurements of Morin and Maita (32) on silicon at higher temperatures. At lower temperatures, over the usual temperature ranges studied, the slope will be constant within experimental uncertainties.

It is frequently assumed that the temperature dependence of the energy gap is a linear function of temperature. The line will usually be a good approximation to the tangent of the curve that gives the correct temperature dependence of the energy gap. The intercept of this tangent line at $T = 0°K$, the extrapolated energy gap at 0°K, is the enthalpy, ΔH_{cv}, at the temperature T where the line is tangent to the curve. These relationships are shown in Fig. 15 and follow from the thermodynamic relationships of Eq. [9], [10], and [11].

An example of how the gap enthalpy, ΔH_{cv}, can be used to clarify a problem is found from the work of Parillo and Johnson (37). They measured the temperature dependence of the electron emission rates from the Au energy level in Si, and after correcting the experimental slope for the temperature dependence of thermal velocities, capture cross sections, and the effective density of states in the conduction band, concluded that they had fixed the position of the level below the conduction band edge. Similar measurements of the hole emission rates fixed the position of the level above the valence band edge. They found, however, that the two energies did not add to give the value of the energy gap at their average temperature, 328°K. Their measurements gave the sum, 1.21 ± 0.03 eV; the value of ΔE_{cv} was 1.12 eV (1.117 ± 0.001 eV present value). The anomaly was explained by assuming that the energy gap and the energy level were functions of temperature, specifically, linear functions of temperature. This led to the conclusion that the energy levels obtained from the temperature dependences of the emission rates were, in fact, energy levels at 0°K. Their sum, 1.21 eV, should compare to the extrapolated energy gap at 0°K, 1.20 eV, giving satisfactory agreement.

This explanation of the anomaly is basically correct. There is no necessity, however, to assume a linear dependence on temperature for the energy gap and the energy level when it is recognized that the energy level measured is an enthalpy level and the sum should be compared to the gap enthalpy, ΔH_{cv}. The comparison is, then, between the sum, 1.21 ± 0.03 meV and ΔH_{cv} at 328°K, 1.204 ± 0.001 eV, with agreement well within estimated uncertainties.

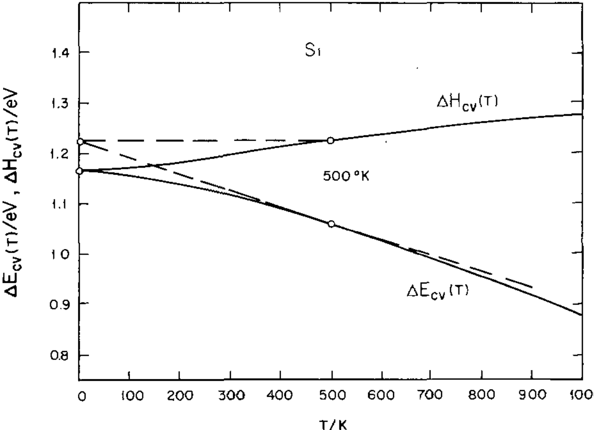

Fig. 15. The forbidden energy gap, ΔE_{cv} in eV, and the enthalpy, ΔH_{cv} in eV, *vs.* T for Si. It is shown that the tangent to the ΔE_{cv} curve at 500°K intersects the $T = 0°K$ axis at a value equal to the enthalpy, ΔH_{cv}, at 500°K. The same relationship holds at any temperature.

A comment about the apparent anomaly of the optically measured energy gap being a Gibbs energy.—In the section on thermodynamics a chemical thermodynamic argument is given for the forbidden energy gap as a Gibbs energy and optical absorption measurements were later used to obtain the energy gap. This implies that the absorption of light by the crystal should occur at constant temperature and pressure since it involves a Gibbs energy, but this certainly is not so. The absorption of a photon by the lattice is a very rapid process. The crystal does not have time to come to thermal equilibrium and therefore absorption of light occurs at constant entropy, and also constant volume. Under these conditions it is the internal energy, U, that changes in the formation of the electron and hole, not the Gibbs energy, G. But a fundamental thermodynamic relationship can be used to show that these two functions are of equal magnitude. The fundamental thermodynamic relationship defines the chemical potential (38)

$$\mu_i = \left(\frac{\partial G}{\partial N_i}\right)_{P,T,N_j} = \left(\frac{\partial U}{\partial N_i}\right)_{S,V,N_j} \qquad [29]$$

The change in total Gibbs energy, G, with the number of atoms of i, N_i, at constant pressure, temperature and all other components, N_j, and the change in the total internal energy, U, with atoms of i at constant entropy, volume and N_j, are both the chemical potential of i, μ_i. It has been shown (section on thermodynamics) that the energy gap is a chemical potential. It follows that the energy gap measured optically at conditions of constant entropy and volume is identical to the energy gap measured at constant pressure and temperature. With recognition that these are, in fact, standard functions and using the symbol N for the number of electron-hole pairs, the equalities can be expressed in a modified form of Eq. [29]

$$\mu_n^\circ + \mu_p^\circ = \Delta E_{cv}(\text{thermal})$$

$$= \left(\frac{\partial \Delta G^\circ}{\partial N}\right)_{P,T} = \left(\frac{\partial \Delta U^\circ}{\partial N}\right)_{V,S} = \Delta E_{cv}(\text{optical}) \qquad [30]$$

[30]

Table columns and figure axes.—The headings of table columns and the labeling of figure axes follows the recommendation of McGlashan (41).

Summary

The Gibbs energy, the enthalpy and the entropy of formation of electrons and holes in Ge, Si, GaAs, and GaP have been obtained over the temperature ranges 0°K to the respective melting points. The Gibbs energy for the electron-hole formation reaction is the forbidden energy gap of the semiconductor. The enthalpy and entropy of the reaction are obtained from the forbidden energy gap as a function of temperature by familiar thermodynamic relationships.

The forbidden energy gaps of Ge, Si, GaAs, and GaP are available in the literature but over limited temperature ranges. A semiempirical equation by Varshni (16) has been used to fit the available forbidden energy gap measurements as a function of temperature and provides the basis for extrapolation to the melting points. A different fitting method from that used by Varshni has led to the resolution of an anomaly found by Varshni for Si. One of the constants of the Varshni equation was expected to have a value near that of the Debye temperature. The value found by Varshni for Si was surprisingly large (1108° *vs.* 645°K). The new fit leads to an acceptable value (636°K).

While the forbidden energy gaps decrease with temperature, the enthalpies slowly increase with temperature implying a positive heat capacity change in the formation of electrons and holes. The entropy changes

are large, approximately 12 cals/deg or 5×10^{-4} eV/deg at high temperatures. It follows that the decrease with temperature of the forbidden energy gaps is predominately due to the relatively large entropies of formation of electrons and holes. These entropies arise from the interaction of electrons and holes with the lattice. The thermodynamic functions ΔE_{cv}, ΔH_{cv}, and ΔS_{cv}, are independent of the concentrations of electrons and holes are the so-called "standard" functions of chemical thermodynamics.

The intrinsic carrier concentrations have been calculated from the forbidden energy gaps and the average density of states effective masses. Estimates of the average effective masses have been made.

