Reproducibility of V-i relationships.—The potential current density relationship at a prereduced electrode is shown in Fig. 1. An anodic current increases slowly with potential up to about 1.4V after which potential it increases more rapidly. However, points on the *i-V* curve from A to B do not represent a "true" steady state: current at any potential decreases with time at first rapidly and then very slowly. No linear *V*-log *i* relationship can be obtained in this first "run up" experiment. Only after an electrode has been kept at a

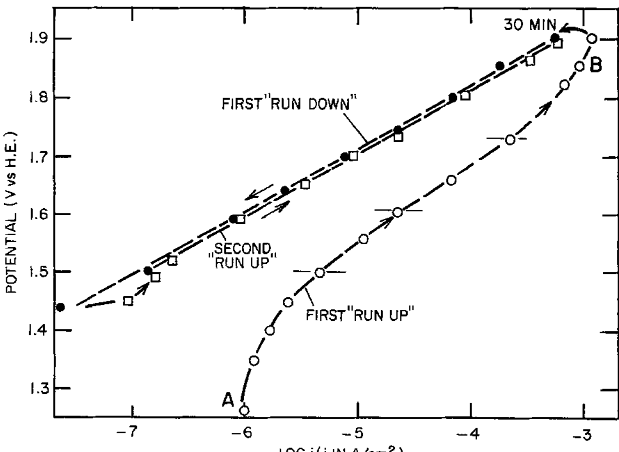

Fig. 1. *V*-log *i* relationships at Pt in H_2SO_4 solution with pH = 0.3. (○), First "run up" experiment; (●), first "run down" experiment after the electrode was kept for 30 min at 1.9V; and (□), subsequent "run up" measurement.

high potential (*e.g.*, $\geq$1.70V), or has been polarized with a high constant anodic current density (*e.g.*, $i \geq 10^{-4}$ A/cm^2) for some time (*e.g.*, 5 min or longer), is the current potential relationship in the process of decreasing electrode potential, or decreasing current density, practically independent of time. In this "run down" measurement a Tafel relationship is observed with a slope close to $2RT/\mathbf{F}$ over several decades of current.[1] Basically the same *V*-log *i* relationship is retraced when subsequently the potential, or current density, is increased in steps but only up to the potential, or current density, of the initial polarization. If an electrode is brought in the first "run down" measurement to a potential below about 1.40V, and is kept there for some time (~30 min or longer), then the Tafel line in the subsequent "run up" measurement is slightly (~20%) shifted towards higher current densities.

The same *V*-log *i* relationships are obtained only when the electrodes are pretreated in the same way, *e.g.*, only when they are initially prereduced and then kept for the same time at a given potential or current density. If either of these factors is changed, the *V*-log *i* lines are shifted parallel with respect to each other. The $\partial V/\partial \log i$ slopes are, however, unaffected by the electrode pretreatment. The examples are given in Fig. 2, 3, and 4.

V-log i relationships.—*V*-log *i* relationships for prereduced electrodes kept at 2.0V in 1*N* H_2SO_4 solution for 5, 10, or 40 min are shown in Fig. 2. The longer the time of polarization, the lower is the activity of the electrode. The $\partial V/\partial \log i$ slopes are all close to 115 mV. In Fig. 3, data are given for the prereduced electrodes that have been kept at different potentials for 30 min [except data marked by (△)]. After the lapse of this time, *V*-log *i* relationships are obtained by decreasing either current density or potential. It is evident that the higher the potential of initial polarization, the lower is the activity of the electrodes.

In Fig. 4, data are shown obtained in 0.1*N* H_2SO_4 solution [except data marked (x)]. The activity of an electrode kept for 30 min at 2.0V is nearly an order of magnitude less than the activity of an electrode kept for the same time at 1.6V. The same trend holds for electrodes that are initially kept for 10 min at 1.8 and 1.5V. The $\partial V/\partial \log i$ slopes are again close to 115 mV. In $10^{-2}N$ H_2SO_4 solutions too, basically the same trend for the dependence of activity on electrode pretreatment is observed [compare (△) and (x) in Fig. 3 and 4].

pH dependence.—From Fig. 3 and 4, it follows that at the same current density (*e.g.*, 10^{-4} A/cm^2) potential

[1] Cf., Ref. (15), (17), (20), and (21).

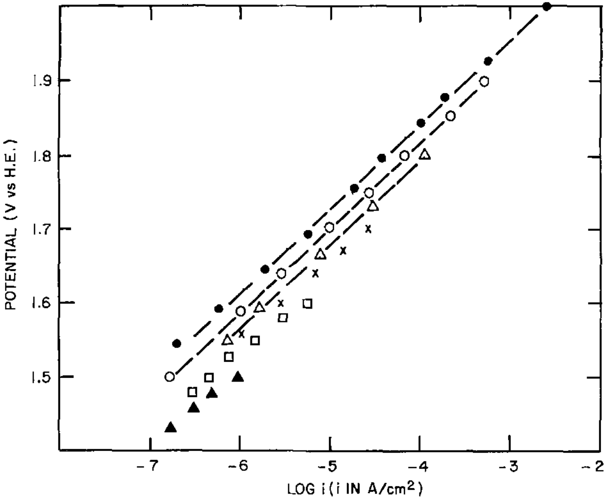

Fig. 3. V-log i relationships for prereduced electrode kept for 30 min in 1N H_2SO_4 at different potentials, except for (△) when the electrode was kept for the same at 1.8V in 10^{-2}N H_2SO_4.

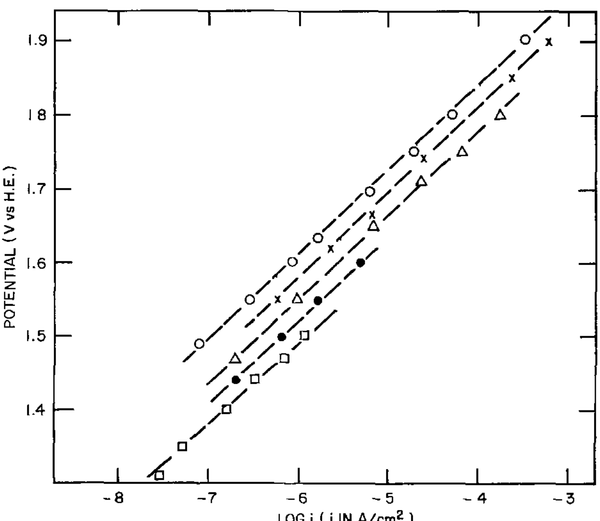

Fig. 4. V-log i relationships. (●), 30 min at 1.6V; (○), 30 min at 2.0V (part of the V-log i is shown only); (□) and (△), 10 min at 1.5 and 1.8V, respectively. Solution 0.1N H_2SO_4. Data (×) obtained in 10^{-2}N H_2SO_4 after 30 min at 1.9V.

with respect to a pH independent scale decreases with increasing pH. The $\partial V/\partial pH$ is close to -60 mV, as shown in Fig. 5 for electrodes initially kept at 1.9 and 2.0V (HE) for the same time.

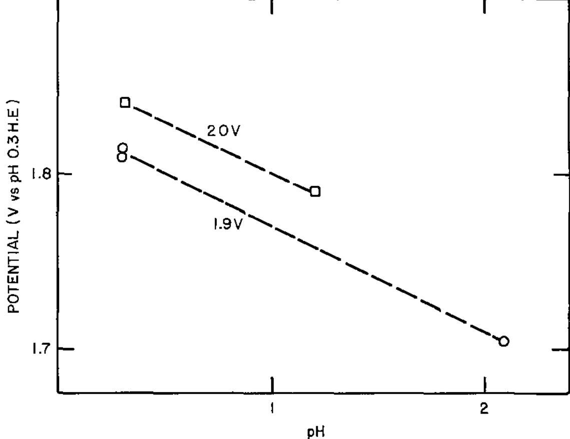

Fig. 5. pH dependence at electrode initially kept at 2.0 or 1.9V (vs. HE) for 30 min (see text). The potentials, that now refer to the hydrogen electrode in pH 0.3 solution, are read off at 10^{-4} A/cm².

To check whether this pH dependence is a true characteristic of the reaction or it reflects a difference in electrode activities arising entirely (or partially) from different degrees of oxidation state of electrode surfaces, *e.g.*, from differences in thickness of surface oxide films that are anodically formed in solutions of different pH, in a second series of experiments after an electrode has been subjected to a constant anodic current for a given time (1 to 2 hr), solutions in both the test and reference electrode compartments were rapidly replaced with solutions of a different pH. The electric circuit during the replacement of solutions was not broken. The electrode potential referred to HE remained essentially unchanged in these experiments. If the oxidation state, *e.g.*, thickness of the oxide films, does not change during the replacement of solutions, as assumed here, then the observed pH dependence reflects the true dependence of the oxygen evolution reaction on pH. Again, $(\partial V/\partial pH)_i$ with respect to a pH independent scale is -60 mV.[2]

In a few experiments K_2SO_4 has been added to H_2SO_4 solutions to a constant ionic strength. No effect of excess of salt on the kinetics has been detected in the solution exchange experiments. As to the dependence on O_2 partial pressure, the same V-log i relationships are obtained regardless whether solution has been saturated with oxygen or argon, *i.e.*, $\partial V/\partial \log p_{O_2} = 0$.

For convenience, data are summarized in Table I. In the same table, some literature data are included for comparison and convenience.

Discussion of the Results

Comparison of the V-log i in the first "run-up" and subsequent "run-down" measurements.—Above 1.0V an oxide phase forms (7-11, 15, 40-45) over platinum surface. Oxygen evolution occurs therefore only at oxide-covered platinum electrodes. Thickness of the oxide film at an electrode that is initally prereduced increases with increasing electrode potential (7 8). As the thickness, *d*, increases, the activity for oxygen evolution reaction, expressed as the exchange current density, i_o, decreases according to (12, 14)

$$i_o = k \exp\left(-\frac{\delta d}{2}\right) \quad [1]$$

where k and δ are constants. Consequently, as the potential in the first "run-up" measurements at a prereduced electrode is increased in a gradual or stepwise manner and the oxide film becomes progressively thicker, the current density decreases according to (12, 14)

[2] Previously reported pH dependence of -30 mV (see Table I) is in error probably due to insufficient care of electrode pretreatment.

$$i = k \exp\left(-\frac{\delta d}{2}\right) \exp\left(\frac{FV}{2RT}\right) \quad [2]$$

i.e., it changes less than expected for a constant value of the exchange current density. In other words, due to the progressive increase in the oxide thickness, the $\partial V/\partial \ln i$ slope in the first "run-up" experiment is higher than expected for an unchanged electrode (*i.e.*, $\partial V/\partial \ln i > 2RT/\mathbf{F}$). As shown in Fig. 1, the slope is not constant but changes with electrode potential.[3]

A different situation exists in the "run-down" and subsequent "run-up" experiments at potentials lower than that at which the electrode has been anodically pretreated. After an electrode has been kept at a high potential (*e.g.*, 1.8-2.0V) for some time (*e.g.*, 5-20 min), and after an oxide film has grown to a nearly constant thickness, the V-log i relationship is observed with the constant value of $\partial V/\partial \ln i$ equal to $2RT/\mathbf{F}$. This is because once the potential at an anodically pretreated electrode is decreased, the oxide films virtually stop growing (12, 46), *i.e.*, there is a hysteresis in the thickness, and V-log i relationship holds for a constant thickness of the oxide film. Since the $\partial V/\partial \log i$ slopes obtained at such electrodes are unaffected by the thickness itself (see below), it follows that the mechanism of reaction too is unaffected by the thickness of the oxide film. What changes in the first "run-up" experiments is therefore only the catalytic activity, or the exchange current density, as discussed above.[4]

Change of the catalytic activity with time.—The catalytic activity of a prereduced electrode decreases also with time of polarization at a given potential. For instance, at 2.0V current densities after 5, 10, or 40 min are close to 6, 4, or 2.5 × 10^{-3} A/cm^2, respectively (cf., Fig. 2 and 6). The decrease can now be related to the reported slow (logarithmic) increase in the thickness of the oxide film: as the thickness increases with time, the catalytic activity at the same potential decreases. The same trend is evident in experiments when an electrode is kept for the same time at different potentials. This is illustrated in Fig. 7 in which the current densities observed in "run-down" experiments at 1.5V are plotted *vs.* the potential at which a prereduced electrode has been anodically polarized for 30 min prior to making measurements. Again, the change in the activity reflects the change in the thickness of oxide films.

It follows from the above discussion that anodic oxide films at platinum form a barrier to electron transfer in oxygen evolution reaction. Resistance to the transfer is not of the ohmic type since an extended, logarithmic dependence of potential on current density (for over six decades), that has frequently been reported,[5] cannot be accounted for in terms of such resistance. A significant drop of potential within the oxide phase is suggested in Fig. 1-4. For the same current density the potential at a more strongly preoxidized electrode is easily higher by 100-150 mV than the potential at a less strongly preoxidized electrode. This drop of potential has to be taken into account in any analysis of the mechanism of the reaction. Fur-

[3] If an electrode is reduced before each measurement at a given potential then, for a fixed time of polarization, $\partial V/\partial \ln i$ becomes again constant. Its value however, is now close to $3RT/F$ instead of $2RT/F$. This is because of a particular dependence of thickness on electrode potential (12).

[4] Anodic current below 1.2V, *i.e.*, below the reversible O_2/H_2O potential, is apparently due to simultaneous dissolution of platinum (47) and formation of anodic oxide film. As the potential increases and as the electrode, due to the oxide film formation, "passivates," oxygen evolution becomes the major reaction. Only at such passive electrodes when the dissolution rate drops (47) below 10^{-9} A/cm^2, is it possible to follow oxygen evolution down to 10^{-9} A/cm^2.

[5] See for instance Ref. (4).

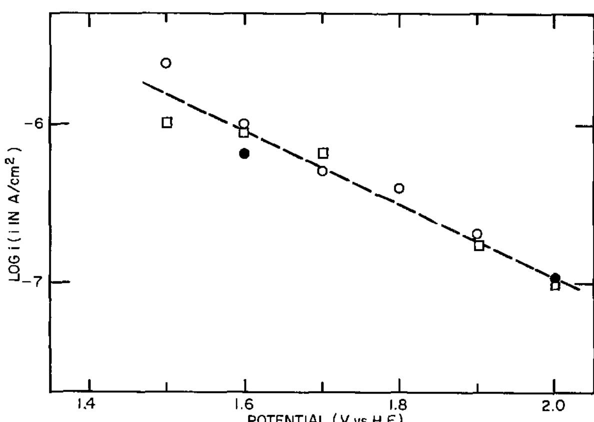

Fig. 7. Current density at 1.5V (HE) *vs.* potential at which an electrode was kept for 30 min prior to making measurements. (○), (●), and (□) refer to 10^{-2}, 0.1, and 1N H_2SO_4 solutions.

ther, for the experimentally obtained kinetic parameters, such as pH or oxygen partial pressure dependence, to be representative of the reaction mechanism, it is essential to ensure that they are obtained for the same oxidation state of the electrode surface. This has been aimed for in the present study.

Mechanism of the Oxygen Evolution Reaction

With the kinetic parameters given in Table I, the rate equation for oxygen evolution at platinum in acid solutions can be written in the form

$$i = k[a_{H^+}]^{-1/2} \exp\left[\frac{\mathbf{F}V}{2RT}\right] \quad [3]$$

Here, k is a constant for a given thickness (and possibly type) of the surface oxide film; it decreases as thickness increases.

The following are the characteristic features of the kinetics. First, the order of reaction with respect to a_{H^+} is fractional and negative. Second, a simple linear Tafel relation, according to [3], extends for several decades (4). Such an extended relationship suggests that the mechanism and rate-determining step remain the same in the whole potential region examined, and that the reaction occurs in the absence of a diffusion control process.

Mechanism under Langmuir conditions of adsorption.—For the reaction

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad [4]$$

under Langmuir conditions of adsorption the negative reaction order of the reaction products, H^+, means that some hydrogen atoms in H_2O have reached the final stage of oxidation, H^+, without passing through the rate-determining step. With water molecules as reactants, the algebraic product of this reaction order with stoichiometric number (ν from 1 to 4), which gives the number of hydrogen ions that have bypassed the rate-determining step for a single act of the over-all reaction,[6] is either $-1/2$, -1, $-3/2$, or -2. The values of $-1/2$ and $-3/2$, and therefore the stoichiometric numbers 1 and 3, can be discarded because the product has to be an integer. The value -1 corresponds to $\nu = 2$. With $\nu = 2$ an even number of products can be formed either in or after the rate-determining step. However, three H^+ are required to complete the over-all process. Similarly, for -2 ($\nu = 4$), either none or $4H^+$ ions should be formed in or after the rate-determining step, but only two are required to complete the over-all process. Hence, neither $\nu = 2$ nor $\nu = 4$ can be ascribed to the rate-determining step. With this simple analysis, therefore, it is not possible to account for the observed pH dependence of the reaction. In a previous study, it was suggested (15) that $\partial V/\partial pH = 0$ in spite of the observed dependence of -30 mV. This then led to the conclusion that the first charge transfer step under Langmuir conditions with water molecules as reactants was rate determining. In view of the pH dependence obtained in the present work under controlled conditions of electrode pretreatment, this conclusion seems invalid.

If, instead of [4], it is assumed that, although in acid solution, the over-all reaction is

$$2\,OH^- \rightarrow O_2 + 2H^+ + 4e^- \quad [5]$$

then again the fractional reaction order cannot be accounted for by this simple analysis. The observed pH dependence precludes, therefore, any simple analysis under Langmuir conditions of adsorption.

Kinetics under Temkin conditions of adsorption.—With any reasonable value for the change of heat of adsorption with coverage, Temkin conditions can hold (17) only for a relatively narrow region of potentials ($\Delta V \approx$ 200-300 mV). This is because the coverage in the range, say, $\theta = 0.1$-0.9 changes rapidly with electrode potential, as shown for oxygen adsorption at oxide-free platinum (18). In the latter case, Temkin conditions hold only for about 150 mV. In view of the extended Tafel region for oxygen evolution reaction, Temkin conditions of adsorption apparently do not hold for oxygen evolution at platinum.

Kinetic equations based on the dual barrier model.—Since the catalytic activity for oxygen evolution decreases as the thickness of the anodic oxide film increases, the film itself is a barrier to charge transfer and a potential difference must exist across the film. The potential difference across the metal solution interface, ΔV, is then a sum of the potential difference across the oxide film, ΔV_{of}, and double layer, ΔV_{dl}

$$\Delta V = \Delta V_{of} + \Delta V_{dl} \quad [6]$$

In a steady state, when the current for oxide growth is negligible, ΔV_{of} and ΔV_{dl} for the same ΔV adjust themselves in such a way that

$$i_{dl} = i_{of} \quad [7]$$

Here, i_{dl} and i_{of} are current densities across the double layer and oxide film, respectively.

The concept of the dual barrier control in a series type of arrangement has been advanced by Meyer (5) in an analysis of cathodic processes at passive Zr electrodes. MacDonald and Conway (6) have used this concept to explain some unusual Tafel slopes in oxygen evolution at Au and Pd electrodes.[7] Here, this concept is used to explain the unusual pH dependence of the oxygen evolution reaction at platinum anodes.

For any constant thickness of the oxide film, combining [3] and [7] one obtains

$$i_{observed} = i_{dl} = i_{of} = kc^{-p} \exp\left[\frac{\alpha \mathbf{F} \Delta V}{RT}\right] \quad [8]$$

where c is the activity of H^+ ions, α is the over-all transfer coefficient ($= 1/2$), and $p (= 1/2)$ is the negative of the reaction order for H^+. In a simple analysis used here, it is assumed that i_{dl} for a given pH is a function of ΔV_{dl} only, and not of ΔV_{of}. Then the current across the double layer is given in the usual way by

$$i_{dl} = B\,c^n \exp\left[\frac{\alpha_{dl}\mathbf{F}\Delta V_{dl}}{RT}\right] \quad [9]$$

It follows that i_{of} is also in the form

$$i_{of} = A\,c^m \exp\left[\frac{\alpha_{of}\mathbf{F}\Delta V_{of}}{RT}\right] \quad [10]$$

Here, α_{dl} and α_{of} are the transfer coefficients, and m and n orders of the reactions with respect H^+. A and B are constants. By combining [8] and [9], taking logarithm and with [6] after rearranging one obtains

$$\Delta V_{dl} = \frac{\alpha_{of}\Delta V + (RT/\mathbf{F})\ln[(A/B)c^{m-n}]}{\alpha_{of} + \alpha_{dl}} \quad [11]$$

and

$$\Delta V_{of} = \frac{\alpha_{dl}\Delta V - (RT/\mathbf{F})\ln[(A/B)c^{m-n}]}{\alpha_{of} + \alpha_{dl}} \quad [12]$$

These equations relate the potential difference across the oxide film and double layer to the potential difference across the whole interface. With either [11] into [9], or [12] into [10], and rearranging, a kinetic equation based on the dual barrier model is obtained

$$i = \{A^{\alpha_{dl}}B^{\alpha_{of}}c^{(\alpha_{dl}m + \alpha_{of}n)}\}^{\frac{1}{\alpha_{dl} + \alpha_{of}}} \exp\left[\frac{\alpha_{of}\alpha_{dl}\mathbf{F}\Delta V}{(\alpha_{of} + \alpha_{dl})RT}\right] \quad [13]$$

[6] Cf., Ref. (48).

[7] See also Ref. (49) and (50).

Table II. Permissible (α_{of}, α_{dl}) for various values of n and m

m	0	−1	−2	−3	−4
$n = 0$	—	(1, 1)	(2, 2/3)	(3, 3/5)	(4, 4/7)
−1	(1, 1)	—	—	—	—
−2	(2/3, 2)	—	—	—	—
−3	(3/5, 3)	—	—	—	—
−4	(4/7, 4)	—	—	—	—

Comparison of [13] and [8] yields

$$k = [A^{\alpha_{dl}}B^{\alpha_{of}}]^{\frac{1}{\alpha_{dl} + \alpha_{of}}} \quad [14]$$

$$\alpha = \frac{\alpha_{dl}\alpha_{of}}{\alpha_{dl} + \alpha_{of}} [= 1/2] \quad [15]$$

$$p = -\frac{n\alpha_{of} + m\alpha_{dl}}{\alpha_{of} + \alpha_{dl}} [= 1/2] \quad [16]$$

These equations are used in the analysis of the mechanism of reaction.

It can be shown, using similar arguments as in the preceding section, that m and n must be either negative integers or zero. Also, $n \neq m$, for if $m = n$ then, from [16], $n = -1/2$. In Table II, calculated values of α_{of} and α_{dl} are given for various values of m and n. Now, from [15], neither α_{dl} nor α_{of} can be zero. Also, any pair of (α_{of}, α_{dl}) with at least one negative coefficient is not a real solution; it would mean that the current decreases as potential increases. An inspection of Table II shows that with these restrictions there are eight solutions. For two solutions both with $\alpha_{dl} = \alpha_{of} = 1$, either $m = 0$ and $n = -1$, or $m = -1$ and $n = 0$. The solution with $m = 0$ is preferred because the rate of the reaction across the oxide-solution interface is more likely to depend on pH than the rate of the reaction across the oxide film. For the same reason, only solutions in the first column ($m = 0$) are acceptable. Solutions with $n = -3$, or -4, involve rather complex mechanisms both for the reaction across the double layer[8] and for the charge transfer across the oxide film. Furthermore, for the solution with $n = -4$, a chemical step that follows four electron transfers is rate determining. This, in turn, requires cathodic Tafel lines with an infinite slope.

Available data for the oxygen reduction at oxide-covered electrodes, however inaccurate due to gradual dissolution of oxides at potentials below about 1.0V, indicate (1, 15, 17, 22) that the slope is close to −100 mV. As for the solutions with $n = -3$, it requires much higher (~160 mV) cathodic slopes than observed. For these reasons, both solutions with $n = -3$ and -4 are not considered further.

The rate equations for the two acceptable pairs of solutions are obtained from [9] and [10]. They are

$$i_{dl} = B\,c^{-1} \exp\left[\frac{\mathbf{F}\Delta V_{dl}}{RT}\right] \quad [17]$$

and

$$i_{of} = A \exp\left[\frac{\mathbf{F}\Delta V_{of}}{RT}\right] \quad [18]$$

for solution with $n = -1$, and

$$i_{dl} = B\,c^{-2} \exp\left[\frac{2\mathbf{F}\Delta V_{dl}}{RT}\right] \quad [19]$$

and

$$i_{of} = A \exp\left[\frac{2\mathbf{F}\Delta V_{of}}{3RT}\right] \quad [20]$$

for solution with $n = -2$. Current densities i_{dl} for these two solutions are analyzed in turn.

Mechanism of the reaction for the solution with $n = -2$.—From [19]

$$\frac{\partial \Delta V_{dl}}{\partial \ln i} = \frac{RT}{2\mathbf{F}} \quad [21]$$

Now, for Langmuir conditions, for which [19] holds, this slope is given by[9]

$$\frac{\partial \Delta V_{dl}}{\partial \ln i} = \frac{RT}{\mathbf{F}}\left\{\beta_k r_k + \frac{1}{\nu_k}\sum_{j=1}^{k-1}(\nu_j r_j)\right\}^{-1} \quad [22]$$

Here, ν_j and ν_k are stoichiometric numbers,[10] and r_j and r_k are the numbers of electrons transferred in a single act of the step j and the rate-determining step k, respectively. β is the symmetry factor usually taken as ½. Values of r can be either zero or one.[11] $\Sigma(\nu_j r_j)$ is equal to number of electrons transferred before the rate-determining step for one act of the over-all reaction. With [22], it is possible to fix the position of the rate-determining step with respect to the number of electrons transferred before or in the rate-determining step. From [21] and [22] it follows that

$$\sum_{j=1}^{k-1}(\nu_j r_j) = \nu_k(2 - \beta_k r_k) \quad [23]$$

This equation gives two solutions, both for $r_k = 0$ and hence for a chemical step as rate determining. In the first, $\nu_k = 1$ and $\Sigma(\nu_j r_j) = 2$. This is the case of a chemical recombination step as rate determining, for instance according to (17)

$$H_2O \rightleftharpoons OH + H^+ + e^- \quad [24]$$

$$2\,OH \rightharpoonup [H_2O_2] \quad [25]$$

$$[H_2O_2 \rightleftharpoons O_2 + 2H^+ + 2e^-] \quad [26]$$

In the second solution, $\nu_k = 2$ and $\Sigma(\nu_j n_j) = 4$. The following reaction path is an example (which, however, would have an infinite cathodic slope)

$$H_2O \rightleftharpoons OH + H^+ + e^- \quad [24]$$

$$2\,OH \rightharpoonup [H_2O + O] \text{ or } 2\,OH \rightharpoonup [H_2O_2] \quad [27]$$

$$[O + O \rightleftharpoons O_2] \text{ or } [2H_2O_2 \rightleftharpoons H_2O + O_2] \quad [28]$$

From data obtained on the anodic side only, no conclusion can be made about the products in the rate-determining step or in the steps that follow. This is indicated by brackets in [25], [26], [27], and [28]. In the second paths too, a chemical recombination step is rate determining. It is questionable whether relatively high current densities (*e.g.*, 10^{-2} A/cm^2 at 2.0V) can be maintained by a chemical recombination step when coverage with reaction intermediates, *e.g.*, OH, is low. Were the coverage high, a chemical recombination step would be independent of potential (51).

For solutions with $n = 2$, current density across the oxide film is given by [20.]. No account for this rate expression is apparent. For this reason, and because high currents cannot be accounted for by a recombination step, solutions with $n = 2$ are not suggested.

Mechanism of the reaction for the solution with $n = -1$.—From [17]

$$\frac{\partial \Delta V_{dl}}{\partial \ln i} = \frac{RT}{\mathbf{F}} \quad [29]$$

and with [29] into [22] and with $\beta = ½$, it follows

$$\sum_{j=1}^{k-1}(\nu_j r_j) = \nu_k\left[1 - \frac{r_k}{2}\right] \quad [30]$$

The only simple solution for $n = -1$ and four electrons

[8] Cf., Ref. (17).

[9] Cf., Ref. (17) and (19).

[10] Strictly speaking stoichiometric number refers to a rate-determining step. Here, however, it is applied to any step j and means the number of times the step j occurs for a single act of the over-all reaction.

[11] Simultaneous two electron transfers are considered unlikely.

in the over-all reaction is with $r_k = 0$, $\nu_k = 2$, and $\Sigma(\nu_j r_j) = 2$. Again, a chemical step after a first charge transfer step is rate determining. Two H^+ ions ($-\nu_k n = 2$) are formed before and have, therefore, bypassed the rate-determining step. A reaction path satisfying this condition would be

$$H_2O \rightleftharpoons H^+ + OH + e^- \qquad [24]$$

$$OH + X \rightarrow [X \ldots OH] \text{ or } [X \ldots O^- + H^+] \qquad [31]$$

where X stands for a site on the surface of the oxide film. The reaction proceeds according to

$$[2X \ldots OH \rightleftharpoons 2X + O_2 + 2H^+ + 2e^-] \qquad [32]$$

If X represents an oxygen atom in the oxide film after the completion of the over-all reaction the same oxygen atom, according to this model, remains in its position. Again, however, there is a difficulty of high current densities for a recombination step that must follow (cf., *e.g.,* [32]).

Direct participation of oxygen atoms in oxide film in O_2 evolution.—An attractive reaction path for the solution with $n = -1$ is suggested here. According to this path, an oxygen atom in the oxide film directly participates in the oxygen evolution reaction. For instance, after step [24] the reaction proceeds according to

with the second step as rate determining.[12]

