This device gives very low background values so that lines of low intensity can easily be detected. In most cases the range of 2θ between 6° and 70° was examined.

Reactions between manganese dioxide and manganous hydroxide.—2g of MnO_2 sample (grain size < 76 μm) were suspended in a solution of 23.4g KOH in 32 ml H_2O stirred magnetically in a beaker which was placed into a closed vessel flushed by oxygen-free nitrogen. That an oxygen-free atmosphere was obtained under these conditions was ascertained by the observation that a suspension of freshly precipitated manganous hydroxide did not darken within 20 hr. Manganous chloride solution 4.6g $MnCl_2 \cdot 4H_2O$ in 6.3 ml H_2O (a) or 3.1g $MnCl_2 \cdot 4H_2O$ in 15 ml H_2O (b)] was added dropwise from a separating funnel fixed in the lid of the vessel. The mole ratios of MnO_2 to $Mn(OH)_2$ being formed in the process were chosen such as to result in an oxidation state of $MnO_{1.5}$ (a) or $MnO_{1.6}$ (b) on complete reaction. The reaction mixture was stirred for 3 hr after which the precipitate was allowed to settle. The supernatant solution was sucked off, the remaining precipitate dried by pressing between filter paper and examined by x-ray diffraction.

Results and Discussion

Discharge in zinc-ammonium chloride electrolytes.—The derivative discharge curves of α-, β-, or γ-MnO_2 from reduction reactions in ammonium-zinc chloride can be resolved into about six peaks designated as O, A, B, C, D, and E as shown in Fig. 1 for γ-MnO_2. Among these peaks A and B depend on the electrolyte composition. Their areas increase with the mass ratio of electrolyte to manganese dioxide in the depolarizer mixtures (3) indicated for γ-MnO_2 in Fig. 2 and Table II (mixes 2, 3, and 4). At very high mass ratios in the mixes or in foil tests (1, 4) peak A predominates and it was shown that during the latter test stoichiometric dissolution of manganese dioxide occurs (3, 5) following the over-all equation

$$MnO_2 + 4H^+ + 2e^- \rightarrow Mn^{++} + 2H_2O \quad [1]$$

It has therefore been proposed that this reaction is related to the occurrence of peak A. Evaluation of numerous discharge experiments made under various conditions, combined with calculations of changes in electrolyte composition during the initial part of the discharge, showed that the reaction related to peak A ends when the pH of the electrolyte reaches 7.5 or 8.5

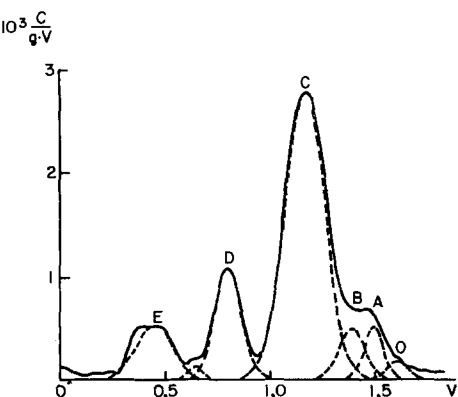

Fig. 1. Derivative discharge curve of γ-MnO_2 in ammonium-zinc chloride electrolyte [dQ/dV (coulombs/g $MnO_2 \cdot$ V) vs. cell voltage (V)].

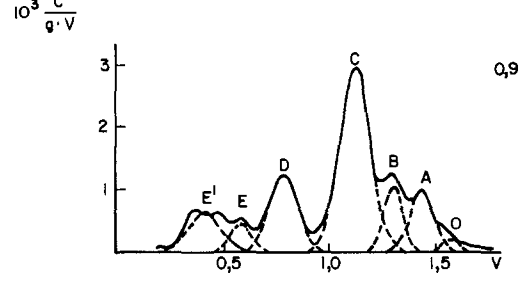

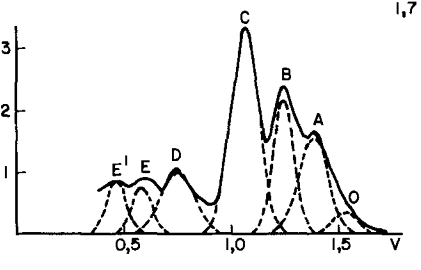

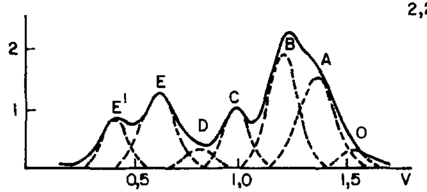

Fig. 2. Derivative discharge curves of γ-MnO_2 [dQ/dV (coulombs/g $MnO_2 \cdot$ V) vs. cell voltage (V)] and effect of electrolyte content in depolarizer mixture (ratios of electrolyte to MnO_2 indicated on drawing).

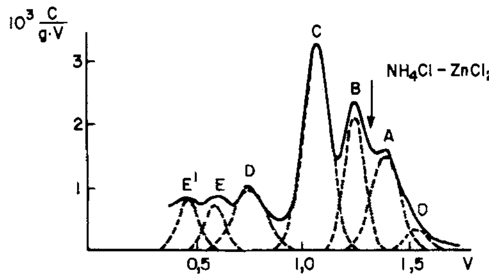

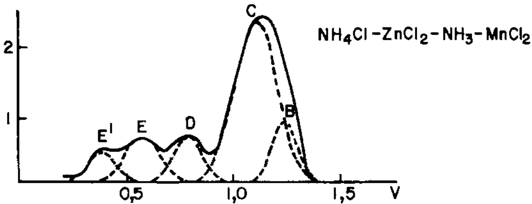

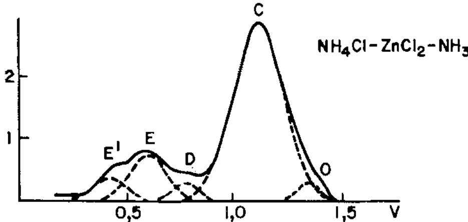

Fig. 3. Derivative discharge curves of γ-MnO_2 in electrolyte compositions simulating partial discharge conditions [dQ/dV (coulombs/g MnO_2 · V) *vs.* cell voltage (V)]. (a, top; b, center; c, bottom.)

during the discharge of β- or γ-MnO_2, respectively (3). In the range of these pH values precipitation of manganous ions, formed during the initial discharge following Eq. [1], as hydroxide is to be expected

$$Mn^{++} + 2H_2O \rightleftharpoons Mn(OH)_2 + 2H^+ \quad [2]$$

Protons liberated in this reaction may thus be available for further reduction of manganese dioxide

$$MnO_2 + 2H^+ + 2e^- \rightarrow Mn(OH)_2 \quad [3]$$

Combination of Eq. [2] and [3] leads to the over-all equation

$$MnO_2 + Mn^{++} + 2H_2O + 2e^- \rightarrow 2Mn(OH)_2 \quad [4]$$

to which peak B may be attributed.

In order to obtain further experimental evidence for these attributions depolarizer mixes corresponding to the calculated compositions for the end of peak A with and without addition of the calculated amounts of manganous ions have been discharged. If peak B is linked to a reaction where manganous ions, or their reaction products with manganese dioxide, are involved it should be observed only for mixtures to which manganous chloride has been added. Figure 3 shows as an example the derivative discharge curves of γ-MnO_2 discharged (a) in normal zinc-ammonium chloride electrolyte, (b) in an electrolyte of the composition calculated for the intersection point between peak A and B near the end of peak A as indicated by the arrow in the upper diagram of Fig. 3, and (c) in an electrolyte similar to the composition used in (b) but without addition of manganous chloride. The curves clearly show that in case (b) peak A has disappeared, peak B is present, although somewhat reduced in comparison to (a) while in case (c) peaks A and B can no longer be observed. The actual values together with those obtained for other mass ratios of electrolyte to manganese dioxide presented in Table III confirm the observations from Fig. 3. When the reactions related to peak A and B are inhibited more manganese dioxide is available for subsequent reactions. This explains the increase of the areas of peak C in cases (b) and (c).

Reduction of adsorbed oxygen.—A small peak O positioned at the highest values of the cell voltage scale of the derivative discharge curves is observed in the reduction of all manganese dioxides examined in zinc-ammonium chloride as well as in alkaline electrolytes. This peak may be attributed to the reduction of adsorbed oxygen as proposed by Drucker (6). The coulombic efficiency above 100% found by Boden *et al.* (7) during the initial discharge of γ-MnO_2 in alkaline electrolyte can also be interpreted as reduction of adsorbed oxygen.

Discharge in 9M KOH electrolyte.—The shapes of the derivative discharge curves of α- and γ-MnO_2 in 9M KOH (Fig. 4) are similar to those of the corresponding curves observed in zinc-ammonium chloride electrolyte with the exceptions of peaks A and B being absent and peak O shifted toward peak C. For β-MnO_2 peaks D and E, which are well developed in zinc-ammonium electrolyte, are not observed in 9M KOH. Peaks are much sharper in alkaline than in zinc-ammonium chloride electrolyte. This fact corresponds, course, to the pronounced steps in the discharge curves which have been observed before (8, 9).

Attribution of the peaks C, D, and E to specific reactions requires identification of reduction products obtained by discharging the depolarizer mix to the end and, when considered necessary, to the center of the respective peaks. The different positions of comparable peaks on the cell voltage scale already suggest that the reduction products obtained after discharging to the end of peaks C and D, formed either directly or

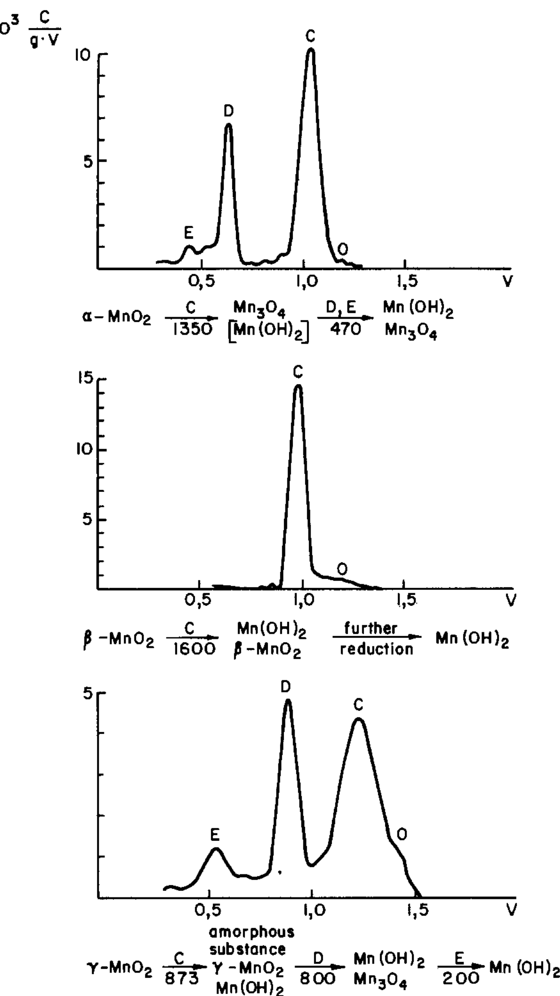

Fig. 4. Derivative discharge curves [dQ/dV (coulombs/g MnO_2 · V) vs. cell voltage (V)] and reduction products of α-, β-, and γ-MnO_2 in 9M KOH electrolyte (figures under arrows: coulombs/g MnO_2).

during secondary chemical reactions taking place within the time available during discharge, cannot be the same for the different types of manganese dioxide examined. The corresponding schemes and products of reduction identified by x-ray diffraction analysis of fresh unwashed samples taken directly after the relevant steps are shown below the graphs of the derivative discharge curves of α-, β- and γ-MnO_2 obtained in 9M KOH (Fig. 4).

Since the x-ray diffraction patterns of γ-Mn_2O_3 and Mn_3O_4 are very similar, it is difficult to decide which of the two substances was present in the reduction products. According to the data presented by Bricker (10) the most important differences between these patterns are the intensities of the $d = 1.82$Å lattice spacings with a relative intensity of 10% for γ-Mn_2O_3 and 50% for Mn_3O_4 and the absence of lines at $d = 1.030$ and 0.985Å for γ-Mn_2O_3. Contrary to this the patterns presented by Ramdohr (11) and by Moore *et al.* (12) for Mn_3O_4 indicate a low intensity of the line corresponding to $d = 1.82$Å. In the diffraction diagrams of the reduction products the line at $d = 1.82$Å had a low intensity and the lines corresponding to $d = 1.030$ and 0.985Å were present. The criteria derived from Bricker's work contradict these findings and do not allow any decisions to be made. If one accepts the work of Ramdohr and Moore *et al.* the observed reduction products are Mn_3O_4 and not γ-Mn_2O_3. We therefore, in agreement with McBreen (18), assume that the reduction product is Mn_3O_4; the conclusions derived from our observations would, however, not be affected if the wrong choice had been made.

Washing and drying normally causes $Mn(OH)_2$ to disappear if present in smaller amounts, and leads further to the formation of secondary products. Among these α-, β-, γ-MnOOH, hydrohausmannite (13, 14), manganous manganite (15), and todorokite (16) were identified. The cathodic reduction of the samples was normally terminated within 3 hr. After storing the discharged depolarizer mixes for 24 hr or after slow discharges during the same time interval, other products such as β- or γ-MnOOH and hydrohausmannite could be identified. Our observations lead to the conclusion that these compounds were formed in secondary reactions from primary reduction products.

Reduction of two, well-crystallized β-MnO_2 samples of different origin and with an x-ray pattern similar to that given by Byström (17) showed only one peak with an area of 1600 coulombs/g MnO_2, which is well above the 1033 coulombs/g necessary to reduce $MnO_{1.936}$ to the trivalent state. At the end of this peak only $Mn(OH)_2$ together with some unreduced β-MnO_2 were identified. Therefore $Mn(OH)_2$ seems to be the only significant reduction product to occur. Another β-MnO_2 ore sample, with x-ray diagram differing somewhat from the previous samples, showed the presence of a small peak D after peak C. In agreement with McBreen (18), no lattice dilation of β-MnO_2 during reduction was observed.

Kozawa and Powers (8) observed a two-step discharge curve for their β-MnO_2 (II and III) in 9M KOH which had been prepared by heating electrolytic γ-MnO_2 for 10 days at 400° ± 10°C, followed by sulfuric acid treatment. Discharge of a sample prepared by us in the same manner confirmed this observation. The x-ray diagram of this sample has fewer and broader lines than those of the above-mentioned β-MnO_2 samples. It may be concluded that the β-MnO_2 obtained by the method of Kozawa and Powers is less crystallized and does not fully represent the pyrolusite phase. In agreement with McBreen (18), who prepared samples in the same way, $Mn(OH)_2$ and Mn_3O_4 are observed on reduction to the end of peak C.

During the reduction of α-MnO_2 mainly Mn_3O_4 together with a small amount of $Mn(OH)_2$ is found after the first step at the end of peak C. On further reduction during the second step, peak D, part of the Mn_3O_4 is converted to $Mn(OH)_2$. On further reduction more $Mn(OH)_2$ is formed but some Mn_3O_4 can still be observed in discharge products sampled at cell voltages indicating the end of peak E.

The derivative discharge curve of γ-MnO_2 in 9M KOH clearly shows three major peaks C, D, and E. After discharging to a voltage indicating the end of peak C some weak lines of γ-MnO_2 are still observed. The shift of their positions indicates that lattice dilation has taken place confirming the findings of Brenet (1), Bell and Huber (19), and Boden *et al.* (7). Some lines of minor intensity indicate the presence of $Mn(OH)_2$. The higher background of the spectra may be explained, in agreement with Boden *et al.* (7), by the presence of an amorphous substance which seems to be the major reduction product after discharge to the end of peak C. On further discharge to the end of peak D $Mn(OH)_2$ and a smaller amount of Mn_3O_4 are found. These may have been formed by the reduction of the amorphous substance and the residual γ-MnO_2. The following peak E is related to the reduction of Mn_3O_4 to $Mn(OH)_2$. Its position on the cell voltage scale is equal to that of peak D observed during the reduction of α-MnO_2 to which the same reaction is attributed.

Discharge of a mixed α, β-MnO₂ ore.—The reduction of an ore sample, which by x-ray analysis proved to be a mixture of 26% α- and 74% β-MnO_2 resulted in a derivative discharge curve (Fig. 5) of a shape very similar to that obtained for pure α-MnO_2 with the exception of peak C being shifted downward by 0.07V.

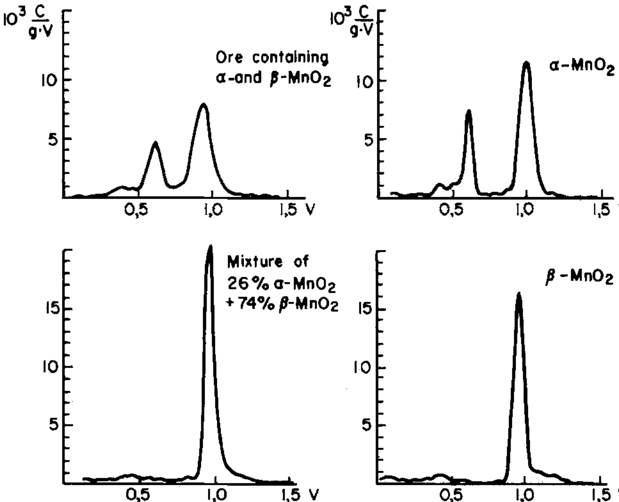

Fig. 5. Derivative discharge curves of an α, β-MnO_2 ore, an artificial mixture of α- and β-MnO_2 and of the single components, α-MnO_2 and β-MnO_2, in 9M KOH electrolyte [dQ/dV (coulombs/g MnO_2 · V) vs. cell voltage (V)].

Discharging an artificial mixture of the same composition prepared from pure α- and β-MnO_2 gave a derivative discharge curve with only one peak situated at a cell voltage approximately 0.02V higher than peak C of β-MnO_2. On account of this observation it may be assumed that an intercrystalline mixture of two MnO_2 phases can behave differently from the corresponding interparticle mixture.

A general model for the discharge mechanism.— Hitherto the reaction corresponding to peak C in the derivative discharge curves was attributed by various authors (8, 20-24) to the solid-state reduction of manganese dioxide following the equation

$$MnO_2 + H^+ + e^- \rightleftharpoons MnOOH \quad [5]$$

However, no indication of the presence of any one of the three known phases of MnOOH at the end of peak C has been found in the fresh samples. Only after washing, drying, or storage of reduced manganese dioxide samples α-, β-, and γ-MnOOH could be identified. Therefore these compounds appear not to be the primary reaction products corresponding to peak C and it is therefore unlikely that a reaction corresponding to Eq. [5] takes place, particularly so during the reduction of α- and β-MnO_2. The amorphous substance observed after peak C during the reduction of γ-MnO_2 cannot be ruled out to be a noncrystalline form of MnOOH so that reaction [5] could be valid for this case. The lattice dilation observed only during reduction of γ-MnO_2 may well support this view.

All our observations point to bivalent manganese always being the primary reduction product, either in the form of manganous ions or as hydroxide depending on the pH of the electrolyte in the depolarizer mixture. In alkaline electrolyte the manganous hydroxide reacts with the remaining α-MnO_2 to yield Mn_3O_4 or with γ-MnO_2 to give the amorphous substance. There is no appreciable reaction between β-MnO_2 and manganous hydroxide in 9M KOH within the time required for the discharge experiment.

In order to obtain further evidence manganous hydroxide was prepared *in situ* in suspensions of either α-, β-, or γ-MnO_2 powders in strong KOH solutions by addition of appropriate amounts of manganous chloride solutions. After stirring the suspensions in an oxygen-free atmosphere for durations comparable to the discharge times applied in the pulse galvanostatic analyzer discharge test the solids were filtered off and, without further treatment, examined by x-ray diffraction. In the case of β-MnO_2 no reaction with manganous hydroxide was observed under these conditions. Practically identical x-ray diagrams were obtained for α- and γ-MnO_2 reduced either electrochemically to the middle or end of peak C or by reaction with the corresponding amounts of $Mn(OH)_2$.

Manuscript received Dec. 30, 1975. This was Paper 9 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by the Chemical Engineering Research Group, CSIR.

Electrochemical Behavior of Sulfur and Sulfide in Molten Sodium Tetrachloroaluminate Saturated with NaCl

R. Marassi,[1] G. Mamantov,* and J. Q. Chambers

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37916

ABSTRACT

The electrochemical behavior of sulfur and sulfide in molten $NaAlCl_4$ saturated with NaCl has been investigated at different temperatures and with different electrode materials. In melts containing sulfur one reduction and one oxidation wave are seen at tungsten and glassy carbon electrodes. At platinum two reduction waves are observed. The oxidation waves are similar for all three electrode materials. Reduction of sulfur leads to the formation of sulfide; the oxidation leads to S(I) or S(II) depending on the temperature, the higher oxidation state being formed at higher temperatures. The data obtained in sulfur solutions have been confirmed by the results obtained in melts containing Na_2S. The mechanism for the electrochemical oxidation of sulfur apparently involves a complex set of charge transfer and chemical steps.

The chemistry and electrochemistry of sulfur in molten salts have received considerable attention in recent years because of the possible use of sulfur as a cathode material in a secondary battery using molten chlorides as solvents and lithium or its alloys as anodes (1-3). A closely related application involves the development of the high temperature sodium-sulfur battery using β-alumina as a solid electrolyte (1-3). The interest has been focused mainly on the electrochemical characterization of the couple S/S^{2-} in molten chlorides (4-8) and thiocyanates (8-10). Some papers have been concerned with the spectroscopic characterization of the sulfur species responsible for the blue or green solutions that result from the interaction of sulfur and sulfide in both melts (11-15). Electrochemical oxidation of sulfur in the molten LiCl-KCl eutectic has also been briefly explored (4, 5).

In a recently published note (16) we reported some preliminary results on the electrooxidation and electroreduction of sulfur in molten chloroaluminates ($AlCl_3$-NaCl mixtures) of different compositions. The electrochemistry of this system is markedly dependent on the melt composition.

It is now well established (17-21) that the acid-base properties of molten chloroaluminates near the 1:1 $AlCl_3$/NaCl mole ratio can be described by the equilibrium

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^- \quad [1]$$

The Lewis acidity can be expressed in terms of pCl ($p\text{Cl} = -\log [\text{Cl}^-]$); the most basic system corresponds to a NaCl-saturated melt in which the pCl is constant in the presence of solid NaCl, and at 175°C is equal to 1.1 (22).

In this paper we report the results obtained in chloroaluminate melts saturated with NaCl; in these melts the electrochemistry of the sulfur system is simpler than in the more acidic melts. The effect of the melt acidity on the oxidation wave of sulfur has been briefly reported in Ref. (16) and will be the subject of a later communication.

Experimental

The melt preparation and other experimental procedures have been reported previously (23, 24).

Sulfur was introduced in the melt after purification by repeated crystallizations from benzene and vacuum sublimation; anhydrous Na_2S (Alfa Products) was used as received.

Results and Discussion

Voltammetry of sulfur and Na_2S solutions.—Sulfur solutions in the $AlCl_3$-$NaCl_{sat}$ melt in the temperature range 175°-300°C are pale yellow in the presence and absence of Na_2S. This is indicative of the absence of equilibria that can generate anionic species such as S_3^- or S_2^- that are responsible for the blue or green solutions of polysulfides in molten chlorides and thiocyanates (11-15).

Sulfur itself is not very soluble in the melt. The concentration of the sulfur electroactive species cannot be quoted since the aggregation state of sulfur is not known. In the temperature range of interest for basic chloroaluminates (> 160°C) sulfur (S_8) undergoes marked structural changes to form open chains and polymers (25). For the sake of comparison and in order to have a reference point, all concentrations in this paper are referred to a hypothetical sulfur monomer. From visual observations the solubility of sulfur (as S) in $AlCl_3$-$NaCl_{sat}$ melt at 175°C is less than 2.1×10^{-2} molal.

In Fig. 1 and 2 voltammograms are presented for sulfur at a glassy carbon electrode at 175°C. The voltammogram in Fig. 1 was obtained by recording the current at 5 sec after the application of potential steps

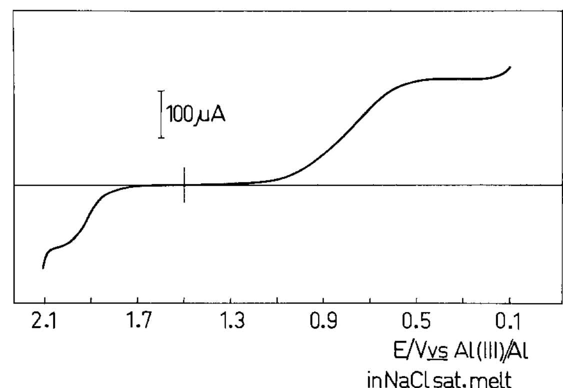

Fig. 1. Voltammogram obtained from current-time curves (current measured 5 sec after the application of the potential step) in a 1.8×10^{-2} molal sulfur (as sulfur monomer) solution in NaCl saturated melt at 175°C. Glassy carbon electrode area: 0.07 cm². Potentials *vs.* Al(III)/Al reference electrode in NaCl-saturated melt.

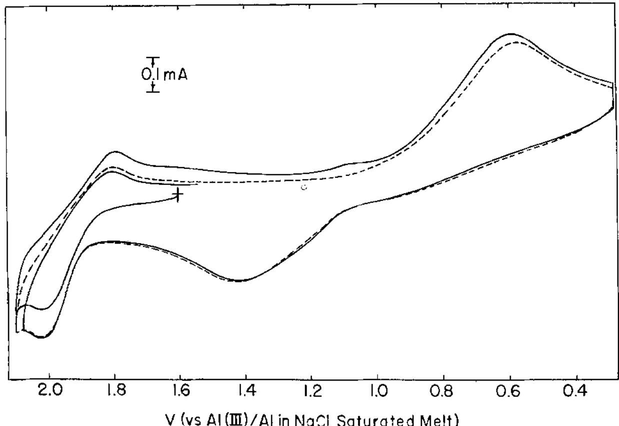

Fig. 2. Cyclic voltammogram at a glassy carbon electrode (area 0.07 cm^2) in a 1.8 × 10^{-2} molal sulfur solution in NaCl-saturated melt at 175°C. Scan rate 0.1 V-sec^{-1}. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt.

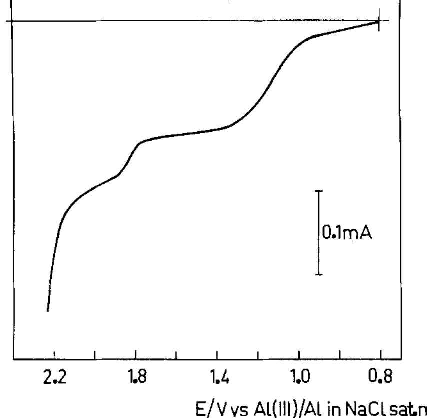

Fig. 3. Normal pulse voltammogram for a 1.04 × 10^{-2} molal Na_2S solution (assuming that the salt is completely dissolved) in NaCl-saturated melt at 175°C. W electrode area 0.07 cm^2. Scan rate 5 mV-sec^{-1}; 57 msec pulse. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt.

of different amplitude to the electrode (23). Similar current-potential curves can be obtained on tungsten electrodes. For both cyclic and pulse voltammograms, the peak or limiting current ratios of the oxidation wave to the reduction wave are *ca.* 0.5.

A different behavior is observed for the reduction wave if platinum is used as the electrode material. The reduction process occurs in two approximately equal steps. At longer times, *e.g.*, 5 sec as in Fig. 1, the constructed voltammograms have the same general shape except that the first reduction wave is larger than the second. The total limiting current measured on the second plateau is, however, twice the limiting current for the oxidation step. The different reduction behavior of the sulfur system at various electrode materials is evident also in the cyclic voltammograms which show that the reduction process takes place in one drawn-out irreversible step at glassy carbon and tungsten, while two waves are again seen at platinum. The nature of the second wave at platinum has not been studied in detail except to note that it depends greatly on the previous history of the electrode and on the number of cycles in the voltammograms.

The shape of the oxidation wave is not, on the contrary, dependent on the electrode materials. Similar oxidation waves were obtained on glassy carbon, tungsten, and platinum working electrodes.

The results for elemental sulfur are complemented by the experiments on Na_2S solutions in the same melt at the same temperature. Sodium sulfide dissolves very slowly in the melt and does not seem to be very soluble; however, the sulfide concentration that can be realized is sufficiently high to allow its electrochemical detection. The oxidation of S^{2-} occurs in two steps as is seen in the pulse voltammogram obtained at a tungsten electrode (Fig. 3). The voltammograms for the sulfide solutions are similar to those of elemental sulfur except for the shift of the zero current line. This correspondence and the limiting current data suggest that sulfur is reduced to a negative two-oxidation state and oxidized to a positive one-oxidation state in these melts. A reaction sequence consistent with these results is shown in Eq. [2] and [3]

$$S^{2-} \rightarrow S + 2e^- \quad [2]$$

$$S \rightarrow \frac{1}{2} S_2^{2+} + e^- \quad [3]$$

in which S_2^{2+} is proposed as the oxidation product. In these equations elemental sulfur is written as S for convenience, although its aggregation state is unknown. Paulsen and Osteryoung have also suggested S_2Cl_2 as the oxidation product of sulfur in basic $NaAlCl_4$ melts (26).

The electrochemical behavior changes at higher temperatures both in the Na_2S and sulfur solutions. The S/S^{2-} couple becomes more reversible on tungsten and platinum electrodes (Fig. 4) and the oxidation wave assumes the shape of an irreversible system at low scan rates. When the scan is initiated in the positive direction, a prewave that is not seen at lower temperatures appears before the main reduction wave. In addition, the limiting current ratio of the oxidation to the reduction wave increases and approaches a value of unity as the temperature is raised. This behavior is evident in Fig. 5 (compared to Fig. 3) and suggests the sequence in Eq. [4] and [5] for the high temperature oxidation

$$S^{2-} \rightarrow S + 2e^- \quad [4]$$

$$S \rightarrow S^{2+} + 2e^- \quad [5]$$

This hypothesis is consistent with spectroscopic evidence in more acidic chloroaluminate melts which indicates that [S_2^{2+}], S_4^{2+}, S_8^{2+}, and S_{16}^{2+} are stable at low temperatures and that S^{2+} can be formed at high temperatures (27, 28). It is also consistent with the general observation that higher oxidation states are more stable in more basic melts which is the case at higher temperatures both due to the increased solubility of NaCl in $NaAlCl_4$ and the greater dissociation of $AlCl_4^-$ (18, 23).

Sulfur oxidation mechanism.—Considerable experimental effort has been expended on mechanistic studies

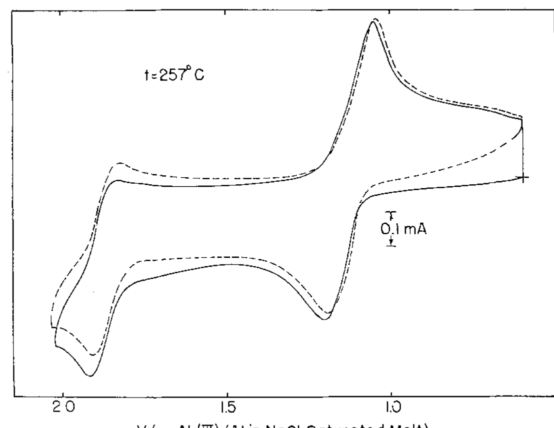

Fig. 4. Cyclic voltammogram for a 1.04 × 10^{-2} molal Na_2S solution in NaCl-saturated melt at 257°C. W electrode area 0.07 cm^2. Scan rate 0.1 V-sec^{-1}. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt.

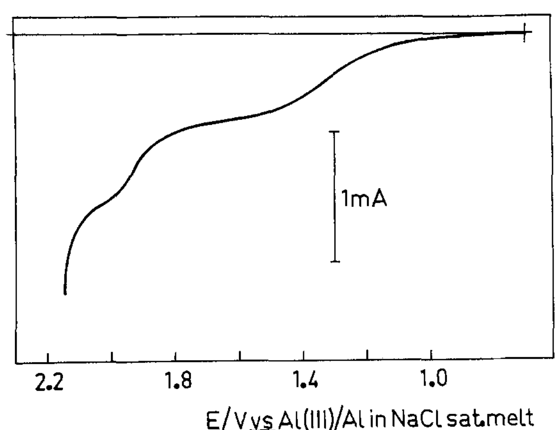

Fig. 5. Normal pulse voltammogram for a 1.04×10^{-2} molal Na_2S solution in NaCl-saturated met at 230°C. W electrode area 0.07 cm^2. Scan rate 5 mV-sec^{-1}; 57 msec pulse. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt.

of the sulfur oxidation wave with only partially satisfactory results. The proximity of the oxidation wave to the anodic background discharge of the chloroaluminate melt and the uncertainty in the actual sulfur concentration made these measurements difficult. However, several observations can be made on the basis of the cyclic voltammetric and chronoamperometric measurements.

The cyclic voltammetric data at platinum are given in Tables I-III (similar results were obtained at glassy carbon and tungsten electrodes). At all temperatures the peak width, the peak separation, and the ratio of the cathodic to the anodic peak current are dependent on sweep rate. At the fastest sweep rates at all temperatures the ratio of peak currents is unity which indicates that the direct product of the oxidation is relatively stable. At these sweep rates the peak separation is considerably larger than that expected for a one-electron (or greater) process, while the peak width of the anodic wave is less than the value for a one-electron process (29, 30). Significantly, the current function, $i_p/v^{1/2}$, is independent of sweep rate within experimental error over a wide sweep rate range. These results suggest that fragmentation of the sulfur molecules in the oxidation process is fast on the voltammetric time scale and that the charge transfer is quasi-reversible. The decrease of the ratio i_p^{cath}/i_p^{an} at lower scan rates becoming more pronounced at higher temperatures (Fig. 6) is indicative of a following chemical reaction.

These results may be (at least partially) rationalized in terms of a generalized model given in Eq. [6] and [7] for the oxidation process. This model involves anodic fragmentation of the sulfur rings which may be initiated thermally or by electron transfer. The overall process leads to formation of sulfur in the +1 oxidation state which is indicated by the limiting current ratios observed for the sulfur and sulfide voltammograms

$$2S_n \rightleftarrows \underset{\text{chains}}{\text{sulfur}} \rightleftarrows nS_2 - 2ne^- \rightleftharpoons nS_2^{2+} \qquad [6]$$

$$2S_n \overset{-2e^-}{\rightleftharpoons} 2S_n^+ \rightleftarrows \underset{\text{chains}}{\text{sulfur}} \overset{-n^1e}{\rightleftharpoons}$$

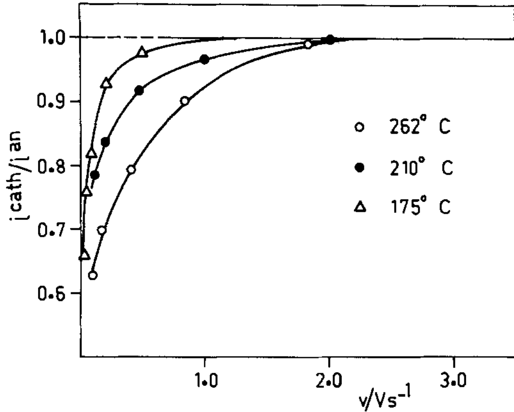

Fig. 6. Variation of the ratio i_p^{cath}/i_p^{an} with the scan rate at different temperatures.

$$S_2^{2+} \overset{AlCl_4^-}{\rightleftharpoons} S_2Cl^+ \overset{AlCl_4^-}{\rightleftharpoons} S_2Cl_2 \rightleftharpoons S_2Cl_{2(g)} \quad [7]$$

Actually a complex set of electron transfer and sulfur-sulfur bond fragmentation reactions may be envisioned between the S_n rings and the S_2^{2+} dications. The quasi-reversible nature of the oxidation wave could be due to oxidation of the fragments over the potential range encompassed by the oxidation wave.

The slopes of the log $[i/(i_d - i)]$ *vs.* E plots for the pulse voltammograms are dependent on the time at which the current is measured. Figure 7 shows two voltammograms obtained at 57 msec (curve A) and 5 sec (curve B). The latter curve is more "reversible" and the slope approaches a value for a two-electron transfer (45 mV at 175°C). The plots are shown in Fig. 8. This behavior is consistent with the above

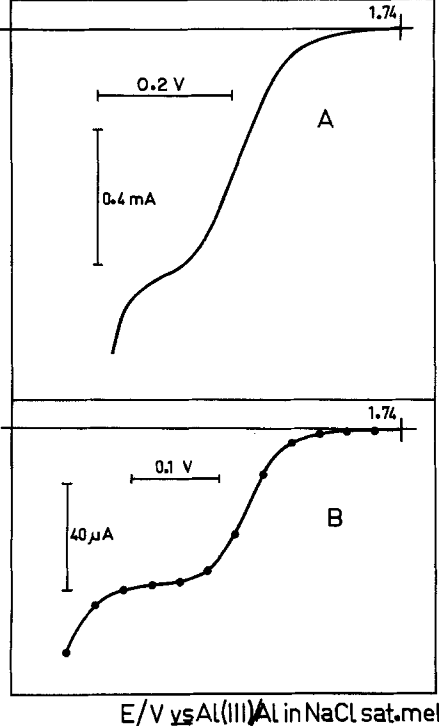

Fig. 7. (A) Normal pulse voltammogram for the oxidation of sulfur in NaCl-saturated melt at 175°C. Sulfur concentration 1.8×10^{-2} molal. Platinum electrode area 0.06 cm^2. Scan rate 2 mV-sec^{-1}; 57 msec pulse. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt. (B) Voltammogram constructed from current-time curves (current measured at 5 sec) for the oxidation of sulfur in NaCl-saturated melt at 175°C. Sulfur concentration 7.7×10^{-3} molal. Potentials vs. Al(III)/Al reference electrode in NaCl-saturated melt.

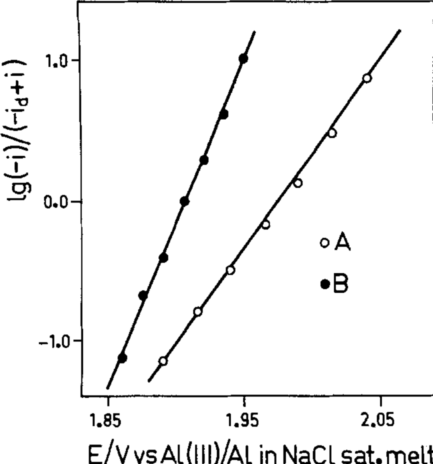

Fig. 8. Plots of log $(-i)/(-i_d + i)$ *vs.* E for the voltammograms in Fig. 7. A corresponds to Fig. 7A (reciprocal slope 74 mV); B corresponds to Fig. 7B (reciprocal slope 44 mV).

scheme in that it suggests a two-electron oxidation of the S_2 molecules at long times. At short times (57 msec pulse) the experimental slope is reasonably close to the expected value for a one-electron reversible charge transfer.

Additional support for the further oxidation at the same potential of the partially oxidized product following one or more chemical steps is provided by the increase of the chronoamperometric $it^{1/2}$ value from 98 to 127 μA-sec$^{1/2}$ with a variation of t from 1.25 to 5 sec (these results were obtained at the tungsten electrode, A = 0.07 cm^2, at 175°C at a potential corresponding to the diffusion plateau of the oxidation wave; S molality 7.7×10^{-3}).

The behavior of the ratio i_p^{cath}/i_p^{an} as a function of sweep rate and temperature indicates that the oxidation product is more rapidly removed from the diffusion layer at the higher temperatures. The nature of this reaction is not fully understood, but complexation of S_2^{2+} by the basic melt is likely. This is shown in Eq. [7] as successive formation of S_2Cl^+ and S_2Cl_2 moieties. A slow step in the complexation of S_2^{2+} or a slow loss of gaseous S_2Cl_2 from the diffusion layer would explain the EC behavior of the sulfur oxidation process.

A better understanding of the oxidation of sulfur in basic chloroaluminate melts should result from spectroscopic and spectroelectrochemical studies. Such studies are in progress in this laboratory as well as elsewhere (27).

Compatibility of Aluminum Nitride in Environments Representative of High Temperature Cells

Ram A. Sharma,* Richard A. Murie, and Elton J. Cairns*

General Motors Corporation, Electrochemistry Department, Research Laboratories, Warren, Michigan 48090

ABSTRACT

Compatibility tests of hot-pressed, high purity AlN of 90-99% of theoretical density were carried out in molten lithium, lithium-saturated LiCl-KCl, lithium saturated LiF-LiCl-KCl, molten 30 weight per cent (w/o) Li_2S-S and molten S at 400°C for up to 10,000 hr, and lithium-saturated LiCl and chlorine-saturated LiCl at 650°C for up to 1430 hr. At 400°C, the AlN was not attacked to any significant extent (<0.5 w/o), whereas at 650°C, AlN experienced intergranular attack by lithium and reacted at a rate of 1% per 100 hr in Cl_2-LiCl.

One of the main problems in the development of high temperature molten salt cells is the identification of a suitable electrical insulating material for use in the cells. This problem occurs because of the very corrosive nature of the materials in such systems (*e.g.,* Li/Cl_2 with LiCl as electrolyte, and Li/S with an alkali halide mixture as the electrolyte). The problem is especially difficult because of the high operating temperatures, *i.e.,* about 650°C for the Li/Cl_2 cell and about 400°C for the Li/S cell (1, 2).

Based on the standard free energy of formation and availability, oxides such as Li_2O, BeO, MgO, Y_2O_3, La_2O_3, ThO_2, and CaO may be considered to be prospective insulators in these corrosive environments. The unsuitability of Li_2O, MgO, La_2O_3, ThO_2, and CaO has been pointed out (3-5), and it has also been reported that Y_2O_3 did not show any appreciable change when tested in 20 atom per cent (a/o) Li-80 a/o S at 375°C for 331 hr. In the case of BeO, the results of compatibility tests varied depending on the type and the quality of BeO used; for example, in early tests, BeO in the form of a porous crucible disintegrated when tested in lithium for 25 hr at 350°C (3, 4). In later tests, high purity, hot-pressed BeO proved to be the most corrosion-resistant material with a corrosion rate near 0.02 mm/yr in lithium at 375°C for 1000-1200 hr (5).

Cairns *et al.* (6) reported that some double oxide compounds, particularly $LiAlO_2$, $MgAl_2O_4$, and $CaZrO_3$, show promise as insulating materials. Fishwick and Yeh (7) investigated the compounds $Li_2O \cdot Al_2O_3$, $Li_2O \cdot 5Al_2O_3$, $Li_2O \cdot ZrO_2$, $CaO \cdot Al_2O_3$, $CaO \cdot 5Al_2O_3$, $CaO \cdot 2.5Al_2O_3$, and $CaO \cdot ZrO_2$, and reported only $CaO \cdot ZrO_2$ to be compatible in lithium as a result of a test in lithium at 580°C for 92 hr.

At General Motors Research Laboratories, earlier material compatibility studies indicated AlN to be a promising material, since only minor degradation of AlN was found after being in contact with lithium at 700°C for about 575 hr (8). Therefore, the present investigation was conducted to test AlN under conditions similar to those existing in the Li/Cl_2 or Li/S cells. The present AlN tests were further warranted because a better quality of material with respect to purity and density has become available (9).

Experimental

Aluminum nitride specimens of 97-99% of theoretical density (but in one case, 90% of theoretical density)

* Electrochemical Society Active Member.

Key words aluminum nitride, insulators, corrosion, lithium, sulfur, high temperature.

were prepared by hot-pressing high purity AlN powder (0.06 weight per cent (w/o) oxygen, 0.35 w/o carbon) in a dense graphite die. Pressures in the range of 17.0-20.5 MPa were applied during gradual heating to about 1700°C to yield samples of ~97% theoretical density; and pressures of 35-41 MPa with heating to 2000°C were used for 99% theoretical density. The pressure and temperature were maintained for 20-60 min, after which the die was cooled slowly to room temperature, while maintaining the pressure. The AlN samples were diamond-ground to remove adherent graphite. After grinding, the color was gray to black. All of the longer term corrosion samples were sliced from the same cylindrical samples with a diamond wafering saw in an attempt to have uniformity of sample properties. A scanning electron micrograph (SEM) of a typical high density sample, Fig. 1, shows this AlN to be well sintered and dense.

The slices of AlN used in the corrosion tests were in various disk shapes (circular, semicircular, rectangular, circular disks with holes, etc.) having dimensions of about 12.7 mm, with a thickness of about 3 mm. (When a number of samples were placed in a single container, the positions of the holes in the samples were used for identification.) The samples were cleaned ultrasonically in methanol or acetone for 15 min, and were baked at 400°-650°C overnight under vacuum before being weighed and placed in the corrosion capsules in a pure helium atmosphere.

Lithium chloride of 99.6% purity and potassium chloride of 99.9% purity were used to prepare the eutectic mixture (59 mole per cent (m/o) LiCl-41 m/o KCl, mp = 352°C). This mixture was purified by bubbling chlorine through the melt at about 500°C for 2-4 hr and subsequently removing the chlorine by bubbling with helium for 1 hr. High purity, optical grade lithium fluoride (used for preparing u.v. filters) was used in the preparation of the ternary LiF-LiCl-KCl eutectic (3.5 m/o LiF-56.0 m/o LiCl-40.5 m/o KCl, mp = 346°C).

Lithium metal of 99.97% purity was used as received, after cutting away the surface metal from the ingot in a high purity helium atmosphere. Sulfur of 99.999% purity was used as received. Lithium sulfide with an analysis of 29.8 w/o Li (*vs.* 30.26 w/o theoretical for Li_2S) was used. The chlorine was 99.8% pure, and the helium had a total impurity level of less than 40 ppm.

The test cells used for the experiments involving lithium were constructed of Type 304 stainless steel and had cooling coils around the top to keep the gasket cool. Figure 2 shows the test cell (300 mm high × 70 mm ID) used for multiple-sample experiments. The samples were suspended from a crow's-foot on a closed-end tube which passed through a Swagelok fitting in the lid. The closed-end tube served as a thermocouple well for monitoring and controlling purposes. Figure 3 shows the arrangement used for experiments involving single AlN samples. This cell also had an inlet and outlet for the passage of helium during the test period. Each test cell was cleaned by washing in distilled water, rinsing in methanol, and hydrogen firing at 1000°C. When cool, the cells were placed in a helium atmosphere glove box for loading of the samples.

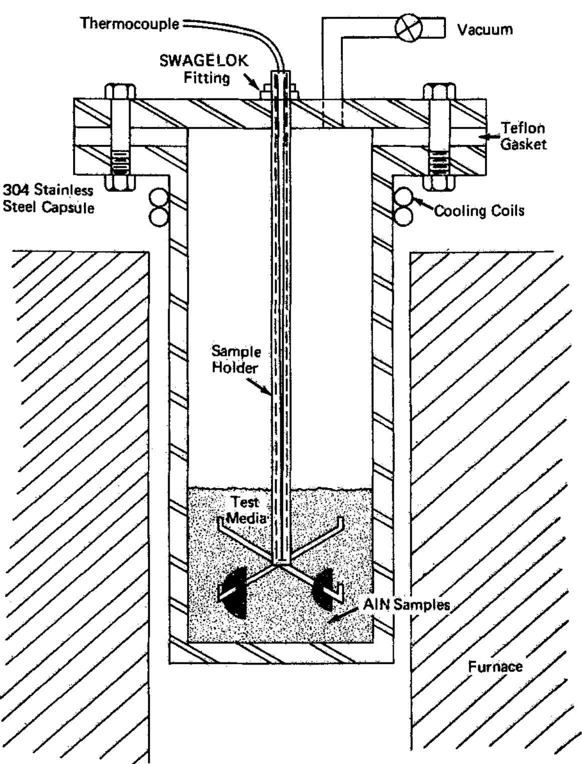

Fig. 2. Stainless steel test capsule containing test media at 400°C. Samples were suspended from "crow's-foot" in melt.

Fig. 1. SEM photograph of a fractured surface of a typical pretest AlN sample.

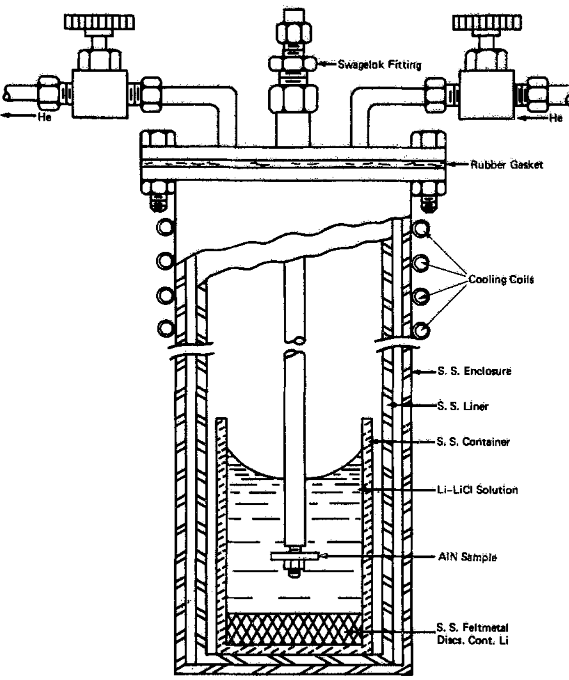

Fig. 3. Schematic diagram of the apparatus for compatibility tests in Li-LiCl solutions.

To load the stainless steel test cells, enough lithium was added to the cell to insure that the AlN sample(s) would be covered when melting occurred. The PTFE gasket was fitted to the cell flange, the tube with the sample(s) was fitted through the Swagelok fitting and adjusted to the proper length to insure that the samples would be totally immersed in the molten lithium. The test cell was then bolted shut, removed from the helium atmosphere, and mounted in a furnace.

The stainless steel test cells used with the molten salts (LiCl-KCl eutectic and LiF-LiCl-KCl eutectic) saturated with lithium were loaded in the same manner as above; however, stainless steel feltmetal disks (40.5 mm diam × 1.27 mm thick) impregnated with lithium were placed in the bottom of the test cell, Fig. 3, prior to adding the salt, providing a lithium source for impregnating the salt.

When a sample from a test cell containing multiple samples (on the crow's-foot) was to be removed, the furnace was turned off and the test cell was cooled to room temperature. The cell was taken into the helium glove box, placed in a furnace well, and heated. When the test medium was molten, the cell cover was removed and a sample was removed from the crow's-foot. The cover was then replaced, the cell was cooled, removed from the dry box, and again placed in the test furnace. The sample was then removed from the dry box, ultrasonically washed in distilled water, methanol, and acetone followed by a 3-4 hr vacuum bakeout at 400°C. When cool, the samples were weighed and sectioned on a diamond wafering saw for microscopic examination.

When a cell contained only a single AlN sample, entry into the dry box for sample removal was not necessary. The Swagelok fitting was loosened, and the sample was raised until clear of the molten test medium. The cell was then cooled and opened for sample removal and cleansing as described above.

The Li_2S-S and sulfur tests were carried out in quartz or Vycor test cells. The design of these test cells is shown in Fig. 4. The AlN and test medium were loaded into the cell in the helium atmosphere. After loading, a small amount of high vacuum stopcock grease was used to lubricate the standard taper joint and the stopcock cap was attached. The cell was evacuated, removed from the helium atmosphere, and sealed, with removal of the standard taper and stopcock cap. The test cell was then inserted into a sand bath which was suspended in a stainless steel container in a furnace, Fig. 5. The sand completely covered the cell and aided in maintaining a uniform temperature. When the test was terminated, the furnace was turned off and the test cell was removed while the test medium was still molten. Holding the cell by the long quartz handle, Fig. 4, and inverting it caused the molten test medium to run into the bottom chamber while the AlN test sample was held on the indentation. When cool, the quartz or Vycor cell was opened, the sample was removed and cleaned in an ultrasonic cleaner using distilled water, methanol, and acetone. Finally, the sample was vacuum dried at 400°C for 4 hr, cooled, and weighed. The vacuum drying also removed any remaining free sulfur adhering to the sample.

Compatibility testing in LiCl through which chlorine gas was bubbled was carried out in the apparatus shown in Fig. 6. To load the sample, a clean dry Vycor enclosure (350 mm long × 65 mm diam) with a Vycor

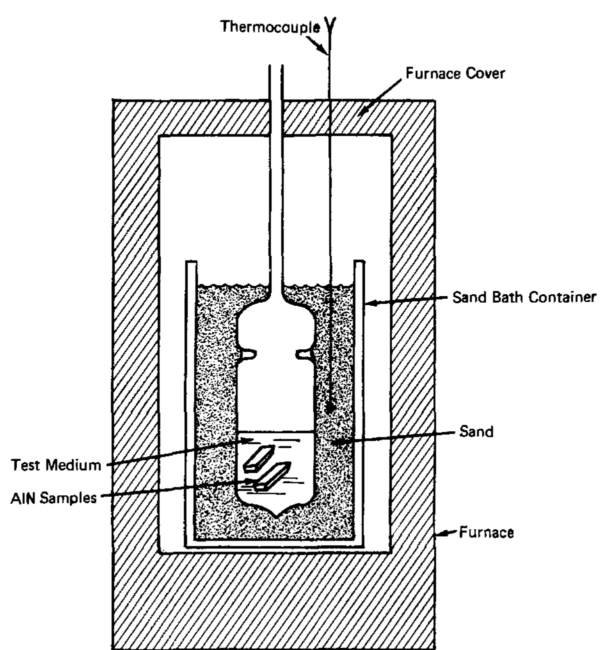

Fig. 5. Quartz test capsule in furnace

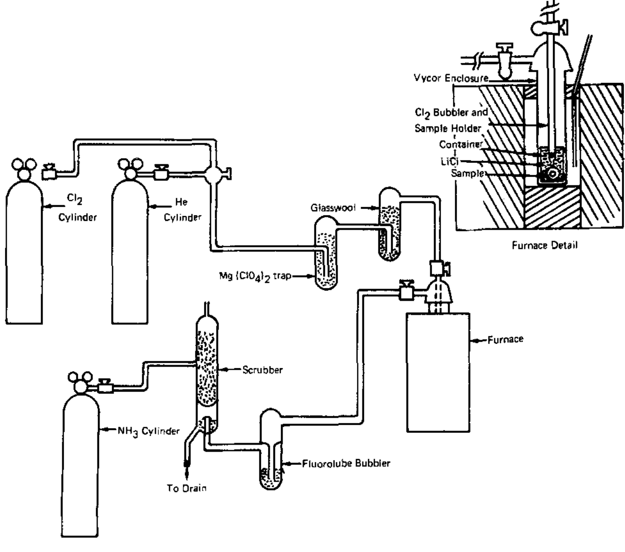

Fig. 6. Schematic diagram of the apparatus for compatibility tests in LiCl through which Cl_2 was bubbling.

container (80 mm long × 55 mm diam) and sample holder was taken into the helium atmosphere. The sample holder was fixed in position in the standard taper joint at the top of the enclosure. The sample was then placed on the hook of the sample holder, which was then placed into the Vycor container. Lithium chloride (about 175g) was placed into the container to cover the sample and to keep it in position on the hook. The container was then carefully slipped into the enclosure without disturbing either the salt or the sample, and the top of the enclosure was set into place. The gas inlet and outlet were closed and the enclosure was removed from the helium atmosphere and placed in the furnace. Helium was passed through the enclosure, and the furnace was heated to 650°C. The helium was then replaced by chlorine gas and the sample was kept under these conditions for the duration of the test. At the end of the exposure period, the chlorine was replaced by helium and the sample was taken out of the melt to cool. The sample was cleaned in methanol, dried, and weighed.

Results and Discussion

The results of all of the compatibility tests are summarized in Table I. The extent of attack is reported in terms of percentage weight change. The samples with numbers having an alphabetic suffix were cut from the same cylinder of hot-pressed AlN. For example, samples 1a, 1b, 1c, and 1d all came from a single cylinder of AlN, having a density of 99.3% of theoretical (3.26 g/cm^3). In addition, samples having this type of number were all exposed to a given melt in the same container and are called multiple-sample tests. The last sample in each of these sets was placed in the container only for the final 1000 hr of the test in order to determine if the corrosiveness of the melt had changed from that of the initial 1000 hr.

Molten lithium at 400°C.—The results of the multiple-sample tests of AlN in molten lithium at 400°C are presented in the upper part of Table I. A total of 12 samples, 4 in each of 3 stainless steel containers, were exposed for periods of 1000-10,000 hr. Examination of the samples by optical microscopy and by SEM up to 3000× revealed no visible attack. The weight change values indicate some loss, about 3% in 6000-7000 hr. The losses of this magnitude are associated with sample breakage, samples 1b and 1c, and crystal pullouts from surface cracks in samples 2b and 2c. Therefore, the weight loss due to nonmechanical causes is probably significantly less than 3% in several thousand hours.

Some SEM photographs of the surface and fracture surfaces of sample 3c are shown in Fig. 7. The fracture surface-exposed edge interface in Fig. 7b and c reveals no lithium penetration and shows the presence of a very thin surface film. This is a typical result. Part d of the figure is typical of the interior of the high density (~99% theoretical) samples.

The small weight losses shown by samples 1d, 2d, and 3d indicate that the corrosiveness of the lithium used in these exposures did not increase noticeably during the experiments. The small weight gains of samples 3b and 3c may be taken as an indication of the precision of these experiments and the difficulties of cleaning the samples after exposure.

Table I. Results of AlN compatibility tests in various media at 400° and 650°C

Sample No.	Environment	Temperature, °C	Exposure time, hr	Theoretical density, %	Initial weight,** g	Weight change, %	Remarks
1a	Molten lithium	400	1,000	99.3	1.6700	0.00	Samples 1b and 1c were broken during removal from the cell. No visible attack; no surface conductance
1b	Molten lithium	400	6,000	99.3	1.5455	−3.25	
1c	Molten lithium	400	7,000	99.3	2.1424	−1.19	
1d	Molten lithium	400	1,000*	99.3	1.2825	−0.08	
2a	Molten lithium	400	1,000	99.0	1.9295	−0.04	Sample intact; no visible attack or surface conductance
2b	Molten lithium	400	6,000	99.0	1.7901	−3.44	Sample intact; no visible attack or surface conductance
2c	Molten lithium	400	7,000	99.0	1.8560	−3.02	Sample intact; no visible attack or surface conductance
2d	Molten lithium	400	1,000*	99.0	1.5417	−0.18	Sample intact; no visible attack or surface conductance
3a	Molten lithium	400	1,000	98.8	0.9958	−0.05	Sample intact; no visible attack or surface conductance
3b	Molten lithium	400	9,000	98.8	1.3138	+0.02	Sample intact; no visible attack or surface conductance
3c	Molten lithium	400	10,000	98.8	1.8171	+0.06	Sample intact; no visible attack or surface conductance

** Weighted on semimicrobalance to nearest 0.01 mg.

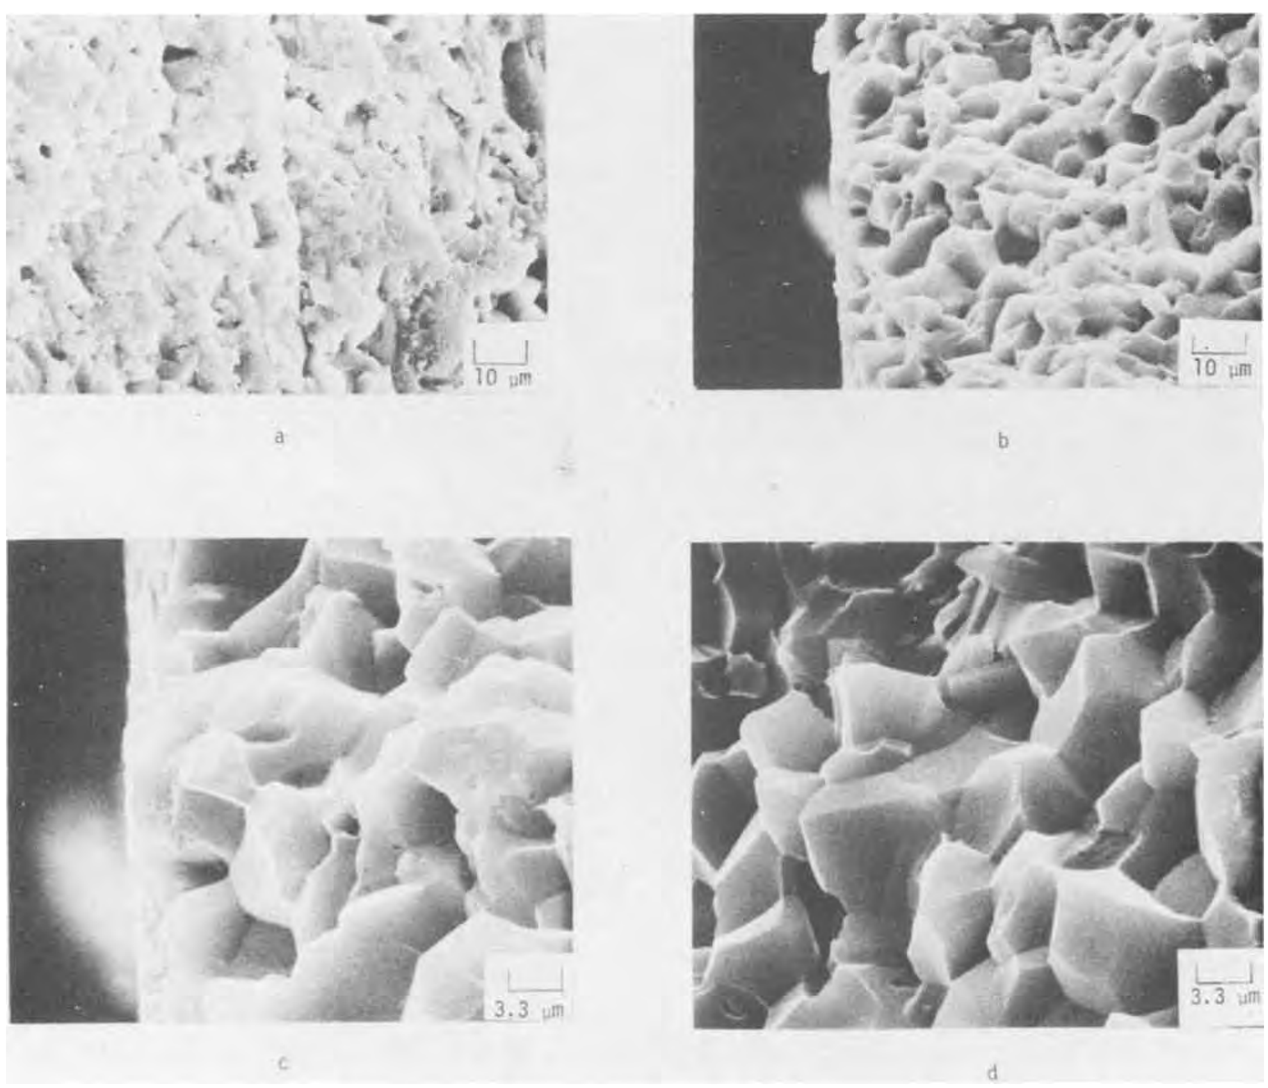

Fig. 7. SEM photographs of sample 3c after 10,000 hr in 400°C lithium. (a) AlN surface after exposure to lithium, (b) fracture surface and edge showing tightly bound crystals of AlN with no penetration of lithium, (c) higher magnification of fracture surface shown in (b), (d) interior fracture surface.

Molten LiCl-KCl saturated with lithium at 400°C.—Aluminum nitride samples 4 and 5 of Table I showed weight loss rates similar to those for AlN in lithium at 400°C. The values are in the range of less than 0.1% for 2600 hr. The samples were intact, with no visible signs of corrosion. All edges remained sharp.

Molten LiF-LiCl-KCl saturated with lithium at 400°C.—The results of this multiple-sample test are consistent with those for lithium and LiCl-KCl saturated with lithium. The weight change was small; the samples looked as they did at the beginning of exposure. The small diamond-saw marks on the surfaces of the samples remained. Figure 8 shows SEM views of samples 6b and 6c, indicating very little attack.

Molten LiCl saturated with lithium at 650°C.—The results of exposure of four samples of AlN (numbers 7 through 10) to lithium-saturated LiCl at 650°C (characteristic of the Li/LiCl/Cl_2 cell) are shown in Table I. At this higher temperature, attack on the samples is clearly evident, predominantly intergranular in nature. Weight losses as large as 10% after 1430 hr were observed. Figure 9 shows low-magnification (4.5×) views of the surface of sample 8 before and after 400 hr of exposure. Note the clear evidence of intergranular attack. In Fig. 10b, it can be observed that little coherency among the AlN grains remains.

The thermodynamic stability of AlN with regard to lithium is expected to be very good, based on the reaction

$$AlN(s) + 3Li(l) \rightarrow Al(s) + Li_3N(s) \quad [1]$$

The free energy of this reaction ranges from about +150 kJ/mole AlN at 400°C to about +160 kJ/mole AlN at 650°C (10). The possibility of excess lithium reacting with the aluminum produced by reaction [1] would yield a lower free energy, as would the dissolution of Li_3N in the molten salt mixture. It appears unlikely that these two effects would result in such a high rate of attack (*e.g.*, 10 w/o in 1400 hr). It is conceivable that the intergranular attack of samples 7 through 10 is associated with either an impurity effect or poor sintering, or both.

Molten 30 w/o Li_2S-70 w/o S at 400°C.—This melt represents a relatively strongly oxidizing environment, in contrast to the strongly reducing conditions represented by the melts discussed above, and was intended to be related to the conditions found in the positive electrode of a lithium/sulfur cell. Two multiple-sample tests of AlN in Li_2S-S were carried out, the results of which are summarized in Table I. The weight losses observed were all less than 0.3%, however some weight gains were also found in the 90% dense samples. This weight gain for samples 12a-12d is probably a reflection

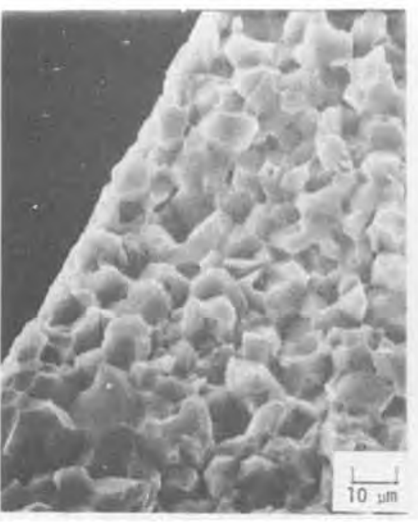

Fig. 8. SEM photographs of AlN samples 6b and 6c after 6000 and 7000 hr, respectively, in LiF-LiCl-KCl eutectic saturated with lithium at 400°C. (a) Surface of AlN sample 6b after exposure for 6000 hr. This surface is typical of AlN samples 6b and 6c. (b) Fracture surface and edge of AlN sample 6b. The grain boundaries are sharp and no evidence of penetration by the test media. (c) Higher magnification of fracture surface shown in (b).

of the difficulty of removing all of the Li_2S-S from the pores of the samples. Examination of the samples by optical microscopy and SEM revealed negligible attack at the sample surfaces, and no penetration, except into occasional pores. Figure 11 shows SEM photographs of samples 11b and 11c, which indicate no attack after as much as 6528 hr.

Molten sulfur at 400°C.—One AlN sample was exposed to molten sulfur at 400°C for 2420 hr. No weight change was found, and no attack on the sample could be observed by optical microscopy or SEM.

Molten LiCl with Cl_2 bubbling at 650°C.—These test conditions were intended to represent the environment at the chlorine electrode of a Li/LiCl/Cl_2 cell, which usually operates in the vicinity of 650°C. The AlN samples, numbers 14-16, experienced significant weight loss rates, in the vicinity of 1%/100 hr of exposure. The samples also changed color from gray to white, and the surfaces became chalky.

Considering the thermodynamics of the situation for AlN in contact with Cl_2, the candidate reaction

$$AlN(s) + 3/2\, Cl_2(g) \rightarrow AlCl_3(g) + 1/2\, N_2(g) \quad [2]$$

has a free energy of reaction at 627°C of −315 kJ/mole AlN (10). It is to be expected, then, that $AlCl_3$ and N_2 would form, resulting in a weight loss. The above reaction has been reported to occur at 600°-700°C (11). In addition to reaction [2], it is possible for other reactions to take place, modifying the rate at which reaction [2] would proceed. Two possibilities are

$$AlN(s) + 3/4\, O_2(g) \rightarrow 1/2\, Al_2O_3(s) + 1/2\, N_2(g) \quad [3]$$

$$\Delta G_{627°C} = -473 \text{ kJ/mole } (10)$$

$$2AlN(s) + 3H_2O(g) \rightarrow Al_2O_3(s) + 2NH_3(g) \quad [4]$$

$$\Delta G_{627°C} = -252 \text{ kJ/mole } (10)$$

These reactions are consistent with the observation of a white film on the surface of the AlN. Furthermore, exposure of AlN powder to ambient air results in an ammonia odor.

Conclusions

1. High density AlN (∼99% theoretical) experiences negligible attack (about 0.5 w/o or less) in the strongly reducing environments of molten lithium, or lithium dissolved in LiCl-KCl, or LiF-LiCl-KCl, at 400°C for periods of 1000-10,000 hr.

2. At 650°C, in Li-saturated LiCl, intergranular attack of AlN was observed after 400-1430 hr on samples less dense than those used in the lower temperature work. Further investigation with higher density samples is in order.

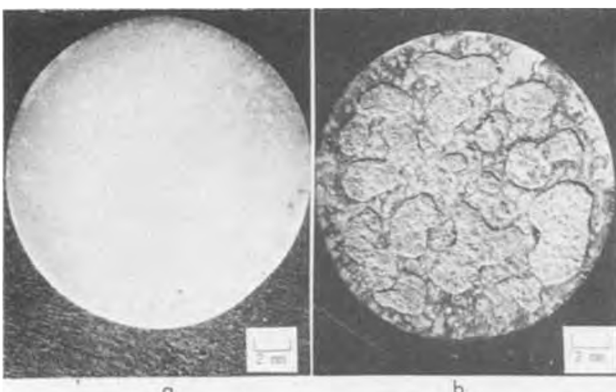

Fig. 9. Photographs of AlN sample. (a) Original sample surface, and (b) sample surface after exposure in Li-LiCl solution for 400 hr at 650°C.

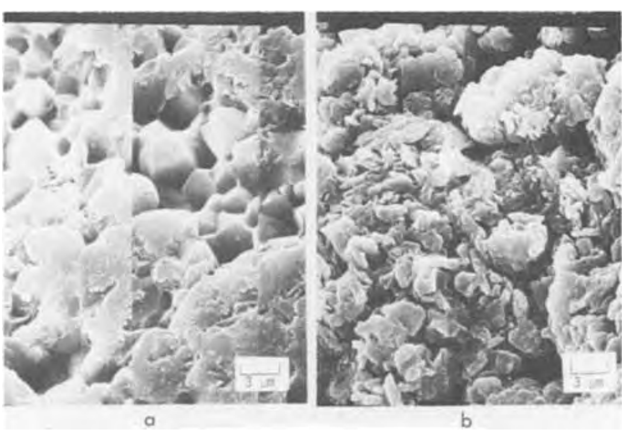

Fig. 10. SEM pictures of AlN sample. (a) Before the test, and (b) after exposure in Li-LiCl solution for 400 hr at 650°C.

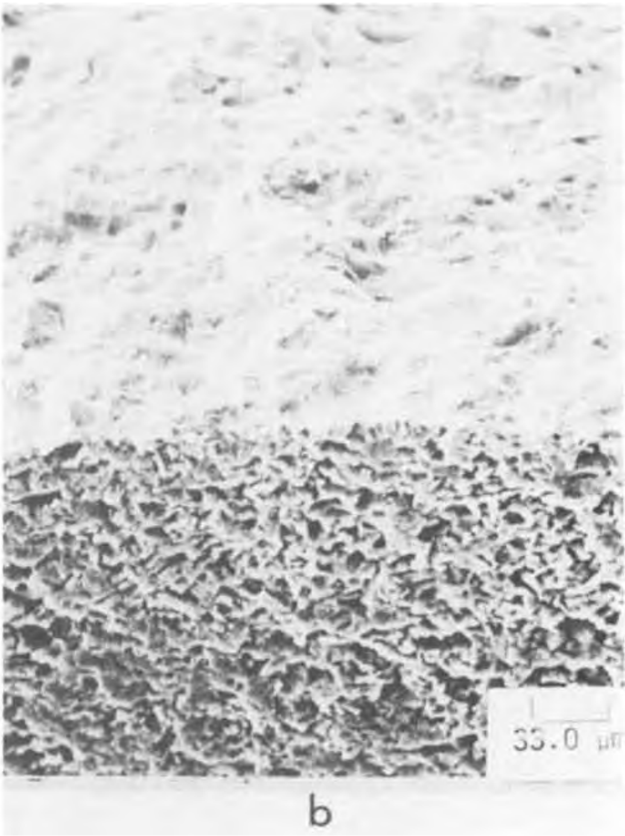

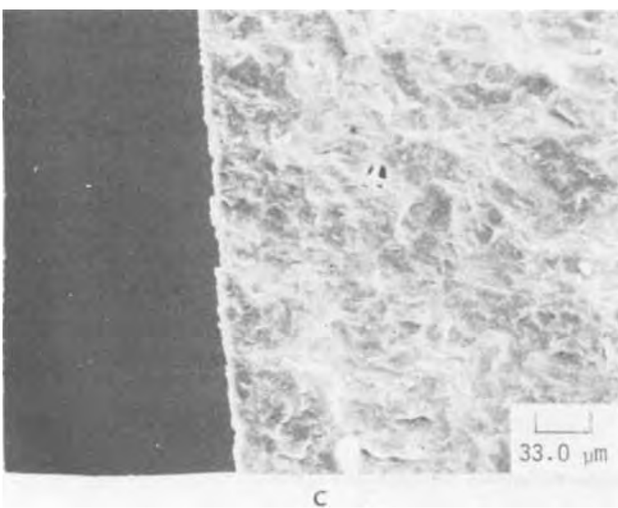

Fig. 11. SEM photographs of AlN samples 11b and 11c after 4128 and 6528 hr, respectively, in Li_2S-S. (a) Exposed test surface of AlN sample 11c. This surface is typical of both samples. (b) AlN sample 11c showing both the exposed test surface and fracture surface. (c) Fracture surface and edge of AlN sample 11c. No penetration is present.

3. No attack (weight loss ≤ 0.28 w/o) was observed on AlN exposed to S or 30 w/o Li_2S-S at 400°C for 1000-10,000 hr.
4. Aluminum nitride is attacked by Cl_2 in LiCl at 650°C, resulting in a weight loss rate of about 1%/100 hr, for periods of 185-1155 hr.
5. Aluminum nitride appears to be a suitable insulator for use in Li/S cells at 400°C.
6. Aluminum nitride is not acceptable at the chlorine electrode and may or may not be acceptable at the lithium electrode in Li/Cl_2 cells at 650°C.

Temperature Dependence of Iron and Cadmium Alkaline Electrodes

Lars Öjefors

Swedish National Development Company, 103 40 Stockholm 40, Sweden

ABSTRACT

The charge and discharge reactions of the alkaline iron and cadmium electrodes go over the soluble intermediates $HFeO_2^-$, FeO_2^-, and $Cd(OH)_4^{2-}$, respectively. The saturation concentrations for these ionic species are rate determining as they directly influence the rates of diffusion and crystallization. By calculating the temperature coefficients for the reactions involved, it is shown that the saturation concentrations for $HFeO_2^-$ and FeO_2^- are highly temperature dependent while this is not the case for the cadmium intermediate. This explains the bad performance of the iron electrode at low temperatures.

The alkaline iron electrode has been used since the beginning of this century, and interest in this electrode material has been maintained due to its high ampere-hour contents (0.96 A-hr/g on the first discharge level), low price, and long life. Other advantages are inexhaustible supply of iron and its energy reserve on the second discharge level.

In spite of these advantages iron has continuously been substituted by cadmium in commercially produced batteries. This depends mainly on three properties: bad performance at low temperature, extensive self-discharge on open circuit, and hydrogen evolution competing with the charge process. The latter two problems depend on an electrode potential more cathodic than what is required for hydrogen evolution and a low hydrogen overvoltage.

Attention is presently again being focused on the alkaline iron electrode as a part of a metal air system for vehicle propulsion. As cadmium active material is expensive, scarce, and causes pollution problems, there are also obvious advantages to replace it with iron in the nickel-cadmium systems. Since 1969 an iron-air battery system has been under development in Sweden jointly carried out by the Swedish National Development Company and Department of Chemical Technology of Royal Institute of Technology, both located in Stockholm.

Previous Works

Iron electrode.—The discharge reactions of the alkaline iron electrode has been the subject of several previous investigations (1-5). These works which have been done with analytical, chemical, and crystallographical techniques show, however, no uniform results according to the products of the discharge processes. The discharged active material has been reported as FeO, $Fe(OH)_2$, Fe_2O_3, Fe_3O_4, FeOOH, and $Fe(OH)_3$.

A voltametric study by Flerov and Pavlova (3) considered the possibility of reactions in dissolved phases, and this has recently been investigated further by Labat *et al.* (5). They explain the discharge reaction by the intervention of the dissolved forms of the divalent and trivalent hydroxides ($HFeO_2^-$ respectively FeO_2^-) which are supposed to be responsible for the slow rate of the electrochemical process. The products are according to x-ray diffraction analysis $Fe(OH)_2$ at the first level, FeOOH and Fe_3O_4 at the second. In normal battery operation only the first "plateau" is being used while the second is not utilized because of its less negative potential although a deep discharge sometimes has a positive effect on the capacity of the electrode.

Recent experimental work using rotating disk electrodes (6) also gives evidence for soluble Fe-intermediates both during the charge and discharge processes.

Cadmium electrode.—Two radically different mechanisms have been proposed in the literature for the anodic oxidation of cadmium: the dissolution-precipitation mechanism (7-13) and the solid-state oxidation mechanism involving ionic transport through a $Cd(OH)_2$-film (14-15). The mechanism of cathodic reduction of $Cd(OH)_2$ has been studied to a much less degree than its anodic counterpart in spite of its importance in the charge process of the battery cadmium electrode (14, 16, 17).

During the last three years the discharge mechanism has been thoroughly studied by Armstrong *et al.* (18) in sintered electrodes and at rotating electrodes by Okinaka (19) and Armstrong *et al.* (20). These investigations give evidence for dissolution-precipitation mechanism which goes over soluble $Cd(OH)_4^{2-}$.

These recent investigations on alkaline iron and cadmium electrodes show that the discharge mechanisms are quite similar and go over soluble intermediates which are precipitated.

Thermodynamic background.—Potential-pH (Pourbaix) diagrams, which present thermodynamic data for metal-water-oxide systems are generally used to interpret results of corrosion experiments (21). They

Key words: iron electrode, solubility of intermediates, temperature dependence.

also give information of the discharge and charge processes of the electrodes. As these alkaline electrodes work in 3-7N KOH solutions which have a pH of more than 14, it can clearly be seen that the electrodes work in the alkaline corrosion areas which are identical to the solubility regions of $HFeO_2^-$ and $Cd(OH)_4^{2-}$ which are supposed to be the soluble species in the Pourbaix diagrams of Fig. 1-4.

Unfortunately the published potential-pH diagrams have been restricted to 25°C, which depends on a lack of thermodynamic data relevant to other temperatures. In order to better define the chemistry of metals and corrosion products in water, thermodynamic studies have been done (22-27) on metals, metal oxides and ions at other temperatures, mainly elevated.

There are two ways of calculating which are in quantitative agreement. One is based on the methods of irreversible thermodynamics, by deBethune *et al.* (22, 28) for calculating the temperature coefficients of the reactions from the ionic entropies of the species involved. The other method uses the "correspondence principle" by Criss and Cobble (29-31) which relates the ionic entropies at 25°C to those at higher temperatures.

The technique used here is determining $\Delta G°$ for a reaction at a temperature T and insert this value in the Nernst equation which gives the half-cell reaction potential for a general chemical reaction in an aqueous system

$$E = E_o - \frac{RT}{z \cdot \mathbf{F}} \cdot \ln \left[\frac{(a_B)^b \cdot (a_{H_2O})^c}{(a_A)^a \cdot (a_{H^+})^d} \right] \quad [1]$$

Since $-\log a_{H^+} = p\text{H}$, $a_{H_2O} = 1$ and $\Delta G^o = -z \cdot \mathbf{F} \cdot E^o$ Eq. [1] will be reduced to Eq. [2]

$$E = -\frac{\Delta G^o}{n \cdot \mathbf{F}} - \frac{2.303 \cdot R \cdot T}{z \cdot \mathbf{F}} \cdot b \cdot \log a_B - a \log a_A - \frac{2.303 \cdot R \cdot T}{z \cdot \mathbf{F}} \cdot p\text{H} \quad [2]$$

The standard free energy change for a reaction at a temperature T is calculated according to Eq. [3]

$$\Delta G^o_T = \Sigma\, \gamma_p \cdot G^o_{T,p} - \Sigma\, \gamma_r \cdot G^o_{T,r} \quad [3]$$

where γ_p and γ_r are the corresponding stoichiometric coefficients.

If heat capacity data are available the free energy of formation of a substance can be calculated by using Eq. [4]

$$G^o_T = G^o_{25} - S^o_{25}\,[T - 298.15] - T \int_{298.15}^{T} \frac{(C^o_p)}{T} \cdot dT + \int_{298.15}^{T} C^o_p \cdot dT \quad [4]$$

Some investigators have assumed that $\Delta C_p = \nu_i G_{Ti} = 0$ in the temperature interval here considered, which essentially simplifies the calculations. Townsend (32) has shown, however, that these calculations are not in as good agreement with experimental data as those when C_P has been estimated. For nonionic substances heat capacity functions are available in literature (Table I), but for ionic ones this is unfortunately not the case. According to MacDonald and Butler (26) Eq. [4] can be transformed into Eq. [5] with an error below 1%

$$G^o_T = G^o_{25} - [T \cdot S^o_T - 298.15 \cdot S^o_{25}] + \frac{T - 298.15}{\ln\left(\frac{T}{298.15}\right)} \cdot [S^o_T - S^o_{25}] \quad [5]$$

The "absolute" entropies S^o_T of the ions are estimated by using the "correspondence principle" by Criss and Cobble (30).

* Calculated from $C_p(FeO)\ C_p(Ca(OH)_2)/C_p(CaO)$.
** Calculated from $C_p(Fe_2O_3)\ C_p(Al_2O_3\ H_2O)/C_p(Al_2O_3)$.
*** Calculated via $S°_{25(abs)} = S°_{25(conv)} - 5.0 \cdot Z$.
**** Calculated by assuming $\log[Cd(OH)_4^{2-}] = -4.5$ at 25°C.

The iron-water system.—For iron there are two systems (21) where alternatively Fe-Fe_3O_4-Fe_2O_3 or Fe-$Fe(OH)_2$-$Fe(OH)_3$ are considered as the only solid substances. At temperatures above 90°C, $Fe(OH)_3$ will convert into well-defined crystals of $FeO(OH)$ which on further heating decomposes to Fe_2O_3. The dihydroxide $Fe(OH)_2$ starts decomposing to Fe_3O_4 at 60°C (the Schikorr reaction). As the electrodes used in this investigation are supposed to work in the temperature interval 0°-60°C the latter of these systems is better suited for studying the charge, discharge, and self-discharge processes.

The chemical species involved in this system are listed in Table I together with thermodynamical data necessary for the calculations.

The following set of equations is used to derive potential-pH diagrams for the iron-water system. Reaction numbers are in accordance with those of Pourbaix (21):

12. $Fe + 2H_2O = Fe(OH)_2 + 2H^+ + 2e^-$

16. $2Fe(OH)_2 + 2H_2O = 2Fe(OH)_3 + 2H^+ + 2e^-$

18. $Fe^{2+} + 2H_2O = Fe(OH)_2 + 2H^+$

19. $Fe(OH)_2 = HFeO_2^- + H^+$

23. $Fe = Fe^{2+} + 2e^-$

24. $Fe + 2H_2O = HFeO_2^- + 3H^+ + 2e^-$

28. $Fe^{2+} + 3H_2O = Fe(OH)_3 + 3H^+ + e^-$

29. $HFeO_2^- + H_2O = Fe(OH)_3 + e^-$

$Fe(OH)_3 = FeO_2^- + H^+ + H_2O$

$HFeO_2^- = FeO_2^- + H^+ + e^-$

a $H_2 = 2H^+ + 2e^-$

b $4\,OH^- = O_2 + 2H_2O + 4e^-$

The cadmium-water system.—For cadmium there are three different oxidation products, namely, CdO, "active" $Cd(OH)_2$, and "inactive" $Cd(OH)_2$. By oxidation in alkaline media "active" $Cd(OH)_2$ is produced which turns into inactive hydroxide by the process of aging (21). Consequently Cd and "active" $Cd(OH)_2$ are considered as the only solid substances. Cd^{2+} and $Cd(OH)_4^{2-}$ are considered as dissolved substances.

Numerical data for the components are listed in Table I.

The following set of equations are used for cadmium-water system:

2. $Cd + 2H_2O = Cd(OH)_2 + 2H^+ + 2e^-$

3. $Cd^{2+} + 2H_2O = Cd(OH)_2 + 2H^+$

4. $Cd(OH)_2 + 2H_2O = Cd(OH)_4^{2-} + 2H^+$

5. $Cd = Cd^{2+} + 2e^-$

6. $Cd + 4H_2O = Cd(OH)_4^{2-} + 4H^+ + 2e^-$

S^o_{25} for soluble intermediates.—Entropy data S^o_{25} can be found in literature (33, 34) for all components except $HFeO_2^-$, FeO_2^-, FeO_2^{2-}, $Cd(OH)_3^-$, and $Cd(OH)_4^{2-}$. For these oxyanions there are two empirical relations available

$$S^o_{25(abs)} = 43.5 - 46.5 \cdot (Z - 0.28\,n) \qquad [6]$$

$$S^o_{25(abs)} = 40.2 + 3/2 \cdot R \cdot \ln M - 108.8 \frac{Z^2}{n \cdot r} \qquad [7]$$

In the first one by Connick and Powell (35) Z is the number of unit charges carried by the ion and n is the number of oxygen atoms excluding those of the hydroxyl groups. By using this relationship S^o_{25} for both $HFeO_2^-$ and $Cd(OH)_3^-$ will be 10.0 cal/mole, °C. The corresponding value for FeO_2^- will be 23.1 cal/mole, °C. The average discrepancy to experimental data is ± 3.7 cal/mole, °C according to the authors.

In the second relationship by Coture and Laidler (36) R is the gas constant and r is the effective iron radius in angstoms, n and Z being the same as before. For the ions considered the value on r is unknown. These radii can be considered as the sum of r_{12} which is the distance between the center of atom and the center of the surrounding oxygen atoms plus 1.40Å, which is the van der Waal radius of oxygen. Consequently r_{12} + 1.40Å represents the radius of a sphere that completely circumscribes the anion. The values on r_{12} can be calculated from the single bond distances Fe-Fe, Cd-Cd, and O-O according to Pauling (37).

Bond length data in (38) give $r_{HFeO_2^-} = r_{FeO_2^-} =$ 2.32Å and $r_{Cd(OH)_4^{2-}} =$ 2.88Å, which inserted in the second relationship give $S^o_{25(abs)}$ data in Table I. The mean deviation against experimental data is declared to be 3.6 eu. For the calculations values from the second relation have been used because it considers the difference in molecular weight.

For all components but FeO_2^-, G^o_{25} data are available in the literature. According to Latimer (43) ferric hydroxide is quite soluble in concentrated alkali with the formation of ferrite ion FeO_2^-. Grube and Gmelin (44) have found in 40% sodium hydroxide solution at 80°C that

$$FeO_2^{2-} = FeO_2^- + e^-; \quad E_{eq} = -0.68V$$

By using the techniques here described for calculating G^o_T for this equilibrium G^o_{25} for FeO_2^- is found to be −84.82 kcal/mole. Thermodynamic data for all components are listed in Table I.

Calculations.—Potential-pH diagrams for 5° and 70°C were calculated on a Compucorp 322 G Scientists by using Eq. [2], [4], and [5]. S^o_T values for ionic species calculated by the correspondence principle (30) are listed in Table II and free energy data for all the components can be found in Table III.

When using the Pourbaix diagrams at different temperatures, consideration must be taken to the change in the dissociation constant of water which strongly influences the pH. The ionic product is exactly $1 \cdot 10^{-14}$ at 24°C and is defined as $k_W = a_{H^+} \cdot a_{OH^-}$. If pH is defined as $-{}^{10}\log(a_{H^+})$ the neutral point will be given by $pk_W/2$.

H_2O	−56.35	−56.68	−57.11	−57.49	

For the temperature levels here considered the following values on the ionic product is given:

Temperature	5°C	25°C	50°C	70°C	80°C
pk_W	14.72	14.00	13.26	12.83	12.65
pH of neutral point	7.36	7.0	6.63	6.41	6.32

In Fig. 1-4 it can clearly be seen that the changes of the diagrams are mainly concentrated to the solubility regions of $HFeO_2^-$ and $Cd(OH)_4^{2-}$.

The saturation concentration in the different cases is given by inserting the pH of 5M KOH at the different temperatures in the log C-pH-relationship where pH for 5N KOH solutions has been calculated from the formulas

$$pOH = -\log[(\gamma_{OH^-,T}) \cdot 5]$$

$$pH + pOH = pk_{W,T}$$

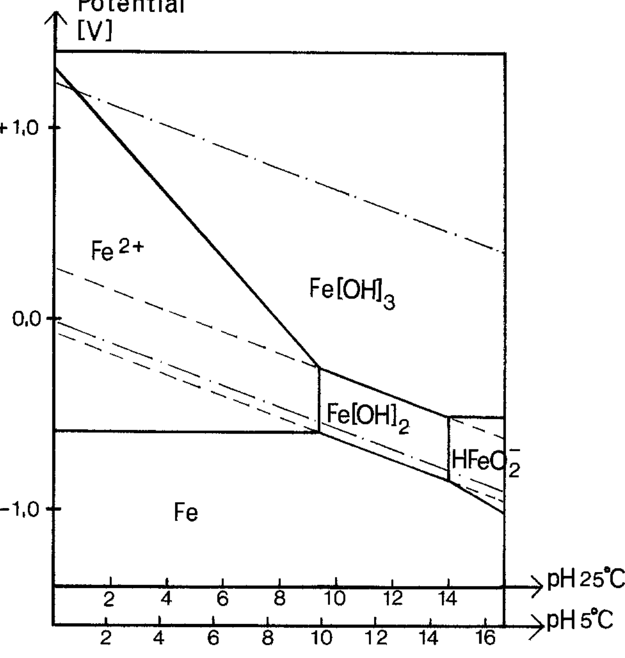

Fig. 1. Potential-pH diagram for iron at 5°C

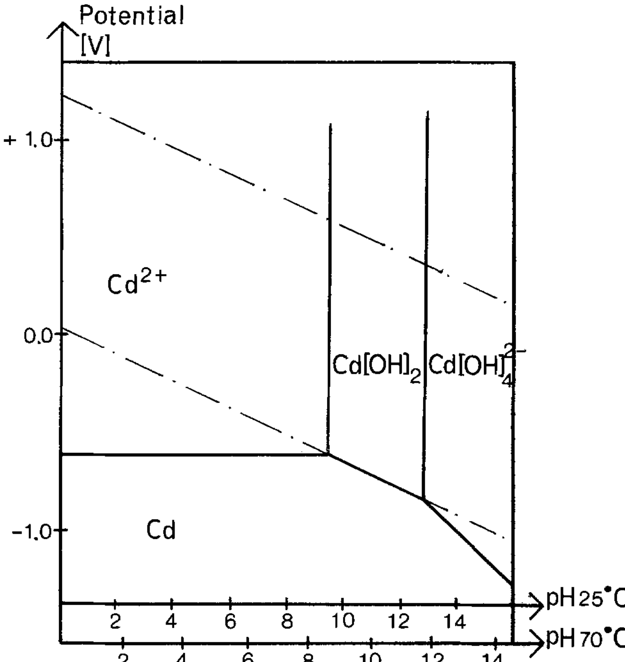

Fig. 4. Potential-pH diagram for cadmium at 70°C

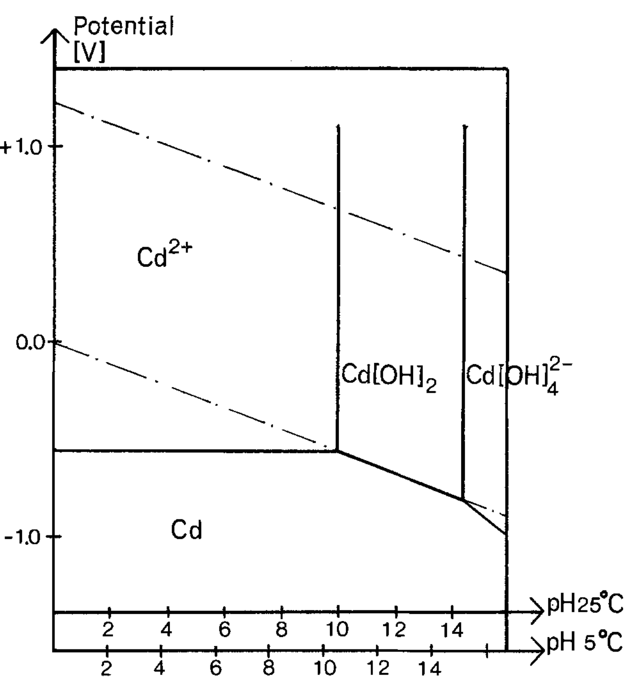

Fig. 3. Potential-pH diagram for cadmium at 5°C

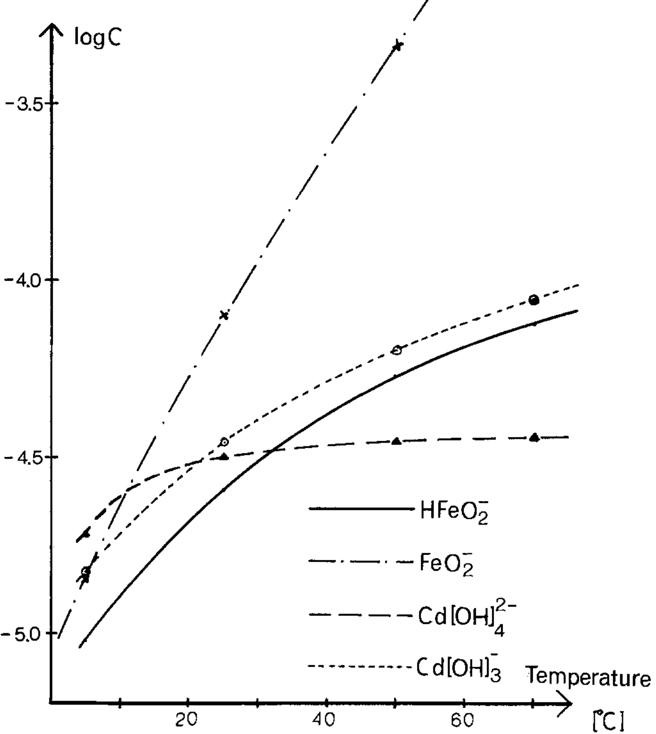

Fig. 5. Calculated solubilities in 5M KOH of Fe and Cd ions at different temperatures.

where $\gamma_{OH^-,T}$ is the active coefficient at the temperature level considered (41). Figure 5 shows that the solubility of $HFeO_2^-$ and FeO_2^- in 5*N* KOH is highly temperature dependent while this is not the case for $Cd(OH)_4^{2-}$.

Relationship between solubility of intermediate and kinetics of porous electrodes.—During discharge the metal will dissolve as $HFeO_2^-$ or $Cd(OH)_4^{2-}$, diffuse through the layers of the discharge products and then precipitate from the supersaturated electrolyte. Vetter (40) has shown for the charge process

$$C_0 > C = K \cdot \frac{I}{D}$$

where *K* is a constant depending on porosity, average pore diameter, and BET-surface of the electrode, *D* is the diffusion constant in the electrolyte, and *I* is current density. Figure 6 gives the concentration symbols. For both processes an increase in C_0 means faster diffusion of the soluble intermediates and less risk for precipitation close to the dissolving center. Also the rate of precipitation increases with C_0. Consequently the value on C_0 directly influences the maximum current density for both the charge and discharge processes.

Experimental

The influence of temperature on current density and capacity of the discharge processes of cadmium and iron electrodes has been investigated by scanning the potential slowly from −1.050 to −400 mV *vs.* Hg/HgO. As the scanning rate is very slow (5.3 mV/min) the

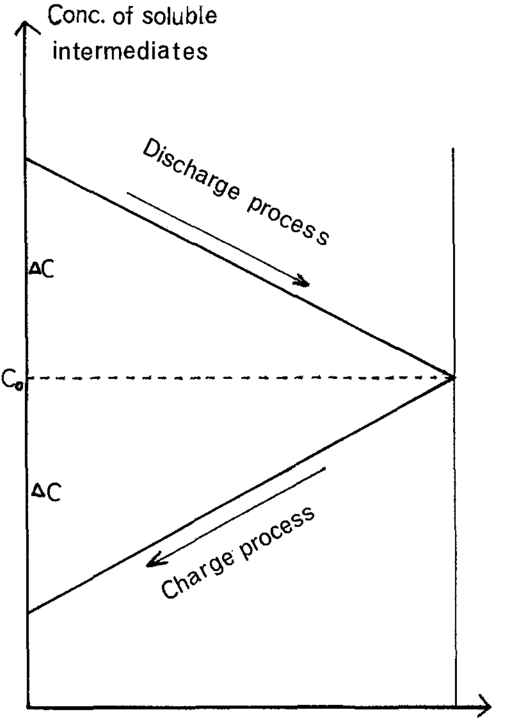

Fig. 6. Concentration of soluble intermediates during charge and discharge.

curves thus obtained are actually those of electrode discharge (Fig. 7-9). If the area under the curve is integrated, it will give the same magnitude of capacity as from constant current discharge during the same time.

As active anode material Jungner Cd and Fe material for pocket electrodes as well as carbonyl iron electrodes from the project mentioned have been used. The latter electrodes were sintered in hydrogen atmosphere (46), 8 mm in diameter, 2.4 mm thick, and weighing 0.32g. As basic material carbonyl iron powder GS 6 from General Aniline & Film Company was used. Two iron nets were incorporated in order to increase mechanical stability and conductivity. The pockets for the Jungner material were 8 mm in diameter and 1

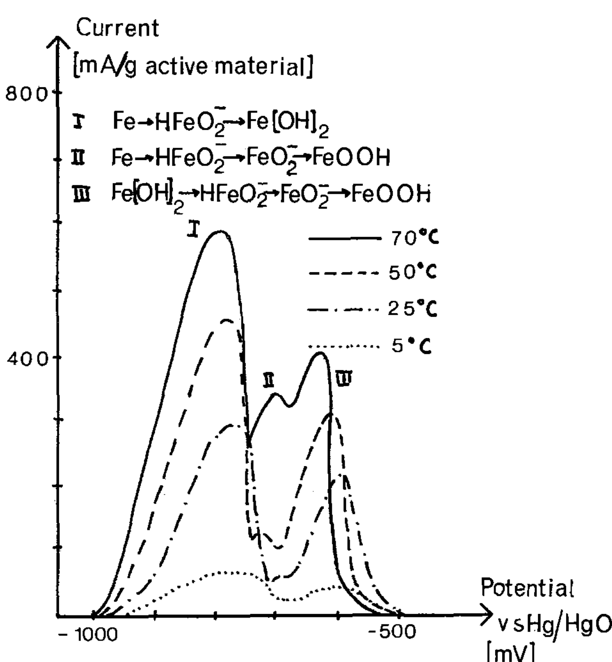

Fig. 7. Potentiodynamic discharge of sintered iron electrode

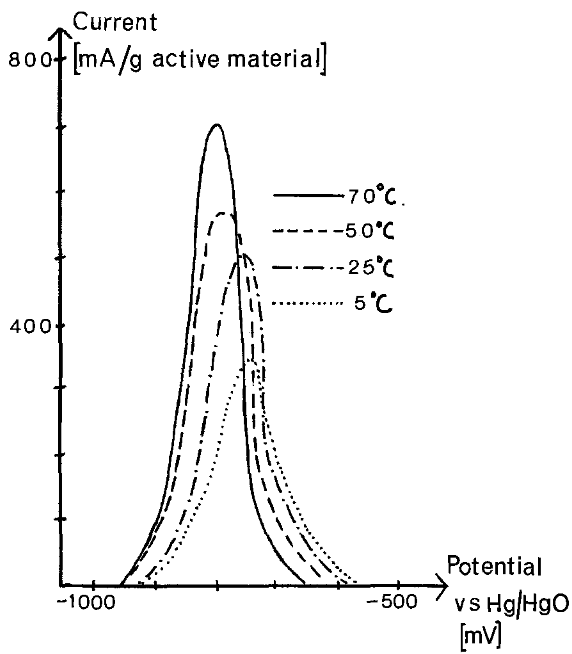

Fig. 8. Potentiodynamic discharge of active Jungner cadmium material.

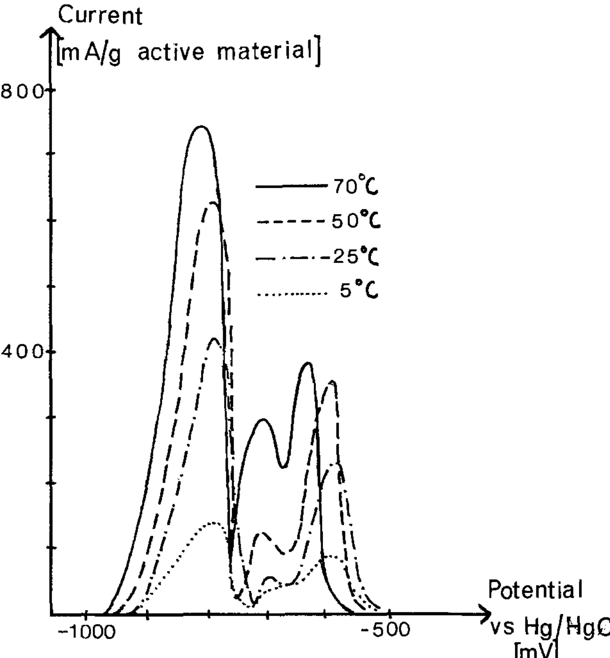

Fig. 9. Potentiodynamic discharge of active Jungner iron material

mm in inner thickness. Before each discharge the electrodes had been discharged and charged to 150% under constant current conditions.

Results

In Fig. 7, 8, and 9 it can clearly be seen that the discharge reactions are favored by higher temperatures and that current densities of the iron electrode are more influenced than those of the cadmium electrode. Especially below 5°C the current density of the iron electrode is very depressed which agrees well with the results of Cnobloch *et al.* (42). It is also evident that the intermediate hump representing direct oxidation of Fe to FeOOH is favored more by temperature than the other reactions.

Discussion

This decrease in capacity and current density for the iron electrode compared to its cadmium competitor

depends evidently on the reported difference in temperature sensitivity for the soluble intermediates. At $C_o < 2 \cdot 10^{-5}N$ this effect seems to have an essential influence on the electrode performance, a fact that is in good agreement with (40). The increased rate for the direct oxidation with temperature can also be explained with Fig. 5 since the saturation concentration for FeO_2^- is probably so low that the reaction of the second anodic step must mainly go via migration of ions and electrons in the solid phase. The rapid increase for this concentration with temperature makes it possible to directly oxidate Fe to FeOOH in dissolved phases. The absolute level for the FeO_2^- line in Fig. 5 might be too high due to uncertainty in the free energy value but this does not influence the actual temperature dependence which is the important factor for these discussions.

The solubility of $Cd(OH)_2$ as a function of KOH concentration and temperature has been investigated by Lake and Goodings (39). These results show, however, higher solubilities at temperatures above 25°C in comparison with our calculations for $Cd(OH)_4^{2-}$, but are in good agreement at lower temperatures. As shown in Fig. 5 the solubility of $Cd(OH)_3^-$, which probably is the more stable intermediate at higher temperatures, is much higher compared to $Cd(OH)_4^{2-}$ in this region. This explains the experimental results of (39) which, according to Armstrong *et al.* (45), are difficult to interpret rigorously due to the possibility of large errors in estimating liquid-junction potentials.

The only published data on the solubility of ferrous hydroxide in alkali is that 1.375*N* NaOH will dissolve $7 \cdot 10^{-5}$ g-equiv. $Fe(OH)_2$ per liter at 20°C (43). At 80°C in 40% NaOH-solution the solubility of FeO_2^- is determined by (44) to 1.5 g/liter which is equal to 2.7 g-equiv./liter. This corresponds well to the values calculated for FeO_2^-.

These calculations also show that the solubility of the intermediates is highly *p*H dependent. In (47) it is shown that capacity decreases at room temperature when the electrolyte concentration is lowered from 6 to 3*N*. This means a decrease in *p*H with about 0.25 units corresponding to a change in log $HFeO_2^-$ from -4.5 to -4.75 at 25°C. Also smaller average pore diameter, increasing thickness, and shielding armor nets have a negative effect on the discharge process due to a higher deficit of OH^-.

These experiments (47) also show that 250g of K_2CO_3 must be added to every liter electrolyte to get a noticeable decrease in capacity during the first cycle. This effect depends on decrease in *p*H. However on continued cycling the electrodes become sluggish and capacity decreases also at lower carbonate concentrations.

Surface Stress Curves for Gold

K. F. Lin* and T. R. Beck**

Department of Chemical Engineering, University of Washington, Seattle, Washington 98195

ABSTRACT

Changes in surface stress of gold ribbon electrodes as a function of potential were measured in various electrolytes with an extensometer instrument. Electrocapillary-type curves were obtained for which the change in surface stress can be equated to change in surface tension. As for mercury, the potential of the surface stress maximum for gold is independent of pH. The observed anion adsorption order on gold was $I^- > Br^- > Cl^- > OH^-$, ClO_4^-, $NO_3^- > SO_4^=$. Experimental surface stress data and charge passed gave approximate agreement with the Lippmann equation in the electric double layer region. Formation of oxide film significantly lowered the surface stress.

Much of what is known about the metal-electrolyte interface derives from measurements made with mercury. A number of review papers have been published describing this work (1-5). One of the important measurements is change in interfacial tension with potential using the Lippmann capillary electrometer. The curve of the interfacial tension against the applied potential is called the electrocapilllary curve. For an ideal polarized electrode, the slope of the electrocapillary curve is equal to the charge density on the electrode with the sign reversed. It follows that the charge is zero at the electrocapillary maximum. Potential of zero charge can be determined in several ways: by electrocapillary methods, capacitance methods, mechanical properties, adsorption, etc. (6). Recently methods have been developed to measure electrocapillary-type curves for solid metals (7-10).

Important differences between mercury and solid metals relevant to measurement of changes in interfacial tension are: (*i*) Mercury is a liquid at room temperature and absolute values of its interfacial tension can readily be measured by means of the pressure required to force it through a capillary of given diameter. (*ii*) The rigidity of a solid metal lattice resists changes in surfaces stress requiring an extremely sensitive measurement with a specimen of small cross section. (*iii*) Mercury is atomically smooth while solid metals have grain boundaries and surface roughness. (*iv*) Clean new surfaces can be easily generated for mercury while unrenewable surfaces with increasing contamination is a severe problem with solid metals. (*v*) Mercury has a wide potential range with ideal polarization, *i.e.*, a region free of faradaic reactions. Many of the solid metals are complicated by formation of oxide, hydride, or other compounds.

Extensometer Instrument

An extensometer instrument (7, 11) provided a promising new means to measure change in surface stress. The change in surface stress with potential causes a change in length of a ribbon, working electrode, which is determined with a sensitive extensometer head. A diagram of the instrument is given in Ref. (7). In the present case, thin gold ribbons were used as both working electrode and counterelectrode. The working electrode is held under slight tension by attachment to a spring-loaded quartz rod in the extensometer head. Both electrodes and electrolyte were contained in a cell of 1.3 cm ID by 58 cm length glass tube.

The relationship between change in surface stress and change in ribbon length is given by[1]

$$\Delta\sigma_s = -(AE/PL)\Delta L \qquad [1]$$

The derivation of Eq. [1] is given in Appendix A.

Surface stress is related to surface free energy (surface tension) by the Shuttleworth equation (12, 13)

$$\sigma_s = \gamma + \frac{d\gamma}{d\epsilon_s} \qquad [2]$$

For liquids, surface stress is equal to surface free energy, *i.e.*, the second term on the right-hand side of Eq. [2] is zero. For solids, surface stress is not generally equal to surface free energy. It can be shown, however, that the design of the extensometer gives a constant second term on the right. The change in surface stress is therefore equal to the change in surface free energy (see Appendix B)

$$\Delta\sigma_s = \Delta\gamma \qquad [3]$$

The instrument measures only the change in surface stress, not the absolute value.

The extensometer head measures the change in ribbon length by comparing a pair of differential capacitors formed between a grounded aluminum bobbin attached to the quartz rod and two axially mounted annular aluminum plates insulated from the head frame wih Teflon holders. The capacitors are balanced by vernier screw adjustment of the annular Teflon holders. The pair of differential capacitors is connected to the input of a Decker Model 906 Delta unit. This instrument develops a d-c potential, across the terminals of a radio-frequency excited neon tube, that is directly proportional to the position of the bobbin (14). The output voltage is thus a measure of change in ribbon length. The length calibration relating voltage to change in surface stress of the ribbon has been described (7). The Decker instrument was modified by placing a quieter, solid-state, Analog 40A operational amplifier in place of the original tube-type amplifier between the neon tube and the plotter.

The extensometer produces an output voltage $V_{\Delta L}$ proportional to the length change ΔL by a capacitance sensor connected to two capactiances c_1 and c_2 (15)

$$V_{\Delta L} = K_1\left(\frac{1}{c_1} - \frac{1}{c_2}\right) = K_2\Delta L \qquad [4]$$

This linear relationship between output voltage and incremental extension was confirmed by hanging known weights on the bottom of the glass tube, which was supported by its upper end, and measuring the voltage output corresponding to the stretch. The stretch is given by

$$\Delta L_t = L_t W/A_t E_t \qquad [5]$$

The stretch is transmitted through the ribbon to the capacitance sensor which reads out a potential.

Key words: electric double layer, Lippmann equation, adsorption, oxide film, electrocapillary curves.
[1] The list of symbols is given at the end of paper.

A typical calibration curve is shown in Fig. 1. The sensitivity of the extensometer was found to be dependent on the average spacing $d = (d_1 + d_2)/2$, where d_1 and d_2 are, respectively, the spacing of the upper and lower capacitors. This dependence is shown in Fig. 2.

Experimental

Electrolyte solutions prepared from ACS specification, reagent-grade chemicals and reverse-osmosis purified water were used in most of the experiments of this paper.

A continuous circulating-electrolyte purification system, as diagrammed in Fig. 3, was used for final cleanup of K_2SO_4 solutions used in the experiments relating to tests with the Lippmann equation. The electrolyte, stored in a 3000 ml three-neck flask, was

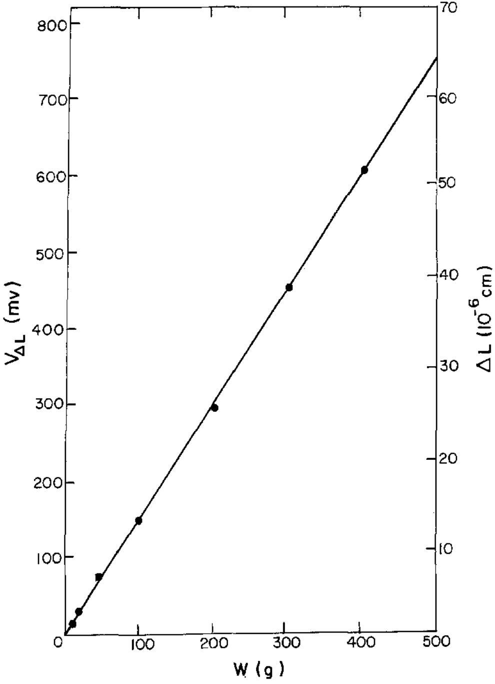

Fig. 1. Typical calibration curve of the extensometer

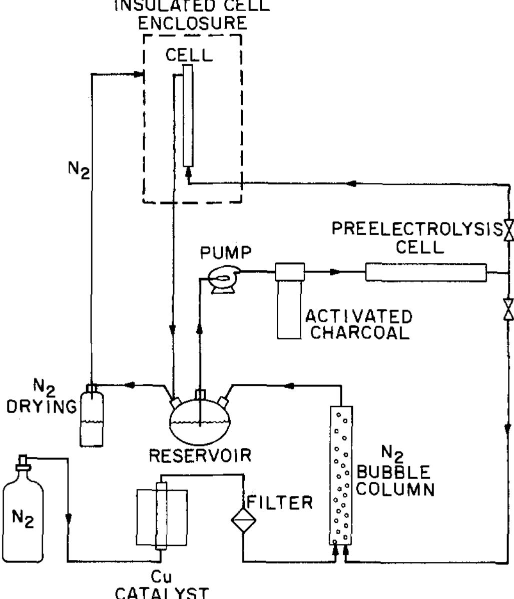

Fig. 3. Electrolyte purification system

pumped by a Teflon pump (Saturn Model SP4000) through a commercially available Millipore carbon bed to adsorb organic impurities from solution. The solution then passed through a (2 cm ID, 55 cm length) preelectrolysis cell, which was employed to remove heavy metal ions. Some organic material could also be oxidized on the anode surface. Gold ribbon electrodes were used to avoid contamination by metals other than gold. The solution was deaerated by bubbling oxygen-free nitrogen through a 5 cm ID by 60 cm length glass tube. All of the tubing in the system was either glass or Teflon. The solution was circulated for at least 5 days before using in the experiment.

Effluent nitrogen from the purification system was passed over concentrated sulfuric acid in a drying bottle to decrease its dew point. This nitrogen was used as inert atmosphere in the insulated box surrounding the extensometer instrument.

The equation for change in concentration of ions deposited in the preelectrolysis cell is

$$C = C_o \exp\left[-\frac{\tau a D}{V\delta}\right] \quad [6]$$

The diffusion layer thickness was estimated to be 6.0×10^{-3} cm from decay of current after an impulse input of Cu^{++} ion. A constant 1.7V was applied to the cell. This was a maximum potential that could be used yet avoid significant hydrogen and oxygen contamination.

The electrolyte purification has been applied to the 0.1M K_2SO_4 solution only in the presently reported experiments. Prior to installation in the extensometer, gold ribbons were washed with acetone to remove organic material on the surface. Before the extensometer was filled with electrolyte, it was cleaned with concentrated nitric acid and thoroughly rinsed in reverse osmosis water. Experimental data were taken after approximate steady-state temperature was reached in the experimental box. At least half an hour was required so that the expansion due to thermal drift became negligible.

A saturated calomel reference electrode was used in the experiments. All potentials were converted to standard hydrogen electrode (V_{SHE}) by adding 0.24V.

Results and Discussion

Gold has a wide range of potential for its electric double layer region as for mercury. It is therefore an appropriate solid metal for initial electrocapillary studies.

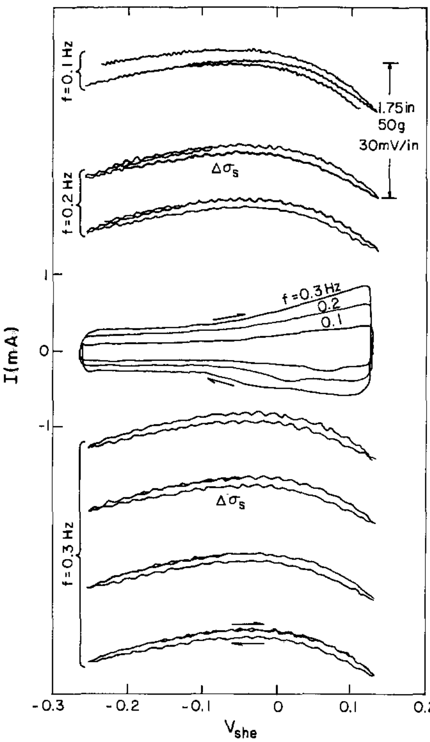

Fig. 4. Surface stress curves (with oscillations) and cyclic voltammograms in 0.1M K_2SO_4 with various sweeping frequencies.

Electrocapillary curve.—Figure 4 shows current and surface-stress data at three sweep frequencies (f = 0.1, 0.2, and 0.3 Hz).[2] The potential was limited to the vicinity of surface stress maximum. The oscillations in surface stress curves were due to vibration in the system (11). For f = 0.1 Hz, the first run, steady-state temperature had not been reached in the experimental cell so that the surface stress curve did not close after one complete cycle. For f = 0.2 and 0.3 Hz, run subsequently, thermal drift became negligible and surface stress curves closed. The source of surface stress hysteresis in the electric double layer region is not known.[3] The procedure of data processing was to take 4 to 6 curves at a given frequency and average to minimize noise. A least squares polynomial was then fitted to the average data.

The stretch of the glass tube due to hanging a 50g weight is seen to give an average 1.75 in. deflection at the scale of 30 mV/in. at the right of Fig. 4. This stretch, calculated from Eq. [5] with L_t = 46.5 cm, W = 50g, A_t = 0.55 cm², and $E_t = 6.4 \times 10^8$ g/cm², was 6.6×10^{-6} cm. A 1-in. deflection in Fig. 4 would therefore correspond to an actual differential length change of 3.77×10^{-6} cm. With $A = 4.8 \times 10^{-4}$ cm², $E = 7.93 \times 10^{11}$ dyne/cm², P = 0.635 cm, and L = 56.5 cm for the gold ribbon, Eq. [1] gives the magnitude of surface stress change as $\Delta\sigma_s$ = 40 dyne/cm/in. deflection in Fig. 4.

Oxide film effect.—Figure 5 shows the surface stress curve and the cyclic voltammogram with 0.1M K_2SO_4 solution of pH 3.6. In the potential range shown, three regions were covered, *i.e.*, hydrogen evolution, electric double layer (EDL), and oxide formation. No hysteresis or change in slope of the surface-stress curve was observed in the hydrogen region. Hydrogen is reported to be neither absorbed on nor dissolved in gold to an appreciable extent (17, 18). The surface stress hysteresis observed on the anodic side was mainly due to the formation and dissolution of oxide film. The oxidation process has been reported as highly irreversible (19, 20).

[2] The convention of plotting increasing positive potentials to the right as is common for electrode kinetics data (16) is used instead of the usual convention for electrocapillary data for mercury (3).

[3] Irreversible adsorption or surface penetration by some species and change of the surface elastic modules, E_s in Eq. [A-7] are possible causes.

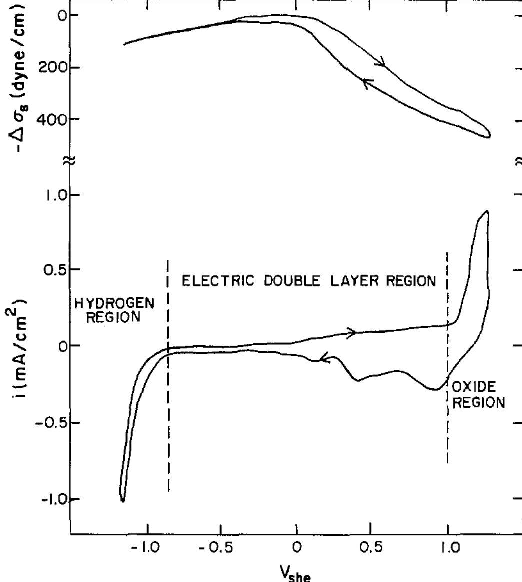

Fig. 5. Surface stress curve and cyclic voltammogram in 0.1M K_2SO_4 + $10^{-4}N$ H_2SO_4, pH = 3.6, f = 0.1 Hz.

The effect of formation of oxide film can be studied by limiting the span to the EDL and the oxide regions. Figure 6 for 1M $HClO_4$ shows that where anodic oxidation started at I, there was a corresponding increase in surface stress deflection. The ratio of charge under the anodic to the cathodic curve is close to unity. The flat plateau anodic current without peaks prior to I, indicates good purity of the electrolyte (19).

A charge density of 0.45 mcoulombs/cm² corresponds to a monolayer of oxide on a gold surface (20). Oxide coverage, calculated from the areas under the current curves is shown in Fig. 7 for both sweep directions. Almost complete removal of oxide is seen on the cathodic sweep. At a fixed potential, hysteresis in surface stress

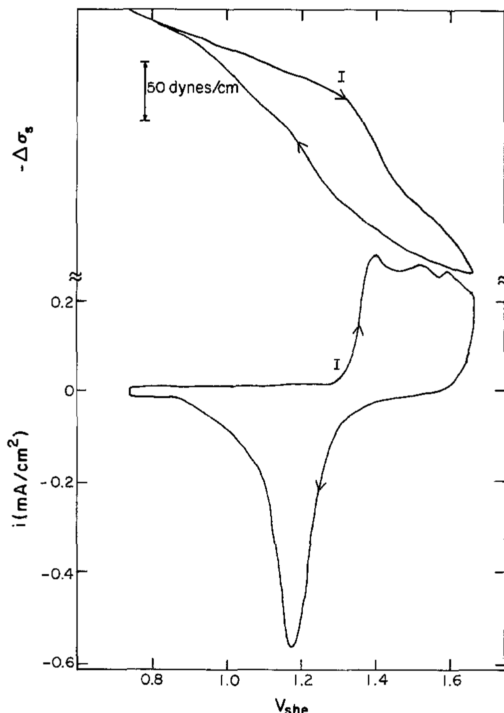

Fig. 6. Surface stress curve and cyclic voltammogram in 1M $HClO_4$, f = 0.1 Hz.

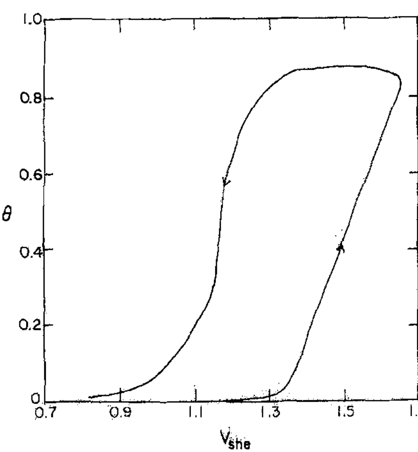

Fig. 7. Oxide coverage in anodic and cathodic sweeps as a function of potential in 1M $HClO_4$, $f = 0.1$ Hz.

and oxide coverage between anodic and cathodic sweeps could be read from Fig. 6 and 7. The maximum difference in oxide coverage occurred at $1.34V_{SHE}$ and corresponded to a maximum difference in surface stress between anodic and cathodic sweeps in Fig. 6.

Effect of pH.—The potential of surface stress maximum ϕ_m as a function of pH is shown in Fig. 8. It is seen that ϕ_m is independent of pH as it is for mercury. Noniski and Lazarova (21) using a scraping technique on gold observed the same behavior for the point of zero charge (pzc), but at high pH, they found that the pzc became linearly dependent on pH.

Effect of surface active anions.—Figure 9 shows plots of surface stress in the anodic sweep with potassium salt solutions of various anions. All curves were made coincident at the negative branch by sliding them along the surface stress axis. The slopes of the curves were identical where they overlapped as for mercury (1).

Table I gives data of ϕ_m and ϕ_{pzc} with solutions of different anions. For mercury the order of adsorption according to increasing pzc and decreasing amount of adsorbed ions is (22-25) $I^- > Br^- > ClO_4^- > Cl^- > OH^- > SO_4^= > F^-$ while for gold it appears that

I^-	−0.74	−0.53	−0.47	−0.46

(a) Present method.
(b), (c) Scraping method.
(d) From integration of capacity data.

$I^- > Br^- > Cl^- > OH^-, ClO_4^-, NO_3^- > SO_4^=$. The following adsorption orders were reported for gold in literature (21, 26) $I^- > Br^- > OH^- > Cl^- > SO_4^= > ClO_4^- > F^-$ and (29) $Br^- > Cl^- > SO_4^= > ClO_4^-$. The reason for the generally more negative values of ϕ_m compared to other reported values of ϕ_{pzc} in Table I remains to be determined. After careful solution purification, ϕ_m did not change with anodic or cathodic prepolarization.

For the strongly adsorbed ions, I^- and Br^-, plateaus in surface stress curves are seen at about −0.36 and $0.14V_{SHE}$, respectively, in Fig. 9. The plateau corresponded to a region of potential associated with a peak at II in the current curve shown in Fig. 10 for I^-. This peak was reversible, as can be seen from the near coincidence in the anodic and cathodic sweeps. The increase in current at III could be due to the reactions $2I^- = I_2 + 2e^-$, or $I^- + Au = AuI + e^-$ (30).

Lippmann equation.—For an ideal polarized electrode, the interfacial tension is related to potential by the Lippmann equation (1)

$$\left[\frac{\partial \gamma}{\partial \phi}\right]_{\mu,T,p} = -q \qquad [7]$$

where q is charge density on the electrode.

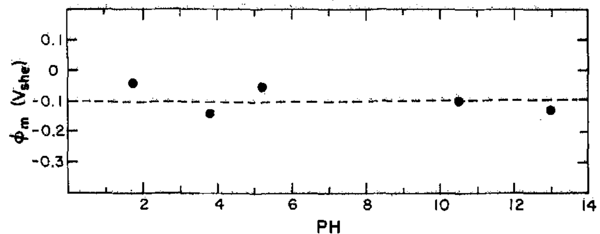

Fig. 8. Effect of pH on the potential of surface stress maximum in 0.1N K_2SO_4.

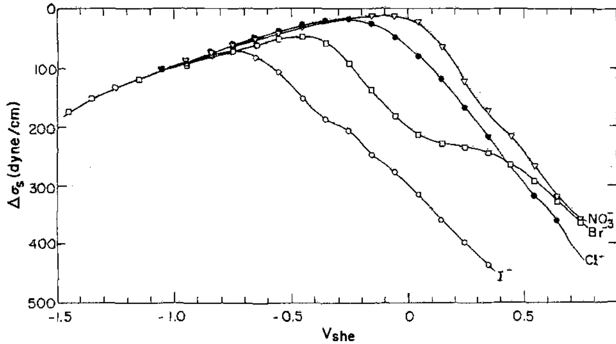

Fig. 9. Surface stress curves for different ions in 0.1N potassium salt, gold electrode anodic sweep.

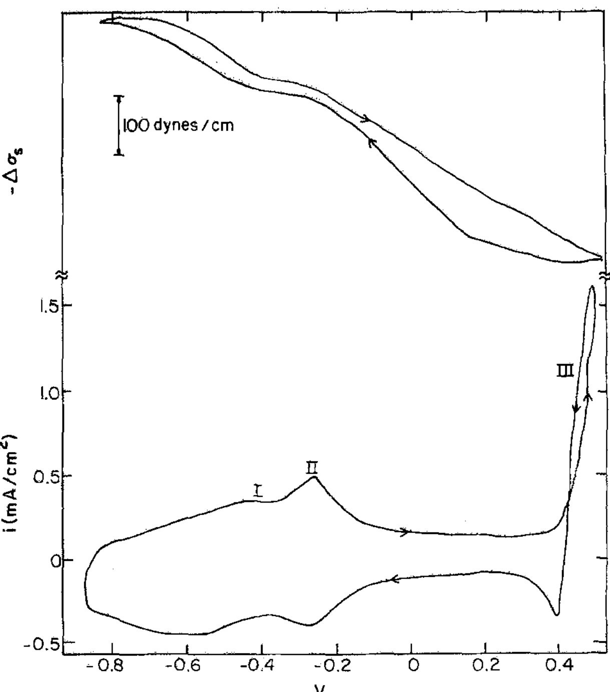

Fig. 10. Surface stress curve and cyclic voltammogram in 0.1N KI, $f = 0.2$ Hz.

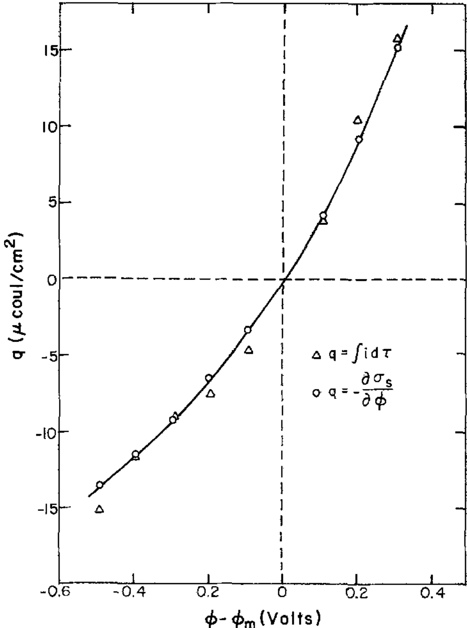

Fig. 11. Charge density as a function of potential in 0.1M K_2SO_4 in electric double layer region.

At the surface stress maximum, charge density is equal to zero. Figure 11 shows the comparison of charge density for a fresh gold electrode in 0.1M K_2SO_4 purified in the system of Fig. 3. One of the charge density curves was obtained from the numerical integration of current data in Fig. 12, starting from potential of surface stress maximum. The other was through Eq. [7] and numerical differentiation of a least squares fitted polynomial of eighth degree to the surface stress data in Fig. 12. Figure 11 shows remarkable check of the Lippmann equation in the electric double layer region for gold, despite more experimental difficulties associated with gold than with mercury. Thus for a first approximation, for gold, the assumptions made in the derivation in Appendix A appear to be justified. The experimental data also agreed with the Lippmann equation in the cathodic sweep. The Lippmann equation had been confirmed with mercury-electrolyte interface by Grahame (1). Surface roughness was assumed to be unity. A SEM photo of gold ribbon at magnification factor of 6000 showed a smooth surface.

Deviation from the Lippmann equation occurs after a number of runs, probably due to the "cycling" effect for the gold electrode (31, 32) or adsorption of impurities. Deviation from the Lippmann equation would also be expected for oxide film or hydrogen evolution and other faradaic reactions. The general Lippmann equation has been derived for a reversible redox system (33). However, there has not been any theoretical relationship for an irreversible system.

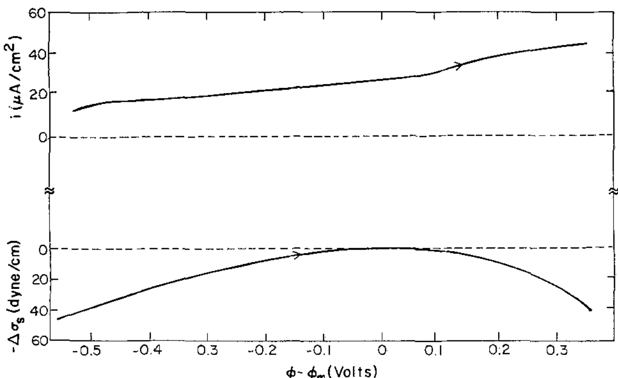

Fig. 12. Surface stress and current data in 0.1M K_2SO_4

Conclusions

The following conclusions can be reached from the study of surface stress of gold.

1. The measured change in surface stress can be shown to be equal to the change in surface free energy.
2. The observed adsorption order of anions based on the potential of the surface stress maximum is $I^- > Br^- > Cl^- > OH^-$, ClO_4^-, $NO_3^- > SO_4^{=}$.
3. Formation of a gold oxide (or hydroxide) film tends to lower the surface stress.
4. For weakly adsorbed ions the potential of the surface stress maximum is independent of pH.
5. Measured change in surface stress and integrated charge density are in agreement with the Lippmann equation in electric double layer region for a new ribbon in a carefully purified system.

APPENDIX A

Derivation of Eq. [1]

Suppose an unstressed metal ribbon and a spring are each attached to respective ends of a tube such that there is a gap ΔL_o between them, as shown in Fig. 13, initial condition 1. Assume the tube is very stiff so that it does not change dimension. The ribbon and spring are stretched to connect their free ends, stretched condition 1. The ribbon is stretched by ΔX_1 and the force on the ribbon and spring is then

$$F_1 = m_r \Delta X_1 = m_s (\Delta L_o - \Delta X_1)$$

in which $m_r = EA/L$. Eliminating ΔX_1, gives

$$F_1 = \frac{m_r m_s \Delta L_o}{m_r + m_s}$$

Going back to the original unstretched condition (Fig. 13) the ribbon is increased in length by an amount ΔL due to a change of the applied potential in the experiment, initial condition 2. This decreases the gap by ΔL. Suppose the ribbon and spring are again stretched to connect their free ends, stretched condition 2. The ribbon is stretched by ΔX_2 and the new force on the ribbon and spring is

$$F_2 = m_r \Delta X_2 = m_s (\Delta L_o - \Delta L - \Delta X_2)$$

(Since ΔL is very small, the spring constant of the

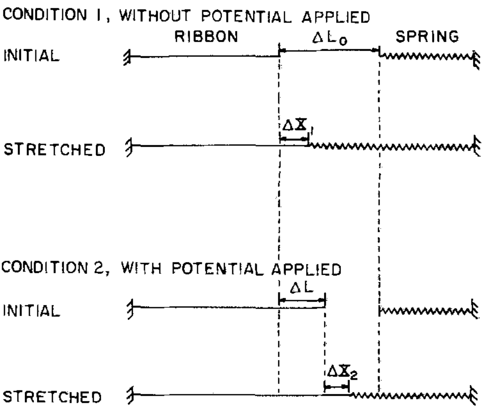

Fig. 13. Schematic diagram of the spring and ribbon system

ribbon is assumed to remain constant after the change in length, ΔL.) Eliminating ΔX_2 gives

$$F_2 = \frac{m_r m_s (\Delta L_o - \Delta L)}{m_r + m_s}$$

The change in force due to the increase in length, ΔL, is then

$$\Delta F = F_2 - F_1 = \frac{-m_r m_s \Delta L}{m_r + m_s}$$

The instrument is designed so that $m_r >> m_s$, giving

$$\Delta F \approx -m_s \Delta L \quad [A\text{-}1]$$

The force balance between the ribbon and spring is shown in Fig. 14. The length of the abscissa is ΔL_o for the initial condition 1 in Fig. 13.

The assumption will be made that the force on the ribbon is resisted by separable bulk and surface stresses, σ and σ_s, respectively. The surface stress is assumed to be in a region of atomic thickness on the surface of the metal. Therefore

$$F = \sigma A + \sigma_s P$$

and

$$\Delta F = \sigma \Delta A + A \Delta\sigma + \sigma_s \Delta P + P \Delta\sigma_s \quad [A\text{-}2]$$

By Hooke's law

$$\Delta\sigma = E \frac{\Delta L}{L} \quad [A\text{-}3]$$

It is assumed that the bulk elastic modulus, E, is unchanged by potential applied to the ribbon, *i.e.,* no lattice penetration occurs.

The change in area is

$$\Delta A = (t + \Delta t)(w + \Delta w) - tw$$

By Poisson's law

$$\frac{\Delta t}{t} = -b \frac{\Delta L}{L}$$

and

$$\frac{\Delta w}{w} = -b \frac{\Delta L}{L} \quad [A\text{-}4]$$

Therefore

$$\frac{\Delta A}{A} = \left(1 - b\frac{\Delta L}{L}\right)^2 - 1 \approx -2b\frac{\Delta L}{L}$$

(neglecting the square term) [A-5]

From Eq. [A-3] and [A-5]

$$\left| \frac{\sigma \Delta A}{A \Delta\sigma} \right| = \frac{2b\sigma}{E} \to 0$$

(since the bulk strain σ/E is very small), or

$$A\Delta\sigma >> \sigma\Delta A \quad [A\text{-}6]$$

An elastic modulus, E_s, is assumed for the atomic layer on the surface of the ribbon. It is assumed to be constant although it may be affected by adsorbed atoms or ions on the surface and penetration of atoms into the surface layer. Then

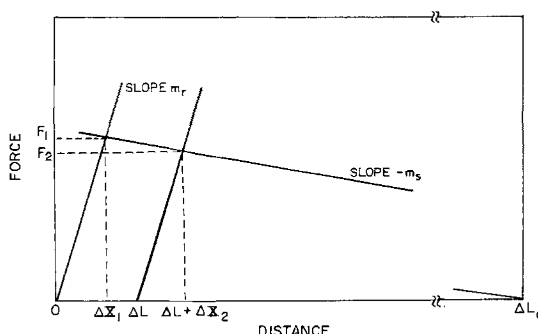

Fig. 14. Force equilibrium in the ribbon and spring system

$$\Delta\sigma_s = E_s \frac{\Delta L}{L} \quad [A\text{-}7]$$

and

$$P \approx 2w \, (w >> t)$$

Therefore

$$\frac{\Delta P}{P} = \frac{\Delta w}{w} = -b\frac{\Delta L}{L} \quad [A\text{-}8]$$

From Eq. [A-7] and [A-8]

$$\left| \frac{\sigma_s \Delta P}{P \Delta\sigma_s} \right| = \frac{b\sigma_s}{E_s} \to 0$$

(since the surface linear strain σ_s/E_s is very small), or

$$P\Delta\sigma_s >> \sigma_s \Delta P \quad [A\text{-}9]$$

From Eq. [A-1], [A-2], [A-6], and [A-9]

$$\Delta F \approx A\Delta\sigma + P\Delta\sigma_s \approx -m_s \Delta L$$

But

$$A\Delta\sigma = AE\frac{\Delta L}{L} = m_r \Delta L \text{ and } m_r >> m_s$$

$$\therefore A\Delta\sigma + P\Delta\sigma_s \approx 0$$

and

$$\Delta\sigma_s \approx -\frac{AE}{PL}\Delta L \quad [A\text{-}10]$$

which is Eq. [1] in the text.

APPENDIX B

Derivation of Eq. [3]

Write Eq. [1] in differential form

$$d\sigma_s = -\frac{AE}{P} d\epsilon \quad [B\text{-}1]$$

where $d\epsilon$ is the differential linear strain (dL/L). Integrating Eq. [B-1]

$$\sigma_s = c_1 - \frac{AE}{P}\epsilon \quad [B\text{-}2]$$

where c_1 is an integration constant.

For a long, thin ribbon, the total surface area S is approximated by

$$S \approx 2wL \quad [B\text{-}3]$$

From Eq. [A-4] and [B-3], the differential surface strain is given by

$$d\epsilon_s = \frac{dS}{S} \approx (1 - b)\, d\epsilon \quad [B\text{-}4]$$

From Eq. [2], [B-2], and [B-4]

$$\frac{d\gamma}{d\epsilon} + (1-b)\gamma - (1-b)\left(c_1 - \frac{AE}{P}\epsilon\right) = 0 \quad [B\text{-}5]$$

The solution is

$$\gamma = c_1 + \frac{AE}{P(1-b)} - \frac{AE}{P}\epsilon + c_2 e^{-(1-b)\epsilon}$$

$$= \sigma_s + \frac{AE}{P(1-b)} + c_2 e^{-(1-b)\epsilon}$$

where c_2 is an integration constant

For $\epsilon \to 0$

$$\gamma = \sigma_s + \frac{AE}{P(1-b)} + c_2$$

Then

$$\Delta\gamma = \Delta\sigma_s \quad [B\text{-}6]$$

which is Eq. [3] in the text.

LIST OF SYMBOLS

A — cross-sectional area of the gold ribbon in the extensometer, cm^2

A_t — cross-sectional area of the glass tube in the extensometer, cm^2

a	surface area of gold ribbon cathode (or anode) in the preelectrolysis cell, cm^2
b	Poisson's ratio, usually between 1/3 and 1/4
C	concentration of reducible (or oxidizable) impurity, $mole/cm^3$
C_o	initial concentration of reducible (or oxidizable) impurity, $mole/cm^3$
c_1	capacitance of the upper capacitor, farad, or an integration constant
c_2	capacitance of the lower capacitor, farad, or an integration constant
D	diffusion coefficient, cm^2/sec
d	average spacing of the upper and lower capacitors, cm
d_1	spacing of the upper capacitor, cm
d_2	spacing of the lower capacitor, cm
E	bulk elastic modulus of gold ribbon, $dyne/cm^2$
E_s	surface elastic modulus of gold ribbon, dyne/cm
E_t	elastic modulus of glass tube, g/cm^2
F	force in the gold ribbon, dyne
F_1	force in the spring (or gold ribbon) without applied potential, dyne
F_2	force in the spring (or gold ribbon) with applied potential, dyne
f	sweeping frequency of the triangular wave, 1/sec
I	current, mA
i	current density, mA/cm^2
K_1	proportional constant, coulomb
K_2	proportional constant, V/cm
L	immersed length of gold ribbon in the extensometer, cm
L_t	length of glass tube from a suport point near the upper end to the weight hanger near the lower end, cm
m_r	spring constant of gold ribbon, dyne/cm
m_s	spring constant of the spring, dyne/cm
P	periphery of the cross section of gold ribbon, cm
p	pressure, $dyne/cm^2$
q	charge density, $\mu coulomb/cm^2$
S	total surface area of gold ribbon in the extensometer, cm^2
t	thickness of gold ribbon in the extensometer, cm
T	temperature, °C
V	volume of electrolyte in the purification system, cm^3
V_{SHE}	potential relative to saturated hydrogen electrode, V
$V_{\Delta L}$	voltage output from the capacitance sensor, V
W	hanging weight, g
w	width of gold ribbon in the extensometer, cm
ΔL_o	gap between the unstretched spring and gold ribbon without applied potential, cm
ΔX_1	length stretched in gold ribbon without applied potential, cm
ΔX_2	length stretched in gold ribbon with applied potential, cm
τ	time, sec
δ	diffusion thickness, cm
γ	surface free energy, erg/cm^2
μ	chemical potential, erg/mole
ϵ	linear surface strain of gold ribbon ($\Delta L/L$)
ϵ_s	surface strain of gold ribbon ($\Delta S/S$)
σ	bulk surface stress, $dyne/cm^2$
σ_s	surface stress, dyne/cm
ϕ	potential, V
ϕ_m	potential of surface stress maximum, V
ϕ_{pzc}	potential of zero charge, V

Stress Corrosion Cracking of Stainless Steel and Nickel Alloys at Controlled Potentials in 10% Caustic Soda Solutions at 550°F

J. R. Cels*

The Babcock & Wilcox Company, Alliance Research Center, Alliance, Ohio 44601

ABSTRACT

Potentiodynamic polarization curves were obtained in deaerated 10% NaOH solution at 550°F for nickel, Inconel 600,[1] Incoloy 800,[1] and Type 304 stainless steel. The curves for the first three materials exhibited narrow current density peaks at the same value of potential, indicating that these peaks were caused by nickel corrosion or by the oxidation of a lower oxide of nickel. Multiple stress corrosion cracking tests were performed on spring-loaded bent-beam specimens in deaerated 10% sodium hydroxide solution at 550°F at controlled potentials and at open-circuit conditions. A well-defined critical potential range was observed for the stress corrosion cracking of Inconel 600 specimens. Cracking of Incoloy 800 specimens at controlled potentials was difficult to reproduce. However, cracking could be reproduced under open-circuit conditions with a nitrogen cover gas.

Type 304 stainless steel was originally selected for the fabrication of heat-exchanger tubing for pressurized water reactors in order to reduce corrosion to a minimum. However, stress corrosion cracks can be formed in this alloy as a result of accidental entry of chlorides into the boiler water. Accordingly, it has now been generally replaced by the nickel alloys, Incoloy 800 and Inconel 600, which are very resistant to chloride attack. They are, nevertheless, susceptible to stress corrosion cracking in solutions of strong alkalies

The heat flux through the steam generator tube can provide a concentrating mechanism for impurities in the boiler water. In regions where the water circulation is restricted, and particularly under conditions of high heat transfer, a steam blanket can form at the tube surface. The thermal insulating effects of the steam then permit the surface to be superheated with respect to the boiler water. This superheat allows impurities to be concentrated by factors which have been estimated to exceed 10^4 so that a few parts per million of free NaOH can build up locally to several weight per cent. This is particularly likely to occur in the hot leg of the U-tube steam generator where the temperature differential between the primary and secondary coolants is greatest (1).

Several investigations of the stress corrosion behavior of stainless steels and nickel alloys in caustic soda solutions at high temperatures have been reported (2-4) but without control of the specimen potential. However, Mazille and Uhlig (5) and Parkins (6) have pointed out the importance of specimen potential on both the occurrence and the rate of caustic stress corrosion cracking. The purpose of this paper is to demonstrate the importance of electrical potential on the stress corrosion cracking behavior of Type 304 stainless steel and the nickel alloys, Inconel 600 and Incoloy 800, in deaerated 10% by weight NaOH solution at 550°F. An attempt is also made to determine the specimen potentials for maximum rates of cracking for each material. The results reported here are a representative selection taken from a larger study made on four heats of Inconel 600, two heats of Incoloy 800, and two heats of Type 304 stainless steel.