The forbidden energy gap as a function of temperature is frequently approximated by a straight line. In general, ΔE_{cv} is not linear in T and the extrapolated value of the energy gap at 0°K is larger than the true value $\Delta E_{cv}(0)$. When the line is a good approximation to the tangent, at T, of the curve giving $\Delta E_{cv}(T)$, the extrapolation to 0°K gives ΔH_{cv}, the enthalpy of formation of electrons and holes at the temperature T.

Acknowledgments

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Bell Laboratories.

LIST OF SYMBOLS

- ΔC_{cv} standard constant pressure heat capacity change for the formation of electrons and holes, Eq. [1]
- ΔE_{cv} forbidden energy gap; the standard Gibbs energy of formation of electrons and holes, Eq. [1]
- ΔE^f_{ex} molar Gibbs energy of formation of an exciton
- ΔE^d_{ex} molar Gibbs energy of dissociation of an exciton
- $\Delta G_{cv}°$ standard Gibbs energy of formation of electrons and holes, Eq. [1, 7]; the forbidden energy gap
- $\Delta G°$ total standard Gibbs energy of formation of electrons and holes, Eq. [1, 30]
- ΔH_{cv} standard enthalpy of formation of electrons and holes Eq. [1]; the enthalpy gap
- h Planck's constant
- k Boltzmann's constant
- m_n, m_p the effective masses of electrons and holes, respectively
- $<m>$ the average effective mass, $(m_n m_p)^{1/2}$
- $n, n°$ electron concentration and reference state electron concentration, respectively, in number/cm^3
- n_c, n_v effective density of states in the conduction band and valence band, respectively
- n_i intrinsic electron concentration, $n_i = n = p$
- $p, p°$ hole concentration and reference state electron concentration in number/cm^3
- ΔS_{cv} the standard entropy of formation of electrons and holes, Eq. [1]; the entropy gap
- $\Delta U°$ total standard internal energy of formation of electrons and holes, Eq. [1, 30]
- x_n electron composition fraction, $n/n°$
- x_p hole composition fraction $p/p°$
- μ_n, μ_p chemical potentials of electrons and holes, respectively

Growth of Single Crystals of CdO by Molten Hydrous KOH Solutions

Krishna Kumar

Department of Physics, Indian Institute of Technology, New Delhi 110029, India

ABSTRACT

Octahedral crystals of CdO have been grown at 450°C using KOH melt as flux. Three dimensional dendrites are also reported. Supersaturation and crystal growth were promoted by the high temperature dissociation of a complex with the solvent.

CdO is a high bandgap, n-type degenerate semiconductor having NaCl structure. The electrical, optical, thermal, and other properties of CdO have not been investigated in detail due to the difficulty in growing single crystals of the material. The high melting point and the absence of suitable crucible material limit its growth by the conventional melt growth technique. The floating zone technique has been unsuccessful in melting the sintered mass of CdO. The low vapor pressure (1) of CdO at the softening temperature of quartz ($\simeq$1200°C) imposes severe restrictions for growth of single crystals by the vapor phase technique. Fahrig (2) used a horizontal tube made of CdO powder supported by a quartz tube at 1200°C and obtained small single crystals. Konak *et al.* (3, 4) and Fischer and Spear (5) succeeded in obtaining bigger size crystals from the vapor phase. In all these cases crystals grew on the charge itself. Thermal decomposition of cadmium oxalate (6, 7) at 600°C resulted in needle-type crystals. The hydrothermal method has been suggested by Moody (8) for the growth of CdO single crystals. The author has attempted to grow CdO single crystals using NaOH and KOH melts as flux; the former was found to be unsuitable whereas the latter proved to be a good solvent for CdO. The present paper deals with the flux growth of single crystals of CdO using KOH melt as the solvent.

Experimental

The experimental setup and the temperature profile of the furnace were similar to those used by Kashyap (9) and Krishna (10), to grow ZnO crystals. To find the optimum amount of CdO to be mixed with KOH, 60g of KOH (AR) was melted in a silver crucible and different amounts of CdO (AR, supplied by Reanal, Hungary) were dissolved in different runs in it by constant stirring with a silver rod, as it was not possible to find the exact solubility of CdO in the KOH melt. The crucible was then covered with a silver lid and kept in the constant temperature zone of the furnace, which was heated at a rate of 50°-60°C/hr to the desired temperatures (400°-600°C) in different runs; the charge was left at this temperature for different durations of time varying from 20-80 hr. After the completion of a run, the furnace was cooled at a rate of 10°-15°C/hr to room temperature. CdO crystals were separated by dissolving the KOH in water; the crystals were investigated by optical microscopy, x-ray (Laue method), and spectroscopic methods.

Results and Discussion

Unlike in other flux growth experiments where supersaturation is achieved either by lowering the temperature of the solution or by evaporating the solvent or by a combination of both, in the present case it is caused by an altogether different mechanism. This was indicated by the fact that when program cooling of the solution was employed no crystal was observed to grow. Again the nonvolatile nature of the KOH suggests that supersaturation cannot be promoted by the evaporation of solvent in the present case. It is suggested that KOH which absorbs water molecules from its surroundings, forms a complex in a fashion similar to the ZnO-KOH system (9). This complex dissociated at higher temperature and gives rise to CdO which leads to the growth of CdO crystals. The rate of dissociation increases with the increase in growth temperature. This was indicated by our observation that at low temperature (400°C) of charge no crystals grew, whereas the use of high temperature ($\simeq$600°C) yielded a large number of small crystals. Best crystals were grown at 450°C when 5g of CdO was dissolved in 60g of KOH melt, which was actually found to contain 40g of KOH and 20g of water, and the duration of growth was 40 hr. Emission spectroscopic analysis confirmed that crystals were of CdO and that the metallic impurities were the same as in the initial charge except that a small amount of Ag ($\simeq$0.001%) was observed.

The crystals were black in color. This has been attributed to the deficiency of oxygen in the crystals (3, 6). The crystals were octahedral in morphology (Fig. 1) with one corner in contact with the crucible wall indicating heterogeneous nucleation. X-ray investigations (Laue photograph) confirmed their single-crystal nature. In many of these crystals hopper growth was observed on (111) faces (Fig. 2), while in many others these faces were smooth. The four (111) faces which were near the wall were invariably rough because of a high initial growth rate; later on the surface area for growth increased resulting in the decrease in local supersaturation and smoother faces. Hopper growth arises near the center of the face of the crystal, probably due to absorption of impurities on the growing face (10) and due to the high viscosity of

the solvent which in turn reduces the supply. Basic morphology of the crystals was found to be independent of growth temperature, only the crystal size changes.

When the solution was rapidly cooled at the end of the run, three dimensional dendritic crystals grew from the corner of the octahedron which is farthest from the wall (Fig. 3 and 4) and also from the wall of crucible near the melt surface (Fig. 5). The arms of the dendrites protruded in four directions, each perpendicular to the main arm. X-ray study (Laue photograph) of these dendrites revealed the branching was along <100> directions.