It may be noted that for this model and sequence of steps, including the rate-determining step, the stoichiometric number would be equal to 1 (instead of 2). Also, $\Sigma(\nu_j r_j) = 1$, and $(-\nu_k n) = 1$. Oxygen vacancy in the surface of the oxide film is subsequently replenished in a parallel reaction with the sequence of steps such as [24] and [31] and oxidation

```

Since this oxygen atom is already in the lattice of the oxide, it enters as a constant term in the over-all rate expression for the oxygen evolution reaction. For this reaction path there is no need for a high coverage with reaction intermediates.

An evidence that an oxygen atom in the surface oxide film participates directly in oxygen evolution reaction is provided by Rosenthal and Veselovski (52). These workers have found, using tracer technique with ^{18}O, that if the platinum surface oxide film is initially enriched with ^{18}O (by anodic polarization in ^{18}O enriched solutions), then the first gas anodically evolved at platinum (in ^{18}O unenriched solutions) is enriched with ^{18}O. At silver electrodes too, direct participation of oxygen in surface oxides in oxygen evolution in alkaline solution has been detected (53).

The over-all rate equation.—According to the dual barrier model, the rate of oxygen evolution reaction across the double layer is best described by [17]. In this rate expression, there is no fractional reaction order with respect to H^+. The corresponding rate equation across the oxide film is then given by [19], and the over-all observed rate, by [13]. The latter rate can be written as

$$i = (AB)^{1/2} c^{-1/2} \exp\left[\frac{F\Delta V}{2RT}\right] \qquad [35]$$

and a fractional reaction order appears in the over-all rate expression. This order now becomes fully accounted for in terms of the dual barrier control of the reaction. The rate across the double layer is controlled by a chemical step that follows a charge transfer step such as in sequences [24] and [31] or [24] and [33].

Factor A in Eq. [18] depends exponentially on the tunneling distance, that is on the average thickness of the surface oxide film (12). A is a constant for a given thickness of the film; it sharply decreases as the film thickness increases. This factor appears also in the over-all rate expression [35] and accounts for the change of the observed rate with time in terms of the change in the thickness of the oxide with time.

[12] "Bonds" and "positions" of atoms only illustrate the model.

Technical Note

Silicon Epitaxial Growth by Electrodeposition from Molten Fluorides

Uri Cohen* and Robert A. Huggins**

Center for Materials Research, Stanford University, Stanford, California 94305

Molten fluoride baths based upon the alkali fluorides have been shown to yield excellent diffused silicide coatings (1), and superior coherent layers can be deposited on many refractory metals (2, 3). It is believed that the fluorides act as fluxing agents for surface oxides, exposing clean metallic surfaces to the solutions. This is essential for the deposition of high quality coatings with good adherency. It is also believed that the stable fluoride ion complexes help to decrease diffusion-control effects, which are responsible for increased interfacial roughness and eventually result in porous, dendritic, or powdery growth. Other attractive features of the alkali fluoride salts are their low melting eutectics, low vapor pressures, low viscosity, high ionic conductivity (and low electronic conductivity), and large decomposition potential range ($>$ 3V). All these features combine to make them ideal electrolytes for the deposition of many elements and compounds.

When applied to materials such as silicon, the electrocrystallization epitaxy (ECE) technique has a number of unique and attractive features. The operating temperature, *e.g.*, 750°C, is quite low compared with typical CVD techniques, whose operating temperatures are about 1200°C. Thus ECE should yield sharper junctions, without the deleterious effects of interdiffusion and dopant redistribution, typical of high temperature processes. Lower operating temperatures are also beneficial with regard to avoiding thermal stresses, and for reasons related to materials handling, compatibility, and energy conservation.

ECE is also a much safer process in some ways, as it does not utilize hazardous gases such as H_2 and $SiCl_4$ or SiH_4, which are extensively used in the CVD techniques.

Probably of most importance, the ECE technique is isothermal and controlled by simple electrical parameters, such as current magnitudes and duration, which may easily be controlled by electronic instrumentation to facilitate precision in the film thickness and morphology. In principle, very thin films, well below the micron range, which might find uses in very fast devices, should be easily prepared by this technique. Thicker layers, as well as quite complex substrate shapes may be coated. These may find future uses in the processing of crystals or devices of various shapes.

Another unique feature of the electrodeposition process is that growth occurs on electrically conductive surfaces only. Insulating masks, through which windows can be cut, might be used to confine the growth, thereby providing a method of device isolation. Insulating masks should, of course, be stable in fluoride melts. Thus, silicon oxide is an inappropriate choice as it is quite soluble in fluorides. Silicon nitride, however, might be attractive for this purpose.

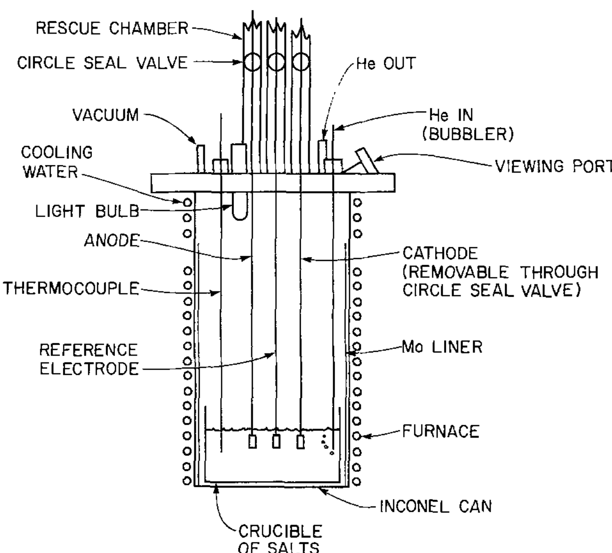

Fig. 1. Schematic drawing of the experimental apparatus

This paper reports experiments which show that such fluoride systems can be used to deposit high quality epitaxial layers of silicon upon single crystalline silicon substrates.

Experimental Procedures

Electrodeposition was done from a fluoride bath held in a molybdenum crucible contained within a molybdenum-lined vacuum tight-chamber filled with an atmosphere of purified helium. Special insulated and vacuum-sealed chambers, equipped with helium and vacuum inlets, allow lowering, raising, and replacement of the various electrodes without changing the bath temperature. A viewing port with a sapphire window and an illumination bulb facilitate observation of the melt and electrodes. This apparatus is illustrated schematically in Fig. 1.

KF-LiF (1:1, mp = 492°C) was used as the solvent, with 5 mole per cent (m/o) K_2SiF_6 as a solute. The mixture was first melted under vacuum with some of the KF replaced by KHF_2. The latter decomposed to KF and HF, which reacted with any residual oxides according to the equilibrium reaction

$$2HF_{(sol'n)} + O^{-2}{}_{(sol'n)} = 2F^{-}{}_{(sol'n)} + H_2O_{(vapor)}$$

This equilibrium was shifted to the right under vacuum, removing the water vapor. This was followed by purging the melt with purified helium to expel any dissolved HF. The purification procedure was completed by a pre-electrolysis step, during which any metallic ions more noble than silicon, as well as some silicon, were plated onto a sacrificial molybdenum strip cathode. The combination of these two purification methods, which remove different types of impurities, was found to be necessary in this case. Elimination of the deoxidation procedure was investigated, but it was found to have especially deleterious effects upon the morphology of the silicon deposit.

High purity silicon was used as a dissolving anode, and a constant current of 2 mA/cm^2 was maintained for 12 hr.

Fig. 2. SEM photographs of (111) Si epitaxial layers grown at (a) 1 mA/cm^2 (10μ thick); (b) 2 mA/cm^2 (10μ thick); (c) 4 mA/cm^2 (2μ thick); (d) 6 mA/cm^2 (10μ thick).

The coated molybdenum strip was then removed, and a silicon wafer with a (111) orientation and a mirror-polished face was introduced into the melt. An anodic current pulse of 50 mA/cm^2 was then applied for 1 sec. This served to achieve an *in situ* etching of the wafer (approximately 150Å). The polarity was then reversed, the Si wafer becoming the cathode, and constant current electrodeposition established for a predetermined period of time. The sample was then removed, cleaned, and examined. A potentiostat (PAR 173) was used for current control.

Results

Epitaxial deposition of silicon readily occurred upon the single crystal substrate. The current density was found to have an important influence upon the morphology of the deposit. Figure 2(a) shows a scanning electron micrograph of the epitaxial growth obtained at 1 mA/cm^2. Poor coverage of the substrate surface, and a hillock and layer structure can be seen. Such a structure is believed to be due to the adsorption of foreign species, probably oxygen or oxides, which hinder the propagation of kinks and steps.

If the adsorption rate is constant for a given impurity concentration and temperature, increased current density (or rate of deposition) should favor step propagation and more uniform growth. This effect can easily be seen in Fig. 2(b-d), which show deposits obtained at 2, 4, and 6 mA/cm^2, respectively. It should be noted that the epitaxial layer in Fig. 2(c) is only 2μ thick, whereas the others are 10μ thick.

Deposit uniformity across the substrate surface was found to be greatly affected by the current distribution. Since Si is a poor electronic conductor, the current density is greater in areas with a shorter current path within the silicon wafer. This results in an enhanced and more uniform growth close to the melt surface, with poorer growth in remote areas.

To produce a more uniform current distribution, a metallic layer with greater conductivity may be attached to the back side of the wafer, either by a mechanical attachment, or as a coating or film. The metal in contact with the back side of the wafer should be compatible with silicon. It must not have a low melting point alloy or eutectic with silicon, and its solid solubility in Si at the operating temperature must be as small as possible. It may also be important that this layer can be easily removed without damaging the wafer.

It was found that a layer of Ag metal 0.5μ thick, obtained by sputtering, resulted in a substantial improvement in the uniformity of the expitaxial layer. Thicker coatings should produce even more uniform layers. Silver may be removed by dipping in dilute HF, which will not attack silicon. Its solid solubility in silicon at 750°C is extremely low, and the Si-Ag system has one eutectic at 840°C.

Back-reflection Laue x-ray patterns have demonstrated that these layers are epitaxially related to the (111) substrate, even when the growth morphology appears rather rough. Results obtained by Auger spectroscopy and electron microprobe analysis have shown the deposit to be of high purity. Some carbon and oxygen were both found upon the surface after growth by Auger spectroscopy. They disappeared from the signal after a layer about 500Å thick was removed by sputtering. Electron microprobe analysis, with a sensitivity of about 100 ppm, detected no impurities beneath the surface.

Brief Communication

The Fluid Motion Due to a Rotating Disk

Ralph White,* Charles M. Mohr, Jr.,*,[1] and John Newman**

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

The solution of the Navier-Stokes equation for fluid motion due to a rotating disk includes characteristic parameters as presented below. We report here the most accurate values available for three of these parameters and compare to them values obtained by a numerical integration technique developed by Newman (3, 5).

In 1921, von Kármán (2) presented a separation of variables solution technique for the motion of an incompressible, Newtonian fluid which transformed the Navier-Stokes equation into a set of coupled, nonlinear, ordinary differential equations. By defining the following dimensionless variables $\zeta = z\sqrt{\Omega/\nu}$, $P = p/\mu\Omega$, $G = v_\theta/r\Omega$, $F = v_r/r\Omega$, and $H = v_z/\sqrt{\nu\Omega}$, the transformed equations may be written as

$$2F + H' = 0 \quad [1]$$

$$F^2 - G^2 + HF' = F'' \quad [2]$$

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
[1] Present address: Aerojet Nuclear Company, Idaho Falls, Idaho 83401.

Key words: laminar flow.

$$2FG + HG' = G'' \quad [3]$$

$$HH' + P' = H'' \quad [4]$$

where the prime designates differentiation with respect to ζ. The boundary conditions are

$$H = F = 0,\ G = 1 \text{ at } \zeta = 0 \quad [5]$$

and

$$F = G = 0 \text{ at } \zeta = \infty \quad [6]$$

Cochran (1) solved Eq. [1-3] (subject to boundary conditions [5] and [6]) by expanding the components of the velocity field first in power series in the dimensionless distance from the disk, which were assumed to be valid near the disk

$$F = a\zeta - \frac{1}{2}\zeta^2 - \frac{b}{3}\zeta^3 + \dots \quad [7]$$

$$G = 1 + b\zeta + \frac{1}{3}a\zeta^3 + \dots \quad [8]$$

$$H = -a\zeta^2 + \frac{1}{3}\zeta^3 + \frac{b}{6}\zeta^4 + \dots \quad [9]$$

and second in exponential series which were assumed to be valid far from the disk

$$F = Ae^{-\alpha\zeta} - \frac{(A^2 + B^2)e^{-2\alpha\zeta}}{2\alpha^2} + \frac{A(A^2 + B^2)e^{-3\alpha\zeta}}{4\alpha^4} + \dots \quad [10]$$

$$G = Be^{-\alpha\zeta} - \frac{B(A^2 + B^2)}{12\alpha^4}e^{-3\alpha\zeta} + \dots \quad [11]$$

$$H = -\alpha + \frac{2A}{\alpha}e^{-\alpha\zeta} - \frac{(A^2 + B^2)}{2\alpha^3}e^{-2\alpha\zeta} + \frac{A(A^2 + B^2)}{6\alpha^5}e^{-3\alpha\zeta} + \dots \quad [12]$$

We (5) followed Cochran's suggestion and required the two sets of expansions to yield, at $\zeta = 1$, the same values of the functions as well as the derivatives of F and G. In this manner we obtained the following values for the characteristic parameters[2]

$$a = 0.51023262,\ b = -0.61592201,\ \alpha = 0.88447411,\ A = 0.92486353,\ B = 1.20221175 \quad [13]$$

Benton (7) solved this problem by utilizing a technique suggested by Fettis (8) and has tabulated to four significant figures the velocity field, its derivatives, and the pressure field.[3]

To demonstrate the utility of Newman's (3-5) solution technique, estimates of the parameters a, b, α, A, and B were obtained by solving this boundary value problem numerically. The governing Eq. [1-3] were first linearized (3-5) about trial values and then cast in finite-difference form accurate to order h^2. The boundary conditions given by Eq. [5] were applied directly, whereas it was necessary to approximate those given by Eq. [6] at some finite value of ζ, ζ_{max}. The following expressions, derived from Eq. [10] and [11], were used for that purpose

$$F' = H_x F - \frac{(F^2 + G^2)}{2H_x} + \dots \quad [14]$$

and

$$G' = H_x G + \dots \quad [15]$$

where H_x was our estimate of $-\alpha$ according to

$$H_x = H + \frac{2F}{H_x} + \frac{(F^2 + G^2)}{2H_x^3}\left(1 + \frac{F}{3H_x^2}\right) + \dots \quad [16]$$

which was developed from Eq. [12]. Equations [14], [15], and [16] were also linearized about trial values and expressed in finite-difference form accurate to order h^2. The resulting system of equations was solved by technique developed (3, 4) and extended (5) by Newman. Estimates of the five parameters obtained this way are

$$a = 0.51023262,\ b = -0.61592201,\ \alpha = 0.88447410,\ A = 0.92486322,\ B = 1.20221104 \quad [17]$$

Clearly, these are very accurate estimates of the parameters given by Eq. [13]. The poorest estimate is for B, which is in error by only seven digits in the eighth significant figure.

The very attractive feature of Newman's solution technique, in addition to its accuracy, is its suitability for solving complicated boundary value problems directly without the development of specialized techniques, such as Cochran's for the present problem.

LIST OF SYMBOLS

English characters:

- a characteristic parameter equal to $F'(0)$
- b characteristic parameter equal to $G'(0)$
- A characteristic parameter
- B characteristic parameter
- F dimensionless radial velocity
- G dimensionless velocity component in the tangential direction
- H dimensionless velocity component in the normal direction (from the disk)
- h dimensionless step size
- P dimensionless dynamic pressure
- p dynamic pressure, dyne/cm^2
- r radial distance from the axis of the disk, cm
- v_r velocity component in the radial direction, cm/sec
- v_θ velocity component in the tangential direction, cm/sec
- v_z velocity component in the normal direction, cm/sec
- z normal distance from the disk, cm

Greek characters:

- α characteristic parameter equal to $-H(\infty)$
- ζ dimensionless normal distance from the disk
- μ viscosity of fluid, g/cm-sec
- ν kinematic viscosity of fluid, cm^2/sec
- Ω rotation speed of the disk, sec^{-1}

Bulk and Surface Conduction in CVD SiO_2 and PSG Passivation Layers

Robert B. Comizzoli*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Measurements of electrical conduction in the bulk of chemical vapor deposited (CVD) SiO_2 and phosphosilicate glass (PSG) passivation layers typically used for over-metal IC protection are reported. Moisture uptake increases the bulk conductivity, and the moisture effects depend on phosphorus content. The bulk current thermal activation energy of CVD SiO_2 (0.6 eV) is constant with varying moisture exposure. Before moisture exposure, phosphorus-containing glass has an activation energy of 0.8 eV, and it decreases with moisture exposure. Surface conductivity is also reported as a function of relative humidity. Conductivity values are related to IC leakage currents, and it is suggested that bulk currents in PSG should not contribute to aluminum corrosion in the absence of defects, such as cracks or pinholes.

SiO_2 and phosphosilicate glass (PSG) are important materials in silicon device passivation (1). Thin layers of PSG (hundreds of angstroms) have been described as useful for Na-gettering under gate metal of MOS devices (2-4). Thin layers must be used to avoid instabilities due to PSG polarization (3, 5-7). For over-metal passivation of IC's, thicker layers (about 10^4Å) can be used (since polarization of the PSG is unimportant in this geometry). Generally, over-metal layers are deposited by chemical vapor deposition (CVD) (8-11). The phosphorus addition lowers intrinsic stress over aluminum metal and provides Na-gettering capability (12), which is particularly useful in plastic packaged devices. In addition, the passivating glass over metal provides important scratch protection during the device production process (13), and serves as insulating protection against loose conducting particles in hermetic packages (14).

The bulk and surface electrical properties of CVD passivation over metal are important in understanding Na-gettering (4, 15) device leakage as affected by lateral charge spreading (16-21), metal corrosion (22-25), and moisture effects (24, 25).

In this report, measurements of bulk electrical conductivity as a function of water uptake and temperature, and surface conductivity as a function of relative humidity (RH) are reported for CVD SiO_2 and CVD PSG. The data are used in estimating electrical and moisture effects typical for IC's.

Sample Preparation

The glass layers were deposited on degenerate n-type (0.01 ohm-cm) silicon wafers at 450°C at a growth rate of about 1000 Å/min to a total thickness of 1 μm, using a reactor described by Kern (11, 26). Phosphorus concentrations, determined by etch rate analysis, are 0, 4.8, and 8.5 weight per cent (w/o) P in the glass. No postdeposition heat-treatments were applied.

Key words: IC's, corrosion, passivation glass, reliability, moisture effects.

Aluminum was evaporated to a thickness of 8700Å on the surface of the CVD layers and delineated by photolithography into an interdigitated electrode pattern. By proper electrical connection, this pattern allows measurement of bulk conductivity through the glass between one aluminum surface electrode and the silicon wafer, with the other surface electrode acting as a partial guard band, or it allows measurements of surface conduction between the two surface electrodes. The interdigitated pattern has an electrode spacing of 1.3×10^{-3} cm, an effective electrode width of 0.23 cm, and an electrode area (used for bulk measurements) of 10^{-3} cm^2.

The wafers were subdivided into chips containing four interdigitated patterns each, and some chips were mounted on headers without hermetic cover for bulk measurements. This provided convenient handling and circuit connection, and allowed exposure to steam. On each header-mounted chip, three surface electrode pairs were connected to leads by means of bonded wire and one connection was provided to the silicon substrate. Other chips were not mounted on headers but were tested "as is" in a probe station for both bulk and surface measurements. Conductive silver-epoxy pastes were used as back electrodes in all cases.

Measurement and Test Procedure

Bulk electrical conductivity.—In all electrical measurements a Keithley 602 or 610B electrometer was used, and a strip chart recorder continuously monitored the current.

Preliminary measurements of bulk and surface current as a function of voltage, temperature, ambient (air or N_2 with varying relative humidity), and autoclave exposure time (in steam at 15 psig, 121°C) established the following:

1. In dry N_2 ambient, measurements of current flow between one surface electrode and the silicon substrate could be made without surface current contributions, thus permitting measurement of bulk properties of the glass. The other surface electrode was used as

a partial guard band to establish that no surface current was detected in dry N_2. Thus, a guard band was not needed.

2. In most cases the time rate of change of current decreased 10-100 times 1 min after voltage application compared to initial values, and after 1 min, the current level was approximately linear with voltage, in the voltage range from 50 to 200V. Little dependence on polarity was observed.

3. Leakage current of the TO-5 header itself was negligible. It was always less than 10% of the sample currents. Based on these preliminary results a test procedure was established and carried out as follows:

(*a*) The current between one surface contact and the substrate was measured in dry N_2 flow at 100V. The current level 1 min after voltage application was selected for evaluation.

(*b*) Measurements were done at three temperatures: 20°, 60 °, and 95°C. Initially, all chips used were measured at the three temperatures. After autoclave stress treatment, each chip was measured at only one of the three temperatures for all succeeding measurements. In the data to be presented each data point at 0 hr autoclave time represents an average of 24 measurements, while each data point after autoclave exposure represents an average of eight measurements.

(*c*) The samples were placed in the steam phase of the autoclave with a cover arrangement to minimize condensate dripping. Exposure was usually 5 hr at a time, with current measurements made at the end of each stress period. After removal from the autoclave the samples were dried for 5 min in dry N_2 flow at room temperature to remove surface water, and the measurements were done immediately thereafter. The current was measured in a small oven whose temperature was continuously monitored; variation was less than ± 2°C.

Surface electrical conductivity.—For these measurements the chips were placed in a probe station to which mixtures of dry and wet N_2 were admitted to achieve controlled, variable relative humidity. All these measurements were done at 23° ± 2°C, and no autoclave stress was used. Two probes were used to contact the interdigitated patterns on the pellet, and the four patterns on each pellet were measured at 100V in the dark. The substrate was grounded. Again, the 1 min current level was chosen for analysis. For RH $\gtrsim$ 60% current reached steady state within 1 min. For lower relative humidity the current decayed very slowly.

Experimental Results

Bulk conductivity.—The time dependence of the current after voltage application depends on the presence of phosphorus. For SiO_2 the current increases slowly to a steady-state value, while with the 4.8 and 8.5 w/o P samples the current decreases after voltage application. This behavior is shown in Fig. 1. As mentioned previously, currents at 1 min are chosen for evaluation in all succeeding analyses. For all samples, evidence of a polarization process exists. If the sample is shorted after voltage application, a reverse current is measured for several minutes.

At 95°C the current in the SiO_2 sample decays upon reaching a maximum value after the initial slow increase. The decay lasts more than 1 hr, and at the end of 1 hr it has decayed to 25% of its peak. For the PSG at all temperatures the decay also continues for at least 1 hr, and the current decreases about an order of magnitude from the 1 min level. Current levels at 1 min were used for analysis for convenience.

As expected, the bulk current increases with cumulative steam exposure. The 0 and 4.8% phosphorus samples show an initial bulk conductivity increase which saturates at about 10 hr moisture exposure. The 8.5% samples show a smaller initial conductivity increase followed by a second increase at about 20 hr. After

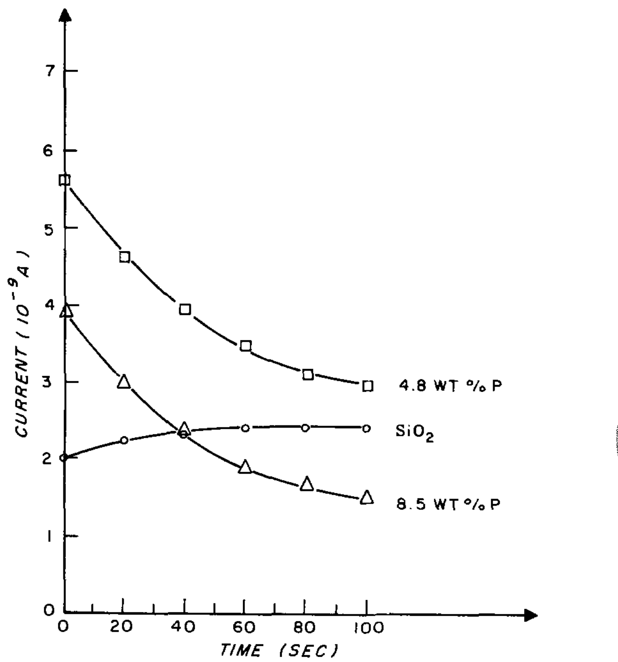

Fig. 1. Bulk current vs. time after voltage application for SiO_2 and PSG at 95°C after 17 hr autoclave stress.

20 hr the conductivity of the 8.5% samples is generally higher than that of the 0 and 4.8% samples. This general dependence was found at all three measurement temperatures. A typical case is shown in Fig. 2.

The dependence of the current level on the phosphorus concentration varies with autoclave time. Before autoclave stress, the current of the phosphorus-containing glass is lower than that of the phosphorus-free glass (SiO_2). This is shown in Fig. 3 for three temperatures. At 10 hr steam exposure, the current is greatest for the 4.8% sample and lowest for the 8.5% sample, as shown in Fig. 4. At 25 hr, Fig. 5 shows that the current level increases with increasing phosphorus content.

The temperature dependence of the current is different for the SiO_2 as compared to the phosphorus-containing glass. As shown in Fig. 6-8, the current-temperature dependence of the SiO_2 is well characterized

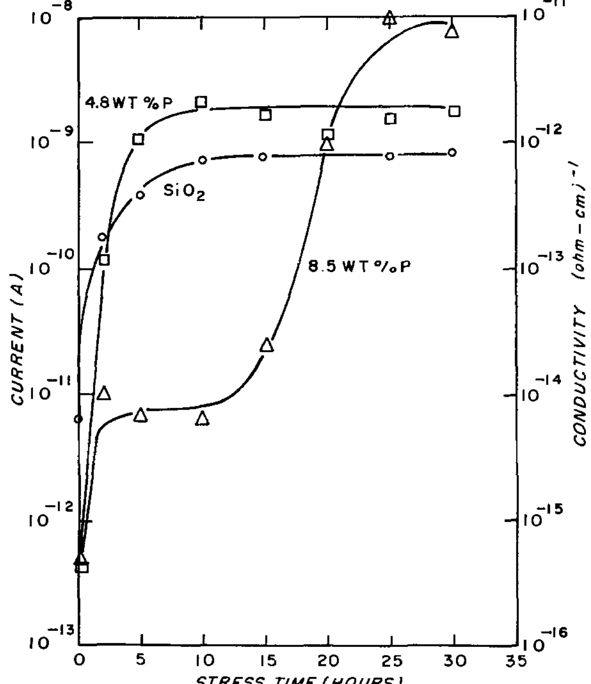

Fig. 2. Bulk current at 60°C vs. autoclave stress time

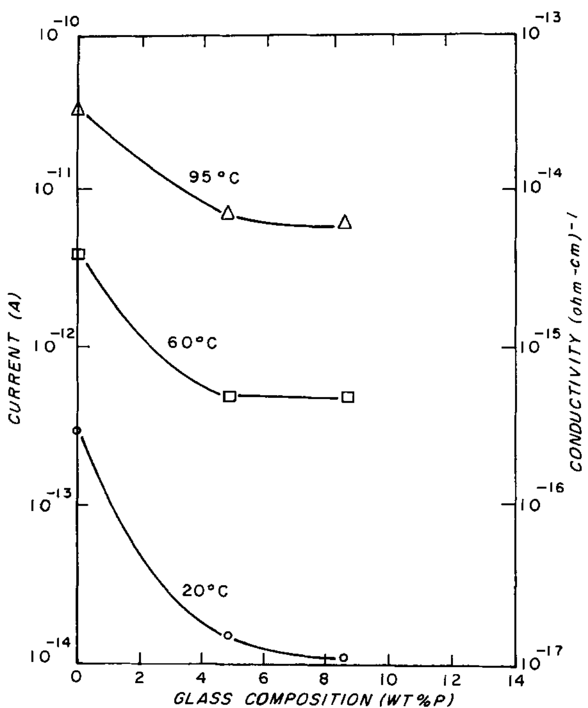

Fig. 3. Bulk current vs. phosphorus content before autoclave stress.

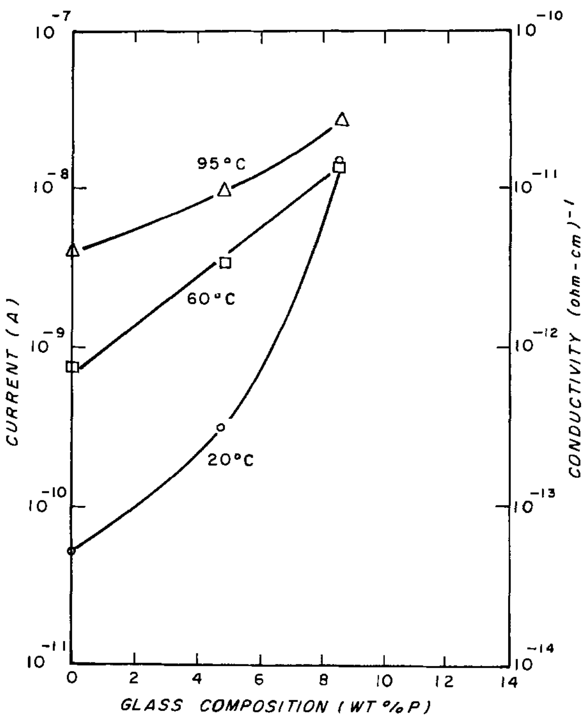

Fig. 5. Bulk current vs. phosphorus content after 25 hr autoclave stress.

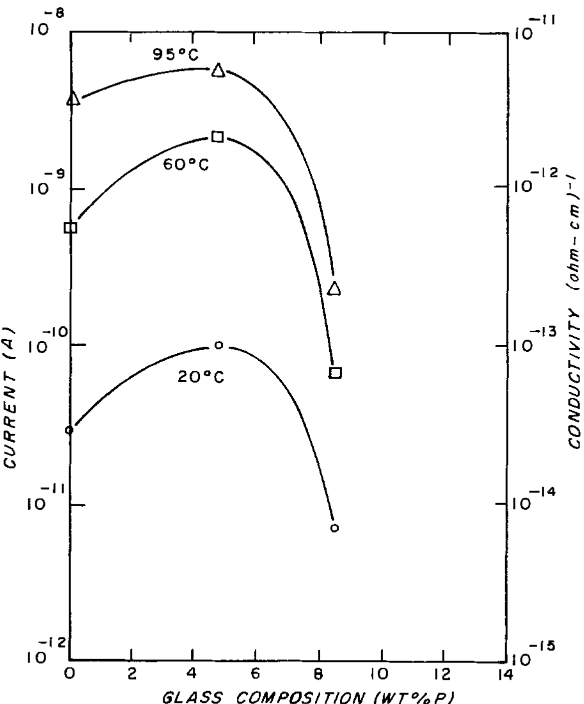

Fig. 4. Bulk current vs. phosphorus content after 10 hr autoclave stress.

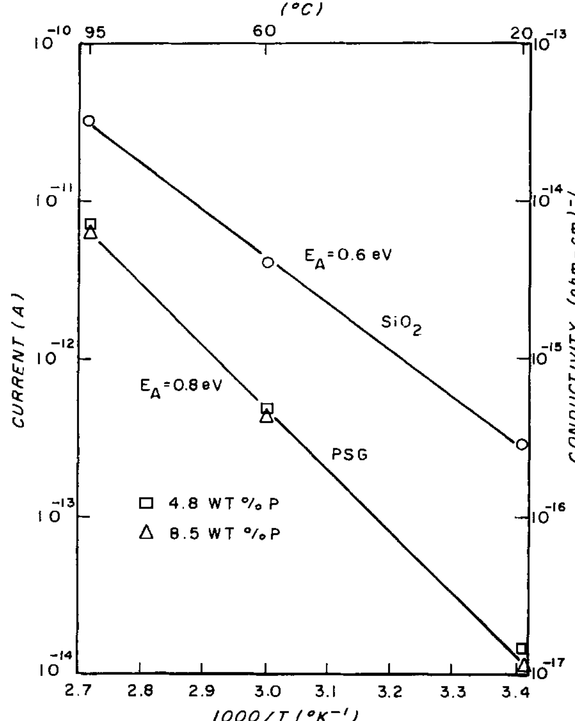

Fig. 6. Bulk current vs. temperature before autoclave stress

by a single activation energy of 0.6 eV, and this energy is independent of autoclave exposure. The current level increases with autoclave exposure, but the activation energy is unchanged.The phosphorus-containing glass before autoclave stress has an activation energy of 0.8 eV, independent of phosphorus concentration, as shown in Fig. 6. After steam exposure, the activation energy tends to decrease for these samples, as shown in Fig. 7 and 8, and in some cases a thermally activated process is not indicated.

For the 8.5% P samples after long autoclave exposure, it was found that a decrease in measured conductivity occurred for the elevated temperature measurement due to the several minute delay between placing the sample in the oven and performing the current measurement. This was at most a decrease of 40% and has little effect on the activation energy determinations.

Surface conductivity.—The current at 23°C is constant and very low below about 30% RH and begins to increase above that value. Below 30% RH the current reflects bulk contributions. The SiO_2 above 30% RH has a greater surface current than the PSG samples as shown in Fig. 9, at least up to about 70% RH.

Effect of cracks in PSG.—In a separate experiment the effect of cracks in PSG over metal was determined. An Al line pair pattern on thermal SiO_2 with electrode

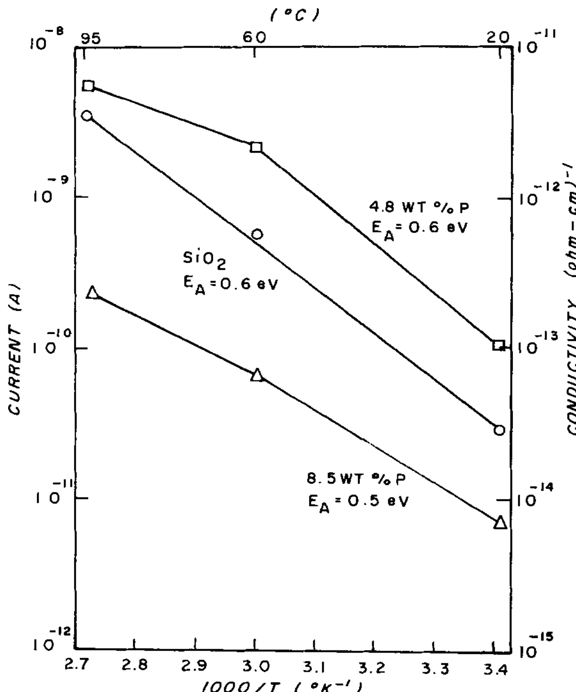

Fig. 7. Bulk current vs. temperature after 10 hr autoclave stress

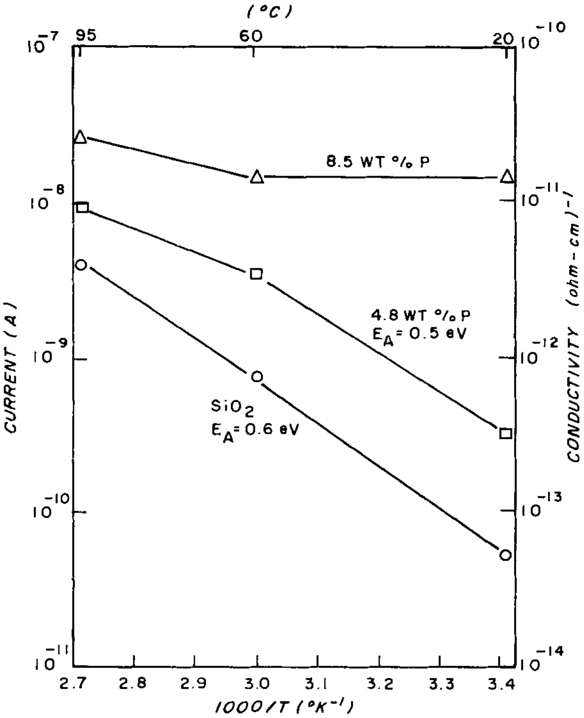

Fig. 8. Bulk current vs. temperature after 25 hr autoclave stress

gap of 1.0×10^{-3} cm and line length of 7.5×10^{-2} cm was overcoated with about 1.0×10^{-4} cm of 5 w/o PSG. In humid N_2 (RH 60%) the current at 100V between line pairs was determined to be about 5×10^{-13}A. Probes were then used to crack the glass over each of the metal line pairs, and the current level increased to about 5×10^{-10}A. Upon introducing a dry N_2 ambient, the current decreased to about 10^{-14}A.

Discussion

Conductivity and activation energies.—The difference in time dependence of the bulk current between the SiO_2 and PSG samples and the fact that before autoclave stress the SiO_2 conductivity is higher than that of the PSG suggests that Na ion motion in the SiO_2 accounts for all or a large part of the observed current. CVD films frequently have high Na content (18). Sources of Na in the films discussed here are not known, but are probably numerous since Na-free Al was not used and MOS fabrication procedures were not followed. Atomic absorption analysis indicated a Na content of about 1×10^{13}/cm^2 in these films as deposited.

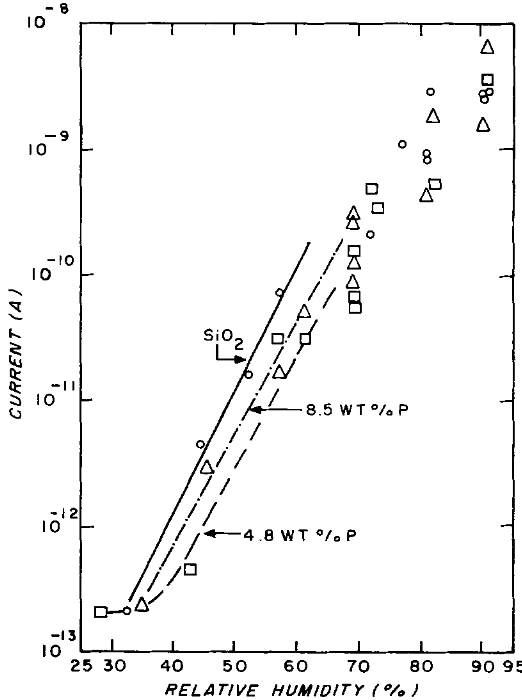

Fig. 9. Surface current vs. relative humidity at 23°C

The long-term steady-state value of current in the SiO_2 samples (greater than that of the PSG) suggests a large reservoir of Na at the aluminum contact interface or at the Si interface. This large reservoir contributes a constant release rate of charge which results in a constant current. At 95°C the release rate is high enough that an effective decrease in the reservoir is observed, leading to a gradually decreasing current. For the PSG samples, Na motion is inhibited so the currents, before autoclave moisture is introduced, are lower.

The activation energy of the bulk conductivity for the SiO_2 layer does not change with moisture content. The value of 0.6 eV may be compared with that of 0.5 eV for thermal SiO_2 contaminated with 1.0×10^{13} Na/cm^2 (4), and with 0.6 eV (thermal oxide) previously reported (27). It should be pointed out that activation energies of Na motion in SiO_2 and PSG depend both on the Na and the P concentration (4). The 0.8 eV activation energy for PSG before autoclave exposure is also in the range reported previously for Na drift in PSG (3, 4).

For thermal SiO_2 at 200°C, resistivity values of 2×10^{15} and 5×10^{16} ohm-cm have been reported for phosphorus doped and undoped layers, respectively (28). Extrapolation of data in Fig. 6 to 200°C yields about 5×10^{11} ohm-cm for both phosphorus doped and undoped CVD SiO_2. CVD PSG films are less dense and have higher etch rates than densified PSG films of similar composition (10), and, thus, greater conductivities might be expected in low temperature CVD films.

As pointed out previously, the SiO_2 is more conducting than the PSG before autoclave exposure. With sufficient autoclave exposure the PSG layers are more conducting than the SiO_2. Note that the SiO_2 and 4.8% PSG currents increase to a saturation value in about 10 hr of steam exposure, while the 8.5% PSG layer

increases in two steps to a saturation value at about 25 hr. These times are functions not only of the glass properties but also of the sample and electrode geometry. In the test samples used in this study, water must penetrate the glass surface and diffuse laterally under the metal to result in current increase. For PSG used as over-metal passivation on an IC it is expected that moisture penetration into the PSG would be faster under the same conditions we describe.

The much greater increase of conductivity after autoclave exposure of the PSG as compared to the SiO_2 is not unreasonable in view of possible phase segregation of the PSG into small pockets of a phosphorus-rich phase in a SiO_2 matrix (29). The presence of two phases furnishes interface paths for water penetration and enhanced electrical conduction. At high autoclave steam temperatures (200°C) it has been reported (30) that the P_2O_5 is actually leached out of the PSG, leaving behind a network structure (30). The authors state that this does not occur at 120°C (30). Phosphorus leaching into saturated water vapor at 120°C has been reported (31) for PSG films of high phosphorus content (about 10 mol per cent P_2O_5 for films deposited at 450°C). This leaching out is easily detected by microscopic examination (30). None of the samples considered here showed this effect. In addition, infrared absorption measurements showed no decrease in P content after cumulative treatment for 1 hr each in water at 25°C, boiling water, and autoclave steam at 15 psig, 121°C (32).

Surface current.—The behavior of the surface current in Fig. 9 is consistent with the presence of Na on the surface and with previous results (19). At low RH (below about 70%) the phosphorus blocks Na ion motion compared to the SiO_2 samples. The large scatter from sample to sample above about 80% RH may reflect the presence of more than a monolayer of water and widely varying Na contamination of the surface from sample to sample.

Leakage effects in IC's.—In this section, a worst case estimate of leakage current for a typical IC in plastic is made, based on the highest bulk and surface conductivities described previously. These values are those after 25 hr of autoclave treatment with current measured at 95°C. For the typical IC we assume the following geometry: electrode gap of 2×10^{-3} cm, length of 0.1 cm, and metal line width of 10^{-3} cm. A metallization overcoat of 5×10^{-5} cm of 8.5 w/o PSG is also assumed. Figure 10 shows the possible current paths in a schematic IC cross section. Path c is an interface path between the thermal oxide and the PSG interface. This current contribution is neglected. Path A represents the bulk conduction through the PSG between buried metal lines. Paths B and b represent the bulk and surface components of the surface path not involving openings in the PSG. Path b alone represents current flow between conductors which have discontinuities in the PSG above them. Leakage current flowing between open bond pad areas to other bond pads or to metallization lines is assumed small compared to that flowing between closely spaced metal interconnects since lateral bond pad spacing is usually large compared to interconnect lateral spacing. We ignore

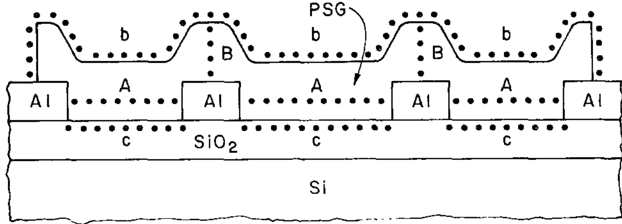

Fig. 10. Schematic cross section of IC showing various current paths associated with PSG passivation layer.

current at the thermal SiO_2-PSG interface and in the SiO_2 and calculate the parallel contributions of the bulk flow component through the PSG between metal lines (path A) and of the surface component (path B-b), which has a series bulk term (path B) for current flow from the line to the surface, and from the surface back through the PSG to the other line. At 95°C, after 25 hr autoclave exposure, the bulk resistivity is about 5×10^{10} ohm-cm (Fig. 8). The surface resistance in humid ambient is about 2×10^{12} ohm/square, obtained by using the value measured at room temperature and extrapolating to 95°C using Koelmans' activation energy of 0.35 eV (24). (We assume that the plastic, at least for a short time, traps water at the PSG surface and that the chip is thus effectively in a humid environment, since we are interested in worst case estimates.) Using these values, and the assumed geometry, we calculate a bulk resistance between lines of 2×10^{13} ohm, and a surface path resistance of 9×10^{10} ohm. This latter term consists of the actual surface component of 4×10^{10} ohm and the two bulk components in series with this of 2.5×10^{10} ohm each. Thus, in this worst case, the surface path contributes essentially all the current and at 15V the contributed leakage current is about 1.5×10^{-10}A. This is negligible for almost all applications and is about four or five orders of magnitude below specified leakage currents for most IC applications.

In a separate experiment (33), a typical IC metallization pattern over thermal SiO_2 (no contact to silicon) overcoated with 5×10^{-5} cm of 8.5 w/o PSG and packaged in plastic showed a leakage current of 3×10^{-11}A at 95°C after 24 hr autoclave. The electrode length in this structure was 0.06 cm; for comparison then, the current should be approximately doubled, yielding 6×10^{-11}A, in reasonable agreement with the previously calculated value of 1.5×10^{-10}A.

Even though bulk and surface leakage currents are negligibly small, they can have indirect effects related to surface charge inversion (16-19, 21). Using a specially fabricated MOS IC, an inversion-induced leakage after autoclave stress was observed (33). The increased leakage occurred between the positively biased N-type regions of the IC and the negatively biased P regions. Upon voltage applications at 60°C, the leakage was constant at 10^{-9}A. After about 30 sec the leakage increased with a time constant of several minutes to 5×10^{-9}A. The increase was limited to this easily tolerable level by proper channel stoppering. In a poorly designed IC (no channel stoppers) the effect could be disastrous, however.

Aluminum corrosion effects.—In this section estimates of the time for complete corrosion of an aluminum line are made. The possibility of cathodic aluminum corrosion in the presence of PSG of sufficiently high P content and water has been reported (25). Several hypothetical test situations are possible, and current between Al lines of the geometry described in the previous section are calculated. From the estimated currents, times for complete corrosion of the negative Al line are determined, assuming a Faraday efficiency of one and uniform current distribution.

The mass of Al available for corrosion is 2.7×10^{-8}g for the geometry used for the previous leakage current calculation and for Al thickness of 10^{-4} cm and the charge needed for complete corrosion is 3×10^{-4} coulomb. This value is used to estimate corrosion time.

Autoclave stress followed by voltage application in dry ambient at elevated temperature is not expected to result in Al corrosion. In this situation the bulk resistance of 2×10^{13} ohm at 95°C for the typical electrode pattern limits the current to 5×10^{-13}A at 10V (path A). The surface conduction in dry ambient is negligible. In time the current will decay, and 5×10^{-14}A is a reasonable value for long-term estimates. This results in a corrosion time of 190 years.

Exposure of a device to humid ambient at room temperature without previous autoclave exposure is also not expected to result in Al corrosion, except at bonding pads, pinholes, or cracks as found previously (25, 32). Paulson and Kirk found that corrosion occurred in areas where the PSG was not continuous over the Al, such as at a bonding pad (25). This indicates that the bulk path resistance (path B) through the PSG to the surface is not grossly affected by long-term high humidity exposure. Thus, we ignore the bulk path resistance (path A) in this case, and note that the surface path resistance is limited by the metal-to-surface resistance through the PSG (path B). This is about 5×10^{13} ohm in this situation. The current is then 2×10^{-13}A, and the corrosion time is 45 years.

The presence of discontinuities at bonding pads, pinholes, or cracks in the PSG layer over the Al acts to shunt out the high bulk resistance of the PSG in surface path conduction (path b). For the conditions of the previous paragraph the surface path resistance is reduced to 4×10^{11} ohm for a surface current of 2.5×10^{-11}A at room temperature. The corrosion time is then 115 days. At 95°C the corrosion time would be reduced to about 10 days using Koelmans' (24) or Paulson and Kirk's (25) temperature acceleration factors. With specially prepared samples containing deliberate cracks and pinholes in the PSG, noticeable cathodic Al corrosion after three days in humid ambient for PSG with greater than 8 w/o P was found (32). The effects of current concentration would decrease further the corrosion times at cracks and pinholes compared to the estimate made here. Since cracks and pinholes can occur over closely spaced metal lines it is expected that these open areas are much more serious corrosion sites than the open bond pad areas, which are much more widely spaced. Even if some corrosion of bond pad metal occurs, it should not affect device performance since on three sides of the pad there is no connection to the circuit, and on the fourth side design consideration can minimize the effects of corrosion.

The three order increase in current between line pairs under PSG in humid ambient resulting from cracking of the PSG establishes directly that surface path conduction is greatly enhanced when openings in the PSG over metal can act to short out the bulk resistance of the surface path conduction (path B of Fig. 10). The decrease in current upon introducing dry N_2 ambient confirms that the increased current after cracking the PSG is actually a moisture-induced surface current.

The occurrence of corrosion at cracks and pinholes is consistent with the observation that cathodic corrosion is much more probable than anodic corrosion (25, 32). If anodic corrosion begins at a pinhole or crack over metal, then the anodizing process will result in an electrically insulating product, which will cut off or decrease current flow in the absence of chloride (24). The anodic current then is furnished at some other crack or pinhole or by a bonding pad area. No such self-limiting process occurs at the cathode.

Summary

The bulk and surface conduction of CVD SiO_2 and PSG have been measured as functions of P concentration. The temperature dependence of the bulk current was also investigated. Effects of autoclave stress were determined. The measured electrical properties of these typical passivation layers were related to IC leakage and were shown to have no direct contribution to leakage currents, apart from the possibility of surface inversion effects. Estimates of times for cathodic Al corrosion were made, and, based on the results, it was shown that the high bulk resistivity of the PSG limits the current sufficiently so that corrosion occurs only at discontinuities in the PSG coverage of the aluminum.

Acknowledgments

The author wishes to acknowledge advice and discussion with G. L. Schnable in all aspects of this paper. R. E. Allen performed the experimental measurements. The CVD work and metallization were done by A. W. Fisher. Samples for the PSG cracking test were supplied by M. Polinsky. Discussions with A. W. Fisher, K. Hang, and W. Kern were useful.

Electrical and EPR Studies of Electrolytically Grown TiO_2 (Rutile)

G. V. Chandrashekhar and R. S. Title

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

An electrolytic technique for growing rutile is described. The crystals obtained show n-type electrical conductivity. The defect structure was studied by EPR. The behavior of the conductivity and the changes in the defect structure as a result of heat-treatment in an oxidizing atmosphere shows the as-grown crystals to be oxygen deficient. An EPR spectrum of Pt^{3+} in rutile is reported for the first time and a spectrum previously attributed to substitutional Ti^{3+} is confirmed as such.

The tetragonal form of TiO_2, rutile, has been extensively studied for many years (1-5). The electrical conductivity properties are especially interesting. The resistivity ranges from 10^8 ohm-cm in stoichiometric rutile down to 10^{-2} ohm-cm in oxygen deficient rutile (5). The conductivity is n-type and is *via* a polaron mechanism (2-3). Although the defect structure in oxygen deficient rutile has been thoroughly investigated by optical (6-9) and electron paramagnetic resonance (EPR) techniques (10-13), there is no general agreement as to whether the defects are oxygen vacancies or Ti interstitials or some combination of these and other impurities.

Almost all of the crystal growth of rutile to date has been by the Verneuil process, a flame fusion technique in an oxy-hydrogen flame. In this paper we describe an electrolytic technique that yields oxygen-deficient rutile crystals. The electrical properties of these crystals are described. We also report EPR studies on several impurities. An observation of Pt^{3+} substitutional on a Ti^{4+} site is reported for the first time and evidence is given that a previously reported resonance is indeed due to Ti^{3+} substitutional at Ti^{4+} sites.

A comparison is made between the oxygen deficient crystals produced by the electrolytic and flame fusion techniques.

Crystal Preparation

As part of a program of synthesis and crystal growth of inorganic transition metal compounds by the fused salt electrolysis technique, a mixture of TiO_2 (United Mineral and Chemical Corporation, 0.9999 pure) and $Na_2Ti_3O_7$ (prepared by heating Na_2CO_3 and TiO_2 at 1000°C) was electrolyzed in a sodium borate-sodium fluoride bath (10% NaF). A platinum double cell similar to the ceramic double cell of Kunnmann and Ferretti (14) was employed. A platinum disk ($\sim$1 cm^2) was used as the cathode and the electrolysis was carried out at 850°C for up to 60 hr with a current density of about 25 mA/cm^2. Dark green crystals that formed on the cathode were extracted from the adhering melt with dilute HCl. An x-ray powder pattern identified the crystals to be rutile. Optical emission analysis showed the following impurities in ppm by weight: B:1000; Si:300; Co:100; Pb:100; Cr:30; Pt:50; Ga:50; Mg:1. Other impurities were looked for, but all were below the detection limits for optical emission.

Unlike the solid crystals of TiO_2 that one generally associates with flame fusion growth (1), the electrolytically grown TiO_2 crystals were generally hollow rods a few mm long and about 1 mm wide. The long axis of the rods was found to lie along the crystalline c-axis and several crystals had flat (110) faces on their sides.

Key words: TiO_2, rutile, electrolytic growth, electrical conductivity, electron paramagnetic resonance.

Electrical Measurements

Electrical contacts to the crystals were made by indium soldering. The crystals were too small to use ultrasonic soldering techniques (2). The surface was, instead, repeatedly punctured by a fine-pointed soldering iron as the indium contacts were applied. Ohmic contacts were obtained. Four contacts were used, two for current and two for the voltage. Because of the hollow nature of the crystals care had to be taken in obtaining resistivity constants from the resistance measurements. The contacts were extended around as much of the diameter of the hollow rods as possible. Even with this precaution, the variation of the cross-sectional area along the length of a crystal does not allow an accurate determination to be made of the area through which the current flows. One can, however, set an upper limit on the cross-sectional area (namely, the entire area of the rod) and, hence, an upper limit on the resistivities determined from the resistance measurements. The upper limits to the resistivities of several as-grown samples were thus determined and found to be in the range 10-40 ohm-cm. A hot probe was used to determine the conductivity type which was found to be n-type. Heat-treatment of the as-grown samples at 1000°C in an oxygen atmosphere for three days caused the resistivity to increase to 10^4 ohm-cm. The relatively high n-type conductivity of the as-grown samples with a subsequent decrease in conductivity on heat-treatment in an oxygen atmosphere may be due to two different causes. One possibility is that it may be due to an oxygen deficiency in the as-grown samples. Rutile deficient in oxygen has been shown to be highly conducting n-type with a polaron conduction mechanism (3). Besides the presence of native defects (oxygen vacancies or Ti interstitials) that could give rise to n-type conductivity, there is also the possibility of the presence of impurity defects. These may be either substitutional (halogens on oxygen sites or Group V elements on Ti sites) or there may be interstitial cation impurities, all of which could give n-type conductivity. To help distinguish the defects responsible for the n-type conductivity, EPR studies were carried out.

EPR Studies

There has been a rather extensive number of EPR studies on TiO_2 (15) and a large number of defects both substitutional and interstitial have been identified. The crystal structure of TiO_2 is especially well suited to distinguish substitutional sites from interstitial sites (15). The EPR studies were performed at 9.16 GHz at temperatures between 1.8°K and room temperature.

The as-grown crystals showed four defect resonances all due to trivalent impurities substitutional at Ti^{4+} sites. Two of these Cr^{3+} and Fe^{3+} have previously been

observed in rutile (16, 17). These two spectra could be observed at all temperatures. Samples heat-treated at 1000°C for three days in an oxygen atmosphere still showed the Cr^{3+} and Fe^{3+} EPR spectra, but with diminished intensity. An EPR spectrum due to Pt^{3+} substitutional at a Ti^{4+} site, previously unreported in TiO_2, was observed in the as-grown crystals. This EPR spectrum is shown in Fig. 1 for the orientations of the magnetic field corresponding to the principal directions of the g tensor, namely the [001] direction (c axis) and the [110] and [1$\bar{1}$0] directions. (The [1$\bar{1}$0] direction has a spectrum identical to that of the [110] direction.) The lines due to Pt^{3+} are the groups of three lines, each consisting of a central line bracketed by two lines approximately one-fourth as intense. A line due to DPPH at $g = 2.0036$ (about 3250G at X-band) is also shown in the figure. The Pt is undoubtedly incorporated from the Pt cathode or from the walls of the Pt crucible in which the TiO_2 crystals were electrolytically grown. The spectrum was identified as due to substitutional Pt^{3+} from its g tensor (see Appendix) and from the hyperfine interaction with the 33.7% abundant isotope Pt^{195} (nuclear spin ½). It is this hyperfine interaction that leads to the two weaker lines about each Pt^{3+} central line. A description and analysis of the Pt^{3+} spectrum is given in the Appendix. Heat-treatment of the as-grown samples at 1000°C in O_2 for 3 days caused the Pt^{3+} spectrum to disappear.

We also observed a fourth EPR spectrum which we attribute to Ti^{3+} substitutional at a Ti^{4+} site. The parameters are given in Table I. The spectrum was only observed at temperatures below 77°K. At about 18°K the spectrum is axial. Below 18°K the spectrum has a g tensor that indicates the orthorhombic symmetry expected for a defect substitutional at a Ti^{4+} site.

The spectra that we observed at 8.5°K are shown in Fig. 2 for orientations of the magnetic field along the principal directions of the g tensor ([001], [110], and [1$\bar{1}$0] directions). The spectrum for the magnetic field parallel to the [100] or [010] directions is also shown. The fact that only a single line is observed in this direction is indicative of substitutional Ti^{3+} and not interstitial Ti^{3+}.

Gerritsen (15) at 4.2°K observed a spectrum with g values similar to those we observe at 8.5°K (Table I), which he also attributed to Ti^{3+} substitutional at a Ti^{4+} site. He reports, but gives no details, of a complicated hyperfine structure. The hyperfine structure is crucial in the identification of the center since there

Fig. 1. EPR spectrum of substitutional Pt^{3+} for the magnetic field parallel to the [110] asd [001] directions. The $g = 2$ reference marker is lined up for the two directions.

Table I. EPR principal values for substitutional Ti^{3+}

T	$g_c = g_{001}$	g_{110}	$g_{1\bar{1}0}$
8.5°K	1.9436 ±0.0005	1.9777 ±0.0005	1.9743 ±0.0005
T	$g_{\parallel} = g_c = g_{001}$		$g_{\perp}$
30°K	1.9436 ±0.0005		1.9762 ±0.0005

are quite a number of centers that have been observed in rutile with g tensors very similar to those of Table I (10-13).

For a general orientation of the magnetic field with respect to the crystalline axes, our hyperfine spectrum was difficult to resolve because of overlapping lines from the two equivalent orientations of the defect and due to the low natural abundances of Ti^{47} and Ti^{49}. However, for the magnetic field oriented along the [100] or [010] directions (midway between the [110] and [1$\bar{1}$0] axes) a single line is observed with a clearly resolved hyperfine structure. The spectrum in this direction is shown with increased gain in Fig. 3. The pattern observed is clearly consistent with the natural abundances and nuclear spins of Ti^{47} (7.75% abundant $I = 5/2$) and Ti^{49} (5.51% abundant and $I = 7/2$). The value of the hyperfine tensor, A_{100}, in this direction was found to be the same for Ti^{47} and Ti^{49} as expected (17) and equal to 7.06×10^{-4} cm^{-1}. This value of the hyperfine tensor is more consistent with the hyperfine tensor usually observed (18-21) for $Ti^{47,49}$ than with the much smaller superhyperfine tensor that results from the superhyperfine interaction of the other defects with $Ti^{47,49}$ in TiO_2 (22). Also the g tensor of Table I is consistent with what would be expected for a single 3d electron on a substitutional Ti^{4+} site and with a $a|x^2 - y^2 > +\sqrt{1 - a^2}|3z^2 - r^2 >$ ground state (23). We conclude that the center we are observing is **a** substitutional Ti^{3+} defect.

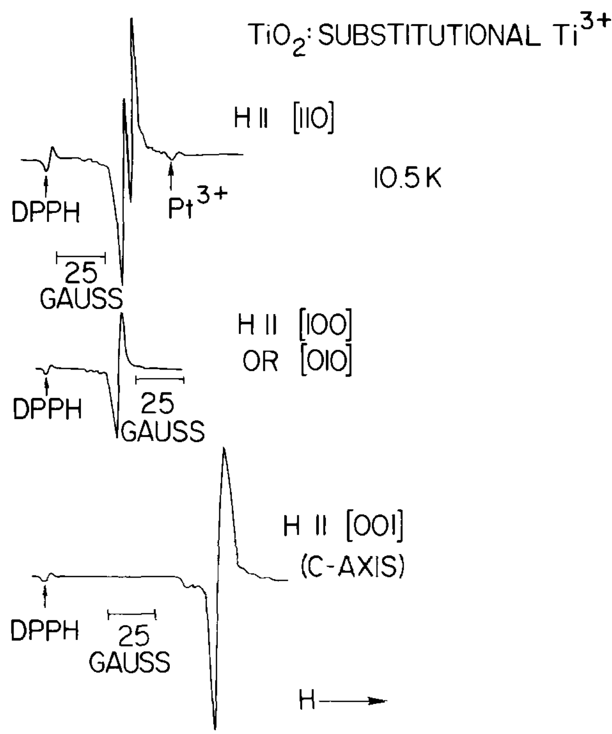

Fig. 2. EPR spectrum of Ti^{3+} substitutional at a Ti^{4+} site. The spectra are for the magnetic field along the [110], [100], and [001] axes. The three spectra are aligned with respect to the DPPH reference. A signal due to Pt^{3+} is visible for the magnetic field in the [110] direction.

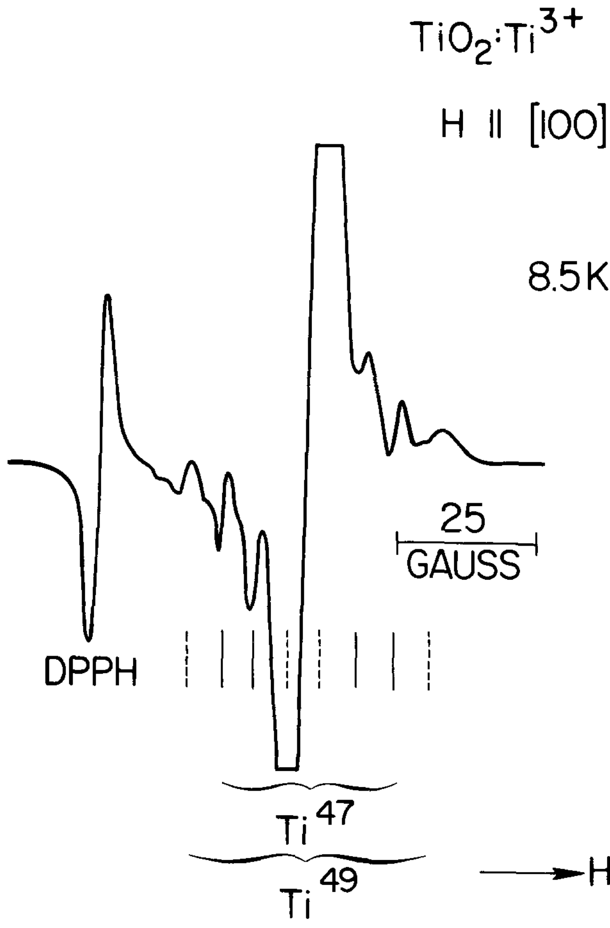

Fig. 3. The spectrum at increased gain for substitutional Ti^{3+} with the magnetic field along the [100] direction.

On annealing the as-grown crystals at 1000°C for 3 days in an TiO_2 atmosphere the Ti^{3+} resonance disappears, as did the Pt^{3+} resonance.

It is also worthwhile reporting a negative result in the EPR studies. There have previously been several reports (10-13) of EPR spectra in conducting rutile which have been attributed to various forms of native defects. The g values of the EPR spectra, but not necessarily their principal axes, are very similar to those of Table I. There is no agreement on the native defects responsible for these EPR spectra. Those that have been suggested include various forms of polarons (10), an oxygen vacancy (11), and interstitial Ti^{3+} (15). More recently, Shen *et al.* (3) from a study of the effects on conducting rutile of treatment in various atmospheres, have suggested that hydrogen must be present in the crystal for the reported spectra (10, 15) to be observed.

Because the electrolytic technique for making conducting rutile differs from the flame fusion growth technique used by the previous workers and because of the controversy as to whether native defects are observable by EPR in conducting rutile, we made a thorough search for the EPR spectra attributed to these native defects (10-13) and found none. Our negative result is in accord with the conclusion of Shen *et al.* (13) that hydrogen is a necessary impurity for the observation of the spectra attributed to native defects. There is no reason for hydrogen to be present in the electrolytically grown conducting rutile.

Discussion

There are a number of conclusions that can be made from the results of the measurements on electrolytically grown rutile. It is clear that in order for rutile to plate out as crystals in an electrolytic process, the crystals must be conducting. This is confirmed by the electrical measurements which in addition show the conductivity to be n-type. The EPR studies, which were undertaken to determine the defects or impurities responsible for the n-type conductivity, detected no defects which alone could give n-type conductivity. Rather a number of trivalent impurities, Cr^{3+}, Fe^{3+}, Pt^{3+}, and Ti^{3+} were observed substitutional on Ti^{4+} sites. These centers have given up one less electron than the host Ti^{4+} they replace and hence the site containing such an impurity is effectively singly negatively charged with respect to the lattice. In order to preserve charge neutrality, centers of positive charge must exist in the lattice to compensate these negative charges. One possibility is the existence of holes, which at low temperature would be localized at the trivalent impurities but at higher temperatures would be free. P-type conductivity should then be observed and not the n-type that is observed. The observation of n-type conductivity is not consistent with compensation by holes and leads us to believe that the electrolytically grown rutile crystals contain native defects (unobserved by EPR) which provide the n-type carriers and may also provide the charge compensation necessary to observe trivalent impurities substitutional on Ti^{4+} sites. Since both the high n-type conductivity and the presence of substitutional trivalent impurities is either considerably diminished or eliminated on exposing the crystals to an oxidizing atmosphere, it is concluded that the native defects result from an oxygen deficiency. It is known that rutile with oxygen as low as $TiO_{1.992}$ does exist (24). Controversy exists as to whether this results in the presence of oxygen vacancies or titanium interstitials (1, 6, 25-31). We did not observe the EPR signals that others have attributed to these defects and conclude that perhaps other impurities in conjunction with defects are required to make these observable (13).

In summary a new technique or growing rutile crystals has been described. The electrical and defect properties of the crystals have been determined and compared with the more conventionally grown rutile crystals.

Acknowledgments

We would like to thank G. Arbach for growing the crystals and R. E. Fern and W. J. Fitzpatrick for help in determining their electrical and resonance properties.

APPENDIX

The Pt^{3+} EPR Spectrum

The Hamiltonian for the Zeeman and hyperfine interactions is given by

$$\mathcal{H} = \beta S \cdot \overline{\overline{g}} \cdot H + S \cdot \overline{\overline{A}} \cdot I \qquad [1]$$

where β is the Bohr magneton, S the effective electron spin, H the magnetic field, I the nuclear spin, and $\overline{\overline{g}}$ and $\overline{\overline{A}}$ the g and hyperfine tensors, respectively. It was observed that the maximum extension of the Pt^{3+} spectrum occurs when the magnetic field is oriented along the [110] or [1$\overline{1}$0] directions (see Fig. 1). This indicates that the principal axes of the g tensor are along the [110], [1$\overline{1}$0], and [001] (c axis) axes. The principal axes of the A tensor were also found to be along these axes. The fact that the principal values of the g and A tensors are along the observed axes identifies the Pt^{3+} as substitutional at a Ti^{4+} site. Pt^{3+} at an interstitial site would have the axes of the g tensor deviate from the [110] and [1$\overline{1}$0] axes.

Table II. EPR principal values for Pt^{3+} in TiO_2 at 87°K

g tensor			10^{-4} cm^{-1}		
$g_c = g_{001}$	g_{110}	$g_{1\bar{1}0}$	$A_c = A_{001}$	A_{110}	$A_{1\bar{1}0}$
2.1485	1.9137 $+0.0005$	2.3338	81.5 ± 1.0	134.7 ± 1.0	59.1 ± 1.0

The parameters for Pt^{3+} in TiO_2 are given in Table II. The values for the g and A tensors are within the ranges that one usually observes (32) for Pt^{3+} ($5d^7$), though the value of g_{110} is somewhat smaller than has been observed in other crystals. The g tensor (including the low g_{110}) may be understood if it is assumed that the spitting of the d orbitals by the orthorhombic crystalline field at a Ti^{4+} site is as shown in Fig. 4 (23, 33). Each d orbital is doubly degenerate. Further, it is required that six of the seven 5d electrons fill the lowest three orbitals and that there is one electron in the $a|3z^3 - r^2 > - \sqrt{1 - a^2}|r^2 - y^2>$ orbital, the so-called high field, low spin, filling scheme (34). Because of spin-orbit coupling there will be an admixture of the $|xy>$ level from above and the $|yz>$ and $|xz>$ levels from below into the $a|3z^2 - r^2> - \sqrt{1 - a^2}|x^2 - y^2>$ orbital (level 4). It is the admixture of the $|xy>$ orbital from above that causes the comparatively large departure of g_{110} from the free spin value of 2.

With the spin-orbit coupling taken into consideration and using formulae given in the literature (23, 35), one can analyze the observed g tensor and account for it in terms of the spin-orbit splitting parameter, λ, and the separations of level 4 from energy levels 2, 3, and 5 (Fig. 4). Neglecting any covalent effects, but taking second order correction terms (23, 35) into account, one obtains

$$\frac{\lambda}{E_4 - E_5} = -0.1501 \quad [2]$$

$$\frac{\lambda}{E_4 - E_3} = \frac{\lambda}{E_4 - E_2} = 0.0448$$

$$\text{and } a = 0.965$$

where a is the coefficient in the level 4 orbital, $a|3z^2 - r^2> - \sqrt{1 - a^2}|x^2 - y^2>$. The spin-orbit parameter, λ, is not known for Pt^{3+} in TiO_2 (27). For the free Pt ion it is 3368 cm^{-1} (36). The parameters show that $|E_4 - E_5|$ is about 0.3 $|E_4 - E_3|$, which is approximately the ratio observed for these 3d orbitals in TiO_2 (28).

With the parameters of [2], one can analyze the A tensor by use of the formulae already given in the literature (23, 35). The only unknowns in these formulae are κ, the spin-dependent exchange parameter between the d electrons and the paired core electrons, and $<r^{-3}>$, where r is the radius of the 5d

ENERGY LEVELS	d-ORBITALS
5	$\|xy>$
4	$a\|3z^2-r^2>-\sqrt{1-a^2}\,\|x^2-y^2>$
3	$\|xz>$
2	$\|yz>$
1	$a\|x^2-y^2>+\sqrt{1-a^2}\|3z^2-r^2>$

Fig. 4. The splitting of the d orbitals in the orthorhombic point symmetry at a Ti^{4+} site [after Ensign *et al.* (33)].

electron orbit. It is found that the observed A tensor can be fitted with the parameters of [2] and with the values

$$\kappa = -0.02 \quad [3]$$

$$<r^{-3}> = 9.75 \text{ atomic units}$$

The small negative value of κ indicates a small contribution of 6s electron character in the 5d orbital (37). No values of $<r^{-3}>$ are generally available for 5d orbitals (34), but they are expected to be larger than $<r^{-3}>$ for the isoelectronic 3d and 4d orbitals (34). For $3d^7$ of Ni^{3+}, $<r^{-3}> = 7.790$ a.u. and, for the $4d^7$ of Pd^{3+}, $<r^{-3}> = 8.487$ a.u. The value obtained for Pt^{3+} in Eq. [3] fits the expected order.

Quantum Efficiency Standard for Ultraviolet and Visible Excitation

A. Bril* and A. W. de Jager-Veenis

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

To determine quantum efficiencies of powder phosphors as a function of exciting wavelength, sodium salicylate is usable in the ultraviolet but not in the visible region. As a powder standard in the excitation region, 200-550 nm red luminescent lumogen powder is proposed. The absolute quantum efficiency has been measured. It varies between 40 and 60% in this region and it has a high absorption.

To determine the efficiencies of powder phosphors it is very helpful to have standard phosphors with which efficiencies of other phosphors can be compared. In this way absolute measurements, which are generally time consuming, can be avoided. Some of the conditions that standard phosphors are required to fulfill is that they should be readily available, stable, and show agreement on the value of the efficiency. However, even when there is some uncertainty about the accuracy it is important to be able to make a comparison between a sample with unknown efficiency and the standard.

For excitation in the wavelength region near 250 nm, the standards issued by the National Bureau of Standards (NBS) in Washington are very suitable. The efficiencies of these phosphors have been measured by us earlier (1), together with other properties like decay time and temperature dependence. For many applications, however, it is often necessary to know the efficiency at other exciting wavelengths in the ultraviolet and visible regions.

For the ultraviolet exciting region up to a wavelength of about 350 nm sodium salicylate is often used, which has a constant efficiency as a function of wavelength from the far ultraviolet up to 350 nm at the long wavelength side. The quantum efficiency of sodium salicylate has been measured by several workers. Table I gives some data for 254 nm excitation taken from Samson's book on far ultraviolet (2) together with our values.

Table I. Absolute quantum efficiency q of sodium salicylate[1] $\lambda_{exc} = 253.7$ nm

Allison, Burns, and Tuzzolino (3) found for the quantum efficiency of sodium salicylate a figure very near unity. In our opinion this cannot be right, as can be readily seen from the fact that at liquid nitrogen temperature the efficiency increases by about 25%, as Kristianpoller and Knapp (4) showed. Nygaard (5) found originally 50% but in a later paper (6) he states the value of Ref. (3) to be right. The low value found by Inokuchi (7) is probably due to the use of very thin layers, so that the exciting radiation is not quite absorbed. The figures of Studer (8), Kristianpoller (9), Vasseur and Cantin (10), and Wrighton, Ginley, and Morse (11) are in agreement with our values. For the intrinsic quantum efficiency we found a value of 60%, *i.e.*, a correction has been made for the absorption of the emitted luminescence in the layer (12). Not corrected for this absorption, the quantum efficiency is found to be 55%.

A disadvantage of sodium salicylate is that its emission is in the blue, so that constant quantum efficiency and high absorption are only found up to about 350 nm. At $\lambda_{exc} = 365$ nm we found a lower quantum efficiency, in agreement with measurements reported by Hamman (13). For longer wavelength excitation use can be made of very diluted solutions of, *e.g.*, rhodamine B or 6G, fluorescine, etc., which are known to show a nearly constant quantum efficiency as a function of exciting wavelength up to their emission region [see the paper by Velapoldi (14)]. Rhodamine B, for instance, emits in the red spectral region, so that it is suitable for excitation up to relatively long wavelengths.

Liquid samples like the ones mentioned, however, are less suitable as standards for comparison with powder phosphors because of the different geometry of the setup needed for the measurement. Another drawback of these liquid samples is that the efficiency is about constant as a function of the exciting wavelength, but the absorption and, as a consequence, the light output vary enormously through the spectrum. This is shown in Fig. 1, where the absorption is given for rhodamine B [see also Eastman (15)]. Low absorption and low light output in the ultraviolet and blue are found with a large maximum near 540 nm and a smaller maximum near 360 nm.

genshtern, Neustruev, and Epshtein (18), and Küttner, Selzle, and Schlag (19) described luminescent "lumogens" with a rather constant efficiency.

For the measurement of efficiencies at still longer exciting wavelengths we chose a red luminescent "lumogen T red GG" as a standard. It is one of a series of "lumogen" pigments available from the B.A.S.F. Company in Ludwigshafen, Germany (20). The luminescence properties of this material are described below.

Experimental

The spectral power distribution was determined with a Spex 1700 II monochromator, which was automatically corrected for the wavelength-dependent instrumental response as was described previously (21). The instrument was equipped with a thermoelectrically cooled EMI Type 9659 QA photomultiplier (S20 response) and a liquid nitrogen-cooled Philips 150 CVP photomultiplier (S1 response). The setup was calibrated with the aid of a calibrated tungsten-halogen standard lamp of the NBS (Washington, D.C.).

The excitation spectra were determined with a Perkin-Elmer-Hitachi grating spectrofluorimeter MPF2A equipped with a red-sensitive Hitachi R446F photomultiplier. The sources used were a deuterium lamp for the ultraviolet and a tungsten-halogen lamp for the visible region. The relative quantum output in the u.v. region was determined as a function of wavelength with respect to that of sodium salicylate, assuming a constant quantum efficiency for the latter (see above). From 160 to 260 nm the excitation spectra were determined with a McPherson Seya-Namioka monochromator Type 235 in combination with an argon-flushed deuterium lamp and a thermoelectrically cooled calibrated EMI 9558 Q photomultiplier.

For the absolute measurements of the efficiency at $\lambda = 365$, 405, 436, and 546 nm, a Philips HPK 125W mercury vapor discharge source was used; the exciting lines were isolated with filters. Measurements were carried out with two detectors: (*i*) a thermoelement (flat power response) and (*ii*) a Philips 150 CVP photomultiplier (S1 photocathode), specially selected in view of a nearly flat response between 400 and 650 nm (not used for $\lambda_{exc} = 365$ nm). The excitation intensity was determined with the aid of diffuse reflection against pure Eastman Kodak $BaSO_4$ (22).

Two measurements were carried out on $BaSO_4$ and each phosphor [for details of the method used see Ref. (1)]. One measurement was done without a filter in front of the photomultiplier and the other measurement with a filter that passes only the luminescence (for $BaSO_4$ the output is then evidently zero). From the two measurements the reflection and radiant efficiency can be determined. The value of the reflection thus calculated should be about the same as the one found in a direct way in a spectroreflectometer (see below).

Actually, the radiant efficiencies were determined from which the quantum efficiencies were calculated. For measurements at liquid nitrogen temperature, a setup was used similar to that described in Ref. (1).

Diffuse reflection measurements were carried out on a Perkin-Elmer Model 13 U spectrophotometer (detector EMI 9558 QA photomultiplier, source deuterium lamp) in the absorption region of the sample. The latter was placed in a specially made Perkin-Elmer attachment (sample between source and monochromator). In the emission region a Beckman DK2 spectroreflectometer with Ulbricht sphere was used (sample between monochromator and detector). The absorption of liquids was measured on a Cary Model 17 spectrophotometer.

Results and Discussion

The spectral power distribution of the lumogen T red GG at room temperature is given in Fig. 2. The maximum of the emission is found at a wavelength between $\lambda = 610$ and 615 nm. The spectral power distribution at liquid nitrogen temperature is given in Fig. 3, showing two peaks at $\lambda = 600$ and 640 nm, respectively.

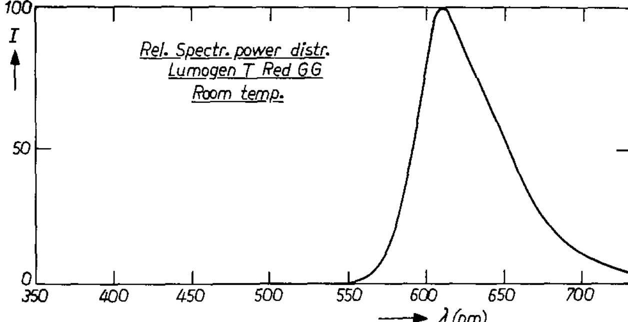

Fig. 2. Relative spectral power distribution of lumogen T red GG at room temperature. *I* denotes the spectral radiant power in arbitrary units.

We measured the quantum efficiency as a function of the exciting wavelength (layer thickness about 2 mm). It proved to be not quite constant, but it varies only in a limited range between 40 and 60% in the spectral region between 220 and 550 nm. This is shown in Fig. 4, where the diffuse reflection curve is also given. An important advantage is that the absorption is high in the whole region; the lowest value is 78% near $\lambda = 380$ nm (diffuse reflection $= 22\%$).

The excitation spectrum was determined in the following way:

1. For $\lambda = 254$ nm the absolute value of the quantum efficiencies was determined in a relative way with the aid of the NBS standard phosphors willemite and Mg-arsenate activated with Mn. The method used has been described in Ref. (1), where the determined absolute values of the latter phosphors are also given.

2. Absolute efficiencies were determined at the excitation wavelengths of the mercury discharge lines:

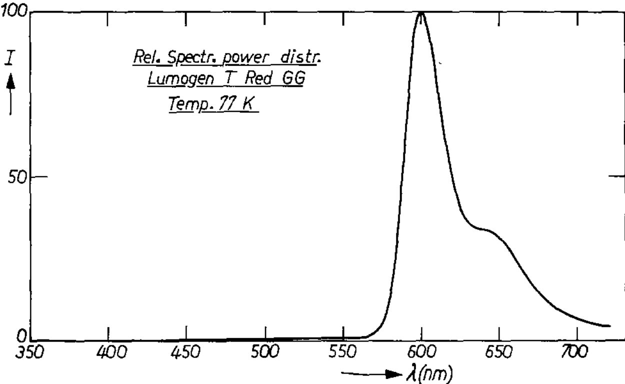

Fig. 3. Relative spectral power distribution of lumogen T red GG at 77°K. *I* denotes the spectral radiant power in arbitrary units.

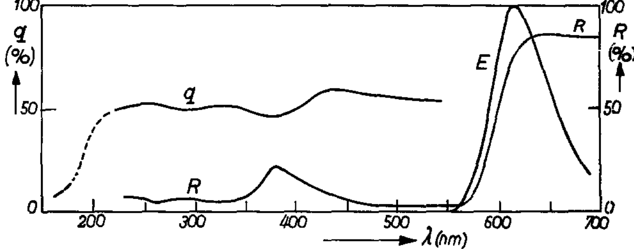

Fig. 4. Quantum efficiency *q*, diffuse reflection *R*, and spectral power distribution *E* of lumogen T red GG as a function of wavelength.

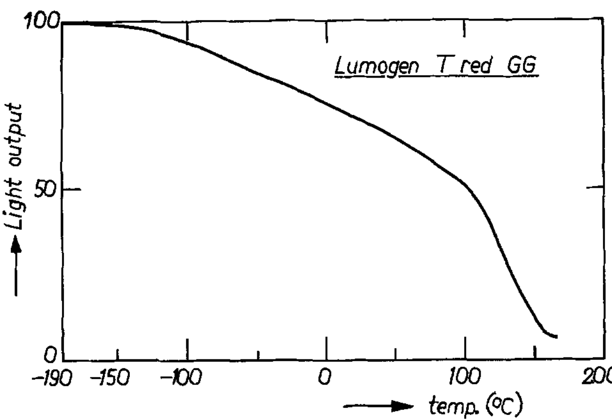

Fig. 5. Temperature dependence curve of lumogen T red GG

λ = 365, 405, 436, and 546 nm with a method similar to that described in Ref. (1).

3. In the middle and near u.v. the relative excitation spectrum was determined with the aid of sodium salicylate as has been explained before, down to 160 nm.

4. To determine the quantum efficiency between 500 and 540 nm, use is made of rhodamine B as a reference. The ratio of the efficiencies of lumogen and rhodamine were determined at λ = 540 and 365 nm where rhodamine has maxima in light output. A constant quantum efficiency is assumed for the rhodamine. Then the efficiency between 500 and 540 nm can be calculated from that at 365 nm, which has been determined in an absolute way as is mentioned above.

The measurements mentioned under 2-4 lead to a fairly constant quantum efficiency in the u.v. and visible region.

Part of the variation in quantum efficiency may be due to the influence of absorption in the polyvinyl chloride in which the luminescent material is dissolved. This may also be the reason for differences in efficiency between various batches of lumogen. (We found a difference of about 10% for two batches.) It is therefore necessary to calibrate every batch.

In addition to the spectral power distribution at the temperature of liquid nitrogen (see Fig. 4), we also determined the quantum efficiency (λ_{exc} = 365 nm) at that temperature which proved to be about 40% higher than its value at room temperature. In Fig. 5 the temperature dependence curve of the relative light output is given.

Acknowledgments

The authors are indebted to Miss R. E. Engelen for part of the measurements and to Mr. P. Vries for the response measurements of the photomultiplier.

Manuscript received Oct. 27, 1975. This was Paper 204 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Philips Research Laboratories.

Factors Influencing the Photoluminescence Behavior of Thoria

P. J. Harvey and J. B. Hallett

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada K0J 1J0

ABSTRACT

The photoluminescence of single crystals of thoria excited with u.v. light consists of sharp line spectra, characteristic of accidentally incorporated rare earth impurities and broad band spectra of the host lattice and other impurities. The effects of (*i*) the annealing atmosphere, the duration of the anneal, and the cooling rate, (*ii*) the deliberate addition of aliovalent Ca^{+2}, Y^{+3}, and Ta^{+5} impurities, and (*iii*) the time and temperature of the u.v. excitation on the photoluminescence behavior are discussed.

Early studies on the optical properties of ThO_2 (1-3) indicated that vacuum or air annealing could change the optical absorbance spectra. Other work on ThO_2 was carried out by Bates (4) and more recently by the present authors (5). Some impurity effects on the optical properties of ThO_2 have also been examined (6, 7). The results of these studies showed many more basic differences than could be accounted for by the varied

Key words: thoria, photoluminescence, impurities, temperature dependence, thermoluminescence.

experimental techniques employed. It was evident that progress in the identification of defect centers in ThO_2 was being impeded because different research groups were working with crystals from a variety of sources and prepared under a variety of conditions. There was insufficient, well-characterized quantitative optical data. The aims of the present paper are to document well-characterized data on the photoluminescence of thoria, to point out that many factors can influence the photoluminescence behavior, and to illustrate these effects. In addition, the present paper correlates the time and temperature dependence of the photoluminescence behavior with recently obtained thermoluminescence data (8).

Experimental

High purity ThO_2 powder obtained from the American Potash Chemical Corporation, West Chicago, Illinois, was subjected to arc fusion by the Norton Research Corporation (Canada) Ltd., Chippawa, Ontario. Single crystals of ThO_2 were cut from the arc-fused boule using a diamond wire saw. Crystals were polished to optical flatness using a series of diamond pastes. The crystal dimensions were 0.25 mm thick and approximately 80 mm^2 surface area. The main impurities, determined by spark source mass spectroscopy, of a nominally pure crystal are listed in Table I. Doped crystals were prepared by adding 0.14 mole per cent (m/o) Y_2O_3, Ta_2O_5, or 0.28 m/o CaO to the ThO_2 powder before arc fusion.

The crystals were annealed at 1675°K in one of four atmospheres so that the effect of oxygen partial pressure on the photoluminescence could be studied. These atmospheres were: (*i*) air, $p_{O_2} \sim 2.026 \times 10^4$ Pa (2×10^{-1} atm), (*ii*) carbon dioxide, $p_{O_2} \sim 1.013 \times 10^2$ Pa, (*iii*) carbon monoxide, $p_{O_2} \sim 1.013 \times 10^{-8}$ Pa, and (*iv*) dry hydrogen, $p_{O_2} \sim 1.013 \times 10^{-17}$ Pa. Crystals annealed in air or carbon dioxide will be referred to as oxidized; whereas crystals annealed in carbon monoxide or dry hydrogen will be referred to as reduced. Annealing times of 3.60×10^2, 8.64×10^4, and 7.20×10^5 sec were chosen and two cooling rates from the annealing to ambient temperature employed. The first, known as the fast cool, occurred when the crystal holder was completely removed from the furnace and cooled with a jet of cold air. From 1675° to 1000°K the cooling rate was $\sim$ 3.5° sec^{-1}. Furnace cooling, the slow cool, gave a rate of 0.35° sec^{-1} over the same temperature range.

All the photoluminescence measurements were made on a Perkin-Elmer MPF-3 spectrofluorimeter using a Xenon arc lamp as the excitation source and a multialkali u.v. glass R446 photomultiplier as the detector. The spectral range examined was restricted to 400-800 nm with a 10 nm band pass. Reflected light made it difficult to make meaningful measurements below 400 nm and no attempts were made to investigate emission in the infrared region of the spectrum. The photoluminescence emission spectra were corrected for variations in the photomultiplier response. The crystals were mounted on a specially designed copper finger enclosed in an evacuated water-cooled quartz jacket. The specimen temperature was monitored using a precalibrated iron-constantan thermocouple embedded in the copper directly behind the specimen. The temperature dependence of the photoluminescence efficiency was measured at a linear heating rate of 0.83°K sec^{-1}. The same heating rate and crystal geometry were used when studying the thermoluminescence.

Results

The effects of varying the u.v. excitation wavelength on the photoluminescence are illustrated in Fig. 1. For a pure crystal annealed in air at 1675°K, fast cooled, and measured at 80°K, a broad asymmetric band is observed at 450 nm with 255 nm optimum excitation. With 280 nm excitation a sharp line doublet is observed with peaks at 497 and 503 nm. An additional broad band occurs at 540 nm resulting from 320 nm excitation and 345 nm excitation produces a peak at 785 nm. The only positive identification is that of the sharp line doublet attributed to transitions from the $^3P_0$ and $^3P_1$ 4f levels to the $^3H_4$ ground state for the trivalent rare earth Pr^{+3} (9).

The effects of the different annealing treatments on the emission intensities for the different types of crystals are shown in Table II. The significant results in this table may be summarized as follows:

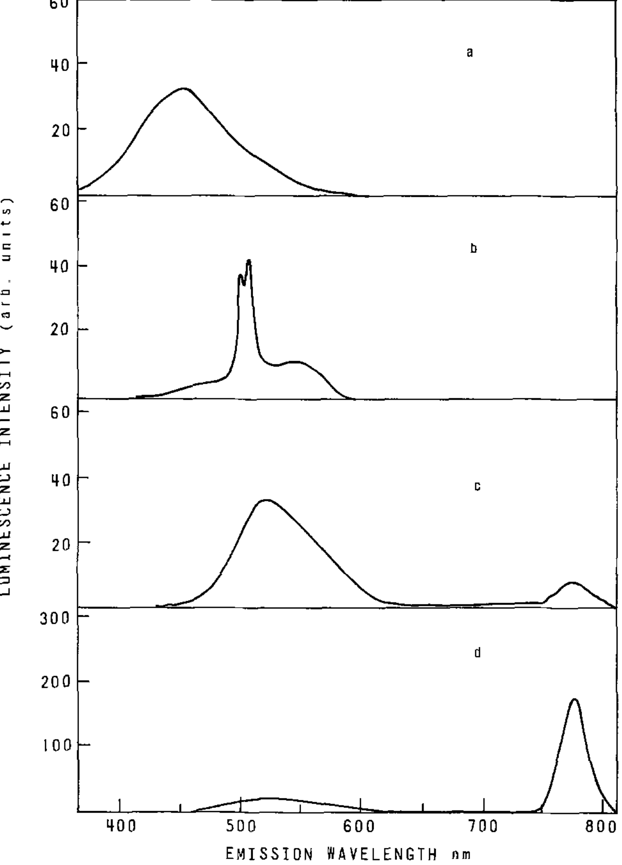

Fig. 1. Luminescence of pure ThO_2 at 80°K after an air anneal at 1675°K. a, 255 nm excitation; b, 280 nm excitation; c, 320 nm excitation; d, 345 nm excitation.

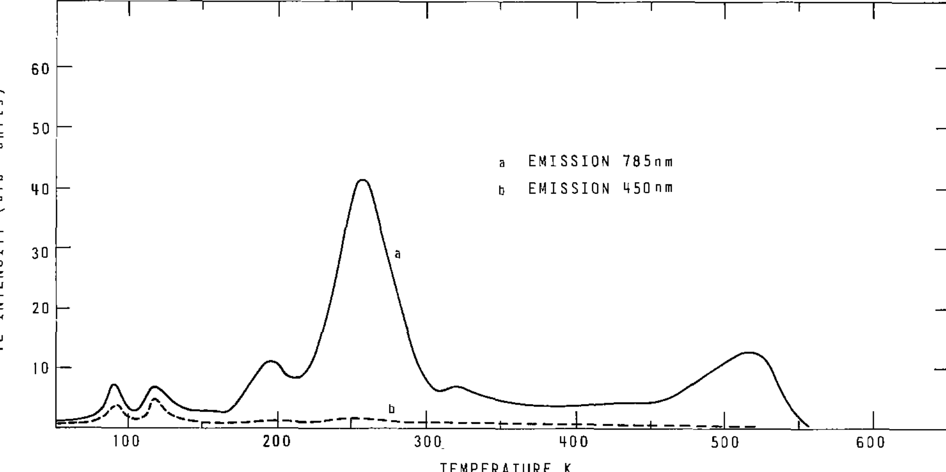

Fig. 2. Thermoluminescence of pure ThO_2 resulting from: curve a, 345 nm excitation at 80°K on oxidized ThO_2; curve b, 255 nm excitation at 80°K on reduced ThO_2.

1. Reducing anneals increase the 450 nm emission intensity.
2. The intensity of the 450 nm emission is also increased for Ca^{+2}- and Y^{+3}-doped crystals which have been subjected to the oxidizing anneals.
3. Doping with Ta^{+5} decreases the intensity of the 450 nm emission in reduced crystals.
4. Doping with Ca^{+2} directly increases the intensity of the 450 nm emission, whereas doping with Y^{+3} introduces an additional band at ~400 nm and doping with Ta^{+5} introduces a long wavelength shoulder at 472 nm.
5. The 500 nm emission (Pr^{+3}) is most severely decreased by doping with Ca^{+2} and Y^{+3} in air-annealed crystals. The relative effectiveness for decreasing the 500 nm emission is $Y^{+3} > Ca^{+2} >> Ta^{+5}$.
6. The intensity of the 540 nm emission is generally decreased by doping.
7. A new band appears at 565 nm when Ca^{+2}-doped crystals are annealed in carbon monoxide.
8. When pure crystals are annealed in dry H_2 a very large and complex band structure develops with broad maxima at 525 and 600 nm, and a sharp line shoulder at 655 nm. The complex new bands mask any 540 nm emission. The complex band structure is eliminated by doping.
9. The 785 nm emission is only observed in oxidized crystals and the intensity decreases on doping.

In general, emission intensities were decreased when the crystals were subjected to the slower cooling rate. In particular, the complex band structure in hydrogen-annealed crystals was almost completely eliminated by slow cooling. The emission intensities did not change with annealing time after a minimum of ~7.2 × 10^3 sec at 1675°K. Shorter anneals, however, appeared to produce only partially oxidized and reduced crystals.

Table II. Effects of impurities and annealing treatments on the intensity of the photoluminescence induced by u.v. excitation

Crystal type	Emission intensities at 450 nm	500 nm	540 nm	785 nm	Annealing atmosphere

† Additional large emission band at 400 nm
* Additional emission band at 472 nm.
‡ Emission shift to 565 nm maximum.

The effect of the excitation time on the photoluminescence emission intensity was also studied. At 80°K excitation of oxidized pure crystals with 345 nm light caused the intensity of the 785 nm emission to decrease with time, whereas excitation with 255 nm light on the reduced pure crystals did not cause the intensity of the 450 nm emission to change with time. The consequences of this behavior are illustrated by the thermoluminescence (TL) glow curves for oxidized and reduced pure ThO_2 in Fig. 2. When reduced ThO_2 is excited with 255 nm light at 300°K the intensity of the 450 nm emission increases with time for both Ca^{+2}-doped and pure crystals, is constant for Ta^{+5}-doped ThO_2, and decreases with time for Y^{+3}-doped crystals. This time-dependent behavior has long been associated with charge trapping (10, 11). In the present study the increase with time is greatest for Ca^{+2}-doped crystals and should be evident in the TL glow curves. The TL data are presented in Fig. 3. A detailed study of the TL of pure ThO_2 has been made by the authors (12). The present study on doped ThO_2 indicates that, contrary to the results of the time-dependent increases, the TL intensity for Ca^{+2}-doped ThO_2 is much lower than that for pure ThO_2.

Thermal quenching of luminescence has also been known for many years (10, 11). An important aspect of the present work was to study the temperature dependence of the luminescence intensity for ThO_2 crystals, both pure and doped, oxidized and reduced. Since it has previously been observed (this paper) that the luminescence intensity is time dependent, the measurements of luminescence intensity as a function of increasing temperature were performed at discrete temperature intervals rather than by continuous monitor-

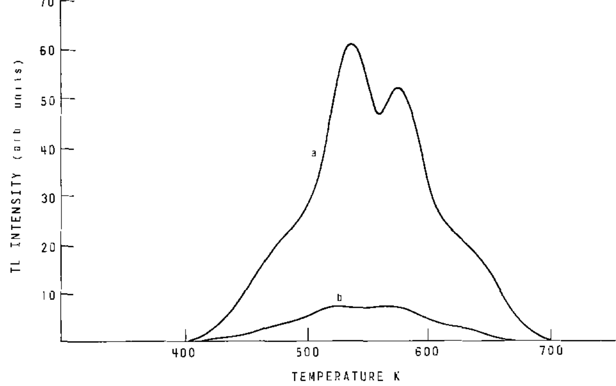

Fig. 3. Thermoluminescence of reduced ThO_2 after 255 nm excitation at 300°K. Curve a, pure ThO_2; curve b, Ca^{+2}-doped.

ing to minimize the time-dependent effects. The temperature dependence of the intensities of the 450 and 500 nm emissions are illustrated in Fig. 4 and 5, respectively.

It can be seen from Fig. 4 that not only does doping with Ca^{+2} and Y^{+3} enhance the intensity of the 450 nm emission at 80°K but the temperature dependence of the emission differs in the pure and doped material. The temperature dependence of the emission intensity also differs for the oxidized and reduced pure crystals. The annealing effects, however, in the doped crystals are much less important than the dopant. For the 500 nm emission the main points to note in Fig. 5 are:

1. Only for reduced pure ThO_2 is there significant 500 nm emission above 400°K.

2. The quenching profiles for Ca^{+2}-, Y^{+3}-, and Ta^{+5}-doped ThO_2 all differ; but are all self-consistent for different annealing atmospheres.

3. In doped crystals, the annealing atmosphere affects the 500 nm emission more than the 450 nm emission.

Discussion

At least four emission bands are observed in ThO_2 as a result of u.v. excitation. One of these consists of a sharp line doublet and is attributed to 4f transitions in the accidentally incorporated trivalent rare earth praseodymium, Pr^{+3}. Impurity analysis indicates that Pr is only present to a concentration of 2 ppm (Table I). While it is well known that ThO_2 is an excellent host for rare earth activators (13), the low Pr concentration and the fact that other rare earth impurities, *e.g.*, Ce, Gd, and Nd, while present in higher concentrations (5-10 ppm) do not show detectable luminescence suggest that the emission from Pr^{+3} is possibly being activated by a charge transfer type of process with neighboring ions (14).

Information regarding the nature of the center or centers responsible for the broad asymmetric 450 nm emission band can be obtained from examination of Table II. The intensity of the emission is enhanced by reduction which increases the oxygen vacancy concentration. The emission intensity is also enhanced by doping with Ca^{+2} and Y^{+3}. Charge neutrality requires an increase in the oxygen vacancy concentration when a Th^{+4} ion is substitutionally replaced by a Ca^{+2} or a Y^{+3} ion. Furthermore, doping with Ta^{+5} which decreases the oxygen vacancy concentration also decreases the 450 nm emission. The evidence suggests that the 450 nm emission is directly dependent on the oxygen vacancy concentration.

Arguments may be proposed that variable valence impurities, *e.g.*, Fe^{+2}, are solely responsible for the 450 nm emission. It seems to the authors, however, that total charge compensation by relatively small amounts of variable valence impurities is highly improbable. The precise role of the oxygen vacancies is not known. One may be observing the F center in ThO_2 (2 electrons trapped at a single anion vacancy). Absorption of 255 nm light may convert some F centers to F^+ centers (15). For MgO the F and F^+ bands overlap and the presence of the F^+ center can only be detected by EPR (16). Although many EPR studies have been made on single crystals of ThO_2 (17-21) no undisputed evidence has yet been advanced for the F or F^+ center. Many of the previous EPR studies either concentrated on signals from deliberately added rare earth impurities, or the

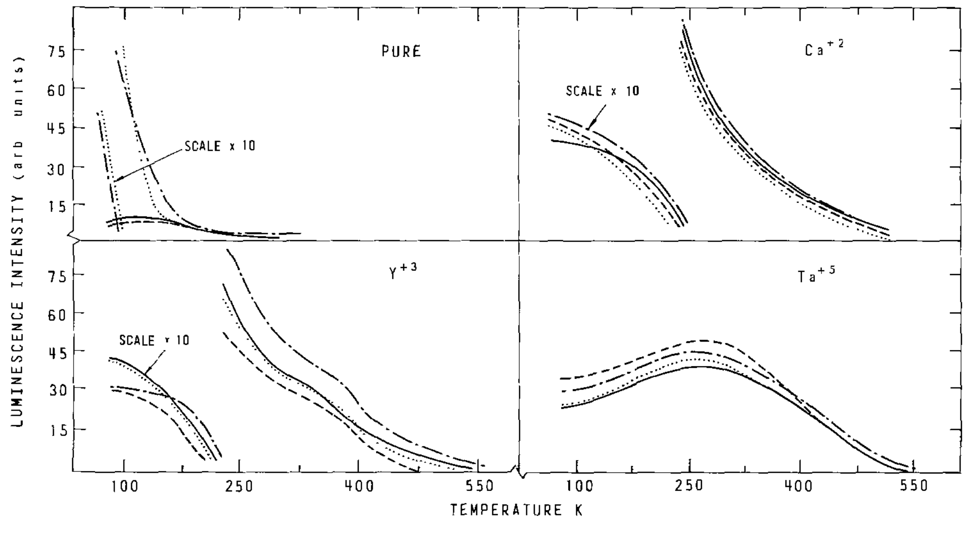

Fig. 4. Effects of the annealing atmosphere on the temperature dependence of the 450 nm emission resulting from 255 nm excitation in pure and doped ThO_2. ———, Air annealed; - - - -, CO_2 annealed; . - . - ., CO annealed; . . . . , H_2 annealed.

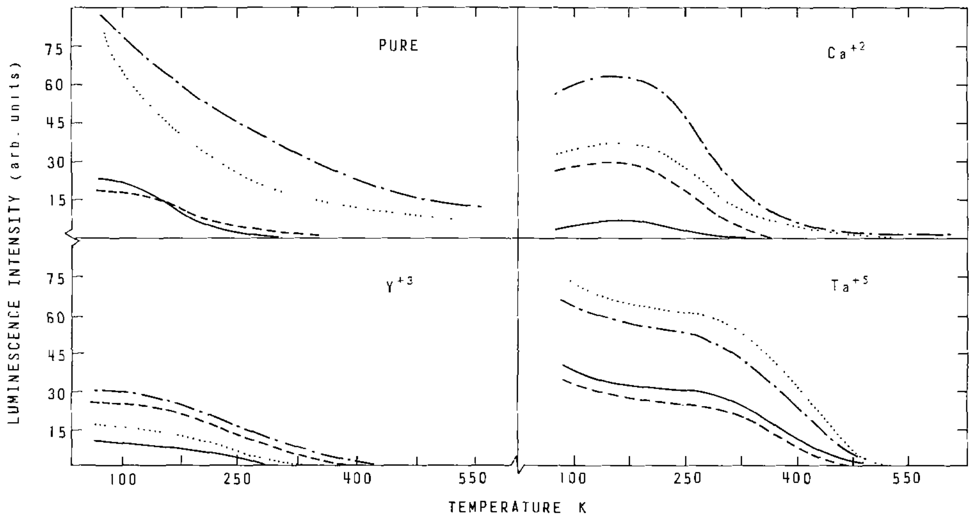

Fig. 5. Effects of the annealing atmosphere on the temperature dependence of the 500 nm emission (Pr^{+3}) resulting from 280 nm excitation in pure and doped ThO_2. ———, Air annealed; - - - -, CO_2 annealed; . - . - ., CO annealed; . . . . , H_2 annealed.

crystals were sufficiently impure that signals from Gd^{+3} or Pb^{+3} ion impurities masked other effects. Detailed EPR studies on well-characterized ThO_2 crystals of high purity, both before and after exposure to u.v. irradiation, are required to resolve this problem, although lack of sufficient nuclei spin in ThO_2 may make positive identification difficult (22).

The identity of the center(s) responsible for the 540 nm emission is not known. TL data (12) indicate that Tb^{+3} and Er^{+3} also act as recombination sites in ThO_2. These rare earths luminesce around 540 nm in ThO_2 (9) but they should show sharp line rather than broad band emission.

The 785 nm emission is only present for oxidized crystals and may be associated with variable valence transition metal ion impurities. V^{+3}, Cr^{+3}, and Mn^{+4} luminesce near this wavelength in other materials (23-25). Cr^{+3} has been unambiguously shown to luminesce above 700 nm in oxidized MgO crystals (26). Present impurity analysis, however, would tend to favor Ti or Fe and taken in conjunction with oxidation-reduction potentials suggest that Fe^{+3} may be the impurity ion responsible for the 785 nm emission. Selective ion implantation studies are attempting to resolve this uncertainty.

The appearance of a band at 400 nm on doping with Y^{+3} suggests that one or both the Y^{+3} ions remain in the vicinity of the oxygen vacancy they create to maintain charge neutrality. The emission characteristics of the center would then be altered. It appears that doping with Ta^{+5} which produces the 472 nm shoulder is involved in a similar process. While doping with Ca^{+2} directly enhances the intensity of the 450 nm emission, a new band at 565 nm is observed in crystals annealed in carbon monoxide. The Ca^{+2} ions may be complexing with the centers responsible for the 540 nm emission thereby producing a new center which luminesces at 565 nm.

The higher luminescence with faster cooling is simply evidence of the nonequilibrium quenching of defects and impurities. While the attempts to correlate the emission centers with defects is of necessity highly speculative it is important to remember that the luminescence behavior of ThO_2 is critically dependent on the purity and annealing treatment of the crystals used.

The luminescence efficiency of rare earth ions in various host lattices has been widely studied during the last decade (27-29). The well-known configuration coordinate models (30,31) are always invoked to explain the presence or absence of luminescence and it has been established that the difference, Δr, between the equilibrium configuration of the excited state of a defect center and that of the ground state must be small if luminescence is to occur. Blasse and Bril (28) have shown that Δr depends on the size of the host lattice ion for which the rare earth has been substituted and on the magnitude of the charge and size of the lattice ions surrounding the rare earth. In the present investigation the rare earth Pr^{+3} is surrounded by highly charged Th^{+4} ions which in the pure crystal give the host lattice great bonding strength, which causes Δr to be relatively small. The introduction of lower charged Ca^{+2} and Y^{+3} ions into the lattice weakens the lattice bonding and increases Δr. The luminescence efficiency of the rare earth ion should, therefore, be lowered in ThO_2 by doing with Ca^{+2} and Y^{+3}. This is in agreement with the results of Table II. The effect of Ta^{+5} doping, however, cannot be explained in this manner. Ta^{+5} should increase the bonding strength and thereby decrease Δr and increase the luminescence. This effect is not observed. Other factors which affect Δr are changes in ionic radius of surrounding ions and changes in the symmetry of the immediate lattice environment. Symmetry effects are frequently very significant (32). Generally the higher the symmetry around a rare earth ion, the lower the intensity of the rare earth emission. Although the factors previously mentioned are undoubtedly important, no completely self-consistent explanation of the changes in luminescence intensity with doping can be advanced at present.

The configuration co-ordinate models also schematically explain the temperature dependence of the luminescence. Nonradiative return from the excited state to the ground state of a defect center is possible via the point of intersection of the two parabolas. The situation at the intersection point, however, is complicated by the intersection of the ground excited states at this point. Little quantitative evidence is available on the effects of changing the ion size, charge, etc. on the temperature dependence of the luminescence. Indeed it is only very recently (33) that the energy levels and wave functions necessary to construct an accurate configuration co-ordinate diagram have been calculated for the F and F^+ in MgO and CaO, and even in these relatively simple centers and simple oxides the temperature dependence effects are still being evaluated (34). It is also only recently in other materials that theoretical studies have been undertaken of the temperature quenching of narrow line and broad band emissions using quantum mechanical single configuration co-ordinate models (35).

The fact remains, however, that doping with Ca^{+2} and Y^{+3} produces dramatic changes in the temperature dependence of the 450 and 500 nm emissions in ThO_2 (Fig. 4 and 5). One of the implications of this is that previously obtained TL data on doped ThO_2 can now be explained.

As was pointed out earlier in this paper the increase of 450 nm luminescence with time of 255 nm excitation was greater for Ca^{+2}-doped ThO_2 than for the pure crystal. Effects of this increase, indicative of trap filling, were not apparent when the glow curves of the pure and Ca^{+2}-doped ThO_2 were measured. Figure 3 shows that the TL intensity is approximately 15 times greater for pure ThO_2 than for Ca^{+2}-doped ThO_2. Previous studies (8, 12) have indicated that in ThO_2 the rare earth ions, in particular Pr^{+3} (500 nm emission), act as the electron-hole recombination sites. The TL intensity, therefore, must be proportional to the luminescence efficiency of the rare earth ion (Pr^{+3}) at the temperature at which the electron-hole recombination takes place. Figure 5 indicates that in the temperature region 400°-600°K the luminescence efficiency of the Pr^{+3} is much less for Ca^{+2}-doped ThO_2 than for pure ThO_2. Hence the observed TL intensity is also much less for Ca^{+2}-doped crystals than for pure ThO_2.

The presence of Ca^{+2} and Y^{+3} ions also influences the temperature dependence of the 450 nm emission intensity (Fig. 4). Both Ca^{+2} and Y^{+3} greatly enhance the 450 nm emission in the region 100°-350°K. The centers giving rise to the 450 nm emission act as the main recombination centers for electron-hole recombination at temperatures below 400°K (12). One would expect, therefore, that the TL emission intensity in this temperature range would be greater for Ca^{+2}- and Y^{+3}-doped ThO_2 than for pure ThO_2. Recent results (36) indicate that this is indeed the case.

Conclusions

Photoluminescence occurs in ThO_2 as a result of u.v. excitation. A broad asymmetric emission band at 450 nm may be due to closely overlapping F and F^+ centers possibly associated with the reduced state of variable valence impurities. A doublet at 497 and 503 nm results from rare earth impurity Pr^{+3}. A second broad band occurs at 540 nm whose origin is unknown. Finally an emission band at 785 nm which probably arises from the presence of transition metal impurities is present in oxidized crystals. Fe^{+3}, Cr^{+3}, or Ti^{+2} are possible sources.

The photoluminescence can be altered by varying the annealing atmosphere, the duration of the anneal, the cooling rate, the time of u.v. excitation, and the temperature of excitation. The photoluminescence can also

be changed by deliberate doping with Ca^{+2}, Y^{+3}, or Ta^{+5}. Impurities have a very marked effect on the temperature dependence of the luminescence efficiency of the emission centers. These effects can explain many of the variations observed in the thermoluminescence of pure and doped ThO_2.

Growth and Structure of Polycrystalline Indium Phosphide Layers on Molybdenum Sheets

Tadashi Saitoh, Sunao Matsubara, and Shigekazu Minagawa*

Central Research Laboratory, Hitachi, Limited, Kokubunji, Tokyo, Japan

ABSTRACT

Pinholeless polycrystalline indium phosphide layers were grown on molybdenum sheets at temperatures lower than 600°C using indium and phosphorus trichloride as the source materials. The low activation energy of the deposition rates and weak dependence of the rates on the partial pressure of indium monochloride suggest that surface processes play an important role in the growth of polycrystalline films. It was ascertained by an x-ray diffraction measurement that the {110} and {331} orientations become noticeable with increasing thickness at higher temperatures, whereas the <111> orientation is dominant at lower growth temperatures. The development of the <110> orientation produces films with a columnar structure, which could be explained by the dependence of the growth rate on the crystallographic orientation.

Indium phosphide is a promising material for solar cells because the indium phosphide cell has high theoretical conversion efficiency (1). In order to obtain low-cost solar cells for terrestrial use, it is necessary to fabricate thin-film solar cells of polycrystalline indium phosphide on low-cost substrate materials.

To date, few papers have been published on the preparation of polycrystalline indium phosphide, although research on the epitaxial growth had been carried out (2-4). In this paper, polycrystalline layers were de-

* Electrochemical Society Active Member.

Key words: deposition rates, grain size, orientation.

posited on thin molybdenum sheets by the reaction of indium with phosphorus trichloride in a hydrogen atmosphere. The indium transport reaction and the process for the deposition of pinhole-free indium phosphide were examined. The rate-determining step of the deposition is discussed. The grain size of the deposited film, which is generally required to be larger than the minority-carrier diffusion length, was measured as a function of deposition conditions since highly oriented polycrystalline films may be essential to realize efficient solar cells (5, 6). The orientation of the polycrystalline films was characterized by the x-ray method and reflection electron micrography.

Experimental

Film growth.—Polycrystalline indium phosphide was deposited on 50 μm thick molybdenum sheets by reaction of In and PCl_3 in hydrogen. The molybdenum sheets were selected because of the small thermal expansion coefficient mismatch between molybdenum and indium phosphide and because of its chemical stability in a growth atmosphere. Prior to growth, the sheets were ultrasonically cleaned in trichloroethylene and subsequently in methanol, and chemically etched in a 1 H_2SO_4-1 HNO_3-3 H_2O solution.

The deposition was carried out in a horizontal reactor with a conventional gas feed system (2, 3), typical for an epitaxial growth of III-V semiconducting materials. The temperature of the indium source was held at 750°C and the temperature of the molybdenum sheets was in the range of 450°-650°C. A typical flow rate of the hydrogen gas was 200 cm^3/min (at room temperature). The partial pressure of PCl_3 in the feed gas was 2-13 $\times$ 10^{-3} atm. The thickness of the deposited layers was determined by measuring the surface line profiles of step-etched samples.

Structure.—Measured x-ray intensities (CuK_α radiation) were normalized by the theoretical values calculated by the following equation (7)

$$I = C \cdot M \cdot P \cdot L \cdot |F|^2 \cdot A \cdot T \quad [1]$$

where C is a constant, M the multiplicity of the planes, P the polarization factor, L the Lorentz factor, F the structure factor, A the absorption factor, and T the temperature factor. For powder samples with a plate-like shape, the absorption factor is described as (7)

$$A = A_o\left\{1 - \exp\left(-\frac{2\mu t}{\sin\theta}\right)\right\} \quad [2]$$

where A_o is a constant, μ the linear absorption coefficient, t the thickness, and θ the x-ray diffraction angle. A is almost equal to A_o if the thickness, t, of indium phosphide is more than 20 μm. The equations used to calculate other factors are those found in Guinier's book (7).

Results and Discussions

Transport of indium.—A source temperature of 750°C was adopted in this experiment because a transport efficiency defined below was reported to saturate and approach an equilibrium value at temperatures higher than 700°C (8). First, the amount of indium consumed during the reaction was measured as a function of the reaction time at a linear flow rate of 0.75 cm/sec, calculated at 750°C. The amount was found to increase in proportion to the reaction time at PCl_3 partial pressures of 2.3 $\times$ 10^{-3}-1.2 $\times$ 10^{-2} atm. As for the effect of the PCl_3 partial pressures in the feed gas, the transport rate of indium increased in proportion to the PCl_3 partial pressure as indicated in Fig. 1.

The transport efficiency, defined by the ratio of the number of moles of indium transported to the number of moles of chlorine fed during the growth time, was 95%. This is in good agreement with the 99% obtained by thermodynamic calculation and an observed value reported for the same reaction in a vertical reactor (4). The result shows that the transport reaction around the source occurs under equilibrium conditions.

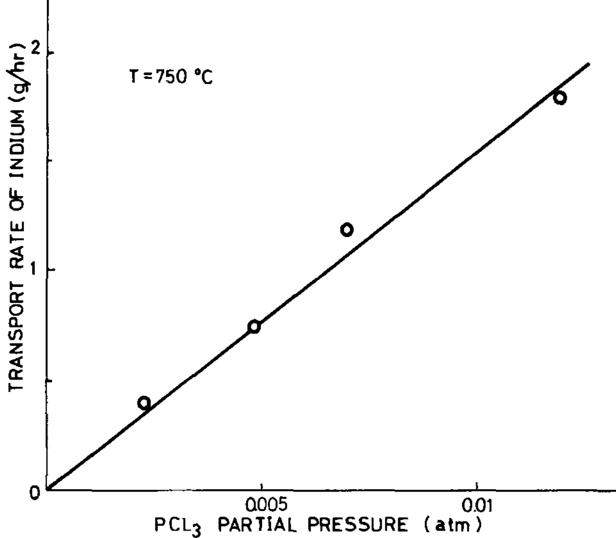

Fig. 1. Transport rate of indium as a function of PCl_3 partial pressure. The temperature of the indium source is 750°C.

Deposition of indium phosphide.—The deposition of polycrystalline indium phosphide was carried out at temperatures lower than 650°C which had been used previously for epitaxial growth on single crystal substrates (2-4). In a film deposited at 650°C, there existed small holes where molybdenum surfaces could be seen, although the grain size was larger than that in a film prepared at lower temperatures. Temperatures lower than 600°C were found to be useful to obtain homogeneous films without pinholes. This suggests that sufficient supersaturation is necessary for uniform polycrystalline growth.

The thicknesses of the polycrystalline deposits were found to increase in proportion to the deposition time except in the initial stage of the deposition. From an Arrhenius plot of the deposition rates shown in Fig. 2, the activation energy was determined to be 15 kcal/mole. This agrees approximately with the activation energies of epitaxial growth on low-index planes (4).

Mass spectroscopic analysis (8) of gases in the deposition zone has shown that indium monochloride reacts with phosphorus compounds according to the reaction

$$InCl(g) + P^*(g) + \frac{1}{2}H_2(g) = InP(s) + HCl(g) \quad [3]$$

where P^* represents P_2 and P_4. Assuming that the

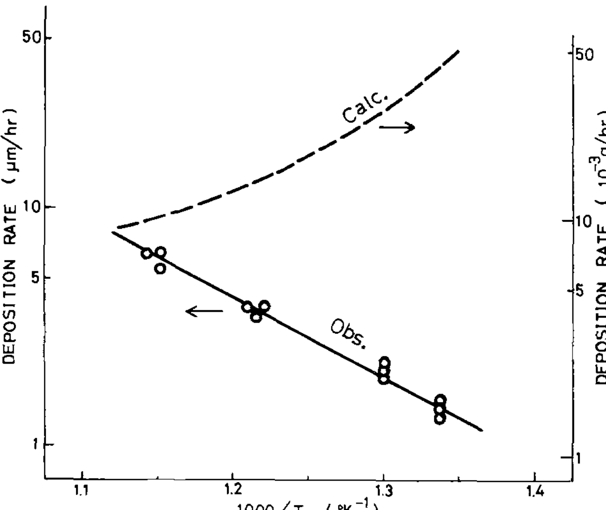

Fig. 2. Arrhenius plot of deposition rate for polycrystalline indium phosphide. The dashed line is calculated under thermodynamic equilibrium. The PCl_3 partial pressure is 7.2 $\times$ 10^{-3} atm.

phosphorus compound in the gas phase is the tetramer, deposition rates were calculated using the above equation. As indicated by the dashed line in Fig. 2, differences were observed on the Arrhenius plots between calculated and observed values. This result shows that the deposition reaction cannot be described as being carried out under thermodynamic equilibrium.

The deposition rate was examined as a function of the PCl_3 partial pressure which corresponds to one-third of the InCl partial pressure appearing in Eq. [3]. The rate increases only slightly with increasing PCl_3 partial pressure as shown in Fig. 3.

The weak dependence of the deposition rate on the partial pressure suggests that the deposition process is not limited by mass transfer of reactants in a gas phase but by surface processes such as surface reaction, surface diffusion, adsorption and desorption processes.

Grain size.—The grain size of the polycrystalline indium phosphide layers tends to increase both with increasing deposition temperature and thickness; moreover, the grain size is not always homogeneous. In the case of a layer deposited at 600°C, the mean value of the grain size measured by the Fullman method (9) was about 7 μm (about 1 μm in a film deposited at 500°C). Roughness of the surface was about 2 μm for a 12 μm thick film deposited at 600°C.

The mean grain size increased and saturated with increasing film thickness as shown in Fig. 4. This tendency is related to the observation that small nuclei on a molybdenum surface grow in size and finally coalesce with each other.

A columnar structure in a cross section of the film shown in Fig. 5 suggests the saturation of the grain size. The columnar structure indicates that each grain grows mostly perpendicular to the substrate. The columns were found to develop with increasing growth temperature and thickness, which relates to the development of preferred orientation as mentioned below. However, the columns were found not to grow immediately from the substrate and not to exist in layers deposited at temperatures lower than about 500°C.

Preferred orientation.—X-ray diffraction spectra of InP films consisted primarily of diffraction peaks of low-index faces such as {111}, {110}, {311}, and {331}. Also, relative intensities of the diffracted peaks were found to vary with the growth temperature and the thickness of the film. For a film deposited at 600°C, {110} and {331} faces developed, whereas {111} and {311} planes diminished with the thicknesses for films thicker than 5 μm as shown in Fig. 6. On the other hand, layers thinner than 5 μm were random in orientation. As for a film deposited at 500°C, the diffracted

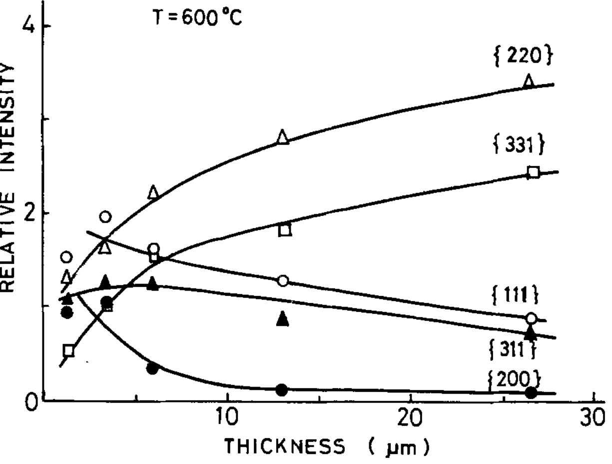

Fig. 6. The variation of relative intensity of x-ray diffraction with thickness for various crystal planes in the films deposited at 600°C.

intensities decreased in the order of {111} > {220} > {311} > {331} ≧ {200} and the tendency held for films varying in thickness. However, the degree of preferred orientation was not found strong.

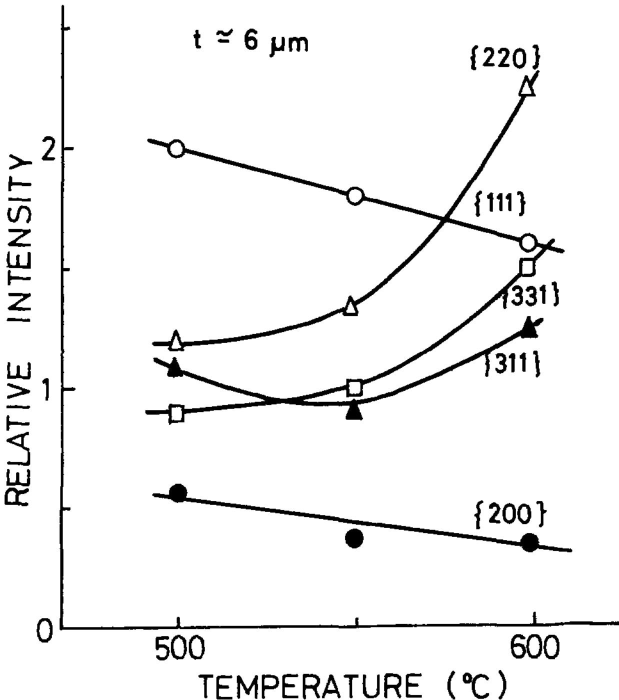

Fig. 7. The variation of relative diffracted intensity with deposition temperature for various crystal planes in the films with thickness of about 6 μm.

Next, we examined the effect of growth temperature on the orientation of the films. In the case of thin films (about 1 μm), relatively random orientation was obtained irrespective of various growth temperatures, although {111} orientation developed to some extent. For the thicker film (6 μm) shown in Fig. 7, {110} and {331} planes developed, {111} and {100} planes diminished, and the {311} plane did not change with increasing growth temperatures. The inverse tendency between the {110} and {111} orientations for increasing temperature is also similar to the result obtained for polycrystalline silicon films prepared by pyrolysis of silane on an oxidized silicon surface (10).

In order to examine the effect of the partial pressure of reactants on the orientation, the partial pressure of PCl_3 was varied from 2×10^{-3} to 1×10^{-2} atm. However, no effect in preferred orientation was observed.

In the x-ray method, the information is obtained over an x-ray penetration depth of tens of microns, while reflection electron microscopy provides information on the degree of preferred orientation with less than a micron of the crystal surface. The reflection electron micrographs of the film deposited at 600°C showed random spots. This indicates that the surface consists of relatively large grains with random orientation. As the {220} intensity was dominant in the x-ray diffraction, the crystallites are oriented in the <110> growth direction, but have randomly oriented surfaces.

On the other hand, for films grown at temperatures less than 550°C, the electron micrographs consisted of Debye rings. And the micrographs showed that among the various planes, the {111} plane was relatively parallel to the substrate surface, but the {110} face was inclined or random in the orientation. Especially, the orientation of the {111} face is consistent with that obtained by x-ray diffraction. This indicates that the orientation near the surface is equal to that in the film.

The <110> preferred orientation of InP films prepared at 600°C is in agreement with that of polycrystalline silicon films (10). The {110} face was reported to be the plane with the fastest growth rate among low index planes for InP (4) and Si (11). In addition, for an epitaxial growth of indium phosphide, the growth rate was in the order of {110} > {111}B > {100} surfaces (4), corresponding to the order of the orientation. Therefore, in the polycrystalline growth of InP, the planes with higher growth rates grow preferentially and, thus, other planes cannot grow in the direction parallel to the substrate surface. As a result, the preferred orientation is formed for the planes with higher growth rates.

Conclusions

Polycrystalline indium phosphide was deposited on molybdenum substrates by vapor-phase growth to investigate the growth mechanism and the structure of the film. The conclusions obtained are as follows:

1. The indium transport reaction with phosphorus trichloride occurs under thermodynamic equilibrium.
2. Homogeneous polycrystalline films are obtained at temperatures lower than 600°C. The activation energy of 15 kcal/mole and the dependence of the deposition rate on the partial pressure of the reactant suggests that surface processes determine the deposition rate.
3. The grain size depends on the deposition temperature but is independent of the partial pressure of PCl_3 in the feed gas.
4. The crystal grains are oriented in the direction of {111} at low temperatures, but the {110} orientation and orientations near the <110> directions developed at higher temperatures and with increasing the thickness.

Acknowledgments

The authors wish to thank R. Takahashi for his advice on the vapor deposition and K. Ohbuchi for performing the x-ray diffraction experiments. The authors are also grateful to Dr. E. Maruyama for his critical reading of this manuscript and Drs. Y. Otomo and T. Tokuyama for their encouragement.

A High Speed X-Ray Topographic Camera for Semiconductor Wafer Evaluation

D. L. Parker and W. A. Porter

Institute for Solid State Electronics, Department of Electrical Engineering, Texas A&M University, College Station, Texas 77843

ABSTRACT

A new x-ray topographic camera is described which reduces the exposure time for the production of useful topographs of semiconductor wafers by at least one order of magnitude. The gain is achieved by holding the wafer with a curved vacuum chuck such that rays from a distant point source strike every portion of the wafer at the Bragg angle. Thus the Rowland focusing feature which has previously been used in many x-ray instruments for spectroscopy and diffractometry has been incorporated in the new camera. Included is an x-ray topograph of an entire 2 in. silicon wafer made on dental film during a 30 sec exposure.

For the past several years x-ray topography has been recognized as the best nondestructive means for the assessment of crystal lattice damage created during each processing step in the fabrication of semiconductor devices (1). However, essentially all previous applications have been in the research groups of the larger semiconductor manufacturers, government labs, and academic institutions. The high cost per topograph has prevented any widespread application of the technique in production process control. The high cost is due to a combination of the expensive equipment required, highly trained personnel, and long exposure times that have been required using conventional techniques. The new x-ray camera described here can be expected to significantly reduce the cost per topograph through the reduced exposure time required.

The Camera Design

The new camera is of the Berg-Barrett type with the additional feature that the specimen is elastically deformed such that all rays from a distant point source of x-rays simultaneously satisfy the Bragg condition for a given set of lattice planes. Thus, the fraction of the total flux from the source that is actually used is increased with a corresponding reduction in exposure time. The exact shape into which the wafer must be deformed can be understood from the diagram in Fig. 1. The curved line represents the path whose tangent line at any point makes a constant angle ψ with a ray from the origin to that point. Elementary calculus may be used to show that the locus is an exponential spiral, i.e.

$$\rho = d \exp [\phi/\tan \psi]$$

where ρ and ϕ are the plane polar coordinates and d is a constant. The local radius of curvature is given by

$$R = \rho/\sin \psi$$

The wafer is, of course, a three-dimensional object which requires compound bending in order to simultaneously satisfy the Bragg condition at all points on its surface for rays diverging from a distant point source. Careful consideration will show that the necessary wafer curvature in planes perpendicular to the central scattering plane is not unique. It is only necessary that the wafer surface take the curved shape shown in Fig. 1 in all planes which (*i*) contain the point source, and (*ii*) are perpendicular to the diffracting planes. In practice the wafer curvature (if any) in planes perpendicular to the central scattering plane is of minor importance just as is the case in conventional topography.

Key words: dislocation, quality control, silicon, processing, diffraction.

Several wafer-bending schemes were tried before a curved vacuum chuck was selected as the most reliable and adaptable technique. A concave spherical shape is currently being used for the vacuum chuck instead of the exact spiral cross section discussed above. A spherical shape was chosen for the following practical considerations:

1. No satisfactory means was found for accurately machining the exponential spiral shape within the necessary tolerances.
2. Random variations in the crystallographic orientation from wafer to wafer (small variations in ψ) make the achievement of perfect bending of all wafers difficult.
3. The symmetry of the spherical chuck allows two alignment axes to be used without remounting the specimen after the initial alignment prior to the exposure.

In order to predict the error introduced by using the spherical chuck the following calculation can be made. Let a circle of radius $d/\sin\psi$ osculate the spiral at the point $x=d$ and $y=0$. The slope of the circle at points intercepted by rays from the origin is given by

$$\left.\frac{dy}{dx}\right|_{\text{circle}} = \tan (\gamma + \phi)$$

where

$$\gamma = \cos^{-1} (\cos\phi \cos\psi)$$

The slope of the spiral at points intercepted by the same rays is given by

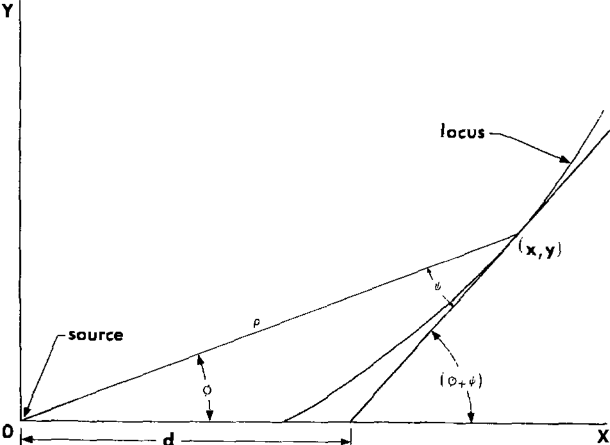

Fig. 1. The curved line is the exponential spiral $\rho = d \exp (\phi/\tan\psi)$ which is the locus that intersects all rays from the origin at the same angle ψ.

$$\left.\frac{dy}{dx}\right|_{spiral} = \tan(\phi + \psi)$$

Thus, the angular error, δ, is given by

$$\delta = \gamma - \psi$$

This theoretical angular error is considerably smaller than the experimental errors observed to date. Indeed, significant improvements in the chuck design are still possible. The failure of the wafer to conform exactly to the chuck shape is related to the partial vacuum pressure, the distribution and size of the vacuum feed points, as well as the hardness of the chuck material. Work continues on improving the chuck design to approach the predicted perfection of the exponential spiral. The problem that no single setting of the deformed wafer will simultaneously diffract x-rays from all portions of its surface is overcome by a slight rotation of the crystal (with film) during the exposure. This rotation is done about an axis through the center of the wafer and perpendicular to the central scattering plane. Thus, all portions of the wafer have equal opportunity to participate in the formation of the image provided the rate of rotation is constant.

Experimental

Although the curved wafer technique is applicable to a wide variety of materials and radiations, work to date has only been done on (111) silicon using copper target radiation and the (440) reflection. This choice makes the angle ψ about 18.1° and the total scattering angle (2θ) for $CuK\alpha_1$ 106.71°. Thus, the diffracted rays leave the wafer at about 88.6° or almost normal to the slice. The distance from the x-ray source to the center of the specimen was chosen to be 30 in. The vacuum chuck is 3 in. in diameter, made of glass, with a spherical depression whose lowest point is at the center of the chuck. The radius of the chuck curvature was chosen as 96 in. which matches the exact spiral shape at the center. With a single vacuum feed hole in the center, the chuck can receive any size slice up to 3 in. in diameter. Of course, each combination of radiation, Bragg reflection, and crystal orientation in general, requires a separate vacuum chuck. A scatter tube is used along with various lead collimators positioned in a slot on the end nearest the specimen. Each lead collimator has a different size elliptical hole to allow total illumination of several wafer sizes and to minimize unwanted scattering from the chuck itself. The film is placed parallel to and 1 in. from the specimen. This distance is optimum to prevent interference with the incoming x-rays from the source.

The essential features of the camera are shown in Fig. 2. Provision is made to rotate the chuck about an axis through the center of the wafer and perpendicular to the drawing in Fig. 2. This rotation is used both for the initial setting of the camera as well as the short scan during the exposure. The film rotates with the chuck about this axis. Provision is also made for rotation of the chuck about an axis in the plane of the drawing, through the center of the wafer, and perpendicular to the wafer. This rotation is used in the initial setting of the camera. A flat edge attached to the face of the chuck to match the wafer flat allows a sequence of wafers from the same batch to be photographed with a minimum of initial adjustments from wafer to wafer.

The x-ray topograph shown in Fig. 3 is of a 2 in. silicon wafer. The wafer had completed all thermal processing steps including metallization and annealing. The devices visible in the topograph are various sized diodes and capacitors. The slip-plane damage near the top and sides was deliberately introduced after the diffusion step as part of a defect-device performance correlation experiment.

The x-ray source was a Rigaku rotating anode generator with copper target operating at 35 kV and 100 mA. The target focus was 0.5 × 5 mm with a 6° take-off angle using one of the point source windows. The film was Kodak Dental Type DF46 (2¼ × 3 in.) with a 30 sec exposure. The scan during the exposure was 0.25° centered on the $K\alpha_1$ diffraction peak. This effectively excludes most of the $K\alpha_2$ image since the angular separation of the two peaks is about 0.2° for this reflection. The rotation during exposure effectively fills in the otherwise washed-out areas that are due to improper bending. However, rotation does reduce the resolution somewhat. If the wafer were perfectly spherically bent no rotation would be required due to the finite angular size of the focal spot. High resolution topographs can be made with the camera in the stationary mode with typical washed-out areas representing 20-40% of the total area of a 2 in. wafer. With the rotating anode generator the optimum exposure time for a 25 μm emulsion nuclear tracking plate is less than 2 min and about 2 hr for a high resolution plate.

One subtle, although significant, advantage of this new camera is its immunity to the usual difficulties encountered in attempting to make topographs of bowed wafers. Conventional topographic cameras require an oscillating or automatic Bragg angle control feature to produce adequate topographs of processed wafers due to the inevitable bowing. Further, this camera is relatively immune to backside lapping damage.

During the development of this camera it was discovered that too much partial vacuum on the chuck will produce high stress points in the wafer. These

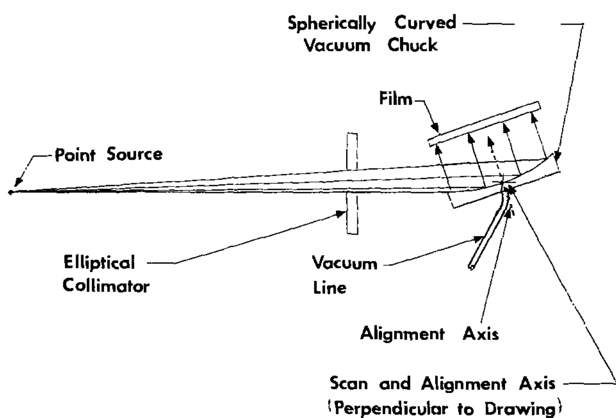

Fig. 2. Schematic diagram of the x-ray camera

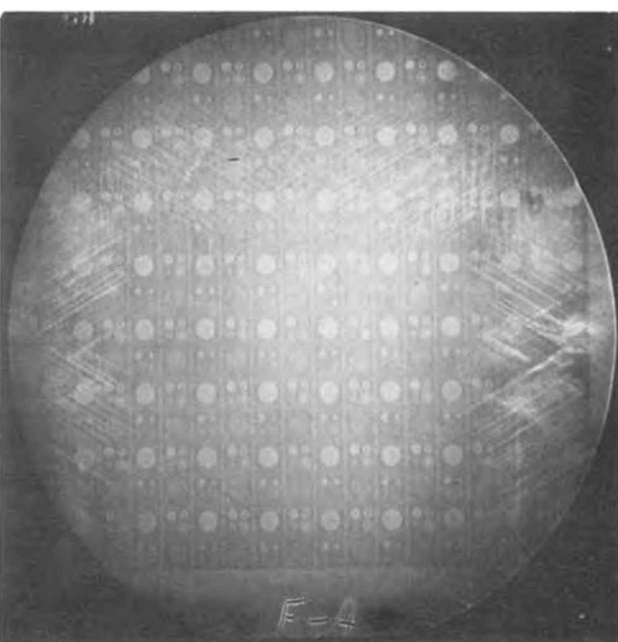

Fig. 3. An x-ray topograph (positive) of a 2 in. silicon wafer made on dental film with a 30 sec exposure.

stress points appear in the topographs as "dimples" particularly at the vacuum feed points. This problem is controlled by the use of a partial vacuum regulator. Typically, 10-15 mil wafers require only about 30 mm Hg differential pressure for bending. The stress required for bending the wafer is several orders of magnitude less than the localized stress produced by impurity atom mismatch and crystal defects. Thus, there is no evidence of the bending in the topograph and no evidence of residual damage to the wafer after the slight bending required during exposure.

Conclusions

In the camera's present configuration and with an automatic dental film processor with a daylight loading hood, one person can produce 20-30 x-ray topographs per hour. A commercial version of the camera designed for rapid wafer loading and alignment could double this throughput. Also, at least two cameras may be operated simultaneously with the same x-ray tube. Further, real-time TV inspection is a possibility (2). These considerations make 100% evaluation of high reliability devices as well as routine quality control inspection at every stage of wafer processing economically feasible.

Boron Segregation at Si-SiO$_2$ Interface as a Function of Temperature and Orientation

J. W. Colby and L. E. Katz*

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

The ion microprobe has been used to study the effects of crystal orientation and oxidation temperature on the segregation of boron at the silicon-silicon dioxide interface. The segregation coefficient was determined by measuring directly the total boron concentration in the oxide and the silicon at the interface, for (100) and (111) silicon, oxidized at 1000°, 1100°, and 1200°C in dry oxygen. It was found that boron segregation coefficients for (111) silicon are higher than those for (100) silicon for corresponding oxidation temperatures, and that these segregation coefficients decrease with increasing temperature. The experimental values of the boron segregation coefficient, m, may be described by

$$m_{(100)} = 0.03 \exp(0.52/kT)$$

$$m_{(111)} = 0.05 \exp(0.52/kT)$$

Diffusion coefficients were extracted from the experimental data using a modeling technique and agree well with the generally accepted values. The diffusion coefficients obtained for oxidizing ambient are given by

$$D_{(100)} = 0.19 \exp(-3.22/kT)$$

$$D_{(111)} = 2.04 \exp(-3.57/kT)$$

Upon thermal oxidation of silicon, an interface is formed which separates the solid silicon from the solid SiO_2 and which advances into the Si as oxidation proceeds. Impurities will redistribute at the interface until their chemical potentials on each side of the interface are equal. The ratio of the equilibrium concentration of boron in silicon dioxide to the equilibrium concentration of boron in silicon at the interface is called the equilibrium segregation coefficient. It is possible that the equilibrium segregation coefficient may not be identical to the experimental segregation coefficient. This will primarily be determined by the chemical potential differences and the kinetics of redistribution at the interface. The experimental segregation coefficient is called the effective or interface segregation coefficient.

Theoretical work has not determined the equilibrium segregation coefficient but merely bracketed it within the range of 10^{-3}-10^{+3} (1). Several studies (2-8) have been made in which a model for diffusion has been formulated, diffusion profiles experimentally determined in the silicon, and a value of the segregation coefficient chosen to force the data to fit the model. Values determined in this way have generally been in the range of 1-10.

Prince and Schwettmann (9) have studied segregation of boron from an implanted source, following steam oxidation. They used both step anodization and ion microprobe analysis to obtain profiles in the silicon and then used a modeling procedure to obtain the segregation coefficient. Their values of segregation coefficient for (111) wafers ranged from ~1.8 at 1200°C to ~5 at 1050°C.

The ion microprobe has been used in this study to determine the boron concentration on both sides of the interface thus providing a direct measure of the segregation coefficient. This avoids dependence on a modeling procedure as required by the above studies

(2-8). Such a technique has been employed (10, 11) previously. In one such study a value ~2 for the segregation coefficient of boron in silicon is quoted, however, such details as temperature of diffusion are not presented. We present here a study of the effect of orientation and temperature on the segregation coefficient of boron in silicon.

Experimental

Wafers from Czochralski grown crystals, boron doped (~$2 \times 10^{19}/cm^3$), with (100) and (111) orientations were used for these studies. Following appropriate cleaning, wafers of each orientation were oxidized (100% dry O_2) at 1000°, 1100°, and 1200°C for 20, 8, and 5 hr, respectively. The times were chosen to keep the oxide thickness approximately in the 4000-5000Å range.

Both the ion microprobe mass analyzer (IMMA)[1] and the direct imaging ion microscope[2] were utilized in the study. The bombarding or primary ions were $^{16}O_2^+$ at current densities (in the static beam of ~3-5 mA/cm^2). The beams were rastered in both machines and the secondary ions $^{11}B^+$, $^{30}Si^+$, and $^{28}Si^{++}$ were monitored and apertured to reduce crater sidewall effects. Values obtained from both machines agreed within two sigma limits.

The oxides were thinned to approximately 300Å and the oxide on the back of the wafer was completely removed prior to profiling, to reduce the effects of charging. As long as the oxide is sufficiently thin to allow some leakage current to flow, space charge does not become a problem, and stable profiles may be obtained even with a positive primary beam. The profiling was initiated in the oxide and continued across the interface into the silicon. The data were reduced to concentration by comparison with uniformly doped standards (boron-doped silicon and silica) which had previously been analyzed by the electron microprobe. Analyses obtained in this way have been shown to be accurate to within ±5% relative (12). Depth calibration is accurate to within ±2% (12). It should also be mentioned that for equivalent conditions of current density and accelerating potential, SiO_2 sputters approximately 8% faster than silicon. This difference in sputtering rate must be taken into account when converting ion probe data to depth profile.

Results and Discussion

A typical ion probe profile, reduced to concentration, is shown in Fig. 1. The boron concentration is shown in depth through the oxide, across the interface and into the silicon. The bulk silicon value, C_B, was measured at a depth >5 μm and is also shown.

Once the data has been appropriately reduced to concentration values as discussed above, the segregation coefficient of boron at the Si-SiO_2 interface is directly obtained by dividing the maximum value of boron concentration in the SiO_2 (C_o) immediately adjacent to the interface by the minimum boron concentration in the silicon (C_s) immediately adjacent to the interface as shown by Fig. 1 This has been done for the three temperatures and two orientations considered and the results are shown in Fig. 2. The results presented in Fig. 2 are an average of three or more determinations. The two sigma limits are also shown. It is immediately obvious that the segregation coefficient for (111) orientation is higher than for (100) orientation over the 1000°-1200°C temperature range considered. From the data, one obtains the following equations describing the segregation coefficient as a function of temperature

$$m = 0.03e^{0.52\ \mathrm{eV}/kT}\ (100) \qquad [1]$$

$$m = 0.05e^{0.52\ \mathrm{eV}/kT}\ (111) \qquad [2]$$

The average values and the two sigma limits for the segregation coefficient vary from 2.95 ± 0.25 at 1200°C to 5.63 ± 0.41 at 1000°C for (111) and from 1.96 ± 0.61 at 1200°C to 3.74 ± 0.29 at 1000°C for (100). These values for bulk samples and dry oxidations are in reasonable agreement with the values of Prince and Schwettmann (9) obtained by modeling for implanted wafers and steam oxidations for (111) orientations; the only reported data on variation of segregation coefficient with temperature. Comparison of segregation coefficient values must be made carefully since diffusion sources, wafer orientation, temperature of diffusion, ambient, and modeling techniques are different in many cases. There are indications (7, 8) however, that

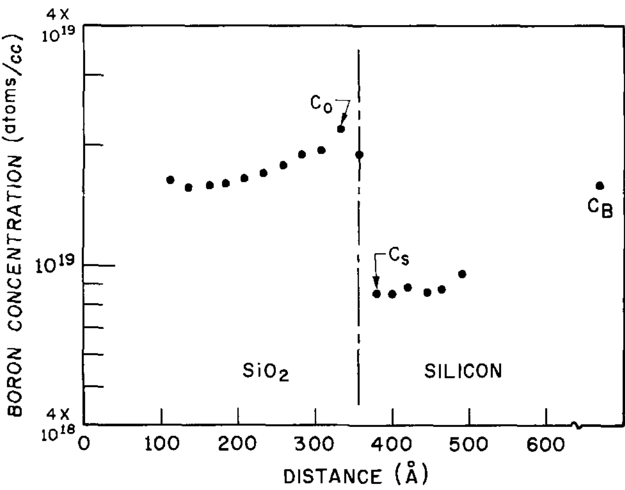

Fig. 1. Ion probe profile reduced to concentration, (100) orientation, 1100°C.

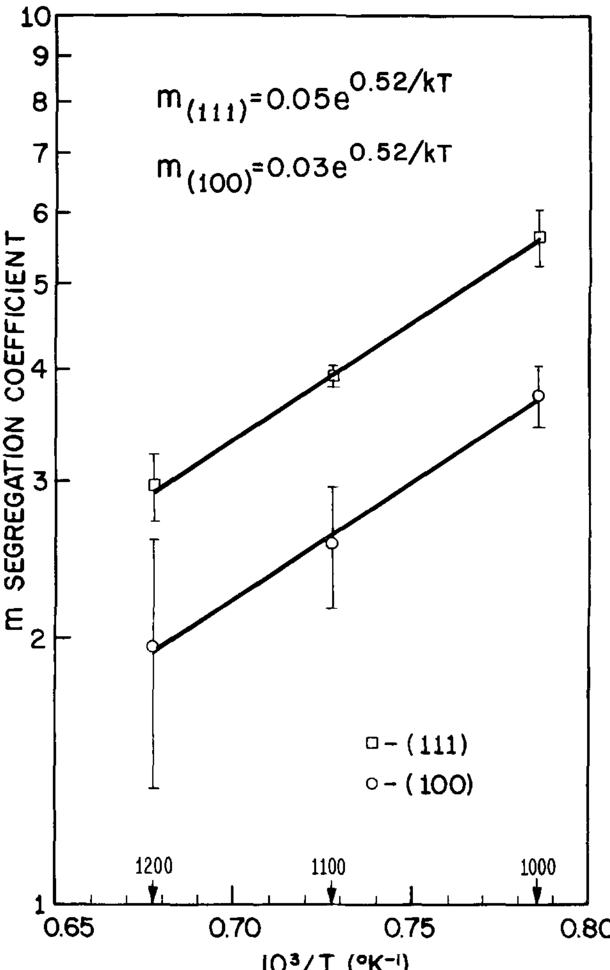

Fig. 2. Segregation coefficient as a function of temperature and orientation.

concentration and oxidation rate may not affect segregation coefficient. The general range of segregation coefficient measured in these experiments is in line with various values reported for modeling techniques with varying experimental conditions. Refinement of modeling techniques (7) has suggested that a value of ~4 at 1100°C for (111) is more valid than higher reported values (4, 5, 13) also based on modeling techniques. The value of 4 at 1100°C for (111) agrees extremely well with our experimentally determined value of 3.93 ± 0.09. Comparison with the only other experimentally determined (10, 11) value (~2) is difficult since the diffusion temperature was not published.

The orientation dependence of the segregation coefficient implies that the measured values for at least one of the orientations is not an equilibrium value and that the kinetic reaction rate across the interface determines the measured value. On the basis of equilibrium thermodynamics, one would not expect to observe an orientation dependence.

Some further interesting results may be obtained from the experimentally determined concentrations, if we take the ion probe values for C_S/C_B and m and consider the model of Grove *et al.* (3) for redistribution of boron upon oxidation of bulk silicon wafers, a value for the diffusion coefficient of boron in silicon can be determined by fitting their model to our experimental data. The model (3) considers solution of the diffusion equation with a moving boundary and the results describe redistribution from uniformly doped silicon. The resulting points are shown in Fig. 3. Least square fitting of these points yields

$$D_{(100)} = 0.192e^{-3.22/kT} \qquad [3]$$

$$D_{(111)} = 2.04e^{-3.57/kT} \qquad [4]$$

These functions are plotted as straight lines in Fig. 3. The orientation dependence of D is, of course, well known (14-24). The diffusivities converge at higher temperature as expected (22). Kendall and De Vries (25) have surveyed the literature and present various values of diffusion coefficients, as well as their estimates for the most valid values based on the experimental conditions and analysis of data. For boron in silicon, the values of Kurtz and Yee (26) are chosen. These values were obtained for surface concentrations generally in the mid $10^{18}/cm^3$ range and apply for temperature from 1050° to 1350°C. The equation is

$$D_{(111)} = 1.4e^{-3.51/kT} \qquad [5]$$

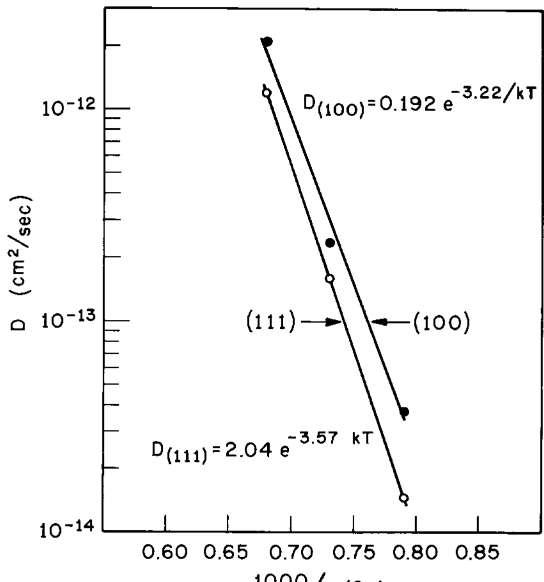

Fig. 3. Diffusion coefficient of boron in silicon-oxidizing ambient

which compares very favorably with the value obtained here (Eq. [4]) based on ion probe data and the model of Grove *et al.* (3).

Using the model of Grove *et al.* (3) for out-diffusion from a bulk wafer during oxidation, C_S/C_B can be calculated as a function of oxidation temperature, assuming m is independent of temperature. Ion probe data and necessary constants were used for such a calculation using the value of m at 1100°C for each orientation. The solid curves shown in Fig. 4 represent this calculation. Performing an identical calculation, but allowing m to vary with temperature as experimentally observed, generates the dotted curves shown in Fig. 4. Inclusion of the orientation and temperature variation of m in modeling calculations provides a more accurate description of the segregation at the oxidizing interface.

Conclusion

The ion microprobe has been used to determine both the temperature and orientation dependence of the segregation coefficient of boron at the silicon-silicon dioxide interface. Observations show that the boron segregation coefficient decreases with increasing temperature in the range investigated, 1000°-1200°C and that boron segregation coefficient values for (111) oriented silicon are greater than (100) oriented silicon at corresponding temperatures over the same temperature range. Diffusion coefficients for boron in (100) and (111) silicon have been extracted from the experimental data using the modeling technique of Grove *et al.* (3). The values agree well with published data. The effect of the variation of the segregation coefficient with temperature and orientation has been demonstrated modeling C_S/C_B, the ratio of the boron surface concentration to the bulk boron concentration, as a function of temperature.

The orientation and temperature variation of the segregation coefficient should be included in device design and modeling techniques.

H_2-Induced B Diffusion in MOS Devices

Dale M. Brown*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

High temperature H_2-induced B diffusion through self-aligned thin film Mo-gate MOSFET's is described. Mo-gate MOSFET threshold voltage and C-V curve shifts are used to detect the increase in B concentration in the Si substrate beneath the Mo gate. This phenomenon is explained by the catalyzed H_2 reduction of B_2O_3 at the Mo-borosilicate glass interface. This occurs because the reaction rate at a given temperature is increased through the change in the free energy due to the entropy increase arising from the interstitial dissolution of the B in the Mo crystal lattice. With this model, it can thus be explained why oxides of elements from the lower rows of the periodic table (*e.g.*, Si, P, and As) are not similarly reduced whenever they are components of a doped glass diffusion source and why Mo films are absolute diffusion blocks for these elements when they are present as oxides at interfaces. The study may shed some detailed insight into the catalytic activity of Mo and Fe in the synthesis of NH_3 from H_2 and N_2 and of other metallic hydrogenation catalysts.

B diffusion through the Mo gate of MOS structures was described previously (1). However, this phenomenon was never completely understood and further experimentation showed that very small amounts of H_2 in the diffusion ambient drastically reduce the masking ability of Mo films against its diffusion. The importance of the enhanced diffusion of B in SiO_2 when heated in H_2 and H_2O ambients (2) has had important consequences for B-doped polysilicon-gate MOSFET's and has been described by others (3-6). Heat-treatment of Si-gate MOSFET's in H_2 and H_2O ambients has been observed to decrease the p-channel enhancement mode MOSFET threshold or produce p-channel depletion mode devices instead of the desired enhancement mode device. Similar effects are observed for Mo-gate p-channel devices when H_2 is introduced into the diffusion ambient.

It is the purpose of this article to explain how and why this happens. The model also explains why Mo films can be absolute diffusion barriers for other elements in glass films (*e.g.*, Si, P, and As in their oxidized states) even when heated at high temperature in H_2-containing ambients. The study also provides insight into a possible basic reason for catalytic activity not previously discussed in detail.

* Electrochemical Society Active Member.

Key words: Mo catalysis, B_2O_3 H_2 reduction, MOSFET's.

Experiments, Methods, and Results

Annular self-registered Mo-gate MOSFET's were made as described in Ref. (7), using a borosilicate glass diffusion source containing 28% B_2O_3 as determined by the infrared absorption technique (8). Gate oxide thicknesses were approximately 1000Å, Mo film thicknesses were about 2000Å. The self-aligning Mo-gate MOSFET source and drain diffusions were carried out as a function of time in Ar, N_2, and 10% H_2 in He at 1100°C.

Two types of MOSFET measurements were carried out: (*i*) gate threshold voltage measurements and gate C-V curves with the source and drain connected to the substrate give the characteristic low frequency C-V curve, (*ii*) C-V curves with source and drain float-

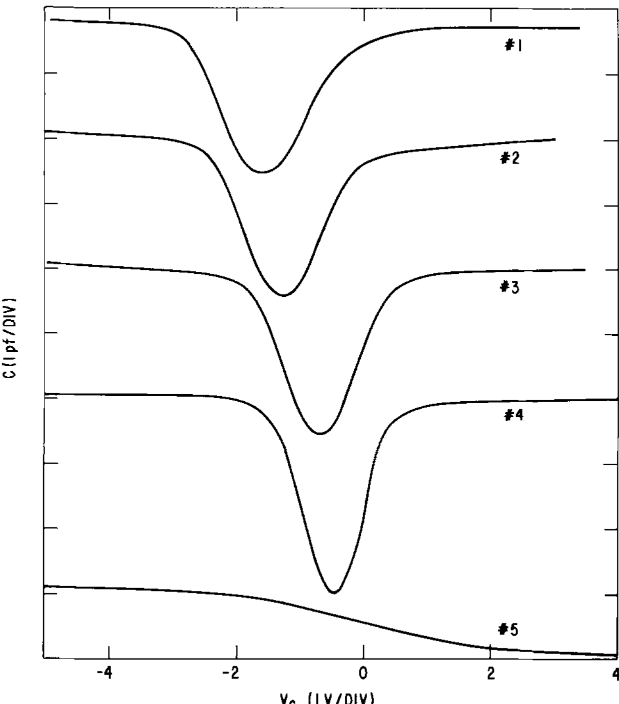

Fig. 1. Gate MOS C-V curves after diffusion with conditions as given in Table I. Capacitance curves are arbitrarily spaced on the C ordinate. Source and drain connected to substrate.

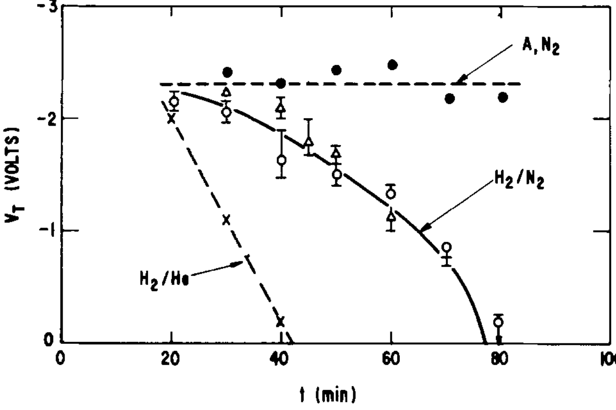

Fig. 2. 10 μA gate threshold voltages vs. diffusion time in three different diffusion ambients, Ar, 10% H_2 in N_2, and 10% H_2 in He. Silicon substrate crystal is n-type (111) phosphorous doped 3-5 ohm-cm.

ing give the high frequency C-V curves with a minimum inversion capacitance occurring at the maximum semiconductor depletion capacitance. The results of these measurements are given in Fig. 1 and 2 and summarized in Table I.

The observed shifts in threshold and C-V curves are caused by the increases in surface resistivity caused by B compensation of the phosphorus ionized donors.

Table I

No.	Ambient	Time (min)	V_T (1 μA)*	N_D**/cm^3	$(N_D - N_A)$†/cm^3
1	Ar, N_2	30-80	−1.8	2×10^{15}	1.6×10^{15}
2	10% H_2/N_2	30	−1.5	8×10^{14}	$\sim 10^{15}$
3	10% H_2/N_2	50	−0.8	$< 10^{13}$	$\sim 6 \times 10^{14}$
4	10% H_2/N_2	60	−0.6	$< 10^{13}$	$\sim 6 \times 10^{14}$
5	10% H_2/N_2	75	$\geqq +5$	—	-1.5×10^{14}

* Measured threshold voltages are specified for a 1 μA channel current using an aspect ratio, W/L = 20, device [Ref. (7)]. Silicon substrate is phosphorous doped with (111) surface orientation.

** N_D from V_T assuming uniform doping and $\phi_{MS} = 0.4$ [Ref. (7)].

† N_D from C-V minimum depletion capacitance [Ref. (9)] which also assumes a uniform doping density (see discussion in text).

As boron atoms penetrate the gate structure, the resultant compensation decreases the ionized donor densities resulting in decreasing thresholds and depletion capacities as shown by the data in Fig. 1 and 2. Some of these results are summarized in Table I for the Ar, N_2, and H_2 in N_2 diffusion ambients. The net ionized donor densities in the next to last column are estimated from standard threshold calculations for Mo-gate devices on (111) surfaces assuming a uniform doping profile and a fixed oxide charge of $2.1 \times 10^{11}/cm^2$ (7). The last column is the net uncompensated donor density arrived at using the gate MOS depletion capacitance which also assumes a uniform doping profile (9). This assumption is, of course, incorrect and probably accounts for the large differences in the estimated ionized donor densities arrived at using those two methods as the threshold approaches and passes through zero. Any detailed analysis of these threshold shifts would therefore have to take into account the nonuniformity of the doping profile caused by the B penetration and ensuing donor compensation. In turn, experimental samples would have to be subjected to detailed profile measurements using the MOSFET deep depletion $d(1/C^2)/dV$ methods recently described (10). Sample 5 is a p-channel depletion mode device as indicated by the positive gate threshold and p-type MOS C-V curve. Threshold changes caused by changes in fixed oxide charge during B penetration of the gate oxide should not be a factor as indicated by previous experiments (1, 6).

Enhancement mode threshold data are shown in Fig. 2. The data are quite reproducible. The spread in the data at each point represents the threshold variation observed in scanning the wafer from left to right and top to bottom. Two sets of data are also shown using two different tanks of N_2 + 10% H_2. Threshold data for He + 10% H_2 are also included in Fig. 2 and in this instance the B penetration occurs much more rapidly. It is obvious from the data that whereas total masking of B is possible for at least 1.5 hr in Ar or N_2 ambients even when very thin Mo films and gate oxides are used (7), the introduction of H_2 results in a drastic reduction in Mo-film diffusion masking. Furthermore, none of these effects have ever been observed when phosphorous-doped glass is used as a diffusion source (11). That is to say, no phosphorous penetration through the gates of self-aligned n-channel Mo-gate MOSFET's has been detected even when the diffusions are carried out in 10% H_2 + N_2 at 1100°C for periods of time as long as 1.5 hr. These observations are very striking and their explanation has to be based on an analysis of the chemical and physical properties of the system.

Discussion

From a chemical point of view, the system is quite "clean," consisting of a lightly doped Si substrate, a thin (approximately 1000Å) film of thermally grown SiO_2 and a thin (approximately 2000Å) film of Mo covered with the B_2O_3-SiO_2 diffusion source. This structure is heated in gaseous ambients and, upon completion of the MOSFET structure by providing appropriate contacts, the Si substrate can be used as a B detector by simple measurements of MOSFET threshold.

One would anticipate that the rate of production of atomic B at the Mo-B_2O_3 interface would be very small since the chemical reduction of B_2O_3 by Mo or H_2 is strongly endothermic. In fact, P_2O_5 should be much more easily reduced by H_2 than B_2O_3. This is shown by the magnitudes of the free energies of formation calculated using the JANAF Thermochemical Tables (12) for these reactions and summarized in Table II. P could, however, not go into interstitial position and diffuse interstitially through Mo whereas B is a small enough atom to do this. Elemental B has a radius of 0.88Å compared to 1-1.2Å for P or Si (13). The cubic body-centered cell of Mo has a radius for the largest interstitial space equal to 0.87Å at 1100°C. However,

Table II. Chemical reactions at 1100°C

Reaction	ΔG (kcal/mole)	Δg (eV/atom)
$2B_2O_3 + 3Mo \rightarrow 3MoO_2 + 4B$	+198	2.15
$B_2O_3 + Mo \rightarrow MoO_3 + 2B$	+126	2.75
$B_2O_3 + 3H_2 \rightarrow 3H_2O + 2B$	+99	2.15
$SiO_2 + 2H_2 \rightarrow 2H_2O + Si$	+77	3.3
$P_2O_5 + 5H_2 \rightarrow 5H_2O + 2P$	+6	0.13

these considerations are not sufficient to explain the data in Fig. 2. Why, for instance, is the B diffusivity so much smaller in the $N_2 + H_2$ ambient than in He + H_2?

Catalytic Reduction of B_2O_3

Heterogeneous catalytic reactions are normally considered to be determined by the adsorption and rearrangement of the reactants on the surface of the catalyst. Possible dissociation and a lowering of the free energy barrier in the transition state are assumed to accompany this surface adsorption and to account for low temperature catalytic reactivity. One of the most famous examples of this is the catalytic synthesis of ammonia from H_2 and N_2. Although the absorption and catalytic activity of a surface is usually thought to have something to do with "active centers" and "the specific steric arrangement of its atoms" (14) there has been no rigorous statistical thermodynamic analysis of any specific system in the literature of the subject. This is not surprising since the chemical systems studied experimentally have been ill defined and complex. As described previously, the system being studied here is relatively simple; and the presence of the semiconductor substrate gives us a good method of monitoring relative rates of reaction.

Mo is an excellent catalyst for the synthesis of ammonia although for economic reasons Fe is used. Both of these materials have body-centered cubic (bcc) crystal structures. The interstitial space in the body-centered cell of Mo will accommodate elements of the first row including N(r = 0.7Å) but not, as pointed out previously, the large atoms of the second row.

In the system under discussion, it appears that the fact that B can dissolve interstitially in Mo at the reaction temperature whereas Si and P cannot plays an essential role in the reduction of the B_2O_3 glass component on the Mo substrate. The free energy change during the endothermic reaction is reduced by $T\Delta S$ where ΔS arises from the entropy of dissolution of the B atoms in the Mo. At low B concentrations in Mo, ΔS has a large incremental value because of the form of the curve of ΔS as a function of the mole fraction of interstitial B in Mo. A low concentration of B can be produced by H_2 reduction of B_2O_3 and can diffuse through the Mo and be detected. The mechanism which is proposed to account for the observed phenomena is analogous to the structural disordering of a solid with the introduction of point defects which occurs with increasing temperature. The production of point defects is an endothermic process, but their distribution in the solid is accompanied by an increase in the entropy of the system. As a consequence, the free energy of the disordered system at a temperature at which the diffusion of point defects is possible is lower than that of the ordered system. The theory of the structural disordering of crystals which is discussed in many publications (15-17) can be adapted to the present problem.

The changes in the Gibbs free energy, ΔG, in Table II are calculated from the change in the enthalpy, ΔH, and the change in the thermal entropy. Changes in entropy associated with the formation of two dimensional adsorbed layers on catalytic surfaces have been discussed (18). The concept that the free energy of a reaction can be lowered by the much larger entropy changes associated with the interstitial substrate dissolution of a product within the volume of the catalyst has not, so far as is known, ever been introduced. Yet this is clearly possible and could occur in the reduction of B by H_2 on a Mo substrate and in the dissociation of H_2 and other molecules on metallic substrates in catalytic hydrogenation reactions.

The entropy of interstitial dissolution of B in Mo can be calculated by the methods of statistical mechanics. The number of the largest interstitial sites/cm^3 in the Mo lattice is given by $N = 3M/2$, where M is the total number of Mo atoms/cm^3. The number of ways of distributing solute atoms over these interstitial sites is

$$\frac{N!}{n!(N-n)!}$$

where n is the number of solute atoms/cm^3. The corresponding entropy of dissolution is then given by

$$S = k[N \ln (N) - (N-n) \ln (N-n) - n \ln (n)]$$

making use of Stirling's theorem.

The free energy change in the reaction ΔG^*, when it occurs on the Mo substrate, is therefore reduced from ΔG by $T\Delta S$ giving

$$\Delta G^* = \Delta G - T\Delta S = n\Delta g - kT[N \ln N - (N-n) \ln (N-n) - n \ln n]$$

where Δg is the free energy change associated with the production of one B atom by the reduction of B_2O_3 by H_2. In the equilibrium state, $\partial \Delta G^*/\partial n = 0$ which gives

$$n/(N-n) \simeq n/N = e^{-\Delta g/kT}$$

The approximation is valid because of the low concentration of the B in Mo at the temperature of reduction.

The number of interstitial positions can be calculated using the unit cell volume, atomic weight, and density of Mo and gives

$$N = 9.6 \times 10^{22}/\text{cm}^3$$

Using the Gibbs free energy data in Table II, the equilibrium concentration of interstitial B produced by the H_2 reduction of B_2O_3 at 1100°C (with Δg = 2.15 eV) is

$$n = 1.2 \times 10^{15}/\text{cm}^3$$

The calculation thus demonstrates that a reaction which could not occur in the absence of a catalyzing system can give rise to B atoms in the Mo substrate which can then diffuse interstitially and be detected by their influence on the properties of the MOSFET. It is clear that since neither Si nor P will dissolve and diffuse interstitially in Mo, SiO_2, and P_2O_5 will not be reduced by H_2 in contact with Mo in agreement with the experimental observations.

The reduction in the B diffusivity in the presence of N_2 is probably accounted for by the catalyzed formation at the surface of NH diatomic molecules by reaction between N_2 molecules absorbed at the surface and H atoms reaching the surface from dissociated H_2 dissolved interstitially in the Mo substrate. The NH molecules can dissociate at the surface (Δh = 3.2 eV) with interstitial dissolution of both the N and the H. The presence of interstitially dissolved nitrogen would reduce the entropy of dissolution of the B by reducing the number of available interstitial sites. This would reduce the concentration of B dissolved in the Mo substrate.

Summary

The importance of the dissolution of B in the Mo substrate explaining the H_2 reduction of B_2O_3 and subsequent diffusion of B through thin Mo films has led to a catalytic model which explains the striking diffusion phenomena associated with Mo-gate MOSFET's. More specifically, it explains the high B diffusivity through the gate into the underlying Si whenever H_2 is introduced into Ar, He, or N_2 diffusion ambients.

Furthermore, this model explains the inertness of Mo films with other glass components like SiO_2, P_2O_5, and As_2O_3 which explains the observed diffusion-masking ability of Mo films against P. This study points out clearly for perhaps the first time the importance of the bulk crystallographic structure of a catalytic agent.

Acknowledgments

Mr. George J. Charney made all the samples and took all the data reported here. The author is especially thankful to Prof. J. W. Mitchell of the Department of Physics at the University of Virginia for pointing out the importance of a decrease in the free energy as a result of the interstitial dissolution of a product in explaining the catalytic phenomena discussed in this paper. Thanks also to Dr. D. W. McKee for reading the manuscript.

Manuscript submitted June 6, 1974; revised manuscript received Nov. 5, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the General Electric Company.

Mixed Electrical Conduction in the Fluorite-Type $Ce_{1-x}Gd_xO_{2-x/2}$

T. Kudo and H. Obayashi

Central Research Laboratory, Hitachi, Limited, Higashi-koigakubo, Kokubunji, Tokyo, 185, Japan

ABSTRACT

The CeO_2-Gd_2O_3 solid solutions exhibit high ionic conduction due to the migration of O^{2-} ions *via* oxygen ion vacancies. The emf of a galvanic cell, $O_2(p_{O_2} = 1\ \text{atm})$,Pt|$Ce_{1-x}Gd_xO_{2-x/2}$|Pt,$O_2(p_{O_2})$, is measured within the temperature range between 700° and 800°C as a function of p_{O_2}. At such high oxygen pressures as in air, the emf changes according to $-(RT/4\mathbf{F}) \ln p_{O_2}$ indicating the ionic transference number in the solid solution is unity. With decreasing oxygen pressure, however, the observed emf becomes smaller than the theoretical value. This indicates the onset of electronic conduction generated by the reduction of the solid solution. The dependence of the emf(E) on p_{O_2} is described by

$$E = \frac{RT}{\mathbf{F}} \ln \left[(1 + p^*{}_{O_2}{}^{1/4}) / (p_{O_2}{}^{1/4} + p^*{}_{O_2}{}^{1/4}) \right]$$

where $p^*{}_{O_2}$ is a constant corresponding to the oxygen partial pressure at which the ionic transference number of the solid solution becomes 0.5. From the temperature dependence of $p^*{}_{O_2}$, partial molar enthalpy changes $(\Delta\overline{H})$ for the reduction of $Ce_{1-x}Gd_xO_{2-x/2}$ are calculated.

Ionic conduction in doped CeO_2 has been reported by Kevane (1), Blumenthal (2), Takahashi (3), and others. It is known that ionic conduction results from the migration of O^{2-} ions over vacant ion sites which are produced by the partial replacement of Ce^{4+} by such dopant ions as Ca^{2+} or La^{3+}. The present authors have also reported the oxygen ion conduction of the fluorite-type solid solution $Ce_{1-x}Ln_xO_{2-x/2}$ (Ln = lanthanoid elements) (4), revealing that the CeO_2-Gd_2O_3 system exhibits excellent electrolytic conduction; the specific conductivity of $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.23$) at 750°C is 6.7×10^{-2} (ohm-cm)$^{-1}$, which rivals the value of calcia-stabilized zirconia at 1000°C.

The ionic transference number of $Ce_{1-x}Gd_xO_{2-x/2}$ has been proved to be substantially unity by the emf measurement of the galvanic cell, $O_2(p_{O_2} = 1\ \text{atm})$, Pt | $Ce_{1-x}Gd_xO_{2-x/2}$ | Pt, $O_2(p_{O_2} = 0.21\ \text{atm})$ (4). At lower oxygen pressures, however, electronic conduction

Key words: ionic conductor, solid electrolyte, cerium-gadolinium oxide, mixed conductor.

seems to set in as reported for the CeO_2-La_2O_3 system (5). The present study investigates the mixed conduction of $Ce_{1-x}Gd_xO_{2-x/2}$ in order to provide the data needed for fuel cells and other applications. In addition, thermodynamic data for the reduction of $Ce_{1-x}Gd_xO_{2-x/2}$ in a reducing atmosphere are also derived from analyses of emf data obtained by the present study.

Mixed ionic-electronic conduction in solid electrolytes has been studied by Schmalzried and Tare (6, 7) on a theoretical basis. In the present work, this theory is applied to $Ce_{1-x}Gd_xO_{2-x/2}$. Electronic conduction under a reducing atmosphere results from excess electrons generated by the reaction

$$O_O = \tfrac{1}{2} O_2(g) + V_O + 2e \qquad [1]$$

where O_O and V_O represent oxygen ions at normal lattice sites and doubly ionized oxygen ion vacancies. The equilibrium constant K for the reaction [1] is

$$K = n_V n_e^2 p_{O_2}^{1/2} \qquad [2]$$

where n_V and n_e are the concentration of vacancies and electrons, respectively. Assuming the number of oxygen ion vacancies generated by Eq. [1] to be negligible compared with that produced by replacement of Ce^{4+} by Gd^{3+} $[V_O]$

$$n_e = (K/[V_O])^{1/2} \cdot p_{O_2}^{-1/4} \qquad [3]$$

Thus, the electronic conductivity is given by

$$\sigma_e = (e\mu)(K/[V_O])^{1/2} \cdot p_{O_2}^{-1/4} \qquad [4]$$

where e is the charge of an electron and μ is its mobility. By substituting Eq. [4] into the equation defining the ionic transference number

$$t_i = \frac{\sigma_i}{\sigma_i + \sigma_e} \qquad [5]$$

we obtain

$$t_i = \frac{1}{1 + (p_{O_2}/p^*_{O_2})^{-1/4}} \qquad [6]$$

where

$$p_{O_2} = (\mu e/\sigma_i)^4 (K/[V_O])^2 \qquad [7]$$

Here, σ_i represents the ionic conductivity. Since σ_i is considered to be independent of p_{O_2}, $p^*_{O_2}$ is a constant corresponding to an oxygen partial pressure at which the ionic transference number becomes 0.5. On the other hand, the emf (E) of the galvanic cell

$$O_2(p_{O_2} = 1\ \text{atm}),\ Pt \mid Ce_{1-x}Gd_xO_{2-x/2} \mid Pt,\ O_2(p_{O_2}) \qquad [I]$$

is given by

$$E = \frac{RT}{4F} \int_{p_{O_2}}^{p'_{O_2}} t_i d \ln p_{O_2} \qquad [8]$$

By substituting t_i in Eq. [8] by Eq. [6], and integrating, we obtain

$$E = \frac{RT}{F} \ln \left(\frac{1 + p^*_{O_2}{}^{1/4}}{p_{O_2}^{1/4} + p^*_{O_2}{}^{1/4}} \right) \qquad [9]$$

This provides the theoretical background for the following discussion.

Experimental

Sample preparation.—Ceria powder (99.99% pure, Shin-etsu Chemical Company) and Gd_2O_3 powder (99.9% pure, same supplier) were weighed, mixed in an agate mortar for 30 min, and heated in air at 1300°C for 8 hr. An x-ray analysis of the resultant specimen showed the diffraction pattern of the fluorite structure only. This specimen was reground in an agate mortar to 325 mesh size. In order to obtain a dense specimen, 3 mole per cent (m/o) of magnesium was added in the form of $Mg(NO_3)_2$. Methyl cellulose was added to this as a binder and the treated powder was cold pressed into 20 mm diameter pellets. The pellets were heated in air at 1800°C for 2~3 hr in a Pt-40% Rh basket. The pellets in their final state were *ca.* 1.5 mm thick and *ca.* 16 mm diameter. Apparent density of the pellets was more than 98% of the theoretical value calculated from the lattice constant.

EMF measurements.—The test pellet was provided with platinum paste electrodes (5 mm diameter) on both sides. The platinum paste (No. 8103, Tokuriki Chemical Company) was baked at 1000°C for 1 hr. SEM observations showed the electrodes to be of a very porous structure, ensuring that equilibrium oxygen pressures would be attained quickly at the electrode/electrolyte interface. This test specimen was attached to an emf measurement apparatus, in which one side of the electrodes was exposed to pure oxygen and the other side to a gas mixture of O_2/N_2 or CO_2/H_2. The specifications of the apparatus have been given in a previous paper (4).

High oxygen pressures ($1 \sim 10^{-5}$ atm) were achieved by using O_2/N_2 mixtures. Low oxygen pressures ($10^{-13} \sim 10^{-20}$ atm at 850°C) were obtained with CO_2/H_2 mixtures by using gas flow meters to control their flow ratio. The H_2 to CO_2 mixing ratio ranged from 0.1 to 250 (or infinite). The gas mixture and oxygen were passed at a total pressure of 1 atm and linear speeds of about 0.5 cm/sec (at room temperature), assuring that the gases were heated to the equilibrium furnace temperatures.

The emf of the galvanic cells was measured by using a potentiometer (Yokogawa Electric, Type P-1). Conductivity measurements were carried out employing a d-c four-probe method. The details of the apparatus used in the conductivity measurements were given in a previous work (4). In all experiments, temperatures were controlled to within ±1°C.

Results and Discussion

The temperature dependence of the total conductivity (σT) *vs.* $1/T$ in air for $Ce_{1-x}Gd_xO_{2-x/2}$ is presented in Fig. 1. The temperature dependence observed for low dopant concentrations ($x = 0.1 \sim 0.3$) may be described in the form

$$\sigma = [T(A_1 \exp(E_1/RT) + A_2 \exp(E_2/RT)]^{-1} \qquad [10]$$

as reported by Bauerle and Hrizo (8) for a ZrO_2-Y_2O_3 electrolyte.

The electrical conduction in air at temperatures between 700° and 850°C was proved to be ionic by using cell [I] in which $p_{O_2} = 0.21$ atm. In the same manner, it was found that the ionic transference number for $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.1 \sim 0.5$) is larger than 0.98 for p_{O_2} from 10^{-1} to 10^{-5} atm at temperatures between 700° and 850°C.

To illustrate the oxygen pressure dependence of the emf given by the galvanic cell [I] under lower oxygen pressures, two isotherms for the compositions $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.2$ and 0.5) are plotted in Fig. 2. For comparison, the observed emf's of the same type $Zr_{1-x}Y_xO_{2-x/2}$ ($x = 0.10$) galvanic cell are also plotted. In the case of ZrO_2-Y_2O_3, the p_{O_2} dependence of the emf is described by

$$E = \frac{RT}{4F} \ln (p'_{O_2}/p_{O_2}) \qquad [11]$$

the relation obtained when $t_i = 1$, or $p^*_{O_2} << p_{O_2}$ in Eq. [9]. Although $p^*_{O_2}$ for $Zr_{1-x}Y_xO_{2-x/2}$ ($x = 0.1$) has not yet been reported, it seems to be less than 10^{-40} atm at 750°C, since Schmalzried (6) has reported that $p^*_{O_2}$ for $Zr_{1-x}Ca_xO_{2-x}$ ($x = 0.15$) is 10^{-43} atm at 800°C. Contrary to yttria-stabilized zirconia, the plotted emf's of $Ce_{1-x}Gd_xO_{2-x/2}$ cells show a deviation from the p_{O_2} dependence expressed by Eq. [11]. This indicates that the electronic conduction in $Ce_{1-x}Gd_xO_{2-x/2}$ is not negligible as compared with the ionic conduction under the oxygen pressures employed in

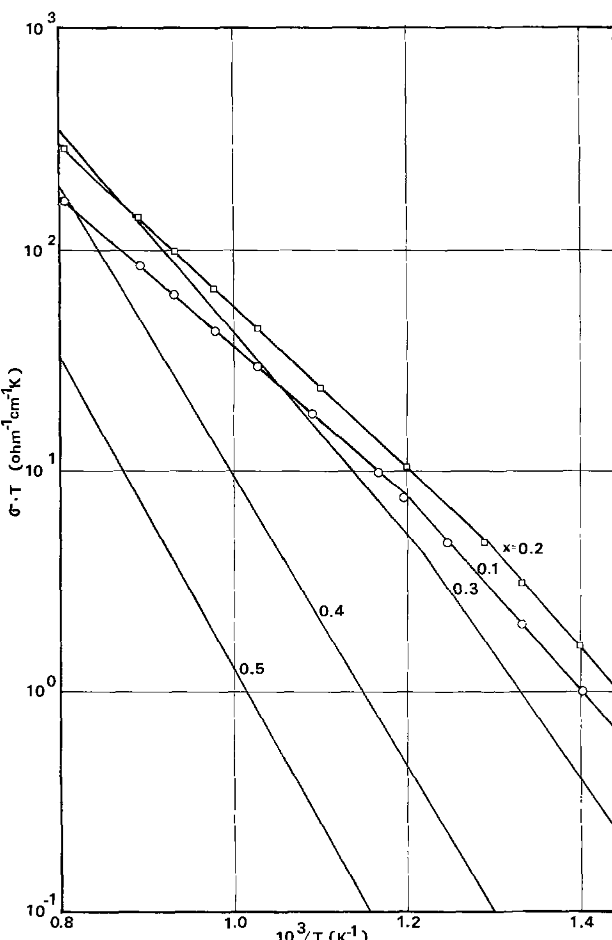

Fig. 1. Conductivity-temperature behavior for $Ce_{1-x}Gd_xO_{2-x/2}$. For the sake of clarity only a few of the measured data points for $x = 0.1$ and 0.2 are shown.

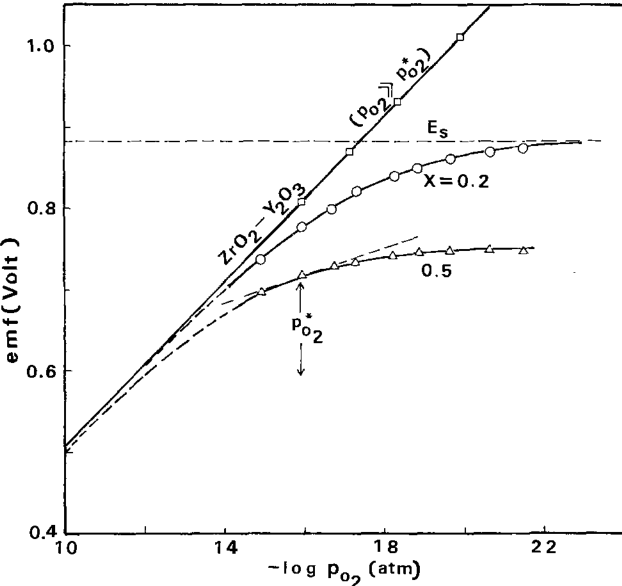

Fig. 2. EMF for galvanic cells, O_2 (1 atm), Pt | $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.2$ and 0.5) | Pt, O_2 (p_{O_2}), as a function p_{O_2} at 750°C. For comparison, data for $Zr_{1-x}Y_xO_{2-x/2}$ ($x = 0.1$) are shown.

these experiments. The dependence of the emf on p_{O_2} is in good agreement with Eq. [9] yielding values for $p^*_{O_2}$ of 3.92×10^{-18} and 1.38×10^{-15} atm for $x = 0.2$ and 0.5, respectively. According to Eq. [9], the emf saturates to a value E_S

Table I. $p^*_{O_2}$ (atm) values for $Ce_{1-x}Gd_xO_{2-x/2}$

x \ T (°C)	700	750	800	850
0.1	1.30×10^{-17}	2.53×10^{-16}	2.43×10^{-15}	3.65×10^{-14}
0.2	1.24×10^{-19}	3.92×10^{-18}	9.2×10^{-17}	1.73×10^{-15}
0.3	3.16×10^{-19}	5.6×10^{-18}	8.5×10^{-17}	9.0×10^{-16}
0.4	9.3×10^{-19}	8.8×10^{-18}	6.3×10^{-17}	3.85×10^{-16}
0.5	1.46×10^{-16}	1.38×10^{-15}	1.12×10^{-14}	6.5×10^{-14}

$$E_S = \frac{RT}{\mathbf{F}} \ln \frac{1 + (p^*_{O_2})^{1/4}}{(p^*_{O_2})^{1/4}} \qquad [12]$$

The emf's observed when hydrogen with a dew point of *ca.* −30°C was introduced into the cells corresponded to E_S calculated from Eq. [12] using $p^*_{O_2}$ derived for $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.1 \sim 0.5$). These are tabulated in Table I. The temperature dependence of $p^*_{O_2}$, which is to be discussed later, gives a straight line in Arrhenius plots.

From the values for $p^*_{O_2}$, the ionic transference number t_i can be calculated as a function of p_{O_2} employing Eq. [5]. This is given in Fig. 3 for the composition $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.2$). The calculated transference number is $\sigma_i/(\sigma_i + \sigma_e)$. This should be distinguished from the "mean" transference number t_m given by

$$t_m = E \Big/ \frac{RT}{4\mathbf{F}} \ln (p'_{O_2}/p_{O_2}) \qquad [13]$$

where p_{O_2} and p'_{O_2} are oxygen pressures in the same asymmetrical cell as cell [I]. The value of t_m defined by Eq. [13] is an important criterion when applications of electrolytes to fuel cells are considered. It is shown in Fig. 3 only for 700°C.

The t_i isotherms at $p_{O_2} = 10^{-20}$ atm and t_m for $p'_{O_2} = 1$ atm and p_{O_2} (in Eq. [13]) $= 10^{-20}$ atm are given in Fig. 4 as a function of dopant (Gd^{3+}) concentration, x. A maximum in t_i appears around $x = 0.2$ at 700°C, but at higher temperatures the maximum point shifts to higher Gd^{3+} concentrations. A maximum in t_m appears at the composition which gives the maximum in t_i.

Though t_i does not exceed 0.37 for all compositions investigated, t_m at 700°C is as large as 0.91 for $x = 0.2$. This suggests that the utilization of $Ce_{1-x}Gd_xO_{2-x/2}$ ($x = 0.2$) in fuel cells is likely to be successful, contrary to $Ce_{1-x}La_xO_{2-x/2}$ solid electrolytes (9). In the case of $Ce_{1-x}La_xO_{2-x/2}$, the transference number is improved by increasing x, while the conductivity is

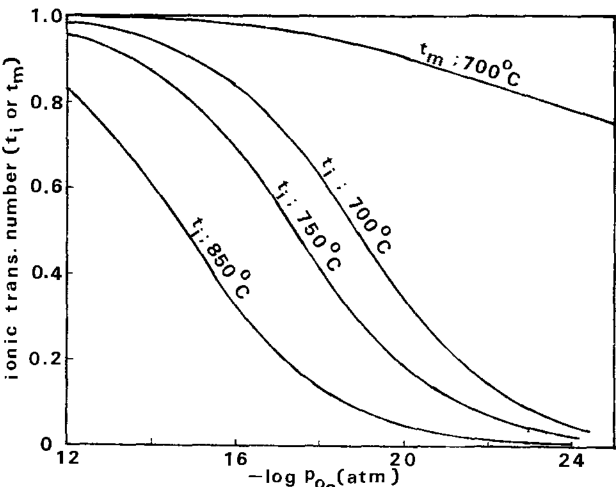

Fig. 3. The ionic transference number, t_i, for $Ce_{1-x}Gd_xO_{2-x}$ ($x = 0.2$) as a function of p_{O_2} as derived from $p^*_{O_2}$ in Table I. The mean transference number, t_m (see text), is also shown for 700°C.

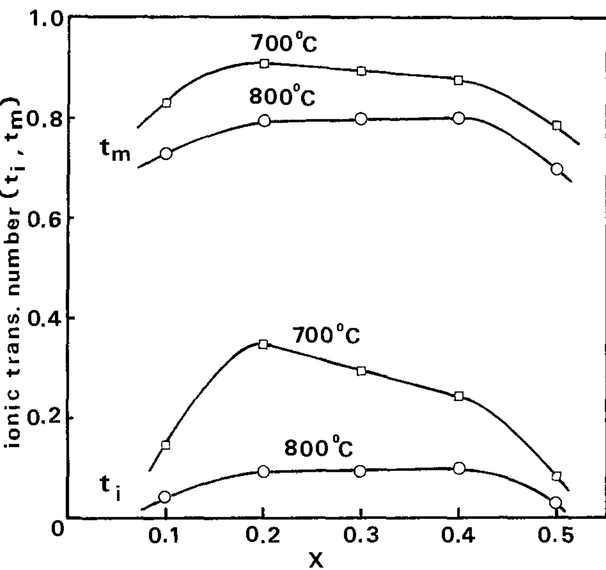

Fig. 4. The ionic transference numbers (t_i and t_m) as a function of x in $Ce_{1-x}Gd_xO_{2-x/2}$.

sacrificed (10). However, $Ce_{1-x}Gd_xO_{2-x/2}$ exhibits the highest transference number at the composition ($x = 0.2$) where the conductivity is approximately maximized (*cf.* Fig. 1 and 4). Moreover, the conductivity of $Ce_{1-x}Gd_xO_{2-x/2}$ at 700°C almost equals the value of calcia-stabilized zirconia at 1000°C.

Let us consider how the composition (x) dependence of the transference number (or $p^*_{O_2}$) arises. As Eq. [5] indicates, the ionic transference number becomes, in general, larger if ionic conductivity increases. At the same time, if the reduction of Ce^{4+} to Ce^{3+} is suppressed, the transference number also increases because the number of excess conduction electrons is decreased. Higher vacancy concentration, *i.e.*, higher x, will shift the reaction given by Eq. [1] to the left-hand side and the concentration of Ce^{3+} ions will decrease. This results in an increase in the ionic transference number. For the CeO_2-La_2O_3 system, the relation between the stability of Ce^{4+} and the dopant La^{3+} concentrations has been studied (10, 11); however, the conclusions are not really clear.

The stability of Ce^{4+} may be determined by the equilibrium constant K of the reaction given by Eq. [1], which has the form

$$K = K_0 \exp(-\Delta\overline{H}/RT) \qquad [14]$$

where $\Delta\overline{H}$ is the enthalpy change of the reaction.[1] Thus, the temperature dependent variables in Eq. [7] are K, σ_i, and μ. The dependence of σ_i on temperature is expressed by Eq. [10]. However, this is well approximated for all compositions in the temperature range between 700° and 850°C by

$$\sigma_i = \frac{\sigma_{io}}{T} \exp(E_i/RT) \qquad [15]$$

where E_i is the activation energy of oxygen ion conduction. This value ranges from *ca.* 0.55 to 1.3 eV as calculated from Fig. 1. On the other hand, μ may be given by

$$\mu = \frac{b}{T} \exp(-E_e/RT) \qquad [16]$$

assuming electrons migrate by a hopping mechanism in this case. Since $E_e << E_i$ (E_i is equal to at least 0.5 eV for $Ce_{1-x}Gd_xO_{2-x/2}$, $x = 0.1 \sim 0.5$), Eq. [7] can be rewritten as

$$p^*_{O_2} = \left[\frac{be}{\sigma_i}\right]^4 \cdot \left[\frac{K}{[V_O]}\right]^2 \qquad [17]$$

or

$$(p^*_{O_2})^{1/4}\sigma_i = be[V_O]^{1/2} \cdot K^{1/2} \equiv \alpha \qquad [18]$$

Equation [17] requires that the temperature dependence of $p^*_{O_2}$ be exponential. This requirement is met as mentioned before. Taking logarithms of Eq. [18] and differentiating with respect to $(1/T)$, one may derive

$$\frac{\partial \ln \alpha}{\partial(1/T)} = \frac{1}{2}\frac{\partial}{\partial(1/T)} \ln K = -\frac{\Delta\overline{H}}{2R} \qquad [19]$$

Hence, $\Delta\overline{H}$ can be calculated from the slope of each line given in Fig. 5, in which α for $Ce_{1-x}Gd_xO_{2-x/2}$ is plotted *vs.* $1/T$.

The $\Delta\overline{H}$ value obtained should be considered as the partial molal enthalpy change for the reduction of the solid electrolytes represented by Eq. [1] at the composition $Ce_{1-x}Gd_xO_{2-x/2-\delta}$ at which $\delta \doteqdot 0$. These are plotted in Fig. 6 as a function of x, where bars at each point indicate the possible errors estimated by a regression analysis of Fig. 5. $\Delta\overline{H}$ is a measure of the stability of Ce^{4+} in the crystal lattice, *i.e.*, the stability increases with an increase of $\Delta\overline{H}$. Since the dependence of $\Delta\overline{H}$ on x is not simple (as seen in Fig. 6), one cannot conclude that dopant Gd^{3+} ions enhance the stability of Ce^{4+}. Moreover, it should be noted that all $\Delta\overline{H}$'s obtained for $Ce_{1-x}Gd_xO_{2-x/2}$ are smaller than that for CeO_2 (107 kcal/½ mole O_2) (12) at the stoichiometric composition.

The complicated relation between $\Delta\overline{H}$ and x causes the somewhat queer shapes of t_i shown in Fig. 4. The sharp increase in t_i between $x = 0.1$ and 0.2 at 700°C corresponds to the $\Delta\overline{H}$ increase in the same composition region. At larger x, however, $\Delta\overline{H}$ changes marginally with the variation of x and, as a result, t_i is controlled mainly by σ_i instead of the stability of Ce^{4+}.

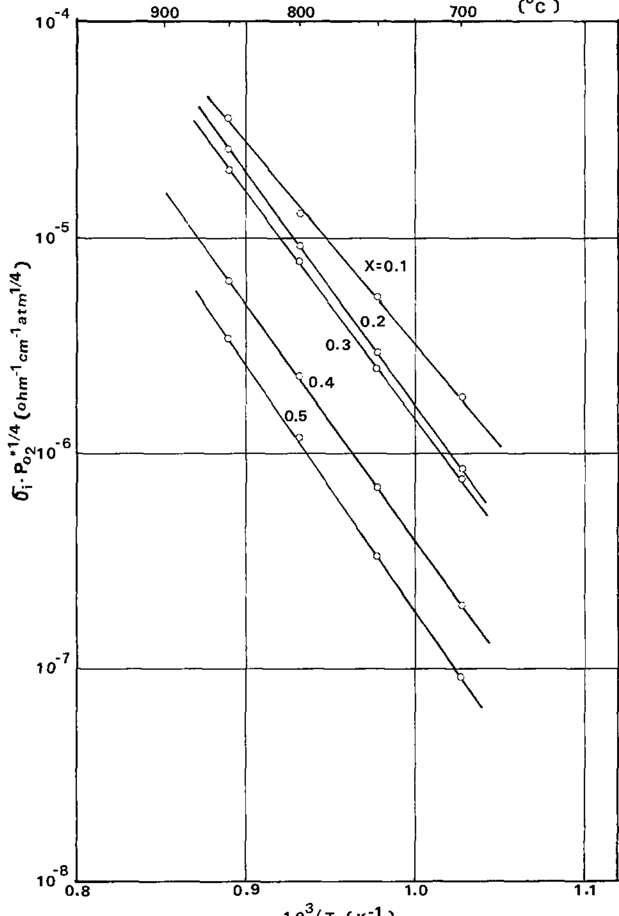

Fig. 5. Variation of ($\sigma_i \cdot p^*_{O_2}{}^{1/4}$) with reciprocal absolute temperature for $Ce_{1-x}Gd_xO_{2-x}$.

[1] $\Delta\overline{H}$ = partial molal quantity discussed later.

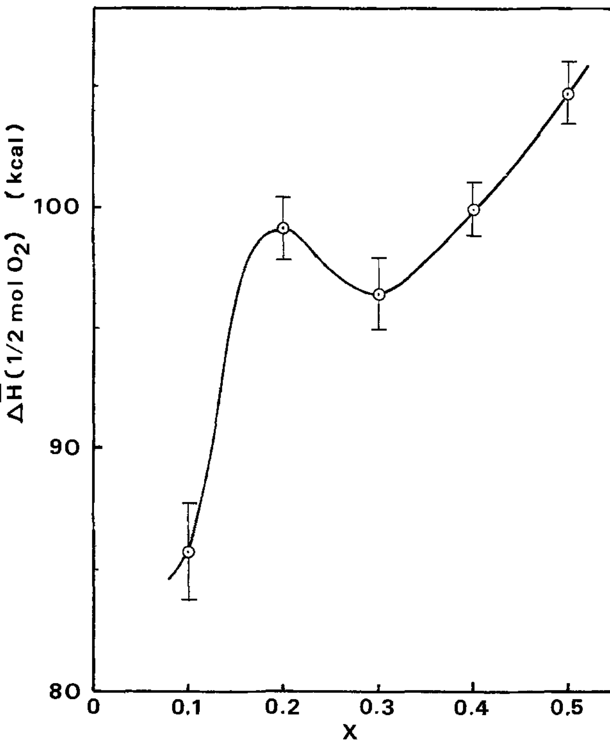

Fig. 6. The partial molal enthalpy change ($\Delta\overline{H}$) for the reaction $O_o = \frac{1}{2} O_2(g) + \underline{V}_o + 2\underline{e}$ at the compositions $Ce_{1-x}Gd_xO_{2-x/2}$ as a function of x.

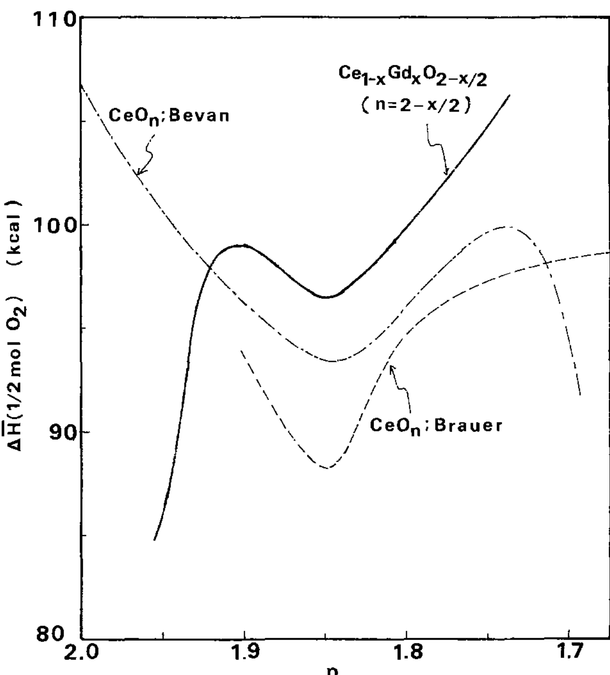

Fig. 7. Comparison of $\Delta\overline{H}$ for $Ce_{1-x}Gd_xO_{2-x/2}$ with those for CeO_n reported by Bevan (12) (— · — · —) and by Brauer (13) (– – – –) as a function of n. For $Ce_{1-x}Gd_xO_{2-x/2}$, n is $(2 - x/2)$.

Nevertheless, at higher temperatures the effect of an increase in $\Delta\overline{H}$, which offsets that of σ_i, becomes appreciable. This effect shifts the maximum in the t_i curve for 800°C to larger x.

Finally, some consideration of the shape of the plot in Fig. 6 is needed. This plot is again shown in Fig. 7 with the partial molal enthalpy composition data for nondoped CeO_n reported by Bevan *et al.* (12) and Brauer *et al.* (13). Here the abscissa represents n in CeO_n instead of x, where n is $(2 - x/2)$ for $Ce_{1-x}Gd_xO_{2-x/2}$. This figure makes it clear that oxygen ion vacancies generated by the reduction of CeO_2 and those produced by the dopant Gd^{3+} have the same effects on $\Delta\overline{H}$ as long as $n < 1.9$. All three curves in Fig. 7 show similar profiles which have their minima at the same composition ($n = 1.85$) in the region where $n < 1.9$, indicating that oxygen vacancies produced by the two different mechanisms influence $\Delta\overline{H}$ in the same manner when defects of the oxygen ion lattice dominate.

In the region where $n > 1.9$, however, $\Delta\overline{H}$ for $Ce_{1-x}Gd_xO_{2-x/2}$ drastically decreases towards $n = 2.0$ in contrast to the results for CeO_n. In the case of CeO_n, the decrease in $\Delta\overline{H}$ to a minimum at the composition $CeO_{1.85}$ can be interpreted as an effect associated with the increase in oxygen ion vacancies, with the increase after the minimum being an effect related to an ordering of lattice defects.

A remarkable decrease in $\Delta\overline{H}$ seen in the small x region for $Ce_{1-x}Gd_xO_{2-x/2}$ should not be attributed to the effect of oxygen vacancies but to the solution of Gd^{3+} itself. Perhaps a complex state between Gd^{3+} and O^{2-} with smaller binding energy is formed in a dilute solid solution, and the maximum at $x = 0.2$ could be interpreted as the result of rapid disappearance of the complexes between the composition $x = 0.1$ and 0.2.

An Improved Photolithographic Method of Metallization Applied to Fabrication of Planar Gunn-Effect Devices

O. Wada, S. Yanagisawa, and H. Takanashi

Fujitsu Laboratories Limited, Kamikodanaka 1015, Nakahara-ku, Kawasaki, Japan

ABSTRACT

It is difficult to provide a fine pattern of metal electrode across a step included in the substrate. In order to overcome this difficulty, we have developed a method in which a deposition mask is constructed photolithographically by using a composite with the multilayer structure of negative photoresist layer-metal layer-positive photoresist layer. The electrode metal is evaporated through the windows opened in the composite mask. The principle of the present method and detailed procedure are described. The effect of the geometrical configuration of the evaporation setup on the broadening of the defined metal edge is also discussed. This method is applied in order to fabricate a planar Gunn-effect device. A Schottky gate electrode with a width of 2 μm is delineated across a bevel with a height of 3.5 μm.

Recently, many workers have investigated the application of the Gunn-effect device with planar structure for high speed logic circuits, using an n-GaAs layer epitaxially grown on a semi-insulating GaAs substrate (1-4). Fabrication of these devices is performed by etching the unwanted area of the n-GaAs layer and preparing ohmic and Schottky contacts (2-4) on the active area which is protected during the etching. In these processes, steps are formed at the peripheries of the active areas. Usually, the height of the step is a few microns or larger (5). From the viewpoint of photolithography, however, the existence of the step is disadvantageous in delineating fine patterns of the electrodes, particularly in preparing the Schottky gate electrode across the step. Both the standard photolithographic method, in which etch-resistant photoresist is used, and the so-called "lift-off method" (7, 8), in which the photoresist pattern is formed prior to metal deposition, are not used successfully (9). On the contrary, improvement of the device characteristics, such as trigger sensitivity (3, 6), is achieved by preparing fine electrodes and controlling the separation between them. Bachem and co-workers avoided such a disadvantage with a completely planar structure (9) in which the n-GaAs layer is protected under the ohmic and Schottky contact patterns including the electrode leads during the sputter etching. However, this structure could possibly degrade the electrical characteristics of the device, due to inhomogeneities of the electric field or the gate capacitance under the electrode lead, especially for devices with minute dimensions.

In this paper, we wish to describe an improved method of defining the electrode patterns across the steps on the substrate. This method utilizes a composite of a photoresist layer, an overlying metal, and a photoresist layer as a deposition mask during the evaporation of the electrode metal. The use of this composite mask has been proposed by Grebe and co-workers (10) for the case where no step is involved. We have extended the method for use in the fabrication of planar Gunn-effect devices. The structure includes steps with 3.5 μm height and line widths of 2 μm.

Method

Figure 1 illustrates the sequence of the processes used to form a fine pattern of electrode across a step on the substrate. Only the key part of the device is shown, and the Schottky gate formation is used as an example; essentially the same process is applied

Key words: pattern delineation, bevel, deposition mask, ohmic contacts, Schottky gate electrodes.

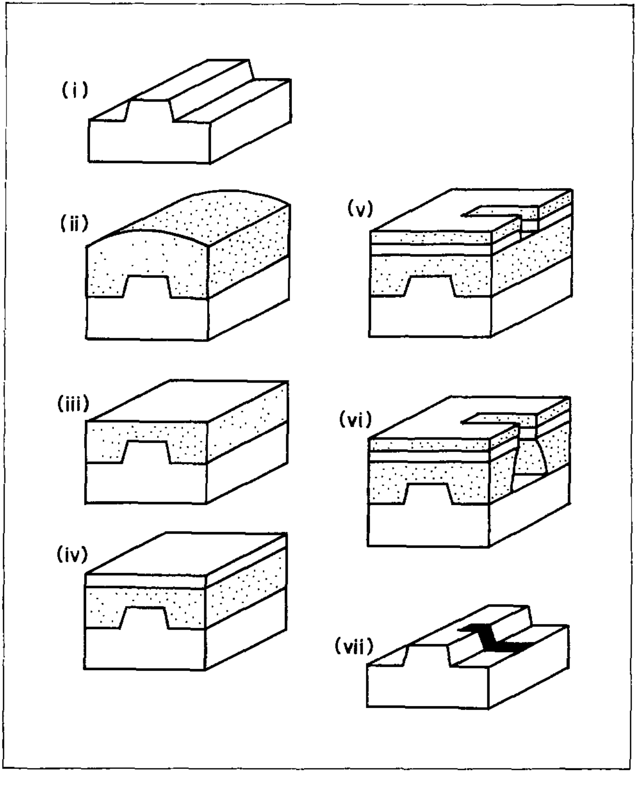

Fig. 1. Schematic representation of the method used to delineate a fine pattern of the metal electrode (Schottky gate) across a bevel on the substrate: (i) etching of the substrate to form a bevel, (ii) coating of the substrate with a positive photoresist layer followed by prebaking, (iii) thinning and smoothing of the resist layer, (iv) evaporation of a metal on the whole surface of the resist layer, (v) pattern formation on the metal layer by chemical etching with a mask produced by a negative photoresist layer using usual photolithographic technique, (vi) overexposure of the positive resist layer followed by development, (vii) evaporation of a metal film through the window in the composite layers and subsequent removal of the layers by immersion in acetone, thus leaving the desired pattern of the metal electrode.

to the ohmic contact formation. Here, we consider a GaAs layer with (100) surface.

(*i*) First, removal of the unwanted area of GaAs layer is performed by usual photoresist protecting technique and chemical etching. In this process, a bevel shape must be formed for the benefit of electrode crossing. The direction of the step edge should be chosen parallel to the <011> crystal axis (11, 12). An etchant, the rate of which is reaction limited (12), is effectively used to obtain the bevel shape.

(*ii*) Positive photoresist, *e.g.*, AZ-1350J,[1] with a thickness large enough to cover the whole substrate surface including the bevel top is coated and baked well (a few hours at 70°-80°C for AZ-1350J).

(*iii*) A flat photoresist surface is needed to minimize the deleterious effect of optical diffraction in the subsequent photoresist process. For this purpose, the resist surface is mechanically polished and smoothed to a thickness about 3-10 μm larger than the bevel height. This process is performed in a way similar to the polishing of various semiconductor surfaces. The resist surface is smoothed by polishing with alumina powder (grain size of 3-0.3 μm) dissolved in water on a flat plate the surface of which is coated with a silk cloth, and is then finished by polishing in flowing water. Shallow scratches which are passively made in this process are not too harmful because the resist layer acts only as a spacer between the substrate surface and the overlying metal layer; the latter is prepared in the subsequent process. Thus, a carefully performed process results in a good uniformity of the residual resist thickness excluding the small area neighboring the wafer edge.

(*iv*) A metal layer is deposited on the whole surface of the resist layer. It is recommended that the procedure (*ii*) to (*iv*) be carried out under darkroom conditions.

(*v*) The electrode pattern is delineated by the usual protecting method and chemical etching. In this process, a positive photoresist layer is applicable as described by Grebe *et al.* (10). In that case, however, the resist is also removed in the next procedure in which the exposure and development of the lower resist layer are carried out. When a negative resist is used, it can still remain on the metal surface during the subsequent process. The use of a negative photoresist layer is advantageous in forming a good deposition mask even when the undercut of the metal layer occurs during etching procedure because the remaining negative photoresist edge works as the pattern-defining mask during the following metal evaporation process.

(*vi*) By the exposure of the whole area followed by the development, the exposed portion of the positive photoresist layer upon which no overlying metal exists is removed. The residual upper resist layer together with the metal layer can work as the deposition mask in the next process. The exposure time should be long enough for the bottom width of the hole in the resist to exceed the width of the metal deposited in the subsequent process. Overexposure is needed to control the pattern definition property only by the deposition process, not by other conditions. This aspect is useful to exclude the critical nature of the exposure and development of a thick resist layer.

(*vi*) Next, the electrode metal is evaporated at an angle normal to the surface, then the resist layers and the upper metal layers are removed by immersion of the substrate in acetone. These processes result in the desired structure.

[1] Shipley Company, Incorporated, Newton, Massachusetts.

In the last step of these processes, the configuration of the evaporation setup influences the quality of the deposited metal edge. The schematic illustration of the setup is shown in Fig. 2. As can be seen in Fig. 2, the broadening, b, and the tilting distance, t, of the edge are expressed by $s(l - m)/2(h - s)$ and $sl/(h - s)$, respectively. In order to reduce these values for a given pattern width, m, it is important to select a large source-substrate separation, h, a small source dimension, l, and a small resist thickness, s. Although a greater amount of metal is required as h increases, broadening and tilting of the edge are greatly suppressed.

Results and Discussion

To demonstrate the performance of the present method, an experimental result is described. A GaAs crystal with (100) surface was etched into bevel shapes, the height of which were 5.8 μm, using the $8H_2O_2 \cdot 1H_2SO_4 \cdot 1H_2O$ system (12). Then the composite mask was constructed using AZ-1350J, an Au layer ($\simeq$0.2 μm), and spin-coated OMR-83[2] ($\simeq$1 μm). The lower resist layer was thinned to about 11 μm on the bevel bottom surface and to about 5 μm on the bevel top surface. The uniformity of the resist thickness was good in the whole wafer area, excluding the area within 150 μm from the wafer edge. After the delineation of the patterns on the Au layer, the positive resist was exposed to ultraviolet light for 10 min by means of a conventional photoresist exposure apparatus. Then the Au layer with 0.7 μm thickness was deposited by using an evaporation source with effective surface dimensions of 1.3 cm $\times$ 0.7 cm (l = 1.3 cm). The substrate was set at a distance of 25 cm from the source (h = 25 cm). Figure 3 presents scanning electron micrographs showing the cross sec-

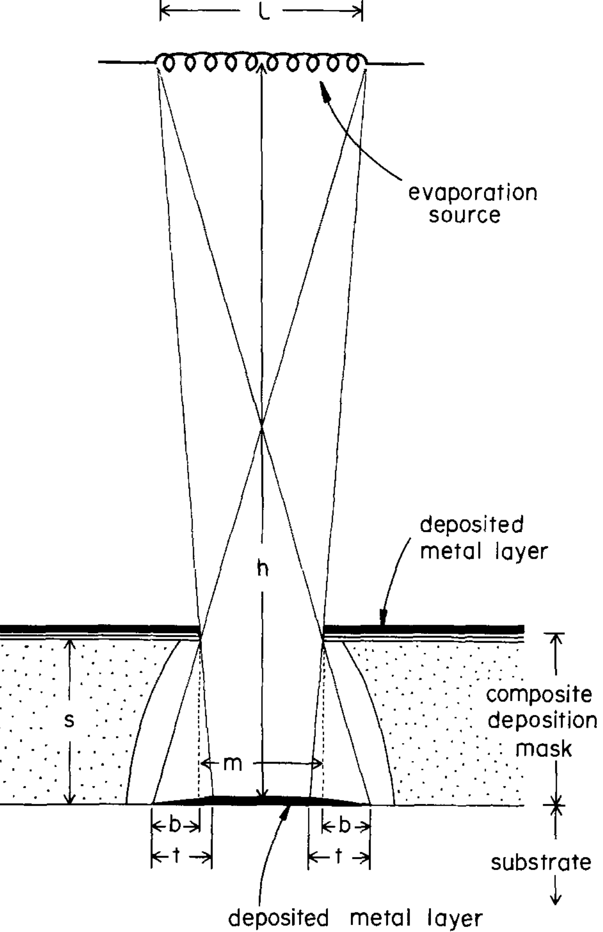

Fig. 2. Schematic drawing of the geometrical configuration of the evaporation source, the composite mask, and the substrate surface.

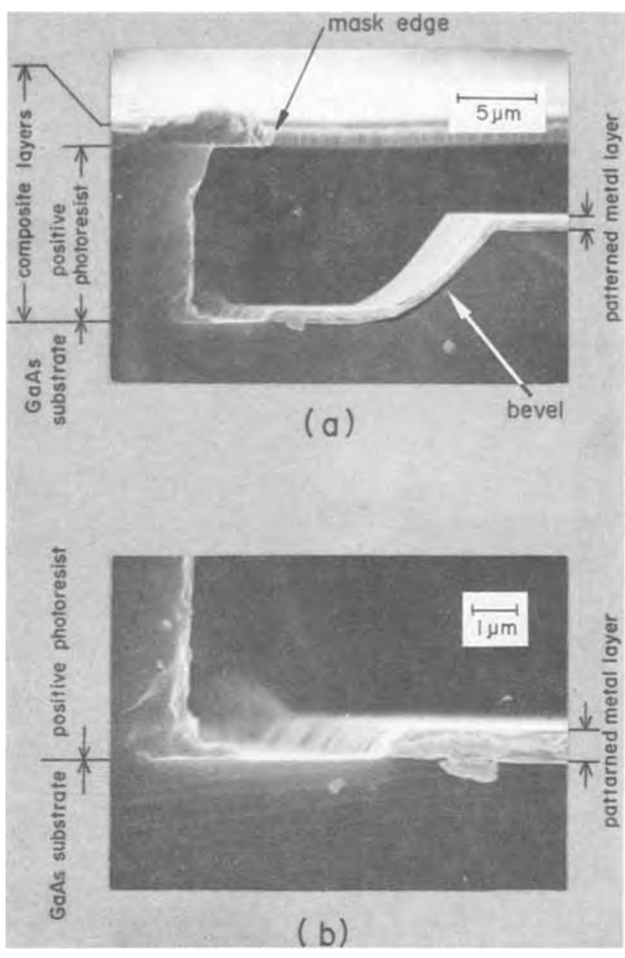

Fig. 3. Scanning electron micrograph of the structure of the substrate which is cross sectioned just after the evaporation of the gold layer. The structure observed for the area near the bevel is shown.

tion of the substrate after metal evaporation. The figure indicates that the deposited metal is delineated by the edge of the upper deposition mask, and that the overexposed lower resist layer works as a spacer. Taking $h >> s$ and $l >> m$ into account, we can calculate the dimensions of the deposited metal edge. In this case, the tilting distance is calculated to be 0.6 μm on the bevel bottom surface and 0.3 μm on the bevel top surface, and the corresponding broadening is one-half of that on each surface. From Fig. 3(b), the tilting distance is measured to be approximately 0.5 μm on the bevel bottom surface. As is expected, this value agrees with the calculated one. Figure 4 shows the scanning electron micrograph of the Au pattern which was revealed after removal of the composite mask. Both the left-hand and the right-hand parts of the photograph show the top and the bottom surfaces of the bevel. A thick metal layer with well-defined edges is formed on each surface. It is also worth noticing that some pile-up of the deposited metal on the edge of the composite deposition mask occurs, as shown in Fig. 3(a). This may cause a narrowing of the window opened in the mask during the course of metal evaporation, particularly in the case where a very thick metal layer is delineated. The tilting of the upper edge of the deposited metal with an angle smaller than the expected one (Fig. 4) may be attributable to this window-narrowing effect.

Planar Gunn-effect devices were fabricated using the same method. An n-GaAs layer with (100) surface grown on a Cr-doped GaAs substrate was etched into a bevel with a height of 3.5 μm. Then the composite mask was formed as described above. To form the ohmic contacts, an Au-Ge-Ni mixture was evaporated to a thickness of about 3000Å. Removal of the composite mask and subsequent alloying of the Au-Ge-Ni films at 430°C for 40 sec provided good ohmic contacts. The Schottky gate electrode was prepared by an aluminum layer with 3000Å thickness. In this fabrication, a smaller source dimension (l = 0.7 cm) and a larger source-substrate separation (h > 30 cm) than those used in the previous experiment were selected. Figure 5 shows the whole structure of the resultant device. The separation between the gate and the cathode and the small width of the gate are both 2 μm on the top of the bevel. It has been confirmed by large magnification measurement that any additional broadening of the gate line width cannot be detected within the measurement accuracy even on the bevel bottom surface.

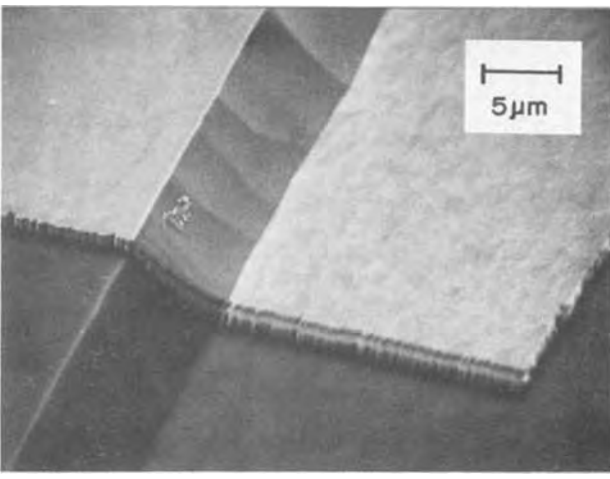

Fig. 4. Scanning electron micrograph of the bevel metallized by a thick metal layer showing the structure after removal of the composite mask. Note that the metal edges both on the top surface (left-hand side) and on the bottom surface (right-hand side) are appreciably well defined.

Figure 6 shows the waveforms of the triggering input and the current output obtained on a device with a gate-anode separation of 25 μm. The device

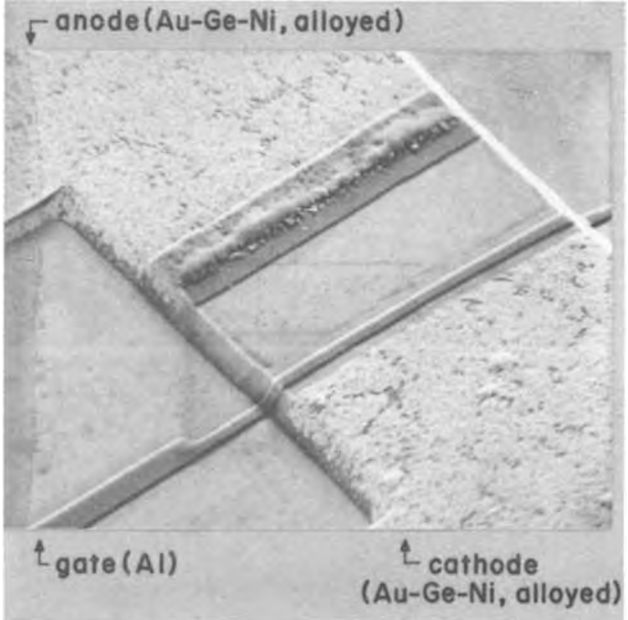

Fig. 5. Scanning electron micrograph of a planar Gunn-effect device with a Schottky gate prepared by using the metallization method described in the text. The distance between the gate and the anode, the width of the active layer, and the bevel height are 20 μm, 60 μm, and 3.5 μm, respectively. The gate width is only 2 μm.

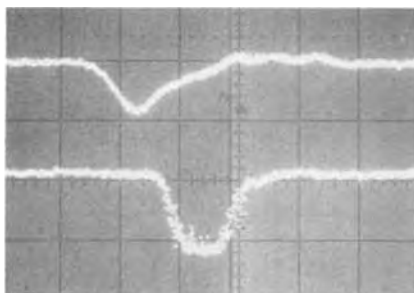

Fig. 6. Waveforms of the triggering signal fed into the gate (upper trace) and the current output detected by a 50 ohm load resistor (lower trace). The device is d-c biased at the subthreshold state. The vertical scale is 100 mV/div, and the horizontal scale is 250 psec/div. The time scale for the upper trace advances that for the lower one by about 100 psec in this photograph.

was d-c biased and the output was controlled by the triggering signal fed into the gate. A rapid response with 300 psec pulse width was obtained on the output by a gate input as small as 80 mV. In fabricating a device with such a large pulse repetition rate, and therefore having such fine dimensions, the method described in this paper is useful.

Conclusions

An improved photolithographic method makes it possible to delineate a fine pattern of the electrode metal across a bevel on the substrate. The method utilizes a deposition mask with a multilayer structure composed of a negative photoresist layer, a metal layer, and a positive photoresist layer. In this method, the deleterious effect of optical diffraction is minimized by using an exposure mask in intimate contact with the flat surface of the upper negative photoresist layer. To obtain the flat surface, the lower photoresist layer surface is mechanically polished. Then windows are opened in the lower photoresist layer using the pattern-defined upper metal layer as an exposure mask. Thus the pattern-defining deposition mask is formed by the upper photoresist layer together with the metal layer. The broadening and tilting of the resulting pattern edge are minimized in the subsequent metal evaporation process by adopting an evaporation source with a small area and by setting the substrate far from the source.

The method has been applied in the fabrication of planar Gunn-effect devices with bevel heights of 3.5 μm. A Schottky gate electrode with a width of 2 μm has been delineated across the bevel. A rapid response characteristic has been achieved, largely due to the fine electrode patterns.

Delineation of a fine pattern across bevels on the substrate is greatly improved by this method. Adding to this, a greater thickness of the deposited metal does not impede the pattern formation. By this method, it is possible to make a narrow, thick metal stripe across a bevel, which has a small longitudinal resistance. Moreover, owing to these features, this method is considered to be of further usage in the microfabrication of GaAs.

Vapor Pressure Dependence of the Relative Composition of III-V Mixed Crystals in Vapor Phase Epitaxy

Kenji Kajiyama

Nippon Telegraph and Telephone Public Corporation, Electrical Communication Laboratories, Musashino, Tokyo 180, Japan

ABSTRACT

It is thermodynamically deduced that the composition x of $In_xGa_{1-x}As$ depends on the arsenic vapor pressure in a vapor phase epitaxy. Calculated results agree with the experiments. A simplified formula of the equilibrium relation is also deduced in the conventional reaction system without excessive arsenic pressure.

Mixed crystals of III-V compounds are promising materials in various applications. Taking the $In_xGa_{1-x}As$ system as an example, the distribution relation of In *vs.* Ga between the source vapor phase and the crystal phase should depend on the As vapor pressure. A simple derivation of the distribution relation is pre-

Key words: III-V, $In_xGa_{1-x}As$, arsenic vapor, vapor phase epitaxy, distribution relation.

sented here, along with a comparison with experimental results. Experiments have been carried out with an (In-Ga)-$AsCl_3$-As-H_2 system (1). As_4 and HCl are produced by the reaction of $AsCl_3$ with H_2 at 850°C. Resulting HCl reacts with In-Ga metal to form InCl and GaCl (870°C). The most significant feature of this system is that the main As source is metallic As, which is evaporated by heating at a temperature from 350° to 460°C. Evaporated As pressure is much larger than the decomposited As pressure from $AsCl_3$. H_2 is used as a carrier gas.

Assuming equilibrium

$$InCl(g) + \tfrac{1}{4}As_4(g) + \tfrac{1}{2}H_2(g) = InAs(s) + HCl(g) \quad [1]$$

$$GaCl(g) + \tfrac{1}{4}As_4(g) + \tfrac{1}{2}H_2(g) = GaAs(s) + HCl(g) \quad [2]$$

with the equilibrium constant K

$$K_{InAs} = a_{InAs}p_{HCl}p_{InCl}^{-1}p_{As_4}^{-1/4}p_{H_2}^{-1/2}$$

and

$$K_{GaAs} = a_{GaAs}p_{HCl}p_{GaCl}^{-1}p_{As_4}^{-1/4}p_{H_2}^{-1/2}$$

where a is the activity and p is the partial pressure (atm) in the crystal growth region. The above formulas are valid in any reaction system with chlorides for the transport of III-group components and H_2 as the carrier gas. Using the regular solution model (2), activities are given with the interaction parameter α

$$a_{InAs} = x \exp [\alpha(1 - x)^2/RT],$$

$$a_{GaAs} = (1 - x) \exp [\alpha \cdot x^2/RT]$$

In the usual experimental temperature region, $p_{InCl_2} << p_{InCl}$, $p_{InCl_3} << p_{InCl}$, $p_{GaCl_2} << p_{GaCl}$, $p_{GaCl_3} << p_{GaCl}$, and $p_{Cl_2} << p_{HCl}$, which have been confirmed by mass spectrometry (3) and the equilibrium constants (4). The molar ratio $y = n_{In}/(n_{In} + n_{Ga})$ of In to the total III-group components in the source vapor is approximated as

$$y/(1 - y) = p'_{InCl}/p'_{GaCl} = (p_{InCl} + x\,p_{HCl})/\{p_{GaCl} + (1 - x)p_{HCl}\} \quad [3]$$

where $p'_{InCl} - p_{InCl} = \gamma \cdot \Delta n_{InAs} = \gamma \cdot x \cdot \Delta n_{In_xGa_{1-x}As} = x \cdot p_{HCl}$ and $p'_{GaCl} - p_{GaCl} = \gamma \cdot \Delta n_{GaAs} = \gamma(1 - x) \Delta n_{In_xGa_{1-x}As} = (1 - x)\, p_{HCl}$ (p' is the starting partial pressure, Δn is the depositing rate of crystal, and γ is the experimental constant), since, in the In-Ga source region, HCl is almost fully consumed by the In-Ga source to form InCl and GaCl (3) and, in the crystal growth region, HCl is regenerated from InCl and GaCl to deposit InAs and GaAs, respectively.

The composition dependence on As pressure is then deduced, using $p_{H_2} = 1 - p_{As_4}$. In the usual experimental condition, $p_{InCl} << 1$, $p_{GaCl} << 1$, $p_{HCl} << 1$, and $p_{As_2} << p_{As_4}$. The last inequality is approved by the equilibrium constant $K = p_{As_2}^2/p_{As_4} << 10^{-3}$ ($T <$ 1100°K) of the equilibrium $As_4(g) = 2As_2(g)$ (4)

$$p_{As_4}^{1/4}(1 - p_{As_4})^{1/2} = \frac{1}{y - x}\left\{\frac{x(1 - y)}{K_{InAs}}\exp\frac{\alpha(1 - x)^2}{RT} - \frac{(1 - x)y}{K_{GaAs}}\exp\frac{\alpha x^2}{RT}\right\} \quad [4]$$

As the left-hand side of Eq. [4] has a maximum $\sqrt[4]{4/27}$ at $p_{As_4} = 1/3$ and a minimum 0 at $p_{As_4} = 0$ or 1, the range of x is restricted for a given y. If $p_{As_4} << 1$, which corresponds to the minimum condition and is the conventional case without metallic As source, Eq. [4] becomes simpler. In this case, the consumption of the III-group components in the crystal growth region is small ($y/(1 - y) = p'_{InCl}/p'_{GaCl} \approx p_{InCl}/p_{GaCl}$)

$$y/(1 - y) = (K_{GaAs}/K_{InAs})\{x/(1 - x)\} \exp\{\alpha(1 - 2x)/RT\} \quad [5]$$

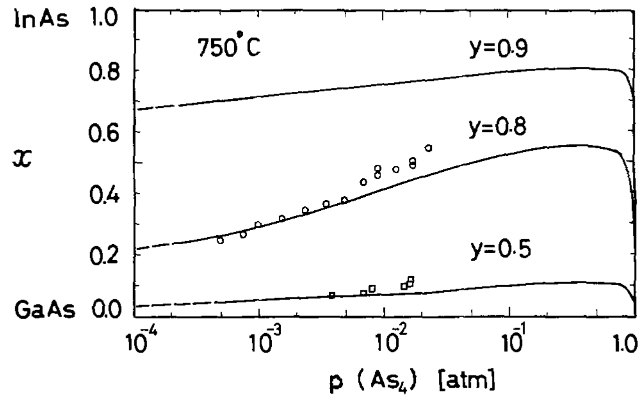

Fig. 1. Composition x of $In_xGa_{1-x}As$ crystal vs. arsenic vapor pressure p_{As_4} with the starting molar ratio y of In. ———: calculated result; point: experiment (1); ○: $z = 0.9$ ($y = 0.83$); □: $z = 0.7$ ($y = 0.61$).

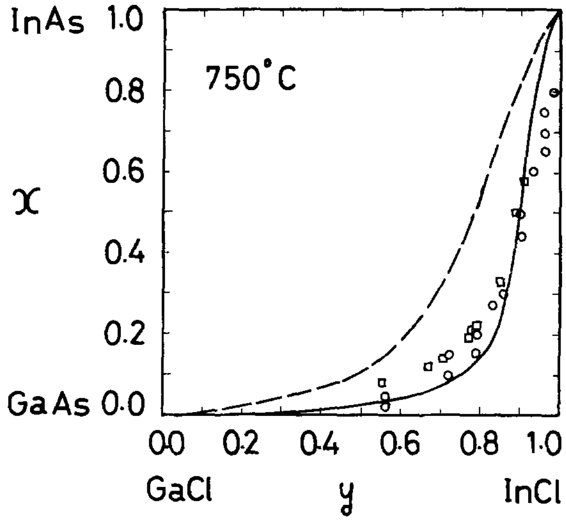

Fig. 2. Distribution relation of the III-group component between y in the starting source vapor and x in the grown crystal. ———: calculated result for the minimum (the case in the conventional experiments); - - - - -: calculated result for the maximum; ○: experiment (7); □: experiment (8).

The As pressure dependence of the distribution relation (Fig. 1) and the range of x (Fig. 2) have been calculated using the thermodynamic coefficients: $\alpha =$ 3000 cal/mole (2), $\log_{10}K_{InAs} = -7.68 + 7595/T$ (5), $\log_{10}K_{GaAs} = -8.04 + 6990/T + 0.35 \times 10^{-3}\,T + 0.22 \ln T$ (4). The calculated As pressure dependence agrees with the experimental results (1).[1] The starting As pressure in the source gas does not exactly equal the equilibrium As pressure in the crystal growth region. But the difference between them, which results from crystal deposit, is small. (p'_{As_4} is much larger than p' of any other component gas in metallic As source system.)

As the In-Ga source has been used in the experiment, the distribution relation between y and the molar ratio z of In in the In-Ga source is needed. The y-z relation is deduced in a similar way to Eq. [5], assuming a thermoequilibrium condition in the In-Ga source region

$$y/(1 - y) = (K_{Ga}/K_{In})\{z/(1 - z)\} \exp\{\alpha_{In\text{-}Ga}(1 - 2z)/RT\} \quad [6]$$

with

$$K_{In} = p_{InCl}p_{H_2}^{1/2}a_{In}^{-1}p_{HCl}^{-1}$$

$$K_{Ga} = p_{GaCl}p_{H_2}^{1/2}a_{Ga}^{-1}p_{HCl}^{-1}$$

[1] If a small quantity of the In-Ga source is used, x increases during the series of experiments, because Ga is consumed faster than In, as shown by the following y-z relation.

where $p'_{InCl_2} << p'_{InCl}$, $p'_{InCl_3} << p'_{InCl}$, $p'_{GaCl_2} << p'_{GaCl}$, $p'_{GaCl_3} << p'_{GaCl}$, and $p'_{Cl_2} << p'_{HCl}$ are assumed in the In-Ga source region (3, 4). Calculated y values for the experimental z values are shown in the caption of Fig. 1. The following thermodynamic coefficients were used: $\alpha_{In\text{-}Ga} = 1060$ cal/mole (6), $K_{In}(900°C) = 4.56$ (3), $K_{Ga}(900°C) = 5.67$ (3).

The calculated x-y relation for the minimum condition agrees with the experimental results (7, 8), but differs somewhat from other detailed calculated results (9). The reason is a difference in the adopted thermodynamic coefficients but not in the simplified theory. The distribution relation depends weakly on the temperature because K_{GaAs}/K_{InAs} and $\exp\{\alpha(1-2x)/RT\}$ vary slowly with temperature.

In a conventional reaction condition, where the partial pressure of the reactant gas is low ($< 10^{-3}$ atm), the distribution relation of III-V mixed crystal is generally simplified[2]

$$y/(1-y) = [(K_1/K_2)\{x/(1-x)\} \cdot \exp\{\alpha(1-2x)/RT\}]^m \quad [17]$$

where m is the number of relevant atoms in a molecule participating in the thermoequilibrium. For example, $m = 1$ in the $In_xGa_{1-x}As$ system (In in InCl and Ga in GaCl) and $m = 4$ in the $InAs_xP_{1-x}$ system (10) (As in As_4 and P in P_4). And the distribution relation depends on the partial pressure of the common atom, *e.g.*, p_{As_4} in the $In_xGa_{1-x}As$ system and p_{InCl} in the $InAs_xP_{1-x}$ system (10).

[2] A detailed discussion of the deduction will appear later with another good example of $InAs_xP_{1-x}$.

Acknowledgments

The author would like to thank Mr. M. Yamaguchi for unpublished data and Dr. Y. Mizushima for his encouragement.

Manuscript submitted Aug. 27, 1974; revised manuscript received ca. Nov. 7, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the Nippon Telegraph and Telephone Public Corporation.

The Preparation of High T_c Nb_3Ge Superconductors by Chemical Vapor Deposition

L. R. Newkirk, F. A. Valencia, and T. C. Wallace

Los Alamos Scientific Laboratory, Los Alamos, New Mexico 87544

ABSTRACT

Bulk layers of Nb_3Ge have been deposited on copper substrates at 900°C by the hydrogen reduction of the chlorides of niobium and germanium with resistive T_c's as high as 22.5°K and current densities up to 1.8×10^6 A-cm^{-2} at 13.8°K. This paper provides a detailed description of the coating process as well as empirical correlations between deposition parameters and T_c. Quantitative chlorination of Nb was found to be possible at $T \approx 250°C$ and for $T > 900°C$ extending the range of delivery rates below those obtainable by powder feeding of $NbCl_5$. Coatings in the range of 10-60 μm thick have been produced with a typical deposition efficiency of 50-65% for mass flow rates of the order of 1g of salt per minute. The superconducting transition temperature has been correlated with a parameter of the form mole ratio $\times$ dilution $\times$ Reynolds number$^{0.22}$, where mole ratio is defined by moles Nb:moles (Ge + O) in the gas stream, and dilution by moles gas:moles salt. In addition, the relationship between mole ratio and dilution which determines the phase produced (Nb_3Ge or Nb_5Ge_3) is defined over the region of major interest. Lattice spacings are presented over a range of T_c's, and microstructure and substrate adherence are discussed.

With the discovery that careful sputtering could produce Nb_3Ge with a transition temperature from 22° to 23°K (1, 2) this previously unexciting material was thrust to the forefront of high-temperature superconductors. In order to study properties requiring bulk quantities of material as well as to show potential for commercial or industrial development, a technique was required which is capable of generating bulk quantities of this material. The authors (3) and others (4-7) have demonstrated that the technique of chemical vapor deposition (CVD) is capable of producing Nb_3Ge with superconducting onsets above 22°K in quantities sufficient for a variety of measurements, and in layers of sufficient thickness to be useful technologically. The superconducting properties of these deposits have been detailed in Ref. (3) and (4), and it is the intent of this paper to describe the deposition process itself and to examine the effects of the various coating parameters.

Key words: superconductivity, niobium-germanide, beta-tungsten, vapor deposition.

Coating Technique

Basic apparatus.—The basic apparatus used in these experiments is depicted schematically in Fig. 1. Argon and hydrogen mixed in the desired proportions are preheated in a 2.5 × 30 cm cylindrical nickel chamber maintained at 500°C, and then mixed in a stainless steel tee at 350°C with $NbCl_5$ vapor generated by one of the methods described later. $GeCl_4$ vapor, produced by passing Ar through liquid $GeCl_4$ in the $GeCl_4$ saturator, is introduced into the gas stream, and the resulting combination passed directly into the mixing chamber. This 5 × 30 cm stainless steel chamber contains 10 nickel baffles which prevent any channeling of the gas through the chamber, and is maintained at 500°C. The plumbing connecting these components is made of Ni tubing or pipe, except where couplings necessitate the use of stainless steel.

After preheating and mixing, the gases and chlorides pass into the coating chamber where reduction takes place at 900°C according to the following reaction

$$3NbCl_4 + GeCl_2 + 7H_2 \rightleftharpoons Nb_3Ge + 14\,HCl \quad [1]$$

The $NbCl_4$ and $GeCl_2$ which enter the reaction are generated from the $NbCl_5$ and $GeCl_4$ by thermal decomposition as the salt temperatures are increased through the coating train, with the excess chlorine reacting to HCl. The deposition area itself consists of the inside surface of a cylindrical hard drawn Cu tube 2.2 × 60 cm with a wall thickness of 1 mm, surrounded by a 1 in. Ni pipe. The Ni pipe serves to protect the Cu tube from direct exposure to the atmosphere as well as to improve the uniformity of the substrate temperature. Temperature is measured by 4 Chromel-Alumel thermocouples placed in mechanical contact with the substrate at ~ 8, 23, 38, and 53 cm from the inlet end. Before being exhausted, the unused gases leaving the coating chamber are passed through an oil bubbler to prevent the back diffusion of air.

Niobium delivery.—Both $NbCl_5$ powder and Nb chlorination were used successfully as sources of $NbCl_5$ vapor. $NbCl_5$ powder of reactor grade purity, but containing significant amounts of $NbOCl_3$, was screened to −100 mesh and entrained on an Ar gas stream by means of a commercial powder feeder (Plasmatron by Plasmadyne Division of Geotel Incorporated). Feed rates varying from 0.8 to 2 g/min were employed with the lower feed rate limited by the equipment. Rates were measured by monitoring an electronic load cell connected to the Plasmatron, with an estimated accuracy of ±5%. The entrained powder is then passed into a 20 liter stainless steel chamber maintained at 400°C, where the $NbCl_5$ is vaporized. This large volume serves the additional function of smoothing fluctuations in the $NbCl_5$ flow caused by irregularities in the Plasmatron or packing of the chloride into small pellets. The argon-$NbCl_5$ vapor mixture is then either passed into the coating train or exhausted through an oil bubbler, depending on the positions of the valves shown in Fig. 1.

The alternate technique of Nb chlorination is carried out in a 5 × 30 cm cylindrical nickel chamber maintained at 250°-260°C, containing reactor grade niobium tubing either in the form of strips or cuttings. A chlorine-argon mixture in the ratio of ~1:4 is introduced into the chamber, and chlorination to $NbCl_5$ takes place. This process is sufficiently free of fluctuations that the $NbCl_5$ vapor can be introduced directly into the coating train following chlorination, without the necessity of passing through a large buffering volume.

Experimental Procedures

Lattice spacings.—Crystal structure and lattice spacings are determined by means of both powder patterns and a diffractometer. Powder patterns are obtained using a 114.6 mm Debye-Scherrer camera with copper radiation, and diffractometer patterns are produced with a Picker Model 3488 K, also using copper radiation. In both cases lattice spacings are determined by a least squares (8) extrapolation against the Nelson-Riley function, and are estimated to be accurate to ±0.002Å.

Superconducting transitions.—Superconducting transitions are measured both inductively (f = 23 Hz) and resistively ($J < 10$ A-cm^{-2}). A complete explanation of measurement techniques and thermometer calibration is found in Ref. (3). In general, temperatures are estimated to be ±0.2°K for both the inductive and resistive measurements.

Oxygen analysis.—The method employed in this study to determine oxygen content depends on the use of a Pt melt to form stable platinides of Nb and Ge, allowing the liberation of oxygen as carbon monoxide (9). A portion of the sample to be analyzed (20-40 mg) is placed in a graphite crucible containing ~3g of Pt. The crucible is placed in a vacuum system and evacuated to a pressure of ~2×10^{-6} Torr, following which the system is sealed off and the crucible rapidly heated to 2000°C for 1 min. The pressure rise in the system is measured using a thermocouple gauge and the oxygen content calculated on the basis of the system volume. Any material suspected of containing small amounts of NbH is first dehydrided by heating to ~700°C in a vacuum of 2×10^{-6} Torr for 2 min. Samples of the evolved gas for the first 15 specimens examined were analyzed on a gas chromatograph and found to consist entirely of carbon monoxide. Oxygen composition determined by this method is estimated to be accurate to ± 10% of the measured value.

Metallography.—Samples examined metallographically were subjected to standard grinding and polishing procedures through 0.05 μm alumina. Etching was carried out for times ranging from 15-60 sec in a mixture of $90H_2SO_4$ and 10HF by volume. Samples were etched by immersion and pumped in a vacuum chamber for 10-15 min following washing to remove any trace of etchant.

Experimental Results

Chlorination of Nb.—The feasibility of Nb chlorination was studied over the full range of possible temperatures (ambient to 950°C) with the intent of determining if the quantitative production of one of the chlorides was possible. The primary hindrance to achieving this is the formation $NbCl_3$ by the reaction of $NbCl_5$ with the excess Nb according to Eq. [2]

$$3NbCl_5 + 2Nb \rightarrow 5NbCl_3 \quad [2]$$

$NbCl_3$, which has a range of homogeneity (10), does not vaporize, but rather slowly decomposes as a function of temperature and $NbCl_5$ vapor pressure, to $NbCl_5$ or possibly $NbCl_4$ if the temperature is sufficiently high. Since the chlorinator must contain excess Nb to insure that all the Cl_2 is reacted, the formation of $NbCl_3$ must be prevented by the choice of temperature. Two temperature ranges have been found where this is possible. Above 900°C $NbCl_3$ does not form, and the Nb is reacted directly to $NbCl_4$, in substantial agreement with the chlorination technique used in Ref. (4). The disadvantage of this technique seems to be in the necessity

Table I. Nb consumption

Series	Calculated Nb consumption	Actual Nb consumption	Error
1	125.9g	120.4g	4.4%
2	200.9g	190.1g	5.4%

of keeping the chloride vapor at a relatively high temperature from production to reaction. Failure to do this can result in decomposition to $NbCl_3$ destroying the quantitative aspects of the process.

The second temperature where quantitative chlorination is possible, and the one employed in this study, is $T = 260°C$. Although $NbCl_3$ is stable at this temperature, the reaction of $NbCl_5$ with Nb does not proceed if the partial pressure of $NbCl_5$ is maintained at or below 0.1 atm. Four chlorinators were examined after producing 150-200g of $NbCl_5$ each and the remaining Nb removed. The Nb was quite clean, indicating the absence of any $NbCl_3$ (a blue-black deposit). The Nb strips were etched or attacked only at the inlet end, indicating complete consumption of the Cl_2. For two of the chlorinators records were maintained of the total chlorine flow over the life of the chlorinators, and the expected Nb consumption was calculated with the results shown in Table I. It is important to note that this technique is quantitative only if the partial pressure of $NbCl_5$ is maintained at or below the value indicated, by dilution with Ar or another inert gas. If it is allowed to approach 1 atm, $NbCl_3$ formation occurs and quantitative transfer of Nb is lost.

Superconducting onset.—The variation of superconducting onset with deposition parameters is shown in Fig. 2. For this figure data were used only for samples taken between 15 and 30 cm from the inlet end since T_c has been found to vary along the length of the coating chamber. For these correlations T_c is determined inductively at 23 Hz and in general is 1-1.5°K lower than the resistively determined onset. The parameter mole ratio × dilution × Reynolds number$^{0.22}$ was arrived at empirically and its possible significance will be discussed later. The mole ratio used in this figure is the mole ratio of $NbCl_5$ to $GeCl_4$ introduced into the apparatus, adjusted for the amount of oxygen found in the deposit. This adjustment is made with the assumption that the oxygen is in solid solution in the A-15 structure and is found on Ge lattice sites. Although no direct evidence exists that this is the case (*i.e.*, neutron or x-ray ordering studies), all attempts to correlate T_c with deposition parameters failed without this assumption. Dilution is defined as the ratio of total moles of gas to total moles of chlorides passed through the system.

Figure 3 shows deposition efficiency as a function of the same parameter. Efficiency was defined as the weight of the deposit divided by the weight of Nb and

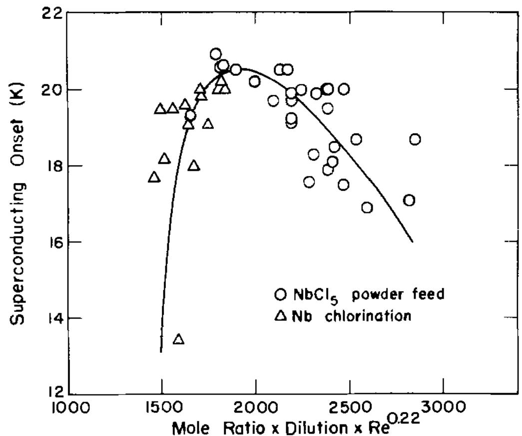

Fig. 2. Variation of T_c with correlation parameter

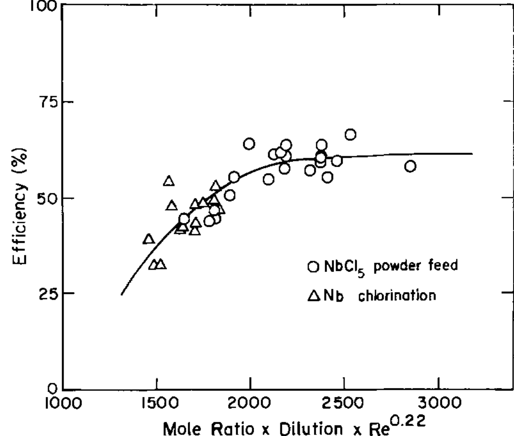

Fig. 3. Variation of efficiency with correlation parameter

Ge delivered, and varies between 30 and 65%. The data from which Fig. 2 and 3 were derived is tabulated in Tables II and III.

Phase relationships.—Figure 4 shows the relationship between deposition parameters and the phase produced. The boundary between the Nb_3Ge region and the Nb_5Ge_3 region does not seem to be sharp and indicates that the phases can coexist over a range of compositions. Whether this overlap is a property of the system or is the result of an inadequate choice of deposition parameters is not clear with the data available. A somewhat better boundary is possible if the scaling

parameter on the x axis is chosen to be dilution only, but the product of dilution × Reynolds number$^{0.22}$ was used to be consistent with the parameters used in Fig. 2 and 3.

Oxygen content.—The oxygen content of ~45 samples has been measured and values ranging from 0.1 to 2.1 weight per cent (w/o) were found. The primary source of this oxygen is $NbOCl_3$ contained in the $NbCl_5$ powder. When chlorination of Nb is carried out carefully instead of the use of $NbCl_5$ powder, material with an oxygen content of 0.1 w/o can be consistently produced. The presence of significant amounts of oxygen does not seem to be harmful to the superconducting properties; in fact, the very best material produced (inductive T_c's of 20.6-20.9°K and J_c's of 1.0-1.8 × 10^6 A-cm^{-2} at 13.8°K) contained from 1.0 to 1.2 w/o oxygen. A similar effect was also noticeable in the x-ray powder patterns, with deposits containing ~1.0 w/o oxygen having the greatest number of lines resolved into α_1 and α_2 doublets.

As noted in the section on superconducting onset, the oxygen content must be taken into account in calculating the A to B atom ratio in the A_3B structure. In addition to the major effect on T_c of altering the A to B atom ratio, it is also important to determine the effect of replacing Ge atoms by O atoms while maintaining the same A to B atom ratio. For the alloys studied, this effect, if it is present, seems to be smaller than the scatter in the data for both T_c and lattice spacings. As a result, neither T_c nor a_o provides direct evidence that the oxygen is in solid solution in the A-15 structure. Due to the difficulty in obtaining completely single-phase material (typical deposits are 80-90% A-15), ordering studies which may provide direct evidence concerning the location of oxygen atoms have not been completed.

Lattice spacings.—Figure 5 shows the inductive transition temperature as a function of lattice spacing. Several types of data are displayed in this figure in the following manner. The points shown for $NbCl_5$ powder feed (with buffer), and Nb chlorination are believed to represent relatively homogeneous material for the reasons explained in the description of the coating technique. Those points labeled $NbCl_5$ powder feed (without buffer) almost certainly contain significant compositional inhomogeneities as evidenced by visible fluctuations in the flow of $NbCl_5$ powder and metallographic evidence of a layered structure in the deposit. The first set of data represents the actual variation of lattice spacing with T_c, and an extrapolation of this data is in good agreement with arc-melted specimens. The second set of data is included to show the error inhomogeneities can cause in determining a relationship of this type. The measurement of lattice spacings from a powder pattern is a true average over the thickness of the material, while a measurement of T_c, even at 23 Hz, tends to be somewhat biased toward the best material present due to a shielding of the poorer material from the flux. For reasons such as this it is always necessary to be certain of the homogeneity of the material before trying to correlate any parameter which is clearly a bulk average with another property which can be influenced by small amounts of material.

Additional properties.—Figure 6 shows a photomicrograph typical of the microstructure of a homogeneous Nb_3Ge deposit. The grains are of the order of a few micrometers in size and seem to be elongated in the direction of growth. In addition, the interface between the Nb_3Ge deposit and the Cu substrate seems to indicate very intimate contact, probably a diffusion bond considering the solubility of Ge in Cu and the reducing properties of H_2 on Cu at 900°C. The only evidence of vapor phase attack on the Cu substrate is the presence in the deposit of 1000 ppm Cu when analyzed spectrographically. This copper is probably concentrated near the deposit substrate interface.

The effects of lower deposition temperatures and several heat-treatments are discussed in Ref. (3). In addition, heat capacity measurements are detailed in Ref. (10), critical current measurements in Ref. (11), and the effects of 1 MeV neutron irradiation in Ref. (12).

Discussion

Although the parameter used to define T_c and efficiency in Fig. 2 and 3 was arrived at empirically, some

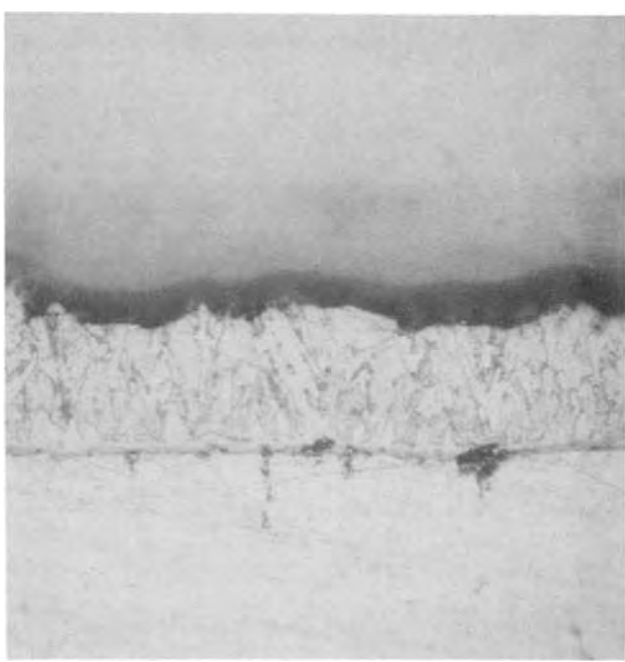

Fig. 6. Photomicrograph of Nb_3Ge deposit X545

insight is possible if the various processes involved in the deposition are considered. Any attempt to understand this dependence probably must begin with the assumption that a relationship exists between T_c and the composition of the deposit. If this is the case, the problem is reduced to finding the relationship between the stoichiometry of the deposit and the composition of the gas stream at the inlet. If one assumes that the composition of the deposit is determined by the relative concentrations of $NbCl_4$ and $GeCl_2$ at the deposition surface, and their respective reduction rates, then it is clear that the initial mole ratio of $NbCl_5$ to $GeCl_4$ and the relative diffusivities of $NbCl_4$ and $GeCl_2$ in the vapor mixture must play a role. While the calculation of these diffusivities in the five component system (Ar, H_2, HCl, $NbCl_4$, and $GeCl_2$) is extremely complicated, it seems likely that both the dilution and viscosity (the latter being contained in the Reynolds number) will be a factor. The other factor to be considered is the relative reduction rates, which depend in part on the products of the reaction. If the reduction is examined as two separate reactions as in Eq. [3]

$$NbCl_4 + 2H_2 \rightleftharpoons Nb + 4HCl$$
$$GeCl_2 + H_2 \rightleftharpoons Ge + 2HCl \quad [3]$$

it is seen that the production of HCl for the Nb reduction is considerably larger than that for the Ge. As a consequence, a change in dilution should have different effects on the rates of the two reactions, resulting in a change in the composition of the deposit.

It is clear from an examination of Fig. 2 that it is possible to produce high T_c material over a wide range of flow conditions and mole ratios. Since, however, this is entirely an empirical relationship and its physical basis is understood in only the most tenuous way, great caution must be exercised in applying the relationship outside the experimentally studied ranges of these parameters. These ranges cover Reynolds numbers from 600 to 2000 (including partial pressures of H_2 from 0.35 to 0.70 atm), mole ratios from 2.0 to 3.0, and dilutions from 140 to 230. The large degree of data scatter in Fig. 2 may be the result of inaccuracies in measuring the various parameters involved, or it may indicate that the correlation parameter used does not have the correct form. For this reason all the original data used to construct Fig. 2 and 3 is presented in Tables II and III in order that the reader is enabled to correlate T_c to parameters which may be more meaningful.

If the assumption is made that the best material produced contains ~25 a/o Ge then an interesting exercise is possible. Based on arc melt data of 5.166Å at 18-19 a/o Ge and CVD data of 5.142Å at 25 a/o Ge, an extrapolation to 0 a/o Ge shows that the lattice spacing of hypothetical A-15 Nb_3Nb might be expected to be in the range of 5.23-5.24Å, a value in close agreement with that obtained by Vieland *et al.* (7). A number of deposits made early in the study showed lattice spacings as large as 5.21-5.22Å, and were not superconducting to 4°K. If the above extrapolation is meaningful, this suggests that Nb_3Ge containing as little as 5-6 a/o Ge can be prepared with the A-15 structure. Since the major area of interest is stoichiometric Nb_3Ge, sufficient data was never acquired concerning the location of the Ge deficient phase boundary to draw any firm conclusions.

Acknowledgments

The authors wish to express their thanks to A. L. Giorgi and E. G. Szklarz for the inductive T_c measurements, and to B. T. Matthias for his help in undertaking and pursuing this project.

This work was completed under the auspices of the Energy Research and Development Administration.

and W. L. Worrell*

Department of Metallurgy and Materials Science, University of Pennsylvania, Philadelphia, Pennsylvania 19174

ABSTRACT

The electrical conductivity of high purity (99.8 pct) AlN has been determined using both a-c and d-c techniques. Measurements were made at temperatures between 700° and 1000°C and in a nitrogen pressure range of $1\text{-}10^{-5}$ atm. The electrical conductivity is independent of nitrogen pressure. Galvanic cell results indicate that ionic conduction is negligible. Over the experimental temperature range, the electrical conductivity of AlN follows the equation

$$\sigma(\text{ohm}^{-1}\text{-cm}^{-1}) = 6.89 \times 10^3 \exp(-E/kT)$$

where the activation energy (E) is 1.82 ± 0.06 eV. It is concluded that the conduction process is extrinsic due to carbon impurities (~350 ppm) present in the AlN.

Aluminum nitride is a potentially useful refractory material, particularly at elevated temperatures. Its oxidation in air at temperatures up to 600°C is low (1, 2), and it is resistant to attack by acids, molten metals, and water vapor (1, 3). Recent studies indicate that AlN is very resistant to chemical attack by lithium at 400°C (4); thus AlN may be a suitable electronic insulator in alkali metal-molten salt batteries. Aluminum nitride also has potential applications in elevated temperature semiconductor devices (5-7). Although these various applications require a detailed knowledge of its conductivity at elevated temperatures, there is considerable variation in the activation energy and magnitude of the electrical conductivity of AlN measured by previous investigators (1, 3, 6, 8-12). In this study the electrical conductivity of high purity (>99%) AlN has been measured using a-c and d-c techniques at temperatures between 700° and 1000°C and at nitrogen pressures between 1 and 10^{-5} atm.

Experimental

Hot-pressed polycrystalline AlN samples were prepared by Cerac/Pure Incorporated. Aluminum nitride powder was synthesized by the electric discharge method (3) and hot-pressed without binder in a graphite die at ~1600°C under a nitrogen atmosphere. The 1 cm diameter AlN rod was machined to remove surface-impregnated carbon and then cut into pellets of different thicknesses. Sample porosity did not exceed 5%. The pellets were annealed in our laboratory at 1400°C for 76 hr in high purity nitrogen. Chemical analyses performed by the supplier both before and after annealing are listed in Table I. It should be emphasized that the purity of the annealed samples (99.8%) is higher than AlN samples used in previous studies.

Gold electrical contacts, which were used in the a-c conductivity measurements, were fabricated using the following procedure. The flat surfaces of the AlN pellets were polished and then rinsed in acetone and petroleum ether. After coating the flat surfaces with du Pont thermosetting gold paste (No. 5780), the pellets were heated slowly in air to 200°C, held for 10 hr, and then annealed for 2 hr at 400°C. Coherent gold contacts with less than 0.1 ohm resistance across each contact surface were obtained. For the d-c conductivity measurements, aluminum powder was added to the gold paste to make gold-rich solid solutions (~0.5 atom per cent Al), which formed coherent electrodes after a similar annealing procedure. A two-phase presintered Cr,Cr_2N mixture was also used to provide electrical contact in one d-c conductivity experiment.

Table I. Chemical analysis (w/o)

Hot-pressed AlN pellets as received from Cerac

Al	66.10	B	0.001
N	33.0	Mn	0.001
Si	0.03	Cr	0.001
C	0.035	Cu	0.001
Ni	0.01	Sn	0.001
Fe	0.01	Ti	0.001
Mg	0.001		

Total measured content = 99.19
Remainder impurity assumed to be oxygen = 0.81%

After annealing in N_2 gas at 1400°C for 76 hr

Al 65.31% (theoretically 65.81%)
N 34.45% (theoretically 34.19%)
AlN = 99.8%

After preparing the electrical contacts, the AlN sample was sandwiched between two gold foils in an alumina reaction tube (Fig. 1). A spring-loaded arrangement was used to maintain good electrical contact between the sample and the gold foils. Platinum wires, which were spot-welded to the gold foils, provided electrical contact to the external equipment. A grounded platinum foil enclosed the alumina reaction tube to minimize any electrical noise originating from the a-c resistance windings.

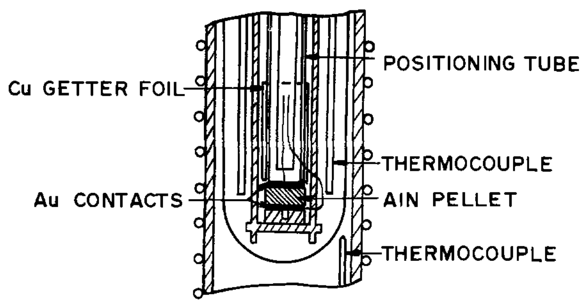

Fig. 1. Experimental arrangement

* Electrochemical Society Active Member.

Key words: extrinsic conduction in AlN, effect of carbon impurities, electronic conductivity in AlN, chromium nitride electrodes.

The AlN sample was equilibrated with nitrogen gas at 1 atm or with N_2/Ar gas mixtures to establish nitrogen pressures at 10^{-2}, 10^{-4}, and 10^{-5} atm. Before being introduced into the apparatus, high purity nitrogen (no detectable impurities in parts per million) was passed through anhydrous $CaSO_4$ and through copper chips at 500°C to remove water vapor and oxygen. High purity argon was passed through $CaSO_4$ and Zr-Ti chips at 850°C. An internal copper foil was placed inside the reaction tube near the sample to further minimize any oxidation effects.

Two-probe a-c conductivity measurements were made using a Wayne-Kerr B221 transformer ratio-arm bridge operating at 1592 Hz and a General Radio 1232-A tuned amplifier and null detector. Voltage across the sample varied from 0.03 to 0.3V rms depending on the bridge range. With the bridge balanced, parallel conductance and capacitance were measured. A Wayne-Kerr S121 audio signal generator was used to vary the frequency from 50 to 20 kHz. For the d-c measurements, a Keithley 630 potentiometric electrometer (input impedance of 10^{13} ohm) was used to measure the potential drop across the AlN sample and across a standard resistor. A variable 12 megohm limiting resistor was used to maintain constant currents between 1 and 50 μA ($\pm 5 \times 10^{-3}$ μA). All components and lead wires were electrically shielded.

After positioning an AlN sample in the reaction tube, the tube was evacuated and checked for gas leaks. Gas flow was then introduced at 20 cm³/min, and the furnace temperature was increased at 200°C/hr to 800°C. Readings were taken over a period of 5-8 hr before the temperature was increased stepwise to 1000°C. Deviations in the measured values were less than 1 pct at each temperature. Cycling the temperature back to 700°C gave subsequent measurements within ±2.5% of those originally observed. The nitrogen pressure was then changed, and the same procedure was followed. Some samples were held at temperature for 1-2 days with no variation in conductance greater than 3%.

Results

A-C conductivity.—The a-c conductivity of each sample is equal to Gt/A, where G is the measured parallel conductance, t is sample thickness, and A is the cross-sectional area. Conductivity results for one sample under 1 atm nitrogen are shown in Fig. 2. Results below 650°C are clearly influenced by impurities and/or grain boundary conduction. It may be significant that the observed activation energy of 0.17 ± 0.01 eV at temperatures between 100° and 300°C is close to the activation energy (0.18 eV) observed for iron-impurity conduction in GaAs (13). As shown in Table I, iron is present (100 ppm) as an impurity in our AlN samples.

At temperatures above 650°C, results for the a-c conductivity are extremely reproducible. Data obtained at 1592 Hz and 1 atm nitrogen pressure are shown in Fig. 3 for four samples, one of which is twice as thick as the other three. A frequency of 1592 Hz is selected for determining the bulk a-c conductivity, because the observed conductivity is constant above 1592 Hz within the experimental uncertainty (±10%). At frequencies below 1592 Hz, the conductivity decreases rapidly with decreasing frequency. A least squares treatment of the data yields the following equation for the straight line shown in Fig. 3

$$\sigma(\text{ohm}^{-1}\text{-cm}^{-1}) = 6.89(\pm 0.04) \times 10^3 \exp(-1.82(\pm 0.06)/kT) \quad [1]$$

where 1.82 eV is the activation energy. The quoted experimental uncertainty in Eq. [1] is two standard deviations, *i.e.*, 95% of the data are within the specified uncertainty. This is equivalent to a ±10% deviation in the conductivity.

As shown in Fig. 4, the a-c conductivity is independent of nitrogen pressure at pressures between 1 and 10^{-5} atm. The solid line in Fig. 4 is calculated from Eq. [1], and the uncertainty bars represent the experimental scatter observed at 1 atm. All conductivity data obtained at lower nitrogen pressures are within the uncertainty bars and are in excellent agreement with those observed at 1 atm.

The effect of carbon concentration on the electrical conductivity is also illustrated in Fig. 4. "Low carbon" AlN samples (~350 ppm carbon) yield results represented by the solid line. However, results obtained with samples having a tenfold increase in analyzed carbon content (~3400 ppm) are a factor of five higher. As shown in Fig. 4, a dotted line, which is parallel to the solid line, provides an excellent fit to the data obtained from the "high carbon" samples.

D-C conductivity.—D-C conductivity data are shown in Fig. 5, in which the solid line is calculated from

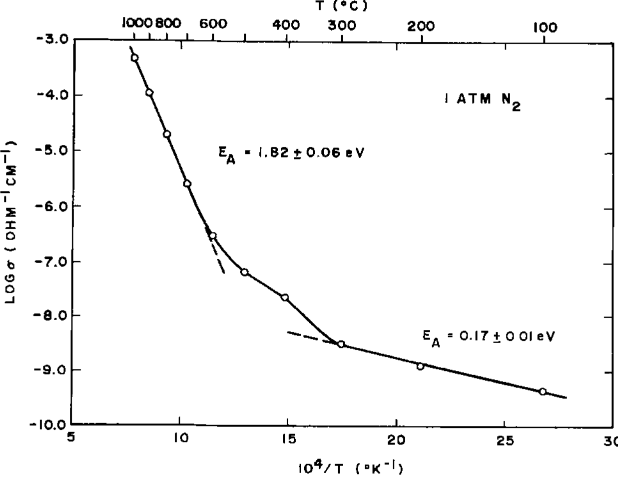

Fig. 2 Electrical conductivity over an extended temperature range.

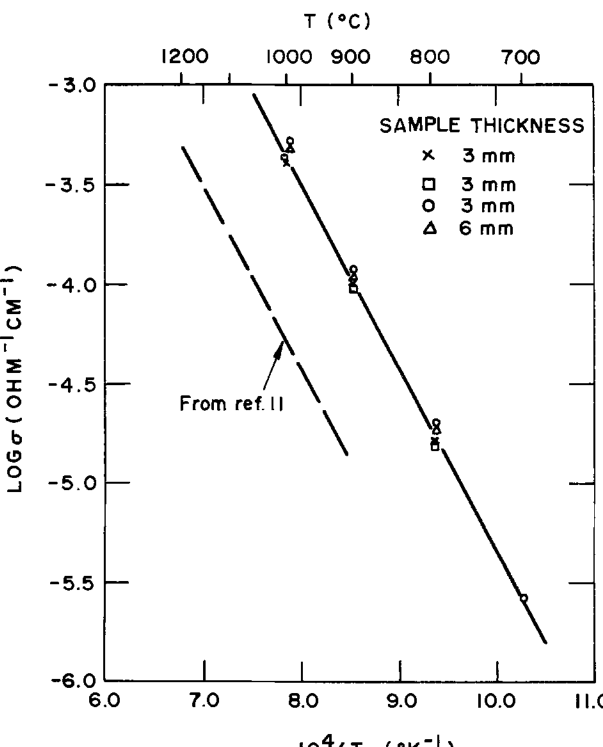

Fig. 3. Temperature dependence of electrical conductivity at 1 atm nitrogen.

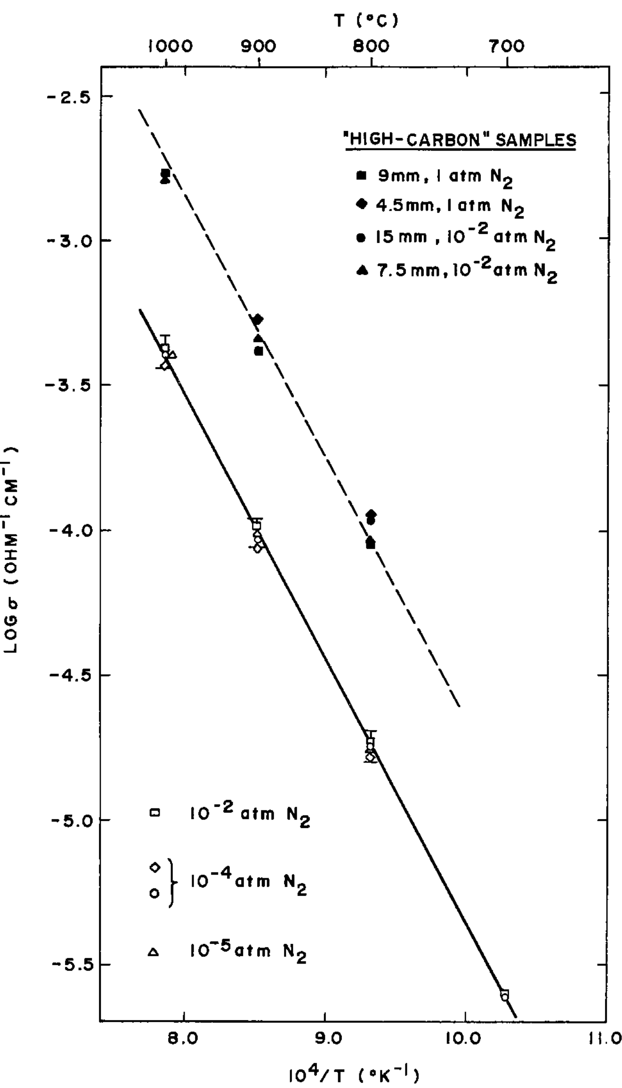

Fig. 4. Effect of nitrogen pressure and carbon concentration on the electrical conductivity.

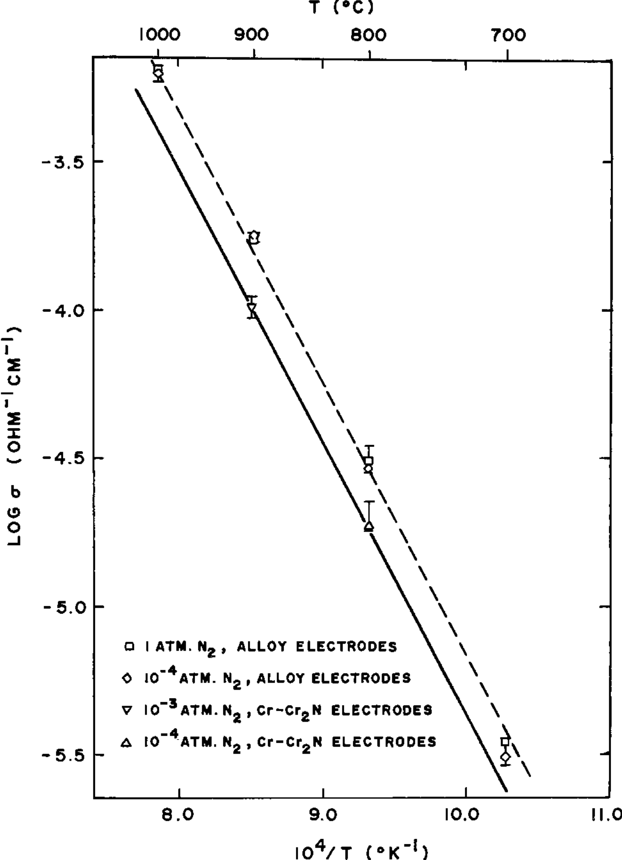

Fig. 5. Temperature dependence of d-c electrical conductivity

Eq. [1]. Excellent agreement is observed between the a-c and d-c results using a Cr,Cr_2N electrode. Although the data obtained using two gold alloy electrodes are about 80% higher than the a-c data, the activation energy is identical. The d-c conductivity data are independent of voltage polarity. With reversal of the applied voltage, no current transients or decays have been observed, which indicates negligible interfacial polarization (14, 15).

Galvanic cell measurements.—The observed independence of conductivity with nitrogen pressure (Fig. 4) indicates that AlN is either an ionic conductor or an electronic conductor having a large concentration of electronic defects. Thus, galvanic cell measurements have been carried out to determine if significant ionic conductivity occurs in AlN. Using Cr,Cr_2N, and Cr_2N,CrN mixtures as two-phase electrodes, the emf established across an AlN electrolyte has been measured. The percentage of ionic conductivity in AlN is equal to the measured cell emf divided by the calculated emf. Cell emf's, which vary between 107 (700°C) and 122 mV (900°C), are calculated from available thermodynamic data for the chromium nitrides (16). Using three different AlN samples, cell emf's have been measured over a period of 2-20 hr with deviations less than 0.2 mV at temperatures between 700° and 900°C. EMF values between +1.0 and −0.3 mV have been obtained, presumably due to thermoelectric effects in AlN (11). A one degree temperature gradient across the cell would account for the generation of such small emf's. Thus ionic conduction in our AlN samples is negligible.

Discussion

Previous results.—Eight investigations of the electrical conductivity have been reported (1, 3, 6, 8-12). In one study (9), results from different samples varied by three orders of magnitude, and no precise data were obtained. In three investigations (1, 3, 10), results are difficult to evaluate because of the high porosity and/or low purity of the AlN samples. A measured activation energy of 2.8 eV was attributed to impurity conduction associated with excess aluminum in two single crystal (~98% pure) studies (6, 8). Using two-probe a-c measurements on hot-pressed samples, conductivity data have recently been obtained at temperatures between 1100° and 1700°C (12). However, a resistivity decrease with increasing gas flow rate was observed, presumably due to spurious electrical transport in the nitrogen gas. Similar phenomena have been observed in measurements of the high temperature resistivity of Al_2O_3 (17). Gorbatov and Kamyshov (11) have measured the a-c conductivity at temperatures between 1000° and 1300°C and under nitrogen pressures of 1 and 10^{-4} atm. To obtain a sample density greater than 95%, they hot-pressed samples in graphite dies. As shown in Fig. 3, their results are lower than those obtained in this study. However, their measured activation energy of 1.9 eV is in good agreement with our value of 1.82 eV.

Conduction mechanism.—The independence of the conductivity on nitrogen pressure (Fig. 4) and the galvanic cell results establish the predominance of electronic conduction in our AlN samples. Before forming conclusions about the conduction mechanism, it is essential to discuss the influence of interfacial effects and gas conduction processes on our results. The independence of the conductivity with sample thickness (Fig. 3 and 4) is experimental evidence

that interfacial resistances are negligible. A particularly striking example is that of the high carbon samples (Fig. 4), in which sample thicknesses vary from 4.5 to 15 mm with no observable effect. Furthermore, all a-c data are obtained in a frequency-independent region, in which interfacial, including grain boundary, effects are presumably negligible. With regard to the possibility of gas conduction processes, it should be noted that the conductivity of air (which is a reasonable estimate for pure nitrogen) is two to three orders of magnitude less than that of AlN in our experimental temperature range (18).

Although the conductivity of the high carbon samples is about a factor of five higher than the low carbon results, the observed activation energy is in excellent agreement, as is illustrated by the parallel lines in Fig. 4. The agreement in observed activation energy indicates a similar conduction process in both the low and high carbon samples, and we conclude that the conduction process in our AlN samples is extrinsic, due to carbon impurities. Because of the similarities in preparation, the carbon concentration in Gorbatov and Kamyshov's samples should be comparable to those used in this study, and one would expect the close agreement in activation energy which is observed (1.9 *vs.* 1.82 eV).

An extrinsic conduction mechanism is consistent with a number of other experimental observations. When one of our AlN samples is reused, the conductivity of the sample increases but the activation energy remains constant. For example, the data shown in Fig. 5 for the Au-Al alloy electrodes are obtained with AlN samples which have been used twice previously. Such conductivity increases can be attributed to an increase in carbon concentration originating from the organic resin in the gold paste. After experimental runs, a small, thin, black residue, presumably carbon, has been observed in isolated areas between the gold contacts and the AlN sample. Chemical analysis of reused samples shows a qualitative increase in carbon concentration with no detectable changes in the concentrations of the other major impurities listed in Table I.