Experimental Procedures

Materials.—The chemical compositions supplied by the manufacturers for the commercial alloys used in this study are presented in Table I. Caustic soda solutions were made up to a concentration of 10% by weight using reagent grade NaOH and distilled deionized water.

Specimens.—Cylindrical specimens, 0.250 in. diameter × 0.600 in. long with an internal threaded hole, were used for polarization experiments. For stress corrosion cracking experiments, strip specimens were machined to the dimensions 1¾ in. long × 3/16 in. wide × 0.040 in. thick. Both sides of the strips were ground in the long direction in order to adjust the final thickness to a value of 0.040 in.

Polarization experiments.—Potentiodynamic polarization experiments were performed in deaerated 10% NaOH solutions in autoclaves at 550°F using standard electrical equipment. The potential scanning rate used was 2 V/hr. The cylindrical test specimens were mechanically polished through 600 grit SiC metallographic paper. They were then mounted on threaded stainless steel rods which passed out of the autoclave head through Conax pressure fittings as shown in Fig. 1. The stainless steel rods were coated with shrinkable Teflon tubing for electrical insulation and were surrounded by ¼ in. diameter stainless steel sleeves. The sleeves were compressed against Teflon gaskets at both ends in order to seal out the test electrolyte from the stainless steel center rods. A set of six equally spaced test specimens encircled a central nickel cyl-

inder specimen which was used as a hydrogen reference electrode. Some experiments were also conducted in a 1 liter stress-relieved Inconel 600 autoclave using a platinized platinum wire as the reference electrode.

The deaerated 10% NaOH test solution was contained in a nickel liner inside a 1 gal Type 316 autoclave. Water occupied the space between the liner and the autoclave and served as a heat transfer medium. A cover gas of 5% hydrogen in nitrogen at an overpressure of 200 psi at room temperature was used for experiments in this autoclave. A similar procedure was followed with the 1 liter autoclave using cover gases of either purified nitrogen or 5% hydrogen in nitrogen.

Stress corrosion cracking experiments.—The surface of the strip specimens was hand abraded through 600 grit SiC metallographic paper. A length of Teflon-coated 0.025 in. diameter Inconel 600 wire was spot welded to one end of the specimen to provide an electrical connection. The specimen was cleaned ultrasonically in 1% Alconox solution, rinsed with distilled water, and dried with Kimwipe tissue. It was then positioned in a special vise and bent to a radius of 1 in. The ends of the bent specimens were gripped between the Inconel 600 washers in the spring-loaded bending fixture shown in Fig. 2, and the Inconel spring was compressed until the specimen could be removed from the fixture without springback. At this point, the span of the bent specimen was 1-9/16 in. The Inconel spring was then further compressed to reduce the span to a final value of 1-7/16 in. as described by Uhlig and White (7).

The stressing fixtures with mounted bent-beam specimens were attached to support brackets bolted to Inconel vanes as shown in Fig. 3. The brackets were

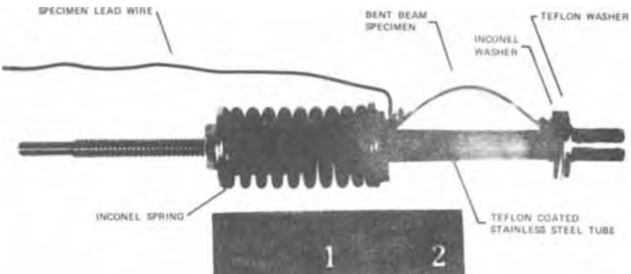

Fig. 2. Stressing fixture with mounted bent-beam specimen

electrically insulated from the Inconel vanes by Teflon sleeves and washers. Individual hydrogen reference electrodes fabricated from 0.040 in. diameter nickel wires were used for each stressed specimen. Each wire was coated with shrinkable Teflon tubing except for a 1 in. length at the end which was positioned close to the apex of a stressed bent-beam specimen. The wires passed out of the autoclave through a Conax six-lead pressure fitting mounted on an air-cooled stainless steel column.

The deaerated 10% NaOH test solution was contained in a nickel liner in the same manner as for the anodic polarization experiments. Its volume was selected so that the solution level at the operating temperature was just below the spot weld on the lead wire. Specimen potentials were independently controlled by individual potentiostats using the autoclave as a common counterelectrode. This necessitated the use of isolation transformers between the potentiostats and the grounded a-c supply. The specimen potentials were either controlled at fixed values with respect to the nickel reference electrodes, or were increased at a slow constant rate over a selected potential range. Both techniques were used simultaneously in some experiments.

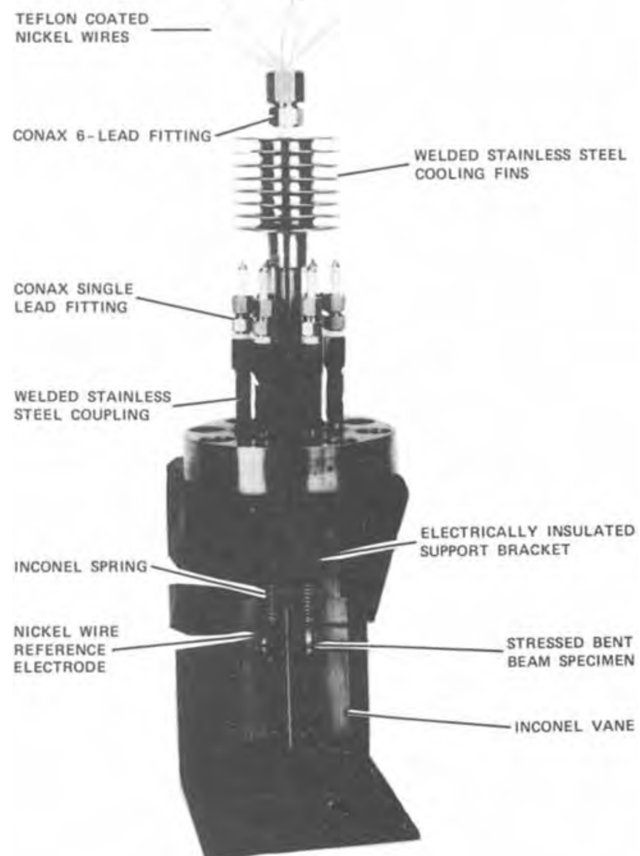

Fig. 3. Head of 1 gal autoclave for stress corrosion experiments

After each stress corrosion cracking experiment, the strip specimen was removed from the stressing fixture, bent slightly, and examined under a metallurgical microscope for the presence of cracks. Polaroid photomicrographs were taken of the surface of all specimens not cracked completely through in order to compare the extent of cracking among the different specimens of a set. Polished and etched metallographic cross sections were also prepared from some specimens to check the mode of cracking.

Results

Anodic polarization curves.—Potentiodynamic polarization curves obtained on cylindrical specimens of nickel, Inconel 600, Incoloy 800, and Type 304 stainless steel in 10% deaerated NaOH solutions at 550°F are presented in Fig. 4. A central nickel cylinder was used as a reference for each curve, and the cover gas was a mixture of 5% hydrogen in nitrogen at an initial overpressure of 200 psi at room temperature. Figure 4 reveals that the potentials of the specimens are all equal to that of the nickel reference electrode at low values of applied current. While the anodic current peak of Type 304 stainless steel is relatively broad, those of nickel, Inconel 600, and Incoloy 800 are very narrow with the current density maximum falling at a potential close to +140 mV in each case. Measurements were repeated on successive days with only a slight change in the potentials of these narrow current density peaks. However, this was not the case for experiments performed using a cover gas of purified nitrogen instead of 5% hydrogen in nitrogen. The results of such measurements made on a cylindrical Inconel 600 specimen in deaerated 10% NaOH solution at 550°F are presented in Table II. These measurements were made in a 1 liter autoclave using a platinized platinum wire as the reference electrode. The open-circuit corrosion potential of the Inconel 600 specimen was equal to that of the platinum wire with a cover gas of 5% H_2 and was about −2 mV in the case of a nitrogen cover gas. With a cover gas of 5% H_2 in N_2, the potential of the current density peak was +144 mV after 22 hr at temperature and it increased to +148 mV in successive runs. However, with a nitrogen cover gas the initial potential of the current density peak was +67 mV and this value increased progressively on successive runs and attained a value of +127 mV after 140 hr at temperature.

Specimen corrosion potentials vs. time.—The results o1 series of measurements of the open-circuit corrosion potentials of unstressed specimens in deaerated 10% NaOH solution at 550°F with a cover gas of 5% H_2 in N_2 are presented in Table III. It can be seen that the potentials of the cylinders of Inconel 600 and of nickel were identical to that of the platinized platinum reference cylinder throughout the test. The nickel wire, which was used as a reference for the stress corrosion cracking experiments, maintained a potential of about −4 mV whereas that of the autoclave itself was about +3 mV.

Stress corrosion cracking at controlled potential.—Stress corrosion cracking results on spring-loaded bent-beam specimens of Inconel 600 in the mill-annealed and heat-treated condition are presented in Table IV. The relative extent of cracking is indicated qualitatively in the last column of the table.

The mill-annealed specimen maintained at a potential of +200 mV cracked completely through in a 72 hr period. The extent of the cracking decreased progressively at lower values of specimen potential and no cracking was observed in the specimen which was allowed to stand under open-circuit conditions. A slow

	+200 to +250	1 mV/hr	General corrosion

* Solution: deaerated 10% NaOH, temperature: 550°F, cover gas: 5% H_2 in N_2.

potential scan at the rate of 1 mV/hr over the potential range +185 to +233 mV was also employed. This specimen was part of the same set as the others and exhibited numerous large cracks.

A similar experiment was conducted with the heat-treated Inconel 600 specimens but the test duration was extended to 175 hr. It is apparent that the extent of cracking was very much reduced compared with the first set in spite of the longer test period. The potential for maximum rate of cracking was in the neighborhood of +200 mV. The results of the potential scan tests showed numerous fine cracks over the potential range +150 to +200 mV and general corrosion with no cracking over the range +200 to +250 mV.

The caustic stress corrosion cracking results for Inconel 600 were quite reproducible. The mode of cracking for this material was intergranular for all specimens examined.

Similar experiments with specimens of Incoloy 800 and Type 304 stainless steel are presented in Table V. The first set represents some early measurements made in the 1 gal autoclave before it was subdivided so that the constant potential tests had to be run in sequence rather than simultaneously. No cracking was observed after a period of 355 hr at open circuit or after 96 hr at a potential of +20 mV. Some small cracks were present in the specimen held at +40 mV but the specimen held at +60 mV was cracked three-quarters of the way through.

The second set of experiments with Incoloy 800 specimens was run simultaneously. A wider range of fixed potentials was selected as well as slow voltage scans over two ranges of potential. According to these results, the potential for maximum cracking was now in the vicinity of +80 mV but the extent of cracking was much less than in the first set. More extensive cracking was observed in the slow voltage scan experiments. Experiments with the heat-treated alloy were conducted under open-circuit conditions with a nitrogen cover gas where the cracking of Incoloy 800 was more reproducible (Table VI).

In the last experiment in Table V, spring-loaded specimens of Type 304 stainless steel were tested for a 72 hr period. One specimen was allowed to stand at open circuit and the other was maintained at a potential of +80 mV. The one at open circuit cracked completely through whereas only a few small cracks were observed in the other at a potential of +80 mV. These results show that the potential for the maximum rate of crack growth lies in the neighborhood of the open-circuit potential for this material.

Photomicrographs were prepared from a number of specimens which cracked in deaerated 10% NaOH solution at 550°F. The crack mode was transgranular for both Incoloy 800 and Type 304 stainless steel.

Table V. SCC results on specimens of mill-annealed Incoloy 800 and Type 304 stainless steel*

Material	Specimen potential (mV)	Time (hr) or scan rate	Results
Incoloy 800	+20	96	No cracking
	+40	96	Few small cracks
	+60	96	Crack ¾ way through
	Open circuit	355	No cracking
	Open circuit	355	No cracking
Incoloy 800	+40	72	No cracking
	+60	72	Few very small cracks
	+80	72	Numerous small cracks
	+100	72	Few very small cracks
	+40 to +80	1 mV/hr	Relatively large, deep cracks
	+50 to +71	0.5 mV/hr	Relatively large, deep cracks
Type 304 SS	Open circuit	72	Specimen cracked through
	+80	72	Few small cracks

* Solution: deaerated 10% NaOH, temperature: 550°F, cover gas: 5% H_2 in N_2.

Stress corrosion cracking at open circuit.—The results of stress corrosion cracking experiments on spring-loaded bent-beam specimens in deaerated 10% NaOH solution at 550°F with a cover gas of purified nitrogen are presented in Table VI. Inconel 600, Incoloy 800, and Type 304 stainless steel were compared before and after a heat-treatment for 18 hr at 1150°F. No cracking was observed with the Inconel 600 specimens in either the mill-annealed or the heat-treated condition. On the other hand, cracks formed in the Incoloy 800 specimens in both the mill-annealed and the heat-treated condition. Cracking was somewhat less severe in heat-treated alloy. The specimen of mill-annealed Type 304 stainless steel showed no cracking, but numerous small cracks were present in the heat-treated alloy.

Discussion

Reference electrodes.—The electrical potential of a test specimen is of crucial importance to properly define the conditions of metal corrosion. Unfortunately, a reliable reference electrode for temperatures as high as 550°F is not yet available. The narrow current density peaks observed in the anodic polarization curve of Inconel 600 in deaerated 10% NaOH solution at 550°F are sufficiently sharp and reproducible to be used as a potential reference. They are associated with the nickel component of the alloy and represent either nickel corrosion or the oxidation of nickel corrosion products. It follows that they should not be dependent on the hydrogen partial pressure within the autoclave.

We can now interpret the results presented in Table II in terms of this potential reference. For the experiment with a cover gas of 5% H_2 in N_2, the potential of the hydrogen electrode was −144 mV after 22 hr at temperature. It was −148 mV after 118 hr and remained unchanged after 214 hr. In the experiment starting with a cover gas of purified nitrogen, the potential of the hydrogen electrode was initially −67 mV. Its potential drifted relatively rapidly in the negative direction and attained a value of −127 mV after 140 hr at temperature. This potential decrease was undoubtedly caused by the slow accumulation of hydrogen in the autoclave due to metal corrosion. These results show that the hydrogen electrode maintained an almost constant potential for experiments in deaerated 10% NaOH solution at 550°F starting with a partial pressure of hydrogen. From the results in Table III, the hydrogen electrode can be fabricated from platinized platinum, Inconel 600, or nickel with identical results. For this reason, a nickel reference electrode was used instead of platinum for most of the experiments described in this paper.

Stressing procedure.—To accelerate the rate of stress corrosion cracking, we have adopted the severe stressing procedure developed by Uhlig and White. This allows measurements to be made on specimens of convenient size which are maintained at levels of stress beyond the yield point. It is also a straightforward matter to control the electrical potentials of these stressed specimens.

Table VI. SCC results on specimens of mill-annealed and heat-treated Inconel 600, Incoloy 800, and Type 304 stainless steel*

Material	Metallurgical condition	Time (hr)	Results
Inconel 600	Mill annealed	123	No cracking
	1150°F/18 hr	120	No cracking
Incoloy 800	Mill annealed	123	Numerous large cracks
	1150°F/18 hr	120	Numerous small cracks
Type 304 SS	Mill annealed	123	No cracking
	1150°F/18 hr	123	Numerous small cracks

* Solution: deaerated 10% NaOH, temperature: 550°F, cover gas: N_2.

Rate of stress corrosion cracking.—Accurate measurements of the rates of cracking require the techniques of fracture mechanics. However, an estimate of cracking rates can be made by comparing the extent of cracking in different specimens under identical test conditions except for electrical potential. Crack initiation times are presumed to be of short duration for highly stressed specimens in an aggressive medium such as 10% NaOH solution at a temperature of 550°F.

Effect of potential on rate of cracking.—From the results presented in Table IV, specimens of Inconel 600 crack most rapidly at a potential around +200 mV in deaerated 10% NaOH solution at 550°F with a cover gas of 5% H_2 in N_2. General corrosion tends to predominate over stress corrosion cracking at higher values of specimen potential. On the other hand, it can be seen from the results in Table V that mill-annealed Type 304 stainless steel specimens cracked much more rapidly at open circuit than at a potential of +80 mV. The dependence of the cracking rate of Incoloy 800 specimens on electrical potential is not clear because of the difficulty of reproducing caustic cracking of this material. However, Incoloy 800 specimens do crack reproducibly in deaerated 10% NaOH solution at 550°F with a cover gas of purified nitrogen. With this cover gas, the specimen open-circuit corrosion potential is only about 36-77 mV more positive than that in an autoclave with a cover gas of 5% H_2 and N_2 where no cracking was observed after a test period of 355 hr.

According to Staehle (8), stress corrosion cracking may take place at values of specimen potential corresponding to the potentials for passive film instability at the upper and lower boundaries of the region of passivity in the anodic polarization curve. It is difficult to see how concepts relating to passive film instability could be applied to an alloy where each constituent would have a different anodic polarization curve. The caustic cracking behavior of Inconel 600 and Incoloy 800 is quite different in spite of the similarity of the anodic polarization curves of these two alloys at potentials up to the current density peak at about +145 mV.

Effect of heat-treatment on rate of SCC.—The results presented in Table IV show that the rate of caustic stress corrosion cracking of Inconel 600 was greatly reduced after a heat-treatment for 18 hr at 1150°F. At a potential of +200 mV, which is close to the value for the maximum rate of cracking, the mill-annealed specimen cracked completely through in a period of 72 hr whereas the heat-treated specimen exhibited only numerous small cracks after the longer test period of 175 hr. A smaller effect was also shown for specimens of Incoloy 800 tested in deaerated 10% NaOH solution at 550°F under open-circuit conditions for a period of about 120 hr as shown in Table VI. Wilson and Aspden (9) also observed a marked increase in the resistance of Inconel 600 to stress corrosion cracking in deoxygenated 10% NaOH solution at 630°F after a sensitizing heat-treatment. A similar result was reported by Blanchet *et al.* (10) for the stress corrosion cracking of Inconel 600 in deoxygenated pure water at 350°C (662°F).

Centro di Studio del C.N.R. sui Processi Elettrodici, Politecnico di Milano, 20133 Milano, Italy

ABSTRACT

The present investigation forms part of a systematic study about the influence of cold plastic deformation on the electrochemical and corrosion behavior of metallic materials, with the aim of determining and elucidating such aspects of their behavior and correlating them with the microstructural effects of the deformation, these being analyzed by metallographic and x-ray techniques and by transmission electron microscopy. In this respect, the influence of cold plastic deformation on the electrochemical and corrosion behavior of two stainless steels (AISI 304 L and 316 L) in different aggressive media (with and without chloride ions) has been studied with reference to the following points: (*i*) deformation type, *i.e.*, tensile stress, cold drawing, or cold rolling, and conditions, *i.e.*, at room temperature and at −196°C; (*ii*) relative orientation of the exposed surface with the deformation direction, *i.e.*, parallel and perpendicular; (*iii*) texture, defects, and martensite transformation.

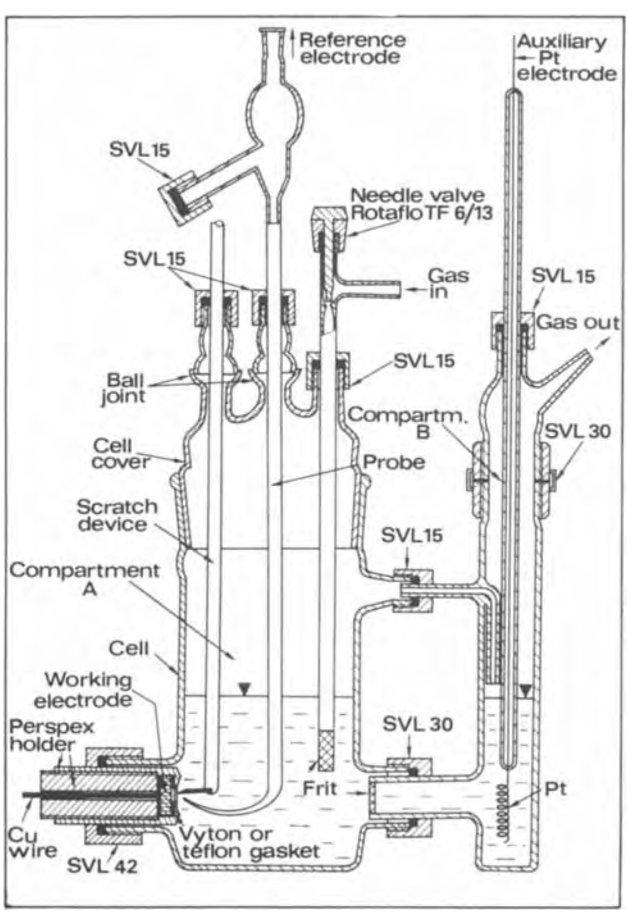

Fig. 1. Test cell (cross section)

The study of the influence of cold plastic deformation on the electrochemical and corrosion behavior of austenitic stainless steels was carried out in our Institute mainly because of the need for a systematic collection of data as a basis for a more reliable utilization of these materials which are often used in the work-hardened state. The correlation between the electrochemical behavior and the structural effects produced by cold plastic deformation, *i.e.*, texture, surface

defectiveness, phase transitions, is undoubtedly important from a basic standpoint as well.

For each material in every state of cold work the main aspects of the electrochemical and corrosion behavior are delineated by the corrosion rates *vs.* time curves (determined, for example, by the Stern-Geary method), by the polarization curves of anodic dissolution and cathodic hydrogen evolution, and by the passivation and passivity parameters. Each state of cold work is characterized by the type of the deformation process and by the rate, temperature and degree of the deformation itself. The effect of the orientation of the specimen surface under study with respect to the deformation direction must be taken into account as well. The development lines of our research and the principal results successively obtained are explained below (1).

Regarding the phenomenological aspects of the electrochemical and corrosion behavior in deaerated sulfuric acid solution of the austenitic stainless steels AISI 304 L, 304, and 316 deformed by application of a tensile stress (AISI 304 L steel was deformed also by cold drawing), the following points came to light.

(*i*) The cold working of the material leads to an increase in the generalized and uniform corrosion rate in the active region. This influence was observed on the surfaces orientated perpendicularly or at 45° to the deformation direction, above a critical threshold of the deformation degree of roughly 15% for all the steels studied. The susceptibility to the effect of the

cold working increases in the sequence AISI 316 < AISI 304 < AISI 304 L.

(*ii*) A decrease in the overvoltage of the cathodic hydrogen evolution always corresponds to an increase

L, T, T_S, and T_L correspond to longitudinal, transversal, short or long transversal sections, respectively. Potential values are relative to SSE.

in the corrosion rate with the deformation degree, whereas the anodic behavior in the active region of the considered materials is not appreciably affected.

(*iii*) Extending the investigation beyond the active region, a larger work hardening of the material results in an unfavorable effect, which is enhanced by the addition of chlorides, on the formation of the passivating films and sometimes on their protective characteristics as well. The surfaces parallel to the deformation direction generally exhibit a more stable passivity.

Regarding the structural effect of the cold plastic deformation, *i.e.*, texture, surface defectiveness, phase transitions, to which the decreases in the hydrogen overvoltage (and the corresponding increases in the corrosion rate) can be ascribed, the following points may be underlined.

(*i*) In the case of deformation by application of a tensile stress, the preferred orientation of the crystal grains is negligible. On the other hand, the drawn steel AISI 304 L assumes a certain degree of fibrous texture in the [111] direction. The measurements performed in our Institute on the various faces of single crystals of

austenitic stainless alloy have shown, moreover, that the highest hydrogen overvoltage values correspond exactly to this direction (2).

The cold plastic deformation which, as already seen, causes the hydrogen overvoltage to decrease must therefore act through the other structural effects (that is, through the increase in structural defects emerging on the specimen surface and/or the occurrence of phase transitions).

(*ii*) The density of the structural defects does not increase progressively with the deformation degree, but shows a steep rise for a deformation value of about 15%. Above this value, the density of the observed deformation bands increases according to the sequence AISI 316 < AISI 304 L < AISI 304. It was found that these bands are also composed of deformation twins, while in the case of the strongly deformed steel 304 L the presence of α'-martensite generated by the phase transformation of austenite to martensite as a consequence of the deformation itself was detected.

The inversion noted between the AISI 304 and AISI 304 L in the relationship between the "structure" (density of the deformation bands higher in the AISI 304) and the electrochemical and corrosion behavior (susceptibility to the effect of cold plastic deformation higher for AISI 304 L) must, in our opinion, be ascribed to the presence of α'-martensite in the AISI 304 L. The research subsequently developed toward isolating the effect exerted on the electrochemical and corrosion behavior of the AISI 304 L and 316 L steels by the phase transformation of austenite to martensite from the one due to the presence of defects.

The choice of these steels was determined not only by their intrinsic structural instability which makes them particularly suitable for the purpose, but also by their importance in technologically advanced fields. In particular, the AISI 316 L is practically insusceptible to intergranular corrosion and is resistant to pitting; its behavior in the work-hardened state is especially interesting in view of its application as a material for surgical plants in the human body.

Experimental

In order to separate and compare the effect of both the martensite and that due to the defects, cold plastic deformation of the AISI 304 L and 316 L steels[2] was carried out by either tension, drawing, or rolling at room temperature as well as at liquid nitrogen temperature (−196°C) so as to obtain significant amounts of martensite.

Details of the material working schedule (solution heat-treatment, deformation,[3] cutting, surface preparation), of the microstructural analysis, and of the electrochemical experimental techniques, polarization cell, and electrode assembly have already been described elsewhere (1, 4).

Cathodic polarization curves relative to the hydrogen evolution on the considered steels were recorded

[2] Chemical compositions and some structure characteristics of the considered steels are given in Table I.

[3] Reductions in the cross-sectional area were always adopted to express the deformation degree.

in a 1M H_2SO_4 solution, deaerated and stirred by circulation of N_2 gas, at a temperature of 25°C. Anodic polarization curves were recorded in both a 1M H_2SO_4 and a 0.1M HCl (5) solution in an atmosphere of N_2 gas at 25°C.

Critical pitting potentials of the considered steels[4] were determined in an artificial "physiological" solution, simulating the aggressiveness of the human body, of the following composition: 8.74 g/liter NaCl, 0.35 g/liter $NaHCO_3$, 0.06 g/liter Na_2HPO_4, 0.06 g/liter NaH_2PO_4, pH 7, in atmosphere of N_2 gas, at 38°C (4). These measurements were performed by applying the "scratching" technique introduced by Pessall and Liu (6). The electrode potential was maintained constant with the potentiostat at a selected value below the ex-

[4] A passivation pretreatment was carried out by dipping the specimens in 30% HNO_3 solution at 55°C for 30 min.

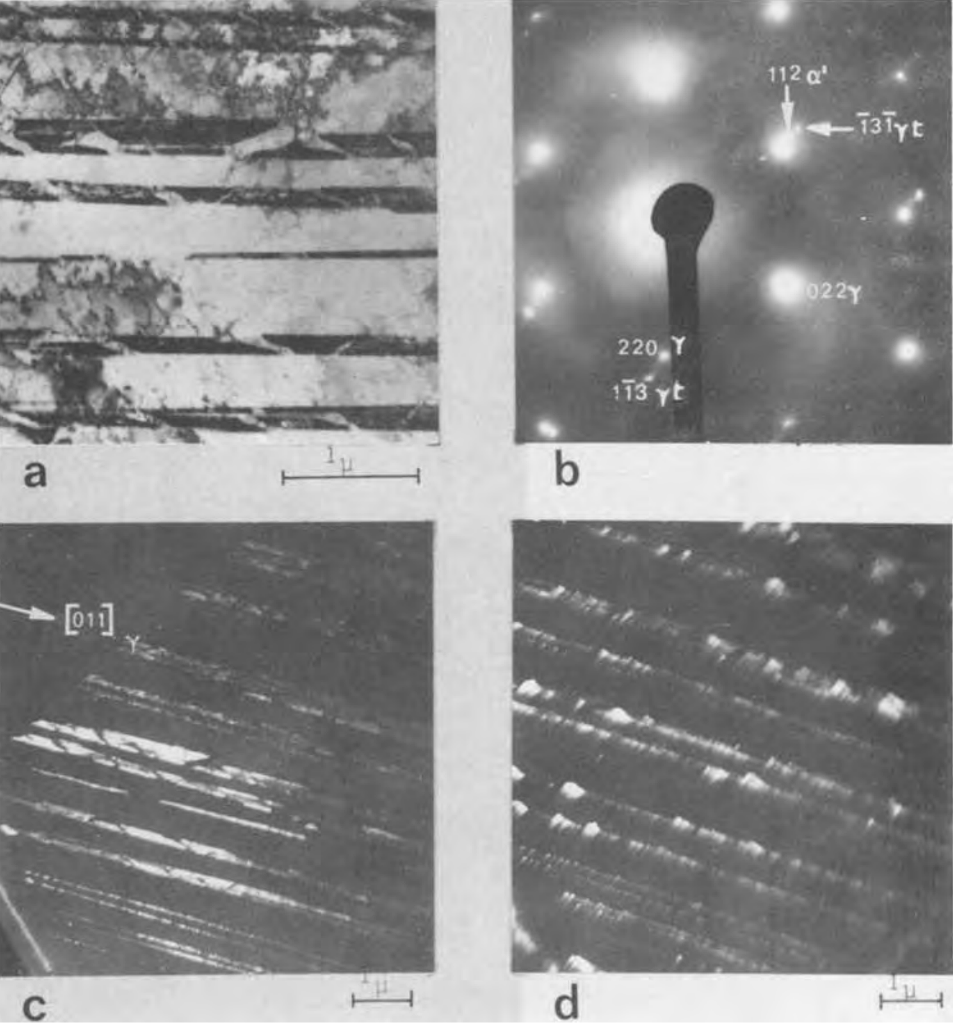

Fig. 13. α'-cubic martensite plates in deformation twins in AISI 304 L steel deformed 15% by tensile stress at room temperature: (a) bright-field image; (b) electron diffraction pattern, $[\bar{1}11]_\gamma$ and $[41\bar{1}]$ γ-twin zone axes; (c) dark-field image obtained by $\bar{1}3\bar{1}$ γ-twin reflection; (d) dark-field image obtained by 112 α'-reflection.

pected pitting potential and then the specimen surface was scratched with a tungsten point (Fig. 1). The current/time relationship was recorded for a few minutes until the specimen repassivated. This procedure was continued with the electrode potential adjusted by 25 mV steps to more and more noble values, until the scratch failed to repassivate, a failure which was indicated by a gradual current rise in time; the presence of pits developed at the scratched site was verified microscopically. The electrode potentials were always referred to the Hg, Hg_2SO_4/K_2SO_4 (saturated) electrode (SSE) whose potential relative to the standard hydrogen electrode at 25°C is +642 mV.

Results and Discussion

Some results of the electrochemical measurements are given in Fig. 2 to 9. The lowering effect on the hydrogen overvoltage produced by increasing the deformation degree is higher when the cold working of the considered steels is carried out at the liquid nitrogen temperature; at room temperature the influence of the cold plastic deformation is much more notable for the AISI 304 L than for the AISI 316 L steel (Fig. 2 and 3).

On the anodic side, the change from sulfuric acid (Fig. 4) to hydrochloric acid (Fig. 5 and 6) solution magnifies the unfavorable effects of the degree of work hardening on the occurrence of the passivation phenomena and on the protective characteristics of the passivating films to an extent which depends on the orientation of the specimen surface with respect to the deformation direction and on the temperature at which the cold plastic deformation is carried out.

All the types of cold plastic deformation—by either tension, drawing, or rolling—cause the critical pitting potential of the considered steels to diminish as shown in Fig. 7-9. Again, a considerable anisotropy of this property was observed; for example, for the rolling the critical pitting potential decreases, the degree of work hardening remaining unchanged, from the longitudinal (L) section to the short transversal (T_S) one and from the latter to the long transversal (T_L) section. An influence of the cold working temperature again came to light (Fig. 8). For the AISI 304 L steel (Fig. 9) the susceptibility to the pitting corrosion is greater (as is well known), but it appears to be less affected by the deformation degree than for the AISI 316 L steel.

The relationship between the previously described aspects of the electrochemical behavior of the considered steels and the structural effects of the cold plastic deformation would need a complete, systematic, and quantitative study of these latter, whereas only some qualitative "flashes" will be shown here. All the same, we think they are already sufficiently meaningful.

First of all, a general idea of the work-hardening effects of the materials is given by the Vickers hardness diagrams of the type in Fig. 10, which, at least in the case of cold rolling at the liquid nitrogen temperature, exhibits an anisotropy of this property.

Investigations by transmission electron microscopy, electron diffraction, and x-ray diffraction enabled us to get a qualitative picture of the structure of the AISI 304 L and 316 L steels deformed by tension at both room and liquid nitrogen temperature. This picture includes dislocations density, presence and nature of the deformation bands [*i.e.*, deformation twins (Fig.

11), ε-hexagonal martensite (Fig. 12), or slip bands which cannot be morphologically distinguished from each other], presence of α'-cubic martensite (Fig. 13), and residual austenite. The results are summarized in Tables II and III.

In the case of deformation at room temperature, the behavior of the considered steels is quite different; the dislocations density as well as the density of the deformation bands is always higher in the AISI 304 L than in the 316 L steel. Moreover, in the strongly deformed 304 L steel, α'-martensite is present in amounts increasing with the deformation degree, whereas the 316 L steel does not exhibit any phase transition even in the state of maximum deformation (in accordance with the M_{d30} values given in Table I).

In the case of deformation at the liquid nitrogen temperature, the behavior of the considered steels becomes essentially the same for both of them in that the phase transition of austenite to martensite is always notable or even prevailing; nevertheless a greater structural instability of the AISI 304 L steel compared with the 316 L is confirmed.

Much more research work must be carried out on the structural aspects, also as regards the spatial distribution and orientation of the formed martensite and the influence on the passivating films, in order to explain the previously described anisotropy effects on the electrochemical behavior of the deformed steels.

Manuscript submitted Feb. 17, 1976; revised manuscript received March 31, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

X-Ray Photoelectron Spectroscopic Study of the Aqueous Oxidation of Monel-400

N. S. McIntyre, T. E. Rummery, M. G. Cook, and D. Owen

Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba, Canada

ABSTRACT

The surface of Monel-400 alloy was exposed to high pH, aqueous corrosion at 285°C, under both oxidizing and reducing conditions. After exposures lasting from 0.3 to 335 hr the surfaces were examined by x-ray photoelectron spectroscopy, scanning electron microscopy, and other techniques. Under reducing conditions, no corrosion film forms on the metal surface, but under oxidizing conditions, the first corrosion layer which forms at the solution interface is entirely $Ni(OH)_2$. This hydroxide, which persists for long times at $pH \sim 10$ but which rapidly converts to NiO at $pH \sim 14$, is shown to result from a precipitation process. The composition of the corrosion film is determined by the relative solubilities of nickel and copper at the interface. A composition profile of the corrosion layer beneath the outermost film shows a gradual increase in cuprous ion concentration with increasing depth, probably due to solid-state migration. This suggests that the aqueous corrosion of Monel-400 involves both solid-state oxide growth and an ionic dissolution and precipitation mechanism.

Monel-400[1] (66% Ni, 32% Cu) is one of the alloys used as heat-exchanger tubing in CANDU-PHW[2] power reactors. As part of a study of the transport of radionuclides in reactor coolant systems, we have investigated the aqueous corrosion behavior of Monel-400 under conditions of high temperature and pressure which simulate those found in the coolant of a power reactor.

Most aqueous corrosion studies of nickel-copper alloys have concentrated on film growth rates (1-10) or on the composition and structure of oxide films which were formed over lengthy periods of corrosion (11-13). One study used electron diffraction to identify the corrosion products $Ni(OH)_2$, NiOOH, and NiO which had formed on some copper-nickel alloys after several hours of aqueous corrosion (14). With the development of other analytical techniques sensitive to surface films no thicker than a few atomic layers, both composition and structure can be determined qualitatively and quantitatively following very brief exposures to corrosion conditions.

In this work, corroded surfaces were studied by x-ray photoelectron spectroscopy (XPS or ESCA) as well as scanning electron microscopy, and, where possible, by x-ray diffraction. In XPS, photoelectrons produced by an impinging x-ray beam emerge from the top 1-2 nm of a surface and their kinetic energies are analyzed (15). The exact kinetic energy of the photoelectron reflects not only the atomic number of the originating element, but also the chemical environment of this element. If this technique is combined with ion sputtering to remove successive layers of surface film, it is possible to obtain a profile of the elemental distribution through the corrosion layer.

XPS provides an average analysis of the elements on several square millimeters of surface. Complementary information about the distribution of crystallites within this area can be obtained using scanning electron microscopy. Also, where a film of sufficient thickness ($\sim$0.1-1 μm) has formed, x-ray diffraction can be used to confirm the XPS analysis.

In two previous XPS studies, corroded copper-nickel surfaces have been examined. Hullet and co-workers (16) examined films on a 70:30 cupronickel alloy which had been anodized in sodium chloride solutions. Above the passivation potential, the surface was found to consist primarily of a nickel-oxygen species whose identity could not be absolutely established. The XPS core line spectra of the nickel-rich surface did not, however, correspond to stoichiometric NiO. Castle (17), however, examined 70:30 copper-nickel alloy surfaces heated in oxygen and in this case was able to identify the nickel phase as NiO. The surface of the oxidized alloy was enriched in nickel compared with the bulk metallic phase. Both cuprous and cupric oxide phases were identified under different oxidizing conditions.

In this work, the corrosion films formed on Monel-400 were studied following brief exposures of the alloy to alkaline ($pH = \sim$10-14), high temperature (285°C) solutions saturated with respect to either hydrogen or oxygen. In each case the XPS spectra of the corrosion products could be clearly identified with the spectra of known nickel or copper species. From the analysis of the surface corrosion products and the elemental depth profile, a mechanism for the aqueous corrosion of Monel-400 is proposed.

Experimental

Mechanically abraded Monel-400 coupons of 3 cm^2 surface area were exposed to 0.1 liter of 1.0 mol/kg and 1×10^{-4} mol/kg Li(OH) solutions at 285°C in a Teflon-lined titanium autoclave. The autoclave was initially purged and filled to a pressure of 0.1 MPa at 25°C with reagent grade hydrogen or oxygen. The inner surfaces of the autoclave, in contact with solution, were lined with Teflon since it was found that even after thorough cleaning microquantities of metallic contaminants remained on the titania surfaces and were readily transported to the Monel-400 surfaces during exposure. The Teflon liner was pretreated under reaction conditions for over 50 hr to eliminate any significant contribution of fluoride and chloride ion to the solution and the absence of these impurities on the Monel-400 surface after treatment was confirmed by photoelectron spectroscopy. Photoelectron spectroscopy also confirmed the absence of elemental impurities, other than adsorbed oxygen and minor quantities of hydrocarbon, on the Monel surfaces prior to exposure.

Effective exposure periods varied from 0.3 to 335 hr. The effective period was taken to be the time at which the surface was corroded at temperatures between 225° and 285°C, and allowed for the time of additional corrosion during heating-up and cooling-down. Following

Key words: Monel, nickel hydroxide, aqueous oxidation, photoelectron spectroscopy, corrosion.

[2] CANDU-PHW = Canada deuterium uranium-pressurized heavy water.

exposure, coupons were cooled *in situ*, washed with distilled water, and transferred to the spectrometer. When the effects of dissolved hydrogen were studied, particular care was required to prevent possible oxidation of the surfaces after exposure, and the transfer to the spectrometer was done under an argon atmosphere. The total quantities of copper and nickel products in solution from each corrosion reaction of Monel were determined using flame or flameless atomic absorption spectroscopy.

A McPherson ESCA-36 XPS spectrometer with a cryogenically pumped sample chamber was used. The excitation radiation used was either the Mg K_α or Al K_α line. The instrument work function (3.8-4.2 eV) was set so that the Au(4f 7/2) peak was at 84.00 eV for a gold metal surface. Rather large charging shifts (1-3 eV) were encountered for all Monel surfaces exposed to aqueous oxidation. The surface charging was corrected by measuring the shift of the background carbon C(1s) line, which normally occurs at 285.0 ± 0.2 eV. In some cases a gold film was evaporated onto the surface and its equivalent charging shift was measured (18). In general, agreement between the two measurements, however, was within ±0.2 eV. Such corrections, however, substantially affect the precision of the peak assignment and the errors quoted result from ten determinations of the peak position.

Appropriate relativistic energy corrections were made to all binding energies reported. A 10 keV argon ion gun was used for depth profile studies. Ion flux on these surfaces was limited to 5 $\mu A\ cm^{-2}$ to minimize effects of chemical decomposition and preferential sputtering. Surface morphology was determined with a Cambridge "Stereoscan" Mark 2A scanning electron microscope. X-ray diffractometry was carried out using a Philips vertical goniometer with monochromated Cu K_α radiation.

XPS Spectra

The x-ray photoelectron spectra of a number of oxides and hydroxides of copper and nickel have been studied in this (19) and other (20-22) laboratories. The binding energies associated with the more prominent metal and oxygen core lines as well as the energy of the major metal LMM Auger transition are given in Table I. In Fig. 1 and 2 the M(2p) and M(3s) spectra for some oxides and hydroxides of copper and nickel are shown. Cuprous oxide is distinguishable from copper metal only by the shift of the Cu Auger LMM line. Cupric oxide and hydroxide are characterized by their differing metal and oxygen core binding energies as well as by the metal "shake-up" satellite spectra located on the high binding energy side of most cupric compounds (23). In the case of the nickel-oxygen system, NiO and $Ni(OH)_2$ can be clearly distinguished using similar criteria as in the copper spectra. Spectra of another nickel-oxygen species have been reported by Kim and Winograd (22) following the low pressure oxidation of polycrystalline nickel surfaces. They suggest that this species is a defect structure containing Ni^{3+}. Similar spectra have been observed in this laboratory (24) during room temperature oxidation of nickel surfaces. Although this oxide has metal and oxygen core line energies rather close to those for nickel hydroxide, the separation is still adequate to provide characterization of either species,

particularly when combined with the quite different satellite and Auger spectra produced by each. The "surface nickel oxide" species of Kim and Vinograd (22) was not observed during the present work.

Results

Exposure in 10^{-4} mol/kg Li(OH)—0.1 MPa H_2 overpressure.—After exposure of a Monel coupon in 285°C solutions (pH ~10) under hydrogen for periods up to 335 hr, no evidence of any significant oxidation product on the surface was seen using XPS. Spectra of the Cu(2p 3/2) and Ni(2p 3/2) lines for a Monel surface were the same as those for pure metal surfaces [Fig. 3(a)]. As little as 0.3 of a monolayer of NiO or $Ni(OH)_2$ could be detected using these lines. The O(1s) spectrum of the Monel surface [Fig. 3(a)] shows a small peak at 531.7 eV due to minor concentrations of a surface oxygen species. Such complexes are normally observed on metal surfaces not treated under vacuum prior to examination. The copper-nickel ratio of the surface was determined from both M(2p) and M(3p) integrated line intensities using prepared copper-nickel alloys of known composition as intensity standards (25). Using the M(2p) line ratios a nickel:copper atom ratio of 75:25 ± 10% (2σ) was determined while an atom ratio of 65:35 ± 7% (2σ) was found using the M(3p) line ratios. The M(3p) photoelectrons with kinetic energies of 1200 eV have a mean escape depth (1-2 nm) around three times larger than the M(2p) photoelectrons which have kinetic energies of 300-400 eV (26). Although the more deeply sampled surface layer has, within experimental error, copper-nickel ratio equivalent to that in bulk of Monel-400, the extreme outer surface appears to be depleted in copper. This could be due to a preferential dissolution of copper or surface segregation as discussed below.

The absence of any oxide is consistent with thermodynamic calculations. Comparison of calculated equilibrium partial pressures for hydrogen reduction of NiO, Cu_2O, and CuO (27) with the hydrogen overpressure of 0.1 MPa used in these experiments indicates that the metallic phase is thermodynamically stable for both nickel and copper.

Exposure in 10^{-4} mol/kg Li(OH)—0.1 MPa O_2 overpressure.—The exposure of Monel-400 under conditions as described above except for an oxygen overpressure resulted in rapid growth of a corrosion film. After an effective exposure of 0.3 hr, a scanning electron micrograph of the surface [Fig. 4(b)] indicated a layer of acicular crystals 0.1 μm in diameter. A micrograph of the reduced surface [Fig. 4(a)] is included for comparison. The needlelike morphology of the crystals suggests that they were formed by precipitation from solution rather than by a solid-state growth process.

Only a nickel phase was detected on the outer surface using XPS. If copper was present at all, it constituted less than 5 atomic per cent (a/o) of the corrosion layer (expressed as CuO). Spectra of the Ni(2p 3/2), Cu(2p 3/2), and O(1s) line regions are shown in Fig. 3(b). The binding energies of the principal lines

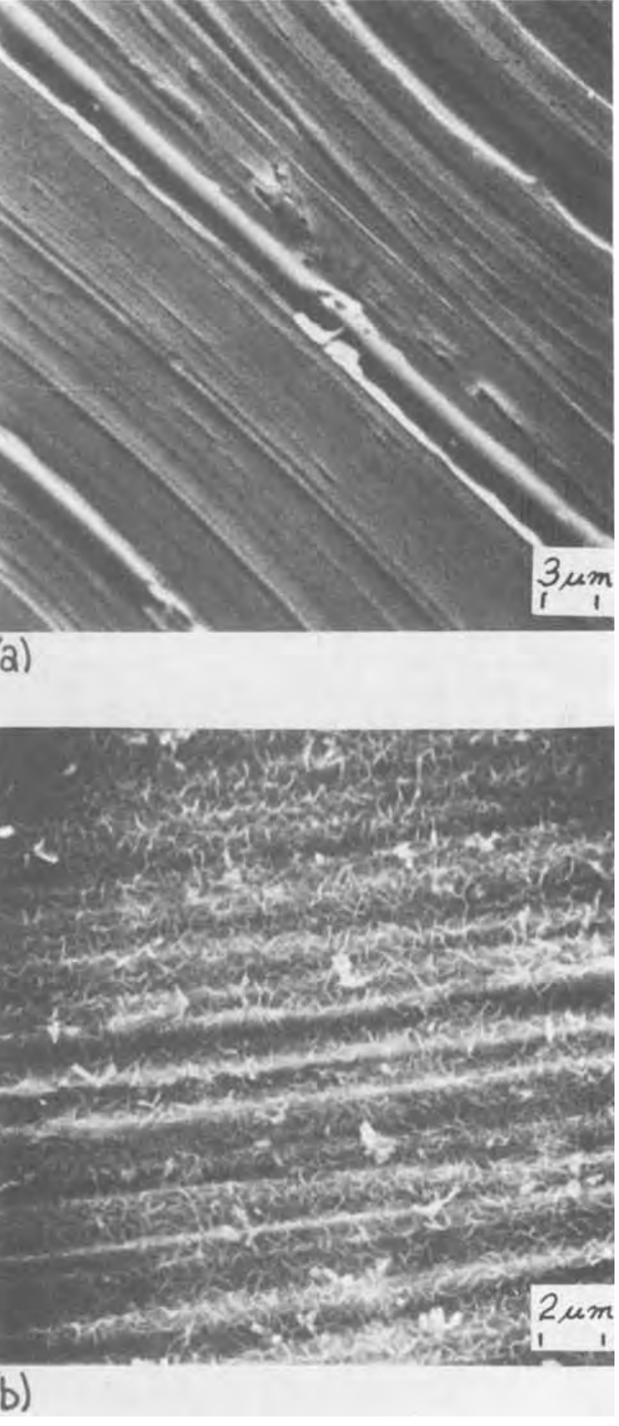

Fig. 4. Scanning electron micrograph of a Monel-400 surface exposed to 1 × 10^{-4}M Li(OH) at 285°C for 0.3 hr, (a) hydrogen overpressure, (b) oxygen overpressure.

correspond within 0.2 eV to those given for bulk $Ni(OH)_2$ in Table I. Moreover, the characteristics of the Ni(2p 3/2) shake-up spectrum (twin peaks at 5.1 and 6.8 eV above the principal line) and Ni(3s) spectrum (strong satellite at 5.1 eV) are the same as those observed for $Ni(OH)_2$. Confirmation of this assignment of $Ni(OH)_2$ as the outer layer was not possible by x-ray diffraction because of the very thin surface film developed, but diffraction analysis of Monel surfaces exposed for periods of 48 hr indicated the presence of $Ni(OH)_2$ as the sole detectable corrosion product phase.

Several possible mechanisms for $Ni(OH)_2$ formation were considered: (*i*) hydration at high temperature or during cool-down of a predominantly NiO surface phase could yield an external film of $Ni(OH)_2$; (*ii*) $Ni(OH)_2$ is known to be unstable in a nonaqueous environment at 285°C (28). Thus the $Ni(OH)_2$ observed could have formed during cooling of the autoclave; (*iii*) $Ni(OH)_2$ could form at high temperature by direct precipitation of an excess of nickel at the solid-liquid interface.

The first premise was tested by exposing a suspension of stoichiometric NiO under similar autoclave conditions for 48 hr, with oxygen or hydrogen overpressures. Under neither condition was there any indication of a significant quantity of surface $Ni(OH)_2$, although when NiO was exposed to oxygen-saturated solutions, evidence of some change in the oxide structure was seen. Production of $Ni(OH)_2$ on Monel surfaces by hydration of NiO is thus not considered likely.

Significant precipitation of $Ni(OH)_2$ during cooling of the autoclave is also considered unlikely. Solubilities of $Ni(OH)_2$ in 10^{-4} mol/kg Li(OH) solutions have recently been determined experimentally in the temperature range 25°-300°C (29). From these, it is estimated that the change in solubility of $Ni(OH)_2$ in cooling down from 300°C is less than 10^{-6} mol/kg. Precipitation of this magnitude would result in a coverage of the sample surface no greater than 0.1 monolayers which is three to four orders of magnitude below the thickness of the $Ni(OH)_2$ films observed in this work.

If $Ni(OH)_2$ is the major corrosion product at 285°C, its stability under such hydrothermal conditions is surprising considering the known instability in nonaqueous conditions at these temperatures (28). Recently, however, Swaddle (30) has measured the stability of bulk $Ni(OH)_2$ under hydrothermal conditions similar to those above. It was found that, although the $Ni(OH)_2$ phase did indeed decompose to NiO at 280°-300°C, the rate was quite slow, typical half-lives being of the order of several hours. Thus, with continual precipitation on the Monel-400 surface it is possible to rationalize the existence of a significant layer of $Ni(OH)_2$ at these temperatures.

The aqueous oxidation of Monel was also carried out for periods considerably longer than 0.3 hr. In all cases, XPS studies of the outermost surface showed the major product to be $Ni(OH)_2$, although small quantities of copper in cupric form were sometimes observed. X-ray diffraction of samples exposed for these periods indicated the presence of $Ni(OH)_2$, but no other copper or nickel corrosion products were detected. Scanning electron microscopy coupled with energy dispersive x-ray spectrometry showed that a second crystallite phase develops on the surface at these longer exposure times. This phase, indicated with an arrow in Fig. 5, contains both copper and nickel and is quite localized, covering no more than 10% of the surface area.

The effect of increased concentration of copper ion in solution on the surface composition was studied by adding a 300 cm^2 copper foil to the autoclave. The surface composition was largely unaffected by the addition except that the surface concentration of cuprous oxide increased to 10-15 a/o compared to <5 a/o observed with no copper source present. SEM photomicrographs (Fig. 6) showed that the morphology of the deposited copper phase is much different from the film observed on a Monel surface with no copper source present (Fig. 5). The addition of an external source of copper causes, at saturation, the formation of relatively pure, localized, large crystallites of a copper phase on the film, leaving the major surface area as $Ni(OH)_2$.

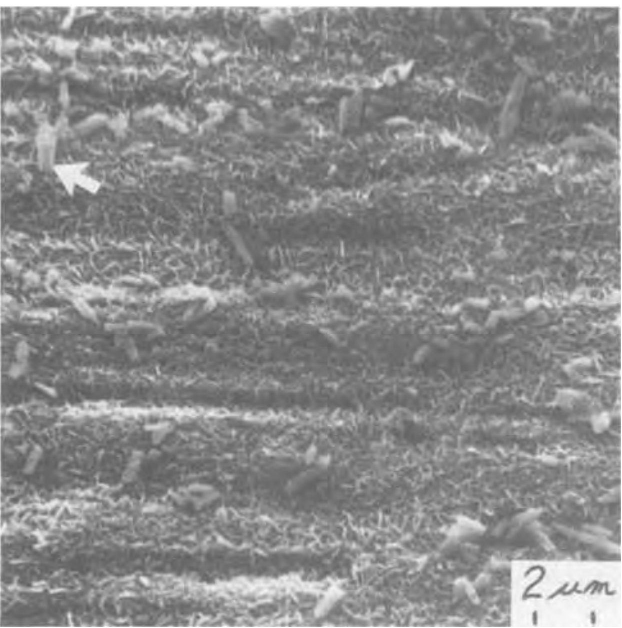

Fig. 5. Scanning electron micrograph of a Monel-400 surface exposed as in Fig. 4(b) for a period of 48 hr. A cupronickel phase is indicated by the arrow.

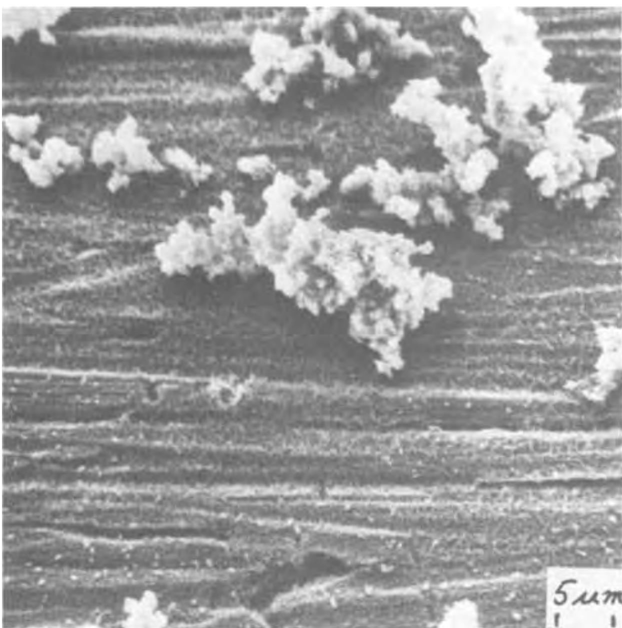

Fig. 6. Scanning electron micrograph of a Monel-400 surface exposed as in Fig. 5 with an additional copper source present in the autoclave.

Elemental intensity profiles of the Monel-400 corrosion films were obtained using argon ion bombardment and a typical one is shown in Fig. 7. Of particular note is the copper phase, undetectable or barely detectable at the original outer surface, but which increases in concentration until it reaches a value about 25% of the nickel concentration [pure Cu_2O and $Ni(OH)_2$ used as intensity standards]. The depth attained in this and in similar profiles was estimated to be 20-100 nm.

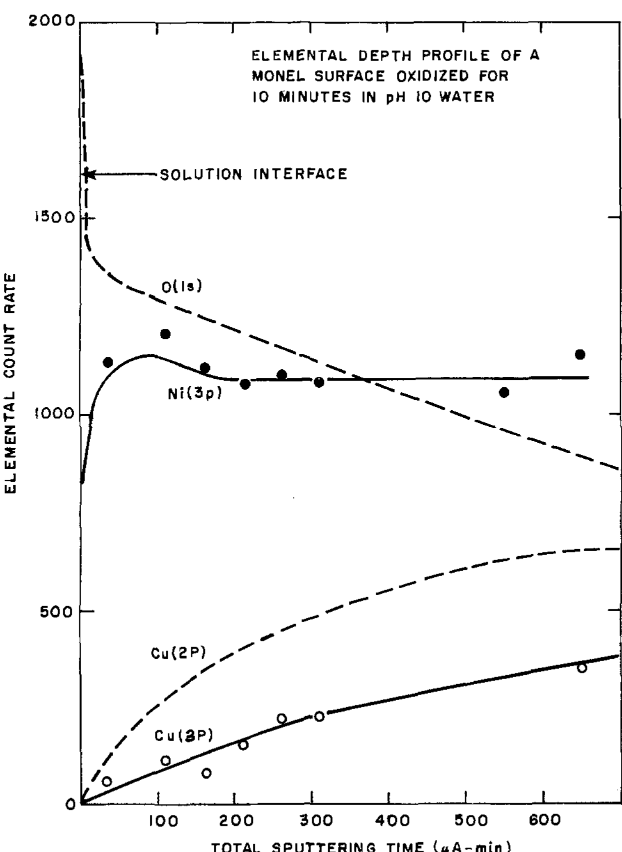

Fig. 7. Elemental intensity profile as a function of integrated sputtering current for a Monel-400 surface exposed to 1×10^{-4}M Li (OH) at 285°C for 0.3 hr under oxygen.

The Cu(2p 3/2), (3p 3/2) and Auger LMM energies indicated the presence of only cuprous oxide. Although 10 keV ion bombardment of cupric oxide has been found to result in some reduction to cuprous oxide, some contribution due to CuO usually remains, particularly in the Cu(3p) spectrum. The Cu(3p) line, because of its higher kinetic energy, samples the surface to a greater depth than the Cu(2p) line and thus minimizes the effect of sputtering damage which occurs largely, but not completely, in the outer 1 nm of surface remaining.

As each film was initially sputtered (0-10 μA-min), rapid changes in metal and oxygen binding energies indicated a partial dehydration of $Ni(OH)_2$ to NiO. This can also be seen from the sharp change in slope of the O(1s) intensity in Fig. 7. The presence of at least some of the NiO is almost certainly due to sputtering-induced decomposition, for it is likely that such a major amount of NiO distributed throughout the film would have been detected by x-ray diffraction. During the remainder of the sputtering profile the ratio $NiO/Ni(OH)_2$ gradually increased, and it is not clear whether this represents the appearance of an NiO phase which was actually present in the original film during formation, or whether it is due to additional ion bombardment damage.

The effect of exposing an oxidized Monel-400 surface for a second period in the autoclave with a hydrogen overpressure was studied. The coupon initially was exposed for 0.3 hr in 0.1 MPa oxygen followed by replacement with a hydrogen atmosphere and continued exposure for 335 hr. SEM photomicrographs showed that features of the surface film were basically unchanged from those seen in Fig. 4(b). XPS analysis of the outer surface indicated that both NiO and $Ni(OH)_2$ were present in comparable quantities, but that no metallic nickel was present on the surface. Thus, aside from some decomposition of $Ni(OH)_2$ to NiO, the surface film was not greatly affected by long exposure to hydrogen, indicating that the reduction of $Ni(OH)_2$ (and NiO) to elemental nickel is very slow under these aqueous conditions.

Attempts to estimate solution concentrations of copper and nickel during the high temperature exposures gave unreproducible results ranging from 10-100 μg/liter for both elements.

Exposure in 1.0 mol/kg Li(OH)—0.1 MPa O_2 overpressure.—To further understand the role played by solution phenomena in the corrosion of Monel-400, experiments were also carried out at 285°C in 1.0 mol/kg Li(OH) (pH ~14). At this pH, solubilities of both copper and nickel were found to be much higher than at pH 10, and autoclave solution concentrations could be estimated and correlated with film surface composition. After a 48 hr autoclave exposure, a film several micrometers in thickness had developed with a morphology much different from the acicular crystals found at pH ~10. A SEM photomicrograph of a typical region is seen in Fig. 8. XPS showed that the surface consisted entirely of NiO. No $Ni(OH)_2$ or copper phases were identified on the surface nor was any copper phase revealed when the surface was sputtered to a depth of several nanometers. The film was sufficiently thick that strong x-ray diffraction lines were obtained showing the bulk corrosion film to be entirely NiO. The detection limit of additional oxide phases such as $Ni(OH)_2$, Cu_2O, or $Cu(OH)_2$ was ~5% in this case.

The observation of NiO rather than $Ni(OH)_2$ is still consistent with a precipitation-based mechanism for film formation. The rate of decomposition of $Ni(OH)_2$ at this pH and temperature has been shown by Swaddle (30) to be very high, and is around two orders of magnitude faster at pH ~14 than at pH ~10.

Solution analyses following Monel exposure at pH ~14 showed the copper concentration to be about 75 times higher than that of nickel (30,000 μg/liter of copper *vs.* 400 μg/liter of nickel).

Exposure in gaseous oxygen.—The compositions of corrosion films formed on Monel-400 under aqueous conditions were compared with those formed under gaseous oxidation at the same temperature. Abraded Monel-400 surfaces were exposed at 250°-300°C to 0.1 volume per cent (v/o) dry oxygen in argon for 0.3 hr. The resultant XPS spectrum, shown in Fig. 9(a), indicated that NiO and Cu_2O were present on the outer

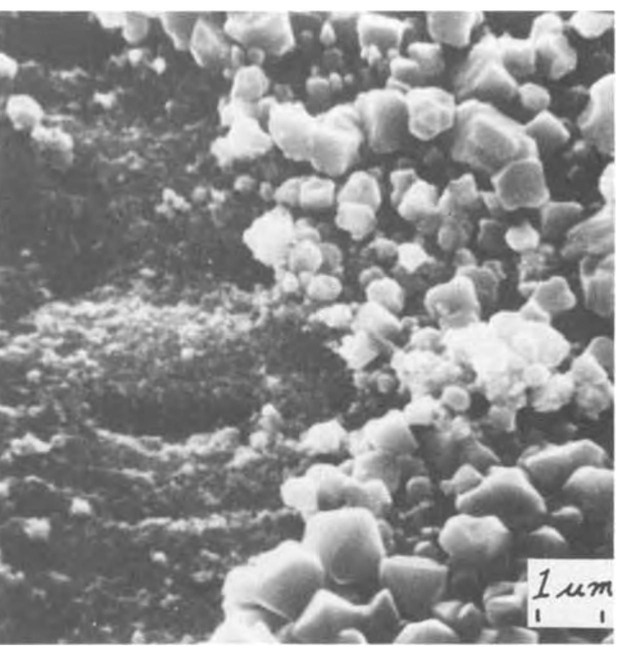

Fig. 8. Scanning electron micrograph of a Monel-400 surface exposed to 1.0M Li(OH) at 285°C for 48 hr.

surface in approximately the 2:1 atomic ratio expected from the alloy composition.

No attempt was made to determine whether the cuprous oxide and nickel oxide formed by gaseous corrosion of Monel-400 are in solid solution or are present as separate oxides, *i.e.,* NiO and Cu_2O. According to Schnal and Muller (31) these oxides are mutually insoluble, and hence one would expect a mixture to form. However, XPS spectra show only one prominent O(1s) line. Since the oxygen binding energy in Cu_2O is different from that in NiO by 0.8 eV (19), one would have expected to see a contribution from both oxygen in Cu_2O and NiO, if separate phases were present. Thus at least on the surface, a mixed cupronickel oxide may be formed.

Discussion

This work shows that, under the experimental conditions used, the aqueous oxidation of Monel-400 is at least partly controlled by a dissolution-precipitation mechanism. At *p*H ~10, the nickel-rich outer corrosion film is believed to be a result of $Ni(OH)_2$ precipitation from a solution not yet saturated with respect to any copper species. When the copper does eventually reach saturation in the closed system, it nucleates in localized areas on the hydroxide surface, leaving the major surface coverage as $Ni(OH)_2$. At *p*H ~14, the copper-nickel solubility difference is much larger and the resultant corrosion film is composed entirely of a nickel phase (NiO) after 48 hr. Longer exposures would eventually result in saturation with respect to copper species, and again a copper phase would be expected to nucleate and grow at the nickel phase-water interface.

The possibility was considered that nickel enrichment in the surface phase could also arise from a higher outward diffusion rate of nickel ions in the solid lattice. However, the oxide film produced by solid diffusion in the gaseous oxidation experiments on Monel-400 contains copper and nickel in quantities proportional to their concentrations in the alloy. Thus, under these time and temperature conditions, it appears that the relative diffusion rates of copper and nickel are approximately the same and are unlikely to result in surface nickel enrichment. Castle (17) previously studied the oxidation layer of a 50:50 Cu/Ni alloy and after heating the specimen in 13 kPa of oxygen for 0.5 hr at 500°C, the surface layer was found to be somewhat richer in copper than in nickel.

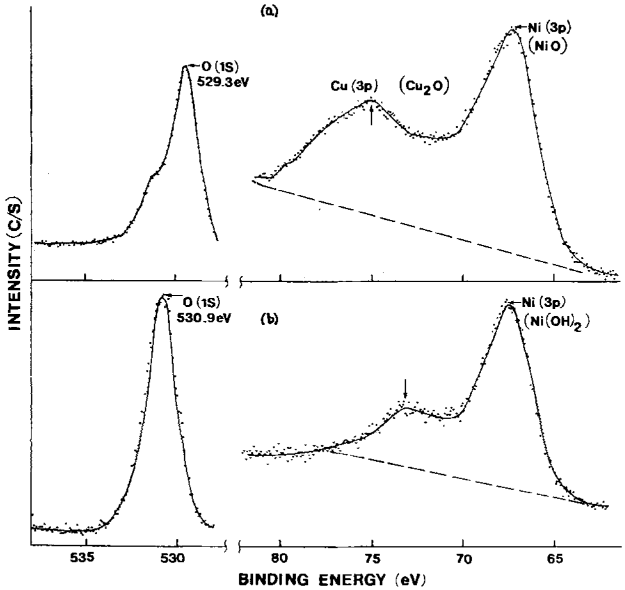

Fig. 9. Comparative XPS spectra of a Monel-400 surface exposed in (a) oxygen and (b) 1×10^{-4}M Li(OH) with an oxygen overpressure. In (b) the shoulder on the Ni(3p) peak indicated by the arrow results from a multi-electron excitation.

One other possibility which might lead to only a nickel oxidation product on the surface is the prior enrichment of one component of the alloy due to phase separation. Copper-nickel alloys are known to exhibit phase separation in this temperature range (32); however, the analyses of Monel-400 surfaces exposed under hydrogen at 285°C show that if separation does take place its extent is clearly insufficient to explain the major compositional change observed here during oxidation.

Under the oxygen partial pressure and temperature used in the aqueous corrosion experiments, film growth must occur by both solid-state diffusion and by dissolution-precipitation. An oxide of copper appears rapidly as the outermost layers of corrosion films formed at *p*H ~10 are removed by sputtering. It is believed that this copper is present in the film by virtue of a diffusion process since, as shown above, copper precipitation has not been found to occur in significant quantities even after lengthy exposure. The rising concentration of copper in the composition profile shown in Fig. 7 is likely controlled by the diffusion rate of the ion and possibly by the rate of leaching of copper by the unsaturated solution. On the other hand, while the presence of a significant diffusion process is based on the observation of copper in the underlying oxide layer, the evidence for a dissolution-precipitation process is based on the identification of $Ni(OH)_2$, a phase which can only form by this mechanism. The occurrence of $Ni(OH)_2$ in a film thick enough to be measured by x-ray diffraction helps to establish that the precipitated layer is not just a negligibly thin layer formed on top of a layer formed largely by solid diffusion, but rather that it constitutes an appreciable portion of the total corrosion product. At *p*H ~14, it is clear that the major corrosion process is dissolution precipitation since no copper phases are detected by any means in the film.

Since the composition of the surface products depends at any time on the solution concentrations of copper and nickel, the effects of exposing Monel-400 in a "once-through" autoclave system are expected to be different from those observed for the "closed" system in the present study.

Manuscript submitted Dec. 8, 1975; revised manuscript received March 29, 1976. This was Paper 75 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Studies in Derivative Chronopotentiometry

IV. Chemical Reactions Preceding Reversible Charge Transfer

ABSTRACT

The derivative technique for the measurement of chronopotentiometric transition times is applied to systems complicated by homogeneous chemical reactions preceding charge transfer. The manner in which the technique may be applied is discussed, and kinetic parameters for two complex systems, cadmium/cyanide and cadmium/nitrilotriacetic acid, are presented. Close agreement between experimental results (derivative and conventional chronopotentiometry) and theoretical predictions is observed; corrected conventional results agree with derivative results where overlap is possible.

Previous papers in this series have dealt with instrumentation and diffusion-controlled systems, analytical applications, and sub-millisecond transition times (1). Material dealing with correction and compensation of charging currents and with details of instrumentation, presented in earlier papers, is not repeated here.

Relationships dealing with the kinetics of homogeneous chemical steps preceding chronopotentiometric charge transfer have been presented by others (2, 3) and have been applied in a recent study (4). Our purpose is to present the theory and model systems illustrating the application of derivative chronopotentiometry in studies of systems complicated by a chemical step preceding reversible charge transfer.

Derivative of the Potential-Time Curve

In order to apply the derivative technique to a system such as

$$Z \underset{k_b}{\overset{k_f}{\rightleftarrows}} O, \quad O \pm ne \rightleftarrows R, \quad K = k_f/k_b$$

it is first necessary to obtain relationships for the potential-time (E-t) curve and for the derivative of the E-t curve, and to relate the transition time, τ, to the value of $(dE/dt)_{min}$, as was done for diffusion-controlled systems (5).

* Electrochemical Society Active Member.
Key words: chronopotentiometry, complexes, kinetics.

For systems with reversible charge transfer, the expressions for the surface concentrations of the oxidized (C_O) and reduced (C_R) forms can be substituted into the Nernst equation to obtain the appropriate E-t expression. Previously, Delahay and Berzins (3) determined the expression for C_O to be

$$C_O = \frac{K}{1+K}\left[C^* - \frac{2i_o t^{1/2}}{n\mathbf{F}(\pi D)^{1/2}} - \frac{i_o}{n\mathbf{F}D^{1/2}}\left(\frac{\text{erf}\,[t^{1/2}(k_f+k_b)^{1/2}]}{K(k_f+k_b)^{1/2}}\right)\right] \quad [1]$$

where $C^* = C_{O(t=0)} + C_{Z(t=0)}$. The appropriate expression for C_R is determined from the flux of this substance at the electrode surface and by application of Duhamel's theorem (3)

$$C_R = 2i_o t^{1/2}/n\mathbf{F}(\pi D)^{1/2} \quad [2]$$

C_O and C_R are valid at the electrode surface, and D is the diffusion coefficient assumed to be equal for O and R. All symbols have their usual significance, as defined in Ref. (3). The expressions for C_O and C_R are substituted into the Nernst equation

$$E = E_{1/2} + (RT/n\mathbf{F})\ln(C_O/C_R) \quad [3]$$

After substituting for C^* (using the condition that, at $C_O = 0$, $t = \tau$ in Eq. [1]), the following is obtained for the E-t curve

$$E = E_{1/2} + (RT/n\mathbf{F})\ln[K/(1+K)] + (RT/n\mathbf{F})\ln\{(\tau/t)^{1/2} - 1 + [\pi^{1/2}/2K(k_f+k_b)^{1/2}] \times [\text{erf}\,\tau^{1/2}(k_f+k_b)^{1/2} - \text{erf}\,t^{1/2}(k_f+k_b)^{1/2}]\}/t^{1/2} \quad [4]$$

A solution for Eq. [4], relating $(dE/dt)_{min}$ to τ, requires differentiating the expression twice and setting (d^2E/dt^2) equal to zero. The resulting expression is used to relate t at the minimum to τ, and this relationship is then substituted into the $(dE/dt)_{min}$ expression. Such a process was attempted for all values of K, t, and τ but yielded intractable expressions of little utility. More useful information was obtained by considering limiting behavior similar to that considered by Delahay and Berzins (3).

When the argument of the error function is small (< 0.1), the function is virtually equal to $(2/\pi^{1/2})$ times the argument [Ref. (6), p. 200]. Applying the conditions

$$\tau^{1/2}(k_f+k_b)^{1/2} < 0.1 > t^{1/2}(k_f+k_b)^{1/2}$$

to Eq. [4] yields

$$E = E_{1/2} + (RT/n\mathbf{F})\ln[(\tau^{1/2} - t^{1/2})/t^{1/2}] \quad [5]$$

which is identical to that for purely diffusion-controlled systems. Thus, as derived in Ref. (5), the differentiation of [5] gives

$$(dE/dt)_{min} = -(27RT)/(8n\mathbf{F}\tau) \quad [6]$$

When the argument of the error function is large (> 2), the function is virtually equal to unity [Ref. (6), p. 199]. Applying these conditions

$$\text{erf}\,\tau^{1/2}(k_f+k_b)^{1/2} > 2 < \text{erf}\,t^{1/2}(k_f+k_b)^{1/2}$$

to Eq. [4] yields

$$E = E_{1/2} + (RT/n\mathbf{F})\ln[K/(1+K)] + (RT/n\mathbf{F})\ln[(\tau^{1/2} - t^{1/2})/t^{1/2}] \quad [7]$$

It is obvious that differentiation of Eq. [7] will lead to Eq. [6] which is therefore valid for this limit also.

Thus, for both the upper and lower limits of the argument of the error function, the expressions for $(dE/dt)_{min}$ are identical to that for diffusion-controlled systems. The transition time can be calculated from the value of $(dE/dt)_{min}$ within these limits, in a fashion identical to that used for diffusion-controlled systems (1, 5). Although the dE/dt expressions are identical, it is interesting to note that the E-t curves are not; the kinetic E-t curve for the case where the argument of the eror function is > 2 contains the additional term $(RT/n\mathbf{F})\ln[K/(1+K)]$.

The procedure to be followed then is to calculate the kinetically influenced τ by use of Eq. [6]. The τ's thus calculated are used in the manner suggested by Delahay (6). It should be noted that the only information lost in using the limiting forms of the derivative technique is identical to that lost in using the limiting forms suggested for the conventional technique; the information lost is the nonlinear section of the $i_o\tau^{1/2}$ *vs.* i_o plot [see Fig. 8-10, p. 201, Ref. (6)]. The disadvantage in using the derivative technique with the procedures described above is that irreversible charge-transfer systems must be excluded from consideration. If such systems are to be considered, equations already available (3) for obtaining the appropriate E-t curve must be used.

Experimental

Chronopotentiometric and derivative chronopotentiometric data were taken using the instrument and readout systems described earlier (1). For the cadmium cyanide experiments, solutions were 10 mM in $Cd(NO_3)_2$ and 1.0M in KCN. For the cadmium nitrilotriacetate (NTA) experiments, four solutions were used. The solutions were 1.0 mM in $Cd(NO_3)_2$, 40 mM in nitrilotriacetic acid, 1.0M in KNO_3, and 0.1M total in acetic acid/sodium acetate buffer, with NaOH added to achieve the desired pH's. The pH's of the solutions were measured and found to be 2.92, 3.37, 3.73, and 4.00. All experiments were performed at ambient temperatures.

Results and Discussions

Cadmium cyanide system.—In these experiments, current densities ranging from 3.91 to 5.71 mA/cm^2 were utilized in obtaining conventional transition times ranging from 90 to 2.7 msec. Derivative transition times ranged from 75 msec to 80 μsec at current densities of 3.82-14.26 mA/cm^2. The current densities were corrected for the double layer charging current by use of the equation

$$i_{o(corr)} = (i_o\tau - B)/t \quad [8]$$

where B is the intercept of the Bard plot (1, 7) for the derivative data corresponding to short transition times. For the conventional data, B was calculated from the initial slope of the E-t curve, as suggested by Noonan (4). The corrected current densities ranged from 3.88 to 4.60 mA/cm^2 for the conventional data and 3.82-8.04 mA/cm^2 for the derivative data.

The data were treated in the manner suggested by Delahay and Berzins (3) for conventional data; their suggestion is based upon their Eq. [22] as follows

$$i_o\tau^{1/2} = (\pi D)^{1/2}n\mathbf{F}C^*/2 - \pi^{1/2}i_o\,\text{erf}[(k_f+k_b)^{1/2}\tau^{1/2}]/2K(k_f+k_b)^{1/2} \quad \text{[Eq. [22] Ref. (3)]}$$

This approach leads to two expressions, [9] and [10]

$$i_o\tau^{1/2} = [n\mathbf{F}(\pi D)^{1/2}C^*]/2 - i_o\pi^{1/2}/[2K(k_f+k_b)^{1/2}] \quad [9]$$

Equation [9] is derived from Eq. [22] of Ref. (3) for the case where the argument of the error function is > 2. It is, therefore, applicable at low current densities (long transition times). It indicates that a plot of $i_o\tau^{1/2}$ *vs.* i_o should be a straight line with an intercept at $i_o = 0$ equal to the product of C^* and the chronopotentiometric constant. The quantity $K(k_f+k_b)^{1/2}$ can be obtained from the slope. At high current densities, the argument of the error function in Eq. [22] of Ref. (3) is < 0.1 and the equation reduces to

$$i_o\tau^{1/2} = [n\mathbf{F}(\pi D)^{1/2}C^*]/[2(1+1/K)] \quad [10]$$

If sufficiently short transition times are experimentally accessible, the value of K may be calculated from the intercept of Eq. [9] and the experimental quantity $i_o\tau^{1/2}$ in Eq. [10].

Data for the cadmium cyanide system are plotted in Fig. 1. The increased range of the derivative data is obvious. The least squares slope and intercept of the derivative data at long transition times (first 10 points) are -1.149 ± 0.045 and 5.43 ± 0.18, respectively. The corresponding values for the conventional data are -1.123 ± 0.040 and 5.52 ± 0.17. Careful examination of the derivative data for short transition times shows that the region of constant $i_o\tau^{1/2}$ values has not been reached. Equations [9] and [10] were solved simultaneously, using the derivative data, to obtain a first approximation for K, and then Eq. [9] was employed to calculate (k_f+k_b). Then Eq. [22] of Ref. (3) was used to obtain an improved estimate of K and this cycle repeated until successive approximations of (k_f+k_b) were constant within 0.1.

The values calculated were 1.20×10^{-2} for K and 4.2×10^3 for (k_f+k_b). These constants were substituted into Eq. [22] of Ref. (3) and theoretical values of $i_o\tau^{1/2}$ and i_o calculated for a number of values of $\tau^{1/2}$. These theoretical points are plotted also in Fig. 1.

Recently, Reinmuth (8) advocated plotting $1/\tau^{1/2}$ *vs.* $1/i_o\tau^{1/2}$. Figure 2 is such a plot of the same data shown in Fig. 1. A least squares calculation of the first 10 points (long transition times) of the derivative data

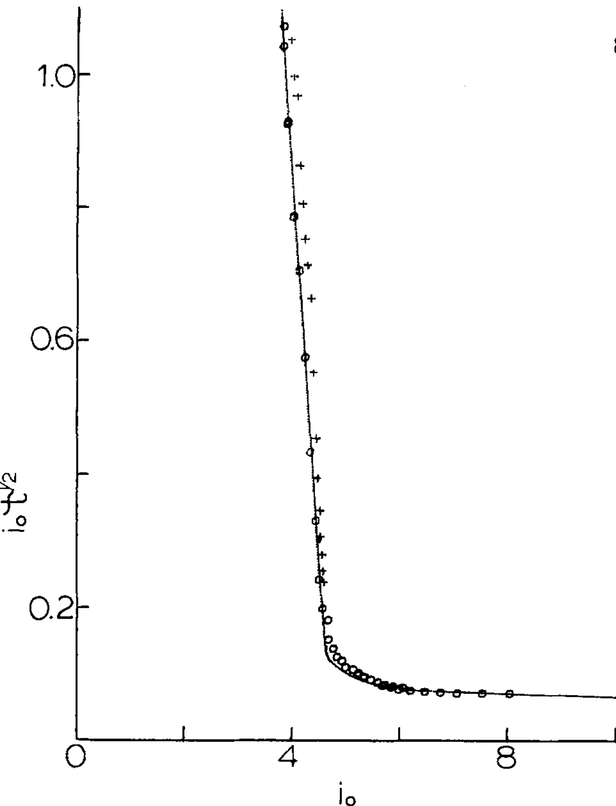

Fig. 1. Delahay (6) plot of chronopotentiometric data for solution 10 mM $Cd(NO_3)_2$, 1M KNO_3. i_o units are mA/cm²; $i_o\tau^{1/2}$ units are mA-sec$^{1/2}$/cm². ○, Derivative chronopotentiometry; +, conventional chronopotentiometry; and —, theoretical line for calculated kinetic parameters.

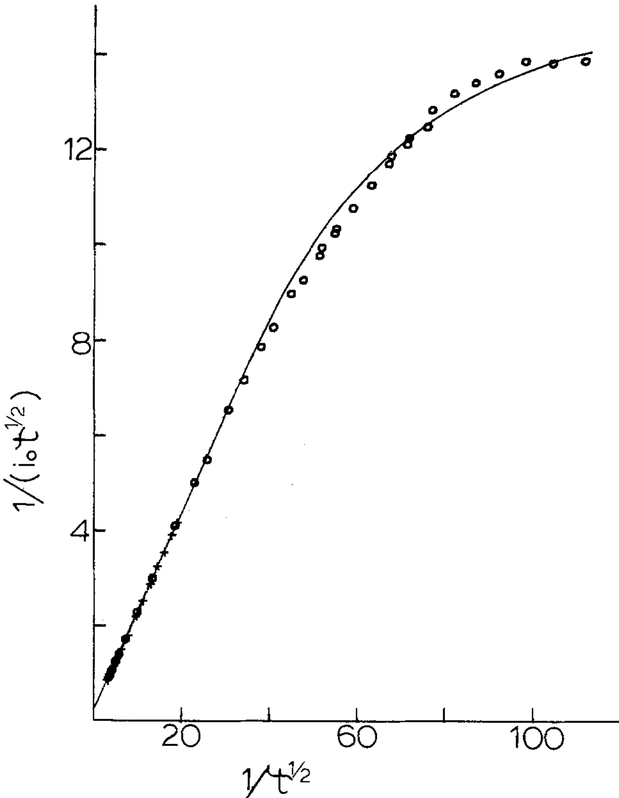

Fig. 2. Reinmuth (8) plot of same data as in Fig. 1

gives 0.212 ± 0.001 for the slope and 0.182 ± 0.003 for the intercept. The corresponding calculations for the conventional data give 0.204 ± 0.001 and 0.177 ± 0.006. The inverse of the intercepts (5.49 and 5.64) compare well with the intercepts of Fig. 1. However, if points in addition to the first 10 are used in the least squares calculations, the calculated values change significantly and the standard deviations increase markedly. Thus, although the Reinmuth plot (Fig. 2) compresses the data for long transition times so that they appear smoother, no significant advantage was found over the Delahay plot (Fig. 1) in the mathematical analysis of these data.

These results indicate that the derivative technique yields data superior to those obtainable using conventional chronopotentiometry since the derivative data are significantly less distorted by double layer effects. Questions, however, now must be asked about the system. The system has been studied by Gierst and Juliard (2), Delahay and Berzins (3), Noonan (4), Gerischer (9), and Flengas (10). Most agree that the species reduced is not $Cd(CN)_4^{-2}$, but rather one of the less highly coordinated complexes. Gerischer and Noonan have suggested that $Cd(CN)_3^-$ is the species reduced. This suggestion is based upon the nature of the electrode reaction (9) and upon the value of K calculated from an estimate of the value of $i_o\tau^{1/2}$ at high i_o (4). However, the derivative results presented here indicate a larger value of K than reported previously (4, 11-13). The reasons for the discrepancy are not clear, though possibilities are noncoincidence of ionic strengths, concentration of complexes, and a possible (though not likely) residual double layer effect. Still another possibility is that the reducible species is an ion pair, perhaps $K[Cd(CN)_4]^-$ or $K_2[Cd(CN_4)]$. In addition, Gerischer (9, 14) has attributed some degree of irreversibility to the reduction of $Cd(CN)_3^-$ and $Cd(CN)_2$. His experiments, however, employed solutions markedly different from ours, the solutions containing substantial amounts of chloride ion.

Cadmium-nitrilotriacetic acid system.—This system has been studied in detail (15-17 and references therein). The system shows two only slightly separated polarographic waves in acetate buffers (≤ pH 5), the second wave being the direct, irreversible reduction of the complex. The wave at more positive potentials is the reversible reduction of cadmium ion to the metal. Two parallel reactions precede this first reduction

$$Cd(NTA)^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Cd^{+2} + NTA^{-3} \quad [I]$$

$$Cd(NTA)^- + H^+ \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} Cd^{+2} + HNTA^{-2} \quad [II]$$

Reaction [II] is much faster than reaction [I]. The results reported here refer to the first reduction wave and are composite rate and equilibrium parameters for [I] and [II].

The system provides a formidable challenge if one is limited to the use of conventional chronopotentiometry. The two waves occur close in potential and merge at high current densities, as ohmic (IR) problems become severe. We chose not to rely upon the conventional technique, and the results in Table I are calculated from derivative chronopotentiometric data exclusively. Results for pH 2.92 (curve a) and 4.00 (curve b) are shown in Fig. 3. The common intercept of 0.502

Table I. Rate and equilibrium parameters for Cd-NTA. Solutions: 1.0 mM $Cd(NO_3)_2$, 40 mM NTA, 1.0 M KNO_3 and 0.1M in acetate buffers at the indicated pH's.

pH	—Slope	$1/K(k_f + k_b)^{1/2}$	K	k_f
2.92	0.14	0.15	—	—
3.37	0.63	0.71	0.026	72
3.73	1.9	2.1	0.016	13
4.00	2.6	2.9	0.014	7.8

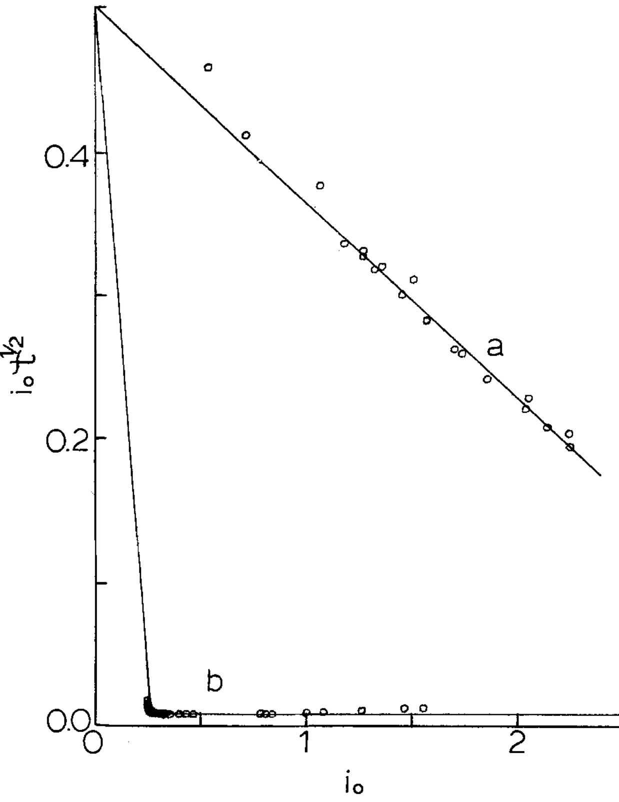

Fig. 3. Derivative chronopotentiometry for Cd-NTA solutions (see Experimental Section). Units same as Fig. 1. ○, Curve a: $pH = 2.92$. ○, Curve b: $pH = 4.00$. Solid lines: theoretical lines for calculated kinetic parameters.

on the $i_0\tau^{1/2}$ axis in the figure is the value obtained for the data at pH 2.92; sufficient data for independent determinations of the intercept value for the other pH's were experimentally inaccessible.

The results in Table I compare favorably with measurements reported earlier by Shuman and Shain (15) and by Carney (16). Discrepancies between ours and the two earlier studies are not so large as the discrepancies between the two earlier sets. Since our primary goal is the introduction of the derivative chronopotentiometric technique, its theory and methodology, we prefer not to speculate either concerning the sources of the discrepancies or concerning the detailed chemistry of the system. We note, however, that our results generally fall between those of the earlier two studies despite the fact that our technique is different from the similar techniques used in those studies.

Conclusions

These combined results confirm the utility of derivative chronopotentiometry in kinetics studies. The technique is obviously superior to conventional chronopotentiometry (and, perhaps, to other techniques) where applicable. The chief disadvantage and limiting feature of the technique is its restriction to systems involving reversible charge transfer following the chemical step.

Effect of Temperature on the Electrochemical Kinetics of Gadolinium in the Curie Region

David W. DeBerry*

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

Anodic dissolution and hydrogen evolution kinetics of Gd were investigated over the range 5°-30°C. Reaction orders with respect to pH for the HER and for anodic dissolution of Gd are temperature independent, as are the transfer coefficients. The apparent activation energy of anodic dissolution changes at the Curie temperature with that above 17°C being smaller. The change for the HER is almost the same but in the opposite direction. For both reactions there is a simultaneous change in the preexponential factor, yielding a practically smooth over-all ln i *vs.* $1/T$ curve. This behavior can be rationalized by addition of a ferromagnetic energy term to the activation energies. A model is proposed based on the existence of paramagnetic surface layers below the Curie temperature and the consequent introduction of an energy gradient for the transport of electrons to and from the metal surface.

The influence of the metal of an electrode on electrochemical reaction rates is of interest both to electrochemical kinetics and practical applications. Comparison of results for different metals is complicated by simultaneous changes in properties which might influence rates, and occasionally by changes in reaction mechanisms. Similar problems exist with alloys where unknown variations may exist between surface and bulk compositions. This research determined rates of electrochemical reactions involving Gd in the paramagnetic (Pm) and ferromagnetic (Fm) states.

Changes in reactivity of metals and alloys at their Curie temperatures (T_C) have been observed, mainly for gas/solid catalysis. Variation in temperature coefficients at T_C is known as the magnetocatalytic or Hedvall effect (1-3). For example, decomposition of formic acid on Co-Pd shows a 30% increase in activation energy (E_A) and a thousandfold increase in preexponential factor (ξ) above T_C (4). Similar results were obtained for the oxidation of Fe-Cr in oxygen (5). In general both E_A and ξ change so as to give a practically smooth over-all Arrhenius curve. The effect is usually explained by qualitative discussions of changes in electronic states, orientation of electron spins, d-band holes, and work function (6, 7).

A related area involves the study of reactions at a series of alloys with compositions changing from Fm to Pm at constant temperature. Conway (8) determined the electrochemical rates and E_A of the HER at a series of Cu-Ni alloys. The apparent E_A's and exchange current densities (i_o) decrease from pure Ni to pure Cu, but beyond 60% Cu the changes were much smaller. The results could only partially be explained by changes in the metal-H bond energy caused by changes in the number of d-holes per atom of Ni. Anodic passivation studies of Ni alloys indicate anomalous changes at critical alloy compositions (9, 10), also attributed to d-electron configuration changes. Recently doubt has been expressed regarding correlation between d-band character and M-H bond energy (11). Surface composition may be quite different from the bulk composition (12).

Key words: hydrogen evolution, anodic dissolution, ferromagnetism, activation energy.

Gadolinium was chosen for this research since its T_C (17°C) is accessible. Electrochemical measurements at a Gd electrode are complicated by the thermodynamic instability of the metal in the presence of water (13). The mixed potential of Gd in aqueous solutions (pH 5-6) has been measured at temperatures including T_C by Prall (14) and Daire (15). Below T_C they observed an increase in mixed potential to more active values with increasing temperature. Prall ascribed the changes to the effects on the work function or sublimation energy while Daire suggested either an abnormal increase in anodic dissolution rate or electronic surface states different from those in bulk metal. He also indicated that it was difficult to explain the changes in terms of classical thermodynamics. Daire found no abnormal changes in the heat of solution of Gd in 1N HCl from 3° to 40°C (16).

Experimental

The Gd (Material Research Corporation) was obtained as 0.25 in. diameter cast rods, prepared from the distilled metal. The typical emission spectrographic analysis supplied with the sample lists the following impurities: 0.005% Eu, Dy, and Y; 0.01% Sm, Tb, Ca, Mg, Si, Fe, and Al. A Beckman rotating electrode assembly was used to drive a rotating disk electrode (RDE) consisting of a Gd cylinder fitted very tightly in a cylindrical Teflon sheath. A rotation rate of 50 rps was used for the results given here. Electrodes were degreased, stored in trichlorethylene, and polished on 3M 600 grit and Buehler 4/0 grit emery paper before use.

Teflon standard taper adapters were used to fit the reference electrode, precision thermometer, and rotating electrode body to the cell. The main body of the cell was jacketed to allow circulation of water from a constant temperature (± 0.03°C) bath. A large area Pt gauze auxiliary electrode was contained in a tube separated from the main cell solution by a fine glass frit. The reference compartment containing a normal calomel electrode at 25°C and bridge were filled with cell solution but were separated from the main compartment by a coarse frit. Test solutions were deaerated with high purity He after removing trace oxygen with Ridox oxygen scavenger (Fisher Scientific

Company) and presaturating with test solution. Water was purified with a two-stage quartz still fed with laboratory deionized water. Suitability of this water for electrochemical measurements was tested by reproducing the accepted current-potential curves at a Pt RDE in 0.5M H_2SO_4. Reagent grade chemicals were used in all solutions.

A scanning potentiostat of conventional design (18) was used to obtain current-potential curves. Ohmic potential drop in the solution was compensated by positive IR_s feedback obtained by galvanostatic pulse measurements. A scan rate of 0.050 V/min was used for the results given here. The cathodic scan was always made first. Equivalent results were obtained for the anodic scan if it was done first, but the subsequent cathodic scan results were erratic. Experimental procedures are described in more detail elsewhere (17).

Results

Selection of electrolyte system.—In acidic aqueous solutions (0.2M $NaClO_4$ + $HClO_4$ to pH 1-3) Gd undergoes rapid attack with vigorous hydrogen evolution. The polarization curves show mass transfer control. In pH 12, 0.5M Na_2SO_4 a fine white precipitate [probably $Gd(OH)_3$] forms on part of the electrode surface. The corrosion rate is substantially decreased in slightly acidic or neutral (pH 5-7) aqueous salt solutions. In this category, solutions of $NaClO_4$, Na_2SO_4, $(NH_4)_2SO_4$, $GdCl_3$, and $Gd(ClO_4)_3$ were used. Reproducible and kinetically useful results are unobtainable in these unbuffered solutions. This is probably due to change in pH, especially near the electrode surface during polarization. In addition, localized corrosion and pitting of the electrode were usually evident, especially in solutions containing Cl^-.

Attempts to study the Gd^{3+}/Gd reaction in acetonitrile and in dimethylformamide were unsuccessful. The open-circuit potential was not reproducible, was more positive (noble) than that expected for this couple, and at times oscillated slowly. The electrode was readily polarized at small current densities (*e.g.*, $\Delta V = 0.5V$ for $i = 10\ \mu A/cm^2$). This behavior is probably caused by oxidation of the metal surface by impurity water to form a stable film. The procedure for the purification of DMF is said to reduce the water to less than 20 ppm (19).

These results indicated that it was desirable to use a buffered, slightly acidic, aqueous electrolyte solution. The acetic acid/sodium acetate buffer system proved satisfactory. There is no apparent localized corrosion or pitting in these solutions. Mixed potential (V_M) values obtained after about 25 min were reproducible to ±0.011V.

Polarization curves and transfer coefficients.—Polarization curves were recorded at each temperature and pH. Some of the results obtained are given in Fig. 1 and 2, where i is the current density and $\pi = V - V_M$. The most linear curves were obtained in the higher pH solutions (pH 5.94 and 6.46) since, in these, the open-circuit corrosion current density is low compared to those at which mass transfer becomes important. The linear Tafel slopes obtained in these solutions were used to obtain the transfer coefficients presented in Table I. The same slopes apply to the lower pH results at moderate current densities. The lower limit is at about pH 5.06, however, since results obtained at pH 4.70 did not show any appreciable linear region. The transfer coefficients are independent of temperature within experimental error (±0.03 in α). A cathodic Tafel slope of 0.170V ($\alpha_c = 0.35$) was obtained by Greene (20) in phosphate buffered solutions at 25°C. He did not obtain linear anodic Tafel slopes in these solutions.

Reaction orders.—The effect of solution pH at 1.00M sodium acetate on the rates of both the cathodic and anodic reactions is shown in Fig. 3-5. The maximum pH-temperature variation estimated from thermodynamic data (21) is about the same as the uncertainty of pH values measured at 25°C (±0.03 pH units); no correction was attempted. The effect of acetate ion concentration on anodic reaction rate at pH 5.45 is shown in Fig. 6. A constant ionic strength ($I = 1.00M$) was maintained by addition of $NaClO_4$.

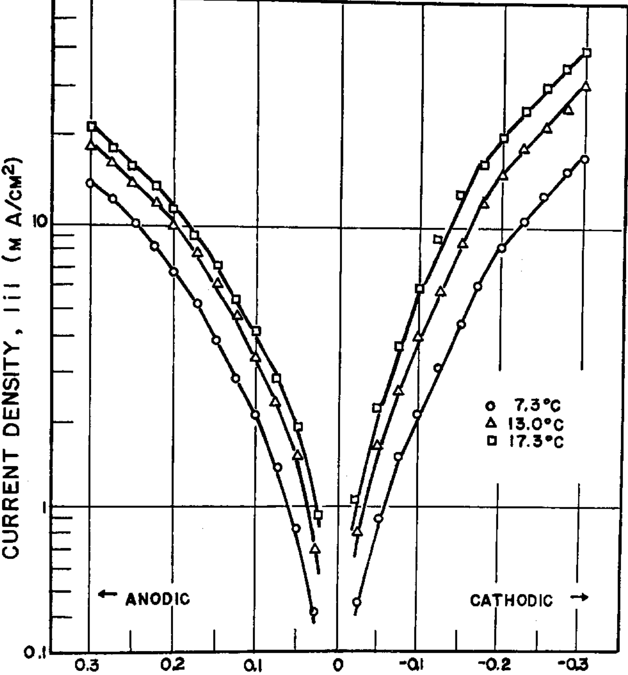

Fig. 1. Polarization curves for Gd in pH 5.45 acetate buffer at 7.3°, 13.0°, and 21.2°C.

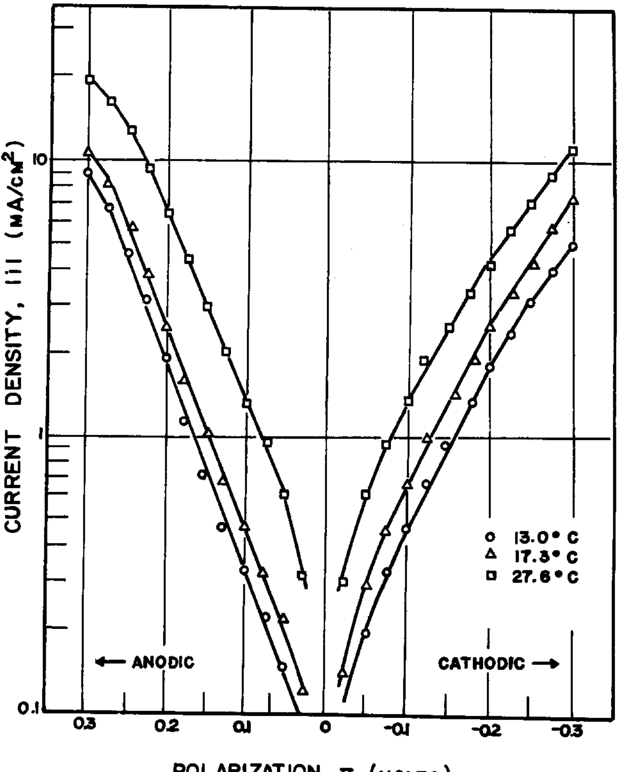

Fig. 2. Polarization curves for Gd in pH 6.46 acetate buffer at 13.0°, 17.3°, and 27.6°C.

Table I. Experimental transfer coefficients

T (°C)	α_c	α_a
5.6	0.31	0.38
7.3	0.33	0.41
10.1	0.30	0.41
13.0	0.33	0.40
16.2	0.34	0.40
17.3	0.35	0.40
19.0	0.34	0.39
21.2	0.36	0.40
23.3	0.34	0.38
25.6	0.33	0.41
27.6	0.35	0.38
29.7	0.32	0.37
Average	0.33	0.40

For the HER the average reaction order is -1.11 ± 0.06 (95% confidence limits). As summarized in Table II, the Gd dissolution reaction orders with respect to both pH and acetate ion are zero within experimental error. In all cases there is no apparent temperature dependence.

Temperature dependence.—The temperature dependence of each reaction rate was determined at a constant cell potential with respect to a reference electrode at room temperature. The thermal liquid junction potential (TLJP) developed in the solution (1.00M NaAc/HAc) salt bridge was estimated from published data (22) and found to be negligible (0.02 mV/deg) over the temperature range used. Most other electrochemical E_A determinations have been made for acidic or alkaline solutions in which the TLJP's are large and not accurately known. This has led to use of isothermal working and reference electrodes which introduces additional uncertainties since the temperature dependence of the reference electrode-solution potential difference is unknown.

Current densities for the HER at -1.220V *vs.* SHE (25°C) were obtained from the experimental polarization curves for all temperatures and pH values. This cell potential was chosen so that i for each run would be in the linear region of the ln i *vs.* π plot. The ln i values for pH 5.06, 5.45, and 6.46 were then converted to the corresponding values for pH 5.94. Results representing 63 runs at 12 temperatures are shown in Fig. 7 with mean deviations. Values of the E's, intercepts (B), and standard deviations calculated for the over-all curve and indicated high and low temperature intervals using replicated data linear least squares method are given in Table III. An analysis of variance of re-

gression was carried out (23). The amount of deviation using the two individual lines is significantly reduced compared to the over-all regression line (ratio of mean squares = 4.13; $F_{0.05,2/59}$ = 3.15). The difference between the slopes of the individual lines is significant at the $F_{0.01}$ level.

The data treatment for the Gd dissolution reaction was analogous to the HER except that no pH normalization was necessary. The *i*'s were measured at −0.920V *vs.* SHE (25°C). Results from 65 runs at 12 temperatures are shown in Fig. 8. Calculated values are given in Table III. A highly significant reduction in the amount of deviation is obtained by using the high and low temperature intervals as compared to the over-all regression line (ratio of mean squares = 10.41; $F_{0.01,2/61}$ = 4.98). This is due primarily to the significant difference in the two individual slopes for which ratio = 19.20; $F_{0.01,1/61}$ = 7.08.

Standard E_A values were not necessary for this study which is concerned only with such changes at a given potential. For completeness the approximate E_A's at the standard potentials, V^o_j, of the H^+/H_2, and Gd^{3+}/Gd electrodes were calculated by adding $\alpha_j F(V - V^o_j)$ to the experimental E_A's and are given in Table III.[1]

25.6	—	—	0.04 ± 0.12

Discussion

The results can be divided into two groups: (*i*) transfer coefficients and reaction orders relating to HER at Gd and the anodic dissolution of Gd, and (*ii*) the rates of these reactions as a function of temperature. There is no detectable change in the quantities of the first group over the temperature range studied. This indicates that the mechanisms of these reactions are the same for paramagnetic and ferromagnetic gadolinium. Both reactions are charge-transfer controlled under the conditions of interest; possible mech-

[1] The V^o value of the Gd/Gd^{3+} electrode, taken as −2.29V *vs.* SHE for these calculations, is based on the heat of solution of Gd measurements given by Spedding (24) and by Daire (16). The V^o value usually quoted (−2.40V) is based on the heat of solution measurements by Bommer (25) which have been criticized by Spedding. Experimental values at 25°C for S^o_{Gd} (16.267 eu) (26) and $S_{Gd^{3+}}$ (−48.0 eu) (27) were used in the calculation of the V^o proposed here.

anisms have been analyzed (17). Aspects of the experimental temperature dependence are examined first. Deficiencies of a model based solely on changes in bulk energy of the electrode to explain the temperature dependence are then discussed. A model based on changes in electronic structure of Gd on magnetic ordering as well as changes in this structure near the metal surface is proposed.

Two observations of the ln i *vs.* $1/T$ curves are especially pertinent. (*i*) The magnitudes of the apparent changes in E_A of the HER and the Gd dissolution reaction at T_C are almost the same (but in opposite directions). (*ii*) For both reactions there is a simultaneous change in the preexponential factor in such a way as to give a practically smooth over-all ln i *vs.* $1/T$ curve. These observations can be rationalized if it is recognized that any possible contribution to E_A due to "magnetic" order in the ferromagnetic state will decrease as T_C is approached. It is reasonable to assume that such contributions are absent in the paramagnetic state and take that as "normal." Then the ferromagnetic contribution to the over-all activation energy below T_C can be written in the form

$$E_F = \kappa f(T/T_C) E^\circ_F \qquad [1]$$

where $f(T/T_C) \rightarrow 0$ as $T \rightarrow T_C$, κ is a constant, and E°_F is the energy contribution at $T = 0$. The assumed form of Eq. [1] implies that κ can be identified with the symmetry factor or Bronsted coefficient appearing in linear free energy relationships. To this approximation, κ is a constant for reactions of similar type and can take on the values $0 < \kappa < 1$. It is often found that $\kappa \simeq 1/2$.

The magnitude of E_F is apparently the same for the HER and Gd dissolution reaction, but the contribution is such that the over-all E_A of the HER is decreased while that of the anodic reaction is increased in the ferromagnetic state. The cathodic and anodic current densities can then be expressed as

$$i_c = B_c \exp[-(E_{c,p} - E_F)/RT] \exp[-\alpha_c FV/RT] \qquad [2a]$$

$$-i_a = B_a \exp[-(E_{a,p} + E_F)/RT] \exp[\alpha_a FV/RT] \qquad [2b]$$

in which temperature-independent terms are contained in the B factors and $E_{c,p}$ and $E_{a,p}$ are the "paramagnetic" cathodic and anodic activation energies. Rearrangement yields Eq. [3]

$$\ln i_c - E_F/RT = -1/RT(E_{c,p} + \alpha_c FV) + \ln B_c \qquad [3a]$$

$$\ln |i_a| + E_F/RT = -1/RT(E_{a,p} - \alpha_a FV) + \ln B_a \qquad [3b]$$

Application of these equations to the experimental data with suitably chosen values of κ, E°_F, and the function $f(T/T_C)$ should result in ($\ln i \pm E_F/RT$) *vs.* $1/T$ plots linear over the entire temperature range. Further discrimination of mechanisms is based on the estimation of E_F and prediction whether the over-all E_A's should be increased or decreased by its application.

At a given potential *vs.* a reference electrode the electronic energy levels in different metal electrodes are considered to be equal. Under this condition, there is essentially no explicit dependence of the rates of an electrode reaction on the work functions of different metals (28). For reactions in which there is strong interaction with the electrode, differences in these rates from one metal to another are thought to be due primarily to differences in the adsorption energy of reactant on the metal (28, 29). The HER, involving the adsorption of hydrogen atoms, is the best known example of this type of dependence. For metal deposition and dissolution reactions, the free energies of ionic solvation, ionization of the metal atom, and cohesion of different metals must also be taken into account.

The results for Gd might be considered to be those for two "different" metals, paramagnetic Gd and ferromagnetic Gd. Therefore, the HER results might be interpreted as being due to changes in the energy of adsorption of hydrogen atoms. For Gd dissolution, the metal cohesion energy and the energy of adsorption of intermediate adatoms or adions might be affected by the degree of magnetic order.

It would be difficult to calculate the energies of adsorption and cohesion in detail. They can be estimated, however, if it is assumed that they are due solely to the bulk exchange energy of the metal. The Weiss molecular field theory is the simplest model that can be expected to give a reasonable estimate of the overall exchange energy of Gd. Calculations based on this theory are given in the Appendix. The calculated contributions to ln i are quite small even with $\kappa = 1$. At the lowest temperature (5.6°C) E_F/RT is 0.10, and decreases rapidly at higher temperatures. There is little effect on the experimental ln i *vs.* $1/T$ plots, and there is still a significant difference between the high and low temperature slopes. Since these calculations represent an expected upper limit, a model based solely on over-all changes in the bulk metal energy as influencing the energies of adsorption and cohesion appears to be inadequate.

Consideration of the probable surface properties of a ferromagnetic substance also leads to difficulties in the interpretation given above. Although little is known about these properties, the collective nature of ferromagnetism alone leads to an expected decrease in the degree of magnetic order near the surface of a ferromagnet. A recent analysis based on a molecular field model indicates that near the Curie temperature the relative magnetization near the surface is (30)

$$\delta \propto (1 - T/T_C) \qquad [4]$$

while the bulk value is

$$\delta \propto (1 - T/T_C)^{1/2} \qquad [5]$$

Therefore near T_C the molecular field quantity U_M should be much smaller near the surface than in the bulk. Observations of the magnetic properties of thin evaporated films of nickel indicate that the apparent T_C decreases with decreasing film thickness (31). A 20Å Ni film has no spontaneous magnetization at room temperature, and the magnetization *vs.* T curves are considerably flatter than those of the bulk metal. A similar decrease in magnetization with decreasing film thickness has been reported for electroplated Ni, Fe, and Co. These observations indicate that very near the surface the electronic structure of a ferromagnetic metal must change more or less abruptly to the corresponding paramagnetic structure. This is expected to be especially true near the T_C of the bulk material.

The magnetic ordering in rare earth metals is thought to occur through an indirect exchange mechanism between the highly localized magnetic 4f electrons via spin polarized conduction electrons. Gadolinium, one of the simpler examples, shows only ferromagnetic behavior below the Curie point. Conduction band and Fermi surface calculations have been made for Gd (32, 33). The calculated conduction bands are quite different from those of the free-electron model and resemble those of the transition metals. There is a high density of states near the Fermi level. Ordering of the 4f moments introduces energy gaps in the conductance bands at or near the Fermi surface and "destroys" large segments of the surface (34). These gaps are about the same magnitude as the exchange coupling, j_{sf}, between the 4f and conduction electrons. There is then an exchange splitting of the conduction bands. This splitting has been used to explain an experimentally observed infrared absorption peak of ferromagnetic Gd (35-37). This peak occurs at about 0.70 eV at low temperature, shifts to longer wavelengths as the temperature is increased, and disappears above T_C.

The shift correlates with the spontaneous magnetization-temperature curve of Gd within the accuracy limits of the measurements (37). The value of j_{sf} estimated from the "excess" moment of Gd (*i.e.*, 7.55 μ_B instead of 7.0 μ_B) and the calculated density of states at the Fermi level is 0.087 eV (34). The value calculated from the absorption peak at 0.70 eV is 0.10 eV.

It is proposed that the existence of such energy gaps at or near the Fermi level of the ferromagnetic bulk metal, relative to the paramagnetic surface layers, introduces an energy gradient for the transport of electrons near the metal surface. The qualitative features of the experimental results could be explained if this gradient favors the transport of electrons to the electrode surface (as in the HER) below the Curie temperature while the transport of electrons to the bulk metal (as in Gd dissolution) is simultaneously retarded. The magnitude of the effect should be the same for the two reactions, in accordance with the results. Futhermore, if it is assumed that $E°_F$ can be identified with j_{sf} and $f(T/T_C)$ with δ, Eq. [1] becomes, with $\kappa = ½$

$$E_F = ½\delta j_{sf} \quad [6]$$

The application of this equation with $j_{sf} = 0.10$ eV to the experimental points using Eq. [3] is shown in Fig. 9 and 10. There is no significant difference between the slopes of the paramagnetic and ferromagnetic curves. The lines drawn in Fig. 9 and 10 correspond to the pooled high and low temperature slopes and intercepts. Although the pooled slopes fit the data quite well, there appears to be small residual changes in the intercepts ($\ln B_j$) at the Curie point. Due to the approximate nature of the model it is not at present possible to comment on the reality of these changes.

An expression for the mixed potential of the electrode can be obtained from Eq. [2] by setting i_c equal to $|i_a|$. Using E_F from Eq. [6], V_M is given by

$$V_M = \frac{1}{(\alpha_a + \alpha_c)F}\left[j_{sf}\delta + E_{a,p} - E_{c,p} + RT \ln \frac{B_c}{B_a} \right] \quad [7]$$

In terms of the pooled E_A's (both referenced to the SHE) and pooled intercepts, V_M can be evaluated as

$$V_M = 0.137\delta - 1.663 + 2.025 \times 10^{-3}T \quad \text{(volts)} \quad [8]$$

Calculated values of V_M as a function of temperature are shown in Fig. 11. The magnitude of the changes and shape of the curve agrees well with the experimental curve (17). Good agreement is also obtained with Daire's (15) data in 0.1M GdCl, after fitting the second and third terms of Eq. [8] to the "paramagnetic" part of his data.

The deduction of Eq. [6] is admittedly rough and intuitive. One of the major assumptions concerns the direction of the proposed energy gap gradient. Photoemission results (38) for Gd indicate that the energy

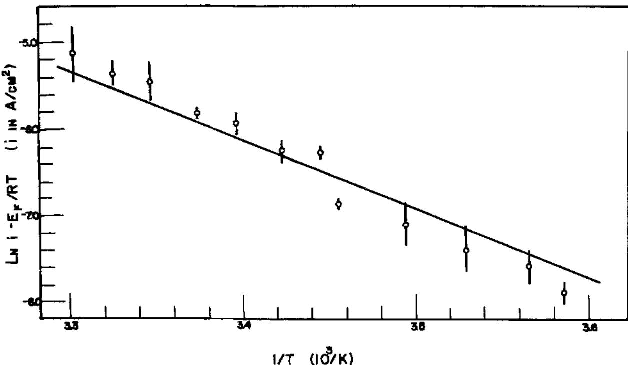

Fig. 9. Cathodic ln $|i|$ — E_f/RT vs. $1/T$

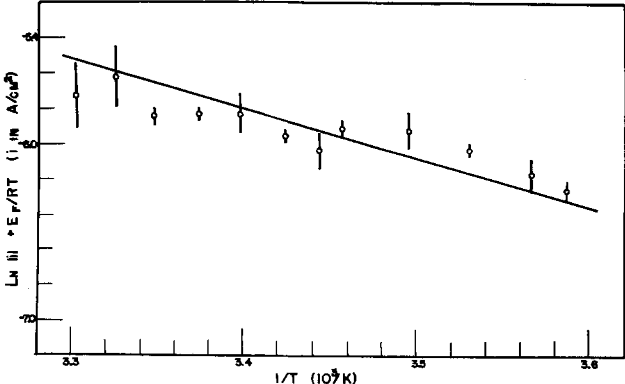

Fig. 10. Anodic ln $|i|$ + E_f/RT vs. $1/T$

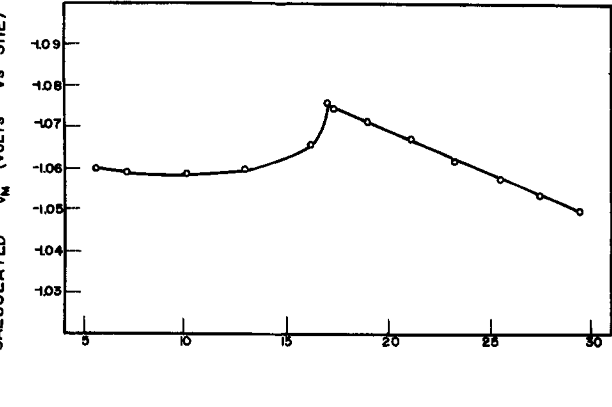

Fig. 11. Calculated mixed potential vs. temperature

distribution curves at −80° and 25°C are identical in shape (the resolution was 0.1 eV). The curve at −80°C is shifted to higher energies by about 0.03 eV from the 25°C curve. Intermediate temperature results lie between these two curves. This gives a rough indication that the Fermi level is higher in the ferromagnetic state than in the paramagnetic state and supports the proposed direction of the energy gradient. Although the identification of j_{sf} as the over-all energy change may be an oversimplification, the experimental results are adequately represented by the magnitude and temperature dependence of this quantity.

Conclusions and Implications

The proposition given above is an attempt to explain the experimental results in terms of the magnetic properties of gadolinium. It is, in part, contrary to most of the commonly accepted notions of the role of a metal electrode in electrochemical reactions. It is difficult to rationalize all of the observations in terms of accepted theories. Although Gd may represent a special case, it is felt that attempts to apply free-electron models to real metals and ignoring possible changes in electron structure very near the metal surface cannot be expected to yield a quantitative description of the electrochemical behavior of a metal electrode.

Acceptance of the proposed model implies that similar considerations may also apply to Fe, Co, and Ni. All are ferromagnetic at temperatures normally encountered in electrochemical measurements, and thermal behavior similar to that considered here is not expected. Although speculative, it is possible that some peculiarities of their electrochemical behavior may be partially explained in terms of the model given here. It is known that chemisorption of some species can alter the magnetization of very small "superparamagnetic" particles (39). Chemisorption on Fe, Co, and Ni electrodes might also modify the "magnetic" properties of

the surface relative to the bulk metal and influence any existing gradient. It is likely that the initial stage of anodic passivation of these metals is accompanied by the adsorption of an oxygen anion (40). This adsorption may result in an increase in the gradient (and increase in activation energy) for metal dissolution. The consequent "electronic inhibition" could be partially responsible for the abrupt and pronounced onset of passivity for these metals when only a very thin "film" is present.

APPENDIX

In the Weiss molecular field theory the total exchange energy contribution to the internal energy of the solid is (41)

$$U_M = -\tfrac{1}{2}\gamma M_s(O)^2\delta^2 \quad \text{[A-1a]}$$

where γ is molecular field constant, $\delta = M_s(T)/M_s(O)$, and $M_s(T)$ is the saturation magnetization at the temperature T. Using γ calculated from the T_C and the experimental value of $M_s(O)$ (42), U_M can be estimated as

$$U_M \simeq -7.0 \times 10^2\delta^2 \quad \text{(cal/mole)} \quad \text{[A-1b]}$$

The experimental temperature variation of δ near the T_C of Gd can be represented by the Brillouin function with $J = 7/2$

$$\delta = \frac{2J+1}{2J}\coth\frac{2J+1}{J}x - 1/2J\coth(x/2J) \quad \text{[A-2a]}$$

where

$$x = (3J/J+1)(T_C/T)\delta \quad \text{[A-2b]}$$

For the experimental temperature range discussed here, $T \rightarrow T_C$ and a series expansion of the coth y terms of Eq. [A-2a] can be used to obtain an explicit expression for δ in terms of T/T_C.

Using the above assumptions and Eq. [A-1a] and [A-1b] the magnitude of the exchange contribution to the E_A's can be expressed as

$$E_F = (\kappa\gamma/2)M_s(O)^2\delta^2 \quad \text{[A-3a]}$$

$$E_F \simeq 7.0 \times 10^2\,\kappa\delta^2 \quad \text{(cal/mole)} \quad \text{[A-3b]}$$

where $f(T/T_C)$ is identified as δ^2.

The Conductance of Heptyl Viologen Dibromide in Water and Methanol

H. T. van Dam

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The conductance of heptyl viologen dibromide in water and methanol has been measured. The data have been treated according to the theory of Murphy and Cohen, extended to account for incomplete dissociation. In water, heptyl viologen dibromide is completely dissociated; in methanol, the dissociation of the second bromide ion is incomplete with a dissociation constant $K = 5.5 \times 10^2$. The heptyl viologen ion obeys the Walden rule in these two solvents.

The 4.4′-dipyridinium compounds (**I**) known as the viologens form a group of 2-1 electrolytes, which are interesting because of their ability to form stable, colored radical ions on reduction. This property proves to be very useful since it provides the basis of a feasible electrochemical display (1)

$$R\!-\!\overset{+}{N}\langle\bigcirc\rangle\!-\!\langle\bigcirc\rangle\overset{+}{N}\!-\!R, \quad 2X^-$$

$$\mathbf{I} = \text{dipy } X_2$$

We found that with a proper choice of the substituent R and the anion X^- in (**I**) the reduced form is insoluble in water. This is not the case in organic solvents such as acetonitrile, acetone, or methanol. We also observed that the reduction potentials depend on the anion concentration only for the case of water. We have explained these differences in behavior as follows (2). In water the electroactive species is the completely dissociated ion dipy^{2+} but in organic solvents one X^- remains attached and dipy X^+ is reduced instead, *i.e.*, we have the following reaction scheme

in water

$$\text{dipy}^{2+} + e \rightleftarrows \text{dipy}^{+}$$

$$\text{dipy}^{+} + X^{-} \rightleftarrows (\text{dipy } X)_{\text{solid}}$$

in organic solvent

$$\text{dipy}X^{+} + e \rightleftarrows (\text{dipy } X)_{\text{solv}}$$

In order to check the above hypotheses, we have measured both in water and in methanol the ionic conductivity of heptyl viologen dibromide as a much-used representative of the viologen. In this way one should be able to obtain information on the presupposed degree of dissociation. Methanol was selected as the organic solvent because accurate measurements of transference numbers in that solvent are available and from these the equivalent conductance of some anions.

Experimental

Materials.—Heptyl viologen dibromide was prepared using the Menschutkin reaction as described previously (2). The product was recrystallized twice from ethanol, the first time with norit. Benzene was added and the ethanol distilled off azeotropically. After filtration the remaining benzene was removed *in vacuo* until constant weight was attained. The analysis of Br^- gave the theoretical value; the optical density of a 0.1 mole liter^{-1} solution in water at 400 nm was less than 0.07.

The water used was obtained by distilling deionized water to which some NaOH pellets and some $KMnO_4$ crystals had been added. The resultant liquid was distilled twice under nitrogen in a quartz still. Conductivity was better than 0.4×10^{-6} ohm^{-1} cm^{-1}. Methanol *p.a.* from Merck was used as received. Conductivity was 0.6×10^{-6} ohm^{-1} cm^{-1}. Potassium chloride suprapure from Merck was dried to constant weight.

Measurements.—All solutions were prepared by weighing. Cell constants were determined according to Lind *et al.* (3). Cell resistances were measured with a Jones conductivity bridge 4666 from Leeds and Northrop using 0.4 V_{rms} at 1 kHz as input signal. The output signal was fed to a Phillips PM 7835 synchronous amplifier. The two d-c outputs of this amplifier were made to vanish by the adjustment of the bridge. A series of measurements was done at different frequencies of 1, 2, 5, and 10 kHz. Extrapolation to infinite frequencies showed a polarization error of 0.04%. The cells were immersed in a 70 liter oil bath kept at 25° ± 0.02°C.

Equations for the conductivity.—For the analysis of the conductivity data we have used the theory of Murphy and Cohen (4), which is an improvement of the Fuoss-Onsager theory and applicable to asymmetric electrolytes. This means that for any electrolyte a distance of closest approach can be calculated from conductance data. It also means that deviations from the theory expected for what we call weak electrolytes can be detected on the same basis for asymmetric electrolytes as for symmetric ones. These deviations are accounted for in the usual way (5); we start from the expression for the equivalent conductance Λ_{th} given by Murphy and Cohen's theory (see Appendix)

$$\Lambda_{\text{th}} \equiv \Lambda_0 + \Lambda_1 \beta\kappa + \Lambda_2{}^1 (\beta\kappa)^2 \ln \beta\kappa + \Lambda_2 (\beta\kappa)^2 \qquad [1]$$

where

$$\beta\kappa = 8.4042 \times 10^6 \times |z_+ z_-| \frac{I^{1/2}}{(DT)^{3/2}}$$

and I = ionic strength $= \frac{1}{2} \sum_i z_i^2 c_i$; c_i = concentration of ion i in mole liter^{-1}; D = relative dielectric constant of the solvent; T = temperature in °K; z_i = valency of ion i. This equation is used to fit conductivity data with a least squares method; Λ_1 and $\Lambda_2{}^1$ are given by the theory while Λ_0 and Λ_2 are adjustable parameters. Λ_0 is the conductance at infinite dilution and Λ_2 is a function of the distance of closest approach, a, between the ions. Once Λ_2 is determined experimentally a can be calculated from the expression for Λ_2 given by Murphy and Cohen.

If the electrolyte $A_{z_2}B_{z_1}$ is not completely dissociated the following equilibrium exists

$$A^{z_1} + B^{z_2} \rightleftarrows AB^{z_1+z_2} \qquad [2]$$

with equilibrium constant

$$K_1 = \frac{[AB^{z_1+z_2}]}{[A^{z_1}][B^{z_2}]} \qquad [3]$$

Key words: viologen, conductivity, electrochromic, display.

When the electrolyte is asymmetric the species $AB^{z_1+z_2}$ is charged and contributes to the conductivity. This means that we now have a mixture whose conductivity can be calculated using the "mixture rule" (6). If a fraction α_1 of A^{z_1} is present this rule states that the specific conductance of the mixture is given by

$$\rho^{-1}_{\text{mixt}} = \alpha_1 \rho^{-1}(A^{z_1}, B^{z_2}) + (1 - \alpha_1)\rho^{-1}(AB^{z_1+z_2}, B^{z_2}) \quad [4]$$

where $\rho^{-1}(A^{z_1}, B^{z_2})$ is the specific conductivity of $A_{z_2}B_{z_1}$ at the total ionic strength. Let us now suppose that the only difference between A^{z_1} and $AB^{z_1+z_2}$ is the electric charge. In that case they have the same mobility and distance of closest approach towards B^{z_2} and their equivalent conductances can be calculated from [1]. Now $\Lambda = 1/\rho c$ where c is the equivalent concentration according to $c = |z_i|c_i$. The equivalent concentration of the complex electrolyte $AB^{z_1+z_2}$, B^{z_2} is therefore given by $|\,|z_1| - |z_2|\,|c_1$ or $|z_2|\,|c_1 - c_2|$ and we have

$$\Lambda_{\text{mixt}} \equiv \frac{1}{\rho_{\text{mixt}} c} = \alpha_1 \Lambda(A^{z_1}, B^{z_2}) + \frac{|\,|z_1| - |z_2|\,|}{|z_1|}(1 - \alpha_1) \times \Lambda(AB^{z_1+z_2}, B^{z_2}) \quad [5]$$

from which

$$\alpha_1 = \frac{\Lambda_{\text{mixt}} - \Lambda(AB^{z_1+z_2}, B^{z_2})\dfrac{|\,|z_1| - |z_2|\,|}{|z_1|}}{\Lambda(A^{z_1}, B^{z_2}) - \Lambda(AB^{z_1+z_2}, B^{z_2})\dfrac{|\,|z_1| - |z_2|\,|}{|z_1|}} \quad [6]$$

Introducing α_1 into [3] we have

$$K_1 = \frac{(1 - \alpha_1)c_1 f_\pm(AB^{z_1+z_2}, B^{z_2})}{\alpha_1 c_1\{c_2 - (1 - \alpha_1)c_1\} f_\pm(A^{z_1}, B^{z_2})} \quad [7]$$

where $\ln f_\pm = -\frac{1}{2}\beta\kappa$ different for the different species because of β.

Introducing a constant γ defined by

$$\gamma c \equiv |z_1|\alpha_1 c_1 + |\,|z_1| - |z_2|\,|(1 - \alpha_1)c_1 \quad [8]$$

we can rewrite [7] as

$$\alpha_1 = 1 - \frac{\alpha_1 c}{|z_2|} K_1 \gamma \frac{f_\pm(A^{z_1}, B^{z_2})}{f_\pm(A^{z_1+z_2}, B^{z_2})} \quad [9]$$

which becomes with the help of [6]

$$\Lambda_{\text{mixt}} = \Lambda(A^{z_1}, B^{z_2}) - \frac{1}{|z_2|} K_1 c\gamma \frac{f_\pm(A^{z_1}, B^{z_2})}{f_\pm(AB^{z_1+z_2}, B^{z_2})} \times \left\{ \Lambda_{\text{mixt}} - \Lambda(AB^{z_1+z_2}, B^{z_2})\left(1 - \left|\frac{z_2}{z_1}\right|\right)\right\} \quad [10]$$

While checking the calculations with measurements taken from the literature, it was found that in solvents with a small dielectric constant negative values for α_1 are obtained. This points to the following equilibrium

$$AB^{z_1+z_2} + B^{z_2} \rightleftarrows AB^{z_1+2z_2} \quad [11]$$

with corresponding constant K_2 given by

$$K_2 = \frac{[AB^{z_1+2z_2}]}{[AB^{z_1+z_2}][B^{z_2}]} \quad [12]$$

With γ defined by

$$\gamma c \equiv \alpha_1 c_1 + |\,|z_1| - |z_2|\,|(1 - \alpha_1)\alpha_2 c_1 + |\,|z_1| - 2|z_2|\,|(1 - \alpha_1)(1 - \alpha_2)c_1 \quad [13]$$

we have similar to [7]

$$\frac{(1 - \alpha_1)\alpha_2}{\alpha_1} = \frac{1}{|z_2|} K_1 c\gamma \frac{f_\pm(A^{z_1}, B^{z_2})}{f_\pm(AB^{z_1+z_2}, B^{z_2})} \quad [14a]$$

and

$$\frac{1 - \alpha_2}{\alpha_2} = \frac{1}{|z_2|} K_2 c\gamma \frac{f_\pm(AB^{z_1+z_2}, B^{z_2})}{f_\pm(AB^{z_1+2z_2}, B^{z_2})} \quad [14b]$$

From the mixture rule we find α_1 in terms of the equivalent conductances of the different species in the mixture as in [6]. Combining, we obtain finally

$$\Lambda_{\text{mixt}} = \Lambda(A^{z_1}, B^{z_2}) - \frac{1}{|z_2|}\left\{ K_1 c\gamma \frac{f_\pm(A^{z_1}, B^{z_2})}{f_\pm(AB^{z_1+z_2}, B^{z_2})} + \frac{1}{|z_2|} K_1 K_2 (c\gamma)^2 \frac{f_\pm(A^{z_1}, B^{z_2})}{f_\pm(AB^{z_1+2z_2}, B^{z_2})}\right\} \times \left\{ \Lambda_{\text{mixt}} - \alpha_2\left(1 - \left|\frac{z_2}{z_1}\right|\right)\Lambda(AB^{z_1+z_2}, B^{z_2}) - (1 - \alpha_2)\left(1 - 2\left|\frac{z_2}{z_1}\right|\right)\Lambda(AB^{z_1+2z_2}, B^{z_2})\right\} \quad [15]$$

The calculation proceeds as follows: with some assumed value for the equivalent conductance at infinite dilution Λ_0, Λ_{mixt} is approximated and using Eq. [6] and [8] a set of values for γ is obtained. With these the Λ_{mixt} is corrected and a new set of γ's is obtained. This process is repeated until it is internally consistent. With a least squares method, values for Λ_2 of Eq. [1], K_1 and K_1K_2 are calculated. In this run α_2 is taken to be equal to 1, from K_2 a set of α_2 values is obtained, and the whole procedure is repeated. If $K_2 < 0$, then K_2 is put equal to 0, the calculation starts again; if now $K_1 < 20$, K_1 is also assumed to vanish. The reason for rejecting small positive K_1 values is that the Λ_2 and the K_1 terms in [14] or rather [9] then show almost the same concentration dependence and discrimination between them becomes difficult. With the values for the parameters obtained in this way, the whole procedure is again repeated until consistent. From Λ_2 a value for the distance of closest approach, a, is determined, which provides a check for the acceptability of the procedure: Λ_2 is a sensitive function of a and only a small range, different for different electrolytes, corresponds with physically reasonable values.

As an example, we have analyzed the precision data (7) of the conductivity of KCl and NaCl in methanol (Table I). The discrepancy between Gordon's results and those of Evers and of Frazer remains and is worse in fact since Gordon used 31.52 for the dielectric constant of methanol. Evers and Frazer's results agree to 0.02% when treated in the same way, but are still inconsistent with the transference numbers of Gordon (8), Λ_0 for KCl being too large and for NaCl too small.

Frazer's data for $AgNO_3$ were also treated because this was the one electrolyte that did not give the correct slope at infinite dilution; it does when a slight association is taken into account.

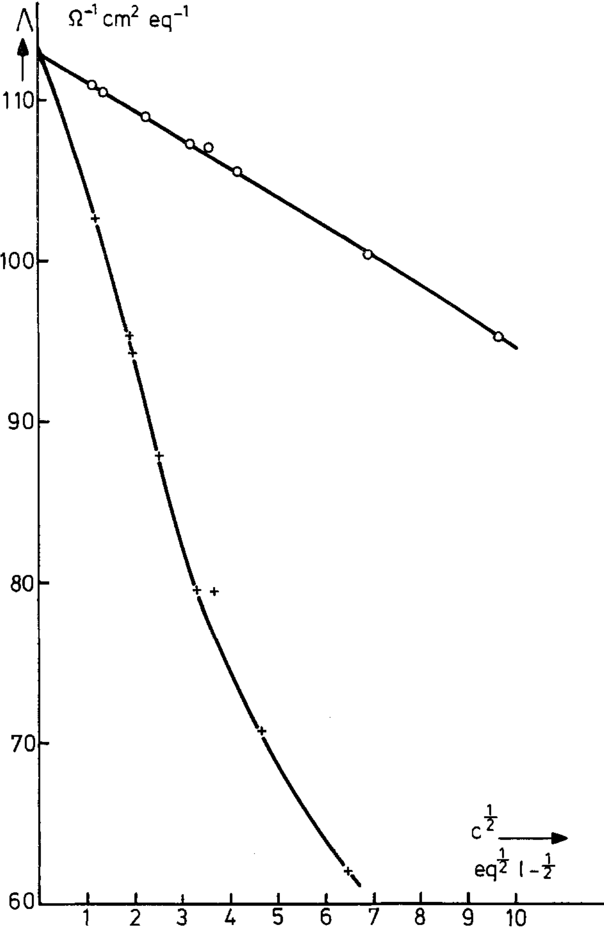

Fig. 1. Equivalent conductance of heptyl viologen dibromide, ○ in water, + in methanol.

Results and Discussion

In Table II the equivalent conductance of heptyl viologen dibromide in water and in methanol is given. In Table III and Fig. 1 the results of the analysis for this compound are given. It is seen that in water this compound behaves as a strong electrolyte and that therefore the species $dipy^{2+}$ occurs exclusively. In methanol however, a finite K_1 value is needed to fit the results, corresponding to a degree of dissociation $\alpha_1 = 0.34$ at a concentration of 0.004 mole liter^{-1}. Here $(dipy\ X)^+$ is the predominant species. These conclusions support the reaction scheme of the reduction of viologen given in the introduction. The similarity between the Λ_0 values in the two solvents is remarkable; this is also observed for some other bis-quaternary ammonium or pyridinium compounds (9). The Walden product of these compounds for the positive ion mobilities only is found to be constant, for heptyl viologen 0.309 in water and 0.305 in methanol. This ion obeys Stokes' law and this implies that it moves freely and is not solvated. Because of this a comparison of reduction potentials in different solvents is meaningful.

Table II. Equivalent conductance of heptyl viologen dibromide at 25°C

Table III. Conductance parameters of heptyl viologen dibromide

Solvent	Λ_0	$-\Lambda_1$	Λ_2'	Λ_2	a(Å)	K_1	Remarks
Water	112.73	28.38	−1.223	−6.78	3.74	0	$\alpha_1 = 0.34$
Methanol	112.48	23.15	2.105	−9.69	4.15	546	At c = 0.002 equiv. l^{-1}

Lastly, we note that the distance of closest approach, a, is about 4Å. The same order of magnitude is found, when analyzed in the same way, for Fuoss' bolaform electrolytes (9), which have a charge distribution similar to the viologens. The magnitude of the molecule as a whole is immaterial, the anions seek the locations of the positive charge. Fuoss *et al.* obtained larger values (about 7Å) from their dissociation constant. This constant, however, describes more than the known electrostatic interactions in contrast to Murphy and Cohen's Λ_2 function.

APPENDIX

For convenience, the expressions for the different coefficients in Murphy and Cohen's equation are given

$$\Lambda_1 = -\frac{q^2\Lambda_0}{3(1+q)} + (z_1 + z_2)\frac{e\mathbf{F}}{6\pi\eta\beta}$$

(the Onsager slope)

$$\Lambda_2' = \frac{q^2\Lambda_0}{6} - (z_1+z_2)\frac{e\mathbf{F}}{6\pi\eta\beta}\left(\frac{q^2}{2} - \frac{(z_1+z_2)^2}{2z_1z_2}\right)$$

where η = the viscosity of the solvent; $\mathbf{F}$ = the Faraday constant; e = elementary charge

$$q = \frac{|z_1z_2|}{|z_1| + |z_2|}\frac{\Lambda_0}{|z_1|\Lambda_0^{(1)} + |z_2|\Lambda_0^{(2)}}$$

where $\Lambda_0^{(i)}$ is the equivalent conductance of ion i at infinite dilution.

$$\Lambda_2 = -\frac{q^2\Lambda_0}{6}\Bigg[-1.154430 + \frac{6q + 15q^2 + 21q^3 - 13q^4 - 35q^5 + 6q^6}{12q^2(1+q)(1-q^2)}$$
$$- \frac{2 - q^2(1-q^2)}{2(1-q^2)}\ln(2+q) - \frac{1-2q^2}{1-q^2}\ln(1+2q)$$
$$- \frac{(1-q^2)^2}{2q^2}\ln(1+q) + Ei(b) - [e^b(23b^2 + 9b + 12)$$
$$- 6b^3 - 8b^2 - 9b - 12](18b^3)^{-1}$$
$$- \frac{(z_1+z_2)^2}{2z_1z_2(1-q^2)}\left(\frac{1}{3} - \frac{2q^2}{1-q^2}\ln\frac{3}{2+q}\right)\Bigg]$$
$$+ \frac{e\mathbf{F}(|z_1| + |z_2|)}{6\pi\eta\beta}\Bigg[\frac{18q + 61q^2 + 21q^3 - 6q^4}{48q^2(1+q)}$$
$$+ [(1 - 2q + q^2 + q^3 - q^5)\ln(1+q)$$
$$- (1+q^2)(1-q)\ln(1-q)$$
$$- (2 + q + q^2 + 5q^3 - q^5)\ln(2+q) + (1+q^2)$$
$$\times (2-q)\ln(2-q)](8q^3)^{-1} + (q^2b)^{-1}$$

$$+\frac{1}{2}[Ei(b)-1.154430]$$

$$+[e^b(-5b^5-36b^4+30b^3+30b^2-18b-36)$$

$$+6b^4-45b^3+6b^2+54b+36](108b^5)^{-1}$$

$$-(q^2z_1z_2)^{-1}\sum_{n=3}^{\infty}\frac{(b/z_1z_2)^{n-2}}{n!\,(n-2)}\left(\frac{z_1^n-z_2^n}{z_1-z_2}\right)^2$$

$$+\frac{(z_1+z_2)^2}{2q^2z_1z_2}\left(0.577215+\ln 3-\ln b+\frac{1}{6}\right)$$

$$-\frac{e\mathbf{F}(|z_1|+|z_2|)}{72\pi\eta\beta\Lambda_0 b^4}\left[e^b(b^4+5b^3+3b^2-12b+6)\right.$$

$$\left.-\frac{9}{2}b^4-3b^3+6b^2+6b-6\right]\Bigg]$$

Murphy and Cohen define the exponential integral $Ei(-x)$ only for $x > 0$. For $x < 0$ we have used in our calculations the principal value of this integral. It is easily shown that for $x > 0$

$$Ei(x) \equiv -PP\int_{-x}^{\infty}\frac{e^{-t}}{t}dt$$

$$= Ei(-x) + \sum_{k=0}^{\infty}\frac{2x^{2k+1}}{(2k+1)(2k+1)!}$$

Concentration Profile of $CuSO_4$ in the Cathodic Diffusion Layer

Yasuhiro Awakura and Yoshio Kondo

Department of Metallurgy, Kyoto University, Sakyo-ku, Kyoto 606, Japan

ABSTRACT

The concentration profile of $CuSO_4$ in the cathodic diffusion layer which is accompanied by the upward natural convection along the plane vertical cathode was measured by holographic interferometry in aqueous solutions containing 0.05 and 0.1 mol/liter $CuSO_4$. The measurement was conducted at various heights from the lower edge of cathode. The cathodic current density was also varied. The theoretical expressions of the concentration difference between the cathode surface and the bulk electrolyte and the thickness of the diffusion layer were derived under the assumption of uniform cathodic current density distribution. Experimental results obtained at the current densities far lower than the limiting value were in good agreement with the theoretical value.

Since it was recognized (1-3) that the natural convection along the surface of a plane vertical electrode plays an important role in the electrolysis of an unstirred aqueous solution, many theoretical and experimental studies have been carried out on the velocity profile of vertical convective flow in the hydrodynamic boundary layer (4-7), the concentration profile in the diffusion layer (8-10), and the resultant distribution of local current densities on the electrode surface (11-13). This convective flow is caused by the density difference between the solution in the diffusion layer and the bulk electrolyte: the direction of convective flow is upward or downward depending on whether the density in the diffusion layer is lower or higher than in the bulk electrolyte.

Wagner (2) studied the vertical distribution of the limiting current density on the surface of a copper plane cathode which is solely determined by the transfer rate of Cu^{2+} ion through the diffusion layer. He also measured the average limiting current density on the copper plane vertical cathode of different heights and demonstrated that the experimental results were in excellent agreement with the theory.

Key words: vertical electrode, holographic interferometry, natural convection, ionic diffusion.

Industrial electrolytic refining and plating are usually conducted below the limiting current density. In this region of lower cathodic current densities, Asada *et al.* (13) proposed a theoretical procedure of calculating the distribution of current density on a plane vertical cathode immersed in an unstirred electrolyte. In order to verify the theoretical current density distribution, Asada weighed the electrodeposited copper after cutting the cathode plate into slices in the horizontal direction.

A few experimental studies have been made, on the other hand, to measure the concentration profile of $CuSO_4$ in the diffusion layer near the cathode surface. However, the thickness of this diffusion layer is about 0.1 cm or less, and the measurements were difficult. The measuring precision of the freezing method conducted by Brenner (8, 9) is supposed to be insufficient. An optical measurement using the technique of Jamin interferometry was proposed by Ibl (10). In this mea-

surement, however, the optical precision imposed on the electrolytic cell is so strict that only cells of smaller size can be used because of the difficulty in the preparation. Thus Ibl measured the concentration profile of $CuSO_4$ at a height of only 0.9 cm from the lower edge of cathode.

Holographic interferometry (14-16) is employed in the present work to measure the concentration profile of $CuSO_4$ in the cathodic diffusion layer. One major experimental advantage of this technique is the employment of common path interference, which is different from the two-beam interference used in the above-mentioned Jamin interferometry. Because of this advantage, it becomes possible to measure the concentration profile along the surface of a taller plane cathode installed in a large electrolytic cell of lower optical precision.

Theoretical

In the hydrodynamic boundary layer, a volume element of $(d \times l \times dx)$ is presumed at a height x from the lower edge of cathode. The integrated Navier-Stokes equation (5) concerning this volume element is expressed as

$$\frac{d}{dx}\int_0^l u^2 dy = \alpha g \int_0^l \theta dy - \nu\left(\frac{du}{dy}\right)_{y=0} \quad [1]$$

The mass balance equation of Cu^{2+} ion is

$$\frac{d}{dx}\int_0^l u\theta dy = \frac{i(1 - {}^*t_1)}{z_1 \mathbf{F}} \quad [2]$$

In order to integrate Eq. [1] and [2], it is presumed according to Ibl (5) that the concentration profile of $CuSO_4$ in the diffusion layer and the velocity profile of upward convective flow in the hydrodynamic boundary layer are expressed by the following equations

$$\theta = \Theta\left(1 - \frac{y}{\delta}\right)^{\omega} \quad [3]$$

$$\left.\begin{aligned} u &= \frac{u_m}{\lambda - 1}\left[\lambda\frac{y}{\tau} - \left(\frac{y}{\tau}\right)^{\lambda}\right] && \text{for } 0 \leqq y \leqq \tau \\ u &= u_m\left[1 - \frac{y - \tau}{\epsilon\tau}\right] && \text{for } \tau \leqq y \leqq (\epsilon + 1)\tau \end{aligned}\right\} \quad [4]$$

respectively. In these equations, $\delta = \eta\tau$ and $l = (\epsilon + 1)\tau$. Substitution of Eq. [3] and [4] in Eq. [1] and [2] yields upon integration

$$0 = \left(\frac{\alpha g}{\omega + 1}\right)\delta\Theta - \left(\frac{\nu\eta\lambda}{\lambda - 1}\right)\frac{u_m}{\delta} \quad [5]$$

and

$$\frac{\Phi}{\eta(\lambda - 1)}\frac{d}{dx}(u_m\Theta\delta) = \frac{i(1 - {}^*t_1)}{z_1\mathbf{F}} \quad [6]$$

respectively. The term on the left-hand side of Eq. [1] is much smaller than each term on the right-hand side of the same equation (2), and it was omitted in Eq. [5]. The symbol Φ in Eq. [6] is

$$\Phi = \frac{\lambda(\eta - 1)^{\omega+2}}{\eta^{\omega}(\omega + 1)(\omega + 2)}\left[\left(\frac{\eta}{\eta - 1}\right)^{\omega+2} - \frac{\lambda - 1}{\epsilon\lambda} - \frac{\omega + 2}{\lambda(\eta - 1)} - 1\right] - \eta^{\lambda+1}B_{1/\eta}(\lambda + 1, \omega + 1) \quad [7]$$

and

$$B_a(b, c) = \int_0^a t^{b-1}(1 - t)^{c-1}dt \quad [8]$$

By eliminating u_m from Eq. [5] and [6], we have

$$\frac{\Phi}{(\omega + 1)\eta^2\lambda}\frac{\alpha g}{\nu}\frac{d}{dx}(\delta^3\Theta^2) = \frac{i(1 - {}^*t_1)}{z_1\mathbf{F}} \quad [9]$$

On the other hand, the mass transfer equation of cation and anion on the cathode surface are written as (3)

$$\frac{i}{z_1\mathbf{F}} = k_1\left(\frac{dc}{dy}\right)_{y=0} + cU_1\left(\frac{d\phi}{dy}\right)_{y=0} \quad [10]$$

and

$$0 = k_2\left(\frac{dc}{dy}\right)_{y=0} - cU_2\left(\frac{d\phi}{dy}\right)_{y=0} \quad [11]$$

respectively. The first and second terms on the right-hand side of Eq. [10] and [11] represent the rate of mass transfer due to diffusion and migration, respectively. After eliminating the term $(d\phi/dy)_{y=0}$ in Eq. [10] and [11] which represents the potential gradient on the cathode surface, we have

$$\frac{i^*t_2}{z_1\mathbf{F}} = D\left(\frac{dc}{dy}\right)_{y=0} \quad [12]$$

where

$${}^*t_2 = 1 - {}^*t_1 = \frac{U_2}{U_1 + U_2}$$

$$D = \frac{k_2U_1 + k_1U_2}{U_1 + U_2}$$

Substitution of Eq. [3] in Eq. [12] yields

$$\frac{\omega D\Theta}{\delta} = \frac{i^*t_2}{z_1\mathbf{F}} \quad [13]$$

It is noted that Eq. [9] and [13] are the basic equations of mass transfer in the cathodic diffusion layer which is accompanied by upward natural convection. The solution of simultaneous Eq. [9] and [13] under the assumption that $\Theta = {}^*c$, for example, reveals the distribution of the local current densities and the thickness of the diffusion layer at the limiting current density. Furthermore, by combining Eq. [9] and [13] with the Laplace equation in the form of $\Delta\phi = 0$, which determines the potential distribution within the electrolytic cell and the rate equation of electrode reactions, it is possible to obtain the general solution which holds below the limiting current density.