Chemical Vapor Deposition of Transparent, Electrically Conductive Tin Oxide Films Formed from Dibutyl Tin Diacetate

James Kane and H. P. Schweizer

Laboratories RCA Limited, Zurich, Switzerland

and Werner Kern*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The reactions of volatile tin organometallic compounds with oxygen have been investigated as a method for preparing transparent, electrically conducting layers of tin oxide. Several organometallic tin compounds were examined before the process was systematically optimized using dibutyl tin diacetate with excess O_2 and H_2O as reactants and N_2 as carrier gas at a substrate temperature of 420°C in 10-20 min of deposition. The presence of water vapor during oxidation is beneficial.

Important optical, electrical, structural, and chemical properties of the films have been examined. Typical SnO_2 coatings are 800-5000Å thick, transmit 90-95% of visible light, have sheet resistances of 500-1700 ohms/square, resistivities of 0.005-0.09 ohm-cm, a carrier concentration of 9×10^{18} cm^{-3}, and a Hall mobility of 10 cm^2/V sec. Films of 0.4-0.5 μm consist of a mixture of polycrystalline tetragonal stannic oxide as evidenced by x-ray diffraction, and of amorphous tin oxide phases as concluded from infrared spectroscopy. Electron diffraction analysis has indicated that the surface layers to a depth of 50Å are amorphous.

Semitransparent, electrically conducting thin films are required in many modern opto-electronic devices. Numerous materials have been prepared for this purpose by a variety of physical and chemical deposition processes (1-5). For many applications not requiring very low sheet resistance, nonstoichiometric (oxygen-deficient) tin oxide without dopant addition is a satisfactory conductor which is reasonably transparent to light in the visible wavelength region.

Tin oxide films are most commonly deposited by vapor or spray hydrolysis of stannic chloride onto hot glass surfaces in the temperature range of 500°-800°C (1-4, 6-12). However, the properties of these films are hard to reproduce, the optical quality is often poor, and the SnO_2 lattice is frequently contaminated with chlorine (12). The object of the present investigation was to develop a convenient, economical, and reproducible process for the preparation, on a production scale, of transparent, electrically conducting layers of tin oxide of high optical quality that are essentially free of chemical and particulate contaminants. A chemical vapor deposition process that is based on the use of a volatile organometallic tin compound has been developed to meet these requirements.

A number of volatile organometallic tin compounds was considered as potential source materials for vapor phase oxidation to tin oxide films at relatively low temperatures (350°-500°C). Initial screening experiments indicated that a deposition process could be developed using any one of a number of compounds, including bis-(tri-n-propyl tin) oxide, bis(tributyl tin) oxide, tetraphenyl tin, tetra isopropyl tin, and dibutyl tin diacetate. Polymeric dibutyl tin oxide, $[C_4H_9SnO]_x^-$, and stannous oxalate did not work, and tetraphenyl tin could be considered to be a failure since most of the compound was not decomposed in the reactor.

The process we now describe was optimized using dibutyl tin diacetate, for a number of reasons. Dibutyl tin diacetate, also known as dibutyl-diacetoxystannate, $(C_4H_9)_2Sn(OOCCH_3)_2$, is an oily, air-stable, colorless liquid compound having a vapor pressure of 1 Torr at 120°C, which makes it convenient for transporting its vapor in CVD work. The compound does not pose severe safety hazards and is much cheaper and more readily available than any of the other compounds we considered.

Most of the experimental work was carried out with 1 in. square plates of polished borosilicate glass. The deposition method is equally applicable to any substrate material that is unaffected by the deposition conditions, namely 420°C in an atmosphere containing oxygen. Transparent, conducting layers of tin oxide were also obtained on a variety of silicate glasses, vitreous quartz, and a number of single crystal materials including silicon, sapphire, spinel, strontium titanate, and gallium phosphide. For analytical purposes representative deposits of tin oxide were prepared on polished, high-resistivity silicon wafers.

Film Deposition

Apparatus.—The deposition apparatus was a single rotation hotplate reactor similar in construction to that devised for oxide and glass coating of semiconductor device wafers (13). The radial temperature profile across the 8 in. diameter rotating plate was checked using a Barnes "TEMPTRON" infrared pyrometer. At a nominal temperature of 420°C the actual temperature range measured across the plate was 420° ± 5°C.

A schematic drawing of the assembled apparatus is shown in Fig. 1. The entire system was constructed in a chemical exhaust hood to avoid exposure to toxic organometallic vapors. The reaction chamber was rigidly mounted to allow the use of stainless steel connections to the gas inlet system. The rotating hotplate unit was mounted on a laboratory jack for easy loading and unloading of the substrates.

The organometallic tin compound was contained in a fritted glass bubbler which was maintained at a controlled temperature in the range 70°-150°C. A

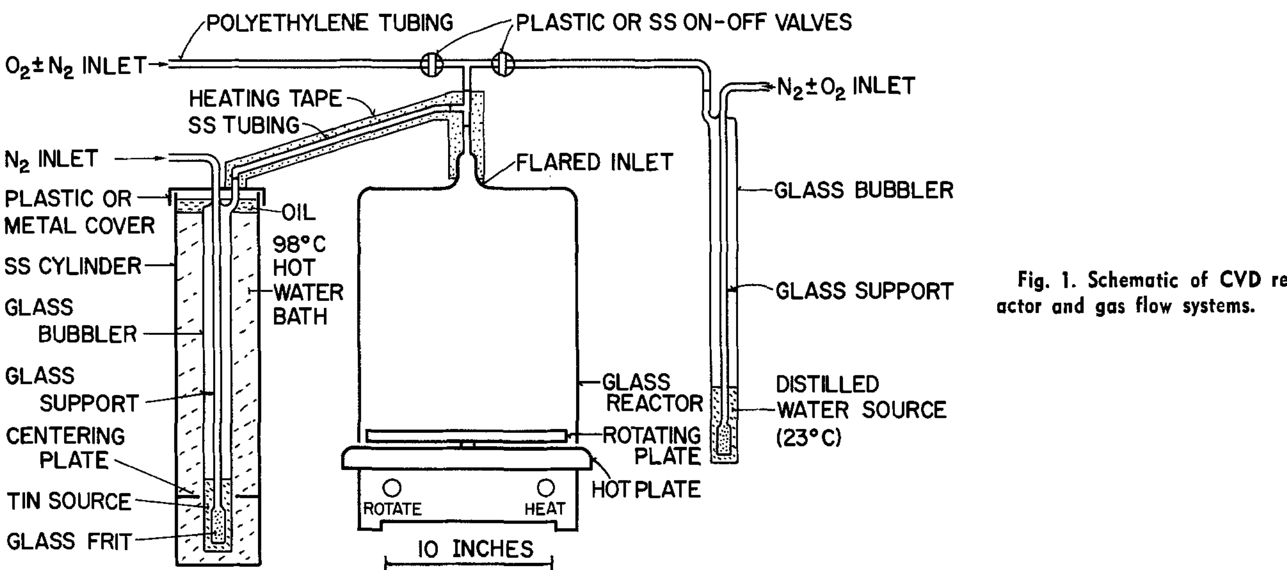

Fig. 1. Schematic of CVD reactor and gas flow systems.

boiling water bath is a simple and convenient method of temperature control.