Although no measurements of the oxygen content of AlN were made, Table I indicates that annealed samples could contain a maximum of 0.2 weight per cent (w/o) oxygen, which is almost as high as the concentration of carbon in the high carbon samples. However, there are several reasons why the effect of oxygen has been ignored in the interpretation of our conductivity results. Oxygen in AlN is most likely an acceptor and would either compensate a carbon donor or decrease the conductivity of n-type AlN. Oxygen absorption bands in AlN are at 4.53 and 4.80 eV (19), which are much higher than the impurity ionization energy of 3.64 eV calculated from our measured activation energy (2×1.82). Optical absorption measurements on AlN crystals prepared in graphite surroundings show an increase in absorption coefficient at $\sim$3.5 eV (19, 20), which is consistent with our impurity ionization energy.

The bandgap for AlN is between 5.7 and 6.2 eV (19, 20). A carbon-impurity ionization energy of 3.64 eV requires that carbon occupies a deep-lying impurity level. Theoretically, carbon in AlN could be either an electron donor or an acceptor. Using thermoelectric emf measurements, Gorbatov and Kamyshov have observed n-type electronic conductivity in carbon-contaminated AlN (11). This observation together with the observed increase in electrical conductivity with increasing carbon content (Fig. 4) indicates that carbon acts as an electron donor in AlN.

Technical Notes

Minimizing Process-Induced Slip in Silicon Wafers by Slow Heating and Cooling

A. Wayne Fisher and G. L. Schnable*

RCA Laboratories, Princeton, New Jersey 08540

The formation of slip regions in single crystal silicon wafers and its influence on device parameters has been studied by numerous investigators. The general conclusion is that the slip and its associated edge dislocations can degrade electrical parameters, especially if precipitation of metals or dopant atoms occurs at their sites.

A number of authors have discussed thermally induced slip in silicon wafers, and the effects of radial thermal gradients arising during high temperature processing sequences (1-9). Although several authors have mentioned that heating rates are a factor (1, 7, 9) in the formation of thermally induced dislocations, the relative importance of heating rates *vs.* cooling rates has not been indicated. A number of papers deal only with cooling rates, and thus imply that cooling rates are the most important factor in determining the amount of thermally induced slip (2, 3, 4, 6, 8).

Several techniques have been described for minimizing slip by reducing the radial thermal gradients (4, 8). Mechanical slow pullers have been used to insert and retract wafers from the furnace slowly, and thus reduce the thermal gradients which cause warpage and slip.

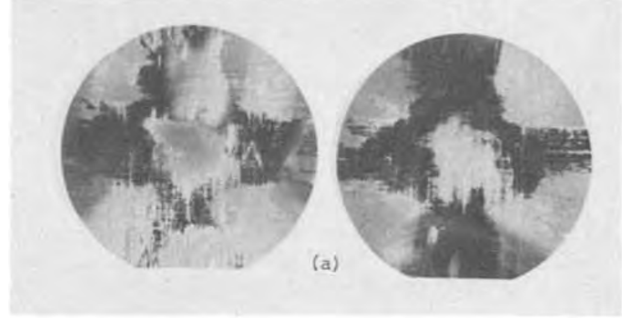
The purpose of this paper is to indicate that in fabricating silicon devices, slow heating of the silicon wafer is as important as slow cooling of the wafer in avoiding slip, and to show that the use of programmable mechanical pullers is a technique for controlling heating and cooling rates.

To evaluate the use of slow pullers as a method for reducing slip, a group of 80 5-cm diameter silicon wafers (0.045 mm thick, (100) orientation, polished on one side) was divided into four lots of 20 wafers each. The wafers were furnaced at 1150°C in dry O_2 by inserting and retracting them from the furnace at different rates. The wafers were held vertically, perpendicular to the gas stream in a 25 cm long slotted quartz boat with supporting slots spaced 2.5 mm center to center. The center portion of the boat was loaded to a length of about 5 cm. Each lot was cycled three times from room temperature to 1150°C, and each time allowed to stabilize at 1150°C for 10 min before being removed for cooling to room temperature.

The work described in this paper was performed in a Lindberg Heavy Duty Furnace[1] with a uniform horizontal heat zone of 60 cm at a temperature of 1150°C. The temperature at the end of the flat heat zone dropped from 1150° to 800°C (800°C is below the temperature at which slip is believed to occur) in a distance of approximately 28 cm. The four lots were temperature cycled in and out of the furnace by the following procedures. Lot No. 1 was inserted and removed rapidly from the furnace, *i.e.*, from the end of the tube into the 1150°C zone in approximately 5 sec, stabilized for 10 min, then retracted to the end of the tube in approximately 5 sec. Upon removal it was observed that the end wafers had cooled uniformly. The wafers in the center region of the boat remained hotter for a longer period of time and their periphery cooled first. The wafers were stripped of the oxide in aqueous HF and Dash etched (12 parts CH_3COOH, 3 parts 70% HNO_3, 1 part 49% HF) (10) for 16 hr to reveal slip regions. The slip was progressively worse on wafers located toward the center of the boat, with the center wafers being warped as well as heavily slipped. Figure 1a shows two wafers taken from the center of the boat after Dash etching for 16 hr.

The second lot of wafers was inserted into the hot zone rapidly (5 sec) and cooled slowly at a rate of 13 cm/min. All wafers appeared to cool uniformly as they traveled from the hot zone to the cold zone of the furnace. However, after oxide removal and Dash etching, all wafers, including the two end ones, had developed slip. As before, the slip was more severe on the wafers in the center of the boat (Fig. 1b). However, the degree of slip was less than observed on the wafers that were inserted fast and retracted fast, and warpage was not present.

The third lot was inserted into the hot zone slowly and cooled slowly at a rate of 13 cm/min for each step. Oxide stripping and Dash etching revealed no appreciable slip on any of these wafers (Fig. 2a).



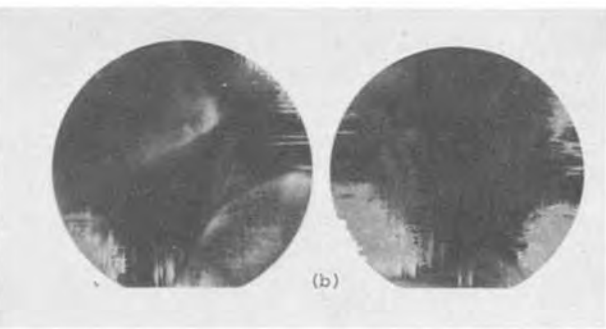


Fig. 1. Wafers taken from center of boat and etched 16 hr in Dash etch: (a) wafers inserted fast and retracted fast, (b) wafers inserted fast and retracted at 13 cm/min.

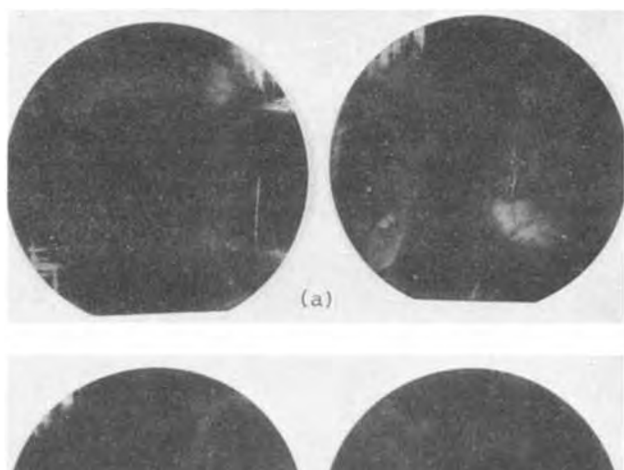
* Electrochemical Society Active Member.

Key words: crystallographic slip, slow heating, slow cooling, mechanical pullers.

[1] Lindberg Engineering Company, Watertown, Wisconsin.



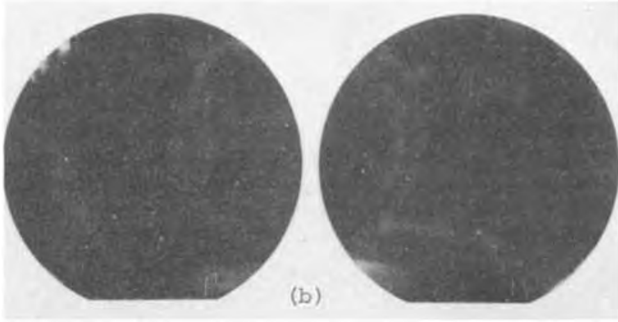


Fig. 2. Wafers taken from center of boat and etched 16 hr in Dash etch: (a) wafers inserted and retracted at 13 cm/min, (b) wafers inserted at 13 cm/min and retracted at 6.5 cm/min.

The fourth lot was inserted into the hot zone at a rate of 13 cm/min and removal was conducted at a rate of 6.5 cm/min. Oxide stripping and Dash etching again revealed essentially no slip (Fig. 2b).

Discussion and Conclusions

Tests have shown that slow retraction of wafers from high temperature furnaces by itself does not eliminate the crystallographic slip. Radial temperature gradients present when wafers are inserted into the furnace also generate crystallographic slip; thus it is necessary to insert the wafers slowly as well as remove them slowly. Slow insertion and slow retraction of silicon wafers into and out of high temperature furnaces at a rate of 13 cm/min using mechanical pullers is a method of reducing the radial temperature gradients to a level where crystallographic slip and associated edge dislocations are minimized.

One disadvantage of this technique is that as the wafers pass into and out of the furnace, the wafers at one end of the boat are heated for a longer time. For some heat-treatments (such as thermal oxidation, pocket diffusion, isolation diffusion, and p+ diffusions), where the total time of heat-treatment is long, this time difference is negligible. For an insertion and pull rate of 13 cm/min, the time differential from one end of a 25-cm boat to the other is about 4 min. For base and emitter diffusions, where control over junction depth is very critical and diffusion times are shorter, this technique will be limited. One possible means of overcoming the problem is to insert wafers at one end of the furnace and remove them from the other, thus averaging out the time when temperature gradient occurs along the length of the boat.

The technique of using mechanical pullers to achieve both slow heating and slow cooling is applicable to many production lines, and is especially desirable to avoid process-induced slip in wafers containing narrow-base bipolar transistors. Various types of equipment are now available for controlled mechanical insertion and removal of boats from furnaces (11). Commercially available slow pullers have independent speed controls for the insertion and retraction portion of the cycle, and travel speeds are adjustable in the range of about 1.2-25 cm/min.

Acknowledgment

The authors wish to thank R. Matenkoski for providing the furnace used in these experiments.

Latent Heat Measurement of Phase Transformations in Potassium Nitrate

E. Y. Wang

Department of Electrical Engineering, Wayne State University, Detroit, Michigan 48202

Potassium nitrate (KNO_3) can exist in three possible phases at normal atmospheric pressure. At room temperature, the structure is orthorhombic and aragonite (phase II) (1). Upon heating to temperature 401°K, the structure transforms to rhombohedral (phase I) and remains the same structure until melting. Upon cooling, the material solidifies in the rhombohedral form which is ferroelectric (phase III). Further cooling generally returns the structure to the orthorhombic form (phase II). All phase transformations are first order and involve latent heats. In this note, we used differential scanning calorimetry (DSC) to obtain directly the latent heats of phase transformations in KNO_3. Results obtained by DSC method for phase II→I are compared with those by differential thermal analysis (2) and other methods (3). Latent heat measurement by a direct method from phase III→II is reported here for the first time. In addition,

the effect of moisture content on the transformation temperature from phase III→II has been studied.

Experimental Results

DSC measurements were made on KNO_3 by using a Perkin-Elmer DSC-1B apparatus. Unlike previous methods (2, 3) DSC yields direct recording of heat quantities by using a close-loop, negative feedback control of the power supplied to specimen and reference systems. When the specimen absorbs or emits energy (heat), more or less power is required to maintain the specimen in equilibrium with the reference system at the same temperature. The differential power is then recorded continuously according to the energy (heat) requirement of the specimen. The specimen was initially in powdered form of 99.0% purity. The powder was placed in an aluminum sample pan and was heated to the melting temperature. The sample pan was mechanically sealed during entire measurements. Figures 1 and 2 show the thermal spectrum. In the heating cycle, the two endothermic peaks correspond to the phase II→I transformation and melting. In cooling cycles, the peaks correspond to crystallization and the phase I→III transformation. The heats of fusion in melting and crystallization are 28.1 cal/g which agrees with previous values (4). The crystallization occurs at a lower temperature than the melting temperature because of supercooling effect, and on subsequent cooling the specimen does not convert from phase III to phase II until exposed to moisture. Moisture was introduced by removing the cover of the sample pan and exposing the specimen to room atmosphere over night. Figure 3 shows the results of cooling cycles for a "wet" specimen and its subsequent thermal cooling cycling. The thermal spectra are "identical" in heating cycles; however, in cooling cycles the phase III→II transformation depends on the amount of moisture content in the KNO_3. As the number of thermal cycles increases, the moisture content is decreased and the transformation temperature from phase III→II is lowered; eventually the KNO_3 remains in phase III "indefinitely." Repeated measurements for different amounts of KNO_3 under the same conditions yield essentially the same results. Latent heats calculated from the thermal spectra are summarized in Table I. A comparison of latent heats with previous works is shown in Table II. It

should be pointed out that in the DSC method transition temperatures depend on scan rate; however, the latent heat is independent of scan rate.

Conclusions

In conclusion, we have used the DSC method to obtain the latent heats for all of the phase transformations in KNO_3. We believe the values obtained here are more accurate in view of the nature of the DSC method. The error in latent heat values is estimated to be within $\pm$ 1%. Particularly, we believe that latent heat measurement from phase III→II is reported here for the first time by a direct method. By direct method we mean that latent heat values were obtained directly from measurements instead of other material parameters such as transition temperature, specific heat, and others. The moisture effect on the transformation temperature of phase III→II is also consistent with previous observations (2-6).

Temperature Asymmetries and Fluctuations in a Barrel Reactor

B. J. Curtis*

Laboratories RCA Limited, Zurich, Switzerland

The work reported in this paper is concerned with a study of thermal conditions in a barrel reactor, similar to but smaller than those used in the production of homoepitaxial silicon. This is a continuation of the investigations reported in Ref. (1-3).

As has been mentioned previously (1, 2), the effects of certain process parameters such as temperature gradients and hydrodynamic effects on the homogeneity and uniformity of melt-grown crystals is relatively well understood. In the case of growth from the vapor phase however, this subject has received detailed attention only during the past few years. In view of the importance of the epitaxial silicon process, any information that can be gained about the prevailing conditions inside the reactor is of potential use in improving the yield and quality of devices. Experience has shown that reactors built nominally to identical specifications behave differently under the same operating conditions. In addition, with the increasing application of large-scale integration, the demand for thin homoepitaxial silicon layers may increase and it seems likely that the growth of such layers will require closer control than the thicker layers that are grown in production at present.

Experimental

A number of factors influenced the design of the reactor. The size was limited by the available rf generator which had a maximum output of 12.5 kW. In designing the reactor, an attempt was made to incorporate as much flexibility as possible so that the same chamber could be operated with either air-or water-cooled walls. Provision was also made for the addition of baffles near the gas inlet should this have been necessary. In addition, the thermocouple used for the temperature measurements was built into the rotatable susceptor since the effects of rotation had not been studied previously. This posed some problems since a gas-tight rotary feed-through was required for the susceptor supporting shaft and thermocouple.

The final design of the reactor is shown in Fig. 1 in which the left side of the drawing shows the reactor with water-cooled walls and the right side with air-cooled walls. Two demountable water-cooled stainless steel end plates sealed the vitreous silica reactor tube and, if required, the Pyrex glass cooling water jacket by o-rings held in compression by four Teflon support rods. These support rods were surrounded by gold-coated glass tubes which shielded them from the radiation from the hot susceptor. The tapered, hexagonal carbon susceptor (for exact dimensions see Fig. 3) was supported by a carbon rod attached to a hollow, stainless steel shaft, the rotary seal to the base plate being achieved by a water-cooled o-ring. The leads from the Chromel-Alumel thermocouple passed through the hol-

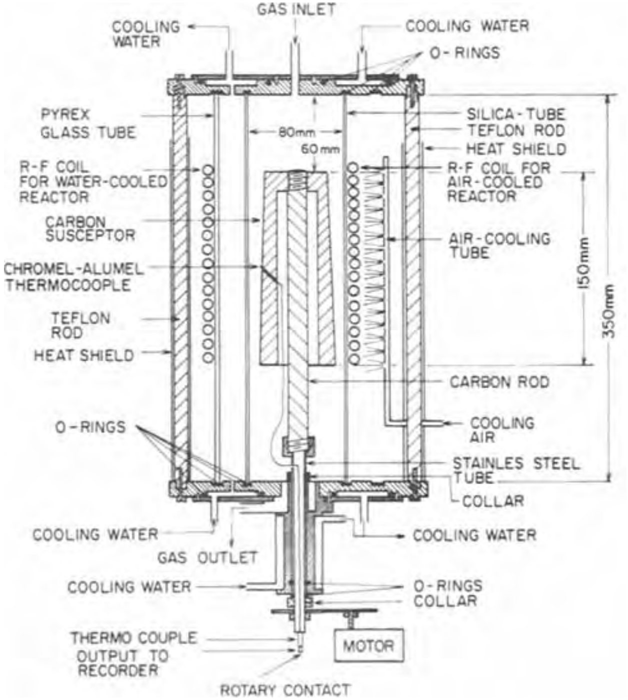

Fig. 1. Barrel reactor with air- or water-cooled walls

* Electrochemical Society Active Member.

Key words: silicon, reactor technology, temperature stability.

low shaft to a rotary contact (see also Fig. 2). Some initial problems arose with hydrogen leaking from a number of points which was eliminated by additional o-rings. The Chromel-Alumel thermocouple itself was fabricated from 100μ diameter wire sheathed in stainless steel with powdered magnesium oxide insulation (Omega Company Type 304-K-MO-020). The stainless steel sheath was found to react with the carbon susceptor at 1200°C and so a piece of alumina tubing was inserted between the thermocouple and the susceptor. The tip of the thermocouple projected 1 mm from the susceptor surface at the midpoint of one of its faces. Since the susceptor could be rotated, a rotary contact was required for the thermocouple. For this purpose, a small co-axial plug and socket was used which proved to be quite suitable at the low rotation speeds used (maximum 6 rpm). As mentioned previously, the reactor could be either water-cooled or air-cooled, the latter being accomplished either by contact with the ambient air (natural air cooling) or by four perforated tubes (Fig. 1 right side) disposed symmetrically around and spaced 35 mm from the vitreous silica tube (forced air cooling).

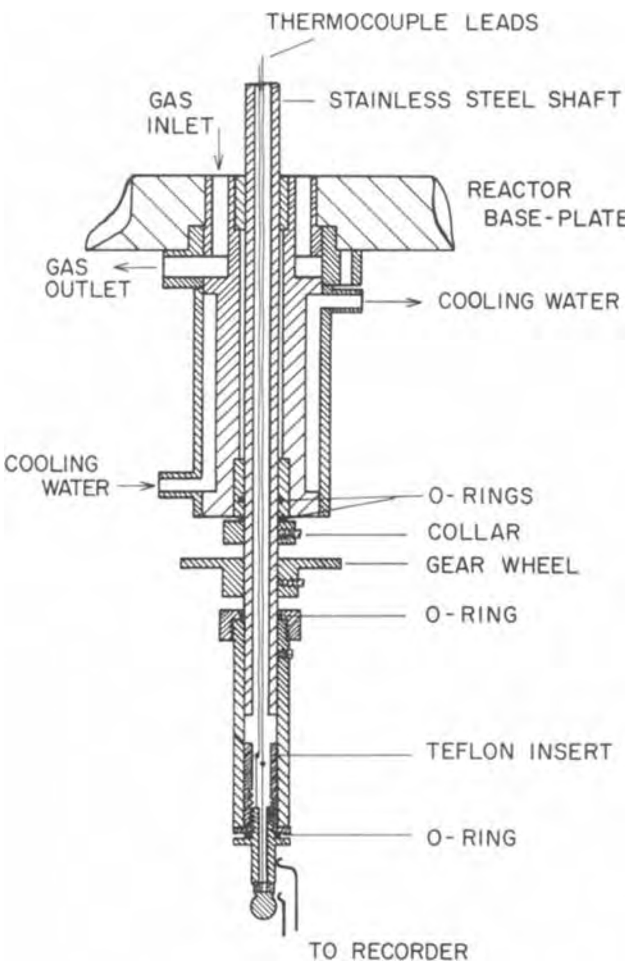

Fig. 2. Rotary feed-through for susceptor support and thermocouple

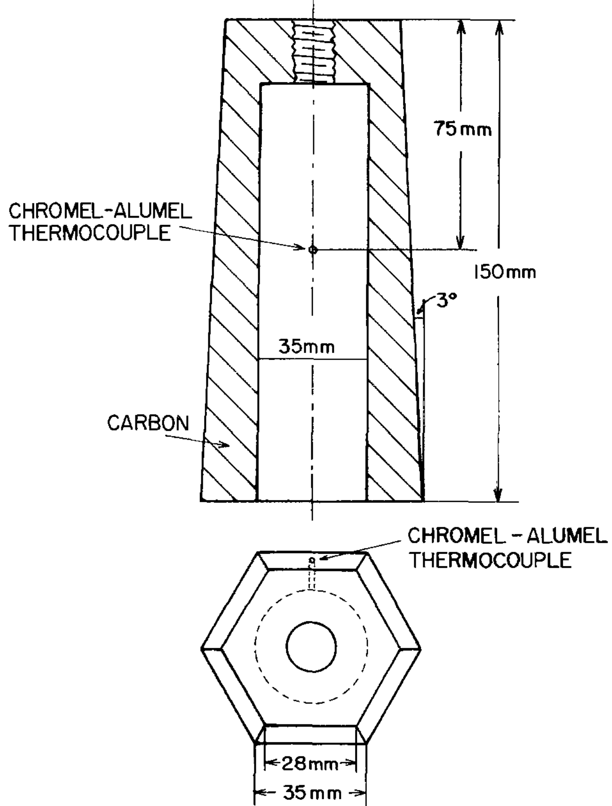

Fig. 3. Carbon susceptor

The output from the thermocouple was partially compensated with a stable millivolt source and displayed on a chart recorder so that temperature changes of about 0.25°C could be detected. A power controller with a feedback loop placed close to the rf coil was used to ensure that the power delivered to the susceptor was held constant. Once the conditions had stabilized, the recorded temperature remained constant to within ±0.5°C over periods of a few minutes with a drift of a few degrees over longer periods.

Results and Discussion

Investigations in a smaller, water-cooled barrel reactor (3) indicated that under certain conditions, temperature instabilities appeared in the gas phase near the hot susceptor which increased as the gas velocity was increased. This effect was large at a position 25 mm downstream on the susceptor surface; at a point 50 mm downstream the effects were small but still detectable.

The measurements to be reported here were made at one thermocouple position as mentioned above and as shown in Fig. 1. This position was 75 mm downstream on the susceptor, thereby allowing the gas a reasonable time to equilibrate and, from previous results (3), relatively stable thermal conditions would be expected at that point. Nevertheless, temperature fluctuations were still detected which tended to increase in magnitude with increasing gas velocity. The gas velocities quoted in this paper are the room temperature values. When corrected for the actual gas temperature, the real gas velocity would be approximately three times the indicated values.

In hydrogen, with the susceptor stationary, temperature fluctuations began at a gas velocity of about 18 cm/sec with air-cooled walls and at 8 cm/sec with water-cooled walls. The maximum amplitude of the fluctuations was 0.5°C in the former and 1.5°C in the latter case. These results illustrate the slightly decreased stability of the water-cooled reactor as compared to the air-cooled reactor. These effects seen in hydrogen were relatively small and are probably not of great importance in practice.

Temperature asymmetries were detected when the susceptor (and with it, the thermocouple) was rotated. With constant power input to the susceptor, the temperature registered by the thermocouple varies in a regular manner as shown in Fig. 4. The upper portion (a) shows the effect with hydrogen; the period of the fluctuations was one revolution and their amplitude increased with increasing gas velocity up to about 5°C at 34 cm/sec. Figure 4(b) shows the effect of turning on the forced-air cooling. Superimposed on the general asymmetry seen in (a) were four peaks, each one resulting from one of the air-cooling tubes. Again, their amplitude increases with increasing gas velocity up to about 8°C at 34 cm/sec.

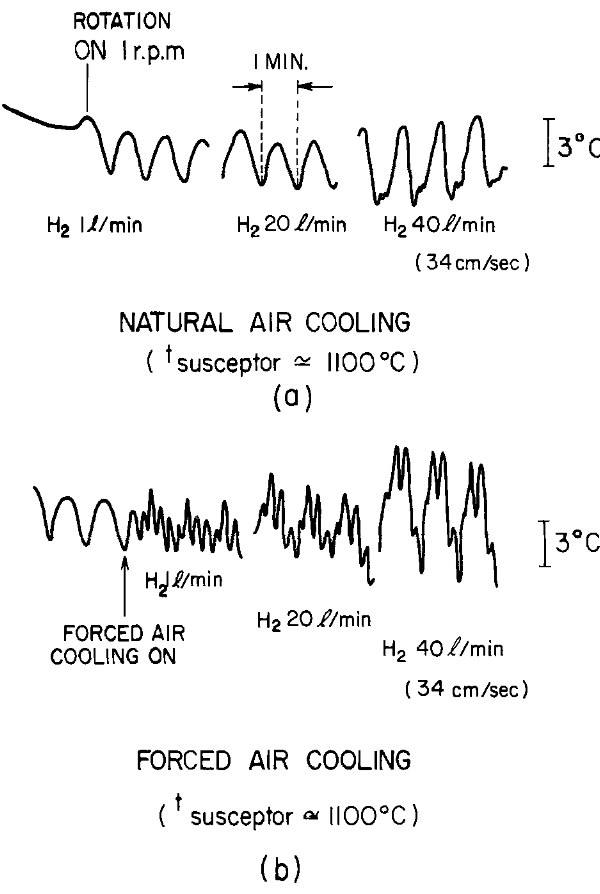

Fig. 4. Rotational temperature asymmetries in hydrogen (1 rpm): (a) with natural air cooling, (b) forced air cooling.

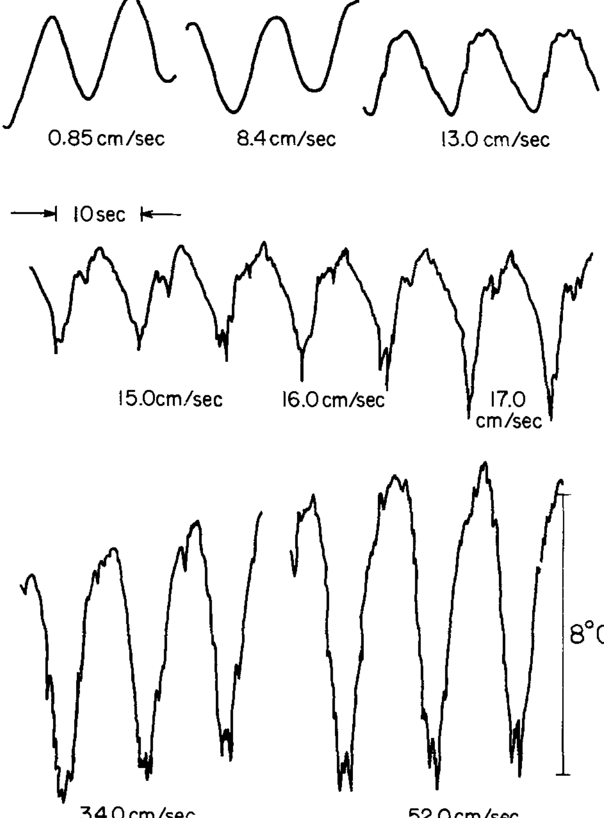

Fig. 5. Effect of gas velocity on rotational temperature fluctuations in hydrogen with a water-cooled reactor.

Since the susceptors in production reactors are rotated at 6 rpm, the drive was changed to give this increased speed since it was possible that the effects measured at 1 rpm would be smoothed out at this higher speed. This was not the case, however; the peaks were merely moved closer together but could still be easily resolved. When nitrogen is substituted for hydrogen, the amplitude of the temperature fluctuations increases to about 35°C as compared to about 8°C for hydrogen. The differences between air and water cooling were not so great but since the susceptor temperature was lower in the latter case, it seems quite likely that the effect would be greater in that instance for equivalent susceptor temperatures.

The type of fluctuations observed with the stationary susceptor is superimposed on the rotational fluctuations. This is shown in Fig. 5 for a water-cooled reactor and a rotation rate of 6 rpm. Between 8.4 and 13.0 cm/sec the stationary fluctuations begin and can be seen in the trace taken at 13 cm/sec. The amplitude of the rotational and stationary fluctuations can be seen to increase with increasing gas velocity. A similar effect was seen with the air-cooled reactor.

Conclusion

Similar effects were seen with the longer susceptor as had been seen earlier (3) with a shorter susceptor without rotation, but their magnitude was probably not sufficient to cause any great problems as regards uniformity or crystal perfection in a practical growth system. In any case, the susceptor used in production reactors has a minimum of 15 cm free surface before the reacting gases reach the substrates so that the stationary fluctuations will be of even smaller amplitude. The presence of the rotational fluctuations, however, could be one factor which causes differences in behavior in apparently identical reactors. It is unlikely that temperature fluctuations in the gas phase would affect the substrate temperature since the thermal mass of the substrate and susceptor is large. But the possibility exists that the diffusive flux of reactants and reaction products to and from the substrate would be affected since diffusion is a temperature-dependent process. This could, then, lead to inhomogeneities and nonuniformities in the grown layer.

The origin of the rotational fluctuations is not entirely clear. The fact that their magnitude is larger with nitrogen than with hydrogen shows that the effect is, to some extent, gas dependent. This, together with the velocity dependence of their amplitude, indicates that their origin is probably a combination of flow and geometrical factors.

The Dissociation Energy of BiS and the Vapor Composition over Bi-S Melts

Daniel Cubicciotti*

Stanford Research Institute, Menlo Park, California 94025

Dissociation Energy

The stability of the BiS molecule relative to the elements was determined in a transpiration experiment (1) a few years ago and the molecule identified in a mass spectrometer study (2). Since that time the molecular constants of the molecule have been measured by Barrow *et al.* (3) so that its thermodynamic functions can be calculated. That information allows a careful interpretation of the transpiration data, as follows.

The equilibrium constants for the reaction

$$Bi(l) + \tfrac{1}{2}S_2(g) = BiS(g) \qquad [1]$$

were taken from Ref. (1). The thermodynamic functions for BiS calculated from molecular constants are given in Table I, while those for Bi and S_2 are from Hultgren (4) and the JANAF Tables (5), respectively. The calculations of the third law enthalpies of reaction ($\Delta H_{298} = -RT \ln K - T\Delta F$) are given in Table II and lead to an average value of 27.9 ± 1 kcal/mole. The temperature coefficient of the equilibrium constant gave an enthalpy change of 25 ± 5 kcal/mole at 1000°K which leads to a value of 29 ± 5 at 298°K in good agreement with the third law value.

The dissociation energy of BiS is equal to the enthalpy change at 0°K for the reaction

$$BiS(g) = Bi(g) + S(g) \qquad [2]$$

The third law value above, when combined with the appropriate enthalpies of atomization from Ref. (4) and (5), leads to a dissociation energy of 72.3 ± 1 kcal/mole for BiS.

Uy and Drowart (6) have measured the equilibrium constant for the reaction

$$BiS(g) + Pb(g) = Bi(g) + PbS(g) \qquad [3]$$

by a mass spectrometer technique. The enthalpy change they measured for the reaction was −7.2 ± 1 kcal/mole at 0°K (with corrected F values). The dissociation energy of PbS is not yet well established. Uy and Drowart gave a value of 80.4 ± 1.5 kcal from mass spectrometer data and 81.8 ± 0.4 from spectroscopic data. The JANAF Tables reviewed the literature and gave 82.4 ± 1.5 as a compromise. The dissociation energy of BiS calculated from those values are 73.2 ± 2.5, 74.6 ± 1.5, and 75.2 ± 2.5, respectively.

Dissociation energies from spectroscopic data that are in good agreement with thermochemical values for a large number of molecules have been derived by a method due to Hildenbrand (8). In his method, the dissociation energy, D_0, is related to the value calculated from a linear Birge-Sponer extrapolation, $D(LBX)$, by the empirical equation

$$\frac{D_0}{D(LBX)} = 0.448 + 0.365\left(\frac{r_x}{r_e}\right) \qquad [4]$$

in which r_e is the equilibrium internuclear distance and r_x is an estimate of the distance at which the ionic and covalent potential curves cross, given by

$$r_x = \frac{14.40\ (\text{eV})}{(\text{ionization potential of metal atom, eV}) - (\text{electron affinity of nonmetal atom, eV})}$$

1500	68.66	75.74	10.604	8.917

* $H_{298} - H_0 = 2.262$ kcal/mole. Molecular constant used [from Barrow (3)]. $r_e = 2.319$Å; $\omega_e = 409$ cm^{-1}. Ground state multiplicity (g) = 2 because of lambda doubling [see Ref. (7)]. The state with spin = 3/2 is expected to have an energy of the order of 8000 cm^{-1} (personal communication from Professor R. F. Barrow).

Table II. Third law evaluation of enthalpy change for reaction [1]

Equilibrium constants measured in Ref. (1), Torr$^{1/2}$	Temperature, °C	ΔF, cal/mole deg	ΔH_{298}, kcal
0.1	705	−17.53	28.0
0.15	740	−17.40	28.0
0.31	800	−16.96	27.8
		Average	27.9

For the BiS molecule we calculate $r_x = 2.76$ so that $r_x/r_e = 1.19$ and $D_0D(LBX) = 0.883$. The value of $D(LBX)$ from Barrow's data is 81.1 kcal so that D_0 calculated by Hildenbrand's method is 71.6 kcal/mole in good agreement with the thermochemical value.

Composition of Vapor over Bi-S Melts

The vapor phase in equilibrium with the condensed phases in the Bi-S system will consist primarily of the species S_2, BiS, Bi_2, Bi in various relative amounts depending on melt composition. There will also be smaller amounts of secondary species such as S and the more complex species, Bi_4, Bi_2S_2, S_8, etc. (9, 10). For the present discussion those secondary species are neglected.

The amounts of the primary species can be calculated from the available thermochemical data for the gases [sulfur species from Ref. (5), bismuth species from Ref. (4), BiS from this paper] and the thermodynamic activities of Bi and S in the melt given in Ref. (1). The results of such a calculation for 800°C (1073°K) are given in Fig. 1.

The predominant vapor species is S_2 over almost the entire composition range. At sufficiently small sulfur content in the melt (atom fraction sulfur <0.05), the species Bi_2 is predominant. The pressure of BiS is always intermediate between those of S_2 and Bi_2. In fact,

* Electrochemical Society Active Member.

Key words: bismuth sulfide, dissociation energy, vapor composition.

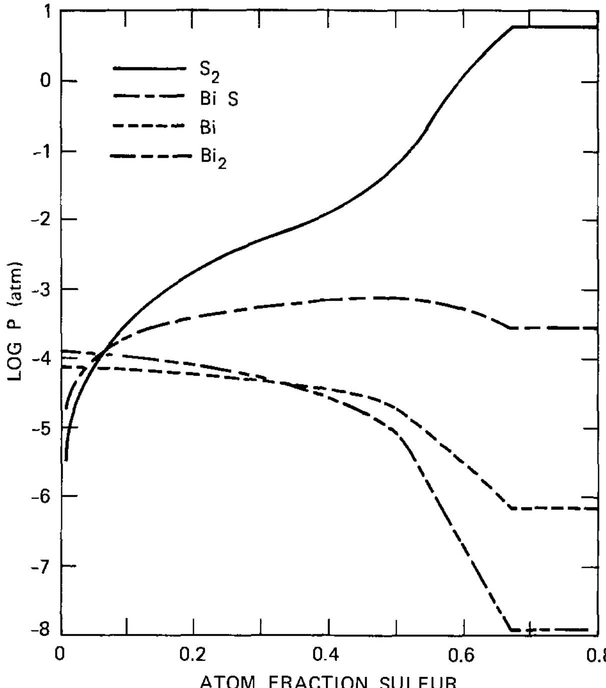

Fig. 1. Partial pressures of species over Bi-S melts at 800°C

as noted in an earlier paper, the dissociation energy of BiS is approximately the mean of those of Bi_2 and S_2 and since there are no large entropy effects the pressure of BiS is approximately the geometrical mean of those of S_2 and Bi_2. The lower two curves in Fig. 2 show the total amounts of S and Bi in the vapor, *i.e.*, the sums of pressures of all species containing S and Bi presented as pressures of monatomic S and Bi.

The curves at temperatures other than 800°C are qualitatively the same. The major differences arise because at temperatures below 775°C solid Bi_2S_3 precipitates, at the melt compositions reported in the phase diagram (11). Above 775°C a second liquid phase separates. The activities of Bi and S are essentially the same functions of composition over a wide temperature range (1).

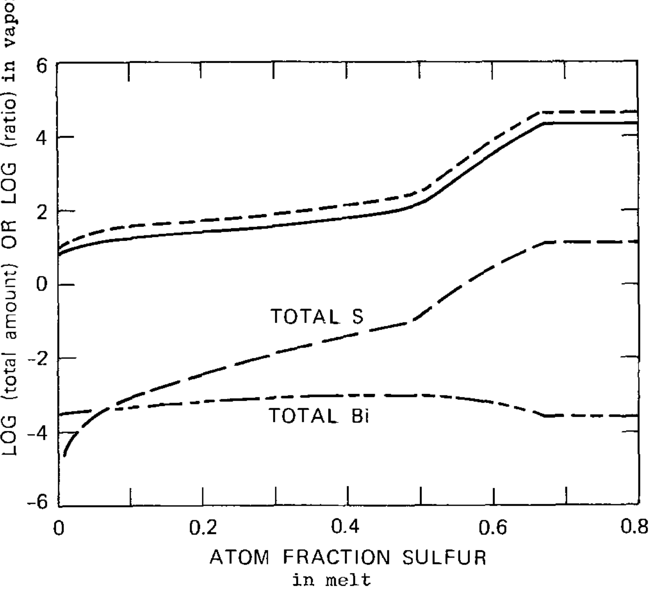

Fig. 2. Composition of gas phase at 800°C. Lower two curves: total amount of sulfur and bismuth in vapor; Total S $= 2\,P(S_2) + P(BiS)$; Total Bi $= 2\,P(Bi_2) + P(Bi) + P(BiS)$. Upper two curves: composition of gas relative to melt; full curve = ratio of gram atoms of sulfur to bismuth in equilibrium gas (calculated from pressures of species) relative to ratio in melt; dotted curve = ratio of gram atoms of sulfur to bismuth in effused vapor (calculated from effusion rates of species) relative to ratio in melt.

The pressure of BiS goes through a maximum at 0.5 atom fraction of S in the melt. However the maximum has no particular significance. The maximum is a necessary consequence of the relationship of the pressure of BiS between the product of the activities of S and Bi in the system and the fact that those activities are monotonic functions of the composition variable (atom fraction S). Thus, in general (12), a vapor species Bi_xS_y will show a maximum in its pressure when the melt composition is given by $N_S/N_{Bi} = y/x$.

The ratio of the relative amounts of sulfur and bismuth in the vapor and in the melt are shown in Fig. 2 as the full curve. That ratio always exceeds unity and therefore there is no composition that evaporates congruently. (Congruent evaporation implies that the vapor composition calculated from the pressures is equal to the melt composition.) The vapor is always richer in sulfur than the melt. As the concentration of sulfur in the melt decreases that ratio drops to a limiting value (6.7 at 800°C). Therefore, in principle, equilibrium vaporization of the melt will always cause it to become enriched in bismuth.

It is interesting to consider vaporization of the melt controlled by an effusion orifice. In that case the ratio of species that evaporates is dependent on their molecular weights as well as their partial pressures. The Knudsen equation (13) for the rate of evaporation is

$$V \alpha P \sqrt{MT} \qquad [5]$$

in which V is the molecular rate of vaporization, P the pressure, M the molecular weight, and T the temperature. Because of the large differences in molecular weights of the species, there is a significant effect on the ratio of sulfur to bismuth that is vaporized. The ratios of amounts of sulfur to bismuth evaporated through an effusion orifice are shown as the dotted curve in Fig. 2. Vapor effused from the system always shows a larger sulfur to bismuth ratio than the equilibrium vapor pressures. The factor is approximately two except for small atom fractions of sulfur where it decreases to about 1.5.

That difference in the composition of the vapor removed from a system by different "equilibrium" processes can be important in an experimental test of the vapor composition of a system. Experimentally one often investigates the composition of the vapor of a system by evaporating a substantial fraction of a sample and analyzing the residue. The above analysis shows that the residue left after a Knudsen effusion evaporation would be poorer in sulfur than a true equilibrium vaporization. The effusion vaporization results could be corrected to the equilibrium situation only with a knowledge of the molecular weights of the vapor species and then relative amounts. In a Langmuir (open surface) vaporization the relative amounts of the components evaporated would be additionally complicated by the possibility of unequal vaporization coefficients. Therefore, the experimental test of vapor composition by measurements of the relative amounts removed by evaporation can give results that are not relevant to equilibrium vapor compositions.

12. The partial pressure of the species Bi_xS_y is related to the activities of the components by $p(Bi_xS_y) = KA^x(Bi)A^y(S)$ in which K is the equilibrium constant. A maximum in the pressure will occur if the derivative with respect to composition is zero; so

$$0 = \frac{dp}{dN(S)} = K \times A^Y(S)A^{x-1}(Bi)\frac{dA(Bi)}{dN(S)} + yA^x(Bi)A^{y-1}(S)\frac{dA(S)}{dN(S)}$$

The Gibbs-Duhem equation can be written

$$\frac{N(Bi)}{A(Bi)}dA(Bi) = -\frac{N(S)}{A(S)}dA(S)$$

and substitution into the above equation leads to the result $N(S)/N(Bi) = y/x$. Thus a maximum in the pressure of a species will necessarily occur at a composition of the melt equal to the vapor composition of that species.

Brief Communication

Anodic Passivation and Coating of AlAs in Aqueous Solutions

W. D. Johnston, Jr.

Bell Laboratories, Holmdel, New Jersey 07733

The close lattice match between AlAs and GaAs is well known and has made possible successful heterojunction semiconductor devices of great potential importance. The instability of pure AlAs in air due to water-vapor attack has hitherto limited interest in AlAs-GaAs systems to alloy compositions of $Al_xGa_{1-x}As$ with $x \lesssim 0.8$. Recently, high performance n-AlAs/p-GaAs large area solar cells prepared by vapor phase epitaxy (VPE) have been demonstrated (1). An essential element in practical solar cell devices is a stable, and preferably antireflective, top surface. We describe here the technique of anodic growth of a stable oxide layer on pure VPE AlAs. The anodic oxidation of GaAs, $Al_xGa_{1-x}As$, and GaP is substantially similar and has been described in detail by Schwartz, Ermanis, and Brastad (2). We will emphasize here only the significant differences for pure AlAs. As in the work of Ref. (2), we employed a Pt cathode and Ta anode contact. We investigated anodic growth on n-AlAs layers ($n \sim 10^{18}$ cm^{-3}, $\rho \sim 0.05$ ohm-cm, $\mu \sim 120$) grown by VPE on (100) GaAs substrates (3), in pH-adjusted H_2O_2 or H_2O electrolytes.

We found that uniform, controlled oxide growth on AlAs is even more critically dependent upon purity of the electrolyte with respect to halide or NO_3^- ion concentration than was found for the Ga compounds (2). We were unable, in fact, to obtain high quality large area anodic growth in 30% H_2O_2 electrolyte anywhere in the pH 1.5-5.0 range, owing, we believe, to residual (1 ppm) Cl^- impurity, although acceptable growth on GaAs was attainable. Similar difficulty was encountered with ordinary distilled H_2O. With multiply filtered, deionized (4) H_2O (18 megohm cm), to which H_3PO_4 had been added to pH 1.9-2.0, however, excellent growth could be attained up to 2500Å under constant current conditions. The final layer thickness was determined to be linearly dependent (approximately 10 Å/V) on supply compliance voltage setting. Current densities of ~2-8 mA/cm² were satisfactory for room temperature baths at pH 2.0. At higher current densities tapering of the oxide was observed, particularly for AlAs epilayers grown on high resistivity substrates. Nonuniformity and pinholing of the oxide occurs at lower current densities. At elevated temperatures a greater range of current densities is permitted, thicker films may be grown, but the optimum pH range of 1.9-2.0 remains unchanged. Our conclusion that Cl^- impurity is responsible for the poor anodization with H_2O_2 and ordinary distilled water is based on the observation that addition of ~1 ppm of Cl^- (from successive dilution of reagent HCl) to the highly pure water gave similarly poor anodization behavior.

Following anodization, the material was baked and annealed at 400°C for 1 hr in a dry N_2 ambient. This serves to drive off water of hydration and improve the stability of the vitreous film. By analogy with Ref. (2), we believe the oxide film to be the form $Al_2O_3 \cdot As_2O_3$. At higher baking temperatures ($\gtrsim$ 550°C, 20 min) devitrification and loss of arsenic oxides sets in. The layers then fracture and "flake off" on cooling.

Key words: oxidation, compound semiconductors, device technology.

The unbaked anodic oxide film is significantly more resistant to attack by concentrated or dilute HCl than is the equivalent anodic oxide grown on GaAs. Total removal of a 1000A film in 50% HCl takes a few seconds for the film on GaAs, and tens of minutes for the film on AlAs. If pinholes, imperfections, or edges are exposed, in fact, the film is detached by attack on the underlying AlAs which is attacked much more rapidly than the oxide. Unbaked films deteriorate over several weeks in room air. The properly baked films are stable in room air and resist deterioration in contact with the photoresists, waxes, glycol phthalate, and shellac-based cements used in device fabrication, all of which attack and deteriorate unprotected AlAs in varying degrees. The baked film is rapidly removed in 10% HF or H_2SO_4 solutions but is not attacked by 20% Br_2:CH_3OH. It may also be removed rapidly in 1M KOH, which has less tendency to attack the underlying AlAs.

Preliminary measurements indicate a refractive index for the baked films of 1.7-1.8 at 600 nm. (The index does not vary from film to film, rather the uncertainty lies in our imperfect knowledge of the optical constants of AlAs, uncertainty in exact film thickness, residual surface roughness effects, etc.) The anodic oxide is thus eminently suitable for an antireflective coating [$n_{AlAs} \sim 3.3 = (1.8)^2$] and we have in fact obtained reflectivities below 2% across the 570-750 nm band on the solar cell devices described in Ref. (1).

Recently, the anodization of GaAs in a solution of ethylene or propylene glycol, tartaric acid, and water was described (5). We have found that this electrolyte does not offer any advantage over pure H_2O/H_3PO_4 for anodization of AlAs or GaAs, and we were only able to obtain poor results, comparable to those with the H_2O_2 bath, for AlAs. We have also tried other conductivity/pH modifiers—citric, acetic and tartaric acids, NH_4OH—in the highly pure water. Results in these electrolytes were less satisfactory, and the anodic oxides formed were less stable in air, whether baked or not.

In summary, stable, uniform anodic oxide films may be grown to reproducible and controlled thicknesses on AlAs by similar techniques as used (2) for GaAs, GaP, and $Ga_{1-x}Al_xAs$ alloy. The stability of the properly baked film is at least as good against attack by water or mineral acid solutions as the films on the Ga-containing compounds, and AlAs treated in this fashion can be handled and processed without the random deterioration, oxidation, and/or hydration which has hitherto precluded much interest in use of this compound in practical devices.

Acknowledgments

We thank W. M. Callahan for growing and characterizing the VPE layers used in this work.

Boundary Layer Replenishment and Unsteady-State Phenomena in Hydrogen-Oxygen Fuel Cells

Lyle F. Albright, T. G. Theofanous, and A. G. Rohrer[1]

School of Chemical Engineering, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

A one-dimensional (for diffusion) platinum electrode immersed in either dilute potassium hydroxide or sulfuric acid solutions was investigated for start-ups and restarts after partial rest periods. The experimental results for both the cathode and anode of the hydrogen-oxygen fuel cell were examined quantitatively to indicate the time periods for surface reaction control, diffusion control, and convection control.

When a fuel cell is started up, *i.e.*, when the circuit of the cell is closed after the cell has been rested, the current surges to a high value and then decays toward a steady-state value. As this occurs, the concentration of oxygen at the surface of the cathode decreases, and a boundary layer of electrolyte that is relatively depleted in absorbed oxygen forms next to the cathode. Hydrogen depletion also occurs at and near the anodic surfaces. When a cell is rested after it has been operated for extended periods of time, oxygen and hydrogen diffuse or transfer back in the regions on or near the cathodic and anodic surfaces, respectively. Relatively little quantitative information is available, however, on oxygen and hydrogen concentrations as a cell is initially rested or during the restarts (after a cell has been partially rested). Information on rest periods and on restarts would appear to be useful in clarifying phenomena that occur during cell operation.

The available information on start-up of a fuel cell indicates that several current-controlling steps may occur during start-up depending on the time after the circuit is closed and on the type of cell (or electrode) used (2-4, 7-10). In the time period immediately after the circuit is closed, the current is high and is sometimes relatively constant. Kinetic control is of major importance during this initial time period. With increased time after closing the circuit, the current often becomes essentially directly proportional to $1/\sqrt{\text{time}}$; the diffusion (or transfer) step of hydrogen or oxygen through the electrolyte to the anode or cathode, respectively, is then the controlling step. A third controlling step, free or natural convection, often becomes important for vertical electrodes several minutes after the circuit is closed (6).

In the present investigation, experimental evidence was obtained relative to the start-ups and restarts (after partial rest periods) for one-dimensional electrodes. This information plus mathematical analysis of the data has helped clarify the phenomena occurring during start-up, the rest period, and restarts.

Key words: fuel cell, electrode, electrolyte, cathode, anode, sulfuric acid, potassium hydroxide.

Equipment and Operating Procedure

The equipment and operating procedures were similar to those used by earlier investigators (2, 3). The test electrode was a piece of platinum foil that was 8 cm high, 3 cm wide, and 0.0125 cm thick. It was either completely or partially immersed in a vertical position in an electrolyte contained in a glass beaker. In some runs, the electrode was positioned in the middle of a 3 cm $\times$ 8 cm rectangular passageway constructed with Plexiglas plastic pieces that were 7 cm long. Since the passageway fitted closely around the edges of the electrode, diffusion of the absorbed gas in the electrolyte (oxygen or hydrogen depending on whether the electrode was being used as a cathode or anode) could, with this shielding, be only perpendicular to the plane of the electrode.

The surface roughness of the test electrode was increased by the electrodeposition of platinum from a 10% solution of chloroplatinic acid using a current density of 13 mA/cm^2 for 240 sec. DeVet (3) has earlier shown that such an electrodeposition technique increases the surface area by a factor of about 150, presumably indicating the presence of some platinum black on the surface.

When the test electrode was the cathode, the electrolyte in the main beaker was saturated with oxygen. The electrolyte around the counterelectrode was, however, saturated with hydrogen. For most runs of this investigation, 1*N* KOH was used as the electrolyte.

The differences in the potentials between the test electrode and the reference electrode (a saturated calomel electrode) were measured. After the open-circuit potential was determined using a Honeywell Model No. 2780 potentiometer, the desired potential difference was established and maintained to within 0.01V with a control system containing a potentiostat (Duffer's Model 600) and a dual power supply (Duffer's Model 620). Continuous measurement of the cell current was recorded on a Sargent SR recorder with a range up to 125 mA.

In some experiments, the fuel cell was modified so that the test electrode was the anode. The flows of oxygen and hydrogen were then reversed. In some cases,

dilute solutions of sulfuric acid were used as electrolyte.

The electrode to be tested was generally activated at the start of each day's operation; to do this it was immersed in 20% nitric acid maintained at a temperature just below its boiling point for 2 hr. The electrode was then rinsed with distilled water for 10 min; and then assembled with the fuel cell, which was immersed in a water bath.

The fuel cell was normally operated at room temperature, *i.e.*, at 25°-29°C. The electrolyte solutions for the cathode and anode were saturated with oxygen and hydrogen, respectively, by bubbling these gases through the electrolyte for 1-2 hr. In order to allow for dissipation of the convection currents in the electrolyte, the gas flows were stopped for at least 20 min before the circuits were closed. This technique of saturating the electrolyte with oxygen and hydrogen is defined here as the initial rest period.

Results

Several runs were made initially to determine if the shielded electrodes provided one-dimensional diffusion of the absorbed reactant gas through the electrolyte. Comparative runs made with a cathode completely immersed in 1*N* KOH, an anode in 1*N* KOH, and an anode in 1*N* H_2SO_4 indicated that the currents generated by shielded electrodes were 5-10% less than currents with unshielded electrodes. Figure 1 shows the currents generated as a function of time after the circuit was closed for a shielded and freshly activated cathode immersed in 1*N* KOH at potentials of 0.2, 0.3, and 0.6V. In all start-up runs, the currents were initially high and decayed to more or less steady-state values after several minutes.

The results of these start-up runs with shielded electrodes were next compared with calculated values obtained using the well-known equation for one-dimensional diffusion of the absorbed gas in the electrolyte. In the case of the cathode, oxygen is the absorbed gas

$$i_s = An\mathbf{F}C(D/\pi t)^{0.5} \quad [1]$$

where i_s = start-up current, mA; A = submerged area of electrode, cm²; n = number of electrons transferred per mole of reactant gas; $\mathbf{F}$ = Faraday number, 9.65×10^7 mA-sec; C = concentration of dissolved reactant in electrolyte, mole/cm³; D = diffusivity of dissolved reactant in electrolyte, cm²/sec; π = 3.1416; and t = time, sec.

A basic assumption of the above equation is that the reactant gas reacts immediately upon reaching the electrode and that the concentration of the reactant at the surface is zero. Values for diffusivity and for equilibrium solubilities of oxygen and hydrogen in dilute electrolyte solutions, such as needed in Eq. [1], are reported in the literature (1, 5). Currents calculated using Eq. [1] agreed in all cases within 4% of the experimental currents for time periods from 15 to 200 sec after the circuit was closed.

Plots of the current *vs.* $(1/t^{0.5})$ were most useful. The straight-line portion of such graphs was in all cases well represented by Eq. [1]. Figure 2 is an example for $(1/t^{0.5})$ values from about 0.07 to 0.25. Other time portions of these graphs will be considered later.

The currents at start-up of other one-dimensional electrodes in addition to those tested in this investigation can probably also be predicted by means of Eq. [1]. To support this conclusion, Eq. [1] resulted in a 10-15% underprediction of the start-up currents obtained by DeVet (3) who used an unshielded cathode immersed in 1*N* sulfuric acid electrolyte.

After the shielded electrodes were found to result in one-dimensional diffusion, a series of runs was made in which a cathode immersed in 1*N* KOH was first started up, then partially rested, and then restarted. When the circuit is first closed (resulting in the start-up current), an oxygen-deficient boundary layer is formed, and it grows in thickness as the circuit remains closed, as confirmed with the appropriate one-dimensional diffusion equations. The length of the start-up period was controlled in a series of runs at either 1.0 or 2.5 min. Following the start-up period, the circuit was opened in order to rest the cell. During this period of time, oxygen diffused into the boundary layer. Longer rest periods replenished to a greater extent the reactant concentrations causing them to approach the equilibrium concentrations that resulted after "complete" resting. Rest periods of 0.5, 1.0, 1.5, 2, 2.5, 5, and 12.5 min were tested. Finally, the circuit was closed once more, and the resulting current is defined as the restart current, i_{rs}. When molecular diffusion is controlling, the magnitude of i_{rs} can be related to i_s by the following equation derived by Rohrer (7)

$$\frac{i_{rs}}{i_s} = \tfrac{1}{2}\int_0^\infty f(y)\left[\frac{y}{Dt_{rs}}e^{-\frac{y^2}{4Dt_{rs}}}\right]dy + 1 \quad [2]$$

where

$$f(y) = \frac{1}{2\sqrt{\pi Dt_r}}\int_0^\infty\left[\operatorname{erf}\left(\frac{u}{2\sqrt{D\tau}}\right) - 1\right]\left[e^{-\frac{(y+u)^2}{4Dt_r}} + e^{-\frac{(y-u)^2}{4Dt_r}}\right]du \quad [3]$$

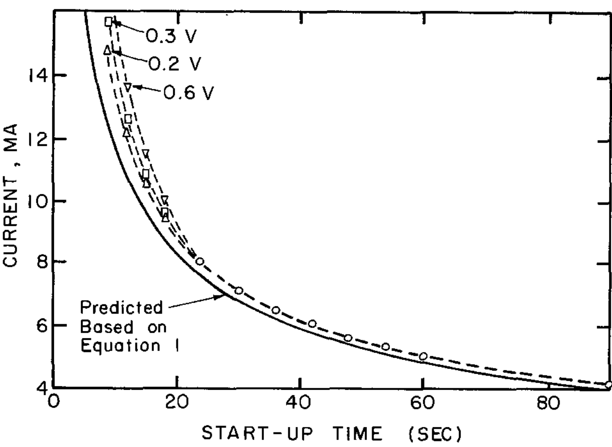

Fig. 1. Current as function of time after start-up of cathode completely immersed in 1*N* KOH at polarizations of 0.2, 0.3, and 0.6V.

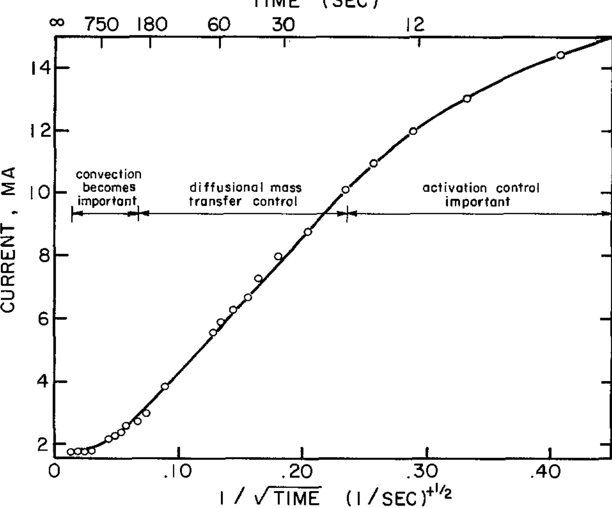

Fig. 2. Plot showing time regions for various controlling steps of start-up of hydrogen-oxygen fuel cell with 1.0*N* KOH electrolyte.

and t_{rs} = time elapsed after restart; t_r = total resting time; τ = the start-up time.

The experimental results of the restarts are reported here as the ratio of the restart current to the start-up current, *i.e.*, i_{rs}/i_s. In all cases, predicted values of i_{rs}/i_s based on the derived mathematical model (7) agreed well with the experimental values in the diffusion-law region (about 15-200 sec). Figure 3 shows the results for runs with the cathode completely immersed in 1*N* KOH and with a polarization of 0.2V. Both increased rest periods and decreased periods of time of closed circuit during start-up resulted in higher i_{rs}/i_s.

The ratio i_{rs}/i_s is a function of only two dimensionless variables (7), $v = t_{rs}/t_r$ and $g = \tau/t_r$. In fact, also using the substitutions

$$n = \frac{y}{2\sqrt{Dt_{rs}}} \text{ and } m = \frac{u}{2\sqrt{Dt_{rs}}}$$

Eq. [2] and [3] become

$$\frac{i_{rs}}{i_s} = 2\int_0^\infty f(n,v,g)e^{-n^2}n\,dn + 1 \qquad [4]$$

and

$$f(n,v,g) = \left(\frac{v}{\pi}\right)^{1/2}\int_0^\infty \left[\text{erf}\left(\frac{v^{1/2}m}{g^{1/2}}\right) - 1\right] [e^{-v(n+m)^2} + e^{-v(n-m)^2}]dm \qquad [5]$$

Figure 4 indicates how i_{rs}/i_s varies for various values of v and g based on the mathematical model. This graph indicated that a rest period as large as five times the start-up period (g = 0.2) is insufficient to completely replenish the boundary layer formed during start-up. When the restart period becomes large as compared to the rest period, *i.e.*, $v >> 1$, then the effect of increased resting becomes less since $i_{rs}/i_s \rightarrow 1.0$.

Results of early time period of start-up.—The current values calculated using Eq. [1] generally do not agree with the experimental values during the first 20 sec after start-up of a well-rested electrode. Figure 1 shows the results obtained with a cathode that had been freshly activated in nitric acid and was then immersed in 1*N* KOH. In this case, the experimental currents in the range of about 2-20 sec after closing the circuit were higher than the calculated values. During this time period, the currents were also sensitive to the magnitude of the imposed voltage. For activated anodes immersed in either 1*N* KOH or 1*N* H_2SO_4, similar findings were also noted. These results can be explained by two factors. Adsorption of hydrogen on the anode and of oxygen on the cathodes during the rest period results in more reactants (and hence higher currents) than are predicted based just on diffusion transfer. At least partial kinetic control is occurring as indicated by increased currents with higher imposed voltages.

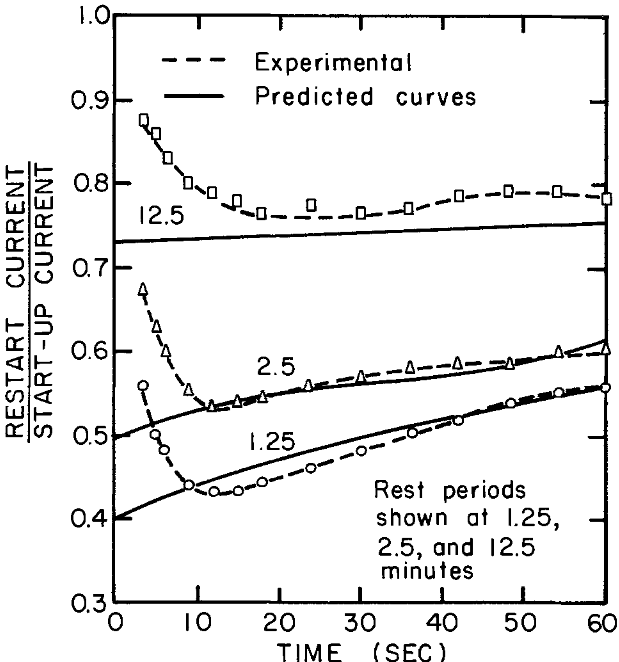

Fig. 3. Comparison of experimental and predicted ratio of restart to start-up currents for cathode immersed in 1*N* KOH and with polarization of 0.2V.

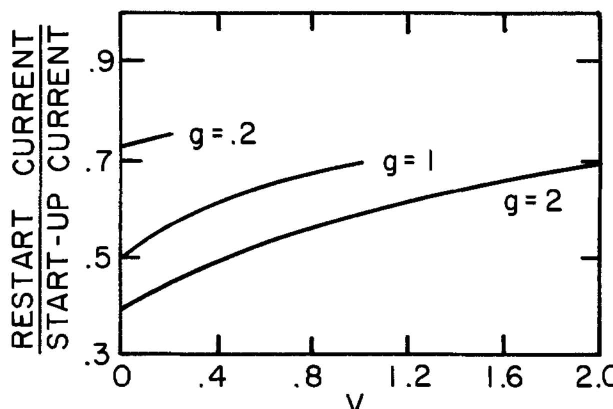

Fig. 4. Restart current/start-up current as function of dimensionless variables *v* and *g*.

For restart runs with a cathode immersed in 1*N* KOH, the poor agreement as indicated by Fig. 3 between the experimental and calculated results in the time period of 2-15 sec can also be explained by oxygen adsorbed on the cathodic surface. During the rest period, part of the oxygen that transfer to the surface is adsorbed on the surface. This adsorbed oxygen is then responsible for currents higher than would be predicted assuming diffusion transfer was the only phenomenon that had to be considered.

Immersion of the cathode in 1*N* KOH slowly deactivated it and may have resulted in diminished adsorption of oxygen on the surface. This conclusion is based on comparative runs with a cathode immersed from 0 to 8 days in 1*N* KOH. As noted in Fig. 5, decreased currents were obtained in the 2-20 sec time period (*i.e.*, $1/t^{0.5}$ from about 0.22 to 0.7) as the time of immersion increased. Extended immersions of an anode in 1*N* H_2SO_4 also deactivated it.

The cathode that was used immediately after being immersed (*i.e.*, zero days immersion) was most active. For values of $1/t^{0.5}$ from about 0.22 to 0.30, the slope

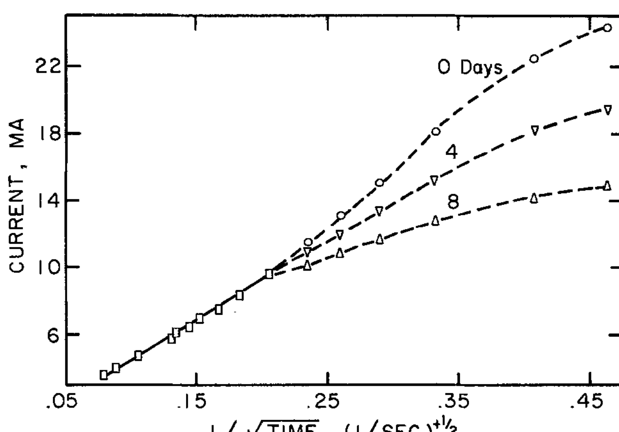

Fig. 5. Effect of aging of cathode in 1*N* KOH solution as related to start-up currents with 1*N* KOH electrolyte and with polarization of 0.2V.

increased rapidly, but at higher ($1/t^{0.5}$) values, *i.e.*, lower time values, the slope decreased and began to level out. For a constant current value, the electrode would be completely activation or kinetic controlled.

Results for long time periods after start-up.—For all electrodes tested, the current always became essentially constant several minutes after start-up. Equation [1], however, predicts that the current would continue to decrease with time until zero current would be obtained at infinite time. Free or natural convection most likely becomes of increased importance as a means of transferring oxygen (or hydrogen) to the electrode surface as the diffusional transfer decreases in importance (6).

Convection currents may also have increased somewhat as boundary layers deficient in oxygen (or hydrogen) were formed around the electrodes; in this latter case, some density gradients were most likely formed in the electrolyte solution near the electrode. The concentration of the electrolyte used sometimes has a significant effect on the current obtained after several minutes of operation. Currents obtained after 120 sec with a cathode immersed in 1*N* KOH were somewhat greater than currents in experiments using 1.5*N* KOH. More random convection currents probably occurred in the more dilute KOH solution because its lower viscosity would result in greater transfer of oxygen to the cathode surface. In addition, increased normality results in somewhat decreased oxygen diffusivity and solubility. It appears that for the electrodes used in this investigation that convection and diffusion steps are both partially controlling at the longer periods of time investigated.

Discussion

Kinetic control, diffusion control, convection control, and adsorption of oxygen on the cathode and of hydrogen on the anode are important considerations needed to explain the results of start-up and restart experiments of this investigation. The levels of current (or current fluxes) that serve as transition regions from one type of control to another have been reported for the flat-plate vertical anode and cathode used in this investigation. Such transition regions will certainly vary with at least the following variables: surface activation and roughness of the electrode; type of electrode being investigated such as either anode or cathode; type and concentration of electrolyte used; and the over-all geometry of the cell. Both roughness and the surface composition of the electrode should be further investigated in order to determine the levels of surface oxides, adsorbed species, etc. on the surface. Preliminary investigations here have already indicated that differences in surface compositions occur as a cathode is used in a fuel cell.

Other important areas that require further investigation are the mechanism of adsorption and the amount of oxygen (or hydrogen) that is adsorbed on the cathode (or anode) during the rest cycle and also the phenomena that occur during the initial stages of start-up when activation control is important.

Acknowledgments

Indiana Gas Association provided generous financial support to this investigation. Messrs. J. J. Schmitz, J. B. Cavender, and R. W. Salnick all made significant contributions in development of the equipment and procedures employed.

Equilibrium Phases Between Lithium Sulfide and Iron Sulfides

Ram A. Sharma

General Motors Corporation, Electrochemistry Department, Research Laboratories, Warren, Michigan 48090

ABSTRACT

The equilibrium phases in the lithium sulfide-ferrous sulfide system were determined by differential thermal analysis and x-ray diffraction analysis. A compound $Li_2S \cdot FeS$, which melts incongruently at 885° ± 5°C to Li_2S, and a liquid containing approximately 50.5 mole per cent (m/o) FeS, and has a transition at 840° ± 5°C, was found. A eutectic between $Li_2S \cdot FeS$ and FeS was observed at 63 m/o FeS and 858° ± 3°C. The terminal liquidus curves, computed by the application of Temkin's model, were found to be in good agreement with those experimentally determined. X-ray diffraction studies confirmed the transition in the compound $Li_2S \cdot FeS$ and also indicated compounds $2Li_2S \cdot Fe_3S_4$ and $Li_2S \cdot Fe_2S_3$, between Li_2S, FeS, and FeS_2.

The lithium-sulfur system appears very promising for developing an electrochemical cell of a high-temperature molten salt battery for vehicular propulsion (1). One of the major problems which has been encountered in developing this type of cell is the containment of sulfur in the positive electrode compartment. This problem arises because the cell operates at about 400°C at which temperature sulfur vapor pres-

• Electrochemical Society Active Member.

Key words: equilibrium phases, lithium sulfide, iron sulfides.

sure is very appreciable (2), and, therefore, sulfur is lost by vaporization.

It has also been observed that a lithium-sulfur liquid of about 65.5 mole per cent (m/o) sulfur (3) which forms during the cell cycling, dissolves in the typical LiCl-KCl electrolyte to an appreciable extent. This dissolved lithium-sulfur liquid reacts with the lithium in the anode forming lithium sulfide. Lithium sulfide is practically insoluble in the electrolyte at the cell operating temperature (0.02 mole/liter) (4). The loss of sulfur-electrode capacity by this self-discharge mechanism is difficult to recover.

The use of FeS_2 in place of sulfur circumvents the problems of sulfur loss by vaporization and the solution mechanism. Therefore, work is in progress to develop Li-FeS_2 cells. Microscopic examination of samples of the positive (FeS_2) electrode (4, 5) have indicated the presence of intermediate product phases during cycling. This investigation was conducted to determine the equilibrium phases in the Li_2S-FeS system and other possible compounds between Li_2S, FeS, and FeS_2. This information should be useful in understanding the cell operation and in the design of practical cells.

Experimental

Materials.—Lithium sulfide was white powder; its lithium content determined by chemical analysis was 29.8 weight per cent (w/o) (30.26 w/o theoretical). Its x-ray powder diffraction pattern indicated only Li_2S. Ferrous sulfide used was a black powder of 99.999% purity, as quoted by the supplier. Pyrite (FeS_2) was technical grade. It was freed from silica or silicates by a "sink-float" technique using tetrabromomethane of specific gravity 2.96. Its chemical analysis gave ~ 97 w/o FeS_2.

Apparatus and procedure for determining the equilibrium phases in the Li_2S-FeS system.—The differential thermal analyzer used consisted of a small resistance heating element furnace suitable for use up to 1600°C; an alumina enclosure for the sample and reference containers, allowing the maintenance of inert atmosphere (helium); a temperature programmer with a digital indicator; and a multipoint recorder for measuring sample temperatures and differential temperatures between the sample and a reference alumina sample, and sample weight. Platinum/platinum-10% rhodium thermocouples which were accurate within 3° in the range of temperature measured were used for temperature determination. Small, specially designed, dense graphite containers which could be closed nearly gastight with threaded caps were used for holding the samples. The graphite containers were fitted on the tops of the alumina thermocouple sheaths. Thin platinum foils were placed between the graphite containers and the thermocouple beads to avoid contamination of the thermocouple beads and to provide good contact between them and the graphite containers. The layout of the sample and reference containers inside the furnace is shown in Fig. 1.

Various salt compositions were prepared by taking weighed amounts of the components and mixing them thoroughly in an agate mortar. The accuracy of the compositions so prepared was checked by chemical analysis which indicated the intended composition within ±1%. About 0.5g of the mixture was placed in the graphite container. The entire manipulation was done in a helium-atmosphere dry box. The graphite container with the sample was removed from the jar only to position it on the top of the alumina sheath of the thermocouple inside the enclosure. Helium was passed through the enclosure. Phase transition temperatures were obtained with heating and cooling rates from 2° to 10°C/min. A typical representation of these curves for a melt of composition of 60 m/o FeS and 40 m/o Li_2S at a rate of 4°C/min is shown in Fig. 2.

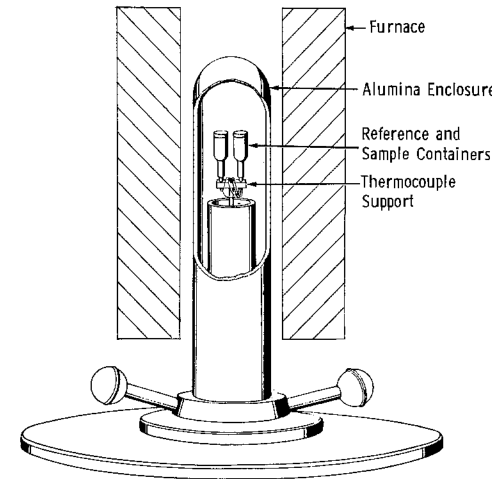

Fig. 1. Layout of samples inside the furnace

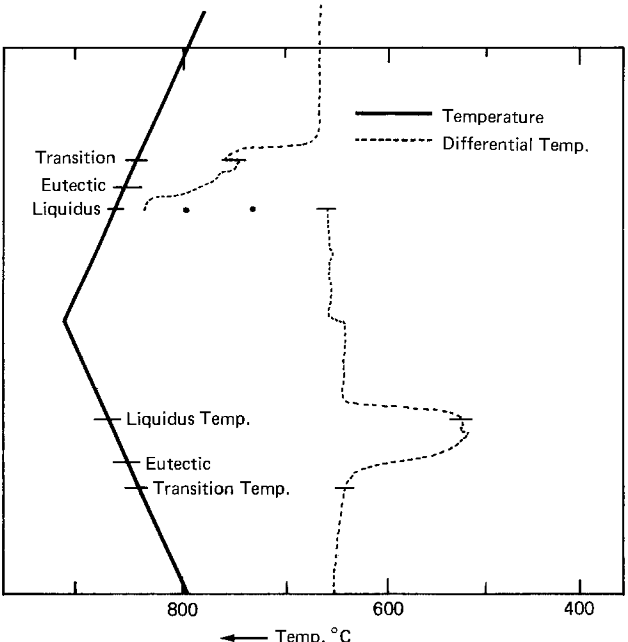

Fig. 2. A typical representation of the DTA curves obtained for a melt of 60 m/o FeS and 40 m/o Li_2S at 4°C/min.

By combining the measurements from the heating and cooling curves, the liquidus temperatures and eutectic temperature could be determined with good accuracy. The uncertainty could be further removed by having the measurements at different heating and cooling rates and, in the case of the eutectic temperature, at various compositions.

Sample preparation and equipment for x-ray diffraction analysis.—For x-ray diffraction analysis, the calculated amounts of Li_2S, FeS, and FeS_2 for the intended compound were mixed thoroughly in an agate mortar inside a helium-atmosphere dry box. About 5g of this mixture was taken into a dense-graphite container (6 cm high and 1 cm ID) which was placed inside a silica capsule. The silica capsule was sealed under vacuum and placed inside a tubular furnace at the desired temperature. After a certain period, the silica capsule was cooled, the sample was taken out of the graphite container and was crushed to a fine powder. The powder was reloaded into the graphite container, and proceeding as above, it was again placed at the desired temperature for another period. It was then taken out of the graphite container and crushed inside a helium atmosphere dry box. A small portion

of this powder was sealed in a fine silica capillary for x-ray diffraction analysis.

The equipment used for the x-ray diffraction analysis was a 143.2 mm camera mounted in conjunction with a vertical x-ray tube on a diffractometer instrument. A copper target tube could not be used because of the fluorescent effect of the copper radiation on the iron within the samples. A chromium target could not be used because of the heavy absorption of the radiation by the capillary (and the sample), and the x-ray powder pattern obtained contained only two lines because of the long wavelength radiation. So a molybdenum target tube CA-7 type with 0.002 in. reactor grade zirconium filter at the window to suppress K_B radiation was chosen.

Molybdenum radiation is short in wavelength and as a result the lines of the generated powder patterns are quite close together. This concentration of lines toward the front reflection region of the camera and the inaccuracies of the front reflection region are undesirable consequences of this radiation choice. However, a check of the two available lines obtained from a sample ($2Li_2S \cdot Fe_3S_4$) showed identical readings using either molybdenum or chromium radiation.

The x-ray diffraction patterns obtained for FeS and FeS_2 (pyrite) were also in complete agreement with the data reported in ASTM cards 11-151 for FeS and 6-0710 for pyrite.

Results and Discussion

The differential thermal analysis data for the Li_2S-FeS system are given in Table I. The equilibrium phase diagram based on the data obtained from both heating and cooling curves is shown in Fig. 3. A compound, $Li_2S \cdot FeS$, occurs in this system, melting incongruently at 885° ± 5°C to Li_2S and a liquid containing approximately 50.5 m/o FeS. A eutectic between $Li_2S \cdot FeS$ and FeS occurs at 858° ± 3°C and at the composition containing 63 m/o FeS. The compound $Li_2S \cdot FeS$ also has a transition temperature at 840° ± 5°C, as shown in Fig. 3.

The scanning electron microscope (SEM) pictures of the solidified melts, obtained from the differential thermal analysis runs, are shown in Fig. 4-7. These solidified samples were metallic black and brittle. They were easily tapped out of the graphite containers indicating that they shrank more than the graphite.

The SEM picture in Fig. 4 of the fractured surface of the solidified melt of 34.3 m/o FeS and 64.7 m/o Li_2S, consisting of 31.4 m/o Li_2S and 68.6 m/o $Li_2S \cdot FeS$, shows clearly two phases in accordance with the phase diagram. The lithium sulfide phase is of granular structure and the $Li_2S \cdot FeS$ phase is of the fibrous (woodlike) structure. The compound $Li_2S \cdot FeS$ appears to have a hexagonal structure which may be inferred from the careful examination of this phase in this picture, *i.e.*, from the obtuse angles of the grains.

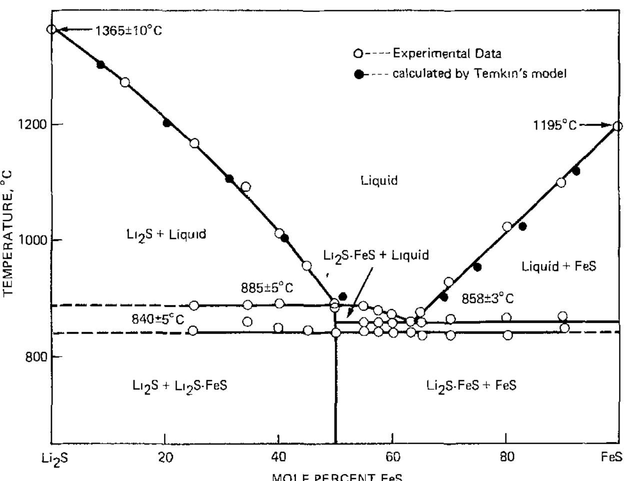

Fig. 3. The Li_2S-FeS system

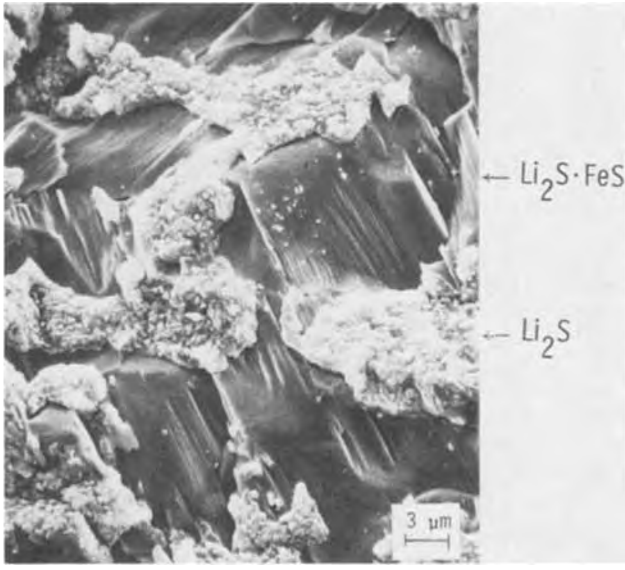

Fig. 4. Microstructure of the fractured surface of the solidified melt of 34.3 m/o FeS and 65.7 m/o Li_2S consisting of 31.4 m/o Li_2S and 68.6 m/o $Li_2S \cdot FeS$.

The SEM picture in Fig. 5 of the solidified melt of 50 m/o FeS and 50 m/o Li_2S consisting of $Li_2S \cdot FeS$ compound indicates a single phase and the flaky structure of this compound.

The SEM picture in Fig. 6 of the fractured surface of the solidified melt of 63 m/o FeS and 37 m/o Li_2S

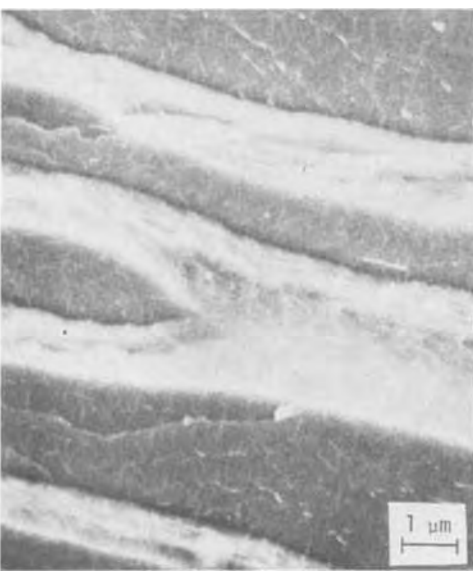

Fig. 5. Microstructure of the solidified melt of 50 m/o FeS and 50 m/o Li_2S, *i.e.*, of the compound $Li_2S \cdot FeS$.

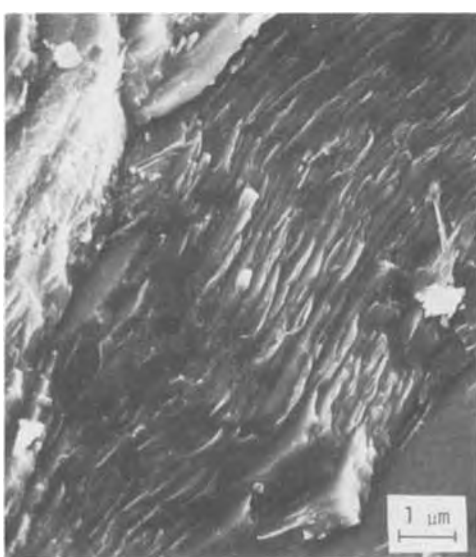

Fig. 6. Microstructure of the solidifed eutectic melt of 63 m/o FeS and 37 m/o Li_2S consisting of 74 m/o $Li_2S \cdot FeS$ and 24 m/o FeS.

shows the structure of the eutectic between the compounds $Li_2S \cdot FeS$ and FeS. It is a typical pearlitic structure, commonly observed as that of a eutectic melt.

The SEM picture in Fig. 7 shows the structure of the solidified melt of 70 m/o FeS and 30 m/o Li_2S consisting of 60 m/o $Li_2S \cdot FeS$ and 40 m/o FeS. Globular grains of FeS which might have precipitated during cooling between liquidus temperature and eutectic temperature, may be observed embedded in the $Li_2S \cdot FeS$ matrix in this picture.

According to Temkin's model (6), the activity, a, of a component in an ideal fused salt solution is equal to the product of its cationic and anionic fractions, *e.g.*, the activity of Li_2S, a_{Li_2S}, in fused Li_2S-FeS melt is given as

$$a_{Li_2S} = (X'_{Li^+})^2 (X'_{S^{2-}}) \quad [1]$$

assuming that the ionic species present are only Li^+ Fe^{2+}, and S^{2-}, where

$$X'_{Li^+} = \frac{2X_{Li_2S}}{2X_{Li_2S} + X_{FeS}} = \frac{2X_{Li_2S}}{1 + X_{Li_2S}} \quad [2]$$

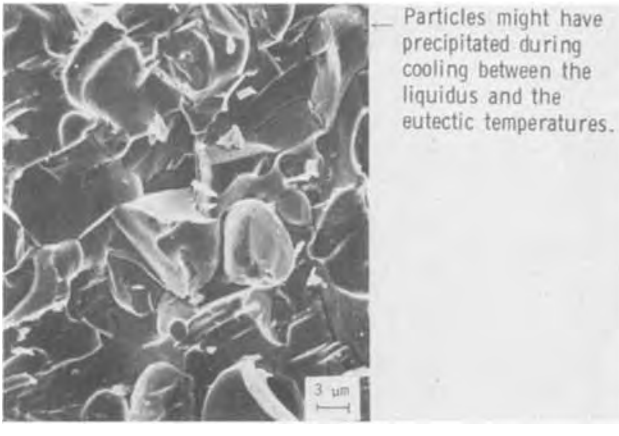

Fig. 7. Microstructure of the fractured surface of the solidified melt of 70 m/o FeS and 30 m/o Li_2S consisting of 60 m/o $Li_2S \cdot FeS$ and 40 m/o FeS.

and $X'_{S^{2-}}$ is unity. X' and X are the mole fractions of the designated ions and components, respectively. Therefore

$$a_{Li_2S} = \left(\frac{2X_{Li_2S}}{1 + X_{Li_2S}}\right)^2 \quad [3]$$

and similarly

$$a_{FeS} = \frac{X_{FeS}}{2 - X_{FeS}} \quad [4]$$

The activity of Li_2S with respect to pure supercooled liquid Li_2S as standard state at a given temperature may be calculated by the equation

$$\ln a_{Li_2S} = -\frac{\Delta H_m}{RT}\left(\frac{T_m - T}{T_m}\right) + \frac{\Delta C_p}{RT}\left[(T_m - T) - T \ln \frac{T_m}{T}\right] \quad [5]$$

where pure solid Li_2S is assumed to be in equilibrium with the melt, ΔH_m is the heat of fusion of Li_2S at T_m, the melting point of Li_2S in degrees Kelvin, T is the equilibrium temperature, and ΔC_p is the difference between the heat capacities of the liquid and the solid at temperature, T. The activity of FeS can also be calculated by a similar equation.

The numerical value of ΔH_m, 7 kcal/mole of Li_2S is calculated assuming that Temkin's model applies to the melts and using the experimental liquidus compositions at low concentrations of FeS. The application of Temkin's model at the low concentrations of FeS appears not unreasonable when it applies well to the melts on the FeS liquidus side of the phase diagram as will be seen later. The value of ΔH_m, 7.73 kcal/mole for FeS is reported in the literature (7); $T_m = 1638°K$ for Li_2S (3) and 1468°K for FeS (7); and $\Delta C_p = 0$ for Li_2S is assumed and for FeS is calculated from the data in the literature (7).

Using the activities of Li_2S and FeS calculated from Eq. [5] and assuming the Li_2S-FeS melts obey Temkin's model, the mole fractions of Li_2S and FeS were calculated by Eq. [3] and [4] at different temperatures, respectively. They are shown as solid circles in Fig. 3. Agreement between the measured and calculated values of mole fractions for both Li_2S and FeS appears to be good, even for this melt of sulfides having cations of different valences.

The x-ray diffraction patterns of the other possible compounds between Li_2S, FeS, and FeS_2 are discussed below.

$Li_2S \cdot FeS(\alpha)$.—The composition for this compound, made by mixing thoroughly the weighed amounts of Li_2S and FeS, was kept at 870°C for 35 days. The x-ray

powder diffraction data of a sample from this composition are given in Table II. The pattern has about 13 d-values different from that of FeS and 17 d-values different from that of Li_2S (3). About 25 d-values of FeS and 33 d-values of Li_2S are not observed in this pattern. Therefore the x-ray diffraction data confirm the compound $Li_2S \cdot FeS(\alpha)$ as indicated by the Li_2S-FeS phase diagram above 840° ± 5°C.

$Li_2S \cdot FeS$ (β).—The x-ray diffraction data of the composition for this compound after keeping at 700°C for 20 days are also given in Table II. As may be seen from the d-values reported in this table, the x-ray diffraction pattern of this compound differs from those of FeS, Li_2S, and $Li_2S \cdot FeS(\alpha)$. This is again in confirmation with the Li_2S-FeS phase diagram, according to which this compound forms below 840° ± 5°C. Compound $Li_2S \cdot FeS$ has also been reported to be formed during cycling of Li-FeS_2 cells at 400°C (5, 8).

The respective compositions for the prospective compounds, $Li_2S \cdot Fe_3S_4$, $2Li_2S \cdot Fe_3S_4$, $Li_2S \cdot Fe_2S_3$, and $2Li_2S \cdot Fe_2S_3$ were kept at about 670°C for 2 weeks, then were ground and kept for additional 6 weeks at this temperature. The temperature, 670°C, was dictated by the decomposition vapor pressure of sulfur over pyrite, which increases sharply above this temperature (9).

Table II. X-ray diffraction data (d-values in Å) of the compounds Li_2S, FeS, FeS_2 (pyrite), and the compositions corresponding to the other possible compounds

$Li_2S \cdot FeS(\beta)$	$Li_2S \cdot FeS(\alpha)$	$Li_2S \cdot Fe_3S_4$	$2Li_2S \cdot Fe_3S_4$	$Li_2S \cdot Fe_2S_3$	$2Li_2S \cdot Fe_2S_3$	Li_2S	FeS	FeS_2

The x-ray diffraction data of the samples from these compositions are given in Table II.

$Li_2S \cdot Fe_3S_4$.—Almost all the d-values of this prospective compound were observed to have the corresponding values in the patterns of Li_2S, FeS, FeS_2, and $2Li_2S \cdot Fe_3S_4$. The present x-ray data discount the formation of this compound from Li_2S, FeS, and FeS_2.

$2Li_2S \cdot Fe_3S_4$.—About ten d-values of this compound were not observed in the patterns of Li_2S, FeS, FeS_2, and $Li_2S \cdot FeS$. Most of the d-values of the compounds Li_2S, FeS, and FeS_2 were not observed in the pattern of this compound. Therefore, the x-ray diffraction data indicate the possibility of the compound $2Li_2S \cdot Fe_3S_4$.

$Li_2S \cdot Fe_2S_3$.—As may be observed from the d-values in Table II, the x-ray diffraction pattern of the composition for this compound differs greatly from those of Li_2S, FeS, FeS_2, $Li_2S \cdot FeS$, and $2Li_2S \cdot Fe_3S_4$. Such compounds with sodium, potassium, rubidium, and cesium, such as $Na_2S \cdot Fe_2S_3$, $K_2S \cdot Fe_2S_3$, $Rb_2S \cdot Fe_2S_3$, and $Cs_2S \cdot Fe_2S_3$ (10, 11), have also been reported in the literature. So the present x-ray diffraction data indicate the possibility of a compound $Li_2S \cdot Fe_2S_3$.

$2Li_2S \cdot Fe_2S_3$.—Almost all the d-values of the composition for this compound are observed in the patterns of FeS_2, FeS, Li_2S, $Li_2S \cdot FeS$, and $Li_2S \cdot Fe_2S_3$. The x-ray diffraction data of the present study do not indicate a compound $2Li_2S \cdot Fe_2S_3$, though the formation of this compound has been reported during the cycling of Li-Al/FeS_2 cells (8).

Conclusions

The equilibrium phase diagram of Li_2S-FeS system was determined. The important characteristics of this system are:

1. A compound, $Li_2S \cdot FeS$, incongruently melting at 885° ± 5°C to Li_2S and a 50.5 m/o FeS melt, and having a transition at 840° ± 5°C was found.
2. A eutectic between $Li_2S \cdot FeS$ and FeS at 63 m/o FeS and 858° ± 3°C was observed.
3. Temkin's model for molten salt melts fits the terminal liquidus curves of the experimental data well, with a calculated value of ΔH_m, 7 kcal for Li_2S and the literature value, 7.73 kcal for FeS (7).

The x-ray diffraction studies confirmed the compound, $Li_2S \cdot FeS$ and its transition. They also indicated the compounds $2Li_2S \cdot Fe_3S_4$ and $Li_2S \cdot Fe_2S_3$ between Li_2S, FeS, and FeS_2.

A High Energy Density Solid-State Battery System

C. C. Liang* and L. H. Barnette

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

The discharge and storage characteristics of a new solid-state battery system, Li/LiI(Al_2O_3)/PbI_2, PbS, Pb were investigated. Results of the discharge tests suggested that both PbI_2 and PbS are cathode active and can be discharged efficiently. A discharge efficiency of 100% was realized on test cells with a stoichiometric capacity of 18 mA-hr/cm² at a drain rate of 10 μA/cm² at room temperature. Results of the storage tests showed that the system is stable on storage. Test cells experienced no capacity loss after a storage period of one year at room temperature, 45°, and 60°C. The discharge and storage characteristics indicate that the system is a practical, low rate solid-state battery system and the practical batteries have a volumetric energy density of 8 W-hr/in.³ (0.49 W-hr/cm³) at a power level of 150 μW/in³.

It was reported in a previous article (1) that the ionic conductivity of polycrystalline LiI can be increased from 10^{-7} (ohm-cm)$^{-1}$ to 10^{-5} (ohm-cm)$^{-1}$ at room temperature by the incorporation of Al_2O_3. The suitability of LiI(Al_2O_3) as a solid electrolyte material was demonstrated by the discharge and storage characteristics of the Li/LiI(Al_2O_3)/PbI_2, Pb solid

* Electrochemical Society Active Member.

Key words: solid-state batteries, solid electrolyte cells, lithium, lithium iodide, lead sulfide, lead iodide.

electrolyte cells. The $Li/LiI(Al_2O_3)/PbI_2$, Pb system is a low rate solid-state battery system which has an extremely long storage life. Hermetically sealed, practical batteries of this system have a volumetric energy density ranging between 3 and 3.5 W-hr/in.^{3} (*ca.* 0.18 and 0.21 W-hr/cm^3) at a power density of about 100 μW/in.^{3} at room temperature. The relatively low energy density is due to the rather high electrochemical equivalent volume of the active cathode material, PbI_2, and to the fact that a considerable amount of Pb and solid electrolyte material must be used in the cathode to facilitate the electronic and ionic conduction during discharge.

In our recent studies of the solid-state battery systems using the $LiI(Al_2O_3)$ solid electrolyte we found that the volumetric energy density of the $Li/LiI(Al_2O_3)$ system can be substantially increased by using a mixture of PbS and PbI_2 as the active cathode material. The results of these studies are reported in this article.

Experimental

Solid electrolyte preparation.—The $LiI(Al_2O_3)$ solid electrolyte was prepared according to the procedures described previously (1). A powder mixture of anhydrous LiI and Al_2O_3 in a mole ratio of 2 to 1 was heated at 550°C for about 17 hr in a helium-filled dry box (Vacuum Atmospheres). The H_2O and O_2 content in the dry box was maintained at less than 15 ppm.

Solid electrolyte cell fabrication.—$Li/LiI(Al_2O_3)/PbI_2$, PbS, Pb solid electrolyte cells (Fig. 1) were fabricated in the dry box. The cathode powder was a well-blended mixture of 40 weight per cent (w/o) PbI_2, 40 w/o PbS, and 20 w/o Pb and the anode was Li metal. The current collectors were Pb for the cathode and steel for the anode. The fabrication procedures were reported previously (1, 2). The cathode, the electrolyte, and the anode with a polypropylene retaining ring were consolidated by pressing in a 1.52 cm (0.6 in.) diameter steel die at 7030 kg/cm^2 (100,000 psi). The geometric area of the cathode was 1.81 cm^2 and that of the anode was 1.48 cm^2. The thickness of the electrolyte was 0.02 ± 0.005 cm (0.008 ± 0.002 in.) and the stoichiometric capacity of the test cell was limited by the amount of cathode. Both single cell and multicell batteries were constructed using the solid electrolyte cells for various discharge and storage tests. The batteries which were discharged outside the dry box were hermetically packaged in steel battery housings with glass to metal seals.

Discharge tests.—The test batteries were discharged at various temperatures under either constant current or constant load conditions. Keithley Model 610B or Model 616 electrometers were used to measure the voltages of the test batteries. For short term discharge tests the voltages were recorded by strip chart recorders. For long term discharge tests the voltages were recorded manually at intervals.

Storage tests.—Solid electrolyte cells having a stoichiometric capacity of 33 ± 2 mA-hr were used for storage tests. They were stacked in glass vials with polyethylene covers and stored at ambient temperature, 45° ± 2°C, 60° ± 2°C, and 100° ± 2°C. Scientific Products temperature block module heaters were used to maintain the temperature above ambient. Since the test cells were not hermetically sealed the storage tests were conducted in the dry box under helium atmosphere.

Inasmuch as the capacity retention of the test cells upon storage was of principal interest for this study, accelerated discharge tests were carried out at 125°C on most of the test cells before and after storage to determine the storability.

Results and Discussion

Approximately 250 solid electrolyte cells were made for various tests. The stoichiometric capacities of the test cells ranged between 14 and 136 mA-hr assuming that both PbI_2 and PbS are cathode active. Cells with stoichiometric capacities of 33 and 136 mA-hr were studied extensively and their characteristics are reported in this article.

It was assumed that the cell reactions are

$$2Li + PbI_2 \rightarrow 2LiI + Pb \quad [1]$$

$$2Li + PbS \rightarrow Li_2S + Pb \quad [2]$$

The open-circuit voltage based on cell reaction [1] is 1.9V at 25°C (1, 3, 4). In order to calculate the open-circuit voltage based on reaction [2] the standard Gibbs free energy of formation ($\Delta G°_f$) for Li_2S was determined from the open-circuit voltages of $Li/LiI/Ag_2S$, Ag and Li/LiI/S, graphite solid electrolyte cells. At 25° ± 2°C the open-circuit voltages of the Li/Ag_2S and Li/S cells were found to be 2.11 ± 0.01V and 2.31 ± 0.05V, respectively. These results are consistent with the fact that the $\Delta G°_f$ for Ag_2S is −9.72 kcal/mole (3), therefore, the difference between the equilibrium potential of the Li/S cell and that of the Li/Ag_2S cell should be 0.21V. Accordingly, we estimated the $\Delta G°_f$ for Li_2S at −106 ± 2 kcal/mole and the open-circuit voltage according to cell reaction [2] at 1.80 ± 0.05V at room temperature (3, 4). The $\Delta G°_f$ (Li_2S) value obtained from the present study agreed rather well with that due to Freeman (5). Freeman calculated the standard heat of formation ($\Delta H°_f$) for Li_2S from the heat of solution data and obtained a value of −107 ± 2 kcal/mole. Furthermore, he estimated the standard entropy ($S°$) for Li_2S at 14 cal/deg-mole. Based on the fact that the standard entropies of Li and S are 6.96 cal/deg-mole (4) and 7.6 cal/deg-mole, respectively, the standard entropy of formation ($\Delta S°_f$) for Li_2S is calculated to be −7.52 cal/deg-mole. Accordingly, the $\Delta G°_f$ (Li_2S) according to Freeman is −104.8 ± 2 kcal/mole. Nonetheless, since the $\Delta G°_f$ (Li_2S) value of the present study was obtained from direct measurements of open-circuit voltage of voltaic cells and consistent results were obtained from cells with different cathodes (Ag_2S and S) we selected to use the value of −107 ± 2 kcal/mole of this study for the calculation of the open-circuit voltage based on reaction [2].

The $Li/LiI(Al_2O_3)/PbI_2$, PbS, Pb cell exhibited an initial open-circuit voltage of 2.00 ± 0.05V. However, after a small capacity had been discharged from the cell, the voltage recovered to 1.91 ± 0.01V upon open circuit indicating that the initial high open-circuit voltage might be due to impurities such as PbO and S in the cathode.

The assumption that both PbI_2 and PbS can be discharged was shown to be correct from the initial discharge tests. Test cells with cathodes weighing 0.23-0.26g were discharged under a 100 kohm load at room temperature. As shown in Fig. 2 a capacity of about 33 mA-hr was realized from each of the 12 test cells under these discharge conditions. The stoichiometric capacity of the test cells was 33 ± 2 mA-hr according to the cathode weight assuming that both PbI_2 and PbS

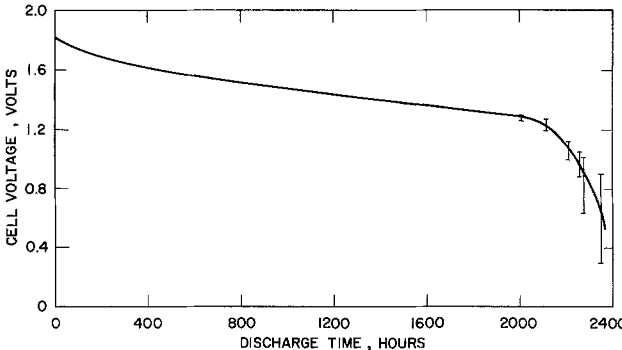

Fig. 2. Discharge curve of the 33 mA-hr cells under a 100 kohm load at room temperature.

are cathode active. The discharge curves of the 33 mA-hr cells at various constant currents at room temperature are shown in Fig. 3. The stoichiometric capacity was not realized at a discharge current of 36 μA or higher.

The discharge characteristics of test cells having a stoichiometric capacity of 136 mA-hr were studied in detail and the results are discussed below.

Under a constant load of 100 kohm at room temperature a capacity of about 65 mA-hr was realized to a cutoff voltage of 1V as shown by the discharge curve in Fig. 4 which represents an average of six test cells. On the other hand, Fig. 5 shows that at higher drain rates (*e.g.*, 36 μA or higher) the realized capacities were about the same as those of the 33 mA-hr capacity cells. The following is a possible explanation for such a behavior. Since the electronically conductive Pb was evenly distributed in the cathode, and the electrolyte was a cationic conductor, the discharge reaction began at the electrolyte-cathode interface and extended toward the cathode current collector. The accumulation of the discharge products had a net effect of reducing the geometric area and increasing the length of the path with respect to the lithium ion transport during discharge. Consequently, similar *IR* losses due to the cathode structure would be experienced by cells of the same diameter which were discharged under similar drain rates at similar discharged capacities.

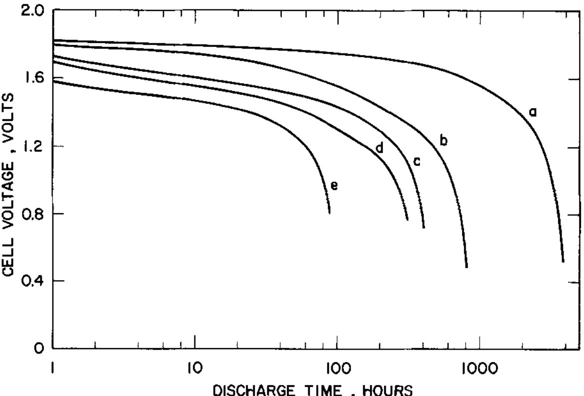

Fig. 5. Discharge curves of the 136 mA-hr cells under various constant currents at room temperature. Curve a, 18 μA; curve b, 36 μA; curve c, 54 μA; curve d, 72 μA; curve e, 90 μA.

Discharge tests were also conducted at 37°C for implantable pacemaker applications. As expected from the conductivity considerations both the realized capacity and the load voltage of the cells were higher at 37°C than at room temperature under otherwise similar discharge conditions as shown in Fig. 6 and 7.

It is noted that since the solid electrolyte cells do not contain any solution electrolyte and all the components are solid with extremely low vapor pressures, it is not necessary to contain the solid electrolyte cells in individual containers for the construction of multi-

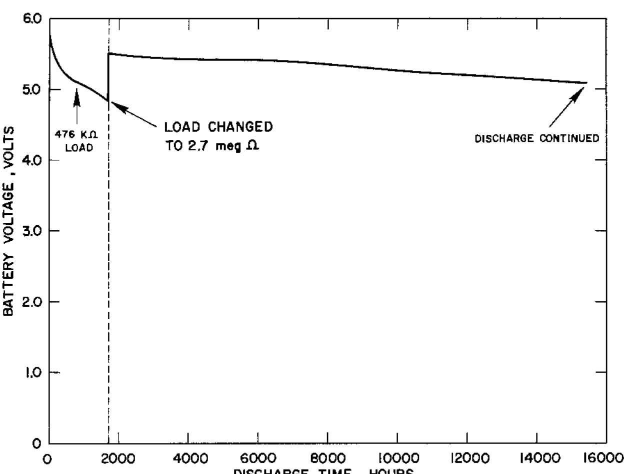

Fig. 8. Long term discharge curve of the single stack (3 cells in series) 6V, 136 mA-hr batteries at 37° ± 2°C.

cell batteries. Any number of the solid electrolyte cells may be connected in series and/or in parallel within a single battery housing. In view of these characteristics, the discharge current of practical batteries for some applications may be as low as 1-1.5 $\mu A/cm^2$ at 37°C. Accordingly, low drain rate tests were conducted on batteries containing three 136 mA-hr cells in series. Six batteries were used for this study. The battery was discharged at 37°C under a load of 476 kohm for 1700 hr. At this point the load was changed to 2.7 megohm for long term low drain tests. Figure 8 shows that after 15,000 hr the load voltage was still above 5V. It is estimated that these tests will be completed 5 years hence.

Accelerated discharge tests were conducted to determine whether or not the stoichiometric capacity of the 136 mA-hr cells can be realized and to determine load voltage at various depths of discharge at low drain rates. The first series of accelerated discharge tests was conducted on batteries containing either a 1 or 2 cells connected in parallel. The load voltage of the battery under a low drain rate was measured at 37°C, then the battery was discharged at 100°C at a considerably higher drain rate (a 10 kohm load for the single cell battery and a 5 kohm load for the 2-cell battery). After the depth of discharge had reached about 40% the load voltage was again measured at 37°C under the low drain rate. The cycle was repeated until the discharged capacity reached 130 mA-hr/cell. At this point the battery was discharged to completion at 37°C under the low drain rate. The results of these tests are summarized in Table I. It is noted from Table I that after a capacity of 130 mA-hr/cell had been discharged the load voltage under a drain rate of 1.5 $\mu A/cm^2$ was still above 1.3V at 37°C.

Similar tests were conducted on a battery containing 4-paralleled stacks of 3 cells in series. The battery had an open-circuit voltage of 6V and a stoichiometric capacity of 544 ± 8 mA-hr. The dimensions of the packaged battery were 0.67 in. OD × 1.1 in. long. After a capacity of about 540 mA-hr had been discharged under high drain rates and at higher temperatures, it was found that the load voltage of the battery at 10 μA at 37°C remained above 4.3V for more than 200 hr. These results strongly suggest that under a drain rate of 1-1.5 $\mu A/cm^2$ at 37°C the stoichiometric capacity of 136 mA-hr/cell (about 75 $mA\text{-}hr/cm^2$) can be realized.

Test cells having a stoichiometric capacity of 33 ± 2 mA-hr were used for the storage tests. The results of these tests are summarized in Table II and discussed below.

The test cells experienced no capacity loss after a storage period of 6 weeks, 3 months, 6 months, or 1 year at room temperature. Figure 9 shows the discharge curves of a 2 and a 6 week old cell under a 100 kohm load at room temperature. No significant difference in discharge characteristics was noted. Furthermore, a discharge efficiency of 100% was realized in both cells. The realized capacities of all the test cells after storage at room temperature are shown in Table II. The stoichiometric capacity of 33 ± 2 mA-hr was realized in all the stored cells. It is noted that since the capacity retention of the test cells was of principal interest, accelerated discharge tests were carried out on the 3 month, 6 month, and 1 year stored cells. The test cells were discharged at 125 μA at 125°C. The stoichiometric capacity was realized in all the tests indicating that no self-discharge process had taken place.

The results of the 45°C storage tests were similar to those of the room temperature storage tests. The test cells experienced no capacity loss after storage as shown in Table II.

Figure 10 shows the discharge curves of 2 test cells before and after a storage period of 1000 hr at 60°C. It is noted that no capacity loss was experienced by the stored cell. However, after a storage period of 3 months we noted that 2 of the 20 stored cells showed low open-circuit voltage. The 2 cells were positioned at the top of the stack in the glass vial. An examination of these 2 cells revealed a dark brown substance on the Li anode. Since an ammonia odor was clearly noted when water was dropped on the dark brown compound we concluded that it was lithium nitride. The nitride formation was caused by the small amount of residual nitrogen in the dry box. Evidently, the rate of nitride formation must be significant at 60°C to cause problems for the unsealed test cells. Nonetheless, 5 cells were selected at random from the remaining cells and discharged at 125 μA at 125°C. The stoichiometric capacity was realized. Consequently, we concluded that the failure of the 2 cells was due to causes other than the intrinsic properties of the system. In order to alleviate the nitride formation problem, the glass vial which contained the remaining test cells was heat sealed in two overlapping 10 mil polyethylene bags and the cells were returned to the 60°C storage.

The 6 month and 1 year stored cells were discharged at 125 μA at 125°C. No capacity loss was experienced by these cells as shown in Table II. Figure 11 shows the typical discharge curves of the test cells before and after a storage period of 1 year at 60° and 45°C.

All the test cells stored at 100°C showed lithium nitride formation on the anode after 3 months. Indeed, the anode of most of the test cells was completely covered with lithium nitride and separated from the electrolyte. It was concluded that lithium nitride formation at 100°C due to the residual nitrogen in the dry box had rendered the storage of the unsealed cells impractical. No attempt was made to discharge these cells.

The fact that the test cells experienced no capacity loss after various storage periods up to 1 year at room temperature, 45°, and 60°C showed that the Li/LiI(Al_2O_3)/PbI_2, PbS, Pb batteries are stable on storage and have a long shelf life. It should be noted, however, that the laboratory cells were not hermetically sealed, the anodes stored at 100°C reacted with the residual nitrogen in the dry box and became defective. Consequently, no conclusion can be made in regard to

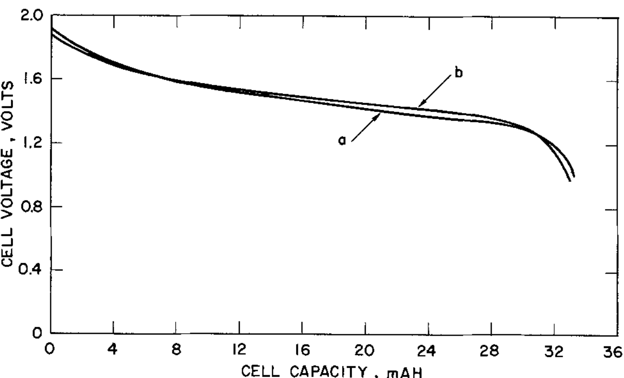

Fig. 9. Discharge curves of the 33 mA-hr cells before and after room temperature storage. Discharge conditions: 100 kohm load at room temperature. Curve a, cell No. 73515-11 (fresh cell); curve b, cell No. 73515-12 (stored at room temperature for 6 weeks).

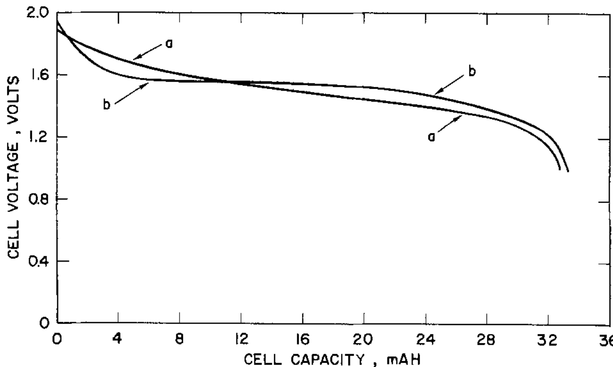

Fig. 10. Discharge curves of the 33 mA-hr cells before and after 60°C storage. Discharge conditions: 100 kohm load at room temperature. Curve a, cell No. 73515-11 (fresh cell); curve b, cell No. 73508-1 (stored at 60°C for 6 weeks).

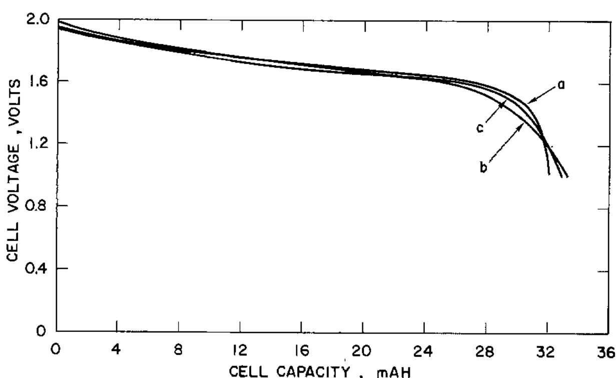

Fig. 11. Discharge curve of the 33 mA-hr cells before and after long term storage. Discharge conditions: 125 μA at 125°C. Curve a, cell No. 73530-4 (fresh cell); curve b, cell No. 73522-12 (stored at 45°C for 1 year); curve C, cell No. 73522-5 (stored at 60°C for 1 year).

the storability of the laboratory type of $Li/LiI(Al_2O_3)/PbI_2$, PbS, Pb batteries at 100°C.

The results of the discharge and storage tests showed that the $Li/LiI(Al_2O_3)/PbI_2$, PbS, Pb system is a practical low rate, high energy density system. Indeed, batteries containing parallel and series stacks of cells have been made for low rate applications. It is estimated based on the low rate and accelerated discharge test results that an energy density of 0.49 W-hr/cm^3 (8 W-hr/$in.^3$) can be realized from these batteries.

The Role of Conductivity Variations Within Artificial Pits During Anodic Dissolution

Richard Alkire,* Daniel Ernsberger,** and David Damon[1]

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Owing to restricted mass transport, the conductivity of electrolytic solution within occluded regions may be different from that of the bulk electrolyte outside the occluded regions. Experimental and theoretical investigations have been carried out on artificial copper pits (length to diameter ratio between 0.93 and 10.3) dissolving in binary copper sulfate solutions (0.001-0.5M at 25°C) in order to clarify conditions under which conductivity effects are appreciable. Both potentiostatic (50-1500 mV) and galvanostatic (1.2-6.8 mA/cm^2) data agree with a mathematical model which includes charge transfer, ohmic, geometric, and unsteady-state mass transport processes. The model generates dimensionless criteria by which the importance of conductivity changes in other chemical systems can be estimated.

Because corrosion processes are complex, it is often difficult to design meaningful accelerated tests and/or to scale up laboratory results to field applications. Therefore model studies on simple analogs of corrosion processes can be helpful even though they may not account for the entire range of possible complexities which actual corrosion systems possess. That is, model studies on seemingly artificial systems can clarify the conceptual groundwork upon which is based intuitive judgments about real systems.

Models of localized corrosion processes, especially pitting and crevicing, have been proposed by several investigators in order to clarify effects of diffusion-limited behavior within the occluded region. Diffusion-limited attack eventually leads to the formation of concentration gradients within the occluded region. As a consequence, the kinetics of the corrosion reactions deep within the occluded region may be very different from those occurring under bulk electrolyte conditions owing to the concentration dependence of the rate constants (1). Also, the increased concentration of species within the occluded region may increase the conductivity of the occluded solution, thereby reducing the ohmic resistance of the corroding system (2). Upon extended dissolution, the precipitation of salt films within the occluded region can eventually occur (3). These processes cause naturally corroding systems to be rather complicated owing to the many possible electrochemical reactions, the complex interfacial phenomena and solution chemistry, and the uncertain geometry of localized corrosion cells.

The purpose of the present study was to employ experiments and mathematical models to investigate the role of conductivity variations within artificial pits during the course of controlled metal dissolution. The program was designed to develop a predictive basis for estimating conditions under which auto-acceleration of dissolution rates in artificial pits can occur owing to conductivity variations (4, 5).

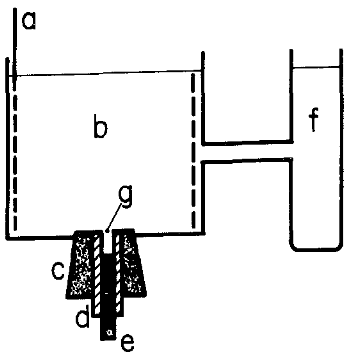

Fig. 1. Electrolysis cell. a, cathode screen; b, electrolyte compartment; c, rubber stopper; d, insulating side walls; e, wire anode; f, reference electrode compartment; g, artificial pit.

Apparatus

Cylindrical artificial pits with inert side walls were fabricated by embedding copper wire[2] in epoxy resin and cutting off one end. The exposed surface was mechanically polished to 600 grade, and the copper was then dissolved to the desired depth by anodic dissolution in flowing sulfuric acid. A flat-bottomed polished surface was subsequently obtained by electropolishing in 50% phosphoric acid. Before and after pitting experiments, microscopic examination of the circular surface was made with an objective having a depth of focus of 0.01 mm, and it was found that every portion of the surface was in sharp focus. Artificial pits were placed facing upward in the corrosion cell as depicted in Fig. 1. The cylindrical cathode consisted of copper screen. A mercurous sulfate reference electrode was used in the side compartment. It was found that the behavior of the pit did not depend on cathode or reference electrode position provided that they were placed more than 1.5 cm (or 10 pit diameters) from the pit entrance. Similarly, it was found that pit behavior was independent of the amount of solution in the cell provided that the solution depth exceeded 1.5 cm. The solution in the cell was not agitated.

The uniformity of the current distribution in the vicinity of the pit mouth was measured analogically by using conductive paper cut in the shape of a two-dimensional slot. A slot with a length to width ratio of unity had a potential distribution that varied by 10% from the edge to the center of the slot mouth. The potential distribution in a circular pit will be less uniform than the slot geometry. Therefore pits with aspect length to diameter ratios appreciably less than unity were not investigated.

Experiments were conducted under both constant potential control (Wenking No. 68TS3) and constant current control (Electronic Measurements No. C633). During the course of some experiments, the potential distribution within the pit was measured directly by lowering a microcapillary probe into the pit. The electrolysis cell was placed on a microscope stage and the probe was mounted in place of the objective lens. The focus knob was connected to the shaft of a precision potentiometer thereby obtaining a voltage signal proportional to probe displacement. An X-Y recorder (Hewlett-Packard No. 7004B) displayed the measured potential as a function of position. The probe cross-sectional area was 8% of the pit cross-sectional area.

[2] See Table I for diameters.

Procedure

Four concentrations of electrolytic solution (0.001, 0.01, 0.1, and 0.5M) were prepared from AR hydrated copper sulfate and deionized, distilled water (conductivity 4×10^{-6} mho/cm).

After electropolishing, pits were rinsed with about 3500 pit volumes of distilled water (a few milliliters and dried. The pit depth was measured to within 0.01 mm by mounting the pit on a microscope stage (Bausch & Lomb UK 128) and focusing first on the metal surface and then on the external epoxy surface; the fine focus micrometer provided a direct measure of pit depth. The pit was then placed in the electrolysis cell, and solution was added with a syringe to assure that no bubbles were trapped within the pit. The make-up solution was held at 25°C.

Constant potential experiments were carried out with solutions of several concentrations, while constant current experiments were carried out with a single solution as indicated in Table I. For each solution, a freshly prepared pit was used for measurements at four different conditions (either applied potential or applied current). The duration of each unsteady-state experiment ranged between 70 and 400 sec. Between each measurement the pit was rinsed with electrolyte of bulk concentration and temperature 25°C. During some constant potential experiments, the potential distribution within the pit was measured by lowering the microcapillary reference electrode probe into the pit until the tip hit the base and flexed; the probe was then withdrawn. Each traverse took about 5 sec.

Upon completion of experiments for each solution, the conductivity of the bulk solution was measured with a resistance bridge (Leeds & Northrup Series 4959). The diameter of the pit was measured optically to within 0.01 mm by placing the pit on the stage of a microscope having a calibrated scale in the eyepiece.

Mathematical Model

The artificial pit geometry is described by a right circular cylinder of radius r and height h. The binary solution of electrolyte in the pit contains a soluble salt of the metal which is undergoing dissolution, for example copper sulfate in the case of copper dissolution. Only one electrochemical reaction oocurs, metal dissolution; the metal does not corrode in the solution. During dissolution the metal surface is assumed to remain smooth and perpendicular to the side walls.

During dissolution, the solubility of the binary metal salt is not exceeded and therefore precipitation does not occur.

For diffusion of a binary electrolyte under stagnant conditions, the one-dimensional unsteady diffusion equation is

$$\frac{\partial c(y,t)}{\partial t} = D \frac{\partial^2 c(y,t)}{\partial y^2} \quad [1]$$

where it is assumed that the diffusion coefficient of the neutral salt, D, is independent of concentration (6). Symbols used in the equation are explained at the end of the text. A migration term does not appear in Eq. [1] since the concentration refers to the movement of the neutral binary salt, not individual ionic species. The initial condition which corresponds to the experimental procedure is that the concentration within the pit is uniform prior to application of power

$$c(y,0) = c_b \quad [2]$$

The boundary condition at the pit entrance ($y = h$) which conforms to the experimental procedure is

$$c(h,t) = c_b \quad [3]$$

At the base of the pit ($y = 0$), the concentration gradient in the metal salt is proportional to the current flowing through the pit

$$\frac{\partial c(0,t)}{\partial y} = -\frac{(1-t_+)i}{n\mathbf{F}D} \quad [4]$$

As the metal dissolves, the pit becomes longer. For the short duration unsteady-state experiments reported in Table I, however, the elongation is less than 0.03% of the initial length. For longer duration steady-state experiments, variation of pit length during dissolution was accounted for with use of Faraday's law.

The potential between the dissolving anode and the reference electrode can be resolved into four component overpotentials which arise owing to charge transfer, concentration differences, resistance effects within the pit, and resistance effects external to the pit mouth

$$\phi = \eta_s + \eta_c + \eta_r + \eta_m \quad [5]$$

The component overpotentials are related to the current density and concentration by

$$i = i_0 \left[\frac{c(0,t)}{c_b} \right]^{0.42} (e^{(\alpha_a \mathbf{F}/RT)\eta_s} - e^{-(\alpha_c \mathbf{F}/RT)\eta_s}) \quad [6]$$

$$\eta_c = \frac{(1+t_+)RT}{\mathbf{F}} \ln \left[\frac{c(y,t)}{c_b} \right] \quad [7]$$

$$\eta_r = \frac{ih}{\kappa^*} \quad [8]$$

$$\eta_m = \frac{\pi r i}{4\kappa_b} \quad [9]$$

where κ^* is the average conductivity of electrolyte in the occluded region. Equation [6] characterizes the $Cu/CuSO_4$ system (7) and Eq. [7] is the Nernst equation written for a binary salt (8). The conductivity of copper sulfate solutions varies with concentration (9-12); a parabolic least squares fit of the data was used (4) to give

$$\kappa = \kappa_b \left(\frac{c}{c_b} \right)^{\gamma} \quad \text{for } 10^{-8}\text{M} < c < 1.43\text{M} \quad [10]$$

where

$$\gamma = 0.706 - 0.214 \ln c_b - 0.0107 \ln \frac{c}{c_b} \quad [11]$$

The agreement between the conductivity data and Eq. [10] is everywhere within 8% of the experimentally measured conductivity. Equation [8] is Ohm's law where the average conductivity is employed. It is recognized from transport theory that Ohm's law is not valid in the presence of concentration gradients owing to diffusion potentials; the suitability of simplifying the analysis by ignoring these restrictions will be in part justified by comparison of theoretical predictions with experimental data in the following sections. Equation [9] is Ohm's law where the resistance is computed for a flat disk embedded in an insulating plane with the counterelectrode at infinity (13).

Method of Solution

The details of the calculations are given in Ref. (4) and are only summarized here. For constant current calculations, an analytical solution by separation of variables is available (4, 14) for the concentration distribution as a function of time. Equations [5]-[9] were then employed to calculate the total overpotential.

For constant potential calculations, an IBM-360 digital computer was used in conjunction with the Crank-Nicolson finite difference scheme to obtain the unsteady-state concentration and potential distributions within the pit during dissolution. At each time step, the current density required by Eq. [4] was chosen by Newton-Raphson iteration such that Eq. [5]-[9] were satisfied under the prevailing concentration distribution. Numerical unsteady-state calculations were found to be insensitive to mesh size between 20-100 mesh points and to initial time increments (Dt/h^2) less than 10^{-5}. The size of the time step was increased by a factor of 1.1 with each successive step.

Results and Discussion

During preliminary experiments, it was found that extended periods of dissolution would often lead to precipitation of a salt film onto the electrode surface owing to supersaturation of solution. Under constant applied current conditions, for example, a sudden voltage rise would occur some time after initiation of electrolysis, to be denoted the transition time. For semi-infinite diffusion, the transition time is related to the other parameters by (15)

$$t^{1/2} = \frac{n\mathbf{F}\sqrt{\pi D}}{2i} (c_{\text{pptn}} - c_b)$$

Measurement of the transition time therefore provides a direct indication of the solute concentration at the electrode surface when precipitation occurs. Experiments performed in several solutions (0.01, 0.1, and 0.5M $CuSO_4$) at applied current densities up to 250 mA/cm^2 gave the consistent result that precipitation occurred when the saturation concentration was exceeded by 2.2-fold.

The short-duration transient experiments reported below were conducted under such conditions that precipitation did not occur. Longer duration experiments were conducted until either a pseudo steady state was attained or else salt precipitation occurred. The results of both types of experiments are discussed separately.

Short duration experiments.—Table I (Part 1) provides conditions under which short duration experiments were performed; the parameters of the binary copper sulfate system for which data were obtained are provided in Table II. These values were used in making theoretical calculations with the above mathematical model. For 24 experiments of 26 performed, it was found that the predicted value of the initial current (or potential) averaged to within 5.0% of the measured value. The range was between 0 and 19% error.

Results of constant potential experiments and calculations are given for two concentrations and two aspect ratios in Fig. 2, 3, and 4. The solid lines corre-

spond to experimental measurements while the dashed lines correspond to theoretical calculations. In each figure, results are given for several different applied potentials. It is seen in every case that the current eventually increased above its initial value, sometimes passing through a minimum which was more or less shallow. In every case, the agreement between experiment and theory is within 10% of the measured value. The increase in current during constant potential electrolysis is due to increased conductivity of solution within the pore, not surface roughening. (If the solution in the pit is stirred part way through an experiment, the current returns to its initial value.) The minimum in the current occurs owing to the competing effects of concentration overpotential and conductivity variation.

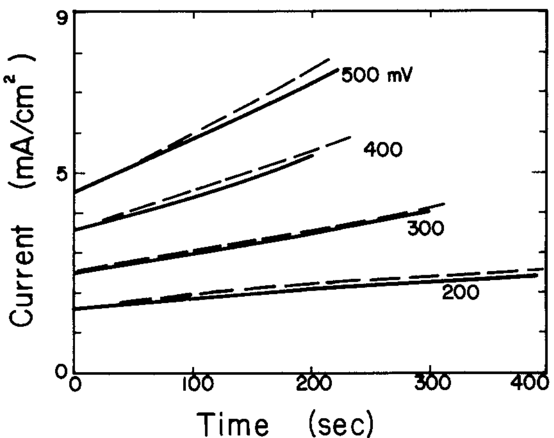

Fig. 2. Current response during constant potential electrolysis (c_b = 0.01M, h/D = 2.26).

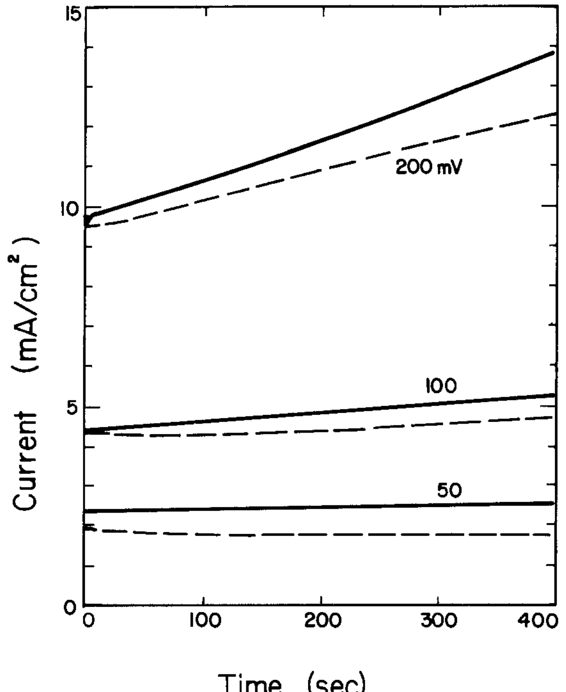

Fig. 3. Current response during constant potential electrolysis (c_b = 0.1M, h/D = 2.15).

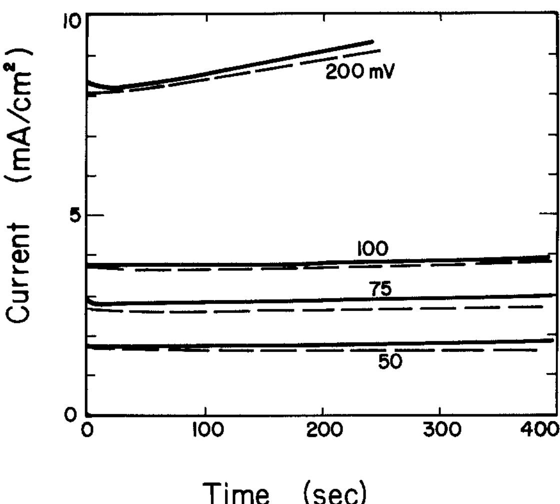

Fig. 4. Current response during constant potential electrolysis (c_b = 0.1M, h/D = 0.93).

A typical potential distribution measured within the pit during dissolution is given by the solid line in Fig. 5. The data show that potential variations external to the pit are important. The theoretical calculations indicated by the dashed line are in good agreement with these data. The hysteresis in the potential traverse is thought to arise from free movement in the microscope gears, not from disturbing the concentration profile; partial traverses showed that even when the probe did not enter the pit, a reversal in traverse direction was accompanied by hysteresis. Insertion of the measuring probe was found to disturb the current by less than 2% of the measured value.

Figure 6 shows results of four experiments on a pit operated at different applied constant currents. In each, the potential (measured between anode and reference electrode) eventually decreased during unsteady-state dissolution. The theoretical model predicted behavior, shown by the dashed lines, which is in accord with the experimental data.

Long-duration experiments.—Experimental conditions under which long-term dissolution experiments were conducted are given in Table I (Part 2). Theoretical calculations were made for each experiment performed. Results are given in Fig. 7 for one series of constant potential experiments in a solution of 0.01M

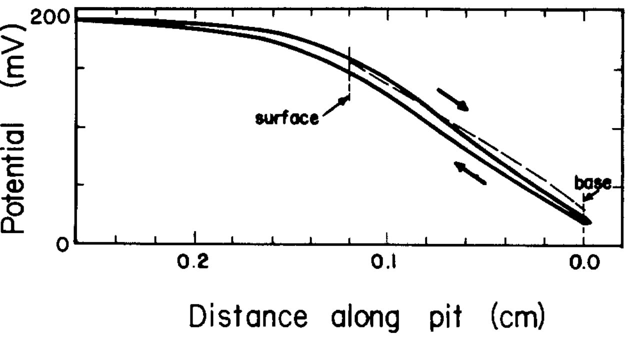

Fig. 5. Potential distribution in an artificial pit during electrolysis (c_b = 0.1M, h/D = 0.93, time = 28 sec after onset of electrolysis).

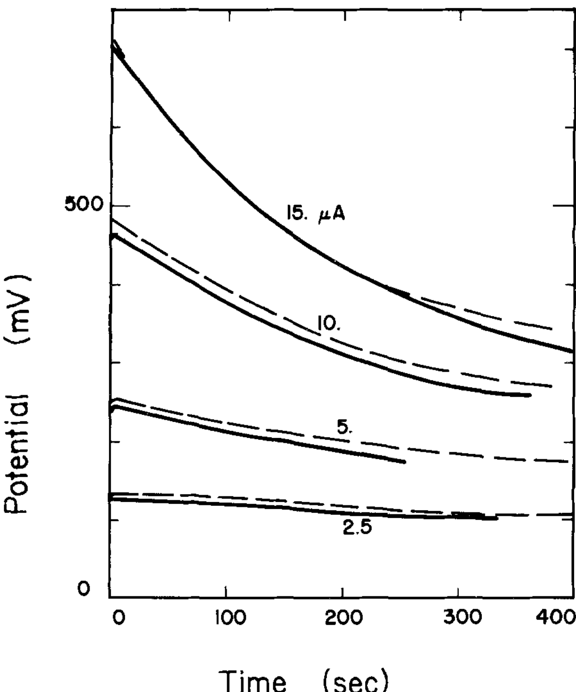

Fig. 6. Potential response during constant current electrolysis (c_b = 0.1M, h/D = 2.26).

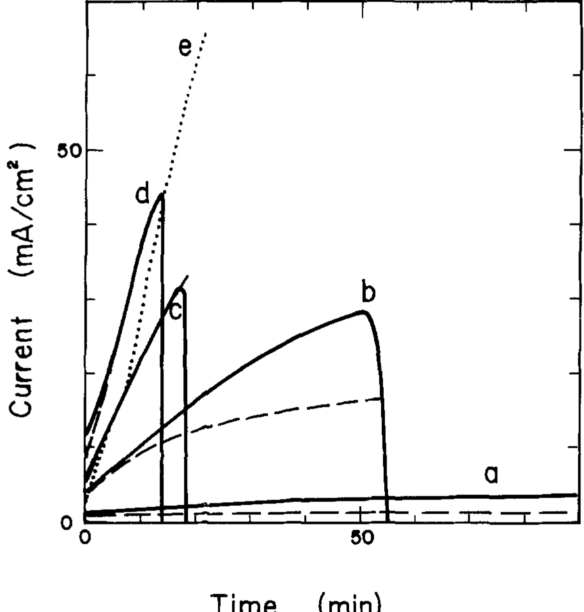

Fig. 7. Current response during constant potential electrolysis. a, 0.01M, 100 mV; b, 0.01M, 300 mV; c, 0.01M, 500 mV; d, 0.01M, 700 mV; e, 0.001M, 1500 mV.

$CuSO_4$. At the higher applied potentials, the current increased by up to five times the initial current and then fell suddenly owing to precipitation within the pit. At lower applied potentials, a steady-state current was obtained. The dotted line marked "e" in Fig. 7 shows experimental data for a highly polarized electrode in very dilute electrolyte. At the moment of salt precipitation, the current had increased by more than 25-fold above the initial value at $t = 0$.

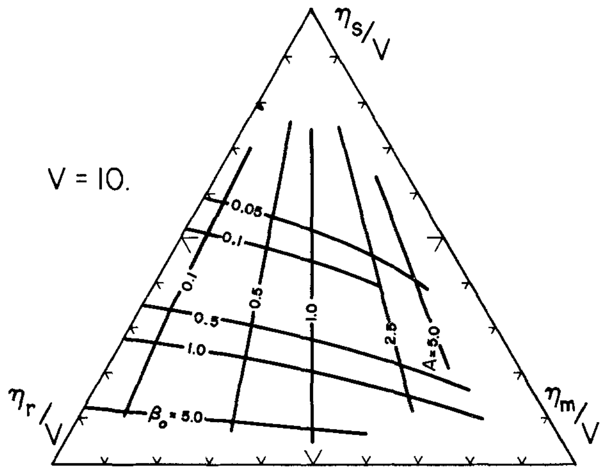

Fig. 8. Overpotential partitioning at onset of electrolysis

The theoretical calculations, shown by the dashed lines, are in good agreement with experimental trends. Table III summarizes the predicted and measured values of current at the end of the experiment (either attainment of steady state or else salt precipitation). It is seen that in every case investigated the theory provides a conservative estimate of the auto-acceleration effect.

Theoretical model.—The foregoing comparison of theory and experiment has been carried out over a wide range of operating conditions including mode of power supply, aspect ratio, pit diameter, solute concentration, rate of dissolution, and duration of experiment. Because the experiments were carefully designed in the sense that no adjustable or uncertain parameters were involved, the good agreement between theory and experiment indicates either that the assumptions were justified, or that any poor assumptions were inconsequential.

By writing the mathematical equations in dimensionless form, it is possible to develop criteria for estimating those situations where the ohmic overpotential is greater than the charge-transfer or concentration overpotentials so that auto-acceleration is possible. A procedure, outlined below, has been developed for predicting the maximum current which would be experienced under given operating conditions. The principal purpose of presenting these results is to provide an example of how dimensionless parameters can be used to assist in determining which physical phenomena control corrosion behavior, in determining what scale-up ratios apply, and in locating the window in parameter space within which the auto-acceleration effect is likely to be most destructive.

Under what conditions is acceleration likely to occur?—Acceleration will occur only if a major portion of the applied potential is consumed by the ohmic resistance within the pit. At the initial moment of switching on the circuit, Fig. 8 shows how overpotentials are distributed between ohmic and surface processes (concentration overpotential being absent). The figure cor-

Table III. Final currents, steady-state experiments

Applied potential (mV)	Concentration (mole/liter)	Aspect ratio	Final current observed (mA/cm²)	Final current predicted (mA/cm²)
100, 300, 500, 700	0.01	4.50	3.8, 28.6, 31.2, 44.3	1.7, 16.5, 31.2, 44.3
500, 1000, 1500	0.001	4.50	29.5, 47.6, 67.8	7.4, 17.7, 29.5
50,100, 150,200	0.01	10.35	0.091, 0.91, 0.98, 2.5	0.081, 0.56, 0.62, 1.8

responds to $V = \phi_A n\mathbf{F}/RT = 10$, or 125 mV for a two-electron reaction. Because η_s, η_m, and η_r sum to the applied potential, each point within the triangle represents a different partitioning between the three overpotentials. The partitioning depends on two dimensionless parameters

$$A = \frac{\pi r}{4h}$$

$$\beta_o = \frac{i_o n\mathbf{F}h}{RT\kappa_b}$$

The parameter A is an aspect ratio, while β_o is the ratio of ohmic resistance to charge-transfer resistance insofar as it contains the ratio of i_o to κ. Figure 8 illustrates how the relative values of the three overpotentials depend on A and β_o. On this basis, it is seen that the ohmic resistance in the pit consumes an appreciable fraction (over 50%) of the applied potential under the conditions

$$A < 1$$

$$\beta_o > 1 \qquad [12]$$

Under the conditions given in Eq. [12], the auto-acceleration effect is likely to be observed.

To what extent will acceleration occur?—It is convenient to arrange the parameters of the system into dimensionless group as follows

$$\theta = -\frac{\kappa_b RT(1 - t_+)}{c_b n^2 \mathbf{F}^2 D}$$

The application of potential $V = \phi_a n\mathbf{F}/RT$ will cause flow of current (initially equal to $\beta_i = i_i n\mathbf{F}h/RT\kappa_b$) which will change to some final steady-state value, ($\beta_{ss} = i_{ss} n\mathbf{F}h/RT\kappa_b$) provided that precipitation of insoluble salts does not occur. For a long narrow pit ($r/h = 0.0127$), the ratio of β_{ss}/β_i is given in Fig. 9 for a wide variety of possible systems and operating conditions. It is seen that a final steady-state current of 50-fold greater than the initial current is possible for some systems. For shorter pits ($r/h = 0.127$) the ratio of β_{ss}/β_i is also given in Fig. 9. It is seen that the auto-acceleration phenomenon is important under conditions such that h/r, V, β_o, θ, and γ are large.

Conclusions

Dissolution of metal within artificial pits can increase the conductivity of solution within the pit sufficiently to initiate auto-acceleration of the dissolution rate. Under such conditions, the rate of dissolution can increase manyfold over the initial rate. A mathematical analysis of concentration and potential variations within artificial pits is in good agreement with data on artificial pits containing binary electrolyte. The theory permits estimation of what conditions are likely to exhibit auto-acceleration and to what extent the dissolution rate is likely to increase. Similar effects occur in multicomponent electrolyte systems, and the methods used in this investigation could be extended to these systems without difficulty.

Naturally corroding pits and crevices are more complex than the artificial pits studied here. Whereas it is often difficult to assign values to the parameters of naturally corroding systems, modeling studies assist in clarifying the interpretation of complex data.

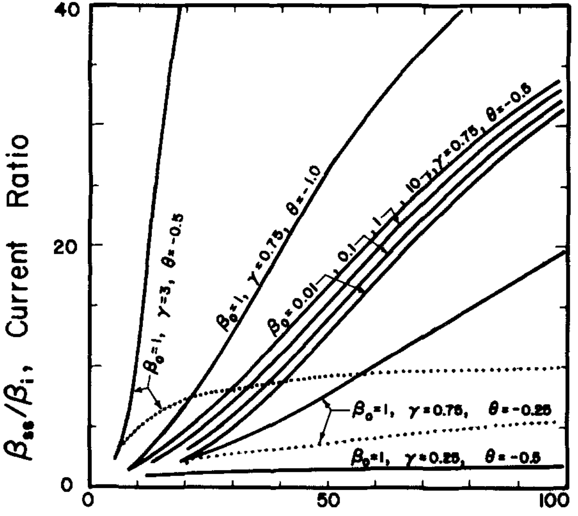

Fig. 9. Extent of auto-acceleration. ——— $A = 0.01$ or $r/h = 0.0127$; . . . . . $A = 0.1$ or $r/h = 0.127$.

LIST OF SYMBOLS

- A — $\pi r/4h$, dimensionless aspect ratio
- c — concentration, mole/cm^3
- c_b — bulk concentration, mole/cm^3
- D — diffusivity of neutral salt, cm^2/sec
- $\mathbf{F}$ — Faraday constant, coulomb/equivalent
- i — current density, A/cm^2
- i_i — initial current density, A/cm^2
- i_o — exchange current density, A/cm^2
- i_{ss} — steady-state current density, A/cm^2
- h — pit length, cm
- n — number of electrons in electrochemical reaction
- R — gas constant, coulomb-V/g-mole °K
- r — pit radius, cm
- t — time, sec
- t_+ — cationic transference number
- T — temperature, °K
- V — $\phi_A n\mathbf{F}/RT$, dimensionless applied potential
- y — spatial variable
- α_a — anodic transfer coefficient
- α_c — cathodic transfer coefficient
- β_i — $i_i n\mathbf{F}h/RT\kappa_b$, dimensionless initial current density
- β_o — $i_o n\mathbf{F}h/RT\kappa_b$, dimensionless exchange current density
- β_{ss} — $i_{ss} n\mathbf{F}h/RT\kappa_b$, dimensionless steady-state current density
- γ — empirical parameter defined by Eq. [11]
- η_c — concentration overpotential, V
- η_m — ohmic resistance overpotential external to the pit, V
- η_r — ohmic resistance overpotential within the pit, V
- η_s — surface overpotential, V
- θ — $-\kappa_b RT(1 - t_+)/c_b n^2 \mathbf{F}^2 D$, dimensionless diffusion parameter

Transport Processes and the Mechanism of Pitting of Metals

Jose R. Galvele*[,1]

The Ohio State University, Corrosion Center, Columbus, Ohio 43210

ABSTRACT

A pit model was developed on the assumption that the metal ions hydrolyze inside the pits and that the corrosion products are transported by diffusion. Concentrations of Me^{2+}, $Me(OH)^+$, and H^+ ions, as a function of pit depth and current density, for Zn, Fe, Ni, Co, Al, and Cr were calculated. The main reason for passivity breakdown at the initial stages of pit growth, was found to be the localized acidification due to metal ions hydrolysis. Assuming a critical *p*H value for pit initiation, the following experimental facts could be explained: (*i*) the effect of the external *p*H on the pitting potential of Fe and stainless steel; (*ii*) the effect of sodium borate concentration on the pitting potential of Zn; (*iii*) the effect of weak acid salts on the pitting potential of Al; (*iv*) the oscillations of the electrode potential of stainless steel and nickel in solutions of $Cl^- + SO_4^=$ ions; (*v*) the existence of a pitting inhibition potential; and (*vi*) the existence of a pitting protection potential. Through analysis of the transport processes inside a pit it was also concluded that the pitting potential of a metal should change with the Cl^- ion concentration according to the equation

$$E_p = E_p^\circ - B \cdot \log [Cl^-]$$

$B = 0.059V$ being the slope of the curve at room temperature.

It is a generally accepted fact that pitting starts at a certain critical potential, known as pitting potential (1). Yet the nature of such a potential still remains uncertain. Several explanations have been given, such as zero charge potential, potential-induced ion migration, electrically produced mechanical breakdown, competitive adsorption, salt-formation equilibrium potential, etc. (1). Nevertheless, none of these mechanisms could account for the way in which variables such as *p*H, ionic concentration, and inhibitor concentration affect the pitting potential. In recent publications, Wexler and Galvele (2) and Alvarez and Galvele (3) reported that the pitting potential was the minimum potential at which localized acidity could be maintained inside a pit. The present paper, based on simple transport equations shows that such acidification can be obtained even at the very early stages of pitting, and that, as was recently reported (4), transport calculations inside the pit explain why variables such as an aggressive anion concentration, nonaggressive anion concentration, external *p*H, presence of weak acid salts, and alloying elements modify the pitting potential of a metal.

It is concluded that most of the observations made so far on the pitting potential can be explained simply by transport phenomena, and that processes like competitive adsorption, salt formation, film contamination, etc., even though present during the pitting process, do not play a major role in fixing the pitting potential.

Several authors have shown that the solution inside a pit, as well as that inside a crack or crevice, has a composition quite different from that in the bulk solution (5-10). As early as 1937 Hoar (11) proposed a mechanism of "autocatalytic" pit propagation, which considered that the main cause of pitting was the drop of *p*H inside the pit. Other authors (12, 13) postulated that the condition for pitting initiation was an increase of chloride ion concentration on the metal-solution interface. In a similar way Kaesche (14) considered the formation of saturated $AlCl_3$ inside a pit the necessary condition for the pitting of aluminum.

After studying the pitting of iron in various environments, Vetter and Strehblow (15, 16) questioned all mechanisms based on local composition changes. These authors assumed that the causes of pitting should be present in all the stages of pit growth, even in the smallest detectable pits. Pits as small as one micron in diameter, growing with current densities of the order of 1-9 A/cm² were detected in iron. According to their calculations, the origin of pitting could not be attributed to changes in *p*H, in potential, or in ionic concentration, since such changes would be meaningless in the initial stages of pitting. However, the pitting model developed by Vetter and Strehblow cannot be taken as a realistic model; according to their model the *p*H inside the pit increases during pit growth, while in practice the *p*H was found to decrease (5-10).

Pickering and Frankenthal (17) developed a much simpler pit model, and they analyzed the changes in

* Electrochemical Society Active Member.
[1] On leave from the Comision Nacional de Energia Atomica, Departamento de Metalurgia, Buenos Aires, Argentina.

Key words: pitting of metals, pitting potential, transport processes, pitting inhibitors.

composition to be expected in the pit. Nevertheless, the model by Pickering and Frankenthal could not be applied in its original form to all pitting cases because, again, it would lead to pH increases inside the pit as the pit grew.

Pit Model

In the present paper a pit model similar to that developed by Pickering and Frankenthal is used (Fig. 1). Their model was developed for a metal that would dissolve in an acid solution and consequently always resulted in a decrease in the pH inside the pit. To overcome this difficulty, the model used herein assumes that the pH of the bulk solution can take any value from acid to alkaline values.

The model by Pickering and Frankenthal takes into consideration the transport of ions both by diffusion and by electrical migration. In this way, complex formulae are obtained when the study of the hydrolysis of the metal ions, or modifications of the external pH are attempted. Since, as shown by Vetter and Strehblow (16), pitting initiation takes place with small changes in the electrolyte composition, it is reasonable to assume that the bulk solution acts as a supporting electrolyte for the metal ions and the hydrolysis products produced during pitting initiation. In this way the transport equations are considerably simplified, since only transport by diffusion remains important. The following are the main modifications introduced in the model used in the present paper:

(*i*) Instead of a single charge transfer reaction, a more general expression is used for the anodic reaction taking place inside the pit

$$Me = Me^{n+} + ne \qquad [1]$$

The dissolution reaction is assumed to take place at the bottom of the pit, (Fig. 1) as in the model by Pickering and Frankenthal. No reaction takes place at the walls of the pit. In this way a unidirectional pit model is obtained, with a considerable simplification in the mathematical treatment.

(*ii*) Reaction [1] is assumed to occur in a sodium salt of an aggressive but noncomplexing anion. The pH of the bulk solution could have any value, and is given as a boundary condition.

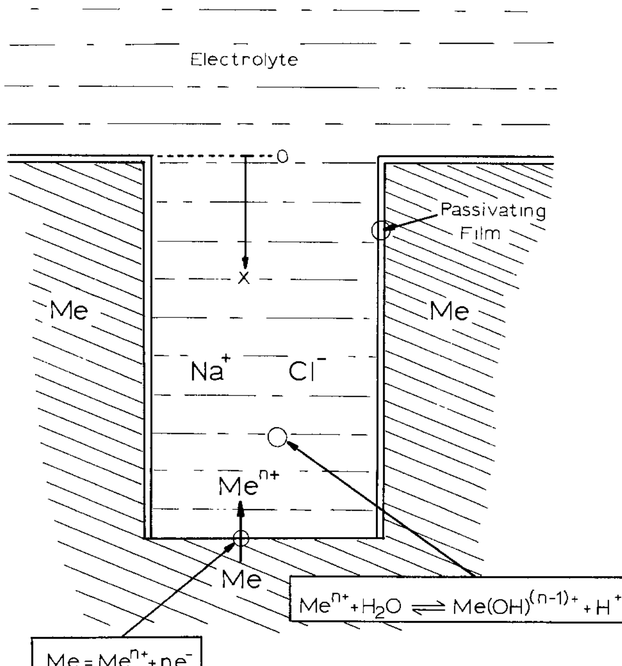

Fig. 1. Unidirectional pit model

(*iii*) It is assumed that reaction [1] is followed by a hydrolysis equilibrium of the type

$$Me^{n+} + H_2O \rightleftharpoons Me(OH)^{(n-1)+} + H^+ \qquad [2]$$

and that this equilibrium is very quickly reached (18).

Reaction [2] is a simplified description of the processes taking place inside a pit. Polynuclear complexes could be formed, or further degrees of hydrolysis could occur. Nevertheless, reaction [2] will give the minimum degree of acidification expected inside a pit. On the other hand, either no polynuclear complexes are reported for the metals used in the present work, or their formation rate is very slow (18, 19).

(*iv*) The last, and most important, modification introduced to the Pickering and Frankenthal model is the assumption that the aggressive anion salt acts as a supporting electrolyte for the ionic species formed in reactions [1] and [2].[2]

Since it is assumed that the bulk solution could have any pH value, reaction [2] has to be rewritten to account for the contribution of the OH^- ions at pH values higher than 7

$$\underset{S_1}{2Me^{n+}} + \underset{S_2}{H_2O} + \underset{S_3}{OH^-} \rightleftharpoons \underset{S_4}{2Me(OH)^{(n-1)+}} + \underset{S_5}{H^+} \qquad [3]$$

From Eq. [3] we find that inside the pit there are five species (S_1-S_5), the concentrations of which should be calculated. The detailed mathematical treatment for a system like this can be found in Vetter's work (20). The five unknown concentrations are calculated by resolution of the five following equations: the flow of the species containing Me atoms will be given by

$$D_1 \frac{dC_1}{dx} + D_4 \frac{dC_4}{dx} = \frac{i}{n \cdot \mathbf{F}} \qquad [4]$$

the flow of the species containing O atoms will be given by

$$D_2 \frac{dC_2}{dx} + D_3 \frac{dC_3}{dx} + D_4 \frac{dC_4}{dx} = 0 \qquad [5]$$

and the flow of the species containing H atoms will be given by

$$2D_2 \frac{dC_2}{dx} + D_3 \frac{dC_3}{dx} + D_4 \frac{dC_4}{dx} + D_5 \frac{dC_5}{dx} = 0 \qquad [6]$$

Finally, the two following equilibrium relations must be considered

$$^*K_1 = \frac{C_4 \cdot C_5}{C_1} \qquad [7]$$

which is the law of mass action applied to reaction [2] and

$$K_w = C_3 \cdot C_5 \qquad [8]$$

which is the ionic product of water. In the above equations, D_j is the diffusion coefficient in cm^2/sec, C_j is the concentration in mole/cm^3 of the species j, n is the charge of the metal ion as given in Eq. [1], $\mathbf{F}$ is the Faraday constant, $^*K_1$ is the equilibrium constant of reaction [2], i in A/cm^2 is the current density of reaction [1], and x is the pit depth in cm where $x = 0$ at the opening of the pit.

The assumed boundary conditions for $x = 0$ are $C_1 = 0$; $C_3 = K_w \cdot 10^{-pH}$ mole/liter; $C_4 = 0$; and $C_5 = 10^{-pH}$ mole/liter. As a first approximation all the diffusion coefficients, except those for H^+ and OH^- ions, are taken as equal to 10^{-5} cm^2/sec; therefore $D_1 = D_2 = D_4 = 10^{-5}$ cm^2/sec, $D_3 = 5.3 \times 10^{-5}$ cm^2/sec, and $D_5 = 9.3 \times 10^{-5}$ cm^2/sec. The equilibrium constants used were taken from the review by Sillen and

[2] This assumption is exact only when the supporting electrolyte is in great excess over the electroactive species. However, it has been shown [Ref. (20), p. 175] that even a minor addition of supporting electrolyte of the order of magnitude of the concentration of the electroactive species reduces to a large degree the influence of the electric field.

Table I. Hydrolysis constants and solubility constants (19)

Metal	Hydrolysis constant ($*K_1$)	Solubility constant (K_{sO})
Cr^{3+}	10^{-4} $(M \cdot 1^{-1})$	10^{-30} $(M^4 \cdot 1^{-4})$
Fe^{2+}	10^{-7} $(M \cdot 1^{-1})$	$10^{-15.1}$ $(M^3 \cdot 1^{-3})$
Co^{2+}	10^{-10} $(M \cdot 1^{-1})$	10^{-15} $(M^3 \cdot 1^{-3})$
Ni^{2+}	10^{-10} $(M \cdot 1^{-1})$	10^{-15} $(M^3 \cdot 1^{-3})$
Zn^{2+}	$10^{-9.15}$ $(M \cdot 1^{-1})$	$10^{-16.6}$ $(M^3 \cdot 1^{-3})$
Al^{3+}	$10^{-5.02}$ $(M \cdot 1^{-1})$	10^{-33} $(M^4 \cdot 1^{-4})$

Martell (19), and the values chosen for the calculations are reported in Table I.

By multiplying Eq. [5] by 2 and subtracting from Eq. [6], the terms for S_2 are eliminated

$$-D_3 \frac{dC_3}{dx} - D_4 \frac{dC_4}{dx} + D_5 \frac{dC_5}{dx} = 0 \quad [9]$$

Equation [8] is solved for C_3, and this expression is substituted for C_3 in Eq. [9]. Equation [7] is solved for C_1, and the resultant expression is substituted for C_1 in Eq. [4]. By integration, the following two equations are obtained

$$\frac{n \cdot \mathbf{F} \cdot D_1}{*K_1} C_4 \cdot C_5 + n \cdot \mathbf{F} \cdot D_4 \cdot C_4 = x \cdot i + k \quad [10]$$

$$D_5 \cdot C_5 - D_3 \cdot K_w \frac{1}{C_5} - D_4 \cdot C_4 = k' \quad [11]$$

Using the above-mentioned boundary conditions, constants k and k' are calculated. Equation [11] is solved for C_4, and the resulting expression is substituted for C_4 in Eq. [10]. By giving values to C_5, the values of the parameter $x \cdot i$ are calculated. With the same values of C_5, the values of C_4 are calculated in Eq. [11]. Then C_1 is calculated in Eq. [7] and C_3 in Eq. [8]. No calculations are made for C_2.

Ionic Concentration Diagrams

The above-mentioned calculations were made for the ionic concentration diagrams of the following systems: Zn/Zn^{2+} (Fig. 2); Fe/Fe^{2+} (Fig. 3); Ni/Ni^{2+} (Fig. 4); Al/Al^{3+} (Fig. 5); and Cr/Cr^{3+} (Fig. 6). The diagram in Fig. 4 applies also to Co/Co^{2+}, since the same $*K_1$ value was used for Ni and for Co (see Table I).

The pH values for the bulk solution were chosen so that the oxide film might be under thermodynamically stable conditions according to Pourbaix diagrams (21). The pH values used were pH 7 for aluminum and chromium, pH 9 for zinc, and pH 10 for iron, nickel, and cobalt.

The straight line $C_{\overline{Me}}$ in the diagrams indicates the total of the concentrations of all the species containing Me atoms. The line is broken for a concentration of 10 mole/liter to indicate that saturation of the Me salt should be reached. Actually, the present treatment is valid only for diluted solutions, and deviations from the calculated diagrams should be expected for such high concentrations.

The ionic concentration diagrams give the concentrations of Me^{n+}, $Me(OH)^{(n-1)+}$, and H^+ ions as functions of $x \cdot i$. If the current density inside the pit is known, the diagram will show the ionic concentrations along the pit. On the other hand, at a certain given pit depth the diagram will show the current density required to get a certain change in the ionic concentration. For example, let us consider the case of iron in 1.0M NaCl solution at pH 10 (Fig. 3). Let us assume that the iron sample has two pits different in size, one of them 10^{-6} cm deep and the other 10^{-4} cm deep. If the current density inside the pits is 1 A/cm², the $x \cdot i$ values will be 10^{-6} and 10^{-4} A/cm, respectively. From Fig. 3 it is concluded that the composition at the bottom of the shallower pit will be 10^{-5}M Fe^{2+}, 5.0 $\times$ 10^{-4}M $Fe(OH)^+$, and pH 8.5. On the other hand, the composition at the bottom of the deeper pit is going to be: 5.0 $\times$ 10^{-2}M Fe^{2+}, 5.6 $\times$ 10^{-4}M $Fe(OH)^+$, and pH 5.1. The diagram predicts that the larger changes in composition and in pH will be found at the bottom of the deeper pit.

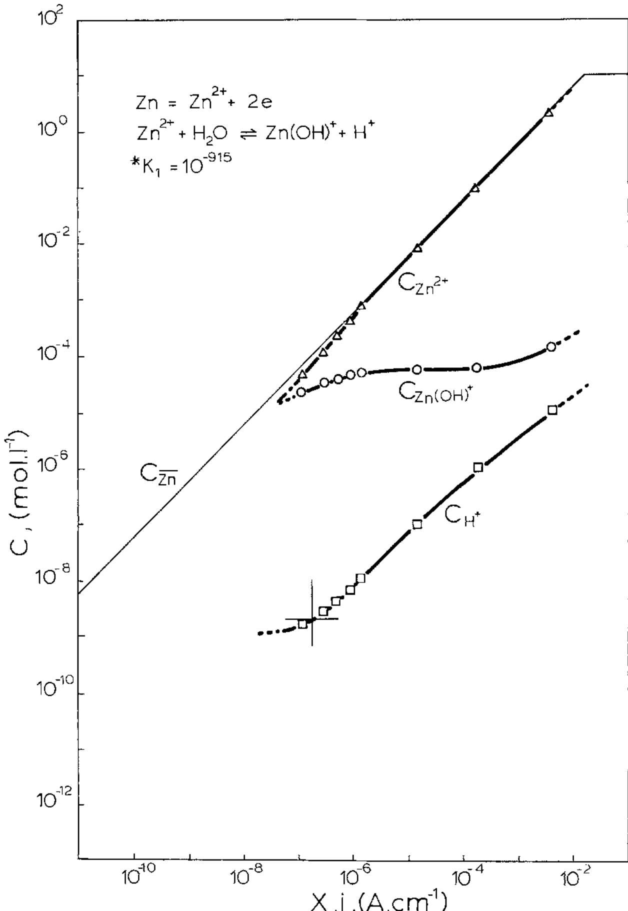

Fig. 2. Concentrations of Zn^{2+}, $Zn(OH)^+$, and H^+ as a function of the product of the depth x and the current density i is a unidirectional pit.

We can also compare two different specimens, with pits of equal size, but with different current densities inside the pits. For example, if the pits are 10^{-3} cm deep in both specimens, but the current density inside the pits is 10^{-1} A/cm² in one of the samples and 10^{-4} A/cm² in the other, the composition at the bottom of the pits is going to be 5.0 $\times$ 10^{-2}M Fe^{2+}, 5.6 $\times$ 10^{-5}M $Fe(OH)^+$, and pH 5.1 in the first specimen ($x \cdot i$ = 10^{-4} A/cm), and 5.0 $\times$ 10^{-8}M Fe^{2+}, 5.0 $\times$ 10^{-5}M $Fe(OH)^+$, and pH 9.95 in the second ($x \cdot i$ = 10^{-7} A/cm). While important changes in composition should occur with current densities of 1 A/cm², virtually no changes should be expected for a current density of 10^{-4} A/cm².

No assumptions are made as to the way in which the current density could be obtained. In practice, it will mean that the electrode potential is properly changed. In most cases of acid solutions, such as those inside a pit, a logarithmic relation between current density and electrode potential should be expected.

Figures 2-6 show that, in spite of what Vetter and Strehblow have indicated, the H^+ ion concentration inside the pit undergoes important changes when the pit size or the current density inside the pit is changed. It is also shown that, as found in practice, the pH inside the pit is lower than that of the bulk solution. From the data in Fig. 3, the pH along a crevice or a crack in iron can be estimated. It was found (Fig. 7) that the pH predicted by the present model is somewhere between 3 and 4, for an external pH of 10. This

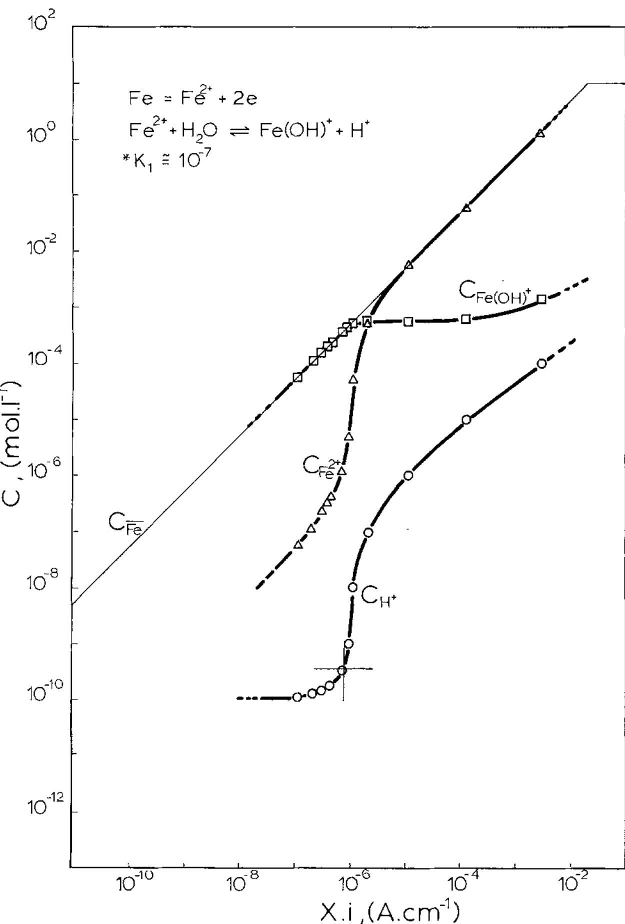

Fig. 3. Concentrations of Fe^{2+}, $Fe(OH)^+$, and H^+ as a function of the product of the depth *x* and the current density *i* in a unidirectional pit.

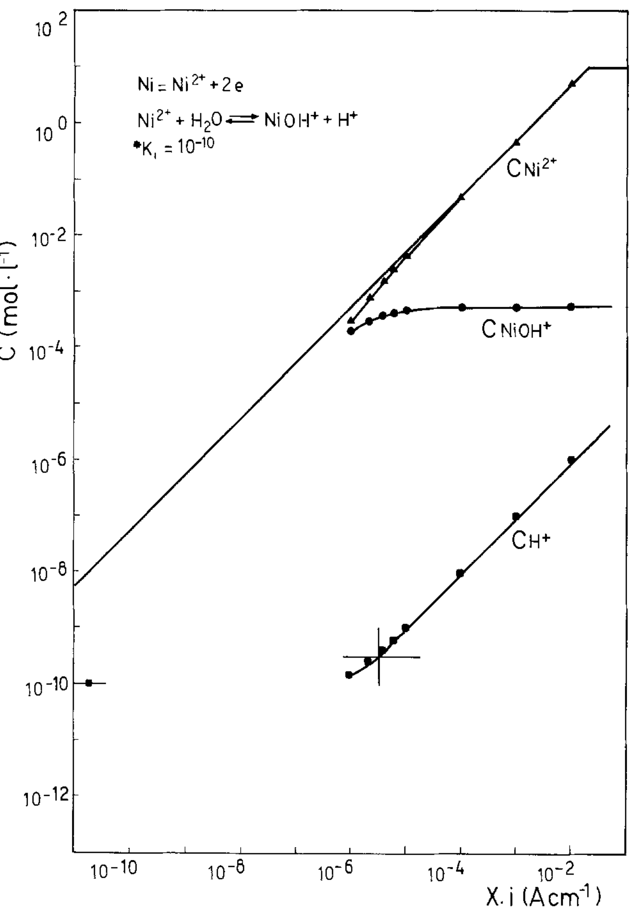

Fig. 4. Concentrations of Ni^{2+}, $Ni(OH)^+$, and H^+ as a function of the product of the depth *x* and the current density *i* in a unidirectional pit.

prediction is in good agreement with the experimental observations reported by Smith, Peterson, and Brown (6).

Critical H^+ Ion Concentration

To be able to use the present ionic concentration diagrams in the study of pitting it is necessary to find the minimum degree of acidification necessary for sustained pit activity.

As a first approximation, the criterion used by Pourbaix for the potential *vs.* pH diagrams (21) was applied in the present paper. Pourbaix separates the passivity zones from the corrosion zones as follows. The solubility product of the passivating oxide film being known, the pH value at which such oxide film will be in equilibrium with a solution containing traces of metal ions is calculated. The concentration of the metal ions is arbitrarily taken as equal to 10^{-6} mole/liter. Such pH values are calculated herein by using the K_{so} values reported in Table I. The calculated pH values are indicated in Fig. 2-6 by means of a cross (+) on the H^+ ion concentration line. The pH values calculated are pH 9.5 for iron, cobalt, and nickel; pH 8.7 for zinc; pH 6.0 for chromium; and pH 5.0 for aluminum. All these values are in reasonably good agreement with those reported by Pourbaix (21), with the exception of chromium which, according to Pourbaix, should be somewhere between 3.5 and 4.8.

Due to the scattering of the K_{so} reported values (19), and to the arbitrarily choosing 10^{-6} mole/liter as the metal ion concentration, the calculated critical pH values have an error of at least plus or minus one unit pH. This criterion of choosing the critical pH values is clearly a rough approximation and experimental information is necessary. In the case of zinc, the pH value calculated, 8.7, is in good correspondence with the experimental results reported by Davies and Lotlikar (22). These authors found that zinc, in galvanostatic measurements, was passivated in solutions of pH 9.2, 10.0, and 11.0, and did not get passive in solutions at pH 8.2.

For iron the estimated pH value was 9.5. Vetter and Strehblow (23) reported passivity to pitting transitions for iron at pH values as low as 8.0. On the other hand, Alvarez and Galvele (24) found that the pitting potential of iron is pH independent for pH values lower than 10, and pH dependent at values higher than 10. It was then concluded that the critical pH for iron should be around 10.

No experimental information is available for other metals or alloys. Nevertheless, the concept of a critical pH for depassivation was applied to stainless steels by Defranoux and Tricot (25). These authors found that the presence of chloride ions produced an increase in the critical pH for depassivation of stainless steels.

Current Density inside the Pits

To be able to use the ionic concentration diagrams it is also necessary to know the current density inside the pits. For aluminum in NaCl solutions, Kaesche (14) reported that the minimum current density inside the pits was recorded at the pitting potential and had a value of 0.3 A/cm^2. For aluminum in 4M NaCl solution, the current density inside the pits increased with the electrode potential, following what seemed to be a logarithmic law with a slope of $b = 0.150V$. At a potential 0.100V over the pitting potential the current density inside the pits was close to 1.1 A/cm^2.

Szklarska-Smialowska and Janik-Czachor (26) measured the current densities within pits for Fe-16Cr alloy in 0.7*N* NaCl + 0.7*N* Na_2SO_4 solution. They

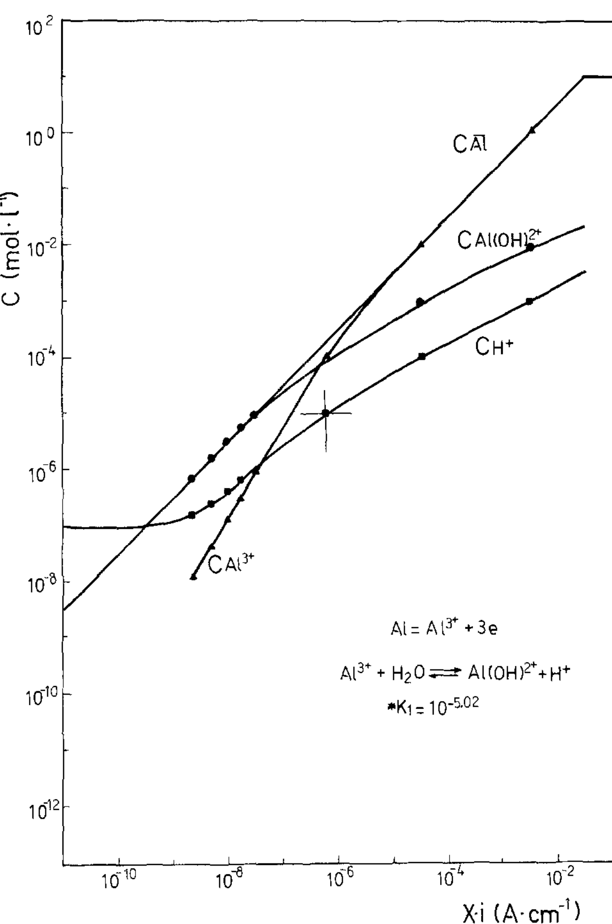

Fig. 5. Concentrations of Al^{3+}, $Al(OH)^{2+}$, and H^+ as a function of the product of the depth x and the current density i in a unidirectional pit.

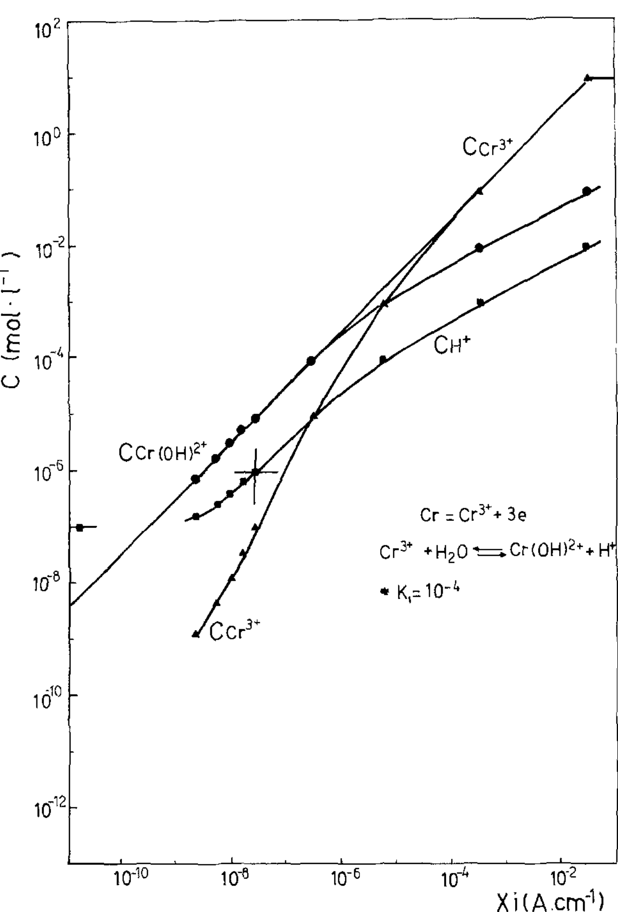

Fig. 6. Concentrations of Cr^{3+}, $Cr(OH)^{2+}$, and H^+ as a function of the product of the depth x and the current density i in a unidirectional pit.

found that the current density inside the pits was a function of potential, and according to the interpretation made by Sato *et al.* (27) it would follow a logarithmic law with a slope of $b = 0.220V$. For the Fe-16Cr alloy Szklarska-Smialowska and Janik-Czachor reported a pit initiation potential of about 0.50V (SCE) and a pit passivation potential of −0.05V (SCE). From Sato's paper it is inferred that the current density at the pit initiation potential was about 8.0 A/cm², while at the pit passivation potential it dropped to 0.1 A/cm².

Sato *et al.* (27) reported that in austenitic stainless steels, for potentials higher than 0.60V (SCE) the current density inside the pits became potential independent, reaching a value of 8 A/cm².

Schwenk (28), working with 18/10 chromium-nickel austenitic stainless steels, reported a current density inside the pits, at the pitting potential, of the order of 0.5 A/cm². He also found that the reaction inside the pit followed a Tafel law, with a slope of $b = 0.087V$.

For pure iron, Vetter and Strehblow (15) reported pit initiation current densities ranging from 0.9 up to 2.0 A/cm². For nickel pits of 1μ diameter, Vetter (29) reported current densities as high as 50-70 A/cm².

From the above-mentioned results, it can be safely assumed that the current density inside a pit, at the initiation stage, is of the order of 1 A/cm².

Pit Initiation Conditions

Figures 2-6 show that for most of the metals studied the critical pH is reached with $x \cdot i$ values lower than 10^{-6} A/cm. Since at pit initiation conditions the current density inside the pit is at least 1 A/cm², it is concluded that the necessary acidification can be obtained in pits as small as 10^{-6} cm. This means that a crack in the passivating oxide film would give a diffusion path long enough to reach the critical pH. If such cracks are present, it would only be necessary to apply a potential high enough to reach the above-mentioned current density.

As for the existence of such cracks in the passive oxide film, there is abundant literature in favor of it. Current oscillations below the pitting potential were reported for aluminum (30), for zinc (31), and for stainless steels (32) showing the presence of a film rupture-reformation process. Vetter and Strehblow (16) reported that a change in the electrode potential, just before the injection of chloride ions, produced a noticeable increase in the pit density in iron. This was interpreted as a production of defects in the oxide film as a result of the potential shift. Sato (33) calculated the tensions induced in the oxide film by electrostriction, and concluded that they were high enough to produce mechanical breakdown of the oxide film. Fromhold (34) also found that the transport of ions through the passive film would produce stresses large enough to cause mechanical breakdown of the oxide film.

It can be concluded that film breakdown is constantly occurring on a passive metal. Nevertheless, the exposure of bare metal does not necessarily lead to localized corrosion. Straining metal experiments (2, 3, 30) have shown that the exposure to bare metal does not lead to pitting, unless the electrode potential is equal to, or higher than, the pitting potential.

Once the crack in the passive film is produced, if the electrode potential is high enough, a net anodic current density will circulate through the fissure. From the diagrams in Fig. 2-6 it should be possible to predict at which current density the critical acidification can be reached, or if the metal will repassivate.

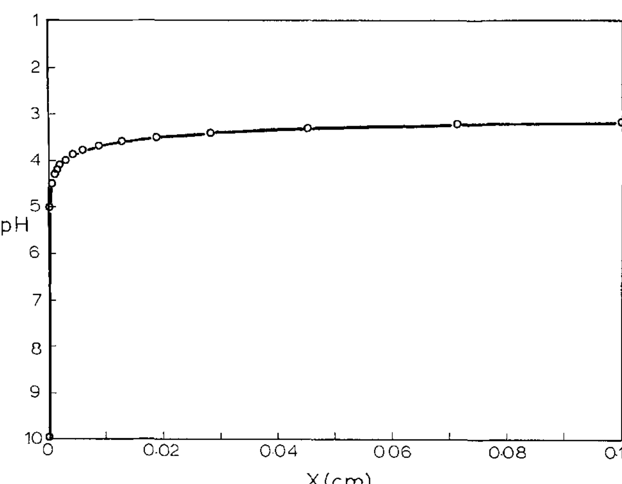

Fig. 7. Calculated pH profile for iron along a pit or crevice. External pH = 10, current density = 1 A/cm², *K₁ = 10⁻⁷ mole/liter.

Figures 2-6 show that the critical acidification varies from metal to metal. For aluminum, for example, it is much higher than for iron or nickel. Nevertheless, in all cases the critical acidification is reached for very low $x \cdot i$ values.

So far it has been assumed that the current density inside the pit is of the order of 1 A/cm². For some metals, as is probably the case with chromium, it might happen that such high current densities could not be reached. Then the metal would not be susceptible to pitting. Nevertheless, the critical $x \cdot i$ value can be reached even with small current densities, provided that a sufficiently long diffusion path is present. That would be the case in a crevice. In this way, a metal could be resistant to pitting, but susceptible to crevice corrosion. From the electrochemical point of view both processes would be equal, the only difference being the length of the diffusion path.

Effect of the External pH on the Pitting Potential

A large increase in the pH of the bulk solution inhibits the pitting process. Leckie and Uhlig (35) reported that the pitting potential of stainless steel was independent of the pH in the range of 1-7, but for pH values higher than 7 the OH^- ion acted as pit inhibitor. In the same way, Venu *et al.* (36) and Rajagopalan *et al.* (37) reported that the presence of NaOH inhibited the passivity breakdown of steels in NaCl solutions.

By appropriate modification of the boundary conditions, it is possible to calculate the effect of the external pH on the concentration profiles in the ionic concentration diagrams. Calculations were performed for iron, assuming external pH values ranging from pH 7 to 12 (Fig. 8). The external pH was found to modify the shape of the H^+ ion concentration curve inside the pit. The critical pH for iron is somewhere between 9 and 10. If the pH of the bulk solution is 10, the critical pH value would be reached with $x \cdot i$ values of about 10^{-6} A/cm. By increasing the external pH to 11, $x \cdot i$ values of 10^{-5} A/cm are required. For pH 12 the critical acidification is reached only with $x \cdot i$ values of 10^{-4} A/cm. The experimental conditions being equal, this means that the current density has to increase one order of magnitude whenever the pH of the bulk solution is increased one unit. If the relation between potential and current density inside the pit follows a logarithmic law, then it should be expected that the pitting potential will follow a law of the type

$$E_p = A + b \cdot \log C_{OH^-} \quad [12]$$

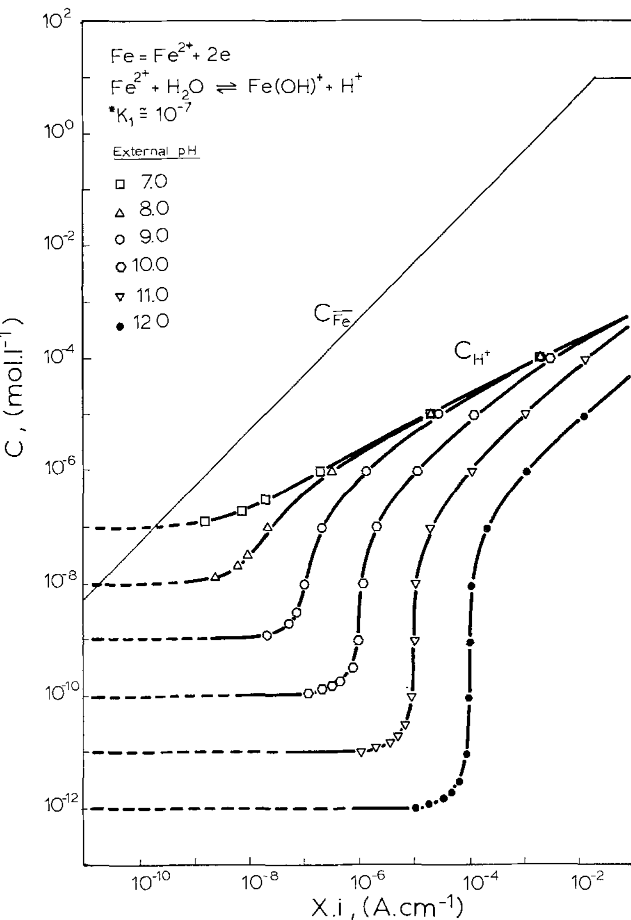

Fig. 8. Effect of the external pH on the concentration of H⁺ as a function of the product of the depth x and the current density i in a unidirectional iron pit.

Through galvanostatic experiments with high purity iron in NaCl solutions, Alvarez and Galvele (24) found that the pitting potential of iron was independent of the pH between pH 7 and 10, but showed a logarithmic relation, as in Eq. [12], from pH 10 to pH 12; the slope of the curve being $b = 0.020$V.

Presence of Anions of Weak Acid Salts

It is known that the presence of weak acid salts inhibits pitting by increasing the pitting potential. The pitting potential of aluminum is increased by the presence of soluble salts of acetate (38), benzoate (38), chromate (38, 39) or tartrate (39). Pitting of zinc is inhibited by a borate buffer (40), and the pitting potential of iron in the presence of a borate buffer (23) is more than 100 mV higher than in its absence (41).

Anions of weak acids, because of their buffer properties, should modify the hydrogen ion concentration profiles in Fig. 2-6. Under these circumstances, the following equilibrium will take place inside the pit

$$LH \rightleftharpoons L^- + H^+ \quad [13]$$

where LH is the weak acid, and L^- is the anion of the weak acid. The equilibrium constant of the reaction will be K_a. The other equilibrium reactions are

$$Me^{n+} + H_2O \rightleftharpoons Me(OH)^{(n-1)+} + H^+ \quad [14]$$

with the equilibrium constant $*K_1$, and

$$H_2O \rightleftharpoons H^+ + OH^- \quad [15]$$

with the equilibrium constant K_w.

The over-all reaction will be

$$\underset{S_1}{2Me^{n+}} + \underset{S_2}{H_2O} + \underset{S_3}{OH^-} + \underset{S_4}{LH} \rightleftharpoons \underset{S_5}{2Me(OH)^{(n-1)+}} + \underset{S_6}{2H^+} + \underset{S_7}{L^-} \quad [16]$$

The boundary conditions are chosen as above, making allowance for the fact that the concentration of protons in the bulk solution will be related to the concentration of the weak acid (LH) and that of its anion (L^-) through Eq. [13].

Figure 9 shows the ionic concentration diagram for zinc in the presence of 10^{-2}M borax plus 1.0M NaCl solution. By comparison with Fig. 2, the presence of the borate salt is found to shift the hydrogen ion concentration line to higher $x \cdot i$ values. This means that, under otherwise equal conditions, in the presence of borax higher current densities are required to reach the critical acidification. Figure 10 shows the degree of shifting of the hydrogen ion concentration line for various borax concentrations. For borax concentrations lower than 10^{-4}, little effect should be expected from the weak acid salt. For higher borax concentrations an increase of one order of magnitude in the concentration of borax results in an increase of about one order of magnitude in the $x \cdot i$ values. If the relation between potential and current density inside the pit follows a logarithmic law, it follows that the pitting potential of zinc should be related to the borax concentration by an equation of the type

$$E_p = A' + b' \cdot \log C_b \quad [17]$$

C_b being the concentration of the buffer salt. The value of b' should be equal to the Tafel slope of the metal in a pitlike solution.

The results in Fig. 9 are in good agreement with the measurements of pitting potentials for zinc reported by Augustynski *et al.* (40). These authors found a

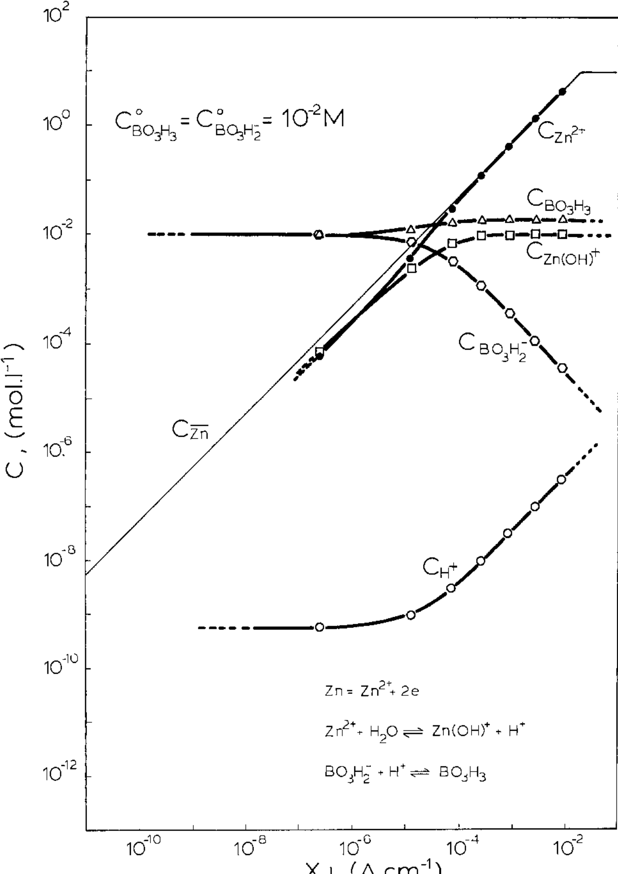

Fig. 9. Effect of 10^{-2}M borax on the concentrations of Zn^{2+}, $Zn(OH)^+$, and H^+ as a function of the product of the depth x and the current density i in a unidirectional zinc pit.

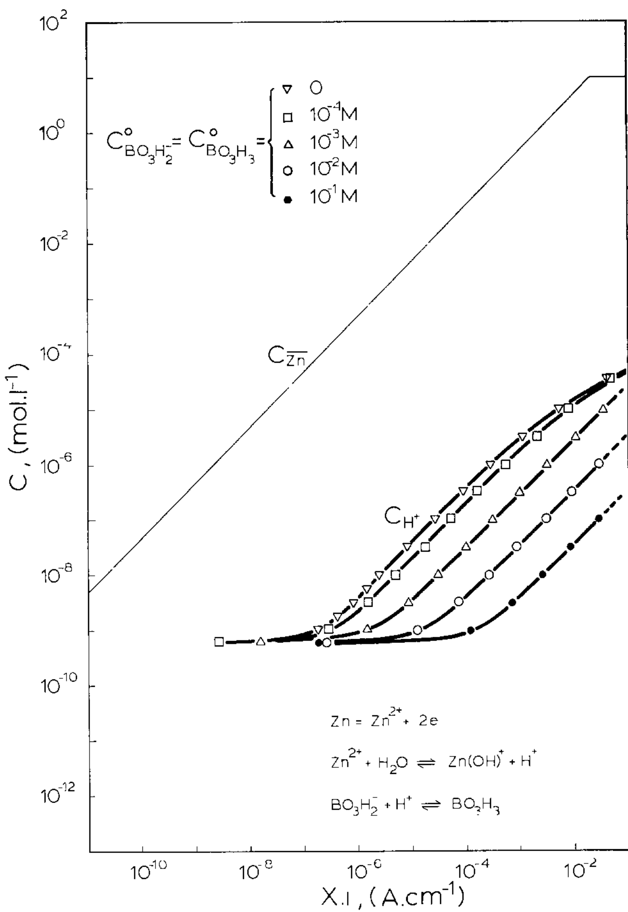

Fig. 10. Effect of the borax concentration on the H^+ concentration as a function of the product of the depth x and the current density i in a unidirectional zinc pit.

logarithmic relation between the pitting potential and the buffer concentration for zinc in NaCl and in $NaClO_4$ solutions. When the buffer concentration is higher than that of the aggressive anion, the pitting potentials measured by Augustinski *et al.* are higher than those predicted by Eq. [17]. The reason for this is that under such circumstances the aggressive anion is not acting as a supporting electrolyte, and the concentration buildup of the buffer anion inside the pit must be accounted for.

Diagrams similar to those in Fig. 10 were found for iron in the presence of borax. Vetter and Strehblow (23) reported a pitting potential of −0.17V (NHE) for iron in a 0.1M NaCl solution containing 0.029M KH_2BO_3 + 0.021M H_3BO_3. In the absence of buffers, Semino and Galvele (41) measured pitting potentials from −0.32 to −0.34V (NHE). A diagram calculated for the solution used by Vetter and Strehblow shows that in their solution the $x \cdot i$ values were about two orders of magnitude higher than in that used by Semino and Galvele. The Tafel slope for iron inside the pit should be somewhere between 0.080 and 0.114V (42). Equation [17] predicts a difference of 0.160-0.230V in the pitting potential values, which fits very well with the difference of 0.150-0.170V found between the experimental results.

From Eq. [13] one would expect that salts from acids of different strength should have different effects on the ionic concentration diagrams. Figure 11 shows the effect of 0.1M weak acid salt on the proton concentration line inside the pit for aluminum. The calculations were made for four different acid strengths, going from

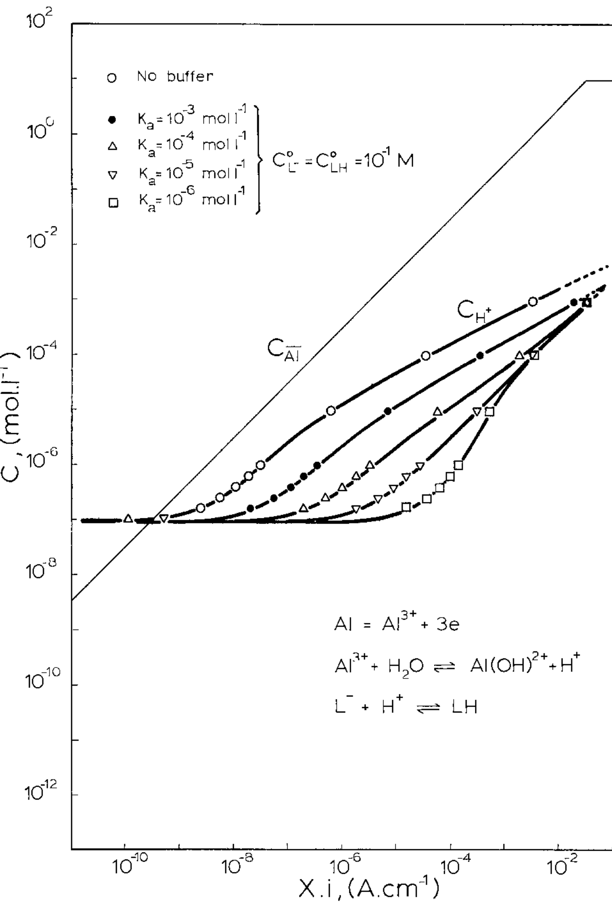

Fig. 11. Effect of the K_a of the buffer on the H^+ concentration as a function of the product of the depth x and the current density i in a unidirectional aluminum pit.

$K_a = 10^{-6}$ up to $K_a = 10^{-3}$ mole/liter. The lower the value of K_a, the higher the $x \cdot i$ values. From Fig. 11 it is concluded that the salt with the lowest K_a should be the most effective pitting inhibitor. Table II shows K_a values for various weak acids. From Table II and from Fig. 11 it can be concluded that from among chromate, acetate, and benzoate, chromate should be the most effective and benzoate the least, in correspondence with the experimental results reported by Böhni and Uhlig (38). Tartrates should be the least effective inhibitors, as reported by De Micheli and Galvele (39). According to Table II silicates and borates should have good inhibitor properties.

The present model does not take into consideration the possibility of formation of insoluble compounds between the metal ions and the weak acid anions. Such precipitates would occlude the pits, thus enhancing the inhibition capacity of the weak acid salt.

Aggressive Anion Concentration

If the concentration of the aggressive anion salt is changed over a wide range of values, the assumption that such salt is acting as a supporting electrolyte is not valid. In this case the electric field inside the pit cannot be ignored, and Eq. [4-6] are not valid. The following equations should be used [Ref. (20), p. 171]

Table II. Ionization constants of weak acids

Aqueous solution	pK_a at 25°C	Reference
Acetic acid	4.76	43
Benzoic acid	4.20	43
Boric acid	9.23	43
Chromic acid $HCrO_4^-/CrO_4^=$	6.50	19
Silicate K_1	11.81	19
Tartaric acid K_1	3.03	43

$$\frac{i \cdot \nu_j}{n \cdot \mathbf{F}} = D_j \left[\frac{dC_j}{dx} + z_j \cdot C_j \cdot \frac{\mathbf{F}}{R \cdot T} \cdot \frac{d\phi}{dx} \right] \quad [18]$$

for the reacting species, where ν_j is the stoichiometric factor of the species S_j, and $d\phi/dx$ is the electric field. For the nonreacting species the following equation is used

$$C_j = C_o \cdot e^{-(z_j \cdot \mathbf{F}/RT) \cdot \phi} \quad [19]$$

A further equation used is the condition of electroneutrality

$$\sum z_j \cdot C_j = 0 \quad [20]$$

The resolution of the above equations for a system where hydrolysis equilibrium is included is quite complex. Nevertheless, the resolution for a simpler system gives very useful information.

Let us assume that the metal is dissolving according to reaction [1]. Neglecting for a while the hydrolysis reaction of the metal ions, we will assume that the only ionic species present are: Me^{n+}; Na^+; and Cl^-. Under these conditions the following set of equations has to be solved

$$\frac{i}{n \cdot \mathbf{F}} = D_{Me} \left[\frac{dC_{Me}}{dx} + n \cdot C_{Me} \cdot \frac{\mathbf{F}}{R \cdot T} \cdot \frac{d\phi}{dx} \right] \quad [21]$$

for Me^{n+} ions

$$C_{Na} = C_o \cdot e^{+\psi} \quad [22]$$

for Na^+ ions, where $\psi = \mathbf{F} \cdot \phi / R \cdot T$

$$C_{Cl} = C_o \cdot e^{-\psi} \quad [23]$$

for Cl^- ions, and the electroneutrality condition

$$n \cdot C_{Me} + C_{Na} - C_{Cl} = 0 \quad [24]$$

C_{Na} and C_{Cl} in Eq. [24] are substituted for Eq. [22] and [23]

$$n \cdot C_{Me} = C_o \cdot e^{+\psi} - C_o \cdot e^{-\psi} \quad [25]$$

Equation [25] is substituted for $n \cdot C_{Me}$ in Eq. [21]. By differentiating Eq. [25], dC_{Me}/dx is obtained, and it is substituted for in Eq. [21]. By integration of Eq. [22], and taking into account the following boundary conditions for $x = 0$ ($C_{Me} = 0$; $C_{Na} = C_o$; $C_{Cl} = C_o$; and $\phi = 0$), Eq. [26] is obtained

$$i \cdot x = C_o \cdot D_{Me} \cdot \mathbf{F} \cdot [(n+1) \cdot e^{+\psi} + (n-1) \cdot e^{-\psi} - 2 \cdot n] \quad [26]$$

For $n = 1$ the equation developed by Pickering and Frankenthal is obtained (17). By solving Eq. [26] for $n = 3$, $D_{Me} = 10^{-5}$ cm²/sec, and $C_o = 1.0$M, the diagram in Fig. 12 is obtained. Up to $x \cdot i$ values of 10^{-3} A/cm, the line for $C_{\overline{Me}}$ in Fig. 12 is the same as $C_{\overline{Al}}$ in Fig. 5. For $x \cdot i$ values higher than 10^{-3} A/cm a small deviation is found. This indicates that the assumption of a suporting electrolyte, made while drawing Fig. 5 was valid, since the correction for ϕ at low $x \cdot i$ values is negligible.

According to Fig. 12, a measurable electrical potential, ϕ, appears only for high $x \cdot i$ values. For 1.0M NaCl solution at $x \cdot i = 10^{-2}$ A/cm, the electrical potential could get up to some 0.035V. For lower C_o values higher electrical potentials are found (Fig. 13). In a 10^{-3}M NaCl solution at $x \cdot i = 10^{-2}$ A/cm, the electrical potential increases up to 0.200V.

If the value of $x \cdot i$ is known, Fig. 13 can be used to evaluate the electrical potential, ϕ, under the experimental conditions of pitting potential measurement. There is not any precise information available, and only a rough estimation can be made. From the information in the literature, as mentioned above, we can assume that the current density inside a pit is of the order of 1 A/cm². As for the size of the pits, when measuring the pitting potential value they are usually visible under the optical microscope, so they must be at least 10^{-2} cm big. Then, an estimate for $x \cdot i$ value,

under stable pitting growth, would be $x \cdot i \geqq 10^{-2}$ A/cm. For such $x \cdot i$ values Eq. [26] is reduced to

$$x \cdot i \cong (n+1) \cdot C_o \cdot D_{Me} \cdot \mathbf{F} \cdot e^{+\psi} \quad [27]$$

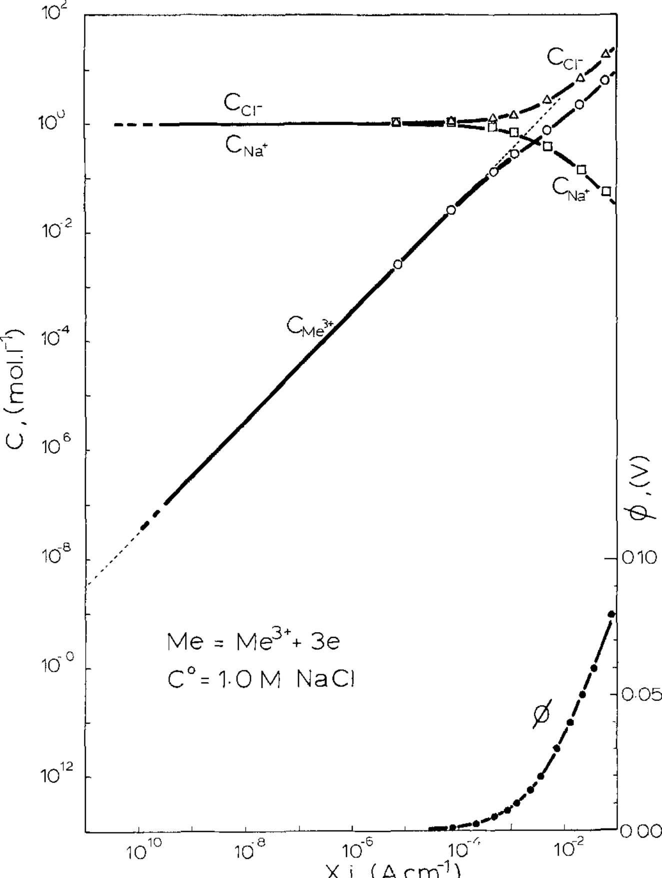

Fig. 12. Concentrations of Me^{3+}, Na^+ and Cl^-, and ϕ as a function of the product of the depth x and the current density i in a unidirectional pit.

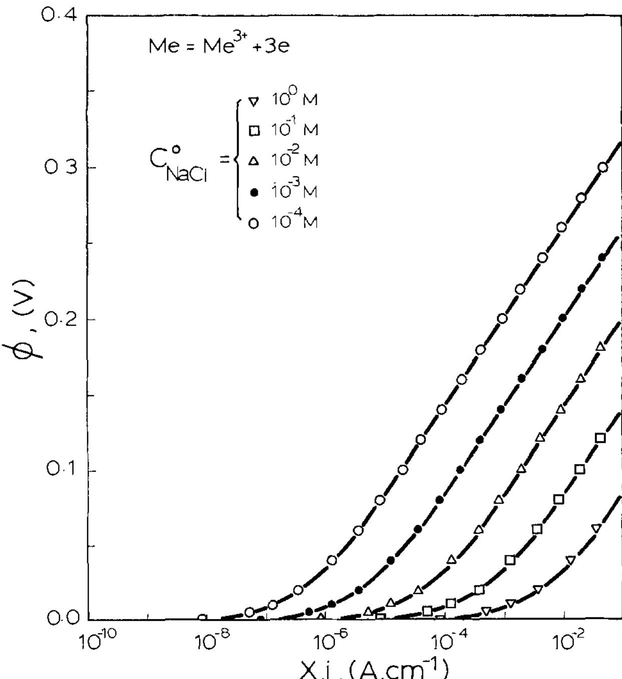

Fig. 13. Value of ϕ for various aggressive anion concentrations as a function of the product of the depth x and the current density i in a unidirectional pit.

If the pitting potentials are measured at approximately constant $x \cdot i$ values, then for two different NaCl concentrations we have

$$C_o^{I} \cdot e^{+\psi_I} = C_o^{II} \cdot e^{+\psi_{II}} \quad [28]$$

Replacing for the value of ψ, and taking logarithms

$$\ln C_o^{I} + \frac{\mathbf{F}}{R \cdot T}\phi_I = \ln C_o^{II} + \frac{\mathbf{F}}{R \cdot T}\phi_{II} \quad [29]$$

reordering and changing to decimal logarithms

$$\phi = \phi_o - \left[\frac{R \cdot T}{\mathbf{F}} \cdot \ln 10\right] \cdot \log C_o \quad [30]$$

Equation [30] would give the change of electrical potential inside the pit when the pitting potential is measured as a function of the NaCl concentration. This electrical potential should be subtracted from the measured pitting potential value to get the real pitting potential.

Equation [30] has a negative slope, with a value $b = 0.059$V at 25°C. Table III shows experimentally measured slopes for pitting potentials *vs.* aggressive anion concentration. If, as assumed above, the $x \cdot i$ values are close to 10^{-2} A/cm, then the electrical potential inside the pits accounts for all the changes in the pitting potential found for iron (24), aluminum (44), aluminum-copper alloys (44), nickel (45), nickel-copper alloys (45), and zirconium (46), and perhaps for stainless steel (47). It also accounts for half the slope found for titanium (48). The agreement between Eq. [30] and the experimental results in Table III is very good in view of the fact that Eq. [30] is valid only for dilute solutions, and that the results in Table III have not been corrected for ohmic drops outside the pits.

Figure 12 also gives information about pit initiation conditions. According to some authors (12, 13) chloride ion buildup on the metal-solution interface would be the key factor for pit initiation. Figure 5 shows that the critical change in H^+ ion concentration is obtained with $x \cdot i$ values of the order of 10^{-6} A/cm. On the other hand, Fig. 12 shows that to get any significant change in the chloride ion concentration $x \cdot i$ values of the order of 10^{-4}-10^{-3} A/cm are required. This means that for pit initiation, where x values are of the order of 10^{-6} cm, the critical proton concentration could be reached with current densities of 1 A/cm², while any measurable change in the chloride concentration would require current densities as high as 100-1000 A/cm². This consideration seems to exclude chloride ion build-up as a primary condition for pit initiation.

Mixed Electrolytes: NaCl + Na_2SO_4 Solutions

Sulfate ions are known to inhibit pitting of stainless steels in chloride solutions (35). Equations [18-20] can also be used to study a mixed electrolyte such as NaCl + Na_2SO_4 solutions. Equations [18] and [19] show that for anions of different charge, those with

Table III. Effect of the aggressive anion concentration on the pitting potential, experimental values for the slope of the curve $E_p = A - B \log C_{X^-}$

Zirconium	−0.058	NaCl solution	46

the highest charge will be preferentially accumulated at the metal-solution interface.

Calculations made for a 0.1M NaCl + 1.0M Na_2SO_4 solution show that the main effect is a reduction of the electrical potential inside the pit due to the presence of the divalent $SO_4^=$ ion. In the absence of sulfate ions the electrical potential, ϕ, for $x \cdot i$ equal to 10^{-2} A/cm is 0.085V. The addition of 1.0M Na_2SO_4 to the solution reduces the electrical potential ϕ to 0.010V.

More significant effects are found with lower ionic concentrations. For mixtures of 0.1M Na_2SO_4 + 0.01M NaCl solution a remarkable buildup in sulfate ion concentration is found for $x \cdot i$ values higher than 10^{-4} A/cm (Fig. 14). Beginning with a $SO_4^=:Cl^-$ concentration ratio of 10:1, ratios as high as 100:1 or higher are easily reached. As soon as a pit is nucleated, a sulfate ion concentration builds up inside the pit, and eventually the pit is repassivated. The pits will not be able to grow any further and sulfate anion would act as pitting inhibitor in NaCl solutions. Figure 14 also explains the potential oscillations, under galvanostatic conditions, found by Szklarska-Smialowska and Janik-Czachor (26) for iron-chromium alloys, and by Szklarska-Smialowska (49) for nickel in NaCl + Na_2SO_4 solutions. As soon as the pits start to grow a buildup in sulfate ions takes place inside the pits, thus deactivating them. Later the diffusion of sulfate ions to the bulk solution reduces the content of sulfate ions inside the pit, and a continuous process of activation and deactivation of the pits is established.

Pitting Potential and Protection Potential

From potentiokinetic measurements, Pourbaix (50) reported two different potentials related to pitting: the pitting potential or rupture potential above which pitting starts, and the protection potential or the potenial below which active pits will stop growing. According to Szklarska-Smialowska and Janik-Czachor (26) the real pitting potential is that which Pourbaix calls the protection potential. These authors found that this potential is equal to the galvanostatically measured pitting potential, and concluded that the higher pitting potential potentiokinetically found is the result of the measuring technique.

The present pitting model can be used to explain the existence of two potentials found in the potentiokinetic measurements. As mentioned above, the oxide film on the passive metal will suffer continuous breaks, thus exposing bare metal to the solution. The current density circulating in those fissures will be a function of the electrode potential. At each potential the cracks in the oxide will show a characteristic $x \cdot i$ value given by the current density and by the length of the crack (Fig. 15a). As soon as the system reaches the minimum $x \cdot i$ value for pit growth, which is $x \cdot i = 1$ in Fig. 15, the pit will start to grow. If the potential remains constant, the current density will also be constant, but x will increase with time, as will $x \cdot i$ ($x \cdot i = 2$ in Fig. 15). If the potential is then lowered, the current density will drop, but the pit will continue to grow while the $x \cdot i$ value is higher than 1. This means that pitting will grow at potentials lower than the initiation potential. Finally the pit will stop either because the $x \cdot i$ value is lower than the minimum for pit growth, or because the electrode potential is lower than the corrosion potential inside the pit, and the acidification disappears as a result of hydrogen evolution.

Szklarska-Smialowska and Janik-Czachor's results can be used to find out whether the above-mentioned changes could take place during a potentiokinetic measurement. During potentiostatic measurements for Fe-16Cr in 0.7N Na_2SO_4 + 0.7N NaCl solution, pitting could start at potentials as high as +0.50V (SCE). The reported current density inside the pits is about 8 A/cm^2. Once started, the same pits will continue to grow at lower potentials, and they would stop at −0.05V (SCE). The current density inside the pits at this potential is 0.1 A/cm^2. Assuming a value for minimum $x \cdot i$ of 10^{-5} A/cm, the pits will start to grow at 0.50V (SCE) in defects of about 1.3×10^{-6} cm. When reducing the potential, the pits should have a minimum size of 10^{-4} cm to be able to grow at the current density of 0.1 A/cm^2. With a current density of 8 A/cm^2 a pit of 10^{-4} cm takes less than 0.4 sec to grow. Since the critical $x \cdot i$ values in Fig. 2-6 are lower than 10^{-5} A/cm, a much shorter time will be required to obtain the two potentials reported by Pourbaix.

Conclusions

As shown in previous publications (2, 3) there is a potential below which no localized acidification can be maintained on the metal-solution interface. This potential is given by the corrosion potential of the metal in the acidified solution, E_c^*. The alloying elements affect the pitting potential mainly by modifying the corrosion potential inside the pit. When measuring the pitting potential, a positive polarization, η, is added to the corrosion potential, E_c^*, to maintain a net anodic

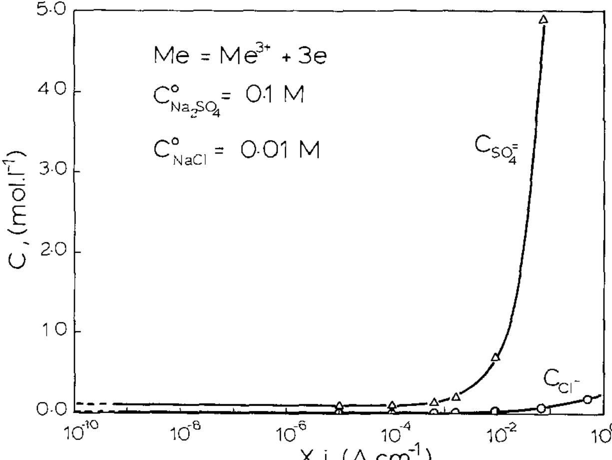

Fig. 14. Concentrations of $SO_4^=$ and Cl^- as a function of the product of the depth x and the current density i in a unidirectional pit.

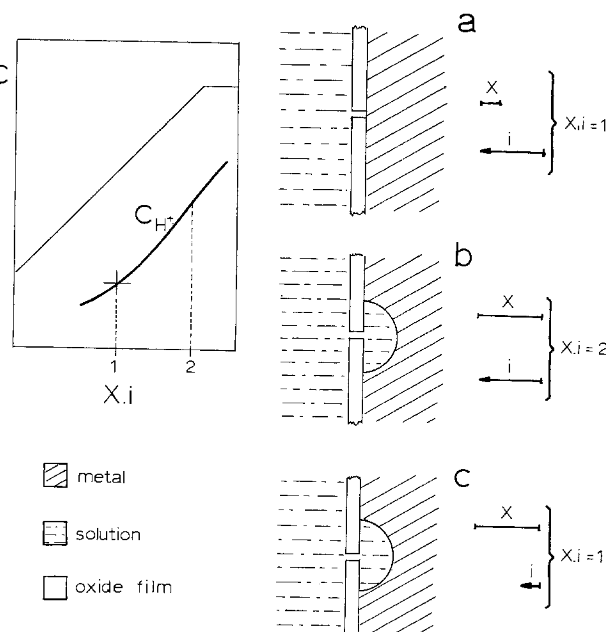

Fig. 15. Events leading to the measurement of pitting protection potentials different from pitting potentials in potentiokinetic experiments.

current density inside the pit, and secure the minimum $x \cdot i$ value. From the present paper it is concluded that a further addition should be made, E_{inh}, when inhibitors like OH^- ions or buffer salts are present.

Since the current density inside the pit is high, another contribution due to the electrical potential, ϕ, must be accounted for. In this way, the measured pitting potential is the total of the above mentioned factors

$$E_p = E_c^* + \eta + E_{inh} + \phi$$

All the observations reported so far in the literature on the pitting potential can be explained by transport phenomena. Processes like competitive adsorption, salt formation, film contamination, etc., even though present during the pitting process, do not play a major role in fixing the pitting potential.

Acknowledgments

Hydrogen Embrittlement of Electroless Copper Deposits

Y. Okinaka* and S. Nakahara*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Transmission and scanning electron microscopes were used to investigate the cause of brittleness of electroless copper deposits. Numerous voids were found in brittle deposits, whereas ductile deposits contained significantly fewer voids. These voids were 20-300Å in diameter and randomly distributed within a grain. Low angle grain boundaries contained larger voids. The ductility was found to improve considerably on prolonged standing even at room temperature. These results, in conjunction with chemical mechanistic considerations, have led to the conclusion that these voids contain hydrogen gas, and that the brittleness is due to the so-called "hydrogen embrittlement" phenomenon rather than the incorporation of Cu_2O or morphological effects postulated by some investigators.

Electroless copper deposits formed in the absence of a "ductility promoter" are known to be brittle. This poor ductility is attributed in the early literature to the incorporation of either hydrogen (1, 2) or Cu_2O in the deposit (3). However, no direct experimental evidence has yet been reported to show the presence of these inclusions. More recently, an attempt has been made to correlate physical properties with the deposit morphology (4), but no clear-cut relationship between ductility and morphology has been found. We carried out a transmission electron microscopic (TEM) study in search for the evidence of inclusions. Except for the surface oxide, we failed to find any Cu_2O within the deposit. On the other hand, it was discovered that a large number of voids ranging in diameter from 20 to 300Å are present in the deposit. On the basis of chemical mechanistic considerations, it is suggested that the voids are filled with hydrogen gas and may be regarded as gas bubbles, and that the poor ductility is due to the phenomenon known as hydrogen embrittlement.

Experimental

Two plating solutions were used. Bath A contained 0.06M $CuSO_4$, 0.15M EDTA, 0.049M formaldehyde, 0.0017% phosphate ester wetting agent (5), and NaOH to make the pH equal to 11.85. This bath was operated at 60°C. Bath B contained 2×10^{-3}M NaCN in addition to the constituents of bath A, and it was operated at 75°C. The plating solutions were analyzed frequently using a polarographic method (6), and necessary replenishments were made to maintain the original concentrations. The plating rate was approximately the same for both baths: 2.8 μm/hr for bath A and 3.0 μm/hr for bath B.

The substrates used for obtaining the transmission electron micrographs shown in Fig. 1 and 2 were textured copper films prepared by cold-rolling and annealing a sheet of OFHC copper. The deposits used for all other observations and ductility measurements were plated on liquid-honed Plexiglas sheets sensitized and activated by the conventional $SnCl_2$-$PdCl_2$ method. Foil specimens for TEM observations were prepared by electropolishing the deposits about 15 μm thick using the conventional window technique.

The ductility was measured with a portable ductility tester developed recently by the authors (7). In this technique the film is rigidly held in a fixture and pushed with a metal sphere in the direction of thickness until fracture. Scanning electron microscopy (SEM) was used to examine the fracture surface.

Experimental Results

TEM observations.—The transmission electron micrographs shown in Fig. 1 and 2 were obtained using the so-called through-focus imaging technique (8, 9), in which the image is obtained under defocused conditions. The bright spots of various sizes surrounded by dark rings are believed to be images of voids contain-

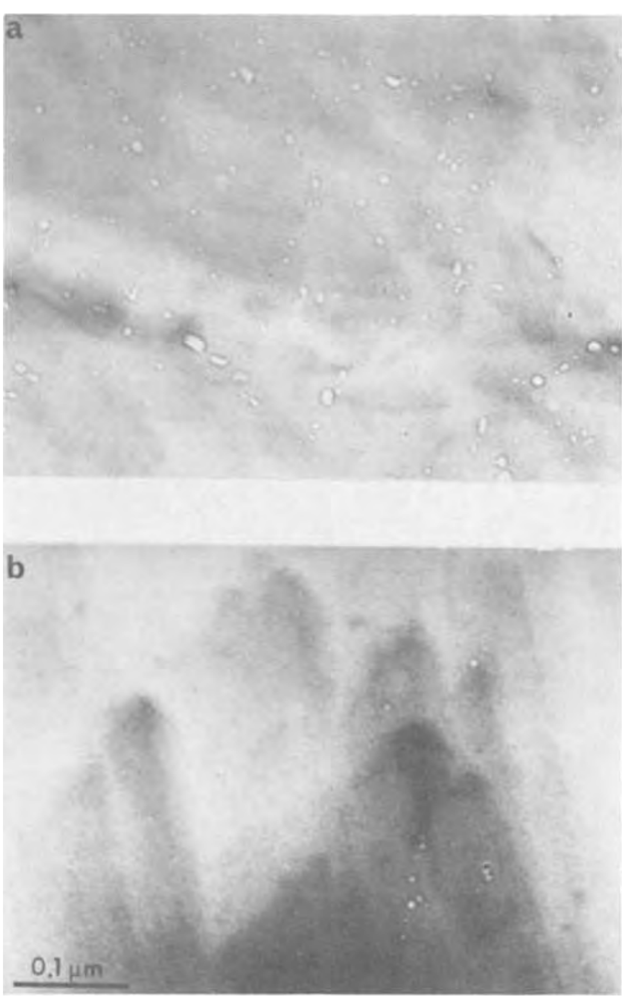

Fig. 1. TEM micrographs of electroless copper deposits formed on textured copper substrate in (a) bath A (no cyanide, 60°C) and (b) bath B (2×10^{-3}M NaCN, 75°C). (Defocusing distance $\Delta f = -3.9$ μm).

ing hydrogen gas. Figure 1a was obtained with a deposit formed in bath A (no cyanide, 60°C), while bath B (with cyanide, 75°C) yielded a deposit shown in Fig. 1b. These two micrographs show images of a single grain. It is seen that the addition of cyanide and the higher plating temperature markedly decreased the void density. The void density calculated from Fig. 1a assuming a specimen thickness of 1200Å is equal to $9 \times 10^{15}/cm^3$, while the corresponding density value for Fig. 1b is about one order of magnitude less, *i.e.*, $\sim 9 \times 10^{14}/cm^3$. Using stereomicroscopy, we confirmed that these voids are randomly distributed within the grain (9).

Very large, somewhat faceted voids (up to 500-750Å) were frequently found at low angle grain boundaries of the deposit formed in bath A as shown in Fig. 2. High angle grain boundaries did not contain such large voids.

Deposits formed on Plexiglas substrates were also examined by TEM. These deposits were not suitable for the observation of voids because they consisted of numerous small grains, and image features associated with many grain boundaries, growth twins, and dislocations obscured the image of the voids. The grain size of the deposits formed in baths A and B was approximately the same (0.5-1 μm). Twin and dislocation densities in the two deposits were also comparable.

Ductility.—Cyanide is known as an effective ductility promoter for electroless copper (1-3). Plating at higher temperatures is also known to yield deposits with higher ductility (3). The ductility values, expressed in terms of percentage elongation, of the 15 μm thick films deposited on Plexiglas in baths A and B were 1.2 and 3.6%, respectively.[1]

It has been reported that the ductility of electroless copper deposits improves significantly upon annealing at relatively low temperatures (100°-400°C) (10, 11). We found that a dramatic improvement of ductility occurs even at room temperature if the films are left standing for an extended period of time. For example, the ductility of the two films mentioned above increased to 4.6% (bath A) and 4.8% (bath B) after standing at room temperature for about six months. It should be noted that the improvement of ductility was significant for both films, and that the two final ductility values were practically the same.

SEM observations.—The surface morphology of the films deposited on Plexiglas substrates in baths A and B is shown in Fig. 3. It is seen that bath A produced a coarser structure than bath B did. Much more dramatic difference was found in the morphology of fracture surfaces of these two films. This is illustrated by the SEM micrographs in Fig. 4, which were obtained with the as-deposited film specimens used for the ductility measurement. The fracture surface of the film plated in bath A was extremely rugged (Fig. 4a), whereas that of the film formed in bath B had a much smoother appearance with necking characteristics (Fig. 4b). The features seen in Fig. 4b were more or less comparable to those of ductile, annealed copper sheets. The specimens of the films tested for ductility after the prolonged standing at room temperature were also examined by SEM. It is significant to note that in spite of the considerable improvement in ductility, the morphology of fracture surfaces of these specimens was similar to that of the fresh films shown in Fig. 4.

[1] The precision of the elongation measurement was approximately ±10% of the measured values.

Discussion

It is well established that the electroless deposition of copper accompanies the evolution of hydrogen gas with the following over-all reaction (12, 13)

$$Cu(II) + 2HCHO + 4\,OH^- \rightarrow Cu + H_2 + 2HCOO^- + 2H_2O$$

The isotope experiment carried out previously (13) using deuterated formaldehyde with H_2O and ordinary formaldehyde with D_2O showed that both hydrogen atoms in H_2 in the above reaction come from the splitting of the C-H bond in the formaldehyde molecule. On the basis of these facts, it is reasonable to assume that if any hydrogen remains trapped within the deposit, an equilibrium exists between the hydrogen atoms in an adsorbed state and the hydrogen gas contained in the voids.[2] Such incorporated hydrogen is most likely to cause the phenomenon commonly known as "internal" hydrogen embrittlement (as opposed to "external" hydrogen-environment embrittlement which occurs when metals are exposed to gaseous hydrogen atmospheres).

The internal hydrogen embrittlement is generally considered to result from either or both of the following two effects: a lowering of the lattice cohesion (atomistic embrittlement), and a build up of high internal pressure in microcracks or voids (pressure effect) (15). When the hydrogen concentration is low as compared to the lattice solubility, the atomistic embrittlement prevails, whereas the pressure effect dominates when the excess hydrogen content is sufficiently high. It is of interest to consider which of the two internal embrittlement mechanisms is predominant for electroless copper. The brittle deposit formed on Plexiglas in bath A was analyzed for total hydrogen using a vacuum fusion technique (Gollob Analytical Service Corporation, Berkeley Heights, New Jersey). The hydrogen content was found to be of the order of 100-200 ppm. On the other hand, the equilibrium solubility of hydrogen in copper is known to be extremely small: 0.055 ppm at 1 atm at 500°C (16) and less at lower temperatures. Thus, it can be concluded that practically all hydrogen found by the chemical analysis is present in the gaseous form within the voids. The internal pressure in the voids calculated using the above hydrogen concentration, the void density ($9 \times 10^{15}/cm^3$), and the average diameter of voids (~50Å) amounts to $2\text{-}4 \times 10^4$ atm.[3] An inevitable conclusion is then that the brittleness of electroless copper deposits is due to the pressure effect associated with the internal hydrogen embrittlement. The improvement of ductility observed on heating at relatively low temperatures (10, 11) or on prolonged standing at room temperature is consistent with this conclusion in view of the known high mobility of hydrogen in metals (18).

The effect of cyanide ions on ductility can be interpreted on the assumption that they strongly adsorb on copper and facilitate the escape of hydrogen gas from the deposit surface. Apparently, the higher plating temperature also accelerates the desorption of hydrogen gas. However, the hydrogen content of the film plated even in bath B with cyanide at a temperature as high as 75°C apparently was significant, as is evidenced by the fact that its ductility did improve considerably (from 3.6 to 4.8%) on standing at room temperature.

The difference in roughness between the two fracture surfaces (Fig. 4) may be related to the corresponding difference observed on the as-deposited surface shown in Fig. 3. On the other hand, in the presence of large voids at grain boundaries (Fig. 2), it is probable that cracks initiate at such voids. This also may produce rugged fracture surfaces. Whatever the cause of the morphological differences may be, it is clear that the ductility is not determined by the deposit morphology; as already mentioned, the fracture surface showed no morphological change after the improvement of ductility on room temperature stand.

Summary and Conclusions

1. Numerous voids ranging in diameter from 20 to 300Å are present within grains of brittle electroless copper deposits. Low angle grain boundaries of such deposits contain voids as large as 500-750Å in diameter. These voids are believed to be filled with hydrogen gas.

2. This study indicates that the brittleness of electroless copper deposits is due to the "hydrogen embrittlement" phenomenon rather than the incorporation of Cu_2O or deposit morphology.

3. An improved ductility results when the plating is performed under the conditions which facilitate the escape of hydrogen gas. The addition of cyanide and plating at higher temperature bring about this effect, although these conditions did not completely eliminate the inclusion of hydrogen in the present experiment.

[2] Lukes (12) proposed a reaction mechanism involving the formation of hydride ion, H^-, on the deposit surface. This mechanism was recently supported by Pearlstein (14). We thought that if this mechanism is indeed operative, copper hydride (CuH) might exist and be detectable especially in brittle deposits. However, an electron diffraction analysis failed to yield any evidence for this compound.

[3] These values, which may seem extremely high, are actually lower than the internal pressure calculated for the hydrogen embrittlement of steel ($10^5\text{-}10^8$ atm) (17).

4. Low temperature annealing or room temperature standing for an extended period of time appears to allow hydrogen to escape and hence further improve ductility.

ABSTRACT

The buildup of copper by electrodeposition onto a high resistance electroless flash has been studied in a roll-to-roll continuous plater employing copper fluoborate at ambient temperature. Input to the plater was circuit-patterned polyimide tape having an initial deposit which ranged from 2.4 μin. electroless copper through 146 μin. electroless plus electroplated copper. Buildup of copper through one (or more) plating loops was traced by atomic absorption analysis of millimeter-sized pattern sections cut from the tape; this analysis followed an abrupt interruption in steady-state plating and a rapid ejection of the tape from the plater. By this technique, copper distributions along and across the tape were determined. Thickness buildups to 400 μin. at tape speeds of 2.3 and 3.1 ft/min are reported. The copper distributions have been used to compute maximum and average cathodic current densities, J_{max} and J_{ave}, respectively, for selected plater configurations and input copper thicknesses. Significant asymmetries in local plating rate due to the high input tape resistance were observed and the ratio J_{max}/J_{ave} was as high as 12/1 in some cases. Since excessive cathodic current densities can degrade performance of the plated product, the regulation of J_{max} within definable limits is a critical aspect of plater design. A correlation of J_{max} to input thickness of the electroless flash and to applied plating currents is presented and its implications with respect to plater design examined.

The fabrication of flexible printed circuits by additive methods (1, 2) usually employs a continuous electroplating step to build up a thin, resistive electroless flash to the required conductor thickness. In this step the metallized flexible substrate, connected cathodically in the plating cell, may receive unwanted extremes of cathodic current density, even though the applied plating currents are set quite moderately. This occurs because the relatively high resistance of the electroless deposit forces a highly nonuniform deposition along the plater axis, with little or no plating at the high resistance (input) side, and well above average plating at the low resistance (exit) side of the

Key words: copper fluoborate plating, cathode current density, plating distributions, pattern plating, fusion current.

system. This effect must be adequately considered in the design and operation of a continuous plater to insure that the quality of the plated deposit is not adversely affected.

In this paper we shall describe experiments in which an electroless flash of 2.3 μin. is built up in stages to as much as 400 μin. by continuous plating in copper fluoborate. Measurements of the observed copper distributions will be presented and from these the average (J_{ave}) and maximum (J_{max}) cathodic current densities calculated for individual plating loops under various conditions. The ratio J_{max}/J_{ave} will be used as an index of the plating rate asymmetry in any loop.

The plating configuration used in our experiments is more complex than the idealized parallel plate configuration, the latter case being more amenable to computation and analysis. Nevertheless, we have attempted to look beyond the complexities introduced by our configuration to provide some understanding of the continuous plating problem.

The starting material in these experiments was patterned electroless copper on polyimide tape. Plating experiments under various combinations of input copper thickness, plating current, plating loop depth, and tape speed, were performed and analyzed to provide a detailed description of the system performance. The buildup of copper through one (or more) plating loops was traced by atomic absorption analysis of millimeter-sized pattern sections cut from the tape. This analysis followed an abrupt interruption in steady-state operations to provide a snapshot record of the plating distribution at all points. The copper distributions were used to compute the cathodic current density at selected positions in the plater.

Representative distributions along the tape have been plotted for runs at 2.3 and 3.1 ft/min tape speed. Results will be given for runs with normal *i.e.*, standard, plater configuration and for two nonstandard configurations which employ either field shields at the plating loop exit, or added cathode connections in solution. The nonstandard configurations are attempts to reduce plating asymmetries and peak cathodic current densities.

The determinations of copper distribution for the normal configuration runs have been used to formulate a plater design based upon the limiting of cathodic current density to a specified maximum in the plater. This is an important first step in the establishment of a generalized design scheme for continuous plating onto high resistance electrodes.

Background

In electroplating onto a high resistance cathode, the plating current flow produces a significant *IR* drop along the cathode (specimen) surface which thus may deviate appreciably from an ideal equipotential. The voltage gradients induced along the cathode act to vary the local surface overpotential and thus the rate of metal deposition. Such variations are in addition to any which occur due to mass or charge transfer effects.

The effects of ohmic electrode resistance on current and potential distributions in various plating cells have received considerable attention in the literature. Weisselberg (3) has reported current and potential distributions for a resistive anode rod suspended along the axis of a nonresistive cylindrical cathode. Wojtowicz *et al.* (4) have reported current and potential distributions for a thin wire resistive anode under conditions of negligible longitudinal potential drops in the electrolyte. Fomichev (5) has calculated current distributions in resistive parallel strip electrodes. Tobias and Wijsman (6) have considered the case of plane parallel electrodes of finite but uniform resistance.

The above papers describe steady-state systems and assume that resistive changes which result from the electrodeposition process are negligible. This assumption is not valid when the resistivity (thickness) varies substantially along the substrate. The effects of spacial thickness variations have been analyzed by Alkire (7) for cathodic electrodeposition onto a thin stationary metal strip of high resistance.

The problem to be discussed in this paper involves steady-state plating in a continuous system. In this, as in all plating cells, the cathodic current distribution (and thus the deposit distribution) is determined by the interaction of several variables: cell geometry, electrolyte composition and temperature, electrolyte agitation and flow pattern, electrode resistances, plus the level of the applied plating current. Our experimental results show deposit distributions which are highly asymmetric along the plater axis when the input copper thickness is ultrathin, but which become more uniform and eventually linear as the input thickness increases. From this result we have surmised that the ohmic resistance of the deposit (cathode) is the main variable determining the cathodic current distribution, with kinetic (charge transfer) or concentration (mass transfer) polarization effects of secondary importance. The properties of the copper fluoborate electrolyte, the configuration applying uniform agitation to the electrolyte, and the relatively low levels of applied current are consistent with this conclusion.

By way of qualitative description, we refer to Fig. 1A which depicts an idealized single loop continuous plater with commonly connected anodes/cathodes. The upper rollers, grounded conductors, provide cathodic connection to the underside of the tape; contact to the reverse side occurs via plated through-holes in the tape. The through-holes are presumed sufficiently conductive to maintain a uniform potential $V(X)$ on either side of the tape at coordinate X measured along the tape axis. The corresponding potential in the electrolyte just beyond the diffusion layer is denoted as $V_S(X)$, and V_o denotes the anode potential relative to ground (cathode). The currents collected on each side of the loop are denoted i and I as indicated. The lower roller is a nonconductor and blanks plating at the bottom of the loop on one side of the tape. The interelec-

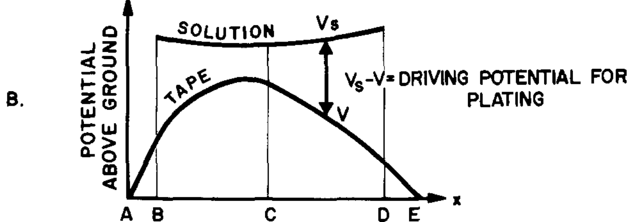

Fig. 1. (A) Schematic diagram of single loop, continuous plater with common anode (V_o) and common cathode (grounded) connections. Coordinate X measures position along the tape while $V(X)$ and $V_S(X)$ are the respective potentials on the tape and in the electrolyte at X. (B) Schematic of potential distributions for the single loop plater.

trode spacing on either side or along the tape is uniform, and the circulation of electrolyte is presumed equivalent at all points. Edge effects near the air-electrolyte interfaces or near the bottom roller are neglected.

In Fig. 1B we sketch the tape and solution potential distributions for a typical plating loop. The difference $V_s(X) - V(X)$ represents the driving potential for plating at X; thus the plating rate varies along the loop. The potential difference $V_s(X) - V(X) = \eta(X) + \phi$, where η is the surface overpotential and ϕ the reversible cell potential for the system. At any X the plating rate increases with $V_s - V$. (The plating rate dependence upon potential is usually given (8) as an exponential function of η.)

Due to the current flow in the resistive tape, a voltage rise must occur as one passes downward along the loop. At a point before C this trend is reversed and as we proceed toward the loop exit, the current reverses direction and flows toward the exit cathode roller. The magnitudes of i and I reflect the relative tape resistances in each portion of the loop. Since thickness increases as the tape passes through the loop, $I > i$. The solution potential V_s is presumed not to vary strongly with X, a reasonable assumption for electrolytes of high conductivity. We see in Fig. 1B that $V_s - V$ (and thus the local deposition rate) decreases as we proceed away from the cathode rollers.

Experimental

Apparatus and plating conditions.—A schematic of the plating system used is presented in Fig. 2. The left-hand sketch shows an unscaled elevation of the plater, the right-hand sketch a scaled plan view of a plater section. The tape orientation is vertical, the spacing between alternate rollers exceeding the 4 in. roller diameter by only 5/16 in. on each side. For the single pass runs, the tape was rethreaded to bypass all but one loop; pass 2 was used for plating at full depth, pass 1 for plating at reduced depth. Anodes were oval-shaped OFHC copper rod, 3 in. nominal width, and centered on the tape in the plater.

For some of the single pass runs, the configuration was modified as shown in Fig. 3. These runs involved addition of shields at the loop exit (3A) or added cathode connections in the electrolyte (3B). The cathode connections were made using ¼ in. formed copper rods, insulated except at their ends to contact the metallized center strip on the key side of the pattern (see Fig. 4).

The plating bath was copper fluoborate operated at ambient temperature. This bath was prepared by diluting two parts of fluoborate concentrate (Allied Chemical Company) with one part deionized water to obtain an electrolyte of 462 g/liter copper fluoborate (124 g/liter as Cu), 7.2 g/liter fluoboric acid, and 30.7 g/liter boric acid. During the runs, the plating solution was pumped and filtered continuously through carbon-charged polypropylene filters.

The electrolyte tank capacity was 70 gal and the circulation rate 5-8 gal/min. Circulation was from the exit side lower corner of the tank (inlet) diagonally across to the entrance side upper corner (exit).

Tape generation and tape removal from the plater.—The tapes for analysis were 2 mil polyimide (du Pont KAPTON®H Film) patterned in electroless copper by the photoselective metal deposition process (2). The patterns on each side are shown in Fig. 4. During plating, the bus side was in direct contact with the cathode rollers, the key side plating by contact via the through-holes. Experiments were performed by executing an abrupt interruption in steady-state operations. For the single loop experiments, the plater power was turned off and the tape section removed after cutting at positions marking the top of the input and output cathode rollers. The tape section was immediately rinsed in deionized water, then dried in air.

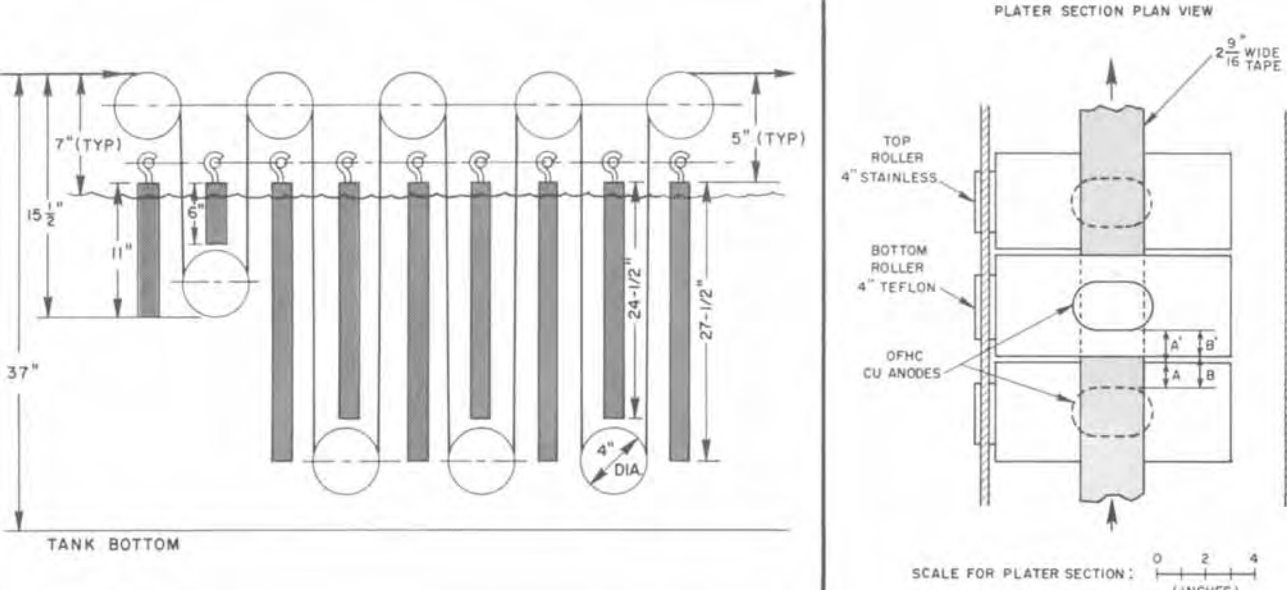

Fig. 2. Schematic of continuous plater in multipass mode (left) and plan view of scaled plater section (right). For single loop runs the tape was rethreaded to bypass the loops not being used. Anodes in the bypassed loops remained in place. The vertical pitch of the tape was as follows: tape to anode at top, A = 1 in., A′ = 1 5/16 in., at bottom, B = 1 5/16 in., B′ = 1 in.

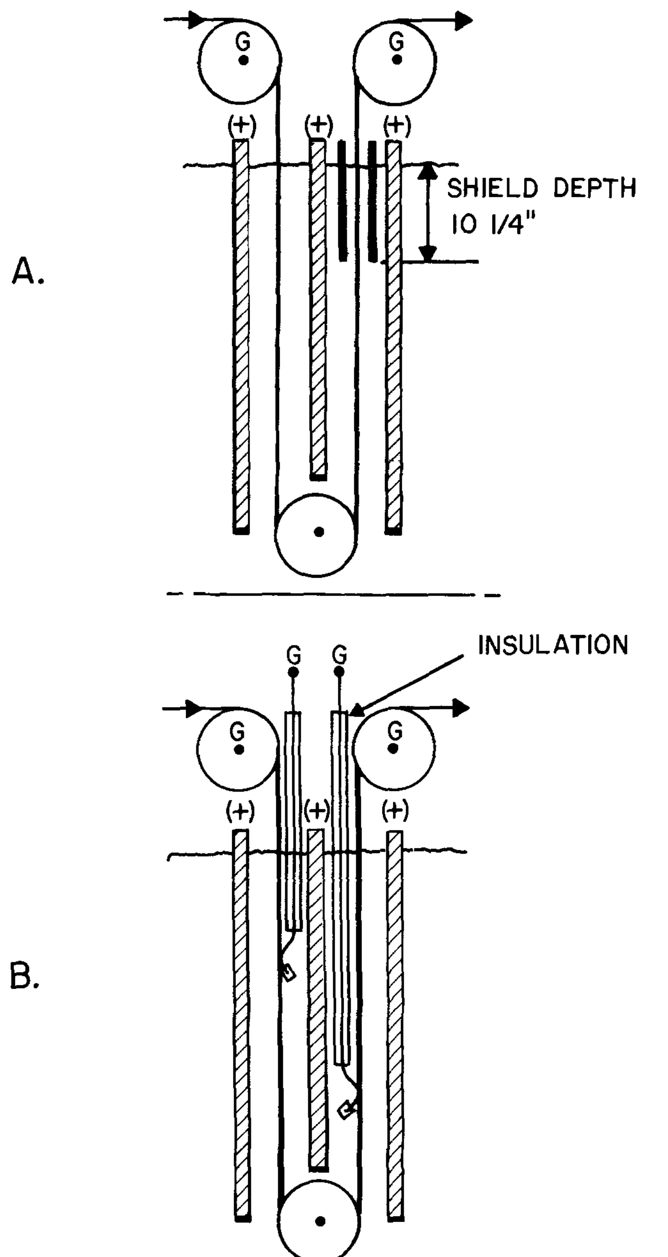

Fig. 3. Schematic diagram of nonstandard plating configuration. (A) Experiment using exit field shield. (B) Experiment using added cathode connections in the electrolyte. The G's indicate connection to ground.

For the multiloop experiments, the tape removal process took somewhat longer as it was necessary to raise the tape transport mechanism out of solution to remove the tape section. The lapsed time between power shutoff and the water rinse in this case was about 2½ min.

Tape indexing and specimen designation.—The center sprocket holes used to transport the tape in the plater provided a convenient coordinate along the tape axis. Thus all tapes were indexed by numbering the sprocket holes, with the zero position at the top of the input cathode roller. Conversion to distance in inches was made using the factor 0.627 in. per sprocket number.

Tape position in the plater at the time of its removal was recorded by fiducial marks locating the tape position at the top of each cathode roller. The location of the air-solution interface was made by ruler measurements on the machine at the time of each run.

The specimen labeling scheme is illustrated in Fig. 4. All measurements to be reported were made on the

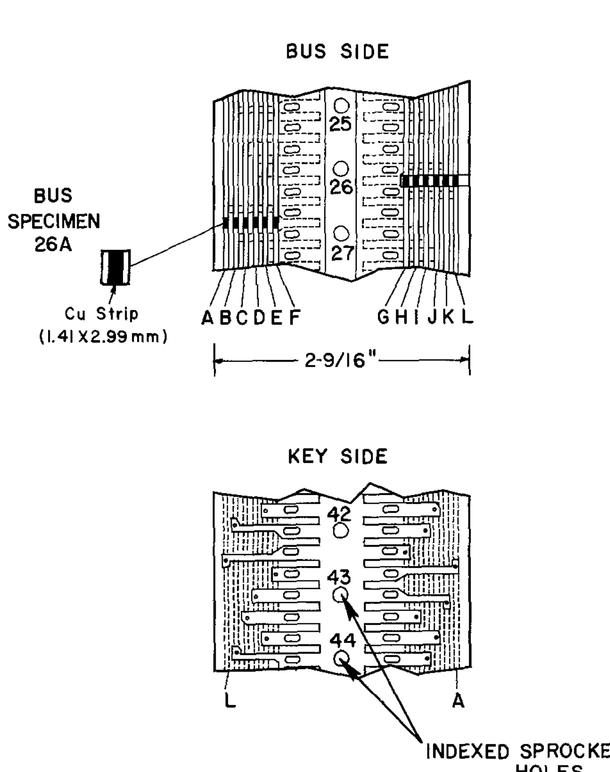

Fig. 4. Description of patterned tape and specimen designation. Specimens for atomic absorption analysis were taken from the bus side of the tape, cut into 1.41 × 2.99 mm strips at each bus. The center sprocket holes were used to register and transport the tape through the plater.

bus side of the pattern, the individual specimens carefully cut from the tape using a razor blade and a steel template.

The area of deposited copper on a specimen was computed from measured values of specimen length and pattern width. The measured dimensions averaged over 20 specimens were

Width: 55.33 ± 1.01[1] mil $= 0.141 \pm 0.0025$ cm

Length: 117.8 ± 1.2[1] mil $= 0.299 \pm 0.0029$ cm

Bus area: $0.0422\ cm^2 \pm 2.8\%$

Copper analysis by atomic absorption spectrometry.—The specimens, cut to size, were immersed in a measured volume of aqua regia to dissolve the copper. The aqua regia was diluted 2 to 1 with deionized water. The volume of solvent varied from 2 to 400 ml depending upon the copper thickness. Dilution was made to maintain the copper concentration near a value of 2 ppm.

Analyses were carried out using a Jarrell-Ash No. 82-536 Atomic Absorption-Flame Emission Spectrometer, using an air-acetylene flame and the 3247.5 Cu line. Solution standards were prepared by an aqua regia dilution of a Spex 1000 ppm/ml spectroscopic standard solution.

The AA data permit determination of the mass per unit area of the deposited copper. Thickness determinations were made from these values using the bulk copper density, 8.93 g/cm^3. Experimental errors in the copper analysis have been determined from the precision and accuracy of the AA analysis and the area measurements on each specimen. The AA analysis at 2 ppm copper concentration is estimated to have a precision of 3.5% and an absolute accuracy of 1%. The

[1] All reported errors are average deviations.

over-all precision in the copper determination is thus 3.5% + 2.8% (error in area) = 6.3%. An additional systematic error in the copper thickness is introduced by the lateral growth as the plating proceeds. This error is approximately linear in total thickness plated and is a maximum of 5% for the thickest specimens.

Calculation of cathodic current density.—The cathodic current density at any position in the plater may be determined from the measured copper thickness distribution on the tape if the tape speed is known. A diagram of an elemental tape section proceeding vertically through the plating cell at speed v is shown in Fig. 5. The X coordinate, measured along the tape axis, locates position in the plater relative to fixed lab coordinates. Upon interruption of the steady state to obtain the plating loop the lab-fixed coordinates transfer to the tape in a one to one correspondence which relates distance along the tape to coordinate location in the plater.

In Fig. 5 a tape section between X and $X + \Delta X$, discharging ions across the element-electrolyte interface of area $\approx W\ \Delta X$ receives a cathodic current $I_c(\equiv J \cdot W\Delta X)$ and a deposit which increases the metal thickness by ΔT. For steady state

$$I_d(X + \Delta X) = I_d(X) + J \cdot W\Delta X \qquad [1]$$

where $I_d(X)$ and $I_d(X + \Delta X)$ are currents flowing through the deposit through cross sections $W \cdot T(X)$ and $W \cdot (T(X) + \Delta T)$, respectively. The corresponding deposit current densities are $J_d(X)$ and $J_d(X + \Delta X)$.

At speed v the deposit thickness increases by ΔT in time interval $\Delta X/v$, thus the deposition rate is $v\ \Delta T/\Delta X$. Using Faraday's law and the bulk density, 8.93 g/cm^3, the cathodic current density J at any X' can be shown to be

$$J(X')\,(\text{asf}) = 12.8v\ (\text{ft/min}) \cdot (\Delta T/\Delta X)_{X'}\ (\mu\text{in./in.}) \qquad [2]$$

Results

The major results to be reported will relate to single loop experiments. These were preferred over the multipass common electrode experiments because they permit the setting of total current and thus the thickness deposited for each pass. However, no distinction is to be made between the two cases. We have included some results from the multipass work to underscore how resistance affects the plating distribution when the individual passes have significantly different input resistances.

Multipass operation.—In Fig. 6 we present transverse copper distributions for a four-pass plating run at 2.3 ft/min and 75A. The copper thickness at each bus is plotted *vs.* distance from the center of the tape for segments cut at the end of each completed pass. Input copper thickness (I) was 2.2 μin. The average thickness over all buses at the respective exits was found to be: pass 1 (II)-7.7 μin.; pass 2 (III)-31.7 μin.; pass 3 (IV)-104.8 μin.; pass 4 (V)-208 μin. The copper deposit across the tape is seen to be highly nonuniform though symmetric about the tape axis, with an appreciably enhanced buildup at the edges.

For the purposes of comparison, we have plotted distributions predicted from the primary current distribution of plane parallel electrodes (9) of the same width and spacing as our electrodes. The primary distribution is based upon cell geometry and is independent of mass and charge transfer effects. (However, electrode kinetic and mass transfer effects would prevent the infinite current densities predicted at the electrode edges.) The primary current distribution curves have been normalized by matching the predicted average thickness with the measured average thickness of the buses. The observed thicknesses do not deviate appreciably from the theoretical curves, thus plater geometry is held primarily responsible for the nonuniformity of the transverse distributions.

In Fig. 6 variations in plating along the tape axis are also observed as we note nonuniform deposit increases in successive passes. A breakdown in the fraction of the total deposit received in each of the four passes, respectively, is 0.011, 0.037, 0.154, and 0.509. The peak

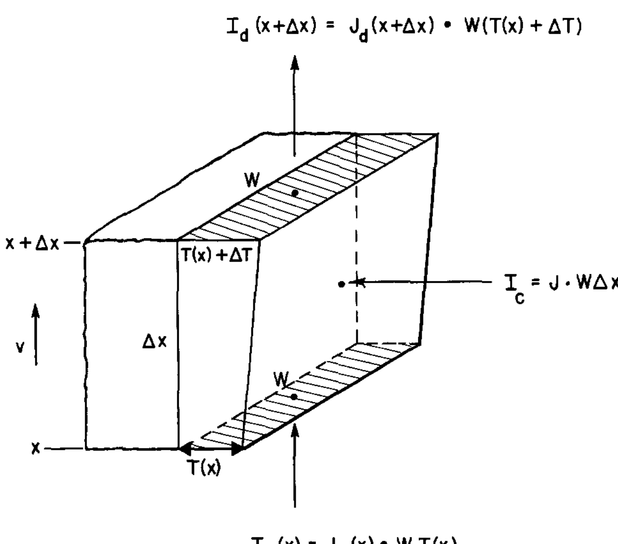

Fig. 5. Elemental tape section in the plater. The section, moving vertically at speed v, receives cathodic current I_c across interface $W \cdot \Delta X$. As a result, deposit thickness increases by ΔT across span ΔX. The deposit current I_d is also increased when this occurs.

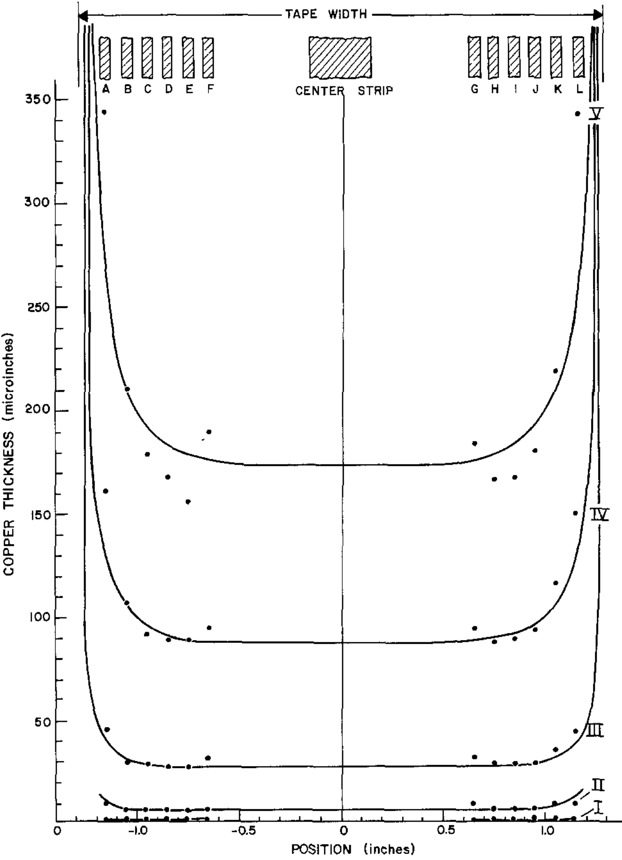

Fig. 6. Transverse copper distributions for multipass run 5/21, 2.3 ft/min at 75A. Measurements at each bus for: I. input electroless deposit: II. exit of first pass: III. exit of second pass: IV. exit of third pass: and V. exit of final pass. The solid lines indicate results predicted from the primary current distributions of equivalent plane parallel electrodes (9).

cathodic current density is seen to occur in the final pass in the plater.

Single pass distributions.—The single pass results show transverse and axial distributions similar to those already discussed. The transverse distributions for single pass runs will not be specified further.

Before presentation of the axial results, it is useful to discuss the relation between the axial and transverse distributions. If the latter are determined by primary current distributions, thus plater geometry, then the axial and transverse depositions may be considered separately and independent of each other. This separation should be possible when ohmic effects control the deposition in the system. On the other hand, if electrolyte polarization effects are appreciable, the plating distributions will be sensitive to the over-all level of cathodic current, and thus the axial and transverse depositions will be related. We shall make some further comments on this separation in the Discussion section after presentation of experimental results. Needless to say, the separation in distributions permits a significant saving in effort since it forestalls the need for a separate axial deposition model at each lateral position.

The axial results presented refer exclusively to measurements at outer bus A. To predict the axial distribution at other positions, we presume that the bus A results could be multiplied by an appropriate scale factor such as that determined to predict the distributions for the plane parallel electrodes in Fig. 6.

Four sequences of single loop experiments were performed as follows: I and II, normal configuration at 2.3 and 3.1 ft/min, respectively; III and IV, speed 3.1 ft/min with modified plater configurations using a field shield or added cathodes in the electrolyte (note Fig. 3). A tabulation of experimental conditions and the corresponding values of peak and average cathodic current density for all runs is presented in Table I. The ratio J_{max}/J_{ave} defining A, the plating asymmetry factor, is also presented for each loop. The asymmetry is seen reduced as the input copper thickness is increased. (However, the effects due only to thickness changes are somewhat masked by the changes in the applied current). Values of J_{max} in the table were calculated in Eq. [2] from values of maximum slope ($\Delta T/\Delta X$) determined from the respective copper distributions.

Axial distributions (measured at bus A in all cases) are presented in Fig. 7 and 8 for normal configurations at 2.3 and 3.1 ft/min, and in Fig. 9 and 10 for experiments at 3.1 ft/min using field shields and added solution cathodes, respectively. In these figures the vertical dashed lines indicate the location of the entrance and exit air-electrolyte interfaces. The vertical arrows indicate the lowest position of the tape in the loop. The cathodic current densities J_{max} reported in the figures are higher than the average over the entire pattern since the plating rate at the outer bus is appreciably higher than the average over the entire pattern.

In Fig. 7 copper distributions for A (15A), B (20A), and C (55A) at 2.3 ft/min are presented. The A and B runs are comparable except for the shorter loop length of A. The effective plating zone for these runs of high input resistance is seen confined to a span of 8-10 in. near the exit air-electrolyte interface. The shortened loop length in A has little effect on the plating distribution in the first half of the loop. The situation is different in C where a less asymmetric plating occurs as a result of increases in input thickness and in the applied current.[2]

We note in Fig. 7 and 8 that the copper deposition does not halt abruptly at the exit interface but continues for 2-3 in. beyond. This effect occurs because an appreciable electrolyte meniscus is formed as the tape is pulled out of solution and is capable of plating until its copper ions are depleted. Current passage in electrolyte menisci has been reported for partially immersed parallel vertical electrodes by Will (10), Bennion and Tobias (11), and Burshtein *et al.* (12). In multipass runs we have also observed a delay in the resumption of plating upon reentry of the tape into the electrolyte. This phenomenon is presumably the result of surface blocking by the ion-depleted layer until mixing with the bulk electrolyte restores the ion concentration at the interface.

In Fig. 8 we observe results for A (10A), B (20A), and C (45A), with tape speed at 3.1 ft/min. A decrease in asymmetry is evident as the input copper thickness is increased. The effects on plating asymmetry due to speed or current variations are difficult to assess by superficial comparison of the two figures.

In Fig. 9 results for the exit field shield experiments are presented. The role of the shield is to reduce the local electric field, thus enhancing the plating rate elsewhere in the loop. Results in Fig. 9 for A (10A), B (10A), C (20A), and D (35A) were obtained at tape speeds of 3.1 ft/min. The region along the tape covered by the shield is indicated by the shading in the figure. In Fig. 9A we have also plotted the copper distribution from run 1/29, a comparable experiment without the shield. The presence of the shield is seen to expand the effective plating zone down into the electrolyte, thus reducing the value of J_{max}. In Fig. 9B and 9C we note that the shield flattens the slope at the exit interface, thus shifting the position of J_{max} to the inlet side of the loop. In Fig. 9D the shield completely blocks the plat-

[2] Further comments on this subject are made in the Discussion.

ing at the exit interface, again forcing the peak cathodic current to occur at the inlet side of the loop.

The experiments with added solution cathodes are presented in Fig. 10 with tape speed at 3.1 ft/min, A (14A) and B (20A). The locations of the solution connections are shown by the asterisks. The effect of these modifications is to enhance the deposition in the vicinity of the solution connections. (The connection near position 58 in. appears slightly mislocated, as the plating enhancement is found near the 53 in. position.)

Constraints on plater operation.—The axial plating asymmetries which have been noted suggest a need to limit average current densities, J (cathodic) or J_d (in the deposit), to values appreciably lower than those used in standard practice for the same electrolytes. This restriction anticipates that values of J or J_d may be excessive at some positions in the plating cell, leading to reduced quality of the plated product. The degradation may result from extremes in either or both variables.

The anticipated product difficulties are (*i*) fusion of the plated deposit, (*ii*) deposition of burned or nodular deposits, and/or (*iii*) damage to the substrate-deposit interface. These three aspects will be discussed separately in the sections which follow.

(*i*) *Deposit fusion.*—The occurrence of fusion requires the rate of ohmic heating produced by the deposit current I_d to appreciably exceed the rate of heat dissipation from the tape. For continuous plating as described here, the point where fusion will occur (if I_d is large enough) is at and beyond the exit air-electrolyte interface.

Figure 11 provides correlations of fusion current I_F *vs.* thickness of deposit for copper-metallized polyimide tapes, either blanket plated (13), or pattern plated (our results). Also plotted for reference are handbook results (14) for copper wire of equivalent rectangular cross section. Note that the units of current are normalized per unit conductor width. The tape results were obtained using 2 mil polyimide substrates metallized on both sides with electroless and electroplated copper and suspended vertically in air during the passage of current. The pattern results were obtained by using the configuration in Fig. 4, with pattern width at the minimum cross section used to normalize the fusion current. The fusion line shift downwards from pattern to blanket to wire reflects the decreasing ca-

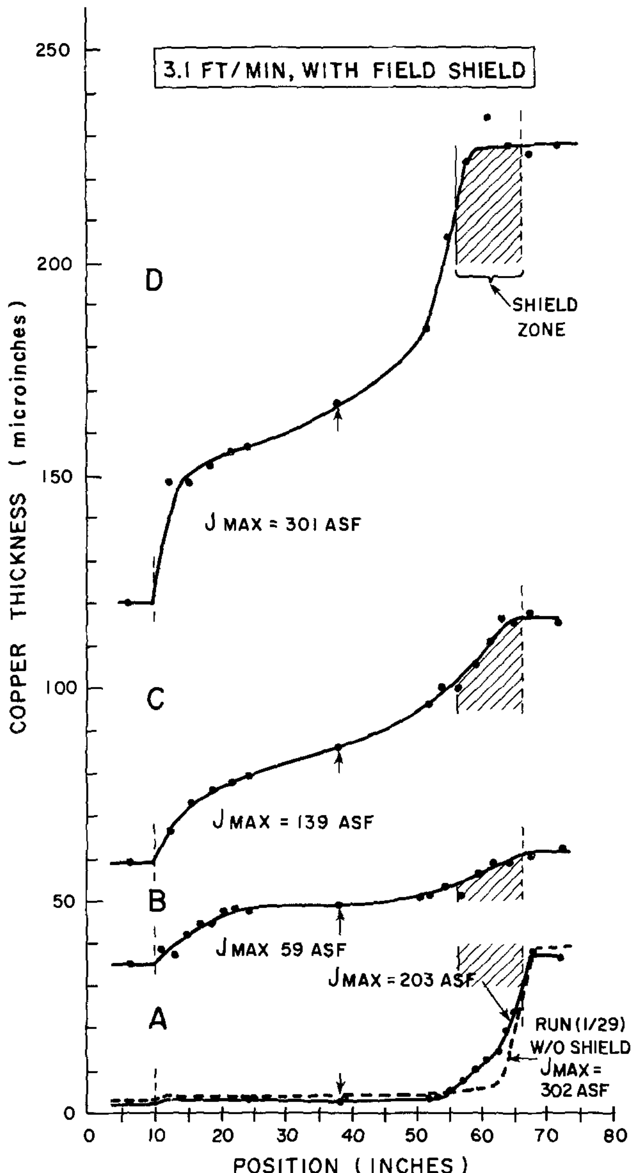

Fig. 9. Axial copper distributions, bus A, with exit field shield. Shield zone is indicated by the shaded area. (A) Run 3/5, 10A; also plotted run 1/29, 10A without shield. (B) Run 3/6, 10A. (C) Run 3/6-A, 20A. (D) Run 3/6-B, 35A. The shield reduces the thickness gradient at the loop exit while increasing the gradient at the entrance side. (An exception is Fig. 9A with 2.4 μin. input.)

pability for heat dissipation of the respective configurations.

Also plotted in Fig. 11 is the correlation between applied plating current I (A/inch of width, mean cross section) and the resulting thickness of the patterned tape at the exit of the plating loop (dashed curve). This curve is based upon the faradaic equivalence of current and deposit and assumes an input thickness of 3 μin. at a speed of 3.1 ft/min.

The occurrence of fusion may be predicted from Fig. 11 by comparing the current in the deposit at the loop exit, $I_d)_{exit}$ to current I_F at which fusion occurs. To avoid fusion $I_d)_{exit}$ must be less than I_F at the exit deposit thickness. As a matter of convenience we can estimate $I_d)_{exit}$ to be very nearly equal to the total plating current I, since very little current flows in the entrance side of the loop for input deposit thicknesses less than about 40 μin. (see Fig. 7 and 8). The criterion for fusion avoidance thus becomes $I < I_F$.

To evaluate a specific case using Fig. 11, consider a loop in which a total current of 3 A/in. at 3.1 ft/min is applied to a 3 μin. patterned or blanket-plated tape, respectively. At this current, fusion is predicted for thicknesses less than or equal to 4 μin. in the patterned tape. 5.8 μin. in the blanket tape. The plating line predicts that the exit thickness will be 9.5 μin., thus fusion is not possible in this case.

The fusion limitations described do not impose severe restrictions on our ability to plate at "useful" rates such as those employed in the work described.

(ii) Occurrence of burned or nodular deposits.—Burned or nodular deposits occur when the local cathodic current density J exceeds the limits of the electrolyte for the conditions of use. Avoidance of such deposits requires limiting the values of J_{ave} so that the corresponding values of J_{max} are not excessive. Alternatively, changes could be made in bath, cell, or tape speed, to reduce the J_{max}/J_{ave} ratio and thus reduce J_{max}.

(iii) Damage to substrate-deposit interface.—The final constraint involves more subtle effects inasmuch as a damaging of the substrate-deposit interface is not always readily evident without additional evaluations. If J or J_d are sufficiently high, excessive heating of the interface or the generation of internal stresses in the

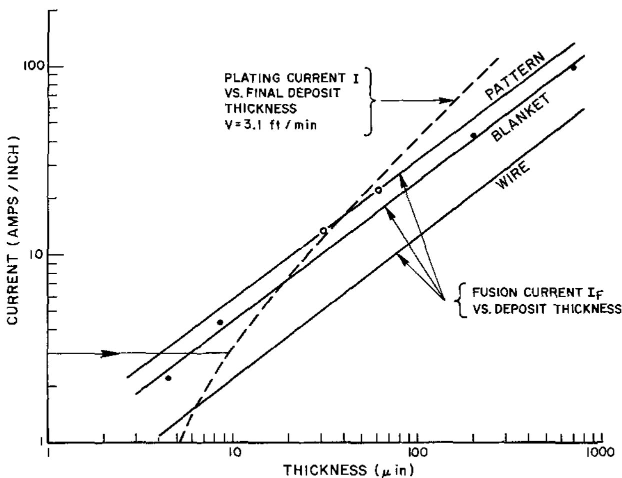

Fig. 11. Plating current I and fusion current I_F vs. copper thickness. The plating current line (dashed) describes the Faraday equivalent current-thickness relation at the exit of the plating loop, for an input thickness of 3 μin. and a tape speed of 3.1 ft/min. Fusion lines describe current limits of specimens in air for wire (14), for blanket plated Cu/polyimide (13), and for patterned Cu/polyimide (our data). The line shifts upward reflect the improved heat dissipation of the respective geometries.

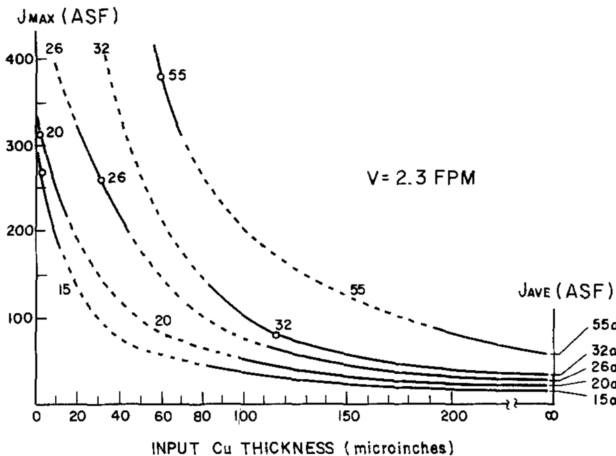

Fig. 12. Peak cathodic current density J_{max} vs. Cu thickness (average over all buses) at the plating loop input; $v = 2.3$ ft/min, plating current I as a parameter. The curves are sketched using experimental results (open circles) plus the extrapolations: $J_{max} = \infty$ at zero thickness, $J_{max} = J_{ave}$ at ∞ thickness.

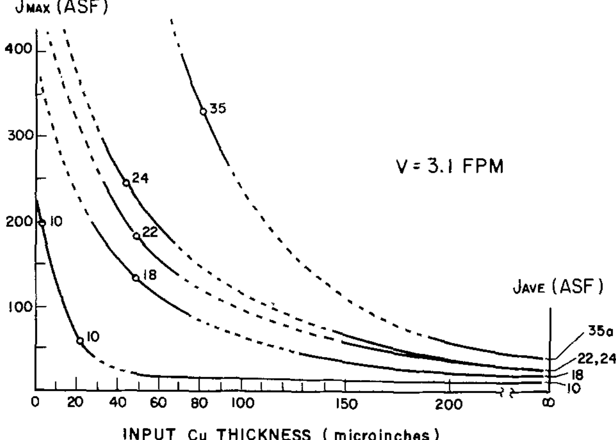

Fig. 13. Peak cathodic current density J_{max} vs. Cu thickness (average over all buses) at the plating loop input; $v = 3.1$ ft/min, plating current I as a parameter.

deposit may lower the substrate-deposit adherence or induce preferential corrosion of pattern edges (undercutting) during plating. These aspects are strongly sensitive to the particulars of the materials plated, thus we cannot *a priori* specify the appropriate limiting values. Such limits must be empirically fixed by careful evaluations of product quality *vs.* the level of currents applied. We do not assert that the cathodic or deposit current densities stand alone as determinants of plating quality, but must certainly be included as major factors.

Plater design.—An empirical scheme based upon the setting of an upper limit for J_{max} is sketched in Fig. 12 and 13 for tape speeds of 2.3 and 3.1 ft/min, respectively. In these figures experimental values of J_{max} (open circles) have been plotted *vs.* input copper thickness for respective single plating loops, with plating current I as a parameter. A family of curves has been sketched making use of the experimental results (open circles) and the following criteria: approaching zero input thickness, the curves must be asymptotic to the positive J_{max} axis; for very large thicknesses, J_{max} must approach J_{ave}. (Note J_{ave} is independent of the plating distribution. Figure 12 and 13 give an indication of how J_{max}, input thickness, and the individual loop currents I are related.)

A design can be accomplished by the following iterations:

1. For a specified J_{max} read or interpolate the allowed loop current I corresponding to the input Cu thickness.
2. For the indicated I, compute the thickness which will be added by plating (via Faraday's law).
3. Repeat for the next loop, using the incremented Cu thickness.

As an illustration, a plater design using $J_{max} = 200$ asf as an upper limit is presented in Table II for speeds of 2.3 and 3.1 ft/min. The implementation of this design requires that each plater pass be electrically isolated from all others. The precision in J_{max} *vs.* thickness data (open circles) is estimated as 10-15%. For regions where no data is available (the dashed portions of the curves), the estimates of J_{max} should be accurate to 20-40%, based upon the degree of extrapolation.

Discussion

Separation of transverse and axial distributions.—The validity of treating the transverse and axial copper distributions as separable is supported by (*i*) experimental results relating J_{max} and J_{ave} at different transverse positions and (*ii*) calculations of cathodic current distributions using the Tobias-Wijsman parallel electrode model (6). Thus:

(*i*) The ratio J_{max}/J_{ave} used as an index of axial plating asymmetry is reported in Table I for measurements on bus A. For runs 12/11 and 12/14, the bus A results were 7.87 and 2.58, respectively. The corresponding ratios for center bus C were found to be 8.77 and 1.84, respectively. Thus the plating asymmetries at different lateral positions appear to be the same, even though the absolute plating rates differ by a transverse position dependent scale factor.

(*ii*) The Tobias-Wijsman calculation (6) of the current distribution in a pair of closely spaced long planar electrodes can be used to evaluate the relative effects of electrode *vs.* electrolyte resistance when cathodic currents are much less than the limiting current density, *i.e.*, negligible concentration polarization. The very high value of limiting current density[3] in fluoborate electrolytes (15) insures the validity of neglecting concentration polarization.

The Tobias-Wijsman parameter ϕ expresses the degree of nonuniformity of the cathodic current density J along the resistive cathode

$$\phi = L\left\{\frac{r}{b + d/K}\right\}^{1/2} \quad [3]$$

where L = electrode length, r = cathode resistance per unit length of a 1 cm strip, b = linear polarization parameter (model assumes $b = d\eta/dJ$, where η is the surface overpotential), d = the electrode spacing, and K = electrolyte conductivity. The expression in brackets denotes the ratio of electrode to electrolyte resistance. When this ratio is large, thus large ϕ, the current density distribution is highly nonuniform.

Applying the above formulae to a typical half-pass in our plater

b = 0.215 ohm-cm^2 [calculated from results in Ref. (16)]
K = 0.15 ohm^{-1} cm^{-1} [from Ref. (15)]
d = 2.94 cm
L = 71.6 cm
r = $0.709/t$ ohm where t = the average copper thickness in the half-pass of the plater

Thus

$$\phi = 13.48\, t^{-1/2} \quad [4]$$

Calculations of ϕ and J_{max}/J_{ave} *vs.* average electrode thickness were made with Eq. [XXX] of Ref. (6) and are presented in Table III. Note that $J_{max} = J(X = 0)$. The calculations indicate that the electrode resistance is appreciably greater than the electrolyte resistance up to about 100 μin. deposit thickness. This supports the assumption that the observed distributions in the early stages of the copper buildup reflect mainly the effects due to cathode resistance.

[3] The supplier's technical bulletin reports a limiting current density of 300 asf at 80°F without agitation, for the electrolyte used in our experiments.

Table III. Calculation of cathodic current distribution vs. mean copper thickness*

Mean copper thickness (μin.)	ϕ	J_{max}/J_{ave}

∞	0.00	1.00

* Model of Tobias and Wijsman (6).

Effect of speed and current on axial distributions.—The experimental results indicate that the plating distributions are affected by changes in tape speed or in applied current, as evidenced by variations in asymmetry factor A. To examine these variations more closely, it is useful to relate A to the measured variables. By using Eq. [2] for J_{ave} and J_{max}, the factor A for a single loop of length L, speed v, and applied current I becomes

$$A = \frac{L}{T_f - T_o}(\text{grad } T)_{max} = L \cdot v/I\, (\text{grad } T)_{max} \quad [5]$$

where $(\text{grad } T)_{max}$ denotes the maximum thickness gradient dT/dX for the loop and $T_f - T_o$ the increment in copper thickness. For two experiments at different I and v but constant L

$$A_1/A_2 = (v_1/v_2)(I_2/I_1)(\text{grad } T_1)_{max}/(\text{grad } T_2)_{max} \quad [6]$$

$$= (v_1/I_1)(v_2/I_2)^{-1}(\text{grad } T_1)_{max}/(\text{grad } T_2)_{max} \quad [7]$$

At constant speed, the A ratio is seen inversely proportional to the applied current ratio and directly proportional to the ratio of maximum thickness gradients. At constant current the A ratio is directly proportional to the speed ratio and to the ratio of maximum thickness gradients. For either speed or current variations, the plated copper increment $T_f - T_o$ will vary and thus the copper distribution curves are difficult to compare and interpret.

An important case is that in which both input and exit copper thicknesses are identical though v and I are varied. This can occur if v_1/I_1 equals v_2/I_2, thus

$$A_1/A_2 = (\text{grad } T_1)_{max}/(\text{grad } T_2)_{max} \quad [8]$$

In the plater described here we expect the kinetic and mass transfer resistances to be unaffected by the moderate speed or current level changes which have been made. For identical input and output thicknesses we expect identical T *vs.* X curves, thus the right side of Eq. [8] should equal unity and $A_1 = A_2$. A test of this assumption can be made using the correlations in Fig. 12 and 13. As an example, for speeds of 2.3 and 3.1 ft/min and input thicknesses of T_o = 10 μin., we calculate $A_1 = 18.4$, $A_2 = 12.2$ for $(v/I)_{1,2} = 0.115$; $A_1 = 15.8$, $A_2 = 12.2$ for $(v/I)_{1,2} = 0.153$; $A_1 = 14.5$; $A_2 = 14.2$ for $(v/I)_{1,2} = 0.230$. The agreement above is only fair, reflecting the approximate nature of the Fig. 12 and 13 correlations.

Single pass runs, normal configuration.—The importance of the cathode resistance in determining the axial plating distribution is readily observed in Fig. 7 and 8. The deposit asymmetry is greatest when plating the thin electroless coating but is reduced as the input copper thickness is increased. In Table I for groups I and II we observe a decrease in asymmetry factor A with input thickness. (J_{ave} in these cases is steady or increasing with thickness.) At the highest input thickness, 146 μin. in run 1/15, A becomes as low as 1.0, indicating that a uniform (linear) plating rate has been attained.

In group II, runs 1/28 and 1/29 were identical except for the input thicknesses, 3.2 *vs.* 2.8 μin., respectively. The strong dependence of the axial distribution on input thickness is seen in the higher A value for run 1/29. (The lack of complete agreement in values of J_{ave} for these two runs at the same current indicates that some run-to-run variation in copper distribution over the pattern has occurred; this type of variation is also seen in comparing several other runs of equal applied cur-

rents.) An additional factor which enhances the input thickness dependence of the axial distribution is the observed variation in electroless copper resistivity[4] with thickness, the thinnest deposits having the highest resistivity values. Thus the ohmic effects due to input thickness (resistance) will be larger than expected from the relative change in deposit thickness.

The preceding comments have generally ignored the question of interpreting the observed asymmetries in the light of changes in the applied current. The separation of asymmetry effects due to current *vs.* thickness changes is not readily accomplished and very likely requires additional experiments at constant current.

In attempting to interpret the asymmetry/thickness/current interaction, we note that the factor A, though proportional to J_{max}, does not take into account the distribution of J values along the entire loop axis. Thus the integrated effects of the asymmetry are not completely taken into account. To examine this idea further, we have defined an additional index, $F_{1/2}$, the fraction of the total plating which occurs in the input half of the plating loop.

In Table IV, we have retabulated the results from normal configuration runs at full pass length, and have added computed values $A \cdot I$ and $F_{1/2}$. The product $A \cdot I$ is a current normalized asymmetry factor (*cf.*, Eq. [5]), while $F_{1/2}$ integrates the asymmetry over each half of the plating loop. For $J_{max} = J_{ave}$, $A = 1.0$ and $F_{1/2}$ approaches (but must be less than) 0.5. In Table IV, $A \cdot I$ shows considerable scatter and does not indicate a strong correlation with input thickness above the scatter. The $F_{1/2}$, on the other hand, shows a clear correlation with input thickness. We expect that $F_{1/2}$ is relatively insensitive to current changes, provided the corresponding values of J_{max} are much less than limiting current values. We have interpreted the $F_{1/2}$ results in Table IV as supporting our basic conclusion that the plating asymmetry along the loop axis decreases with input thickness of deposit.

Single pass runs with exit field shield.—The exit field shield experiments show that peak current density can indeed be reduced (note Fig. 9A). The measured J_{max} for the runs with the shield (3/5) and without the shield (1/29) were 203 asf and 302 asf, respectively. The input tape thickness in run 3/5 was slightly less than that in run 1/29, thus the differences in maximum current density due to the presence of the shield should be even greater.

Single pass runs with added cathodes in solution.—The runs made using added cathode contacts in solution show noticeably enhanced plating rates in the vicinity of the cathode connections, note Fig. 10. They also show relatively low values of J_{max}. These reduced values are largely the result of extraneous plating, as an appreciable fraction of the applied current is consumed by deposition onto the cathode connections. Thus Faraday's law cannot be used to predict the deposit thickness in this case. As an example, in run 3/13 (Fig. 10A) with $I = 14$A at 3.1 ft/min, an average of 13 μin. Cu was added to all buses while the deposit predicted by Faraday's law is 26 μin., a reduction of 50%. Over thicker deposits, *e.g.*, run 3/14 (Fig. 10B), the copper loss was only 14% of the Faraday value. The practical application of this method awaits a useable cathode connection which can be continuously deplated of the deposited copper.

[4] J. F. D'Amico and M. A. De Angelo, unpublished results. Four-point probe measurements of ⅜ × 5 in. electroless copper-polyimide strips produced with a similar bath gave resistivity values of 21 μohm-cm at 2.8 μin., 16 μohm-cm at 3.2 μin., and 4.5 μohm-cm at 10 μin.

Table IV. Computation of $A \cdot I$ and $F_{1/2}$ for normal configuration runs at full pass length

Plater design via limits on J_{max}.—The plater design scheme outlined in Fig. 12 and 13 is presented not as a final solution but as a preliminary exercise on how to attack the continuous plating problem. The curve family which has been drawn through the available but limited data could be improved by addition of more data. We would also point out that the correlations presented are highly specific to our plater and electrolyte and should be extrapolated with caution. The lack of applicability of these results to other geometries and electrolytes restricts the usefulness of this approach and supports the formulation of a mathematical model to provide the needed generalization. The results of this work could be used to verify the predictions of such a model.

Summary

The cathodic electrodeposition of copper onto high resistance platings has been studied in a continuous copper fluoborate electroplater. The effects of cathode resistance were found to dominate the plating distribution for high input resistances, producing highly asymmetric distributions of deposits along the plater axis. These asymmetries reflect the highly nonuniform cathodic current densities produced by the ohmic effects, and are in addition to thickness variations due to the primary current distribution or to electrolyte polarization effects. As thicker, less resistive electrodes are plated, the axial asymmetries were reduced, approaching a state of uniform plating.

In view of the observed asymmetries, the peak cathodic current densities possible in the plater, even at moderate values of applied current, can be excessive and may produce degradation of the physical properties of the plated deposits. Thus the effects of high input resistance must be carefully considered in the design and operation of this type of system.

A plater design scheme for continuous plating in copper fluoborate has been presented. This scheme, based upon imposed limits in cathodic current density, should prove useful as a starting point for the analysis of other continuous plating systems, and should provide a valuable input for the development of a theoretical model.

For any substrate-electrolyte combination, a definitive determination of cathodic current density *vs.* product quality must be developed as corollary information if a proper plating design is to be achieved.

Acknowledgments

The authors gratefully acknowledge Mr. F. McLarnon for his valuable critique, suggestions, and assistance, especially in the application of the Tobias-Wijsman model to this problem. They also acknowledge Mr. L. R. Johnson for his technical assistance during plater operations and tape sampling.

Manuscript submitted June 17, 1975; revised manuscript received Nov. 17, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the Western Electric Company.

Mass Transfer on Horizontal Wires in the Presence of Free and Combined Forced and Free Convection

Aladar Tvarusko*

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

Mass transfer was measured on horizontal copper and nickel wires (0.51 and 0.25 mm diameter) in acidified $CuSO_4$ and alkaline ferro-ferricyanide solutions, respectively, in the presence of forced and free convection. The mass transfer measurements were made in practical overflow cells of two sizes over a limited range: $1422 < Sc < 3433$, $0.112 < Re < 4.40$, $0.023 < Gr < 16.6$, $37.9 < Ra < 5.7 \times 10^4$. The mass transfer was proportional to $Re^{0.4}$ and its magnitude was markedly affected by the concentration of the solution. Both forced and free convection are operative in most of the present forced-convection mass transfer measurements which correlate well if plotted as $(Sh/Re^{1/2})(Re^2/Gr)^{1/2}$ against $Gr/(Re^2Sc^{1/3})$. It is to be noted that the boundary layer thicknesses and the wire diameters are of comparable magnitude.

Heat and mass transfer to circular cylinders (tubes, wires) are of great technological importance and have been studied in various fluids under various geometrical and hydrodynamic conditions (1-3). The applications range from hot-wire anemometers (4) through heat-exchangers to chemical vapor deposition (5) and electrodeposition (6). Vertical and horizontal circular cylinders have been mostly studied.

Since heat and mass transfer are analogous, the results of either are of considerable interest to both. Most of the heat transfer measurements to horizontal cylinders, however, were done in air, *i.e.*, at a low Prandtl number ($Pr \simeq 0.7$). The application of these heat transfer data to mass transfer in liquids of high Schmidt numbers ($Sc \geqq 1000$) is frequently not successful because of the marked influence of Sc on the processes involved (1-3).

The magnitude of mass and heat transfer is markedly affected by the fluid flow present. Heat and mass transfer measurements were made over a wide range of forced convection, $10^{-5} < Re < 10^6$ and natural or free convection, $10^{-9} < Gr < 10^9$, $10^{-9} < Ra < 10^{11}$ (1-3, 7). The present mass transfer measurements were made over a limited range: $1422 \leqq Sc \leqq 3433$, $0.112 \leqq Re \leqq 4.40$, $0.023 \leqq Gr \leqq 16.6$, $37.9 \leqq Ra \leqq 5.7 \times 10^4$. The author is unaware of any mass transfer measurements on horizontal cylinders under the aforementioned natural convection conditions. The mass transfer data of Dobry and Finn (8) are the only ones which were measured under forced convection conditions ($Sc \simeq 1200$, $0.023 \leqq Re \leqq 8.1$) similar to those used in the present study. These data and other relevant heat transfer correlations are described in connection with the discussion of the present data.

In most heat and mass transfer measurements either the forced or free convection dominates and the other can be neglected. At certain combinations of Re, Gr, and Sc (Pr) numbers, however, both forced and free convection must be taken into consideration. Heat and mass transfer to horizontal cylinders have been studied in the presence of the extremely complex mixed convection in air (2-4, 7, 9-13) and reacting gases [$Pr \sim 1$, (5, 14, 15)], respectively. The mixed (combined) convection heat transfer has been theoretically analyzed for various Prandtl numbers (7, 16-18).

The subject of this paper is the mass transfer to horizontal copper and nickel wires in aqueous electrolytes of two types in a simple, practical overflow cell of two sizes in the presence of free and combined forced and free convection. The mass transfer is correlated in terms of appropriate dimensionless numbers.

Experimental

A large portion of past heat and mass transfer studies on cylinders was made in carefully chosen geometries, such as a circular tube of large diameter with a large hydrodynamic entrance region which usually facilitated the correlation of the results. Cells or containers for these heat and mass transfer measurements are usually designed to maintain the fluid flow constant and well defined at and near the body being studied. This is not always the case in practical cells where other aspects must also be taken into considera-

* Electrochemical Society Active Member.

Key words: mass transfer, wire, free convection, combined forced and free convection.