When the current density is lower than about one-half of the limiting value, it was shown (12, 17) that the local current density is regarded as being equal from bottom to top of the cathode surface. Under this condition of i = const, the following expressions of concentration difference and diffusion layer thickness are obtained from Eq. [9] and [13]

$$\Delta c = \Theta = \frac{\eta E}{\omega}\frac{{}^*t_2}{z_1\mathbf{F}D}\left(\frac{z_1\mathbf{F}\nu D^2}{g\alpha{}^*t_2}\right)^{1/5} i^{4/5}x^{1/5} \quad [14]$$

$$\delta = \eta E\left(\frac{z_1\mathbf{F}\nu D^2}{g\alpha{}^*t_2}\right)^{1/5} i^{-1/5}x^{1/5} \quad [15]$$

where

$$E = \left[\frac{\omega^2(\omega + 1)\lambda}{\Phi\eta^3}\right]^{1/5}$$

Furthermore, the modified Grashof number of

$$Gr^* = \frac{g\alpha{}^*t_2 i x^4}{z_1\mathbf{F}\nu^2 D} \quad [16]$$

and the Sherwood number in the form of

$$Sh_x = \frac{k_x x}{D} \quad [17]$$

where the mass transfer coefficient k_x is defined as

$$\frac{i^*t_2}{z_1\mathbf{F}} = k_x\Delta c \quad [18]$$

are employed together with the Schmidt number

$$\mathrm{Sc} = \frac{\nu}{D} \qquad [19]$$

Equations [14] and [15] are then rewritten as

$$\mathrm{Sh_x} = \frac{\omega}{\eta E}(\mathrm{Sc}\cdot\mathrm{Gr}^*)^{1/5} \qquad [20]$$

and

$$\frac{\delta}{x} = \eta E(\mathrm{Sc}\cdot\mathrm{Gr}^*)^{-1/5} \qquad [21]$$

respectively.

Experimental

The experimental arrangement employed in the present work is schematically illustrated in Fig. 1. A helium-neon gas laser emitter L of 10 mW output was used as the light source. The laser beam was split into two beams by a half-mirror B. A reference beam was reflected on the mirrors M_1 and M_4 and expanded by a lens E_2, and the beam intensity was adjusted by an attenuation polarizer A. Then it was transmitted to a photographic plate H. Another beam was collimated to a diameter of 1.2 cm by the lenses E_1 and L_1. After passing through the vicinity of the cathode surface in the electrolytic cell C, it was joined with the reference beam on the same photographic plate: the image of the vicinity of the cathode surface was magnified about fifteen diameters and the back edge of the cathode surface facing the camera was focused on the screen SC by a lens L_2. After the photographic plate was developed, the hologram was reset at the same position in the frame of the plate holder. With the reference beam incident upon this hologram, the wave front of the beam which was passed through the electrolytic cell was reconstructed. By superposition with the beam which was passed through the electrolytic cell, a parallel interference fringe was easily obtained on the screen. Then the position of the cathode surface of the reconstructed image and the real image was finely adjusted by a rack and pinion mechanism within an error of 10μ. When the electrolysis was started, this fringe was shifted due to the concentration gradient formed in the diffusion layer. Then the real silhouette of the cathode surface on the screen SC appears to be advanced into the solution side of the interface due to the gradient of the refractive index. However, the position of the cathode surface of the reconstructed image does not change during the electrolysis, and this position was taken as the origin of horizontal distance from the cathode surface.

The electrolytic cell is illustrated in Fig. 2. The inner dimensions of the cell were 0.7 cm thick, 13 cm wide, and 10 cm high. The copper electrodes were 0.47 cm square and 16 cm long, and the effective electrode area was $0.47 \times 9.0\ \mathrm{cm}^2$. The distance between both electrodes was maintained at 10 cm. As mentioned above, the thickness of the cathodic diffusion layer is less than about 0.1 cm, and it was essential to install the cathode surface parallel to the incident beam. In order to realize this, a revolvable cathode holder was employed, and after the cell wall on the light-entrance side was adjusted to be at right angles to the incident beam, the cathode was gently revolved and maintained at a position where the enlarged silhouette of the cathode surface on the screen SC recedes farthest.

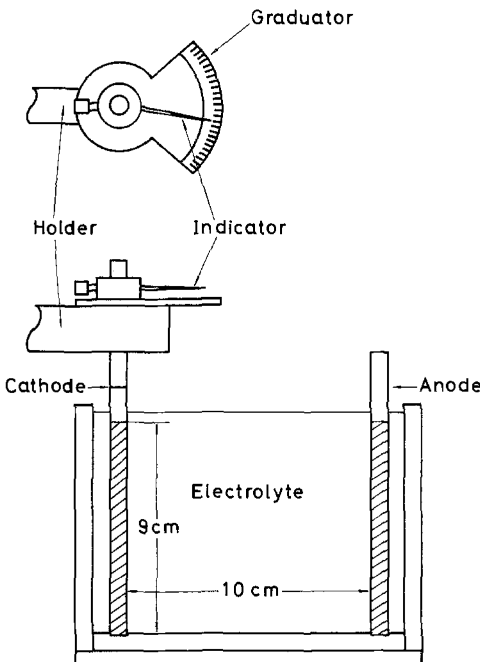

Fig. 2. Electrolytic cell

Analytical reagent grade $CuSO_4$ and deionized water were used, and the aqueous $CuSO_4$ solution was prepared. The experimental conditions are summarized in Table I. The measurement was conducted at 23° ± 1°C.

The current-potential curves were measured with the electrolytes shown in Table I, and they are demonstrated in Fig. 3. The average cathodic current densities at which the concentration profile was measured are also shown in the figure. It is seen that the applied current densities ranged up to the limiting value in the solution containing 0.05 mol/liter $CuSO_4$ and were below one-half of the limiting value in the solution of 0.1 mol/liter $CuSO_4$.

A few examples of holographic interferograms are shown in Fig. 4. A holographic interferogram near the cathode surface before the start of electrolysis is shown in Fig. 4(a). The horizontal interference fringe in this figure was employed as the reference for measuring the concentration profile. Figures 4(b) through (d) demonstrate the interferograms of 0.05 mol/liter $CuSO_4$ solution at an average cathodic current density of 1.84 $\mathrm{mA/cm^2}$. The measuring height was varied at 1, 4, and 8 cm from the lower edge of the cathode, respectively. They were filmed after 10 min had elapsed from the start of electrolysis: it was confirmed that the diffusion layer is maintained at the steady state. As seen in Fig. 4(b) through (d), the thickness of diffusion layer increases in the upper portion of cathode. This is due to the upward flow caused by natural convection.

The relationship between the change of the refractive index of the solution and the fringe shift is given

Table I. Experimental conditions

Concentration of $CuSO_4$ (mol/liter)	0.05, 0.1
Distance from lower edge of cathode (cm)	1.0, 2.0, 4.0, 8.0
Average cathodic current density ($\mathrm{mA/cm^2}$)	0.473, 0.946, 1.42, 1.84, 2.29, 2.76, 3.65, 4.60

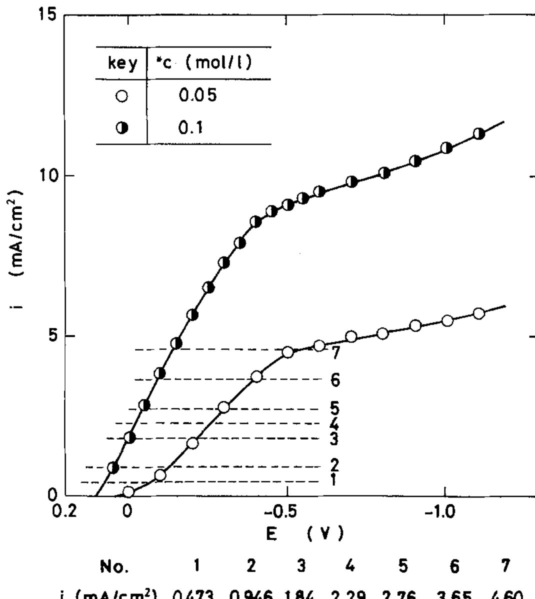

Fig. 3. Current potential curve

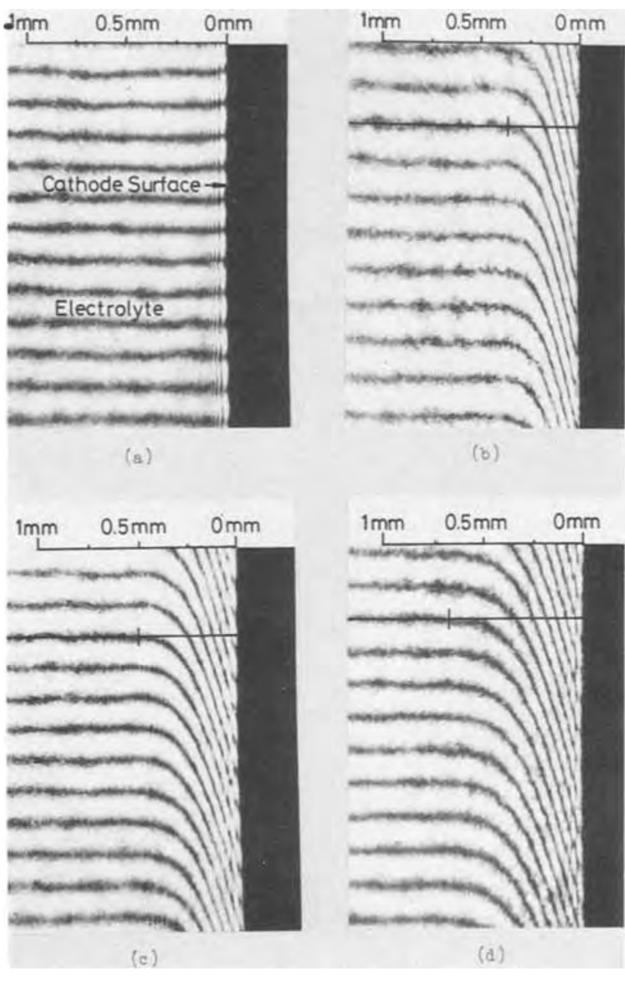

Fig. 4. Holographic interferograms of cathodic diffusion layer: (a) before the start of electrolysis, (b) $x = 1$ cm, (c) $x = 4$ cm, and (d) $x = 8$ cm during the electrolysis of 0.05 mol/liter $CuSO_4$ solution at $i = 1.84$ mA/cm^2.

by (10)

$$\frac{({}^*n - n)d}{\lambda'} = N \quad [22]$$

When the incident beam is transmitted into a solution with a varying refractive index, however, the valid profile of the refractive index is not obtained from Eq. [22] (18, 19). This is because the incident beam in the diffusion layer is deflected toward the direction of higher refractive index as shown in Fig. 5 (20).

The corrected profile of the refractive index in the diffusion layer was obtained as follows. The optical path length p along this deflected trajectory in the solution is obtained from the holographic interferogram as

$$p = {}^*nd - \lambda' N \quad [23]$$

Assuming that the direction of incident beam is at right angles to the inner wall of the electrolytic cell, the beam trajectory in the solution is obtained by the following differential equation (21)

$$\frac{d^2y}{dz^2} = \frac{1}{2n_i^2}\frac{dn^2}{dy} \quad [24]$$

When the change of refractive index is linear in the solution, we have

$$n = n_i + ky \quad [25]$$

By substituting Eq. [25] in Eq. [24], the maximal difference between the length of this beam trajectory and the electrode width $(s - d)$ and the maximal deflection Δy of the incident beam within the solution were calculated along the cathode surface to be 0.42 and 55μ, respectively, at the average cathodic current density of 4.6 mA/cm^2 in the solution containing 0.05 mol/liter $CuSO_4$. As shown later, $n_i = 1.3344$ and $k = 6.6 \times 10^{-2}$ under these experimental conditions. Since $(s - d)$ is very trivial and Δy is far lower than the electrode width, it can be assumed that the refractive index expressed by p/d represents the mean value along the beam trajectory and that the trajectory is linear. The refractive index obtained corresponds to the value at the middle point M shown in Fig. 5.

The position of point M was calculated in the whole diffusion layer as follows. Provided that the local profile of the refractive index in any small portion of the diffusion layer is expressed as

$$n^2 = b + ay \quad [26]$$

the solution of Eq. [24] is obtained under the following boundary conditions.

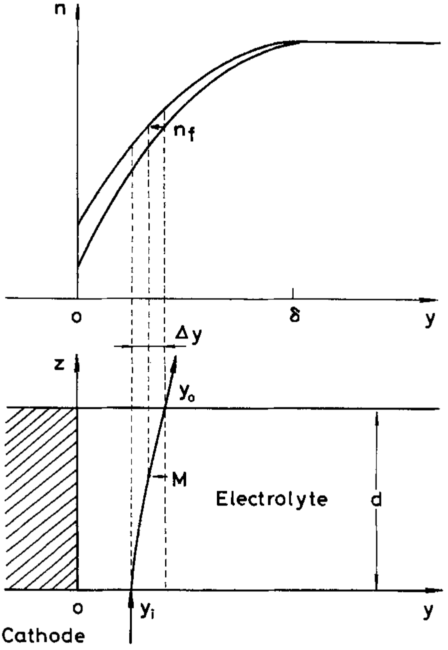

Fig. 5. Schematic illustration of beam deflection and correction of refractive index.

When

$$\left.\begin{array}{ll} z = 0, & y = y_i \\ z = d, & y = y_o \end{array}\right\} \quad [27]$$

$$\Delta y = y_o - y_i = \frac{ad^2}{4n_i^2} \quad [28]$$

Then the position of point M is obtained as

$$y_o - \frac{\Delta y}{2} = y_o - \frac{ad^2}{8n_i^2} \quad [29]$$

The constant a and the refractive index n_i in this equation were estimated from the holographic interferogram: the refractive indices obtained near point y_o were substituted in Eq. [26] and a was estimated by the least squares method. The difference between n_i and the mean refractive index obtained from the interferogram was minor and the latter index was used in the calculation. Thus the corrected profile of the refractive index in the solution was obtained.

From the regression of the refractive index upon $CuSO_4$ concentration in the solution, the concentration was calculated. The regression was expressed as

$$n = 1.3330 + 28.44c \quad [30]$$

in the aqueous $CuSO_4$ solution below 0.5 mol/liter at 23°C.

A few examples of the corrected concentration profile are demonstrated in Fig. 6, which was obtained in the 0.05 mol/liter $CuSO_4$ solution at a height of 4 cm. The uncorrected concentration profiles at each current density are also shown. It is seen in this figure that $CuSO_4$ concentration on the cathode surface is lowered and the thickness of the diffusion layer is decreased when the average cathodic current density is raised. It is furthermore seen that the above-mentioned correction becomes significant when the concentration profile is steeper.

Discussion

Although the calculating procedure of the profile of the refractive index from the obtained holographic interferogram employed in this work is an approximation, it is thought to be satisfactory for calculating the concentration profile in the diffusion layer with a relatively small concentration gradient. Assuming that the variation of the refractive index in the vicinity of the cathode surface is linear as shown in Eq. [25], the deviation of concentration due to the approximation was estimated. In this calculation, the effect of refraction within the back wall of the electrolytic cell was neglected (18).

When the direction of the incident beam is at right angles to the direction of the refractive index gradient in the solution, the optical path length p along the beam trajectory and the deflection Δy of the incident beam are derived from Eq. [24] (18) as

$$p = \frac{n_i d}{2} + \frac{n_i^2}{4k} \sinh\left(\frac{2kd}{n_i}\right) \quad [31]$$

$$\Delta y = -\frac{n_i}{k} + \frac{n_i}{k} \cosh\left(\frac{kd}{n_i}\right) \quad [32]$$

respectively. From Eq. [31] and [32], the difference between the refractive index p/d obtained in the preceding section and the refractive index at $\Delta y/2$ is obtained as

$$\Delta n = \frac{p}{d} - \left(n_i + k\frac{\Delta y}{2}\right) = \frac{n_i}{2} \cosh\left(\frac{kd}{n_i}\right)\left[\frac{n_i}{kd} \sinh\left(\frac{kd}{n_i}\right) - 1\right] \quad [33]$$

From Eq. [30], on the other hand, the concentration difference Δc_e which corresponds to Δn is

$$\Delta c_e = \frac{\Delta n}{28} \quad [34]$$

The Δc_e-value represents the deviation due to the approximation in estimating the concentration mentioned in the preceding section. From Eq. [34], the maximal Δc_e on the cathode surface was calculated at several cathodic current densities in the solution containing 0.05 mole/liter $CuSO_4$ and demonstrated in Table II. The refractive index gradient k on the cathode surface was calculated by using Eq. [12] and [30] together with the property constants (10, 22, 23) shown in Table III. Furthermore, the average concentration difference $\overline{\Delta c}$ between the bulk electrolyte and the cathode surface in the vertical direction was obtained from the interferogram and shown in Table II. The relative deviation $(\Delta c_e/\overline{\Delta c}) \times 100$ is also demonstrated.

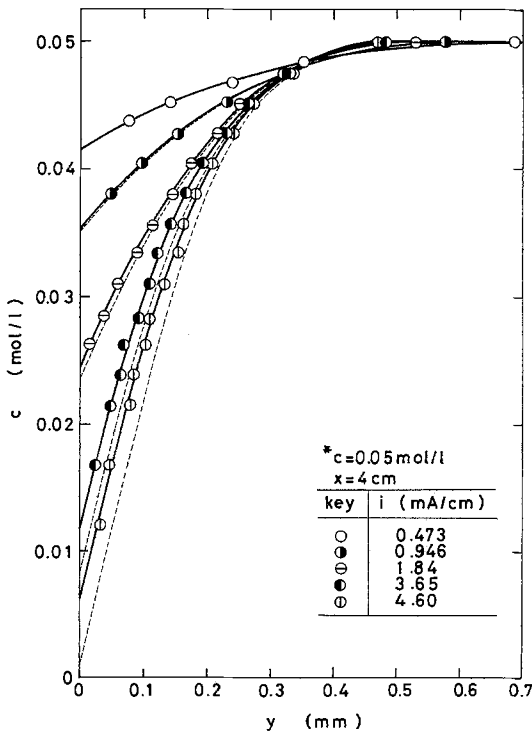

Fig. 6. Concentration profile of $CuSO_4$ in the cathodic diffusion layer (broken lines show the uncorrected concentration profile).

Table II. Error due to approximation in 0.05 mol/liter $CuSO_4$ solution

i (mA/cm²)	k (cm⁻¹)	Δy (μ)	Δc_e (mol/liter)	$\overline{\Delta c}$ (mol/liter)	$[\Delta c_e/\overline{\Delta c}] \times 100$ (%)
0.473	6.79×10^{-3}	5.6	0.0000164	0.0084	0.195
0.946	1.36×10^{-2}	11.3	0.0000862	0.0145	0.594
1.42	2.04×10^{-2}	16.9	0.000204	0.0198	1.03
1.84	2.64×10^{-2}	21.9	0.000340	0.0234	1.45
2.29	3.29×10^{-2}	27.2	0.000532	0.0265	2.01
2.76	3.96×10^{-2}	37.8	0.000771	0.0307	2.51
3.65	5.24×10^{-2}	43.4	0.00121	0.0353	3.43
4.60	6.60×10^{-2}	54.6	0.00215	0.0439	4.90

Table III. Property constants used in the calculation

Concentration of $CuSO_4$ in solution (mol/liter)		0.05	0.1
z_1 (—)		2	2
D_1 (cm²/sec)	(22)	6.5×10^{-6}	6.0×10^{-6}
ν (cm²/sec)	(23)	1.043×10^{-2}	1.002×10^{-2}
α_1 (cm³/mol)	(10)	151.5	151.5
t_2 (—)	(10)	0.643	0.643

As seen in this table, the deviation of concentration on the cathode surface is minor when the average cathodic current density is lower. At higher current densities of 3.65 and 4.60 mA/cm², the relative deviation increases to 3.43 and 4.90%, respectively. It is thought, however, that this has only a minor effect on the variation of Δc in the vertical direction, because the deviation is of the same order of magnitude at various heights when the applied cathodic current density is constant.

In order to calculate the concentration difference and the thickness of the diffusion layer by Eq. [14] and [15], respectively, it is necessary to obtain the numerical values of the parameters involved in these equations. The parameter ω which influences the concentration profile of $CuSO_4$ was determined as follows. The logarithm of (θ/Θ) in the 0.05 mol/liter $CuSO_4$ solution was plotted against $\log(1 - y/\delta)$ in Fig. 7 according to Eq. [3]. As seen in this figure, almost all of the experimental data are scattered within the region between the slopes of 2.0 and 3.0, and ω was determined as 2.39 by the least squares method. From a similar plot obtained for the 0.1 mol/liter $CuSO_4$ solution, the parameter ω was estimated to be 2.31: Ibl (5) obtained the numerical value of 2.3 from the interferometric measurement in the 0.6 mol/liter $CuSO_4$ solution at a height of 0.9 cm. The other parameters λ, ϵ, and η involved in Eq. [4], which influence the velocity profile of natural convection, were presumed to be 1.7, 10, and 2.1, respectively, from the experimental results obtained by Awakura *et al.* (6).

In order to examine the validity of Eq. [14] and [15], the logarithmic concentration difference between the bulk electrolyte and the cathode surface, $\log \Delta c$, was plotted against the logarithmic average cathodic current density, and Fig. 8 and 9 were obtained for the solutions of 0.05 and 0.1 mol/liter $CuSO_4$, respectively. As seen in these figures, the slope of all straight lines is 4/5 which is equal to the theoretical value derived from Eq. [14].

The dependence of $\log \Delta c$ on the logarithmic height from the lower edge of cathode was also examined: $\log \Delta c$ in the solutions of 0.05 and 0.1 mol/liter $CuSO_4$ was plotted against $\log x$ in Fig. 10 and 11, respectively. By comparing the experimental slopes with the theoretical value of 1/5 from Eq. [14], it is seen that the measured slopes in Fig. 10 are equal to 1/5 when the

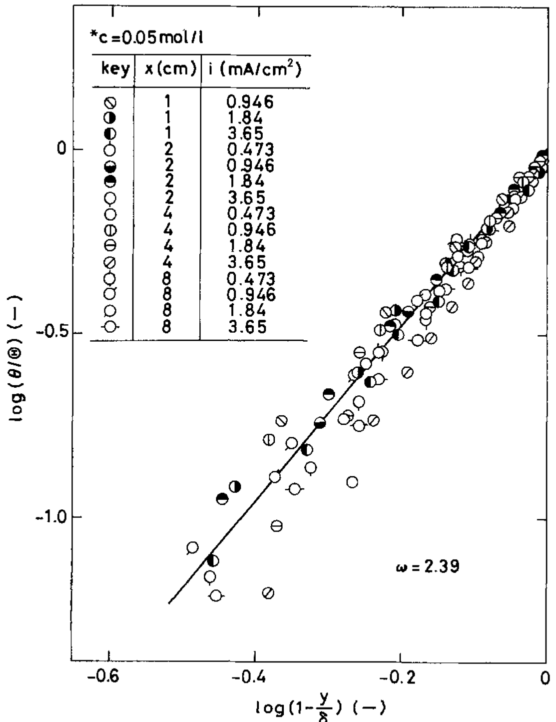

Fig. 7. Plot of $\log (\theta/\Theta)$ vs. $\log (1 - \gamma/\delta)$

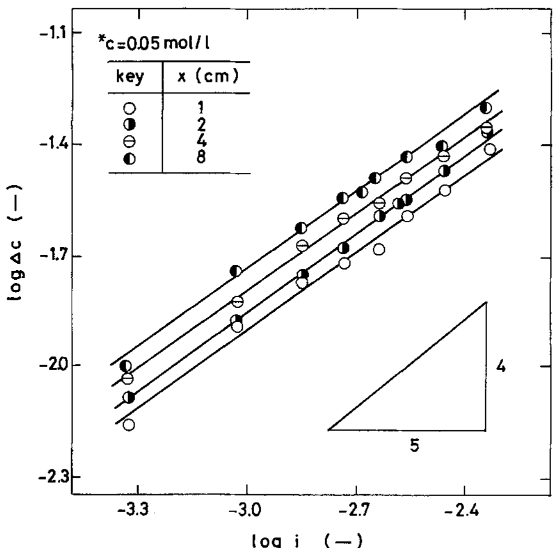

Fig. 8. Relationship between concentration difference and average cathodic current density ($^*c$ = 0.05 mol/liter).

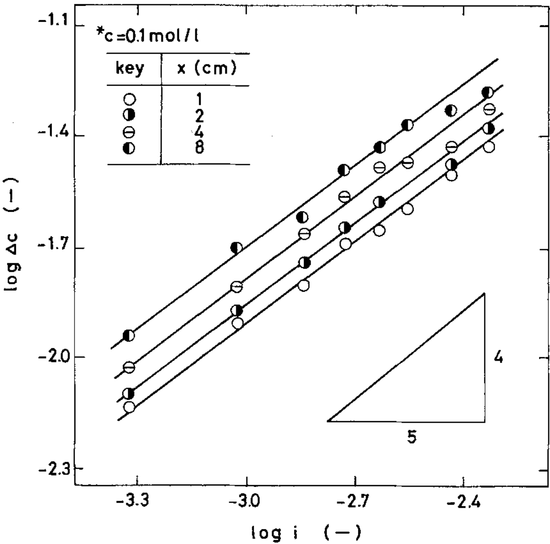

Fig. 9. Relationship between concentration difference and average cathodic current density ($^*c$ = 0.1 mol/liter).

average current density is below 2.76 mA/cm² and the slope decreases when the average current density becomes higher than 3.65 mA/cm². This may suggest that the local cathodic current density varies in the vertical direction above 3.65 mA/cm². By comparing Fig. 11 with Fig. 10, it was also revealed that the slopes in Fig. 11 are nearly equal to the theoretical value of 1/5 up to the current density of 4.6 mA/cm². This is due to the relatively lower current densities rather than the limiting value.

The dimensionless numbers of Sh_x, Gr^*, and Sc were calculated by using the experimental data in addition to the property constants shown in Table III, and $\log(Sh_x)$ was plotted against $\log(Sc \cdot Gr^*)$ in Fig. 12. The theoretical value was calculated from Eq. [20] and is shown in this figure. It is seen that the experimental results obtained at lower current densities are in fairly good agreement with the theoretical value.

Next, the theoretical relationship demonstrated in Eq. [15] was examined. The logarithmic thickness of the diffusion layer in both electrolytes is plotted against the logarithmic average current density in Fig. 13 and 14. As seen in these figures, the slopes in the region of the lower current densities are in fairly good agreement with the theoretical value of $-1/5$, and the slopes decrease at higher current densities.

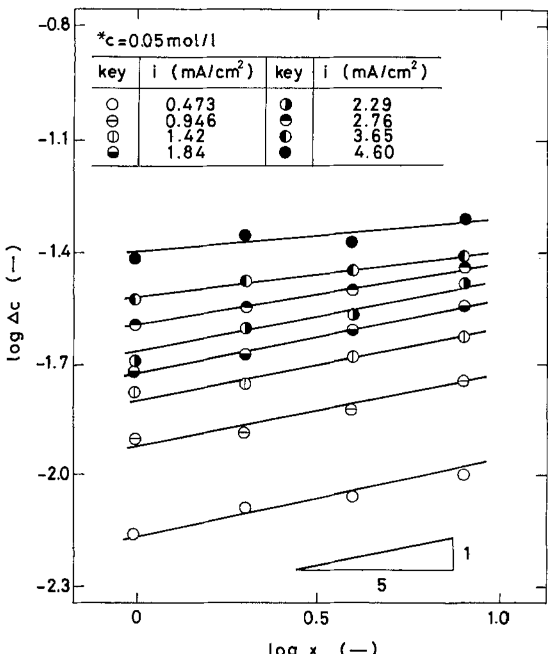

Fig. 10. Relationship between concentration difference and height from lower edge of cathode (*c = 0.05 mol/liter).

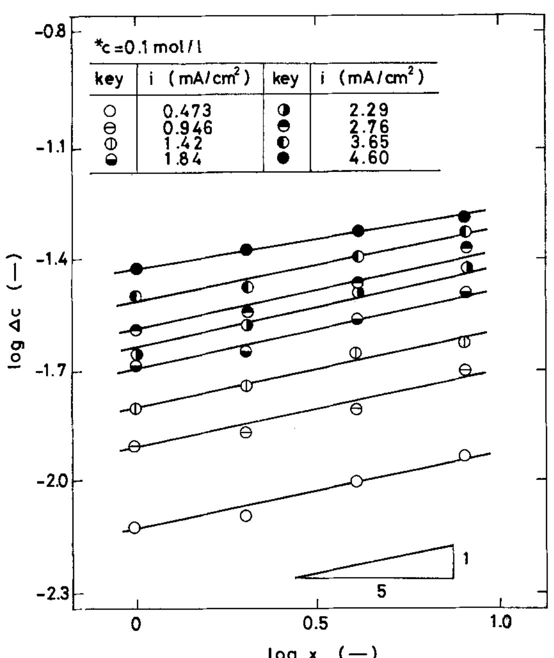

Fig. 11. Relationship between concentration difference and height from lower edge of cathode (*c = 0.1 mol/liter).

From a theoretical calculation of the diffusion layer thickness under the boundary condition that °c = const which is valid at the limiting current density, it was revealed (3) that δ's are constant at various current densities. Furthermore, a comparison of Fig. 14 with Fig. 13 reveals that the theoretical slope of −1/5 is maintained up to the higher current densities in the 0.1 mol/liter $CuSO_4$.

In order to determine the dependence of the diffusion layer thickness on the height from the lower edge of the cathode surface, the logarithmic thickness measured in both solutions of 0.05 and 0.1 mol/liter $CuSO_4$ were plotted against log x, and Fig. 15 and 16 were obtained. The theoretical slope of the straight line is 1/5 from Eq. [15]. As seen in these figures, this linear relationship is reasonably well confirmed. The scatter of δ values is thought to be related to the lower precision in the measurement of the diffusion layer thickness.

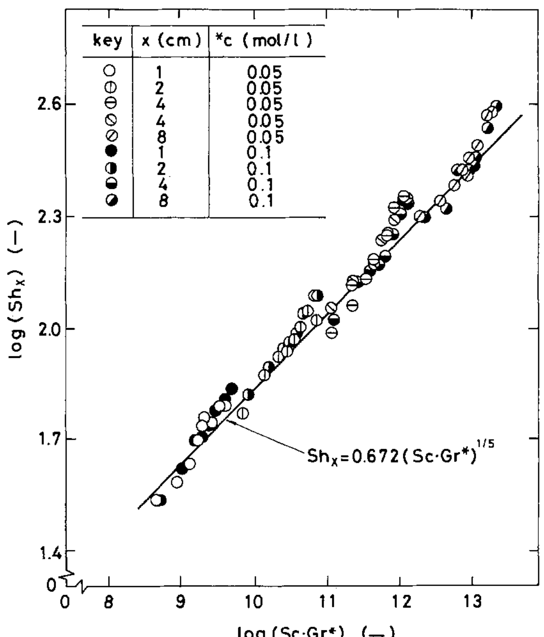

Fig. 12. Plot of log (Sh_x) vs. log (Sc · Gr*)

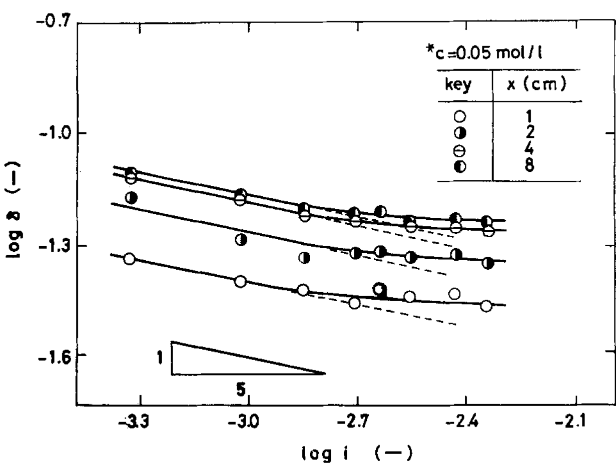

Fig. 13. Relationship between thickness of cathodic diffusion layer and average current density (*c = 0.05 mol/liter).

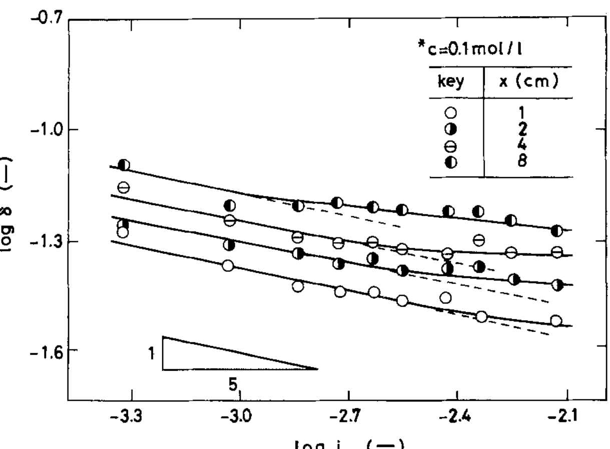

Fig. 14. Relationship between thickness of cathodic diffusion layer and average current density (*c = 0.1 mol/liter).

For the comparison of the measured and theoretical thickness of the diffusion layer, the experimental log(δ/x) was plotted against log(Sc · Gr*) in Fig. 17.

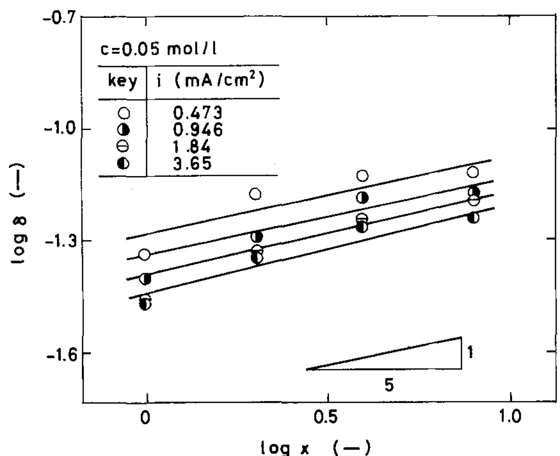

Fig. 15. Relationship between thickness of cathodic diffusion layer and height from lower edge of cathode (*c = 0.05 mol/liter).

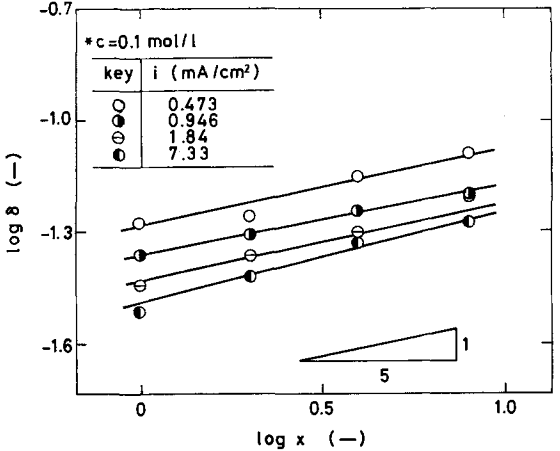

Fig. 16. Relationship between thickness of cathodic diffusion layer and height from lower edge of cathode (*c = 0.1 mol/liter).

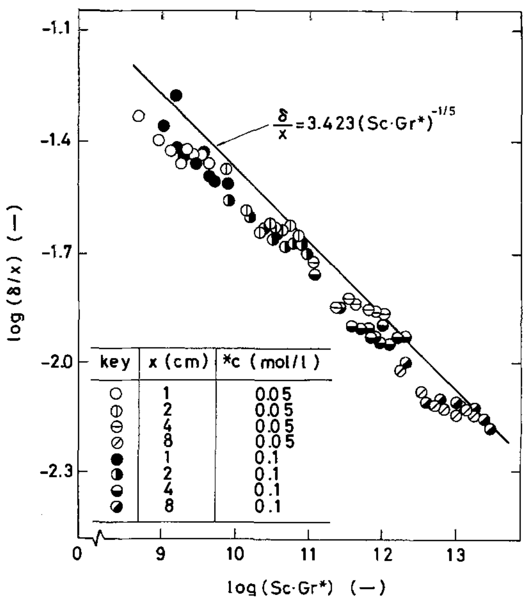

Fig. 17. Plot of log(δ/x) vs. log(Sc · Gr*)

In addition, the parameters and property constants were substituted in Eq. [21], and the theoretical line is also demonstrated in the same figure. It is seen in this figure that the experimental results may be explained by Eq. [21], although the experimental data in this figure are somewhat lower than the corresponding theoretical values.

Summary

The measurement of the concentration profile of $CuSO_4$ in the cathodic diffusion layer which is accompanied by the upward natural convection is indispensable for studying the rate of mass transfer of cation through this layer. By using the technique of holographic interferometry, it becomes feasible to measure the concentration profile because of the principle of common path interferometry employed in this technique.

The concentration profile in the aqueous 0.05 and 0.1 mol/liter $CuSO_4$ solutions was measured at various cathodic current densities below the limiting value and at various heights from the lower edge of cathode. In the derivation of the concentration profile from the holographic interferogram, the effects of beam refraction in the diffusion layer were considered and an approximation was employed to interpret the holographic interferogram. Furthermore, the deviation due to the approximation was estimated at several current densities. It was found that the approximation was appropriate under the experimental conditions employed in this work. It was disclosed then from the experimental results that the concentration of $CuSO_4$ on the cathode surface is lowered and the thickness of the diffusion layer is decreased when the average current density is increased. It was also revealed that the thickness of the diffusion layer is increased in the upper part of the plane vertical cathode at a constant cathodic current density.

From the integrated Navier-Stokes equation and the mass balance equation of Cu^{2+} ion with regard to the hydrodynamic boundary layer together with the assumed concentration and velocity profiles in the generalized form and the mass transfer equations of Cu^{2+} and SO_4^{2-} ions at the cathode surface, the basic equations of mass transfer in the cathodic diffusion layer were derived. When the cathodic current density is lower than about one-half of the limiting value, the local current densities remain equal in the vertical direction. Under this condition, the concentration difference and the thickness of the diffusion layer are expressed by Eq. [14] and [15], respectively.

In order to examine the validity of these theoretical expressions, the dependences of measured log Δc and log δ on the logarithm of the current density and the height were evaluated. At the cathodic current densities far lower than the limiting value, the above dependences were confirmed. At higher current densities, on the other hand, the experimental results start to deviate from the theoretical value. This is supposed to be caused by the unequal local current densities in the vertical direction. The following dimensionless equations were derived from Eq. [14] and [15]

$$Sh_x = \frac{\omega}{\eta}\left(\frac{\Phi\eta^3}{\omega^2(\omega+1)\lambda}\right)^{1/5} (Sc \cdot Gr^*)^{1/5}$$

and

$$\frac{\delta}{x} = \eta\left(\frac{\omega^2(\omega+1)}{\Phi\eta^3}\right)^{1/5} (Sc \cdot Gr^*)^{-1/5}$$

The first equation concerns the concentration difference. In order to further confirm the theoretical relationship, the experimental parameters which influence the concentration difference and the diffusion layer thickness and the property constants were substituted in the above dimensionless equations, and the theoretical values were compared with the experimental results. It is shown that both theoretical and experimental values are in good agreement with each other in the region of the lower current densities.

Hydrogen Gas Absorber Made of Manganese Dioxide

Akiya Kozawa*

Union Carbide Corporation, Battery Products Division, Cleveland, Ohio 44101

Manganese dioxide catalyzed with palladium (1) or silver was found to be a good hydrogen absorber. Manganese dioxide alone (without a catalyst) has practically no ability to absorb hydrogen gas at room temperature (2). This note describes the preparation conditions and the properties of the hydrogen absorber and also a few possible applications.

Experimental

A typical method for preparing the hydrogen gas absorber is as follows. The components listed in Table I are mixed thoroughly. An appropriate amount of water (for example, 300g of water per 1000g of the dry mix) is added, and the mixture is well blended to produce a moldable paste. The paste is extruded or molded into various shapes (rod, pellet, sheet, etc.) depending on the application. Then it is dried at 75°-80°C overnight. The shaped body becomes rigid because the cement sets during the drying process. The stainless steel wool is not necessary but makes the porous body strong, particularly in the case of sheets. The solid body is porous and most of the water added in the blending step is removed in the drying process.

The rate of hydrogen absorption was tested with the apparatus shown in Fig. 1 and 2 for fast adsorption and slow absorption, respectively. The absorption is a chemical reaction between H_2 gas and MnO_2. The apparatus shown in Fig. 1 is used to test the initial absorption rate employing a 1 ~ 2g sample. The apparatus shown in Fig. 2 is used to measure the total absorption capacity employing a 100-200 mg sample.

To operate the apparatus (Fig. 2) first the air in the test tube (B) was replaced by N_2 gas by purging while the mouth of the test tube was maintained slightly above the oil level (H). Then the oil level in the test tube was raised to around (I) by applying a vacuum. Finally H_2 gas was introduced and the oil level was brought down to (H). All the fine plastic tubes (D) were then removed. The oil level was read from time to time to measure the hydrogen gas uptake by the sample. This was not a very accurate measurement (±0.5 cm^3), but satisfactory for the present purpose.

* Electrochemical Society Life Member.

Key words: hydrogen, manganese dioxide, palladium, gas absorber.

Table I. Components of the hydrogen gas absorber

	Typical example	Range
1. Manganese dioxide*	73.7% (by wt)	50-80% (by wt)
2. Binder (Portland cement)**	18.5	10-40
3. Pd-catalyzed carbon***	4.6	0.4-20
(or Ag_2O or AgO)	(3.0)	(1-10)
4. Chopped steel wool	2.3	0-5

* Electrolytic manganese dioxide for dry cell such as I.C. MnO_2 No. 1, 2, and 3 (6).
** Eliminate Portland cement in the case of Ag_2O or AgO catalyst.
*** Obtained from Engelhard Industries, Incorporated. This material contained 5% Pd, 45% carbon, and 50% H_2O.

Results and Discussion

Absorption capacity.—When 100 mg of the absorber having the composition shown in Table I was tested in the apparatus shown in Fig. 2, the material absorbed about 17.5 cm^3 of H_2 gas in 5 days as shown in Fig. 3. According to the reaction ($MnO_2 + H_2 \rightarrow MnO + H_2O$), the MnO_2 contained in the absorber should absorb about 19 cm^3 of H_2 gas. This result (Fig. 3) indicates that MnO_2 is reduced almost to MnO. In the case of Ag_2O or AgO catalyst, MnO_2 was reduced to only MnOOH or slightly more than MnOOH.

Absorption rate.—The absorption rate is fast initially and becomes slower and steady after 1 hr. The steady rate depends on the amount of the catalyst as well as binder as shown in Table II for Pd-catalyzed absorbers and Fig. 4 for silver-catalyzed absorbers. The test temperature and particle size of manganese

Table II. Effect of the catalyst content on the H_2 absorption rate (data given in this table are the average of two experiments)

Catalyst content* (%)	Actual sample tested (g)	Amount of MnO_2 in the sample (g)	Maximum H_2 to be absorbed (cm^3)	H_2 absorbed in 2 hr at 45°C (cm^3)	H_2 absorbed in first 30 min (cm^3)	Absorption rate after 1 hr (cm^3/hr)
0.8	1.51	0.97	200	9.0 ± 0.5	3.0 ± 0.5	4.5 ± 0.5
2.0	1.47	0.95	195	23.0	10.0	7.0
4.0	1.45	0.90	187	32.0	15.0	11.0
9.2	1.35	0.76	162	48.0	27.0	11.0
16.8	1.38	0.73	151	54.0	32.0	13.5

* The basic composition is as follows, the catalyst content being varied: MnO_2: 160g, Pd-carbon: 0.4-16.8%, acetylene black: 2g, binder (Portland cement): 80g, steel wool: 5g.

dioxide influence the absorption rate as seen in Fig. 5 and 6.

Use of H_2 gas permeable film.—If the hydrogen gas to be absorbed coexists with a solution, *e.g.*, in the alkaline manganese dioxide-zinc cell, this porous hydrogen absorber may be wrapped with a thin polyethylene film through which H_2 gas is permeable at a sufficient rate but which prevents the solution from going into the porous body. A 1 mil thick polyethylene film (such as Zendel made by Union Carbide Corporation) has a sufficient hydrogen gas permeability for most applications.

Other catalysts.—The catalyst can be platinum black or other noble metals; palladium dispersed on carbon is satisfactory and inexpensive compared to other noble metal catalysts. The function of the palladium would be the dissociation of hydrogen molecules to atomic hydrogen.

Bonding agent.—Among various bonding agents including organic plastics dissolved in organic solvents, a few inorganic binders, water, glass, and cement were found to be most convenient. Organic plastics (polyethylene, polysulfone, etc.) sometimes deactivate the catalyst, probably because the polymer covers the active centers of the palladium.

CO absorption.—It was found in a preliminary test of this Pd-catalyzed hydrogen absorber for CO absorption that this material does have a relatively good capability for CO adsorption.

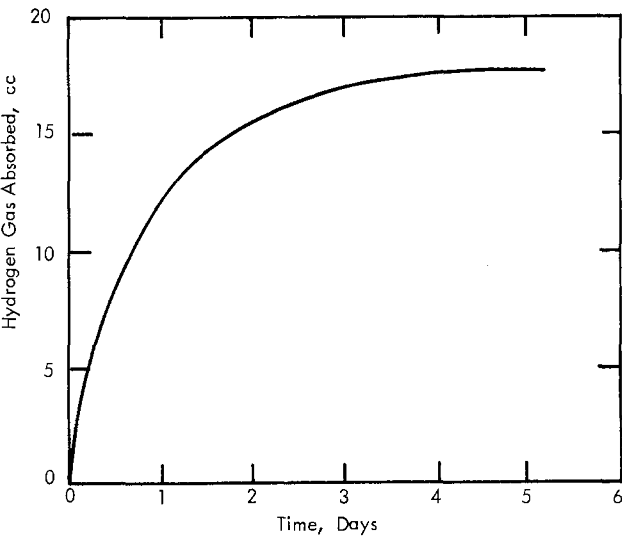

Fig. 3. Hydrogen gas absorption by a 100 mg crushed sample having a formula shown in Table I.

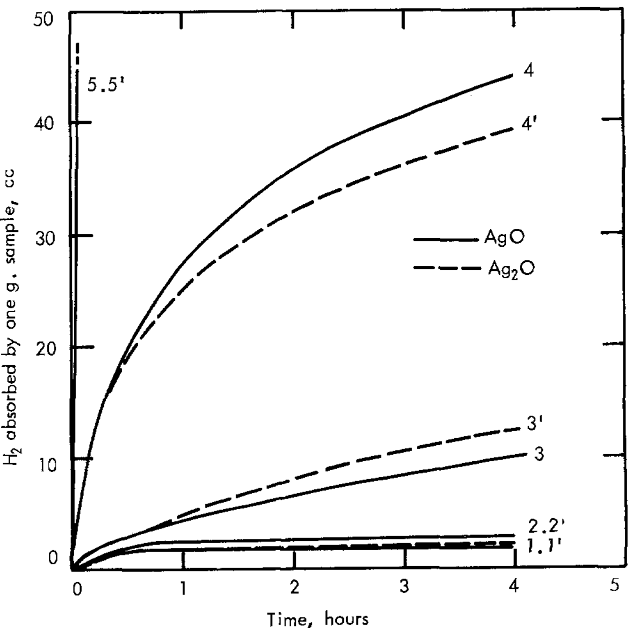

Fig. 4. Hydrogen gas absorption by 1g sample (MnO_2 + Ag_2O or AgO). Ag_2O or AgO content was as follows: 1.1':0.1%, 2.2':0.3%, 3.3':1%, 4.4':3%, 5.5':10%.

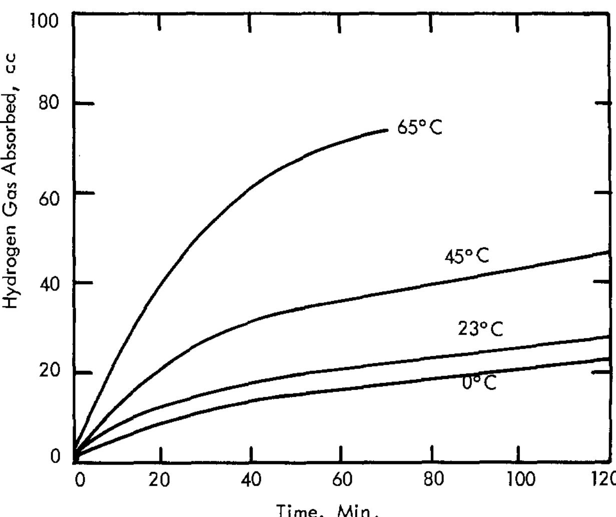

Fig. 5. Effect of temperature of the hydrogen gas absorption rate. The composition of the absorber was as follows: MnO_2: 160g, Pd-catalyzed carbon: 25g, cement: 80 g, acetylene black: 2g, steel wool: 5g. The sample of each test had about 1.5g in a crushed powder form.

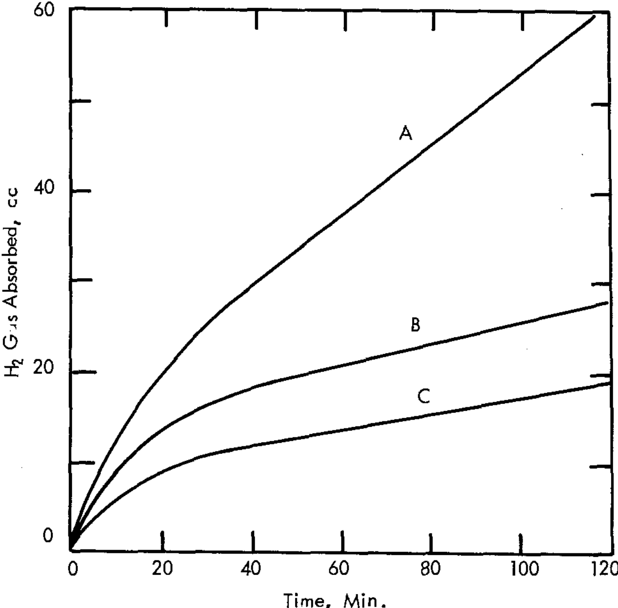

Fig. 6. Effect of particle size of manganese dioxide used in the adsorber having a formula as follows: MnO_2: 160g, Pd-catalyzed carbon: 10g, acetylene black: 2g, cement: 40g, steel wool: 5g. Particle size of MnO_2: A: less than 40μ, B: 50-100μ, C: 150-300μ.

Mechanism of MnO_2 reduction.—The reduction of MnO_2 in dry cells has been extensively studied (3-5). According to the studies, the electrochemical reduction process is a proton injection into the MnO_2 lattice at least up to $MnO_{1.5}$, as shown below

$$MnO_2 + H_2O + e^- \rightarrow MnOOH + OH^-$$

The reduction of MnO_2 by H_2 gas would involve the same mechanism, although the source of protons is H_2 (= 2H) instead of H_2O (= $H^+ + OH^-$).

Stability in air.—A hydrogen absorber was prepared with 0.4% palladium-carbon catalyst, stored in air for 5 years and tested. Although the absorber contained only 0.4% of the catalyst, it was possible to maintain almost the same absorption rate as the fresh sample. The total absorption capacity, however, decreased to 70% of the initial capacity during the 5 year storage in air at 23°C. The reduced MnO_2 in the hydrogen absorber by the reaction with hydrogen gas is reoxidized up to about 30-60% by oxygen in air. The regeneration feature of this material is important for certain applications.

Applications

One application of the hydrogen absorber is the removal of hydrogen gas in sealed cells (1). In sealed cells such as alkaline MnO_2-Zn cells, H_2 gas evolved from the zinc anode by corrosion accumulates, and this hydrogen must be removed before the internal pressure becomes too high. A rod or pellet form of this hydrogen absorber, which is wrapped with a thin polyethylene film, can be used for this purpose.

Another application is the removal of accumulated hydrogen gas in confined areas or compartments, since any possible explosion hazard must be eliminated for safety. Such confined areas include underwater vessels or closed rooms in which hydrogen gas may be leaked from a pipeline or generated by various chemical or radiochemical reactions or from lead-acid batteries.

Another application is the removal of hydrogen gas generated from a battery power pack which operates adjacent to electronic equipment. Hydrogen gas is often generated from dry batteries and rechargeable batteries and alters the characteristics of the capacitors and resistors in the electronic circuit. This type of problem can be easily eliminated by using the present hydrogen absorber at the top of the battery pack.

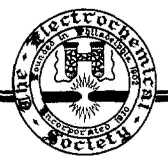
Brief Communications



Solid Lithium-Silicon Electrode

San-Cheng Lai*

Rockwell International, Atomics International Division Canoga Park, California 91304

Lithium-metal sulfide high energy density batteries are being developed at the Atomics International Division of Rockwell International and at Argonne National Laboratory for use in load leveling and electric vehicles (1-3). The battery system is operated with an electrolyte of LiCl-KCl eutectic salt at temperatures of 400°-450°C. Iron sulfide compounds are employed as the active material for the positive electrode with either elemental lithium or a solid lithium alloy as the anode.

Two approaches to the lithium anode have been studied. A porous lithium-aluminum alloy, suitably supported, can retain up to 20 weight percent (w/o) of lithium as a solid (3-5). One disadvantage in using this electrode is the loss of 0.3V *vs.* pure lithium, thus reducing the theoretical energy density attainable when coupled with the various metal sulfide electrodes. An alternative approach is retention of liquid lithium metal in a porous metal substrate which avoids the voltage loss associated with the alloy. However, retaining lithium on metallic substrates in molten lithium-potassium halide salt mixtures saturated with Li_2S has been difficult (1).

Other binary lithium alloys electrochemically formed by depositing lithium from a LiCl-KCl fused salt electrolyte, such as Li-Bi, Li-Pb, and Li-Sn, have been reported (6). These binary lithium alloys have lower potentials *vs.* lithium than does Li-Al and the lithium content in the alloy is low. Lead and tin, for example, form alloys containing lesser amounts of lithium than does aluminum, and the high molecular weight of these elements would thus reduce the energy capacity of a lithium electrode. None of these alloys were found to be practical for the application to the secondary batteries. Possibly a need still exists for a lithium electrode which upon continued cycling will retain its capacity and will operate at a potential nearer that of liquid lithium. This paper presents the result of the preliminary investigation of a solid lithium-silicon electrode.

Experimental

All experiments reported in the paper were performed in a helium-atmosphere dry box where the concentrations of oxygen, nitrogen, and water were removed to below the parts per million level to avoid reactions with lithium.

Lithium metal from Foote Mineral Division of Newmont Mining Company was used in all experiments. Silicon, 97% pure, purchased from MC/B, Manufacturing Chemists, was used in the preparation of the alloys. Highly prepurified electrolyte salts were purchased from Anderson Laboratories for the tests described here. A titanium fiber mat was purchased from Gould Laboratory, Cleveland, Ohio. It had fibers approximately 100μ diameter, having an apparent density of 19%.

A laboratory cell design shown in Fig. 1 was used during the course of this investigation. The cell consists

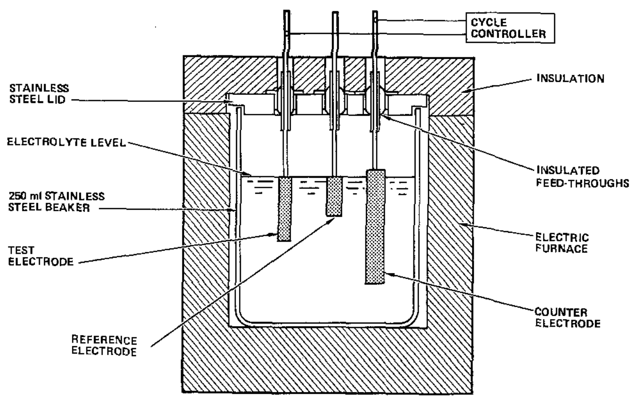


Fig. 1. Laboratory investigation cell

of a stainless steel beaker (250 ml) where a eutectic electrolyte, 59 mole percent (m/o) LiCl-41 m/o KCl, was retained. A lithium-silicon electrode was prepared by impregnating the titanium fiber mat with a molten alloy containing 60 w/o of lithium and 40 w/o of silicon at 700°C. Titanium was chosen for the supporting structure because the solubility of this metal in lithium is low and it therefore resists attack by the molten alloy during the impregnation process. A copper Feltmetal panel impregnated with pure lithium metal was used as the counterelectrode. A nickel Feltmetal panel impregnated with pure lithium was used as the reference electrode. The electrode leads were mounted through insulated feed-throughs brazed to a close-fitted cover for a beaker containing the KCl, LiCl eutectic salt electrolyte. A thermocouple permitted the temperature of the electrolyte to be monitored accurately.

A series of measurements was made to characterize the voltage plateaus and to identify the alloy compositions corresponding to each. Entropy calculations were also made by measuring the variations in the potential, *E*, of the alloy electrode *vs.* pure liquid lithium at each plateau at different temperatures ranging from 360° to 440°C.

The electrode was discharged through the successive voltage plateaus, disregarding the first plateau which had essentially the same potential as liquid lithium. From the known weight of the alloy in the electrode and the quantity of lithium discharged past each transition point, it was possible to calculate the alloy compositions.

Results and Discussion

Figure 2 shows the experimental result of the discharge of a lithium-silicon electrode having an initial composition of 60 w/o of lithium and 40 w/o of silicon [86 atom percent (a/o) lithium] five distinct voltage plateaus *vs.* pure lithium were observed. For comparison, the lithium-silicon alloys described in the available literature (7, 8) are also shown in Fig. 2. The compositions, Li_5Si and Li_2Si, have been established with some certainty. The empirical formula, $Li_{4.1}Si$, may

* Electrochemical Society Active Member.

Key words: lithium-silicon alloy, molten salt, high temperature secondary battery.

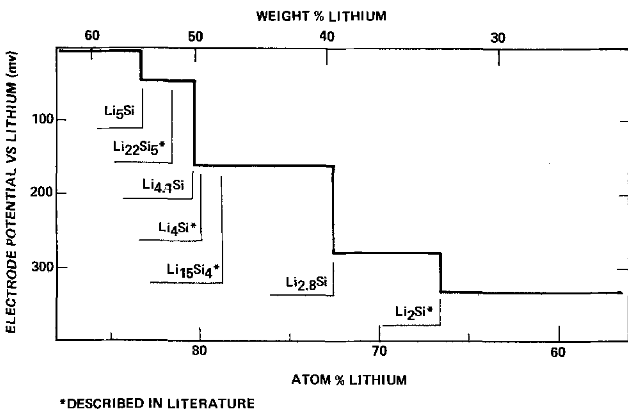

Fig. 2. Discharge voltage plateaus of 60Li-40Si (w/o) electrode in LiCl-KCl eutectic electrolyte at 400°C.

actually represent Li_4Si. More precise tests will be required to establish the exact stoichiometric ratio. No reference has yet been found to a composition even approximating that of $Li_{2.8}Si$. It is planned in the near future to identify the compositions corresponding to each voltage plateau by chemical and/or metallurgical methods.

The average potential over the four plateaus corresponding to solid alloy is 228 mV positive to lithium as contrasted to 300 mV for lithium-aluminum alloy. The total capacity of the solid alloy regions is 2.12 A-hr/g.

The variation of potential with temperature was sufficiently linear so that a straight line formula could be written for each plateau using the least squares method. The voltage-temperature relationship derived in this manner is shown in Table I.

These measurements permitted calculation of $\Delta S°_f$, $\Delta H°_f$, and $\Delta G°_f$ for each alloy composition from the well-known thermodynamic functions

$$\Delta S = n\mathbf{F}(\Delta E/\Delta T)_p$$

where ΔS = entropy change, $\mathbf{F}$ = Faraday constant, ΔE = change in cell voltage, ΔT = change in cell temperature, n = number of electrons, and p signifies a constant pressure.

The free energy and enthalpy functions could then be calculated from the following relationships

Table I. Temperature dependence of emf of lithium-silicon alloys vs. lithium metal at 400°C

Voltage plateau at 400°C	Temperature dependence (mV *vs.* °K)
+48	137.7-0.1336T
+158	276.5-0.1761T
+280	332.1-0.0771T
+336	430.7-0.1402T

Table II. Thermodynamic data for lithium-silicon alloys at 400°C

Alloy	$\Delta G°_f$ (kcal/mole)	$\Delta S°_f$ (eu)	$\Delta H°_f$ (kcal/mole)
Li_5Si	−26.4	−15.9	−37.1
$Li_{4.1}Si$	−25.4	−13.2	−34.3
$Li_{2.8}Si$	−20.7	−7.9	−26.0
Li_2Si	−15.5	−6.5	−19.9

$$\Delta G = -n\mathbf{F}E$$

$$\Delta H = \Delta G + T\Delta S$$

where ΔG = change in Gibbs free energy and ΔH = change in enthalpy. The results of these calculations appear in Table II.

This preliminary investigation has shown that lithium-silicon alloy contains substantially higher usable lithium content in the alloy (~83 a/o) and has less potential penalty than the other alloys mentioned above. It is therefore promising as an excellent anode material for high energy density batteries. Further work is under way to incorporate lithium-silicon alloy anodes with metal sulfide cathodes to achieve high specific power and energy density batteries for load leveling and electric vehicle propulsion applications.

Stochastic Process of Chloride Pit Generation in Passive Stainless Steel

Norio Sato*

Corrosion Research Group, Faculty of Engineering, Hokkaido University, Sapporo, Japan

Pitting corrosion of passivated metals takes place in two apparently different stages, pit nucleation and growth. Pit generation is frequently characterized by a critical pitting potential, defined as the least noble potential at which pits can be generated, and by an induction time for pit initiation after introduction of aggressive ions at constant potential.

The generation of pits on stainless steel is a random phenomenon discrete in time and location on the sur-

* Electrochemical Society Active Member.
Key words: pitting frequency histogram, pit generation probability, pitting potential.

face, and therefore may be regarded as a stochastic process. It has recently been suggested that probability theory can be applied to the induction time for pit generation in stainless steel (1); the induction time has often been equated, though approximately (2), to the inverse of the pit generation rate (3, 4).

The present paper describes an application of the theory of the Markov process to potentiostatic pit generation in a rotating stainless steel electrode in an acid solution containing sulfate and chloride ions.

Pit Generation Intensity

If pit generation takes place in the restriction of the Markov property that the future probability of pit nucleation is uniquely determined once the state of the system at the present stage is given, the probability, $P(\Delta t)$, of another pit breaking out in a time interval larger than Δt after the preceding pit has opened is given by (5)

$$dP(\Delta t)/P(\Delta t) = -\lambda(\Delta t)dt \quad [1]$$

where $\lambda(\Delta t)$ is the pit generation intensity or relative pit generation rate, equivalent to the pit generation probability for unit time at time interval Δt. Consequently, the following equation is obtained

$$\lambda(\Delta t) = -2.3026\{d \log P(\Delta t)/dt\} \quad [2]$$

Frequency Histogram of Pit Generation

In a previous paper (2), a number of potentiostatic pit generation experiments with 18Cr-8Ni stainless steel have been carried out to measure the time interval, Δt, for pits successively breaking out at constant potential in a solution containing chloride ions. A rotating stainless steel electrode of surface area 3.54 cm^2, potentiostatically passivated for 1 hr in 0.1M Na_2SO_4 of pH 3 prior to introduction of chloride ions, was used, and the solution was 0.2M NaCl containing 0.1M Na_2SO_4 at 25°C. The classical induction time for the first pit to appear was excluded from Δt because of different physical meaning (2).

Figure 1 shows the relative frequency histogram of the pit generation at three different potentials. The relative frequency which is given by $N_{\Delta t \sim \Delta t + \delta t}/N_T$, with N_T the total number of measurements and $N_{\Delta t \sim \Delta t + \delta t}$ the number of measurements in which the pit generation time interval is in the range $\Delta t \sim \delta t$, is related to the probability $P(\Delta t)$ in Eq. [1] as follows

$$P(\Delta t) = \frac{\sum_{\delta t=0}^{\infty} N_{\Delta t \sim \Delta t + \delta t}}{N_T} \quad [3]$$

Figure 2 shows the logarithm of $P(\Delta t)$ as a function of pit generation time interval Δt. It is observed that there is essentially a linear relationship between log $P(\Delta t)$ and Δt, giving an integral function of Eq. [1]

$$2.3026 \log P(\Delta t) = -\lambda \cdot \Delta t \quad [4]$$

where λ, the pit generation intensity, is independent of Δt, and is given by $\lambda = 0.175$ min^{-1} at +0.85V (SHE), $\lambda = 0.500$ min^{-1} at +0.95V, and $\lambda = 0.614$ min^{-1} at +1.05V. For unit area of the surface, therefore, $\lambda_o = 0.0494$ min^{-1} cm^{-2} at +0.85V (SCE), $\lambda_o = 0.141$ min^{-1} cm^{-2} at +0.95V, and $\lambda_o = 0.173$ min^{-1} cm^{-2} at +1.05V.

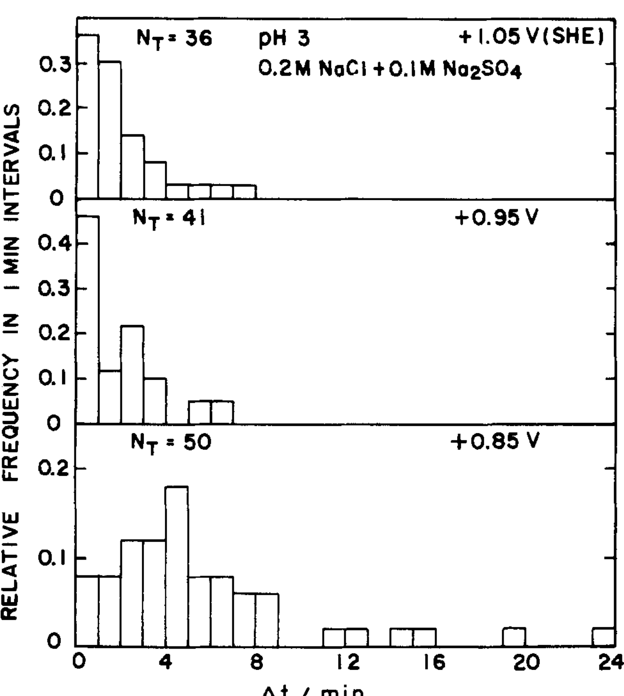

Fig. 1. Frequency histogram of potentiostatic pit generation on a rotating 18Cr-8Ni stainless steel electrode.

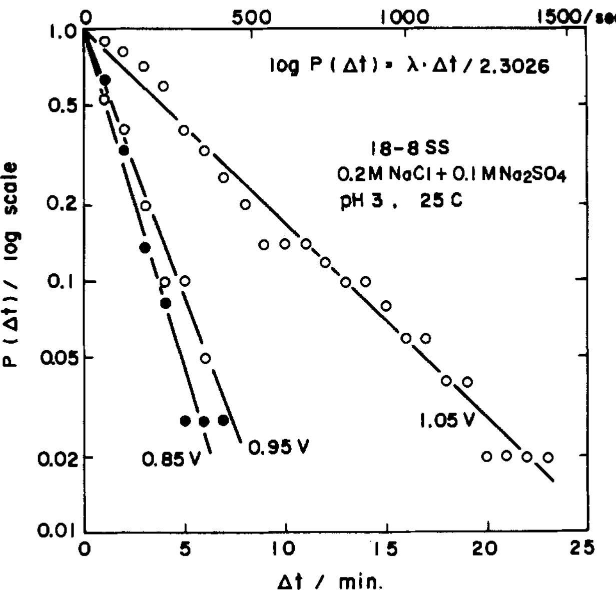

Fig. 2. Cumulative relative frequency curve for pit generation time interval at three different potentials.

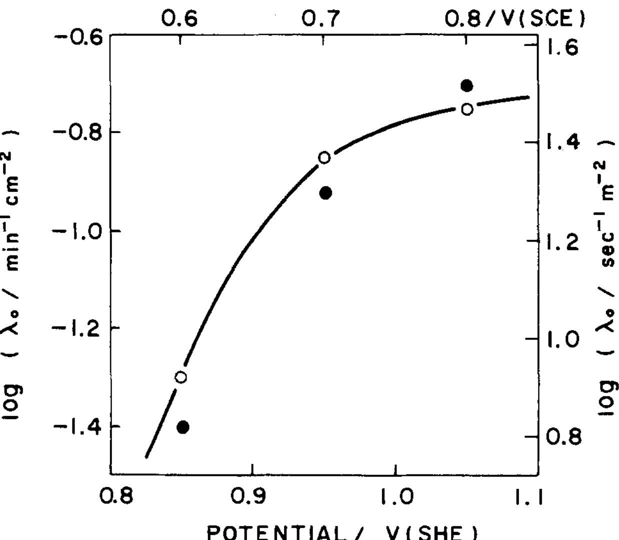

Fig. 3. Pit generation intensity for unit surface area as a function of potential; ○ = present calculation by the stochastic method, ● = previous calculation by the least squares method (2).

In Fig. 3, the pit generation intensity, λ_0, for unit area of the surface is plotted against the potential at which pits are generated; the pit generation rate estimated by the least squares method is also shown for comparison. The pit generation probability increases and appears to approach a ceiling asymptotically as the potential becomes more noble.

In view of stochastic process, the critical potential for pit generation may be defined as the least noble potential at which the pit generation probability is practically recognizable. Notice that the pit generation probability depends on the area of the metal surface.

Evaluation of Electrochemical Information Transfer System

I. Effect of Electric Fields on Living Organisms

Andrew A. Marino, Thomas J. Berger, B. Peter Austin, and Robert O. Becker

Veterans Administration Hospital and Upstate Medical Center, Syracuse, New York 13210

and Francis X. Hart

University of the South, Sewanee, Tennessee 37375

The concepts of electrochemical information transfer occurring at membrane interfaces in biological systems (1,2) imply that exposure of living organisms or cells to electromagnetic fields will produce nonthermal effects. In view of the widespread alteration of the electrical environment produced by electrical power transmission facilities, the question of a resultant biological effect becomes significant. A preliminary study involving chronic exposure of rats to 60 Hz, 150 V/cm, electric fields is reported herein. Our object was to determine whether such exposure would; (*i*) act as a body stressor, *i.e.*, direct glandular (cell) effect, (*ii*) affect the blood proteins, *i.e.*, the cells which produce them, (*iii*) affect the growth rate of immature animals. To these ends we measured the concentration of serum corticoids, the relative distribution of serum proteins, and body weight.

Methods

Twenty-one day old male Sprague-Dawley rats, fed and watered *ad libitum*, were exposed continuously for one month to a 60 Hz electric field generated between the plates of a capacitor which was oriented to produce an electric field vertical to the earth's surface (3).

Each experimental and control group consisted of a minimum of 11 rats. In the first three experiments, the rats were weighed at the end of the exposure period, decapitated, and the sera from each group was pooled and analyzed. In the fourth experiment, the rats were subjected to a cold stress (−13°C for 1 hr) at the end of the exposure period, after weighing and prior to sacrifice. All experiments were performed consecutively.

The relative percentages of the four major groups of serum proteins were determined by electrophoresis on cellulose acetate with planimetric integration (3). The concentration of 11-hydroxycorticosterone in the pooled sera (serum corticoids) was measured fluorometrically by Mattingly's method (4) as modified by Purves and Sirett (5).

Key words: electric field, information transfer, stressor.

Results

The final weight of all four experimental groups was lower than that of the corresponding control group, significantly so ($P < 0.05$) in two experiments (Table I). In the three experiments in which they were measured, a statistically significant elevation in albumin percentage and a statistically significant decrease in gamma globulin percentage was noted, compared to the corresponding control group (Table II). In the first three experiments, the serum corticoids were consistently lower in the experimental group as compared to the corresponding control group (Table I). All experimental and control animals were autopsied at sacrifice and no gross pathology was observed.

Experiment 4 was performed to determine whether the observed disturbances in the adrenal-pituitary system (control system for serum corticoids) would prevent the exposed rats from responding to a known stress. When subjected to a cold stress, the serum corticoids in both groups rose markedly (Table I), indicating that the exposed rats remained capable of responding to a known stress in the predictable fashion.

All the observed metabolic alterations are consistent with the effect of chronic exposure to a non-

1	Experimental	$59.1 \pm 1.7^*$	$22.3 \pm 1.0^*$	12.2 ± 0.9	$6.4 \pm 1.4^*$
	Control	53.8 ± 1.6	24.1 ± 0.9	13.6 ± 0.9	8.6 ± 1.2
2	Experimental	$52.4 \pm 2.8^*$	25.7 ± 1.0	14.6 ± 1.1	$7.5 \pm 0.8^*$
	Control	49.2 ± 1.0	26.9 ± 1.0	14.7 ± 0.6	9.2 ± 0.7
3	Experimental	$52.7 \pm 1.4^*$	25.9 ± 2.1	14.8 ± 0.9	$7.3 \pm 0.9^*$
	Control	49.1 ± 3.3	27.2 ± 2.4	14.0 ± 0.6	9.6 ± 1.2

* $P < 0.05$.

specific environmental stressor (6-8), with the development of the general adaptation syndrome as described by Selye (6). Since data were obtained only at the termination of one month's exposure, the initial stages of this reaction were not documented.

In summary, the results support the concept of electrochemical information transfer in biological systems, and indicate that it involves at a minimum, direct cellular and glandular responses quite distinct from that due to Joule heating.

Kinetics of the Reactive Sputter Deposition of Titanium Oxides

K. G. Geraghty[1]

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, Berkeley, California 94720

and L. F. Donaghey*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The reactive sputtering of titanium was studied in an rf plasma containing argon and oxygen. The kinetics of the reactive sputtering process and the properties of deposited titanium oxide films were studied as a function of the oxygen partial pressure in the plasma, bias voltage, and rf power. Models for the transient oxidation of titanium were explored in relation to oxidation mechanisms. Model parameters were determined from experimental studies. The sputter etch rate of the titanium target reached a maximum at an oxygen mole fraction of 0.002. The sputter deposition rate was found to decrease sharply at a critical oxygen mole fraction equal to 0.007, corresponding to the onset of target oxidation. The time dependence of the target oxidation process was found to be in qualitative agreement with a reactive sputter-oxidation model.

Titanium dioxide is an important dielectric material for refractory, optical, and electronic applications. In optical and microelectronics applications, TiO_2 thin films can be sputter deposited by the rf sputtering of titania, or by the reactive sputtering of titanium in a plasma containing a partial pressure of oxygen (1-3). The optical properties of TiO_2, particularly its high refractive index, have proven invaluable to the optics industry for over 25 years, and much thin film research in this industry has been carried out in the preparation of TiO_2 lens coatings (4, 5). Titania can also be deposited as a protective coating (6). In addition to the practical importance of titanium dioxide, the Ti-O system is of theoretical interest because of the large number of phases in this system, and because the kinetics of reactive sputter deposition of these phases have not been established. Bailey has reported that essentially all film physical properties of sputtered films are strongly dependent on deposition parameters such as time, deposit rate, argon pressure, cathode-anode distance, and substrate temperature (7). The establishment of kinetic rates and conditions for the deposition of TiO, of the Magneli phases Ti_nO_{2n-1} where $n \geqq 2$, and of TiO_2 by reactive sputtering is the subject of the present study.

The Ti-O System

There is considerable literature on the condensed phases of the Ti-O system. Several investigators have determined the phase diagram of this system during the last 20 years (8-10). The low temperature portion of the phase diagram for the Ti-O system after Roy and White is reproduced in Fig. 1 (10). This diagram indicates that temperatures above 800°C are required to produce rutile crystals under equilibrium conditions. Below this temperature, anatase is the stable phase. Thus, in order to obtain rutile, it is necessary to insure that the effective deposition temperature be maintained

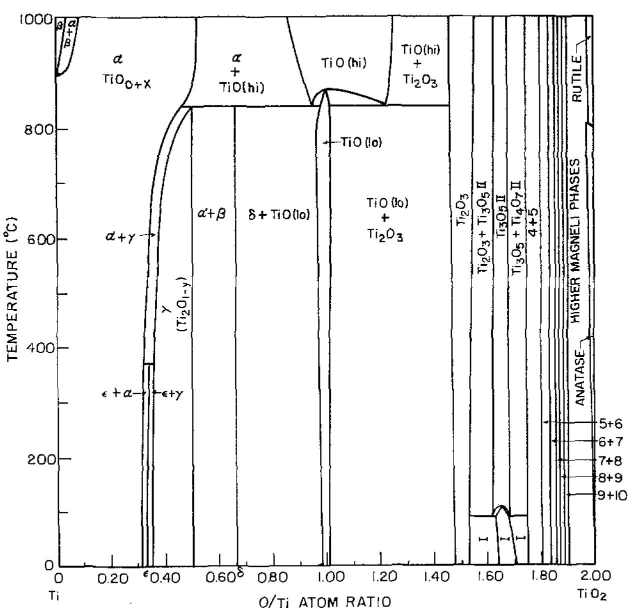

Fig. 1. Low temperature condensed phase diagram for the Ti-O system. The Magneli phases have the form Ti_nO_{2n-1} where $n = 4,5,6, \ldots, \infty$.

above 800°C, either by heat generated from the impacting atoms themselves or through external heating of the substrate.

The stability range of Ti_3O_5 and the Magneli phases with regard to temperature and oxygen fugacity was determined by Porter (11). These studies confirmed the existence of an indeterminate number of intermediate oxide phases between TiO and TiO_2. Of these, Ti_2O_3 and Ti_3O_5 are distinct phases, while the Magneli phases form a closely related series of shear-defect compounds with the homologous formula Ti_nO_{2n-1} where $4 \leq n \leq \infty$ (12).

Figure 2 summarizes the stability ranges of these phases as a function of the reciprocal temperature and oxygen fugacity. The figure shows that TiO_{2-x} (anatase) is the stable oxide phase at an estimated target surface temperature of 400°C and an oxygen fugacity near unity. For substrate temperatures below 800°C, TiO_{2-x} (anatase) should be the thermodynamically stable, but not necessarily the kinetically favored, phase deposited by reactive sputtering with Ar/O_2 over a range of oxygen fugacity.

Theories of Target Oxidation

The sputtering process consists of accelerating positively charged plasma ions into a target material under the influence of a bias electric field. The incident ions eject atoms of the target material from the target surface by initiating a chain-collision energy transfer process through the crystal lattice. Reactive gaseous components in the plasma can react with the target causing oxidation of the target surface, and energetic ions have sufficient energy to be implanted into the target to cause internal oxidation.

While a d-c bias voltage suffices for sputtering conducting materials, an rf field is required for sputtering of dielectrics in order to remove the negative charge buildup at the target surface by highly mobile plasma electrons. In addition, rf power can also cause sputtering of conducting materials.

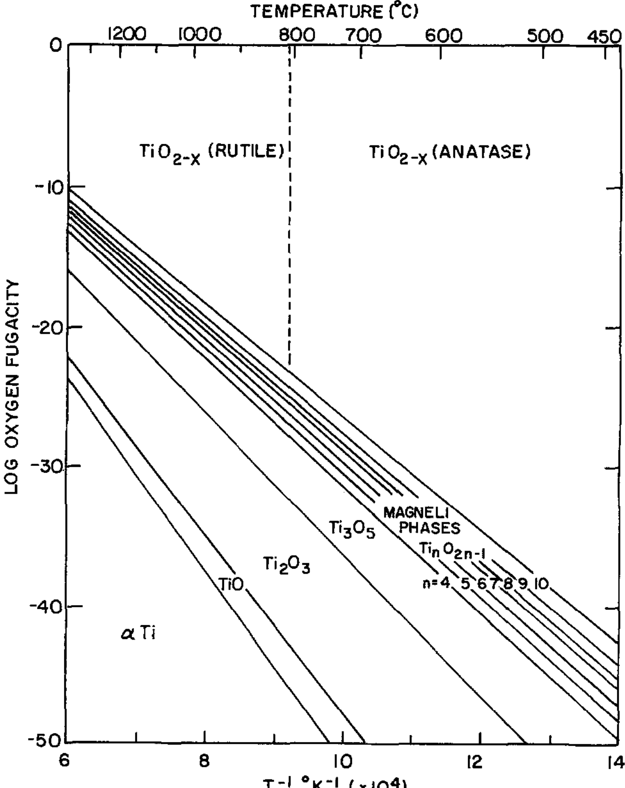

Fig. 2. Stability ranges of titanium oxides as a function of reciprocal temperature and oxygen fugacity.

The plasma gas for the sputtering process is normally an inert gas, typically argon. Introducing a reactive gas with the argon allows reactive sputtering, wherein the sputtered target atoms react with the active gas, and the products are collected on the substrate. The mechanism of this reaction is not clearly understood, as the precise time of reaction has not been determined. The oxidation reaction could occur at the target surface, on collision with the substrate, or by diffusion and reaction following deposition on the substrate. Oxidation reactions in the gas phase are negligible because of the low collision cross sections and low pressures involved.

The subject of target oxidation has received even less attention than the reaction-chemistry mechanism of reactive sputtering, perhaps because commercial applications are primarily concerned with the materials deposited during sputtering and not with the target condition or rate kinetics. However, new contributions to the mechanisms of target oxidation are available from recent developments in the analogous field of plasma anodization and oxidation (13-15).

The plasma anodization model.—Plasma anodization is the process of growing an oxide film on a metallic substrate by immersing the substrate in an oxygen plasma and applying an electric field (14). Plasma oxidation is virtually the same technique lacking only the externally applied bias voltage. The current interest in these technologies stems from their application to the fabrication of oxide tunnel barriers for thin film Josephson junction devices.

The pioneering work of Miles and Smith offered the first indication of the potential uses of plasma anodization for both tunneling barriers and thin film dielectrics (13). They offered a qualitative explanation of the oxidation process, and concluded that positive metal ions dissolve into the surface oxide layer under the influence of the electric field. The ions, under a combination of drift and diffusion, move to the oxide-plasma interface, and react chemically with gaseous oxygen, thereby initiating oxide growth. They further observed that for a constant bias potential, the oxide growth reaches a certain thickness and then ceases. Thickness control can be exercised by varying the applied field strength.

A few years after this work, Schroen looked at the physics of the oxidation process and presented a molecular model for the reaction (14). The initially neutral substrate is raised to a negative potential by the mobile plasma electrons. This negative potential attracts O^+ and O_2^+ positively charged oxygen molecules to the target surface. These ions enter the target as O_2 neutrals, diffuse into the metal lattice, and react to form an oxide. The model is still tentative, and lacks any quantifying formulae.

O'Hanlon (15) reviewed plasma anodization, and presented a model very similar to Schroen's for the plasma anodization process in terms of two distinct mechanisms. One mechanism is that of Schroen, whereby O_2^+ ions dissociate upon impact and diffuse into the target. A second mechanism is that O^+ and O_2^+ ions originating in the plasma are implanted directly into the oxide. This model is supported by Whitlock and Bounden (16) and by Thompson (17), who were unable to detect any measurable negative ion current density in the negative glow of an oxygen discharge.

Miles and Smith have studied oxide growth rates on aluminum by plasma anodization (13). An essential requirement for oxide growth by this method is the formation of a "priming oxide layer" by exposing the aluminum to an O_2 plasma for a period of 600 sec before applying a bias potential. Without the priming period, no oxide was formed. The thin oxide layer (<20Å) formed after the priming period by plasma anodization without external bias potentials was shown by O'Hanlon (15) to have a logarithmic dependence on

time given by

$$x = x_o + k \ln t \quad [1]$$

where $t > 1$ min. Using the same data, however, one can show that a parabolic growth law is followed during the same time period

$$x = k'\sqrt{t} \quad [2]$$

where $t > 0$. Thus, it appears that a diffusional mechanism could drive the plasma anodization process at zero bias.

The oxidation rate of Ti metal in pure O_2 at 1 atm pressure has been measured by Kubaschewski and Hopkins (18). The oxidation time dependence can be described by the parabolic dependence of oxide thickness on time with a rate constant given by

$$K_p = 0.16 \exp(-45{,}050/RT) \quad [3]$$

(550°-850°C) where K_p has the units [$g^2\ cm^{-4}\ sec^{-1}$], $R = 1.98719$ cal_{th} $mole^{-1}$ $°K^{-1}$, and T is in °K. Thus, the TiO_2 oxide thickness x in centimeters has the time dependence

$$x = \{10^{-1.027-4923T^{-1}}\}t^{1/2} \quad [4]$$

where time t is in seconds. This equation indicates that temperatures of ~1000°C are needed to form a 1 μm thick oxide layer in 10^3 sec, whereas an oxide layer of 10Å forms at only 385°C in the same time. Although a water-cooled sputtering target remains within a few degrees of the coolant temperature during sputtering, the temperature at the sputtering collision site can reach a significant fraction of the melting point. Therefore, it can be anticipated that the oxidation rate in an oxygen-containing plasma is partly diffusion controlled, in spite of the finite sputtering process.

The reactive sputter-oxidation models.—The first quantitative analysis of the oxidation phenomena was advanced by Greiner, who investigated rf sputter etching in oxygen (19). The basis of Greiner's theory is the assumption that the sputtering and oxidation rates are independent and concurrent. The rate of change of oxide thickness on the target, dx/dt, is then

$$\frac{dx}{dt} = R_{ox} - R_{sp} \quad [5]$$

where R_{ox} is the oxidation rate and R_{sp} is the sputter rate of the target phase. In this model, Greiner invokes two assumptions. First, the oxide thickness follows a logarithmic time dependence given by $x = x_o + k \ln t$, and, second, the sputter each rate, R_{sp}, is constant. Consequently

$$R_{ox} = Ke^{-x/x_o} \quad [6]$$

Using Greiner's assumption, the total rate of change of oxide thickness becomes

$$\left(\frac{dx}{dt}\right)_{total} = Ke^{-x/x_o} - R_{sp} \quad [7]$$

This differential equation has the integral form

$$x = x_o \ln\left[\frac{K}{R_{sp}} - \left(\frac{K}{R_{sp}} - e^{x_i/x_o}\right) e^{-R_{sp}t/x_o}\right] \quad [8]$$

where x_i is the oxide thickness at time $t = 0$. This equation has a transient time constant x_o/R_{sp} and a steady-state limit given by

$$\lim_{t\to\infty} x = x_o \ln(K/R_{sp}) \quad [9]$$

The steady-state limit can also be obtained by setting $dx/dt = 0$ in Eq. [7]. Note that this theory predicts that a finite thickness of oxide is present on the target only if $K > R_{sp}$, and that the time constant for transient oxidation is x_o/R_{sp}.

In a more recent model, Heller presented an analysis of the results of his work on reactively sputtering metals in oxidizing atmospheres (20). Heller found the existence of a critical oxygen partial pressure in the plasma, p_{O_2}*, below which no oxidation of the target takes place. For $p_{O_2} < p_{O_2}$*, the sputter rate exceeded the oxidation rate and no oxide layer formed on the target. For $p_{O_2} > p_{O_2}$*, an oxide layer of finite thickness formed. These experimental results are not inconsistent with Greiner's study in that Greiner never explored the range of p_{O_2} values below which no oxide formed.

Heller improved Greiner's assumption concerning R_{ox} and R_{sp} by introducing the following oxidation equation. He defined

$$R_{ox} = \frac{A(P)}{\rho} e^{-x/x_o} \quad [10]$$

where the parameter $A(P)$ is a pressure-dependent function and ρ is the density of the sputtered target phase. The target oxide density will vary with composition from 4.5 g/cm^3 for Ti to 4.26 g/cm^3 for TiO_2. Heller assumes that R_{sp} is a monotonically decreasing function which yields the correct sputtering rates at $x = 0$ and $x \to \infty$, i.e.

$$\left(\frac{dx}{dt}\right)_{sp} = R_{sp} = R_{sp,o} + (R_{sp,m} - R_{sp,o})e^{-x/x_o} \quad [11]$$

where $R_{sp,o}$ and $R_{sp,m}$ are the sputtering rates of target oxide and metallic Ti, respectively. This model was tested in a second paper by Greiner who obtained sufficient data to determine the unknown parameters of the model (21).

Notwithstanding the previous efforts to arrive at a quantitative analysis of the oxidation phenomenon, Leslie and Knorr have concluded, from their investigation of the plasma oxidation of tantalum, that the complex interrelation of system parameters and the present dearth of experimental work prohibit the formulation of any complete model (22).

Experimental

Sputtering apparatus.—The experimental equipment consisted of modular diode-sputtering system together with a 1 kW rf power supply. The sputtering system was attached to a vacuum system consisting of an NRC series VHS, 6 in. (15.2 cm) diffusion pump with a pumping speed of 2400 liter-air/sec, a Welch liquid nitrogen cold trap, and a 7 liter-air/sec centrifugal roughing pump. This system, shown in Fig. 3, could achieve an ultimate pressure below 10^{-7} Torr[2] (1.3×10^{-5} Pa).

Chamber pressure was monitored simultaneously by a Pirani GP-310 gauge for pressures below 0.1 Torr and an Autovac Type 3294-B gauge for pressures in the range from 1 mTorr to 1000 Torr. The main purpose of

[2] 1 Torr = 133.3224 Pa.

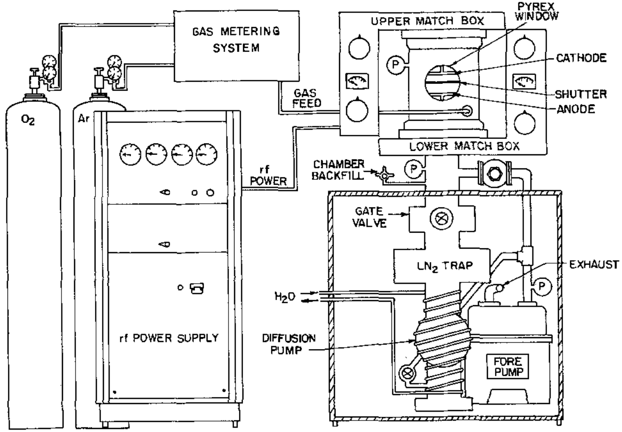

Fig. 3. RF sputtering system and ancillary apparatus

the dual meter system was to eliminate errors due to meter fluctuations after calibration.

The O_2 flow was controlled and monitored by means of a microflowmeter capable of measuring flow rates between 0.2 and 15 ml/min. The oxygen was mixed with Ti-getter purified argon stream and passed through a Hastings-Raydist mass flowmeter, where the total gas flow, and, by difference, the argon flow rate were measured.

The maximum volumetric gas flow through the chamber was determined by the limitations of the diffusion pump. The maximum foreline pressure was chosen as a conservative 200 mTorr. At this pressure, the argon flow rate reached an upper limit of 150 ml/min. Since the microflowmeter could resolve as low as 0.2 ml/min, the minimum measurable O_2 volume fraction attainable was 0.0013. The volume fraction of O_2 is identical to the mole fraction at the low chamber pressures involved (25 mTorr).

A calculation of the amount of O_2 removed from the plasma during the deposition of stoichiometric TiO_2 film indicates that negligible oxygen partial pressure change occurs by the deposition reaction. Only 1.3% of the total gaseous O_2 would be entrained at an oxygen plasma mole fraction of 0.007 provided that the maximum gas flow rate is maintained.

Materials.—Titanium targets 6 in. (15.2 cm) in diameter were fashioned from 0.032 in. (0.081 cm) thick sheet metal.[3] The purity was assayed at 99.9% and the results of a spectrographic analysis indicated that iron was the only significant impurity (0.1%). Several targets were used to ensure oxide-free surfaces for each phase of the research. The anode was covered with a Ti disk to minimize film impurities due to backsputtering.

Three different substrates were used: microscope slides for thickness measurements, microscope cover slides for weight change measurements, and type 10 quartz plate for electron diffraction, optical, and electrical measurements. The quartz plates were precut into 1.3 $\times$ 1.3 cm squares for electron microscopy and spectrophotometric analyses. High optical quality substrates were essential in order to obtain reliable u.v. spectra.

Procedure.—Sputtering was performed in the range of oxygen mole fraction y ranging from 0 to 0.15. Titanium was sputtered in pure Ar ($y = 0$) as a standard for comparison in assessing the effects of O_2 on sputtering parameters. A minimum deposition time of 30 min was chosen for this series to generate films sufficiently thick for characterization purposes.

A sputtering pressure of 24 mTorr, determined by mean free path considerations, produced the optimum initial power match. Forward and reflected power settings were normally 500 and 90W, respectively, delivering a d-c bias voltage of about 1.9 kV. These values were not constant throughout a run, however, and provided an early indication of change in the target surface state, which was subsequently interpreted as oxidation. The chamber pressure remained constant during all experiments.

Following reactive sputtering, substrate specimens were examined by reflection electron microscopy to determine their structure. Spectral absorbance of the samples was measured in the ultraviolet, visible, and infrared regions of the optical spectrum. The u.v. and visible absorbances were obtained on a Cary Model 118 spectrophotometer, while the Perkin-Elmer Model 421 spectrophotometer was used for the infrared spectra. A four-point conductivity apoaratus was constructed to measure the conductivity of metallic and semimetallic films.

The target oxidation phenomenon was studied by the following procedure. The target was first sputter etched of all surface oxide in Ar. Then O_2 and Ar were simultaneously admitted at a given oxygen mole fraction y for a measured time interval. The O_2 flow was then shut off and the target again sputter etched in Ar. The etch time was recorded.

Possible contamination of the system by atmospheric oxygen was minimized by completely evacuating the system for 30 min before each run. After each opening of the system to air, a complete sputter cleaning was required before a new run was possible. A minimum of 10 min was necessary to remove the chemisorbed oxide layer which formed on the target surface. The *in situ* determination of the target oxidation state was made from measurements of reflected power bias potential and plasma color.

Results

The titanium oxide films deposited under various conditions were characterized to determine the effects of reactive sputtering variables on the physical, optical, and electrical properties of deposited films and to determine reactive sputtering rate kinetics.

Deposition rates.—A significant transition in density and deposition rate was observed at an oxygen mole fraction $y^* = 0.007$, as shown in Fig. 4. Deposition rates and film densities were independent of y for $y > y^*$. Deposition rate data showed a sharp decrease by an order of magnitude as y increased above y^*, as shown in Fig. 4. The significance of these results becomes apparent when one contemplates the conditions needed to deposit films of constant and reproducible properties. For $y > y^*$, the data indicate film properties are invariant with y, which allows for easy control of film parameters, particularly in large volume commercial applications. However, the low deposition rate for $y > y^*$ represents a drawback for operations requiring rapid processing rates.

Physical properties.—Films were found to etch rapidly in concentrated HNO_3. The rapid etching characteristics of reactively sputtered TiO_x films with $x < 2$ suggest that the films are amorphous. This assumption was borne out by electron microscopy studies, using a Hitachi HU-125 operated at 100 keV. Figure 5 shows the radial dependence of the photodensity of a typical film which demonstrates the amorphous structure of the films. The Au coating was applied by evaporation on the films to prevent electrostatic charging, but too thick a layer interfered with the reflection pattern. The photodensitometric effect of the 50Å Au film was subtracted from the composite pattern to yield the TiO_x diffraction pattern alone.

The density of reactively sputter-deposited films was determined from weight change and thickness measurements. The results are shown in Table I. A significant increase in film density occurred for y near y^*. All

films deposited at $y > 0.035$ showed essentially no absorption in the visible range, and were in fact transparent to the eye. Films deposited at very low y (≤ 0.002) were metallic and showed some visible absorbance while films deposited at $y = 0.02$ possessed a slight gold tint. From optical data it was inferred that the yellow-gold colored samples were TiO.

Table I. Reactively sputter-deposited titanium oxide film densities

Film phase	Plasma composition	ρ(g/cm³)
Ti	$y = 0$	2.05
TiO	$y \lesssim y^*$	~5
TiO_x ($x \sim 2$)	$y >> y^*$	3.9

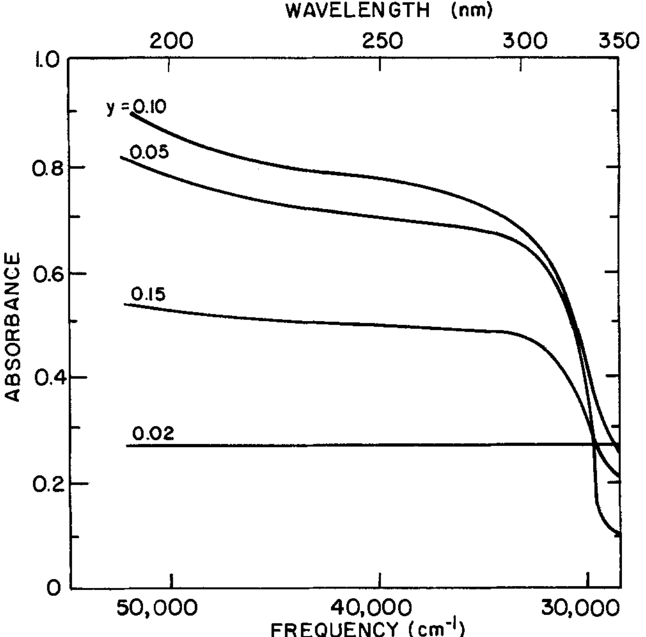

Fig. 6. U.V. spectrograph of TiO_x thin films deposited at several oxygen plasma conditions.

The u.v. spectra of deposited films show an absorption edge at about 330 nm. These spectra are shown in Fig. 6 and correspond to a bandgap of 3.76 eV for TiO_2.

Target oxidation-etch rates.—Target oxidation at different oxygen partial pressures was studied by exposing the target to the reactive gas mixture for a fixed time, then measuring the etching time to remove the oxide. The experimentally measured oxidation and etch times are shown in Table II.

Discussion

The phase diagram for the Ti-O system shown in Fig. 1 indicates that the anatase phase of TiO_2 would be expected for low temperature deposition. Presumably the amorphous phase persists because of the high impact energy of the depositing atoms, which destroys any crystalline lattice which would otherwise form. A heat transfer calculation showed that the substrate surface temperature was 20.3°C. In order to deposit a crystalline phase, it will be necessary to provide an external heating source capable of maintaining the substrate several hundred degrees above its unheated tem-

perature. This will provide sufficient kinetic energy to the already deposited material for annealing.

Flm physical properties exhibited a strong dependence on the state of target oxidation. In particular, film density followed the trend shown by the deposition rate with increasing y. An obvious transition at y^* was again found, with film density remaining constant for y above this value. The invariance of both deposition rate and density for y above y^* can be taken as an indication that film stoichiometry no longer changes, and that the target oxide here in fact is stoichiometric TiO_2.

Lakshmanan reports spectra for TiO_2 reactively deposited in pure O_2 remarkably similar both in shape and value to that shown in Fig. 6. The bandgap energy of 3.65 eV which he reports agrees quite closely with the value of 3.76 eV obtained in this study for amorphous TiO_2 (23).

The spectrum for the sample deposited at $y = 0.02$ shows low absorption throughout the u.v. range, probably for TiO. The films deposited at 0.05, 0.10, and 0.15 mole fraction of O_2 in the plasma all absorb strongly below 300 nm and are probably amorphous Magneli phases. The species deposited at $y = 0.15$ represents an anomaly in that it absorbs less below 330 nm than the oxide films formed with lower y.

The films deposited with $y = 0.035$ were found to give less u.v. absorbance than did films deposited at $y = 0.05$ or 0.10. Because no target etching was performed before each successive deposition of these samples, the oxidation state of the target should have affected the amount of oxygen incorporated into successively deposited films. This hysteresis effect is evident in experimental data.

The effects of exposing a clean titanium target to an oxidizing plasma were studied as a function of exposure time and oxygen concentration. The steady-state target oxide thickness was formed by oxidation in an Ar/O_2 plasma for a time sufficiently long to achieve steady state. The dependence of the steady-state oxide thickness developed on the target at different oxygen molar concentrations in the plasma was measured indirectly by the time required to etch the target clean of oxide in an Ar plasma. Figure 7 shows the dependence of the etch time on the plasma oxygen mole fraction. In this figure, the end of the etching period was determined from the color change of the plasma. The etch times shown are the average of several experiments for each value of y. Since the Ar-plasma etch time is the product of sputter yield times the oxide thickness, the proportionality between oxide thickness and etch time holds only if the oxide properties are independent of y. It is possible that the sputter yield for films deposited for $0.01 < y < 0.02$ is lower than for $y > 0.02$ to give the peak observed in Fig. 7. A low sputter yield is expected for the highly stable phases Ti_2O_3 and Ti_3O_4.

Figure 7 shows that no oxide formed on the target for $y < y^* = 0.007$. There was an increase in etch time at y^*, then a drop and a gradual rise with increasing y. The initial increase can be attributed to the formation of a highly stable phase such as Ti_2O_3 or Ti_3O_4 on the target surface. The dashed line tangent to the curve for $y > 0.03$ delineates the approximate increase in O_2^+ ions resulting from a rise in y and indicates that target oxide thickness is proportional to y in that range. This result is somewhat in contradiction to models for the reactive sputter-oxidation process which predicts that the oxide thickness is proportional to ln (KR_{sp}^{-1}), unless different phases form on the target, each with different values of K and R_{sp}.

The dependence of the deposition rate on y was found to exhibit an order-of-magnitude decrease if the deposition rate occurs near y^*. Part of the rise in target oxide etch time depicted in Fig. 7 is probably due to an increasing oxygen incorporation in the deposited film provided by O_2 in the plasma, and, to a lesser extent, to an increasing sputter etch rate due to O_2^+ ions superimposed on a constant Ar sputter etch rate. The nonreactive Ti sputtering rate of 5.6 Å/sec is an order of magnitude higher than the extrapolated sputtering rate of 0.48 obtained for $y >> y^*$, indicating that titanium metal has a much higher sputter yield than does TiO_2. This disparity is larger than would be expected if the sputtering process removed individual atoms from the target, since the Ti-Ti bond energy is 112.6 kcal/mole compared to a Ti-O bond energy of 157 kcal/mole (24) and since the sputter yield should vary with the square root of the atom binding energy. Thus, molecular groups such as TiO and TiO_2 are probably removed from the target during reactive sputtering at high values of y_{O_2}.

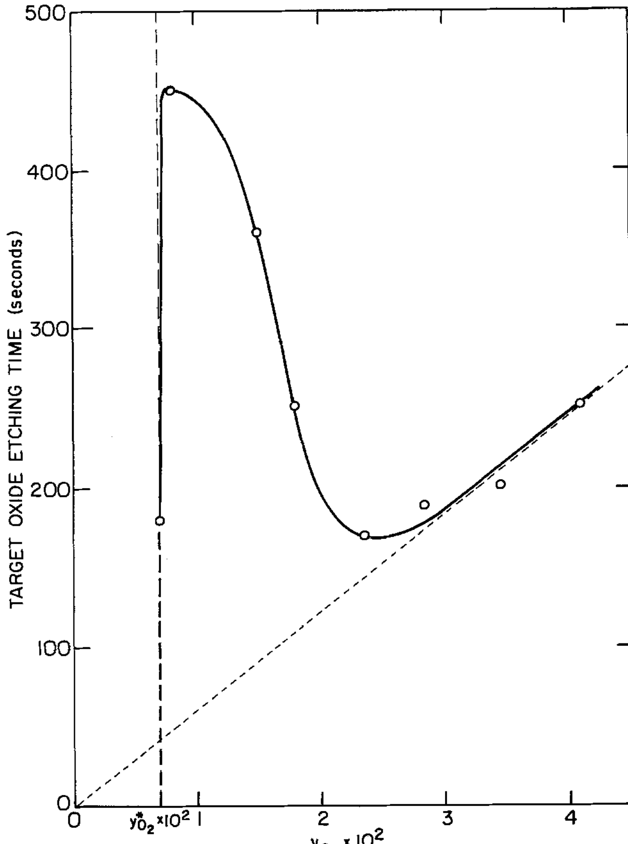

Fig. 7. Target etch time following target oxidation as a function of y_{O_2}.

The transient growth of oxide on the Ti target in an Ar/O_2 plasma for which $y_{O_2} = 0.014 = 2y^*$ was also studied by measurement of Ar plasma sputter etching times needed to remove the oxide films. Again, the oxide thickness was assumed proportional to the Ar plasma etch time provided that the sputter yield of the oxide is independent of oxide thickness. The oxide thickness increased monotonically with time. If the steady-state oxide thickness corresponds to a target oxide sputter etch time of 400 sec, then the time constant for transient oxidation can be found by comparing the data with Eq. [4] and [8]. The experimental data were found not to show a parabolic oxidation rate as would be required by diffusion-controlled kinetics. On the other hand, the time constant for the exponential time dependence of the reactive sputter-oxidation model, Eq. [8], was found to be (20)

$$KR_{sp}^{-1} = 67 \pm 11$$

Since the oxide sputtering rate at a bias voltage of 1.9 kV was independently measured experimentally to be 0.48 Å/sec, the apparent oxidation constant for the anodic oxidation theory was $x_o = 32$Å. This data is in

qualitative agreement with the reactive sputter-oxidation model, with significant deviations at short sputter-oxidation times.

Conclusion

This study of the reactive sputter deposition rates of titanium oxides showed that amorphous films were deposited at room temperature over the entire range of oxygen mole fractions studied. Deposited films were generally metallic αTi for oxygen mole fractions $y < 0.002$, and dielectric TiO_2 for $y > 0.035$. A sharp transition in deposition rate took place at $y^* = 0.007$, where TiO is deposited, and corresponded to the onset of oxidation of the titanium target.

Models describing the target oxidation phenomenon were tested against experimental data. The dependence of the target oxidation rate on oxygen mole fraction indicated that the target oxidation process is influenced by oxygen-atom incorporation in the target and by sputter etching of the target oxide by oxygen ions. The time dependence of the target oxidation process cannot be described by a parabolic time dependence. The reactive sputter-oxidation model is in qualitative agreement with the experimental data.

On the Behavior of Mobile Ions in Dielectric Layers of MOS Structures

W. Marciniak and H. M. Przewlocki

Nauk. Prod. Centrum Polprzewodnikow, 02-675 Warszawa, Komarowa 5, Poland

ABSTRACT

Equilibrium and nonequilibrium behavior of mobile charges in dielectric layers of MOS structures have been investigated. A variety of MOS structures has been studied using the TVS method, and a newly developed technique of quasi-continuous registration of the C-V characteristic shifts (ACVS method). Basic models are considered, and an image force trapping model is proposed to interpret the measurement results.

The existence of mobile charges in dielectric layers of MOS structures may cause instability of MOS device parameters. Due to this fact, the behavior of mobile ions in thermally grown SiO_2 layers on Si substrates has been extensively studied in recent years. A concise summary of current understanding of the nature and properties of these and other charges in the thermally oxidized silicon structures has been given by Deal (1). Some of the properties of mobile charges in SiO_2 layers have been explained already, while other properties are not fully understood. It was, for example, demonstrated experimentally that mobile ions have a tendency to accumulate in the neighborhood of the electrodes (metal or silicon) rather than in the bulk of the SiO_2 layer. It was also observed that the activation energy for ion motion in SiO_2 from the metal to the silicon electrode is higher than for the motion in the opposite direction. These properties of mobile charges in SiO_2, have not been fully explained as yet.

In the present work, equilibrium and nonequilibrium behavior of mobile ions has been studied experimentally. Several models have been considered which may explain the observed phenomena. Triangular voltage sweep (TVS) method has been used in experimental studies of equilibrium behavior of mobile ions, while a newly developed method of automatic registration

Key words: MOS instabilities, ion transport, dielectrics.

of C-V characteristics shifts (ACVS) has been used for nonequilibrium measurements. A variety of MOS capacitors was measured, with both n- and p-type silicon substrates of various resistivities and with different metal electrode materials. Based on the models considered, certain characteristics of MOS structures have been calculated and compared with the experimentally observed ones. Conclusions are drawn as to the validity of these models.

Experimental Procedure

Sample preparation.—Metal-SiO_2-Si capacitors were prepared on 250 μm thick, <111> oriented silicon substrates with chemically-mechanically polished surfaces. Silicon wafers were oxidized in dry oxygen at 1200°C to obtain the 1300Å thick SiO_2 layer. Metal electrodes, 800 μm in diameter and 0.3 μm thick, were evaporated on the SiO_2 layer through mask holes. A variety of samples was prepared with n- and p-type silicon substrates of different resistivities, and with different metal electrode materials such as Al, Au, Cr, Mn, W, Ti, Pt, which were evaporated using either the tungsten filament source, or the E-gun heated source.

Measurement methods.—Properties of mobile ions were investigated using two principal methods: the triangular voltage sweep (TVS) method, and the automatic registration of the C-V curve shifts (ACVS) method.

(*i*) *The TVS method.*—Theoretical foundations of this method were given by Chou (2) and were modified and extended to a more general form by the authors of this work (3). The experimental setup for TVS measurements was similar to the ones described in Ref. (2) and (4). Triangular wave function generator was used to provide sweep rates in the range of from 2 mV/sec to 2 V/sec. The shielded probe set contained six movable probes and a resistance-heated pedestal, which allowed measurements in the temperature range of up to 500°C. MOS capacitors were measured at different temperatures and with different sweep rates. It was demonstrated that at a temperature $T = 250°C$ the normalized TVS current-voltage characteristic, $I_G/\delta = f(V_G)$, does not depend on the sweep rate δ, if $\delta \leq 5$ mV/sec, which means that quasi-equilibrium conditions (2) are fulfilled for $\delta \leq 5$ mV/sec at $T \geq 250°C$ (see Fig. 4). It was also shown that with very few exceptions the electrodes are blocking up to the temperature of about 300°C. At higher temperatures, double-peaked TVS curves were usually obtained, indicating the onset of electrode reactions (2) (see Fig. 3). The voltage ramp amplitude of $\pm$ 3.5V was found sufficient to obtain meaningful results (*i.e.*, application of higher ramp amplitudes did not result in any changes of shapes and heights of the TVS current peak). Densities of mobile charges Q_j (in C/cm²) were calculated by finding the area under the reduced TVS current peak (2), and by measuring the reduced TVS current peak height (3). The agreement between the results obtained was used as a self-consistency criterion for the proper choice of measurement conditions.

(*ii*) *The ACVS method.*—The principal method widely used to investigate redistribution of mobile charges in the dielectric layer was based on measurement of high frequency CV characteristic shifts under bias-temperature (BT) stresses. Usually point-by-point measurements were made subsequent to cycles of heating and cooling the MOS structure under test. In this work, a new method was developed which allows quasi-continuous automatic registration of the C-V characteristic shifts. This method makes use of the pulsed MOS capacitor deep-depletion characteristics, which are just as sensitive to changes in flatband voltage (ΔV_{FB}) as the high frequency C-V characteristics, and are easily measured at elevated temperatures. As in the case of the classic high frequency C-V method, ΔV_{FB} can be detected as changes in the gate voltage value, V_1, which corresponds with a given value of capacitance, C_1, in a deep-depletion C-V characteristic.

The ACVS apparatus, shown schematically in Fig. 1, was used for automatic registration of the flatband voltage changes obtained at different BT stresses. The ACVS apparatus works as follows. Short triangular voltage pulses are applied to the MOS capacitor gate, giving rise to currents in the R resistor, which are proportional to momentary values of the MOS capacitor differential capacitance C. The duration of the voltage pulses is adjustable in the range from 10 μsec to 1 msec. The time dependence of the voltage drop in the R resistor, $V_R(t)$, corresponds in this case with the deep-depletion type C-V characteristic of the MOS capacitor under test. Such characteristics are shown schematically in the insert of Fig. 1. The $V_R(t)$ signal is amplified and compared with a preset reference voltage, V_1, which is so chosen as to correspond with a certain value, C_1, of the capacitance. A pulse sent from the comparator causes the $V(t)$ voltage value which corresponds with C_1 capacitance to be applied into a sample-and-hold circuit, and recorded continuously by a X-Y recorder. The horizontal input of the X-Y recorder is driven by a signal which sets the time scale or is proportional to the temperature applied. This way, $\Delta V_{FB}(t)$ or $\Delta V_{FB}(T)$ curves are automatically recorded. Triangular voltage pulses are superimposed at the output of the generator on a biasing voltage, which can be set in the range from -10 to $+10$V. This voltage forces redistribution of charges in the dielectric. The triangular pulses are applied to the gate of the MOS capacitor in the from-accumulation-to-depletion direction. Measurements made with the pulses applied periodically, with periods ranging from 2 to 120 sec, pulse amplitudes in the range from 5 to 100V, and pulse duration in the range from 20 μsec to 1 msec, have shown that these pulses do not affect the drift behavior (due to their short duration and low repetition rate). In cases of very short V_{FB} relaxation times ($\tau < 10$ sec), measurements were made using the method of ionic polarization current integration (5).

Results and Discussion

Results of TVS measurements.—All the MOS capacitors measured in the course of this work exhibited asymmetric TVS characteristics, which remains in agreement with previously published results for Al-SiO_2-Si and Au-SiO_2-Si structures (6), Cr-SiO_2-Si structures (4, 7, 8), and Pt-SiO_2-Si structures (2). The shape of the TVS current-voltage characteristic obtained for the from-positive-to-negative voltage sweep remains in agreement with the curve calculated using formulae derived in Ref. (3). The reduced TVS current peak obtained for the from-negative-to-positive voltage sweep is much wider, and not so well defined, as shown in Fig. 2. The areas under TVS current peaks

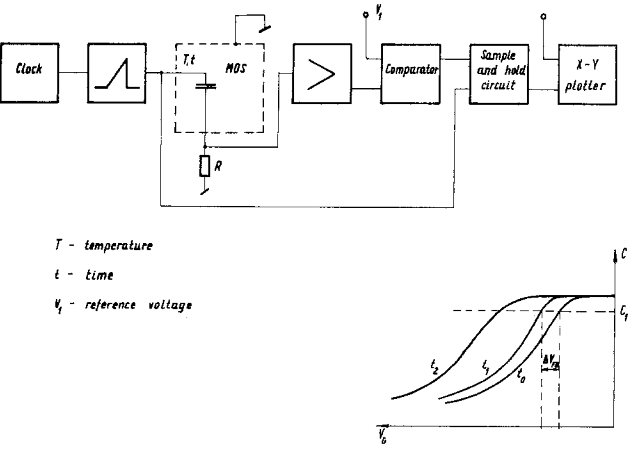

Fig. 1. Schematic diagram of the ACVS apparatus, and illustration of the drift of C-V deep-depletion characteristics (insert).

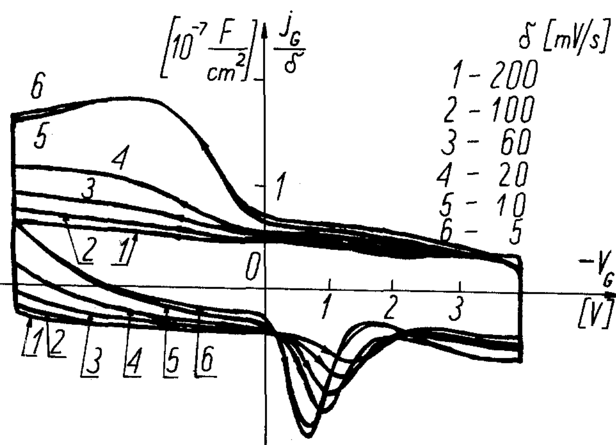

Fig. 2. The reduced TVS current vs. voltage curves of a Al-SiO_2-Si structure for $T = 250°C$ and various sweep rates.

for negative-to-positive and positive-to-negative voltage sweeps are close to each other, while the peak heights differ significantly. This property of TVS characteristics suggests that the same amount of mobile charge is transported in both directions through the dielectric layer, but the ions are trapped in deep traps at the metal-dielectric interface. Due to this fact, quasi-static condition is usually not fulfilled for the transport of ions from the metal to the silicon electrode, and the shape of the reduced TVS current peak for negative-to-positive voltage sweep is primarily determined by the properties of the metal-dielectric interface. For higher temperatures at which the electrodes are not ideally blocking any more, additional extrema (M_F) appear in the TVS current-voltage characteristics, as shown in Fig. 3.

Results of our measurements of different MOS capacitors are summarized in Fig. 4. It can be seen in Fig. 4 that for all measured MOS capacitors, a "saturation" of Q_j and V_{Gmax} values is practically obtained for $250°C < T < 300°C$, and $\delta = 5$ mV/sec (V_{Gmax} is voltage corresponding with TVS current peak). This fact proves that quasi-equilibrium is maintained and that the electrodes are blocking in this temperature range, resulting in a constant value of Q_j as assumed in derivation of basic relations for the TVS method (2, 3).

Measurements of MOS capacitors built on p- and n-type silicon substrates of different resistivities have shown that the V_{Gmax} value changes with the resistivity of the substrate as predicted by the theory presented in Ref. (3). The agreement between theory and experiment is very good for Au-SiO_2-Si capacitors, and slightly worse for Al-SiO_2-Si capacitors, as shown in Fig. 5. The additional displacement of the TVS current peak along the voltage axis $\Delta V_{Gmax} = 0.2$-0.4V which is observed in the case of Al-SiO_2-Si capacitors is probably due to the existence of a negative immobile charge in the SiO_2 layer.

Results of ACVS measurements.—Metal-SiO_2-Si capacitors with Al, Au, Pt, and Ti metal electrodes were measured using the ACVS method described above. The range of temperatures used was from 70° to 200°C and the range of voltages applied to force the drift of mobile charges in the dielectric was from −6 to +6V. Changes of the flatband voltage ΔV_{FB} and the biasing voltage V_B were of opposite signs (with the exceptions mentioned below). Time constants of drifts observed in the case of a positive voltage on the

metal electrode (positive BT stress) were one or two orders of magnitude higher than the time constants of drifts observed for opposite polarity (negative BT stresses). Typical drift $\Delta V_{FB}(t)$ characteristics observed in the case of a positive BT stress are shown in Fig. 6. Drift characteristics of Al-SiO_2-Si capacitors remain in good agreement with previously published data (11), *i.e.*, for small values of *t*, are quite well described by a simple formula: $\Delta V_{FB} = k\sqrt{t}$, where *k* is a constant. For Pt-SiO_2-Si capacitors a nearly linear dependence of ΔV_{FB} on *t* was observed for small values of *t*. The Au-SiO_2-Si capacitor $\Delta V_{FB}(t)$ curves are often characterized by two values of time constants. The relaxation process is initially very fast, but becomes much slower later (see Fig. 6). The time constant of the initial (fast) relaxation process is comparable with the time constant of the drift observed for negative BT stresses. The $\Delta V_{FB}(t)$ characteristic of a Ti-SiO_2-Si capacitor differs significantly from analogous characteristics of MOS capacitors with electrodes made of other metals, and is included in Fig. 6 to demonstrate the possibilities offered by the ACVS method. The shape of this curve is due to the simultaneous action of ionic and trap instabilities, which tend to change the flatband voltage in opposite directions. Based on the temperature dependence of the above-mentioned time constants, activation energies of the relaxation processes were found for both positive and negative BT stresses. The activation energy, W_A, for positive BT stress conditions is 1.05 eV $\leq W_A \leq$ 1.48 eV, and for negative BT stresses is 0.6 eV $\leq W_A \leq$ 0.8 eV. Assuming that for positive BT stresses ions are emitted from Frenkel-Pool type trapping centers at the metal-SiO_2 interface, the trap potential well width may be found from the dependence of time constants on the value of biasing voltage (12). It was found that the trap potential well width, *d*, is 20Å $\leq d \leq$ 100Å.

The theory of redistribution of mobile ions in the dielectric of a MOS capacitor, which is caused by a voltage step, was developed in Ref. (11) and (12). In Ref. (11) a simplified model was considered in which redistribution of ions was diffusion limited. This diffusion was assumed to take place from a thin layer at the electrode-SiO_2 interface in which the ions were present in high concentration. This led to a classic formulation and solution of a diffusion problem. In Ref. (12) it was assumed that ions are trapped at the electrode-SiO_2 interface and ion emission from traps was considered the rate-limiting factor.

In this work two models were considered in detail (see Appendix). In the first case it was assumed that redistribution of ions is a bulk-limited process. Transport equation was solved numerically in this case, taking into account the existence of diffusion and drift components as well as built-in (Poisson-type) electric fields and various distributions of immobile charges in the dielectric. In the second case, it was assumed that the only mechanism that determines the rate of the relaxation process is the emission of ions from traps located at the electrode-dielectric interface. Calculations of $\Delta F_{FB}(t)$ characteristics were made, based on these two models, and the results of these calculations are compared in Fig. 7 with a typical experimental curve obtained for Al-SiO_2-Si capacitors. The best agreement is obtained if ion trapping at the electrode-SiO_2 interface is assumed to be the rate-limiting factor. Higher values of activation energies obtained for redistribution processes occurring during positive BT stresses indicate the presence of deep ion traps at the metal-SiO_2 interface The lower values of activation energies for relaxation processes occurring at negative BT stresses may be due either to the temperature dependence of ion mobility (bulk-limited process) or to the existence of shallow ion traps at the SiO_2-Si interface (surface-limited process).

In the first case one would expect a nearly linear $\Delta V_{FB}(t)$ dependence for small values of *t*, while in the second case a parabolic $\Delta V_{FB}(t)$ curve would be expected (similarly as in the case of positive BT stress, illustrated in Fig. 7). Comparison of experimentally observed $\Delta V_{FB}(t)$ characteristics, obtained at negative BT stresses with the curves calculated using both models described above, suggests that ion trapping at the Si-SiO_2 interface is more likely to be the rate-limiting factor.

Different values of activation energies obtained for drifts observed at positive and negative BT stresses may be due to different depths of potential wells created by the interaction of mobile ions with their image charges induced in the electrodes. Rough estimation of these potential wells (see Appendix), yields 0.94 eV for the metal-SiO_2 interface and 0.47 eV for the Si-SiO_2 interface. The lower limit of the activation energy found experimentally for drifts at negative BT stresses (0.6 eV) does not differ significantly from the depth of the image force potential well at the Si-SiO_2 interface (0.47 eV). This indicates the importance of image forces in the effect of ion trapping at the Si-SiO_2 interface.

The image force model alone is not sufficient, however, to explain the drift behavior of mobile ions at positive BT stresses. The experimental values of acti-

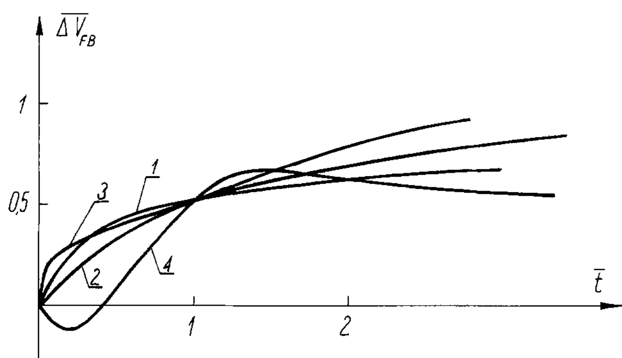

Fig. 6. Typical $\overline{\Delta V_{FB}(t)}$ drift characteristics for various MOS structures at positive BT stress. 1. Al-SiO_2-Si structure, 2. Pt-SiO_2-Si structure, 3. Au-SiO_2-Si structure, 4. Ti-SiO_2-Si structure. $\overline{\Delta V_{FB}} = \Delta V_{FB}/\Delta V_{FB}(sat)$, $\bar{t}$ = normalized time, $\bar{t} = 1$ for $\overline{\Delta V_{FB}} = 0.5$.

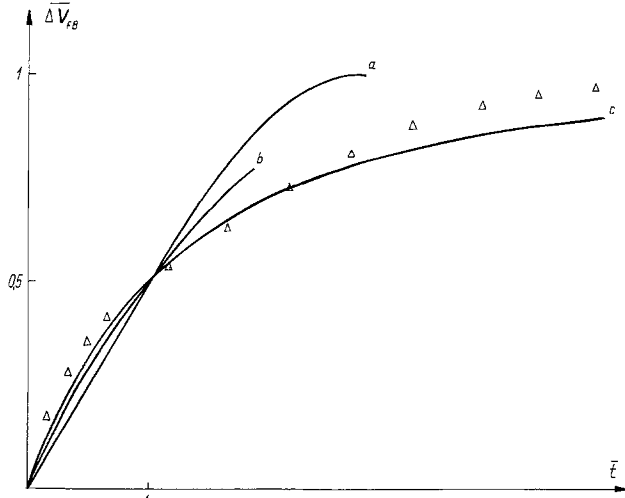

Fig. 7. Typical experimental $\overline{\Delta V_{FB}(t)}$ drift characteristic at positive BT stress for a Al-SiO_2-Si structure (triangles) and curves calculated (solid lines) using three models: (a) the model in which diffusion and drift are taken into account, but the built-in field is assumed to be negligible, (b) the model in which drift, diffusion, and the built-in field are taken into account, (c) the model in which only emission of ions from traps at the electrode-SiO_2 interface is taken into account.

vation energies, the spread of these values, and a significant width of the potential well obtained indicate that besides the effect of image forces, another mechanism of ion trapping exists at the metal-SiO_2 interface. It is assumed in this work that this "additional" trapping mechanism is due to the presence of a thin layer of immobile negative charges in the dielectric, next to the metal-SiO_2 interface. Calculations have shown (see Appendix) that parabolic $\Delta V_{FB}(t)$ curves, similar to the ones observed experimentally, are obtained if the presence of immobile negative charges at the metal-SiO_2 interface is assumed. Apart from the physical origin of the traps existing at the electrode-SiO_2 interfaces, excellent agreement between experimental and calculated $\Delta V_{FB}(t)$ curves may be obtained for Al-SiO_2-Si and Pt-SiO_2-Si capacitors if adequate energy spectrum of traps is assumed. The "fast' and "slow" components of the drift observed in the case of Au-SiO_2-Si structures may be due to the fact that only a part of the mobile ions is trapped at the interface. This may be caused by the presence of traps in a layer of SiO_2 (next to the metal-SiO_2 interface) which is thin in comparison with the width of the mobile ion distribution. Part of the mobile charge which is not trapped is responsible in this case for the "fast" component of the relaxation process, while ions emitted from traps are responsible for the "slow" component.

Conclusions

Equilibrium and nonequilibrium properties of mobile charges in dielectric layers of MOS structures were studied experimentally. Basic models were proposed and discussed, allowing interpretation of measurement results. The main results of this work may be summarized as follows.

1. A wide variety of MOS structures was studied using the TVS method. It was shown that in most cases the TVS method yields meaningful results when applied in the temperature range of $T = 250°\text{-}300°C$, with the voltage ramp speed of $\delta \leq 5$ mV/sec.
2. A new technique of quasi-continuous registration of the flatband voltage shift was developed (ACVS method) and proved to be useful in studies of nonequilibrium behavior of mobile ions.
3. Numerous MOS structures were measured using the ACVS method. The asymmetric properties of ion transport in MOS structures were always observed. It was also observed that the shape of the $\Delta V_{FB}(t)$ curve depends on the material of the metal electrode.
4. Models were considered for nonequilibrium behavior of mobile ions, and calculations were made for the model in which V_{FB} relaxation processes are bulk limited and for the model in which electrode-SiO_2 interface properties determine the V_{FB} relaxation process.
5. By comparing the experimentally observed $\Delta V_{FB}(t)$ curves with the curves calculated using the above-mentioned models, it was found that best agreement is obtained if trapping of mobile ions at the metal-SiO_2 interface is assumed. It is postulated that this trapping is primarily due to image forces and to the negative charges that may be present in the neighborhood of the metal-SiO_2 interface.

Manuscript submitted Dec. 3, 1975; revised manuscript received April 7, 1976. This was Paper 139 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

APPENDIX

Two models of the dynamic behavior of mobile ions in the dielectric of a MOS capacitor are considered.

Model (a).—It is assumed that uncompensated positive mobile ions are present in the dielectric as well as negative immobile charges of various distributions. The redistribution of mobile ions is a bulk-limited phenomenon. With other assumptions being the same as in Ref. (10), this problem is represented for $0 \leq x \leq l$, and $t \geq 0$ by the following set of equations

$$\frac{\partial P(x,t)}{\partial t} = D\frac{\partial^2 P(x,t)}{\partial x^2} - \mu\frac{\partial}{\partial x}[E(x,t)P(x,t)] \quad \text{[A-1]}$$

$$j(x,t) = q\mu P(x,t)E(x,t) - qD\frac{\partial P(x,t)}{\partial x} \quad \text{[A-2]}$$

$$\frac{\partial E(x,t)}{\partial x} = \frac{q}{\epsilon_i}[P(x,t) - N(x)] \quad \text{[A-3]}$$

where j is the current density, $N(x)$ the concentration distribution of immobile negative charges, $P(x,t)$ the concentration of positive mobile charges, D the diffusion coefficient, μ the mobility, E the electric field, q the electron charge, and ϵ_i is the permittivity of the dielectric.

Based on the solution obtained for steady-state distributions (10), the initial condition (initial distribution) is assumed to be

$$P(x) = P(0)\exp\left(-\frac{x}{\lambda_p}\right) \quad \text{[A-4]}$$

for $t = 0$, where $P(0)$ is the value of P for $x = 0$, and λ_p is the parameter of the $P(x)$ distribution for $t = 0$.

Boundary conditions are given by the assumption of blocking electrodes

$$\left.\frac{\partial P(x,t)}{\partial x}\right|_{x=0} = \frac{\mu}{D}E(x,t)\,P(x,t) \quad \text{[A-5]}$$

The biasing voltage is assumed to be

$$V_B(t) = \int_0^l E(x,t)\,dx \quad \text{[A-6]}$$

where the voltage drop in the semiconductor electrode was assumed to be negligible.

$$E(x,t) = E_B(t) - E(0,t) + \frac{q}{\epsilon_i}\int_0^x [P(x,t) - N(x)]\,dx \quad \text{[A-7]}$$

$$E(0,t) = \frac{Q_P}{\epsilon_i}[1 - X_{cl}^P(t)] - \frac{Q_N}{\epsilon_i}[1 - X_{cl}^N] \quad \text{[A-8]}$$

$$X_{cl}^P(t) = \frac{\int_0^l x\,P(x,t)\,dx}{\int_0^l P(x,t)\,dx} \quad \text{[A-9]}$$

$$X_{cl}^N = \frac{\int_0^l x\,N(x)\,dx}{\int_0^l N(x)\,dx} \quad \text{[A-10]}$$

where $E_B(t) = V_B(t)/l$, and Q_P and Q_N are the densities (per unit area) of positive mobile charges and negative immobile charges, respectively. The time dependence of the flatband voltage shift ΔV_{FB} is given by

$$\Delta V_{FB}(t) = \frac{Q_P}{C_i}X_{cl}^P(t) \quad \text{[A-11]}$$

Equations [A-1]-[A-11] were solved numerically using the sparse matrix method and implicit discretization schemes, similarly as was done in the solution of the problem of carrier transport in p-n junctions (14, 15). Calculations were made for different concentrations of both mobile and immobile charges, and different biasing voltages. Examples of the results obtained are illustrated in Fig. 8 which shows the time dependence of mobile charge distributions for a MOS structure without immobile negative charge (a), and for a MOS structure with immobile negative charges residing in a thin layer adjacent to the metal-SiO_2 in-

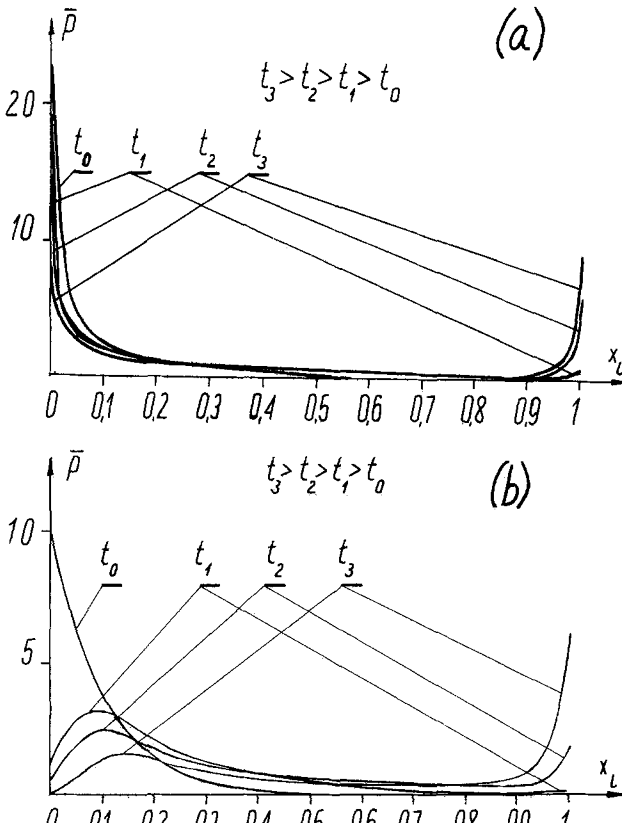

Fig. 8. Illustration of the time dependence of mobile charge distribution in SiO_2 layer of a MOS structure without immobile negative charges (a), and with immobile negative charges residing in a thin layer adjacent to the metal-SiO_2 interface (b). MOS structure with following parameters was considered: $Q_j = 10^{12}$ e/cm^2, $\epsilon_{ri} = 3.9$, $l = 10^{-5}$ cm, $T = 538$°K, $V_B = 4.6$V; in case (b) the immobile negative charge $Q_N = 10^{12}$ e/cm^2 is located at the metal-SiO_2 interface. $\bar{P}$ is normalized mobile charge concentration, $\bar{x}$ is normalized distance.

terface (b). The shape of the $\Delta V_{FB}(t)$ characteristic depends on the relation that exists between the externally applied field and the internal fields created by the space charge distributions. The $\Delta V_{FB}(t)$ curve becomes nearly a straight line for very strong externally applied fields ($E_B > Q_P/C_i l$), and becomes nearly a parabolic curve $\Delta V_{FB} = k\,t^{1/n}$ for relatively weaker externally applied fields ($E_B < Q_P/C_i l$).

Model (b).—It is assumed that the emission of ions from traps at the electrode-SiO_2 interfaces is the only mechanism that determines the $V_{FB}(t)$ relaxation process. In this case, the time constant of the ion emission process, τ_e, is higher than the transit time of the ions across the dielectric layer. For a discrete trap level one obtains (12)

$$\overline{\Delta V_{FB}(t)} = 1 - \exp(-t/\tau_e) \qquad \text{[A-12]}$$

where $\overline{\Delta V_{FB}(t)}$ is the normalized flatband voltage shift. For a gaussian distribution of traps and assuming that the emission of ions is governed by the Boltzmann statistic, one obtains (13)

$$\overline{\Delta V_{FB}(t)} = 1 - \frac{1}{\sigma\sqrt{2\pi}}\int_0^\infty \exp\left[-\frac{(W-W_o)^2}{2\sigma^2} - \frac{t}{\tau_e}\right] dW \qquad \text{[A-13]}$$

where σ is standard deviation, and τ_e is given by

$$\tau_e = \tau_e(W_o)\exp\left(\frac{W-W_o}{kT}\right) \qquad \text{[A-14]}$$

One of the possible causes of ion trapping at the electrode interfaces is the existence of image forces (16). Assuming that the electrode-SiO_2 interface is a plane, and considering potential energy of an ion in the electrostatic field of its image charge, the following relation was obtained (16)

$$W(x) = \frac{q^2}{16\pi\epsilon_{ri}\epsilon_o x}\left(\frac{\epsilon_{ri}-\epsilon_{re}}{\epsilon_{ri}+\epsilon_{re}}\right) \qquad \text{[A-15]}$$

where ϵ_{ri} and ϵ_{re} are relative permittivities of the dielectric and the electrode material, respectively ($\epsilon_{ri} = 3.9$ for SiO_2, $\epsilon_{re} = 11.8$ for Si electrode, and $\epsilon_{re} \to \infty$ for metal electrode), and x is the distance of the ion from the interface plane. Equation [A-15] reflects the difference in the potential barriers at metal-SiO_2 and SiO_2-Si interfaces, which is one of the causes of the asymmetry of ion transport properties in MOS structures. For example, for $x = 1$Å, which is considered to be the lowest distance of the ion from the interface plane for which Eq. [A-15] still holds (16), one obtains $W = 0.94$ eV for the metal-SiO_2 interface and $W = 0.47$ eV for the SiO_2-Si interface.

Galvanostatic Analysis of Polycrystalline Beta Alumina Resistivity

G. C. Farrington*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

Polycrystalline Na^+-beta alumina resistivity has been examined with a fast response d-c technique using galvanostatic square waves of 7×10^{-9} sec risetime. Intragrain and intergrain resistance and capacitance components can be separately distinguished in many samples by resistivity analysis over the *ca.* 50 MHz-10 kHz effective frequency range of this technique. Polycrystalline beta alumina appears to be an aggregate of essentially single crystal grains separated by grain boundaries of markedly lower conductivity. Intrinsic intergrain and intragrain resistivities are typically 10^7 and 68 ohm-cm, respectively, at 23°C. Large intragrain capacitance effects which jeopardize the usefulness of multifrequency or galvanostatic analysis for separating intragrain and intergrain resistivity components in practical beta alumina ceramics have been observed. These effects, modeled as intragrain capacitance, are more likely initial observations of localized Na^+ ion exchange among the three nonequivalent sites available for mobile ion occupation in the beta alumina conduction plane.

Na^+-beta alumina, a two-dimensional, solid ionic conductor into which a variety of monovalent cations including Ag^+, Tl^+, and K^+ (1) can be substituted, has a single crystal resistivity of 72 ohm-cm at 23°C (2), comparable to that of common nonaqueous organic electrolytes. For ease of fabrication, strength, and omnidirectional conductivity, it is generally used in practical devices as a dense, polycrystalline ceramic.

The bulk resistivity of polycrystalline beta alumina is typically 200-2000 ohm-cm at 23°C, more than that of single crystal material. It is divisible into intragrain and intergrain components. Intragrain resistivity is influenced by intrinsic grain composition and by the conduction path tortuosity, that is, the difference between the actual and apparent conduction path lengths between two points in a ceramic. The intergrain resistivity component varies widely and is highly dependent upon specific conditions of ceramic preparation and densification.

In optimizing ceramic processing, it is useful to separate total d-c resistivity of a specimen into its intragrain and intergrain components. Powers and Mitoff (3) have reported results of such an analysis of polycrystalline beta alumina resistivity obtained with a multifrequency, a-c technique. Their technique was useful in describing intergrain resistance and capacitance effects in a variety of beta alumina ceramics. But it was limited to a maximum frequency of 500 kHz which proved inadequate for characterizing many beta alumina specimens.

The present work was undertaken to examine the usefulness of a galvanostatic technique capable of examining the resistivity response of polycrystalline beta alumina over on effective frequency range of *ca.* 50 MHz-10 kHz. It was hoped with this simpler procedure to obtain intergrain resistance and capacitance data for a wider variety of beta alumina ceramics and describe intragrain ion transport at very short response times.

Experimental Technique

Galvanostatic pulse analysis was used in this study for its simplicity in gathering resistivity data over a broad effective frequency range. Pulse and a-c measurements yield equivalent data from which real and imaginary impedance components can be derived as functions of frequency. However, Fourier analysis is necessary to extract both of these components from pulse data. Fourier treatment has not been applied here.

Typical samples were tubes of fine-grained polycrystalline Na^+-beta alumina, approximately 1.1 cm OD, 1.0 cm ID, and 9 cm in length. Tubes were prepared from Alcoa 'XB-2' beta alumina powder. Additional components were Y_2O_3 (added as the oxalate), MgO (from the basic carbonate), and ZrO_2 (from grinding media wear). After mixing, the powder was calcined at 1400°C, suspended in amyl alcohol, and milled using zirconia grinding media. Tubes were formed by electrophoretic deposition and sintered in air at 1700°-1825°C.

The two specimens discussed in this paper, 6G3-2 and 6M2-2, differed only by 0.5% Y_2O_3 incorporated in 6G3-2 as a sintering aid. Both specimens had random grain orientation and were single phase beta alumina.

Each sample was contacted at four points along its longer axis with ring electrodes of vapor-deposited Ag. Ag was chosen for electrodes because it can be applied readily and is electrochemically oxidized to an ion mobile within beta alumina. Since a pulse measurement repetitively passes unidirectional current, in contrast to a-c analysis, depletion of oxidizable material at the positive electrode occurs, gradually increasing sample resistance. Although these measurements neglect interfacial polarization, too large a sample resistance degrades pulse risetime and limits the time range of analysis. It is important, therefore, that the positive contact electrode be amply supplied with ions capable of injection into beta alumina. Ag serves this function well.

Alternate contact electrodes include tight Pt wire loops wetted with a solution of $NaClO_4$ in propylene carbonate. The advantage of Pt loops is their ease of attachment and removal. After analysis, a methanol wash quickly removes residual propylene carbonate solution and restores the sample to its original condition. However, the boiling point of propylene carbonate (241°C) and comparable liquids restricts the temperature range of analysis.

To measure resistivity, a constant current square wave is applied to the outer two electrodes and the differential voltage response between the inner electrodes recorded.

Figure 1 shows a sample tube mounted for study. Pt loops contact the Ag electrodes and suspend the sample in a small oven (Fig. 2). Binding lugs are provided on

Fig. 2. Galvanostatic pulse generator and sample oven

the oven top for pulser and probe contact. The oven is warmed by heating tape and cooled by chilled dry N_2 for multitemperature experiments.

Figure 3 is a circuit diagram of the constant current pulse generator used for all experiments reported here. Figure 2 shows the complete pulser which has an output range of 40 μA-6.0 mA. The pulser was designed to minimize stray capacitance which would degrade output risetime. Output terminals protrude directly from the base of the pulser to minimize connecting lead lengths. Pulser output is off at a trigger input of ≤ -2V and switches on for a trigger transition to $\geq$0V.