Study of deposition parameters.—The effects of deposition variables on film properties were systematically explored to define optimum process conditions. The variables included source and substrate temperatures, rate of film growth, reactant and carrier gas flow rates, concentration of water vapor, and nature of substrate. In general, one variable was tested at a time by keeping all other variables constant. It was found that a minimum tin source temperature of 70°C was required to start film deposition, but that 90°C was needed to produce sufficient vapor for acceptable film deposition rates. Temperatures up to 150°C have been used with satisfactory results. A temperature of 98°C was adopted so that a boiling water bath could be employed for automatic temperature control.

Substrate temperatures in excess of 375°C were found necessary to oxidize the dibutyl tin diacetate vapor for depositing tin oxide films. All work was conducted at a fixed temperature of 420°C, which was found to yield good deposition rates. A heat-up time of 5 min was required to thermally equilibrate the substrates before starting the deposition. A postdeposition flush nitrogen of ½ min was sufficient to exhaust the reactant vapors from the bell jar before opening.

A relatively large nitrogen flow rate was used to suppress homogeneous gas phase nucleation and to avoid the formation of powdery wall deposits. Similar results have already been obtained in silicate glass synthesis by CVD (14, 15). The optimum flow rate was selected in conjunction with uniformity and other properties of the films, including absence of particulate defects.

The oxygen flow rate, in relation to the organotin input, affects the stoichiometry of the resulting tin oxide to some extent but is not very critical as long as some oxygen is present. The presence of water vapor has beneficial effects on the optical and electrical properties of the films.

The rate of film deposition was controlled primarily by the flow rate of nitrogen carrier gas through the tin source bubbler. A deposition time of 5 min was considered a minimum period to allow good control of film thickness, whereas periods greater than 20 min were undesirable due to the deterioration of the electrical properties of the films.

Once conditions for good film deposition had been established a series of runs was conducted to test the reproducibility of the films in terms of electrical resistance. The effect of variations in the flow of oxygen and water vapor was also studied. The results of these experiments are summarized in Table I. The beneficial effects of water vapor are evident from the marked improvement in film conductivity.

Film Properties

Surface morphology.—The films were deposited under the conditions listed in Table I. The general features of the tin oxide film surfaces were established by visual examination and by low-power optical microscopy, including Nomarski differential interference contrast. Typical samples exhibited very smooth, structureless surfaces on which could be found an occasional impurity particle that may have originated from the vapor phase during CVD.

Details of surface morphology on borosilicate glass were studied at magnifications up to 20,000X by scanning electron microscopy in the secondary electron emissive mode with a Cambridge "Steroscan." No pretreatment of the specimens was required, since the SEM image is generated by secondary electrons emitted from the surface being scanned. Typical scanning electron micrographs of three CVD samples (Fig. 2A-C) were compared with one sample that had been produced by the standard tin halide spray-deposition process (Fig. 2D). The photographs for the CVD films exhibit a very fine-grained surface with few defects; in contrast, the spray-deposited film is grainy, nonuniform, and covered with deep scratches and particulate impurities.

Electrical properties.—The electrical resistance of the films was measured using a conventional four-point probe. Resistance and resistivity data for samples obtained under various gas flow rate conditions are presented in Table I. The conditions stated are particularly desirable and have been selected from a large number of experiments. Sheet resistance values for

Additional constant deposition conditions as follows: carrier gas through tin source (N_2-Sn), 4400 cm³/min; Sn-source temperature, 98°C; H_2O source temperature, 23°C; substrate temperature, 420°C; substrate thermal equilibration time, 5 min; postdeposition purge time, ½ min N_2.

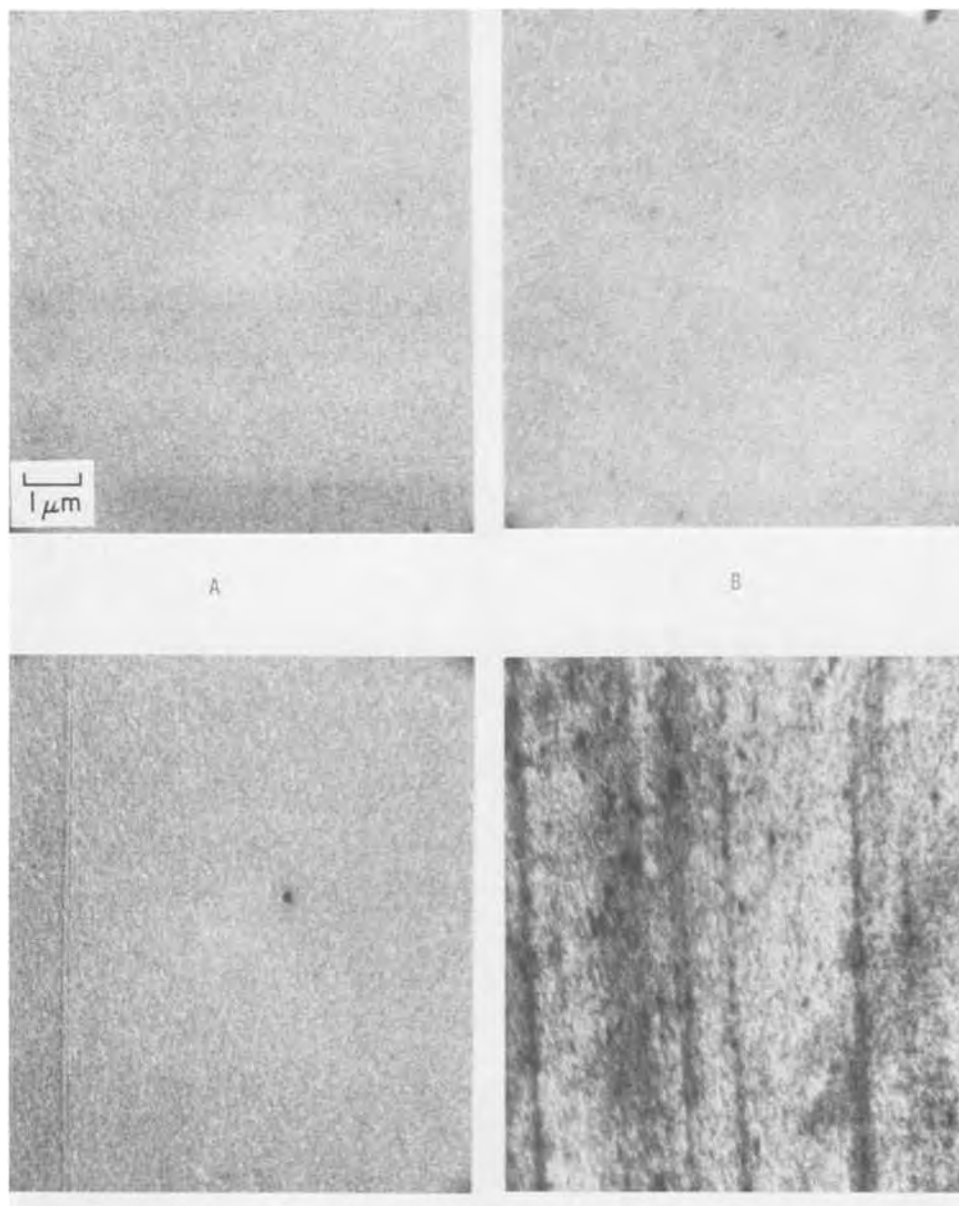

Fig. 2. Scanning electron micrographs of tin oxide films on glass plates (at a tilt of 45°). Three typical CVD samples (A, B, C) compared with a typical tin halide spray-deposited sample (D).

typical wet and dry CVD conditions are also shown graphically as a function of deposition time in Fig. 3. These curves show decreasing resistivity as the film thickness increases up to about a 20 min deposition period. With longer periods of deposition, especially in the case of dry CVD conditions, there is an increase in sheet resistance, perhaps due to the diffusion of ionic impurities from the substrate and the effect of annealing on the stoichiometry of the tin oxide.