tion (*e.g.*, engineering, economics). This means that the fluid flow in a cell is not necessarily well defined in a hydrodynamic sense but is characteristic for the cell in question.

The overflow cell, shown schematically in Fig. 1, is one of the simplest and most frequently used electrochemical cells. The solution enters near its bottom and flows through the cell and over some of its inner walls. Overflow cells of two lengths, L, 8.2 and 45.7 cm, and fluid flow cross-sectional areas, S, 38.7 and 667.7 cm^2, respectively, were used. The design of these cells has been described in detail earlier (6, 19). Since the equivalent diameter of both overflow cells (using any definition) is greater than the entrance region, *i.e.*, the distance between the horizontal wire and fluid entrance, the fluid flow cannot be considered to be fully developed. However, in view of the small average fluid velocities, U, used in these overflow cells (0.026-0.90 cm/sec) and the small wire diameters in a large volume of fluid in the cell (large S), the fluid flow for all practical purposes is considered to be more or less uniform along the wire except at the highest U values in the long cell (0.036M $CuSO_4$, 0.36M H_2SO_4 solution).

The fluid after entering the cell suddenly expands, flows through it toward the overflow(s) at one or both end walls, and the angle of attack (the angle between stream direction and cylinder axis) at the wire may deviate from normal. According to Kutateladze (20), the heat transfer from a cylinder remains practically constant in the range of $90° \pm 20°$ angle of attack outside of which it decreases substantially. In view of this and the small U values, the relatively large fluid volume in the cell, the small wire diameters, and the obtained results, the flow can be considered to be practically normal to the wire.

The mass transfer rates on the horizontal wires were obtained electrochemically by measuring potentiodynamically the cathodic limiting current density, I_L. The experimental details were described earlier (6, 21). Nickel and copper wires of 0.25 and 0.51 mm diameter, d, respectively, were used for the mass transfer measurements.

The I_L values were obtained in two types of aqueous solution. One was a deaerated 0.005 equimolar solution of the potassium ferro- and ferricyanide redox couple in 1M KOH and will be designated as 0.005M. The ferricyanide anion is reduced and only electron transfer takes place at the cathode. In the other solutions, the metal ion is reduced on the cathode to metal and removed from the solution. These solutions contained various amounts of $CuSO_4$ and ten-fold H_2SO_4. In both types of solution, the species to be reduced must diffuse through the diffusion layer to the cathode whereas only the ferrocyanide has to diffuse toward the bulk solution. Since the electroneutrality condition must be fulfilled, the concentration of the other species will also change in the diffusion layer(s) and must be estimated, especially in the case of free convection (22-25).

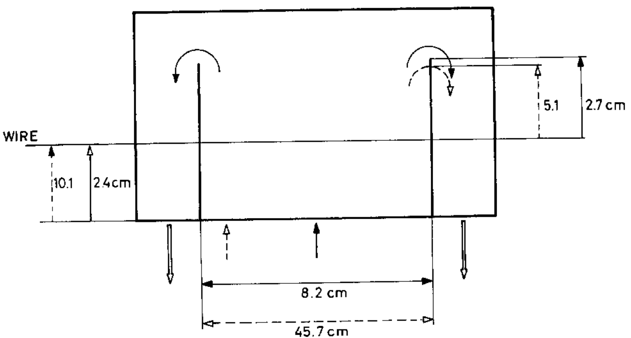

Fig. 1. Schematic diagram of an overflow cell. The solid and dashed lines indicate the most pertinent dimensions and fluid flow in the small and large overflow cell, respectively.

Free or natural convection is caused by the difference in solution density at and near the surface, $\Delta\rho$. These values were calculated by the procedure of Selman and Newman (23, 24) who state that the density difference calculated by the traditionally used method of Wilke, Eisenberg, and Tobias (25) can lead to appreciable errors. These two methods predict very different sulfuric acid concentrations at the cathode (23, 24) and thus, different $\Delta\rho$ and Gr values are obtained. A complete dissociation of bisulfate ions to sulfate and hydrogen ions was assumed in the present calculations. The densities, viscosities, and diffusion coefficients of the solutions were calculated using the appropriate equations of Fenech and Tobias (26) and Gordon, Newman, and Tobias (27).

The data of Selman-Newman (23, 24) are strictly valid for the vertical electrode whereas the present mass transfer measurements relate to a horizontal electrode. Their estimation method for the interfacial concentrations is quite general and can be applied to other than vertical configurations by changing the power according to which the mass transfer coefficient, k, depends on the respective diffusion constants (23). According to Boeffard (28), the exponent in question is 2/3 for free convection at horizontal electrodes whereas it is ¾ for vertical electrodes (23). The effect of this power change was calculated using the traditional Wilke-Eisenberg-Tobias procedure (25). The interfacial ferrocyanide concentrations were calculated (28) to be within 2% of each other for these two powers. In the case of the acidified $CuSO_4$ solutions, the difference in the Grashof numbers deviated by less than 2%; this was calculated with the densification coefficients, α, of Selman and Newman (23, 24) using the formula of Fouad and Ibl (29). In view of these small errors in the interfacial concentration estimations, the data calculated by the Selman-Newman procedure were used in this study without any correction.

The dimensionless numbers were calculated with mean fluid properties (ρ, μ, ν, D), averaged between the bulk solution and electrode surface. The normalized density difference for Gr was calculated with fluid properties as required. The wire diameter was used for the characteristic length.

Results and Discussion

Forced convection.—The limiting current densities were measured on two wires in two different solutions of various concentrations in overflow cells of two lengths. Figure 2 shows I_L to increase linearly with the

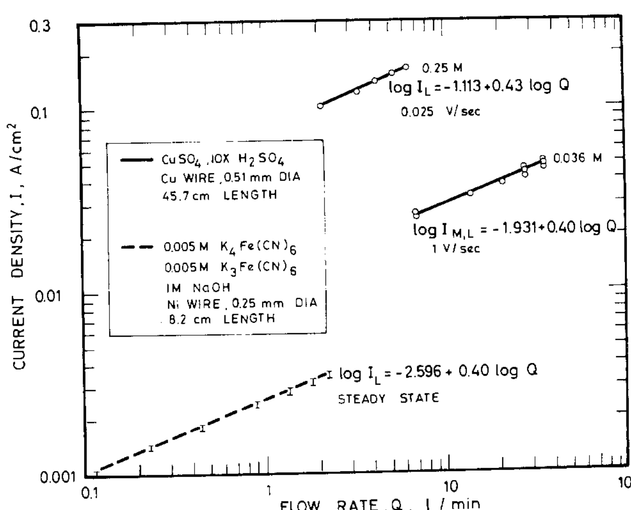

Fig. 2. Limiting current density as a function of volumetric flow rate in overflow cells of two sizes.

volumetric flow rate, Q, in a logarithmic plot in all cases. The slope is 0.40 at low concentrations regardless of the nature of the electroactive species and solution, cell length, and wire characteristics, but increases to 0.43 for the concentrated solution. The magnitude of I_L is markedly affected by the concentration of the electroactive species as expected.

The same I_L values are obtained under most conditions by steady-state and potentiodynamic measurements in a large number of simple redox and metal salt solutions (30). The steady-state I_L values are obtained from potentiostatic pulses located along the I_L plateau in the I-V curves. It is more convenient to obtain I_L potentiodynamically. The I_L plateau is present only at low sweep rates of potential whereas at greater sweep rates I goes through a maximum and subsequent minimum (21, 31). It was shown elsewhere (31) that the I maximum and minimum (I_M) in the I-V curve are absent in the presence of fluid flow at markedly greater sweep rates than usually used. The permissible sweep rate increases with increasing fluid flow rate. The higher sweep rate leads to the minimization of the surface change along the I_L plateau in the presence of electrodeposition and also to time saving. The I-V curves for the 0.036M acidified $CuSO_4$ contained a shallow, very small current dip (I_M) at the lowest flow rate at 1 V/sec sweep rate but I_M was absent at higher Q. The I_L-Q correlation is not affected by taking these I_M values of negligible difference at the lowest flow rate used.

$Sh/Sc^{0.3}$ is widely used for the correlation of heat transfer. Figure 3 shows the data of Fig. 2 replotted in terms $Sh/Sc^{0.3}$ and Re. It contains also the I_L values obtained in acidified $CuSO_4$ solutions of various concentrations flowing at 6 liter/min which were described elsewhere (31). It is obvious that correlation of the present data is not satisfactory; the pre-exponential factors of the two extreme curves differ by a factor of two.

Figure 3 also shows some of the relevant heat and mass transfer correlations. Dobry and Finn (8) measured the I_L values in approximately 0.002M equimolar ferro-ferricyanide solutions with supporting electrolytes on 0.13 mm diameter Pt, Ni, and Cu wires and 0.025 mm diameter Cu wire. The equation given in Fig. 3 was obtained by regression analysis of all their data [Table I (8), using their solution properties]. The slope of this regression line is the same as those of the present data. The magnitude of their mass transfer however, is considerably smaller than that of the present study.

The broad-based heat transfer equations of Ulsamer [(32), recalculated from $Sh/Sc^{0.31}$ to $Sh/Sc^{0.3}$] and McAdams (1) are shown in Fig. 3 to be situated between the mass transfer data of Dobry and Finn (8) and the present ones. The heat transfer correlation for water by Piret *et al.* (33) is also shown. It can be seen that the indicated correlations predict practically similar heat transfer values at Re of interest here even though their coefficients differ markedly; this is possible for these forms of equations (4).

The discrepancy between these data and the present results is considerable. The greater mass transfer values could be due to the presence of upstream turbulence of the free stream and flow nonuniformity. The effect of turbulence was calculated by the Galloway-Sage equation modified by Brauer (3) and the results are shown in Fig. 4 in terms of the frequently used $Sh/Sc^{1/3}$ ratio. This equation is given in Fig. 4 and is valid in the range of $10^{-2} < Re < 4 \times 10^5$ and $0.73 < Pr < 300$. In view of the Pr limitation and Sc values of the present study (up to an order of magnitude greater), the results plotted in Fig. 4 can be considered only as approximative. The influence of Sc is small and is illustrated by the two $Tu = 0$ curves where Tu, the intensity of turbulence, is the ratio of the root mean square of the velocity fluctuation and time-mean main-stream velocity (34, 35). Therefore, the effect of turbulence intensity is shown only for Sc of the acidified 0.25M $CuSO_4$ solution. It can be clearly seen in Fig. 4 that the turbulence intensity cannot account for the present greater mass transfer in the Re region of interest, not even at the high $Tu = 0.2$; $Sh/Sc^{1/3}$ increased only by an additional 15% when Tu was increased to unity and is not shown. This is naturally subject to the assumption that the validity of the Galloway-Sage/Brauer equation can be extended to Sc of interest here without great error. It is to be noted that the magnitude of the error is likely to be smaller for an extrapolation from $Pr \sim 300$ than only from $Pr \sim 0.7$. Furthermore, the effect of turbulence intensity at small Sc becomes significant only at significantly higher Re ($\sim 10^4$).

It was mentioned earlier that the fluid flow is likely nonuniform near the horizontal cylinder (because of the short entrance region) especially in the acidified 0.036M $CuSO_4$ solution. The mass transfer measurements clearly reveal (Fig. 3 and 4) that the data for the slower flowing acidified 0.25M $CuSO_4$ are greater than those for the aforementioned solution. In view of this and the same functional dependence of Sh on Re (power of 0.40-0.43) at low flow velocities, it can safely be assumed that the nonunformity of fluid flow is not responsible for the deviation of the measured mass transfer.

Wire vibration could also be the cause of the greater mass transfer. However, no wire vibration was observed by the naked eye and the data in the acidified $CuSO_4$ solutions in the same cell would again be con-

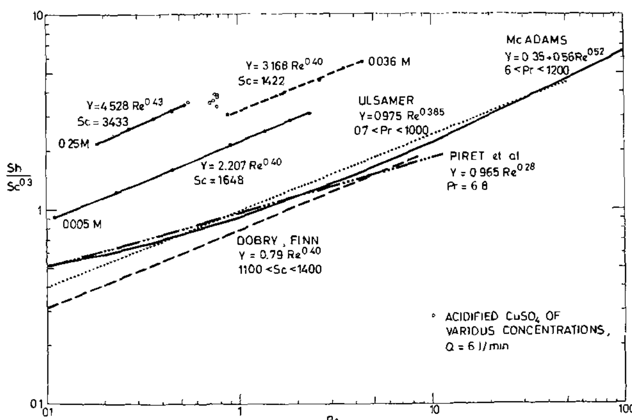

Fig. 3. Mass and heat transfer on horizontal cylinders in forced convection. The experimental data and the relevant correlations are expressed as $Sh/Sc^{0.3}$.

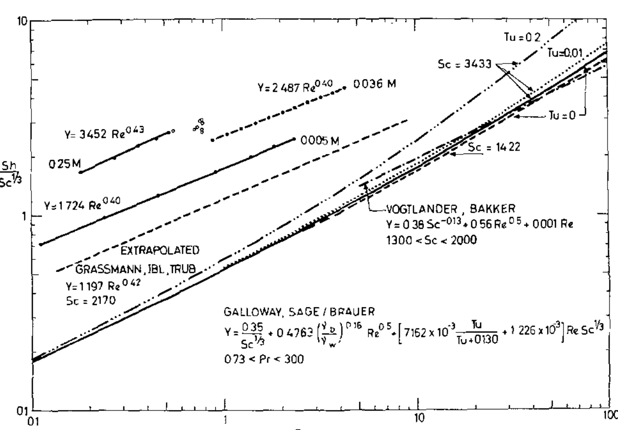

Fig. 4. Mass and heat transfer on horizontal cylinders in forced convection are given as $Sh/Sc^{1/3}$. The effect of turbulence intensity is calculated by the Galloway-Sage equation modified by Brauer.

tradictory. Furthermore, van der Hegge Zijnen (35) states that his data for turbulent air "show that the heat transfer from a wire vibrating in the direction of a uniform flow is somewhat lower than the heat transfer of a stationary wire in the same flow." In view of this, wire vibration is ruled out as being the cause for the deviation.

Figure 4 also shows the correlating equation of Vogtländer and Bakker (36) who measured the I_L in alkaline ferro/ferricyanide solution on short wires ($0.5 < d < 1$ mm, $L \sim 20$ mm) at higher Re ($5 < \text{Re} < 100$). The extrapolation of their data to Re of interest here would yield considerably lower mass transfer than measured here. On the other hand, the extrapolated data of Grassmann, Ibl, and Trüb (37) for thin cylinders ($d = 5$ mm, $L = 40$ mm, $200 < \text{Re} < 6000$) are closer to the present data even if the cylinder blockage is considered in the calculation of the fluid velocity (36). The data extrapolated from the correlation ($\text{Sh}/\text{Sc}^{1/3} = 0.508\ \text{Re}^{0.5}$) of Rao, Raju, and Rao (38) for horizontal cylinders ($2.6 < d < 7.6$ mm, $L = 50$ mm, $100 < \text{Re} < 4000$, reduction of ferricyanide) fall just below the Galloway-Sage/Brauer curve at $Tu = 0$ and run parallel to it. They found that the mass transfer rate increased with decreasing cylinder diameter. The extrapolation of the mass transfer data to smaller Re is questionable, especially in view of the reported change in the form of the Nu-Re relationship taking place at $\text{Re} = 44$ (4).

The correlations up to now contained Sc to power 0.3 or 1/3. Two correlations contain Sc to 0.4 power which are shown in Fig. 5 together with the present data. Kutateladze's equation is valid at $5 < \text{Re} < 80$ and $\text{Pr} \neq 0.72$ (20) and Nu is proportional to $\text{Re}^{0.4}$ just as found in the present data. The pre-exponential factor for the least concentrated solution (0.005M) is 14% higher than that of Kutateladze and considerably higher for the other two solutions. Kutateladze states that the validity of his equation is confirmed by experiments of various authors. The correlation of Perkins and Leppert (39) is valid at $\text{Re} > 40$, and $0.7 < \text{Pr} < 300$, and is close to that of Kutateladze in the overlapping region.

Hatton, James, and Swire (4) recently measured the heat transfer on horizontal cylinders ($0.1 < d < 1.26$ mm, $L = 121$ mm) in forced air ($10^{-2} < \text{Re} < 45$) the direction of which was parallel, counter, or normal to the direction of gravity. Assuming a $\text{Sc}^{0.4}$ dependence for the heat transfer, the equation in Fig. 5 was obtained for the present case, *i.e.*, the forced flow is parallel with the direction of the free convection flow (counter to gravity). Their original equation contains a temperature loading factor the neglect of which (and its analogous ratio of kinematic viscosities) results in a maximum difference of -0.4% in the magnitude of Nu. Their curve runs close to the other two from literature (Fig. 5) and intersects the line for the least concentrated solution. They state that their correlation predicts higher Nu at $\text{Re} < 5$. The assumption of the $\text{Sc}^{0.4}$ dependence of Sh is arbitrary since the heat transfer was measured only in air.

The separation of the data is not eliminated by increasing the power of Sc to 0.4 but the agreement of the data for the least concentrated solution has markedly improved. The deviation of the present data increases with the increasing concentration of the electroactive species. This clearly indicates the influence of a concentration-dependent variable which is the density difference. This determines the magnitude of the free convection the presence of which is clouded by the good correlatability of Sh with Re in all three solutions. Before discussing the combined forced and free convection, the results of free convection are discussed.

Free convection.—The local and over-all heat and mass transfers on horizontal circular cylinders under free convection have been widely studied [(1-3, 13, 40-42) and references therein]. The local heat and mass transfer around the circumference of the cylinder is very complex because of the presence of hydrodynamically stable and unstable conditions at the two extreme vertical positions and their combinations of various degrees around the circumference. The local heat and mass transfer is considerably higher in the hydrodynamically unstable region than in the stable region which in the present case (cathodic reduction) roughly corresponds to the upper and lower halves of the cylinder, respectively. This is well documented in the literature (3, 40, 41).

The over-all Sh is usually plotted as a function of Ra. Figure 6 shows the various correlations of the literature [(1, 3, 9), Tsubouchi, Masuda through Ref. (4)] which are different and their coefficients vary but the physical shape of the curves changes only little. The experimental data, obtained in acidified solutions of various $CuSO_4$ concentrations (31), are more or less parallel to the correlations (dashed line) at the upper end of Ra studied whereas at the lower end of Ra the decrease of Sh with decreasing Ra is small (solid regression line). It is to be noted that Nagendra *et al.* (43) obtained a similar heat transfer behavior on vertical cylinders, *i.e.*, the power of the Ra d/L group decreased from 0.25 (short cylinders) with decreasing values of this group (Ra is diameter-based). Nu was found to be proportional to $(\text{Ra}\ d/L)^{0.16}$ for long cylinders and 0.05 was the power for wires. In view of the closeness of the correlations for vertical and horizontal cylinders (1, 2), such a behavior could be expected for both cylinder orientations.

The experimental data are greater than those predicted by the heat transfer correlations (Fig. 6). According to Gebhart and Pera (13), the heat transfer

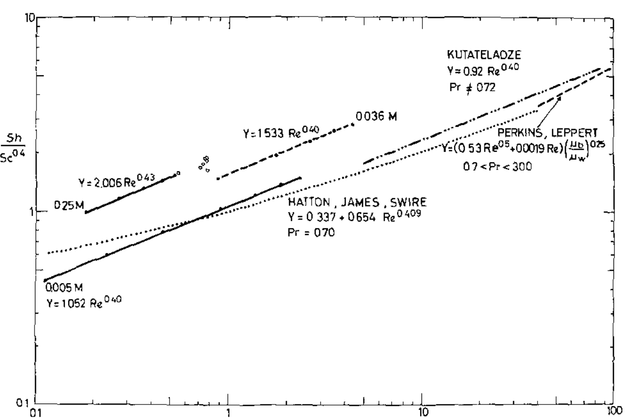

Fig. 5. Mass and heat transfer on horizontal cylinders in forced convection are shown as $\text{Sh}/\text{Sc}^{0.4}$. The correlations are given in their range of validity.

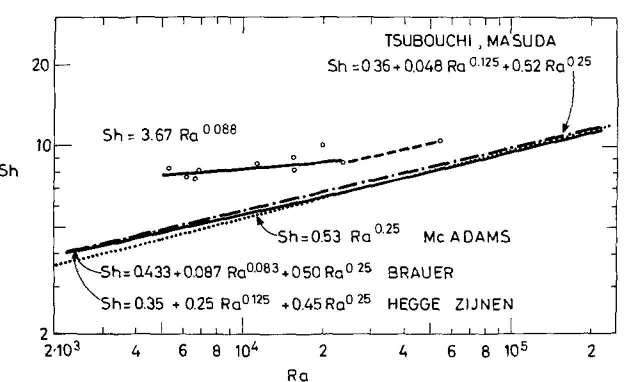

Fig. 6. Heat and mass transfer on horizontal cylinders in the presence of free convection as a function of Rayleigh number.

data at various Pr do not correlate well in the presence of natural convection and a systematic deviation of the data with Pr can be observed in past correlations (the $Ra < 10^{-2}$ range is discussed). On the other hand, the mass transfer data in the range of $Ra > 10^6$ are also somewhat above the corresponding heat transfer values [Fig. 7.13 in (3), (40, 42)].

It is to be noted that the boundary layer thicknesses are comparable to the wire diameter magnitudes. Therefore, only qualitative similarity can be expected with the results where the boundary layer thicknesses are very small in comparison to the cylinder diameter.

Combined forced and free convection.—In most heat and mass transfer cases, either the forced or free convection is dominating and the other can be neglected. Under certain conditions, however, both convections must be taken into consideration. It was shown that the mass transfer increases with increasing forced convection ($Sh \propto Re^{0.4}$) and the magnitude of mass transfer (Sh/Sc^m, $0.3 \leq m \leq 0.4$) increases with increasing concentration of the electroactive species and the deviation is considerable. These aspects and the magnitude of Sh in the presence of free convection point toward the influence of both convections.

Heat transfer in the presence of combined (mixed) convection was studied on horizontal cylinders by several authors (2-4, 7, 9, 10-13) but the mass transfer was investigated only in the gas phase up to now (5, 14, 15). The local and over-all heat transfer in the presence of combined convection was also studied theoretically (7, 16-18). The heat and mass transfer is often correlated as a function of the vectorial sum of forced and free convection parameters (4, 5, 9, 14, 15). The vectorial addition is relevant only for the parallel forced and free convection flow (7). According to Acrivos (16), the two transfer mechanisms, however, are nonadditive and the transition between the two pure convections is gradual, especially at high Pr. The present mass transfer data could not be correlated on the basis of vectorial addition of Gr and Re.

The heat transfer on horizontal cylinders in the presence of combined convection is usually correlated as a function of the parameters Gr/Re^2 (2, 3, 11, 12, 16, 17), $Gr/Re^{2.5}$ (10, 18), or $Pr\ Re^3/Nu\ Gr$ [to various powers at very small values of Re and Gr (7)]. Free convection is negligible if $Gr/Re^2 \rightarrow 0$ and the forced convection can be neglected if $Gr/Re^2 \rightarrow \infty$. The influence of free convection is said to be negligible for a flat plate at $Gr/Re^2 < 0.02$ for all Pr (16) or when the measured Nu values on horizontal cylinders are within 5% of the calculated parallel forced-flow values in air, *i.e.*, $Gr/Re^2 < 0.28$ (11) or <0.10 (12). The range of present mass transfer data is $0.0042 < Gr/Re^2 < 500$ which means that almost all data are within the combined convection zone. The correlation of Gr/Re^2 *vs.* Sh normalized to a calculated pure forced-convective Sh (11, 12) or pure free-convective Sh shows a marked improvement over the correlations with vectorial addition of Gr and Re but is still not completely acceptable; its success depends entirely on the use of proper convective correlations which represent the data well.

According to Acrivos (17), the combined convection problem at large Pr values is characterized by the $Gr/(Re^2Pr^{1/3})$ group. The upper curve in Fig. 7 shows the present mass transfer data plotted as $(Sh/Re^{1/2})(Re^2/Gr)^{1/2}$ against $Gr/(Re^2Sc^{1/3})$ instead of the originally proposed Gr/Re^2 group (16). The data fall on a single curve the form of which is the same as the form of curves given by Acrivos for a vertical flat plate in an upward forced flow of fluid with $Pr \leq 100$ (16). According to a subsequent analysis by Acrivos (17), the results given in his earlier paper (16) were "substantially in error" at high Pr values where the presence of two distinct boundary layers (heat transfer and hydrodynamic) was not accounted for. The magnitude of the error is unfortunately not given and therefore, no comparison can be made.

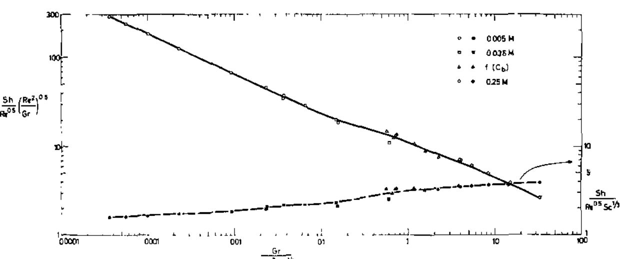

Fig. 7. Correlation of the present mass transfer data in the presence of combined parallel forced and free convection.

Acrivos (17) derived for general surface geometries that $Nu_l/(Re^{1/2}Pr^{1/3})$ is a function of $Gr/(Re^2Sc^{1/3})$ where Nu_l is the local Nusselt number. Since the local and over-all heat and mass transfer equations are of similar forms, the over-all mass transfer values of the present study were also expressed as $Sh/(Re^{1/2}Sc^{1/3})$ and are plotted in Fig. 7 as a function of $Gr/(Re^2Sc^{1/3})$. This curve is similar to the curve given by Acrivos for the local heat transfer in the stagnation region of a constant temperature heated horizontal cylinder with upward flow at $Pr \rightarrow \infty$. The spread in the transition region between the pure forced and free convection zones ($Gr/(Re^2Sc^{1/3}) \sim 1$) is somewhat greater than in the corresponding region of the upper curve. Furthermore, the data at higher $Gr/(Re^2Sc^{1/3})$ values do not fall close to the assumable pure free convection asymptote (17). In view of the definite forced convection dependence of the mass transfer even at the highest Gr (0.25M solution), this deviation is not surprising. The effect of the forced convection seems to be better accounted for by the $(Sh/Re^{1/2})(Re^2/Gr)^{1/2}$ group than by the other group. It is unfortunate that these two curves (Fig. 7), which represent the present data well, cannot be directly and quantitatively compared with those of Acrivos (16, 17).

Conclusions

Mass transfer in aqueous solutions in practical overflow cells increased with increasing forced convection and was proportional to the 0.40-0.43 power of the fluid flow; this is in good agreement with some of the previous correlations. The magnitude of mass transfer, however, was markedly higher in both forced and free convection than predicted by the various correlations given in the literature, and the difference increased with increasing concentration of the electroactive species. In most of the present forced-convection mass transfer measurements both forced and free convection are operative. The effect of the combined convection on the present mass transfer data could not be correlated on the basis of vectorial addition of Gr and Re whereas the normalized Sh (to a pure forced-convective Sh) Gr/Re^2 curves yielded improved but still not completely acceptable correlations. The relations developed by Acrivos (16, 17) correlate the present mass transfer data well especially if plotted as $(Sh/Re^{1/2})(Re^2/Gr)^{1/2}$ against $Gr/(Re^2Sc^{1/3})$.

It is to be noted that the boundary layer thicknesses are comparable to the wire diameters used, and therefore only qualitative agreement can be expected with results for which the boundary layer thicknesses are small in comparison to the cylinder diameter. Furthermore, the theoretical correlations assume that the fluid properties remain constant in the boundary layers with the exception of fluid density. In order to account for fluid property changes in the boundary layers, the various dimensionless numbers were correlated with mean fluid properties.

It is shown that the data obtained in practical overflow cells can be correlated well by the relationship

developed, through and for carefully and purposely chosen experimental conditions and designs.

Discharge Mechanism of MnO_2 Electrodes as Influenced by the Solubility of the Reaction Products

Paul Ruetschi*

Leclanché S.A., 1400 Yverdon, Switzerland

ABSTRACT

An ultrathin electrolytic cell has been used to study by means of microscopic observation morphological changes of MnO_2 particles at magnification of $1500\times$ *in situ* during discharge in various electrolytes. It is shown that the solubility of three-valent manganese species plays an important role in certain electrolytes, depending on pH. The discharge mechanism is discussed in the light of the observed dissolution and on the basis of x-ray data of the solid reaction products.

Morphological changes occurring during electrochemical reduction of MnO_2 particles are difficult to observe by conventional microscopic means since the individual particles are very small and since MnO_2 electrodes contain normally acetylene black or graphite, which reduce optical contrast to unacceptable levels.

Experimental

Recently, an ultrathin electrochemical cell was described (1) which allowed optical observation of electrode reactions *in situ* at maximum magnification. This technique was applied in the present study to MnO_2 electrodes.

The ultrathin MnO_2 electrodes were prepared by suspending 100 mg of finely ground electrolytic γ-MnO_2 (Tekkosha Type HH, BET area 43.2 m^2/g) in 1 ml of chloroform and dipping a 2 mm wide and 20 mm long strip of very fine Ni or Pt screen (wire diameter 0.05 mm, 300 mesh) into this slurry. After drying, there remained 0.2-0.6 mg of MnO_2 on the screen. The electrode was then compressed at 5000 kg between polished steel dies and mounted flat, by means of epoxy resin, on a microscope slide, side by side with ultrathin counter- and reference electrodes. These latter consisted of 2 mm wide, 20 mm long, and 0.05 mm thick foils (Goodfellow Metals Ltd., Ruxley Towers, Claygate-Esher, Surrey, England) of amalgamated zinc (for KOH, NH_4Cl, and $ZnCl_2$ solutions) or of electroformed porous lead (for H_2SO_4 solutions). A cover glass of 0.15 mm thickness was placed on top of the electrodes and epoxy resin was applied around its periphery, effectively sealing the cell. The cell was filled with electrolyte through an intentional opening in the epoxy seal by applying vacuum (Fig. 1).

The electrodes were discharged at slow linear potentiodynamic sweep (3 mV/min) using a Wenking potentiostat 68 TA 1 and scanning potentiometer SMP 69. Photographs were taken at $1500\times$ optical magnification using oil immersion, a $100\times$ objective lense, vertical illumination through the microscope tube (Metallurgical Microscope Olympus, Type MF), and a Polaroid Type 107 film.

Alkaline Solutions (KOH 10.2M)

Two peaks (Fig. 2) were observed in the current-voltage diagram (2), the first at 1.3V *vs.* Zn/ZnO and the second at 0.9V *vs.* Zn/ZnO. During the first peak no change in the shape of the original MnO_2 particles was observed. However, sudden dissolution of the grains started during the descending branch of the peak. Finally, only the bare substrate remained. During the second peak small hexagonal platelets of $Mn(OH)_2$ began to crystallize out of solution onto the substrate (Fig. 3).

Growth of hexagonal crystals of $Mn(OH)_2$ can be followed even better in Fig. 4, obtained under similar conditions, Patience and luck combined determined if a good spot was chosen for one picture series.

The observation that partially reduced MnO_2 becomes quite soluble in KOH is of practical importance with respect to the self-discharge behavior and voltage recovery on open circuit of commercial alkaline cells.

The reaction mechanism in KOH can be represented as follows (3)

$$MnO_2 + H_2O + e^- \xrightarrow{\text{Reduction}} MnOOH + OH^- \quad \text{(first peak)}$$

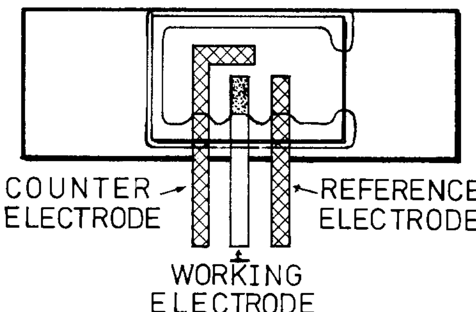

Fig. 1. Ultrathin cell for optical observation of electrode processes at 1500X magnification, viewed from the top.

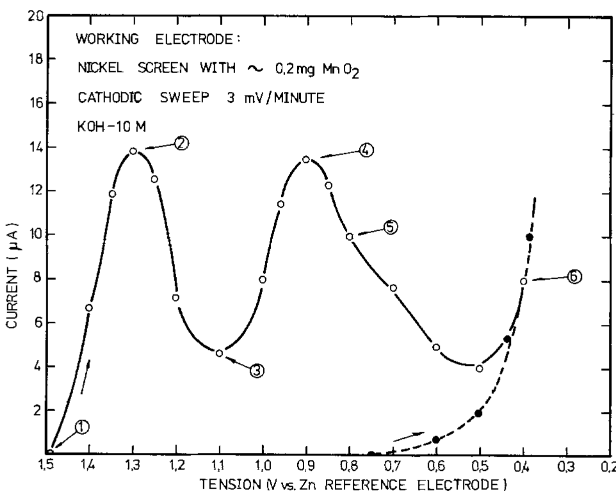

Fig. 2. Linear potentiodynamic cathodic sweep at 180 mV/hr in 10.2M KOH. Dotted line is run without MnO_2.

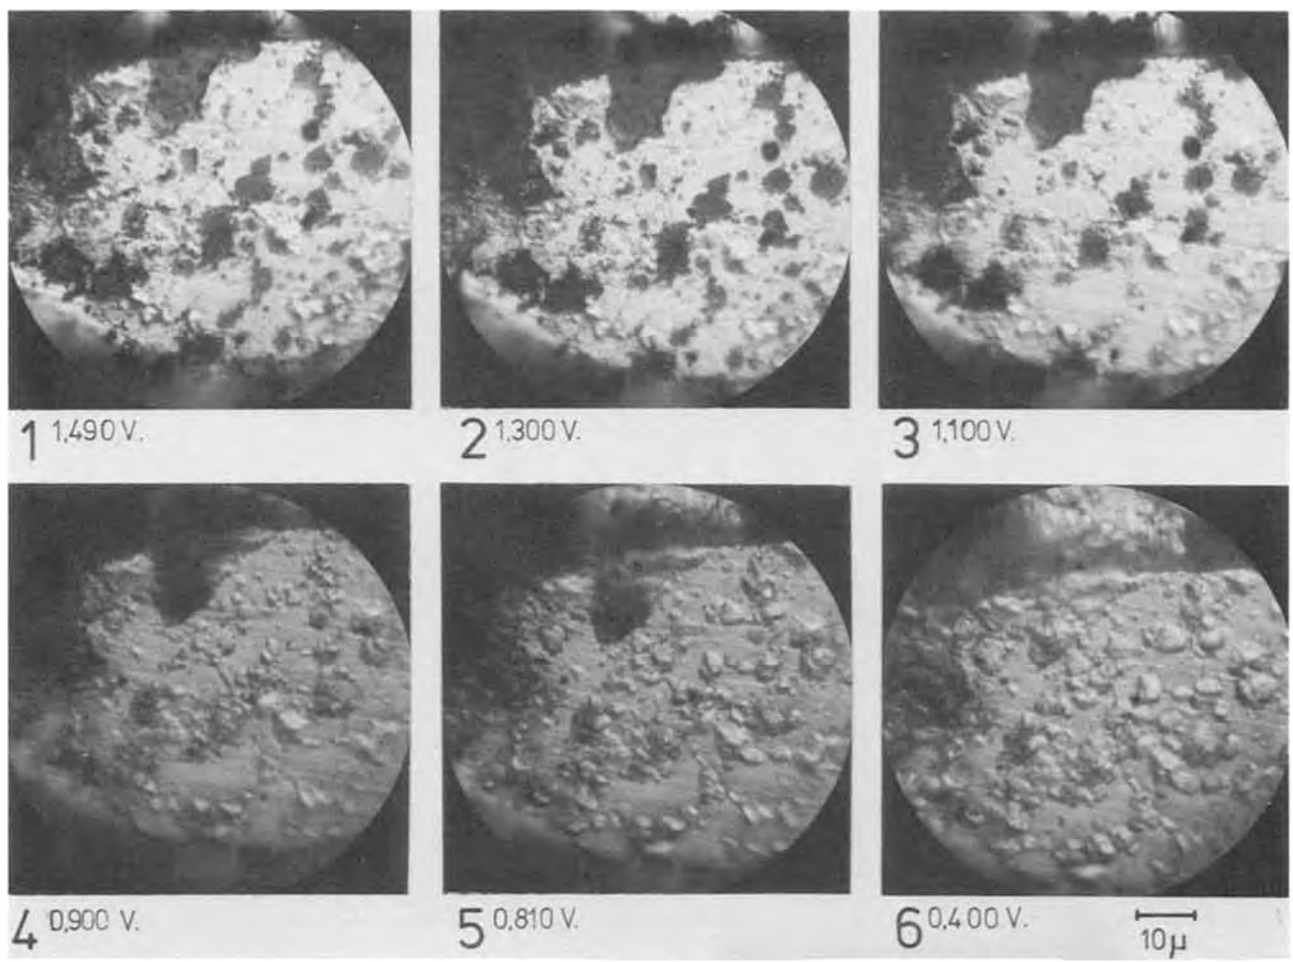

Fig. 3. Dissolution of MnO_2 upon reduction in 10.2M KOH. Optical magnification 1500X. Pictures refer to the indicated points in Fig. 2

$$MnOOH + H_2O + OH^- \xrightarrow[\text{Dissolution}]{} Mn(OH)_4^-$$

$$Mn(OH)_4^- + e^- \xrightarrow[\text{Reduction}]{} Mn(OH)_4^{-2} + (\text{2nd peak})$$

$$Mn(OH)_4^{-2} \xrightarrow[\text{Crystallization}]{} Mn(OH)_2 + 2\,OH^-$$

The height of the first current peak may vary from one run to the next, depending on the extent and strength of bonding achieved between substrate and MnO_2 particles. No binders, and no carbon blacks or graphites, were used in these ultrathin electrodes, in order to facilitate optical observation.

In some runs, the nickel screen substrate was replaced by a thin pyrolytic graphite foil. Optical contrast was very poor and the second peak was much reduced in height, or disappeared completely. This means that reduction of $Mn(OH)_4^-$ requires a catalytically active, extended surface area.

The current decrease after the first peak is in part due to γ-MnO_2 depletion and in part to the formation of resistive MnOOH layers between remaining MnO_2 grains and substrate.

The reaction mechanism shown above is supported by x-ray data, obtained with larger MnO_2 samples (200 mg), pressed into a nickel screen electrode and reduced potentiostatically for 2 weeks at +0.7V *vs.* Zn in 10.2M KOH. Reflections due to γ-MnOOH (manganite) were readily apparent. Furthermore, strong lines corresponding to α-MnO_2 (cryptomelane) were visible. The α-MnO_2 was apparently formed by reoxidation of $Mn(OH)_4^-$ and $Mn(OH)_4^{-2}$ ions in the presence of K^+ ions, on MnO_2 grains not in electrical contact with the substrate Ni screen. Such secondary processes, including also precipitation of Mn_3O_4 (hausmannite) from solutions containing both two- and three-valent manganese species, are not considered here, although they might be occurring in technical electrodes.

In order to detect and demonstrate the presence of reducible, three-valent manganese in solution, some ultrathin cells were mounted with an additional sensing electrode near the working electrode. The sensing electrode consisted of a 0.05 mm thick platinum foil, held potentiostatically at +0.7V *vs.* the Zn reference. The current to the sensing electrode was monitored and was found to increase from near 0 to 40 nA as the current to the working electrode decreased, following the first peak.

Neutral Solutions (5M NH_4Cl or 3.5M $ZnCl_2$)

Only one single peak (at 1.35V *vs.* $Zn/ZnCl_2$) was discernible during the cathodic sweep (Fig. 5). Dissolution of MnO_2 particles became apparent only after the peak, at 1.2V *vs.* $Zn/ZnCl_2$ (Fig. 6). No precipitation or recrystallization was detectable under the conditions prevailing in the ultrathin cells, down to the potential of H_2 evolution.

A very small second hump in the current-voltage curve, at about 0.75V *vs.* Zn, was sometimes observed, probably due to some dissolved three-valent manganese.

Since during reduction of MnO_2, OH^- ions are generated the *p*H may locally increase at the reaction site, such that some MnOOH might dissolve as $Mn(OH)_4^-$ or mixed hydroxide-chloride complexes. However, these species would undergo disproportionation into MnO_2 and Mn^{+2} when meeting a solution zone of lower *p*H.

Some γ-MnOOH (manganite) was detected by x-ray analysis of larger MnO_2 samples, pressed into Pt screens and reduced potentiostatically in 5M NH_4Cl for 2 weeks at +0.7V *vs.* Zn. In accordance with the *p*H-potential diagram, reduction in the *p*H range between

Fig. 4. Crystallization of $Mn(OH)_2$ from solution

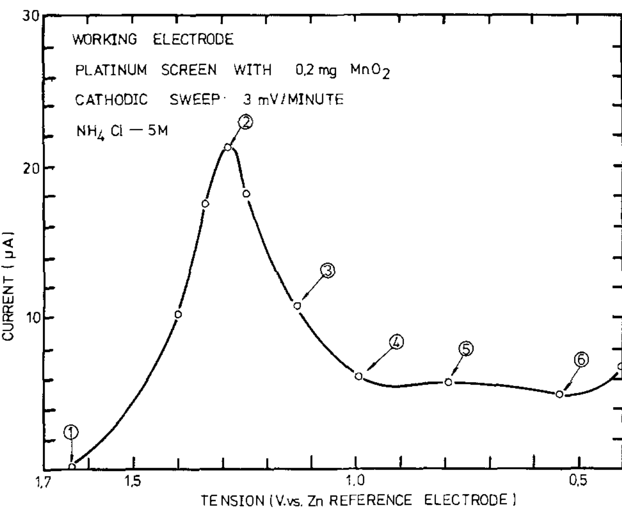

Fig. 5. Linear potentiodynamic cathodic sweep at 180 mV/hr in 5M NH_4Cl.

0 and 7 can proceed directly to the two-valent state (Fig. 7). In other words, the reduction of the intermediate MnOOH should theoretically occur simultaneously with, and at the same potential of, that of γ-MnO_2. The reduction mechanism can thus be written as

$$\left.\begin{array}{l} MnO_2 + H_2O + e^- \xrightarrow[\text{Reduction}]{} MnOOH + OH^- \\ MnOOH + H_2O + e^- \xrightarrow[\text{Reduction}]{} Mn^{+2} + 3\,OH^- \end{array}\right\} \text{(one peak)}$$

The second reaction indicated above might be considerably suppressed, or completely inhibited, by resistive effects, due to the poor conductivity of MnOOH. As already mentioned, it may involve partial dissolution of MnOOH and disproportionation into MnO_2 and Mn^{+2}, as explained below in more detail for acid solutions.

In technical electrodes, the soluble two- and three-valent manganese species produced on discharge may be reoxidized electrochemically by unreacted γ-MnO_2 to form lower oxides, $(MnO_2)_{2n-3} \cdot (MnOOH)_{4-2n} \cdot mH_2O$, reducing, in turn, MnO_2 to a lower oxidation state electrochemically. In the simplest form the sum of the two individual processes then results in an over-all process which might be written schematically

$$Mn^{+2} + 2H_2O + \gamma\text{-}MnO_2 \rightarrow 2MnOOH + 2H^+$$

which is formally equivalent to "ion exchange" (Fig. 8).

In solutions containing many zinc ions, zinc hydroxychloride will precipitate, due to the increasing pH in the electrodes

$$5Zn^{+2} + 2Cl^- + 9H_2O \rightarrow Zn_5(OH)_8Cl_2 \cdot H_2O + 8H^+$$

Also, Mn_3O_4 (hausmannite) might precipitate according to

$$2Mn^{+3} + Mn^{+2} + 4H_2O \rightarrow Mn_3O_4 + 8H^+$$

The stability of three-valent manganese in solution will depend on pH, Cl^-, and Mn^{+2} ion concentration.

Experiments with ultrathin cells having been equipped with sensing electrodes, consisting of 0.05 mm thick Pt foil, held at +0.7V *vs.* Zn, did not reveal

Fig. 6. Dissolution of MnO_2 upon reduction in 5M NH_4Cl. Optical magnification 1500X. Pictures refer to the indicated points in Fig. 5

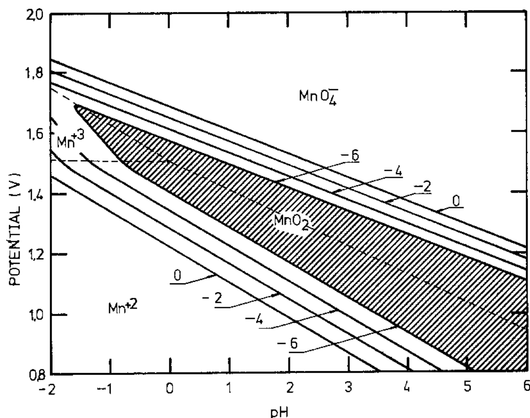

Fig. 7. pH-potential diagram of manganese dioxide in acid solution.

the presence of measurable amounts of Mn^{+3} in 5*N* NH_4Cl solution, as long as the Mn^{+2} ion concentration remained small.

It was also noted that dissolution of MnO_2 grains in ultrathin cells stopped completely when interrupting discharge at various potentials, between 1.3 and 0.7V *vs.* Zn. This indicates that dissolution of MnOOH in NH_4Cl is very slow or very small.

Acid Solutions (2M H_2SO_4)

In order to carry out experiments in 2M H_2SO_4 it was necessary to first equilibrate and saturate the acid with γ-MnO_2, otherwise spontaneous dissolution of MnO_2 particles interfered with the observation of the discharge process. The spontaneous dissolution of γ-

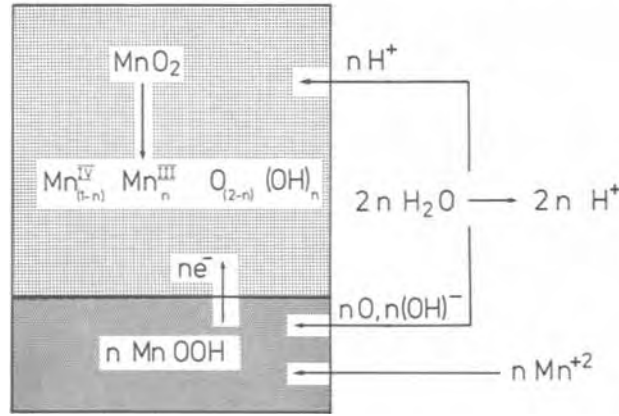

Fig. 8. Redox mechanism between dissolved Mn^{+2} and MnO_2

MnO_2 in untreated 2M H_2SO_4 was much larger than expected, resulting in complete disappearance of entire grains in less than 24 hr. Dissolution could theoretically occur according to

$$MnO_2 + 2H_2SO_4 \rightarrow Mn(SO_4)_2 + 2H_2O$$

(little is known about the stability of dissolved Mn^{+4}) but could possibly be accompanied also by disproportionation

$$4\gamma\text{-}MnO_2 + 8H_2SO_4 \rightarrow Mn^{+7} + 3Mn^{+3} + 8SO_4^{-2} + 8H_2O$$

Three-valent manganese ions are stabilized at high acid concentration.

During discharge in MnO_2-saturated H_2SO_4 with slow potentiodynamic cathodic sweep, two current peaks were observed, one at 1.5V *vs.* $Pb/PbSO_4$ and the second at 0.8V *vs.* $Pb/PbSO_4$ (Fig. 9). Dissolutions of the grains had already started during the first peak (Fig. 10). It appeared that initially γ-MnO_2 was reduced to MnOOH and that the acid reacted rapidly with the discharge product, resulting in dissolution and loss of contact with the substrate.

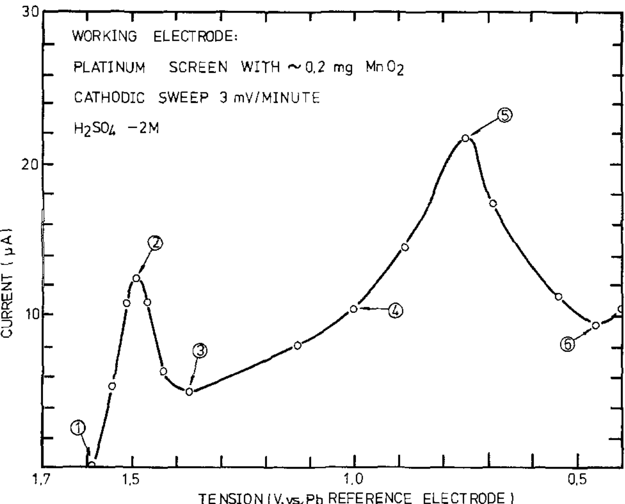

Fig. 9. Linear potentiodynamic cathodic sweep at 180 mV/hr in 2M H_2SO_4.

The second peak appeared to be due to a dissolved, reducible manganese species, probably a complexed Mn^{+3} ion. Reduction of this species must be highly irreversible, involving a large cathodic overvoltage (see *p*H-potential diagram, Fig. 7).

The second peak was also present when the platinum screen support was replaced by a thin graphite foil.

Experiments with sensing electrodes of 0.05 mm platinum foil, held at + 0.5V *vs.* $Pb/PbSO_4$, proved that a reducible species was removed from solution on the working electrode during the second peak. The current of the sensing electrode, due to reduction of soluble Mn^{+3}, dropped rapidly as the working electrode went through the second peak.

A poorly reducible MnO_2 was possibly formed by disproportionation of Mn^{+3} on top of remaining γ-MnO_2 grains. Reduction of this secondary MnO_2 might have been contributing to the background current in the current-voltage diagram. In thicker electrodes, Mn^{+3} ions might also be reoxidized on unreacted MnO_2 particles, not in electric contact, to form manganese dioxide with a lower degree of oxidation, as discussed for neutral solutions. The reduction potential and availability for reduction of precipitated MnO_2 will depend on the extent and nature of substrate surface and binder material. These aspects are of practical importance for the manufacture of acidic MnO_2 cells (4).

The mechanism in acid can be summarized as follows

$$\left.\begin{array}{l} MnO_2 + H^+ + e^- \xrightarrow[\text{Reduction}]{} MnOOH \\ MnOOH + 3H^+ + e^- \xrightarrow[\text{Reduction}]{} Mn^{+2} + 2H_2O \end{array}\right\} \text{first peak}$$

$$MnOOH + 3H^+ \xrightarrow[\text{Dissolution}]{} Mn^{+3} + 2H_2O$$

1 1.590 V. 2 1.490 V. 3 1.380 V.

4 1.000 V. 5 0.750 V. 6 0.490 V. 10 μ

Fig. 10. Dissolution of MnO_2 upon reduction in 2M H_2SO_4. Optical magnification 1500X. Pictures refer to the indicated points in Fig. 9

$$2Mn^{+3} + 2H_2O \xrightarrow[\text{Disproportionation}]{} Mn^{+2} + [MnO_2]_{inact} + 4H^+$$

$$\left.\begin{array}{l} Mn^{+3} + e^- \xrightarrow[\text{Reduction}]{} Mn^{+2} \\ [MnO_2]_{inact} + H^+ + e^- \xrightarrow[\text{Reduction}]{} [MnOOH]_{inact} \end{array}\right\} \text{second peak}$$

The results of this investigation demonstrate the importance of dissolution-precipitation mechanisms in MnO_2 electrodes (5). Dissolution processes may have considerable consequences in the performance of technical electrodes and cells.

Manuscript received Sept. 26, 1975. This was Paper 4 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Leclanché S. A.

Electrochemical Reduction of Beta-Ketoesters: The Tafel Rearrangement

Stanley Wawzonek* and Judith E. Durham

Department of Chemistry, The University of Iowa, Iowa City, Iowa 52242

ABSTRACT

The electrochemical reduction of ethyl α-butylacetoacetate at a lead cathode in aqueous sulfuric acid formed n-octane, 2-heptanone, 2-octanol, 3-octanol, 2-octanone, 3-octanone, 2,3-octanedione, ethyl caproate, and *erythro*- and *threo*-ethyl α-n-butyl-β-hydroxybutyrate. These products indicate that the Tafel Rearrangement proceeds through a cyclopropane intermediate. Studies of the reduction of 2-methyl-2-carbethoxycyclohexanone, 2,5-dicarbethoxycyclohexane-1,4-dione, and 2,5-dibenzyl-2,5-dicarbethoxycyclohexane-1,4-dione found that this method was not suitable for the preparation of cycloheptane and cyclooctane derivatives.

The electrochemical reduction of α-alkylacetoacetic esters in a mixture of ethanol, water, and sulfuric acid at a lead cathode forms a straight chain saturated hydrocarbon by what has become to be known as the Tafel Rearrangement

$$CH_3COCHRCOOC_2H_5 + 6e + 10H^+ \rightarrow CH_3(CH_2)_3R + 2H_2O + HOC_2H_5$$

Although this rearrangement has been known for more than 60 years and there has been speculation about its mechanism (1-5) no concrete evidence has been presented for the actual steps involved.

The present work reports studies of the mechanism of the Tafel Rearrangement and the application of this reaction to β-ketoesters in the cyclohexane series.

Results and Discussion

Studies of the mechanism of the Tafel Rearrangement were based on an investigation of the electrochemical reduction of ethyl α-n-butylacetoacetate in a mixture of ethanol, water, and sulfuric acid at 60°C; the result was a complex mixture of products. In agreement with Tafel (2), n-octane was obtained in good yields when the electrolysis was allowed to proceed for 6-8 hr. Other products obtained and isolated were 2-heptanone, 2-octanol, 3-octanol, 2-octanone, 3-octanone, ethyl caproate, and *erythro*- and *threo*-ethyl α-n-butyl-β-hydroxybutyrate. The yellow color and mass spectrum of one of the fractions indicated that 2,3-octanedione was also formed but the amount present was too small to isolate or characterize as a quinoxaline.

The electrochemical reduction of ethyl α-n-butylacetoacetate was also studied at a mercury cathode in 50% aqueous acetonitrile. The ester shows in this medium a polarographic reduction wave at $-2.14V$ (*vs.* mercury pool) using $0.2N$ tetra-n-butylammonium bromide as a supporting electrolyte. The products obtained were 2-heptanone, 2-heptanol, and ethyl caproate. The ketone and ester result from a basic cleavage of the starting material and 2-heptanol is formed by the electrochemical reduction of 2-heptanone.

Based on the products obtained the following steps are proposed for the Tafel Rearrangement

$$\underset{\mathbf{1}}{CH_3C(=O)-CH(C_4H_9)COOC_2H_5} \xrightarrow{2H^+} \underset{\mathbf{2}}{CH_3C(=OH^+)-CH(C_4H_9)C(=O^+H)-OC_2H_5}$$

$$\mathbf{2} \xrightarrow{2e} \underset{\mathbf{3}}{CH_3\dot{C}(OH)-CH(C_4H_9)-\dot{C}(OH)OC_2H_5} \rightarrow \underset{\mathbf{4}}{CH_3C(OH)-C(OH)(OC_2H_5)\ [\text{cyclopropane ring with } C(C_4H_9)(H)]}$$

* Electrochemical Society Active Member.

Key words: lead cathode, cyclopropanone intermediate, ethyl α-n-butylacetoacetate.

$$4 \rightleftarrows \underset{\underset{\underset{\displaystyle C_4H_9}{|}}{CH}}{CH_3\overset{\overset{\displaystyle OH}{|}}{C}\!\!-\!\!\!-\!C\!=\!O} + HOC_2H_5$$

5

$$5 \rightarrow CH_3\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle O}{\|}}{C}-CH_2C_4H_9$$

6

The absence of rearranged products from the reduction of the ester **1** in nonacidic medium indicates that protonation of the ester is an important step in the rearrangement. Reduction of the protonated form **2** is considered to form a diradical **3** which cyclizes to a cyclopropane derivative **4**. Intermediates of this type have been proposed to explain the rearranged products obtained in the Clemmensen reduction of β-diketones (6) and α,β-unsaturated ketones (7).

The possibility also exists for the addition of two electrons solely to the ketone carbonyl followed by an addition of the resulting carbanion to the ester group with the formation of **4**. Such a carbanion is apparently formed but is protonated rapidly and yields the ethyl α-n-butyl-β-hydroxybutyrates which were isolated.

Intermediate **4** exists in equilibrium with the hydroxycyclopropane **5** which can undergo a retroaldol condensation and form 2,3-octanedione **6**. This diketone upon further reduction would yield n-octane and the derivatives of n-octane isolated. Such a behavior was confirmed by the electrochemical reduction of 2,3-octanedione **6** under acid conditions; n-octane, 2-octanol, 2-octanone, 3-octanone, 3-octanol, and ethyl caproate were isolated and identified.

Ethyl caproate and 2-heptanone formed in the electrochemical reduction of ethyl α-n-butylacetoacetate are formed mainly by chemical reactions of the latter with acid.

Attempts to trap the hydroxycyclopropanone **5** by carrying out the electrochemical reduction of ethyl α-n-butylacetoacetate in the presence of anthracene and of 9,10-dimethylanthracene gave no Diels-Alder adduct. Cyclopropanones are known to react in such a manner with conjugated dienes at low temperatures (8). This result suggests that the concentration of the hydroxycyclopropanone **5** is low because of its rearrangement to 2,3-octanedione **6**.

The hemiacetal **4** cannot be ruled out as a precursor of 2,3-octanedione **6**. Cleavage of this compound **4** in a similar manner to that reported for the hemiacetal of 2,2,3,3-tetramethylcyclopropanone (9) would yield the diketone **6**, ethyl α-n-butyl-β-hydroxybutyrate, ethyl α-methyl-α-hydroxyenanthate, and 2-hydroxy-4-ethoxy-3-octanone. The last two compounds were not detected, however, among the products of the electrolysis.

Studies of the applicability of the Tafel Rearrangement to 2-methyl-2-carbethoxycyclohexanone, 2.5-dicarbethoxycyclohexane-1,4-dione, and 2,5-dibenzyl-2,5-dicarbethoxycyclohexane-1,4-dione found that this reduction was not suitable for the preparation of synthetically useful cycloheptane and cyclooctane derivatives. The reduction of 2-methyl-2-carbethoxycyclohexanone gave a 56% yield of a liquid which, when examined by gas liquid chromatography was found to contain eleven compounds. The isomeric 2-carbethoxy-2-methylcyclohexanols were the main products and accounted for approximately 41.5% of the mixture. Other products isolated and identified were starting ester (13.4%), 3-methylcycloheptane (5%), and 2-methyl or 3-methylcycloheptanol (5%).

2,5-Dicarbethoxycyclohexane-1,4-dione was not reduced electrochemically at a lead cathode in a mixture of ethanol or dioxane, water, and sulfuric acid. The dibenzyl derivative on the other hand gave mainly cleavage products of the cyclohexane ring from which only ethyl α-benzylbutyrate was identified. The resistance of the first compound to electrochemical reduction can be ascribed to its dienolic structure. This behavior is different from that observed polarographically in alcohol-water solutions for 1,3-diketones; enolized 1,3-diketones were more easily reduced than nonenolized diketones (10). The results for the dibenzyl derivative parallels the observations reported for the reduction of 1,4-cyclohexanedione (11); 2,5-hexanedione was obtained with other products.

Experimental

Infrared data were recorded using a Perkin-Elmer infrared double beam recording spectrometer and NMR data were obtained using a Varian A-60 or HA-100 spectrometer. Mass spectral data were obtained with a Hitachi RMU6E spectrometer.

Gas-liquid chromatographic (GLC) analyses were carried out with a Hewlett Packard Model 5750 B gas chromatograph and a F and M Model 5750 programmed temperature gas chromatograph. All preparative GLC's were carried out with the F and M instrument.

The following columns were used in the gas-liquid chromatographic separations and analyses:

Column A: 6 ft × ⅛ in., 5% SE-30 on 100-120 mesh Chromosorb P.

Column B: 6 ft × ¼ in.. 15% Carbowax 4000 on 100-120 mesh Chromosorb P.

Column C: 10 ft × ¼ in., 15% SE-30 on 100-120 mesh Chromosorb P.

Column D: 10 ft × ¼ in., 15% Carbowax 4000 on 100-120 mesh Chromosorb P.

Electrolytic cells.—Cell 1 consisted of a 800 ml beaker fitted with a porous unglazed porcelain cup (6 in. high × 2 in. in diameter). The anode was a cyclindrical lead sheet (3 in. high × 3.25 in. in diameter) and surrounded the cathode compartment (cup). The cathode was a hollow lead pipe (2.5 in. × 0.75 in. in diameter) sealed at one end and cooled with water. The porous cup was sealed with a rubber stopper which held the cathode, thermometer, addition funnel, and a tube leading to a gas trap for collecting volatile compounds formed.

Cell 2 was similar to cell 1 and consisted of a 1 liter beaker fitted with a cylindrical lead sheet anode (4.5 in. high × 3.5 in. in diameter). The cathode compartment was a porous cup (5.125 in. high × 3 in. in diameter) and was sealed with a rubber stopper which held the cathode, thermometer, addition funnel, and a fitting which could be attached to a gas trap or condenser. The cathode was a hollow lead pipe (5.5 in. long and 1 in. in diameter) containing 12 holes (0.25 in. in diameter) which allowed the hydrogen formed to escape into the cathode compartment. The cathode was sealed with a rubber stopper.

Cell 3 consisted of an 800 ml beaker fitted with a porous cup (3.75 in. high × 2 in. in diameter) which served as the anode compartment. The anode was a platinum foil cylinder (1 in. high × 1 in. in diameter) and the cathode was a mercury pool.

Electrolytic reduction of ethyl α-n-butylacetoacetate.
—Isolation of n-octane.—Using cell 1 ethyl α-n-butylacetoacetate (2) (10g) and 30% sulfuric acid (30g) were diluted to 100 ml with ethanol and placed in the cathode compartment. The anode compartment was filled with 30% sulfuric acid. Electrolysis was carried out using a current of 3.5A for 6.5 hr at 60°C. Sixty per cent sulfuric acid was added as necessary during the electrolysis. Gases formed were trapped using a salt-ice bath as a coolant. Upon completion of the electrolysis the material in the trap was combined with the catholyte and the combined solutions extracted with ether. The ether extract was washed successively with

water, 10% sodium carbonate, and water until neutral. The ether layer was dried and the ether was removed using a fractionating column. The residue was distilled using a steam bath and gave a liquid (1.22g) which when analyzed by gas liquid chromatography contained diethyl ether and *n*-octane in a ratio of 1:1.1. The retention times using column A (He flow 30 ml/min; injection port 240°C; detector 270°C; column 79°C) were 24 and 60 sec, respectively, and agreed with those of authentic samples. Preparative chromatography using column C (He flow 40 ml/min; injection port 205°C; detector 225°C; column 125°C) gave a pure sample of *n*-octane which showed a mass spectrum identical to that of an authentic sample.

Isolation of byproducts.—Using electrolysis cell 2 ethyl α-*n*-butylacetoacetate (25g) and 30% sulfuric acid (75g) were diluted to 250 ml with ethanol and added to the cathode compartment. The electrolysis was carried out at a current of 3.5A for 3 hr at 60° in a similar fashion to that given above. The product (23g) was isolated by the procedure given above and analyzed by gas liquid chromatography using columns C and D. Preparative GLC using column D (He flow 35 ml/min; injection port 208°C; detector 235°; column 150°) gave the following compounds (the retention times and relative areas are given in parenthesis): *n*-octane (1.3 min, 1.0), 2-heptanone (2.5 min, 2.3), ethyl caproate (6.4 min, 1.5), 2-octanone (8.1 min, 3.5), 3-octanone (9.1 min, 3.1), 2-octanol (13.0 min, 2.9), 3-octanol (13.9 min, 3.6), ethyl α-*n*-butylacetoacetate (36.6 min, 11.6), and *erythro*- and *threo*-ethyl α-*n*-butyl-β-hydroxybutyrate (52.4 min. 6.9 and 61.8 min. 6.9).

n-Octane was identified by its mass spectrum. 2-Heptanone, ethyl caproate, and 2-octanone were identified by their infrared, NMR, and mass spectra.

The 3-octanone fraction was yellow in color and gave only one peak by GLC analysis. The mass spectrum showed the following fragments: m/e 144, 142, 129, 128, 117, 115, 112, 101, 99, 88, 72, 71, 57, 43 (base), and 41. An authentic sample of 2,3-octanedione showed the following mass spectrum: m/e 142, 99, 71, 57, and 43. An attempt to isolate the diketone as a quinoxaline by treating the fraction with o-phenylenediamine was not successful. This derivative was prepared from an authentic sample of the diketone and is a low melting solid.

The peak at 144 in this fraction is caused by a trace of ethyl caproate.

The 2-octanol and 3-octanol were isolated in amounts sufficient only for mass spectral analysis. The spectrum of the former was identical with that of an authentic sample. 3-Octanol gave an M-2 peak at m/e of 128, a peak at 101 for the loss of an ethyl group, and a peak at 59 for the $C_3H_7O^+$ ion.

Ethyl α-*n*-butylacetoacetate was identified by its retention time and infrared and mass spectra.

Erythro- and *threo*-ethyl α-*n*-butyl-β-hydroxybutyrates were identified by a comparison of their retention times and mass spectra with those of authentic samples (12).

Electrochemical reduction of ethyl α-n-butylacetoacetate at a mercury cathode in 50% aqueous acetonitrile.—The ester (10g) was reduced in cell 3 in a 1:1 aqueous acetonitrile (400 ml) solution containing 0.2*M* tetrabutylammonium bromide using a current of 0.4A for 8 hr. Extraction with ether gave 8.9g of a liquid which by GLC analysis using column D (He flow 35 ml/min; injection port 206°C; detector 235°C; column 140°) consisted of 2-heptanone, ethyl caproate, 2-heptanol, and starting material. Fractionation at 72°-93°C (10 mm) gave 0.83g of a mixture of the first three compounds in a ratio of 2.7:1.1:1.0.

Electrochemical reduction of 2,3-octanedione.—Using cell 1 and a gas trap, a mixture of 2,3-octanedione (5.0g) and 30% sulfuric acid was diluted to 100 ml with ethanol and electrolyzed with a current of 2-4A at 60°C for 10 hr. The cooling trap contained pure *n*-octane (1 ml). Ether extraction of the catholyte gave a liquid (2.1g) which by preparative GLC on column D yielded the following compounds (the relative amounts are given in parenthesis): ethyl caproate (7.3), 2-octanone (1.0), 3-octanone (1.5), 2,3-octanedione (3.7), 2-octanol (1.2), and 3-octanol (1.5).

Electrochemical reduction of 2-methyl-2-carbethoxycyclohexanone.—Using cell 2 fitted with a condenser the ester (9.24g) and 60% sulfuric acid (45g) were diluted to 250 ml with ethanol and electrolyzed for 4 hr at 60° with a current of 3.5A. Extraction with ether in the usual manner gave 5.2g of a yellow liquid. Gas-liquid chromatographic analysis using column D (He flow 35 ml/min; injection port 205°C; detector 240°C; column 140°C) indicated the presence of about 11 compounds. By preparative GLC at 100° and 125° the following compounds were isolated in sufficient amounts for identification (the migration times and relative amounts are given in parenthesis): 3-methylcycloheptane (3 min, 4.0), 2-methyl-2-carbethoxycyclohexanone (19.0 min, 11.0), 2-methyl or 3-methyl-cycloheptanol (27.6 min, 4.1), and *erythro*- and *threo*-2-carbethoxy-2-methylcyclohexanols (74.6 min, 20.4 and 131.2 min, 13.6). Identification of all fractions except the starting material was made using mass spectral data. The starting ester was characterized by its migration time.

Electrochemical reduction of 2,5-dibenzyl-2,5-dicarbethoxycyclohexane-1,4-dione (13).—A mixture of *cis* and *trans*-2,5-dibenzyl-2,5-dicarbethoxycyclohexane-1,4-dione (6.5g), 30% sulfuric acid (75g), and ethanol (50 ml) was diluted to 350 ml with dioxane and electrolyzed in cell 2 at 70°C with a current of 2.5A for 23 hr. Extraction with methylene chloride gave 4.55g of a yellow oil. Thin layer chromatography on silica gel indicated the presence of numerous compounds. Column chromatography on a 3 ft × 1 in. silica gel column using benzene and methylene chloride as eluants followed by preparative layer chromatography on silica gel using methylene chloride gave six apparently pure compounds. Mass spectral analysis of two of these gave molecular ion peaks at m/e 206 which corresponds to ethyl α-benzylbutylrate. Three of the components gave no molecular ion peaks; the highest discernible peaks were at m/e 320, 321, and 171. The last component gave a molecular ion at m/e 202.

2-Methyl-3-pentylquinoxaline.—A mixture of 2,3-octanedione (14) (0.71g) and o-phenylenediamine (0.5g) was heated at 100° for 1 hr. Upon cooling a solid (0.8g) was formed and recrystallized from a mixture of methanol and water; mp 45°-46°C.

Anal.: Calcd. for $C_{14}H_{18}N_2$: C, 78.50; H, 8.41; N, 13.08. Found: C, 78.94; H, 8.29; N, 13.12.

Electrodissolution of Nickel in Molten LiCl-KCl

D. L. Piron,* S. Asakura, and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The electrodissolution of nickel in molten eutectic LiCl-KCl has been investigated by quasi-steady-state potentiostatic and transient polarization techniques. The results indicate that electrodissolution is diffusion controlled. In addition, anodic passivation behavior is observed. Passivation is surmised to be due to the deposition of a chloro-nickel complex. Diffusion coefficients of Ni(II) have been determined from the chronoamperometric and chronopotentiometric data and found in accord with values reported in the literature.

Studies of the anodic behavior of nickel and other transition metals in aqueous electrolytes have been quite extensive. On the other hand, there has been much less work reported on the anodic behavior of nickel and other common metals in molten salts. This paper reports on the anodic dissolution studies of nickel in molten LiCl-KCl eutectic mixture. Since the rate of electrodissolution should be fast due to the high temperatures and highly corrosive environment, transient polarization techniques have been utilized.

Equations to describe diffusion-controlled metal electrodissolution during chronopotentiometric and chronoamperometric experiments can be obtained by solutions of Fick's second law of diffusion

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C}{\partial^2 x} \qquad [1]$$

with the following initial and boundary conditions

(*i*) chronopotentiometry

$$C(x,0) = C^\circ \qquad [2]$$

$$\frac{\partial C(0,t)}{\partial x} = \frac{i}{n\mathbf{F}D} \qquad [3]$$

$$C(\infty,t) = C^\circ \qquad [4]$$

(*ii*) chronoamperometry

$$C(x,0) = C^\circ \qquad [2]$$

$$C(\infty,t) = C^\circ \qquad [4]$$

$$C(0,t) = C^\circ \exp(n\mathbf{F}E/RT) \qquad [5]$$

Equation [2] is the initial condition for both cases where C° is the bulk concentration of the metal cation. Equation [5] is the boundary condition at the metal-electrolyte interface during a chronoamperometric experiment, *i.e.*, the electrode potential follows the Nernst equation.

For chronopotentiometry, Eq. [1]-[4] lead to Eq. [6]

$$i\sqrt{\tau} = \frac{n\mathbf{F}}{2}\sqrt{\pi D}\,C^\circ\left[\exp\left(\frac{n\mathbf{F}E_\tau}{RT}\right) - 1\right] \qquad [6]$$

where τ is the transition time and E_τ is the electrode potential at τ.

Equations [1], [2], [4], and [5] lead to Eq. [7] which describes the current transient for metal electrodissolution during a constant potential pulse

$$i = \frac{n\mathbf{F}\sqrt{D}\,C^\circ}{\sqrt{\pi t}}\left[\exp\left(\frac{n\mathbf{F}E}{RT}\right) - 1\right] \qquad [7]$$

Experimental

Reagent grade LiCl and KCl were mixed in the mole ratio of 59/41 to prepare the eutectic salt. $NiCl_2$ (0.1 mole/kg of eutectic salt) was added to the electrolyte. Purification of the eutectic salt was performed with an HCl atmosphere to remove water, oxygen, and hydroxides during melting according to the method described by Laitinen *et al.* (1). After the purification process, nitrogen replaced the HCl atmosphere.

The test, auxiliary, and reference electrodes were prepared by sealing nickel 200 wire (0.4 mm diameter) in Pyrex tubes with differing lengths of wire exposed; 1 mm, 2 cm, and 70 cm, respectively. The latter was coiled to provide a more compact volume.

Appropriate function generators with an Anotrol controller were utilized to provide constant potentials, constant currents, and linear potential sweeps. Oscillographs, oscilloscopes, and a dual-channel recorder were used to measure current transients, potential transients, and potential-current behavior, respectively.

Results

Quasi-steady-state potentiostatic anodic polarization of nickel was performed by applying each potential value for 30 sec, measuring the current at the end of this time interval and then increasing the potential to the next value. Figure 1 shows a typical anodic polarization curve. All potential values in this paper are given relative to the nickel reference electrode. An active-passive transition is observed at about 125 mV, and it is seen that the passivation current is about two orders of magnitude larger than the passive current.

Figure 2(a) shows typical current transient behavior during an anodic potential step. At low polarization values the current is inversely proportional to the square root of the time as shown in Fig. 2(b). Similar plots are obtained at higher temperatures up to 565°C

* Electrochemical Society Active Member.

Key words: corrosion, molten salts, anodic dissolution.

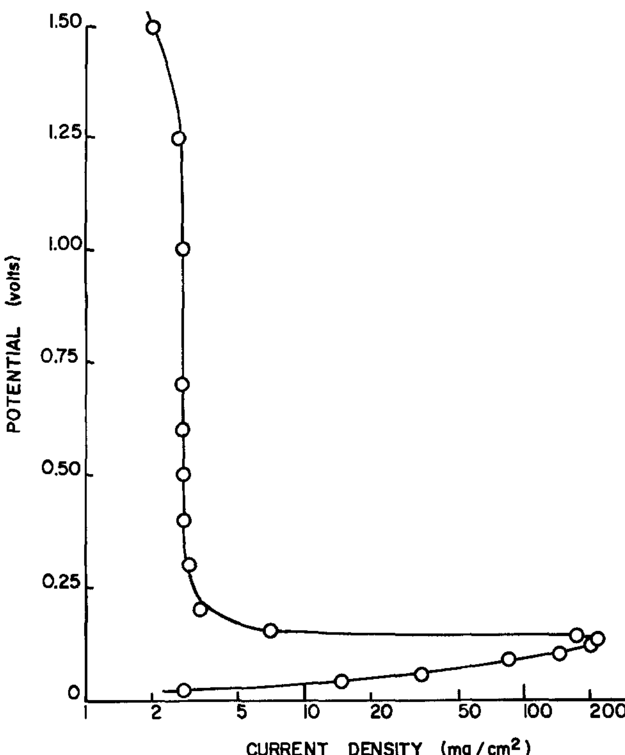

Fig. 1. Potentiostatic anodic polarization, 370°C

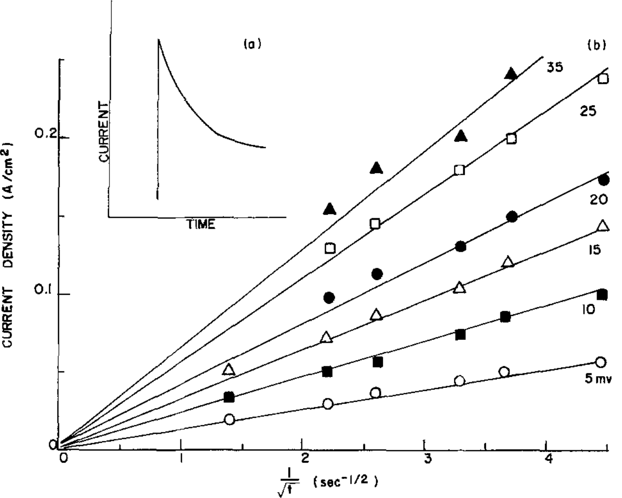

Fig. 2. Chronoamperometric results: (a) typical current transient at $E \leq 40$ mV, (b) current vs. $1/\sqrt{t}$ at 375°C.

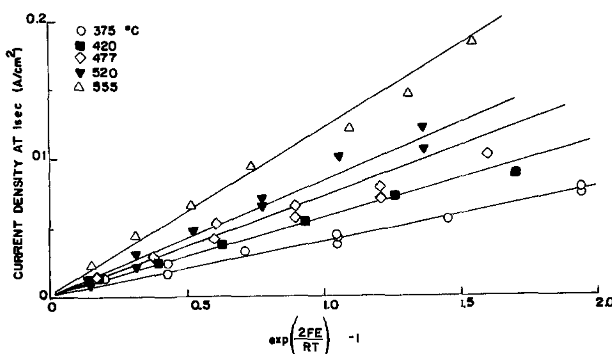

Fig. 3. Chronoamperometric results, current vs. [exp (2FE/RT) — 1] plots.

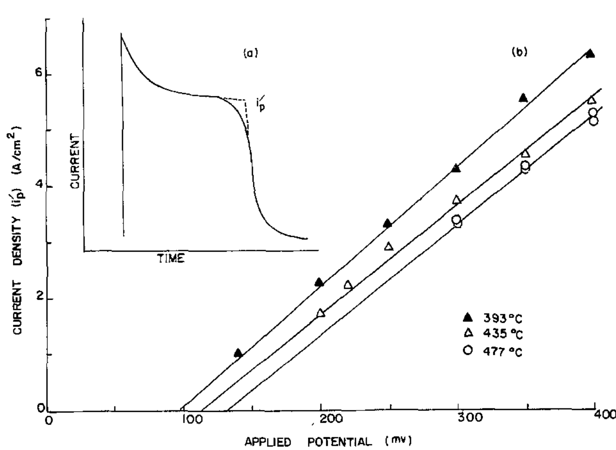

Fig. 4. Chronoamperometric results: (a) typical current transient at $E > 150$ mV, (b) i'_p vs. E plots.

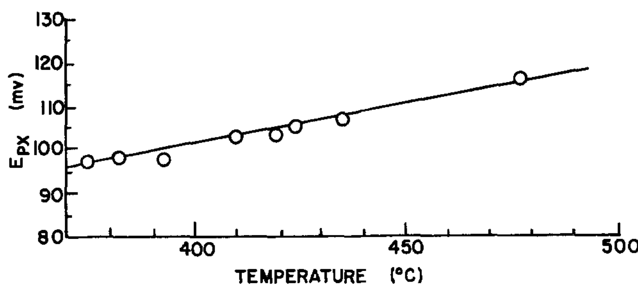

Fig. 5. Passivation potential (E_{px}) vs. temperature

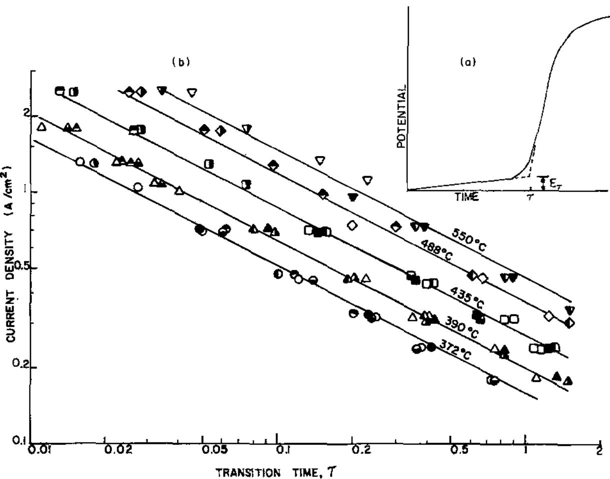

Fig. 6. Chronopotentiometric results: (a) typical potential transient, (b) current vs. transition time, τ plots.

and are given elsewhere (2). These linear i vs. $1/\sqrt{t}$ plots are obtained up to a polarization of 40 mV. Figure 3 shows plots of $i\sqrt{t}$ vs. [exp $(2\,\mathbf{F}E/RT) - 1$]. The slopes of these linear plots increased with increase in temperature. The linear relationships shown in Fig. 2(b) and 3 are in accord with Eq. [7], and indicate that the electrodissolution of nickel in the molten LiCl-KCl eutectic mixture is diffusion controlled.

Figure 4(a) shows typical current transient behavior at higher polarization potentials (>150 mV). A current arrest (i'_p) was observed during the decay. The current, i'_p, and the corresponding potential, E'_p, are the passivation parameters. A plot of i'_p vs. E'_p, as shown in Fig. 4(b), gives a linear relationship. By extrapolation of these plots to $i'_p = 0$, the passivation potential corrected for the ohmic potential drop, E_{px}, is obtained. Figure 5 shows that the passivation poten-

tial, E_{px}, varies linearly with the temperature.

A typical potential transient behavior during an anodic current step is shown in Fig. 6(a). A log-log plot of the current and the transition time, τ, gives a linear relationship with a slope of $-1/2$ as shown in Fig. 6(b). These results are in accord with Eq. [6] and indicate, as the chronoamperometric experiments, that the electrodissolution of nickel is diffusion controlled.

Active-passive polarization behavior similar to that obtained during quasi-steady-state potentiostatic anodic polarization was obtained for the linear potential sweeps as shown in Fig. 7. It is seen that the peak current, i_p, and the peak potential, E_p, both increase with increase in the sweep rate.

Discussion

The diffusion coefficient in Ni(II) in molten LiCl-KCl can be determined from Eq. [6] and [7] and the chronopotentiometric and chronoamperometric data, respectively. The calculated diffusion coefficients at various temperatures are given in the Arrhenius plots of Fig. 8. A comparison with the diffusion coefficients obtained by other workers is presented in Table I. It is seen that there is good agreement between the values obtained in this work and others. The activation energies obtained from the slopes of the chronoamperometric and chronopotentiometric Arrhenius plots are 11.2 and 10.4 kcal/g mole, respectively. The activation energy reported by Poignet and Barbier (3) is 7.1 kcal/g mole, which is substantially lower than the values obtained in the present study.

Transient polarization techniques as well as the quasi-steady-state potentiostatic polarization experiments show that nickel in molten LiCl-KCl exhibited passivation behavior. In the active region, electrodissolution of nickel is shown to be diffusion controlled, and the concentration of Ni(II) at the metal-electrolyte interface, $C(0,t)$, can be determined by the Nernst relation (Eq. [5]). Since the bulk concentration of Ni(II), $C°$, is 0.1 g mole/kg, eutectic salt, $C(0,t)$ at 375°C and 100 mV (approximately the passivation potential) is 3.6 g mole/kg eutectic melt. The diffusion-controlled electrodissolution and the passivation behavior suggest a dissolution-precipitation mechanism for passivation. It is surmised that precipitation of a metal chloride salt, such as K_2NiCl_4, occurs when the concentration of Ni(II) reaches saturation conditions, *e.g.*, at 100 mV and 375°C, $C_{sat} = C(0,t) = 3.6$ g mole/kg eutectic melt). Passivation is ascribed to the deposition of this salt precipitate on the nickel surface. As long as saturation concentrations of Ni(II) exist at the metal-electrolyte interface passivation is maintained.

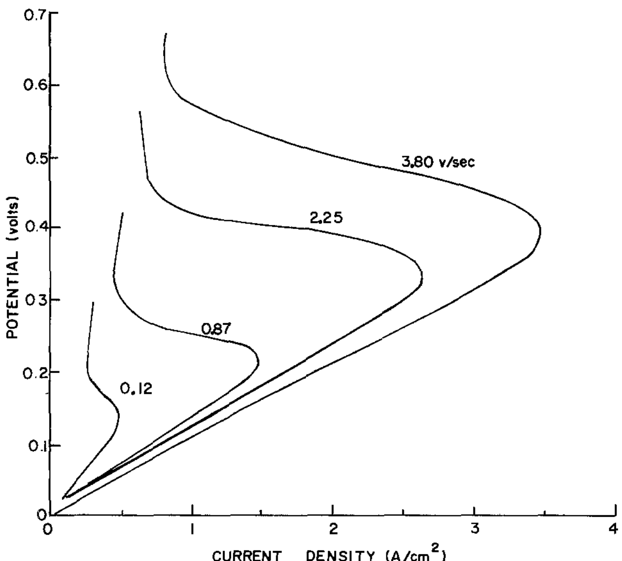

Fig. 7. Potential-current behavior at various sweep rates, 365°C

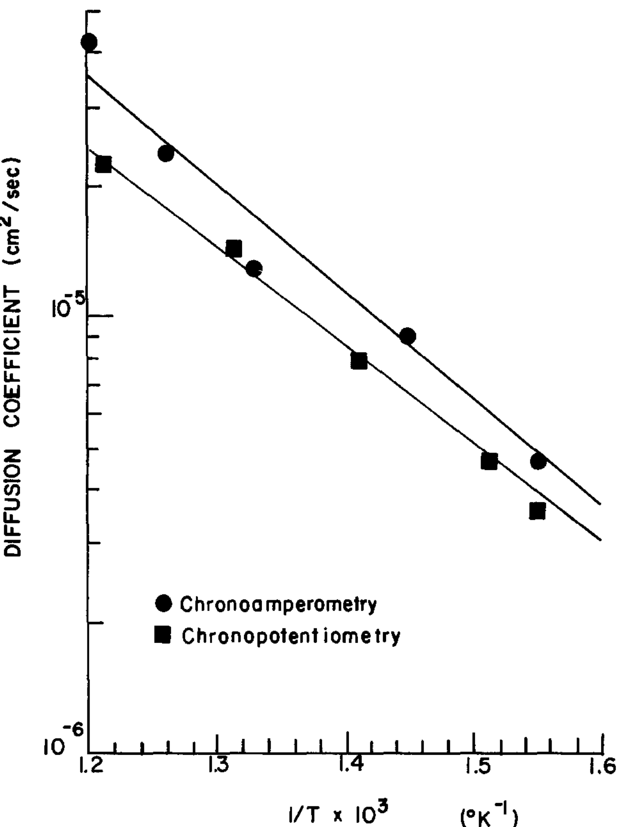

Fig. 8. Arrhenius plots for electrodissolution of nickel

Piontelli *et al.* (6) had previously reported passivation of nickel in $NiCl_2$-KCl melts, and they have attributed this behavior to solid metal chloride deposits. Passivation of platinum in molten LiCl-KCl eutectic mixture at 450°C has been observed by DeHaan and van der Poorten (7) who ascribed this behavior to the formation of the chloroplatinum complex, K_2PtCl_6. Since previous work in this laboratory (8) has shown that chloride concentrations of 0.5 weight per cent (w/o) NaCl and greater precludes passivation of nickel in aqueous solution (1*N* H_2SO_4), the chemical character of the passive film formed on nickel in aqueous solutions at room temperature must be substantially different than that formed on nickel in chloride melts at elevated temperatures.

The Transient Behavior of an Ideally Polarized Porous Carbon Electrode at Constant Charging Current

M. Yaniv[1] and A. Soffer

Nuclear Research Centre, Negev, Department of Chemistry, Beer-Sheva, Israel

ABSTRACT

The porous, high surface carbon electrode obeys the simple model of distributed resistivity and capacity, indicating that at least in transient behavior it approaches the ideally polarized electrode properties. Two potential transients at constant charging currents were simultaneously recorded at the (front) side facing the counterelectrode and at the opposite (rear) side, and compared with the theoretical curves. Some disagreement with theory was experienced at the front side, resulting in an apparently higher solution resistivity. This was attributed to micropore ionic resistivity which slows down the rate of charging of the front side. It is shown that direct and simple graphical means of calculating double layer capacity and electronic and ionic conductivity of the porous electrode phases are possible by measuring the rear side potential transients. At the front side, the solution resistivity of the porous electrode can only be obtained by curve fitting. Inserting a reference electrode in an isolated solution at the rear side of the porous electrode provides a simple means of measuring *IR* free electrode potential.

One of the major problems in practical electrochemistry is the slowness of the interfacial electrode reaction as compared to the rate of transport between the electrodes. In order to increase the rate of electrode reaction per unit of geometric surface area of electrode, it is necessary to increase the ratio A_t/A_a of the true to apparent surface areas. This frequently leads to a porous electrode structure.

The porous electrode is essentially three dimensional, *i.e.*, the electrode process takes place within a volume rather than on a plane. However, the electrode process does not proceed evenly throughout the thickness of the electrode. It is faster on parts located closer to the counterelectrode. This is mainly because of two reasons: (*i*) the *IR* drop in the solution within the pores of the electrode and (*ii*) the screening by the electrode network, provided it is a better conductor than the solution. The screening effect is represented by appropriate impedances across the interface distributed along the porous electrode, in addition to the ohmic resistance of the solution.

Transient behavior is exhibited in cases where the above impedances are associated with local energy storage, *i.e.*, concentration gradients and double layer capacitances in its generalized sense (1). This essentially includes all charge-consuming processes capable of changing the interfacial structure of the electrode surface.

The distributed impedances can be divided into four types, namely, ohmic, double layer capacitance, Faradaic reaction, and diffusion polarization. If all four or even three types of impedances are accounted for, the resulting equations are quite complex and are very difficult to compare with experimental results; this is especially so in cases of transient behavior. In fact such trials are scanty and have been examined only for the steady state (2-4).

The combination of ohmic, Faradaic, and diffusion polarizations were studied by Rangarajan (5) and compared with calculated results of other authors. A most general case was also theoretically studied by De Levie (6) for the semi-infinite porous electrode. This model included ohmic, Faradaic, capacitance, and diffusion polarizations. Newman and Tobias (7) treated the steady-state behavior of a porous electrode where Faradaic and diffusion processes play a role.

The approximation of the heterogeneous porous electrode to a continuous medium of evenly distributed impedances was first introduced by Ksenzhek and Stender (8) and was adopted by many other authors. Later Ksenzhek and Stender treated galvanostatic transients for the case of combined double layer and Faradaic impedances (9).

The simplest case of distributed interfacial capacitance and solution resistance, namely, the case of the ideally polarized porous electrode, is of special interest. This is because it is easily approached by experiment (10-13) and the corresponding differential equations can be solved explicitly. Therefore, theory can be thoroughly compared with experiment. Moreover, once a satisfactory model is at hand, three important properties of the porous electrode can be experimentally determined from the shape of the current or voltage transients, *i.e.*, the double layer capacity and the solution and electrode resistivities. The resistivities are of obvious importance for fuel cell technology, while the double layer capacity could play a role in energy storage available for high instantaneous discharge rate from a fuel cell of a lower, steady-state power (14).

This simple model had been treated by De Levie (15) for the case of a semi-infinite porous electrode.

[1] Present address: Department of Chemistry, Tel-Aviv University, Tel-Aviv, Israel.

Key words: double layer, porous electrode, transients.

The finite electrode case was considered by Bonemay *et al.* (16) for a fuel cell porous electrode terminating in a resistance R_f equivalent to the gas fuel cell reaction. The more general form of a finite electrode where the above resistance is absent is especially considered here. In this respect, Posey and Morozumi (17) had solved the problem for galvanostatic, potentiostatic, and triangular current modes. It is worth noting however, that the so-called current density $j(x,t)$ distribution given in Fig. 4 of Ref. (17) is rather the derivative of the current $i(x,t)$ with respect to the location x, and not the current itself passing in direction x within the electrode. The expression $j(x,t)$ was obtained by Posey and Morozumi by differentiating with respect to time the expression of the potential $\eta(x,t)$ given in Eq. [4] of their paper. The true current $i(x,t)$ within the porous electrode had to be obtained by differentiating Eq. [4] with respect to x.

In this case, the steady-state distribution $i(x,\infty)$ of the current should be linear, reading zero at $x = 0$, in agreement with the boundary condition, but the term $j(x,t)$ approaches constant value at the steady state, as well as the derivative $\partial i(x,t)/\partial x$.

Recent publications by Gagnon (10, 11) together with a previous work (18) are perhaps the only experimental works on ideally polarized porous electrodes where the transient behavior is compared with theory. In the work by Gagnon the current transient due to triangular voltage sweep was followed. If any potential function is used the (experimentally non-avoidable) outer solution resistance between the reference and the porous electrode R_0 will inherently influence the transient behavior of the system. The solutions obtained thence (16, 17, 19) contain transcendental expressions in R, the solution resistance of the porous electrode. This prevents one from obtaining an explicit expression of this important value, which can then be evaluated only by somewhat tedious curve fitting.

By using a galvanostatic step, however, the potential equations of the porous electrode edges contain both C, the double layer capacitance, and R in explicit forms and can be directly evaluated from experimental results as shown by Posey and Morozumi (17).

It will be shown that computing R from the potential function of the front edge (the side where the constant current is applied) of the electrode also involves some experimental difficulties.

The location of a reference electrode at the rear side of the porous electrode (opposite the auxiliary electrode) will be shown to make it possible to use a very simple graphical procedure of obtaining both C and R; such a reference electrode enables the measurement of an almost IR free potential of the porous working electrode.

Experimental

The electrochemical cell and the electrical instrumentation are described elsewhere (20). A scheme of the electrochemical cell and the corresponding equivalent circuit are given in Fig. 1. The rear side solution is electrically isolated from the entire cell solution at the front of the porous electrode. Obviously the two solutions are interconnected through the open pores of the electrode. The solution was aqueous NaCl, 0.10*N*. The experiments were performed at 25° ± 0.1°C. The porous carbon electrode was a Pure Carbon Product (St. Marys, Pennsylvania), Type FC-13. It has a BET surface area of 450 m^2/g. The electrodes were disk shaped, 9 mm in diameter, 1 and 3 mm thick. Its macropore and micropore volumes, given by the manufacturer, are respectively, 0.28 and 0.24 cm^3/g. The macropores, which are responsible for fluid permeability, have pore diameters in the range 3.7-0.8μ. The average micropore diameter is about 21Å. The micropores are responsible for the major part of surface area, and hence of capacity. Due to the enormous double layer capacity of the high surface porous electrode (~45 farad/g), concentration changes could occur within the pores of the electrode because of ion adsorption or desorption (1). In order to keep constant concentration, the solution was pumped back and forth through the electrode by means of pressure-vacuum steps of nitrogen applied at the upper solution (Fig. 2). Constant concentration is essential for the fundamental assumption of the model presented, where the ionic conductivity within the pores is considered constant. It can, however, be easily shown that at sufficiently low charging currents and small charging periods, the diffusion flux is enough to prevent any significant concentration polarization in the pores. Pumping was therefore stopped whenever accurate voltage transients were recorded. At such conditions, potential jumps, probably streaming potentials, were experienced on reversal of pumping direction.

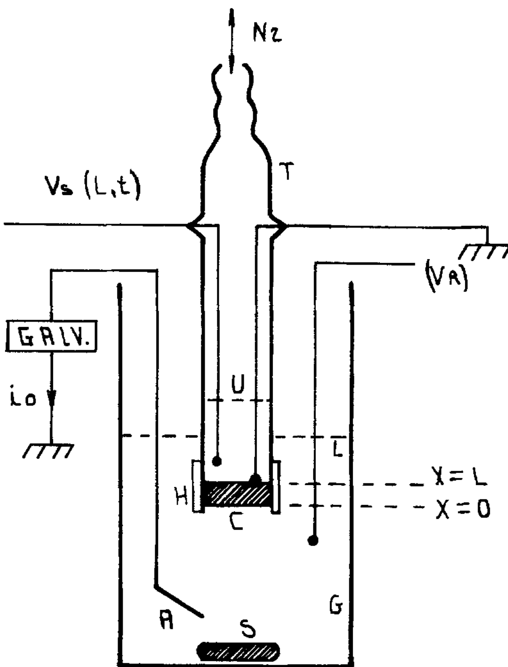

Fig. 1a. Schematic description of the system. A, Auxiliary electrode; C, porous carbon electrode; G, glass vessel; H, a special Teflon tube heat-contracted to fasten and seal porous electrode to glass tube, T; N_2, nitrogen pressure-vacuum pulses to pump solution through electrode; L, U, lower and upper (variable) solution levels. $V_s(L,t)$, $V(R)$, reference electrode connections measuring appropriate potentials; i_o, constant current supplied by galvanostat, GALV.

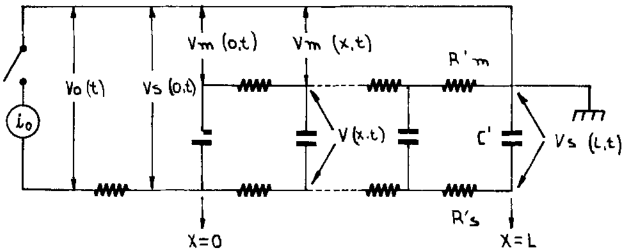

Fig. 1b. The equivalent circuit of the porous electrode. R'_m and R'_s, electronic and ionic resistivity permit length of the porous electrode, respectively; $V_0(t)$ and $V_s(L,t)$ are, respectively, front and rear side reference electrode potentials *vs.* porous electrode. (The potentials $V_0(t)$, $V_s(L,t)$, and $V_m(0,t)$ are easily measurable.)

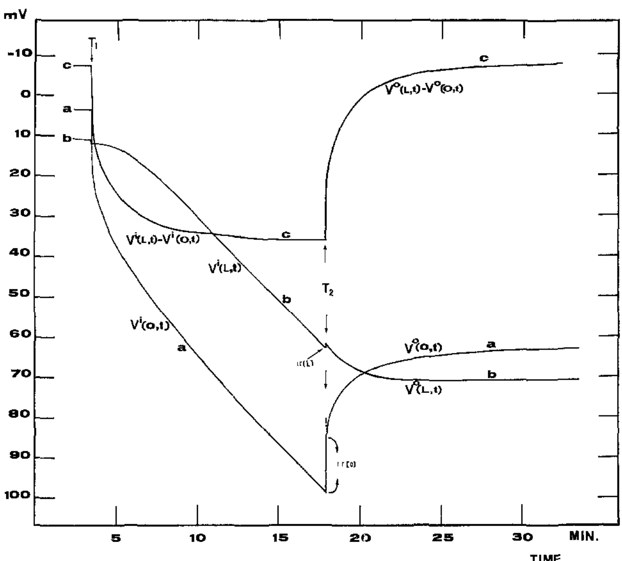

Fig. 2. Experimental voltage transients of the rear and front sides of the porous electrode.

Results and Discussion

Description of the model.—The solution resistance of the porous electrode exists within the bulk of the pores while the double layer capacitance is associated with the interface, *i.e.*, with the walls surrounding the pore. An ionic unit charge, moving within the electrode pores, encounters ohmic and double layer capacitance impedances at different positions within the pore. If, however, the dimensions of the largest pores are much smaller as compared to the electrode dimension, the resistance and capacitance impedances of one pore unit become small compared to the corresponding over-all magnitudes. Under such conditions, the continuous model of distributed impedances is justified (8). It is treated hereafter for the unidimensional case, and later is discussed again.

Consider a porous electrode enclosed in an insulating tube of constant cross section and flooded by an electrolytic solution. The two ends of the tube are in contact with separate solutions of the same composition as is described in Fig. 1a.

The current i_o is passed between the porous (working) electrode through a contact at $x = 0$ and a counterelectrode situated at the side $x = 0$ of the porous electrode.

At any location x, Ohm's law is given for the solution phase by

$$i_s(x,t)R'_s = -\partial V_s(x,t)/\partial x \qquad [1]$$

and for the metallic phase by

$$i_m(x,t)R'_m = -\partial V_m(x,t)/\partial x \qquad [2]$$

where, as shown in Fig. 2b, i is the current and R' the resistivity per unit length of the electrode, along the x axis. The subscripts s and m denote the solution and electrode phases, respectively. $V_m(x,t)$ is the electrode potential referred to the edge $x = L$ (opposite the counterelectrode side) of the electrode phase, taken as $V_m(L,t) = 0$. $V_s(x,t)$ is the solution potential (as obtained by a hypothetical reference electrode located within the pores) referred to the same point $x = L$ at the electrode phase. The electroneutrality condition requires that

$$i = i_s = -i_m \qquad [3]$$

By means of the last three equations and denoting $V(x,t) = V_s(x,t) - V_m(x,t)$, the expression

$$\partial V(x,t)/\partial x = -i(R'_m + R'_s) \qquad [4]$$

is obtained.

The current i_s is in the direction x. The decrease of this current is equal to the rate of the double layer charging associated with the increase $\partial V/\partial t$ in the potential difference across the double layer, thus

$$\partial(V_s - V_m)/\partial t = \partial V(x,t)/\partial t = -(1/C')(\partial i(x,t)/\partial t) \qquad [5]$$

It is assumed in this model that R'_m, R'_s, and C' are constants in both time and location. Differentiating Eq. [4] with respect to x and substituting in Eq. [5] the expression

$$\frac{\partial^2 V}{\partial x^2} = R'C' \frac{\partial V}{\partial t} \qquad [6]$$

is obtained (10, 17),[2] where $R' = R'_s + R'_m$.

Step function current mode.—The following boundary and initial conditions must exist for a constant current step beginning at $t = 0$

$$i(L,t) = -\partial V(L,t)/\partial x = 0 \qquad [7a]$$

$$i(0,t) = -(1/R')(\partial V(0,t)/\partial x) = i_o \qquad [7b]$$

$$i(x,0) = (1/R')(\partial V(x,0)/\partial x) = 0 \qquad [8a]$$

$$V(x,0) = V_o \qquad [8b]$$

The last condition means that the porous electrode is at equilibrium at $t = 0$. The solution of Eq. [6] according to conditions [7] and [8] is

$$V^i - V^i_o = i_oR'L \left[-\frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau} \right) \cos \frac{n\pi x}{L} + \frac{1}{2}\left(\frac{x}{L}\right)^2 - \frac{x}{L} + \frac{t}{\tau} + \frac{1}{3} \right] \quad (21, 17)^3 \qquad [9]$$

where $\tau = L^2R'C'$. The superscript i is for the step function current mode. The first term in Eq. [9] is a transient which decays with time. The second and third terms represent parabolic distribution of potential $V - V_o$ after the transient decay. The fourth term shows a linear increase of $V - V_o$ at long times.

The current function is obtained by differentiating Eq. [9] with respect to x and using Eq. [1]

$$i(x, t) = i_o \left[1 - \sum_{n=1}^{\infty} \frac{2}{n\pi} \exp\left(-n^2\pi^2 \frac{t}{\tau} \right) \sin \frac{n\pi x}{L} - \frac{x}{L} \right] \qquad [10]$$

The current has a linear distribution at long times and is always zero at $x = L$.

Interruption of prolonged step function current.—In this case, the linear current distribution will serve as the initial condition, namely $i(x,0) = i_o(1 - x/L)$ and substitution of the last expression in Eq. [1] gives

$$\frac{\partial V(x, 0)}{\partial x} = -\frac{i_o}{R'}\left(1 - \frac{x}{L} \right) \qquad [11]$$

The solution of Eq. [6], subject to condition [11] can be shown to be

$$V^o - V^o_\infty = \frac{2i_oR'L}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(- n^2\pi^2 \frac{t}{\tau} \right) \cos \frac{n\pi x}{L} \qquad [12]$$

The superscript o stands for the interrupted current mode.

[2] In Ref. (10) and (17), the resistivity of the electrode is neglected. This is a particular case where $R' = R'_s$ and $V = V_s$, which is also the case in the experimental system presented here.

[3] The solution in Ref. (21) is given for the coordinate $L - x$. In Ref. (17) the terms $\frac{1}{2}\left(\frac{x}{2}\right)^2 - \frac{x}{2}$ are included within the infinite series as a Fourier expansion.

The potential V^o_∞ is the equilibrium value approached at infinite time. The same transient is obtained as before but with the opposite sign.

The current function is accordingly

$$i = \frac{2i_o}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) \sin\frac{n\pi x}{L} \quad [13]$$

Particular cases.—In an experimental setup it is very difficult to install potential measuring probes within the porous electrode (at $0 > x > L$) without disturbing its macroscopic homogeneity. It is however easy to insert reference electrodes in the solution at the sides $x = 0$ and $x = L$, as well as two electronic contacts with the porous electrode at $x = 0$ and $x = L$. The last point will serve as the zero reference potential as assumed above. The measurable potentials at the other three points are $V_m(0, t)$, $V_s(0, t)$, and $V_s(L, t)$ (Fig. 1b).

The electronic potential $V_m(0, t)$ results from the IR drop in the electrode phase and is obtained by integration of Eq. [10] and [13] and by using Eq. [2] and [3]

$$V^i_m(0, t) = -R'_m i_o L \left\{ \frac{1}{2} + \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) [(-1)^n - 1] \right\} \quad [14a]$$

$$V^o_m(0, t) = \frac{2R'_m i_o L}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) [(-1)^n - 1] \quad [14b]$$

The amplitude of the transient in Eq. [14a, b] is given by

$$|V_m(0, 0) - V_m(0, \infty)| = \frac{1}{2} R'_m i_o L \quad [15]$$

which provides a direct experimental evaluation of R'_m.

In order to have an expression for $V_s(0, t)$, let us start from

$$V_s(0, t) = [V_s(0, t) - V_m(0, t)] + V_m(0, t)$$

The first term is obtained by substituting $x = 0$ in Eq. [9] or [12], while the second is given by Eq. [14a, b]. Substituting accordingly, $V_s(0, t)$ is given by

$$V^i_s(0, t) - V^i_o = i_o L \left\{ (R'_s + R'_m) \frac{t}{\tau} + \frac{2R'_s - R'_m}{6} - \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) [R'_s + R'_m(-1)^n] \right\} \quad [16a]$$

$$V^o_s(0, t) - V^o_\infty = \frac{2i_o L}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) [R'_s + R'_m(-1)^n] \quad [16b]$$

Equation [16a] has a linear term in t which remains after the decay of the transient. The slope of this linear part is

$$\frac{dV^i_s(0, t \to \infty)}{dt} = \frac{i_o}{LC'} t \quad [17a]$$

Its intercepts with the time and potential axes are, respectively

$$t_\infty = \frac{2R'_s - R'_m}{6} C'L^2 \quad [18a]$$

which is a characteristic time of the transient term in Eq. [16a, b] and

$$V_\infty = \frac{2R'_s - R'_m}{6} i_o L \quad [18b]$$

The amplitude of the transient Eq. [16b] is given by

$$V^o_s(0, \infty) - V^o_s(0, 0) = \frac{i_o L}{6} (2R'_s - R'_m) \quad [18c]$$

Thus by measuring the amplitude [15], the slope [17a], and one of the magnitudes given on the left-hand side of Eq. [18a, b, c], it is possible to calculate the parameters R'_m, C', and R'_s of the porous electrode. However, in practice it is very difficult to measure $V_s(0, t)$ and the associated values given in Eq. [18a, b, c]. This is because the IR drop between the electrode surface $x = 0$ and the reference electrode at the front side $x = 0$ is superimposed on the potential $V_s(0, t)$. Moreover, the initial slope of Eq. [16a, b] is infinite as well as that of the IR drop voltage step. This makes it impossible to subtract the IR drop contribution from the experimental potential measured by the reference electrode in order to obtain $V_s(0, t)$. Consequently the intercepts and the transient amplitude given in Eq. [18a, b, c] cannot be determined.

On the other hand, the potential-time curve recorded by means of the rear side reference electrode ($x = L$) is almost completely free from IR drops, has finite initial slopes, and can thus provide much better means of calculating R'_s. The appropriate practical equations for this side are

$$V^i(L, t) - V^i_o = i_o L (R'_s + R'_m) \left[-\frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) - \frac{1}{6} + \frac{t}{\tau} \right] \quad [19a]$$

$$V^o_s(L, t) - V^o_\infty = \frac{2i_o L}{\pi^2} (R'_s + R'_m) \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp\left(-n^2\pi^2 \frac{t}{\tau}\right) \quad [19b]$$

By analogy with Eq. [17a] and [18a, b, c] one obtains from Eq. [19a, b]

$$\frac{dV^i(L, t \to \infty)}{dt} = \frac{i_o t}{LC'} \quad [17b]$$

$$t_{Lo} = \frac{\tau}{6} = \frac{(R'_m + R'_s)C'L^2}{6} \quad [20a]$$

$$V_{Lo} - V^i_o = -i_o L/6 (R'_s + R'_m) \quad [20b]$$

$$V^o_s(L, \infty) - V^o_s(L, 0) = i_o L/6 (R'_s + R'_m) \quad [20c]$$

Equations [20a, b, c] can serve to calculate R'_s from experimental results as is shown for Eq. [18a, b, c].

Comparison of Experimental Results with Theory

Considering the manufacturer's specifications of the porous carbon electrodes used in this work, their specific resistivities are some orders of magnitude smaller than that of the solution used. Therefore $R'_m << R'_s$ and R'_m can be dropped from Eq. [16], [18], [19], and [20].

Typical graphs of the potentials of the rear and front sides of the porous electrode *vs.* time are given in Fig. 2. The complete separation of the rear and front side solutions in this system gives negligible IR drop; $I \cdot R(L)$ for the rear side electrode as compared with $I \cdot R(0)$ for the front side. This emphasizes the advantages of measuring the working electrode potential by means of a rear reference electrode, which

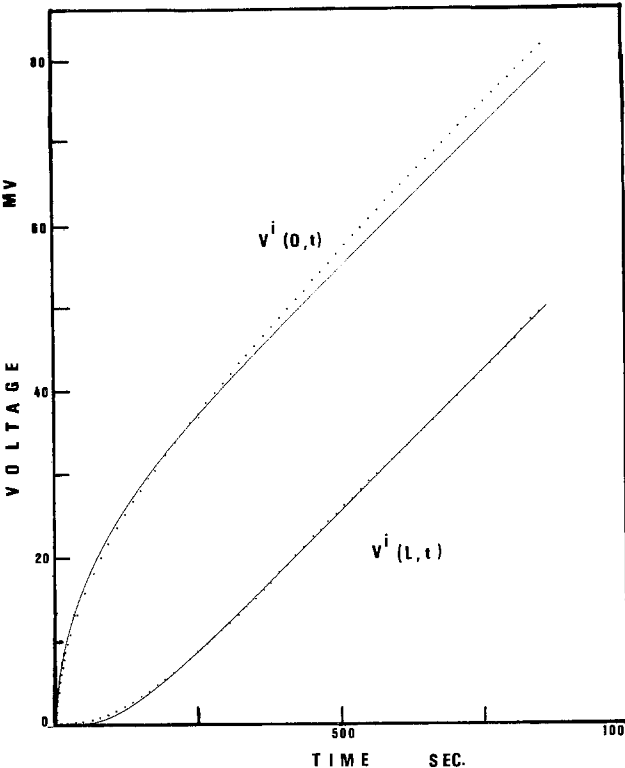

Fig. 3. Comparison between experimental (points) and theoretical (line, a computer plot) voltage transients of a 3 mm thick porous electrode, at the current step function mode. The curves $V^i(0,t)$ and $V^i(L,t)$ are, respectively, the front and rear side transients.

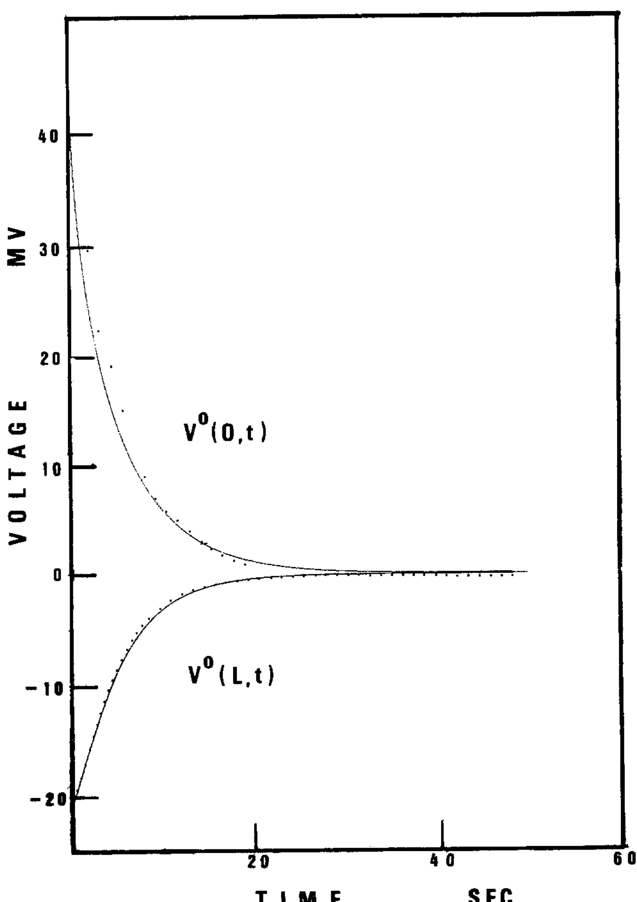

Fig. 4. The same as Fig. 3 but for the mode of interruption of prolonged current step function.

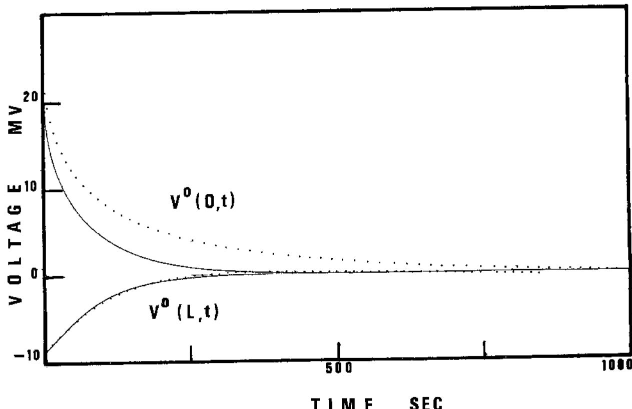

Fig. 5. The same as Fig. 4, but for 1 mm thick porous electrode

is screened from the IR drop by the porous working electrode.

The comparison of the theoretical and experimental curves is given in Fig. 3-5. The parameters C' and R'_s for the rear reference electrode potential $V^i(L,t)$ (Fig. 3) were calculated by means of Eq. [17b] and [20b]; for V^o (L,t) (Fig. 4 and 5) by Eq. [17b] and [20c]. The specific capacitance C' for the front side reference electrode potentials $V^i(0,t)$ and $V^o(0,t)$ were calculated according to Eq. [17a], whereas R'_s for these curves was obtained by curve fitting rather than utilizing Eq. [18a, b, c]. This was because of the limitations discussed above.

The parameters C' and R'_s characterizing the ideally polarized porous electrode are calculated by the various experimental results and are given in Table I together with the tortuosity factor.

The tortuosity factor T is given by the expression

$$\rho_P = \rho_B T \cdot 100/P \qquad [21]$$

where ρ_B is the specific resistivity of the bulk electrolyte solution and ρ_P is the apparent specific resistivity of the solution within the porous electrode assuming cell dimensions identical with that of the whole electrode.

The magnitude ρ_P is obtained experimentally from the transient amplitude $V^i(L,t)$. P is the porosity in volume per cent. It is given by 100 V_P/d, where V_P and d are, respectively, the pore void volume and the density and are given by the manufacturer. The tortuosity T_{mac} given in Table I is calculated by the macroporosity volume per cent, while T_t is obtained according to the total (micro and macro) porosity. The tortuosity expresses the elongation of the conduction path as compared to straight tunnels parallel to the x axis. It must therefore be considerably greater than unity. As seen in Table I, this requirement is not fulfilled if only macroporosity is responsible for the ionic conductance of the pores.

It appears, therefore, that at least part of the micropores participate in ionic conduction.

It is seen from Fig. 3-5 that the coincidence of the experimental and theoretical curves is quite satisfactory for the rear side reference electrode $V(L,t)$. Significant discrepancy is shown however by the front side transient $V(0,t)$, especially in the case of the

thinner 1 mm electrode (Fig. 5). Also the value of R'_s (Table I) obtained by the front side transient through curve fitting is considerably higher than that obtained by the rear side transient. These discrepancies can be qualitatively explained by some more detailed description of the porous structure of the carbon electrode. Similar to many other types of activated carbons, the pore structure of the carbon studied exhibits two completely distinct ranges of pore radii. The micropores which practically accommodate all the surface area and double layer capacity are of an average pore diameter of 21Å.[4] These may be viewed as long and narrow branched tunnels terminating at the macropores which are about thousandfold larger[4] in diameter. The corresponding equivalent circuit of such a structure must account for the combined resistive and capacitative impedances of the micropores and for the merely resistive contribution of the macropores. An appropriate circuit is given in Fig. 6 together with a schematic of the pore structure of the electrode. This equivalent circuit differs from the previous one (Fig. 2b) by an extra (distributed) micropore resistivity R_{mic} extending along the macropores. An ionic current $\Delta i(x = L)$ charging the double layer of the rear side $x = L$ of the porous electrode faces mainly the macropore resistivity R'_sL due to the long (1 or 3 mm) pathway L. The rear side transient is therefore insensitive to the micropore resistivity, that is why it is in good agreement with the simple model of Fig. 2. The front side, on the other hand, is charged through a very short pathway with the specific linear resistivity R'_s; therefore, the contribution of R_{mic} is sensible. This results in a charging rate [slope of transients $V(0, 1)$] which is slower than that predicted by the simpler model, and in an apparently higher R'_s (Table I). The relative contribution of R_{mic} is obviously larger for the thinner (1 mm) electrode, therefore the greater variance of experiment from theory for the transient $V(0, t)$ of that electrode.

The electrode model described in Fig. 6 will merit further study once it is accompanied by more experimental results to which theory should be compared.

[4] Average pore diameters are calculated by $r = 2V/s$, where V is the pore void volume and s is the specific surface area per gram (22). The macropore distribution function of this carbon, provided by the manufacturers, shows practically no contribution to porosity at diameter ranges below 8000Å.

Manuscript submitted Jan. 6, 1975; revised manuscript received Aug. 4, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Technical Note

Mass Spectrometric Studies on High Temperature Reaction Between Hydrogen Chloride and Silica/Silicon

Sin-Shong Lin

Army Materials and Mechanics Research Center, Watertown, Massachusetts 02072

The high temperature chemical reaction between hydrogen chloride and silica is widely employed in the fabrication of solid-state devices (1). This reaction is especially used to eliminate surface oxides of silicon substrates for epitaxial growth of silicon wafers. The reaction is carried out at 1200°C under 1 atm pressure of HCl by assuming that the interaction takes place according to

$$SiO_2(s) + 4HCl(g) = SiCl_4(g) + 2H_2O(g) \quad [1]$$

Thus the formation of silicon tetrachloride and water vapors eliminates oxide surfaces and exposes growth sites in bulk silicon substrates.

Although the chemical reaction is thermodynamically feasible, the reaction may not be the only reaction occurring at the surfaces of silicon substrates. Other interactions such as

$$Si(s) + 4HCl(g) = SiCl_4(g) + 2H_2(g) \quad [2]$$

$$Si(s) + SiO_2(s) = 2SiO(g) \quad [3]$$

are competitive and may occupy dominant roles in the elimination mechanism of surface oxides. Also the formation of high temperature silicon chloride vapor species is highly probable (2, 3), and these species may play more important roles in the reaction mechanism.

The work reported here is a part of research aimed to investigate the nitridation kinetics of silicon (4). Attempts have been made to modify and to accelerate the nitridation process by use of HCl to eliminate oxide layers of silicon. During the course of the present study, the interaction of HCl and SiO_2 is found to deviate considerably from the assumed reaction [1]. Thus the elucidation of this reaction becomes essential for a better understanding of the important industrial process.

The description of the present setup is detailed elsewhere (5, 6). The solid sample,[1] silica, silicon, or silicon monoxide (equimolar mixture of Si and SiO_2), is loaded onto an alumina boat which is then placed near the tip of the closed end alumina combustion tube of a specially designed miniature furnace. A 0.006 in. diam orifice is drilled axially to the closed end so that all vapors in the reaction chamber are directed into a vacuum for sampling. Hydrogen chloride or an 8.1% HCl nitrogen mixture is introduced into the furnace at a flow rate of 10 cm^3/min. The temperature of the furnace is set and regulated by a Pt-10% Rh/Pt thermocouple attached to a proportional temperature controller in a range 800°-1400°C. Under the given flow rate, the pressure of the chamber varies from 100 to 400 mm Hg depending on temperature, orifice, and pumping speed. The effusates from the gas-solid interaction through the orifice are modulated and detected by a quadrupole mass spectrometer. The identity of an ion is established from the mass number and the isotopic distribution.

Some experimental results are tabulated in Table I. The first group of the experiments was performed between silica and HCl or the HCl/N_2 mixture. At temperatures below 1200°C, no reaction product was observed. Mass spectra consist solely of reactant ions, such as HCl^+, Cl^+, and Cl_2^+ (plus N_2^+ and N_2^{++} in the HCl/N_2 run). Ion species resulting from the interaction begin to appear starting from 1250°C, and their relative abundances vary with increasing temperature up to 1400°C. Ions $SiCl^+$, $SiCl_2^+$, and $SiCl_3^+$ are observed, but $SiCl_4^+$ is never detected. A trace amount of O_2^+ and SiO^+ is detected only in the HCl runs. The presence of H_2O^+ ion is hard to establish due to a high background peak at this mass.

The second run was made with SiO and the HCl/N_2 mixture. The interaction is so favorable that all ions containing Si and Cl atoms are observed such as $SiCl^+$, $SiCl_2^+$, $SiCl_3^+$, and $SiCl_4^+$. The relative abundances of these Si-Cl ion species are comparable to that of the unreacted HCl^+. Moreover the first three Si-Cl species become more abundant than $SiCl_4^+$ as the temperature increases. The SiO^+ ion is clearly detected at 1400°C, and the intensity is comparable to that of $SiCl^+$. Neither O_2^+ nor H_2O^+ is observed.

The third run was made with silicon and the HCl/N_2 mixture. The interaction between them is so strong that all ions species described previously are observed at all temperatures of the experiments. The ion intensity ratios of $SiCl^+$, $SiCl_2^+$, and $SiCl_3^+$ to $SiCl_4^+$ are nearly constant except at the highest temperature of 1400°C. These ratios are found to increase significantly reflecting the contributions to these ions from other molecules. The H_2^+ ion is detected and separated from noisy background of low mass spectra.

From relative abundances of observed Si-Cl species, it is evident that the extent of the HCl + solid interaction decreases drastically from silicon to silicon monoxide, and to silica. At 1200°C large amounts of Si-Cl ion vapors are observed in the Si run, but no reaction product is observed in the SiO_2 run. Consequently little interaction occurs between HCl and SiO_2 at this temperature. Although reaction [1] is thermodynamically feasible, it is kinetically unfavorable and proceeds at a very slow rate. One might reason that the HCl pressure in the present experiments is not comparable to the 1 atm pressure commonly used. Since the pressures of these runs are about one-fourth of 1 atm, such deviation should not change the situation significantly.

The interaction between HCl and Si from 800° to 1200°C presumably produces $SiCl_4$ as a major gaseous species as shown in reaction [1]. Upon electron impact

ionization, $SiCl_4$ dissociates (7, 8) extensively into $SiCl_4^+$, $SiCl_3^+$, $SiCl_2^+$, $SiCl^+$, and Si^+ (obscured by background N_2^+), so that mass spectra obtained consist mostly of these peaks and reactants. The formation of chlorosilane is believed to be minor and is discounted, because no hydrogen containing Si-Cl ion is observed. As the temperature is increased to 1200°C or higher, the contribution to these fragmented ions from high temperature vapors $SiCl_2$ and $SiCl_3$ increases. Thus at the highest temperature of the experiment, the abundances of $SiCl_2^+$ and $SiCl_3^+$ increase more than would be expected from the fragmentation of $SiCl_4$. This observation is consistent with available thermodynamic data. In Fig. 1, vapor pressures of Si-Cl neutral species calculated from the HCl + Si interaction under 1 atm pressure of HCl are plotted *vs.* temperature. At 1000°K $SiCl_4$ is the major species from the interaction, but above 1200°C, the vapor consists of comparable magnitudes of $SiCl_4$, $SiCl_3$, and $SiCl_2$.

The appearance potential measurement made during the Si run also establishes that molecules $SiCl_2$ and $SiCl_3$ in addition to $SiCl_4$ exist at high temperatures. The appearance potentials of $SiCl^+$, $SiCl_2^+$, $SiCl_3^+$, and $SiCl_4^+$ ions are 16.0, 12.6, 12.5, and 11.5 ± 0.7 eV, respectively, at 800°C. However at 1200°C, the appearance potentials of $SiCl^+$, $SiCl_2^+$, $SiCl_3^+$, and $SiCl_4^+$ become 12.0, 10.0, 12.2, and 12.0 ± 0.7 eV, respectively. The lower appearance potentials of $SiCl_2^+$ and $SiCl_3^+$ suggest that at higher temperatures these ions are derived from other molecules in addition to $SiCl_4$.

Although the interaction between HCl and SiO_2 does not occur to a measurable extent at 1200°C as described in the preceding paragraphs, it has taken place above this temperature. The ion species $SiCl^+$, $SiCl_2^+$, and $SiCl_3^+$ are detected from 1250° to 1400°C, but no $SiCl_4^+$ is detected within the sensitivity of the instrument. Since the largest Si-Cl ion observed in the system is $SiCl_3^+$, the ion is probably derived from the direct ionization of $SiCl_3$ vapor. Moreover relative abundances of $SiCl^+$, $SiCl_2^+$, and $SiCl_3^+$ vary with increasing temperatures. Especially at 1400°C, the ion intensity of $SiCl_2^+$ increases more rapidly than that of $SiCl_3^+$. This possibly indicates that $SiCl_2$ molecule exists and is a more dominant species than $SiCl_3$. Therefore the reactions written in best agreement with the experiments are

$$SiO_2(s) + 3HCl(g) = SiCl_3(g) + 1/4\,O_2(g) + 3/2\,H_2O(g) \quad [4]$$

$$SiO_2(s) + 2HCl(g) = SiCl_2(g) + ½\,O_2(g) + H_2O(g) \quad [5]$$

The presence of SiCl in the vapor phase is not confirmed experimentally due to the fact that large portions of $SiCl^+$ are fragmented ions, but from the thermodynamic calculation, SiCl molecule is present in an insignificant amount. The vapor pressure data shown in Fig. 1 disagree with the present SiO_2 results. The calculated data indicate that $SiCl_4$ should be a dominant species at all temperatures of the experiment. An explanation of this discrepancy is that the formation of Si-Cl species with a large number of Cl

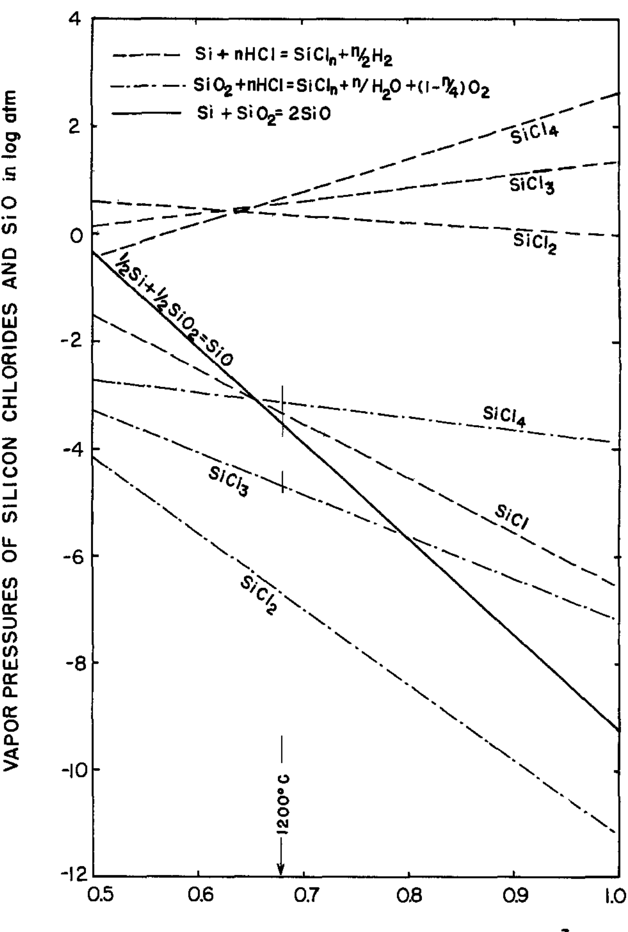

Fig. 1. Equilibrium vapor pressures of Si-Cl and SiO. The pressures are calculated from the gas-solid reactions indicated on the graph under 1 atm pressure of HCl and unity activity of solid. All thermodynamic data are taken from the JANAF tables.

atoms is kinetically unfavorable from the HCl + SiO_2 interaction. Consequently $SiCl_4$ is not observed, and $SiCl_3$ is detected in a lesser amount.

The SiO^+ is detected over the SiO sample and in some of the SiO_2 runs. The vapor pressure of SiO over Si and SiO_2 solids as indicated by reaction [3] become significant at temperatures above 1200°C. As shown in Fig. 1 the equilibrium vapor pressure of SiO is found to be greater than vapor pressures of $SiCl_2$ and $SiCl_3$ from the HCl + SiO_2 reaction. Since $SiCl_4$ is not detected during the SiO_2 runs, the evaporation of SiO from the contaminated silicon surfaces is believed to be more competitive than any reactions between SiO_2 and HCl. Moreover this evaporation is accelerated by escape of silicon chloride vapors resulting from the interaction between silicon substrate and HCl. The vapor pressure of $SiCl_4$ resulting from the latter reaction is found to be five orders of magnitude larger than that of SiO, which does promote the SiO evaporation. The vapor phase reaction between SiO and HCl to form Si-Cl vapors is also a highly probable mechanism, however the present data cannot distinguish this alternative process.

In summary, the interaction between HCl and SiO_2 produces high temperature vapors $SiCl_2$ and $SiCl_3$ but not $SiCl_4$ above 1250°C, and no interaction is observed below 1200°C. $SiCl_4$ molecule is found to be a major vapor species formed by the interaction between HCl and Si at low temperatures, and other species such as $SiCl_2$ and $SiCl_3$ may become important at higher temperatures. The elimination of contaminated silicon surface oxides by HCl gas is mainly due to simple vaporization of SiO from the silicon substrates. This vaporization is further promoted by the formation of silicon chloride vapors from the interaction between HCl and Si. The direct interaction between SiO_2 and HCl to form silicon chloride vapors and water plays a minor role in the etching process of the silicon substrates.

Passivation of High Breakdown Voltage p-n-p Structures by Thermal Oxidation

R. E. Blaha and W. R. Fahrner

Institut für Angewandte Festkörperphysik der Fraunhofer-Gesellschaft, 78 Freiburg, Germany

ABSTRACT

Experiments for the thermal oxidation of silicon power devices are carried out on symmetrical p-n-p junctions with breakdown voltages of 1.2 and 2.8 kV, respectively. A new etching procedure is developed for the surface cleaning. For the 1.2 kV samples, the oxidation procedure is optimized with respect to temperature, time, and cooling rate. The smallest leakage current is obtained when silicon boats are used during the thermal oxidation. No yield is found for a junction bevel angle larger than 7°. For the 2.8 kV diodes additional precautions must be taken, most important of which is the use of silicon furnace tubes. To obtain thick (≈1000Å) oxide layers, a dry-wet-dry oxidation cycle is used.

Long term stability of thyristors is improved by a passivation step which protects the critical p-n junctions of the structure. Very often passivation is carried out by depositing silicone rubber or glasses. These techniques are not always successful because they do not prevent ion migration. A better way consists of introducing a thermal oxidation step followed by a silicon nitride deposition. In this case, the main problem is the oxidation, especially when devices with a high breakdown voltage U_B (in our case approximately 1.2 and 2.8 kV) are to be passivated. The high temperature process introduces impurities which soften the abrupt I-V characteristics of the diode.

This paper deals with the technological conditions for a reduction of impurities. The investigations are carried out with two symmetrical p-n-p structures which are the essential part of the final thyristors. In Fig. 1, a cross section of a 3 kV device is shown. The starting material is nominally 110 ohm-cm n-type silicon. First of all, the wafer of 16 mm diameter and 700 μm thickness is diffused with Al to a junction depth of 95-100 μm. A second diffusion step introduces Ga to a junction depth of 50 μm. Then, boron silicate gettering (10 μm, 1-2 · $10^{17}/cm^3$) removes the impurities in the preceding steps. The wafers are beveled at the edge with an angle between 1.6° and 1.8°. Finally, they are etched with Syton polish and CP 8 (1). The 1.2 kV wafers differ only slightly in doping level, in diameter (19 mm), and in thickness (550 μm). The above process steps are carried out by the BBC laboratories in Lampertheim, Germany, and Baden, Switzerland, respectively.

Experiments and Results

The experiments are subdivided into two groups. In the first one, 19 mm diameter p-n-p structures of 1.2 kV breakdown voltage and 3° bevel angle are investigated. In the second one, p-n-p structures of 2.8 kV breakdown voltage and a bevel angle of 1.6° are examined. To obtain reliable statistics, more than 60 runs are carried out for either group. This means that the effects of each parameter quoted below are checked by the measurements of five or more runs.

An important condition for successful passivation is the cleaning of the surface of the device. The usual MOS cleaning is developed for polished surfaces and fails for our case of lapped surfaces. We find that these need a removal of more than 1000Å of the surface. In addition the MOS cleaning of 2 hr/run consumes too much time. After a trial and error procedure, we have obtained the best results by applying the following steps: (*i*) HF 40% (Merck suprapur), 30 sec; (*ii*) Millipore SQ-H_2O rinse (18 Mohm-cm); (*iii*) perchlorate etch (74.5% volume HNO_3 of 65%, 7.5 % volume CH_3COOH of 96%, 10.5% volume HF of 40%, 7.5% volume $HClO_4$ of 70%, all Merck suprapur) for 10 sec, corresponding to a surface removal of 1700Å; (*iv*) H_2O as in (*ii*); and (*v*) drying with a spinner, 60 sec.

The sample is introduced into the furnace immediately after cleaning. The oxidation is carried out in a Heraeus-Heralux® quartz tube. For each sample, the I-V characteristics are measured first after the etch cleaning and then after oxidation and subsequent annealing. As a criterion for "acceptable characteristics," the manufacturers of power devices adopt a standard of 20 mA. In this investigation, we reduce this level to

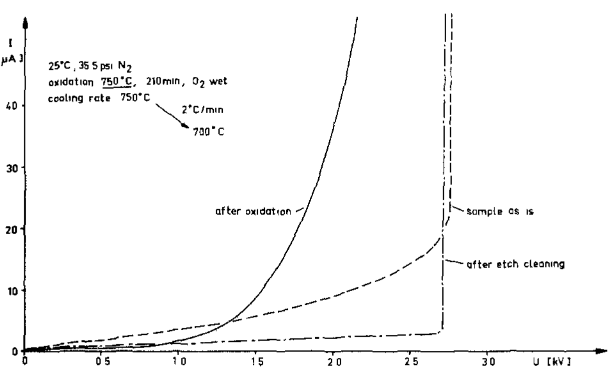

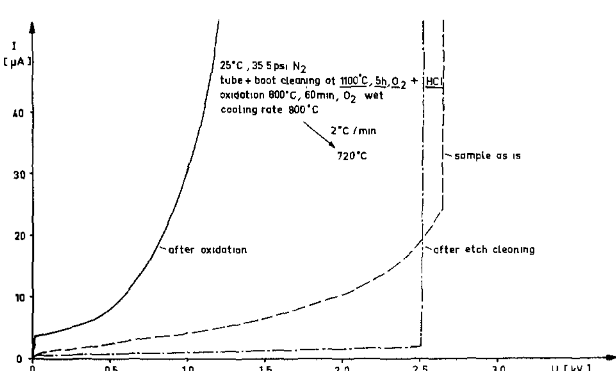

Fig. 6. I-V characteristics after reducing the oxidation temperature and varying the preparation of the tube and boat.

100 μA. Furthermore we use the inverse radius of curvature at breakdown as a measure for "better" or "worse" characteristics. The breakdown point is given when the conductance increases to 100 μA/10V. Since the characteristics are almost identical in either voltage direction, only the first quadrant is shown. In Fig. 2, I-V characteristics of 1.2 kV diodes with different oxidation conditions are plotted. The results obtained from these and other curves for higher oxidation temperature are the following: (*i*) Oxidation temperatures above 850°C do not give good I-V characteristics. (*ii*) The optimum condition is an oxidation temperature of 800°C and a constant cooling rate of 2°C/min from 800° to 720°C. (*iii*) A constant heating rate up to the oxidation temperature does not improve the diodes.

Retaining the oxidation conditions (800°C, 60 min, wet oxygen, 2°C/min cooling from 800° to 720-C) we

now investigate the effects of a variation of the bevel angles. In Fig. 3, typical examples of diodes with 7°, 11°, 30°, and 45° are given. It turns out that only bevel angles up to 7° maintain abrupt I-V characteristics whereas a high leakage current and soft I-V characteristics are found for larger angles.

A further improvement is obtained by using silicon instead of quartz boats (Fig. 4). Two diodes otherwise identically processed show significantly different I-V characteristics. This is attributed to the different impurity concentrations in quartz and silicon (2). It is found, for instance, that the sodium content in Dow Corning and Siemens silicon used for the boats is negligible (0.0 to 0.6 ppba) whereas in quartz, high values (260 ppba) are measured. Note that the leakage current is below 1 μA.

The know-how of the first experimental series must be extended when 2.8 kV diodes are to be oxidized as demonstrated in Fig. 5. In the upper half of the figure, the characteristics of a 2.5 kV diode and of a 1.2 kV diode are presented for comparison. The same problem arises for a nitride passivation, as shown in the lower half of the figure. After the etch cleaning, a Si_3N_4 layer is deposited on a 1.2 and a 2.2 kV diode by reactive sputtering. All process parameters are identical. Due to these results we have to find new ways for preparing good oxides. We have varied the following parameters: the cleaning procedure, the tube and boat cleaning, the steam content, the oxide temperature, the oxidation time, and the cooling rate after oxidation. As shown in Fig. 6, a diode oxidized in wet oxygen for 210 min at 750°C and slowly cooled down to 700°C with 2°C/min exhibits soft characteristics and a high leakage current. The same result is obtained when the sample is oxidized at 800°C for 60 min in wet oxygen after the tube and the boat are precleaned with HCl at 1100°C for 5 hr.

In Fig. 7, (top), a dry 800°C oxide of 60 min oxidation time and a cooling rate of 2°/min is shown. Again the results are unsatisfactory. This is also true for the sample shown below where dry oxygen of 1200°C for 15 min is applied. The cooling rate is 60°C/min until room temperature is reached. The blocking characteristics of the diode have completely disappeared due to impurities (mostly metal ions) induced by the high temperature.

In order to test the effects of impurities introduced by oxygen and steam, we replace the oxidation by a heat-treatment in nitrogen ambient of the same temperature as the oxidation. The results are given in Fig. 8. The upper curves correspond to a sample annealed for 5 min, the lower for 30 min. Two conclusions can be drawn from this figure: (*i*) the oxygen and steam are not responsible for the degradation of the diode, since the 30 min sample fails, and (*ii*) the degradation is proportional to a "contact time" with impurities in the furnace.

Finally the quartz environment (tube and boat) are identified as the essential source of contamination during the process. This is proved in Fig. 9. Two diodes are processed with identical conditions. The first one is oxidized in a quartz tube (upper half of the figure); for the second one, we use a silicon tube. This result of hard I-V characteristic and a low leakage current of less than 2 μA is completely reproducible. In order to increase the oxide thickness, we use wet oxygen. Unsatisfactory results are obtained. However, when we switch over to a dry-wet-dry or a dry-wet cycle, the characteristics are as good as for the solely dry oxidation (Fig. 10). The dry-wet-dry oxidation conditions are: 33 min dry oxygen, 70 min wet oxygen, and 15 min dry oxygen. The cooling rate from 800° to 720°C is 2°C/min. For the dry-wet oxidation, we use 10 min dry oxygen, 8 min wet oxygen, and a cooling rate of 3.3°C/min. By comparison we find that low leakage currents are maintained by the initial dry oxidation.

Conclusion

The experiments on the thermal oxidation of power devices are carried out first with symmetrical diodes of a breakdown voltage of 1.2 kV. Bevel angles are 3°, 6°, 7°, 11°, and 45°. The investigations are extended to diodes of a breakdown voltage between 2.2 and 3.1 kV and bevel angles of 1.6°-1.8°.

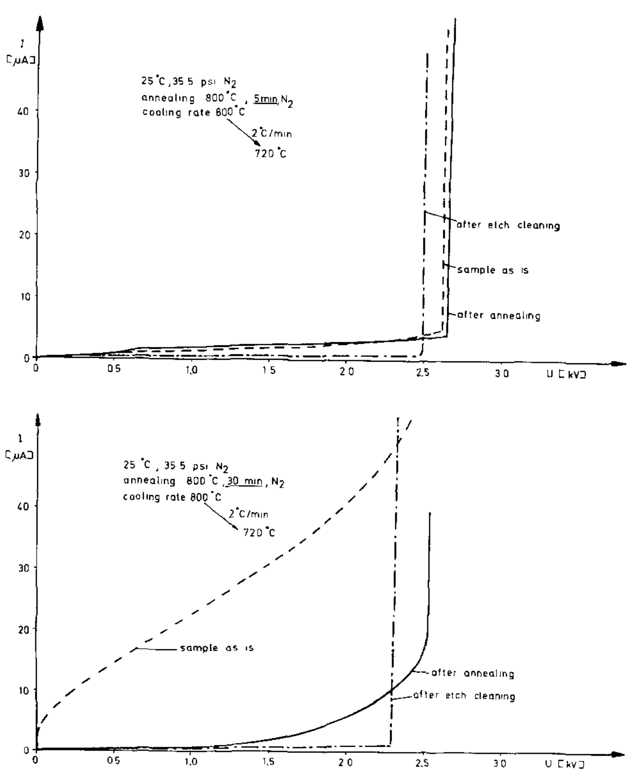

Fig. 8. I-V characteristics after annealing for different times

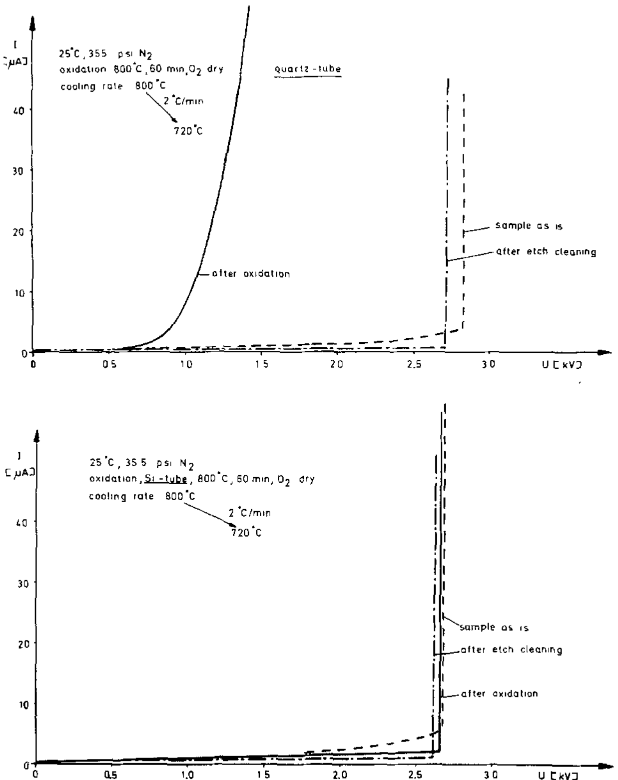

Fig. 9. The influence of the tube material on I-V characteristics. All other parameters are unchanged.

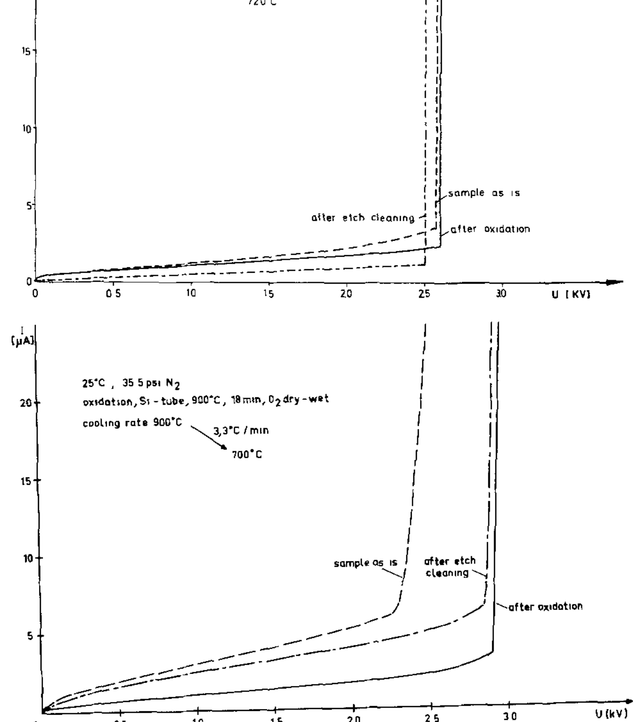

Fig. 10. Extension of the successful oxidation of Fig. 9 (bottom) to thicker oxide layers (800-1200Å) by a dry-wet-dry and a dry-wet oxidation cycle.

For the surface cleaning of the device, an etch cleaning is developed. For the 1.2 kV diodes, the best oxidation temperature in a quartz tube is 800°C with a subsequent cooling of 2°C/min. This procedure is successful for bevel angles up to 7°. A further improvement is obtained when silicon boats are used for the oxidation.

This technique fails in the case of the 2.8 kV diodes. It is found that the use of silicon tubes saves the initial abrupt I-V characteristics. Again, we use a dry oxidation temperature of 800°C, and a cooling rate of 2°C/min. It turns out that temperatures up to 900°C and cooling rates up to 4°C/min can be successfully applied with a silicon tube. To obtain thicker layers, a dry-wet-dry or dry-wet cycle is used. It can be concluded that for the first time, to our knowledge, passivation by thermal oxidation of 2.8 kV diodes can be carried out.

Chemically Vapor Deposited Fe_2O_3 Films

Donald R. Mason*

Harris Semiconductor, Melbourne, Florida 32901

ABSTRACT

The kinetics of the oxidation of iron pentacarbonyl by oxygen in the presence of water vapor have been investigated. Thin films having a composition closely resembling Fe_2O_3 are obtained. The reaction sequence comprises, first, homogeneous nucleation and heterogeneous growth of particles which appear as smoke. Termination occurs by pyrolysis and oxidation of the smoke particles on the hot deposition surface. The H_2O acts as an inhibitor on the film deposition rate. This mechanism is different from that normally proposed for homoepitaxy and from that proposed by Sladek for Si_3N_4 deposition.

Metal oxide films for use as photolithographic masks have been prepared and evaluated by several investigators. Metal oxide masks are potentially superior to emulsion and some metal masks because they are harder (hence more scratch resistant) and partially transparent in the visible spectrum.

Sinclair, Sullivan, and Fastnacht (1, 2) evaluated a wide range of compositions of oxide films made by d-c reactive sputtering at 60 Torr and 10-100% O_2. Requirements for good films would be that they transmit less than 1% of the incident energy below 4000Å, more than 30% of the incident energy above 5890Å, are etchable in reagents compatible with photoresist processes, and can resolve lines separated by 2 μm or less. Films of iron-vanadium oxide came closest to meeting the proposed properties desired for the masks.

Meanwhile, MacChesney, O'Connor, and Sullivan (3) prepared iron oxide films on soda lime glass plates by chemical vapor deposition using iron pentacarbonyl ($Fe(CO)_5$) vapor in an argon carrier gas and reacting it in ambient gas atmospheres of argon, carbon dioxide, oxygen, or oxygen-water vapor. These films met the proposed criteria if prepared properly. Upon oxidation, the over-all reaction which takes place is

$$2Fe(CO)_5 + mO_2 \rightarrow Fe_2O_3 + pCO + qCO_2 \quad [1]$$

The detailed mechanisms of these reactions are not yet known. In oxygen without water vapor, the rates were (3) "... approximately proportional to carrier gas flow rate and were not believed to be temperature dependent above 140°C." Water vapor not only drastically reduced the deposition rate, but the deposition rate *vs.* temperature now showed an activation energy of 12.7 kcal/mole. They postulated without discussion that the decomposition of iron pentacarbonyl to iron oxide proceeds by a surface catalyzed reaction (inferentially as the rate-limiting step.)

Peters, Sinclair, and Sullivan (4) have prepared FeO_x films by sputtering and indicate that, at least for them, sputtering is more convenient than chemical vapor deposition. More recently, Sullivan (5) has indicated that good quality CVD films can be prepared at 100°C that meet all requirements, using CO_2 as a carrier gas.

Cotton, Fischer, and Wilkinson (6) investigated the structure and properties of iron pentacarbonyl. The latent heat of vaporization is +8.9 kcal/mole. The enthalpy of combustion at 298°K according to the reaction

$$Fe(CO)_5(l) + \frac{13}{4} O_2(g) \rightarrow \tfrac{1}{2} Fe_2O_3(s) + 5CO_2(g) \quad [2]$$

is −385.9 kcal/mole. This represents an energy release of 16.8 eV per molecule of $Fe(CO)_5(l)$ oxidized, or 17.2 eV per molecule of $Fe(CO)_5(g)$ oxidized. Irradiation of $Fe(CO)_5$ with near u.v. light produces iron enneacarbonyl, $Fe_2(CO)_9$, and carbon monoxide (7)

$$2Fe(CO)_5 + h\nu \rightarrow Fe_2(CO)_9 + CO \quad [3]$$

When pure, it is unattacked by air. It is insoluble and nonvolatile, and unique among carbonyls. The compound decomposes at 100°C to give iron, CO, some $Fe(CO)_5$, and some iron dodecacarbonyl, $Fe_3(CO)_{12}$. Iron dodecacarbonyl exists as green monoclinic crystals. It is volatile in steam without decomposition, but if heated alone above 100°C, it breaks down into metallic iron and carbon monoxide.

Experimental

Our preliminary work was carried out using N_2 as a carrier gas for the $Fe(CO)_5$, which was introduced by a bubbler. The remainder of the gas was made up of O_2 and CO_2.

Following the over-all reaction mechanism given by Eq. [1], wherein all of the liberated CO is converted to CO_2, then a maximum of 3.25 volumes of O_2 are needed for each volume of $Fe(CO)_5$. This restriction was met in all cases; usually with more than a 100% excess of oxygen. Temperature ranges studied extended from 90° to 160°C.

In order to obtain reaction time-temperature relationships, the process observations were made by noting film color changes with time. The reaction was terminated when the appropriate color fringe on the film was observed, and the times noted. This technique is dependent on chamber-wall cleanliness and is also subjective, even with an experienced observer, with an error of typically ±5 sec.

The times required to form the first purple (950Å) fringe and the first red (1700Å) fringe were noted and the deposition rate over this thickness interval computed from the time interval difference. By using this "steady-state" deposition rate, the apparent elapsed time to form the first 950Å was calculated. By substracting this time interval from the time noted to form the first purple fringe, an apparent induction period for the reaction was calculated. Time measurements were to the nearest 5 sec.

A gas control system was hard plumbed with copper tubing and equipped with thermoelectric coolers for temperature control of the iron carbonyl and water bubblers. The reaction chamber was an inverted 8 in. diameter funnel whose lip had been ground to give a snug fit onto the hot plate surface. Its volume was 1700 cm³. Depositions were made on 2½ in. square soft glass plates, polished on one side, and cleaned thoroughly just prior to deposition. All work was done in a laminar flow hood. Residual small particles on the glass often caused large pinholes. Typically, the carrier gas was saturated with iron carbonyl at room temperature and equilibrated by going through a second

* Electrochemical Society Active Member.

Key words: CVD mechanism, iron oxide film, iron pentacarbonyl oxidation, photolithographic masks.

bubbler maintained at 20°C. Water vapor at 0°, 10°, and 20°C was introduced in the oxidizer stream.

In order to assess the nonsteady-state conditions existing during reaction, the chamber was treated as a continuous stirred tank reactor system (8). In conditions of operation, a substrate plate was placed on the hot plate surface, and the reaction funnel placed over it, defining $t = 0$. The apparent start of deposition, t_o, was determined as above. During purging of the reactor, assuming this reaction to be first order with respect to iron carbonyl, the reactant concentration builds up in accordance with the relationship (8)

$$C_a = \frac{C_{a,o}}{Q}\left(1 - \exp - \frac{Qt}{\theta}\right) \quad [4]$$

where $Q = (k^* + F/V)\theta = (k^*\theta + 1)$; $\theta = V/F$, sec; k^* = first order reaction velocity constant, sec^{-1}; F = total volumetric flow rate through the reactor, cm^3/sec; V = volume of the reactor, cm^3; C_a = $Fe(CO)_5$ concentration in reactor at time = t, mole fraction; and $C_{a,o}$ = $Fe(CO)_5$ concentration in the feed gas stream, mole fraction. Initially, it was assumed that $k^* << F/V$. For example, at 115°C, 22.8 cm^3 per minute of $Fe(CO)_5$ were fed to the reactor for 4.22 min to form a film 1700Å thick. This corresponds to 223 mg Fe in the gas, from which only 19.5 mg Fe deposited on the hot plate areas.

The concentrations of $Fe(CO)_5$ were calculated using Eq. [4] at $t = t_{950}$ and at $t = t_{1700}$, the times when the films were "950Å" (first purple) and "1700Å" (first red) thick. This corresponds to the time interval over which the deposition rate was measured.

With the increase in $Fe(CO)_5$ concentration, the H_2O concentration was also decreasing. Assuming a 50% relative humidity and nominal room temperature of 24°C (p_{H_2O} = 22 mm Hg), then the chamber contained 14,500 ppm H_2O at the initiation of the purge cycle. The decrease in water vapor content with time is (9)

$$C_{H_2O} = C_{H_2O,o} + (A_{H_2O} - C_{H_2O,o}) \exp - t/\theta \quad [5]$$

where C_{H_2O} = actual water vapor concentration in reactor at time = t, ppm; $C_{H_2O,o}$ = water vapor concentration in reactant feed stream, ppm; and A_{H_2O} = initial water vapor concentration in reactor, assumed 14,500 ppm, as described above. The carbonyl and water concentrations were calculated at t_{950} and t_{1700} and a mean concentration used. Errors were typically about 5-10%.

A series of 39 additional sets of runs with from three to nine observations at each set of conditions was made varying iron carbonyl concentration (from 0.53 to 1.5%), water concentration (from 0.063 to 0.24%), and temperature (13 runs at 104°C, 13 runs as 115°C, and 13 runs at 127°C). Flow rate was typically 1350 cm^3/min. All data were analyzed as outlined above. Results plotted on Fig. 1 and 2 show deposition rates in Å/min at 104°C, plotted *vs.* water vapor concentration and $Fe(CO)_5$ concentration in mole fraction, respectively. Similar plots were obtained at 115° and 127°C. Water vapor concentration was more difficult to control than carbonyl concentration.

The plots in Fig. 1 and 2 indicate that the deposition rate varies approximately with the iron carbonyl concentration to the 1.5 power, and with the water concentration to the -1 power. In order to evaluate these exponents more carefully as well as the pre-exponential coefficient, A, and the activation energy, ΔE, the data were subjected to a multiple regression analysis on a computer. The results were

$$R^* = \frac{3.738 \times 10^7 \, (C_1)^{1.575}}{(C_2)^{0.93}} \exp \frac{-8124}{RT} \text{ Å/min} \quad [6]$$

where R^* = deposition rate, Å/min; C_1 = iron carbonyl concentration, mole fraction; C_2 = water concentration, mole fraction; A = pre-exponential coefficient = 3.738×10^7; ΔE = activation energy, -8124 ± 366 cal/g mole; m = concentration dependence of C_1, 1.575 ± 0.030; and n = concentration dependence of C_2, -0.930 ± 0.024, where the $\pm$ values indicate one sigma limits.

At low water concentrations, the deposition rate was very rapid, and the chamber became smoky and cloudy very rapidly. Water vapor suppressed smoke formation and reduced deposition rate.

The sensitivity of the deposition rate to various operating parameters can be determined by differentiating the rate expression with respect to the independent variables. For example, a variation of $\pm$ 2°K in deposition temperature can cause a total of 10% change between minimum and maximum film thick-

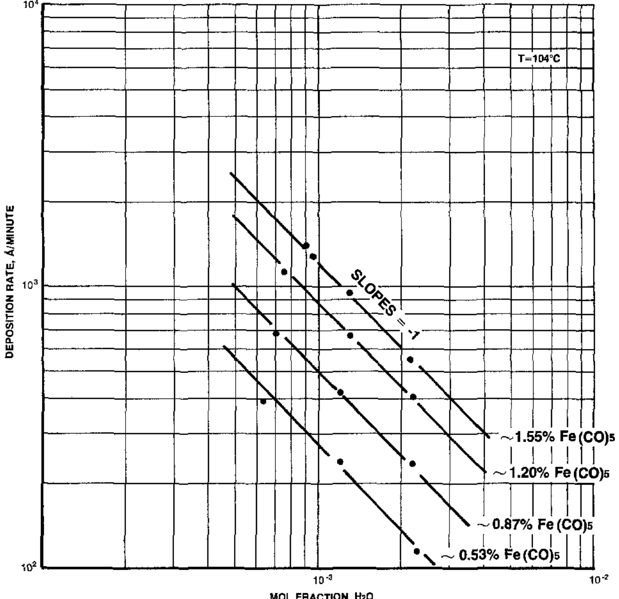

Fig. 1. Film deposition rate, R^*, in Å/min *vs.* water vapor concentration in mole fraction as functions of iron pentacarbonyl concentration at 104°C.

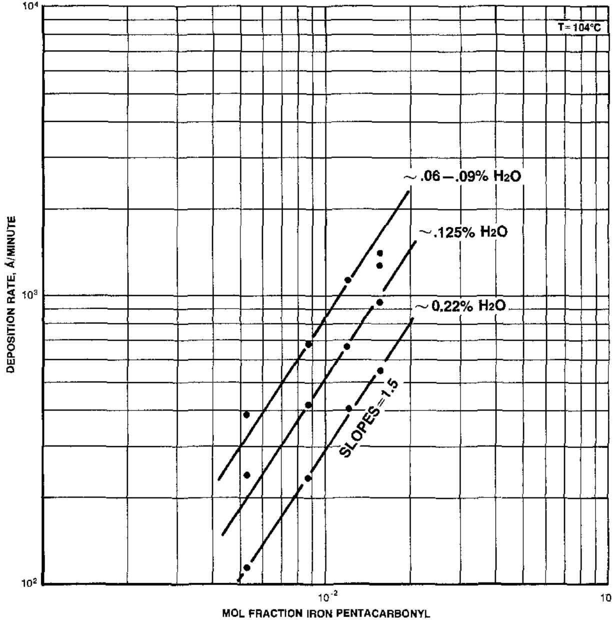

Fig. 2. Film deposition rate, R^*, in Å/min *vs.* iron pentacarbonyl concentration in mole fraction as functions of water vapor concentration at 104°C.

ness. Good temperature control is necessary for good deposition rate reproducibility and film uniformity.

When compared to the activation energy found by MacChesney *et al.* of 12.7 kcal/mole, our significantly lower activation energy of 8.1 kcal/mole indicates that the presence of large amounts of CO_2 changes the reaction path. These activation energies were both determined for the reaction system containing water vapor.

Results

When it was observed that small foreign particles on the substrate surface seem to exert a retarding influence on oxide film deposition well beyond the particle dimensions, it appeared that the system might be sensitive to electrostatic influences. To investigate this effect, two Al foil electrodes 2.5 cm square were placed in the reaction chamber about 5 cm apart and a potential ranging from 6 to 15 kV applied, while the reaction was proceeding under highly smoke-forming conditions. There was a large accumulation of negatively charged dark reddish brown soot containing 61.4 weight per cent (w/o) Fe around the positive electrode and a much smaller amount of positively charged blackish and gray-colored soot containing 46.3% Fe around the negative electrode. Hence ions are formed in the vapor as part of the reaction mechanism. This type of behavior is unusual for a vapor-phase reaction. At every high (15 kV) potential, the soot was cleared almost instantaneously from the vapor phase and deposition essentially ceased. When the potential was lowered to 6 kV, it reappeared. No detectable current was noted on a milliammeter.

To ascertain the degree of smoke particle formation, a fractional portion of the exhaust stream from the reactor was introduced into a particle counter. After 4 min, the rate of generation of particles greater than 0.5μ in diameter attained a steady state of about 250,000 particles/ft^3 min.

To ascertain whether or not there actually is an induction period for deposition, plates were slid into and out of the funnel reactor while it was operating under steady-state conditions. Reproducible results were obtained but a negative induction period was indicated. This may possibly be attributed to a condensation on the glass plate surface as it is warming to reaction temperature, to an electrostatic effect which accelerates the initial deposition or retards later depositions, or to some other effect involving the initial deposition on the surface.

Film Characterization

Density.—The density of a film was determined by measuring a 7.8 mg weight increase after deposition of a 4000Å thick film. On a 2½ in. × 2½ in. × 0.060 in. glass substrate

$$\rho = \frac{7.8 \times 10^{-3}}{40.4 \times 0.4 \times 10^{-4}} = 4.84 \text{ g/cm}^3 \qquad [7]$$

A 1400Å film weighing 2900 μg on one side of two 2 in. diameter silicon wafers gave a density calculation of 5.07 g/cm^3. This is lower than that observed for any oxide of iron (Table I).

Composition.—Film compositions were measured using atomic absorption spectra intensities and comparing against standard solutions. Precision is expected to be about ± 0.5%. Results on films as-made as well as powders attracted to the positive electrode and negative electrode are listed in Table I along with properties of some iron compounds.

The film taken from the hot plate (69.4% Fe) apparently is Fe_2O_3 (69.8% Fe), and was formed after prolonged exposure at the deposition temperature of 127°C. The normal film (68.6% Fe) has a higher iron composition than the negatively charged ions (61.4% Fe) or the positively charged ions (47.3% Fe) that are

Table I. Iron compositions of various samples and compositions, density and index of refraction of various iron compounds

Sample	w/o Fe	Density	Index of refraction (5896Å)
Normal film	68.6	4.84 (5.07)	3.0 ± 0.2
Powder at anode	61.4	(negatively charged ions)	
Powder at cathode	47.3	(positively charged ions)	
Film from hot plate	69.4		
Fe_2O_3	69.8	5.24	3.01 (5896Å) 2.94 (6708Å)
Fe_3O_4	72.3	5.18	2.42
FeO	77.6	5.7	2.32
$FeCO_3$	47.6	3.8	1.663(?)
$Fe(CO)_5$	28.0		
$Fe_2(CO)_9$	30.6	2.08	
$Fe_3(CO)_{12}$	33.2		
$Fe_2(CO)_4$	49.9		
$Fe_2(CO)_5$	44.2		
Fe(CO)	66.5		
MacChesney 155°C film	67.0		
MacChesney 200°C film	68.2		

formed during the reaction. This indicates that pyrolysis and oxidation does take place during the termination phase of the reaction after the smoke particles deposit on the hot glass surface. The positively charged ions (47.3% Fe) have an iron composition similar to $FeCO_3$ (47.6% Fe).

Transmission electron microscope pictures.—Transmission electron microscope pictures using the replica technique, and Talyscan surface profiles were made on some of the films. As the project progressed, various data were correlated to define an interpretation of the reaction kinetics (see below). As part of this study, two films at $t = 10$ sec and $t = 15$ sec showed characteristics different from each other and from the completed films. (Where $t = 0$ is time of introduction of plates into the reactor.)

(*i*) $t = 10$ *sec.*—It appeared that there was a substantial amount of initial deposition of reacted product on the glass surface. This supports the "negative induction period" observed with the kinetic studies. The particle size distribution was large with 2 particles/μ^2 having 0.2 μm diameter or greater.

(*ii*) $t = 15$ *sec.*—The particle size distribution became narrower, with fewer particles (1 per μ^2) having diameters greater than 0.2 μm. A transmission electron microscope photograph at 21,000X is shown in Fig. 3.

(*iii*) *Completed films.*—These films (about 1700Å thick) showed even a narrower particle size distribution (1 per 20-25 μ^2) and a much finer grained structure.

Reaction Kinetics Interpretations

Our observations lead us to speculate on the nature of the reaction mechanism in order to explain the kinetic behavior of the system.

The presence of H_2O promotes the oxidation of CO to CO_2 (3, 10) but inhibits the growth of FeO_x films (3, this work).

The presence of smoke or fog in the reacting system indicates a homogeneous nucleation mechanism. By considering the limiting reaction step in the film growth rate to occur on the surfaces of smoke particles via a heterogeneous reaction mechanism, a good approximation can be made for the observed results. The iron content of the smoke particles lower than that of Fe_2O_3 indicates that some CO is still held chemically to the iron at this stage. Hence, the final stage of film deposition is then assumed to occur by way of a combination of thermal decomposition and oxidation reaction of the smoke particles on the surface of the glass plate. Analysis of the as-made films (68.4 w/o Fe) indicates the probable inclusion of some CO.

A complete set of reaction step equations would be impossible to construct, but some speculations can be made nevertheless. It was desired to establish a model

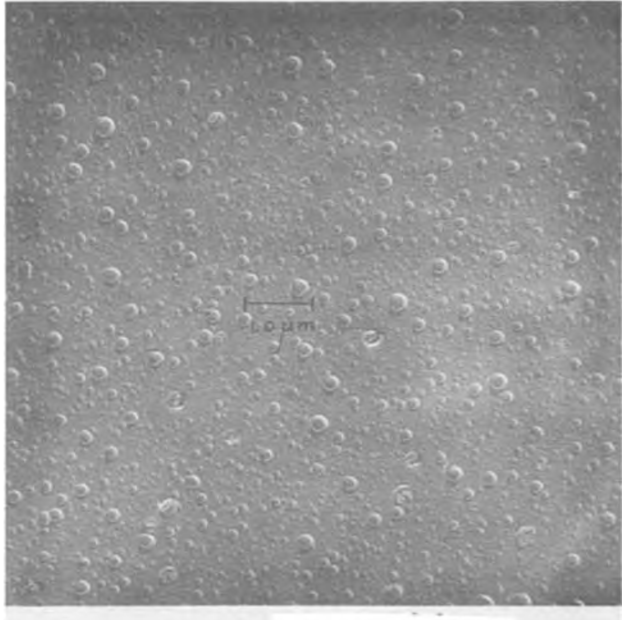

Fig. 3. Transmission electron microscope photograph of iron oxide film after initial 15 sec of deposition. Spheroidal particles, some partially shattered, demonstrate vapor-phase nucleation and particle growth, followed by pyrolysis on the glass surface. Composition change between particles and films indicates that oxidation accompanies pyrolysis (9000X after reduction).

so that the somewhat unusual values of the concentration exponents in Eq. [6] could be explained. It is assumed that the partially oxidized FeO_x particles have semiconductive properties, and the limiting step is the catalytic oxidation of adsorbed $Fe(CO)_5$ by O^- adsorbed on the smoke particles, leaving $Fe(CO)_4$ to be further oxidized and incorporated into the smoke particles as a semiconducting material.

Lee and Mason (11) have analyzed the possible conditions which can exist to promote the catalytic oxidation of CO by O_2 on a semiconductor catalyst. This category of reaction involves the simultaneous adsorption of positive (CO^+) and negative (O^-) ions and oxygen atoms and CO molecules, with the most probable limiting step being the surface migration of adsorbed ions, atoms and molecules, to combine to form CO_2 as the reaction product. For the reaction

$$CO(s) + O^-(s) \rightarrow CO_2(s) + e^- \rightarrow CO_2(g) \qquad [8]$$

Lee and Mason's theory can show that the rate equation can have the following form, if the adsorbed ions have surface concentrations so as to generate a negative space charge region beneath the semiconductor catalyst surface

$$R^* = \frac{K_f p_{O_2}{}^{1/2} p_{CO}{}^{5/3}}{(1 + K_4 p_{CO_2})^{8/3}} \qquad [9]$$

Under conditions relevant to these experiments, the positive adsorbed surface ion concentration (CO^+) would have to be in excess of the negative adsorbed surface ion concentration (O^-) in order to form the required negative space charge region beneath the surface of the smoke particles.

In the experimental section, it was found that the deposition rate varied as the 1.575 power of the iron carbonyl concentration, which is close to the predicted 1.67 power of the CO in this reaction mechanism. For the experimental evidence to be consistent with Lee and Mason's theory, the pressure of iron pentacarbonyl must be substituted for the pressure of carbon monoxide.

By using the narrow concentration ranges of O_2 and CO_2 which occurred more or less by accident in our deposition system, the data were again subjected to a series of multiple regression analyses on the computer. In this situation, it was necessary to select values of K_4 in order to generate the 8/3 exponent for the CO_2 adsorption isotherm in the denominator. The results are

$$R^* = \frac{8.459 \times 10^7 (p_{Fe(CO)_5})^{1.34} (p_{O_2})^{0.26} \exp \frac{-8093}{RT}}{(p_{H_2O})^{0.924} (1 + 0.422\, p_{CO_2})^{2.68}} \text{ Å/min} \qquad [10]$$

However, standard errors and F-level tests of statistical significance (one sigma limits) indicate that there was not sufficient variation in these quantities to verify their exponents quantitatively.

The inhibiting influence of water vapor may be explained by the competitive adsorption of (H_3O^+) molecules on the surface in place of the (CO^+) or equivalent molecules from the $Fe(CO)_5$. This mechanism would decrease the adsorbed $Fe(CO)_5$ concentration and decrease the rate of smoke particle growth, without affecting the reaction order of the $Fe(CO)_5$. The competitive adsorption of the nonreacting H_2O would probably introduce a term of $(1 + Kp_{H_2O})^{-1}$ into the rate expression.

The state of the theory is such that adsorption isotherms are not available for three species of charged particles simultaneously adsorbed on a semiconductor surface.

Particle Growth Kinetics

During normal epitaxial deposition, it is generally assumed that one or more molecular species containing components of the epitaxial composition strikes the surface and becomes incorporated into the structure essentially as an atomic entity after reaction and desorption of carrier atoms. This assumption seems to be valid for silicon, germanium, III-V compounds perhaps, and many other systems.

More recently, Sladek (12) has considered the case of competition between reactions on the surface and homogeneous reactions which produce a powder in the gas phase which is not incorporated into the film. He cites experimental evidence for the formation of silicon nitride films to support his theory.

In the Fe_2O_3 deposition reaction considered here, we postulate still a third mechanism. The reaction proceeds via homogeneous nucleation to form a smoke particle which grows via a heterogeneous mechanism. The smoke particles then form the epitaxial film through a termination reaction involving pyrolysis and oxidation. The film deposition rate may be controlled by the competition between adsorption of two similarly charged ions, only one of which contributes to the reaction mechanism. By occupying surface adsorption area, the second like-charged ion acts as a reaction inhibitor.

The experimental evidence (smoke, compositions, transmission electron microscope pictures) confirms the theory in the case of iron pentacarbonyl oxidation even though the quantitative kinetic evidence for the heterogeneous mechanism is far from conclusive.

Summary

High quality, defect-free films of iron oxide that are suitable for making semitransparent photolithographic masks have been prepared on soft glass plates by oxidation of iron pentacarbonyl. These films correspond generally to the composition Fe_2O_3. The chemical vapor deposition kinetics have been analyzed and a film growth mechanism has been proposed.

Acknowledgments

Mr. William J. Willis performed the experimental work and made many valuable suggestions. Mr. R. K.

Lowry performed the chemical analyses and Mr. R. E. Flutie took the transmission electron microscope pictures. Dr. P. W. Chiang participated in several discussions of the manuscript which increased the clarity of presentation. The clarity of this paper was improved significantly by the peer review system used by **This Journal**.

The Anodic Oxidation of Vanadium: Transport Numbers of Metal and Oxygen and the Metal/Oxygen Ratio in the Oxide Films

W. D. Mackintosh and H. H. Plattner

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada

ABSTRACT

The techniques of ion implantation and Rutherford backscattering analysis have been used to determine the transport numbers of metal and oxygen during the anodic oxidation of vanadium. These were found to be 0.28 ± 0.05 and 0.72 ± 0.05, respectively. The Rutherford backscattering analysis simultaneously gives the ratio of V/O in the film. This was found to be 0.4 ± 0.02 thus indicating that the films are V_2O_5. The result was confirmed by use of the nuclear reaction $^{16}O(d,p)^{17}O$.

In 1965 Keil and Salomon (1) demonstrated that adherent oxide films could be grown on vanadium provided that an electrolyte of borax in glacial acetic acid was used. They also studied the film composition using Faraday's law, attenuated total reflectance spectroscopy, and electron paramagnetic resonance spectroscopy. In a later publication, Keil and Ludwig (2) explored the relationship between ion current migrating through the oxide films and the electrostatic field across the dielectric over a potential range of 100V utilizing the open-circuit transient method. Ellis, Hopper, and De Smet (3) simultaneously published a similar study. While investigating anodic oxidation and subsequent film stripping as a technique for sectioning vanadium, Arora and Kelly (4) devised a method for stabilizing the films so that they were not subject to reaction with the atmosphere which otherwise occurs within 60 sec of removal from the electrolyte. They also measured the rate of dissolution of vanadium in the electrolyte during anodic oxidation.

In this present work we have used ion implantation and nuclear analytical techniques to determine the transport numbers of metal and oxygen ions and to investigate the film composition. These objectives were achieved by a method similar to that described in a previous publication (5) where it was shown that the energy spectra of He ions backscattered from aluminum, recorded before and after anodic oxidation, could be interpreted to give both the thickness of the oxide films and the final position of foreign atoms introduced into the surface layers of the metal before oxidation. Implanted noble gas atoms were used to act as an immobile marker and hence to deduce the transport numbers of metal and oxygen. It was also shown to be possible to establish whether or not the films were stoichiometric Al_2O_3. In this latter application the Rutherford backscattering method, unlike x-ray analysis, can be used on amorphous films and, unlike electron paramagnetic resonance spectroscopy, does not require that the film be dissolved from the substrate before analysis.

In addition, we have used the $^{16}O(d,p)^{17}O$ reaction (6) to determine the oxygen content of the films. These measurements served to confirm the oxide thickness and the V/O ratio obtained by Rutherford backscattering.

Experimental

The vanadium specimens were cut from sheets, 0.5 mm thick, using a jig to ensure reproducibility. The areas were 4×1 cm except that a rectangular section was removed from one corner to leave a lug 5×3 mm

Key words: vanadium, anodic oxidation, transport numbers, Rutherford backscattering analysis, oxide stoichiometry.

to which the electrical connections were made. Surfaces were prepared by abrading with fine metallurgical paper followed by vibratory polishing with 0.3 μm alumina. Residual alumina was removed by ultrasonic cleaning in distilled water. The specimens were then rinsed in ethanol and dried in air. This was followed by three cycles in which the specimens were anodized then stripped of oxide in a dilute ($\sim$ 0.1%) solution of KOH (4).

All anodizations were carried out in the electrolyte proposed in Ref. (1), namely glacial acetic acid containing 0.02 mole/liter $Na_2B_4O_7 \cdot 10\,H_2O$ and 1.0 mole/liter additional H_2O. The temperature was 23°C. For the most part the procedure followed that of Ref. (4), that is, the specimens were immersed in the electrolyte to a depth of 3.5 cm facing a larger platinum electrode at a distance of 1 cm. The vessel was open to the atmosphere and not stirred. The electrolyte was discarded after two hours' use. A constant voltage power supply was used and an external variable resistance was connected in the circuit so that limits to both the current and voltage could be preset. In anodizing in this manner, we standardized on a maximum current of 3 mA/cm^2 and a time of 6 min as this had been shown in Ref. (4) to be the optimum condition for obtaining the minimum loss of vanadium to the electrolyte. Immediately following anodization each specimen was rinsed briefly in glacial acetic acid to prevent deposition of the solid component of the electrolyte on the surface. The specimens were then rapidly dried in a jet of dry air.

Some specimens were anodized in a manner closer to that described in Ref. (1) *viz.* the electrolyte was contained in a closed vessel, and was purged with Ar to keep the solution stirred. In these cases the current was kept constant at 1 mA/cm^2 and the voltage allowed to rise to the desired value with no limitation on time. These too were washed in acetic acid and dried in a stream of air.

Noble gas ions accelerated to energies of 50 keV were implanted into specimens which were covered with an oxide film 25 μg/cm^2 thick. At this energy the implanted atoms were located entirely within the preformed oxide and served to mark this layer. The number of ions implanted was commensurate with the sensitivity of the Rutherford scattering method for each species; 2×10^{15} of Xe and 4×10^{15} atoms/cm^2 of Kr.

The experimental arrangement for obtaining the spectra of backscattered He ions was identical with that described in Ref. (5). Briefly, it consists of a Van de Graaff accelerator delivering a beam of 2 MeV He ions, a target chamber and a surface barrier detector (resolution 17 keV FWHM) placed to observe ions scattered through 150°, together with the usual electronics and pulse height analyzer. For oxygen analysis a beam of 900 keV deuterons was used and the detector was covered with Mylar 19 μm thick (6); otherwise the arrangements were identical to those for backscattering.

The basis of the Rutherford scattering technique for surface analysis, for film thickness measurements, and for locating the position of foreign atoms has been described [Ref. (7) and references therein]. The essence of the method is that, if a He ion of known energy (in this case 2 MeV) is scattered from a surface atom, the resultant energy loss can be calculated from the kinematics of the system. Any additional energy loss observed is due to the fact that the struck atom is not on the surface and therefore the He ion suffers energy loss in both its ingoing and outgoing trajectories. This loss can be interpreted to give the depth of the atom.

The area of the peak obtained by backscattering from implanted ions is dependent on the number of implanted atoms present. It is possible to obtain the absolute amounts (7), but for these experiments it was sufficient to compare areas after normalization to the same integrated beam current (*i.e.*, same number of incident particles) to observe any changes in the amount of implant occurring during anodization.

The details of how the spectra are interpreted are, again, given in Ref. (5). We present a very brief illustration by means of Fig. 1. It was obtained from a specimen of V after the oxide had been thickened to 60 μg/cm^2. In the spectrum, the peak to the right is derived from scattering from the Xe. The continuum to the left containing a marked step is derived from scattering from the V atoms. The lower step is obtained from V atoms in the oxide, the higher from V atoms in the metal substrate. The peak on the substrate continuum is derived from backscattering from O atoms in the oxide layer. It has poor statistical significance and hence is unsatisfactory for determining the oxygen content.

The width of the step in the continuum, indicated by the vertical dashed lines in Fig. 1, is a measure of the oxide thickness and this can be calculated as described in Ref. (5). However, as noted in this reference, it is necessary to know the ratio of metal to O atoms in the oxide to carry out the calculation accurately as the energy loss sustained by the He ions is dependent upon the composition of the medium through which they are passing. We assumed that this ratio was not known with certainty and calculated two possible values for the rate of energy loss; one based on a composition of VO_2 and one on V_2O_5. We then calculated for each of the two compositions what the ratio of the step heights should be and compared this calculated ratio with the observed ratio. The composition leading to the best fit was considered the correct one. The choice and additional evidence for the correctness of the choice are given below.

The position of the dashed vertical line above the Xe peak on the energy scale of Fig. 1 corresponds to Xe atoms if they were on the surface. The actual Xe position indicates that the Xe atoms are buried. The depth of the Xe is calculated from this energy shift. The precision obtainable for this measurement and for the thickness of the oxide film is 2 μg/cm^2.

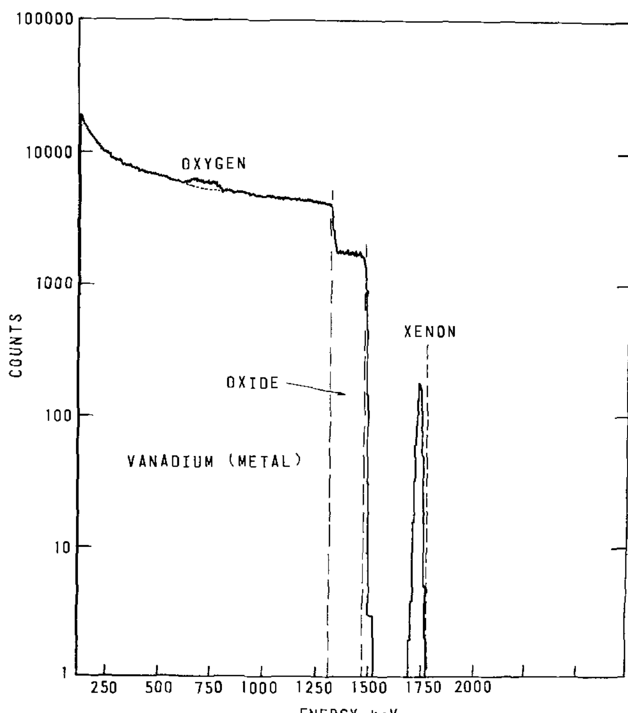

Fig. 1. Rutherford backscattered spectrum from xenon in anodized vanadium.

The procedure for the nuclear reactions $^{16}O(d/p)^{17}O$ was much as described in Ref. (6). The peak in the spectrum derived from the proton product of the reaction was identified from its energy. The area of the peak was compared to that derived from a comparative standard exposed to the same integrated beam current. The comparative standard was Ta covered by an oxide layer known to be 2579Å thick and to contain 37 $\mu g/cm^2$ of oxygen.

Results

Oxygen to vanadium ratio.—In Fig. 2 the count data in the region of the step in the vanadium continuum have been replotted as a function of depth by interpolating into the data of Fig. 1. Figure 2A assumes the oxide is V_2O_5, Fig. 2B that it is VO_2. These show a difference of only 3 $\mu g/cm^2$ in the thickness as the energy to depth calculations are little affected by moderate differences in the composition of the oxide. The dashed lines represent the standard deviation of the least squares fit to the data points. The point $\oplus$ is the fitted count in the first channel of data derived from the vanadium substrate. Using this number and assuming a stoichiometry for the oxide it is a straightforward matter to calculate the number of counts that should be obtained from the vanadium in the oxide film for the chosen stoichiometry. These calculated curves are shown as solid lines for V_2O_5 and VO_2 in Fig. 2A and 2B, respectively. (Curves for V_2O_3 and VO diverge further from the data.) The relative standard deviation of the calculated curves was 2% (indicated by $\updownarrow$ in the figures), that of the observed data, 2.5% (indicated by the dashed lines in the figures). Of 30 spectra we have examined, the calculated curves based on a V/O ratio of 0.4 (V_2O_5) fitted the observed data within these limits so it can be said that the V/O ratios were within 4.5% of stoichiometric V_2O_5.

Results obtained from another experiment confirm that the film is indeed V_2O_5. In Fig. 3 we show the weight of oxide per cm^{-2} of surface for seven samples which were anodized at applied voltages of 40, 50, 60, 70, 70, 80, and 90, respectively. In all cases the initial current was 3 mA/cm^2 and the anodization time was 6 min. Each of the samples was analyzed in three ways: by weighing, by the $^{16}O(d,p)^{17}O$ reaction, and by Rutherford backscattering. The values marked ∇ were obtained by converting the oxygen results found by the $^{16}O(d,p)^{17}O$ reaction to oxide assuming the oxide was V_2O_5 while those marked ■ assume the oxide was VO_2. The precision of these results depends on two factors, counting statistics and the reproducibility of the measurement of incident beam dose on sample and comparative standard. The values plotted in the figure are the averages for triplicate analyses; the widest range observed was $\pm$ 2 $\mu g/cm^2$ for the thickest samples. The points ○ are the Rutherford backscattering results asuming V_2O_5, ▲ assuming VO_2. In this experiment these diverge more than the results shown in Fig. 2 because we tilted the specimens at an angle to the target beam to increase the total path length of the incident and emergent particles. Due to the increased path length the method is then more sensitive for distinguishing between the two possible oxides. The points marked ● are the values obtained from the difference in weight between the anodized specimen before and after stripping. The standard deviation found during weighing in quintuplicate was 2.5 $\mu g/cm^2$. It can be seen from this figure, bearing in mind the precision of each result, that the weight calculated from Rutherford backscattering and the $^{16}O(d,p)^{17}O$ reaction data on the assumption that the film is V_2O_5

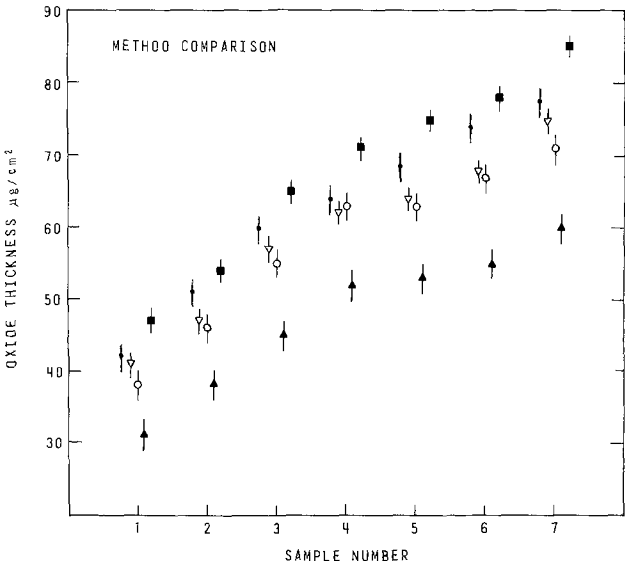

Fig. 3. The results of Rutherford backscattering analysis, nuclear reaction analysis, and conventional weighing. The assumption that the oxide is V_2O_5 is compared with the results on the assumption the oxide is VO_2. ∇ $^{16}O(d,p)^{17}O$ if V_2O_5; ○ Rutherford backscattering if V_2O_5; ▲ Rutherford backscattering if VO_2; ■ $^{16}O(d,p)^{17}O$ if VO_2; ● conventional weighing.

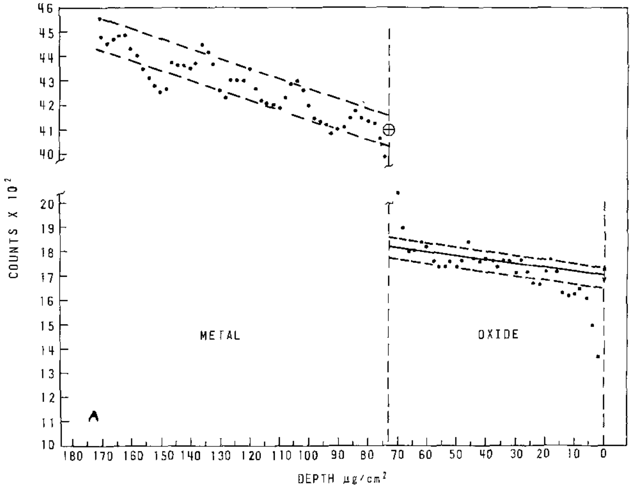

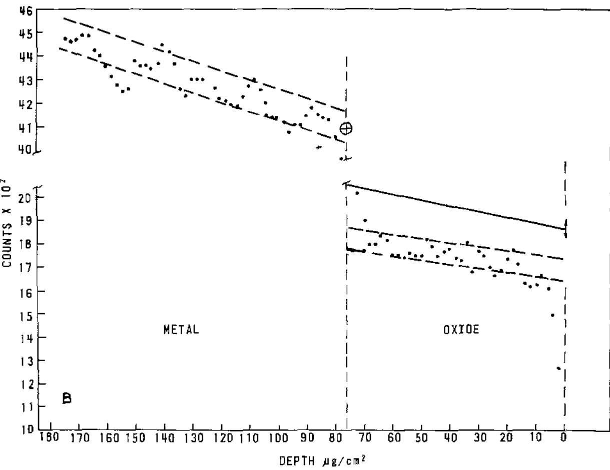

Fig. 2. Rutherford backscattering yield derived from the vanadium in the oxide and top layers of the substrate plotted as a function of depth. (A) The calculated spectrum shape in the oxide step (solid line) has been obtained on the assumption the oxide is V_2O_5, (B) on the assumption the oxide is VO_2.

agree quite closely. On the other hand, the points diverge in opposite directions when it is assumed the film is VO_2. In addition, weights determined by conventional weighing agree more closely with those obtained by Rutherford backscattering and the $^{16}O(d, p)^{17}O$ reaction assuming the film is V_2O_5 while converting the data to weight. It is therfore concluded that the oxide film is V_2O_5.

This conclusion is in contradiction to that of Keil and Salomon (1) who contended that the oxide was VO_2. Our normal method of oxidation differed from theirs. However, we anodized 8 specimens in their manner, *i.e.*, in a closed vessel with Ar purging, at a constant current of 1 mA/cm^2, and an electrode spacing of 1 cm. The oxide thicknesses produced ranged from 20 to 85 μg/cm^2. In every case, the Rutherford backscattering spectra showed that the heights of the steps derived from the vanadium in the oxide film corresponded to V_2O_5. These differences in results are difficult to reconcile. The advantage of the Rutherford backscattering method is that the film is examined *in situ* while the electron paramagnetic resonance method used involved determination of the valence of V after dissolution. It would take little SO_3^{--} in the sulfate-bisulfate solution used to dissolve the oxide, to reduce V_2O_5 to the vanadyl ion.

Transport number.—The metal transport number is given by the ratio D/T when D is the amount of oxide grown above an immobile marker and T is the total thickness of oxide grown during the anodization. The method by which this ratio is obtained from ion implantation and Rutherford backscattering experiments is illustrated in Fig. 4. The vertical lines denoted t_1 represent the preformed oxide layer while the points X mark the position of the immobile marker atoms implanted within this film. The thickness of the film and the depth of the marker d_1 are obtained from backscattering spectra of specimens before anodization. The depth d_2 of the implant below the outer surface of the specimen and the thickness of the oxide t_3 are likewise obtained from backscattering spectra after the specimen has been anodized. The thickness t_2 represents the oxide equivalent of the amount of V that has been dissolved in the electrolyte during anodization. Expressing all depths in μg/cm^2, the required ratio D/T is therefore given by the following expression

$$\frac{d_2 - d_1 + t_2}{t_3 - t_1 + t_2}$$

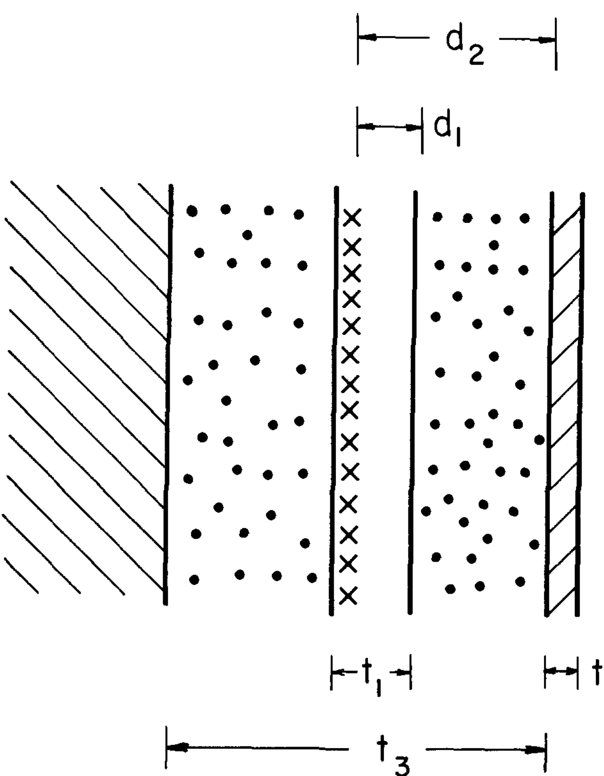

Fig. 4. Illustration of the parameters used in calculating the metal transport numbers.

Arora and Kelly (4) found that on anodizing for 6 min at 50V with an initial current limited to 2 mA · cm^2, the loss of vanadium to the electrolyte was 4.2 μg/cm^2 which, as V_2O_5, would give a value of 7 μg/cm^2 for t_2. On the other hand, Keil and Salomon (1) found no loss on reanodizing a specimen to 100V at a constant current of 0.555 mA/cm^2 that had a preformed film formed at 20V. Since neither condition corresponded exactly with ours, we determined the value under our circumstances. Six weighed specimens were anodized to 40V with an upper limit to the current of 3 mA/cm^2 and for a time of 6 min. These were reweighed. Half of them were then stripped of oxide and weighed again. The remainder were reanodized to 80V again limiting the current to 3 mA/cm^2 and the time to 6 min. These were weighed, stripped, and reweighed. From the first set we found the loss of vanadium to average 7 μg/cm^2, the second set averaged 11 μg/cm^2. We therefore concluded that the vanadium loss in our marker experiments, *i.e.*, during anodization of a specimen covered with a preformed oxide film, was the difference between these values, that is, 4 μg/cm^2 of V or 7 μg/cm^2 as V_2O_5, essentially in agreement with Arora and Kelly despite the fact that the conditions differed.

The metal transport numbers are given in Table I for a number of oxide thicknesses. Two additional specimens were anodized in the manner of Keil and Salomon (1) to voltages of 60 and 85, respectively. We found, as did Arora and Kelly, that specimens anodized in this way did not have oxides of even thickness right out to the edges of the specimens. However, the measurements were made in the region (75-85% of the total area) that was evenly colored. The transport numbers agreed with those for our normal method of anodizing, when the same allowance was made for vanadium loss to the electrolyte but would be half this value were there no loss as claimed in Ref. (1).

The table notes that the standard deviation of these results is 0.02. However, the same correction factor for vanadium loss to the electrolyte was applied to each calculation. When we add in the probable error of this correction factor ($\pm$3 μg/cm^2), the total error becomes 0.05.

The results could conceivably be in error if the presence of the implanted material effects a change in the oxidation process. The maximum concentration of noble gas atoms in the marked volume is ~5 atom per

Table I. Oxide thickness and metal transport numbers

No.	Implant species	Oxide thickness, μg/cm^2	Transport number of metal
1	Xe	77	0.25
2	Xe	83.5	0.24
3	Xe	67	0.20
4	Xe	71	0.23
5	Xe	60	0.30
6	Xe	49	0.26
7	Xe	58	0.26
8	Xe	56	0.35
9	Xe	73	0.32
10	Kr	71.5	0.31

12	Xe	44	0.25
13	Xe	47.5	0.26
14	Xe	63	0.25
15	Xe	76	0.32
16	Xe	78.5	0.29
		Average	0.28
		Std. Dev.	0.02

cent (a/o). However, in the specimens used, the area of the implant covered only one-third of the total area. We were able, therefore, to determine oxide thickness and the V/O ratio both in the implanted and off-implant regions. Within the precision of the measurements no differences were ever detected although the implanted region was visually distinct, presumably due to the radiation damage producing a difference in reflectivity.

Conclusions

In these experiments, V has been anodically oxidized in glacial acetic acid containing 0.02 mole/liter of $Na_2B_4O_7 \cdot 10\,H_2O$ and 1.0 mole of additional water. Some specimens were anodized in the manner of Keil and Salomon (1) and some in the manner of Arora and Kelly (4). Irrespective of the method used and whether or not the specimen is or is not covered by a preformed oxide layer, substantial loss of V to the electrolyte is obtained. Both methods yield films in which the V/O ratio is close to that of V_2O_5 over the thickness range of 20 to 85 $\mu g/cm^2$.

In both methods the oxidation takes place by both inward migration of O and outward migration of V. The metal transport number was found to be 0.28 $\pm$ 0.05 for films ranging from 20 to 85 $\mu g/cm^2$ in thickness. This value is very similar to those for Ta, Nb, and W which have been reported to be in the ranges 0.24-0.31, 0.22-0.33, and 0.30-0.37, respectively (8, 9).

Electrochromism and Photochromism in MoO_3 Films

Thomas C. Arnoldussen

General Motors Corporation, Research Laboratories, Warren, Michigan 48090

ABSTRACT

Electrical properties of amorphous evaporated electrochromic MoO_3 (molybdenum trioxide) films were studied in various ambients. It is shown that at a given applied voltage there is a "humidity threshold" below which coloration does not occur. The transient behavior of the current and remnant voltage in low humidity (precoloration), high humidity (postcoloration), and in the transition stage is shown to be consistent with an electrochemical interpretation of the coloration process. Changes in solubility upon electrical coloration and u.v. photocoloration verify that a chemical change accompanies the color change.

Electrochromic materials have been the subject of a number of recent studies (1-10). They are of interest for passive alphanumeric displays. MoO_3 and WO_3 have been most discussed, though other transition metal compounds and organics are possibilities.

Electrochromic materials can, in general, be colored by high energy irradiation (1-3) (u.v. light, ion bombardment, etc.) as well as by electrical means. Optical and electrically colored MoO_3 and WO_3 have been studied by Deb (1, 2) and Tubbs (3) and the absorption spectra have been found to be similar for both coloration techniques. The absorption shows a broad peak centered in the red portion of the spectrum (8000-10,000Å) with a minimum in the violet blue; hence the characteristic blue purple color.

Optically induced coloration can be produced in air or in vacuum. Electrical coloration was reported by Deb (2) to occur in air but not in vacuum, suggesting that water vapor may facilitate electrical coloration. He also reported (2) that amorphous, oxygen-deficient films colored more readily.

Deb (1, 2, 4) proposed that coloration is caused by electron injection and filling of color centers, *e.g.*, oxygen vacancy electron traps present in the film as a result of the deposition process, analogous to alkali halide color centers. In recent work, others (5-9) have explored coloration of WO_3 and other materials in electrochemical cells employing a liquid or gelled electrolyte such as H_2SO_4. Chang and Howard (5) pointed out the electrochemical redox nature of coloration in some such devices and showed the optical absorption spectrum of electrochemically reduced WO_3 to be qualitatively similar to WO_3 colored in air using Au electrodes; though higher contrasts were achievable with the H_2SO_4 electrolyte. Hurditch (10) demonstrated the dependence of coloration time and voltage on the water content of hydrated $WO_3 \cdot H_2O$ films postulating the dissociation of H_2O and formation of blue hydrogen tungsten bronze $WO_{3-x}(OH)_x$ at the cathode.

We show here that for evaporated MoO_3 films there exists an ambient humidity threshold for coloration which, interpreted as an electrochemical reaction, is related to the voltage threshold for coloration in these materials. Moreover, the fact that MoO_3 undergoes a drastic change of solubility in water when chemically reduced allows us to demonstrate that a chemical

Key words: MoO_3, photochromic, electrochromic.

change accompanies electrical coloration and u.v. optical coloration as well.

MoO_3 Sample Preparation

MoO_3 was electron-beam evaporated from a pressed and sintered pellet of 99.9% pure MoO_3 powder. Parallel Au electrodes 1.88 mm wide, spaced 117μ apart were deposited on a glass slide. A 0.67 μm film of MoO_3 was then evaporated over the electrode gap with about 0.5 mm overlap on each electrode. X-ray diffraction showed the evaporated MoO_3 was amorphous. Electrical leads were attached to the Au pads with Ag paste.

MoO_3 Electrical Characteristics in Vacuum and Air

Current *vs.* voltage characteristics were measured in a 10^{-6} Torr vacuum. These results are shown in Fig. 1. Since the device structure is basically symmetric, the designated voltage polarity was arbitrarily chosen. It can be seen that at low voltages the I-V curve is slightly asymmetric while this asymmetry is not apparent in the range from 100 to 1000V (~10^4-10^5 V/cm). In vacuum the response time for current upon change of voltage was much less than a second, and no coloration resulted.

With the sample chamber open to air and −100V applied, the current decayed exponentially with a time constant ~50 min. After allowing the "charging current" to decay for 1½ hr, the voltage source was zeroed. The remnant voltage, V_R, on the sample was initially ~0.75V, with polarity in opposition to the original applied voltage, decaying to half that value in ~5 min, followed by a slower decay. Time constants of this magnitude could not be accounted for by any electronic capacitance associated with the sample or measurement circuit. They are more characteristic of slow ion motion or chemical reactions.

The device was recharged in air and the remnant voltage monitored as the sample chamber was sequentially evacuated, reexposed to air, reevacuated, etc. Each evacuation caused V_R to drop to near zero ($\lesssim 1$ kT/e) and each reexposure to air caused it to return to the original decay curve as shown in Fig. 2. The charging process did not produce coloration and the remnant voltage was typical of ionic polarization

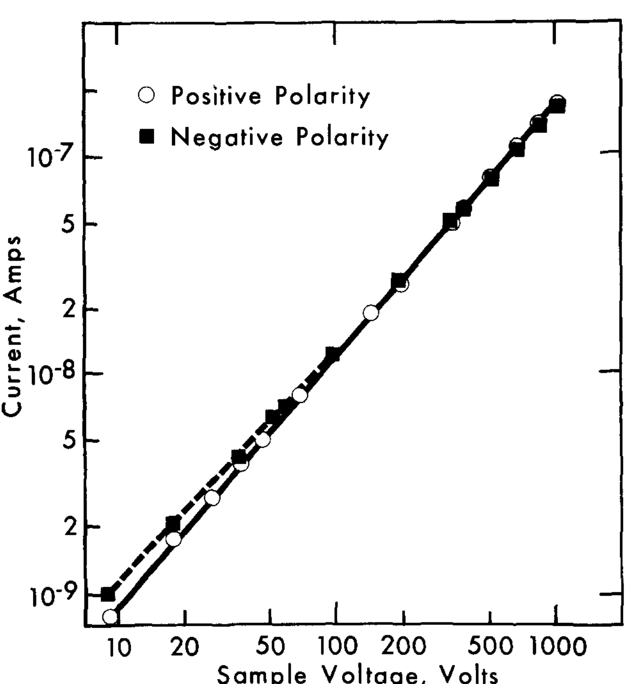

Fig. 1. Current vs. voltage in vacuum for sample of dimensions given in the text. Curve is slightly greater than linear, $I \propto V^{1.13}$ at higher voltages.

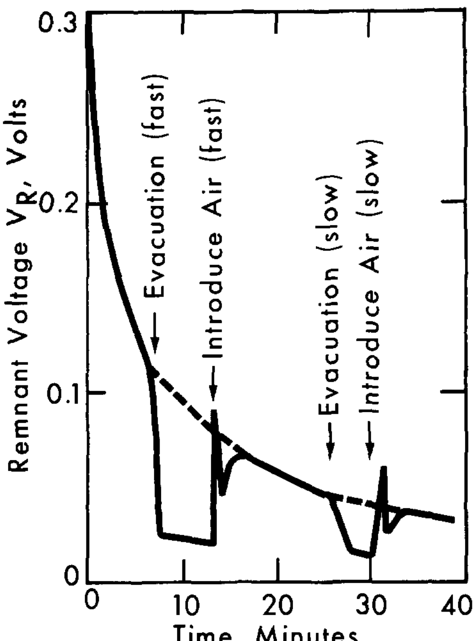

Fig. 2. Remnant voltage decay showing disappearance and reappearance upon evacuating and reintroducing air into the sample chamber. This type of decay is characteristic of polarized but uncolored MoO_3 films. Colored films show a much slower V_R decay which also disappears and reappears when water vapor is removed or introduced.

rather than an electrochemical potential, as indicated by the comparatively rapid initial decay of V_R. Adsorbed water vapor was the suspected source of ions, giving rise to separated H^+ and OH^- or $MoO_4^=$ ions. The drop in V_R upon evacuation is believed due to desorption of water from the surface with the resulting immobilization of the polarized ions. Hurditch (10) showed the apparent dependence of H^+ ion mobility on the water content of WO_3. Because the MoO_3 is not a perfect electronic insulator, charge on the electrometer capacitance leaks off without replenishment (the decreased ion mobility freezes the relaxing ion polarization in place) resulting in a drop in measured voltage. When air is reintroduced the ions resume diffusion and the measured voltage increases. The V_R overshoot/undershoot occurring when air is reintroduced is probably due to competing charging discharging processes, the increased ion diffusion driving the electrometer voltage up and the electronic leakage resistance driving it down. The fact that the form and magnitude of this transient is roughly independent of the air reentry rate suggests that it is related to the absolute water vapor partial pressure.

Electrical Characteristics in N_2, O_2, H_2, and H_2O Vapor

To ascertain that water vapor was responsible for the polarization behavior, the I-V and I-time characteristics of an identical device were observed in vacuum, in pure N_2, pure O_2, forming gas (96% N_2, 4% H_2), and forming gas plus O_2. The electrical behavior was essentially the same as in vacuum for all of these ambients.

When water vapor was introduced by bubbling N_2 through water prior to leaking it into the sample chamber, the behavior was drastically changed. With 200V applied, the current (originally 3.7×10^{-8}A in vacuum) showed no change until the water vapor partial pressure reached ~1 Torr, at which point the current began decreasing. As the pressure continued rising the current reached a minimum of 1.8×10^{-8}A (water vapor pressure ~5 Torr), then sharply increased. As the total pressure reached ~1 atm (water vapor partial pressure ~20 Torr) the current reached a steady value of 7.5×10^{-6}A (see Fig.

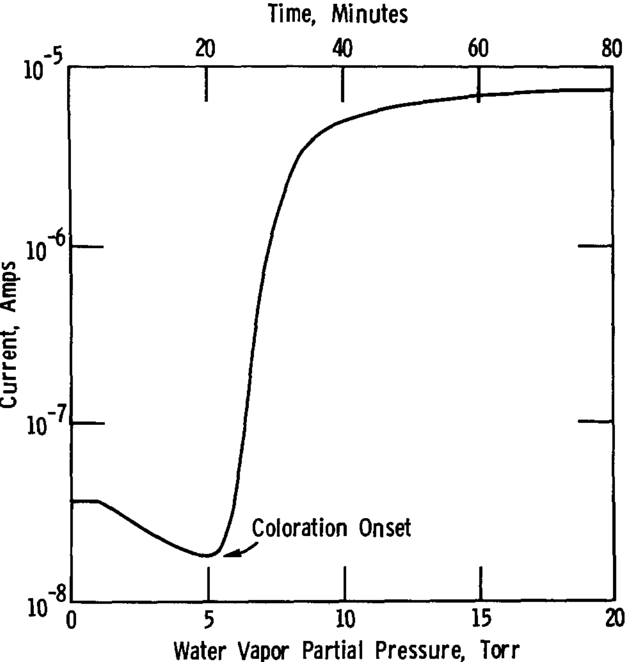

Fig. 3. Current vs. water vapor partial pressure and time for constant leak rate. Current is constant up to ~1 Torr, decreases as ionic polarization proceeds, increases sharply above ~5 Torr as coloration occurs, then saturates at high pressures.

3). During the time the current and water vapor were rising the device became colored dark purple. Evacuation caused the current to drop to 5×10^{-8}A as compared with 3.7×10^{-8}A before H_2O vapor introduction and coloration.

Microscopic inspection of this device revealed that dark purple coloration occurred in the MoO_3 overlapping the Au cathode, while little color change was discerned in the gap region between cathode and anode. This is shown in Fig. 4. The deepest coloration occurred along the periphery of the Au cathode overlaid by MoO_3, not simply along the cathode edge adjacent to the gap. This form of the coloration coupled with the return of the current to near the precoloration value upon evacuation suggests a high surface ion conductance in the presence of high humidity.

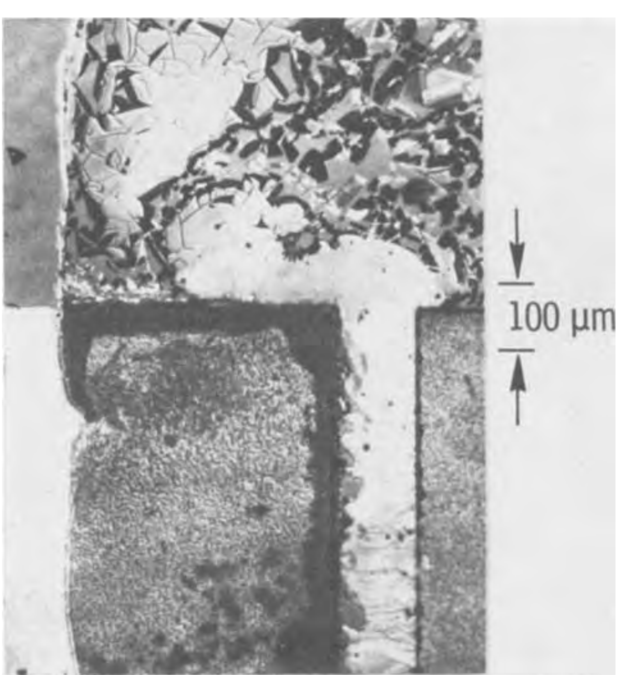

Fig. 4. MoO_3 film colored to completion in high humidity. Coloration is principally along the cathode periphery (left). Striations between anode (right) and cathode suggest mass flow. Crystallization has occurred in the fringing field region (top).

We interpret the various stages of the above coloration process as follows:

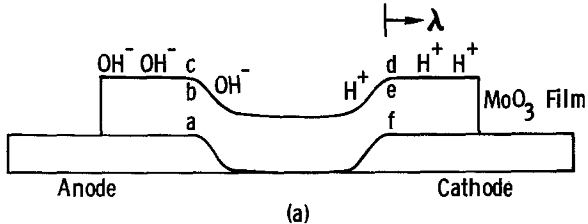
(*i*) For water vapor pressures (p_{H_2O}) ranging from vacuum to ~1 Torr, the current is predominantly electronic and carried in the bulk of the film.

(*ii*) For 1 Torr $\lesssim p_{H_2O} \lesssim$ 5 Torr, the current decays monotonically without coloration. During this stage adsorbed H_2O is present in sufficient quantity to permit H^+ migration and polarization to occur, H^+ ions moving to and accumulating at the upper surface of the MoO_3 over the cathode, forming an electrochemical double layer. During this stage the voltage drop across this double layer is insufficient to cause the chemical reduction of MoO_3 to proceed. As p_{H_2O} increases the surface ion conductance increases, causing a larger voltage drop at the double layer.

(*iii*) As the water vapor reaches a critical pressure (~5 Torr), the double layer voltage drop is sufficient to permit electrochemical reduction of the MoO_3 to occur. This is depicted in Fig. 5. The lower oxides of Mo and W are blue to black and metallic. An example of such a reduction reaction is

$$MoO_3 + XH^+ + Xe^- \rightarrow MoO_{3-x}(OH)_x$$

forming a hydrogen molybdenum bronze. One formulation of the well-known dye "moly blue," $(MoO_2)_2(MoO_4) \cdot H_2O$—molybdenum molybdate, is also of this form. Mo^{+5} is usually identified with a blue color (11). MoO_3 reduction (coloration) proceeds from the upper surface down to the Au cathode (e to f in Fig. 5). The effective cathode is moved to the top



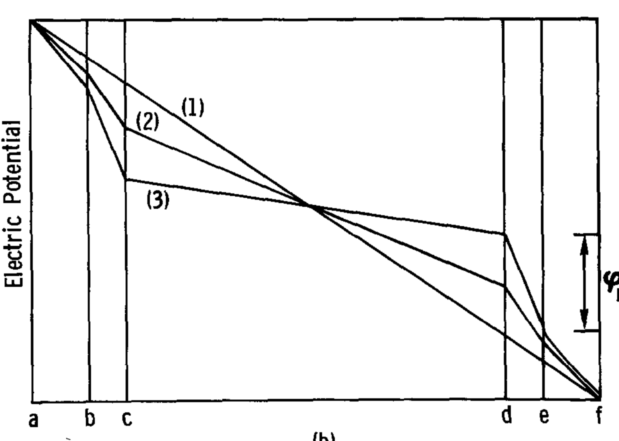


Fig. 5. (a) Cross section of MoO_3 film with representative points a,b,c,d,e,f indicated ab = ef = film thickness = 0.67 µm. cd = electrode gap = 117 µm. (b) Potential profile using representative points from top figure for the case of (1) vacuum, (2) low water vapor, and (3) critical water vapor pressure. Potential drops through film and across double layers bc and de are exaggerated for clarity. When double layer potential drop becomes $\geq \phi_r$, the reaction potential, electrochemical redox reaction proceeds.

surface by virtue of the metallic nature of the $MoO_{3-x}(OH)_x$.

(*iv*) At the high water vapor pressures attained here, the surface ion conductance dominates. Once the MoO_3 over the cathode has been reduced, the dominant current path is from the Au cathode through the $MoO_{3-x}(OH)_x$ above the cathode and across the H_2O adsorbed surface. Further coloration of the MoO_3 between the electrodes is short circuited by the surface where direct electrolysis of H_2O is suggested by the large constant current which disappears when the chamber is reevacuated.

One can show that for a film of bulk resistivity ρ_B(ohm-cm) and surface resistivity ρ_S(ohm/square) the potential at the top surface of the film overlapping the electrode falls off as

$$V(\lambda) = V_{edge} \exp [-\lambda/\sqrt{l\rho_B/\rho_S}]$$

where V_{edge} is the potential directly above the electrode edge (point d in Fig. 5), l is the film thickness, and λ is the distance from this edge into the interior area defined by the electrode (Fig. 5). The potential is relative to the electrode. Thus within several lengths $\sqrt{l\rho_B/\rho_S}$ the potential of the top surface of the film is at virtually the electrode potential. In the sample just described, if we assume the current measured in vacuum gives us ρ_B, and the current measured in high humidity gives us ρ_S then

$$\frac{V(\lambda)}{V_{edge}} = \exp\left[\frac{-\lambda}{9.5\ \mu m}\right] \cdot V(\lambda)/V_{edge} = 10^{-1}$$

for $\lambda = 22\ \mu m$

Since the field through the film is appreciable only within a distance $\sim\lambda$ of the electrode edge, we expect coloration to occur primarily in this region. Figures 4 and 6 do show the peripheral colored region to be ~25-50 μm wide, in good agreement for this idealized model. This is further evidence that, for this device geometry and high humidity, the ionic conduction is principally on the surface rather than in the bulk.

Prolonged coloration resulted in irreversible effects seen in Fig. 4. Not only has coloration formed over the cathode, but crystallization has occurred in the region of the electrode fringing field. Notice also the striations in the electrode gap suggesting large scale mass flow.

Discharge Current

To observe whether the remnant voltage on a colored sample is characteristic of an electrochemical emf rather than a polarization voltage, another sample was placed in a water vapor-saturated N_2 atmosphere with 200V applied until just the initial stages of coloration were observed. The voltage source was zeroed and coloration halted before any gross irreversible effects occurred. The remnant voltage was 1.08V and decayed less than 5% in 5 min; much slower than the remnant voltage decay observed in samples not brought to coloration. This would be expected if the emf were electrochemical in origin and associated with the coloration. The sample was removed for microscopic observation which revealed coloration only along the cathode periphery as before, but much fainter (Fig. 6).

A half-hour later, this sample was replaced in the measurement chamber open to air and V_R had decayed to only 0.5V. The current delivered by this emf was recorded as a function of time (Fig. 7). After 13½ hr, the current had decayed to about 1% of the initial value. The integrated current, or total charge delivered by the cell during this time, was 2.4×10^{-6} coulombs. This corresponds to $\sim 10^{16}$ e/cm^2 based on the peripheral area colored. This charge stored in the electrical capacitance between the top MoO_3 surface and the Au electrode would require a dielectric constant in excess of 10^4. If stored in an electrochemical double layer capacitance, assuming (12) a hydrated double layer dielectric constant ~30, the voltage drop per angstrom of double layer would be ~5V, sufficient to cause almost any electrochemical reaction to proceed. We can only conclude that this charge is stored neutrally as a chemical potential of a newly formed chemical specie.

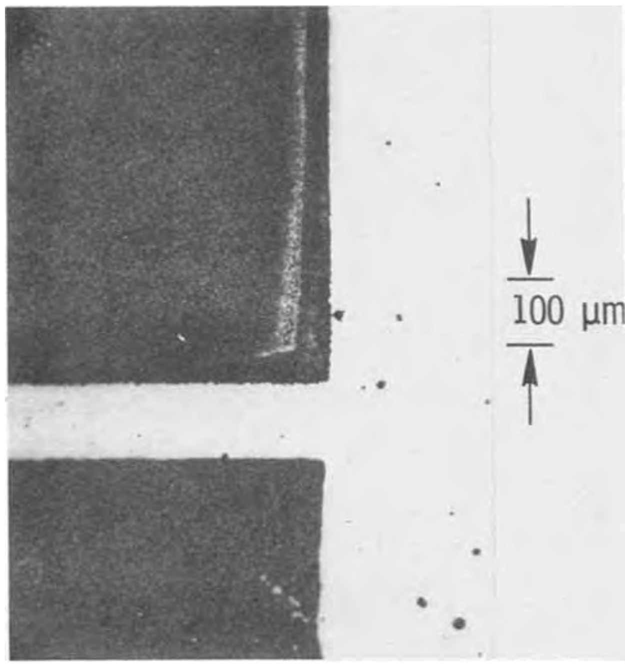

Fig. 6. MoO_3 film brought to partial coloration in high humidity. Coloration, along cathode (top) periphery, was halted before gross irreversible effects occurred.

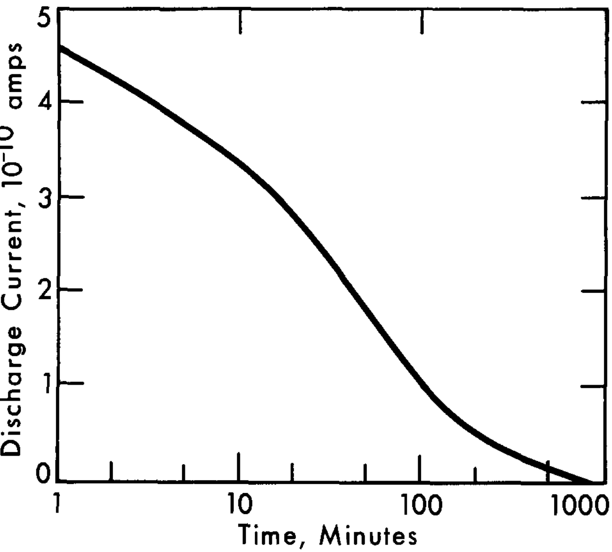

Fig. 7. Discharge current driven by V_R in air for partially colored device shown in Fig. 6. Total charge delivered in 13½ hr was 2.4 μC or ~2 mC/cm² based on the peripheral area colored.

Solubility Change

Quantitative chemical analysis of dehydrated colored and uncolored EC films might resolve the question of whether the film is chemically changed. However, standard analysis techniques are of questionable value. Auger spectroscopy and electron microprobe analysis tend to generate sufficient heat to alter the film during measurement. In addition the latter is not particularly sensitive to oxygen. ESR can detect a change in Mo^{+5} concentration, but cannot distinguish between filling of color center traps already present in the film and Mo^{+5} formation by chemical reaction.

A wet chemical analysis technique does, however, provide qualitative evidence of a chemical change. MoO_3 is quite soluble in water while reduced oxides and hydroxides are relatively insoluble. Immersing electrically colored samples in water caused the uncolored regions to dissolve while the colored regions remained insoluble. Neither coloration nor decreased solubility were observed in the crystallized region of the sample shown in Fig. 4. Furthermore, this same technique showed that films colored by Ne^+ ion bombardment and by u.v. light became insoluble. Such a change in solubility is a thermodynamic characteristic of a phase change and in this case a chemical change.

Conclusion

Based on electrical characteristics correlated with observed solubility changes of MoO_3 electrochromic films, we conclude that electrical coloration occurs by means of an electrochemical redox reaction with adsorbed water vapor as the electrolyte. Furthermore, it seems that optical coloration occurs by photochemical reduction.

It is believed that water vapor is adsorbed on the surface of the MoO_3 film forming H_2MoO_4 on the surface. As suggested by Hurditch (10), the H^+ ions become increasingly mobile as the water content increases. For low water vapor pressures, ionic polarization occurs without coloration of the MoO_3 film since voltages less than the electrochemical reaction potentials are dropped across the double layers due to the high surface electrolyte impedance. As the water pressure is increased, the H^+ ion concentration and mobility increase, causing more of the voltage to be dropped across the double layers. At a critical water vapor pressure (for a given voltage), the ion conductance is great enough to cause the voltage drop across the electrochemical double layer to equal the reaction potential.

Beyond this point the electrochemical reduction reaction proceeds, accompanied by coloration and increased current. When the MoO_3 over the cathode periphery has colored to completion, the large, steady current observed in high humidity is attributed to electrolysis of water on the surface. The counterpart of this "water vapor threshold" at fixed voltage would be the voltage threshold at fixed atmosphere reported by Deb (4) and at fixed water content of intentionally hydrated WO_3 films reported by Hurditch (10).

In the case of optical (u.v.) coloration, it is believed that the high energy radiation actually results in photodecomposition such as

$$MoO_3 \xrightarrow{\text{radiation}} MoO_{3-x} + \frac{x}{2} O_2$$

Ambient water vapor does not seem to be an essential factor since photochromism can occur even in vacuum though it is enhanced in humid atmosphere (2). However, water of hydration is known to be incorporated in vacuum evaporated WO_3 and MoO_3 (10,13) in significant quantities and may facilitate photodecomposition.

Acknowledgments

I would like to thank Dr. Martin C. Steele for his continuing interest and the fruitful discussions we have had in this research.

Automatic Chemical Processing for Silicon Wafers

D. R. Oswald

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

Apparatus has been designed to make the treatment of silicon wafers with wet chemicals an automatic, unattended operation. The wafers remain in a single process vessel while reagents enter and leave in a preprogrammed sequence to make up a given total treatment procedure. The approach avoids a number of deterrents to good process control inherent with the traditional method of transferring wafers from vessel to vessel. For example, there is no potential for debris floating on a liquid surface being deposited onto the wafers because there is no withdrawal through a liquid-air interface. In addition, there is no chance of contaminants entering a treatment solution through the open-air pouring of chemicals or through the use of utensils that might be unclean.

Description of the Apparatus

Figure 1 illustrates schematically how three component parts—a solenoid valve network, a process vessel, and a chemical metering and dispensing system—combine to make up the complete automated system. A fourth component, not shown, is a sequence programmer to operate the various valves.

Key words: chemical processing, wafer cleaning, silicon surfaces.

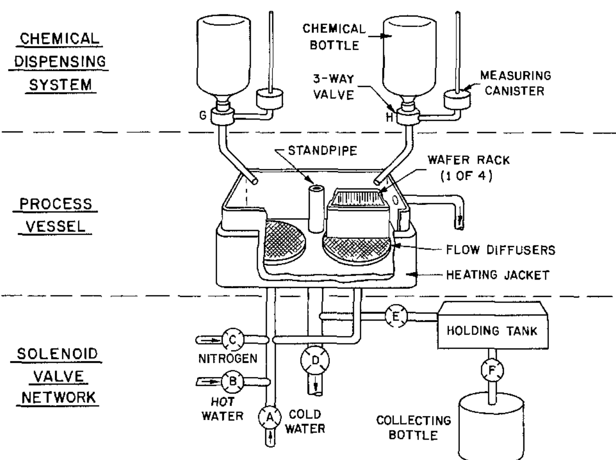

Fig. 1. Automatic processor diagram

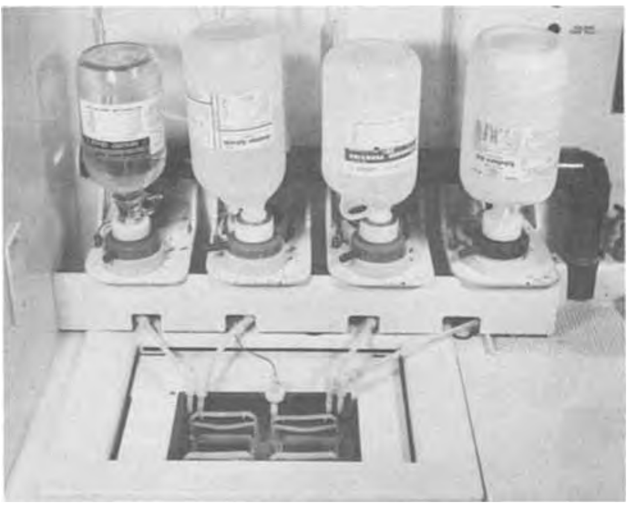

Fig. 2. Process vessel and chemical dispensers

Solenoid valve arrangement.—The valves designated A and B in Fig. 1 can permit either cold or hot water, respectively, to enter the process vessel from the bottom, through flow diffusers that create a uniform upward flow of water over essentially the whole horizontal area of the vessel. Through valve C, nitrogen can be bubbled into the vessel for the purpose of solution agitation and mixing.

Valve D can establish liquid volume in the vessel at two possible levels. When it is closed, the vessel can fill to an overflow level. In the open position, it operates in combination with valve E to establish a liquid level at the top of an adjustable-height standpipe and to direct the out-going flow to either a drain or a "holding tank."

Process vessel.—This is a rectangular tank of appropriate size for the type of wafer holders to be used and the number of them that are to be simultaneously accommodated. Materials of construction that have been used are stainless steel, either by itself or coated internally with "Kynar,"[1] and fused quartz.

Chemical metering and dispensing system.—Liquid chemicals are injected into the process vessel from above, directly from the container in which they were shipped, with no intermediate pouring, open-air exposure, or handling. To accomplish this, the screw cap of the jug or bottle in which the chemical was shipped is removed and a specially designed check valve is screwed on in its place. The container is then inverted and clamped into a measuring-dispensing system that positions it at a slightly higher elevation than the process vessel. Figure 2 shows the process vessel area of a typical processor, with three 1 gal polyethylene bottles and one 8 lb glass bottle clamped in position above the vessel. The manner in which the chemicals are metered and dispensed is illustrated in Fig. 3. As the bottle is clamped into position, a plunger opens the check valve that made possible its being inverted without spillage. Liquid can then flow from the bottle through a three-way Teflon solenoid valve into a measuring canister whose inside volume equals that to be dispensed (Fig. 3A). The liquid will fill the canister and will flow up the inside of an air-venting tube attached to the canister until it reaches the same level as the liquid in the bottle. A second venting tube, a permanent part of the screwed-on check valve assembly, admits air at the same time to the cavity above the liquid in the inverted container. When voltage is applied to the solenoid valve it switches to the position of Fig. 3B and the liquid in the canister empties into the process vessel. Because the volume of liquid that flows up the vent tube dispenses along with

[1] Kynar is a polyvinylidene fluoride, equal in inertness to polyethylene, that can be applied to a metallic base by spraying and baking.

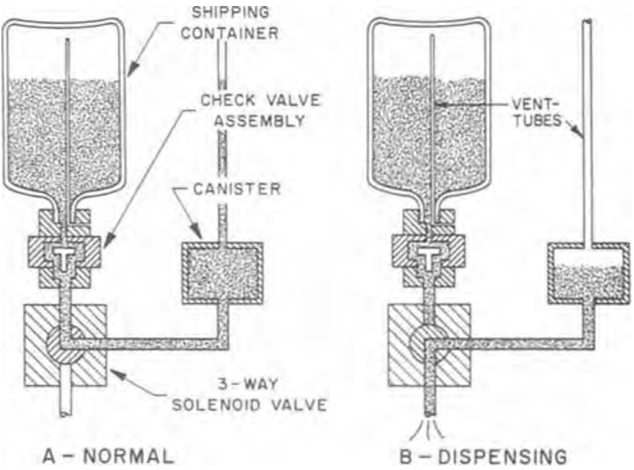

Fig. 3. Technique for metering chemicals

the canister volume, a small variation occurs from run to run in the total volume dispensed as the jug empties. A tube with an inside diameter of only 0.090 in. is adequate, however, and results in only a 1 ml difference from the full-bottle to empty-bottle conditions for a 1 gal container. For most applications such an error is tolerable.

Valve programming system.—The fourth and final major component of the automatic processor is an electrical control system for operating the solenoid valves to program the flow of chemicals and water into and out of the process vessel. A rotating-cylinder type of sequence timer, where switch activating buttons are inserted into slots on the cylinder's circumference, can provide suitable programmability and sequence flexibility. With this arrangement cylinders can be preprogrammed and stored so that a change from one chemical procedure to another is a simple matter of changing cylinders.

Operation of the Automatic Processor

A chemical treatment for etching or cleaning silicon wafers typically requires the following procedure: (*i*) prepare a solution of one or more chemicals mixed with water; (*ii*) immerse rack-held wafers in the solution; (*iii*) heat the solution; (*iv*) maintain solution temperature for the necessary reaction time; (*v*) stop the reaction by flushing away the solution with water; (*vi*) discard the spent solution into a drain or, when it is ecologically harmful, into a collection vessel for

discarding by other means; (*vii*) rinse the wafers with flowing, high purity water.

The valve actions and liquid flows to automatically perform this simple but commonly used sequence proceed as follows:

Action 1.—(Fig. 4a) The apparatus is in its static, between-run condition here, with valve A open to admit cold, high purity water while all other valves are closed. This keeps water overflowing through the process vessel to avoid stagnation and the collection of environmental particulates. Rack-held wafers are inserted into the vessel while it is in this condition and the treatment sequence begins with valve A closing and valve B opening to replace the overflowing cold water with hot water.

Action 2.—(Fig. 4b) After sufficient hot-water overflow for temperature equilibrium in the vessel, valve B closes. Valve D opens to lower the water level in the vessel to the top of the open-ended standpipe, thereby establishing the volume of water with which the chemicals to be added as the next step will be diluted. Dilution ratios and vessel size are chosen such that the wafers remain fully immersed at this lowered water level.

Action 3.—(Fig. 4c) Valve D closes and valves G and H open to inject a premeasured volume of each of the chemicals into the vessel, while a heating tape surrounding the vessel maintains the desired bath temperature. Valve C bubbles nitrogen through the solution to mix the reagents and water.

Action 4.—(Fig. 4d) Valve A opens to introduce cold water and valve E opens to direct the resultant flow of rapidly diluting solution into a "holding tank." When the liquid reaches a level sensor in this tank, valve E closes and D opens to switch the continuing flow to a drain. This arrangement provides the means for collecting ecologically harmful chemicals that cannot enter a drain except in very dilute form. The volume of spent chemical that is collected in the holding tank before diversion to a drain, and therefore the dilution achieved before the drain is used, can be varied by adjusting the height of the level sensor in the holding tank. By means of push-button operated valve F, the holding tank can be emptied between runs into a larger collecting bottle. An essential safety feature is that sensors will not allow the electrical circuitry to operate in the automatic mode if either the holding tank or collecting bottle is full.

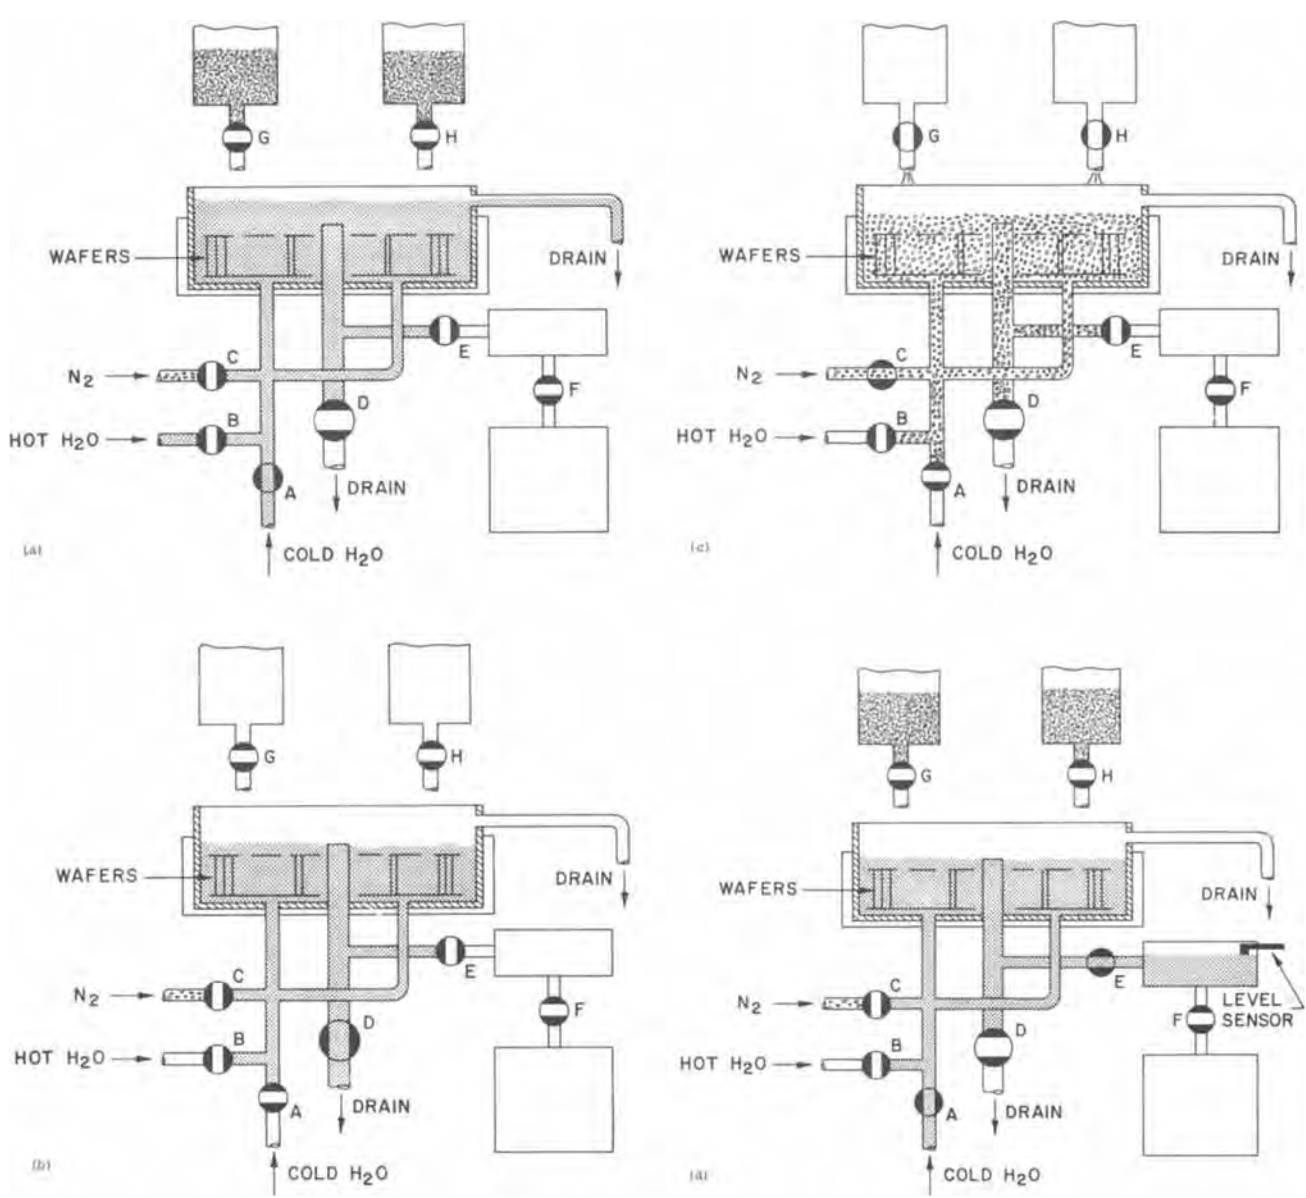

Fig. 4. A typical automatic sequence: (a) cold water overflow; (b) water volume adjustment; (c) dispensing chemicals; (d) collecting spent chemicals.

Action 5.—(Fig. 4a) As the final action, valve A opens to bring in cold water and return the apparatus to its original condition of overflow flushing. When the conductivity of the overflowing water indicates that rinsing has been adequate, the wafers are withdrawn and are dried by centrifugal spinning.

Apparatus Performance as a Wafer Cleaner

One wet-chemistry procedure that has been automated with this apparatus, in which the sequence of valve actions and liquid flows proceeds essentially as in the example illustrated,[2] is the cleaning of wafers with a solution of hydrogen peroxide, ammonium hydroxide, and water (1, 2) after they have been polished. Cleaning after polishing is necessary because some surface-deposited residue, especially in the form of discrete and scattered particulates up to a few microns in size, is practically unavoidable with the abrasive suspensions or slurries used for polishing. It is common practice after such postpolish cleaning to visually inspect the wafers to be sure the cleaning has been effective.

An instrument has been developed to perform such an inspection in a mechanized nonsubjective fashion by scanning a wafer surface with a laser beam to count the number of discrete residual defects, down to one micron in size, that are present on a surface (3). The data of Fig. 5, collected on several thousand 2 in. diameter polished wafers, show an improvement in the effectiveness of automatically performed NH_4OH-H_2O_2-H_2O cleaning over the manual, bath-to-bath transfer method for the same procedure. The median count of defects left after cleaning was reduced from 23 to 7 by the automation. To avoid a possible influence on the count by particles collected on the wafer surfaces during the interval between cleaning and inspecting, each wafer was scrubbed before entering the laser scanning instrument in apparatus that uses a brush and detergent solution to dislodge and wash away loosely attached particles (4).

[2] The only deviation from the described sequence is that the spent solutions enter a drain directly for disposal and are not collected.

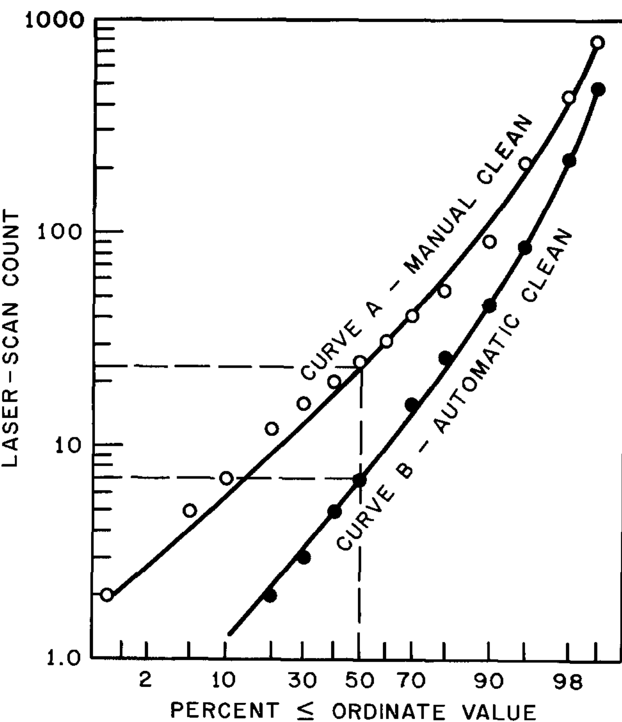

Fig. 5. Laser scan data to compare manual and automatic wafer cleaning.

Summary

The automated concept for wet-chemistry as implemented by the apparatus described provides significant benefits over traditional bath-to-bath transfer methods for sequential chemical treatments. They can be summarized as follows:

1. Opportunities for residue deposition often associated with the draining of liquid across wafer surfaces or evaporation of liquid films from the surfaces are eliminated because there is no wafer withdrawal from a liquid except at the end of a processing sequence, when the liquid is flowing, high purity water with no static meniscus to hold floating debris.
2. Solution composition is reproduced exactly from run to run because chemicals are measured by volume in a positive way.
3. Process parameters such as bath temperature and reaction times require no operator judgment or attention because they are under the automatic and repeatable control of a sequence programmer.
4. Structural materials for components that contact the chemicals or reagents are limited to inert materials (Teflon, polyethylene, quartz). There is no metallic exposure and no ionic contamination of solutions. Liquid movement is by gravity flow to avoid a need for pumps or other corrosion-prone components.
5. Performing a given chemical treatment sequence in automated fashion is much more efficient than an equivalent procedure performed manually. For the wafer cleaning procedure and the particular apparatus described here, for instance, total process time is 15 min for 100 wafers. The only operator attention needed besides the loading-unloading function is to occasionally replenish the chemical supply by clamping new bottles into position, which can be done while a cycle is in progress so no time is lost. One person can easily operate more than one apparatus or can perform additional functions.
6. In procedures where the chemicals are normally discarded after one use, automation can result in more efficient use of chemicals. In the illustrated cleaning process, for example, chemical consumption for a given number of wafers has been halved over the manual process the automation has replaced.

The Effects of High Temperature Annealing on MNOS Devices

James A. Topich* and Eugene T. Yon

Engineering Design Center, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

The effects of high temperature annealing on the conduction and memory properties of MNOS memory devices was studied. The results showed that the conductivity of the nitride increased with annealing time and temperature and that the memory retention qualities of the device were degraded. These results can be explained by the hypothesis that the heat-treatment has increased the number of traps in the silicon nitride. The correlation of the theoretical and experimental results indicates that the traps are uniformly distributed through the silicon nitride layer and are not localized at the oxide nitride interface.

Annealing as one step in the fabrication process for producing MNOS memory devices has been used by many workers in this field (1-4). However, no detailed investigation into the effects of this step on the properties of the devices was undertaken. In this study, all samples used were fabricated in an identical manner and then subjected to annealing treatments for various times from 5 to 120 min and at various temperatures in the range 800°-1000°C. After the devices were completed, the conduction and memory properties were analyzed in order to provide information about the effects of the annealing on certain parameters which characterize the silicon nitride film.

Fabrication Procedure

All devices tested were fabricated on phosphorous-doped (111) polished silicon wafers of 0.5-0.88 ohm-cm resistivity. The silicon wafers were degreased using 3 min soaks in hot trichloroethelene, acetone, and methanol; followed by a rinse in deionized water down to 10 megohm-cm; a 1 min etch in buffered HF; and a second water rinse. The silicon surfaces were further cleaned using a 5 min soak in a hot solution of 5 parts deionized water, 1 part ammonium hydroxide, and 3 parts of hydrogen peroxide; a rinse in deionized water; a 5 min soak in a hot solution of 5 parts deionized water, 1 part hydrochloric acid, and 2 parts of hydrogen peroxide; and a final rinse in deionized water.

Ellipsometric measurements showed that after the cleaning procedure approximately 10Å of silicon dioxide was present on the silicon surface, as has been reported by others (5, 6). Since the primary purpose of this work was to investigate the silicon nitride layer, no additional oxide was grown.

Immediately after being cleaned, 750-1000Å of silicon nitride was pyrolytically deposited at 700°C on the wafers using silane and ammonia with hydrogen as a carrier gas. The silane and ammonia were in the ratio of 1 to 100 and were purchased from Matherson under the trade name N-gas.

Following the silicon nitride deposition, the samples were annealed in dry nitrogen at either 800°, 900°, 950°, or 1000°C for various lengths of time. For each batch of samples fabricated, one wafer was left as a control to which the experimental data could be compared. Table I lists the various samples along with their annealing temperatures and times.

Next, aluminum was evaporated on top the Si_3N_4 and photolithography was used to outline circular electrodes 35 mils in diameter giving an area of 6.23 $\times$ 10^{-3} cm^2. To provide a good electrical contact to the back side, it was cleaned and etched prior to the evaporation of an aluminum layer. After metallization, the wafers were tested without being diced.

Theory

The theory and equations which are given below are presented so that the experimental data could be used to extract values for some of the parameters which characterize the silicon nitride. This material has been presented and expounded on by many without complete agreement by all of the authors. These differences will be discussed in the text as they come up. The main thrust of this work was to determine the effect of annealing on these parameters and then to go back and try to correlate the results with some of the variations in the theories.

Conduction properties.—Because of the thin oxide employed in the devices which were studied, the conduction properties will be dominated by the silicon nitride. It has been shown (7-10) that at room temperature and with electric fields in the range of 10^6-10^7 V/cm, the current density in the silicon nitride is governed by the Poole-Frenkel field-enhanced thermal excitation of trapped carriers. The equation describing this mechanism is

$$J_N = C_N E \exp\left(\{(e^3 E/\pi \epsilon_N \epsilon_O)^{1/2} - e\phi_t\}/rkT\right) \quad [1]$$

where J_N is the current density, E the electric field in the layer, e the electronic charge, ϕ_t the trap depth, k

Key words: charge trapping, silicon nitride, nonvolatile memory, heat-treatment, tunneling.

Boltzmann's constant, T the absolute temperature, ϵ_0 the permittivity of free space, ϵ_N the high frequency dielectric constant of the silicon nitride, and C_N and r are constants which will be discussed later.

The value for the high frequency dielectric constant which has been used by most authors is given by $\epsilon_N = n^2$ where $n = 2$ is the index of refraction in the visible range (10-12). Sze (9), however, points out that the dielectric constant for visible wavelength is not necessarily the correct value to use. His calculations show that the dielectric constant in the infrared region might be more appropriate for the Poole-Frenkel effect in silicon nitride. In this work, a value of 5.5, as taken from Sze (9), was used for the high frequency dielectric constant. As far as the results presented here are concerned, the uncertainty in the value which should be used for the dielectric constant is not of major importance for two reasons; first, it is the square root of the dielectric constant which is employed in the calculations, so even large variations in the value of the dielectric constant would result in much smaller variations in other calculated values, and secondly, in this work concern was for variations in parameters caused by the annealing which would show up regardless of the value used for ϵ_N.

C_N, the preexponential factor in Eq. [1], has the units of conductivity. It is generally accepted that C_N is a function of the density of traps (7, 9-12), but there are differences in terminology which can cause confusion as to the correct functional form. What Kendall (7), Sze (9), and Brown *et al.* (13) refer to as traps are called donor sites by Yeargan *et al.* (10) and Simmons (11). Simmons' (11) neutral traps are the acceptor sites of Yeargan *et al.* (10). In this work the term "trap" is used instead of donor site, and compensation takes place by means of the acceptor sites. Once the differences in terminology are taken into account, all of the above-mentioned works show that an increase in the trap density, N_t, will result in an increase in C_N and that C_N is also a function of the acceptor site density N_a. The exact functional form varies as the relative densities vary, with C_N proportional to $N_t^{1/2}$ for traps only and proportional to $(N_t - N_a)/N_a$ with compensation.

The parameter r is a unitless constant whose value can range from 1 to 2 depending on the relative position and density of traps and acceptor sites in the silicon nitride (7, 10, 12). As with the factor C_N, some confusion can arise because of the differences in terminology used by various authors, but if one uses the terminology employed in this work then r approaches 1 as compensation of traps by acceptor sites takes place.

When the conduction data is plotted as $\ln(J/E)$ *vs.* $E^{1/2}$, a straight line should result if the conduction mechanism is due to the Poole-Frenkel effect. From the slope of the plot, the value of r can be calculated using the equation

$$r = (e^3/\pi\epsilon_N\epsilon_0)^{1/2}/SkT \quad [2]$$

where S is the slope of the plot. Once a value for r is determined, a value for C_N can be calculated from the experimentally measured currents and voltages. Any change of the trap density in the silicon nitride should be reflected in a change in C_N. Even though it is possible to calculate a value for C_N, it is not possible to extract an exact value for the trap density because (*i*) both traps and acceptor sites play a role in the conduction mechanism and (*ii*) one of the terms in C_N is the mobility for which published values vary by at least two orders of magnitude (10). Nevertheless, changes in C_N will indicate qualitatively what changes may have occurred in the trap density.

By measuring the current through the devices at a constant electric field but at different temperatures, a value for the trap depth, ϕ_t, can be determined. The resulting data are plotted as $\ln(I_N)$ *vs.* T^{-1}, and the slope, S, of the plot is then used in Eq. [3] below to calculate the value of ϕ_t

$$\phi_t = -(Sk/e) + (eE/\pi\epsilon_N\epsilon_0)^{1/2} \quad [3]$$

Thus, by the proper manipulation of the conduction data obtained from devices which have undergone varied annealing treatments, an understanding of the effects of annealing on the silicon nitride layer can be deduced.

Memory retention.—Since the major functional use of thin oxide MNOS devices is for nonvolatile memory applications, the effects of annealing on the memory properties were also investigated. Earlier work on MNOS devices (13, 14) leads investigators to conclude that the charges were trapped at the oxide nitride interface. If this were the case, then the decay of the threshold voltage would be a simple exponential characterized by a single time constant. However, it has been reported by many that the decay is logarithmic (15, 16) and this can be explained theoretically with a spatial distribution of trapped charges in the silicon nitride.

The theory which was used in this work to explain the flatband-voltage decay was first published by Lundkvist, Lundström, and Svensson (6) and was based on a direct tunneling theory using the WKB method. A similar result was obtained by Ross and Wallmark (17), but for the charging of MNOS devices as a function of the applied voltage and time. Figure 1 shows the band structure used in the theory (1, 2) and Fig. 2 shows the assumed trapped charge density in a

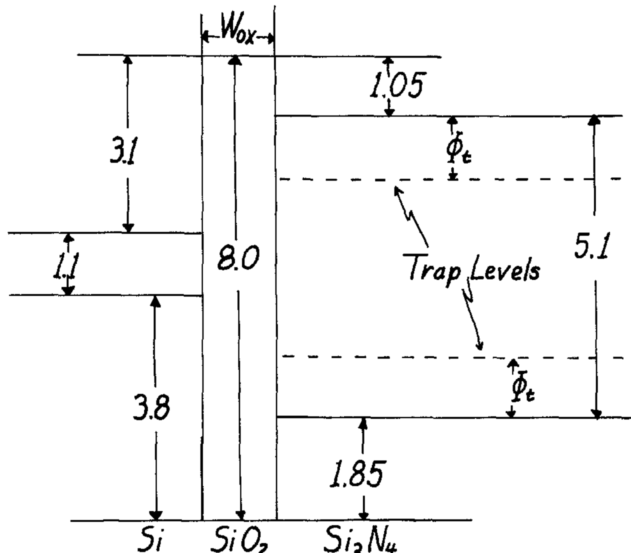

Fig. 1. Energy band diagram of the MNOS structure

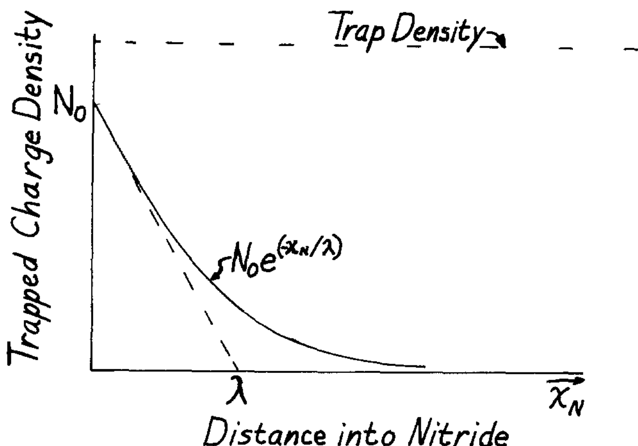

Fig. 2. Trapped charge distribution used in the discharge theory

spatially uniform distribution of traps. One should note that the maximum for the trapped charge density, N_o, which is a function of the applied voltage, is less than the trap density N_t, and that the total number of trapped charges is given by $N_o\lambda$, where λ is a mean trapping distance which is inversely proportional to the density of traps. The resulting equation describing the quantity of charge remaining in the silicon nitride at a time t is given by

$$Q_t = Q_o\{1 - (2.3B_N/\lambda) \log (t/\tau_1)\} \quad [4]$$

where Q_0 is the initial charge stored in the nitride as given by $eN_o\lambda$, τ_1 is a characteristic time constant associated with the start of the discharge after the end of the switching pulse and is a function of the oxide thickness, and B_N is a constant given by $2(2m^*e/\hbar^2)^{1/2}\phi_t^{1/2}$.

If the traps were to saturate because of a switching pulse, then the resulting trapped charge density would have approximately a rectangular shape with the total number of trapped charges given by N_td, where d is the maximum distance into the nitride at which charges are trapped. If this were the trapped charge density then Eq. [4] would be modified to

$$Q(t) = eN_td\{1 - (2.3B_N/d) \log (t/\tau_1)\} \quad [4a]$$

From Eq. [4a] the decay rate would be given by $e2.3B_NN_t$ which is independent of the applied voltage. On the other hand, Eq. [4] gives a decay rate of $eN_o2.3B_N$ which is a function of the applied switching voltage because of the factor N_o. Results to be presented below show that the decay rate is a function of applied voltage, which supports the assumed exponential trapped charge density.

Since it is much easier to measure the flatband-voltage rather than charge decay, Eq. [4] can be modified from charge to flatband-voltage decay by dividing $-Q(t)$ by C_o, the capacitance of the device. In doing this the metal-silicon work function difference is ignored since it is more than an order of magnitude smaller than the initial flatband voltages which are considered. The theoretical expression for the flatband-voltage decay rate, D_N, of thin oxide MNOS devices can be expressed as

$$D_N = -V_{FBO}2.3B_N/\lambda \quad [5]$$

with V_{FBO} the initial flatband voltage immediately after pulsing. From Eq. [5], the observed decay rate should increase in magnitude with a decreasing mean trapping distance λ. Since λ is inversely proportional to the trap density, as the number of traps increase the decay rate should also increase.

In order to compare the various samples in the study it would be more appropriate to focus attention on what will be referred to as a normalized decay rate, D_{NO}, which is obtained by dividing the observed decay rate by minus the initial flatband-voltage after pulsing. The theoretical expression for the normalized decay rate is then given by

$$D_{NO} = D_N/(-V_{FBO}) = 2.3B_N/\lambda \quad [6]$$

where D_{NO} is a function of the trap depth and the mean trapping distance which is inversely proportional to the number of traps.

Experimental Procedures and Results

Due to the various methods of silicon nitride deposition and the wide variations in deposition parameters, there is no one published value for the dielectric constant which can be universally used. Because the electric field needs to be accurately known in order to derive meaningful numbers, it was imperative that an accurate value for the dielectric constant be obtained for the devices under test. Knowing the area of the capacitor and dielectric constant, the thickness of the nitride film can be calculated from a capacitance measurement and the electric field determined from the applied voltage.

The multiple beam interferometer method of Tolansky (18) was used in conjunction with capacitance measurements to calculate the dielectric constant for the silicon nitride at 1 MHz. Both annealed and unannealed samples were tested and a value of 5.6 was calculated irrespective of the annealing treatment.

For the conduction measurements the samples were placed in a shielded box and held down by a small vacuum pump on a metal plate which could be heated. The applied voltages were obtained from a 90V battery and a simple voltage divider. Before each device was tested, the capacitance was measured under heavy accumulation in order that the nitride thickness could be calculated. This was done so that all measurements could be made at known electric fields, thus enabling different devices to be unambiguously compared.

Figure 3 shows the resulting data for three samples from the batch annealed at 950°C. The parallel displacement of the curves indicated that the preexponential term, C_N in the Poole-Frenkel equation has increased in value with the annealing. From this increase it can be inferred that the trap density has also increased with annealing. Since the plotted lines are almost parallel, the values of r calculated from the slopes using Eq. [2] will be very nearly the same. For all samples tested, r was calculated to be 1 ± 0.08. This implies that there are both traps and acceptor sites and that their relative ratio is not affected by the annealing. Similar changes in the conduction properties were obtained for all annealing temperatures except 800°C where there were no observed changes in the conduction properties. This is reasonable since all measured quantities varied the least for the 800°C anneal.

A second set of conduction measurements was made on the two batches of samples annealed at 1000°C. In these tests the electric field in the nitride was held constant at 5.5×10^6 V/cm and the temperature of the device was varied. Figure 4 shows the resulting data for a number of devices. Using the slope, S, of these plots and Eq. [3], the value of the trap depth, ϕ_t, was calculated. The values obtained from all of the plots

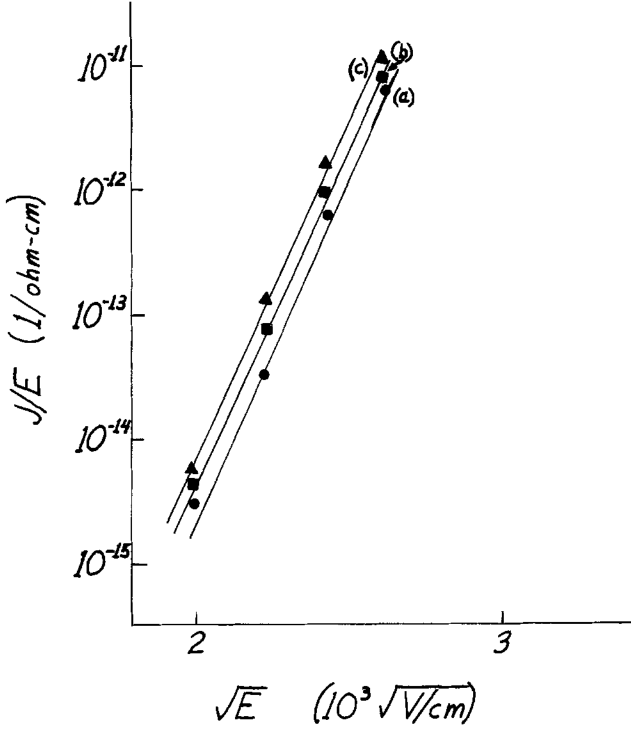

Fig. 3. Poole-Frenkel plot of the conduction data: (a) T-H-2, (b) T-H-3, and (c) T-H-5.

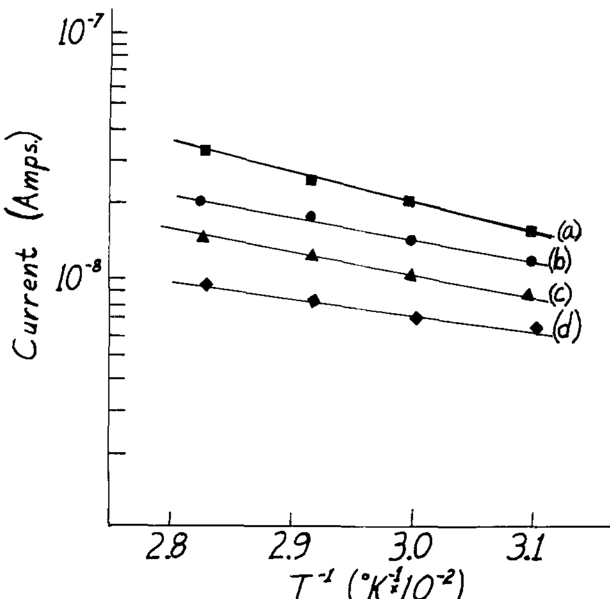

Fig. 4. Log of the current vs. T^{-1} at a constant electric field: (a) T-C-8, (b) T-C-5, (c) T-E-2, and (d) T-E-4.

varied between 0.9 and 0.996V with an average of 0.946V, but there was no trend to the variations which could be correlated with the annealing treatment. Since the 1000°C anneal was the most severe heat-treatment any sample was to undergo and since there was no apparent effect on the trap depth due to the annealing, this type of measurement was not made on the samples annealed at other temperatures and a value of 0.95 was used for ϕ_t in subsequent calculations.

The second area of study was the effect of annealing on the memory retention properties of the devices. For each device tested a high frequency C-V plot was made and by knowing the substrate resistivity the flatband capacitance was calculated (19). Knowing the flatband capacitance, an automatic recording setup was adjusted so as to periodically record the flatband voltage of the device under test. The duration of the recording process was only 1 sec, and the voltages applied to the device were less than that needed to induce the switching action, thus minimizing the possibility of enhancing the discharge process. Before being connected to the recording setup, each device was subjected to a +40V pulse of 5 sec duration and then a −40V pulse of like duration. Immediately following the end of the negative pulse the device was connected to the automatic measurement circuitry and the discharge recorded.

The results for samples annealed at 950°C are shown in Fig. 5. As can be seen from the plots, there is no apparent trend in the observed decay rates which can be correlated with the annealing time. If one goes back to Eq. [5], it can be seen that the decay rates are influenced not only by the physical properties of the silicon nitride, but also by the initial flatband-voltages to which the devices were shifted. Thus valid comparisons can be made by looking at the normalized decay rate. D_{NO}, given by Eq. [6].

Before doing this, it will be shown that the concept of a normalized decay rate being a property of the device is legitimate. Figure 6 is a plot of normalized decay rates vs. initial flatband-voltage for a sample in the T-H batch. As can be seen from the plot, the initial flatband voltages varied by a factor of three whereas the normalized decay rates were within 5% of each other. This constancy of the normalized decay rate justifies its use as a device property.

Results of the comparisons of the normalized decay rates for all samples are shown in Fig. 7. The linear dependence of normalized decay on annealing time is evident along with the fact that at higher annealing temperatures the rate of increase is larger. The variations of the intercepts on the ordinate axis are most probably due to slight processing variances.

In order to unify analysis of the data for different annealing temperatures, the slopes of the four lines in Fig. 7 were plotted vs. the reciprocal of the annealing temperature in degrees Kelvin. This plot is shown in Fig. 8 along with the activation energy of 1.59 eV which was calculated from the slope of the line. From

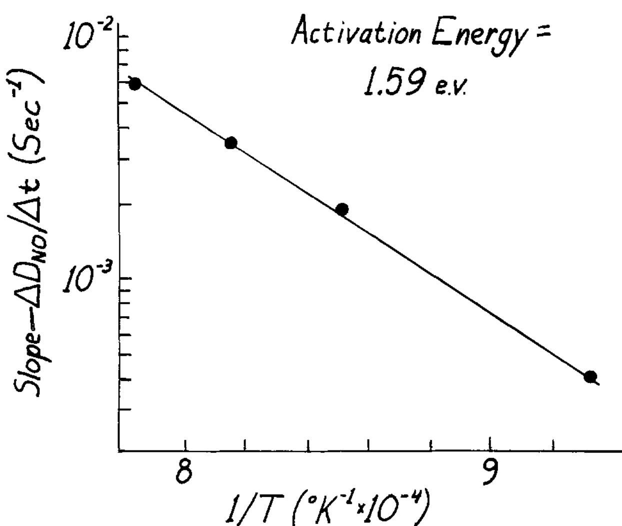

Fig. 8. Slope of the plots in Fig. 7 vs. the reciprocal of the annealing temperature.

the information contained in Fig. 7 and 8, an empirical formula can be written for the normalized decay rate as a function of both the annealing time, t, and the annealing temperature, T, as follows

$$D_{NO} = D_O + D_1 t \exp(-E_{ACT}/kT) \quad [7]$$

where D_O and D_1 are constants which will depend on the silicon nitride deposition parameters and E_{ACT} is the activation energy mentioned above.

From the normalized decay rates, the value of λ for each device can be calculated using Eq. [6] and a value of $10^{10}m^{-1}$ for B_N. In this work, λ varied from 58Å for the smallest decay rate to 12Å for the largest. From the observed decrease in λ with increased annealing time and temperature, it can be inferred that the trap density in the silicon nitride has increased because of the annealing step.

Summary and Conclusion

This study of the effects of high temperature annealing on MNOS devices has demonstrated the detrimental effects that a high temperature processing step can have on the memory performance of a device if it is done after the nitride deposition.

Two independent sets of data, conduction and decay, along with the theoretical works presented show that the observed changes are consistent with an increase in the trap density. This increase can be associated with an increase in the number and size of small crystalline regions in the otherwise amorphous film. The presence of these traps would be caused by the incomplete bonding structure present at the edges of the small crystallites due to a deficiency of one of the atomic species (16, 20). The additional traps would be generated when the thermal energy of the annealing process initiates further growth of these small crystallite regions. Electron diffraction patterns showed that these crystallites are present and that their size is on the order of 10Å, but no information as to the number of crystallites present could be obtained from the pictures taken.

The results of this work also provide further evidence for the theory that the memory property of MNOS devices is not due to interface traps as was originally believed, but rather that the trap sites are an inherent property of the silicon nitride and that the trapped charges are spatially distributed in the nitride. The thin oxide merely acts as a barrier which enhances the critical voltage needed to initiate the switching action.

The Influence of Fixed Interface Charges on the Current-Gain Falloff of Planar n-p-n Transistors

Wolfgang M. Werner

Institut für Theoretische Elektrotechnik, Technische Hochschule Aachen, 51 Aachen, Templergraben 55, Germany

ABSTRACT

The influence of the fixed interface charge, Q_{sc}, at the surface of the base region on the common emitter current gain of planar n-p-n transistors has been investigated. Various values of Q_{sc} were realized by means of appropriate annealing processes and by using differently oriented substrates. The value of Q_{sc} was measured by applying the MOS capacitance-voltage technique. It was shown that the current gain at low collector currents increases with decreasing interface charge density. To obtain the lowest possible value of Q_{sc}, diffusion and oxidation processes were carried out in an MOS furnace. The transistors produced in this way show a current gain which is constant over six decades of collector current.

It is well known that in silicon planar technology each p-n junction is limited by a $Si\text{-}SiO_2$ interface. This fact results in interface effects influencing the characteristics of a p-n junction. The $Si\text{-}SiO_2$ interface itself is characterized mainly by the positive fixed interface charge, Q_{sc}, and the interface states N_{ss} (1-5), which are both located in a 20Å thick layer at the $Si\text{-}SiO_2$ interface (6). This sheet charge causes an accumulation of majority charge carriers on the surface of n-doped silicon and a depletion of majority charge carriers on the surface of p-doped silicon. With a higher charge density, inversion can also occur on the surface of p-doped silicon. In connection with experiments carried out with gate-controlled planar silicon diodes, Grove *et al.* (7) show that the recombination-generation current is considerably dependent on the gate voltage which simulates interface charges. Figure 1 shows the current of a forward-biased diode as a function of the gate voltage (7). As can be seen, the current increases considerably, especially at low forward voltages, if the surface under the gate electrode becomes depleted. The current maximum occurs if the surface is approximately intrinsic. This is the case for the transition between depletion and weak inversion. Interface states, which act as recombination centers, are responsible for this current maximum, because only those centers whose energy levels are near the intrinsic Fermi level contribute significantly to the recombination rate. The current decreases again, although not to its original value, when the surface becomes strongly inverted. The latter is easily explained by the actual enlargement of the diode area.

According to Grove *et al.* (7), an estimation of the recombination current of a forward-biased diode (see Fig. 1) is given by

$$I_{rec} = \frac{1}{2} q\, n_i \left[\frac{W}{\tau_J} A_J + \left(\frac{d}{\tau_s} + S_o \right) A_s \right] \exp\left(\frac{qV_F}{2kT} \right) \quad [1]$$

where A_J is the area of the metallurgical p-n junction, A_s is the area of the depleted surface, τ_J and τ_s are the effective lifetimes in the corresponding regions, and W is the thickness of the space-charge region of the metallurgical p-n junction. The width of the space-charge region at the surface d is proportional to the total interface charge density

$$d = \frac{Q_{sc}}{qN_A} \quad [2]$$

where N_A is the impurity concentration of the p-doped region. This equation is valid for the cases of depletion and weak inversion.

The surface recombination velocity, S_o, is proportional to the interface state density

$$S_o = \sigma\, v_{th}\, N_{ss} \quad [3]$$

Here, σ is the capture cross section of the generation-recombination centers and v_{th} is the thermal carrier velocity.

In the case of an NPN transistor, all of the recombination current will appear as a base current. Since the current caused by recombination in the space-charge regions decreases with the factor $q|V_F|/2kT$, whereas the collector current decreases with the factor $q|V_F|/kT$, the current gain $h_{fe} = I_C/I_B$ will decrease with decreasing collector current.

Reddie (8) has shown by means of a gate-controlled n-p-n transistor that the current-gain falloff at low current levels is strongly influenced by the gate voltage. In the work of Khajezadeh *et al.* (9), two different interface charge densities were realized employing <100> and <111> oriented material. The transistors fabricated with <100> oriented silicon slices result in a considerably smaller current-gain falloff, which is caused by the lower interface charge density, in opposition to <111> material.

In this paper the influence of the fixed interface charge, Q_{sc}, on the current gain at low current levels has been investigated. The transistors with the lowest value of Q_{sc} show a current gain which is constant

over six decades of collector current. The development of such devices is important for low power and low noise applications.

Sample Preparation

Various values of Q_{sc} were realized by annealing the samples in nitrogen or oxygen at the end of the emitter diffusion process, and by using <111> and <100> oriented substrates. Moreover, two different diffusion and oxidation furnaces, a quartz-tube furnace and a special MOS furnace with an SiC tube, were used. Figure 2 shows in principle the dependence of the fixed interface charge on the above-mentioned parameters and on the temperature of the final heat-treatment. The highest value of Q_{sc} was observed when <111> oriented silicon slices, a quartz-tube furnace, and an annealing process in O_2 were employed. The lowest possible value of Q_{sc} was obtained using <100> oriented material, the MOS furnace, and an annealing process in N_2 (1).

The starting material for the production of n-p-n transistors was phosphorus-doped silicon with an impurity concentration of $2.5 \cdot 10^{15}$ cm^{-3}. This has an etch-pit density of 4000 cm^{-2}. The base and emitter regions were formed using two different diffusion sources: doped oxides (10) and gaseous sources. When using doped oxides, the surface concentrations are about $1.5 \cdot 10^{18}$ cm^{-3} for the base region (see Table I)

Table I: Dependence of the fixed charge Q_{sc}, the impurity concentration at the surface of the base region, and the normalized current gain on the annealing ambient, the silicon orientation, and the diffusion furnace used

Type of diffusion furnace	Crystal orientation	Annealing ambient at 1000°C	Q_{sc} / $q10^{11}cm^{-2}$ Collector	Q_{sc} / $q10^{11}cm^{-2}$ Base	C_s / 10^{18} cm^{-3} Base	h_{fe} / $h_{fe\,max}$ at 1μA
Quartz-tube furnace	⟨111⟩	O_2	5.2	18.0	1.10	0.75
		N_2	1.8	7.8	1.54	—
	⟨100⟩	O_2	1.9	11.0	1.60	—
		N_2	0.5	4.6	2.06	0.97
MOS furnace	⟨100⟩	O_2	1.3	5.2	1.30	0.94
		N_2	0.2	2.6	1.90	1.00

and about $5 \cdot 10^{19}$ cm^{-3} for the emitter region (LCE, low concentration emitter). Applying the gaseous sources, B_2H_6 for the base and $POCl_3$ for the emitter, the surface concentrations are $1 \cdot 10^{18}$ cm^{-3} and $5 \cdot 10^{20}$ cm^{-3} for the base and emitter regions, respectively (HCE, high concentration emitter). The base surface concentrations were determined by MOS capacitance-voltage measurements and the emitter surface concentrations were calculated from the sheet resistance and the junction depth applying Irvin curves (11). The metallization of the slices with aluminum was carried out by an electron gun. The substrate temperature was kept at room temperature during the evaporation process. Before the last photoresist operation step, the samples were annealed at 500°C in nitrogen in order to reduce fast surface states. The base area of the transistors was 50 × 40 μm^2 and the emitter area was 17.5 × 25 μm^2. The material used for the production of the MOS samples, which are required for the measurement of Q_{sc}, was boron-doped <100> and <111> oriented silicon slices with an impurity concentration of $6 \cdot 10^{15}$ cm^{-3}. These slices were treated exactly like the n-p-n transistors with respect to the high temperature and annealing processes. After the first oxidation, which yields the masking oxide for the base, the oxide was entirely etched away before the base diffusion was carried out. After the emitter diffusion process the oxide was etched down to an oxide thickness of about 1300Å. Reduction of the oxide thickness is necessary to reach a sufficient sensitivity for the measurement of Q_{sc}. The field plates were prepared by evaporating aluminum through a metal mask resulting in circular dots 500 μm in diameter. After this evaporation process, the samples were annealed in the same way as the n-p-n transistors. The value of Q_{sc} was measured applying the MOS capacitance-voltage technique (12, 13), using a work function difference of $\phi_{MS} = -\phi_F - 0.22V$ (14) where $\phi_F = -(E_F - E_I)/q$.

Results and Discussion

The d-c common emitter current gain $h_{fe} = I_C/I_B$ of the n-p-n transistors was measured at an applied voltage of $U_{BE} = U_{CE}$, if not otherwise indicated. Table I shows the values of Q_{sc} at the surface of the base region and the normalized current gain at a collector current of 1 μA as a function of the annealing ambient, crystal orientation, and type of diffusion furnace used. In this case, base and emitter regions were formed applying doped oxides. As can be seen, the normalized current gain increases with decreasing interface charge. For the lowest value of Q_{sc}, the current-gain falloff is zero. The calculations to determine Q_{sc} also provide the surface concentration of the base area. They are specified in the sixth column. As can be seen, the surface concentrations of the samples annealed in N_2 are about 30% higher than those annealed in O_2. This can be explained by the segregation coefficient of boron at the Si-SiO_2 interface which is in the range of 0.3 (15). For comparison, the values of Q_{sc} at the surface of n-doped silicon with an impurity concentration of $2.5 \cdot 10^{15}$ cm^{-3}, which is also the starting material for the n-p-n transistors, are specified in the fourth column. These values are much lower than those at the surface of the base region. Thus it is evident that the base diffusion process generates fixed interface charges. The measured fixed interface charge density at the surface of the base region of the devices produced with gaseous sources is in the same order of magnitude as that of the devices fabricated with doped oxides. They are $8.7 \cdot 10^{11}$ qcm^{-2} and $4.5 \cdot 10^{11}$ qcm^{-2} for <111> and <100> oriented slices, respectively, both being annealed in nitrogen.

As mentioned above, interface states are also responsible for current-gain falloff. Therefore it is of interest to note that normally there exists a strong correlation between interface states and interface charges (16). For the annealing parameters used in

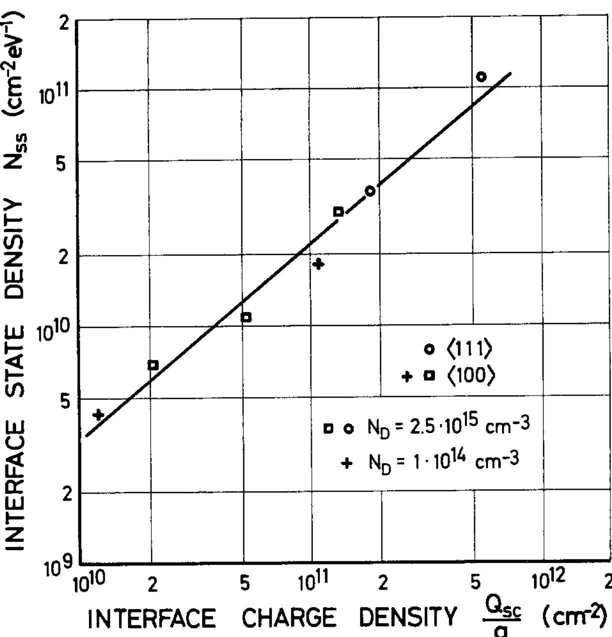

Fig. 3. Illustration of the correlation between interface charges and interface states.

this work, this correlation is shown in Fig. 3, for n-doped <100> and <111> oriented slices with impurity concentrations of $2.5 \cdot 10^{15}$ and $1 \cdot 10^{14}$ cm^{-3}. The values of N_{ss} represented in Fig. 3 are located in the middle of the energy gap. N_{ss} was measured by means of the quasi-static technique of Kuhn (7).

Figure 4 shows the normalized current gain as a function of the collector current. Parameters are the diffusion furnace used, the annealing ambient, the crystal orientation, and the surface concentration of the emitter region. When comparing the curves marked quartz/N_2/<100>/LCE and quartz/N_2/<100>/HCE, it becomes evident that the impurity concentration of the emitter region also influences the current-gain falloff. The current gain of the transistors characterized by the parameters MOS/N_2/<100>/LCE is constant over nearly six decades of collector current, the parameters corresponding to the lowest value of Q_{sc}. In this case the base current is composed entirely of neutral-region recombination (diffusion) terms, which increase exponentially with qV_{BE}/kT. From these results it can be concluded that the current-gain falloff of the low concentration emitter devices is caused by the recombination centers at the surface of the base region. The current-gain falloff of the high concentration emitter devices is mainly caused by recombination mechanisms in the emitter-base space-charge region because the interface charge density at the surface of the base region of these devices is in the same order of magnitude as that of the devices fabricated with doped oxides. The variations of collector and base currents as a function of the base-emitter voltage are shown in Fig. 5. It is clearly seen that the slope of the base current of the devices with the lowest interface charge density is the same as the slope of the collector current. Figure 6 shows typical curves of the current gain *vs.* collector current of these devices. Parameter is the base width. It was 0.58 μm for a current gain of 500 and 0.98 μm for a current gain of 35. The curve with the highest current gain shows a slight deviation from ideal beta-linearity. The increase of current gain at low current levels is caused by the reverse current of the collector-base junction. This is demonstrated in Fig. 7, where the current gain is shown as a function of the collector current with the collector-base voltage as parameter. As can be seen, the current gain in the linear region is also dependent on the collector-base voltage. This is caused by the actual shortening of the

base width as a result of the expansion of the base-collector space-charge region.

Conclusion

The influence of the fixed interface charge at the surface of the base region on the d-c common emitter current gain of planar n-p-n transistors has been investigated. The results obtained indicate that the current gain at low collector currents increases with decreasing interface charge density. It was shown that it is possible to produce n-p-n transistors without current-gain falloff at low collector currents. This was obtained by employing MOS preparation techniques, which yield the lowest possible value of Q_{sc}.

Dependence of Recombination in p-Type GaP(Zn,O) on Dopant Concentrations

J. A. W. van der Does de Bye

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The luminescence of p-type GaP(Zn,O), a semiconducting material for light emitting diodes, is controlled by the transitions of the excited free electrons and by those of the electrons bound to the luminescent nearest-neighbor ($Zn_{Ga}O_P$) complexes. The results of the determination of the internal quantum efficiency (η) on a large number of samples, prepared by solution growth and by liquid phase epitaxy and covering a zinc concentration range of 10^{17}-$5 \cdot 10^{18}$ cm^{-3}, lead to the conclusion that an Auger effect acting on the bound electrons is the dominant cause of the reduction of the internal efficiency of the samples with a free hole concentration (p) above $4 \cdot 10^{17}$ cm^{-3}, where also the trapping by "killers" becomes negligible. The Auger constant was derived, being $\approx 3 \cdot 10^{-11}$ cm^3 sec^{-1}. Below this concentration the thermalization of the electrons bound to the complexes is the more important effect enhancing the otherwise relatively small action of the killers. The best value for η is $\approx 40\%$ at p $\approx 5 \cdot 10^{17}$ cm^{-3}. Decay time (τ) measurements, using pulsed and sine-wave modulated excitation, provide insight in the effect of screening by free holes on the radiative and Auger transitions by using in the interpretation of the data the quantity (η/τ) which is proportional to the effective radiative recombination rate (including the effect of screening mentioned). Both radiative and Auger transition probabilities are reduced by a common screening factor as low as 0.2. Electron diffusion length measurements on the epitaxial samples show a strong decrease of the minority carrier lifetime with increasing zinc concentration which is ascribed mainly to the trapping by the (ZnO) complexes whose concentration increases with the zinc dope. This study also provides information on the oxygen incorporation during the crystal growth. This incorporation probably takes place at thermal equilibrium between the oxygen source and the solid GaP. [O] increases with [Zn] reaching $\approx 10^{18}$ cm^{-3} at [Zn] $\approx 5 \cdot 10^{18}$ cm^{-3}.