The rising edge of a 100 μA current pulse into a 500 ohm resistor is shown in Fig. 4. Its risetime (t_r; 10-90%) of 7 $\times$ 10^{-9} sec is typical of the pulses used in this study. The rising edge shape follows an approximate RC response curve in which R is the total resistive

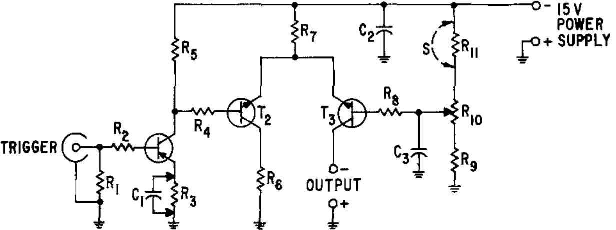

Fig. 3. Circuit diagram of galvanostatic pulse generator

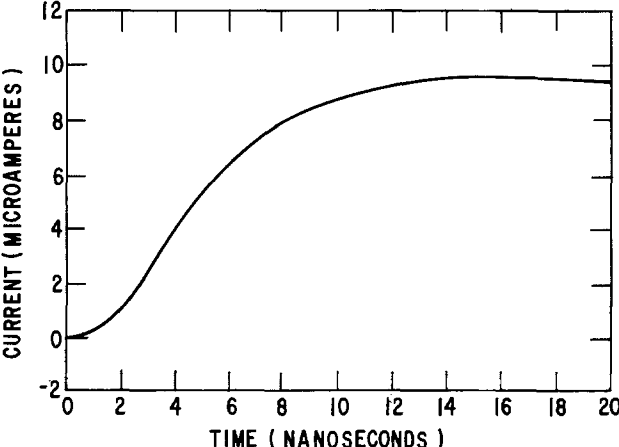

Fig. 4. Representative pulse rising edge; 1000 μA into 500 ohm in series with sample.

load and C the capacitive load shunting the pulser output to ground. R is fixed by the sample under analysis. C has components within the pulser circuitry and distributed along the output load. Stray capacitance occurring within the pulser degrades the output before it encounters the sample and introduces no error into resistivity measurements. Capacitance distributed along the output load does cause error by creating disparity between the observed pulse shape monitored across the current-sensing resistor and the pulse shape actually perturbing the sample. Both sources of stray capacitance have negligible effects if the sample resistance is small (<1500 ohm) and data are not measured at times <0.90 t_r.

For a resistivity measurement, one outer Ag electrode is connected through a 50 ohm high frequency current-monitoring resistor to pulser ground. The negative pulser terminal is connected to the opposite outer Ag band. For each elapsed time range, such as 10-40 nsec, the voltage rise as a function of time during a current pulse of appropriate duration is recorded with reference to pulser ground first across the high frequency current-sensing resistor and then at each of the two center sample electrodes. Each time range, thus, involves three separate current pulse measurements. The differential voltage rise as a function of time between the two center contacts is calculated and divided by the instantaneous current level monitored across the sensing resistor, yielding resistivity as a function of time. Analyses of six to ten time ranges are necessary to gather data from 10^{-8} to 10^{-3} sec.

Potential transients were captured with a Tektronix 7633 storage oscilloscope using a 6B53A time base and 6A11 vertical amplifier. Unit gain, 150 MHz bandwidth, and 1 megohm input impedance are three features of the 6A11 amplifier essential for these measurements. The probe-oscilloscope combination has a 60 MHz bandwidth, 5.9 nsec risetime, and vertical deflection accuracy of 3%. Stored traces were photographed for subsequent manual retrieval of potential/time information. The assembled apparatus was operated in a

single pulse mode by triggering the oscilloscope and pulser with a Datapulse Model 110B pulse generator.

Results and Discussion

Model circuit.—The resistivity/time behavior of a typical beta alumina tube (6G3-2) is shown in Fig. 5. Two impedance plateaus are apparent at 23°C, one between 10^{-8}-10^{-6} sec and a second in the region of 10^{-4} sec. Each resistivity characteristic shifts toward longer elapsed times (lower frequencies) with decreasing temperature.

An equivalent circuit modeling this resistivity/time response is shown in Fig. 6. R_b and C_b are grain boundary resistance and capacitance, respectively; R_c and C_c are comparable grain parameters. Generally, $R_b > R_c$ and $C_b > C_c$; polycrystalline beta alumina, therefore, is considered an aggregate of essentially single crystal grains separated by grain boundaries of markedly lower conductivity. Maxwell and Wagner (4) first described the frequency dispersion of conductivity and dielectric constant expected for such a heterogeneous conductor. Koops (5) applied the circuit shown in Fig. 6 to model the a-c impedance of grain structured NiZn ferrite, and Mitoff (6) has suggested this circuit as a model for the resistivity of polycrystalline beta alumina.

Individual voltages arising from R_cC_c and R_bC_b are additive during perturbation by a constant current square wave

$$V_T = V_c + V_b \quad [1]$$

or

$$V_t = I_{in}\left[\frac{1}{C_c\left(s+\frac{1}{R_cC_c}\right)} + \frac{1}{C_b\left(s+\frac{1}{R_bC_b}\right)}\right] \quad [2]$$

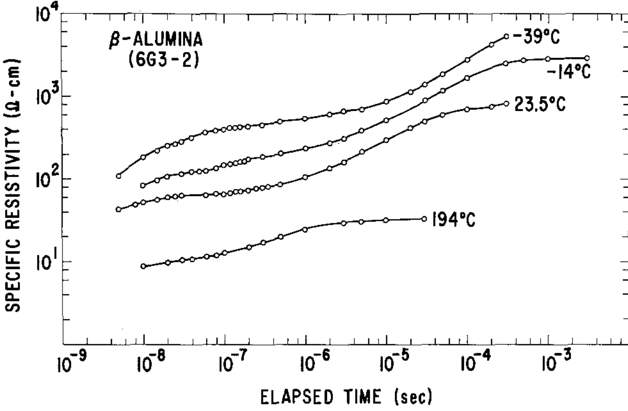

Fig. 5. Specific resistivity behavior of sample 6G3-2 as function of temperature.

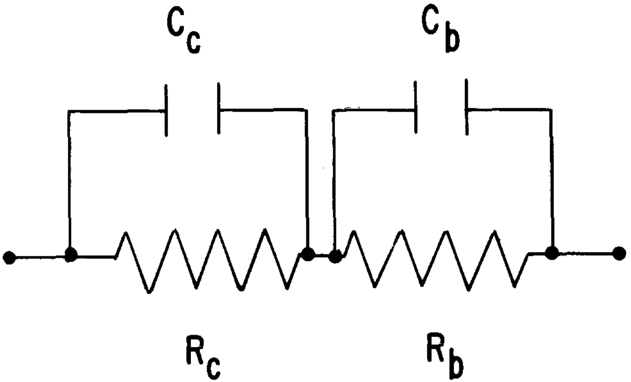

Fig. 6. Model circuit, ion transport in polycrystalline beta alumina.

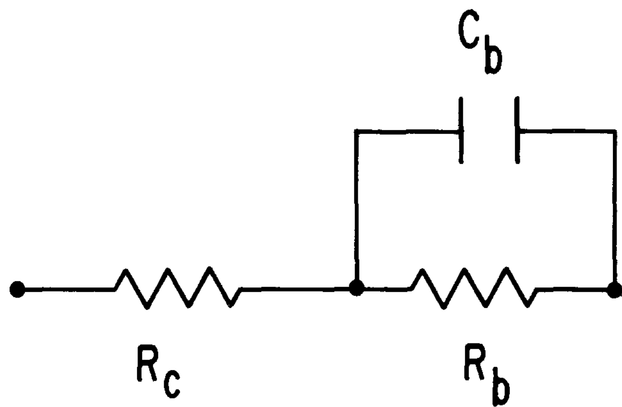

Fig. 7. Simplified model circuit, ion transport in polycrystalline beta alumina.

where s is the LaPlace operator and t is the elapsed time from the moment of current initiation, a point here defined as 10% t_r.

The response of this circuit to a constant current step

$$I_{in} = \frac{I_o}{s} \quad [3]$$

reduces to

$$\frac{V_T}{I_o} = R_t = R_c(1 - e^{-t/R_cC_c}) + R_b(1 - e^{-t/R_bC_b}) \quad [4]$$

If $R_cC_c << R_bC_b$, as is the case for 6G3-2, the effects of R_cC_c are essentially resolved before those from R_bC_b become significant. The equivalent circuit in Fig. 6 then can be simplified to that shown in Fig. 7 and Eq. [4] reduces to

$$R_t = R_c + R_b(1 - e^{-t/R_bC_b}) \quad [5]$$

Circuit resistance as a function of time is theoretically independent of pulse current magnitude. This is true for polycrystalline beta alumina over at least the 85-1650 μA current range as the data for sample 6G3-2 in Table I demonstrate.

Observed sample characteristics.—Table II lists R_b, R_c, and C_b observed as functions of temperature for sample 6G3-2 and 6M2-2. Certainly the most accurate figures are those for R_{dc}, which were obtained by extrapolating pulse data to direct current. Separating R_{dc} into R_b and R_c and calculating C_b is complicated by the failure of real ceramics to exhibit idealized resistivity behavior.

By comparing the observed resistivity response for 6G3-2 at 23°C with that predicted assuming R_b = 732 ohm-cm, R_c = 68 ohm-cm, C_b = 3.1 × 10^{-8} F-cm^{-1}, and C_c = 0, Fig. 8 illustrates that R_bC_b in a real ceramic is not a single time constant, but actually the mean of a time constant distribution. The observed response is more gradual than that predicted. Nonideal behavior arises because a single RC circuit can only approximate the three-dimensional RC network needed to accurately model conduction in polycrystalline beta alumina and because variations in intrinsic grain boundary

characteristics occur within any particular ceramic specimen.

In sample 6G3-2, R_bC_b and R_cC_c are sufficiently different that its behavior at times $> 10^{-8}$ sec can be modeled by the equivalent circuit shown in Fig. 7. With this simplification, it is possible to determine average values or R_c, R_b, and C_b and 6G3-2 despite the distribution of R_bC_b time constants.

R_b is equal to $R_{dc} - R_c$. R_c can be estimated from the second impedance plateau or determined more accurately by plotting ln $(R_{dc} - R_t)$ *vs.* t at points in the intergrain transition region.

For a model circuit such as Fig. 7 in which R_bC_b is a single time constant, ln $(R_{dc} - R_t)$ *vs.* t is a straight line of slope $= -1/R_bC_b$ and intercept of ln $R_{t=0}$, where $R_{t=0} = R_b$. The distribution of R_bC_b time constants introduces curvature into this relationship, but the plot is still sufficiently linear at times near the R_c plateau that R_c can be accurately determined.

C_b is calculated at the inflection point of the intergrain transition where, for a symmetrical dispersion of grain boundary properties, $R_t = (R_cR_b)^{1/2}$. Were R_bC_b a single time constant, a constant value of C_b could be calculated at any point on the intergrain transition. However, calculation of C_b at multiple points on a distributed grain boundary transition (Fig. 8) yields a range of C_b values centering on that calculated at the inflection. Each value of C_b is that which brings a model R_bC_b transition into coincidence with the observed transition at its point of calculation.

The effects of R_cC_c and R_bC_b, separated in sample 6G3-2, merge in sample 6M2-2 (Fig. 9) and, when combined with a distributed R_bC_b response, make precise calculation of R_c extremely difficult. To obtain the values of R_b, R_c, and C_b for 6M2-2 at various temperatures summarized in Table II, samples 6G3-2 and 6M2-2 were considered identical in intragrain conduction behavior. R_c (6M2-2) at 23°C was taken to be 68 ohm-cm and its intragrain conduction activation energy, E_c, to be 4.1 kcal/mole. Implicit is the assumption that the presence (6G3-2) or absence (6M2-2) of Y_2O_3, because of the size of Y, has no effect on intragrain conduction.

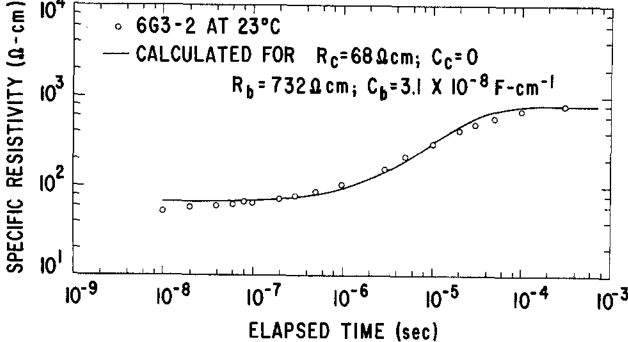

Fig. 8. Observed and calculated intergrain transition response, sample 6G3-2.

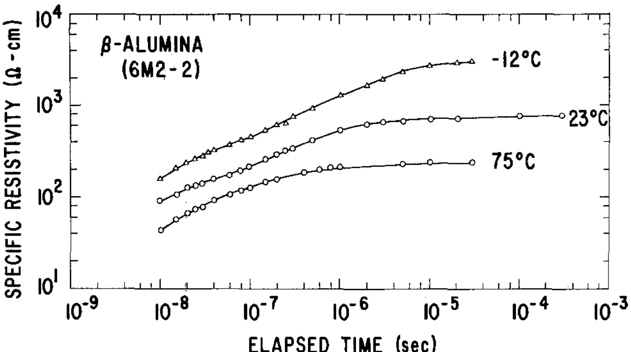

Fig. 9. Observed and calculated intergrain transition response, sample 6M2-2.

Nature of R_c and R_b.—R_c is not identical to but approximates the intrinsic resistivity of single crystal beta alumina. For sample 6G3-2, R_c at 23°C is 68 ohm-cm, close to that of 72 ohm-cm reported at 23°C by Whittingham and Huggins (2). Variation of R_c among different specimens and discrepancy between R_c and the intrinsic resistivity of single crystal beta alumina can arise from differences in composition and because the grains comprising polycrystalline samples are randomly oriented and separated by grain boundary regions. R_c is increased by a tortuous conducting path and decreased by capacitive shunting of grain boundaries.

R_b is an aggregate grain boundary resistivity and should be contrasted with ρ_b, the intrinsic resistivity of an individual grain boundary. The difference between R_b and ρ_b lies in the geometric factor introduced in converting an observed sample d-c resistance (ohm) into resistivity (ohm-cm). That factor for these measurements is the annular tube area divided by the spacing between the center pair of electrodes. Grain boundaries, *per se*, occupy only a small portion of the ceramic between these two sensing electrodes; but the geometric factor measures the over-all area and distance between the sensing electrodes, not the actual grain boundary parameters.

Similarly, C_b, expressed in units of F-cm^{-1}, is the aggregate capacitance of many individual grain boundaries, not an intrinsic grain boundary capacitance.

The aggregate grain boundary properties, R_b and C_b, vary with techniques of ceramic preparation, especially with grain size and distribution and the presence of sintering additives. One sintering additive that appears to concentrate at grain boundaries and greatly affects their electrical characteristics is Y_2O_3. Sample 6G3-2 was prepared with 0.5% Y_2O_3 added as a sintering aid; sample 6M2-2 is free of Y_2O_3. The effects of Y_2O_3 on grain boundary characteristics are evident in the relative values of C_b calculated for these two samples listed in Table II. In each case, C_b is independent of temperature within measurement accuracy but the average value of C_b is 41 times greater for 6G3-2 than 6M2-2.

A precise model of grain boundary behavior must consider that observed response results from many individual grain boundaries summed in a complex distributed series-parallel network. With great simplification, grain boundaries may be lumped to a single region of thickness, d, bounded by parallel plates of equal area, A. Thus

$$R_bC_b = \left(\rho_b \frac{d}{A}\right)\left(\epsilon_o\epsilon_b \frac{A}{d}\right) \quad [6]$$

in which ρ_b and ϵ_b are the specific intrinsic resistivity and dielectric constant of an individual grain boundary and $\epsilon_o = 8.85 \times 10^{-15}$ **F**-cm^{-1}, the permittivity of free space.

At 23°C, R_bC_b and R_b are 2.3×10^{-5} sec and 632 ohm-cm, respectively, for 6G3-2 and 5.6×10^{-7} sec and 712 ohm-cm, respectively, for 6M2-2.

Considering

$$\frac{\left[\left(\rho_b \frac{d}{A}\right)\left(\epsilon_b\epsilon_o \frac{A}{d}\right)\right](6G3\text{-}2)}{\left[\left(\rho_b \frac{d}{A}\right)\left(\epsilon_b\epsilon_o \frac{A}{d}\right)\right](6M2\text{-}2)} = \frac{R_bC_b\ (6G3\text{-}2)}{R_bC_b(6M2\text{-}2)} \quad [7]$$

and

$$\frac{R_b(6G3\text{-}2)}{R_b(6M2\text{-}2)} = \frac{\rho_b \frac{d}{A}\ (6G3\text{-}2)}{\rho_b \frac{d}{A}\ (6M2\text{-}2)} \quad [8]$$

Then

$$\frac{\epsilon_b \frac{A}{d}\ (6G3\text{-}2)}{\epsilon_b \frac{A}{d}\ (6M2\text{-}2)} = 46 \quad [9]$$

Making the somewhat arbitrary assumptions that A/d (6G3-2) $= A/d$ (6M2-2) and ϵ_b (6M2-2) is a typical value such as 5, then ϵ_b (6G3-2) $= 230$, ρ_b (6G3-2) $= 1 \times 10^7$ ohm-cm, and ρ_b (6M2-2) $= 1 \times 10^7$ ohm-cm at 23°C. Clearly, these are simplifications; nevertheless, the essential conclusion that the intrinsic resistivity of grain boundaries is approximately 10^5 times greater than that of grains is reasonable.

If ρ_b (6G3-2) $= 1 \times 10^7$ ohm-cm at 23°C, then the aggregate grain boundary thickness between the two larger faces of a 1 cm^2 $\times$ 0.1 cm section of the ceramic, assuming a model of alternating parallel grains separated by grain boundaries, is 5×10^{-4} cm. A 1V potential drop across the ceramic in a direction normal to the larger faces produces a field of 2×10^3 V/cm across the grain boundaries and 8×10^{-1} V/cm across the grains at 23°C, and 1.2×10^3 and 3.7 V/cm, respectively, at 350°C.

Localized grain boundary fields of greater intensity may arise from inhomogeneities in grain boundary resistivity and in grain size and distribution. For example, the total resistivity of a relatively large grain embedded in a matrix of smaller grains is lower than its neighboring region. Current flows preferentially through the grain, increasing the current density at its boundaries, producing greater localized fields than exist generally in the sample. These large grain boundary fields may be significant factors in the initiation and propagation of cracks that often appear in polycrystalline beta alumina upon extended electrochemical ionic transport.

Variation of R_c and R_b with temperature.—Arrhenius plots for intragrain and intergrain conductivity in sample 6G3-2 and intragrain conductivity in sample 6M2-2 are shown in Fig. 10 and 11, respectively.

The intragrain activation energy of 4.1 ± 0.1 kcal/mole measured for sample 6G3-2 is slightly greater than that of 3.8 kcal/mole reported by Whittingham and Huggins (2) for beta alumina single crystals. Tortuosity of a polycrystalline sample should not influence the slope of its intragrain Arrhenius plot. The difference between these activation energies is significant, therefore; its cause may lie in small compositional differences between the samples of beta alumina analyzed.

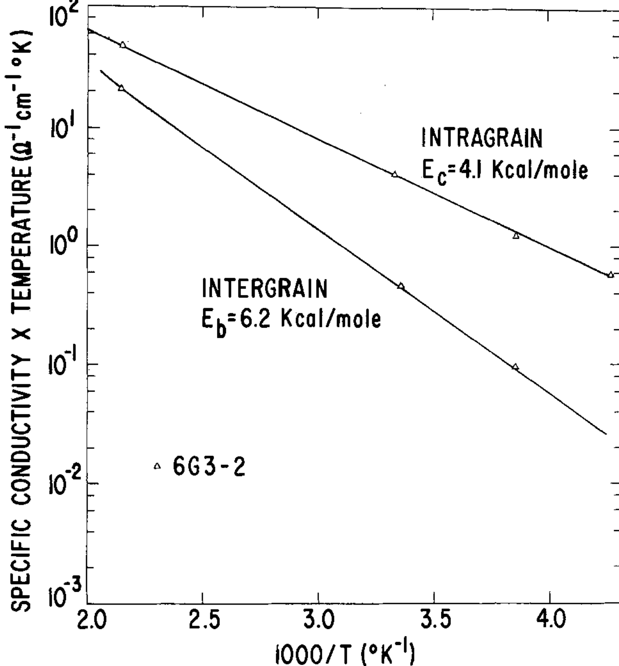

Fig. 10. Arrhenius plot, 6G3-2

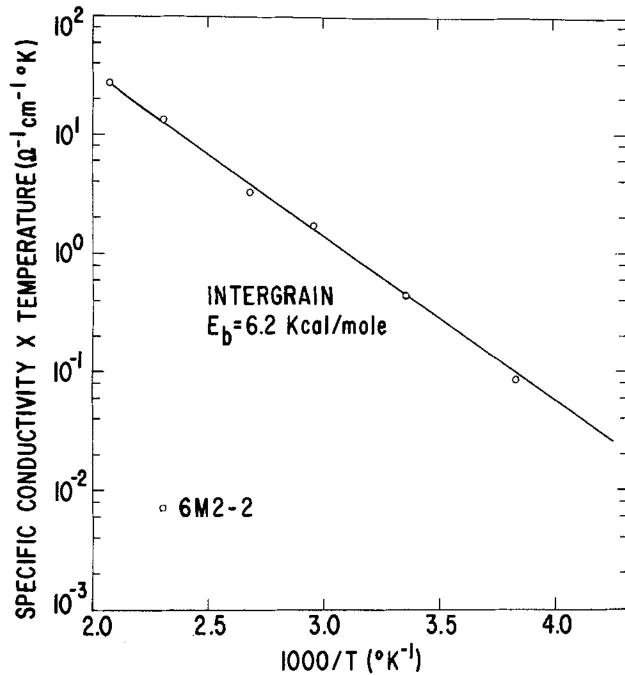

Fig. 11. Arrhenius plot, 6M2-2

Intergrain activation energies are the same, 6.2 kcal/mole, regardless of the presence (6G3-2; Fig. 10) or absence (6M2-2; Fig. 11) of Y_2O_3.

Nonlinear Arrhenius behavior might be observed for the temperature variation of polycrystalline beta alumina resistivity if the elapsed time, or its counterpart in frequency, at which resistivity is monitored falls on the intergrain or intragrain transition regions at some point in the temperature range of interest. For example, if the grain boundary conductance of sample 6G3-2 were monitored at 100 kHz from −58° to 300°C, the resulting Arrhenius plot would be linear above *ca.* 150°C, in which range 100 kHz falls on the intergrain plateau, but would deviate from linearity at lower temperatures at which anomalously high conductivity would be observed. In deriving the Arrhenius plots presented here, the points at which resistivities were recorded for intergrain and intragrain transport were

adjusted with changing temperature to be clearly on the resistivity plateaus of interest.

Nature of C_c.—As Fig. 5 and 9 show, the resistivity of polycrystalline beta alumina decreases below R_c at short elapsed times. This effect, barely observable at 23°C but clear at −39°C, is modeled in the equivalent circuit (Fig. 6) by C_c, the intragrain capacitance. C_c expresses many polarization processes intrinsic to single crystal beta alumina, but is too large to result solely from electronic polarizations. Also, a simple geometric capacitance should not have so large a temperature variation.

Most materials have optical dielectric constants in the range 1-10. Were the intrinsic dielectric constant of beta alumina at 23°C a value such as 5, C_c (23°C) would be 4.5×10^{-14} **F**-cm^{-1} and R_cC_c, considering $R_c = 68$ ohm-cm, would be 3.0×10^{-12} sec. An RC response of this time constant should have a value of 0.9 R_c or 62 ohm-cm at 7×10^{-12} sec. Actually, R(6G3-2) is 62 ohm-cm at 1.14×10^{-8} sec (23°C), making $C_c = 8.9 \times 10^{-11}$ **F**-cm^{-1} and $R_cC_c = 6.1 \times 10^{-9}$ sec. From Eq. [6], $R_cC_c = \rho_c\epsilon_c\epsilon_o$, where $\rho_c =$ single crystal beta alumina resistivity and $\epsilon_c =$ single crystal dielectric constant. Then, $\epsilon_c = 10^5$ to explain the observed behavior. Since 10^5 is an unreasonable optical dielectric constant, R_cC_c (see Fig. 6) must be a generalization of a more complex equivalent circuit needed to model intragrain, or single crystal, beta alumina impedance at shorter elapsed times than those encountered here. Possible origins for this complexity can be found in the structure and nature of ionic motion in the beta alumina conduction plane.

The structure of beta alumina was first determined by Bragg (7) and refined by Beevers and Ross (8) and Peters *et al.* (9). The work of Peters *et al.* addressed particularly sodium ion distribution within its conducting planes. Figure 12 maps the sodium and oxygen ion arrangement within the conducting plane. Two close-packed oxygen layers, the top removed and the bottom shown, symmetrically sandwich the conducting plane. Sodium ions are shown in d sites, one of three sites, d, b, and MO, available for mobile ion occupation.

A sodium ion in the center of each d site is hexagonally coordinated 2.88Å from each of three oxygens in the lower and three in the upper close-packed planes and equidistant at 3.25Å from three oxygens in the conducting plane. Sodium in the mid-oxygen (MO) is also hexagonally coordinated to six close-packed oxygens, three in each plane at a distance of 2.88Å, but its nearest neighbors are two oxygens in the conducting plane at a distance of 2.80Å. The b site, like the d site,

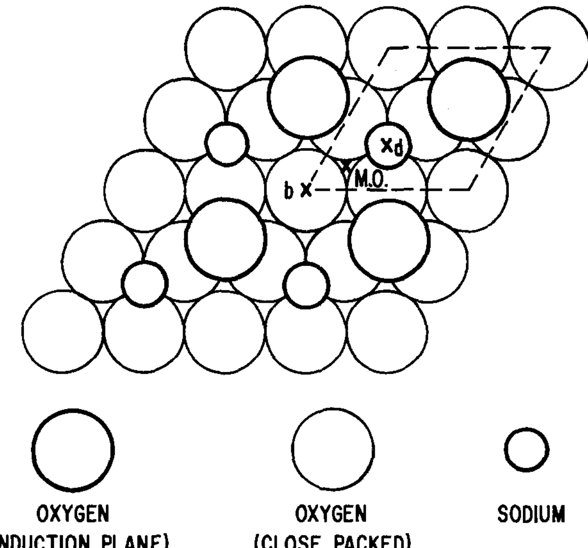

Fig. 12. Ionic arrangement in beta alumina conduction plane

has sodium trigonally coordinated 3.25Å away from three conduction-plane oxygens but placed between two close-packed oxygens only 2.38Å away.

If the Na^+ ion distribution presented by Peters *et al.* (11), which is averaged over many unit cells, actually represents ion distribution at the unit cell level, then Na^+ ion density at room temperature is concentrated in the d and MO sites. Density in the d site is shaped as a triangle with apical maxima 0.39Å from site center each pointing toward one of three neighboring MO sites; each d site has not one but three density maxima. Secondary density maxima occur at each MO site. Occupation of b sites is low in comparison. This density distribution becomes more uniform with increasing temperature. More sophisticated experimental techniques have essentially confirmed these observations (10).

The nonequivalency of Na^+ ion sites in beta alumina and of ion densities within those sites implies that a number of energetically different site-site ion transitions can occur. Therefore, measurement of intragrain (single crystal) beta alumina resistivity over an appropriate response range should reflect in its structure several different ion response times. The decline in resistivity at short elapsed times in Fig. 5 and 9 may be initial manifestations of these effects.

The resistivity data presented here only hint at what might be observed with more detailed measurements. For example, using NMR analysis, Story, Glowinkowski, and Roth (11) and Jerome and Boilot (12) report observing at least two distinct activation energies for Na^+ ion motion in beta alumina.

Summary and Conclusions

Galvanostatic analysis is a useful approach for identifying and analyzing the several components of resistivity, both intergrain and intragrain, in polycrystalline beta alumina. Precise calculation of R_b and R_c is possible when $R_bC_b >> R_cC_c$ and R_bC_b is within the frequency range of measurement.

Grain boundaries dominate the resistivity of typical fine-grain beta alumina. Though their physical dimensions are small, they account for 92% of the d-c resistivity of sample 6G3-2 and 85% of the d-c resistivity of 6M2-2 at 23°C. Their properties are pivotal in determining the applications and temperatures for which polycrystalline beta alumina is a practical electrolyte.

A grain boundary can be modeled as an area of extremely low conductivity separating intragrain regions of much higher conductivities. Because of their large electrical fields, *e.g.*, 10^3 V/cm, grain boundaries may be focal points of electrochemically induced ceramic degradation.

Intragrain capacitance effects are observed in the elapsed time region of 10^{-8}-10^{-9} sec at 23°C and are considered the result of several different ion transitions possible among the three structurally nonequivalent sites available for mobile ion occupation in beta alumina. As a result, the intragrain transition region, beginnings of which are seen in these measurements, should not follow a single time constant but should exhibit complexity arising from multiple ion motions possible on a localized scale in the beta alumina conducting plane. An elucidation of the intragrain resistivity transition will require analysis at shorter elapsed times (higher frequencies) than those encountered here, but may illumine the intrinsic nature of ion transport in beta alumina.

Occurrence of intragrain capacitance effects at elapsed times as long as 10^{-8} sec has one very practical consequence: it jeopardizes the usefulness of galvanostatic or multifrequency resistivity analysis in guiding beta alumina ceramic development. It was hoped that such techniques could be used to separate intragrain and intergrain resistivity components in polycrystalline beta alumina. Though satisfactory separation is ob-

served with yttria-containing ceramic such as 6G3-2, yttria is considered deleterious to ceramic life. Elimination of yttria yields samples such as 6M2-2 which appear to have approximately equivalent d-c resistivity to yttria-containing material but much smaller grain boundary capacitance. Consequently, the grain boundary (R_bC_b) resistivity transition in 6M2-2 merges with its intragrain transition. Since the grain boundary response is not single valued and the nature of the intragrain transition unknown, resolution of R_c and R_b is not straightforward. Multifrequency analysis or its equivalent may be of little use in separating intragrain and intergrain resistivity components in such "improved" specimens of polycrystalline beta alumina.

Cathodoluminescence Saturation Phenomena in Y_2O_2S:Eu

D. J. Robbins

Royal Radar Establishment, Malvern, Worcestershire WR14 3PS, England

ABSTRACT

The importance of a thermal perturbation of Y_2O_2S:Eu (0.1%) under excitation by long (up to 30 msec) electron beam pulses is investigated using the measured differential thermal behavior of luminescence lines originating in the $^5D_2$, $^5D_1$, and $^5D_0$ states. An observed droop in light output, equivalent to a saturation of the phosphor brightness, is found to be inconsistent with a thermal perturbation of the system. Other experiments involving a-c electric field modulation of the luminescence from the ^5D states suggest that the droop may be caused by electric field perturbation of the system. The saturation characteristics of the phosphor are changed reversibly during a 30 msec pulse, and irreversibly by mixing with a conducting matrix. It is suggested that space-charge fields are generated by trapping of charge in surface states of the phosphor grains, and a simple kinetic model for the saturation mechanism involving field-induced ionization of the charge transfer state and quenching of the $^5D_2$ state is in qualitative agreement with the experimental data. The relevance of the model to saturation phenomena and to aging in CRT screens is discussed.

Most phosphors show some degree of saturation in their brightness *vs.* current density characteristic under electron beam excitation (1, 2). This saturation can clearly limit the brightness achievable from any CRT screen incorporating such a phosphor, and can prove troublesome in maintaining color balance in multicolor tubes (3-6). The phenomenon is therefore of great technological interest. Several workers have described techniques whereby the saturation characteristics of phosphors can be parameterized (3, 4, 7), but there have been rather few experimental investigations which can be used to provide insight into the fundamental mechanisms involved. This study was undertaken in order to test some of the generally accepted theories of current density saturation in phosphors.

Saturation of light output as pumping density increases is primarily a kinetic problem, and detailed kinetic models have been developed to explain the phenomenon in light-emitting semiconductor materials (8). In contrast the models applied to phosphor materials are much more general and qualitative in nature (9, 10), but the most probable causes of saturation may be summarized in the following way:

(*i*) A perturbation of the system kinetics at high current densities. It is usually assumed that this perturbation is thermal (3, 11) and that a temperature rise causes saturation by reducing the luminescent efficiency of the phosphor. However it should be remembered that excitation by a charged particle beam is involved in the CRT so that the perturbation might be electrical in nature.

(*ii*) True activator saturation, *i.e.*, excitation of a large fraction of available activator sites causing significant depletion of the ground state population. Although this effect is often assumed in the analysis of phosphor kinetics (9) it is less likely to be significant in rare earth phosphors with several percent of activator ions in the lattice than in sulfide phosphors with activators at the ppm level. Such effects will also be sensitive to activator lifetimes.

(*iii*) The increasing importance at high excitation densities of higher order recombination pathways, or

Key words: phosphors, CRT, aging, space-charge electric field, surface states.

of self-absorption phenomena caused by the buildup in population of low energy excited states just above the ground state (12).

There is a lack of experimental data which can be used to decide the relative importance of the above mechanisms, but for rare earth phosphors and reasonable excitation densities mechanism (*i*) would appear most probable. Our first aim has therefore been to monitor the kinetics of a rare earth phosphor at increasing excitation current densities in order to determine whether effects related to saturation of light output were consistent with a thermal perturbation of the system. We thus sought a system with its own "internal thermometer," *i.e.*, with spectral features sensitive to temperature in the range 300°-400°K. Such a system could be "calibrated" by measurement of its spectrum at various fixed temperatures, so that if a thermal perturbation were assumed to occur under electron beam excitation the effects could be predicted and the predictions checked against the experimental data. We shall show that for the rare earth phosphor material investigated here the kinetics are perturbed at higher current densities, but that the results cannot be explained by a rise in temperature of the system. However we shall present other evidence, including the electric field modulation of photoluminescence, which demonstrates that the effects are consistent with a perturbation of the kinetics caused by the buildup of an electric field in the phosphor particles during electron beam bombardment. This space-charge field may be created by trapping of charge in surface states of the phosphor.

The system chosen for study was Y_2O_2S:Eu (0.1%). The temperature dependence of the photoluminescence (PL) spectrum of this system has been extensively investigated by Struck and Fonger (13, 14), who have shown that between 300°-450°K emission from the $^5D_2$ state is rapidly quenched, probably via the charge transfer (CT) state, whereas similar quenching of the lower lying $^5D_1$ and $^5D_0$ states does not begin until much higher temperatures. The relative intensities of the emission from $^5D_2$, $^5D_1$, and $^5D_0$ therefore constitute the internal thermometer which we have used to monitor the effective temperature of the luminescent ion as excitation current density is increased, and hence to determine the significance of any thermal perturbation. The energy level scheme and the wavelengths of the lines monitored are shown in Fig. 1.

Following the onset of electron beam excitation, energy transferred to the lattice phonons is rapidly relaxed; this relaxation is generally considered to be complete in a time $<< 10^{-10}$ sec, so that on the time scale of interest in our experiments the phonon subsystem can be considered to be instantaneously in local equilibrium with the electronic configuration of the activator ion. The relaxation between different electronic levels is much slower however, and can be strongly influenced by the strength of the electron-lattice coupling and by the mean phonon occupation numbers. The electronic relaxation times are obtained from the decay times of the states involved, and are of the order $\tau \sim 1 - 5 \times 10^{-4}$ sec for the $^5D_2$, $^5D_1$, $^5D_0$ states of Eu^{3+} at 300°K, and estimated to be $<< 10^{-8}$ sec for the charge transfer state (13). When an electron beam pulse is applied to the system the excitation rate is constant while the pulse is on, and the relative populations of the $^5D_2$, $^5D_1$, and $^5D_0$ electronic states will adjust to the new steady-state conditions in a time corresponding to $\sim 5\tau$, *i.e.*, $\sim$0.5-2 msec. Since the kinetics are most easily interpreted in the steady-state condition rather than during the initial rapid rise of luminescence, relatively long electron beam pulses (up to 30 msec) have been applied to the system so that a steady-state condition should be reached. The temperature is expected to rise through the pulse, but as long as the rate of change is slow compared with the

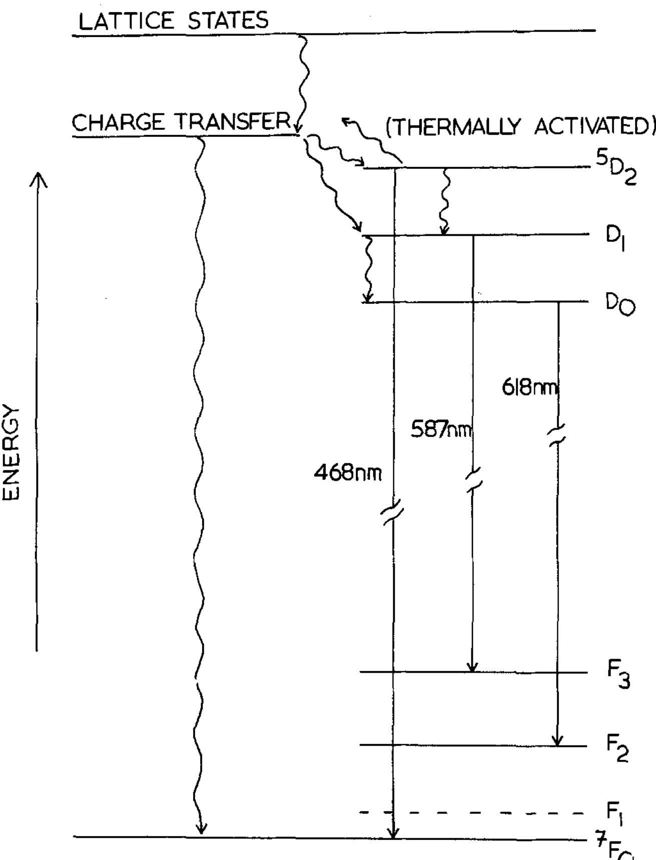

Fig. 1. Schematic energy level diagram for Y_2O_2S:Eu. The wavelengths of the emission lines used to monitor the kinetics of the excited states are shown.

electronic relaxation rates the relative populations of the excited states should reflect the effective temperature of the system throughout the pulse. Since the relative thermal behavior of the $^5D_2$, $^5D_1$, $^5D_0$ states in Y_2O_2S:Eu (0.1%) is known (13), the relative populations of these states during electron beam excitation can be used to determine whether there is a signficant thermal perturbation of the system as current density is increased.

It might seem more straightforward to calculate the expected temperature rise directly rather than use the experimental approach adopted here. However there are severe problems associated with such a calculation for a thin layer of phosphor powder settled on a substrate, not the least of these being the thermal conductivity to be used for small grains of material in point contact and associated with binder in the layer, and the volume and nature of the excitation caused by an electron beam penetrating a randomly oriented array of irregular particles. Archard and Einstein (15) have considered the problem of heating in phosphor screens under pulse electron beam excitation and have shown that the temperature rise can be treated as the sum of two parts: first, a rise in mean temperature, superimposed upon which is a pulse temperature rise occurring during the excitation period. If the electronic processes taking place at the excited activator ions are fast compared with the relaxation time of the thermal pulse, then the effective temperature experienced by the activator during the luminescence process will be higher than the mean screen temperature.

In view of these difficulties we have preferred to determine experimentally whether the light output of the phosphor system is significantly affected by thermal perturbation. Nevertheless it is useful to obtain a qualitative picture of the probable rate of change of temperature through the pulse using the method described by Carslaw and Jaeger (16), and used by

Archard and Einstein (15), since this will indicate whether our assumption that the rate of temperature change is slow compared with the electronic relaxation times is reasonable. If we assume the beam to penetrate a depth l into a semi-infinite solid with heat generated at a constant rate Q per unit time and area for time $t > 0$, and with no heat loss at the surface, then the temperature rise at depth l will be of the form (16)

$$T = \frac{KQt}{2kl}\left(1 - 4i^2 \operatorname{erfc} \frac{l}{\sqrt{Kt}}\right) \quad [1]$$

where $K = k/\rho c$, k is the thermal conductivity, ρ the density, and c the specific heat. The function $i^2 \operatorname{erfc}(x)$ is tabulated in Ref. (16). Archard and Einstein (15) have measured a thermal conductivity for settled ZnS

$$k = 4 \times 10^{-4} \text{ cal cm}^{-1}\,{}^{\circ}\text{c}^{-1} \text{ sec}^{-1} \quad [2]$$

This is approximately the thermal conductivity of dry sandy soil (16), which is perhaps reasonable for a phosphor settled in silicate binder. Assuming this value for Y_2O_2S, and

$$\rho \approx 5 \text{g cm}^{-3}$$

$$c \approx 0.1 \text{ cal g}^{-1}\,{}^{\circ}\text{c}^{-1} \quad [3]$$

then for a current density of 0.5 mA cm^{-2}, the maximum used in our experiment, the predicted temperature rise of the phosphor through a 30 msec electron beam pulse is shown in Fig. 2. With a repetition time of approximately 100 msec the background rise in temperature of the system calculated according to Archard and Einstein should be less than 10°C. The absolute magnitudes of these rises can only be crude estimates since we have neglected, among other things, heat losses to the metal substrate and to the surroundings, and the nonuniform intensity profile of the electron beam. However the calculation is sufficient to indicate that the rate of change of temperature through the pulse should be slow compared with the electronic relaxation times, and that therefore the relative intensities of emission from the $^5D_2$, $^5D_1$, and $^5D_0$ states of Eu^{3+} at any instant should reflect the temperature prevailing in the system.

With this background it is now possible to discuss the experimental results.

Experimental

The Y_2O_2S:Eu (0.1%) was prepared at GEC Ltd. (Hirst Research Centre) by firing Y_2O_3 with sulfur, Eu_2O_3, and Na_2CO_3 at 1200°C for 2 hr in an open tube furnace and subsequently washing. The phase of the sample was checked by x-ray powder diffraction, and the activator content by x-ray fluorescence analysis. The cathodoluminescence (CL) measurements were made using an apparatus which has been described elsewhere (17). The electron beam was approximately 800μ in diameter and was variable from 0.3-20 μA at the sample. The spot could be pulsed with variable dwell time and prf. The emitted light was focused onto the entrance slit of a 0.25m grating monochromator and detected by a photomultiplier with a 1 kΩ load. The signal/noise ratio was improved by averaging the output in a Hewlett-Packard 5480B multichannel signal analyzer with a time resolution of 10 μsec/channel. The stored signal could then be displayed on a chart recorder. With this instrumentation it was possible to observe the light output profile throughout the electron beam pulse, and to measure decay times on switching off the pulse. All measurements were made at room temperature and with a 20 kV gun potential.

The phosphor was either gravity-settled through a dilute silicate binder using standard methods (18) onto small conducting glass or aluminum substrates, or dusted onto a thin layer of conducting silver-loaded epoxy adhesive (Johnson-Matthey Chemicals Ltd.) spread on an aluminum disk. The substrates were approximately 1 cm^2 in area and the coverage approximately 8 mg cm^{-2}. The substrates bearing the phosphor samples were fixed to a rotating metal sample holder by conducting silver-DAG, so that each could be brought under the beam in turn. The samples were not aluminized, and were viewed from the electron-beam irradiated side.

Photoluminescence measurements were made in this laboratory by excitation at 350-360 nm with u.v. lines of an Ar^+ laser used in conjunction with a u.v. band pass filter to remove interfering visible fluorescence lines, and by excitation at 250 nm with the monochromated output of a 150W Xe arc source at GEC Ltd. Photoluminescence decay times were obtained using a N_2 laser producing pulses with 2 nsec half-width at 337 nm. Variable temperature measurements were made using a commercial temperature controller in conjunction with an electrically heated sample mount.

Results

Figure 3(a) shows the temperature dependence of the emission intensity from $^5D_2$, $^5D_1$, and $^5D_0$ states of Eu^{3+} for 250 nm excitation (19), and emphazises the particular sensitivity of the $^5D_2$ state in this temperature range. The system shows the same behavior under 350-360 nm excitation using the Ar^+ laser, which excites into the CT band directly. The special role played by the CT state in feeding the ^5D states has been discussed by Struck and Fonger (13, 14) and explains why excitation by electrons or photons at energies equal to or higher than the CT state energy produce the same relative emission intensities from the various ^5D states of Eu^{3+} in Y_2O_2S.

Figure 3(b) shows the variation with temperature of the photoluminescence decay times. The data for $^5D_2$ became uncertain at the higher temperatures because

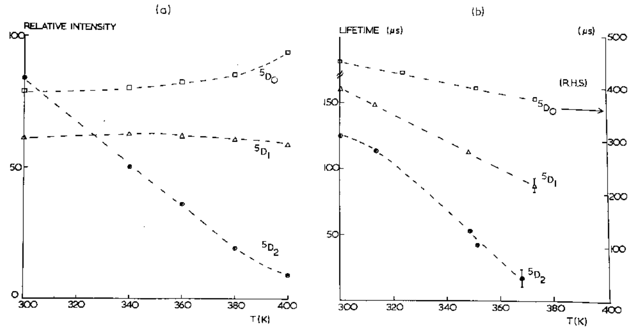

Fig. 3 Temperature dependence of PL of $^5D_2$, $^5D_1$, and $^5D_0$ states. (a) Relative intensity under 250 nm excitation. (b) Lifetime under 337 nm pulse excitation. ($^5D_2$, $^5D_1$—L.H. scale, $^5D_0$—R.H. scale.) Quoted lifetimes are approximations to simple exponential behavior (see text).

the decay time approaches the resolution limit of the detection system used. With the time resolution available (10 μsec/channel) the rise time of the $^5D_2$ state in response to the N_2 laser pulse excitation was too fast to be measured, but the $^5D_1$ and $^5D_0$ emissions showed delayed buildup periods of approximately 50 μsec and 200 μsec, respectively, before the maxima in the emission intensity were reached. The reason for this difference in behavior is that the $^5D_1$ and $^5D_0$ states are fed partially or wholly via higher lying f-electron states with relatively slow relaxation rates, whereas the $^5D_2$ state is fed principally from the CT state (13). The quoted decay times for the various states were measured over approximately one decade from the maxima in the response curves. The decays were reasonably approximated by exponential functions over this range, but since the decay characteristics of the $^5D_1$ and $^5D_0$ states are not simple first order decays from the end of the excitation pulse it is clear that the quoted decay times are not simply the characteristic decay times of the emitting states, but rather some combination of these.

Figure 4 shows typical measurements of the light output characteristics of the same Y_2O_2S:Eu (0.1%) phosphor material mounted in different ways and exposed to 30 msec electron beam pulses of increasing current density with a 300°K phosphor mount temperature. The behavior of lines originating from the $^5D_2$ and $^5D_1$ states only are shown for clarity, the $^5D_0$ state having a characteristic very similar to that of $^5D_1$.

Consider first the results in Fig. 4(a) for phosphor settled through silicate binder onto a conducting glass substrate (similar results were obtained using aluminum substrates). Recalling the earlier discussion, the light output would be expected to rise, reaching a steady state in a time ~1 msec, and, in the absence of other perturbation to stay constant though the pulse and finally decay rapidly at the end of the pulse. This is in fact the characteristic observed at the lowest beam currents, but as the current density is increased a "droop" appears in the output which would cause a sublinear increase in integrated light output with current density, *i.e.*, a saturation effect. This droop is sensitive to the settling process, since the characteristic varied a little over the sample surface and a sample settled independently showed a more accentuated form of droop. For the samples reported in Fig. 4(a), the form of the droop was reasonably constant in time and the results were reproducible on increasing and subsequently decreasing the beam current within the quoted limits. There was a slow general decrease in over-all intensity of all the lines after prolonged exposure to the beam; this may have resulted from beam induced damage or contamination, or from the kind of energy storage phenomena described by Struck and Fonger (20) leading to a depletion of the ground state activator concentration.

When the pulse length was shortened to 10 msec the light output obtained was the same as the curves for the first 10 msec period in Fig. 4(a), followed by rapid decay on switching off the pulse. The droop is also characteristic only of the excited state involved since the form of the curves was found to be independent of the final level when emissions from $^5D_2$ to several components of the ^7F ground state were measured. This shows that the droop is not the result of self-absorption phenomena caused by an increase in population of components of the ^7F state just above the ground state (12).

At first sight it might appear that the droop is caused by a temperature rise through the pulse, and indeed previous reports of similar droop phenomena attributed them to thermal perturbation (11). However, consideration of the following points shows that this is unlikely to be the cause in our experiment:

1. The droop becomes significant for both $^5D_2$ and $^5D_1$ (and $^5D_0$) states at approximately the same beam current, and although the droop of the $^5D_2$ emission is greater than that of $^5D_1$ the latter is quite substantial. The $^5D_2$ state however is much more sensitive to temperature than $^5D_1$ [see Fig. 3(a)], and indeed the intensity of emission from the latter is little changed over a temperature range which virtually quenches $^5D_2$ emission. For a thermal perturbation one would therefore expect a large droop in the $^5D_2$ characteristic before any significant effect on $^5D_1$ occurred, and this conflicts with the experimental observation.

2. At higher currents the droop increases and the system tends to approach a limiting or equilibrium light output for long pulses which is not very sensitive to beam current. Again this is not expected for a thermal perturbation since the maximum temperature reached during the pulse should increase approximately linearly with beam current density (see Eq. [1]) and it would be necessary to argue that the increased pumping rates at higher current were exactly offset by increased thermal quenching. In fact this behavior is more characteristic of an electrical charging phenomenon, which would approach a steady state determined by the capacitance of the sample.

3. The droop observed is similar for phosphor settled on conducting glass and on aluminum substrates, *i.e.*, is insensitive to the thermal conductivity of the substrate.

4. The power from the d-c Ar^+ laser used in PL measurements corresponded to an excitation density of approximately 1W cm^{-2}, which is only a factor of 2-3 smaller than the highest mean excitation density used in the electron beam experiments. The PL temperature dependence data taken with the Ar^+ laser were the

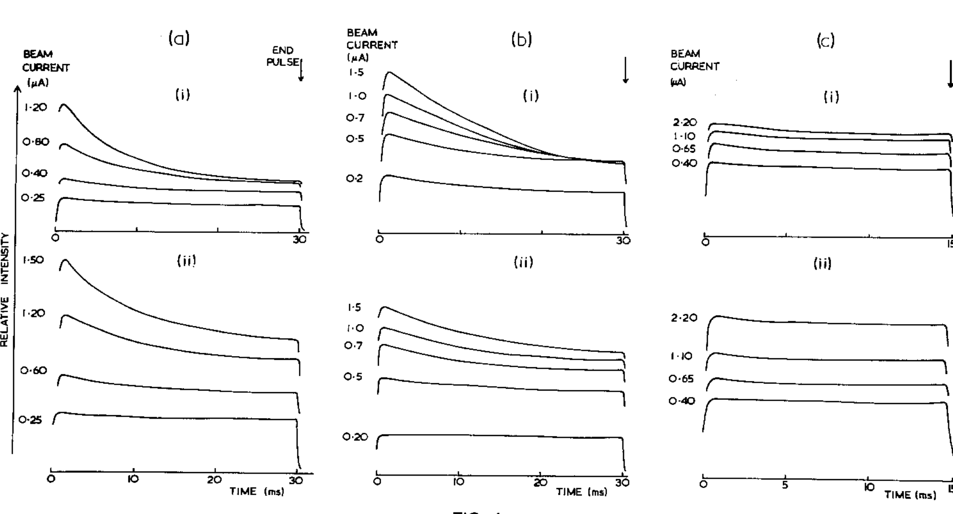

Fig. 4. Light output profile of Y_2O_2S:Eu (0.1%) in response to long electron beam pulses of increasing current density. (i) Indicates $^5D_2 \rightarrow {}^7F_0$ emission and (ii) indicates $^5D_1 \rightarrow {}^7F_3$ emission. (a) Powder settled on conducting glass substrate. (b) Sealed, aluminized CRT screen. (c) Powder spread on conducting adhesive matrix. The beam current (μA) corresponding to each curve is also shown. The arrows mark the end of the excitation pulse.

same as those taken at much lower power density with the monochromated Xe arc, showing that this level of excitation density does not produce significant perturbation of the luminescence process under photon excitation.

True activator saturation phenomena would not produce a droop characteristic, and it is unlikely that the droop can be caused by a depletion of the ground state activator concentration following CT dissociation and long-term energy storage (20), since this would affect all the ^5D states equally and produce considerable changes in the light output characteristic as the number of pulses to which the sample was exposed increased. This was not observed in the measurements taken at 10 Hz prf. However since there is some evidence that the droop is associated with electrical charging effects, there exists the possibility that it is an artifact of the demountable system using nonaluminized samples. To eliminate this possibility sealed aluminized CRT screens were prepared by Ferranti Ltd. (Special Components Department) using the same phosphor material. The excitation conditions used in the demountable system were reproduced in the CRT, and the results are shown in Fig. 4(b) (21). These results are in excellent qualitative agreement with the demountable measurements, and show that the droop effect is not significantly altered by aluminizing the sample.

Two experiments were then carried out to test the sensitivity of the system to electrical perturbation. In the first the phosphor was lightly dusted onto a thin layer of conducting epoxy adhesive spread on an aluminum disk, and the excess shaken off. Any particles adhering were then in intimate contact with the conducting adhesive, so that the surface electrical properties of the particles were presumably quite different from those of the settled material. The light output observed on applying a long electron beam pulse is shown in Fig. 4(c), and it is clear that there is no significant droop. The mean brightness of these samples was also lower, probably as a result of the electric-field-induced quenching effects discussed later. However it is clear that changing the electrical properties of the phosphor layer markedly affects the droop characteristic.

In the second experiment a sandwich cell was constructed so that an electric field could be applied to the phosphor while it was being excited into the charge transfer state by the Ar^+ laser (Fig. 5). The phosphor was settled in silicate binder onto a conducting glass plate which formed a transparent electrode transmitting the laser beam. The electrodes were nonblocking, and an a-c field was used to prevent polarization. With no field applied, the phosphor gave a steady d-c light output level. However on applying 200V a.c. (rms) at 50 Hz, the light output was modulated at twice the field frequency as shown schematically in Fig. 5(b). At this field there was no interference from electroluminescence (EL), although a weak ACEL signal was observed at a field of 230V.

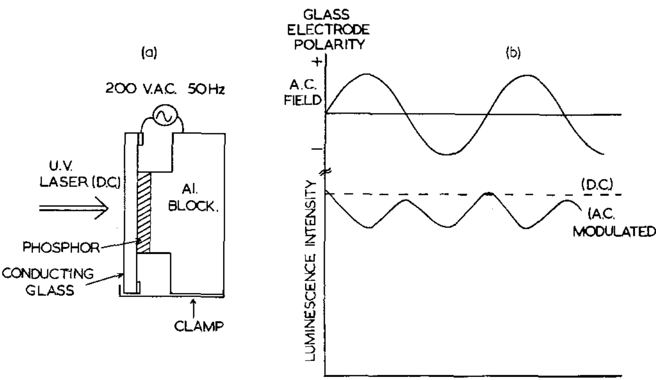

Fig. 5. (a) Sandwich cell structure used in a-c electric field modulation of PL under Ar^+ laser excitation. (b) Upper curve shows phase of applied electric field. Lower curves show schematically the PL output in the absence of field (- - - - -) and when a field is applied (————). The form of the modulation is similar for all ^5D states.

It should be noted that the light output is a maximum whenever the applied field is zero, and is partially quenched by any nonzero field. The form of the modulation was basically similar for all the ^5D_j ($j = 2,1,0$) states, the peak-peak modulation as a fraction of the unmodulated d-c light level being shown in Table I. Hence all three states are sensitive to the application of an electric field, the $^5D_2$ being slightly more sensitive. This is in fact the same relative pattern of behavior as is observed in the drooping under electron beam excitation. Thus whereas the droop phenomenon cannot be explained by a thermal perturbation of the system kinetics the experimental data are entirely consistent with an electrical perturbation. The nature of this perturbation, and a possible model, are discussed in more detail below.

Electric Field Effects on Cathodoluminescence

The quenching of both PL and CL of phosphor materials by electric fields is a well-known phenomenon and has been extensively reviewed by Ivey (22). Both bulk conductivity and surface effects may be important when considering the effects on the luminescence process. For example Dean and Male (23) have demonstrated a correlation between the bulk electrical conductivity of diamond, measured as conduction counting efficiency, and the electric field induced quenching of β-scintillations, the electric fields extracting secondary carriers and causing spatial separation of electrons and holes. Similarly Satchell (24) has shown that electric field modulation of the CL of ZnS:Mn crystals only occurred when the whole crystal volume between the electrodes was excited by the electron beam, *i.e.*, when the bulk conductivity in the interelectrode region was increased by excitation.

The importance of surface effects has been shown in many ways. Kallman and his collaborators (25) have made extensive investigations of the changes in electrical conductivity which can occur when fields are applied to excited phosphors, and have shown that a state of "persistent internal polarization" can be created by separation of charges in the bulk material. Accumulation of charge at the natural barrier formed by the crystal surface may occur, and could be particularly important in powder material with a large surface/volume ratio. Charge storage near the surface of ZnS crystals has similarly been directly demonstrated (26), and in 1956 Laponsky *et al.* (27) postulated that space charges were created in a phosphor screen during exposure to the electron beam, and that these space charges acted to control the secondary electron emission ratio of the screen. This postulate was necessary in order to explain the lack of a definite "sticking potential" for nonaluminized powder screens.

There have also been more direct demonstrations of the effect of surface charges on luminescence. For example Sedgwick (28) has shown that both quenching and enhancement of luminescence in ZnO can occur according to whether the surface is charged negative or positive by corona discharge, and the importance of space charge in the surface region of II-VI crystals in controlling both the Gudden-Pohl memory and luminescence quenching has been discussed by Peka and Proskura (29).

Table I. Approximate percentage modulation of PL intensity by application of an a-c electric field to Y_2O_2S:Eu(0.1%)

State	Modulation (%)
$^5D_2$	16
$^5D_1$	11
$^5D_0$	10

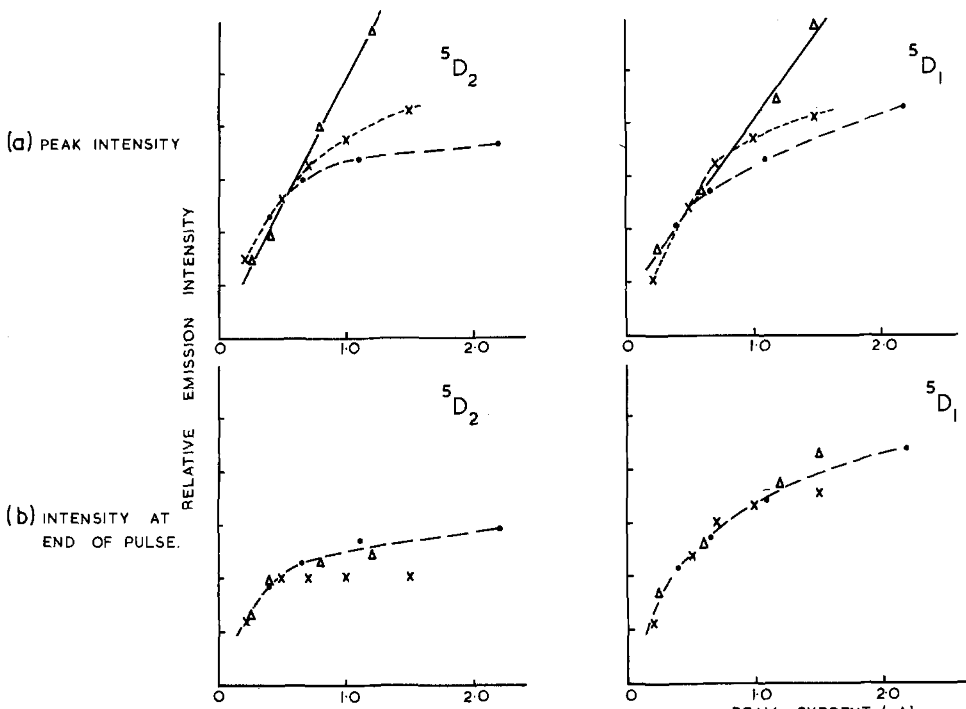

Fig. 6. Current saturation of Y_2O_2S:Eu(0.1%) plotted from Fig. 4. △ = Powder settled on conducting glass substrate; × = sealed, aluminized CRT screen; ● = powder spread on conducting adhesive matrix. (Curves normalized at 0.5 μA.)

There is thus a considerable accumulation of evidence to support the idea that some electrical perturbation could quench the light output and therefore be responsible for the droop phenomenon in Y_2O_2S:Eu, and that this perturbation might be caused by the buildup of surface charge and associated space charge fields under electron beam bombardment. The effects on the saturation characteristics of the phosphor are shown in Fig. 6, where the peak light intensity and the intensity at long times after the onset of the electron beam pulse are plotted as a function of beam current for the materials whose output profiles are given in Fig. 4 (30). The significant points are: (*i*) The saturation of both $^5D_2$ and $^5D_1$ emission is generally more pronounced at long times, except for the epoxy-mounted material which shows the same behavior throughout the pulse. (*ii*) Emission from the $^5D_2$ state shows greater saturation effects than that from $^5D_1$ (or $^5D_0$). (*iii*) At short times after the onset of the pulse the nonaluminized settled sample shows the least, and the epoxy-mounted material the greatest saturation, the aluminized screen being intermediate between these two. At long times all the samples reach an equilibrium output and show similar saturation behavior for any particular emitting state.

There are two particular experiments which provide useful guidelines for developing at least a qualitative explanation of these effects in Y_2O_2S:Eu. First, Struck and Fonger (20) have shown that the CT state can be thermally ionized leading to energy storage by charge separation and trapping; secondly, Dobrov and Buchanan (31) have shown that excitation into both the CT state and into the $^5D_2$ state produces photoconductivity in La_2O_2S:Eu single crystals, and that there is a correlation between the temperature dependence of the photoconductive response for $^5D_2$ excitation and thermal quenching of the $^5D_2$ state. In contrast excitation of $^5D_1$ and $^5D_0$ does not lead to conductivity at 300°K. Both experiments suggest that the dissociation

$$Eu^{3+}\ (CT) \rightleftarrows Eu^{2+} + \text{hole} \qquad [4]$$

produces mobile holes as majority carriers.

In order to explain the experimental results reported above we therefore propose the following model: that accumulation of charge in surface states of the Y_2O_2S:Eu phosphor generates electric fields within the powder grains which can accelerate dissociation of the CT state, creating charge separation, and which can cause quenching of the $^5D_2$ state directly. By analogy with the photoconductive response of La_2O_2S:Eu, there would be no significant direct emptying of the $^5D_1$ and $^5D_0$ states by these fields at 300°K. The precise form of the electric fields is not clear, but it is possible that accumulation of negative charge in surface states of the grains would cause drift of the mobile holes towards the surface region, and would markedly affect the nature of the surface states and surface potential which largely determine the nonradiative recombination probability for excess carriers reaching the particle surface. The data in Fig. 6 may then be interpreted to mean that there exist surface states of Y_2O_2S:Eu lying above the Fermi level which can be filled either by capture of low energy secondary electrons generated by the incident beam, as in the conventionally settled material, or by intimate contact with the silver-loaded epoxy adhesive which is assumed to have a Fermi level above the surface states. In the latter case the states are filled irreversibly before excitation so that the incident beam has little further effect on the surface potential, the equilibrium light output characteristic of the quenched state is reached instantaneously, and no droop is observed. When the phosphor is settled in the normal way, however, the surface states are largely empty and come to equilibrium relatively slowly following application of the electron beam as low energy secondary electrons are trapped. In this case the light output initially rises rapidly towards some steady-state level characteristic of the phosphor with empty surface states, but is then quenched towards the new equilibrium value as the surface states are filled. The traps fill and empty reversibly during the duty cycle, giving rise to the observed droop behavior. When the traps are filled by either mechanism the phosphor shows a common saturation behavior, as shown by Fig. 6(b), *i.e.*, the states induced by a long pulse and by mixing with a conducting matrix are similar.

The qualitative effect of the space charge field associated with the filled surface traps on the relative populations of the ^5D_j states may be illustrated in the following way. In the absence of electric field perturbation and activator ion saturation the steady-state populations of the CT state and the ^5D_j states may be written as

$$C = \frac{G + \sum_j a_{jc} D_j}{\sum_j a_{cj}} \quad [5]$$

$$D_j = \frac{a_{cj} C + \sum_{j'} a_{j'j} D_{j'}}{a_{jc} + a_j} \quad [6]$$

where G is the rate of CT excitation, a_{cj} is the crossover rate from the CT state to ^5D_j etc., a_j is the sum of rates for all downward transitions from ^5D_j, $a_{jc} \propto a_{cj} \exp[-E_j/kT]$, and E_j is the energy gap between the CT state and ^5D_j. The effects of an electric field can be introduced in a simplified fashion if we assume that the induced field is a function of both beam current and pulse length

$$E = E(I, t) \quad [7]$$

and that it approaches some steady value E° for sufficiently long pulses. The steady-state equations [5] and [6] would then be modified to include field-dependent term

$$C^e = \frac{G + \sum_j a_{jc} D_j^e}{\sum_j a_{cj} + a_{ce} E^\circ} \quad [8]$$

$$D_j^e = \frac{a_{cj} C^e + \sum_{j'} a_{j'j} D_{j'}^e}{a_{jc} + a_j + a_{je} E^\circ} \quad [9]$$

where a_{ce} and a_{je} represent rates of field-induced loss processes from the CT state and from ^5D_j. In fact the photoconductivity data show that at 300°K a_{je} is only significant for $j = 2$, *i.e.*, for the $^5D_2$ state (31). Analysis of these equations shows that an electric field will lead to quenching of the steady-state populations of the CT state and of all ^5D_j states ($j = 2, 1, 0$). Because of the term in a_{2e}, however, the $^5D_2$ state is quenched to a greater extent than $^5D_1$, and $^5D_0$, these latter states being expected to behave rather similarly. This is in qualitative agreement with the droop behavior of the lines (Fig. 4) and with the observed modulation of the line intensities by an applied a-c field (Table I).

Discussion

We first consider the relevance of these observations to practical CRT screens (6). The dwell time of the beam at TV scan rates is of the order $0.5\text{-}1.0 \times 10^{-7}$ sec, much shorter than the pulses used in our experiments, so that the results reported here are more directly relevant to slow writing speeds or cursive displays. However the rate of filling of surface traps will rise with beam current, and at moderate drive currents in CRT's ($\sim$ 1-5 A cm^{-2}) total charge dosage similar to that in our experiments could be delivered during a short dwell time. Charge loss by leakage would certainly be less during a short excitation period. Hence the light output from the CRT screen might be perturbed by these effects if sufficient charge were deposited during the dwell time to change significantly the surface potential, or if the surface states were relatively slow to relax so that a gradual accumulation occurred during screen operation. The existence of a state of persistent internal polarization in phosphor materials is evidence of the possibility of such long-lived space-charge fields. The concept of space-charge fields may also be relevant to the irreversible loss in light output often observed in CRT screens, *i.e.*, to the problem of aging. Laponsky *et al.* (27) have shown that during the life of a nonaluminized tube the secondary electron emission ratio is changed, and it was suggested that this was caused by changes in the space-charge fields in the phosphor layer affecting the "sticking potential." It is therefore conceivable that as the total charge dosage received by the screen increases the nature of the phosphor surface states and the space-charge distribution are changed in such a way as to produce greater perturbation of the light output. For example any residual organic matter on the phosphor after aluminizing, the silicate binder, or the phosphor itself could be gradually decomposed by the beam, thereby changing the effective surface properties of the screen. Indeed the decomposition of willemite has recently been reported under electron beam bombardment (32).

In order to reduce these field-induced quenching effects one might conceive the preparation of phosphor particles essentially free of surface trapping states, or with bulk conductivities sufficiently large to screen the interior of the particle from the surface potential. It might also be possible to include in the screen a material with a Fermi level lying below the level of the phosphor surface states in such a way that it acts as a sink for emptying these states, rather than filling them as in the case of the silver-epoxy. In addition however it is probable that CRT screening methods can affect the surface properties and hence the saturation characteristics of the phosphor, since from Fig. 6 it can be seen that the degree of saturation of the sealed CRT at short times after application of the electron beam pulse is worse than that of the nonaluminized settled material. The implication is therefore that the screening process leads to partial filling of the existing surface traps in the material, or changes the nature or number of these traps so that they are more rapidly filled by the incident beam.

Finally we note that the proposed quenching mechanism, involving field-induced ionization of the CT state and subsequent spatial separation of electrons and holes, is formally similar to the Poole-Frenkel effect in semiconductor materials, in which the ionization energy of a donor is lowered by an applied electric field (33). It should be noted that the activator concentration in this investigation has been kept deliberately low so that emission from the $^5D_2$ state could be observed. This situation is probably favorable to field-induced quenching since the diffusion length of separated electrons and holes will not then be limited by retrapping at activator sites, with subsequent light emission. The droop effect reported here may then be less significant at higher activator concentrations. Similarly the inclusion of co-dopants in the lattice could affect the electrical properties of the phosphor, and in this connection it is of interest to note the report by Yamamoto *et al.* (34) that small quantities of Pr^{3+} or Tb^{3+} in Y_2O_2S:Eu reduced the current saturation of the phosphor. These ions are often considered to act as hole trapping centers and may therefore limit the field-induced drift of holes towards nonradiative recombination centers in Y_2O_2S:Eu.

Conclusions

It has been shown that the saturation characteristics of conventionally settled Y_2O_2S:Eu (0.1%) are different at short and long times after the onset of electron beam excitation, and that the transition between the two limits is associated with a droop in the CL light output during long electron beam pulses. This droop and the associated saturation cannot be caused by an increase in phosphor temperature as commonly suggested for other systems (11), since the data are not consistent with the known differential thermal behavior of the various excited ^5D_j states. Neither can the droop be explained by depletion of the activator ground state population, nor by gross charging effects because the phenomenon is also observed in an aluminized screen.

Since none of the conventional models of current saturation can successfully account for these observations, a new model has been proposed. In this model saturation is the result of kinetic perturbations caused by space-charge electric fields which are themselves created by the filling of surface states in the phosphor

particles. These states may be filled either by application of sufficient charge to the phosphor, as during prolonged pulses of low current density, or by intimate mixing of the phosphor with a material having a relatively high Fermi level, *e.g.*, the silver-loaded epoxy adhesive. Whatever the means of filling the traps, the data in Fig. 4 and 6 show that the result is to produce a quenched light output, and a common saturation curve. Predictions based on a simple kinetic model involving field-induced ionization of the CT state and quenching of the $^5D_2$ state are in qualitative agreement with the observed droop characteristics. Such a model would be consistent with the general observation that CL saturation effects are greater at lower beam potentials (1), since the excitation is then produced nearer the surface and the system kinetics will be more sensitive to the surface potential. Improved control of the surface properties of a phosphor may therefore produce both better saturation characteristics and higher efficiency under low energy excitation.

At sufficiently high current densities of course an appreciable temperature rise may also occur at the screen. What we suggest here is that saturation phenomena may be caused by space-charge field effects at more moderate current densities, before significant heating takes place, if the particular activator/lattice combination involved is itself susceptible to electric field quenching of the luminescence.

Submicron GaAs Epitaxial Layer from Diethylgalliumchloride and Arsine

Yoshiro Nakayama, Shinji Ohkawa, Hisao Hashimoto, and Hajime Ishikawa*

Fujitsu Laboratories Limited, Nakahara-ku, Kawasaki, Japan 211

ABSTRACT

A submicron GaAs epitaxial layer has been grown using diethylgalliumchloride (DGC) and arsine on semi-insulating substrates. Layers with a mirror-smooth surface have been grown at a low temperature of 530°C. The growth rate can be controlled and 0.01 μm/min is easily obtained by adjusting the temperature of the DGC source. The epitaxial layer without intentional doping is n-type and carrier concentration depends on the mole ratio of arsine to DGC in the gas introduced into the reactor. The mole ratio dependence of carrier concentration shows the opposite tendency to that in the growth using TMG or TEG. Carrier profile with steep decrease at the interface is obtained in the epitaxial layer.

The epitaxial growth of GaAs from an alkylgallium compound and arsine has the following advantages over growth in a $Ga\text{-}AsCl_3\text{-}H_2$ system: (*i*) a simple apparatus having only one high temperature zone, (*ii*) a relatively low growth temperature which decreases the autodoping effect, and (*iii*) ease of heteroepitaxy (1, 5). In most studies concerned with this growth technique, trimethylgallium, $(CH_3)_3Ga$ (TMG), or triethylgallium $(C_2H_5)_3Ga$ (TEG), was used as a gallium source (1-6). A very thin GaAs epitaxial layer is required for microwave electronic devices, *e.g.*, a 0.2-0.3 μm thick layer for field effect transistors. Diethylgalliumchloride, $(C_2H_5)_2GaCl$ (DGC), has lower vapor pressure and lower reactivity than TMG and TEG (7), properties of which are well suited to obtaining such a thin layer. This paper reports the growth characteristics and the electrical properties of the submicron GaAs epitaxial layer grown on (100) oriented semi-insulating GaAs substrate using DGC as the gallium source and arsine as the arsenic source.

Experimental Conditions

Growth apparatus.—The growth apparatus is schematically shown in Fig. 1. The reactor is a horizontal quartz tube containing a SiC-coated carbon susceptor heated inductively. The diameter and the length of the tube are 63 mm and 80 cm, respectively. DGC was obtained commercially and used without further purification. Vapor of DGC was transported to the substrate by bubbling nitrogen gas through the liquid DGC. The concentration of the DGC vapor was controlled by heating the bubbler and/or by varying the flow rate of the bubbling gas. The temperature of the bubbler was in the range of room temperature to 60°C. The concentration of DGC was determined from amounts of CO and CO_2 formed by the reaction of DGC on oxygen. The mixture of nitrogen through the liquid DGC and oxygen at a flow rate of 100 ml/min was heated to 800°C. At this temperature, carbon atoms in the DGC molecule reacted on oxygen and became CO and CO_2, amounts of which were determined by the gas phase chromatography. Arsine diluted to 1% in nitrogen gas was mixed with DGC vapor just before entering into the reactor. In addition, hydrogen gas at a flow rate of 1000 ml/min and nitrogen gas were used as carrier gases. The flow rate of the nitrogen gas was controlled to make the total gas flow rate constant, 2500 ml/min. In this system, oxygen and water were eliminated by passing through a purifier. Concentrations of oxygen and water in the carrier gas after purification were less than 2 and 5 ppm, respectively.

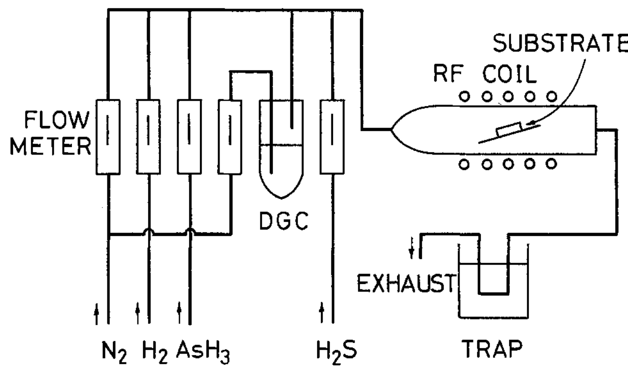

Fig. 1. Schematic of growth apparatus

Stainless steel tubing is widely used in the growth apparatus when TMG or TEG is employed as a gallium source. In this experiment, however, Teflon tubing was used because DGC potentially reacts on stainless steel.

Procedure.—The epitaxial growth was carried out on the boat-grown semi-insulating GaAs substrate doped with chromium. The orientation of the substrate was (100) or 2° off from (100) to (110). The substrate was obtained commercially with one face polished and was etched to remove 20-30 μm from the depositing surface with H_2SO_4:H_2O_2:H_2O (90:5:5) etchant just before the deposition. The substrate was placed on the susceptor and heated in the hydrogen-nitrogen mixture. When the temperature of the substrate was raised to 500°C, arsine was introduced into the reaction tube to prevent substrate decomposition. At a desired temperature, the substrate was maintained for additional 10 min before the introduction of DGC. Arsine flow was continued until the temperature dropped to 500°C after the growth had been completed. In this procedure, the temperature was monitored by an optical pyrometer. The error of the temperature measurement was less than 5° at 550°C.

Thickness determination.—The thickness of a grown layer was determined by the following methods.

(*i*) A substrate was partly covered with 2000Å thick SiO_2 film. After the growth, the SiO_2 film was etched off and the thickness of the epitaxial layer was determined by Talystep (Taylor Hobson). The layer was thicker near the edge of the covering SiO_2 film; therefore, thickness was measured at a distance of more than 500 μm from the edge.

(*ii*) A cleavaged plane was stained by HF:H_2O_2:H_2O (1:1:10) staining solution. The thickness of the stained layer was measured by a microscope. For a submicron

layer, scanning electron microscope was employed to determine the thickness.

(*iii*) Schottky barriers were formed on the grown layer. The thickness of the layer was obtained from the carrier profile determined by *C-V* measurement. This method was used only for the sample in which the depletion region reached the interface between substrate and epitaxial layer within the breakdown voltage of the Schottky barrier.

Growth Characteristics

Surface feature.—In the case of growth without hydrogen gas, the surface of a wafer appeared to be brownish. This was caused by a thin film covering the surface, which was not etched with an etchant for GaAs. By introduction of hydrogen gas into the reactor, deposition of this thin film was eliminated. These results show that the carbon from the ethyl radical in a DGC molecule is deposited on the wafer. This may be interpreted as follows: in the reaction system without hydrogen, partial pressure of nitrogen is high because nitrogen gas is used as the carrier and arsine is diluted with nitrogen. An ethyl radical in a DGC molecule may be thermally decomposed into carbon and hydrogen in this system. In order to prevent this decomposition, it is necessary to increase the partial pressure of hydrogen by introduction of hydrogen gas. Thus the ethyl radical forms a gaseous hydrocarbon such as ethane and is exhausted from the reactor.

Effects of the substrate off-orientation and the growth temperature on the surface feature were examined. A mirror-smooth layer was obtained on the substrate 2° off-oriented from (100) to (110) over the growth temperature of 530°-600°C, while many hillocks, as shown in Fig. 2(a), were observed in the layer deposited on the (100) oriented substrate over the same temperature range. For growth at a temperature higher than 600°C or lower than 530°C, a fine-ripple feature was observed even on 2° off-oriented substrate as shown in Fig. 2(b). The characterization of the epitaxial layer was carried out for the mirror-smooth layer in this experiment.

Electron diffraction patterns of the 2 μm thick layer were observed by the reflective method. A halo pattern was observed on the as-grown surface while Laue spots and Kikuchi lines were observed on a few hundred angstroms etched surface. This shows that the amorphous layer of a few hundred angstroms thick is formed on the as-grown layer. In the growth stage after stopping DGC flow, an anomalous growth may take place due to the imbalance between the concentrations of arsenic and gallium. This causes the thin amorphous layer at the surface.

Growth rate.—Growth was carried out under the following conditions: temperature of 500°-700°C, DGC flow rate of 2×10^{-6}-1×10^{-4} mole/min, and arsine flow rate of 2×10^{-5}-3×10^{-4} mole/min. The growth rate at the arsine flow rate of 2×10^{-4} mole/min is shown in Fig. 3 as a function of the growth temperature and the DGC flow rate. The growth rate is slightly changed with the growth temperature, but increases considerably with the DGC flow rate. The dependence of the growth rate on the DGC flow rate is linear. This shows that the growth rate is limited by the mass transport mechanism under the above conditions.

Uniformity of thickness.—The effect of a facing angle of the substrate to the gas flow on a thickness uniformity over the surface was examined. Curve 1 in Fig. 4 shows the thickness distribution of the epitaxial layer grown on the substrate which was placed parallel with the gas flow. The abscissa of Fig. 4 represents the distance from the upper edge of the substrate. The thicker layer is observed at the upper edge and the change in thickness is considerably large near the edge. Curve 2 shows the thickness distribution in the layer on the substrate placed perpendicular to the gas flow in the reactor. As can be seen, the uniformity of thickness was improved by placing the substrate perpendicular to the gas flow. The growth rate of GaAs depends mainly on the flow rate of DGC, namely the gallium concentration, in this experiment as shown in Fig. 3. Concentrations of gallium and arsenic in the reactor decrease downstream since gallium and arsenic atoms are used for GaAs deposition. Therefore, the growth rate also decreases downstream, that is, the thickness of the layer grown on the parallel-placed substrate decreases downstream. On the other hand, in the case of the growth on the substrate placed perpendicular, the thickness uniformity depends mainly on the distribution of the reacting species over the cross section of the reaction tube. When the area of the substrate is smaller than the cross-sectional area of the reaction tube, good uniformity of thickness could be obtained. The evaluation of the epitaxial layer was carried out for the layer grown on the perpendicular-placed substrate.

Electrical Properties

Schottky diodes and a Hall bridge with a Schottky barrier which introduces a depletion region were fab-

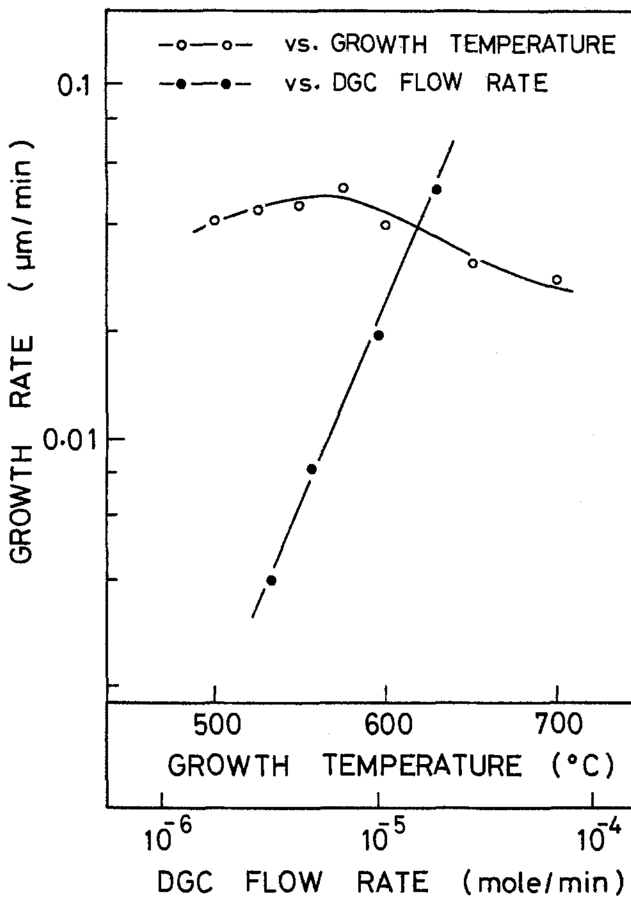

Fig. 3. Growth rate *vs.* growth temperature and DGC flow rate at arsine flow rate of 2×10^{-4} mole/min.

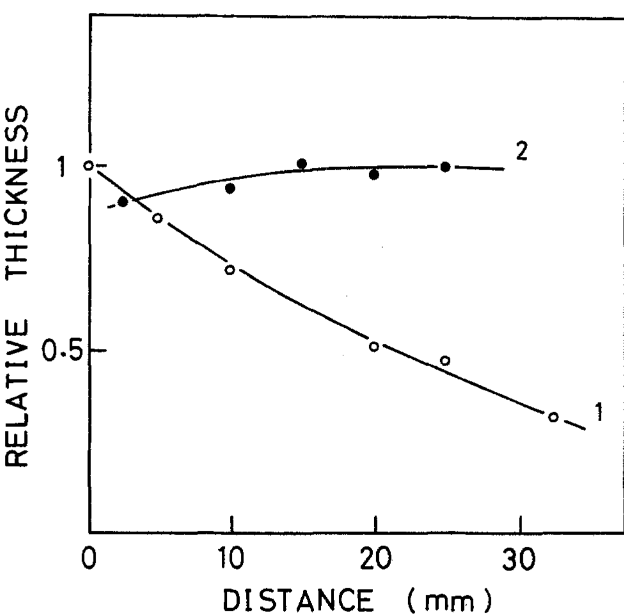

Fig. 4. Thickness distribution over the surface. Curves 1 and 2 represent thickness in the layer placed parallel and perpendicular to the gas flow, respectively.

ricated in the epitaxial layer for determination of electrical properties. The schematics of these devices are shown in Fig. 5. The width of the depletion region and hence the cross section of the conducting channel could be varied by biasing the Schottky barrier. The Schottky barrier was formed by evaporating Al and the ohmic contact was formed by alloying Au-Ge at 450°C.

Carrier concentration.—From the Hall measurement, all the epitaxial layers grown in this experiment were

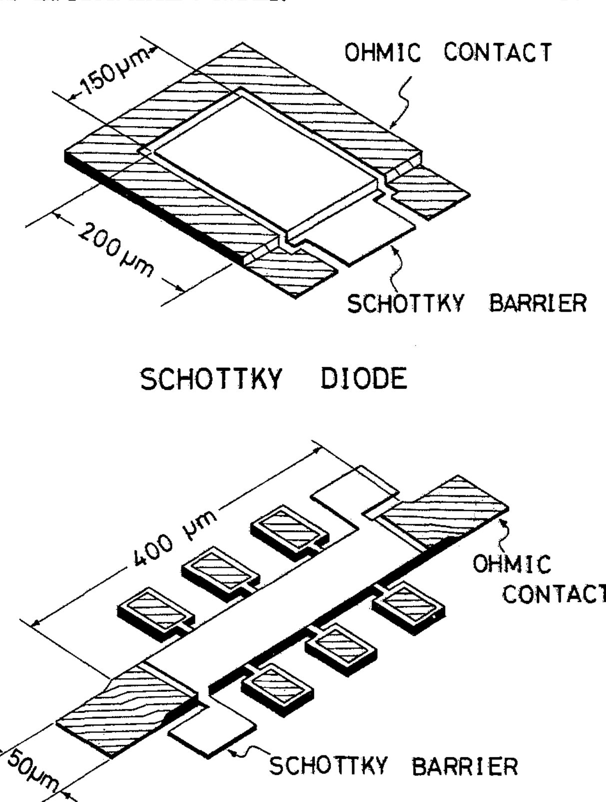

Fig. 5. Schottky diode and Hall bridge used for electrical property determination.

found to be n-type without intentional doping. Figure 6 shows the carrier concentration determined by C-V measurement as a function of the concentration ratio of arsenic to gallium, namely the mole ratio of arsine to DGC. The carrier concentration decreases with increasing the concentration ratio and very low carrier concentration was obtained for the large value of the ratio. It has been reported that conductivity of the epitaxial layer grown by using TMG or TEG depends on the mole ratio of arsine to the gallium source (5,

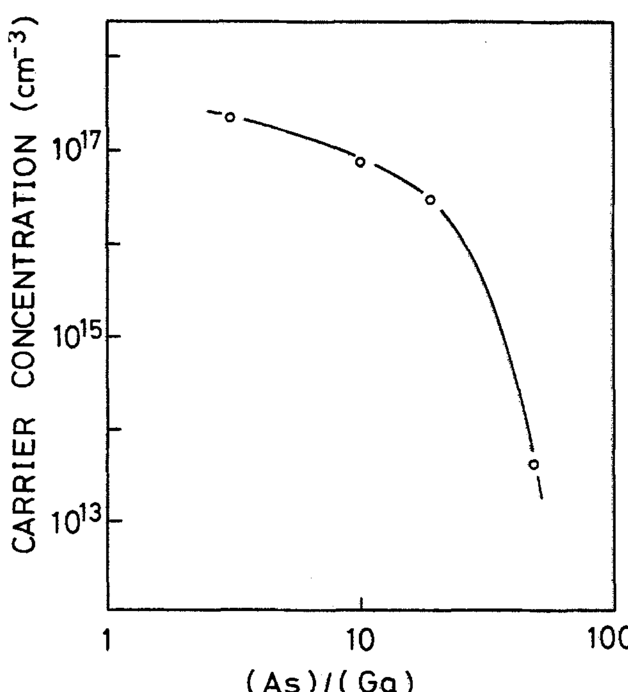

Fig. 6. Carrier concentration *vs.* concentration ratio of arsenic to gallium (As)/(Ga).

6). In those cases, carrier concentration of the n-type layer increases and that of the p-type layer decreases with increasing the mole ratio. This has been interpreted as follows: an atom of amphoteric impurity in a gallium site acts as a donor and that in an arsenic site acts as an acceptor. This amphoteric impurity is estimated to be an element of Group IV such as carbon or silicon contained in the gallium source. This interpretation, however, is not applicable to the result obtained here, in which the dependence of n-type carrier concentration on the mole ratio is opposite to that of the TMG or TEG source as described above. The mole ratio dependence in this experiment suggests that an atom of Group VI element in an arsenic site, rather than an atom of Group IV element in a gallium site, acts mainly as a donor.

Hall mobility.—Average Hall mobilities over the epitaxial layer determined by using the Hall bridge with a Schottky barrier were 5070 and 3500 cm^2/V sec for the carrier concentration of 5×10^{16} and 2×10^{17} cm^{-3}, respectively. These values are almost equal to the mobility of the epitaxial layer grown in the Ga-$AsCl_3$-H_2 system. The average Hall mobility $\bar{\mu}(z)$ and the sheet conductance $\sigma_S(z)$ in the conducting channel were measured as a function of the distance from the interface, z, by biasing the Schottky barrier of the Hall bridge. The absolute Hall mobility $\mu(z)$ was calculated using the following equation (8)

$$\mu(z) = \bar{\mu}(z) + \sigma_S(z)\partial\bar{\mu}(z)/\partial\sigma_S(z)$$

Figure 7 shows the profiles of the carrier concentration and the absolute mobility of the layer grown on the semi-insulating substrate. The carrier concentration changes very steeply near the interface between the grown layer and the substrate. Hall mobility decreases abruptly at the position of about 800Å from the interface toward the surface. It is observed also in the epitaxial layer grown in the Ga-$AsCl_3$-H_2 system that Hall mobility decreases at a point shallower than the interface determined from the profile of carrier concentration. This may be mainly caused by the increase of the space-charge scattering which is due to an anomalous growth such as deviation from the stoichiometry in the initial stage of growth (9).

Figure 8 shows the temperature dependence of Hall mobility at a distance of 0.26 μm from the surface, together with the corresponding mobilities calculated

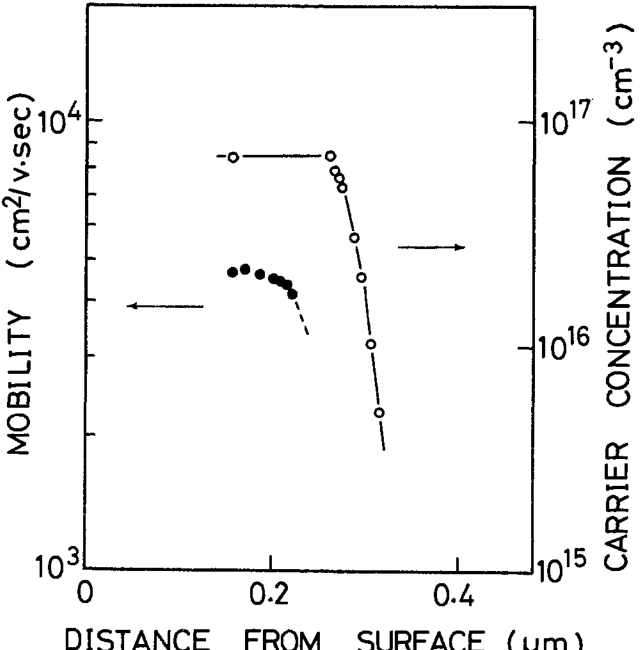

Fig. 7. Profiles of carrier concentration and Hall mobility

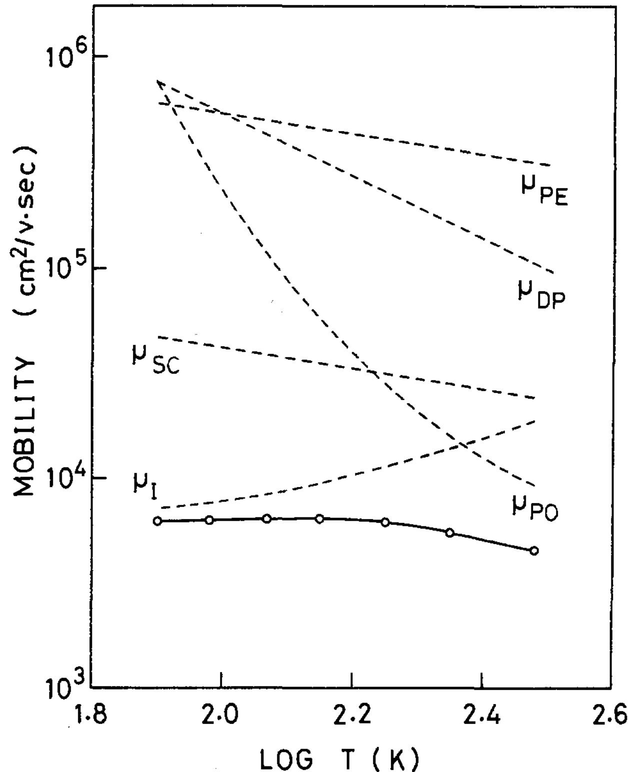

Fig. 8. Temperature dependence of Hall mobility. μ_{SC}, μ_I, μ_{PO}, μ_{DP}, and μ_{PE} represent the mobilities corresponding to space-charge, ionized impurity, polar optical phonon, deformation potential, and piezoelectric scattering, respectively.

for the various scattering mechanisms. μ_{DP}, mobility due to deformation potential scattering (10), and μ_{PE}, mobility due to piezoelectric scattering (11), are functions of absolute temperature, and μ_{PO}, mobility due to polar optical phonon scattering (12), is a function of absolute temperature and carrier concentration which were determined by C-V measurement. Therefore, μ_{DP}, μ_{PE}, and μ_{PO} can be calculated. μ_{SC}, mobility due to space-charge scattering (13), and μ_I, mobility due to ionized impurity scattering (14), are functions of absolute temperature and N_sA, and absolute temperature and concentration of ionized impurity, $N_A + N_D$, respectively, where N_sA is the product of the density and scattering cross section of the space-charge regions. The reciprocal of absolute mobility is expressed as the sum of the reciprocals of these mobilities due to various scattering mechanisms. The open circles in Fig. 8 represent the measured values and the solid line is the theoretical curve with an optimum fit to the measured points.

The value of μ_I is somewhat smaller, that is, the acceptor concentration is somewhat higher, but μ_{SC} is considerably larger than that of the layer grown in the Ga-$AsCl_3$-H_2 system. An amphoteric impurity, such as carbon generated from DGC, in an arsenic site may cause the higher acceptor concentration. The smaller space-charge scattering is estimated to be a result of lower growth temperature.

Doping Characteristics

The carrier concentration of the epitaxial layer depends on the mole ratio of arsine to DGC as mentioned above. In this experiment, a low concentration ratio of (As)/(Ga), that is, a high flow rate of DGC and/or a low arsine flow rate, was necessary to grow an epitaxial layer with higher carrier concentration. A high DGC flow rate results in a high growth rate which makes the growth of a very thin layer difficult and a low arsine flow rate may cause the unstable growth. In order to (i) obtain a carrier concentration higher than 10^{18} cm^{-3} without increasing the growth rate and

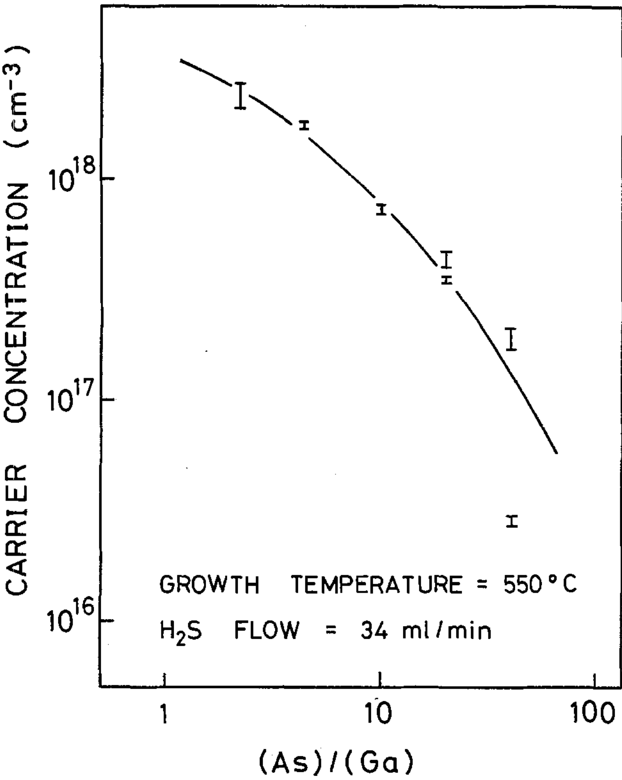

Fig. 9. Carrier concentration of sulfur-doped layer vs. (As)/(Ga)

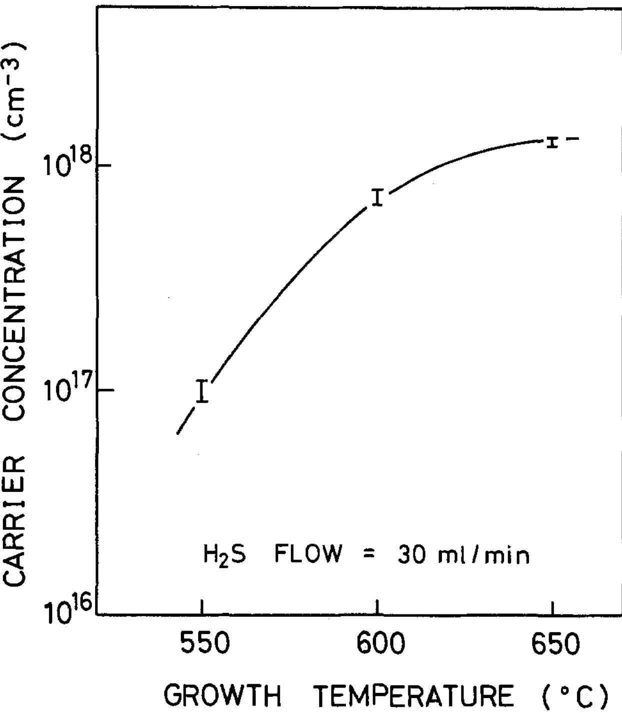

Fig. 10. Growth temperature dependence of carrier concentration of sulfur-doped layer.

(*ii*) control the carrier concentration with more accuracy, impurity doping was investigated.

Hydrogen sulfide diluted to 0.01% in nitrogen gas was used as a doping source. The doping gas was introduced into the reactor together with arsine when the substrate temperature was raised to 500°C. No considerable effect of the doping gas introduction was observed on the surface feature and the growth rate. Figures 9 and 10 show the carrier concentration as a function of the concentration ratio (As)/(Ga), which is equal to the mole ratio of arsine to DGC, and of the growth temperature, respectively. The mole ratio dependence of the carrier concentration has a similar tendency to that of the undoped epitaxial growth. This confirms the suggestion that the donor impurity in the undoped layer is an element of Group VI. By using this doping technique, a carrier concentration as high as 2-3 $\times$ 10^{18} cm^{-3} was easily obtained. Electrical properties of the sulfur-doped layer were almost similar to those of the undoped layer having the same carrier concentration.

Conclusion

Very thin GaAs epitaxial layers have been grown from DGC and arsine. The growth rate depends mainly on the concentration of gallium in the gas introduced into the reactor and can be easily controlled to lower than 0.01 μm/min by adjusting the temperature of the DGC source. Without intentional doping, n-type layers are obtained and the carrier concentration in the layer can be changed by varying the mole ratio of arsine to DGC in the gas flow, the increase of which results in the decrease of the carrier concentration. From the mole ratio dependence of the carrier concentration, the donor impurity is considered to be an element of Group VI in an arsenic site.

The carrier concentration of the epitaxial layer on a semi-insulating substrate decreases steeply at the interface between the epitaxial layer and the substrate. Hall mobilities of a 0.3 μm thick layer are 5070 and 3500 cm^2/V sec at room temperature for the carrier concentrations of 5 $\times$ 10^{16} and 2 $\times$ 10^{17} cm^{-3}, respectively.

Acknowledgments

The authors wish to thank Dr. M. Maeda for useful advice and encouragement during the course of this work. The electron diffraction study was performed by Mr. T. Furusawa and the measurement and analysis of Hall mobility were performed by Mr. N. Yokoyama. We also thank Mr. T. Matsumura for sample preparation.

Incorporation of Si in Liquid Phase Epitaxial InP Layers

G. G. Baumann, K. W. Benz, and M. H. Pilkuhn

Physikalisches Institut und Kristallabor, Universität Stuttgart, 7000 Stuttgart 80, West Germany

ABSTRACT

It is demonstrated that Si is always incorporated in InP LPE layers as a shallow donor, *i.e.*, it does not exhibit the amphoteric behavior known to LPE GaAs. Si-doped InP layers were grown with a concentration of $N_D - N_A = 1 \cdot 10^{16}$-$5 \cdot 10^{19}$ cm^{-3} on (111), (110), and (100) oriented InP substrates. The growth temperature was varied from 715° to 550°C. The segregation coefficient for Si in InP LPE layers was estimated to be $k_{Si} \simeq 30$. The layers were characterized by photoluminescence measurements at 1.8°K and Hall data. No emission line (energy range 1.42-1.35 eV) due to a shallow Si acceptor was observed. The difference in amphoteric behavior of Si in InP and GaAs is discussed on the basis of the atomic radii involved.

Si is one of the most frequently used and most important dopants in III-V compound semiconductors. In principle it behaves as an amphoteric dopant depending on whether it substitutes the Group III or Group V element. In AlSb (1), GaSb (2), and InSb (2), Si enters Sb sites and acts as an acceptor. In InAs (3, 4), however, Si enters on an In site and acts as a shallow donor. In GaAs (2, 5) and GaP (6) it can be incorporated on a Ga or As(P) site, acting as donor or acceptor.

By suitable control of the growth conditions during liquid phase epitaxy of GaAs, p-type and n-type material may be grown. High efficiency electroluminescent diodes have been fabricated by this technique with Si as the dopant in both the p- and n-type side of the junction (7). The p-type material can be grown below a certain conversion temperature, T_c. T_c is dependent on substrate orientation, which was experimentally shown for GaAs by Ahn *et al.* (8). For 0.1 atomic per cent (a/o) Si in the solution, T_c lies between 770° [(111)B substrates] and 918°C [(111)A substrates].

In previous studies, it was reported that InP:Si is always n-type (9, 10), even in the case of LPE layers, while the material was found to be rather inhomogeneous (10). The aim of this paper is to investigate what percentage of Si can be incorporated during LPE on P sites as a shallow acceptor. Detailed photoluminescence measurements at 1.8°K as well as Hall measurements were made at a series of LPE layers. The growth and incorporation of Si as a function of growth temperature and substrate orientation in search of a possible conversion temperature, T_c, was studied.

Low temperature photoluminescence measurement is a very sensitive tool in detecting a compensating acceptor level. The result of this study is that Si is not incorporated as a shallow acceptor even at high donor (Si) concentrations.

Experimental Procedure

The layers were grown by LPE using a horizontal tipping system (11). The arrangement of the apparatus and the way in which the growth process was performed is discussed in more detail elsewhere (12).

Before the Si dopant was added to the In-P solution, high purity InP layers were grown in order to test the purity of the whole epitaxial system. The best values of net electron concentration and Hall mobility of these undoped layers were $n = 2 \cdot 10^{14}$ cm^{-3} (300°K) and $\mu = 35{,}000$ cm^2 V^{-1} sec^{-1} (77°K). A very important point in our study of the doping behavior of Si was the elimination of additional donors and acceptors other than Si in the layer.

Key words: InP, liquid phase epitaxy, Si doping behavior, photoluminescence.

Special care was taken to determine the saturation temperature, T_s, before every growth series. Each growth series consisted of several growth runs. During each series the In-P solution remained unchanged. With the exact knowledge of T_s one can establish reproducible growth conditions at the beginning of each growth series.

On the basis of the amounts of In (Cominco, U.S.) and InP (MCP, England, $n = 2 \cdot 10^{15}$ cm^{-3}), T_s was roughly calculated from the phase diagram (13). For an experimental and more exact determination of T_s, the baked In-P solution was heated up in a few minutes from room temperature to a temperature several degrees below T_s. After that, the solution was heated up in small temperature steps. At the various levels the temperature remained constant for 1 hr, and the solution was agitated gently by rotating the boat along its long axis. In approaching the saturation temperature, T_s, only some small InP crystallites were visible at the top of the solution. The crystallites disappeared within a temperature interval of 0.5°C, *i.e.*, T_s could be estimated with an accuracy of 0.5°C.

Prior to each run, the In-P solution was heated up 50°C above T_s in order to dissolve the InP quickly (Fig. 1). Then the solution was cooled down to the temperature T_{K1} which was 1°C below the previously measured saturation temperature, T_s. Before tipping the solution onto the substrate, the solution temperature was kept at T_{K1} for 5 min for homogenization. The small supersaturation of 1°C prevented an etchback of the substrate and initiated the growth of the epitaxial layer. After tipping, the solution was held at T_{K1} again for 5 min and was slowly agitated as described above.

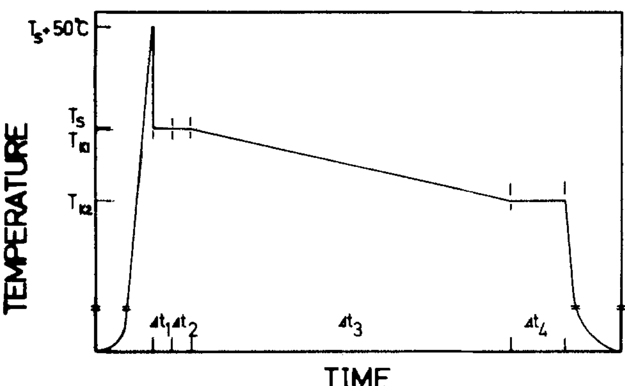

Fig. 1. Solution temperature vs. time during an epitaxial run. T_S: saturation temperature; T_{K1}, T_{K2}: tipping temperatures; $\Delta t_1 = \Delta t_2 = 5$ min; Δt_3: cooling and growth period; $\Delta t_4 = 15$ min.

Then the growth system was cooled down at a constant cooling rate. At the end of the cooling process, substrate and solution remained in contact for 15 min at the temperature T_{K2}. Finally, the substrate was withdrawn from the solution. During the whole process, no solid InP appeared at the top of the solution. Therefore, T_{K2} represented the tipping temperature, T_{K1}, for the next run.

Silicon has a rather low solubility in In (0.1 a/o at 700°C and 0.03 a/o at 610°C) (10). In order to get a low Si concentration in the layer, small Si ingots (30-90 μg) in 10g In solution were needed. Prior to use, the Si pieces ($N_D + N_A < 10^{13}$ cm^{-3}, Wacker-Chemitronic, Germany) were etched in high purity HF to remove SiO_2 and taken into the graphite boat very quickly in order to prevent oxidation.

Under these conditions, we have grown single InP layers on (111), (110), and (100) undoped and Cr-doped InP substrates. The polished substrates which were available were cut ± 2° off orientation and were etched in a solution of 1% bromine in methanol and finally rinsed with 18 megohm water (Millipore System, England). In the different experimental runs, T_{K1} was varied between 715° and 590°C. The growth time was 1.5-4 hr and the cooling rate 4°-25°C/hr.

Growth Results and Discussion

Table I shows growth results and conditions for different substrate orientations for some Si-doped layers with Si concentrations ranging from $5 \cdot 10^{19}$ to $1 \cdot 10^{16}$ cm^{-3}. All grown layers were n-type, independent of growth temperature and orientation of the substrates.

We have estimated the segregation coefficient, k_{Si}, for Si in InP LPE layers as the ratio of net electron concentration in the layer to the amount of Si in the solution. This can be written as

$$k_{Si} = (N_D - N_A) \frac{AW_{Si} \cdot W_{Sol}}{N \cdot W_{Si} \cdot \delta_{In}}$$

where $N_D - N_A$ = net electron concentration assumed equal to the concentration of Si atoms in the layer (cm^{-3}), AW_{Si} = atomic weight of Si, W_{Sol} = weight of the In solution, W_{Si} = weight of the added Si, δ_{In} = density of In = 7.30 gcm^{-3}, and N = Avogadro's number. We obtained a value of $k_{Si} \simeq 30$, which lies higher than that reported in the literature [$k_{Si} \simeq 4$ (10)]. It should be pointed out that after the first run there is a decrease in Si concentration from run to run mainly due to traces of water or oxygen which may enter the growth system and oxidize the Si to SiO_2 (14). Exact knowledge of the amount of Si in the solution is not available for later runs. Therefore, we have estimated the segregation coefficient using only the first runs from several series.

In comparing the surface morphology of Si-doped layers with that of undoped layers, we find the following.

(*i*) The undoped layers grown on (100) and (111) surfaces show two types of surface structures: a shed structure for layers grown at tipping temperatures $T_{K1} \gtrsim 650$°C (12) and a terrace structure for layers grown at $T_{K1} \lesssim 650$°C. These structures are due to misorientation of the substrates (15).

(*ii*) The surface structures of the Si-doped layers are dependent on the Si concentration and the misorientation of the InP substrates. Figure 2(a-c) shows the surfaces of layers with various Si concentrations for (100) substrate orientation. The layers with $n > 5 \cdot 10^{18}$ cm^{-3} (Fig. 2a) have a fairly flat mirrorlike surface. With decreasing Si concentration in the layer, the surface shows the typical terrace behavior of the undoped layers (Fig. 2c). An explanation of this effect may be the fact that higher Si concentration creates conditions that favor the formation of a large number of nucleating centers at the beginning of the growth (16). This will cause a reduction in step heights of the terrace structure and, as a result, the surface will be much smoother.

There is no difference in surface structure between (111)A, (111)B, and (100) surfaces. However, layers grown on (110) InP substrates always show, especially at high Si concentration, a new type of surface structure, depicted in Fig. 2d.

Photoluminescence Results and Discussion

The Si-doped LPE layers were investigated by high resolution photoluminescence measurements at 1.8°K. The layers were excited with a He-Ne laser (P = 5 mW, λ = 632 nm) or a Kr^+ laser (P = 11 mW, λ = 647 nm). The majority of the investigations were carried out on LPE layers grown on Cr-doped, semi-insulating InP substrates. These samples exhibit a broad emission near the bandgap as already reported by Astles *et al.* (10). The quantum efficiency of this emission is lower than in the case of doped layers on undoped substrates or high purity layers.

Figure 3 depicts the observed photoluminescence spectra at 1.8°K with various Si concentrations. In the energy range between 1.36-1.60 eV, two emission lines (A and B) can be resolved. With increasing Si concentration in the LPE layer, line A shifts from 1.42 eV ($n = 1 \cdot 10^{16}$ cm^{-3}) to 1.60 eV ($n = 5 \cdot 10^{19}$ cm^{-3}). At low Si concentrations line A is observed at approximately the energy gap [E_g = 1.4235 eV (17)]. Line B remains nearly constant at 1.38 eV. Figure 4 shows the position of the emission maximum of line A as a function of the net electron concentration. The half-width of the high energy line A increases significantly with doping which is shown in Fig. 5. The half-width of the emission line B does not vary with electron concentration. The position and half-width of line A remains constant with increasing excitation intensity, whereas line B shifts from 1.3759 to 1.3772 eV by increasing the excitation intensity from 4 to 76 Wcm^{-2}.

It was found unambiguously that the major emission connected with the incorporation of Si is line A, whereas line B is associated with other residual impurities as discussed later. The major observed features of line A, its shift to higher energy and line broadening with increased doping, its dependence on excitation intensity, and its position, all indicate that it is due to band-to-band transition. The shift to higher energy can be explained by a Burstein-Moss shift, resulting from the incorporation of Si as a donor. The shift of Fermi level with carrier concentration n can be expressed in the following way

$$n = 4\pi (2m^*/h^2)^{3/2} \int_0^\infty \frac{E^{1/2}}{1 + \exp[(E - E_F)/kT]} dE$$

where electron effective mass $m^* = 0.2\, m_{eo}$ (18); E is the energy related to the conduction band minimum, and tail states are neglected. The position of the Fermi level, $\xi = E_F - E_g$, was calculated with the aid of a

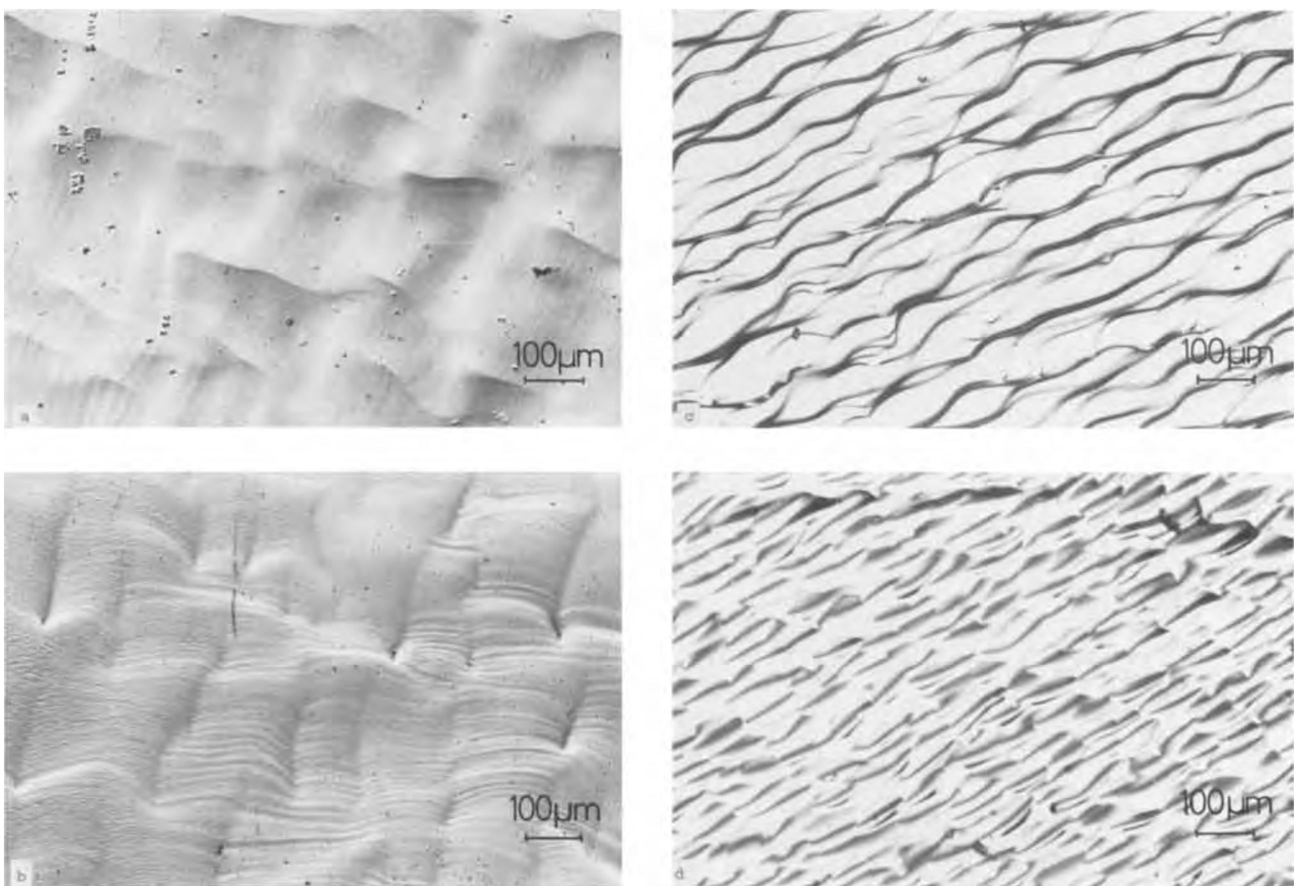

Fig. 2. Typical surfaces of InP:Si epitaxial layers grown on (100) oriented substrates (a-c) and (110) oriented substrate (d); net electron concentration of the layers: $n = 2 \cdot 10^{19}$ cm^{-3} (a), $8 \cdot 10^{18}$ cm^{-3} (b), $4 \cdot 10^{17}$ cm^{-3} (c), and $2 \cdot 10^{19}$ cm^{-3} (d).

nomogram published by Pankove and Annavedder (19). Experimentally, ξ was estimated from the high energy cutoff of line A and compared with the theoretical values for ξ (20). The experimentally deduced value for ξ and the theoretical one are plotted in Fig. 6 as a function of the net electron concentration.

The results in Fig. 6 can be taken as sufficient evidence for a Burstein-Moss shift; the deviation of the experimental data from the theoretical curve is the typical one found for InP:Te (20). The deviation is due to tail states and/or the nonparabolicity of the conduction band. In agreement with the concept of band-to-band emission and with corresponding results in InP:Te (20), the linewidth increases with carrier concentration.

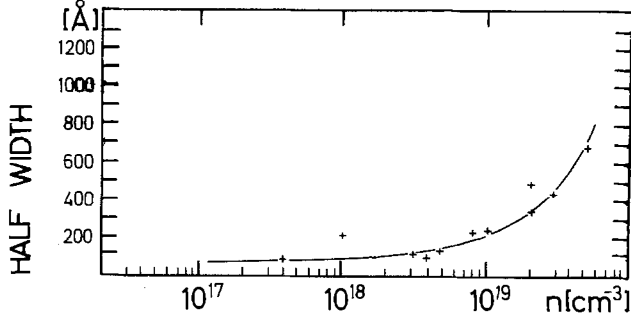

Fig. 5. Half-width of the emission line A at 1.8°K vs. net electron concentration n.

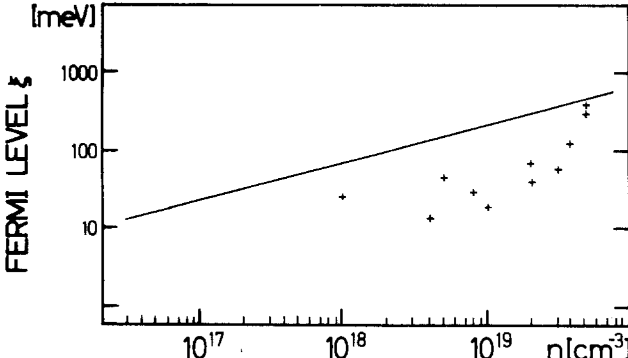

Fig. 6. Shift of Fermi level ξ with concentration n; + experimental values; — theoretical curve.

From our results it can be concluded that the incorporation of Si can be described by a donor behavior leading to electron concentrations as high as $5 \cdot 10^{19}$ cm^{-3}. The question arises how much Si is incorporated as a compensating acceptor which may be expected in particular at high doping levels. Compensating acceptors would give rise to a band acceptor transition, *i.e.*, an emission line which follows the A line in its energy shift with increasing doping at a distance of the acceptor binding energy. No such line is observed in high sensitivity photoluminescence, *i.e.*, no evidence for any Si being incorporated as an acceptor was found.

Line B which is also observed in our samples is a well-known donor-acceptor pair transition due to the acceptor Zn (12). This Zn acceptor is incorporated as an undesired impurity in an uncontrolled manner in low-doped regions of the layer. Emission from regions with lower electron concentration is much more pronounced if undoped substrates are used. In the latter case, even the typical bound exciton emission lines (A°, X) and (D°, X) (12) may be observed in addition to the band-to-band luminescence induced by incorporation of Si.

Conclusion

The main result of this investigation is that Si is incorporated in InP as a donor, *i.e.*, on an In lattice site, whereas no incorporation on a P site as an acceptor was detected. This is different from the amphoteric behavior of Si in LPE GaAs. The incorporation of Si in InP on an In site can be explained qualitatively by the difference in covalent tetrahedral atomic radii of the elements In, P, and Si. Recent data of these radii (21) and those for Ga, Ge, Sn, As, and Sb are compiled in Table II. From early theoretical considerations by Welker (22), it is obvious that the doping element substitutes the lattice element with the greater tetrahedral radius in III-V semiconductors.

Let us first consider the incorporation of Si. In III-V compounds with nearly equal atomic radii of the components, Si shows the typical amphoteric behavior as observed in the case of GaAs and, though less pronounced, in GaP. Si in InP prefers the In site because there is a large difference between the atomic radii of In and P. Similar conclusions can be made for GaSb [Si predominate acceptor (23)] and InAs [Si predominate donor (4)].

The doping elements Ge and Sn in InP, having still larger atomic radii than Si, should also prefer to be incorporated on an In site as a donor, which is actually observed (10). Only C, with a very small atomic radius

Table II. Covalent tetrahedral atomic radii r[Å] (21)

Al : 1.229	Si : 1.173	P : 1.127
Ga : 1.225	Ge : 1.225	As : 1.225
In : 1.405	Sn : 1.405	Sb : 1.405

(r = 0.774Å) should be able to enter on a P site as an acceptor. In fact, the shallow "A_1-acceptor" in InP with a binding energy of 41.1 meV (12) is presumably due to C on a P site.

On the Maximum Position of Thermally Stimulated Depolarization Bands

A. Kessler

Institute of Physics, University of Stuttgart, Stuttgart, Germany

ABSTRACT

It is shown by theoretical argument and by experiment that only in the case of a first order kinetics polarization do the TSD peaks occur invariably at a fixed temperature. Otherwise their position is shifting in a characteristic way with changing initial polarization. In the case of a space charge release, for example, the maximum temperature is increasing with polarization temperature and polarization time. Thus, peak position data for varying polarization conditions allow one to decide in particular whether a peak is due to a first order depolarization process, *e.g.*, complex reorientation, or to the release of a space charge.

The thermally stimulated depolarization (TSD) of polar crystals by an increasing temperature usually shows several bands or peaks. This indicates that the depolarization is realized by several different processes. Two such processes are well known: the relaxation of aligned impurity-point defect complexes (1) and the relaxation of a space charge caused by mobile point defects accumulated at the electrodes (2, 3). But there are still other processes which cause TSD peaks which have not yet been identified (1, 4).

It is one of the fundamental problems of any investigation of TSD to relate the observed peaks to specific depolarization processes. From the experimental point of view, there are three quantities which characterize a given TSD peak, on which an analysis may be based: the maximum position, the magnitude of the peak, and the slope of the initial rise of the peak. The magnitude of the peak is eventually (1) a measure of the number of defects causing the polarization. The determination of the slope of the initial rise, which should yield the activation energy of the depolarization process, is in general a delicate task and if the peaks overlap too much, possibly no meaningful value can be obtained at all. However, it is comparatively easy to determine the approximate peak positions. We shall show how the peak position depends on the initial polarization of a sample, and that this can provide some information on the depolarization processes causing the peaks in question.

Some General Considerations Concerning TSD

The TSD is usually investigated by measuring the "depolarization current" $I_m(t,T)$ of a polarized sample of cross section A and thickness L which is connected to a galvanometer. The measured current density $i_m(t,T) = I_m(t,T)/A$ is equal to the sum of the charge transport rate density $e \cdot j(x,t)$ and the displacement current density $\partial D(x,t)/\partial t$ at any arbitrary cross section of the investigated sample. Under ideal conditions, the measurement is carried out without any potential drop between the electrodes, $\Delta V = \int_0^L E(x,t) \cdot dx = 0$, and without any charge transfer to the electrodes, *i.e.*, $j(o,t) = j(L,t) = 0$. Under these conditions solely the displacement current density

$$i_m(t,T) = \left\{ \frac{\partial D(x,t)}{\partial t} \right\}_{x=o,L} \quad [1]$$

due to the redistribution of charges inside the sample is measured.

In general, there exist several different causes of polarization. However, we shall restrict ourselves here to two major cases: to the polarization due to an accumulation or/and depletion of mobile point defects (5) and to the polarization due to the reorientation of impurity defect complexes (1,5). Both the motion and the reorientation of these defects are thermally activated processes. For such processes, the rate of depolarization is expected to be proportional to some characteristic rate constant $K(T) = K_0 \exp(-U/kT)$ with a pertinent activation energy U and to some "driving force" $F(t)$. It follows that the same is to be expected of $i_m(t)$, *i.e.*

$$i_m(t) = -K(T) \cdot F(t) \quad [2]$$

where the temperature T is a given function of time t, $T = f(t)$. The derivative of $i_m(t)$ with respect to t is thus

$$\frac{di_m(t)}{dt} = -K(T) \left\{ \frac{dT}{dt} \cdot \frac{U}{kT^2} \cdot F(t) + \frac{dF(t)}{dt} \right\} \quad [3]$$

$F(t)$ is decreasing with time and consequently dF/dt is negative. Hence there will exist a limiting rate of temperature increase, dT/dt, below which $i_m(t)$ is monotonically decreasing and above which it is, for small values of t at least, increasing. Because $i(t)$ becomes zero eventually, a current maximum must occur when $\left\{ \frac{dT}{dt} \frac{U}{kT^2} + \frac{dF(t)/dt}{F(t)} \right\} = 0$, with $t = t_{mx}$, and $T = T_{mx} = f(t_{mx})$. If the value of $dT/dt = b =$ const, the maximum temperature T_{mx} will depend only on the properties of $F(t)$ and on the value of the activation energy U.

Let us consider now the particular case of a polarization caused by impurity-vacancy complexes. Then $F(t) = P(t)$, the instantaneous polarization, and (5)

$$\frac{dP(t)}{dt} = -1/\tau \cdot P(t) \quad [4]$$

with $\tau(T) = \tau_0 \cdot \exp(U/kT)$, the relaxation time of reorientation. It follows from Eq. [4] that $(dF/dt)/F(t) = -1/\tau(T)$. Given $b > 0$, the maximum temperature will depend solely on the activation energy of reorientation U and on the relaxation time $\tau(T_{mx})$ as found by Bucci and Fieschi (1); $T_{mx} = \{(1/k) \cdot b \cdot U \cdot \tau(T_{mx})\}^{1/2}$. It is to be noted, that Eq. [4] is a first order kinetics equation. It can, therefore, be concluded that, for any depolarization process with first order kinetics, T_{mx} will have a fixed value.

Let us now consider a depolarization with second order kinetics (6)

$$\frac{dP(t)}{dt} = -\gamma(T) \cdot P(t)^2; \; \gamma(T) = \gamma_0 \cdot \exp\left(-\frac{U}{kT}\right) \quad [5]$$

Key words: thermally stimulated depolarization, current maxima, space charge relaxation, impurity-point defect complexes.

For a constant value of $b > 0$, the solution of Eq. [5] for a given initial polarization P_o is

$$P(T) = \left[\frac{1}{P_o} + \gamma_o/b \cdot \int_{T_o}^{T} \exp\left(-\frac{U}{kT'} \right) dT' \right]^{-1} \quad [5a]$$

and the condition for the occurrence of a maximum is $\left\{ \frac{bU}{2kT^2} - P(T)^{-1} \right\} = 0$. The maximum position thus depends on $P(T)$ and, consequently (see Eq. [5a]), on the initial polarization P_o. It is easily shown that T_{mx} decreases as P_o is increased. P_o is determined by the conditions under which the sample was polarized. It may be said, therefore, that in the case of a depolarization process with second order kinetics, T_{mx} is a function of the polarization conditions.

A more intricate situation arises when the polarization is caused by an accumulation or/and depletion of mobile defects (5). In that case, $K(T)$ stands for the mobility of the defects which cause the peak and $F(t)$ is a function of the instantaneous defect concentration distribution $n = n(x,t)$. As shown in more detail in the Appendix

$$F(t) = \frac{e}{L} \int_o^L dx \int_o^x \frac{\partial}{\partial \xi} \left[n(\xi,t) \cdot E(\xi,t) - \frac{kT}{e} \cdot \frac{\partial n(\xi,t)}{\partial \xi} \right] d\xi \quad [6]$$

where L is again the sample thickness, and E is the polarization field in the sample as it follows from the space charge distribution.

A general solution of the space charge formation and release, which would allow for a straightforward evaluation of $[dF(t)/dt]/F(t)$, is not known. But as demonstrated in Fig. 3, T_{max} depends in principle on the initial TSD current density $i_m(o)$ and on the integral of $i_m, Q_m = \int_o^\infty i_m(t)\,dt$. Because of reasons which are given in the Appendix, it is to be expected that under favorable conditions the initial TSD current density $i_m(o)$ increases with polarization temperature T_p or polarization time t_p less than the corresponding value of Q_m. In consequence, T_{mx} should increase with T_p or t_p and vice versa. If, on the other hand, a polarized sample is gradually depolarized, Q_m is decreased by each partial depolarization less quickly than $i_m(o,T_o)$. Therefore, repeated partial depolarization should result in a shift of T_{mx} to higher temperatures with each new heating cycle.

There is yet another property of the space charge relaxation which is of importance in connection with the TSD peak position. To achieve a complete relaxation of the polarization due to defect complexes, one-half of the complexes has to be activated. In the case of a space charge, any one of the accumulated defects has to be activated many times before the concentration gradient of the defects is leveled out. If one takes into account the fact that the activation probability of the defects associated into complexes and that of free defects is of about the same order of magnitude, it becomes evident that the space charge relaxation peaks ought to occur at higher temperatures than the peaks due to the relaxation complexes.

Experimental Data for the TSD Peak Position under Various Polarization Conditions

A number of TSD measurements on NH_4Cl and $NH_4Cl:NiCl_2$ crystals polarized at different temperatures between $-60°$ and $+25°C$ and for two different polarization times have been carried out recently (7). These measurements always exhibited four peaks which were due to the polarization of the samples by an external field. The peak positions T_{mx} as a function of T_p and t_p are plotted in Fig. 1. The maximum positions of bands 1 and 2, which, occur at lower temperatures, are clearly independent of T_p and t_p. The maximum positions of bands 4 and 5, which occur at higher temperatures, however, increase with T_p and t_p and vice versa. One should thus expect the low temperature peaks to be caused by depolarization processes with first order kinetics; the high temperature peaks to be caused by space charge release.

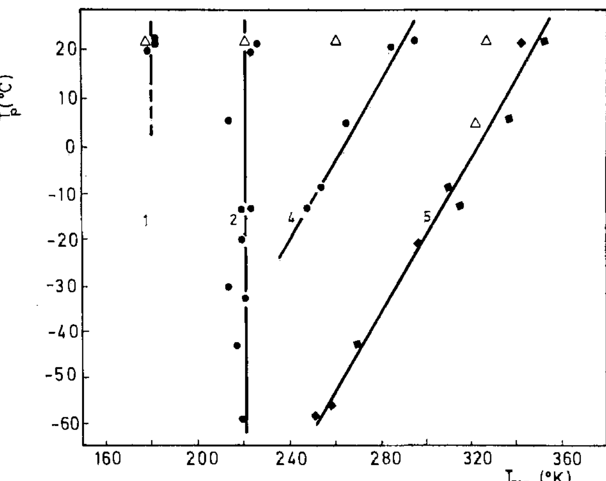

Fig. 1. Maximum position (T_{mx}) of peaks 1, 2, 4, and 5 of NH_4Cl as a function of the polarization temperature T_p for a polarization time t_p of 30 min (●, ◆) and 15 min (△), respectively.

It has been shown (7) that the magnitudes of peaks 1 and 4 increase with the $NiCl_2$ concentration of the crystals. As, at the same time, the activation energy determined from the initial rise of peak 4 was found to be in good agreement with the activation energy of the motion of cation vacancies determined from conductivity data of $NiCl_2$-doped material (7), it seems highly probable that peak 1 is due to a relaxation of Ni^{2+}-cation vacancy complexes and that peak 4 is due to the relaxation of space charge formed partly by cation vacancies. The experimental results are thus found to agree with the theoretical predictions.

A further example of the dependence of T_{mx} on the polarization conditions is provided by Fig. 2, where the results of a "peak cleaning" *i.e.*, a successive depolarization of the TSD of NH_4Cl crystals, are found. It can be seen that the maximum of peak 5 in Fig. 1 is shifted with the proceeding depolarization toward higher temperatures, as predicted for the case of a gradual depolarization of a space charge. Peak 5 has been ascribed to the release of anion vacancies from the space charge in the undoped samples (7).

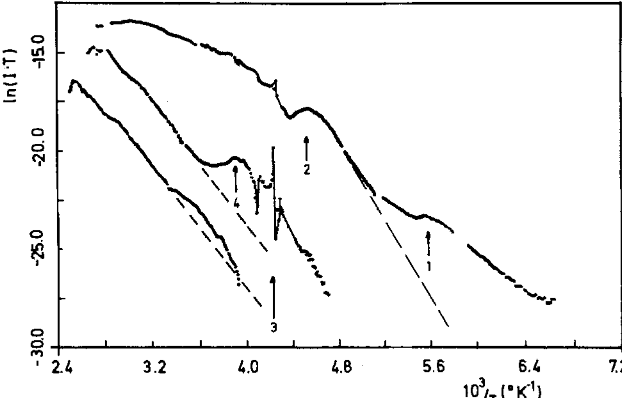

Fig. 2. Three consecutive runs of a partial TSD (peak cleaning) of undoped NH_4Cl. Peak 5 $10^3/T = 3.2$-2.5.

Table I. Dependence of the TSD peak positions of CdF_2:NaF on polarization temperature T_p

Peak	T_p (°K)	193	300
1	T_{mx} (°K)	105-106	103-106
2		138	140
3		202-203	254

TSD measurements were also carried out on CdF_2: NaF crystals polarized at different temperatures (8). Three peaks have been observed below room temperature, the maximum temperatures of which are found in Table I.

Peak 1 is due to defect-complex reorientation (2, 8), peak 3, according to Kessler and Caffyn (3), to a space charge caused by mobile point defects. It can be seen from Table I that T_{mx} is increasing with T_p for peak 3 and is independent of T_p for peak 1 as is to be expected.

Finally, it is worth mentioning that TSD measurements by other workers on CaF_2 crystals yielded a single peak which was assumed to be related to a second order kinetic depolarization process (6). This assumption was based, among others. on the fact that the experimental data fit Eq. [5] over three orders of magnitude of the depolarization. It was further found [see Fig. 3, Ref. (6)] that T_{mx} increases with decreasing initial polarization. The observed shift of T_{mx} is thus in agreement with theory.

Summary

It has been shown theoretically that the TSD maximum positions are expected to depend in a characteristic way on the polarization conditions. Particularly in the case of a space charge polarization, the maximum temperature should increase with the polarization temperature and polarization time, whereas in the case of a first order kinetics depolarization, the maximum position should be invariable and occur at lower temperature than the space charge depolarization maxima. A comparison with experimental data on NH_4Cl and on CdF_2 shows a good agreement between experiment and theory. This makes it possible, in particular, to find out whether a peak is due to first order kinetics or due to space charge release, if its maximum temperature as a function of polarization temperature or time is known.

APPENDIX

If a steady-state current is to pass through a polar crystal, all the ions arriving at the electrodes are to be "discharged." But at the moment the field is applied to the crystal, the rate of discharge will not necessarily be equal to the transport rate in the bulk. The effect that not all the defects arriving at an electrode are discharged is called blocking of the electrode. As a result of the blocking, defects are accumulated and/or depleted at the electrodes until the transport and the discharge rates become equal and a nonuniform concentration distribution of defects is established. If there is only one kind of mobile defect, the concentration of which is $n_1 = n_1(x,t)$, and the concentration of the complementary immobile defects, n_2, is constant, the displacement, D, caused by this defect distribution is

$$D(x,t) = e\int_o^L [n_1(x,t) - n_2] \cdot dx + D(o,t) \quad \text{[A-1]}$$

where $D(x,t)$ has to satisfy the condition

$$\int_o^L E(x,t) \cdot dx = V_{apl} \quad \text{[A-2]}$$

This gives for a depolarization when $V_{apl} = 0$

$$D(o,t) = \frac{en_2L}{2} - \frac{e}{L} \cdot \int_o^L dx \cdot \int_o^x n_1(\xi,t) \cdot d\xi \quad \text{[A-3]}$$

and thus the depolarization current is according to Eq. [1]

$$i_m(t) = -\frac{e}{L} \cdot \int_o^L dx \int_o^x \frac{\partial n_1(\xi,t)}{\partial t} \cdot d\xi \quad \text{[A-4]}$$

The derivative of $n_1(x,t)$ may be expressed from the differential equation describing the defect distribution (5)

$$\frac{\partial n_1(x,t)}{\partial t} = \mu_1(T) \frac{\partial}{\partial x}\left[n_1(x,t) \cdot E(x,t) - \frac{kT}{e}\frac{\partial n_1(x,t)}{\partial x} \right] \quad \text{[A-5]}$$

By identifying the mobility of the defects $\mu_1(T)$ with the activation rate $K(T)$ of Eq. [2], one obtains for $F(t)$ the expression given in Eq. [6]. Using Eq. [A-4] and assuming that the sequence of integrations can be interchanged, one obtains for Q_m

$$Q_m = -\frac{e}{L}\int_o^\infty dt \left\{ \int_o^L dx \int_o^x \frac{\partial \mu_1(\xi,t)}{\partial t} d\xi \right\}$$
$$= -\frac{e}{L}\int_o^L dx \int_o^x [n_1(\xi,\infty) - n_1(\xi,0)]\, d\xi \quad \text{[A-6]}$$

The first term in the brackets is a constant which is equal to the equilibrium defect concentration n_2 for

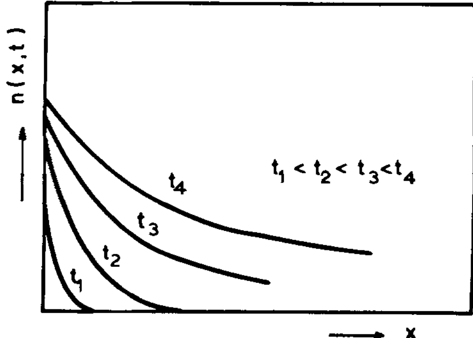

Fig. 4. Illustration of the buildup of a space charge with proceeding of time of polarization t_p · x is the depth below the crystal surface.

crystals which are neutral. The second term is the initial defect concentration distribution.

Both $i_m(o)$ and Q_m depend on the "shape" of the defect distribution and on the amount of accumulated defects. But while a steeper distribution of a fixed quantity of defects will decrease Q_m, $i_m(o)$ will be increased, at least in the case when the diffusion term in Eq. [6] is dominating. Consequently, T_{mx} would then be found at lower values (see Fig. 3).

A steeper distribution will occur if T_p is decreased because, as follows from the Nernst-Einstein relation, the diffusion is decreasing more rapidly with a decreasing temperature than the field drift (conductivity). Further, the distribution will become steeper if t_p is decreased. This follows directly from the way the space charge is built up with the proceeding polarization time (see Fig. 4).

On Some Thermally Stimulated Depolarization Maxima in NH_4Cl Due to Spontaneous Polarization

A. Kessler

Institute of Physics, University of Stuttgart, Stuttgart, Germany

ABSTRACT

Two TSD peaks, which are observed in NH_4Cl crystals even if they are not polarized, were investigated. One, which occurs at the phase transition temperature at $-30.6°C$, is due to a spontaneous polarization of the crystal in the course of the phase transition of crystals containing divalent impurities. The other, which occurs above 0°C, is due to a spontaneous current caused by an injection of defects formed under the influence of moisture on the sample surfaces.

The thermally stimulated depolarization (TSD) of NH_4Cl crystals exhibits several maxima as the temperature is increased (1, 2). But not all these maxima are due to the polarization caused by the field applied to polarize the investigated samples. Two of the maxima were observed during the heating even if the samples were not polarized previous to the heating. One peak occurs when the sample is undergoing the phase transition at $-30.6°C$. Hence it will be called a phase transition maximum. The other peak is observed above room temperature and is due to a spontaneous current in the samples. This paper is a first report about these effects of which the former has already been observed by Uebele (3).

The Phase Transition Peak

Current peaks at phase transition.—If a sample of a NH_4Cl crystal is placed between electrodes which are connected to a galvanometer, every time the temperature is decreased below or increased above the phase transition temperature, $T_{ph} = -30.6°C$, a current peak is observed. The peak is detected even if the electrodes are insulated, and its maximum value I_{mx} was found to increase proportionally to the rate of temperature change dT/dt. The integral of the measured current $\int_0^\infty I(t)dt$ has, for a given sample, a fixed value which changes the sign if the sample is heated instead of cooled and vice versa. To insulate the crystal samples, transformer oil was applied to the crystal electrode interfaces, because only in that way could both insulation and a good and reproducible thermal contact be achieved.

The above-mentioned facts show that a displacement current is measured, and that the spontaneous polarization, P, the change of which causes the measured current, is in the first approximation a function of the temperature T only

$$I(t) = \frac{dP}{dt} = \frac{dT}{dt} \cdot \frac{dP}{dT} \qquad [1]$$

A graph of P *vs.* T is shown in Fig. 1.

Correlation of the spontaneous polarization with the phase transition.—To avoid any possible perturbation of the measurements, only the temperature of the electrodes was measured. If it is assumed that the "thermal resistance," r, between the sample and the electrode has a fixed constant value, the lag ΔT of the mean temperature of the sample behind T should be proportional to $1/r$ and to dT/dt, because $(mc) \cdot dT = 1/r \cdot \Delta T \cdot dt$, where (mc) is the heat capacity of the sample. An extrapolation of $T_{mx} = f(dT/dt)$ for $dT/dt \rightarrow 0$ should thus yield the true temperature at which the current peak occurs. As shown in Fig. 2, this temperature, for both NH_4Cl and ND_4Cl, is in good agreement with the respective phase transition temperatures [see, for example, Ref. (4)]. This and the fact that the $P(T)$ *vs.* T dependence is similar in principle to the dependence on T of both the order parameter of the NH_4^+ ions (5) and the integral of the specific heat (6) shows that both polarization and depolarization are correlated with the phase transition.

Dependence of the total polarization ΔP on the impurity content of the crystals.—The phase transition current peak $I = f(t, T)$ of samples containing different impurity concentrations was measured and $\Delta P = \int_{T_0}^{T_1} I(t)dt$ for $T_0 << T_{ph} << T_1$ calculated. The results are given in Table I. It is obvious that ΔP depends on the kind and quantity of the impurities built into the crystal. The highest polarization occurred in crystals

Key words: spontaneous polarization, phase transition, defect formation.

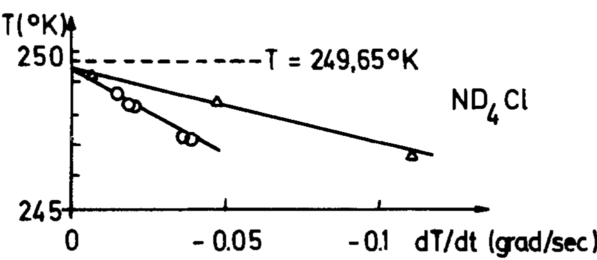

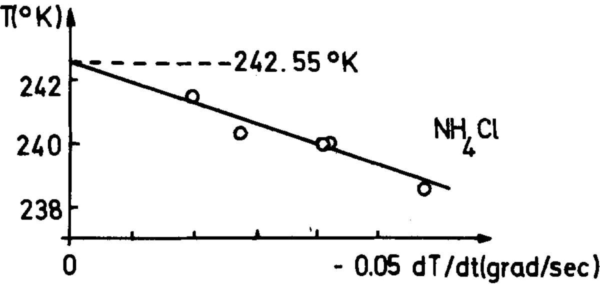

Fig. 2. Dependence of the observed peak position on the rate of temperature increase: △, sample insulated with transformer oil; ○, sample insulated with machine oil.

with built-in divalent impurities, which form impurity complexes with vacancies (2). In that case, ΔP is clearly increasing with the concentration of the impurities. For crystals containing high concentrations of divalent copper in an interstitial position which forms neutral centers with NH_3 [Cu^{2+}-center II (7)] or with H_2O [Cu^{2+}-center I (7)], the value of ΔP is the same or smaller than for undoped crystals. Even if we take these results with some caution, we arrive at the conclusion that the polarization is not an inherent property of NH_4Cl but that it is caused by the built-in impurities. While for $T > T_{ph}$ the complexes are no doubt randomly oriented, it seems possible that for $T < T_{ph}$ there exists a preferential orientation. An alignment of

Table I. The total polarization, ΔP, due to phase transition of crystals containing different kinds and concentrations of impurities

Crystal	Method of growth	Dopant	P(C/cm²)	dT/dt (grad/sec)
ND_4Cl	Melt	—	$2.45\text{-}5.0 \times 10^{-11}$	−0.07-0.11
NH_4Cl	Melt	—	$2.1\text{-}3.2 \times 10^{-11}$	−0.04-0.14
NH_4Cl	Melt	10 ppm $CuCl_2$	$1.4\text{-}2.4 \times 10^{-10}$	0.05-0.18
NH_4Cl	Solution	5000 ppm Cu^{2+} in center I	$1.0\text{-}2.0 \times 10^{-12}$	0.1
NH_4Cl	Solution	5000 ppm Cu^{2+} in center II	$4.0\text{-}5.5 \times 10^{-11}$	0.1
NH_4Cl	Solution	100 ppm $NiCl_2$	$4.9\text{-}8.1 \times 10^{-10}$	0.11-0.16

the complexes would yield roughly a polarization like the measured one. Dipole moments caused by a geometric distortion of the lattice due to the built-in impurities, on the other hand, should be randomly oriented even for $T < T_{ph}$ and would hardly yield a value which could account for the measured polarization. The centers I and II, which have normally no dipole moment and which are immobile, most probably do not contribute to P.