Hall measurements were performed at room temperature using the standard Van der Pauw technique. The magnetic field was 16 kG. The tin oxide was found to be n-type with an average carrier concentration of 9×10^{18} cm^{-3} and a mobility of 10 cm^2/V sec.

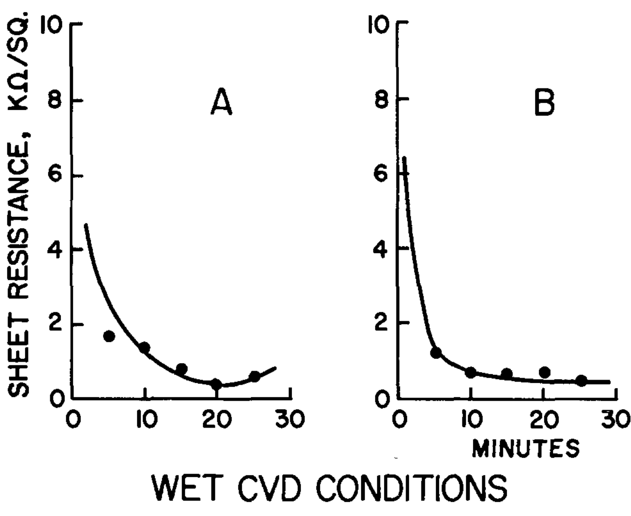
No controlled tests were conducted on the long term film stability although the electrical resistance remained constant for periods of at least several months. The films showed no signs of devitrification.

Optical properties.—For device fabrication the tin oxide films are required to have good optical transmission throughout the visible spectrum in addition to low electrical resistance. The transmission spectrum of a 6500Å thick film of tin oxide together with the corresponding reflection spectrum are shown in Fig. 4. As can be seen from a comparison of these two curves, the actual absorption losses are quite small. Since tin oxide is a high refractive index material, a considerable proportion of the incident radiation is reflected.

The transmission spectrum was measured with an uncoated glass plate in the reference beam of the spectrometer. Per cent transmission values measured for the wavelengths 4000, 4400, 4800, 5200, 5600, and 6000Å are presented in Table II for the same samples listed in Table I. An optical transmission of 85% net with a sheet resistance of 2000 ohms/square is readily attainable.

Since the most important film characteristics are sheet resistance and optical transparency, a figure of merit for the films has been derived from these characteristics to facilitate comparison. This figure has been calculated by dividing per cent average light transmission (arithmetic mean of per cent transmission at 4000, 4400, 4800, 5200, 5600, and 6000Å) by the sheet resistance. Figures of merit for preferred deposition conditions are included in Table II. Figure 5 exemplifies graphically the effect of film growth time on the figure of merit for a wet and a dry CVD condition.

The refractive index of tin oxide films deposited under various reaction conditions was measured using a Rudolph ellipsometer (Model 436-200 E) at a wavelength of 5461Å. For these measurements representative films were deposited on polished silicon wafers.



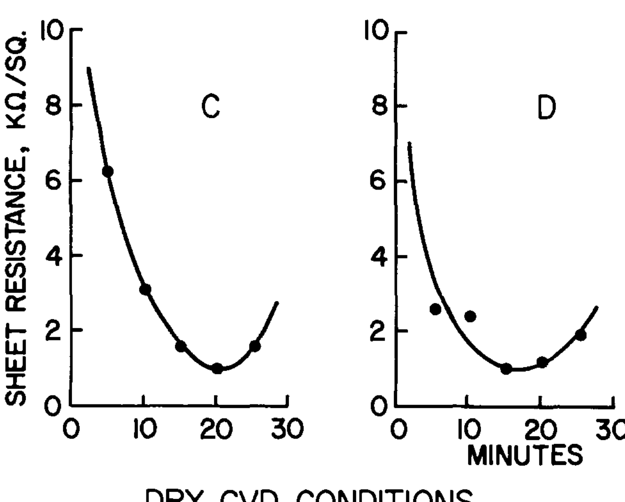


Fig. 3. Sheet resistance of tin oxide films as a function of growth time for typical wet (A, B) and dry (C, D) CVD deposition conditions.

The films were assumed to be nonabsorbing and the optical constants of the silicon substrate were taken to be 4.05 for the real part of the refractive index and 0.28 for the imaginary part. The angle of radiation incidence used was 70°. Samples prepared with various tin-to-oxygen vapor ratios, both with and without water vapor, were examined. The addition of water vapor reduced the refractive index but there was no obvious correlation of the refractive index with the oxygen-to-tin vapor ratio. The results are summarized in Table III.

niques described previously for silicate glasses (16). Double-beam infrared recording spectrophotometers (Perkin Elmer Model 137-B and Model 457 for detailed studies) were used, scanning the wavelength range from 2.5 to 40 μm. Infrared absorption spectra from samples prepared by dry or wet oxidation were weak, showing broad band absorption centered about 500 cm^{-1} and, possibly, some weak discrete band structure near 600, 450, and 230 cm^{-1}. For comparison, the oscillator frequencies for stannic oxide single crystals are $E_{\perp c}$ 243, 284, and 605 cm^{-1} and $E_{\parallel c}$ 465 cm^{-1} (17). The presence of combined broad and discrete structure in our samples suggests that the coatings contain both amorphous and crystalline phases.

Lattice structure.—Examination of the surfaces of several tin oxide coatings by electron diffraction showed an amorphous structure to a depth of 50Å. This is in contrast to the spray-deposited material which is polycrystalline with ordering. Both dry and wet grown films were analyzed with the same results.

Since the tin oxide coatings were too thin to be examined directly by x-ray diffraction, samples were removed for x-ray powder diffraction studies. The coating was composed of very fine tetragonal tin dioxide crystallites of less than 1000Å maximum dimension.

Chemical impurities.—Gaseous impurities given off by the tin oxide coating at elevated temperatures would be detrimental in certain applications. To ascertain the nature and quantity of these impurities, several samples were analyzed using a AEI MS-10 gas mass spectrometer.

Samples were contained in an evacuated quartz ampul at controlled temperatures up to 300°C. Outgassing of the samples was compared with samples of the uncoated substrate glass. The analysis showed that the gaseous impurities which could be attributed to the tin oxide were insignificant. The major outgassing impurities, carbon dioxide and water vapor, were evolved in similar quantities from both coated and uncoated samples.

Routine chemical analysis of the films using an AEI MS-7 solids mass spectrograph revealed only minor quantities of metallic impurities. Calcium and chlorine in quantities up to 25 ppm together with smaller quantities of other metals were found in all samples analyzed. Since only reagent grade chemicals were employed, the presence of small quantities of metallic impurity was not unexpected. Chlorine is also a likely contaminant of the organometallic compound.