Semiconductor diodes that emit visible light are of increasing importance for certain applications, *i.e.*, for indication and for display of symbols. The luminescence efficiency of such diodes is generally much below 100%. Various causes exist for this circumstance part of which are peculiar to the semiconductor material used and to the devices made from them. These causes are still a matter of conjecture. In this respect the subject of this paper, p-type gallium phosphide doped with zinc and oxygen, is no exception. Partly these causes arise from the properties of the light emitting layer, *i.e.*, p-type GaP(Zn, O). Another cause, generally of minor importance for this type of material, is the limited efficiency of injection of electrons into this layer.

A study of dopant-dependent recombination in p-type GaP(Zn, O) is useful to elucidate the relevant properties of this layer with respect to both bulk efficiency and injection efficiency.

With regard to the bulk efficiency results have been published by Dishman, DiDomenico, and Caruso (1) and Jayson, Bhargava, and Dixon (2). They used the dopant dependence of two observables, quantum efficiency and decay time. In Ref. (1) it was tried to determine the internal quantum efficiency, a difficult experimental problem, while Ref. (2) emphasized the decay measurements. In view of the large number of model parameters *a priori* statements on some of these parameters were used, partly based on a theoretical study by Sinha and DiDomenico (3). References (1) and (2) essentially used a recombination model for which Fig. 1 shows a simplified level and transition diagram. It is seen that the losses arise from two groups of nonradiative transitions labeled r_{nk} and r_n which act on the free and bound electrons, respectively, and which parallel the transitions r_{nt} and r_r that lead to the luminescence. The luminescent centers N_t, to whose concentration the rate of transitions r_{nt} is proportional, are nearest-neighbor complexes of one zinc ion and one oxygen ion (4) (on the gallium and phosphorus sites, respectively). These complexes have an electron binding energy $E_t \approx 0.3$ eV. The thermal emission (r_{tn}) in which E_t is active has the effect of enhancing the electron losses through the path r_{nk}. This effect (5), causing a temperature-dependent reduction of the efficiency, can be important at room temperature for the p-type GaP(Zn, O) used in light emitting diodes. The transitions r_{nk}, r_n, and r_r which are not specified in detail in Fig. 1 terminate in hole levels. For r_n and r_r such levels are close to both valence band and equilibrium Fermi level, requiring the knowledge of hole statistics in the recombination studies (5). r_r was found to arise from two radiative mechanisms, *i.e.*, exciton annihilation and complex-to-zinc-acceptor transitions both of which contribute to the red luminescence (4, 6). The former mechanism is generally the stronger one.

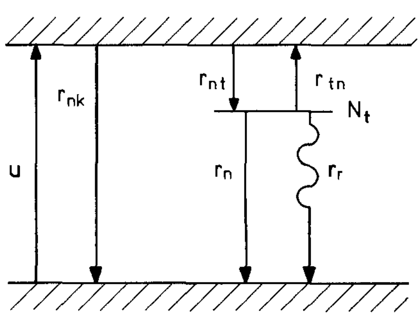

Fig. 1. A simplified recombination model for p-GaP(Zn,O)

Key words: light emitting diodes, quantum efficiency, oxygen incorporation, free carrier screening.

A different approach which involves few *a priori* statements was used by Henry, Bachrach, and Schumaker (7) who invoked the decay behavior of the free electrons, measured through the green exciton luminescence, to obtain data on the competition between the transitions r_{nt} and r_{nk}. Using these measurements in addition to internal quantum efficiency results and decays of the red emission, data were found on the competition between the transitions r_r and r_n. For the study of the dopant dependence of the competition between r_{nk} and r_{nt} the method of using the green exciton decay is, however, not suitable owing to the immeasurably short lifetimes of the free electrons in samples of high zinc concentration. This is borne out by our findings on the diffusion length (also to be discussed in the present paper). For the study of the energy losses through the paths r_{nk} and r_n the present paper emphasizes the dopant dependence of the internal quantum efficiency of the red luminescence. As it will be shown this approach involves only a few *a priori* assumptions. The efficiency (η) is conveniently expressed by the quantity $(1 - \eta)/\eta$ to show the effects of the two energy losses. The decay time (τ) of the red luminescence plays a secondary role and serves to provide information on the effects of screening and hole statistics on the bound excitons that yield most of the red luminescence. The study of these effects uses the quantity η/τ that is free from many model parameters that act on the separate quantities η and τ.

Another subject is discussed in the present paper, namely, the rate of transitions r_{nt} which is connected with the diffusion length of the electrons in p-GaP(Zn, O) through the minority carrier lifetime. Findings on this quantity are helpful in understanding the injection efficiency of a light emitting diode containing the GaP(Zn, O). The present paper, however, deals with these findings in a different context, *i.e.*, that of the rather intangible problem of the oxygen incorporation in GaP. The connecting link with r_{nt} is the proportionality of r_{nt} with the concentration of the (ZnO) complexes.

The following section covers the preparational and experimental techniques. It contains a somewhat extended discussion on the problem of determining the internal quantum efficiency. In subsequent sections are discussed the measurements; the results of decay and efficiency measurements in order to assess the importance of killers (r_{nk}) and Auger transitions (r_n); and the diffusion length measurements in order to reach conclusions on the oxygen incorporation.

Preparation of the Samples and Experimental Techniques

Two techniques were used for the crystallization of GaP from a saturated solution in pure Ga (6*N*, Alusuisse). Both use as the starting material GaP which was synthesized from PH_3 and Ga yielding spectrochemically pure crystals[1] which contain less than 1 ppm of sulfur. One technique of sample preparation is by spontaneous growth in an evacuated and sealed quartz ampul ("solution-grown" or SG samples). The other technique is by liquid phase eitaxy (LPE samples) (9) using n-type GaP substrates being themselves LPE material or GaP obtained by the liquid encapsulation technique[2] (LEC crystals). The LPE technique also provides the p-n junctions to enable the measurement of diffusion lengths.

The SG samples were grown by cooling the solution from 1130° to 800°C with a rate of 5° or 13°C/hr while the data for the LPE samples are 1050 (10) 500°C, followed by an anneal at 500°C for 12-14 hr. This annealing which also occurs during a good part of the time of growth promotes the formation of the luminescent (ZnO) complexes. For the SG samples this annealing was carried out separately at 500°C in air for 168 hr, with a preanneal at 560°-600°C.

Both techniques use zinc additions to the solution so as to cover a zinc acceptor concentration range from $1 \cdot 10^{17}$ to $5 \cdot 10^{18}$ cm^{-3}. Sufficient oxygen was added, as Ga_2O_3, to obtain amply saturated solutions in Ga for the LPE technique whereas for the SG technique the amounts added vary, being 10^{-1}, $2 \cdot 10^{-2}$, and $4 \cdot 10^{-3}$ mol per cent. It is convenient to state in this section that in a previous investigation of a large number of SG samples no clear correlation was found between the Ga_2O_3 admixture and the two physical quantities measured on the SG material, *i.e.*, efficiency and decay time. Therefore no discussion is given on effects of variation of the Ga_2O_3 admixture in the present paper.

In addition to the internal quantum efficiency and the decay time constant of the luminescence which were determined on all samples, the electron diffusion length and the free hole concentration were measured on the LPE samples. For the latter quantity a conventional Hall measurement technique was applied using the van der Pauw method (10). Regarding the SG samples batch averages were determined for the zinc concentration using an atomic absorption analysis preceded by the extraction of the zinc from GaP which was dissolved in aqua regia (11).[3] With regard to the Hall effect results a finding by Foster, Woods and Lewis (12)[4] must be mentioned. p as measured was found to be approximately equal to [Zn] and is therefore larger than the true value of p. In the discussion of the concentration-dependent recombination it is to be understood that p, acting as an independent variable, is the measured quantity, in accordance with the practice in Ref. (1) and (2). The values of quantities that multiply p in equations are therefore different from the true values. Inasmuch as the measured value of p is approximately proportional to the true value no essential change is necessary in the interpretation of the recombination results.

Using a scanning electron microscope electron diffusion lengths were determined by the evaluation of the electron beam induced currents in the p-n junctions of the LPE samples (13). The technique and types of results are similar to those described by Hackett, Saul, Dixon, and Kammlott (14).

Two methods were used to determine the decay time constants, *i.e.*, sine-wave modulated excitation and pulsed excitation. In the former method a 514.5 nm laser beam from a Coherent Radiation argon ion laser, Model 52, was modulated by a Lasermetrics electrooptical modulator, Model EOM 3064, up to 50 MHz, using a built-in electrical network to match the output circuit of a wideband amplifier, Model GA-15, from the same firm. Both laser beam and luminescence were perceived by photomultipliers with a trialkali cathode, Philips or Amperex Type 56TVP, which provided the luminescence and reference signals for a Hewlett Packard vector voltmeter, Model 8405 A. This instrument measured the phase difference (ϕ) between the luminescence and the excitation as a function of the frequency (F). The interpretation uses the relation between ϕ and the decay time τ

$$\tan \phi = 2\pi \cdot F \cdot \tau \quad [1]$$

which is appropriate for systems having a single decay time. The results are generally in good agreement (within 10-20%) with those obtained by the other method which used 350 kV electron pulses of 2 nsec duration and 1 mA peak current. In the latter method the decay was measured by photon counting using a "delayed coincidence" method (15) or storage in a

[1] The crystals were prepared in a production facility of Philips at Maarheeze, The Netherlands, according to a procedure described by Grimmeiss, Kischio, and Scholz (8).

[2] LEC crystals were grown by Mr. H. J. A. van Dijk at this laboratory.

[3] The [Zn] determination was carried out by Mr. L. H. Bastings and co-workers of this laboratory using a dithizon extraction method according to Ref. (11).

[4] According to our calculations on the oxygen incorporation the concentration of the zinc incorporated is higher than the measured free hole concentration by a factor of roughly 1.5.

fast multichannel buffer memory (16). Generally the decays measured were exponential over at least one decade of intensity and frequently over 1½-2 decades.

The internal quantum efficiency was determined from a set of values of the external quantum efficiency applying immersion of the sample in liquids of different indices of refraction. Each liquid was contained in a spherical glass vessel which was positioned in an integrating sphere which provided the required 4π geometry. The excitation was by the same laser source mentioned earlier. The detection of the excitation and luminescence light employed a calibrated photomultiplier in combination with suitable filters.[5] The samples, *i.e.*, planparallel epitaxial samples and more irregular solution-grown samples, were reduced in size to achieve a good transparency. At sufficient size reduction the external efficiency should approach the internal efficiency. Nevertheless immersion in liquids of increasing optical density still leads to an increasing efficiency value. The immersion fluids used were air, ethanol, trichloroethylene, and in a few cases methylene iodide having indices of refraction equal to 1, 1.359, 1.4765, and 1.738, respectively.

In the interpretation of the efficiency results a Stern plot (17) is used where it is assumed that the external and internal efficiencies are related to an average transfer function T_{avg} by

$$\eta_{int}/\eta_{ext} = 1 + S/T_{avg} \quad [2]$$

A plot of $1/\eta_{ext}$ against $1/T_{avg}$ should then extrapolate to $1/\eta_{int}$ at $1/T_{avg} = 0$. T_{avg} is the probability for a photon to exit into the less dense outer medium when arriving at the interface. The slope constant S in Eq. [2] varies considerably between samples. Obviously a small value of this constant is favorable. This is also true from a theoretical point of view. In deriving Eq. [2] it is supposed that (*i*) a photon undergoes a large number of reflections prior to exit into the outer medium, and (*ii*) this large number leads to randomization of the propagation directions within the sample. These assumptions may not remain true when the ratio of the indices of refraction approaches unity. A deviation from Eq. [2] might therefore occur when the experiment could be continued with outer media of higher optical density implying that the extrapolated value would differ from the true value of the internal efficiency. This difference is probably lessened by reducing the slope constant.

Experimental Results

The experiments to be described were all carried out at room temperature.

Bulk quantities.—Internal quantum efficiency (η) and decay time constant (τ) were measured at 293°K. Figure 2 shows η against p. It is seen that η decreases with increasing p from a maximum of about 40% at $p \approx 5 \cdot 10^{17}$ cm^{-3}. This decrease is discussed later. The symbol + refers to a measurement of Ref. (7). Figure 3 shows τ against p and includes the measurement of Ref. (7) and those of Ref. (2). The results on our SG samples were plotted by interpolation between those on our LPE samples for which p is known in order to assign p values to the SG samples.[6] This interpolation enabled the plots of other quantities against p, including the plot in Fig. 2. Since Fig. 3 will not be directly involved in the interpretation of the measurements (nor will Fig. 2) in the section on efficiency and decay results, some discussion is given here. In contrast to η, Fig. 2, the scatter in τ is small. This is understandable as the sample dimensions that influence the efficiency determination are not expected to have an influence on τ. Some of the scatter may arise as the value of p may change by the reduction in size of the samples

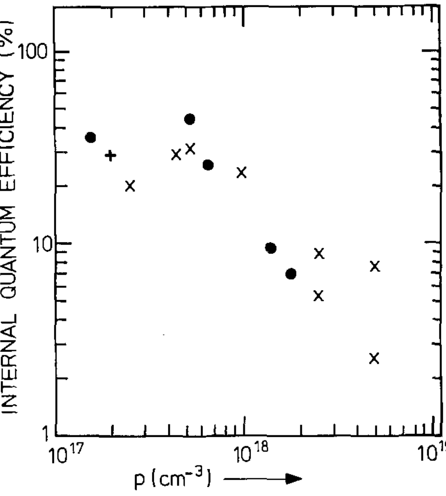

Fig. 2. Internal quantum efficiency of the red luminescence against free hole concentration. The dots indicate solution-grown samples; the crosses, liquid phase epitaxial samples. Symbol + refers to a measurement of Ref. (7).

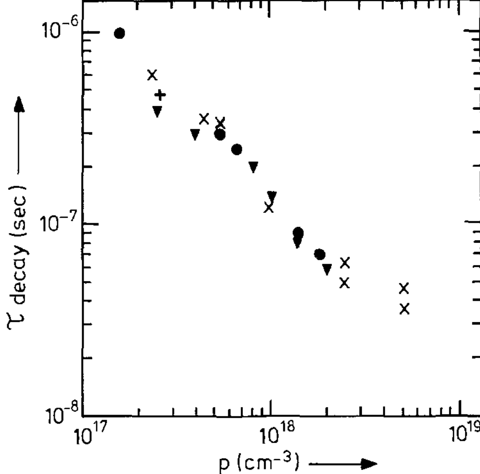

Fig. 3. Decay time of the red luminescence of the same samples as in Fig. 2 and in addition those of Ref. (2) (triangles).

that was necessary for the η measurements. This change in p may arise from the separation of a small part from a somewhat inhomogeneous, large sample on which the Hall measurement was carried out. The results of Ref. (2) and of the present paper are in fair agreement.

The η and τ results will be used to find information on the energy losses by killers and by an Auger effect and on screening, in a later section.

Diffusion length.—For the technique and interpretation reference can be made to Hackett *et al.* (14). Short diffusion lengths, down to 0.16 μm, as occur in samples with a high [Zn] value, could be determined without much difficulty. This is shown in Fig. 4a along with a case of a longer diffusion length of a sample with a low [Zn] value (Fig. 4b). The linear parts from which the diffusion length is determined generally exceed one decade of the electron beam induced current. Figure 4a shows the effect of the finite excitation volume becoming comparable to the diffusion length, the slope from which this length was determined being far from the p-n junction. The electron beam current was a few times 10^{-12}A at 10 kV.

Results (on LPE samples only) are stated in terms of the minority carrier lifetime (τ_{MIN}) which is related to the diffusion length by the known expression

$$L^2_{ep} = D_{ep} \cdot \tau_{MIN} \quad [3]$$

[5] Care was taken to avoid saturation of the luminescent complexes in the samples for both η and τ determinations.

[6] This procedure is supported by the batch data on the zinc incorporated in the SG samples assuming $p \simeq$ [Zn] (12).

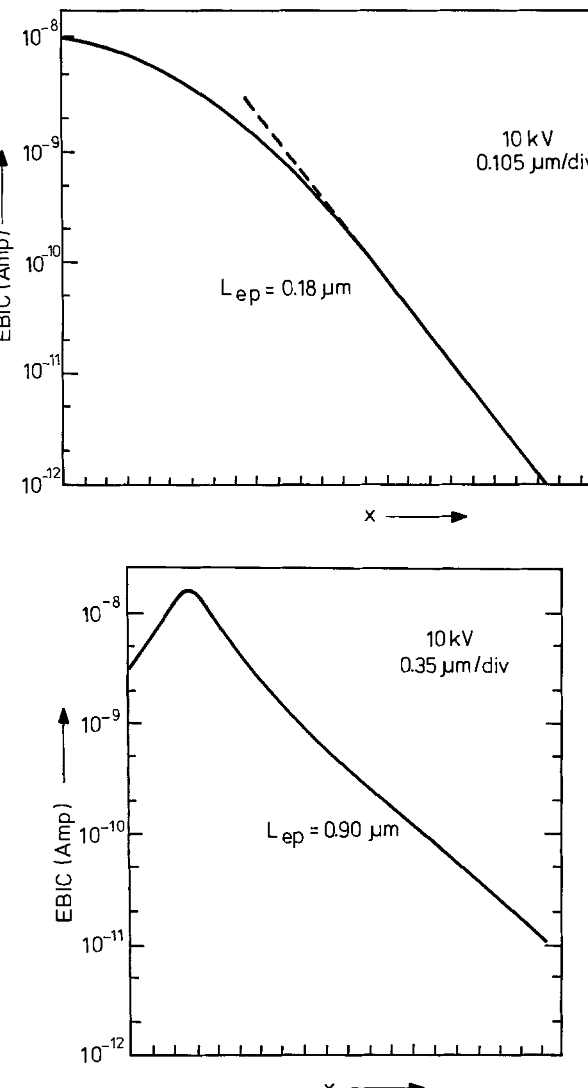

Fig. 4. Typical plots for the electron-beam-induced current (EBIC) as functions of the position x in the p-n diode, measured with a scanning electron microscope on: (a, top) a sample having a high zinc concentration and a short diffusion length (L_{ep}), and (b, bottom) a sample having a lower zinc concentration and a longer diffusion length.

D_{ep} taken to be 2.5 cm^2-sec^{-1}. The results are plotted in Fig. 5 and show a strong decrease of τ_{MIN} with increasing free hole concentration.

A comparison is made in Fig. 5 with results (18) on GaP(Zn), without intentionally added oxygen, for which a representative curve was drawn (curve 3). It is seen from this comparison that there is a reduction of the minority carrier lifetime with respect to the oxygenless samples, pointing to the involvement of oxygen in the creation of the relevant capturing centers. In view of the dopant dependence of τ_{MIN} zinc must also be involved in the creation of these centers. It is reasonable to identify these centers with the luminescent (ZnO) complexes. A few results from Ref. (14) on GaP(Zn, O) are also included in Fig. 5, part of which agrees with our findings. One point, however, shows a rather large upward deviation. In view of our conclusion on the involvement of O and Zn we would suspect a (relative) oxygen deficiency for the sample in question.

Discussion of the Efficiency and Decay Results

In the discussion of Fig. 1 two causes for the reduction of the efficiency were mentioned, *i.e.*, the recombination through killers and the Auger effect, as well as an additional cause, *i.e.*, the thermal quenching

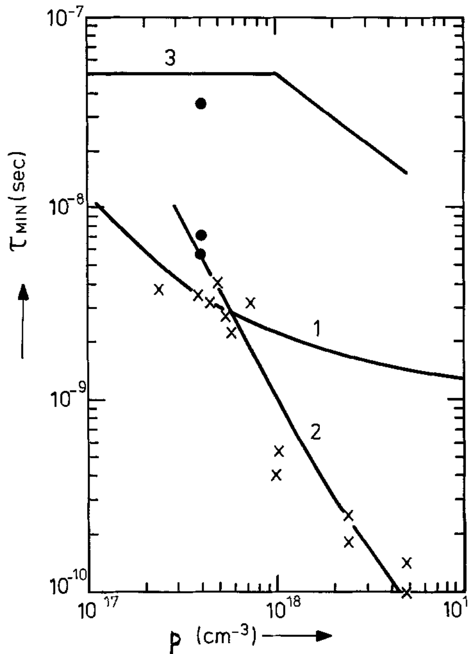

Fig. 5. The minority carrier lifetime (τ_{MIN}) as functions of the amount of zinc incorporated ([Zn]). Curves 1 and 2 describe the cases of nonequilibrium and equilibrium incorporation of oxygen in GaP. Oxygen and zinc are involved in the formation of (ZnO) complexes which trap most of the minority carriers. Results obtained on our samples are indicated by crosses. Similar results of Ref. (14) are indicated by dots. Curve 3 represents the higher lifetime values of Ref. (18) measured on p-GaP(Zn) not containing intentionally added oxygen. In the calculation of curves 1 and 2 account was taken of the thermalization of the captured electrons which is important at low p.

which depends on the presence of killers. An extension of this discussion is now necessary to take account of the existence of two excited states of the luminescent center (4) as well as of the influence of the hole statistics which cause these states (the single electron and exciton states) to change into each other by the transfer of the exciton hole from and to the valence band. Figure 6 shows the relevant level and transition scheme. (See List of Symbols.)[7] Linearized expressions for η and τ were derived in Ref. (1 and 2). The linearization is justified by the application of low excitation densities to the samples so as to avoid saturation of the luminescent centers. Various radiative and Auger transitions involving the luminescent centers have been discussed in Ref. (1-3). We shall only invoke the

[7] These symbols are the same as in Ref. (1-3) except that time constant τ is replaced by its reciprocal, rate r, for a more convenient statement of various equations.

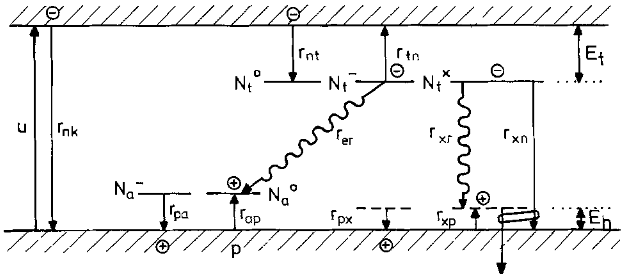

Fig. 6. Recombination model describing the three states of the (ZnO) complexes and various transitions in p-GaP(Zn, O). (See List of Symbols.) For the Auger effect (r_{xn}) it is assumed that the exciton hole is the particle to carry off the transition energy (19). Two types of radiative transitions occur (r_{xr} and r_{er}). The single electron transitions (r_{er}) are negligible.

stronger ones, *i.e.*, the annihilation of the exciton states by radiation and by the Auger effect (rates r_{xr} and r_{xn}). The resulting expression for η

$$\frac{1-\eta}{\eta} = \frac{1-s}{s} + \frac{1-s}{s}\cdot\frac{p_h}{p}\cdot\frac{r_{tn}}{r_{xr}} + \frac{1}{s}\cdot\frac{B_o p}{r_{xro}}\cdot\frac{g_a}{g_r} \quad [4]$$

is stated so as to expose the three causes of efficiency reduction mentioned above, each in terms of competition between two types of transition. The first term on the right-hand side is the killer term where s $(= r_{nt}/[r_{nt} + r_{nk}])$ is the ratio of branching the excited free electrons to the luminescent centers (N_t). The loss through killers is enhanced by the thermal quenching. The second term is an extension of the first term by including the competition between the thermal emission (r_{tn}), affecting the single electron states (N_t^-), and the radiative transitions (r_{xr}) of the exciton states (N_t^*). This competition invokes the relative probabilities of finding these excited states, *i.e.*, respectively $(1 - f)$ and f. Assuming thermal equilibrium between these states these probabilities are represented by the factor p_h/p, a Boltzmann-type expression which depends on the ionization energy E_h of the exciton hole, the density of states of the valence band, and a degeneracy factor. The Auger effect (r_{xn}) is expressed by the third term to be in competition with the radiation, rewriting their rates as $B_o \cdot p \cdot g_a$ and $r_{xro} \cdot g_r$ to show the dependence on p and that on screening. The screening factors g_a and g_r, both being below unity, multiply the basic constants B_o and r_{xro}. The second and third terms, depending on p, allow 45° line approximations in a double log plot of $(1 - \eta)/\eta$ against p.

Figure 7 shows the experimental $(1 - \eta)/\eta$ results for the more efficient samples selected from Fig. 2. It is seen that for p above $4 \cdot 10^{17}$ cm^{-3} the experimental

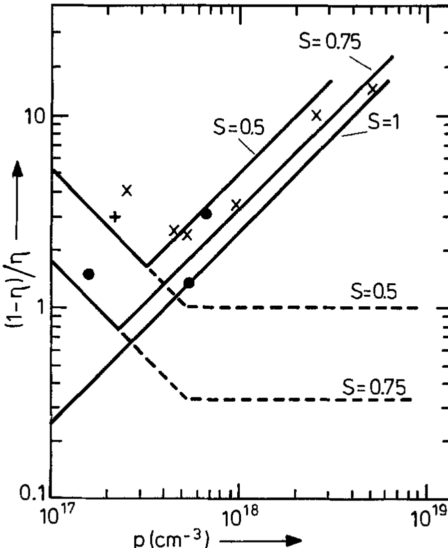

Fig. 7. $(1 - \eta)/\eta$ against p. The theory (Eq. [4]) is approximated here by sets of straight lines, having the free electron branching ratio s as the parameter. The lines with slope $+1$ indicate the Auger effect to be the dominant effect in reducing the efficiency. The s-values indicated were assigned to the sets of lines, taking $s = 1$ for the lower one. The lines with slope -1 describe the detrimental effect of the thermalization of the captured electrons at low p. The horizontal lines describe the action of killers without assistance of this thermalization and are relatively unimportant. Most samples have high values of s, in most cases above ½. The symbols have the same meaning as in Fig. 2. It is seen from this presentation of our experimental efficiency values that the combined action of the Auger and thermalization effects suggests an optimum p-value around $4 \cdot 10^{17}$ cm^{-3}. Incidentally this is also close to practical values for light emitting diodes.

points can be approximated by a straight line under 45° pointing to the dominance of the third term of Eq. [4]. This implies that the multiplier of p in this term is essentially constant. Excluding the possibility of covariance of s and g_a/g_r as functions of p it is fair to assume $g_a/g_r = 1$, as it was done in Ref. (1-2), and s = constant. Regarding s it is implausible to use a value much below unity. The reason for taking $s \approx 1$ follows from the discussion of the minority carrier lifetimes in the next section; the trapping rate r_{nt} of the luminescent complexes, being proportional to [ZnO] which increases with p, would require the killer action to increase proportionally to maintain a constant value of s being smaller than unity. For such proportionality no plausible model is, however, known. Using then $g_a/g_r = s = 1$ as fair conclusions (20) from the application of Eq. [4] to experiment, B_o/r_{xro} can be estimated at $2.5\text{-}3.8 \cdot 10^{-18}$ cm^3. Assuming the low temperature value of r_{xro}, being 10^7 sec^{-1} (6), to be applicable to GaP(Zn, O) at room temperature we obtain $B_o = 2.5\text{-}3.8 \cdot 10^{-11}$ cm^3-sec^{-1}.

Figure 7 contains various broken line approximations of Eq. [4] using s as the parameter and $B_o = 2.5 \cdot 10^{-11}$ cm^3-sec^{-1}. It is seen that for the values of s used the first term of Eq. [4] is unimportant. In contrast to the third term no confirmation can be found for the dependence on p of the second term, which gives the other (negative) 45° approximation, owing to the small number of samples for which p is known [including one measurement of Ref. (7)]. For these samples accidental killers may play a role giving rise to differences in s. Using values $4.5 \cdot 10^6$ sec^{-1} for r_{tn} (2) and $1.2 \cdot 10^{18}$ cm^{-3} for p_h (to be discussed later) a few low-p samples are still found to have s values in excess of 0.5.

We emphasize the following findings from Fig. 7, using Eq [4]. The loss through killers is unimportant above $p = 4 \cdot 10^{17}$ cm^{-3}, more so in comparison with the loss by the Auger effect. The basic rate constant of the Auger effect, B_o, was found to be $\approx 3 \cdot 10^{-11}$ cm^3-sec^{-1}, using these efficiency results only. The free electron branching ratio s is high, exceeding 0.5 for most samples and being probably equal to unity at high p. The screening by free holes affects the radiative and Auger transitions in about the same way. At $p < 4 \cdot 10^{17}$ cm^{-3} the killers predominate mainly through the thermal quenching (at room temperature).

In discussing the effects of screening we shall use a single screening factor, g, and express η in a different way[8]

$$\eta = s \cdot (r_r \cdot \tau) \quad [5]$$

where η is seen to be reduced below unity in two steps, *i.e.*, branching of the free electrons (s) and branching between the radiative and all other transitions to which the electrons on the luminescent centers are subject. The former transitions (rate r_r) and latter transitions constitute the decay rate $1/\tau$. Putting the observable quantities η and τ on one side and re-expressing r_r by $f \cdot g \cdot r_{xro}$ we obtain

$$\eta/\tau = s \cdot f \cdot g \cdot r_{xro} \quad [6]$$

f being, as stated earlier, the probability of finding the excited luminescent center in the exciton state.

When s is known, using the findings on η of Fig. 7, it is possible to use Eq. [6] to obtain information on the screening. Figure 8 shows the experimental η/τ results along with a theoretical curve to be discussed later in this section. According to the findings on η, s is close to unity for $p > 4 \cdot 10^{17}$ cm^{-3}. Taking as before $r_{xro} = 10^7$ sec^{-1} it is then immediately concluded that the product $f \cdot g$ is of the order of 0.1-0.2 for most samples. In other words the radiative lifetime is then effectively 0.5-1 μsec. Since f will be close to unity at

[8] See also Eq. [A5b] of Ref. (2); Ref. (5) contains a similar equation [8b].

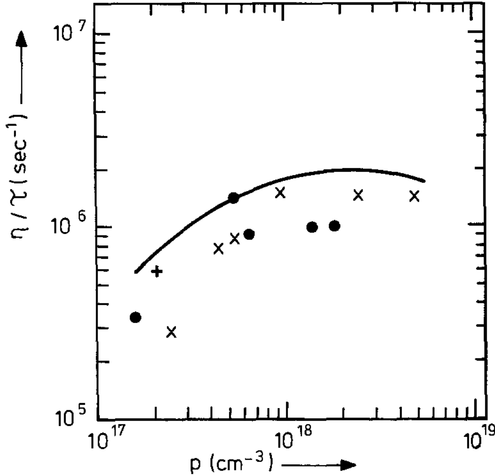

Fig. 8. Quantity η/τ against p. This quantity is the free electron branching ratio, s, divided by the effective radiative lifetime, $(f \cdot g \cdot r_{xro})^{-1}$ (see Eq. [6]). In view of the values $r_{xro} = 10^7$ sec^{-1} [Ref. (6)] and $s \approx 1$ this plot shows a strong action of the screening (g) and the occupancy (f) of the exciton hole level on the radiative transitions. The theoretical curve was calculated, using a mathematical approach for f and g and taking $s = 1$.

high p (in view of $f = p/(p + p_h)$, g can therefore be estimated at, say, 0.2 implying a strong reduction of the transition probability by screening.

No confirmation of some screening model was found possible using the η/τ findings. Known theories (1-3) employ a few parameters for which we could not obtain a unique set of values. Another consequence is that we are not well able to establish separate functions for f and g. The theoretical curve in Fig. 8 is based on an arbitrary mathematical approach of the screening effect. At the lower p values, however, where the screening should be weak ($g \approx 1$) f may be estimated leading to the value of p_h we have applied in the discussion of the $(1 - \eta)/\eta$ results, *i.e.*, $1.2 \cdot 10^{18}$ cm^{-3}.

The considerations in this section depend critically on the assumption of a value for the basic quantity r_{xro}. In view of Eq. [4] the basic Auger rate constant B_o also depends on this assumption. It may be tried to reduce both quantities by a same factor in order to obtain an alternative interpretation for the findings of Fig. 7 and 8. The screening will then decrease and becomes absent when this factor is about 3. The fit of theory to Fig. 3 (τ against p) is, however, best using the accepted value for r_{xro}.

At this point it may be useful to comment on findings on Auger effect and screening by other workers. Assuming *a priori* certain values of the screening parameters $B_o = 3 \cdot 10^{-11}$ cm^3-sec^{-1} was arrived at in Ref. (2) while in Ref. (1 and 3) higher values were proposed, *i.e.*, respectively $5 \cdot 10^{-11}$ and 10^{-10} cm^3-sec^{-1}. The latter values must be considered too high, predicting a stronger decrease in efficiency with increasing p than we have actually found. The same conclusion applies to the value of $5.5 \cdot 10^{-11}$ cm^3-sec^{-1} we have derived from findings in Ref. (7). The latter result is rather surprising since in this reference no modifiable assumption could be found.

Various opinions on screening also exist differing mainly in the adjustment of parameters (1, 2). It was objected by Dapkus, Hackett, Lorimor, and Bachrach (21) that the screening as described in Ref. (2) would be too strong for the existence of "green" excitons (bound to isoelectronic nitrogen centers in GaP) at values of p above a few times 10^{17} cm^{-3}. The effect of screening was therefore deemed overestimated for both green and "red" excitons. Our results supporting those of Ref. (2), however, imply that the objection of Ref. (21) is not justified with regard to the red excitons.

Concluding the discussion on screening it can be said that, using the $(1 - \eta)/\eta$ and the η/τ results in combination, plausible experimental evidence on the effect of screening on the red exciton annihilation could be obtained. This evidence shows this effect to be quite appreciable.

Minority Carrier Lifetime and Oxygen Incorporation

In this section we try to deduce from the minority carrier lifetime results data on the oxygen incorporation. The connecting link between lifetime (τ_{MIN}) and this incorporation is provided by the (ZnO) complexes which act as capturing centers for the minority carriers (electrons).

Such deduction is complicated by the thermalization of the electrons from the (ZnO) complexes. τ_{MIN} does therefore not arise from a simple addition of the trapping rates of the complexes and the killers (r_{nt} and r_{nk} of Fig. 1). Above a certain value of p the Auger effect will, however, dominate the thermalization, enabling this simple addition. It was also found that the killer action is probably weak for most samples (see preceding section). For large values of p, τ_{MIN} can therefore be approximated by the expression

$$\tau_{MIN}^{-1} = B_{nt} \cdot [ZnO] \quad [7]$$

where B_{nt} is the capture rate constant of the complexes. Assuming for B_{nt} a value of about 10^{-8} cm^3-sec^{-1} (22) it can be directly inferred from the experimental data (see Fig. 5) that [ZnO] can reach values up to 10^{18} cm^{-3}, a result that has not been thought probable before.

The remaining part of this section is concerned with the functional behavior of [ZnO] in order to provide insight in the oxygen incorporation. This incorporation and the complex formation which occur at different temperatures, *i.e.*, $\approx$ 1000°C and $\approx$ 500°C, are two problems of defect chemistry. At these temperatures zinc and oxygen, acting as acceptors and donors on the gallium and phosphorus sites, respectively, are completely ionized. Assuming that in their interaction these ion species remain on the sites mentioned and that no vacancies[9] are involved we shall apply for the complex formation a model by Wiley (23). This model uses the electrostatic binding energy of the two ion species to calculate the reaction constant in

$$[Zn^-] \cdot [O^+] = K_c \cdot [ZnO] \quad [8]$$

which is a first approximation. In the calculations we have followed the refinements in Ref. (23) taking non-nearest-neighbor complexes into account. Clearly data on [Zn] and [O] must be provided. [Zn] was applied as an independent variable. For [O] some theory is necessary. For such theory we tried ideas of Jordan, Trumbore, Wolfstirn, Kowalchik, and Roccasecca (24) who suggested that oxygen might be incorporated in an "equilibrium" or a "nonequilibrium" mode. This problem was also studied by Peters and Vink (25). In the nonequilibrium case the oxygen incorporation is assumed to be surface controlled owing to a fixed Fermi level at the surface (26). This implies a constant value of n in the reaction equation

$$n \cdot [O^+] = K_i \cdot [O_{source}] \quad [9]$$

In the other case no such restriction on the incorporation occurs owing to, presumably, inclusions of Ga_2O_3 which are forced into the solid GaP by a supersaturation of the Ga liquid with this oxide.[10] As it is proper for an equilibrium case the following equations are invoked to control the value of n, *i.e.*

$$n \cdot p = n_i^2 \quad [10]$$

[9] Lacking data on energy and charge state we have not taken the P- and Ga-vacancies into account.
[10] This occurred in the preparation of our LPE samples.

and the neutrality condition, neglecting other donors and acceptors

$$p + [O^+] = [Zn^-] + n \quad [11]$$

For the two cases of nonequilibrium and equilibrium incorporation theoretical curves were calculated for Fig. 5 using in both cases Eq. [8] and [9]. For the former case the quantities n, K_i and $[O_{source}]$ of Eq. [9] may be assumed to be constant for the LPE samples investigated. This implies a constant oxygen addition to the solid GaP; for curve 1 $[O^+] = 10^{17}$ cm^{-3} was taken. With regard to the equilibrium case, curve 2, we have taken for the relevant quantities the following values: $n_i = 1.6 \cdot 10^{17}$ cm^{-3}; $K_i \cdot [O_{source}]/n_i^2 = 0.4$; and $B_{nt} = 10^{-8}$ cm^3-sec^{-1}. Clearly the experimental data are best explained assuming the equilibrium mode of incorporation to occur. The steps in the calculation for the equilibrium case are illustrated in Fig. 9 which shows the dopant dependence of the various oxygen concentrations which are linked by Wiley's theory.

The above determination of the oxygen incorporated depends on the value taken for the capture rate constant B_{nt}. Other values are known, *i.e.*, a value of $\approx 4 \cdot 10^{-8}$ cm^3-sec^{-1} that was derived from measurements of the decay time of the red luminescence by Jayson, Bachrach, Dapkus, and Schumaker (27), and a value of $\approx 2 \cdot 10^{-8}$ cm^3-sec^{-1} inferred from a transient capacitance study on a p-n junction by Lang (28), a more direct determination. Application of the latter value would reduce the concentration values of Fig. 9 by a factor of two to a first approximation. Lang also determined the concentration of the (ZnO) complexes and the O donors, *i.e.*, $4.3\text{-}11 \cdot 10^{15}$ cm^{-3} and $1.1\text{-}1.9 \cdot 10^{16}$ cm^{-3}, respectively, the latter value being supported by a photocapacitance study by Kukimoto, Henry, and Merritt (29) on the same sample. These concentration values are lower than the values predicted by Fig. 9 (for a zinc concentration of $\approx 4 \cdot 10^{17}$ cm^{-3}), being $\approx 3 \cdot 10^{16}$ cm^{-3} and $\approx 10^{17}$ cm^{-3}, by a factor of five (or a factor of 2-3 using Lang's value for B_{nt}). The discrepancy found above may, as also indicated in Ref. (25), be explained by differences in sample preparation.

Conclusions

Measurements of the internal quantum efficiency which were carried out on samples of small size and good transparency show an Auger effect to be the dominant cause of losses by nonradiative transitions above $p \approx 4 \cdot 10^{17}$ cm^{-3}. In addition the other nonradiative transitions, *i.e.*, trapping by killers, become negligible. Below this p value the effect of the killers is noticeable owing to the thermalization of the minority carriers from the luminescent (ZnO) complexes. The better efficiency values are found in the lower p range with a maximum of $\approx 40\%$. A fairly direct determination was found possible for the rate constant of the Auger effect, *i.e.*, $\approx 3 \cdot 10^{-11}$ cm^3-sec^{-1}.

Using the decay time results in addition to the efficiency results screening by free holes was found to have an appreciable effect on both radiative and Auger transition probabilities of the excitons bound to the (ZnO) complexes. The theoretical interpretation does not allow a confirmation of a screening theory, however.

The measurement of the diffusion length against p provides an insight in the problem of the oxygen incorporation into GaP, the oxygen being connected with the main electron trapping centers, *i.e.*, the (ZnO) complexes. The oxygen concentration increases with p, becoming $\approx 10^{18}$ cm^{-3} at $p \approx 5 \cdot 10^{18}$ cm^{-3}. This increase points to an equilibrium mode of oxygen incorporation in our samples which is presumably made possible by the presence of Ga_2O_3 inclusions in the solid GaP during the crystal growth.

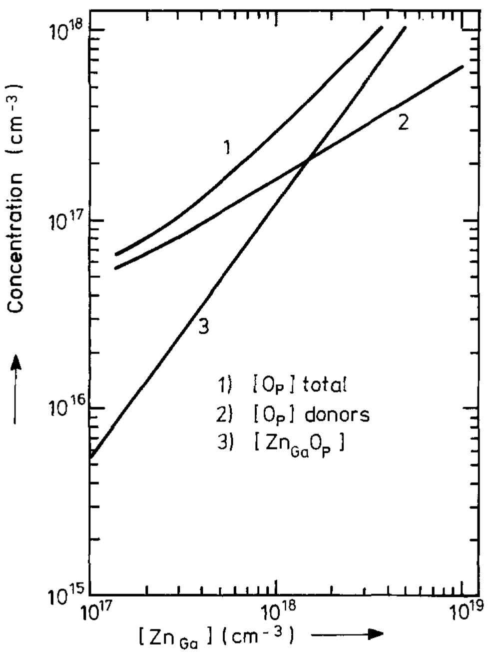

Fig. 9. Various concentrations of oxygen in GaP as function of [Zn] assuming the incorporation of O in GaP to take place in equilibrium. Curve 3 was used in Fig. 5 to describe τ_{MIN}.

Acknowledgments

LIST OF SYMBOLS

N_t	concentration of the (ZnO) complexes
N_t^o, N_t^-, N_t^x	*idem.*, applying to the ground state, the single electron state, and the exciton state, respectively
r_{nt} and r_{tn}	single-electron trapping and thermalization rates (sec^{-1}). For r_{tn} a value of $4.5 \cdot 10^6$ sec^{-1} was taken (2)
E_t	energy of binding the single electron to a complex, being approximately 0.3 eV and a parameter of r_{tn}
B_{nt}	rate constant of r_{nt} and r_{tn}, approximately 10^{-8} cm^3-sec^{-1}
r_{nk}	rate of the nonradiative transitions of the free electrons
u	generation rate (cm^{-3}-sec^{-1})
r_{xn}	exciton annihilation rate by the Auger effect which is proportional to p
B	rate constant (cm^3-sec^{-1}) in $r_{xn} = B \cdot p$, which is reduced by free hole screening, the basic rate constant being B_o
r_{xr} and r_{er}	radiative rates for the excitons and the complex-acceptor pairs. r_{xr} is also reduced by the screening from a basic rate r_{xro}, its value being 10^7 sec^{-1} [Ref. (6)]
r_{px} and r_{xp}	rates of trapping and thermalization of the exciton hole, being proportional to p and p_h, respectively
p and p_h	free hole concentration and effective valence band density of states, referred to

	the exciton hole level. p_h is subject to the screening, which modifies the basic rate p_{ho}, for which the value of $1.2 \cdot 10^{18}$ cm^{-3} was taken. At low p, $p_h \approx p_{ho}$
E_h	exciton binding energy, being implicit in $p_h \cdot E_h$ is reduced by screening from a basic energy E_{ho}
f	occupancy of the exciton hole level
s	fraction of the excited free electrons captured by the (ZnO) complexes
g_a and g_r	screening factors, modifying the Auger and radiative transition probabilities. Usually replaced by single factor g

ABSTRACT

The performance of sulfur hexafluoride as an *in situ* etchant for silicon during epitaxial growth processes has been examined as a function of temperature and partial pressure. Below 1060°C etching was preferential, producing pitted substrates, while above 1060°C etching was smooth. However, above 1060°C, both the SiO_2 masking layers on the substrates and the quartz reactor walls were attacked during the etching of the silicon. This occurred in both helium and hydrogen ambients. High resistivity silicon substrates were etched *in situ* with SF_6. Silicon epitaxial layers were deposited subsequent to *in situ* etching with SF_6. Both etched substrates and etched substrates with epitaxial layers were examined optically for the presence of active sulfur donor sites. The concentration of active sulfur donor sites resulting from etching with SF_6 was found to be less than 1×10^{13} cm^{-3} in both the etched substrates and the silicon layers deposited subsequent to SF_6 etching.

As modern semiconductor devices have grown in complexity and performance, it has become increasingly important to reproducibly grow high-quality silicon epitaxial layers on silicon or sapphire substrates. Since semiconductor devices are usually fabricated in the epitaxial layer, the critical physical processes which determine the electronic characteristics of these devices take place in the epitaxial layer. This close relationship between semiconductor device

Key words: silicon etching, epitaxial deposition, impurities, silica etching, sulfur hexafluoride.

performance and the physical nature of the epitaxial layer makes work toward improving this incompletely understood process worthwhile.

In the ideal situation, the epitaxial deposition process gives control over the dopant concentration profile while maintaining a high degree of perfection in the crystalline structure of the deposited material. In order to adequately accomplish this task it is necessary that the surface layers of the substrate be essentially ideal. The introduction of an etchant before silicon epitaxial deposition has been used to obtain better uniformity in the deposited layer thickness (1). Surface oxides, films, and mechanical damage on the substrates can introduce severe perturbation into the crystal structure if they are not removed prior to epitaxial growth. Because of this, substrates are etched *in situ* by vapor etching prior to epitaxial deposition. The vapor etchants which have been reported to be suitable for this purpose are Cl_2 (2), HI (3), HBr (4), HCl (3, 5), H_2S (6, 7), SF_6 (8), and water vapor (9).

Although hydrogen chloride is the etchant most commonly used for this purpose, the high temperature required (1100°-1200°C) and the transport of impurities by HCl cause severe impurity redistribution problems (10-12). In addition, the highly corrosive nature of HCl causes expensive periodic replacement of gas regulators, mass flow controllers, lines, etc. Gupta has found that even the introduction of very small amounts of HCl degrades both the surface of the deposited layer and the impurity concentration profile. The undesirable characteristics of HCl has led to the investigation of alternate sources of a less corrosive etchant which will allow etching at a lower temperature. Of the etchants which have been investigated SF_6 seems to be most promising for this and many other applications in semiconductor processing. Many of these applications and the physical and thermodynamic properties of sulfur hexafluoride have recently been reviewed by Adler and Yaws (14).

Rai-Choudhury (8) has investigated the feasibility of utilizing SF_6 as a low temperature *in situ* etchant for the Si epitaxial deposition process. The reported results indicated that the etched surfaces were very smooth and the subsequently deposited silicon layers were high quality. The entire etching and deposition process could be carried out at temperatures less than 1100°C.

Gupta (13) has suggested the use of sulfur hexafluoride during epitaxial growth at low concentrations to improve epitaxial deposition uniformities since sulfur hexafluoride gives good surfaces at lower temperatures and does not degrade the impurity concentration profile as severely as HCl. Although SF_6 appears to be quite promising, little has been reported about the effects on the electrical and optical properties of sulfur doping in the epitaxial layer resulting from etching with SF_6. The diffusion rate of sulfur in silicon is quite rapid, 1×10^{-8} cm²/sec at 1100°C and 2×10^{-9} cm²/sec at 1000°C (15). The maximum solubility of sulfur in silicon has been reported by Carlson *et al.* (15) to be 3×10^{15} atoms/cm³, easily high enough to significantly affect the electrical behavior of the deposited layers. Sulfur is a two level donor in silicon with energy levels at 0.18 and 0.37 eV below the conduction band edge (16). The properties of these donor states have been studied both experimentally (16, 17) and theoretically (18, 19). The hole capture cross section is small, but electrons are easily captured.

It is the purpose of this study to investigate the performance of SF_6 as an *in situ* etchant for the silicon epitaxial deposition process and to investigate the effect of sulfur doping on the characteristics of the deposited material.

Experimental Procedure

Silicon wafers were etched with SF_6 *in situ* in an epitaxial reactor over a wide range of temperatures and SF_6 partial pressures. The epitaxial reactor used for this work consisted of a 20 kW, computer-controlled RF (450 kHz) heated horizontal reactor with a 3 in. diam round tube configuration which was cooled by forced air. The silicon wafers were mounted on a silicon carbide coated graphite susceptor which was adjusted to provide optimum flow characteristics for uniform layer etchant or growth characteristics. The sulfur hexafluoride was injected into the main gas stream of palladium purified hydrogen. The reactant flow rates were monitored and controlled with automatic mass flow controllers accurate to within 2%. The substrate surface temperatures were directly monitored with an infrared radiometer viewing normal to the wafer surface. The temperature readings were corrected for emissivity errors and absorption losses. The silicon wafers were (1, 1, 1) oriented, ~50 ohm-cm p-type with acceptor concentration (boron) of $1.0\text{-}1.5 \times 10^{14}$ cm^{-3}. The wafers were mechanically and chemically polished. To minimize substrate surface contamination, a thorough cleaning and degreasing procedure was given the wafers prior to entering the reactor.[1] The etch rates were measured by weight loss techniques using an analytical balance accurate to 20 μg. The etched surfaces were examined under a scanning electron microscope for evidence of preferential etching or pitting.

After a suitable range in temperatures and SF_6 partial pressures was found, a series of silicon wafers, coated with thermally grown oxide and strips of the oxide removed by standard photoresist and etch techniques, was etched in SF_6. These wafers were examined under a scanning electron microscope to make qualitative measurement of the degree of attack and of undercutting of the oxide masks by the SF_6. In addition, other wafers without the oxide were etched and several microns of silicon deposited over the layers using SiH_4 as the silicon source. These were also examined under the scanning electron microscope for the presence of crystal defects. Defects would indicate an inadequate removal of surface impurities or of preferential etching.

The samples were optically studied for the evidence of sulfur doping using a MacPherson monochromator in the experimental setup described in the Appendix. Samples were prepared by lapping the back (nondoped) side of each slice and then etching it down in silicon etch to a thickness of 3-8μ. Transmission samples were placed with one flat side perpendicular to the beam between the output slit and the photomultiplier tube. Measurements were taken for wavelengths from 12.0 to 1.0μ in search of evidence of active sulfur donor sites.

Results

Sulfur hexafluoride etches silicon according to the reaction

$$4Si(s) + 2SF_6(g) \rightarrow SiS_2(s \text{ or } l) + 3SiF_4(g) \quad [1]$$

The free energy of the reaction is −706.81 kcal/mole at 1400°C (11). Thus sulfur hexafluoride etches silicon spontaneously and irreversibly producing volatile sulfides and fluorides of silicon.

The silicon etch rate dependence on temperature found is shown in Fig. 1 for a SF_6 concentration of 0.1%. As indicated in Fig. 1, the etch rate tends to level off at a value determined by either the mass transfer of the reactants to the substrate surface or by the mass transfer of the reaction byproducts away from the surface. For temperatures less than 1100°C and a fixed partial pressure of SF_6 the etch rate (R') dependence on temperature is as given in Eq. [2]

$$R' \propto \exp\left(\frac{-Ea}{RT}\right) \quad [2]$$

In the foregoing expression, Ea is the activation energy, determined to be ~17 kcal/mole, R is the gas constant, and T is the absolute substrate temperature.

[1] The cleaning process involved immersion in transistor grade TCE, acetone, and methyl alcohol with a 15 min boil in nitric acid.

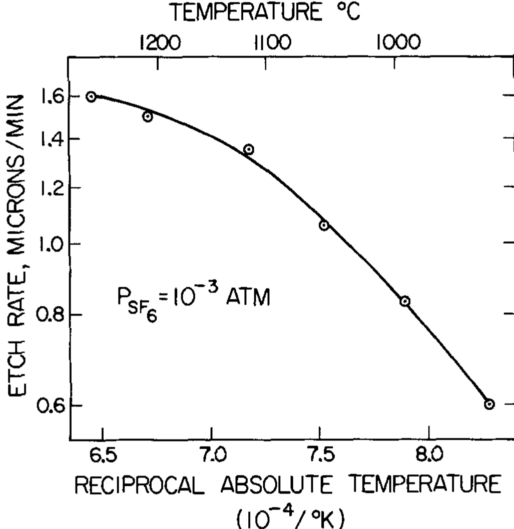

Fig. 1. Silicon etch rate vs. substrate temperature for SF_6 pressure of 10^{-3} atm.

Sulfur hexafluoride etching was found to be preferential for temperatures of 1050°C and below over an SF_6 concentration range of 0.01-0.1% by volume. The preferential etching produced cloudy surfaces, which, as revealed by scanning electron microscopy, were the result of pitting. A typical substrate surface which was etched at a temperature below 1050°C is shown in Fig. 2. The etchant is judged unsuitable for use at temperatures below 1050°C due to the morphology problems which would result from epitaxial deposition on such a pitted surface.

The silicon etch rate dependence on SF_6 partial pressure was characteristic of a first-order reaction with the etch rate being approximately directly proportional to the SF_6 partial pressure. The silicon etch rate dependence on SF_6 partial pressure for a substrate temperature of 1060°C is shown in Fig. 3. As indicated on Fig. 3, the SF_6 partial pressure range investigated was from 10^{-4} to 10^{-3} atm. SF_6 partial pressures of less than 10^{-4} atm were not used since the etch rate was too low to be of economic interest. Increasing the SF_6 concentration above 10^{-3} atm resulted in a white fibrous growth of material along the gas exit end of the susceptor. The use of higher carrier gas velocities (~100 cm/sec) to sweep away the reaction byproducts was found to be effective for reducing the amounts of the deposits. Etching at SF_6 partial pressures of 10^{-4}-10^{-3} atm resulted in no observable deposits on either the reactor chamber or the substrate.

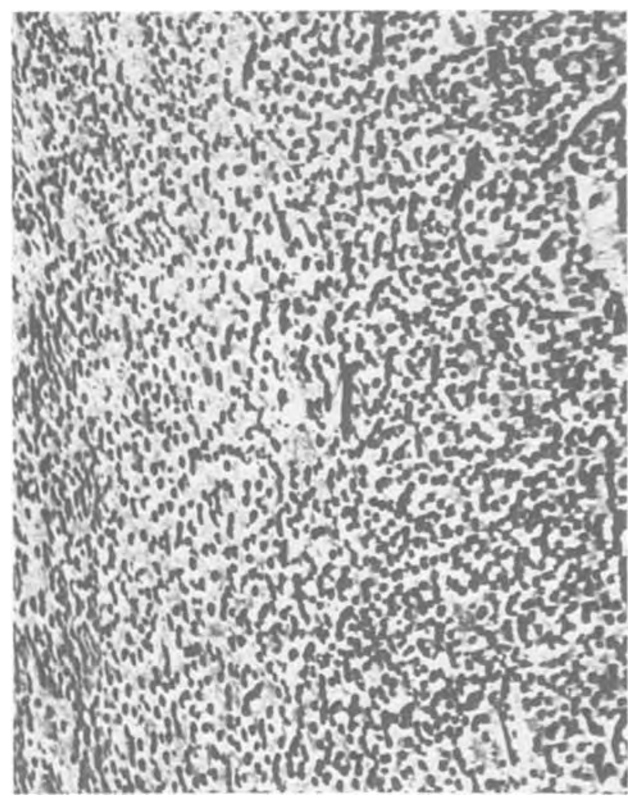

Fig. 2. Pitted substrate surface from SF_6 etching at $T < 1050$°C. Scanning electron microscope at a magnification of 80×.

Etching at temperatures above 1060°C produced smooth mirrorlike surfaces. Epitaxial layers subsequently deposited on the silicon surfaces which were etched at temperatures greater than 1060°C were of high quality with a stacking fault density of < 2/cm^2. Although etching produced smooth surfaces at the higher temperatures, the oxide masks on each wafer and quartz reactor walls were attacked. Repeated etching with SF_6 resulted in frosting the quartz reactor tube in the warmest areas surrounding the susceptor. This was, however, a slow process requiring a period of several months (approximately 20-30 runs) before any reactor tube had to be discarded. This may not present a problem in those cases where a water-cooled reactor tube is used.

The SF_6 attack of the oxide mask presents a more serious problem. At a substrate temperature of 1275°C and SF_6 concentration of 0.06% the oxide attack was of such severity that a half-micron oxide mask was entirely consumed in approximately 2.0 min. Reducing the SF_6 concentration to 0.01% resulted in a somewhat lower oxide etch rate. However, the half-micron thick oxide layer was consumed in approximately 7 min. Reducing the substrate temperature to 1100°C, approaching the minimum temperature of interest, resulted in a more preferential etching of the oxide and again within about 15 min the SF_6 had penetrated the mask to the silicon underneath. The oxide etch rate was found to be more sensitive to temperature than to SF_6 concentrations but even at the lower temperatures was at least an order of magnitude higher than the maximum allowable. Etching in a helium ambient to eliminate the possibility of HF formation and subsequent attack of the oxide yielded no apparent change. Again the half-micron thick oxide was penetrated in less than 7 min. Etching in both ambients is consistent with the model holding that the fluorine ion is responsible for the oxide attack. A typical oxide which had undergone SF_6 attack in a helium ambient is shown in Fig. 4 at the point of ultimate failure of the oxide mask.

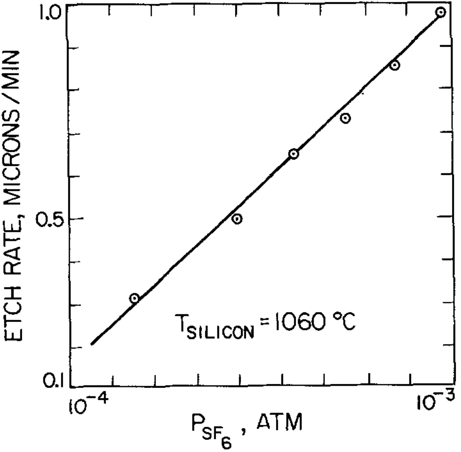

Fig. 3. Silicon etch rate vs. SF_6 partial pressure

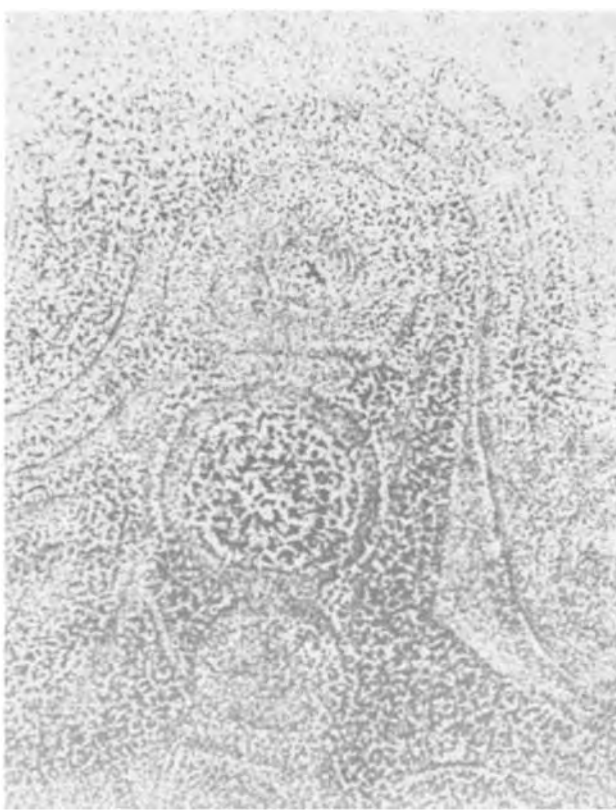

Fig. 4. Silica mask attack by SF_6 in He ambient. Scanning electron microscope at a magnification of 120×.

As a result of the work, we judge that most sulfur hexafluoride etching will take place between 1050° and 1100°C in order to strike a balance between preferential etching and the effects such as outdiffusion, autodoping, etc. brought on by high temperature operations. At these temperatures the diffusion constant, D, will be in the 5-10 $\times$ 10^{-9} cm²/sec range and the maximum sulfur concentration in the silicon will lie close to $10^{15}/cm^3$.

High resistivity p-type silicon wafers with acceptor (boron) concentrations of 1-1.5 $\times$ $10^{13}/cm^3$ were etched in the temperature range of 1050° and 1100°C. Testing for the presence of active sulfur donors was done optically using a MacPherson monochromator in the procedure described in the Appendix. Measurements were taken for wavelengths from 12.0 to 1.0μ. No evidence of an active sulfur donor was found in either the etched substrates or in the deposited epitaxial layers. A slice of the original p-type material was placed in a small furnace and sulfur diffused at 1100°C for 16 hr. It was prepared for transmission measurements and the presence of sulfur at both 0.18 and 0.37 eV was observed. A capacitance-voltage analysis of gold and aluminum Schottky barriers on epitaxial layers deposited on SF_6 etched substrates gave no indication of the presence of sulfur. We conclude that after sulfur hexafluoride etching sulfur is not present in silicon in amounts greater than $1 \times 10^{13}/cm^3$.

Summary

In summary, sulfur hexafluoride was found to be an effective etchant for *in situ* etching of silicon at substrate temperatures above 1060°C. The low etching temperatures of this process, together with deposition from silane, allow the complete epitaxial deposition operation to take place at temperatures of less than 1100°C. The attack on the oxide masks by this etchant over the temperature range required for nonpreferential etching renders the etchant unusable in those instances where localized etching and deposition are desired. Measurement of sulfur doping in either substrates etched with SF_6 or in silicon epitaxial layers deposited subsequent to *in situ* etching with SF_6 indicated that sulfur was not present down to the detection limit of the measurement technique ($\sim 10^{13}/cm^{-3}$).

Manuscript submitted Aug. 25, 1975; revised manuscript received Nov. 12, 1975. This was Paper 97 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

APPENDIX

Optical Transmission Measurements

A schematic of the optical experimental apparatus is shown in Fig. 5. Input power from a Jarrell-Ash light source cooled by a small electric fan is modulated by a 200-Hz Bulova chopper. A single-grating MacPherson monochromator selects the wavelength and the beam passes through the quartz beam-splitter at A. The reflected beam (about 2% of the input power above 3000Å) is measured with a United Detector Technology u.v.-sensitive silicon photodetector (Model 500-UV) B, and the transmitted beam strikes the output mirror C, and is reflected through the output slit D, and into the photomultiplier tube E. The photomultiplier output is processed by a PAR lock-in amplifier.

Calibration measurements were made with no samples in the path of the beam. The beam-splitter at A introduces three possible sources of error in the measurements. The first of these is caused by the approximately 40° angle between the beam direction and the normal to the quartz plate. This causes an effective shift in wavelength which is a function of the angular dispersion A of the monochromator grating, the angle of incidence on the beam-splitter, the beam-splitter thickness t, and the index of refraction n of the quartz. The path difference Δ introduced by the beam-splitter is shown in Fig. 5, and is given by Snell's law (assuming the index of refraction of air is unity) as $\Delta = (t \sin \theta)/n$. For a 1/16 in. quartz slide this gives a Δ of $6.2 \times 10^{-4} m$. (The index of refraction of quartz is approximately 1.55 throughout the visible and near infrared regions.) The angular dispersion of the grating is given by

$$\frac{\Delta\phi}{\Delta\lambda} = \frac{m}{d \cos \phi}; \quad \Delta\phi = \frac{d\Delta\phi \cos \lambda}{m} \qquad \text{[A-1]}$$

Here d is the grating spacing and m is the order number of the spectrum. The worst-case shift is in the first-order spectrum. The path length, L from grating to beam-splitter is 1.58 met and hence $\Delta\phi$, the angular separation of the reflected spectral lines, is $t/L = 1.01 \times 10^{-3}$ rad. The approximate angle of reflection from the grating is 15°, so a calculation yields $\Delta\lambda = 16$Å. This is a function of wavelength and must be applied to the lock-in amplifier output spectrum. The corresponding energy error is 0.005 eV.

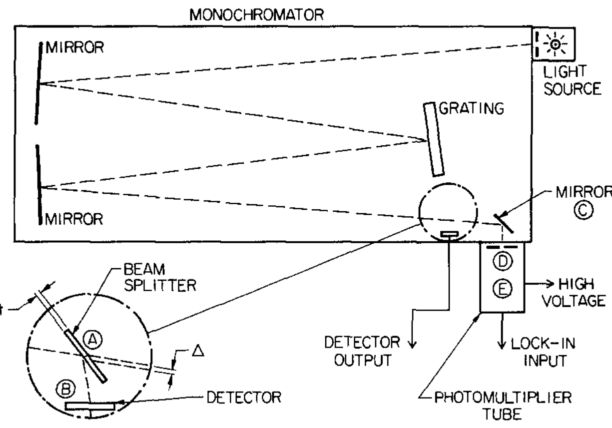

Fig. 5. Optical measurement apparatus

The second error due to the beam-splitter is a result of the finite width of the photodetector. Fluctuations in amplitude of the light source output cause fluctuations in detector output over a bandwidth of wavelengths given by Eq. [A-1]. The angular separation $\Delta\phi$ is calculated using L as before and W, the detector width, as 0.5 in. $= 1.3 \times 10^{-2}$. Calculating as before the value $\Delta\lambda = 120$Å is obtained. Thus a variation in intensity of the light source over the range $\lambda - \Delta\lambda$ to $\lambda + \Delta\lambda$ will be measured by the detector while the monochromator output signal will respond only to changes in the intensity over the wavelength range covered by the slit. This will not cause significant error provided the percentage change in intensity output of the lamp is constant with wavelength over the range $\lambda - (\Delta\lambda/2)$ to $\lambda + (\Delta\lambda/2)$. Since the fluctuations in light source intensity were observed to be of a short-term, random nature (by measuring light source output with the photomultiplier tube at constant wavelength every 10 sec for 15 min and every 15 min thereafter for 2 hr) rather than statistical fluctuations as in Johnson noise, then it is assumed that the variations in intensity result from power supply transients. Thus it can reasonably be assumed that the relative intensity distribution will not change over the range $\lambda - (\Delta\lambda/2)$ to $\lambda + (\Delta\lambda/2)$, only the total intensity will vary.

The final possible error resulting from insertion of the beam-splitter occurs in wavelength regions where the rate of change of the quartz transmission coefficient with frequency is much greater than the light source intensity variation. The transmission is constant at wavelengths greater than 3300Å, the region used.

The minimum amount of sulfur detectable by the system was determined as follows: Several samples of silicon were prepared by pulling (111) oriented ingots from melts containing a known amount of sulfur. The maximum solubility of sulfur in silicon is approximately 4×10^{16} (20) and the calculated concentrations of sulfur in the test ingots was kept well below this (10^{14}, 10^{13}, 10^{12}, and $10^{11}/cm^3$). Samples from each of these ingots were placed in the beam of the monochromator and a search made for the absorption peaks at 0.18 and 0.37 eV. Evidence was strong at the $10^{14}/cm^3$ and slight at the $10^{13}/cm^3$ impurity concentrations. No evidence was seen at 10^{12} or $10^{11}/cm^3$. A cross check was then made by using sample wafers into which sulfur diffusions had been made. The diffusion profile was calculated for the sulfur and the wafers polished down to the regions of desired maximum sulfur concentration. For samples with sulfur concentration ranging from 10^{14} to $10^{13}/cm^3$ we could observe absorption with the monochromator. With samples with sulfur concentrations between 10^{13} and $10^{12}/cm^3$ we could observe some slight absorption and none at all was observable for any sample with maximum concentration below $8 \times 10^{12}/cm^3$. (For the UCSB monochromator system and using 3-8 mm thick samples we find the minimum detectable sulfur concentration to be $10^{13}/cm^3$.)

Nucleation of Al_2O_3 Layers on Cemented Carbide Tools

J. N. Lindström and R. T. Johannesson[1]

Sandvik AB, Coromant Research Center, S-126 12 Stockholm 42, Sweden

ABSTRACT

Aluminum oxide was deposited with a CVD technique onto polished TiC-coated and uncoated cemented carbide substrates. Experiments of short duration were performed with varying process parameters. The density of Al_2O_3 nuclei on the (Ti, W)C phase in cemented carbide and on the TiC coating was measured for each experiment. The corresponding chemical equilibria of the gas phase were calculated. The supersaturations of reactants ($p_{i,in}/p_{i,eq}$) were compared with the nuclei densities. It was found that the densities of nuclei vary with the supersaturation of the oxygen donors (CO_2 and H_2O). In these experiments there was a relative shortage of oxygen donors. The early stage of the Al_2O_3 deposition is supposed to influence the adhesion of the coating in two ways. First, voids that form in the cemented carbide substrate surface during heating up may cause pores, which decrease the strength of the interface. Second, too sparse a nucleation weakens the bond between the coating and the substrate. By using TiC-coated cemented carbide as the substrate it is possible to avoid the void formation and to obtain an evenly distributed nucleation.

For half a decade 5 μm CVD titanium carbide layers deposited on cemented carbide cutting tools have proved their efficiency in increasing the wear resistance, especially in turning operations (1-3). Titanium nitride, carbonitride, and similar compounds have also been used (4).

The improvements achieved by these thin layers seem to be caused mainly by the retardation of chemical processes contributing to the wear, especially dif-

[1] Present address: Linköping University, S-581 83 Linköping, Sweden.

Key words: chemical vapor deposition, titanium carbide, supersaturation, density of nuclei, whiskers.

fusion and oxidation. Thus in the case of uncoated tool tips the workpiece tends to react with the cemented carbide binder (cobalt alloy) at the high cutting temperatures of about 1000°C. Therefore the chemically resistant oxide layers, *e.g.*, aluminum oxide ought to be even more suitable for this application than carbides and nitrides.

The important question in the production of coatings is which of the parameters are the critical ones in the control of the nucleation process and of the growth process. The supersaturation is such an important factor for the growth morphology of whiskers as shown by Campbell (5). It may be regarded as a measure of the driving force of the nucleation process (6-7).

The nucleation in turn is important and often critical in determining the adhesion and the kind of subsequent growth of a desired layer. Therefore the influence of supersaturation on the nucleation process for aluminum oxide onto cemented carbide has been studied in our laboratory (8) and elsewhere (9). The nucleation on the multiphase cemented carbide substrate was found to be different on the different phases in the surface at given process conditions.

A possibility for avoiding this difficulty is to deposit an Al_2O_3 layer using an intermediate TiC coating. The purpose of the present work is to study empirically the interaction between supersaturation (different process conditions) and nucleation on TiC-coated cemented carbides compared with uncoated cemented carbide in the pilot plant scale.

Experimental

Equilibrium calculations.—Among the different conventional systems possible to use for depositing Al_2O_3 coatings, the $H_2O/AlCl_3$ system seems to be too reactive (9, 10), whereas the $O_2/AlCl_3$ system is very slow (10). Therefore the experiments were done in the system $CO_2/H_2/AlCl_3$.

The components of the following reactions were considered

$$CO_2 + H_2 \rightarrow H_2O + CO \quad [1]$$

$$2AlCl_3 \rightarrow Al_2Cl_6 \quad [2]$$

$$2AlCl_3 + 3H_2O \rightarrow Al_2O_3(s) + 6HCl \quad [3a]$$

$$Al_2Cl_6 + 3H_2O \rightarrow Al_2O_3(s) + 6HCl \quad [3b]$$

Due to the relatively moderate deposition temperatures used (<1350°K), some possible compounds might be regarded as present only in negligible amounts, *e.g.*, the lower aluminum chlorides (10) and oxides (11-12). Aluminum oxychlorides are formed only at relatively low temperatures (13).

The thermodynamic data for the equilibrium calculations were taken from Kubaschewski (14).

For the process conditions used the equilibrium according to reactions [1]-[3] was found to be considerably shifted to the right. From the input partial pressures $p_{i,in}$, and the equilibrium partial pressures $p_{i,eq}$ of each component i, a supersaturation Σ_i, was calculated according to equation

$$\Sigma_i = p_{i,in}/p_{i,eq} \quad [4]$$

Σ_{H_2O} is defined $p_{CO_2,in}/p_{H_2O,eq}$ due to reaction [1], which is supposed to be completely converted. $\Sigma_{Al_2Cl_6}$ is defined analogously with regard to Σ_{AlCl_3} and reaction [2].

The supersaturations of the components are given in Table I.

Experimental Procedure

In comparison with previous investigations (8) extra precautions were taken in order to minimize the moisture remaining in the apparatus.

The remaining experimental procedure was performed in accordance with the previous investigations (8).

The nucleation of Al_2O_3 on cemented carbide substrates and TiC-coated cemented carbide substrates was studied in a pilot plant CVD apparatus (Fig. 1-2). The volume of the reaction chamber was $0.015 m^3$ and it was heated by a resistance furnace. The temperature was measured with thermocouples placed in a sealed tube inserted into the reactor from above. The accuracy of the temperature measurements was ±8°K.

Twenty-five per cent of the gas came from an $AlCl_3$ generator. The $AlCl_3$ was formed by reacting HCl with small aluminum pieces (99.8% pure, main impurities Fe and Si). The $AlCl_3$ flow was analyzed before each experiment to guarantee a complete conversion of HCl. The $AlCl_3$ part of the flow was thoroughly mixed in extended pipes with the CO_2-containing flow (75%) before entering the reactor. The hydrogen was purified in a Pd-Ag diffusion cell. The purity of HCl and CO_2 was 99.98%. A Reynold's number of about 50 implies a laminar flow.

The substrates were cemented carbide inserts, Type SPUN 120308, of a ISO P30 grade containing 86% WC, 5.5% Co, and the balance cubic carbides TiC, TaC, and NbC (forming γ-phase). Some inserts were TiC coated. In order to make the Al_2O_3 nuclei visible the samples were polished on one side. They were placed on alsint supports in a tube of alsint.

A rather extended heating up period was needed due to the relatively large pilot plant deposition reactor.

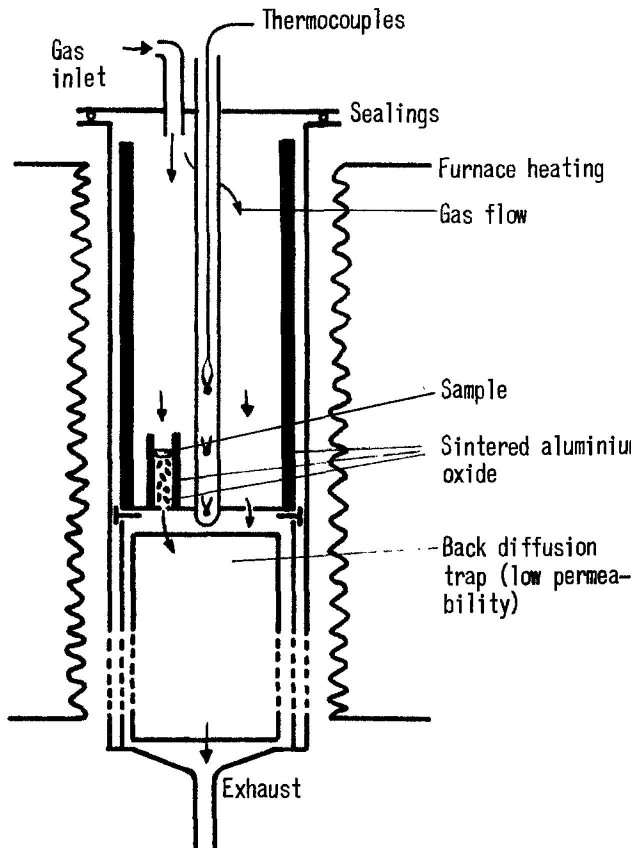

Fig. 1. Deposition chamber

Fig. 2. Gas supply and exhaust system

During this heating the $AlCl_3$ generator was started by feeding HCl + H_2 through it. This flow bypassed the deposition reactor. During the last minute before the deposition the desired flow rates of the gases were adjusted while being bypassed and the two gas flows were then simultaneously shunted over to the reaction chamber. The process was continued for 60 sec in most of the experiments and was then terminated by passing the remaining flow directly to the exhaust, followed by an evacuation of the reactor to about 0.05 kPa. After refilling the reactor with hydrogen the furnace was removed. The minimum time of deposition for consistency of the process conditions was about 20 sec. The process conditions are shown in Table I.

Blank runs (experiments 17-19) were carried out in order to make the distinction between Al_2O_3 and titanium oxide nuclei possible (Fig. 3 and 4).

In the central variant of each chain of process conditions ($AlCl_3$ and CO_2 partial pressures, temperature, and pressure) the ratio $p_{AlCl_3,in}/p_{CO_2,in}$ is stoichiometric.

The substrates were studied in the scanning electron microscope (SEM), where the density of nuclei on TiC and on the γ-phase (cubic carbides) of the cemented carbide surface was counted. The same techniques were used as in the previous investigation (8).

Results and Discussion

The transformation of the surface to be coated starts during heating up in H_2. On uncoated cemented carbide the binder (Co alloy) diffuses away leaving voids behind (Fig. 3). Probably the binder covers the carbide surface with a thin layer. The moisture that inevitably is present in the gas slightly attacks the cemented carbide surface and the TiC-coated surface, respectively, by oxidation. The WC phase is at least partially

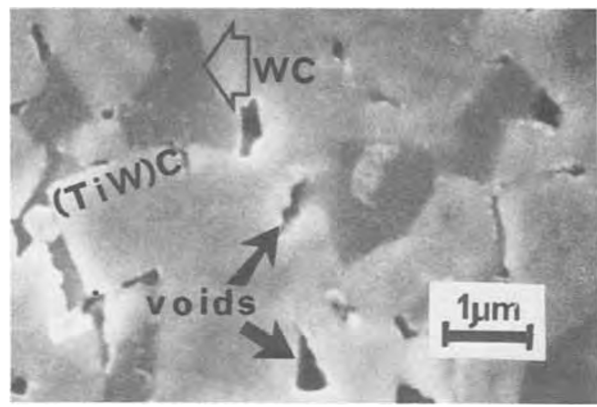

Fig. 3. Cemented carbide surface of run No. 18 in Table I (blank run, no Al_2O_3 nuclei). SEM image.

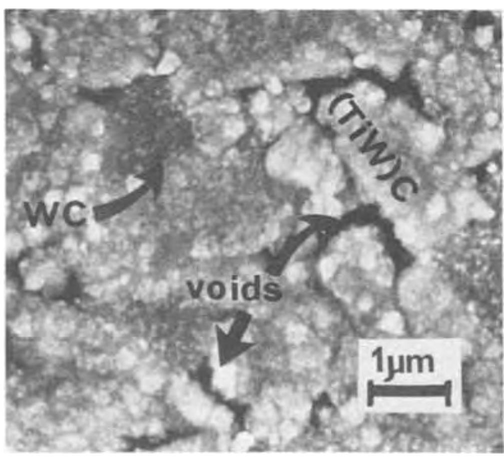

Fig. 4. Cemented carbide surface run No. 12 in Table I with Al_2O_3 nuclei.

converted to carbide of η-phase type (*e.g.* Co_6W_6C). However, in all experiments, where the gas contained $AlCl_3$, the attack was so mild that it was possible to count the Al_2O_3 nuclei both on the (Ti, W)C grains of the uncoated surfaces of the cemented carbide (Fig. 4) and on the polished surfaces of the TiC-coated inserts (Fig. 5). The densities of nuclei in the different experiments are given in Table I. We note that the nuclei density varies with temperature, $AlCl_3$ content, CO_2 content, and total pressure in a significant way. Of course the uncertainty in the measurement of nuclei density is too large to put significance to every single figure. However, the trends are quite clear for nucleation on TiC-coated substrates but less clear for the nucleation on uncoated cemented carbide substrates.

Let us distinguish between the supersaturation of (*a*) aluminum donors (the chlorides) and (*b*) oxygen donors (CO_2 and H_2O). If we let only the temperature vary, experiments 1-5, we note that all supersaturations increase, which is also true for the density of nuclei (Table I). If we let the input pressure of CO_2 decrease by altering the content of CO_2, experiment 9-11, we obtain an increase in the supersaturation of oxygen donors, while the supersaturation of the aluminum donors decreases. The density of nuclei follows the supersaturation of oxygen donors under these conditions. If we increase the content of $AlCl_3$, experiments 6-8, the conditions are somewhat more complicated. The supersaturations of the oxygen donors decrease while those of the aluminum donors increase. Possibly there is a certain decrease in the density of nuclei showing a weak relationship with the supersaturation of the oxygen donors. If we increase the total pressure keeping the percentage of reactants constant, experiments 12-14, the supersaturations of the aluminum donors remain relatively constant ($AlCl_3$ decreases and Al_2Cl_6 increases) while the supersaturation of the oxygen donors increases. The density of nuclei increases with the supersaturation of the oxygen donors.

In conclusion the density of nuclei on TiC-coated substrates seems to agree with the supersaturation of the oxygen donors Also the nucleation on cemented carbide, on the (Ti, W)C phase, shows the same trend (Table I) although as mentioned previously with less significance.

When concluding the comparison we should bear in mind, that the differences between the calculated supersaturations of the different gas compositions (experiments 6-11) are exaggerated compared to the ones encountered by the samples. The gas is partly converted before reaching the substrate surface.

These results seem to be in disagreement with those reported previously for nucleation on uncoated cemented carbide substrates (8). We discuss this below.

When comparing CVD experiments in the same chemical system, it is obvious that we must consider experiments with similar values of the process parameters. In our previous study of the nucleation of alumina on the (Ti, W)C phase in cemented carbide we used $AlCl_3/CO_2$ ratios around 0.33 and in the present study ratios around 0.67. Thus in the previous series of experiments the aluminum donors were in relative shortage and the density of nuclei was governed by the supersaturation of the aluminum chlorides while in this series of experiments the oxygen donors were in relative shortage. Furthermore the current experimental series was carried out under as moisture-free conditions as possible.

Hence, it seems natural to assume that the critical event in the nucleation of a CVD coating is the formation of stable "clusters" of some intermediate products of that reactant which is in shortage.

The two series of experiments agree in that the same temperature-nuclei density relationship was established.

From a production point of view TiC coating of the substrates prior to alumina coating has two aspects. First, the adhesion of the coating seems to be bad if the initial density of nuclei is too low due to incorrect supersaturation. Bad adhesion can also result from the deterioration of the substrate surface during heating up in hydrogen. Using TiC-coated substrates will improve adhesion by giving an even density of nuclei and by preventing substrate deterioration. Second, difficulties will arise in large production charges due to small amounts of cobalt being dissolved probably as chlorides from uncoated cemented carbide substrates. This will cause the coating to grow by a whiskerlike structure. Compare the structure of a coating obtained in a small charge (Fig. 6) to that obtained in a large charge (Fig. 7). In the latter case the reactant gas

contained dissolved cobalt chlorides. Again using TiC-coated substrates will reduce the tendency to whisker formation by protecting the cobalt from being attacked by the reactants.

Conclusions

The supersaturation of reaction components for Al_2O_3 layer formation is shown to have a pertinent influence on the nuclei density and thus subsequently on the adhesion of the layer.

The deposition of Al_2O_3 on TiC-coated cemented carbide is found to be advantageous. First, it isolates the cobalt and stops it from interfering with the alumina nucleation and growth and, second, it secures an even density of alumina nuclei.

Surface Oxidation of Silicon Nitride Films

S. I. Raider,*[1] R. Flitsch, J. A. Aboaf,* and W. A. Pliskin*

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

ESCA is used to characterize silicon nitride surface oxidation. Si 2p, N 1s, and O 1s binding energies and photoelectron line intensities of oxidized nitride films are compared with the corresponding lines from thick reference films of silicon, silicon nitride, silcon dioxide, and a series of oxynitrides. Rapid initial oxidation of silicon nitride surfaces occurs at room temperature on exposure of nitride films to air. A graded oxidized nitride film forms between the film surface and the nitride. Similarly, oxynitride films with gradations in composition are obtained upon oxidation of nitride films at high temperatures.

Silicon nitride thin films deposited on silicon or on silicon dioxide have received considerable attention for applications in semiconductor device structures because of their cited chemical stability and resistance to diffusion of impurities. However, an Si-N bond is chemically reactive and should oxidize when exposed to air. The free-energy changes (1) for silicon nitride oxidation in oxygen or water vapor, *i.e.*

$$Si_3N_4(s) + 3\,O_2(g) \rightarrow 3SiO_2(s) + 2N_2(g) \qquad [1]$$

$$\Delta F_{298^\circ K} = -304 \text{ kcal/mole}$$

and

$$Si_3N_4(s) + 6H_2O(g) \rightarrow 3SiO_2(s) + 4NH_3(g) \qquad [2]$$

$$\Delta F_{298^\circ K} = -147 \text{ kcal/mole}$$

indicate that nitride surface oxidation at room temperature is thermodynamically feasible. Silicon nitride films have been intentionally oxidized in oxygen or water at temperatures $\geqq$ 900°C (2). The kinetics of nitride surface oxidation indicate that the conversion process at these temperatures is slow. Little is known of nitride reactivity at lower temperatures. Sato *et al.* (3) have reported on chemical instabilities at a silicon nitride surface when films were exposed to high-pressure water or to water vapor in an autoclave at temperatures up to 300°C. From Auger spectra, Maguire and Augustus (4) have recently identified oxygen at a nitride surface, but have suggested that a high-temperature reaction with either oxygen or water vapor impurities in the carrier gas stream led to surface oxidation.

The presence of an oxidant impurity in a reactant gas stream during nitride-film deposition at elevated temperatures results in the formation of homogeneous oxynitride films. These films form a continuous series of compounds with changing oxygen and nitrogen content rather than a mixture of silicon dioxide and silicon nitride (5, 6). The oxygen content of oxynitrides can be related to the film index of refraction (n) (7), which ranges from about 2.0 for silicon nitride to 1.46 for silicon dioxide. The indices of refraction of oxynitride films, obtained from measurements of reflective interference minima at two angles of incidence at an energy of about 2 eV, have been found to vary linearly with the oxygen content of the film (7).

In this investigation, products of surface oxidation of nitride films formed at room temperature and at 1070°C are characterized using x-ray photoelectron spectroscopy (ESCA) (8). ESCA spectra of oxidized reaction products at nitride surfaces are compared with spectra of silicon dioxide, of silicon nitride, and of homogeneous oxynitride reference films.

Experimental

Film preparation.—Silicon nitride samples were prepared by chemical vapor deposition on cleaned silicon substrates at 800°C. The silicon wafers were induction-heated on a carbon susceptor coated with silicon carbide. A reaction mixture of silane (semiconductor grade) and ammonia (99.99% pure) in a ratio of 1:100 was carried by nitrogen gas into a quartz reaction chamber. Some silicon nitride films were prepared from silicon tetrabromide (9); some were prepared by reactively sputtering silicon with nitrogen gas (10). Oxynitride films were deposited at 1000°C by adding oxygen to the silicon nitride reaction mixture. Silicon dioxide films were prepared by oxidation of silicon in dry oxygen at 1000°C. The thickness and refractive index of each film on silicon substrates were measured with a Rudolph ellipsometer. Film thicknesses ranged from 400 to 2000Å.

The reactivity of silicon nitride films in air at temperatures of 25° ± 2°C and 30-50% relative humidity was examined by exposure to air in a clean hood for times up to one month. Nitride films were also oxidized in dry oxygen at 1070°C for times up to 7 hr. The oxide films which formed after oxidation at 1070°C were etched at 25°C with buffered HF (7 parts 40% NH_4F: 1 part 49% HF) diluted with 10 parts water. The etch rates for silicon dioxide and silicon nitride films are 2.2 and 0.075 Å/sec, respectively. Silicon oxynitride films etch at intermediate rates depending on the oxygen content of the film. In some cases, silicon nitride films were etched in a 10:1 diluted HF solution to remove surface oxide which might have formed in air.

ESCA.—Data were obtained with an AEI ES 100 electron spectrometer. Samples were mounted on a copper block fixed to the end of a rotatable probe and inserted into the spectrometer. A magnesium-targeted x-ray source (Mg $K\alpha_{12}$ radiation = 1253.6 eV) was used to analyze most of the samples, but an aluminum source (Al $K\alpha_{12}$ radiation = 1486.6 eV) was also used. The spectrometer was examined for linearity by measuring the photoelectron lines corresponding to the Cu $2p^{3/2}$ (932.8 eV) and the Au $4f^{7/2}$ (83.8 eV) levels (11) with Mg $K\alpha_{12}$ and Al $K\alpha_{12}$ x-ray radiation. Photoelectron lines obtained using these two x-ray sources should differ in energy by 233.0 eV. Appropriate adjustments were made to the spectrometer high-voltage supply to obtain this difference between the atomic levels for both Cu $2p^{3/2}$ and Au $4f^{7/2}$. After these adjustments had been made, the correction factor for the spectrometer was evaluated using the Au $4f^{7/2}$ line.

A broad energy scan of all samples was first obtained at 2 eV/sec. The strong photoelectron lines were then scanned over a 15V range at a rate of 0.02 eV/sec. All data were referenced to the Au $4f^{7/2}$ line to correct for surface charging effects. The O 1s, N 1s, C 1s, and Si 2p

lines were examined from each sample. The C 1s line is due to carbon contamination found on all samples.

Intensity data were obtained by integration of the photoelectron line areas. Intensity ratios of ESCA data are compared so as to eliminate errors resulting from surface contamination. The sample plane was generally tilted 10° from the normal to the electrostatic analyzer entrance slit to obtain maximum line intensities. Some intensity data were obtained as a function of sample inclination to the analyzer entrance slit to vary the emitted-electron sampling depth. A decrease in angle between a sample surface and the detector slit results in a decrease in sampling depth from which photoemitted electrons are collected (12).

Results

ESCA spectra of Si_3N_4.—A typical ESCA broad-energy scan of a 0.1 μm thick unetched silicon nitride film with a refractive index of 2.00 is shown in Fig. 1. In addition to nitrogen, silicon, and carbon photoelectron lines, an oxygen line is also observed. This sample was subsequently heated to 350°C in the spectrometer vacuum chamber. The C 1s line intensity was somewhat decreased by this heat-treatment, whereas the O 1s line intensity was not decreased. An oxygen line was also present on ESCA spectra of reactively sputtered silicon nitride films and on deposited films, independent of whether the reactant used to form silicon nitride was silicon tetrabromide or silane. The surfaces of all silicon nitride films examined appeared to be rich in oxygen.

Chemically etching the silicon nitride surface with diluted HF (1:10) reduces the O 1s photoelectron line intensity (Fig. 2a) when compared with the nonetched surface (Fig. 1). However, the O 1s line of an etched sample increases in intensity on exposure to air at room temperature. The increase in O 1s line intensity after 3 days and after 30 days is shown in Fig. 2b and c, respectively. The thickness of the surface film formed in air at room temperature, in terms of silicon dioxide film thickness, is estimated from ESCA line intensities (13) to be 2-3Å for a freshly etched film, 3-5Å after 3 days, and from 6 to 9Å after one month's exposure.

Comparison of Si 2p, N 1s, and O 1s binding energies, half-widths, and intensities.—ESCA spectra of silicon, of silicon dioxide, and of a series of oxynitride films were compared with data from etched and nonetched silicon nitride spectra. Shifts in Si 2p, N 1s, and O 1s binding energies for the various samples are illustrated in Fig. 3. As the oxygen content of the films increases, the binding energies increase. For example, the binding energies of the oxynitride films increase as their refractive indices approach the value of 1.46 for silicon dioxide. The magnitude of the binding energy changes for the photoelectron lines examined and decreases in the order Si 2p (4.4 eV) > N 1s (0.9 eV) > O 1s (0.4 eV). Compositional differences in the surface regions of these films are most readily identified from the Si 2p photoelectron spectra for which the largest changes in binding energies are observed.

The Si 2p binding energy for nonetched silicon nitride (n = 2.00) is less than that of etched silicon nitride (n = 1.99), but coincides with the Si 2p line for silicon oxynitride with a refractive index of 1.90. The Si 2p binding energy data clearly indicate that the oxygen that is present on nonetched nitride or that appears on etched nitride films (Fig. 1 and 2) is chemically bound to the silicon at the film surface. Changes in refractive indices obtained from ellipsometry are indicative of the composition of an entire film rather than only of a film surface.

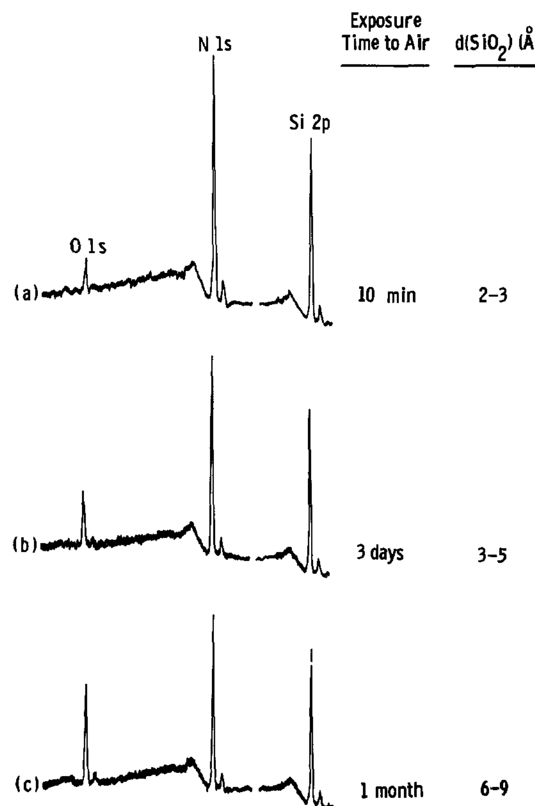

Fig. 2. Changes in O 1s photoelectron line intensity as a function of exposure time to air at room temperature after etching a silicon nitride surface with dilute (1:10) HF. Film thickness, $d(SiO_2)$, estimated from O 1s/Si 2p intensity ratio.

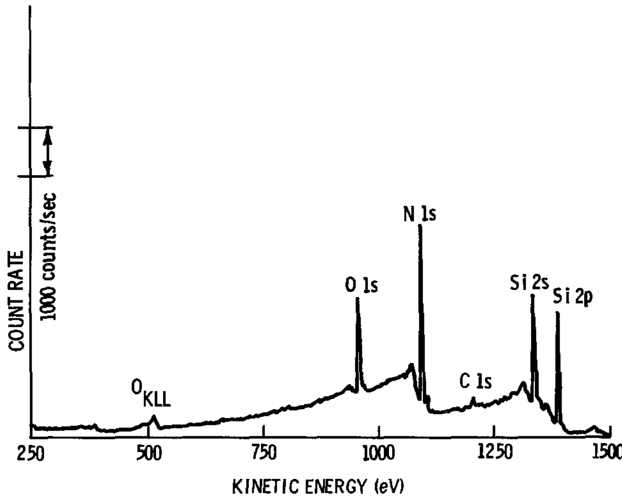

Fig. 1. Broad-energy ESCA spectrum of nonetched silicon nitride

	Sample	d(Å)	n
①	Si_3N_4	1010	2.00
②	Etched Si_3N_4	997	1.99
③	SiON	822	1.90
④	SiON	808	1.74
⑤	SiON	1173	1.67
⑥	SiON	860	1.61
⑦	SiO_2	1100	1.46
⑧	Si	—	—

Fig. 3. Comparison of Si 2p, N 1s, and O 1s binding energies as a function of oxygen content in different samples.

Differences are observed in the half-widths of the photoelectron lines. The largest variation in half-widths is observed for Si 2p lines

$$HW(\text{Si 2p}): \text{Si substrate (1.4 eV)} < SiO_2 = \text{etched } Si_3N_4 \text{ (1.8 eV)} \leq Si_3N_4 \text{ (1.9 eV)} < SiO_xN_y \text{ (2.1 eV)}$$

An increase in half-width can indicate that a greater distribution of species with different binding energies is contributing to an observed photoelectron line. A broader range of silicon compounds contributes to the oxynitride films than to the nitride, etched nitride, or dioxide, while the narrowest range of energies contributes to the silicon single crystal line.

The relative photoelectron line intensities are plotted in Fig. 4 for those compounds whose binding energies are shown in Fig. 3. On the basis of similar correlations (7), the film index of refraction is plotted as a linear function of photoelectron line intensity ratios over the continuous range of homogeneous compounds extending from silicon dioxide to silicon nitride. Refractive indices and relative photoelectron line intensities of silicon dioxide and of etched silicon nitride films are used as reference points for the lines drawn in Fig. 4. A comparison of etched and nonetched silicon nitride indicates that the oxygen line intensity is relatively high and the nitrogen line intensity low in the nonetched sample. The O 1s/Si 2p intensity data for oxynitride films are high with respect to the reference line, whereas the nitrogen intensity data fit the nitrogen reference line.

Variation in sampling depth for emitted photoelectrons.—Photoelectron line intensity ratios are plotted in Fig. 5 as a function of angle, θ, of sample inclination from perpendicularity to the detector slit (12). As the sample angle, θ, decreases with respect to the detector slit, the photoelectron line intensity from a carbon contamination surface film is increased while line intensities from the bulk film are decreased.

The O 1s/N 1s and O 1s/Si 2p intensity ratios for a nonetched silicon nitride film increase as the angle of inclination decreases. A greater increase in intensity ratio is observed for the O 1s/N 1s ratio. The N 1s/Si 2p intensity ratio decreases with decrease in angle θ. No change is observed in the binding energies of the photoelectron lines with variation in sample angle.

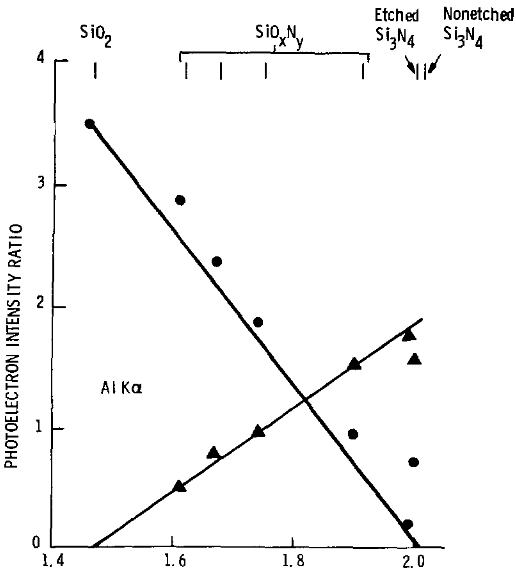

Fig. 4. O 1s/Si 2p (●) and N 1s/Si 2p (▲) photoelectron line intensity ratios as a function of sample refractive index.

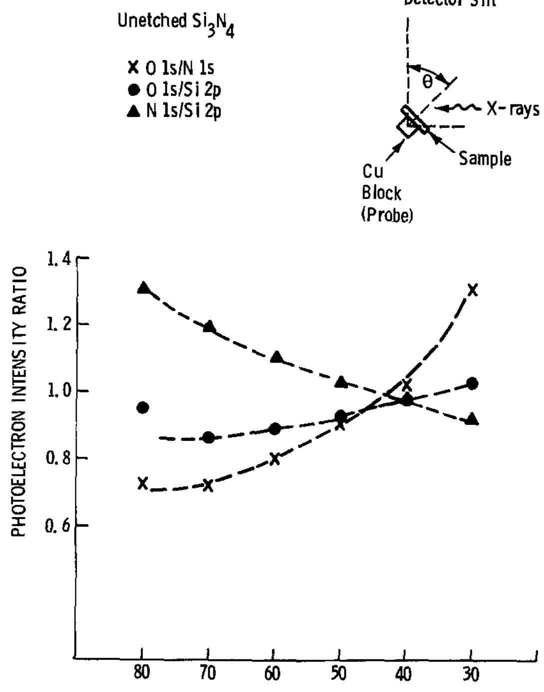

Fig. 5. Photoelectron line intensity ratios for a nonetched silicon nitride film as a function of variation of sample angle, θ, of inclination from perpendicularity to the detector slit.

However, the Si 2p line half-width increases about 20% with a 60° decrease in sample angle of inclination, whereas the O 1s line increases about 10%; no change in half-width is observed for the N 1s line.

Oxidation of silicon nitride at an elevated temperature.—Nitride films were oxidized in dry oxygen at 1070°C for times from ½ to 7 hr, and the films formed were characterized using ESCA. Binding-energy and line half-width data are given in Table I, and intensity ratios of observed photoelectron lines are plotted in Fig. 6. Single Si 2p lines are observed for each sample, although the line half-widths increase and pass through a maximum after 1 hr of oxidation. As the oxidation time is increased, the Si 2p binding energies of the oxidized samples approach the Si 2p binding energy of silicon dioxide. After oxidation for 7 hr, the binding energy and the line half-width are close to those of silicon dioxide. From etch-back data, the oxidized film is estimated to be 188Å thick after 4 hr of oxidation and 292Å thick after 7 hr. The large half-

widths of the Si 2p lines for samples oxidized for a half-hour and for 1 hr indicate that a distribution of components contributes to these lines. The oxygen-to-silicon intensity ratio is not equal to that of silicon dioxide until the nitride has been oxidized for ≥ 4 hr. A trace of nitrogen is still detected in the sample oxidized for 7 hr. More nitrogen and less oxygen are present in the samples oxidized for shorter times.

Discussion

ESCA.—ESCA binding energies of an element are related to the fractional atomic charge about an element and, therefore, to the electronegativities of neighboring atoms. Pauling electronegativities of the elements of interest increase in the order Si(1.8) < N(3.0) < O(3.5). The binding energy of a photoelectron line increases as the electronegativity of a neighboring atom increases.

The magnitude of the binding energy is a function of core electron promotion from a particular atom in a solid to the reference Fermi level of that solid. Any change in reference level in going from one material to another is assumed to modify the magnitudes of the respective Si 2p, N 1s, and O 1s binding energies equally.

The intensity of photoelectrons of a given energy from a homogeneous material is proportional to the density of the film attenuated by a factor $e^{-x/\Lambda}$, where x is the distance through the material that the photoelectron must travel and Λ is the mean escape depth of an electron and depends on the energy of the photoelectron and on the nature of the material. Photoelectron lines with kinetic energies of about 1 keV have mean escape depths of <30Å. Contributions to the intensity of a photoelectron line are therefore significantly affected by the composition of the film surface. Surface contamination, film inhomogeneities, or multilayer structures will alter the intensity of a single line. A decrease in the sample angle of inclination with respect to the electron detector slit effectively decreases the sampling depth from which electrons are collected. The signal from the film surface is therefore maximized relative to the bulk and spectral contributions from the surface, and the underlying substrate may be differentiated.

ESCA of reference films.—Silicon, silicon dioxide, etched silicon nitride, and oxynitride films were chosen as homogeneous reference materials to be characterized by ESCA from which the silicon nitride surface oxidation products could be identified. The Si 2p binding energies increase with increasing electronegativity of the neighboring atoms in changing from silicon (99.3 eV) to etched silicon nitride (101.4 eV) to silicon dioxide (103.7 eV). The increases in binding energy of silicon nitride and silicon dioxide with respect to silicon are about one-half the bandgaps of these dielectric films. Intermediate Si 2p binding energies located between those of etched silicon nitride and those of silicon dioxide are observed in each of the spectra of the oxynitride films.

The absence of distinct Si 2p lines at 99.3 and 103.7 eV indicates that $Si\text{-}(O)_4$ and $Si\text{-}(Si)_4$ tetrahedral groups, found in silicon dioxide and silicon, respectively, do not make a significant contribution to the nitride or oxynitride structures. From the Si 2p data, silazane (Si-N-Si) bridge structures found in silicon nitride are apparently changed by oxidation to siloxane (Si-O-Si) bridge structures and these structures are the predominant ones present in the oxynitride films. The ESCA Si 2p data indicate that SiO_xN_y is not a mixture of silicon dioxide and silicon nitride, but rather that siloxane and silazane groups are blended on a molecular scale. Chemical bonding near the surfaces of SiO_xN_y films, as determined from ESCA spectral data, is consistent with models of chemical bonding in bulk SiO_xN_y films deduced from optical properties of the films (14).

Smaller increases in N 1s and O 1s binding energies are observed as the oxygen content of the films is increased. These data are insufficient to uniquely identify corresponding changes in the films. It is likely that changes in composition from $N_3Si\text{-}N\text{-}SiN_3$ to $O_3Si\text{-}N\text{-}SiO_3$ and from $N_3Si\text{-}O\text{-}SiN_3$ to $O_3Si\text{-}O\text{-}SiO_3$ are the causes of a significant portion of the observed binding-energy shifts. Modifications of surface charging (15) resulting from the higher oxygen content of the films, or the formation of species such as Si-O-N-Si and Si-O-O-Si, may also contribute to the observed binding-energy changes.

A linear relationship was established between oxygen content and refractive indices of homogeneous oxynitride reference films (7). A similar linear relationship between photoelectron line intensity ratios of N 1s and O 1s relative to Si 2p and change in refractive index of homogeneous reference films is to be expected and is observed in Fig. 4. The O 1s/Si 2p ratios for the oxynitride films are somewhat high when compared with the O 1s/Si 2p reference and indicate that the films may be oxygen rich near the film surfaces. The N 1s/Si 2p data do not indicate that these films are nitrogen deficient. However, the N 1s/Si 2p reference line is determined from the intensity ratio for etched silicon nitride, which is already nitrogen deficient at the film surface because it is partially oxidized.

Silicon nitride surface oxidation.—Oxygen detected in the ESCA spectrum of unetched silicon nitride shown in Fig. 1 is a component of an oxidized surface film. Evidence that nitride surfaces are oxidized is provided by ESCA binding energy and intensity data. Silicon atoms at the unetched film surface are bound to oxygen atoms, which are more electronegative than nitrogen atoms and cause the Si 2p line maximum to be shifted to a higher binding energy. The surface oxide layer significantly shifts the binding energy of the Si 2p line, since the contributions to the line intensity are exponentially dependent on the depth from which the electrons are emitted. As a result, the silicon nitride film with an oxidized surface layer ($n = 1.99$) has a binding energy similar to that of an oxynitride film, with a refractive index of 1.90. Refractive indices are characteristic of bulk, rather than surface, properties. If the oxidized surface layer on the nitride surface were silicon dioxide, separate Si 2p lines at 101.4

and 103.7 eV would have been observed. The oxidized surface is likely to be a graded oxynitride layer, which is oxygen rich at the surface.

The O 1s and N 1s intensities, relative to the Si 2p intensity, also indicate that an unetched nitride film is oxygen rich and nitrogen deficient when compared with these components in an etched silicon nitride film. Nitride surface oxidation partially results in a replacement of nitrogen bound to silicon with oxygen bound to silicon. The intensity ratios for unetched silicon nitride are similar to the intensity ratios for an oxynitride film, with a refractive index of about 1.91 indicating good agreement between binding energy and intensity data.

The angular dependence of the intensity offers a means of differentiating surface and bulk species. A comparison of line intensity from the surface to the bulk film is significantly enhanced at small angles θ of emission (12). Variations in relative photoelectron intensity with sampling depth (Fig. 5) from spectra of nonetched silicon nitride give further indications of nonuniform nitride-film composition. An increase in O 1s/N 1s and O 1s/Si 2p intensity ratios with a decrease in angle is consistent with the formation of an oxidized surface film on silicon nitride. The larger increase in O 1s/N 1s intensity ratio with a decrease in angle is related to the increase in oxygen content and to the decrease in nitrogen content near the film surface. An oxidized silicon nitride surface deficient in nitrogen near the film surface also causes the N 1s/Si 2p intensity ratio to decrease with a decrease in sample angle.

Changes in the O 1s line intensity in spectra of etched silicon nitride upon exposure to air as a function of time (Fig. 2) indicate that the nitride surface, initially, is rapidly oxidized in air at room temperature. The oxidant at room temperature may be either oxygen or water vapor in the air. The oxidation rate is greater for water vapor than for oxygen at elevated temperatures, but little is known of their relative reactivity at room temperature.

The reactivity of nitride films with oxidants at room temperature has not been previously recognized although oxygen has been identified as an impurity in silicon nitride films. Bound oxygen, if present, is generally believed to be located at the nitride-silicon interface because of rapid surface oxidation of silicon. Nuclear microanalysis data obtained by Croset *et al.* (16), indicating the presence of oxygen in a nitride film on silicon, were interpreted in terms of oxide at the interface, but might also have been partly explained as due to rapid oxynitride formation at the nitride surface. Rapid surface oxidation of a nitride film is also consistent with the result of Maguire and Augustus (4), in which oxygen was identified at a silicon nitride surface by Auger spectroscopy.

High-temperature oxidation of silicon nitride.—An oxidized film is present at a silicon nitride surface after oxidation at 1070°C in dry oxygen. Binding-energy data indicate that silicon dioxide is not a major component of the oxidized film unless the nitrides are oxidized for more than 1 hr. The film formed after oxidation for one-half hour is mainly oxynitride on silicon nitride, with no evidence of the presence of significant silicon dioxide. N 1s photoelectrons are detected even in the film oxidized for 7 hr. The oxidized film surfaces are oxygen rich and resist etching in a nitride etchant (boiling phosphoric acid).

The thickness of an oxide film formed at elevated temperatures can be estimated in terms of silicon dioxide from etching and ESCA intensity data. A decrease in nitride film thickness after etching the oxidized film in buffered HF provides one basis for estimating oxide film thickness (Table I). The thickness of the oxidized film is also estimated from the N 1s/Si 2p intensity ratio of the oxidized surface layer. The intensity of N 1s photoelectron lines from an underlying layer is calculated by assuming that the oxidized film, *i.e.*, the oxide equivalent of the silicon nitride film removed by etching, is silicon dioxide (Table I). In Fig. 7, a normalized N 1s/Si 2p intensity ratio, R, is determined as a function of the silicon dioxide film thickness, $d(SiO_2)$, and of the mean escape depth, Λ(N 1s), for nitrogen photoelectrons attenuated by a silicon dioxide film, from the equation

$$R = \frac{I(\mathrm{N\,1s})}{I(\mathrm{Si\,2p})} \Big/ \frac{I(\mathrm{N\,1s})_{Si_3N_4}}{I(\mathrm{Si\,2p})_{Si_3N_4}}$$

$$= \frac{D^{N}{}_{Si_3N_4} e^{-d(SiO_2)/\Lambda(\mathrm{N\,1s})_{SiO_2}}}{D^{Si}{}_{SiO_2} + (D^{Si}{}_{Si_3N_4} - D^{Si}{}_{SiO_2})\, e^{-d(SiO_2)/\Lambda(\mathrm{Si\,2p})_{SiO_2}}}$$

where I = photoelectron intensity, $\Lambda(\mathrm{Si\,2p})_{SiO_2}$ = mean escape depth of Si 2p photoelectrons in silicon dioxide = 25Å, $D^{N}{}_{Si_3N_4}$ = concentration of nitrogen atoms per unit volume of silicon nitride = [(4 × atomic weight of nitrogen)/ (molecular weight of Si_3N_4)] × $\rho_{Si_3N_4}$, ρ_{SiO_2} = silicon dioxide density = 2.3 g/cm^3, and $\rho_{Si_3N_4}$ = silicon nitride density = 3.4 g/cm^3. The experimentally observed intensity ratio is normalized with respect to etched silicon nitride. Though Λ(N 1s) is not known, it is assumed to be between Λ(O 1s) and Λ(Si 2p) in silicon dioxide (20Å) (13, 17).

The experimentally obtained N 1s/Si 2p intensity ratios are not in agreement with calculated density ratios obtained by extrapolation of the experimental data to the Λ(N 1s) curve equal to 20Å (Fig. 7). The oxide-film thickness estimated from etching data is greater than the oxide film thickness estimated from ESCA data. This is to be expected for a graded oxynitride film. Etching in buffered HF removes silicon dioxide and oxynitride and overestimates the silicon dioxide film thickness. ESCA underestimates the oxide-film thickness by assuming that the oxidized film is silicon dioxide and that N 1s photoelectrons are emitted from an underlying silicon nitride layer. The intensity data are consistent with binding-energy data and indicate that the oxidized films are generally incompletely oxidized and contain nitrogen.

The N 1s/Si 2p and O 1s/Si 2p intensity ratio data for a nitride film oxidized at 1070°C do not correspond to a single homogeneous oxynitride film with a specific refractive index value (Table II). Refractive indices of oxynitride films formed at 1070°C were determined from Fig. 4 with intensity ratio data obtained for the oxidized films. The O 1s/Si 2p intensity ratios yield lower estimates of refractive indices than the N 1s/Si 2p intensity ratios. The oxidized films are apparently not homogeneous, but are graded, being oxygen rich near the surface and nitrogen rich as the oxygen-free nitride film is approached. In such a case, the refractive index determined from O 1s/Si 2p in-

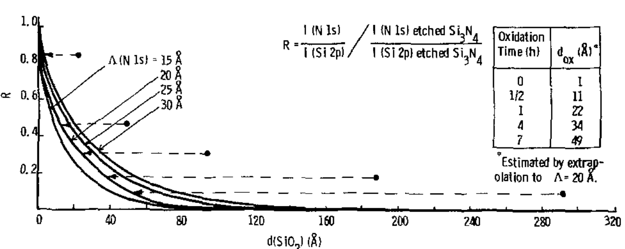

Fig. 7. Comparison between a calculated and an observed (normalized) N 1s/Si 2p photoelectron line intensity ratio for an oxide film of variable thickness on a thick silicon nitride film. It is assumed in calculating the intensity ratio that the oxide film, whose thickness is determined by etching and ellipsometry, is pure silicon dioxide. Silicon dioxide film thickness, $d(SiO_2)$, is estimated by extrapolation of the experimental N 1s/Si 2p intensity data (●) to the Λ(N 1s) curve = 20Å.

Table II. Comparison of I(N 1s)/I(Si 2p) and I(O 1s)/I(Si 2p) intensity ratios between silicon nitride films oxidized at 1070°C in dry oxygen and homogeneous oxynitride films

Oxidation time (hr)	I(N 1s) / I(Si 2p)	Homogeneous oxynitride refractive index (n) (from Fig. 4)	I(O 1s) / I(Si 2p)	Homogeneous oxynitride refractive index (n) (from Fig. 4)
0.5	0.85	1.70	2.62	1.59-1.62
1	0.58	1.62	2.92	1.55-1.57
4	0.34	1.56	3.5	1.46
7	0.19	1.51	3.5	1.46

tensity ratio data overestimates the amount of oxygen present, whereas N 1s/Si 2p intensity ratio data underestimate the amount of nitrogen present.

Conclusions

An ESCA study of reaction products of silicon nitride oxidation and of homogeneous oxynitride films indicates that oxidation of a silicon nitride surface occurs rapidly at room temperature in air. The oxidation product of room-temperature oxidation is an oxynitride film. A graded oxynitride film, which is oxygen rich at the surface, is formed after oxidation of silicon nitride at 1070°C in oxygen. The ESCA data also indicate that the homogeneous oxynitride reference films are composed of a range of species blended on a molecular scale and are not mixtures of silicon dioxide and silicon nitride.

Elimination of Process-Induced Stacking Faults by Preoxidation Gettering of Si Wafers

II. Si_3N_4 Process

P. M. Petroff,* G. A. Rozgonyi,* and T. T. Sheng

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A simple and novel process which prevents the formation of oxidation-induced stacking faults (SF) during the fabrication of Si devices is described. The process involves the deposition of a Si_3N_4 film on the back of the wafer followed by a preoxidation annealing. This procedure eliminates the nucleation centers and impurities, which occur during the oxide growth, involved in the formation of SF. The Si_3N_4 process has also been found to effectively reduce the wafer contamination by impurities such as Cu and Au. Application of this preoxidation gettering process to device processing is shown to be effective in drastically reducing leakages in p-n junctions and in eliminating the nucleation centers associated with the SF tetrahedron often found in the fabrication of Si bipolar devices.

There is now a large body of literature (1-5) dealing with crystallographic defects in silicon and their role on device performance. One type of electrically active structural defect which is often found in Si device structures is the oxidation-induced stacking fault (hereafter designated as SF). Studies on these defects, which form during a high temperature oxidation treatment of the Si wafer, have produced the following results:

(*a*) Oxidation-induced SF produce leakages in p-n junction devices (2-6).

Key words: silicon defects, transmission electron microscopy, gettering, silicon device processing.

(b) Oxidation-induced SF may be nucleated at centers which are introduced during the crystal growth (4, 5, 9) or at centers introduced by the processing operations preceding or concurrent to the oxide growth (7, 11, 13). In the case of process-induced SF nucleation centers, small precipitates which form at or near the SiO_2-Si interface have been identified (7, 8, 10). In the case of SF nucleation centers introduced during the crystal growth, the oxidation-induced SF distribution usually follows a swirl distribution for float-zone silicon (5, 11) or a coring distribution (11) for Czochralski silicon. The swirl distribution of stacking faults suggests that the precipitates and dislocation loops observed (14) in the swirl pattern of dislocation-free float-zone silicon act as nucleation centers to the SF introduced during oxidation.

(c) The oxidation-induced SF have an extrinsic nature and grow by a climb mechanism from an interfacial Frank dislocation presumably emitted by precipitates (7, 8).

(d) In some instances impurities have been found to play an important role in promoting the formation of SF (7, 11). A wafer surface orientation dependence on the appearance of SF has also been reported (12, 13). In the case of HF-treated, wet oxidized Si wafer, it has been found that {111} surfaces (13) or surfaces with orientation 3° to 10° "off" {100} (11) do not show stacking faults after oxidation.

This apparent wealth of experimental results has not yet produced an oxide formation process which could prevent the SF formation during the fabrication of Si devices and it would appear that a number of important questions still need to be answered before their formation mechanism is understood and a solution for their elimination could be proposed. Among these unanswered questions are: (a) the nature of the precipitates which act as nuclei to the SF formation, (b) the nature of the impurities and point defects involved in the precipitate formation and the growth of SF, and (c) the nature of the extrinsic fault. The SF could be composed of an oxygen-rich plane (15), as some recent data seem to indicate, or of an extra plane of Si atoms.

Since the answers to these questions require complex analytical techniques in many cases not yet available, an empirical solution to the SF problem has been sought after by using gettering methods. The leading idea behind these gettering experiments was that such methods could eliminate the impurity nucleation centers and affect the growth mechanism of the SF. These gettering methods which are applied to the Si wafer prior (16, 17) to or during the oxidation treatment have proven effective in eliminating oxidation-induced SF. The present work describes in detail a simple and novel processing scheme which relies on the gettering action of a Si_3N_4 film deposited on one side of the Si wafer to suppress the formation of SF on the device side of the wafer. The possible mechanisms for the SF suppression are discussed. Examples of the effectiveness of this technique which is compatible with most device processing operations are given for the case of p-n junctions and for the case of Si epitaxial films on {111} Si substrates.

Experimental

Si_3N_4 films have been deposited by low temperature (300°C) rf sputtering or by chemical vapor deposition (at 800°C) on the back side of Si wafers; the front side of the wafers were Syton polished and were used to study the SF. The wafer orientation was {100} or {111} and both Czochralski and float-zone, dislocation-free, n-type silicon were used in these experiments. The wafer thicknesses ranged from 275 to 425 μm and the Si_3N_4 film thicknesses deposited were typically 4000Å for the sputtered and the CVD Si_3N_4 films.

The defect distribution in the wafers after these processing treatments was revealed by etching in a Secco etch solution (18) for 10 min. Examination of the etch features was carried out by optical microscopy with a Zeiss ultraphot microscope using Nomarski interference contrast optics. In some instances the defect nature and distribution were obtained by transmission electron microscopy (TEM) and x-ray topography (XRT).

Preoxidation gettering of defects.—To evaluate the gettering process on the same wafer only one-half of each wafer was covered with the Si_3N_4 film. A half-silicon wafer was used as a mask to limit the Si_3N_4 coverage to one-half of the back of the wafer. After Si_3N_4 deposition and standard cleaning the wafers were annealed in N_2 + 1% O_2 or in Ar atmosphere; the annealing temperatures were varied from 1000° to 1200°C and annealing times ranged from 1 to 4 hr.

Gettering of oxidation-induced defects.—Some of the wafers which were preannealed as described above were cleaned and steam oxidized to grow 4000Å of SiO_2 at 1050°C for 35 min. The Si_3N_4 layer was left on the back of the wafers during the oxide deposition; for some pregettered wafers the Si_3N_4 layer was removed prior to the oxide growth. After a Secco etching treatment of 10 min the defect nature and distribution in these wafers were then inspected by optical microscopy, XRT, and TEM.

Chemical impurity analysis.—The chemical impurities in the starting material and in the wafers subsequent to the Si_3N_4 deposition, annealing and oxidation steps were measured by neutron activation analysis. In addition, several impurity profile distributions through the wafer thickness were obtained after repeated thinning of the gettered wafers. The wafers were thinned by mechanical lapping; a careful rinse in a jet of nonpreferential Si etch solution followed the lapping operation to completely remove small particulates left on the sample by the lapping operation. A final rinse in DI water preceded the neutron activation analysis. The relative amount of material removed during the thinning operation was obtained from weight measurements of the samples with a microbalance.

Device applications of the pregettering Si_3N_4 process.—The effectiveness of the pregettering method in producing lower p-n junction leakage and higher device yields was tested on two types of structures. First, leakage currents in p-n junction devices which were part of a typical integrated circuit test pattern were measured on wafers which had been pregettered with the Si_3N_4 process prior to the first oxidation. These leakage measurements were compared to the leakages of the same devices in monitor wafers which were not pregettered. Both pregettered and ungettered wafers were processed simultaneously. Twelve wafers, each containing 100 devices, were measured for leakage at 28V on devices with a 35V breakdown voltage with an automatic prober. A more detailed description on the application of the Si_3N_4 gettering process to device processing is given in Ref. (20).

Results

In the remainder of this paper, the elimination of defects is referred to as "gettering" of defects by analogy to the well-known gettering of impurities.

Preoxidation gettering of defects.—The difference in the defect structures between the gettered and ungettered parts of an unoxidized Si wafer are shown in the photomacrograph in Fig. 1A and in the optical micrograph in Fig. 1B. These micrographs show the front side of a wafer which was gettered on only one-half of the wafer back side. The etch features associated with defects in the silicon are clearly visible only on the ungettered part of the wafer in Fig. 1B. In the higher magnification micrographs in Fig. 2B-D these etch features appear as saucer pits with a density between 1-4 × $10^6/cm^2$ in the ungettered part of the wafer while the front surface of the gettered half of the wafer the pit density is from zero to 10 cm^2. The

D, Surface of the ungettered half of the wafer front side.

CVD Si_3N_4 and the sputtered Si_3N_4 gave identical results for a 1 hr anneal at 1050°C.

Elimination of oxidation-induced stacking faults.— The wafers, which were subjected to a preoxidation gettering as described above, exhibited, after a steam oxidation ($\simeq$3000Å of SiO_2) process, a distinctly lower defect concentration from that in ungettered wafers. Figure 3A and B illustrate for a pregettered and steam-oxidized wafer the absence of etch features characteristic of stacking faults on the side of the wafer opposite to the Si_3N_4 film. Higher magnification micrographs of the front side of an oxidized wafer which was pregettered are seen in Fig. 4A and B. The etch features seen in the ungettered part of this wafer (Fig. 4B) have indeed been correlated with the different etching stages of SF as shown in the transmission electron micrographs in Fig. 5. The x-ray topograph shown in Fig. 6 illustrates the effectiveness of the pregettering process in preventing the SF formation. If a wafer

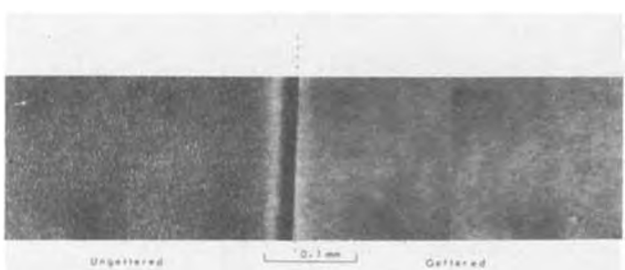

Fig. 6. Transmission x-ray topograph of a wafer after preoxidation gettering and oxidation (wet oxide deposited at 1050°C for 2 hr). The right part of the micrograph which corresponds to the half of the wafer coated with Si_3N_4 on the back is essentially free of defects. The left part of the micrograph corresponds to that half of the wafer not coated with the Si_3N_4; a high density of SF associated with black-white spots is observed in this half of the wafer.

was pregettered as indicated above the suppression of the SF was equally effective when the Si_3N_4 layer was removed prior to the oxide growth.

Metallic impurity gettering.—A number of authors have reported (10, 11, 13) on the importance of metallic impurities in promoting the SF formation during steam oxidation. Since the Si_3N_4 preoxidation gettering process was proved to be effective in suppressing the SF formation, its possible role as a metallic impurity gettering process was also checked by neutron activation analysis. The results of neutron activation analysis on 14 wafers taken at various stages of the processing are summarized in Table I along with the chemical analysis of control wafers. These analyses

indicated that two sources of metallic impurities, namely, Cu and Au, were introduced during the wafer processing. A comparison of the Au and Cu concentrations in samples 1,2 and 3,4 indicated that the Si_3N_4 deposited by rf sputtering was contaminated with Au and Cu. The origin of these metallic elements was traced to the lining of the anode in the sputtering system used for the Si_3N_4 deposition. Both Au and Cu are very fast diffusing elements (19) in Si at temperatures higher than 1000°C and the sputtered Si_3N_4 is then expected to behave as a Cu and Au source during the preoxidation gettering. The second source of contamination is introduced by annealing in the ovens as shown by comparing the Au and Cu concentrations in samples 1,2,5 and 6,7 and 8. Both these contamination sources increase the Cu and Au content in the wafers by roughly an order of magnitude. After the preoxidation gettering, the measurements on samples 9,11,12 and 10,13,14 indicated that the Si_3N_4 retained and trapped the Cu and Au atoms and in effect acted as a gettering medium for both these elements. The concentration of Cu in the preoxidation gettered wafers was essentially that found in clean uncontaminated wafers (compare the measurements on samples 1,2 and 9,13 and 14). The gettering action of the Si_3N_4 layer was also evident in the Cu and Au concentration profiles shown in Fig. 7 and 8. The precision in the Cu concentration measurements was not as good as for Au as indicated by the error bars and was essentially limited by the short lifetime of the Cu radioisotope. These figures also showed that the trapping action of the Si_3N_4 film was less pronounced for Au than for Cu.

Applications of the Si_3N_4 preoxidation gettering process to device processing.—Application of the Si_3N_4 gettering process to the fabrication of devices revealed that the effectiveness of this process on (100) wafers depends, in part, on the origin of the stacking faults. Recent work by Rozgonyi and Kushner (20) describes two classes of oxidation-induced SF: surface- or contamination-induced SF, and bulk or native defect nucleated SF. The electrical properties and device yields have been studied in detail for both preoxidation gettered and ungettered wafers (20). The results reported by Rozgonyi and Kushner (20) indicate that for (100) or (111) wafers which would normally form surface SF, the Si_3N_4 gettering will produce p-n junctions completely free of SF with correspondingly lower leakage currents and increased device yields. However, the Si_3N_4 preoxidation gettering procedure is not as effective for eliminating

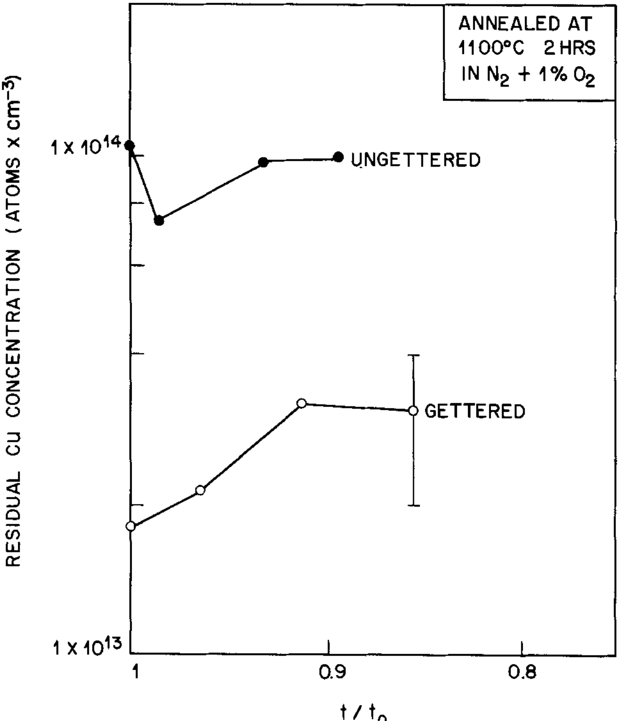

Fig. 7. Distribution of the residual Cu concentration as a function of the relative wafer thickness t/t_0; t_0 and t correspond respectively to the wafer thickness prior to and after successive polishing of the back side of the wafer. The concentration of profiles are shown after a preoxidation gettering for the gettered half and the ungettered half of the same wafer.

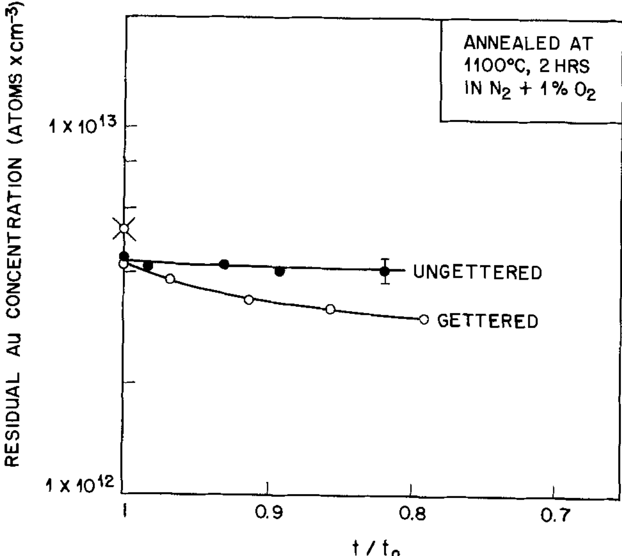

Fig. 8. Distribution of the residual Au concentration as a function of the relative wafer thickness t/t_0; t_0 and t correspond respectively to the wafer thickness prior to and after successive polishing of the back side of the wafer. The concentration profiles are shown after a preoxidation gettering for the gettered half and ungettered half of the same wafer.

the formation of bulk SF as opposed to the surface SF. In this case a more severe preoxidation gettering, *e.g.*, introduction of misfit dislocations (16, 20) on the back of the wafers must be used to improve the device yields.

Discussion

As pointed out at the beginning of this paper, the understanding of the SF formation process during steam oxidation is still very poor. However, the previous studies (11, 16, 17) on this problem have shown that both the crystal growth and the wafer processing introduce the nucleation centers (C), the point defects (N), and impurities (I) needed to the SF formation. The experiments described in this paper confirmed that the successful suppression of the SF formation may be achieved by trapping or elimination of either C, N, or I. Indeed, the chemical impurities analysis of gettered wafers indicated that the Si_3N_4 film was actively trapping metallic impurities such as Au and Cu. In addition the results on preoxidation gettered wafers from which the Si_3N_4 layer was removed prior to the oxide deposition, suggest that the elimination of nucleation centers is also a major mechanism in the elimination of SF.

The gettering mechanism which effectively eliminates the nucleation centers or the impurities or the point defects is now discussed. First, the effects of the internal stresses of the Si_3N_4 film should be considered as a possible source of driving forces in the gettering mechanism. The stress measurements in CVD Si_3N_4 (21) indicate that in the temperature range 25°C $\leq T \leq$ 1000°C the stresses are tensile and range between 1 and 3 $\times$ 10^{10} dynes/cm^2. No stress measurements in the sputtered Si_3N_4 films are available at high temperature; however, room temperature stress measurements (22) in these films showed compressive stresses in the range 5 $\times$ 10^9 to 1 $\times$ 10^{10} dynes/cm^2. It is surprising that the gettering is equally effective in wafers strained in tension or compression at room temperature since the strain gradient $\partial\epsilon/\partial z$ through the wafer thickness is expected to control the gettering kinetics. If we assume that a point defect concentration gradient $\partial c/\partial z$, is rapidly established (*i.e.*, nonequilibrium condition), the total flux of defects leaving the sample is given by

$$J = c \frac{\partial G}{\partial \epsilon} \frac{D}{kT} \frac{\partial \epsilon}{\partial z} - D \frac{\partial c}{\partial z} \quad [1]$$

where D and c are respectively the defect diffusion coefficient and concentration; $\partial G/\partial\epsilon$ is the change in the defect-free energy along the z direction orthogonal to the wafer surfaces. When the stress is changed from tensile to compressive, the sign of $\partial\epsilon/\partial z$ is reversed and different solutions are expected for Eq. [1]. The influence of the strain gradient sign on $\partial G/\partial\epsilon$ is negligible with the result that impurities or point defects should be gettered on opposite sides of the wafers when the strain gradient is reversed. To account for the effectiveness of the gettering for both the tensile and compressive Si_3N_4 films, one is led to the conclusion that the stress in the compressive films becomes tensile at high temperatures ($T >$ 1000°C). Recent stress measurements at high temperatures (24) indeed suggest that this is the case for plasma-deposited Si_3N_4 films which are compressively strained at room temperature.

Simultaneously to the strain enhanced elimination of point defects and nucleation centers, a gettering due to the nonstoichiometry of the Si_3N_4 may also occur. Recent density and composition measurements (23) of sputtered Si_3N_4 indicate that the deposited films are not stoichiometric and that in general they are deficient in Si. At high temperatures the diffusion of Si atoms across the Si-Si_3N_4 interface could take place to form one or several layers of the stoichiometric Si_3N_4 films at the interface. The resulting gradient in the point defect concentration in the Si wafers may then provide the additional driving force for the point defect elimination.

Conclusions

We have shown that a novel process which involves the deposition of a Si_3N_4 film on the back of Si wafers followed by a preoxidation annealing effectively eliminates the formation of contamination-induced stacking faults on the device side of the wafers. The gettering of the Si_3N_4 layer has been found to effectively

reduce the contamination of the wafers by impurities such as Cu and Au. The defect gettering action of the Si_3N_4 film is probably related to the stress induced in the Si wafers by the Si_3N_4 film. Application of this preoxidation gettering process to actual device processing was proved to be effective in drastically reducing leakages in p-n junctions and in eliminating the nucleation centers which are associated with the formation of contamination-induced stacking faults.

Acknowledgments

The authors wish to thank S. P. Murarka and V. Kumar for their valuable help with the neutron activation analytical part of this work. R. Kushner, D. Boulin, B. Deysher, and C. Pearce are also thanked for having applied this gettering process to the fabrication of Si devices.

The Elimination of Stacking Faults by Preoxidation Gettering of Silicon Wafers

III. Defect Etch Pit Correlation with p-n Junction Leakage

G. A. Rozgonyi* and R. A. Kushner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Recently described procedures for the elimination of oxidation-induced stacking faults have been incorporated into a device processing line to yield data on the leakage in p-n junction tester diodes. The gettering processes, which take place on the back side of a wafer before the first oxidation, include the deliberate introduction of misfit dislocations and/or the deposition of a highly strained layer of Si_3N_4. The results show that leakage currents can be reduced by several orders of magnitude and diode yields[1] increased from about 10% to greater than 90%. By doing "post mortem" chemical etch pit studies on previously electrically mapped 10×10 arrays of diodes the relative effectiveness of the two gettering schemes are compared. Factors such as the type of stacking fault, whether it be related to a native or process-induced source, or whether it is clean or decorated are discussed as well as the influence of slip-type dislocations.

It has recently been shown (1, 2) that a preoxidation gettering of the other side, *i.e.,* the back of silicon wafers (hereafter called the POGO approach) will result in a front side that is free of stacking faults. The basic idea is that removal or isolation of stacking fault nuclei before the initial oxidation will prevent stacking faults from forming during the actual oxidation step itself. The POGO approach is to be distinguished from those gettering treatments (3, 4) which effect a deactivation or annihilation of previously formed stacking faults. That is, the gettering process is aimed at removing stacking fault nucleation sites and not stacking faults. In addition, by maintaining the gettering source on the back side, it is possible to protect the wafer from process-induced nuclei which may be

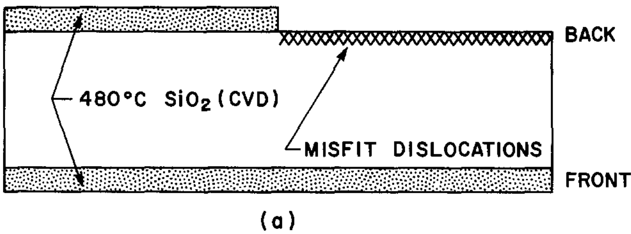
[1] Per cent of diodes with junction leakage less than 100 nA cm^{-2} at 28V.

Key words: silicon defects, defect gettering, device leakage.



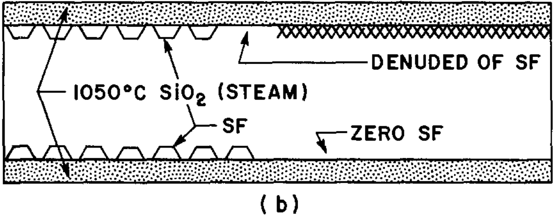


Fig. 1. Schematic of preoxidation gettering sequence for POGO I process. (a) Misfit dislocations on half of back side of wafer masked with a low temperature oxide. (b) Stacking faults nucleated after steam oxidation are confined to nongettered half of wafer.

introduced, not only during the initial oxidation, but also at later stages of device fabrication. In this regard the process differs from preoxidation gettering by high temperature annealing (5), which only operates on native defects.

Two gettering schemes have been successfully used on as-received, Syton polished, silicon wafers. One depends on the gettering action of misfit dislocations (1) which are deliberately introduced by diffusion of phosphorus into the back side of a wafer. The second procedure is to deposit a layer of Si_3N_4, also on the back surface, where it is believed that the strain gradients (2) introduced in the substrate by the highly stressed nitride layer will getter stacking fault nuclei. Although the precise nature of the defect interactions, gettered species, stacking fault nuclei, etc., are not fully understood, the two procedures themselves were found effective enough to warrant limited introduction into a device processing line.

The initial defect studies indicated that misfit dislocations (1) were effective in gettering stacking fault nuclei whose origins were either process-induced (contamination) or growth-induced (native defects). The Si_3N_4 process (2), which is basically an elastic effect and introduces much less lattice distortion than misfit dislocations, was found to be mainly effective in suppressing process-induced nuclei. However, native defects such as the so-called "swirl" of A and B complexes (6, 7) were not eliminated or deactivated by a Si_3N_4 POGO treatment. The differences between stacking faults that result primarily from processing and those related to a bulk source are discussed in this report. However, the main objective of the present paper is to correlate the presence or absence of stacking faults with the leakage in individual p-n junction diodes and thereby evaluate the effectiveness of these POGO processes in an actual device. In addition to the oxidation-induced stacking faults, the electrical effects of process-induced dislocations were also studied.

Experimental Procedures

The wafers used in this study were grown by the Czochralski technique and supplied by Western Electric. The wafers were (100) oriented with the back side chemically etched and the front side Syton polished. They were 2 in. diameter, 400 μm thick, p-type, with a nominal resistivity of 6-12 ohm-cm.

The as-received wafers were divided into groups, depending on the initial treatment they were to receive. One group received no preoxidation gettering treatment and served as a control. Prior to any POGO treatment the remaining wafers all had 1 μm of chemical vapor deposited (CVD) silicon dioxide deposited on the front side at 480°C in a Silox reactor. This was done in order to confine diffusion-induced dislocations to the back side of the wafers. Some wafers, for which gettering of only half the wafer was desired, also received a deposited oxide on the back side. Standard photolithographic procedures were used on these wafers to strip the oxide from half the back. At this point the wafers were further divided into two groups. One POGO group had 2000Å of CVD silicon nitride deposited on the back side in a Nitrox reactor at 800°C to generate a strain gradient. This was followed by 4000Å of CVD silicon dioxide. The silicon dioxide was deposited to protect the nitride from reaction during subsequent device processing and was retained at each photolithographic step. The second POGO group received a phosphorus diffusion from a $POCl_3$ source for 60 min at 1100°C which served to generate misfit dislocations as shown schematically in Fig. 1a. This group also received back side layers of CVD silicon nitride and silicon dioxide which provided a cap over the heavy phosphorus layer and prevented transfer of this dopant to the front sides of other wafers during subsequent processing. The deposited masking oxide was then removed from the front side of all the wafers and the control group was added. Table I summarizes the two gettered structures which will be referred to as the POGO I and POGO II processes, while the etch pit and leakage results on various wafers are listed in Table II.

In order to monitor the effectiveness of the POGO treatment some wafers from the POGO I group were removed prior to the CVD Si_3N_4 cap and given an oxidation in steam at 1050°C to grow 4000Å of oxide. Examination usually revealed stacking faults on the ungettered halves of the wafers, as shown schematically in Fig. 1b. A denuded region, N, was observed at the boundary of the gettered and ungettered portions of the wafer back side which was at least as wide as the wafer thickness, as described previously (1).

The device fabrication sequence followed was the same as that used to fabricate memory devices in the Murray Hill MOS laboratory. The order of operations was retained and all thermal cycles were included. A mask set was utilized which generated a 10 $\times$ 10 array of test chips, each of which had, among other features, a large area diode (4.8 $\times$ 10^{-4} cm^2) and a substrate contact. The diode was formed by PBr_3 predeposition at 1000°C and subsequent diffusion during steam reoxidation to give a diode with a resistance of 15 ohm/□

Table I. Preoxidation gettering summary

Label	Primary gettering component	Gettering procedure	Additional steps*	Stacking faults Gettered
POGO I	Misfit dislocations	Phosphorus diffusion at $T \geqq 1100°C$	Encapsulate n-skin with Si_3N_4	Bulk and surface
POGO II	Strain gradient	Si_3N_4 layer with $\sigma > 1 \times 10^{10}$ d-cm^{-2}	Anneal Si_3N_4 layer at 1000°C for 60 min	Surface

* The gettering medium is retained throughout all subsequent device processing.

and a junction depth of 2.5 μm. The substrate contact step followed the junction formation step and was generated by a 1050°C BN predeposition (sheet resistance = 20 ohm/□) and a steam reoxidation. The processing included a boron chanstop implant to raise the surface acceptor concentration in order to pin the breakdown voltage of the n^+-p junctions at about 35V. The chanstop implant was done early in the processing and any implant damage was annealed during the subsequent 1200°C drive-in. The particular device whose junction leakage required improvement has the specification that the leakage current be less than 100 nA-cm^2 at 28V reverse bias. This is a rather severe restriction in light of the 35V breakdown voltage. The 10 $\times$ 10 array was mapped for junction leakage using an automatic prober. The metal and underlying oxides were then removed prior to the preferential etch pit procedure. In this way it was possible to correlate the measured electrical characteristics of the p-n junctions with the observed defect characteristics.

Defects were delineated using the Secco etch (8) and studied using Nomarski interference contrast microscopy. Two kinds of structural defects are discussed in this report, stacking faults and dislocations. The oxidation-induced stacking faults have been further divided into two groups which are designated as bulk or surface. The bulk stacking faults are most easily identified by their occurrence in a striated or "swirled" pattern, as shown in Fig. 2a, which can readily be traced to the nonuniform distribution of native defects, *i.e.*, stacking fault nuclei, incorporated in certain material during crystal growth (6, 9). Surface stacking faults, on the other hand, will often have a spotty and essentially random distribution, see Fig. 2b. These defects are generally related to contamination of the wafer or of the oxidation furnace, or to process-induced surface damage, and can be distinguished from the bulk stacking faults by the nature of the etch pits, as shown in Fig. 3. Note that a wafer with bulk stacking faults will have pits of varying size, as shown by arrows SF_B in Fig. 3a. Also, new pits will appear as the sample is step-etched. However, surface stacking faults are all the same size, see arrows SF_S in Fig. 3b, and do not change their density if the sample is step-etched to obtain a depth profile.

A dislocation-free wafer which undergoes slip due to thermal asymmetries produced during high temperature processing will typically have a defect distribution as shown in Fig. 2c where the dislocation density is highest in the four corners, near the flat, and in the central core region. Etch pits of slip dislocations are shown in Fig. 3 by the arrows D.

Experimental Results

Macrophotographs of three device wafers which have been given a "post-mortem" preferential etch after electrical mapping and stripping down to the substrate are shown in Fig. 4. The wafer in Fig. 4a was not gettered prior to oxidation, while those in Fig. 4b and c were respectively gettered according to the POGO I and POGO II schedules outlined in Table I. The overriding defect common to all wafers is the high dislocation density in the four corners of each wafer. Diode junction leakage is always high and device yield low in these corners where the dislocation density is greater than 10^6 cm^{-2}. The rest of the wafer will gen-

erally have from 10^4 to 10^5 dislocations/cm^2 except for the central core region where the dislocation density may be 10^6 cm^{-2} locally, compare Fig. 4b and 2c. A diode leakage map of sample G25 (Fig. 4b) is shown in Fig. 5 with an outline of the wafer superimposed. The map scale is such that one unit equals 10×10^{-12}A, which can be converted to a leakage density of 22×10^{-9} A-cm^{-2}. The double asterisk corresponds to numbers greater than 999. If those diodes with leakages greater than 100 picoA are isolated from the rest of the 10×10 array the resulting profile of the map in Fig. 5 matches the wafer slip pattern, see Fig. 4b. Therefore, any attempts at correlating gettering of stacking faults with device properties must be done on wafers with a process-induced dislocation density less than 10^5 cm^{-2}. The fact that most of the wafer, with a dislocation density from 10^4 to 10^5 cm^{-2}, has extremely low diode leakage is consistent with a companion study on diode leakage in p-tub CMOS devices where it was shown that a dislocation density of less than 5×10^4 cm^{-2} will not influence the diode leakage (10). Because this report is primarily devoted to the effects of stacking faults, and since slip dislocations can be suppressed by proper control of the wafer heating and cooling cycles (11), to be discussed below, the differences in leakage for the 3 wafers shown in Fig. 4 will only be compared where the dislocation density is low.

If the slip dislocations are neglected, the 3 wafers shown in Fig. 4 represent three different stacking fault situations. The first, monitor wafer G30, is dominated by surface stacking faults, compare the hazy regions of Fig. 4a with Fig. 2b; while the third sample, POGO II wafer G22 (see Fig. 4c), illustrates a swirl pattern typical of bulk stacking faults (recall Fig. 2a). No stacking faults at all are present in wafer G25 (see Fig. 4b) which had the POGO I treatment. The diode leakage map for this stacking fault free sample (see Fig. 5) gave an average leakage of about 60×10^{-12}A, for the 50 diodes which were not in the heavily

slipped regions. This should be compared to an average of 30×10^{-9}A for similar regions of the non-POGO treated wafer, G30. Sample G22 was processed using the Si_3N_4 POGO II sequence, which did not appear to suppress bulk stacking faults, as shown in Fig. 4c, and yielded the leakage map presented in Fig. 6. These data vary quite erratically with asterisks found next to ones in many cases. Note that the map scale in Fig. 6 has been increased by a factor of 100 over that in Fig. 5 in order to illustrate this apparently erratic distribution. At this point it was necessary to microscopically examine each individual diode to determine the local dislocation and stacking fault density. When this was done it was found that all of the diodes with leakages of 1×10^{-9}A or less (a 1 on the map), were free of stacking faults. Adjacent diodes with asterisks, which were often located along a swirl band, would have bulk stacking faults within the diode area, similar to those shown in Fig. 3a.

We can, therefore, conclude from these data that both bulk and surface stacking faults will increase the leakage in p-n junction diodes. Also, it appears that the Si_3N_4 POGO II process is only effective in suppressing the formation of surface stacking faults, whereas the POGO I treatment is required to produce diodes free of stacking faults.

By combining the POGO approach with suitable modifications (11) of the wafer cooling rates following all high temperature treatments it is possible to reduce the density of slip dislocations as well as the stacking faults. This reduction in slip is illustrated in Fig. 7 which shows samples F-8 and D-2 which are monitor and POGO I wafers from the same device processing lot. Dislocations did not play a role in the evaluation of the diode leakage maps for these wafers. Although the reduction in slip is not complete it is significantly reduced over the wafers in Fig. 4. Also, once the dislocations are suppressed the swirl pattern of bulk stacking faults becomes more prominent in the nongettered monitor wafer F-8, see Fig. 7a. The leakage map of this device showed a yield of only 5%, *i.e.*,

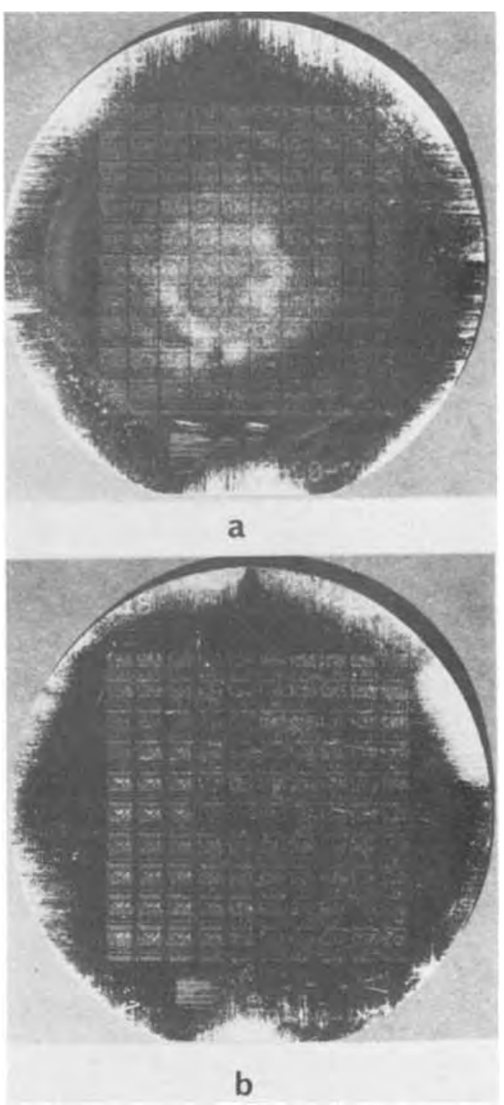

Fig. 7. Secco etched wafers with 10 × 10 array of tester diodes which were slow cooled during all high temperature processes illustrating reduced density of "slip" type dislocations in addition to (a) heavy swirl of bulk stacking faults in wafer F-8 which did not receive a POGO treatment. (b) POGO I treated wafer.

diodes with junction leakage less than 100 nA-cm^{-2}. It should be noted that the monitor wafer with a high density of slip dislocations, see Fig. 4a, actually had a 15% yield. It is possible that wafers with process-induced dislocations may provide a beneficial "self-gettering" for a small number of devices in regions where the dislocation density is low enough not to produce high leakage paths on its own.

This reduction in yield has also been observed (12) when comparing the storage times of arrays of MOS tester devices which were gradually or rapidly withdrawn from the oxidation furnace. The slow cooling eliminated the slip but gave rise to a high density of stacking faults which essentially wiped out the whole wafer. However, the fast cooling with slip produced a lower stacking fault density and a reasonable yield away from the slipped corners. This potential interaction between different kinds of defects which depends, in part, on the nature of the starting material, makes it extremely difficult to empirically optimize furnace operations and wafer cooling cycles. It is essential, therefore, that the microstructure of the defects be examined before and after any perturbation of the high temperature process.

Returning to the slow cooled wafer which also had a POGO I treatment (D-2, Fig. 7b) we note a combined reduction in slip and absence of the heavy swirl observed in Fig. 7a. The diode leakage map of sample D-2 showed a yield of 98%, which should be compared to the 5% yield of the non-POGO monitor wafer F-8, and the 72% yield of the fast cooled, POGO I wafer G25, previously discussed in Fig. 5 and 4b. A third slow cooled wafer which had the POGO II process had a yield of 36%. This wafer did have bulk stacking faults and a prominent swirl pattern, similar to Fig. 7a. However, the 36% yield indicated that the stacking faults of the POGO II wafer did not appear to be as electronically active as those in the monitor wafer. This can be explained as follows. Although the POGO II process is not as effective as POGO I in suppressing stacking fault formation, it will reduce the amount of contamination in the bulk of the wafer which will then lead to a cleaner, less decorated stacking fault with reduced electrical activity.

Support for the idea of stacking faults with varying amounts of decoration and electrical activity was obtained by microstructure examination of pits in sample D-1, a POGO I wafer which did have a low density of bulk stacking faults, although none were evident in the macrophoto. Figure 8 gives a comparison of clean stacking fault etch pits from wafer D-1 with decorated pits from a monitor wafer, F-8, which was processed with D-1. Note that the black pits in Fig. 8a are symmetric with relatively smooth side walls. Also, the small background "saucer" pits are isolated entities. However, in the non-POGO treated, heavily swirled wafer (see Fig. 8b) the black pits are irregularly shaped with a knobby structure, while the background saucer pits tend to aggregate into clusters (see arrows A in Fig. 8b). This distinction between clean and decorated defects has been observed previously (13) when comparing dislocation etch pits in saucer-pit free GaP LPE layers with GaP substrates containing 10^7 saucer pits/cm^2.

The reason for the occurrence of stacking faults, *i.e.*, the incomplete nature of the POGO I treatment for sample D-1, is believed to be related to the quality of the starting material, other samples of which had an unusually high density of native microdefects. Work is in progress both on evaluating defects in the as-received wafers and in using the SEM in the EBIC mode to examine the differences between clean and decorated stacking faults. For example. leakage currents at 28V of samples D-1 and F-8, Fig. 8a and b, were typically 22 nA-cm^{-2} or 1 μA-cm^{-2}, respectively. However, the 87% yield of wafer D-1 was noticeably lower than

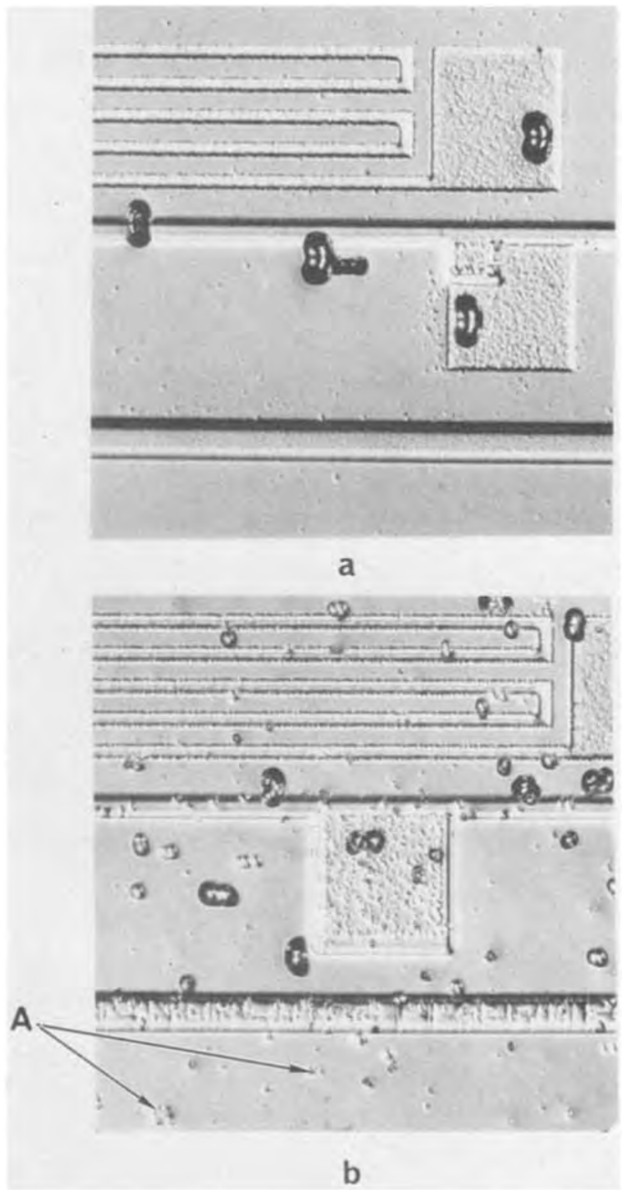

Fig. 8. Comparison of etch pits of bulk stacking faults which are (a) clean (wafer D-1), and those which are (b) decorated (wafer F-8). Note aggregates of saucer pits, arrows A in (b).

the 96-98% yield of other POGO I wafers from this group. Since most of the 13 bad devices were in the higher stacking fault density regions it is likely that, like slip dislocations, a high enough density of clean stacking faults will increase the diode leakage.

Summary and Conclusions

The results of this study can be briefly summarized in the following statements:

1. Both dislocations and stacking faults can cause increased diode leakage and reduced yield for devices with leakage requirements less than 1 μA-cm^{-2} at 28V, especially if the defects are decorated and their density is greater than 10^4 cm^{-2}.

2. The suppression of stacking faults by preoxidation gettering with misfit dislocations will reduce leakage currents by two to three orders of magnitude and increase yields of tester diodes from 10% to greater than 90%, provided the slip dislocation density is below 5×10^4 cm^{-2}.

3. Preoxidation gettering with the Si_3N_4 process is not effective in eliminating bulk stacking faults which have native defect origins, although surface stacking faults related to processing are gettered. However, the

level of decoration of the bulk stacking faults is reduced compared to nongettered wafers, with a resulting improvement in device yields from about 10 to 30 or 40%.

4. The occurrence of bulk stacking faults and the completeness of the misfit dislocation gettering process appears to be related to the density of native defects in the starting material.

Acknowledgments

The authors would like to thank Mrs. M. H. Read for carrying out the chemical etching procedures reported in this study. Also, discussions with P. M. Petroff and D. M. Boulin proved most useful and are gratefully acknowledged. Comments on the final manuscript by R. B. Marcus and E. N. Fuls are also appreciated.

Technical Notes

The Effect of Structural Change on Electrical Conductivity in InSe

Kazuaki Imai and Yutaka Abe[1]

Department of Nuclear Engineering, Hokkaido University, Sapporo 060, Japan

Indium selenide, a layered semiconductor, has been investigated by several authors with respect to the optical (1-3) and electrical (4-6) properties. However, these experimental results seem to depend on the process by which the crystal was grown and the perfection of the crystals.

In this note, we report the several characteristic changes in activation energies of the electrical conductivity in InSe and the relation between a structural change and the conductivity in the high temperature range.

Experimental

For the measurements of electrical conductivity, single crystals of InSe which had been grown by the Bridgman method were cut from the ingot and cleaved perpendicular to the C axis. The typical dimensions of the specimens were $3 \times 7 \times 0.5$ mm^3. In order to measure the temperature dependence of electrical conductivity, the samples were cooled in a vacuum cryostat and heated in a vacuum furnace.

Te-Au contacts were attached to the specimens. These contacts had good ohmic characteristics at room temperature and below. Below 190°K there was a slight deviation from the ohmic behavior but the deviation was less than 15% and could be neglected. Above room temperature, Cu pressure contacts were used. These contacts also showed good ohmic behavior.

The electrical conductivity was measured along the cleaved surface, *i.e.*, parallel to the C plane, of the specimens. The dark conductivity of our specimens at room temperature was 2.2×10^{-5} (ohm-cm)$^{-1}$, with a variation of this value for different specimens of about 10%.

The typical temperature dependence of electrical conductivity from 80° to 950°K is shown in Fig. 1. These curves are qualitatively similar to those in Ref. (4). The characteristics can be divided into five distinct temperature regions, namely, (I) below 190°K, (II) 190°~429°K, (III) 429°~600°K, (IV) 600°~827°K, and (V) above 827°K. In region I, the conductivity seems to be limited by crystal purity. In regions II, III, and 600°~750°K in IV, there is a linear relation $\log \sigma - 1/T$, and in these regions the activation energies are calculated as II = 0.42 eV, III = 0.34 eV, and IV = 1.05 eV, respectively. In region V, the conductivity has a metallic temperature dependence.

In order to find the relation between the variation of activation energies and the crystallographic change in our specimens, we have investigated the change of x-ray diffraction patterns using a high temperature Debye-Scherrer camera.

[1] Present address: Division of Engineering, Brown University, Providence, Rhode Island 02912.

Key words: electrical conductivity, structural change, phase change.

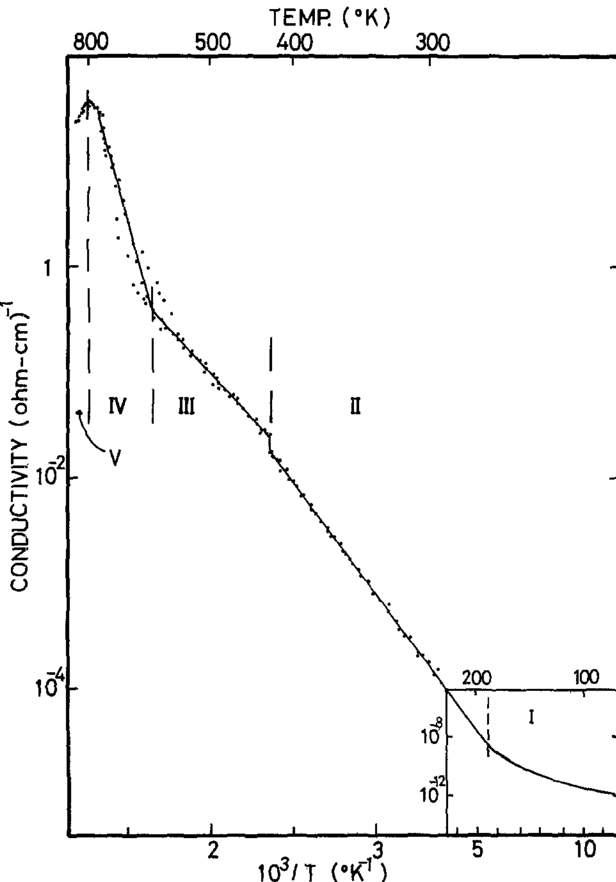

Fig. 1. The temperature dependence of electrical conductivity. The experimental results in the lowest temperature region are plotted on a different scale.

The specimens for this experiment were prepared as follows: stoichiometric amounts of indium (99.999%) and selenium (99.999%) were enclosed in a quartz holder in a vacuum of 10^{-5} Torr. After fusion, cooling of the melt led to formation of a polycrystal of InSe. This crystal was cut in pieces of 0.4 $\times$ 0.4 $\times$ 7 mm^3.

CuKα line was used as an x-ray beam. A typical result is shown in Fig. 2. The calculated lattice parameters of InSe in a hexagonal structure at room temperature are $a = 4.001 \pm 0.003$A and $c = 16.639 \pm 0.005$A. No appreciable change in the patterns is observed at 429° and 827°K, whereas a drastic change is found around 600°K as easily seen in Fig. 2. This structural change is irreversible: when the specimen is cooled slowly to room temperature, no change around 600°K is observed.

Discussion

In this note, we deal mainly with regions II, III, and IV. As indicated by optical absorption, the indirect energy gap of InSe is 1.187 eV (3). On the other hand, the two activation energies in regions II and III in our experiments are 0.42 eV (190°~429°K) and 0.34 eV (429°~600°K), respectively. This fact indicates that the electrical conductivity of our specimens is trap controlled even in the higher temperature ranges.

We could not find a definite structural change around 429°K by x-ray analysis but we have observed a distinct peak in the specific heat measurement (7) in our specimens, which indicates that a slight phase change might occur at this temperature. We conjecture that the step in the activation energy at 429°K is correlated with this slight phase change.

As described above, we found a drastic change of x-ray patterns around 600°K. Above 600°K, InSe cannot be considered to have structures such as D_{6h},

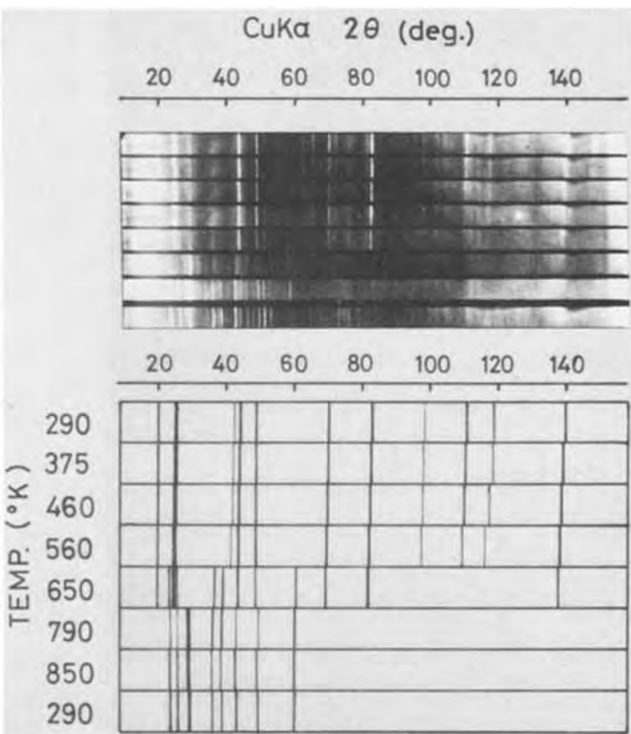

Fig. 2. The temperature dependence of x-ray Debye-Scherrer patterns. Strong lines taken from the photographs are shown in the lower figure.

D_{3h}, or C_{3v}; there is a complex change in crystal structure. This transition occurs at the point where there is a kink in the electrical conductivity. If we alternatively assume the onset of intrinsic conduction in this temperature range, our experimental results would yield an energy gap width of 2.1 eV which was almost twice as large as the energy gap obtained by optical experiments. Therefore it must be concluded that electric conduction of InSe above 600°K is entirely controlled by the structural change rather than by intrinsic conduction.

Also, we would like to point out that the structural change of InSe may be very sensitive to the external pressure of Se vapor. We have observed that a slight amount of excess Se added in the process of heat-treatment of InSe effectively quenched the phase change. We conjecture that vapor pressure of Se in our specific heat measurement on InSe, where we used quartz capillary packed entirely by InSe, was high enough for the quenching and therefore we could not observe the large phase change around 600°K.

More detailed experiments on the phase diagram with the temperature and external pressure, in particular with respect to the partial pressure of Se, are now in progress and will be reported elsewhere.

Acknowledgments

Effects of Oxide Thickness and Substrate Dopants on Irradiated MOS Capacitors

W. R. Haller,[1] S. Share, and A. S. Epstein

Harry Diamond Laboratories, Adelphi, Maryland 20783

and V. Kumar and W. E. Dahlke

Lehigh University, Bethlehem, Pennsylvania 18015

In our previous publications dealing with the effect of oxide thickness on oxide charge buildup in MOS (metal-oxide-silicon) structures (1, 2), there were indications that the density of radiation-induced fast interface states was dependent on the oxide thickness. In the following note, we have explored this dependence more fully. In addition, the effect of various p-type substrate dopants on the interface-state density is discussed.

The dopants, their concentrations, and oxide thicknesses (t_{ox}), are listed in Table I. The oxides were grown on <111> oriented silicon substrates by a wet oxide technique, described elsewhere, at a temperature of 925°C (1). The thermal oxidation of silicon can permit the incorporation of the substrate dopants (in our study, Ga, In, Al, or B) at the interface and into the oxide (3-6). Aluminum contacts were used on the oxide, and either gold or aluminum served as the back contact to the silicon substrates. The areas of the MOS capacitors ranged from 5×10^{-4} to 2×10^{-3} cm^2. An effective thickness of the oxide was calculated from the oxide capacitance in accumulation, the metal electrode area, and by assuming a dielectric constant for the oxide of 3.8.

The capacitors were irradiated at ^{60}Co gamma source (dose rate 2×10^6 rads(Si)/hr) to a dose of 10^6 rads(Si). Measurements were initiated within 1 hr after the irradiation. The samples were unbiased (floating) during the irradiation (7).

Changes in oxide charge density and fast interface-state density resulting from irradiation of the MOS capacitors were obtained from capacitance-voltage (C-V) measurements at frequencies of 1 MHz and 100 Hz. Additional confirmation of the interface-state density was provided by conductance-voltage (G-V) measurements (8). Ionizing irradiation normally causes a parallel shift, ΔV, of the C-V characteristics toward the negative voltage direction (Fig. 1). This shift is generally interpreted as a buildup of positive charge in the oxide. Calculation of the oxide-charge density from C-V data requires a knowledge of the distribution of oxide charge over the oxide layer. Since this is difficult to attain, an effective value (image) of the oxide charge density can be calculated from $\Delta Q_{ox} = q\Delta N_{ox} = \epsilon_{ox}\Delta V/t_{ox}$ where ϵ_{ox} is the SiO_2 dielectric constant, q is the charge of an electron, t_{ox} is the oxide thickness, and ΔN_{ox} is an effective density of the radiation-induced oxide states. The shift of the flatband voltage in high frequency (1 MHz) C-V curves (Fig. 1) was used to obtain values of ΔV, since the high frequency curves minimize the contribution of fast interface states. Ionizing radiation also causes large changes in the low frequency C-V characteristic (*i.e.*, increased dispersion) as shown in Fig. 1. This is usually attributed to an increase in the fast interface-state density. Using high (1 MHz) and low (100 Hz) frequency C-V characteristics, the interface-state density distribution can be obtained by a procedure outlined by Castagne and Vapaille (9) both before and after 10^6 rads(Si) irradiation. The interface-state distribution of some of the samples was also obtained from the G-V data by a procedure outlined by Nicollian and Goetzberger (8), using a single time-constant surface-state circuit model. The effects of inhomogeneities and lateral nonuniformities are not considered in our discussion.

The effect of irradiation on MOS capacitors with various oxide thicknesses and dopants is found in Table I. The data are arranged in the order of decreasing oxide thickness. Listed in Table I along with the oxide thicknesses, t_{ox}, are the effective density of radiation-induced oxide states, ΔN_{ox}, after 10^6 rads(Si) ir-

radiation, the peak values of the fast interface-state density distribution after 10^6 rads(Si) irradiation, N_{SS}, and the change of the total density of fast-interface states (cm^{-2}) induced by irradiation, ΔN_s. The latter is obtained by taking the difference between the total density of interface states after and before 10^6 rads(Si) irradiation. For all except the Ga-doped sample, the values of N_{SS} and ΔN_s increase with increasing oxide thickness. The peak energy of the state distribution lies at about 0.30-0.35 eV above valence band edge. The value of the total density of interface states prior to irradiation is on the order of 10^{11} cm^{-2} for all oxide thicknesses. The variation of ΔN_s with oxide thickness as noted in Table I has, to our knowledge, not been reported so directly before. A result similar to this has recently been inferred from radiation experiments performed on CMOS integrated circuits (10). On the other hand, the increase of ΔN_{ox} with oxide thickness has been noted in our previous work (1). This latter trend was found to be indicative of a buildup of positive charge in the oxide located within 160Å of the Si-SiO_2 interface. Reference to the last column in Table I reveals that the ratios of ΔN_{ox} to ΔN_s for all the thicknesses of the B-doped samples as well as the In- and Al-doped samples are approximately equal (~3). This suggests that ΔN_s is directly proportional to ΔN_{ox} and that there is a direct relation between the effect of oxide charge buildup and radiation-induced fast interface states; namely, the thickness dependence of both processes are similar for the wet oxides studied here.

The total radiation-induced interface-state density, ΔN_s, shows a difference for the Ga-doped substrate dopant as seen by the larger ratio of ΔN_{ox} to ΔN_s in Table I. It is not immediately obvious why the Ga-doped sample should have a reduced density of radiation-induced fast interface states. It may be related to the higher diffusion coefficient of Ga in SiO_2 (4). If the density of fast-interface states is related to an impurity, then the deeper the dopant diffuses into the oxide, the less likely the communication of the interface state with the silicon.

These results have been deduced from a straightforward analysis of C-V data. Castagne and Vapaille have shown in their analysis of C-V data that the effects of oxide charge inhomogeneities can produce apparent changes in the fast interface-state density (11). The probability that the radiation-induced interface state densities in our experiment are due to inhomogeneities is considered unlikely since analyses of both C-V and G-V data provide similar state distributions (11).

Conclusion

A variation of the radiation-induced fast interface-state density (ΔN_s) with oxide thickness has been observed in MOS capacitors fabricated by the wet oxide technique. Comparing the effect of oxide charge buildup ΔN_{ox} with ΔN_s for each thickness yields a constant value of $\Delta N_{ox}/\Delta N_s$ (~3) for all devices fabricated on B-doped substrates. This result can also be extended to include other p-type substrate dopants, including Al and In. A larger value of $\Delta N_{ox}/\Delta N_s$ (~5), however, has been found for the Ga-doped sample because of the smaller value of ΔN_s.

Selective Etching of GaP Crystals with Hot Phosphoric Acid

T. Uragaki, H. Yamanaka, and M. Inoue

Matsushita Electronics Corporation, Research Laboratory, Takatsuki, Osaka, Japan

The chemical etching of GaP is one of the important processes in the fabrication of the light emitting devices (1, 2). Aqua regia (3) has been conventionally used for groove formation on a $(\bar{1}\bar{1}\bar{1})$ wafer, along which the individual chips are mechanically separated. However, irregularly grooved patterns are often observed in prolonged etching as a result of lateral etching at the mask edges. In addition, the mechanical cutting of the shallow grooves for chip separation, by a diamond saw or a laser beam, gives rise to profound surface damages to the crystal which may degrade the device performance.

This report describes a new technique for pattern etching of GaP crystals with phosphoric acid. Well-defined grooves, uniform in width and depth, are formed on the $(\bar{1}\bar{1}\bar{1})$ surface regardless of the pattern orientation. The cross-sectional view of the grooves obtained is so sharply V shaped that no mechanical cutting process should follow for chip separation. The pattern etching technique can use a vacuum-deposited film of gold or gold alloy as the mask, which will be contact electrodes.

Experimental Procedure

The GaP wafers used for the etching experiments are (111), $(\bar{1}\bar{1}\bar{1})$, or (100) oriented and doped with sulfur to a carrier concentration of $4{\sim}8 \times 10^{17}$ cm^{-3}. The etch pit density was $3{\sim}5 \times 10^5$ cm^{-2}. The mechanically polished wafers were further etched chemically with a solution of 2 vol HCl + 1 vol HNO_3 + 2 vol H_2O (4) at 60°C for 1~2 min.

For the mask etching, a gold film of 3000Å thickness was deposited in vacuum onto the wafer surface at 300°C, being followed by pattern formation with a mixed solution of 25g I_2 + 50g KI + 500 ml H_2O.

The etching was carried out with reagent-grade H_3PO_4 (85%) at a temperature of 150°~200°C. Gas evolution during etching provides vigorous stirring of the etching solution. Measurements of the etch depth and width were made with a microscope. For detailed geometrical observation of the revealed surfaces, the scanning electron microscope was used.

Results and Discussion

Etching rate.—The etching rate was determined for the (111), $(\bar{1}\bar{1}\bar{1})$, and (100) surfaces. Figure 1 shows the change in wafer thickness with increasing etching time. The decrease in wafer thickness is seen to be a linear function of time up to 10 min and the etching rate, which is defined as the thickness removed per unit time, is therefore constant. The etching rate at 180°C for the $(\bar{1}\bar{1}\bar{1})$ wafer was found to be about 20 times higher than that for the (111) or (100) wafer, probably due to the crystallographic anisotropy in chemical reactivity of the zinc blende structure.

The temperature dependence of the etching rate for the $(\bar{1}\bar{1}\bar{1})$ surface is shown in Fig. 2. The etching rate is practically controllable between 5 and 25 μm/min by varying the temperature from 150° to 200°C.

Pattern etching.—Using a vacuum-deposited gold film on the $(\bar{1}\bar{1}\bar{1})$ surface of GaP as an etch mask, the exposed circular region of 60 μm diameter was etched with H_3PO_4 at 180°C. Figures 3(a) and 3(b) are the <$\bar{1}\bar{1}\bar{1}$> top view and the <$\bar{1}10$> cross-sectional view of a hollow formed by 6 min etching, respectively, in which the hollow is found to be of threefold symmetry surrounded by the $(\bar{2}\bar{2}1)$ and $(\bar{1}\bar{1}7)$ facets.

A selective etching was also carried out for stripes of 60 μm width oriented in the $[1\bar{1}0]$ direction. Figure 4 [(a) to (e)] shows the change in shape and size of the cross section of the grooves during the successive etching for 1~8 min. At the first stage of etching the grooves were flat bottomed [Fig. 4(a) and (b)] and then grew to be asymmetrical V shaped [Fig. 4(e)]. It was observed that the angles between the revealed facets and the $(\bar{1}\bar{1}\bar{1})$ surfaces were unchanged throughout the etching period. These angles were measured to be 45° and 55°, and are in good agreement with the calculated angles of 44.5° and 54.7° assuming the $(\bar{1}\bar{1}7)$ and $(\bar{2}\bar{2}1)$ planes for the revealed surfaces.

For the practical application of stripe etching, there is a need to know the dependence of the resulting groove profile on the crystallographic direction of the mask pattern. Grooves parallel to three typical directions, $[1\bar{1}0]$, $[11\bar{2}]$, and 45° off $[1\bar{1}0]$, were formed on a $(\bar{1}\bar{1}\bar{1})$ wafer, of which cross sections are compared in Fig. 5. As is seen in Fig. 5, the V shapes formed are not so much different from one another, where the bottom angles between the revealed surfaces are in the range of 70°~80°. The strictly symmetrical cross

section is obtained only when the stripe is parallel to the [11$\bar{2}$] direction.

Application to Device Fabrication

The etching technique with H_3PO_4 was applied to the mesa-formation process of GaP LED's. A ($\bar{1}\bar{1}\bar{1}$) LPE wafer of p/n/n$^+$ structure was pattern etched using an Au-Zn or Au-Be alloy film as the mask. The stripe lines were directed parallel to the [1$\bar{1}$0] and [11$\bar{2}$] directions in 400 μm intervals, as shown in Fig. 6(a). The width and depth of the V-shaped grooves obtained were 60 μm and 40 μm, respectively. After the mesa etching, the Au-alloy film was again photoetched in order to leave the electrode patterns for ohmic contact to the p-layer. The separation of individual chips was easily accomplished by bending the wafer with a roller after reduction of the wafer thickness to about 200 μm. Figure 6(b) shows an LED chip mounted p-side up on a TO-18 stem. When the diode is mounted p-side down, the inclined facets formed by the mesa etching act as efficient internal reflectors giving rise to an increase of light output.

Profile Parameters of Implanted-Diffused Arsenic Layers in Silicon

Richard B. Fair* and Joseph C. C. Tsai

Bell Laboratories, Reading, Pennsylvania 19604

In a previous paper, the diffusion of ion-implanted As in <100> Si was discussed as well as the electrical quality of implanted-diffused layers. It is the purpose of this paper to derive equations that describe the important characteristic profile parameters, and to support these equations with experimental data. A discussion of total As surface concentration, junction depth, and profile gradient will be presented, which will be followed by an analysis of the sheet resistance of implanted-diffused As layers and the surface concentration of the electrically active As.

Analysis

Total As surface concentration, C_{T0}, and junction depth, x_J.—It was shown previously (1) that the implanted-diffused total As profile shape is approximately described by the equation

$$C = C_{T0}\,(1 - 0.87Y - 0.45Y^2) \qquad [1]$$

where

$$Y = x(8C_{T0}D_it/n_i)^{-1/2} \qquad [2]$$

t is the diffusion time (sec), D_i is the intrinsic As diffusivity (cm²/sec), n_i is the intrinsic electron concentration, and C_{T0} is the As surface concentration (atom/cm³) assumed to be greater than $\sim 1 \times 10^{19}$ cm^{-3}.

Equation [1] is a Chebyshev polynomial approximation to the solution of the diffusion equation with a linear concentration-dependent diffusion coefficient and constant surface concentration, C_{T0}. It is probable that the polynomial coefficients are time-dependent for the case of nonconstant C_{T0}, such as the case of a redistributing impurity distribution. For the case of implanted As in Si, C_{T0} decreases as $t^{-1/3}$, and the constant C_{T0} approximation is not an unreasonable assumption. In any case, the functional form of Y would not be different (Eq. [2]).

In order to solve for the junction depth as a function of time, temperature, and implant dose, Eq. [1] can be solved for Y at $C(x_J)$ and the result substituted into Eq. [2]. Thus, at the junction

$$x_J = (8C_{T0}\,D_it/n_i)^{1/2}\,\frac{\left(0.64 - 0.45\dfrac{C(x_J)^{1/2}}{C_{T0}} - 0.435\right)}{0.45} \qquad [3]$$

When $0.45\,C(x_J)/C_{T0} << 0.64$, then Eq. [3] becomes

$$x_J = 2.3\,(C_{T0}\,D_it/n_i)^{1/2} \qquad [4]$$

and $Y_J = 0.81$.

When diffusion occurs from a predeposited As layer in Si, the total concentration, Q_T (atom/cm²), remains constant. Thus, integrating Eq. [1] over x gives the result that

$$Q_T = K\,C_{T0}\,x_J \qquad [5]$$

with $K = 0.45$ (valid for $C_{T0} \gtrsim 1 \times 10^{19}$ cm^{-3}). For the case of a redistributing implanted layer, K would be slightly time dependent to balance the nonconstant C_{T0}. Q_T *vs.* $C_{T0} \cdot x_J$ data from the measured As profiles described in Ref. (1) are plotted in Fig. 1, and it is found that K averages out to be $(1.9)^{-1} \simeq 0.53$ (50 keV implantations). Thus the time dependence of the polynomial coefficients and, thus, K, is not significant.

Substitution of Eq. [5] into Eq. [4] yields

$$x_J = K_1\left(\frac{Q_T\,D_it}{n_i}\right)^{1/3} \qquad [6]$$

with $K_1 = 2.16$. Data are shown in Fig. 2 where x_J values at $C = 0.01\,C_{T0}$ as determined by direct profile measurement by secondary ion mass spectrometry are plotted as a function of implant dose and diffusion time and temperature. The data represent diffusions in the temperature range of 1000°-1250°C. For diffusions performed in neutral ambients or in oxygen, Eq. [6] can be used to fit these data slightly better with $K_1 = 2$. Thus

$$\boxed{x_J = 2\left(\frac{Q_T\,D_it}{n_i}\right)^{1/3}} \qquad [7]$$

for $C_{T0} \gtrsim 1 \times 10^{19}$ cm^{-3}.

Diffusions performed in steam ambients represent a special case, and are discussed in Ref. (1). It can be seen, however, in Fig. 2 that the discrepancy in x_J between diffusions performed in steam ambients and N_2 or O_2 ambients decreases as x_J increases. This result indicates that the As diffusion in steam is being controlled by a surface effect associated with the oxidation process.

The time and temperature dependence of the surface concentration, C_{T0}, can now easily be obtained by combining Eq. [5] and [7]. Thus

$$\boxed{C_{T0} = 0.94\left(\frac{Q_T^2\,n_i}{D_it}\right)^{1/3}} \qquad [8]$$

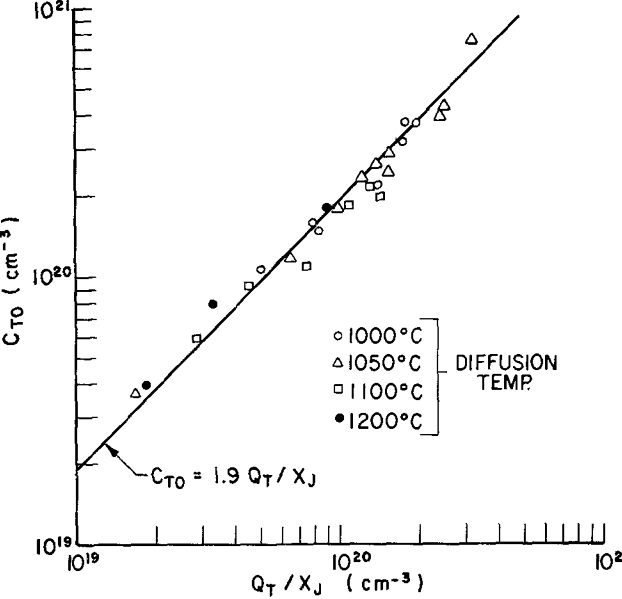

Fig. 1. Total As surface concentration vs. the average doping for implanted-diffused layers in Si.

* Electrochemical Society Active Member.

Key words: ion implantation, arsenic diffusion, sheet resistance, junction depth.

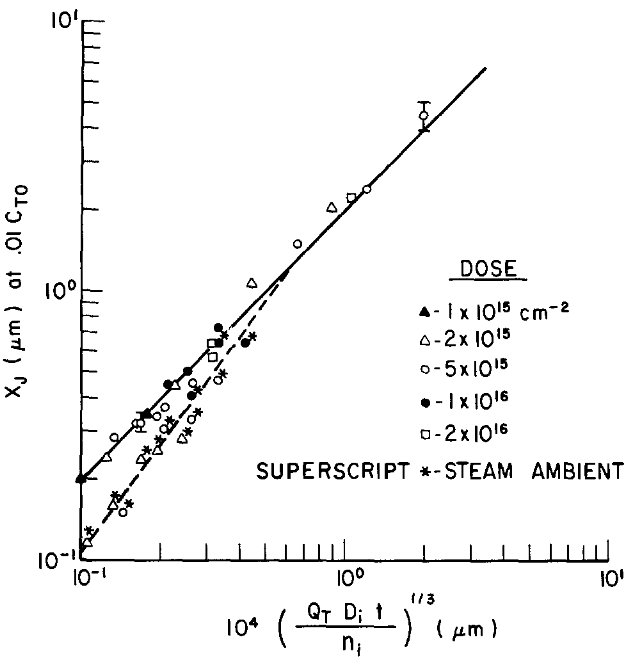

Fig. 2. Time, temperature, and dose dependence of the junction depth of implanted As layers diffused in N_2, O_2, and steam ambients.

Equation [8] predicts that for a given temperature and dose, the surface concentration will decrease as $t^{-1/3}$. The data plotted in Fig. 3 (from measured profiles) agree quite well with Eq. [8].

Profile gradient calculation.—The gradient of the As profile at the junction can be calculated by differentiating Eq. [1] and substituting Eq. [2]. Thus, for $C(x_j) << C_{T0}$

$$\left.\frac{dC}{dx}\right|_{x=x_j} = -0.565\,(C_{T0}\,n_i/D_i t)^{1/2} \quad [9]$$

or

$$\boxed{\left.\frac{dC}{dx}\right|_{x=x_j} = -1.24\,C_{T0}/x_J} \quad [10]$$

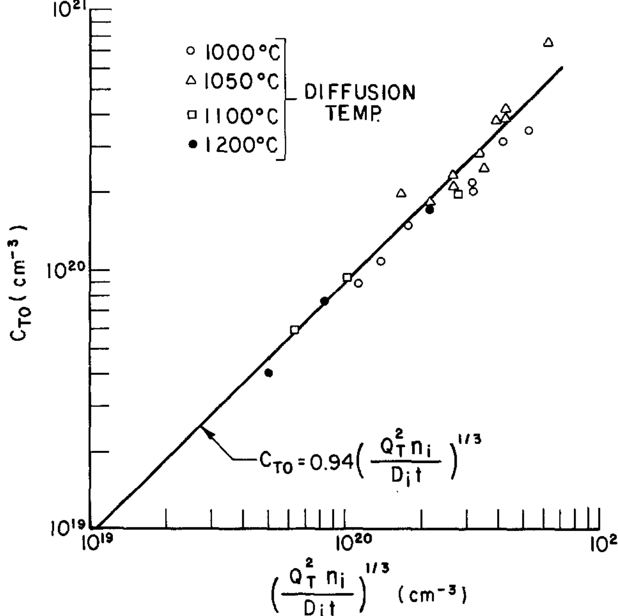

Fig. 3. Time, temperature, and dose dependence of implanted-diffused As surface concentration.

Gradient data from measured implanted-diffused As profiles, plotted in Fig. 4, show that Eq. [10] is applicable at $C(x_j) = 0.1\ C_{T0}$. Data from chemical source As diffusions (▲ — data) are also shown. However, the gradient is not constant with decreasing concentration for a given value of C_{T0}/x_J. At $C(x_J) = 0.01\ C_{T0}$ the gradient has decreased by a factor of 4 below the value at $C = 0.1\ C_{T0}$. The significance of this result is unclear in view of the uncertain accuracy of the measurements.

Sheet resistance and electrically active As surface concentration.—The expression for the sheet resistance of a diffused layer is

$$R_S = 1 \Big/ \left(q\,\bar{u}\int_0^{x_J} C_A dx\right) \quad [11]$$

where C_A is the electrically active As concentration and $\bar{u}$ is the effective bulk carrier mobility (cm²/V-sec) given by

$$\bar{u} = \frac{\int_0^{x_J} u\,C_A dx}{\int_0^{x_J} C_A dx} \quad [12]$$

When the implanted-diffused As is 100% electrically active, *i.e.*, $C_{T0} = C_{A0}$ (active As surface concentration), then using Eq. [5] and [11], C_{A0} can be expressed in terms of the measurable quantities R_S and x_J. Thus

$$C_{A0} = \frac{1.9}{q\,\bar{u}\,R_S\,x_J} \quad [13]$$

In order to determine the concentration dependence of $\bar{u}$, use will be made of the mobility data in Ref. (4, 5) which can be described approximately by the expression

$$u = \frac{28.2 \times 10^7}{C_A^{1/3}}\ \text{cm}^2/\text{V-sec} \quad [14]$$

for the As concentration range of 10^{19} cm^{-3} $< C_A <$ 6×10^{20} cm^{-3}. Substituting Eq. [1], [2], and [14] into Eq. [12], the effective mobility can be determined from numerical integration. However, using the fact that the As profile is almost a step function and the average doping is approximately $Q_T/x_J = 0.53\ C_{A0}$, a simple expression for $\bar{u}$ has been found which is

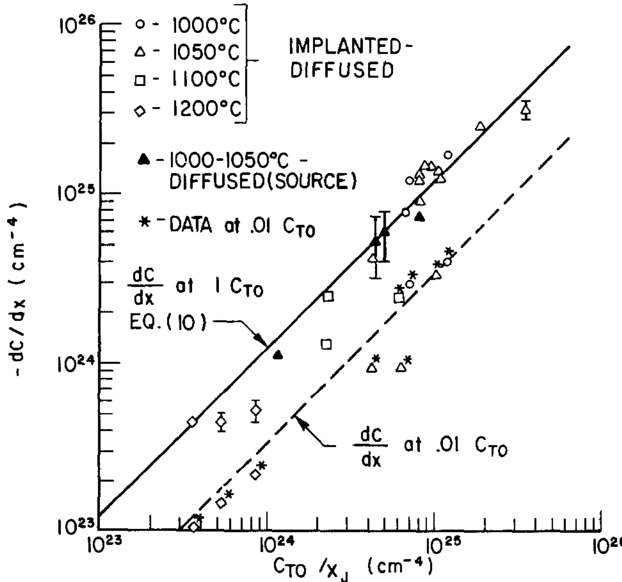

Fig. 4. Arsenic layer junction profile gradient vs. surface concentration/junction depth at two concentrations.

$$\bar{u} = \frac{28.2 \times 10^7}{(0.53\ C_{A0})^{1/3}} \quad [15]$$

The 0.53 C_{A0} term represents an equivalent uniform As distribution over the diffused layer. Substituting Eq. [15] in Eq. [13], the following expression for C_{A0} is obtained

$$C_{A0} = \frac{6.26 \times 10^{15}}{(R_S\ x_J)^{3/2}} \quad [16]$$

This equation for C_{A0} differs from the result obtained for diffusion from a chemical source (2) where a constant mobility was assumed

$$C_{A0} = \frac{1.56 \times 10^{17}}{R_S\ x_J} \quad [17]$$

Experimental data of C_{A0} *vs.* ($R_S\ x_J$) are shown plotted in Fig. 5 along with Eq. [16] and [17]. The experimental values of C_{A0} were determined from differential conductivity measurements on implanted-diffused As layers and the revised resistivity *vs.* electron concentration curve for As in Si [Fig. 1 of Ref. (1)]. The effect of using the revised ρ *vs.* n curve for As is to increase the magnitude of the slope of the C_{A0} *vs.* $R_S\ x_J$ curve (on log-log scales), as compared to using Irvin's ρ *vs.* n curve (6). Irvin's curve underestimates electron concentration, n, when $\rho > 8 \times 10^{-4}$ ohm-cm. Most of the data displayed in Fig. 5 showed 100% electrical activity. However, at high doses and short diffusion times, C_{T0} may be greater than the solid solubility of active As, $C_{A,SOL}$ (1). Data for which $C_{T0} > C_{A,SOL}$ are indicated in Fig. 5 by an (*).

Sheet resistance can be determined as a function of implant dose and diffusion time and temperature by combining Eq. [11] with the expression for $\bar{u}$ of Eq. [15] to yield

$$R_S = \frac{1.7 \times 10^{10}}{Q_T^{7/9}} \left(\frac{n_i}{D_i t}\right)^{1/9} \quad [18]$$

Equation [18] predicts that for a fixed temperature and dose, $R_S \propto t^{-1/9}$. This expression is shown plotted in Fig. 6 along with sheet resistance data obtained

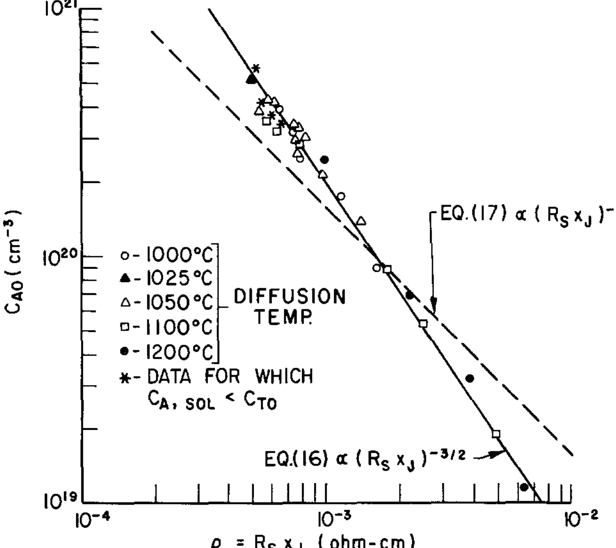

Fig. 5. Electrically active As surface concentration vs. the implanted-diffused layer resistivity. The dashed line was obtained from data on chemical-source As diffusions in Si.

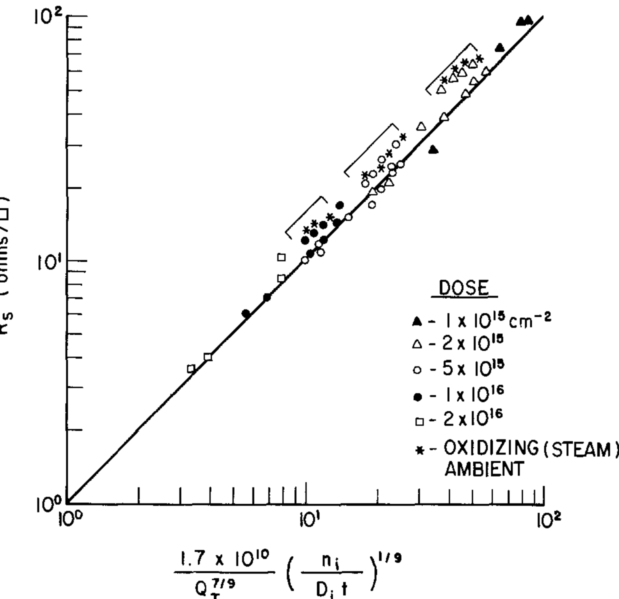

Fig. 6. Time, temperature, and dose dependence of the implanted-diffused As layer sheet resistance.

over the range 1000° < T < 1250°C. For diffusions performed in neutral ambients or in oxygen, the agreement with theory is good. However, diffusions in steam consistently yield R_S values that are 10-20% higher than predicted. This result is consistent with the fact that As diffusion in steam yields shallower junctions and higher (lower $\bar{u}$) average concentrations than diffusions in O_2 or N_2.

Discussion

It should be pointed out that the curves in this paper are derived for 50 keV As predepositions. The energy of the predeposition implantation is important for shallow junction diffusions. The projected range and standard deviation (7) for 50 keV As in Si are R_P = 324Å and ΔR_P = 120Å, respectively. For 100 keV As in Si, R_P = 584Å and ΔR_P = 211Å. Thus, a junction depth difference of ~500Å should be expected for shallow junction drive-ins from 100 keV implants. However, for buried layer-type diffusions (>1 μm), little difference, if any, should be expected between 50 and 100 keV predepositions. It is also expected that the results in the present study are applicable for an implant energy of 30 keV.

Summary and Conclusions

Equations have been derived that describe the important profile variables that are required to characterize the diffusion of As implanted layers for which the surface concentration is greater than ~1 × 10^{19} cm^{-3}. In addition, data obtained from differential conductivity profile measurements and SIMS profile measurements (1) have been used to obtain experimental parameters for these equations.

In Situ Thickness Monitoring of Thick Polycrystalline Silicon Film and Its Application to Silicon Epitaxial Growth

Katsuro Sugawara,* Yukiyoshi Nakazawa, and Takeo Yoshimi

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

The development of high performance silicon semiconductor bipolar devices has increased the requirement for precise control of silicon epitaxial layers. One of the precise control methods is an "in process" monitoring system. Dumin first devised a monitoring method using optical interference to control the thickness of the SOS (silicon-on-sapphire) epitaxial layer (1), and this method was extended to monitor thickness in Al_2O_3 (2), sputtered SiO_2 (3), CVD SiO_2 (4), and polycrystalline silicon (5, 6) film formation. In this note, the monitoring of polycrystalline silicon film thickness was investigated to evaluate the monitoring capability of silicon epitaxial layer thickness which was inferred by measuring the thickness of simultaneously deposited polycrystalline silicon films on insulator-covered substrates.

The following problems were anticipated in the case of monitoring silicon epitaxial growth which took place in a hotter atmosphere than amorphous or polycrystalline CVD film formation:

(*i*) Intensity of background in the infrared radiation emitted from the substrate was stronger.

(*ii*) The substrate covered with insulating film degraded in severe ambient conditions such as hot hydrogen and hydrogen chloride.

(*iii*) Correlation between the deposition rate of the polycrystalline silicon film and that of the single crystal silicon layer when the thickness of the silicon epitaxial layer was indirectly monitored as the polycrystalline silicon film thickness.

Both methods of infrared radiation (1, 5) and infrared laser (6) were tried for this purpose and the improved former method was selected due to the larger monitoring capability for higher temperature deposition.

The experiment was carried out in a horizontal epitaxial reactor of rf-heated type with a SiC-coated graphite susceptor. The cross section of the reactor tube was 120 × 65 mm. In this reactor, polycrystalline silicon films produced by $SiCl_4$-H_2 or SiH_2Cl_2-H_2 (7, 8) system were deposited on two kinds of substrates; thermally grown SiO_2 films of 1.2 μm in thickness and CVD Si_3N_4 films of 3000Å formed on silicon substrates. The silicon deposition was performed at a $SiCl_4/H_2$ ratio of 0.005 in the temperature range from 1060° to 1330°C for the $SiCl_4$-H_2 system and SiH_2Cl_2/H_2 ratio of 0.005 from 950° to 1280°C for the SiH_2Cl_2-H_2 system at H_2 flow rate of 60 liter/min. The reaction temperature was corrected for emissivity according to Allen's data (9).

During the deposition, the infrared radiation emitted from the substrate was received by a PbS photocell with a filter (10) which allowed only 2.0 μm wavelength to pass through. The signal from the photocell was then amplified and recorded as an inteference wave pattern. Since the peak-to-peak of waves corresponded to the deposition film thickness, the thickness of the epitaxial layer could be estimated from the correlation curve between the polycrystalline silicon thickness and the silicon epitaxial layer growth. After the deposition, the thickness of the silicon epitaxial layer and that of the polycrystalline silicon film were determined by means of an angle lapping and staining technique in addition to Talystep measurements.

Figure 1 shows a typical pattern obtained in the case of a polycrystalline silicon film deposition at 1120°C on Si_3N_4 film using the SiH_2Cl_2-H_2 reaction. One cycle of the interference wave was approximately 0.28 μm in film thickness when glancing angle of the photocell was 40°. Under these conditions the maximum monitoring thickness, d_{max}, which was the thickness at the point where the amplitude of the observed signal could not be recognized, reached nearly 3.9 μm for the polycrystalline silicon film. With increase of film thickness the interference wave drawn in the polycrystalline silicon deposition was observed to decay rapidly.

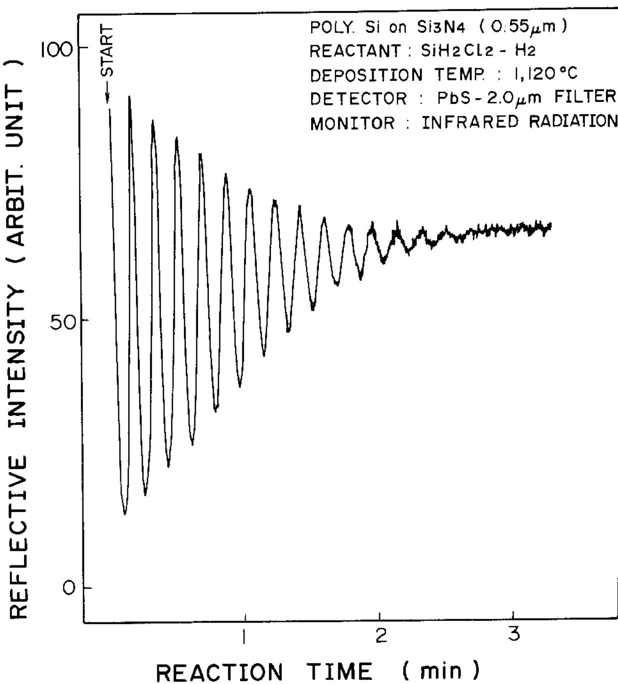

Fig. 1. Observed pattern of interference wave when the polycrystalline silicon film was formed by the SiH_2Cl_2-H_2 reaction on the Si_3N_4 substrate.

* Electrochemical Society Active Member.

Key words: polycrystalline silicon deposition, infrared radiation, $SiCl_4$-H_2 reaction, SiH_2Cl_2-H_2 reaction, precise control of film thickness.

The temperature dependence of d_{max} was plotted for the thermally grown SiO_2 substrate in Fig. 2 and for the CVD Si_3N_4 substrate in Fig. 3 as a function of deposition temperature. In both reactions d_{max} showed a tendency of increasing to a maximum, then decreasing. From these figures, the following features could be discerned: (*i*) d_{max} deposited at 1120°C by the SiH_2Cl_2-H_2 reaction was a little larger than that at 1220°C by the $SiCl_4$-H_2 reaction; (*ii*) thickness monitoring of the SiH_2Cl_2-H_2 reaction was applicable in a wider temperature range than that of the $SiCl_4$-H_2 reaction; and (*iii*) Si_3N_4 film was less liable to degenerate than SiO_2 film (11) in such a hot hydrogen atmosphere. However, the difference of the optical refractive index between Si and Si_3N_4 was a little smaller than between Si and SiO_2 and hence this difference brought about a smaller interference intensity.

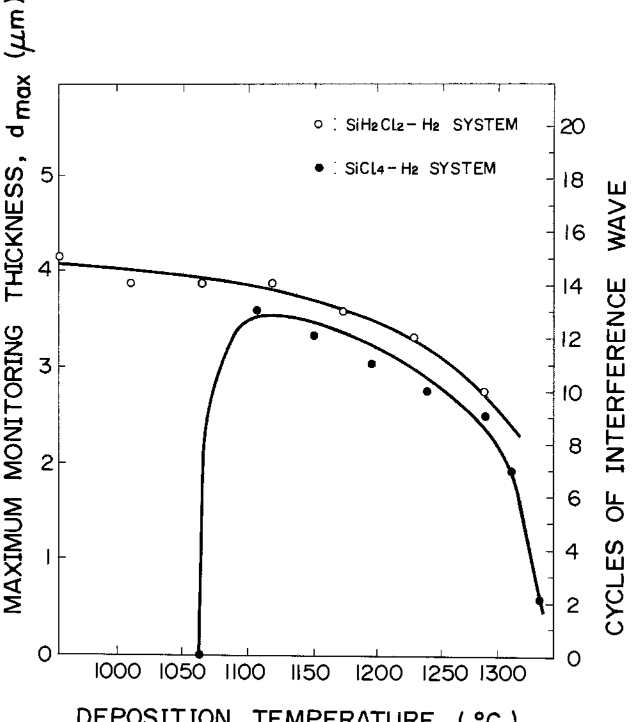

Fig. 2. Dependence of the maximum monitoring thickness, d_{max}, on the deposition temperature when the polycrystalline film was deposited on the thermally grown SiO_2 substrate.

Accuracy control of the film thickness could be obtained by selecting the wavelength of the filter used independent of the film thickness. A filter of 2.0 ± 0.05 μm was selected in this experiment because it was at this wavelength that one received the maximum radiation energy emitted from a black body heated at 1400°K (12) which corresponded to the deposition temperature in this experiment.

Figure 4 shows the correlation between the thickness of the polycrystalline silicon film on the thermally grown SiO_2 of 1.2 μm in thickness and that of the epitaxial layer on a boron-doped <111> oriented silicon substrate with a resistivity of 10 ohm-cm. Both wafers were adjacent to each other on the susceptor and the deposition was done at 1120°C by the SiH_2Cl_2-H_2 reaction. The relation of the single crystal thickness, y μm, to the polycrystalline silicon thickness, x μm, was given by the following experimental formula shown by a dashed line (Fig. 4)

$$y = 0.95x \quad [1]$$

The solid line indicates the relation of $y = x$. Single crystal film grew 5% thinner than the polycrystalline one.

For the purpose of precise control of the silicon epitaxial layer thickness, the thickness monitoring of the CVD films was further developed for thick polycrystalline silicon film. An improved thickness monitoring method using infrared radiation through a filter with a definite wavelength was adapted for this aim. Values of maximum monitoring thickness were: (*i*) 3.9 μm in the polycrystalline silicon film, corresponding to 3.7 μm in the single crystal layer, deposited at 1120°C by the SiH_2Cl_2-H_2 reaction, and (*ii*) 2.8 μm in the polycrystalline film, grown at 1220°C by the $SiCl_4$-H_2 reaction on the Si_3N_4 substrate, corresponding to 2.7 μm in the epitaxial layer.

The observed rapid decay of refractive intensities in the interference wave with increasing film thick-

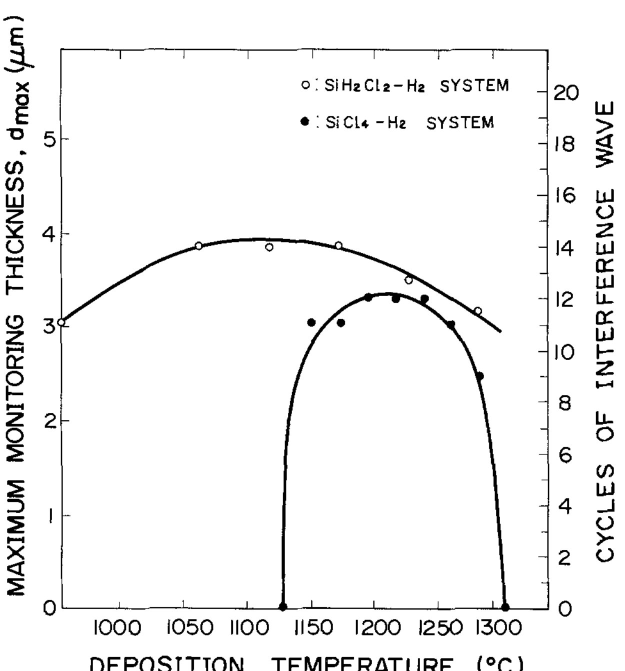

Fig. 3. Dependence of the maximum monitoring thickness, d_{max}, on the deposition temperature when the polycrystalline silicon film was deposited on the CVD Si_3N_4 substrate.

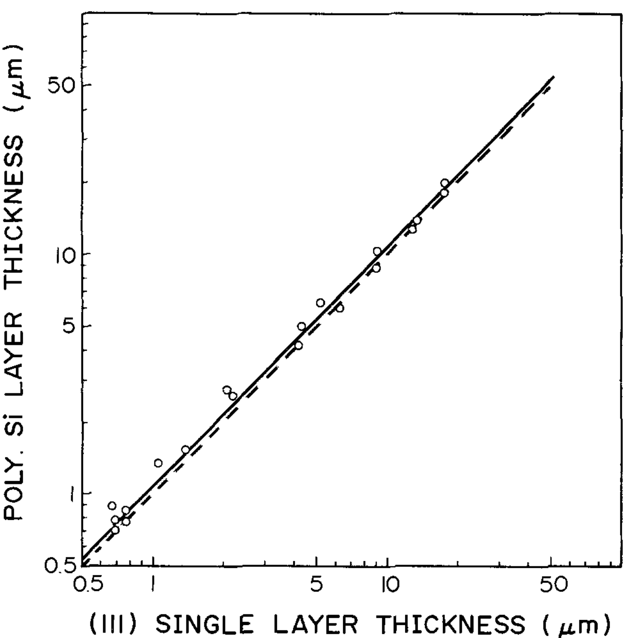

Fig. 4. Correlation between the thickness of the polycrystalline silicon film on the thermally grown SiO_2 and that of the silicon epitaxial layer grown on the <111> oriented silicon substrate.

ness may be caused by scattering by the grains or the surface roughness of the polycrystalline silicon film or an increased absorption coefficient in the silicon substrate at high temperature. The interpretation of this decay will be pursued in the next paper (13).

Acknowledgments

The authors express their sincere appreciation to Mr. S. Nishida, Mr. M. Ono, and Dr. Y. Sugita for valuable discussions and continued support throughout this work and to Mr. S. Yasuda for the technical discussion of the epitaxial growth.

Manuscript submitted Aug. 5, 1975; revised manuscript received Dec. 29, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

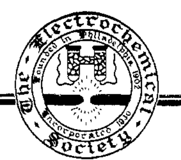
Brief Communication



Raman Line Broadening in the Superionic Conductors, $Ag_2[HgI_4]$, and $Cu_2[HgI_4]$

D. F. Shriver, G. Joy III, and D. Greig

Department of Chemistry and Materials Research Center, Northwestern University, Evanston, Illinois 60201

In this communication we report observations on the Raman linewidths of some solid-state ionic conductors and suggest that measurements of this type may be useful in screening potential ionic conductors. Silver mercuric iodide and copper mercuric iodide, which have been well characterized by conductivity and x-ray structural studies (1-6) are known to undergo a transition somewhat above room temperature into a disordered phase which exhibits high Ag^+ or Cu^+ mobility. We investigated the variation of the Raman bandwidths as these two materials are taken through the order-disorder phase transition, and these results are compared with a related thallium compound, $Tl_2[HgI_4]$, which does not exhibit high ionic mobility.

The salts were prepared by literature methods (7, 8) and characterized by x-ray powder patterns and elemental analysis for Ag, Hg, Tl, and Cu. The samples were contained in 12 mm outside diameter Pyrex tubes which were rotated in a variable temperature spinning sample holder (9), and spectra were recorded with a Spex 0.85m double monochromator using backscattering sample illumination and digital data acquisition. Owing to instability of the samples under blue or green laser irradiation, the laser excitation wavelengths 632.8, 676.4, or 799.3 nm were employed. To minimize instrumental line broadening, the monochromator bandpass was maintained at one-half wavenumber or less. The laser power was typically between 5-15 mW, which in conjunction with the use of a line focus and sample spinning insures that local heating was negligible. Temperatures were measured by means of an iron-constantan thermocouple placed in close proximity to the sample.

The dominant feature in the spectra of all samples is a band at *ca.* 123 cm^{-1} (Fig. 1) which is assigned as the symmetric HgI_4^{2-} stretching mode by analogy with data on this species both in solution and in the solid state (10, 11). The A symmetry designation applies to this mode for the two HgI_4^{2-} ions in the S_4^2 unit cell characteristic of the β-phase. The corresponding formal designation is A_1 for the disordered (high temperature) α-phase which belongs to the T^2_d space group. Other features in this general region of the spectrum include two peaks at 80 and 105 cm^{-1} in the β-phase, which transform to a very broad feature centered around 84 cm^{-1} in the α-phase. From data on AgI (12) and a variety of AgI complexes (13), these bands are assigned as silver-iodine stretching modes. It is significant that these bands are broad at room temperature even though there is no evidence for disorder.

As shown in Fig. 1, the phase transition at 323°K for the silver salt brings about two very noticeable changes in the 123 cm^{-1} region: the 123 cm^{-1} feature

Key words: Raman spectra, solid electrolytes, phase change.

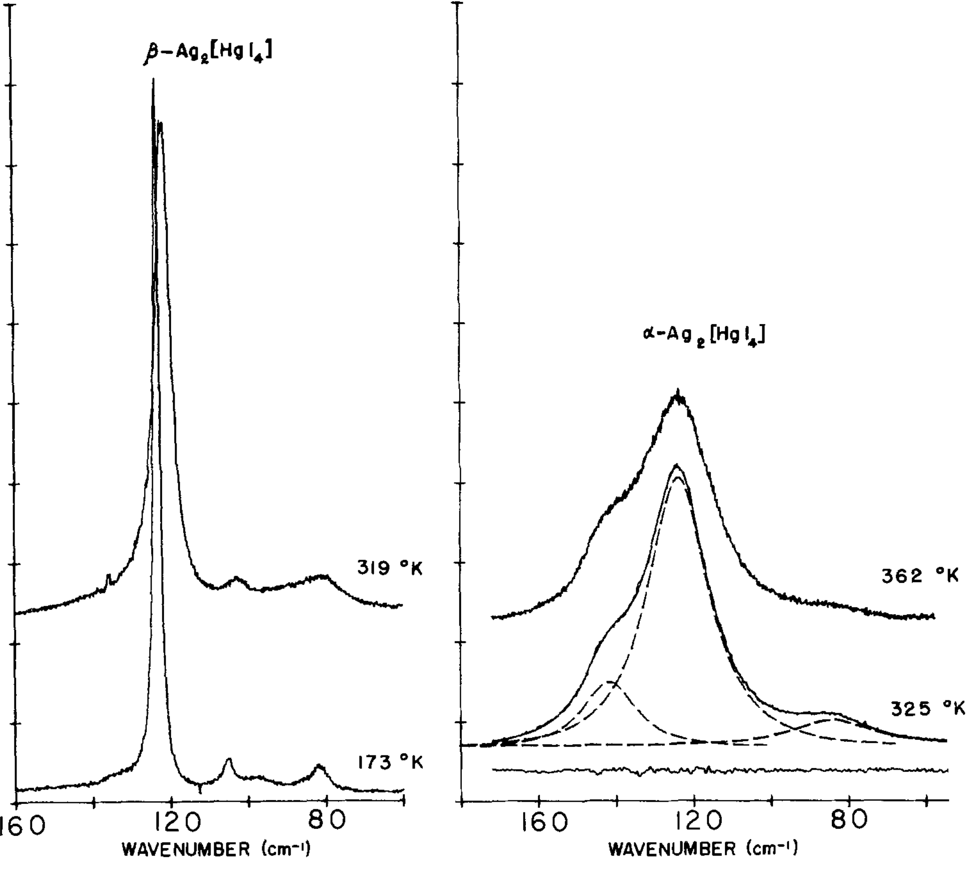


Fig. 1. Raman spectrum for the low and high temperature phases of $Ag_2[HgI_4]$ in the vicinity of 120 cm^{-1}. For the α-phase, resolved components of the spectrum are shown as dashed lines, and the difference between the observed and calculated spectra is displayed at the bottom.

is broadened considerably, and a distinct shoulder appears around 141 cm^{-1}. A similar broadening is observed for the corresponding band in $Cu_2[HgI_4]$ when the sample undergoes the order-disorder transition at 343°K, but it is not observed for $Tl_2[HgI_4]$, which does not appear to have a solid phase transition, and which is not a good ionic conductor (Table I).

Since disorder is a common feature in superionic conductors, the detection of disorder via Raman spectroscopy should be useful for identification of potential new conductors (14, 15). The utility of various screening techniques for ionic conductors has been discussed by Whittingham, who lists direct measurement of ionic conductivity, ion exchange, dielectric loss, and nuclear magnetic resonance as useful methods (16). As with NMR, the Raman measurement is a spectroscopic tool which can be applied very readily to polycrystalline samples if the basic Raman instrumentation is available. For example, we routinely employ Raman spectroscopy to characterize new heavy metal halide phases. The measurement may be carried out directly on the Pyrex or fused silica tube in which the sample was prepared, and as the Raman scattering cross sections for heavy metal halides are quite large, high sensitivity is obtainable. It also is a straightforward matter to perform the Raman measurements at a series of temperatures to detect the onset of disorder.

Table I. Linewidths at half-height vs. temperature*

	$Ag_2[HgI_4]$ (122 cm^{-1} band)			
Temperature, °K	173	319	332	391
Linewidth, cm^{-1}	2.0	4.7	19.8	24.5
	$Cu_2[HgI_4]$ (127 cm^{-1} band)			
Temperature, °K	153	342	355	
Linewidth, cm^{-1}	1.4	4.1	ca. 18	
	$Tl_2[HgI_4]$ (129 cm^{-1} band)			
Temperature, °K	153	295	405	
Linewidth, cm^{-1}	2.5	2.9	6.5	

* Transition temperatures: $Ag_2[HgI_4]$, 323°K; $Cu_2[HgI_4]$, 343°K.

The scope of the Raman method is different from that of NMR line narrowing because Raman spectroscopy is not limited by the existence of suitable nuclear properties for the mobile ion. On the other hand, Raman spectroscopy is not highly sensitive to light metal oxides, and therefore is not an attractive tool for β-alumina type systems where fluorescence from impurities tends to obscure the Raman spectrum unless careful sample preparation is employed. As with NMR, a positive Raman test will not ensure that the sample will be a good ionic conductor, but will indicate that the more complex conductivity measurements are warranted. High ionic conductivity will not accompany Raman line broadening if the disorder is localized between sites which do not communicate with the remainder of the crystal, or if the disorder is static, with little ion motion between sites. In principle, infrared line broadening could be used analogously to the Raman technique; however, the latter will generally be the most convenient, particularly with heavy metal halides.

There are several possible origins for the broadening of certain infrared and Raman modes in disordered phases. In the disordered phase, the wave vector, k, no longer retains its meaning so the $k \simeq 0$ selection rule is relaxed with the resulting observation of transitions over a range of the phonon dispersion. Disorder also introduces new decay channels for the lifetime broadening of optical transitions (17). Additional broadening will occur if the correlation time for ion motion occurs on an appropriate time scale (18). Finally, it is possible that a variety of discrete new structures in the disordered phase will produce a series of overlapping bands which give the appearance of simple line broadening. Clearly, the line broadening experiments contain potentially useful information beyond their application in screening; however, the unraveling of individual contributions to the broadening may be difficult.

The origin of the 141 cm^{-1} shoulder in the Raman spectrum of α-$Ag_2[HgI_4]$ is not obvious, but two alternate explanations appear likely. It may correspond to a maximum in the phonon density of states which is observed owing to a breakdown of the periodicity, or it may correspond to a discrete structural feature which is unique to the disordered phase. A likely new structure is the Hg_2I_7 moiety, which would arise in the crystal by the occupation of two adjacent tetrahedral sites by Hg^{2+} ions. Normal coordinate analyses on isolated HgI_4^{2-} and $Hg_2I_7^{3-}$ indicate that a high frequency mode should appear in the spectrum of the latter. Since the details are not essential to the purpose of the present note, further discussion of the 141 cm^{-1} feature will be deferred.

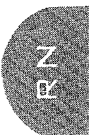
Energy—The Short and Long of It[1]

John S. Foster, Jr.
TRW Incorporated, Redondo Beach, California 90278

Thank you very much, President Beck, for that very generous and flattering introduction. At the outset I want to express my appreciation for the honor and privilege of being invited to present the semiannual Electrochemical Society Lecture.

I should begin with a few words about the title chosen for this lecture. Each of you has been called upon to make presentations and speeches from time to time. In addition you are asked to supply a subject and title. In my case the subject came easily—ENERGY. The rest of the title, however, was born out of a sense of frustration—frustration being experienced by almost everyone involved in energy; those who search for new sources and development and production, processes, distribution, and final use. And also those who are frustrated by the difficult and tedious social, political, economic, environmental, legislative, and legal aspects. This frustration has been growing for the last twenty years.

Perhaps it started with the debates in the early 1950's culminating in the 1954 congressional decision to regulate the price of gas at the wellhead. The subsequent controls to keep the price of gas low held down prices for oil and reduced our use of coal. We went to the Middle East for cheaper oil and became dependent on that source to fuel the future growth of America. And all the while we have been debating the pros and cons of our actions. We chose the course of enforcing cheaper fuel prices for energy at the risk of not facing up to the costs of energy for the long haul. In 1973 OPEC pulled the string on our short-term strategy realizing that by then we were ill prepared to do without them. So in spite of two decades of debate, the short and the long of it is that we are drifting deeper and deeper into trouble. It was the sense of frustration that despite endless debates we have stuck to the wrong course that prompted me to assume it might be possible to say something succinct, hence the title, "Energy—The Short and Long of It."



America and the rest of the world may have finally awakened to the fact that we have an energy crisis on our hands, and that it's going to get worse before it gets better.

Our energy needs are increasing while our supplies of oil and gas are dwindling. We're at the mercy of the petroleum exporting countries, more so today than we were at the time of the embargo back in 1973. We may have to deal with a shortage of natural gas this winter. And both oil and gas supplies are limited. One day they're going to be gone.

It's everyone's problem—government, industry, universities, the man on the street. The solution is going to be devilishly difficult, and everyone is going to have to get involved.

We need a plan of action, for both the short term and long term, if we're going to solve the dilemma. And that's a part of what I want to talk about today, at the risk perhaps of belaboring the obvious. Some things do bear repeating, lest we get so busy fighting alligators that we forget that our original objective was to drain the swamp.

It seems to me that the energy crisis and the way out of it can best be understood if we look at three fairly well-defined aspects of the problem. First off, there is the people problem, which has to do with the general public and its relationship to the energy crisis. Make no mistake about it, if we can't solve this one, if we can't get the public behind us, then "Project Independence" isn't likely to be any more successful than "Project Prohibition" was half a century ago.

Second, we have the problem of method and approach; how we're going to attack the energy crisis, arrive at decisions about what to do, the associated risks, and how best to use the nation's capabilities.

Third, there are the specific programs, schedules, and approvals for achieving our objectives. If the schedule slips too much, if we make too many wrong guesses about what we ought to be doing, the crisis is going to turn into a full-scale disaster.

Now let's look at the short and long of it for each of these categories.

The people problem.—Some of the shorts and longs of the "people problem" are: we're short on energy

[1] This is The Electrochemical Society Lecture delivered at the Dallas, Texas, Meeting of the Society, October 6, 1975.

resources, long on waste. Short on action and decisions, long on proposals, ideas, and schemes. Short on trust, long on suspicion. Short on personal concern and commitment, long on fingerpointing and accusations. Short on enabling legislation, long on restrictive legislation. Long on political profit, short on economic profit.

It's very difficult to get people, except those already deeply and professionally involved with energy, to realize that we do have a crisis. To most people, the energy crisis has come and gone. They want to keep their heavy and low-mileage cars. They want the thermostat up to 75° or 80° in the winter and down to 70° or 75° in the summer. We're short on the long view, long on the short view.

What we're going through right now is kind of like a remission in cancer: some of the symptoms have disappeared, but the disease is still there. We'd better do something to treat it, because it can be terminal.

The people are recovering, or trying to recover, from a series of painful blows. In the past few years, we've seen America all but torn apart by the controversy over Vietnam. We've lived through the shame and shambles of Watergate. We've held our breath and tried to resolve the Middle East crisis before it blows up in our faces. We've tried and are still trying to cope with runaway inflation in the midst of a recession. (Perhaps recession is not the right word. If your neighbor is out of work, that's an "economic readjustment." If you're out of work, that's a "recession." And if your wife is out of work, that's a "depression.")

Now, after all these overlapping traumas and crises, we're told that we have to learn to live with less oil for our furnaces and cars and electric power plants. Is it any wonder that people are either apathetic about the energy problem, or simply refuse to believe that it is a problem? Or that some are convinced that it's another high-level conspiracy designed to line the pockets of the "haves" at the expense of the "have-nots"?

Of course, it's actually a cop-out to even talk about the problem in the context of our own country exclusively. The fact is, and we all know this even though we may not like to admit it, the energy problem is a global one. Anything we do to cope with it on a national basis is only going to be a stopgap measure at best. We already consume 35% of the world's energy with only 6% of its population. How much longer can we get away with that?

There are some very tough choices that have to be made. President Ford realized this when he began to review the Project Independence Blueprint during his Christmas vacation last year. Every alternative seemed to have two or three unacceptable aspects to it. Some alternatives would play hell with the economy, others would further degrade the environment, almost all of them present severe economic problems. Everything interacts with everything else. We don't just have an energy problem, we have the Four Big E's: Energy, Environment, Economics, and Education.

Everyone who tries to cope with these problems suffers from some kind of built-in bias. Any program the President proposes has, of necessity, a political aspect and requires negotiation and compromise with the Congress. Each member of Congress has a constituency back home to answer to, with their own sets of built-in biases and regional interests. The same applies to industry; any changes they propose have to be evaluated in terms of profit-and-loss and accountability to the stockholders. Who among us is going to volunteer to become a nonprofit corporation in order to save a few barrels of oil? But the fact is we can save energy and make more profit.

It comes down to this: we're short on self-sacrifice, long on self-interest. That's what created the energy problem in the first place, and that's what's delaying the solution. It's going to take nothing less than a restructuring of all the old thought patterns, from the top down and from the bottom up. We've got to start living by the Golden Rule instead of just giving it lip service. And since America has been the biggest consumer of energy, I think it's pretty much up to us to take the lead in alleviating the crisis.

The method and approach.—How should we approach this amorphous mass known as the energy crisis? Some of the shorts and longs that apply here are: we're short on incentives, long on requests. Short on trained people, long on unemployed people. We're short on coordinated, integrated programs, long on individual pet projects. Worst of all, we're short on time, long on problems to be solved in time.

Dr. Edward Teller, in his report to the Energy Panel of the Commission on Critical Choices for Americans, said that we should not try to solve the energy problem forever. We can't expect to provide answers to all the new problems and possibilities that may show up in the 21st century. I think that's an important point to remember. It provides a sharper focus and makes the over-all problem a little more manageable.

We need to look at the whole picture, the four Big E's that I mentioned. In one sense, there's no such thing as solving the energy problem, the enviromental problem, the economic problem, the education problem any more than we can expect to solve the old age problem or the health care problem. We can only improve the situation in each case by solving hundreds and thousands of individual problems, one at a time.

It's different than going to the moon or fighting a war and it's even more complex. But some of the same tools and skills can be used and are being used. The systems approach, computer modeling and synthesis, these techniques help identify key elements of the problem, analyze various functions and how they interact, but the name of the game is to spot the leverage points that can increase the energy supply, reduce the cost, improve the environment, and motivate people to do their part.

There are a lot of dedicated people in industry, government, and education working on these problems. Of these the most immediate and pressing burden falls on those in government, for without question it is their judgments and actions which will chart our course toward energy independence. Unfortunately, almost all of these civil servants are terribly overloaded. Those at the top are very able people who must be involved in an enormously complicated and demanding range of activities. The coordination of government agencies, preparation and presentation of testimony, speaking engagements, program development and review are just part of the burden. To the levels below them falls the responsibility for creating analyses of important questions, program detail, endless meetings with support contractors, etc. With such heavy loads there is a tendency to handle each problem as it comes up and not be able to devote the time necessary to address and resolve the major problems.

It seems to me that the effectiveness of various agencies could be significantly improved, particularly in the energy areas, if the largest or more important efforts could be identified, and government/industry teams selected to give them the attention they deserve. While this may seem to be quite a departure from present practice, it is just the method we have used in the past—in World War II to produce synthetic rubber, in the late fifties to overcome the missile gap, and in the sixties to go to the moon and return successfully. In the same way, it seems to me we can forge government/industry teams to accelerate the development of *in situ* coal and shale, liquefaction and gasification of coal, and other areas where the name of the game is to reduce technical and economic uncertainties. In this regard one of the things our government does best is to take those actions necessary to improve the market environment by the removal of technical risk, provision of front end capital, etc. One of the things that government frequently does not do well is the implementation of programs; hence, the reason for suggesting a government/industry team.

It will take years to perform a complete analysis of the over-all energy problem and all the alternative solutions. But in the meantime, we can and must begin working on some of the major requirements that have already been identified, like expanding our coal production and usage, building more nuclear power plants, intensifying the search for new oil and gas deposits, and doing extensive research and development on new energy sources such as oil from shale, gas from coal, and solar energy conversion.

Of course the energy problem is nothing new to electrochemists. You've been working on more efficient ways to convert and store energy ever since the discovery of electricity back in the 18th century, and the contributions of electrochemists include batteries, fuel cells, and solar cells. Your work has made possible self-starting cars, portable radios, flashlights, calculators, manned flight, and long-term planetary probes. And today, electrochemistry still faces a host of challenges. The world needs low-cost, efficient ways of reducing our dependence on fossil fuels. Fuel cells, for example, can nearly double the efficiency of converting fossil fuels to electricity, provided low-cost, long-life catalysts can be found. Inexpensive photogalvanic or photovoltaic devices can provide us with an almost inexhaustible supply of energy. And economical, long-life, efficient secondary batteries can provide the load leveling needed to operate large coal and nuclear power plants at maximum efficiency. There's no doubt about it, you've got your work cut out for you. We all have.

Programs and schedules.—The things we have to do to deal with the energy crisis are related to our two major objectives: reduce energy demands and find new energy resources. It sounds a lot simpler than it really is.

For the short term, I see at least six steps that need to be taken, all of which will help for the long term, too. They are: conservation, building a reserve supply, finding new gas and oil deposits, switching from petroleum to coal wherever possible, stepping up construction of nuclear power plants, and, last but by no means least, training the necessary talent. For the long term, we have only one step to take, but it's a giant one: we have to find new substitutes, in addition to nuclear power and coal, to replace the oil and gas which will all be gone within the next generation or two unless of course we can gain a little time through the unlikely discovery of major new deposits that we don't yet know about.

Eliminating waste through conservation can relieve the energy crunch faster than any other single step. This will also alleviate the economic crunch to some extent and, in many cases, ease the environmental pollution problem. It's amazing but true that even a one per cent saving or improvement in efficiency would reduce our oil consumption by 100 milion barrels each year. At today's prices, that's more than a billion dollars saved. There are other fringe benefits, too. For instance, the 55 mile-per-hour national speed limit, even though it's pretty loosely enforced, not only saved a lot of gas but reduced highway fatalities by 20% in 1974. (Apparently this idea of taking things slower is catching on with the younger generation. My secretary tells me that the kids are not only driving slower, they're even dancing slower, and closer, too.)

The automotive industry has finally embarked on a program of conversion to energy-saving cars. It's been a slow and painful process, but it's working. To the rest of industry, conservation means planning for the future in new ways like more efficient heating and cooling systems, more efficient machines and equipment and use of materials. To labor, conservation may mean the loss of some jobs for the short term, but it will mean more jobs in the long run as more energy becomes available for critical industrial needs, and as new sources of energy are developed.

But what about the man on the street again? What can be done on an individual basis to make people stop wasting energy? The whole thrust of the American way of life has been the idea of upward mobility, increasing our standard of living, and that means burning up more energy. But we must have the cooperation of the general public or we're not going to solve the energy problem. Government and industry need the public's support and confidence. We've got to work like the devil to restore the people's faith in their leaders and in science and technology. Beyond that, we've got to somehow get people to do what's best for the greater number, even if it means giving up some of their personal conveniences. This may require rationing and enforced scarcity, unless we can find the kinds of incentives that will make it happen voluntarily.

Close on the heels of this conservation program, we need to begin building a reserve stockpile of gas and petroleum. We should start small, say, a six-month supply, while continuing to study the situation to figure out whether we really need a six-month, two-year, four-year supply or whatever. This will help take us out of the panic mode and also put us in a little better negotiating position. Naturally, this plan is not going to work unless we can make the first step, conservation, work.

We've got to keep looking for more oil and gas, that goes without saying. We need to explore the outer continental shelf, in spite of the risk of pollution. The techniques to avoid blowouts and spills or to minimize their consequences are improving every day. The risk is small, but in my view it is one that we have to take. It is, after all, a much smaller risk than the one we're already taking—the risk of running out of oil altogether before we have a viable substitute.

Further, we need to switch from oil and gas to coal wherever possible and to step up production of coal, for which the supply is numbered in hundreds rather than tens of years. To make the switch, we have to solve some economic problems and environmental problems, but they are within the reach of today's technology. We can't just sit back and say that we mustn't burn coal because it pollutes, or because it's too expensive to convert the power plants. We can raise the money and we can control the pollution.

Nuclear power offers one of the most promising ways to get out from under our petroleum dependency, in spite of the economic problem and public controversy associated with it. There is concern about reactor safety, radiation exposure, waste management, and terrorism. Some of these fears are valid, but so is the need to build reactors. We should get to work in both areas, but with a new partnership between government and industry.

Finally, we need to increase the supply of trained professionals in the energy fields. We look to the universities and colleges for the solution to this problem but government and industry can help by publicizing their needs. We need specialists in fossil energy, solar energy, geothermal energy, and nuclear energy reactors. And we need people whose interests and education span more than one discipline. We've got to avoid the kind of polarization we've seen in recent years that pits the environmentalists and the energists against one another, and the economists against both.

For the long term, we must start now to look for the substitutes that will keep us going after the gas and oil run out. There are enormous uncertainties, and it's going to take continuing study and experimentation to remove these uncertainties so we can decide where to spend our time and money.

For example, we need to work the oil shale, particularly in situ approaches to find out whether the oil can be extracted economically and what the environmental considerations are. We need to drill more geothermal wells to find out whether in fact we have enough resources to provide the estimated 20,000 megawatts of

electric power we need by 1985. There's little point in solving the technological problems if the resources aren't there. We need to put a lot of effort into experimenting and evaluating the opportunities from solar energy. But here again, there are a host of social, and financial as well as technical problems to be identified and solved.

The short and the long of it is that we have perhaps two to three years to adjust the international political and economic situation to avoid the strangulation of several of our allies. We have from five to ten years to find several major new sources of oil and gas, and fifteen to twenty-five years to develop alternative energy sources before the oil and gas are gone. These are the milestones we must pass, and on schedule.

It isn't going to happen by accident, or by executive fiat, or by legislation. It will happen only if everyone works together instead of at cross-purposes; scientists, energists, environmentalists, politicians, economists, businessmen, and educators being concerned and working together for the common good.

During the next four days of sessions and discussions many of you will have your minds on the general subject of energy, and within the discipline of electrochemistry which permits us to solve many of the problems that limit not only the availability of energy, but also the flexibility and efficiencies in its use. I hope these remarks will turn out to be of some value in your deliberations. My time is up as of this minute, I thank you for yours.

REVIEWS AND NEWS

FEBRUARY 1976

Marcel J. N. Pourbaix—Palladium Award Medalist

R. W. Staehle[1]

R. W. Staehle delivers introductory remarks about the Palladium Award Medalist.

It is a great honor for me to introduce Marcel Pourbaix on the occasion of his receiving the 1975 Palladium Medal from The Electrochemical Society. Pourbaix represents not only a specific set of contributions but signifies an important era in the development of corrosion science and engineering. It is certainly appropriate that The Electrochemical Society bestow its highest honor on a person who has contributed so extensively and so generously.

I should like first to review briefly important aspects of his early history. Secondly, I should like to comment on Pourbaix the man since the products of a man are so closely related to his personal inclinations.

The task of preparing this presentation was facilitated by a recently published biography of Pourbaix prepared by B. F. Brown describing Pourbaix's background (1) on the occasion of his seventieth birthday.

Pourbaix was born in 1904 in Myshega, Russia, of Belgian parents. He was graduated from high school in 1922 and received, for his scholarship, the Prix d'Excellence from the Belgian government. In the same year he was admitted to the Faculty of Applied Science of the Université Libre de Bruxelles.

In 1927 Pourbaix graduated "with great distinction" from the Université Libre de Bruxelles and served as an assistant from 1927-1928. He received his first exposure to engineering during the period of 1928-1934 while he was an engineer in the Belgian Chemical Union. Thereafter, he returned to U.L.B. where he has been ever since. Here, he worked on problems of general chemistry, electrochemistry, applied physical chemistry, catalysis, and metallurgy.

By 1938 he had devised a potential-pH diagram and first published it in the bulletin of the Belgian Chemical Society (2).

In 1940 Pourbaix delivered to the Faculty of Sciences an extensive dissertation entitled: "Experimental Contributions to the Study of Corrosion on Ferrous Metals." This large thesis was accompanied by three ancillary ones; the title of one was "Thermodynamics of Dilute Aqueous Solutions" which was submitted to the Technical University of Delft with F. E. C. Scheffer and W. G. Burgers as sponsors. He finally received two doctoral degrees, one from the Technical University of Delft and one from the University of Brussels.

Even before World War II U. R. Evans had been impressed by the elegance of Pourbaix's presentation and had encouraged him. Following the War, Evans arranged for John Agar to translate "The Thermodynamics of Dilute Aqueous Solutions;" this was published in 1949 by Arnold publishers (3) with an extensive foreword by U. R. Evans.

In Evans' foreword to Pourbaix's first book he noted: "It is likely that the research group at the Université Libre de Bruxelles, which Dr Pourbaix is now organizing, will come to be one of the world's centers for the experimental and theoretical development of the numerous subjects on which he is now working."

We have seen Evans' prediction realized. Most of the details since that time are chronicled in the article by Brown (1).

Turning now to Pourbaix, the man, and his effect on his science, I wish to enumerate three themes which seem to characterize him. First, he has a highly developed intuitive concern for the structure of things. This applies not only to his technical views but also to the structure of institutions in which the technical processes must be encouraged and developed. The potential-pH diagram, *i.e.*, the Pourbaix diagram, provides such a structure for arranging important information with respect to key thermodynamic variables. His selection of potential and pH was a master stroke in organizing information relative to corrosion. The potential controls the solubility of metals relative to their ions; and the pH controls the stability of the protective films. Pourbaix was always careful to point out that the diagrams furnished a framework within which kinetic process might be interpreted, but that the thermodynamic predictions were never a substitute for kinetic information. The potential-pH diagram furnishes a framework within which the kinetic information can be organized, much the same as the binary equilibrium diagram of metallurgy, with its coordinates of temperature and composition, furnishes a similar

[1] Introductory remarks by R. W. Staehle, Department of Metallurgical Engineering, The Ohio State University, on the occasion of the presentation of the Palladium Medal Award to Marcel J. N. Pourbaix on October 7, 1975, at the Dallas Meeting of the Society.

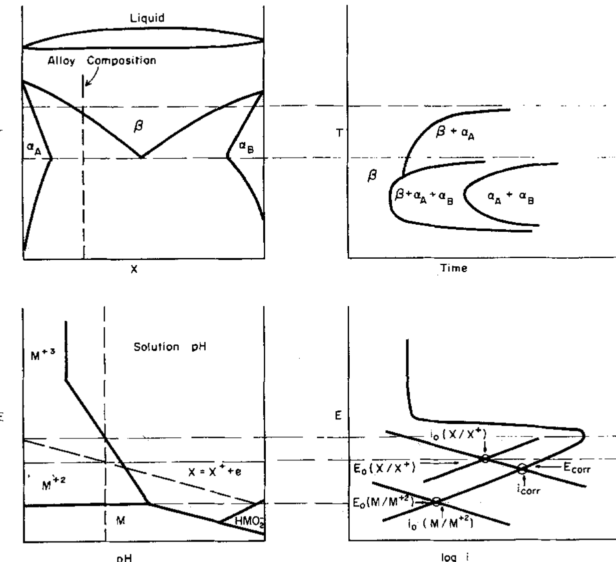

Fig. 1. Upper two diagrams show schematic relationship between binary equilibrium diagrams and TTT curve. Lower two diagrams show relationship between Pourbaix diagrams and polarization curve. Diagrams at left are thermodynamic and at right are kinetic.

framework for the TTT curves. This correspondence is shown in Fig. 1.

On this occasion, it would be somehow inappropriate not to show a sample of his diagrams and the appropriate one is for palladium shown in Fig. 2. The regions pertinent to corrosion are shown as based upon the solubility or boundary lines. Here palladium is in its immune state below line 2 where the metallic palladium is stable. Above line 2 a succession of hydroxides and oxides are stable and provide the circumstance of passivity. To the left, Pd^{++} is stable and suggests the possibility of corrosion.

An important aspect of his concern for structure is his early observation that the diagrams applied not only to corrosion but also to a broad range of chemical phenomena. In particular they supply a framework within which to consider geochemistry, electroplating, batteries, water treatment, and both homogeneous and heterogeneous chemical processes.

Pourbaix's concern for the structure of things has also produced important institutional pillars within which corrosion science and technology operate. This includes significant publications as well as organizations devoted to corrosion and electrochemistry. The encyclopedic "Atlas of Electrochemical Equilibria in Aqueous Solutions" (4) provides immediate access to these important diagrams. These diagrams have served as models for the development of other equilibrium diagrams which describe chemical stability. A relatively recent noteworthy development applies the concept of these diagrams to hot salt corrosion in gas turbines where the stability diagram for aluminum in sulfur-containing environments has been developed, by Goebel *et al.* (5). The correspondence of the hot salt and aqueous diagram is shown in Fig. 3. Finally, his recent publication, "Lectures on Electrochemical Corrosion," embraces both the thermodynamic and kinetic bases which underlie corrosion.

Pourbaix founded CITCE in 1949. CITCE is an acronym for the International Committee for Electrochemical Thermodynamics and Kinetics where both the kinetic and thermodynamic aspects for corrosion and electrochemistry are subjects of joint consideration. He founded CEBELCOR in 1951 which serves as the institutional basis for combining science and engineering in the service of corrosion. CEBELCOR is again an acronym, for the Belgium Corrosion Center.

In 1952 Pourbaix founded the Electrochemistry Commission of the International Union of Pure and Applied Chemistry; he was the founder of working group six (test and control methods) for the European Federation of Corrosion. In 1970 he formed the corrosion department of the University of Brussels and in 1972 developed a collaboration with the University of Florida.

The second thematic stream in Pourbaix's background seems to be based upon a strong incentive to relate fundamental understandings to the needs of the world at large. In the present vernacular this is called "technology transfer." However, Pourbaix's personal efforts have epitomized the concepts in technology transfer throughout his career. He is the first of the corrosion missionaries. He has established short courses, which he terms "corrosion weeks," in Brussels, Pittsburgh, Gainesville, Lisbon, Rio de Janeiro, Dubrovnic, and Clermont. He has been unceasing in his enthusiasm for spreading the gospel of corrosion. To use the words energetic and peripatetic in this enterprise seem most appropriate. The zeal and selflessness which he has exhibited in this enterprise deserve, by themselves, the Palladium Medal.

Finally, and perhaps most characteristic of Pourbaix is his personal generosity, He encourages young workers to dedicate their enthusiasm and confidence to unravelling the complications of corrosion problems. He never recoils from starting yet again with still another young mind. He has especially encouraged the development of new groups in developing countries.

Another side of this generous spirit is epitomized in his charming tradition of sending postcards to corrosionists throughout the world. He always arranges for a card to be sent to U. R. Evans from significant meetings and often arranges to have those present add their

signatures. He is unfailing in this acknowledgment of those who have gone before him and who have contributed to the foundations upon which his work has spread still further.

It is especially appropriate to conclude this introduction by acknowledging his wife, Marcelle. He gives her loyal and unfailing support which she returns to him. They have three children. One is an architect, one a doctor, and one his successor. They have a charming country home outside Brussels where Mme. Pourbaix raises flowers from seeds obtained during their corrosion travels. In addition to being a charming companion, Mme. Pourbaix is a significant artist in her own right and specializes particularly in sculpture.

I omit an enumeration of the honors which have been accorded to Pourbaix. These may be found readily in the article by Brown. Further, listing the honors which he has received would be redundant. For Pourbaix the honor has always been in the giving.

Some Applications of Potential-*p*H Diagrams to the Study of Localized Corrosion

Marcel Pourbaix[2]

Marcel J. N. Pourbaix presents the Palladium Medal Address

Dear Roger, you are really, as everybody knows, a fine, fair, and faithful friend. Thanks a lot for your very kind words.

Dear Ted and Mr. President, first of all I wish to express to The Electrochemical Society and to you my feelings of deep gratitude for having extended to me such a high distinction, which enables me, as Palladium Medallist, to join eleven outstanding friends of the United States and of other countries, among whom two are present today: Herb Uhlig and Norman Hackerman. Referring to the six non-American medallists (Carl Wagner, Ulick Evans, the late Karl Bonhoeffer, Aleksandr Frumkin, Thomas Hoar, and Veniamin Levich), as well as to Paul Delahay who is also from Belgium, I may tell you how much the Palladium Medal since the day it was created, has been appreciated throughout the whole world, and how much it has contributed to promoting international friendship and collaboration, which is a duty for all of us. In the kind presentation which was published in the September issue of the **Journal** of your Society, the creation of CITCE in 1949 was mentioned. I wish to remind you that one of those who has actively contributed to the creation of CITCE is Pierre Van Rysselberghe, who, for reasons of health, is unable to attend the present meeting, who also comes from Belgium, who is presently retired from Stanford Uni-

[2] Palladium Medal Address delivered October 7, 1975 at the Dallas Texas, Meeting of The Electrochemical Society. The medal was struck from palladium supplied by the International Nickel Company, 67 Wall Street, New York, New York 10005.

versity, and who was the first president of CITCE. I also wish to pay tribute to my many friends, and especially to the members of the team of CEBELCOR, who have collaborated on the work which is crowned today by the Palladium Medal.

Passivation by Palladium

Mr. President, ladies and gentlemen, as you all know, palladium is really a fine metal, which altogether is corrosion-resistant in most environments and has practically no overpotential for the hydrogen evolution. This means that, if palladium is in contact with another metal under conditions where hydrogen may be evolved under atmospheric pressure, its electrode potential is along the "hydrogen line" α of the potential-pH diagrams (Fig. 1). If this line is in the corrosion area of another metal, as is generally the case for iron (Fig. 2), it will promote corrosion of this metal because it will increase its corrosion affinity, which is measured by the vertical distance between the electrode potential of the metal and its immunity potential. But if the hydrogen line α is in the passivity area of a metal or alloy, and above its corrosion area, palladium may promote passivity, and thus reduce or even stop corrosion. This is in agreement with the work which was begun in 1953 by N. D. Tomashov and co-workers concerning the influence of "cathodic additions" (Cu, Ag, Pt, Pd, Re) on the passivating ability and the corrosion resistance of some high-alloy steels (1) [see details in Ref. (2)], it's being understood that such an effect may be beneficial only if the corrosion area of the alloy steel (Fig. 3 and 4), which depends notably upon the nature of the steel, is not too close to the hydrogen line; if too close, or if the passivity is not perfect due for instance to a too high chloride content of the solution, palladium may be harmful instead of being beneficial. Palladium should thus be used only with precautions for improving the corrosion resistance of alloy steels. A similar, and more spectacular and safe effect of palladium, exists on titanium which, as shown in Fig. 5, has a corrosion area far below the hydrogen line and may be perfectly passive even in the presence of chloride. And this is why, as shown by the fine work begun in 1958 by M. Stern (3) and begun in 1961 by N. D. Tomashov (2, 4), the addition of palladium to titanium may be very beneficial. As said in 1970 by M. G. Fontana (5), "one of the great triumphs of corrosion science is the development of titanium alloys containing noble metal additions." However, it should be borne in mind that these noble metal additions may be effective only when the dangerous "corrosion triangle shown in Fig. 3, 4, and 5, is entirely below the hydrogen line α, and preferably far below, so that any danger of localized corrosion (crevice corrosion, and eventually stress corrosion cracking) be avoided. In the cases of both alloy steels and titanium, palladium may be used either as alloy-element or as a deposit on the metal (2).

But, Ted, I think that you know more than I about titanium. As far as palladium is concerned, I hope that I shall resist the temptation to use the beautiful specimen which International Nickel and you just gave to me for making corrosion and protection experiments.

I shall now present two examples of the application of potential-pH diagrams to the study of localized corrosion phenomena and to the setting up of remedies to such corrosion relating respectively to copper, to iron, and to their alloys.