Occurrence of more than one current peak at phase transition.—Sometimes more than one peak is observed which, moreover, may vary in sign. It is believed that this effect is due to the existence of domains [see Ref. (8)] in the crystal. Because of the heat transmission to or from the crystal, there is necessarily a temperature gradient inside the crystal due to which the domains reach T_{ph} at different times. Furthermore, the existence of a hysteresis of the phase transition, which was observed between −72° and −28°C and is also attributed to the existence of domains (9), points to the above explanation of the multiple peaks. As far as the different signs of the peaks are concerned, they may be understood as a consequence of different orientations of the domains arranged so as to minimize the total polarization energy of the sample.

Spontaneous Current Peak

The occurrence of a spontaneous current I_{sp} of some 10^{-11}-10^{-8}A at room temperature is observed if a fresh, unpolarized sample of NH_4Cl crystal provided with graphite electrodes is connected to a galvanometer (2). The cross section of the samples was about 1 cm². As the resistance of the samples is of the order of 10^{11} ohm, voltages up to several thousands of volts would be needed to cause such currents to pass through the samples. As may be verified by using insulated electrodes, the current is caused "by the sample itself."

Dependence of the spontaneous current on the quantity of adsorbed H_2O.—One finds that I_{sp} is proportional to the water vapor pressure, p, acting on the contact surfaces of the samples (Fig. 3). This is achieved by sealing off the cylindrical surfaces of the samples and providing the contact surfaces, *e.g.*, by a layer of colloidal graphite. The effect is strongest if only one contact surface is exposed to the water vapor (Fig. 3, curve 1). If the water vapor has access to both electrodes (Fig. 3, curve 3), I_{sp} is more than two orders of magnitude smaller. It is interesting to note that when vacuum-evaporated gold electrodes are used, I_{sp} is still increased if a high enough water vapor pressure is built up, but with a considerable delay after the build-up of p. Any decrease in p is followed by a decrease of I_{sp} after some delay. This delay shows that the H_2O molecules reach the crystal surface by diffusion through the metal layer.

Below $p \sim 4$ Torr, I_{sp} is roughly independent of p. This is easily understood if it is assumed that there exists a certain minimum concentration of H_2O adsorbed on the crystal surface which depends mainly on the temperature and not on p. This notion is supported by the fact that, by heating the sample in a vacuum of 5×10^{-2} Torr to 100°C, I_{sp} at first decreased to less

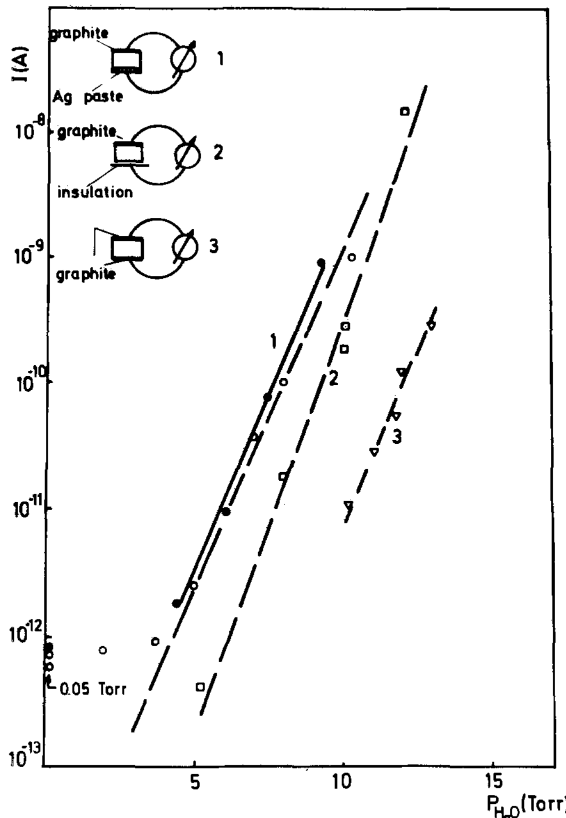

Fig. 3. Spontaneous current, I_{sp}, of a NH_4Cl crystal sample as a function of the water vapor pressure, p, in the measuring cell and of the electrode material.

than 10^{-14}A at room temperature, but increased later to the original value of about 8 × 10^{-13}A. It is to be noted that above 100°C transitory decrease of the pressure in the measuring cell is observed, obviously due to an enhanced release of water.

Dependence of the spontaneous current on temperature and time.—If the temperature of the sample is decreased, one finds I_{sp} decreasing proportionally to exp $(-U/kT)$ with $U \sim 1$ eV (2) for undoped samples. If the temperature is increased above room temperature, a current maximum is observed (Fig. 4). The maximum position varies widely according to experimental conditions. All NH_4Cl crystals exhibit a spontaneous current, however, the magnitude is determined by the "history" of the sample. If I_{sp} is higher than 10^{-12}A, it will decrease markedly with time, and the higher the initial value of I_{sp}, the higher the rate of decay.

A first tentative interpretation of the findings.—It is known that the abnormally high sublimation rate of NH_4Cl is caused by catalytic decomposure of NH_4Cl into NH_3 and HCl. These neutral molecules are bound to the crystal with a lower energy than that of the NH_4^+ and Cl^- ions. Consequently, they are easily "evaporated" (10). It seems that due to such a process vacancies should be created. It is to be expected that, due to an increasing amount of H_2O on the crystal surface, the decomposure will be enhanced. Because vacancies (and also NH_3) are mobile in NH_4Cl crystals, they should penetrate into the bulk of the crystal (the cation vacancies at a higher rate) because they are more mobile (11). This should cause a net charge flow and if only one electrode is exposed to H_2O a current should be observed. In due time, an equilibrium will be reached, due to the buildup of a double layer.

It should be noted that the highest measured value of I_{sp} (see Fig. 3) would imply a rate of 10^{11} vacancy/cm^2 sec entering the crystal. This is an extremely high, but still acceptable figure as compared with the *ca.*

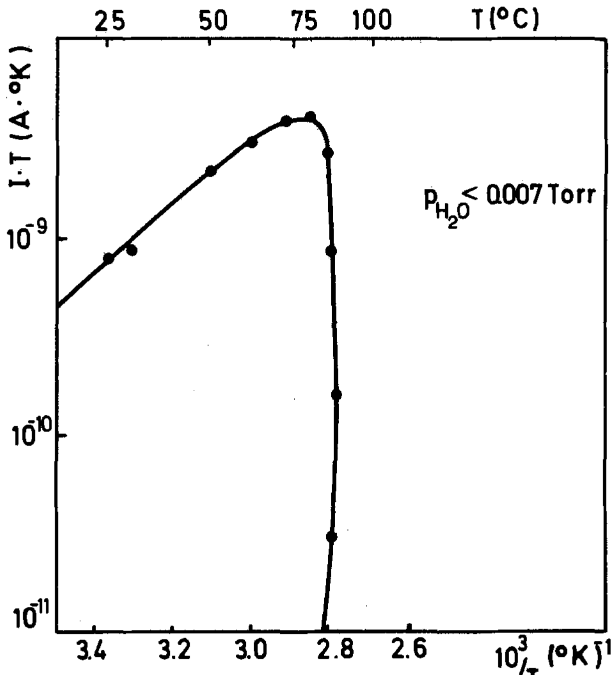

Fig. 4. Spontaneous current peak observed above room temperature on heating of an unpolarized sample.

6 × 10^{14} unit cells of the surface and taking into account the rapid decrease of I_{sp} after exposure.

If both electrodes are provided with permeable electrodes, theoretically, no current should be observed. But if no special provisions are made to safeguard identical conditions at both electrodes, a difference of about 1/100 of the current obtained with one single exposed electrode (see Fig. 3) seems a realistic value.

The decrease of I_{sp} with time should be a consequence of the buildup of a double layer, which to some extent can be compared with the double layer predicted by Lehovec (12). But a TSD peak as shown in Fig. 4 is most probably caused by the combined effect of the temperature dependence of the spontaneous current and by the evaporation of H_2O from the crystal surface. The peak occurs at a temperature at which the rate of loss of H_2O is higher than the increase in the mobility of the vacancies. Only in that way can the sudden drop in the current by orders of magnitude be understood.

Finally, it is to be emphasized that by the same mechanism, *i.e.* by the formation of mobile defects due to the catalytic effect of H_2O and the evaporation of the adsorbed H_2O at higher temperatures, some features of the conductivity of NH_4Cl have been explained (2).

Impurity and Substrate Diffusion in a Thin Contact Layer

R. P. Goel[1]

Department of Mechanical Engineering, North Carolina Agricultural and Technical State University, Greensboro, North Carolina 27411

and F. E. Bader

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

Based on simplifying assumptions, diffusion phenomena of substrate and impurity through a thin contact layer have been compared. Results are presented in terms of nondimensionalized parameters k (a measure of diffusion rate, time, and contact thickness) and $\bar{l}/l$ (film thickness/contact thickness). A single master curve is shown to represent each diffusion process. Numerical examples of practical interest are presented and the limitations of the theory are discussed.

Noble metals are typically used as contact layers because of their superior contact properties. In view of the high cost of these materials, it is desirable that a minimum thickness be used to attain a contact of desired quality. However, contact films resulting from mass diffusion of substrate material to the surface at elevated operating temperatures may set a lower limit on contact layer thickness. Impurities which are initially present in the contact layers may also diffuse to the surface and form films which degrade contact performance. In the case of electroplated gold, the most commonly used layer, small amounts of cobalt or nickel impurities are deliberately added to harden the gold.

The purpose of this study is to compare theoretically the relative rates of substrate and impurity diffusion. Although it is known that the presence of an impurity influences substrate diffusion and *vice versa*, it will be assumed that the processes are independent of each other. It will be shown that there may be regimes of time and temperature where one mechanism or the other will be clearly dominant.

The increasing use of elevated temperatures for various accelerated tests is another reason that diffusion rate studies are important. Contact resistance and/or film thicknesses are measured after elevated temperature exposures, and the data extrapolated to contact ambient temperatures. This can yield erroneous results if the dominant mechanism at elevated temperature is not the same as that at the operating temperature.

Equations governing the diffusion processes and their solutions along with the simplifying assumptions used to derive the solutions are presented below. Some examples of practical importance in the system of cobalt-hardened gold on a copper substrate are also discussed using diffusion rate data developed by Pinnel and Bennett (1) and Tompkins (2). Design guidelines are suggested, along with limitations of the present theory.

[1] Bell Laboratories Visiting Professor.

Theory

Diffusion in an electrical contact can be idealized by considering the following: (*i*) diffusion occurs only in the thickness direction of the medium (also called solvent) which is bounded by two planes, *e.g.*, the planes at $x = o$ and $x = l$; (*ii*) no intermetallic compounds are formed; (*iii*) the substrate and impurity coefficients, D_s, D_i, respectively, are independent of their respective concentrations; (*iv*) the two diffusion processes are independent of each other; (*v*) the contact layer is homogeneous throughout; (*vi*) the impurity and substrate arriving at the contact surface are oxidized instantaneously.

Diffusion through a homogeneous medium can be adequately described by Fick's second law. Thence, for substrate and impurity diffusion, respectively, we have

$$\frac{\partial C_s}{\partial t} = D_s \frac{\partial^2 C_s}{\partial x^2} \quad [1]$$

$$\frac{\partial C_i}{\partial t} = D_i \frac{\partial C_i}{\partial x^2} \quad [2]$$

where C and t represent concentration and time and subscripts s and i denote substrate and impurity, respectively.

Let us assume that the initial concentration of the impurity, C_{io}, is uniform throughout the medium and the medium is free from any substrate material at time $t = 0$. Therefore, we have

$$C_s(x, o) = 0 \quad [3]$$

$$C_i(x, o) = C_{io} \quad [4]$$

Assumption (*vi*) implies sink effect at the contact surface, $x = l$. Such an assumption would be reasonable at lower temperatures at which diffusion rates are very low. However, if large oxide films are formed on the contact surface, this assumption will no longer hold. But by that time the contact material may already have

lost its effectiveness. In our applications, ambient temperature is relatively low and thus assumption (*vi*) is reasonably applicable. Hence we have

$$C_s(l,t) = 0 \quad [5]$$

$$C_i(l,t) = 0 \quad [6]$$

The impurity content present nearer to the contact surface will diffuse out at a faster rate than that present farther away from the surface because of high concentration gradient near the surface. And, therefore, this gradient at the interface of the substrate and the contact layer (farthest point from the contact surface) will virtually be zero. Consequently, we can simplify the solution of the boundary value problem by including its mirror image, which implies

$$C_i(-l) = 0 \quad [7]$$

(See Fig. 1.) One more condition is needed to solve Eq. [1]. That can be obtained by assuming that the Matano interface remains stationary, which implies that C_s remains constant at 50 atom per cent (a/o) at $x = 0$. Thus

$$C_s(o,t) = C_{so} = 50 \text{ a/o} \quad [8]$$

It should be noted that concentration C can be given in a variety of units, but the flux is usually expressed in mass/area/time. Therefore, C must also be expressed in mass/volume units when using flux equations. The following conversion factors, CF, may be used to transform atom per cent or weight per cent (w/o) to mass/volume

$$\frac{C(\text{mass/vol})}{C(\text{a/o})} = \frac{\rho_1\rho_2}{\rho_2 + \dfrac{M_2}{M_1}\rho_1\dfrac{100 - C(\text{a/o})}{C(\text{a/o})}} \equiv \text{CF}$$

$$\frac{C(\text{mass/vol})}{C(\text{w/o})} = \frac{\rho_1\rho_2}{\rho_2 + \rho_1\dfrac{100 - C(\text{w/o})}{C(\text{w/o})}} \equiv \text{CF}$$

in which ρ_1, ρ_2, M_1, and M_2 denote mass densities and atomic weights of the solute (substrate or impurity) and the solvent (contact layer), respectively.

Equations [1] and [2] along with the respective boundary and initial conditions are straightforward problems. Following Carslaw and Jaeger (3) and Crank (4), the solutions can be written as

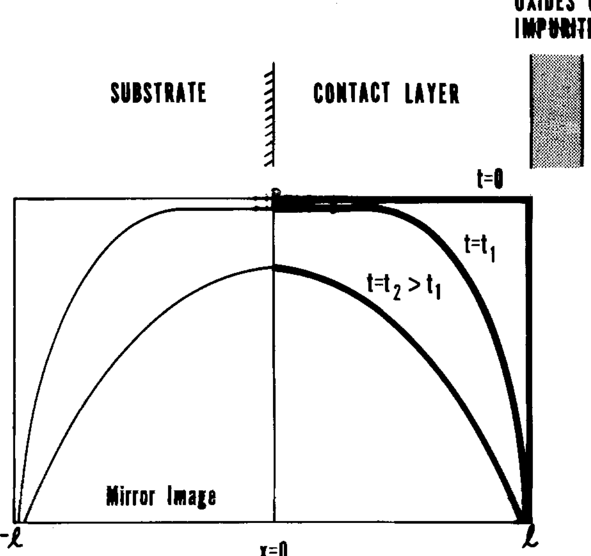

Fig. 1. Boundary conditions

$$C_s = C_{so}\left[1 - \frac{x}{l} - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin(n\pi x/l)\exp(-n^2\pi^2k_s)\right] \quad [9]$$

$$C_i = C_{io}\sum_{n=0}^{\infty}\frac{(-1)^n}{\pi(2n+1)}\cos((2n+1)\pi x/2l)\exp[-(2n+1)^2\pi^2k_i/4] \quad [10]$$

where k is a nondimensionalized parameter and is given by $k = Dt/l^2$.

If Q_s denotes the amount of substrate material appearing on the contact surface, then it can easily be given by

$$Q_s = \text{area} \times \left[-\int_o^t D_s\frac{\partial C_s}{\partial x}\bigg|_{x=l} dt\right] \quad [11]$$

Substituting Eq. [8] and [9] into [11] and after some algebraic manipulations, we get

$$Q_s = C_{so} \times \text{area} \times l\left[k_s + \frac{2}{\pi^2}\sum_{n=1}^{\infty}(-1)^{n+1}\frac{1}{n^2}\{\exp(-n^2\pi^2k_s) - 1\}\right] \quad [12]$$

Similarly, following Tompkins (2), we can obtain the amount of impurity appearing on the surface, which is given by

$$Q_i = C_{io} \times \text{area} \times l\left[2 - \frac{16}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\{-(2n+1)^2\pi^2k_i/4\}\right] \quad [13]$$

Equation [13] can be approximated by the following simplified expression for times up to which 60% of the total impurity has diffused

$$Q_i = C_{io} \times \text{area} \times l\left(\frac{4}{\pi}k_i\right)^{1/2} \quad [14]$$

In fact, the above approximation is an exact solution for a semi-infinite thick contact layer. It leads to quite an interesting result which we shall discuss later. Moreover, the underlying assumptions of the previous analysis are violated for times longer than that at which 60% or more of the total impurity has diffused out, and therefore, Eq. [14] would adequately describe the impurity diffusion process.

The aforesaid Eq. [12] and [14] yield the total amounts of substrate and impurity diffusants that have arrived at the contact surface at any given time. It may be more useful to know film thicknesses instead. This can be easily done by dividing both sides of Eq. [12] and [14] by area $\times$ ρ_1 resulting in the following equations (normalized by dividing by the layer thickness)

$$\frac{\bar{l}_s}{l} = \frac{C_{so}}{\rho_1}\left[k_s + \frac{2}{\pi^2}\sum_{n=1}^{\infty}(-1)^{n+1}\frac{1}{n^2}\{\exp(-n^2\pi^2k_s) - 1\}\right] \quad [15]$$

$$\frac{\bar{l}_i}{l} = \frac{C_{io}}{\rho_1}(4/\pi k_i)^{1/2} \quad [16]$$

where $\bar{l}$ denotes the film thickness. As mentioned earlier, concentration C is usually expressed as atom per cent or weight per cent and thus conversion factors CF must be applied. Using appropriate CF's and assuming $C_{so} = 50$ a/o, Eq. [15] and [16] are solved for different values of k. Results are presented in Fig. 2 in which k and (1/2 MCF) $(\bar{l}/l)$ represent the ordinate and abscissa, respectively. MCF $=$ CF$/\rho_1$ is called the

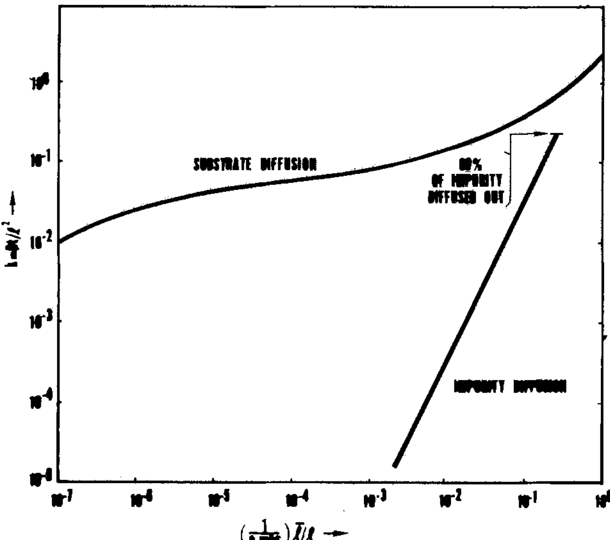

Fig. 2. Impurity and substrate diffusion

modified conversion factor. For any binary couple MCF can easily be calculated from the known values of atomic weights, mass densities, and concentration values.

Let us reexamine Eq. [16] and state the results observed by Tompkins (2) in his study of cobalt-hardened gold. Rewriting Eq. [16] and replacing k_i by D_it/l^2 we get

$$\bar{l}_i = \frac{C_{io}}{\rho_1}\left(\frac{4}{\pi}D_it\right)^{1/2} \quad [17]$$

which implies that the impurity film thickness, $\bar{l}_i$, is independent of contact thickness for times up to which less than 60% of the initial impurity content diffuses out of the contact layer. This occurs at $k_i \approx 2 \times 10^{-1}$. Note, however, $\bar{l}_i$ is directly proportional to initial concentration, C_{io}.

Figure 2 represents two master curves, one for substrate diffusion and the other for impurity diffusion for all impurity concentration levels. For any binary planar couple which satisfies the assumptions stated earlier, one can estimate the film thicknesses at a given time and temperature. Next, we discuss some examples of practical interest to illustrate the use of these curves.

Examples

The degradation of thin gold electroplates by mass diffusion of the base metal (copper) and interdiffusion of cobalt in cobalt-hardened gold are possible failure mechanisms in typical electrical connectors. Therefore, the results of the present theory will now be applied to cobalt-hardened gold on a copper substrate. Note that we have assumed the two processes to be independent of each other.

Diffusion rates for copper and cobalt through gold have been investigated, among others, by Pinnel and Bennett (1) and Tompkins (2), respectively. At test temperatures of 150°C, the rates were found roughly to be the same. Thence, we shall assume $D_i \approx D_s = D$ in our numerical examples.

Two examples of diffusion through 2.54 μm (100 μin.) and 1.27 μm (50 μin.) thick layers of gold at test temperature of 150°C are considered. The only impurity in gold is taken to be cobalt wtih an initial concentration of 0.25 w/o.

From Ref. (1, 2) we have

$$D_{Cu} \approx D_{Co} = D \approx 4 \times 10^{-16}\ cm^2/sec$$

Modified conversion factors for Au-Cu (C_{so} = 50 a/o) and Au-Co (C_{io} = 0.25 w/o) are as follows

$$2\ MCF_{Au\text{-}Cu} = 0.8156$$

$$2\ MCF_{Au\text{-}Co} = 1.0875 \times 10^{-2}$$

If we assume the test time periods to be 1 day, 30 days, and 200 days then the corresponding values of k are given in Table I.

For each value of k, we can obtain (1/2 MCF) $(\bar{l}/l)$ from Fig. 2. Since we have assumed instantaneous oxidation of the solute (substrate and/or impurity) as it arrives at the contact surface, and if we further assume that Cu and Co are oxidized into Cu_2O and CoO, respectively, then the film thicknesses of Cu and Co, obtained from Fig. 2, can be converted into oxide film thicknesses by multiplying by 1.7278 and 1.9424, respectively. Results are presented in Table II which shows that in the early stages of diffusion very little copper has arrived at the surface while cobalt has appeared almost immediately. As the time progresses, Cu_2O film starts building up on the surface and soon exceeds the CoO film. It is quite possible that CoO film, almost instantaneously formed on the surface, may retard the formation of Cu_2O film or even the formation of CoO film may become slow for lack of free oxygen. But, nonetheless, the present analysis provides us with some degree of qualitative and quantitative relative measure of the two films.

Discussion

Based on simplifying assumptions, diffusion phenomena of substrate and impurity through a thin contact layer have been compared. Results are presented in terms of nondimensionalized parameters k and (1/2 MCF) $(\bar{l}/l)$. A single master curve is shown to represent each diffusion process.

On a log-log scale the substrate diffusion curve concaves down in the beginning but soon becomes concave up. It implies that substrate film thickness builds up slowly at first, then increases at a fast rate, and eventually becomes unbounded. However, as stated earlier, the later part of the curve is irrelevant because the underlying assumptions of the theory are violated.

Figure 2 suggests that there is a narrow range of k (between 0.01-0.1) over which most of the substrate diffusion, especially in applications of our interest, occurs. Therefore, the film thickness is very sensitive to the value of $k = Dt/l^2$. For a given material system, time, and temperature, the only parameter which a designer can effectively control is the contact thickness. Hence, once an upper limit on an acceptable substrate film thickness is determined, the designer can put a lower limit on the contact thickness assuming D is known. In the given example of gold on a copper substrate, recent data by Kulpa (5) and others have shown copper diffusion far in excess of that of Ref. (1). This is believed to be a "short circuit" mechanism, not predictable by analysis of the diffusion profile, and highly dependent on layer and substrate structure. This variability of the diffusion coefficient indicates the need for caution when using diffusion data

Table I. Value of $k = Dt/l^2$

l (μm) \ t (sec)	8.64×10^4 (1 day)	25.92×10^5 (30 days)	17.28×10^6 (200 days)
1.27	2.143×10^{-3}	6.429×10^{-2}	4.285×10^{-1}
2.54	5.36×10^{-4}	1.61×10^{-2}	1.07×10^{-1}

Table II. Oxide film thicknesses (Å)

	2.54 μm		1.27 μm	
t (days)	Cu_2O	CoO	Cu_2O	CoO
1	0	7	0	7
30	<1	40	9	40
200	179	91	2678	91

and the desirability of further diffusion rate studies. For times up to which 60% of total impurity has diffused, the impurity film thickness depends upon the initial impurity content only, and this thickness does not depend upon the contact thickness.

As stated earlier, severe restrictions were imposed on the theory by making simplifying assumptions such as no interdependence of substrate and impurity diffusion processes, instant oxidation, etc. However, at low temperatures the diffusion rates are very small, the scatter in diffusion rate data is wide, and there exists very little quantitative information and relative comparison on diffusion of substrate and impurity processes, in spite of the relative importance of the subject. The present study, while being cognizant of its limitations, could provide an engineer with a useful design tool.

Technical Notes

On the Enhancement of Silicon Chemical Vapor Deposition Rates at Low Temperatures

Chin-An Chang[1]

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, Berkeley, California 94720

Chemical vapor deposition (CVD) has been a widely used technique for thin film device fabrication. It is especially applicable to thin film silicon solar cells. A deposition rate of a few microns per minute can be easily obtained, and a p-n junction can be made by mixing silicon chemical vapors, such as silane and silicon tetrachloride, with dopant gases, like diborane and phosphine. In general, CVD of silicon is carried out at a substrate temperature *ca.* 1000°-1200°C, and a single crystal silicon wafer is used for an epitaxial growth of thin films. However, to make economic thin film solar cells for terrestrial photovoltaic applications, noncrystalline and often nonsilicon substrates are required. Furthermore, interaction between the substrate thus chosen and the silicon thin film deposited should be kept minimal. For example, at a substrate temperature *ca.* 1200°C, silicon thin films deposited on graphite show a significant diffusion of silicon and carbon and the formation of silicon carbide (1). Much less diffusion is noted, however, when the substrate temperature is below 800°C (2). Similar high temperature interaction between the silicon films deposited and other types of substrate has also been reported (3). Preferably, one should use the lowest possible substrate temperatures to minimize such interactions and diffusion.

At low substrate temperatures, however, other problems arise. First, silicon film thus deposited is polycrystalline with small grain size (4). Second, a much lower deposition rate than that at high substrate temperature is obtained using the CVD technique (5). Small grain size means a shortening of lifetime for the charge carriers due to trapping at the grain boundaries (6); low deposition rate makes CVD a noneconomic technique for deposition. To solve the former problem, this author has developed a technique to increase the silicon crystallinity at low substrate temperatures. An enhancement of two to four orders of magnitude is obtained for the silicon films deposited on quartz and graphite at a 600°C substrate temperature (2, 7). The next goal is to increase the deposition rate of low temperature CVD. In doing so we make use of the observations that certain dopant gases enhance the silicon CVD rate and others hinder it (8). An understanding of these facts will obviously be useful to the enhancement of the silicon CVD rate at low temperatures. However, as pointed out later, these dopant gas effects cannot yet be consistently accounted for by the existing theories. Therefore, this paper presents a conceptual model which consistently explains the known dopant gas effects on the rate of silicon CVD. We believe that this work will not only lead to an enhancement of the low temperature silicon CVD rate needed for economic solar cells, but also be useful to guide experimentalists in carrying out the CVD process more effectively and to stimulating interest among theorists about the problems related to this topic. The proposed model is further tested for its predicted dopant gas effects on different CVD systems and other relevant work which needs to be done is also discussed.

It is well known that the silicon deposition rate using silane and silicon tetrachloride is increased by diborane and boron tribromide, and decreased by phosphine and arsine (8). Existing theories considering either active site blocking (8b) or strong bonding between the chemical vapor molecules and both types of dopant gas molecules (8c) have not been advanced

[1] Present address: IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598.

Key words: silicon, CVD, enhanced rates, dopant effects, surface model.

enough to explain the known effects in a consistent way, nor can they be used to predict the dopant gas effect on other CVD systems. In this work we make use of the fact that diborane and boron tribromide, both p-type dopant gases for silicon, have an opposite effect on the deposition rate of silicon chemical vapor from that of phosphine and arsine which are n-type dopant gases. This implies a possible correlation between the electronic structure of the dopant atoms with the observed effects cited. The mechanism involved in the CVD process is, therefore, first analyzed, in order to see whether and how this property can be incorporated into the deposition process.

Chemical vapor deposition can be viewed as a two-step process: adsorption of the chemical vapor molecule on the substrate surface followed by its thermal decomposition. As an example, deposition of silane follows

$$SiH_4(g) \rightarrow SiH_4(\text{adsorbed}) \xrightarrow{\text{heat}} Si(s) + 2H_2(g)$$

The thermal decomposition involves a transfer of thermal energy from the substrate to the chemical vapor molecule needed for its decomposition. At a fixed substrate temperature, the maximal amount of thermal energy which can be acquired by the molecule is constant. The efficiency of this energy transfer, however, depends on the residence time of the molecule on the substrate surface. In other words, for an effective decomposition of the molecule to take place on the surface, a sufficient amount of thermal energy for such decomposition should be transferred to the molecule before it desorbs from the surface. Therefore, at a fixed substrate temperature, adsorption of the molecule determines its decomposition rate. This argument is in agreement with the work of Farrow who found that silane adsorption is the rate-limiting step for the decomposition of this molecule (8c). Accordingly, at a given substrate temperature, any factors which favor the adsorption of the molecule on the substrate surface should also enhance its decomposition and therefore its deposition rate. Our problem is thus simplified to that of the effect of dopant gas on the adsorption of silicon chemical vapor molecules.

Diborane, phosphine, and arsine all readily decompose on a hot surface into the dopant atoms and hydrogen. Boron tribromide also readily releases its boron upon reduction by hydrogen at high temperatures. Diborane and boron tribromide have quite different structures and polarities and such differences could have profound effect on their interactions with the silicon surface (9). The fact that both diborane and boron tribromide enhance the silicon CVD rate and that they both easily produce boron at high temperatures makes it reasonable to assume the dominant role of boron adatoms in determining the observed boron dopant gas effects. The same assumption is applied to the n-type dopant gases, *i.e.*, phosphine and arsine. The available data on diborane and arsine further show that, upon thermal decomposition, both boron and arsenic atoms strongly adsorb on the silicon surface (8c). In addition, complete coverage of the silicon surface with boron gives the highest silane deposition rate among all the experiments using various silane-diborane mixtures (8c). Some correlation with the boron adatom concentration is also noted. For a rigorous treatment of the dopant gas effects, the contribution from the adsorbed undecomposed dopant gas molecules, if any, should also be taken into account. However, this cannot yet be done due to the lack of knowledge on the surface lifetimes of these molecules on a hot silicon surface. Therefore, only the dopant adatom effect is considered here which is justified by the experimental facts cited above.

From a chemical point of view, silane has the partially ionic Si^+-H^- bonds (10). Being tetrahedral, such a molecule possesses no net dipole moment (11). However, the ionic character mentioned would make silane a molecule with four negatively charged hydrogen atoms surrounding a positively charged silicon atom in the center. A molecule of such polarity would be attracted by a surface with positive surface potential and be repelled from one with negative surface potential. In other words, making the surface potential more positive would enhance silane adsorption on the surface. The same argument applies to silicon tetrachloride which has Si^+-Cl^- ionic bonds, similar to those in silane.

First, we define a reference surface to be a silicon surface with only adsorbed silicon atoms. This is the case when pure silicon chemical vapor is used. A boron-adsorbed silicon surface can be seen to be different from the reference one. Boron, being a p-type dopant and electron deficient relative to silicon, should, relative to the reference surface, lower the local electron density on the surface silicon atoms around the adsorption site. This would increase the electron affinity of the local silicon surface around the adsorbed boron (12). According to Allen and Gobeli, an increase in surface electron affinity increases the positive surface potential (12). This has been observed on both Si and Ge (9, 12). A boron-adsorbed silicon surface would thus attract molecules like silane and silicon tetrachloride better than the reference surface. This should enhance the adsorption and, therefore, the deposition rate of these molecules. On the other hand, phosphorus and arsenic, which are n-type dopants and electron-excessive relative to silicon, would make the surface potential more negative than the reference one. Accordingly, the deposition rate of silane and silicon tetrachloride should be lowered when they are mixed with phosphine and arsine. The observed dopant gas effect on the deposition rates of silicon chemical vapor is thus satisfactorily and consistently explained. These results are summarized in Table I.

One further support to our model is the agreement between the predicted and observed deposition rate dependence on the dopant atom concentration. This can be better understood if we describe our model using the surface-state concept (13). Compared with a reference surface defined earlier, adsorbed boron atoms decrease the surface-state electron density, whereas phosphorus and arsenic atoms increase it. The induced local surface dipoles have their positive and negative ends, respectively, pointed toward the vacuum. Interaction with silane is, therefore, more attractive in the former case and more repulsive in the latter than in that of the reference surface. Both types of interaction increase with increasing coverage of the dopant adatoms on the surface. As the adatom concentration reaches *ca.* 10^{12} atom/cm^2, the induced surface dipoles emerge into a continuum (13). Furthermore, it is reasonable to assume the dominance of short-range interactions between the chemical vapor

Table I. Predicted and observed dopant gas effects on the deposition rates of silicon and carbon chemical vapors*

	SiH_4	$SiCl_4$	CH_4	CCl_4

[a] Ref. (8).
[b] Ref. (17).

molecule and the surface (8c). One, therefore, expects appreciable dopant adatom effect beyond the concentration of 10^{12} atom/cm^2 on the adsorption of silicon molecules. The observed onset of significant changes in the deposition rate of silane and silicon tetrachloride at the above dopant adatom concentration (8) is thus consistent with the theory.

A quantitative treatment of this problem involves calculation of the interaction between an adsorbed chemical vapor molecule and a differently dopant-atom adsorbed silicon surface. To date, such calculations are extremely difficult, if not impossible (14, 15). Therefore, only a qualitative test is given here. Some semiquantitative work is in progress to estimate the dopant adatom effect on the local surface electron densities.

To test our model qualitatively, we chose a CV molecule of opposite polarity to that of SiH_4 and $SiCl_4$. The dopant gas effect on the deposition rate of this chosen molecule should then be opposite to that for SiH_4 and $SiCl_4$. One possible molecule is methane. Methane is also tetrahedral but has the C^--H^+ type of ionic bond. The polarity of methane is, therefore, opposite to that of silane. When carbon tetrachloride is used as a chemical vapor gas, its dopant gas effect should be similar to that of silane due to the C^+-Cl^- polarity of this molecule. The predicted dopant gas effects for methane and carbon tetrachloride are also listed in Table I. For a meaningful test of our model in carbon CVD, data on diamond deposition should be used. This is because the structure of diamond is similar to silicon, whereas the layer structure of graphite would complicate the deposition mechanism (16). The available literature data on the dopant gas effect on diamond deposition concern the methane-diborane system (17). The results clearly show that mixing methane with diborane lowers the diamond deposition rate from that observed using only methane. This is exactly the effect predicted by our model.

Although limited by the available information for a full qualitative test of our model, agreement with the existing data is encouraging. It is, therefore, worthwhile to point out some useful work that will be necessary to a better understanding of the CVD process. (*i*) Experiments for the lacking information listed in Table I should be carried out for a complete test of our model. Also, doping with other p- and n-elements, such as aluminum, should provide further testing of the model. (*ii*) As a test of the dopant adatom effect on the surface potential, a bias voltage of the proper polarity should be applied to the substrate and observation made of its effect on the deposition rate of pure chemical vapor molecules. A similar test should be made by the application of an electric field to the surface. (*iii*) Surface properties for silicon and diamond should be studied in the presence of adsorbed boron, arsenic, phosphorus, and other dopant atoms. Such properties include the surface states and work function, and surface lifetimes of adsorbed chemical vapor molecules. This study would allow a direct understanding of the adsorbed dopant atom effect on the surface properties and is essential to our final understanding of the problem discussed in this paper.

Once the suggested experiments are shown to support our model proposed above, it will then be possible to increase the deposition rate of silicon CVD at low temperatures. For example, by applying a suitable bias voltage which matches favorably with the polarity of the chemical vapor molecule, the substrate surface potential can be adjusted to increase the deposition rate beyond the current limit. It is also obvious that the right combination of molecule and dopant gas to allow the maximal increase in deposition rate must be chosen. Examples from Table I are SiH_4-B_2H_6, CH_4-PH_3, CCl_4-B_2H_6, etc. The remaining limiting factor will be the amount of thermal energy available at low substrate temperatures. One needs then to find a compromise between the maximal thermal energy available and the minimal interaction and diffusion allowed between the deposited thin film and the substrate chosen. All these principles should also be applicable to the CVD of other types of thin films, such as those for Si_3N_4, SiC, W, etc.

Finally, since our model is concerned mainly with the effect of one adsorbed species on the adsorption of another molecule, this work should also be useful to surface catalysis studies. In surface catalysis, molecular adsorption plays an essential role before decomposition or chemical reaction takes place. By varying the surface potential as described in this paper, one should observe changes of the chemical reaction rates between adsorbed molecules. This should allow a better understanding and control of the chemical reactions under study. In addition, varying the magnitude and sign of the surface potential should provide important information on the formation and strength of the chemisorptive bonds between the adsorbed molecule and the surface. Again, more experimental and theoretical work along this line is needed to further advance our idea to surface catalysis.

Improvement of Lead-Free Flux Systems for the Growth of Bismuth-Substituted Iron Garnet Films by Liquid Phase Epitaxy

J. M. Robertson*

Philips Research Laboratories, Eindhoven, The Netherlands

It has been shown that the Bi-substituted iron garnets are possible candidates for use in a magnetic bubble display (1) or in a beam-accessed thermomagnetic memory device (2). The first films grown for these purposes were from a PbO melt (3, 4), but they lacked the required optical properties. In particular the optical absorption coefficient, α, was too large, and this was attributed to the simultaneous incorporation of Pb^{2+} ions from the flux that occurs at the low growth temperatures required for high Bi substitutions (5).

Robertson *et al.* (6, 7) have shown that the use of a flux system based on $Bi_2O_3:MeO_2$ with Me = Si, Ge, Ti, or Ce leads to improved magneto-optic properties of the grown layers. A value for the figure of merit $\theta/\alpha = 4.7°/dB$ at 560 nm was obtained and this is very near to the 5°/dB required to make an efficient display device (1).

Several problems were encountered when using these new flux systems and this paper presents the work performed in improving the fluxes so that high quality Bi-substituted iron garnet films can be grown using the isothermal dipping technique of liquid phase epitaxy (8).

Disadvantages of the Flux Systems

The incorporation of the Me^{4+} ions of the flux into the garnet leads to higher optical absorption due to charge-compensating Fe^{2+}. Thus it would be better if all four valent ions were eliminated from the fluxes. The second problem was the nature of the liquids themselves. When garnet growth is performed with the substrate in the horizontal plane, it is usual at the end of film growth, after the sample has been removed from the melt, to rotate it at high speed to throw off any remaining flux droplets. In the case of the present liquids this does not happen and instead the liquid gathers at the axis of rotation where it freezes and causes a degradation of the quality of the film by cracking or producing etch pits and mesas. This problem was solved to a large extent by dipping the substrate in the vertical plane and applying double harmonic motion in the manner as described by Brice *et al.* (9).

When we attempted to try to solve this second problem in another manner, *i.e.*, by lowering the surface tension of the liquids, we found that the first problem was also solved.

Use of Alkali Metal Oxides in Flux Systems

A study was made of the effect that alkali-metal oxides would have on the surface tension of the flux system $Bi_2O_3:MeO_2$ discussed above. Table I gives a summary of some of the results obtained by Davies (10) when K_2O was added to the system $Bi_2O_3CeO_2$. At the measurement temperature of 850°C it can be seen that the first 4 weight per cent (w/o) of K_2O added has quite an effect on the value of the surface tension. Further additions do not have so much effect. With 6 w/o K_2O the surface tension is very similar to that of $PbO;Bi_2O_3$, which was used to grow films of good quality (3, 4). The numbers in parentheses indicate the values of other published data.

To verify these results, we used a melt containing 6 w/o K_2O to grow garnet films by LPE. The melt composition was as follows: $Bi_2O_3:CeO_2:Y_2O_3:Fe_2O_3:Ga_2O_3:K_2CO_3$ = 349.5:1.30:2.10:11.2:1.5:30.8 (all values given in grams). The saturation temperature of the melt was ~ 870°C and the films grown had a lattice match within ± 0.01Å of the $Gd_3Ga_5O_{12}$ substrates. Films of good quality were grown and the viscoelastic nature of the liquids was no longer a deleterious factor.

The surface tension apparatus also allows an estimate of the melting points to be made. These data are also included in Table I, from which it can be seen that the addition of K_2O lowers the melting points. If the viscosity remained low, it would be possible to eliminate the MeO_2 from the fluxes and thus reduce the tetravalent ion contamination in the garnet films.

Table II summarizes some data for the values of surface tension measured at 850°C and the melting points of the flux systems Bi_2O_3 + 4 w/o R_2O, where R = Li, Na, K, Rb, or Cs. It can be seen from the data that the lowest melting points are achieved with the system $Bi_2O_3:Na_2O$ and the lowest values for the surface tension with the system $Bi_2O_3:K_2O$, although there is not much to choose between these two systems. For a trial growth of garnet films, the system $Bi_2O_3:K_2O$ was chosen and a melt of composition $Bi_2O_3:Y_2O_3:Fe_2O_3:Ga_2O_3:K_2CO_3$ = 349.5:2.10:11.00:3.5:20.5 (all values given in grams) was premelted under oxygen into a crucible. This procedure was used to reduce the attack on the platinum crucibles [see Ref. (11) for more details]. The saturation temperature of the melt

was about 827°C. With a $Gd_3Ga_5O_{12}$ substrate vertically dipped (no rotation) into the melt at 804°C for 30 min, the resulting film had the following properties. The lattice parameter misfit was $\Delta a = 0.011$Å, film thickness = 6.55 μm, uniaxial anisotropy Ku = 13.8 × 10^3 erg cm^{-3}, saturation magnetization = 124G, and the magnetic bubbles had a mobility of 5000 cm/oe sec.

Particulars of other garnet film compositions grown from the system Bi_2O_3:Na_2O have been reported by Krumme *et al.* (12). Finally, although the evaporation rate has not been measured absolutely, it seems, from inspection of the tops of the furnaces, that the lead-free fluxes are less volatile than the Bi_2O_3:PbO mixtures.

Conclusions

Improvements to flux systems that contain no lead have been investigated for the growth by LPE of bismuth-substituted iron garnet films and the best results were obtained with the system Bi_2O_3 4 w/o R_2O where R = K, which has the lower value for the surface tension.

Acknowledgments

The author would like to thank J. Davies for the use of his results on the surface tension and viscosity prior to publication and to M. Jansen for growing the films. F. de Leeuw and P. K. Larsen are thanked for their measurements on the layers. J. C. Brice and P. F. Bongers are thanked for their useful comments during the preparation of this manuscript.

Manuscript submitted Dec. 22, 1975; revised manuscript received March 29, 1976. This was Paper 224 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Mechanical-Chemical Technique for Removal of Epitaxial Spikes

L. E. Katz* and W. C. Erdman**

Bell Laboratories, Allentown, Pennsylvania 18103

Epitaxial spikes have been a recurring problem over the years although defect levels have decreased with improved cleaning and handling techniques. The existence of these defects, which range in height from a fraction of a micrometer to several micrometers can result in mask damage when contact printing is used. It is the purpose of this paper to describe a simple, effective, and efficient technique for removing these defects without introducing any additional damage to the wafer. Proper utilization of the technique removes virtually all epi-spikes and results in a wafer which can be contacted to a mask without causing mask damage.

Prior attempts to remove or reduce the number and size of spikes have involved various mechanical methods which included scraping with a razor blade, crushing, or abrading. All of the simple mechanical removal techniques tend to be inadequate because of poor removal efficiency and an attendant high risk of surface contamination from particulates. A chemical etching technique was developed earlier (1) to selectively expose spikes to chemical etching. While the removal efficiency is high, the method suffers from an intermittent background of extraneous[1] etch pits that is intolerable, especially as chip size is increased. An additional impetus for a new approach arises from the number of processing steps of the previous process which increases wafer cost.

Experimental Procedure

The evaluation procedure involved counting and mapping the number of epi-defects on a particular group of wafers. Twenty-nine chips of the ~90 chips (~0.23 × 0.30 cm) present were mapped. The wafers were then subjected to the spike removal process and once again mapped; this time for spike removal pits. Counting repeatability was generally within ± 1 defect per 29 chips. The defects were examined optically to determine if the spike had been entirely eliminated. It is important that extraneous pits not be introduced since this can cause other processing problems later on. This new spike removal technique was also evaluated for mask damage. The procedure involved obtaining a defect count from a blank chrome mask, using a laser scanner (2). The wafer, after spike removal, was then contacted to the mask and once again a defect count obtained using the laser scanner. Since the number of defects was generally low, the damage was magnified either by multiple contacting of wafers to the same mask, or using wafers which had been grown with thick epi-layers in such a manner as to maximize the number of spikes. Such techniques provided a critical evaluation for the spike removal technique.

** Deceased.
Key words: defects, mask damage, silicon.
[1] Extraneous etch pits are defined here as pits not related to epi-spikes but to the spike removal process. Spike removal pits are defined as those pits present, after spike removal, at the identical site of an epi-spike.

When a precision steel edge, typical of a commercial razor blade, is drawn across the surface of an epitaxial silicon wafer, any spikes present on the wafer have a high probability of being fractured. The remainder of a spike can be as damaging to a contact mask as the spike itself before the mechanical removal step. Earlier attempts to use mechanical methods as a sole treatment suffered from the effects of a fluctuating but significantly high number of partially removed spikes together with debris from the mechanical fracturing process. This "residual" spike effect can be almost totally eliminated by following the spike-fracturing step with a chemical etch, provided a protective oxide film is present.

The present method involves thermally oxidizing the epitaxial wafer to produce a film from 0.3 to 0.5 μm thick. The wafer is then scraped with a commercial razor blade while the wafer is secured on a stable planar platform using a vacuum chuck. The blade is held on a machine assembly which draws the blade with a constant force, angle, and speed over the wafer surface. A few drops of dilute detergent (1000 parts deionized water to 1 part Triton X-100) placed on the wafer prior to fracturing the spikes is beneficial in removing the debris formed during the spike-fracturing process. The chuck is arranged to index to 90° of the original presentation to the blade and the blade is run again over the surface. The double mechanical treatment serves to increase the probability of at least some fracture to almost all spikes without causing appreciable extraneous surface damage. Hand manipulation of a blade is effective and can be used in lieu of a machine as long as the wafer is well secured on a vacuum chuck or equivalent.

After mechanical treatment, the wafer is placed in an etch bath of 5M aqueous KOH at 85°C for 15 min. The etch rate typical of the etchant, approximately 2 μm/min on all silicon planes except the (111), is sufficient to destroy all damaged spikes within the 15 min interval. It should be noted that the spike need only be superficially fractured by the mechanical step to be removed if the protective oxide film is ruptured. The undamaged oxide film over the remainder of the epitaxial wafer is extremely efficient in protecting the surface. This is true because of the low inherent pinhole density of thermal oxide films of this thickness and the relative slow etch rate of thermal SiO_2 in KOH solution (~50 Å/min). The etch step in KOH is easily adapted to usual batch processing techniques. The etch bath can be easily thermostated (±1°C is sufficient) in a controlled external water bath.

Experimental Results and Discussion

Spike removal.—Wafers from different lots were mapped with respect to spikes with the oxide present, and were mapped again after spike removal. Evaluation consisted of counting the total number of spikes on 29 chips on each wafer. Values obtained for various wafers ranged from 0 to 6. The number of spike removal pits for each wafer corresponded to the original number of spikes. The conclusion from this experiment is that the mechanical-chemical spike removal process is capable of removing spikes with little or no "background" of extraneous pits. This is not the case, as discussed previously, with the chemical etching technique.

Figure 1 shows a wafer surface including a spike at different stages of mechanical-chemical projection removal. The undamaged spike is shown in Fig. 1(a). Figure 1(b) shows the appearance of the spike after the mechanical damage step. Clearly only part of the spike is removed. It is obvious that mechanical removal alone is less than adequate for most purposes. The appearance of the spike site and surrounding wafer surface after KOH etching shows the total absence of debris and the complete removal of the spike as seen in Fig. 1(c).

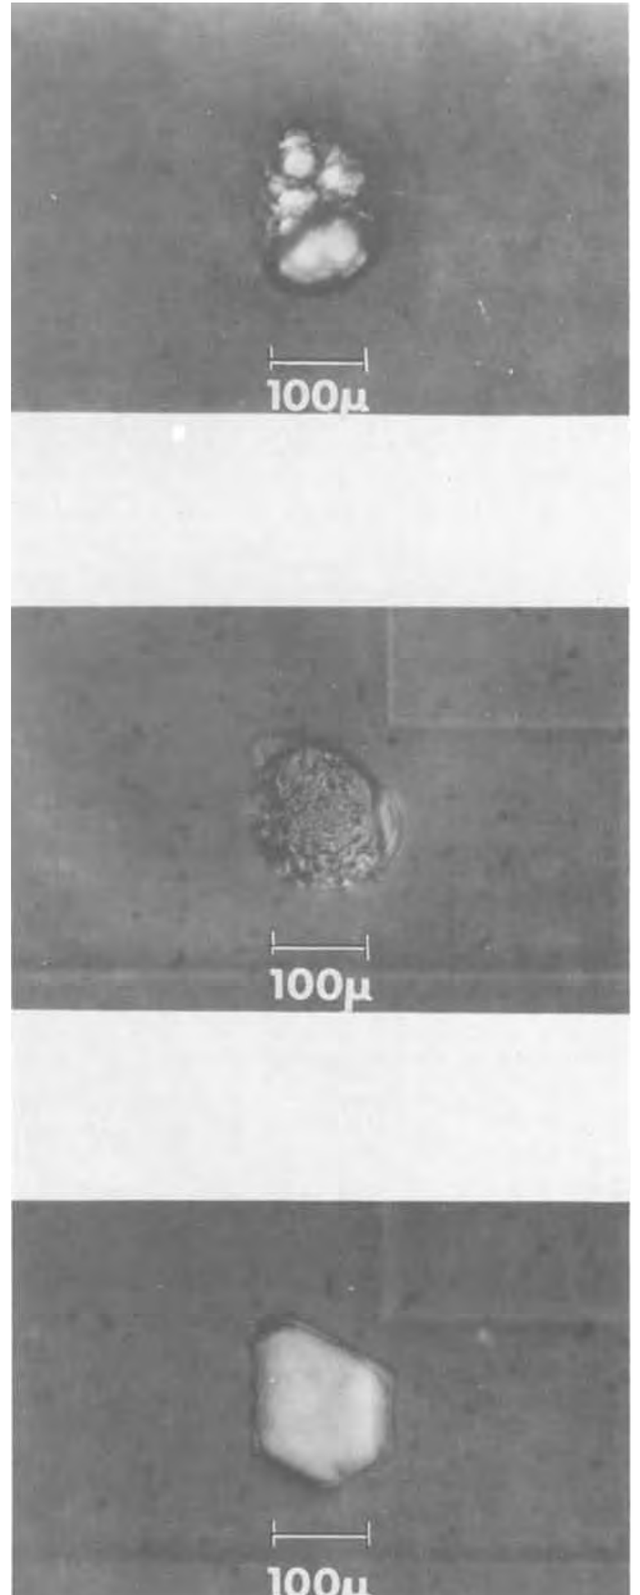

Fig. 1. Epitaxial silicon spike: (a, top) prior to spike removal; (b, center) after mechanical damage; (c, bottom) after mechanical-chemical spike removal.

Mask damage.—The procedure using blank chrome masks and laser inspection was described previously. The laser counting statistics involve an error bar equal to plus or minus the square root of the number of defects. The mask area examined was a 3.8 cm square. In all cases, two laser counts were taken on each mask prior to contacting and those masks showing a large number of the defects were discarded. The laser scan-

ner is capable of measuring defects ≧ 1.8 μm in size. After contacting, two additional laser counts were taken.

Results showed that the mask defect density could be reduced from 10-60 (for wafers not subjected to spike removal) down to 1-2 (for wafers subjected to spike removal). These results were confirmed when several wafers which had been subjected to spike removal were contacted to the same mask.

As a severe test of the capability of the spike removal process, epi was grown on silicon substrates in such a manner as to obtain a high density of large spikes. Such wafers put through the spike removal process showed little or no mask damage within statistical limits. When high spike density wafers were contacted without the spike removal process, the mask defect counts were very high (>50). The conclusion is that even high densities of large spikes can be successfully removed from the wafer with little or no subsequent mask damage.

Conclusions

A new mechanical-chemical spike removal technique has been devised which effectively removes epi-spikes without introducing extraneous pits. No photoresist operations are involved. A mask damage evaluation technique has been described and used to evaluate masks contacted to wafers subjected to the new spike removal technique. Results based on the mapping of defects and mask damage studies lead to the conclusions that the new spike removal technique efficiently removes epi-spikes and that wafers subjected to this process produce little mask damage when contacted to blank chrome masks.

Although epi-spike densities are generally low, this simple process guarantees that no damage will result from the few spikes which may have initially been present.

The Diffusion of Compensating Impurities in Single Crystal Cadmium Sulfide

J. L. Sullivan

University of Aston, Gosta Green, Birmingham, England

With a bandgap of about 2.5 eV, one would expect single crystal cadmium sulfide to exhibit high resistivity at room temperature. Due to a nonstoichiometric crystal structure, however, room temperature resistivities of 1 ohm-cm are typical in ultrahigh purity material. If a Group I impurity such as Cu, Ag, or Au diffuses into the crystals, the occupation of Cd lattice sites by the impurity atom results in the formation of deep electron traps. Thus a high resistance region is formed where the concentration of impurity atoms occupying Cd vacancies is great enough to remove most of the electron from the conduction band. This property is used in the production of many photoconductive devices.

It has been widely suggested that an interstitial-substitutional mechanism is dominant in compensating impurity diffusion. The CdS lattice is a tetrahedrally bonded wurtzite structure which is equally open in all directions. There are two major interstitial sites available for an impurity atom: a tetrahedral site of mean radius 0.10 nm and an octahedral site of mean radius 0.14 nm. Allowing for thermal relaxation, both sites are sufficiently large to accommodate an impurity. It is thus most likely that diffusion takes place via these sites and that an interstitial-substitutional mechanism is indeed responsible. If net compensation of crystal resistivity is to occur, however, the time spent by an impurity in an interstitial position must be very much less than that spent in a Cd vacancy. If this were not so, electrons donated to the conduction band by the interstitial impurity would compensate for those removed by impurities occupying vacancies and no net change in resistivity would occur. Thus we must regard the energy required to remove an impurity from an interstitial site as very much less than that to remove the impurity from a substitutional site.

Key words: diffusion, cadmium sulfide.

The Migration Energy of Diffusion

Following an approach due to Glyde (1), an impurity atom residing at a Cd lattice site makes a jump to an adjacent interstitial site when its displacement from the equilibrium position is large enough and when the surrounding atoms move so that the impurity may pass. The probability of an atomic displacement u_α along the α axis (2) is

$$P(u_\alpha) = (2\pi <u_\alpha^2>)^{-1/2} \exp - \frac{1}{2} \left\{ \frac{u_\alpha^2}{<u_\alpha^2>} \right\} \quad [1]$$

If, for simplicity, we consider a cubic crystal [the difference between the wurtzite and zinc blende structures is small enough to make this assumption valid; for example, Bocchi and Ghezzi (3) have shown that the ratio of the mean square amplitudes parallel and perpendicular to the c axis in CdS is 1.09], it may then be shown (1, 4) that

$$P(u_\alpha) = \left\{ \frac{6\pi kT}{m\theta_D^2} \left(\frac{h}{k}\right)^2 \right\}^{-1/2} \exp - \frac{1}{6} \left(\frac{k}{\hbar}\right)^2 \frac{\theta_D^2 u_\alpha^2 m}{kT} \quad [2]$$

where m is the mass of the diffusing atom, k is the Boltzmann constant, T is the absolute temperature, and $\theta_D = \hbar\omega_D/k$.

If the distance between a Cd vacancy, V_{Cd}, and an adjacent interstitial site, I, is b, then a jump occurs when $u = b/2$, and

$$P(b/2) = \left\{ \frac{6\pi kT}{m\theta_D^2} \left(\frac{\hbar}{k}\right)^2 \right\}^{-1/2} \exp - \frac{1}{24} \left(\frac{k}{\hbar}\right)^2 \frac{\theta_D^2 b^2 m}{kT}$$

Similar expressions may be derived (i) for the subsequent $I \rightarrow V_{Cd}$ jump and (ii) for the movement of the surrounding atoms to allow the jumps to take place. The total probability of impurity movement from one vacancy to the next is the product of the individual probabilities. The effect of (i) is to modify the preexponential terms by a constant amount and to introduce a constant, g, into the exponential. The probabilities (ii) are not dependent on impurity mass and the effect of these is to change the preexponential term by a constant amount. Thus the total probability of impurity movement from one vacancy to the next is

$$P = \text{constant} \left\{ \frac{6\pi kT}{m\theta_D^2} \left(\frac{\hbar}{k}\right)^2 \right\}^{-1/2} \exp - \frac{g}{24} \left(\frac{k}{\hbar}\right)^2 \frac{\theta_D^2 b^2 m}{kT} \quad [3]$$

We may imagine the potential acting on an impurity atom in moving from vacancy A via an interstitial B to the next vacancy C to be as shown in Fig. 1 if the impurity compensates crystal resistivity $E_{m_V} >> E_{m_I}$ and the constant g is very close to unity.

Then from Eq. [3] we may write the diffusion jump rate as

$$\Omega = \Omega_o \exp - \frac{E_m}{kT}$$

where E_m is the mean impurity migration energy, but $\Omega \propto P$. Hence

$$E_m = \frac{1}{24} \left(\frac{k\theta_D b}{\hbar}\right)^2 m \quad [4]$$

The Activation Energy of Impurity Diffusion

The activation energy of the diffusion process may be written

$$Q = E_f + E_m \quad [5]$$

where E_f is the vacancy formation energy. If the impurity concentration is low, the vacancy formation energy is independent of the impurity atom. The activation energy for impurity diffusion therefore consists of a constant term, E_f, plus a term representing the migration energy of the diffusing species and dependent on the mass of that atom. Then

$$Q = E_f + \frac{1}{24} \left(\frac{k\theta_D b}{\hbar}\right)^2 m \quad [6]$$

If all the impurity atoms follow the same net diffusion route, b is also constant and a plot of Q *vs.* m is linear of slope S and intercept on the Q axis equal to E_f. Inserting values of physical constants in Eq. [6] and rearranging in terms of b we have

$$b = 3.08 \times 10^{-13} S^{1/2} m \quad [7]$$

This value of b identifies the migration route of the diffusing atom and hence isolates the diffusion mechanism. The value of θ_D used in Eq. [7] is that derived by Bocchi and Ghezzi (3) from mean square amplitudes.

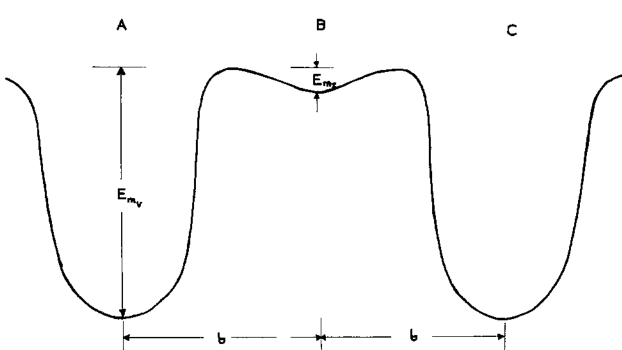

Fig. 1. Two-dimensional representatives of the potential acting on an atom in moving from vacancy A to vacancy C via an interstitial B.

Discussion

Figure 2 shows the dependency of Q (taken from a series of recent measurements for atoms occupying Cd lattice position) on m. Considering the many different techniques employed in the measurements, the curve is reasonably linear. From the curve $E_f = 0.6$ *eV* and $b = 0.248$ nm, the expected error in b is ±12%.

In his prediction of migration routes in spinels, Grimes (6) found that atoms behaved as though they were hard spheres. If we follow this approach there are two possible interstitial sites in CdS capable of accommodating the impurity ion: the tetrahedral interstitial site at a distance of 0.253 nm from a Cd lattice site and the octahedral site at distance 0.293 nm. The distance between the two interstitial sites is 0.245 nm. Due to close packing of the sulfur atoms, the only jump possible for an impurity atom occupying a Cd vacancy is to a tetrahedral interstitial site, a distance of 0.253 nm. Interstitial-interstitial migration is then possible, but since the time spent in interstitial positions must be small, the most likely movement of the impurity is to a Cd vacancy. Thus, the most probable diffusion route is $V_{Cd} \rightarrow I_{tet} \rightarrow V_{Cd}$ with a mean jump size of 0.253 nm, although the route $V_{Cd} \rightarrow I_{tet} \rightarrow I_{oct} \rightarrow I_{tet} \rightarrow V_{Cd}$ is possible. Here the mean jump size is 0.249 nm.

Conclusion

Using a "hard-sphere" model, the expected mean jump size for an interstitial-substitutional diffusion mechanism lies between 0.249 and 0.253 nm and is probably much closer to the higher figure. From a relation-

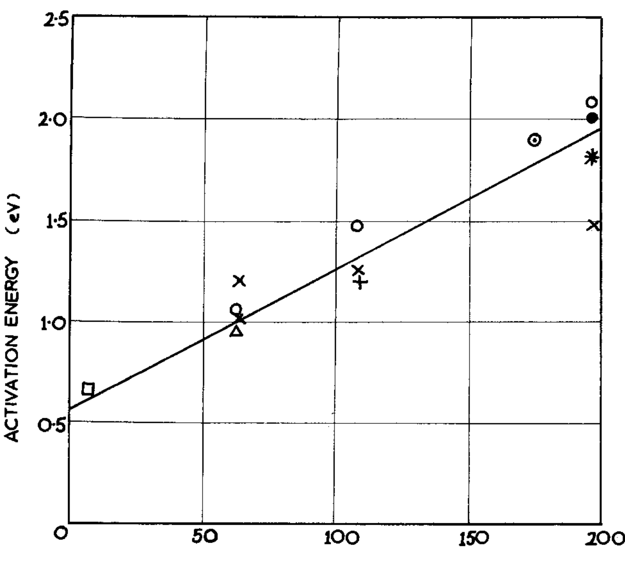

Fig. 2. Dependence of the activation energy for diffusion of compensating impurities in CdS on the mass of the diffusion atom. ⊙ Anderson and Chang (7), □ Dobrovinskya et al. (8), ● Malysheva (9), * Nebauer (10), △ G. A. Sullivan (11), ○ J. L. Sullivan (12), + Woodbury (13), × Zmija and Damianiuk (14).

ship established between the migration energy and the mass of the diffusing element, the mean jump size calculated from recent experimental data is 0.248 nm ±12%. Very acceptable agreement is thus found from the mean jump size derived from experimental data and that to be expected for an interstitial-substitutional mechanism. The agreement strongly suggests that this is the dominant mechanism for compensating impurity diffusion in single crystal CdS.

Brief Communications

Vacuum Ultraviolet Excitation Spectra of Phosphors for Use in Gas Discharge Display Panels

A. W. de Jager-Veenis and A. Bril*

Philips Research Laboratories, Eindhoven, The Netherlands

For use in gas discharge display panels, phosphors are required that have a high efficiency and a high light output (high absorption, *i.e.*, low reflection) for vacuum ultraviolet (v.u.v.) excitation, *e.g.*, from Xe, Kr, or Ar discharges. Well-known phosphors that could be used for this purpose are, for instance, willemite (Zn_2SiO_4-Mn) with low Mn concentration as a green-emitting phosphor, $CaWO_4$-(Pb) as a blue-emitting one, and the halophosphate Sb-Mn, which has a white emission (1-7). The relative excitation spectra of rare earth activated phosphors like Y_2O_3-Eu^{3+} and YVO_4-Eu^{3+} (red emitting), Y_2O_2S-Tb^{3+} and $SrGd_2S_4$-Eu^{2+} (green emitting), and Y_2SiO_5-Ce^{3+} and $Sr_3(PO_4)_2$-Eu^{2+} (blue emitting) have also been reported (2, 3, 6). In their experimental display panels, Ohishi *et al.* (6) used Y_2SiO_5-Ce in the blue, Zn_2SiO_4-Mn in the green, and Y_2O_3-Eu or YVO_4-Eu in the red region. Fukushima *et al.* (7) used $M(P,V)O_4$, Zn_2SiO_4-Mn, and $M(P,V)O_4$-Eu^{3+}, respectively (M = rare earth).

Searching for a guide to find an efficient "v.u.v. phosphor" we looked among the well-known efficient cathode ray (CR) phosphors and middle ultraviolet (m.u.v.) phosphors (*e.g.*, fluorescent lamp phosphors). With CR excitation, the excitation energy is absorbed in the host lattice, so that there should be transfer of absorbed energy to the luminescent centers. Many efficient m.u.v. phosphors are excited directly in the centers. These mechanisms might also hold for the respective types of phosphors when the excitation is extended to the v.u.v. energy region. However, although the very efficient m.u.v. phosphor halophosphate-Sb-Mn, for example, is a good v.u.v. phosphor, too, YVO_4-Eu and Y_2O_2S-Eu are both efficient CR and m.u.v. phosphors with a poor light output in the v.u.v.

Experimental

Our excitation measurements extended from $\lambda = 160$ up to 260 nm, at which latter wavelength the absolute quantum efficiency can be readily measured (8). If no light output could be obtained by excitation at $\lambda = 260$ nm, the Cd spectral line at $\lambda = 228.8$ nm was used as a radiation source for absolute measurements.

The excitation spectra were measured on a Seya-Namioka type McPherson 235 monochromator, the radiation source was a deuterium lamp with suprasil window, and the emitted (visible) radiation was detected with a spectrally calibrated EMI 9558Q photomultiplier (S20 cathode).

Results and Discussion

We measured among our own samples the excitation spectra and quantum efficiencies of some of the phosphors mentioned in Ref. (1-7) and found a reasonable agreement with those figures, as far as they are given absolutely. We did not measure the (low) diffuse reflections below $\lambda = 220$ nm. The efficiency values below that wavelength were calculated on the assumption that the diffuse reflection and consequently the absorption did not change from $\lambda = 220$ to 160 nm. None of the phosphors were optimized to obtain the highest efficiency for v.u.v. excitation. We found a rea-

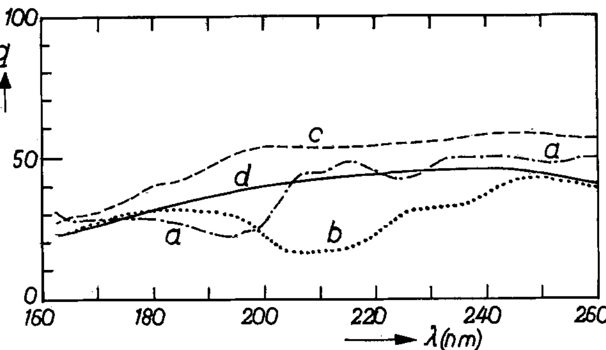

Fig. 2. The excitation spectra of (a) $CePO_4$-Tb^{3+}; (b) $2CaO \cdot Al_2O_3 \cdot SiO_2$-$Ce^{3+}$; (c) YVO_4-Bi^{3+}, Dy^{3+}; (d) $CaWO_4$-Tb^{3+}, Nb^{5+}.

sonably good efficiency at $\lambda_{exc} = 160$ nm for the phosphors made in our laboratories: (Ca,Mg)SiO_3-Ti (blue emission) (9), $(Sr,Eu)_{5.5}Mg_6Al_{55}O_{94}$ (blue) (10), $BaMg_2Al_{16}O_{27}$-Eu^{2+} (blue) (10), $CeMgAl_{11}O_{19}$-Tb^{3+} (green) (10), which are known already to be good m.u.v. phosphors (applied in new generation "de luxe" fluorescent lamps), $Sr_3(PO_4)_2$-Tb^{3+} (green) (11), and CeF_3-Tb^{3+}. The latter has a green Tb^{3+} and u.v. Ce^{3+} emission; the ratio of green to u.v. emission shifts to green at higher Tb^{3+} concentrations (12). The v.u.v. radiation is absorbed in the Ce^{3+} ion and transferred partially to the Tb^{3+}: in the excitation spectrum the Ce^{3+} absorption dominates the Tb^{3+} peaks [see Ref. (13)]. In particular, the phosphors $CeMgAl_{11}O_{19}$-Tb^{3+} and CeF_3-Tb^{3+} have a rather constant and high efficiency throughout the spectrum (see Fig. 1). We intend to describe separately the mechanism of energy absorption and transfer in the phosphors. Somewhat lower quantum efficiencies are found, for instance, for the phosphors: $CePO_4$-Tb^{3+} (green), $2CaO$-Al_2O_3-SiO_2-Ce^{3+} (gehlenite; blue), YVO_4-Bi,Dy^{3+} (yellow), and $CaWO_4$-Tb^{3+},Nb (blue green). The excitation curves are given in Fig. 2.

Acknowledgments

The authors are indebted to Miss R. B. Engelen for part of the measurements, to J. M. P. J. Verstegen of the Light Division for the preparation of the Eu- and Tb-activated aluminates, and to J. L. Sommerdijk for the preparation of the $CaNbWO_4$-Tb and YVO_4-Bi,Dy.

Manuscript received March 17, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Air Anneals of Unencapsulated InP/CdS Solar Cells

Sigurd Wagner and J. L. Shay

Bell Laboratories, Holmdel, New Jersey 07733

and K. J. Bachmann* and E. Buehler

Bell Laboratories, Murray Hill, New Jersey 07974

The p-InP/n-CdS heterodiode solar cell (1-3) is a candidate for large scale terrestrial application. However, prior to its extensive development, a satisfactory operating lifetime and development of a polycrystalline thin film device are required. In this paper, we present results of annealing experiments in ambient air which provide convincing evidence for the stability and long life expectancy of this cell.

n-Type films of CdS were grown on p-type Cd-doped single crystals of InP essentially as previously reported (1, 2). However, for the present experiments, the Cd source temperature was raised from 350° to 375°C to increase the Cd to S flux ratio from 4.5 to 5.8. The InP substrates were kept at 240°C. Room temperature Hall

measurements on a typical CdS film with a thickness of 10 μm gave the following results: $\rho = 0.0063\ \Omega$-cm, $\mu = 140\ cm^2/V$-sec, $n = 7.1 \times 10^{18}\ cm^{-3}$.

We have previously shown (2) that there is no appreciable interdiffusion of the components in the InP/CdS cell during 15 min anneals in air at temperatures up to at least 500°C. The capacitance-reverse voltage characteristic was unchanged by these anneals. However, for annealing temperatures above 400°C, the resistivity of the CdS with $n \approx 2 \times 10^{18}\ cm^{-3}$ increased enormously, as shown by the squares in Fig. 1. Such large CdS resistivities lead to large series resistances which dissipate power internally, thereby greatly reducing the solar cell efficiency. Nonetheless, it is intuitively obvious that rather long useful lifetimes will result under operating conditions ($T \lesssim 50°C$) since temperatures greater than 400°C are needed to deteriorate a cell's performance in 15 min.

It was with these observations in mind that we began a program of accelerated life tests for the InP/CdS cell. The objective of the program was to measure the time required for the CdS resistivity to increase to a value ($\sim$1 Ω-cm) such that the fill factor and power delivered are appreciably ($\sim$50%) reduced. If these "lifetimes" are plotted *vs.* T^{-1} and extrapolated to operating temperature ($\sim$50°C), an upper limit to the useful lifetime can be estimated. (Of course, the extrapolation assumes identical degradation mechanisms at temperatures of test and of operation.)

Instead, we have found that the resistivity of CdS films with $n \approx 1 \times 10^{19}\ cm^{-3}$ is not appreciably altered by air anneals, and that it will not be the limiting factor determining the lifetime in ambient air. As shown by the circles in Fig. 1, the resistivity of these highly conducting films is essentially unchanged by 15 min anneals in air for temperatures up to 600°C. The error bars for 550°C indicate the spread in values obtained for three different samples. In Fig. 2, we show the variation of CdS resistivity for much longer anneals in air at 485°C. Whereas the resistivity of the earlier samples increases from 0.019 to 2 Ω-cm in 15 min, the resistivity of the new films only increases from 0.006 to 0.04 Ω-cm after 7 days at 485°C. A simple extrapolation of these data to $\rho \sim 1\ \Omega$-cm indicates a lifetime of 1 month at 485°C. The open-circuit voltages indicated in Fig. 2 for $\sim$ 1-3 day anneals are higher than both the maximum value of 0.72V previously reported (2) and

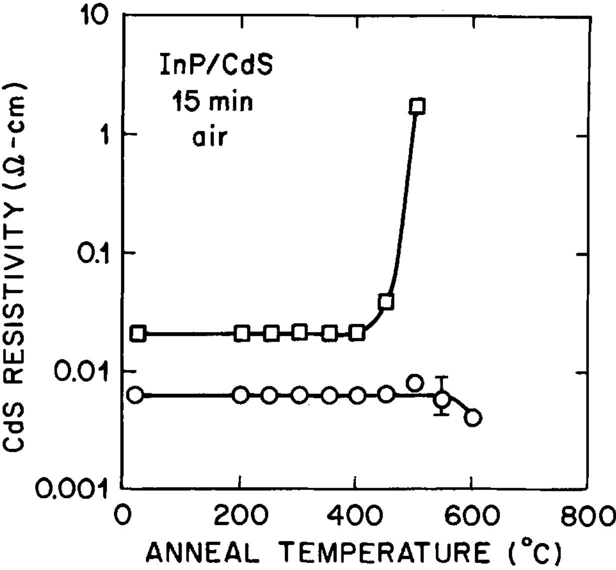

Fig. 1. Resistivity of CdS films (on p-InP substrates) subsequent to 15 min anneals in ambient air at various temperatures. The films with lower initial resistivity were prepared by having a larger Cd to S flux ratio.

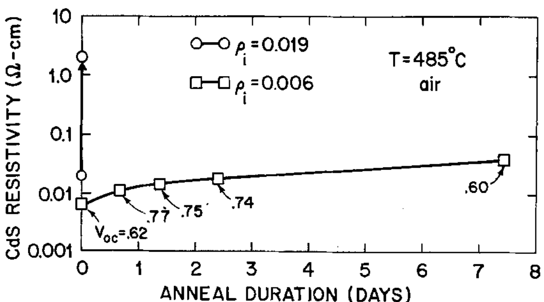

Fig. 2. Resistivity of CdS films (on p-InP substrates) for long duration air anneals at 485°C. Open-circuit voltages measured with a 3200°K tungsten-halogen lamp and a KG2 filter to simulate AM1 conditions (93 mW/cm²). No antireflection coatings were applied to the solar cells.

the band bending in the InP (0.65V) determined from capacitance measurements (4).

Since such a slight increase in resistivity is observed at 485°C, higher temperatures are required for accelerated life testing. We now show that higher temperature anneals change the morphology of the CdS film, and that these changes impair the effectiveness of the solar cell. The data shown in Fig. 1 are limited to temperatures $\leq$ 600°C since for anneals at 650°C in air or in forming gas (15% H_2 + 85% N_2) the CdS becomes porous. The CdS layer detaches from the InP if an attempt is made to apply Ga-In or soldered In contacts. This behavior results from an attack of the CdS by ambient air (oxidation to CdO and SO_3) or by forming gas (reduction to Cd and H_2S). A very thin, whitish, resistive film, probably of CdO, developed on the CdS during the long duration anneals shown in Fig. 2. It was necessary to buff off this film using Linde B (0.05 μm) in order to perform the electrical measurements.

We have shown that this morphological change does not result from a chemical reaction between the InP and the CdS by annealing samples of InP/CdS in flowing argon, saturated with Cd and S vapor from an upstream source of CdS powder. During 15 min anneals at temperatures up to 750°C, the diodes are chemically

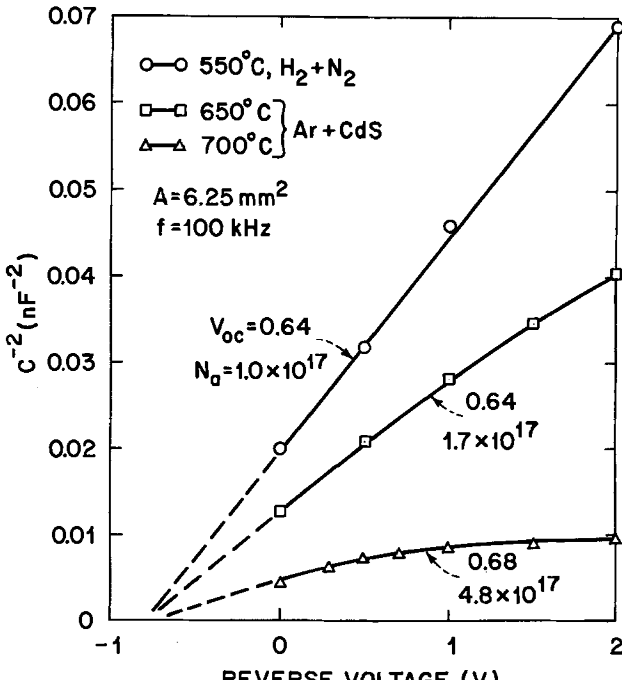

Fig. 3. Capacitance-reverse voltage characteristics for InP/CdS solar cells annealed for 15 min in argon plus CdS at 650° and 700°C, respectively. Capacitance measurements at 1 kHz and 10 kHz were typically a few percent larger.

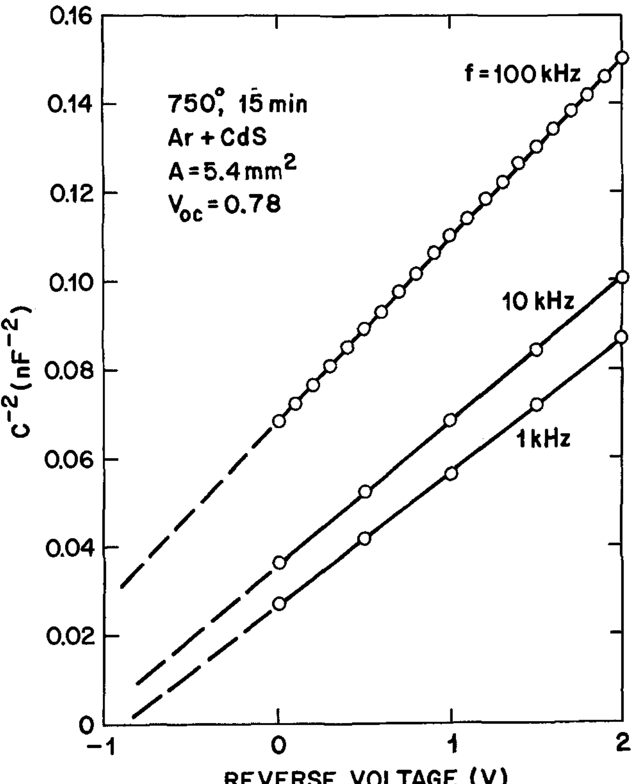

Fig. 4. Capacitance-reverse voltage characteristics for an InP/CdS solar cell annealed for 15 min in argon plus CdS at 750°C.

stable. At 800°C the CdS layer separates from the InP due to interfacial buildup of higher than atmospheric pressure of In_2S, Cd, phosphorus, and sulfur. There is no significant interdiffusion of the components up to ~ 700°C, since the capacitance-voltage curves are well behaved (Fig. 3) and evidence only a gradual increase in the InP acceptor concentration from 1.0×10^{17} cm^{-3} initially up to 4.8×10^{17} cm^{-3} subsequent to the 700°C anneal. This increase in acceptor concentration may result from diffusion of excess Cd from the CdS into the InP. For an anneal at 750°C, the capacitance-voltage characteristic becomes frequency dependent as shown in Fig. 4.

From all of these results, we conclude that the useful lifetime of the InP/CdS solar cell in ambient air will be limited ultimately by a deterioration of the CdS morphology. Accelerated life testing under these conditions will be difficult since contacts must be applied initially which can withstand the high temperature anneals. Although our attempt to measure an accelerated lifetime for the InP/CdS cell has been frustrated by the electrical stability of the CdS films, it has certainly led to an encouraging result for terrestrial applications.

Etch Polishing of GaP Single Crystals by Aqueous Solutions of Chlorine and Iodine

A. Milch

Philips Laboratories, Briarcliff Manor, New York 10510

Investigations of the halogen etching of III-V semiconductors, GaP in particular, reported in the literature have employed two basic attack modes (1-4). They are a halogen dissolved in an organic liquid (1, 2, 3), or an aqueous solution of NaOCl and HCl (4). A third method is described in which the attack medium is an aqueous I_2-KI-HCl solution, but was used only for the etching of gallium arsenide (5).

The present work originated with the need for a clean polishing etch for the controlled removal of material from very thin epitaxial layers of p-type GaP on n-type substrates. What was required was a chemically clean surface on a p-layer of about 3 μm thickness. The Cl_2/methanol or Br_2/methanol systems, cutting at values of approximately 10 μm/min (1), would necessitate uncontrollably short etch times. Moreover, the Cl_2/organic solvent system is inconvenient and possibly dangerous.

The aqueous NaOCl-HCl etchant has the drawbacks of introducing nonvolatile alkali ions which have been known to degrade semiconductor performance (6, 7), and, insofar as the available literature reveals (4), requires electrolytic methods rather than the operationally simpler chemical etch techniques. An obvious expedient is to consider the halogen-water system since, in doing so, all of the above disadvantages are eliminated at once.

This communication recounts some observations on the etching and polishing of single crystal epitaxial GaP by aqueous solutions of chlorine and iodine. Disproportionation of both these halogens occurs (8) in aqueous solution according to the reaction

$$X_2(aq) + H_2O \rightleftarrows HX + HOX \qquad (X = \text{halogen})$$

where both the dissolved halogen and the hypohalous acid may act as oxidizing agents. Note that with X = Cl, the system is somewhat equivalent to the NaOCl/HCl system mentioned above, but with the potentially deleterious effects of the Na^+ ion removed.

[a] Sample held directly in bubble stream.
[b] One determination.

roughness) was waxed to a glass slide and suspended in the stirred etchant for a known period of time. The quantity of material removed was determined by weight loss using a Sartorius microbalance readable to ±0.001 mg on an optically projected vernier scale. Actual repeatability after successive weighings was generally better than ±0.01 mg while actual weight loss measurements were generally greater than 0.5 mg. Knowing the density of GaP (4.13 g/cm^3), the thickness removed and etch rate are readily obtained.

The saturated chlorine solution was freshly prepared each day by bubbling the gas through distilled water for about 15 min prior to etching in order to achieve saturation. Following this, active bubbling was maintained throughout the etching experiments. Stirring was provided by the agitating action of the gas bubbles. Results of experiments conducted at four different temperatures on both B-face (111) and (100) surfaces are given in Table I. It is evident that etch values are sensitive to agitation as indicated by the high rates in the bubble stream. There appears to be a very weak peak in etch rate slightly above room temperature. This is presumably due to the strong and opposing effects of temperature on the solubility of Cl_2 in water on the one hand and on the reaction rate of the dissolved chlorine with the GaP on the other. The effects of agitation appear to be quite significant and may explain the spread of values in some of the grouped data. Nevertheless, the range of observed etch rates is very satisfactory if it is desired to remove very thin layers of GaP.

Samples for etch experiments were chosen for heavy faceting in order to test the polishing action of the etchants. A typical result is displayed in Fig. 1. Visual comparisons indicate that (111) surfaces polish more readily than (100) surfaces and that the etch polishes about as effectively near room temperature as at 6°C. Etch rates at 67°C are so slow as to produce no visible changes over very protracted periods of time. It can be seen from the caption accompanying the photographs that considerable thickness of material had to be removed in these experiments in order to demonstrate polishing. This is an obvious result of the deliberate choice of heavily faceted material to begin with.

Iodine as an etchant.—Assuming no chemical reaction with water, the molar concentration of standard chlorine water at room temperature is about 0.1M. Accordingly, a 0.1M solution of iodine in about ½M HI was prepared and tested.[1] The etching action is practically zero: in two experiments, an etch rate of about 0.006 μm/min was observed during a 50 min etch period (equivalent to the removal of about 100 μg of GaP). In addition, considerable staining of GaP was observed. Hence iodine was quickly abandoned as a reasonable etchant for gallium phosphide.

Conclusions

Water saturated with chlorine at room temperature is an excellent etch medium for GaP. It is convenient and clean, and the etch rate of about ½ μm/min is ideal for the metered removal of reasonable thickness of material with an acceptable degree of precision. It is a good polishing etch, with slightly better results being obtained with the (111) B-face of GaP. Aqueous HI_3 solutions are almost ineffective for etching GaP.

Acknowledgments

I would like to thank Dr. E. H. Stupp for his encouragement and Mr. L. Dahlstedt for technical assistance during this work.

[1] Iodine is virtually insoluble in water. It dissolves in iodide solutions by virtue of the formation of the I_3^- ion.

Control of Palladium Adherence to Silicon Dioxide for Photolithographic Etching

M. S. Shivaraman and C. M. Svensson

Research Laboratory of Electronics, Chalmers University of Technology, Gothenburg, Sweden

The purpose of this note is to report a method for defining a pattern in a palladium film on silicon dioxide. The problem is the very low adherence of palladium to silicon dioxide (1) in which the Pd film may lift off the substrate immediately upon application of photoresist and also may lift off completely upon etching.

In our experiments, a silicon wafer was oxidized in dry oxygen to a thickness of 100 nm (at 1200°C). After that, 100 nm palladium was evaporated by e-gun evaporation. To be able to apply photoresist on the film the adherence to the substrate had to be increased. We then tried different annealing treatments. Annealing in argon at 500°C led to strong oxidation of the palladium probably due to trace amounts of water vapor or oxygen in the gas (the oxidized film could not be etched at all). Annealing in forming gas (10% H_2 in N_2) for 5-15 min did not increase the adhesion. Instead, if it was done after an air anneal (see below), the adhesion decreased. Annealing in air at 150°C gave some increase in adhesion after a long annealing time ($\sim$ 16 hr). Annealing in air at 200° and 250°C did increase adhesion considerably; specifically, a treatment at 200°C in air for 30 min was found to give excellent results. After such a treatment the palladium film could be processed through photoresist application, drying, exposing, developing, and baking with no tendency to lift (using AZ 1350 positive resist). Annealing in air at 300°C again led to oxidation of the Pd film, making etching impossible.

In order to etch the film after photoresist patterning several etches were used. An etch consisting of sodium cyanide and ammonium sulfate described in the literature (2) did not work; instead, different forms of aqua regia were used. Standard aqua regia (3:1 HCl:HNO_3) etched the palladium but before completion of the etching the whole film was lifted off the substrate. No damage of the photoresist was observed under the microscope. Modified aqua regia, with less HCl and more HNO_3, gave, however, satisfactory results. By further moderating the etch with acetic acid, excellent results were obtained with smooth etching and no tendency for film lift-off. The etch used was 1:10:10 HCl:HNO_3:CH_3COOH with an etch rate of about 100 nm/min. After etching, the wafer was rinsed in distilled water and the resist was removed in acetone and rinsed in water again.

Key words: palladium, adhesion, etching.

The method can be summarized in the following way: (*i*) annealing in air at 200°C for 30 min; (*ii*) application of photoresist AZ 1350, spinning, drying, exposure, developing, and baking according to the standard procedure for this resist; (*iii*) etching with the etch described above (at 25°C); (*iv*) resist removal in acetone.

Discussion

The above observations suggest that hydrogen may play an important role in the adherence of palladium to silicon dioxide. It is well known that hydrogen diffuses rapidly through palladium at low temperatures (3). It is not expected that oxygen will diffuse through the film at temperatures of 500°C or less. The oxygen may, however, help extract hydrogen from the film (4).

The air annealing at 200°C is therefore assumed to extract hydrogen from the Pd-SiO_2 interface, and therefore increase the adhesion. The SiO_2 surface is probably covered with nonreactive silanol groups initially (5), and by extracting hydrogen from some of these groups the SiO_2 surface will become more reactive, thus increasing the adhesion. This hypothesis is also supported by the fact that a 500°C anneal in forming gas decreased the adhesion again.

During etching in standard aqua regia (HCl:HNO_3 3:1) we may expect that H_3O^+ may take part in the oxidation of palladium, forming hydrogen adsorbed in the film. This may lead to a decrease of the adhesion between Pd and SiO_2. With an excess of the stronger oxidant NO_3^-, this oxidant will dominate the process and no adsorbed hydrogen will be formed.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

JUNE 1976

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1975 the following graduate students received $1000 each, representing the three Summer Fellowship Awards of The Electrochemical Society.

Miss Mary R. Suchanski, Northwestern University, Evanston, Illinois, was awarded the Edward Weston Fellowship.

Mr. James B. Flanagan, California Institute of Technology, Pasadena, California, was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. Thomas P. DeAngelis, University of Cincinnati, Cincinnati, Ohio, received the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his work.

The Edward Weston Summer Fellowship Report

Miss Suchanski's report is given below.

Resonance Raman Spectroelectrochemistry of Tetracyanoquinodimethane Dianion and Tetrathiofulvalene Monocation

The planar aromatic molecules tetracyanoquinodimethane (TCNQ) and tetrathiofulvalene (TTF) are currently of great interest as the 1:1 complex TTF-TCNQ exhibits near-metallic behavior over a broad temperature range (1-3). Room temperature conductivities of TTF-TCNQ are on the order of 500 (ohm^{-1} cm^{-1}) and increase by approximately one order of magnitude down to 58°K at which point a metal to insulator transition occurs (3). [Compare the room temperature conductivity of Cu which is 6×10^5 (ohm^{-1} cm^{-1}) (4).] The d-c conductivities of TTF-TCNQ are among the highest of all known organic conductors. Full characterization of the physical and chemical properties of highly conducting complexes such as TTF-TCNQ is necessary in developing criteria for designing organic metals with even better electrical behavior. This also involves study of the isolated components of such complexes.

The new technique of resonance Raman spectroelectrochemistry (RRSE) is valuable in studying species comprising organic charge transfer complexes. The highly resolved vibrational spectra obtained reflect the molecular geometry and the electronic distribution in the molecule. Other spectroelectrochemical techniques can yield this type of information. *IR* spectroelectrochemistry (5) provides molecularly specific vibrational data but is at least two orders of magnitude less sensitive in terms of sample concentration required. ESR spectroelectrochemistry compares more favorably with RRSE in terms of sensitivity and also yields structural data through the hyperfine coupling constant (6). While ESR is restricted to those molecules having net spin, resonance Raman spectroscopy requires only electronic absorption in the region of the excitation source.

As a spectroelectrochemical technique, RRSE also has the potential of other spectroelectrochemical methods for identifying the products of reaction sequences following electron transfer and monitoring the kinetics of such reactions. The feasibility of obtaining rate constants in the millisecond time range has recently been demonstrated (7).

The feature unique to RRSE is its ability to yield information about molecular excited states. While the observables in resonance Raman (RR) spectroscopy are those of molecular ground states, the actual process involves vibronic interactions between ground and excited states. Excited-state properties are related to the ground-state observables through the vibronic expansion of the Kramer-Heisenberg-Dirac dispersion relation for light-scattering processes (8). A recent study of the TCNQ radical anion in which the intensity of a ground-state vibrational mode is monitored as a function of excitation wavelength has yielded values of excited-state frequencies and excited-state vibronic level widths (9). Studies of this nature are valuable in the development of resonance Raman scattering theory.

A specific application of the utility of RRSE in studying ground-state properties of TTF and TCNQ is that of comparing frequency shifts which occur upon electron transfer with the corresponding computed bond order changes. This permits evaluation of those MO treatments which have calculated bond orders for the various TTF (10) and TCNQ (11, 12) moieties.

In addition, as vibrational frequencies are influenced by the electronic charge of a molecule, information about ground-state charge densities can be obtained via RRSE. The extent of charge transfer in TTF-TCNQ is a point of great contention, (13-19). Values have been estimated in the range of 0.5-1.0 electron transferred from TTF to TCNQ. From knowledge of radical ion and corresponding neutral vibrational frequencies, one can estimate the extent of electron transfer in solid conducting organic complexes. This comparison between solid-state and solution data is valid, as the frequency shifts in going from solution to a solid are small in comparison to those accompanying electron transfer. For example, see the work of Pecile *et al.* on TCNQ salts (20).

Reported here is an example of the use of RRSE in detecting and identifying decay products of electrochemically produced species. Positive identification of

the O_2 decay product of $TCNQ^{2-}$ has been made. Subsequent chemical routes led to isolation of $TCNQ^{2-}$ in forms suitable for investigation via normal Raman (NR) spectroscopy. The NR spectra of two such $TCNQ^{2-}$ moieties are reported. The vibrational frequencies obtained were used to compare computed CNDO bond order changes (12) with corresponding frequency changes accompanying electron transfer and electronic excitation in $TCNQ^{\bar{\cdot}}$.

Finally, the Raman spectroscopy of TTF is discussed. RRSE was employed to study TTF cation radical. The vibration data for TTF neutral were obtained via NR spectroscopy. A tentative assignment of the totally symmetric modes observed in the $TTF^{\dot{+}}$ RR spectrum is made. Computed bond order changes are compared with the frequency changes accompanying the one electron oxidation process to form $TTF^{\dot{+}}$.

Experimental

Several experimental configurations exist for obtaining Raman data via RRSE. The RRSE experiments reported here were all performed in the controlled potential electrolysis mode in which the species of interest are generated by exhaustive bulk electrolysis in a cell of conventional design with subsequent laser excitation of the species. The laser beam is scattered directly off the walls of the coulometry cell in oblique 180° scattering geometry. The details of the experimental configuration, cell construction, and solution preparation have been described earlier (21).

The $TCNQ^{2-}$ was generated at $-0.7V$ *vs.* SCE in thoroughly deoxygenated spectro grade acetonitrile solutions containing 2.0×10^{-4} to $1.5 \times 10^{-3}M$ TCNQ and 0.1M tetrabutylammonium perchlorate (TBAP). The TTF cation radical was formed under similar conditions at $+0.5V$ *vs.* SCE in solution containing 1.0×10^{-4} to $3.0 \times 10^{-3}M$ TTF.

The reported resonance Raman scattering spectra and the normal Raman scattering spectra were obtained by excitation with a Spectra Physics Model 164 Ar^+ laser, a Coherent Radiation Model CR-8 Ar^+ laser, and a Coherent Radiation Model 490 jet stream dye laser pumped all-lines by the CR-8. Spectra were collected using either a 0.85m Spex Model 1401 double monochromator or a 0.75m Spex Model 1400-II double monochromator. Wavelengths reported are accurate to $\pm$ 2 cm^{-1}. Further information regarding spectral calibration and data collection has been published (21).

Normal Raman scattering spectra of $TCNQ^{2-}$ complexes and of neutral TTF were obtained by the rotating cell technique described by Shriver and Dunn (22). The powdered samples were sealed under vacuum in Pyrex ampuls to avoid air decomposition.

The TCNQ was purchased from Aldrich Chemical Company and was purified by a combination of high vacuum (10^{-5} Torr) sublimation at 150°C and recrystallization from acetonitrile. Neutral TTF was obtained from IBM Corporation and used without further purification.

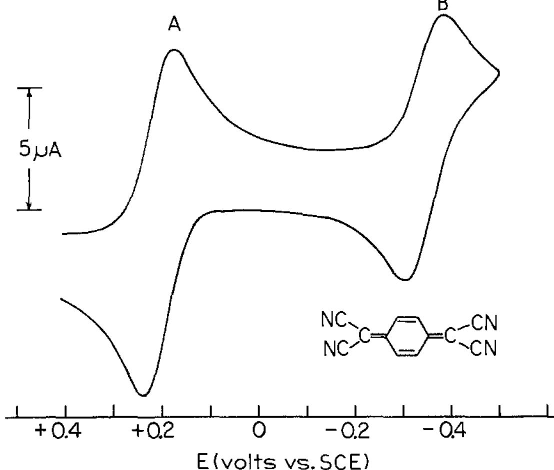
The dianion of TCNQ was chemically prepared by two methods. The procedure of Basolo *et al.* (23) was followed for the reaction of TCNQ with the Schiff base complex N,N'-ethylenebis(acetylacetoniminato) cobalt (II), [Co(acacen)] in the presence of pyridine to form $[Co(acacen)(py)_2]_2TCNQ$. Analysis calculated for $C_{34}H_{32}CoN_8O_2$: C, 62.10: H, 5.54: N, 15.52; found: C, 66.20: H, 5.39: N, 15.29.

Elemental analysis was performed by H. Beck of this department. The sample of dilithium tetracyanoquinodimethandiide tetrahydrofuranate ($Li_2TCNQ \cdot THF$) was synthesized by Dr. Allen R. Siedle at NBS. Two equivalents of *n*-butyllithium are added to TCNQ in tetrahydrofuran at -78°C to produce the white salt ($Li_2TCNQ \cdot THF$) (24).

Results and Discussion

The cyclic voltammogram of TCNQ and the optical spectroscopy of TCNQ dianion are shown in Fig. 1. Peak A corresponds to formation of $TCNQ^{\bar{\cdot}}$ (E_{pc} = +0.172V *vs.* SCE, scan rate V = 100 mV sec^{-1}). At peak B $TCNQ^{\bar{\cdot}}$ is converted to $TCNQ^{2-}$ (E_{pc} = $-0.362V$ *vs.* SCE, scan rate V = 100 mV sec^{-1}). Measurement of the ratio of cathodic peak current to anodic peak current for peak B ($i_{pc}/i_{pa} = 1.00 \pm 0.03$) indicates reversible formation of $TCNQ^{2-}$ on the cyclic voltammetric time scale. In addition, at sweep rates lower than 100 mV sec^{-1} the anodic and cathodic peak separation $\Delta E_p = 0.060V$, indicating electrochemical reversibility.

The only previously reported optical spectrum of $TCNQ^{2-}$ (11) had an absorption maximum at 2.6 eV (477 nm). Attempts to repeat this work are shown by the solid line in Fig. 1. This electronic absorption spectrum of $2.55 \times 10^{-4}M$ TCNQ was recorded less than 5 min after bulk electrolytic generation under absence of O_2. In contrast to the results of Jonkman and Kommandeur (11), the absorption maxima occur at 3.75 eV (330 nm), 5.16 eV (240 nm), and 5.9 eV (210 nm). Upon leakage of O_2 into the bulk electrolysis cell, the



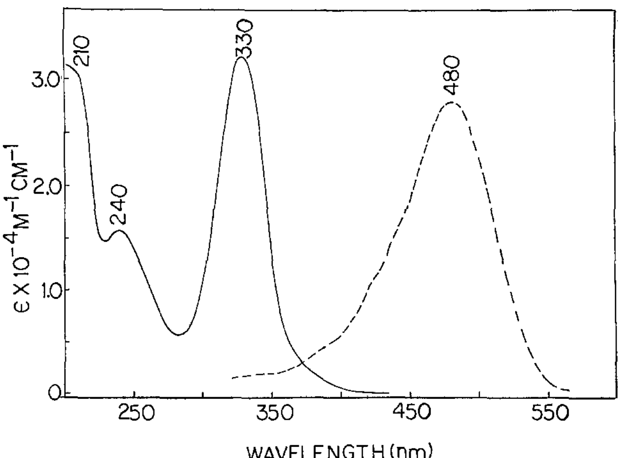


Fig. 1. Upper: First-scan cyclic voltammogram of 0.66 mM TCNQ in acetonitrile containing 0.01M TBAP at a platinum disk microelectrode. The scan rate = 0.100 V sec^{-1}. Lower: Electronic absorption spectra of $2.55 \times 10^{-4}M$ TCNQ in 0.1M TBAP-acetonitrile solution following exhaustive $2e^-$ reduction at $-0.70V$ vs. SCE. Solid line: $TCNQ^{2-}$ absorption spectrum obtained by rigorous exclusion of O_2 from the solution. Dotted line: absorption spectrum obtained by electrogenerating $TCNQ^{2-}$ in the presence of O_2 or by bubbling O_2 through the solution originally giving the solid line spectrum. The extinction coefficient scale is quantitatively accurate for $TCNQ^{2-}$ (solid line) spectrum only.

originally colorless solution of $TCNQ^{2-}$ immediately turns orange. The ensuing visible absorption spectrum is indicated in Fig. 1 by the dotted line. The absorption maximum and extinction coefficient at the peak agree with that previously reported by Jonkman and Kommandeur (11) as being due to $TCNQ^{2-}$.

It was concluded that the orange product formed upon admitting O_2 to a solution of $TCNQ^{2-}$ was an oxygen decay product of $TCNQ^{2-}$. The identity of this species was established using resonance Raman as the spectroscopic monitor The highly resolved vibrational Raman spectra are unique for each particular molecule or ion. Therefore, provided one has a good "guess" as to the identity of a product of an electrode reaction, comparison of a known sample to the unknown provides unambiguous identification.

Searching the cyanocarbon literature for oxygen containing compounds related to TCNQ, it was discovered that a carbanion [α, α-dicyano-*p*-toluoyl cyanide ($DCTC^-$)] has an absorption maximum at 480 nm (26). The sodium salt of this carbanion can be prepared by the reaction of TCNQ neutral and $NaNO_2$ (25). Figure 2 compares the RR spectrum of a solution of electrochemically generated $TCNQ^{2-}$ exposed to air with that of a solution of $DCTC^-$ formed from TCNQ neutral. The striking similarity of the two spectra confirms the identity of the $TCNQ^{2-}/O_2$ decay product. The broad Raman signal at 1638 cm^{-1} is probably a composite of C=C ring stretch and of carbonyl stretching. The 2214 cm^{-1} band is ascribed to conjugated nitrile stretching. The corresponding bands in the infrared spectrum of $DCTC^-$ are at 1645, 2150, and 2200 cm^{-1} (25).

A possible mechanism for formation of the carbanion is given by Scheme I. Triplet oxygen reacts via a two-step radical addition or by a $\pi^2{}_s + \pi^2{}_a$ cyclo-addition to form a dioxetane intermediate. Rearrangement of the intermediate results in $DCTC^-$ formation with elimination of cyanate ion.

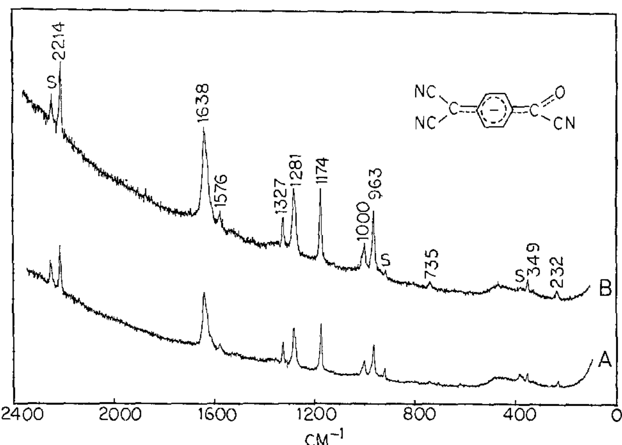

Fig. 2. Resonance Raman spectra of: (A) electrogenerated $TCNQ^{2-}$ saturated with O_2; $[TCNQ^{2-}] = 1.42 \times 10^{-3}M$, laser power at 4579Å = 80 mW, bandpass = 2.3 cm^{-1}. (B) Authentic $DCTC^-$ in CH_3CN: H_2O (10:1); $[DCTC^-] = 1.43 \times 10^{-3}M$, laser power at 4579Å = 30 mW, bandpass = 2.3 cm^{-1}. $TCNQ^{2-}$ was electrogenerated by controlled-potential coulometry at −0.70V vs. SCE in 0.1M TBAP CH_3CN. All spectra were scanned at *ca.* 50 cm^{-1} min^{-1} using a 1.00 sec counting interval. Plasma lines were removed with a 4579Å interference filter.

vibrational designations of $TCNQ^{\overline{\cdot}}$ (7) and by comparison with the lines in the $Li_2TCNQ \cdot THF$ Raman spectrum. Although both nontotally symmetric and totally symmetric modes can be observed in NR spectroscopy, it is a general rule that the totally symmetric vibrations are more intense (26). Hence, all bands in the $Li_2TCNQ \cdot THF$ spectrum are attributed to totally symmetric modes.

Table I summarizes the vibrational data for $TCNQ^{\overline{\cdot}}$

$TCNQ^{2-} + O_2 \rightarrow$ [$(N\equiv C)_2\bar{C}$–C_6H_4–C(·O—O·)(C≡N)–C=C=N⁻]

(DCTC⁻) **I**

To obtain the RR spectrum of $TCNQ^{2-}$ necessitates u.v. excitation. Not having u.v. excitation sources available at that time required developing routes to prepare $TCNQ^{2-}$ in a form suitable for investigation via normal Raman (NR) spectroscopy, *i.e.*, a solid. Two such solids were made chemically: (*i*) a brown, air-stable, diamagnetic cobalt Schiff base complex $[Co(III)(acacen)\text{-}(py)_2]_2TCNQ$ discovered by Basolo (23) and (*ii*) a white, air-sensitive salt $Li_2TCNQ \cdot THF$ prepared by A. Siedle (24). The NR spectra of these two compounds are shown in Fig. 3. The extra bands in the $[Co(III)(acacen)\text{-}(py)_2]_2TCNQ$ spectra are ascribed to small amounts of resonance-enhanced $TCNQ^{\overline{\cdot}}$ (339, 610, 677, 715, 1187, 1387, 1609, 1949, and 2191 cm^{-1}), to the acacen ligand (431 and 481 cm^{-1}), and to Lewis-coordinated pyridine (647, 1024, and 1048 cm^{-1}). Assignment of the Raman signals at 2106, 1304, 1194, and 731 cm^{-1} to the totally symmetric modes ν_2, ν_4, ν_5, and ν_7 of $TCNQ^{2-}$ is made in analogy with the

in its ground state, $TCNQ^{\overline{\cdot}}$ in its lowest $^2B_{1u}$ state, and $TCNQ^{2-}$ in its ground ^1A_g state. The frequency changes occurring upon excitation of $TCNQ^{\overline{\cdot}}$ to its lowest $^2B_{1u}$ state and upon converting $TCNQ^{\overline{\cdot}}(^2B_{3g})$ to $TCNQ^{2-}(^1A_g)$ are also listed. A more extensive tabulation of vibrational frequencies for the TCNQ system will be published (24). An analysis of this type reveals the extent of electronic structure change corresponding to the various electron transfer and excitation processes. Modes ν_2 (terminal C≡N stretch) and ν_4 (C=C ring + C=C wing stretch) appear to be most sensitive to their electronic environment. For both processes (see Table I), the shift to lower frequencies reflects the promotion or addition of an electron to an antibonding orbital. One would expect the bond order changes accompanying these alterations to agree in relative order of magnitude with the corresponding

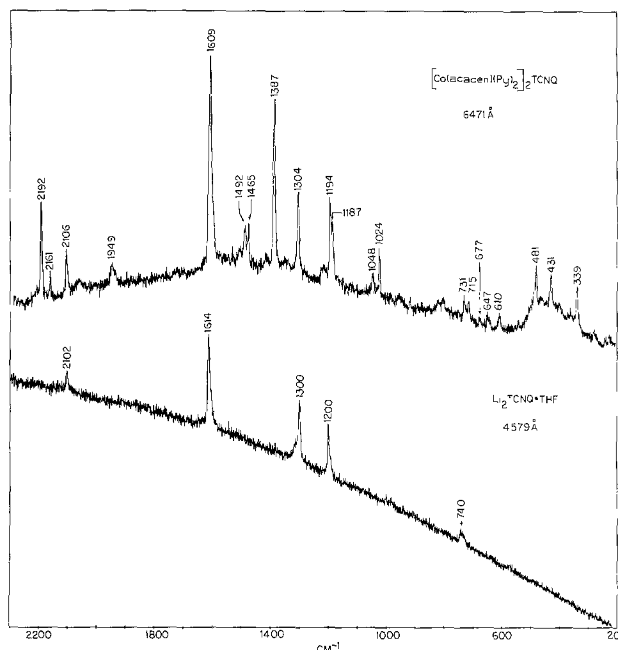

Fig. 3. Normal Raman scattering spectra of: (A) $Li_2TCNQ \cdot THF$, laser power at 4579Å = 10 mW, bandpass = 2.0 cm^{-1}. (B) $[Co(acacen)(py)_2]_2TCNQ$, laser power at 6471Å = 20 mW, bandpass = 4.0 cm^{-1}. Both samples were solid powders. Spectra were scanned at ca. 50 cm^{-1} min^{-1} using a 1.0 sec counting gate. Plasma lines were removed at 4579Å with an interference filter and at 6471Å with a Claassen filter.

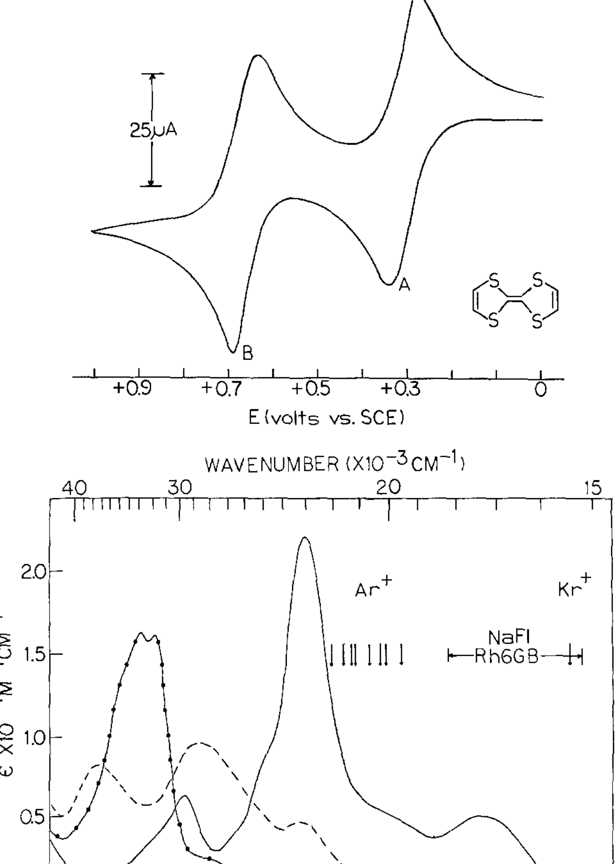

Fig. 4. Upper: First-scan cyclic voltammogram of 6.0 mM TTF in acetonitrile containing 0.10M TBAP at a platinum disk microelectrode. The scan rate = 0.10 V sec^{-1}. Lower: Electronic absorption spectra of TTF, $TTF^{\overset{+}{\cdot}}$, and TTF^{2+}. (●-●-●-●-●-) 4.38 × 10^{-4}M TTF in acetonitrile. (————) $TTF^{\overset{+}{\cdot}}$ electrogenerated at +0.50V vs. SCE in acetonitrile containing 0.1M TBAP. $TTF^{\overset{+}{\cdot}}$ = 4.38 × 10^{-4}M, cell pathlength = 0.10 cm. (- - - - - - - -) TTF^{2+} electrogenerated at +0.90V vs. SCE in acetonitrile containing 0.1M TBAP. TTF^{2+} = 4.0 × 10^{-4}M, cell pathlength = 0.10 cm. Residual $TTF^{\overset{+}{\cdot}}$ may be contributing to the TTF^{2+} absorption spectrum.

frequency changes. Such concurrence between bond order changes computed from CNDO/S MO theory for the TCNQ system (12) and the vibrational frequency changes does exist. This good agreement supports the frequency assignments of the totally symmetric modes in $TCNQ^{\overline{\cdot}}$ $(^2B_{1u}{}^{(1)})$. Further discussion of the excited state frequency assignments can be found elsewhere (27).

Turning to the other half of the conducting charge transfer complex TTF-TCNQ, the results for the tetrathiofulvalene neutral and monocation systems will be discussed. Figure 4 shows the cyclic voltammogram of TTF and the optical spectra of TTF neutral, $TTF^{\overset{+}{\cdot}}$ and TTF^{2+}. The two one-electron oxidations in the cyclic voltammogram correspond to generation of $TTF^{\overset{+}{\cdot}}$ (peak A, E_{pa} = +0.34V *vs.* SCE at a scan rate, V, of 100 mV sec^{-1}) and to generation of TTF^{2+} (peak B, E_{pa} = +0.68V *vs.* SCE at a scan rate, V, of 100 mV sec^{-1}). Formation of TTF monocation is both chemically and electrochemically reversible, the former being demonstrated by the constancy of the quantity i_{pa} $V^{-1/2}$ C° as sweep rate V is varied.

[a] All Raman data pertain to TCNQ systems in CH_3CN solution and the frequencies are accurate to ± 2 cm^{-1} unless otherwise indicated.
[b] ± 5 cm^{-1}.

[c] $Li_2TCNQ \cdot THF$ solid.

[d] $\nu_i(TCNQ^{\overline{\cdot}}[^2B_{3g}]) - \nu_i(TCNQ^{\overline{\cdot}}[^2B_{1u}{}^{(1)}]) \pm 10\ cm^{-1}$.

[e] $\nu_i(TCNQ^{\overline{\cdot}}[^2B_{3g}]) - \nu_i(TCNQ^{2-}) \pm 4\ cm^{-1}$.

In the lower half of Fig. 4 are the optical spectra of solid TTF neutral, of electrochemically generated $TTF^{\overset{+}{\cdot}}$, and of electrochemically generated TTF^{2+}. The regions of $TTF^{\overset{+}{\cdot}}$ absorption are ideal from the standpoint of existing laser excitation sources. (See Fig. 4.) Among the various MO treatments of $TTF^{\overset{+}{\cdot}}$; PPP (10), self-consistent statistical exchange multiple scattering (28), and Hückel (29), the PPP results with limited configuration interaction of Zahradnik *et al.* (10) are in best agreement with the transition energies and oscillator strengths of the $TTF^{\overset{+}{\cdot}}$ optical absorption spectrum. Hence, any further analysis of $TTF^{\overset{+}{\cdot}}$ electronic transitions are based on Zahradnik's results.

The RR spectrum of TTF cation radical was obtained upon excitation into the region of the $^2B_{1u}$ to $^2B_{2g}{}^{(2)}$ transition (4579Å excitation). (See Fig. 5.) Also reported in Fig. 5 is the NR spectrum of solid TTF neutral (excitation at 6000Å). Of the seven totally symmetric (A_g) Raman active normal modes predicted for $TTF^{\overset{+}{\cdot}}$ (based on a d_{2h} point group), at least four have been ascribed to bands in the RR spectrum of $TTF^{\overset{+}{\cdot}}$. These Raman lines are located at 265, 757, 1041, and 1427 cm^{-1}. In comparing these vibrations with corresponding ones in the TTF spectrum, it is again assumed that all major bands are attributed to totally symmetric species. It is further assumed that site-symmetry effects and factor-group splitting are not manifested to any great extent in the neutral Raman spectrum. The TCNQ neutral Raman spectrum has been interpreted similarly (30).

The very intense fundamental at 1427 cm^{-1} in the $TTF^{\overset{+}{\cdot}}$ RR spectrum is ascribed considerable central C=C character. This is in analogy with the C=C stretch in the RR spectrum of tetracyanoethylene anion radical ($TCNE^{\overset{-}{\cdot}}$) at 1421 cm^{-1} (21). The corresponding vibration in the TTF neutral spectrum occurs with equal intensity at 1513 cm^{-1}. This shift upward of 86 cm^{-1} is equated with strengthening of the central C=C bond when a bonding electron is added to $TTF^{\overset{+}{\cdot}}$. Designation of the 1427 cm^{-1} mode as ν_2 is made on the basis that ν_1 is due to the symmetric C—H stretch, even though it is not observed in the RR spectrum. The ν_3 fundamental at 1041 cm^{-1} in the $TTF^{\overset{+}{\cdot}}$ spectrum (corresponding neutral band at 1089 cm^{-1}) is of unknown origin. Some C—S stretching may contribute to the Raman band of $TTF^{\overset{+}{\cdot}}$ at 757 cm^{-1} (neutral frequency 796 cm^{-1}). Cyclic sulfides exhibit C—S stretching in the 550-700 cm^{-1} region (31). Finally, the low frequency mode designated ν_6 at 265 cm^{-1} is associated

ν_7		—	—	—	—

[a] All frequencies reported are accurate to ± 2 cm^{-1}.
[b] w = weak, m = medium, vs = very strong.
[c] The bond order changes are based on the SCF calculations of R. Zahradnik et al. [Ref. (10)].

with the neutral band at 249 cm^{-1}. It is possible that internal angle bending in the five-membered sulfur heteroatom ring contributes to this vibration. Low frequency modes in planar conjugated organic molecules have been attributed to bending motions (20, 30). Regarding ν_2 and ν_7, no definitive assignment in either the $TTF^{\overset{+}{\cdot}}$ RR spectrum or TTF neutral Raman spectrum has been made. These results are summarized in Table II along with the PPP bond order changes.

Work is now underway to investigate the RR spectra $TTF^{\overset{+}{\cdot}}$ upon excitation with existing dye laser sources (5500-6500Å). It is hoped that complete characterization of the RR spectra of TTF moieties coupled with the related work on TCNQ species will ultimately lead to identification of the oxidation states of TTF and TCNQ in the highly conducting organic metal TTF-TCNQ.

Acknowledgments

The author would like to thank Dr. Allen R. Siedle for his synthesis of $Li_2TCNQ \cdot THF$ and Dr. Jerry B. Torrance for supplying samples of TTF. The assistance of Dr. Richard P. Van Duyne throughout the course of this work as well as the support of this research by The Electrochemical Society is greatly appreciated.

The Colin Garfield Fink Summer Fellowship Report

A summary of Mr. Flanagan's report is given below.

Some Numerical Methods in Electrochemistry

The investigation into the use of fast, large potential step coulostatics to study electrode kinetics as described in the report previously published was pursued as far as using the technique to study the relatively slow Zn^{+2} reduction on mercury. The nonlinear regression-digital simulation proved to be quite successful in reproducing the values of the standard rate constant and transfer coefficient obtained by chronocoulometry. The maximum absolute rate observable by this technique seems to be about 0.3 cm/sec, a limit primarily imposed by the rate of injection of the charge. The injection must be very fast in order to measure the faster rates of electron transfer, and the existence of only a few ohms of uncompensated resistance is very effective in limiting the speed which can be obtained. New electrode designs are being studied which will facilitate the rapid injection of charge and thus make even faster electron transfer rates observable.

A new project was undertaken during the summer which was the study of differential pulse polarography as a tool in the observation of adsorption of electroactive species. An enhancement in the peak current is observed when adsorption of either product or reactant species is present. Equations were derived from approximate boundary conditions to try to quantify the effect. The use of differential pulse polarography in adsorption studies has several possible advantages: Adsorption can be studied easily in the region of the half-wave potential rather than by potential steps between the limiting-current regions as with chronocoulometry, thus making possible the study of potential dependence of adsorption in the region of the polarographic wave. Using differential pulse, the absolute amount of adsorption is not important, but rather the magnitude of the effect is related to the magnitude of the adsorption coefficient K, where $\Gamma = KC_{surface}$. Thus the limits of detection of adsorption are in principle set only by the sensitivity of the instrument at low concentrations. The lower limit on K seems to be about 10^{-4} cm^1 for differential pulse sample times of greater than 5 msec. Evaluation of the raw data may be difficult for the worker without access to a computer, so if the technique proves to be generally useful, tabular or graphic working curves could be generated for distribution. The relevant equations, boundary conditions, and some experimental results for halide-induced adsorption of Cd^{+2} have recently been published in a preliminary note on the technique (1). Work is continuing on the study by using digital simulation to include the effects of uncompensated resistance and double-layer charging on the current response.

The Joseph W. Richards Summer Fellowship Report

Mr. DeAngelis' report is given below.

Mercury Film Electrodes: Voltammetric and Optical Applicability

Since their inception thin film mercury electrodes (TFE) have found widespread applications in voltammetric analysis and have shown potential in spectroelectrochemical studies (1, 2). In both cases, desirable features are a working electrode with maximum hydrogen overvoltage and mercurylike characteristics. This necessitates that the substrate for the TFE interfere as little as possible with the thin mercury film, particularly with optically transparent electrodes (OTE), where, to retain transparency, one is restricted to a very thin mercury film.

Thin layer electrodes (TLE) have been used to good advantage in spectroelectrochemistry (3, 4) and in a variety of electrochemical measurements (5, 6) but have yet to be applied extensively in voltammetric analysis. The TLE does have the advantage of rapid electrolysis as a result of a short diffusional path and the capability of using small (<100 μliter) solution volumes. Since the volume of solution available for analysis is sometimes small, particularly in biological samples, combining one of the most sensitive electroanalytical techniques, differential pulse anodic stripping voltammetry (DPASV), with the TLE would be advantageous. This should provide trace analysis capabilities on very small solution volumes. The TFE is ideally suited to the thin layer electrode configuration.

The objective of this study was (*i*) to develop a thin layer cell for DPASV on small solution volumes using a thin film mercury electrode and (*ii*) to evaluate substrates for TLE's. The substrates would be applicable to both mercury OTE's and TLE's using DPASV where no transparancy is necessary.

Experimental

Apparatus.—The thin layer cell was constructed of Lucite and Teflon. Details of the construction of the electrode will be published elsewhere (7).

A potentiostat of conventional operational amplifier design was used for electrochemical measurements. A Princeton Applied Research Model 174 polarographic analyzer was used for the differential pulse voltammograms. Signals were recorded on a Houston Instrument 2200-5-6 X-Y recorder.

Electrodes.—The following metal foils (Alfa Ventron) used were: tungsten, 0.127 mm thick; vanadium, 0.025 mm thick; iron, 0.0125 mm thick; chromium, 0.020 mm thick, epoxy backed.

Reagents.—The mercuric solution used for deposition on carbon and the metal foils was $5.2 \times 10^{-3}M$

$Hg(NO_3)_2 \cdot H_2O$ (Baker, Analyzed), $1.0M$ KNO_3 (Mallinckrodt) at pH 6.4. Alternately, a $5.9 \times 10^{-4}M$ $Hg(NO_3)_2 \cdot H_2O$ solution in $0.1N$ HNO_3, $0.5M$ KNO_3 was also used to coat the metal foils. Methyl viologen dichloride (K and K Laboratories) was used without further purification. Lead solutions were prepared by dilution of 1000 μg/ml atomic absorption standard (Fisher Scientific Company). Supporting electrolyte used for dilution of metal ion solutions was $1.0M$ potassium acetate (Baker, Analyzed) and $2M$ in acetic acid (E. I. du Pont) at pH 4.0. All solutions were diluted with distilled, deionized water.

Procedure.—The thin layer cell was assembled with a polished wax impregnated graphite electrode (WIGE) press-fitted into the Teflon plate. The $5.2 \times 10^{-3}M$ mercuric solution was then added to the cell and mercury deposited at -0.3V *vs.* SCE until the current dropped and remained constant (usually 1-2 min). Mercuric solution was added and mercury deposited 14 more times. This gave a mercury film thickness of 300-400Å. Analyte solution was then added to the cell and the analysis performed.

The metal foils were prepared and coated with mercury in the following manner. A 1 cm^2 piece of foil was epoxied to a piece of Lucite leaving only one surface exposed. The electrode was dipped halfway into a small solution cup. Connection was made with a spring clip to the top half. A mercury film was formed on the foil by deposition of mercuric ions at -1.5V *vs.* SCE with moderate stirring. In between experiments the metal foils were wiped clean with a Kim Wipe. After coating with the appropriate mercuric solution, the sample to be analyzed was entered into the cell. All solutions were degassed with pure nitrogen for 20 min prior to use with the metal foil electrodes.

Results and Discussion

Previously, the only OTE with mercurylike characteristics was the Hg-Pt OTE (8). Another approach to a mercury transparent electrode which was more easily adapted to the thin cell configuration was the mercury nickel minigrid electrode (9). In addition to its optical transparency, the Hg-Ni electrode showed potential for trace analysis of metal ions. However, the high residual current of the electrode at large negative potentials precluded its effective use in DPASV at levels below 300 ng/ml. An effort to lower this detection limit led to the present work, a search for better electrode substrates for use in voltammetric analysis in the TLE and mercury film OTE's. Metals which amalgamate very little with mercury were tried as substrates in an attempt to reduce the interference of the substrate metal with the mercury film.

Thin layer cell.—In many situations requiring analysis of samples, particularly biological samples, the amount of material the analyst has to work with is small. To analyze for heavy metals by DPASV one normally requires at least 2 ml total solution volume. This often requires dilution of the sample which introduces error into the analysis. In addition, DPASV normally requires solution degassing, reproducible stirring rates, and in the case of the HMDE, reproducible drop size, all of which tend to limit the effectiveness of the technique. The author has developed a cell which eliminates some of these sources of error.

The analyte lead solution was entered into the cell and deposited at a potential which reduced oxygen in the sample to water. The lead is exhaustively deposited into the thin film from the volume of solution above the carbon rod, very rapidly by diffusion, thus eliminating the necessity of stirring. Reproducible results were obtained when the cell was thoroughly rinsed with supporting electrolyte before each sample addition. Duplicate analyses on the same solution were easily accomplished by depositing and stripping as many times as desired.

Three types of graphite were investigated for use in the thin layer cell: POCO FXI spectroscopic graphite, pyrolytic graphite (PG), and glassy carbon (GC). The POCO FXI WIGE was found to give the best results. A freshly cleaved pyrolytic graphite surface gives peak heights comparable to the WIGE; however, erratic results are obtained due to solution penetration of the edges of the PG. To try to overcome this problem in one case the outside of the PG rod was coated with epoxy and, in another, press-fitted into Teflon. This did not prevent solution from getting in between the graphite planes. This caused higher residual current and, at times, bubble formation at the edge of the electrode. GC was found difficult to coat evenly with mercury. The mercury film tended to form large mercury droplets visible on the surface of the GC. These were often lost when aspirating sample out of the cell. The very nature of GC makes it difficult to polish. Its small diameter (3 mm), compared to the POCO FXI WIGE, also makes edge concentration of analyte more pronounced.

Data collected with the WIGE gave peaks which are well defined with good resolution. The reproducibility of the data is well within acceptable limits for electrochemical trace metal analysis. Each analysis takes less than 5 min total time compared to approximately 30 min for DPASV in conventional electrochemical cells. Details of the use of this electrode and its applications will appear in the literature shortly (10).

Metal foil electrodes.—Vanadium, tungsten, chromium, and iron are very resistant to amalgamation with mercury (11). In addition, all except iron are quite corrosion resistant (12). First, the metals themselves were characterized as electrode materials and compared to presently available materials. Table I gives the cathodic potential limit as determined by the onset of hydrogen evolution for each metal at the given pH. Deposition of mercury to give various thicknesses did not increase the hydrogen overvoltage of the electrode. Cyclic voltammetry of MV^{2+} on the mercury-coated and uncoated electrodes showed multiple peaks and, in general, poor voltammetric behavior. There seems to be no advantage as yet to using these materials as optically transparent electrodes over currently available substrates such as platinum or nickel.

Conclusion

A mercury, thin film, thin layer, electrochemical cell has been prepared and shown to be applicable to trace metal analysis on small volumes of solution. Of the various substrates for the mercury thin film which were tried, POCO FXI spectroscopic graphite, wax impregnated, gave the best results. The thin layer cell eliminates some of the sources of error, is as easy to use, and permits more rapid analysis on smaller sample volumes than conventional electrochemical cells.

Various metals were also evaluated for possible use as mercury film optically transparent electrode substrates. The metals used in this study as electrode sub-

Table I. Cathodic potential limits

Metal	H_2 evolution[a] (V *vs.* SCE)	H_2 evolution[b] (V *vs.* SCE)
Tungsten	−1.00	−0.57
Vanadium	−1.15	−0.43
Chromium	−1.00	−0.64
Iron[c]	—	—

[a] $1.0M$ KNO_3 solution at pH 6.4. H_2 evolution measured at I = 25 μA.

[c] Hydrogen evolution was not obtainable due to high (> 100 μA) residual current.

strates do not amalgamate well with mercury; however, this fact apparently does not necessarily make the metal a good substrate for mercury film electrodes. Work is continuing in this area and will be reported in full at a later date.

Physical Properties of SnO_2 Materials

I. Preparation and Defect Structure

Z. M. Jarzebski

and J. P. Marton*[,1]

Welwyn Canada Limited, London, Ontario, Canada

ABSTRACT

Stannic oxide in its pure form is an n-type wide-bandgap semiconductor. Its electrical conduction results from the existence of point defects (native and foreign atoms) which act as donors or acceptors. Some unique properties of SnO_2 make the material useful for many applications. Therefore, increasing attention is being paid to studies on this oxide, especially on the methods of preparation, and its electrical and optical properties. The purpose of this work is to provide a general up-to-date review of the investigations carried out and to help identify important areas for further studies. This part is concerned with the preparation and defect structure of single crystals, sintered polycrystalline samples, and thin films. Parts II and III[2] are reviews of the electrical and optical properties of SnO_2 materials.

SnO_2 crystallizes with tetragonal rutile structure with space group D_{4h}^{14} [$P4_2/mnm$ (1)]. The unit cell contains six atoms, two tin and four oxygen as illustrated in Fig. 1. Each tin atom is at the center of six oxygen atoms placed approximately at the corners of a regular octahedron, and every oxygen atom is surrounded by three tin atoms approximately at the corners of an equilateral triangle. Thus, it is the structure of 6:3 coordination. The lattice parameters determined by Baur (2) are $a = b = 4.737$Å and $c = 3.185$Å. The c/a ratio is 0.673. The ionic radii for O^{2-} and Sn^{4+} are 1.40 and 0.71Å, respectively (3).

It is generally agreed that SnO_2 in its undoped form is an n-type, wide-bandgap semiconductor. Various specific and unique properties of this material make it very useful in many applications. Polycrystalline thin films and ceramics of SnO_2 have been extensively used for the production of resistors (4). Conducting SnO_2 films are well known as transparent electrodes, and when deposited on glass it is known as Nesa glass (5). SnO_2 films are also used as transparent heating elements (6), for the production of transistors (7, 8), for transparent antistatic coatings (9), and other parts in electric equipment where transparency is required. A polarized memory effect has also been observed in a Se-SnO_2 system (10).

Because of its practical importance, an increasing amount of work has been done on crystals and films in recent years. A great deal of experimental research has been carried out on the electrical and optical properties of single crystals, thin films, and sintered SnO_2 in the hope of gaining a detailed understanding of the semiconducting nature of this material. It is the purpose of this report to provide a general up-to-date review of these investigations and to help identify important areas for further studies.

Growth of SnO_2 Crystals

The growing of pure and intentionally doped single crystals of stannic oxide of good quality presents a difficult problem. However, since 1961 a rapid development in the techniques has taken place. The methods applied by various authors are compiled in Table I.

On the basis of past work, two techniques appear to be most promising, namely the growth of crystals by reaction of stannic chloride vapor with water vapor (13, 23) and growth using the reaction of stannic chloride vapor with hydrogen and oxygen (19, 24).

The first method described by Nagasawa *et al.* (13) is based on the following reaction

$$SnCl_4 + 2H_2O \rightleftarrows SnO_2 + 4HCl \quad [1]$$

* Electrochemical Society Active Member.

[1] Present address: Department of Engineering Physics, McMaster University, Hamilton, Ontario, Canada.

[2] To be published in THIS JOURNAL, September and October 1976, respectively.

Key words: single crystals, sintered material, thin films, native defects, doping, impurities.

Table I. Methods of growing SnO_2 single crystals

Year	Author	Reference	Method
1961	Marley and MacAvoy	(11)	Vapor phase growth from tin oxide powder based on reversible reaction $SnO(g) + \frac{1}{2} O_2 \rightleftarrows SnO_2(s)$ in a stream of mixture of helium and oxygen at 1920°K
1962	Reed, Roddy, and Mariano	(12)	Growth by a process involving the production of SnO(g) by the oxidation of tin followed by subsequent reoxidation and deposition of SnO_2 at 1620°K
1965	Nagasawa, Shionoya, and Makishima	(13)	Growth based on the reaction $SnCl_4 + 2H_2O \rightarrow SnO_2 + 4HCl$ at 1570°K
1965	Kunkle and Kohnke	(14)	Growth from a Cu_2O flux at 1520°K
1965	Kusmina and Litvin	(15)	Hydrothermal growth using a solvent of LiOH solution at about 770°K and 2000 atm pressure
1966	Morgan and Wright	(16)	Growth by vapor reaction of tin vapor with oxygen at 1620°K
1968	Van Daal	(17)	Growth on top of sintered pellets of SnO_2 placed in a semiclosed alumina vessel and heated at 1920°K
1968	Gruner	(18)	Growth based on the reversible reaction $SnO(g) + \frac{1}{2} O_2 \rightleftarrows SnO_2(s)$ at 1570K
1969	Fonstad, Linz, and Rediker	(19)	Growth using the reaction $SnCl_4 + 2H_2 + O_2 \rightarrow SnO_2 + 4HCl$ at 1520°K and 10 Torr pressure
1969	Crabtree, Mehdi, and Wright	(20)	Growth based on reaction $SnCl_4 + 2H_2O \rightarrow SnO_2 + 4HCl$ as employed by Nagasawa *et al.* (13) with some modifications (*e.g.*, including tin and using growth temperature of 1670°K)
1969	Caslavska and Roy	(21)	Epitaxial growth of SnO_2 on rutile single crystals using reaction $SnI_4 + 2H_2O \rightarrow SnO_2 + 4HI$ in the temperature range of 720°-920°K
1973	Takizawa and Sakurai	(22)	Growth similar to that used by Reed *et al.* (12) with some modifications; growth temperature was 1540°K
1974	Crabtree	(23)	Growth according to reaction $SnCl_4 + 2H_2O \rightarrow SnO_2 + 4HCl$ at 1520°K

A horizontal-type electric furnace with a constant temperature zone of 1570°K at the center was used together with an alumina-ceramic muffle tube as shown in Fig. 2. A fused quartz tube was fixed at the center of the furnace to provide a substrate on which to grow crystals. To introduce the vapors into the growing zone, two thin fused quartz tubes were used, one for water vapor, the other for $SnCl_4$ vapor. $SnCl_4$ and H_2O were stocked separately in glass vessels immersed in thermostats to maintain the vapor pressures at constant values. Oxygen and nitrogen were used as carrier gases to transport H_2O and $SnCl_4$ molecules, respectively, into the growing zone. The temperatures of the vapor sources were between 290° and 320°K. The flow rates of carrier gases were between 25 and 150 cm^3/min. Single crystals with sizes up to 2 × 5 × 15 mm could be obtained in 24 hr.

Crabtree *et al.* (20) obtained SnO_2 single crystals applying the method which resembles that used by Nagasawa *et al.* (13). However, they have used an alumina liner tube instead of silica, employed a growth temperature of 1670°K, included a boat containing tin, and have also used argon as a carrier gas instead of nitrogen. The crystals produced had dimensions up to 2 × 2 × 12 mm.

In Fig. 3 a modification of the technique used by Crabtree *et al.* (20) is shown. The crystal growth occurs according to reaction [1]. $SnCl_4$ and H_2O vapors are introduced to the furnace center by means of the tubes shown in Fig. 3. The temperature of the furnace center was 1520°K. The crystals of mm size have been grown within a few days (23).

The second method of growing SnO_2 single crystals mentioned above has been reported by Fonstad, Linz, and Rediker (19). The crystals obtained by their technique had higher Hall mobilities and higher purity than those grown by other methods. Furthermore, this method is compatible with introducing dopants during the growing process. The experimental arrangement for crystal growth is shown in Fig. 4, and is based on the reaction

$$SnCl_4 + 2H_2 + O_2 \rightleftarrows SnO_2 + 4HCl \quad [2]$$

The crystals grow in a quartz tube at 1520°K at 10 Torr pressure. Stannic chloride is produced by passing chlorine gas through a mesh of tin metal at 370°K

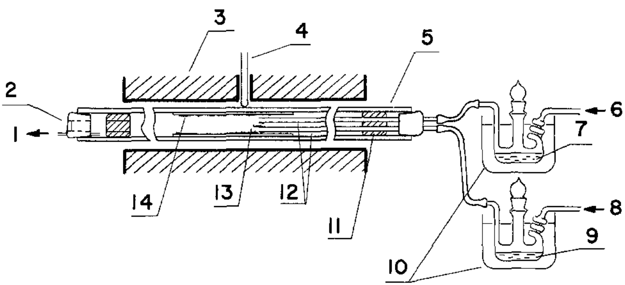

Fig. 2. Assembly for SnO_2 crystal growth by vapor reaction method using $SnCl_4$ and H_2O vapors according to Nagasawa *et al.* (13). 1, gas blowoff; 2, viewing port; 3, electric furnace; 4, thermocouple; 5, muffle tube; 6, oxygen inlet; 7, water; 8, nitrogen inlet; 9, $SnCl_4$; 10, thermostats; 11, alumina brick; 12, inlet tubes (fused quartz); 13, crystals; 14, growing tube (fused quartz).

Experimental arrangement for growth of SnO_2 crystals by reaction of $SnCl_4$ and H_2O vapors according to Crabtree (23). 1, refractory brick insulation; 2, SnO_2 crystal; 3, SiC element; 4, quartz tube; 5, dry argon; 6, $SnCl_4$ at 373°K; 7, water bath; 8, steam argon; 9, ether temperature control; 10, thermocouple.

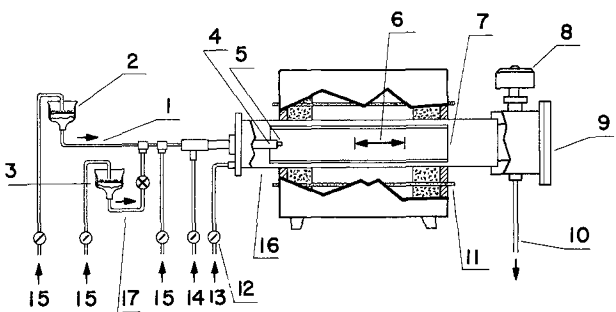

Fig. 4. Growing system of SnO_2 crystals based on reaction of stannic chloride, oxygen, and hydrogen (19, 24). 1, $SnCl_4$; 2, pure reactor (Sn); 3, doping reactor (Sn + dopant); 4, quartz nozzle for hydrogen; 5, zirconia nozzle for $SnCl_4$; 6, region of growth; 7, quartz tube; 8, pressure gauge; 9, viewing port; 10, to cold trap and vacuum pump; 11, globar heater; 12, needle valves; 13, oxygen inlet; 14, hydrogen inlet; 15, chlorine inlet; 16, mullite tube; 17, $SnCl_4$ + doping chloride.

and at 10 Torr pressure according to the rection

$$Sn + 2Cl_2 \rightleftarrows SnCl_4 \quad [3]$$

The reaction of tin with chlorine occurs in a Pyrex funnel kept at temperature about 370°K, sufficient at the pressure of 10 Torr to give a uniform and complete reaction. Dopants are introduced into the growing crystals by using reactors similar to those which generate $SnCl_4$ vapor in parallel with the $SnCl_4$ reactor, in which reactors the tin contains small amounts of the desired dopants, *e.g.*, antimony. The mullite furnace tube is horizontally mounted in a globar furnace and is sealed with end caps. The O_2, H_2, Cl_2, and $SnCl_4$ inlet tubes enter through the input end cap. The output end cap provides a mount for a pressure gauge, a quartz viewing window, and a connection to the cold traps and vacuum pump. A quartz tube fitting inside the main tube is used as the growing substrate. The crystals obtained by this technique were reported (24) to have carrier mobility of 8800 cm^2/V sec at 77°K and of 13,500 cm^2/Vsec at 45°K, which gives evidence of their high purity.

Other methods of single crystal growth include the one with the reaction

$$SnO(g) + \frac{1}{2} O_2 \rightleftarrows SnO_2(s) \quad [4]$$

Historically, this was the first reported method used to grow SnO_2 crystals, and was described by Marley and MacAvoy (11). The crystals are grown in a horizontal two-zone platinum wound tube furnace. Both zones are independently controlled to allow a flexible temperature gradient. The temperature distribution is a constant high temperature zone maintained at 1920°K, followed by an area containing a decreasing temperature of approximately 20°K/in. Marley and MacAvoy used sintered alumina-ceramic muffle tubes throughout the furnace except where crystal deposition occurred. In this zone a removable mullite tube was substituted since at these temperatures the mullite provides a substrate to which crystals could firmly anchor. A gas entrancement apparatus was attached to the furnace and the furnace tube was charged with high purity SnO_2 powder which was placed in the high temperature zone. A stream of a mixture of helium and oxygen was passed over the SnO_2 powder to transport the resulting SnO vapor into the growing zone where supersaturation and crystal growth took place. In this way crystals up to 2 × 4 × 30 mm were obtained.

Van Daal (17) described the growth of SnO_2 crystals by a modification of this technique. Sintered pellets were placed in a semiclosed alumina vessel and then heated at 1920°K in air. Relatively large crystals were grown on top of these pellets. However, they contained appreciable amounts of various impurities, especially Al.

The growth of SnO_2 crystals by the reaction of tin vapor with oxygen was described first by Reed, Roddy, and Mariano (12). Zone-refined tin was placed in a quartz crucible having a neck for slow admission of air for oxidation of the tin. The crucible was kept at the temperature of 1620°K for several days. The SnO vapor produced by the oxidation of tin was reoxidized near the neck where the oxygen pressure was comparatively high, and SnO_2 crystals were deposited. They were up to 3 cm long and to 5 mm across. These crystals contained, however, a considerable amount of Si and other impurities.

In order to minimize the inclusion of Si, Takizawa and Sakurai (22) have recently grown SnO_2 crystals by this method at lower temperatures using a smaller crucible. They found that the most favorable growth occurred when 1g of zone-refined tin was put in a quartz crucible 10 cm long with a neck 20 cm in length, which was kept at the temperature of 1540°K for 7 days. The crystals obtained in this way have been smaller than those prepared by Reed *et al.*, but had better qualities.

Applying a similar technique, Morgan and Wright (16) have grown SnO_2 crystals at 1720°K in about 10-15 days. They used a constant flow of a mixture of argon and oxygen upon an alumina boat, containing pure tin. The crystals grew on this boat, but they contained large amounts of various impurities. To obtain antimony-doped crystals, another alumina boat containing metallic Sb was introduced into the furnace.

Hydrothermal (15) and flux (14) methods may also be used to grow stannic oxide single crystals, but the possibility of contamination is much greater. Therefore, these methods are not popular for tin oxide crystal growth.

Other methods for the growth of single crystals of oxides in general may be found in a recent review on the subject (25) for further reference.

Preparation of Sintered SnO_2 Materials

Conducting properties of pressed and sintered tin oxide have been investigated (26-32) as early as 1910. Recently, Van Daal (17) has described a method of preparing pure sintered tin oxide with a high density of about 95% of the bulk density by applying a gas transport reaction method (25). HBr was chosen as a transporting gas. The reaction between SnO_2 and HBr is exothermic, and the transport of SnO_2 in the apparatus is from the low temperature region of 1070°K to the high temperature region of 1170°K, producing a polycrystalline solid.

Loch (29) has obtained Sb-doped sintered SnO_2 by mixing reagent grade tin oxide with Sb_2O_3 in an acetone slurry. The mixing was continued until the acetone evaporated and the dry powder was pressed at 8000 psi. Sintering followed at 1670°K in air.

Matthews and Kohnke (30) have prepared Zn-doped polycrystalline SnO_2 by adding an amount of ZnO to reagent grade tin oxide, treating the mixture with an acetone binder solution, pressing at 10,000 psi into pellets, and firing at 1730°K in air for 4 hr. In this way, sintered material of 95% theoretical density has been achieved.

Vincent and Weston (31) have described in detail a method of producing polycrystalline tin oxide by precipitation from solution. Sb-doped SnO_2 was prepared by coprecipitation with ammonium hydroxide of antimony and tin hydroxides from appropriate mixtures of antimony and tin chloride solutions in HCl, followed by a washing and heat-treatment. Samples obtained in this manner were subjected to heat-treatment at temperatures up to 1470°K.

Deposition of SnO_2 Films

The current interest in applications of tin oxide films has led to more careful study of the techniques which can be employed to deposit these films and also to study the dependence of SnO_2 films on the mode of preparation. The methods applied by various authors are compiled in Table II. Earlier reviews were written by Bauer (33) and Fischer (34).

As can be seen from the table, many methods have been used to obtain SnO_2 thin films; however at present it seems that only two of them are promising for future development. These are gas-phase hydrolysis of volatile tin compounds, principally $SnCl_4$ using various carrier gases, and reactive sputtering.