Discussion of Results

A set of optimized deposition parameters is shown in Table I. The basis for selection was sheet resistance (arbitrary maximum of 3000 ohms/square) and optical transmission (minimum 85%) in the wavelength range of 4000-6000Å. Additional criteria were acceptable film uniformity, freedom from particulate contaminants, and film stability. Due to optical interference effects it is possible to maximize the transmission of thin films at a particular wavelength. This is a useful technique to extend the transmission at the blue end of the visible spectrum if the sheet resistance is low enough to meet the specifications. The optical transmission of a relatively thick layer of tin oxide (2500Å) is shown in Fig. 4 to demonstrate these interference effects.

The distinct minimum in the sheet resistance which occurs after a deposition time of 20 min can be attributed to a number of factors: migration of alkali cations from the substrate into the oxide layer, changes in the oxygen stoichiometry, or crystallization of the tin oxide. All of these processes are known to occur and all lead to higher resistivity material.

By comparison of data from quartz and soda lime substrates it was clear that in the case of soft soda lime glass substrates the diffusion of alkali metal cations is the dominant process. The mobile alkali cations act as a p-type doping agent in the n-type tin oxide film, thus neutralizing some of the charge carriers. All attempts to prepare a 1000Å tin oxide with a sheet resistivity of 2000 ohms/square on such glass were unsuccessful. The sheet resistivities were at least a factor of 10 higher than comparable layers on borosilicate glass or vitreous quartz. The effect of the alkali metal contamination is so strong that the mere presence of soda lime glass in the reaction chamber during a tin oxide deposition significantly affects the film resistance on other substrates being coated. Subsequent deposition runs are also affected and a thorough cleaning of the apparatus is required before high-quality films can again be produced.

To examine the effect of heat-treatment on the oxygen stoichiometry a number of samples on glass, quartz, and silicon substrates were annealed for 15 min at 420°C in air or in nitrogen. All samples increased in sheet resistance, regardless of substrate material. The increase was by a factor of 15-25 in the case of the air annealed samples and of 1.5-3.0 for the nitrogen annealed material. These data indicate that the resistance increases are predominantly due to oxidation effects of nonstoichiometric (oxygen deficient) tin oxide (SnO, stannous oxide) shifting toward stannic tin dioxide (SnO_2, stannic oxide) structure. This is in accordance with the thermodynamic stability of the two oxides, the stannic oxide being the more stable compound (18).

Conclusions

Dibutyl tin diacetate at a deposition temperature of 420°C was found particularly suitable for preparing tin oxide films by vapor phase oxidation. Nitrogen is a suitable diluent and carrier gas to transport the organotin vapor from the liquid source maintained at 98°C. Oxygen is necessary as an oxidizing agent, but the ratio of organotin vapor to oxygen is not critical. In addition, water vapor is beneficial in producing high-quality tin oxide films.

Important optical, electrical, structural, and chemical properties of the films have been examined. Typical SnO_2 coatings on borosilicate glass are hard, clear, uniform, and 800-5000Å thick. They transmit 90-95% (net) of visible light. The ellipsometrically determined index of refraction varies with the conditions of film deposition, particularly the presence of water vapor. The films are n-type semiconductors, having sheet resistances of 500-1700 ohms/square and resistivities of 0.005-0.09 ohm-cm.

The infrared absorption spectra of 0.6-0.75 μm thick layers deposited on silicon indicate the presence of both amorphous and crystalline phases. Surface layers to a depth of about 50Å are amorphous, as shown by electron diffraction analysis. On the basis of x-ray diffraction, thicker layers (0.4-0.5 μm) are polycrystalline and were identified as tetragonal SnO_2. Scanning

electron microscopy at 10,000X magnification exhibited rather smooth surfaces with very much less particulate contamination and film damage than observed on tin halide spray-deposited samples.

On the basis of results obtained from mass spectrographic analysis we conclude that the films are essentially free of volatile impurities. Gas mass spectrometry showed that CO_2, CO, and H_2O were given off on heating but in quantities similar to those observed for the uncoated substrate glass.

The electrical resistance of tin oxide films deposited by this process on substrates high in alkali, such as soda lime glasses, is very high due to p-type doping by alkali ions. The resistance of films of comparable thickness on vitreous quartz or silicon is about half of that on a borosilicate glass containing 1 weight per cent (w/o) Na_2O and 8 w/o K_2O.

The growth period for the films should be the minimum period compatible with control of the film thickness. Periods beyond 20 min lead to rapid increases in resistivity due to chemical changes in the film stoichiometry and the diffusion of alkali metals from the glass substrate.

It must be realized that these conductive tin oxide films are nonstoichiometric and are therefore metastable compounds with fluctuating properties that cannot be controlled with high precision. For many applications these undoped tin oxide coatings are quite satisfactory; but if higher conducting or thermal stability is required then a suitable dopant must be introduced. We have found that antimony in the form of the pentachloride is compatible with the present process and can be used to produce more highly conductive films of SnO_2:Sb (19).

Technical Notes

A Note on the Chemistry of Lead Sulfide Sensitization for Infrared Detection

G. M. Wolten

The Aerospace Corporation, El Segundo, California 90245

The chemical deposition of mirrorlike films of PbS has been known for at least 65 years (1). It is the basis for the production of modern lead sulfide detectors for near infrared radiation. In order to render the films highly photoconductive, an "oxidant," usually hydrogen peroxide, is added to the deposition bath. Published speculations concerning the role of H_2O_2 ignore a body of basic chemical information that has been readily available for many decades.

Key words: lead sulfide detectors, chemical deposition.

For example, a 1937 textbook (2) describes the following quantitative reaction

$$PbS + 4\,H_2O_2 \rightarrow PbSO_4 + 4\,H_2O \qquad [1]$$

In the manufacture of PbS photodetectors, H_2O_2 is present in the solution of thiourea and a lead salt before it is rendered highly alkaline ($pH^+ > 10$) to commence the reaction. In order to test the validity of reaction [1] under these conditions, a typical "deposition" was carried out with the H_2O_2 content in-

creased to the stoichiometric equivalent (100%) of the lead content instead of the typical 30%. Under these conditions, the sole product, identified by x-ray diffraction, was $PbSO_4$. The reaction proceeded in two recognizable steps, as follows

$$Pb(OH)_2 + H_2O_2 \rightarrow Pb(OH)_4 \quad [2a]$$

$$Pb(OH)_4 + S^{=} \rightarrow PbSO_4 + 4\,H^+ \quad [2b]$$

Kunze *et al.* (3) have pointed out that it is theoretically possible for H_2O_2 to oxidize thiourea to aminoiminomethanesulfinic acid (AIMSA), which then hydrolizes to sulfoxylic acid, as indicated in the following sequence

```
NH               NH        OH          NH
||      H2O2     ||       /     H2O    ||
C—SH ———————>    C   — S       ———>    C   — OH
|                |       \             |
NH2              NH2      O            NH2
Thiourea         AIMSA                 Urea
                                  + H+ + (SO2H)-
                                   Sulfoxylic acid
```