Localized Corrosion of Copper and of Copper Alloys

In 1961, the International Copper Research Organization, INCRA, asked CEBELCOR to try to elucidate some fundamental electrochemical aspects of the pitting corrosion of copper tubes in cold water, which was at that time a severe problem in several countries such as Belgium, Germany, The Netherlands, the United Kingdom, and the U.S.A., but not in France.

Thanks to pioneer work performed in the U.K. in the early fifties by H. S. Campbell (6) and R. May (7), it was already known that most copper pits contained white cuprous chloride, CuCl (7); and that the existence of pits was often associated with the presence on the surface of the metal of a carbonaceous film formed during manufacture of the tubes (6a) attributed to breakdown of drawing lubricant residues during bright annealing of the half-hard tubes. However, copper tubes covered with such a "deleterious film" did not pit in all waters: no trouble occurred in some surface waters, such as the water of the river Thames, containing an unidentified organic fluorescent inhibitor (6b). The circulation of electric currents between external cathodic areas and internal anodic cavities had already been observed, but it was also observed by R. May that, for some unknown reason, the currents sometimes flowed "in the wrong direction": the pit sometimes became "cathodic" instead of "anodic."

In the research which we undertook in this field (8), we first tried to form artificially a pit similar to the natural ones by simply immersing in running Brussels water a copper plate on which was sealed a thin plastic tube containing some CuCl (Fig. 6); but, after about a month of immersion, we observed with surprise just the contrary of what we expected: instead of a pit there was a deposit of metallic copper under the CuCl-containing tube. We then used another experimental device (Fig. 7) consisting of a series of glass tubes containing open sections of copper tubes cut at 120°. Water was passed continuously through the glass tubes at a velocity of 20 mm/sec, and, as a function of time, we measured the values of the electrode potentials of the copper specimens and we observed visually their surface conditions. Tests were also made on thin copper wires, where the development of a pit was detected by a rupture of the wire.

Figure 8 shows a typical electrode potential-time curve for 10% PO_4H_3-pickled electrolytic copper in flowing Brussels water. During a first period of about ten days, the electrode potential remains at relatively low values (about -50 to -10 mV_{sce}) and the surface becomes covered with a reddish deposit of cuprous oxide Cu_2O; during a second period of about ten days, the potential increases steadily to about $+40$ mV_{sce}, and some greenish flakes of basic carbonate malachite $CuCO_3 \cdot Cu(OH)_2$ are progressively formed on the surface; during a third period, periodic drops and rises of electrode potential occur.

We observed that illumination of the copper with a 200W tungsten flash lamp (which we used occasionally for observing the surface condition of the metal) does not affect its electrode potential during the first period shown in Fig. 8 (after 1 hr at -38 mV_{sce}) (Fig. 9), but during the third period (after 145 days at $+77$ mV_{sce}) it promotes very quickly, during a fraction of a second, a considerable potential drop of about 320 mV (until -250 mV_{sce}), which is only temporary. We also observed that a stagnation of the water (Fig. 10) leads, during the first period, to a slight increase (of about 20 mV) of the electrode potential, but that, during the

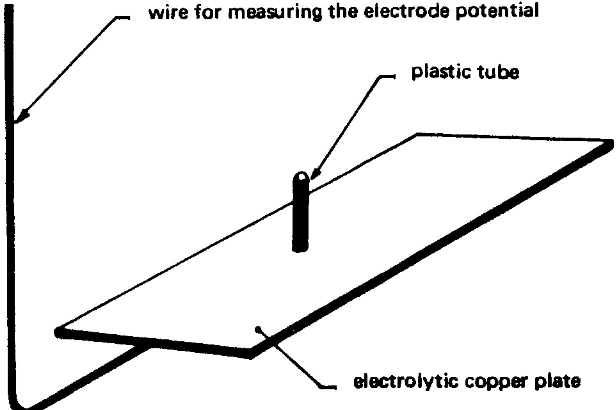

Fig. 6. Copper specimen used in experiments for attempting to produce artificial pits (first attempt).

third period, it promotes a slow and important decrease of the potential to the same value as does illumination (-250 mV_{sce}), and this also temporary. I have to confess that these funny results were at that time quite incomprehensible to us, and that they even led some members of the team working with us to question the interest and the validity of electrode potential measurements. Besides this, we had performed numerous potentiokinetic and potentiostatic experiments, most of which were helpless and hopeless, until finally, after having tested for about 155-367 days 207 specimens of different composition (electrolytic copper, deoxidized phosphorous, arsenic, etc.), of different initial surface conditions (pickled, as coming from the factory, with or without "aquablasting," etc.), isolated or coupled with graphite or with different metals (gold, platinum, rhodium, silver, tin), with or without some additions (Fe^{++}, MnO_2, NaClO) to the Brussels water we were using for the tests, we made an unexpected observation which brought hope and confidence back to us (Fig. 11 and 12).

Among these 207 specimens, 51 did show pitting and the 156 others did not. And, all the 51 pitted specimens had reached, during the third period of the experiments conducted with the device shown in Fig. 7, an electrode potential higher (*i.e.*, more positive) than a critical value, which was about $+100$ mV_{sce} for wires and $+170$ mV_{sce} for tubes; these specimens were the only ones which reached such high values: all the 156 other specimens, which did not show pitting, had lower potentials. In trying to understand our experimental observations, we looked to cross sections through copper pits and we used potential-*p*H equilibrium diagrams.

Figure 13 shows a cross section through a copper pit in Brussels water. At the bottom of the pit there is some white cuprous chloride, CuCl, and a large amount of reddish cuprous oxide, Cu_2O; the top of the pit is covered with green malachite $CuCO_3 \cdot Cu(OH)_2$ (with some white calcium carbonate, $CaCO_3$). Needless to say, the solution in the presence of which the copper pit develops is not the bulk of the water, but a solution saturated in both CuCl and Cu_2O. Figure 14 shows a

further cross section through a copper pit, similar to the one shown in Fig. 13, which clearly shows that most of the Cu_2O has disappeared from the cavity and is thus a loose secondary corrosion product.

Figure 15 shows a potential-*p*H equilibrium diagram for the binary system Cu-H_2O, at 25°C where, notably, the equilibrium conditions of Cu, Cu_2O, and CuO, may be seen; in the presence of pure water of *p*H 7, the stable oxidation product of copper is Cu_2O if no oxygen is present; it is CuO if oxygen is present. Figure 16 shows a potential-*p*H equilibrium diagram for the

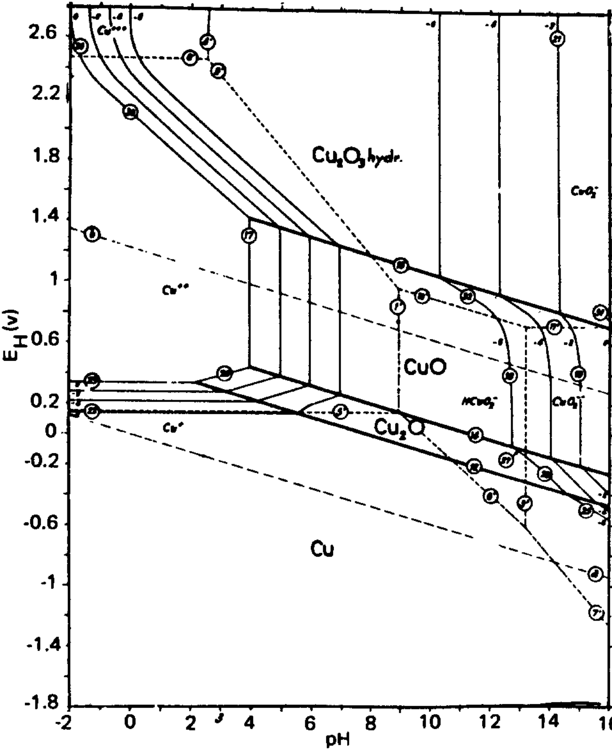

Fig. 15. Potential-*p*H equilibrium diagram for the copper-water system at 25°C.

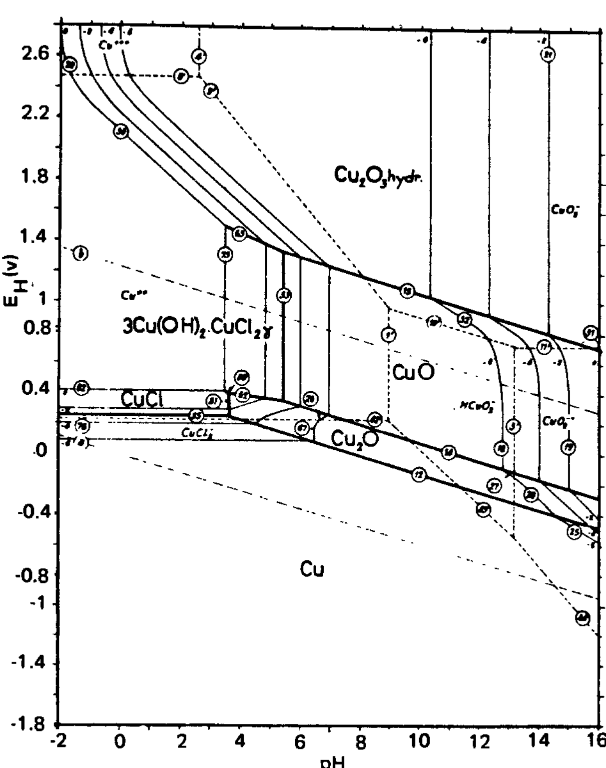

Fig. 16. Potential-*p*H equilibrium diagram for the three-component system, Cu-Cl-H_2O, for solutions containing 355 ppm Cl^- (10^{-2} g · ion/liter).

ternary system Cu-Cl-H_2O valid for solutions containing 10^{-2} g·ion Cl^-/liter, which is about the amount of Cl^- in a solution saturated in CuCl. This figure shows that CuCl is not stable in a neutral solution of *p*H 7, where the stable form of univalent copper is Cu_2O; CuCl should thus, in such a solution, hydrolyze according to the reaction $2CuCl + H_2O \rightarrow Cu_2O + 2H^+ + 2Cl^-$. The only point of the diagram where Cu, Cu_2O, and CuCl, which are coexisting at the bottom of a pit, are simultaneously stable, is the point of intersection of the three lines 12, 51, and 55. This point, whose coordinates are $E = +270$ mV_{ehs} and $pH = 3.5$, thus represents the equilibrium conditions at the bottom of the pit. For this point, the equilibrium concentrations in dissolved copper are, assuming that the solution is "perfect": $10^{-2.44}$ as Cu^{++}, $10^{-3.37}$ as $CuCl_2^-$, and $10^{-4.31}$ as Cu^+, *i.e.*, a total of $10^{-2.43}$ (or 234 ppm) dissolved copper; the equilibrium concentrations in dissolved Cl are $10^{-2.17}$ as Cl^- and $10^{-3.07}$ as $CuCl_2^-$, *i.e.*, a total of $10^{-2.12}$ at·g/liter or 270 ppm dissolved Cl. Under these conditions of electrode potential and *p*H, the corrosion reaction of copper is reversible; it is thus easy to understand that any such pit will grow if the electrode potential inside the pit is higher (more positive) than +270 mV_{she} (*i.e.*, +20 mV_{sce}); on the contrary, such a pit will be stifled, with redeposition of metallic copper, if this electrode potential is lower (more negative) than +270 mV_{she}. And this is the very simple criterion which governs the problem of copper pitting in waters containing some chloride: for avoiding the development of copper pits in such waters, it is necessary and sufficient to prevent any increase of the electrode potential inside the cavities above +270 mV_{she} (or +20 mV_{sce}). As electrode potentials inside cavities are usually not easily measurable, it is convenient to correlate them with the electrode potentials outside the cavities (Fig. 17) which, due to the existence of a diffusion potential, are generally about 80-150 mV higher (about +350 to +420 mV_{she} or +100 to +170 mV_{sce}). And we thus have the explanation of the critical protection potential against copper pitting (about +100 to +170 mV_{sce}) which was observed experimentally.

Figure 18 shows, together with the theoretical corrosion-immunity and passivation conditions of copper in water at 25°C, the equilibrium conditions inside a copper pit ($E = +270$ mV_{she} and $pH = 3.5$) and the possible extreme electrode potential values of copper in the presence of water of *p*H 8 (from 0 to about +600 mV_{she} according to the oxygen content of the water and to the surface condition of the metal). One sees that the protection potential against copper pitting (about +350 to +420 mV_{she}) lies between these two possible extreme values, and that copper pits may thus, in fact, grow or be stifled.

This criterion was in harmony with all previously known facts and has opened the way to new methods of protection and control. The presence of carbon on the surface of copper, which, thanks to H. S. Campbell (6a), has been known since 1950 to promote pitting, increases the electrode potential of more or less perfectly passive copper up to about +300 mV_{sce}, *i.e.*, much above the critical value (8b). The addition of ferrous sulfate to seawater, which was shown in 1961 by T. W. Bostwick to prevent the pitting corrosion of brass exchanger tubes (9), depresses the electrode potential below this critical value. Extensive exposure trials of different kinds of copper tubes in different water supplies with measurements of the electrode potentials have been recently performed by F. J. Cornwell, J. Wildsmith, and P. T. Gilbert (10). As shown by Fig. 20 and 21, all the results of these tests are in full agreement with the above-mentioned criterion: whatever the metal and whatever the water, pitting only occurs (and always occurs) if the electrode potential is higher than about +100 to +170 mV_{sce} (*i.e.*, +350 to +420 mV_{she}).

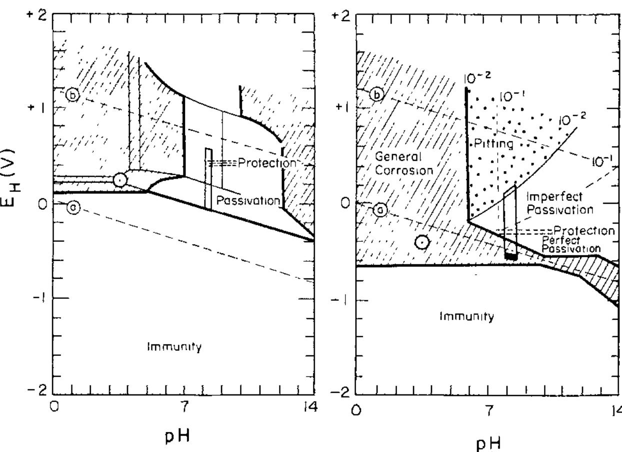

Fig. 18. (left) Copper in Brussels water. *p*H and electrode potential conditions inside pits in equilibrium: $pH = 3.5$, $E = +270$ mV_{she}. Possible electrode potentials outside pits at $pH = 8$: $E = 0$ to +600 mV_{she}. Protection potential against localized corrosion: about +350 to +420 mV_{she}.

Fig. 19. (right) Armco iron in solutions containing chloride (10^{-2} and 10^{-1} g · ion/liter). *p*H and electrode potential conditions inside oxygen-free living pits: $pH = 3.8$, $E = -325$ mV_{she}. Possible electrode potentials outside pits at $pH = 8$: $E = -0.5$-0 mV_{she} for 10^{-2} g · ion Cl^-/liter. Protection potential against localized corrosion: about −300 mV_{she}.

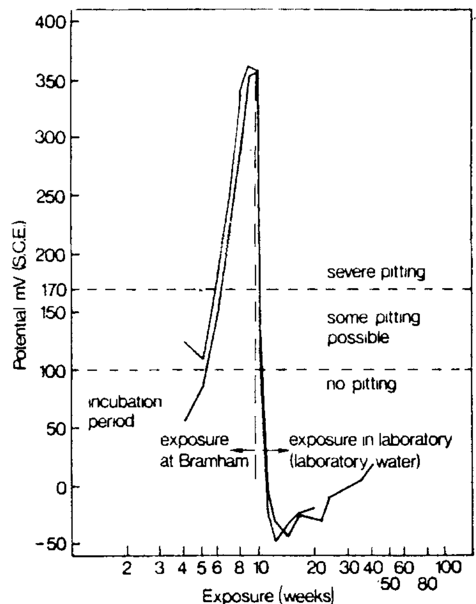

Fig. 20. Effect of transferring uncleaned copper tubes undergoing pitting at Bramham to the laboratory (Leeds water), after Cornwell *et al.*

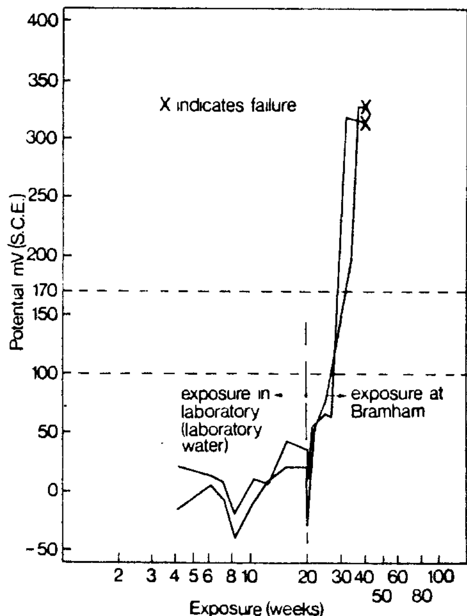

Fig. 21. Effect of transferring uncleaned copper tubes from the laboratory (Leeds water) to Bramham, after Cornwell et al.

Since 1962, new precautions and new remedies have been suggested as a result of this criterion, being understood that, if not only pitting corrosion but also any general corrosion should be avoided, the protection potential should be dropped from +270 to +100 mV_{she} (or from +20 to −150 mV_{sce}). When in the presence of a corrosive water or of a corrosive atmosphere, copper should not be in contact with any substance whose zero-current electrode potential in the considered environment is higher than the critical one, such as carbon and gold, for example; and this explains the recently observed deterioration of so many bronze sculptures which were covered with a porous gold deposit (the doors of the Baptistery in Firenze, the horses of Praxiteles in Venice, etc.). Silver and tin have lower electrode potentials and are thus not harmful to copper, and this is why silvered and tinned copper utensils may be used for cooking. Since about 1966, the copper hot-water tanks placed on the roofs of many houses in London, whose corrosion has been for many years the source of great concern, have been protected cathodically after a recommendation of B.N.F.M.R.A., using temporary so-called "protector rods" of aluminum alloys which depress the electrode potential below +100 mV_{she} (11). A general method has been proposed for checking the pitting susceptibility of different sorts of copper and of copper alloys in different waters (Fig. 25) (8d, f, g), as well as for clarifying the mechanism of dealloying copper alloys, such as the removal of nickel from copper nickels and the removal of zinc from brasses (12, 13). However, much work remains to be done before these problems might be considered as really mastered.

Now, coming back to the experiments which were mentioned at the beginning of this talk, what is the mechanism of copper pitting? What is the explanation of the "funny results" which were obtained concerning the influence of light and stagnation on the electrode potential?

During the first stage of the experiment, whose results are shown in Fig. 8, copper undergoes general corrosion in the bulk of the water (Fig. 22) with formation of Cu^+ and Cu^{++} ions and, eventually, solid CuCl which hydrolyzes, for instance according to the reaction $2CuCl + H_2O \rightarrow Cu_2O + 2H^+ + 2Cl^-$, with formation of solid Cu_2O which deposits on the metal and of hydrochloric acid HCl which is washed away by the water. According to Fig. 23, which is the equilibrium potential-pH diagram of the quinary system $Cu\text{-}Cl\text{-}CO_2\text{-}SO_3\text{-}H_2O$ for the contents of Cl, CO_2, and SO_3 existing in Brussels water, malachite $CuO_3 \cdot Cu(OH)_2$ is the stable form of copper in the presence of aerated Brussels water of pH 8 (e.g., at point 3) and this is why, during the second stage of the experiment, Cu_2O becomes progressively covered with malachite which, being relatively protective (8e), forms a screen which progressively prevents the hydrochloric acid from being washed away by the bulk of the water. The pH inside the cavity thus decreases until, when the third stage is reached, the solution inside the cavity becomes saturated in CuCl which is being deposited on the metal; the solution inside the cavity then has a pH of about 3.5 and is then about 0.01M in CuCl; as previously stated, the cavity increases in depth with dissolution of copper if the electrode potential is higher (more positive) than +270 mV_{she}; on the contrary, the pit heals with redeposition of metallic copper if the electrode potential is lower (less positive) than +270 mV_{she}.

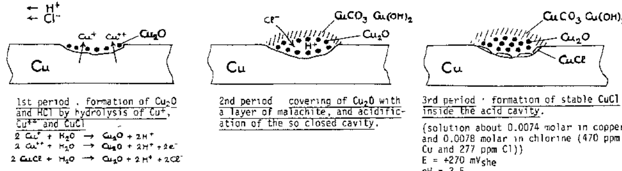

Fig. 22. Initiation and evolution of a copper corrosion pit in the presence of water containing chloride.

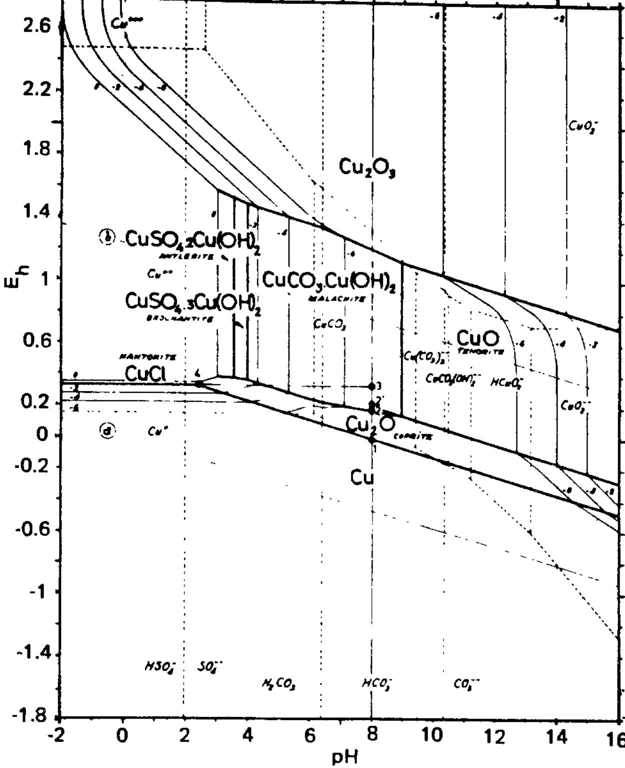

Fig. 23. Potential-pH equilibrium diagram for the five component system $Cu\text{-}Cl\text{-}CO_2\text{-}SO_3\text{-}H_2O$ at 25°C for solutions containing 229 ppm CO_2 ($10^{-2.28}$ g · ion/liter), 46 ppm SO_3 ($10^{-3.24}$ g · ion/liter), and 22 ppm Cl ($10^{-3.21}$ g · ion/liter).

As we have seen, both an illumination of the metal and a stagnation of the water lead, during the third stage of the experiment, to a temporary potential drop (which is sudden in the case of illumination and slow in the case of stagnation), and this to the same value: −250 mV_{sce} (i.e., 0 mV_{she}). As may be seen in Fig. 23 (point 1), this value 0 mV_{she} is, for the pH 8 of Brussels water, the equilibrium electrode potential of the

system $Cu-Cu_2O$. It is thus likely that, during the third stage of the experiment, both an illumination of the copper and a stagnation of the water lead to a temporary contact of truly metallic copper with the bulk of the water. We think, without having had so far the opportunity to check this extensively, that:

(*i*) This sudden action of illumination of copper during the third stage of the experiment is due to an immediate photochemical action of light on CuCl with formation of metallic Cu (as the action of light on AgCl with formation of Ag in photography). Such an effect of light should thus indicate the presence of CuCl on the surface of the copper, and might thus detect an early stage of pit formation.

(*ii*) This slow action of stagnation of the water is due to a progressive opening of some active cavities (Fig. 24), probably as a result of a chemical attack of the external malachite layer by the internal chlorhydric acid, with formation of "chimneys" through which gaseous CO_2 escapes from the cavity and the bulk of the water penetrates to the bottom of the cavity, where copper is really in a pickled metallic state. Such an effect of stagnation should thus detect an advanced stage of pit formation.

(*iii*) Both these actions are temporary because, due to the presence of oxygen in the bulk of the water, metallic copper becomes quickly oxidized.

As a result of all this, the testing device shown in Fig. 25 has been established. Water is passed through a series of four corrosimeters containing copper specimens, recording the electrode potentials of these specimens as a function of time. In the corrosimeters No. 1, 2, and 3, which are intended for checking the behavior of different samples of copper and/or copper alloys in a given water, water is continuously passed in darkness (No. 2), in darkness with periods of stagnation (No. 3), and continuously with periods of illumination (No. 1). In corrosimeter No. 4, which is intended for appreciating the danger of pitting in a given water, the water to be tested is continuously passed in the darkness on pickled copper partially covered with gold, supposed to represent a "deleterious surface condition."

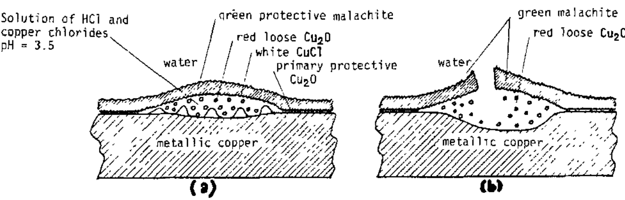

Fig. 24. Copper pit. (a) closed pit (in running water) $E = +20$ to $+77$ mV_{sce}; (b) open pit (in stagnant water) $E = -250$ mV_{sce}.

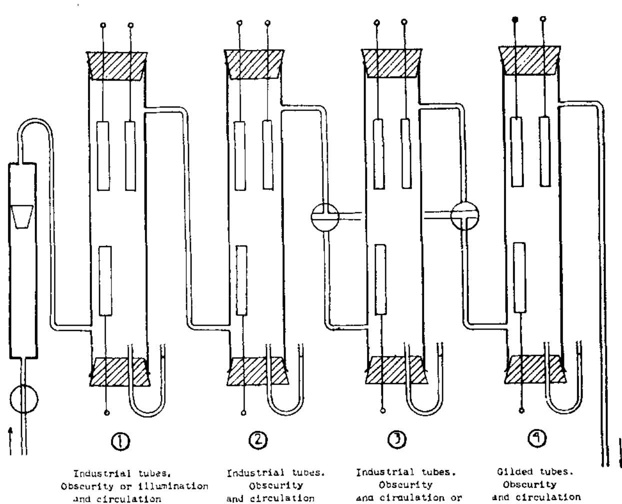

Fig. 25. Device for testing the pitting behavior of copper in water

Now, why is the pitting corrosion of copper tubes for cold-water delivery not a problem in France, as it is in many other countries? Probably because France mostly uses hard tubes which, contrary to the soft ones, are not annealed in a reducing atmosphere and are free of the deleterious carbon film likely to be formed by the cracking of some oils.

Before closing this statement on copper, I wish to remind that, as has been emphasized by R. M. Garrels (14), potential-*p*H equilibrium diagrams may be useful in geology. Figure 26 indicates some stability conditions of the chlorides nantokite and γ paratacamite (which is the chilese copper mineral). Figure 27 may be useful for checking the conditions of stability of the basic copper carbonates malachite and azurite. Figure 28 may be useful for checking the conditions of stability of the basic copper sulfates brochantite and antlerite, as well as the conditions where patinas formed on copper roofing may be the black tenorite or the green brochantite.

Localized Corrosion of Iron and Steels

Figure 29 shows a theoretical potential-*p*H diagram for the $Fe-H_2O$ system at 25°C. Figure 30a shows experimental potentiokinetic polarization curves for iron in the presence of chloride-free aqueous solutions of different *p*H's and Fig. 30b shows the corresponding experimental potential-*p*H conditions for immunity, general corrosion, and passivity of iron (15). Figure 31a shows experimental potentiokinetic polarization curves for iron in the presence of solutions similar to those of Fig. 30a, but containing chloride; these curves show, besides passivation potentials which are the same as in Fig. 30a, pitting potentials and protection potentials against localized corrosion, and make it possible to represent at Fig. 31b experimental potential-*p*H conditions for immunity, general corrosion, pitting corrosion, imperfect passivity where no new pits are formed but

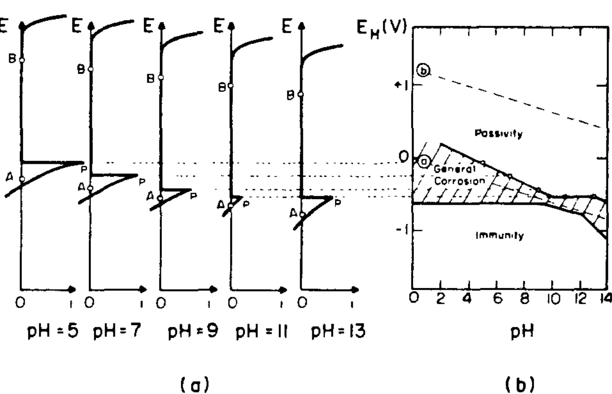

Fig. 30. Behavior of iron in chloride-free solutions. (a) polarization curves in the presence of solutions for pH 5-13; (b) experimental conditions of immunity, general corrosion, and passivity.

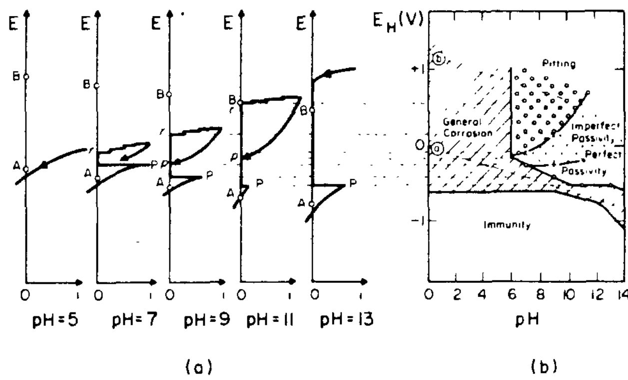

Fig. 31. Behavior of iron in solutions containing chloride (355 ppm): (a) polarization curves in the presence of solutions for pH 5-13; (b) experimental conditions of immunity, general corrosion, perfect and imperfect passivity, and pitting. Protection potential against localized corrosion.

Figure 19 shows, together with the experimental potential-pH conditions of immunity, general corrosion, pitting corrosion, and perfect and imperfect passivity shown in Fig. 31b, the potential and pH conditions inside an active oxygen-free corrosion pit or crevice, or other "occluded corrosion cell" or OCC as it has been called by B. F. Brown ($E = -325$ mV_{she} and $pH \simeq 3.8$), and the possible extreme electrode potential values of iron in the presence of water of pH 8 (from about -550 to $+100$ mV_{she} according to the oxygen content of the water). One sees in this figure that the protection potential against localized corrosion of iron is, as it is for copper (Fig. 18), very close to the electrode potential inside an active OCC.

Figure 32 shows a device which permits, by passing oxygen and nitrogen on, respectively, the external and the internal part of a duplex iron specimen, the production on the internal part, as a result of differential aeration, of a crevice under conditions which notably permit the measurement of the pH and the electrode potential on both the cathodic and the anodic areas (which is an "occluded corrosion cell"). Figure 33 shows, as a result of experiments performed with such a device by J. Van Muylder *et al.* (16), the influence of a slow external cathodic polarization on the potential and pH conditions inside an iron crevice. It is seen that this polarization progressively increases the pH inside the cavity and that, when the external potential reaches the "protection potential against localized corrosion," this solution is not acid anymore and the iron has become immune; however, there is still inside the cavity a hydrogen evolution whose affinity, which is measured by the vertical distance between the line relating to the crevice and the hydrogen equilibrium line α (about 100 mV), remains about the same until the solution becomes neutral and increases very much when the solution has become definitely alkaline. When measuring, during a rapid external cathodic polarization, the current flow between a large external area and a small internal cavity of pH 5.5, Antoine Pourbaix has observed the two polarization curves shown in Fig. 34 (17). It may be seen that, when the external cathodic polarization is increased, the cavity progressively ceases to act as an anode, reaches at -0.43 mV_{she} the state of zero current, and afterwards acts as a cathode. When the protection potential -0.38 mV_{she} is reached on the external area, the potential inside the cavity has become -0.44 mV_{she}; the cavity has then become immune and the cathodic current density, which is about 2 $\mu A \cdot cm^{-2}$, totally corresponds to a hydrogen evolution. Figure 35 shows the results obtained by B. F. Brown in his famous work on the cathodic polarization of steel cracks when using his freezing method (18). One sees that Brown's curve on cracks is very similar to Van Muylder's curve on crevices, and this confirms the assumption that the chemistry and the electrochemistry of crevices and cracks, as well as of any other form of OCC (pits, cor-

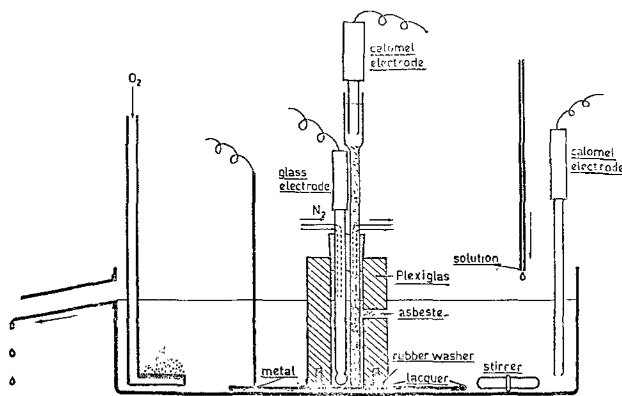

Fig. 32. Device for studying crevice corrosion

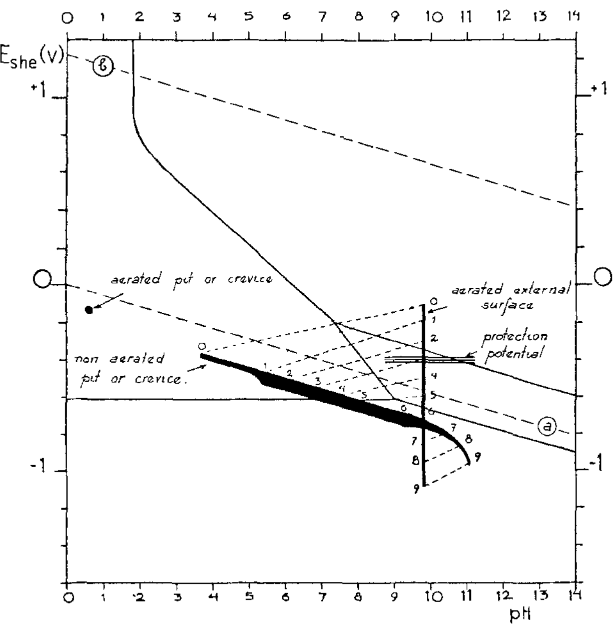

Fig. 33. Influence of a slow cathodic polarization on the potential and pH conditions inside a crevice (mild steel with an aerated solution of 0.001M NaOH and 0.001M NaCl), after J. Van Muylder, L. Sathler et al.

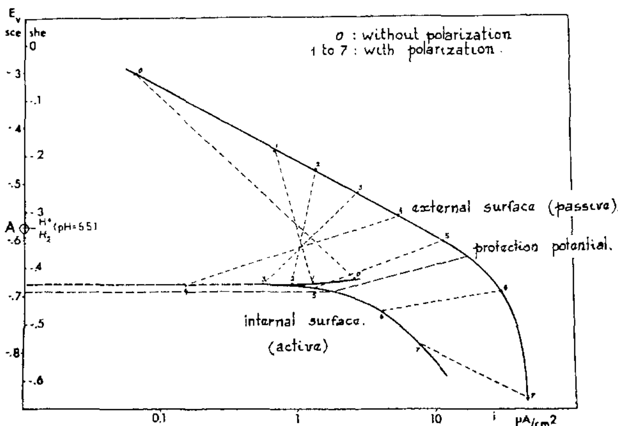

Fig. 34. Influence of a rapid external cathodic polarization on the electrochemical behavior of mild steel outside and inside a crevice (external pH = 9.5; internal pH = 5.5), after Antoine Pourbaix.

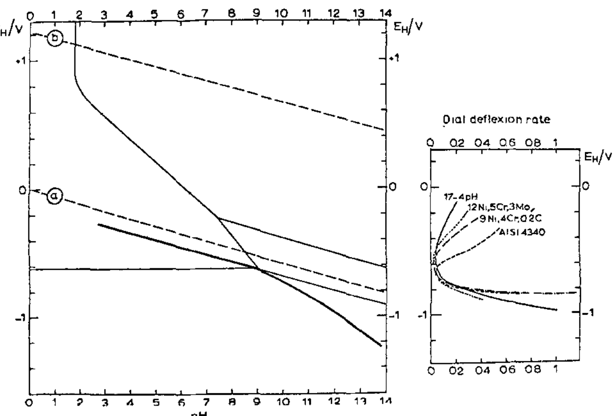

Fig. 35. Influence of a cathodic polarization on the electrochemical characteristics and propagation rate of a stress corrosion crack (chromium steel AISI 4340 in contact with NaCl 3.5% solution), after B. F. Brown.

rosion in recesses, intergranular corrosion, etc.), is the same.

As the representative point of the OCC in both Fig. 33 and 35 is below the "hydrogen line" α, hydrogen is being evolved inside both crevices and cracks, even if the bulk of the solution is alkaline. This means that cathodic protection below the "protection potential against localized corrosion" (usually about −200- −400 mV_{she}), which may often prevent any localized corrosion of iron and steels, may be fully effective against deterioration of the material only if this material is not susceptible to hydrogen embrittlement. Needless to say, this is of particular importance for stress corrosion cracking.

Conclusions

Coming to the end of this rapid survey, I wish to raise attention to the fact that, in the cases of both copper and iron in the presence of solutions containing chloride which we have been considering in the present lecture, the solution existing inside the OCC is, in fact, a solution of a chloride of the considered metal ($CuCl$ or $FeCl_2 \cdot 4H_2O$) which is thermodynamically unstable in the bulk of the water and thus hydrolyzes, with formation of a stable oxide (Cu_2O or Fe_3O_4), with decrease of the pH and increase of the chloride concentration until the solution becomes saturated in this chloride (about 0.01M and pH 3.5 for CuCl, and about 4.6M and pH 3.8 for $FeCl_2 \cdot 4H_2O$). The system then ceases to be univariant and becomes invariant.

Such solutions may be prepared synthetically by simply saturating oxygen-free water with this chloride in the presence of the metal in powder form. This makes it possible to prepare very easily a solution similar to the solution really existing inside a crevice or a crack, or along a corroding grain-boundary, or in any other OCC, and this in any desirable quantity (100 cm^3 or 1000 cm^3, or more) which might be suitable for any analysis and electrochemical experiment. This was done for copper in 1962 by Jean Van Muylder (8), and for iron in 1973 by C. T. Fujii (19) and in 1974 by Lucio Sathler (20). Both C. T. Fujii and L. Sathler have obtained for the OCC of iron in chloride solutions at 25°C a very concentrated solution, respectively 4.2 and 4.6M in FeCl and pH 3.8. According to L. Sathler, isolated iron corrodes in this solution with a velocity of 1.2 $\mu A \cdot cm^{-2}$ (13 $\mu m \cdot year^{-1}$), and passivates at −185 mV_{she} with a passivation current of 2.5 $mA \cdot cm^{-2}$ (27 $mm \cdot year^{-1}$). If oxygen penetrates into this solution, the pH decreases from 3.8 to about 0.6, and the zero-current electrode potential of iron increases from −325 mV_{she} to −125 mV_{she} (Fig. 33), where it corrodes with a velocity of about 0.7 $mA \cdot cm^{-2}$ (8 $mm \cdot year^{-1}$) and may not become passive.

Finally, I think that it is important to realize fully that, in any case where localized corrosion is to be considered, such corrosion does not develop in the bulk of the solution and at the electrode potentials existing on the external surfaces, but inside an OCC where the composition of the solution and the electrode potential of the metal may be very different from what it is outside these cavities. For instance, many problems related to intergranular corrosion might be better understood by systematic research related to the electrochemical behavior of substances existing along these grain boundaries in these solutions.

Besides this, as stated recently (21), it is likely that by adding to copper, to iron or to other metals alloying elements which when dissolving in the solutions existing inside the OCC of these metals would render these solutions less aggressive and/or lead to the deposition of a less soluble salt or element under the existing conditions of pH and electrode potential, etc., it would be possible to better explain than presently the beneficial influence of some alloying elements to nonferrous metals (As and Fe in copper alloys? Sb and Bi in aluminium alloys?) and to some steels (Mo?), and to set up new and better alloys as far as their resistance to localized corrosion is concerned.

This last phrase was written several months ago, at a moment when no proof of the exactitude of this statement was available, as far as I know. Today, three hours ago, at 2.30 p.m., T. Kodama and J. R. Ambrose, co-workers of Jerry Kruger at the National Bureau of Standards, presented at the present meeting of The Electrochemical Society an outstanding paper (Abstract 75) entitled "Effect of Molybdate Ion on the Repassivation Kinetics of Iron in Sodium Chloride Solutions." According to this paper, and in full agreement with the present theory, molybdenum would dissolve in an iron OCC as molybdate ions and would form with the dissolved ions insoluble ferrous molybdate $FeMoO_4$. It is most likely that this is the fundamental reason of the beneficial effect of molybdenum on the pitting and crevice behavior of alloy steels (such as the AISI 316); the just-mentioned concept for setting new and better alloys might thus perhaps be correct.

As a conclusion, I wish to emphasize that any time one has to study localized corrosion, and notably crevice corrosion, intergranular corrosion, and stress corrosion cracking which have a so-great practical importance, there is a great interest in the measurement of electrode potential and pH values outside and inside the cavities, and to interpret the so-obtained values on the basis of both electrochemical thermodynamics and electrochemical kinetics. Such researches would preferably include a thorough study of the chemistry and of the electrochemistry of the solutions existing inside the occluded corrosion cells and of the anodic and cathodic behavior of the constituents of the considered metal or alloy in these solutions (23).

English as the World Language of Science

G. Wranglén*

Royal Institute of Technology, Stockholm, Sweden

Throughout the Middle Ages and well into modern times, Latin was used by scholars of all kinds as the international language of learning. At the universities, Latin was generally used in lectures until about 1750 and in dissertations until about 1850. With the rise of nationalism and the development of the national languages, the role of Latin as a common language of scholars gradually disappeared. An attempt to revive Latin in simplified form for use within the sciences has been made in our time. The result, Interlingua, as romantic as Romanic, was published in 1951 and has met with some favorable response in medical circles. However, the chances for a more general acceptance of this artificial language would seem very small indeed. On the other hand, English is rapidly developing into an international language of science with a standing similar to that once held by Lâtin. That rational, practical, and economic factors contribute toward this fortunate development is apparent in many different ways.

Until ten to fifteen years ago, it was still usual to provide simultaneous translations at international scientific conferences. Apart from the fact that such translations were usually unsatisfactory, this practice has now had to be abandoned for economic reasons. Instead, contributors to such conferences are required or at least encouraged to speak in English. A natural consequence is that the corresponding paper is also published in that language.

At national or regional conferences or symposia, *e.g.*, in the Scandinavian countries, it is now common practice that although the papers are presented in the author's own native tongue or in some regional language understandable to all participants, the papers are simultaneously or later published in a common volume in English and hence made available to a worldwide audience of readers.

The situation is similar with national scientific journals, with the unfortunate result that valuable material has been buried and forgotten in publications in uncommon languages and with small circulations. While it is still important and necessary to publish technical, commercial, and educational articles in Journals using the language of the country concerned, it is becoming more and more usual, particularly in small countries, to use English as the preferred or exclusive language for material of a purely scientific nature. This usually means a highly increased circulation of and efficiency in the journal concerned.

A number of multilingual international journals, published in Western Europe, present a special problem. These journals publish articles in either English, German, or French and abstracts of each individual article in all of these three languages and occasionally in Russian. These journals are often official organs of international scientific societies with the majority of their members in West European countries and with English, German, and French as official languages, although English is by far most generally used by the members. Publishers are finding it increasingly difficult and costly to publish these multilingual journals due to the lack of trained personnel in the printing works capable of handling articles in several languages and the excess time taken and cost involved in setting such material. Abstracts in several languages are likewise time consuming and costly to translate and set. Because of lack of expertise by the translators, they are often inaccurate. For these reasons, some publishers have concluded that they can no longer publish multilingual journals and have consequently decided to accept papers and publish abstracts in English only. This is a fortunate development which should be greeted with satisfaction. In order to assure a scientific contribution as large a circle of readers as possible, there is no question but that it should be published in English. It should therefore be in the interest of both the author himself and the journal concerned that a contribution be published in that language. Particularly among young authors of various nationalities, it is becoming common practice to publish their papers in English. It is natural, therefore, that the proportion of non-English papers has been continuously decreasing in multilingual journals in recent years, even before the decisive impact of economic considerations.

The only opposition to this natural and inevitable development seems to come from French-speaking scientists. Other nationalities seem to welcome or at least accept the use of English as the sole means of communication both at international meetings and in international journals. This is particularly true of non-European scientists, such as Japanese and Indians who usually cannot understand or read any European language other than English. Indeed, the same seems to be true of many Americans.

In this context, some statistics may be of interest. According to a study carried out a few years ago and

* President, International Society of Electrochemistry.

presented in "An Overview of Worldwide Chemical Information Facilities and Resources,"[1] the languages used in articles dealing with the chemical sciences and reported in "Chemical Abstracts" in the period 1962-1966 had a percentage distribution as follows

Language	%
English	55%
Russian	21%
German	7%
French	5%
Japanese	3%
Italian	2%
Polish	2%
Other languages	5%
	100%

In addition, about three-fourths of the articles in Russian were translated into English, which means that about 70% of the contents of chemical journals was available in the English language. If a similar study were made today, the dominance of English would probably be found to be still greater.

These figures reflect the very desirable development toward the use of English as the world language of science. In view of these figures, it seems hard to find rational, not only historical, reasons for maintaining German and French as official languages of journals which pretend to be truly international and not only West European. If abstracts should be published in, say, two languages in such journals, these languages should obviously be English and Russian, not English and French. However, Eastern Europe has apparently adapted itself to a situation with Russian as a common regional language of science and English as a common world language of science. It might be argued that this gives West an unfair advantage over East. Actually, this is not so. Since most Russian and other East European scientists today can read and understand English while only a very few in the West have a command of Russian, we are the handicapped ones.

It is sometimes argued, furthermore, that the use of only English in a journal instead of, say, English-German-French would make the journal less international in character. Indeed, just the opposite is true. Whereas practically all prospective readers, and even those preferring German or French, can immediately understand an article published in English, a great many, and perhaps a majority of those outside Western Europe, would have to resort to a translation or at least a dictionary in order to comprehend the content of an article published in German or French. Hence, much is gained and little is lost by using English as the sole language of publication.

In conclusion, it would seem, therefore, that the development of English toward the world language of science and hence as the sole means of communication in international journals and at international scientific meetings is not only a practical and economic necessity but also a great service to the scientific community of the world. A common world language of science facilitates communication and personal contacts and favors friendship among scientists of different nationalities. It is also to be hoped that it may therefore contribute to international understanding and friendship on a larger scale and in a broader sense.

Molten Salt Metalliding of Nickel Alloys[1]

Ned Godshall*,[2]

Imperial College of Science and Technology, University of London, London SW7, England

The electrodeposition and metalliding of nickel-base alloys to improve high temperature strength and stress-corrosion properties in connection with gas turbine applications has long been viewed as a desirable goal. Specifically, the aqueous plating and subsequent surface diffusion of aluminum, cobalt, chromium, platinum, and yttrium into nickel-base alloys has been observed to impart these enhanced properties. However, established electrolytic techniques are (*i*) unable to deliver these metalliding elements to the surfaces of restricted areas, such as turbine blade cooling holes (approximately 0.030 in. diameter) or (*ii*) may deliver them unevenly, *e.g.*, to yield unfavorable accumulation at sharp curvatures of turbine blades.

For these reasons, a molten salt electrochemical technique was sought to establish a means by which aluminum could be coated onto the surface of nickel-base alloys and concurrently diffused into the interior approximately 2-6μ. The high temperature aspect of the molten salt technique would have the added advantage of providing essentially a one-step technique; not requiring the additional heat-treating step necessary with standard electrolytic plating processes for the diffusion of the metalliding element beyond the surface.

The general electrochemical and diffusional equations may be illustrated by

anodic reaction $$Al_{(l)} \rightarrow Al^{+3}_{(\text{molten salt})} + 3e \quad [1]$$

cathodic reaction

$$Al^{+3}_{(\text{molten salt})} + 3e_{(Ni)} \xrightarrow{\text{emf}} Al_{(\text{plated})} \quad [2]$$

diffusional reaction $$Al_{(\text{plated})} + Ni \rightarrow NiAl \quad [3]$$

where NiAl represents the various dispersion-hardening compounds.

Experimental Procedure

Cell design.—All experiments were conducted in a molten salt bath under an inert argon atmosphere at a temperature of 800°C (1472°F). Equimolar sodium-potassium chloride (NaCl-KCl) was selected as the fused-salt medium because of its relatively high thermal stability and the proximity of its melting point (660°C, 1220°F) to that of aluminum (657°C, 1215°F), the metalliding element under study. In addition, equimolar NaCl-KCl retains its favorable electrical transport properties at elevated temperatures; specifically, high ionic conduction and low electronic conduction.

300g NaCl-KCl were contained in a 70 mm diameter alumina crucible, which was enclosed within a 20.32 cm (8 in.) Inconel cylinder (Fig. 1). The cylinder was capped with a specially designed brass head which included movable vacuum-tight ports for the electrode assemblies, argon circulation, and specimen ingress/egress.

The electrode assemblies were composed of (*i*) a Nimonic cathode (working electrode), (*ii*) a liquid aluminum anode (counterelectrode), (*iii*) a reference bulb electrode (0.1M silver chloride, AgCl; balance: equimolar NaCl-KCl), and (*iv*) a platinum foil auxiliary electrode (4.50 cm^2). A schematic diagram of the electrode arrangement is given in Fig. 2.

High temperature aspects.—Standard fused-salt procedures were utilized as much as possible during experimentation; however, operation at the elevated experimental temperature, 800°C (1472°F), necessitated several significant changes.

(*i*) A liquid aluminum anode was required. This was provided by containing 14.0g of high purity aluminum in an alumina crucible suspended above the molten salt surface. The crucible was lowered into the melt when both the NaCl-KCl and aluminum reached the liquid state.

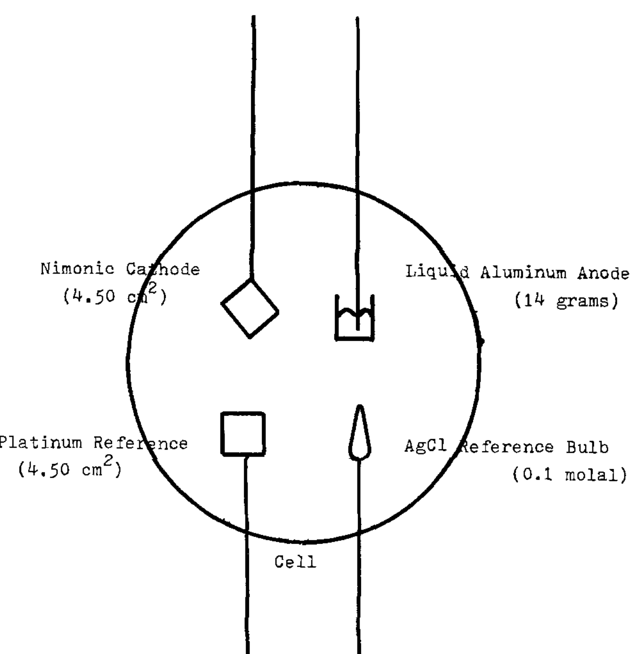

Fig. 2. Electrode assemblies

(*ii*) All electrodes were necessarily constructed of either high quality quartz or alumina, rather than of the lower melting point Pyrex glasses commonly used in molten salt experiments.

(*iii*) An extensive fused-salt drying process was required to minimize attack of the quartz electrodes by residual water and to prevent the fused-salt from "bumping" due to gas evolution during the initial testing. This was accomplished by predrying the fused-salt mixture, followed by 72 hr of concurrent vacuum treatment and slow incremental heating, until the melting point of the salt was reached (660°C, 1220°F).

(*iv*) Drying and purification of the inert argon atmosphere used during experimentation was likewise found necessary in order to eliminate water and oxygen from the cell environment.

Test material.—The nickel-base alloy selected as the substrate for experimentation was Nimonic 80A (carbon: 0.10%, Cr: 20.5%, Mn: 0.80%, Fe: 3.0%, S: 0.010%, Cu: 0.2%, Al: 1.4%, Ni: balance; manufactured by Henry H. Wiggins, Limited, England). Nimonic 80A was chosen as the test material because of its age-hardenable, creep-resisting properties, and service temperature of 815°C (1499°F). In addition, its major applications currently lie within the gas turbine industry.

Electrical circuitry.—A 50V d-c power supply provided the emf for the electrodeposition reaction. The electrical parameters of the aluminum deposition reaction were monitored using the electrical circuit illustrated in Fig. 3. The Hermes coulombic integrator was initially calibrated by shorting the cell from the circuit, which allowed a direct coulombic measurement of aluminum ion transport within the cell.

A bismuth "starter" electrode was originally used as the cathode, in place of the Nimonic test specimens, to establish an initial concentration ($10^{-2}M$) of aluminum ions (Al^{+3}) in the NaCl-KCl melt. Steady-state aluminum ion concentration was maintained thereafter, since an equal number of Al^{+3} ions were released from the liquid aluminum anode as were deposited onto the cathodic test specimens.

Discussion of Results

Aluminum ion instability in NaCl-KCl.—Nimonic test specimens were immersed in the NaCl-KCl melt and subjected to alluminiding conditions and potentiostatic measurements. The length of immersion time and the current density were independently varied. The effects of time and current density variation were determined by visual inspection, x-ray fluorescence, and microhardness measurements (Table I).

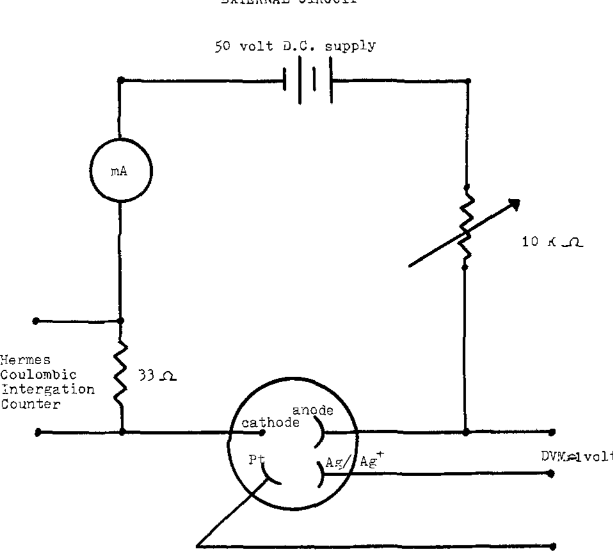

Fig. 3. External circuit

It was concluded that little or no elemental aluminum adhered to, or diffused into, the Nimonic 80A test specimens despite the fact that coulombic measurements indicated high levels of Al^{+3} ion transport to the specimen surface.

Fluoride additions.—Aluminum fluoride (AlF_3) and sodium fluoride (NaF) were added to the equimolar NaCl-KCl melt at concentrations of 2×10^{-2} and $1.5 \times 10^{-2}M$, respectively, in order to reduce the volatility and vapor pressure of the melt and to provide for greater stability of the aluminum ions. Significant changes in the surface properties and weight of the test samples were detected (Table II).

Experimentation time and current density effects.—The effect of reaction time on the weight change for specimens immersed in both fluoride-doped and fluoride-free melts is illustrated in Fig. 4. The weight gain of a sample was found to increase exponentially with time rather than linearly as was expected from con-

80	5.511	4.7	205

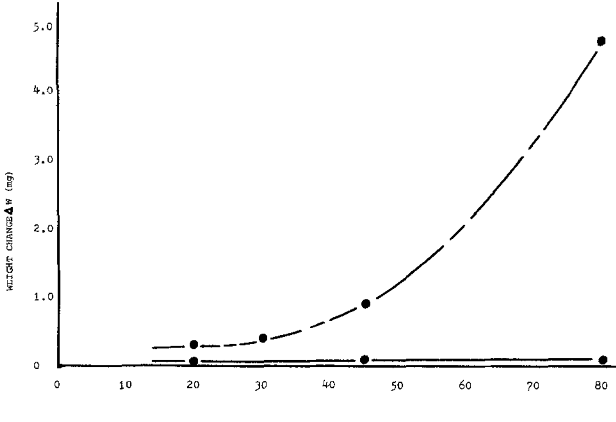

Fig. 4. Weight change *vs.* time, ———— without fluorides, — — — with fluorides.

stant current, constant Al^{+3} ion transport reasoning. This exponential character has been attributed to a diffusion-limiting step whereby much of the aluminum reaching the specimen surface in the early minutes of testing is unable to diffuse beyond the surface before dripping off the specimen, back into the melt.

The effect of current density on weight change seemed somewhat more limited than the effect of time (Fig. 5). The weight gain of specimens reached a plateau at a current density of approximately 2 mA cm^{-2}, above which an increase yielded no increase in coated or diffused aluminum on the samples.

Microhardness measurements.—The effects of time and current density on the mechanical properties of the specimens were determined by means of GKN microhardness tests. Surface hardness increased sharply with reaction time, when fluorides were present in the melt, due to the development of NiAl dispersion-hardening compounds (Fig. 6). The less-pronounced increase in hardness during fluoride-free tests was attributed to secondary thermal treatment of the substrate nickel alloy and not to any NiAl development, since x-ray fluorescence measurements detected little aluminum on or near these surfaces.

Surface hardness increased with increasing current density (Fig. 7). Once again, however, an increase in current density beyond approximately 2 mA cm^{-2} yielded no increase in physical properties, indicating the point at which interface transport and subsurface diffusion reach a steady state.

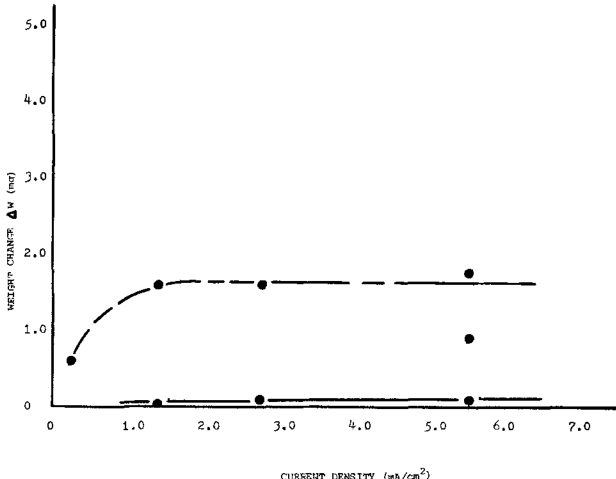

Fig. 5. Weight change *vs.* current density, ———— without fluorides, — — — with fluorides.

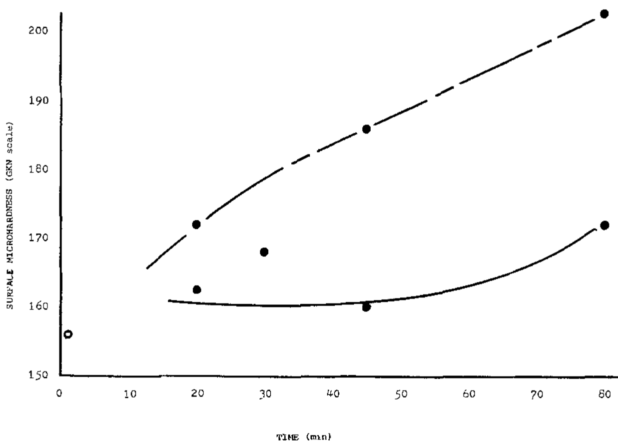

Fig. 6. Surface microhardness *vs.* time, ○ original hardness, ———— without fluorides, — — — with fluorides.

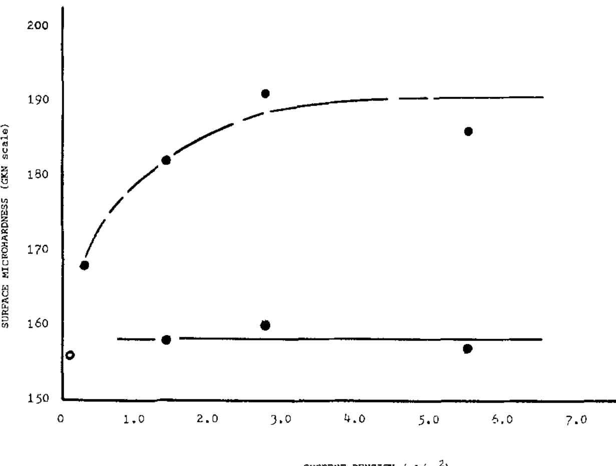

Fig. 7. Surface microhardness *vs.* current density, ○ original hardness, ———— without fluorides, — — — with fluorides.

Shape effects.—The effect of complicated shape changes was evaluated by bending and drilling 0.030 in. (0.76 mm) diameter holes in several specimens prior to testing. Samples were sectioned and examined metallographically and were qualitatively found to exhibit no unusual amounts of aluminum at points of stress concentration, such as at acute or obtuse bends or at small diameter openings.

Self-driven process.—The over-all metalliding reaction, shown in Eq. [1]-[3] was found to be self-sustaining and not dependent on an external power source. The 50V d-c source was removed from the circuit and the anode "shorted" to the cathode (Table II, first experiment). The resultant current flow and aluminum deposit indicated a free energy decrease ($-\Delta G$) and the self-sustaining nature of the reactions

$$\text{anodic} \quad Al_{(l)} \rightarrow Al^{+3} + 3e$$

$$\text{cathodic} \quad Al^{+3} + 3e \rightarrow Al_{(Ni)}$$

The electrode potentials were calculated using the Nernst equation

$$E = E^{o} - \frac{RT}{3F} \ln a_{Al^{+3}}$$

and were found to correspond adequately with observed results. The potentials of the Nimonic specimens (cathode) usually approximated $-1.65V$ with respect to the 0.1M AgCl reference, while the potential of the liquid aluminum (anode) averaged $-0.95V$ with

respect to the reference. Variance, in both cases, was ±0.15V.

Process efficiency.—The weight of aluminum which was available for adherence to the Nimonic specimens (Al_{Th}) was calculated through the use of the coulombic integrator shown in the external electric circuitry (Fig. 3). The calculated (Al_{Th}) (see Appendix) varied widely from that observed experimentally (Al_{Ex}), leading to reaction efficiencies (Al_{Ex})/(Al_{Th}) of 45-60% for the melts with fluoride additions.

Conclusions

The stability of the aluminum ion (Al^{+3}) in equimolar NaCl-KCl is much too low for it, alone, to be a realistic molten salt aluminum transport medium. However, the addition of small amounts of fluorides greatly enhances the stability of aluminum ions and, therefore, greatly improves the prospects of molten salt metalliding. However, increased chemical attack of quartz by fluorides has been observed, so that cell design should be modified in future work.

Current molten salt metalliding processes are, unfortunately, very time and temperature dependent because of the diffusion-limiting steps involved. High current densities are unable to shorten the time requirement. The rate of diffusion of aluminum into the Nimonic is slow compared with the rate of deposition of aluminum onto the Nimonic surface.

Smooth, uniform deposition of aluminum over large areas has been attained. This uniform coating is, however, possible only when fluorides are present in the melt. In addition, the electrodeposition and diffusion of aluminum into small diameter openings seems feasible, although more in-depth study is required to define the limitations.

The deposition reaction can be carried out on a self-sustaining basis on a laboratory scale. However, longer deposition times are required because of the low currents generated when no external source is utilized.

The current efficiency of the experiments carried out to date has been low. Further elucidation of the causes of this poor current efficiency is necessary before development of higher electrodeposition and diffusion rates is possible.

Recommendations

The sodium chloride-potassium chloride molten salt system is unsuitable for aluminum electrodeposition work at high temperatures. Therefore, in the future, all work should be carried out in melts where fluorides are at least present, preferably in fluoride-based systems.

The effect of temperature should be studied because diffusion has been found to be the rate-limiting step.

In addition, the concentration of aluminum ions in the melt could be treated as a variable in future work to ascertain the causes for the low current efficiencies observed to date. Likewise, stirring or bubbling gas through the melt could be introduced to determine the effects of mixing.

The electrodeposition of metals other than aluminum should be explored. Elemental yttrium and/or platinum are promising substitutes.

Continued work could also easily incorporate corrosion studies of prepared specimens, and would be highly informative since corrosion resistance is an important criterion in the use of the diffused substrate.

APPENDIX

Calculation of Theoretical Aluminum Deposit (Al_{Th})

Example

Current = 12.4 mA
Area of specimen = (1.5 cm^2) × 2 = 4.50 cm^2
Current density = I/A = 2.755 mA/cm^2
Number of integrator units (empirical) = 1217 units
1 coulomb = 36.07 units at 0.410V across the integrator
1217 units × 1 coulomb/36.07 units = 33.74 coulombs
Number of moles = $C/n\mathbf{F}$
Number of moles = 33.74 coulombs/(3)(96,500) = 1.166×10^{-4} moles

$$1.166 \times 10^{-4} \text{ moles} \times \frac{27\text{g Al}}{1 \text{ mole Al}} = 3.15 \times 10^{-3}\text{g Al} = 3.15 \text{ mg Al}$$

(Al_{Th}) = 3.15 mg Al

Efficiency Calculation

The actual weight of aluminum deposited onto the above sample (Al_{Ex}) was 1.6 mg. Therefore

$$\text{Efficiency} = (Al_{Ex})/(Al_{Th}) = \frac{1.60 \text{ mg}}{3.15 \text{ mg}} = 51\%$$

Interfacial Na^+ Transport in the Beta Alumina/Propylene Carbonate System

Gregory C. Farrington*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

Na^+ transport across a polycrystalline β-alumina/propylene carbonate interface has been studied at 23°C as a function of current density from 1.0 to 6600 $\mu A/cm^2$ under dry and hydrated conditions. Constant current transient analysis from 10^{-7} to 10^2 sec was used to distinguish interfacial and bulk resistivity components during ion entry into and exit from β-alumina. The resistance associated with Na^+ exit increases significantly after exposure of the β-alumina to water vapor. Interfacial current/voltage relationships for dry and hydrated samples are nonlinear but qualitatively similar. Na^+ entry phenomena are obscured by a steadily increasing interfacial resistance which accompanies ion transport into the β-alumina, a process reversed by extended electrolysis out of the interface. The results suggest that interfacial transport involves an adsorbed intermediate state and is influenced by an equilibrium between adsorbed Na^+/H_2O and Na^+/H_3O^+ substituted into the β-alumina.

Ion transport across a solid electrolyte/liquid electrolyte interface involves a fundamental change in ionic environment. Restricted motion within the solid electrolyte contrasts with ionic association, solvation, and random diffusion in the liquid. Clearly, this step is influenced by the molecular structure and dielectric constant of the liquid electrolyte and by the structure of the solid electrolyte.

Beta alumina (*ca.* 1.2 $Na_2O \cdot 9Al_2O_3$) is a solid electrolyte of interest in a variety of novel electrochemical energy storage systems. It is stable in a range of chemical environments and has high conductivity for several monovalent cations, especially Na^+. It is also ideally suited for the study of ionic transport between dissimilar phases.

Ion transport across solid electrolyte/liquid electrolyte interfaces has been previously examined in ion exchange membrane/aqueous electrolyte systems. Kressmen and Tye (1) and Peers (2) discussed the effects of ionic depletion at specific ion selective membrane interfaces. Sandblom, Eisenman, and Walker (3, 4) presented a theoretical examination of ideally permselective, liquid ion exchange membranes, specifically addressing ion transport effects within the membranes. Results of a preliminary examination (5) of β-alumina/propylene carbonate interfacial transport at 25°C performed in this laboratory revealed that a large increase in interfacial impedance for Na^+ entry and exit ensues from exposure of the β-alumina to water vapor. Similar effects were noted by Voinov and Tannenberger (6) who speculated that protons may be irreversibly driven into the β-alumina under the influence of an electric field, increasing its resistivity.

The present work was undertaken to examine Na^+ transport across a propylene carbonate/β-alumina interface under nominally anhydrous conditions and in the presence of adsorbed water. To separately distinguish interfacial and bulk resistivity effects and differentiate Na^+ entry into the solid electrolyte from Na^+ exit, a fast risetime, constant current technique was used.

Experimental

Beta alumina ceramic rods were prepared from Alcoa XB-2 β-alumina powder. The powder was ground with ZrO_2 grinding media, dried under vacuum, screened, and hydrostatically pressed into rods approximately 1.6 cm in diameter and 15 cm long. The rods were cut into 1.6 cm segments and fired at 1700°C. The resulting ceramic was single phase, polycrystalline β-alumina of 98% theoretical density, containing approximately 1% MgO and 1% ZrO_2.

Rods were sliced with a diamond saw into disks 1.3 cm in diameter and 4 mm thick. A 0.6 mm hole was drilled 3 mm into each disk from its circumference halfway between each face. Sample faces were polished through 600A grit SiC paper, washed in methanol, and fired for 24 hr at 700°C. Between individual experiments, samples were wet polished with methanol through 600A grit SiC paper, rinsed with methanol, and baked at 400°C in vacuo. They were transferred in vacuo to a Vacuum Atmospheres Ar dry box and polished briefly on dry 600A grit SiC paper immediately before use.

In the following experiments "dry" β-alumina is that which has been treated as above. "Hydrated" β-alumina was prepared identically except for exposure to 100% relative humidity at 23°C for 20 min or 28 hr before analysis.

Samples were mounted in the Teflon experimental cell shown in Fig. 1 and held in place with silicone rubber gaskets. Burdick and Jackson "Spectroscopic" propylene carbonate was dried by multiple percolation through a 16 × 2 cm column of alumina which had been activated at 500°C in vacuo for 24 hr.

* Electrochemical Society Active Member.

Key words: solid electrolyte, electrolysis, ion transport, water.

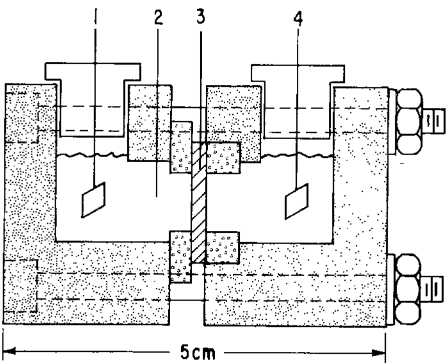

Fig. 1. Experimental cell constructed of Teflon; gaskets of silicone rubber; drawn to scale.

Baker anhydrous reagent NaI and Southwestern Analytical anhydrous tetrabutylammonium tetrafluoborate ($TBABF_4$) were baked 48 hr at 110°C in vacuo, weighed into appropriate volumetric glassware, and baked a second time under identical conditions before dilution. Two electrolyte solutions were prepared: solution 1, 0.010*M* NaI + 0.100*M* $TBABF_4$; and solution 2, saturated NaI and $TBABF_4$. Solution 1 was the test solution and is referred to in this paper by its Na^+ concentration. The second was used in the unmonitored compartment of the experimental cell.

The assembled cell incorporated four electrodes, an outer current carrying pair of Pt foil (electrodes 1 + 4) and an inner reference pair (electrodes 2 + 3). Each reference electrode was an Au wire into which either Tl or Na amalgam was dissolved. No difference in results was observed between Tl or Na electrodes. A small amount of electrolyte was injected into the disk reference electrode hole to improve contact. Observed with a Keithley Model 616 digital electrometer, these electrodes established a potential difference satisfactorily stable for the experiments described here.

Galvanostatic data (10^{-7}-10^{-3} sec) were obtained by applying single, fast risetime ($<5 \times 10^{-8}$ sec) constant current square waves to electrodes 1 + 4 while monitoring the differential voltage response across electrodes 2 + 3. A broad range of elapsed time was covered by applying pulses of differing widths. The result is a plot of voltage drop associated with ion transport between electrodes 2 and 3 at constant current from 10^{-7} to 10 sec from current initiation. Voltage *vs.* time was converted to resistivity *vs.* time by dividing by current and multiplying by the geometrical β-alumina surface area exposed to propylene carbonate. All the transient data reported were obtained at a current density of 138 $\mu A/cm^2$. The pulse generator used has been previously described (7).

Potential transients were captured with a Tektronix 7633 storage oscilloscope using a 6B53A time base and 6A11 vertical amplifier. The probe-oscilloscope combination has a 60 MHz bandwidth, 5.9×10^{-9} sec risetime, and vertical deflection accuracy of 3%. Stored traces were photographed for subsequent manual retrieval of potential-time data. The apparatus was operated in a single pulse mode by triggering the oscilloscope and pulser with a Tektronix Model 115 pulse generator.

Experimentation in the 10^{-1}-100 sec time range was performed with a PAR Model 173 potentiostat/galvanostat, PAR Model 175 programmer, Keithley Model 616 digital electrometer, and Hewlett-Packard 7004 x-y recorder.

Results and Discussion

Dry β-alumina-Na^+ exit.—Typical data from galvanostatic analysis of Na^+ exit from β-alumina into propylene carbonate across a dry interface are plotted in Fig. 2. Three major resistivity components comprise the response shown: (*a*) propylene carbonate

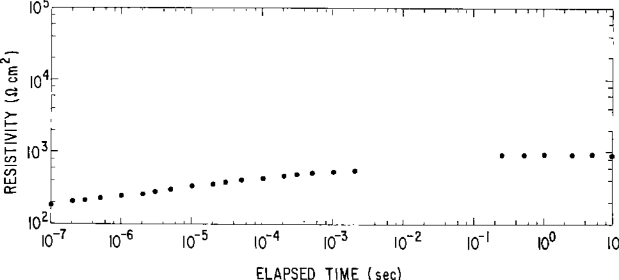

Fig. 2. Na^+ exit from β-alumina through dry interface; 0.010*M* Na^+ at 23°C.

electrolyte resistance; (*b*) interfacial polarization; and (*c*) bulk resistivity of polycrystalline β-alumina. These components occur electrically in series; each can be approximated by a simple parallel *RC* circuit. The circuit shown in Fig. 3, then, approximates the resistivity-time behavior in this system.

The resistance-time response of each individual *RC* pair in Fig. 3 upon perturbation by a constant current square wave has been previously derived (7) and is shown in Eq. [1]. Figure 4 is a plot of R_t as a function of *t* as predicted by Eq. [1]

$$R_t = R(1 - e^{-t/RC}) \quad [1]$$

From Fig. 4, it is clear that if the time constant of the *RC* components shown in Fig. 3 are sufficiently different and each falls within the range of analysis, a staircase resistivity-time behavior will be observed for the model circuit from which all values of *R* and *C* can be calculated. Moreover, so long as $(RC)_{int}$ is 10^2-10^3 times larger than $(RC)_{PC}$ and $(RC)_{beta}$, interfacial polarization can be separated from solution and β-alumina resistance.

The anticipated time constant for propylene carbonate relaxation shown in Fig. 3 was confirmed experimentally. Time constants for the β-alumina were

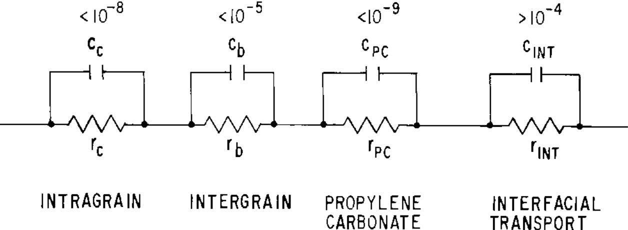

Fig. 3. Model circuit approximating ion transport across a polycrystalline β-alumina/propylene carbonate interface; figures above each *RC* pair are anticipated time constants in seconds.

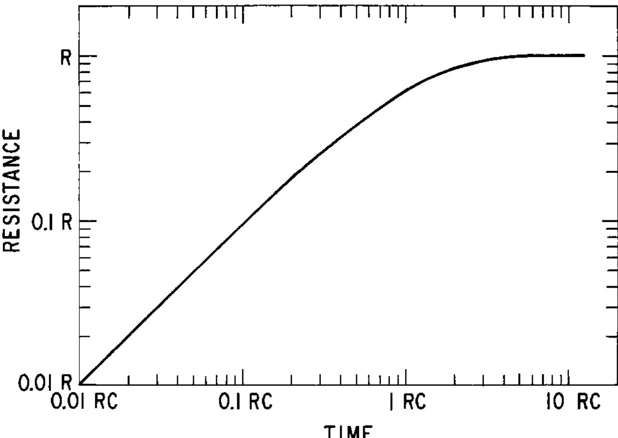

Fig. 4. Resistivity *vs.* elapsed time response of an ideal *RC* parallel circuit upon application of a constant current square wave of infinitely short risetime.

determined by a four-probe galvanostatic technique previously described (7). Interfacial response was estimated by considering double layer capacitance to be 10^{-5} **F**/cm² and interfacial resistivity to be 10^2-10^3 ohm-cm². At $t > 10^{-5}$ sec, therefore, the resistivity associated with ionic transport within β-alumina and propylene carbonate is constant. Any further resistance increase results from interfacial polarization.

No interfacial resistivity component can be clearly distinguished in Fig. 2. However, a detailed examination of the relationship between total voltage drop across the interface, including bulk *IR* drop in each electrolyte, and constant current magnitude, shown in Fig. 5, reveals a significant nonohmic component that cannot be associated with bulk effects.

Four different curves are displayed in Fig. 5: I, taken immediately after cell assembly; II, after the first, and III, after 2×10^{-2} coulombs of Na^+ had been electrolyzed out of the β-alumina sample at 1640 μA/cm². The decreased polarization observed in curves II and III at low current densities is temporary; both gradually rise to meet I as more relaxation time is introduced between one electrolysis and the next.

Background voltage drop arising from bulk resistance of the propylene carbonate and β-alumina, which is expected to be ohmic, is the fourth plot in Fig. 5. It was derived by considering the resistivity observed at 10^{-5} sec in Fig. 2 to be bulk resistivity exclusive of interfacial polarization. The validity of this assumption is discussed in a following section.

The divergence of curves I-III at low currents and their sensitivity to prior electrolysis suggest that sustained Na^+ electrolysis out of the interface temporarily removes a species inhibiting transport. Trace water, present in the propylene carbonate electrolyte despite scrupulous precautions, can easily be suspected of involvement with these effects.

In gathering data for Fig. 5, total voltage was constant from 0 to 20 sec after constant current initiation for currents less than 1000 μA/cm²; points were taken at 3 sec. At higher current densities, the voltage wave had a positive slope. This imparts an increasing slope to data in Fig. 5 at higher current densities. A hypothesis explaining this is presented in a later section.

Dry β-alumina-Na^+ entry.—Experimental examination of Na^+ entry into β-alumina is complicated by interfacial Na^+ depletion and accumulation of impurities transported into the solid electrolyte as the result of current passage. Interfacial Na^+ depletion produces a gradual increase in interfacial resistivity with time. Impurity accumulation results in spurious and nonreproducible resistivity behavior.

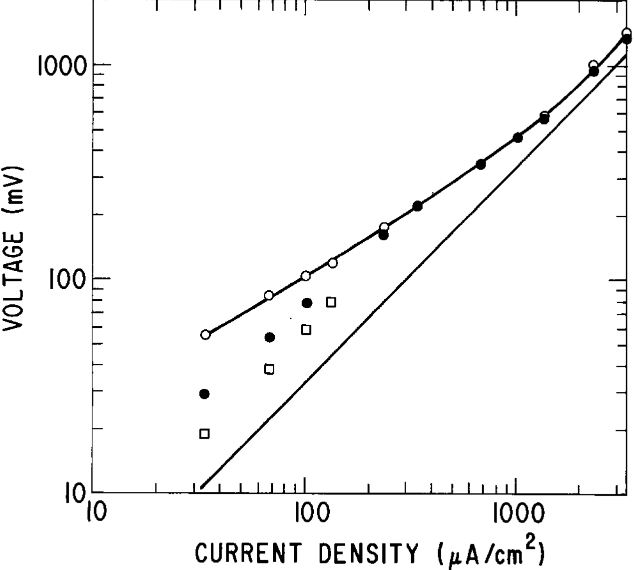

Fig. 5. Interfacial transport through dry interface; Na^+ exit into 0.010*M* Na^+; total voltage vs. current density. Straight line is background voltage due to bulk β-alumina and propylene carbonate resistance. 23°C; ○, curve I; ●, curve II; □, curve III.

Na^+ interfacial depletion was observed by electrolyzing Na^+ into β-alumina from a quiescent solution of 0.010*M* Na^+ with a linearly increasing controlled current. Theory (8) predicts that the total voltage will increase slowly until the interfacial Na^+ concentration is zero. At this critical "transition" time, the rate of Na^+ transport into the electrolyte exceeds its rate of diffusion to the interface. The voltage should increase sharply until it is artificially limited or a second cation capable of injection into the solid electrolyte is produced.

Figure 6 shows the experimental results. Curve I was recorded immediately after cell assembly and has a transition time of 4.5 sec as measured at the intersection of tangents drawn on each of the curve legs.

Murray and Reilley (8) have derived a theoretical relationship (Eq. [2]) between mobile ion concentration (*C*), diffusion coefficient (*D*), current sweep rate (*B*), and the critical time (*t*), at which the interfacial mobile ion concentration becomes zero. Assuming $C = 0.010M$, $B = 164$ μA/cm²/sec, $n = 1$, and $D = 10^{-6}$ cm²/sec, Eq. [2] predicts a critical time of 3.9 sec. Both *D* and *B* were estimated in this calculation, the first in the absence of an exact value and the second because a precise measure of the actual conducting surface area of the β-alumina is not known. Since the sample is polycrystalline, interfacial transport across some portions of the surface is blocked by improper grain orientation, making the actual current density greater than that estimated from the apparent geometric surface area. Considering these uncertainties, the agreement between observed and calculated transition times is surprisingly good.

$$t^{3/2} = \frac{3n\mathbf{F}D^{1/2}\pi^{1/2}C}{4B} \qquad [2]$$

More interesting in Fig. 6 are curves II and III. The former was recorded under identical conditions to I but after 1.2×10^{-2} coulombs of Na^+ was electrolyzed into the solid electrolyte. This extended electrolysis of Na^+ into the interface clearly resulted in adsorption or injection of species which drastically increase interfacial polarization. Initial response is restored after extended Na^+ electrolysis out of the interface.

This electrolysis-dependent polarization is similar to that shown in Fig. 5 in which Na^+ exit interfacial polarization was found to decrease temporarily after extended Na^+ electrolysis out of β-alumina. It precludes further examination of Na^+ interfacial entry. The suspicion that trace water may be involved in

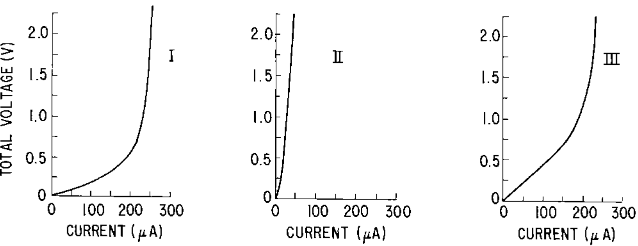

Fig. 6. Interfacial transport through dry interface; Na^+ entry from 0.010*M* Na^+; linear current sweep at 50 μA/sec; exposed β-alumina area = 0.304 cm², (curve I) initial, (curve II) after 1.2×10^{-2} coulombs Na^+ entry at 329 μA/cm², (curve III) following curve II but after 1.7×10^{-2} coulombs Na^+ exit at 329 μA/cm²; 23°C.

these effects prompted more detailed examination of its effects on interfacial transport.

Hydrated β-Alumina-Na^+ exit.—Galvanostatic data in Fig. 7 contrast Na^+ exit into 0.010*M* Na^+ from dry β-alumina and from β-alumina after 20 min hydration. Both curves are essentially identical at short times, corroborating the assertion that this region (10^{-7}-10^{-4} sec) represents bulk *IR* effects in the two electrolytes. Both diverge at longer times, the hydrated response to a value constant at $t > 10^{-2}$ sec. There is clear evidence of an interfacial resistivity component at 10^{-3} sec.

Voltage as a function of constant current for Na^+ exit into 0.010*M* Na^+ from β-alumina hydrated 20 min and 28 hr is plotted in Fig. 8. Little difference is apparent.

Figure 8 also contrasts Na^+ exit from dry and hydrated β-alumina. Voltage drop for the hydrated sample is greater than that observed with the dry sample, especially at low current densities. However, all three curves are qualitatively similar. In both hydrated and dry experiments, constant current densities greater than 1000 μA/cm² produce steadily rising voltage/time relationships. This rise is resolved for the hydrated case in the curious behavior seen in Fig. 9, in which at 3290 μA/cm² a large interfacial voltage transition occurs after several seconds.

Interfacial transport mechanism.—Interfacial polarization is a significant nonohmic component of the total voltage arising from Na^+ transport through a β-alumina/propylene carbonate interface. The current/

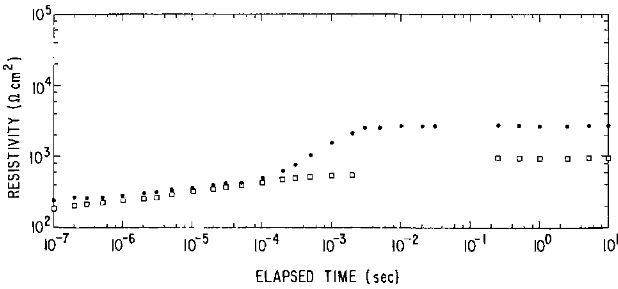

Fig. 7. Interfacial transport; Na^+ exit into 0.010*M* Na^+; ● interface hydrated 20 min; □ nominally dry interface; observed with constant current of 138 μA/cm²; 23°C.

voltage relationships for Na^+ exit from β-alumina into propylene carbonate under dry and hydrated conditions (Fig. 8) are similar in general structure. Both deviate from bulk *IR* resistivity at low current densities, approach bulk *IR* resistivity at higher currents, and again diverge at highest current densities. Extended Na^+ entry into both dry and hydrated interfaces results in resistivity increases which are reversed only upon sustained Na^+ exit (Fig. 6). These observations suggest that adsorbed water significantly affects β-alumina/propylene carbonate interfacial transport.

Various aluminas are adsorbents for a number of species including H_2O and Na^+. Raman analysis of water adsorbed on α-alumina concludes that Na^+ ions and water molecules compete for Lewis acid sites (9). Na^+ adsorption is thought to cause α-alumina catalyst "poisoning" in Na^+-containing environments. Infrared spectroscopic analysis of pyridine adsorption on α-alumina concludes that pyridine adsorbs at nonprotonic Lewis acid sites in the absence of water. Proton activity is observed in the presence of water.

A variety of data also implies that water is absorbed directly into the conducting planes of β-alumina. Kline *et al.* (10), in broadband NMR measurements, found that the ^{23}Na spectrum in β-alumina, which is sharply narrowed by rapid localized ion motion at room temperature, broadens in the presence of water vapor. One inference from this is that diffusion of water into the conduction plane significantly decreases local Na^+ motion, and, as a consequence, Na^+ conductivity. Heating restores a normal spectrum. Weight change measurements corroborate the reversibility of the exchange (11).

Thus, water adsorbed at a β-alumina, interface may diffuse into the β-alumina, lowering bulk conductivity in the interfacial region, and is also a source of ionic hydrogen species such as H_3O^+ and H^+. Both these ions can replace Na^+ in β-alumina.

H_3O^+ β-alumina has been prepared by exchanging Na^+ β-alumina in concentrated H_2SO_4 (12). H^+ β-alumina is synthesized by exposing Ag^+ β-alumina to a reducing atmosphere of H_2 (13). Both H^+ and H_3O^+ ions, therefore, are capable of diffusing spontaneously or under the influence of a field into β-alumina.

The preceding information suggests that water adsorbs on the β-alumina surface and ionic hydrogen species, such as H_3O^+, diffuse into the solid electrolyte, partially exchanging with surface Na^+ ions. The result is a mixture of Na^+, OH^-, and H_2O adsorbed on the electrolyte surface and a mixed H_3O^+/Na^+ composition within the conducting planes adjacent to the surface.

Under the influence of an appropriate field, both Na^+ and H_3O^+ move out of the interface, both initially to adsorption sites on the surface. Subsequent

solvation and desorption steps maintain Na^+/H_2O equilibrium at the interface. The locally elevated Na^+ concentration alters the adsorption equilibrium at the interface as long as current flows, and increases the Na^+/H_2O and Na^+/H_3O^+ ratios on the surface and in adjacent conducting planes.

Sustained Na^+ exit temporarily decreases the concentrations of adsorbed H_2O and exchanged H_3O^+ and results in the temporary decrease in interfacial polarization observed at low current densities in Fig. 5. Similarly, ion entry increases the proportion of H_3O^+ in the conduction planes, decreasing conductivity. This is reversed by extended ion transport out of the interface, as seen in Fig. 6.

Na^+ exit, thus, is hypothesized to involve an intermediate adsorbed state at low current densities. If the current is increased to the point at which surface adsorption sites become saturated, ion transition must take place through a secondary mechanism requiring greater energy. This results in the upwardly sloping voltage/time curves observed at higher currents during ion exit and culminates in the voltage transition shown in Fig. 9.

Conclusions

Interfacial polarization associated with Na^+ transport across a polycrystalline β-alumina/propylene carbonate interface is nonohmic and can be separately distinguished from bulk resistivity. It is increased by water adsorbed on the interface. Interfaces which have been dried exhibit significantly lower polarization than those purposely hydrated by exposure to water vapor.

The results presented are consistent with the hypothesis that interfacial Na^+ ion transport occurs through an intermediate state in which Na^+ is adsorbed on the β-alumina surface, transport between the conducting planes and surface being more rapid than transport directly to the solvated state. Water competes with Na^+ for surface adsorption sites and provides a source of ionic hydrogen species, such as H_3O^+, which can diffuse into β-alumina. A dynamic equilibrium between adsorbed Na^+/H_2O and Na^+/H_3O^+ substituted into the adjacent conducting planes is established and results in increased interfacial resistivity in the presence of water. Extended Na^+ electrolysis into β-alumina gradually enlarges the region of decreased conductivity by transporting ionic hydrogen species more deeply into the electrolyte. Extended electrolysis out reverses the effect, essentially "cleaning" the interface.

Oxidation and Corrosion of Tin-Coated Zircaloy-4

K. Hauffe* and V. Martinez*

Institute of Physical Chemistry, University of Göttingen, 34 Göttingen, West Germany

ABSTRACT

Because of the lack of the adhesion of the growing oxide layer on zirconium alloys, tin-coated Zircaloy-4 has been oxidized in 250 Torr oxygen at 500°C and corroded in high pressure water at 349°C and 176 atm. The rate of both reactions was decreased with increasing thickness of the tin layer (up to 0.1 μm). Simultaneously, the transition point was shifted to longer periods. Presumably this enhancement was caused by the tin layer which exists between the alloy and the oxide operating as liquid agent.

A great number of atomic reactors, such as stationary units for electrical power supply or for ship reactors, operate as high pressure water reactor type, where Zircaloy-2 and -4 are used as construction material. The use of these alloys continues to be attractive for fuel cladding and pressure tubing applications. Besides the creep strength, the corrosion behavior of these alloys is very important for the durability and security of these reactors. Besides Zircaloy-2 and -4, zirconium-niobium alloys with 2.5-3.5 weight per cent (w/o) Nb, either without or with about 1 w/o Sn, have become of importance because of their higher creep strength with similarly good corrosion resistance under reactor conditions (1). All these alloys form, at high temperatures under high pressure water, zirconium oxide containing more or less amounts of foreign ions caused by immigration of alloying elements. However, the oxide layers exhibit only a limited

* Electrochemical Society Active Member.

Key words: plasticity, layer, interface, crevices, stresses.

adherence which is responsible for the premature destruction of this material.

As today it is well known on the basis of an extensive study and of experience, the ductility of ZrO_2 is rather small. Therefore, when the oxide layer has attained a critical thickness, the shearing stresses between the alloy and the growing oxide become so large that crevices and pores are formed in the oxide scale. Associated with this is transition to prevailing transport of O_2 molecules in these crevices and pores, causing a faster oxidation or corrosion characterized by a transition from a parabolic rate law to an approximately linear rate law of oxidation. Simultaneously, a color change of this oxide layer occurs from dark gray, in consequence of an oxygen deficiency, to white, due to its attaining a stoichiometric composition. Initially, near the transition point white spots appear in the gray oxide layer which become larger during the oxidation. As known, this color is connected with a postoxidation of the initial nonstoichiometrically composed oxide layer oxygen vacancies and free electrons in consequence of an oxygen deficit.

As long as the contact of the oxide layer with the alloy is not interrupted and the number of pores and crevices per unit area of the oxide layer is not too large, sufficient oxygen ion vacancies and free electrons are available in the oxide layer for the transport of oxygen ions to the alloy-oxide interface. In the later period of oxidation, however, the density of crevices and pores has become so large that transport of oxygen as O_2 molecules in crevices and pores prevails. In consequence of this fact the oxide layer is oxidized to a stoichiometric composition in which the concentration of oxygen ion vacancies and of free electrons has been strongly reduced. The oxide layer becomes white. This transition, which is correlated with the appearance of a porous oxide layer and with an increase in the rate of oxidation, can be easily recognized by a break in the oxidation-time curve (Fig. 1).

While, in the pretransition oxidation period, the rate of oxidation is determined mainly by a transport of electrons and/or holes and of oxygen ions via vacancies and/or via interstitial positions, characterized by a parabolic rate law, the subsequent oxidation period fits a linear rate law of oxidation rather well, because transport processes through the porous oxide layer no longer determine the oxidation rate. However, other rate laws, for instance a cubic and a logarithmic rate law in the pretransition period, have been found (2). The problem which had to be solved was by what means the rate of oxidation could be decreased, a question which is correlated with the shift of the transition point to longer oxidation time. This problem is intimately connected with the aim of preventing the appearance of pores and crevices in the oxide layer. Ignoring the various possible ways of solving this problem discussed elsewhere (3), only one possibility was tentatively employed which seemed to offer some success. This was the introduction of a plastic or a liquid layer between the alloy and the growing oxide layer.

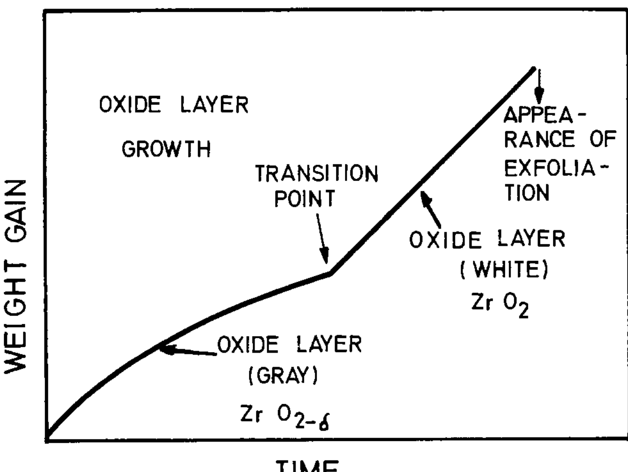

Fig. 1. Schematic representation of the kinetics of oxidation of Zircaloy.

The introduction of a plastic oxide layer is a rather complicated problem because the oxide must have not only a predominantly defect structure, but must also exhibit a high mobility of the lattice defects at temperatures between 280° and 350°C, the temperature range of an operating high pressure water atomic reactor. These requirements are necessary in order to decrease the shearing stresses at the oxide/alloy interface due to diffusion of oxygen ion vacancies into the interface, and to prevent the formation of crevices and pores. Attempts to solve this problem which have met with success are not known.

The second way, in which a plastic or liquid metal layer is deposited between the alloy and the growing oxide layer, and which remains unoxidized during the corrosion, seems to be more successful. The application of this method was stimulated by experiments on the high temperature oxidation of Fe-Cu and Fe-Sn alloys, where the noble metals Cu and Sn are precipitated at the interface steel/oxide. These metals, because of the high oxidation temperature of $> 1000°C$ are in a liquid state and act simultaneously as a liquid interface and as a blocking layer to prevent a porous structure in the oxide layer and decrease the rate of oxidation (4).

On account of the favorable influence of tin on the oxidation behavior of Zircaloys and its low melting point, which promises to prevent shearing stresses due to its liquid state at the temperature of an operating reactor, tin was selected as liquid metal layer. It was deposited in various thicknesses on Zircaloy-4 sheets and tubes before oxidation. To what extent other metals would operate in this manner between 280° and 400°C is unknown. However, only metals with a low melting point ($< 280°C$, the lowest operating temperature of a reactor) can be employed. Furthermore it must be taken into account that a quick diffusion of zirconium atoms must occur through the metal interlayer, so that the following arrangement is present

zirconium alloy/liquid tin layer/zirconium oxide [I]

and a SnO and/or SnO_2 growth must not occur. In the first stage of oxidation, however, involving a layer of "dark ZrO_2" before the transition point, the activity of SnO in ZrO_2, $a_{SnO(in\ ZrO_2)}$, next to the interface liquid Sn/ZrO_2 is extremely low so that tin is practically not converted to SnO as can be estimated from thermodynamic data.[1] Unfortunately in the later period of oxidation after the transition point tin is not sufficiently inert (3) and a mixed-oxide can be formed.

In spite of this complex mechanism, described by Douglass and Wagner (6) in more detail, we want to show here that indeed a liquid tin layer is acting favorably between the alloy and zirconium oxide in the manner mentioned above.

[1] According to Wagner (private communication) after the equilibrium at 500°C

$$Sn(l) + \tfrac{1}{2} ZrO_2(s) = SnO(in\ ZrO_2) + \tfrac{1}{2} Zr(in\ Sn(l))$$

practically no formation of SnO can be expected because one obtains

$$a_{SnO(in\ ZrO_2)} \approx 10^{-18}/a_{Zr(in\ Sn)}$$

and if the value for $a_{Zr(in\ Sn)} \approx 10^{-4}$ is introduced employing the equilibrium

$$Sn(l) + Zr(in\ Sn) = SnZr(s)$$

with

$$a_{Sn} \times a_{Zr(in\ Sn)} = \exp(\Delta G°_{SnZr}/RT)$$

with $\Delta G°_{SnZr} = -14{,}000$ cal/mole [see Wagner (5)] then we obtain

$$a_{SnO(in\ ZrO_2)} \approx 10^{-14}$$

as an upper limit if saturation of liquid tin with the intermetallic SnZr governs. On the basis of this calculation we may assume that $a_{SnO(in\ ZrO_2)}$ may be even lower than 10^{-14} if the liquid alloy is not in equilibrium with the intermetallic SnZr.

First of all, corrosion experiments with flowing water were carried out in a high pressure autoclave in the Research Centre of the Atomic Reactor Station at Tesperhude (7). This autoclave was constructed with four mounting frames and a lock chamber in order to take out samples under high pressure during the experiments without any interruption of the corrosion of the remaining samples. This experimental arrangement is necessary in order to prevent a cooling of the remaining samples which causes thermal stresses in the oxide layer.

Experimental

Apparatus.—The specimens were oxidized in oxygen at normal pressure in an oxidation apparatus well known in the literature. The oxidation in high pressure water vapor and the corrosion in high pressure water were measured is an autoclave.

The oxidation apparatus (Fig. 2) consisted of a vertical quartz tube connected with a Sartorius electronic microbalance capable of weighing to ± 1 μg, this being completely enclosed in the vacuum system. The furnace temperature was controlled to ± 1°C with a temperature controller. Oxygen of a purity 99.995 volume per cent (v/o) supplied by Messer-Griesheim was used in the tests requiring an oxygen atmosphere. As carrier gas pure argon was employed.

For the corrosion of Zircaloy-4 samples in high pressure water an autoclave with lock chamber was constructed (Fig. 3). At the bottom of this autoclave are four drawing junction pieces which are correspondingly connected with four ball valves by means of intermediate water-cooled connections. On the lower junction of these ball valves the lock chamber is placed, connected with these ball valves through a flareless tube fitting. This lock chamber consists of lock tube, packroom, drain valve, and axially movable drawing rod. This arrangement makes possible the introduction or taking out of samples during the experiments. The autoclave can operate at a maximum temperature of 500°C and a maximum pressure of 250 atm. We feel that our experimental arrangement has several advantages over that of the other authors particularly for long time experiments. While taking out several samples it is not necessary to cool the reacting system and therefore probable crevice formation in the oxide layer of the remaining samples in consequence of thermal stresses is suppressed. In spite of its steel construction, the thermal isolation was so designed that in the middle of the autoclave the temperature accuracy in a width of 15 cm was ± 0.5°C at 349°C and 176 atm water pressure. Deionized water used as a corroding environment had 0.04-0.026 mg/liter O_2, a specific conductivity of 0.5-1.7 μmho-cm^{-1} and a pH value of 7.5-6.4. The applied flow rate of water was measured continuously during the experiments.

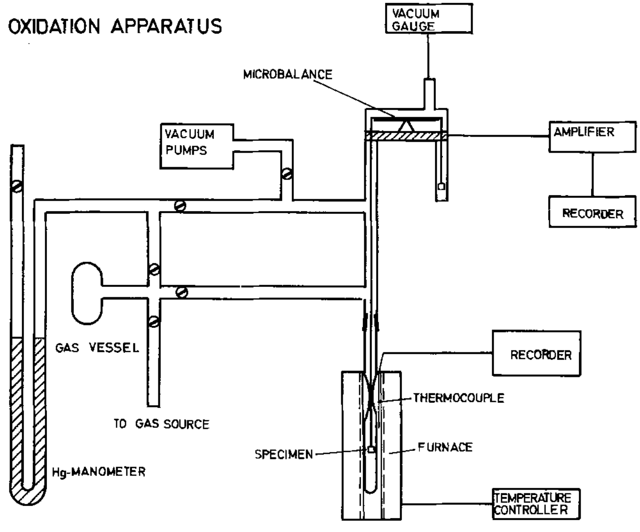

Fig. 2. Oxidation apparatus

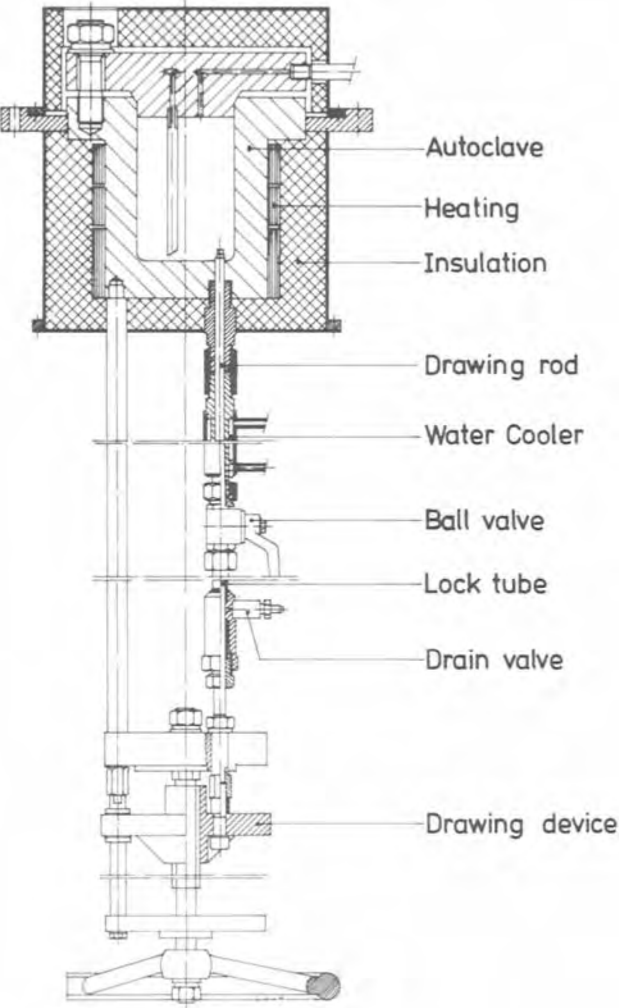

Fig. 3. Autoclave for high-pressure water oxidation experiments

Sample preparation.—Zircaloy-4 samples[2] measuring 15 × 10 × 0.8 mm were cut from strips, polished on 800 grid silicon carbide paper, degreased, and then pickled in the following pickling solution: 45 v/o HNO_3, 5 v/o HF diluted with deionized water at about 20°C. Following this, we tried to deposit tin layers on Zircaloy-4 samples. First of all the samples were immersed, under vacuum and at 700°C, in a tin bath. At this temperature and greater, unfortunately, the undesirable and brittle Sn_2Zr principally was formed. The presence of this compound on the samples by no means reduces the oxidation rate (Fig. 4). Zirconium diffuses quickly through this alloy and reacts at the outer interface with the oxygen. At lower temperatures ($<$ 600°C) longer time is necessary in order to get a thin compact layer with a tin content of larger than 95 w/o. Unfortunately this layer was not uniform and had a poor adherence.

No suitable tin layers were obtained by means of electrochemical methods, with and without adding organic compounds as inhibitors, at temperatures between 20° and 90°C. Thin and uniform tin layers were deposited therefore by evaporation under vacuum (10^{-5} Torr) with a Balzers microevaporator MIKRO-BA-3. The thickness of these evaporated tin layers was estimated through optical comparison of the samples with other Zircaloy-4 samples previously weighed and calibrated by light absorption of evaporated tin onto glass.

[2] Zircaloy-4 is a zirconium alloy which mainly contains 1.2-1.7 w/o Sn; 0.07-0.13 w/o Cr; 0.18-0.24 w/o Fe, and 0.10-0.15 w/o O_2 (8).

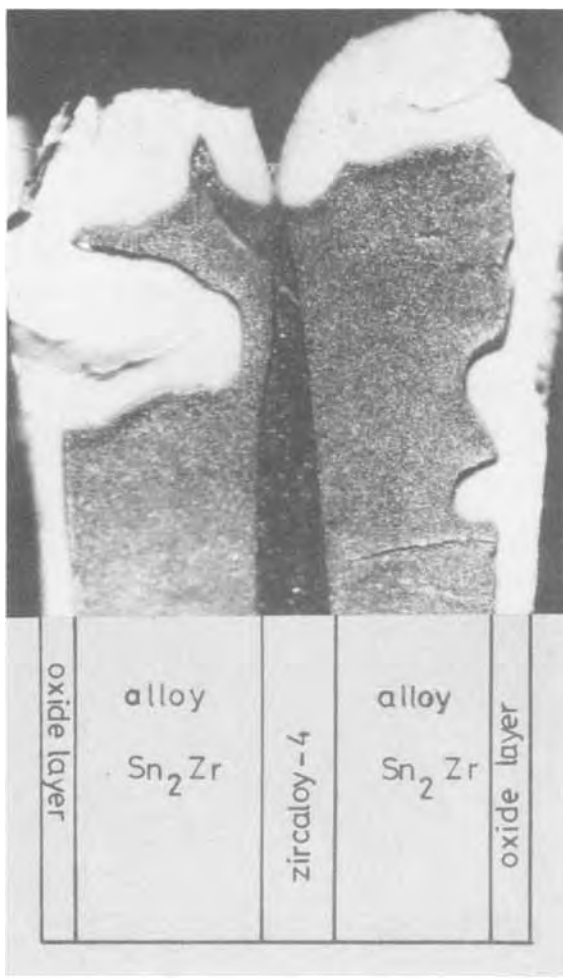

Fig. 4. Cross-section photograph of an oxidized tin coated Zircaloy-4 sample ($T = 500°C$; $p_{O_2} = 300$ Torr; $t = 4$ days) (X63).

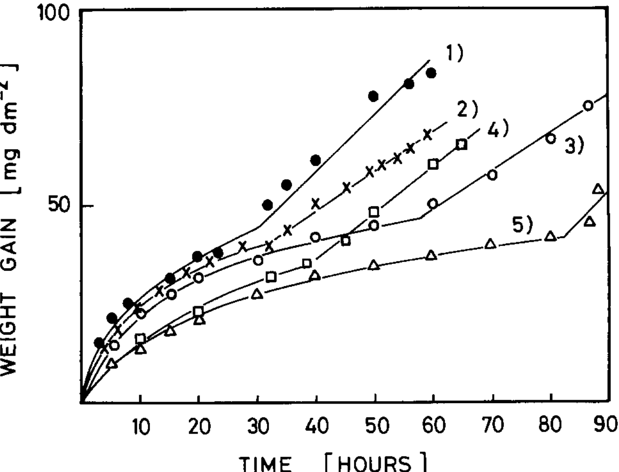

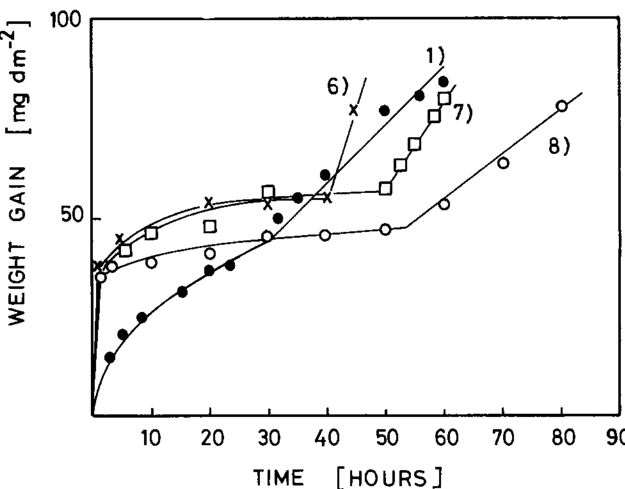

Fig. 5. (a,top) Oxidation of tin-coated Zircaloy-4 specimens at 500°C and 250 Torr oxygen: curve 1, no tin; curve 2, 200Å; curve 3, 300Å; curve 4, 500Å tin; curve 5, 800Å tin coating thickness. (b,bottom) Oxidation of tin-coated Zircoloy-4 samples at 500°C and 250 Torr oxygen: curve 1, no tin; curve 6, 0.1 μm; curve 7, 0.18 μm; curve 8, 0.23 μm tin coating thickness.

Experimental Results

Oxidation with oxygen.—First, samples with tin coatings of different thickness were oxidized in 250 Torr oxygen at 500°C. Figure 5 shows that the oxidation rate decreases with the thickness of the tin layer. In spite of the scatter in results, we found a shift of the transition point to longer oxidation times. In the pretransition period the initial oxidation rate of the samples with thick tin coatings (between 0.1 and 0.3 μm) is higher than the oxidation of the samples with thinner tin coatings ($<$ 0.1 μm). This unexpected initial weight increase probably is caused by the simultaneous oxidation of tin.

On the other hand, Fig. 5 shows that transition time increases up to 800Å tin and this dependence is approximately linear as shown by Fig. 6. The dependence of the parabolic rate constant on the thickness of the tin layers in the first period of oxidation is shown in Fig. 7. Figure 5 represents also the kinetics of the post-transition oxidation, the time dependence now being linear. Practically no change of the oxidation rate in this post-transition period by means of these coatings was observed. On account of their lack of effectiveness for oxidation resistance, thick tin layers ($\gtrsim$ 0.1 μm) were not employed in subsequent experiments.

Figure 8 shows the increasing dependence of the oxidation rate on the oxygen pressure of a Zircaloy-4 sample with a 400Å thick tin coating at 500°C. Furthermore in Fig. 9 there is plotted the parabolic rate constant k_p *vs.* the oxygen pressure in a logarithmic scale yielding $k_p \sim p_{O_2}^{1/8}$. Meanwhile, in the post-transition stage the linear rate constant k_L increases with a fourth root of the oxygen pressure as can be seen from Fig. 9. This dependence of the parabolic rate constant on the oxygen pressure forced us to assume that the rate-determining diffusion must occur in the p-type region of the oxide layer near the outer surface according to

$$\text{Zr-alloy} \mid \text{n-type } ZrO_2\text{-p/n transition-p-type } ZrO_2 \mid \text{oxygen} \quad [II]$$

while the diffusion in the n-type region must be fast enough. A remarkable observation is also the decrease of the transition time with increasing oxygen pressure (Fig. 10) which seems to be correlated with a faster growing p-type oxide region.

The dependence of the oxidation rate of a Zircaloy-4 sample on the temperature with a 800Å thick tin coating in 250 Torr oxygen is shown in Fig. 11. The values of the oxidation constants were found to be increased with increasing temperature. From these results an activation energy of 27.7 kcal/mole was calculated. Since this value agrees with that for the oxidation of pure Zircaloy, the mechanism of both may be assumed to be identical.

By means of microprobe measurements with a microprobe analyzer (Geoscan), an enriched tin zone could be identified at the alloy/oxide interface. Figure 12 shows the distribution of both metals, tin and zirconium, in the oxide layer.

High pressure water corrosion.—In addition to the oxidation experiments, Zircaloy-4 samples with tin

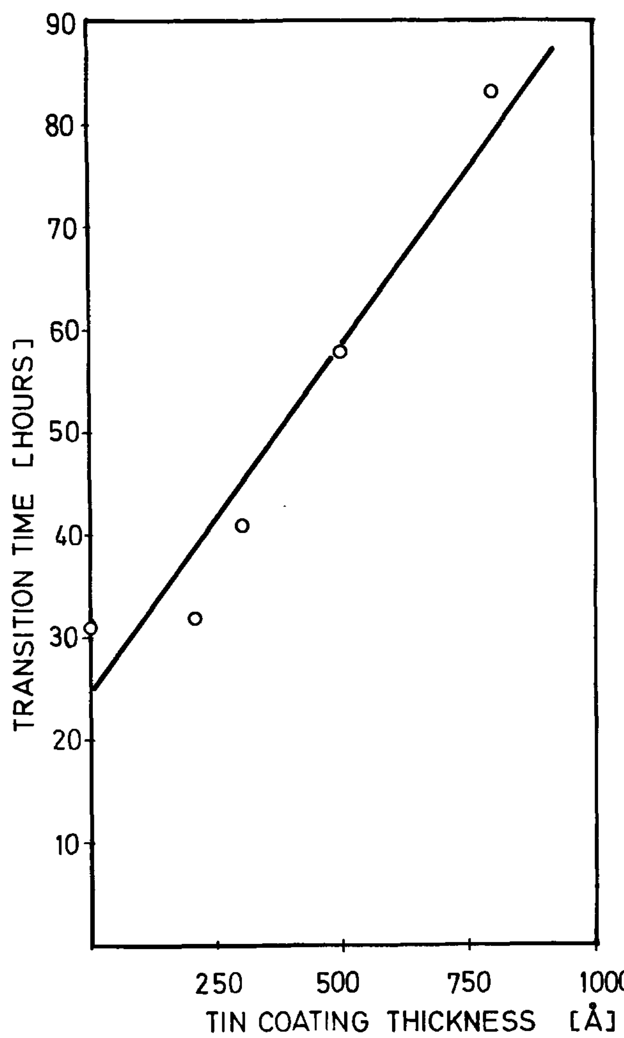

Fig. 6. Dependence of the oxidation transition time on the tin coating thickness at 500°C and 250 Torr oxygen.

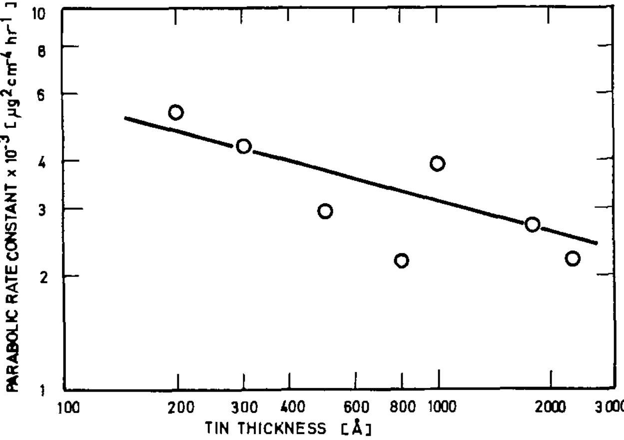

Fig. 7. Dependence of the parabolic oxidation rate constant on the tin coating thickness at 500°C and 250 Torr oxygen.

coatings were corroded in high pressure water in the autoclave at 349°C and 176 atm. Both the time dependence and the tin thickness dependence of the corrosion rate was measured. The samples were taken out without interrupting the corrosion of the remaining samples, as described in the experimental section. A small decrease of the oxidation rate with increase of the thickness of tin coatings was observed (Fig. 13).

Water vapor oxidation.—Zircaloy-4 samples with tin deposited were oxidized at 403°C and 48 atm water vapor pressure. In spite of the scatter in the results a

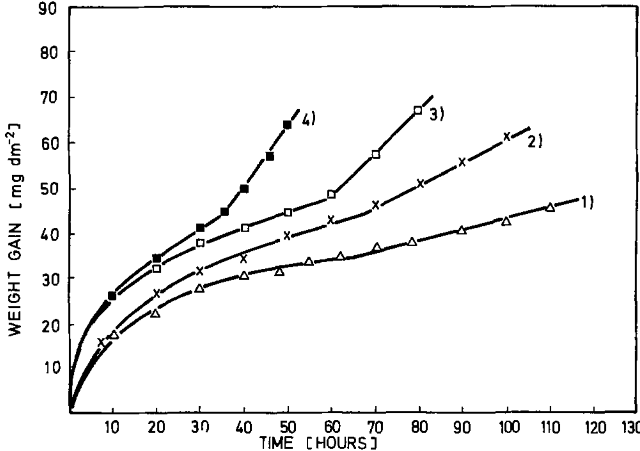

Fig. 8. Dependence of the oxidation rate on the oxygen pressure at 500°C and tin coating thickness of about 400Å: curve 1, 8×10^{-4} atm; curve 2, 8.7×10^{-3} atm; curve 3, 3.3×10^{-1} atm; curve 4, 6.3×10^{-1} atm.

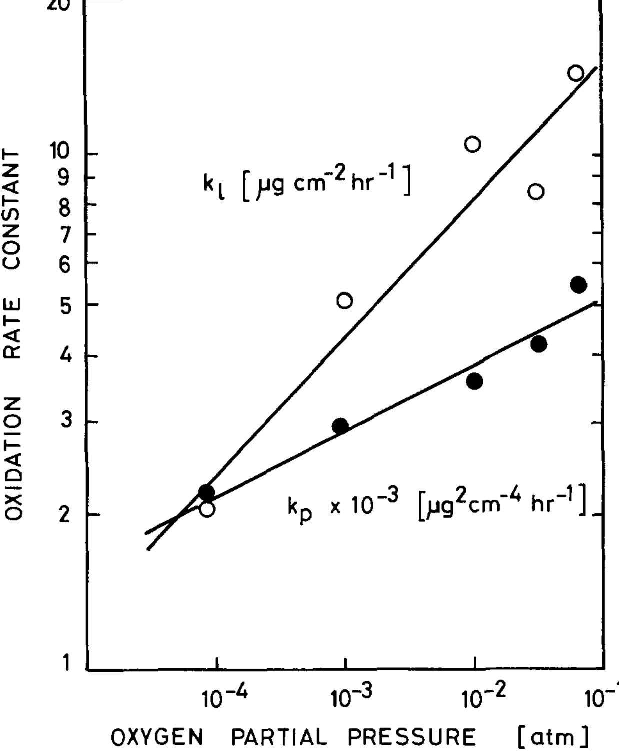

Fig. 9. Dependence of the parabolic and of the linear oxidation rate constant on the oxygen pressure at 500°C and tin coating thickness of about 400Å.

small decrease of the oxidation rate with increasing thickness of the tin layer was detected as shown in Fig. 14.

Electron microscope photographs.—On comparing an oxidized Zircaloy-4 sample without a tin coating (Fig. 15a) with an oxidized tin-coated Zircaloy-4 sample (Fig. 15b) it can be recognized that the oxide layer of the tin-free specimen exhibits a greater number of pores and crevices.

Photographs of these pore-free zones allow the conclusion that this tin treatment causes the growth of a more coherent oxide layer at 500°C and 250 Torr oxygen. The thicknesses of all these oxide layers have been obtained close by the transition point or in the linear oxidation region, *i.e.*, beyond the transition point. This transition occurs at about 40-55 mg-dm^{-2}.

Discussion

Since zirconium oxide exhibits an intrinsic lattice defect behavior according to

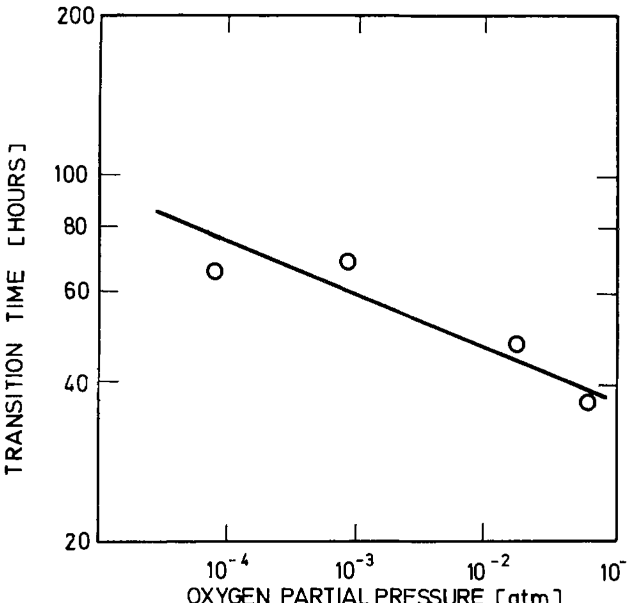

Fig. 10. Dependence of the oxidation transition time on the oxygen pressure at 500°C and tin coating thickness of about 400Å.

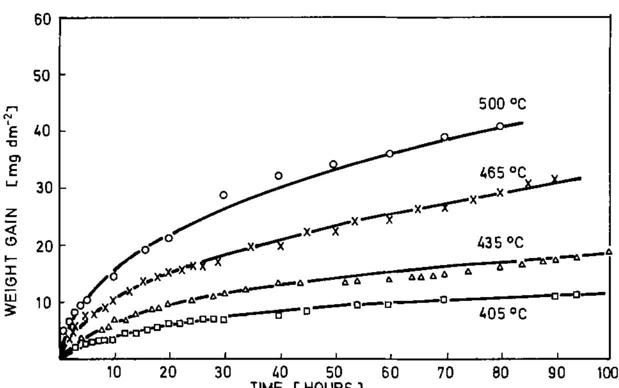

Fig. 11. Dependence of the oxidation rate of tin-coated Zircaloy-4 samples on the temperature at 250 Torr oxygen and tin coating thickness of about 800Å.

$$\tfrac{1}{2}\, O_2(\text{gas}) = O'' + 2\,|e|^{\cdot} \quad \text{p-type } ZrO_2 \quad [3]$$

with the temperature-dependent equilibrium

$$O'' + |e|^{\cdot} \rightleftharpoons O' \quad [4]$$

we may tentatively assume that the oxidation of zirconium and its alloys occurs by diffusion of oxygen ions through the oxide layer via oxygen ion vacancies $|O|^{\cdot\cdot}$ and $|O|^{\cdot}$ and via interstitial positions O'' and O' with the equivalent number of free electrons e' and holes $|e|^{\cdot}$ for electroneutrality.

Taking into account the ΔG° values for the formation of ZrO_2, SnO_2, and SnO at 500°C (− 57, − 28, and − 24 kcal/equiv.) and the experimental results of the oxidation of zirconium alloys with Cu, Cr, Fe, and Mo additions (9), it is concluded that tin remains initially precipitated at the alloy/oxide interface. This metal separating the growing oxide from the alloy should decrease the shearing stresses between the alloy and the oxide. Because of the relative small quantity of tin in the alloy it is questionable whether a homogeneous precipitation of this metal at the interface is possible.

At the beginning of oxidation and corrosion of the Zircaloy-4 samples with thin tin coatings, at tempera-

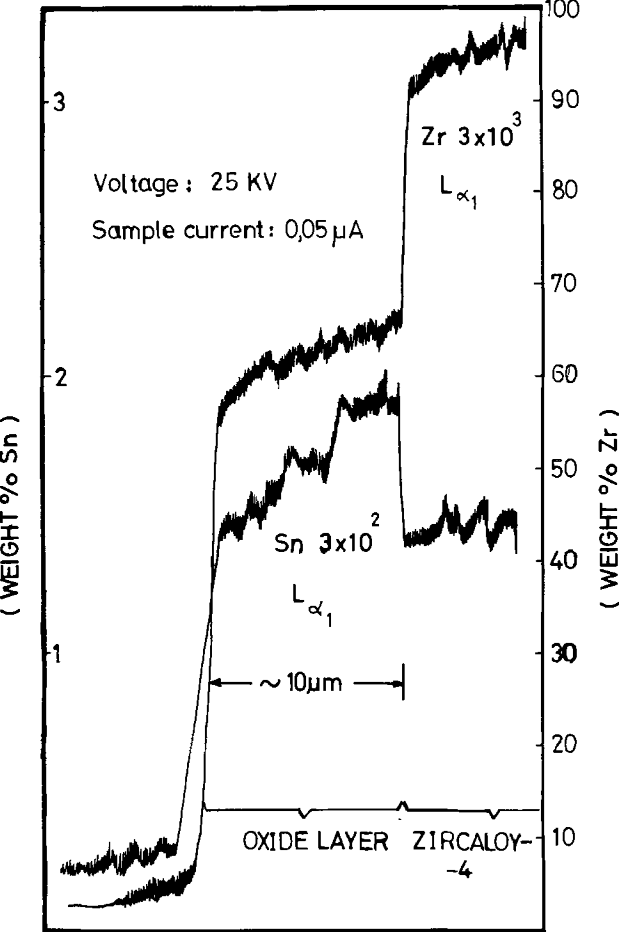

Fig. 12. Distribution of zirconium and tin in the oxide layer of an oxidized Zircaloy-4 sample (tin coating thickness 400Å; $T = 500°C$; $p_{O_2} = 477$ Torr).

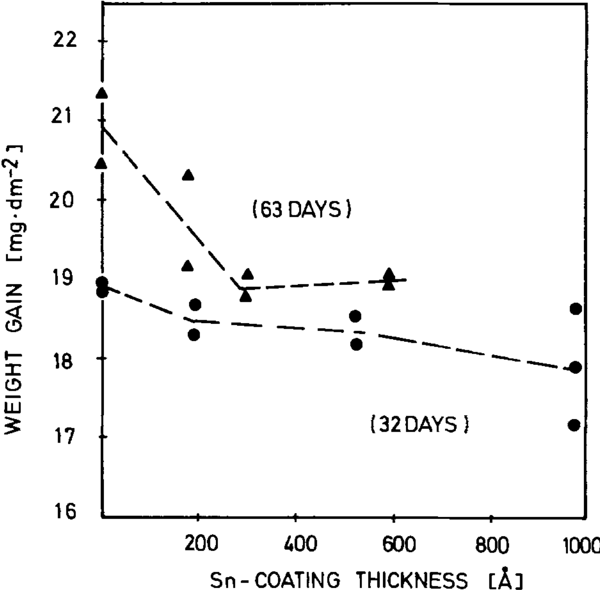

Fig. 13. Corrosion of Zircoloy-4 samples at 349°C and 176 atm water pressure ($t_1 = 32$ days; $t_2 = 63$ days).

tures between 350° and 500°C a liquid tin layer should be expected at the alloy/oxide interface. During corrosion zirconium dissolves in liquid tin and migrates through this tin layer toward the interface tin/oxide where the following reaction occurs

$$Zr\,(\text{in } Sn(l)) = ZrO_2 + 2|O|^{\cdot} + 2e' \quad [5]$$

independent of the oxidizing ambient. During the oxi-

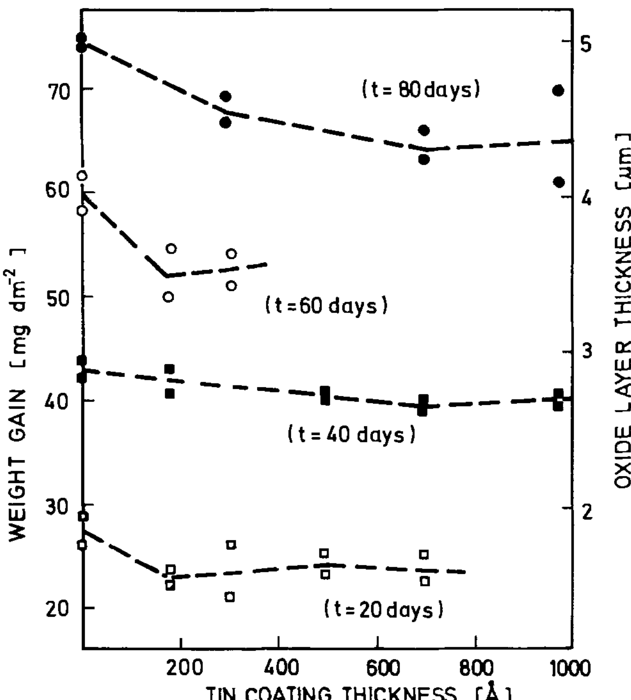

Fig. 14. Oxidation of Zircaloy-4 samples at 403°C and 48 atm water vapor pressure (t_1 = 20 days; t_2 = 40 days; t_3 = 60 days; t_4 = 80 days).

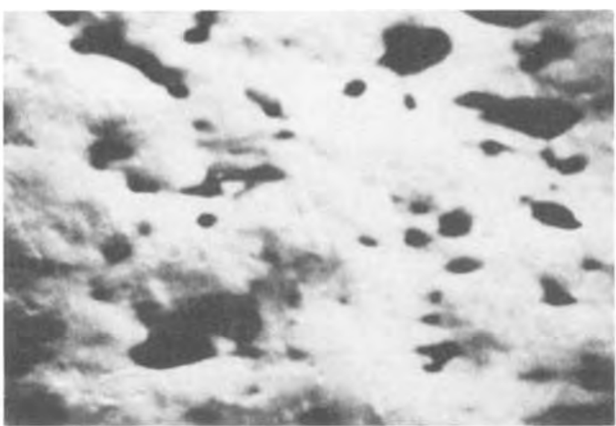

Fig. 15. Electron microscope photographs of oxidized Zircaloy-4 samples (T = 500°C; p_{O_2} = 250 Torr; t = 85 hr). (a, top) Weight gain: 110 mg-dm^{-2} (×300). No tin. (b, bottom) Weight gain: 95 mg-dm^{-2} (×360). Tin-coated sample.

dation in oxygen, these oxygen ion vacancies $|O|^{\cdot}$ migrate with free electrons in an ambipolar diffusion through the oxide layer only toward the p-type region, where oxygen ions in interstitial positions and holes are the migrating species [3].

During the corrosion in high-pressure water, the growing oxide layer is homogeneously n-type due to the low oxygen pressure. Therefore, only free electrons are available besides oxygen ion vacancies produced by reaction step [5]. We can consider that the first reaction step is adsorption of H^+ and OH^- onto the ZrO_2 surface

$$H_2O \rightleftharpoons H^+(\text{ads}) + OH^-(\text{ads}) \qquad [6a]$$

followed by entering of hydrogen into the oxide lattice

$$H^+(\text{ads}) \rightarrow H^{\cdot}\ (\text{in } ZrO_2) \qquad [6b]$$

Simultaneously, the OH^- ions enter the oxide lattice occupying oxygen ion vacancies

$$OH^-(\text{ads}) + |O|^{\cdot} = OH|O|^x \qquad [7a]$$

producing electrically neutral species which can react with protons at the surface

$$2\,OH|O|^x + H^+(\text{ads}) = H_2(\text{aq}) + H^{\cdot}\ (ZrO_2) \qquad [7b]$$

under formation of hydrogen dissolved in water and protons in the oxide lattice.

Assuming a fast migration of protons into the oxide lattice and a slow one for the electrons, mainly protons are discharged at the Sn/ZrO_2 interface, according to

$$H^{\cdot}\ (ZrO_2) + e' \rightleftharpoons H\ (\text{in Sn}) \qquad [7c]$$

Since, however, the solubility of hydrogen in tin is very small, the reaction step [7c] is precluded. Therefore, in the presence of a tin layer one is forced to assume the following reaction sequence with hydrogen formation at the ZrO_2/H_2O interface, according to the following steps

$$OH^-(\text{ads}) + |O|^{\cdot} \rightarrow H^x(\text{ads}) \qquad [8]$$

and

$$H^x(\text{ads}) + H^+(\text{ads}) + e' \rightarrow H_2(\text{aq}) \qquad [9]$$

Due to the tin coating we need free electrons and, therefore, a migration of electrons through the oxide layer is necessary in order to make possible the reaction steps [8] and [9].

As soon as the tin layer has disappeared during a longer oxidation period due to its inclusion in the oxide layer experimentally detected by our microprobe measurements, then the oxidation continues in the same way as an untreated Zircaloy-4 producing pores and crevices in the oxide layer which are responsible for the appearance of the transition to a faster rate of oxidation and a quasi-linear rate law. In this case we might suppose that the appearance of transition is closely connected with the disappearance of the liquid tin layer. At present, however, the available experimental results cannot be tendered in evidence.

In conclusion, the presence of a liquid tin layer at the alloy/oxide interface promotes the formation of a coherent and pore-free zirconium oxide layer which temporarily prevents a faster oxidation which occurs after the transition point is attained. Unfortunately, the initially precipitated tin disappears soon due to its dissolution in Zircaloy-4 and/or due to its inclusion in the oxide layer.

Corrosion of Lead Alloys at High Anodic Potentials

J. L. Weininger* and E. G. Siwek

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The corrosion of expanded grids of lead-antimony, lead-calcium, and lead-calcium-tin alloys maintained at constant high float charge was measured metallographically. Linear growth rates were determined for oxide growth on all three alloys. X-ray scans and maps served to locate the presence of $PbSO_4$ at the interfaces and in the bulk of the PbO_2 corrosion product. The results are consonant with corresponding high temperature corrosion work.

Different alloys of lead are used in a variety of lead-acid battery designs and applications. This makes it necessary to examine the behavior of a given alloy under the conditions of its prospective use, for example, float charge.

The anodic corrosion of pure lead was first studied in detail by Lander (1). Combining a thermodynamic and a kinetic approach, he related the mechanism of the positive plate reactions to the actual conditions of battery service. Lander's work showed that the grid of the Pb/PbO_2 electrode is passivated at a potential corresponding to mild overcharge, which is encountered in battery-"float" service. It had already been shown by Haring and Thomas (2), in their introduction of Pb/Ca alloys to the battery industry, that the Pb/Ca alloy corroded much slower than Pb/Sb and at a rate comparable to that of pure Pb. The Pb/Ca alloy was at first used in emergency standby batteries (3); it is now gaining acceptance in maintenance-free batteries and other applications (4).

The present work involves the corrosion of Pb/Sb, Pb/Ca, and Pb/Ca/Sn alloys at a constant high anodic potential (overvoltage *vs.* $PbO_2/PbSO_4 = 0.25V$) at room temperature. The pertinent electrochemistry has been discussed by Milner (5). A similar approach at elevated temperature is described by Cannone, Feder, and Biagetti (6) for accelerated corrosion and life tests of the Bell System's lead-acid battery. Very recently, another such accelerated life test of Pb/Sb grids for heavy duty cycling has been described by Maskalick (7).

Experimental

Different methods of observing the course of corrosion may be used. Willihnganz (3) and others (6) determined the percentage growth of the corroding grid over the original Pb grid thickness. Maskalick (7) measured the actual thickness loss of lead after removal of the corrosion product. In the present case, the depth of corrosion of the alloys was determined directly by metallographic observation. References (3) and (6) describe the axial extension of the grid whereas the lateral dimensional changes (7), resulting directly from the conversion of lead to lead dioxide is used in the present work. The axial extension is caused by the lateral expansion; both are measures of grid corrosion to the extent that the grid growth is proportional to the depth of corrosion (8). The microscopic method was chosen in this work because the condition of room temperature corrosion, combined with a potential close to that of maximum anodic protection (9), resulted in very small rates of corrosion. Furthermore, small samples could be selected from relatively small test electrodes.

Expanded grids, prepared from the following three alloy compositions, were tested: (*i*) Pb-5% Sb (standard antimonial grid alloy), (*ii*) Pb-0.07 ± 0.01% Ca, and (*iii*) Pb-0.06 ± 0.01% Ca-0.84 ± 0.05% Sn.

The following variables of electrode preparation or operation were used to observe their effect on grid corrosion.

(*a*) Grid preparation before pasting: (*i*) a phosphoric acid etch, which involved successive washings in acetone, ethanol, water, and a 10 min etch in 10% H_3PO_4; and (*ii*) ultrasonic cleaning in a commercial cleaning solution containing tetrachloroethylene.

(*b*) Pasted *vs.* unpasted grids: One-half of each expanded grid was left unpasted in order to study the effect of the presence of the paste on the grid.

(*c*) Flooded *vs.* "starved" condition of electrodes: (*i*) The electrode was immersed in an ample supply of 1.28 sp gr acid, and (*ii*) the electrodes were wrapped with several layers of separator which extended into a pool of 1.28 sp gr acid and kept the electrode in a wet, but electrolyte-"starved" condition.

Fifteen electrodes with a surface area of 2.5 × 3.1 cm (each side) were assembled in three test cells for the flooded and starved electrolyte conditions. (The Pb/Sb grids were tested only in the electrolyte-starved cell in order to avoid antimony poisoning of the negative electrodes which would occur in the flooded case). The positive test electrodes were interleaved with negative counterelectrodes. They were connected in parallel to a potentiostat for a constant overcharge at

* Electrochemical Society Active Member.
Key words: lead-acid battery, corrosion, passivation, lead-calcium alloys, oxide growth, cell failure mechanism.

1.34V *vs.* a Hg/Hg_2SO_4 reference electrode at room temperature. This corresponds to an overvoltage of 0.25V with respect to the theoretical $PbSO_4/PbO_2$ potential, and also to a high float-charge according to Willihnganz (3), but in terms of the anodic passivation established by Lander (9), this potential is near the minimum of oxide growth and lower than the potential at which appreciable oxygen evolution occurs. Our own experiments with positive plates having Pb/Ca grids (10) showed that gas evolution just begins at this potential in a cell after substantial cycle life with a total cell charging voltage of about 2.45V. At the positive potential of 1.34V *vs.* Hg/Hg_2SO_4, the corrosion current densities for the flooded and starved cells were 50 and 43 $\mu A/cm^2$, respectively.

Small samples were taken from the grids at periodic intervals over a total test time of 5000 hr. The samples were washed with distilled water, dried, and mounted for microscopic observation of the corrosion layer. Since intergranular corrosion was involved, the actual depth of corrosion was defined as the fraction of a line normal to the Pb/PbO_2 electrode-H_2SO_4 electrolyte interface, which covered the oxide. An average of 20 readings per sample gave a measure of the corrosion depth within $\pm$ 20%.

In addition, at 2300 hr and at the end of the tests at 5000 hr, representative samples of the three alloys were mounted for an electron microprobe analysis, from which scanning electron micrographs, x-ray scans, and x-ray maps were obtained.

Results

The graphs in Fig. 1-3 show the corrosion of the three alloys as a function of time. The data were fitted by the least squares method by a linear equation (solid lines in Fig. 1-3)

$$\Delta y = k + m \cdot t \qquad [1]$$

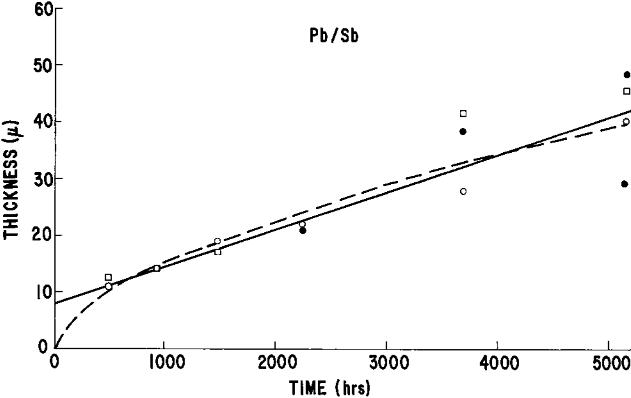

Fig. 1. Oxide growth on Pb-Sb alloy, starved electrolyte; ○ and □ bare grids; ● grids of pasted electrodes.

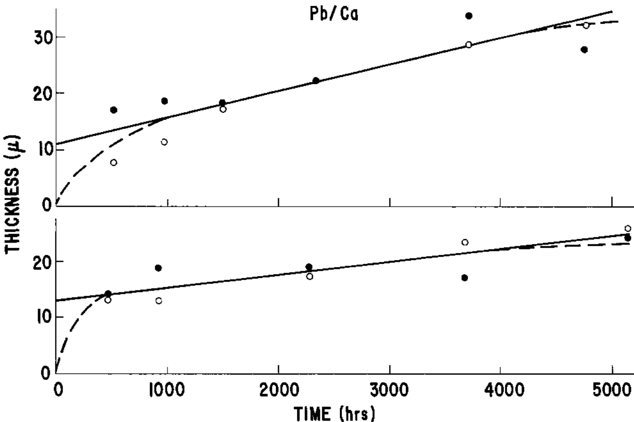

Fig. 2. Oxide growth on Pb-Ca alloy; top, flooded; bottom, electrolyte-starved cells; ○ bare grid; ● pasted grid.

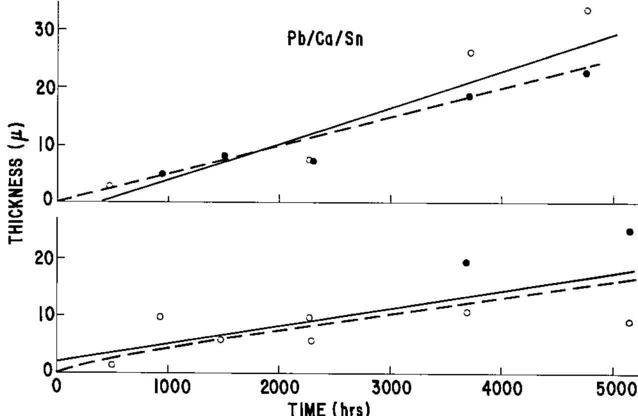

Fig. 3. Oxide growth of Pb-Ca-Sn alloy; top, flooded; bottom, electrolyte-starved cells; ○ bare grids; ● pasted grids.

and by an exponential equation (dashed lines in Fig. 1-3)

$$\Delta y = k' \cdot t^x \qquad [2]$$

where Δy is the thickness of the oxide layer, grown at time t, and m is the linear growth rate. k, k', and x are constants.

Table I gives the numerical values of the constants in the rate expression. With these constants, the growth of the oxide was extrapolated from the seven-months experimental data, to periods of one, two, and five years (Table II).

Although the scatter in the experimental data is large, the data were also expressed in exponential equations because this type of relation has been encountered before (7) and, indeed, it is expected for a diffusion-controlled mechanism of corrosion. All fitted curves should pass through the origin. The extent to which this does not occur in the linear least square fits reflects the experimental error.

The error limit in individual determinations was about $\pm$ 20%. It was large because the experimental conditions combined to make the corrosion effect small. However, as seen in Fig. 1-3, for the first 5000 hr of corrosion at room temperature, the linear relation gives a larger corrosion rate than the exponential one.

As shown in Table II, under the given experimental conditions, the antimonial grid corroded two to three times as fast as the calcium alloys in the electrolyte-

* s and f: electrolyte-starved and flooded cells.

starved cell. The Ca-alloys had a comparable corrosion rate, at least for the extrapolated first year value. They corroded twice as fast in the electrolyte-flooded as in the electrolyte-starved environment. Other variations in the preparation of the PbO_2 electrodes, *i.e.*, the method of cleaning the grid before pasting, or the presence or absence of the paste on the grid, did not have any influence on the corrosion rates within the experimental error. Data for unpasted and pasted grids were combined in Fig. 1-3, and in the evaluation of the corrosion rates.

Optical and Electron Microscopy

For microscopic examination, it was found that a coarse and fine mechanical polish was satisfactory for observing the oxide layer, but for x-ray scanning an ultra microtome cut gave an oxide surface with the least distortion. Figure 4 is a micrograph of such a cut. It represents the Pb/Ca/Sn alloy and its corrosion layer after 4800 hr on test. The grid had been originally cleaned with the solvent; it was pasted and tested in the flooded condition. Some fragments of the active material are still near the oxide-electrolyte interface.

Figures 5 through 7 are pairs of backscattered electrons (BSE) micrographs and sulfur x-ray maps of the same location for the three grid alloys. The BSE micrographs give a better indication of the topography of the sample than optical micrographs and they also serve to locate x-ray scans, as in Fig. 6. The sulfur x-ray maps were obtained by tuning the crystal spectrometer to the $K\alpha$ line of sulfur.

Figure 4 shows clearly the intergranular nature of the oxide growth on the Pb-Ca-Sn alloy. Material in islands close to the oxide/electrolyte interface, stemming from the battery paste, contains a considerable amount of $PbSO_4$ (Fig. 5a). This is noted in the sulfur x-ray map of the area (Fig. 5b). It was also observed in several sulfur x-ray scans (not shown) which indicated a surface concentration of $PbSO_4$ at the oxide-electrolyte interface. The sulfur x-rays may have originated not only in the above-mentioned remnants of the active material, but also in a thin surface skin

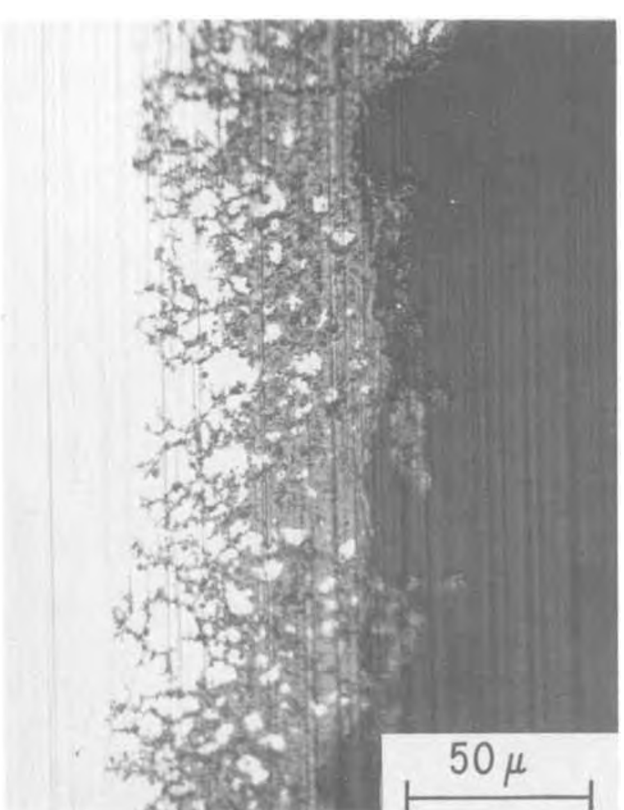

Fig. 4. Pb-Ca-Sn grid after 4800 hr of corrosion, 500X

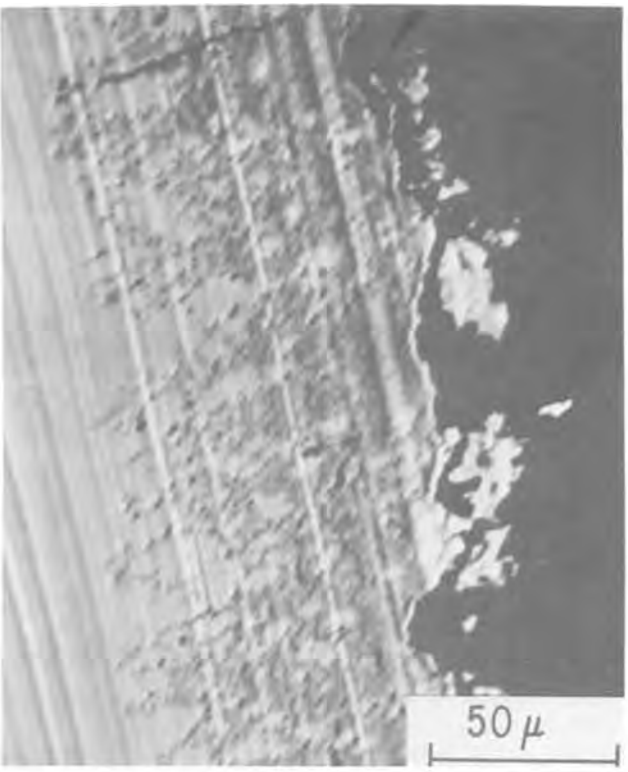

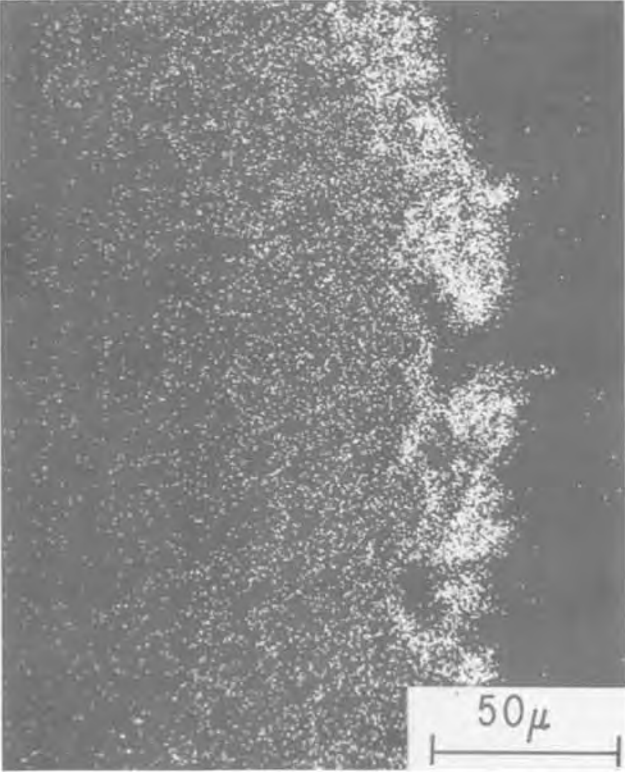

Fig. 5. (a, top) BSE micrograph of Pb-Ca-Sn; (b, bottom) sulfur x-ray map of same location as Fig. 4 and 5a. 500X.

of $PbSO_4$ which could have formed during sampling of the electrode.

In the Pb-Sb sample, the sulfur content of the oxide layer, even at the electrolyte interface, was very low as shown by the scan in Fig. 6a and the uniform and scarce sulfur x-ray map in Fig. 6b.

However, $PbSO_4$ accumulates at the grid-oxide interface in the case of the Pb-Ca alloys. Figure 7a shows the sulfur scan which corresponds to the interfaces and location of the x-ray map (Fig. 7b) as drawn

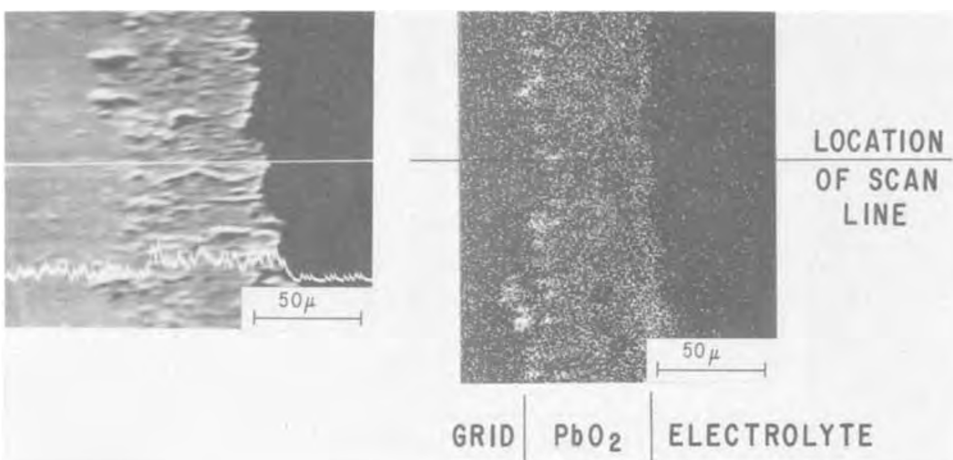

Fig. 6. (a, left) BSE micrograph of Pb-Sb with sulfur x-ray scan; (b, right) sulfur x-ray map of same location. 600X.

on the periphery of the micrographs. This location of $PbSO_4$ at the grid-oxide interface was found consistently in different samples as well as in different locations on the same sample.

Discussion

The corrosion data of the lead alloys can be represented either by a linear or by an exponential growth rate. In the early stages of corrosion, these descriptions of the oxide growth are quite similar (Fig. 1-3). The last column of Table I gives a slope for the curve $\log \Delta y = \log k' \pm x \cdot \log t$. With one minor exception, this slope x has a value of one (linear rate) or smaller.

Extrapolation of high temperature results by others (3, 6, 7) to room temperature with an Arrhenius-type function would lead to the same conclusions for the beginning of corrosion. The mechanism of the corrosion process cannot be described precisely .(1) without knowing the details of the film structure; for example, the extent of porosity. However, a linear rate implies that the reaction at one of the interfaces, rather than ionic migration through the film, is rate determining. While the film is still thin, this seems plausible. Furthermore, if it is assumed that for all cases a linear rate represented the maximum corrosion rate, it is

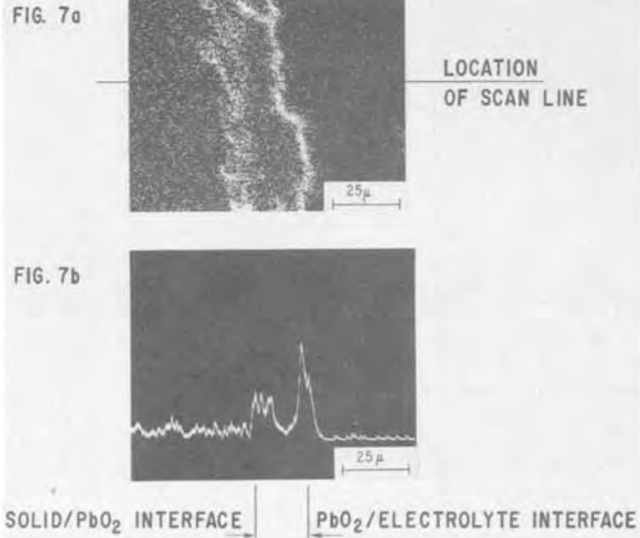

Fig. 7. (a, top) Sulfur x-ray scan on Pb-Ca alloy; (b, bottom) sulfur x-ray map of same location. 1000X.

possible to make estimates of the minimum lifetime of a battery in which failure is due to grid corrosion.

It is possible to compare the results of this work with that of others, although each investigator chooses different experimental conditions and reports corrosion data differently. As pointed out above, lead alloy corrosion data have been given as percentage grid growth (5, 6) or in terms of the amount of lead removed during corrosion (4, 7). In this study, a direct metallographic procedure was chosen, which had been successful for the determination of silver tarnishing in halogen vapors (12). Assuming that the PbO_2 film has a porosity of 20%, then 1μ of lead lost per square centimeter (1.135 mg) corresponds to a buildup of 1.51μ of oxide layer. If the original grid thickness is given, these relative measures can also be related to the percentage increases of the grid thickness.

In the Bell Laboratories work (6), pure Pb and the Pb-Ca alloys were described by a corrosion rate law with an exponential time dependence larger than linear. This is the one example in which the corrosion rate increased with time. The high temperature corrosion, extrapolated to room temperature and to shorter periods of time, gave 0.90 and 18 μ/yr for Pb-Ca and Pb-Sb alloys as compared with the values of 52 μ/yr (electrolyte-flooded) and 66 μ/yr (electrolyte-starved) in the present work. The difference may be traced to and may be consistent with the use of different acid concentration (1.21 *vs.* 1.28 sp gr H_2SO_4), different anodic potentials (1.17 *vs.* 1.34V), different grid design and preparation (cast *vs.* wrought), and also different surface area/cross-sectional area ratios. Finally, the Pb-Ca data were extrapolated in Ref. (6) by a quadratic equation which would give lower values for the initial stages of corrosion than a linear one.

In other reports on Pb-Ca grid corrosion, Willihnganz (3) measured over-all dimensional changes of the grid so that the observed percentage growth cannot be related to actual scale growth. However, Feliu *et al.* (13) determined weight losses corresponding to a growth of 4.4-16μ for oxide layers on Pb-Ca alloy in a 100-day period. The values depended on grain structure and current density and correspond to the present 100-day result of 14μ for the binary electrolyte-flooded Pb-Ca alloy.

A further interesting comparison exists in the case of Pb-Sb grids, which Maskalick (7) tested under the more rigorous condition of battery cycling, when the grid is in a lower, more active potential region for at least part of the test time. The corrosion rate extrapolated to 25°C was 230 μ/yr as compared with 66 μ/yr

for Pb-Sb in the electrolyte-starved condition of the present experiments.

The optical and electron microscopy showed the expected intergranular progress of the Pb/Ca alloy corrosion. It has been pointed out that the effect of grain structure on corrosion will be different for wrought and cast grids (4). In the present study, wrought grids were used; the binary Pb/Ca and ternary Pb-Ca-Sn showed about the same extent of corrosion. This was to be expected on the basis of the relation between corrosion rate and grain size (4). The latter were determined for the two alloys to have ASTM grain size numbers 11.5 and 11.1 (14). This corresponds to average grain sizes of 7.5 and 6.8μ, respectively.

Another possibly important observation was that of a $PbSO_4$ layer between the metal and oxide. This was observed only in the case of the Pb-Ca alloy. The x-ray map and scan of Fig. 7 clearly show the presence of $PbSO_4$ at the location for the Pb-Ca alloy. They do not, however, indicate a continuous barrier layer which had been observed by others (11) during cycling tests. That work attributed poor cycle life of cells with Pb-Ca grids to the presence of the $PbSO_4$ interface layer, which was said to enhance shedding of active material. In our test, the site of $PbSO_4$ concentration may extend over a distance of about 1μ. Only the presence of $PbSO_4$ is indicated, not the inhibition of an electrode reaction. At least for the overcharge condition, corrosion was neither accelerated nor inhibited by the presence of $PbSO_4$.

Effect of Heat-Treatments on Magnetic Properties of Electroless Nickel Alloys

Morton Schwartz*,[1] and Glenn O. Mallory*

The Richardson Company, Allied-Kelite Products Division, Los Angeles, California 90012

ABSTRACT

Electroless deposits from various ammoniacal and acid formulations were evaluated for their ferromagnetic properties and the effects of artificial aging on these properties. Deposits from ammoniacal solutions were ferromagnetic as deposited. Deposits from acid solutions were nonferromagnetic. After heat-treatment, all deposits exhibited ferromagnetism through a maximum, the temperature-time relationship being different for each deposit. This phenomenon appeared to be related to the type of ligand in the solution and to the substrate rather than the phosphorus content of the deposit. Ammoniacal deposits retained magnetism at higher levels after heating for 96 hr at 400°C than any of the acid systems with the pyrophosphate deposit values being higher than citrate deposits. Deposits on aluminum substrates exhibited higher magnetization than on brass substrates or foils separated from substrates.

Electroless nickel deposits exhibit inferior magnetic properties when compared to electrodeposited nickel (1), in fact, deposits with high phosphorus content are nonferromagnetic (2). Such deposits are used as undercoats for subsequent hard magnetic cobalt alloys (containing phosphorus and other elements) in memory systems. The very fine polycrystalline solid solution, bordering on amorphous or liquid (glass)-like metastable structure (3-5) of electroless Ni-P deposits provides the structure required for nonferromagnetic behavior. Such structure also minimizes epitaxial growth of subsequent deposits.

Key words: electroless nickel, magnetics, heat-treatment, computer.

For computer applications, it would be desirable to increase the hardness of the electroless nickel undercoats by suitable heat-treatments which have been studied extensively (6-8). Unfortunately, after artificial aging the electroless Ni-P deposits develop ferromagnetic properties which may affect the over-all magnetics of the memory disk or drum. This change in ferromagnetic behavior is a result of the developing equilibrium between the newly formed Ni_3P intermetallic phase and the Ni phase, with increasing grain size and heterogeneity of the deposit.

It would also be desirable in some applications to eliminate the use of a thin deposit of rhodium or chromium as a final wear resistant surface (with its adverse effect on magnetics). In such cases, disks and drums are heated in air to produce the desirable thin

* NaOH used for neutralization in acid baths, NH_4OH in alkaline baths.
+ Although proprietary (General American Transportation Company), composition made up as published (with 0.002 ppm Pb^{++} as stabilizer).
[a] Deposits from low pH (3.8-4.0) baths of same composition were also studied. The rate of deposition decreased to about 0.08 μm/min and the phosphorus content of the deposit increased to about 12-16 w/o P in all cases.
[b] $NiCl_2 \cdot 6H_2O$.
[c] A 50 g/liter Hydrac bath (Hydrac II) was also used. Deposits were dull and rough and did not exhibit any significantly different magnetic properties.
[d] Lactic acid, 88%.

oxide coating on the magnetic cobalt alloy surface which improves its wear characteristics and the "ridability" of the heads. When such thermal treatments are used, the electroless Ni-P undercoat may develop ferromagnetism.

This phenomenon of increasing ferromagnetic behavior has been reported by several investigators. Gorbunova and Nikiforova (9) reported quantitative data indicating that deposits from acid solutions are nonferromagnetic while deposits from alkaline (citrate) solutions are magnetic (H_c = 4.1 oe, B_r = 45G, B_s = 140G). After heat-treatment at 400°C, 1 hr, both types of deposits showed increased magnetics with the coercive force (H_c) reaching 140 oe, the alkaline solution deposits achieving B_r 3000-3300G/B_s 3400-3700G, and the acid deposits less than one-half of these values. Gorbunova *et al.* (9a) extended their studies on the ferromagnetic behavior of deposits (on copper substrates) from the ammoniacal citrate solutions and concluded that the as-plated magnetic properties depended on the phosphorus content of the deposit which, in turn, was determined by the composition of the solution. Further, the variations of magnetic properties of the deposits due to annealing temperatures were also considered as related to the phosphorus content and changes in phase and structural transitions. Bondar (10) reviewed results obtained mostly by Russian investigators relating the magnetic changes to P content and being due to structural transformations and formation of the Ni-Ni_3P system; neither methods of measurement nor substrates used were indicated. Data (11) on the coercivity of deposits from various alkaline citrate formulations indicate that all these deposits exhibit low coercivities in the as-plated condition with increased values after heat-treatment at 350°C. Alberts *et al.* (12) observed that citrate formulations produced deposits with coercive forces (H_c = 10-80 oe) when ammonia was used to maintain the pH of the solutions and that zero coercivity was obtained when sodium hydroxide was used; these results were reflected in the considerable differences in the phosphorus content of the deposits (3-6 w/o P in NH_3 controlled solutions and 10-17 w/o P in NaOH controlled solutions, devoid of ammonium ions).

The purpose of this investigation was to evaluate the magnetic characteristics of electroless nickel-alloy deposits from various electrolytes and to study the effects of brass and aluminum (6061) alloy substrates and thermal exposure on these properties. The selection of these substrates was determined by the practice of utilizing brass Hull cell panels as a convenient substrate to check out the solutions and then actually producing deposits on aluminum alloy disks or drums.

Experimental

The electroless plating solutions were prepared from individually purified (carbon-treated) stock solution concentrates of the constituents. Deionized water was used exclusively. Tables I and II give the use compositions and conditions. (Bath 8 was made up with proprietary concentrates and used according to supplier directions.) The deposits produced from each bath are henceforth identified by the designated bath number.

A 100-125 cm^2/liter area to volume relationship was employed, the total volume of each solution being 1.8 liter. Solutions were stirred by occasional manual agitation of the panel. Each panel was plated in a freshly prepared solution and was then sliced into test specimens for heat-treatment and testing, thus ensuring uniformity of deposit for each test.

The brass Hull cell panels (8.5 × 12.5 × 0.33 cm) were cleaned with solvent, followed by an alkaline cleaner and acid dip (10% v/v HNO_3). Electroless

plating was initiated by contact with an aluminum wire.

The aluminum (6061) alloy panels (7.5 × 15 × 0.078 cm) were prepared by cleaning in a suitable inhibited alkaline cleaner, followed by an acid cleaner and a 15-20 sec dip in a zincate solution. All electroless plating solutions were made up with nickel sulfate to minimize corrosive effects of the anion. The rate of deposition on the aluminum substrates was 10-25% higher than on brass substrates.

The electroless nickel foils were produced by plating on aluminum substrates which were masked on one side. The mask was removed with solvent and the aluminum dissolved in 1M NaOH containing sodium gluconate. The foils were cut into 0.64 cm (0.25 in.) wide strips and aged. Most of the (as-plated) electroless nickel foils were quite free of stress and easily handled; a notable exception being the deposit from the pyrophosphate solution which was under considerable tensile stress and could not be used. After heat-treatment (especially at 400°C), many of the foils became brittle and some were destroyed in handling.

The sulfamate nickel deposits were all plated from the same solution (3.5 liter) using the above preparation cycles and the technique of immersion into the plating solution with a "live" lead. Electrodeposited foils were produced by plating on a partially passivated stainless steel panel and removed by peeling off the deposit after grinding the edges. The foils were reduced 0.64 cm (0.25 in.) on each edge to minimize current density effects. The sulfamate solution composition and plating conditions were

nickel sulfamate (anhy.)	325 g/liter
(nickel metal	75 g/liter)
boric acid	40 g/liter
chloride	2 g/liter
anti-pit	0.35 g/liter
pH	4.0
temperature	55°-60°C
current density	2.7 A/dm^2
deposition rate	0.5-0.55 μm/min

All the deposit thicknesses were determined by supermicrometer measurements using 1 oz pressure on the anvil.

Heat-treatment of test strips (0.635 cm wide) was done in Hodgkins ovens, controlled with Weather-Measure TPC-N Type K controllers and powerstats to prevent overshooting. Chromel-Alumel thermocouples were attached to the specimen containers and checked with reference thermocouples and a Leeds & Northrup potentiometer. Temperature variations were determined to be within ± 5°C.

The heat-treatment was carried out in air. This was considered justified since it is "normal" practice in the magnetic plating of disks and drums. Further, it appeared that the superficial oxides formed did not seem to influence the magnetic measurements significantly. It should be noted that the interference oxide colors formed varied as a result of the type of solution used.

The magnetic characteristics were measured with a calibrated low frequency (60 Hz) hysteresis loop tester. This instrument consists of a large coil conducting sufficient current to provide a coercive field of 1000 oe. A smaller coil (wrapped around a Teflon tube) is adjusted (zeroed) to be at rest, eliminating any distortion. An 0.635 cm wide test strip (minimum length 3.2 cm),[2] attached to a micarta holder, is inserted into the Teflon tube. The test specimen, if magnetic, becomes saturated, distorting the field. This distortion is picked up and displayed on an oscilloscope as the material's characteristic magnetic hysteresis loop.

The field intensity or field (H) is measured on the x axis of the oscilloscope grid. The coercive force, H_c (oe), is the force required to demagnetize the material being tested and is measured at the loop intercept of the x axis.

The y axis of the grid measures the total flux (maxwells, cgs units) permeating the material. Since the field intensity (H) is at least 4-5 times stronger than the coercive force, H_c, of the materials tested, it is assumed that the ϕ_s measurements represent magnetic saturation. ϕ_r or remanence is the magnetism retained when $H = 0$ and is measured at the y intercept. These values are converted to flux density, B (G), by dividing the total flux (maxwells) by the total cross-sectional area (cm^2) of the magnetic coating on the test specimen.

The values of B_s, B_r, and H_c are required to characterize magnetic properties of the material. Hard magnetic materials are characterized by large B_r and large H_c values; soft magnetic materials have small H_c values. The ratio B_r/B_s can be used to indicate the squareness of the hysteresis loop. The ratio B_s/H_s is the permeability, μ, of the material.

B_s is a physical property of the composition of the magnetic alloy. B_r and H_c are structure sensitive which depend on strains, crystal structure and orientation, and anisotropy of the ferromagnetic phase (15). In precipitation-hardened alloys, such as these electroless nickel deposits, the ferromagnetic phase (Ni) results from the precipitation of the nonferromagnetic phase, Ni_3P, from the supersaturated Ni-P alloys.

An increase in coercivity may involve the precipitation of individually high coercive particles which are small enough to exhibit single domain behavior. It may also be a result of an order-disorder transformation induced by heat-treatment.

Two dissimilarities with the hard magnetics of computers should be noted: (*i*) computers utilize frequencies in the megacycle range whereas the instrument required only 60 Hz, as stated, and (*ii*) bulk magnetics are measured, whereas a computer head measures some indefinite surface magnetism, the depth of which depends on the frequency, magnetic permeability, signal strength, gap, and (possibly) other parameters. Thus, the data obtained are valid for the magnetic properties of the coating per se, but require interpretation for application to computer memory systems or may be used as controls once correlation is established.

Results and Discussion

The nickel electrodeposits exhibited similar saturation induction with some variation in remanent induction on both substrates and foil; the coercivities being the same. Table III shows the large changes and divergence in the induction which occurred as a result of the various heat-treatments. For example, the induction in foils increased 2.5-3X after aging 1 hr at 275°C, these increases being reduced by one-half when aged at 300°C for the same time. On aluminum substrates, induction increased 2-3X at 300°C, 48 hr treatment, while the smallest increase developed on brass substrates at 300°C, 1 hr. The effect on coercivity was reversed, i.e., H_c reduced immediately for all deposits and then remained fairly constant with annealing times up to 72-96 hr. Thus there appears to be a temperature-time optimum, providing maximum ferromagnetism for each deposit, depending on the kind of substrate or lack of substrate.

Ni-P deposits from ammoniacal solutions.—The Ni-P alloys produced from ammoniacal solutions (baths 5 and 6) contained approximately the same phosphorus content yet exhibited different magnetic behavior as shown in Table IV. On substrates, the initial H_c of deposit 6 was higher than 5. The latter remained low (20-40 oe) until aged 72 hr at 300°C, or at higher tem-

[2] Unfortunately, some of the aged electroless nickel foils were broken remnants and shorter. This could reduce the magnetization values (B_s and B_r) but would not affect H_c significantly. No distinction of the shorter-length foils were noted at the time of measurement.

† Deposits too brittle to handle and oxidized.

peratures at which point H_c increased to 120-150 oe. H_c of deposit 6 increased gradually from 40 to 105 oe over the entire heat-treatment series. On aluminum substrates, the initial H_c was 90 oe, reaching a maximum of 120 oe at 400°C, 1 hr and decreasing as time was extended to 48 hr. A similar but reverse trend is shown for the magnetic induction, *i.e.*, the deposit 5 initially was larger but was exceeded by 700-1000G by deposit 6 as a result of the heat-treatments, both deposits being on brass substrates.

Heating deposit 5 for 96 hr at 275°C produced the same magnetization as the 300°C, 1 hr treatment. Of the heat-treatment conditions tested, the maximum induction was obtained after aging at 375°C, 2 hr; this also gave the squarest hysteresis loop ($B_r/B_s = 0.97$).

Number 5 foil gave much lower magnetics. The maximum B_s was obtained after aging 48 hr at 300°C, while B_r reached a maximum after 24 hr at 300°C and 1 hr at 400°C. Heat-treatment at 400°C beyond 1 hr resulted in difficult to handle, brittle deposits which were quite oxidized. The H_c on the foils ranged between 8-14 oe.

Comparison of No. 6 deposits shows the magnetism induced was larger on aluminum substrates initially, reaching a maximum after 48 hr at 300°C and decreasing with further aging at 400°C. While the deposit on the brass substrate exhibited a flat "loop" with small induction, it responded immediately to heat-treatment exhibiting larger induction after 1 hr at 300°C, and reached a maximum (B_r = 3100G, B_s = 3400G) after aging 1 hr at 400°C with a squareness of 0.91.

Figures 1 and 2a show the progressively increasing hysteresis loops and similarity of these ammoniacal

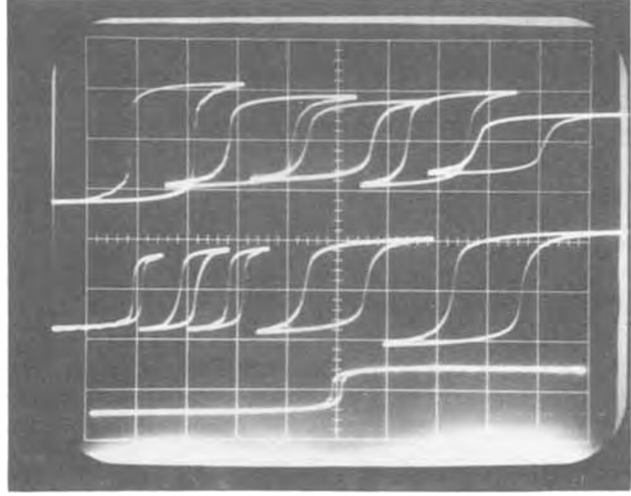

Fig. 1. Hysteresis loops; ammoniacal citrate deposits on brass. Left to right heat-treatment times: 1, 24, 48, 72, 96 hr. Lower series aged 300°C; upper, 400°C, ϕ = 1 maxwell/cm, H_c = 200 oe/cm.

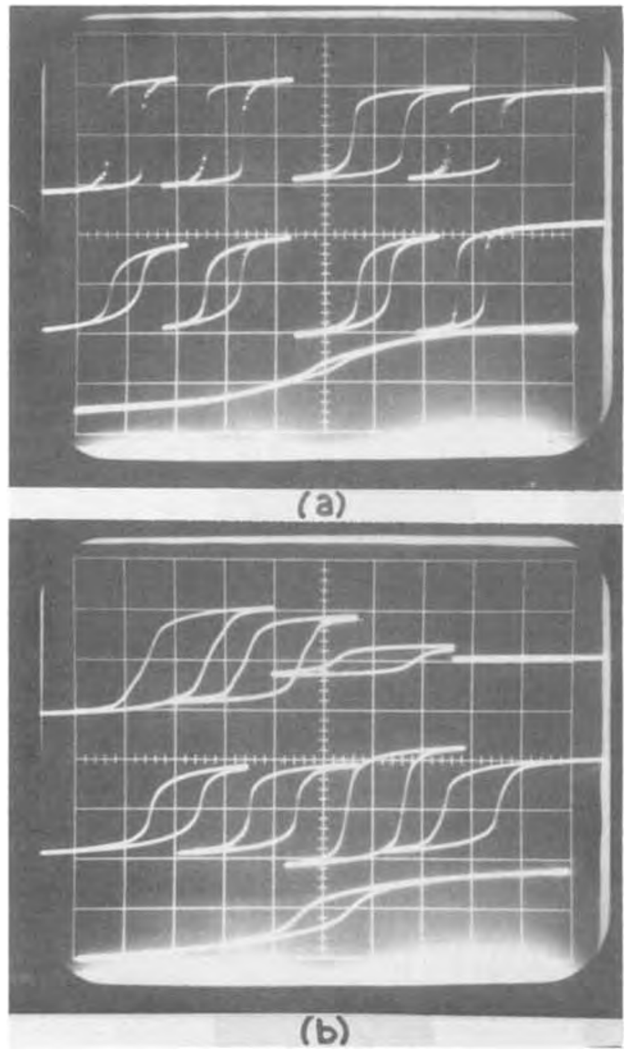

Fig. 2. (a) Hysteresis loops, ammoniacal pyrophosphate deposits on brass. Left to right heat-treatment times: 1, 24, 48, 72 hr. Lower series aged 300°C, upper, 400°C, $\phi = 1$ maxwell/cm, $H_c = 200$ oe/cm. (b) Hysteresis loops, ammoniacal pyrophosphate deposits on aluminum. solution deposits on brass when aged at 300°C and the decreasing magnetic induction and slightly increasing coercivity for the 400°C series. The effect of substrate on magnetic changes due to aging is seen when Fig. 2a and 2b are compared.

Along with bath 10 (see Table V) which was also an ammoniacal solution, the deposits from these solutions retained magnetism at considerably higher levels after heating at 400°C for 96 hr than any deposits from the acid baths.

Ni-P deposits from acid solutions.—Figures 3-6 show that the influences of the substrate and the solution's complexing ligand on the deposit's magnetic characteristics after various heat-treatments were also evident for acid solutions used at the usual *p*H ranges of 4.5-5.5.

With regard to brass substrates (Fig. 3), deposit 4 exhibited slightly larger magnetic induction than deposit 1, and continued to be magnetic after 96 hr at both 300° and 400°C whereas deposit 1 became nonmagnetic after 72 hr. Figures 4a and 5a show the actual hysteresis loops for these two deposits on brass. At 400°C, the citrate deposit (No. 3) was nonmagnetic after only 1 hr and the Hydrac deposit (No. 2) after 48 hr. The acetate deposit (No. 1) developed the same coercive and induction values for both temperatures, but showed a lower H_c (140 oe) and only slightly

(b) Hysteresis loop, acetate bath (*p*H 5.5) deposits on aluminum. Lower series, left, as-plated, remainder aged 300°C, 1-96 hr. Upper series, aged 400°C, $\phi = 1$ maxwell/cm, $H_c = 200$ oe/cm.

smaller magnetic induction ($B_r = 740$G, $B_s = 870$G) when heated at 275°C for 96 hr. The H_c of deposits from all the baths varied through a range of 60-240 oe after 1 hr at heat, but converged to the narrower range of 190-200 oe after 72 hr. Saturation induction

generally followed the same trends as remanent induction.

Deposits from these solutions (citrate not run) on aluminum substrates (Fig. 6) developed a somewhat different pattern. All deposits were still magnetic after 96 hr at 300°C. At 400°C, deposit 4 was magnetic after 48 hr while the others became nonmagnetic after 24 hr. The coercivities remained spread over a wide range. Deposit 1 aged at 300°C behaved differently from the other deposits with a rising curve for both its lower coercivity and larger induction.

The changing hysteresis loops for deposits from baths 1 and 4 are shown in Fig. 4 and 5. While the changes in magnetics for deposit No. 4 are quite similar for both substrates, the differences due to substrates are quite evident with regard to acetate deposits.

The data obtained with foils produced from these acid solutions are shown in Fig. 7. The H_c of deposit 2 ranged from 140 to 200 oe, followed by deposit 4 and deposit 1. Deposit 3 showed large variations in H_c due to aging temperatures with aging at 400°C producing the highest H_c. At 300°C, only deposit 1 was magnetic after 1 hr aging, the other deposits required longer times to develop magnetic properties.

Deposits from acid baths operated at pH's below 4 contain at least 13-16% phosphorus. As-plated deposits from the citrate and acetate baths showed no ferromagnetism. Figure 8 shows the effect of aging these deposits. At 300°C, both deposits were ferromagnetic with the flux density and coercivity of the acetate deposit increasing steadily from 1 hr aging (B_r = 310G, B_s = 620G, H_c = 60 oe) to 96 hr at heat (B_r = 930G, B_s = 1240G, H_c = 160 oe). The citrate deposit exhibited maximum induction (B_r = 250G, B_s = 500G) after 24 hr at heat and became nonmagnetic after 72 hr with H_c increasing very closely to that of the acetate bath.

Aging at 400°C resulted in higher H_c (180-200 oe) but the magnetism was lost after 24 hr for the acetate deposit and after only 1 hr for the citrate deposit.

Electroless ternary (Ni-Cu-P) alloys.—The ternary deposits produced from proprietary acid formulations (baths 8 and 9, Table II) generally exhibited somewhat lower ferromagnetism (after heat-treatment) than binary deposits from acid solutions. However, the amount of copper in the deposit influenced the magnetic properties as shown in Table V.

Neither deposit exhibited magnetism after aging at 300°C for 1 hr. Deposit 8 developed magnetism on both substrates and foil within 24 hr whereas deposit 9 gave only slight indications of magnetism (not measurable) on brass and considerably lower values on aluminum substrates.

Aging at 400°C initially resulted in increased magnetism for deposit 8 on both brass and aluminum substrates with the deposit on brass retaining some magnetism after 96 hr while only slight indications of magnetism were obtained after 24 hr on aluminum substrate.

Deposit 9 on brass substrates showed only slight indication of magnetism at 300°C with magnetism developing at 400°C within 1 hr but lost after 24 hr. The results obtained with aluminum substrates were reversed. These deposits developed less magnetism at either heat-treatment temperature, the difference being twice the copper content.

Table V also shows large increases in the coercivity of these deposits as a result of the higher aging temperature, especially for deposit 8 on brass.

The lower magnetic properties developed by deposits from these baths was also evidenced in foils. The H_c of foils produced in bath 9 was lower and decreased with time while the H_c of foil 8 increased with time at both temperatures.

The ternary deposit (Ni-4Cu-5P) from the ammoniacal bath 10 developed considerable magnetism while aging, being higher for deposits on aluminum substrates than on brass substrates. There was a gradual decrease in magnetic induction with time at both temperatures. This followed the same trend as the ammoniacal binary deposits with the hysteresis loops being very similar. The principal difference was the continued low coercivity at 300°C and the larger induction values. These deposits exhibited and retained the highest magnetic induction of all alloys tested.

Electroless quaternary (Ni-2Cu-8Sn-16P) alloys.—This alloy was interesting since it had the same composition as that from bath 9 with the added 8 w/o tin. However, this alloy also developed ferromagnetic prop-

erties on aging, as shown in Table VI. Deposit 11 developed magnetism on brass substrates at 275°C reaching a maximum at 350°C (B_r = 1850G, B_s = 3100G, H_c = 120 oe) which reduced sharply at 375°C. Referring to deposit 9, Table VI, it is seen that the ternary deposit exhibited only slight unmeasurable indications of magnetism at 400°C which was lost after 24 hr,

whereas the quaternary alloy retained a larger magnetism until after 48 hr at heat. Thus it appeared that the tin increased the magnetization of the alloy due to artificial aging, probably by competing for the phosphorus with tin-phosphorus compounds forming at lower temperatures. It is suspected that the quaternary alloy is also deposited as a supersaturated solution.

Electroless nickel-molybdenum alloy.—Emission spectrographic analysis of deposit 7 (Table II) indicated that it was a nickel alloy containing 17 w/o Mo (a slight trace of phosphorus reported, 0.2%). This alloy did not show any evidence of ferromagnetism as deposited or after aging at 300° and 400°C for 96 hr. These negative results were obtained with 2.54 μm deposits on both aluminum and brass substrates and 5 μm thick foil (which did not appear stressed).

X-ray diffraction studies of this deposit on a steel substrate and as foil revealed a poorly ordered structure with crystallite size approximately 60 ± 10Å. The foil sample showed a higher degree of orientation in the (111) direction than in the (200) direction. A discrepancy between the broadening measurements for the (200) direction on the foil *vs.* the deposit on the substrate was attributed as most likely due to stress factors.

Heat-treatment of the plated substrate at 400°C, 1 hr in air showed only minor changes which could be attributed to stress relief. Heat-treatment at 500°C, 1 hr showed some structural changes and crystal growth with the (200) reflection indicating a grain size of approximately 150Å. However no evidence of new phase transformation was found. At 680°C, 1 hr (in nitrogen) considerable change was noted with the

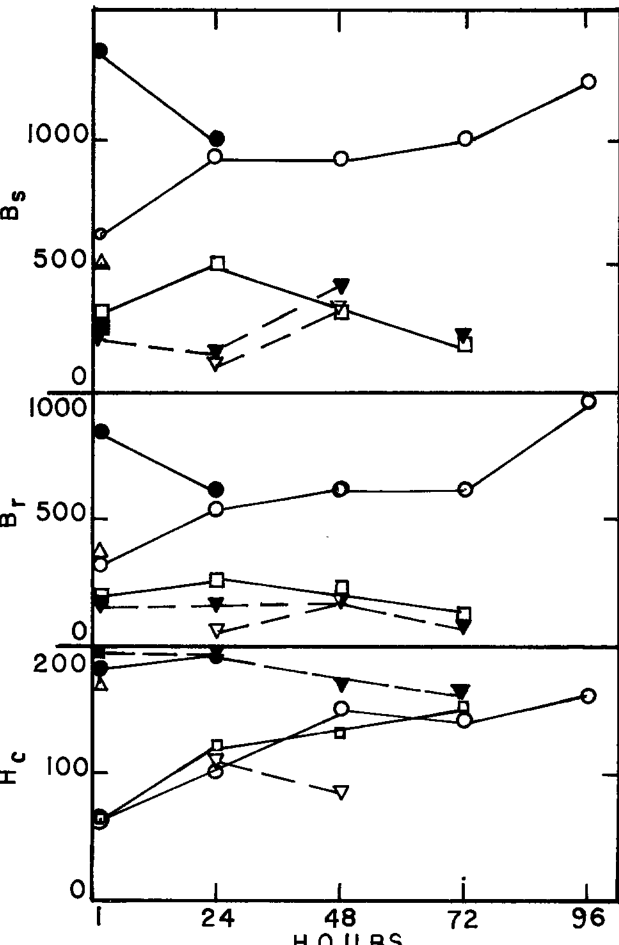

Fig. 8. Ferromagnetic properties of binary Ni-P alloys for low pH (<4) solutions. Acetate: ○ 300°C, ● 400°C; Citrate: □ 300°C, ■ 400°C, △ 375°C; Citrate foil: ▽ 300°C, ▼ 400°C.

crystallite size growing to about 800Å as determined from the (200) peaks.

When foils were heated at 600°C for 1 hr in air, a structural change occurred and a strong NiO phase was found along with a trace of MoO_2.

These results help explain the absence of ferromagnetic properties after aging at 400°C. A further observation with regard to this alloy was that very little visible oxidation developed during aging at 400°C, even after 96 hr.

Deposit 4 on the aluminum substrate was selected for x-ray diffraction studies since it exhibited a gradual increase in magnetic induction at 300°C and a gradual decrease at 400°C aging cycles; these were accompanied by continued increasing coercivities (Fig. 5a and 5b). The as-deposited specimen indicated an amorphous appearing deposit, with an approximate crystallite size of 10-50Å. An aluminum substrate signal strongly showed through the deposit. The 400°C, 1 hr heat-treatment produced a marked change in crystal structure; the nickel showed a crystal size in excess of 1000Å and the new Ni_3P phase with a minor amount of surface oxide (NiO) appeared. Aging for 48 hr produced a somewhat stronger Ni_3P phase with some evidence of diffusion with the substrate producing a $NiAl_3$ phase. Deposits aged at 72 and 96 hr appeared to be similar with Ni_3P and $NiAl_3$ peaks becoming stronger; elemental Ni showed up only as a minor constituent or phase.

These observations agree quite well with the sequence of hysteresis loops in Fig. 5b. The development of crystal order is one of the transformations induced by heat-treatment; this alters the magnetic properties significantly. The high coercivities exhibited by most of these electroless alloys appears to be the result of an order-disorder transformation with the ordered phase precipitating in a matrix of the disordered solid solution (15). The amount of phosphorus in the deposit determines the relationship of the phases developing (3, 6) and influences the magnetic properties. The influence of substrate being plated and the type of ligand in the plating solution on the magnetic properties of as-deposited film may be explained by composition of deposit and stresses produced. However, their continued effects after artificial aging remain unclear.

Summary and Conclusions

Deposits from all ammoniacal solutions studied were ferromagnetic directly as plated. Of the acid solutions studied, only the acetate deposit on aluminum substrates showed some evidence of magnetism (B_r = 75G, B_s = 175G, H_c = 7.5 oe) (Fig. 4b). The sulfamate nickel electrodeposits were considerably more magnetic.

Artificial aging increased magnetic induction of all deposits through some maximum, the temperature-time relationship being different for each deposit. The coercive force was also usually increased; however, H_c was lowered by one-half or more for the nickel electrodeposits.

The ferromagnetic properties of the deposits and their changes due to heat-treatment varied significantly on the two substrates as well as free foils. These variations were also related to the different ligands in the electroless solutions. Mallory (16) drew similar conclusions with regard to the corrosion characteristics of electroless deposits.

The ferromagnetism induced in foils deposited from acid solutions increased with aging at 300°C and decreased with aging at 400°C. This effect appeared to be related to the solution's complexing ligands in the following order: acetate > lactate-propionate > hydroxy-acetate > citrate. The order was reversed for increasing coercivities.

The same relationships might be considered for the deposits on substrates (from the same acid solutions). In the case of deposits on brass substrates heat-treated at 300°C, however, the order was slightly changed with lactate-propionate > acetate > citrate > hydroxy-acetate.

The low pH (high P) deposits also exhibited magnetism after aging at 300°C within 1 hr, with acetate deposits continuing to increase with time and the citrate deposit remaining fairly constant. At 400°C, the citrate deposit became nonmagnetic after 1 hr, the acetate deposit after 24 hr. It is suggested that whatever free nickel exists is dispersed in the developing predominant Ni_3P matrix.

Ternary deposits from acid solutions developed only slightly lower induction than the binary alloys, the 2 w/o copper alloys being less magnetic than the 1 w/o copper alloy. The ternary (Ni-4Cu-5P) alloy from the ammoniacal solution, however, exhibited the largest magnetic induction with the lowest coercive force of all the alloys studied, suggesting a more complete transformation of a Cu_3P phase with a larger amount of a nickel phase remaining.

Additions of 8 w/o tin to the Ni-2Cu-16P alloy resulted in increased magnetization of the alloy after artificial aging, reaching a maximum at 350°C and reducing sharply at 375°C. This also suggests a competing transformation with the presence of a nickel phase.

A Ni-17Mo electroless alloy did not develop any ferromagnetism with aging up to 400°C. This result was in agreement with the fact that no phase transformation occurred below approximately 600°C as determined by x-ray diffraction studies.

New Solid Conductors of Na^+ and K^+ Ions

J. Singer, W. L. Fielder, H. E. Kautz, and J. S. Fordyce*

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

A search through 40 structure types for solid conductors of Na^+ and K^+ ions has produced three types capable of ion transport with conductivities in the vicinity of 10^{-5} (ohm-cm)$^{-1}$ at 25°C: (*i*) the pyrochlores $NaTaWO_6$ and $NaTa_2O_5F$; (*ii*) the bcc-Im3 phase of $NaSbO_3$; and (*iii*) the Na and K niobates near the composition $2M_2O \cdot 3Nb_2O_5$. Of these five compounds, only the K niobate (whose structure has not been elucidated) can be fully sintered without transformation. A number of phase diagrams have been developed during the course of the work.

A search for new solid conductors of alkali metal ions was initiated after the publication of the work on beta alumina (1, 2) for the purpose of finding additional types of electrolytes for high energy-high power density secondary batteries. The approach was to select a variety of "open" structures, to prepare alkali metal representatives of these structures, and to screen them in the form of preliminary preparations by a suitable fast method. Direct measurement of ionic transport upon improved specimens was reserved for compounds showing promise in the screening. This report considers principally the five best conductors found in the search through about 40 structure types. Additional information related to this report may be found in the separate publications from the three laboratories involved, as referred to below.

Background and Structural Aspects of Materials with $\sigma_{ION} = 10^{-5}$(ohm-cm)$^{-1}$

$NaSbO_3$ bcc, Im3.—This phase was first reported by Kafalas (10) as the K analogue resulting from the high pressure transformation of the ilmenite form of $KSbO_3$. On the basis of their structure analysis, Hong *et al.* (11) predicted and confirmed that the new phase would readily undergo ion exchange with salts of monovalent ions and that, among the MBO_3 analogues, the Na exchange product would exhibit the highest ion mobility. They further report that (*i*) $NaSbO_3$ (Im3 phase) indicated in preliminary a-c measurements on ionic conductivity like that of β-alumina; (*ii*) its metastability prevents sintering to dense specimens; and (*iii*) in ceramic form, it is slowly attacked by molten Na.

The structure of the Im3 phase may be briefly described as follows (11): M^+ ions in disordered partial occupancy of sites in tunnels which consist of face-shared octahedra running parallel to the [111] directions. The mobility of a given M^+ ion depends on its size relative to the openings of the oxygen octahedra, Na^+ appearing to be at an optimum.

During the course of this work, it was first suggested that the F^{-1} ion could stabilize the Im3 phase to permit 1 atm direct synthesis (12) and then demonstrated that this was feasible (5, 6, 12, 13). Also, it was found (5) that the Na compound produced by ion exchange from $TlSbO_3$ or $KSbO_3$ may incorporate up to 25% more Na than the ion displaced.

Pyrochlores.—The general formula of the fully occupied pyrochlore structure of the cubic space group Fd3m may be written as $A_2B_2X_6X'$ or $A_2B'B''X_6X'$ (14). Structural features of this structure type are: (*i*) the B_2X_6 or $B'B''X_6$ groups represent a subarray of octahedra with the B atoms, like Ta, Nb, Sb, and others,

* Electrochemical Society Active Member.

Key words: sodium pyrochlores, sodium antimonate, alkali niobates, solid electrolyte.

in the centers of the octahedra of the X_6 ions (which are usually $O^=$, OH^-, Cl^-, or F^-); (*ii*) the *A* cations (of mono-, di-, or trivalent atoms) may be in any of several crystallographic sets, depending on the ions' size, charge, and number, thus offering ways to control *A*-ion mobility; (*iii*) the "seventh" anion (14, 15), X', which is similar to but not necessarily the same as *X*, is not bound to the octahedra; its site occupancy determines whether *A* ions have a clear path through the structure.

The ability of the pyrochlore structure to accommodate a wide range of atom species and to permit some degree of control over site occupancies is what made it a promising candidate. The defect pyrochlores measured in this program are $NaTaWO_6$ and $NaTa_2O_5F$. The former was suggested by Raveau (16-18) who also supplied a powder sample for the first specimens. The oxyfluoride was decided upon as possibly more resistant to reaction with a Na electrode than the W-containing pyrochlore might be. Both these pyrochlores are of the $AB'B''X_6$ type (19); the absence of the X' anion promised the maximum openness of the structure for the *A* cation. The size of the Na^+ ion is distinctly optimal for passage, with the handicaps that Na pyrochlores have to be made by ion exchange from the other alkali metal analogues and, concomitantly, are unstable at the temperatures required for sintering to fully dense bodies.

Niobates $2Na_2O \cdot 3Nb_2O_5$, $2K_2O \cdot 3Nb_2O_5$.—A number of compounds found in the six binary systems (6)

Li_2O		Nb_2O_5
Na_2O	*vs.*	
K_2O		Ta_2O_5

were tested for ionic conductivity by the methods described elsewhere (4). Among these, the only structure type found capable of appreciable alkali ion transport was the niobate close to, but not exactly at, the 2·3 composition, most probably at 41 $K_2O \cdot 59\ Nb_2O_5$. This compound has an orthorhombic unit cell with $a = 7.822A$, $b = 33.019A$, $c = 6.481A$, and crystal growth of this phase was first reported by Nassau (21). Geometrical considerations have led to postulating that the K^+ ions are in layers between the Nb-O octahedra and that they should be mobile (6) as was demonstrated subsequently (see below). The crystal structure analysis has yet to be done.

Most of the other alkali niobates and tantalates, found to be tunnel structures more or less related to the bronzes, were screened out as being poor conductors.

Experimental

Specimen preparation.—$NaSbO_3$, Im3 phase.—A special high pressure apparatus was employed to transform $KSbO_3$ from the ilmenite form to the Im3 polymorph at about 20 k bar and 700°C (11). The pure transformation product, as verified by x-ray diffraction, was powdered and mixed with 10 times its molar quantity of molten $NaNO_3$. The exchanged compound was water leached to remove excess nitrates and finally checked by x-ray diffraction for single phase. Disks of the $NaSbO_3$ were then made by pressing finely powdered material ($\sim 1\mu$) in a tungsten carbide die in a partial vacuum at 30,000 psi and held at pressure ($\sim 1\mu$) at 600°C for $\sim$ 1 hr; 2 weight per cent (w/o) $NaNH_2$ was mixed with the starting powder to help achieve the high densities of the disks, $\sim$ 95% of theoretical.

$NaSbO_3 \cdot 1/6$ NaF, Im3.—The K analogue was made by reacting a 2:1 weight ratio of $K_2H_2Sb_2O_7 \cdot 4H_2O$ and KF at 900°C for 2 hr. Excess KF and $KSbO_3$ ilmenite was then leached with water and the pure fluorided antimonate, probably Pn3, ion exchanged three times in molten $NaNO_3$ at 325°C. The product, Im3 with a nominal composition at about $NaSbO_3 \cdot 1/6$ NaF, was analyzed chemically and by x-ray structure analysis (13). The F^- stabilization of the phase unfortunately did not extend to permit sintering the Na compound without a protective atmosphere, and disks of $NaSbO_3 \cdot 1/6$ NaF had to be made the same way as the $NaSbO_3$ without F^-; similar densities were obtained.

$NaTaWO_6$, pyrochlore.—The first measurements were made on disks pressed from powder (supplied by Professor B. Raveau of Caen). The highest densities without transformation were obtained at 40,000 psi at 500°C with 2% by weight $NaNH_2$ added. Other preparations behaved similarly; they were made by ion exchanging the K analogue which had been synthesized from K_2CO_3, WO_3, and Ta_2O_5 by conventional techniques.

$NaTa_2O_5F$, pyrochlore.—This type of pyrochlore offered the possibility of greater chemical inertness than the W compound (5). The Rb analogue, but not the K, could be made directly from the components. RbF and Ta_2O_5 were fired at 750°C in argon for two days; grinding and refiring had to be repeated for a total of three times to produce single phase. Single crystals were also prepared using excess RbF as a flux. A single 1150°C firing of a 4:1 molar ratio of RbF and Ta_2O_5 yielded small crystals suitable for structure analysis. The Na exchange in this pyrochlore required two stages, first Rb $\rightarrow$ K, followed by K $\rightarrow$ Na.

Ceramic disks of $NaTa_2O_5F$ were pressed under conditions similar to those for $NaSbO_3$; however, lower densities were obtained. As with $NaTaWO_6$, the oxyfluoride probably had some H_2O in the lattice.

$2M_2O{:}3Nb_2O_5$.—As fully described elsewhere (7), anhydrous disks of the K and Na compounds were difficult to prepare. The synthesis of single phase powder of the K compound by conventional solid-state reaction procedures required the exact ratio of $K_2CO_3{:}Nb_2O_5$ for the composition $41K_2O{:}59Nb_2O_5$. The product, as well as the Na analogue made by ion exchange in molten $NaNO_3$, was extremely moisture sensitive, and the following schedule was required to fabricate a sound, dense disk: single phase powder $\rightarrow$ prepress, 700 psi $\rightarrow$ isostatically press, 20,000 psi $\rightarrow$ dry at 220°C, 0.5 hr $\rightarrow$ sinter, 1050°C, 2 hr $\rightarrow$ seal into evacuated capsule; operations were conducted in a dry box or, where that was not possible, above 220°C, where H_2O is not absorbed, all with minimal exposure to air.

Electrical measurements.—The five materials described in the foregoing were investigated by two- and four-probe a-c and d-c conductivity methods; elimination of the majority of candidate materials was based on special a-c methods, such as dielectric loss, which were less dependent on specimen perfection (3, 4) than conventional a-c methods. Blocking electrodes (sputtered Pt or C paint) were used for a-c conductivity measurements over a range of frequencies. Reversible electrodes were either (*i*) Na_xWO_3 made directly on the sample (for Na compounds only) (20), (*ii*) propylene carbonate solutions (PC) of Na- or K-PF_6, as appropriate, (*iii*) molten alkali metal, or (*iv*) fused $NaNO_3$. The d-c current usually employed was 14 μA.

Results

The data obtained are summarized in Table I and Fig. 1-4. Figure 3 includes conductivity data for beta alumina (curves 1 and 2) which are presented as validation of the simpler two-probe PC electrode procedure generally employed to evaluate ionic transport.

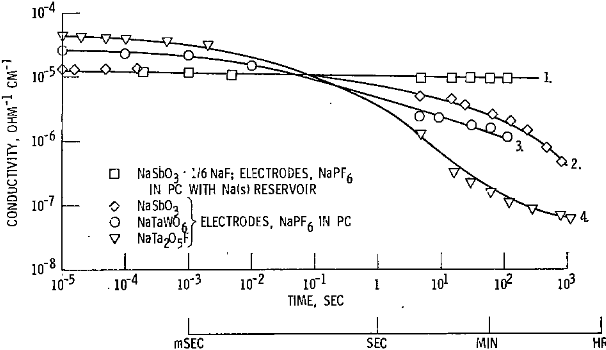

Fig. 1. D-C conductivity of cubic materials with time (300°K)

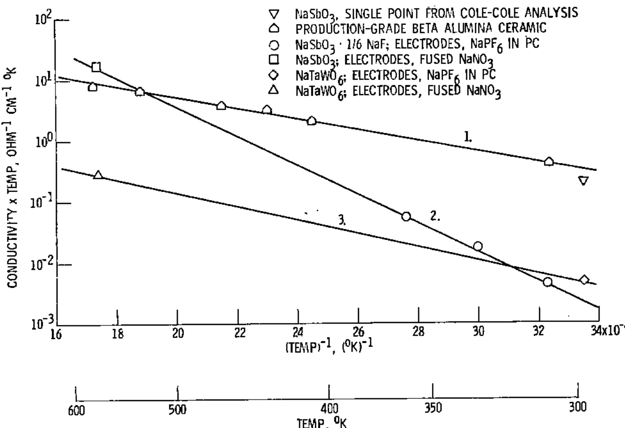

Fig. 2. Conductivity of cubic materials with temperature; comparison with "production" beta alumina ceramic.

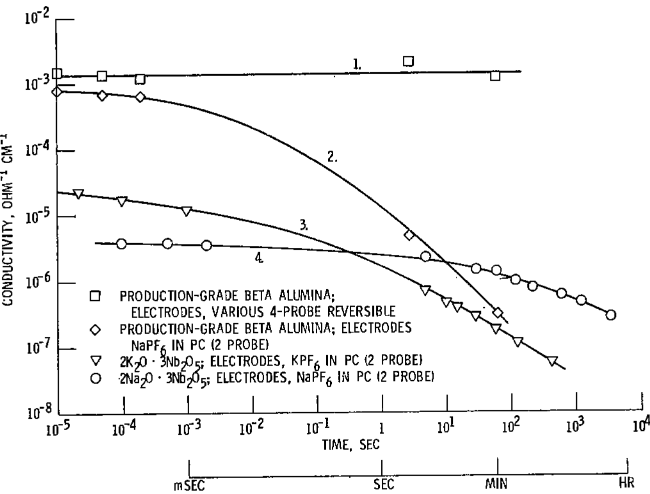

Fig. 3. D-C conductivity of planar materials with time (300°K)

The validation consists of the observation of but little more polarization occurring in the first 10^{-2} sec after application of field in the two-probe experiment (curve 2) compared with the absence of polarization over the entire time of measurement where more completely reversible electrodes were used (curve 1). A similar comparison is presented in Fig. 1 for $NaSbO_3$-Im3, where curve 1, taken with the more reversible electrodes (due to solid Na availability), coincides for 10^{-1} sec with the two-probe PC data (curve 2). Rejected candidates showed early onset of polarization, from 10^{-6} sec after application of field, and much more rapid polarization continuing linearly with time (9).

The conductivity values used in constructing Fig. 2 and 4 were the values given by extrapolation to the zero time axis of the two-probe PC data plus other types of data as indicated. Activation energies calculated from Fig. 2 and 4 are included in Table I.

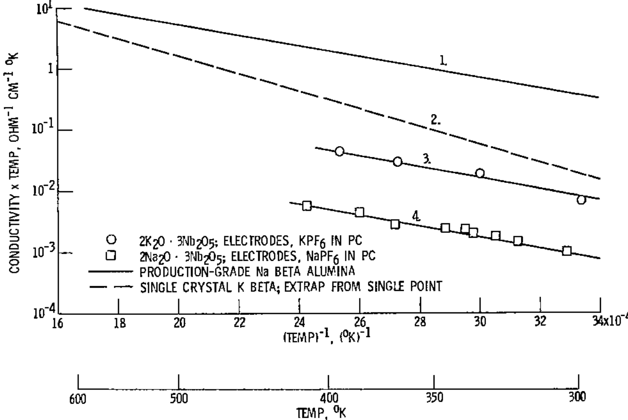

Fig. 4. Conductivity of planar materials with temperature; comparison with beta alumina.

Discussion

About 40 structure types were surveyed in the total study (9). The five compounds of Table I, representing altogether three structure types, were the ones whose properties came closest to the goals of the survey. Among those eliminated were a number of "tunnel" types, *i.e.*, with cations in unidirectional linear channels. Some of those screened out which have appeared elsewhere as being of some interest are hollandite (3, 22) and β-eucryptite (23).

Further development might increase the conductivities given in Table I. Ceramic quality could be improved for each of the compounds. For the pyrochlores, compositions other than those given here could well be explored, particularly for the purpose of trying more and less than eight alkali ions per unit cell. In the present work, further, the specimens of the pyrochlores at the time and conditions of measurement were probably not truly anhydrous, and water molecules in the lattice would be in sites to inhibit cation motion.

Of particular interest among the findings are: (*i*) the antimonate has about the same Na^+ ion conductivity as beta alumina at about 280°C, and (*ii*) the K niobate has about the same K^+ ion conductivity as K-beta ceramic may be presumed to have.

Summary

Five compounds in three structure types have been discovered to be good solid conductors of alkali metal ions. A unique bcc form of $NaSbO_3$, a unique orthorhombic layer structure of the composition $2M_2O \cdot 3Nb_2O_5$ (M = Na or K), and the Na pyrochlores $NaTa_2O_5F$, $NaTaWO_6$, each show alkali ion transport with conductivities of $\sim 10^{-5}$ (ohm-cm)$^{-1}$ at 25°C. Ion exchange is required to make each of these Na compounds; only the $2K_2O \cdot 3Nb_2O_5$ can, so far, be synthesized directly from the oxides, and so is the only one which can be sintered readily. The niobate is about as good a conductor of K^+ ion as is K-beta alumina; the $NaSbO_3$ compares well with Na beta at 280°C.

The Standard Free Energy of Formation of Liquid Na_2CrO_4, 1100°-1220°K

Winston W. Liang* and John F. Elliott**

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The standard free energy of sodium chromate has been determined employing the reversible cell

W, WS_2(s) Na_2S(s)	Na^+ (β-alumina)	Na_2CrO_4(l), P_{O_2}, Pt Cr_2O_3(s)

The results of the measurements give

$$2Na(l) + 5/4\,O_2(g) + 1/2\,Cr_2O_3(s) = Na_2CrO_4(l)$$

$$\Delta G° = -648{,}900 + 106.94T \text{ (J/mole)}$$

and

$$2Na(l) + 2\,O_2(g) + Cr(s) = Na_2CrO_4(l)$$

$$\Delta G° = -1{,}209{,}900 + 233.1T \text{ (J/mole)}$$

These results are valid in the vicinity of 900°C.

Chromium is the vital alloying element for corrosion resistance of stainless steels and iron-, nickel-, and cobalt-based superalloys. Deposits of liquid sodium sulfate have been associated with accelerated corrosion of these metals (1), and during simulated sodium sulfate-induced hot corrosion of nickel-based alloys, sodium chromate has been found as a corrosion product (2-6). The formation of sodium chromate was suggested to result from the reaction of sodium sulfate with the protective oxide, Cr_2O_3

$$2Na_2SO_4(l) + Cr_2O_3(s) + \frac{1}{2}O_2(g) = 2Na_2CrO_4(l) + 2SO_2(g) \quad [1]$$

However, lack of accurate information on the standard free energy of formation of fused sodium chromate did not allow an adequate thermodynamic description of the reaction. The only available thermochemical data on sodium chromate was its standard heat of formation at 298°K which was determined calorimetrically (7). This information and recently determined data on the low and high temperature heat capacities and enthalpy increments of the compound have permitted calculation of $\Delta G°_f$ for Na_2CrO_4 at elevated temperatures (8).

The recent development of a sodium reference electrode using β-alumina as the solid electrolyte (9, 10) makes it possible to investigate the thermodynamic properties of fused sodium chromate by the cell

W(s), WS_2(s) Na_2S(s)	Na^+ ($Na_2O \cdot 11Al_2O_3$)	Na_2CrO_4(l) (Na_2O) Cr_2O_3(s), P_{O_2}, Pt

[A]

The over-all cell reaction may be written

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

Key words: thermodynamics, sodium chromate, emf measurements.

$$\frac{1}{2}W(s) + Na_2S(s) + \frac{5}{4}O_2(g) + \frac{1}{2}Cr_2O_3(s) = Na_2CrO_4(l) + \frac{1}{2}WS_2(s) \quad [2]$$

For which

$$\Delta G°_2 = -2\mathbf{F}\epsilon + 5/4\,RT \ln P_{O_2}$$

F is Faraday's constant and ϵ is the reversible potential of the cell. The liquid chromate is saturated with $Cr_2O_3(s)$. Alternatively, the over-all cell reaction may be written

$$\frac{1}{2}W(s) + Na_2S(s) + \frac{1}{2}O_2(g) = \frac{1}{2}WS_2(s) + (Na_2O) \quad [3]$$

where the sodium oxide is in solution in liquid sodium chromate at the cathode. By reaction [3], the activity of sodium oxide relative to pure sodium oxide can be determined from the reversible potential of the cell when the oxygen pressure in the cathode chamber is fixed

$$-2\mathbf{F}\epsilon = \frac{1}{2}\Delta G°_f(WS_2) + \Delta G°_f(Na_2O) - \Delta G°_f(Na_2S) + RT \ln a_{Na_2O} - \frac{1}{2}RT \ln P_{O_2} \quad [4]$$

Similarly, the standard free energy of formation of liquid sodium chromate can be obtained from ϵ and P_{O_2}

$$-2\mathbf{F}\epsilon = \frac{1}{2}\Delta G°_f(WS_2) + \Delta G°_f(Na_2CrO_4) - \Delta G°_f(Na_2S) - \frac{1}{2}\Delta G°_f(Cr_2O_3) - \frac{5}{4}RT \ln P_{O_2} \quad [5]$$

It is to be noted that the experimental cell potential must be corrected for the thermoelectric effect of the W-Pt junction (20-30 mV) to obtain the values of ϵ used in Eq. [4] and [5].

The standard free energy of formation of sodium chromate by the reactions

$$2Na(l) + \frac{5}{4}O_2(g) + \frac{1}{2}Cr_2O_3(s) = Na_2CrO_4(l) \quad [6]$$

can be obtained from Eq. [5] utilizing the data in Table I

$$\Delta G°_6 = -2\mathbf{F}\epsilon + \frac{5}{4}RT \ln P_{O_2} - 267{,}350 + 46.06T \quad [6a]$$

and for the formation from the elements

$$2Na(l) + Cr(s) + 2\,O_2(g) = Na_2CrO_4(l) \quad [7]$$

$$\Delta G°_f(Na_2CrO_4) = -2\mathbf{F}\epsilon + 2\,RT \ln P_{O_2} - 828{,}370 + 172.2T \quad [7a]$$

Thus the information obtained from the cell can be used to determine the standard free energy of liquid sodium chromate.

Experiments

The anode materials consisted of 99.9% pure tungsten powder and reagent grade WS_2 and Na_2S. These materials were mixed in the molar ratio of 1:1:4 and were dried overnight at 80°C before use. The cathode materials consisted of reagent grade Na_2CrO_4 and Cr_2O_3. The chromium oxide was either in the form of a powder or small pieces that were obtained by sintering the powder at 1600°C in argon having an oxygen pressure of approximately 10^{-12} atm. The density of the pellets was 3.87 g/cm^3. In the case that the chromium oxide powder was used, 2g of it and 20g of powdered sodium chromate were dried at 220°C under vacuum for 1 week prior to use (14). If the chromium oxide pellet was used, the sodium chromate powder was dried as described and the pellet was added to the cell along with the powder.

Table I. Thermodynamic data

Compound*	$\Delta G° = \Delta H° - T\Delta S°$, J/mole	Reference
$Cr_2O_3(s)$	−1,122,040 + 252.3T	(11)
$Na_2S(s)$	−435,550 + 124.3T	(12)
½ $WS_2(s)$	−168,200 + 73.24T	(13)
$Na_2O(l)$	−353,550 + 88.91T	(12)

* Reference states: Na(l), Cr(s), W(s), O_2(g), and S_2(g); all at 1 atm pressure.

The crucibles of β-alumina used for the electrolyte were processed from Monofrax H bricks (Carborundum Company). The bricks were crushed to +8 mesh particles. The crushed material was ground in an alumina ball mill for 30-40 hr. Then 2 weight per cent (w/o) Na_2CO_3, 1 w/o MgO, and ½ w/o Y_2O_3 in powder form were added and mixed in a tumble mixer for 10 hr. The resulting mixture was calcined in a platinum crucible for 1 hr in air (15). This calcined material was reground in an alumina ball mill for 10-15 hr to obtain a final particle size of 0.5-1 μm. Cylindrical rods 12.5 mm × 6-8 cm long of this material were obtained by first pressing them in a die at 2000 psi followed by isostatically pressing at 32,000 psi. The rods were prefired at 1100°C for 1 hr while packed in coarse β-alumina powder. They were then drilled with a 6 mm drill, packed in coarse β-alumina powder, and fired in air at 1750°C (16). The maximum temperature was held for a period of 20-30 min. These sintered crucibles were 93% dense and crack free, and had no open porosity. The electrochemical characteristics of β-alumina which makes it suitable as the electrolyte in the cell are well described (17, 18).

The arrangement of the cell is shown in Fig. 1. When used, the β-alumina electrolyte was a straight-walled crucible 11 mm OD × 6 mm ID × 60 mm high. The anode chamber containing W, WS_2, and Na_2S powders and the W lead was sealed with soft glass as the cell was brought to temperature.

The cathode consisted of a platinum wire within an alumina tube. The tip of the tube was positioned approximately 5 mm below the surface of the liquid sodium chromate. A gas of known composition, Ar + O_2 or air, was bubbled through the melt at a rate of a few centimeters (STP) per minute. The gases were carefully dried before they entered the cell and the Vycor furnace tube was maintained at a pressure

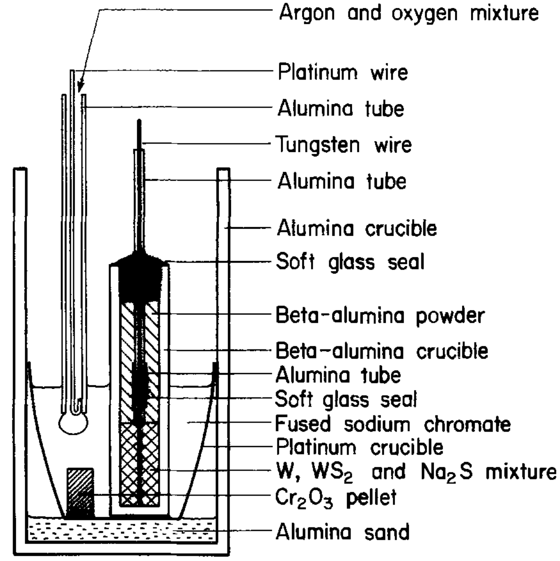

Fig. 1. Cell arrangement

slightly in excess of atmospheric by throttling the outflow of the gas.

The temperature of the cell was measured with a Pt/Pt-10% Rh thermocouple and it was known with an uncertainty of not more than ± 1.0°C. The cell potential was measured with a Beckman pH meter (10^{14} ohms impedence).

After being brought to temperature, the cell required 8 hr for its potential to stabilize. Subsequently the potential was very steady and reproducible. When the temperature was changed, the potential reached a new steady state within 1-2 hr which was approximately the time required by the system to reach thermal equilibrium. If the temperature was altered and then returned to the original value, the cell potential was reproducible within 1 or 2 mV. The potential also varied less than 1 mV when the gas flow was changed in the range of 0-5 cm^3/min (STP). All measurements were made at a rate of 2 cm^3/min. With a change in oxygen pressure in the cathode gas, the cell reached a new steady value in 7-9 hr. Polarization of the cell with a current of 50 mA for 10 sec in either direction caused a displacement of the cell potential by 350 mV above or below the previous steady-state reading. The potential returned to the previous value within 30 sec after the polarizing current was turned off.

Experimental Results and Discussion

The experimental measurements are shown in Table II and the results in terms of $\Delta G°_2$ are shown in Fig. 2. The line is the least squares line for all points; its equation is

$$\Delta G°_2 = -381,500 + 60.88T \quad [3a]$$

with uncertainties of approximately ±1500 J/mole in free energy, ±3000 J/mole in enthalpy, and ±3 J/mole·°K in entropy. Inserting these results into Eq. [6a] gives

$$\Delta G°_6 = -648,900 + 106.94T \quad [6b]$$

and into Eq. [7a] gives for the liquid

$$\Delta G°_f(Na_2CrO_4) = -1,209,900 + 233.1T \quad [7b]$$

with uncertainties of approximately ±12,000 J/mole·°K in free energy, ±14,000 J/mole in enthalpy, and 9 J/mole·°K in entropy.

There are no direct measurements at elevated temperatures of the standard free energy of Na_2CrO_4

* Corrected for W-Pt thermoelectric effect.

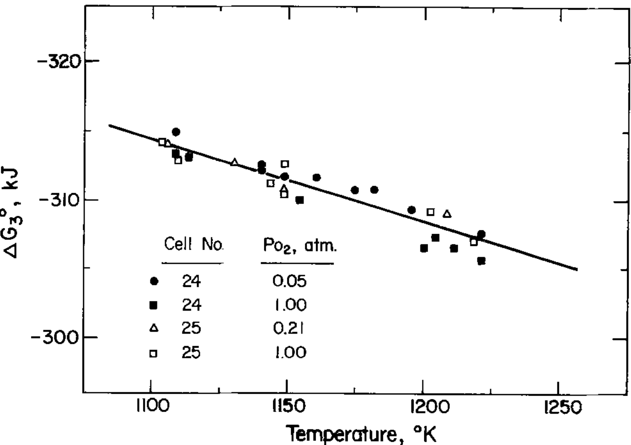

Fig. 2. Experimental results in terms of Eq. [2]

which can be used for comparison with the present results. There are, however, data on the specific heat and the enthalpy increment by Ferrante, Stuve, and Krug (8) and the standard enthalpy of formation of the compound at 298°K by Nelson, Moss, and Hepler (7). These data permit calculation of the thermodynamic properties of Na_2CrO_4 in the temperature range of this study (8). The resulting equation for the liquid is

$$\Delta G°_f(Na_2CrO_4) = -1,278,600 + 301.25T \quad [7c]$$

Subtracting from this one-half the standard free energy of formation of Cr_2O_3(c) gives

$$\Delta G°_6 = -717,600 + 175.10T \quad [6c]$$

It is to be seen that at 1100°K the results obtained from the experiments reported are lower than those obtained from the thermochemical data (7, 8, 11) by approximately 6200 joules (1500 cal). At 1200°K the differences are approximately 13,000 joules (3000 cal). The agreement in the values of the standard free energies is felt to be reasonably good considering the diverse data that have been used in obtaining the two sets of equations.

The set of equations [6b] and [7b] differ from the set [6c] and [7c] principally in the entropy terms. If one back calculates from reaction [6] and Eq. [6b] using the appropriate data from Table I to get an equation for $\Delta G°_2$, one obtains a line in Fig. 2 based on the thermal data that crosses the experimental line but which has a much greater (negative) slope. The disagreement appears to be much greater than that which results from the uncertainties in the various data used in determining these two lines. It may be due to either, or both, of the following reasons:

(*a*) Uncertainties in the thermochemical data for Na_2S and WS_2 which may be large because of the experimental difficulties when working with these compounds.

(*b*) The entropy term in Eq [7b], which is derived from the cell measurement, may include a term that is related to a change in composition with temperature of Na_2CrO_4 when saturated with Cr_2O_3(s).

The possible change in composition of Na_2CrO_4 with temperature mentioned above probably would be small in view of the very low activity of Na_2O in the salt and also the fact that it does not change appreciably either with a change in oxygen pressure or temperature. It is to be noted that there was no evidence during the experimental work that the composition of the liquid chromate deviated appreciably from Na_2CrO_4.

For conditions in which liquid sodium chromate and Cr_2O_3 coexist, it is concluded that the free energy of formation of Na_2CrO_4 according to Eq. [7b] should be used.

Using the data of Ferrante and co-workers (8) on the melting of Na_2CrO_4 (ΔH_m = 24,300 J/mole, T_m =

1065°K), one obtains for the reaction to form the solid

$$2Na(l) + Cr(s) + 2\,O_2(g) = Na_2CrO_4(s) \quad [8]$$

$$\Delta G°_f = -1{,}234{,}200 + 255.92T \quad [8a]$$

This equation applies to the superheated solid phase in the temperature range of 900°-1200°C.

Summary and Conclusions

The standard free energy of formation of sodium chromate has been measured by a high temperature emf cell. The results apply to the reaction

$$Na(l) + \frac{5}{4} O_2(g) + \frac{1}{2} Cr_2O_3(s) = Na_2CrO_4(l)$$

$$\Delta G°_R = -648{,}900 + 106.94T$$

and to

$$Na(l) + Cr(s) + 2\,O_2(g) = Na_2CrO_4(l)$$

$$\Delta G°_f = -1{,}209{,}900 + 233.1T$$

The equations are based on measurements obtained in the temperature range of 1100°-1220°K.

ABSTRACT

The electrochemical oxidation of substituted iminodimethylenediphosphonic acids $[RN(CH_2PO_3H_2)_2]$ in strong aqueous acid leads cleanly to the secondary amine $(RNHCH_2PO_3H_2)$ in most cases. Voltammetric data, NMR data, and the products of the oxidations suggest that unprotonated amine is available for oxidation even in strongly acidic aqueous solution.

The only reported electrochemical oxidation of a simple phosphonic acid was that of methylphosphonic acid which led to cleavage of the carbon-phosphorus bond (1). Oxidation of N-phosphonomethyliminodiacetic acid, however, did not lead to cleavage of the phosphonate portion of the molecule (2). It has previously been reported that nitrilotrimethylenetriphosphonic acid may be electrochemically oxidized, resulting in cleavage of the methylenephosphonic acid group (3). The present study was made to determine if that was a general reaction, useful for the preparation of a wide variety of secondary aminomethylenephosphonic acids.

Tertiary iminodimethylenediphosphonic acids are conveniently made by the reaction of an amine with formaldehyde and phosphorous acid (4)

$$RNH_2 + 2H_2CO + 2HPO_3H_2 \rightarrow RN(CH_2PO_3H_2)_2 \quad [1]$$

Stoichiometric quantities of reagents, however, produce a mixture which is very difficult to separate (5), so that a simple, clean synthesis

$$3RNH_2 + 3H_2CO + 3HPO_3H_2 \rightarrow RNH_2 + RNHCH_2PO_3H_2 + RN(CH_2PO_3H_2)_2 \quad [2]$$

Key words: N-substituted aminomethylenephosphonic acids, voltammetry, preparative electrolysis.

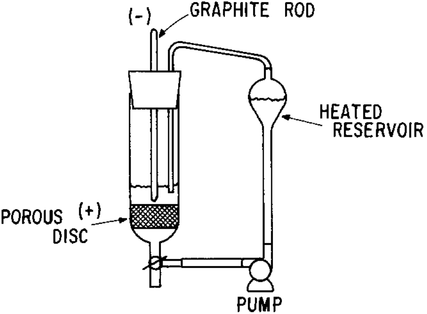

Fig. 1. Recirculating electrolysis system with a porous graphite anode.

of secondary aminomethylenephosphonic acids was unknown.

Experimental

Cyclic voltammetry was carried out in a three-compartment cell with a glassy carbon anode (5 mm diameter button in glass tubing), Pt wire cathode, and a saturated calomel reference electrode. A Wenking Model 66TA1 potentiostat, Exact Electronics, Inc., Model 505 function generator, and Moseley 7035 AM X-Y recorder were used for obtaining voltammograms. A scan rate of 6.8 mV/sec was used, and the depolarizer concentration was 5 mM in 0.2*M* H_3PO_4, except for compounds X-XIII which were run in 50% H_3PO_4 because they are insoluble in dilute acid.

NMR spectra were obtained with a Varian T-60 NMR spectrometer with 20% HCl or concentrated HCl as the solvent and 3(trimethylsilyl)propanesulfonic acid as the internal reference.

All of the starting tertiary amines were prepared by the procedure of Moedritzer and Irani (4) involving reaction of the primary amine with formaldehyde and phosphorus acid.

Most of the electrolyses were conveniently carried out in the apparatus shown in Fig. 1. However, equally good results may be obtained by electrolysis at a graphite plate anode in a beaker.

Typical electrolysis procedure.—A 40g sample of nitrilotrimethylenetriphosphonic acid was dissolved in 20 ml of 20% HCl by warming on a steam bath. The solution was added to the reservoir (Fig. 1) which was heated to maintain the solution at 70°C. The solution was circulated through the cell (8.5 $cm^2 \times 1$ in. thick, Union Carbide PG45 porous graphite anode and graphite rod cathode) by a Gorman-Rupp MI-2095 metering pump at 100 ml/min. Current was supplied to the cell by a Harrison Model 865B constant-current power supply. After electrolysis at 1A for 4 hr (NMR indicated 57% conversion), the current was lowered to 0.6A and electrolysis was continued for an additional 5 hr. The NMR spectrum of the solution then indicated the absence of starting material. The solution was concentrated to an oil on a rotary evaporator. The oil was boiled with isopropanol, cooled in a refrigerator overnight, and filtered to give 25g (91%) of dried iminodimethylenediphosphonic acid, identical to an authentic sample (5).

Using the above procedure, the following oxidations were carried out as indicated in Table I. Order of presentation is starting material, product, product melting point, and product elemental analyses.

III, $CH_3(CH_2)_{11}NHCH_2PO_3H_2 \cdot ½H_2O$, 230°-250°dec., calc for $C_{13}H_{31}NO_{3.5}P$: C, 54.21; H, 10.85; N, 4.86; P, 10.75. Found: C, 54.40, 54.15; H, 10.84, 11.23; N, 4.74, 4.65; P, 10.99, 11.03.

IV, $C_6H_5CH_2NHCH_2PO_3H_2 \cdot H_2O$, 277°-279°, calc for $C_8H_{14}NO_4P$: C, 43.83; H, 6.43; N, 6.39. Found: C, 43.36, 43.62; H, 6.42, 6.45; N, 6.33, 6.32 [in addition, $HN(CH_2PO_3H_2)_2$ was formed in this reaction].

V, $C_6H_5CH_2CH_2NHCH_2PO_3H_2 \cdot 2H_2O$, 265°-270°, calc for $C_9H_{18}NO_5P$: C, 43.02; H, 7.72; N, 5.58; P, 12.33. Found: C, 43.99, 44.0; H, 6.09, 5.95; N, 5.46, 5.56; P, 12.60.

VII, $HO_2C(CH_2)_3NHCH_2PO_3H_2$, 177°, calc for $C_5H_{12}NO_5P$: C, 30.46; H, 6.14; N, 7.11; P, 15.71. Found: C, 29.64. 29.66; H, 6.39, 6.61; N, 7.11, 7.18; P, 15.74.

VIII, $HO_2C(CH_2)_4NHCH_2PO_3H_2 \cdot ½H_2O$, 207°-209°, calc for $C_6H_{15}NO_{5.5}P$: C, 32.74; H, 6.87; N, 6.37; P, 14.07.

Table I. Voltammetry data and oxidation products of substituted iminodimethylenediphosphonic acids

Compound	Structure ($Y = CH_2PO_3H_2$)	E_p (V *vs.* SCE)	i_p (μA)	Product(s) ($Y = CH_2PO_3H_2$)
I	NY_3 Nitrilotrimethylenetriphosphonic acid	0.92	108	HNY_2 Iminodimethylenediphosphonic acid
II	CH_3NY_2 N-methyliminodimethylenediphosphonic acid	1.05	80	CH_3NHY N-methylaminomethylenephosphonic acid

XII, $H_2O_3PCH_2NH(CH_2)_8NHCH_2PO_3H_2 \cdot 4H_2O$, 190°, calc for $C_{10}H_{34}N_2O_{10}P_2$: C, 29.70; H, 8.48; N, 6.93. Found: C, 29.13, 29.19; H, 6.50, 6.80; N, 6.67, 6.60.

XIII, $H_2O_3PCH_2NHCH_2(1,4\text{-}C_6H_{10})CH_2NHCH_2PO_3H_2 \cdot H_2O$, 305°-310°, calc for $C_{10}H_{26}N_2O_7P_2$: C, 34.47; H, 7.53; N, 8.04. Found: C, 34.21, 34.14; H, 7.49, 7.42; N, 7.25, 7.22.

XIV, $(H_2O_3PCH_2NHCH_2CH_2)_2O$, 289°-293°, calc for $C_6H_{18}N_2O_7P_2$: C, 24.66; H, 6.21; N, 9.59. Found: C, 23.98, 23.86; H, 5.96, 6.14; N, 8.80, 8.86.

Electrolysis in a beaker.—In a 100-ml beaker with graphite plate anode (35 cm^2) and Pt wire cathode was placed 80 ml of 20% HCl and 8g of $CH_3N(CH_2PO_3H_2)_2$ (II). This was electrolyzed at 250 mA for 26 hr at room temperature using a Harrison Model 865B power supply. The NMR spectra for the starting solution, partially oxidized solution, and completely oxidized solution are shown in Fig. 2. The solution was concentrated on a rotary evaporator and the residue crystallized from ethanol-water giving 3.7g (80%) of $CH_3NHCH_2PO_3H_2$, mp 274°-275°.

Analysis. calc for $C_2H_8NO_3P$: C, 19.21; H, 6.45; N, 11.20; P, 24.76. Found: C, 18.76, 18.85; H, 6.40, 6.35; N, 11.21, 11.43; P, 24.29.

Isolation of formylphosphonic acid.—The electrolysis was run in the cell shown in Fig. 1. Twenty grams of nitrilotrimethylenetriphosphonic acid in 100 ml of 0.1*M* HCl was electrolyzed at room temperature for 5.75 hr at 0.5A. The solvent was removed on a rotary evaporator and 100 ml CH_3CN was added to the residue to precipitate $HN(CH_2PO_3H_2)_2$. The filtrate was concentrated on a rotary evaporator and the residue extracted with acetone. The acetone extract was concentrated to a glass at reduced pressure. NMR analysis indicated pure $HC(=O)PO_3H_2$. Elemental analysis: calc for $CH_3O_4P \cdot H_2O$: C, 9.38; H, 3.93; N, 0.00. Found: C, 9.15, 9.31; H, 3.97, 3.74; N, 0.78, 0.70.

The material did not form an insoluble semicarbazone (6) and would not form a precipitate with a saturated sodium bisulfite solution. A portion of the material was made basic with aqueous NaOH, heated, cooled, and reacidified with concentrated HCl. The acidification was accompanied by gas evolution (presumably CO_2). Proton NMR indicated the presence of HPO_3H_2 (upfield peak at $\delta = 1.05$) and $HOCH_2PO_3H_2$ ($\delta = 3.98$, $J_{HP} = 7$ Hz) in the acidified solution.

Results

Cyclic voltammetry was carried out in 0.2*M* H_3PO_4 at a glassy carbon anode. None of the compounds showed reversible oxidation. The peak potentials (E_p) for the oxidations of the substituted iminodimethylenediphosphonic acids are shown in Table I.

The products of the macroelectrolyses are also shown in the table along with the melting point and elemental analysis. Many of the secondary amine products are shown as hydrates based on elemental analysis.

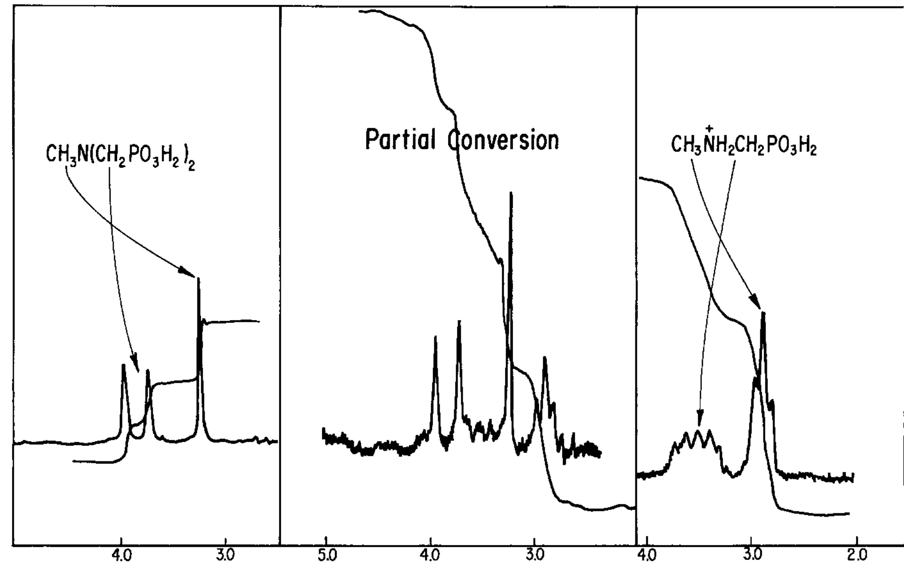
In each case another major product, formylphosphonic acid, was formed (as evidenced by its ^1H NMR doublet at $\delta = 5.38$) but was generally not isolated. A crude form of that compound was isolated, as is shown in the experimental section.

Except for $\phi CH_2N(CH_2PO_3H_2)_2$, $CH_2{=}CHCH_2N(CH_2PO_3H_2)_2$, and $(H_2O_3PCH_2)_2NCH_2CH_2N(CH_2PO_3H_2)_2$ the oxidations proceeded cleanly to the secondary amine as indicated by proton NMR. The reactions were easily followed by ^1H NMR because the tertiary amines exhibit a sharp doublet at around $\delta = 3.8$ with a separation of about 14 Hz. That signal which is due to the methylene between phosphorus and nitrogen shifts upfield and becomes a multiplet because of quadrupole coupling to nitrogen for the secondary amine products (see Fig. 2). In most cases it was difficult to initiate crystallization of the product so that product isolation was not optimized for each product.

Discussion

The cyclic voltammetry data shown in Table I indicates that the site of the oxidation is the same in each case since the range of oxidation potentials is so narrow. Note that this is the same potential region in which tertiary amines are known to oxidize (7).

There seem to be several groupings of compounds based on peak current. First, compounds I, II, and VI-IX (i_p ranging from 80 to 112) might be considered to be the normal monoamine oxidation. Compounds XIV and XV have higher values of i_p, presumably because two amines are available on each molecule. Compounds X-XIII would be expected to have lower values of i_p because they were run in the more viscous



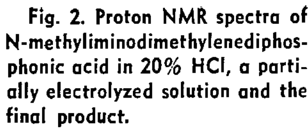


Fig. 2. Proton NMR spectra of N-methyliminodimethylenediphosphonic acid in 20% HCl, a partially electrolyzed solution and the final product.

medium of 50% H_3PO_4. It is not clear why compounds IV, V, and XIII have abnormally high values of i_p. Dodecyliminodimethylenediphosphonic acid (III) was not sufficiently soluble in 50% H_3PO_4 to obtain a voltammogram.

The general reaction path suggested by the product is

The preparative electrolyses were carried out in 20% or concentrated HCl for several reasons. First, graphite anodes are unstable in phosphoric or sulfuric acids. HCl may be removed from the product by distillation. At the current densities used there is no problem of overoxidation of the product when HCl is used as the

$$RN(CH_2PO_3H_2)_2 \xrightarrow{-1e} \overset{+\cdot}{RN}(CH_2PO_3H_2)_2 \xrightarrow{-H^+} R\text{—}N\text{—}\dot{C}HPO_3H_2 \;(\text{N bears } CH_2PO_3H_2)$$
$$\xrightarrow{-1e} R\text{—}\overset{+}{N}{=}CHPO_3H_2 \;(\text{N bears } CH_2PO_3H_2) \xrightarrow{H_2O} RNH(CH_2PO_3H_2) + O{=}CHPO_3H_2 \quad [3]$$

This is similar to the oxidation pathway suggested for simple tertiary aliphatic amines (8). However, the related α-aminophosphinic acids were shown to cleave both the carbon-nitrogen and carbon-phosphorus bond on electrochemical oxidation (9). The evidence for the structure of the cleaved portion of the molecule ($H\overset{O}{\overset{\|}{C}}PO_3H_2$) includes the data in the experimental section. Further, the ^1H NMR spectrum in 20% HCl consists of a doublet ($J_{HP} = 9$ Hz) at $\delta = 5.38$ for the hydrogen attached to the carbonyl. The similar hydrogen on glyoxylic acid ($H\overset{O}{\overset{\|}{C}}CO_2H$) has a similar chemical shift. The disproportionation in basic solution parallels the reaction of glyoxylic acid in basic media (10)

$$2H\overset{O}{\overset{\|}{C}}PO_3H_2 \xrightarrow{OH^-} HOCH_2PO_3^{=} + {}^-O_2CPO_3^{=} \quad [4]$$

$${}^-O_2CPO_3^{=} \xrightarrow{H^+} CO_2\uparrow + HPO_3H_2 \quad [5]$$

As is indicated in Table I, some of the compounds gave more than one secondary amine product. For compound IV both methylenephosphonic acid and benzyl were cleaved in a nearly statistical amount. Presumably, the benzyl is cleaved according to the following pathway

solvent because the O_2 evolution potential is very near that of the tertiary amine oxidation. Therefore, when the starting material is completely consumed, only O_2 evolution occurs, so that a constant current power supply rather than a potentiostat may be employed. Aqueous HCl was not the solvent for voltammetry because the peaks were too close to the background.

Both the voltammetric data and reaction pathway suggest that these compounds behave as free amines even in concentrated aqueous acid. That is further supported by the ^1H NMR spectra of these compounds in 20% HCl. All of the tertiary amines show a doublet in the NMR spectrum, due to the hydrogens on the carbon attached to phosphorus. These appear as a doublet because of coupling to phosphorus. They are not further split by quadrupole coupling to nitrogen which generally occurs with protonated or quaternary nitrogen. However, secondary amines containing only one methylenephosphonic acid group do show quadrupole coupling to nitrogen, so that the methylene between nitrogen and phosphorus appears as a multiplet. [This was incorrectly attributed to coupling with hydrogen attached to nitrogen in the previous communication (3).] The NMR spectra shown in Fig. 2 illustrate this phenomenon. Note that the methyl group is a singlet for N-methyliminodimethylenediphosphonic acid, whereas the methyl on N-methylaminomethylenephosphonic acid is a triplet due to quadrupolar coupling to pro-

$$C_6H_5CH_2N(CH_2PO_3H_2)_2 \xrightarrow{-1e} C_6H_5CH_2\overset{+\cdot}{N}(CH_2PO_3H_2)_2 \xrightarrow{-H^+} C_6H_5\dot{C}HN(CH_2PO_3H_2)_2$$
$$\xrightarrow{-1e} C_6H_5CH{=}\overset{+}{N}(CH_2PO_3H_2)_2 \xrightarrow{H_2O} C_6H_5CHO + HN(CH_2PO_3H_2)_2 \quad [6]$$

Benzaldehyde was detected in the NMR spectrum of the products.

Compound V was included because it was thought that benzyl cation might be cleaved from the intermediate cation radical; however, only methylenephosphonic acid cleavage occurred.

Compound VI probably underwent cleavage of both the allyl and the methylenephosphonic acid groups. Unfortunately, no single product could be isolated from the reaction mixture.

Compound X apparently has two cleavage pathways, the normal methylenephosphonic acid cleavage and cleavage of the carbon-carbon bond. The second pathway is visualized as follows

tonated nitrogen. Similarly, the methylene appears as a doublet (split by phosphorus) in the tertiary amine and as a multiplet in the secondary amine due to coupling to phosphorus and nitrogen.

Voltammetric and Related Studies of $NbCl_5$ in Molten Chloroaluminates

G. Ting,[1] K. W. Fung,[2] and G. Mamantov*

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37916

ABSTRACT

The electrochemical reduction of $NbCl_5$ in $AlCl_3$-NaCl melts of compositions varying from a NaCl saturated melt [~50-50 mole per cent (m/o)] to a 63 m/o $AlCl_3$ melt was investigated by chronoamperometry, linear sweep voltammetry, chronopotentiometry, and differential pulse polarography. The reduction mechanism is determined to a large extent by the melt composition and temperature which, in turn, determine the Lewis acidity of the melt. The formation of lower oxidation states results in dimerization and cluster formation. The standard electrode potential of the Nb(V)/Nb(IV) couple and the diffusion coefficient of Nb(V) in the NaCl saturated melt are reported.

Molten chloroaluminates ($AlCl_3$-MCl mixtures where M^+ is an alkali cation) (1) are interesting solvents for electrochemical and spectral studies. The Lewis acidity (2-6) of these low-melting ionic liquids can be readily changed by varying the $AlCl_3$-MCl ratio. The acidic compositions are particularly good media for stabilization of lower oxidation states, such as Cd_2^{2+} (7), Bi^+, Bi_5^{3+} (8, 9), Hg_3^{2+} (10), and Te_2^{2+} and Te_4^{2+} (11).

Recently we have become involved in electrochemical studies of selected metal ions of Groups IVB-VIB (refractory metals) in chloroaluminate melts. We are particularly interested in the effect of melt acidity, as determined by melt composition and temperature, on the redox chemistry and the mechanisms of electrode processes involving refractory metal ions. Possible formation of metal clusters (12) is also of interest. In a previous paper (13) we have reported on the electrochemistry of zirconium (IV) in these media. In this paper we report on the reduction of $NbCl_5$ in $AlCl_3$-NaCl melts of different compositions by electrochemical techniques, such as chronoamperometry, chronopotentiometry, pulse polarography, and linear sweep voltammetry.

The electrochemistry of niobium in molten halides has been studied previously (14-27), mostly in the LiCl-KCl eutectic and the equimolar NaCl-KCl melt. In these studies niobium solute species were usually produced by anodic dissolution of niobium metal; there is disagreement in the literature as to the nature of the niobium species produced. Gut (14) has studied the reduction of $NbCl_5$ in $AlCl_3$-containing melts. He reported that Nb(V) is reduced to Nb(III) in two steps at a platinum electrode in the $AlCl_3$-NaCl-KCl [50-25-25 mole per cent (m/o)] melt at 200°C; in the more acidic melt, $AlCl_3$-NaCl-KCl (60-26-14 m/o), at 120°C the two steps almost overlap. Gut interpreted the process as being due to a one step two-electron reduction; however, E *vs.* log $(i_d - i)/i$ plot was not linear.

Experimental

Melt preparation, electrochemical cell, instrumentation, and procedures have been described previously (10, 28). Differential pulse polarograms were obtained with the Princeton Applied Research Model 174 polarographic analyzer. Both platinum and tungsten wires (electrode areas 0.10 cm^2) were used as working electrodes. The reference electrode was an aluminum wire immersed in $AlCl_3$-NaCl (63-37 m/o) and separated from the main compartment by a thin Pyrex membrane.

$NbCl_5$ (from Alfa Inorganics) was purified twice by sublimation through a Pyrex frit at 220°C. The yellow granular crystals were identified by Raman spectra (29).

Results and Discussion

$AlCl_3$-$NaCl_{sat}$ melt.[3]—*Mechanism of the reduction of Nb(V).*—Polarograms constructed from current-time curves (10) for the reduction of Nb(V) at both

Key words: niobium, chloroaluminates, $NbCl_5$, $AlCl_3$-NaCl melts.

[3] The liquidus composition at 175°C is ~49.8 m/o in $AlCl_3$ (3).

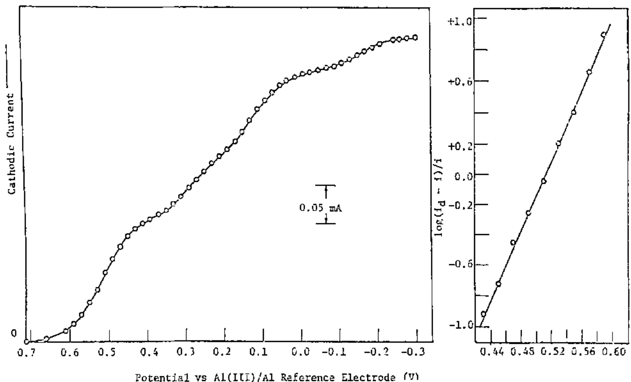

Fig. 1. Polarogram constructed from current-time curves for the reduction of Nb(V) at platinum electrode at 180°C; plot of E vs. log $(i_d - i)/i$ for the first wave. Melt composition, $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2; Nb(V) concentration, 2.68 × 10^{-2}M; current measured at 5 sec.

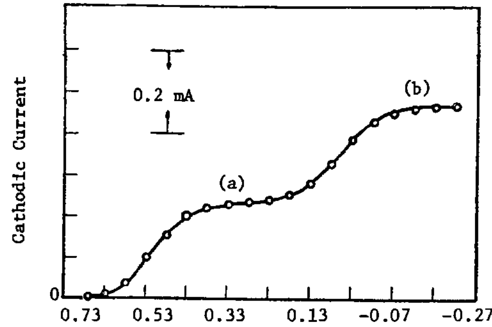
platinum and tungsten working electrodes exhibit four reduction steps at longer current measuring times (5 sec) in the temperature range 160°-180°C (Fig. 1) (at > 180°C the over-all polarograms were ill-defined). The dependence of the diffusion currents on the concentration of Nb(V) is shown in Table I. Diffusion current ratios with respect to the first reduction step were approximately 1:0.5:0.5:(0.2-0.3). The first reduction step is well-defined; the slope 2.3 $RT/n\mathbf{F}$ of the log $(i_d - i)/i$ *vs.* E plot for the first reduction step (Fig. 1) corresponds to a one-electron reversible process. At lower concentrations (6.8 × $10^{-3}M$) and short current measuring times (0.1 and 0.02 sec) only two reduction steps were observed; the corresponding log plots (Fig. 2) result in $n_1 = 0.97$ and $n_2 = 0.92$. Differential pulse polarographic, chronopotentiometric (at low current densities), and linear sweep voltammetric (at low scan rates, ≤ 0.1 V/sec) studies also resulted in four reduction steps. Typical chronopotentiograms and cyclic voltammograms are shown in Fig. 3 and 4, respectively. Chronopotentiograms taken at high current densities and linear sweep voltammograms taken at fast scan rates exhibit three reduction steps (the third reduction step was observed at higher concentrations than those corresponding to polarographic conditions of Fig. 2).



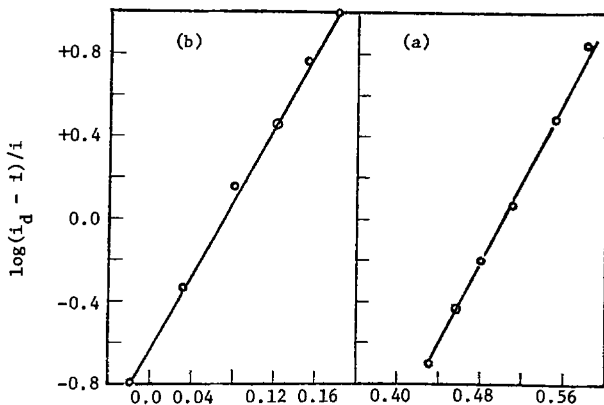


Fig. 2. Polarogram constructed from current-time curves at tungsten electrode at 180°C. Plot of E vs. log $(i_d - i)/i$ for the two waves shown. Melt composition, $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2; Nb(V) concentration, 6.8 × 10^{-3}M; current measured at 0.1 sec.

The cyclic voltammogram for the first step is shown in Fig. 5; the summary of the voltammetric data for the first step at a platinum electrode is shown in Table II (similar results were obtained at a tungsten electrode). The peak current, $i_{p(1)}{}^c$, for the first reduction step was directly proportional to Nb(V) con-

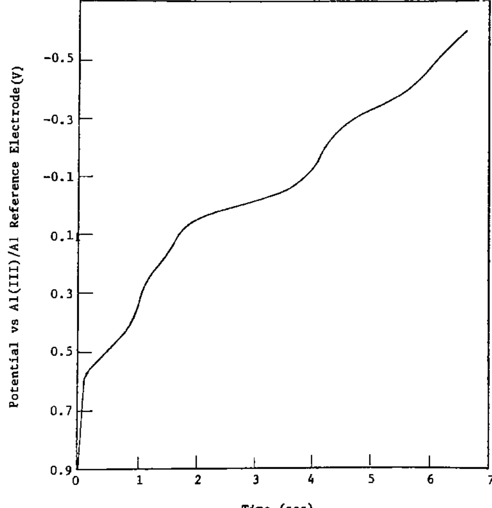

Fig. 3. Chronopotentiogram for the reduction of Nb(V) at tungsten electrode at 160°C. Melt composition, $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2; Nb(V) concentration, 5.19 × 10^{-2}M; current density, 10 mA/cm^2.

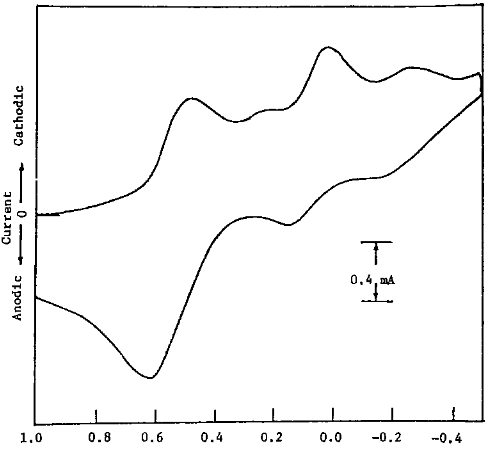

Fig. 4. Cyclic voltammogram (first scan) for the reduction of Nb(V) at platinum electrode at 160°C. Melt composition; $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2; Nb(V) concentration, 5.19 × 10^{-2}M; scan rate, 0.1 V/sec.

centration in the range studied; the parameter $i_p/v^{1/2}$ is almost independent of the scan rate (v was varied from 0.02 to 10 V/sec) at temperatures 180°-260°C. Comparison of experimental and theoretical (30) peak potential separations ($E_p{}^c - E_p{}^a$), peak widths ($E_p - E_{p/2}$), and anodic and cathodic peak current ratios [$i_p{}^a/i_p{}^c$, calculated using Nicholson's semi-empirical formula (31)] leads to the conclusion that the first reduction step is essentially a one-electron reversible diffusion-controlled process. This conclusion was verified by: (*i*) peak width measurements of the first peak in the differential pulse polarogram (32); (*ii*) chronopotentiometric E *vs.* log $(\tau^{1/2} - t^{1/2})/t^{1/2}$ plot for the first reduction step; (*iii*) values of n_1 of 1.01 and 1.05 determined from the ratio of voltammetric $i_p/v^{1/2}$ to chronoamperometric $it^{1/2}$ and chronopotentiometric $i\tau^{1/2}$. For these determinations of n, concentration, diffusion coefficient, and electrode area do not need to be known. These ratios are given as (33)

$$\frac{i_p/v^{1/2}}{it^{1/2}} = 86.31\ (n/T)^{1/2} \qquad [1]$$

$$\frac{i_p/v^{1/2}}{i\tau^{1/2}} = 54.86\ (n/T)^{1/2} \qquad [2]$$

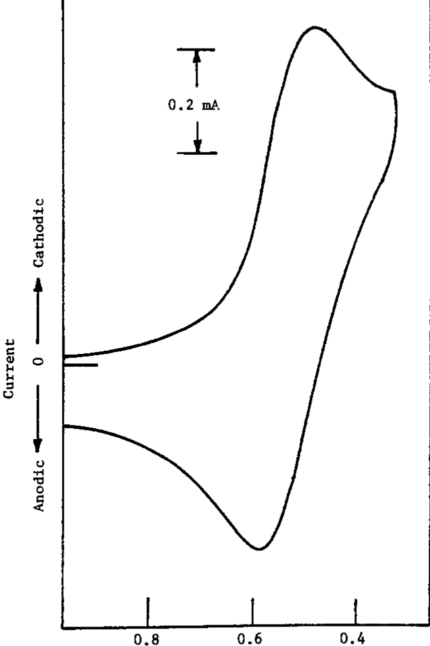

Fig. 5. Cyclic voltammogram for the reduction of Nb(V) at tungsten electrode at 180°C. Melt composition, $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2; Nb(V) concentration, 2.68 × 10^{-2}M; scan rate, 0.2 V/sec.

However, it should be noted (Table II and Fig. 6) that the voltammetric peak potential, $E_{p(1)}{}^c$, shifts anodically with increasing Nb(V) concentration. An anodic shift of $E_p{}^c$ with increasing solute concentration for the case of the soluble product may be caused either by a mechanism involving reversible charge transfer followed by reversible or irreversible dimerization (34-38) or by a disproportionation reaction following a reversible charge transfer (39). The latter mechanism may be eliminated by the observed linear dependence of the peak current on concentration. According to Saveant and Vianello (36) for the case of reversible charge transfer followed by a reversible dimerization, when the extent of dimerization is small, the peak potential is given by

$$E_p = E_{1/2} - 0.70\ RT/n\mathbf{F} - RT/4n\mathbf{F} \ln D_o/D_z - RT/2n\mathbf{F} \ln K + RT/2n\mathbf{F} \ln C \qquad [3]$$

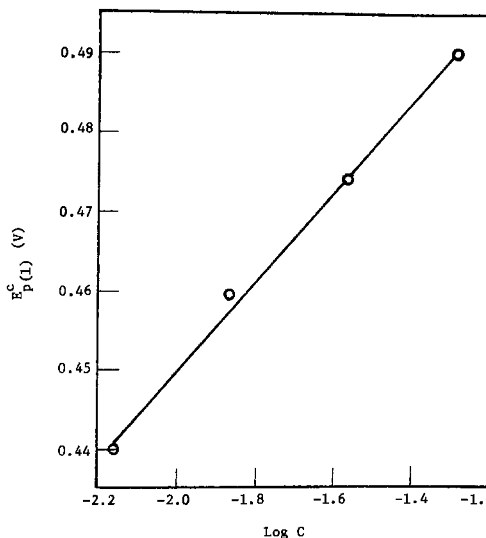

Fig. 6. Plot of $E_{p(1)}{}^c$ *vs.* log C for the reduction of Nb(V) to Nb(IV) at platinum electrode at 180°C. Melt composition, $AlCl_3$-$NaCl_{sat}$; electrode area, 0.10 cm^2.

where D_o and D_z are diffusion coefficients of the oxidized and the dimer forms and K is the equilibrium constant for the dimerization process. Thus, E_p *vs.* log C plot should be linear with a slope 2.3 $RT/2n\mathbf{F}$. The observed slope (Fig. 6) results in $n_1 = 0.92$, thus, providing strong evidence for the presence of some dimerization following the first reduction step.

The presence of a preceding chemical reaction before the second reduction step is also supported by a $\sim$ 20% decrease in the chronopotentiometric $i_o\tau_2^{1/2}$ when the current density is increased from 6 to 25 mA/cm^2 (33).

The results obtained by several methods point to the reduction mechanism of the ECEEE type, at least at longer times (slower scan rates in linear sweep voltammetry and lower current densities in chronopotentiometry). The mechanism believed to be present is

$$Nb^{5+} + e^- \rightleftharpoons Nb^{4+} \qquad E_1\ (n_1 = 1) \qquad [4]$$

$$2Nb^{4+} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Nb_2^{8+} \qquad C\left(K = \frac{k_b}{k_f}\right) \qquad [5]$$

$$Nb_2^{8+} + e^- \rightleftharpoons Nb_2^{7+} \qquad E_2\ (n_2 = 0.5) \qquad [6]$$

$$Nb_2^{7+} + e^- \rightleftharpoons Nb_2^{6+} \qquad E_3\ (n_3 = 0.5) \qquad [7]$$

$$3Nb_2^{6+} + 2e^- \rightleftharpoons 2Nb_3^{8+} \qquad E_4\ (n_4 = 0.33) \qquad [8]$$

Decreasing K (see Eq. [5]) values for dimerization of Nb(IV) in more acidic melts are expected by considering a reaction, such as

$$2NbCl_6^{2-} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Nb_2Cl_9^- + 3Cl^- \qquad [9]$$

This reaction will be driven to the right by the reaction of $Al_2Cl_7^-$ ions with Cl^- ions to form $AlCl_4^-$ ions. It would, therefore, be expected from equilibrium considerations that in the melt saturated with NaCl, complications due to dimerization in this basic melt composition should be only minor; this expectation is borne out by the experimental results. Saveant *et al.* (40) reported that a pure diffusion-controlled process should be seen for an ECE mechanism with a large K for the following chemical reaction. The number of electrons in the reduction steps occurring after the dimerization process is based primarily on the observed polarographic diffusion current ratios. The existence of Nb_2^{7+} (no conclusions may be drawn from the existing data regarding the number of Cl^- ions associated with this or other entities) has not been reported as yet; however, Caton and Freund (15) have reported that niobium ions with an average n value of 3.64 were generated by controlled potential electrolysis in LiCl-KCl eutectic. Also Yang *et al.* (24) have found that mixed valence states between Nb^{3+} and Nb^{4+} prevailed in concentrated LiCl-KCl eutectic. Formation of Nb_3^{8+} in LiCl-KCl eutectic has been reported by Saeki and Suzuki (17, 25).

The results obtained at shorter times (or faster scan rates) indicate that the first two reduction steps involve simple reversible electrode reactions

$$Nb^{5+} + e^- \rightleftharpoons Nb^{4+} \qquad [4]$$

$$Nb^{4+} + e^- \rightleftharpoons Nb^{3+} \qquad [10]$$

The chemical reaction following the first reduction step does not have enough time to occur. The third reduction step observed in the chronopotentiograms and voltammograms is possibly due to a higher order electrode reduction of Nb^{3+}; the observed flatness of the third wave is in agreement with the theoretical prediction (41) that the voltammograms for higher order processes are smaller and broader than the corresponding first order voltammograms.

Standard electrode potential of the Nb(V)/Nb(IV) couple.—The half-wave potential $E_{1/2}$ for a reversible process $O + ne^- = R$ may be taken as the voltammetric equivalent of the standard electrode potential $E°$, assuming that the diffusion coefficients and activity coefficients are equal (33). The $E_{1/2}$ values for the process $Nb(V) + e^- \rightleftharpoons Nb(IV)$ are listed in Table II with respect to Al(III)/Al (in $AlCl_3$-NaCl, 63-37 m/o) reference electrode. Assuming that the complications due to dimerization of Nb(IV) are small at low solute concentrations and that the half-wave potential is a good estimate of the standard electrode potential, useful thermodynamic information may be obtained. At Nb(V) concentration of $1.34 \times 10^{-2}M$, E *vs.* T plot is linear in the temperature range 160°-300°C resulting in

$$E = 0.732 - 4.79 \times 10^{-4}T\,(V) \qquad [11]$$

The entropy change for the cell reaction is

$$\Delta S = n\mathbf{F}\left(\frac{\partial E}{\partial T}\right)_P = -11.05\ (\text{eu}) \qquad [12]$$

After correcting for the potential difference due to melt composition difference between bulk and reference electrode compartments [ΔE between $AlCl_3$-$NaCl_{sat}$ and the 63-37 m/o is 0.60V at 175°C (3, 5)], the cell voltage in the range 160°-300°C becomes

$$E = 1.33 - 4.79 \times 10^{-4}T \qquad [13]$$

(in the above equation it is assumed that the temperature coefficient is independent of the melt composition).

The equilibrium quotient for the reaction

$$NbCl_{5(d)} + 1/3\,NaCl_{(d)} + 1/3\,Al \rightleftharpoons NbCl_{4(d)} + 1/3\,NaAlCl_{4(d)} \qquad [14]$$

$Q = X_{NbCl_4}/X_{NbCl_5}$, is, therefore, given by

$$\log Q = -2.41 + 6.70 \times 10^3/T \qquad [15]$$

This equation shows that the lower the temperature the higher is the stability of Nb(IV) in the $AlCl_3$-$NaCl_{sat}$ melt. This result is in agreement with the previous observations (3, 42) that the Lewis acidity of chloroaluminates increases with decreasing temperature and that an increase in acidity favors the lower oxidation state.

Diffusion coefficient of Nb(V).—Assuming that the effect of dimerization is small, the diffusion coefficient of Nb(V) in molten $AlCl_3$-$NaCl_{sat}$ may be calculated from the Randles-Sevcik equation (see Table II). A linear log D *vs.* $1/T$ plot in the temperature range 160°-300°C was obtained for the Nb(V) concentration of $1.34 \times 10^{-2}M$. The resulting equation is

$$\log D = -2.70 - 1100/T \qquad [16]$$

From this equation the activation energy for the diffusion of Nb(V) in this melt has been calculated as 5.0 kcal/mole.

The diffusion coefficient for Nb(V) at 180°C was also calculated from the chronopotentiometric data using the Sand equation; the values of 4.9×10^{-6} and 4.5×10^{-6} cm^2/sec at Nb(V) concentration of 2.68×10^{-2} and $5.19 \times 10^{-2}M$, respectively, were obtained. Chronoamperometric results at short times (0.02 and 0.1 sec) resulted in the D value of $\sim 4.8 \times 10^{-6}$ cm^2/sec for the Nb(V) concentration of $2.68 \times 10^{-2}M$. Thus, the agreement between D values obtained by three different methods is at best reasonable; similar deviations were observed in studies of Ti(II) in molten chloroaluminates (42).

Adsorption effects.—At platinum (but not tungsten) electrode, sharp characteristic (43) adsorption-desorption peaks were observed in linear sweep voltammograms before the third reduction step after $\sim$1 day at

experimental temperature (220°C) at the Nb(V) concentration of $2.68 \times 10^{-2}M$. At lower scan rates ($\leq$ 2 V/sec) the adsorption and desorption peak currents are symmetric; at faster scan rates the adsorption peak shifts cathodically and the desorption peak anodically; the amount of this shift increases with increasing scan rate. The adsorption-desorption peaks become broad and skewed. The parameter $i_p/v^{1/2}$ increased with scan rate as expected (43). These observations are consistent with the theory of linear sweep voltammetry of systems involving kinetic adsorption of the products (44).

$AlCl_3$-NaCl (55-45 m/o) melt.—The melt composition has a pronounced effect on the reduction characteristics of Nb(V). The polarogram constructed from current-time curves using a platinum electrode at 180°C is shown in Fig. 7; two reduction steps are observed. Similar results were obtained at 260°C and with a tungsten electrode. A value of $n = 1.9$ was obtained from the E *vs.* log $(i_d - i)/i$ plot for the first reduction step. Upon lowering the temperature to 140°-150°C the first step is split into two steps (Fig. 8) for which nonlinear log plots were obtained. Similar results were obtained by chronopotentiometry and linear sweep voltammetry. The experimental observations ($n = 2$ for the first reduction step at 180°C, the splitting of this step into two steps of approximately equal height at 140°-150°C, and the nonlinearity of log plots) point to the formation of Nb^{4+} followed by dimerization and further reduction to Nb_2^{6+} in the first reduction step at 180°C or the first two steps at 140°-150°C. The reduction step at 0.26V (Fig. 7) occurs at approximately the same potential [after correcting for melt composition difference (3, 5)] as the last step in the NaCl-saturated melt. This evidence as well as the observed diffusion current ratio and the broad nature of the peak at this potential in the cyclic voltammogram pointing to higher reaction order (41) lead us to conclude that the formation of Nb_3^{8+} is probably involved at this potential. The splitting of the first reduction step at 180°C into two steps at 140°-150°C is probably caused by the increase in k_f value (or decreasing K, $K = k_b/k_f$, see Eq. [5]) at lower temperatures due to the increasing acidity of the melt at lower temperatures. Saveant *et al.* (39) have reported that the peak potential should shift anodically with increasing k_f value (decreasing K value) for an ECE mechanism involving a reversible chemical reaction. According to Nicholson and Shain (45) anodic shift of the first wave and the appearance of a second wave should be observed at large values of k_f for an ECE mechanism with an irreversible chemical reaction. The observed results are in agreement with the theoretical predictions as stated above.

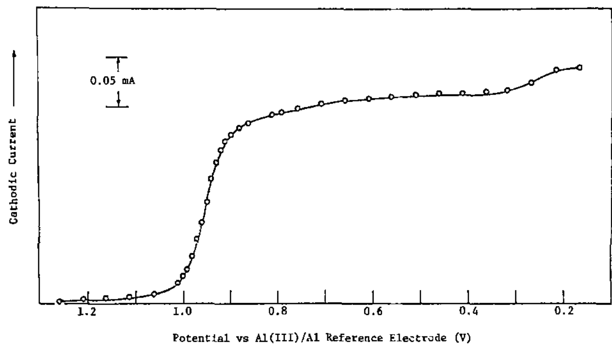

Fig. 7. Polarograms constructed from current-time curves for the reduction of Nb(V) at platinum electrode at 180°C. Melt composition, $AlCl_3$-NaCl (55-45 m/o); electrode area, 0.10 cm^2; Nb(V) concentration, $1.42 \times 10^{-2}M$; current measured at 5 sec.

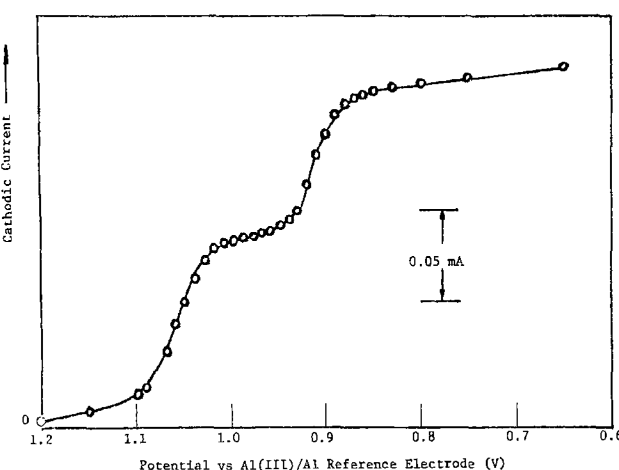

Fig. 8. Polarogram constructed from current-time curves for the reduction of Nb(V) at platinum electrode at 140°C. Melt composition, $AlCl_3$-NaCl (55-45 m/o); electrode area, 0.10 cm^2; Nb(V) concentration, $1.42 \times 10^{-2}M$; current measured at 5 sec.

$AlCl_3$-NaCl (63-37 m/o) melt.—The electrochemical behavior of Nb(V) in this very acidic melt at 180°-260°C is very similar to that in the 55/45 melt at 180°C. Two reduction steps were observed. For the first well-defined step $E_{1/2} = 1.04$V at 180°C; the voltammetric peak current is proportional to Nb(V) concentration. The second poorly defined step occurs at the same potential (after correcting for the composition difference) as the last step in the NaCl-saturated melt. The presence of kinetic complications in the first reduction step may be deduced from several experimental results, such as a very small reoxidation peak current at a potential 0.3-0.5V more anodic (depending on the scan rate) than the cathodic peak potential; a decrease in the $i_p/v^{1/2}$ parameter with increasing scan rate, the anodic shift of the cathodic peak potential with increasing concentration, and nonlinear log plots using polarograms constructed from current-time curves. It is concluded that the reduction scheme of Nb(V) in this melt is the same as in the 55/45 melt.

Conclusions

The results presented in this paper for the reduction of Nb(V) and in previous papers for the reduction of Zr(IV) and the oxidation of Ti(II) (13, 42) in molten chloroaluminates demonstrate that the electrochemical reduction pathway is, to a large extent, determined by the melt composition and temperature. Since both of these parameters determine the Lewis acidity of the chloroaluminate melts (2-6), a direct relationship to that parameter is apparent.

This work, as well as related studies on the electroreduction of Ta(V) and W(VI) (46), also illustrates that the formation of lower oxidation states of the refractory metal in these melts results in dimerization and cluster formation. This result is in agreement with those of McCarley and co-workers (47, 48). No evidence for the deposition of niobium metal in these melts has been obtained.

Studies in Derivative Chronopotentiometry

III. Application to Submillisecond Transition Times

P. E. Sturrock*

ABSTRACT

The derivative technique for the measurement of chronopotentiometric transition times is applied to millimolar solutions of cadmium and lead at the dropping mercury electrode. Linear Bard plots are obtained down to transition times of 15 μsec with calculated chronopotentiometric constants having a relative accuracy of better than 3%. The present limitations to the measurement of short transition times, for reversible electrode reactions, appear to be due to instrumentation.

The chief disadvantage in chronopotentiometry is the strong influence that the double-layer charging has over the output waveform and the concomitant difficulty in measuring the parameter of interest, the transition time. With the advent of derivative chronopotentiometry, the disadvantages of the conventional

Key words: DME, current correction, reversible reactions.

technique are lessened or removed. In previous papers (1-2) we have discussed instrumentation, diffusion-controlled systems, and application to analysis. We present here some measurements of short transition times (<1 msec). Since the measuring technique and double-layer influences were discussed in the previous two papers (1-2), that material and pertinent references will not be repeated here.

In order to make rapid repetitive chronopotentiometric measurements on a reproducible electrode, we decided to utilize the classical dropping mercury electrode, DME. Some results obtained on this electrode were presented previously (1-2). However, unless short transition times can be measured accurately, the use of the DME results in a rather narrow range of usable transition times. Thus, successful measurements of short transition times greatly enhance the practical applications of chronopotentiometry with the DME and also serve as a further check on the split-current model and correction techniques.

Experimental

Derivative and conventional (200 mV) chronopotentiograms were obtained with two solutions: 1 mM $Pb(NO_3)_2$ in 1M KNO_3 and 1 mM $Cd(NO_3)_2$ in 1M KNO_3. The chronopotentiograms were obtained with an instrument described previously (1) and recorded on a Tektronix 564A storage oscilloscope equipped with a 10 MHz dual-trace vertical amplifier. The chronopotentiograms were then photographed with a Tektronix C-12A camera and the data read from the photographs. At each current setting several repeats were made, each one on a fresh drop. In most cases the repeated traces superimposed so well that they appeared to be only one trace.

The experiments were first performed using a Beckman hanging mercury drop assembly to produce a 1 μliter HMDE. The area of this electrode is calculated to be 0.0484 cm². Due to the current limitations of the instrument, the fastest transition time measured with this electrode was 261 μsec. The experiments were then repeated on a DME. By varying the time between drop detachment and switching from prebias potential to constant current, different electrode areas could be utilized; therefore, higher current densities, leading to shorter transition times could be obtained within the current limitations of the instrumentation. While estimates of the DME area could be made by measuring the mercury flow rate and delay times, the areas reported were obtained by comparison with the transition times obtained with the HMDE.

The instrument can use either a diode gate (Philbrick SPG-1) or a mercury-wetted relay for switching from the prebias to current mode. The switching time for the diode gate is much faster than that of the relay, but the diode gate can pass a maximum of only 2.5 mA current and has the added disadvantage of having a small current offset, the magnitude of which is dependent upon duty cycle. The relay used was of the bridging type so that the current pulse was applied before the prebias was released. However, the prebias circuit has sufficient current capacity that the application of the current pulse resulted in only a slight drift in the effective prebias while the relay was bridged. The small time delay for the relay switching adds to that of the timing circuit and results in increased time delays and consequently larger DME areas than when the diode gate was used. All of the experiments with the cadmium solution were performed using the relay switching while those with the lead solutions were performed with the diode gate. The difference in switching devices explains the larger DME area reported for the cadmium experiments. The use of the diode gate and its limited current capability required a second, smaller DME area for the lead experiments at the shortest transition times.

Positive feedback was not used to compensate for the double-layer charging in these experiments since the rise time of the compensator circuit limits its use to transition times of greater than 100 μsec.

Results

The experimental results are summarized in Table I. All experimental points are retained since, in no case, is the deviation of a single point more than 4 standard deviations from the average of the other points of that series. The large standard deviation of the cadmium results with the DME originates from the transition times below 12 μsec where the current was > 5 mA. If these 8 points are deleted, the chronopotentiometric constant for this series becomes 435 ± 7. However, the worst point (transition time = 3.25 μsec) is only high by 3.2 standard deviations from the series or a relative deviation of 10.1%.

The Bard-plot intercepts for the derivative data correspond to an average of 21.3 and 24.7 μf/cm², respectively, for the cadmium and lead series.

Figure 1 shows the short transition time end of the DME series for both metals. The dotted lines are the best fit lines for the complete series of 45 and 50 points. Figure 2 shows the derivative HMDE series for both metals. The dotted lines are the best fit lines from the fast DME data, identical with the lines of Fig. 1.

The 200 mV technique results in higher values for the chronopotentiometric constant for both metals than does the derivative technique. This same trend can also be seen by comparing the results in Tables II and III of Ref. (1) and is probably due to the 200 mV interval extending past the point at which the surface concentration of the depolarizer reaches zero. Thus, the last portion of the curve included in the 200 mV region contains faradaic current in excess of the amount that should be contained in the transition time. The 200 mV technique also results in an intercept in the Bard plot that corresponds to a double-layer capacitance that is too large. The values for the cadmium and lead series in Table I are 36 and 41 μf/cm², respectively. Noonan (3) suggested using the slope of the initial potential change in the *E-t* curve to evaluate the double-layer capacitance and hence the correction factor for the 200 mV technique. However, the results of this study indicate that even if the correct double-layer capacitance is obtained, the correction factor is

inadequate and the technique results in too large a value for the chronopotentiometric constant.

Conclusions

Using our present equipment, it appears that transition times for reversible processes can be measured with a relative precision of 2-3% down to about 15 μsec. Below that point the precision deteriorates. The present limitations on the measurement of fast transition times appear to be due to the instrumentation. The problems of current capacity and switching have been discussed above. The other instrumentation problem is the speed and accuracy of the differentiator. The amplifier used for this purpose is a Philbrick P-45AU with a nominal unity-gain bandwidth of 200 MHz and a current output of 20 mA. Even with this amplifier, it is difficult to design a stable differentiator circuit with a rise time significantly less than 1 μsec. In addition, slight errors in the calibration of the differentiator lead to large errors in the corrected short transition times where the Bard-plot intercept is more than 50% of the total experimental $i_0\tau$ values.

As was pointed out in Ref. (1), the charging current is a problem at short times and low concentrations. In Fig. 1 it can be seen that the charging current is about 50% of the total current for the fastest transitions measured in this study. If lower concentrations had been employed, the charging current would be a larger fraction of the total current at these transition times and the scatter of calculated chronopotentiometric constants should be greater. Conversely, at higher concentrations the results should be improved or even faster transitions should be measurable.

With the extension of the measurement of transition times to < 10 μsec by the derivative technique, the use of the DME for chronopotentiometry now becomes much more feasible. Previously, a planar electrode was needed in order to obtain data over so many orders of magnitude. Thus, the application to analysis and kinetic studies appears more viable. Future papers in this series will deal with applications to chemical kinetics coupled to reversible charge-transfer reactions.

Manuscript submitted Oct. 28, 1975; revised manuscript received Jan. 14, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the Georgia Institute of Technology.

The Effect of Nonuniform Concentration on the Distribution of Potential and Electrochemical Reaction Rate in Molten Polysulfide Electrodes

Y. K. Kao and P. C. Wayner, Jr.

Department of Chemical and Environmental Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

A nonuniform concentration model for the sulfur electrode of the Na/S battery is presented. Numerical results obtained using a hypothetical concentration distribution demonstrate that a concentration gradient in the polysulfide phase region of the phase diagram will cause a significant shift in the reaction distribution from that predicted by a uniform concentration model. The effect of concentration on the local double layer potential difference significantly enhances the operation of the sulfur electrode.

The use of the sodium sulfur fused salt systems as a secondary battery is desirable because of its high theoretical energy density, high open-circuit cell voltage, and the intrinsic low cost of the reactants. Current research on this battery concerns a device that consists of reservoirs of sodium and of sulfur which are separated by a solid ceramic electrolyte, β-alumina, which is a conductor of only the sodium ions. This system was first described by Kummer and Weber (1). Since that time considerable research has been done on this system (*e.g.*, 2-5). The fully charged cathode usually consists of a conductive graphite felt matrix imbedded in a pool of the nonconductive liquid sulfur. During discharge, the sodium ions, having given up an electron to the external circuit, migrate through the solid electrolyte to form various polysulfides (Na_2S_x) at the surface of the porous graphite cathode. The operating range of the cell is limited and complicated by the formation of various phases as described by its phase diagram (6). Upon discharge insoluble Na_2S_2 precipitates out when the over-all composition reaches a critical value. When the amount of sulfur present in the cell is greater than that equivalent to an over-all composition of about Na_2S_5, two immiscible liquid phases (S, Na_2S_5) coexist. Previous work (7) on the kinetics of the electrode reaction of carbon or graphite in Na_2S_3, Na_2S_4, Na_2S_5 melts at 300°-350°C has revealed that the exchange current density is extremely high. The porous electrode operation is believed to be transport limited as a result of the high exchange current density. complicated phase relationship, and the nonconductivity of sulfur phase.

Using a uniform concentration model, Gibson (8), demonstrated that gross heterogeneity in the reaction distribution can severely limit the operation of the cell. However, a uniform concentration model cannot evaluate the more important effect on cell operation resulting from the high dependency of open-circuit voltage on composition. Herein, a model of the polysulfide/sulfur electrode which includes the effect of composition on cell operation is developed. The predominant effect of composition on cell operation is numerically demonstrated for various hypothetical composition distributions. This effect significantly enhances the operation of the sulfur electrode.

Physical Parameters

The selection of a theoretical approach was influenced by a thorough search of the available data on the Na/S system. Fortunately, sufficient data was available so that the effect of concentration gradients could be included. Data on the transference number and activity of sulfur have been obtained by Cleaver and Davis (9). They report the Washburn number for sulfur which is defined as the number of moles of atomic sulfur which pass through a plane which is stationary with respect to the sodium ions per Faraday of charge. The open-circuit voltage data are available in Ref. (6, 9), and the conductivity data are presented in Ref. (9, 10). The conductivity of a representative graphite felt is also available along with some information on the limiting current at the polysulfide/graphite electrode (11).

Key words: battery, porous sulfur electrode, sodium-sulfur cell.

The following interpolation equations for a temperature of 350°C, is obtained from Cleaver's experimental data for use in the computations described below.

1. The conductivity of the melt can be approximated by

$$k_1 = 1.5376 - 1.9264 w_s \text{ (in ohm}^{-1}\text{-cm}^{-1}) \quad [1]$$

in which w_s is the weight fraction of atomic sulfur.

2. The density data are best fitted by

$$v = 37.1683 - 18.6457 m_s \text{ (in cm}^3\text{/mole)} \quad [2]$$

in which v, $1/(c_1 + c_3)$, is defined as the volume occupied by one mole of Na_2S and S, and m_s is defined as $c_1/(c_1 + c_3)$.

3. The chemical potential of atomic sulfur can be approximated by (in mV)

$$\frac{RT}{2\mathbf{F}} \ln a(s) = -690.9970 + 384.9642x - 74.8151x^2 + 5.0553x^3 \quad [3]$$

where $a(s)$ is the activity of atomic sulfur in Na_2S_x and x is the x in Na_2S_x.

Sulfur Electrode Model

The sulfur electrode is composed of a graphite felt matrix immersed in a pool of molten sulfur and/or polysulfide. A cross-sectional diagram of the cylindrical electrode is shown in Fig. 1. It is bounded on the inner side by the ceramic tube, with outer radius R_o, which serves as sodium container. On the other side, it is bounded by a conductive tube which also serves as a container for the cathodic material. The space is filled with porous graphite felt which serves as an electronic path since sulfur is a nonconductive material.

The analysis herein follows the continuum model approach of Newman and Tobias (12) which assumes that the system is adequately described as the superposition of two continua: the electrolyte and the graphite matrix. The current-potential relationship for the graphite phase is described by Ohm's law

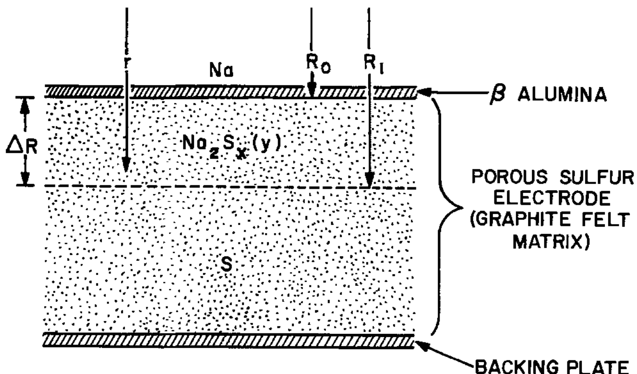

Fig. 1. Cross-sectional drawing of the cylindrical electrode

$$\frac{d\phi_2}{dr} = -\frac{1}{k_2} i_2 \quad [4]$$

The current-potential relationship for the melt phase with concentration gradient has to be developed, following the approach proposed by Newman, Bennion, and Tobias (13), from the multicomponent diffusion equation

$$c_i \nabla \mu_i = \sum_j K_{ij}(v_j - v_i) \quad [5]$$

Equations [6]-[8] are then obtained by assuming the melt is composed of the following species: (*i*) free sulfur atom, S, denoted by subscript 1; (*ii*) sodium ion, Na^+, denoted by subscript 2; and (*iii*) sulfide ion, S^{2-}, denoted by subscript 3.

$$c_1 \nabla \mu_1 = K_{12}(v_2 - v_1) + K_{13}(v_3 - v_1) \quad [6]$$

$$c_2 \nabla \mu_2 = K_{21}(v_1 - v_2) + K_{23}(v_3 - v_2) \quad [7]$$

$$c_3 \nabla \mu_3 = K_{31}(v_1 - v_3) + K_{32}(v_2 - v_3) \quad [8]$$

In these equations μ_i, K_{ij}, and v_i are the electrochemical potential, the drag coefficient, and the velocity. After choosing v_2 as the reference velocity and introducing the current equation

$$i_1 = z_3 c_3 \mathbf{F} (v_3 - v_2) \quad [9]$$

where z_3 and c_3 are the charge number and the concentration of species 3 and $\mathbf{F}$ is the Faraday constant, and using the chemical potential of the electrolyte which is defined as

$$c\nabla\mu = c_2 \nabla \mu_2 + c_3 \nabla \mu_3 = (K_{21} + K_{31})(v_1 - v_2) - K_{31}(v_3 - v_2) \quad [10]$$

and after eliminating the v_i's of Eq. [6]-[8] by [9] and [10] we arrive at the following expressions of the molar fluxes

$$N_1 = \frac{K_{31}c_1}{(K_{21} + K_{31})c_3 z_3} \frac{i_1}{\mathbf{F}} + \frac{c_1}{K_{12} + K_{13}} c\nabla\mu + c_1 v_2 \quad [11]$$

$$N_2 = c_2 v_2 \quad [12]$$

$$N_3 = \frac{i_1}{z_3 \mathbf{F}} + c_3 v_2 \quad [13]$$

Eliminating v_1, v_2, and v_3 in Eq. [11]-[13], the following equation is obtained

$$c_3 \nabla \mu_3 = \frac{i_1}{z_3 c_3 \mathbf{F}} \left\{ -\frac{(K_{31}K_{21} + K_{21}K_{32} + K_{31}K_{32})}{K_{21} + K_{31}} \right\} + \frac{K_{31}}{K_{21} + K_{31}} \frac{c}{c_3} \nabla\mu \quad [14]$$

Assuming the reference electrode has the reaction

$$S^{=} \rightleftarrows S + 2e^-$$

one can define the potential gradient in the melt as

$$\nabla\mu_3 - \nabla\mu_1 = -2\mathbf{F}\nabla\phi_1 \quad [15]$$

Applying Eq. [14] and the Gibbs-Duhem equation: $c\nabla\mu + c_1\nabla\mu_1 = 0$ one obtains the following

$$\nabla\mu_3 - \nabla\mu_1 = \nabla\mu_3$$

$$-\frac{c}{c_3}\nabla\mu = \frac{i_1}{z_3 c_3 \mathbf{F}} \left[\frac{K_{31}K_{21} + K_{32}K_{21} + K_{31}K_{32}}{K_{21} + K_{31}} \right] + \frac{K_{31}}{K_{21} + K_{31}} \frac{c}{c_3} \nabla\mu + \frac{c}{c_1} \nabla\mu = -2\mathbf{F}\nabla\phi_1 \quad [16]$$

Then define

$$i_1 = -k_1 \nabla\phi_1 \text{ when } \nabla\mu = 0$$

$$k_1 = \frac{-2\mathbf{F}^2 c_3^2 z_3 (K_{31} + K_{21})}{(K_{31}K_{21} + K_{32}K_{21} + K_{31}K_{32})} \quad [17]$$

Hence, the current equation for the melt phase is

$$i_1 = -k_1\nabla\phi_1 - \frac{k_1}{2\mathbf{F}} \left[\frac{1}{c_1} + \frac{1}{c_3} \frac{K_{31}}{K_{21} + K_{31}} \right] c\nabla\mu \quad [18]$$

According to Cleaver's result: $K_{31} >> K_{21}$, K_{32}, therefore

$$i_1 = -k_1\nabla\phi_1 + \frac{k_1}{2\mathbf{F}} [1 - 2W_s] \nabla\mu_1$$

where W_s is called the Washburn number and is defined (9) to be $-c_1/2c_3$.

The above equation then becomes

$$i_1 = -K_1 \frac{d\phi_1}{dr} + \frac{k_1}{2\mathbf{F}} \times \frac{d\mu_1}{dr} \quad [19]$$

The conservation of charge in each phase leads to the following equations

$$\frac{di_1}{dr} = -\frac{1}{r} i_1 - a i_s \quad [20]$$

$$\frac{di_2}{dr} = -\frac{1}{r} i_2 + a i_s \quad [21]$$

The conservation of charge, assuming there is no capacitance in the electrode, is given by one equation

$$(i_1 + i_2) r = I_{R_o} R_o \quad [22]$$

Past research on electrokinetics (14, 15) indicated that the process was diffusion controlled. This result is substantiated, at least for part of the discharging cose near the reversible potential, in the recent comprehensive discussion of the electrokinetics of the sodium polysulfide electrodes (16). For the redox reaction $S + 2e^- \rightleftarrows S^=$, the diffusional overpotential η can be expressed in terms of the limiting current densities of sulfide ion, $i_{ds^=}$, and sulfur, i_{ds}, by the following equation (17)

$$\eta = \frac{RT}{2\mathbf{F}} \ln \frac{\left(1 - \frac{i_s}{i_{ds}}\right)}{\left(1 - \frac{i_s}{i_{ds^=}}\right)} \quad [23a]$$

where i_{ds} is negative and $i_{ds^=}$ is positive. Taking $|i_{ds}| = |i_{ds^=}| = i_l$ in Eq. [23a] and assuming that the total overpotential is due to concentration polarization gives

$$i_s = -i_l \tanh(\alpha\eta); \quad \eta = \phi_2 - \phi_1 - \Delta\phi_e, \quad \alpha = \frac{\mathbf{F}}{RT} \quad [23b]$$