Hydrolysis.—The method of hydrolysis is based on the reversible endothermic reaction [1] in the presence of HCl gas. Because this reaction proceeds very rapidly, the $SnCl_4$ is mixed with alcohol, some organic acid, or both (5). When spraying an atomized mixture of this solution onto a heated substrate, the reaction occurs in the forward direction resulting in the deposition of tin oxide in the form of a smooth, closely ad-

Table II. Deposition of SnO_2 films

Year	Author	Reference	Method
1953	Holland and Siddal	(9)	Reactive sputtering of Sn cathode
1954	Aitchison	(5)	Hydrolysis of $SnCl_4$ on heated glass substrate based on reaction $SnCl_4 + 2H_2O \rightleftarrows SnO_2 + 4HCl$ at temperature range 770°-1070°K
1958	Ishiguro, Sasaki, Arai, and Imai	(35)	Solution of $SnCl_4 5H_2O$ crystal or $SnCl_4$ liquid in distilled water or in ethyl alcohol was sprayed on the glass, fused silica, or rock salt plates at temperatures 770°-870°K. The obtained SnO_2 films were comprised of crystallites.

herent transparent film. The reaction proceeds slowly at 770°K, and is very rapid at temperatures higher than 1070°K. If the temperature of the substrate is higher than about 1270°K, metallic tin is formed. The optimum temperature range for SnO_2 film formation appears to be different in the experience of different workers. Aboaf and Marcotte (58) claim good results in the temperature range of 650°-870°K, while other authors (35, 5) prefer temperatures of 770°-870°K and 770°-1070°K.

An analysis of the SnO_2 films obtained in this way suggests contamination of chlorine and deviation from stoichiometry (36, 58). Cl contamination and oxygen deficiency are responsible for the rather high conductivity found in these films which are made without intentional doping (36, 37, 54). Usually, however, high conductivity tin oxide films are obtained by doping them with antimony (32, 36, 52, 60), boron (60), or other elements (58). To obtain SnO_2 films doped with antimony or boron, various percentages of $SbCl_3$ (or $SbCl_5$) or H_3BO_3 (60) are added to the acidified-atomized solution of $SnCl_4$.

Because reaction [1] is reversible the structure and composition of SnO_2 films depend on the temperature, pressure, and rate of deposition. Recently, Aboaf and Marcotte (58) have described the deposition of SnO_2 films on heated silicon substrates by $SnCl_4$ hydrolysis at various temperatures between 650° and 870°K using ambients of N_2, O_2, and H_2 Nitrogen gas was used to transport the high purity grade tin tetrachloride into the furnace tube by which either nitrogen, oxygen, or hydrogen was flowing. H_2O vapor-saturated N_2 was fed into the furnace through a nozzle situated at some distance (about 5 cm) from the uniform hot zone for minimizing the reaction of $SnCl_4$ with H_2O. The tin oxide films obtained in this manner were clear and virtually insoluble in acids and bases. The chlorine content was lowest when the films were deposited in a hydrogen atmosphere. SnO_2 films prepared by the method of hydrolysis of $SnCl_4$ exhibit a small temperature coefficient of resistivity and are chemically stable at slightly elevated temperatures, but they are polycrystalline.

Caslavska and Roy (21) have obtained epitaxial oriented SnO_2 thin films on a rutile single crystal substrate by the reaction

$$SnI_4 + 2H_2O \rightleftarrows SnO_2 + 4HI \quad [5]$$

in the temperature range of 720°-920°K. The experimental assembly consisted of a horizontal clam-shell furnace fitted with a silica-Pyrex reaction tube through which H_2O vapor was flowing continuously. In the center of the reaction tube a rutile substrate was placed and was heated separately. The SnI_4 material was in a platinum crucible and was kept at a predetermined temperature at distances of 8, 11, and 20 cm from the substrate. The surface of the single crystal substrate was polished in a given orientation which was determined by x-ray diffraction.

Reactive sputtering.—Reactive sputtering is used by a number of investigators (25, 57, 59) to deposit SnO_2 films on various substrates. A simple system using two electrodes (55) has been used recently by Giani and Kelly (59). It consisted of an Sn cathode and substrates of chemically polished Al, Ta, and V, cleaved KCl, and air-annealed SnO_2 which were placed on the anode table 3 cm beneath the cathode. The d-c sputtering voltage ranged from 1000 to 3000V and the current was about 10 mA. As working gas, a 1:1 mixture of oxygen and argon was used at about 10^{-2} Torr pressure. The sputtered SnO_2 films were amorphous as deposited on KCl or Ta substrates in the temperature range of 170°-470°K, and polycrystalline as deposited on SnO_2 at 470°K.

A more complicated apparatus is described by Lieberman and Medrud (50). It is constructed in such a way that it enables the simultaneous rotation and

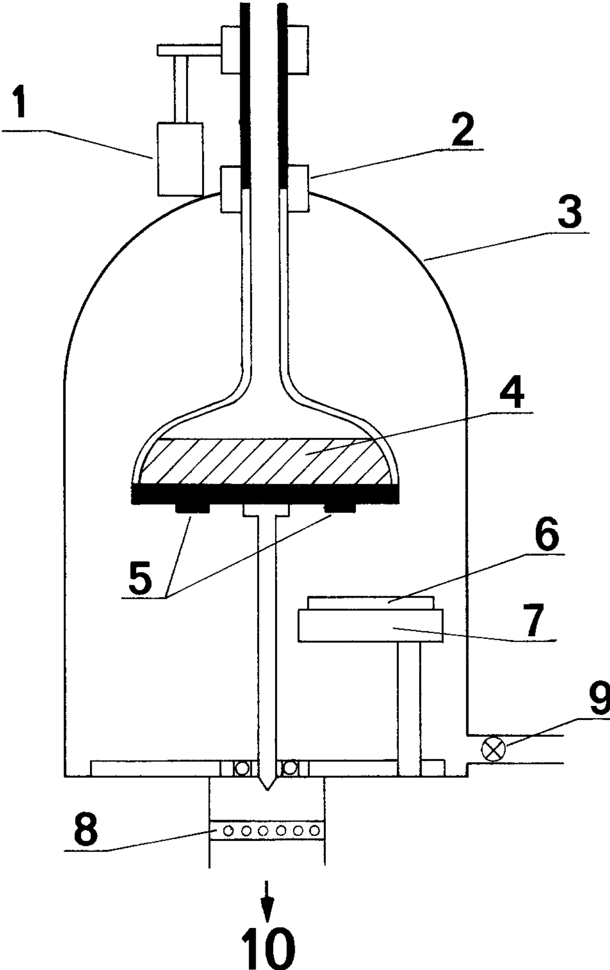

Fig. 5. Reactive sputtering apparatus which enables the simultaneous rotation and refrigeration of substrate during the sputtering process (50). 1, driving motor; 2, rotary seal; 3, bell jar; 4, refrigerant; 5, substrates; 6, tin cathode; 7, shield; 8, chewron baffle; 9, gas inlet; 10, vacuum pump.

refrigeration of substrates during the sputtering process. The outline of the apparatus is shown in Fig. 5. The rotation of the substrate helps to obtain films with uniform thickness, and also assists in the dissipation of heat from the substrate. The substrates are cooled by liquid nitrogen to increase the possibility of obtaining amorphous films. The liquid nitrogen-cooled vacuum flask is made of stainless steel, the base plate of this flask is a copper plate to which the glass substrates are attached, and the cathode is cooled by water flowing through the cathode supports.

Yamanaka and Oohashi (51) have prepared sputtered SnO_2 films using the cathode in the form of a tin oxide disk sintered from SnO_2 powder at 1770°K in air. The distance between the cathode and substrate was 6 cm and the sputtering voltage was 4500V.

The method of sputtering was used also by other authors for the etching of SnO_2 films (61). Descriptions of other reactive sputtering methods used to deposit oxide films may be found elsewhere (25, 57).

Other methods.—Bartholomew and Garfinkel (47) used anhydrous $SnCl_2$ as a starting material for preparing SnO_2 films. Stannous chloride with the melting point of 519°K was fused and subsequently oxidized to SnO_2 by the following reaction

$$SnCl_2 + O_2 \rightarrow SnO_2 + Cl_2 \quad [6]$$

The experiments were carried out either in an open or a closed system. The open system consisted of a Vycor glass crucible containing the SnO_2. The crucible in turn was placed in a Vycor beaker and the whole assembly was put in the furnace for fusing and oxidizing. In the closed system, a silica glass tube was used instead of the beaker. The tube was sealed at one end and had a silicone oil trap at the other end. The system was flushed with dry argon continuously while a film formed on the silica glass tube. Heat-treatment in air followed at temperatures between 670° and 800°K, with times ranging from 1 to 72 hr. In the case of a completely sealed system, no SnO_2 films was formed after 72 hr of heat-treatment.

Aoki and Sasakura (8) have prepared SnO_2 films by transporting dimethyl tin dichloride $(CH_3)_2$ $SnCl_2$ vapor onto a substrate surface by means of dried air, where the vapor was successively decomposed and oxidized. The assembly used by these workers is shown in Fig. 6. The thickness of the SnO_2 films was controlled by changing the flow rate of the air and the time of reaction, and their electrical conductivity was controlled by changing the temperature of the substrate.

Conductive tin oxide films have been grown by the evaporation of tin on a suitable substrate and the subsequent oxidation in an atmosphere containing oxygen (46, 53).

Giani and Kelly (59) have also prepared SnO_2 thin films by a high voltage anodizing method. The anode was an Sn sheet and the cathode was either an Al sheet or a Pt cylinder. The electrolyte used was an ammonium pentaborate in ethylene glycol which was varied by adding water. The anodizing voltage was 50V d.c. producing a current density of 10 mA/cm².

Defect Structure

As it is well known, physical properties of oxides depend strongly on deviation from the stoichiometric composition (native disorder) and on nature and concentrations of foreign atoms incorporated into the crystal lattice (25). Because tin oxide is a semiconductor of n-type, therefore either oxygen vacancies, V_o, or interstitial tin atoms, Sn_i, are expected to be donors in pure SnO_2 (5, 11, 13). Thus, either defect reactions

$$SnO_2 \rightleftarrows Sn_{Sn}^{4+} + O_o^{2-} + V_o^{2-} + \tfrac{1}{2} O_2 \quad [7]$$

or

$$SnO_2 \rightleftarrows Sn_i^{4+} + O_2^{(g)} \quad [8]$$

may take place.

Recently, Samson and Fonstad (62) have concluded that in the partial oxygen pressure range from 10^{-2} to 1 atm, and in the temperature range from 1370° to 1600°K, the doubly ionized oxygen vacancies predominate in SnO_2 according to the defect reaction [7] and following reaction

$$V_o \rightleftarrows V_o^{\cdot\cdot} + 2e' \quad [9]$$

together with the neutrality condition

$$2[V_o^{\cdot\cdot}] = [e'] \quad [10]$$

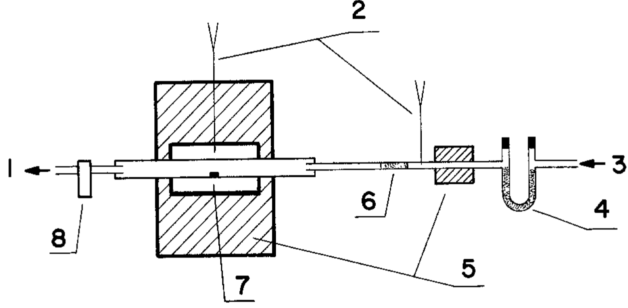

Fig. 6. An apparatus (8) for deposition of SnO_2 thin films from dimethyl tin dichloride $(CH_3)_2$ $SnCl_2$. 1, to aspirator; 2, thermocouple; 3, air inlet; 4, drying agent; 5, electric furnace; 6, $(CH_3)_2$ $SnCl_2$; 7, substrate; 8, flow meter.

This conclusion was based on the one-sixth dependence of electrical conductivity on the oxygen pressure $\sigma \sim p_{O_2}^{-1/6}$. It is well known, however, that from conductivity measurements similar results may be obtained also assuming the predominance of tin interstitials Sn_i^{4+}. If the mass action law is applied to defect reaction [8], and if the reaction

$$Sn_i \rightleftarrows Sn_i^{4+} + 4e' \quad [11]$$

is used together with the neutrality condition

$$4[Sn_i^{4+}] = [e'] \quad [12]$$

we can obtain the dependence: $\sigma \sim p_{O_2}^{-1/5}$. Taking into account possible impurities incorporated into the crystals during the heat-treatment as well as the narrow oxygen pressure range investigated, it is difficult at present to decide which type of defect predominates in SnO_2 materials. Thus, more detailed investigation is necessary to confirm the suggestion of Fonstad and Samson. Careful self-diffusion coefficient measurements as a function of oxygen pressure and temperature in thermodynamic equilibrium conditions may provide a more decisive answer.

It has been expected that SnO_2 single crystals or thin films grown using the hydrolysis of $SnCl_4$ may contain chlorine. This has been shown recently (58) for thin films. Aboaf and Marcotte (58) have found from x-ray measurements that chlorine is incorporated into SnO_2 lattice either interstitially or substitutionally. Both interstitial and substitutional chlorine atoms give rise to donor levels and thus increase the charge carrier concentration in SnO_2 films. This leads to increased conductivity.

The investigations of dislocations in SnO_2 crystals grown by the vapor reaction method, described by Marley and MacAvoy (11), have been carried out by Koffyberg (63). However, his work is not discussed because the crystals obtained by this method are not of good quality.

Little is known about doped SnO_2 materials in general. Recently, Vincent (32) reported a study on the thermodynamic stability of the oxides of tin and antimony. He concluded that the most probable configuration of tin-antimony oxide is a structure containing Sb_2O_3 in SnO_2. This comes about because the reaction

$$2SnO_2 + Sb_2O_3 \rightarrow 2SnO + Sb_2O_5 \quad [13]$$

is not probable, due to the relative instability of SnO with respect to SnO_2. However, it is not known whether the antimony atoms are substituted in Sn sublattice (37) or placed in the interstitial positions. It is expected that both cases may take place.

The nature of other impurities in the crystal lattice of SnO_2 is not known. Depending on their relative positions to tin in the Periodic Table, they may act as either donors or acceptors.

Conclusions

The best quality SnO_2 single crystals are obtained by two techniques, namely the growth of crystals by the reaction of $SnCl_4$ vapor with water vapor and growth using the reaction of $SnCl_4$ vapor with hydrogen and oxygen. Pure sintered SnO_2 material may be obtained by applying the gas-transport reaction method, *e.g.*, by reaction between SnO_2 and HBr.

The most promising methods for obtaining good SnO_2 thin films are gas-phase hydrolysis of volatile tin compounds, especially $SnCl_4$, and reactive sputtering.

The nature of defect structure of pure SnO_2 is not elucidated yet. Both doubly ionized oxygen vacancies and interstitial ions have been proposed, and either one is possible.

The detailed structure of doped SnO_2 materials is not known at the present time.

A Sodium-Water Primary Cell with a Rotating Cathode

D. A. Fustier, W. F. Graydon,* and F. R. Foulkes*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

A primary cell utilizing the direct reaction of sodium metal with water is described. The cell was capable of delivering steady-state current densities in excess of 40 A/cm² at an output voltage of 0.3V. The cell mechanisms and the effects of several operating parameters such as sodium-feed rate and rotational speed of the steel disk cathode are discussed.

Recently, there has been much interest in electrochemical systems which utilize highly reactive substances such as sodium and lithium because of the high energy and power densities associated with these materials. One of the problems encountered in such systems is that conventional cathodes are not capable of sustaining the high discharge rates available at the anode, with the result that overvoltages prevailing at the cathode substantially limit cell capabilities. Furthermore, because of the relatively high operating temperatures and the corrosivity of the reagents involved, existing high power density systems such as sodium-sulfur, lithium-chlorine, and others require costly design and manufacturing techniques.

Recent work (1-4) has shown that alkali metals are able to develop a surface film in aqueous media when the composition of the medium is carefully controlled. The film acts somewhat like an ion-exchange membrane, permitting the anodic dissolution of the metal, $M \rightarrow M^+ + e^-$, while partially impeding the direct oxidation reaction with water. A substantial potential difference can be generated between metallic sodium and a solution if a convenient cathodic reaction is added to the system. If the cathodic process is simply the evolution of hydrogen from water, an inexpensive sodium-water-mild steel primary cell can be obtained.

A preliminary investigation was undertaken in order to ascertain the feasibility of such a system and its potential capabilities. It was decided to construct a cell of the "dynamic type" (1, 2), because of the high current densities reported for such a device.

Experimental

Figure 1 shows the experimental apparatus. Metallic sodium was pressed mechanically onto a mild steel rotating disk moistened with water. In such a configuration the sodium becomes the anode, the steel the inert cathode, and the sodium hydroxide which is generated the electrolyte.

Prior to a run, the sodium was loaded into the brass container by means of an extrusion procedure using a manual hydraulic press. The inside surface of the brass container was previously polished and dried in an oven. (Runs were also preformed with sodium metal which had been placed in the extruder in liquid form and allowed to solidify. No difference in results was obtained for this method of loading.) Sodium was

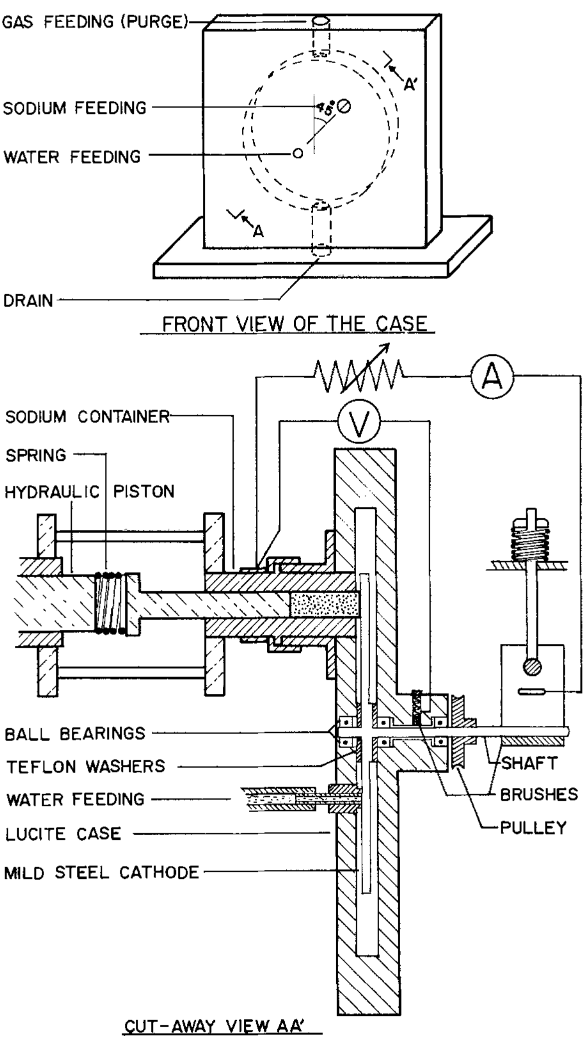

Fig. 1. Experimental apparatus

* Electrochemical Society Active Member.

Key words: sodium primary cell, high energy electrochemical cell, alkali metal primary cell.

handled under a nitrogen atmosphere, and it was believed that the small amounts of sodium nitrides and sodium oxides eventually built up at its surface did not significantly affect the results.

During a run the sodium was extruded, by means of another hydraulic press fitted with a pressure gauge graduated from 0-2000 psi, through a rectangular aperture which measured ⅜ × 0.060 in. (0.145 cm^2) and was situated about 1/32 in. from the rotating steel disk. The ratio of the sodium extrusion pressure over the hydraulic pressure was 9:1. Contact between the corrosion-sensitive brass and the electrolyte was prevented by covering the exposed brass with a Lucite frame. The sodium slab thus obtained was orientated so that its large dimension was directed toward the center of the rotating disk, the distance between the middle of the sodium aperture and the axis of the disk being 2 in.

The disk was driven by a 1/3 hp a-c electric motor fitted with a cone type Kopp variable drive for speed control. A belt and pulley coupling was employed to prevent electrical interaction between the motor and the cell.

The surface of the disk was mechanically polished with fine emery paper and buffing soap followed by a rinsing with distilled water and methanol. Only distilled water was used to rinse the cathode between consecutive runs.

The water was fed to the disk in a thin layer stream through a Tygon tube close to the surface of the disk, 1 in. from its axis and diametrically opposite the sodium. The entire cell, including the ball bearings used to stabilize the rotation of the disk shaft, was enclosed in a Lucite case.

The current on the cathode side was collected from the shaft through a spring-loaded brush made from Union Carbide Cophite 157 (93% copper, 7% carbon alloy). A second brush of the same type was added to monitor the cell potential without undergoing the *IR*-drop of the current collecting brush which had a resistance of 0.013Ω. The anode current was collected through a copper ring (2.5 $in.^2$ surface area) which was tightly fitted to the brass cylinder containing the sodium. The high pressure of sodium inside the container (~3000 psi) and its continuous motion were believed to provide good electrical contact between the sodium metal and its holder.

The voltage-current output of the cell was determined through the use of a variable resistive load placed in series in the external circuit. The current output was monitored through a Simpson 263 ammeter while the voltage output was recorded by means of a 610C-370 Keithley electrometer-recorder assembly. The quality of the d-c voltage output was continuously checked by means of an oscilloscope.

Throughout a run the cell was purged with either nitrogen or oxygen to prevent accumulation of explosive mixtures of hydrogen.

The cell was operated at room temperature with various water-feed rates. A water-feed rate of 0.35 cm^3/min was found to optimize cell output characteristics under the conditions of sodium-feed rate discussed below. The cell output was quite insensitive to variations in water-feed rate. Unless otherwise stated, the rotational speed of the disk was maintained at 1000 rpm (corresponding to a velocity of 532 cm/sec 2 in. from the axis). Faradaic efficiencies were calculated by measuring sodium consumption and the number of coulombs passing through the external circuit. The over-all efficiency is defined as the product of the voltage efficiency and the Faradaic efficiency.

Results and Discussion

As a consequence of the over-all reaction of sodium with water, a solution of sodium hydroxide is formed. The electrolyte, then, is self-generated and forms a thin layer adjacent to the disk. Although this layer of electrolyte is continuously removed by the action of centrifugal force, it is also continuously regenerated by the reaction between fresh sodium and water, so that a steady-state sodium hydroxide concentration, probably in the order of 50-75% by weight (4), develops.

The operation of the cell can be explained by assuming that the sodium is converted to sodium hydroxide by two simultaneous processes:

I. Direct chemical combination at the sodium/electrolyte interface

$$Na + H_2O \rightarrow NaOH + \tfrac{1}{2} H_2, \ \Delta H^\circ = -43.87 \text{ kcal/mole} \quad [1]$$

Conversion via reaction [1] results only in the production of heat.

II. Electrochemical conversion

$$\text{Anode (sodium): } Na \rightarrow Na^+ + e^-, \ \epsilon^0 = -2.71V \quad [2]$$

Cathode (steel disk):

$$e^- + H_2O \rightarrow \tfrac{1}{2} H_2 + OH^-, \ \epsilon^0 = -0.82V \quad [3]$$

$$\text{Over-all cell: } Na + H_2O \rightarrow \tfrac{1}{2} H_2 + NaOH, \ \epsilon^0 = 1.89V^{1} \quad [4]$$

The over-all electrochemical reaction [4] produces the electrical energy collected in the external circuit ($\Delta G^\circ = -43.49$ kcal/mole). The Faradaic efficiency gives the extent of the occurrence of process II relative to I.

It is also likely that reaction [3] occurs to some extent at the sodium, so that the anode potential is a mixed potential, and is somewhat more noble than −2.71V.

Faradaic and Over-all Efficiencies

At constant sodium-feed rate the maximum obtainable current, *i.e.,* 100% current efficiency, is fixed. Therefore the Faradaic efficiency is simply proportional to the current drawn, as shown in Fig. 2.

On the other hand, the over-all efficiency can be seen to pass through a maximum with increasing current density.

Open-Circuit Voltages

When attempts were made to run the cell at low current densities under the high prevailing sodium-feed rates indicated in Fig. 2, cell operation became unstable. Under these conditions of extremely low efficiency the excessive heat production was observed to melt the sodium, not only giving rise to the erratic voltage-current behavior indicated in Fig. 2 at current densities below 10 A/cm^2, but also making it impossible to obtain meaningful values of the open-circuit voltage. It was found that the open-circuit voltage could only be monitored at sodium-feed rates lower than about 0.4 $g \cdot cm^{-2} \cdot min^{-1}$ (corresponding to a maximum theoretical current density of about 29 A/cm^2). Under these conditions of low sodium-feed rate, when the cell was purged with nitrogen the open-circuit voltage was about 1.50V, whereas with an air or oxygen purge it was about 2.10V. This latter value, which is noticeably higher than the theoretical 1.89V, is believed to result from an increase in the potential of the steel cathode brought about in the presence of oxygen by the establishment of a mixed potential between reaction [3] and a reaction such as

$$\tfrac{1}{2} O_2 + H_2O + 2e^- \rightarrow 2\,OH^-, \ \epsilon^0 = +0.401V \quad [5]$$

Cell Polarization Behavior

Figure 2 shows typical cell polarization behavior at three sodium-feed rates. Each curve was obtained by averaging the experimental results of three different runs. Reproducibility of the data was good (about ±5%) except, as mentioned earlier, for current densities less than 10 A/cm^2. At the maximum feed rate shown (0.934 $g \cdot cm^{-2} \cdot min^{-1}$) current densities

[1] The reversible cell voltage will differ from 1.89V, because the reactants and products are not precisely at unit activity. Local overheating will not significantly affect the value.

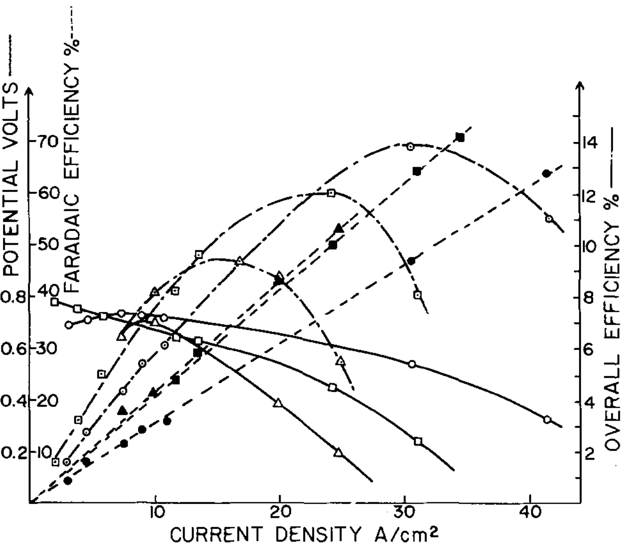

Fig. 2. Water-feed rate: 0.35 cm^3/min. Rotational speed of the cathode: 1000 rpm. ○—○ Potential at an average sodium-feed rate, SFR = 0.934 $g \cdot cm^{-2} \cdot min^{-1}$; □—□ potential at an average sodium-feed rate, SFR = 0.692 $g \cdot cm^{-2} \cdot min^{-1}$; △—△ potential at an average sodium-feed rate, SFR = 0.652 $g \cdot cm^{-2} \cdot min^{-1}$; ●----● Faradaic efficiency at SFR = 0.934 $g \cdot cm^{-2} \cdot min^{-1}$; ■----■ Faradaic efficiency at SFR = 0.692 $g \cdot cm^{-2} \cdot min^{-1}$; ▲----▲ Faradaic efficiency at SFR = 0.652 $g \cdot cm^{-2} \cdot min^{-1}$; ⊙----⊙ over-all efficiency at SFR = 0.934 $g \cdot cm^{-2} \cdot min^{-1}$; ⊡----⊡ over-all efficiency at SFR = 0.692 $g \cdot cm^{-2} \cdot min^{-1}$; ◬----◬ over-all efficiency at SFR = 0.652 $g \cdot cm^{-2} \cdot min^{-1}$.

greater than 40 A/cm^2, were obtained at about 0.3V with Faradaic efficiencies in the order of 70%.

Table I summarizes some of the output characteristics of the cell at the maximum over-all efficiency for each sodium-feed rate. The irregular polarization behavior at current densities less than 10 A/cm^2 is attributed to the initiation of the melting of the sodium which was referred to earlier.

The discharge of hydroxyl ions from water, reaction [3], is known to display Tafel behavior with a Tafel slope of −0.12V/decade up to current densities as high as 100 A/cm^2 (6). In conventional cells, however, much of the overvoltage encountered with this reaction at very high current densities results from mass transport limitations, with the result that the over-all overvoltage is much greater than that from activation alone (6). For the present cell, as indicated previously, cell behavior was quite independent of water flow rate, indicating that mass transport limitations do not pose a serious problem. This effect is to be expected considering the dynamic nature of the cell. Furthermore, the extremely high *IR*-drops which have been found by other workers (5), and which have been attributed to increases in the resistance of the electrolyte resulting from the presence of hydrogen bubbles therein, are also not encountered in the dynamic cell because the hydrogen is removed before it can nucleate into macroscopic bubbles. Therefore activation polarization accounts for most of the cathodic voltage losses.

Table I. Output characteristics of the cell for 3 different sodium-feed rates and at a maximal over-all efficiency. ϵ_t (over-all efficiency) and E_S (specific energy) are based on sodium utilization.

Sodium-feed rate ($g \cdot cm^{-2} \cdot min^{-1}$)	i (A/cm^2)	E (V)	ϵ_F (%)	ϵ_t (%)	P (W/cm^2)	E_s (Whr/kg)
0.910	30	0.56	48	14	17	313
0.707	24	0.45	50	12	11	254
0.652	15	0.55	33	9.5	8	210

Table II. Output characteristic of the cell for 3 different rotational speeds of the cathode at maximum current density obtainable (external resistance of 0.077Ω). Sodium feed rate 0.886 $g \cdot cm^{-2} \cdot min^{-1}$.

Rotation speed (rpm)	i (A/cm^2)	E (V)	ϵ_F (%)	ϵ_t (%)
600	32	0.25	53	6.9
1000	38.5	0.30	63	9.9
1400	31	0.24	50	6.3

A simple calculation using $i_o \approx 10^{-6}$ A/cm^2 as the exchange current density for reaction [3] on iron (6) and −0.12 V/decade as the Tafel slope for this reaction indicates a cathodic activation polarization of about 0.89V at 25 A/cm^2, which is consistent with observed values of cell voltage (Fig. 2). Halberstadt (2) observed comparable polarization behavior, but at much higher current densities, which were achieved through the use of thinner anode slabs (0.04 cm wide) than were used in this work. Halberstadt's results could not be confirmed because the design of the present cell did not permit sufficiently high sodium-feed rates under comparable anode area to observe cell behavior at such high current densities.

Rotational Speed of Disk

Table II shows that increasing the speed of rotation of the disk from 600 to 1000 rpm results in a minor improvement in cell performance which can be attributed to improvements in the mass transport processes discussed in the previous section. However, when the speed is increased to 1400 rpm a decline in performance is observed which is probably due to mechanical difficulties such as vibration, frictional heat generation. and erosion of the film.

Conclusions

A primary electrochemical cell utilizing the reaction between sodium and water has been built and operated at current densities in excess of 40 A/cm^2 at 0.3V. The hydrogen evolved in the cell processes could be used as a further source of electrochemical energy.

The key to the useful harnessing of the reactions between alkali metals and oxidizing media lies in a clearer understanding of the nature of the anode film, and of the kinetics of the anodic dissolution taking place. These aspects are currently being investigated by the authors.

Experimental Optimization of Li/SOCl₂ Primary Cells with Respect to the Electrolyte and the Cathode Compositions

A. N. Dey*

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The optimization of the Li/$SOCl_2$ C-size cells with respect to the parameters such as concentration of $LiAlCl_4$ source or purity of $LiAlCl_4$, and the Teflon content of the carbon cathode showed that low Teflon content, low $LiAlCl_4$ concentration, and pure $LiAlCl_4$ improve the intrinsic capacity of the cells. The optimum cell performance at moderate to high rates was obtained with 1(M) salt concentration and 10% Teflon in the cathode.

The lithium-inorganic electrolyte system comprising Li anode, carbon cathode, thionyl chloride ($SOCl_2$) depolarizer (and solvent), and $LiAlCl_4$ salt has been described in both the scientific (1, 2) and the patent (3, 4) literature. Earlier investigations in our laboratory (5) have shown the system to be capable of delivering high energy densities in unoptimized C-size (5) and D-size (6) cells. The object of this investigation is to optimize the system in regard to its fresh performance at ambient temperature. Based on the available data (1, 5) in regard to the material compatibility and the performance characteristics of experimental cells, the following specific materials were chosen for the optimization: Li anode, $SOCl_2$ solvent and depolarizer, $LiAlCl_4$ electrolyte salt, Teflon-bonded Shawinigan Black cathode on nickel exmet, and glass filter paper separator. The optimization was carried out with respect to the parameters such as concentration of $LiAlCl_4$ source or purity of $LiAlCl_4$, and the Teflon content of the Shawinigan Black cathode according to a factorial matrix set up with several levels of each of the above parameters. The test vehicle chosen for the above factorial experiment was a C-size cell for which most of the hardware and the tooling were already available. At least four cells were made under each of the eighteen conditions and were tested at currents of 0.1, 0.3, 0.5, and 1.0A. The experimental details are furnished below.

Experimental

A nickel-plated cold-rolled steel can (OD = 0.94 in., hgt = 2.00 in.) was used as a cell container. The Li anode (7.5 × 1.5 in.), the carbon cathode (8 × 1.5 in.), and the glass filter paper separator were wound into a tight roll and were packaged in the cell can. Other details of the cell construction are available elsewhere (5).

Two types of electrolytes were used for the optimization studies: (*i*) as prepared in our laboratory referred to as LPS electrolyte, described elsewhere (5); and (*ii*) as prepared from $LiAlCl_4$ received from Foote, referred to as Foote electrolyte. The latter type of electrolyte was prepared by dissolving known quantities of Foote $LiAlCl_4$ in distilled $SOCl_2$. The color of this electrolyte was deep purple and it left an organic residue on the glass vessels after it was washed with water. The chemical composition of this residue has not been determined. However, it is soluble in CCl_4. The LPS electrolyte, on the other hand, was colorless to light amber in appearance and did not leave any residue on the glass after washing with water.

The electrolytes were stored and dispensed from an all-glass (Pyrex) system. The weight of electrolyte added to each cell was recorded and was controlled to maintain 20 ± 2g.

* Electrochemical Society Active Member.

Key words: thionyl chloride, lithium, inorganic electrolyte, high energy density, primary cells, C-size cell, carbon cathode, lithium aluminum chloride.

The carbon cathodes were made by pasting carbon and an appropriate amount of colloidal Teflon (du Pont) in water on the expanded nickel current collector. The electrodes were vacuum dried (1). Each cathode was weighed and the average weight of the carbon mix for all the cells was 1.62 ± 0.11g. The thickness of the cathodes was approximately 0.026 in. The porosity of the cathodes was approximately 70-80%.

The cells were tested at 25°C within 8 hr of cell filling at constant currents of 0.1, 0.3, 0.5, and 1.0A for each condition of cell construction. In adddition, some cells were tested at −30°C at 0.3A. The cell potential was recorded as a function of time and the cell capacities were determined to a 2.0V cutoff.

Results and Discussion

The cathode limiting nature of the C cells was established by constructing the cells in a cylindrical Teflon fixture (having the same internal diameter as the C-size cell described above) which had a Li reference electrode located above the electrode stack. The cells were discharged at currents of 0.1-3.0A and the potentials of both the carbon cathode and the Li anode were monitored against the Li reference electrode. The plots, shown in Fig. 1, indicate the cathode as the limiting electrode.

The variability of the performance of the C cells was determined by discharging four cells at 0.5A. The capacities to the 2.0V cutoff were 3.70, 3.60 3.80, and 3.65 A-hr, respectively, indicating a standard deviation of ±0.085 A-hr or ±2.3%. This is exceptionally low. A

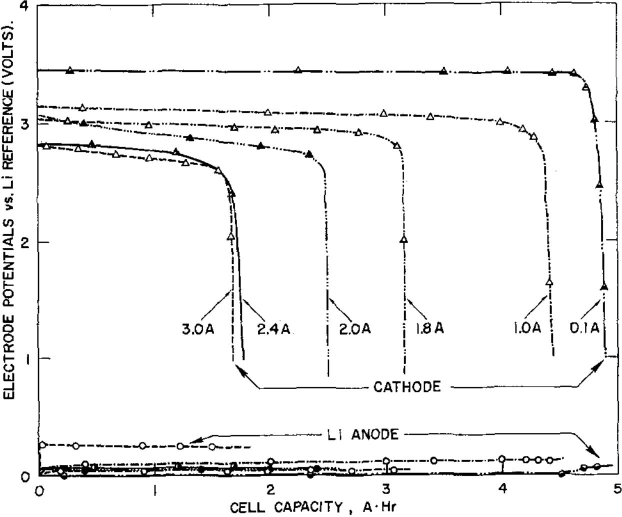

Fig. 1. Discharge curves of Li/$SOCl_2$ C-size cells with reference electrode. 1.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolyte and 10% Teflon in the cathode, tested at 25°C at constant currents of 0.1, 1.0, 1.8, 2.0, 2.4, and 3.0A.

standard deviation of ±5% is considered to be typical for these cells.

Typical discharge curves of a group of cells made with 1.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolyte and 10% Teflon in the carbon cathode and tested at room temperature (25°C) at currents of 0.1, 0.3, 0.5, and 1.0A are shown in Fig. 2. Note that the cell voltage drops sharply at the end of the discharge and the cell capacities up to the 2.0V cutoff are very similar to the capacities up to the 3.0V cutoff.

The effect of Teflon content in the cathode on the performance of the C cells is shown in Fig. 3 which represents semilog plots of cell capacity *vs.* current for cells with 1.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolyte and three levels (10, 20, and 30% by weight) of Teflon content in the cathode. The cell performance deteriorates with increasing Teflon content. This may be explained from the fact that Teflon acts as a binder of the carbon particles on which the $SOCl_2$ is discharged. Therefore, the quantity of the carbon is important in determining the cell capacity. Increasing the amount of Teflon automatically results in the decreasing of the total carbon content of the cathode, thus leading to a lower cell capacity. However, a minimum amount of Teflon is necessary in order to maintain the physical integrity of the carbon cathode. Experimentally, this minimum was found to be aproximately 10% by weight.

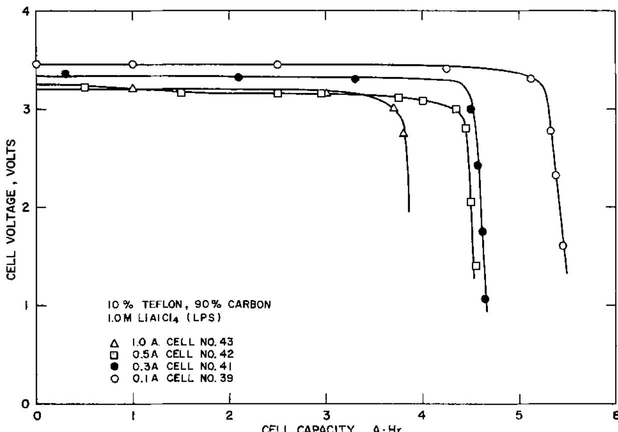

Fig. 2. Discharge curves of C-size cells made with 1.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolyte and 10% Teflon in the cathode, tested at 25°C at constant currents of 0.1, 0.3, 0.5, and 1.0A.

The importance of the physical integrity of the cathode was further emphasized by the fact that while the capacity expressed in terms of ampere hours per weight of carbon mix (including Teflon) decreased with increasing Teflon content, the capacity expressed in terms of ampere hours per weight of carbon only increased with increasing Teflon content. The possible deactivation of the carbon particle due to the coating by the Teflon must be insignificant.

The effect of salt ($LiAlCl_4$) concentration on the performance of the cells is demonstrated in Fig. 4 which shows semilog plots of cell capacity *vs.* discharge currents of cells made with 10% Teflon in the cathode and 0.5, 1.0, 1.5, and 2.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolytes. At moderate to high currents (0.1-1.0A), the cells with 1.0(M) electrolyte performed significantly better than the other cells. We did not test the cells at lower currents. However, the graphical extrapolation of the data indicates that at low currents (0.03A) highest capacities may be obtained with 0.5(M) electrolyte. We found this to be true in the case of the D-size cells (7) The higher intrinsic capacity with low salt ($LiAlCl_4$) concentration is explained as follows.

The cell reactions that conform to all the findings (5, 8) so far are

$$4Li \rightarrow 4Li^+ + 4e$$
$$2SOCl_2 + 4Li^+ + 4e \rightarrow 2SO + 4LiCl$$
$$2SO \rightarrow S + SO_2$$
$$2SOCl_2 + 4Li \rightarrow 4LiCl + S + SO_2 \quad [1]$$

The formation of LiCl and S was found (8) to be quantitative. However, the SO_2 analysis was ambiguous because of its possible formation from the slow chemical decomposition of $SOCl_2$. LiCl was found (8) to precipitate quantitatively in the cathode whereas S precipitates throughout the cell because of its solubility in $SOCl_2$. Therefore, it is reasonable to assume that the limiting process involves the passivation of the carbon cathode by the precipitation of LiCl in its pores. In view of the fact that $SOCl_2$ is consumed during the discharge thereby causing the concentration of $LiAlCl_4$ to increase with the depth of discharge, the precipitation of $LiAlCl_4$ itself is expected to occur at a certain depth of discharge at which the concentration of $LiAlCl_4$ exceeds its solubility in $SOCl_2$. The solubility of $LiAlCl_4$ in $SOCl_2$ was determined to be approximately 4.65(M) at room temperature (25°C). The change in concentration of $LiAlCl_4$ with the depth of discharge was calculated assuming cell reaction [1] and

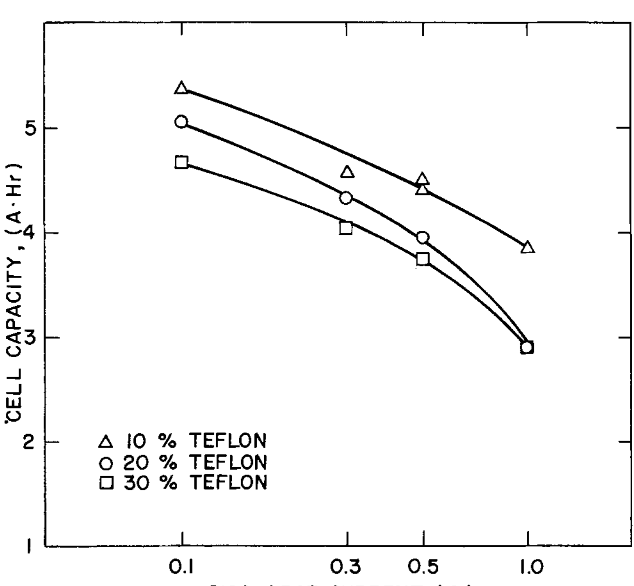

Fig. 3. Semilog plots of cell capacity vs. discharge current of C-size cells made with 1.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolyte and 10, 20, and 30% by weight of Teflon in the carbon cathode.

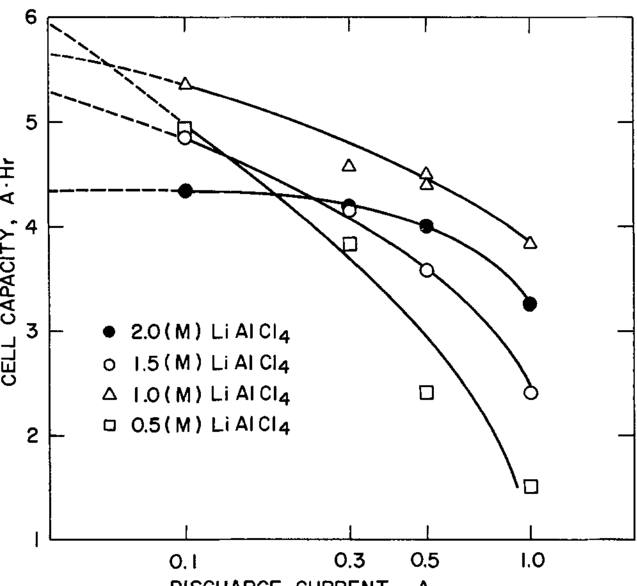

Fig. 4. Semilog plots of cell capacity vs. discharge current of C-size cells made with 10% Teflon in the cathode and 0.5, 1.0, 1.5, and 2.0(M) $LiAlCl_4$ (LPS)-$SOCl_2$ electrolytes.

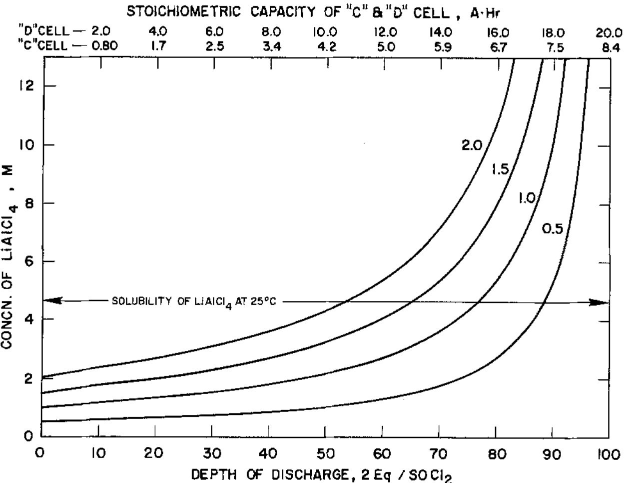

Fig. 5. Plots of $LiAlCl_4$ concentrations as a function of the depth of discharge of C- and D-size cells calculated according to the cell reaction [1].

the plots for the various starting salt concentrations are shown in Fig. 5 for both the C- and D-size cells. The cell capacities for the various depths of discharge are also shown in the figure. It is clear that the depth of discharge at which $LiAlCl_4$ begins to precipitate increases with the decrease in the starting salt concentration. This explains the higher intrinsic cell capacity with lower salt concentration.

The effect of the source or the purity of $LiAlCl_4$ on the cell performance is demonstrated in Fig. 6 which shows semilog plots of capacity *vs.* current of cells made with 10% Teflon in the cathode, 1(M) salt, and two sources of $LiAlCl_4$. The LPS $LiAlCl_4$ is clearly superior to the Foote $LiAlCl_4$ which appeared to contain organic impurities. The organic impurities may enhance the passivation of the cathode.

Conclusions

The following conclusions are drawn from the optimization studies.

1. The lowering of the Teflon content in the carbon cathode improves the performance of the $Li/SOCl_2$ C cells.

2. The intrinsic capacity of the cells appears to increase with the decreasing salt ($LiAlCl_4$) concentrations in the electrolyte. However, the best performance for moderate to high rate applications was obtained with 1(M) $LiAlCl_4$-$SOCl_2$ electrolyte.

3. The performance of the cells appears to depend on the purity of the $LiAlCl_4$; better performance was obtained with laboratory-prepared $LiAlCl_4$.

Casting and Properties of Grid Alloys for Maintenance-Free Batteries

T. W. Caldwell,[1] U. S. Sokolov,* and L. M. Bocciarelli

NL Industries, Incorporated, Central Research Laboratory, Hightstown, New Jersey 08520

ABSTRACT

Microstructure, hardness, castability, and hydrogen evolution rate of cast SLI battery grids were determined for a wide range of Pb-Ca and Pb-Ca-Sn alloy compositions. Calcium oxidation rate of the molten alloys was also studied. These properties were determined as a function of alloy composition, trace element content, and casting conditions. Grids were cast on a commercial calcium-lead grid casting machine under production conditions. Grids were cast from two base leads: a low bismuth primary lead and a refined secondary lead containing bismuth, antimony, copper, and silver. Calcium was found to affect hardness and initial aging rate, while tin influenced grain size, castability, and calcium oxidation rate. Hydrogen evolution rate was also found to be a function of alloy composition. Trace element additions influenced hardness and hydrogen evolution in Pb-Ca-Sn alloys, and calcium oxidation rate and castability in Pb-Ca alloys. Casting conditions influenced grain size and hardness at some alloy compositions.

A new type of lead-acid battery is under development for automotive applications. Called the maintenance-free battery, it is sealed and requires no periodic addition of water. Therefore, the rate of gassing during charging must be minimized to prevent excessive water loss. This restriction requires new low gassing grid alloys, as the conventional Pb-Sb alloys contribute heavily to hydrogen evolution (1). A low gassing Pb-Ca system has been employed for years in standby applications (2), and considerable attention is being given to the Pb-Ca and Pb-Ca-Sn systems for automotive application.

Recently, the effects of trace elements in typical commercial base leads on certain metallurgical and electrochemical properties of Pb-Ca and Pb-Ca-Sn alloys have been investigated (3, 4). At the compositions studied, it was found that typical levels of bismuth, antimony, copper, and silver did not significantly affect the microstructure or hydrogen evolution rate under cathodically polarized conditions. As-cast and short term aged hardness increased at some alloy compositions in the presence of these trace elements. These investigations were performed on laboratory samples specially cast to duplicate actual grid solidification conditions.

In this study, the microstructure, hardness, castability, and hydrogen evolution rate of cast grids were determined for a wide range of Pb-Ca and Pb-Ca-Sn alloy compositions. The calcium oxidation rate of the molten alloys was also studied. These properties were determined as a function of alloy composition, trace element content, and casting conditions. "Alloy" refers to calcium and tin, and "trace elements" refers to bismuth, antimony, copper, and silver.

Experimental

Grids were cast from both low bismuth primary and refined secondary base leads. Calcium and tin were added as a Pb-1Ca master alloy and Straits tin, respectively. Table I gives the compositions of the two base leads and the Pb-Ca master alloy, determined by emission spectroscopy. Elements are reported in ranges due to the use of more than one lot of each. Trace elements other than those indicated were each <0.001%. It is expected that antimony will be substantially removed by Ca_3Sb_2 intermetallic formation when calcium is added to the base lead. A composition range of 0.05-0.12Ca was studied with additions of 0, 0.5, 0.75, and 1.0Sn.

A Wirtz calcium-lead grid casting machine was employed for casting the grids. Nitrogen was used in place of natural gas as a melting pot cover gas, with a flow rate of 55 SCFH metered from two liquid N_2 tanks containing internal evaporators. Propane was employed to heat the metal transfer lines and as a pouring ladle cover gas. Modifications of ladle cam shape, tilt angle, and mold ejector pin settings were made from those normally prescribed for the machine to improve mold filling and grid ejection and to decrease dross buildup in the ladle. The standard pressure pad assembly in the trimming and planishing die was replaced with a specially designed water-cooled pressure pad to reduce thermal distortion of the trim die due to uneven cooling. The scrap return and ingot loading ports on the melting pot cover were sealed. Trim scrap was remelted only at the end of each run.

Figure 1 shows the cast grid configuration. The surface cut, 4M-type grid had a 9 × 23 wire pattern, 0.060 in. frame, and 0.055 in. wire thickness, and weighed 144g per twin. Over 100 casting runs were made, generally producing 1000-2000 grid twins/run. The duration of each run was sufficient to include mold coat deterioration; therefore the casting runs were representative of commercial production conditions. Longer runs of up to 4400 grid twins were made at some compositions. Casting conditions were held as constant as possible, producing 12 grid twins/min at a mold temperature of 400°-425°F, gate temperature of 475°F, and a pouring temperature of 900°-925°F.

Additional runs were made employing a second grid configuration, a staggered cut, 4H-type grid having an 8 × 26 wire pattern, weighing 148g per twin. Higher mold and metal temperatures were required to fill this mold because of the thinner and increased number of wires. Resulting grid properties were essentially the same as found with the 4M mold, except for a decrease in castability of about 11% at the compositions studied.

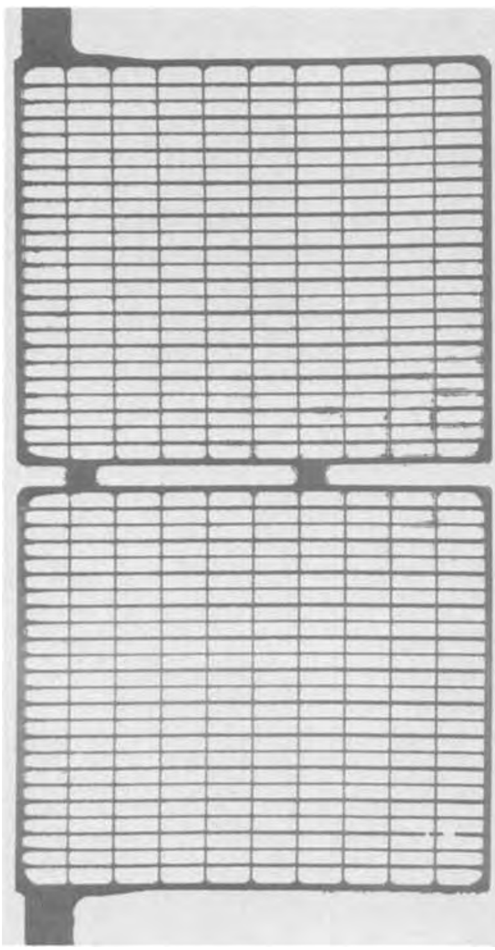

Fig. 1. Cast 4M grid configuration

Grid sections were mounted and examined metallographically. An acetic acid-hydrogen peroxide attack polish-etch was used, followed by an ammonium molybdate-citric acid etchant. The molybdate etch was effective only when all of the cold-worked surface produced during polishing was removed by the attack etching procedure. This was determined by the appearance of a bright surface after a number of polish-etch cycles.

A Barber-Coleman 936 Impressor was employed to measure grid hardness. This device was suitable for testing small cross-section specimens such as grids, and was sufficiently sensitive to measure the effects of composition, aging, and casting conditions. Hardness was measured at one day intervals from the time of casting to five days later. Fifteen hardness readings, five each from the top, side, and bottom borders of the grid twin, were averaged to obtain a single hardness reading for the grid at each time of measurement. Differences in hardness were observed among the top, side, and bottom borders of the grid, but the ranking of these three locations was not consistent. Generally, the bottom border gave the highest hardness readings. Analysis of hardness data was performed on a GE 635 time sharing computer using a nonlinear regression analysis to generate an age-hardening curve for each alloy. The best curve fits were obtained using a three parameter function

$$y = a + b/(x + c)$$

where y and x are 936 hardness and time, respectively, and a, b, and c are constants determined by the regression program for each curve. The index of determination for each curve, R^2 averaged 0.96, signifying excellent correlation between the computed curves and the actual data. (This index is the fraction of the overall variability in the data which is accounted for by the regression equation.) Molten metal and mold temperatures were held constant to eliminate effects of casting conditions on hardness.

The dependence of hardness on base lead composition was investigated with a statistical test for differences in hardness, performed at all combinations of calcium and tin composition where hardness data existed for both base lead systems. Because of the limited number of data points, the "T Statistic" method was employed with a 90% level of significance procedure. The test was performed at half-day intervals up to three days after casting, as differences between alloys of various trace element contents had been found previously to be significant only for a few days after casting (3).

The hydrogen evolution rate on cathodically polarized grids was measured as a function of potential, alloy composition, and trace element content. The grids were positioned symmetrically between two counter-electrodes in a glass and Teflon test cell. Grids were tested as-cast, with no surface preparation. The hydrogen evolution rate was expressed in terms of cathodic current density, measured at fixed potentials in 1.250 sp gr preelectrolyzed sulfuric acid at 70°F. Standard potentiostatic techniques were used with a saturated $Hg/HgSO_4$ reference electrode. Originally, the gas was collected and its volume measured. Once it was established that the coulombic input accounted for better than 97% of the gas evolved, gas collection was discontinued and only the current recorded. Since the property of interest is the current density, an electrostatic technique was developed to measure grid surface area. A test cell was constructed in which a grid was the middle plate of a three plate planar capacitor, positioned symmetrically between two solid lead sheets. The cell capacitance was measured using an impedance bridge and the grid surface area was determined by comparing the measured capacitance with a calibration curve. Calibration curves of capacitance *vs.* surface area were obtained by inserting lead sheets of known surface area in the cell in place of the grid and measuring the capacitance, using Nujol and toluene as dielectrics. Two dielectrics were used to determine if differences in dielectric surface tension would significantly affect wetted grid surface areas, and therefore capacitance. Surface area differences were $<0.5\%$, illustrating the insensitivity of the technique to the choice of dielectric. In fact, surface area differences of $<5\%$ between grids of different casting lots could be reproducibly detected. The average grid surface area was 250 cm^2.

One-hundred percent inspection of grids was performed employing representative criteria for antimonial lead grid production (5). Two types of rejects were classified: mold rejects which included porosity, flashing, and misfills, and mechanical rejects, which included grids damaged moving through the trim die and miscuts from the trimming operation.

The calcium content was measured at one-half hour intervals by atomic absorption spectrophotometry during each casting run. The tin content was measured only once during a run as it was found to be quite stable.

Results and Discussion

Microstructure.—Figure 2 summarizes the major compositional influences on microstructure which were found. Grid side frame sections are shown. From left to right, the addition of calcium to the base lead refines the grain size (Fig. 2b) as is well known. The addition of tin (Fig. 2c and 2d) to Pb-Ca alloys results in an increase in grain size to approximately that of the base lead alone (3). Variations in tin level influence grain size, but not as significantly as when tin is first added to Pb-Ca. Grain size was not a function of base lead composition as shown by Fig. 3.

While not shown, it was found that as calcium was increased from 0.5 to 0.12 weight percent (w/o), grain

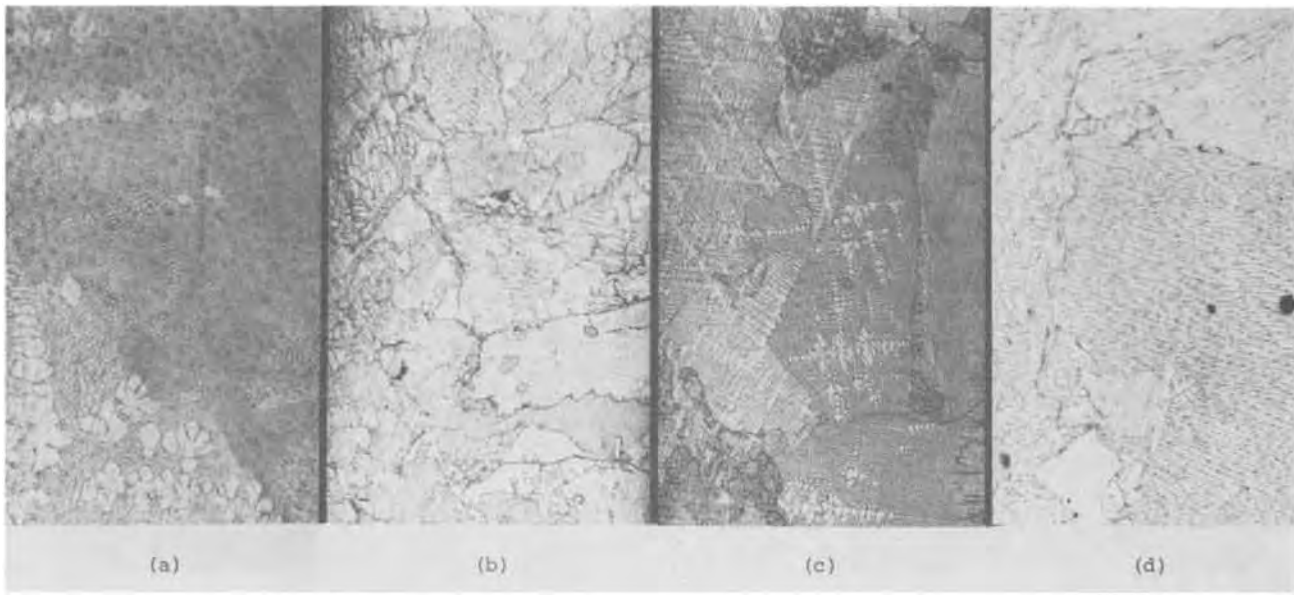

Fig. 2. Effects of alloy composition on microstructure, (a) base lead, (b) Pb-0.081Ca, (c) Pb-0.083Ca-0.45Sn, and (d) Pb-0.082Ca-1.0Sn, 52X.

size decreased in Pb-Ca alloys but the magnitude of grain refinement was found to be less than that reported in much of the literature (6-9). Part of this discrepancy may be due to the influence of solidification rate on grain size (7, 10), since specimens were produced under differing conditions in these studies. However, the molybdate etchant used herein is believed responsible for the particular grain sizes found and for the fibrous dendritic and branched dendritic structures within the grains which were always observed. The etching procedure used was more effective in removing the cold-worked surface layer formed during polishing than the standard acetic acid etchants. Many of the small, irregular grains and rows of grains in structures observed in the literature can be shown to violate Euler's law for the distribution of grain edges, corners, faces, and bodies in a space-fitting aggregate of polyhedral bodies (3, 11), and are therefore artifacts.

The fibrous dendritic morphology within grains as previously described (3, 8) was commonly observed. Breakdown of this structure into stubby-armed branched dendrites was also found (Fig. 2-4). Fibrous dendritic or cellular structures have previously been observed in Pb-Ca alloys by other investigators (12-14). These structures have been extensively studied in dilute lead and tin-base alloys (15-20) and investigated in other alloy systems as well (21-23). While this structure has been described in Pb-Ca as an etching artifact (24), it is clearly real. Its significance is in its influence on the distribution of intragranular microstructural features which affect both hydrogen evolution (10) and corrosion (25). The presence of trace elements in the base lead had no observable effect on microstructural features.

Figure 4 indicates the variation of grain size with location in the grids. Grain size increased quickly away from the grid frame. There was some variation in grain size around the grid frame, but the variation along the frame was smaller than between frame and wire sections. Branched dendrites were observed in wire cross sections. A small but observable variation in grain size with casting conditions was also found, *e.g.*, grain size

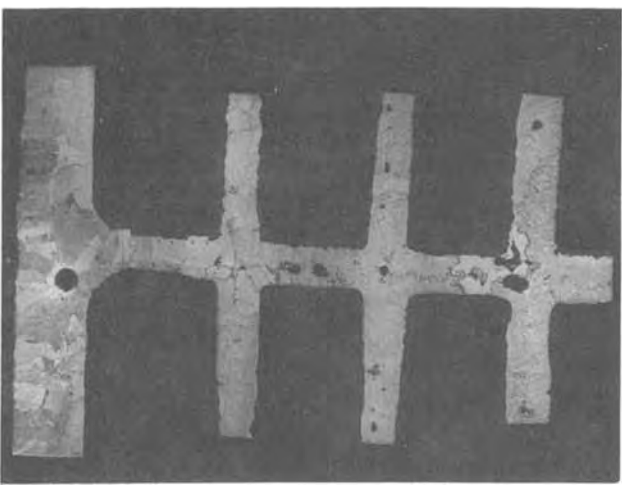

Fig. 4. Variation of grain size with location in grid, low Bi primary Pb-0.07Ca-0.75Sn, composite photograph, 52X.

increased as pouring temperature was raised from 900° to 1000°F at a constant 400°F mold temperature, in alloys containing 0.75Sn. Measurements were not made at other tin levels.

Hardness.—Hardness was measured as an indication of both tensile properties and grid handleability. While arbitrary hardness scales are generally nonlinear and values may be compared only on a qualitative basis, hardness measurement is an effective means of screening alloys and providing production quality control. Reasonably good correlation between hardness and tensile strength has been shown for Pb-Ca alloys (26). A cross plot of additional data in that study shows a reasonable correlation between hardness and yield strength, also.

Figure 5 illustrates the typical age-hardening behavior of Pb-Ca and Pb-Ca-Sn alloys. A similar plot was generated for alloys of other tin contents studied in both base lead systems. Hardness is observed to increase with both time and calcium content, as reported previously for Pb-Ca alloys (hardness or tensile strength) by many investigators (9, 14, 27, 28). Initial aging rate was also observed to increase with increasing calcium content. The addition of tin to Pb-Ca alloys decreased hardness over the time interval studied, with hardness decreasing slightly as the tin content was increased from 0.5 to 1 w/o. However, tin additions did not influence initial aging rate within the accuracy of the measurement technique employed. Myers *et al.* (9) have shown that tin additions to Pb-Ca completely inhibit the onset of aging for at least 1 hr. The one day test interval used in this study was not designed to detect such short term effects. Tin is expected to have a positive influence on hardness at longer times (29, 30).

Mold and metal temperatures were held constant to eliminate effects of casting variables, as hardness was significantly influenced at some compositions by the particular ladle and mold temperatures employed, as shown in Fig. 6. On the left, the effect of three combinations of ladle and mold temperatures on the hardness of Pb-0.085Ca-0.75Sn is shown. Mold and ladle temperatures are in degrees Fahrenheit. The upper and lower mold temperatures were equal. Increases in both mold temperature (bottom and middle curves) and ladle temperature (bottom and top curves) increase hardness measurably. On the right, three curves are shown for Pb-0.075Ca-1Sn, but no strong dependence on ladle and mold temperature is evident, although some variation in initial hardness is indicated.

Figure 7 presents graphically the results of the statistical test for differences in hardness as a function of base lead composition. The data points indicate the calcium and tin compositions at which the significance test was performed. The solid circles identify compositions at which refined secondary lead alloys were statistically harder than low bismuth primary lead alloys. The solid squares identify compositions where the opposite was found. The open circles represent compositions where no statistical differences were indicated. No data is presented for Pb-Ca alloys as not enough hardness data were available for comparison between base leads.

It is observed that there are fairly well-defined compositional fields in which differences are observed between alloys of the two base leads. Below approximately 0.085Ca, refined secondary lead alloys exhibit higher hardness than low bismuth primary lead alloys. Above approximately 0.1Ca, a low bismuth primary lead alloy exhibited higher hardness. In the region between these compositions, there is no statistical difference. Within the limits of the available data, tin content did not influence the rankings, however, more data points would be required for clarification.

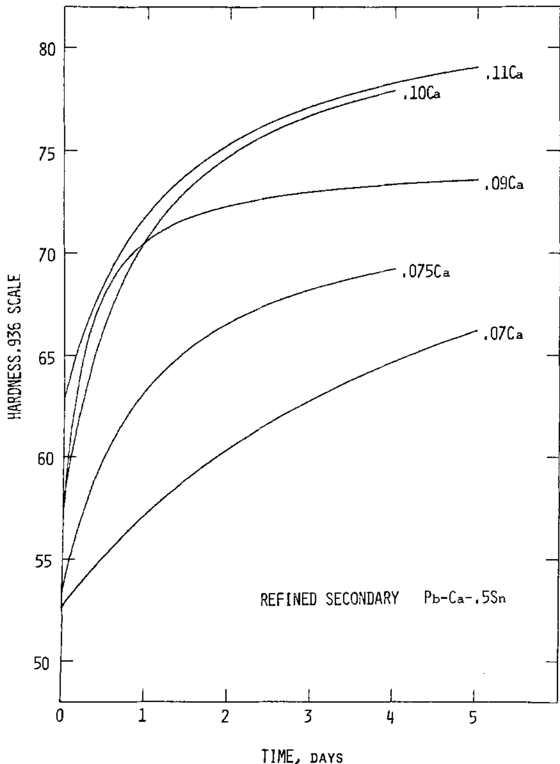

Fig. 5. Hardness vs. time after casting

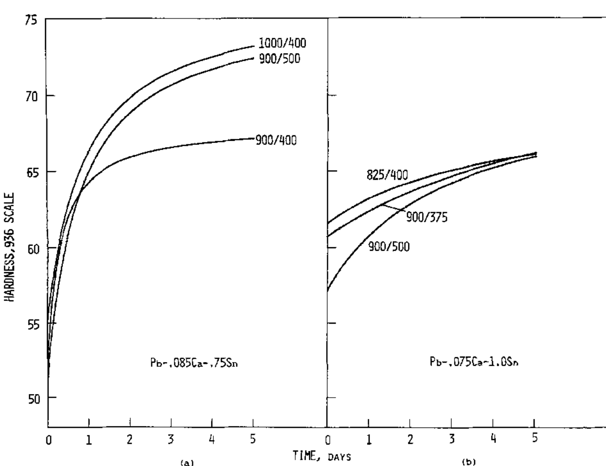

Fig. 6. Hardness vs. casting conditions in two alloy classes, (a) Pb-Ca-0.75Sn, and (b) Pb-Ca-1.0Sn, for different metal/mold temperature conditions.

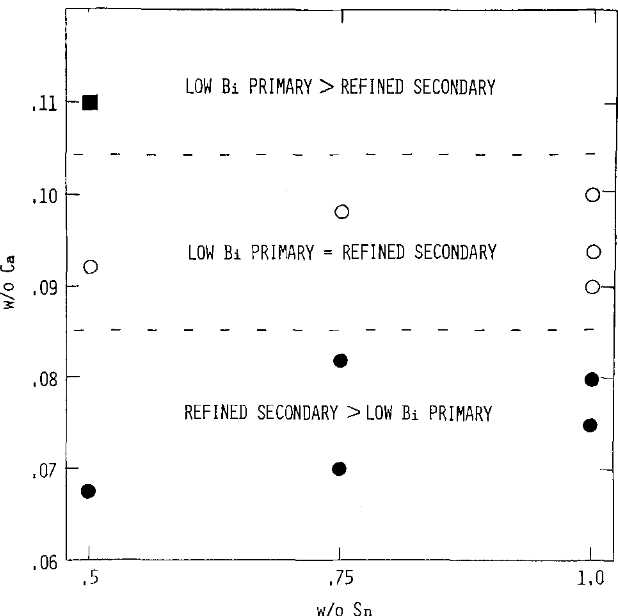

Fig. 7. Hardness vs. base lead composition at given calcium and tin levels.

The existence of fairly well-defined zones in which trace elements in the base lead have varying observed effects on hardness may be explained as follows: At low calcium levels where as-cast hardness is low, strengthening by trace elements is likely to be quite noticeable, as previously observed (3, 9). In Pb-Ca alloys, grain refinement has been suggested as the hardening mechanism (9). In Pb-Ca-Sn alloys, where no grain refinement is found [this study and others (3, 9)], some other mechanism such as solid solution strengthening must be operating. At higher calcium levels where as-cast hardness is higher, the effect of trace elements may not be observable (9). At very high calcium levels, *i.e.*, higher than likely to be employed in a maintenance-free battery for reasons of corrosion resistance, the lattice straining effect of the trace elements in solid solution might contribute to overaging of the Pb_3Ca precipitates, causing low bismuth primary lead alloys to be harder. However, only one datum point exists where low bismuth primary Pb-Ca-Sn was harder than refined secondary Pb-Ca-Sn, and this effect must be investigated further.

At all calcium contents of interest, the results of this study indicate hardness is more easily controlled by adjustments in alloy composition and casting conditions than by adjusting base lead composition.

Hydrogen evolution.—The calibration technique developed for measuring grid surface area was found to be accurate and insensitive to the choice of dielectric. This was important since the accurate measurement of grid surface area was required to compare results on individual grids. The test cell is shown in Fig. 8. Table II lists results for Pb-Ca grids of different composition in both base leads. Unalloyed refined secondary base lead results are included for comparison. Unalloyed low bismuth primary base lead grids were too soft to handle and were not tested. The average rate of gassing is given for each potential. In all but one case, increasing calcium content increases gassing on both base leads. However, compared to the gassing on unalloyed refined secondary lead, it is not clear whether calcium increases or decreases gassing, or has any effect at all. It has previously been reported that calcium at similar compositions has no effect on gassing (31).

Table III presents results for Pb-Ca-Sn grids, for a number of different alloy compositions. Here, variations in gassing of 50% are observed as a function of alloy composition. At some compositions, *e.g.*, Pb-0.085Ca-1.0Sn, refined secondary lead gasses less than low bismuth primary, while at others, *e.g.*, Pb-0.07Ca-0.75Sn,

* *Vs.* Hg/Hg_2SO_4 reference electrode.

the opposite is true. It is not clear what is the general effect of calcium, tin, and trace element content on gassing, but it is observed that differences in gassing due to base lead composition are smaller than the effects due to variations in alloy content. Hence, gassing rate is more easily controlled by adjusting alloy content than by adjusting base lead composition. Recently, hydrogen evolution was measured in Pb-0.1Ca test cells in which trace elements were added to the electrolyte (32). This study indicated that antimony and arsenic at electrolyte concentrations > 1 ppm, and copper and bismuth at concentrations > 500 ppm increased gassing. However, it has yet to be demonstrated how electrolyte trace element concentration relates to grid alloy composition. Certainly, not all of a trace element in the grid alloy is available for solution into the electrolyte.

Castability

Industrial experience in the manufacture of Pb-Ca industrial batteries has indicated that the castability of Pb-Ca alloys would be inferior to that of antimonial lead in SLI grid configurations. Castability is defined here to be the combination of all factors influencing the net grid output of a casting machine per unit time. Figure 9 shows the reject percentage as a function of tin and base lead composition for all casting runs in the range 0.07-0.095Ca. The mold reject data points relate to the properties of the molten alloys and the skill of the machine operator. The difference between the total reject and the mold reject data points represents the percentage of mechanical rejects, which is related to grid strength and machine design.

A comparison of the two curves indicates that a mechanical reject percentage of 10-12% is quite constant at all compositions. This indicates that differences in hardness are not contributing to these rejects, rather, machine design must be modified if this 12% mechanical reject figure is to be reduced. The addition of 0.5Sn almost halves the total reject rate, but additions from 0.5 to 1.0Sn only have a small positive effect. Base lead composition has a significant effect only in Pb-Ca alloys. Differences between Pb-Ca-Sn alloys of different base leads are attributed to increased operator experience only, as the low bismuth primary lead alloys were cast first during the study. The effects of trace elements on hardness and castability reported herein conflict with those reported in a bench scale casting operation (33). In this study, repeated runs at a given composition often result in higher castability, indicating an operator learning factor, and that the results presented herein only indicate trends and general relationships.

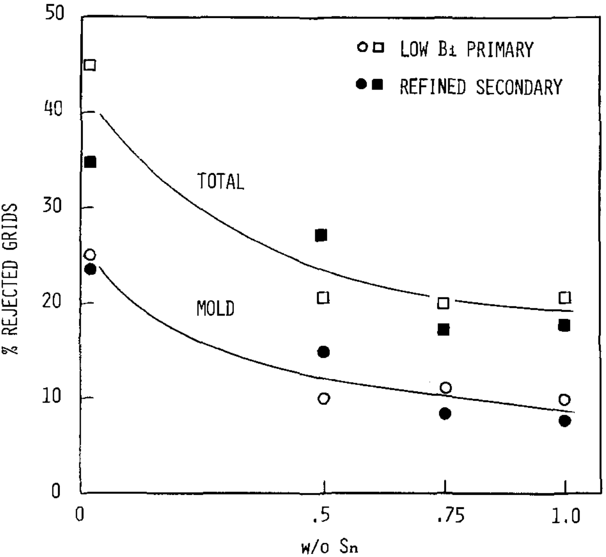

Fig. 9. Castability vs. tin and base lead composition showing mold and total reject percentages.

Furthermore, the absolute reject percentage is obviously a function of mold design and the inspection criteria employed.

Calcium Oxidation Rate

Unlike antimonial lead, molten calcium-lead alloys oxidize rapidly, even with the use of an enclosed melting pot and metal transport system. Figure 10 presents the rate of calcium loss as a function of tin content for the range 0.065-0.095Ca. Each data point represents the averaged loss rate for all casting runs in the given composition range. At all compositions, the calcium content decreased linearly with time, within the accuracy of the analytical technique.

While not shown, the calcium loss rate decreases somewhat with increasing calcium at each tin content. Oxidation rate in Pb-Ca is markedly lower for refined secondary base lead.

In Pb-Ca-Sn alloys, differences in loss rate with base lead composition are small. The frequency and thoroughness of drossing of the melting pot affect the absolute loss rates obtained, along with the effectiveness of the gas cover and scrap recycling procedures employed.

Conclusions

The most significant effects of calcium, tin, base lead compositions and casting conditions on the properties of Pb-Ca and Pb-Ca-Sn alloys studied herein are summarized as follows:

1. Hardness and initial aging rate increase with calcium content in the range 0.05-0.1Ca.
2. The addition of 0.5Sn to Pb-Ca alloys increases grain size and castability and decreases calcium oxidation rate. Further additions up to 1 w/o increase these properties slightly.
3. The addition of 110-180 ppm bismuth, 5-20 ppm antimony, 5-10 ppm copper, and 20-30 ppm silver increase hardness at <0.085Ca in alloys containing 0.5-1.0Sn.
4. The addition of the stated amounts of these elements also increases compositional stability and castability of Pb-Ca alloys but has no effect on Pb-Ca-Sn alloys for the compositions studied.
5. A capacitance method has been developed for accurately determining the surface area of cast grids, which for the grid design employed averaged 250 cm^2.
6. The hydrogen evolution rate on cathodically polarized grids as a function of alloy composition varied in a seemingly random manner. Variations in calcium and tin composition affect gassing more than variations in trace element content.
7. At some compositions, casting conditions can exert as large an effect on hardness as changes in alloy composition.

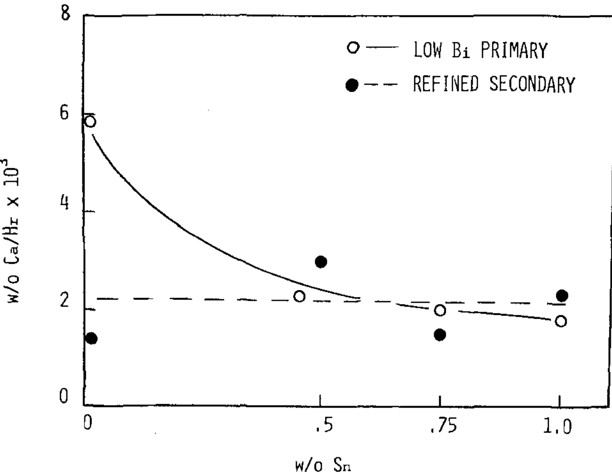

Fig. 10. Rate of calcium loss vs. tin and base lead composition

8. The doubling of tin content from 0.5 to 1.0 w/o has only a small effect on microstructure, hardness, castability, and calcium oxidation rate.

Acknowledgments

The authors wish to thank Mrs. L. J. Crosby, R. A. Garini, D. Goodmacher, and K. Bibbo for assisting in the experimental portions of this work, S. Blinder for the statistical analyses, and members of the Analytical Services Department for the chemical analyses. The authors would also like to thank E. R. Hein and G. R. Kotler for helpful discussions and NL Industries for permission to publish this work.

Manuscript received April 23, 1976. This was Paper 36 presented at the Boston, Massachusetts, Meeting of the Society, Oct. 7-11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by NL Industries, Incorporated.

Some Observations on the Prediction of the State of Discharge of Batteries

F. Kornfeil*

United States Army Electronics Command, Electronics Technology and Devices Laboratory, Fort Monmouth, New Jersey 07703

ABSTRACT

A galvanostatic test method is described to determine the state of discharge of cells of the system Zn/KOH/HgO and the results compared with data obtained in loaded voltmeter tests. In a general treatment of battery testing equations are derived which show, *inter alia*, that for all electrochemical systems the sensitivity of galvanostatic tests is higher than the sensitivity of the loaded voltmeter method and which allow, *e.g.*, the calculation of the value of the external resistance yielding the maximal sensitivity attainable in a loaded voltmeter test.

Owing to the variety of electrochemical systems presently in use numerous test methods (1-3) to determine the state of discharge (SOD)[1] of galvanic cells have been employed, some modified with varying degrees of success to meet the demands of specific applications, chiefly to prevent the waste of still usable primary cells and, perhaps somewhat less importantly, to discern the need to replenish the charge of secondary batteries. One of the simplest and most widely used techniques is the loaded voltmeter test (4), so called because a voltmeter with a constant resistance (load) in parallel is attached to the cell terminals and the resulting voltage E used as an indication of the SOD of

* Electrochemical Society Active Member.

Key words: battery testing, galvanostatic test method, loaded voltmeter test, electrode polarization, zinc-mercuric oxide cells.

[1] In this paper the term "state of discharge" is used instead of the more prevalent "state of charge" because the latter conveys the concept of rechargeability, at least to this author's ears.

the cell. The loaded voltmeter test consists therefore, in effect, of the utilization, at constant external resistance R, of the overvoltage η of the cell as a function of the state of discharge and is known to produce results of acceptable accuracy with some, but by no means all. electrochemical systems.

It was the rather low sensitivity of the loaded voltmeter method when applied to cells of the system Zn/KOH/HgO (mercury cells) which prompted the investigation reported in this paper. Its aim was twofold: to devise a rapid and nondestructive method of greater sensitivity for the prediction of the SOD of mercury cells; and to explore the consequences of a more generalized treatment of the polarization phenomena related to battery testing, thus perhaps eliminating at least part of the sometimes tedious empirical procedures.

Experimental

Test procedure.—All experiments were performed at room temperature (21° ± 1°C) on mercury cells[2] of Type RM-4. These cells deliver from 30 to 33 hr of service when subjected to a continuous discharge through a 12Ω resistance to a cutoff voltage of 0.90V. Their open-circuit voltage E_o of 1.355V is remarkably uniform and stable and is very nearly constant over the entire discharge range, since no solid solutions between reactants and products are formed at either electrode and the electrolyte concentration remains virtually unchanged during discharge of the cells. E_o can, therefore, not be used as an indication of their SOD.

A series of preliminary experiments designed to explore the possible usefulness of the tangents drawn to E-i curves at various currents as a function of the SOD proved unsuccessful, mainly because of the impossibility of attaining quasi-steady states at currents $i > 200$ mA and at SOD's > 40% of full capacity. These experiments lead, however, to the following galvanostatic test procedure.

The terminal voltage E of a fresh cell is measured 90 sec after the start of a constant discharge current, the current interrupted, and the cell, after recovery of the cell voltage to the original open-circuit value E_o, discharged through a 12.0Ω resistance for a recorded period of time. This procedure is repeated until the cell is almost completely discharged. Its remaining capacity is then determined by discharging it to an end voltage of 0.90V, this point representing the SOD of 100%.

Three curves obtained with this test method at different currents are shown in Fig. 1. Each curve represents the mean values of E of about thirty cells, plotted against the state of discharge C expressed in percent of the total cell capacity C_o. At the test currents used the cell voltages exhibit a scatter of ± 40 mV. Except for the initial 10% of the abscissa E is seen to be a practically linear and rather sensitive function of the state of discharge. As an example, the slope of the linear portion of the curve obtained with a test current of 300 mA is 7.8 mV/%, contrasting quite favorably with loaded voltmeter tests performed under comparable conditions, as will be demonstrated below in greater detail. The interval of 90 sec before measuring E constitutes a compromise involving several factors. A period too short for a significant part of the mass transport to occur may result in the loss of a portion of the diffusion overpotential, thereby reducing the sensitivity of the test method.[3] Conversely, an unnecessary prolongation of the span may carry the system close to or into the limiting current condition and falsify the results, particularly when larger test currents are used. In addition, it is always desirable in any test to remove as minute a part of the cell capacity as possible. In the case of RM-4 cells one test of 90 sec duration at i = 300 mA diminishes the capacity of a fresh cell by approximately 0.3%, a reasonably small fraction.

Results and Discussion

General considerations.—At this point the question arises why, in fact, the overvoltage of a galvanic cell depends on its state of discharge. This is undoubtedly a problem of considerable complexity, however, for the purposes of the present discussion it is sufficient to consider only two factors. Firstly, as the cell is discharged the consumption of the electrode materials results in progressively smaller active electrode areas and consequently in correspondingly higher current densities and, therefore, higher overpotentials. Secondly, the accumulation of solid reaction products at the electrode surfaces changes the conditions of mass transport, giving rise to a gradual increase of the diffusion overpotential. These considerations will be valid for all systems in which a solid phase of the electrode participates directly in the electrode reaction but will not apply to redox systems (*e.g.*, fuel cells) with inert electrodes whose sole function is to render the charge transfer step possible. It is fortunate that in these cases special methods to determine the state of discharge are not required since the reactants are stored outside of the galvanic cells and their quantities are easily measurable by other means.

Relative sensitivity at i = const and R = const.—The results depicted in Fig. 1 show that the test voltage E is a function of C, the state of discharge defined as 100 C_r/C_o, where C_r denotes the capacity removed during a 12Ω continuous discharge and C_o is the total capacity available to an end point of 0.90V. A convenient way of treating the observed phenomena is to look at the decrease of E with increasing C as the result of a progressive increase of the total internal resistance R_i of the cell, *i.e.*, $E = f(R_i)$. Then $R_i = d\eta/di$, η being the sum of the charge transfer, diffusion, reaction, crystallization and resistance overpotentials present at both electrodes (5).

From the equivalent circuit of the cell shown in Fig. 2, we observe that

$$E = E_o - iR_i \quad [1]$$

and

$$E = \frac{E_o R}{R + R_i} \quad [2]$$

expressing $E = f(R_i)$ with either the current i or the external resistance R as the parameter. Capacitive effects are neglected because $dE/dt \simeq 0$ in all situations under discussion.

[3] It is for this reason that, *ceteris paribus*, tests using current pulses in polarization measurements are subject to a certain amount of scepticism. The use of pulse currents in the determination of, *e.g.*, double layer capacities as a function of the SOD is, of course, another matter.

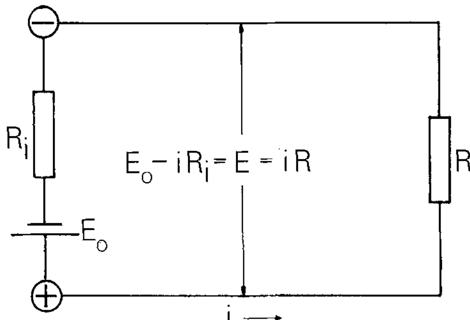

Fig. 2. Equivalent circuit and fundamental relations

Since R_i will, in general, be dependent on the current as well as the state of discharge it is convenient formally to separate R_i into two components, $f(i)$ and $F(C)$, such that $df(i)/dC = dF(C)/di = 0$

$$R_i = f(i) + F(C) \quad [3]$$

$f(i)$ and $F(C)$ may be any single-valued function whatever of the current and the state of discharge, respectively, subject only to the following restrictions. Since $d\eta/di > 0$ on thermodynamic grounds, $f(i)$ must always be a positive quantity. $F(C) = 0$ for $C = 0$ and increases to a maximum at $C = 100\%$ ($C_r = C_o$), *i.e.*, $dF(C)/dC = dR_i/dC > 0$ for all values of C which condition, obviously, is the *sine qua non* for the applicability of any test method based on electrode polarization.

Combining Eq. [1] and [3] we get

$$E = E_o - i[f(i) + F(C)] \quad [4]$$

and

$$E = \frac{E_oR}{R + f(i) + F(C)} \quad [5]$$

The sensitivities S_i of the galvanostatic method and S_R of the loaded voltmeter test are obtained by differentiation of Eq. [4] and [5] with respect to C

$$S_i = -(\partial E/\partial C)_i = i \cdot dF(C)/dC = \frac{E}{R} dF(C)/dC \quad [6]$$

$$S_R = -(\partial E/\partial C)_R = \frac{E_oR}{[R + f(i) + F(C)]^2} dF(C)/dC$$

$$= \frac{E}{R + f(i) + F(C)} dF(C)/dC \quad [7]$$

Division of Eq. [6] by Eq. [7] results in

$$S_i/S_R = 1 + \frac{f(i) + F(C)}{R} \quad [8]$$

Several interesting conclusions can immediately be drawn from the preceding equations. Since the second term on the right-hand side of Eq. [8] is always a positive quantity it follows that, for the same value of E, $S_i > S_R$ for every electrochemical system, no assumptions pertaining to its nature having been made in the derivation. Therefore, the galvanostatic method must invariably be more sensitive than a loaded voltmeter test performed at any load R, provided only that their respective E-C curves have one point in common. Moreover, the ratio of the sensitivities will become greater as a cell of a given system approaches the state of full discharge [large $F(C)$] and the more easily polarizable the system in question is [large $f(i)$].

That this is indeed the case is illustrated in Fig. 3. In this diagram the solid line is the result of the galvanostatic tests performed at 300 mA and is a reproduction of curve 2 of Fig. 1. The dotted curves 1, 2, and 3 were obtained in loaded voltmeter tests in which E was also measured 90 sec after closing the circuit. The values of the external resistances were chosen such that

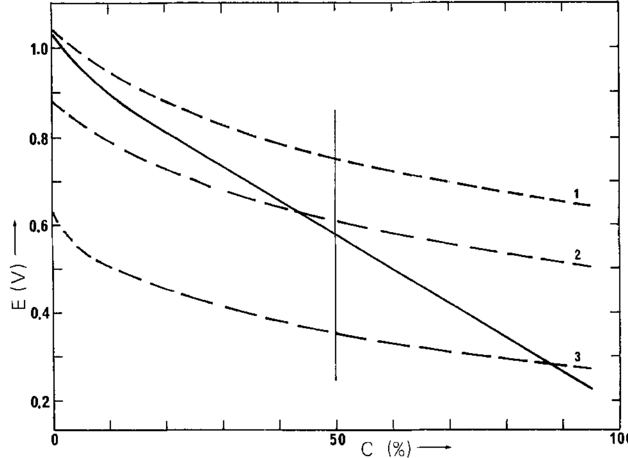

Fig. 3. Galvanostatic and loaded voltameter test results. Solid line = galvanostatic test at 300 mA. Dotted lines = loaded voltmeter tests. Curve 1, 3.3Ω; curve 2, 2.2Ω; curve 3, 1.0Ω.

the curves would coincide with the galvanostatic line at states of discharge of approximately 0, 50, and 100%, respectively. As predicted, in all three series of loaded voltmeter tests the slopes are smaller than the slope of the galvanostatic curve. Obviously, the most appropriate comparison is made with curve 2 ($R = 2.2\Omega$) because here the average current is roughly the same in the two tests, whereas in curve 1 ($R = 3.3\Omega$) the loaded voltmeter test current is smaller and in curve 3 ($R = 1.0\Omega$) larger than 300 mA for all states of discharge. The numerical values of the sensitivities, measured at $C = 50\%$, are $S_i = 7.8$ mV/% and $S_R = 3.0$ mV/%, *i.e.*, at the midpoint the galvanostatic test is more sensitive by a factor of 2.6. This factor increases with increasing C, again in accordance with prediction, and reaches a value as high as 6.5 at $C = 90\%$.

The significance of the higher sensitivity of the galvanostatic test is brought out more clearly by considering the scatter of the test voltage due to the less than perfect uniformity achieved in the manufacture of the cells. Referring to Fig. 4, the maximal uncertainty ϵ associated with a particular test method is related to its sensitivity S and the voltage scatter σ by the expression $\epsilon = 2\sigma/S$. As pointed out previously, σ is approximately 40 mV in the current range under consideration. Using this value the maximal uncertainty of the galvanostatic method is about 10% over the entire range at 300 mA, compared to about 27% for the loaded voltmeter test at $C = 50\%$. Taking an average slope of 2.1 mV/% between 50 and 90% discharge $\epsilon = 38\%$ and it becomes clear that for mercury cells a loaded volt-

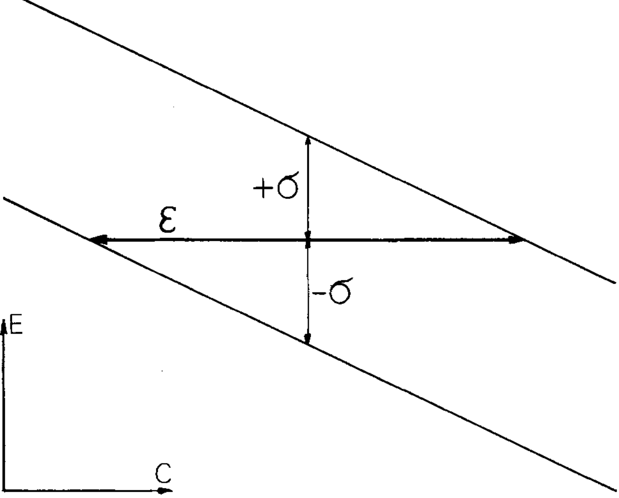

Fig. 4. Uncertainty due to scatter of test voltage

meter test with an average current of 300 mA is not accurate enough to distinguish a half-discharged from a nearly fully discharged cell with any degree of confidence.

Absolute sensitivities.—Referring to Eq. [4] it follows from the linearity (at least for mercury cells) of the galvanostatic E-C curves that $F(C)$ increases proportionally to C and that $dF(C)/dC$ = const. According to Eq. [6] one should therefore expect S_i to increase linearly with the test current. Figure 5 shows this to be true, at least up to 400 mA, the highest value used to date (the quantity $(\bar{S}_R)_{max}$ in the diagram will be discussed later). It should be noted that at this current cells of $C > 85\%$ already exhibit a test voltage $E < 0$, requiring the use of an external d-c power source, a practice which was, at any rate, resorted to in all galvanostatic tests to facilitate the condition i = const during the 90 sec period. Accordingly, it appears that S_i can be raised to any desired value by increasing the test current, as long as the limiting current region is not reached, and provided that a possibly higher voltage scatter does not cancel the advantage so gained.

The relationship between the sensitivity S_R of the loaded voltmeter test and the external resistance R is rather more complicated than the simple linear dependence of S_i on the current. One aspect of this relationship becomes immediately apparent from an inspection of the slopes of the dotted lines shown in Fig. 3. Despite a more than threefold change of R the slopes at corresponding points on the abscissa differ by only about 30% and, at first perhaps surprisingly, actually increase with increasing R. The numerical values are, again at $C = 50\%$, $S_{R=1.0} = 2.3$, $S_{R=2.2} = 3.0$, and $S_{R=3.3} = 3.4$ mV/%. This behavior can easily be understood by the following consideration. The external resistance chosen for a loaded voltmeter test can, obviously, have any value between $0 \leqslant R \leqslant \infty$. For both extremes the resulting S_R must be zero, independently of the state of discharge of the cell tested, since at $R = 0$ $S_R = 0$ because the cell is short-circuited and $E = 0$, while at $R = \infty$ $E = E_o$ and again $S_R = 0$ unless E_o is itself a function of the state of discharge. Therefore, a maximal value $(S_R)_{max}$ and a corresponding R_{max} must exist, and the question of whether the sensitivity increases or decreases with R depends entirely on the external resistance being smaller or larger than R_{max}.

It now remains to determine the position of $(S_R)_{max}$ and, ideally, to calculate the absolute values of $(S_R)_{max}$ and R_{max}.

Values of $(S_R)_{max}$, R_{max}, $(\bar{S}_R)_{max}$, $\bar{R}_{max}$.—Equation [7] can be rewritten in the form

$$S_R = \frac{E_o R}{(R + R_i)^2} dR_i/dC \qquad [9]$$

and we see at once that the condition $S_{R=0} = S_{R=\infty} = 0$ is satisfied because $\lim_{R\to 0} R/(R + R_i)^2 = 0$ and also $\lim_{R\to\infty} R/(R + R_i)^2 = 0$. Equation [9] allows the calculation of the sensitivity of a loaded voltmeter test for any value of R, at any given state of discharge of the cell, once a single galvanostatic test curve has been established, since E_o is known and the numerical values of R_i and $dR_i/dC = dF(C)/dC$ are readily accessible from Eq. [1] and [6], respectively. Although the knowledge of S_R for various values of R may be of interest in some particular instances, a determination of R_{max} will ordinarily be sufficient. Differentiation of Eq. [9] with respect to R and setting the result equal to zero yields

$$1/(R + R_i)^2 - 2R/(R + R_i)^3 = 0 \qquad [10]$$

The value of R satisfying this equation is

$$R_{max} = R_i \qquad [11]$$

Substitution into Eq. [9] leads to

$$(S_R)_{max} = \frac{E_o}{4} \frac{d}{dC} \ln R_i \qquad [12]$$

Thus, at a given state of discharge, the maximal sensitivity of a loaded voltmeter test depends on the relative change of R_i and is realized when the external resistance used is equal to the internal resistance at this point. The calculated values of S_R, at $C = 50\%$, for the tests presented in Fig. 3, are $S_{R=3.3} = 3.3$, $S_{R=2.2} = 3.2$, and $S_{R=1.0} = 2.4$ mV/%, in good agreement with the experimental data.

In the derivation of Eq. [10] R_i was assumed to be independent of R, an obvious simplification since R_i contains the term $f(i)$ and must consequently also be a function of R. However, the error due to this assumption is negligible, at least for mercury cells and probably also for other systems, as can be shown in the following way. A series of galvanostatic tests was carried out, at various currents, on fresh ($C = 0$) cells for which $F(C) = 0$, by definition. Equation [4] then takes the form $f(i) = (E_o - E)/i$, permitting the plotting, as a function of i, of $f(i) = R_0$, the value of R_i at $C = 0$. Figure 6 shows how after an initial decrease $f(i)$ reaches a practically constant value of 1.3Ω between 200 and 400 mA, the range of currents used in the galvanostatic tests and, as will be demonstrated below, also in the loaded voltmeter tests conducted at maximal sensitivity. Remembering that $f(i)_{C=0} = d\eta/di$, the same curve can be obtained by drawing the tangents to the $\eta - i$ curve of a fresh cell shown in Fig. 7. The rather long linear part of the curve is most likely caused by the gradual preponderance of the diffusion overpotential η_d (6), for which $d^2\eta_d/di^2 > 0$, over the charge transfer overpotential η_t (7), with $d^2\eta_t/di^2 < 0$. The question of whether this extended constancy of $f(i)$ also occurs in other

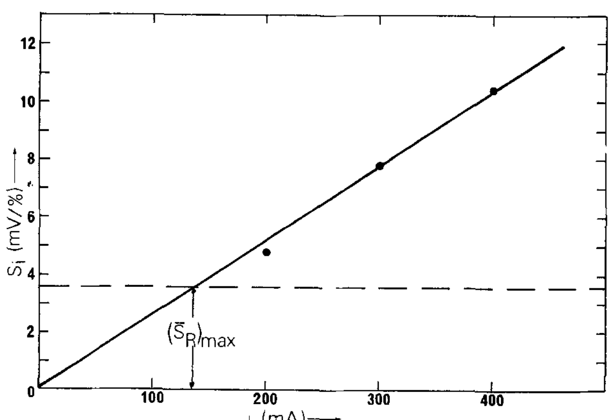

Fig. 5. Dependence of sensitivity of galvanostatic test on current

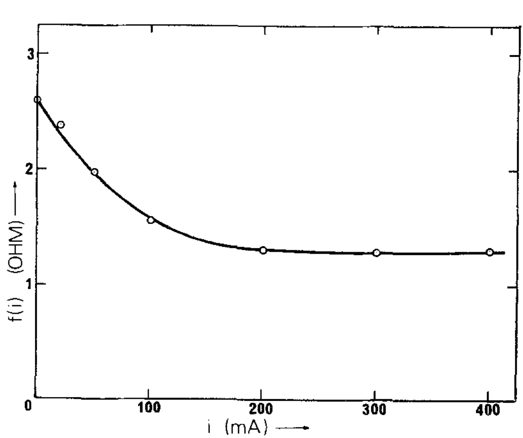

Fig. 6. *f(i)* as a function of current

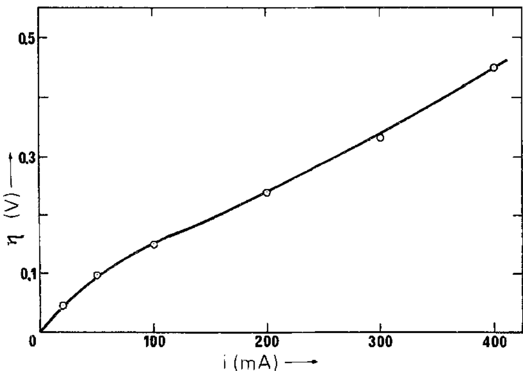

Fig. 7. Overvoltage of RM-4 cells as a function of current

systems is awaiting further experimentation and will be discussed in a subsequent publication.

It should perhaps be pointed out that it is not an uncommon mistake to assume $(R_i)_{i\to 0}$ to be the ohmic component of the internal resistance because η approaches zero. Although η indeed vanishes $(d\eta/di)_{i\to 0}$, the polarization resistance (8), does not, and would be zero only if the exchange current densities, the diffusion coefficients of all species participating in the electrode reactions, and the rate constants of all chemical reactions preceding and following the charge transfer step were infinite.

Equations [11] and [12] refer to a specific point on the C-axis and hence to the individual value of R_i at that point and can, therefore, not directly be used to calculate $(S_R)_{max}$ and R_{max} of a practical loaded voltmeter test for which, of course, a single value of R_{max} is required. To this end it is necessary to maximize $\bar{S}_R$, the average sensitivity over all states of discharge. Consequently, we have

$$\bar{S}_R = 1/100\int_0^{100} S_R dC$$

$$= \frac{E_o(R_{100} - R_0)}{100} \frac{R}{(R + R_0)(R + R_{100})} \quad [13]$$

where use of Eq. [9] has been made and R_0 and R_{100} denote the values of R_i at $C = 0$ and $C = 100$, respectively. Setting the derivative $d\bar{S}_R/dR$ equal to zero we obtain the equation

$$\frac{1}{(R + R_0)(R + R_{100})} - \frac{R(2R + R_0 + R_{100})}{[(R + R_0)(R + R_{100})]^2} = 0 \quad [14]$$

the solution of which is

$$\bar{R}_{max} = \sqrt{R_0 R_{100}} \quad [15]$$

i.e., in a loaded voltmeter test the external resistance yielding the maximal average sensitivity over the entire range of discharge of the cell is the geometric mean of the initial and final values of its internal resistance.

Substitution into Eq. [13] leads to

$$(\bar{S}_R)_{max} = \frac{E_o(R_{100} - R_0)}{100} \frac{1}{2\sqrt{R_0 R_{100}} + R_0 + R_{100}} \quad [16]$$

Extrapolation of the linear part of a galvanostatic curve to $C = 0$ and $C = 100$ and use of the resulting values of E gives, in the case of the mercury cells tested, $R_0 = 1.31$ and $R_{100} = 3.90\Omega$. Substitution into Eq. [15] and [16] demonstrates that the average sensitivity of a loaded voltmeter test of RM-4 cells can never exceed 3.6 mV/% and is attained with an external resistance of 2.3Ω. It is easily calculated that in this loaded voltmeter test the current varies between 220 and 380 mA and is within the range of virtual constancy of $f(i)$,

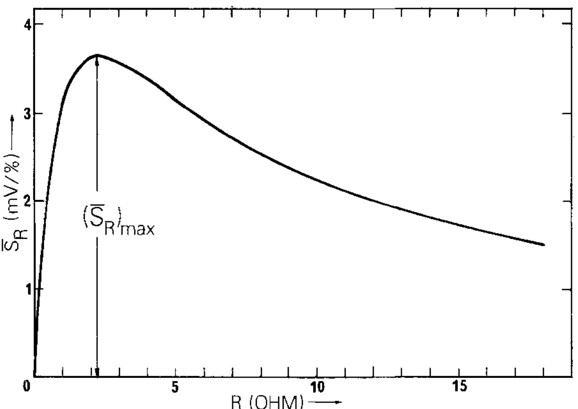

Fig. 8. $\bar{S}_R$ as a function of the external resistance, calculated with $R_0 = 1.31\Omega$, $R_{100} = 3.90\Omega$.

again justifying the assumption $dR_i/dR = 0$ implicit in Eq. [13], [15], and [16].

Figure 8 shows $\bar{S}_R$ as a function of the external resistance, according to Eq. [13]. The sensitivity of the loaded voltmeter test increases rather slowly with decreasing R, reaches a maximum at $R = 2.3\Omega$ and then decreases sharply at still lower values of R. In order to facilitate the comparison of the galvanostatic and loaded voltmeter tests $(\bar{S}_R)_{max} = 3.6$ mV/% has been inserted in the diagram of Fig. 5. It is apparent that a sensitivity of 3.6 mV/% can be achieved with a constant test current of only 140 mA, while the galvanostatic tests at 300 and 400 mA have sensitivities of 7.8 and 10.4 mV/%, respectively, clearly demonstrating the higher accuracy of the galvanostatic method.

One should, however, remember that the results reported here refer to cell capacities obtained at a single discharge rate (12Ω) at only one temperature (21°) and are likely to vary when these conditions are changed, a problem common to most, if not all, test methods. Experimental work is currently being conducted on mercury cells to permit the appropriate corrections to be made and also to test the application of the galvanostatic method, and its underlying theory, to different electrochemical systems.

In Situ Studies of the Passivation and Anodic Oxidation of Cobalt by Emission Mössbauer Spectroscopy

I. Theoretical Background, Experimental Methods, and Experimental Results for Borate Solution (*p*H 8.5)

G. W. Simmons,* Elsie Kellerman, and Henry Leidheiser, Jr.*

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

This paper is the first in a series of three that describe the application of emission Mössbauer spectroscopy to the *in situ* study of the cathodic and anodic behavior of cobalt. A brief review of the emission technique is given, along with a review of the chemical effects and Auger "after effects" that are associated with this experimental method. The surface sensitivity required to study thin anodic films was obtained by electrodepositing from 20 to 200Å thick Co^{57} active layers on cobalt surfaces. Emission Mössbauer spectra from Fe^{57} daughter ("probe") atoms were obtained during polarization (*vs.* SCE) of specimens in buffered borate, *p*H 8.5. The specimens were free of surface oxide during cathodic polarization at −1100 mV. The spectra of specimens polarized at low passivating potentials, −100 mV, indicated the presence of both +2 and +3 charges. The +3 oxidation state of the Fe^{57} probe in the anodic film formed at this potential may arise from Auger after effects or chemical effects rather than from +3 states of the parent Co^{57}. At higher passivating potentials +200 and +500 mV only the +3 oxidation state was observed. The existence of +2 oxidation state cannot be ruled out, however, because of the possibility for stabilization of defect charge states. Evidence for the +4 oxidation state in addition to +3 was found for specimens polarized at potentials in the transpassive range, +800 mV.

Since the first reported observation of passivity, a considerable amount of research on this subject has been published. Yet because of the complexity of the phenomenon and the limited experimental techniques available for *in situ* studies of surface films, there remains considerable uncertainty about many aspects of passivation. Passivity has been the subject of three international conferences co-sponsored by The Electrochemical Society and more recently it was the subject of a joint Japanese-American meeting in Hawaii in March 1975 (1). This latter conference resulted in three consensus summaries; and one of the principal objectives for future research was stated as follows: "It is hoped in the future to establish theoretical models to explain the cause of passivity and film-growth and dissolution kinetics in more detail and to *develop critical experimental techniques which enable us to clarify the structure and composition of passive films.*" This paper describes an experimental technique which has led to the determination of the structure and composition of passive films on cobalt.

The electrochemical methods for studying passivity include galvanostatic and potentiostatic measurements which have been supplemented in some cases by potentiodynamic studies, a-c impedance investigations, and coulometry. These methods have been useful in characterizing the anodic behavior of metals, but the electrochemical techniques have not provided unambiguous information about the chemical composition and structure of anodically produced surface films. The nonelectrochemical approaches used thus far have also been of limited value. Electron diffraction investigations require that the specimen be removed from its initial environment, and reasonable objections to the interpretation of results can be raised because of possible changes in composition of the specimen surface, such as dehydration, that may occur during the diffraction analysis. Although ellipsometry is a highly surface-sensitive technique and is applicable to *in situ* studies, the measured parameters for thin films, 10-50Å, lead only to information about the thickness. Mössbauer spectroscopy, on the other hand, offers the possibility of obtaining direct compositional and structural information about thin anodic films under *in situ* conditions. The major objective of our research has been to evaluate the emission Mössbauer spectroscopic technique for *in situ* determination of the chemical composition and structure of cobalt surfaces associated with the electrochemical behavior of this metal. Emission Mössbauer spectroscopic studies of the passivity of iron perhaps would have been more desirable than studies of cobalt because of the more extensive literature about the experimental and theoretical treatment of the passivation phenomena of iron. For reasons that are given later, the complications encountered in emission studies of iron surfaces are avoided in the cobalt system. Some aspects of this study, however, may also be helpful in understanding anodic behavior of the other ferrous metals iron and nickel. See Ref. (2) for studies of the passivation of iron by transmission Mössbauer spectroscopy.

The full report of our research has been divided into three parts. In the present paper, I, the experimental details are described, and theoretical considerations of

* Electrochemical Society Active Member.
Key words: passivity, Mössbauer spectroscopy, cobalt, anodic oxidation, Co^{57}, Fe^{57}.

emission Mössbauer spectroscopy are presented along with details of experimental results in buffered borate solution, pH 8.5. Reference spectra of the cobalt compounds that may be constituents of anodic films on cobalt, are necessary for the interpretation of spectra obtained from cobalt during anodic polarization. There is only a limited amount of literature on emission Mössbauer spectroscopy of cobalt oxides, hydroxides, and oxyhydroxides, and therefore part II describes the spectra obtained from these compounds. Part III interprets the emission spectra obtained from anodic films formed on cobalt under different polarization conditions, and the results are discussed in terms of the electrochemical behavior of cobalt.

Principles of Emission Mössbauer Spectroscopy Utilizing Co^{57}

The decay scheme of Co^{57} is shown in Fig. 1. The initial decay of Co^{57} by K-electron capture results in the formation of Fe^{57} with nuclear excited states which further decay to the ground state by γ-ray emission. The 14.4 keV γ-ray emitted from $I = 3/2 \rightarrow I = 1/2$ transition is used in Mössbauer spectroscopy. The isomer shifts, quadrupole splittings, and magnetic hyperfine splittings of the $I = 3/2$ and $I = 1/2$ nuclear states of Fe^{57} are determined by the electron environment characteristic of the host matrix. The emission spectrum of the Fe^{57} nuclei is obtained by resonance absorption of the emitted radiation with an absorber that is designed to have only a single transition. The values obtained for the hyperfine parameters yield information about the chemical composition and structure of the emitter.

Many electrochemical reactions are slow in comparison to the average lifetime of the nuclear excited state of Fe^{57} ($\sim 10^{-7}$ sec), and thus the application of emission Mössbauer spectroscopy is well suited to studies of cobalt. In other words, the time between the formation of the excited Fe^{57} nucleus and the emission of the γ-ray is so short that it is unlikely that the emission spectrum will contain any information about the chemical reactions of iron. The information derived from the spectra therefore depends principally on chemical changes in the parent Co^{57} atoms, although the γ-ray emission is actually from the Fe^{57} daughter atoms. Differences between the chemical potential of Co^{57} and substrates other than cobalt make the application of the Co^{57} doping technique impractical for studies of the oxidation behavior of other metals such as iron. For example, when the surface of iron is doped with Co^{57} and the specimen is oxidized at 300°C in air, the cobalt dopant remains in the elemental state as indicated by the Mössbauer emission spectrum. Presumably under these experimental conditions, the equilibrium for the reaction, $Fe_xO_y + Co \rightleftharpoons Co_mO_n + Fe$, lies to the left.

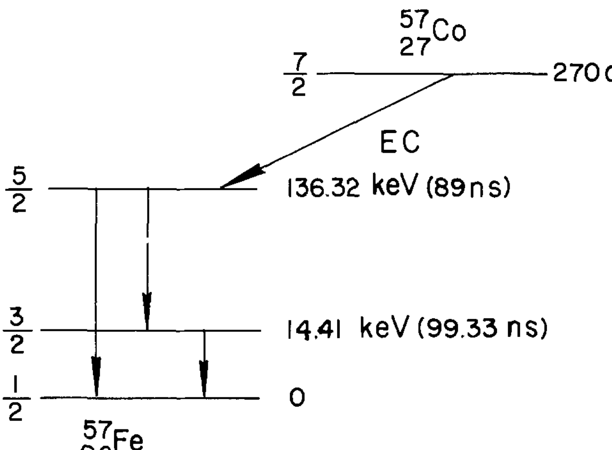

Fig. 1. Decay scheme of Co^{57} to Fe^{57}. Electron capture by the Co^{57} nucleus produces daughter Fe^{57} with nuclear excited states which decay to the ground state by γ-ray emission.

The surface sensitivity required for studying passivation and anodic oxidation phenomena is obtained by controlling the amount of Co^{57} deposited on the specimen surface. The surface sensitivity of the emission method has been demonstrated in studies of surface lattice dynamics (3) and in investigations of the magnetic properties of thin films (4, 5) in which surface sensitivities approaching submonolayer dimensions were obtained. The composition and structure of thin anodic films can, therefore, be elucidated from the emission Mössbauer spectra of Fe^{57} probe atoms that have been incorporated into the anodic films as Co^{57}.

In the interpretation of emission Mössbauer spectra, two important chemical effects must be considered. One is the chemical influence of the host lattice environment on the Fe^{57} impurity atom, and the other, termed "after effects" is the variety of chemical consequences produced by the electron capture decay of Co^{57} to Fe^{57}. Details of chemical effects and after effects in emission spectroscopy can be found in published reviews on this subject (6, 7). Therefore, only a brief discussion of the origin of the chemical effects and after effects is presented.

The after effects are a result of the deexcitation of the vacant iron K level created after capture of a K electron by the Co^{57} nucleus. Deexcitation takes place by competitive x-ray fluorescence and Auger emission processes. When the deexcitation takes place only by x-ray emission the hole in the K level moves out to the valence levels, and in the absence of chemical interactions with the matrix, the daughter Fe^{57} has the same charge state as the parent Co^{57}. There is a probability for aliovalent species to be formed because of the likelihood for deexcitation by a radiationless process with the emission of electrons (Auger effect) and further ionization of the Fe^{57} atoms. The hole in the K shell may be filled by an electron from the L shell, and instead of K_α x-ray emission, an electron may be ejected from the L shell. This process is termed a KLL Auger transition. The holes in the L levels are subsequently filled by electrons from the M levels with further emission of Auger electrons. This process is termed "Auger cascade" and can give rise to highly charged states on Fe^{57}. Pollak (8) has determined the probabilities for various charge states on Fe^{57} produced by the Auger cascade that follows electron capture decay of Co^{57}, and these results are given in Table I. After effects are not observed in metals because the time for charge equilibration of the high ionic states by the free conduction electrons is short compared to the lifetime of the Fe^{57} excited state ($\sim 10^{-7}$ sec). In insulators, on the other hand, the highly ionized states (defect charge states) may have a sufficiently long lifetime to alter profoundly the immediate chemical environment of the Fe^{57} atoms, and these after effects are observed in the emission spectrum. The observable effects depend strongly on the nature of the host lattice, and it has

[a] Two cases are considered: (a) cobalt initially in a 2+ charge state and (b) cobalt initially a neutral atom. Data taken from Ref. (8).

not been possible to predict *a priori* details of these effects. Furthermore, the mechanisms for producing the after effects in some cases are still poorly understood.

Radiolysis, size effects, and charge compensation have been proposed as mechanisms for the creation and/or stabilization of charge states in various types of compounds. An increasing tendency toward the stabilization of defect charge states with increasing degree of hydration in divalent cobalt salts has been attributed to the radiolysis of water molecules by the Auger electron ionization (9, 10). The oxidation of Fe^{+2} to Fe^{+3} in hydrated salts is suggested to be caused by the OH radicals produced during the radiolysis. The observation of Fe^{+3} lines in the transmission Mössbauer spectra of hydrated Fe^{+2} salts that have been subjected to ionizing radiation has been offered as supporting evidence for the radiolysis mechanism (11, 12).

Pollak (8) suggested that Fe^{+3} would be stabilized in divalent lattices whose metal ion is smaller than Fe^{+2}. Supporting evidence from data of Co^{57} doped metal fluorides with the rutile structure has been reported in which it was found that the smaller Fe^{+3} ion is preferentially stabilized in a lattice site smaller than that of Fe^{+3} in FeF_2 (13). The differences in ionic sizes are not considered as completely sufficient for stabilization of the Fe^{+3} charge. It is assumed that charge compensating defects, such as trapped electrons or ionic vacancies, are also necessary. These defects are assumed to be produced by the Auger electron emission process and by the resulting highly charged states.

The Fe^{+3}/Fe^{+2} ratio in the emission spectra of CoO has been found to be a sensitive function of the method of specimen preparation (14-18). The presence of preexisting charge compensating defects associated with the nonstoichiometry of the oxide is the generally accepted explanation for the stabilization of the Fe^{+3} charge state.

Cruset and Friedt (19) have proposed thermodynamic criteria for defect charge stabilization. The stabilization condition is given as

$$\Delta U \geqq U_{ip} - E_{exc}$$

where U_{ip} is the ionization potential of Fe^{+2} in the solid state and E_{exc} is the energy of the electronically excited state produced by the electron capture decay. ΔU is the electrostatic energy change associated with the substitution of Fe^{+2} by Fe^{+3} and is given by

$$\Delta U = [Z(Fe^{+3}) - Z(Fe^{+2})] \frac{e^2}{a} M$$

where M is the electrostatic potential at the Fe lattice site and a is the length of the unit cell. In general, therefore, the stability of the defect ionic species would be expected to increase with the macroscopic lattice energy of the host matrix. This correlation has been found in fact in a number of different chemical systems.

The charge state on the daughter iron atoms (ions) may be different from the parent cobalt for reasons that are completely independent of the Auger cascade. Specific charge states may be stabilized by chemical equilibration of the iron ions with the host matrix. Evidence for chemical or matrix effects is found for specimens in which 100% of the original Co^{+2} is observed in the emission spectrum as Fe^{+3}. Since there is a 5% probability for the empty K level to be filled by outer level electrons with emission of only x-rays (8), a few percent of Fe^{+2} should always be observed when only after effects mechanisms are operative. Complete valence change, Co^{+2} to Fe^{+3}, has been observed in emission spectra of Co^{57}-doped Co_3O_4, $CoRh_2O_4$, and $CoFe_2O_4$ (20). The fact that iron impurity in a trivalent charge state substitutes for divalent cobalt on the A sites in $CoRh_2O_4$ has been suggested as further evidence that the change Co^{+2} to Fe^{+3} may be determined by a chemical preference rather than by after effects. These results do not rule out any possible after effects, but do suggest that chemical stabilization must be considered when complete conversion of Co^{+2} to Fe^{+3} is observed in Mössbauer emission spectra. In addition to the charge compensating defects, ionic size, and crystalline energy considerations presented earlier, chemical stabilization mechanisms must also include crystal field effects and possible interactions such as red-ox reactions with surrounding cations.

From the narrowest point of view the after effects and chemical effects discussed above may be considered a limitation to the study of thin films by emission Mössbauer spectroscopic technique. As these phenomena become better understood, the complications with regard to interpretation of spectra become less serious, and in fact, the conditions for defect charge stabilization can be used for a more complete characterization of the chemical system under investigation. The studies of the passivation and anodic oxidation of cobalt were undertaken with a clear understanding of both the possible limitations and potential of the emission method for studying surfaces.

Experimental

The cathodic and anodic behavior of cobalt polarized in deaerated borate solution, pH 8.5, was chosen for study. The polarization curve for cobalt was determined potentiostatically, and the current at each potential (*vs.* saturated calomel electrode, SCE) was recorded after the system reached steady state. Emission Mössbauer spectra were obtained at specific applied cathodic and anodic potentials in order to characterize the surface chemical species present during polarization. The growth rate and stability of the surface films that formed during polarization were determined from measurements of anodic current and of specimen radioactivity as a function of time.

Specimens used in the emission studies were prepared by casting 10 × 10 × 0.5 mm samples of 99.7% cobalt into the center surface of a 3 cm diam, 0.5 cm thick epoxy mount with the face of one side of the cobalt specimen parallel to the surface of the mount. Electrical contact was provided by means of a copper wire approximately 6 cm in length that was spot welded to the opposite face before the cobalt specimen was placed in the cast. The entire length of this wire was coated with epoxy to prevent its contact with the plating solution or with the solution used during the polarization studies. The specimen surfaces were first mechanically polished and then electrochemically etched in 50% phosphoric acid at a current density of 200 mA/cm^2. The etching was done in the same cell in which depositions were made. Efforts were made to minimize the time the specimen was exposed to air during rinsing and solution changes. The deposition of Co^{57} onto the specimen surface was accomplished in a manner similar to that described by Dézsi and Molnár (21). To maximize the yield of Co^{57} deposition from the dilute solutions, the plating cell was designed to permit depositions from solution volumes of 5-10 ml. The solution used for the depositions was 2.5g/100 ml ammonium citrate with 2.5g/100 ml hydrazine hydrate adjusted to pH 10 with ammonium hydroxide. For current densities of 5-10 mA/cm^2 and plating times on the order of 1 hr, the plating efficiency has been reported to be on the order of 30% (21). The thickness of the Co^{57} active layer was controlled by adding specific amounts of natural cobalt ($CoCl_2$) along with carrier-free Co^{57} (in HCl) to the plating solution. Relatively thin deposits (20-50Å) were required to obtain sufficient sensitivity to study changes in the cobalt surface at low passivating potentials. For anodic potentials in the range from the middle of the passive region to beyond the transpassive region, thicker deposits (50-200Å) were used. The actual thickness or uniformity of the active layer was not determined. An approximate range of deposit thickness was estimated from the plating efficiency and the cobalt content of the plating solution.

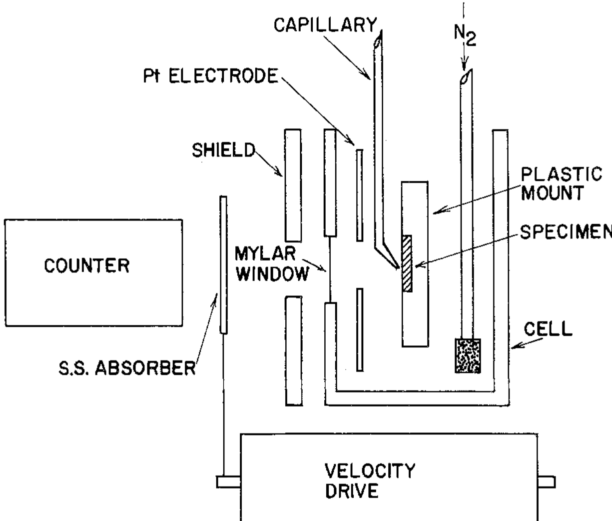

Fig. 2. Schematic of experimental arrangement used to obtain emission Mössbauer spectra of Fe^{57} cobalt during *in situ* polarization.

The experimental arrangement used for obtaining emission Mössbauer spectra of cobalt during polarization is shown schematically in Fig. 2. The cell was constructed from Plexiglas and was designed to minimize the amount of solution in the path of the emitted γ-rays. The distance between the specimen surface and a 0.04 mm thick Mylar window was approximately 3-4 mm. A SCE was separated from the polarization cell, and electrical continuity of the standard electrode with the cell was established via a capillary. Nitrogen gas was used to deaerate the solutions. A platinum counter-electrode was used; and an aluminum-brass-lead shield was mounted between the cell and the radiation detector in a manner that minimized the count rate from radiation originating from deposits of Co^{57} that formed on the platinum electrode during polarization of the specimen. Although Co^{57} ions that enter the solution during anodic polarization contribute to the background count rate, the Fe^{57} ions in solution produce no recoilless γ-rays and therefore do not contribute to the Mössbauer spectra. The specimen (emitter) was kept stationary, and the Mössbauer spectra were generated in the usual manner by measuring count rate as a function of velocity of a Fe^{57}-enriched stainless steel absorber. Positive velocities correspond to the absorber moving toward the specimen.

At all polarization potentials used in this study, with the exception of low passivating potentials, the corrosion rate was sufficiently slow that the surface active region was not lost during the time required to obtain the Mössbauer spectra. Additional experimental procedures were developed to make emission Mössbauer studies possible at low passivating potentials. A thin (20-50Å) Co^{57} active surface region was required to resolve the spectrum of the thin passive film formed at the low passivating potentials. Since the corrosion rate at these potentials was relatively high, the radioactive surface was stabilized by quenching the specimen and solution to liquid nitrogen temperature, and interrupting the applied potential after the passive film had formed. The specimen used in this case was prepared by epoxy coating a $3.5 \times 9 \times 0.5$ mm sample of cobalt, except for a 1 cm² area on which the Co^{57} layer (20-50Å) was deposited. One end of this specimen was attached to a brass block just outside of the electrolytic cell. This block was attached to a Dewar and could be readily maintained at liquid nitrogen temperature. The other end of the specimen was mounted in the cell in the manner already described (see Fig. 2). When the passive currents were reached and the count rate began to decrease, the Dewar was filled with liquid nitrogen. After the electrolyte had frozen, the applied potential was removed. The spectrum was then obtained while the specimen was maintained near liquid nitrogen temperature. It was assumed that the quenching procedure and potential interruption did not produce significant changes in the passivated surface. A limitation of this procedure, not serious in our case, is the fact that Co^{57} ions that enter the solution and undergo hydrolysis during passivation may contribute to the emission spectrum since some fraction of the γ-rays emitted from the daughter Fe^{57} ions in the frozen solution are recoilless. The quenching procedure was only required for experiments conducted at low passivating potentials. Emission spectra were obtained at all other potentials at room temperature while the potential was maintained.

Results and Discussion

Polarization of cobalt in the buffered borate solution produced a classical potential *vs.* current dependence as shown in Fig. 3. An active-to-passive transition occurs between −500 and −300 mV and cobalt remains passive at higher anodic potentials up to +500 mV. Above +500 mV, thick anodic film formation and oxygen evolution occurred commensurate with an increase in anodic current. Five specific polarization potentials were chosen for study which represented the different characteristic regions of the polarization curve shown in Fig. 3. These potentials were as follows: (*a*) cathodic potential of −1100 mV, (*b*) low passivating potential at −100 mV which is about 200 mV above the onset of passivity, (*c*) potential of +200 mV near the center of the passive region, (*d*) potential of +500 mV near the onset of transpassive behavior, and (*e*) potential of +800 mV which is in the transpassive region. Several experiments were conducted for each of these potentials. In some preparations of the surface active layer, it was found that a residual "oxide" layer could not be removed by cathodic reduction, and in other cases the surface sensitivity was not sufficient to detect the surface film that formed during anodic polarization. For the experiments in which cathodic polarization produced a "clean" surface and in which changes in the spectra were observed during anodic polarization, the results for each polarization potential were found to be reproducible. In the following sections typical results are presented for each of the polarization potentials.

Cathodic polarization, −1100 mV.—All of the specimens were polarized cathodically prior to the application of the anodic potentials. The emission Mössbauer

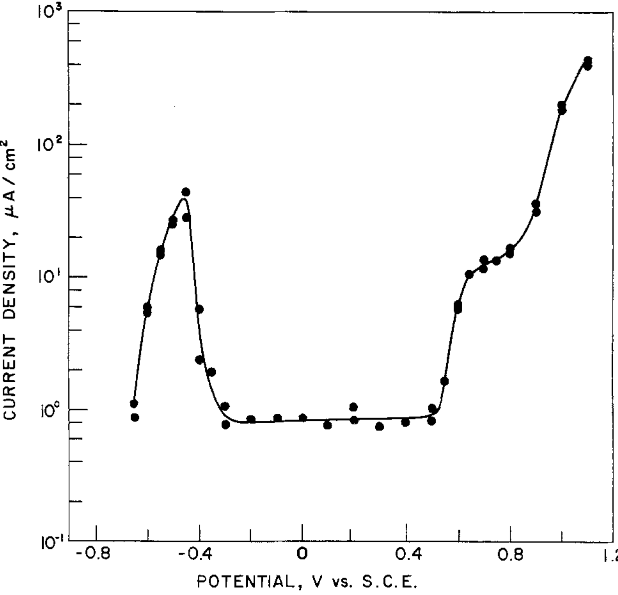

Fig. 3. Polarization curve of cobalt in buffered borate solution, *p*H 8.5. Potential is with reference to SCE.

spectra obtained during cathodic treatment were used to monitor the reduction of oxide or corrosion films that had formed subsequent to deposition of the Co^{57} layer or formed during previous anodic polarization of the specimen. Typical spectra obtained before and during cathodic polarization at −1100 mV, current density 20 mA/cm^2, are shown in Fig. 4 and 5 for two specimens with different active layer thickness. The results obtained from these two specimens are discussed separately.

The relatively intense lines at the center of the spectrum shown in Fig. 4a for a 100-200Å specimen is indicative of a corrosion film that was present after preparation of the active Co^{57} layer. Cathodic polarization of the specimen gave rise to the spectrum presented in Fig. 4b which shows only the six lines expected from the magnetic hyperfine splitting of Fe^{57} in metallic cobalt. This result suggests that the corrosion film, which formed subsequent to the deposition of the active layer, was readily reduced by the cathodic treatment. Values of the hyperfine interactions measured for the 100-200Å film during cathodic polarization are summarized in Table II. Also summarized in Table II for comparison are results obtained for a bulk specimen which was annealed below the hexagonal to cubic transition temperature (400°-500°C) and for a bulk specimen annealed above this temperature. The major differences in the hyperfine interactions of Fe^{57} nuclei in the bulk specimens which were annealed at 400° and 800°C is in the internal magnetic field. The difference of approximately 10 koe is attributed to the possibility that the 400°C specimen is hexagonal and that the 800°C specimen is mostly cubic. This result is consistent with studies in which the cubic phase was reported to be stable in fine grain specimens at room temperature (22, 23) after quenching from temperatures above 500°C. The hyperfine parameters in Table II indicate that the 100-200Å film is physically different from either of the bulk specimens. Impurities and de-

fects in the film would contribute to lower values of the internal magnetic field and to the difference in isomer shift as compared with the bulk (24, 25). The measured parameters for the film may be a manifestation of the thickness of the specimen, of the fact that hydrogen may be present in the film during cathodic treatment, and of defects and impurities in the film. Further studies are required to ascertain the factors that determined the hyperfine interactions that were measured for the 100-200Å films during cathodic polarization.

As indicated in Fig. 4b, the relative intensities of the magnetic hyperfine lines of the thin cobalt surface layers were found to vary from the 3:2:1:1:2:3 expected from a bulk polycrystalline specimen. The relative intensities of the six line magnetic hyperfine spectra of Fe^{57} is a function of the angle, θ, between the direction of γ-ray propagation and the principal axis of the magnetic field and are given by $3:x:1:1:x:3$ where $x = 4 \sin^2\theta/(1 + \cos^2\theta)$ (26). Ordinarily the angular dependency becomes important in studies of single crystals in which θ is well defined. For thin polycrystalline ferromagnetic films, however, the magnetization vector and hence the axis of the internal magnetic field is parallel to the film surface. The angle θ approaches 90° as the film thickness decreases, and the ratios of the peak intensities tend toward values of 3:4:1:1:4:3.

The spectrum shown in Fig. 5a was taken during anodic polarization of a 20-50Å cobalt film; and the relatively intense line(s) at the center of the spectrum originates from the anodic film. Subsequent cathodic polarization of this specimen effectively reduced the anodic film as evidenced by the reduction in the intensity of the center line(s) as shown in Fig. 5b. The spectra of the (20-50Å) cobalt surface films were considerably different from the spectra of the (100-200Å) cobalt surface films; compare spectrum of (20-50Å) film in Fig. 4b with spectrum of (100-200Å) film shown in Fig. 5b. The spectrum of the (20-50Å) specimen, Fig. 5b, indicates an apparent relaxation of the effective internal magnetic field of the Fe^{57} nuclei (26-28). The small peak at the center of the spectrum in Fig. 5b is probably the result of relaxation of the magnetic field, but it cannot be ruled out that this peak may originate from remnants of the corrosion film that was not reduced by the cathodic polarization. Relaxation of the hyperfine field in the thin surface film, in this case, is similar to that reported in Mössbauer spectroscopic studies of the magnetic properties of thin films (4, 5, 29). The relaxation spectra in the referenced studies may have been, in part, owing to superparamagnetism in ferromagnetic particles formed by growth of isolated "islands" of the metal on nonmagnetic substrates. Superparamagnetism is less likely to account for the apparent relaxation in the present studies, because magnetic isolation of the deposit probably did not occur on the magnetic cobalt substrate, even for a case of nonuniform deposition. The broadening of the lines shown in Fig. 5b may, therefore, be caused by a reduction of the magnetic moment on Fe^{57} nuclei in the surface of the film and/or by magnetic dilution of the Fe^{57} daughter atoms. Shinjo *et al.* (30) concluded in their

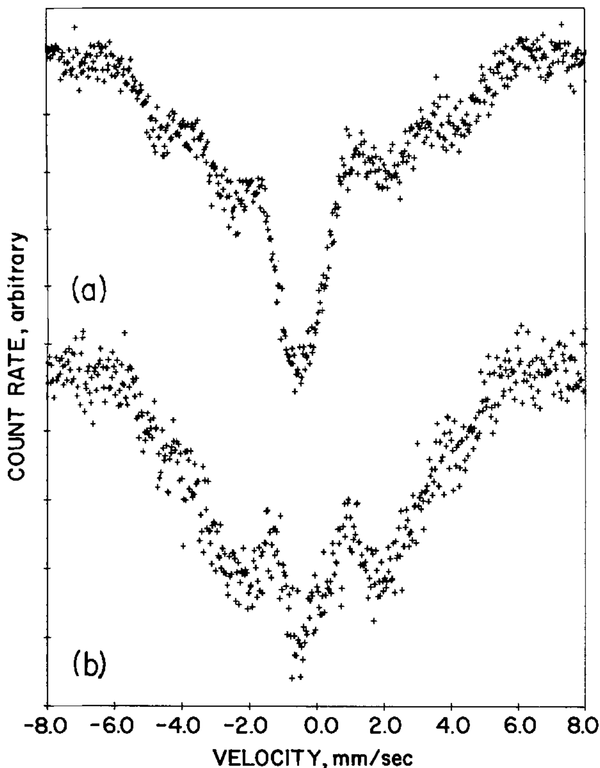

Fig. 5. (a) Emission spectrum of Fe^{57} in cobalt with anodic film present on surface. (b) Emission spectrum of same specimen taken during cathodic polarization at —1100 mV. (Co^{57} active layer approximately 20-50Å.) Spectra taken at room temperature.

emission Mössbauer studies of monolayer Co^{57} deposits on cobalt substrates that the magnetic moment at the surface was not significantly different from the bulk value. They proposed that the line broadened spectra can be interpreted on the basis of a distribution of magnetic fields owing to the presence of vacancies and impurities such as stable Fe^{57}. Since specimens with thin surface active layers were deposited from very dilute solutions, the relative amounts of impurities that codeposit with the cobalt is much higher than that encountered in the deposition of thicker films from more concentrated solutions. The concentration of defects and missing nearest neighbor atoms is also expected to be high in a thin film with high surface to volume ratio. It was not possible in the present study to determine whether relaxation effects or magnetic dilution effects are the predominate cause of the line broadening in the thin (30-50Å) specimens.

Anodic polarization, —100 mV.—The potential of —100 mV is just above the onset of passivity. The relatively high corrosion rate of cobalt at this potential did not permit *in situ* emission Mössbauer spectra to be obtained at room temperature. The specimen and solution were quenched to low temperature after the formation of the passive film as described in the experimental section. Since it was anticipated that the anodic film would be relatively thin at this potential, a specimen with Co^{57} surface layer on the order of 30-50Å thick was used. The specimen was cathodically reduced before application of the anodic potential. Figure 6 shows the changes in current and radioactivity of the specimen as a function of time after the —100 mV potential was applied; and the times at which the system was quenched and the potential interrupted are also indicated. Anodic film formation and anodic dissolution account for the integrated current, which corresponds to the conversion of a surface region that is 2-3 times the estimated thickness of the Co^{57} active layer. Only approximately 30% of the radioactivity of the specimen, however, was lost during the anodic treatment.

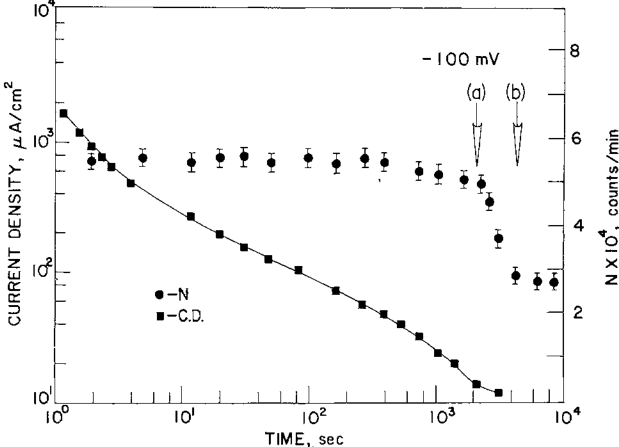

Fig. 6. Anodic current and count rate vs. time for specimen polarized at —100 mV, (a) quenching initiated and (b) applied potential interrupted.

These facts suggest that the anodic film formation and dissolution did not take place uniformly over the specimen surface.

The emission Mössbauer spectrum of the specimen after polarization at —100 mV is shown in Fig. 7. Resolution of the spectrum of the anodic film was enhanced by removing the background contribution of the unreacted metal. This was accomplished by subtracting an appropriately scaled spectrum of the same specimen taken during the cathodic polarization. The results of this subtraction are shown in Fig. 7b. The simplest combination of Lorenzian curves that gave a satisfactory computer fit to the spectrum is also shown in Fig. 7b. The spectrum apparently consists of two sets of quadrupole doublets, and the values for the isomer shift and quadrupole splitting of these resonant lines are

[b] Measured at liquid nitrogen temperature.
[c] Values constrained during computer fitting.

given in Table III. The value of −1.31 mm/sec for the isomer shift and the relatively large quadrupole splitting of 2.83 mm/sec for one set of lines correspond to Fe^{57} (+2) in the anodic film. An isomer shift of −0.59 mm/sec and a relatively small quadrupole splitting of 0.78 mm/sec for the other set of lines correspond to Fe^{57} (+3). Because of the possibility of Auger after effects and chemical effects which were discussed earlier, the Fe^{57} (+3) daughter atoms may not have originally existed as Co^{57} (+3) parent atoms. It is possible therefore that the passive film formed at low passive potentials consists essentially of a divalent oxide or hydroxide.

Anodic polarization, +200 and +500 mV.—The experimental results obtained at +200 and +500 mV were found to be similar, and these results are, therefore, discussed together. Current and radioactivity measured as a function of time for specimens anodized at +200 and +500 mV are shown in Fig. 8 and 9, respectively. The thickness of the Co^{57} layer on these specimens was on the order of 100-200Å. The logarithmic time dependence of the initial changes in anodic current exhibited by cobalt at these potentials has been observed in other systems (31, 32). This current *vs.* time behavior has been attributed to the growth of the anodic film. Deviations from the logarithmic dependence at the longer times is caused by anodic dissolution. The rate of anodic dissolution was sufficiently slow at +200 and +500 mV, as indicated by the small changes in radioactivity, that emission Mössbauer spectra could be readily obtained *in situ* at room temperature without recourse to freezing. The corrosion rate after the surface was passivated was higher at the +200 mV potential than at the +500 mV potential as evidenced by the differences in the deviation of the current from logarithmic behavior and by the differences in the rate of decrease of radioactivity.

The emission Mössbauer spectra taken at +200 and +500 mV are shown in Fig. 10 and 11, respectively. The spectra taken at these two potentials are shown before

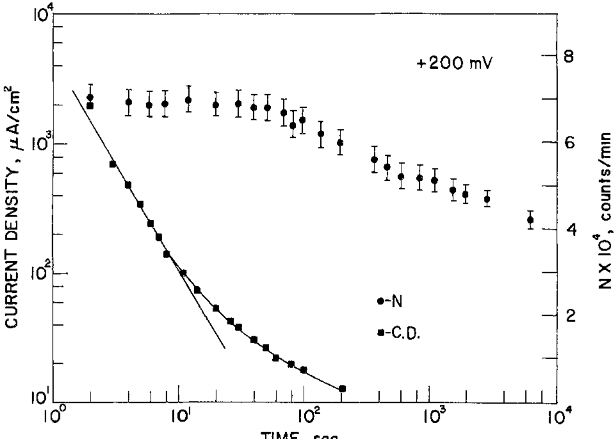

Fig. 8. Anodic current and count rate vs. time for specimen polarized at +200 mV.

and after subtraction of the unreacted metal background. Two Lorenzian lines of equal intensity gave a satisfactory computer fit to the spectra obtained from both specimens. The isomer shift and quadrupole splitting associated with these lines for each specimen are listed in Table III and were essentially identical for each case. The values of −0.54 and −0.55 mm/sec for the isomer shifts and the small quadrupole splittings of 0.81 and 0.94 mm/sec are indicative of Fe^{57} (+3). The composition of the passive films at +200 and +500 mV is apparently different from that of the film formed at −100 mV, since no evidence of Fe^{57} (+2) was found at these higher anodic potentials. The possible presence of Co^{+2} in the anodic film formed at the higher potentials cannot be ruled out, however, since the daughter Fe^{57} (+2) ions could have been converted to Fe^{57} (+3) by Auger after effects or chemical effects.

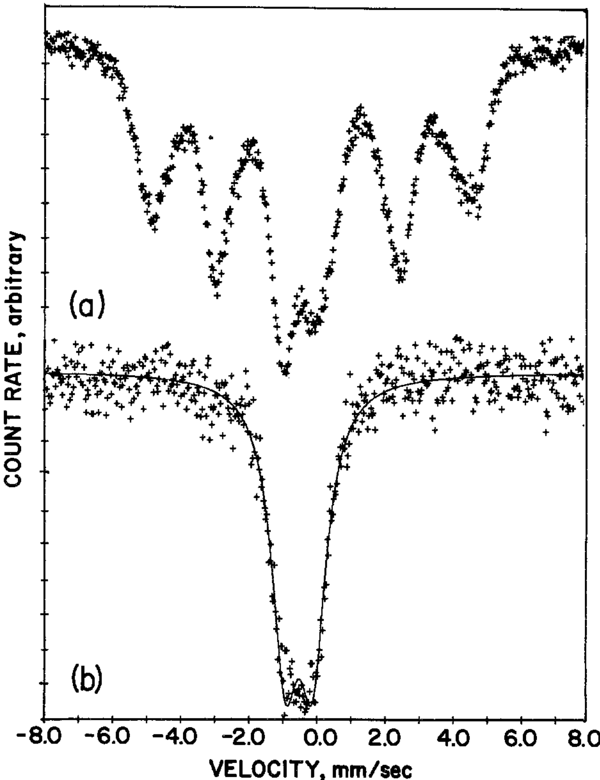

Fig. 11. Emission spectrum of Fe^{57} in cobalt anodically polarized at +500 mV, (a) initial spectrum and (b) spectrum after subtraction of contribution from unreacted metal. Spectrum taken at room temperature.

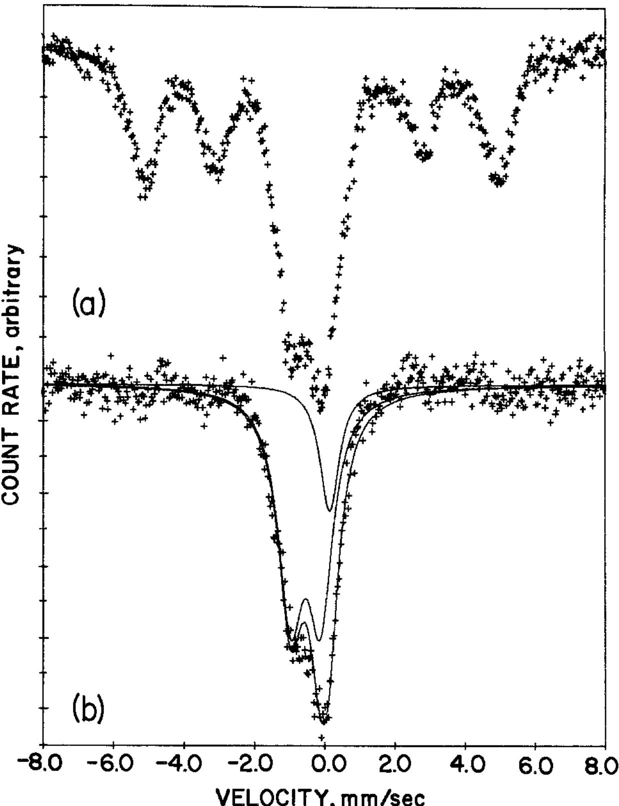

Fig. 12. Emission spectrum of Fe^{57} in cobalt anodically polarized at +800 mV, (a) initial spectrum and (b) spectrum after subtraction of contribution from unreacted metal. Spectrum taken at room temperature.

Anodic polarization, +800 mV.—The region of the polarization curve at which thick anodic films are formed and oxygen evolution occurs is referred to as transpassive. The potential of +800 mV is approximately 300 mV above the onset of this transpassive region. An emission Mössbauer spectrum obtained at this potential is shown in Fig. 12 before and after the subtraction of the unreacted metal contribution. The spectrum of the anodic film formed at +800 mV is similar to the spectra for the surface anodically treated at +200 and +500 mV. The asymmetry of the spectrum suggests, however, that anodic polarization at transpassive potentials produces a characteristic change in the anodic film. Apparently the major component of the film, in this case, is the same as that formed at the passive potentials, but part of the surface has been converted to a higher oxidation state. A satisfactory computer fit to the spectrum was obtained with a set of quadrupole split lines, similar to those found for the passive film, and an additional line with an isomer shift of 0.14 mm/sec. The hyperfine parameters based on the computer analysis are given in Table III. The isomer shift of 0.14 mm/sec for the resonance line that is characteristic of anodic polarization at +800 mV indicates the presence of Fe^{57} (+4) in the surface of the anodic film. In the computer fitting, the hyperfine parameters for the major component of the spectrum of the transpassive film were assumed to be identical with parameters obtained from the passive films formed at +200 and +500 mV.