The sulfoxylate ion is a strong reducing agent that would reduce lead ions to metallic lead. Kunze *et al.* therefore proposed that the sensitization was due to metallic lead. They obtained highly sensitive films by substituting AIMSA or other sulfur-bearing organic compounds for H_2O_2. What they overlooked was that reduction of lead ions by sulfoxylate necessarily leads to oxidation of the sulfoxylate ion. In order to investigate this reaction, AIMSA was added to a solution of a lead salt. The gray precipitate obtained contained colloidal lead and, after drying, gave a diffraction pattern of $PbSO_4$ and nothing else. The reaction is

$$3\,Pb(OH)_2 + H_2SO_2 \rightarrow 2\,Pb^{\circ} + PbSO_4 + 4\,H_2O \quad [3]$$

Two patents, assigned to the Eastman-Kodak Company (4, 5), describe the use of sodium sulfite, Na_2SO_3, or metabisulfite, $Na_2S_2O_5$, respectively, in place of H_2O_2. These do not differ substantially since the metabisulfite ion hydrolyses to sulfite in solution

$$S_2O_5^{=} + H_2O \rightarrow 2\,SO_3^{=} + 2\,H^+$$

Since the sulfite ion will react with lead ions according to reaction [4]

$$2\,Pb^{++} + SO_3^{=} \rightarrow Pb^{\circ} + PbSO_4 \quad [4]$$

it is clear that lead sulfate is formed in all the sensitization procedures discussed here.

Vinchakov (6) proposed, on the basis of electrical measurements, that $PbSO_4$ or $PbO \cdot PbSO_4$ are likely identities for the sensitizing centers.

Normally, not enough $PbSO_4$ is incorporated into the films to be detectable. Roth *et al.* (7) have reported finding Lanarkite, $PbO \cdot PbSO_4$.

One would suppose that if the sulfate ion is responsible for sensitization, it would have to be present as part of the PbS structure rather than as a separate phase and that its concentration would be likely to be the same as the carrier concentration, which is of the order of $5 \times 10^{16}/cm^3$.

The ionic radius of $S^{=}$ is 1.84Å, and its tetrahedral covalent radius is 1.04Å. According to Dalven (8), PbS is about 50% ionic, and this suggests an effective radius of 1.44Å. The ionic radius of $SO_4^{=}$ is quite close to this, namely 1.49Å.

We therefore expect that during deposition, a solid solution, containing a low concentration of $PbSO_4$ in PbS, is formed. This does not necessarily mean that the $SO_4^{=}$ ion itself is responsible for the sensitization. It is conceivable that the sulfate, once it is formed, may undergo further processes of an as yet unknown nature.

Manuscript submitted Dec. 2, 1974; revised manuscript received April 9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by The Aerospace Corporation.

Growth and Characterization of $Al_xGa_{1-x}Sb$

S. M. Bedair[1]

Electrical Engineering Department, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

The preparation of a number of ternary III-V semiconductor compounds is now of interest, due to the need for materials with a wide range of energy gaps. It has been suggested that the Al-Ga-Sb heterojunction (1) may be of interest for optoelectron devices.

In this work liquid-phase epitaxial layers of $Al_xGa_{1-x}Sb$ are grown on GaSb substrates. The liquidus and the corresponding solidus isotherms in the Ga rich corner of the Al-Ga-Sb phase diagram have been determined at 600°C. Variation of the optical energy gap with the AlSb concentration in the grown layer has also been examined.

[1] Permanent address: Nuclear Engineering Department, Alexandria University, Alexandria, Egypt.

Key words: liquid phase epitaxy, phase diagram, energy gap.

A horizontal growth system with a palladium purified hydrogen environment and a graphite boat similar to the one for multiple layer epitaxy (2) was used. A saturation technique was applied to determine the liquidus composition along the 600°C isotherm. Such a technique has been previously used to determine liquidus isotherms and gave results in agreement with those obtained by differential thermal analysis (3, 4). Known weights of Ga (about 2g), and Al were contained in a separate compartment of the boat and by sliding were moved onto or off the GaSb single crystal seed used for liquid saturation. The boat was tightly covered to decrease any losses of Sb by vaporization. In each saturation experiment the Al + Ga solution was initially maintained at 600°C, then contact with

the seed crystal was achieved. Heating times of the order of days were found to be necessary for high Al concentrations in the melt after which the solution was removed from the seed and the boat was cooled to room temperature. The antimony solubilities in this ternary system are calculated from the weight loss of GaSb seed. No correction has been applied to allow for any vaporization of Sb, since no vapor deposits were observed on the growth tube. The liquidus isotherm at 600°C is shown in Fig. 1.

Saturation was considered to be attained when further heating for periods equal to those which have been previously applied resulted in an increase in the Sb dissolved by less than 1%. Thus, this stop in the seed dissolution with time indicates that a true equilibrium had been established. This probably occurs by the formation, on the surface of the seed that was initially in contact with the liquid, of a very thin epitaxial layer of the equilibrium ternary alloy, which protects the seed from further dissolution. A similar phenomenon is observed in the Al-Ga-As and the Al-Ga-P systems (3, 4).

Epitaxial layers of $Al_xGa_{1-x}Sb$ were then grown from saturated Ga solutions on (110) and (111)B oriented GaSb substrates. The growth cycle starting with a saturated melt at 600°C involved cooling at a rate of 0.2°C/min over a temperature interval of 10°C. Grown layer thicknesses were between 15 and 50 μm, with the higher growth rate for low Al concentration in the melt. Surfaces of the grown layers on the (111) substrates were smooth and shiny, whereas those grown on the (110) substrates showed some roughness. X-ray back Laue patterns showed that the grown layers were single crystals with the same orientation as the corresponding substrate.

The compositions of the grown layers were determined by electron microprobe analysis with the Colby correction program applied (5). The solidus isotherm for the Al-Ga-Sb system derived is shown in Fig. 2. Since the growth range was from 600° to 590°C, the resulting changes in the concentrations of the grown layers are within the standard deviation error expected for the electron microprobe technique, and the observations showed no depletion in the Al concentration in the grown layers. There are no published data, of which we are aware, to compare with the present results.