where i_l is the limiting current density and $\Delta\phi_e$ is the value of $\phi_2 - \phi_1$ at $i_s = 0$.

The boundary conditions are

$$i_1(r - R_o) = I_{R_o}$$

$$i_2(r = R_o) = 0$$

$$\phi_1(r = R_o) = 0$$

$$i_2(r = R_1) = I_{R_o}R_o/R_1$$

where R_1 denotes the position where the polysulfide/sulfur interface, or the position of the backing plate. The active electrode lies between $r = R_o$ and $r = R_1$.

Eliminating ϕ_1, ϕ_2, and i_2 between Eq. [4] and [19]-[23] the following single equation for i_1 is obtained

$$\frac{d^2i_1}{dr^2} = -\frac{1}{r}\frac{di_1}{dr} + \frac{1}{r^2}i_1 + ai_l\alpha\left[1 - \left(\frac{1}{ai_l}\right)^2\left(\frac{di_1}{dr} + \frac{1}{r}i_1\right)^2\right] \cdot \left[\left(\frac{1}{k_1} + \frac{1}{k_2}\right)i_1 - \frac{I_{R_o}R_o}{k_2 r} - \frac{1}{\mathbf{F}}(1 - 2W_s)\frac{d\mu_1}{dr}\right] \quad [24]$$

Using, $\mu_1 = \mu_1{}^* + RT \ln a(s)$ and introducing the dimensionless variable $j = i_1/I_{R_o}$ and $y = (r - R_o)/(R_1 - R_o)$, the following equation is obtained

$$\frac{d^2j}{dy^2} = -C_t\frac{dj}{dy} + C_t{}^2j + \left[1 - \beta^2\left(\frac{dj}{dy} + C_tj\right)^2\right] \cdot \left[\gamma\left(j - \frac{k_1}{k_1 + k_2}\right)\left(\frac{R_o}{R_o + y\Delta R}\right) - \delta \times (b' + 2c'x + 3d'x^2)\frac{dx}{dy}\right] \quad [25]$$

where

$$C_t = \frac{\Delta R}{y\Delta R + R_o}$$

$$\beta = \frac{I_{R_o}}{ai_l\Delta R}$$

$$\gamma = ai_l\Delta R^2\alpha\left(\frac{1}{k_1} + \frac{1}{k_2}\right)$$

$$\delta = \frac{ai_l\Delta R}{I_{R_o}}\frac{\alpha RT}{2\mathbf{F}}$$

For this study, $\alpha = \mathbf{F}/RT$, then

$$\delta = \frac{ai_l\Delta R}{I_{R_o}} = \frac{1}{\beta}$$

Equation [25] now becomes

$$\frac{d^2j}{dy^2} = -C_t\frac{dj}{dy} + C_t{}^2j + \left[1 - \beta^2\left(\frac{dj}{dy} + C_tj\right)^2\right] \cdot \gamma\left[j - \frac{k_1}{k_1 + k_2}\left(\frac{R_o}{R_o + y\Delta R}\right) - \frac{x}{\beta}(b' + 2c'x + 3d'x^2)\frac{dx}{dy}\right] \quad [26]$$

where

$$b' = \frac{bn\mathbf{F}}{RT}$$

$$c' = \frac{cn\mathbf{F}}{RT}$$

$$d' = \frac{dn\mathbf{F}}{RT}$$

with boundary conditions

$$j(0) = 1, \quad j(1) = 0$$

Numerical Results

Equation [26] was solved using the orthogonal collocation method (18) with 10 interior collocation points. The limiting current density was assumed to be 50 mA/cm^2 and the surface area per unit volume, a, was assumed to be 100 cm^{-1}, which was based on experimental results (11) and previous numerical experience. This value showed good agreement between the model predicted internal resistance and experimental results for cells operating in the two-phase region(3).

In Fig. 2 and 3, the reaction rate distributions and the corresponding reaction overpotentials for various values of $\beta(\propto I_{R_o}/\Delta R)$ at constant $\gamma(\propto[\Delta R]^2)$ are presented. In Fig. 4, the reaction overpotential distribution for various values of γ at constant β are presented. The broken curves denote the results for a uniform concentration whereas the solid curves represent the results for the following hypothetical concentration distribution: the concentration of Na_2S in Na_2S_x varies linearly from a value of $x = 5.0$ at $y = 0$ to $x = 5.25$ at $y = 1$. The broken curves in Fig. 2 show the effect of current load on the reaction rate distribution for an electrode of fixed thickness. The results are similar at low current loads, *i.e.*, $I_{R_o} = 0.12345$, 0.24690 A/cm^2. However, at higher current densities, $I_{R_o} = 0.49380$, the shape of the curve changes in the high rate region which is characteristic of this type of kinetics. At a reaction rate near its limiting value, the rate becomes much less sensitive to a change in the reaction overpotential. The corresponding curves of overpotential presented in Fig. 3 are all similar in shape. In addition, if linear polarization kinetics were used, Eq. [26] would be invariant to the current load, I_{R_o}. Then the broken curves in Fig. 2 and 3 would be exactly proportional to their current load. The broken curves presented in Fig. 4

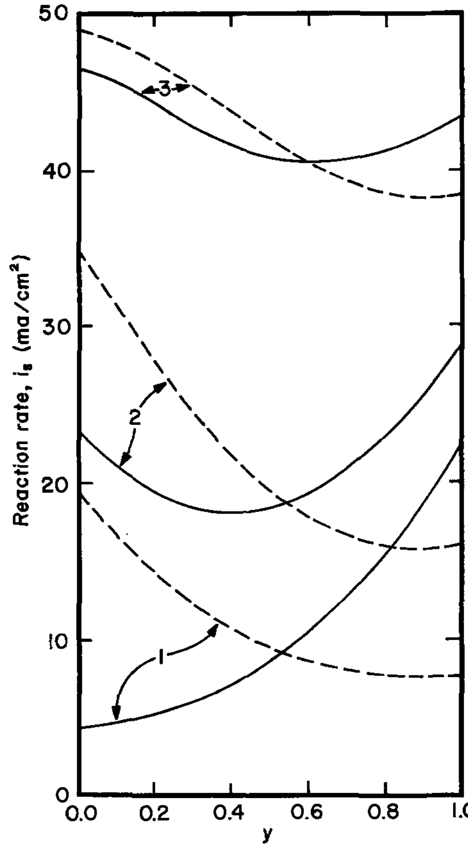

Fig. 2. Reaction rate distribution for: curve 1, $I_{R_o} = 0.12345$ A/cm^2; curve 2, $I_{R_o} = 0.24690$ A/cm^2; curve 3, $I_{R_o} = 0.49380$ A/cm^2. ($R_o = 0.3$ cm, $\Delta R = 0.1$ cm, $k_2 = 3$ $ohm^{-1}\text{-}cm^{-1}$, $a = 100$ cm^{-1}, $i_l = 0.05$ A/cm^2.) Solid curves represent nonuniform concentration and broken curves represent uniform concentration.

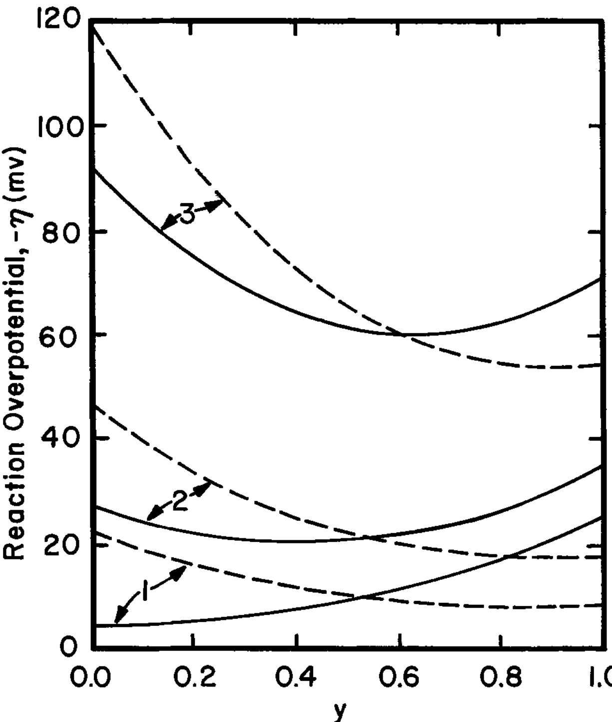

Fig. 3. Reaction overpotential distribution for conditions listed in caption for Fig. 2.

demonstrate that the reaction distribution becomes more heterogeneous as the thickness of the electrode increases.

The concentration term of Eq. [26] is inversely proportional to the parameter β. As I_{R_0} becomes smaller, corresponding to smaller β, the concentration term becomes more dominant. As illustrated by the solid curves in Fig. 2 and 3 at lower current loads, the hypothetical concentration distribution shifts the high reaction zone located near $y = 0$ in the uniform concentration case to $y = 1$. Therefore, the tendency for Na_2S_2 to precipitate at the ceramic interface is reduced and the operation of the cell is improved. At a higher load, the concentration effect becomes less dominant. When $\beta(\propto I_{R_0}/\Delta R)$ is kept constant while varying $\gamma(\propto[\Delta R]^2)$, the concentration effect becomes less dominant as the thickness of the electrode increases, which is illustrated by the solid curves in Fig. 4. Therefore, an increase in electrode thickness partially offsets the enhancement of cell operation resulting from the concentration effect.

In Fig. 5, the reaction overpotential distribution is presented for the case of $k_2 = 0.3$ ohm^{-1}-cm^{-1}. (In the previously described results $k_1 = 3.0$ ohm^{-1}-cm^{-1}.) For the uniform concentration cases, the reaction distribution is more symmetrical. For the same hypothetical concentration variation used previously, the reaction shifts toward the sulfur-rich region of the electrode. As the magnitude of the concentration variation increases, part of the electrode can operate in the charging mode while the average operation is one of discharge. This is shown in Fig. 6 for the case: $\Delta R = 0.025$ cm, $I_{R_0} = 0.1234$ A/cm^2, and a concentration variation of $x = 3.0$ at $y = 0$ to $x = 5.25$ at $y = 1$.

In Fig. 7, the variation of cell voltage with discharge is presented for different load conditions for the uniform concentration case. The slight density change is accomplished in this model by (*i*) changing the position of the polysulfide/sulfur interface in the two-phase region, and (*ii*) varying the position of the back-

Reaction overpotential distribution for: curve 1, $I_{R_0} = 0.12345$ A/cm^2, $\Delta R = 0.05$ cm; curve 2, $I_{R_0} = 0.24690$ A/cm^2, $\Delta R = 0.1$ cm; curve 3, $I_{R_0} = 0.49380$ A/cm^2, $\Delta R = 0.2$ cm. ($R_0 = 0.3$ cm, $k_2 = 3$ ohm^{-1}-cm^{-1}, $a = 100$ cm^{-1}, $i_1 = 50$ mA/cm^2.)

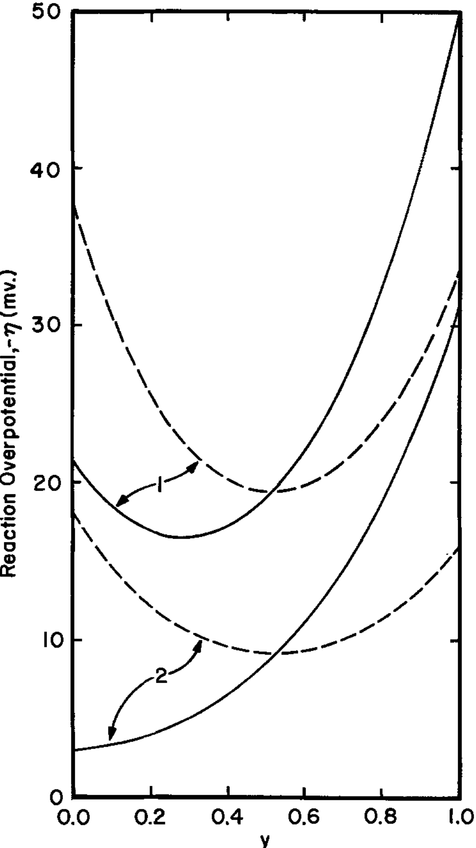

Fig. 5. Reaction overpotential distribution for melt and felt conductivities of the same order of magnitude. Curve 1, $I_{R_0} = 0.24690$ A/cm^2; curve 2, $I_{R_0} = 0.12345$ A/cm^2. ($k_2 = 0.3$ ohm^{-1}-cm^{-1}, $R_0 = 0.3$ cm, $\Delta R = 0.1$ cm, $a = 100$ cm^{-1}, $i_1 = 50$ mA/cm^2.)

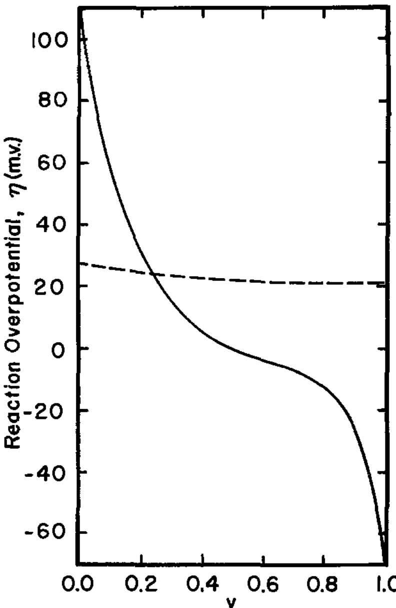

Fig. 6a. Reaction overpotential distribution for maximum concentration variation. (I_{R_o} = 0.12345 A/cm², ΔR = 0.05 cm, k_2 = 3 ohm^{-1}-cm^{-1}, a = 100 cm^{-1}, i_l = 50 mA/cm².)

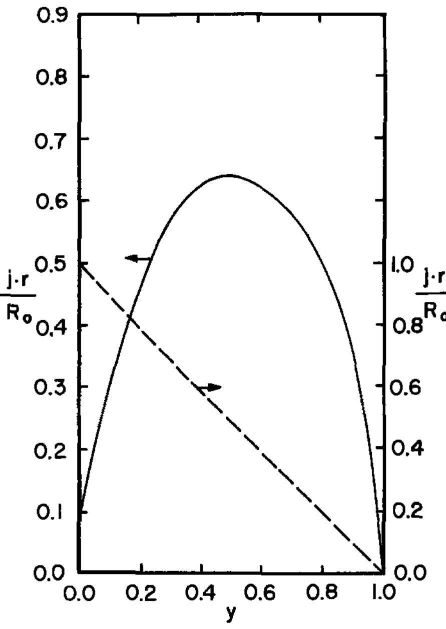

Fig. 6b. Current distribution for same conditions as listed in caption for Fig. 6a.

ing plate in the one-phase region. The equations that describe this effect are

$$R_1 \frac{dR_1}{dt} = \frac{I_{R_o}R_o}{2\mathbf{F}} (2V_{Na} + V_{s=} + V_s) \qquad [27]$$

for single phase region, and

$$R_1 \frac{dR_1}{dt} = \frac{I_{R_o}R_o}{2\mathbf{F}c_3}$$

for two-phase region.

The total potential loss is computed as the sum of the following four terms: (*i*) the total potential drop in the melt; (*ii*) the reaction overpotential loss at $y = 1$; (*iii*) the ohmic potential loss in the ceramic electrolyte with ID = 0.4 cm, OD = 0.6 cm, and a resistivity of 5 ohm-cm; and (*iv*) the contact potential loss between the

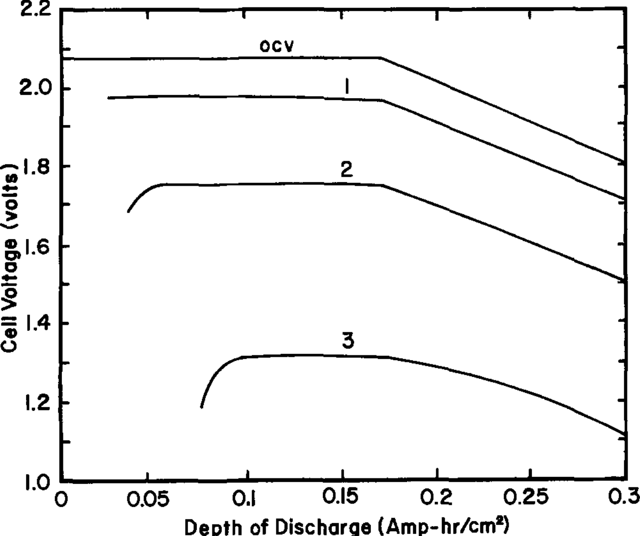

Fig. 7. Computed cell voltage of Na/S cell vs. depth of discharge for the uniform concentration model. Cell dimensions for fully charged state are R_o = 0.3 cm and ΔR = 0.225 cm. Curve 1, I_{R_o} = 0.1235 A/cm²; curve 2, I_{R_o} = 0.37035 A/cm²; curve 3, I_{R_o} = 0.823 A/cm².

graphite felt and the backing plate with a resistance of 0.1 ohm-cm². There is an increase in the cell voltage at the earlier stage of discharge due to the reduction in the reaction overpotential loss as the thickness of the active electrode increases. Beyond this point the OCV decreases because the dominant effect now is the ohmic loss which increases as the electrode becomes thicker.

Discussion

The numerical results for the uniform concentration case agree with the results of Newman and Tobias (12) and Gibson (8). Briefly, the region of most reaction is determined by the relative values of the melt and felt conductivities. Based on the results reported in an earlier modeling study of the Na/S battery by Gibson (8), the Na/S battery should not operate as well as it does (3). The very fact that the cell operates as well as it does when the felt conductivity is much greater than the melt conductivity can be explained by the inclusion of a concentration effect as developed herein. Simply stated, the dominant effect of concentration shifts the reaction to the region where the reactant is more abundant. This can be easily seen by comparing the following two cells

$$Na|\beta\text{-alumina}|Na_2S_3|C$$

which has an OCV of 1.8V at 350°C; and

$$Na|\beta\text{-alumina}|Na_2S_{5.25}:S|C$$

which has an OCV of 2.078V. The sum of the overpotential losses in the melt, felt, and due to reaction is less than this 280 mV difference. Therefore, the particular heterogeneous reaction distribution predicted by the uniform concentration model cannot continue throughout the operating life of the cell.

The following is a more detailed account of the effect of concentration on the various overpotentials in the sulfur electrode (same conditions as Fig. 2). First, the computed cell voltages at the same depths of discharge are higher for the previously described concentration profile (Fig. 2) than for the uniform concentration profile.

In Table I the results in terms of potential losses of the highest OCV value of 2.078 excluding those ohmic losses in the solid electrolyte and due to the contact resistance between the graphite and the backing plate are summarized.

Table I. Potential losses (mV) in the sulfur electrode

I_{R_o} (A/cm²)		ΔR (cm)			
		0.025	0.05	0.1	0.2
0.12345	u	111.67	43.94	34.24	34.05
	N	103.19	34.77	26.71	31.11
0.24690	u	*	107.34	59.92	59.09
	N		97.23	51.15	54.84
0.49380	u	*	*	134.19	116.18
	N			119.85	107.66

u = uniform, N = nonuniform.
* Not available, because of the volume of the electrode is insufficient to sustain the current loads.

The concentration profile has four effects: (i) A cell operating at the assumed concentration profile has a higher OCV at $y = 1$ than a cell operating at uniform concentration; (ii) the assumed concentration profile reduces the potential loss across the melt because of the migrating current contribution; (iii) the assumed concentration profile shifts the reaction distribution away from the ceramic resulting in an increase of reaction overpotential at $y = 1$; and (iv) as a consequence of (iii), the ohmic potential drop in the melt increases because more current has to flow through a larger section of the melt. The first two effects depend on the concentration profile. The second effect has a slight variation due to the electrode dimension only because of the cylindrical geometry. These effects result in a gain in the cell voltage relative to the uniform concentration case of about 11 mV due to effect (i) and about 21 mV due to effect (ii). Effect (iii), the increase in reaction overpotential at $y = 1$, depends on the electrode thickness and varies slightly with the current load because of the nonlinear kinetics. These results are summarized in Table II. The fourth effect is summarized in Table III. Superficially, the results shown in Table I indicate that the effect of the concentration profile diminishes as the thickness increases. However, a larger variation in concentration is needed to obtain the same result with thicker electrodes.

Although the entire description of the porous electrode cannot be presented until the transport effects are included in a complete transient model, the results of the nonuniform concentration model presented herein are a better description of cell operation than those obtained using a uniform concentration model.

Table II. Increase in reaction overpotential at $y = 1$. Comparison of varying concentration case to the uniform concentration case (mV)

I_{R_o} (A/cm²)	ΔR (cm)			
	0.025	0.05	0.1	0.2
0.12345	23.51	21.03	17.19	11.24

Interfacial Phenomena at Solid Aluminum Electrodes in Solutions of $AlBr_3$/KBr in Aromatic Hydrocarbons

A. Reger, E. Peled,* and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

Solutions of $AlBr_3$ and KBr in toluene, mesitylene, or their mixture have been prepared under high purity conditions on a vacuum line. Anodic dissolution and cathodic deposition at a pure aluminum electrode were studied. Special attention was focused on the mechanism of rupture of the oxide film initially present on the surface and the formation of pits under the surface. The apparent exchange current density was found to depend on the anodic current density employed to activate the surface. The current density was found to be a linear function of potential over *ca.* 0.2V on both sides of the reversible potential. This was interpreted as being due to the solution resistance inside small flaws (pinholes) in the oxide layer on the surface.

Recent studies of the electrodeposition of aluminum from aromatic hydrocarbons containing $AlBr_3$ with small amounts of HBr or water (1) or with an alkali bromide (2) have indicated that this system may be useful as a plating bath for a variety of industrial applications. While this system has been known since the early thirties (3, 4), an understanding of the fundamental electrode processes taking place during anodic dissolution and cathodic deposition is still lacking.

Aluminum bromide is quite soluble in toluene (5) and in other aromatic hydrocarbons (6). At low concentrations (in the millimolar range) the solutions are colorless but at high concentrations (1-3M) a pale yellow color is observed, depending on the hydrocarbon employed as the solvent (5).[1] The conductivity of these solutions is very low, but it has been observed in the earliest studies of this system (4) that addition of KBr or any other alkali bromide increases the conductivity significantly, to the point that electrochemical measurements can readily be made. The conductivity increases with increasing concentration of KBr, reaching a maximum in the range of 1-6 $mMho\text{-}cm^{-1}$ (depending on the total concentration of $AlBr_3$ and on the hydrocarbon employed) when the molar ratio $AlBr_3$/KBr is 2:1 (3, 4, 7, 8). This observation, combined with the fact that KBr itself is not soluble in aromatic hydrocarbons, implies that a complex of the type $Al_2Br_7^-$ probably exists in solution. This was verified recently by preliminary transference number measurements (2b). Cryoscopic studies of these systems indicated that polyions of the type $(K^+Al_2Br_7^-)_n$ where $n \leq 4$ may also exist (9).

The first kinetic studies in this type of system were performed by Plotnikov and Yakubson in 1928 (8). An aluminum anode and a platinum cathode were used. Large current densities, in the range of 60-100 mA/cm^2 were employed. The faradaic efficiency was low both at the anode and at the cathode, some free bromine was formed, and the solution turned dark and viscous.

Key words: aluminum electrodes, interfacial phenomena, aromatic hydrocarbons, aluminum bromide, aluminum oxide.

[1] Recent experiments in our laboratory, to be reported elsewhere, indicated that persistent purification with an aluminum amalgam in contact with the solution results in a colorless solution even at high concentrations of $AlBr_3$.

The kinetics of electrodeposition and dissolution of aluminum has been studied in molten salts (10, 11). Values of the exchange current densities observed by different authors under similar conditions differ markedly, probably because not enough care has been taken to remove the surface oxide formed spontaneously on aluminum. In another study employing an $AlCl_3$/MCl melt (12), well-defined transition times were observed during anodic polarization. These were ascribed to the formation of a layer of poorly conducting Al_2Cl_6 on the surface of the electrode.

In the present paper the results of studies of electrodeposition and dissolution of aluminum are reported. Toluene, mesitylene, or a mixture of both were used as the solvent. Aluminum bromide and potassium bromide in molar ratios of about 3:1 served as the electrolyte. Measurements were taken on high purity aluminum wires. Great care was taken to prepare highly purified and rigorously dried solutions and to prepare reproducible clean aluminum surfaces for evaluation of kinetic data.

Experimental

The cell and electrodes—The cell and electrodes are shown in Fig. 1, together with the separate compartment used for preparation of solutions. A cylindrical geometry was employed to achieve a uniform current distribution on the working electrode and to minimize *IR* drop during measurements. An aluminum wire (Hopkin and Williams 99.99% purity) served as the working electrode. Another Al wire of the same purity, situated parallel to the working electrode at a distance of about 2 mm, served as the reference and a third such wire formed as a helix served as the counterelectrode. Electric contact was made to tungsten wires sealed through the cell cover. The cell was sealed with glass flanges employing neoprene O-rings which were not in direct contact with the solvent in the cell. Connection to the vacuum line was made through Rotaflo valves with Teflon heads. The cell could be evacuated to a pressure of less than 10^{-4} mm Hg.

The Al electrodes were cleaned by degreasing in acetone, dipping in 1M NaOH at 60°C for about 30 sec, rinsing in triple distilled water, washing with AR grade acetone to remove the water, and pumping off

The cell: a, solution preparation compartment; b, the electrochemical cell; c, connection to high vacuum line; d, connection to $AlBr_3$ sublimation container; e,f, Rotaflo valves; g, tungsten wires; h, cell cover; i, O-rings, neoprene; j, stainless steel connectors; k, working electrode; l, reference electrode; m, counterelectrode.

the remaining acetone on the vacuum line to a pressure of about 10^{-4} mm Hg. In some experiments aluminum-plated copper wire was used as the reference electrode, the copper wire was cleaned in an acid mixture consisting of equal volumes of HNO_3, CH_3COOH, and H_3PO_4 instead of dipping in alkali, all other steps being the same. Before measurements the working electrode was pretreated by pulsing it anodically at different current densities in the range of 0.2-70 mA/cm^2 with solution stirring. The reference electrode was pretreated in a similar manner. The copper reference electrode was plated in a stirred solution with a layer of *ca.* 1μ aluminum, at a current density of 2-10 mA/cm^2. In a freshly prepared solution the thin layer of aluminum tended to dissolve after a few hours, probably due to small traces of impurities (O_2 or HBr) in the solution. After preelectrolysis the system was stabilized and the aluminum coating on copper dissolved only after several days. As a rule addition of mesitylene to toluene tended to stabilize the solution and decrease the rate of chemical dissolution of freshly deposited aluminum in it.

All measurements were taken at 20° ± 2°C.

Preparation of solutions.—A weighed amount of KBr (Baker Analyzed) was placed in the solution-preparation compartment (compartment a in Fig. 1) and held at 150°C for *ca.* 15 hr with continuous pumping to remove traces of water. $AlBr_3$ (97% purity, obtained from Merck) was purified by subliming twice under vacuum at 80°-100°C. In the second step the material was transferred through tube d into compartment a and the tube was sealed off while the cell was still under vacuum. White translucent crystals of $AlBr_3$ were obtained in this manner. Toluene or mesitylene (Frutarom, analytical grade) was refluxed for several hours over sodium, then transferred for several hours to an evacuated flask containing P_2O_5 or molecular sieve. Finally, the solvent was transferred under vacuum to compartment a through joint c and valve e. As soon as the solution was prepared the cell was wrapped with a black cloth to avoid photodecomposition which has been observed to occur in certain cases. The solution was transferred to the electrochemical cell b by opening valve f and tilting the whole assembly. This was usually done just before the experiments. The exact composition of the solution was determined at the end of a series of experiments by measuring the concentration of K and Al with an atomic absorption spectrophotometer (Perkin Elmer, Model 403). The concentrations of $AlBr_3$ and KBr were around 2.5 and 0.8M, respectively, in all experiments.

Solutions prepared in the manner described above were colorless or pale yellow and were found to be stable in the dark for periods of several months.

IR correction.—The combination of a relatively low specific conductivity and high exchange current density (see below) makes it rather difficult to perform accurate measurements. In a typical case, the equivalent reaction resistance may be as low as 10-20% of the solution resistance in series with it, and accurate measurement of the latter hence becomes of major importance. All measurements were performed galvanostatically employing an Elron CHG-1 galvanostat with a risetime of 2 μsec. The galvanostat was combined with a homemade pulse generator to provide square current pulses of any desired length from a few microseconds up to a few seconds. The solution resistance was determined from the fast initial jump in potential upon application of the pulse, as seen in Fig. 2. The overpotential was determined by measurement on a much slower time scale, as shown in Fig. 3. To check the values of *IR* obtained in this way another method was employed to measure the same quantity: A small a-c voltage V_{wc} was applied between the working and the counterelectrode and the resulting voltage V_{wr} developed between the working and the reference electrodes was measured. The effective resistance R_{wr} to be used in computing the *IR* correction was then calculated from the simple equation.

$$R_{wr} = R_{wc}(V_{wr}/V_{wc}) \quad [1]$$

The resistance R_{wc} between the working and the counterelectrodes was measured with a conductometer. All above measurements were performed at a constant frequency of 3×10^3 Hz. Occasional comparison at higher frequencies gave identical results.

The values of *IR* obtained by the above a-c method agreed, within experimental error, with those calculated from the fast galvanostatic transients and the latter were used in all subsequent experiments.

Results

Reference electrodes.—An aluminum wire or an aluminum-plated copper wire dipped in the solution was employed as the reference electrode. Thus all potentials measured (after *IR* correction) represent overpotential measurements for electrodeposition or dissolution of Al. To ensure that the reference electrodes operated properly, several such electrodes were introduced into the solution and the potential difference between them was measured for periods of several weeks. This was always found to be 0 ± 1 mV, after an initial time for stabilization, which could be as long as several hours. The potential remained constant after activation by anodic pulses. A freshly formed Al surface on a copper wire exhibited the same potential. When the cell was opened in a glove box under an inert atmosphere and a new clean Al wire was put in the cell its potential also agreed with that of another refer-

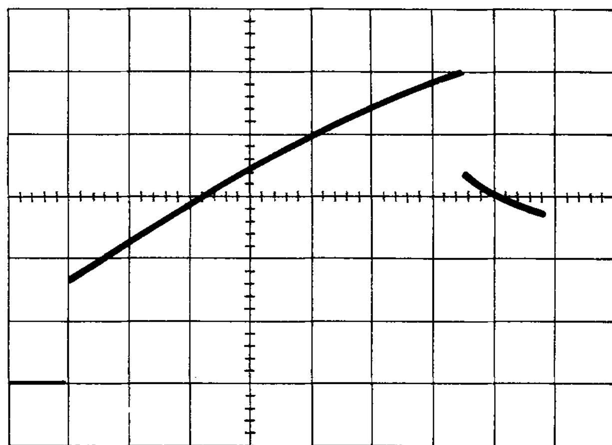

Fig. 2. Fast galvanostatic transient on Al wire. Scale: 1 mV/div; 20 μsec/div; electrode area, 0.55 cm^2. Current: 0.05 mA. Solvent: toluene 85%, mesitylene 15%.

ence electrode, which had been in the same solution for a long time, to within 1 mV.

Effect of anodic pulses on the apparent exchange current density.—Several anodic current pulses of a few seconds duration each were applied to the working electrode to try to remove the oxide layer which was formed between the time the wire had been taken out of the NaOH cleaning solution and the time it was placed in the cell solution. Figure 3 shows typical short anodic galvanostatic transients in the range of 0.11-0.44 mA/cm^2 following initial activation by anodic pulses (5-10 sec) of 4.4 mA/cm^2. Transients in the cathodic direction were identical. The relationships between current density i and overpotential η (corrected for IR) are shown in Fig. 4 for electrodes pretreated with anodic pulses at different current densities. The apparent exchange current densities were calculated from these lines employing the equation

$$i = i_o \frac{n\mathbf{F}\eta}{\nu RT} \quad [2]$$

in which $n = 3$[2] and the stoichiometric number ν is arbitrarily assumed to have a value of unity. These are shown in Table I together with the corresponding reaction resistances. The values of i_o are referred to as "apparent" exchange current densities since, as is discussed below, the surface oxide film has not been entirely removed and the current/potential relationship observed cannot be related directly to the rate of exchange of electrons at a clean Al surface. When the electrode was activated with anodic pulses of 70 mA/cm^2, the apparent exchange current density was too high to be measured properly and the result given in Table I above should only be considered as an estimate of the lower limit for this quantity.

[2] This represents the number of electrons needed to deposit one atom of Al. Recently it was shown (2b) that the over-all reaction may be rather more complicated and only 3/7 of an electron is required per molecule of $AlBr_3$ taking part in the over-all electrode reaction.

Table I. Reaction resistance and apparent exchange current density as a function of current density during anodic activation

CD for activation, mA/cm^2	1.0	2.2	4.4	30	70
Apparent i_o, mA/cm^2	0.06	0.75	1.0	3.2	>32
Reaction resistance, ohm · cm^2	145	11.5	8.6	2.7	<0.27

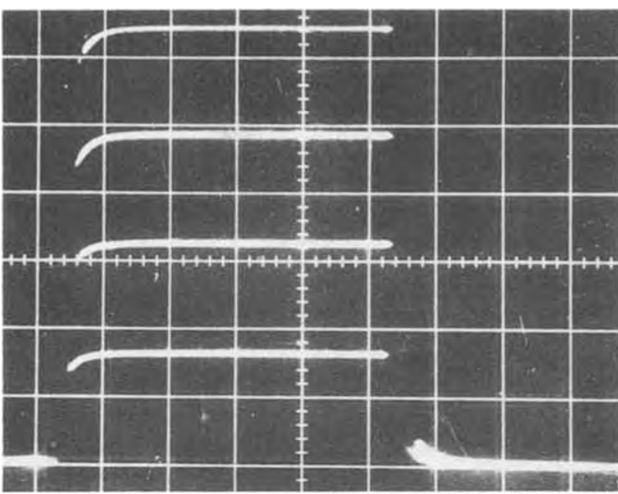

Fig. 3. Galvanostatic transient on Al wire electrode following anodic pretreatment at 4.4 mA/cm^2. Scale: 2 mV/div; 0.1 msec/div; electrode area, 0.45 cm^2. Polarization currents: 0.05, 0.10, 0.15, and 0.20 mA. Solvent: toluene 85%, mesitylene 15%.

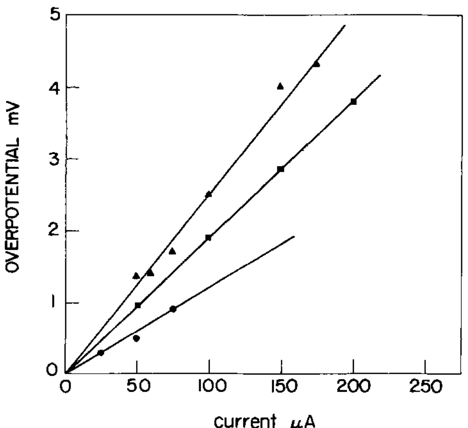

Fig. 4. Micropolarization measurements on Al wire electrodes (short pulses). Solvent: toluene 85%, mesitylene 15%. Anodic pretreatment of electrodes at (a) ▲ 2.2 mA/cm^2; (b) ■ 4.4 mA/cm^2; (c) ● 30 mA/cm^2.

Differential capacitance of the interface.—The capacitance C of the interface was estimated from the rising part of the galvanostatic transient just after the jump in potential due to IR drop, as can be seen in Fig. 2. From the equation

$$i = C(dV/dt)_{t \to 0} \quad [3]$$

the capacitance is obtained by measuring the initial value of dV/dt. In most measurements the value of C was obtained from the first 10-50 μsec in the duration of the transient. Values ranged from 1 to 3 μF/cm^2 and did not seem to be affected significantly by anodic pretreatment of the electrode up to *ca.* 30 mA/cm^2. Activation of the electrode at higher anodic current densities increased the measured capacitance by more than an order of magnitude.

Buildup of potential during high anodic polarization.—In Fig. 5 a typical behavior of an Al wire freshly placed in solution during an anodic pulse can be seen. A few seconds after the current has been applied the potential jumps suddenly by 2-3V and reaches a new, nearly constant value. If the experiment is repeated, a higher anodic current density has to be used to obtain the same transient. The transition time and the height of the potential jump are not reproducible, but the general shape of the curve is the same in all experiments. This phenomenon is only observed during anodic polarization. In the cathodic branch the potential remains in the low region indefinitely.

Polarization at high overpotential (short pulses).—In Fig. 6 the η/i relationship is plotted over a wide range of overpotential, on both the anodic and the cathodic side of the reversible potential. A linear relationship is

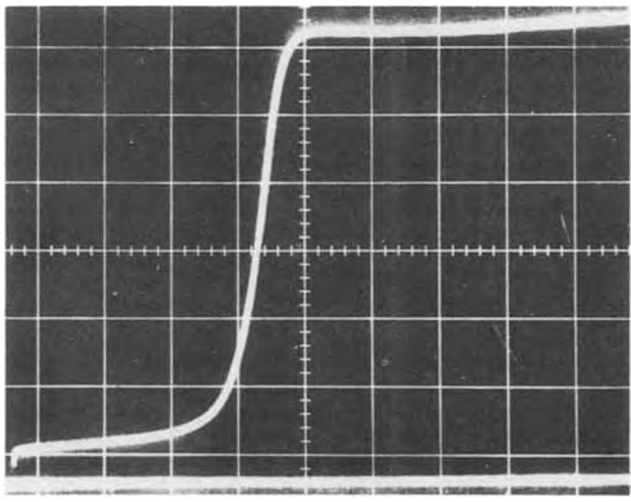

Fig. 5. Variation of potential during anodic dissolution. Scale: 0.5 V/div; 1 sec/div; electrode area, 0.60 cm^2. Current: 1.0 mA. Solvent: toluene.

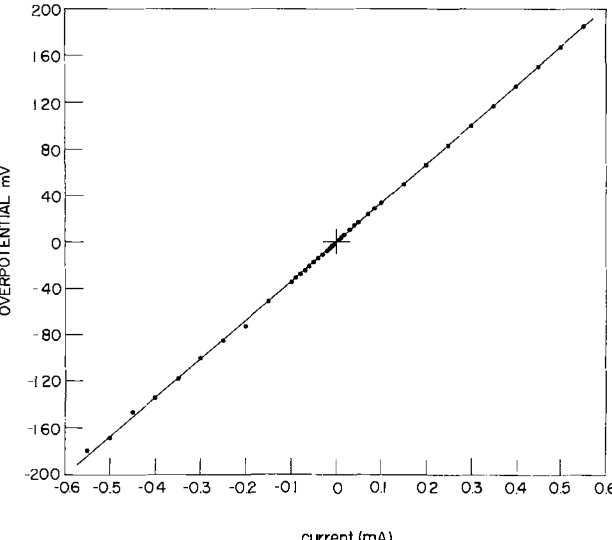

Fig. 6. Current/potential relationship (short pulses) after mild anodic pretreatment (1 mA/cm²). Solvent: mesitylene. Electrode area: 0.44 cm².

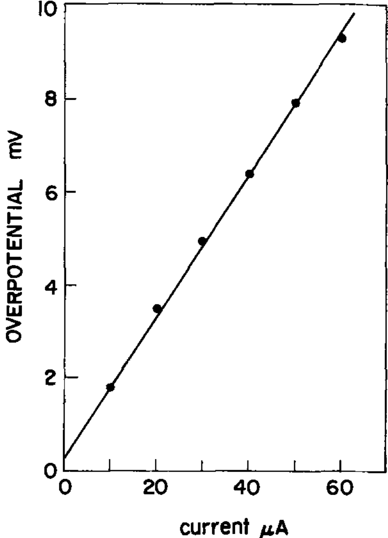

Fig. 8. Micropolarization measurements on Al wire electrodes from steady-state transients. Solvent: toluene 85%, mesitylene 15%.

observed throughout this range, contrary to expectation. In the experiment shown in Fig. 6 anodic pretreatment was rather mild, at 1 mA/cm² only, and as a result the apparent exchange current density was low. However, the linearity in the η/i relationship was extended to 0.1-0.2V in all cases, independent of the current density applied during pretreatment by anodic pulsing. If an electrode is not pretreated at all, the resistance due to the surface oxide film is in the range of 10-50 kohm·cm² in most experiments.

Steady-state polarization measurements.—When the variation of potential with time is viewed on a rather fast scale, as in Fig. 3, steady state is reached within less than 0.1 msec, and the potential does not seem to change at all during the next few milliseconds. If, however, the time scale is extended by about four orders of magnitude, the behavior shown in Fig. 7 is observed. The overpotential rises slowly and a new steady state is reached after 10-15 sec. The resulting η/i plot is shown in Fig. 8. The value of i_0 calculated from these data is 0.12 mA/cm², compared to 0.75 mA/cm² calculated above from short transients following anodic activation at the same current density. The steady-state overpotential after longer times depends on the current density during anodic pretreatment in much the same way as shown in Fig. 4 for short-time measurements. Identical transients were obtained for anodic and cathodic polarizations.

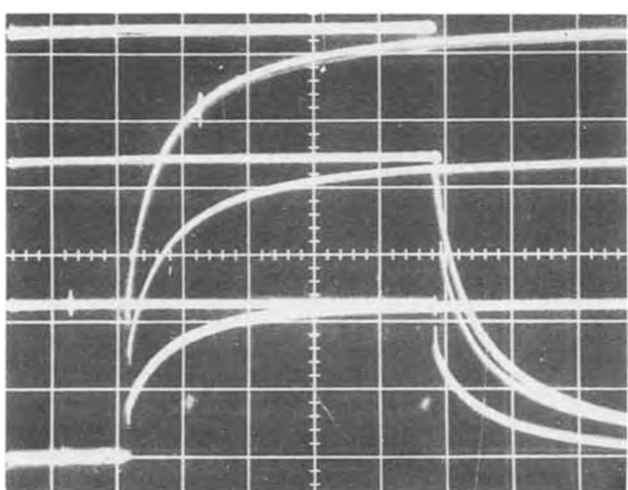

Fig. 7. Steady-state galvanostatic transients on Al wire electrode following anodic pretreatment at 2.2 mA/cm². Solvent: toluene 85%, mesitylene 15%. Scale: 1 mV/div; 1 sec/div; electrode area, 0.45 cm². Polarization currents: 10, 20, and 30 μA. Duration of each pulse: 15 sec.

Discussion

While the chemistry and electrochemistry of the $AlBr_3$/MBr/aromatic hydrocarbon solvent system has been studied by a number of authors, little is known of the interfacial phenomena occurring when a solid electrode is dipped in this solution. This system is unique in that it possesses a fairly high conductivity combined with a low dielectric constant. The mechanism of charge transfer and the structure of the double layer at such a system is therefore of great interest. Apart from the fundamental aspects, this solvent system can be used as a plating bath for Al, and it is important therefore to understand the phenomena taking place both at the anode and at the cathode so that conditions can be chosen to obtain high quality electroplated products and long lifetimes of the baths. Of particular interest in this respect is the anodic behavior of Al electrodes, which are always covered with an oxide film (air formed after the anode has been cleaned in acid or alkali) since efficient anodic dissolution during plating operation is essential for the stability of the bath.

The reaction resistance of electrodes which have not been activated by anodic pulses is *ca.* 10-50 kohm-cm² and the capacitance of the interface is in the range of 1-3 μF/cm². Activation of the electrode by anodic pulses of up to 30 mA/cm² caused a decrease of the reaction resistance to a few ohm·cm² (cf. Table I), but the capacitance remained essentially unaltered. Activation of the electrode at even higher anodic current densities caused a further decrease in the reaction resistance by an order of magnitude or more, while the capacitance tended to increase by about the same factor.

The thickness of the oxide layer on a fresh surface (which has not been activated) can be estimated from the capacitance of the interface. Assuming a dielectric constant of $\epsilon = 5$ for the oxide this turns out to be *ca.* 15-50Å, in agreement with values reported in the literature for air-formed oxide layers (13). In view of the fact that the capacitance of the interface is not significantly affected by anodic pulsing (up to 30 mA/cm²) it must be concluded that most of this layer is not removed by the activation process. The lowering of the reaction resistance, however, implies that the layer must be ruptured and a bare aluminum surface must be exposed to the solution as a result of activation by anodic pulses.

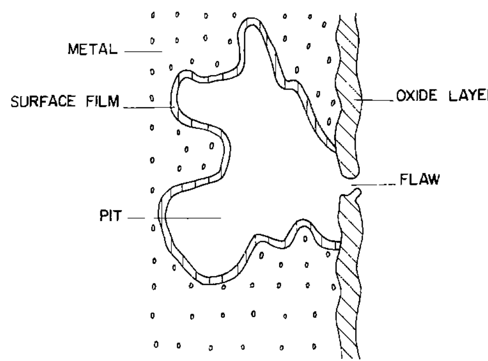

Fig. 9. Schematic representation of a flaw and pit model of an oxide-covered aluminum surface.

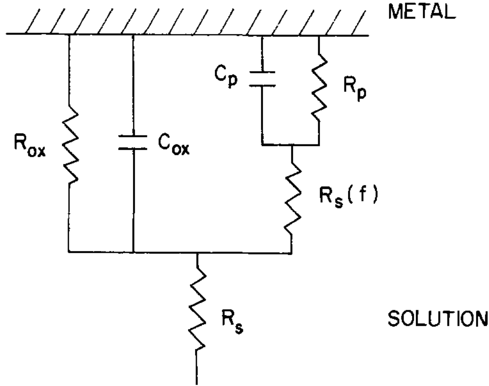

Fig. 10. Equivalent circuit for the model shown in Fig. 9. R_{Ox}, C_{Ox}: resistance and capitance of oxide film. R_p, C_p: resistance and capitance of interface inside pit. $R_s(f)$: resistance of solution inside flaw. R_s: solution resistance.

A model has been proposed by Richardson and Wood (13) to account for observations during the chemical corrosion and anodic dissolution of aluminum in aqueous solutions. It seems that a similar model may apply to our system as well. A modification of the model of Richardson and Wood is shown schematically in Fig. 9. The corresponding equivalent circuit is shown in Fig. 10. According to this model a fresh aluminum electrode (which has not been activated) is covered with an oxide film having a few flaws or pinholes. The total area of these holes is too small to affect the resistance of the interface, and the measured reaction resistance is that due to the oxide film (R_{Ox}). During anodic activation, pits are developed under the flaws. The area of the pits can be very much larger than the area of the flaws and as a result a certain degree of collapse of the film can occur causing an increase in the diameter of the flaw.[3] The resistance of the solution in the flaws and inside the pits ($R_s(f)$) becomes smaller than the resistance of the oxide layer in parallel with it and this is probably the quantity given in Table I. As long as the resistance R_s(f) is large compared to the impedance associated with the capacitance of the interface inside the pit C_p, the latter will not affect the total capacitance measured, as found experimentally. If anodic activation is carried out at $i > 30$ mA/cm^2 the radii of the flaws increases so that $R_s(f)$ becomes negligible and one measures the capacitance (C_p) and reaction resistance (R_p) of the oxide-free surface inside the pits. It should not be concluded from the above reasoning that inside a pit the interface consists of a pure aluminum surface in contact with the solution. There is clear evidence (14) that corrosion of aluminum and attendant reduction of the solvent occur (even in ultrapure, colorless solutions) at such a rate that a film of reaction products a few monolayers thick could form on the surface within seconds. Preliminary experiments employing copper electrodes plated with aluminum *in situ* have indicated that such a film is indeed formed in the present system.

[3] It should be noted that during most of the polarization measurements the current is applied for only short periods of time, mostly less than 1 msec, while anodic activation is affected by several pulses of a few seconds duration each. It is thus unlikely that the area of the flaws would be significantly changed during polarization measurements.

The model proposed above can also account for the linear η/i relationship found in a wide range of overpotential (cf. Fig. 6). It would seem that the apparent exchange current density and the corresponding reaction resistance measured on electrodes activated by anodic pulses are in fact a measure of the solution resistance $R_s(f)$ in the flaws. Thus the linearity of the η/i plot is maintained over a wide range.

The slow approach to steady state shown in Fig. 7 is probably due to mass-transport limitation through the flaws, causing changes of concentration of reactants or products in the pits. As would be expected, the reaction resistance measured on this time scale also decreases with increasing current density during anodic activation, due to an increase in the diameter of the flaws.

The sudden change in potential shown in Fig. 5 for anodic polarization of an electrode which has not been activated by anodic pulses can be associated with blocking of the flaws in the oxide surface by reaction products (e.g., Al_2Br_6), a phenomenon which has also been observed during anodic dissolution of aluminum in an $AlCl_3$ melt (12). A similar behavior is not observed when the electrode is polarized cathodically, since dendrite growth does not allow blocking of the surface.

Influence of Inhibitors on the Structure of Silver Deposits Obtained by Electrolysis of Aqueous Nitrate Solutions

J. Vereecken* and R. Winand*

Laboratory of Metallurgy and Electrochemistry, Free University of Brussels, Brussels, Belgium

The aim of this study is to determine the experimental conditions for the electrolysis of aqueous solutions of silver nitrates to obtain a smooth and coherent deposit of pure silver at a silver cathode. Indeed the actual conditions of the industrial silver electrorefining from golden silver in silver nitrate solutions lead to dendritic deposits. This involves several disadvantages such as scrapers, great volume of the cells, difficult recovery of the pure metal, loss of electrolyte, and so on.

In order to find out whether it is possible to improve the structure of those deposits we studied systematically the influence of several parameters of the electrolysis: composition of the electrolyte (concentration in $AgNO_3$, $NaNO_3$, and HNO_3 and concentration in addition agent) cathodic current density, temperature, time of the electrolysis, and stirring.

We can find in the literature (1. 2) very important reviews concerning electrocrystallization in relation to inhibitors. For the purpose of this study, it is only necessary to summarize the different studies concerning the influence of inhibitors on electrocrystallization of silver from nitrate solutions. Studies on this subject are not numerous; one of the reasons being the very rapid change of the surface of the deposit during the electrolysis.

Glazunof, Teindl, and Halik (3) observed an increase in the smoothness of silver deposits with an addition of 0.03-0.15% agar-agar to the solution. Vagramyan (4) studied the influence of dextrine and benzoic acid and concluded that the nucleation rate is a function of the active surface area. Fischer (2, 5) found that nitric acid can have an inhibitor effect on the silver deposit. Taft and Hiebert (6) carried on investigations with 169 addition agents in an attempt to determine a relationship between the nature of the addition agent and the nature of the silver deposit: They found that certain products such as diglycol stearate, ammonium laurate, and particularly amino methane are good inhibitors. Taft and Horseley (7) and Hodge and Lutness (8) found that sodium acetate and ferrous sulfate improve the structure of the deposit. But they found no obvious relationship between the molecular structure of the wetting agent and the form of the deposit.

Experimental Conditions

A particularly important problem in electrocrystallization is to avoid edge effects; this is why we used a parallelepipedic cell which was held at constant temperature. The useful area of the cathode was 10 cm^2. These electrodes were degassed, polished, and degreased prior to electrolysis. High purity reagents were used. During the electrolysis we recorded the cell voltage and the cathodic galvanic potential (the reference electrode was a mercurous sulfate electrode). The current efficiency was measured in a classical way. The quality of the deposit was evaluated as follows: We measured (Fig. 1) the thickness of coherent deposit t_{cd} and the thickness of total deposit t_{td} and we calculated the ratio t_{cd}/t_{td}. During the electrolysis we also observed the deposit with an optical microscope by means of a special electrolysis cell. After the electrolysis the structure of the deposit was observed with metallographic cross sections. Several different electrolytes were studied. They are mentioned in Table I.

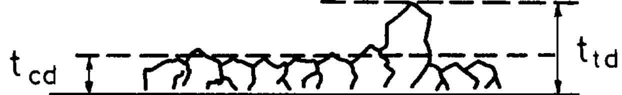

Fig. 1. Principle of the measurement of the quality of the deposit by means of metallographic cross sections: t_{cd}, thickness of coherent deposit; t_{td}, thickness of total deposit.

Results and Discussion

Microscopic observations made during galvanostatic pulse experiments enabled us to confirm the first part of the theory of Ibl (9): Dendrites appear at the transient time. Figure 2 represents the variation of the cathodic galvanic potential as a function of time during an electrolysis at constant current density. The cathodic galvanic potential increases with time but after the formation of the dendrites the potential begins to decrease. This is probably due to an increase of the surface.

We also found a good agreement with Sand's relationship: The product of the cathodic current density with the square root of the transient time is proportional to the concentration in silver ions (Fig. 3). This shows clearly that diffusion laws are obeyed, even for our relatively large electrodes. We are thus entitled to calculate the diffusion limiting current density on the basis of the theory summarized by Vetter (11) in the case of natural convection. Details about this calculation may be found in Ref. (12).

Table I. Characteristics of the different electrolytes used in this work

Electrolytes	C_{Ag^+} (g/liter)	C_{NaNO_3} (g/liter)	C_{HNO_3} (g/liter)	$J_{c\ lim}$ (A/dm^2)
E_1	15	100	2.26	1.24
E_2	45	100	3.46	3.73
E_3	135	100	2.7	11.2
E_4	405	100	2.7	33.6
E_1*	170	—	2.7	14.1
E_3*	320	—	2.7	26.5
E_2**	135	100	—	11.2

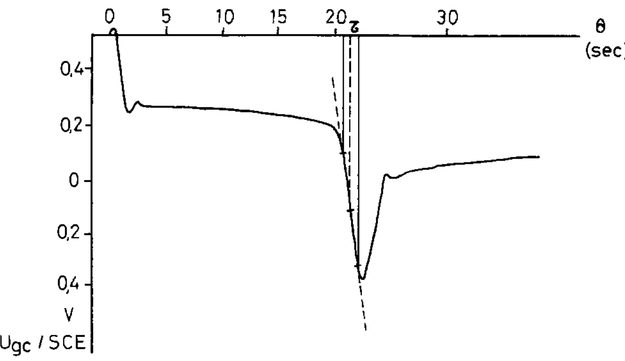

Fig. 2. Potential-time relationship during a constant current step (τ is the transient time).

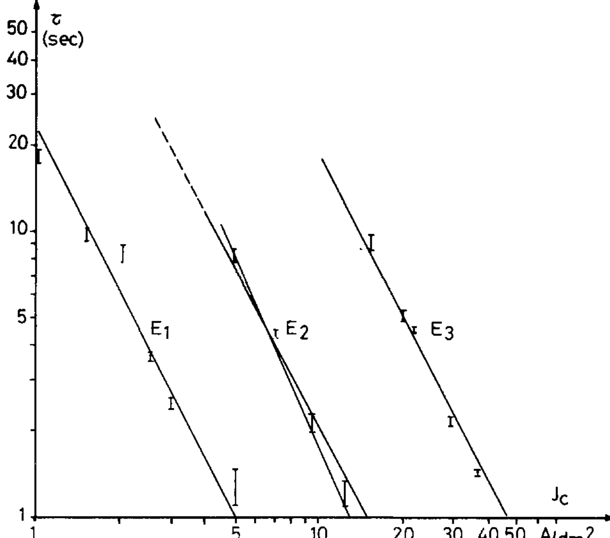

Fig. 3. Logarithmic plot of the transient time τ as a function of the cathodic current density.

Our other experimental results, *i.e.*, long lasting electrolysis below the limiting current density, show that the deposits obtained without inhibitors and with current density lower than the diffusion limiting current density are smooth only at the beginning of the electrolysis, the smoothness of the deposits decreasing when time increases. Thus deposits containing protruding single crystals can be obtained without reaching the diffusion limiting current density. This is in opposition with the second part of Ibl's theory (9).

Another conclusion of this study is that an increase in the duration of the electrolysis increases the thickness of coherent deposit only if the cathodic current density is low enough; a maximum time of electrolysis exists for each value of the current density above which the deposit becomes very rough.

The effect of other electrolysis parameters can be summarized as follows:

1. The quality of the deposit increases with the Ag^+ ion concentration.

2. The presence of $NaNO_3$ can lead to different results: With a constant concentration in $AgNO_3$ the conductivity of the electrolyte increases. This improves the throwing power. On the other hand, according to Fischer (2) $NaNO_3$ is an inhibitor for silver electrodeposition. But the presence of $NaNO_3$ can increase the diffusion overpotential; that is why we worked with electrolytes with different concentrations in $NaNO_3$ but constant conductivity. The final conclusion is that a decrease in the concentration in silver nitrate favors the formation of a good deposit.

3. The pH of the industrial electrolytes must be between 1 and 5 to avoid the precipitation of $Cu(OH)_2$ or Ag_2O. We studied the influence of nitric acid with the same restriction as for $NaNO_3$ and we concluded that the presence of nitric acid has a good influence on the formation of a coherent deposit (Fig. 4).

4. An increase in the temperature (in the range of 25°-45°C) and a stirring of the solution have no considerable influence on the structure of the deposit.

We conclude that it is impossible to find conditions to produce a smooth and coherent silver deposit without addition of inhibitor. We investigated different organic molecules and we found that thiourea improves the quality of the deposit (Fig. 5). It is unfortunately impossible to exceed a concentration of 100 mg/liter because of the small solubility of thiourea in the electrolyte. We also found that the presence of thiourea does not change the cathodic current efficiency and that the amount of thiourea occluded in the deposit is low. For example, at 1 A/dm^2 the concentration in sulfur in the deposit is 0.55 ppm after spectrophotometric absorption determination.

A particularly interesting way to summarize the influence of some of the most important parameters of the electrolysis is to use the classification of Fischer (2) in the way proposed by Winand (13-15) in a graph with the ratio $J_c/C_{Me^{z+}}$ in abscissa and the concentration of inhibitor in ordinate. In the present case, we found four different types of structure (Fig. 6): BR, basis-oriented reproduction type; BR*, BR with partial coverage of the initial surface; FI, field-oriented isolation type; and UD, unoriented dispersion type.

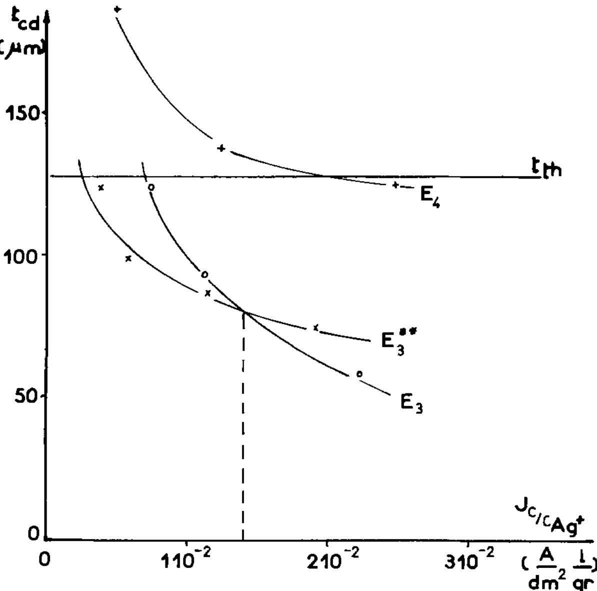

Fig. 4. Influence of the HNO_3 concentration on the quality of the deposit. Comparison of t_{cd} as a function of the ratio J_c/C_{Ag^+} for three electrolytes described in Table I.

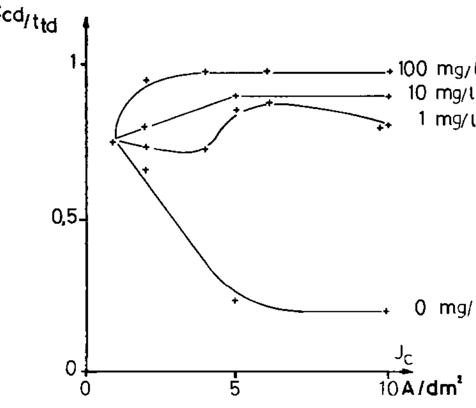

Fig. 5. Influence of the concentration of thiourea on the quality of the deposit.

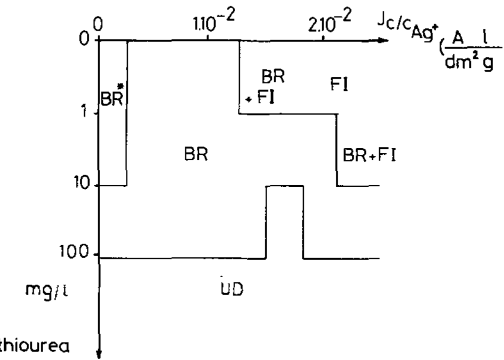

Fig. 6. Nature of the deposit in function of the ratio J_c/C_{Ag^+} and the concentration of thiourea: BR, basis-oriented reproduction type; FI, field-oriented isolation type; and UD, unoriented dispersion type.

We established also in a recent study (10) that potassium and sodium tartrate can very markedly improve the quality of the deposit (Fig. 7).

With a scanning microscope it is very easy to see the very different nucleation types of silver obtained from a silver nitrate electrolyte. Without inhibitor (Fig. 8) we observe a very irregular nucleation; the cathode is not completely covered and big crystals are growing besides very little ones.

In the presence of thiourea (Fig. 9), the electrode is completely covered with big uniform well-faced crystals. An addition of tartrate changes completely the shape of the crystals (Fig. 10) which are in this case very fine and badly formed.

We have thus found experimental conditions allowing us to produce a smooth and coherent deposit. These conditions are summarized in Table II. We intend to elucidate the way the inhibitor acts in future studies.

Summary

The aim of this study was to determine the best experimental conditions to obtain a smooth and coherent silver deposit from a nitrate solution.

ture, and stirring. It was impossible to obtain and keep a good cathodic deposit structure under any of the investigated conditions. Observing the deposit with a microscope while it was growing, we noticed that the dendritic growth took place even at a current density lower than the limiting current density. We thus added several inhibitors to the bath, and we observed that the presence of thiourea and sodium and potassium tartrate diminished the roughness of the deposit.

The observed types of structures were interpreted in terms of Fischer's theory and were plotted as a function of the ratio J_c/C_{Ag^+} and the concentration of thiourea.

Heterogeneous Charge Transfer Rates of the Ferrocene Oxidation in Sulfolane

N. R. Armstrong[1] and Rod K. Quinn*

Sandia Laboratories, Albuquerque, New Mexico 87115

and N. E. Vanderborgh

The University of New Mexico, Albuquerque, New Mexico 87131

During investigations of the electrochemistry of several organic compounds in the aprotic solvent sulfolane, we have observed unusually low charge transfer rates for both heterogeneous and homogeneous reactions (1, 2, 3). The charge transfer involving the bimolecular reproportionation of the p-nitrobenzaldehyde dianion with the parent species ($k_f = 5 \times 10^2$ liter/mole·sec) and the heterogeneous charge transfer rates of both nitrobenzene and benzaldehyde reduction reactions (k_s near 10^{-3} cm/sec) appear anomalously slow. We discuss here cyclic voltammetric investigations for other charge transfer steps in sulfolane, especially the heterogeneous oxidation rates of ferrocene and heterogeneous reduction of nitrobenzene.

The deviation of these rates of charge transfer from predicted values is explored as well as the possible effect on charge transfer rate of varying electrode material (metal type and surface topography).

Predictions of charge transfer rates can be made by Marcus theory calculations provided estimates of solvent and intramolecular rearrangement energies can

* Electrochemical Society Active Member.

Key words: vapor-deposited electrodes, heterogeneous charge transfer, Marcus rate theory, sulfolane.

be accurately made. Several examples of agreement of the predicted and observed rates of charge transfer for inorganic and organic redox couples are available in the literature (4). We made similar calculations for the ferrocene oxidation in sulfolane to test for this type of agreement in the rather unusual solvent sulfolane and found large deviations between predicted and observed rates of charge transfer. The reduction rates of nitrobenzene in sulfolane, being of the same order of magnitude, are also reported here. These results should stimulate further studies in similar solvent systems.

Previous studies have explored possible differences in charge transfer rates that might result when electrode materials were varied (5-8). In general, these investigations have demonstrated only small effects of electrode type, *e.g.*, Au, Pt, Pd, on charge transfer rate, for nonadsorbed reactant systems. Results presented here generally concur with these findings. The effect of varying electrode surface structure on reaction kinetics was tested using this ferrocene system. The investigations reported here use a number of different electrode materials to explore the effects of metal type and surface topography upon the charge transfer process. Unique vapor-deposition facilities permitted the fabrication of high purity metal electrodes as thin films on optically flat, inert substrates (9). Both the ferrocene oxidation and nitrobenzene reduction in sulfolane on Pt, Pd, and Au vapor-deposited electrodes are described.

Experimental

Methods for purification of the chemicals used in this study have been previously described (1) except for ferrocene (Eastman Chemical Grade) which was purified by sublimation.

Electrochemical measurements were made in a cell similar to that used for spectroelectrochemistry (2, 3). This was fabricated of Teflon and had a solution volume of 2 ml. The reference electrode was made from a silver wire, 1.5 mm in diameter, positioned within 0.5 mm of the working electrode surface. This electrode was anodized in a perchlorate solution prior to use. The potential maintained by this electrode (AgRE) remained constant to < 2 mV over the time period of an experiment. A difference of -740 mV exists between the oxidation potential of ferrocene found with this reference electrode from that found with an isolated $Ag/AgClO_4$ reference described previously (1). The counterelectrode used here was a large platinum foil positioned along the cell wall. Working electrodes were mounted against one of the outer cell walls. Solution contacted the working electrode surface through a channel drilled into the cell maintaining a geometric area of 0.106 cm^2. The working electrode was positioned by another Teflon cover bolted to the cell body. An O ring, positioned between the working electrode and the cell body, precisely defined the active electrode area. Electrical contact to the film electrodes was made through a platinum foil; contact resistance was less than 5 ohm. Thermostated oil, circulated through hollow bolts in the cell body, was used to maintain constant solution temperature. This temperature was monitored by a thermistor positioned in the solution.

Two different types of working electrodes were used. Highly polished bulk metal electrodes were positioned directly on the cell. Vapor-deposited thin films were prepared on flat quartz substrates (2, 9). These films, between 20 and 1000 nm thickness, were fabricated of platinum, gold, and palladium. Under conditions of high target bias and low background argon pressure in the sputtering step, relatively high density films were produced. Reversing these conditions, *i.e.*, low target bias and high argon pressure, produced more porous films. The porous films showed surface defects as large as 3000 nm.

Electrochemical measurements were made using either of two different potentiostats. One, previously described (1), was modified by including a positive feedback circuit to compensate for electrode and solution resistances. The other, a PAR 173 potentiostat equipped with a 179 digital coulometer and a 175 universal waveform source, also was equipped with this compensation circuitry. The rate coefficients for charge transfer were in the range where the cyclic voltammetric technique described by Nicholson (10) is valid.

Techniques used with ring-disk electrodes have been previously described (11). All electrodes were preconditioned prior to a measurement by scanning several times between -1 to 1V *vs.* AgRE in a solution not containing electroactive components.

Results and Discussion

The oxidation of ferrocene is a one-electron process leading to a chemically stable cation, the ferricenium ion. This process is shown in the cyclic voltammogram in Fig. 1. Superimposed on this figure is a residual current trace taken with a platinum electrode in a 0.10*M* TBAP sulfolane solution. A wide potential window, between the cathodic and anodic limits, of 3.5V is available using this system. The chemical reversibility of the ferrocene oxidation was tested.

Cyclic voltammetric experiments showed the peak current ratio, $i_{p,c}/i_{p,a}$, is unity at voltage sweep rates as low as 10 mV/sec. This value suggests that the product cation has high stability. The chemical stability of the ferricenium cation was also explored using rink-disk voltammetry. The collection efficiency was measured as a function of angular velocity. During this experiment the potential of the disk was poised at the convection-limited current region of the ferrocene oxidation while the ring electrode was positioned at the convection-limited plateau of the opposite process, the reduction of the cation. Measured collection efficiencies were independent of the angular velocity (30-300 rad/sec) and, within limits of error, equal to the theoretical efficiency, N_0, of 0.308. All of these data emphasize the high stability of this cation in this solvent system. Similar chemical stability has not been observed in several other solvents (12-14). For example, Diggle and Parker (12) have demonstrated that the ferricenium cation reacts in aqueous and nonaqueous media through a slow chemical step thought to be a solvolysis reaction. The data do not suggest a similar process in sulfolane.

Data also indicate that the oxidation step is diffusion controlled. In Fig. 2, a linear relationship between peak current and the square root of scan rate is shown. The zero intercept suggests that no adsorption is involved. Under conditions of constant depolarizer concentration, the slope of this curve is proportional to the square root of the diffusion coefficient and to the electroactive area. The slope remained at a constant value as the supporting electrolyte was changed

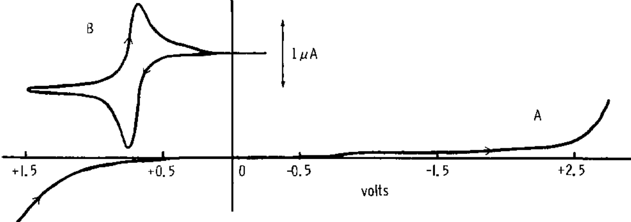

Fig. 1. Cyclic voltammetry of ferrocene in sulfolane. (A) Residual voltammogram taken at a Pt electrode in 0.1*N* TBAP/sulfolane. (B) Cyclic voltammogram of ferrocene oxidation in sulfolane. The potential axis is defined with respect to the AgRE pseudo-reference electrode. The applied scan rate was 16.7 mV/sec. The electrode area was 0.1064 cm^2. The bulk concentration of ferrocene in (B) was 2.0×10^{-4} *M*.

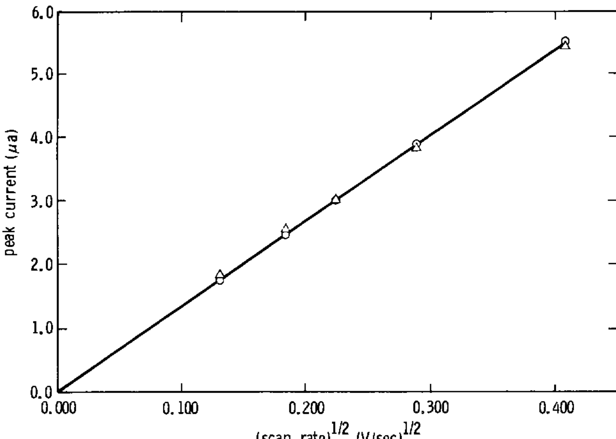

Fig. 2. Cyclic voltammetric peak current ($i_{p,a}$) (μA) vs. (scan rate)$^{1/2}$ (V/sec)$^{1/2}$ for the ferrocene oxidation in sulfolane; ○ = 0.1N TBAP solutions, △ 0.1N $KClO_4$ solutions.

from 0.1M TBAP to 0.1M $KClO_4$. This suggests that the diffusing species is unaffected by this change in the cation of the supporting electrolyte. Moreover, the slope remained constant when various electrode types, different metallic surfaces of various porosities, were used.

The diffusion constant for ferrocene has been previously measured using a RDE method (1). The determined value, calculated from the Levich equation, was 1.03×10^{-6} cm²/sec. This compared favorably with a determination made using Stokes' law (1.06×10^{-6} cm²/sec) and suggests that the diffusing species is neutral and unsolvated. Diffusion coefficients for ferrocene measured in other nonaqueous media are typically one order of magnitude larger (15). This lower value in sulfolane may be explained, in part, by the higher viscosity of this solvent. Sulfolane exhibits a liquid crystal phase near room temperature with extensive ordering in two dimensions (16). To some degree this ordered solvent structure might persist at the temperatures of these studies, 323°K. This possibility is explored later in this paper.

Separation of the cyclic voltammetric peak potentials was between 65-150 mV at sweep rates between 10-200 mV/sec. Measurements of the heterogeneous rate coefficients, k_s, of the ferrocene oxidation indicated a slow kinetic process which varied little in velocity as the electrode type was changed. These data are shown in Table I. Triplicate results were obtained for at least five scan rates between 10 and 200 mV/sec. The data in Table I are average values; the precision of these k_s measurements was ±10%. The apparent activation energy was estimated by observing the variation in these rates between 303° and 353°K. Results showed that the activation energy is low, less than 3 kcal/mole, and virtually the same for each substrate. The rate coefficients were measured

Table I. Kinetic parameter for the oxidation of ferrocene and reduction of nitrobenzene in sulfolane

Substrate	k_s (50°C),* cm/sec
Ferrocene:	
Pt bulk (polished)	1.9×10^{-3}
Pt film (200A) (annealed)	1.8×10^{-3}
Pt film (200A) dense	5.0×10^{-3}
Pt film (200A) porous	3.5×10^{-3}
Au film (300A) dense	3.9×10^{-3}
Pd film (200A) dense	3.2×10^{-3}
Nitrobenzene:	
Pt bulk (polished)	2.0×10^{-3}

* Taken at 5 or more sweep rates between 10 and 200 mV · sec⁻¹ and averaged. Average deviation of rate coefficients at each electrode is less than ±10%. All rates determined in 0.1N TBAP solutions at 50°C. Reactant concentrations were $1.0 \times 10^{-3}M$.

Table II. Standard rate coefficients of the oxidation of ferrocene as a function of supporting electrolyte

Substrate	k_s (50°C), cm/sec
Pt bulk (0.1M TBAP)	1.9×10^{-3}
Pt bulk (0.1M $KClO_4$)	0.9×10^{-3}
Pt film (200A) annealed (0.1M TBAP)	1.8×10^{-3}
Pt film (200A) annealed (0.1M $KClO_4$)	0.9×10^{-3}

in both TBAP and $KClO_4$ solutions; this data is shown in Table II. All data show slow charge transfer rates although those in $KClO_4$ are consistently slower than those found in TBAP solutions. This lack of variation of the charge transfer rate with electrode material, combined with information proving diffusion control of the oxidative process, indicates an electron transfer process not involving direct electrode interaction. This is an expected consequence for charge transfer reactions involving nonadsorbed or deposited species (4, 7). The primary effect observed is electrostatic in nature. This effect was found to be small for the noble metal films reported even though the roughness factors varied considerably (17). Investigations of metal deposition reactions will be reported where the electrode interaction is more pronounced and obvious differences between the behavior of the thin film electrodes is observed (17). There are no data to suggest that other electrode processes, such as oxide formation, proceed concurrently with the charge transfer step. The reduction of p-benzoquinone in DMF on several bulk electrodes (Pt, Pd, Au, Ir, and Rh) has been recently reported (4). Rates of charge transfer for that process are similar to those reported here for the ferrocene oxidation and, like those, are invariant with electrode type.

The charge transfer rates in sulfolane will be influenced by the fact that the oxidation occurs at potentials removed from the zero charge potential for platinum. Differential capacitance experiments showed that the charge transfer step occurs at potentials slightly positive of the estimated zero charge potential in TBAP solutions (17). This leads to a calculated inner Helmholtz potential of 35 mV and would result in a relatively small (less than 50%) negative adjustment in the rate coefficients.

These experimental values for charge transfer were compared to those predicted theoretically (4, 18, 19). Assuming that work terms can be neglected, a value for the activation free energy ($\Delta G^{\circ\dagger}$) was estimated from a combination of the solvent and internal rearrangement energies

$$\Delta G^{\circ\dagger} = (\lambda_i + \lambda_o)/4 \quad [1]$$

The solvent reorganization energy (λ_o) can be evaluated as 0.119 eV using optical and bulk dielectric constants. We estimated an internal rearrangement energy, λ_i, using data from the activation energy of self-exchange of the ferrocene-ferricenium couple measured in methanol (20). An upper limit of 0.10 eV for λ_i was determined from this data. A worst-case assumption is suggested by the internal rearrangement measured for the ferri-ferrocyanide couple of 0.379 eV (4). For these estimates of $\lambda_i + \lambda_o$, the calculated value of $\Delta G^{\circ\dagger}$ is consequently less than 0.12 eV.

Using this value and assuming a collision frequency of 10^4 cm/sec, the heterogeneous rate coefficient is estimated to be at least 10^2 cm/sec. Similar values can be predicted from the relationship between heterogeneous and homogeneous charge transfer (18, 19)

$$(k_{ex}/Z_{homo})^{1/2} = (k_s/Z_{het}) \quad [2]$$

A value of the homogeneous exchange coefficient of 10^8 liter/mole·sec and values of 10^4 cm/sec and

10^{11} sec^{-1} for the heterogeneous and homogeneous collision frequencies (4), respectively, suggest a value of k_s of $10^{2.5}$ cm/sec.

Charge transfer steps for other redox couples in sulfolane appear similarly slow. An average value of the heterogeneous rate coefficient for the one-electron reduction of nitrobenzene, determined using the cyclic voltammetric technique, is included in Table I. The stability of the anion produced in this process has been previously demonstrated (1-3). The value of this rate coefficient, $k_s = 2.0 \times 10^{-3}$ cm/sec, is similar to that found for the ferrocene oxidation, and appears slow for a nitrobenzene reduction. Studies in other nonaqueous media show a k_s for this process in excess of 0.1-1.0 cm/sec (21-23). Double-layer corrections for the reduction rate coefficient were estimated to be less than one order of magnitude. Such slow electron transfer rates as found for the ferrocene oxidation have been explained by assuming localization of the unit charge. For instance, such slow rates for nitro-substituted hydrocarbons have been attributed to large differences in charge distribution between the parent and anion resulting in an unusually large rearrangement energy (21).

The charge transfer parameters for several inorganic and organic redox couples have been successfully predicted using the Marcus theory in both aqueous and nonaqueous solutions (9). The rates for these processes are typically large ($k_s > 10^{-2}$ cm/sec) with corresponding small rearrangement energies. Oxidation of ferrocene should not involve large energies for rearrangement since both the neutral and charged species are essentially spherical (15). However, the solvent may contribute larger-than-predicted rearrangement energies. Evidence suggests that solvents such as DMSO and sulfolane exhibit long-range, second-order structuring (16, 24, 25). This type of order will not be reflected in either the optical or bulk dielectric constants (9).

This solvent structure may also be the cause of slow rates for homogeneous charge transfer and chemical reactions previously observed in sulfolane (1-3). The solvent effect may reflect itself in both the rearrangement energies which make up the activation free energy and in the preexponential term of the absolute rate equation. We have assumed for purposes of the above calculations that the collision frequency, Z, is only slightly affected by solvent viscosity. At most, such an effect would lead to less than an order of magnitude correction in the rate coefficient. Assessment of a possibly larger, more specific effect of solvent structure on the preexponential factor awaits a study of temperature dependence on rate coefficients in a variety of solvent media. Although our understanding of this phenomenon is only qualitative and considerable additional work is necessary to explore the reasons for these slow chemical and electron transfer steps, we suggest that similar retardation might be found in other structured solvents such as DMSO and hexamethylphosphoamide.

A Zinc Chlorine Molten Salt Cell

Samuel vonWinbush[1] and Anthony F. Sammells*

Gould Incorporated, Gould Laboratories—Energy Research, St. Paul, Minnesota 55165

There are several high energy batteries currently being investigated that use molten salt electrolytes. These battery systems operate at temperatures significantly above ambient. For example, the proposed normal temperature of operation for the lithium/chlorine (1), lithium/iron sulfide (2), and aluminum/chlorine (3) cells are 650°, 425°, and 150°C, respectively. For these systems it is, of course, mandatory that the electrolyte used be a molten salt if the battery is to be rechargeable. Considerable work has been reported on the deposition of aluminum from organic nonaqueous electrolytes at ambient temperatures (4) which may at some time make an ambient temperature aluminum chlorine battery worth consideration.

The zinc chlorine aqueous battery system has been investigated over the last several years (5). This system operates at ambient temperatures and uses a flowing electrolyte of aqueous zinc chloride in which a gradual stoichiometric change takes place (6) during charge and discharge.

Until this time, little work has been done to determine the feasibility of a zinc chlorine molten salt cell. Pure molten zinc chloride is impractical for such a system because it is a highly viscous liquid consisting mainly of complex species such as $(ZnCl_2)_n$, $ZnCl_4^{2-}$, $ZnCl_3^-$, and $ZnCl_2$ (7) with very little Zn^{2+} existing in the vicinity of the melting point. Molten zinc chloride has a relatively low conductivity, varying from 1.31×10^{-3} ohm^{-1} cm^{-1} at its melting point to 8.4×10^{-2} ohm^{-1} cm^{-1} at 501°C (8). Several investigators have shown that the addition of small amounts of alkali halides to molten zinc chloride greatly decreases its viscosity with a corresponding increase in the conductivity (8, 13). For example, the conductivity of zinc chloride at 475°C can be increaased from about 3.1×10^{-2} to 4×10^{-1} ohm^{-1} cm^{-1} by the addition of 30 mole per cent (m/o) KCl. Upon discharge of a molten salt zinc chlorine cell, some increase in *IR* polarization will therefore be expected as a result of the stoichiometric change taking place in the melt.

Molten zinc chloride dissolves zinc metal to a small extent (0.61 m/o at 600°C) with the formation of a subhalide (9). This solubility, however, decreases with the addition of alkali chlorides which destabilize the apparent Zn_2^{2+} species in the melt (10).

Zinc chloride forms many eutectics with sodium chloride and potassium chloride and mixtures thereof. These eutectics enable one to work at temperatures below 300°C, with liquidus lines sufficiently shallow to allow moderate concentration changes to occur without precipitation of salts on the electrodes of a zinc chlorine cell. Preliminary work is reported here to determine the feasibility of such a system.

Experimental

Electrolyte preparation.—Electrolyte melts were made from high purity NaCl, KCl, and $ZnCl_2$ obtained from the Fisher Chemical Company. Mixtures initially prepared in the dry box were heated to 110°C under vacuum overnight and then at 190°C for two days to assure complete removal of moisture. Melts were then transferred under vacuum to the dry box. All melts used were clear and showed no discoloration.

Dry box.—All cell assembly and coulometric studies were performed in a Vacuum Atmospheres dry box with an HE-193-2 Vacuum Atmospheres dry train.

Cell voltages were recorded on an HP3430A digital voltmeter.

Constant current source used in the coulometric study and in cell discharge was a J. Fluke Model 351A.

Cell assembly.—The eutectic mixtures used were first melted in the electrolyte holder of the cell in the dry box. The cell cap containing the electrode components was then inserted. A seal was achieved between the two halves by a suitable clamping device around the ground-glass lip. Cell temperatures were recorded via a Chromel-Alumel thermocouple. The porous chlorine electrode was fabricated from POCO AX grade graphite. UCAR C-34 graphite cement was used to seal the chlorine electrode to the tungsten feedthrough.

Scanning electron microscope photographs were taken with a Cambridge Model S4-104 SEM.

Results and Discussion

In order to determine coulombic efficiencies for zinc deposition and dissolution that might be expected in the molten salts studied, use was made of the coulombic efficiency cell shown schematically in Fig. 1. From the weight changes for the cathodic and anodic processes shown in Table I, it can be seen that coulombic efficiencies close to 100% were observed with all the melts investigated, the results shown representing typical values of repeated runs. Discrepancies from 100% coulombic efficiency can be explained by oxidation of the zinc after removal from the molten salt and prior to weighing. The interelectrode separation in this experiment was typically 0.5 cm.

The zinc deposited from the molten salts was typically crystalline as shown in the 20X SEM photograph (Fig. 2), the hexagonal appearance of the individual zinc crystals being shown in the 200X SEM photograph (Fig. 3). Altering the current density produced little change in the zinc morphology, except the occurrence of dendritic growths increased with current density.

The utility of these molten salts as an electrolyte in a zinc chlorine galvanic cell was then investigated. The experimental setup for the galvanic cell is shown in Fig. 4. The cell container was made from Pyrex glass and contained tungsten feedthroughs for electrode

contacts. The cell was initially run as a primary, at which time the graphite negative electrode was substituted for a high purity zinc strip of approximately the same dimensions. For this cell configuration, a load curve is shown in Fig. 5, where current densities at the chlorine electrode (the limiting electrode) of 7 mA/cm² could be achieved at 1.0V indicating considerable polarization at this electrode. The open-circuit potential for this system was found to be around 1.73V at temperatures of 288°C which compares with a zinc chloride breakdown potential of 1.71V at 300°C (11). This significant polarization indicated in Fig. 5 was partially due to *IR* losses caused by the fairly large interelectrode spacing of 0.7 cm, which was dictated by convenient experimental design.

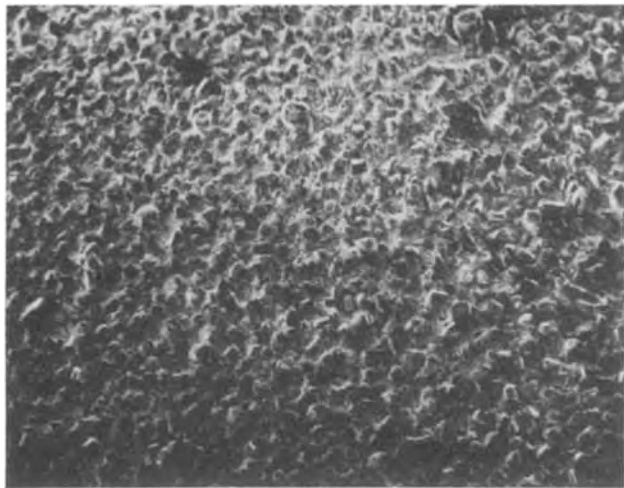

Fig. 2. 20X SEM photograph of zinc deposited from $ZnCl_2$-NaCl-KCl eutectic.

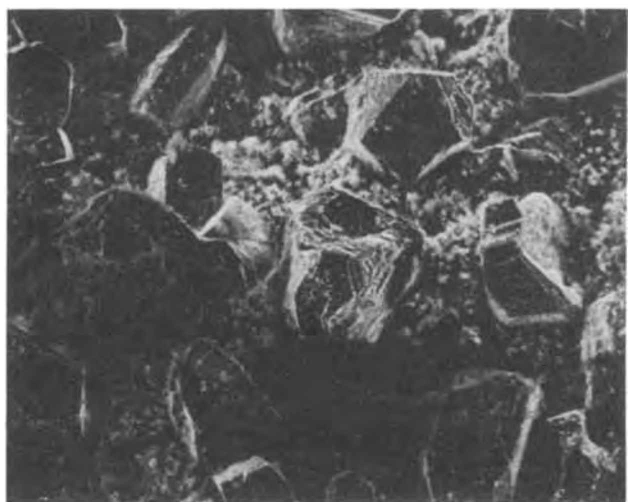

Fig. 3. 300X SEM photograph of zinc deposited from $ZnCl_2$-NaCl-KCl eutectic.

The electrode reactions in this system during discharge can be predicted as

anode: $Zn \rightarrow Zn^{2+}_{(melt)} + 2\bar{e}$

cathode: $Cl_{2(g)} + 2\bar{e} \rightarrow 2Cl^-_{(melt)}$

over-all reaction: $Zn + Cl_{2(g)} \rightarrow ZnCl_2$

A discharge curve for this cell configuration is shown in Fig. 6, using the ternary eutectic shown in Table 1, over a 30 hr period using a current density of 1.19 mA/cm². The break in the discharge curve at around 24 hr was caused by deterioration of the graphite cement which was used to make contact to the positive lead. Erosion of the graphite cement in the molten salts used proved a serious experimental problem.

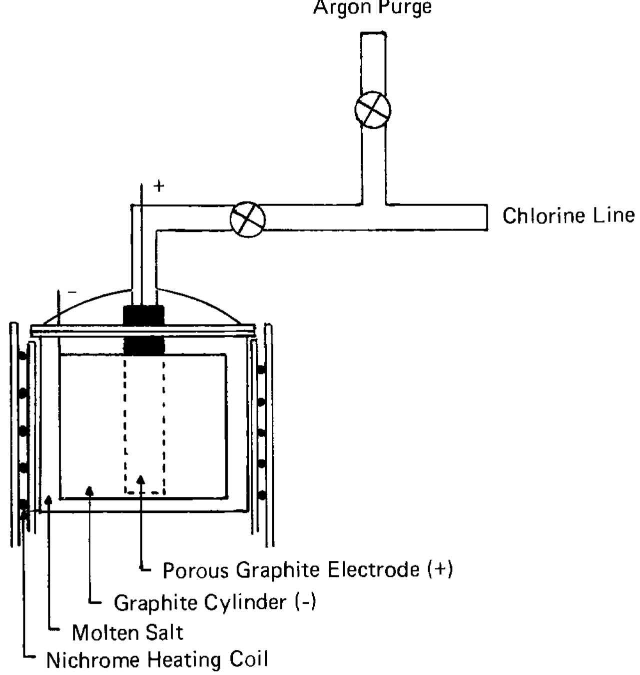

Fig. 4. Experimental arrangement of galvanic cell

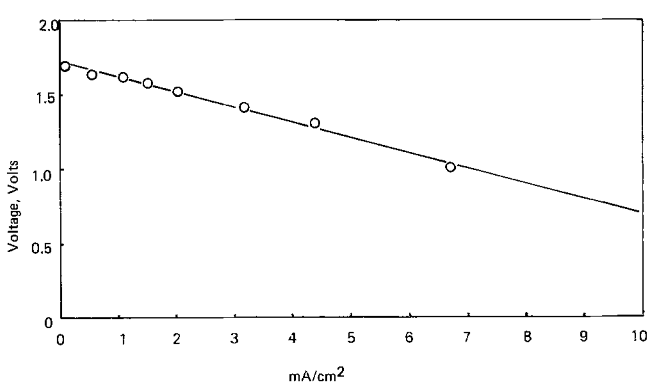

Fig. 5. Load curve for Zn/Cl_2 molten salt cell

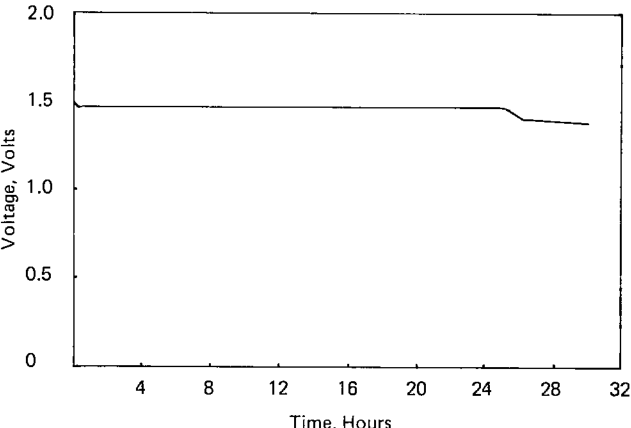

Fig. 6. Discharge curve for Zn/Cl_2 molten salt cell at 1.19 mA/cm^2.

When using a graphite negative electrode, the cell was run in the secondary mode. The apparent coulombic efficiencies of cycled cells varied between 10 and 100%. A charge-discharge curve is shown in Fig. 7 for the cell initially charged at 7 mA/cm^2 (at the zinc electrode) and discharged at 0.7 mA/cm^2 giving apparently high coulombic efficiency. It should, however, be pointed out that this cell had cycled several times and this high efficiency may reflect the presence of excess zinc not removed during earlier cycles. Figure 7 does, however, give an idea of the electrochemical performance with the cell configuration used. The reduction in charging voltage during charge probably reflects a gradual reduction in polarization at the chlorine electrode.

Some difficulty was encountered in determining the coulombic efficiency that would be expected from this system, since the discharge performance was very sensitive to chlorine pressure at the porous graphite used as the chlorine electrode and required frequent adjustment. Presumably, maintenance of the optimized three-phase interface between the graphite, molten salt, and gaseous chlorine was greatly influenced by the chlorine gas pressure. Two other factors could also explain variations from 100% coulombic efficiency. The first of these was the generally poor adhesion of the electrodeposited zinc on the graphite cylinder upon charge. Such deposits could be expected to prematurely fall off the electrode upon discharge, giving a low round-trip coulombic efficiency in some runs. Secondly, it has been shown (9) that zinc has a finite solubility in molten $ZnCl_2$ caused by the reaction

$$Zn + Zn^{2+} \rightarrow Zn_2^{2+}$$

giving the zinc subhalide species. It has been calculated that the solubility of zinc in molten $ZnCl_2$ at 288°C is around 79 ppm. In the presence of alkali halides the Zn_2^{2+} species is destabilized. It has been directly shown (12) that the addition of alkali halides to melts of $CdCl_2$ saturated with the species Cd_2^{2+} is greatly decreased. For example in $CdCl_2$ melts containing KCl at concentrations comparable to the melt compositions used in this study, the dissolved Cd was reduced from 14 m/o to less than 0.02 m/o by the addition of the alkali halide. It would not be unreasonable to expect a similar reduction in dissolved zinc in the systems investigated in this study. We would expect the concentration of dissolved zinc to be less than 10 ppm. However, in the small cells used in this study, this represents around 0.019 mA-hr of zinc in the form of the subspecies Zn_2^{2+} available for the direct reaction

$$Zn_2^{2+} + Cl_{2(g)} \rightarrow ZnCl_2 + Zn^{2+}$$

Any coulombic losses by this path will therefore be dictated by the rate of the above reaction.

By reference to Fig. 8, the composition change that might be realized in the KCl-$ZnCl_2$ melt (66.7 m/o $ZnCl_2$, 33.3 m/o KCl) upon cycling is shown. Starting with a galvanic cell that contains 10 ml of this electrolyte at a temperature of 288°C, it can be seen that the $ZnCl_2$ concentration can vary between 47 m/o upon complete cell charge to 77 m/o upon discharge as indicated by the arrow in Fig. 8. This represents a potential charge capacity of 8.7 A-hr. However, no cells are reported here that were cycled between these concentration limits.

Conclusion

It therefore remains to be seen whether molten salt electrolytes can be of utility in the zinc chlorine system. It is clear from this study that considerable work will have to be performed on optimization of the zinc deposition in molten salts so as to ensure good adhesion to the substrate, together with a greater understanding of possible self-discharge mechanisms. It would seem unlikely that very high current densities are practical with the molten salts reported here. Greater discharge rates may result from increased electrolyte conductivities and optimization of the chlorine electrode performance. However, this preliminary work does show the couple feasible under these conditions even though not practical at this time.

Predeposition in Silicon as Affected by the Formation of Orthorhombic SiP and Cubic $SiO_2 \cdot P_2O_5$ at the PSG-Si Interface

S. Solmi, G. Celotti, D. Nobili, and P. Negrini
C.N.R. LAMEL Laboratory, 40126 Bologna, Italy

ABSTRACT

The phenomena limiting heavy phosphorus predeposition in silicon have been studied in the temperature range 850°-1000°C by using electrical measurements and x-ray diffraction, together with optical and electron microscopy and Rutherford backscattering of He ions. It is reported that increasing the flux of dopant across the oxide layer, either by reducing oxygen pressure or by increasing that of $POCl_3$, leads ultimately to anomalous doping kinetics associated to segregation of orthorhombic SiP and cubic $SiO_2 \cdot P_2O_5$ at the PSG-Si interface, and to damage and loss of adhesion of the surface oxide. Increasing temperature acts in opposition to the onset of this phenomenon due to the increased competitivity of bulk silicon diffusivity. Segregation is sensitive to the orientation of the slice: the (111) being the most favorable, followed by the (110) and (100), respectively. The parameters leading to interface segregation are analyzed and discussed.

An extensive investigation on the predeposition and solubility of phosphorus in silicon is underway in our laboratory, with the aim of contributing to clarification of the basic physicochemical aspects of the doping technology.

Previous research, carried out in the temperature range 850° ÷ 1200°C using $POCl_3$ and oxidizing conditions (1), has shown that the total content, Q, of predeposited phosphorus increases with time following a parabolic law $Q = \sqrt{Kt}$. A similar kinetic, $X_0 = \sqrt{Bt}$, is observed for the thickness X_0 of the surface oxide. The rate-determining step for both processes is the diffusion of the reacting species across the oxide layer.

With increasing $POCl_3$ concentration in the gas, the chemical potential of phosphorus at the oxide-silicon interface and in the adjacent silicon matrix can overcome the value corresponding to the solubility limit, and silicon phosphide precipitates of orthorhombic structure (2) can nucleate and grow, in the course of the process, within the diffused region of the crystal.

Diffusion of the dopant in the bulk competes with the precipitation process, and the amount, Q_{el}, of phosphorus electrically active after predeposition is limited by the solubility and diffusivity of this element in silicon. These conditions are satisfied in a wide range of temperature, time, and flux composition typical of device technology. The fraction of electrically inactive dopant increases with the concentration of $POCl_3$ and decreasing predeposition temperature.

The present research concerns the phenomena occurring with increasing dopant flux and concentration. The formation of phosphorus-rich compounds at the interface of silicon and heavily doped PSG has been reported by several authors (3-6).

Key words: phosphorus predeposition, phosphosilicate compounds, silicon monophosphide, interface segregation, anomalous doping.

Kooi (3), after standard predeposition using a P_2O_5 solid source, observed the presence at the PSG-Si interface of crystalline phosphorus-rich compounds. The structure of these phases was not analyzed.

Schmidt *et al.* (4) reported the presence of orthorhombic SiP in the surface layers of Si diffused from doped anodic oxide and observed that segregation depends on the orientation of the slice (5).

Segregation phenomena and the structure of the precipitates have not yet been systematically studied in function of the main parameters of the predeposition process. The present research aims at contributing to clarification of these problems which are of practical importance for device technology.

Experimental

We used dislocation-free silicon slices about 300 μm thick and mirror finished on one side as produced by Wacker. The (111) orientation has been studied more extensively; and a limited number of experiments was also performed on (100) and (110) oriented specimens. Our slices were of Czochralski type, boron doped, of nominally 1 ohm·cm.

Predeposition has been carried out mainly at 920° and 1000°C. Some treatments have also been performed at 850°C. We used oxidizing conditions, together with the apparatus and procedures described in our previous paper (1).

A set of predepositions has been carried out changing only the partial pressure of oxygen, and another set changing only that of the phosphorus oxychloride. In all cases the total gas flow was kept constant (1580 ml/min) by adjusting the main nitrogen flow. To remove

the doped oxide layer, a standard 3 min etching in 5% HF solution was performed before the drive-in treatments.

We have accurately measured the total and the electrically active phosphorus content, Q and Q_{el}, in the predeposited silicon slices. These quantities have been determined by using the techniques already reported in detail; that is, neutron activation analysis and electrical resistivity measurements. The latter were performed after predeposition as well as after suitable drive-in (1).

The features of the oxide films have been observed by using a Leitz M M 5 optical microscope, and their thickness and surface roughness accurately measured by a Talystep. The roughness has been analyzed by using a special sharp stylus of truncated pyramidal form (nominal tip dimensions $\sim$ 0.1 $\times$ 2.5 μm) and applying a stylus force of about 10 μ newton.

The composition of the oxide film has been checked by Rutherford backscattering of He ions with energy 1.8 MeV, obtained from the 2 MeV Van der Graaf of the Laboratorio Nazionale of Legnaro (Italy). The overall resolution was estimated $\sim$ 18 keV and the beam divergence was kept lower than 10^{-4} rad. The data analysis has been performed as described in Ref. (7).

In a range of experimental conditions, the oxide films turned out to be loose; therefore it was possible to collect powder specimens suitable for x-ray examinations. We verified the absence of contamination by comparing the spectra of powders obtained by using tools of different materials (glass, Plexiglas, and stainless steel).

The powders were observed by the Debye-Scherrer technique employing a Philips 114.6 mm ϕ camera, and Cu Kα radiation. To detect the presence of small quantities of crystalline phases embedded in the amorphous oxide matrix, we performed rather long exposures on Kodak Kodirex film.

Parallel examinations have been performed directly on the oxide films lying on their silicon substrates, by using a Rigaku-Denki SG-7 powder diffractometer equipped with scintillation counter and potentiometric recording, Cu Kα radiation, and the usual Bragg symmetric reflection geometry. Photographic methods have been discarded because they were unsuccessful for both the transmission and reflection geometry, even with very long exposures.

The two techniques turned out to be complementary because the undesired scattering (amorphous SiO_2 from matrix in Debye-Scherrer, and Si (111) from substrate with the diffractometer) masked different angular regions.

Results

Anomalous doping and oxide damage.—We report first the values of total and electrically active phosphorus, Q and Q_{el}, for 27 min predepositions at 920°C.

In Fig. 1 these quantities are plotted *vs.* the concentration of $POCl_3$ at a constant oxygen concentration of 5.7%. In Fig. 2 Q and Q_{el} are reported *vs.* the concentration of O_2 at a constant phosphorus oxychloride concentration of 0.27%.

In Fig. 3 and 4, respectively, we report the results of the corresponding predeposition experiments carried out at 1000°C. The concentration ranges explored in these latter experiments are about three times larger than in those performed at 920°C.

We notice that in a wide range of gas compositions the content of phosphorus, Q, increases with phosphorus oxychloride concentration. A sudden deviation from this trend takes place at about 0.5% $POCl_3$ in the 920°C experiments. This phenomenon is observed at 1000°C only for the highest $POCl_3$ concentrations.

As is shown in Fig. 2 and 4, in a wide range of flux compositions the content of phosphorus increases with decreasing oxygen concentration. A sudden deviation from this trend is observed at about 3% oxygen in the 920°C predepositions. This phenomenon is absent at 1000°C.

To analyze the phenomena observed at 920°C we have studied the time dependence of the values of Q and Q_{el} for two distinct phosphorus oxychloride con-

centrations. Figures 5 and 6 show the results obtained with 0.27 and 0.53% $POCl_3$, respectively. Oxygen per cent is kept constant (5.7%). It is observed that a deviation from the parabolic law of phosphorus doping,

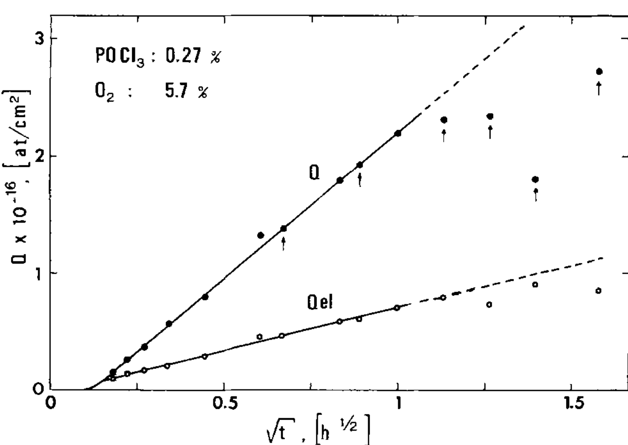

Fig. 5. Time square root dependence of the total, Q, and electrically active phosphorus, Q_{el}, in predepositions carried out at 920°C. Doping gas composition is 0.27% $POCl_3$ and 5.7% O_2. The arrows indicate the samples analyzed by x-ray.

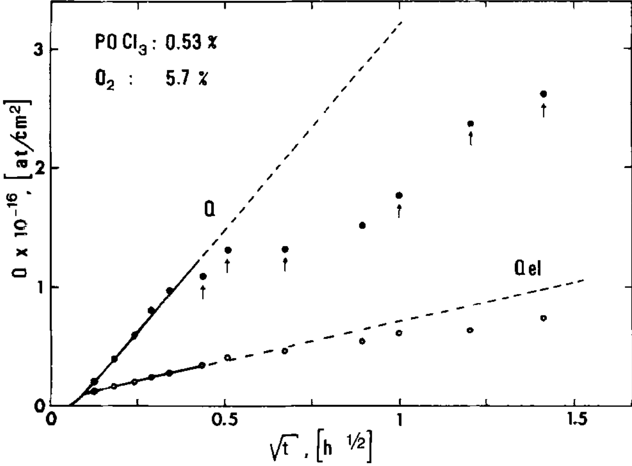

Fig. 6. Time square root dependence of the total, Q, and electrically active phosphorus, Q_{el}, in predepositions carried out at 920°C. Doping gas composition is 0.53% $POCl_3$ and 5.7% O_2. The arrows indicate the samples analyzed by x-ray.

$Q = \sqrt{Kt}$, takes place at a time which decreases as the $POCl_3$ concentration increases. Above these limits (~60 and 10 min, respectively) the dopant content in the silicon matrix turns out to be markedly lower than expected.

The electrically active dopant, Q_{el}, is a property less sensitive to the above phenomenon; this is probably the reason its occurrence remained unobserved. In Fig. 7 we report the values of the oxide thickness in the same predeposition experiments of Fig. 5 and 6. Also, these plots show a deviation, taking place at the above-mentioned times, from the well-known time dependence of the oxide growth $X_o = \sqrt{Bt}$.

In fact, both effects correspond to modifications in the doped oxide films which no longer appear uniform and smooth, but present a damage whose density and features depend on time and flux composition. An optical micrograph representative of the initial stage of damage at 920°C is reported in Fig. 8, associated with the corresponding roughness profile determined by the Talystep. In this stage the oxide presents circular defects of two distinct types: bubbles and small craters. These are also evidenced by the roughness profile. At longer predeposition times the whole surface of the slice is damaged and the defects overlap.

These modifications are associated with loss of adhesion and consistency of the oxide. The phenomenon involves the whole surface film including the region lying between isolated defects. The oxide becomes loose and can be easily scraped off, leaving the underlying silicon surface clean. Actually, Talystep measure-

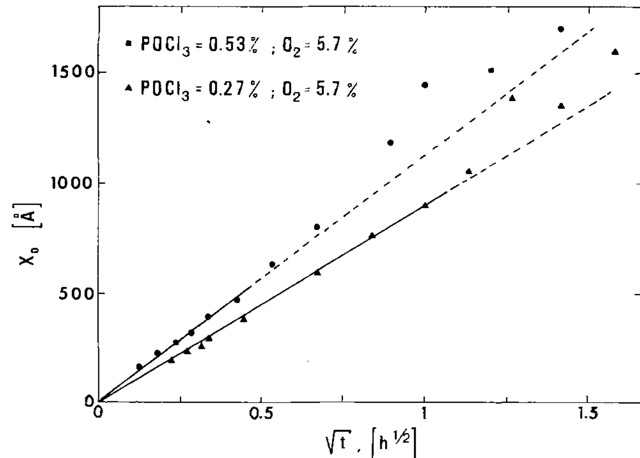

Fig. 7. Oxide thickness, X_o, vs. square root predeposition time. The experimental conditions are the same as in Fig. 5 and 6.

Corresponding roughness profile (bottom) determined by the Talystep. The horizontal magnification is the same as the optical micrograph while the vertical magnification is 40Å per division.

ments have shown that the silicon surface is also made slightly rough and the amount of this effect increases with predeposition time.

The features and consistency of the oxide layers for specimens predeposited at 850°C under conditions giving rise to anomalous doping, are similar to those described above. At 1000°C the onset of damage was present only at the highest phosphorus oxychloride concentrations which could be realized, still maintaining a good reproducibility, in our predeposition apparatus. The oxide turned out to be simply softer than the normal one. As is shown in Fig. 9, the damage resulting at this temperature is associated with the formation of clusters of irregular shape which look like those observed by Ghezzo in arsenic glass at high temperature (8).

Analysis of the surface film.—In order to obtain information on the chemical composition of the oxide layers, we have performed some backscattering analysis of our specimens. Our spectra allow the exclusion of chlorine and nitrogen which, although in remarkable concentrations in the gas phase, are absent in the solid within the limits of sensitivity of this technique (about 0.1% for chlorine and 1% for nitrogen). As an example, we report in Fig. 10 the spectrum concerning a sample predeposited 11 min under the same conditions of Fig. 6. The peaks account for the presence of oxygen, silicon, and phosphorus, which are the only observed components. The energy corresponding to chlorine (1160 keV) is not reported in Fig. 10 due to the absence of any measurable effect.

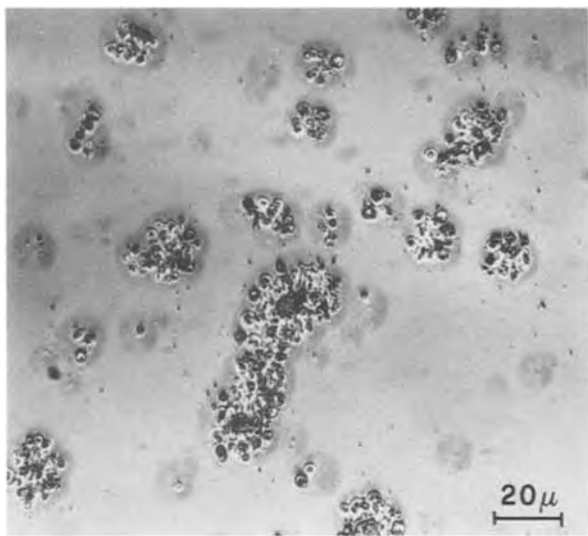

Fig. 9. Optical micrograph of the oxide grown during a predeposition of 27 min at 1000°C. Doping gas composition is 2.2% $POCl_3$ and 5.7% O_2. Damage appears in the form of clusters of irregular shape.

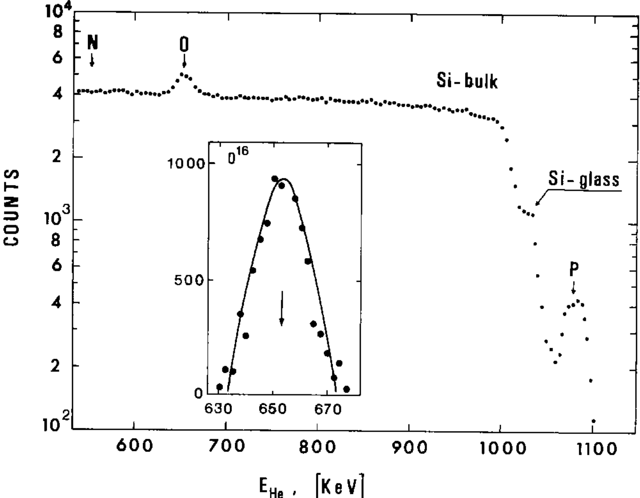

Fig. 10. Backscattering energy spectrum of 1.8 MeV-He ions incident on a silicon sample predeposited 11 min at 920°C, as in Fig. 6. The resulting oxygen peak is reported on the bottom. For better clarity we reported only half of the experimental points.

Considering the composition of a typical phosphorus glass, our surface layers show a defectiveness of oxygen; for example, the atomic percentages in Fig. 10 are approximately: 65% oxygen, 27% silicon, and 8% phosphorus. These results are in agreement with the presence, reported below, of remarkable concentrations of SiP in the defective oxide films.

In order to reveal the presence of crystalline phases in the surface layer, we performed a systematic x-ray analysis of the specimens shown by arrows in Fig. 3, 5, and 6. Loose oxide films were studied both by the diffractometer and the Debye-Scherrer technique.

Two crystalline phases have been found in the specimens predeposited under conditions giving rise to anomalous doping. Their reflections are reported in Tables I and II, respectively. The former shows those attributed to orthorhombic SiP, and, for comparison, the major powder reflections given by Wadsten (9, 10). The latter shows the interplanar distances that we attribute to cubic $SiO_2 \cdot P_2O_5$ in comparison with the powder data of this phase, which Tien and Hummel call high temperature form (11) and Liebau *et al.* AI form (12). The data of these authors are complementary. We notice first that, accounting also for the

angular regions masked by undesired scattering, the agreement of the results of our two techniques is satisfactory.

The identification of the phases has also taken into account the intensity of the reflections, and is fairly sure. The line with $d = 3.03Å$, visible in Debye-Scherrer photographs, is the only superposition of strong reflections belonging to both crystalline compounds. In some cases, x-ray examinations have also shown clear evidence of the presence of α-quartz.[1]

The diffractometric reflection spectra show the presence for both the SiP and the $SiO_2 \cdot P_2O_5$ of orientation effects; in fact, to account for the observations of only two lines, which moreover are not the strongest ones, pertaining to the orthorhombic SiP, these crystallites have to present their (001) or (010) planes, parallel to the (111) surface of the silicon slice. As for the $SiO_2 \cdot P_2O_5$, the enhanced relative intensity of the (300) reflection in Table II suggests that this phase is partially oriented with its (100) faces parallel to the (111) planes of silicon.

Finally, we notice that the intensity of the lines associated with the SiP and the $SiO_2 \cdot P_2O_5$ generally increases with predeposition time. Further, the intensity of the reflections of both compounds was slightly lower in the specimens predeposited at 1000°C, although, as shown in Fig. 3, the latter correspond to a flux much richer, by more than a factor 3, of $POCl_3$.

The diffractometric analysis of the specimens predeposited under conditions which did not result in anomalous doping, did not show any reflection. This result is not in contradiction with the presence, discussed in our previous work, of SiP precipitates in the Si matrix. In fact, their prevalent orientations, determined by electron diffraction (2), are such that the observation is inhibited with our diffractometric method; only a small fraction, far below the sensitivity of our x-ray technique, is oriented with their (010) planes parallel to the (111) surface of the silicon slice (16).

[1] Formation of crystalline phosphosilicates and α-quartz was observed also in SiO_2 heavily predeposited with phosphorus (13-15).

Localization of the crystalline phases.—To define the position of the observed compounds within the oxide layer, we performed chemical etching of the surface films by HF solutions of different concentrations, followed by Talystep measurements of the thickness of the dissolved oxide and diffractometric examinations.

These observations have shown that in all cases the $SiO_2 \cdot P_2O_5$ and the SiP were essentially localized at the oxide-silicon interface. These conclusions have also been confirmed by observations after mechanical abrasion of the oxide film performed in order to avoid effects due to selective etching.

A typical example of our results is shown in Fig. 11 which reports, in dependence of the degree of chemical etching, the intensity of characteristic x-ray diffractometer reflections in a specimen predeposited 150 min at 920°C with a flux composition of 0.27% $POCl_3$ and 5.7% O_2. It can be noticed that a fraction of the crystalline compounds is still present after the last strong etching.

The above results have been further quantitatively confirmed by electrical resistivity measurements. These were performed on identical specimens, etched or mechanically abraded in order to obtain increasing surface removal (the most aggressive process was anodic

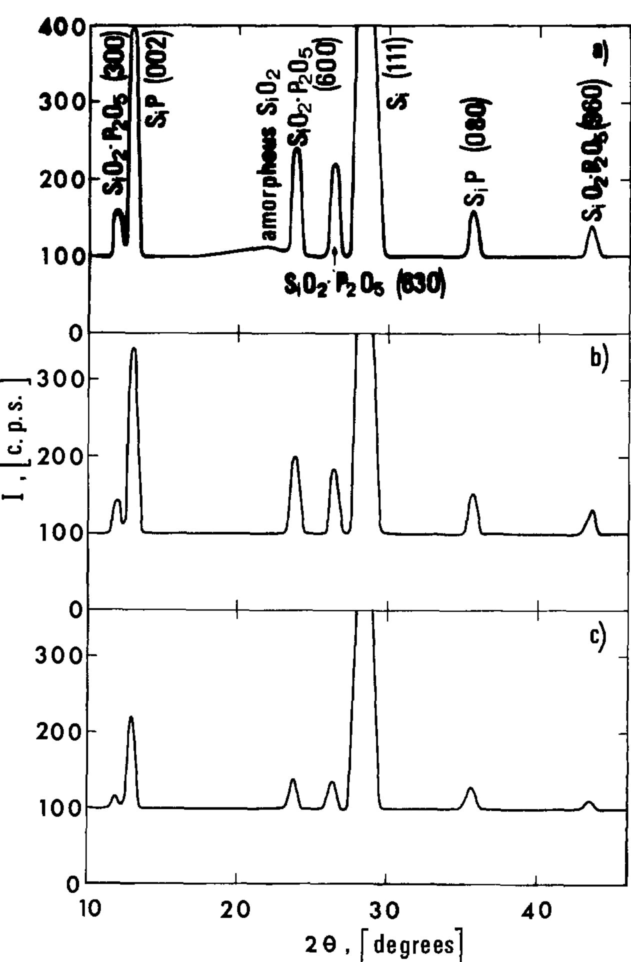

Fig. 11. Intensity of characteristic x-ray reflections of a specimen predeposited 150 min at 920°C with the same flux composition as in Fig. 5 (diffractometer, CuKα radiation): (a) refers to the initial state, (b) after 5 min etching in 0.5% HF, and (c) after 5 min etching in 49% HF.

oxidation and dissolution), followed by surface resistivity measurements both before and after suitable drive-in treatments. These determinations give the electrically active, Q_{el}, and the total phosphorus, Q, respectively (1): the values of Q_{el} monitor the etching of the silicon matrix, while the differences of Q measure the phosphorus content of the etched material. An example of our results is reported in Table III.

In addition, these measurements confirm, with a sensitivity greater than that attributed to our x-ray technique, that the phosphorus-rich layer is absent in the specimens which present a normal doping behavior.

Finally, we noticed that the phosphorus content in the matrix of silicon in the anomalously doped specimens cannot be exactly defined any more; a remarkable fraction, about 50% in the above example, is in fact localized in an interfacial region, a few hundred angstroms thick.

Effect of the crystallographic orientation of the slices.—In order to verify whether the oxide-silicon interface plays a role in the nucleation and growth of the crystals of SiP and of $SiO_2 \cdot P_2O_5$, we have performed experiments at 920°C, processing together silicon slices of different orientations. A 30 min predeposition has been carried out in a flux with 0.53% $POCl_3$ and 50, 80, and 150 min predepositions in a flux with 0.27% $POCl_3$. Oxygen per cent was kept constant (5.7%). These experiments have evidenced a remarkable effect of the crystallographic orientation of the surface of the slices: the (111) is the most favorable for the onset of the phenomenon of anomalous doping, followed in order by the (110) and by the (100) orientation.

TEM examinations suggest that surface diffusivity plays a role in the rapid growth of precipitates; as an example we report in Fig. 12 large SiP crystals grown at the oxide-silicon interface of a (111) oriented specimen processed as in Fig. 11. The size of these precipitates which lie along the <110> directions of silicon is about 10 times that of those found inside the silicon matrix.

Correlation between segregation at the interface and in the bulk silicon.—The present results and those reported in Ref. (1) indicate that interface segregation is enhanced by the same parameters which increase the amount of electrically inactive phosphorus (SiP precipitates in the silicon matrix) formed in the stage preceding the onset of the phenomenon. This connection is further evidenced by predeposition experiments on slices previously oxidized in order to form thin oxide layers. These reduce the flux of phosphorus, thus decreasing the amount of SiP in the bulk silicon (1). All other conditions, except the concentration gradients, remain unaltered, after an initial transient, as long as SiP precipitates are present.

Oxide films of thickness 120, 200, and 380Å have been obtained by thermal oxidation at 920°C in a dry oxygen atmosphere. These specimens have been processed 80 min at 920°C, together with unoxidized slices

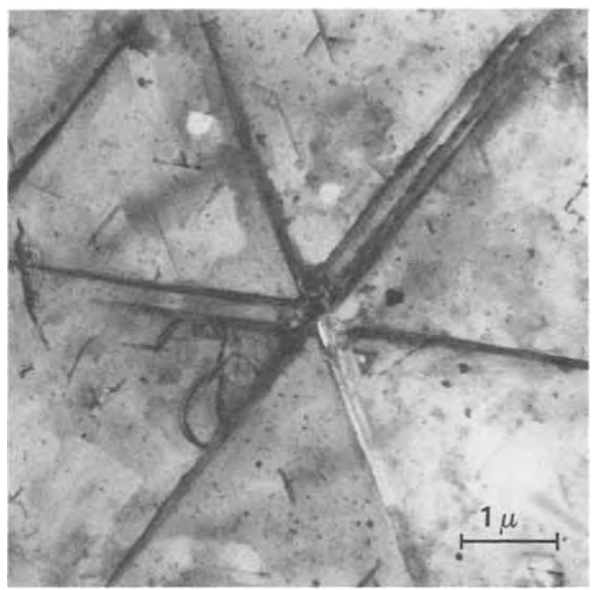

Fig. 12. Electron micrograph showing large SiP precipitates lying along <110> directions. Specimen has been processed as those in Fig. 11.

of the same (111) orientation, in a flux with 0.27% $POCl_3$ and 5.7% oxygen.

Oxide damage was observed only in the unoxidized slices and, in a very limited amount, in those slices with the thinnest preformed film (~ 120Å). The formation of SiP and of $SiO_2 \cdot P_2O_5$ was revealed, by x-ray examinations, only in the unoxidized slices.

More detailed information results from the study of the effect of temperature. We show, as an example, in Fig. 13 the chemical and electrical concentration profiles of phosphorus in slices processed for the same time (27 min), in fluxes of the same composition (0.27% $POCl_3$ and 5.7% O_2), at 920° and 1000°C, respectively. These profiles have been obtained using the technique of neutron activation and that of electrical measurements already reported in detail (17, 18). The concentration dependence of mobility has been taken into account (19).

It is seen that, while the amount of electrically inactive dopant is comparable, the surface concentration attained in the process at 920°C is more than two times higher. This effect results from competition between the diffusivity across the oxide and that in the bulk silicon; the latter being characterized by a higher absolute value of the exponential term (1).

These experiments show that interface segregation is connected to the concentration of SiP in the region near the interface.

Discussion and Conclusions

Our observations show that the kinetics of phosphorus predeposition can be altered by a phenomenon

Table III. Comparative effects of surface removal on regularly and anomalously doped slices

Predeposition T = 920°C, t = 27 min, O_2 = 5.7%	Technique of surface removal	Q_{el} (at/cm²)	Q (at/cm²)	Q/Q_{el}
$POCl_3$ = 0.53% Anomalously doped (see Fig. 6)	HF 0.5% 3 min	4.40×10^{15}	1.41×10^{16}	3.20

which reduces the amount of dopant in the silicon matrix and is associated with damage and loss of coherency of the doped oxide. The hypothesis of a chemical reaction between the furnace gas and the surface being responsible for this effect has been discarded on the basis of the composition results obtained by backscattering analysis. It is shown that the phenomenon results from segregation of orthorhombic SiP and cubic $SiO_2 \cdot P_2O_5$ taking place at the PSG-Si interface.

As is evidenced by Fig. 5 and 6, the onset of interface segregation does not depend primarily on the amount, Q, of phosphorus predeposited in silicon, but on the flux of dopant across the surface oxide. These conclusions are confirmed by the observation that previous slight oxidation of the slices inhibits the segregation process. The flux can be increased either by increasing $POCl_3$ concentration or by decreasing that of oxygen. This gives rise to the maximum in Fig. 1 as well as to the change of slope in Fig. 3; in fact, the specimens processed in a richer flux of $POCl_3$ undergo interface segregation in shorter times. The maximum corresponds to the concentration of $POCl_3$ just giving rise to the onset of segregation in the chosen predeposition time (27 min). The same reasoning accounts for the maximum observed in Fig. 2 with decreasing the concentration of oxygen.

The segregation phenomena depend on the crystallographic orientation of the surface of the slice; the (111) being the most favorable, followed in order by the (110) and the (100). These results and the observed preferential orientation of the precipitates indicate that the surface plays a role in the nucleation and growth processes.

As for the SiP, we observe that, contrary to what might be expected by considering only the supersaturation gradient, precipitation takes place first within the silicon matrix. This phenomenon, studied in our previous work (1), is also evidenced by the chemical profiles in Fig. 13, representative of situations which precede interface segregation. Its occurrence shows that a higher supersaturation of dopant is needed for nucleation at the interface.

Steeper supersaturation gradients in the silicon matrix, as can be obtained either by increasing the flux across the surface oxide or by decreasing the temperature, result in local accumulation of the SiP and enhance the nucleation at the interface of suitably oriented crystals.

The nucleation of the $SiO_2 \cdot P_2O_5$, which is always found associated with the SiP, should be enhanced by the latter. In fact, phosphorus oxide concentration is maximum at the surface; nevertheless $SiO_2 \cdot P_2O_5$ segregation takes place at the PSG-silicon interface.

We observe, finally, that the conditions for interface segregation are not unusual in predepositions at 920°C using $POCl_3$. They are satisfied also with other sources as is shown by the results reported by Schmidt *et al.* (4, 5) and suggested by those of Kooi (3). It is likely that interface segregation occurred also in the experiments using heavily doped oxide sources reported by Ghezzo (20); in fact, the surface damage that he observed looks like that shown in Fig. 8.

Acknowledgments

We wish to thank G. G. Bentini for having performed the backscattering analysis of our specimens; M. Servidori and A. Armigliato for their electron microscopy results and the useful discussion. Acknowledgments are due to E. Gabilli and S. Guerri for cooperation in setting up the experimental facilities.

Diffusional Growth of Cobaltous-Ferrous Oxide Scales on Cobalt-Iron Alloys

P. Mayer*,[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Co-Fe alloys containing up to 10 weight per cent (w/o) Fe oxidize parabolically by formation of a cobaltous-ferrous oxide [(CoFe)O] scale when exposed at 1200°C to oxygen at 10^{-2}, 10^{-1}, and 1 atm. The values of the parabolic oxidation constants were directly dependent on the iron contents of the alloys. The iron profiles within the scales exhibited maxima which shifted toward the center of a scale away from its outer surface with increasing oxygen pressure. It is demonstrated on the basis of a ternary diffusional analysis that these findings are consistent with independent measurements on the ratio of metal self-diffusion coefficients in this oxide and with the postulate that the relative migration rate of cobalt and iron at positions in a scale is dependent upon the magnitude of the oxygen activity.

Cobalt and iron form a homogeneous solid solution at high temperatures. The oxygen potential Co-Fe-O phase diagram (1, 2) illustrates that (CoFe)O exists as the stable phase on alloys containing up to ~30% Fe in oxygen ranging to 1 atm pressure at 1200°C. We previously found, as anticipated, that cobalt alloys with iron ranging up to 10% oxidized parabolically by formation of a (CoFe)O scale when exposed at this temperature to oxygen at 10^{-4} and 10^{-3} atm (3). The iron gradients within the scales increased with increasing outward distance due to iron migrating more rapidly than cobalt. A diffusion model based upon equations derived by Wagner (4) for metal transport through a scale under chemical activity gradients led to a correlation between the parabolic oxidation constants and the iron gradients.

The metal self-diffusion parameters in (CoFe)O are unusual. Crow (5) has determined the tracer diffusion coefficients of cobalt and iron in this oxide. At 1200°C, the ratio D_{Fe}/D_{Co} equals 1.6 at oxygen pressures of 10^{-4} and 10^{-3} atm and it equals 0.7 at pressures greater than 10^{-1} atm. One would, therefore, predict from the above diffusion model that an iron concentration profile exhibiting a maximum could develop in the (CoFe)O scale when an alloy containing up to 10% Fe is oxidized at oxygen pressures greater than 10^{-3} atm. The present communication demonstrates that these predictions are actually valid.

Experimental

Disk-shaped Co-Fe alloy specimens (10 × 2 mm) were metallographically polished to 1μ diamond abrasive and oxidized at 1200°C for periods up to 30 min in flowing ultrahigh purity oxygen at pressures 10^{-2}, 10^{-1}, and 1 atm using a continuously weighing semimicrobalance. Measurements of the metal concentration profiles in cross-sectioned specimens were measured by an electron-microprobe analyzer. The preparation of the alloys, experimental assemblies, and methods have been described (3). The actual iron contents of the nominal 1, 2, 4, 6, 8, and 10 w/o Fe alloys are 0.93, 2.1, 4.1, 5.5, 7.7, and 9.6 w/o Fe, respectively.

Results

It was found that the oxidation rate at each pressure followed a parabolic time dependence. Figures 1-3 show the oxidation curves plotted in parabolic form for cobalt and the six alloys at the three test pressures. The values of the parabolic oxidation constants, which were accurate to within ±10% based on the deviations from the average value of four runs completed on each alloy, are shown in Fig. 4. These constants show a direct dependence on the iron contents of the alloys.

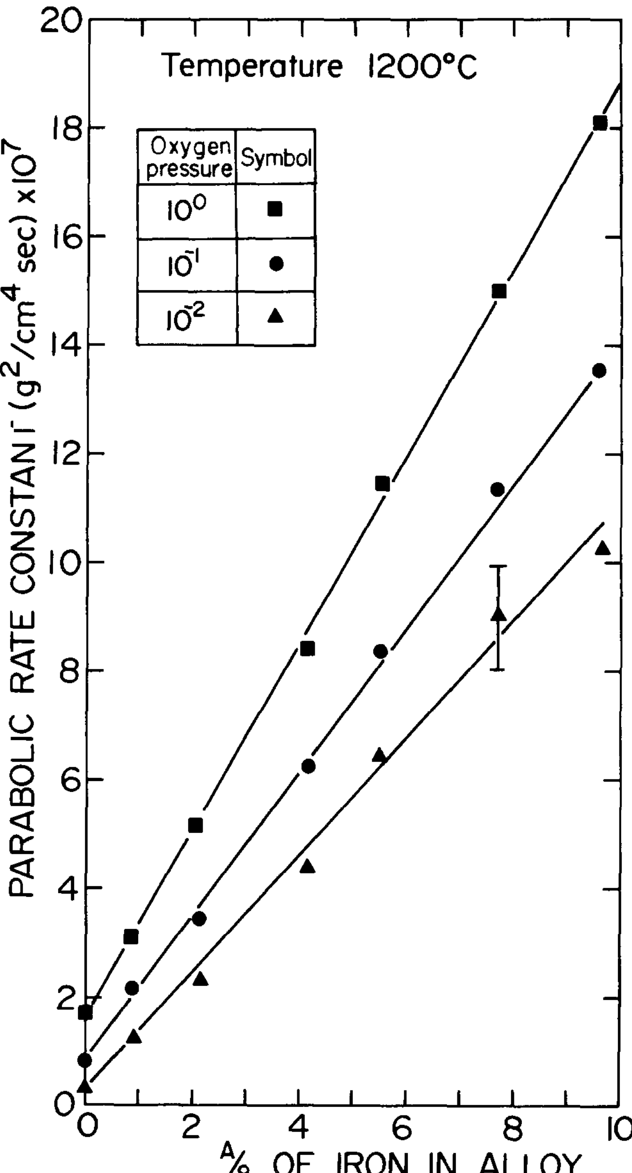

Fig. 4. Variation of the parabolic oxidation constants with alloy iron content of the Co-Fe alloys at 1200°C.

X-ray diffraction lattice parameter measurements on the powdered scales confirmed that they were composed of (CoFe)O. Figures 5 and 6 show typical scale cross sections. The alloy-oxide interfaces were planar and the alloys did not exhibit internal oxidation. Examination of several cross sections revealed that the scales were composed of large columnar grains and regions in the vicinity of the scale-gas interface of small discontinuous precipitates of submicron size (typically $\sim 0.5\mu$); the density of these precipitates decreased with increasing iron content and decreasing oxygen pressure. These precipitates are believed to be $(CoFe)_3O_4$ resulting from the quench of the specimens from the reaction temperature.

Iron compositions within the scales formed on each alloy expressed as the atom fraction of iron or mole fraction wustite in (CoFe)O at the three investigated pressures are shown in Fig. 7-9. These determinations are based on analysis taken from scales on each particular alloy at different times of exposure using the electron microprobe point count method at normalized distances $y = x/x_s$ from the alloy surface where x_s is a total scale thickness. These normalized distances could be reproduced within $\pm 10\%$. Significant variations of iron concentration within the scales were not observed when measured parallel to an alloy surface. It was possible to conclude from these determinations

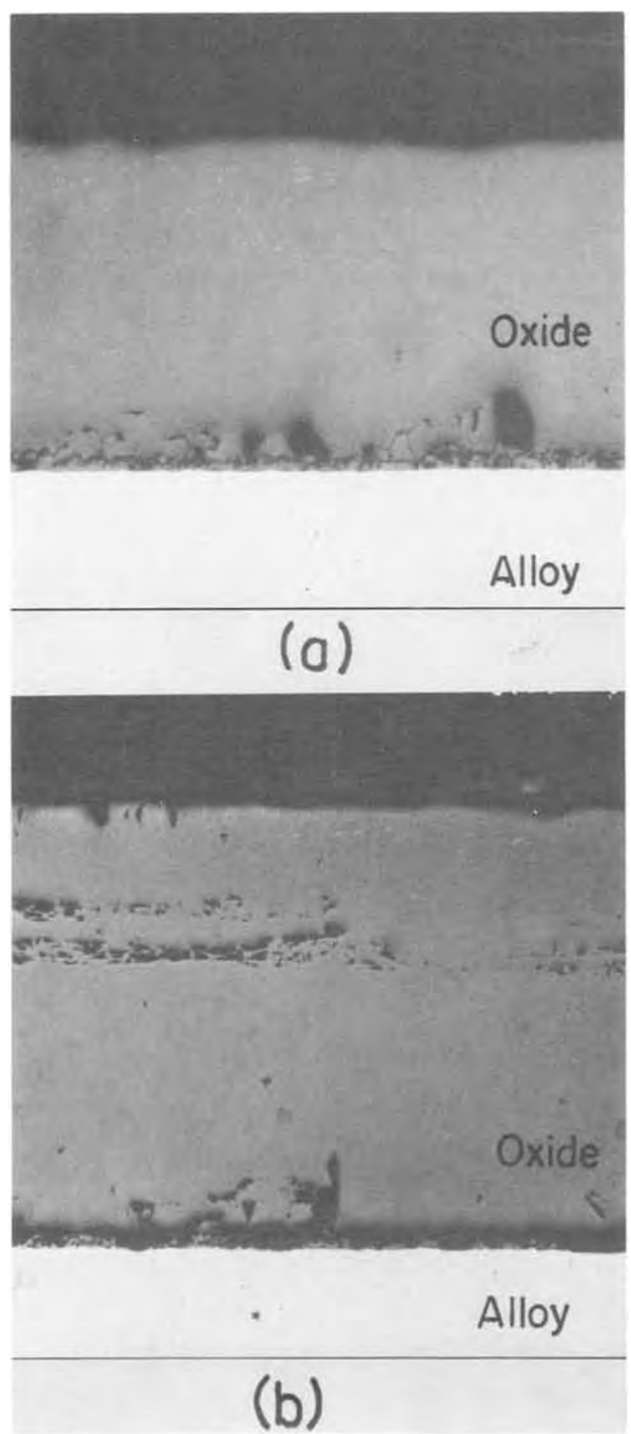

Fig. 5. Cross sections of oxide scales formed at 1200°C in oxygen at 1 atm pressure (200X): (a) Co-1 w/o Fe alloy oxidized for 60 min; (b) Co-10 w/o Fe alloy oxidized for 15 min.

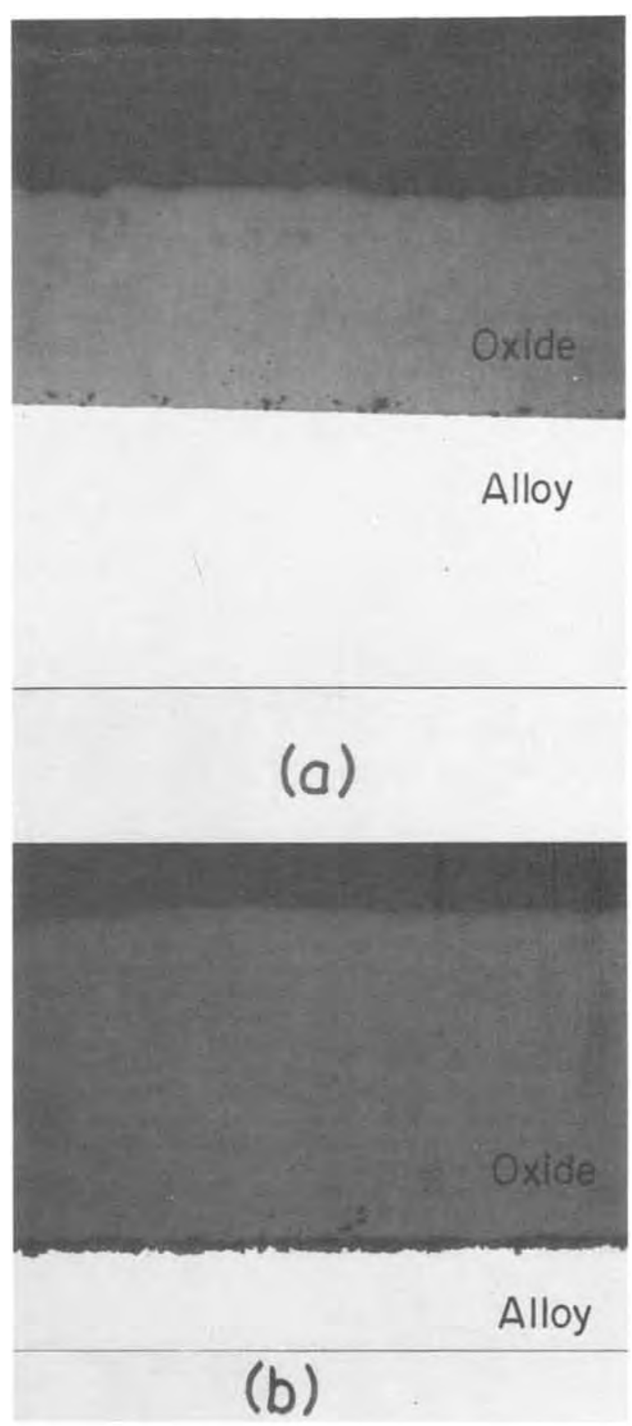

Fig. 6. Cross sections of oxide scales formed at 1200°C in oxygen at 10^{-2} atm pressure (200X): (a) Co-1 w/o Fe alloy oxidized for 60 min; (b) Co-10 w/o Fe alloy oxidized for 15 min.

that the iron content of a scale corresponded to that of the alloy and that the iron profiles exhibited maxima, the positions of these maxima shifting toward the center of a scale away from the outer interface with increasing oxygen pressure.

Discussion

In an earlier publication an excellent correlation was obtained between the parabolic reaction kinetics and the normalized metal profiles in the scales formed on the alloys of this investigation at oxygen pressures of 10^{-4} and 10^{-3} atm (3). This interpretation involving ternary diffusion in conjunction with compositional, diffusional, and thermodynamic data accounted for the uphill diffusion of iron against its concentration gradient in the (CoFe)O scale by its more rapid diffusion (larger self-diffusion coefficient) under the influence of the oxygen activity gradient. We now demonstrate that the observed iron profiles exhibiting maxima in the scales can be calculated from the same basic diffusion model assuming a variation in the related rates of metal diffusion with oxygen activity. This ternary diffusion model was originally advanced by Wagner (4) and the reader is referred to his paper and to our previous paper for its application to the Co-Fe-O system (3), mathematical derivations, and applications of the diffusion flux and mass balance equations.

The (CoFe)O scale growth is determined by the outward diffusion of cobalt and iron via vacancies, and Eq. [11] from Ref. (4) for the parabolic oxidation constant becomes

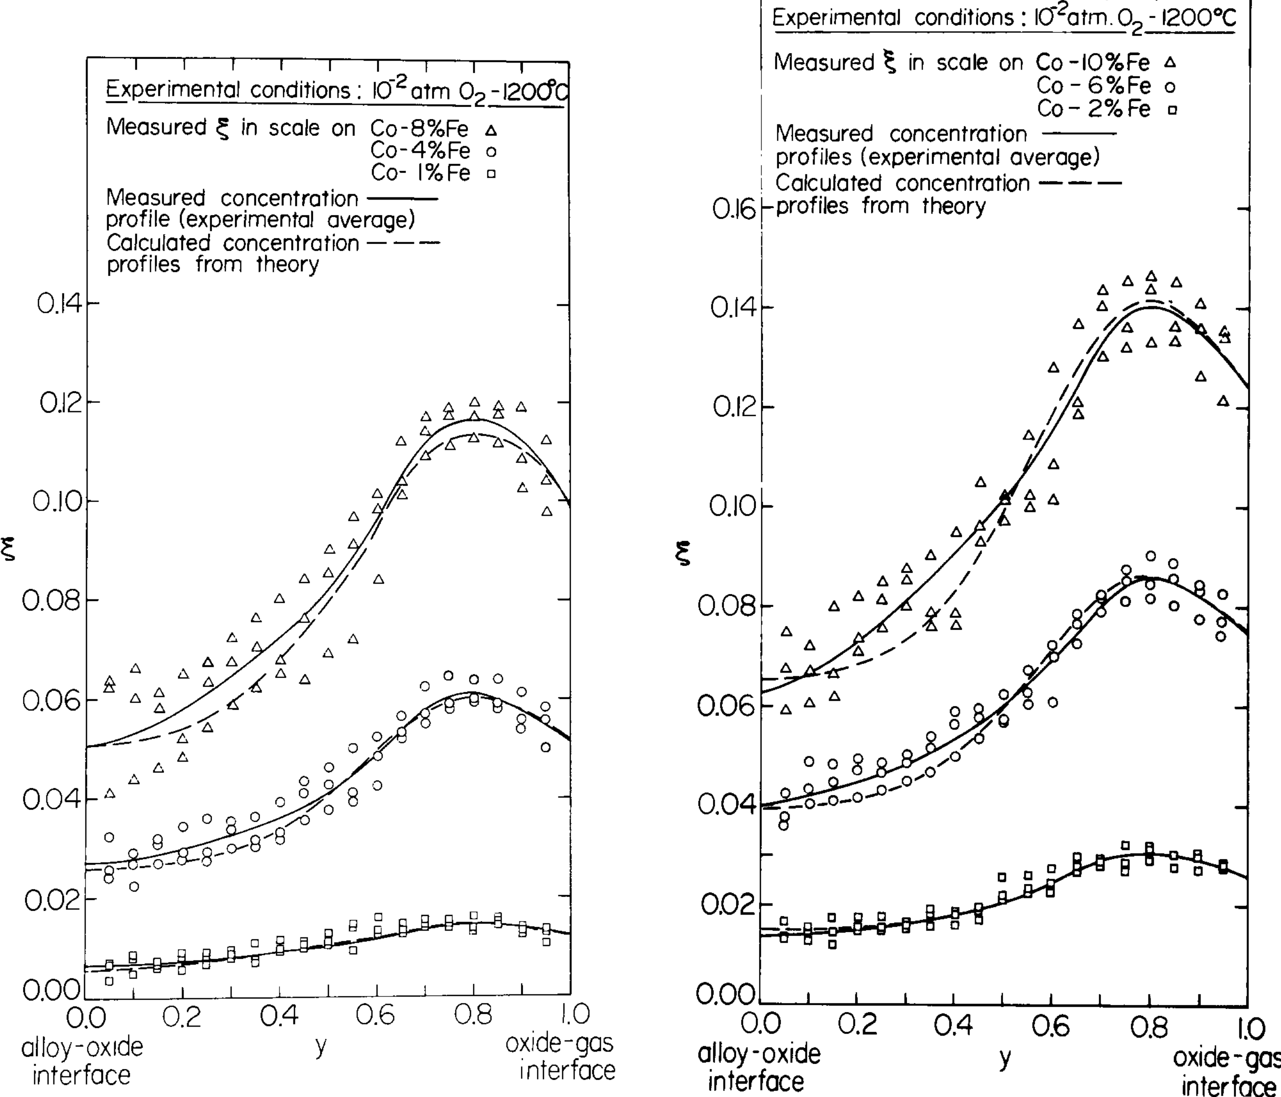

Fig. 7. Mole fraction FeO, ξ, as a function of normalized distance coordinate y in (CoFe)O scales at 10^{-2} atm oxygen pressure: (a, left) Co-1, 4, and 8 w/o Fe; (b, right) Co-2, 6, and 10 w/o Fe.

$$D_{Co}(1-\xi)\left(\frac{-d\ln a_{CoO}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Co}}{Z_o}\frac{d\ln a_O}{dy}\right)+D_{Fe}\xi\left(\frac{-d\ln a_{FeO}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Fe}}{Z_o}\frac{d\ln a_O}{dy}\right)=k \quad [1]$$

In this expression, D is a metal self-diffusion coefficient, a is a local activity, Z is a valency, ξ is the atom fraction of iron or mole fraction of wustite in (CoFe)O, and $y = x/x_s$ is the normalized scale thickness.

For Henrian solution behavior of wustite in cobalt oxide, $p = D_{Fe}/D_{Co} = D_{Fe}°/D_{Co}°$, $Z_{Co} = Z_{Fe} = |Z_o| = 2$, $k' = k/D_{Co}°\gamma$ and $N_V = \gamma a_O{}^n\xi$, Eq. [1] becomes Eq. [8] of Ref. (3)

$$\frac{d\ln a_O}{dy}=\left[\frac{k'}{a_O{}^n\xi}+(p-1)\frac{d\xi}{dy}\right]\Big/\left[1+(p-1)\xi\right] \quad [2]$$

In the above expressions, $D_{Co}°$ and $D_{Fe}°$ are the cobalt and iron vacancy diffusivities, N_V is the atom fraction of vacancies in (CoFe)O, γ and n are empirical constants.

Equation [19] from Ref. (4), which describes the metal gradient in a scale using the divergence equation for the metal flux, becomes Eq. [9] and [10] of Ref. (3)

$$yk\frac{d\xi}{dy}=\frac{-d}{dy}\left[D_{Fe}\xi\left(\frac{d\ln a_{FeO}}{d\xi}\frac{d\xi}{dy}-\frac{d\ln a_O}{dy}\right)\right] \quad [3]$$

and after substitution

$$yk\frac{d\xi}{dy}=-\frac{d}{dy}\left[p\cdot D_{Co}°\cdot\gamma\cdot a_O{}^n\cdot\xi^2\cdot\left(\frac{1}{\xi}\frac{d\xi}{dy}-\frac{d\ln a_O}{dy}\right)\right] \quad [4]$$

The intended differentiation of Eq. [4] after rearrangement leads to

$$\frac{d^2\xi}{dy^2}=\left\{-\frac{yk'}{pa_O{}^n\xi^2}\cdot\frac{d\xi}{dy}-\left[\frac{1}{p}\cdot\frac{dp}{dy}+\frac{2}{\xi}\frac{d\xi}{dy}+n\frac{d\ln a_O}{dy}\cdot\left(\frac{1}{\xi}\cdot\frac{d\xi}{dy}-\frac{d\ln a_O}{dy}\right)\right]+\frac{1}{\xi^2}\left(\frac{d\xi}{dy}\right)^2-\frac{k'}{[1+(p-1)\xi]\cdot a_O{}^n\xi}\cdot\left(\frac{1}{\xi}\frac{d\xi}{dy}+\frac{nd\ln a_O}{dy}\right)-\left\{\frac{d\ln a_O}{dy}\Big/[1+(p-1)\xi]\right\}\cdot\left[\frac{d\xi}{dy}(p-1)+\frac{dp}{dy}\xi\right]+\frac{1}{[1+(p-1)\xi]}\cdot\frac{dp}{dy}\cdot\frac{d\xi}{dy}\right\}\cdot\frac{1}{\left(\frac{1}{\xi}-\frac{(p-1)}{[1+(p-1)\xi]}\right)} \quad [5]$$

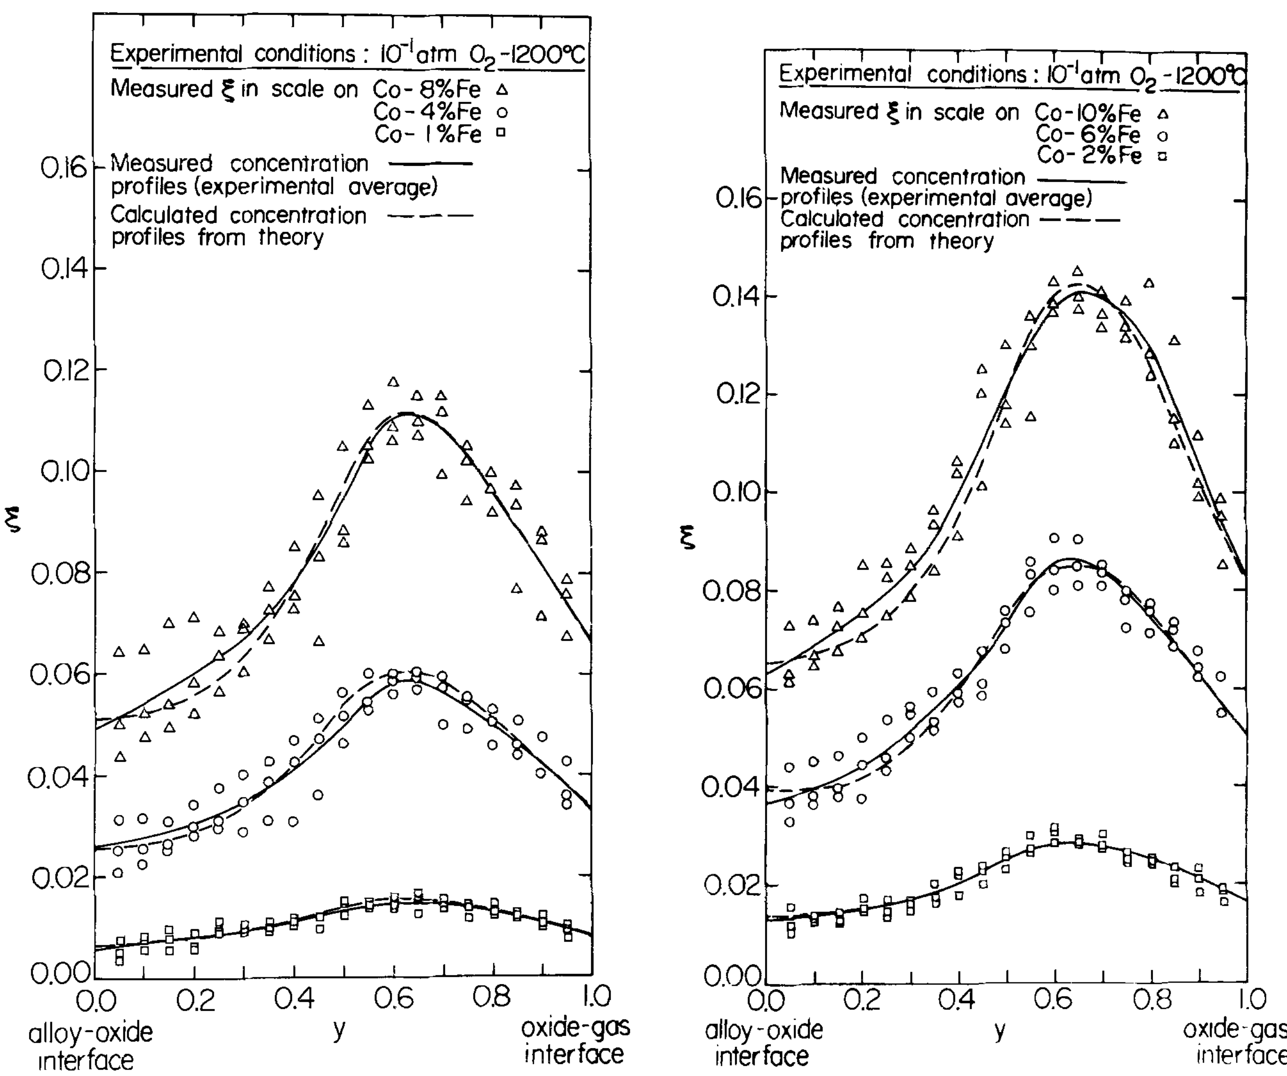

Fig. 8. Mole fraction of FeO, ξ, as a function of normalized distance coordinate y in (CoFe)O scales at 10^{-1} atm oxygen pressure: (a, left) Co-1, 4, and 8 w/o Fe; (b, right) Co-2, 6, and 10 w/o Fe.

Equations [2] and [5] describe the variation of the mole fraction of FeO, ξ, and the oxygen activity, a_O, as a function of y. Unfortunately, the dependent variables ξ and a_O are inseparable and an analytical solution does not exist. Therefore, these differential equations must be solved simultaneously using a numerical method with appropriate conditions to obtain ξ and a_O as a function of y. The equation describing the material balance at the alloy-oxide interface can be employed as an auxiliary equation in this numerical analysis. Since an insignificant degree of internal oxidation occurred, the ratio for the flux of cobalt to iron in the scale at its inner interface is equivalent to the metal ratio in the bulk alloy. Equation [35] in Ref. (4) gives

$$\left(\frac{d\xi}{dy}\right)_{y=0} = \frac{k'}{a_O'^n\xi'}\left\{\frac{p'\xi' - [1 + (p' - 1)\xi']\xi_{\text{alloy}}}{p'}\right\} \quad [6]$$

where the prime refers to the inner scale surface and ξ_{alloy} is the atom fraction of iron in the alloy.

A stable fourth-order integration procedure (6) (modified Haming's predictor-corrector) was used to generate the iron concentration and oxygen activity profiles over the scale normalized thickness, $y = 0$ to $y = 1$. We have shown in our previous paper that the empirical constants relating the cation vacancy concentration to the composition and the oxygen activity of (CoFe)O at 1200°C are $\gamma = 0.60 \pm 0.11$ and $n = 0.15 \pm 0.03$. The vacancy diffusivity of cobalt was also shown to be $D_{Co}° = 1.46 \pm 0.04 \times 10^{-6}$ cm²/sec. The ratio, p, of cobalt and iron vacancy diffusivities in (CoFe)O is estimated from the Co^{60} and Fe^{55} diffusion measurements on single crystals of pure and iron-doped CoO reported by Crow (5). The interpolated relation of p *vs.* oxygen pressure from these measurements is shown in Fig. 10. A value of k' was obtained from the parabolic oxidation constant, k_p, given in Fig. 4 from the relationship $k' = \frac{k_p}{2D_{Co}°\gamma}(V/16)^2$ where V is the molar volume of the oxide. The iron profiles were calculated from Eq. [2] and [5] as an initial value problem using the auxiliary Eq. [6] to relate $(d\xi/dy)_{y=0}$ to ξ', a_O', k', and p. These calculated profiles are compared to those experimentally obtained in Fig. 7-9.

The good agreement of the calculated to the measured iron profiles substantiates the basic tenets of the ternary diffusion model. An analysis based on these concepts, moreover, leads to an explanation of the hitherto unobserved observations on the growth of a solid solution oxide scale on a binary alloy in which a metal gradient exhibits maxima dependent on the growth rate of the scale governed by the magnitude of the atmospheric oxygen activity. From the diffusional analysis, we conclude that the observed metal profiles exhibiting maxima can be calculated based upon the variation of a kinetic parameter which in this case is the ratio of the metal self-diffusion coefficients, D_{Fe}/D_{Co}. Figure 11 depicts the oxygen activity profile in the scale which monotonically increases with increasing scale thickness. One can conclude by compar-

Fig. 9. Mole fraction of FeO, ξ, as a function of normalized distance coordinate y in the (CoFe)O scales formed at 1 atm oxygen pressure: (a, left) Co-1, 4, and 8 w/o Fe; (b, right) Co-2, 6, and 10 w/o Fe.

ing the graphs of Fig. 9, 10, and 11 that iron diffused more rapidly against its own gradient than cobalt down its own concentration gradient in the inner region of a scale at low oxygen activity less than 10^{-3} atm because $D_{Fe}/D_{Co} = 1.6$. This tendency was reversed at higher oxygen activity since the above ratio of diffusion coefficients underwent a transition from 1.6 to 0.7 over oxygen activities corresponding to the

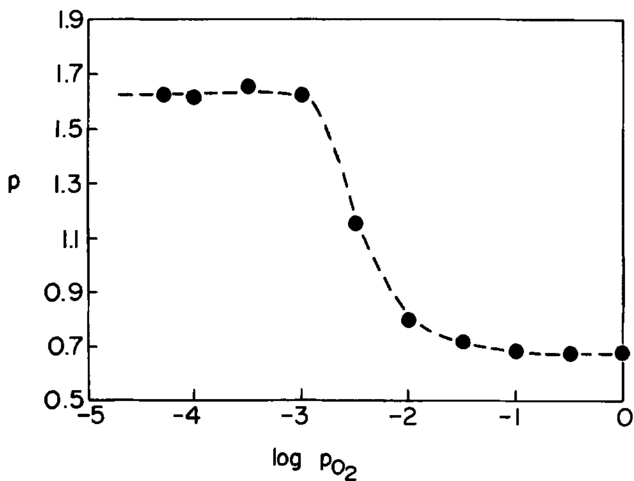

Fig. 10. Ratio of tracer diffusion coefficients of Fe^{55} and Co^{66} in single crystal CoO at 1200°C as a function of oxygen pressure.

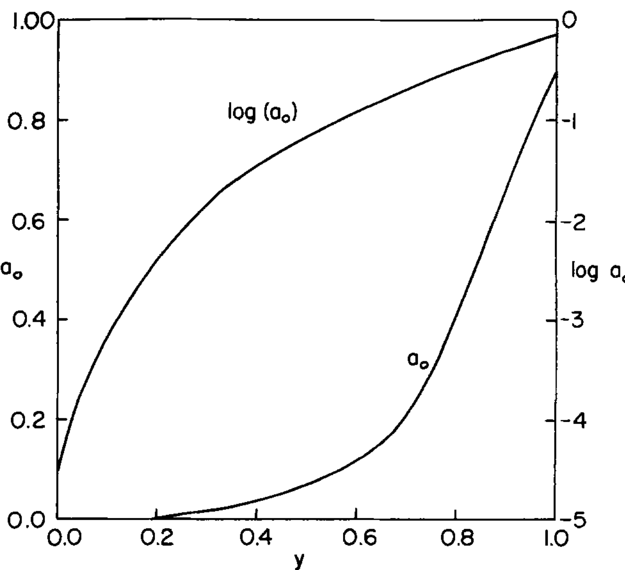

Fig. 11. Oxygen activity profile in the (CoFe)O scale formed on the Co-10 w/o Fe alloy at 1 atm oxygen pressure.

pressure range 10^{-3}-10^{-1} atm. Accordingly, more rapid cobalt diffusion and the subsequent decrease in iron concentration caused a maximum in the iron profile within a scale. The height and position of this maximum is interrelated to the kinetic diffusion coefficients and the oxygen activity gradient driving force. It is also interesting to note that the development of this maximum in the iron profile near the midpoint of a scale when the atmospheric pressure is 1 atm corresponds to a bell-shape profile.

We emphasize finally that the analysis based on ternary diffusion is to be regarded as a simplified empirical description of the oxidation properties of Co-Fe alloys under conditions for growth of a (CoFe)O scale. As illustrated in our earlier paper on this subject, a more fundamental analysis cannot be attempted until additional definitive knowledge becomes available on the structural, thermodynamic, and metal transport properties of (CoFe)O. The analysis, nonetheless, does lead to an explanation of metal profiles exhibiting maxima in an oxide scale formed on a binary alloy.

D-C Field Dependence of Tantalum Film Capacitors

Peter W. Wyatt

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

The capacitance of tantalum film capacitors changes on the order of 1% when a field of a few MV/cm is applied. It is shown in this paper that the $C(E)$ dependence of anodic Ta_2O_5 is produced by at least three separate physical processes. An equation for $C(E)$ is given in which each process is represented by one term. The effects on each process of oxide thickness, anodization soak time, counterelectrode material, nitrogen doping, heat-treatment, measurement frequency and temperature, and the rate of rise of bias voltage during measurement are discussed. It is shown that one of the processes affects the capacitance through a field-dependent bulk polarizability. The other two processes may also involve field-dependent polarizability, but there is evidence that one or perhaps both of them are produced by a change in the oxide thickness with field. A physical model for the asymmetry in $C(E)$ is proposed.

It is well known that the small-signal capacitance of Ta film capacitors depends on the d-c bias voltage (1, 2). In a previous paper (2) is was shown that the voltage, or more accurately the field, dependence at liquid nitrogen temperature is produced entirely by bulk oxide effects and not by interface effects. That is, the physical processes which cause the field dependence are distributed uniformly through the oxide thickness rather than being localized at the metal-oxide interfaces. This observation is particularly interesting in view of the asymmetry of the capacitance-field [$C(E)$] curve, since it indicates that the amorphous Ta_2O_5 dielectric must have a built-in anisotropy. In the present paper the nature of the processes which produce the field dependence is considered.

Capacitors have been made and measured with variations in several experimental parameters, described in the next two sections. The $C(E)$ curve is complicated in shape, so to characterize the dependence on these parameters the curve must be separated into components which behave in a simple fashion. An empirical equation is presented which accomplishes this separation, and it is shown that each of the three major terms of the equation represents a different physical process. The experimental results show how each process depends on the parameters which were varied. In the last section the nature of each process is discussed and a simple physical model for the anisotropy is presented.

Key words: anisotropy, anodization, amorphous.

Samples

All samples were made using standard processing (2), with modifications described below. Two sample geometries were used. The one illustrated in Ref. (2) is a planar arrangement in which none of the films is etched and no photoresist is used. In the other, which is more conventional, patterns are defined in both the Ta and counterelectrode using photoresist and the metals are chemically etched. These samples are not planar, since the edge of the Ta film is part of the capacitor area. Despite this substantial dissimilarity, no difference has been observed between the $C(E)$ curves of the two patterns.

The capacitor consists of a layer of d.c.-sputtered Ta about 3000Å thick, an anodic Ta_2O_5 dielectric

layer, and an evaporated metal counterelectrode. The substrate is glass or glazed ceramic protected by a thermal Ta_2O_5 underlay. No effect of substrate material on the capacitance-field characteristics has been observed.

The Ta film serves as one electrode and is anodically oxidized to form the dielectric. In most of these experiments it contains up to a few atomic per cent (a/o) nitrogen, added as a dopant in the sputtering gas, and has the β (tetragonal) crystal structure (3). Nitrogen is commonly added to β-Ta because it improves capacitor quality (4). In one experiment capacitors were made with nitrogen doping ranging from zero to a level sufficient to produce bcc Ta crystal structure (5).

The Ta_2O_5 was produced in all cases by anodization in 0.01 weight per cent (w/o) citric acid in water at room temperature using a Ta sheet cathode. Samples were anodized at a current density of 0.16 mA/cm^2 until a final voltage, V_f, was reached. V_f was then held for a soak period, t_s. Standard values are 230V and 1 hr, which produce an oxide 4100Å thick, but each of these parameters was varied in some experiments. For the standard values the average electric field at the end of the soak period, E_f, is 5.5 MV/cm.

The standard counterelectrode is a thin film of NiCr (500Å) backed by a thicker film of Au (5000-15,000Å), sequentially evaporated by electron-beam heating. Evaporation from resistance-heated filaments was used in one experiment, and several other metals were used.

In standard processing the samples are not intentionally heated except during several cleaning steps, where the maximum temperature is 120°C for drying in air. They are also heated by radiation from the evaporant source during counterelectrode evaporation; the temperature reached is not known. One annealing experiment was done in which the finished capacitors were heated at 200°C for times from 15 min to 4 hr.

Measurements

Capacitance-voltage data were recorded using the system described in Ref. (2). A slow linear ramp bias voltage is applied to the capacitor while the change of capacitance and phase angle is monitored with a General Radio 1654 impedance comparator. For the small values of interest the phase angle is essentially equal to the dissipation factor. The comparator uses a small a-c voltage added to the d-c bias to measure the capacitance, so that one actually measures a differential capacitance. The change in capacitance, ΔC, normalized by the zero-voltage capacitance, C_o, is recorded *vs.* voltage both on an X-Y recorder and a digital printer. The change in phase angle is simultaneously recorded on the X-Y recorder. The voltage scale is converted to average electric field, defined as $E = V/d$, using the oxide thickness, d, determined by ellipsometry.

Both the bias rise rate and the magnitude of the a-c voltage have little effect on the measurement, so precise control is not required. For 230V capacitors, 1V/sec and 1 V_{rms} were used. For other oxide thicknesses the bias rise rate was varied roughly in proportion to the thickness. The a-c voltage was reduced to 0.3 V_{rms} for the thinnest oxides. The most commonly used frequency was 1 kHz, but many samples were also measured at 0.1, 10, and 100 kHz.

The accuracy of the ΔC measurement is estimated to be about 0.01% of C_o. Random errors, such as noise, are clearly less than 0.01%. There are several known sources of systematic error, but none of them is likely to cause more than 0.01% of C_o distortion of the curve under the conditions of these measurements. An NPO ceramic capacitor measured under similar conditions exhibited essentially zero $C(V)$ dependence.

For a typical measurement the comparator is balanced at 0V d.c., the voltage ramp is started, and the change in capacitance is recorded. After a high voltage has been applied and removed, the sample remains partially polarized for a period of hours or even days. It is therefore not practical to measure a given sample more than once or, in particular, to use the same sample for both negative and positive bias voltages. Therefore, for most measurements two adjacent capacitors on the same substrate are used, one for positive and the other for negative bias.

Most samples were measured at room or liquid nitrogen temperature. Most of the analysis reported here is for measurements at 77°K, for which the capacitor was simply immersed in liquid nitrogen. A few measurements were also made of samples immersed in liquid helium at 4.2°K. A series of measurements between liquid nitrogen and room temperature were made using a Delta Design temperature chamber with liquid N_2 coolant. Temperature measurements in that case were made with an iron-constantan thermocouple, taped to the substrate, and a Leeds and Northrup potentiometer.

Empirical Model

Typical data for liquid N_2 temperature are shown in Fig. 1 (solid line). The electric field is defined as positive when the Ta electrode is positive relative to the counterelectrode. The two capacitors used for this curve (one for +, the other for −) were standard units, *i.e.*, they were made using a 230V anodization with 1 hr soak and NiCr-Au counterelectrode. The a-c signal was 1 V_{rms} at 1 kHz, and the bias rise rate was 1 V/sec.

It is evident that the change in capacitance produced by a d-c field is on the order of 1% or less, and that it is asymmetric. This asymmetry is apparent even at very low field and, as we shall see, at all temperatures and frequencies investigated.

When experimental parameters such as measurement temperature or anodization soak time are varied, this curve changes in a complex way. In order to describe these changes the field dependence must be separated into components which behave simply with the varied parameter. The means for such a separation can be developed by considering two experiments.

In the first, two groups of capacitors were made in which everything was the same except the anodization soak time. $C(E)$ curves were recorded for a pair of units from each group (remembering that the oxide thickness depends on soak time), and the difference between the two curves was calculated. This difference, for samples with 2 min and 300 min soak time, is plotted in Fig. 2. It is obviously very close to linear in the field.

Now let us consider one of the $C(E)$ curves, the 300 min one to be specific. By subtracting a straight line of the appropriate slope, corresponding to the line in Fig. 2, one finds the curve plotted in Fig. 3. The significance of this curve is that it is almost exactly symmetric in the electric field. Thus essentially all of the asymmetry of the $C(E)$ curve can be expressed by a simple linear dependence. Moreover, the physical process which produces the asymmetry is affected by the anodization soak time, while those which produce symmetric changes in C are not. Therefore they must be different processes.

The curve in Fig. 3 can be further separated by considering the frequency dependence. Nominally identical pairs of samples were measured at 100 Hz and at 100 kHz, and the difference between the two curves was calculated. This difference is shown in Fig. 4, together with its symmetric and antisymmetric parts. (The symmetric part of a capacitance curve is $[\Delta C(E) + \Delta C(-E)]/2C_o$ and the antisymmetric

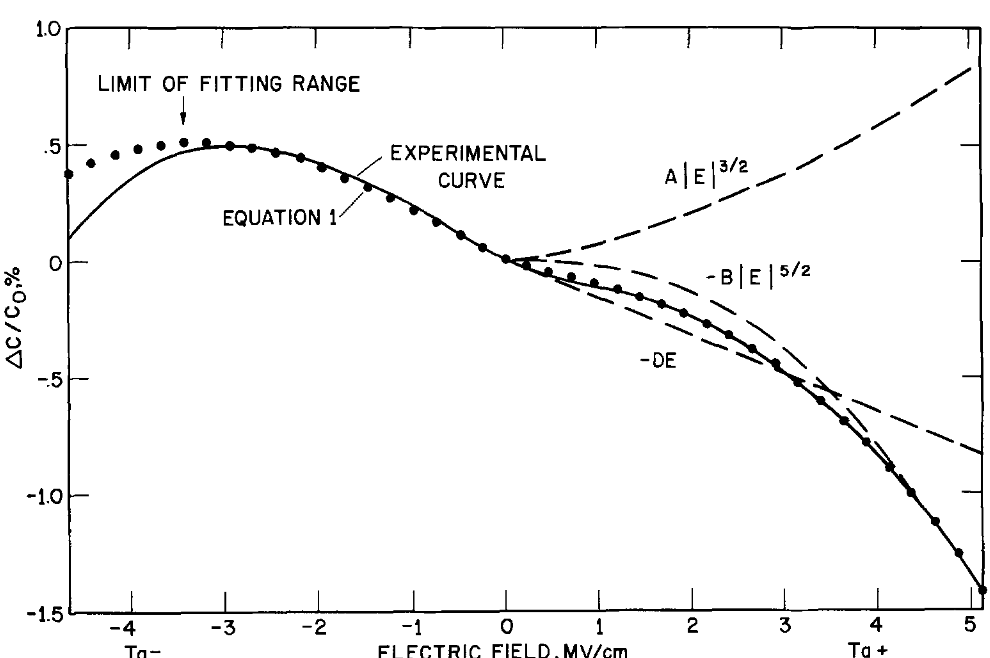

Fig. 1. Solid line: a typical $C(E)$ curve for a pair of capacitors measured at 1 kHz and 77°K. Points: calculated values obtained by fitting Eq. [1] over the field range -3.4 to $+5.0$ MV/cm. Dashed curves: the three field-dependent terms of Eq. [1].

part is $[\Delta C(E) - \Delta C(-E)]/2C_0$, defined for $E > 0$.) Comparing the symmetric part with Fig. 3, one sees that taking the difference has eliminated the decrease in ΔC at high field. By plotting the symmetric part of the difference on log-log scales in Fig. 5 one finds that it varies essentially as $E^{3/2}$. Thus there are two symmetric contributions to $C(E)$. One is an increase in capacitance as $E^{3/2}$ which is frequency dependent. The other is a decrease in capacitance which is independent of frequency, and which one finds by adjusting coefficients varied as $E^{5/2}$. By arguments directly analogous to those used in the soak time discussion, these two contributions must be produced by two different physical processes.

The above discussion can be neatly summarized in an equation for the normalized change in capacitance

$$\frac{\Delta C}{C_0} = A|E|^{3/2} - B|E|^{5/2} - DE + H \qquad [1]$$

This equation can be fit to any given experimental

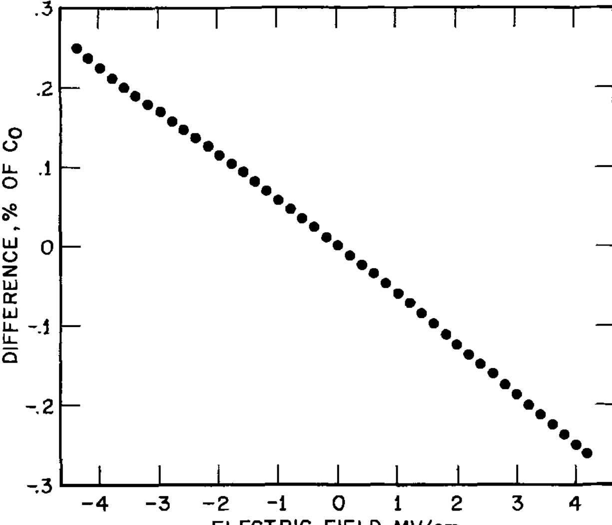

Fig. 2. $\Delta C(E)/C_0$ for samples with 5 hr soak time minus $\Delta C(E)/C_0$ for samples with 2 min soak time, plotted vs. field.

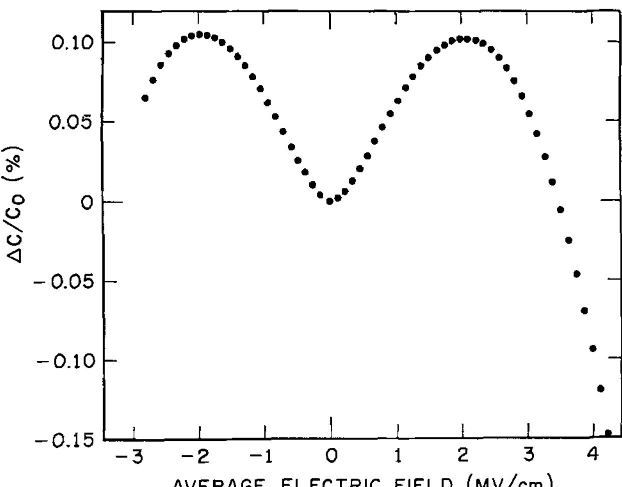

Fig. 3. $\Delta C(E)/C_0$ for one of the samples in Fig. 2 minus a straight line. The curve is nearly symmetric.

curve by adjusting the four coefficients, A, B, D, and H, using a computer library routine which weights all points equivalently. The result for one curve is shown by the dots in Fig. 1. The three field dependent terms are plotted separately as dashed lines. The constant, H, allows the $E = 0$ point to be treated equivalently with all the others and improves the fit somewhat. It is always very small and has no apparent physical significance.

It is obvious in Fig. 1 that Eq. [1] fits the data very well except at high negative field, where evidently an additional mechanism becomes important. Because of this deviation the coefficients which one finds depend somewhat on the field range used for fitting. In Fig. 1 the range used was -0.6 to $+0.9$ E_f, where E_f is the field at the end of anodization, 5.5 MV/cm. This dependence causes some confusion in data analysis, but if the same field range is used for fitting all curves in an experiment, meaningful results can be obtained. The dependence on field range is not large provided that (*i*) the negative limit is not much beyond -0.6 E_f, and (*ii*) the absolute value of the negative limit is less than the positive limit.

The importance of Eq. [1] lies in the fact that each of the field dependent terms represents a different physical process, or perhaps more than one process. The exact form of each term is less important, since one or even all of them may not be precisely correct. The three terms are very different in form: the first is positive and symmetric, the second is negative and symmetric, and the third is antisymmetric. As a result the equation allows one to separate the data unambiguously and study the contribution from each physical process independently of the others. Thus, by doing experiments in which experimental parameters are varied one can learn how each process depends on those parameters.

The dissipation factor also depends on electric field, and a similar analysis can be done. The dependence at low temperature has the form

$$\Delta DF(E) = L|E|^{3/2} - ME \qquad [2]$$

the same as Eq. [1] except that the negative symmetric term is missing. There is also an additive contribution due to electronic leakage current. The magnitude of the first term can be large; larger than the zero field value of the DF. The second term is much smaller. No attempt has been made to determine the effect on Eq. [2] of the various experimental parameters. Its significance in this paper lies in its resemblance to Eq. [1], discussed in a later section.

Experimental Results

A considerable number of parameters have been varied in these experiments. The effects of each one are summarized in Table I. The oxide thickness was considered in Ref. (2). It was shown there that when the anodization for different thicknesses is done consistently the $\Delta C/C_0$ *vs.* E curve, and hence all three coefficients of Eq. [1], are independent of oxide thickness over the range 2700-5400Å, and only very weakly dependent on thickness down to 900Å. From this result it was argued that $\Delta C(E)$ must be produced by bulk oxide effects. The soak time and frequency experiments described in the last section and in more detail below tell us that at least three such effects must be involved.

Soak time.—In the soak time experiment six Ta films from the same sputtering batch were anodized together at constant current until 230V was reached. The voltage was then held constant and samples were removed at six different times, from 0 to 24 hr. During the 24 hr soak the oxide thickness increased from 3620 to 4460Å, determined by ellipsometry. Counterelectrodes were deposited simultaneously on all six samples, and measurements were taken as usual. Equation [1] was fit to the data at 77°K, 1 kHz over the range -2.8 to $+4.2$ MV/cm. The results are shown in Fig. 6. It is evident that within the expected sample-to-sample scatter of several per cent, the coefficients A and B of the two symmetric terms are independent of soak time, t_s, as expected from the previous discussion, while the coefficient D of the antisymmetric term increases approximately as log t_s, at least for times larger than a few minutes. The sample with zero soak time, plotted to the left of the log scale, is consistent with the others. A somewhat better fit, including the $t_s = 0$ point, is obtained by setting $D = D_o \log (t_s + t_o)/t_1$), where t_1 is a

Table I. Dependence of the coefficients of Eq. [1] on the varied parameters

Parameter	A	B	D
Oxide thickness	All three coefficients nearly independent		
Increasing anodization soak time	Independent	Independent	Increases
Increasing frequency	Decreases	Nearly independent	Decreases slowly
Increasing temperature	Increases, → 0 as $T \to 0$	Independent	Increases slowly, > 0 as $T \to 0$
Increasing bias rise rate	Increases very slightly	Independent	Increases very slightly
Counterelectrode material	Large variation is probably due to different heating during counterelectrode evaporation		
Nitrogen doping of the Ta film	No effect for concentrations from <<1 to 5 a/o N in the Ta		
Heat-treatment at 200°C	Decreases	Independent	Decreases

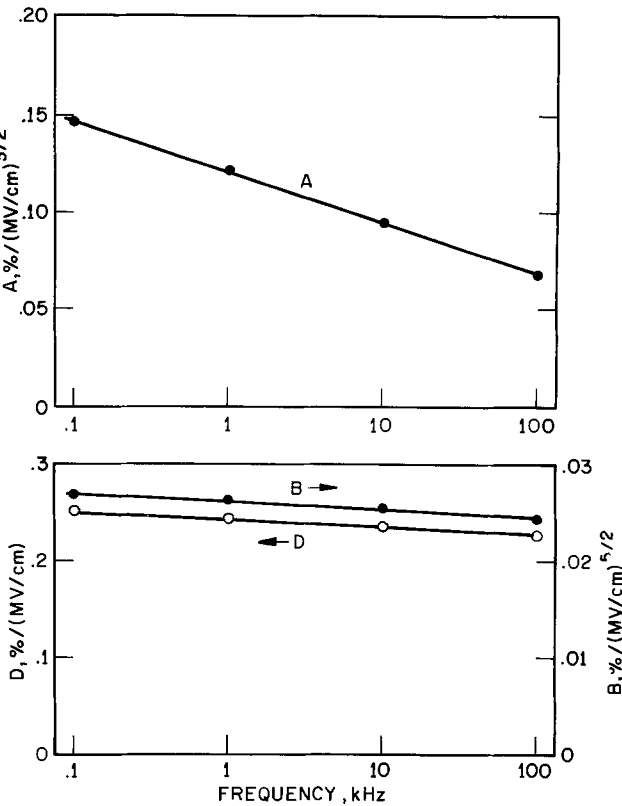

Fig. 7. Dependence of the coefficients on measurement frequency. The slope of B is often much less negative than for this sample.

constant and t_0 is about 5 min. Physically, this suggests that the effect of the soak period is also produced, to a small extent, by the constant-current part of the anodization.

Frequency.—Capacitance-field curves were measured at four different frequencies, 0.1-100 kHz. Data for a set of standard samples, recorded at 77°K and fit over the range -0.5 to $+0.75$ E_f, are shown in Fig. 7. Similar data have been recorded for many sets of samples. In all cases A varies approximately as log $(1/f)$, extrapolating to zero between a few MHz and a few tens of MHz. B, in contrast, varies only slowly if at all with frequency, usually decreasing slightly with increasing f. In some sets of capacitors it has appeared independent of f for the four frequencies measured, while in a few a slight increase occurred with increasing frequency. The difference in slope among different sets is probably due to variation among the capacitors of each set. These calculations confirm that the positive symmetric term in $\Delta C(E)$ is strongly frequency dependent, while the negative symmetric term is nearly independent of f. The coefficient, D, of the antisymmetric term always decreases with increasing frequency, but much more slowly than A.

Temperature.—The temperature dependence of the three coefficients and the rms error for measurements at 1 kHz are shown in Fig. 8. The points from 77° to 182°K are from capacitors all on the same substrate. They were fit over the range -0.5 to $+0.7$ E_f. The points at 4.2°K are from a single capacitor on a different substrate from the same processing group, fit over a different range, -0.17 to $+0.7$ E_f. Smooth curves are drawn through the points above 100°K and extrapolated somewhat arbitrarily to absolute zero. The remarkably close agreement of these extrapolations with the 4.2°K data can only be considered fortuitous in view of the difference in field range.

The 77°K points do not lie on the same curves as the higher temperature ones. Also, the fit to Eq. [1]

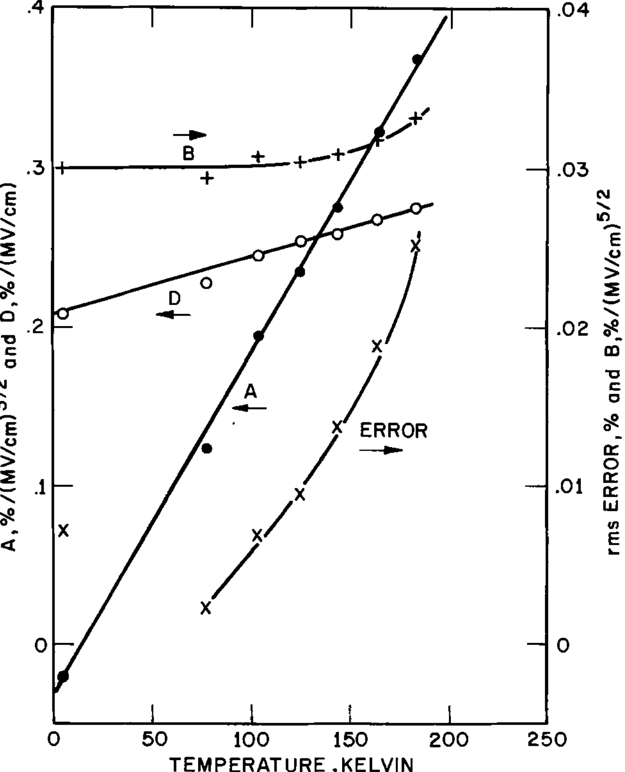

Fig. 8. Temperature dependence of the coefficients and rms fitting error of Eq. [1].

is not nearly as good at higher temperatures or at 4.2°K as it is at 77°K. The fixturing used at temperatures other than 77°K was not carefully designed and used substantial lengths of unshielded hookup wire. It is likely that this fixturing contributes to the inconsistency and possibly to the poor fit. It is also likely that temperature measurement inaccuracy and variation of temperature during the time required

to record a curve contribute additional errors at the higher temperatures.

The inconsistency of the data and the poor fit make it impossible to precisely determine the temperature dependence of the three coefficients. However, several points are nevertheless apparent in Fig. 8. (*i*) The coefficient, A, of the positive symmetric term decreases approximately linearly as the temperature is lowered, becoming very small as $T \rightarrow 0$. It is very unlikely that A actually becomes negative, as appears true in the rather poor fit at 4.2°K. (*ii*) The coefficient, B, of the negative symmetric term depends much less on temperature and does not become small as $T \rightarrow 0$. The apparent magnitude of B at the higher temperatures depends strongly on the field range used for fitting, but all reasonable ranges give approximately the same low temperature extrapolation. (*iii*) The coefficient, D, of the antisymmetric term decreases as T is lowered, but much more slowly than A does. The asymmetry clearly does not disappear at low temperature.

Equation [1] does not fit the $C(E)$ curve at room temperature, so evidently additional physical processes contribute at such higher temperatures. These probably include some interface effects as well as the bulk processes which dominate at 77°K. Unfortunately, the data for 103°-182°K are not accurate enough for precise extrapolation to room temperature.

Bias rise rate.—The rate of rise of the bias voltage during measurement has been varied from 0.005 to 0.24 (MV/cm)/sec. The usual rate is 0.024 (MV/cm)/sec. No major difference is apparent between different rise rates. The coefficients A and D tend to increase slightly with increasing rate, but the difference is not much larger than typical capacitor-to-capacitor variation.

One sample was measured using a bias voltage which increased in steps of 10-30V instead of linearly. Each voltage was held constant for 1 hr and then a data point was recorded. One finds that the curve for stepped voltage differs from the others only by an amount comparable to typical capacitor-to-capacitor variation.

Counterelectrode material.—The effect of counterelectrode material is very complicated. The materials which have been used are: NiCr backed by Au (the standard), NiCr without Au, Ti backed by Pd and Au, Au alone, Cr, and Cu. The low temperature $C(E)$ curves for all of these are qualitatively similar, and all fit Eq. [1] reasonably well. There are, however, quantitative differences as large as a factor of 1.5 between otherwise similar capacitors with different counterelectrode types. One is tempted to conclude that the counterelectrode material is responsible for these differences, but heating during deposition is a more likely cause.

Large differences in the coefficients are also found for nominally identical capacitors whose counterelectrodes were deposited in different evaporators, or to a lesser degree in the same evaporator at different times. It is likely that this variation results from different degrees of heating of the sample surface by radiation from the evaporant source, with a possible contribution by electron or ion bombardment from the source. One expects the degree of heating to be even more different for nonstandard counterelectrode materials or thicknesses, so this heating effect is probably the reason for the apparent dependence on counterelectrode material.

Nitrogen doping.—The size of the coefficients also depends somewhat on the nature of the Ta film, which may vary slightly for different sputtering runs. It is well known that other characteristics of Ta film capacitors are affected by details of the Ta film. A particularly striking example is the effect of nitrogen incorporated into the Ta. Huttemann, Morabito, and Gerstenberg (4) have shown that 1 a/o nitrogen in the Ta reduces the leakage current at 50V by several orders of magnitude. This effect has not been explained, but to take advantage of it N_2 is added to the sputtering gas for capacitor film. Even if it is not added intentionally, a small amount of nitrogen is likely to be present due to residual or leaking air in the vacuum system. When the Ta is anodically oxidized, the nitrogen is incorporated into the oxide with a nonuniform distribution (6), almost all the N atoms being in the 3/4 of the oxide nearer the Ta electrode.

Capacitors were made on Ta containing N concentrations from near zero to 4 a/o. Each group was anodized separately and had counterelectrodes deposited at different times, so that substantial differences in the coefficients, ~50%, were found even between groups made from the same lot of Ta. The dependence of the coefficients on N concentration was small compared with this large variation.

In another experiment, reported in Ref. (2), the oxide was chemically thinned after anodization. The Ta for those units contained about 1 a/o N, which as usual was incorporated nonuniformly into the oxide (7). Before thinning, the N was located only in the 60-70% of the oxide closest to the Ta. Thinning removed the N-depleted layer, so for the thinnest sample all the oxide contained some nitrogen (7). Despite this gross difference in N distribution, the $C(E)$ curves for different degrees of thinning were essentially the same as for a sample which was not thinned (2).

Thus, it is quite clear that a high concentration of nitrogen impurity centers, typically present in Ta film capacitors, is not responsible for any of the three terms in the low temperature $C(E)$ dependence. Note, however, that probably none of the samples in this experiment contained truly zero nitrogen. The possibility remains that low levels of N impurity might contribute to $C(E)$ in an effect which saturates at much less than 1 a/o.

Heat-treatment.—The last parameter investigated was the effect of heat-treatment at 200°C after complete fabrication of the capacitor. Two substrates were investigated, each containing 24 capacitors. The samples were heat-treated by placing them in an oven at 200°C for periods of 15 min-4.3 hr. The coefficients of Eq. [1] for one substrate fit over the range -0.43 to $+0.65$ E_f are plotted *vs.* heat-treatment time in Fig. 9. (Time $= 0$ is plotted at the left of the logarithmic scale.)

Before any heat-treatment the $C(E)$ curves for capacitors of the two substrates were very different from each other, and on the one shown there were substantial differences from capacitor to capacitor. The two sets of points plotted at time $= 0$ indicate the difference for two pairs of capacitors. After heat-treatment for as short a time as 15 min, the samples became essentially identical and there was no longer any variation among capacitors on either sample. It is evident from Fig. 9 that heat-treatment at 200°C causes a decrease in magnitude of the positive symmetric term, A, and the antisymmetric term, D, of $C(E)$. The negative symmetric term, B, in contrast, is unaffected.

Discussion

The experimental results summarized in the last section and in Ref. (2) constitute a sizable body of information about the behavior of Ta film capacitors. They demonstrate that at least three bulk processes contribute to the $C(E)$ dependence at low temperature and that interface processes do not contribute significantly. They tell us much about the nature of the three processes, although it is still not possible to specifically identify the physical mechanisms involved. In this section, the behavior of the three processes,

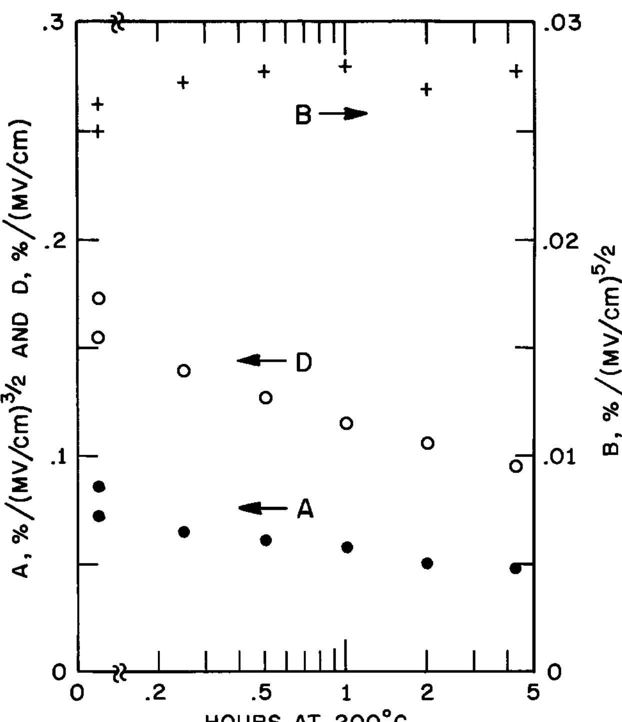

Fig. 9. Effect on the coefficients of heat-treatment at 200°C

each represented by a term in Eq. [1], is summarized and possible physical mechanisms are discussed.

Positive symmetric term.—The first term has the form $A|E|^{3/2}$, representing an increase in capacitance with increasing field. Its magnitude is frequency dependent, so the change in capacitance must be due to a change in polarizability rather than changes in thickness or area. The magnitude increases as the temperature is raised or the frequency is lowered. This change is in the same direction as for a Debye-type polarization. However, the form of the dependence is $A \propto \log(1/f)$ and (approximately) $A \propto T$, which is entirely different than the form for a single relaxation time. Hence, one must assume that the modes which are responsible for this part of the polarizability are distributed over a wide range of relaxation times. Each mode contributes to the polarizability for frequencies much lower than the inverse of its relaxation time and not for frequencies much higher. For frequencies near the inverse of its relaxation time, the mode contributes to the field dependence of the dissipation factor, producing the dominant $|E|^{3/2}$ term in $DF(E)$. The fact that the distribution of inverse relaxation times extends to rather low frequencies, 100 Hz or less, indicates that ionic motion is involved.

The magnitude of this term is reduced by heat-treatment at 200°C. This suggests that the polarization in question is associated with defects, that is, local instabilities which are annealed out at high temperature. One might expect that purely structural defects, involving unstable arrangement of Ta and O ions, would be reduced by a long anodization soak time, since the ionic current drops by a large factor during the soak period. However, we have seen that the positive symmetric term is not affected by the duration of the soak period. Hence it is plausible, though by no means proven, that impurities may be responsible for this polarization. Nitrogen, which is present in the films, is not a candidate unless the effect saturates at low concentrations.

Negative symmetric term.—The second term in Eq. [1], $-B|E|^{5/2}$, represents a decrease in capacitance with increasing field. Reference to Table I yields the surprising result that this term is independent of every parameter which we have investigated within the accuracy of the determination. This independence suggests that the process involved is a fundamental property of anodic Ta_2O_5, not affected by impurities or other defects. There is no corresponding term in the field dependence of the dissipation factor.

Cornish and Young (8) have reported a similar phenomenon at visible light frequency and room temperature. They used an ellipsometer to study the index of refraction and thickness of an anodic Ta_2O_5 film on single crystal bulk Ta with a sulfuric acid counterelectrode. They found that under an applied d-c electric field the oxide becomes uniaxially anisotropic, that both indices of refraction decrease, and that the oxide thickness increases. (The latter is in addition to any growth due to further anodization.) Both of these changes are proportional to the square of the electric field. The index of refraction is, of course, just the square root of the high frequency dielectric constant, so both of these changes with field would result in a high frequency capacitance decreasing as E^2.

The changes reported by Cornish and Young are in the same direction and of similar magnitude to the negative symmetric term observed in the present work. The form is not quite the same, but Young has indicated (9) that a 5/2 dependence might fit the optical data adequately. In similar ellipsometric work with a liquid counterelectrode, discussed further in the next subsection, Wang and Ord (10) have found that the index of refraction and oxide thickness do not vary simply as E^2. So it is quite possible that the negative symmetric term is the same effect as that which Cornish and Young observed at a frequency 10^{12} times higher. Repeating the ellipsometric measurements at several other temperatures would probably show whether the two effects are the same. If so, the changes in thickness and index of refraction should be independent of temperature.

If the two observations are in fact the same, then clearly the nonlinearity in the dielectric response must be produced by electronic polarizability. Cornish and Young (8) have suggested five general mechanisms which might produce the optical effect. The first two, a direct modification of the electronic polarizability by the d-c field and an indirect modification of it due to small ionic displacements, are consistent with the present experiments. The last three, however, involve redistribution of ions or electrons or creation of defects, all of which would be very much slower at 77°K than at room temperature. Thus, while these mechanisms may explain the slow part of the ellipsometric results, they cannot explain the present results.

Antisymmetric term.—The third term in Eq. [1], $-DE$, expresses the asymmetry of $C(E)$. The fact that it is linear means that $\Delta C(E)$ approaches zero at $E = 0$ with a finite slope. Thus the physical mechanism responsible for the asymmetry is active even at low fields. This rules out any mechanism involving emission of carriers either from the electrodes or from bulk traps, since such processes involve an exponential field dependence and are negligible at low field. The linear dependence also indicates that the asymmetry does not result from anisotropy induced by the field, such as the uniaxial anisotropy reported by Cornish and Young (8). Rather, the anisotropy is already present, frozen into the oxide.

The antisymmetric term varies with frequency and temperature in the same direction as the first term of Eq. [1], but more slowly. Unlike the first term, it does not become small as the temperature approaches zero. Its magnitude is reduced by heat-treatment, but increased by increasing anodization soak time.

Cornish and Young (8), as discussed above, found that the oxide thickness and index of refraction vary as E^2 for positive fields, a form which is not likely to be asymmetric. Wang and Ord (10), however, found that a linear term had to be added in order to fit their data. The thickness increase and index decrease could be fit equally well by $AE + BE^2$ or $A'E + B'E^3$. Obviously, one would expect $A''E + B''E^{5/2}$, which matches the second and third terms of Eq. [1], to fit just as well. A crude comparison with some of Wang's data indicates that both terms are of the same order of magnitude in the two experiments. So there is a strong possibility that Wang and Ord are seeing with visible light the effects which produce both the negative symmetric and antisymmetric terms at audio frequencies. There is still, however, considerable doubt that the two observations are the same due to the apparent conflict between the two ellipsometric experiments (8, 10). The question of whether there is asymmetry in those measurements needs to be resolved. Ideally one would like to do the ellipsometric experiment using a transparent solid film counterelectrode so that reverse fields could be applied. In such an experiment any asymmetry would be immediately apparent, even at low fields.

If the thickness does in fact change linearly with field, it means that the amorphous oxide is piezoelectric, a remarkable result. If, in contrast, further ellipsometric work shows that there is no such dependence, then the asymmetry in $C(E)$ at audio frequencies indicates an asymmetric polarizability, a result which is also rather surprising. A simple physical model for such a polarizability is discussed in the remainder of this section.

Anodic Ta_2O_5 grows by transit of Ta and O ions through the existing oxide. From the point of view of an individual ion the amorphous oxide appears as an irregular set of possible occupation sites separated by potential barriers. These sites and barriers are formed by other ions, which are themselves capable of moving, so one must think of this as an instantaneous picture of a dynamic situation.

Because the oxide is amorphous, the barriers and occupation sites are not all the same. Some will have a much higher potential barrier on one side than on the opposite side. An ion which lands in such a site will tend to remain there much longer if the higher barrier is on the downfield side, *i.e.*, in the direction of current flow for the ion in question, than if the lower barrier is on the downfield side. Pringle (11) has suggested as a result of work with radioactive tracers that the charge transfer event does not consist simply of one ion jumping between adjacent sites, but rather involves simultaneous motion of a group of both Ta and O ions. If this picture is correct, then when an ion leaves its site the surrounding ions are rearranged and the symmetry of the site is likely to be changed. A site with a low barrier downfield is more likely to lose its occupying ion than other sites, and therefore is more likely to be rearranged. Thus its lifetime is shorter, and in equilibrium the density of such sites is expected to be less than that of sites with a high barrier downfield. In this way a preferred orientation of asymmetric sites might be formed.

This picture can be made more explicit for a highly simplified case. We consider asymmetric sites only, and assume that there are only two types, those with the high barrier downfield (h) and those with the low barrier downfield (l). We further assume that when an ion leaves its site the disturbance is sufficient to completely rearrange the site so that the two orientations are equally likely.

In equilibrium, at a fixed ionic current density, the number of sites of each orientation being created must equal the number being destroyed. We have assumed above that the two types of sites are created at the same rate, so in equilibrium they must be destroyed at the same rate. The rate of destruction of each type, R, is equal to the emission probability for that type, P_h or P_l, times the density, N_h or N_l

$$R = P_h \times N_h = P_l \times N_l \qquad [3]$$

The density of each type of site must adjust itself in consideration of the difference in emission probabilities to produce this equality.

The emission probabilities, according to the usual simple model of hopping from site to adjacent site, are

$$P_{h(l)} = P_o \exp - (aW_{h(l)} - bE)$$

where $W_{h(l)}$ is the height of the high (low) barrier and P_o, a, and b are constants. Combining these equations shows that in equilibrium the difference in density of high and low sites is

$$\Delta N = N_h - N_l = \frac{R}{P_o}(e^{aW_h} - e^{aW_l})e^{-bE} \qquad [4]$$

So, indeed, a preferred orientation of asymmetric sites is formed, with the degree of orientation dependent on the degree of asymmetry. In the real oxide, of course, sites will have some distribution of degrees of asymmetry.

The response to an electric field of an ion in an asymmetric site is asymmetric. As a simple, one dimensional, classical example, consider a potential of the form $V = ax^2 + bx^3$, where a and b are both positive and we are interested only in small displacements. This potential has a minimum at $x = 0$, rises rapidly for $x > 0$, and rises more slowly for $x < 0$. Thus the preferred orientation of the preceding discussion is with $+x$ in the downfield direction.

Applying a d-c electric field, E, adds a term $-Ex$ to the potential, where $E > 0$ is parallel to the anodization field and $E < 0$ is antiparallel to it. The ion occupying this potential well is centered at the potential minimum, which is

$$x_o = [-2a + (4a^2 + 12bE)^{1/2}]/6b$$

The small signal polarizability, which is essentially what is measured in these experiments, is proportional to the rate of change of x_o with respect to E. That is

$$\text{polarizability} \propto dx_o/dE = (4a^2 + 12bE)^{-1/2}$$

For small displacements all but the first order term can be neglected, and we have

$$\text{polarizability} \propto (1 - 3bE/2a^2)/2a$$

This polarizability is obviously asymmetric, and for a potential with the preferred orientation it is smaller for positive field than for negative. One expects to find in the amorphous oxide a wide range of degrees of asymmetry and sites with all orientations. But if there is a preference for one orientation due to the mechanism described above, then polarization of these sites will produce a $C(E)$ curve with the observed asymmetry.

Now let us compare this model with the experimental results. The proposed polarization involves ionic motion so its speed is limited to about phonon frequencies, which are slower than visible light frequency. Therefore its absence in the Cornish and Young (8) experiment is expected. (Of course this conflicts with the Wang and Ord (10) result.) It is not temperature activated, so it should remain observable at very low temperature, in agreement with experiment. The polarization discussed above, however, would be independent of temperature and frequency, which does not agree with experiment, since the antisymmetric term does have a small dependence on those parameters. It is possible that quantum

effects could provide the required dependence, since an ion in a fixed potential well does not simply sit at the point of minimum potential. It is distributed over a small volume, and its average position in an asymmetric potential depends on its energy level which in turn depends on the temperature. Alternatively there could be more complex occupation sites, involving multiple minima separated by very low barriers, as discussed by Argall and Jonscher (12) for silicon oxide. So while the temperature and frequency dependence do not agree with this model in its simplest form, that does not necessarily invalidate the idea.

One would expect that exposure to a high temperature would, through diffusion, reduce the degree of preferred orientation of asymmetric sites and the asymmetry of the sites themselves. Thus heat-treatment should reduce the asymmetry of $C(E)$, in agreement with experiment.

The effect of anodization soak time is not so obvious. During the soak period the oxide continues to grow, so the electric field and hence the ionic currents decrease. One might expect the density of asymmetric sites to change due to that decrease. Unfortunately one cannot predict with any certainty the form or even the direction of such a change. This prediction would be a key test of the physical ideas of this model, but it would require a much more sophisticated treatment of the anodization process.

To summarize, a highly simplified, qualitative model for the asymmetry of $C(E)$ has been discussed, based on the dynamics of the anodization process. It assumes that the asymmetry is not present at optical frequency, which agrees with the work of Cornish and Young (8) but conflicts with that of Wang and Ord (10). The model is not sufficiently detailed to allow precise derivation of the dependence on various experimental parameters. It agrees with the presence of asymmetry in $C(E)$ at very low temperature and with the reduction in asymmetry due to heat-treatment. It does not explain in its simplest form the small frequency and temperature dependence of the asymmetry, but it is quite possible that this disagreement is due to oversimplification in the model, so it does not indicate that the physical idea is wrong. The model is not sufficiently sophisticated to predict a soak time dependence.

Summary

The dependence of small-signal capacitance on d-c electric field at low temperature has been shown to be produced by at least three separate physical processes, all of which are bulk oxide effects (2). The first one causes the capacitance to increase as $|E|^{3/2}$ when a field is applied. The data are consistent with a set of polarizations which require thermal activation and which have relaxation times corresponding to frequencies broadly distributed throughout and beyond the range 100 Hz to 100 kHz. It is likely that these polarizations are associated with defects in the oxide.

The second process causes the capacitance to decrease approximately as $|E|^{5/2}$. This process appears to be an inherent property of anodic Ta_2O_5, since its magnitude is not affected by any of the varied parameters. It is likely, though not certain, that this is the same effect observed in ellipsometric measurements (8-10). If it is the same, then it is produced by an increase in oxide thickness with increasing field and an associated decrease in dielectric constant.

The third process produces the asymmetry in $C(E)$ and is approximately linear in the field. It indicates that the amorphous oxide has a built-in anisotropy. It may be the same effect observed in one ellipsometric experiment (10), in which case the oxide is apparently piezoelectric. But if another ellipsometric experiment (8) is correct, then the asymmetry must be a measure of a nonlinear polarizability produced by ionic motion. Such a polarizability would result if ions are located in asymmetric sites which are preferentially oriented. A crude model was introduced to show how the dynamics of anodization might produce such a preferred orientation. This model agrees qualitatively with some of the experimental results, but a much more sophisticated version of it would be required to show whether the physical picture involved is consistent with other results.

Acknowledgments

Thanks are due to W. P. Wang for providing some of his ellipsometric data and to L. Young for useful discussions.

Preferential Etching of GaAs Through Photoresist Masks

Mutsuyuki Otsubo, Takao Oda, Hisao Kumabe, and Hidejiro Miki

Mitsubishi Electric Corporation, Central Research Laboratory, Itami, Hyogo, Japan

ABSTRACT

The citric acid-hydrogen peroxide-water system has been developed for preferential etching of GaAs through photoresist masks. Etching rates depend strongly on the composition of the solution and on the crystal orientation of GaAs, with the rates in the order (111)B > (100) > (111)A. Flat-bottomed holes were obtained for all compositions of the solutions. The solution does not erode photoresist masks, thereby providing preferential etching of GaAs through such masks.

Significant progress in GaAs materials and device technology has been made such that it is now possible to produce reliable n-type GaAs Schottky-barrier field-effect transistors (MESFET's) with gate length of 1 μm (1-3).

The active layer thickness of n-type GaAs MESFET's should be controlled with an accuracy of several hundred angstroms in order to adjust the pinch-off voltage. GaAs MESFET's are usually fabricated by a lift-off technique (4) in which the GaAs surfaces are chemically etched slightly through photoresist masks in order to clean the surfaces before evaporation of the metals. For this purpose, the etching solution should satisfy the following conditions: (*i*) It should have a slow etching rate; (*ii*) it should not erode the photoresist masks; and (*iii*) it should provide flat etching profiles when the crystals are etched through windows in photoresist masks.

Many etching solutions have been developed during the years. Most commonly used of these are the H_2SO_4-H_2O_2-H_2O solution (5-6), the Br_2-CH_3OH solution (7-8), the NaOH-H_2O_2-H_2O solution (9), and the NH_4OH-H_2O_2-H_2O solution (10-11). Since these all tend to erode photoresist masks, however, they cannot be used for preferential etching of GaAs crystals through photoresist masks.

In the present experiments, a new etching solution composed of citric acid [$C_3H_4(OH)(COOH)_3 \cdot H_2O$], hydrogen peroxide ($H_2O_2$), and water has been developed for preferential etching of GaAs crystals through windows in photoresist masks. In this paper, the etching characteristics of GaAs crystals in this newly developed solution are described.

Experimental

Etching solution.—The $C_3H_4(OH)(COOH)_3 \cdot H_2O$-$H_2O_2$-$H_2O$ solutions were prepared by mixing 50 weight per cent (w/o) $C_3H_4(OH)(COOH)_3 \cdot H_2O$ aqueous solution and 30 w/o H_2O_2 prior to each etching experiment. The composition of the etching solution was varied by changing the proportions of 30 w/o H_2O_2 and 50 w/o citric acid; the ratio (by volume measure) of citric acid to H_2O_2 is defined by the parameter k, which was varied between 0.1 and 100 over the course of our experiments. The chemicals used were all of reagent grade. The temperature of the solution was varied between 5° and 55° ± 0.5°C.

Sample.—The physical and electrical properties of GaAs crystals used in the etching experiments are summarized in Table I. These wafers were sliced within 1° of the low-index planes and then lapped with 4000 mesh alumina abrasive. After being degreased and rinsed they were chemically etched in a 10% Br_2-CH_3OH solution for 30 sec at room temperature and finally etched in a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution for 60 sec at 60°C prior to the etching experiments.

Key words: field effect transistors, compound semiconductors, citric acid, etching rate.

Table I. Physical and electrical properties of the samples used in these experiments

Sample	Crystal	Growth method	Dopant and type		Orientation	Carrier concentration (cm^{-3})
A	GaAs	LEC	Sn	n	100	1.0×10^{18}

J	GaSb	H.B	None	p	100	2.0×10^{16}

Photoresist masks.—A photoresist (AZ-1350 and/or OMR) was coated on the crystal surface, and rectangular windows, set parallel to the [110] directions, were cut into the masks by using standard photoresist techniques. The [011] and [0$\bar{1}$1] directions in the (100) plane were distinguished with aid of Sirtl's etch figures as demonstrated in GaAs crystals (8, 12).

Etching rate.—Etched depth was measured from a step height between an etched and unetched surface by using Dektak (manufactured by Sloan Corporation). Average etching rate was calculated by dividing the measured depth by the elapsed etching time. The accuracy of the measurement was about 100Å.

Results and Discussion

Composition dependence of the etching rate.—Figure 1 shows the dependence of the average etching rate on solution composition, k, for (100) planes of GaAs (sample A) etched for 10 min. The solution was kept at 24°C during etching experiments. In Fig. 1, the volume ratio of 50 w/o $C_3H_4(OH)(COOH)_3 \cdot H_2O$ aqueous solution to 30 w/o H_2O_2, k, was chosen as a variable. Open and closed circles denote the etching rates as the etching was carried out with and without stirring, respectively. For low values of k, the etching rates increased with increasing k in both cases and reached a maximum value of 100 Å/sec at $k = 2$. The average etching rate then decreased with k increasing still further. No stirring effects were observed for solutions with $k > 2$. On the other hand, the etching rates considerably increased by stirring the solutions with composition $k < 2$. These curves show that the factors controlling the etching are different in the two compositional regions. It is desirable to use the solutions with composition $k > 2$ in order to control the etched depth precisely and to eliminate stirring as a vari-

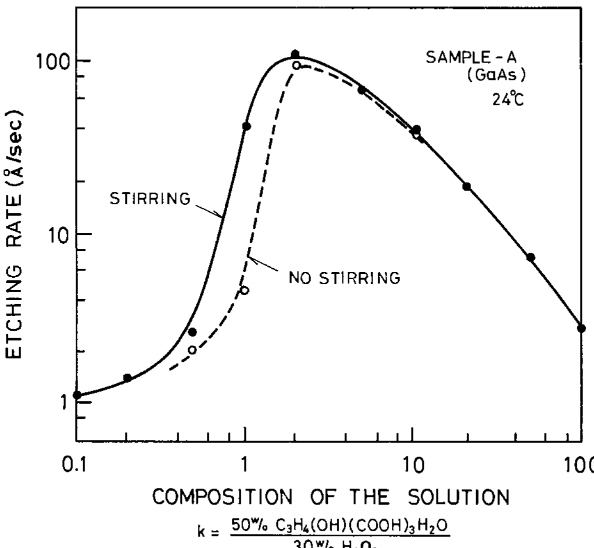

Fig. 1. Composition dependence of the etching rates for a sample A. ●, Stirring; ○, no stirring.

able in the etching process. For the fabrication of GaAs MESFET's, the slow etching rates demonstrated in Fig. 1 are highly desirable.

Etching rates of 1 ~ 4 Å/sec were obtained in the solution with $k < 1$ and $k > 30$, such slow rates are also desirable for profiling the characteristics of thin films such as epitaxial layers for GaAs MESFET's, ion-implanted layers, and diffused layers. To date, anodic oxidation techniques have often been used for such evaluation (13-14).

Temperature dependence of the etching rate.—Figure 2 shows the temperature dependence of the etching rates in the solution with $k = 10$ on three kinds of III-V compound semiconductors. In this experiment, InSb and GaSb were also etched in order to decide whether the etching process is reaction limited or diffusion limited. The etching rates increased exponentially with increasing etching temperature in all cases. The activation energies were obtained to be 11.2 kcal/mole for GaAs (sample A), 11.1 kcal/mole for InSb (sample I), and 12.7 kcal/mole for GaSb (sample J). The etching shows markedly different etching rates on these crystals. No stirring effects were observed on the GaAs crystals (sample A) in the solution, and the etched depth increased linearly with etching time as shown in Fig. 3. From the different etching rates, we conclude that the etching process in the solution with $k > 2$ is chemical reaction rate limited.

Figure 4 shows the temperature dependence of the etching rates for the GaAs sample A in the solution with $k = 1$. Considerable stirring effects were observed. That is to say, the etching rates and the activation energy were increased when the solution was violently stirred. The activation energies obtained were 15.3 kcal/mole in the stirred solution and 8.4 kcal/mole in the unstirred solution. This suggests that a diffusion-controlled rate-limited process participates in the etching process for the solution with $k = 1$. Relation between etched depth and etching time in the solution with $k = 1$ for sample A is shown in Fig. 5. The etched depth did not increase linearly with etching time, in contrast to that for the solution with $k = 10$. If the etching process in the solution with $k = 1$ is controlled by a diffusion rate-limited process, the etched depth should increase in proportion to the square root of the etching time. Since this was not observed (as shown in Fig. 5), the etching process in the solution with $k = 1$ is probably controlled by both a reaction rate-limited process and a diffusion rate-limited process.

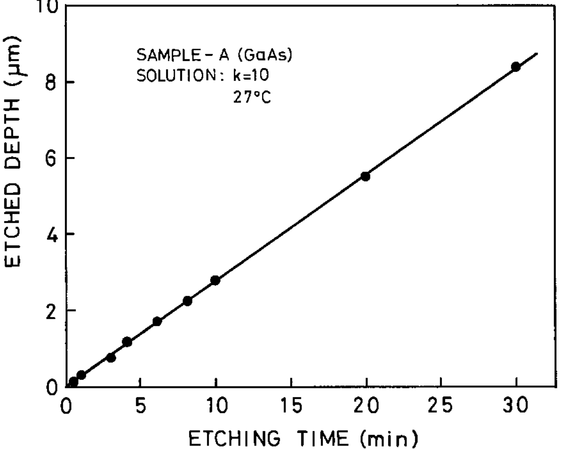

Fig. 3. Relation between etched depth and etching time in the solution with $k = 10$ for sample A.

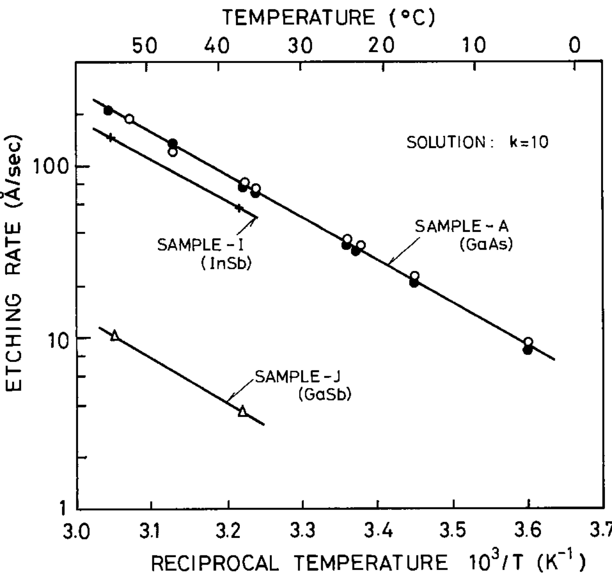

Fig. 2. Temperature dependence of the etching rates for GaAs (sample A), InSb (sample I), and a GaSb (sample J) in the solution with $k = 10$.

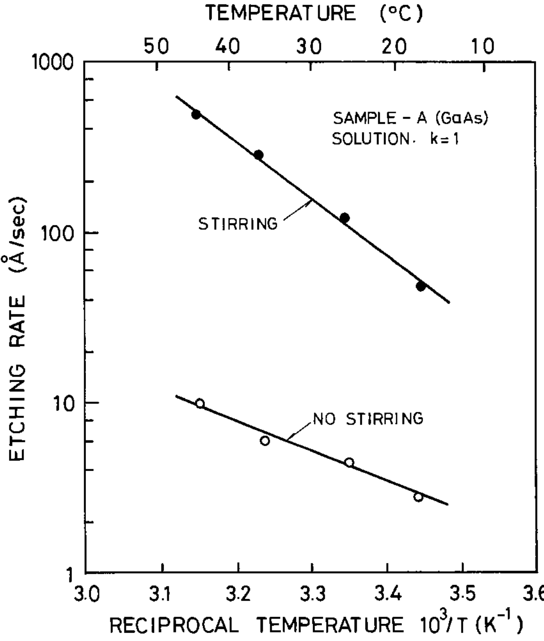

Fig. 4. Temperature dependence of the etching rates in the solution with $k = 1$ for sample A.

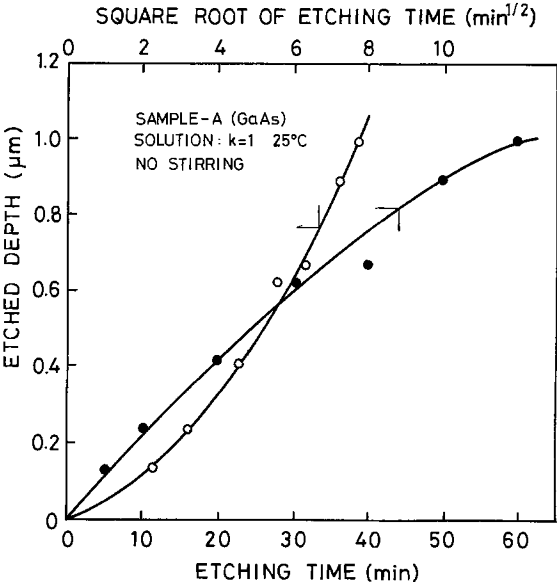

Fig. 5. Relation between etched depth and etching time in the solution with $k = 1$ for sample A.

Orientation dependence of the etching rate.—Figure 6 shows the temperature dependence of the etching rates for the solution with $k = 10$ for three different GaAs crystallographic planes. The order of magnitude of the etching rates was (111)B > (100) > (111)A. The etching rates on the (111)A surface were about 60% of that on the (100) surface and were the smallest of all surfaces investigated. The activation energies obtained for each of these planes were about the same (11.2 kcal/mole). This also indicates that the solution with $k = 10$ is controlled by a reaction rate-limited process.

GaAs crystals with different doping concentration and with different dopants (as shown in Table I) were etched in the solution with $k = 10$ at 29°C for 10 min. No doping concentration dependence was observed within our experimental conditions.

Etching profile.—The exposed GaAs surfaces defined by a photoresist mask (AZ-1350), whose geometry was shown in Fig. 7(a), were etched in the solution with $k = 10$ at room temperature. The etching profiles were examined by cleaving the wafer along [011] and [011] directions. The etching profiles are demonstrated in Fig. 7(b)-(d). Figure 7(b), (c), and (d) show the cross section cleaved along [011] and [0$\bar{1}$1] directions,

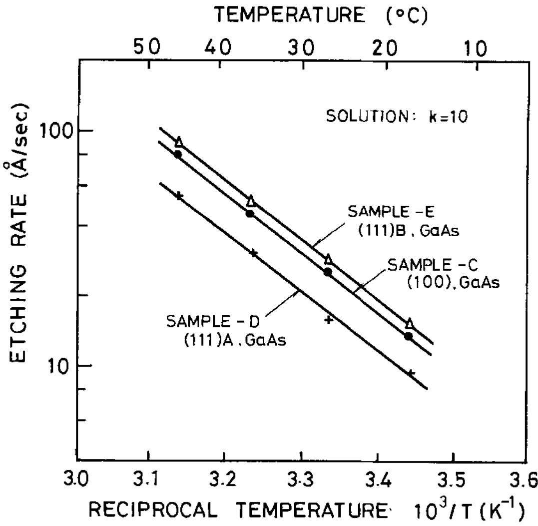

Fig. 6. Orientation dependence of the etching rates in the solution with $k = 10$.

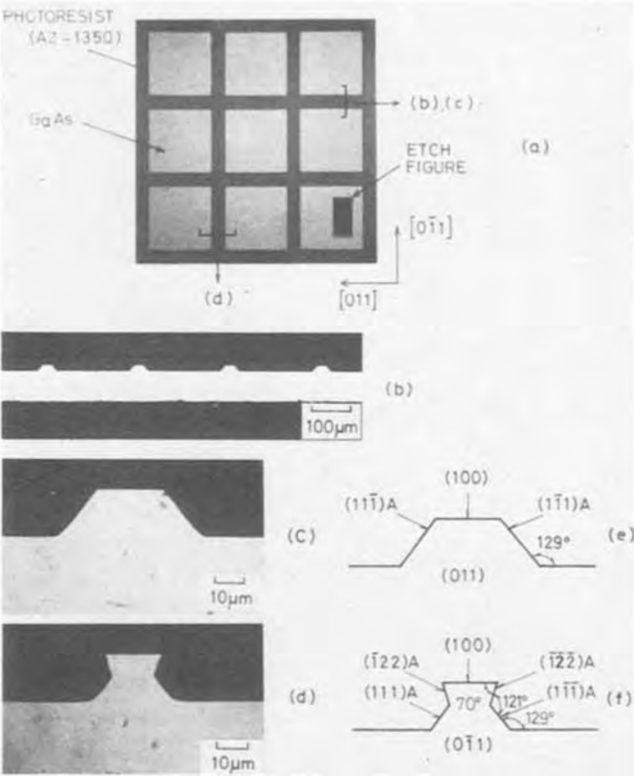

Fig. 7. Typical etching profiles on the cross section cleaved along [011] and [0$\bar{1}$1] directions for sample A (GaAs). The sample surfaces defined by a photoresist mask (AZ-1350) were etched in the solution with $k = 10$.

respectively. Flat-bottomed holes were obtained for all compositions of the solutions, as shown in Fig. 7(b).

A trapezoidal structure was formed on the cross section cleaved along [011] direction. These etching profiles were thought to occur due to the difference in the etching rates between (111)A planes and the other planes, as demonstrated in GaAs crystals etched with Br_2-CH_3OH solution (8), H_2SO_4-H_2O_2-H_2O solution (6), and NH_4OH-H_2O_2 solution (11).

On the other hand, the etching profiles for the cross section cleaved along the [0$\bar{1}$1] direction were a hand-drum shaped structure, resembling a Japanese "tsuzumi," which was asymmetrical to that for cross sections cleaved along the [011] direction. The etching profiles also were different from that obtained by etching the (100) GaAs crystals in Br_2-CH_3OH (8), H_2SO_4-H_2O_2-H_2O (6), and NH_4OH-H_2O_2 solutions (11), where reverse mesa-shaped structures were obtained. The observed angles and the most probable planes deduced from these angles are shown in Fig. 7(e) and (f). These planes are (1$\bar{1}$1)A and (11$\bar{1}$)A on [011] cross section and (1$\bar{1}\bar{1}$)A, ($\bar{1}2\bar{2}$)A, (111)A, and ($\bar{1}$22)A on [0$\bar{1}$1] cross section.

Although the differences in our etching profiles and those observed for a Br_2-CH_3OH solution (5) are not clear, it is possible that these differences are due to the differences in the planes and the etching ratio (100)/(111)A for both solutions.

Erosion of photoresist.—The erosion of the photoresist used as a mask in the preferential etching of GaAs crystals with the $C_3H_4(OH)(COOH)_3 \cdot H_2O$-$H_2O_2$-$H_2O$ solution was investigated to compare it with that used for etching with the H_2SO_4-H_2O_2-H_2O system. GaAs MESFET patterns were defined by a standard photoresist technique with AZ-1350, which is a positive-type photoresist, and with OMR, which is a negative one. The exposed GaAs surfaces were etched 5000Å. The times to etch 5000Å are 2.5 min for the

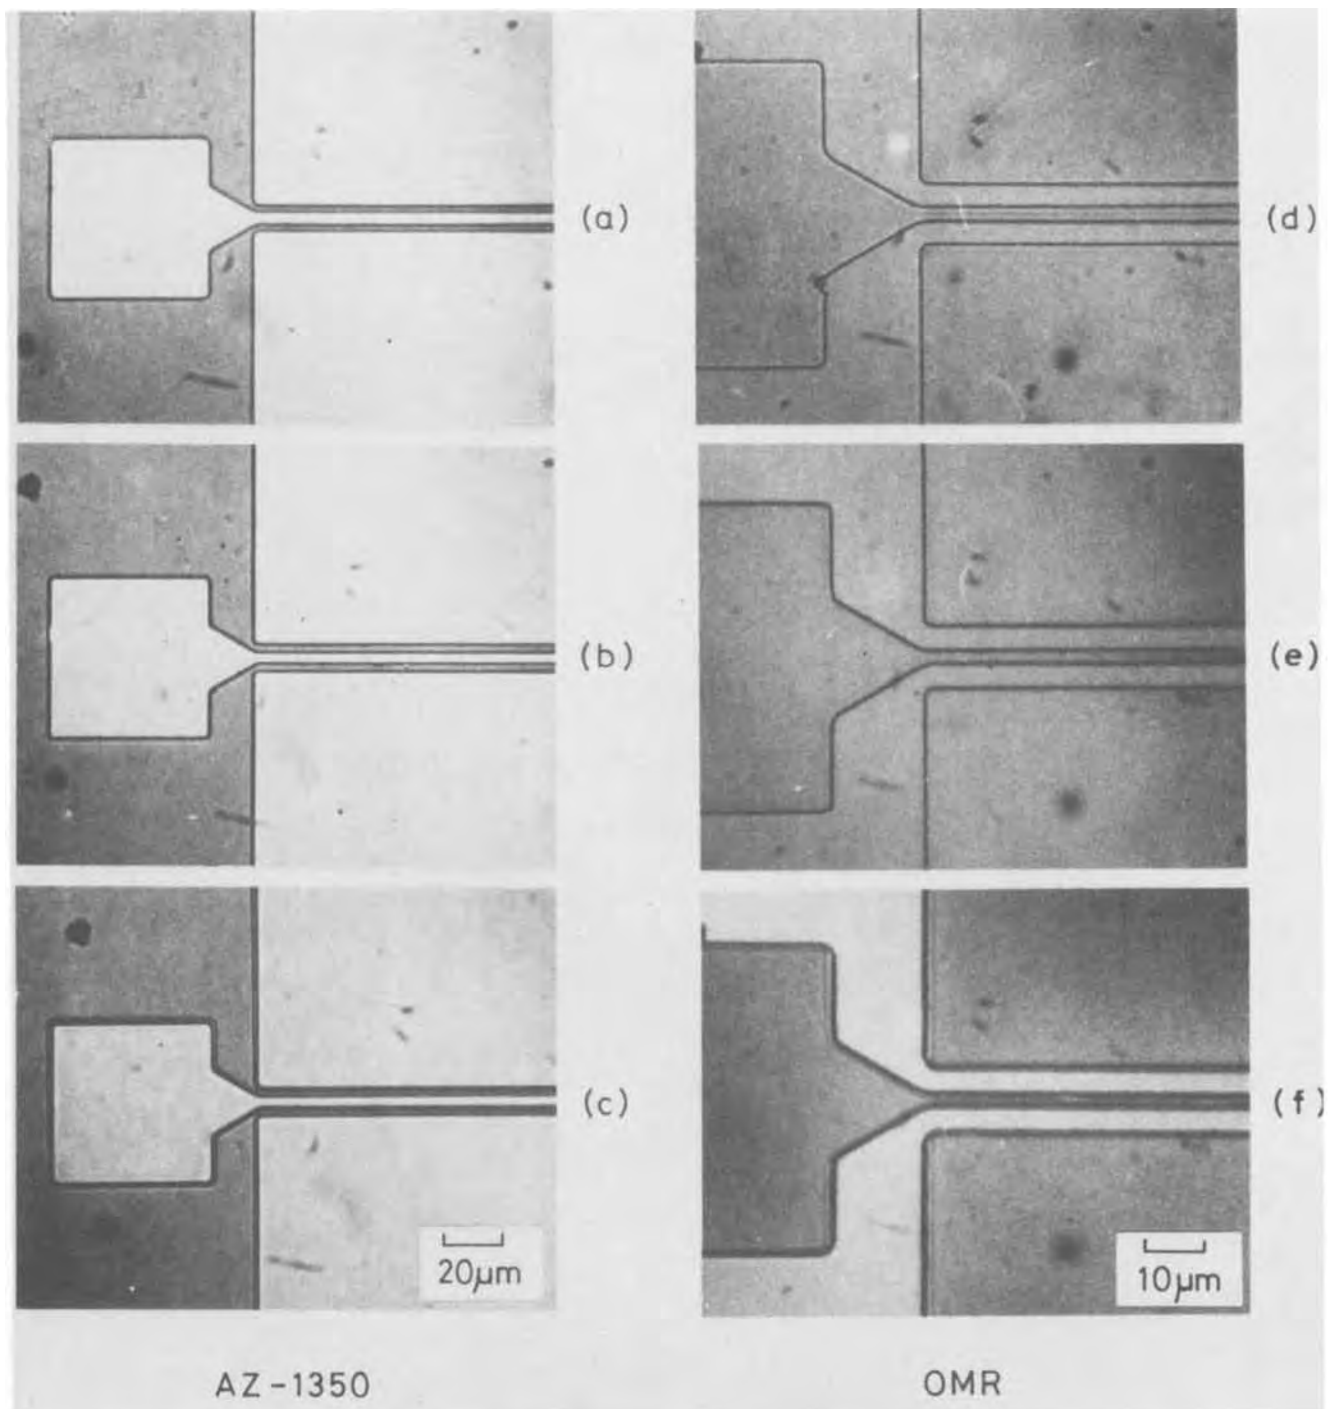

Fig. 8. Comparison of erosion of photoresist masks [(a)-(c) for AZ-1350, (d)-(f) for OMR] due to etching with the $C_3H_4(OH)(COOH)_3 \cdot H_2O$-$H_2O_2$-$H_2O$ system and the $3H_2SO_4$-$1H_2O_2$-$1H_2O$. (a), (d) patterns before etching; (b), (e) etched in the solution with $k = 10$ for 2.5 min (0.5 μm); (c), (f) etched with $3H_2SO_4$-$1H_2O_2$-$1H_2O$ at 60°C for 3 sec (0.5 μm).

hydrogen peroxide-citric acid solution with $k = 10$ at 23°C, and 3 sec for a $3H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 60°C. The results are shown in Fig. 8. Figure 8(a) and (d) are the original patterns used in the experiment. The erosion of the photoresist masks by $3H_2SO_4$-$1H_2O_2$-$1H_2O$ is apparently seen in Fig. 8(c) and (f). In this case, part of the photoresist masks have been dissolved into solution and the pattern size has changed. The Br_2-CH_3OH, $NaOH$-H_2O_2, and NH_4OH-H_2O_2 solutions also erode the photoresist masks as in the case of the H_2SO_4-H_2O_2-H_2O system.

On the other hand, no erosion of the photoresist masks by the solution with $k = 10$ is observed, as shown in Fig. 8(b) and (e), and pattern size is the same as those in the original one. No erosion was observed for all compositions of the solution examined in these experiments. The photoresists used in this experiment did not dissolve perceptibly in solution even when the etching was carried out for 60 min at room temperature.

From the above-described results, it is believed that the solution developed here should be of general use to GaAs device technology.

Summary

An etching solution for the preferential etching of GaAs through photoresist masks has been developed. The solution consists of citric acid, hydrogen peroxide, and water. Etching rates vary from 1 to 100 Å/sec, depending on the composition of the solution. The etching process for solutions containing a higher composition of citric acid ($k > 2$) is chemical reaction

rate limited, for solutions containing a lower concentration of citric acid ($k < 2$), it is chemical reaction rate limited and diffusion rate limited. The etching rates depend on crystal orientation, with the rates for the solution with $k = 10$ decreasing in the order (111)B > (100) > (111)A.

Flat-bottomed holes are obtained for all compositions of the solution. However, the hole structures in preferential etching on the crystals display asymmetrical patterns.

This etching solution does not erode the photoresist masks, thereby providing improved resolutions and definition for fine photoresist patterns such as n-type GaAs MESFET's.

Ionic Conductivity in Solid Electrolytes Based on Lithium Aluminosilicate Glass and Glass-Ceramic

Ralph T. Johnson, Jr., R. M. Biefeld, M. L. Knotek, and B. Morosin

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

Ionic conductivity measurements on $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$, *i.e.*, $LiAlSiO_4$, glass and glass-ceramic have shown these materials to be good lithium ion conducting solid electrolytes at high temperatures. This composition crystallizes in the β-eucryptite structure which is attractive for solid electrolyte applications because of its low thermal expansion. The glasses were prepared by quenching from the melt and were annealed to remove strain. The glass-ceramic (β-eucryptite) samples were crystallized (aided by TiO_2 and ZrO_2 nucleating agents) by using a heat-treatment determined through differential thermal analysis. The conductivity (σ) was measured (to 650°C) with a variety of techniques, including 2-terminal a.c., 3-terminal guarded a.c., 4-terminal a.c., 2-terminal d.c., and a pulsed method. Vapor-deposited Cr contacts were used. Different sample geometries, contact geometries, and measurement circuitries were employed. The results from the various measurements are in excellent agreement. The a-c techniques appear to be the most versatile and accurate of the methods examined. In these materials the conductivity is thermally activated ($\sigma = \sigma_0 e^{-E/kT}$) with typical values of $\sigma_0 = 1.9 \times 10^2$ (ohm-cm)$^{-1}$ and $E \approx 0.68$ eV for the glasses, and $\sigma_0 = 2.1 \times 10^4$ (ohm-cm)$^{-1}$ and $E \approx 1.05$ eV for the glass-ceramics. The TiO_2 and ZrO_2 nucleating agents [concentrations up to 2.8 mole per cent (m/o)] did not appear to influence the ionic conductivity. Data were also taken on a (β-eucryptite) glass-ceramic with a composition near the β-eucryptite/β-spodumene phase boundary. The ionic conductivity of this material is lower than that of the $LiAlSiO_4$ materials. Data are also provided on β-spodumene material.

This paper reports on the ionic conductivity in lithium aluminosilicate glasses and glass-ceramics. The materials examined have compositions near that of stoichiometric $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$, *i.e.*, $LiAlSiO_4$. Materials of this stoichiometry form the basis of the class of materials which, when in crystalline form, exhibit the β-eucryptite structure (1-11). These materials are of interest for high temperature solid electrolyte applications (12), *e.g.*, thermal batteries (13), because of the combined characteristics of low thermal expansion (6-11) and high lithium ionic conductivity at elevated temperatures (14). In these studies, ionic conductivity measurements were made over the temperature range from room temperature to ~650°C with a 3-terminal guarded a-c technique and a 4-terminal a-c technique. These experimental techniques are shown to give accurate values and are in excellent agreement with other experimental techniques examined. The data obtained on the stoichiometric $LiAlSiO_4$ materials are compared with similar data taken on a glass-ceramic obtained from Corning Glass Works which also exhibits the β-eucryptite structure, but which has a composition near the β-eucryptite/

Key words: solid electrolytes, lithium ion conductors, ionic conductivity, lithium aluminosilicate glass and glass-ceramic, β-eucryptite structure.

β-spodumene phase boundary. Data are also provided on material with the β-spodumene phase (4-8, 15-17).

The lithium aluminosilicate materials examined in this study are of the general class $Li_2O \cdot Al_2O_3 \cdot nSiO_2$. Compositions with n ≈ 2 crystallize in the β-eucryptite structure whereas for n ≈ 4-11 the β-spodumene phase is formed (4-8, 16, 17). These materials have low thermal expansion characteristics which are composition dependent (6-8, 17-19) and structure dependent (7, 20). A variety of commercial applications have utilized the low thermal expansion characteristics (18, 19, 21), but have not utilized the Li^+ ionic conduction characteristics. The more notable applications to date include cookware, cooking surfaces, and heat exchangers which are based on β-spodumene materials (18, 19, 21). These materials have a lower Li content than the β-eucryptite materials. The commercial developments to date appear to have been directed toward reducing the Li_2O content in order to lower the conductivity of the material to avoid electrical shorting at high temperatures (19). However, for solid electrolyte applications it is obviously important to enhance the ionic conductivity, and for this reason we have examined the β-eucryptite materials.

Some information on ionic conductivity is available on lithium aluminosilicates in the β-spodumene phase (19, 22-24); however, there is very little information published on the β-eucryptite materials (24), and none on the glass or glass-ceramic. Recent nuclear magnetic resonance (NMR) experiments (25) in conjunction with Raman scattering experiments (26) have shown that Li^+ motion does occur in $LiAlSiO_4$ glass and glass-ceramic (β-eucryptite) materials. The results reported here on our ionic conductivity measurements on $LiAlSiO_4$ show that at high temperatures (≈600°C) the Li^+ ionic conductivity of these materials compares favorably with that of other lithium ion conductors of interest for solid electrolyte applications (22, 27).

In this paper, we first describe the method of preparation of the $LiAlSiO_4$ glasses and glass-ceramics and the characteristics of the Corning glass-ceramic. The method of electrically contacting the samples is then discussed. This is followed by a section which outlines the methods used for measuring the ionic conductivity (which include 2-terminal a.c., 3-terminal guarded a.c., 4-terminal a.c., 2 terminal d.c., and a pulsed method). Another section then describes experiments designed to compare the measurement techniques and to establish the reliability of the measurements. The final section gives the results obtained from the ionic conductivity studies on the glass and glass-ceramic materials, and also mentions possible solid electrolyte applications.

Material Properties

The glass-ceramic obtained from Corning Glass Works (Corning designation code 99QHA) was in the form of large slabs (15 × 12 × 0.3-0.6 cm), and was a "good quality" glass-ceramic. This material had uniform compositional, structural, and electrical properties as determined from chemical analyses, x-ray diffraction, and ionic conductivity measurements. The exact composition and method of preparation (*e.g.*, heat-treatment, etc.) are not completely known.

Table I gives the composition of the starting materials used by Corning (information provided by Corning), and the composition of the starting materials used in our laboratories for the preparation of the $LiAlSiO_4$ glass and glass-ceramic materials. From this information, it is seen that the Corning glass-ceramic has a much lower Li_2O content, and that TiO_2, ZrO_2, and P_2O_5 were used as nucleating agents (28). Results from chemical analysis performed in our laboratories were consistent with the information provided by Corning on the starting materials. This material has a composition near the β-eucryptite/β-spodumene phase boundary and it can be considered as a β-eucryptite/β-quartz solid solution (6, 7).

Table I. Composition derived from starting materials

Material	Composition (m/o) Li_2O	Al_2O_3	SiO_2	TiO_2	ZrO_2	P_2O_5

[a] From information provided by Corning Glass Works.

In preparation of the $LiAlSiO_4$ materials in our laboratories, reagent grade chemicals (99% purity or better) were used. The glasses were prepared by mixing about 250g of Li_2CO_3 and the required oxides in a twin-cone blender for 1-2 hr and then melting in Pt crucibles at 1600°C. The melts were stirred with platinum stirrers for 17 hr and allowed to stand for 2 hr after stirring at 1600°C. The glass was then cast onto a water-chilled copper plate, cooled for 20 sec, and placed into an annealing furnace at 370°C. The temperature of the annealing furnace was then raised at a rate of 20°C/min to 650°C, held there for 5 min, and then cooled to room temperature at the natural cooling rate of the furnace. X-ray powder diffraction photographs of the glasses revealed no crystalline structure. The heat-treatment schedules used for producing the glass-ceramic materials varied and depended upon the nucleating agents (5, 28). The $LiAlSiO_4$-B material with the TiO_2 nucleating agent (see Table I) was crystallized by heating the glass to 925°C at a rate of 5°C/min. The glass was held at that temperature for 5 hr and then the temperature was increased to 960°C and held there for 5 hr. The glass was then cooled to room temperature in 8 hr. The glass-ceramic with the TiO_2 and ZrO_2 nucleating agents ($LiAlSiO_4$-C) was produced by heat-treating the glass through a schedule which involved raising the temperature to 560°C at a rate of 5°C/min, holding at that temperature for 4 hr, and then increasing the temperature (over 1.5 hr) to 930°C and holding at that temperature for 4 hr. The material was then cooled to room temperature in 8 hr.

The above heat-treatments were determined from differential thermal analysis (DTA) performed on rapidly cooled and unannealed glass samples and from x-ray powder diffraction photographs taken of samples heated to different temperatures and then rapidly cooled. The DTA data were taken with a du Pont 990 thermal analyzer. The results are shown in Fig. 1. The DTA on $LiAlSiO_4$-B was carried out at a rate of 10°C/min with Al_2O_3 as the reference. A glass transition temperature (T_g) of 650°C was found. The phase

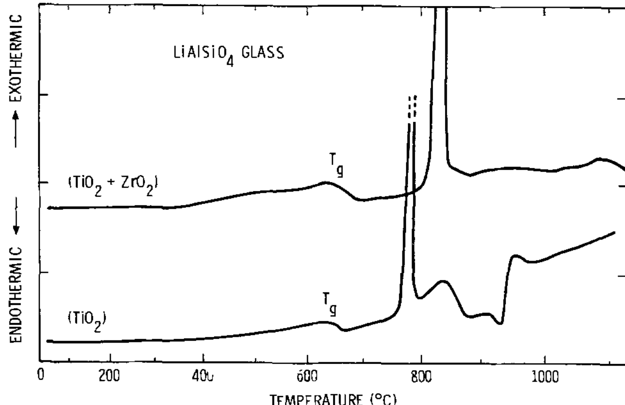

Fig. 1. Differential thermal analysis data on $LiAlSiO_4$ glasses with nucleating agents of TiO_2 and TiO_2 + ZrO_2. Composition information is given in Table I. T_g is the glass transition temperature. The exotherms result from crystallization as discussed in the text.

changes responsible for the observed heat effects between 770° and 950°C are due to the crystallization of β-eucryptite and an unidentified phase. These results are similar to those reported by Barry *et al.* (5) on similar materials except that they observed different (hexagonal and tetragonal) phases. In our studies, the intensities of the reflections due to the unidentified phase are stronger than the intensities of the β-eucryptite reflections following heat-treatment at low temperatures (770°-800°C); however, these unidentified reflections become weaker at higher heat-treatment temperatures (800°-850°C) and disappear above 950°C. Above this heat-treatment temperature only the β-eucryptite phase is detected. Thus, in the DTA of the TiO_2-nucleated $LiAlSiO_4$, the exotherm from 770° to 800°C can be associated primarily with the formation of the unidentified crystalline phase. The complex behavior observed from 800° to 950°C is probably caused by the conversion of this unidentified phase to the β-eucryptite phase.

The DTA results for the $LiAlSiO_4$-C glass (TiO_2 and ZrO_2 nucleating agents) reveal a T_g of 650°C and the existence of only one crystalline phase, β-eucryptite. The formation of this phase is responsible for the exotherm from 805° to 830°C.

X-ray analysis of the as-obtained Corning material revealed the presence of the β-eucryptite structure. However, heat-treatment of this glass-ceramic to 1120°C resulted in conversion to the β-spodumene phase (6). Similar heat-treatment of the $LiAlSiO_4$ materials resulted in no new phases.

The density of these materials was determined by displacement with toluene. The densities of the $LiAlSiO_4$-B and -C glasses were found to be 2.45 and 2.49 g/cm^3, respectively. After heat-treatment the densities of the corresponding glass-ceramics were slightly lower (2.38 and 2.41 g/cm^3, respectively). The density of the "as-obtained" Corning glass-ceramic (β-eucryptite phase) was found to be 2.57 g/cm^3. Scanning electron micrograph studies suggested that the as-obtained Corning material also contained more glassy phase (or smaller crystallites) than the $LiAlSiO_4$ glass-ceramics. The density of this material increased to 2.62 g/cm^3 after conversion to the β-spodumene phase. These bulk densities may be compared with the theoretical crystal densities of 2.351, 2.391, and 2.399 g/cm^3 for n = 2 (β-eucryptite) and n = 3 and 4 [β-spodumene (16)], respectively.

Electrodes

The samples used for the ionic conductivity measurements were cut with a diamond saw and were polished (first with dry emery paper then with an oil-based diamond polish) on the surfaces to be contacted. They then were cleaned with acetone and ethyl alcohol. Vacuum evaporated ($\sim 10^{-6}$ Torr) thin-film electrodes of Cr, Al, or Li were applied. Results obtained with these electrodes were evaluated. For general discussions of important electrode and measurement criteria see Ref. (29) and (30).

For studies of thin-film Li electrodes, the Li was evaporated at ~ 150°C utilizing the reaction: $2LiCl + Ca \rightarrow CaCl_2 + 2Li$. Only marginal results were obtained from these experiments. The contacts frequently appeared to be "ineffective" (possibly evaporated off the samples) as the sample temperature was increased. Generally, sample temperatures > 100°C were needed in order for the sample conductance values to be in a range which could be measured with the instrumentation. The results which were obtained with Li electrodes were in agreement with those obtained with Cr and Al.

Good results were obtained with both Cr and Al electrodes. These contacts were evaporated onto the samples with the samples at 300°C. Contacts evaporated at this temperature were found to be more mechanically (and electrically) stable than those evaporated at room temperature. Electrical leads were then contacted by either spring loading or using silver paint. Some of the studies showed that contact effects can significantly influence the results. In several experiments where contacts were applied to the samples with various surface treatments, the conductivity was found to vary by an order of magnitude. For this reason, much care was exercised in sample surface preparation and in applying the electrodes. With properly applied contacts, our results indicated that while Cr and Al are not reference electrodes, there was no great effect due to their inactivity. Generally the results obtained with Cr and Al contacts were very similar, except that there was an indication of more polarization-related effects for the Al contacts at the higher conductivities. For this reason, most work was done with Cr electrodes, and only results obtained by using Cr electrodes are reported here.

Electrical Measurement Techniques

Electrical measurements were made by using a variety of techniques which included 2-terminal a.c., 3-terminal guarded a.c., 4-terminal a.c., 2-terminal d.c., and a pulsed method. These methods were complementary in that the measurement circuitries and the sample and contact geometries were considerably different, *e.g.*, area-to-length ratios differed by factors of up to $\sim 10^3$. By comparison and cross-correlation of results from the various techniques, a high reliability could be assigned to the conductivity data.

2-Terminal d-c method.—The 2-terminal d-c technique was used primarily as a check of the a-c and the pulsed method results. It also gave an indication of the extent of electronic conduction within the samples (31, 32). The measurements were made on samples with dimensions of approximately $2 \times 2 \times 0.1$ cm. The contacts were evaporated onto the 2×2 cm sample faces. The electrical measurements were made with a Keithley digital electrometer, Model 615 (fast current mode), in series with a constant voltage source (0.5V). When the circuit was closed, the instantaneous current was used to measure the total (ionic and electronic) current. The time variation in current through the sample gave an indication of the polarization which occurred at the electrodes. The final stabilized current is related to the electronic contribution to the conductivity (31, 32).

For measurements as a function of temperature, thermocouples were bonded to the sides of the sample with porcelainlike cement (Omega CC high temperature cement). The sample was encased in a thin ceramic holder which supported the electrical leads. This assembly was placed between two Ta strips which formed the heater arrangement. This entire assembly was mounted in a vacuum system, and measurements were made at $\sim 10^{-6}$ Torr. The temperature gradient across the sample was 1°-2°C at ~ 400°C.

Pulsed method.—A pulsed method (2-terminal measurement) was examined since it is one of the techniques which can be used to measure ionic conductivity in the presence of polarization effects. The sample configuration is similar to that for the 2-terminal d-c method. As with the d-c technique, the pulsed method measures the "instantaneous" current. In this case the current is in response to a small-amplitude square-wave voltage pulse. The experimental arrangement is illustrated in Fig. 2, and is a modification of a method developed by Nissen and Carlsten (33). The basic circuit includes a pulse generator (Tektronix Type 114 with a Tektronix X10 attenuator), a current-sensing (standard) resistor in series with the sample (resistance a factor of ~ 10 lower than that of the sample), and fast-rise oscilloscopes (Hewlett-Packard Models 180 and 183) for determining the sample voltage and

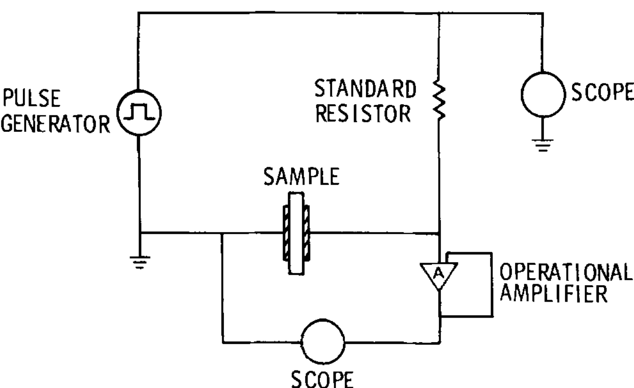

Fig. 2. Schematic diagram of the pulsed conductivity measurement circuit.

current. The operational amplifier (Burr-Brown Model 3503T) was used to increase the effective input impedance of the scope measuring the sample voltage. The scopes were triggered several microseconds before the pulse generator was triggered in order to record complete traces of the voltage and current pulses. Voltage pulses of $\sim$ 100 mV magnitude and $\sim$ 200 μsec duration were used. This method was limited to measuring conductances $\gtrsim 10^{-6}$ ohm^{-1}.

2- and 3-Terminal a-c methods.—Both 2-terminal a-c and 3-terminal guarded a-c measurements were made on samples prepared in the same manner as for the d-c and pulsed experiments. The experimental arrangement is shown in Fig. 3. The measurements were made using a Hewlett-Packard 4800A vector impedance meter with a 4810A direct measurement plug-in. This instrument covers the frequency range from 5 to 5×10^5 Hz. The impedance range is from 1 ohm to 10 megohm. The sample is connected to the instrument through two shielded coaxial cables. The shields are grounded at the instrument to minimize cable capacitance effects. The 2-terminal and 3-terminal measurements were the same except that the 3-terminal measurements were on samples which had a grounded (guard) electrode around the sample edge. This helped minimize problems due to leakage currents across the surface of the samples as well as to minimize field fringing effects. In preparing samples for the guarded measurements, a circular groove was cut through the Cr contacts with sand-blasting techniques (alignment of the grooves on opposite surfaces was within $\approx 2\%$). This defined a center electrode area (~ 0.35 cm^2) and an outer electrode area on each surface. The center circular electrodes were used for the conductance measurements (the length-to-area ratio, l/A, used for conductivity determinations was ≈ 0.35 cm^{-1}). The leads to the outer electrodes were connected to the grounded shields on the coaxial cables which were also tied to a common system ground. For measurements of low conductances, a resistor (10^7 ohm) was used in parallel with the sample to extend the lower limit of the effective sample conductance measurement range from $\sim 10^{-7}$ to $\sim 10^{-8}$ ohm^{-1} (with some loss in accuracy). The rms voltage across the samples with this instrumentation varies from about 2.7 mV to 2.7 V (dependent upon the impedance), and has values < 270 mV for conductances $> 10^{-6}$ ohm. Conductance *vs.* frequency measurements were made over the frequency range from 50 to 5×10^5 Hz.

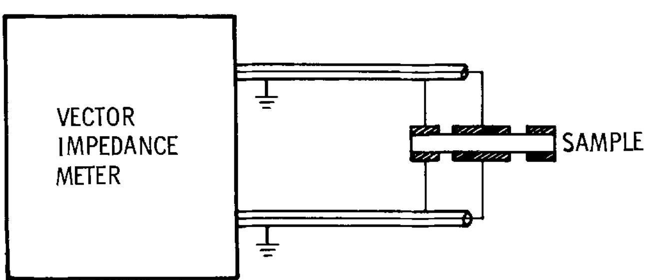

Fig. 3. Experimental arrangement for 2-terminal a-c and 3-terminal guarded a-c measurements. These measurements differ only in that for the 2-terminal measurements the outer guarded electrodes are either not used or are not grounded, *i.e.* no leads attached.

4-Terminal a-c method.—The 4-terminal a-c measurements were made with the circuit and sample geometry shown in Fig. 4. Bar-shaped samples with dimensions of about $1 \times 1 \times 15$ mm were used. Two electrodes were evaporated onto the ends of the sample and served as current lead contacts. The voltage contacts consisted of two strips 1 mm wide which encompassed three sides of the sample. These electrodes were $\sim$ 7 mm apart and were centered on the sample. With this arrangement $l/A \approx 70$ cm^{-1}.

The sample was coupled to the internal oscillator output from a Princeton Applied Research Model 124A lock-in amplifier through a voltage-to-current transducer, *i.e.*, the sample was inserted in the feedback loop of an operational amplifier. The current through the feedback loop of the operational amplifier was determined by the output voltage of the oscillator, $V(t)$, and the input resistor, R, with $i(t) = V(t)/R$. Thus the sample was driven with a sinusoidal current whose phase was fixed relative to the input voltage $V(t)$. This alleviates the problems associated with polarization at the current contacts to the sample, since this configuration will always drive $i(t)$ through the sample irrespective of any polarization that is occurring. Thus the only problem with polarization in this method is the polarization at the voltage contacts. This polarization, however, can be accurately monitored because any polarization will result in a phase shift between $\phi(t)$ and $i(t)$. We need merely adjust the frequency of the measurement until the phase shift is negligible to get accurate values for the bulk conductance. Phase shifts of less than 1° could easily be measured. With this circuit, any impedance from 10 to 10^8 ohm could be accurately measured in the frequency range from 2 Hz to $\approx$ 10 kHz. The ability to use very low frequencies while alleviating polarization problems is important when inferring d-c conductivity from such measurements due to the intrinsic dispersion which is likely to be present in systems such as these. In the case of

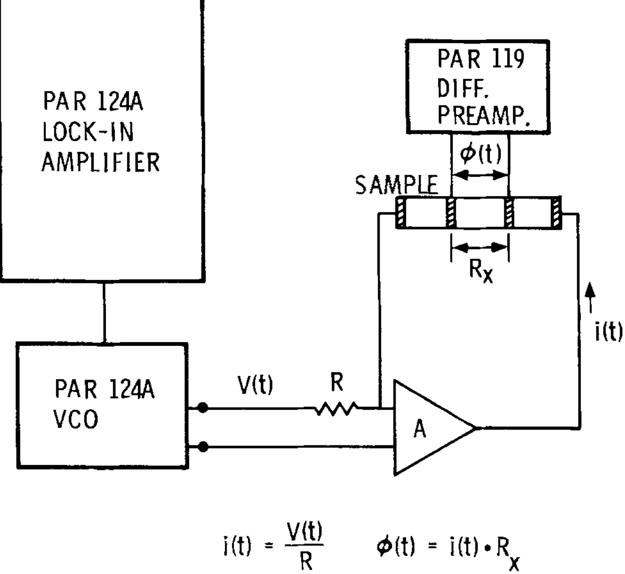

Fig. 4. Schematic diagram of the 4-terminal a-c measurement technique. The operational amplifier is an analog device Model 41L ultralow input offset bias current FET amplifier.

these materials, however, there appears to be no dispersion.

All measurements were taken with the peak-to-peak value of $i(t) < 10^{-9}$A. This resulted in a-c voltages $\varphi(t)$, applied across the sample, of ≤ 10 mV. The measurement apparatus also contained a calibration resistor which could be inserted in place of the sample. Between data points the apparatus was switched to the calibration resistance and all leads to the sample were shorted to ground. This allowed any polarization which had built up to drain off. There was finite input offset bias current ($\approx 10^{-12}$A) present in the operational amplifier and the d-c polarization of the current contacts due to this current was monitored. This polarization was kept below 0.05V to avoid contact injection.

For measurements as a function of temperature, the sample was bonded to alumina plates with the Omega porcelain cement. One or more Chromel-Alumel thermocouples were affixed to the sample at various points by using the same cement. Nichrome wires were attached to the electrodes with Ag paint. This assembly was placed in a tube furnace and the data were taken with the sample in air. The data were taken at 7 Hz and the phase angle between the input current and the sample voltage was always $< 5°$.

Comparison of Measurement Techniques

In order to compare these conductivity measurement techniques and to investigate effects due to sample and contact geometry, two different sets of experiments were performed. The same material (the Corning β-eucryptite glass-ceramic and in some cases sister samples) was used in all the experiments. The first set of experiments was designed to compare the 2-terminal techniques (a.c., d.c., and pulsed), whereas the other experiments compared the 3- and 4-terminal a-c techniques.

2-Terminal (a-c, d-c, and pulsed) experiments.—These experiments were performed on the same sample, with the same contacts, and were mounted in the same sample holder. The attempt here was to vary only the measurement circuitry. Ring-shaped Cr electrodes were used. This contact configuration was chosen for evaluation as a possible base-electrode structure (electrically conductive) over which other more active, but possibly less conductive, electrodes (*e.g.*, Li) could be deposited (or attached). It also provided a completely different electrode geometry than that used for the 3- and 4-terminal experiments. Since the ring-shaped electrode is not the normal (more conventional) electrode configuration and the effects of fringing fields are not known, the data are presented as conductance rather than conductivity, *i.e.*, no attempt was made to determine the exact geometry factors appropriate for a conductivity determination.

The results obtained from the 2-terminal (a-c, d-c, and pulsed) measurements are shown in Fig. 5 and 6. Figure 5 gives the conductance values determined from the d-c and pulsed measurements as well as the frequency-dependent data obtained from the a-c measurements. The data were obtained for temperatures ranging from 100° to 450°C. The d-c results were obtained from the "instantaneous" (time = 0) current values obtained when the circuit was closed. The time-dependent results from the d-c measurements suggested that the current is carried by ions [presumably Li^+ ions (25, 26)], in good agreement with recent NMR and Raman scattering experiments (25, 26). Furthermore, the electronic contribution to the conductivity is many orders of magnitude less than the ionic contribution. For example, measurements made at 400°C indicate that at this temperature the electronic conductivity is over three orders of magnitude less than the ionic conductivity. The ionic conductivity at this temperature is $\sim 10^{-4}$ (ohm-cm)$^{-1}$.

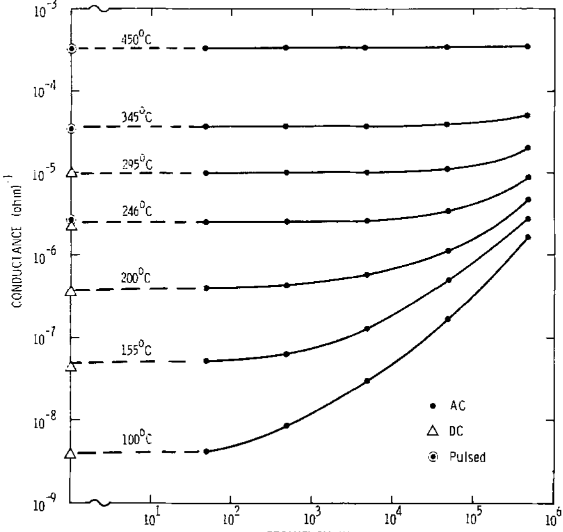

Fig. 5. Ionic conductance data obtained by using 2-terminal a-c, d-c, and pulsed measurement techniques on a glass-ceramic (β-eucryptite) sample at the temperatures indicated.

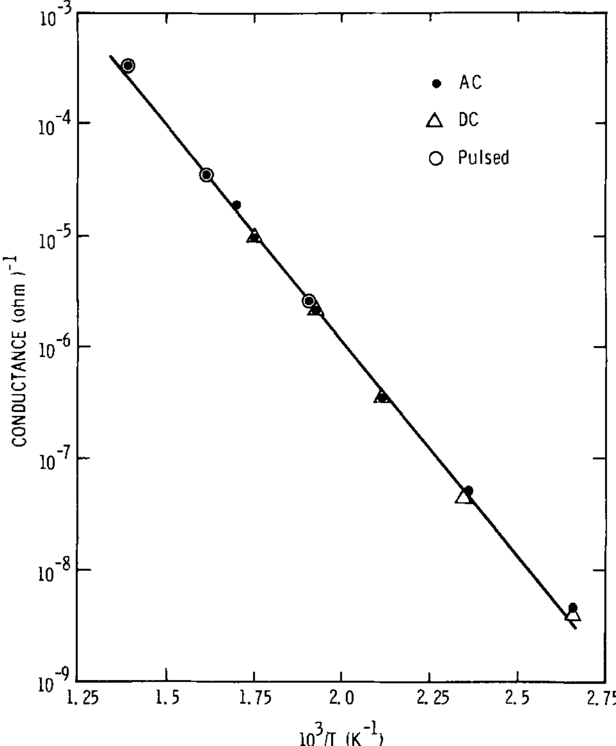

Fig. 6. Temperature dependence of the ionic conductance determined from the data in Fig. 5 for the β-eucryptite sample. The data were obtained with a-c, d-c, and pulsed 2-terminal techniques. Results show *(i)* excellent correlation between the measurement techniques, and *(ii)* that the conductivity is thermally activated with an activation energy of ~0.78 eV for this sample.

Results in Fig. 5 from the pulsed measurements are, as they should be, in good agreement with the d-c results. The extrapolated a-c data, or a-c data in the frequency independent region, are also in good agreement with the d-c and pulsed results. In the frequency-dependent region, the a-c data indicate an increase in conductance with increasing frequency. This is especially pronounced for the low conductance (or low temperature) data, and is due to the experimental arrangement (cabling, etc.) and is not (necessarily) due to the sample. A similar frequency dependence was observed when the sample was replaced by a resistor. Any dispersion due to the sample was masked, in our case, by circuit effects.

These conductance results are compared further in Fig. 6 where conductance is plotted as a function of reciprocal temperature. The a-c conductance results are those obtained from the frequency-independent region. This plot also shows the excellent agreement obtained between the various techniques. Furthermore, the results show that the conductivity of this material (Corning β-eucryptite glass-ceramic) is thermally activated with an activation energy of $\sim$ 0.78 eV.

3- and 4-Terminal a-c experiments.—This set of experiments was designed to accurately determine the conductivity of the material. In order to provide completely independent determinations of the conductivity with these two techniques, different measurement circuitries, different sample geometries (slab *vs.* bar-shaped samples), different contact configurations (l/A ratios varied by $\sim 200\times$), and different sample holder/heater arrangements were used. Even the ambient environment was changed.

The results from the 3- and 4-terminal measurements are shown in Fig. 7 (for the β-eucryptite phase). The agreement between results is within 10%. (Similar results were obtained on the $LiAlSiO_4$ materials.) This is remarkable considering the factors that were different in the two measurements. The results are also in good agreement with the 2-terminal data (Fig. 6) in that the same activation energy is obtained. An estimate of the l/A ratio for the 2-terminal experiments gave conductivity values within less than a factor of 2 of the values in Fig. 7. As noted before, there is considerable uncertainty and error in this estimate of l/A, so this agreement appears to be reasonably good. All of these results give us confidence in our ability to measure the bulk ionic conductivity of these materials.

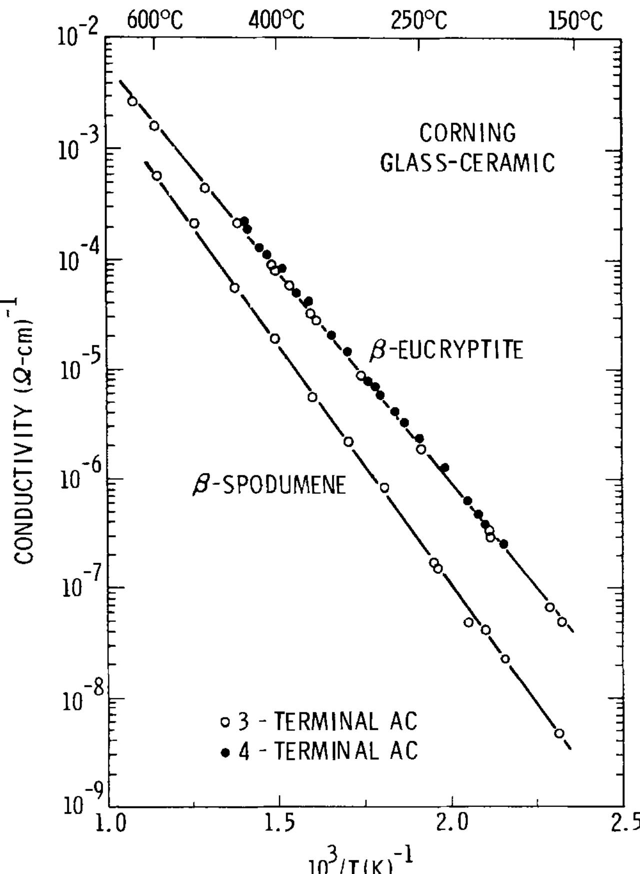

Fig. 7. Ionic conductivity of the Corning glass-ceramic in the as-obtained β-eucryptite phase and in the β-spodumene phase (induced by heat-treatment). Data were obtained by using 3- and 4-terminal a-c techniques and are in excellent agreement. Results are summarized in Table II.

Conclusion.—The study in this section has provided a useful comparison of five different ionic conductivity measurement techniques. The pulsed technique was the most difficult technique to use. This technique was also limited to measuring conductances $\gtrsim 10^{-6}$ ohm^{-1}. The 2-terminal d-c technique was the most inaccurate method to use because of polarization effects encountered with inactive electrodes. For ionic conductivity determinations the most meaningful and useful techniques are the 4-terminal a-c and 3-terminal guarded a-c techniques. These techniques are complementary in that different sample geometries, contact configurations, and measurement circuitries are employed. The 4-terminal a-c measurement has the advantage (or at least has the potential) of minimizing undesirable contact effects. Where possible, both of these techniques should be used to measure the conductivity in order to establish the reliability of the data. Furthermore, these experiments have shown that the conductivity in these materials is not significantly dependent upon sample geometry, contact geometry, or the measurement circuitry. Thus it is concluded that ionic conductivity values obtained are those of the bulk material.

Materials Ionic Conductivity Studies

Most of the studies of ionic conductivity in the glass and glass-ceramic materials were made with the 3-terminal guarded a-c and 4-terminal a-c techniques. Data were taken over the temperature range from room temperature to $\sim$ 650°C.

Results.—Results on the Corning material in both the β-eucryptite and β-spodumene phases are shown in Fig. 7. These data were obtained on the same sample; that is, the conductivity data for the sample in the β-spodumene phase were obtained after the sample had been converted (via heat-treatment) to the β-spodumene phase. The results show that the ionic conductivity (σ) is thermally activated

$$\sigma = \sigma_0 e^{-E/kT}$$

with activation energies, E, of 0.78 and 0.87 eV for the β-eucryptite and β-spodumene materials, respectively. Values for E and the preexponential factor, σ_0, for all of the materials examined in this study are summarized in Table II.

The results in Fig. 7 show that the conductivity of the β-spodumene material is less than that of the β-eucryptite material in the temperature range examined ($\leq$ 650°C). In the conversion of the β-eucryptite material to the β-spodumene material, E increased from $\sim$ 0.78 to $\sim$ 0.87 eV and σ_0 increased from $\sim$ 50 to $\sim$ 65 (ohm-cm)$^{-1}$. The degree to which this change is associated with the conversion to the β-spodumene crystalline structure as compared to changes in other materials properties, *e.g.*, glass phase and/or relative amounts of glass and crystalline phases, is not known. For the β-spodumene phase, results published by Pizzini and co-workers (22, 23) on polycrystalline sintered pressed pellets show a larger activation energy ($\sim$ 1.16 eV) than that reported here, but a σ_0 of about the same value. Thus the conductivity of the sintered polycrystalline β-spodumene samples they examined is even lower than that of our β-spodumene glass-ceramic

Table II. Activation energy, E, and preexponential factor, σ_0, determined from ionic conductivity measurements; using $\sigma = \sigma_0 e^{-E/kT}$

Material	Structure	E (eV)	σ_0 (ohm-cm)$^{-1}$
$LiAlSiO_4$ glass	Noncrystalline	0.68	1.9×10^2
$LiAlSiO_4$ glass-ceramic	β-eucryptite	1.05	2.1×10^4
Corning glass-ceramic	β-eucryptite	0.78	5×10^1
Corning glass-ceramic	β-spodumene	0.87	6.5×10^1

samples. This would suggest that the crystalline phase alone does not dominate the electrical properties of these materials. In the polycrystalline sintered material the interface between the crystallites (grain boundaries, etc.) may significantly influence the electrical properties; whereas in the glass-ceramic, the glass phase as well as the interface between the glass and crystalline phases is probably important. The importance of the glass phase in glass-ceramics has recently been pointed out by McMillan (34). Furthermore, our experiments on the $LiAlSiO_4$ materials (reported below) suggest that the glass phase may play a very important role in ionic transport in these materials.

The ionic conductivity data on the $LiAlSiO_4$ glasses and glass-ceramics (β-eucryptite) are shown in Fig. 8, and are compared with the data (from Fig. 7) on the Corning β-eucryptite glass-ceramic. Results show that the conductivity of the $LiAlSiO_4$ material is higher than that of the Corning material (at high temperatures), and is also higher than that reported for other β-eucryptite materials (24). The lower conductivity of the Corning materials may be due, at least in part, to the lower lithium content of these materials (see Table I). Some data reported by Hammel (19) suggest that the lithium content does significantly influence the ionic conductivity, in a manner which is consistent with our results.

The results in Fig. 8 also show that the conductivity of the $LiAlSiO_4$ glass is greater than that of the glass-ceramic over the temperature range examined. In the conversion of this material from a glass to a glass-ceramic, both the activation energy increases (from $\sim$ 0.68 to $\sim$ 1.05 eV) and the σ_0 value increases [from $\sim 1.9 \times 10^2$ to $\sim 2.1 \times 10^4$ (ohm-cm)$^{-1}$]. Similar changes in ionic conductivity have been observed in other glass and glass-ceramic systems (34, 35).

It is also seen from the data in Fig. 8 that nucleating agents do not affect the ionic conductivity in the glass phase (at least to the concentrations studied here). The glass-ceramic data presented here are for the glass-ceramic prepared with the TiO_2 nucleating agents. Slightly higher E and σ_0 values were observed for the glass-ceramic with the $TiO_2 + ZrO_2$ nucleating agents, but whether this is due to the nucleating agents or

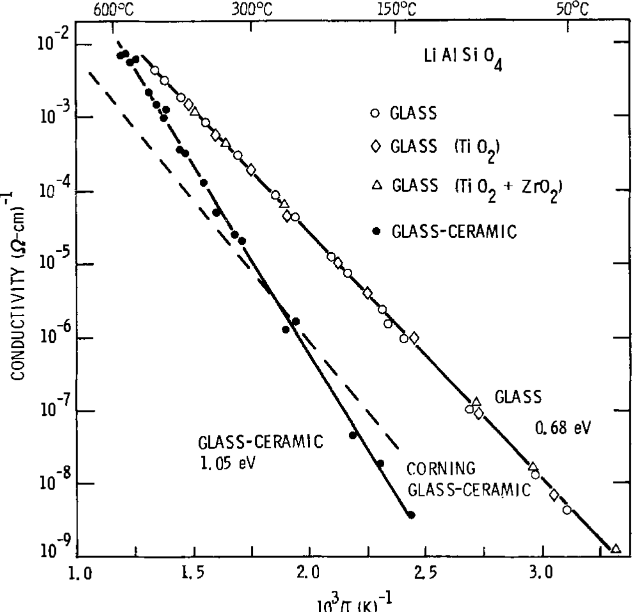

Fig. 8. Ionic conductivity of $LiAlSiO_4$ glass, glass with nucleating agents, and glass-ceramic (see Table I). The glass-ceramic (β-eucryptite material) was prepared by heat-treating the glass. The dashed line is the data from Fig. 7 on the Corning (β-eucryptite) glass-ceramic. Conductivity results are summarized in Table II.

(more probably) other materials properties is not known.

Comparison.—In comparing the conductivity of $LiAlSiO_4$ glass and glass-ceramic, and in interpreting the results, it is important to note that the composition of the glass and crystalline phases in the glass-ceramic should be about the same, *i.e.*, $LiAlSiO_4$, since the initial glass composition is near that of stoichiometric β-eucryptite. (This assumes, of course, only one glass phase and that this phase is the same as that for the $LiAlSiO_4$ glass.) This feature plus the fact that the conductivity of the glass-ceramic is less than that of the glass suggests that, in the glass-ceramic, the contribution to the conductivity from the glass phase is greater than that from the crystalline phase. In arriving at this interpretation, one cannot ignore the possible importance of other properties, such as more than one phase (or a different phase) in the glassy region, effects associated with crystal anisotropies, and glass/crystalline interface effects. However, we want to emphasize that our results do strongly suggest that in these materials the glass phase is important in Li^+ ion transport. Furthermore, the results from these experiments also suggest that it may be possible to further enhance the conductivity of the β-eucryptite materials by varying materials properties, such as composition.

Applications.—Since the $LiAlSiO_4$ materials have conductivity values of the order of 10^{-2} (ohm-cm)$^{-1}$ at high temperatures ($\sim$ 600°C), they are of interest for high temperature solid electrolyte applications (12, 13). Other lithium silicates and lithium aluminosilicates also have conductivity values in this range. West (27) has recently reviewed some of this literature and it is clear that other materials at high temperatures exhibit lithium ionic conductivities with similar or in some cases even slightly higher conductivity values than those reported here. The advantage that the β-eucryptite materials possess for solid electrolyte applications is their low thermal expansion characteristics (6-8, 17-19). The β-spodumene materials also possess low thermal expansion characteristics but the conductivity is lower, possibly due to the lower lithium content.

Some possible applications for these β-eucryptite materials include thermal batteries (13) and special electrothermal devices, etc. (12), which would utilize Li^+ ion transport. For many of these applications one would like a material with a higher ionic conductivity than that reported here. For example, for thermal battery applications one would like conductivity values about an order of magnitude higher, while maintaining about the same activation energy (that is, about 1 eV). Future efforts will be devoted to determining the extent to which the ionic conductivity of these materials can be increased and to defining potential solid electrolyte applications.

Acknowledgments

Selective Etching of III-V Compounds with Redox Systems

R. P. Tijburg and T. van Dongen

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Redox systems are particularly suitable for use as etching solutions for GaAs and $Ga_{1-x}Al_xAs$. It is found that solutions with a certain composition and pH selectively etch GaAs with respect to $Ga_{1-x}Al_xAs$ and that other solutions containing the same chemicals but with a different composition and/or pH selectively etch $Ga_{1-x}Al_xAs$ with respect to GaAs. The same behavior is seen on GaP-InGaP and GaP-GaAlAs heterostructures. A survey of the redox systems studied and examples of the applications are given.

In heterojunction laser technology or, more general, in multilayer device technology it may be necessary to etch fine patterns in structures consisting of compounds like, *e.g.*, GaAs and $Ga_{1-x}Al_xAs$. Important factors determining the choice of a chemical etching agent are generally the etch rate for the materials in question, the degree of undercutting, the chemical aggressiveness of the solution to other materials present, and whether or not the etchant etches one compound selectively with respect to the other. Logan and Reinhart (1) described a very useful bath with which GaAs can be etched selectively with respect to $Ga_{1-x}Al_xAs$. It is an aqueous solution of hydrogen peroxide (superoxol 30%) in water to which ammonium hydroxide is added so as to make the pH = 7. Kobayashi and Sugiyama (2) have referred to the selective etching of GaAs with respect to $Ga_{1-x}Al_xAs$ in a solution of superoxol and sodium hydroxide as an undesired behavior of the etchant.

In some of the etching solutions, in addition to the selective etching, one also observes preferential etching of some crystal planes as well. This behavior has been described for GaAs by Marinace and Rutz (3), Gennon and Nuese (4), and Tarui, Komiya, and Harada (5). The present paper draws attention to a new class of etching solutions. Redox solutions are able, depending on their composition and/or pH, to etch GaAs selectively with respect to GaAlAs and con-

Key words: optical waveguides, GaAs laser, preferential etching of III-V compounds.

versely to etch GaAlAs selectively with respect to GaAs. In addition to this some etching solutions preferentially reveal A{111} planes because the etch rate of these planes is slower than that of all other low index planes (5). Other redox solutions show clear differences in etch rate between p- and n-type GaAlAs or p- and n-type GaAs. The selective etching of redox systems is not restricted to GaAs-GaAlAs structures; GaP-InGaP and GaP-GaAlAs structures also display this behavior. Systems which are stable in both acidic and basic environment, such as potassium iodide-iodine, potassium, ferricyanide-potassium ferrocyanide, and quinone-hydroquinone, were studied. Two other etchants which are stable only in an acidic environment, namely, ferrichloride-ferrochloride and cerium (IV) sulfate-cerium (III) nitrate are described.

Materials and Sample Preparation

The GaAs-GaAlAs heterojunction layers used for etching experiments were laser structures grown onto (100) oriented GaAs substrates by liquid phase epitaxy. While the layer thicknesses varied, typical values used were 0.3-0.7 μm for the GaAs active layer between two $Ga_{0.7}Al_{0.3}As$ layers which were several microns thick. The carrier concentration of the GaAs p-type top layer was $2 \cdot 10^{18}$ cm^{-3}, the p-type GaAlAs layer was $4 \cdot 10^{17}$ cm^{-3}, and the n-type GaAlAs layer was $2 \cdot 10^{17}$ cm^{-3}. The laser layer was p-type GaAs ($p = 5 \cdot 10^{17}$ cm^{-3}) while the substrate was n-type GaAs ($n = 2 \cdot 10^{18}$ cm^{-3}). A cross section of such a slice is given in Fig. 1. To study selective etching, freshly cleaved {110} surfaces were placed in 50 ml of etching solution at room temperature for a time varying between 5 sec and 15 min. The etchant was agitated by a magnetic stirrer. After etching and rinsing, the {110} plane perpendicular to the etched one was cleaved and the sample studied with the scanning electron microscope. The depth of etching was measured with a calibrated microscope using an unetched part of the surface as reference.

Experimental Results

Two steps that can be distinguished in the etching of semiconductor materials are the oxidation of the semiconductor and the subsequent dissolution of the oxidation products. It is to be expected that the etch rate, *i.e.,* the oxidation rate and/or the dissolution rate, will depend on the composition of the semiconductor compounds. In a redox system the oxidation strength of a solution is influenced by the concentration ratio of the oxidizing agent to the reducing agent. The dissolution of the oxidation products can be influenced by changing the *p*H of the solution.

Figure 2 illustrates the selective etching behavior of the redox system potassium ferricyanide-potassium ferrocyanide ($K_3Fe(CN)_6$-$K_4Fe(CN)_6$). The *p*H of the redox system is plotted on the ordinate and the molar ratio of the oxidizing and reducing agent along the abscissa. The molar ratio was varied by modifying

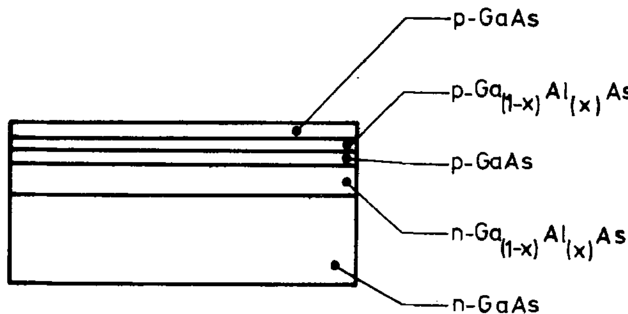

Fig. 1. Cross section of a double heterojunction GaAs-GaAlAs slice. An n-type $Ga_{1-x}Al_xAs$ layer, a p-type GaAs layer, a p-type $Ga_{1-x}Al_xAs$ layer, and a p-type GaAs layer are successively grown with liquid phase epitaxy on an n-type GaAs substrate.

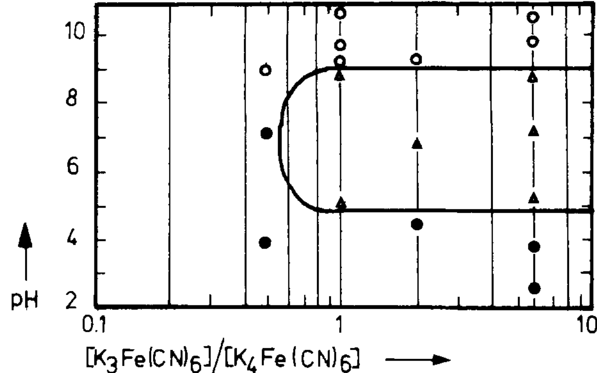

Fig. 2. Diagram of the etching properties of the potassium ferricyanide-potassium ferrocyanide system. The *p*H of the etching solution is entered on the ordinate and the molar ratio of the redox compounds on the abscissa. The potassium ferricyanide concentration is kept constant at 0.3 mol/liter. ○, Selective etching of GaAs; △, selective etching of $Ga_{0.7}Al_{0.3}As$; ●, no selective etching.

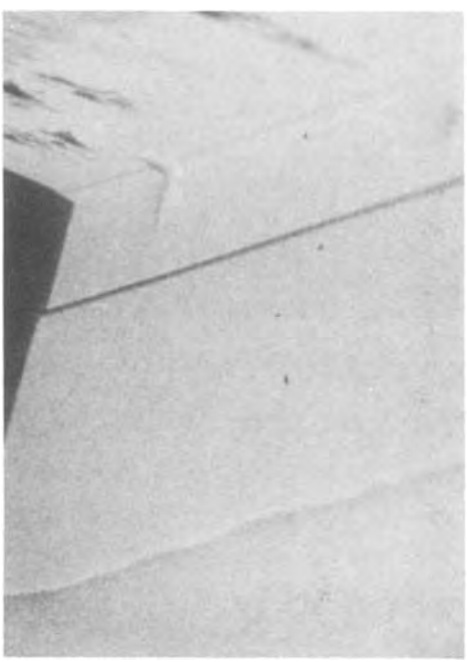

Fig. 3. A secondary emission image of a slice as shown in Fig. 1, etched in a potassium ferricyanide-potassium ferrocyanide solution containing 0.1 mol/liter $K_3Fe(CN)_6$ and 0.1 mol/liter $K_4Fe(CN)_6$; *p*H is 9.7. The three GaAs layers are etched selectively with respect to the GaAlAs layers. The etching time is 3 min.

the concentration of the reducing agent, while the concentration of the oxidizing agent was kept constant at 0.3 mol/liter in all the experiments covered by this graph. The *p*H was varied by dissolving the chemicals in buffer solutions[1] with the desired *p*H values or by adding NaOH or HCl to the etchants. Triangles indicate selective etching of $Ga_{0.7}Al_{0.3}As$, circles selective etching of GaAs, and dots low selectivity and/or etch rate. Selective etching of GaAs occurs mainly at *p*H values greater than 9 over a large range of molar ratios, whereas $Ga_{0.7}Al_{0.3}As$ selective etching was found for *p*H values between 5 and 9. At *p*H values lower than these the selectivity is not so clear and possibly depends on the impurity concentration of the compounds. Figure 3 gives an example of selective GaAs etching. The etching solution is given in Table I, No. 1. Figure 4 gives an example of $Ga_{0.7}Al_{0.3}As$ etching with solution 2 of Table I.

[1] The buffer solutions used are from Ref. (6).

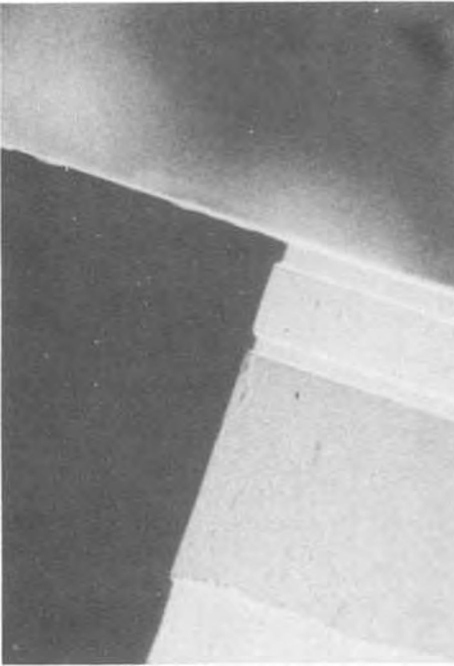

Fig. 4. A secondary emission image of a slice as shown in Fig. 1. The etching solution consists of 0.225 mol/liter $K_3Fe(CN)_6$ and 0.225 mol/liter $K_4Fe(CN)_6$; the pH is 7. The two GaAlAs layers are etched selectively. The etching time is 10 min.

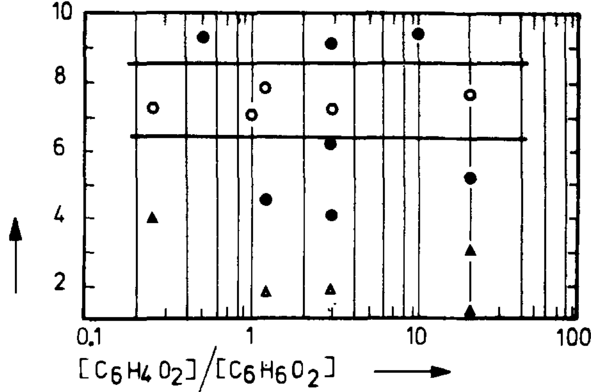

Fig. 5. Diagram of the etching properties of the quinone-hydroquinone system. The pH of the etching solution is entered on the ordinate and the molar ratio of the redox compounds on the abscissa. The total amount of $C_6H_4O_2$ and $C_6H_6O_2$ is kept constant at 0.03 mol/liter. ○, Selective etching of GaAs; △, selective etching of GaAlAs. ●, no selective etching.

The organic system quinone-hydroquinone ($C_6H_4O_2$-$C_4H_6O_2$) forms another redox couple which is stable over a large range of pH values and hence suitable for the selective etching of GaAs and $Ga_{0.7}Al_{0.3}As$ (Fig. 5). Merely by changing the pH from 1 to 10 a solution of quinone and hydroquinone successively becomes an etchant for GaAlAs and an etchant for GaAs, separated by a region in which hardly any etching occurs. The third redox system which is stable over a large range of pH values is the iodine-potassium iodide (I_2-KI) solution. This system shows the highest etch rates of all the investigated systems and yet the selectivity for GaAs or GaAlAs is extremely good.

Figure 6 is an SEM photograph of a laser slice with a 0.1 μm thick active GaAs layer. The etching solution is given under No. 3 in Table I. In cases where the active layer contains a few per cent of aluminum this solution does not etch at all. Aluminum-containing active layers can be etched with mixture 4 of Table I. With this etchant even a layer with an aluminum content of 15% sandwiched between two $Ga_{0.7}Al_{0.3}As$ layers can be etched selectively.

Redox systems such as ferrichloride-ferrochloride ($FeCl_3$-$FeCl_2$) and cerium IV sulfate-cerium III nitrate [$Ce(SO_4)_2$-$Ce(NO_3)_3$] are stable only in acidic solutions and therefore the dissolution of the oxides cannot be influenced. Both systems etch only GaAlAs selectively. Apart from the GaAs-$Ga_{1-x}Al_xAs$ selectivity, some of the etching solutions also show a selectivity for a specific type of conductivity. Figure 7 shows an example of selective etching of p-type $Ga_{1-x}Al_xAs$. Starting from a high mesa structure (8), p-type as well as n-type $Ga_{1-x}Al_xAs$ is exposed to a selective etchant. The p-type $Ga_{1-x}Al_xAs$ is partly removed while the n-type $Ga_{1-x}Al_xAs$ is hardly etched. This selective etching of p-type $Ga_{1-x}Al_xAs$ occurs in the cerium (IV)-cerium (III) system as given under No. 5 in Table I.

Table I. Preferred etching solutions

Solution No.	Properties	Composition of the etchant	Figure
1	Selective GaAs etching	0.1 mol/liter $K_2Fe(CN)_6$ 0.1 mol/liter $K_4Fe(CN)_6$ pH 9.7	2
2	Selective $Ga_{0.7}Al_{0.8}As$ etching	0.225 mol/liter $K_2Fe(CN)_6$ 0.225 mol/liter $K_4Fe(CH)_6$ pH 7	3
3	Selective etching of GaAs without any aluminum	0.3 mol/liter KI 0.04 mol/liter I_2 pH 9.4	6
4	Selective etching of $Ga_{1-x}Al_xAs$ ($x \leq$ 0.15)	0.3 mol/liter KI 0.1 mol/liter I_2 pH 9	—
5	Selective etching of p-type $Ga_{1-x}Al_xAs$	0.0025 mol/liter $Ce(SO_4)_2 \cdot 4H_2O$ 0.0025 mol/liter $Ce(NO_3)_3 \cdot 6H_2O$ pH <2	7

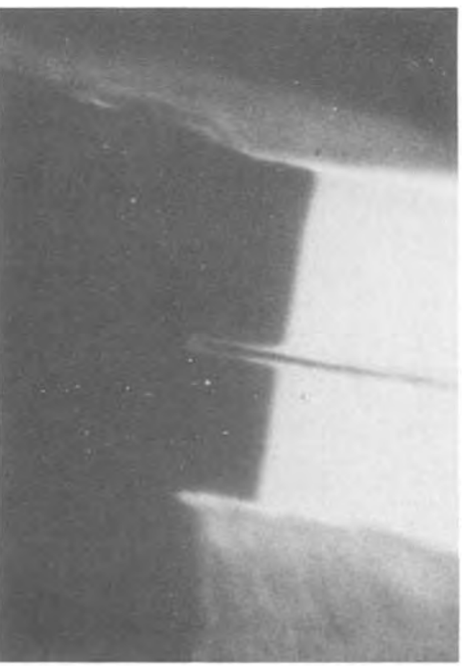

Fig. 6. A secondary emission image of a slice as shown in Fig. 1, etched in an iodine-potassium iodide solution. The solution contains 0.04 mol/liter I_2 and 0.3 mol/liter KI; the pH is 9.4. The GaAs layers are etched selectively. The etching time is 30 sec.

Preferential etching occurs in many I_2-KI solutions. In Fig. 8 the left and the right part show both a cleavage perpendicular to the two {110} planes of a double heterojunction GaAs laser slice. The figure demonstrates that the etch rate of the A{111} planes is slower than those of other planes. The I_2-KI solutions can also be used to etch GaP selectively with respect to InGaP or GaAlAs. The composition of the etchant is the same as that used for etching Al-con-

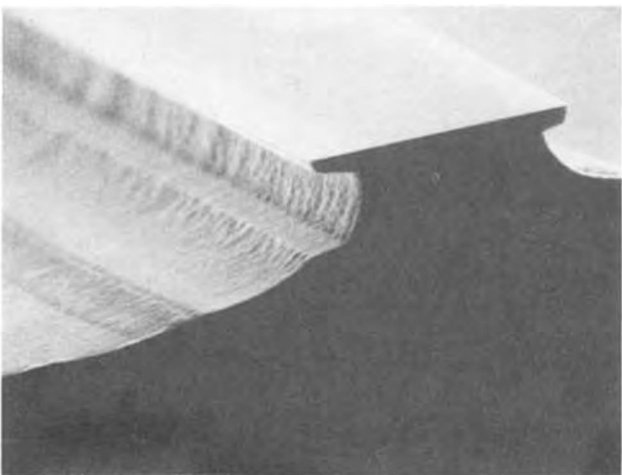

Fig. 7. A secondary emission image of an under-etched mesa structure. The high mesa structure (8) is obtained by etching the slice with a H_2SO_4:H_2O_2:H_2O (3:1:1) mixture. The p-type as well as the n-type $Ga_{1-x}Al_xAs$ are exposed to the etchant. Only the p-type $Ga_{1-x}Al_xAs$ is etched. The etchant contains 0.0025 mol/liter $Ce(SO_4)_2$ and 0.0025 mol/liter $Ce(NO_3)_3$; the pH < 2.

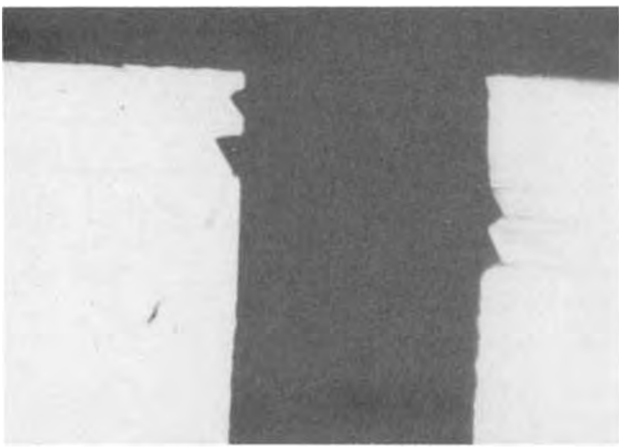