Summary and Conclusions

Emission Mössbauer spectroscopy technique was successfully demonstrated to be an effective method for *in situ* studies of changes in cobalt surfaces as a function of polarization. Despite the possible ambiguities introduced by effects associated with the emission technique, characteristic spectra were found for cobalt surfaces at specific applied potentials. These results are summarized as follows: (*a*) The cobalt was shown to be essentially free of a corrosion film during cathodic polarization (−1100 mV). (*b*) Resonance lines from both +2 and +3 oxidation states were found in the emission Mössbauer spectra of anodic films formed at low passivating potentials (−100 mV). (*c*) At potentials in the passive region of the polarization curve (+200 and +500 mV) the spectra indicated that the passive film contained primarily +3 oxidation state. (*d*) The anodic film formed at transpassive potentials (+800 mV) was found to consist of +3 and +4 oxidation states, and the +3 component of this film was shown to be likely the same as that formed at the passive potentials.

Auger after effects and chemical effects may give rise to a charge state on the Fe^{57} daughter (probe) that is different than the original charge on the parent Co^{57}. Further interpretation of the spectra obtained in this study, however, is possible with reference emission spectra for the oxides, hydroxides, and oxyhydroxides of cobalt. These reference spectra have been obtained and are described in paper II. Based on the interpretation of the spectra obtained during the anodic polarization of cobalt, the composition and structure of the anodic films are presented in paper III in conjunction with a description of the electrochemical behavior of cobalt.

Structure of Electroplated Hard Gold Observed by Transmission Electron Microscopy

Y. Okinaka* and S. Nakahara**

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Transmission electron micrographs of gold films plated in baths containing cobalt or nickel as the hardening agent showed the presence of uniformly distributed nonmetallic objects with diameters ranging from 20 to 70Å. These objects are believed to represent single molecules, and their agglomerates, of the so-called "polymer" which has been isolated by several investigators in the form of a transparent film upon dissolution of gold deposits in aqua regia. Micrographs of gold films plated in room temperature baths containing no hardening agents revealed the presence of much larger nonmetallic objects (up to 150Å), which appeared to be gas bubbles, in addition to the features attributable to polymer molecules. Based on a comparison of the polymer content, estimated from the analysis of electron micrographs, with the total carbon content, it is suggested that the polymer is not the only source of carbon contamination in electroplated hard gold films. Possible effects of the codeposition of polymer on grain size are also briefly discussed.

Hard gold deposits formed in acid cyanide baths containing a cobalt or nickel salt as the hardening-brightening agent are known to contain up to 1% carbon in addition to nitrogen, hydrogen, oxygen, potassium, and cobalt, or nickel (1-7). Munier (1) was the first to isolate transparent films, which were presumed to be an organic polymer, upon dissolution of gold deposits in aqua regia. On the basis of this result, it was suggested that the "polymer" is present in the deposits in the form of discrete layers. Holt and Stanyer (2) made a study using $KC^{14}N$ of the dependence of β-emission count rate on deposit thickness, and concluded that the carbon is distributed uniformly across the thickness rather than in the form of layers. They speculated that the carbon-containing species are situated mainly at grain boundaries. On the other hand, Antler (6) made a scanning electron microscope study of fracture surfaces of hard gold deposits, and suggested that the polymer is occluded in discrete pockets (<1000Å) in the deposits. As far as the chemical identity of the carbon-containing material is concerned, no agreement exists among investigators as to whether the carbon is de-

posited as a cyanide complex of codepositing metals (3, 7, 8), a cyanide of gold and/or potassium (7, 9), or an organic polymer (1, 6, 8).

The present study was prompted by the consideration that if the carbon-containing species is indeed present in the deposit in the form of an organic polymer, it may be directly observable by transmission electron microscopy (TEM) with the through-focus imaging technique, which is known to be a powerful method for observing nonmetallic inclusions in metal matrices (10-12).

Experimental

Plating.—Cobalt-hardened gold films were plated from citrate-based proprietary as well as nonproprietary baths. The proprietary bath used was purchased from Sel-Rex Corporation (Autronex CI), whereas the nonproprietary bath contained 8.2g Au/liter as $KAu(CN)_2$, 110 g/liter citric acid, 50 g/liter KOH, and 0.1g Co/liter as $CoSO_4$. Both baths were operated fresh at 10 mA/cm^2 at room temperature. The pH was adjusted to 4.0. Since the two baths yielded essentially the same electron microscopic information and more detailed analysis was made for the deposit from the proprietary bath, only the results obtained with the latter are presented. Nickel-hardened gold films were plated from Sel-Rex Corporation's Autronex N bath, which was also citrate-based and operated under the same experimental conditions as for the cobalt-containing baths. The cobalt- and nickel-containing baths will be called Co-bath and Ni-bath, respectively. Hard gold films from baths containing no metallic additives were prepared by J. J. Chick using the following two different baths: a citrate bath with pH 4.8 containing 40 g/liter $KAu(CN)_2$ and 100 g/liter dibasic ammonium citrate, and a phosphate bath with pH 4.5 containing 40 g/liter $KAu(CN)_2$ and 100 g/liter KH_2PO_4. These baths (hereafter called "additive-free baths") were operated at 15.5 mA/cm^2 and 25°C. All films were deposited on copper substrates prepared by cold-rolling OFHC material and annealing at 800°C for 2 hr in a hydrogen furnace. The substrate prepared in this manner consisted of very large grains and was suitable for observing epitaxy and grain refining phenomena involved in the process of deposit growth. The annealed copper substrate was etched in 1:2 HNO_3 before plating.

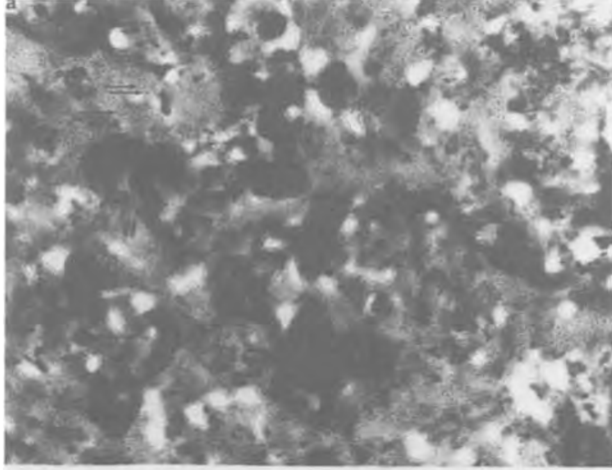
Specimen preparation.—Specimens were prepared from deposits ranging in thickness from 0.025 to 50 μm. Thin deposits were stripped off the copper substrate in a mixture of CrO_3 and H_2SO_4 and collected on a microscope grid for direct observation. Thick deposits were electropolished using the conventional window or jet-polishing technique after stripping off the substrate. A cyanide-containing polishing solution described by Silcox and Hirsch (13) was used initially, but results were not satisfactory. Subsequently better results were obtained with a mixture of 25 ml ethyl alcohol, 25 ml glycerin, and 50 ml concentrated HCl (14).

Transmission electron microscopy.—TEM micrographs were taken with a JEM-200 electron microscope operated at 200 kV. The conventional imaging technique based on diffraction contrast is known to be unsuitable for observing organic or gaseous inclusions especially when they do not exert elastic strain and/or when their size is small (11). On the other hand, the technique known as through-focus imaging allows observation of such inclusions in metal matrices under defocused conditions. The images obtained by this technique are due to phase contrast arising from a difference in mean inner potential between the included material and metal matrix. Such inclusions are therefore generally called "phase objects" (10).

Results and Discussion

Deposits from Co- and Ni-baths.—TEM examinations of gold deposits from the Co-bath were made with several samples of different thicknesses. The two micrographs in Fig. 1 were obtained with a nominally 500Å thick film in over-focused (a) and under-focused (b) conditions. The plating time used was only 10 sec, and no polishing was required. It is seen that numerous dark, circular features surrounded by white rings in Fig. 1(a) reverse their contrast when focusing conditions are reversed. This is characteristic of phase objects. Large, irregularly shaped white features with fringes (Fresnel fringes) in both micrographs are holes in the specimen. Large, black regions represent thick areas of the specimen through which electrons did not penetrate. Figure 2 is a stereo pair corresponding to a selected area of Fig. 1(a). It is seen that the phase objects are distributed uniformly throughout the thickness of the specimens. Several specimens prepared from thicker films (up to 25 μm) by electropolishing both sides showed images with essentially identical size and spatial distributions of phase objects. Deposits formed in the Ni-bath also yielded micrographs which are qualitatively similar to those in Fig. 1 and 2.

Figure 3 shows the size distribution of the phase objects in the above two deposits. A total of 100 measurements were made from each deposit. The data shown for the deposit from the Co-bath were obtained from Fig. 1a (thin deposit), while a specimen prepared from a 25 μm thick deposit gave an essentially identical distribution curve. The deposit



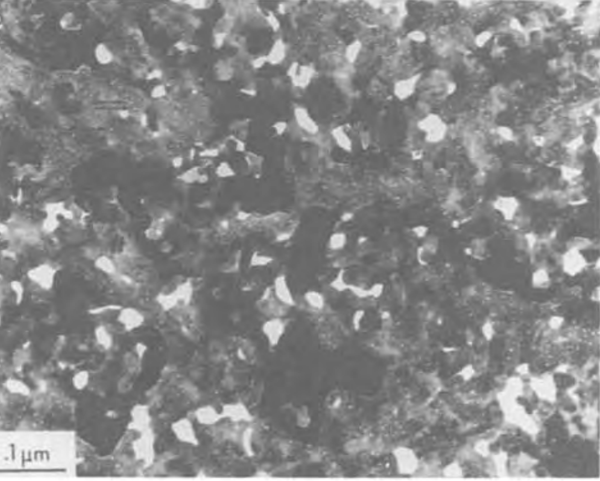


Fig. 1. TEM micrographs of 500Å thick cobalt-hardened gold deposoit. (a) Over-focused, $\Delta f = +3.9$ μm; (b) under-focused, $\Delta f = -3.9$ μm.

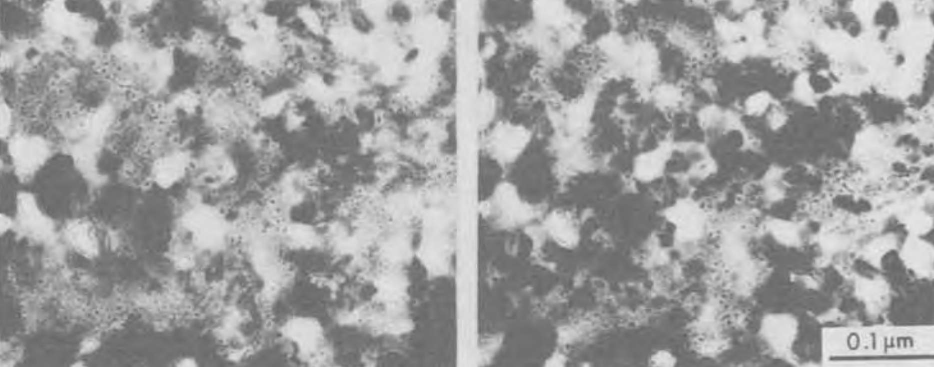

Fig. 2. Stereo pair showing spatial distribution of phase objects in deposit from Co-bath.

from the Ni-bath used to obtain the size distribution data was about 5000Å thick before polishing. It is noteworthy that the two distribution curves were practically identical; about 80% of the objects measured 25-35Å in diameter, and a small distinct peak was present at 50Å.[1] The fact that the majority of objects possess nearly the same size suggests that these objects may be the molecules of polymer that have been postulated to be present in hard gold deposits, rather than voids or gas bubbles. The objects giving the peak at 50Å may simply be agglomerates of the single polymer molecules. It is also possible that more than one kind of phase objects is involved, but this question cannot be resolved without carrying out more detailed studies. It is of interest to note in passing that deposits obtained with a proprietary high-speed hard gold plating bath yielded a distribution curve with only one sharp peak at 25Å. This bath was also citrate-based and contained a cobalt salt as the hardener and about 32g Au/liter in the form of $KAu(CN)_2$. It was operated at 150 mA/cm^2 at 75°C with vigorous agitation.

Sanwald (15) described his finding of nonmetallic inclusions with diameters ranging from 20 to 200Å in electrodeposited gold. His study indicates that they were gas-filled voids, but no information is given in his paper concerning the plating bath and conditions used. More recently, Willcox and Cady (16) reported that 0.4% nickel-hardened, electroplated gold contains gas-filled voids with a diameter of approximately 50Å. They gave a void density value of 10^{17}/cm^3 and a volume density of 0.6%, which are close to what we found for the polymer molecules in our deposits (see Table I). Based on the fact that the deposition of hard gold is a low current efficiency process and a significant quantity of hydrogen gas evolves during the deposition, they assumed that the "voids" are filled with hydrogen. Willcox (17) states that no evidence was found of the existence of carbon or carbon-containing material in the gold deposits that he studied. We also observed features which obviously looked like gas bubbles or gas-filled voids in some gold deposits, but the size and shape of these bubbles were clearly more random and nonuniform than those of the objects which we attribute to polymer molecules in this paper. The bubbles were found in the deposits from additive-free baths described in the next section as well as in some deposits formed in extensively used, citrate-based, cobalt-containing baths. We also reported recently on electron micrographs of electroless copper deposits containing numerous gas bubbles ranging from 20 to 300Å in diameter (18). These bubbles also had a shape and size distribution distinctly different from that of the polymer molecules.

In regard to the uniformity of spatial distribution of the polymer molecules, a question can be raised as to whether the molecules are situated at grain boundaries or within the grains, or both. Because of the small grain size (which is discussed in a subsequent section), the micrographs did not provide information concerning exact location of the molecules with respect to single grains.

[1] The true size of phase objects is generally different from the image size. With overfocused conditions, this difference is relatively small; for example, when $\Delta f = +3.9$ μm (the amount of overfocus used for the size distribution measurement) and the image size <80Å, the image size is approximately equal to the true object size (12).

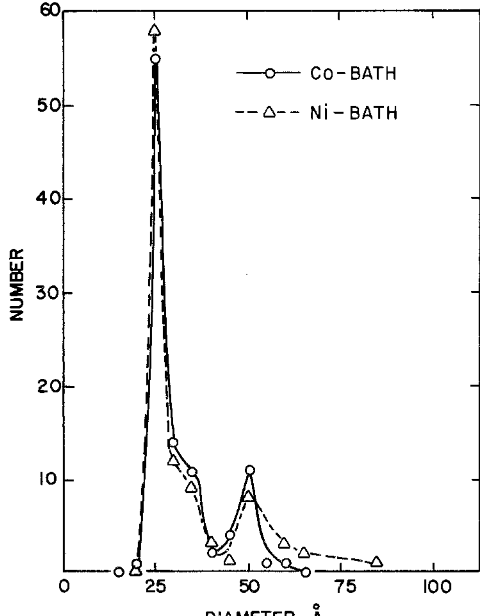

Fig. 3. Size distribution of phase objects in deposits from Co- and Ni-baths.

Deposits from additive-free baths.—Munier (1) found that carbon-containing species codeposit even from baths containing no hardening agents, if they are operated at low current-efficiency conditions, *i.e.* at room temperature. Reinheimer (9) recently made a detailed investigation of carbon codeposition in such additive-free systems. Their results show that gold deposits formed in these baths contain less carbon

Table I. Comparison of polymer content, carbon content, and grain size of deposits from different paths

Bath	Population density (cm^{-3})	Volume density (%)	Calculated** maximum carbon content (%)	Grain size (A)
Co-bath	3×10^{17}	0.59	0.07	225-275
Ni-bath	5×10^{17}	0.98	0.11	100-250
NH_4-citrate (no additive)	1×10^{17}*	0.21	0.02	250-750
K-phosphate (no additive)	1×10^{17}*	0.25	0.03	250-750

* Phase objects greater than 75A were not included in the count.
** See text for definition.

(up to ~0.1%) than cobalt- or nickel-hardened deposits. This was reconfirmed more recently by Raub, Knödler, and Lendvay (7).

The electron micrograph shown in Fig. 4 was obtained in an overfocused condition with a film plated in the additive-free citrate-buffered bath at 25°C. It is seen that this film contained phase objects with widely varying sizes. The size distribution is shown by the broken line in Fig. 5. The appearance of the large and small peaks at 25 and 50Å is strikingly similar to that found with the deposits from the Co- and Ni-baths (Fig. 3). This fact, with the broad distribution up to 150Å, is believed to indicate that this film contains both polymer molecules and gas bubbles. The gas bubbles perhaps consist of hydrogen. Deposits formed in the additive-free phosphate bath also appeared to contain both polymer molecules and bubbles. The size distribution of phase objects in these deposits is shown by the solid line in Fig. 5. Again, the peaks at 25 and 50Å are very distinct and essentially identical to those observed with other films. These results suggest that the polymer molecules formed in the additive-free baths are the same as those deposited from the Co- and Ni-baths.

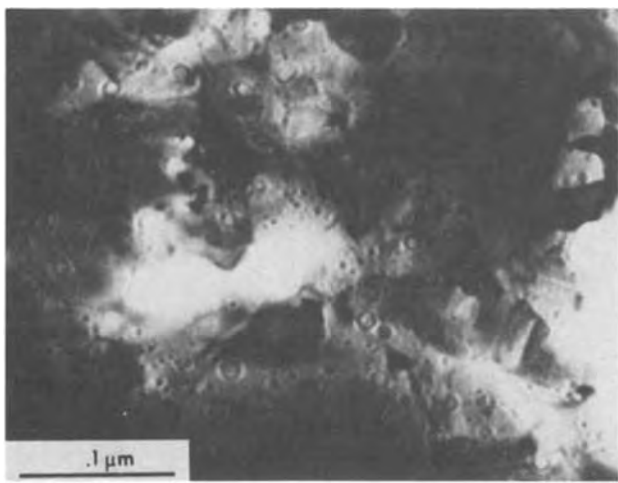

Fig. 4. TEM micrograph of deposit formed in additive-free citrate bath ($\Delta f = +3.9$ μm).

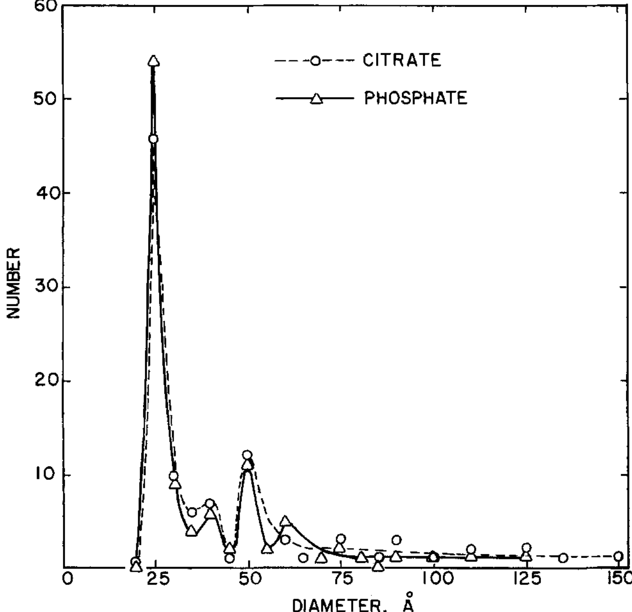

Fig. 5. Size distribution of phase objects in deposits from additive-free baths.

Concerning the form of incorporated carbon-containing species, Reinheimer (9) postulated that the carbon in gold deposits plated in additive-free baths is in the form of simple CN-containing species such as KCN, AuCN, $KAu(CN)_2$, or HCN rather than in the form of a polymer. This suggestion was made on the basis of the finding that the carbon does not originate at the anode, where cyanide is known to form polymeric materials. As is discussed in the next section, the polymer apparently is not the only source of carbon contamination, but the codeposition of these simple CN-containing species may also be important.

Polymer content, carbon content, and grain size.—Table I lists the population density and volume density of the polymer molecules, the calculated maximum carbon content (see below), and the grain size of the deposits formed in the various baths. If a certain number is assumed for the specific gravity of the polymer, the weight percentage of this substance can readily be calculated from the volume density. If the specific gravity of graphite (2.25) is used, the weight percentage found may be regarded as a maximum possible carbon content attributable to the polymer. The values calculated in this manner are included in Table I as "Calculated maximum carbon content." The actual carbon content associated with the polymer should be appreciably less than this calculated carbon content, because most organic materials have specific gravity values much smaller than that of graphite. For the deposit formed in the Co-bath the calculated carbon content was 0.07%, which was significantly less than the total carbon content (~0.25%) found by the combustion technique. Although no actual analytical data are available for the deposit from the Ni-bath, the recent study by Raub, Knödler, and Lendvay (7) indicates that the total carbon content of the nickel-hardened deposit from the type of bath employed in this study is not greatly different from that of the Co-bath. Thus, the calculated maximum carbon content of the deposit from the Ni-bath is also likely to be significantly lower than its total carbon content. A similar difference between calculated and total carbon contents was found for the deposit from the additive-free ammonium citrate bath. The total carbon content of this deposit was ~0.04% as compared to the calculated maximum carbon content of 0.02%. Even if the uncertainty in the estimate of foil thickness is taken into consideration (a nominal value of 500Å was used), the differences described above are still considered quite significant. It is apparent from these comparisons that the polymer accounts for only a small fraction (~10 to 25%) of the total carbon content. The rest of the carbon must be present in some other form(s) which is not visible by electron microscopy. Simple K-Au-CN species and/or Co-CN species are such possibilities (7, 9). It is of interest to note that both $Au(CN)_2^-$ (19) and $Co(CN)_4^{--}$ (20) are known to adsorb strongly on mercury.

A common feature of all hard gold deposits is the extremely small grain size. Since such small individual grains are difficult to resolve in micrographs taken in the bright-field, dark-field imaging was used to measure the grain size. A typical dark-field micrograph obtained with the deposit from the Co-bath is shown in Fig. 6. This specimen was prepared by electropolishing a 25 μm thick film. The grain size of this film was quite uniform, 250 ± 25Å. We also examined the early stages of deposit formation on large grains (>10 μm) of textured copper substrates. It was found that the deposit grows epitaxially only at the very early stages (up to only ~150Å), and subsequently becomes very fine-grained. On the other hand, deposits from high temperature, soft gold baths were found to grow epitaxially to a considerable thickness (>1 μm). Soft gold is known to contain very little

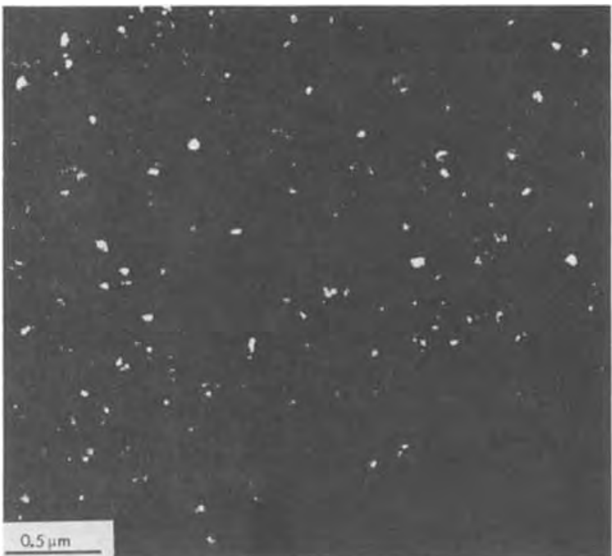

Fig. 6. Dark-field TEM micrographs of deposit from Co-bath (25 μm deposit electropolished to about 750Å).

carbon (1), and indeed no phase objects were found in such deposits. The deposit from the Ni-bath contained the largest quantity of polymer, and its grain size was smallest (Table I). On the other hand, as shown in Fig. 7(a) and (b), some large grains were found in the deposits from the additive-free baths, which contained the least amount of polymer (Table I). From these results it would appear that the polymer content and grain size are interrelated. It is possible that the codeposited polymer molecules have a grain-refining effect which is due to the inhibition of crystal growth. Since the polymer is evidently not the only source of carbon, it is not clear whether the observed differences in grain size between the various deposits are entirely due to the differences in polymer content, or whether other carbon-containing species are also responsible. As already mentioned, the deposits from the additive-free baths appeared to contain gas bubbles. Unlike organic molecules or other adsorbed species, gas bubbles or voids are not likely to alter the grain size. With electroless copper deposits containing numerous gas bubbles, we observed no grain refining effect; epitaxial growth continued up to tens of micrometers (21).

It is generally recognized that the hardness of deposits is influenced by grain size. The Knoop hardness of the deposits from the four baths studied here ranged from 150 to 200 at 25g load. The relationship between grain size and hardness was not clear, and no effort was made to establish such a relationship in this investigation.

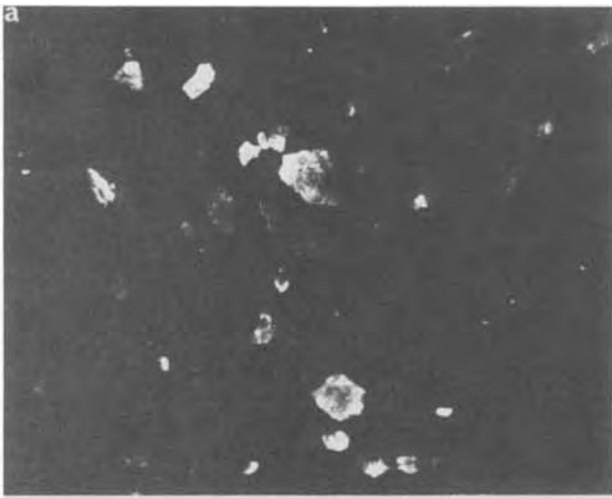

Fig. 7. Dark-field TEM micrographs of deposits from additive-free citrate (a) and phosphate (b) baths.

Summary and Conclusion

1. Small phase objects (nonmetallic objects) ranging in diameter from 20 to 70Å found in hard gold deposits by the through-focus imaging technique of transmission electron microscopy are most likely to be single molecules and their agglomerates of the so-called polymer which has been isolated as a transparent film upon dissolution of gold in aqua regia. The polymer molecules appear to be distributed uniformly throughout the deposit.

2. The size distribution of the phase object is very tight and identical for deposits obtained from various different baths. Nearly 80% of the phase objects measure 25-35Å in diameter. This is considered as evidence to support the conclusion that these objects are polymer molecules rather than voids or gas bubbles.

3. Features which appeared to be gas bubbles were found in deposits from the room temperature, additive-free baths as well as in deposits from an extensively used cobalt-containing bath. The shape and size distribution of these features are random and distinctly different from those of the polymer molecules.

4. A comparison of the polymer content estimated from the analysis of electron micrographs with the total carbon content indicates that the polymer accounts for only 10-25% of total carbon in gold deposits.

Thermodynamics of the System $LiF\text{-}AlF_3$

E. W. Dewing*

Aluminum Company of Canada, Research Centre, Arvida, Quebec, Canada

ABSTRACT

It is demonstrated from the liquidus curve that solid Li_3AlF_6 is stoichiometric. Solid-electrolyte concentration cells have been used to determine the free energy of

$$3LiF(s) + AlF_3(s) = Li_3AlF_6(s)$$

as $\Delta G^\circ = -3668 - 7.051T$ cal (870°-1058°K) and $\Delta G^\circ = -4138 - 6.510T$ cal (773°-870°K) with a standard deviation of ± 11 cal. At 1073°K liquid concentration cells with alumina diaphragms have given free energies of mixing for the system, the results being calculated with a transport number of Li^+ ions of 0.957 ± 0.008 determined by coulometric titration of added AlF_3. For liquid Li_3AlF_6 the discrepancy between the results of the liquid cells and extrapolation of the results from solid cells is 100 cal. The free energies of mixing at 1073°K can be interpreted in terms of the equilibrium

$$AlF_4^- + 2F^- \rightleftharpoons AlF_6^{3-}$$

with $K = 14.9$ (in terms of anion fractions).

In earlier work, the free energy of the solid compounds Na_3AlF_6 and $Na_5Al_3F_{14}$ was determined with solid-electrolyte concentration cells (1), and activities in liquid $NaF\text{-}AlF_3$ mixtures saturated with alumina were determined with concentration cells with alumina diaphragms (2). The object of the present work is to use similar methods on the $LiF\text{-}AlF_3$ system. At the same time a check is made to see whether solid Li_3AlF_6 is nonstoichiometric in the same way that Na_3AlF_6 seems to be (3).

Romberger and Braunstein (4) measured the emf of concentration cells in the system $LiF\text{-}BeF_2$. In that case the activities were already known, so that transport numbers could be calculated. In the present case neither activities nor transport numbers are available; it has thus been necessary to measure the transport number of Li^+ independently in a Hittorf-type experiment.

Solid Li_3AlF_6

The check for nonstoichiometry is made by plotting the liquidus curve for Li_3AlF_6 on the basis of log $(n_{LiF}{}^3 \cdot n_{AlF_3})$ against $1/T$ (3). If the compound is stoichiometric the two branches of the liquidus will have at least a common tangent and may be superimposed. Figure 1, based on the results of Jensen (5), Rolin *et al.* (6, 7), and Matiasovsky and Malinovsky (8) shows that there is no effective separation of the lines except at the lowest temperature, and that consequently Li_3AlF_6 may be treated as stoichiometric.

* Electrochemical Society Active Member.

Key words: lithium fluoride, aluminum fluoride, activities, transport number, concentration cell, lithium cryolite, dissociation.

The determination of the free energy of formation of solid Li_3AlF_6 with a solid electrolyte cell is simple since the lithium analogue of chiolite, $Na_5Al_3F_{14}$, does not exist. Hence, one cell

$$Al \left| \begin{matrix} LiF \\ Li_3AlF_6 \end{matrix} \right| \begin{matrix} Li_3AlF_6 \\ (Li^+) \end{matrix} \left| \begin{matrix} Li_3AlF_6 \\ AlF_3 \end{matrix} \right| Al \quad [I]$$

gives the desired result; if its emf is E, then for

$$3LiF(s) + AlF_3(s) = Li_3AlF_6(s) \quad [1]$$

$$\Delta G^\circ = -3\mathbf{EF}/2 \quad [2]$$

[The theory of such cells has been given previously (1).]

The electrolyte was Li_3AlF_6 doped with Mg^{2+}. Crystals were recovered from a slowly cooled melt containing 8.4% MgF_2 and 7.5% excess AlF_3. (This AlF_3 is equivalent to 3/2 MgF_2.) The crystals were not analyzed. On each side of the doped material pure Li_3AlF_6 was placed, and the powders were compacted into 5 mm ID alumina tubes, as in the earlier work. The liquid aluminum electrodes were kept in place by layers of graphite and silver.

EMF's were measured with a Guildline potentiometer and a Keithley 600 B electrometer as null-detector. The latter has an internal impedance of $10^{14}\Omega$ and a recorder output, so that out of balance current could be recorded continuously with a sensitivity of 10 mV full scale. The emf's were in fact steady to a few tenths of a millivolt.

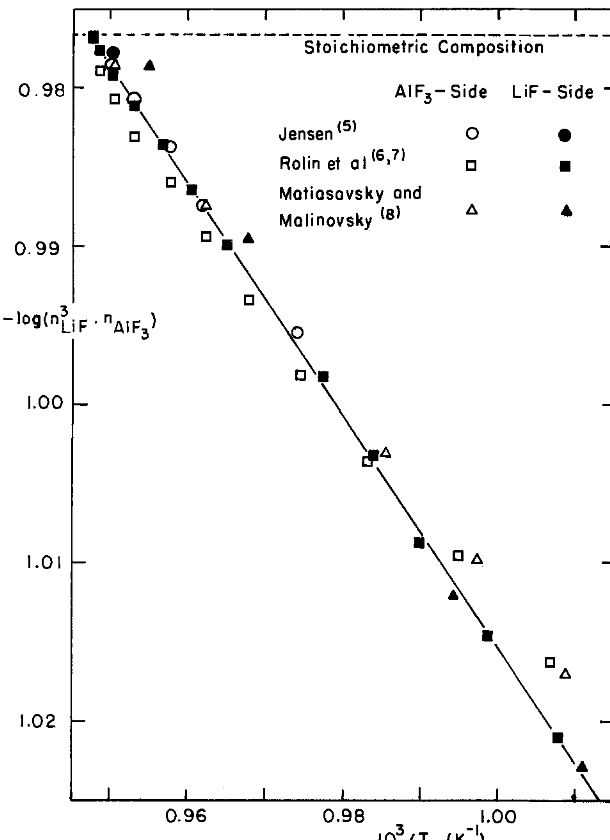

Fig. 1. Liquidus curve for Li_3AlF_6. (Some points omitted for clarity.)

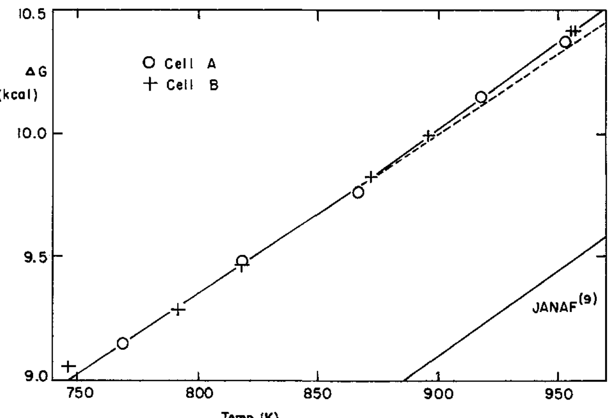

Fig. 2. Free energy of $3LiF(s) + AlF_3(s) = Li_3AlF_6(s)$

The results are given in Table I in the order in which they were measured and are plotted in Fig. 2.

According to Jensen (5) Li_3AlF_6 has transitions at 870° and 783°K. With the exception of the point at 745°K, which is well below the lower transition, the data were fitted by least squares to two straight lines intersecting at the upper transition point. The two equations are

$$\text{above } 870°\text{K:} \quad \Delta G° = -3668 - 7.051T \qquad [3]$$

$$\text{below } 870°\text{K:} \quad \Delta G° = -4138 - 6.510T \qquad [4]$$

The enthalpy of transition is 470 cal. The standard deviation of the points from the line is 11.5 cal, corresponding to 0.33 mV.

For comparison, Fig. 2 also shows the free energy given by the JANAF Tables (9). It differs by 0.9 kcal from this work.

Liquid $LiF-AlF_3$ Mixtures

The basis of the thermodynamic measurements is concentration cells with transport of the type

$$\text{Al} \left/ \begin{matrix} \text{LiF} \\ \text{AlF}_3\text{(sat)} \end{matrix} \right\| \left| \begin{matrix} \text{LiF} \\ \text{AlF}_3 \end{matrix} \right| \text{Al} \qquad [\text{II}]$$

B	955.6	301.1	10,416
	745.6	261.7	9,053
	957.0	301.1	10,416
	896.1	288.9	9,993
	872.0	284.0	9,824
	818.6	273.6	9,464
	792.1	268.5	9,288

The left-hand side has a fixed composition since it is always saturated with AlF_3; the right-hand side is variable. The mixtures were held in alumina tubes; since these are penetrated by cryolite melts the liquid junctions were formed within them. The electrodes were tungsten rods previously dipped in molten aluminum; effectively, for a period of minutes, they acted as reversible aluminum electrodes.

Mixtures were made up by weight from Reagent Grade LiF (Baker & Adamson-Allied Chemical) and AlF_3 purified by sublimation. The latter contained 0.08 weight percent (w/o) NaF. They were put into 5 mm ID × 8 mm OD alumina tubes, enough to give 1-2 cm depth when melted. The tubes were immersed in a $LiF-Li_3AlF_6$ eutectic mixture (64.6 w/o LiF, 35.4 w/o AlF_3) in a graphite crucible of 2 in. ID (Fig. 3). Seven tubes in all were immersed; five containing mixtures, one in the center containing a Pt-10% Rh thermocouple, and the other containing liquid aluminum. The latter served for coating and recoating the tungsten rods (1.5 mm diam) used as electrodes.

A few additional results were obtained in the course of the transport number work described below.

To make a measurement the two tungsten rods were taken out of the aluminum and placed in the reference mixture [~60 mol percent (m/o) AlF_3 saturated with AlF_3] and the one to be studied. An emf steady to within a millivolt or so was usually obtained within a few minutes. The electrodes were then removed,

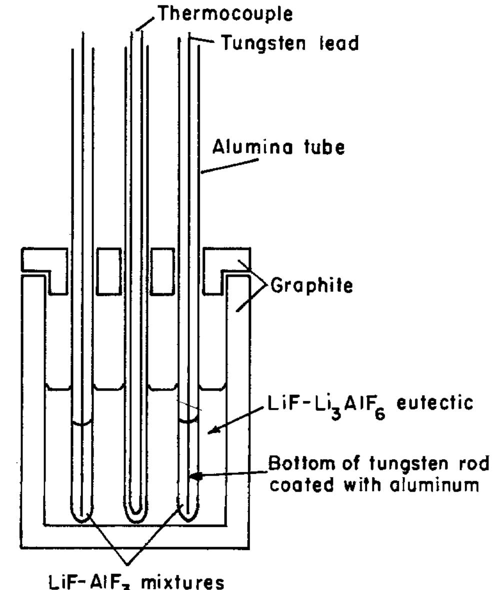

Fig. 3. Apparatus

cleaned of electrolyte with a file, and replaced in the aluminum.

Table II shows the results obtained at 1073° ± 2°K as a function of composition, and Table III shows the results as a function of temperature for a pair of electrodes in mixtures saturated with solid AlF_3 and solid LiF, respectively.

The theory of cells of this type has been given previously (2, 4, 10, 11). Activities are derived from emf by

$$d \ln a_{LiF} = -\frac{3F}{RT} \cdot \frac{dE}{r + 3t} \quad [5]$$

and

$$d \ln a_{AlF_3} = \frac{3F}{RT} \cdot \frac{r}{r + 3t} \cdot dE \quad [6]$$

where r is the molar ratio LiF/AlF_3 and t is the transport number of Li^+ ions. [It is assumed that the transport number of F^- ions is $(1 - t)$, and hence that $t_{Al3+} = 0$, which is reasonable if it is entirely complexed as AlF_6^{3-} and AlF_4^- (12).] Since these are differential equations they involve integrations and bring in unknown integration constants. These can be fixed if the integration can be started at a phase boundary where the activity is known.

From the phase diagram (5, 7) the LiF liquidus at 1073°K may be taken to lie at 8.1 m/o AlF_3. The activity with respect to liquid LiF may be calculated from the JANAF (9) free energy of fusion as $\Delta\bar{G}_{LiF} = -283$ cal, and $a_{LiF} = 0.876$. This provides the necessary integration constant for Eq. [5].

Figure 4 is a plot of the results. Examination shows that the line is not quite straight (there is no reason why it should be); and it has been represented by three straight-line segments

$n_{AlF_3} < 0.25$

$$E = 524 - 123.1\, n_{AlF_3} \text{ mV}$$

$0.25 < n_{AlF_3} < 0.30$

$$E = 554 - 135.2\, n_{AlF_3} \text{ mV}$$

$n_{AlF_3} > 0.30$

$$E = 494 - 115.3\, n_{AlF_3} \text{ mV}$$

The last of these extrapolates to zero at 42.8 m/o

Al | LiF, AlF_3(sat) || LiF, AlF_3 | Al

AlF_3, about 1.5 m/o higher than would be expected from the liquidus curve (5, 6) but hardly beyond experimental uncertainty.

The over-all standard deviation of the points from the lines is ±5.6 mV.

Integration of Eq. [5] and [6] was first carried out numerically with the assumption that $t = 1$; step size was 1 m/o. It was found that the $\Delta G°$ of formation of a 25 m/o AlF_3 mixture (*i.e.*, for 0.75 LiF + 0.25 AlF_3) was −3009 cal (starting from liquid LiF and solid AlF_3). This may be compared with the value derived from the free energy of formation of solid Li_3AlF_6 (Eq. [3]). With the enthalpy of fusion of Li_3AlF_6 of 21,000 ± 300 cal at 1058°K given by Holm and Grønvold (13) this gives for

$$3LiF(s) + AlF_3(s) = Li_3AlF_6(l) \quad [7]$$

$$\Delta G° = 17{,}332 - 26.900T \quad [8]$$

and at 1073°K, $\Delta G° = -11{,}532$. To make comparison with the integral ΔG of mixing this value must be divided by 4 (to put it on the basis of 1 mole total), and then -283×0.75 cal must be added to transfer to the liquid standard state for LiF. The final result is $\Delta G = -3095$ cal. The discrepancy of 86 cal corresponds to 344 cal in the free energy of formation of Li_3AlF_6, and is an error of the order of 10 mV in the emf. One therefore questions whether the assumption of unit transport number for Li^+ ions is valid. If it be assumed that t is independent of composition, a value of 0.94 is needed to get rid of the discrepancy.

The transport number of Li^+ was determined by the direct coulometric titration of AlF_3. The procedure was that a melt was made up by weight to have a molar ratio LiF/AlF_3 of 3. It was placed in an alumina tube which was in turn immersed in a LiF-Li_3AlF_6 eutectic melt, as in the earlier work. The only difference was that the tube was 12 mm ID and the reference electrode was in a tube 8 mm ID. Dry argon was passed via a narrow alumina tube into the tube to exclude moisture; the top was plugged with glass wool. Aluminum-plated tungsten electrodes were used as before, except that the main one was not subsequently removed for replating. Aluminum was added to the crucible to act as anode.

At the start of a run, the emf between the two electrodes was found. A carefully weighed piece of coarsely crystalline AlF_3 was then dropped in, and the emf was redetermined. A current was then passed between the graphite crucible and the main electrode (cathodic) until the emf was above (or at least close to) the initial value. The duration of current was carefully timed and its value was measured with a calibrated resistor. (Since it had a small temperature

coefficient and since it heated when current was passed, its value was determined with a Kelvin bridge immediately after use. The current, from a Hewlett-Packard 6200B Power Supply, was kept flowing through the resistor at all times to ensure that it stayed at steady state.) Linear interpolation was made on the emf-time line to determine the number of coulombs passed when the potential was restored to its original value. More AlF_3 was dropped in, and the process repeated. In this way a plot of coulombs *vs.* weight AlF_3 added was obtained.

Figure 5 shows part of the emf-coulombs sequence, and Fig. 6 is the final plot of moles of AlF_3 added *vs.* equivalents of charge passed. The slope of the least squares line is 1.5317 with a standard error of ±0.0025 equiv./mole. The standard deviation is ±0.079 mole equiv., or ±7.6C. This is based on 9 points, including the origin. If the origin is omitted the standard deviation increases, showing that it is a valid point. If, on the other hand, a tenth point is brought in the standard deviation again increases (by a factor of 1.6), implying that something is wrong with it. Possibly a fragment of the AlF_3 failed to reach the bottom of the tube. It has been omitted from the final result.

If the slope of the line is n equiv./mole, the transport number is calculated as follows. Of 1 mole AlF_3 added, $n/3$ is destroyed by plating out Al onto the cathode. To restore the composition to the original molar ratio of 3, $3(1 - n/3)$ moles LiF must be transported in. The transport number is thus

$$t = 3(1 - n/3)/n$$
$$= 3/n - 1$$
$$= 0.9586 \pm 0.0032$$

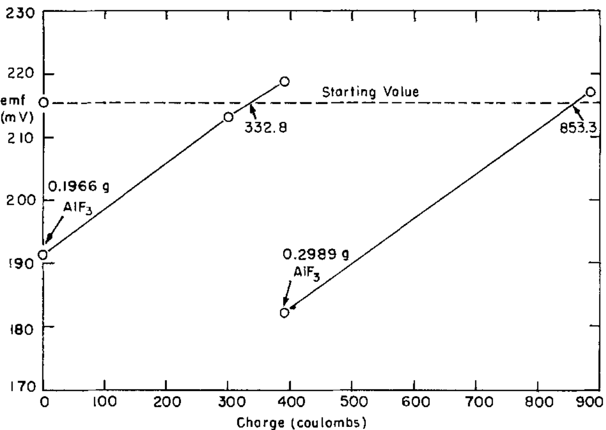

Fig. 5. Part of emf-coulombs sequence

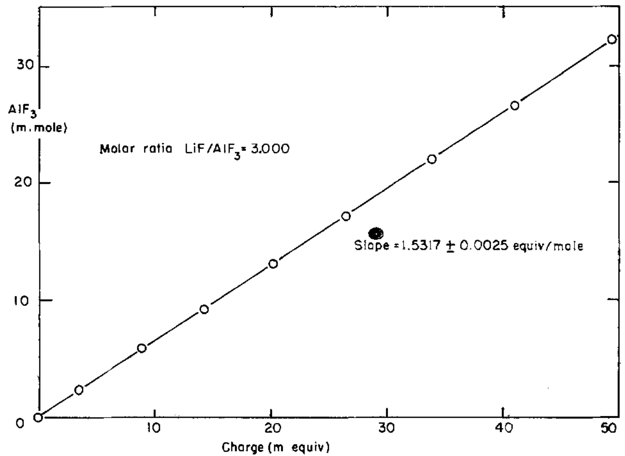

Fig. 6. Coulometric titration of AlF_3

If it be assumed that the 0.082% NaF is the only impurity in the AlF_3 (it is the most likely one), the value of t is reduced to 0.957.

The error quoted is a statistical standard error; systematic errors are much harder to estimate. The resistor was measured *in situ* with a precision of about ±0.2%, timing the duration of the current is, say, ±1 sec in 10 min or about 0.17%. The over-all precision on the coulombs is thus about ±0.26%. This will make ±0.52% in the value of t. If one takes this and two standard errors the over-all uncertainty is $\sqrt{0.0064^2 + 0.0052^2} = \pm 0.0083$. We may thus take $t = 0.957 \pm 0.008$.

Since t is very close to unity it is unlikely that a significant variation with composition could be determined experimentally, and it is assumed that it is constant. Integration of Eq. [5] and [6] is then straightforward, and the result is shown in Table IV. The ΔG for (0.75 LiF, 0.25 AlF_3) is now −3070 cal; the ±0.008 uncertainty in the transport number makes ±11 cal. The discrepancy with the calculated value of −3095 cal is 25 cal, which is not really big enough to worry about. It would correspond to 3 mV in the emf.

Discussion

That solid Li_3AlF_6 is the only one of the alkali metal cryolites which does not show premelting effects (13) is probably associated with the fact demonstrated here that it is stoichiometric. The implication could be that the others are not.

It has been assumed in this work that alumina is essentially insoluble in lithium cryolite. Rolin and Muhlethaler (6) stated that the solubility was less than 1%; in fact their figures (14) indicate that it is about 0.2% at 1073°K. There was no obvious attack on the alumina tubes used in the concentration cells, and it is not believed that the solubility is high enough to have affected the thermodynamic values.

Although the values obtained are completely independent of any model of the melts it is interesting to see if they can be fitted to a reasonable model. One which has been adopted by numerous authors is the equilibrium

$$2F^- + AlF_4^- \rightleftharpoons AlF_6^{3-} \quad [9]$$

it being assumed that the various anionic species mix ideally. In the past it has been necessary to calculate for temperatures and compositions along the liquidus curve, but now isothermal data covering the whole composition range are available.

Since Li^+ is the only (uncomplexed) cation present, and since we are assuming that the anionic species are mixing ideally, we may identify the activity of LiF as measured with the anion fraction of F^-. Having found that, and knowing the over-all composition,

0.100	−14057	−408	−1773	0.00137	0.826
0.081	−15316	−283	−1501	0.00076	0.876

we can calculate the anion fractions of AlF_4^- and F^-, and then see if the model is working insofar as the equilibrium constant

$$K = a_{Li_3AlF_6}/(a_{LiAlF_4} \cdot a_{LiF}^2) \quad [10]$$

is constant.

If we start with an over-all composition n_{LiF} and n_{AlF_3} (the total = 1), and x_{LiF}, x_{LiAlF_4}, and $x_{Li_3AlF_6}$ denote numbers of moles of the individual species present, then

$$x_{LiAlF_4} + x_{Li_3AlF_6} = n_{AlF_3} \quad [11]$$

$$x_{LiF} + x_{LiAlF_4} + 3x_{Li_3AlF_6} = n_{LiF} \quad [12]$$

By substituting [11] in [12]

$$x_{LiF} = n_{LiF} - n_{AlF_3} - 2x_{Li_3AlF_6}$$

$$= 2n_{LiF} - 1 - 2x_{Li_3AlF_6} \quad [13]$$

since $n_{AlF_3} = 1 - n_{LiF}$. The sum of the x's is from [12]

$$x_{LiF} + x_{LiAlF_4} + x_{Li_3AlF_6} = n_{LiF} - 2x_{Li_3AlF_6} \quad [14]$$

Hence

$$a_{LiF} = \frac{x_{LiF}}{\text{Total}} = \frac{2n_{LiF} - 1 - 2x_{Li_3AlF_6}}{n_{LiF} - 2x_{Li_3AlF_6}} \quad [15]$$

and, rearranging

$$x_{Li_3AlF_6} = \frac{n_{LiF}(2 - a_{LiF}) - 1}{2(1 - a_{LiF})} \quad [16]$$

Once this is known, insertion into [11] gives x_{LiAlF_4}, and division by the sum of the x's (Eq. [14]) gives the activities of Li_3AlF_6 and $LiAlF_4$.

If the model is working, and the equilibrium constant is constant, then a plot of a_{LiF} against $\sqrt{a_{Li_3AlF_6}/a_{LiAlF_4}}$ should be straight. In Fig. 7 the results for $n_{AlF_3} > 0.25$ are plotted. The line is remarkably straight. For $n_{AlF_3} < 0.25$ problems arise because the quantity of AlF_4^- present is so small that accuracy is lost, and another approach must be tried.

Fundamentally, the problem is: given the experimental emf's and assuming the model is applicable, what is the value of the equilibrium constant K which will minimize the scatter of the calculated and experimental emf's? The problem can be treated directly without doing any integrations since, for any composition, if K is specified the activities can be calculated uniquely and hence emf's with respect to some arbitrary standard composition. The only adjustment necessary is a constant to bring the arbitrary standard in line with the real one. In making the calculation it is of course necessary to insert the same transport number as used previously.

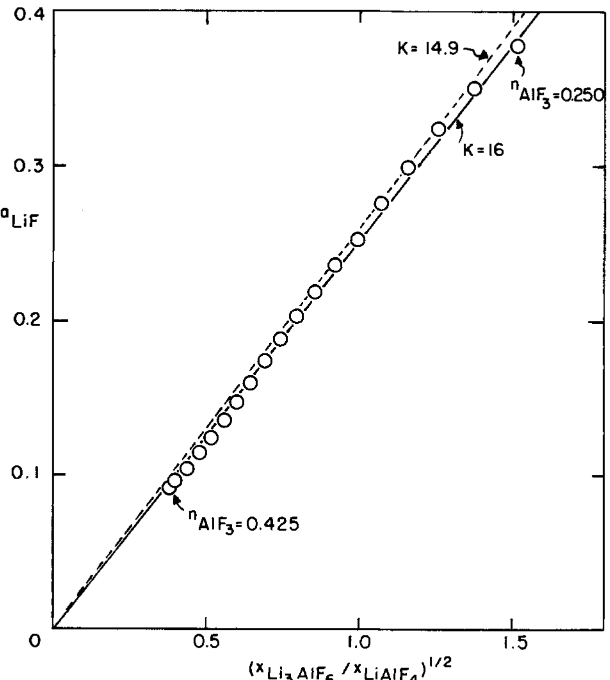

Fig. 7. Plot of a_{LiF} vs. $(x_{Li_3AlF_6}/x_{LiAlF_4})^{1/2}$

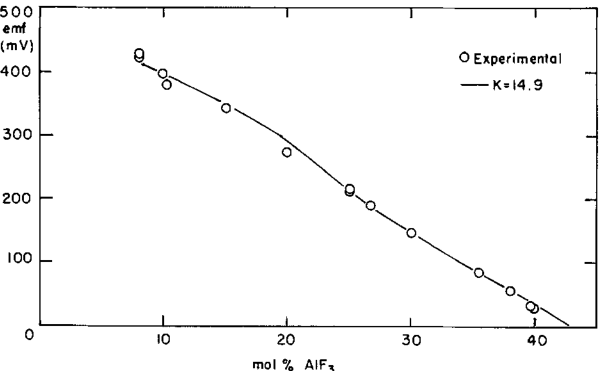

Fig. 8. Calculated emf-composition curve

The best value of K is found to be 14.9. The resulting line is shown for comparison in Fig. 7 and the calculated emf composition curve is compared with the experimental points in Fig. 8. The standard deviation is ±8.5 mV, which may be compared with the ±5.6 mV standard deviation from the straight line segments. On the AlF_3-side of Li_3AlF_6 the fit is very good (as it is also in Fig. 7), but on the LiF-side there is a bend in the calculated curve which is not reproduced by the experimental values.

The simple dissociation model thus looks like a good first approximation, and is not inconsistent with Ratkje and Rytter's (15) finding that by Raman spectroscopy of LiF-Li_3AlF_6 eutectic mixture (15 m/o AlF_3) they could detect distorted AlF_6^{3-} groups but no AlF_4^-. With the value of the dissociation constant of 14.9 the composition is expected to be 74 m/o F^-, 23 m/o AlF_6^{3-}, and 2.8 m/o AlF_4^-. It is thus perhaps not surprising that it was not detected. On the other hand, Gilbert, Mamantov, and Begun (16) did not see any AlF_4^- in a Li_3AlF_6-Na_3AlF_6 eutectic at 790°C. If K is around 15, then there should be 19 m/o AlF_4^-. It is therefore quite possible that cation effects are not negligible, and that K varies with both the cation and the temperature. The assumption of ideal mixing of the anionic species may also be of limited application.

Now that thermodynamic functions are available it would be very interesting to have Raman spectra for the whole range of composition of LiF-AlF_3 mixtures at 1073°K. A direct comparison between activities and concentrations of various species would then be possible.

Manuscript submitted Oct. 20, 1975; revised manuscript received May 18, 1976. This was Paper 396 presented at the Washington, D. C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by the Aluminum Company of Canada.

Preparation and Applications of Graphite Substrate Lead Dioxide (GSLD) Anode

K. C. Narasimham and H. V. K. Udupa*

Central Electrochemical Research Institute, Karaikudi 623 006, India

ABSTRACT

The GSLD anodes have been developed for obtaining suitable size anodes for use in high amperage cells in the production of chlorates and perchlorates. The performance characteristics of the anodes in the preparation of chlorates and perchlorates are described. The use of the GSLD anode in other inorganic preparations like bromates iodates, and periodates is also included.

In recent years the quest for the development of indestructible anodes either as a substitute for costlier anodes or to increase the life of anodes in electrochemical processes has intensified. Increasing interest in the scientific development of inert and insoluble anodes provided a healthy atmosphere meriting considerable research effort both in the improvement of existing anodes and in the development of new anodes. The complex nature of the evaluation problem stems from the number of variables involved, such as electrode life, operating conditions of the cell, and replacement costs.

Graphite and platinum are widely well-known anodes in electrochemical processes and, less frequently, materials like magnetite, lead, and lead-silver or lead-antimony alloy are employed. But the recent researches on the indestructible or inert anodes are largely centered around the development of (*i*) platinum or its alloy coated over titanium and (*ii*) coating of oxide or mixed oxides of certain metals on suitable substrates.

The main requirements for an oxide anode are: (*i*) the possibility of forming ions of different valences to provide for high electrical conductivity, (*ii*) a high anodic potential at evolution of oxygen, (*iii*) absence of rectifying contacts at the boundary of oxide-metal current lead, and (*iv*) chemically inert.

The high cost of platinum has prompted several attempts to replace this metal by cheaper material. In the last two decades interest in the use of lead dioxide as anode in the place of platinum for the preparation of inorganic and organic electrochemicals (1) has been very much in evidence as seen by the considerable amount of work carried out to obtain lead dioxide deposits in a form suitable for anodes in the production of chlorates and perchlorates.

The successful development of a suitable GSLD anode for commercial scale operations in chlorates and perchlorates has been engaging the attention of the Central Electrochemical Research Institute. This paper reviews the developmental work on this project. Earlier attempts to prepare the lead dioxide electrodes as well as the difficulties encountered by previous workers have been reviewed earlier by Narasimham and Udupa (2-4). Recently, Carr and Hampson (5) reviewed the studies on the electrodeposition of lead dioxide laying emphasis on the kinetics of electrodeposition.

Preparation of GSLD Anode

A survey of the literature shows a continuous interest in the preparation of lead dioxide anodes beginning in 1934. Lead dioxide satisfies the major requirements given above for the oxide anode. Angel and Mellquist (6) reported the deposition of lead dioxide from lead tartrate bath. Though electrolysis of almost all soluble salts of lead (5, 7-10) gives lead dioxide deposit under suitable conditions on the anode, the lead nitrate bath is preferred since it may be readily controlled over long plating periods and also due to the high quality of deposit obtained from the bath over a wide range of operating conditions. β-PbO_2, which has an oxygen overvoltage higher than α-PbO_2, is obtained from the nitrate bath. Japanese workers (11-16) used this nitrate bath extensively for depositing lead dioxide on nickel or mild steel substrate. When lead nitrate alone is used, a dendritic form of lead is also deposited on the cathode resulting in the shorting of the electrodes. Even though a diaphragm cell has been suggested (17) to prevent lead deposition on the cathode, the addition of copper salt to the extent of 2-3% to the bath for preventing the deposition of lead is by far the most important contribution (12) in the field of electrodeposition of lead dioxide. The copper, being more electropositive than lead in the electrochemical series, deposits preferentially on the cathode. Grigger *et al.* (18) and Schumacher *et al.* (19) reported the formation of lead dioxide from the nitrate bath on tantalum or platinum-clad tantalum.

Although much work had been done as described above, the preparation of lead dioxide electrodes involved certain disadvantages. In the process developed by the Japanese workers (11-16), massive lead dioxide electrodes were prepared by depositing lead dioxide up to 1 cm thick or more, then removing the same from the substrate, and finally cutting the deposit into suitable shapes with either an alundum or carborundum

* Electrochemical Society Active Member.

Key words: electrodeposition, chlorates, perchlorates, insoluble anodes.

grinding stone. This operation needs special care as the deposit is brittle as well as very hard. The conventional clamp current-contact produces local heating and hence suitable modifications have to be done. On the other hand, costlier substrates were described for depositing lead dioxide in the methods described by Grigger *et al.* (18) and Schumacher *et al.* (19).

The successful electrodeposition of lead dioxide from lead nitrate-copper nitrate bath on graphite substrate carried out simultaneously by the authors (2, 20, 21) and by Gibson (22, 23) in the U.S. obviates the difficulties experienced by earlier workers. While Gibson (22) used a nonionic surface active agent in the bath, Narasimham and Udupa (2, 20, 21) employed rotation for the cylindrical rods and to-and-fro motion for the plates during deposition to inhibit gas bubbles from sticking to the surface, thereby avoiding pinholes and pitting in the coating. Although hydrodynamic factors, such as the decrease in the thickness of the diffusion layer and also the easy transport of ions to the interphase, do exist during the movement of the electrode, the important aspect in this case happens to be the dislodging of gas bubbles adhering to the surface of the electrode. Similarly, the use of surfactant lowers the interfacial tension, thereby enabling the easy release of gas bubbles from the anode surface. The electrodes thus developed have the following advantages: (*i*) a thin coating of lead dioxide on graphite is adequate; (*ii*) the graphite provides mechanical strength for the deposit and is completely protected against anodic attack; (*iii*) electrical contact to lead dioxide can conveniently be made on graphite; and (*iv*) preparation of such anodes for large scale operation does not present undue difficulty.

Cell assembly for oxide deposition differed with the size and shape of the anodes required to be coated. The electrolyte contained 325-350 g/liter lead nitrate and 25-30 g/liter copper nitrate, with an initial *p*H between 4 and 4.5. During electrolysis the *p*H became acidic due to the production of nitric acid and was maintained at 1-1.5 by adjusting the flow rate of the electrolyte. The acid produced was neutralized outside the cell by the addition of lead carbonate or lead monoxide and copper carbonate. Deposition was carried out at current densities of 3-5 A/dm^2 and at a temperature of 58°-65°C. It is most important to have precleaning operations for the graphite anode prior to deposition, which consist in electrolyzing a 10% (W/V) sodium hydroxide solution with the graphite as anode for 30 min, dipping the anode in 10% (V/V) nitric acid for 10 min, and finally washing it thoroughly with distilled water. Different rods and plates of GSLD prepared are given in Table I. These have been used in 200, 800, and 5000A cells for the production of chlorates and perchlorates. The thickness of the deposit depends on the process in which GSLD is used, *e.g.*, 1.5-2.5 mm thick is sufficient for chlorate production while the thickness must be more than 3.5 mm for the production of perchlorate. Even if the lead dioxide peels off without any attack on the graphite surface, the lead dioxide can be deposited again on the same graphite. Some of the GSLD anodes given in Table I include such once or twice redeposited electrodes. Calculations for optimizing the size of the anode with respect to weight of graphite needed for different diameter graphite rods show that either 7.5 or 10 cm diameter GSLD rods are preferable (24).

Table I. GSLD rods and plates

Rods			Plates			
Length (cm)	Diameter (cm)	No. of specimen	Length (cm)	Width (cm)	Thickness (cm)	No. of specimen
30	5	60	30	15	1.25	148
30	7.5	65	30	15	2.5	86
60	7.5	100	90	18	3.0	48
75	20	8				

Figure 1 shows GSLD plates and rods of different sizes. The flow diagram of the process is given in Fig. 2.

The addition of different surface active agents to avoid pinholes has been described previously (13, 14, 25-27). In the course of the study on measurements of stress in electrodeposited lead dioxide (28), the authors found the addition of quaternary ammonium surfactants not only lowered the stress but also helped in obtaining a pore-free deposit on stationary graphite even at higher anode current densities (29).

Application of GSLD Anodes

Chlorates.—Sodium chlorate.—A 200A cell with GSLD anode and stainless steel (30) or mild steel (31) cathode was operated continuously; the electrolyte being a solution containing 220-250 g/liter sodium chloride and 180-240 g/liter sodium chlorate with 1*N* HCl to maintain the *p*H between 6.4 and 6.8. Though this composition is not critical, but on cyclic use, the solution attained this composition after two or three runs. Table II gives the operating conditions of the cell. The anodes gave satisfactory service for 24 months with 50% of the anodes still in good condition. A current efficiency of 70-80% was obtained while depleting the chloride concentration of electrolyte from 250 to 100 g/liter. The energy consumption varied from 6.0 to 6.4 kWhr (d.c.)/kg of sodium chlorate (30). When the mild steel was used as container-cum-cathode the anode could be used for 12 months (31) at higher current density, thereby showing almost the same quantity of production per anode.

Based on the above results, scaling up of the cells to 800A was done for the production of sodium chlorate using GSLD (7.5 cm diam × 60 cm long) anodes (32). Two cells were operated continuously, one cell with a concrete container and stainless steel cathode and the

Duration of working (months)	24	12	24	13
Current efficiency (%)	75-80	68-73	72-78	68-75
Energy consumption (kWhr/kg of $NaClO_3$)	6.0-6.4	6.8-7.2	7.0-7.6	8.5-9.0

other with a mild steel container-cum-cathode. The performance of the cells employing the operating conditions given in Table II confirmed the results obtained with 200A cells. The chloride content could be brought down to less than 5 g/liter in the cell with the stainless steel cathode. No perchlorate formation was observed even at such low chloride concentration.

The recent trend in preparation of chlorates is in the use of 30% iridium-platinum coated titanium anodes. Considerable improvements in the efficiency of the electrolytic production of sodium chlorate are claimed for a process developed by Krebs (33,34). Major differences with usual practice lie in the anodes and in the use of higher current densities (30 A/dm^2) and higher temperatures (>60°C) than current procedures. The consumption of activated alloy is reported to be 400-500 mg/ton of sodium chlorate. The advantage claimed with these anodes is the reduction in the power consumption, *viz.*, 4800-5400 kWhr/ton of chlorate (34) as against 6000-6500 kWhr/ton in the existing processes. However, at present the preparation of this anode in India is dependent on the import of all the raw materials.

An electrolytic process for the preparation of sodium chlorate liquor of high concentration (630-660 g/liter $NaClO_3$ with 5-10 g/liter NaCl), suitable for the *in situ* production of chlorine dioxide for textile or paper industries, was developed by employing a GSLD anode and stainless steel cathode (35). The high concentration of sodium chlorate could be attained by saturating the cell liquor with solid sodium chloride during electrolysis with a current efficiency of 55-65% and an energy consumption of 8.8-11.5 kWhr (d.c.)/kg of $NaClO_3$. However, the advantage of this method is that the cell effluent can be directly used for the production of chlorine dioxide without processing the liquor for getting solid sodium chlorate and this is possible only with the lead dioxide anode (and perhaps Pt-Ir coating the titanium anode), not with any other conventional anodes.

Potassium chlorate.—Potassium chlorate, which is mainly used in the manufacture of matches, was prepared by the electrolytic oxidation of potassium chloride in the 800A cell using GSLD anodes and stainless steel cathode (36). The cell was operated at an anode current density of 5 A/dm^2, a temperature of 55°-60°C, and a *p*H of 6.0-7.0. A current efficiency of 82-85% was obtained with the energy consumption of 6.3-6.5 kWhr (d.c.)/kg of potassium chlorate. Efficiency in the production of potassium chlorate higher than sodium chlorate may be attributed to (*i*) the operation of the cell at higher temperature and consequent lowering of voltage by 0.1-0.2V and (*ii*) the conversion of less chloride to chlorate in view of solubility factors. A 5000A cell (37), which can be considered as a prototype commercial cell, was operated for about 150 days with a GSLD anode employing an anode current density of 15-17 A/dm^2 and a temperature of 50°-60°C. The cell voltage was 3.5-3.7V. The higher anode current density has the advantage of using a smaller cell with less initial investment on graphite. The cell effluent, being clear and free from suspended impurities, could be processed further without filtration and pure potassium chlorate (>99%) was obtained by recrystallization.

Another process (38) using a GSLD anode for the production of potassium chlorate was developed on a 800A as well as on a 5000A scale (37) (Fig. 4) which consisted of the oxidation of sodium chloride to sodium chlorate using a mixed electrolyte consisting of sodium chloride, sodium chlorate, and potassium chlorate in the cell. Potassium chlorate was precipitated by adding solid potassium chloride. The chloride and chlorate concentrations in the electrolyte were maintained between 5 and 1 M/liter, respectively, in the feed electrolyte and *vice versa* in the effluent. The advantage of this method is that a higher concentration of sodium chlorate in liquor can be obtained in the cell which can be reacted with solid potassium chloride to precipitate the potassium chlorate, and the solution, after filtering off potassium chlorate, can be directly used as feed liquor. The novelty of this process is in the working out of the suitable range of compositions of feed and effluent liquor.

Advantages of GSLD anodes in chlorate production.—It has been experimentally proved that GSLD anodes have the advantage of a life longer than the treated graphite anodes in the chlorate production (consumption of treated graphite is taken as 25-30 kg/ton of chlorate). Small dimensional change of the graphite anodes by the coating of PbO_2 does not call for much alteration in the design of the existing cells in industry. With GSLD anodes the cell effluent is clear and hence processing can be carried out without filtration. It is also possible to employ a higher current density which in turn helps in using a smaller cell with less initial investment on graphite.

Perchlorates.—Oxidation of sodium chlorate to sodium perchlorate.—Due to increasing demand for ammonium perchlorate in rocketry, attention was given to the replacement of costly platinum with GSLD anode in the production of perchlorate. At present, as metal oxide-coated titanium electrodes (like DSA) are not suitable, GSLD is the only alternative anode to platinum for the production of perchlorate. On the basis of results obtained on laboratory scale (39, 40), two cells of 75A and one of 400A were operated for the production of perchlorate using the GSLD anode (7.5 cm diam × 30 cm long with a deposit of 5 mm thick) (41). Six anodes were used in the 400A cell and only one anode in the 75A cell. A saturated solution of sodium chlorate containing NaF (2 g/liter), added to increase the oxygen overvoltage of the anode (13) and also to increase the current efficiency of the process, was electrolyzed using the anode current density of 15-25 A/dm^2, temperature of 40°-45°C, and *p*H between 6 and 7. The current efficiency was 70-75% with an energy consumption of 3-3.3 kWhr (d.c.)/kg of sodium perchlorate. The presence of even small quantities of chromate in the electrolyte affected the current efficiency of the formation of perchlorate at lead dioxide (current efficiency of only 42%), thereby confirming the results of Sugino and Yamashita (42) and Schumacher *et al.* (19). It was pointed out that an insoluble film of lead chromate might be forming on the surface of lead dioxide and

thereby hindering the formation of perchlorate. It was found that the thickness of the deposit had a definite effect on the life of the anode and experiments showed that a thickness of 3.5-5 mm would be needed in the preparation of perchlorate (43).

Direct oxidation of sodium chloride to sodium perchlorate.—The methods so far in vogue for the electrolytic preparation of perchlorates involve two stages; the first stage being the oxidation of chloride to chlorate using graphite (44) or magnetite (45) or lead dioxide anodes (30-32), and the second stage being the oxidation of chlorate to perchlorate using platinum (46-49) or lead dioxide anodes (18, 19, 39, 40). In between these two stages, the electrolyte obtained in the first stage has to be processed to isolate the sodium chlorate and recover the unconverted sodium chloride.

Sugino (11) reported the direct oxidation of chloride to perchlorate using a lead dioxide anode having two discrete electrochemical stages wherein the temperatures of the electrolysis were different and the addition of sodium fluoride was made after all the chloride was converted to chlorate. Udupa *et al.* (50-52) found that GSLD could be used for preparing sodium perchlorate directly from sodium chloride in one cell without recourse to process in between to isolate chlorate. The operating conditions are given in Table III.

Large scale trials have been carried out (52) with two cells of 75A capacity and one 400A cell. The cells were run continuously at an anode current density of 20 A/dm^2 and a temperature of 45°-50°C. Six GSLD rods (7.5 cm diam × 30 cm long with 4-5 mm thick deposit) were used as anodes in the 400A cell and one rod was used in the 75A cells. The electrolyte was a saturated solution of sodium chloride containing NaF (2 g/liter). The loss due to evaporation was made up with further quantities of sodium chloride solution in such a way that the final cell liquor concentration would be 650-700 g/liter sodium perchlorate. Figure 3 is a graph showing the variation of the concentrations of chloride, chlorate, and perchlorate with duration of the electrolysis. The GSLD anode could be used for more than 450 days of continuous electrolysis in this process. A typical prototype commercial cell of 5000A (Fig. 4) was designed and operated continuously for 9 months at the optimum conditions (24). A current efficiency of 55-62% with energy consumption of 12.8-14.5 kWhr (d.c.)/kg of sodium perchlorate was obtained.

The novelty of this process is the oxidation of chloride to perchlorate in the same cell without alteration of operating conditions or recourse to intermediate processing. In contemplating the direct oxidation of sodium chloride to sodium perchlorate, none of the commoly used anodes, *viz.*, graphite, magnetite, or platinum, can be successfully employed as a single anode material and GSLD is the natural and economic choice at present. The addition of sodium fluoride can be made either at the begining of the electrolysis or after the conversion of chloride (52).

Sodium perchlorate liquor obtained by both the above methods and having less than 10 g/liter sodium chlorate was used for double decomposition with either potassium chloride or ammonium chloride to give potassium perchlorate or ammonium perchlorate, respectively, and the products conformed to the required specifications (24).

Table III. Operating conditions for direct oxidation of sodium chloride to sodium perchlorate using GSLD anode

Condition	Value
Anode current density (A/dm^2)	15-20
Current concentration (A/liter)	18.5-25.0
Temperature (°C)	40-50
pH	6.2-6.8
Bath voltage (V)	4.0-4.6
Current efficiency (%)	53-60
Energy consumption (d.c.) (kWhr/kg of $NaClO_4$)	11.5-12.3

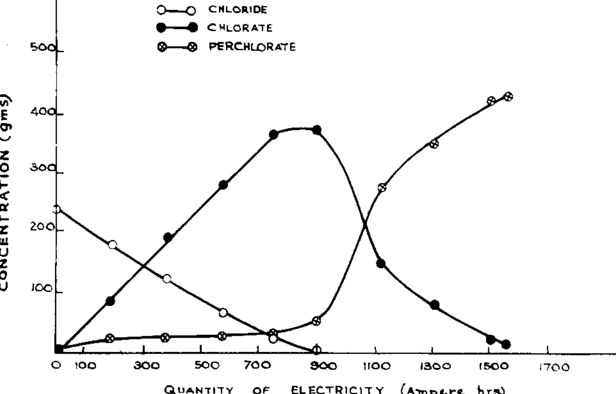

Fig. 3. Variation of the concentrations of chloride, chlorate, and perchlorate of sodium with quantity of electricity.

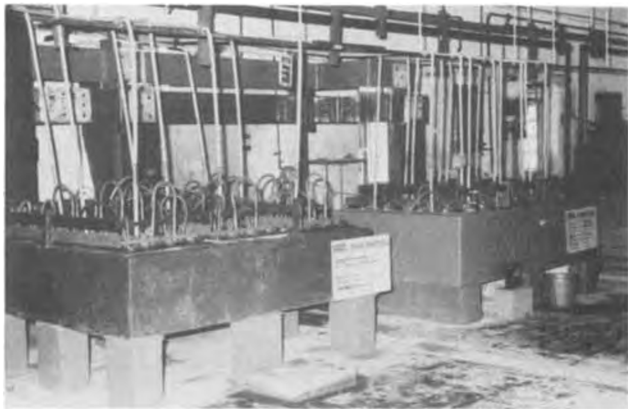

Fig. 4. Photograph of the 5000A chlorate and perchlorate cells

Bromates, iodates, and periodates.—Based on the resultant conditions of laboratory experiments (53), one 75A cell was run with a GSLD anode for the production of bromates employing an anode current density of 16-20 A/dm^2 and temperature of 55°-60°C. A current efficiency of 90-95% was obtained with an energy consumption of 4.0-4.5 kWhr (d.c.)/kg of sodium bromate. By treating highly soluble sodium bromate liquor with potassium bromide, potassium bromate could be obtained.

The electrochemical preparation of sodium iodate from iodine was studied using a GSLD anode and a nylon cloth-wrapped stainless steel cathode (54). Based on the laboratory scale experiments, one 250A cell was run and a current efficiency of 73-77% was obtained corresponding to an energy consumption of 3.0-3.4 kWhr (d.c.)/kg of sodium iodate.

In the oxidation of iodic acid to periodic acid (55), a GSLD anode with rough surface or prepolarized surface of lead dioxide gave better efficiency.

Conclusion

Electrodeposited lead dioxide shows the promise of developing a high efficiency as an inert and insoluble anode in electrochemical processes and, at present, it is the only alternative anode to platinum for the production of perchlorates. Since the current-carrying capacity of GSLD is critical in view of the difference in the coefficients of graphite and lead dioxide, the proper choice of graphite plate or rod has to be made for depositing lead dioxide depending on its subsequent use. The deposition of lead dioxide on other substrates like titanium will have a better future.

Electrochemical Reduction of $Al_2Cl_7^-$ Ions in Chloroaluminate Melts

P. Rolland and G. Mamantov*

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37916

ABSTRACT

The electrodeposition of aluminum at glassy carbon, platinum, and tungsten electrodes in slightly acidic chloroaluminate melts has been studied using cyclic voltammetry, chronopotentiometry, chronoamperometry, and related techniques. The reduction of $Al_2Cl_7^-$ ions involves a nucleation process at glassy carbon electrodes and to a lesser extent, at the platinum and tungsten electrodes. At platinum electrodes alloy formation is also involved. The discrepancies in the values of diffusion coefficients obtained by three different methods may be attributed to the nucleation effect.

The electrochemical behavior of aluminum in chloroaluminate melts ($AlCl_3$-MCl mixtures where M^+ is an alkali cation) (1, 2) has been studied using primarily aluminum electrodes (3-7). In acidic ($AlCl_3$-rich) melts the oxidation of aluminum results in the formation of a poorly conducting (passivating) Al_2Cl_6 layer at the electrode surface (5, 6). No evidence for the subvalent aluminum ions in these melts was obtained (7). Schulze and Hoff (4) from their galvanostatic double-pulse results calculated exchange current densities and transfer coefficients for the deposition and dissolution of aluminum in these melts.

It is well known (8-13) that the concentration of anions $AlCl_4^-$ and $Al_2Cl_7^-$ changes with the $AlCl_3$-MCl ratio. According to Tremillon and Letisse (3) Al(III) is reduced in two consecutive steps

$$4Al_2Cl_7^- + 3e = Al + 7AlCl_4^- \quad [1]$$

and

$$AlCl_4^- + 3e = Al + 4Cl^- \quad [2]$$

$[Al_2Cl_7^-]$ changes from $\sim 10^{-4}$ to $\sim 1M$ in going from a NaCl saturated [$\sim$49.8 mole percent (m/o) $AlCl_3$ at 175°C] melt to a 52 m/o $AlCl_3$ melt.

In this work we examined the electrochemical reduction of $Al_2Cl_7^-$ ions at foreign substrates in melts of composition range 50.1-51 m/o $AlCl_3$, corresponding to $[Al_2Cl_7^-]$ of 6×10^{-2} to $4 \times 10^{-1}M$. The purpose of this work was twofold: (*i*) To reach a better understanding of electrochemical reactions occurring at very cathodic potentials in these melts. This is necessary since some of the electrochemical reactions involving lower oxidation states of refractory metals, such as zirconium (14), hafnium (15), niobium (16), tantalum (17), and tungsten (18) occur at potentials near the deposition of aluminum. (*ii*) To learn whether the deposition of aluminum at solid electrodes other than aluminum itself involves nucleation phenomena of the type previously observed for the deposition of iron and the formation of insoluble $ZrCl_3$ in these melts (14). Nucleation effects in the deposition of silver on platinum from molten alkali nitrates have been thoroughly studied by Hills, Schriffrin, and Thompson (19, 20). These workers, however, pointed out that it is unlikely that similar nucleation effects would be observed in molten halides where predeposition reactions to form a monolayer frequently occur (21). Our results presented below show that nucleation phenomena are important in molten chloroaluminates.

Experimental

Procedures for preparing acidic melts and most other experimental procedures have been described previously (14, 22). The background current density at the glassy carbon electrode was found to be about 240 $\mu A/cm^2$ at $v = 0.1$ V/sec at +100 mV with respect to the aluminum reference electrode in the same melt. Our value of the background current density at the glassy carbon electrode is $\sim$50% lower than the value reported by Boxall *et al.* (23) with the tungsten working electrode in molten $NaAlCl_4$ at 0.1V with respect to the aluminum reference electrode.

The procedure for making the glassy carbon electrode is similar to that of Gupta (24). This electrode was made of a 3.3 mm diameter glassy carbon rod (obtained from Beckwith Carbon Corporation, Van Nuys, California) sealed under vacuum in Pyrex tubing, then cut, polished with 0.5μ alumina and checked for leaks between the glass and carbon. The connection of the glassy carbon to a platinum wire was made with silver paint (Engelhard Industries) to give a good contact. Tungsten electrodes were cleaned by repeated oxidation and reduction using a saturated sodium hydroxide solution containing a small amount of sodium nitrite. Voltammograms and current-time curves were obtained with a PAR Model 174 pulse polarograph coupled to a PAR Model 175 universal programmer. The curves were recorded with either a Hewlett-Packard 7045A X-Y recorder or a Tektronix Model 549 oscilloscope.

$Al_2Cl_7^-$ concentrations were obtained from the known $AlCl_3$/NaCl mole ratios and the calculated mole fractions of Boxall *et al.* (10). Conversion to molar concentrations was made using the melt densities obtained by Fannin *et al.* (25). Molarities of $Al_2Cl_7^-$ are given in Table I.

Results and Discussion

Voltammetric results.—A typical cyclic voltammogram at a glassy carbon electrode in a slightly acidic melt is shown in Fig. 1. The voltammetric peak may be attributed to the $Al_2Cl_7^-$ reduction. The peak current increases with the scan rate and with the $AlCl_3$/NaCl ratio (see below). This peak is followed by the $AlCl_4^-$ reduction (3). Since $AlCl_4^-$ is the main anionic constituent of the solvent, its concentration does not

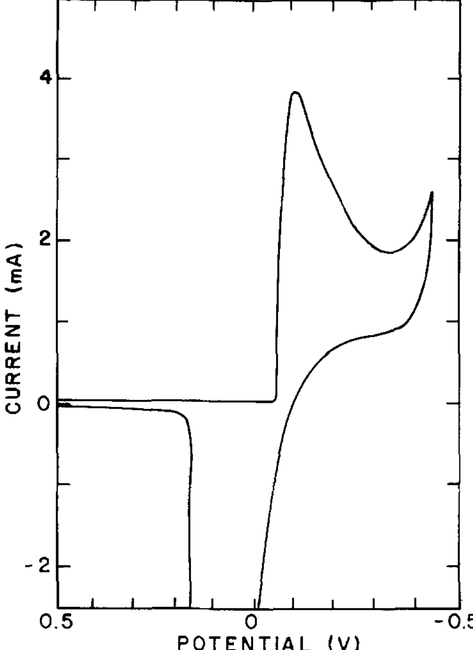

Fig. 1. Cyclic voltammogram at a glassy carbon electrode. v = 0.1 V/sec; t = 175°C; [$Al_2Cl_7^-$] = 0.28M; electrode area: 0.085 cm^2. Potentials expressed with respect to the aluminum reference electrode in the same melt.

change significantly in the composition range studied (10). The reduction potential of $AlCl_4^-$ remains constant in the melt composition range used for this study. When the acidity decreases the peak current decreases and shifts toward the reduction potential of $AlCl_4^-$, as expected for the case of an insoluble deposit (26). This peak disappears in basic melts; in this case only the $AlCl_4^-$ limit is found. The equilibrium potential of an aluminum electrode is given by (3)

$$E = E^\circ + 4/3\, RT/\mathbf{F} \ln [Al_2Cl_7^-] \quad [3]$$

With the electrodes used, the activity of the aluminum metal is not fixed before the reduction and an underpotential deposition could occur (26). Such deposition at activity smaller than unity was observed at the platinum electrodes (Fig. 2). The reduction peak is preceded by an increasing current starting around +100 mV *vs.* the potential of the aluminum reference electrode. For the slow scan rates (<0.2 V/sec) this increase is small but it becomes larger as the scan rate is increased; this is accompanied by the change in the shape of the wave from that corresponding to an insoluble deposit (26) to that of a soluble product. At the same time the reoxidation occurs in two steps; a second peak around +0.4V increases and shifts toward anodic potentials with the scan rate. If the aluminum reduction is avoided, the background does not show a reoxidation current peak at these potentials. This effect was observed only at platinum electrodes and may be attributed to alloy formation.

With the glassy carbon electrode (Fig. 1) an overpotential of ~50 mV was observed. A change in the slope of the reduction current at platinum (Fig. 2) occurs around the same overpotential value. At the tungsten electrode overpotential was much smaller.

For different melt compositions (Table I) the peak current increases with the square root of the scan rate (for slow scan rates) at the three electrodes. The results for the glassy carbon electrodes are shown in Fig. 3. Peak currents are proportional to the $Al_2Cl_7^-$ concentration (Fig. 4).

At fast scan rates the peak current is no longer proportional to $v^{1/2}$ (Fig. 5). A very large cathodic shift with increasing scan rate is also observed for the peak potential E_p (Fig. 6). Hills *et al.* (19) found a similar shift for the deposition of silver in nitrate melts, which was attributed to a nucleation process. In our case, however, the currents are much larger and ohmic drop effects are very difficult to separate from other causes of this shift. It should be noted that the shift is larger for the glassy carbon electrode and, therefore, in this case is not solely caused by an ohmic drop (the currents were comparable at the glassy carbon and tungsten). At platinum electrode the decrease of the param-

eter $i_p/v^{1/2}$ with scan rate is probably caused by alloy formation which along with underpotential deposition becomes more important as the scan rate is increased.

Chronoamperometric and chronopotentiometric results.—Polarographic curves constructed from current-time curves (22, 27) at the tungsten electrode resulted in a linear relationship between E and log ($i_d - i$) which shows that the reduction results in an insoluble product (26). The usual current decay with $t^{-1/2}$ was observed. The slope for the log ($i_d - i$) *vs.* E plot results in an n value of 0.8 ± 0.1, which is in reasonable agreement with the expected value of n = 0.75 for reaction [1].

At glassy carbon electrodes the current-time curves show a different behavior. At small overpotentials there is no reduction current, which is in accord with the overpotential observed in linear sweep voltammetry for the same electrode. For overpotentials larger than −15 mV, after the capacitive current decay, the current increases slowly (Fig. 7a, b) then decreases after reaching a maximum (the decrease is not shown). The time to reach this maximum decreases as the applied cathodic potential is increased. It decreases from 1 min for an overpotential of −20 mV to very short times for potentials corresponding to the polarographic plateau. At the plateau potentials the parameter $it^{1/2}$ for the current decay was constant indicating that the reduction is diffusion limited (this was true for the three electrodes used).

The increasing current has been attributed by Hills *et al.* (19) to the formation of growing nuclei at the electrode. This phenomenon has been previously observed in chloroaluminate melts for the reduction of Fe(II) and Zr(IV) (14). The current growth for the reduction of $Al_2Cl_7^-$ was found to be linear with $t^{1/2}$ with a slope that increases with the overpotential, similar to the results of Hills *et al.* (19). This has been attributed (19) to an instantaneous three dimensional nucleation followed by a growth controlled by hemispherical diffusion of ions to the nuclei. The reproducibility of the slope was affected by the history of the electrode. In order to get reproducible results in the nucleation studies, a stripping potential (1-2V) had to be applied for 10-20 min after the deposition of aluminum. The formation of chlorine at the electrode had to be avoided; if some chlorine was produced at the electrode the increasing current became very small and lasted for very long times even at high overpotentials

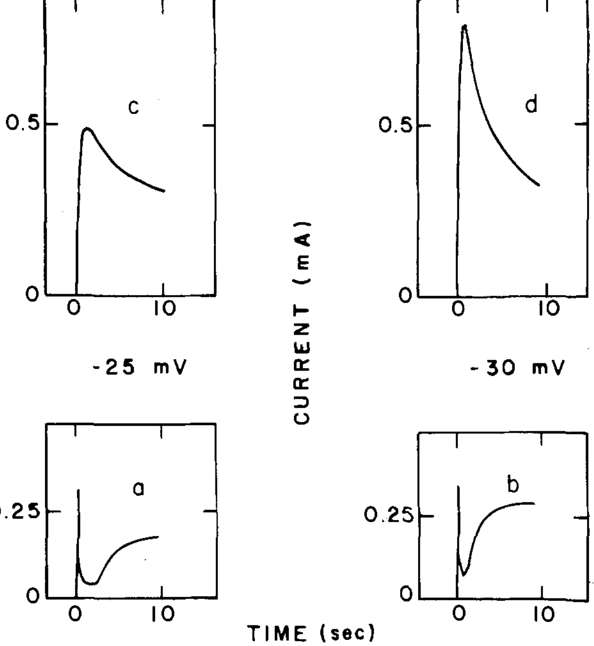

Fig. 7. Current-time curves at a glassy carbon electrode: (a) and (b) single step from the stripping potential (see text) to η; (c) and (d) potential applied in two steps: stripping potential to +10 mV, then to η. (a) and (c): η = −25 mV; (b) and (d): η = −30 mV. t = 175°C; [$Al_2Cl_7^-$] = 0.28M; electrode area = 0.085 cm^2.

indicating a completely different state of the surface of the electrode. For the stripping potentials used (1-2V) if the stripping time was less than 10 min, the nucleation current was found to increase after each cycle. In order to decrease the capacitive current observed when the step from the stripping potential to the reduction potential was applied, two potential steps were used. At first the potential was stepped to a positive potential (+10 mV) where no aluminum reduction occurs at the glassy carbon electrode. The residual current decays to a very small value in a few seconds. The reduction step was then applied and the current obtained (Fig. 7c, d) was much greater than in the case of a single step (Fig. 7a, b) from the stripping potential to the same reduction potential. The nucleation overlap (19) related to the time spent to reach the maximum, was reached in a shorter time and the beginning of the reduction was observed at a lower overpotential (−15 mV) than in the case of the direct step (−20 mV).

It should be stressed that the stripping parameters (time, potential) do not affect the current-time behavior observed at potentials corresponding to the *i-E* plateau for the reduction of $Al_2Cl_7^-$. To show the effect of nucleation at small overpotentials a double pulse technique (20) was used. The potential was first stepped from the stripping potential to the potential η_G (Fig. 8). At this potential (0 to −20 mV with respect to the Al reference electrode) no reduction occurs if there are no nuclei sufficiently large to grow; only a small decreasing residual current is observed. The potential was then stepped for a short time t to a value η_P, where the nuclei are produced and grow. Upon stepping back to potential η_G, for nuclei of sufficient size, a current different from the residual current measured earlier was observed. Now the reduction occurs at η_G resulting in an increasing current. By changing the time spent at η_P a time lag can be found (19); for a time shorter than this time lag no growing current is observed; for a longer time the growth of nuclei is observed. The time lag *vs.* η_P at η_G = −10 mV and −15 mV is shown in Fig. 8.

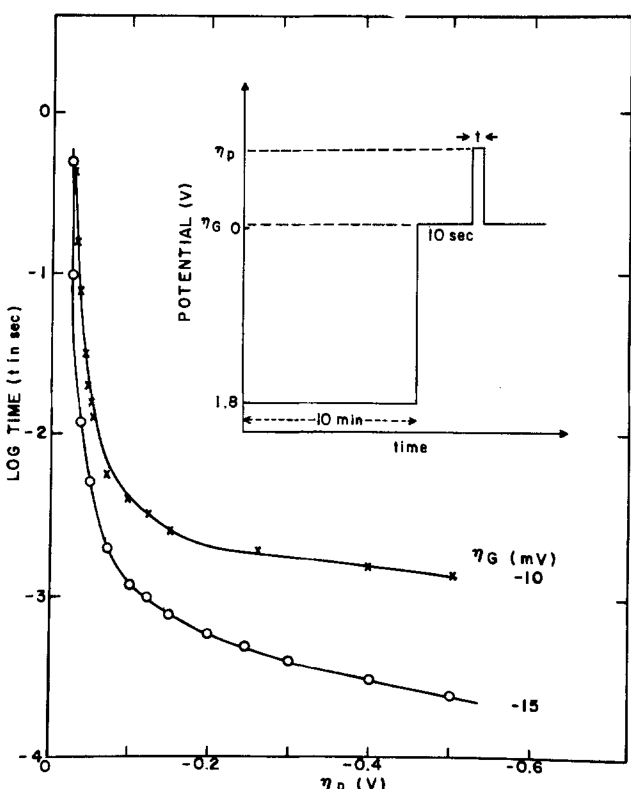

Fig. 8. Time lag *vs.* η_p at two η_G's (see text). Glassy carbon electrode; same conditions as in Fig. 7. Potential-time sequence shown in the insert.

Table II. Diffusion coefficients (cm²/sec) of $Al_2Cl_7^-$ ions determined using different electrodes and methods (t = 175°, $[Al_2Cl_7^-]$ = 0.28M)

Method	Glassy carbon (A = 0.085 ± 0.005 cm²)	Platinum (A = 0.100 ± 0.005 cm²)	Tungsten (A = 0.12 ± 0.01 cm²)
Chronopotentiometry	5.0×10^{-6}	9.6×10^{-6}	3.7×10^{-6}
Chronoamperometry	8.7×10^{-6}	4.6×10^{-6}	5.0×10^{-6}
Cyclic voltammetry	5.5×10^{-6}	3.2×10^{-6}	4.1×10^{-6}

Support for the presence of a nucleation process was also found by chronopotentiometric results. The chronopotentiograms are distorted by an overshoot (14, 28, 29) due to a nucleation overpotential which can be as large as 100 mV at the glassy carbon electrode. The product $i\tau^{1/2}$ is constant for glassy carbon and tungsten electrodes. For these electrodes the ratio of the reverse transition time τ_R and the forward time t was found to be equal to one which indicates that the deposit is insoluble (30). For the platinum electrode, the shape of the chronopotentiogram changes with the current density. For small currents, a small overshoot is observed; the ratio τ_R/t is close to one. When the current is increased the overshoot disappears, the curve becomes less well defined and the ratio τ_R/t becomes 0.3 which shows that the reduction results in a soluble product (30).

Diffusion coefficients.—The diffusion coefficients were calculated using the straight portion of the linear sweep voltammetric i_p *vs.* $v^{1/2}$ plot, the chronoamperometric i *vs.* $1/t^{1/2}$ plots obtained at plateau potentials, and the chronopotentiometric $i\tau^{1/2}$ results. The value of n = 0.75 was used in the equations (see Eq. [1]; this was verified for the constructed polarograms at the tungsten electrode). The results are reported in Table II for the three methods and the three electrodes used. Hills *et al.* (19) found that the presence of the nucleation process introduces discrepancies in D values. This is also reflected in our results, particularly at the platinum electrode where nucleation and alloy formation occur at the same time.

Electrohydrodimerization Reactions

VI. Rotating-Ring Disk Electrode and Macroscale Electrolysis Studies of the Second Reduction Wave of Diethyl Fumarate

Jean-Maxime Nigretto[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The reactions occurring at potentials of the second reduction wave of diethyl fumarate (DEF) in dimethylformamide solutions, where a current dip is frequently observed in the voltammograms in the absence of added proton donors, was investigated. The over-all reaction order was determined by rotating disk electrode studies of the variation in the current at the dip with DEF concentration and theoretical results obtained by digital simulations. Analysis of products of macroscale electrolyses by NMR and mass spectroscopy was also undertaken. Several mechanisms are considered and one in which the electrogenerated dianion is protonated by the parent DEF to produce a carbanion which can initiate formation of dimeric and trimeric species is proposed.

In recent years there have been numerous investigations dealing with the electrochemical reduction of diactivated olefins in aprotic media (1). For example, Baizer *et al.* (2) carried out polarographic, cyclic voltammetric, and macroscale electrolysis experiments and showed that the polarography of these compounds is characterized by two separate reduction waves. Numerous experimental studies of such systems (3-11), utilizing such electrochemical techniques as cyclic voltammetry, double potential step chronocoulometry, rotating-ring disk electrode (RRDE) voltammetry, and electron spin resonance (ESR) spectroscopy have shown that the predominant pathway of the electrohydrodimerization (EHD) reaction for reduction at the first wave consists of formation of the radical anion, $RH_2^{\overline{\cdot}}$, followed by dimerization and protonation

$$RH_2 + e^- \rightarrow RH_2^{\overline{\cdot}} \quad [1]$$

$$2RH_2^{\overline{\cdot}} \rightarrow R_2H_4^{2-} \quad [2]$$

$$R_2H_4^{2-} + 2H^+ \rightarrow R_2H_6 \quad [3]$$

where RH_2 represents the diactivated olefin. Very little work has been reported on the processes occurring at the second reduction step. The polarographic curves for many of the compounds studied show a second reduction wave, while others, like diethyl fumarate (DEF), (*trans*- $C_2H_5O{\cdot}CO{\cdot}CH = CH{\cdot}CO{\cdot}OC_2H_5$) exhibit a current decrease or dip where a wave is expected (2). The presence of a dip where the dianion DEF^{2-} is supposed to be formed has been interpreted as oligo- or polymerization initiated by the dianion. The mechanism of this reaction has not been established. By using cyclic voltammetric techniques and anhydrous working conditions with special steps taken to decrease the rate of the following homogeneous reaction(s) [through temperature reduction to −70°C in DMF (9, 10) or the use of the low electrophilic solvent liquid ammonia at −43°C (11)], the DEF dianion will exist for a sufficient time in the vicinity of the electrode surface to allow its observation. Its reactivity toward incoming parent molecules apparently can also be decreased by adding a proton source to the solution; the protonation of the doubly charged species then takes place, leading to the protonated species, RH_4. In this case, the dip at the second polarographic wave is suppressed and a definite wave is produced. Thus the final distribution of reaction products depends on the concentration of proton source present in the solution, including accidental sources, such as residual water. Cyclic voltammetric and ESR studies show that a third species, probably one formed after the first step, undergoes a reduction at a more negative potential (3, 9, 12). When stationary electrodes are used, the chemical reaction involving the dianion appears to produce some filming of the electrode surface, hindering complete usage of the experimental behavior following the first step for elucidation of the reaction path. However the forced radial convective flux near the electrode surface of the RRDE apparently sweeps away the products quickly enough to avoid these filming difficulties.

This work is aimed at extending the study of the reduction mechanism of DEF in N,N-dimethylformamide (DMF) at the second reduction step. The polarographic behavior exhibited by DEF has been sometimes encountered before with other redox systems and

Key words: dianions, reductive coupling, rotating disk electrode, activated olefins, base-catalyzed reactions.

qualitatively interpreted. However, no quantitative treatment of this behavior at the RRDE has been reported. Because of the reactivity of the dianion toward any proton source, especially careful drying and purification procedures for the solvent and the electrolyte were employed. The second part of this paper deals with the identification of products obtained through bulk electrolysis and a proposed mechanism for the reaction.

Experimental

The general experimental techniques were the same as those reported previously (3-5).

Materials.—The solvent, DMF, was purified as previously described. The supporting electrolyte, *tetra*-n-butylammonium iodide (TBAI), polarographic grade (Southwestern Analytical Chemicals, Austin, Texas) was dried under vacuum and stored under an inert atmosphere. Diethyl fumarate, puriss. (Aldrich Chemical Company, Incorporated, Milwaukee, Wisconsin), was used as received without further purification.

Apparatus.—Coulometric and preparative electrolysis experiments were carried out with a PAR Model 170 Electrochemistry System (Princeton Applied Research Corporation, Princeton, New Jersey). For the RRDE experiments, a Tacussel Electronique potentiostat Model BIPAD-2 was used. A Wavetek function generator provided the potential ramp for voltammetric studies recorded on a Mosley Model 2D-2 X-Y recorder. The RRDE, manufactured by the Pine Instrument Company (Grove City, Pennsylvania) was the same one as previously used (13); the platinum disk in it had a radius of 0.145 cm and was embedded in Teflon. It was driven with a Motomatic Model E 150 tachometer/generator motor (Electrocraft Corporation, Hopkins, Minnesota) using feedback control. The entire motor-electrode assembly was encased in a vacuum-tight mount, equipped with electrical feedthroughs to the motor and electrodes (13). The electrochemical cell used in the RRDE experiments had five glass joints leading to the working electrode assembly, the auxiliary electrode, and the reference compartment, with the remaining joints being devoted to solvent and solute transfers. The cell had a 50 ml capacity. A silver wire isolated in a compartment closed with a fine porosity sintered-glass disk was used as a reference electrode; its potential in the DMF-TBAI system was quite stable during each experiment. The auxiliary electrode was a platinum wire. The electrochemical cell used in preparative electrolysis and coulometric experiments comprised four compartments (auxiliary, intermediate-buffer to prevent catholyte contamination, reference, and working, the last having a 150 ml capacity). A mercury pool electrode was used as a working electrode; the auxiliary and reference electrodes were the same as those described above.

All the experiments were carried out in a glove box filled with a positive pressure of high purity helium (99.995% Matheson Gas Products, La Porte, Texas) and care was taken that neither purified solvent nor supporting electrolyte was ever in contact with the atmosphere following their purification. Furthermore, the following additional procedure was undertaken before each experiment to diminish the concentration of residual water or dissolved air in the solution. A weighed amount of supporting electrolyte was dissolved in the solvent under inert gas pressure and poured into a transfer vessel. After freezing and pumping of the solution, 5 ml of spectrograde benzene were added. Three freeze-pump-thaw cycles were performed and the water-benzene azeotrope was eliminated through vacuum distillation. The solution was then transferred under vacuum into the electrochemical cell, brought to atmospheric pressure with helium, and allowed to equilibrate. Before assembly the electrochemical cell was pumped down for about 1 hr and the platinum disk electrode polished with alumina. The same procedure for purifying the solvent was used for the bulk electrolysis experiments. The catholyte solution had a volume of 120 ml and was saturated with supporting electrolyte (for TBAI, about 0.5*M*). Up to 0.2*M* depolarizer was added in several fractions and the electrolysis was conducted until each fraction had been converted before adding the next fraction. The basicity of the solution increased during electrolysis, and to avoid possible contamination a glass-embedded, rather than Teflon stirring bar, was used. After completion of the experiment, protonation of the remaining reactive species was achieved by pouring about 20 ml water into the solution. The mixture was then evaporated, the residue extracted with ether, washed with water, and the organic layer dried with anhydrous sodium sulfate. The solvent was removed by distillation and the analysis of the reaction products carried out.

Results

A typical RRDE voltammogram of DEF is shown in Fig. 1. The disk curve exhibits a one-electron reduction wave, with $E_{1/2} = -0.76V$ *vs.* the silver wire-reference electrode (Ag-RE), followed by a dip commencing at approximately $-1.60V$ *vs.* Ag-RE. After the short plateau, characterized by the current $i_{d,l}$, the disk current, i_d, increases, due to the background limiting reduction of the DMF-TBAI system on platinum. For the same working conditions, the $i_{d,l}$ value is reproducible within the experimental error and no appreciable filming of the electrode surface seems to occur, since two consecutive runs are essentially superimposable. On the same figure, curve b represents the ring current, i_r, as a function of disk potential, E_d, with the ring potential, E_r, held at 0.0V *vs.* Ag-RE. In absence of kinetic complication, the ratio i_r/i_d (the collection efficiency, N) is only a function of the geometry of the electrode and can be calculated theoretically. In the case of RRDE curves of DEF, the experimental value of N for the first reduction wave equals its theoretical value (0.555 for this electrode), because the second-order rate constant, k_2, of the EHD reaction involving the $DEF^{\overline{\cdot}}$ radical anion, [2], is so small that appreciable reaction of $DEF^{\overline{\cdot}}$ does not occur during its transit from the disk to the ring [$k_2 = 44$ liter/msec (3-6)]. At more negative E_d values, however, the concommitant decrease of i_d and especially i_r, which finally drops to zero, shows evidence of the high instability of the electrogenerated species.

The i_d value in that potential region is proportional to the concentration at the disk surface of species able to undergo reduction, DEF and $DEF^{\overline{\cdot}}$. Hence, the decrease of i_d in a region where the dianion, DEF^{2-}, is presumably formed (by comparison with the behavior

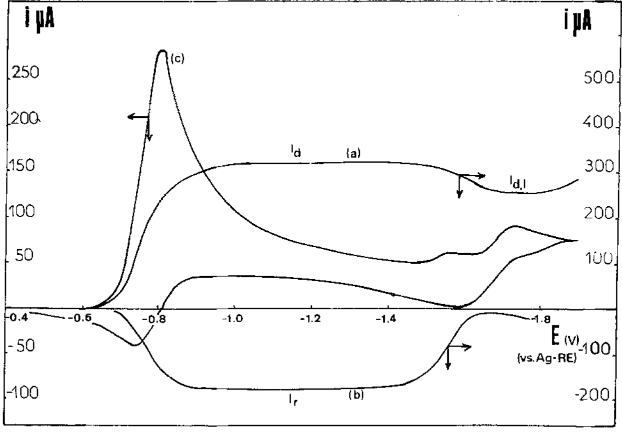

Fig. 1. Diethyl fumarate voltammograms in 0.1*M* TBAI-DMF solutions. RRDE voltammograms. $\omega = 45\ sec^{-1}$; $C = 9.4$ mM. (a) i_d *vs.* E_d, (b) i_r *vs.* E_d with $E_r = 0.0V$ *vs.* Ag-RE. Cyclic voltammogram (c) 200 mV/sec, $C = 12$ mM.

of olefins of similar structure) reveals the existence of a chemical stage involving the interception of incoming parent molecules by the dianion and/or by species formed after reactions of it. Thus the reaction kinetics are concentration dependent, so that for a sufficient concentration of DEF, the $i_{d,l}$ value is lowered to a value smaller than that of the first diffusion plateau. A study of the variation of $i_{d,l}$ with concentration of DEF, C, can then provide information about the nature and the kinetics of the reactions in this potential region. The "information content" of such an $i_{d,l}$ *vs.* C plot is not sufficiently high that the elementary steps or their rate constants can be determined individually. What can be obtained is the over-all reaction order and rate constant. Our approach was to use digital simulations (14) of different reaction sequences involving the dianion assumed to be produced in the region of the dip. We assumed that no further reduction of the dianion at the electrode occurred at these potentials and that the predominant reaction of the dianion was that with DEF. Thus the rate of disappearance of the monomer DEF, by reaction with the dianion could be expressed as

$$-d[\mathrm{DEF}]/dt = k_n[\mathrm{DEF}^{2-}][\mathrm{DEF}]^n \qquad [4]$$

where $n + 1$ represents the order of the equivalent over-all reaction and k_n is a composite rate constant, which is a function of the rate constants of the elementary bimolecular reactions involved in the reaction mechanism, as described later in this paper.

Digital simulation procedure.—A digital simulation of $i_{d,l}$ for different values of k_n and n was undertaken. The general procedure involved the same theoretical treatment as that used previously for a variety of electrochemical and RRDE problems (3-5, 14-17). Its extension to the study of the DEF second reduction wave process of the RDE is fairly straightforward. The program written previously by Prater (15, 16) needed some modifications, with the diffusion and hydrodynamic parts remaining unaltered. The expression for the flux at the electrode surface, and accordingly the normalized current, was written to take care of the new boundary conditions involved in the two-step reduction. To do the simulation in terms of dimensionless parameters, it is convenient to define the current by the ratio of $i_{d,l}$ over the value of twice the limiting current of the first reduction step. This ratio was called CONID. Another dimensionless variable used was $XKTC^n$, defined as

$$XKTC^n = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}k_n\omega^{-1}C^n \qquad [5]$$

which contains the rate constant k_n and the DEF concentration, C. We assumed the same diffusion coefficients for all of the species, D. The other parameters have their usual meaning. The digital program was tested by the simulation of an electrochemical process characterized by two separate reduction steps without kinetic complications. Simulated working curves were obtained for CONID as a function of $\log(XKTC^n)$ for several values of n. One difficulty which often arises in the simulation of electrochemical systems with coupled chemical reactions with large rate constants is that the reaction layer thickness becomes much less than that of the diffusion layer so that only a few elements describe the concentration profile and the accuracy is diminished. In the present study this difficulty was overcome by determining the limiting CONID value for $k_n \rightarrow \infty$ (practically 10^7-10^8), *i.e.*, by the simulation of a totally irreversible reaction of DEF^{2-} with n DEF molecules. Working curves spread across the whole range of normalized rate constants could be obtained by interpolating the accurate values at smaller rate constants toward the limiting one; typical working curves are shown in Fig. 2. From these results curves of CONID *vs.* log(C) for each n and for several values of log(XKT) (where $XKT = XKTC^n/C^n$) were obtained and compared with the corresponding experimental points (Fig. 3). In the experiment $i_{d,l}$ was taken

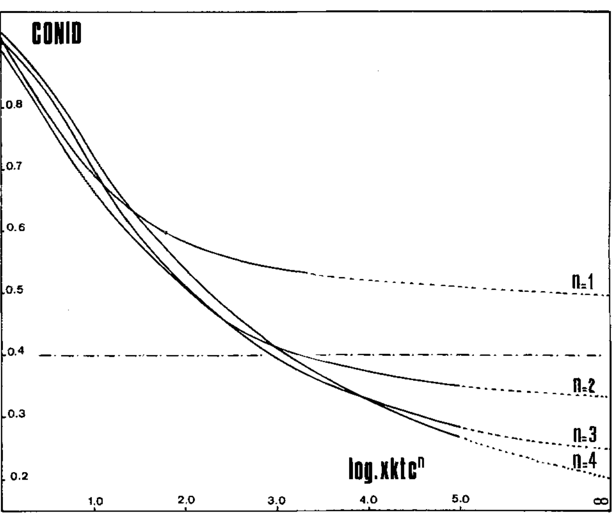

Fig. 2. Simulated CONID *vs.* log($XKTC^n$) curves for several values of *n*.

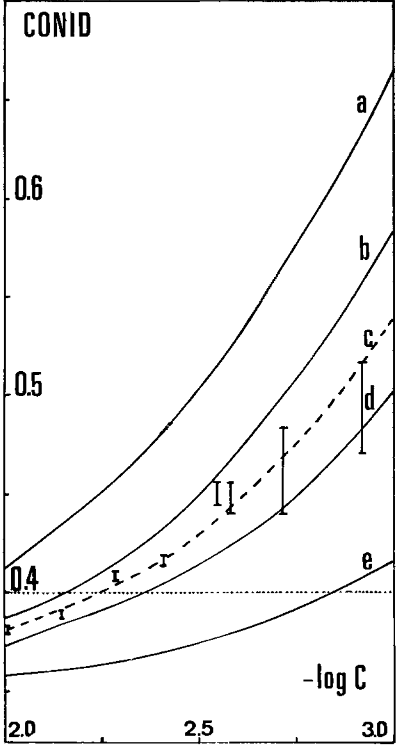

Fig. 3. Simulated CONID *vs.* log *C* curves for $n = 2$ and *XKT* values of: (a) 7×10^7, (b) 3×10^7, (d) 10^8, (e) 10^9. (c) (Dotted line) best fit to experimental results (yielding $XKT = 5.6 \times 10^7$).

at $E = -1.8$V and the concentration was varied between 10^{-2} to $10^{-3}M$. This concentration range proved to be the best for accurate measurements. At concentrations below $10^{-3}M$ side reactions of the dianion with impurity proton donors may be a problem. Measurements were difficult at the relatively high currents observed for concentrations greater than $10^{-2}M$. The choice of the reaction order parameter was made as follows. The slopes of the simulated CONID *vs.* log C plots, such as Fig. 3 at a given point (*e.g.*, CONID = 0.4) differ for different values of n. A plot of the slope for different values of log $XKTC^n$ (Fig. 4) provides working curves which allow a more precise comparison of experimental and simulated data; this comparison leads, within the assumed mechanism, to an n of 2. Once n is known, the value of k_n can be estimated through the best fit between experimental and calculated CONID *vs.* (−log C) curves. The average value for k_n was $7 \times 10^8 M^{-1}\mathrm{sec}^{-1}$.

Macroscale electrolysis results.—Bulk electrolysis experiments were performed to identify reaction products. The same working conditions as the RRDE experiments were used. The reduction was carried out at a continuously stirred mercury pool cathode at a controlled potential of $-1.65V$ *vs.* Ag-RE in anhydrous DMF. For concentrations between 5×10^{-3} and $0.2M$, the apparent number of faradays per mole of DEF, n_{app}, was about the same as for the coulometric reductions performed after the first reduction wave. The vicinity of the third reduction peak and of the background reduction limit did not allow an accurate measurement of n_{app}, but most of the values fell in the range of 0.55-0.65. Thus n_{app} less than one is consistent with the existence of a reaction consuming parent molecules. During electrolysis, the working compartment solution showed a transient yellow color before turning gradually amber. The middle compartment remained colorless. Cyclic voltammograms taken during electrolysis showed a decrease of both reduction peaks with time. At all times during electrolysis no additional peaks were detected and the viscosity of the solution was apparently unchanged.

After completion of the electrolysis, no precipitate could be isolated, which might be formed by a polyaddition reaction initiated at the electrode and continuing in the bulk solution. Systematic attempts using gas chromatography to detect any ethanol (or ethanolate) that might be formed as a result of a subsequent reaction were unsuccessful. Such a possible pathway was first suggested by Nelson (18) to explain results based on ESR measurements. Recently, it was shown that a Dieckmann-type elimination of ethoxide stabilizes the dimeric cinnamate ester dianion (19, 20); however such a mechanism involves a different olefin under different working conditions. Our results demonstrate that EtO^- elimination from the DEF dianion does not occur. A proton NMR analysis was carried out on the isolated electrolysis products and the spectra compared with those of pure samples of hydrodimer, diethylsuccinate, and DEF. The results indicated that no dihydroproduct was formed. Moreover, no peak relative to protons carried by an sp^2 carbon could be detected. The spectra exhibited two major groups at $\delta = 4.15$ ppm(CH_2) and $\delta = 1.30$ ppm(CH_3), arising from several nonequivalent ethyl groups. These major peaks were separated with numerous small groups in the CH and CH_2 region. Integration of this region led to a value of 1.2 nonethyl protons/ethyl group. These results were qualitatively confirmed with C-13 NMR. We attempted to obtain additional information about the molecular weight of the reaction products by using mass spectroscopic techniques. The mass spectrum of pure hydrodimer (M = 346) shows characteristic sequences of peak groups separated by loss of C_2H_5O units ($m/e = 45$) and C_2H_5COO units ($m/e = 73$) beginning with peaks at $m/e = 301$. The parent peak was absent. Qualitatively, the same type of spectra were obtained with the reaction products. The three first peak groups started, in the high range of m/e ratios, at 471, 472, 473-442, 443, 444 and 426, 427, 428. In the lower range, groups of peaks were positioned at m/e ratios arising from loss of units of 45 and 73. Since no peaks were detected at m/e values higher than the above limit, the mass spectra suggest formation of isomeric trimers as the predominant higher molecular weight species.

Discussion

The experimental results indicate that formation of the dianion does not lead to polymer formation and both the RDE results (showing $n = 2$) and the n_{app} results suggest predominant dimer and trimer formation. The absence of ethanol as a product demonstrates that a Dieckmann-type intramolecular cyclization does not occur. Three possible reaction schemes can be suggested, depending on the mode of reaction of the DEF dianion (RH_2^{2-}) with parent molecule (structures are shown in Fig. 5).

1. *Proton transfer scheme.*—The DEF dianion is a strong base and could abstract a proton from incoming parent monomer

$$RH_2^{2-} + RH_2 \rightleftarrows RH_3^- + RH^- \qquad [5]$$

This type of reaction between electrogenerated dianion (as a base) and a second molecule has been discussed by Baizer and co-workers (21, 22) and Iverson and Lund (23). The carbanion RH^- could then react with an additional molecule of incoming parent

$$RH^- + RH_2 \rightarrow R_2H_3^- \qquad [6]$$

in a Michael reaction, with the dimeric species being protonated to yield R_2H_4 or reacting with yet another molecule of RH_2 to form the trimer, R_3H_6. If [5] is rapid and [6] is the rate-determining step, a kinetic expression of the form of [4] would result, with $n = 2$. The n_{app} found for this scheme would depend upon the fate of the RH_3^- species and whether protonation of any of the intermediates (*e.g.*, RH_3^- or $R_2H_3^-$) generates RH^-.

2. *Electron transfer scheme.*—The transfer of an electron between the dianion and parent is thermodynamically favored and would lead to two radical anions (reaction [7])

$$RH_2^{2-} + RH_2 \rightarrow 2RH_2^{\overline{\cdot}} \qquad [7]$$

This route would lead to hydrodimer, R_2H_6, via reactions [2] and [3]. Since the radical anion coupling reaction is relatively slow, about 44 M^{-1}-sec^{-1} under these conditions (3-6), a large fraction of the $RH_2^{\overline{\cdot}}$ produced in the vicinity of the electrode will be reduced to dianion before coupling. The coupling intermediate $R_2H_4^{2-}$ cannot be the major source of the current decrease in the vicinity of the second wave, since it is also produced at the first wave as well.

3. *Direct addition scheme.*—The direct addition of the dianion to parent would lead to a species formally the same as that resulting from the coupling of two radical anions

$$RH_2^{2-} + RH_2 \rightarrow (RH_2)(RH_2)^{2-} \qquad [8]$$

RH_2 RH^-

$R_2H_4^{2-}$ $R_2H_3^-$

R_2H_6 R_2H_4

R_3H_8 R_3H_6

Fig. 5. Structures of various possible species. Y = —C(=O)—OEt

If this species were identical to the $R_2H_4^{2-}$ of reaction [2] appreciable reaction of it with parent, reaction [9], would not be expected. However if this species were different, at least for the time needed to undergo the

$$(RH_2)(RH_2)^{2-} + RH_2 \rightarrow (RH_2)_2RH_2^{2-} \quad [9]$$

subsequent reaction, then production of the trimer, R_3H_8, would be possible at potentials of the second wave. The sequence of reactions [8] (rapid) and [9] (rate determining) would lead to an equation of the form of [4] with $n = 2$. The way in which the two dimeric dianionic species may differ might be analogous to the difference in behavior found in the cross-coupling and self-coupling rates of the radical anions of the *trans*- and *cis*-pair diethyl fumarate and diethyl maleate (17, 24). In that case the *trans*-radical anion couples rather slowly and does not react with acrylonitrile (AN), while the *cis*-radical anion, which isomerizes quite rapidly to the *trans*-form (25, 26), couples about two orders of magnitude more rapidly and reacts with AN. This rather speculative suggestion, that the dimeric dianion has some memory of its origin, at least for a time long enough for it to react further, will require more definitive experiments, probably in a less complicated system, before it can be considered established.

At this time scheme 1, the proton transfer scheme, appears most reasonable, although we did not detect an ethylenic double-bond in the products by NMR analysis, as would be expected in the unsaturated dimer or trimer R_2H_4 or R_3H_6. These species might also be reducible at potentials of the second wave, since they contain the basic DEF grouping, and thus undergo further reduction and protonation in the macroscale electrolysis experiments. Addition of proton donor, even a relatively weak one such as water, causes an increase in the current at the second wave by competing with RH_2 as a proton source. In the absence of RH^- interception of the incoming parent compound is avoided.

Glow Discharge Polymerization of Tetrafluoroethylene, 1,1 Difluoroethylene, and Chlorotrifluoroethylene

D. W. Rice* and D. F. O'Kane*

IBM Corporation, General Products Division, Materials Science Laboratory, San Jose, California 95193

ABSTRACT

Thin polymer films were prepared by electrodeless glow discharge polymerization of tetrafluoroethylene ($CF_2{=}CF_2$), 1,1 difluoroethylene ($CF_2{=}CH_2$), and chlorotrifluoroethylene ($CFCl{=}CF_2$) monomers. The chemical composition of the films prepared both in and out of the glow discharge region was measured by x-ray photoelectron spectroscopy (XPS) and compared to bulk polymer standards. The glow discharge polymers exhibit a complex carbon 1s XPS spectrum as compared to the bulk standards. A minimum of four bonding states for carbon is clearly seen, with relatively high concentrations of —CF_3, $-\overset{|}{\underset{|}{C}}-F$, $-\overset{|}{\underset{|}{C}}-$ in addition to —CF_2—. The polymer surface composition is clearly dependent on position with respect to the discharge region. The bond assignments are in close agreement with a simple electrostatic model. Polymer surface tensions were obtained using the concepts of critical surface tension and dispersion forces. They correlated well with the concentration of —CF_3, —CF_2— on the surface as measured by XPS. The porosity of the films is shown to be significantly less than metal coatings of similar thickness.

Glow discharge polymerization offers an exciting alternative to classical methods of polymer synthesis. The types of polymers are potentially limitless because the combination of gases entering the discharge are equally as large. Thin, uniform, amorphous, pore-free films can be prepared with a variety of properties for optical, electronic, corrosion, wear, and surface applications. A large number of film types have been prepared by this process (1). The detailed deposition mechanisms are poorly understood. Electrons, metastables, ions, atoms, and free radicals are all present in the plasma and may be important in the polymerization process (2). Further complications are the presence of rf-generated photons and surface sputtering processes.

This study was designed to compare the deposition of thin polymer films prepared by the electrodeless glow discharge polymerization of tetrafluoroethylene ($CF_2{=}CF_2$), chlorotrifluoroethylene ($ClCF{=}CF_2$), and 1,1 difluoroethylene ($CF_2{=}CH_2$) monomers. The former two monomers were chosen because of the excellent chemical stability and low permeability of bulk polymers prepared from them. The latter monomer, $CF_2{=}CH_2$, was chosen to test the relative stability of the two types of carbene free radicals; $:CF_2$ and $:CH_2$. Particular emphasis was given to the polymer composition as a function of distance from the rf coils. A previous paper that discussed the process details for polymers prepared from $CF_2{=}CF_2$ showed this to be very important (3). X-ray photoelectron spectroscopy, surface energy, and corrosion protection properties are the main topics of this paper. Fluorocarbon-type films have been deposited by glow discharge polymerization in a capacitively coupled electrode-type system; the films that were deposited on alkali halide crystals were pinhole free, chemically resistant, and adherent (4).

Experiment

Figure 1 shows the thin polymer film deposition system. A 500W, 13.56 MHz rf generator (LFE Corporation) was used to inductively couple to the respective monomers flowing through a fused silica tube. No carrier gas was used in these experiments.

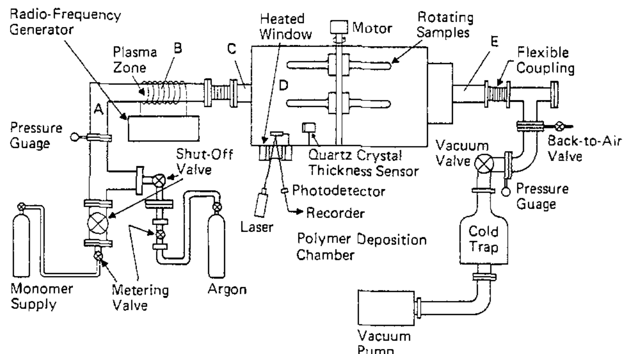

Fig. 1. Glow discharge thin polymer film deposition system

The unique feature of this system is the deposition chamber outside of the rf coil region. This minimizes substrate heating of materials that couple to the rf source. Deposition was carried out on NiFe (100 nM) coated glass microscope slides placed in regions A to E; however, for this report films prepared in the rf plasma (region B) and in the deposition chamber (region D) will be the focus of our attention. A piezoelectric quartz thickness monitor in the deposition chamber was used to monitor film growth. Generally, the rate of deposition in the plasma region was 10^3 greater than in the deposition chamber. The substrates were ultrasonically cleaned in hexane, acetone, and isopropanol, followed by an *in situ* argon (60W) plasma cleaning just prior to polymerization. Table I shows the process conditions used for the three monomers in this report.

X-ray photoelectron spectra, commonly referred to as ESCA, were measured on a dispersion-compensated monochromatized spectrometer using Al($K\alpha$) radia-

tion (Hewlett Packard ESCA 5950A). The resolution of this instrument is 0.8 eV for the carbon 1s binding energy (*BE*). The gold $4f_{7/2}BE$ at 83.95 eV was used as the reference energy by evaporating a fraction of a monolayer of Au onto the polymer surface in the spectrometer. Argon ion etching was used to demonstrate the fragile nature of these type polymer materials to sputtering, a fact clearly demonstrated by Collins for bulk PTFE (5).

XPS is surface sensitive due to the short path length of the escaping photoelectrons. For example, 90% of the intensity comes from the top 3.5 (35Å), 2.3 (23Å), 3.7 (37Å) nM for the C(1s), F(1s), and Cl(2p) electrons, respectively, if one uses the escape depths published for homogeneous materials (6). There is considerable debate regarding the applicability of these escape depths to amorphous systems and the actual escape depth may be twice that given above. We assume the surface composition is the same as the bulk for this study. Evidence to support this assumption is that the bulk analysis of carbon and fluorine in a plasma polymer deposited from $CF_2{=}CF_2$ agreed within 4% with the XPS quantitative results. Both peak position (*BE*) and integrated intensity (*I*) were measured. Manual curve fitting of the complex 1s spectrum was also used in making quantitative statements about the bonding of carbon. Sensitivity factors used in this study were based on our bulk standards work. These were 1.0, 0.20, and 0.48 for F(1s), C(1s), and Cl(2p), respectively.

XPS is well suited to fluoropolymer studies because of the highly electronegative fluorine atom that causes large C(1s) shifts and the long-lived final states that minimize relaxation effects observed in transition metals. The technique has been extensively applied to bulk fluorocarbon polymers (7, 8). We repeated bulk studies on FEP Teflon $[(CF_2{-}CF_2)_x\ (CF_2{-}CF(CF_3){-})_y]$, polyvinylidene fluoride $[(CF_2{-}CH_2)_x]$, and polychlorotrifluoroethylene $[(ClCF{-}CF_2)_x]$ for comparison to the plasma polymer analogs and as a check on our *BE*'s. Table II shows the measured *BE* of the bulk polymers and compares them to the values obtained by Clark and Feast (7). The carbon (1s) levels are in good agreement; however, our F(1s) BE_3 are generally lower by 1-2 eV. It is not clear why these differ if one assumes both instruments were calibrated over the complete *BE* scale. Based on this assumption, the facts suggest our polymers had more ionic character in the C—F bond than those of Clark and Feast.

The surface energies of the deposited films were evaluated using both the concept of critical surface tension developed by Zisman (9) and dispersion force arguments popularized by Fowkes (10). The two methods agreed within experimental error, therefore, only an average solid surface tension (γ_S) is reported. Contact angles were measured with a Rame Hart Model A-100 goniometer using hexane, heptane, tetradecane, hexadecane, 1 methylnaphthalene, ethylene glycol, and polyethylene glycols as reference fluids. Infrared spectra were taken on a Perkin Elmer 457 spectrometer. The complex nature of the deposited films coupled with the lack of precise group absorption assignment for macromolecules and broad CF stretching bands makes the infrared work very qualitative.

The pore density of the coatings was measured optically after exposing the polymer-coated reactive NiFe metal/glass substrates to an accelerated gaseous test environment. The test conditions are given in Table III with time a variable. This environment "decorates" pores in the polymer film by corroding the metal film.

Results and Discussion

Polymers were deposited from all three monomers. The deposition rate in the chamber (region D) differed by approximately a factor of 10; $CF_2{=}CH_2$ going down most rapidly and $ClCF{=}CF_2$ least. The plasma polymers are quite different from bulk and exhibit a strong composition dependence on location with respect to the rf coils in most cases. The surface energy reflects these differences. Strong evidence for very high cross-linking is given. The polymers prepared in the plasma tend to be brittle and nonadherent. The films in this region take on a yellow to light brown color. The polymers deposited in the chamber (region D) are adherent and colorless. The failure of the reactive metal undercoat is via pores in the film not general film degradation. The pore density is significantly less than gold coatings of similar thickness. The polymers prepared from $CF_2{=}CF_2$ and $CF_2{=}CH_2$ are insoluble in Freon PCA while those prepared from $ClCF{=}CF_2$ are soluble.

Table IV gives the XPS and surface energy results for the three systems studied. Figure 2 graphically illustrates the carbon (1s) region of the XPS and clearly demonstrates the differences between plasma and bulk polymers. With these few introductory remarks, we will now discuss each system separately except for the pore density study.

$CF_2{=}CF_2$.—These glow discharge polymers show strong evidence of cross-linking and a relatively high concentration of $-CF_3$ functional groups in the XPS spectra. The assignment of particular C(1s) binding energies to a given functional group is based on a combination of the bulk standards and a simple electrostatic potential model for group electronegativities (11). Using the relative sensitivity and *BE* data in Table IV allows us then to calculate both total atomic composition and distribution of this composition between various functional groups. Table V summarizes these results.

The polymers prepared in the plasma show an atomic composition that is quite rich in carbon com-

pared to the starting monomer, while the chamber-deposited polymer shows enhanced levels of fluorine. Furthermore, as shown in Fig. 2, the polymers pre-

pared in the plasma have approximately equal quantities of the four major carbon functional groups ranging from carbon with four carbon nearest neighbors to $-CF_3$. The network structure of this polymer is quite complex and suggests a high concentration of cross-links. The chamber-deposited polymer (region D) shows a preponderance of $-CF_2-$ with a relatively high concentration of $-CF_3$ (13%). The two lower *BE* peaks are small but significant. It is interesting to note that the FEP standard showed evidence of $-CF_3$ and $-\overset{|}{\underset{|}{C}}-F$ in addition to the main $-CF_2-$ group. No evidence was seen for a carbon surrounded by four carbon nearest neighbors. When the chamber-deposited polymer is sputter etched for 60 sec with argon ions (1000V), the surface is dramatically converted to a spectra like that observed in the plasma region, *i.e.*, high carbon contents and large $C-\overset{|}{\underset{|}{C}}-C$ concentrations. This merely suggests resputtering plays an important role in the plasma deposition process.

Millard and Pavlath have studied the plasma deposition of $CF_2=CF_2$ on wool fabric and plastic surfaces. In their capacitively coupled system, they find a complex polymer much like that observed in our glow region. Our *BE* are in reasonable agreement; however, their functional group assignment is complicated by the presence of oxygen in the polymer and poor instrument resolution (12).

The infrared spectra of the polymers deposited in the two regions are quite different. The plasma-deposited films yield a very diffuse spectrum, while the deposition-chamber polymers have a spectrum much like PTFE. A small shoulder at 975 cm^{-1} provides some evidence for C-F groups in agreement with XPS (3).

The surface tension (γ_S) of the glow discharge polymers is consistent with the XPS results. The chamber-deposited films have a very low surface tension, 12 dyne/cm, indicative of a high surface concentration of $—CF_3$ (9). This is considerably lower than bulk FEP. The surface purity of the glow discharge polymers is significantly better than the bulk polymers. The XPS O(1s), N(1s), and C(1s) hydrocarbon intensities were used as a measure of purity. This may be an alternative explanation for the low surface tension in the chamber polymers. The polymers prepared in the plasma have higher surface tensions than the standard. The higher concentration of lower binding energy forms a carbon dominate in this latter case.

The lifetime of the reactive components, be they surface or gas phase, are quite different as indicated by the large differences in polymer composition with respect to the rf coils. One can speculate that in the deposition chamber adsorption of the monomer to free radical chain ends is the dominate propagation step. Resputtering is probably very minimal and, hence, the side groups would be formed in the gas phase. In the plasma zone resputtering processes are speculated to remove fluorine or $—CF_2—$, $—CF_3$ groups preferentially, yielding a far more complex propagation step.

$CF_2{=}CH_2$.—The polymers prepared from $CF_2{=}CH_2$ show marked similarity in both the plasma and deposition chamber compared to the significant differences observed for the $CF_2{=}CF_2$ materials. They are quite complex and have a fluorine surface concentration significantly less than the bulk polymer. Table VI shows group assignments and distribution of carbon functional groups. It is important to note that XPS cannot detect hydrogen and, hence, interpretation of this system is more speculative. The low binding energy form of carbon can be a complex combination of carbon with four nearest carbon neighbors or $C—CH_2—C$ (hydrocarbon). Infrared spectra confirm the presence of both CH stretching (2930 cm^{-1}) and deformation (1450 cm^{-1}).

The surface tensions for polymers prepared in both regions are greater than the bulk polymer. This supports the reduced levels of $—CF_2—$ groups observed in the XPS study.

The deposition mechanism for this mixed hydro- and fluorocarbon system is not simply the deposition of a material originating from difluoro carbene in one region and dihydro carbene in another. The important reactive monomer may, however, be monofluoroacetylene originating from HF removal in the plasma. The carbon-to-fluorine ratio is consistent with this picture; however, the complex C(1s) XPS shows this not to be the whole story.

$ClCF{=}CF_2$.—Examination of the two deposition regions clearly demonstrates the complex nature of these plasma films compared to bulk polychlorotrifluoroethylene. Bond assignments are complicated in this system because of the various combinations of the constituents that yield similar binding energies, for example, the calculated *BE* of $—CCl_2F$ is within 0.2 eV of $—CF_2—$ (11). The atomic composition, as measured by XPS (Table VII), shows both fluorine and chlorine at lower levels in the plasma polymers. Just as in the $CF_2{=}CF_2$ system, the polymers prepared in the plasma show a higher concentration of the lower binding energy forms of carbon.

The surface tension measurements show that the polymers prepared in both regions have lower values than the bulk. For the chamber-deposited films, where the γ_s is close to that of PTFE, the XPS peak at 291.0 must be predominately due to $—CF_2—$ groups.

The relatively low concentration of chlorine in the chamber polymers supports preferential removal of —Cl from the monomer compared to fluorine.

Barrier Properties

The pore density tests using a reactive transition metal (NiFe) substrate show convincingly that the polymers deposited in the deposition chamber provide superior atmospheric protection to metallic coatings of similar thickness. The pore sizes increased linearly as a function of test exposure time while the pore density reached a plateau. This is used as indirect evidence that these polymers are not severely degraded by the accelerated test conditions. Figure 3 shows the pore density of the chamber-deposited $CF_2{=}CF_2$ films as a function of thickness and compares them to gold overcoats on nickel (13). The insert shows the time behavior of the pore size and pore density. The low pore density is speculated to result from the amorphous character of these materials coupled with the uniform *in situ* cleaning and deposition. These results support the work of Hollahan, Wydeven, and Johnson (4).

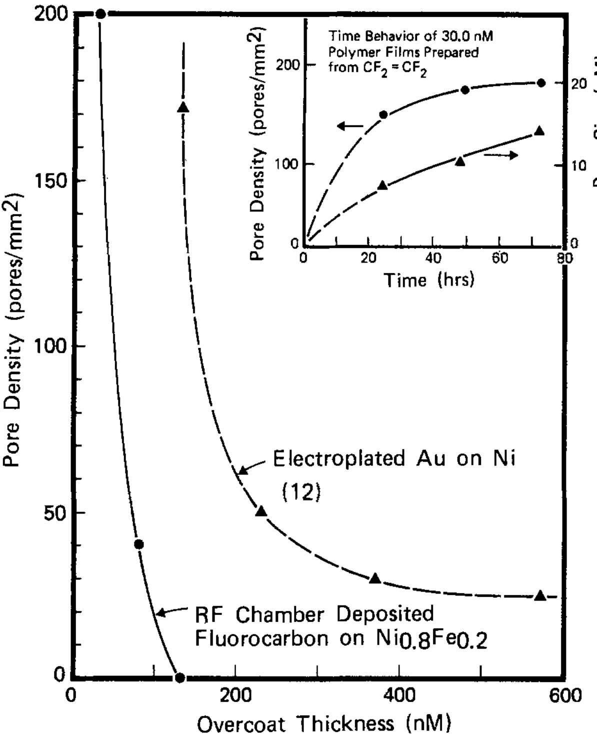

Fig. 3. Pore density as a function of film thickness for fluorocarbon-like plasma polymer on $Ni_{0.8}Fe_{0.2}$ and Au on Ni. Insert shows time behavior of pore density and pore size for 30.0 nM polymer film.

$CFCl=CF_2$ monomers exhibit compositions and surface tensions significantly different than bulk polymers prepared from these monomers. The XPS data clearly demonstrate a deposition location dependent composition for the fully halogenated monomers. This method of deposition may provide valuable indirect evidence of reactive specie lifetime. A multitude of C(1s) binding energies are observed for all polymers deposited in the plasma (region B). The low binding energy form suggests cross-linking and complex network formation. The solid surface tensions can generally be rationalized by the relative amounts of CF_3, $—CF_2—$ surface concentrations. The barrier properties of these films are much better than crystalline metallic coatings of similar thickness.

Electrochemical Investigations Concerning Ca^{2+} Binding to Spectrin

E. Brauer,* K.-D. Kupka, and V. Rudloff

Institute of Physical Chemistry, University of Frankfurt/Main and

Max Planck Institute of Biophysics, Frankfurt/Main, Germany

ABSTRACT

Spectrin, a protein located at the inner surface of the red blood cell membrane, was isolated and investigated with respect to the binding of calcium. Aggregation phenomena were found to be due to the age of spectrin. The electrostatic interaction factor using the Linderstrøm-Lang method was found to be very weak, $w < 0.01$. Calcium binding occurred at 780 sites as indicated by Scatchard plots based on titration curves using a calcium-sensitive electrode. Titration curves showed in addition the occurrence of conformational changes. The presence of calcium caused the formation of filaments seen in the electron micrographs. The results of binding studies of calcium to spectrin may give information about the influence of calcium on the change of shape of red cell membranes in which spectrin is suggested to be involved.

In red cell membranes (RBC membrane) the presence of calcium controls the membrane transport and even determines the cell shape. Many investigations have been done for elucidating the mechanism of the calcium action with respect to cell shape (1-5). The interaction between calcium and the inner part of the cell membrane was found to be the reason for this phenomenon. Some investigators suggested a high molecular weight protein was responsible for the binding of calcium (6, 7). It was Marchesi (8) who first isolated a protein located at the inner surface of the membrane and called it spectrin.

Since the development of Ca^{2+}-sensitive electrodes by Ross (9), it is possible to examine directly the amount of Ca^{2+} ions bound by the protein and to estimate the interaction between this divalent cation and the protein, especially if it relates to the changes of cell shape.

Preparation of the Material

Red blood cells were prepared according to the method of Dodge *et al.* (10). Spectrin was extracted by washing cells several times with Tris/HCl buffer, *p*H 7.6, and then haemolyzing them in the diluted buffer solution. The deciding step of separating the protein from its surroundings was bringing it into solution of low ion content. The composition of the material and the yield varied with *p*H, temperature, and the duration of incubation. It underwent an aging process which was dependent on such parameters as temperature, time between the isolation and the beginning of measurements, etc. (11).

Standard preparation was carried out in the following way: dialysis of the protein solution in low ionic strength solvent against distilled water adjusted with NaOH to *p*H 8 over night in the cold, thereafter separating the solubilized and unsolubilized membrane components in an ultracentrifuge at 50,000 rpm for 3.5 hr at *p*H 8. The material was controlled by SDS-gel electrophoresis, immediately after preparation as well as just before being used in the binding experiment. Neither EDTA nor mercaptanes were used during preparation. Electrophoretic analysis indicated that 80% of the solubilized material was spectrin and higher molecular aggregates of spectrin. Figure 1 shows a densitometer trace of spectrin prepared by the standard method.

Key words: calcium binding, bioelectrochemistry, Ca^{2+}-sensitive electrodes, spectrin.

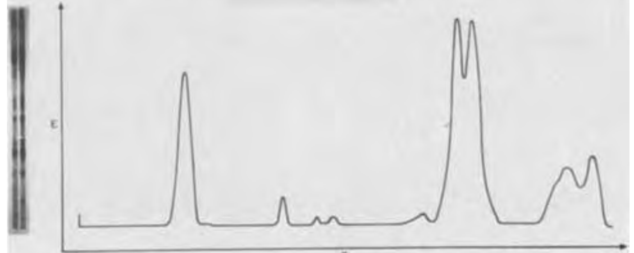

Fig. 1. Densitogram of an electrophoretic run of spectrin prepared at *p*H = 8.5.

Electrometric Titration with Pure Spectrin

A possible way to identify ionizable amino acid side chains of a protein is afforded in principle by an electrometric titration. Spectrin prepared in the standard manner shows a maximum number of titrable groups in the alkaline region to be a function of time after preparation, Table I. It is obvious from these data that spectrin undergoes a process of aging finished 20 hr after preparation. This final state is found in presence of calcium ions (1 mmole/liter) immediately after preparation.

The complete titration curve allows the number of all groups titrable in spectrin to be estimated. There is protonation in an acid branch representing about 1000 groups and deprotonation in the alkaline branch representing about 500 groups. The total number of about 1500/molecule of spectrin is in rather good agreement with the recently published value of 1663 by Fuller (12).

Multiple equilibria.—The titration curve within a range of *p*H 2-11.5 was found to be reversible. Fuller (12) referring to a molecular weight of 460,000 reports 122 histidine imidazole groups. These groups have been reported by Tanford (13) to deprotonate from *p*H 7-9.5.

Table I. Titrable groups in the alkaline range as a function of the time after preparation

Time	No. of titrable groups
15 min	Not detectable
1 hr	136
2 hr	187
6 hr	235
20 hr	500

Since in this region no other groups dissociate or associate the application of the treatment developed by Linderstrøm-Lang (14) seems to be justified.

The model of Linderstrøm-Lang takes into account the electrostatic interaction of binding sites. One may obtain a measure of the interaction by evaluating the factor w, according to the equation

$$p_K - 0.868wz = \mathrm{pH} + \log\left(\frac{\bar{\nu}}{n - \bar{\nu}}\right)$$

where p_K = internal p_K for imidazole groups, not identical with p_K for a single group, w = electrostatic interaction factor, z = number of elementary charges per molecule, $\bar{\nu}$ = number of dissociated groups of a kind, and n = maximum number of $\bar{\nu}$.

Using the ionic strength of 0.01 we found $w < 0.012$ with pH $\sim$ 8. That means the electrostatic interaction is very weak. A comparison with the data of Tanford (Table II) shows a tendency of electrostatic interaction factor to decrease with increasing molecular weight.

Ca^{2+} Binding

Electron micrographs.—A growing tendency to form fibrils with increasing concentration of $CaCl_2$ could be detected by electron microscopic examination (Fig. 2). Alignment and formation of long chains were obviously a function of calcium ion content although this effect is overlapped by the drying process.

Sedimentation constants.—The conditions of aggregation in the original solution can be obtained using the analytical ultracentrifuge (Beckman/Spinco, Model E). The sedimentation constant of spectrin determined on solution (0.75 OD/ml), free of Ca^{2+} in good agreement with Clarke (15), was found to be 5.3 sec. A solution containing 1 mmole/liter of $CaCl_2$ resulted in 10.4 sec, a twofold increase. It seems to be justified to assume that dimers of spectrin are built up in the presence of $CaCl_2$.

Titration with Ca^{2+} sensitive electrode.—Direct information concerning Ca^{2+} binding was obtained by using the Ca^{2+} ion selective electrode of Orion. It determines the concentration of free Ca^{2+} in a solution. When the total Ca^{2+} concentration of the sample is known, the amount of bound Ca^{2+} can be calculated. A surprisingly high number of about 780 binding sites for Ca^{2+} per molecule spectrin was found (Fig. 3).

Provided that the binding sites for Ca^{2+} are equivalent and independent the representation of the results by a Scatchard plot (16) (Fig. 4) gives a straight line for each species of binding site. In the case of spectrin one can distinguish two kinds of sites. One branch indicates strong binding with a maximum number of n_1 = 180 sites and k_{assoc} of 22 $\times$ 10^3 liter/mole and a weaker binding with a maximum number n_2 = 600 and k_{assoc} = 0.93 $\times$ 10^3 liter/mole.

The titration curve obtained on protein after one and three days does not fulfill the conditions for application of the Scatchard plot.

To give an idea of the mechanism of Ca^{2+} binding the influence of pH can be used. Variation of pH showed clearly an increment of Ca^{2+} binding with increasing pH. This may be interpreted as a competition effect of H^+ and Ca^{2+} binding to the same amino acid side chains.

Table II. Calculated values for w at 25°C for different proteins according to Tanford (13)

Protein	Mol. wt	w for ionic strength 0.01
α-Corticotropin	4,541	0.218
Ribonuclease	13,683	0.137
β-Lactoglobulin	35,500	0.088
Serum albumin	65,000	0.066
Spectrin	460,000	<0.012

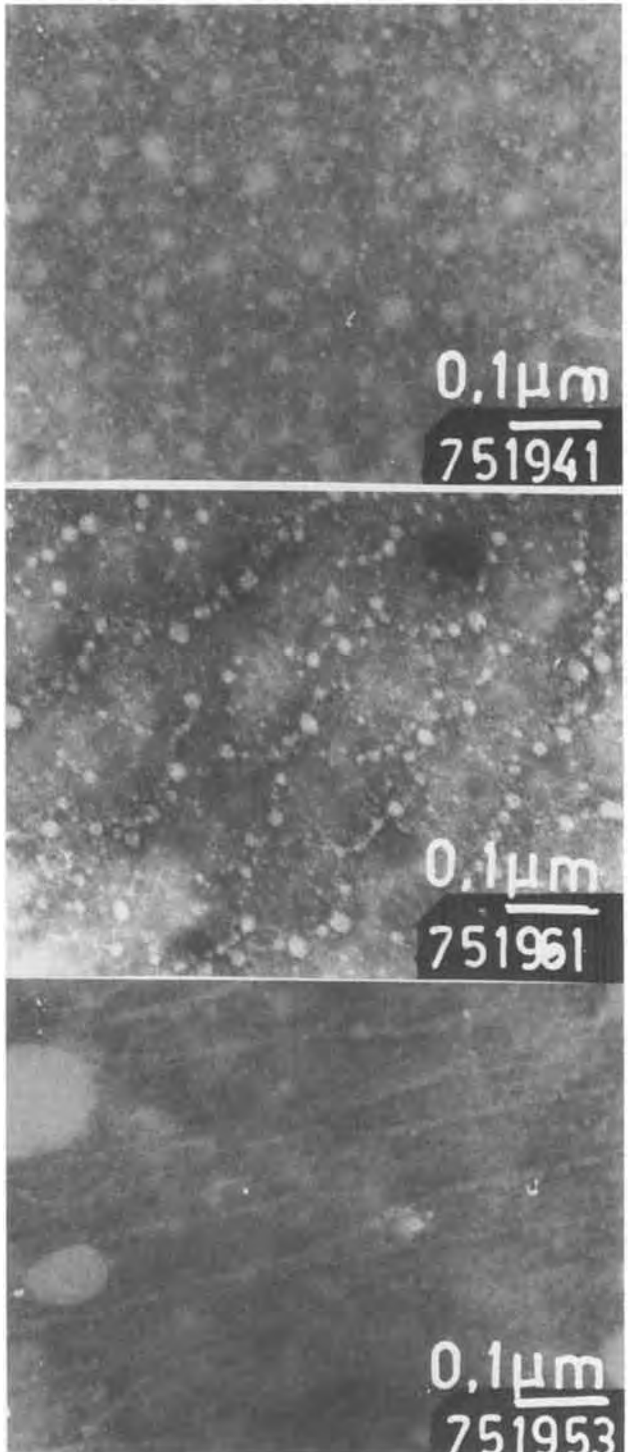

Fig. 2. Electron micrographs of (a, top) spectrin pure, (b, center) spectrin in 1 mmole/l $CaCl_2$, and (c, bottom) spectrin in 2 mmole/l $CaCl_2$, negative staining in 0.1 OD/ml spectrin, 1/100,000.