In order to determine the variation of the optical absorption with AlSb concentration in the grown film, samples were mounted on separate glass (or quartz) sides with transparent wax. The GaSb substrate was ground off, followed by lapping until the grown layer became shiny. In the lapping process water was avoided (replaced by alcohol) to minimize any oxide growth on the grown layer especially for those having high AlSb concentration. The absorption measurement was done at room temperature on a Cary 14 double beam spectrometer with a reference aperture on a glass plate having the same area as the film under test. Measurements were performed on grown layers with AlSb concentrations varying from zero (GaSb) to 90% and typical transmission spectra are shown in Fig. 3. The optical energy gap was calculated at the intercept of the absorption edge (6) with the zero-transmission abscissa and the results are shown in Fig. 4. Extrapolation of these results gives 1.6 eV for the energy gap for AlSb in agreement with previous measure-

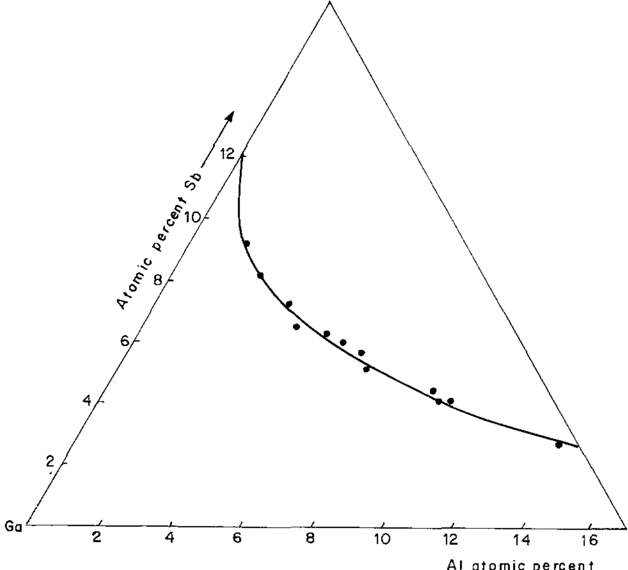

Fig. 1. Liquidus isotherm for the Al-Ga-Sb system at 600°C

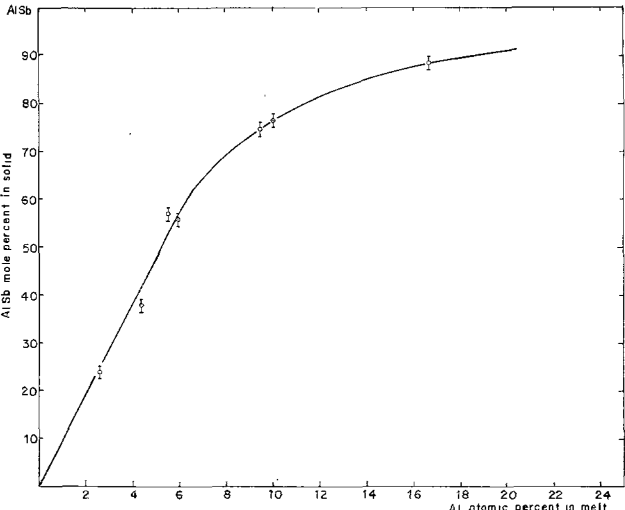

Fig. 2. Solidus isotherm for the Al-Ga-Sb system at 600°C

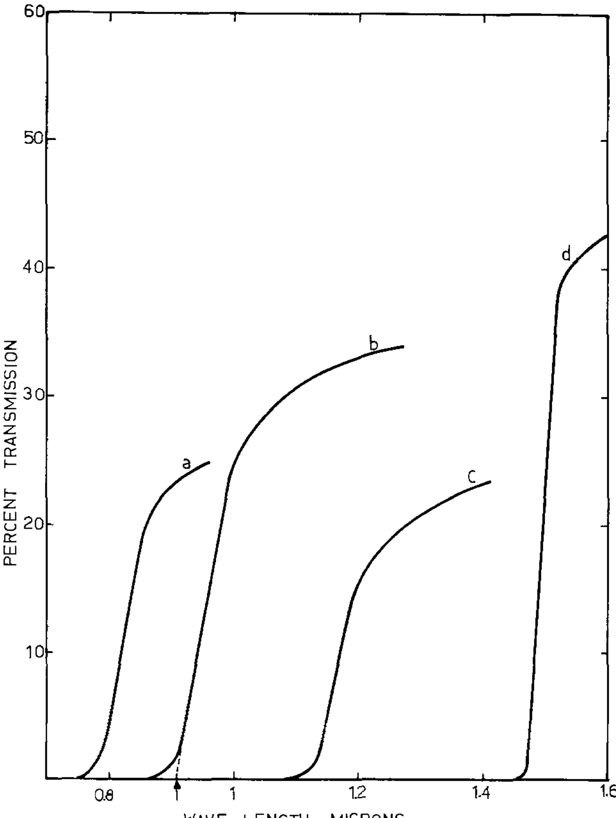

Fig. 3. Transmission spectra for different AlSb mole per cent. a, 81%; b, 56%; c, 34%; d, 13%. Sample thickness after the lapping process was about 1 mil, and the optical energy gap is determined at the intercept of the absorption edge with the zero transmission abscissa as shown for case (b).

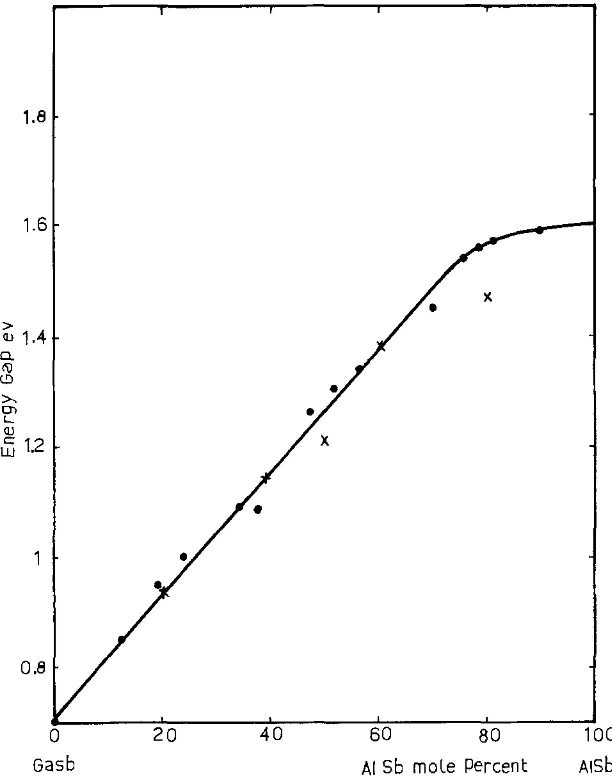

Fig. 4. Dependence of the optical energy gap on the AlSb concentration in $Al_xGa_{1-x}Sb$ mixed crystal. (●) Present work, film grown by liquid phase epitaxy; (×) from Ref. (9) alloyed polycrystalline film.

ments (7) and 0.1 eV higher than that obtained from photoresponse measurements (8). In Fig. 4, we have also included some results (9) obtained for AlSb-GaSb polycrystalline alloys prepared by a zone casting method. For high AlSb concentration these data for energy gap fall below the corresponding ones in the present work. This may be because alloys prepared by this method (10) show a decrease in the AlSb concentration as the solidification process proceeds, possibly since the Al has a higher distribution coefficient than Ga in the Al-Ga-Sb system. Inhomogeneous polycrystalline mixed crystals result in a lower value for the optical energy gap than a homogeneous one with the same average composition. Similar observations of the effect of inhomogeneity on the effective energy gap had been reported for the Al-Ga-As system (11).

Acknowledgments

The author is indebted to Professors A. G. Milnes and D. L. Feucht for helpful discussions and for financial assistance. The author wishes also to thank UNESCO for financial support. The work was supported in part by the U.S. Army Research Office, Durham.

Manuscript submitted June 27, 1974; revised manuscript received Feb. 27, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1976 JOURNAL. All discussions for the June 1976 Discussion Section should be submitted by Feb. 1, 1976.

Publication costs of this article were partially assisted by Carnegie-Mellon University.