Fig. 8. Cross sections of etched heterostructure slices. The etched surface shown in (a, left) is a (011) plane. The etched surface of (b, right) is the (011) plane, which is perpendicular to the (011) plane of (a). The preferential etching is obtained with an etchant consisting of 0.3 mol/liter KI and 0.2 mol/liter I_2; the pH is 4. The etching time is 10 sec.

taining GaAs layers (solution No. 4 Table I), the pH, however, must be 11 (see Fig. 9).

Applications

Selective etching is of great assistance in the characterizing of heterostructures and can be of great importance for device technology. Examples of these two aspects are given here. A fast selective etchant as the iodine-potassium iodide system was used successfully for the delineation of the active GaAs layer in GaAs-$Ga_{1-x}Al_xAs$ laser structures. A few per cent of aluminum in the GaAs layer is enough to stop the etching. The etch rate is about 1 μ/min which is faster than with the superoxol (30% H_2O_2)-ammonia etch used hitherto (1). The I_2-KI etchant (solution 3 Table I) is also very useful for the complete removal of the GaAs substrate in order to study the aluminum content of the n-type GaAlAs layer, while no special measures have to be taken to protect this layer as was done by Brown *et al.* (7) removing the GaAs substrate with the superoxol-ammonia etchant (1). The selective $Ga_{0.7}Al_{0.3}As$ etching with the cerisulfate-ceronitrate system is used to make an "under-etched" mesa structure. Starting from a low mesa structure (8) the active region was narrowed by under-etching

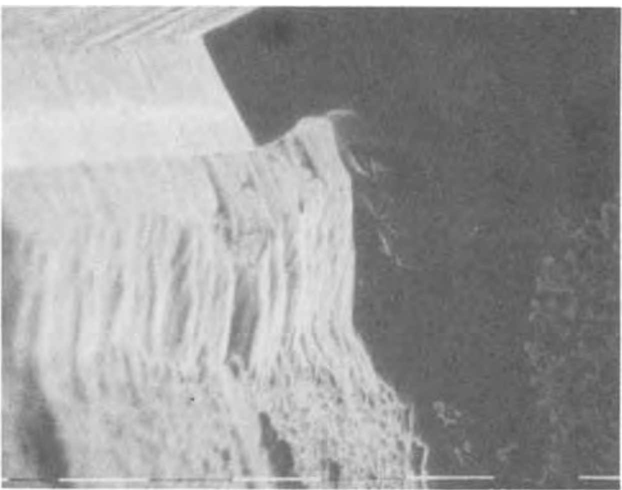

Fig. 9. A secondary emission image of a GaP-InGaP heterostructure. The GaP is selectively etched with a solution consisting of 0.3 mol/liter KI and 0.2 mol/liter I_2; the pH is 11. The etching time is 90 min. The temperature of the etching solution is 45°C.

the p-type $Ga_{1-x}Al_xAs$ layer, which is sandwiched between the top GaAs layer and the active GaAs layer. This structure has the advantage of a larger contact area combined with a narrow active region. The contact resistance and the thermal resistance are found to be superior to those of the classical mesa structure (8) (see Fig. 10). The etch rate of the p-type GaAlAs closely depends on whether the heterojunction between the p-GaAs active layer and the p-type $Ga_{0.7}Al_{0.3}As$ layer on top of it is exposed to the etching solution or not. An exposed heterojunction increases the etch rate of the GaAlAs by a factor of 3 to 5.

Conclusions

The etching experiments described have shown conclusively that selective etching in a redox system can be performed successfully. This new approach to obtaining etching solutions gives technologists numerous alternatives. Acidic or basic environment, or even a neutral one, may be chosen if this is required to etch either GaAlAs or GaAs. Dissolving of the photoresist or of the metal contacts, and many other problems, can now be avoided by a suitable choice from numerous etching solutions available.

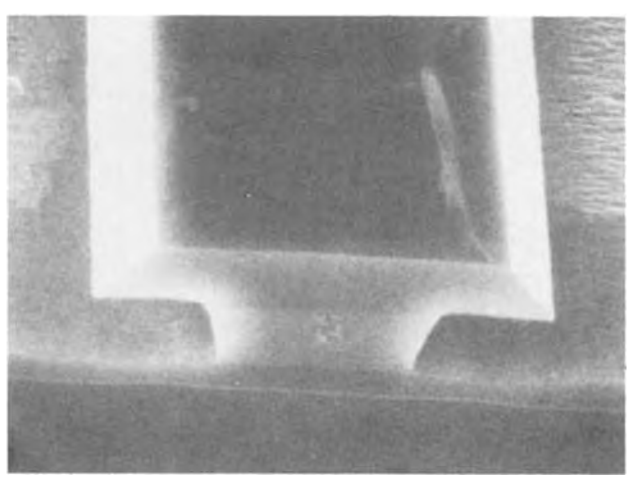

Fig. 10. A secondary emission image of an under-etched mesa-stripe laser. The standard mesa structure is obtained by etching the slice with a H_2SO_4:H_2O_2:H_2O (3:1:1) mixture. The p-type GaAlAs layer is partly removed by the additional processing step of selective etching. The sharp edges show the high degree of selectivity. The etchant contains 0.0025 mol/liter $Ce(SO_4)_2$ and 0.0025 mol/liter $Ce(NO_3)_3$; the pH < 2.

This paper is concerned with preliminary experimental results of etching GaAs and GaAlAs with redox systems. The study is being continued in order to achieve a better understanding of the mechanism underlying this kind of etching behavior.

Acknowledgments

The authors wish to thank Dr. D. de Nobel and Dr. J. Kelly for stimulating discussions and encouragement and Mr. W. Nijman for providing the GaAs-GaAlAs heterostructure material and Miss C. Fisher of Mullard Research Laboratories for providing the GaP-InGaP material. We also thank Mr. C. Geenen, who made the SEM photographs.

Eu^{2+} Luminescence in Hexagonal Aluminates Containing Large Divalent or Trivalent Cations

A. L. N. Stevels and A. D. M. Schrama-de Pauw

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The Eu^{2+} luminescence in hexagonal aluminates containing large divalent or trivalent cations was studied in relation to the crystal structures of the host lattices. It was found that these can be divided into three groups: compounds with the magnetoplumbite structure like $MeAl_{12}O_{19}$ (Me = Ca, Sr, Eu); the La-containing aluminates ($La_{1-x}Al_{11\,2/3+x}O_{19}$ and $LaMgAl_{11}O_{19}$) which have a structure quite close to magnetoplumbite; and phases with the β-alumina structure like $MeMgAl_{10}O_{17}$ (Me = Sr, Eu, Ba) and $Ba_{1-x}Al_{11}O_{17.5-x}$ ("$BaAl_{12}O_{19}$"). In the first type of host lattice, the Eu^{2+} luminescence is at a relatively short wavelength, in the last group at relatively long wavelength. The La aluminates doped with Eu^{2+} take an intermediary position in this respect. The existence of various types of host lattices is also reflected in the shape and the position of the excitation spectra of the Eu^{2+} luminescence. Their complicated shapes allow only a qualitative discussion of the position of the excited 5d levels of the Eu^{2+} ion. The quantum efficiency of the luminescence was found in most cases to be high. The temperature dependence curves of the intensity of the Eu^{2+} luminescence can be divided into two groups: those of the magnetoplumbite(like) phosphors and those of the β-alumina type phosphors. The experimental quenching temperatures are discussed in relation to a model proposed by Blasse and Bril.

Hexagonal aluminates of the general formula $MeAl_{12}O_{19}$ (Me = Ca, Sr, Ba) have been known for a long time (1). The existence of a La aluminate with a similar composition was found in 1958 (2), while $LaMgAl_{11}O_{19}$ was reported only quite recently (3).

The luminescence of Eu^{2+} ions in hexagonal aluminate host lattices was reported by Blasse and Bril (4) who found differences in the optical properties of $CaAl_{12}O_{19}{:}Eu^{2+}$, $SrAl_{12}O_{19}{:}Eu^{2+}$, and $BaAl_{12}O_{19}{:}Eu^{2+}$. Quite recently many aluminates and gallates have been prepared in our laboratories as host lattices for luminescence (5-9). As far as the hexagonal aluminates are concerned, an important step was taken by Verstegen (9) who prepared Mg-containing aluminate phosphors with compositions derived from $MeAl_{12}O_{19}$ by analogy with the well-known hexagonal ferrites (10). It was established (6, 9) that most of these Mg-containing aluminate-Eu^{2+} phosphors had luminescence properties different from $MeAl_{12}O_{19}{:}Eu^{2+}$ (Me = Ca, Sr, Ba). Moreover, it was concluded (6) that these compounds also have crystal structures deviating from the magnetoplumbite type which was supposed to be common to the $MeAl_{12}O_{19}$ compounds. In the same paper (6), the crystal structure of $BaAl_{12}O_{19}$ was also said to deviate from the magnetoplumbite type.

The purpose of the present paper is to report in more detail on the luminescence properties of Eu^{2+}-activated $MeAl_{12}O_{19}$ and related Mg-modified aluminate phases. In addition, La aluminate:Eu^{2+} and $LaMgAl_{11}O_{19}{:}Eu^{2+}$ have been included in our discussion of emission and excitation spectra, of quantum efficiencies of the luminescence, and of concentration-quenching or temperature-quenching phenomena.

Parallel to the luminescence investigations, an x-ray diffraction study was carried out in our laboratories in order to establish the crystal structures of the host lattices involved. Not only have magnetoplumbite-type structures been found, but also lattices of a related (β-alumina) type. These differences in crystal structure account for many "anomalies" in the luminescence properties as reported earlier (4, 6, 11).

Experimental

The samples were prepared by standard ceramic techniques (firing temperatures between 1200° and 1600°C) from highly reactive (γ-) Al_2O_3, MgO, and $MeCO_3$ (Me = Ca, Sr, Ba) or La_2O_3. The Eu activator is introduced in the form of Eu_2O_3; by heating

Key words: luminescence, aluminates, Eu^{2+}, β-alumina structure, magnetoplumbite structure.

in N_2 containing a few per cent H_2, it is reduced to its divalent state. Introduction of minor amounts of the cations in the form of fluorides (MeF_2 or AlF_3) proved to be essential to stimulate host lattice formation and grain growth. Single crystals were obtained from slowly cooled melts or by the Czochralski method. The luminescence measurements were carried out as described in Ref. (12).

Phase Analysis and Crystal Structures of the Host Lattices

The $MeAl_{12}O_{19}$ series (Me = Ca, Sr, Ba).—The hexagonal aluminates $MeAl_{12}O_{19}$ (Me = Ca, Sr, Ba) were studied by Adelskjöld in 1938 (1). The crystal structure of these compounds was said to be of the magnetoplumbite ($PbFe_{12}O_{19}$) type. A projection of the unit cell on the $[1\bar{1}0]$ plane is shown in Fig. 1(a). It consists of two blocks with the spinel structure separated by layers containing the large cation (Me), one small cation (Al), and three oxygen ions.

Kato and Saalfeld (13) refined the crystal structure of $CaAl_{12}O_{19}$ and confirmed its isotypism with $PbFe_{12}O_{19}$. For $SrAl_{12}O_{19}$ and $BaAl_{12}O_{19}$, no structure refinements have been published up to now, but it has been generally assumed (4, 14) that these compounds are of the magnetoplumbite type.

However, recent analysis of luminescence and crystallographic data provided evidence that the structure of $BaAl_{12}O_{19}$ might be of a deviating type. This prompted an extensive x-ray diffraction study at our laboratories on single crystals of this material. Since full details will be published elsewhere (15), we briefly summarize here the results:

(*i*) The unit cell actually found has a volume threefold that of a magnetoplumbite-type unit cell.

(*ii*) Two of the three subunits of this large cell have the structure of the β-alumina type and have consequently the formula $BaAl_{11}O_{17}$.

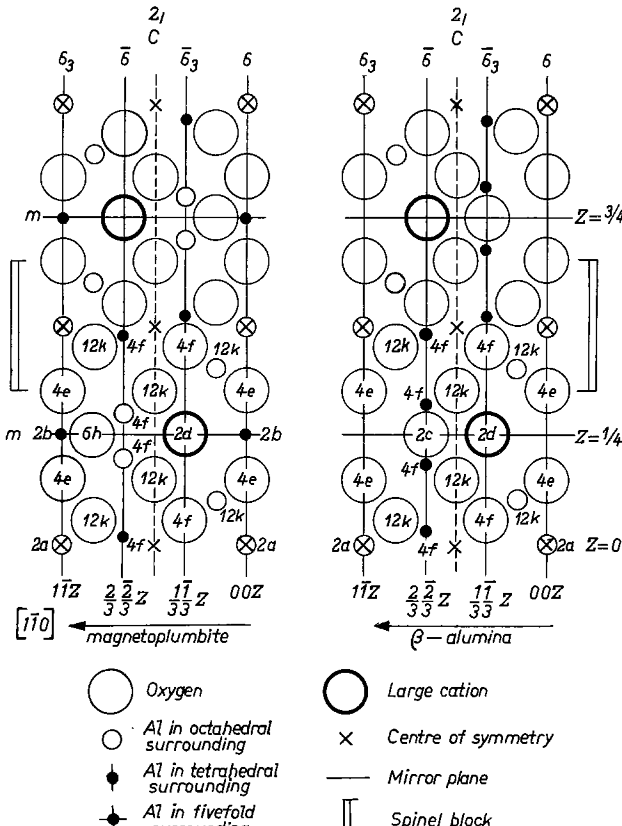

Fig. 1. Projection on the $[1\bar{1}0]$ plane of unit cells of the (a, left) magnetoplumbite and (b, right) β-alumina crystal structures, Ref. (10).

(*iii*) The third subunit has a more complicated structure. It is strongly defective in Ba, but contains extra oxygen atoms.

(*iv*) As a consequence of *ii* and *iii* the approximate composition of Ba aluminate is rather $Ba_{1-x}Al_{11}O_{17.5-x}$ rather than $BaAl_{12}O_{19}$.

The β-alumina structure type is shown in Fig. 1(b). As for magnetoplumbite, the unit cell consists of two spinel blocks separated by intermediate layers. In the β-alumina type only two atoms are positioned in these layers, *viz.*, the large cation Me and one oxygen ion. Their configuration is such that a relatively large space is available for the Me cations. It has been concluded earlier (6) that in magnetoplumbites this space is much less and that cation-oxygen distances can become very small with increasing radius of the cations. This possibly explains why Ba aluminate ($r_{Ba^{2+}}$ = 1.33Å) is of a (distorted) β-alumina type, whereas $SrAl_{12}O_{19}$ ($r_{Sr^{2+}}$ = 1.12Å), Pb ($r_{Pb^{2+}}$ = 1.20Å), and Eu ($r_{Eu^{2+}}$ = 1.13Å) and Ca ($r_{Ca^{2+}}$ = 0.99Å) aluminates have the magnetoplumbite structures.

Mg-substituted aluminates.—In a recent publication, Verstegen (9) has drawn attention to the fact that a structural relationship exists between ferrites like $MgFe_2O_4$ (or Fe_3O_4 = $FeFe_2O_4$) and $BaFe_{12}O_{19}$, gallates like $MgGa_2O_4$ and $MeGa_{12}O_{19}$ (Me = Sr, Ba), and aluminates like $MgAl_2O_4$ and $MeAl_{12}O_{19}$ (Me = Ca, Sr, Ba). On the basis of this analogy, Verstegen has studied aluminate compositions which are counterparts of more complex hexagonal ferrites like $BaFe_2^{2+}Fe_{16}^{3+}O_{27}$ (the so-called W-type), $Ba_2Fe_2^{2+}Fe_{12}^{3+}O_{22}$ (Y-type), $Ba_2Fe_2^{2+}Fe_{28}^{3+}O_{46}$ (X-type), and $Ba_3Fe_2^{2+}Fe_{24}^{3+}O_{41}$ (Z-type). These compounds have magnetoplumbite structures in which additional $Fe^{2+}Fe_2^{3+}O_4$ spinel blocks are intercalated or from which Fe_3O_4 has been subtracted.

By substituting Al^{3+} for Fe^{3+} and Mg^{2+} for Fe^{2+}, Verstegen (9) found aluminate phases which showed very effective activation of luminescence with, *e.g.*, Tl^+, Eu^{2+}, or Ce^{3+} ions. Although it was concluded that large quantities of $MgAl_2O_4$ can be taken up in the magnetoplumbite lattice, no indications were found for the existence of phase analogous to the corresponding hexagonal ferrites.

A somewhat different approach (6) leading to samples with similar compositions as discussed above is direct "substitution" of Mg^{2+} for Al^{3+} in $MeAl_{12}O_{19}$ (Me = Ca, Sr, Ba) compounds. It was reported in Ref. 6 that for compositions like $SrMgAl_{11}O_{18.5}$ and $BaMgAl_{11}O_{18.5}$ both the lattice parameters and also the intensities of several diffraction lines deviate from the nonsubstituted aluminates with magnetoplumbite structure. It was concluded that this type of phases had a close similarity with Ba aluminate.

The combination of the results of the above-mentioned investigations and the fact that Ba aluminate has a pronounced β-alumina character suggested that in $MgAl_2O_4$-modified or Mg-substituted aluminates, β-alumina type phases may in fact occur. By analogy with compounds having this structure and containing monovalent metal ions (like $NaAl_{11}O_{17}$ and $KAl_{11}O_{17}$), the ideal composition of the β-alumina containing large divalent cations and Mg^{2+} was predicted as $Me^{2+}MgAl_{10}O_{17}$. A single crystal study made by Braun *et al.* (15) on $BaMgAl_{10}O_{17}$ indeed confirmed our conjecture.

By powder diffraction methods, a large number of compounds has been identified as being isostructural to $BaMgAl_{10}O_{17}$. Their ideal compositions, lattice parameters, and c/a ratio of the hexagonal axes are listed in Table I. It can be concluded from this table that c/a increases with the ionic radius of the large divalent cation. A similar result has also been found for the β-alumina containing monovalent cations.

On studying $Eu^{2+} \rightarrow Mn^{2+}$ energy transfer in hexagonal aluminates (16), it was found that, apart from

Table I. Lattice parameters of $Me^{2+}MgAl_{10}O_{17}$ and $Me^{2+}MnAl_{10}O_{17}$ phases

Lattice	a(Å)	c(Å)	c/a	Radius of Me^{2+} (Å)
$SrMgAl_{10}O_{17}$	5.6255 ± 0.0001	22.3902 ± 0.0006	3.9801	1.12

$Ba_{1-x}Al_{11}O_{17.5-x}$	5.5910 ±0.0003	22.720 ± 0.002	4.064	1.33
$BaMgAl_{10}O_{17}$	5.6224 ± 0.0001	22.6268 ± 0.0006	4.024	1.33
$BaMnAl_{10}O_{17}$	5.593 ± 0.005	22.42 ± 0.03	4.009	1.33

being a luminescence center, Mn^{2+} ions can act in a way similar to Mg^{2+} ions as a "structure modifier" of magnetoplumbite types. A number of lattice parameters of Mn-containing β-alumina is also listed in Table I.

The homogeneity range of the phases of which the "ideal" composition is listed in Table I could not be established very well. This seems to be due to the slow reaction kinetics in the aluminate systems considered. Even for the fastest reacting qualities of the Al_2O_3 starting material, only small differences could be established between slowly cooled or rapidly quenched samples.

As can be seen from Table I, no CaMg aluminate with β-alumina type structure could be prepared. In the Al_2O_3-rich part of the CaO-MgO-Al_2O_3 system only a highly defective magnetoplumbite-type phase with possible composition $CaMg_xAl_{12-2/3x}O_{19}$ was found; the lattice parameters suggest that Mg indeed enters the lattice. In the same part of the SrO (or EuO or PbO)-MgO-Al_2O_3 systems, a phase separation between β-alumina and magnetoplumbite phases was found. As far as could be established, the homogeneity range of the magnetoplumbite phases in these ternary systems tends to narrow in the direction of increasing ionic radius of the large cation, that is, in the direction $Sr^{2+} \rightarrow Eu^{2+} \rightarrow Pb^{2+}$.

With the preparation conditions used, there were no indications that in these systems a kind of ordered intermediate phase, *e.g.*, with alternating "β-alumina" and "magnetoplumbite" layers between the spinel blocks of the crystal structure, occurs.

In the Al_2O_3-rich part of the BaO-MgO-Al_2O_3 system, a complete miscibility was found between, *e.g.*, $BaMgAl_{10}O_{17}$ and $Ba_{1-x}Al_{11}O_{17.5-x}$. Apparently the distortion of the β-alumina lattice as found for the latter composition can take place in a continuous way.

In Fig. 2 we have summarized the results presented above. This figure suggests that the "β-alumina tendency" increases with increasing ionic radius of the cation and with the addition of Mg, whereas the magnetoplumbite character decreases in the same order.

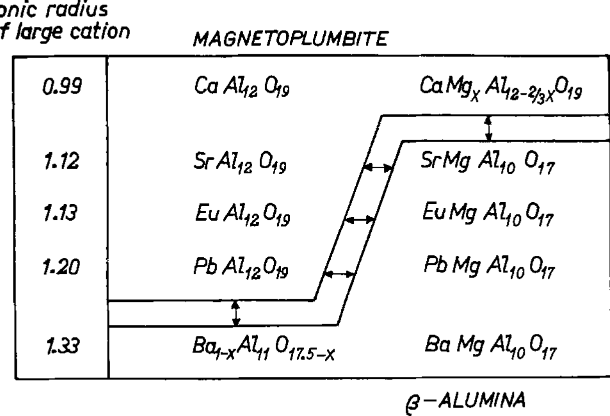

Fig. 2. Schematic drawing of magnetoplumbite-β-alumina relations. The double arrows represent phase separations.

In the systems described above, we have also looked for phases analogous to the complex W, Y, X, and Z ferrites which can be derived from the β-alumina type, similar to the way W, Y, X, and Z ferrites can be derived from magnetoplumbite. Keeping in mind that β-alumina can be derived from magnetoplumbite by subtracting one formula unit Al_2O_3 and adding one unit MgO for each large cation present in the formula, examples for the BaO-MgO-Al_2O_3 system are listed in Table II.

With powder synthesis it was not possible to prepare samples containing phases with any of the crystal structures mentioned in Table II. From a melt of MgO-rich Ba aluminates, however, crystals of the β-W phase $BaMg_3Al_{14}O_{25}$ were obtained [see also Ref. (15)].

Hexagonal aluminates containing large trivalent cations.—By replacing Me^{2+} in $MeAl_{12}O_{19}$ by a trivalent ion of similar ionic radius (*e.g.*, La^{3+} or Ce^{3+}) and simultaneously substituting Mg^{2+} for one of the Al^{3+} ions, compounds of the composition $LaMgAl_{11}O_{19}$ and $CeMgAl_{11}O_{19}$ can be derived. Such compounds were indeed reported by Verstegen *et al.* (3), who described these phases as being isomorphous to $SrAl_{12}O_{19}$, that is, of magnetoplumbite type.

In a similar way as Mg^{2+} was substituted for Al^{3+} in aluminates containing divalent large cations, we can in the trivalent case substitute Al^{3+} for Mg^{2+}. In this way La aluminates of approximate composition $LaAl_{12}O_{19.5}$ are derived. Such a La compound has been reported in the literature by Roth and Hasko (2); its crystal structure was said to be of the β-alumina type. In the patent literature (17) the existence of a possibly isomorphous Ce aluminate is mentioned.

In Table III we have summarized the lattice parameter data of the phases discussed above. We see that the c/a ratios of $La_{1-x}Al_{11\,2/3+x}O_{19}$ (3.960) and $Ce_{1-x}Al_{11\,2/3+x}O_{19}$ (3.978) are slightly beyond the limits where the magnetoplumbite crystal structure was found [between 3.915 and 3.954, see Ref. (6)]. Preliminary results of x-ray diffraction work at our laboratories show, however, that the La and Ce aluminates have crystal structures at least closely resembling magnetoplumbite. A further indication for this strong similarity may be our observation that a continuous series of solid solutions exists between $LaMgAl_{11}O_{19}$ and $La_{1-x}Al_{11\,2/3+x}O_{19}$ and in the corresponding Ce system.

Emission and Excitation Spectra

Emission spectra.—In Fig. 3 and 4 we plot the emission spectra at 300°K of Eu^{2+}-doped magnetoplumbite and β-alumina phases. The wavelengths of the maxima of the bands are summarized in Table IV. In the

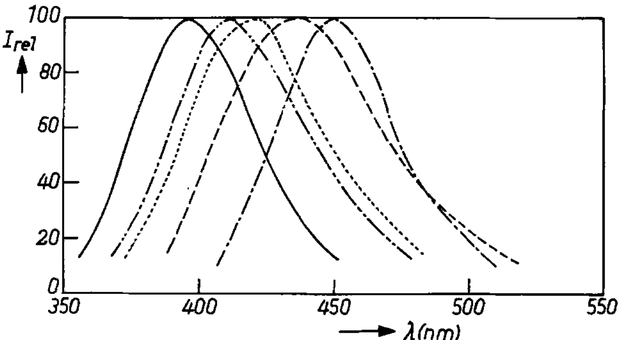

Fig. 3. Spectral energy distribution at 300°K (under 250-270 nm excitation) of the magnetoplumbite $SrAl_{12}O_{19}:Eu^{2+}$ (———), $CaAl_{12}O_{19}:Eu^{2+}$ (—--—), $EuAl_{12}O_{19}$ (- - - -), $La_{1-x}Al_{11\,2/3+x}O_{19}:Eu^{2+}$ (— — —), and $LaMgAl_{11}O_{19}:Eu^{2+}$ (— - —).

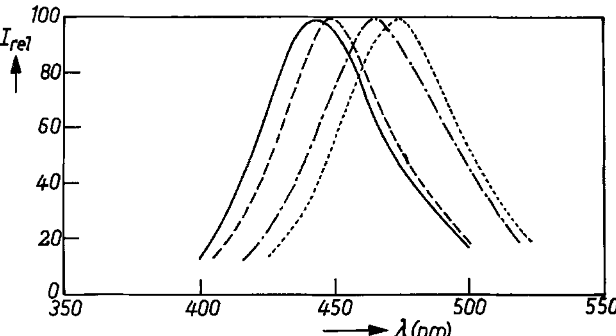

Fig. 4. Spectral energy distribution at 300°K (under 250-270 nm excitation) of the β-alumina $Ba_{1-x}Al_{11}O_{17.5-x}:Eu^{2+}$ (———), $BaMgAl_{10}O_{17}:Eu^{2+}$ (— — —), $SrMgAl_{10}O_{17}:Eu^{2+}$ (— - —), and $EuMgAl_{10}O_{17}$ (- - - -).

magnetoplumbite group, $SrAl_{12}O_{19}:Eu^{2+}$ has a maximum at the shortest wavelength (395 nm), the $CaAl_{12}O_{19}:Eu^{2+}$ band is peaking at 410 nm, and the $EuAl_{12}O_{19}$ band at 420 nm. The luminescence of the La compounds is situated at longer wavelengths: 435 nm for $La_{1-x}Al_{11\,2/3+x}O_{19}:Eu^{2+}$ and 450 nm for $LaMgAl_{11}O_{19}:Eu^{2+}$.

Generally, the β-alumina emits at longer wavelengths, the shortest wavelength (of $Ba_{1-x}Al_{11}O_{17.5-x}:Eu^{2+}$) is found at 440 nm, which is only 10 nm below the longest wavelength emission of the magnetoplumbite ($LaMgAl_{11}O_{19}:Eu^{2+}$ at 450 nm). The $BaMgAl_{10}O_{17}:Eu^{2+}$ and $SrMgAl_{10}O_{17}:Eu^{2+}$ bands peak at 450 and 465 nm, respectively; the $EuMgAl_{10}O_{17}$ at 475 nm.

The above-mentioned maxima of the luminescence band can be shifted to a small extent by changing the amount of Eu^{2+} and/or the Mg^{2+} present in the samples.

On increasing the Eu content in the host lattices, the maxima of the luminescence bands of the phosphors gradually shift to 420 nm ($EuAl_{12}O_{19}$) or to 475 nm ($EuMgAl_{10}O_{17}$). The increase of the Mg content in $MeMgAl_{10}O_{17}:Eu$ leads to shifts to a longer wavelength of 10-15 nm. This tendency is parallel to what can be seen on comparing the emission maxima of Ca aluminate (410 nm) and Ba aluminate (440 nm), respectively, with Ca-Mg aluminate (425 nm) and Ba-Mg aluminate (450 nm).

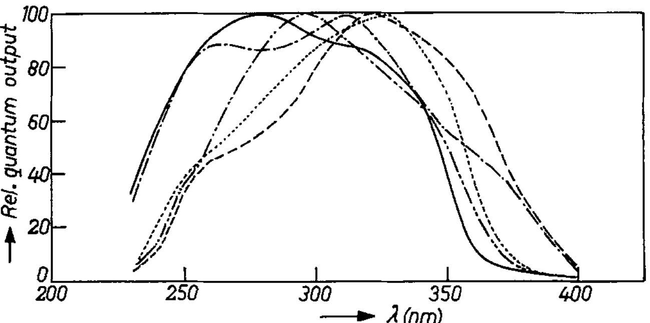

Fig. 5. Excitation spectrum at 300°K of the magnetoplumbite $SrAl_{12}O_{19}:Eu$ (———), $CaAl_{12}O_{19}:Eu^{2+}$ (— - - —), $EuAl_{12}O_{19}$ (- - - -), $La_{1-x}Al_{11\,2/3+x}O_{19}:Eu^{2+}$ (— — —), and $LaMgAl_{11}O_{19}:Eu^{2+}$ (— - —).

Part of the emission spectra shown has been published earlier (4, 6). There is good agreement between the earlier data and those of the present investigation.

In Eu^{2+} ions the luminescence usually takes place from excited 5d levels to the 4f ground state. Two factors determine the wavelength of the emission band: on the one hand, the splitting of the 5d levels by the crystal field of the surrounding oxygen ions and, on the other hand, the energy gap between the 4f ground state and the "center of gravity" of 5d excited levels. The latter energy is dependent on the covalent character of the central ion-ligand bonds. More information about the energies involved can be obtained from diffuse reflection and excitation spectra. Due to strong absorption, the reflection spectra are less suitable for obtaining appropriate data. The excitation spectra and their relation to the position of the luminescence bands will be discussed in the next section.

Excitation spectra.—Excitation spectra at 300°K for the maxima of the luminescence bands are presented in Fig. 5 and 6. In the magnetoplumbite hosts (Fig. 5) broad, rather superimposed bands in the u.v. region are found. The 2(b) position of the Eu^{2+} activator ions (Fig. 1) has a D_{3h} local symmetry, so that the excited 5d levels of Eu^{2+} are expected to split into three levels (A′, E′, and E″) in the crystal field. Although the form of the excitation curves differs from host to host, the three-band character of each of them can be easily recognized. The spectra suggest further that the center of gravity of the 5d levels remains at about the same wavelength (≈ around 300 nm). In view of this, we conclude that the crystal field on the Eu^{2+} ions is the strongest in $LaMgAl_{11}O_{19}$, where the lowest excited level can be identified at about 375 nm. In a similar

Table IV. Luminescence data of Eu^{2+}-doped aluminates

* λ_{max} = Position of the maximum of the luminescence band (250-270 nm excitation) 300°K.
** Q.E. = Quantum efficiencies of non-optimized samples doped with 2% Eu at 300°K (250 270 nm excitation).
*** T_{50} = Quenching temperature (= temperature at which the intensity of the luminescence is half of that at 77°K) of samples doped with 2% Eu.

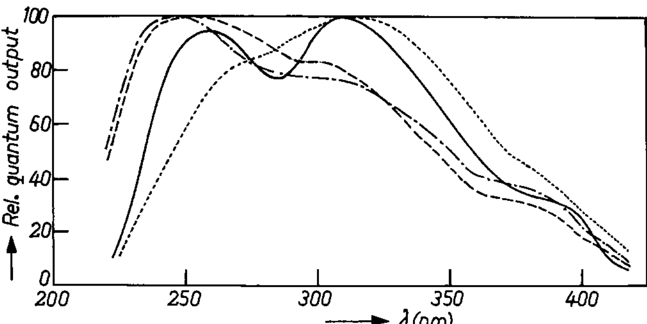

Fig. 6. Excitation spectrum at 300°K of the β-alumina $Ba_{1-x}Al_{11}O_{17.5-x}$:$Eu^{2+}$ (———), $BaMgAl_{10}O_{17}$:Eu^{2+} (— — —), $SrMgAl_{10}O_{17}$:Eu^{2+} (— - —) and $EuMgAl_{10}O_{17}$ (- - - -).

way, this level can be situated at about 360 nm for La aluminate:Eu^{2+}, at ±355 nm for $EuAl_{12}O_{19}$, at ±345 nm for $CaAl_{12}O_{19}$:Eu^{2+}, and at about 340 nm for $SrAl_{12}O_{19}$:Eu^{2+}. On confrontation with the results of emission measurements we find that a striking parallelism exists: the phosphor with the lowest lying excitation level has also the Eu^{2+} emission at the longest wavelength, the Stokes shift between excitation and emission being about 4500 cm^{-1} in the whole series.

In the β-alumina host lattices, where the 5d levels are also expected to be split into three bands, the excitation spectra are somewhat better resolved (Fig. 6). Again, the center of gravity of the 5d levels is situated at about the same wavelength for all phosphors considered (300 nm). The lowest lying excitation band is better separated from bands in the 300-350 nm region, but espcially in the Mg-containing host lattices some additional splitting of this band seems to occur so that it is difficult to define unequivocally its position. If, however, we extend the parallelism between the position of the lowest lying excitation bands and the position of the emission bands as found for the magnetoplumbites, we conclude that the β-alumina phosphors will emit at longer wavelength than the former group. This is actually observed (see above), with the exception of $Ba_{1-x}Al_{11}O_{17.5-x}$:$Eu^{2+}$. This may be attributed to the fact that the Stokes shift of the luminescence in Ba aluminate is much smaller (±2500 cm^{-1}) than in magnetoplumbites (±4500 cm^{-1}). The shape of the excitation spectra (but not the position of the excitation bands) was found to be dependent on the preparation conditions of the samples (raw materials, firing temperature), It may be possible that the slight differences between the excitation spectra of the present investigation, those of Blasse and Bril (4) for $MeAl_{12}O_{19}$:Eu (Me = Ca, Sr, Ba), and those of Tamatani (11) for Ba and La aluminate are due to such reasons.

Eu^{2+}-Eu^{2+} energy transfer.—In order to discuss concentration quenching phenomena (see below) and the energy transfer from Eu^{2+} to Mn^{2+} ions (16) in more detail, we have also considered the Eu^{2+}-Eu^{2+} energy transfer in hexagonal aluminates. Since the 4f → 5d transition in Eu^{2+} is an allowed one, the transfer will mainly occur by dipole-dipole interaction (18). The probability, P, of energy transfer between Eu^{2+} ions by this interaction has been given as (18, 19)

$$P_{Eu^{2+}\text{-}Eu^{2+}} = 3 \cdot 10^{12} \cdot \frac{P_A}{R^6 \tau_{Eu}} \cdot \frac{1}{E^4} \int f_{Eu}(E) F_{Eu}(E) dE \quad [1]$$

where P_A = the oscillator strength of the 4f → 5d transition in Eu^{2+}; R = the distance between the Eu^{2+} ions (in Å); τ_{Eu} = the decay time of the luminescence (in sec); E = the energy transferred (in eV); and $\int f_{Eu}(E) F_{Eu}(E) dE$ = the overlap between emission and excitation bands. $f_{Eu}(E)$ and $F_{Eu}(E)$ represent the normalized shape of the emission and the lowest energy absorption (excitation) bands.

For the phosphors under consideration, the problem of determining the overlap integral is to separate a well-defined "lowest excitation level" from the excitation spectra as shown in Fig. 5 and 6. For the β-alumina materials a reasonable estimation can be made; we find for this group an energy overlap of about 0.1 eV^{-1}. For the magnetoplumbites the energy overlap can be said to be in the same order of magnitude. Such a figure compares well with energy overlap data of Blasse (19) for Eu^{2+} ions in $BaZrO_3$ (0.05 eV^{-1}) and $BaBPO_5$ (0.3 eV^{-1}). If we substitute in formula [1] P_A = 0.01 (the usual figure for 4f → 5d transitions), R = 5.6Å (the distance for nearest Eu^{2+} neighbors in the lattice), 1 μsec for $\tau_{Eu^{2+}}$ (16), and 3 eV for E, we find $P_{Eu\text{-}Eu} = 10^9$ sec^{-1}. Since the probability of radiative decay (P_{rad}) is about 10^6, we conclude that efficient energy transfer is found between nearest neighbor Eu^{2+} ions in aluminate host lattices.

With the help of Eq. [1], it can also be concluded that the energy transfer between Eu^{2+} ions positioned in the same intermediate layer is much more effective than that between Eu^{2+} ions in different intermediate layers across the spinel block (Fig. 1). Since, in the latter case, the distance between the ions is about 11Å, we find for the ratio of the probabilities of transfer between nearest neighbors

$$\frac{P\text{ (different layer)}}{P\text{ (same layers)}} \approx \left(\frac{5.6}{11}\right)^6 \approx 0.017$$

Quantum Efficiency of the Luminescence

Quantum efficiency data.—In Table IV we list typical quantum efficiencies at 300°K for aluminates doped with 2% Eu^{2+} ions, using 250-270 nm excitation. In general, we can say that the efficiency of the phosphors is high, especially if we take into account that the maximum of the excitation spectrum is not always situated in the 250-270 nm range. Since the aluminate phosphors were found to have almost flat reflection spectra in the 230-350 nm range, the excitation spectra give directly the quantum efficiency as a function of wavelength. It should be noted that the figures given in Table IV are typical ones. By optimizing the preparation conditions, still higher values can be obtained (9).

Concentration quenching.—The usual explanation for the occurrence of concentration quenching, that is, the decrease of the measured quantum efficiency if the activator concentration exceeds a certain level, is that efficient energy transfer from the luminescent centers to, for example, defects in the lattice, which act as radiationless "sinks" takes place. A study by Blasse (19, 20) showed that, as can be expected, the efficiency of the energy transfer between the luminescent centers is in many cases the determining factor for concentration quenching.

As a yardstick for the effectiveness of energy transfer by dipole-dipole interaction, Blasse (19) defined a critical distance, R_c, between two luminescent centers, S and A, as the distance for which the probability of transfer from S to A equals the probability of radiative emission of S. In terms of Eq. [1] this means that $P_{Eu\text{-}Eu} \cdot \tau_{Eu} = 1$. Therefore, R_c can be found from the equation

$$R_c^6 = 3 \cdot 10^{12} \cdot \frac{P_A}{E^4} \int f_S(E) F_A(E) dE \quad [2]$$

By substituting for the parameters the data given previously, we find for the critical distance of Eu^{2+}-Eu^{2+} energy transfer in the aluminates figures of about 18Å.

The distance R_c can also be estimated from geometrical considerations (19) with help of the formula

$$R_c \approx 2\left(\frac{3V}{4\pi x_c N}\right)^{1/3} \quad [3]$$

where R_c = the critical distance (in Å); V = the volume of the unit cell (in $Å^3$); x_c = the activator atom fraction ("the concentration") at which the quenching starts, the so-called critical concentration; and N = the number of sites per unit at which the activator atoms enter.

The problem in Eu^{2+}-doped aluminates is to establish the critical concentration, x_c. We can, however, follow the reverse way and estimate x_c from values of R_c calculated from Eq. [1]. Since in the aluminates the energy transfer within each intermediate layer is much more efficient than that across the spinel blocks, the volume of the intermediate layers is substituted for V. We find in this way $x_c \approx 0.04$ both for magnetoplumbites and β-alumina host lattices.

In Fig. 7 we plot quantum efficiency *vs.* Eu^{2+} concentration for the $Sr_{1-x}Eu_xAl_{12}O_{19}$ and $Ba_{1-x}Eu_xMgAl_{10}O_{17}$ systems. The solid line refers to the Sr system, the dashed line to the Ba-Mg system. At first sight, the observed x_c for $Sr_{1-x}Eu_xAl_{12}O_{19}$ agrees fairly well with the calculated figure of ≈ 0.04. However, in $Ba_{1-x}Eu_xMgAl_{10}O_{17}$, the measured curve runs almost completely flat. In such a case, it is impossible to estimate a reliable figure for x_c.

Since in both systems considered the energy transfer between Eu^{2+} ions is about equally efficient, this parameter cannot account for the differences in concentration-quenching behavior. This implies, rather, that the defect situation (the "sinks") may influence the form of the concentration-quenching curves. Such a conclusion is supported by experiments in which we have substituted low concentrations of various types of "foreign" atoms (in low concentrations) in, *e.g.*, $Sr_{1-x}Eu_xAl_{12}O_{19}$. The effect of this substitution is shown in Fig. 7. The quantum efficiency *vs.* Eu content curve of Sr aluminate: Eu can even take the form of that of BaMg aluminate: Eu. The last-named curve is not changed by the substitution of foreign atoms.

This observation suggests that the agreement between observed and calculated x_c in Sr aluminates: Eu^{2+} is rather accidental. In fact, we do find that, as long as the nature of sinks and the kinetics of radiationless losses of excitation energy are not known, it may be misleading to draw conclusions about energy transfer in phosphors from concentration-quenching data especially if the energy transfer seems to be efficient.

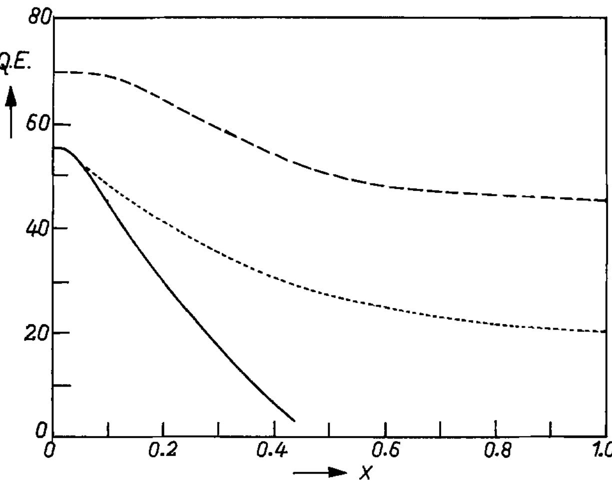

Fig. 7. Concentration-quenching curves. The quantum efficiency (Q.E) is plotted *vs.* the Eu^{2+} content x. The solid and the dotted lines represent $Sr_{1-x}Eu_xAl_{12}O_{19}$ samples prepared with and without addition of small amounts of foreign atoms, the dashed line represents the $Ba_{1-x}Eu_xMgAl_{10}O_{17}$ system.

Temperature Quenching of the Eu^{2+} Luminescence

Temperature-quenching data.—In Fig. 8 and 9, we present on a relative scale (I at 77°K = 100) temperature-dependence curves of the light output of magnetoplumbite and β-alumina type aluminates doped with 2% Eu^{2+} (some data on the effect of the Eu^{2+} concentration on temperature quenching are given below) and for the Eu aluminates themselves. On comparing Fig. 8 and 9, a first conclusion is that the quenching of the Eu^{2+} luminescence in the β-alumina occurs at much higher temperatures than for the magnetoplumbites. If we take T_{50}, the temperature at which the intensity of the luminescence is half of that at 77°K, as an indicator, we find a difference of about 150°-200°K (Table IV). Temperature-quenching data for several aluminates $MeAl_{12}O_{19}:Eu^{2+}$ (Me = Ca, Sr, Ba, La) have also been published by Blasse and Bril (4, 20) and Tamatani (11). The T_{50} figures which can be derived from the curves published by these authors agree fairly well with those of the present investigation.

On further consideration of Table IV, it can be seen that within both structural groups the compounds with the largest cations tend to have the highest quenching temperatures. In $MeAl_{12}O_{19}:Eu^{2+}$, T_{50} for Me = Sr (385°K) is larger than for Me = Ca (380°K); in $MeMgAl_{10}O_{17}:Eu^{2+}$, T_{50} for Me = Ba (610°K), higher than for Me = Sr (575°K). The Eu aluminates have a more or less special position due to their high activator content. For that reason we cannot compare directly the T_{50} figures of these materials with the other phosphors.

In the Eu^{2+} La aluminates, the divalent Eu is introduced an a La^{3+} site without charge compensation, so that these compounds will have quenching properties different from the aluminates with large divalent cations. We note, however, that as for $Ba_{1-x}Al_{11}O_{17.5-x}:Eu^{2+}$ and $BaMgAl_{10}O_{17}:Eu^{2+}$ (ΔT_{50} = 75°K), the Mg-containing La aluminates have slightly higher quenching temperatures than the La aluminate itself (ΔT_{50} = 10°K).

Blasse and Bril (20) and Blasse (21) have discussed temperature-quenching phenomena in terms of a con-

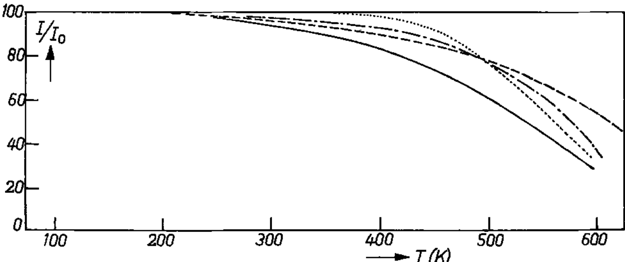

Fig. 9. Temperature dependence of the light output of β-alumina phosphors ($[Eu^{2+}]$ = 0.02). $Ba_{1-x}Al_{11}O_{17.5-x}:Eu^{2+}$ (——), $BaMgAl_{10}O_{17}:Eu^{2+}$ (— — —), $SrMgAl_{10}O_{17}:Eu^{2+}$ (—·—), $EuMgAl_{10}O_{17}$ (- - - -).

figuration-coordinate model. For Eu^{2+} ions replacing divalent cations, the quenching temperature was said to be relatively high in rigid lattices (the so-called "lattice effect") and in cases where Eu^{2+} substitutes for large cations ("size effect"). The data in Table IV indeed confirm these predictions. As far as the lattice effect is concerned, we note that in β-alumina the bonds of the divalent metal ions are strong due to the presence of oxygen ions at a very small distance (in the 2(c) position). This lattice can therefore be considered to be "rigid." In magnetoplumbites the oxygen ions in the intermediate layer are positioned at 6(h) which is much further away. The bond strength is much less so that the lattice can be said to be "weaker." The predicted size effect is also apparent from Table IV (see above), although not so pronounced as for the lattice effect. The replacement of Al^{3+} by Mg^{2+} results in an increase of the unit cell volume and is therefore equivalent to the introduction of a cation in the 2(c) position (see Fig. 1) of larger size.

If divalent Eu replaces a trivalent cation like La, the luminescent center has formally an effective charge. On considering temperature quenching, Blasse (21) explained that two factors play an important role in such a situation. On the one hand, the lattice is relatively more rigid due to strong La^{3+}-O bonds than for the case where Eu^{2+} replaces a divalent ion. This will give a higher T_{50}. On the other hand, the Eu^{2+} ground state is more "expanded" due to the presence of lanthanum ions. This results in a lower T_{50}. The latter can be considered as a kind of a "size effect." Similar to what we have found for the magnetoplumbites with divalent large cations, the lattice effect is supposed to be more important than the size effect so that a higher T_{50} is expected for the La phosphors. This is indeed the case (410° and 400°K instead of about 380°K).

Influence of activator concentration on T_{50}.—Since concentration quenching is not very effective (see above), no drastic changes in T_{50} are to be expected if the activator content increases. In Fig 10 we show this for the $La_{1-x}Al_{11\,2/3+x}O_{19}$:Eu (change in $T_{50} \approx 10$°K)

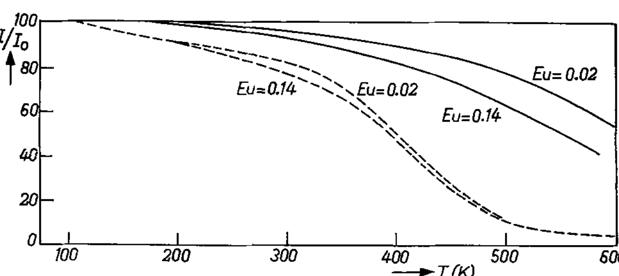

Fig. 10. Concentration effect on the temperature-dependence curves of $BaMgAl_{10}O_{17}$:Eu^{2+} (————) and $La_{1-x}Al_{11\,2/3+x}O_{19}$: Eu^{2+} (— — —).

and $BaMgAl_{10}O_{17}$:Eu^{2+} systems (maximum change in $T_{50} \approx 60$°K). In some of the other aluminate host lattices, more important changes in T_{50} were observed. X-ray diffraction indicates that a phase separation on introduction of large amounts of Eu^{2+} (*e.g.*, in $Ba_{1-x}Al_{11}O_{17.5-x}$:$Eu^{2+}$) is responsible for these changes in T_{50}.

Acknowledgments

The authors wish to thank Dr. J. L. Sommerdijk and Dr. J. M. P. J. Verstegen for helpful discussions. Dr. P. B. Braun and his research group are thanked for their x-ray diffraction studies and Mr. J. P. M. Damen and G. Verspui for the preparation of the single crystals.

Manuscript submitted Nov. 17, 1975; revised manuscript received Jan. 19, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Philips Research Laboratories.

ABSTRACT

GaAs doping with Sn, S, Zn, and Cd during growth in an open chloride vapor transport system was studied. The dopant concentration dependences on growth rate, growth temperature, and vapor pressure were measured. Based on an analysis of the results, it follows that the doping depends on both the substrate orientation and on the electrical nature of the impurity. The observed dependence of impurity concentration on vapor pressure can be obtained, assuming that impurity equilibrium is established, but the carrier concentration in the GaAs at the growth temperature is not determined by the impurity concentration. The binding energies and entropies of various impurities in Ge, Si, and GaAs calculated from the solidus curves of the impurity-semiconductor system are reported.

A study of epitaxial layer doping mechanisms is necessary to grow the layers with preset properties and, in particular, to clear up the nature and the sources of uncontrolled impurities. It is necessary to know a number of the kinetic coefficients related to the processes which govern the impurity incorporation in order to determine the absolute doping level.

Impurity incorporation in the growing crystal is a multistage process, which consists of impurity trapping in an adsorption layer, transformation and motion within the adsorption layer, and, finally, transport from the adsorption layer into the crystal. The relationships describing the rates of the different stages are quite different. If the rate of the last process is determining, the over-all incorporation of the electrically active impurity would be sensitive to the electrical nature of the impurity and to the carrier concentration in the semiconductor surface layer. For the other cases the rate would be determined only by the chemical nature of the doping impurity.

If the incorporation of the impurity into the growing layer is limited by the kinetics of one of these stages, an increase in the growth temperature must lead to an increase in impurity concentration, because kinetic rates normally increase with temperature. Furthermore, the concentrations must approach their equilibrium values as the rates increase. In this connection, it would be very useful to compare the experimental concentrations with those calculated on the assumption of complete equilibrium. Certain features of impurity behavior during GaAs growth by the halide chemical vapor transport method used here have already been published (1-3). The present experiments extend these GaAs doping results, notably for doping with sulfur, tin, zinc, and cadmium.

Experimental

The growth of gallium arsenide epitaxial layers was carried out by an open-tube chloride vapor transport process on semi-insulating GaAs substrates. High purity $AsCl_3$ was used as the chloride source. The gallium source was either metallic Ga or GaAs. The growth parameters were: source temperature, 800°-850°C; substrate temperature, 700°-750°C; $AsCl_3$ temperature, 0°C; flow rate, 150-300 ml·min^{-1}; substrate temperature gradient, 5°C·cm^{-1}. It was possible to obtain undoped layers with carrier concentrations $n \sim 10^4$ cm^{-3} and electron mobilities up to 100,000 cm^2/V·sec at 77°K when grown on (100) substrates by a Ga/$AsCl_3$/H_2 system (4). The carrier concentration in undoped layers was 10^{15} cm^{-3} and the mobility was reduced to 30,000 cm^2/V·sec at 77°K, when undoped GaAs was used as the source.

The doping sources for Zn and Cd were Zn_3As_2 and Cd_3As_2 loaded into quartz ampuls of known volume, which were sealed at one end. The $AsCl_3$ and the products of its decomposition were allowed to diffuse into the hot ampul and etched the Zn_3As_2 or Cd_3As_2 forming gaseous chlorides which diffused out of the ampul. The ampul was placed in a separately controlled temperature zone set at 400°C ahead of the substrate zone. At this temperature neither dissociation of Zn_3As_2 or Cd_3As_2 nor condensation of arsenic and chlorides of zinc or cadmium occurs.

The requirements on the precision of maintaining the temperature of the dopant zone are not severe because diffusivity in the gas phase depends only weakly on temperature. Weighing of the ampul before and after the experiment allowed us to determine the total quantity of dopant used. GaAs was used as the Ga source in these experiments because molten elemental gallium could dissolve some of the impurity and lead to errors in calculating the net quantity of impurity in the gas phase.

Doping by tin was carried out either by the introduction of tin into elemental gallium used as the gallium source or by the introduction of tin chloride into the growth zone through a special channel. It was not possible to determine the tin concentration in the gas phase when the first method was used.

Sulfur doping was accomplished by adding hydrogen sulfide to the reactant stream. The hydrogen sulfide, obtained by decomposition of sulfides, was introduced into the reactor through a special inlet. The hydrogen sulfide vapor pressure was controlled by the sulfide temperature.

The resultant carrier concentrations were measured by the Van der Pauw method (precision of determining carrier concentration is ±15%). The electron and hole concentrations allowed us to estimate the electrically active impurity concentrations. This is the core of our investigation. To do this, it was necessary to take into account the degree of compensa-

Key words: chemical vapor deposition,GaAs—growth, impurities, CVD, doping, segregation, facet effects, S, Sn, Zn, Cd.

tion by (unwanted) impurities of opposite electrical type.

The concentrations of Sn and Zn in the grown layers was determined directly by mass spectrometric and emission spectral methods. For these samples, the measured electron and hole concentrations corresponded closely to the Sn and Zn densities, respectively, determined directly. Hence, residual impurity donors and acceptors must be present only at levels below our lowest intentional doping levels. No such conclusions can be drawn for electrically inactive impurities.

The homogeneity of the layers in a direction perpendicular to the face of the substrate was checked by layer-by-layer etching and subsequent measurement of carrier concentration and mobility, and sometimes by mass spectrometry as well. A reduction of carrier concentration near the film-substrate transition was sometimes observed when doping with tin.

Results and Discussion

A strong variation of dopant concentration with crystallographic orientation has already been established (1-3). However, it was noted that if the carrier concentrations in films grown on substrates of different orientations were plotted against the growth rates on those orientations the results were simple. Although growth rates depend on orientation, dopant densities correlated only with the growth rates (5). Films on different orientations have the same impurity concentrations when their growth rates are equal.

Figure 1 shows the results of films doped by two different Sn concentrations in the gas phase. When polycrystalline GaAs was used as the source (upper curve), the growth rate was changed by varying the amount of gallium arsenide (not exposed surface area) in the source zone. The resultant change of gas phase saturation allowed us to vary the growth rate by two orders of magnitude. The gas phase composition calculated from the net change of source weight during the growth experiment shows that the partial pressures of the components change only a factor of two or three, while the growth rate changes two orders of magnitude. Hence the effect must be kinetic in nature, a departure from equilibrium in the growth zone. When liquid gallium saturated with arsenic was used as the source (lower curve), the growth rate was changed by varying the substrate temperature gradient. The mean substrate temperature was held constant. The lower curve was drawn by using the results from Ref. (5). The points on this curve are the results of our present experiments for characteristic growth rates on (100), (111)A, and (111)B planes. The present results agree with the data from Ref. (5).

Note that the curve of carrier concentration *vs.* growth rate has a minimum. This minimum is shallower for the upper curve obtained at higher Sn concentrations in the gas phase (where the doping was carried out by introduction of Sn chlorides through the special channel). This may imply that the orientation dependence reduces as the doping level increases. One can see that the free electron concentrations in films grown on planes (111)B and (100), and also on (111)A and (100), are equal if their growth rates are equal (upper curve). A similar effect was observed during doping with Zn and S (to be published). The calculated equilibrium Sn concentrations corresponding to the upper curve are less than the measured carrier concentrations. (The calculation of impurity equilibrium concentrations is discussed below.)

The dependence of electron concentration on growth rate has a minimum for S doping also. This minimum also occurred for a growth rate 0.2 μm/min as with Sn doping (Fig. 2).

The dependence of hole concentrations on growth rate for Zn and Cd doping had a maximum at the same growth rates. This is in agreement with the results of another investigation (6). For Zn, the carrier concentrations in films grown on (111)A and (100) planes were equal when their respective growth rates were equal as for the Sn results noted earlier. The growth rates of (111)A and (111)B planes differed by more than one order of magnitude, while the corresponding hole concentrations in films on (111)B ($7.7 \cdot 10^{17}$ cm^{-3}) were one-half order of magnitude less than on (111)A ($4.1 \cdot 10^{18}$ cm^{-3}). This is also in agreement with the previous investigations (6). The variations of the growth rates on substrates of different orientations became smaller and, correspondingly, the orientation influence on Zn segregation was reduced at high doping levels ($\sim 10^{19}$ cm^{-3}).

Orientation dependence during Te doping was observed by Williams (7). If we order his orientations in terms of increasing growth rate, then the associated Te concentrations exhibit a minimum *vs.* growth rate, similar to our donor data.

It is not possible to explain such complicated dependences of doping levels on growth rate with a simple model of material crystallization (1-3). Only

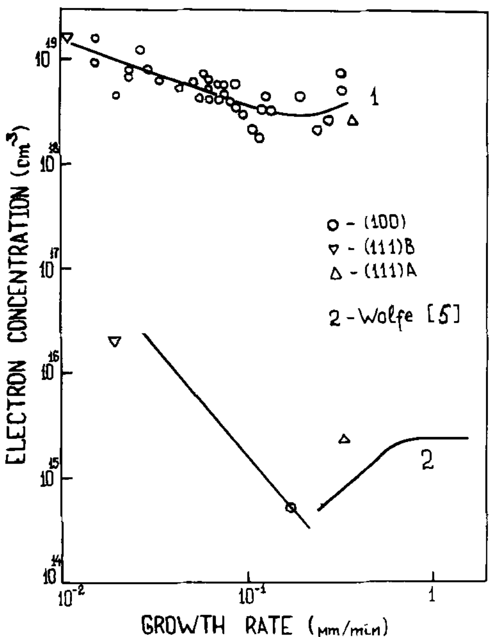

Fig. 1. Dependence of electron concentration on growth rate for Sn doping.

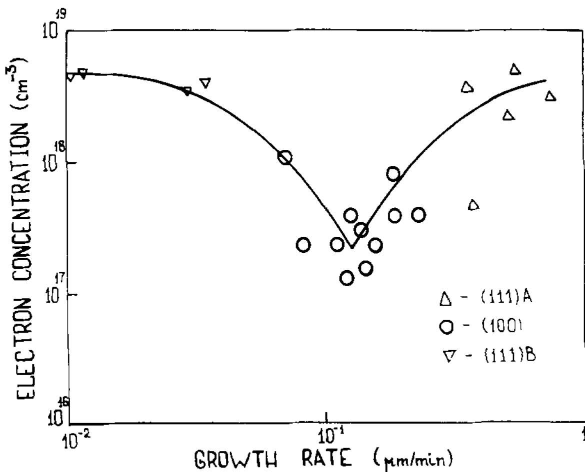

Fig. 2. Dependence of electron concentration on growth rate for S doping.

a monotonic dependence of doping level on growth rate can be predicted (1-3).

However, it is clear that it is primarily the electrical nature of the dopant (donor or acceptor) that determines the observed orientation dependence of the solubility and not the lattice site nor the chemical nature of the dopant nor its molecular form in the gas phase. The donors Sn, S, and Te exhibit a minimum in concentration *vs.* growth rate, whereas the acceptors Zn and Cd exhibit a maximum. In the reaction zone, Sn is present as $SnCl_2$ whereas the other dopants are in elemental form. The donors S and Te occupy As sites, while the acceptors Zn and Cd lie on Ga sites. The donor Sn occupies a Ga site, but its concentration-growth rate behavior is that of the other donors, not that of the other Ga site occupiers. Hence the incorporation of the impurities is sensitive to their electrical nature.

The dependences of Zn and Cd concentrations on the growth temperature for different vapor pressures of these impurities are given in Fig. 3 and 4, respectively. One can see that the Zn concentration hardly depends on the growth temperature. The Cd concentration decreases slowly with temperature at low doping levels and does not depend on growth temperature at high doping levels. The predicted equilibrium Zn (curve 1′ in Fig. 3) and Cd concentrations decrease very slowly with temperature. (The calculation technique is given below.)

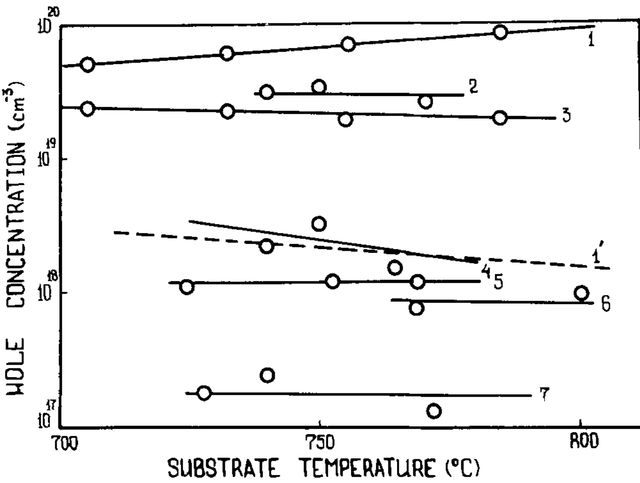

Fig. 3. Dependence of hole concentration on growth temperature for Zn doping, for different vapor pressures P^*_{Zn}: curve 1, $1.12 \cdot 10^{-4}$; curve 2, $1.28 \cdot 10^{-4}$; curve 3, $2.34 \cdot 10^{-5}$; curve 4, $7.87 \cdot 10^{-6}$; curve 5, $5.1 \cdot 10^{-6}$; curve 6, $1.37 \cdot 10^{-6}$; curve 7, $9.75 \cdot 10^{-7}$ (atm). Curve 1′, equilibrium concentration of Zn for $P^* = 1.12 \cdot 10^{-4}$ atm.

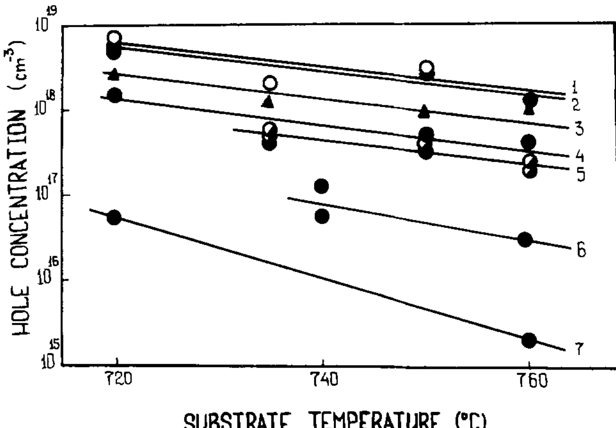

Fig. 4. Dependence of hole concentration on the growth temperature for Cd doping, for different vapor pressures P^*_{Cd}: curve 1, $9.3 \cdot 10^{-3}$; curve 2, $5.2 \cdot 10^{-3}$; curve 3, $3.2 \cdot 10^{-3}$; curve 4, $1.78 \cdot 10^{-3}$; curve 5, $9.5 \cdot 10^{-4}$; curve 6, $1.7 \cdot 10^{-4}$; curve 7, $2.6 \cdot 10^{-5}$ (atm).

If there are some slowly proceeding kinetic stages during the doping, the concentrations of impurity in the film must be less than the corresponding equilibrium concentrations because the impurity equilibrium has no time to be established. The rates of such kinetic processes usually increase with temperature, and it is natural to expect a decrease in the difference between the equilibrium and the experimental impurity concentrations. However, the small (or even slightly negative) differences observed in the experiments (the experimental concentration, curve 1, is greater than the equilibrium one, curve 1′, Fig. 3) and the independence of this difference upon temperature means that the mechanisms determining the impurity segregation cannot be limited by kinetics (in addition, the growth rates of the samples for curve 1 are only weakly dependent on the growth temperature, Fig. 5). Hence, the impurity concentration must be in equilibrium. The differences between the experimental and the theoretical equilibrium impurity concentrations in the films show that some of the assumptions made in the calculations of the equilibrium concentrations are not valid.

The dependence of the impurity concentration in the films on its content in the gas phase (Fig. 6) was studied for Zn and Cd for a growth rate of 12-15 μm/hr. The impurity concentrations in the films increased linearly with the pressure of Zn and Cd. The same dependence was observed for Sn, if the Sn vapor pressure was assumed to be proportional to its content in the Ga source. The observed dependence of the impurity concentration in the film on its vapor pressure could occur only if the carrier concentration in the surface layer of the growing film was not determined by the impurity concentration at the source.

The equilibrium concentration of segregated impurity in the solid can be represented by

$$N_{tot} = \eta \cdot N_o = \eta \cdot K \cdot \frac{P_i}{P_{A(B)}} \quad [1]$$

when the degree of ionization η is significant. Here N_{tot} is the total impurity concentration in the crystal, N_o is the neutral impurity concentration, K is the equilibrium constant, which we shall determine further, and P_i, $P_{A(B)}$ are the pressures of monoatomic vapors of impurity and of the component replaced by impurity, either Ga or As, respectively. The pressures of the component vapors are calculated from their

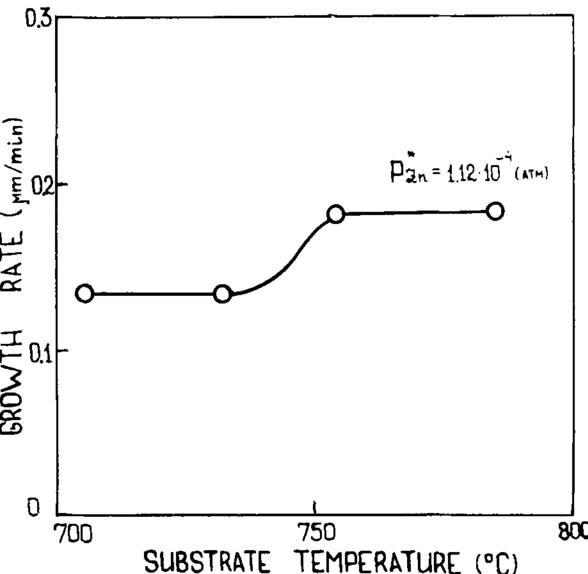

Fig. 5. Dependence of the growth rate on the growth temperature

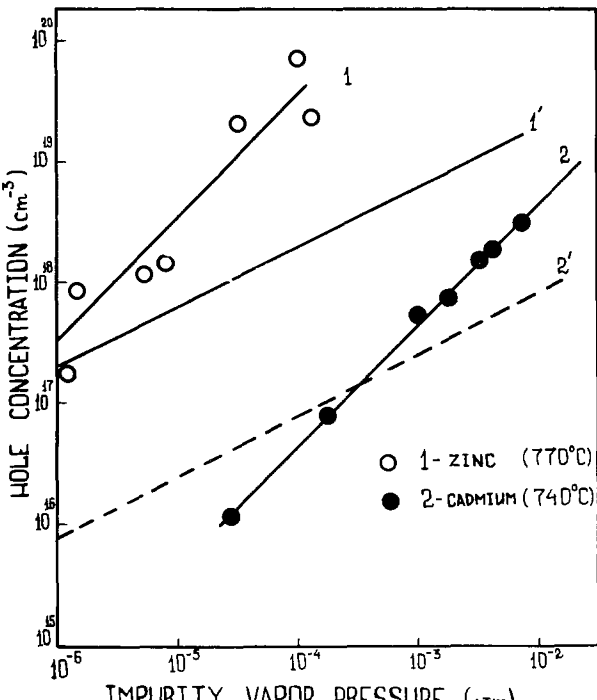

Fig. 6. Dependence of impurity concentration in the layers on its content in the gas phase for Zn and Cd. The experimental concentrations, curves 1 and 2, and the equilibrium concentrations, curves 1' and 2', for Zn and Cd.

gas phase content. The Fermi-Dirac distribution can be approximated by that of Maxwell-Boltzmann in many cases. Then one can obtain a very clear relation: $\eta = N_{C(V)}/2n(p)$ where $N_{C(V)}$ is the density of states in the conduction (valence) band and n(p) is the free electron (hole) concentration. Then we have

$$N_{tot} = \frac{N_{C(V)}}{2n(p)} \cdot K \cdot \frac{P_i}{P_{Ga(As)}} \quad [2]$$

The carrier concentration is equal to the impurity concentration if $N_{tot} >> \eta_i$, where η_i is the intrinsic concentration, *i.e.*, $n(p) = N_{tot}$. (Such a case is shown in Fig. 6 where $n_i \cong 10^{16}$ cm^{-3}.) Here

$$N_{tot} = \sqrt{N_{C(V)} \cdot K \cdot \frac{P_i}{P_{Ga(As)}}} \quad [3]$$

and the equilibrium impurity concentration in the film must vary proportionally to the square root of its monoatomic vapor pressure. For Cd it is the total pressure of its vapors. Sn is present in the gas phase in molecular form as $SnCl_2$ and the pressure of monoatomic Sn vapor is proportional to the $SnCl_2$ vapor pressure. For Zn, the monoatomic vapor pressure differs slightly from the total vapor pressure of the Zn components.

The experimental dependences of the impurity concentrations in the film *vs.* the pressures of their monoatomic vapors are close to being linear. However, with our assumptions, the equilibrium concentration should be proportional to the square root of the monoatomic vapor pressure. To obtain agreement between the experimental and the theoretical equilibrium concentrations, it is necessary to suppose that the carrier concentrations at the growth temperature (near the surface of the growing crystal, at least) are not determined by the impurity concentration. The actual bulk properties of epitaxial GaAs films at the growth temperatures were determined separately by special measurements (8). It turned out that, at 1000°K, the free electron concentration was equal to 10^{18}-10^{19} cm^{-3} in films doped with either donor impurities or with acceptors and did not depend on impurity concentration. In the presence of such a constant free electron concentration, the equilibrium concentration of impurity in the film becomes simply proportional to the pressure of the monoatomic impurity vapors. However, for the acceptor impurities the calculated values of the equilibrium concentrations of impurity were significantly higher than the experimental concentrations; for tin they were lower.

A possible mechanism can explain the independence of carrier concentration in the layer of crystal near the growth surface (where the impurity segregation is determined). It is a surface charge and the "surface quasi-neutrality" connected with it. The influence of surface charge is considered in Ref. (9). To our regret, we cannot see any straightforward ways of determining the carrier concentration in such a layer close to the growing film surface during the film growth. The experimental impurity concentration in the as-grown film is the only information source we have relating to charge carrier concentration. Inserting it in Eq. [2], one can calculate backwards the carrier concentrations which existed during growth. The only way to check the validity of these results is by a comparison of the charge carrier concentrations obtained for different impurities. These have to be connected by the relation $n \cdot p = n_i^2$. The accuracy of the equilibrium constant used in Eq. [2] is important in such calculations. An assumption on the invariability of the semiconductor vibration spectrum independent of impurity concentration was made in Ref. (10) when calculating K. This corresponds to assuming the equality of the doped crystal entropy with that of the pure semiconductor. A treatment of solidi of Ge-impurity and Si-impurity systems has shown that in a general case this assumption is not valid. The results of this calculation as a dependence of the excess entropy ΔS_{exc} of an impurity in a semiconductor crystal ($\Delta S_{exc} = S_{i,sol} - S_{semicond.}$) on E_{Bind} are shown in Fig. 7 (10). The excess entropy increases with decreasing E_{Bind}. The calculated values for Ge and Si give the same dependence. For GaAs, the necessary data turned out to be accessible only for the impurities Zn (11), Sn (11), P, In, Al, and Sb (13). The calculated values of E_{Bind} and ΔS_{exc} for these impurities in GaAs do not fall on the curve for Ge and Si because, for all of them, the excess entropy is close to zero. It is obvious that under sufficiently small binding energies the excess entropy has to increase. It is also possible that E_{Bind} and ΔS_{exc} for impurities in GaAs do not correlate with each other. In any case one can determine the equilibrium constant with satisfactory reliability only for two elements from those considered, and they are Sn and Zn. Similar calculations give for Sn, $n_s = 4 \cdot 10^{16}$ cm^{-3}, and for Zn, $p_s = 9 \cdot 10^{16}$ cm^{-3}. Their product, $n_s \cdot p_s = 3.6 \cdot 10^{33}$ cm^{-6} is close to n_i^2 for GaAs at 1000°K ($3.1 \cdot 10^{33}$ cm^{-6}) which says that the suggested model at least is not in contradiction with the experimental

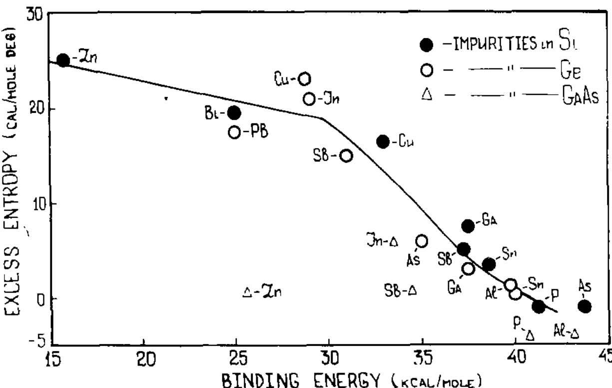

Fig. 7. Dependence of excess entropy on binding energy

results. One can obtain values of p_s for Cd close to those obtained for Zn, if we assume that ΔS_{exc} for Cd is situated in a region between zero and the curve for impurities in Ge and Si.

Thus, the orientation dependence of impurity segregation can be explained (within the framework of these ideas) by the dependence on growth rate and carrier concentration in the crystal layer near the growth surface (and a surface charge of the growing crystal).

Using data from the literature, we can assess the applicability of these ideas for other methods of film growth and for other materials. GaAs doped with Zn (14) and with Cd (15-17) during growth by liquid phase epitaxy also shows a linear dependence between the impurity concentrations in the solid and in the liquid phases. A calculation of the carrier concentrations near the growing surface gives $n_s \sim 10^{19}$ cm^{-3} for Sn and $p_s \sim 10^{19}$ cm^{-3} for Zn. In LPE layers, the incorporation both of donor and acceptor impurities was less than that expected from equilibrium considerations.

The doping of Si epitaxial layers grown by $SiCl_4$ pyrolysis by B, As, and P was studied (18). The values E_{Bind} and ΔS_{exc} calculated from the experimental data (15) give points lying higher than the curve for impurities in Ge and Si (Fig. 7). This divergence means that during pyrolysis impurity incorporation exceeds the equilibrium distribution and there is no correlation with the electrophysical nature of the impurity in Si.

Conclusions

A study of the orientation dependence of doping densities of donor and acceptor impurities in GaAs grown by chloride vapor transport shows that the impurity segregation is sensitive to the electrical nature of the impurities in GaAs. The dependence of impurity concentration on the pressure of its vapors and on temperature can be described in an equilibrium approximation. However, the experimental results require the assumption that the charge carrier concentration in the layer of growing crystal close to the growth surface is not determined by the segregated impurity.

The ideas developed here should be useful in explaining impurity segregation for other growth methods and for other materials.

ABSTRACT

A new electrochemical technique has been developed for etching platinum in the processing of silicon integrated circuits. A periodically varying potential is applied to a silicon wafer in a room temperature hydrochloric acid solution. The waveform has been designed to overcome problems associated with the passivation of the platinum surface and with the relatively high resistance of the metallization. The process has the following properties: the resolution of electroetched test patterns is good; the process is compatible with both positive and negative photoresists; the etch time is a few minutes for the platinum thicknesses commonly used in integrated circuits; the process lends itself to instrumentation for determination of the completion of platinum removal; the dissolved platinum can be recovered. The electroetching process is also applicable to the etching of other noble metals and to the etching of metallizations on other substrates.

One metallization used in the manufacture of silicon integrated circuits is titanium-platinum-gold. In one method of delineating patterns using this metallization scheme, the titanium and then the platinum are evaporated or sputtered onto the substrate; then the platinum pattern is defined by photoresist and etched. Subsequently, a new layer of photoresist is applied and gold is selectively electroplated. Finally, the exposed titanium is etched. The areas to be etched and the spacings between them may be as narrow as 5-10 μm, while the thicknesses of the platinum and titanium layers are of the order of 2000 and 1000Å, respectively. There are several chemical etches for titanium that can be adequately controlled. The platinum is usually etched in hot aqua regia; however, controlling the etch rate, determining the end point, and preventing undercutting of the photoresist are serious problems.

An electrolytic process is desirable because it offers numerous advantages in the areas of control, automation, and instrumentation. Raub and Buss (1) have etched the noble metals at significant rates using an alternating current in solutions that form complexes with these metals, for example, cyanides and chlorides. Black (2) adapted this technique to the electroetching of platinum metallizations on semiconductor devices. Yahalom (3) used square potential pulses of 1 msec duration in a hydrochloric acid solution at room temperature to etch platinum wires at rates as high as 4000 Å/min. During the anodic pulse at +1.0V (SCE) the platinum dissolves but concurrently the surface is passivated, thereby reducing the rate of dissolution. During the cathodic pulse at −0.3V, the passivating film is reduced. Yahalom showed that platinum would also etch, but at a slower rate, if a triangular potential-controlled waveform between the potential limits of −0.3 and +1.0V were used; the etch rate increased with the frequency of the waveform.

In this paper we report the development of a rapid, reproducible electrolytic method for etching patterns in platinum on semiconductor slices and on other substrates. We describe the method, the theory behind it, and present some results on its application to integrated circuit test patterns.

Experimental

The surface of each silicon slice, 1.5 in. (3.8 cm) in diameter, was thermally oxidized. Each slice was then coated with 2000Å of chemical vapor deposited silicon nitride, 1000Å of titanium, and 2000Å of platinum. The thicknesses of the platinum and titanium were controlled no better than ±10%. A metallization test pattern was defined on the platinum with either a positive (Shipley AZ135OH or AZ135OJ) or a negative (Eastman Kodak KMER or Hunt Chemical WAYCOAT Type III) photoresist. The test pattern contains a continuous metal line meandering from the top to the bottom of each chip. In addition, there are 21 lines adjacent to the meander. The pattern can be tested for shorts between the lines and for opens in the meander.

The etching cell was a 1500 cm^3 beaker in which was placed the slice to be etched (working electrode), a graphite auxiliary electrode, and a saturated calomel reference electrode. The slice was held in a titanium ring by four ¼ in. long titanium knife edges spaced equally around the periphery of the slice. Titanium is inert under the conditions of the test. The electrolyte solution, 3M HCl made from reagent grade acid and distilled water, was not deaerated and was stirred with a magnetic stirrer. All experiments were conducted at room temperature. Potentials are reported relative to the saturated calomel electrode (SCE).

The potential was controlled by a Princeton Applied Research Model 173 potentiostat and the desired waveforms were obtained from a Tektronix Model 114 pulse generator and Tacussel Model GSTP-2 function generator. The waveforms from the two signal generators were superimposed, as described later. The current was monitored on a Tektronix 5103N oscilloscope with a Model 5A13N preamplifier.

At the conclusion of the etch, the sample was removed from the cell with the potential still applied and was quickly rinsed in 3M HCl solution to prevent the redeposition of platinum from the residual solution layer. The sample was then rinsed in distilled water and dried in a stream of nitrogen.

The quality of the etch was judged by (*i*) optical or scanning electron microscopy; (*ii*) electron microprobe analysis for residual platinum; and (*iii*) etching the exposed titanium; the titanium will etch only if the platinum has been completely removed.

The resistance of the metallization on the slice was measured across a diameter with a volt-ohmmeter by contacting the metallization at the circumference of the slice. The resistance between the titanium holder and a point in the center of the slice was also measured. These resistances are important because of the voltage drop they introduce during electrolytic etching.

Results

Potential-controlled square wave pulses and a triangular waveform with potential limits of −0.3 and 1.0V, both of which have been used successfully to etch bulk platinum (3), did not etch the platinum metallization on silicon slices. However, a triangular waveform with potential limits of −0.3 and 1.4V and a modified triangular waveform (described below) with the same potential limits were found to etch the platinum metallization and to resolve the patterns completely and distinctly. No significant undercutting of the photoresist occurred during the time required to etch the platinum.

The following discussion is divided into two sections. In the first, we discuss the reasons why the techniques for etching bulk platinum must be modified when etching thin films on semiconductors or on insulators. In the second, we discuss the results of this new method and its application to the processing of integrated circuit slices.

Modification of electrochemical etch for thin films.—The difference in etching behavior between the platinum metallization on silicon wafers and bulk platinum was traced to an ohmic potential (*IR*) drop within the silicon-metallization specimen caused by the relatively high resistance of the metallization on the insulating substrate compared to the resistance of bulk platinum. The metallization has a significant resistance that is a function of the film thickness and the resistivities of its components. Figure 1 shows the resistance across the diameter of a Ti(1000Å)-Pt film on a 1.5 in. (3.8 cm) slice as a function of platinum thickness. The resistance varies linearly with reciprocal thickness down to about 200Å. For thinner films, the resistance approaches that of the underlying titanium layer. It is evident that during platinum etching the resistance, and hence the *IR* drop, will increase. However, during pattern etching the resistance never approaches the value corresponding to zero platinum thickness because a pattern of platinum remains; the final value depends on the fractional area etched and the pattern geometry.

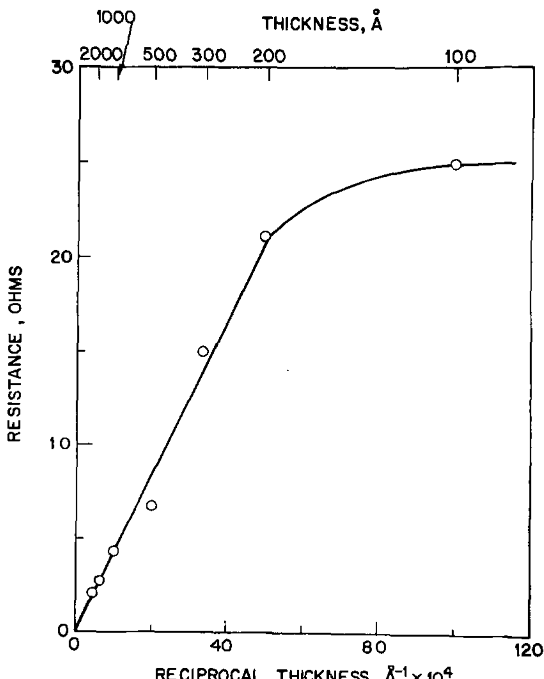

Fig. 1. The effect of platinum film thickness on the resistance of the metallization Ti(1000Å)-Pt across a 1.5 in. (3.8 cm) slice. At low thicknesses the resistance approaches that of the titanium film.

When a square wave potential is used to etch a thin platinum film on a silicon slice, the potential for the anodic reaction may initially be great enough to dissolve platinum. However, as the platinum is etched and the *IR* drop on the slice increases, the potential available for etching will in time decrease to a value too low for platinum dissolution to occur. The same is true for a triangular waveform with a maximum anodic potential of 1.0V. The lower limit of the anodic potential for etching platinum at an appreciable rate in this solution is approximately 0.7V (3). The upper potential limit appears to be between 1.0 and 1.2V. At higher potentials the rate of passivation becomes so great as to decrease the effective rate of dissolution markedly (4).

To compensate for the constantly increasing *IR* drop, a triangular waveform with an upper potential limit equal to or greater than 1.0V plus the maximum *IR* drop may be used (Fig. 2). With this waveform there will always be a window of approximately 0.3V on the ascending ramp in which etching will occur. Initially this window will be from 0.7 to 1.0V. When the *IR* drop is 0.1V, the window will be from 0.8 to 1.1V, etc. Such a waveform has been used to etch test patterns on metallized silicon slices, and good etching is obtained when the maximum anodic potential is between 1.4 and 1.6V. Thus, the maximum *IR* drop appears to be approximately 0.5V.

Since most of the etching occurs over a narrow potential band from 0.7 to 1.0V on the ascending ramp,[2] only 5-10% of a triangular waveform is utilized for etching. To increase the efficiency, the waveform shown in Fig. 3(a) was used. This waveform is constructed by superimposing a ramp and a square wave, shown in Fig. 3(b). Thus the potential jumps from −0.3 to 0.7V followed by a ramp from 0.7 to 1.4V; then the potential drops instantaneously to that for the cathodic reduction of the passivating film. The time for cathodic reduction in this case has been reduced to 0.7 msec, while the anodic ramp is 1.0 msec long. With this waveform, etching occurs over approximately 25% of the cycle. The efficiency could probably be increased further by modifying this waveform. However, this course was not pursued because the etch time of approximately 2 min is sufficiently short for practical considerations.

Application of the electroetching process.—The process has been applied primarily to the etching of platinum on oxidized silicon wafers for integrated circuits. It can also be used to etch other noble metal

[2] On the descending branch the platinum is passivated and will not dissolve at an appreciable rate.

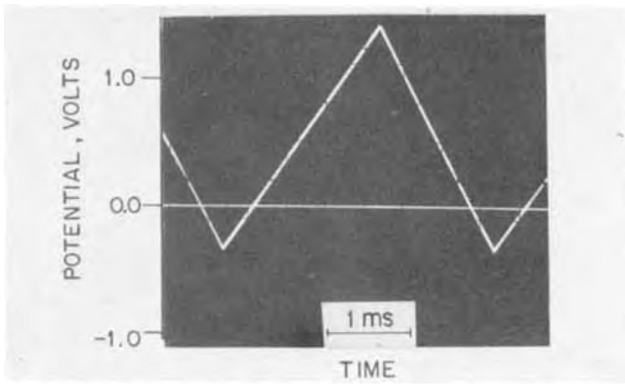

Fig. 2. Triangular waveform that corrects for the increasing *IR* drop during etching.

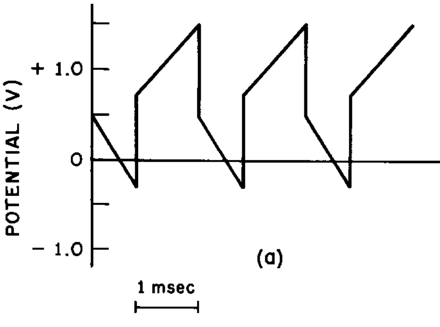

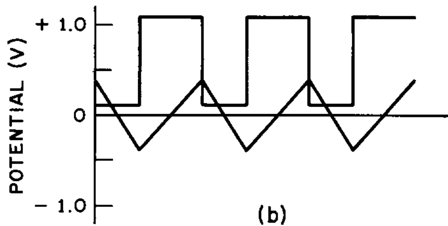

Fig. 3. The composite potential waveform for the electroetching process (a) is the sum of a square wave and a triangular wave (b).

thin films and metal films on high-resistance substrates other than silicon.

For a silicon slice having the metallization Ti(1000Å)-Pt(2000Å), a micrograph of a typical test pattern after electroetching the platinum and chemically etching the titanium is shown in Fig. 4. The dark areas have been etched revealing the silicon nitride layer; tests for the quality of the etch showed no residual platinum on the slice. The light areas are platinum, patterned in this case with a positive photoresist. The results of etching many samples indicate that the etching process is compatible with both positive and negative photoresists. The photoresists are not degraded by the electrolyte solution within the time required for etching, which is nominally 2 min for a 2000Å platinum film. Undercutting is not severe, even for etch times up to 6 min.

The electroetching process has a number of advantages over a hot aqua regia etch. (*i*) The electroetch is a room temperature process. (*ii*) The electrolyte solution, 3M HCl, is easier and safer to use. (*iii*) The etching is more controlled so that a constant etch time can be used. Alternatively, the end point can be determined electrically, as discussed below. (*iv*) It should be possible to etch a batch of slices at a time. (*v*) The dissolved platinum can easily be recovered.

The possibility of determining the end point electrically can be seen by comparing the current-time waveforms for the platinum-covered surface (Fig. 5a) and the platinum-free surface (Fig. 5b). The anodic (+) and cathodic (−) currents decrease significantly

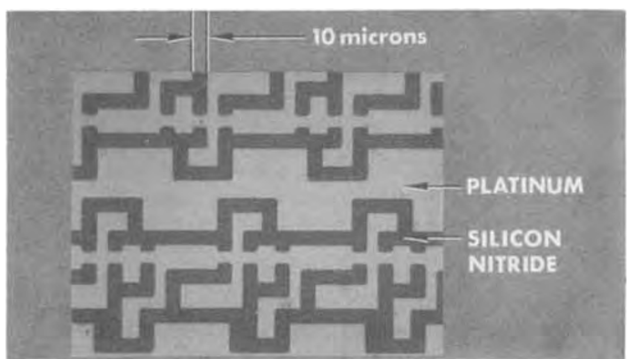

Fig. 4. Micrograph of an electroetched test pattern showing that the process defines the pattern clearly and sharply. The dark areas have had the platinum and titanium etched revealing the silicon nitride layer; the light areas are platinum.

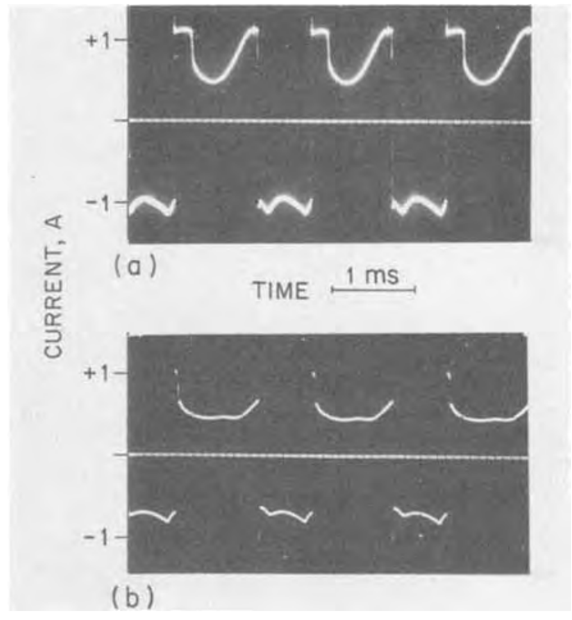

Fig. 5. Current transients (a) on platinum covered surface and (b) on titanium surface from which platinum has been etched. Comparison of transients shows the marked changes that can be used to determine the end point of the etching reaction.

when the platinum has been removed. The residual anodic current is due to the oxidation of chloride ions and water, while the cathodic current is caused by the reduction of hydrogen ions and oxygen. Since the overpotentials for these reactions are greater on titanium than on platinum, the currents are lower on the former metal for a given applied potential. The end point of the etching reaction could therefore be determined by monitoring the anodic waveform[3] and observing the time at which no further change occurs. A safety margin of about 2 min can be added without adverse effects.

The dissolved platinum could easily be recovered. Since it is necessary to agitate the solution to prevent redeposition of the dissolved platinum, the solution could be recirculated through a two-compartment cell, in which etching occurs in one and platinum recovery takes place in the other.

The electroetching process can be applied to the etching of any noble metal provided the resistance of the underlying conductive layer, *e.g.*, titanium, is not too great. We have successfully etched rhodium deposited over 500Å Ti on silicon; line spacings of 1 μm in the test pattern were clearly resolved. Platinum and rhodium over titanium have been etched on ceramic substrates.

One major precaution must be observed when using the electroetching process on thin films: the resistance between the contact point(s) and any point on the substrate must be minimized. For example, with silicon integrated circuits of the type discussed here, contact must be made to the periphery of the slice at several points so that the resistance between the slice holder and any point on the slice, as measured with a volt-ohmmeter, does not exceed one ohm. If the resistance is larger, the resulting *IR* drop may prevent complete etching.

Etching of GaN Using Phosphoric Acid

Akira Shintani and Shigekazu Minagawa*

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Hot phosphoric acid is found to be useful for etching and characterizing epitaxial GaN crystals grown on (0001) sapphire substrates. The obtained etch rates are 0.2-1.0 μm/min and the activation energy is about 4.4 kcal/mole in the temperature region of 50°-200°C. Hydration of Ga ion is considered the rate-determining step of the etching action. The x-ray diffraction and the infrared spectrometric studies indicate that the *ortho* and *meta* phosphoric ions play an important role as attacking ions in etching. This phosphoric acid etching reveals crystal defects in undoped (n), Zn-doped (i), and i-n structure GaN epitaxial crystals. Conical hexagonal pyramid pits and truncated hexagonal pits develop in the undoped layers, and they tend to be arranged along the slip direction and are attributed to certain dislocations. These hexagonal pits are densely generated near the interface of the epitaxial layer and the substrate. The density of the pits decreases exponentially with crystal growth. The pits are apt to increase in density and size when the carrier concentration is high (10^{19}-10^{20} cm^3). The rounded etch figures develop in Zn-doped crystals and sometimes in the undoped crystals with a high carrier concentration (10^{19} cm^{-3}). Etching also indicates that there is a significant difference in growth patterns between the Zn-doped and the undoped crystals even if the Zn-doped layer is continuously deposited on the undoped layer. This implies a difference in the crystal growth mechanism between these crystals.

Gallium nitride is a very promising compound semiconductor for a blue and a violet light emitting diode due to the wide bandgap [3.5 eV (1)] of its direct transition nature. Since Maruska and Tietjen grew epitaxial single crystals of GaN on sapphire substrates by a vapor deposition technique (2), many investigators have studied the preparation techniques and properties of GaN epitaxial layers. However, the crystal characterization has not been as widely investigated as the optical properties, since no appropriate crystal characterization technique has been established for GaN. To date, epitaxial GaN crystals have been characterized by measuring their carrier concentrations and mobilities. They have never been evaluated crystallographically.

Although chemical etching is a useful method for crystal characterization, no suitable etchant for GaN has been found because of its chemical stability against various mineral acids and aqua regia. Heretofore, molten sodium hydroxide, potassium hydroxide, and potassium pyrosulfate at 800°C (3) and a 50% sodium hydroxide aqueous solution (4) were the only known etchants for GaN. The first three etchants are not very useful because they require such a high temperature that GaN decomposes (5). Chu reported that a 50% sodium hydroxide aqueous solution can etch epitaxial GaN grown by the decomposition of $GaBr_3:NH_3$ and that the activation energy for etching is 18 kcal/mole in the temperature range of 5°-90°C (4). However, Pankove was not able to reproduce this technique for the epitaxial layers prepared by Maruska and Tietjen's technique (6). He attributed this difference to the fact that the epitaxial layers prepared by Chu were possibly more porous than those prepared by himself. It is also reported by Chu *et al.* that a 40% sodium hydroxide aqueous solution is still useful for etching GaN layers grown by ammonolysis of GaCl, and they showed a triangle etching pattern due to stacking faults which appeared on the $(\bar{2}110)$ plane (7). Pankove applied the jet electrolytic etching technique to his GaN layers using 0.1*N* sodium hydroxide aqueous solution as electrolyte, and he freed a Zn-doped i-layer from an i-n structure grown on a sapphire substrate (6). Recently Morimoto reported the etch rate of GaN by phosphoric acid (8), but the details of his experimental procedure and conditions were not clear.

As is described, the previous reports did not make clear whether the above etching technique and the experimental conditions were useful for crystal characterization of GaN or not, nor did they explain the etching mechanism. In this work, we investigated the etching mechanism by means of x-ray diffraction and the infrared absorption of the products grown on GaN powder treated with phosphoric acid, and found the acid is useful for the characterization of crystal defects in GaN crystals.

Experimental

Epitaxial layers.—The GaN epitaxial layers were grown on (0001) sapphires by a chemical vapor deposition technique based on the Maruska and Tietjen method (2). The technique has been described in detail (9). Most of the layers obtained were below 15 μm in thickness and their carrier concentrations were 10^{18}-10^{20} cm^{-3} in n-type.

As it is difficult to introduce impurity atoms into GaN by thermal diffusion, the Zn-doped growth was performed by admitting the Zn vapor to the reaction chamber. The inlet nozzle for the dopant was placed parallel to other nozzles for introducing reaction gases. The Zn vapor was transported by an Ar or H_2 carrier

* Electrochemical Society Active Member.
Key words: etching mechanism, etching figures, slip direction, crystal growth mechanism.

flowing over a metallic Zn source heated to 600°C. Because the Zn vapor was partly absorbed into the Ga melt placed downstream to the Zn boat, a higher temperature than that in Pankove's experiments (10) was required in order to compensate for the native donors.

Etchant and etching method.—Commercial 85% phosphoric acid was heated to an etching temperature in a 100 cm^3 platinum beaker. The etching temperature was monitored with a Pt-PtRh thermocouple. The sample, held in a platinum basket, was immersed in this etchant during which the etchant was stirred by moving the sample holder. The temperature used for gaining clear etch figures was around 190°C.

Etch rate.—Thickness reduction by etching was measured at more than three points on the cleaved edge of each specimen under an optical microscope. The average value per unit etching time was used as the etch rate.

Qualitative analysis of etchants.—In order to know component variations of the etchant due to heating, four kinds of etchants (phosphoric acid without heating, one kept at temperatures between 140° and 150°C for 3 hr, one kept at 200°C for 4-5 hr, and one kept at 300°C for 5-7 hr) were analyzed qualitatively employing silver nitrate, zinc acetic acid, and barium chloride, respectively, for *ortho*, *pyro*, and *meta* phosphoric ions.

X-ray diffraction and infrared absorption spectra measurements.—In order to clarify the etching mechanism, the reaction products of the phosphoric acid-treated GaN powder surface were investigated. The GaN powder gathered from the wall of the reactor near the substrates was immersed in phosphoric acids at room temperature, 200°, and 300°C for 5-8 hr. These powders, after rinsing in water (not warmed) and drying, were subjected to x-ray diffraction and infrared absorption (KBr disk) analyses.

Results

Etching.—Etchant.—It is well known that heating causes compositional variations in phosphoric acid due to condensation and evaporation of water. With a view to ascertaining the effective chemical species for the etching, commercial phosphoric acid was heated to 150°, 190°, and 300°C for several hours. Then, the composition of each heated acid was qualitatively analyzed. The results of the analysis were that both the original phosphoric acid and the acid heated below 150°C contained three kinds of phosphoric ions: *ortho*, *pyro*, and *meta* types. The phosphoric acid kept at boiling temperature (190°C) for 4-5 hr sometimes showed no evidence of the presence of *ortho* phosphoric ion, and one kept at 300°C did not contain this ion at all but did contain the other two ions.

Etch rate.—If phosphoric acid is heated under different temperature conditions, the above compositional variation may produce a different influence on etching even at the same temperature. In fact, the etch rate of Si_3N_4 film decreases slowly with heating time at a constant temperature, whereas that of SiO_2 film is contrary to this (11). In the case of GaN, however, the etch rate at a constant temperature was almost independent of the heating time (less than 100 min), although the etch rate at etchant boiling temperature was reduced steeply during the first 10 min. The etch rate of GaN was apparently almost constant during heating up to 100 min as long as the etchant does not go through the boiling process. This largely decreases the water concentration.

The temperature dependence of the etch rate was investigated using two kinds of etchants of which the compositions were very different. Etchant "A" was thermally untreated 85% phosphoric acid. While, "B" was made by heating this 85% acid to 320°C for 6 hr, and cooling it to near room temperature. The results obtained are shown in Fig. 1 in the form of an Arrhenius plot. Though the etch rates in etchant A

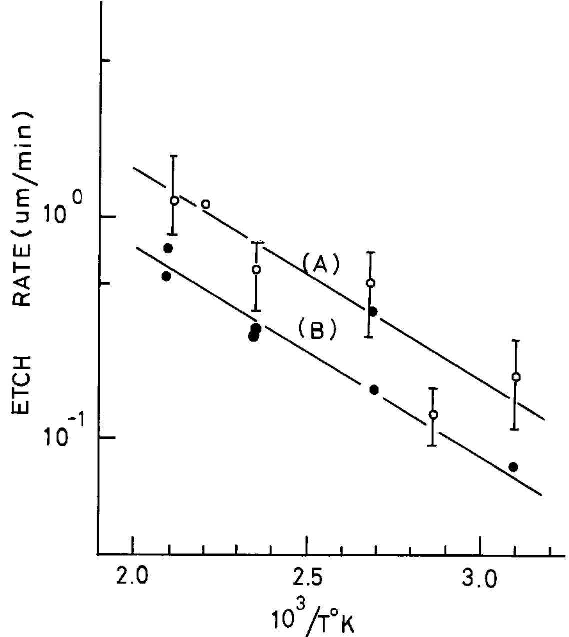

Fig. 1. Temperature dependence of the etch rate. The line (A) —○— and the (B) —●— represent etchant A and B, respectively.

were higher than those in B through all temperatures, the same activation energy, 4.4 kcal/mole, was found for both etchants. This indicates that the rate-determining step of the etching process is the same or similar for both etchants.

X-ray and infrared measurements.—Although the same activation energies were found for the above two etchants, the GaN powder immersed in phosphoric acid at three different temperatures (room temperature, 200°, and 300°C) for about 8 hr showed very different x-ray diffraction patterns and infrared absorption spectra. The x-ray diffraction peaks of the powder treated at room temperature were equal to those of the original GaN powder. However, the powder treated at 200°C showed some other medium intense peaks, *e.g.*, at 2θ = 26.49, 20.94, 38.89, etc. (Bragg angles), besides the diffraction peaks of GaN. These different peaks could be assigned to $Fe(PO_4)$ by inspecting the ASTM cards, although the nature of a few very weak peaks remained unknown. As Fe ions were not detected in the powder by means of spectrochemical analysis and a sufficient amount of Fe^{+3} ion to give the x-ray diffraction cannot be present in this etching system, it is naturally thought that the peaks assigned to $Fe(PO_4)$ were diffracted from $Ga(PO_4)$. The diffraction patterns of the powder treated at 300°C became more complicated because of the addition of the peaks due to $Ga(PO_3)_3$. The most intense peak belonged to $Ga(PO_3)_3$, whereas that of the powder treated at 200°C was assigned to GaN. These results were supported by the infrared absorption measurements of GaN powders immersed in phosphoric acid at the above-mentioned temperatures. The absorption peaks are summarized in Table I with those of some phosphates.

Etch figures.—Etch figures developed on the surfaces of the undoped layers.—Many hillocks of various sizes were observed on the as-grown surfaces of the epitaxial layers grown at 980°C with a carrier concentration of 7×10^{19} cm^{-3} (Fig. 2A). A number of spotlike or linelike figures were developed on these surfaces by etching (Fig. 2B). Observation of these etch figures under a microscope proved that they were pit structures. These etch pits revealed each hillock had a hexagonal structure (Fig. 2A), *i.e.*, the grown surface was of (0001) orientation. The more definite shapes of the etch pits were on the surface of the crystal grown at 1020°C with a carrier concentration of 1×10^{20} cm^{-3} (Fig. 3). The basic shapes of the

etch pits were hexagonal which reflects the crystal symmetry of GaN. Unclear etch pit shapes could be made definite by re-etching. These etch pits were classified roughly into two types; truncated pyramid pits indicated by the arrows (a) in Fig. 3A and conical pyramid pits by (b), both of which were similar to the etch pits developed on SiC (12-16), CdS (17, 18), and BeO (19). Some irregularly shaped pits (Fig. 3B) were also developed in regions other than the area giving the above clearly shaped pits in the same surface. These irregular pits possibly consisted of some continuous conical pyramid pits, because their bottoms were not as flat as those of truncated pit. The above etch pits were partly arranged in the direction toward cross-points of crystal growth step lines or parallel to them.

Other-shaped etch figures were sometimes spread all over the surface of the epitaxial layers with a carrier concentration ranging from 10^{19} to 10^{20} cm^{-3} (Fig. 3C). These figures seemed to be prominent, that is, not pits, under a microscope. This surface seemed to be a white muddy color due to light scattering on the rough surface caused by these figures. In the case of such crystal, the figures could be developed even with an etching time of less than 20 sec.

The spiral growth hillocks were observed on the surface of the epitaxial layer with a carrier concentration of 10^{18} cm^{-3} (Fig. 4A). In this case, the etch pits

were densely developed at the edges of growth steps of each spiral hillock (Fig. 4B) but were not so well arranged in a fixed direction as shown in Fig. 3B. The etch pits were in the shape of more defined regular hexagons in Fig. 4B than in Fig. 3A, and their size was smaller.

Etch pits developed on an angle-lapped surface of an undoped epitaxial layer.—Observation of the etch pits on the angle-lapped surface is useful for gaining some information on the variations of the crystal quality along the crystal growth direction. Figure 5A is an etched 3°-angle-lapped surface of an epitaxial layer of 14 μm in thickness with a carrier concentration of 3×10^{18} cm^{-3}. The etch pits appear as dark spots (Fig. 5A). They were most dense in the strip of 40 μm in width (2 μm in epitaxial thickness) at the interface of the epitaxial layer and the substrate, and were reduced steeply along the growth direction. It was also observed that the etch pits were arranged along a direction making angles of 60° or 120° with each other (arrows designated a, b, and c in Fig. 5A). The etch pits were the same in structure as those in Fig. 3A, that is, truncated and conical hexagonal pyramids as seen in Fig. 5B and C. The truncated pits are shallow and flat-bottomed and the conical pyramid pits are deep and circular-bottomed.

In the case of the crystal with a carrier concentration higher than 10^{19} cm^{-3}, the etch pit density on the angle-lapped surface was too high for the pits to be clearly observed.

Etch figures on a Zn-doped and an i-n structural layer.—A study of the differences in the morphology of the etch figures between the undoped and the Zn-doped or the i-n layers offered some important information on their crystal quality and crystal growth mechanism. The as-grown surfaces of the Zn-doped layers consisted of hexagonal facets or pyramidal hillocks (Fig. 6). The etching made these surfaces a white muddy color due to light scattering on highly dense etch figures. The shape of the figures almost resembled the etch figures shown in Fig. 3C. These figures also were not possibly of pit structure. The morphology of the etch figures on the i-n structural layer varied with etching time (Fig. 7). At the beginning of the etching the etch figures developed only around the bases of the hexagonal pyramidal hillocks (Fig. 7A). The distribution of these figures extended over the faces of the hillocks with increase of etching time (Fig. 7B), Then a larger etch figure was develcped at the apex of the

pyramid. Figure 7C shows the surface of the i-n layer when the n-layer came into sight by etching. The dark parts indicated by arrows (a) are the Zn-doped layer hillocks. The etch pits along the spiral growth step of the n-layer, as indicated by arrows (b), displayed some net pattern.

(1$\bar{1}$02) substrate.—Etching also made the GaN crystal grown on (1$\bar{1}$02) sapphire substrates turn a white muddy color due to the rough surface. The developed etch figures were not clear in structure or in shape due to the many growth ridges.

Discussion

Etching mechanism.—Figure 1 reveals that the variation of the etchant composition remarkably affects the etch rate. The constant etch rates, however, were obtained in the etchants heated for less than 100 min at a normal temperature (not boiling temperature). The reason for this is that the evaporation of water at a normal temperature is not so violent as that at boiling temperature. According to this the change in the etchant composition at a normal temperature apparently does not become effective for GaN etching. The etch rates in the etchant preheated for a long time, as seen in Fig. 1, are slower on the average than those in the original etchant. From these experimental facts we can conclude that the etching of GaN in phosphoric acid is inhibited by large condensation of the acid. This is similar to the case of Si_3N_4 described previously. However, there is a large difference in the etching activation energy between the two. Gelder and Hausen found an activation energy of 22.8 kcal/mole for Si_3N_4, which has been attributed to the hydrolysis of Si_3N_4(11). This activation energy is close to that of UN hydrolysis, 21 kcal/mole (20). Compared with these energies, the activation energy of GaN etching is considerably smaller. This indicates that such a rate-determining step as hydrolysis in GaN etching does not exist. Enumerating the phenomena of Ga^{+3} ions in phosphoric acid of which the activation energy verges comparably upon 4.4 kcal/mole, there are: hydration of Ga ion [6.3 kcal/mole (21)] and the diffusion of a cation in strong phosphoric acid [10 kcal/mole (22)]. If this hydration is the rate-determining step in GaN etching, the etch rate is controlled by the amount of water in the etchant and this qualitatively agrees with the results explained previously. On the other hand, if the diffusion process is the rate-determining step, the activation energy must depend on the chemical composition of the etchant. This is because the diffusion coefficient is not the same for various phosphoric acid compositions. This is not in agreement with the obtained results. Here another process may be considered as the rate-determining step; surface diffusion of ions attacking an active site of the GaN crystal surface, the reaction between Ga ions on surface and attacking species, or desorption of its products from the surface.

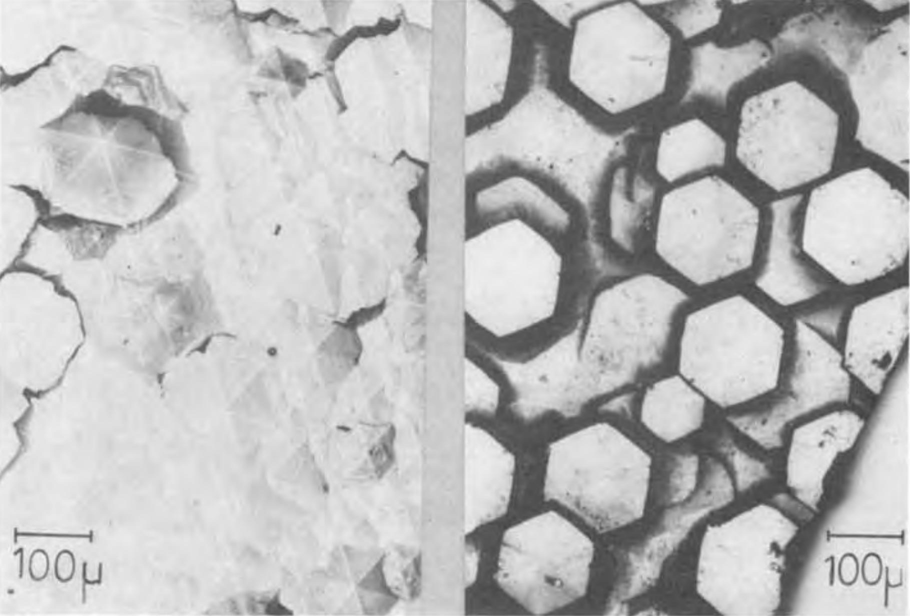

Fig. 6. Two kinds of as-grown surfaces of the Zn-doped GaN.

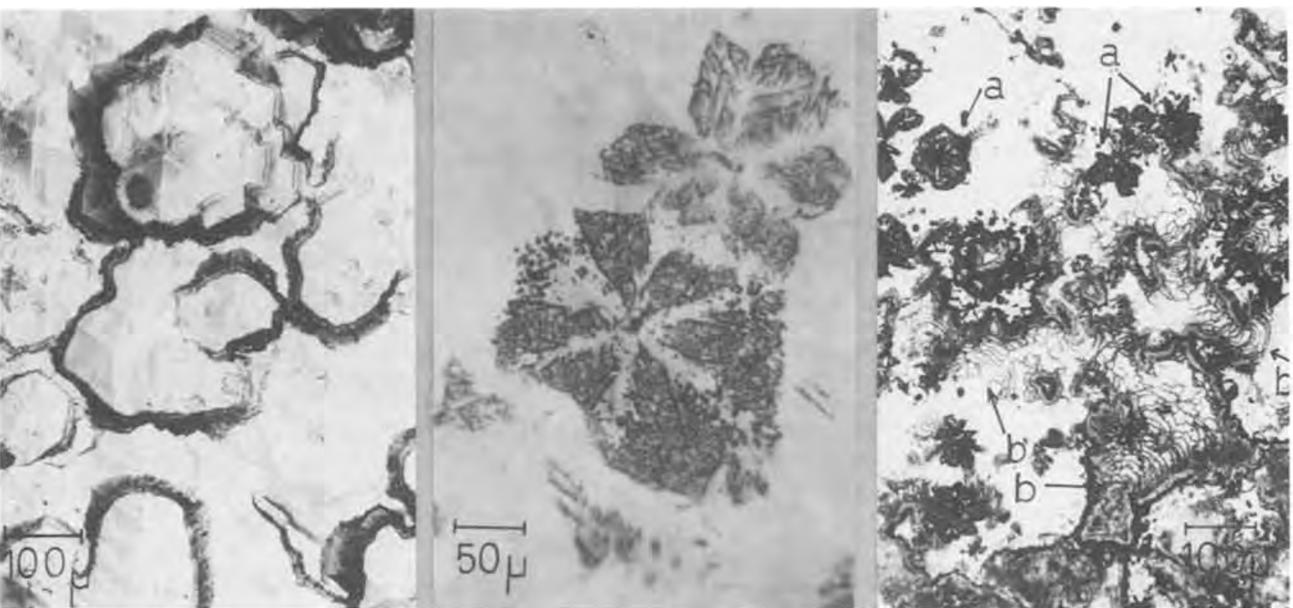

Fig. 7. Variation of the etch patterns developed on the i-n structural GaN with etching time. (A, left) The surface etched for 15 sec, (B, center) 45 sec, and (C, right) 3 min.

The activation energies, however, of these phenomena are not clear.

The above discussion does not give the detailed etching mechanism. The detection of $GaPO_4$ in the powder immersed in phosphoric acid at 200°C suggests the following mechanism: PO_4^{-3} ions attack the active sites of the GaN crystal surface to dissociate Ga-N bonds and Ga ions are hydrated, then the hydrated ions are removed from the surface. These hydrated Ga ions react with PO_4^{-3} ions to form $GaPO_4$ molecules, which are not dissociated in water, during the cooling process. Although the concentration of pyrophosphate ions in this etchant or in the etchant treated at higher temperature is higher than that in the original phosphoric acid as confirmed by qualitative analysis, no gallium pyrophosphate could be found in the powder immersed in phosphoric acid at 200° or 300°C. This is plausible because Ga ion cannot have a +1 charge and then it can hardly form pyrophosphate. When the temperature of the etchant goes up farther and the resulting concentration of *meta* phosphoric ion increases, the attack on the GaN crystal surface of this ion becomes remarkable similarly to that of *ortho* phosphoric ions at lower temperatures, and $Ga(PO_3)_3$ molecules are formed.

In the case of the Si_3N_4 etching, Gelder and Hauser assumed that N atoms could be removed from the crystal surface in the form of an ammonium phosphate. No x-ray diffraction peaks attributed to any ammonium phosphate could be found in the present work. However, it may also be supposed that some ammonium phosphate is formed in one step of GaN etching. Since both powders, as explained already, were sufficiently washed in flowing water before diffraction and infrared measurement in order to extract the viscous phosphoric acid from them, some ammonium phosphate may have been washed away at that time.

Etch figures.—Etch figure morphology on the n-layers.—Conical pyramidlike pits, one of the two kinds of etch pits developed on SiC and CdS, were associated with a dislocation (13, 16, 17). Renolds and Czyazk thought that the movement of the dislocation due to stress in the crystal results in the development of the truncated pits (17). Dislocation trapping impurities can be another plausible cause of these pits. In view of this and the re-etching that made the etch pits clear in shape, it can be said that both the conical and truncated etch pits on the GaN epitaxial layer are associated with dislocations.

The rounded etch figures seen in Fig. 3C have also been reported for Cds (17), SiC (16), and BeO (19). The orientations of these crystal surfaces were all $(000\bar{1})$ anion surfaces. One mechanism for the development of these was proposed for BeO by Smith *et al.* (19) using Gatos and Warekois's surface bonding model. The $(000\bar{1})$ surface has two electrons per atom in the cut bonding orbital, and is more active toward an electrophilic reagent than the (0001) surface having no electron which is available for bonding. The shapes of the etch figures on the $(000\bar{1})$ surface resultingly became dull. However, GaN etching was performed by *ortho* and *meta* phosphoric ions. Since these ions are negatively charged in an aqueous solution, they cannot be electrophilic in character. Therefore, in the case of GaN, the surface orientation developing the round etch pits was not confimed. We do not understand the generation of the rounded etch figures.

Figure 8A is a photograph of the etch pit arrangements developed on the GaN taken only by the reflected light from the etched surface. Figure 8B is a photograph of the same area taken with the addition of transmission light through the surface. In a detailed observation of these photographs, the lines along the etch arrangements can be seen (Fig. 8B) and they are composed of a network pattern. This pattern can be attributed to the crack lines. Clear crack lines in the crystal run parallel to the growth steps of the hexagonal spiral hillocks. Thus, crack lines are in the $\langle 10\bar{1}0\rangle$ direction. These crack lines can be ascribed to a slip in the crystal plane. A slip direction of $\langle 10\bar{1}0\rangle$ is plausible because the cleaved surfaces in the wurtzite-type crystal are {0001}, $\{10\bar{1}0\}$, and $\{1\bar{1}20\}$ (23). A simple edge dislocation line is perpendicular to the slip direction and is included in a slip plane. Since edge dislocations are distributed easily along the slip direction, etch pits associated with the dislocation can be set reasonably in an array of $\langle 10\bar{1}0\rangle$ direction.

Variation of etch pit density with crystal growth.—The relationship between the etch pit density and the distance from the interface between the GaN layer and the substrate was derived from the magnified photograph in Fig. 5A. The result is shown in Fig. 9. The etch pits developed along the slip direction were omitted from the density calculation because the slip lines would be thermally generated after crystal

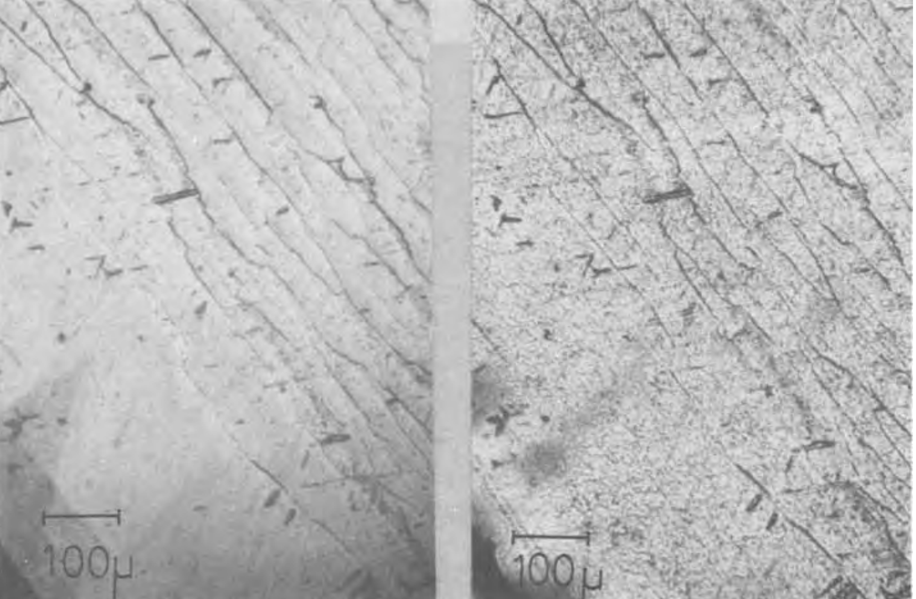

Fig. 8. The etch pit arrangements and crack lines generated in the undoped layer. (A, left) The photograph taken by the reflected light and (B, right) taken by the reflected and transmission light.

growth as described above. This means that they are not intrinsic characteristics of the GaN crystal growth. The fluctuation of each set of data increases with distance from the interface. This is due to the increasing lack of uniformity of the etch pit distribution with distance. The experimental equation for the density of the etch pits at x μm from the interface is

$$N = N_0 \exp(-\alpha x) \quad [1]$$

where N_0 is the etch pit density at the interface and α is a parameter indicating a reduction magnitude of 0.12 μm^{-1}. This exponential reduction of the dislocation has been obtained for GaP grown on GaAs with α of 4.1-5.3 mm^{-1} (24). No theoretical analysis of this relation has been reported. The parameter N_0, however, will depend both on the differences in lattice constant and crystal structure between a substrate and an epitaxial crystal, and on impurity incorporation from the substrate. Another parameter will depend on the difference in the lattice constant and Young's modulus

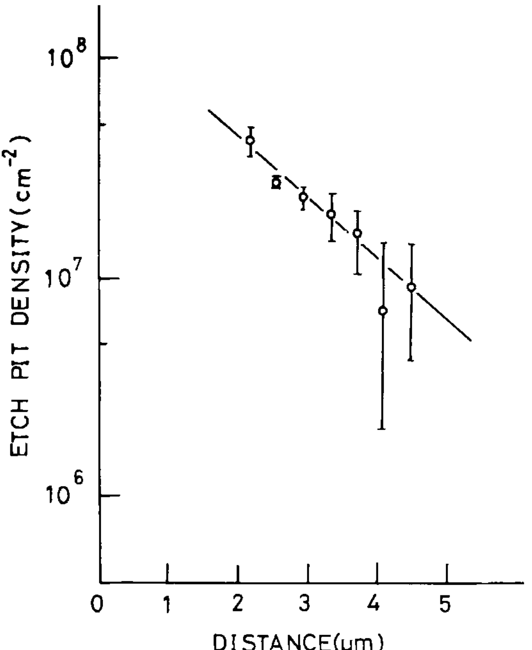

Fig. 9. The relation of the etch pit density to the distance from the interface between the GaN layer and the substrate.

between the nucleus of crystal growth and a strain-free crystal. It further depends on chemical bond strength factors. The number of the dislocations will decrease to that of the bulk crystal with crystal growth.

As the etch pits developed on an epitaxial surface having a spiral growth hillock become more dense at the periphery of the growth step as shown in Fig. 4B, it is difficult to determine the etch pit density. Therefore, from the extrapolation of the line in Fig. 9, an etch pit density is found to be 3×10^4 cm^{-2} for the surface of a crystal with a carrier concentration of 10^{18} cm^{-3}. The density of the etch pits was estimated at 10^7 cm^{-2} at least for a crystal with a 10^{19}-10^{20} cm^{-3} carrier concentration. These facts indicate that the etch pit density is closely related to carrier concentration. Since the development of the etch pits is correlated to certain dislocations, it can be said that carrier concentration depends on crystal defects. Growth conditions have some influence on crystal defect formation and etch figure morphology varies with the conditions as described previously.

Etching of the i-layer and the i-n structure layer.—A number of irregularly formed etch figures are developed on the i-layer surface as shown previously. These indicate that doped crystals are poorer in crystal quality than undoped crystals, and especially that the base planes and the faces of their pyramidal hillocks are of very low quality (Fig. 7). The etch figures developed on these areas do not arrange themselves in array with a fixed direction. These results imply that the kind and the origin of lattice defects developing the etch figures on the Zn-doped layer are different from those of the undoped ones. These irregular etch figures are attributed to the defects generated by doping a large amount of Zn atoms.

Figure 7C signifies that there exists a difference in the crystal growth mechanism between the undoped and Zn-doped crystals. Though the undoped crystal grows according to the spiral crystal growth mechanism, a lot of doped Zn atoms decorated the spiral steps of the n-layer and made them inactive as nuclei for the growth. Even if a Zn-doped crystal grows according to a spiral crystal growth mechanism, the origin of it is different from that of the undoped crystal growth. When Zn^{+2} ions with larger ionic radii than that of Ga^{+3} (Zn/Ga=1.36) are incorporated in the GaN lattice, the crystal deformation or strain in the doped crystal becomes large, generating a number of dislocations, impurity clusters, and vacancies in the crystal.

Anodic Oxidation of GaAs in Mixed Solutions of Glycol and Water

H. Hasegawa[1] and H. L. Hartnagel

Department of Electrical and Electronic Engineering, University of Newcastle upon Tyne, The Merz Laboratories, Newcastle upon Tyne, NE1 7RU, United Kingdom

ABSTRACT

A native oxidation of GaAs by anodization in mixed solutions of glycol and water (AGW) is described. A detailed comparison between the AGW process and anodization in aqueous solutions (AAS) shows the basic importance of (*i*) the simultaneous oxide dissolution during growth and (*ii*) the initial electrochemical active-passive transition of the GaAs anode. The results demonstrate the substantial superiority of the AGW process over various AAS processes. Factors relevant for uniform, stable, and reproducible oxidation are studied which include the effects of illumination, sample edges, and stirring. The dependence of the thickness-voltage rate constant on the current density is established. The AGW process exhibits a high current efficiency.

The usefulness of a semiconductor material depends very much on the availability of a suitable process to form an insulating layer of acceptable qualities on its surface, as has been fully demonstrated by the impressive success of the planar technology of silicon integrated electronic devices. Although it possesses unique features of light emission, of the transferred electron effect, of high electron mobility, of high radiation resistance, etc., which are not readily available in silicon, the use of GaAs material has been limited so far by several factors, particularly by the difficulty of its proper oxidation. However, with the successful demonstration of advanced high-performance microwave and optoelectronic devices using GaAs in recent years, a need exists for a suitable technology to form an insulator on GaAs with good dielectric and interface properties, particularly in view of applications to surface passivation, MOS-type devices and processing steps for planar integration, and fabrication of various devices.

The main difficulty associated with thermal oxidation of GaAs is related first to the volatile component, namely As, which will cause at high temperature, decomposition of GaAs, and second to the even higher volatility of As_2O_3 which has about 1 atm vapor pressure at about 320°C so that the thermal formation of a native oxide with As properly incorporated would probably only be possible with great technological difficulties. In fact, the thermal oxides grown so far seem to contain only Ga_2O_3 (1), and little information is available so far on the electrical and chemical properties (such as diffusion of impurities) of this oxide and the oxide-semiconductor interface.

An alternative way of utilizing the deposition of various oxides or nitrides by pyrolysis or other suitable

[1] On leave from Department of Electrical Engineering, Hokkaido University, Sapporo, Japan.

Key words: gallium arsenide, anodization, native oxide, surface passivation.

chemical reactions (2-5), some of which can be carried out at reasonably low temperatures, seems to be of a limited value owing to the formation of porous films, poor adhesion, poor interface properties, a large lateral diffusion of impurity atoms encountered in diffusion-mask applications, etc.

The present paper is concerned with a new and promising electrochemical oxidation process of GaAs which is basically an anodization in a mixed solution of glycol and water (AGW process). It will be shown that the new AGW process is an extremely stable, reliable, and reproducible process leading to the formation of uniform and glassy native oxide films. Thicknesses of up to 7200Å can be grown at room temperature within 10 min of anodization, although the results presented in this paper are based on films of up to 3000-4000Å thickness. A brief first description of the process only was published in a letter form elsewhere (6).

An anodic oxidation of GaAs was first reported by Revesz and Zaininger (7) in 1963 but resulted in a severely pitted surface. Dell'Oca, Yan, and Young (8), and Harvey and Kruger (9) also reported anodization of GaAs in various aqueous electrolytes with limited success. The anodic process on GaAs can also be carried out in a gaseous state by the so-called plasma oxidation process (10, 11). This seems to result in uniform but fairly highly conducting films. Growth of uniform films with low conductivity was first reported in 1973 by Logan, Schwartz, and Sundburg (12) using a constant voltage anodization in an aqueous solution of H_2O_2. Various applications have also been suggested and experimentally verified, based on this encouraging success, which include masks for mesa etching (12) and selective Zn-diffusion (13), and controlled wafer thinning (14) for microwave MESFET's.

However, the above H_2O_2 scheme has unfortunately the following problems (12) which would make its practical exploitation rather difficult: (*i*) the process is extremely unstable against impurities, (*ii*) the grown oxide cannot stand the vacuum deposition of Au, (*iii*) the grown oxide allows leakage currents of $10^{-5} \sim 10^{-6}$ A/cm^2, which is still rather high, and (*iv*) the maximum film thickness available for room temperature electrolytes is limited to about 3000Å whereas the initiation of an anomalous growth by boiling the electrolyte seems to be associated with an electrical breakdown in the oxide (15).

The present AGW process can completely solve the above problems, being extremely stable and producing impervious films with a $10^3 \sim 10^5$ times higher resistivity and increased dielectric breakdown field-strength. A capacitance-voltage study on MOS devices using such native oxides revealed that interface properties can be dramatically improved by a suitable postgrowth annealing as reported elsewhere (16).

The purpose of the present paper is to establish the optimum conditions for uniform, stable, and reproducible anodic oxidation of GaAs using the AGW process. Most experiments were undertaken with a particular type of AGW electrolyte, namely a mixture of a buffered aqueous solution of tartaric acid and propylene glycol. However, a limited study using either citric acid or phosphoric acid instead of tartaric acid, and ethylene glycol instead of propylene glycol has also shown that each of such combinations works equally well. The results in this paper also indicate that the essential components of the present electrolyte is water and glycol. Therefore, a more generalized formula of the AGW electrolyte will be (*i*) glycol (diol or more generally polyhydric alcohol), (*ii*) water, and (*iii*) a suitable acid, base, or salt. The role of the water is that of the anodic oxidant of GaAs, and the role of component (*iii*) is to establish a suitable ionic conduction in the electrolyte. A careful choice has to be made for (*iii*) so that no disastrous effect on the oxide growth such as strong oxide dissolution etc. is introduced by it.

As for component (*i*), glycol was used in the past in the anodic oxidation of Al (17), Ta (18), and Si (19). But, the experimental results appeared to indicate that its effect is far more essential in the present case. Therefore, a comparison is presented here of the AGW process with the corresponding anodization process in the aqueous solution without glycol (the AAS process), where the same aqueous solution as in the AGW process was used, but with the glycol omitted.

On the basis of our experimental observations it is concluded that simultaneous dissolution of oxide occurs during the growth and that the classical active-passive transition of the anode (20) plays an important role.

Recently, another successful electrolyte for GaAs (21) has been reported which contains water and N-methylacetamide. This appears to have a similar makeup as the present AGW electrolyte. However, an anomalous growth seems to start at a voltage as low as 45V so that detailed electrical and chemical measurements have to substantiate still the quality of this oxide. Also the bath conditions including the *p*H adjustment seem to be much more critical.

Experimental

Slices of p-type bulk material with the carrier concentrations of 2.2×10^{16} cm^{-3} and 1.4×10^{17} cm^{-3} (both Zn-doped), of n-type bulk material with the carrier concentration of 1.0×10^{18} cm^{-3} (Si-doped), of n-type epitaxial material with the carrier concentration 7.6×10^{14} cm^{-3} (undoped, mobility = 6600 cm^2/V·sec, supplied by Monsanto Ltd.) were used in the experiments. In-Ge-Ag or Ag-Sn were used for the ohmic back contacts to n-type material, and In-Ag or In-Zn-Ag for those of p-type material. In all cases, contacts were provided by the deposition of metals in vacuum, followed by a subsequent brief annealing in a hydrogen flow at about 600°C.

The three important low-index planes (100), (111), and $(\bar{1}\bar{1}\bar{1})$ orientations were used. The surfaces to be anodized were chemomechanically polished in an aqueous solution of NaOCl in the case of bulk materials. Wafers were cut into pieces by the use of a wire saw or by cleaving. Various sample surface areas from about 5 to 100 mm^2 were used with typical standard size being 5 × 5 mm. Before the start of anodization, each sample was subjected to a series of "pre-epitaxy" cleaning procedures.

The experimental setup employed for the anodization as reported here is on purpose kept simple by omitting more refined facilities such as a potential probe, because the aim is the development of a reliable production-type technique. It will be shown, however, that this does not prevent the authors from obtaining a good understanding of the basic phenomena involved, and only now a more accurate quantitative study would require the use of a potential probe. The setup is shown in Fig. 1. Pyrex glassware and a cathode of a platinum plate (2 × 2 cm^2) were used. The samples were attached to a capillary tube using a high-quality wax, and an electrical contact was made to the back side by a spring through a capillary tube. The generally small sample (Fig. 1 is not to scale, the sample surface area being typically 25 mm^2) was placed sufficiently deeply into the electrolyte in order to prevent current crowding on that part of the anode surface which is closest to the cathode. In connection with the sample edges, two different cases were studied, namely (*i*) the side areas and edges being carefully covered by the wax and (*ii*) the side areas and edges being exposed to the electrolyte. In each case, the values of current density reported here are averaged ones obtained by dividing the total current by the total sample

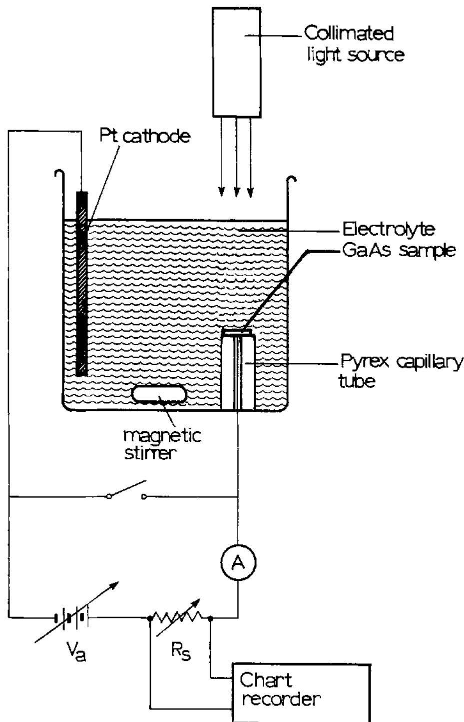

Fig. 1. Experimental setup for anodic oxidation

area exposed to the electrolyte, ignoring the nonuniform current distribution near edges and side areas. For the illumination of the samples during anodization, a collimated light source was used which was a typical microscope lamp with a tungsten bulb.

The circuit for anodization is a simple one where the electrodes are connected to a variable d-c constant-voltage source through a variable resistor R_s. External circuit conditions are specified by the source voltage V_a and the short-circuit current density $j_s = V_a/r_s$, where r_s denotes the series resistance per unit area of the sample given by R_sS, with S being the area to be anodized. As seen later in Eq. [2], r_s determines the time constant of the oxide growth. In spite of its simplicity, the present circuit is very flexible and suitable for the analysis of the kinetic behavior of the process, permitting one to change the anodization conditions widely from a nearly constant-voltage condition to a nearly constant-current condition.

For the measurement of thickness of the oxide and GaAs consumed, steps were produced by covering some part of the surface with wax or Shipley photoresist (AZ 1350). Dissolution of the grown oxide layers was undertaken in an HCl solution, followed by a quick but thorough rinse in distilled and deionized water. The thickness was determined by a Zeiss interference microscope and a Dektak profile plotter with both instruments exhibiting an accuracy of about $\pm$ 50Å in our cases. Agreement between these two methods was found to be reasonably good.

As already mentioned, a particular type of AGW electrolyte was used throughout the present study. It is produced by first preparing a 3% aqueous solution of tartaric acid if necessary buffered by NH_4OH to obtain a certain pH value (this solution is also referred to regarding our AAS here), and second mixing this with propylene glycol.[2]

Therefore, the pH value of the AGW electrolyte in the present text means the pH value of the buffered aqueous acid solution before mixing with glycol.

As a convenient way to specify the makeup of the electrolyte, the mixing ratio of the electrolyte is defined hereafter as the volume of the glycol divided by that of the acid solution (or water). Thus, an AAS electrolyte has the ratio of null.

Results and Discussion

The effect of pH.—Figure 2 shows the effect of the pH value on the anodic oxide growth for AGW and for its corresponding AAS. Anodization was performed for a fixed time of 10 min and fixed circuit conditions of V_a = 150V and j_s = 1 mA/cm^2 on p-type samples with covered edges. The mixing ratio of the AGW electrolyte was 2. In both the AAS and the AGW processes, the anodization current drops with time in a roughly exponential way if it does drop, resulting in the growth of an oxide whose thickness is compared in Fig. 2. Clearly, the AGW process is much more immune to pH variations and gives thicker films than the AAS process. Oxidation by the AAS process is restricted to a relatively narrow pH range. Outside this range, a nonuniform anodic dissolution (etching) takes over, and the current stays constant (except for the initial small drop) instead of showing an exponential drop. The transition from the oxide growth takes place in a very abrupt manner with respect to pH.

Another characteristic feature observed in the AAS process is that it is extremely sensitive to contamination and tends to be irreproducible. The data shown in Fig. 2 were taken by using utmost care not to contaminate the bath. It has been experienced very often that the oxidation suddenly turns into etching from one anodization to the next having nominally the same conditions. It is also noted that anodization can be restarted in such a case by increasing the current density j_s sufficiently. In general, both the pH range for oxidation and the reproducibility of the AAS process increased with the current density.

Even more difficult situations were experienced when a limited study was done at an early stage of the present study on the AAS process using a 30% aqueous solution of H_2O_2 of the British arristar grade. With this H_2O_2, which contains more than 1 ppm of HCl, and HNO_3 when supplied by the manufacturer, oxide growth was impossible in its pure state under all the conditions tried, and after many trials, it was found that the oxide starts to grow only when sufficient H_3PO_4 or NH_4OH is added to change the pH toward the acid or base direction (*i.e.*, when the electrolyte conductivity is increased) and when the anodization is done with a small series resistance (nearly constant-voltage condition). Obviously this growth is only possible for very large current densities.

In contrast, the AGW process has been found always very stable and reliable, and the result is always reproducible even after many times of anodization.

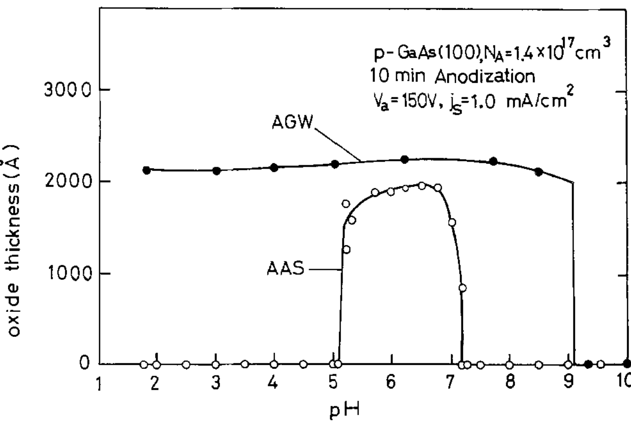

Fig. 2. Effect of pH on anodic oxide growth (AAS: 3% aqueous solution of tartaric acid, buffered by NH_4OH to a certain pH value; AGW: the same as for AAS plus glycol, of the volume ratio 1:2, respectively).

[2] Such mixing tends to result in precipitation of tartrate around a pH = 3 ~ 4, but a complete dissolution can be obtained by treating the system up to around 50°C and cooling down.

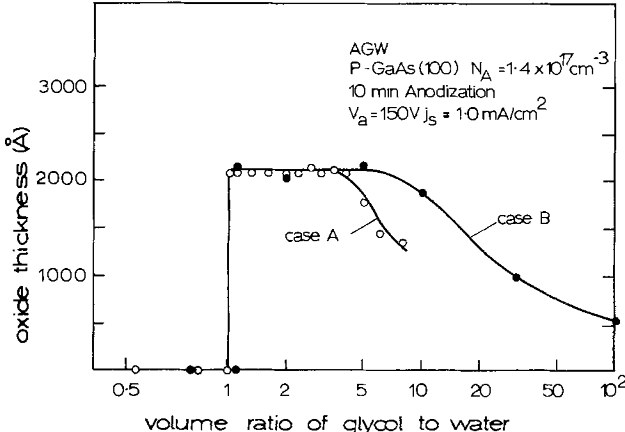

Fig. 3. Effect of mixing ratio of glycol and water on anodic oxide growth.

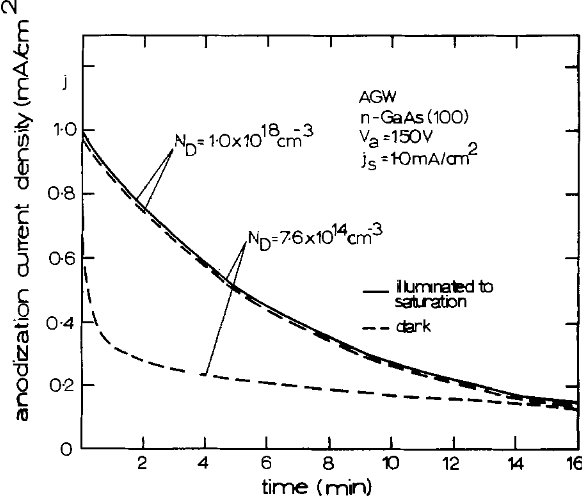

Fig. 4. Effect of illumination on anodic oxide growth on n-type samples.

The effect of the mixing ratio.—Figure 3 shows the effect of the mixing ratio of glycol to water of the AGW process on the anodic oxide growth. The GaAs samples and the circuit conditions are the same as with Fig. 2. Two different ways of mixing were employed here. In case A, an unbuffered aqueous solution consisting of 3g of tartaric acid and 100 cm^3 of water (resulting in a pH = 1.8) was prepared at first and glycol was added to the required volume ratio. In case B, the solution consisted of 3g of tartaric acid and 100 cm^3 of glycol[3] at first and water was subsequently added to the required volume ratio. For a given mixing ratio, the actual concentration of the tartaric acid in the mixed solution is therefore quite different for the two cases except in the neighborhood of the volume ratio of unity. Nevertheless, both cases behave in a similar way showing an abrupt transition from anodic dissolution to anodic film formation at about the mixing ratio of unity. In the range of the mixing ratio from 1 to 4, film growth is independent of mixing ratio and concentration of tartaric acid.

The above results concerning pH and mixing ratio indicate that the present AGW bath has a broad empirical optimum at around pH = 6.2 and the mixing ratio of 2 to 4 for stable oxide growth using a moderate anodization current density of the order of 1 mA/cm^2. Therefore, all further experimental studies of the process have been carried out by standardizing the AGW bath conditions to pH = 6.2 (adjusted by NH_4OH before mixing) and the mixing ratio of 2. Similarly, for comparison, the AAS bath is standardized to pH = 6.2 which is approximately the center of the pH range in Fig. 2.

Effect of illumination.—Another factor which could have a large effect for a uniform and stable growth is the condition concerning illumination. Therefore, some preliminary experiments were carried out using the standard AGW bath and it was found that illumination of the semiconductor surface by a uniform light source has indeed a very large effect on anodic oxidation of n-type samples, particularly when the carrier concentration is low. The difference in the anodization current under illuminated and dark conditions is shown in Fig. 4 for two different carrier concentrations. In both cases the anodization current at a given instant of time increases as the light intensity is increased, and becomes saturated under sufficiently strong illumination. The anodization current behavior and oxide growth under an illumination at saturation level were found to be independent of the carrier concentration as seen in Fig. 4. This also results in a very uniform oxide layer. On the other hand, the anodization current and oxide growth in the dark are strongly dependent on the carrier concentration. In the case of the epitaxial sample with a low carrier concentration (10^{14} cm^{-3}), an extremely slow and nonuniform oxide growth resulted, where as the sample with the higher carrier concentration yielded a very uniform layer. Nonuniform growth can be visibly seen as a nonuniform pattern of oxide interference colors. A repeated careful study of this nonuniform growth has shown that the initial rapid current drop corresponds to a rapid oxidation near the fringe of the sample, and after this slow oxide growth starts from the fringe toward the inner area. It was also noted that anodization reveals several small spots on the surface around which the oxide growth takes place apparently more rapidly. Under a microscope, these spots were identified as defects in the epitaxial layer. The final thickness of the oxide on the sample with the lower concentration after 16 min anodization was about 2600Å in the case of the sufficiently illuminated surface and about 600Å on average in the case of the dark surface.

On the other hand, no appreciable effect of light was observed with the anodization of p-type samples, and the anodization current curve coincides with the solid curve in Fig. 4.

A similar marked difference in the behavior between n-type and p-type samples was known for the anodic oxidation of Si (22). It was reported recently that anodic dissolution of n-type GaAs shows an effect of illumination similar to the present case (23). These results indicate that the carriers which are taking part in the anodic reaction at the GaAs anode are holes, irrespective of whether this reaction leads to oxide growth or dissolution. Since the electrolyte-semiconductor interface is basically a Schottky junction, the rate of anodic reaction at the n-type GaAs anode is limited by the thermal generation rate of holes in the reverse biased depletion layer in the semiconductor, unless holes are generated sufficiently by such processes as illumination, thermal generation, or impact ionization.

It is well known that the thermal generation rate of minority carriers decreases as the doping is reduced so that for the lower donor density N_D of Fig. 4 insufficient holes are provided as long as the applied voltage remains sufficiently small to prevent field or impact ionization. However, it is likely that our results for high N_D values, when no reduction in the anodization process was found, have to be understood by thermal or impact generation of holes. The latter mechanism is supported by avalanche breakdown results of reverse-biased Schottky junctions.

Similarly, minority carrier generation is likely to be high near the sample fringes and in the neighborhood

[3] Complete dissolution was attained by heating up to about 50°C and cooling down.

of various defects. The effects mentioned here concerning illumination would have a series of interesting applications such as selective anodization, a study of defects on the surface, and delineation of various junctions. However, since uniform and reproducible oxidation is the main purpose of the present paper, further studies on anodization of n-type samples have been done under sufficiently illuminated conditions.

Behavior of anodization current density.—The anodization current density is plotted *vs.* time in Fig. 5 and 6 for the AAS and AGW process, respectively. The current density is normalized for convenience by the short-circuit current density j_s. By direct comparison,

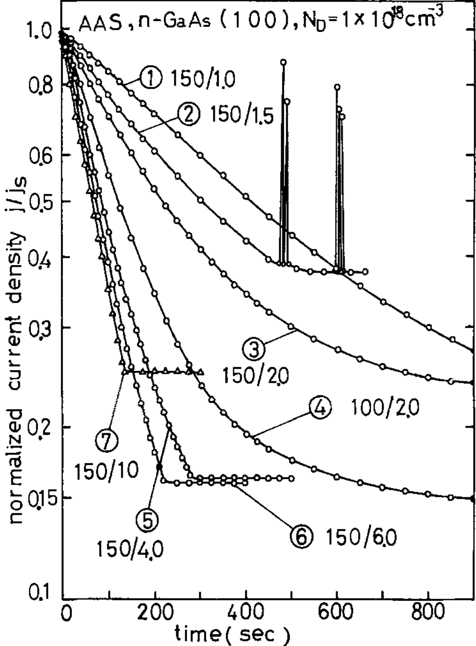

Fig. 5. Normalized anodization current density vs. time for the AAS process. The parameter is V_a (volt)/j_s(mA/cm^2). Curve 7 is taken on a sample with exposed edges.

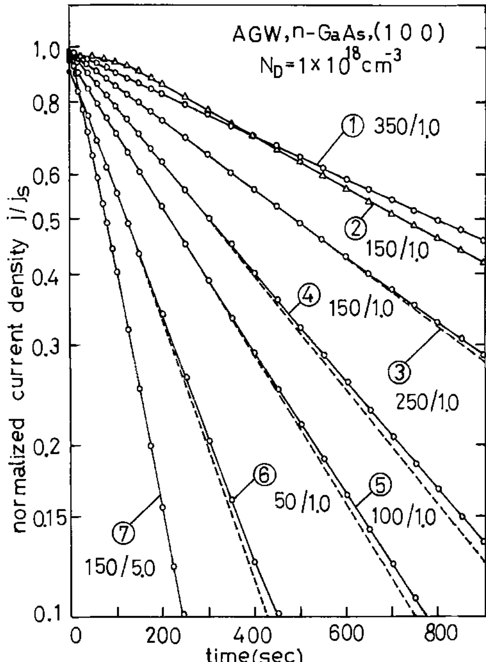

Fig. 6. Normalized anodization current density vs. time for the AGW process. The dashed lines demonstrate when after longer time the experimental curve deviates from an exponential law. The parameter is V_a (volt)/j_s (mA/cm^2). Curve 2 is taken on a sample with exposed edges.

one can see that the AGW process behaves in a much simpler and reproducible way, and that its deviation from an exponential current decrease is only noticeable much later than for the AAS.

The experimental data of these two figures can be understood by an oxide growth rate which is proportional to the anodization current minus an approximately constant dissolution rate. A simultaneous dissolution of oxide into the electrolyte during growth was pointed out by Harvey and Kruger in their analysis of oxide growth based on a potential-sweep method (19). Assuming (*a*) a constant quasi-steady state field E_{ox} in the oxide whose dependency on the current density can be ignored, (*b*) a constant current efficiency, (*c*) a constant oxide dissolution rate f_d, and (*d*) an ohmic bath resistance R_b leads to the following expression for the normalized anodization current density

$$\frac{j}{j_s} = \frac{j_o - j_d}{j_s} \exp\left(-\frac{t}{\tau_f}\right) + \frac{j_d}{j_s} \quad [1]$$

where

$$\tau_f = \frac{r_s + r_b}{E_{ox}A} \quad [2]$$

is the time constant of growth, which we call the formation time constant; A is the formation rate (defined here as the increase in film thickness per unit charge passed through unit area); $r_s = R_sS = V_a/j_s$ is the external circuit resistance related to anode area (see Fig. 1); and $r_b = R_bS$ is the bath resistance for unit area of anode

$$j_o = \frac{V_a - V_r}{r_s + r_b} = j_s \frac{1 - (V_r/V_a)}{1 + (r_b/r_s)} \quad [3]$$

is the initial current density; V_r is the rest potential of the anodization cell; and

$$j_d = \frac{1}{A} f_d \quad [3a]$$

is the equivalent current density, corresponding to film dissolution.

The corresponding thickness x is given by

$$x = x_\infty \left[1 - \exp\left(-\frac{t}{\tau_f}\right)\right] \quad [4]$$

where x_∞ is the film thickness in the steady state and is given by

$$x_\infty = \frac{1}{E_{ox}} (V_a - V_r) \left(1 - \frac{j_d}{j_o}\right) \quad [5]$$

As shown later, assumption (*a*) does not hold very accurately. However, the deviation is reasonably small and one is still justified to use these simple equations for small variations of current density or for a general description of the process.

In order to exhibit dissolution more clearly also for the AGW process Fig. 7 shows a long-time growth. The value of the film dissolution rate estimated by comparing experimental data with Eq. [1] gives ranges from 1-3 Å/sec for the AAS process and from 4-6 $\times$ 10^{-2} Å/sec for the AGW process, approximately two orders of magnitude a smaller value for the AGW process. For this estimation the experimentally determined values of E_{ox} and $E_{ox}A$ were used which is discussed later.

In order to confirm such values of f_d, a separate etching experiment was carried out where oxide films formed by the AGW process were kept in the AAS or AGW electrolyte without passing a current, and their thickness was measured after constant intervals of time. The result of the experiment is shown in Fig. 8 where thickness dissolved is plotted *vs.* time. The oxide

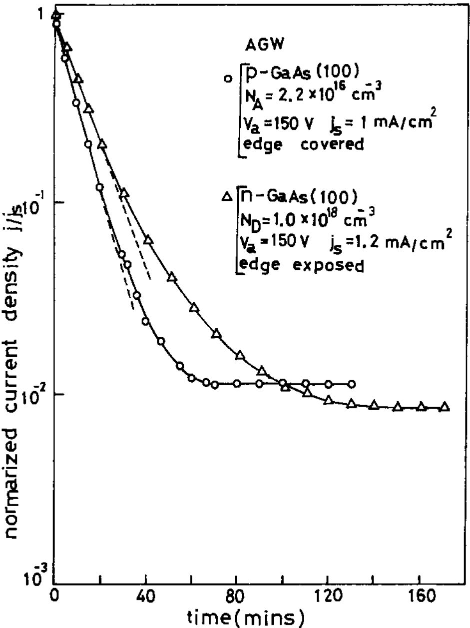

Fig. 7. Current density vs. time for the AGW process for a longer period of anodization.

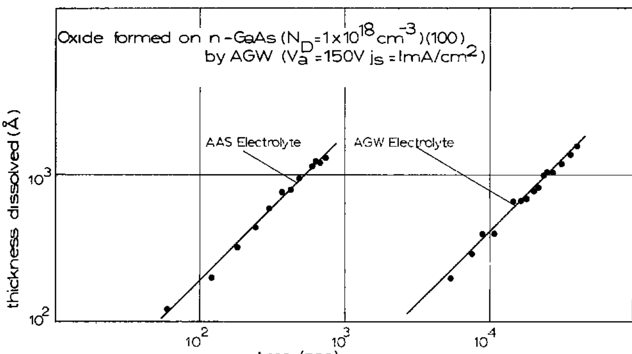

Fig. 8. Etching of oxides in the AAS and AGW electrolyte

dissolution rate f_d determined by this experiment is 1.9 Å/sec for the AAS electrolyte and 4.2×10^{-2} Å/sec for the AGW electrolyte, and these are indeed in agreement with the previous estimates. This also should be compared with the value of $f_d = 1.37$ Å/sec reported by Harvey and Kruger for a different AAS electrolyte (9).

For a given value of the external circuit voltage V_a, the large effect of oxide dissolution on the growth in the AAS process can be in principle counteracted by passing a larger current through and speeding up the growth. Curves 5, 6, and 7 in Fig. 5, however, show what actually happens in such a case. In addition to the fact that growth proceeds more rapidly with a reduced deviation from the exponential line, as one would expect, the current drop suddenly stops at a certain point and the current stays more or less constant after that with small spiky fluctuations ignored in the drawing. The oxide film grown in such a way shows a whitish granular appearance superimposed on the ordinary interference color, similar to the anomalous growth reported by Logan, Schwartz, and Sundburg (12). A more detailed study showed that the grown oxide is uniform and does not have the anomalous appearance if the growth is stopped before the singular point of the current density is reached, and as soon as this point is reached, the whitish pattern starts to spread from the fringe of the sample toward the inner area and eventually covers the whole surface. A scanning electron micrograph ($\times$804) of the boundary between the still uniform area and the area with whitish granular

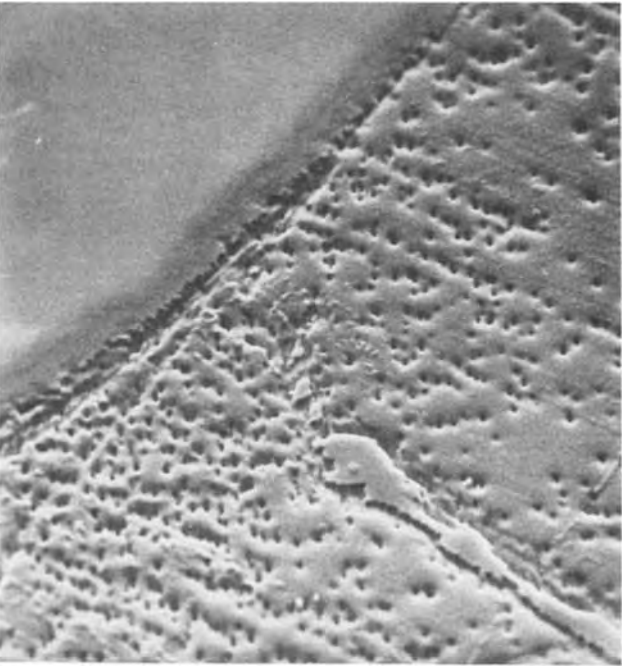

Fig. 9. SEM micrograph of boundary between normal area and anomalous area (804X).

appearance is shown in Fig. 9. The formation of pits is seen in the anomalous region suggesting that serious electrical breakdown took place in the oxide, resulting in the damage of the semiconductor surface. A similar interpretation was given by Spitzer, Schwartz, and Weigle (15). It was indeed found that the whitish granular appearance stays on the surface after the oxide is dissolved away in an HCl solution. In curves 5 and 6 of Fig. 6, both of which are for the samples with covered edges, this breakdown occurred at around 130V, whereas in the curve 7 for the sample with the exposed edges, it took place around 100V.

Curve 2 in Fig. 6 shows yet another anomalous behavior of the AAS process producing current spikes. It has been found that such current spikes correspond again to the formation of pits which are, however, of much larger sizes.

The effect also seems purely local in this case and does not show the tendency of spreading over the entire surface. Except for the pits, the rest of the surface remains uniform. These spikes appear sometimes at very early stages of anodization although they are more frequently observed at later stages, and it looks as if they are caused by a sudden local dissolution of oxide, followed by a rapid regrowth at high current density rather than initiated by breakdown in the oxide. The fact that spikes are more frequently observed in those baths which have been used many times suggests that such a partial dissolution is most probably triggered and enhanced by certain impurities in the electrolyte. In general, the slower the process, or the longer the sample stays in the bath, the higher the probability of producing current spikes. Such an observation was also made by Dell'Oca, Yan, and Young on a different type of AAS electrolyte (8).

Formation time constant.—The experimentally determined formation time constant τ_f is plotted *vs.* series resistance per unit area r_s in Fig. 10 for the various conditions of anodization as indicated in the insert. Most of the data was taken with $j_s = 1.0$ mA/cm^2, although somewhat larger values were used for the AAS process for the accurate determination of τ_f making the effect of oxide dissolution less serious. It is interesting to note that all the data taken on samples with carefully covered edges fall reasonably well on the common straight line with a slope of unity irre-

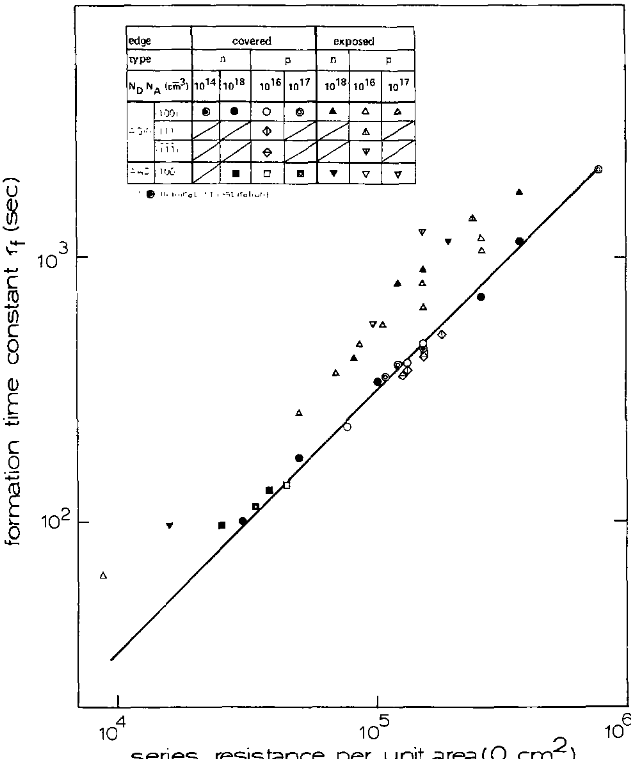

Fig. 10. Measured formation time constant τ_f vs. series resistance per unit area, r_s.

spective of whether it is the AAS or the AGW process and also irrespective of the conduction type, carrier concentration, and crystal orientation. Since all the anodization shown in Fig. 10 was carried out in the situation of $r_b << r_s$, the result here basically confirms the validity of Eq. [2]. It also strongly suggests that the basic oxide formation process is the same for the AAS and the AGW processes having water as the common anodic oxidant.

As no orientation dependence was observed, it is suggested with reference to the work by Dewald on InSb (24) that, at the field strengths corresponding to the current densities of around 1 mA/cm^2, the rate-limiting factor of the total process is the ionic transport through the oxide rather than the ionization process at the oxide-semiconductor interface provided that sufficient illumination is given in the case of n-type samples. The straight line of Fig. 10 gives with Eq. [2] and [5] a value for AE_{ox} of 3.2 $\times$ 10^2 cm^2 farad^{-1} for a moderate growth rate starting from around 1 mA/cm^2. This corresponds to a voltage formation rate of 0.32 V/sec for the constant current anodization at 1 mA/cm^2, which is in agreement with the value of 9.5 V/min reported for a constant-current anodization at 0.5 A/cm^2 in a different electrolyte (21). This agreement demonstrates the similarity of the oxidation processes with various electrolytes containing water, and it shows that our convenient circuit of Fig. 1 also gives growth of a quasi-steady-state nature.

For the anodization at moderate current densities in the standard AAS and AGW baths, the relation of $r_s >> r_b$ was almost always satisfied resulting in $j_s \simeq j_o$. However, when the mixing ratio in the AGW bath exceeded 5, the bath resistance was no longer small as compared with the series resistance which was clearly indicated by the decrease in the initial current density j_o. Reduction in the thickness of the grown oxides at high mixing ratios seen in Fig. 3 can therefore be explained partly by the increase of bath resistance which leads to a slower growth with an increased time constant according to Eq. [2]. Thus, the reason why case A starts to show slower growth at smaller mixing ratios than case B can be simply understood by the difference in the amount of tartaric acid which is related to the ionic conduction in the bath.

However, it was found that the actual amount of increase in time constant was found to be too large to be explained quantitatively by the experimentally estimated value of r_s through Eq. [2]. The anodization curves also showed greatly increased values of f_d at high values of mixing ratios, with the result that films with reasonable thickness could not be obtained even if one waited for a long time. These two facts show that the whole situation should be explained not only by the increase of bath resistance but also by a marked decrease of the formation rate A or current efficiency as the mixing ratio becomes high. The latter strongly indicates again that water is the basic anodic oxidant of the process.

Initial stage of growth.—The above experimental observation that the formation rate takes more or less the same value for the standard AAS and AGW electrolytes with $pH = 6.2$ suggests that this rate will also remain more or less constant when the pH is changed. A careful check has shown that this is indeed the case and that the differences in the thickness of the grown oxides for the AAS and AGW processes in Fig. 2 should therefore be explained primarily by the difference in the oxide dissolution rate f_d.

However, when the question is considered what the reasons are for the sharp transitions between anodic oxidation and anodic dissolution as observed in both Fig. 2 and 3, an explanation based only on a variation of oxide dissolution rate with bath parameter does not work because one would have expected a more gradual change if such were the case. In fact, an etching experiment of oxide in the unbuffered 3% aqueous solution of tartaric acid has shown that f_d of such an AAS bath is 5-6 Å/sec which corresponds to j_d = 0.7-0.8 mA/cm^2. Thus, one should have been able to anodize the sample with the moderate current density of a few milliamperes per square centimeter, which was, however, found always impossible. A further experiment showed the importance of the initial process, in which a sample was anodized in an AGW bath to a few volts corresponding to oxide growth of several ten angstroms, and, after being taken out and subjected to a thorough cleaning and drying, it was immersed into a bath of an unbuffered tartaric acid solution. The result showed that oxide growth can be kept on going in such a case at a moderate current density where oxidation was previously impossible.

Because of this indication of the importance of the initial stage of growth, a more detailed measurement was undertaken using an AGW bath for various current densities. The result is shown in Fig. 11 which clearly shows the presence of a time delay before the initiation of the exponential growth. The length of delay is dependent on the current density rather than the source voltage. The data in Fig. 11 were taken without stirring of the electrolyte. When the electrolyte was stirred, the transition from the flat to the exponential region became more gradual and also the time delay was increased at the same current density.

The observed relationship between time delay and current density is plotted in Fig. 12 for unstirred and moderately stirred conditions. A similar experiment with an AAS bath showed the presence of such a time delay, but no meaningful relationship has been established owing to a large scatter of data and lack of reproducibility which again suggests the extremely sensitive nature of the AAS bath.

All these observations including the abrupt transition from anodic dissolution to anodic oxidation (passivation of the anode), the presence of a mimimum threshold current density for oxidation, and the presence of a time delay for oxidation provide strong evidence that the classical active-passive transition of the

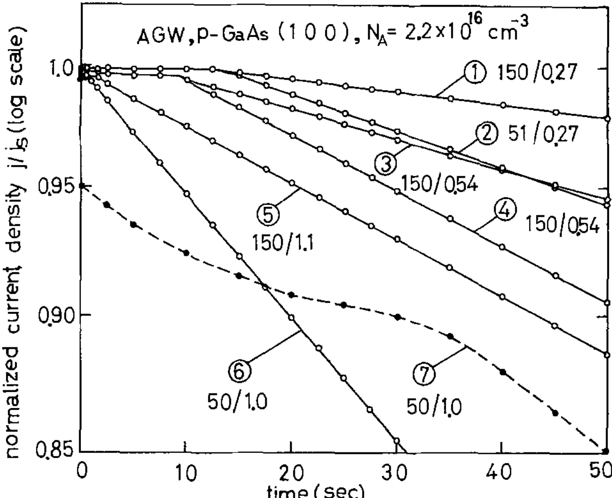

Fig. 11. Initial stage of growth showing passivation time t_p. The parameter is V_a (volt)/j_s (mA/cm^2). The dashed curve is taken on a sample with exposed edges.

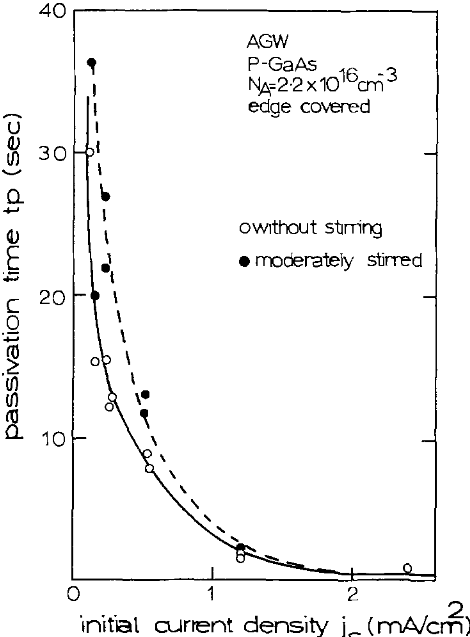

Fig. 12. Passivation time t_p vs. current density j_s

anode takes place at the initial stage of growth. Such a transition has been known to be very common among certain metals from old times (20), but little practical importance has been attributed to the case of semiconductor materials. Harvey (25) and more recently Harvey and Kruger (9) studied the electron behavior of the GaAs anodes and observed this transition under certain conditions. But, these excellent studies did unfortunately not lead so far to any practical control of such a transition.

The extreme sensitivity of the AAS bath and the observed sharp transitions in Fig. 2 and 3 can be best explained by the fact that the limiting current density j_l for the active-passive transition is high and it varies very much with the bath parameters and by the introduction of contaminations in the AAS bath. A repeated measurement has shown that the value of j_l for the present AAS bath at the optimum pH value of 6.2 lies typically in the range of 0.8-5 mA/cm^2, and that of the AGW bath is about 1.0×10^{-1} mA/cm^2 as seen in Fig. 12.

The observed time delay is obviously the so-called passivation time t_p of the active-passive transition. The data in Fig. 12 fit better the relation, $(j - j_l)\, t_p^{1/2} =$ const, rather than, $(j - j_l)\, t_p =$ const, indicating the establishment of a supersaturated region against the diffusion convection transport (20). A further detailed study seems to be necessary to fully clarify the situation. The reason for the reduction of the limiting current density by the addition of glycol would be either a decrease in the solubility of the initial anodic products, or a reduction in the transport rate of such products, or both, leading to an easier establishment of supersaturation.

The fact that stirring increases the passivation time is obviously consistent with the present picture, and alhough it thus makes the establishment of the desired situation for growth more difficult, its effect on the AGW process at moderate current density is very small, and, moreover, a continuous stirring at a moderate speed has been found practically very important for uniform growth because, without stirring, any bubbles, accidently introduced by sample immersion or produced spontaneously, tend to stick on the surface and prevent the initiation of uniform oxidation. Stirring seems also to be important for successful growth of thick films.

The usual anodic film growth takes place thus in the passive region of the GaAs anode after the above transition. Electron diffraction studies confirmed the amorphous glassy nature of such "passive" films for both of AGW and AAS processes in agreement with the previous results on similar films. An electron microprobe analysis has shown the ratio of numbers of Ga and As atoms in the grown films to be unity on average. Other important properties of the AGW oxide films have been described elsewhere (16).

When the current density is below the limiting current, the GaAs anode remains in the active region and the anodic dissolution continues without showing the current drop (or voltage buildup). This dissolution process is a nonuniform one, apparently having higher dissolution rates at mechanically damaged parts and edges, producing sharp ditches at the waxed boundary and leaving characteristic pits and lines on the surfaces. When the anodization current density is just below the limiting current density, it was observed that the entire GaAs surface changes quickly into a brownish, whitish appearance with the current showing no drop. This surface layer could not be removed by HCl, KOH, or NH_4OH, each of which is an etchant of the amorphous passive oxide. It was first thought that this film was similar to the porous, polycrystalline "active" oxide formed in the active region under certain conditions by Harvey and Kruger (9). However, an electron diffraction study showed only the single crystal pattern of GaAs, and a high magnification scanning electron microscope showed a pattern which looks like a roughened surface of GaAs. Thus, the presence of such an active oxide or hydroxide has not been confirmed yet in the present case.

Effects of bath contamination.—One of the most important features of the new AGW process is that it is much more immune against contaminations than the AAS process. The present study confirmed that among various commonly used acids and bases, HCl seems to have the strongest effect on the oxide growth. On the other hand the present AGW process exhibits an impressive stability, even up to the level of $10^{-3}N$ of HCl, as already reported elsewhere (6).

A result of a series of experiments which demonstrate the striking stabilizing effect of glycol is shown in Fig. 13. The final vertical portion of each curve shows the moment of stop of anodization. Curve 1 is the anodization curve for the uncontaminated AAS bath which was taken near the limiting current as indicated by a large passivation time (20 sec). After an artificial introduction of about $7 \times 10^{-4}N$ of HCl, anodic oxidation stops as shown by curves 2 and 3. At an increased current level by about 2.5 times, it starts

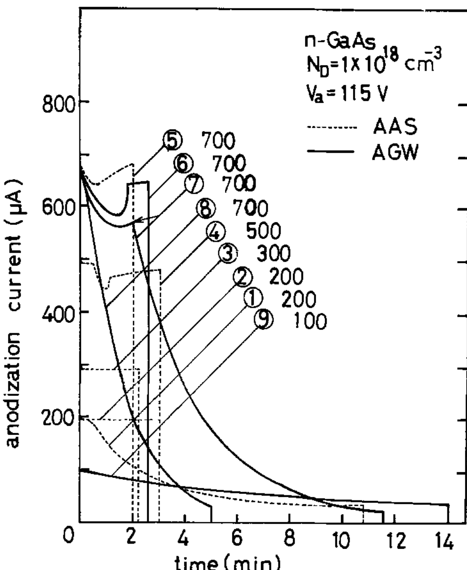

Fig. 13. Action of glycol in the contaminated bath. The parameter is the short-circuit current $I_s = j_s S$ in μA. The sample area is 5 mm^2 with exposed edges.

again after a large passivation time of 30 sec as shown by curve 4, but somehow fails, probably because of a high oxide dissolution rate acting in a nonuniform way. Further increases in the current do not improve the situation very much as shown by curve 5. At this stage, glycol is added with a mixing ratio of 0.5 with an appreciable improvement as shown by curve 6. With a mixing ratio of unity (curve 7), the improvement is remarkable but still insufficient. At the point indicated by an arrow on curve 7, glycol is further added to the ratio of 1.5 and a completely normal anodization is restored, which was repeated from the beginning as shown by curve 8. Curve 9 shows that after the addition of glycol the anodization became possible even at a smaller current density with which the anodization was originally impossible.

Thickness-voltage rate constant.—The thickness of the grown oxide layers are plotted *vs.* voltage across the oxide for various anodization conditions in Fig. 14. Three different ways of growth were employed, *i.e.,* case A: started from $j_s = 1$ mA/cm^2, and stopped as the predetermined voltage across the oxide is reached with the current density of $j = 0.1 \sim 0.3$ mA/cm^2; case B: started either from $j_s = 1$ mA/cm^2 and left until the current density is reduced to more or less the steady state with $j \simeq 1 \times 10^{-2}$ mA/cm^2, or started as above, then changed to constant voltage anodization at the predetermined voltage when the voltage across the oxide reaches that value, and left until it reaches the steady state with the current density $j \simeq 1 \times 10^{-2}$ mA/cm^2; case C: rapid growth, started from $j_s \simeq 5 \sim 10$ mA/cm^2 and stopped at $j \simeq 2 \sim 3$ mA/cm^2. In each case, the voltage across the oxide was determined simply by $V = V_a\,(j_o - j)/j_o$ where the effect of bath resistance is included, but any correction to obtain the exact oxide-producing overpotential is ignored. A separate experiment has shown that such a potential correction is less than 1V, and for the large voltage values (> 50V) employed in the present study with the not so accurate means of thickness determination, such a detailed correction seemed rather insignificant. Figure 14 indicates clearly that the thickness-voltage relationship varies as a function of the current densities employed. This is consistent with the various theories of ionic transport which relate the current density j with the steady-state oxide field E_{ox}, generally in the form of $j = j_o \exp(-W(E_{ox})/kT) \exp(qaE_{ox}/kT)$ (26).

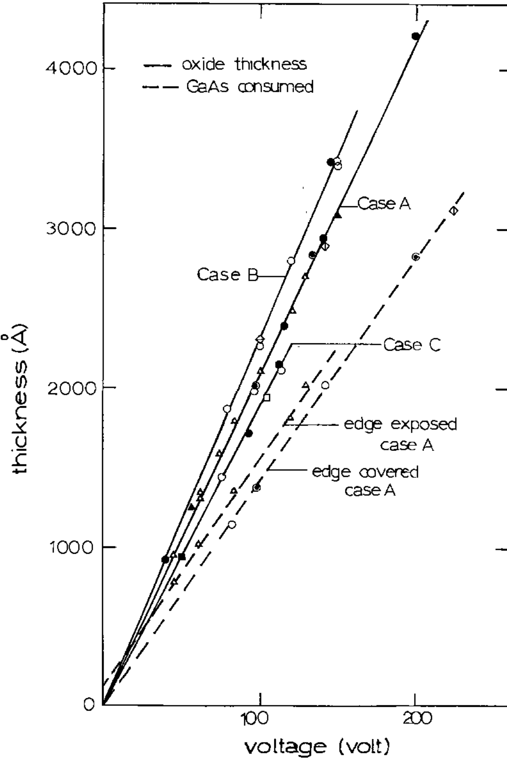

Fig. 14. Oxide thickness and amount of consumed GaAs vs. voltage. Symbols are the same as Fig. 10.

The averaged value of the thickness-voltage constant is 21 Å/V for case A, 23 Å/V for case B, and 19 Å/V for case C. This result explains why different values ranging from 18 to 22 Å/V were reported in the past (8, 9, 12, 15, 21) and indicates that the current density must be carefully determined for the accurate control of the process which is, for instance, important for fine thinning of wafers for the purpose of profiling (21) and wafer tailoring for FET's and other devices (14). Within the experimental accuracy no dependence of the rate constants on the carrier concentration or orientation was observed. The amount of GaAs consumed is also shown for case A of growth in Fig. 14 and the average consumption rate is 14 Å/V for the samples with carefully covered edges.

On the basis of a more careful study of the rate constants as a function of the final anodization current density j_f, a plot of this current density *vs.* the electric field E_{ox} is obtained as shown in Fig. 15 which shows approximately a simple Mott-Cabrera type exponential dependency on the field (23), given by

$$j_f = 3.75 \times 10^{-15} \exp(6.58 \times 10^{-6} E_{ox}) \quad [6]$$

or

$$\text{rate constant} \equiv \frac{1}{E_{ox}} = \frac{19.8}{1 + 0.069 \log_{10} j_f}\ \text{Å/V} \quad [7]$$

where the field and current density have to be expressed in the units of V/cm and mA/cm^2, respectively. This again confirms the quasi-steady-state nature of our growth. Our results are obviously consistent with the theory of ionic transport (26).

It is not clear at the moment whether the observed small deviations from the exponential line at high fields is due to the experimental error, the transient nature of the experiment, or a more complex dependency on field.

The grown oxides show a regular occurrence of intense interference colors which corresponds to the refractive index of 1.8. Although no detailed ellipsometric measurement has been done, the change of the refractive index with the change of growth conditions

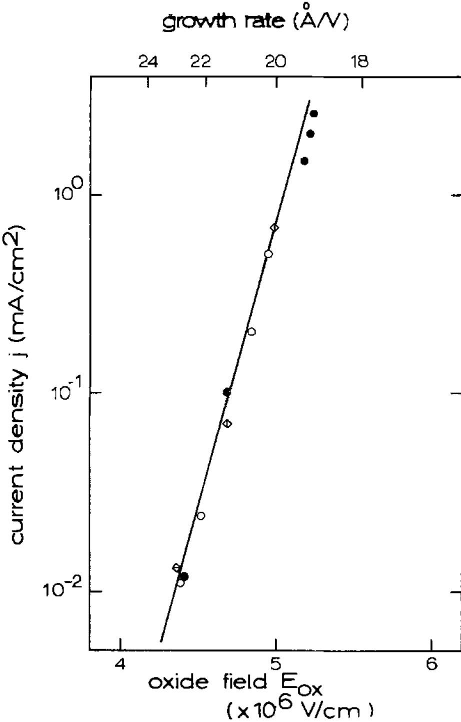

Fig. 15. Current density j vs. oxide field E_{ox}. Symbols are the same as Fig. 10.

seems to be very small as compared with the above-mentioned fairly large change in growth rate.

Effects of exposed edges.—As already indicated in various figures of the present paper, exposure of sample edges, in particular, mechanically damaged area, has extremely large effects which can become one of the important causes for quantitative irreproducibility of the process. The main effects observed experimentally are as follows: (*i*) slow down of the process as seen clearly as an increase in formation time constant τ_f in Fig. 10, (*ii*) increase in the passivation time t_p with a very gradual change in current as shown in Fig. 6 and 11, (*iii*) increase in the rate of GaAs consumption as shown in Fig. 14, (*iv*) generation of fluctuations in the anodization current, and (*v*) lowering of the breakdown voltage in the oxide as shown for the AAS process in Fig. 5.

The effects (*i*) and (*ii*) indicate that the exposed mechanically damaged parts (wire sawed for example) behave effectively as if they have a much larger surface than their actual geometrical area. The graded active-passive transition also suggests that the transition does not take place at the same time all over the surface but proceeds nonuniformly, starting perhaps from the edges. The effect (*ii*) seemed to be particularly large in the anodization of $(\bar{1}\bar{1}\bar{1})$ faces, sometimes resulting in the impossibility to cause the transition. The effect (*iii*) is related most probably to (*ii*) rather than the oxide dissolution because the latter is too small in the AGW baths to account for it. Owing to the delayed and nonuniform proceeding of the transition from the edge, the anodic dissolution continues perhaps for a much longer time on the front surface, resulting in a loss of an appreciable amount of GaAs. Some preliminary results (6) taken on samples with exposed edges thus showed a higher consumption rate of GaAs than for results reported previously. This was originally incorrectly interpreted as a higher density of the oxide.

The data in Fig. 14 indicates that such a loss of GaAs is 100∼150Å in case A of growth, and this result shows the vital importance of coverage of the edges in the application of controlled thinning of wafers. The effects (*iv*) and (*v*) are most probably related to high current densities and high fields at the edges causing partial breakdown and partial dissolution of loose oxide.

Current efficiency.—Finally, a crude estimate of the current efficiency of the AGW process will be made. From Fig. 15, one obtains $E_{ox} = 5.05 \times 10^6$ V/cm for $j_s = 1.0$ mA/cm², which gives, combined with the value of $E_{ox}A$ previously given, $A = 6.4 \times 10^{-5}$ cm³/coulomb. Since no direct density measurement has been done so far, a crude estimate is made as follows. From the case B growth in Fig. 14, one obtains the oxide coating ratio (= oxide thickness divided by GaAs consumed) of 1.5, assuming the loss of GaAs at the initial process is negligible for samples with covered edges on the basis of observed good proportionality. Then, if one assumes that the oxide is an amorphous mixture of Ga_2O_3 and As_2O_3 and ignores the possible effect of hydration on the basis of the detailed analysis of a similar oxide (27), the density of the oxide is estimated as 4.7.

A simple Faradayic analysis based on these data, assuming that each of the Ga and As atoms are ionized to its tripositive state as shown by Harvey and Kruger (9) for a similar oxide growth [Revesz and Zaininger (7) reported the oxide with penta positive As, but it does not seem to be the present case], gives a value of the current efficiency of 90% which is of course due to the small amount of dissolution. The reported anodization of Si has on the other hand a surprisingly low current efficiency of only 1-8% (19, 26).

Conclusions

By detailed comparisons, certain common features of various AAS processes have become clear, and the essential superiority of the AGW process is established on the basis of the detailed experiments and the theoretical understanding. Factors which affect the uniform and reproducible oxidation have been clarified and relevant process equations and data are given. The AGW process characterized by its easy use, its stability, and reproducibility, seems to be one of the most promising ways of forming insulating layers with acceptable qualities on GaAs. The main conclusions are as follows:

1. Water is a good anodic oxidant of GaAs, and a variety of aqueous solutions can anodize GaAs (AAS process). Anodization in water undergoes the electrochemical active-passive transition at the initial stage, which is characterized by the limiting current density and the passivation time.

2. The limiting current density of the AAS process is high and sensitive to contaminations which make it extremely difficult to anodize at a moderate current density of a few milliamperes per square centimeter in a stable, reliable, and reproducible way.

3. The AAS system is also characterized by a high rate of oxide dissolution which leads to the growth of loose and less impervious oxide films, enhanced partial dissolution of oxide during growth, and premature breakdown in the oxides at fairly low voltages. The oxide dissolution rate is also sensitive to contaminations which provide another cause for unstable and irreproducible results.

4. By the introduction of a fairly large amount of glycol to the AAS system, the limiting current density and oxide dissolution rate is greatly reduced (AGW process), and the process becomes extremely stable, reliable, and reproducible. Optimum bath conditions using tartaric acid and propylene glycol are established.

5. The main factors which affect a uniform and reproducible oxidation are illumination on n-type samples, coverage of sample edges, and a moderate stirring of the electrolyte.

6. The rate thickness-voltage constant shows a fairly large current density dependence.
7. The AGW process has a high current efficiency.

Quantitative Detection of Oxygen in Silicon Nitride on Silicon

P. H. Holloway and H. J. Stein

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The carbon, oxygen, and nitrogen levels in 500-2000Å films of CVD silicon nitride (Si_3N_4) films have been measured using Auger electron spectroscopy in conjunction with inert gas ion sputtering. The quantitative depth distribution of oxygen throughout the film was determined and interfacial oxides 10Å thick were clearly resolved. Oxygen concentrations in various nitride films were observed to range from 0.4 to 7% (atomic), whereas carbon was below the detection limits. It was shown that bulk oxygen and carbon levels down to 0.05 and 0.2%, respectively, are detectable. The influence of oxygen on the silicon/nitrogen Auger peak height ratio was demonstrated and the presence of oxygen was correlated with changes in the optical index of refraction.

The semiconductor industry has developed thin film silicon nitride both as a barrier for sodium diffusion and as an active element in electrically variable nonvolatile MNOS memory devices (1). The properties of silicon nitride can be varied over a wide range depending on the deposition technique and conditions, and these conditions are adjusted to obtain desired characteristics (2). For example, it is known from studies of electrical conductivity *vs.* deposition conditions that silicon nitride grown by chemical vapor deposition (CVD) at temperatures between 700° and 900°C with a high ammonia to silane ratio yields low conductivity films suitable for MNOS memory devices (3, 4). However, the quantity and distribution of impurities which are included by a selected growth process have not been fully characterized. A brief study of surface impurities by Auger electron analysis has been reported (5). Variations of optical properties (*e.g.*, refractive index, optical and infrared spectra, etc.) have been used to investigate impurities in silicon nitride (2, 6), but the sensitivity and depth resolution are generally not adequate for complete characterization of supported silicon nitride films.

We will demonstrate that Auger electron spectroscopy (AES) in conjunction with inert gas sputtering is a powerful tool for detecting very thin SiO_2 layers

Key words: silicon nitride, Auger electron spectroscopy, memory devices, depth profiling, quantitative analysis, detection limits.

at the nitride/silicon interface, for analyzing the quantity and depth distribution of impurities in thin silicon nitride (abbreviated Si_3N_4) films, and for obtaining a relative measure of the nitrogen to silicon ratio within the films. Oxygen concentrations in excess of 1 atomic per cent (a/o) were observed in the present memory-quality silicon nitride films.

Experimental

The Si_3N_4 films were supplied by Sperry Research Center and were chemically vapor deposited at 750°C with an ammonia-to-silane ratio of 1000:1. The ratio of silane to total flow (argon carrier gas) was 2×10^{-4} with the total flow rate being 15 liters/min. The ammonia was supplied by Air Products with a purity of 99.999+%. The ultra high purity (UHP) argon was supplied by Matheson Gas Products with a purity of 99.999+%. The semiconductor grade silane was also supplied by Matheson Gas Products at 1% dilution in UHP argon. There was no deliberate contamination of the gases and the observed oxygen content is believed to have entered the process from an improperly capped graphite susceptor.

Gas flow was regulated by flow meters and the nitride reactor was a cold-wall quartz horizontal type with an RF induction-heated graphite susceptor (12.7 × 35.6 cm). Prior to insertion into the reactor, silicon wafers were cleaned with NH_3-H_2O_2, rinsed in deionized (DI) water, exposed to HCl-H_2O_2 followed by a DI water rinse, etched with buffered HF followed again by a DI water rinse, the blown dry with nitrogen. The Si_3N_4 films were approximately 500-2000Å thick.

Generally, a 10Å thick native oxide film existed at the nitride/silicon wafer interface, but two silicon substrates had thicker SiO_2 grown before Si_3N_4 was deposited. A 30Å SiO_2 film was formed by heating to 810°C in 99.999+% N_2O. A 420Å SiO_2 film was grown in dry oxygen at 1000°C. The 30Å SiO_2 film was used to check the resolving power of AES for interfacial oxides, while the 420Å SiO_2 film was used to standardize AES for quantitative oxygen analysis. A silicon wafer upon which SiO_2 was formed by heating in air to 1000°C was also used for AES standardization.

AES (7) was performed with an ion pumped spectrometer from Physical Electronics Industries, Inc., using a cylindrical mirror analyzer and primary electrons from a coaxial gun. The primary electrons had an energy of 5 keV and a beam current of 10 μA. The analyzer modulation was 4 eV peak-to-peak, unless otherwise noted, and the spectra were taken in the derivative mode (7). For sputter profiling, *i.e.*, measuring the Auger electron (AE) derivative peak height while sputter removing surface atoms, a beam of 1 keV argon ions was used. The system argon pressure was 5×10^{-5} Torr, and the sputter rate for Si_3N_4 was varied between 0 and 100 Å/min by varying the ion current striking the sample.

Index of refraction data were taken on a Gaertner L119 ellipsometer with a mercury-xenon light source. The light beam was incident at 60° and was monochromatized to the 5461Å mercury line. A two-layer model was used to extract the index from the raw data by a digital computer for the 10 and 30Å interfacial oxides, and simultaneous deposition on a bare substrate was used to verify the index for the nitride deposited on the 420Å oxide.

Results and Discussion

Auger electron analysis.—The silicon AE peaks (near 80 and 1600 eV) and nitrogen AE peak (379 eV) were relatively weak while the carbon AE peak (270 eV) and oxygen AE peak (506 eV) were relatively strong on the as-received Si_3N_4 surface (shown in Fig. 1a). This strong oxygen signal probably results from room temperature formation of oxide as shown by the shift of the silicon $L_{2,3}VV$ peak to 78 eV (8), and the strong

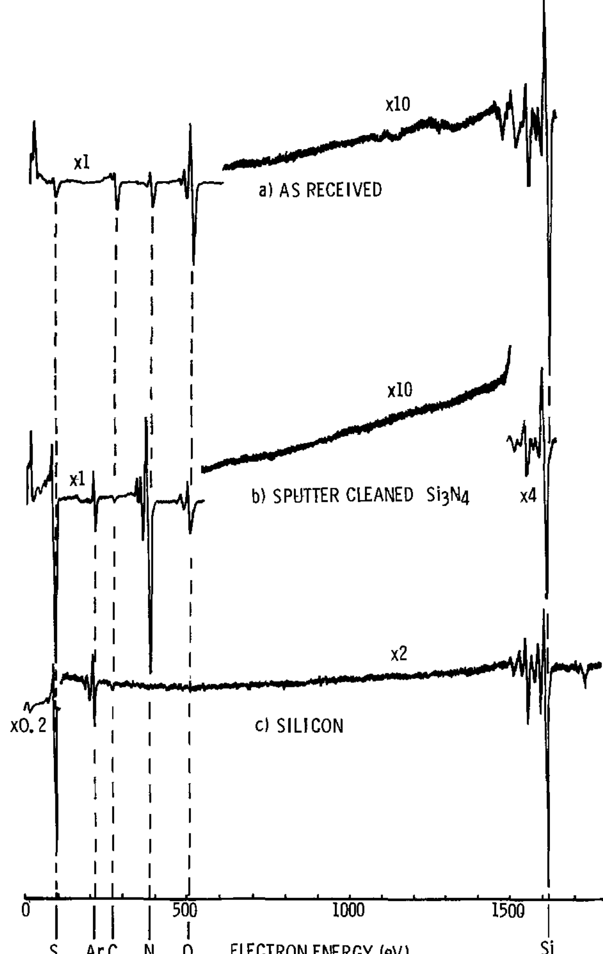

Fig. 1. Spectra from (a) as-received surface, (b) sputter cleaned silicon nitride surface, and (c) silicon surface with Si_3N_4 removed. Note the residual carbon and occluded argon in (b) and (c).

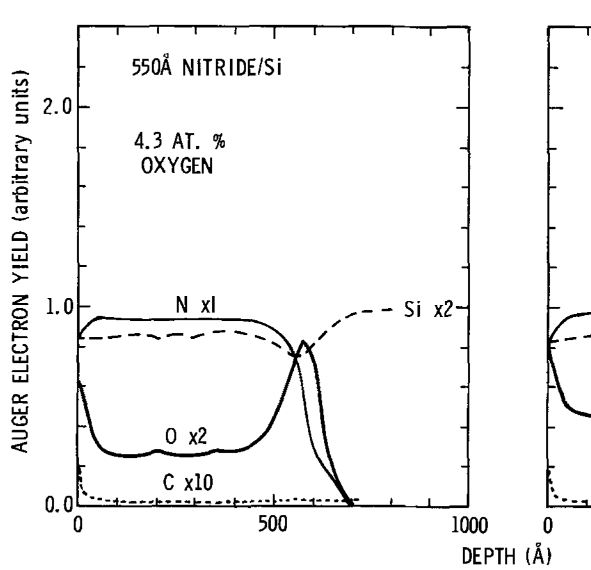
carbon signal probably results from the adsorption of carbon-containing atmospheric gases. Sputtering for short times (removing ~ 50Å) was sufficient to remove the high surface concentrations of oxygen and carbon, so that AE signals from silicon and nitrogen are increased in intensity, while those from oxygen and carbon are very weak (Fig. 1b). In addition, new peaks are evident with the strongest transition at 216 eV; these result from argon atoms implanted during sputtering for Auger electron analysis. After sputtering completely through the Si_3N_4 film, AE peaks from silicon, argon, and carbon are detected as shown in Fig. 1c. Chemical shifts of the Auger electron peaks from silicon in Si_3N_4 make them distinct from Auger electron peaks from elemental silicon or SiO_2, as discussed elsewhere (8).

Typical plots of the silicon KLL transition (~ 1615 eV), oxygen 506 eV, nitrogen 379 eV, and carbon 270 eV AE peak heights *vs.* depth of material removed by ion sputtering are shown in Fig. 2. In this instance, sputter time was converted to sputter depth by knowledge of the Si_3N_4 film thickness. It was assumed that the sputter rate was independent of the presence of surface and interfacial oxides and that the sputter rate was the same in silicon as in Si_3N_4. While these assumptions are probably in error, this is not significant to the discussion below. The sputter profiles show an interfacial oxygen concentration, a significant concentration of oxygen throughout the Si_3N_4 film with no detectable concentration in the silicon substrate, and a small concentration of carbon throughout the Si_3N_4 and into the Si substrate. The sample shown in Fig. 2a had no intentional oxide grown at the nitride/silicon interface while that in Fig. 2b had 30Å of oxide grown as



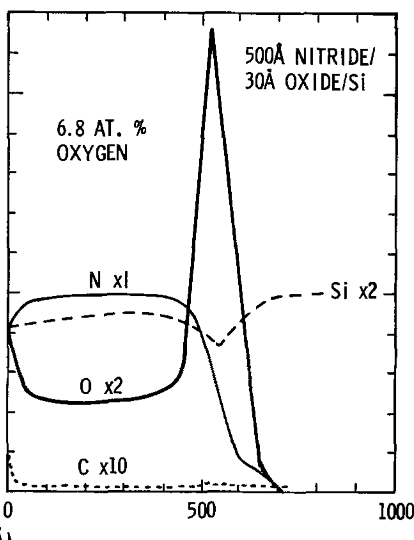


Fig. 2. Auger electron peak heights of silicon, carbon, nitrogen, and oxygen vs. depth for Si_3N_4 films with bulk oxygen concentrations of (a, left) 4.3%, and (b, right) 6.8%. The interfacial oxide in (b) is 30Å thick, while the oxide in (a) is approximately 10Å thick.

described in the experimental section. The silicon LVV Auger transition peak shape changed consistent with SiO_2 being present at the nitride/silicon interface. Based on the processing history of silicon substrates prior to Si_3N_4 deposition and based on literature data (9), a native oxide film 10Å thick is expected at the nitride/silicon interface. A relative estimate of interfacial oxide thickness can be made by integrating the area under the oxygen AE peak height *vs.* time (10). (The thickness cannot be estimated from the abscissa because of nonplanar removal of the Si_3N_4, Si_3N_4 thickness variation, knock-on effects, Auger electron escape depths, etc.) In arbitrary units, the area under the oxygen peak at the interface in Fig. 2a is 54 while the area in Fig. 2b is 144, *i.e.*, a ratio of 54/144 = 0.37. This is quite consistent with the expected ratio of 10Å/30Å = 0.33. It is obvious from data in Fig. 2 that 10Å of oxide under 500Å of Si_3N_4 is easily resolved, and it appears that oxides significantly thinner than 10Å would be resolvable.

Quantification of bulk impurity levels.—Turning our attention to the oxygen and carbon distributed through the bulk of the Si_3N_4 films (*i.e.*, the steady-state AE signals observed after removal of the surface contaminants), it is desirable to quantitatively evaluate these impurity concentrations. To accomplish this quantification for oxygen, the AE signal from SiO_2 formed at 1000°C on silicon and the silicon 1618 eV signal from elemental silicon (after sputter removal of the SiO_2) were measured. In addition, the SiO_2 oxygen signal and the elemental 1618 eV silicon signal from the substrate of the special nitride sample (prepared with a 750Å Si_3N_4 film on top of a 420Å SiO_2 film on a silicon substrate) were measured The oxygen AE peak height from the bulk of the Si_3N_4 film was measured and the bulk oxygen concentration C_{O,Si_3N_4} (a/o) calculated from the equation

$$C_{O,Si_3N_4} = 67 \frac{I_{O,Si_3N_4}/I_{Si,N}}{I_{O,SiO_2}/I_{Si,O}} \quad [1]$$

where I_{O,Si_3N_4} is the oxygen AE signal from the nitride film, I_{O,SiO_2} is the oxygen AE signal from SiO_2, $I_{Si,N}$ and $I_{Si,O}$ are the silicon 1618 eV signals from the silicon substrate after the nitride or oxide films, respectively, have been completely sputter removed. The factor 67 represents the atomic per cent of oxygen in SiO_2. This is essentially the calibration procedure discussed by Chang (7). Here we take oxygen in SiO_2 as our reference material and assume all other effects such as surface roughness, backscatter factor, escape depth, etc., are all the same for SiO_2 and Si_3N_4. In addition, the intensity of the elemental silicon 1618 eV AE peak height is used as a standardization to eliminate error from day-to-day variations in the system gain. The silicon peak from silicon nitride was not used for standardization to avoid error caused by chemical shifts and composition variations. The ratio, $I_{O,SiO_2}/I_{Si,O}$, was measured over a period of time for both the oxidized silicon wafer and the special nitride sample, and the ratio was found to be 4.3 ± 0.3. The bulk oxygen levels in the various nitride films were calculated using Eq. [1] and are shown in Table I. As shown, the oxygen concentration was found to vary between 0.4 and 6.8%. However, because of variations in experimental conditions such as surface roughness, film density, electron backscattering, preferential sputtering, matrix chemical effects, etc. (7), the accuracy of the oxygen concentration is estimated to be only ± 40%.

It is important to consider whether the oxygen signal observed through the bulk of the Si_3N_4 film is a "true" signal from oxygen impurities or an artifact of the analyzing technique. The possibility of artifact exists since oxygen-containing residual gases (*e.g.*, CO_x) can readsorb from the vacuum onto the surface during analysis or can be implanted by the ion gun during analysis. The possibility of these effects being large for oxygen is discounted by the facts that (*a*) all oxygen measurements were made while sputter removing surface atoms, and (*b*) the oxygen level in the silicon substrate (onto which readsorption or implantation would also occur) was very low. However, the probability seems high that the carbon signal is not a true signal since its intensity is uniform in going from Si_3N_4 to silicon and in going from one sample to another.

A finite surface concentration of carbon and oxygen will always exist because of the steady-state balance between adsorption or ion implantation and sputter removal. These effects have been studied experimentally and theoretically as discussed in the Appendix. The conclusions from these considerations are that none of the oxygen levels reported in Table I are influenced by adsorption or implantation, but the re-

Table I. Bulk oxygen concentration, N/Si Auger electron peak height ratio, and index of refraction for various silicon nitride films

Oxygen concentration (a/o)	N/Si AE peak height ratio	Index of refraction
0.4*	2.08	1.96
1.2	2.05	1.93
3.6	1.96	1.91
4.3	1.97	1.885
4.5	—	1.88
6.8	1.85	1.86

* Special nitride film grown over 420Å of SiO_2 on Si substrate.

sidual carbon levels shown in Fig. 2 are not true signals but result from adsorbed or implanted carbon which sputtering did not remove. From the Appendix discussion, it is clear that the balance between adsorption/implantation and sputter removal controls the detection limit for oxygen and carbon. Data are presented showing that in the present case, the detection limit for oxygen is 0.05% and for carbon is 0.2% (atomic).

Comparison of oxygen concentration, refractive index, and nitrogen-to-silicon Auger peak height ratio.—Oxygen concentration and the corresponding Auger peak height ratio of the nitrogen to silicon 1613 eV peak (from Si_3N_4) determined for each film is listed in columns 1 and 2 of Table I and plotted in Fig. 3. The correlated decrease in nitrogen with an increase in oxygen concentration indicated in Table I and Fig. 3 is further illustrated in Fig. 4 where a sputter profile has been made through a film in which a peak in the oxygen concentration and a corresponding decrease in the nitrogen concentration is observed in the middle of the film. The correlation between the oxygen and nitrogen concentration supports the bonding model of oxygen substitution for nitrogen in the atomic structure (11). The profiling results in Fig. 4, together with those in Fig. 2 demonstrate the detail which can be obtained about the nitride film and the interface region by using the sputter-Auger technique, and this technique is believed to be one of the best available at this time for depth profiling of the film composition.

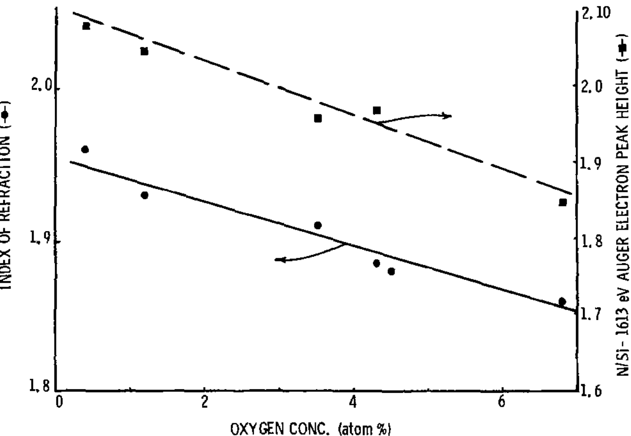

Fig. 3. Correlation between the bulk oxygen concentration and the nitrogen to silicon (1613 eV) Auger electron peak height and the refractive index at 5160Å for Si_3N_4.

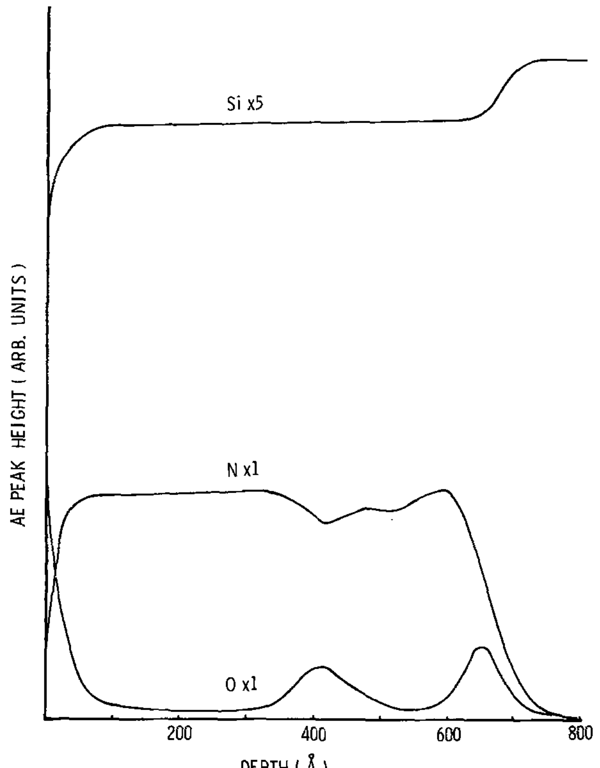

Fig. 4. Auger electron peak heights of silicon, nitrogen, and oxygen vs. depth for a Si_3N_4 film showing an increased oxygen concentration in the middle of the film. Note the complementary decrease in nitrogen as oxygen increases.

Refractive indices for the films are also listed in Table I, and the dependence of the index upon the oxygen concentration is further illustrated in Fig. 3. Reduction of the refractive index by the incorporation of oxygen in the film has been demonstrated previously (2, 6, 11), but deposition parameters such as temperature and ammonia-to-silane ratio also affect the refractive index. Auger electron analysis provides a method for quantifying the oxygen concentration and calibrating the refractive index as a measure of the oxygen concentration for a particular growth situation.

Summary

It has been demonstrated that Auger electron spectroscopy is a powerful technique for measuring the quantity and distribution of impurities in thin Si_3N_4 films. Interfacial oxide films thinner than 10Å can be detected. The detection limits in the present system for bulk oxygen and carbon are 0.05 and 0.2%, respectively. For the present memory-quality Si_3N_4 films, the actual carbon contamination level was below 0.2%, but oxygen concentrations between 0.4 and 6.8% were observed. Variations in oxygen content between samples were correlated with variations in the refractive index and in the nitrogen-to-silicon ratio.

APPENDIX

Steady-State Relationship between Adsorption, Sputter Removal, and Detection Limits

The surface of a solid in a vacuum will always be bombarded with residual gas molecules, and a certain fraction of these molecules will stick (adsorb) onto the solid. If the sample is being sputtered, atoms will be removed from the surface, including adsorbed residual gas molecules, until a steady state is reached where the rate of adsorption equals the rate of sputter removal of residual gas molecules. This can be modeled as follows.

Assume that the adsorption rate of the jth residual gases, $\dot{A}_j$, is independent of the sputter rate, then it may be written as $\delta_j \dot{I}_j$ where δ_j is the sticking coefficient and $\dot{I}_j$ is the ideal gas impingement rate of the jth residual gas. $\dot{I}_j$ is given by

$$\dot{I}_j = \frac{P_j}{(2\pi m_j k T_g)^{1/2}} \qquad \text{[A-1]}$$

where P_j is the pressure of the jth gas, m_j is the molecular mass, k is Boltzmann's constant, and T_g is the absolute gas temperature. The sputter removal rate of the jth adsorbed species, $\dot{S}_j$, may be written

$$\dot{S}_j = y_j i^+ \frac{\sigma_j}{\sigma_{oj}} \quad [A\text{-}2]$$

where y_j is the sputter yield (*i.e.*, the number of the jth atoms sputtered per incident ion), i^+ is the ion current, σ_j is the number of adsorbed jth molecules per unit area, and σ_{oj} is the number of jth adsorption sites per unit area (*i.e.*, σ_j/σ_{oj} is the probability that an incident ion will collide with a jth adsorbed molecule). At the steady state between adsorption and sputtering, $\dot{A} = \dot{S}$, therefore

$$\frac{\delta_j P_j}{(2\pi m_j k T_g)^{1/2}} = y_j i^+ \frac{\sigma_j}{\sigma_{oj}} \quad [A\text{-}3]$$

or

$$\sigma_j = \frac{\sigma_{oj}\delta_j P_j}{y_j i^+ (2\pi m_j k T_g)^{1/2}} \quad [A\text{-}4]$$

Thus, for a constant adsorption rate (*i.e.*, constant P_j in Eq. [A-4]), as the sputter rate decreases (*i.e.*, i^+ decreases in Eq. [A-4]), the steady-state concentration of adsorbed molecules should increase. Data in Fig. 5 demonstrate that this effect was observed. Figure 5 shows the AE peak heights of oxygen and carbon on either a Si_3N_4 or silicon surface as a function of the ion current. As the ion current (and therefore the sputter rate) decreases to 5 μA or less, the AE peak heights increase indicating a significant readsorption effect on oxygen or carbon concentration measurements. Assuming that the sticking coefficient, δ_j, and sputter yield, y_j, is independent of the adsorbed molecule concentration (over the range of interest), then

$$\sigma_j = \frac{K}{i^+} \quad [A\text{-}5]$$

where K is a constant. Since the AE peak height is proportional to σ_j, Eq. [A-5] has been tested by plotting the AE peak height of oxygen on silicon or Si_3N_4 *vs.* $1/i^+$ (see Fig. 6). The Si_3N_4 data are differences between the measured signal and the signal due to residual bulk oxygen. The straight line indicates that this simple model is a reasonable first approximation, and order of magnitude estimates for K in Eq. [A-5] supports this conclusion.

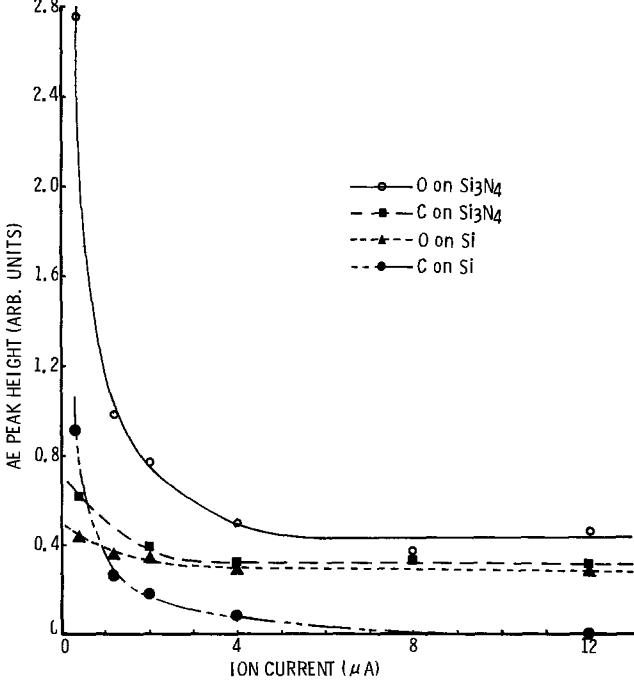

Fig. 5. Auger electron peak heights of carbon and oxygen on silicon or Si_3N_4 *vs.* ion current striking the target. As the sputter rate decreases (*i.e.*, the ion current decreases), adsorption of residual gases from the vacuum occurs, adding to the detected signals. The residual oxygen level shown for Si_3N_4 corresponds to a bulk oxygen concentration of 0.4%.

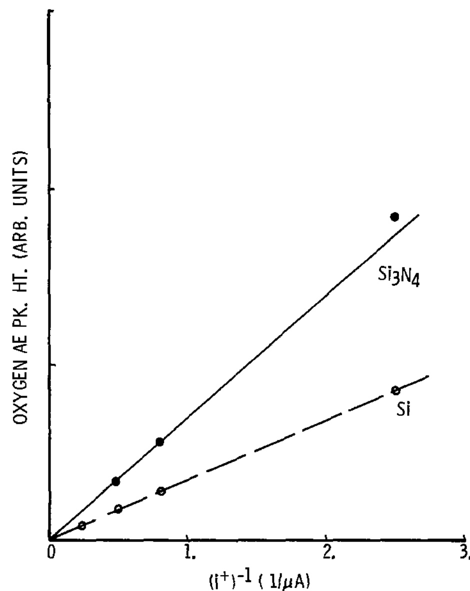

Fig. 6. Oxygen Auger electron peak height on silicon or Si_3N_4 *vs.* the inverse of ion current striking the sample. The straight line agrees with the model discussed in the text.

Obviously then, the detection limits for oxygen or carbon (*i.e.*, the minimum detectable "true" concentrations) are dependent on both the residual gas pressures and the rate of sputter removal of adsorbed residual gases. Using our calibration for oxygen concentrations, at high sputter rates the detection limit for oxygen is approximately 0.05% (atomic). To avoid readsorption artifacts in the oxygen content of Si_3N_4, all measurements were made with more than 6 μA of ion current striking the substrate. Thus it appears that the detection limit for oxygen in silicon nitride is controlled by the balance between gas adsorption and sputter removal.

The straight line fit in Fig. 6 is fortuitous in many respects. We have assumed a steady-state condition both for gas adsorption and for sputtering effects such as "knock-on," defect enhanced diffusion, and ion drift. But perhaps the most serious assumption is that no implantation occurs by ionization of gas phase impurities in the argon. If implantation occurs, it may cause a surface concentration independent of the sputtering rate, and may also cause the detection limit for an element to be high.

A case in point may be carbon which was always detected both on the Si_3N_4 films and on the silicon support (see Fig. 1 and 2). The origin is believed to be either residual carbon which cannot be removed by ion sputtering, or a carbon implanted by the ion gun. The residual carbon is not accompanied by an equivalent oxygen peak for the silicon substrate, which suggests that there is no significant oxygen associated with it on the Si_3N_4 either. This peak does, however, cause the detection limit for carbon in Si_3N_4 to be higher than for oxygen. The carbon concentration was estimated using sensitivity factors reported by Palmberg *et al.* (12), and the residual carbon peak was calculated to be equivalent to a bulk carbon concentration of 0.2%. The actual carbon impurity concentrations in the Si_3N_4 films were all less than this detection limit, *i.e.*, all less than 0.2%. If this carbon signal originated from implantation, it must indicate that hydrocarbons (*e.g.*, methane, etc.) were present in the argon. This seems unlikely since a sublimation pump was used to clean the argon. Another explanation for the carbon is that at small residual concentrations, the sputter yield in Eq. [A-2], approaches zero. Such a phenomena has been reported by Tarng and Wehner (13) for sputter removal of molybdenum from a number of different substrate materials. However, neither the implantation nor the zero yield postulate can be substantiated by the present data.

Oxygen Gettering in Green GaP:N LED's Grown by Overcompensated LPE

P. C. Mürau and R. N. Bhargava

Philips Laboratories, Briarcliff Manor, New York 10510

ABSTRACT

Improvement in the minority carrier diffusion lengths has been obtained in GaP:N LED's by controlling the oxygen contamination during LPE with getter dopants such as Al, Mg, or Si. Experimental data are presented which show a limited range in which one can achieve oxygen gettering in GaP without reducing the incorporation of nitrogen. Excess Al produces free exciton emission with an external quantum efficiency of 0.02% at 4 A/cm^2.

Luminescence from the isoelectronic nitrogen center in GaP has been the subject of considerable study (1, 2). Over the years it has been demonstrated that high efficiency green electroluminescence (EL) in GaP:N can be achieved by double liquid phase epitaxy (LPE) (3-8) and vapor phase epitaxy (VPE) (9). The commonly employed acceptor impurity in the p-layer has been Zn, whereas either Te or S has been used as the donor impurity in the n-layer.

At present, one of the problems in the LPE growth of the p-n junction in GaP:N is elimination of the red emission from bound excitons at (Zn-O) complexes which accompanies the green emission. The combination of red and green emission in an LED produces a distinctly yellow green color. Lorimor and Weiner (10) have eliminated the (Zn-O) red component by replacing Zn with another acceptor such as C or Mg, but at the same time a reduction by approximately a factor of five in the EL efficiency was observed.

It has been established (11, 12) that a deep oxygen donor by itself does not act as a nonradiative center in GaP. However, associated complexes of oxygen such as Si-O (13), V_{Ga}-O (14), etc., may play a role in the recombination efficiency in both the n- and p-layers of an LED. Evidence to support this hypothesis has been reported by a number of workers (15-18). It is therefore clear that in order to improve the EL and generate purer spectra in green LED's all traces of oxygen must be removed from both the n- and p-layers.

In order to remove the background oxygen impurity, certain precautions can be taken in the LPE process itself. Further reduction in the oxygen level, however, may be achieved by gettering action through intentional codoping of the Ga melt with elements such as Al, Mg, or Si, which are known to form stable oxides.

In this paper we discuss the reaction chemistry between getter dopants with oxygen and nitrogen during LPE, and their effect on N incorporation. We present results which show that O gettering leads to longer minority carrier diffusion lengths. In the case of excess Al doping, an improvement in the efficiency of free exciton emission has been achieved.

Key words: GaP light emitting diodes, O gettering in liquid phase epitaxy.

Chemical Interactions of Getters with Oxygen and Nitrogen

Before considering the gettering action of oxygen by Al, Mg, or Si in a Ga melt, it is helpful to consider some fundamental chemical reactions that can occur during the LPE process. In Table I we list a number of reactions along with their calculated equilibrium constant and free energy of formation at 900°C (19).

Let us first consider LPE performed in an inert atmosphere, such as He or Ar. If the Ga is contained in a

Table I

		900°C $K_{eq.}$	900° ΔF_f (kcal/mole)
1.	Ga(l) + 1/4SiO_2(s) = 1/2Ga_2O(g) + 1/4Si(s)	1.0×10^{-3}	+16.2
2.	Ga(l) + 1/2SiO(s) = 1/2Ga_2O(g) + 1/2Si(s)	1.4	−0.8
3.	Ga(l) + 3/4 O_2(g) = 1/2Ga_2O_3(s)	1.2×10^{15}	−81.2
4.	Ga(l) + 3/2H_2O(g) = 1/2Ga_2O_3(s) + 3/2H_2(g)	7.7×10^{2}	−15.5
5.	Ga(l) + 1/2H_2O(g) = 1/2Ga_2O(g) + 1/2H_2(g)	2.2	−1.9
6.	H_2(g) + 1/2 O_2(g) = H_2O(g)	1.3×10^{8}	−43.7
7.	SiO_2(s) + H_2(g) = SiO(g) + H_2O(g)	1×10^{-13}	+70.1

quartz crucible, then we have to consider reactions between the Ga and quartz (reactions 1 and 2) and reactions between the Ga and traces of O_2 and H_2O in the gas stream (reactions 3-5). According to the values in Table I, reaction 3 is the most favorable, making oxygen contamination of the Ga melt under an inert atmosphere likely.

If, instead of an inert gas, we use H_2 as the carrier gas, we must assume that traces of O_2 in the gas stream react with H_2 at 900°C to form H_2O (reaction 6), and reactions with traces of H_2O vapor must also be considered. In addition, as Weiner (20) has shown, Si contamination of the Ga melt via H_2 reduction of the quartz (reactions 7 and 8), must also be considered.

In order to reduce the O and Si contamination level in the Ga melt due to quartz and control the reactions between quartz and the getter dopants, an inert crucible material such as pyrolytic BN or pyrolytic graphite should be considered. Residual traces of oxygen in the Ga melt or oxygen present in the gas stream could be further reduced by using O getters such as Mg, Al, or Si. Reactions between these getter elements and O_2, H_2O, and Ga_2O_3 are also listed in Table I (reactions 9, 10, 14-16, 18-20).

However, LPE for green GaP LED's also requires N doping by addition of ammonia to the H_2 gas stream. This complicates matters since nitrides of O getters are also quite stable. Therefore, competing reactions between the getter dopants, the oxygen bearing species, and the ammonia have to be considered. Lorimor and Weiner (10) have calculated the permissible doping levels of Al, Mg, and Si in Ga at 900°C in the presence of NH_3. Similar calculations between the getter dopants and dissolved Ga_2O_3 in the Ga melt, at 900°C, show that the oxides are more stable. As will be shown later, oxygen can be effectively removed from the Ga melt before nitride formation limits the incorporation of N into the GaP.

According to the calculations (10), only very small quantities of Al can exist in the melt at reasonable ammonia pressures. However, as we shall see later, in this nonequilibrium LPE process, not all of the unreacted Al precipitates out as the nitride; some unreacted Al gets segregated into the GaP layer (21).

Experimental

LPE by overcompensation.—The LPE layers were grown in an open-flow dipping system described earlier (22). The system (Fig. 1) was slightly modified to accommodate p-n formation by overcompensation (6). With the exception of the crucible and substrate holder, the system is constructed entirely from quartz (GE 204). The crucible and substrate holder are made from either pyrolytic BN or pyrolytic graphite (Union Carbide) to avoid O contamination and prevent attack by the getter dopants (Al, Si, Mg). The substrate holder is constructed to fit the quartz drop tube blowup in Fig. 1) in a lock-and-key arrangement. The whole assembly can be rotated, raised, and lowered within the reaction tube without coming apart. Two substrates fitted back-to-back to the holder rest in angled grooves to prevent them from falling out while simultaneously permitting good melt wipe-off after "dipping." Therefore, with this holder close control of substrate diameter or shape is not essential.

For LPE by overcompensation, the system was prepared as follows. The quartz system along with crucible and holder were first acid cleaned, vacuum dried at 800°C (10^{-3} mm Hg), and purged and cooled under H_2. This step is required to remove adsorbed moisture and volatile contaminants. The Ga melt was saturated with GaP, (0.01 mole fraction), vacuum dried at 200°C, and purged with H_2. Sufficient Te was added to the melt to produce a doping density of 1-2 $\times$ 10^{17} cm^{-3} (Fig. 2). The hydrogen atmosphere (UHP Matheson) was passed over a Pd diffuser through stainless

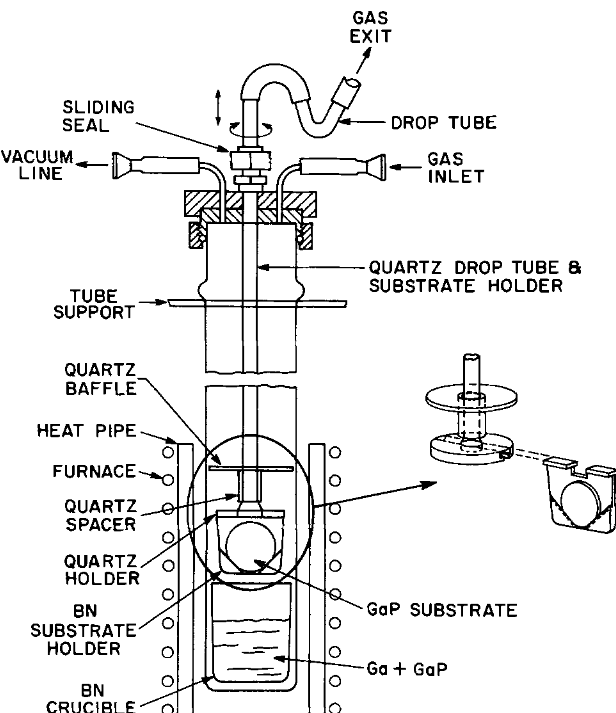

Fig. 1. Vertical dipping system used in the LPE overcompensation technique, with a close-up of the substrate holder arrangement.

steel piping at a flow rate of 100 cm^3/min. The assembly was lowered into a resistance furnace fitted with a heat pipe and heated to 945°C until all GaP is dissolved. The heat pipe provides for improved thermal stability. The temperature was then lowered to 920°C, allowing about ½ hr for thermal equilibrium to be attained. The substrates were then lowered into the melt. At this point the getter dopant, either Al or Si, was added to the melt via the drop tube. To avoid attack on the quartz drop tube, the Mg getter dopant was added to the melt before heating. The substrates in this case were maintained in the cool zone of the reaction tube to avoid thermal etching of the substrate surface which results in poor surface wetting.

After allowing for some reasonable time (½ hr) for the getter dopants to react with the O species and for the substrates to reach thermal equilibrium with the melt, N doping is commenced. This is accomplished by the addition of slightly less than 0.3% by volume of NH_3 from a 1% NH_3/H_2 mixture (UHP Matheson) to the H_2 stream. This is the optimum NH_3 concentration required before GaN precipitates out at 900°C (10).

Before the Ga melt is sufficiently saturated with N, we must assume at this stage that any unreacted O getter dopant left in the melt either precipitates out as the nitride and/or segregates into the epilayer during growth. This will reduce the N incorporation into the epilayer. It is therefore important to add only small quantities of O dopants sufficient to getter the oxygen but not the nitrogen.

The n-LPE was initiated by cooling the melt from 920° to 890°C at a rate of 0.44 °C/min. On conclusion of n-LPE and while the substrates remained immersed in the melt, the furnace was held at constant temperature until the necessary amount of Zn was dropped into the melt through the drop tube to produce a doping density of 1-2 $\times$ 10^{18} cm^{-3} (X_{Zn}^{l} = 1.8 $\times$ 10^{-3} atomic fraction). After allowing about 15 min for the Zn to dissolve, which was enhanced by oscillatory, circular motion of the substrate holder, p-LPE was initiated by cooling the melt from 890° to 825°C at a rate of 0.44 °C/min. On completion of p-LPE at 825°C, the NH_3 flow was stopped and the substrates pulled out of the melt. The holder was rapidly removed from the furnace and the substrates allowed to cool in hy-

drogen. The wafers were not intentionally annealed. This growth schedule produces a total n- and p-layer thickness of 30-40 μm. The low temperature schedule summarized in Table II provides superior surface morphology and perfection.

For the n^+np^+ structure employed here ($N_D - N_A = 1\text{-}2 \times 10^{17}$ cm^{-3}, $N_A - N_D = 1\text{-}2 \times 10^{18}$ cm^{-3}), LPE by overcompensation provides certain inherent advantages over the normal two-step LPE process (6, 22). It has been our experience as that of Lorimor *et al.* (6) that epilayers grown by overcompensation

Table II. Summary of growth schedule by overcompensation

NH_3 conc. in gas ambient	0.3%	0.3%

resulted in longer diffusion lengths and higher green efficiencies. This technique in itself leads to a significant decrease in the number of (Zn-O) centers or other O-related complexes in GaP. Oxygen gettering serves as a further refinement of the technique. Oxygen reduction in either or both the epitaxial n-layer and the Ga charge was achieved in part by maintaining the substrate with the n-epilayer submerged within the Ga melt prior to p-LPE. This prevented exposure of the p-n interface to an oxidizing or contaminating ambient. This is normally a problem encountered in a two-step LPE process. The technique has three additional important advantages: (*i*) maintaining thermal stability near the p-n interface which results in improved junction uniformity, (*ii*) no meltback and therefore better control of compensation near the interface, and (*iii*) no surface damage due to thermal etching.

In addition, the oxygen solubility of the melt is obviously reduced by two additional factors: (*i*) by performing LPE at a lower temperature (920°C) as compared to the higher temperature (1100°C) normally used, and (*ii*) through the use of inert crucible and substrate holder material such as pyrolytic BN or pyrolytic graphite.

Material evaluation.—

Doping assessment.—The net donor and acceptor concentration at the epitaxial surface was determined by a standard Schottky barrier diode technique. The net donor carrier density of an unintentionally doped layer grown in pyrolytic BN from 920° to 890°C was less than 10^{16} cm^{-3}. Epitaxy by overcompensation was performed at significantly lower temperatures (920°-825°C) as compared to the range (1050°-1010°C) normally employed for double LPE (22). We may therefore assume that the variation in $N_A - N_D$ between the p-n junction and the surface is small because of the following reasons: (*i*) the loss of Zn due to volatilization in our dipping system is negligibly small, (*ii*) the distribution coefficient, C_S/C_L, at these temperatures is low, and (*iii*) the grown p-epilayer is thin (6, 23).

The N concentrations in various LPE layers were determined by measuring the absorption of the A line at 2.310 eV at 77°K (24, 25). The results are listed in Table III.

Diode efficiency.—The external EL quantum efficiency of various diodes was determined on fabricated structures which had an evaporated contact similar to the one described by Schumaker *et al.* (26) for red LED's. The 20 × 20 mil die was shaped by laser scribing, mounted on a TO-18 header, and encapsulated in a high refractive index epoxy. Measurements were then performed at 4 A/cm² in an integrating sphere and cross-checked (27, 28).

Photoluminescence and optical absorption measurements.—Electroluminescent and photoluminescent spectra were taken using a Spex F/7.8, 0.85 meter Czerny Turner double monochromator in conjunction with a grating blazed at 1 μm. A slit width of 500 μm was used corresponding to a resolution of 3Å. Signals were detected by an extended S-20 photomultiplier (EMI9658 AR). This combination provided a spectral response with sensitivity at 18,000 cm^{-1}, a factor of five higher than at 14,000 cm^{-1}. This correction factor was used when estimates of the ratio of the green and red components in the LED's were made. The intensity of the red emission due to Zn-O complexes was used to monitor the relative amount of oxygen in p-LPE layers. Photoluminescence in the GaP:N samples was generated at 77° and 300°K using the 4880 or 5145Å line of an Ar ion laser.

Diffusion length measurements.—The minority carrier lifetimes in green LED's were determined by the recombination time through the shunt path (13, 18). A measure of the minority carrier lifetime or the diffusion length thus reflects the concentration of the nonradiative centers. We measured the diffusion length of epitaxial layers near the p-n junction using a scanning electron microscope (SEM) (30-32). A 20 kV electron beam was scanned across a freshly cleaved p-n junction and the beam-induced current was recorded on a logarithmic picoammeter (Keithley Model 26000). The diffusion length in the n-layer and p-layer is determined from the slope of the straight line portion several micrometers from the junction (32).

Results and Discussion

As discussed earlier, O getters should be able to control the oxygen level in the Ga melt by forming very stable oxides and thereby reducing the number of (Zn-O) centers present in p-type GaP. On the other hand, O getters can also form stable nitrides and, therefore, an excess of them could also seriously limit N incorporation in the GaP and affect the performance of a green LED. In this section we present the results and examine the influence of O getters on such important parameters as: (*i*) the carrier density in GaP LPE layers, (*ii*) N incorporation into GaP, (*iii*) emission spectra, (*iv*) minority carrier diffusion lengths, (*v*) electroluminescent efficiency, and (*vi*) ratio of green-to-red emission.

An important consideration is the influence of O getters on the carrier concentration. Silicon, for example, is an n-type dopant in GaP; its incorporation into GaP in the absence and presence of ammonia is illustrated in Fig. 2. The n-epilayers were grown from 920° to 890°C in a pyrolytic BN crucible. In the presence of NH_3, the Si incorporation in GaP is reduced by an order of magnitude. This implies that, although the NH_3 vapor above the melt provides for an infinite source of N, insufficient N gets dissolved in the Ga during LPE to consume the unreacted Si and prevent Si from segregating into the LPE layer (16). In other words, LPE is far from being an equilibrium process.

Magnesium on the other hand is a p-type dopant in GaP. However, the Mg concentration range used in our experiments was so low ($X_{Mg}^l = 1\text{-}7 \times 10^{-5}$) that no noticeable effect on the net donor carrier density ($N_D - N_A = 1\text{-}2 \times 10^{17}$ cm^{-3}) was observed. Aluminum is a neutral dopant in GaP and did not influence the carrier density in our samples.

Absorption measurements on the A line at 77°K were made to obtain the absolute N concentrations as well as relative variations of N incorporation in GaP. Figure 3 illustrates the influence of the Al concentration in the melt on the relative absorption intensity at the A line. The background absorption peak is a measure of nitrogen in the 200 μm LEC substrate and a 30 μm thick LPE layer not doped intentionally with nitrogen. It should be noted here that the data in Fig. 3 is the relative transmission intensity; the measured values of the epilayer thicknesses were used to calculate absolute [N]. We note that the N incorporation decreases with increasing Al concentration in the melt. Similar results were obtained with Mg and Si dopants. The results on the incorporation of N, as calculated from the absorption data, are tabulated in Table III. It is clear from this table that even small quantities of O getters inhibit N incorporation into the epilayer. Based on the chemical reactions and thermodynamic calculations presented previously, and since oxides of getter dopants are generally more stable than the nitrides, the above results on the N incorporation indicate that the initial oxygen contamination of the LPE system is quite low and that N is being consumed by the excess O getter in the Ga melt. Furthermore, the reduction of N concentration is consistent with the formation of stable nitrides of these O getters. It reemphasizes the fact that for effective O gettering of the melt and optimum N incorporation in GaP, only very small quantities of getters are required.

Photoluminescence spectra of LPE layers grown from O-gettered melts were taken at 77°K. The spectra for the Al-gettered case is reproduced in Fig. 4. The N doping level can also be estimated from the relative peak intensities of excitonic recombination at isolated substitutional N atoms (A-O line) and nearest neighbor pairs of N atom (NN_1 line) (9). The decrease in N incorporation with increasing getter dopants is consistent with the data obtained from the absorption

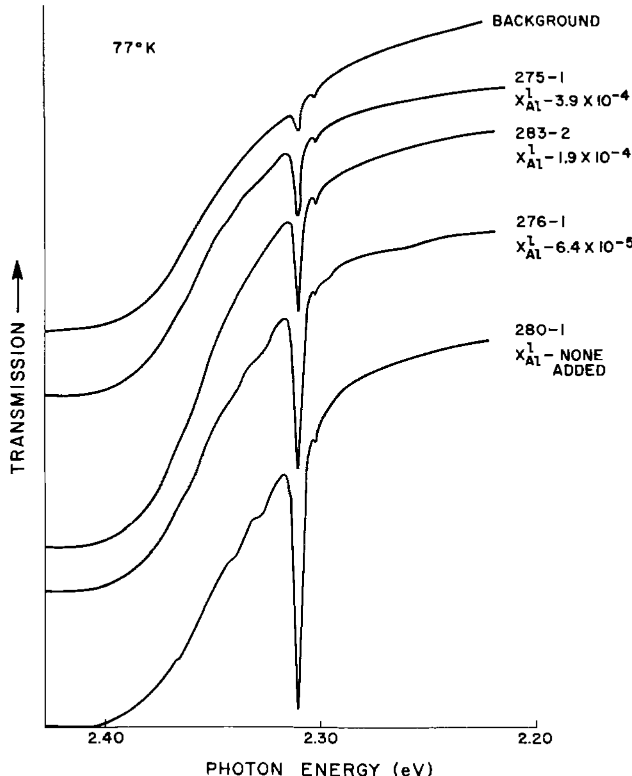

Fig. 3. Transmission spectra of A line (2.31 eV) at 77°K. 30-40 μm p-n layers on 200 μm LEC substrates (No. 149-34) with Al concentration in melt as indicated. NH_3 concentration ~0.3%. The background spectrum is of an undoped epitaxial layer on the LEC substrate.

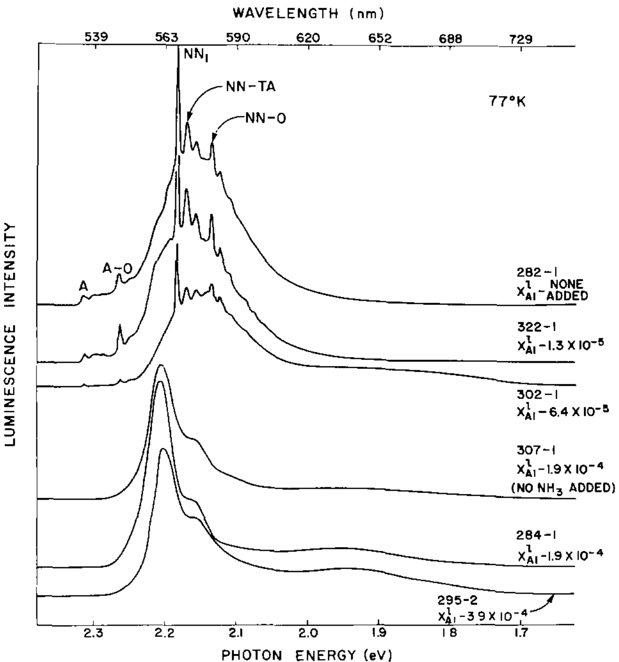

Fig. 4. Photoluminescence spectra at 77°K of p-n layers with Al concentrations in melt as indicated. No. 282-1 was not gettered with Al. With the exception of No. 307-1, NH_3 concentration ~0.3%, p-layer concentration 1-2 $\times$ 10^{18}cm^{-3}, n-layer concentration 1-2 $\times$ 10^{17}cm^{-3}.

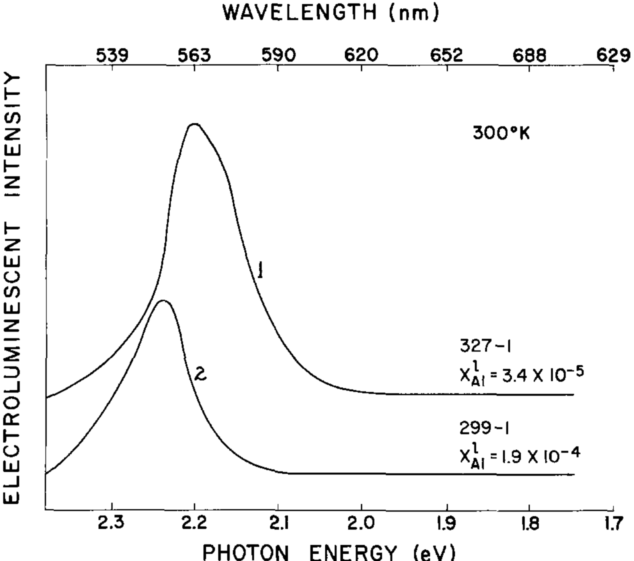

Fig. 5. Electroluminescence spectra at 300°K of two p-n GaP:N LED's with different Al concentrations. At low Al concentration, bound excitonic emission due to N is observed while at the higher Al concentrations free exciton emission is observed.

measurements. A similar trend was observed for epilayers which had been grown from Mg- and Si-gettered melts.

Associated with an increase in Al concentration, a general increase is also observed in the free exciton emission around 2.2 eV. Ga melts doped in excess of 1.9 $\times$ 10^{-4} atomic fraction of Al no longer exhibit the normal spectral features of GaP:N. A spectrum of an Al-gettered run (307-1) which was not intentionally doped with N is included for comparison. The emitted radiation is primarily due to free exciton recombination with a peak emission at 2.24 eV (554 nm) (8, 33-35). Free exciton emission is especially dominant in run 299-1-Al (Table III) in which the measured [N] is only 1.7 $\times$ 10^{17} cm^{-3}. This suggests that in order to obtain efficient green LED's with free exciton emission, the N concentration should be maintained below ~ 2 $\times$ 10^{17} cm^{-3}; this seems consistent with some earlier data of Bachrach and Lorimor (35). A broad band around 1.9-2.0 eV in Fig. 4 is normally associated with these high Al-gettered runs. The source of this band is not known. The emission peak (Fig. 5) is shifted by 0.05 eV toward higher energies relative to the peak emission of a normal GaP:N diode when operated at room temperature.

Minority carrier diffusion lengths in GaP epilayers are dependent on a number of factors, among which are carrier density, O content, and the LPE process. We observed that the carrier-density dependency is consistent with results reported by Dapkus *et al.* (18, 36). We therefore maintained the following structure throughout our experiments: n^+np^+, where $N_D - N_A = 1\text{-}2 \times 10^{17}$ cm^{-3} and $N_A - N_D = 1\text{-}2 \times 10^{18}$ cm^{-3}.

We observed, however, a sharp decline in diffusion length values whenever LPE was performed either at a high temperature (1050°C), by a two-step LPE process, or in quartz crucibles. Typical values for L_e = 0.5-0.6 μm and L_h = 0.7-0.8 μm were not uncommon. We associated these low values to high O contamination near the p-n junction since green GaP:N diodes prepared from such material nearly always produced a strong red component due to (Zn-O) centers.

LPE by overcompensation performed at a lower temperature (920°C) and in an inert crucible produced epilayers with significantly higher diffusion length values: L_e = 1.4 μm and L_h = 1.5 μm (see Table III). The refinement of our LPE technique with O getters increased the diffusion lengths still further. This is consistent with the recent results of Lorimor *et al.* (15) who report that deliberate addition of small amounts of oxygen to the inlet gas produced a pronounced reduction in the quantum efficiency and minority carrier lifetimes.

Recent photocapacitance measurements on red GaP diodes have shown that increased oxygen concentration near the p-n junction decreases the efficiency of red diodes (37). This is interpreted to be due to the presence of oxygen-induced killer centers, which are possibly also effecting the green LED efficiency.

As has been discussed earlier, an excess of O getters in the melt leads to a reduction in the number of N centers in the GaP and to a decrease in the EL efficiency of GaP:N diodes (Table III). Controlled amounts of getter dopants in the melt can, however, lead to optimum N incorporation and an improvement in the EL efficiency. This is evident when we compare the EL efficiency of an ungettered run (282) with lightly gettered runs (320 and 323) in Table III. All three maintain the same efficiency value (0.05% at 4 A/cm^2). However, diodes which had been fabricated from material grown from highly gettered melts (299) no longer produce the normal GaP:N spectrum. The efficiency values marked with an asterisk in Table III are for free exciton emission. The quantum efficiency of these diodes is typically a factor of five lower than those of optimally N-doped GaP:N LED's. However, the slight downshift in the emitted peak wavelength from 565 to 554 nm in these LED's (Fig. 5) makes these greener free exciton diodes quite attractive. This change in color quality provides a 40% improvement in chromatic discrimination threshold in a 10^4 ft-*L* illuminated background (38), and which can be filtered to produce improved contrast (39).

The objective of O gettering was to maintain a high N incorporation and a high green EL efficiency while reducing the O concentration in GaP to a level such that it will lead to a decrease in the red emission from the p-epilayer. Such results are reported in Table III as the green-to-red emission ratio in GaP:N LED's. A 1.5-2.5 factor in improvement in green-to-red ratio has been achieved for the gettered runs (320 and 323) over the ungettered run (282), while for Al-gettered runs a

factor in improvement in excess of 70 in green-to-red ratio was realized.

Conclusions

LPE has been performed by the overcompensation technique at a lower temperature and in inert crucibles. This technique produced epilayers for GaP:N LED's with EL efficiency equal to the present state of the art (0.1% at 4 A/cm^2).

A problem accompanying all green GaP:N LED's is the red emission associated with the (Zn-O) centers in the p-layer. We have presented experimental data whereby traces of O in the Ga melt can be effectively gettered with either Al, Mg, or Si. We have shown that close control of the getter concentration is required since the getters also form stable nitrides and prevent high N incorporation in GaP, a necessary requirement for high green EL efficiency. Aluminum has an especially strong affinity for N in the melt. Even at very low Al concentrations, N incorporation into the GaP is hindered. As a consequence, diodes from such material produced primarily free exciton emission of superior color contrast, but, so far, of low EL efficiency (0.02% at 5 A/cm^3). For the n^+np^+ structure grown by LPE for this study, O gettering produced improved minority diffusion lengths in both n- and p-layers.

Acknowledgments

We are in debt to J. Jacco for his assistance in the Schottky barrier measurements and LED fabrications, to S. Herko for the optical measurements, to A. Sicignano and C. Michel for the diffusion length measurements, and to W. K. Zwicker and R. L. Bronnes for the growing and polishing of the GaP LEC substrates, respectively. We gratefully acknowledge S. K. Kurtz for his encouragement in this work and for his critical comments on this manuscript.

A Comparison of Chemical Etches for Revealing ⟨100⟩ Silicon Crystal Defects

D. G. Schimmel

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

The Sirtl etch is commonly used for <111> and <100>Si crystal defect evaluation although it is known that misleading results can occur for <100>Si due to lack of etch pit formation. A few of the known factors governing Si etching are presented for a qualitative approach to the understanding of defect etch formulations. In particular, the etch pit results from the Sirtl, Secco, Dash, and an experimental etchant are compared for shallow diffused structures as well as initial starting Si wafers. The best etch pit results were obtained from the Secco etch.

The development of etch pits which denote the emergence of dislocations on Si surfaces by chemical etching is simple and of considerable value in determining the degree of Si crystal perfection (1-5). Various factors which can influence etch pit results are crystal orientation, impurities on the defects, conductivity type, and the various substrate-diffusion combinations which may change the chemical activity of the Si surface with respect to the etching solution.

Historically, the well-known etch formulations of Sirtl and Dash were developed and used principally for evaluating the effects of crystal growing conditions on the resultant crystal perfection. Today, however, chemical etching to produce etch pits at crystal defects has been extended to the evaluation of wafers at various stages of processing. The extended use of chemical etching to Si devices containing p-n junctions creates additional conditions for the etch reaction which, for the most part, enhances the defect etch rate.

Factors Influencing Etching of Si Defects

The basic reactions in the dissolution of a Si surface are an oxidation of the Si followed by removal of the oxide with HF. In order to delineate a crystal defect as an etch pit, the defect area must be oxidized and removed at a faster rate than the surrounding area. If HF is in excess in the etching solution, the oxide is removed as fast as it forms. Under this condition then, the delineation of the defect will be determined by the oxidation rate differential; *i.e.*, etch rate differential, between the defect and surrounding areas. A logical approach to accentuate this etch rate differential between the defect site and surrounding surface is to slow down the solution etch rate. This is particularly pertinent for (100)Si surfaces which are known to etch at a faster rate than (111)Si surfaces. Since many of the commonly used Si etches consist of various HNO_3-HF combinations (6, 7), it is of interest to briefly review the oxidizing properties of HNO_3. In solution, HNO_3 can act either as a reducing agent (acid) or an oxidizing agent (base), depending on the solvent system. For example, HNO_3 in water as the solvent is an acid, but it is a strong oxidizing agent in HF as the solvent (8). Thus, even very small quantities of HNO_3 in HF would promote etching of Si. By doing so, preferential etching of the defect may result.

Key words: dislocations, ion implant, silicon integrated circuits.

In addition, Brattain and Garrett determined the following relationships between an electrolyte and a semiconductor surface (9): (*i*) Holes are required for an oxidation process. (*ii*) Hole-electron pairs are generated by surface illumination. (*iii*) The effect of light on the majority carrier density is not very great but it is possible for a large relative change in the density of minority carriers to occur. Thus, the effect of light on the electrode potential for a p-type anode (oxidation electrode) is small; but for an n-type anode, it is rather large.

The formulation of an experimental preferential defect etchant was predicated on the factors which influence etching as presented in the preceding paragraphs. The intent was to keep the etch formulation simple, using only HF and HNO_3, and thereby determine if the approach presented to defect etching was valid. A few survey experiments were performed to determine the HNO_3 concentration necessary to produce etch pits at defects on (100) surfaces. The resultant experimental etch formulation is labeled the "Schimmel" etch and is included in Table I. Because of the lower etch rate, the alternate Secco etch formulation was used for the present comparison. For comparison, the etch formulations in Table I are presented as ratios with the last column listing the mequiv. (milli-equivalents) of oxidizing agent for each etch formulation. This enables a direct comparison of oxidizing agent present in the various etch formulations and will be considered in more detail in the Discussion section.

Table I. Comparison of Sirtl, Secco, Dash, and Schimmel etch formulations

Etch	Formula	Moles/cm³ oxidizing agent	Mequiv. oxidizing agent	Etch rate
Sirtl	$HF:CrO_3$ (5M) 1:1	2.5×10^{-3}	7.5×10^{-3}	Nonlinear ~3.5 μ/min
Secco	$HF:K_2Cr_2O_7$ (0.15M) 2:1	5×10^{-5}	3×10^{-4}	1.5 μ/min with ultrasonic agitation
Alternate Secco	$HF:CrO_3$ (0.15M)) 2:1	5×10^{-5}	1.5×10^{-4}	~1 μ/min with ultrasonic agitation
Dash	$HF:HNO_3$:HAc* 1:3:10	3.4×10^{-3}	3.4×10^{-3}	Nonlinear ~0.1 μ/min with light n-substrate
Schimmel	$HF:HNO_3$ 155:1**	1×10^{-4}	1×10^{-4}	Nonlinear ~1.8 μ/min with light n-substrate

* Abbreviation used for CH_3COOH, acetic acid.
** Ratio is equivalent to 0.1*N* HNO_3 with HF as the diluent based on conc HNO_3 = 15.6*N*. HF conc = 28.9*N* (49%).

Comparison of Etch Results

Experimental.—Whenever possible, test sample substrates were scribed and broken into four pieces (one for each etch solution) to facilitate the comparison of the etch results. Regardless of any test sample processing just prior to etching all samples were immersed in conc HF followed by an overflow deionized water rinse. The etching time for the Sirtl etch was kept constant at 1¼ min while the etching times for the other etches varied from 1 to 10 min, depending on the sample being etched. The times for each etch are noted in the figure captions. In order to minimize surface roughness artifacts due to bubble formation with the Secco etch, ultrasonic agitation was used and resulted in shorter etching times also.

It was found that sample surface illumination, as indicated in the preceding section, did enhance the etching of defects in some instances, but only for the clear (not colored) etching solutions of Dash and Schimmel. However, the combination of etch solution (Dash as well as Schimmel etches) and surface illumination resulted in staining the Si surface. The stain was readily removed with a solution of 1 part conc NH_4OH and 4 parts water in about 1 min which did not appear to change the Si surface topography. Ultrasonic agitation also aids in the stain removal.

Etch comparison.—In general, it is possible to tell from the appearance of the various etch pits if they are shallow or deep defects. Usually by re-etching for a longer time, the shallow defects will slowly disappear. It should be noted that the results shown in the following etch pit comparison photographs have been substantiated by numerous subsequent etching samples.

n- and p-Type starting wafers.—For n- and p-type wafers, both the Dash and Schimmel etches were unsatisfactory due to virtually no etch pit formation for short etching times. The effect of extended etch time was not pursued. As seen in Fig. 1, dislocation etch pits denoting dislocations into the bulk were formed by both the Sirtl and Secco etches on n- and p-wafers. It is quite clear from the photographs that the Secco etch pits are larger and easier to distinguish. Also, saucer pits denoting possible nucleation sites for future oxidation-induced stacking faults are evident in the Secco etched samples, both n- and p-type, but not in the Sirtl etched samples. The line type etch results for the Sirtl etched n-type substrate could be

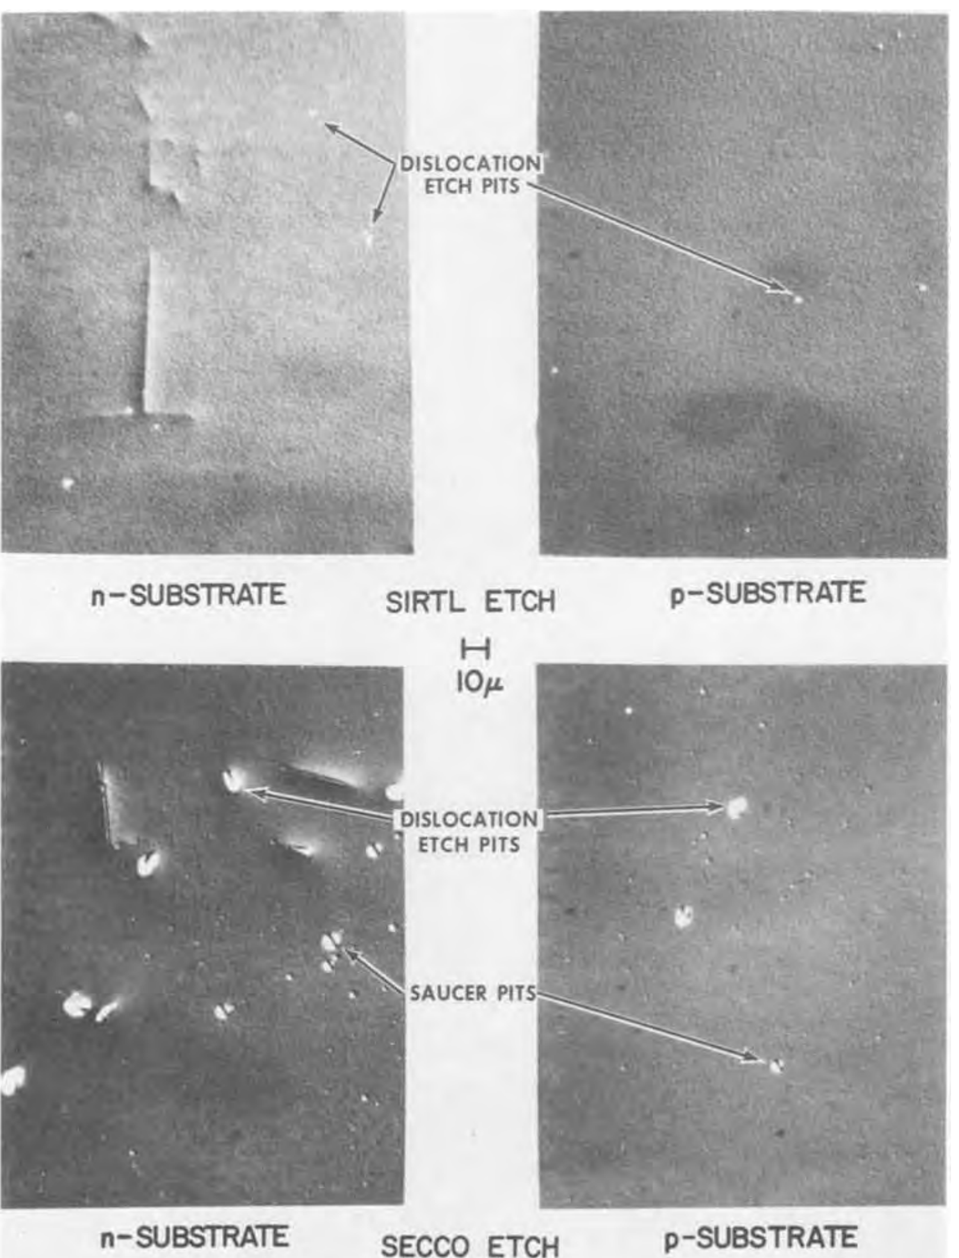

Fig. 1. n- and p-starting wafers with Sirtl etch (1¼ min) and Secco etch (5 min).

either dislocations or etching artifacts while those of the Secco etched sample are probably crystal defects because of the etched surfaces. In addition, the Sirtl etch pit formation on the p-type wafer in particular is less dense than that of the Secco etch. Consequently, the Sirtl etch results imply a lower defect density than is shown to exist by the Secco etch. This is also substantiated by copper decoration and will be described in a later section. Thus for both n- and p-wafers, the Secco etch appears best.

Oxidized wafers.—The wafers used in this series of experiments were steam oxidized at 1050°C for 2 hr. Just prior to etching, the oxide was removed in conc HF.

n-Type.—The Dash and Schimmel etches again were unsatisfactory for the oxidized n-type wafers due to virtually no etch pit formation. The effect of extended etching time again was not pursued. The Sirtl etch produced stacking fault and dislocation etch pits and some mounds, which were well distributed across the wafer. Well-distributed and somewhat larger stacking fault and dislocation etch pits were produced by the Secco etch. While there is little difference in etch pit distribution between the Sirtl and Secco etches, the Secco is preferred because of the larger etch pit formation and because the Sirtl etch also produced mounds which may or may not be relevant to crystal defects (1, 4).

p-Type.—It was found that for an oxidized p-wafer, surface illumination during the Dash etch apparently inhibited etch pit formation on the Syton-polished surface. The reason for this is not known. Thus, surface illumination was only used for the Schimmel etch and not the Dash etch.

The oxidation-induced stacking fault and dislocation etch pits formed by the Sirtl, Secco, Dash, and Schimmel etches are shown in Fig. 2 for an oxidized p-type substrate. The most well-defined and crystallographic-oriented stacking fault etch pits were produced by the Dash etch. However, these defects were found only in a few small isolated areas across the sample. While the stacking fault and dislocation etch pits formed by the Sirtl and Schimmel etches were easily seen, their density and distribution across the wafer were not equal to those from the Secco etch. Fewer dislocations and oxidation-induced stacking faults were revealed than actually exist as verified by the consistent results of other etch samples. The validity of the Secco etch

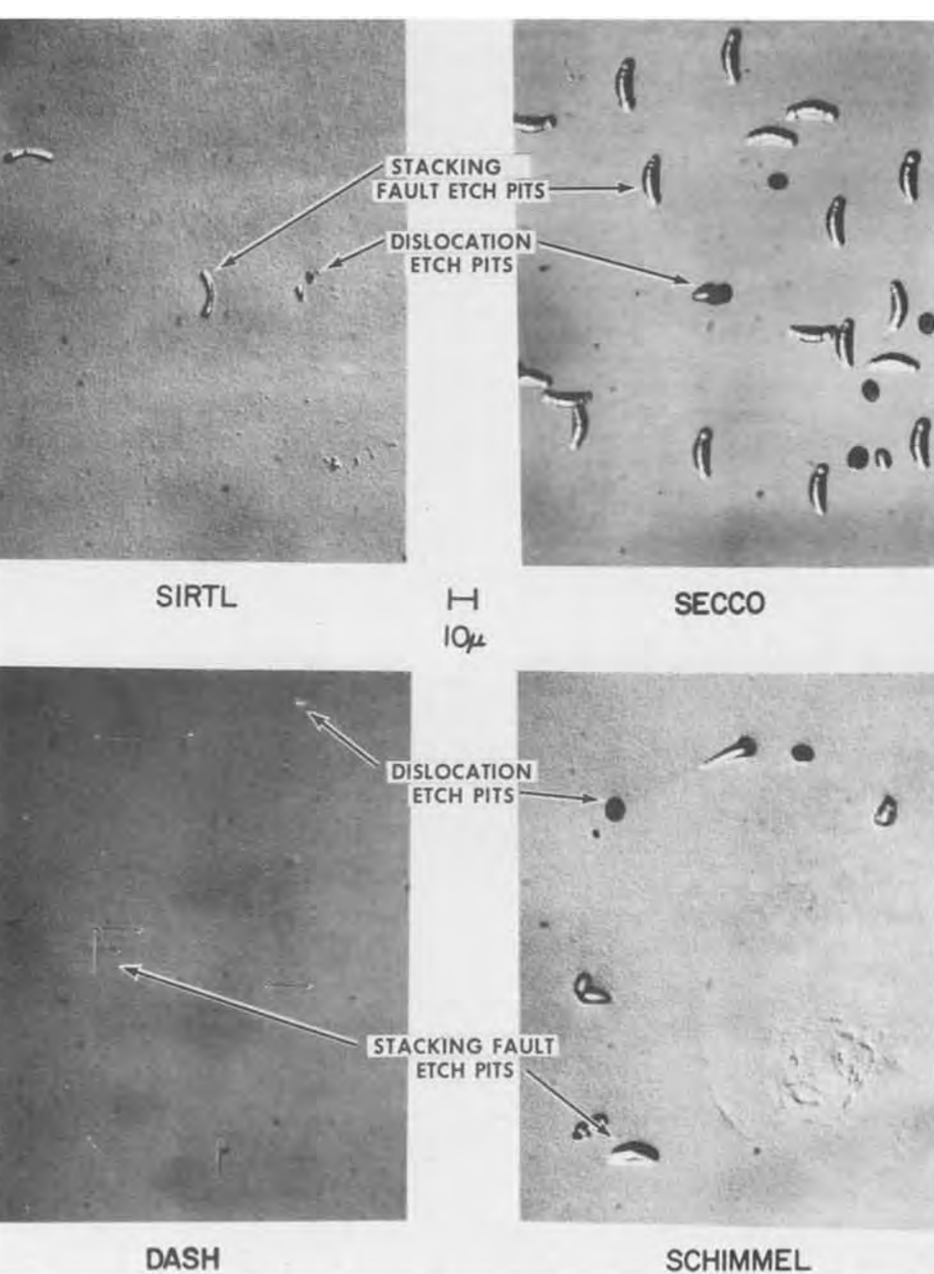

Fig. 2. p-wafer with 2 hr, 1050°C steam oxidation. Sirtl etch, 1¼ min; Secco etch, 5 min; Dash etch, 5 min with no added illumination; Schimmel etch, 1½ min with surface illumination.

pit results was established by the Cu decoration method and shown in the next section.

Correlation between Secco etch pits and dislocations.—A simple method for observing defects within the bulk of a Si substrate is by Cu decorating the dislocation and viewing it by infrared transmission (3). Slip dislocations were created in an n-type substrate by a 30 min, 1000°C, Ar atmosphere furnace treatment with a moderate quench (1000° to ~600°C in ~5 sec) withdrawal. The wafer was then Secco-etched to reveal the dislocations generated by the heat-treatment. The front of the wafer was protected and the back side chemically polished to facilitate viewing with the infrared transmission microscope. Immediately after the chemical polish, a thin film of Cu was deposited from dilute HF onto the back side of the wafer. After cleaning the wafer to remove the front protection, the Cu was diffused in at 1000°C in Ar for 30 min.

The top left photograph of Fig. 3 illustrates the etch pits formed originally by the Secco etch after the above furnace quench treatment. The top right-hand side of Fig. 3 shows the picture of infrared transmission through the wafer after Cu diffusion. The Cu decorated dislocations trailing down from the etch pits can be readily seen. The higher magnification photograph at the bottom of Fig. 3 shows the Cu decorated dislocation in greater detail as well as other near surface line defects. The focus in this picture is essentially at the surface of the wafer. It should be noted that the somewhat mottled background of the lower magnification infrared transmission photograph is due to back surface roughness remaining after the chemical polish.

From the photographs of Fig. 3, it can be seen that the Secco etch pits do form at dislocations, thus the validity of Secco etch pit results is confirmed. Since the Cu was deposited only onto the back side of the wafer, the Cu decorated "tail" was not generated from the etch pit by Cu diffusing from the front.

Implanted B base and $POCl_3$ diffused emitter.—Defects result from the drive-in step following a boron implant. Base dopant introduced by implanting boron which is subsequently driven in at 1150°C in 100% O_2 and then oxidized in steam at 1050°C is an excellent test vehicle to demonstate the differences in etching results of the various etch formulations. This damage essentially remains unchanged after the emitter diffusion which consists of a $POCl_3$ deposition and drive-in. Figure 4 illustrates these process-induced defects after both emitter and base operations. Referring to Fig. 4, all four etch formulations result in some degree of etching

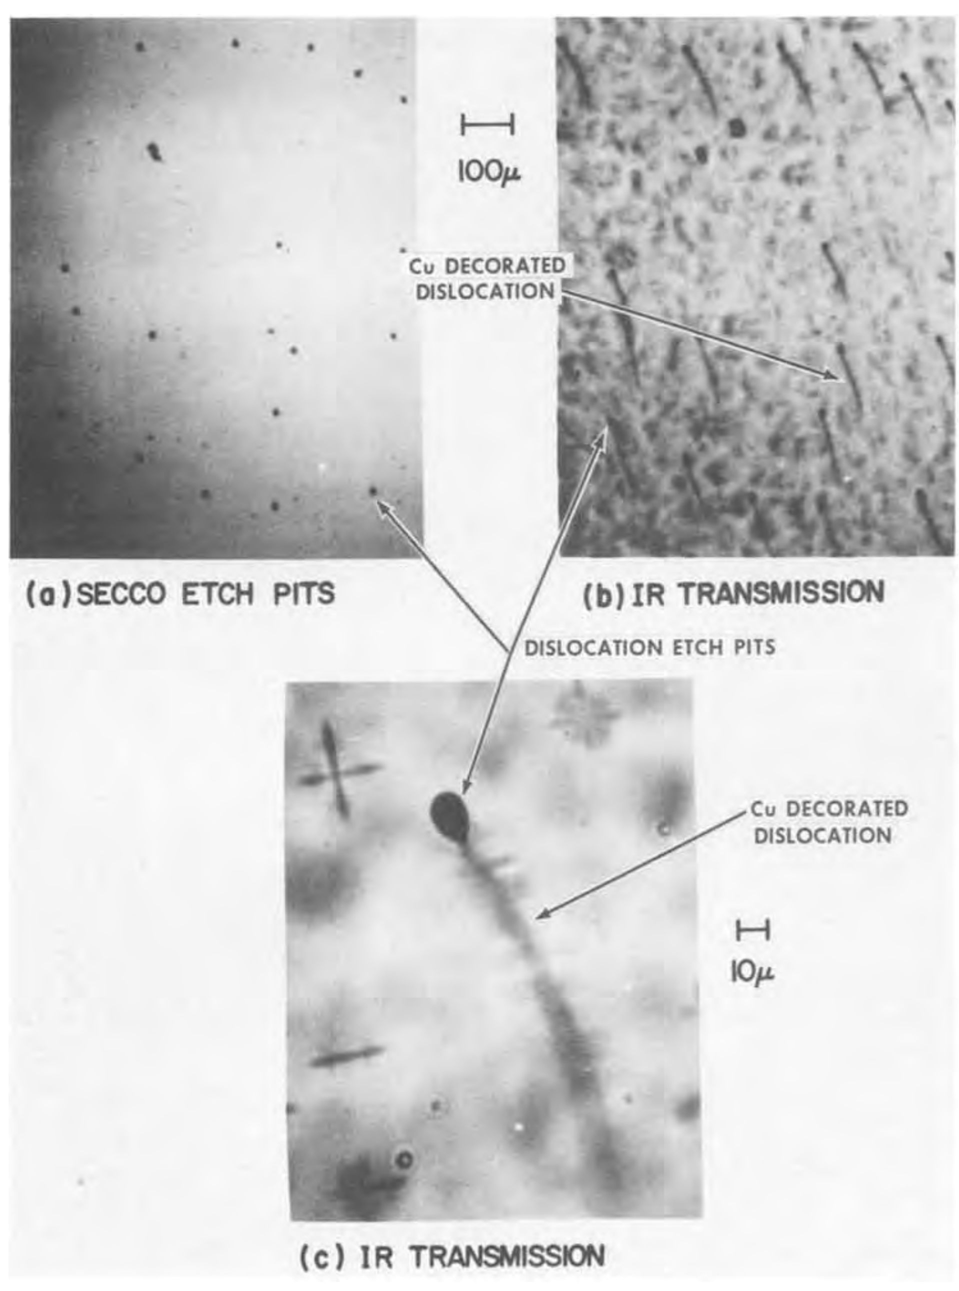

Fig. 3. Top left photograph is of slip dislocation etch pits after Secco etch (10 min). Top right is an infrared transmission photograph of Secco etched sample after Cu decoration. Bottom photograph is a higher magnification infrared transmission photograph of Cu decorated dislocation.

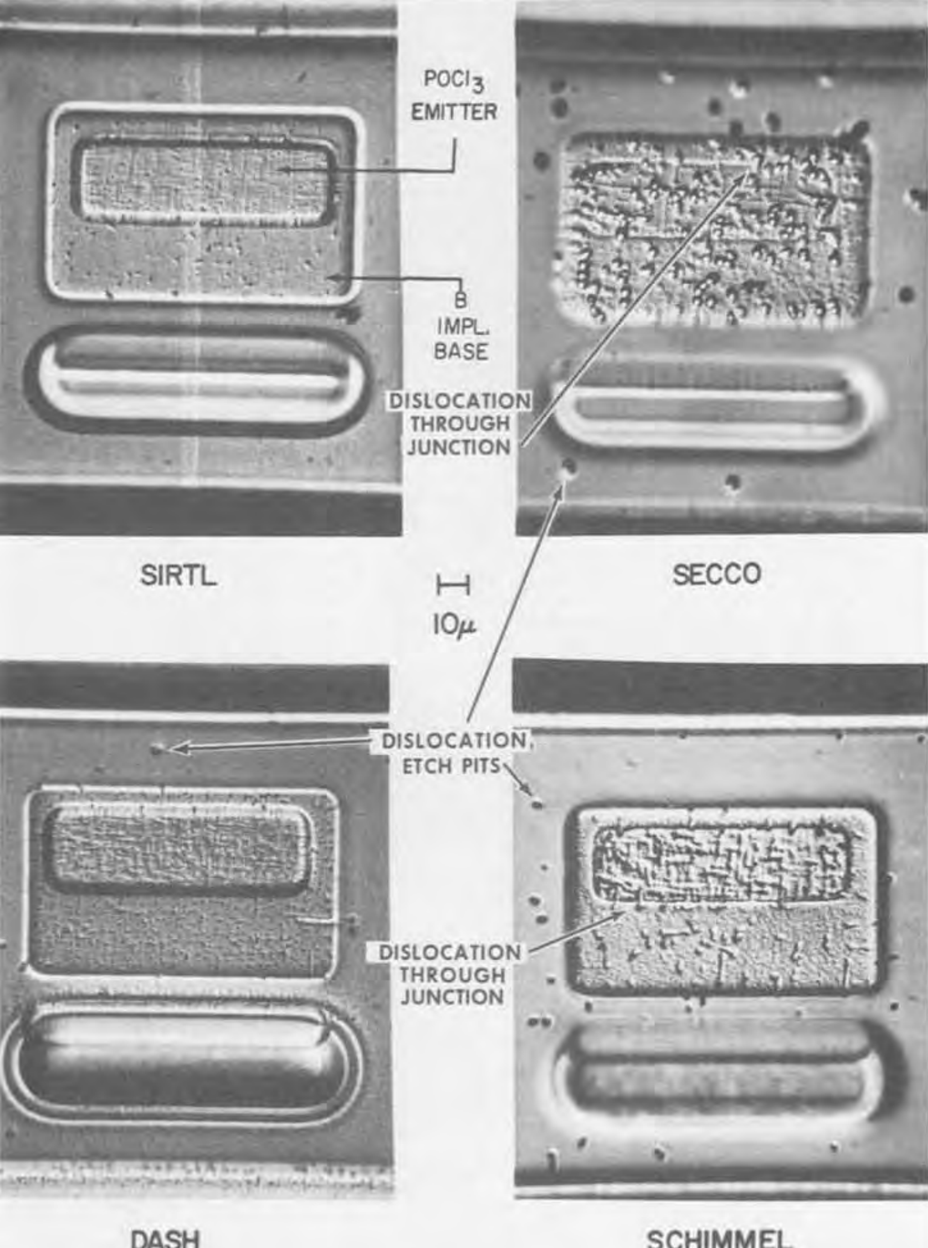

Fig. 4. Etchant comparisons for n-epi with implanted B-base and P ($POCl_3$ source) diffused emitter. Sirtl etch, 1¼ min; Secco etch, 2 min; Dash etch, 2 min with surface illumination; Schimmel etch, 1 min with surface illumination.

in both the base and emitter areas. However, the best detail is found in both the Secco etch and Schimmel etch. Line defects (crystallographically oriented) are readily seen on the sample with the Schimmel etch in the base area. Some of these line defects, presumably misfit dislocations, can be seen to extend through the emitter-base junction edges. Also quite visible are dislocation etch pits in the surrounding epi surface. Essentially the same results are evident from the Secco etch with the exception that circular or elliptical etch pit forms are in the B-implanted area rather than the line type probably due to a faster etch rate than the Schimmel etch. The primary difficulty with the Secco etch in this instance is a tendency to overetch in the active areas. This can be compensated for by reducing the etch time from 2 to 1 min. The Dash etch and Sirtl etch both indicate defects in the active regions, but not as distinctly as with the Secco and Schimmel etches. The biggest drawback to the use of the Sirtl etch, as seen in Fig, 4, is the lack of dislocation etch pit formation in the substrate (or epi) areas which leads to a wrong conclusion; *i.e.*, that no dislocations are present in these areas.

$POCl_3$ diffused in n-substrates.—Figure 5 shows the etch pit formation on P diffused from $POCl_3$ into an n-substrate. Again, the absence of dislocation etch pits at the intercepts of the long line defects must be noted for the Sirtl etch. While the Dash etch denotes dislocations at the intercepts of the line defects by virtue of rectangular etch pits, the Secco etch gives more information on the initial direction of the dislocations into the substrate from the etch pit shape and depth. The Secco etch is the first choice in this case with the Dash etch a close second.

Boron into p-substrate.—In this section, the sample used for the etching comparison was a p-type substrate with boron implanted-diffused areas. It should be noted that the previous n-substrate and n-epi samples etched with the Dash and Schimmel etches for the etching times used, required sample illumination for etch pits to develop. With p-substrates, however, the Schimmel etch with illumination created excessive etching of the boron implanted areas. Consequently, the use of the Schimmel etch on p-substrates containing p-n junctions is done with room illumination only. Conversely, the Dash etch not only requires sample illumination to promote etch pit formation with p-substrates containing junctions, but an extended etch time as well (increased from 2 to 5 min).

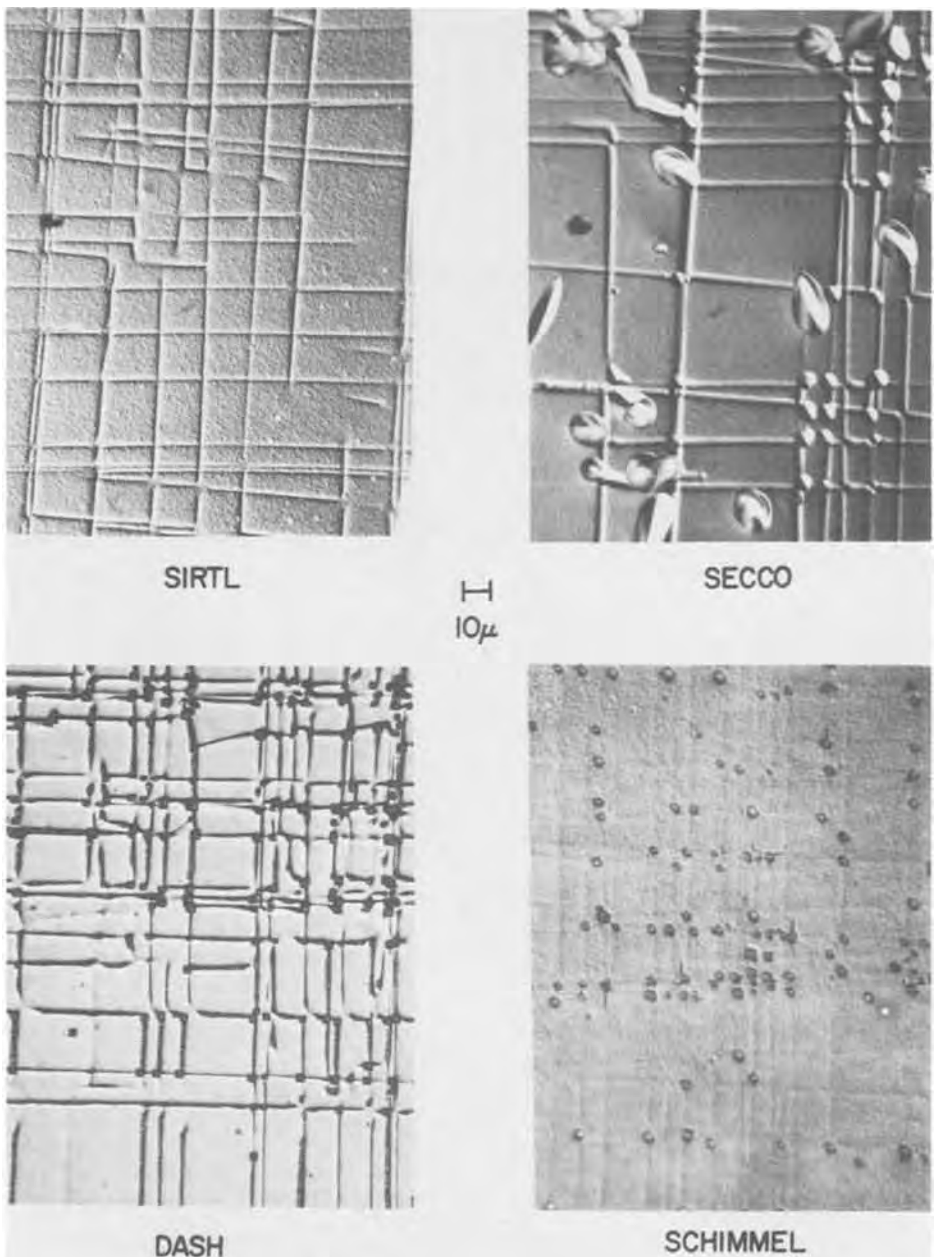

Fig. 5. Etchant comparisons for n-substrate with diffused P ($POCl_3$ source). Sirtl etch, 1¼ min; Secco etch, 10 min; Dash etch, 2 min with surface illumination; Schimmel etch, 1 min with surface illumination.

Three of the four pictures in Fig. 6 are typical examples of etch pit formation of probable misfit dislocations for boron implants from the Secco, Dash, and Schimmel etches. The Sirtl etch has the poorest etch figure development. When considering the implanted B, the Secco, Schimmel, and Dash etches are all equivalent in etch results.

An illustration of the large effect that sample illumination can have on the formation of etch pits at defect sites is shown in Fig. 7. The photo on the left shows the etch pit formation with a 5 min Dash etch without sample illumination. The photo on the right is a sample from the same substrate, etched for the same length of time except with the sample illuminated with a microscope light during etching.

Discussion

Referring to Table I, it is shown that the Sirtl etch (2) contains the greatest amount of oxidizing agent, 7.5×10^{-3} mequiv. or equiv./cm^3. This etchant works best on (111) surfaces which, as noted earlier, have a lower etch rate than (100) surfaces. Two distinct characteristics of this etch solution are: etch pit shapes are mostly determined by crystallographic orientation, and relatively short etching times in the order of 30 sec to 5 min. The Sirtl etch is definitely a preferential etch which is very widely used to determine dislocations in Si crystals. However, Hallas and Mendel (1) showed that mounds rather than etch pits form at dislocations on (100) surfaces, and difficulties in interpreting etch pit results may occur. These mounds are not necessarily related to dislocations with respect to (100) surfaces. Thus, the Sirtl etch specified as an ASTM test, F47-70, is applicable only to (111) surfaces. As was seen in the etch pit comparison figures, misleading information can result because of a lack of etch pit formation on (100) surfaces.

The Secco etch was formulated by F. Secco d'Aragona and published in 1972 for grown crystal evaluations. It is essentially a modification of the Sirtl etch. The oxidizing agent, chromium (VI), concentration has been significantly reduced with an accompanying increase in HF. The etch pit results differ from the Sirtl etch in two ways. First, it is an isotropic etch in that dislocation etch pits form on surfaces of any orientation; and second, the etch pit shape is not necessarily determined by crystal symmetry alone, but also determined by the direction of the dislocation near the surface. Thus, the pits are principally circular or elliptical.

It is interesting to note that the reduction in oxidizing agent concentration results in a significant decrease

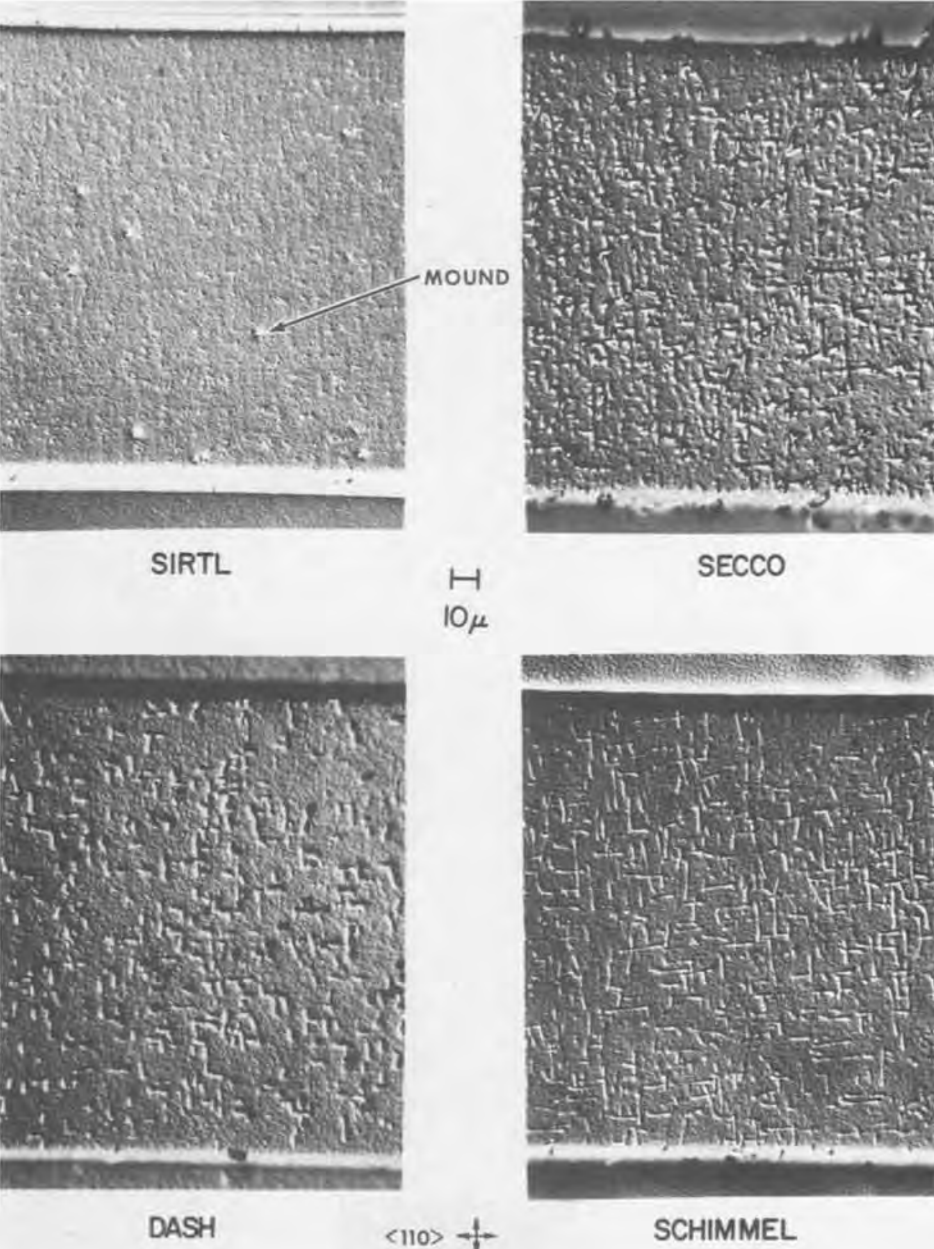

Fig. 6. Etchant comparisons for p-substrate with a B implanted-diffused layer. Sirtl etch, 1¼ min; Secco etch, 2 min; Dash etch, 5 min with surface illumination; Schimmel etch, 1½ min without added surface illumination.

in etch rate. In Table I there are two Secco etch formulations listed. The first formulation is the original published Secco etch and has a 1.5 μ/min etch rate when used with ultrasonic agitation. This formulation etches at a slightly higher rate than the alternate formulation using 0.15M CrO_3. Here the chromium (VI) containing ion concentration is reduced to 1.5×10^{-4} mequiv. with an accompanying reduction in etch rate.

The Dash etch (3), at first glance, appears to contradict the facts as developed thus far. Even though it has an oxidizing agent concentration nearly that of the Sirtl etch, 3.4×10^{-3} mequiv. *vs.* 7.5×10^{-3} mequiv. for Sirtl, it is considered to be an isotropic etch. Even the etch rate is lower than would be expected from this concentration of HNO_3. Obviously, this anomalous behavior is due to the use of acetic acid as the diluent, which reduces the oxidizing capability of the HNO_3 to less than that indicated. Because the HF is not in excess, the reaction of HF on the oxide is also probably diffusion limited. While the Dash etch is isotropic, its widespread use has been deterred by reported long etch times (in the order of hours) required for substrate crystals (1, 3). Drum and Van Gelder, however, reported etch pit results on wafers with a 5 min etch time (10). It was also shown earlier that etch pit development is greatly enhanced for the Dash etch in some instances by strong illumination (focused microscope light) and also by the presence of p-n junctions.

The Schimmel etch formulation was the result of an empirical approach to Si defect etching and it was developed to test the proposed mechanism. It is interesting to note that the HNO_3 concentration determined experimentally is quite close to the oxidizing agent concentration of the other etches. The etch pit shape appears to be influenced by crystallographic orientation to a greater degree than the Dash or Secco etches. The main drawback of this etch formulation is the rough surface which results from gas bubble formation during etching. The use of ultrasonic agitation to alleviate this condition was not completely satisfactory. While the surface roughness diminishes the aesthetic qualities of appearance, the etch pit figures are readily discernible. It should be noted that the use of surface illumination and the presence of p-n junctions also greatly enhanced etch pit formation by the Schimmel etch.

Conclusions

Preferential chemical etching of Si surfaces is a fast and reliable method for determining the effects of

processing on Si crystal perfection. In order to avoid misleading etch results for (100)Si surfaces in particular, the proper choice of etch formulation is important. It has been demonstrated that for the Si sample conditions of interest in SIC, the alternate Secco etch formulation produces acceptable etch pit results for the widest range of <100>Si substrate and shallow junction combinations. In most instances for (100)Si surfaces, the Sirtl etch does not produce the best possible results and may even result in misleading conclusions in specific instances where etch pits are not formed. The recommended etch formulations for various combinations of <100>Si substrates and junctions are presented in Table II.

Table II. Recommended etch formulations for <100> Si

Code: 1, Recommended; 2, Acceptable; 3, Marginal; N, Not recommended; (L), Surface illumination.

Test sample	Etch			
	Sirtl	Secco	Dash	Schimmel
Plain substrates (n + p)	2-3	1	N	N
Oxidized n-substrate	2	1	N	N
Oxidized p-substrate	2	1	3-N	2(L)
n-Substrate or n-epi with impl. diffused boron	3	1	2(L)	1-2(L)
n-Substrate or n-epi with P diffused ($POCl_3$ source)	3	1	2(L)	3(L)
p-Substrate with impl. diffused boron	2-3	1	1(L)	1

Etch	Formula
Sirtl	$HF:CrO_3$ (5M) 1:1
Alternate Secco	$HF:CrO_3$ (0.15M) 2:1
Dash	$HF:HNO_3:HAc$ (acetic acid) 1:3:10
Schimmel	$HF:HNO_3$ 155:1