Electrometric titration of spectrin solution containing Ca^{2+}.—In contrast to the acid-base titration of fresh pure spectrin we got a complete electrometric titration curve if Ca^{2+} was present. Moreover this curve was not reversible in the range pH 7.5-10, which suggests conformational changes due to the presence of Ca^{2+} (Fig. 5).

Discussion

The Ca^{2+} binding to spectrin depending on pH allows the estimation of the mechanism thereof. A competition between H^+ ions and Ca^{2+} ions for the binding sites of the amino acid side groups seems to be possible.

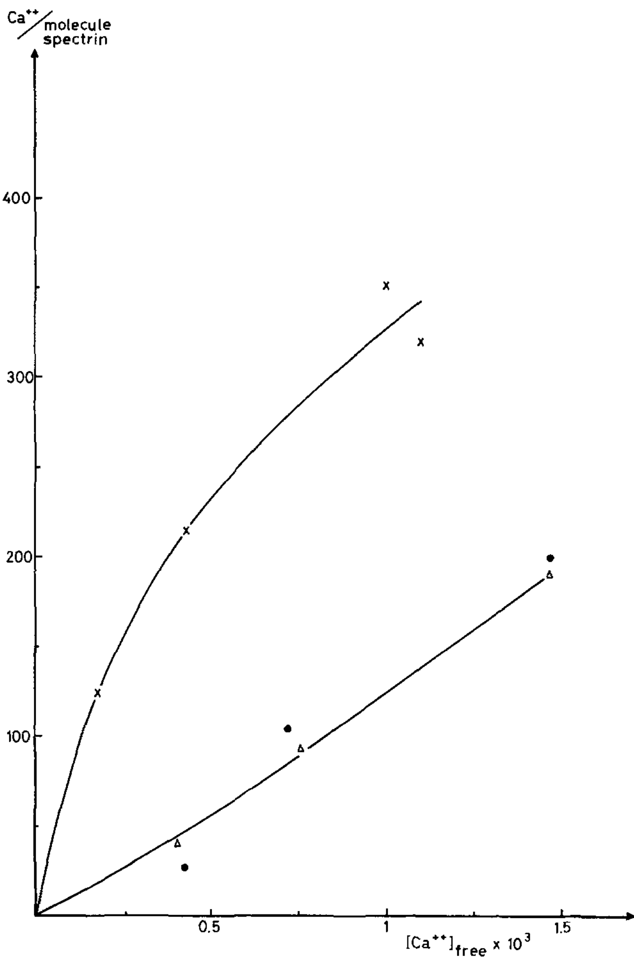

Fig. 3. Ca^{2+} binding on spectrin prepared at $pH = 8$, measured at 22°C. × freshly prepared spectrin, △ after 1 day, ● after 3 days.

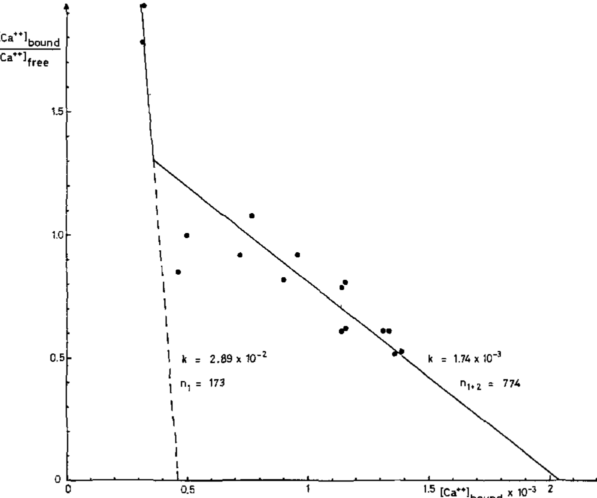

Fig. 4. Ca^{2+} binding on spectrin. Scatchard plot of binding curve measured immediately after preparation at $pH = 8$ at 0°C (curve x in Fig. 3).

Forstner and Manery (17) state that carboxylic groups of glutamic acid and aspartic acid are responsible for high affinity calcium binding. Mikkelsen and Wallach (18) find high affinity calcium binding to the phenolic hydroxyl groups of tyrosine.

Another interpretation of the binding mechanism is offered for the low affinity binding sites. There are two reasons: (*i*) the high number of sites, and (*ii*) the observation of dimers and fibrils of spectrin in the presence of $CaCl_2$. By analogy to the adsorption of Ca^{2+} ions to the electrically charged surface of erythrocytes reported by Seaman *et al.* (19) the accumulation of Ca^{2+} ions on spectrin molecules could be based on the electrostatic attraction of the negative charges, the number of which is determined by electrometric measurements being about 450 in the *p*H range 7-8.

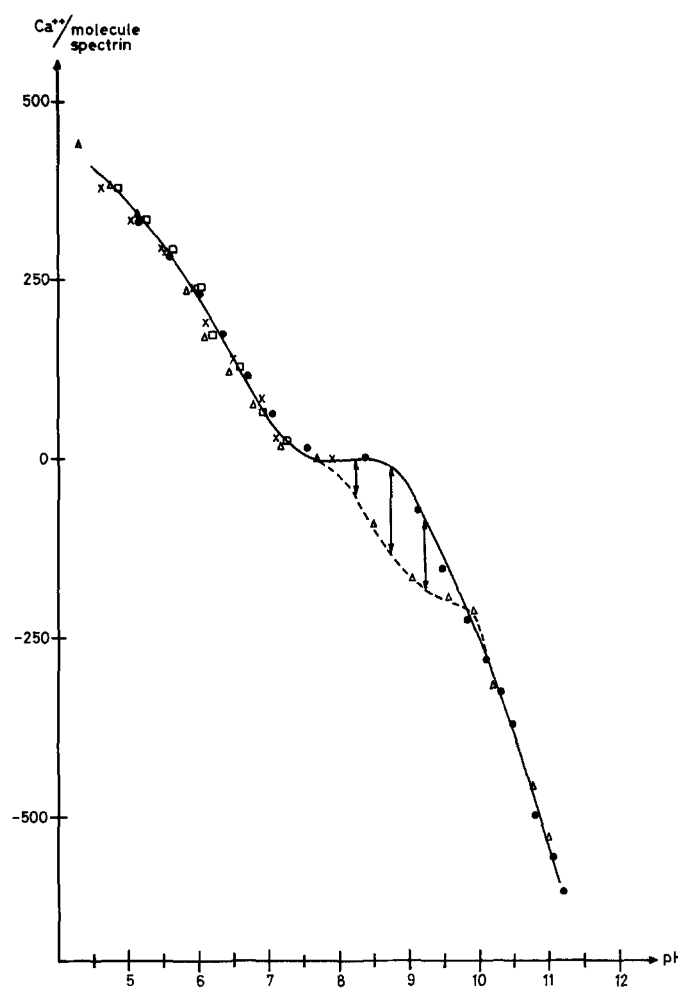

Fig. 5. Electrometric titration on spectrin freshly prepared with 1 mmole $CaCl_2$. × neutral-acidic direction, ● acidic-basic direction, △ basic-acidic direction, □ acidic-neutral direction.

The weak electrostatic interaction of the sites, found by the Linderstrøm-Lang analysis, indicates the binding sites to be relatively strongly fixed in their surroundings. That means that a probable geometric arrangement of the Ca^{2+} ions would be bridging two sites of neighboring molecules, respectively, thus causing the aggregation of spectrin molecules.

Long and Mouat (20) find the Ca^{2+} binding to ghosts (haemolized erythrocytes) to be three times more effective than to intact erythrocytes. Duffy and Schwarz (7) suppose that 80% of the Ca^{2+} binding to the RBC membrane is caused by the protein fraction. Therefore spectrin, as a prominent protein of the inner membrane surface [see Haggis (21); Nicolson, Marchesi, and Singer (8e)], is suggested to be responsible for the Ca^{2+} binding.

This assumption is stressed by some observations that can be made under the influence of calcium on ghosts as well as on a solution containing 80% of pure spectrin in the protein fraction.

Rosenthal *et al.* (6) report on long chains 40-60Å in diameter that are built up by a fibrous protein of the RBC membrane in 2 mmoles $CaCl_2$ solution. Fibers of this protein extracted from the membrane under conditions of low ionic strength can be seen on the inner surface of ghost cells with the aid of electron micrographs (obtained by the same authors). This protein

could well be spectrin. Our own electron micrographs show exactly the same structures of spectrin.

Forstner and Manery (22) find a maximum of 300 μmoles Ca^{2+}/g protein bound to high affinity sites of ghosts. The high affinity Ca^{2+} binding to spectrin reported in this paper gives a value about one order of magnitude higher than that. The big difference can be due to several washings of the ghosts after Ca^{2+} incubation and/or to the specific Ca^{2+} binding conditions of spectrin. These authors also report an increase in Ca^{2+} binding to ghosts as a function of *p*H. We obtain the same results by measuring solutions of isolated spectrin.

Long and Mouat (20) detected three branches in the Scatchard plot of Ca binding to erythrocytes. One of them is due to sialic acid, the other two by proteins. That fits very well the observation of two branches in the Scatchard plot of Ca^{2+} binding to spectrin.

For all these reasons spectrin should be an important factor in Ca^{2+} binding to the RBC membrane and could easily be responsible for the shape changes of the RBC too.

Tunable Voltage Clamp Method: Application to Photoelectric Effects in Pigmented Bilayer Lipid Membranes

Felix T. Hong and D. Mauzerall

The Rockefeller University, New York, New York 10021

ABSTRACT

Pulsed dye laser excitation of magnesium porphyrins contained in bilayer lipid membranes produced a transient electrical response across the membrane caused by electron transfer from the pigment to the acceptor (ferrocyanide ion) in the adjacent aqueous phase, followed by their return. The photoresponse is measured by a tunable voltage clamp (TVC) method which is essentially a potentiostatic method with adjustable access impedance (time resolution 150 nsec). Comparison with the ideal potentiostatic and the ideal galvanostatic methods shows that the TVC method is superior in providing a complete characterization of the system in terms of an irreducible equivalent circuit. An intrinsic relaxation time constant identified with the reverse interfacial electron transfer is uniquely determined. This time constant can be decomposed into a resistive and a capacitative element. This novel chemical capacitance is required to account for the experimental observations. The model and the method are relevant to vision and photosynthesis research. The TVC method is also potentially applicable to photoelectrochemistry wherever an interfacial photoreaction is present.

Photoelectrochemistry is a particular area of electrochemistry where light-induced emf's instead of the usual current and voltage are used as perturbations of the system. The advent of lasers has made the method of pulsed light perturbation a powerful tool to investigate the fast kinetics of photoelectrochemical relaxations. The study of interfacial photoreactions is of particular interest to biologists because of their relevance to photobiological systems such as photosynthesis and vision. In these photobiological systems, the light-sensitive elements are bound to the membranes. In applying the conventional electrophysiological techniques to such membrane systems or their models, one encounters difficulty in achieving sufficient time resolution to study the fast kinetics of the photoevents. This is because of the presence of membrane capacitance which distorts the photoelectrical relaxation. We, therefore, propose a method of measurement and analysis which is specifically applicable to this type of problem. For reasons which will become apparent later, we call it the tunable voltage clamp (TVC) method. We shall illustrate this method with data obtained from a pigmented membrane system. Similar systems have been studied by means of conventional methods by a number of laboratories (1-5). The literature has been summarized by Tien (6).

Description of the Measurement Method and Circuitry

The TVC method is a modified potentiostatic ("voltage clamp" as known to electrophysiologists) method with adjustable access impedance. The effect of this access impedance is included in a circuit analysis of the complete system: pigmented membrane system + electrodes + amplifier. The advantages of including a variable access impedance are discussed later.

The TVC method can be implemented in a number of ways. It suffices to describe a prototype: a two-electrode system as shown in Fig. 1, along with the equivalent circuit of the pigmented membrane system. Basically, a single 100 MHz operational amplifier is used in a negative feedback circuit. The same pair of electrodes are used for voltage sensing and for current injection. A d-c and pulsed command voltage source is connected in series with the membrane system. In a measurement by means of the TVC method, the command voltage is maintained at a fixed d-c level and a short light pulse causes a perturbation to the pigmented membrane system. The negative feedback circuit is normally operated under the virtual ground condition. The circuit will operate as an ideal potentiostat if the access impedance of the electrodes plus the intervening electrolyte solutions is negligible as compared with the (source) impedance of the pigmented membrane system. This is indeed the case for relatively low frequency and d-c measurements. In the megahertz range, the source impedance may become as low as the access impedance because of the presence of membrane capacitance. The effect of the access impedance would then become quite significant. The system is potentiostated at the electrode inputs to the negative feedback circuit rather than at the two membrane-water interfaces. The error voltage at the interfaces is the voltage

drop across the access impedance. As it is well known to electrochemists, it is difficult to completely eliminate the access impedance. The present method chooses to circumvent the difficulty by including the access impedance in the analysis. Variable precision resistances are added in series to the already existing access impedance of the electrodes and the electrolyte solutions. The total access impedance can be tuned to optimize the measurement (see section on Advantages of TVC Method). The negative feedback loop consists of a parallel *RC* network, which has the effect of a low pass filter on the output voltage ($V_o(t)$ in Fig. 1) of the amplifier. There is a gain-bandwidth trade-off. The feedback resistance R_f, being proportional to the amplifier gain, must be kept high for maximum gain. On the other hand, the feedback *RC* time constant ($\tau_f = R_fC_f$) must be kept small for good time resolution. Since it is difficult to reduce the feedback capacitance C_f to less than a few picofarads, further improvement of the instrumental time resolution can only be accomplished by reducing the feedback resistance R_f at the expense of the amplifier gain. We have found that a feedback capacitance of 15 picofarads (pf) (including stray capacitance) is sufficient to stabilize the amplifier. In order to achieve a time constant of 150 nsec, the feedback resistance R_f must then be 10 kohms. The over-all gain is still acceptable. This is because of the relationship of the photoemf $E_p(t)$ and the *RC*'s in the pigmented membrane as shown in Fig. 1. The reduction of the feedback resistance is compensated by the reduction of the source impedance at high frequence due to the presence of capacitances in the pigmented membrane system. The final consideration is then the signal-to-noise (S/N) ratio. By reduction of extraneous noise sources and experimental artifacts (due to the laser flash discharge) and finally by signal averaging, good instrumental time resolution ($\sim$150 nsec) and an acceptable S/N ratio ($>$ 100 for the positive peak and $>$ 10 for the negative peak) can be achieved simultaneously.

The square wave command voltage pulse (V_c) (rise-time $<$ 5 nsec) permits measurements of parameters required for a complete macroscopic characterization of the pigmented membrane system: the effective access resistance R_e, the membrane capacitance C_m, and the feedback time constant τ_f.

The access impedance is measured by applying a square voltage pulse through the electrodes and the electrolyte solutions in the absence of a membrane. Although the electrode impedance has a complex frequency dependence because of the electrode capacitance, the access impedance was experimentally determined to vary less than 1.6% in the range of interest from 100 nsec to 500 μsec. In terms of a simple circuit, this is because of the resistance in series with the electrode capacitance. It can therefore be replaced by an effective (pure) resistance for the circuit analysis in this frequency range. Henceforth, Z_e shall be regarded as a pure resistance and takes on the real value R_e. Application of a square pulse command voltage in the presence of a membrane permits the measurement of the charging time constant $\tau_m \approx R_eC_m$, which in turn leads to the determination of the membrane capacitance C_m, knowing the value of R_e. Application of a square wave command voltage with a precision resistor instead of the membrane and the electrodes at the input gives the instrumental time constant τ_f.

The membrane resistance R_m can be determined by measuring the current response to a d-c command voltage change. The d-c pigment resistance is determined by means of the null current method described elsewhere (7).

The voltage output of the negative feedback amplifier passed through a second stage of amplification to avoid quantization error in the digitizer. The final output is then digitized by a transient recorder (Biomation Model 8100; time resolution 10 nsec; 8 bit resolution), which is interfaced either to a Fabri-Tek Model 1060 signal averager or to a PDP 8/E minicomputer for signal averaging and data recording. The photocurrent response curve relaxes with two exponential components of opposites signs, with the time constant τ_s and τ_l, respectively ($\tau_s < \tau_l$).

The light source is a flash-lamp-pumped dye laser (0.3 μsec pulse duration; maximal output 120 mj with rhodamine 6G at 590 nm). The laser beam is focused to the thin bimolecular region of the membrane to exclude bulk liquid effects from the thick annular region (8).

Materials and Methods of Forming Pigmented Bilayer Lipid Membranes

The phospholipid used here in the preparation of a bilayer lipid membrane (BLM) is egg lecithin (Sylvana, Millburn, New Jersey). The formula of the membrane-forming solution and the methodology of its formation are standard and have been described elsewhere (7, 8). The membrane-bound pigments are aliphatic esters of magnesium mesoporphyrin IX: diethyl and di-n-amyl. The preparation of these esters has been described (9). The pigment-containing BLM is formed on a Teflon plate (0.01 in.) around a hole of 2 or 3 mm^2, and separates two aqueous KCl or NaCl solutions (1M) of 5 ml in volume. Potassium ferricyanide and ferrocyanide of specified concentrations are added to either or both aqueous solutions.

The chemistry of the pigmented BLM-aqueous redox system has been described in detail [Ref. (9) and Fig. 2 of Ref. (10)]. Photoexcitation of the pigmented membrane causes interfacial electron transfer from the excited pigment molecule in the membrane to the ferricyanide molecule in the aqueous phase. Subsequent reverse interfacial electron transfer from the ferrocyanide molecule in the aqueous phase to the pigment monocation in the membrane completes the cyclic reaction.

Results

The current response of the pigmented BLM to a short pulse of light is biphasic: An initial positive peak is followed by a prolonged negative component which leads to restoration of the original dark level (Fig. 2). The polarity of the initial positive peak is in the direction expected for electron transfer from pigment in the membrane to the acceptor-rich aqueous phase. The physical meaning of the negative component is discussed later. The photocurrent relaxation can be fit with two exponential functions of opposite polarity; the ratio of their amplitudes closely equals the reciprocal of the ratio of their respective time constants. The dotted or noisy curves in Fig. 2 show the photocurrent response displayed on two different scales to clearly show the two components. It was measured by means of the TVC method at 0 mV with an effective access resistance R_e = 5.1 kohms and an instrumental time constant of 1.5 μsec. The apparent relaxation time constants of the two photocurrent components are 29 and 63 μsec. The charging time constant τ_m is determined to be 42 $\pm$ 0.5 μsec for this particular membrane. The laser pulse is delivered at t = 0 μsec. The data of Fig. 2 are analyzed in detail in the next section.

Figure 3 shows the rise of the photocurrent response to a single laser flash on a pigmented BLM, measured by the TVC method at 0 mV with an effective access resistance of 380 ohms and an instrumental time constant of 150 nsec. The laser pulse is also shown.

Equivalent Circuit Analysis

The experimentally observed photocurrent relaxation can be accounted for quantitatively by the equivalent circuit shown in Fig. 1. This equivalent circuit includes a novel feature. A chemical capacitance (C_p) in series with the photoemf is present in addition to the ordinary membrane capacitance (C_m). In parallel with C_p is the transmembrane pigment resistance R_s which

represents the conductance pathway due to diffusion of pigmented molecules, both charged and uncharged. The photoevent is represented by an electrical channel in parallel with and independent of the ionic conductance channel represented by R_m. This independence has been established by a shunting experiment with nystatin which decreases the ionic resistance R_m (7). This proves the independence of the photoevent and the ionic event. A reason for introducing C_p is given later.

The equivalent circuit plus the access impedance can be explicitly analyzed by applying the two Kirchhoff rules (Appendix I). The photocurrent at zero voltage (with a nonzero R_e) is found to be

$$I(t) = \frac{1}{R_e C_m \left(\frac{1}{\tau_s} - \frac{1}{\tau_l}\right)} \left[\left(\frac{1}{\tau_s} - \frac{1}{R_s C_p}\right) \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_l}\right) du - \left(\frac{1}{\tau_s} - \frac{1}{R_s C_p}\right) \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_l}\right) du \right] \quad [1]$$

where

$$\frac{1}{\tau_s} = \frac{1}{2}\left[\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right) + \sqrt{\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right)^2 - 4\left(\frac{1}{R_pC_mR_sC_p} + \frac{1}{\tau_p\tau_m}\right)}\right] \quad [2]$$

$$\frac{1}{\tau_l} = \frac{1}{2}\left[\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right) - \sqrt{\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right)^2 - 4\left(\frac{1}{R_pC_mR_sC_p} + \frac{1}{\tau_p\tau_m}\right)}\right] \quad [3]$$

$$\frac{1}{\tau_p} = \frac{1}{R_pC_p} + \frac{1}{R_sC_p} \quad [4]$$

$$\frac{1}{\tau_m} = \frac{1}{R_eC_m} + \frac{1}{R_mC_m} \quad [5]$$

In Eq. [2] and [3], τ_s and τ_l are expressed in terms of various RC parameters: R_p, C_p, and R_s are unknown, the remaining parameters τ_s, τ_l, τ_m, R_m, and R_e are experimentally measurable. A third equation that is required to solve for the parameters R_p, C_p, and R_s is given by

$$R_s + R_p = R_{sp} = \text{d-c pigment resistance} \quad [6]$$

The parameter $1/R_{sp}$ is the difference between the conductance of pigmented BLM-redox system and that of a plain BLM, and can be readily measured by the null current method (7).

Although R_p, C_p, and R_s can be solved for explicitly, it is hardly necessary to do so. Time-integration of the photocurrent shows the response goes to zero at long time. This indicates that R_s is relatively large. In fact, $R_s >> R_p$ and hence $R_s \simeq R_{sp}$ = d-c pigment resistance. For TVC measurements with $R_e << R_s$, no significant error in computing R_p and C_p occurs by setting R_s to infinity (Appendix II). This leads to a simplified explicit solution for R_p and C_p

$$\tau_p = \frac{\tau_s\tau_l}{\tau_m} \quad [7]$$

$$C_p = \frac{1}{R_e}(\tau_s + \tau_l - \tau_m - \tau_p) \quad [8]$$

$$R_p = \frac{\tau_p}{C_p} \quad [9]$$

Therefore, there is a unique solution for R_p and C_p.

For the system shown in Fig. 2, we find that $R_p \simeq 34$ kohms, $C_p = 1.3$ nf, and $\tau_p = 44$ μsec.

It remains to be demonstrated that the equivalent circuit predicts the correct time course of the photocurrent, given the above parameters. It is interesting to note that substitution of a delta function $\delta(t)$ for the photoemf $E_p(t)$ leads to the following expression

$$I(t) = \frac{1}{R_pR_eC_m\left(\frac{1}{\tau_s} - \frac{1}{\tau_l}\right)}\left[\frac{1}{\tau_s}\exp\left(-\frac{t}{\tau_s}\right) - \frac{1}{\tau_l}\exp\left(-\frac{t}{\tau_l}\right)\right] \quad [10]$$

which states that the photocurrent is biphasic and consists of two exponential terms of opposite polarity with the amplitude ratio equal to the reciprocal of the ratio of their respective time constants. This is indeed consistent with experimental observations.

In carrying out the detailed computation of the photocurrent $I(t)$, the photoemf $E_p(t)$ is assumed to follow the time course of the light pulse. This assumption is reasonable because of the following consideration: The singlet state of magnesium porphyrin lives about 1 nsec, and the triplet state less than 100 nsec under aerobic conditions. Thus the electron transfer from the excited state must be fast compared with the present instrumental time constant (150 nsec).

We also take into account the effect of the negative feedback loop as a low pass filter on the output photocurrent. The filtered current $I_f(t)$ is given by

$$I_f(t) = \frac{1}{\tau_f}\int_0^t I(u)\exp\left(\frac{u-t}{\tau_f}\right) du \quad [11]$$

where $\tau_f = R_fC_f$ and $I(u)$ is substituted with Eq. [1]. The computed time course is normalized with respect to its peaks and is shown in Fig. 2 as smooth curves. The theoretical positive and negative peak amplitude ratio of 6.6 compares favorably with the experimental peak amplitude ratio of 6.2.

A similar computation is also carried out for the rise phase of the photocurrent in Fig. 3 (smooth curve). The sigmoid-shaped rise of photocurrent is accountable by the low pass filter effect of the feedback RC constant of 150 nsec and the finite rise time of the laser pulse.

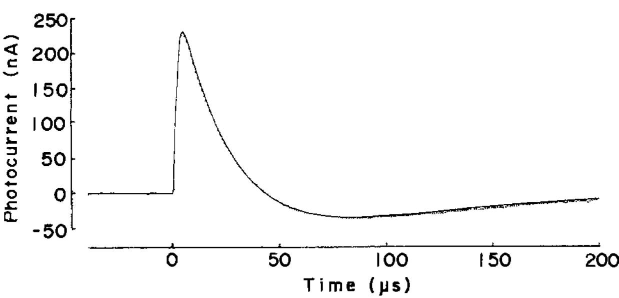
Evidence That a Chemical Capacitance Does Exist

A pertinent question to raise is whether the equivalent circuit shown in Fig. 1 is a unique representation of the photoevent in the pigmented BLM. The circuit, being equivalent, is by no means unique because a more elaborate model can always be proposed which describes just as well or even better the photoevent. We shall demonstrate that to the best of our knowledge the equivalent circuit is unique in the sense that it is irreducible, being the simplest in the homologous series of circuits which are equivalent to the pigmented BLM system.

The distinct feature of the present equivalent circuit is the presence of a chemical capacitance C_p. Is there an alternative model without a C_p that describes the photoevent just as well? This alternative model without C_p can be ruled out by the following analysis. The photocurrent response of this model in the presence of a nonzero access resistance R_e is given by

$$I(t) = \frac{1}{R_eC_m}\int_0^t \frac{E_p(u)}{R_p + R_s}\exp\left(\frac{u-t}{\tau}\right) du \quad [12]$$

where $1/\tau = 1/R_eC_m + 1/R_mC_m + 1/(R_p + R_s)C_m \simeq 1/\tau_m$, since $R_s >> R_e$. In words, the photocurrent is the response of the photoemf $E_p(t)$ to a low pass filter of time constant τ_m. Without assuming a physically unrealistic time course of the photoemf and without as-



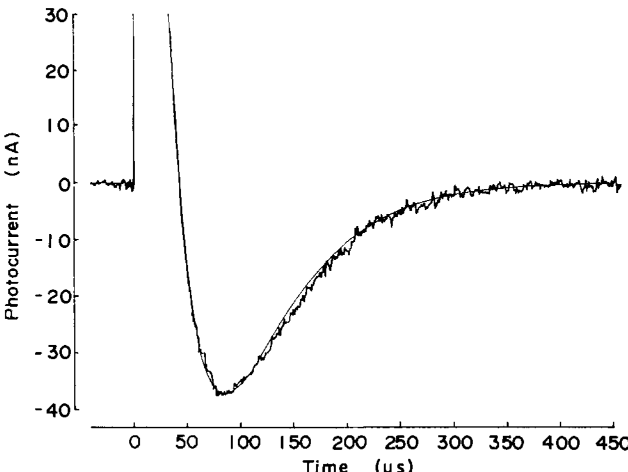


Fig. 2. Measured (dotted or noisy curve) and computed photoresponses to a dye laser pulse (0.3 μsec) by means of the TVC method. The measured response is taken by means of the TVC method at 0 mV with $R_e = 5.1$ kohms. The BLM is made from a membrane-forming solution which contains ~5 mmolars magnesium mesoporphyrin IX di-n-amyl ester. The BLM separates two aqueous phases with 20 mmolars potassium ferricyanide and 0.5 mmolars potassium ferrocyanide on the acceptor-rich side and 20 mmolars potassium ferrocyanide on the donor-rich side. Both aqueous solutions also contain 1M NaCl and 10 mmolar phosphate buffer at pH 7.2. The temperature is maintained constant at 26°C. The exciting laser beam is focused to illuminate 19% of the thin bilayer of area 1.7 mm^2. The instrumental time constant is 1.5 μsec ($R_f = 100$ kohms, $C_f = 15$ pf). The average of 16 measurements from the same membrane is obtained with a signal averager. The same averaged record is displayed on two different scales. The computed response is based on the equivalent circuit of Fig. 1, assuming $E_p(t)$ to have the time course of an equilateral triangular pulse with a half-width of 0.3 μsec, the same as the exciting laser pulse. The input parameters for this computation are: $R_e = 5.1$ kohms, $R_m = 1.5 \times 10^9$ ohms, $C_m = 8.2$ nf, $R_p = 34$ kohms, $C_p = 1.3$ nf, $R_s = 10^9$ ohms. The computed curves are normalized with respect to the peaks. See text for details.

suming complex time dependence of the circuit parameters, the alternative model without C_p predicts a passive relaxation no faster than τ_m (42 μsec in Fig. 2). This prediction is contradicted by experiments in that a relaxation of 29 μsec (τ_s in Fig. 2) and indeed as fast as 5 μsec can be observed (11).

To demonstrate that the fit does not depend on particular choices of the access impedance, the photocurrent responses measured from the same pigmented BLM under identical conditions except with two different values of R_e are compared (Fig. 4). Equivalent circuit analysis of the data in Fig. 4A and in Fig. 4B separately gives the following results: $R_p = 40$ kohms, $C_p = 1.1$ nf, and $\tau_p = 43$ μsec for Fig. 4A ($R_e = 4.6$ kohms), and $R_p = 37$ kohms, $C_p = 1.2$ nf, and $\tau_p = 44$ μsec for Fig. 4B ($R_e = 11$ kohms). The errors in this case are less than 5% except for the case of C_p, where the error is from 10 to 15%. The peak amplitudes of the

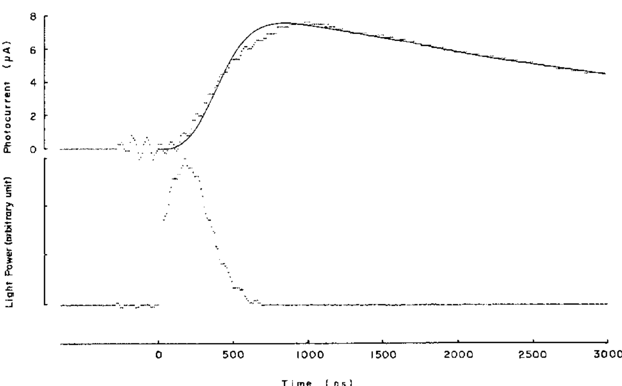

Fig. 3. The rise phase of the photocurrent and the time course of the laser pulse. The dotted curve is a single measurement from a BLM of area 2.5 mm^2 by means of the TVC method at 0 mV with $R_e = 380$ ohm (25°C) and an instrumental time constant of 150 nsec. The quantization steps are present because of the 8 bit resolution of the digitizer. The pigmented BLM system has the same composition as that of Fig. 2, except that the pigment is the diethyl ester and that KCl replaces NaCl in the aqueous solutions. The solid smooth curve is the computed response including the 150 nsec instrumental time constant, as in Fig. 2. The laser pulse is measured by a photodiode (rise time 5 nsec). The spark gap discharge artifact is seen to precede the onset of the laser pulse. The jitter of the timing circuit and the breakdown delay of the spark gap in the dye laser is less than 40 nsec. The laser pulse is measured immediately following the photocurrent measurement. Fluctuations of the shape of the laser pulse produce an uncertainty of about 100 nsec in the peak of the pulse.

effective photoemf[1] $E_p(t)$ are determined to be: 90 mV for Fig. 4A and 95 mV for Fig. 4B.

The mutual consistency of these two sets of data from the same membrane can be further visualized by using the data obtained at $R_e = 4.6$ kohms to compute the photocurrent at $R_e = 11$ kohms, and vice versa. These are shown as smooth curves in Fig. 4A and 4B.

Three sets of measurements referred to in this paper (Fig. 2, 4A, and 4B) are for the same experimental conditions and their agreement can be used to judge the precision of the analysis. These experiments demonstrate that the pigmented BLM does behave in accordance with the equivalent circuit of Fig. 1 at various access impedance. One is therefore free to "tune" the access impedance in order to optimize the measurement.

Error Voltage

Because of the presence of the access impedance, the potentiostatic condition is not strictly fulfilled. The specified potential difference is maintained at the electrode inputs (points A and B in Fig. 1), but the two membrane-water interfaces are not at strictly constant potential difference. The error voltage is given by the voltage drop across the access impedance, $I(t)R_e$. In the example shown in Fig. 2 where the peak photocurrent is 230 nA and the effective access resistance 5.1 kohms, the maximal error voltage is 1.2 mV. For a nonlinear system such as the nerve membrane near its discharge threshold, an error voltage of a few millivolts would be significant. For a linear system such as the present photosystem, a voltage shift of $\pm$ 100 mV causes only a barely discernible change of the fast photocurrent responses. Thus, the effect of the error voltage is negligible.

Advantages of the TVC Method

To appreciate the advantages of the TVC method, we must examine the ideal potentiostatic and the ideal galvanostatic methods. These are the two limiting

[1] The parameter $E_p(t)$ is regarded as an effective photoemf because no attempt has been made to take into account the effect of focused illumination and the distinction of the forward charging and the reverse discharging interfacial resistance (R_p) (10, 11).

cases with the access impedance equal to zero and to infinity, respectively. The circuit analyses are therefore similar to that of the TVC method with a finite and nonzero access impedance.

The photocurrent as measured by means of the ideal potentiostatic method at zero voltage is given by

$$I(t) = \frac{E_p(t)}{R_p} - \left(\frac{1}{\tau_p} - \frac{1}{R_sC_p}\right) \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_p}\right) du \quad [13]$$

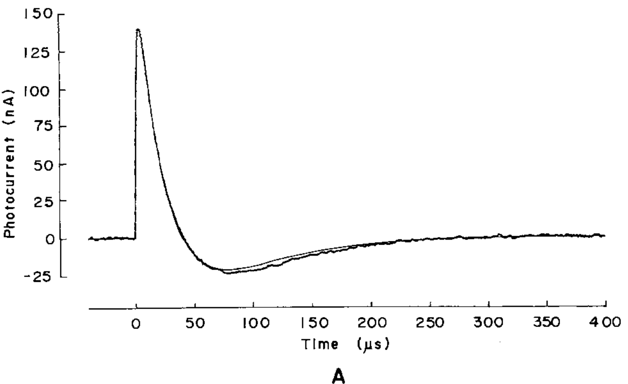
where τ_p is given in Eq. [4]. Using the measured and calculated parameters given in Fig. 2, the photocurrent response for an instrumental time constant of 1.5 μsec is shown in Fig. 5. Notice that the filtered photocurrent retains the biphasic waveform. However, the data provide only one useful time constant τ_p; the other time constant is the instrumental time constant τ_f. A decomposition of τ_p is terms of R_p and C_p is not possible. The presence of a small access impedance in the TVC method causes interaction of the photochemical event with the membrane capacitance C_m to give rise to two useful time constants, τ_s and τ_l. This makes the decomposition of τ_p possible. Thus more information can be obtained by means of the TVC method than by means of the ideal potentiostatic method.

The photovoltage as measured by means of the ideal galvanostatic method at zero current ("open-circuit" method) is given by

$$V(t) = \frac{\dfrac{1}{\tau_s'} - \dfrac{1}{R_sC_p}}{R_pC_m\left(\dfrac{1}{\tau_s'} - \dfrac{1}{\tau_l'}\right)} \int_0^t E_p(u) \exp\left(\frac{u-t}{\tau_s'}\right) du - \frac{\dfrac{1}{\tau_l'} - \dfrac{1}{R_sC_p}}{R_pC_m\left(\dfrac{1}{\tau_s'} - \dfrac{1}{\tau_l'}\right)} \int_0^t E_p(u) \exp\left(\frac{u-t}{\tau_l'}\right) du \quad [14]$$

where

$$\frac{1}{\tau_s'} = \frac{1}{2}\left[\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m'}\right) + \sqrt{\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m'}\right)^2 - 4\left(\frac{1}{R_pC_mR_sC_p} + \frac{1}{\tau_p\tau_m'}\right)}\right] \quad [15]$$



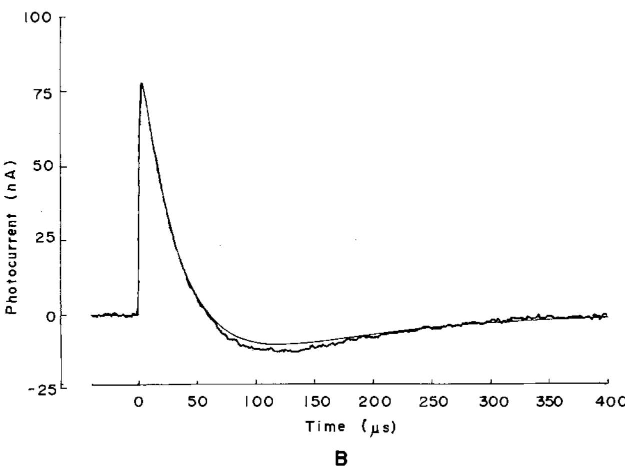


Fig. 4. Tuning the access impedance. The two measured photocurrent responses (noisy curve) are taken from a pigmented BLM (composition identical with that in Fig. 2) by means of the TVC method at 0 mV with $R_e = 4.6$ kohms (A) and $R_e = 11$ kohms (B). The instrumental time constant is 1.5 μsec. The smooth curve in A is that computed with data obtained from the measured response in B but with R_e of 4.6 kohms, and vice versa for the smooth curve in B. The measurements were carried out on a single membrane. Even the absolute amplitudes agree to within 20%: measured amplitude 139 nA and predicted amplitude 172 nA for $R_e = 4.6$ kohms; measured amplitude 77 nA and predicted amplitude 62 nA for $R_e = 11$ kohms.

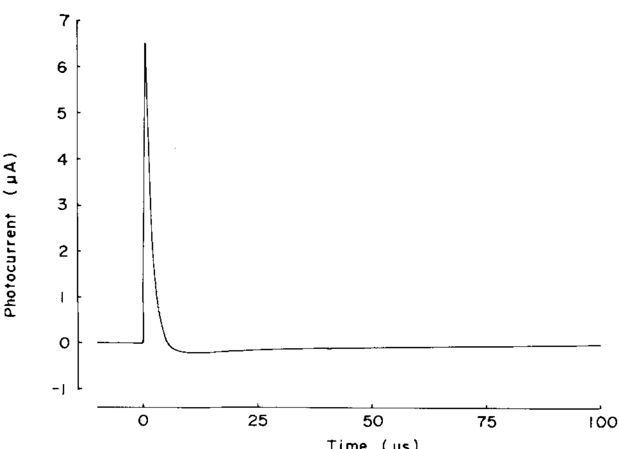

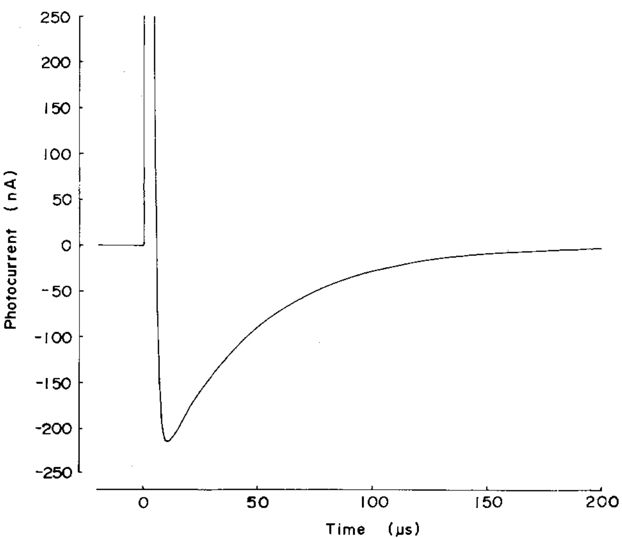

Fig. 5. The computed photocurrent response under ideal potentiostatic condition at zero voltage. The input data for the computation are from Fig. 2. The instrumental time constant of 1.5 μsec is included. The response is displayed on two different scales.

$$\frac{1}{\tau_l'} = \frac{1}{2}\left[\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m'}\right) - \sqrt{\left(\frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m'}\right)^2 - 4\left(\frac{1}{R_pC_mR_sC_p} + \frac{1}{\tau_p\tau_m'}\right)}\right] \quad [16]$$

$$\frac{1}{\tau_m'} = \frac{1}{R_mC_m} \quad [17]$$

and τ_p is again given by Eq. [4]. These expressions are similar to Eq. [1]-[5] except that $\tau_m \simeq R_eC_m$ is replaced by $\tau_m' = R_mC_m$. Using the same parameters as in Fig. 2, the computed photovoltage is shown in Fig. 6. Notice that two useful time constants τ_s' and τ_l' are available from such a measurement. In principle, a decomposition of the time constant τ_p into a resistive element R_p and a capacitative element C_p is possible. In practice, this is hardly feasible. The computed photovoltage shows that the two components differ both in amplitudes and in time constants by over four orders of magnitude. The following analysis will clarify the situation.

From TVC data (*e.g.*, Fig. 2), $\tau_p << \tau_m'$, $\tau_s' << \tau_l'$ and, to a crude approximation, $C_p \simeq C_m$, $R_s \simeq R_m$. Therefore the following order-of-magnitude approximation is valid

$$\frac{1}{\tau_s'} \approx \frac{1}{\tau_s'} + \frac{1}{\tau_l'} = \frac{1}{R_pC_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m'}$$

$$\approx \frac{1}{R_pC_m} + \frac{1}{\tau_p} \approx \frac{2}{\tau_p} \quad [18]$$

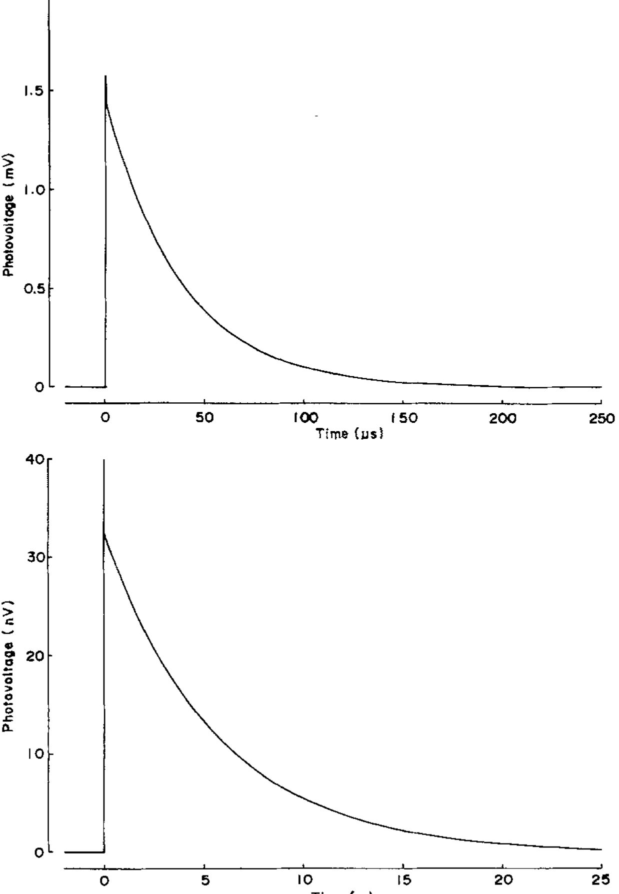

Fig. 6. The computed photovoltage response under the ideal galvanostatic condition at zero current. The input data for the computation are from Fig. 2. The instrumental time constant is taken to be zero since it does not appreciably affect this response. The response is displayed on two different scales. Notice that the units of both voltage and time in the two displays differ by over four orders of magnitude.

$$\frac{1}{\tau_s'\tau_l'} = \frac{1}{R_pC_mR_sC_p} + \frac{1}{\tau_p\tau_m'} \approx \frac{2}{\tau_p\tau_m'} \quad [19]$$

That is, to a crude approximation

$$\tau_p \approx 2\tau_s' \quad [20]$$

and

$$\tau_m' \approx \tau_l' \quad [21]$$

Except for a numerical factor of approximately 2, the representation of τ_p by the negative component in the ideal potentiostatic conditon is now replaced by its representation by the fast component in the ideal galvanostatic conditon. The slow component in the latter case is almost purely membrane *RC* response. This is the case of excessive interaction between the photochemical event and the membrane capacitance. The calculation of R_p and C_p from the experimental data would involve subtraction of large numbers which are very close to each other, and is therefore not feasible. The present method of tuning the value of R_e enables us to optimize the measurement by bringing the two components into a range feasible for accurate measurements and calculation. The presence of the access impedance is therefore an asset rather than a nuisance. However, adequate *S/N* ratio is still necessary for the decomposition of τ_p into R_p and C_p. Whereas the error in τ_p is linear in τ_l, this is not true for R_p and C_p. For example, a 5% variation of τ_l in the data of Fig. 2 causes a change of τ_p by 5% but a change of R_p by 10% and C_p by 15%.

Conclusions

We have applied the TVC method to a model pigmented membrane system and have proposed an equivalent circuit to explain the observed photocurrent. The equivalent circuit has been interpreted in molecular terms (10). The presence of a chemical capacitance is the novel feature of the equivalent circuit and is required to account for the experimental results, in particular, the biphasic waveform of the photocurrent. This chemical capacitance has its physical origin in the photogenerated pigment monocation (10). These photogenerated pigment monocations can be regarded as fixed space charges which are localized at the acceptor-rich interface, on the microsecond time scale. Incomplete screening of these space charges by the electrical double layer near the acceptor-rich interface leads to polarization of the membrane dielectric. This interpretation has been substantiated by a theoretical calculation based on the Gouy-Chapman double layer theory (12). This later theoretical study indicates that the chemical capacitance is a characteristic of interfacial photoreaction involving membrane-bound pigment. The light-induced absorbance change in chloroplasts related to membrane potential (13) and the early receptor potential (ERP) in visual photoreceptors (14) have very fast rise times which are expected from our view of the chemical capacitance. The model and the method are therefore relevant to photobiology.

The TVC method applies specifically to a photoelectrochemical system in which a photogenerated interfacial emf is present. Viewed from outside the membrane system, the photoemf is connected in parallel with the membrane capacitance C_m but in series with the chemical capacitance C_p. It is this peculiar network relationship that makes the TVC method exquisitely sensitive and powerful in analyzing the fast interfacial kinetics. The photoemf injects current inside the double layer in contrast with perturbation due to an externally applied voltage.

In the TVC method, the effect of membrane capacitance is not eliminated but is reduced to such an ex-

tent (through proper choice of a small access impedance) that the perturbing effect can be accurately taken into account and that actually more information is made available than with the ideal potentiostatic method. The small value of R_p in the presence of a large R_s can still be measured accurately. This is not possible with the method of externally applied voltage perturbation when R_p and R_s are considered to be in series. The interfacial resistance R_p and the corresponding interfacial voltage drop have definite physical meanings (10). The TVC method thus provides a rapid and sensitive way of measuring interfacial photochemical kinetics. The calculated rate constant $1/\tau_p$ is interpreted as the pseudo first-order rate constant of the reverse interfacial electron transfer reaction (where the aqueous ferrocyanide concentration on the acceptor-rich side is kept constant)

$$P^{+}{}_{(BLM)} + Fe(CN)_6{}^{4-}{}_{(aq.)} \rightarrow P_{(BLM)} + Fe(CN)_6{}^{3-}{}_{(aq.)} \quad [22]$$

and is proportional to the constant concentration of the aqueous ferrocyanide solution. The calculated apparent second-order rate constant is $(3.5 \pm 0.4) \times 10^7 M^{-1} sec^{-1}$ (10).

Although it might seem desirable to measure τ_p explicitly by means of the ideal potentiostatic method, the latter method represents an unattainable ideal limit in experimental systems such as a pigmented membrane. Because of the presence of the chemical capacitance, the source impedance is reduced from its d-c value by several orders of magnitude in the megahertz range. A few hundred ohms of access impedance (*e.g.*, due to electrodes and the electrolyte solutions) in the presence of a low source impedance cannot be considered negligible. On the other hand, this drastic reduction of source impedance enables one to achieve good instrumental time resolution and good S/N ratio simultaneously. With further reduction of noise and artifacts, it is not impossible to reach the ultimate time resolution set by the bandwidth of presently available operational amplifiers, namely 100 MHz.

With improved time resolution, it may be possible to study directly the relaxation of the electrical double layer using interfacial photoemf as a perturbation. The study of the photocurrent rise time in the present model system does not indicate any significant lag (<100 nsec) of the photocurrent following the stimulating light pulse.

The TVC method is potentially applicable to photoelectrochemistry where an interfacial photoreaction is involved, *e.g.*, mercury electrode photoemission in electrolyte solutions (15). It is also potentially applicable in vision and in photosynthesis research.

APPENDIX I

Equivalent Circuit Analysis

The equivalent circuit with access impedance Z_e is shown in Fig. 1. The following analysis gives the explicit expression for the photocurrent $I(t)$ as measured by the TVC method at zero voltage and with an effective access resistance R_e. The TVC circuit keeps the summing point always at ground potential.

By definition

$$i_c = \dot{q}_c \quad [A\text{-}I\text{-}1]$$

$$i_p = \dot{q}_p \quad [A\text{-}I\text{-}2]$$

Application of Kirchhoff's two rules to the equivalent circuit results in the following relations

$$I = i_c + i_r + i_p + i_s \quad [A\text{-}I\text{-}3]$$

$$IR_e = -i_r R_m \quad [A\text{-}I\text{-}4]$$

$$i_s R_s = \frac{q_p}{C_p} \quad [A\text{-}I\text{-}5]$$

$$IR_e = E_p - \frac{q_p}{C_p} - (i_p + i_s) R_p \quad [A\text{-}I\text{-}6]$$

$$-\frac{q_c}{C_m} = E_p - \frac{q_p}{C_p} - (i_p + i_s) R_p \quad [A\text{-}I\text{-}7]$$

By differentiating Eq. [A-I-7], multiplying through by $-C_m$, and using Eq. [A-I-1], [A-I-2], and [A-I-5], we have

$$i_c = R_p C_m \left(\ddot{q}_p + \frac{\dot{q}_p}{R_p C_p} + \frac{\dot{q}_p}{R_s C_p} - \frac{\dot{E}_p}{R_p} \right) \quad [A\text{-}I\text{-}8]$$

By eliminating i_r, I, and i_c from Eq. [A-I-3], [A-I-4], [A-I-6], and [A-I-8], using Eq. [A-I-2] and [A-I-5] and the definition for τ_p and τ_m (Eq. [4] and [5]), we have

$$\ddot{q}_p + \left(\frac{1}{R_p C_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m} \right) \dot{q}_p + \left(\frac{1}{\tau_p \tau_m} + \frac{1}{R_p C_m R_s C_p} \right) q_p = \frac{\dot{E}_p}{R_p} + \frac{1}{\tau_m} \frac{E_p}{R_p} \quad [A\text{-}I\text{-}9]$$

The initial conditions for this second-order linear differential equation are

$$q_p(0) = 0 \quad [A\text{-}I\text{-}10]$$

and

$$i_p(0) = \dot{q}_p(0) = 0 \quad [A\text{-}I\text{-}11]$$

Standard techniques yield the following solution

$$q_p(t) = \frac{\frac{1}{\tau_s} - \frac{1}{\tau_m}}{\frac{1}{\tau_s} - \frac{1}{\tau_l}} \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_s}\right) du - \frac{\frac{1}{\tau_s} - \frac{1}{\tau_m}}{\frac{1}{\tau_s} - \frac{1}{\tau_l}} \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_l}\right) du \quad [A\text{-}I\text{-}12]$$

where τ_s and τ_l are defined by Eq. [2] and [3]. Knowing $q_p(t)$, it is then straightforward to obtain the explicit expression for $I(t)$ as given by Eq. [1].

APPENDIX II

Existence and Uniqueness of Solution of Eq. [2] and [3] for R_p and C_p

Solution of Eq. [2] and [3] for R_p and C_p when R_s is not small enough to be negligible is included here for completeness.

The following Eq. [A-II-1] and [A-II-2] are equivalent to Eq. [2] and [3]

$$\frac{1}{\tau_s} + \frac{1}{\tau_l} = \frac{1}{R_p C_m} + \frac{1}{\tau_m} + \frac{1}{\tau_p} \quad [A\text{-}II\text{-}1]$$

$$\frac{1}{\tau_s \tau_l} = \frac{1}{\tau_m \tau_p} + \frac{1}{R_p C_m R_s C_p} \quad [A\text{-}II\text{-}2]$$

We thus have

$$C_p = \frac{\dfrac{1}{R_p} + \dfrac{1}{R_s}}{\dfrac{1}{\tau_s} + \dfrac{1}{\tau_l} - \dfrac{1}{\tau_m} - \dfrac{1}{R_p C_m}} \quad \text{[A-II-3]}$$

The explicit solution for R_p and C_p follows

$$\frac{1}{R_p} = P \pm \sqrt{P^2 + Q} \quad \text{[A-II-4]}$$

$$C_p = T \pm \sqrt{T^2 - \frac{\tau_s \tau_l}{R_s^2}} \quad \text{[A-II-5]}$$

where

$$P = \frac{1}{2}\left\{ SC_m + \frac{\dfrac{\tau_m}{\tau_s \tau_l} - \dfrac{1}{\tau_m}}{R_s\left(\dfrac{1}{\tau_m} + \dfrac{1}{R_s C_m}\right)} \right\} \quad \text{[A-II-6]}$$

$$Q = \frac{SC_m}{R_s + \dfrac{\tau_m}{C_m}} \quad \text{[A-II-7]}$$

$$T = \frac{\tau_s \tau_l}{2}\left[SC_m\left(\frac{1}{\tau_m} + \frac{1}{R_s C_m}\right) + \frac{1}{R_s}\left(\frac{\tau_m}{\tau_s \tau_l} + \frac{1}{\tau_m}\right)\right] \quad \text{[A-II-8]}$$

$$S = \frac{1}{\tau_s} + \frac{1}{\tau_l} - \frac{1}{\tau_m} - \frac{\tau_m}{\tau_s \tau_l} \quad \text{[A-II-9]}$$

It remains to be shown that one pair of solutions for R_p and C_p is physically meaningful and that the other pair is not. From Eq. [A-II-9], [A-II-1], and [A-II-2], it follows that

$$S = \frac{\tau_m}{R_p C_m}\left(\frac{1}{\tau_m} - \frac{1}{R_s C_p}\right) \approx \frac{\tau_m}{R_p C_m}\left(\frac{1}{R_e C_m} - \frac{1}{R_s C_p}\right) \quad \text{[A-II-10]}$$

For TVC measurement with the access resistance $R_e < R_s$, we have $S > 0$, since C_m and C_p are roughly of the same order of magnitude. Thus from Eq. [A-II-7] and [A-II-8] we have $Q > 0$ and $T > 0$. As a consequence, we also have $P + \sqrt{P^2 + Q} > 0$ and $P - \sqrt{P^2 + Q} < 0$. Therefore, there is one and only one physically meaningful solution for R_p, namely

$$\frac{1}{R_p} = P + \sqrt{P^2 + Q} \quad \text{[A-II-11]}$$

and one is forced to choose for C_p

$$C_p = T + \sqrt{T^2 - \frac{\tau_s}{R_s^2}} \quad \text{[A-II-12]}$$

because of the choice of Eq. [A-II-11] for R_p. C_p must be real because of Eq. [A-II-3], and also positive because of Eq. [A-II-5] and $T > 0$.

This completes the proof of existence and uniqueness of R_p and C_p for the case with R_e smaller than R_s.

The Effects of Counterion Size on the Equilibrium Properties of Charged Interfaces

W. R. Fawcett* and T. A. McCarrick

Department of Chemistry, University of Guelph, Guelph, Ontario, Canada

ABSTRACT

The adsorption of iodide ion at mercury has been studied from two systems at constant ionic strength, namely, xM NaI + $(0.25 - x)$M NaF and xM KI + $(0.25 - x)$M KF. The surface excess of adsorbed iodide ions was calculated from differential capacity data using a modified version of the Hurwitz-Parsons analysis which takes into consideration variation in ionic activity coefficients with solution composition. The iodide surface excess was found to depend on the nature of the cation for a given bulk concentration and electrode charge density; comparison of the present data with those previously published shows a marked dependence of adsorbed surface excess on ionic strength. The effect of counterion nature on ionic adsorption is discussed within the framework of an electrostatic model for adsorption which takes the discrete nature of the charge at the interface into consideration. Counterion effects at charged monolayers, bilayer lipid membranes, and real membranes are compared with those observed at mercury.

Although numerous studies of the adsorption of ions at the mercury/solution interface have been carried out (1), the effect of the nature of the nonadsorbed counterion on the amount of adsorption and electrostatic properties of the interface has not been investigated. Thus, the adsorption of halide ions has been studied from aqueous solutions of KCl (2), KBr (3), and KI (4) at varying ionic strengths, and also from solutions of KCl + KF (5), KBr + KF (6), NH_4Br + NH_4F (7), and KI + KF (8) at constant ionic strength. In analyzing these data it has been customary to assume that neither the cation nor the fluoride anion in the mixed solutions is adsorbed on mercury. On the other hand, Grahame (9) showed that the double layer capacity in the absence of anion specific adsorption depends on the nature of the electrolyte cation when the latter is predominant in the double layer. These results can be interpreted as evidence that the thickness of the inner region of the double layer, x_d, increases with hydrated radius of the cation at the outer Helmholtz plane. Thus, the potential distribution in the inner layer and the electrostatic potential at the charge center of an adsorbed anion should depend on the nature of the nonadsorbed counterion. It then follows on the basis of the electrostatic model of ionic adsorption (10) that the amount of adsorption should depend on the nature of the counterion for constant charge on the electrode and constant bulk concentration of the adsorbing ion.

In order to test the above hypothesis, the adsorption of iodide ion has been studied from solutions of NaI + NaF and KI + KF at the same constant ionic strength (0.25M). Na^+ and K^+ were chosen as counterions because of their importance in biological systems where K^+ is the predominant cation in the intracellular fluid and Na^+, predominant in the extracellular fluid.

Experimental

Differential capacity against potential data for the mercury/aqueous solution interface were collected for 20 systems of composition xM NaI + $(0.25 - x)$M NaF and xM KI + $(0.25 - x)$M KF where x had the values 0, 0.0063, 0.01, 0.016, 0.025, 0.04, 0.063, 0.1, 0.16, and 0.25M. The capacity was measured at 1 kHz for 50 mV increments in potential except in potential regions where the capacity changed markedly with potential; the potential increment was then reduced so that the capacity increment was $< 5 \mu F\ cm^{-2}$. The data were obtained with an a-c bridge built according to the design of Hills and Payne (11), the potential of the mercury electrode being measured with respect to a saturated calomel electrode. The cell and associated electrodes have been described elsewhere (12). All experiments were carried out at $25.0° \pm 0.1°C$. Procedures for determining the area of the drop at balance and the potential of zero charge have been described previously (11, 12).

Variation in NaI activity with solution composition was determined by measuring the emf of the cell

$$\text{Na glass electrode}/x\text{M NaI} + (0.25 - x)\text{M NaF/AgI/Ag} \quad [1]$$

The emf was determined by a null technique using a high input impedance electrometer ($R > 10^{14}\Omega$). The sodium electrode was a Corning Model NAS 11-18 glass membrane electrode; the silver/silver iodide electrode was prepared by depositing silver iodide on silver using the procedure given by Ives and Janz (13).

The salts used were of AnalaR grade and were further purified by double recrystallization from pure water. The drying operation for the fluoride salts was carried out in platinum vessels. Conductivity grade water was obtained by doubly distilling deionized water.

Analysis of the Thermodynamic Data

The original thermodynamic analysis for the mercury/mixed electrolyte solution interface at constant ionic strength by Dutkiewicz and Parsons (8) is limited to the case that the activity coefficients of the individual ions do not vary significantly with solution composition. More general analyses have been given by Hurwitz (14) and Lakshmanan and Rangarajan (15). The problem of activity coefficient variation is reconsidered here for simple 1-1 electrolyte mixtures for which Harned's rule is valid.

According to simple models for single ion activity coefficients (16), the activity coefficients for the ions in a MI-MF solution may be expressed as a function of the ionic strength μ and the concentrations of oppositely charged ions. Thus, the activity coefficient for the cation M is given by

$$\ln \gamma_M = \frac{-A\mu^{1/2}}{1 + B\mathring{a}_M\mu^{1/2}} + \beta_{MI}c_I + \beta_{MF}c_F \quad [2]$$

* Electrochemical Society Active Member.

Key words: adsorption, double layer, iodide layer, counterion effects.

and for either anion by

$$\ln \gamma_J = \frac{-A\mu^{1/2}}{1 + B\mathring{a}_J\mu^{1/2}} + \beta_{MJ}c_M \quad [3]$$

A and B are the Debye-Hückel constants, $\mathring{a}_i$, the ionic size parameter for ion i, c_i, its concentration, and β_{MJ}, the interaction coefficient between cation M and anion J. Since the ionic strength and concentration of the metal ion are held constant, only variation in γ_M with solution composition need be considered.

The Gibbs adsorption isotherm for the mixed electrolyte system may be written

$$-d\gamma = qdE_+ + \Gamma_I d\mu_{MI} + \Gamma_F d\mu_{MF} \quad [4]$$

where γ is the surface tension, q, the electrode charge density, E_+, the potential of mercury with respect to an electrode reversible to cation M^+, Γ_J, the surface excess of anion J, and μ_{MJ}, the chemical potential of salt MJ. Then, following Dutkiewicz and Parsons (8)

$$d\mu_{MI} = RT\, d \ln x + RT\, d \ln \gamma_M \quad [5a]$$

and

$$d\mu_{MF} = \frac{-x\,RT}{(1-x)} d \ln x + RT\, d \ln \gamma_M \quad [5b]$$

where $x = c_I/(c_I + c_F)$. For strong adsorption the position of the outer Helmholtz plane (OHP) is determined by the distance of closest approach of the cation and the Gibbs adsorption isotherm becomes

$$-d\gamma = qdE_+ + \Gamma_I{}^a RT\, d \ln x + (\Gamma_I + \Gamma_F) RT\, d \ln \gamma_{Na}$$

$$= qdE_+ + \Gamma_I{}^a RT\, d \ln x + (\Gamma_I + \Gamma_F) RT\, \beta x\, d \ln x \quad [6]$$

where $\Gamma_I{}^a$ is the surface excess of iodide ion adsorbed in the inner layer and $\beta = (\beta_{MI} - \beta_{MF})\mu$.

When β is significant, the electrode potential measured with respect to a constant reference electrode E_r is related to the thermodynamic potential E_+ by the equation

$$dE_r = dE_+ + \frac{RT}{\mathbf{F}} d \ln \gamma_M = dE_+ + \frac{RT}{\mathbf{F}} \beta\, dx \quad [7]$$

Thus, the electrode potential measured may be converted to a thermodynamic scale if β is known.

Introducing Parsons' function $\xi_+ = \gamma + qE_+$ and converting surface excesses to the corresponding surface charge densities, Eq. [6] becomes

$$d\xi_+ = E_+ dq + q_a \frac{RT}{\mathbf{F}} (1 + \beta x) d \ln x + q_J{}^d \frac{RT}{\mathbf{F}} \beta x\, d \ln x \quad [8]$$

where q_a is the adsorbed charge density due to iodide ions and $q_J{}^d$ is the surface excess of anions in the diffuse layer.

The usual way of determining ξ_+ is to integrate capacity against potential curves twice from a fixed negative potential E_+ where adsorption of anions may be considered negligible and thus the charge on the electrode independent of solution composition. However, from Eq. [8], it is apparent that γ and ξ_+ will not be independent of solution composition when $q_I{}^a$ is zero. At constant charge density, the value of ξ_+ at a fixed reference potential, $\xi_+{}^r$ is given by

$$\xi_+{}^r = \xi_+{}^{ro} + q_J{}^d \cdot \frac{RT}{\mathbf{F}} \beta x \quad [9]$$

where $\xi_+{}^{ro}$ is the value of $\xi_+{}^r$ when $x = 0$. Using this relationship the necessary integration constants may be calculated and $\Delta\xi_+ = \xi_+ - \xi_+{}^\circ$ determined for any value of E_+ or q.

Having determined ξ_+ as a function of solution composition at constant q, one may determine $q_I{}^a$ by differentiation. From Eq. [8]

$$\frac{\mathbf{F}}{RT} \frac{1}{(1+\beta x)} \left(\frac{\partial \xi_+}{\partial \ln x} \right)_q = q_a + q_J{}^d \frac{\beta x}{(1+\beta x)} \quad [10]$$

When $/q + q_a/$ is large, $q_J{}^d$ approaches a constant value, given by $(RT\epsilon\mu/2\pi)^{1/2}$ where ϵ is the dielectric constant of the pure solvent. Thus, an approximate value of q_a may be calculated using the limiting value of $q_J{}^d$. The estimate is then improved using an iterative technique and the exact expression for $q_J{}^d$ from Gouy-Chapman theory.

Examination of existing activity coefficient data reveals that the mean ionic activity coefficient for KI is approximately 1% higher than that for KF whereas that for NaI is 7% higher than that for NaF. Thus, any variation in γ for the KI-KF system would be difficult to determine experimentally and it is probably legitimate to assume $\beta \simeq 0$ for this system; however, as is shown below, variation in γ_{Na} in the NaI-NaF system can be detected experimentally. Thus, the exact analysis presented above was used for the latter system.

Results

Experimental values of the emf of cell [1], ϵ together with the corresponding values of $\epsilon + (RT/\mathbf{F}) \ln c_{Na}c_I$ are recorded in Table 1 for varying values of x with $\mu = 0.25$M. From the Nernst equation for this cell

$$\epsilon + \frac{RT}{\mathbf{F}} \ln c_{Na}c_I = \epsilon_0 - \frac{RT}{\mathbf{F}} \ln \gamma_{Na}\gamma_I \quad [11]$$

where ϵ_0 is the standard emf. The derivative $d(\epsilon + (RT/\mathbf{F}) \ln c_{Na}c_I)/dx$ is equal to 2 mV; thus, assuming γ_I is independent of solution composition, $\beta = d \ln \gamma_{Na}/dx$ is equal to 0.078. From Eq. [10], it is apparent that neglect of variation of γ_{Na} would result in q_a being overestimated by approximately 8% when $x = 1$. The relative error decreases with decrease in x. It is also apparent that any variation in γ_K in the KI-KF could not be detected by using the equivalent cell to [1] for the K^+ system when the precision of the emf measurements is ± 1 mV. Thus, β for the K^+ system was assumed to be zero.

Typical capacity against potential curves for the KI-KF system are shown in Fig. 1. A small decrease in the slope of these curves followed by a steady increase is observed at potentials just positive of the point of zero charge. Similar but more pronounced effects are observed on capacity curves for Cl^- and Br^- systems (2, 3, 5-7) in water but are absent for the I^- systems in nonaqueous solvents (17). This effect is normally attributed to changes in the dielectric properties of the inner layer due to water molecule reorientation (1).

The capacity-potential curves were twice integrated from negative potentials ($E_+ = -1.596$V at $q = -21$ μC cm^{-2} for the KI-KF system and $E_+ = -1.610$V at $q = -21$ μC cm^2 for the NaI-NaF system) where anion adsorption could be assumed negligible and $\Delta\xi_+$ calculated for integral increments in q using well-established technique (3, 12) modified to take into account the variation in γ_{Na^+} in the NaI-NaF system as described above. The adsorbed charge density due to I^- was calculated according to Eq. [10], the derivative $(\partial\Delta\xi^+/\partial \ln x)_q$ being estimated by numerical differentiation using a least squares fit of a cubic equa-

tion to $\Delta\xi^+$ against ln x data over the total experimental range (18).

Adsorption isotherms for the KI-KF system at constant charge density are shown in Fig. 2. The curvature of these plots changed with q indicating that the isotherm is not congruent in this electrical variable. Similar results have been found for the adsorption of Br^- (6, 7) and Cl^- ions (5) whereas the adsorption isotherm for I^- ion from solutions of higher ionic strength (8) was found to be congruent in electrode charge density. The latter data were obtained only at more negative electrode charge densities ($q < -6$ μC cm^{-2}) which may account for the difference in behavior with that observed here over a wider range of q. Comparison of the present data with those of Dutkiewicz and Parsons (8) also shows that the adsorbed charge density due to I^- ions, $|q_a|$ is significantly less in the system of lower ionic strength. Although the amount of adsorption is less, similar adsorption isotherms are obtained for the NaI-NaF system. Results obtained at a bulk concentration of 0.1M I^- in the present and previous studies are shown as a function of electrode charge density in Fig. 3. A large increase in $|q_a|$ with ionic strength is readily apparent; a small but significant increase in q_a when the counterion is changed from Na^+ to K^+ at constant ionic strength is also observed.

Plots of the potential drop across the inner layer, ϕ^{md}, against the adsorbed charge density, q_a, at constant electrode charge density are shown for the KI-KF system in Fig. 4. The plots were linear within experimental error but their slopes changed significantly with q indicating that the absorption could not be described by an isotherm congruent in electrode charge density. The plots for the NaI-NaF system were similar in appearance but had higher slopes. The reciprocals of the slopes of the above plots, that is, $(\partial q_a/\partial \phi^{md})_q$ is plotted against electrode charge density in Fig. 5. In terms of the simple electrostatic model of the inner layer $(\partial q_a/\partial \phi^{md})_q$ is equal to the integral capacity of the region between the adsorp-

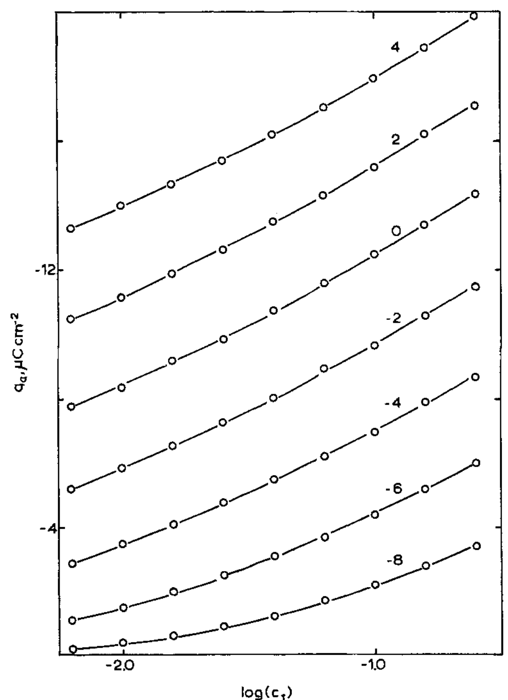

Fig. 2. Plots of the adsorbed charge density due to I^-, q_a against the logarithm of I^- concentration in the bulk, log (c_I) for various constant charge densities on the electrode (indicated by the integers adjacent to each curve) for adsorption from the KI-KF system.

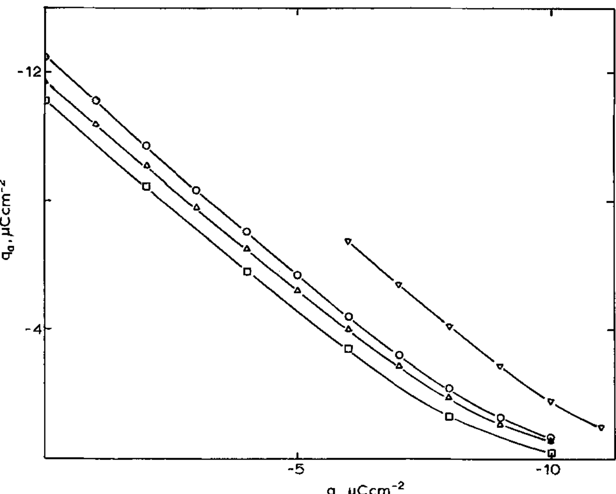

Fig. 3. Plots of the adsorbed charge density due to I^-, q_a against the electrode charge density, q for constant bulk I^- concentration (0.1M) but varying ionic strength and counterion: □, 0.1M KI [Grahame (4)]; △, 0.1M NaI + 0.15M NaF (this work); ○, 0.1M KI + 0.15M KF (this work); ∇, 0.1M KI + 0.9M KF [Dutkiewicz and Parsons (8)].

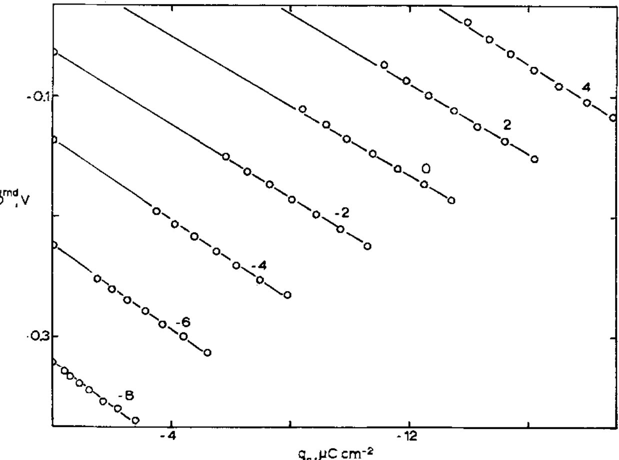

Fig. 4. Plots of the potential drop across the inner layer, ϕ^{md} against the adsorbed charge density, due to I^-, q_a at constant electrode charge density (indicated by the integer adjacent to each plot) for adsorption from the system xM KI + (0.25 − x)M KF.

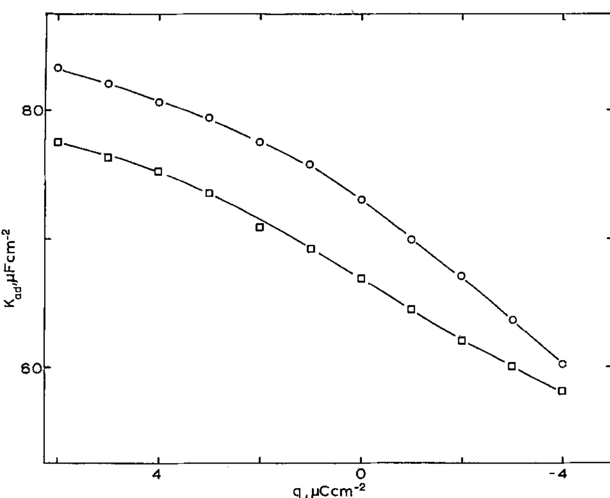

Fig. 5. Plots of the integral capacity of the region between the inner Helmholtz plane and the outer Helmholtz plane, K_{ad} against the electrode charge density, q for the NaI-NaF system (□) and KI-KF system (○).

tion or inner Helmholtz plane (IHP) and the OHP, that is, K_{ad}. The fact that K_{ad} is significantly lower for the NaI-NaF system suggests that the thickness of this region is greater in the Na^+ system than in the K^+ system.

The function $\ln(-q_a/c_I) - f\phi^d$, where ϕ^d is the potential drop across the diffuse layer and $f = \mathbf{F}/RT$, is plotted against q_a in Fig. 6. The linearity of these plots suggests that a virial isotherm with a term correcting for the diffuse layer (19) accounts for the data obtained. This type of adsorption isotherm is expected when the simple electrostatic model for ionic adsorption (10) is applicable and electrode coverage is small so that the entropic term in the isotherm, $\ln(1 - \theta)$ may be approximated by the first two terms in its series expansion (19).

Discussion

Effects of activity coefficient variation.—Two aspects of activity coefficient variation should be considered here: the variation in activity of iodide ion with nature of the cation for constant bulk concentration and ionic strength, and the variation in metal ion activity with solution composition for constant ionic strength and metal ion nature. From tabulated activity coefficient data, the mean ionic activity coefficients in 0.25M NaI and KI solutions are 0.741 and 0.718, respectively. Assuming $\mathring{a}_{Na} = 4Å$, $\mathring{a}_K$ and $\mathring{a}_I = 3Å$ (20), and applying Eq. [2] and [3], β_{NaI} and β_{KI} are estimated to be 0.019 and 0.016, respectively, Thus, $\gamma_I = 0.727$ in 0.25M NaI and 0.718 in 0.25M KI. Other factors ignored, one would then expect more adsorption of I^- from the NaI system since its activity is higher at the same concentration. It then follows that one cannot attribute the decreased adsorption from the NaI system to a corresponding decrease in the bulk activity of the I^- ion.

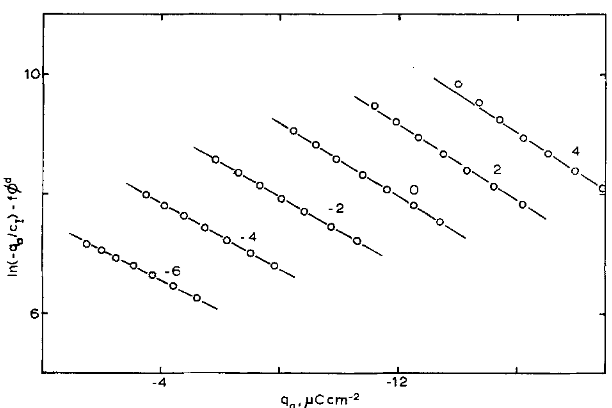

Fig. 6. Plots of the function $\ln(-q_a/c_I) - f\phi^d$ against charge density due to adsorbed I^-, q_a at constant electrode charge density (indicated by the integer adjacent to each plot) for the KI-KF system.

The applicability of the above model may be tested by comparing the experimentally measured value of β for the NaI-NaF system with that estimated using Eq. [2] and [3]. Assuming $\mathring{a}_F = 3.5Å$ (20), $\beta_{NaF} = -0.001$ and $\beta = (\beta_{NaI} - \beta_{NaF})\mu = 0.079$. This result agrees very well with that obtained experimentally and confirms that the estimates of single ion activities may be considered reliable.

It is worth mentioning that, although one might expect significant variation in single ion activities in some of the systems studied previously using the Hurwitz-Parsons method, only one attempt appears to have been made to consider this variation in the thermodynamic analysis (21). In that salt activities may be measured relatively easily using the emf technique with specific ion electrodes, this aspect of the Hurwitz-Parsons analysis of ionic adsorption should not be overlooked in future work. The data for systems with nonnegligible β previously published should also be reexamined.

Adsorption of iodide ion at mercury.—Although the data reported here are qualitatively similar to those presented earlier for halide ion adsorption (2-8), they can be used to elucidate several problems regarding ionic adsorption discussed in the recent literature (1). One point which has received a great amount of attention is the question of whether an isotherm congruent in either electrode charge density or electrode potential could be used to describe ionic adsorption. In more recent work it has been emphasized that a term to account for the contribution to the free energy of adsorption due to the potential drop across the diffuse layer must appear explicitly in the adsorption isotherm (7, 19). Since ϕ^d is a function of both electrode charge density and bulk iodide ion concentration it follows that congruency in one or other of the electrical variables can be observed only when the diffuse layer term is negligibly small or fortuitously constant with change in bulk concentration of the adsorbing ion.

The present results provide direct evidence of the necessity of including the diffuse layer term in the isotherm. Thus, to a first approximation, the increase in $/q_a/$ with increase in ionic strength at constant q may be attributed to a corresponding decrease in $/\phi^d/$, that is, to a decrease in the repulsive field of the diffuse layer. More precisely, the electrostatic contribution to the free energy of adsorption of a monovalent anion may be written (10)

$$(\Delta G_a)_e = -\mathbf{F}\phi^d - \mathbf{F}(q + q_a)/K_{ad} + \xi_{sa} + \xi_{ds} \quad [12]$$

where the first two terms account for the difference between the average potential on the adsorption plane and that in the bulk of the solution, ξ_{sa} is the contribution due to the self-images formed by the adsorbing ion in the metal and diffuse layer (self-atmosphere potential) and ξ_{ds}, that due to the fact that the ion occupies finite area on the adsorption plane (disk potential). Other than the change in ϕ^d, one may distinguish two other factors which contribute to a decrease in $(\Delta G_a)_e$ with increase in ionic strength for constant q and q_a. It can be argued that the effective thickness of the inner layer decreases with increase in ionic strength; this change results mainly in an increase in K_{ad}, the effective capacity of the region between the adsorption plane and the outer Helmholtz plane (8) and thus in a decrease in $(\Delta G_a)_e$.

At the same time the self-atmosphere contribution ξ_{sa} becomes more negative due to the increased efficiency of image formation in the diffuse layer. The above effects are reduced somewhat by a decrease in the value of $/\xi_{ds}/$. The disk term is negative and given approximately by $\xi_{ds} = Fg\, K_{md}\, q_a/K_{ma}\, K_{ad}$ where K_{md} is the integral capacity of the inner layer, K_{ma}, the capacity of the region between the metal and adsorption plane, and g, a dimensionless parameter approximately equal to unity (23). The increase in K_{ad} results in a smaller increase in K_{md} and thus a small decrease in $/\xi_{ds}/$. It is easily shown by calculations on the basis of models developed by Levine *et al.* (10, 22, 23) that the total effect of increase in K_{ad} with ionic strength is a corresponding decrease in $(\Delta G_a)_e$.

The variation in q_a with counterion nature at constant q and ionic strength can also be accounted for on the basis of the above electrostatic model. Although ϕ^d is independent of counterion nature to a first approximation, K_{ad} increases when the counterion is changed from Na^+ to K^+ (Fig. 5). As argued above, this will result in a decrease in the second and third terms in Eq. [12], an increase in the fourth term, and an over-all decrease in $(\Delta G_a)_e$. Thus, one observes an increase in the difference in q_a for the Na^+ and K^+ systems as the difference between the corresponding values of K_{ad} increases. An alternative explanation of the cation effect on iodide ion adsorption is to attribute it to cation coadsorption, the amount of cation adsorption being larger in the K^+ system. However, one would expect the amount of cation adsorption to increase as the charge on the electrode becomes more negative, and thus the difference between q_a in the Na^+ and K^+ systems to become more pronounced at negative charge densities. The present results show exactly the opposite trend and thus are evidence against this explanation of the cation effect. All results obtained are consistent with a model of the inner layer in which its thickness at negative charge densities is determined by the distance of closest approach of a solvated cation, the solvated radius of Na^+ being larger than that of K^+. A similar explanation can be offered to account for all or part of the cation effect observed for the kinetics of electron transfer reactions occurring at negative charge densities on mercury (24, 25).

The Christie plots presented in Fig. 4 are normally interpreted in terms of a simple electrostatic model of the inner layer according to which

$$\phi^{md} = \frac{q}{K_{md}} + \frac{q_a}{K_{ad}} \qquad [13]$$

If K_{md} and K_{ad} are independent of q_a for fixed q, then the slope of the Christie plot is equal to $1/K_{ad}$. In the more general case, the slope is given by

$$\frac{\partial \phi^{md}}{\partial q_a} = \frac{1}{K_{ad}} + q_a\left(\frac{\partial(1/K_{ad})}{\partial q_a}\right)_q + q\left(\frac{\partial(1/K_{md})}{\partial q_a}\right)_q \qquad [14]$$

Since the Christie plots are linear, one may conclude that $\partial(1/K_{ad})/\partial q_a \simeq 0$. Considering the fact that the plots are not parallel, one would expect some contribution from the third term in Eq. [14]. However, its magnitude must be small or approximately independent of q_a for the range of values of q and q_a considered in Fig. 4. Since $/q/$ is not large in this range and no curvature is apparent, one may conclude that the slope of the Christie plots is approximately equal to $1/K_{ad}$ in the present case. Dutkiewicz and Parsons (8) found K_{ad} to be approximately constant (59 μ**F**-cm^{-2}) in the 1M KI-KF system at negative charge densities ($-12 < q < -6$ μcoulombs-cm^{-2}). The values obtained here are somewhat smaller ($K_{ad} = 50$ μ**F** cm^{-2} at $q = -8$ μcoulombs-cm^{-2}) and appear to decrease as the charge on the electrode becomes more negative (Fig. 5). Several explanations could be offered for the disagreement. First, the numerical differentiation technique used to determine q_a becomes very inaccurate at large negative charge densities where the total change in $\Delta\xi_+$ at constant q is small. On the other hand, Dutkiewicz and Parsons assumed that the isotherm is congruent and thereby avoided numerical differentiation, the values of q_a being obtained from ΔE_+, the potential shift due to adsorption at constant electrode charge density (8). However, their procedure may be considered as a particular kind of data smoothing which necessarily results in approximately parallel Christie plots and a constant value of K_{ad} (1). The value of $(\partial\phi^{md}/\partial q_a)$ obtained by Grahame (4) in pure KI solutions at the point of zero charge agrees well with that obtained here. At more negative or positive charge densities the agreement is poor. If K_{ad} changes with ionic strength, the disagreement can be attributed to increased contributions from the terms $\partial(1/K_{ad})/\partial q_a$ and $\partial(1/K_{md})/\partial q_a$ in Eq. [14].

Several attempts have been made (19, 26) to analyze adsorption data similar to that obtained here on the basis of the electrostatic model developed by Levine *et al.* (10, 23). In the case that the adsorbing ion is small, the adsorption isotherm may be written

$$\ln\theta - \ln(1-\theta) = \ln_{\Gamma}{}^{a} - (\Delta G_a)_c/RT - (\Delta G_a)_e/RT \qquad [15]$$

where $\theta = q_a/q_m$, q_m being the maximum adsorbed charge density, and $(\Delta G_a)_c$ is the part of the free energy of adsorption which is independent of the electrical state of the interface. Since the coverage obtained in these experiments is small, q_m cannot be easily determined. Furthermore, the component capacities of the inner layer K_{ma} and K_{ad} can only be determined approximately from the Christie plots so that further analysis of the data presented in Fig. 6 does not seem worthwhile at present. However, it should be noted that the contribution to the free energy of adsorption due to the self-atmosphere potential (Eq. [12]) has been overlooked in previous analyses. Calculations have shown that this term is not negligible (22). Although it may not vary much with q_a, one would expect it to vary significantly with q.

Counterion effects at other charged interfaces.—From a biological point of view studies of counterion effects at charged monolayers and bilayer lipid membranes (BLM) may be useful in elucidating the electrical behavior of membranes in living systems (26a). In this regard one may distinguish two cation effects at negatively charged monolayers and BLM. The first is the selectivity for cation transport which is often observed in these systems and which depends both on the chemical nature of the film and also on the presence of lipid soluble carriers such as valinomycin (27-29). The second effect and that with which this paper is concerned is the nature of the average and local potential profiles at the interfaces of the system and its influence on adsorption of other ions and dipolar molecules and on transport through the film.

Goddard and co-workers (30-33) have studied the effects of counterion nature on the surface pressure and potential at both positively and negatively charged monolayers. For negatively charged head groups, these properties depend both on the nature of the head group and on the nature of the cation in solution. The surface potential of an expanded arachidic acid monolayer ($-COO^-$ head group) is negative in alkali metal hydroxide solutions and decreases in magnitude in the sequence $K^+ > Na^+ > Li^+$. In the case of expanded docosyl sulfate monolayers, the sequence is reversed. Thus, Goddard (32) has argued that alkali metal cation interaction with ionized fatty acid monolayers increases as the crystallographic radius

of the cation decreases ($Li^+ > Na^+ > K^+ > Rb^+ > Co^+$) whereas interaction with alkyl sulfate monolayers increases as the hydrated radius of the cation decreases ($Co^+ \simeq Rb^+ > K^+ > Na^+ > Li^+$). In fact, the situation is undoubtedly much more complex. Examination of the literature on cation effects at negatively charged colloids reveals that cation interaction depends very much on the nature of the anionic group and that more than the above two interaction sequences for alkali metal cations are observed experimentally (34). Cation interaction with BLM does not appear to have been studied in any detail (28, 29) but electrical properties such as BLM capacitance have been found to depend on the nature and concentration of the electrolyte in the surrounding solution (28).

Erlander (34) has shown that cation interaction sequences at negatively charged colloids can be rationalized on the basis of the Frank and Wen model (35) of water structure surrounding the interacting ions with consideration of their effective dielectric constants. Accordingly, ions with high charge to radius ratios are surrounded by A-type water which is strongly bound to the ion by ion-dipole interactions. Most ions are also surrounded by B-type water in which the normal structure is broken and neither ion-dipole nor dipole-dipole interactions predominate. The normal water structure which is determined by dipole-dipole interactions and hydrogen bonding is designated C-type. Thus, Li^+, Mg^{++}, Ca^{++}, Sr^{++}, and Ba^{++} ions are surrounded immediately by A water with a layer of B water beyond the tightly bound dipoles. Cs^+, Rb^+, K^+, Cl^-, Br^-, and I^- do not have any ordering effect and thus are surrounded by a B region only. Na^+ and F^- are considered to have an A region but no B region. Erlander has estimated the effective dielectric constant of the B region surrounding the ions and has argued that ion-ion interaction increases when the effective dielectric constants are similar in magnitude (36). In order to apply these ideas to biological membranes one must know something about the effect of the charged groups at the surface on the structure of the surrounding water molecules. Erlander has argued that the phosphate group in phospholipids which is in close proximity to a base is surrounded by B water with a low effective dielectric constant. Thus, it interacts most strongly with K^+ which has similar characteristics. The interaction sequence ($K^+ > Na^+ > Rb^+ > Li^+ > Cs^+$) then depends on whether the cation has an A region and on the effective dielectric constant of the B region. Similar concepts can be applied to cation interaction with other common negative sites such as carboxylate (34).

In order to develop an electrostatic model for the potential distribution at the membrane/solution interface one must know the relative positions of the charged head group and counterions. At mercury the counterions are normally assumed to be ~5Å from a homogeneous, geometrically smooth metal/solution interface; more precisely, the distance of closest approach of the counterion and thus the potential distribution at the interface depend on the nature of the interaction of both the charged metal surface and the counterion with surrounding water molecules. Considering the structure of phospholipid molecules it is quite possible that the counterions could penetrate beyond the plane through the charge centers of the phosphate groups. Since the membrane also contains protein and more than one type of phospholipid molecule (36a), often distributed in different ways on the inside and outside walls of the membrane (37), the local potential profile near the interface undoubtedly varies considerably over the surface of the membrane. Reeves and co-workers (38, 39) have developed an NMR technique for studying the orientation of double layer ions at model membranes based on lyotropic liquid crystals. Application of this technique or another spectroscopic method to real membrane systems could be of considerable help in elucidating the spatial distribution of charged groups and ions at the membrane's surfaces. Levine et *al.* (40) have reviewed the electrostatic models developed to account for the surface potential and surface pressure observed at charged interfaces. They have emphasized the importance of considering the discrete nature of the charge as well as the distribution of counterions with respect to the charged head groups. Undoubtedly, the models developed for charged monolayers could be modified to deal with the potential distribution at each of the charged interfaces of the membrane. An understanding of the electrostatic situation could then be used to elucidate electrosorption, ionic surface excesses, and eventually the electrostatic factors which play a role in ion transport.

Surface Charges on Nerve Membranes and Artificial Lipid Bilayers

B. Neumcke

I. Physiologisches Institut der Universität des Saarlandes, 665 Homburg, Saar, Germany

ABSTRACT

The determination of membrane surface charges is described for membranes of unmyelinated and myelinated nerves and for artificial lipid bilayer membranes. In nerve membranes negative surface charges are found. Their density is larger at the external than at the internal interface. This result is discussed in terms of "flip-flop" transfer of charges between both surfaces across the membrane which is controlled by the electric field. Surface charge densities at lipid bilayer membranes formed from lipids with charged polar groups are higher than the corresponding densities at nerve membranes. The importance of discreteness of charge effects on the determination of membrane surface charges is estimated for nerve membranes and lipid bilayers and is illustrated by several examples.

Biological membranes are thin layers of proteins and lipids. Due to electrostatic and hydrophobic interactions the polar groups of these molecules are oriented toward the extra- and intracellular solutions whereas the lipophilic parts form the interior of the membrane. Charged polar groups thus are preferentially located at the membrane-solution interfaces. There is now growing evidence that these surface charges are essential for the structure and function of membranes. For example, the stability of membranes is critically affected by mutual repulsions of surface charges tending to disorder the orientation of polar head groups in the surface layers (1). The electrical conductivity of membranes depends on the membrane surface potential and can be controlled by specific surface charges near ion selective channels (2). Furthermore, surface charges may be sites for the adsorption of uncoupling agents (3) or even of macromolecular phages (4).

In this contribution surface charges are characterized for nerve membranes and compared with those at the surface of artificial lipid bilayers. For both types of membranes the exact shape of the surface and the location of charges are unknown. We, therefore, have to apply several idealizations: The membrane surface is considered as a plane interface separating two homogeneous phases with different dielectric constants. Dipole potentials and layers of adsorbed ions are neglected, and the surface charges are treated as uniformly distributed over the membrane surface. Some effects of discrete charge distributions are discussed in the last section of this contribution.

Determination of Surface Charges

In principle there are two different approaches for determining membrane surface charges.

Key words: nerve membrane, lipid bilayer, membrane surface charge, discrete charge distributions

1. *Change of intramembrane field strength.*—The membrane surface potential depends on the ionic composition of the solutions in contact with the membrane. If a new solution is applied in which a different surface potential is generated, a corresponding change of the electric field strength in the membrane will occur though the externally applied voltage is kept constant. All field-dependent membrane parameters then are shifted along the voltage axis. The measured shift (corrected for the voltage drop at the membrane series resistances and for liquid junction potentials between the test solutions used) is equal to the change of the surface potential from which the density of surface charges can be calculated by applying the Gouy-Chapman theory of the diffuse double layer.

2. *Change of stationary ion flux.*—A change of the surface potential also affects the stationary ion flux. If the ion transport across the membrane is described as jump over a single symmetrical activation energy barrier, the stationary flux Φ of univalent cations is proportional to (compare Eq. [A-9] of the Appendix)

$$\Phi \simeq \exp\left[-\frac{\mathbf{F}}{2RT}(\Psi' + \Psi'')\right] \left[c' \exp\left(-\frac{\mathbf{F}U}{2RT}\right) - c'' \exp\left(\frac{\mathbf{F}U}{2RT}\right)\right] \quad [1]$$

where U is the externally applied voltage, c' and c'' the bulk cation concentrations in the solutions, Ψ', Ψ'' the surface potentials at the outer and inner membrane surface; **F** Faraday constant; R gas constant; and T absolute temperature. Thus Φ is a function of the sum $\Psi' + \Psi''$ of both surface potentials. For a symmetrical membrane and for identical ionic compositions of the solutions it is $\Psi' = \Psi'' = \Psi$ and the expression [1] con-

tains the Boltzmann factor $\exp(-\mathbf{F}\Psi/RT)$. The same result can be derived in the ohmic region $U \rightarrow 0$ using the Nernst-Planck diffusion equation (5). The surface potential Ψ of a symmetrical membrane then can be determined in the following way: If the stationary ion flux through this membrane and the flux through a membrane without surface charges but otherwise identical composition are measured, the flux ratio is equal to the Boltzmann factor $\exp(-\mathbf{F}\Psi/RT)$ from which Ψ can be obtained.

Surface Charges on Nerve Membranes

If the ionic strength of the internal perfusate of squid giant axons is lowered, the sodium inactivation curve is shifted along the voltage axis in the positive direction (6). This effect was attributed to the presence of negative fixed charges at the inside of the nerve membrane and the change of the internal field strength after altering the ionic strength. With the method 1 described above a density $-1e_o/(27\text{Å})^2$ (e_o is the elementary charge) was calculated for internal surface charges (6). At normal ionic strength of the intracellular solution this surface charge produces a surface potential of about $-$ 17 mV. The surface charge density at the external membrane surface of squid giant axons was determined by varying the concentration of divalent cations in the extracellular solution. Higher amounts of these ions shift the potassium conductance-voltage curve in the positive direction from which a density $-1e_o/(11\text{Å})^2$ of negative outer surface charges and a surface potential of -46 mV at physiological Ca concentrations were obtained (7). Shifts of almost identical size were found at squid giant axons for the curves relating the time constant of potassium activation and membrane potential at various extracellular Ca and Mg concentrations (8).

Surface charges at myelinated nerve fibers were determined for the nodal membrane of frog sciatic nerves. For this preparation the surface charge density can be calculated from the shifts of the ionic conductances in the positive direction which are induced by lowering the extracellular *p*H. This results in a density of $-1e_o/(20\text{Å})^2$ and an intrinsic $pK_a = 4.3$ for unspecific external surface charges (2). [See also Ref. (8a, 8b).] The surface charge density at the internal surface of the nodal membrane cannot be determined directly. However, an estimate of $-1e_o/(29\text{Å})^2$ for this density can be derived by the hypothesis that the observed spontaneous shift of the steady-state sodium inactivation curve during long lasting voltage clamp experiments is caused by a decrease of negative interior surface charges (9). With the appropriate ionic compositions of intra- and extracellular solutions the surface potentials -19 and -48 mV are found for the internal and external surface potentials of myelinated nerves under physiological conditions.

It is evident that for squid giant axons and myelinated nerves the charge density at the external surface exceeds that at the internal one. This distribution would follow if the surface charges were not fixed at one interface but were able to diffuse across the hydrophobic interior of the nerve membrane toward the opposite membrane-solution interface. In this case the amount of surface charges at the external and the internal surface would be governed by the electric field strength in the membrane. This was recognized by McLaughlin and Harary (10) who calculated the equilibrium distribution of surface charges at giant axons at various membrane potentials. They concluded that at the resting state the charge density and surface potential at the outer surface would be substantially greater than the corresponding values at the inner surface. This prediction of the "flip-flop" diffusion of surface charges is in agreement with the charge densities found for the inner and outer surface of nerve membranes. If the redistribution of surface charges in nerve membranes were possible, more negative surface charges would be driven from the inner to the outer membrane surface at holding potentials which are more negative than the resting potential. The surface potential ϕ' at the outer membrane surface then would assume more negative values whereas the corresponding surface potential ϕ'' at the inner membrane surface would become less negative. This would modify the stationary ion flux Φ at a given external voltage u according to the Eq. [A-6] derived in the Appendix. Increase or decrease of Φ were determined by the asymmetry parameter α. For $\alpha = 1$ (energy barrier located at the inner membrane surface) the flux Φ would decrease for flip-flop of negative surface charges from inside to outside (compare [A-8]). Instead an increase of the sodium and potassium currents was measured at more negative holding potentials than the resting potential (11). Therefore, the energy barrier must be located near the outer membrane surface if the observed increase of the ionic currents is caused by transverse motion of negative surface charges from inside to outside. In this case a change of the internal field strength should occur which should affect all field-dependent membrane parameters. However, no significant shift of the steady-state sodium inactivation was measured during fixed test pulses starting from different holding potentials (11, Fig. 2). Also, no evidence for a transmembrane motion of surface charges could be found during long depolarizations at squid axon membranes (12). Thus the existence of flip-flop of surface charges induced by a change of the holding potential is still questionable. However, a possible transverse diffusion of charged macromolecules in the interior of the nerve membrane can be inferred from the kinetics of the slow variations of the sodium current following changes of the holding potential or the extracellular *p*H. This analysis has been published elsewhere (13).

Surface Charges on Lipid Bilayers

Artificial lipid bilayer membranes can be formed from various lipids with two hydrocarbon chains per lipid molecule. As in biological membranes the polar end groups of the molecules are preferentially located at the lipid-solution interfaces whereas the hydrocarbon chains are oriented toward the interior of the membrane. Bilayer membranes from lipids with charged polar groups thus bear surface charges. For lipids of known composition the approximate area per lipid molecule at the surface of lipid bilayers and thus the surface charge density can be estimated. As an example a value of about 62Å^2/molecule was reported for phosphatidylcholine (14). Similar surface densities are expected for other lipid molecules.

The surface potential of charged lipid bilayer membranes can be determined by comparing the stationary conductivity of membranes with and without surface charges (method 2, see above). In this way a high density of $-1\, e_o/38\text{Å}^2$ was obtained for negatively charged phosphatidylserine bilayer membranes from conductance measurements at these membranes and at neutral phosphatidylethanolamine bilayers (15). The binding of a *p*H sensitive fluorescence probe to a charged interface offers another possibility for determining its charge density. This probe will indicate the local *p*H at the interface thus showing a pK_a shift with respect to the bulk *p*H. Calculations on the basis of these shift measurements lead to charge densities at lipid-solution interfaces between $1\, e_o/50\text{Å}^2$ and $1\, e_o/100\text{Å}^2$ (16, 17). Thus the interpretation of the measured pK_a shifts in terms of membrane surface charges gives reasonable surface charge densities. Finally, the binding of the hydrophobic fluorescence probe ANS^- (1-anilino-8-naphthalene sulfonate) to phospholipid membranes responds to the membrane surface potential and this probe, too, can be used to determine surface charge densities. An average distance of approximately 8Å between charged centers at the membrane surface was deduced from these binding experiments (18). In the

same investigation significant deviations from the ideal Gouy-Chapman behavior were found and interpreted in terms of discreteness of charge. These discrepancies between discrete and uniform charge distributions are discussed in the following section.

Discrete Charge Distributions

Since the arrangement of surface charges on biological membranes and lipid bilayers is unknown, the values of surface charge densities given in the previous sections were calculated by ignoring the discreteness of charges, *i.e.*, by smearing the ions in the membrane-solution interface. Such an approximation can lead to serious errors. This complication was recognized very early in investigations of charge distributions near electrode surfaces and there have been many attempts to calculate surface potentials at electrode-solution interfaces when charge discreteness is not neglected [as an example compare with Ref. (19)].

In the physiological literature there have been only a few contributions dealing with discrete charge and dipole distributions (20-25). Cole (21) estimated that deviations between discrete and homogeneous charge distributions are negligible if the product κb between the reciprocal of the Debye-Hückel length $1/\kappa$ in the solution and the separation b of surface charges arranged in a hexagonal lattice is less than 1. For $\kappa b > 1$ more discrete than uniformly distributed surface charges are required to obtain a given surface potential. We test this condition by inserting the values cited above for nerve membranes and lipid bilayers: For squid giant axons it is $1/\kappa \approx 4\text{Å}$ (ionic strength of the extra and intracellular solution approximately 500 mmoles). With a surface charge density of $-1e_o/(27\text{Å})^2$ at the inner (6) and $-1e_o/(11\text{Å})^2$ at the outer membrane surface (7) we have $\kappa b \approx 7$ and 3 for these two interfaces indicating a significant difference between surface potentials generated by equal amounts of uniform and discrete charge distributions. Similar values of κb are obtained for the membrane of myelinated nerve. Taking $1/\kappa \approx 10\text{Å}$ (ionic strength of the extra and intracellular solution approximately 100 mmoles) and the densities $-1e_o/(29\text{Å})^2$ and $-1e_o/(20\text{Å})^2$ for inner (9) and outer surface charges (2) we arrive at $\kappa b \approx 3$ and 2, respectively. Thus all surface charge densities at nerve membranes cited above have to be considered as lower limits. The actual density of discrete charges may be significantly higher to be in accordance with the magnitude of measured surface potentials. For $1/\kappa = 10\text{Å}$ the concept of uniform charge distributions can be used for charge separations less than 10Å. Therefore, no corrections have to be applied to the charge densities reported for lipid bilayer membranes.

As an example for significant deviations between smeared and discrete charge distributions we discuss the determination of negative surface charges at the outer membrane surface of myelinated nerves. From our experiments the decrease of the surface potential at lowered extracellular pH values is obtained. By applying a smeared charge model these results can be fitted with a uniform surface charge density of $-1e_o/(20\text{Å})^2$ and an intrinsic $pK_a = 4.3$ (2). If instead four discrete univalent negative charges are arranged around an ion selective channel of the nerve membrane, a charge distance of 10Å from the center of the channel and a $pK_a = 4.3$ are needed to be in accordance with the experimental results. The calculation of the titration curve of these discrete surface charges was performed in close analogy to the work of Nelson and McQuarrie (25). Thus the pK_a value of the surface charges is the same for both charge distributions whereas significantly higher discrete than smeared charge densities are obtained.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

APPENDIX

Derivation of Eq. [1]

The stationary ion flux across a membrane will be calculated for the general case of different bulk ion concentrations in the solutions on both membrane sides, for unequal surface potentials at the outer and inner membrane surface, and for an asymmetrical potential barrier in the interior of the membrane (see Fig. 1).

We assume that the rate-limiting step for the ion transport is the passage through the interior of the membrane. This implies that diffusion polarization effects in the unstirred solution layers near the membrane can be neglected and that equilibrium for ion adsorption and desorption processes at the membrane-solution interfaces is maintained even in the stationary state. The aqueous concentrations c'_m, c''_m of univalent cations at the membrane surfaces then are connected with the corresponding bulk concentrations c', c'' by the Boltzmann distribution

$$c'_m = c' \exp(-F\Psi'/RT)$$
$$c''_m = c'' \exp(-F\Psi''/RT) \quad [A\text{-}1]$$

(Ψ' and $\Psi'' < 0$ for negative surface charges.) For the ion transport of these univalent cations across the membrane interior we use Eyring's absolute rate theory (26) and assume one single activation energy barrier. The height H of this barrier is determined by the thickness and dielectric constant of the hydrophobic region of the membrane phase and by the radius of the permeant ion (27). Due to the externally applied voltage U (= potential in internal minus potential in external bulk solution) and due to surface potentials Ψ' and Ψ'' at both membrane surfaces the activation energy B' of an ion jump from outside to inside is different from the energy B'' for the reverse jump. Introducing the normalized quantities

$$h = \frac{H}{RT}; \quad b' = \frac{B'}{RT}; \quad b'' = \frac{B''}{RT}$$
$$u = \frac{FU}{RT}; \quad \phi' = \frac{F\Psi'}{RT}; \quad \phi'' = \frac{F\Psi''}{RT} \quad [A\text{-}2]$$

we obtain from Fig. 1

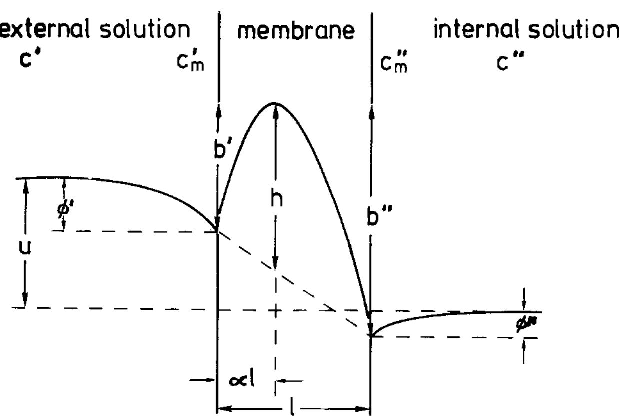

Fig. 1. Schematical plot of an asymmetrical energy barrier in the interior of the membrane and of the potential profile in the aqueous solutions for different surface charge densities on the outer and inner membrane surface.

$$b' = h + \alpha(u - \phi' + \phi'') \quad \text{[A-3]}$$

$$b'' = h - (1 - \alpha)(u - \phi' + \phi'') \quad \text{[A-4]}$$

The asymmetry parameter α may assume values between 0 and 1. For $\alpha = 0$ the energy barrier is located at the outer and for $\alpha = 1$ at the inner membrane-solution interface. Following Eyring the stationary flux Φ of univalent cations from outside to inside is proportional to

$$\Phi \simeq c'_m \exp(-b') - c''_m \exp(-b'') \quad \text{[A-5]}$$

The quantities contained in the proportionality factor (jump length, frequency factor) are assumed to be the same on both membrane sides and to be independent of the ion concentrations and membrane surface potentials. Inserting Eq. [A-1], [A-3], and [A-4] into [A-5] yields

$$\Phi \simeq c' \exp[-(1-\alpha)\phi' - \alpha(u + \phi'')] - c'' \exp[(1-\alpha)(u - \phi') - \alpha\phi''] \quad \text{[A-6]}$$

This general expression can be simplified for the following special cases:

(a) energy barrier located at the outer interface ($\alpha = 0$)

$$\Phi \simeq \exp(-\phi')[c' - c'' \exp(u)] \quad \text{[A-7]}$$

(b) energy barrier located at the inner interface ($\alpha = 1$)

$$\Phi \simeq \exp(-\phi'')[c' \exp(-u) - c''] \quad \text{[A-8]}$$

(c) symmetrical energy barrier ($\alpha = ½$)

$$\Phi \simeq \exp\left(-\frac{\phi' + \phi''}{2}\right)\left[c' \exp\left(-\frac{u}{2}\right) - c'' \exp\left(\frac{u}{2}\right)\right] \quad \text{[A-9]}$$

If the energy barrier is located at one interface, the stationary ion flux is determined solely by the surface potential of this membrane surface. For a symmetrical energy barrier the flux Φ depends on the sum $\phi' + \phi''$ of both surface potentials (compare Eq. [A-9] which is identical to [1])

The Electrochemistry of Micelle-Solubilized Ferrocene

Peter Yeh* and Theodore Kuwana†

Department of Chemistry, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The electrochemistry of ferrocene solubilized by the use of nonionic detergent in aqueous phosphate solutions *p*H 7.0 was studied. The ferrocene molecules were incorporated as micelles which readily transferred electrons with a platinum electrode. Cyclic voltammetric and potentiometric data indicated that the electron transfer reaction was reversible. Micelle size calculated from electrochemical diffusion and light scattering data gave radii between 40-45Å and molecular weights of *ca.* 130,000. The ferrocene-micelle served as an excellent mediator-titrant to couple electron transfer between an electrode and the heme proteins of cytochrome c, cytochrome c oxidase, and mixtures thereof.

Recently, ferricinium ion electrogenerated from ferrocene solubilized by the use of nonionic detergent has been employed for the redox titration of cytochrome c, cytochrome c oxidase, and mixtures thereof in aqueous *p*H 7.0 solutions (1). The detergent apparently formed micelles with the incorporation of ferrocene. The ferricinium/ferrocene couple is then acting as a mediator to couple the electron transfer between the electrode and the heme proteins.

Ferrocene-micelles represent part of our effort to find water-soluble mediator-titrants (M-T's) with redox potentials suitable for use in the study of biological electron transport components. Requirements sought for these M-T's are: (*a*) both species of the redox couple of the M-T's need to be soluble in aqueous media buffered at or near *p*H 7; (*b*) the solubility of the M-T's should be 1 mM or more; (*c*)

* Electrochemical Society Student Member.
† Electrochemical Society Active Member.

Key words: electrochemistry, ferrocene, micelle, mediator-titrants.

the rate of electron transfer with both electrode and heme proteins should be rapid; (*d*) the chemical stability should be adequate so that interferences with heme proteins be avoided; (*e*) the redox reaction mechanism should be uncomplicated, preferably involving one electron transfer ($\underline{n} = 1$); and (*f*) the optical absorbance of the M-T's should not interfere with those of the heme proteins. Very few M-T's fulfill all of the above requirements.

For working in the negative potential ranges, say −100 to −500 mV *vs.* NHE, the 4,4'-bipyridylium salts (commonly known as viologens or paraquats) have proved to be extremely useful (2). At potentials positive of *ca.* +300 mV *vs.* NHE, the number of usable M-T's has been extremely limited. Ferricyanide/ferrocyanide has been commonly used, but has been found to produce deleterious effects or to complex with the hemes (2, 3). It is desirable to find M-T's with similar redox chemistry whose redox potentials could be altered through simple structural modifications.

From previous experience (4) with the electrochemistry of metallocenes in nonaqueous solvents, it was known that ferrocene, for example, underwent a fast one electron redox reaction at a positive potential. However, the low solubility of ferrocene (*ca.* 10^{-5} *M*) in aqueous solutions prevented its use. Therefore, approaches to solubilization of these metallocenes were explored. Tween 20 was chosen for the present work because of our experience in the use of this surfactant in solubilizing heme proteins (2).

The number of electrochemical studies in which surfactant concentrations were deliberately increased above the critical micelle concentration for the solubilization of electroactive species has been limited. Hayano and co-workers (5, 6) have reported the use of several kinds of surfactants for the solubilization of dye molecules which exhibited reduction currents at dropping mercury electrode. Their results indicated that diffusion-limited currents could be attained and that the rate was limited by the diffusing micelle particles containing the dye. The effect of the surfactant-dye concentration ratio to the size-volume of the micelle was calculated from the experimentally obtained diffusion coefficient using the Stokes-Einstein relationship.

Westmoreland, Day, and Underwood (7) in 1972 reported the solubilization of azobenzene using surfactants such as sodium lauryl sulfate, cetylpyridinium chloride, and lauryltrimethylammonium bromide. Again, a diffusion-controlled wave attributable to micelle was found, and the reduction of azobenzene appeared to approach reversible behavior as the surfactant concentration decreased. In the above examples, reversibility and mechanism could be assessed only conditionally because of the fairly complex nature of the electron-transfer reaction, *i.e.*, $\underline{n}$ values greater than unity and possible involvement of protons.

In addition to our heme proteins studies (1), ferrocene (or dibutylferrocene) has been used as a mediator to couple electron transfer through lipid membranes as a model system for mitochondrial ion transport and respiratory control (8, 9). Ferrocene in these lipids (black lipid membranes and phospholipid vesicles) provided the coupling of electron transfer through the membrane with external redox reactants. The environment for ferrocene in the micelle is probably quite similar to that in the hydrophobic lipid membrane. Thus, a detailed study of the electrochemical and physical properties of ferrocene-micelle was of considerable interest and has stimulated the present work. The assessment of the formal redox potentials, $E^{o\prime}$, of cytochrome *c* and cytochrome c oxidase using the ferrocene-micelle are discussed.

Experimental

The electrochemical cell and instrumentation were similar to those previously described (9). A platinum optical transparent electrode (OTE) with surface resistance of *ca.* 10 Ω/sq was used for the electrochemistry. For optical measurements, another Pt OTE was placed in the reference beam of the spectrophotometer (Cary Model 15). The current-potential (*i-E*) curves were recorded using a Hewlett-Packard (Moseley Division) Model 7005B X-Y recorder. A silver-silver chloride (1*M* KCl) reference electrode was used for measurements of cell emf. The electrode potential of this reference half-cell was evaluated to be 0.232V *vs.* NHE by measuring its potential *vs.* several reference saturated calomel electrodes. Temperature was maintained at 20° ± 1°C. The silver-silver chloride reference electrode was used because of the desire to duplicate the electrochemical cell used for heme protein studies (9).

Turbidity and refractive indices of the surfactant solutions were measured with the Brice-Phoenix light scattering photometer (Universal 1000 series) and a differential refractometer (Phoenix Precision Instrument). Viscosity measurements of solutions were made using a Ubbelohde viscometer (No. 1B-A356) which had been calibrated as described by Cannon (10). Filtration experiments were done with an ultra filtration cell (Model 202, Amicon Corporation) and Diaflo ultrafilters XM50 and XM100A under 15 psi of pressure.

An ultrasonic vibrator-cleaner (Heat Systems Ultrasonics, Incorporated) was used to assist in the solubilization of ferrocene and to pretreat glasswares for cleaning purposes.

Ferrocene (dicyclopentadienyliron) was obtained from Strem Chemical Company and was triply recrystallized from reagent grade ethanol. Tween 20 (Polysorbate 20, polyoxyethylene sorbitan monolaurate) with average molecular weight of 1650 was obtained from Sigma Chemical Company. It was purified by treatment through an alumina (aluminum oxide, basic, Alupharm Chemicals) column (18 in. long, 0.5 in. diameter). A very light straw-colored fraction was left on the column. Phosphate buffer, pH 7.00 ± 0.02 (Buffer Titrosol, Merck and Company) was used for buffering all solutions. J. T. Baker and Company reagent grade potassium chloride and silver sulfate were used without further purification. Prepurified grade nitrogen gas (99.998%) was supplied by American Oxygen Service Corporation. Doubly distilled water was used to prepare all solutions.

The solubility of ferrocene is less than 10^{-5}*M* in water at room temperature. It was solubilized by adding purified Tween 20 and a few milliliters of phosphate buffer directly to a weighed amount of ferrocene in a 100 ml volumetric flask. The amount of Tween 20 added was determined by the percentage of Tween desired in the final solution. The mixture was stirred and then agitated in an ultrasonic vibrator for about 30 min. The flask was filled to the mark and then stirred with a magnetic stirrer for another 12 hr. Attempts to solubilize ferrocene in water by dissolving ferrocene initially in alcohol or benzene and then adding water were unsuccessful since ferrocene precipitated as water was added.

Results and Discussion

Cyclic voltammetry of ferrocene-micelle.—Since ferrocene was being investigated as a possible mediator-titrant, the working range of concentration selected for study was between 0.1 and 0.5 m*M*. At Tween 20 concentrations below about 0.5% by volume of final solution, ferrocene was not totally solubilized as was evidenced by the nonreproducible electrochemical results. In the concentration range of 1.0-5.0% of Tween 20, ferrocene was completely solubilized and the cyclic voltammetric *i-E* curves were reproducible. A typ-

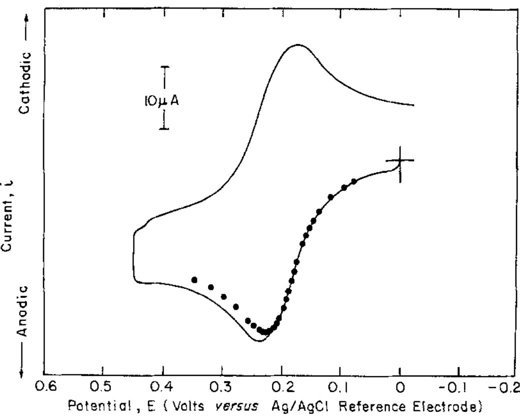

Fig. 1. Cyclic voltammetric *i-E* curve of ferrocene (0.5 m*M*) and Tween 20 (3% v/v) in phosphate buffer (*p*H 7.00 ± 0.02). Dotted curve is computer simulated according to Nicholson and Shain (11).

ical *i-E* curve for micelle-solubilized ferrocene in phosphate buffer at *p*H 7.00 is shown in Fig. 1.

The experimental curve is well defined and is in close agreement with one which is computer-simulated for a reversible, one-electron transfer, electrode reaction using the relationship of Nicholson and Shain (11). The background *i-E* which was added to the theoretical curve, was obtained for a Tween 20 solution in the absence of ferrocene. The value of the diffusion coefficient, *D*, chosen for the calculation was one which gave the closest match of the simulated *i-E* curve to the experimental one. More will be said about the experimental *D* values shortly.

The dependence of Tween 20 concentration on the reversible electrode potential ($E_{0.85}$ for cyclic voltammetry) and the separation of anodic and cathodic peak potentials (ΔE_p) is summarized in Table I. The ferrocene concentration was constant at 0.5 m*M*, the scan rate, ν, was 96 mV/sec, and the Tween 20 concentration was varied between 1 and 3.5% by volume. The $E_{0.85}$ and ΔE_p values appear quite independent of Tween 20 concentration at this particular scan rate. The ΔE_p of 60 mV indicates that the electrode reaction is essentially reversible under these particular experimental conditions.

The plots of the anodic peak current, i_p, *vs.* ferrocene concentration were linear for any given Tween 20 concentration at a constant scan rate. Also, i_p increased linearly proportional to the square root of scan rate as expected for a diffusion-limited electrode reaction for a constant Tween 20 and ferrocene concentration. However, the i_p was dependent on the Tween 20 concentration. In Table II, these i_p values (corrected for background current) are tabulated for Tween 20 concentration varying between 1 and 3.5% by volume. The ferrocene concentration was kept constant at 0.5 m*M*. The *D* values given in Table II were calculated from the slopes of the plots of i_p *vs.* $\nu^{1/2}$ for each Tween 20 concentration. The calculation assumed the validity of the well-known Randle-Sevcik relationship

Table I. Dependence of $E_{0.85}$ and ΔE_p on Tween 20 concentration

Tween 20 concentration (% vol)	$E_{0.85}$ (mV *vs.* Ag/AgCl)*	ΔE_p (mV)
1.0	+180	60
1.5	190	63
2.0	195	65
2.5	190	63
3.0	190	60
3.5	208	60
	Avg 192 ± 6	62 ± 2

* Each value is the average of 3 separate runs.

Table II. *D* and i_p values and dependence on Tween 20 concentration and scan rate

Scan rate (V/sec)	Peak currents* (μA) at various Tween 20 concentrations (% vol) 1%	2%	2.5%	3.0%	3.5%
0.023	8.75	12.0	12.1	14.3	12.3
0.047	13.5	16.5	17.1	19.0	16.0
0.071	15.8	21.2	20.7	22.5	20.7

Table III. Viscosities of Tween 20 solutions

Concentration Tween 20 (% v/v)	Viscosity (cs)*
0	1.04
0.5	1.07
1.0	1.08
1.5	1.11
2.0	1.14
2.5	1.17
3.0	1.21
3.5	1.24
4.0	1.28

* Viscosity, η, in centistokes was calculated using $\eta = kt - b/t$, where k is viscometer constant, b is calibration constant, and t is the time required for the test solution meniscus to pass between the two flow marks on the viscometer stem (k = 0.05193 and b = 0.60). All values are the average of 10 results.

$$i_p = kn^{3/2}AD^{1/2}C^o\nu^{1/2} \quad [1]$$

A value of 2.64×10^5 was used for k in the computation of *D* (12). The *D* values decreased as the Tween 20 concentration increased.

The i_p and *D* value dependence on Tween 20 concentration was assumed to be due to the changing viscosity of the solutions. Thus, viscosities of Tween 20 solutions at concentrations between 0.5 and 4.0 volume percent (v/o) were determined using an Ubbelohde viscometer. The viscosity was found to vary linearly with concentration between 1.0 and 4.0 v/o Tween 20. The data are summarized in Table III.

In a simple diffusing system, the *D* value should be inversely proportional to the viscosity, η, assuming validity of the Stokes-Einstein relationship (13)

$$D = kT/6\pi\eta r \quad [2]$$

In Fig. 2, *D* value is plotted *vs.* $1/\eta r$. The linearity of the plot is excellent.

Calculation of micelle size.—The radius and molecular weight of the micelle can be computed from know-

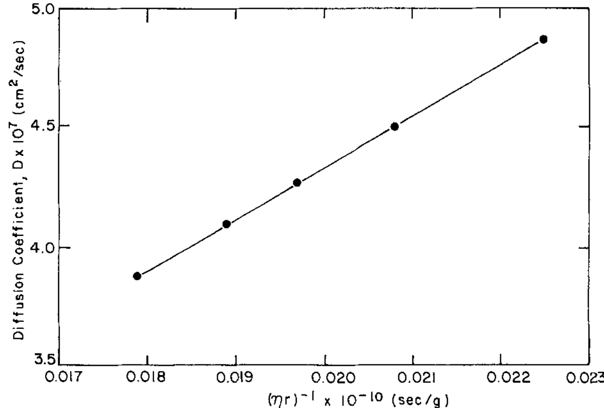

Fig. 2. Diffusion coefficient *vs.* reciprocal of η_r

ing the values of diffusion coefficients and viscosities. The shape of the micelle is assumed as spherical. The volume fraction, ϕ, of the dispersed spherical micelles is determined by using the Guth and Simha equation (14, 15)

$$\eta/\eta_0 = 14.1\phi^2 + 2.5\phi + 1 \quad [3]$$

where η/η_0 is the relative viscosity of the solution. The value of viscosity of the phosphate buffer solution in the absence of Tween 20 and ferrocene was used for η_0. The effective specific volume, $\overline{V}$, of one gram of surfactant, including any hydrated water, can be expressed as

$$\overline{V} = \phi/C' \quad [4]$$

where C' is the concentration of surfactant in the solution (grams/cubic centimeter).

The micelle weight, M, can be given in terms of the calculated $\overline{V}$

$$M = \frac{(kt)^3 N}{162\pi^2\eta^3 D^3 \overline{V}} \quad [5]$$

where N is Avogadro's number. The radius can be calculated from the value of $\overline{V}$, again assuming a spherical particle. Values of D, $\overline{V}$, r, and M as a function of Tween concentration are tabulated in Table IV. The average radius and molecular weight are 43Å and 127,000 for the data listed in Table IV. From the data in this table, a slight increase in the radius and molecular weight of the micelles as the concentration of Tween increases can be seen. Whether or not this increase actually reflects size change due to increased amount of Tween 20 per micelle cannot be accurately ascertained. Similar increases of measured radius or molecular weight with increase of nonionic surfactant concentration have been previously reported (16). However, these increases may very well reflect changes in the micelle shape from spherical to ellipsoidal or in the number of hydrated water molecules associated with the micelle as a function of Tween 20 concentration.

The molecular weight of the micelle was also determined independently using the Debye method of light scattering (17). Measurements of turbidity of Tween 20 between 0 and 5% concentration in phosphate buffer were made with a Brice-Phoenix light scattering photometer at 0° and 90°. This photometer was calibrated with a dilute solution of Ludox (SM, du Pont) in water. The solute turbidity, or excess turbidity, upon which the molecular weight depends, is the apparent turbidity, τ, of the solution with micelle minus the apparent turbidity, τ_0, of the solvent, *i.e.*, phosphate buffer without Tween 20 or ferrocene. The apparent difference in turbidity caused by the micelles and the refractive indices of the surfactant solutions can be related to molecular weight, M, through Eq. [6] and [7] as follows (17)

$$HC'/\tau = 1/M + 2BC' \quad [6]$$

and

$$H = \frac{32\pi^3 n_0^2 (n - n_0)^2}{3\lambda^4 N (C')^2} \quad [7]$$

B is a constant depending on the solvent. All measurements were made with a blue filter (λ = 463 nm).

Table IV. Micelle parameters as a function of Tween 20 concentration

Tween 20 (% v/v)	C' (g/cm³)	$\overline{V}$ (cm³/g)	$r \times 10^8$ (cm)	M
1	0.010	1.48	41.2	119,000
2	0.020	1.68	42.2	113,000
2.5	0.025	1.57	43.4	132,000
3	0.030	1.67	43.7	127,000
3.5	0.036	1.60	45.1	144,000

Table V. Apparent turbidity and refractive index of Tween 20 solutions

Tween 20 (% v/v)	$\tau \times 10^3$ (cm⁻¹)	η^{25}_{463}
0	0.09*	1.34127**
1	1.59	1.34221
2	2.35	1.34314
3	3.33	1.34421
4	2.49	1.34500
5	3.00	1.34600

* Light scattering photometer calibration using dilute solution of Ludox (SM, du Pont).
** Calibrated with KCl solution (0.09635 g/ml).

The apparent turbidities and the dependence of the refractive indices on Tween 20 concentration are tabulated in Table V. The refractive indices of the surfactant solution at temperature of 25°C was found empirically to follow the relationship

$$n = n_0 + 0.000944C' \quad [8]$$

where the value of n_0 was determined to be 1.34127.

The molecular weight of micelle was determined by calculating HC'/τ for the surfactant solutions and by plotting HC'/τ *vs.* C' (Fig. 3). The extrapolated curve to zero concentration gave an intercept whose reciprocal value was equal to the molecular weight, which was 143,000. The over-all error was estimated to be ±10%. The light scattering method assumes that the micelle size is independent of surfactant concentration and that the number of micelles is increasing with increased C'. There appears to be reasonable agreement between the molecular weight of the micelle as evaluated from both the electrochemical and the light scattering data.

Assuming the average molecular weight of Tween 20 to be 1650, the average aggregation number of micelle (data of Table IV) is in the order of 77 ± 5 (molecules/micelle). An order of magnitude estimate of the ferrocene to micelle ratio is about 3:1 for a 2% by volume Tween 20 and 0.5 m*M* ferrocene concentration. For all of the experiments reported herein, the number of moles of ferrocene was greater than the number of moles of micelle present in the solution.

$E^{o\prime}$ values.—An accurate assessment of the formal redox potential, $E^{o\prime}$, is important for the use of the ferrocene-micelle as a M-T (2). The $E^{o\prime}$ value (assuming $E^{o\prime} \equiv E_{0.85}$) evaluated from cyclic voltammetry gave an average of 424 ± 6 mV *vs.* NHE. As a further confirmation, $E^{o\prime}$ values were determined from potentiometric data for titration using Ag_2SO_4 as oxidant and from $\overline{A\text{-}E}$ data obtained during the exhaustive coulometric oxidations. The concentration of ferricinium ion was monitored at wavelength of 615 nm

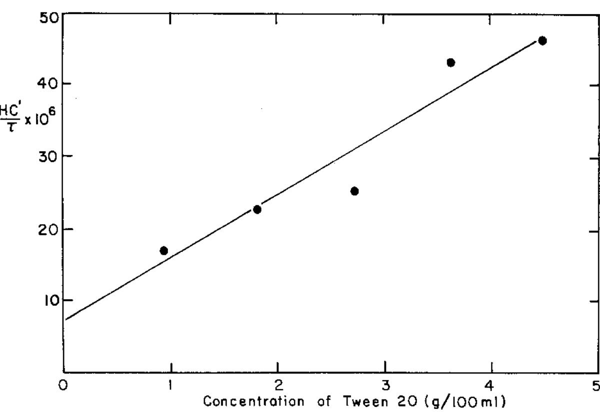

Fig. 3. Reciprocal specific turbidity of Tween 20 solutions

for the latter experiments. Nernstian slopes of 58 ± 2 mV were obtained and the average value of $E^{o\prime}$ was 425 ± 10 mV *vs.* NHE. The $E^{o\prime}$ values determined by these methods are in excellent agreement with that evaluated by cyclic voltammetry. Ferrocene had been proposed (18) as a redox standard from solvent to solvent because both ferrocene and ferricinium ion supposedly were minimally solvated. The formal potential for ferrocene has been reported to be 400 mV *vs.* NHE (18).

Hinkle (8) in his lipid work found the addition of small amounts of the anion tetraphenylboron to greatly enhance the effectiveness of ferrocene as a mediator. He suggested that the tetraphenylboron increased the solubility of ferricinium cation in the lipid phase of the membrane. Thus, the effect of tetraphenylboron to the cyclic voltammetry of ferrocene-micelle was examined. In a solution containing 2% Tween, 0.74 m*M* ferrocene, and 0.40 m*M* sodium tetraphenylboron, the cyclic *i-E* curves were completely reversible with a ΔE_p of 60 mV ± 2 mV. The $E_{0.85}$ was 390 mV *vs.* NHE. The shift of potential to less positive value is consistent with stabilization of ferricinium ion by the anion, tetraphenylboron. Whether ferricinium ion interacted with tetraphenylboron inside of the micelle and thus shifted the equilibrium of reaction [11] could not be ascertained from the present data.

Ferricinium ion.—Ferricinium ion is known to be quite water soluble. Its partitioning between the micelles and solvent was qualitatively examined by filtering a ferricinium solution through a Diaflo filter (Amicon, XM50; M.W. separation 50,000) at 15 psi pressure in a stirred cell. The blue ferricinium ion was electrogenerated from ferrocene by controlled potential electrolysis in the Tween 20/phosphate buffer solution. The blue-colored filtrate indicated that ferricinium ion went through the filter and was not totally micelle bound. A similar experiment was performed with the ferrocene-Tween 20 solution. The filtrate in this case was clear and did not contain ferrocene, suggesting that ferrocene is indeed micelle bound. The reactions for the ferrocene/ferricinium system in the presence of micelle are suggested as

$$Fe(C_5H_5)_2 + \text{micelle} = Fe(C_5H_5)_2 \ldots \text{micelle} \quad [9]$$

$$Fe(C_5H_5)_2 \ldots \text{micelle} = Fe(C_5H_5)_2^+ \ldots \text{micelle} + e^- \quad [10]$$

$$Fe(C_5H_5)_2^+ \ldots \text{micelle} = Fe(C_5H_5)_2^+ + \text{micelle} \quad [11]$$

The K_{eq}'s are assumed to be greater than unity for both reactions [9] and [11].

The optical absorbance band at 615 nm was monitored during controlled potential coulometric oxidation of ferrocene to ferricinium ion in a stirred solution. The optical absorbance, $\underline{A}$, at 615 nm changed linearly with the number of coulombs of charge.

The molar absorptivities, ϵ, calculated for ferricinium ion and also ferrocene-micelle are tabulated in Table VI and compared to literature values (19). The large discrepancy of the molar absorptivity between our value and the literature value at wavelength of 250-235 nm is presently unexplored.

Ferricinium ion in aqueous media has been reported (19) to undergo decomposition. Thus, the stability of ferricinium ion was determined by following the decrease of the absorbance of the 615 nm band. A half-life of 14 hr was obtained for the ion in the pH 7.0 phosphate-buffered solution at temperature of 25°C. At pH 2.0, the half-life increased to 26 hr. This loss of ferricinium ion can affect results of long-term experiments or those where the ion concentration is high.

Table VI. Spectral properties of ferrocene-micelle and ferricinium ion

	Wavelength maxima (nm)	Molar absorptivity ($M^{-1}cm^{-1}$)
Ferrocene-micelle	325 (325)*	96 (52)*
	440 (440)	120 (91)
Ferricinium ion**	250 (235)	3,860 (12,000)
	615 (617)	335 (340)

* Literature values (19) in brackets; ferricinium ion data reportedly taken in solution alcohol-water containing tetraphenylborate anion.
** Ferricinium ion generated by controlled potential coulometry.

Ferrocene-micelle as mediator-titrant for heme proteins.—As previously mentioned, methyl viologen was used as the M-T for the reduction of cytochrome c, cytochrome c oxidase, and mixtures thereof (2). In the respiratory chain, c($\underline{n}$ = 1) is the component which transfers electrons to the enzyme bound cytochrome c oxidase ($\underline{n}$ = 4). Oxidase is the enzyme which is responsible for the fast turnover of molecular oxygen to water and for coupling to oxidative phosphorylation.

The charge distribution between these heme components has been evaluated from the change in the optical absorbance, $\Delta\underline{A}$, at 550 nm (cytochrome c) and 605 nm (cytochrome c oxidase) during indirect coulometric titration experiments (2). The plot of the oxidative ΔA-q (q = electrochemical charge) was not a mirror image of the reductive one (20). The oxidant was O_2($\underline{n}$ = 4) and the reductant was the viologen radical cation ($\underline{n}$ = 1; $E^{o\prime}$ = −446V *vs.* NHE) (9). Besides the obvious difference in the $\underline{n}$ values, a difference in the reactivity toward cytochrome c exists between the reductant and oxidant. The viologen radical reduces both the cytochrome c and cytochrome c oxidase rapidly (21). On the other hand, O_2 oxidizes natured cytochrome c slowly. Thus, in a mixture of cytochrome c and cytochrome c oxidase, cytochrome c must be oxidized primarily by cytochrome c oxidase when O_2 is used as the oxidant.

With use of electrogenerated ferricinium ion from the ferrocene-micelle, the ΔA-q curves were mirror images of the reductive ones (reductant: viologen radical) (1). These results suggest that the charge distribution between cytochrome c and the redox centers of cytochrome c oxidase are at equilibrium when the redox properties of the reductant and oxidant are similar.

Results to date indicate that the $E^{o\prime}$ values for cytochrome c oxidase are 215 ± 15 and 345 ± 15 mV *vs.* NHE. Each value of $E^{o\prime}$ involves two electrons and the metal centers of one iron and one copper. Since these $E^{o\prime}$ values are for cytochrome c oxidase isolated from the membrane (low lipid concentration) there is a question whether these values accurately reflect the cytochrome c oxidase potential in the mitochondrial system. It is also a question of why nature would have the $E^{o\prime}$ of cytochrome c ($E^{o\prime}$ = 257 ± 17 mV *vs.* NHE) (9) midway between the two potentials of cytochrome c oxidase.

Solubilization of M-T's by micelle formation provides (*a*) access to a wider variety of M-T's with opportunity for graded $E^{o\prime}$ values; (*b*) means of designing experiments to model biological electron transfer mechanisms a la Hinkle (8); and (*c*) an approach to kinetic studies to test whether electron-transfer rates to components in membranes can be accelerated by interactions with micelle bound M-T's.

There has been suggestion (22) that ". . . the detergent solution, which consists of lipoidal micellular regions dispersed throughout an essentially aqueous

phase, resembles the colloidal nature of biological environment."

ABSTRACT

Adsorbed hydrogen phenomena on a platinum electrode were investigated by an impedance method which draws potentiodynamically the in-phase and quadrature components of electrode admittance. The kinetic behavior of hydrogen adsorbed on platinum was examined in full with the complex capacitance representation. The kinetic experimental results were well explained on the basis of the proposed equivalent circuit which was composed of the pseudocapacitance, Warburg impedance, and ohmic component associated with the adsorption-desorption process of adsorbed hydrogen, together with the reaction resistance due to the Volmer reaction.

Impedance measurements at the electrode/solution interface have been developed recently (1) and used extensively in solid electrode/solution systems (2-4). The impedance measurements can be classified into two groups: that using a-c bridges and that directly measuring the alternating current through a cell. The former enables us to determine the in-phase and quad-

* Electrochemical Society Active Member.
Key words: dynamic impedance measurement, hydrogen adsorption phenomena.

rature components separately and to obtain accurate data. However, it has a disadvantage in that it requires too much time for measurement. Measurement using the latter technique has been developed as a well-known Breyer-type a-c polarography, and we can easily and rapidly get some data with this method. However, the results are scalar quantity, not divided into vector components. Therefore, the dynamic measurement of in-phase and quadrature components of alternating current has been recently attempted by some workers (4-6) for the purpose of removing the disadvantage mentioned above. The authors also constructed an instrument for dynamic impedance measurement as a function of electrode potential with the aid of a lock-in amplifier and by making use of the principle of the Breyer-type a-c polarograph. Since the heart of a lock-in amplifier is a phase sensitive detector, the impedance through the electrode/solution interface which is measured as the magnitude of cell admittance can be detected with the lock-in amplifier, dividing the alternating current into two components of in-phase and quadrature.

The hydrogen adsorption phenomena on a platinum electrode have been investigated by many workers (3, 7, 8). In particular, Frumkin (7) reviewed the kinetic behavior of adsorbed hydrogen on platinum from the results of impedance measurements. Recently, this subject has been discussed by some workers (9-13) from several points of view. In this paper, the kinetic behavior studied with the dynamic impedance circuit is discussed in reference to previous work.

Instrumental

Principle.—The schematic arrangement of the dynamic impedance method is a small a-c level of frequency f imposed upon the d-c voltage controlled with a potentiostatic instrument. It is convenient to represent the equivalent circuit of a cell in a parallel combination of capacitance C_p and resistance R_p. The admittance of parallel circuit of C_p and R_p can be given as follows

$$Y = Z^{-1} = G + jS = R_p^{-1} + j\omega C_p \qquad [1]$$

where ω is the angular velocity ($\omega = 2\pi f$), G the conductance, and S the susceptance. The alternating current through the electrode/solution interface can be divided into two components of I_i and I_q by a lock-in amplifier, and they correspond to EG and ES, respectively, because $I = I_i + I_q = E \cdot Y = E(G + jS)$. Therefore, we can measure directly and potentiodynamically R_p^{-1} as conductance and C_p as susceptance against the electrode potential with the scanning unit.

The instrumental circuit.—A block diagram of the present circuit is shown in Fig. 1. A small a-c voltage supplied by oscillator or function generator (OSC) is superimposed upon the scanning voltage, applied through potentiometer (P) and ramp generator (Ramp). The a-c voltage of the sinusoidal wave is adjusted with the attenuator to be less than 3 mV. Such a voltage is supplied to the working electrode by a fast-rise potentiostat (PS). The frequency range of the instrument is from 5 to 2000 Hz, which is checked with the dummy cell from the linearity of C_p or R_p^{-1}. The conductance and susceptance of the electrode/solution interface, which are directly proportional to the potential drop across the resistance r_s, are measured by the lock-in amplifier (L.I.A.) and calibrated with a standard resistance and capacitance as a dummy cell. After amplification with a lock-in amplifier, the voltage through the cell is supplied to a X-Y_1-Y_2 recorder, directly drawing the conductance-potential and susceptance-potential relations, respectively.

Experimental

A smooth platinum disk (0.07 cm^2) was used as the working electrode. The counterelectrode was a platinum net having sufficiently large surface area. The potential was determined in reference to the hydrogen electrode in the same solution (HE). The working electrode, cleaned with concentrated nitric acid, was pretreated by scanning the potential between 0.05 and 1.4 V_{HE} at 10 V/sec for several decades of minutes. The reproducibility of the activated conditions of electrode was confirmed by the shape of i-E (current-potential) curves in the above potential range. Solutions were prepared with reagent grade chemicals and triply distilled water. All the experiments were conducted in an atmosphere of purified nitrogen at 25°C in sulfuric acid.

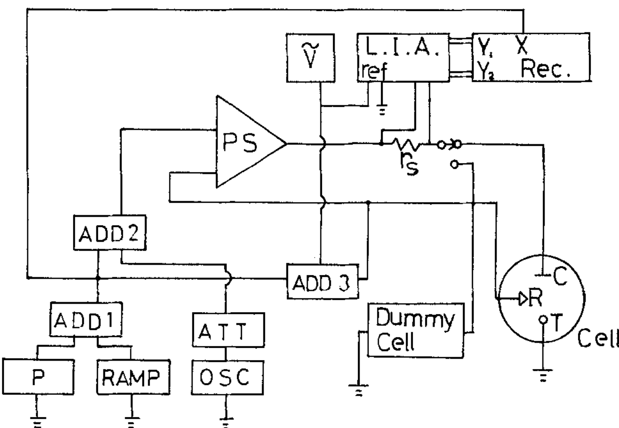

Fig. 1. Block diagram of dynamic impedance circuit. L.I.A. = lock-in amplifier (Princeton Applied Research, Model 129A), PS = potentiostat, P = potentiometer, RAMP = ramp generator, OSC = function generator (NF Circuit Design Block Company, Limited, Model FG-121B), ADD = adder, ATT = attenuator, X-Y_1-Y_2 Rec. = 2-pen X-Y recorder (Yokogawa Electric Works Limited, Type 3078), V = electronic volt meter, r_s = standard resistance, T = test electrode, C = counterelectrode, R = reference electrode.

Results and Discussion

Potential dependence of C_p and R_p^{-1}.—The parallel capacitance C_p and conductance R_p^{-1} are potentiodynamically measured in the adsorbed hydrogen region on platinum with the scan rate of 2 mV/sec (shown in Fig. 2 and 3). During the anodic scan the adsorbed hydrogen is removed in acidic solutions according to the Volmer reaction in the so-called hydrogen region

$$H_3O^+ + e^- \rightleftarrows H_{ads} + H_2O \qquad [2]$$

Two pronounced peaks of capacitance or conductance appear in the C_p-E or R_p^{-1}-E curves similar to two current peaks in the anodic i-E curves obtained by triangular scanning. There are some indications of the existence of a third peak in the adsorbed hydrogen region on platinum in the i-E curves (10, 13, 14) and the small third current peak in acidic solution is observed. However, the third peak corresponding to the above is not revealed in the C_p-E and R_p^{-1}-E curves shown in Fig. 2 and 3. The potentials (*i.e.*, 0.15 and 0.27 V_{HE}) of the peaks in the C_p-E and R_p^{-1}-E curves are in agreement with those in the i-E curves. These peak potentials in Breiter's results (3) shift to the cathodic side somewhat (*i.e.*, 0.1 and 0.2V), while the data in Fig. 2 agree with those of Bagotzky *et al.* (25). The peaks in the C_p-E curves in the low frequency region disappear gradually and become one peak with the increase in frequency, while the peaks in the R_p^{-1}-E curves do not disappear in the frequency range observed. As shown in Fig. 2 and 3, the shapes of C_p-E and R_p^{-1}-E curves obtained with various frequencies in the adsorbed hydrogen region are approximately similar to those of Breiter (3) and Dolin *et al.* (15), obtained point by point. As for the frequency dispersion of C_p, the results in Fig. 2 differ from those of Bagotzky *et al.* (25) in which the parallel capacitance C_p depends on the

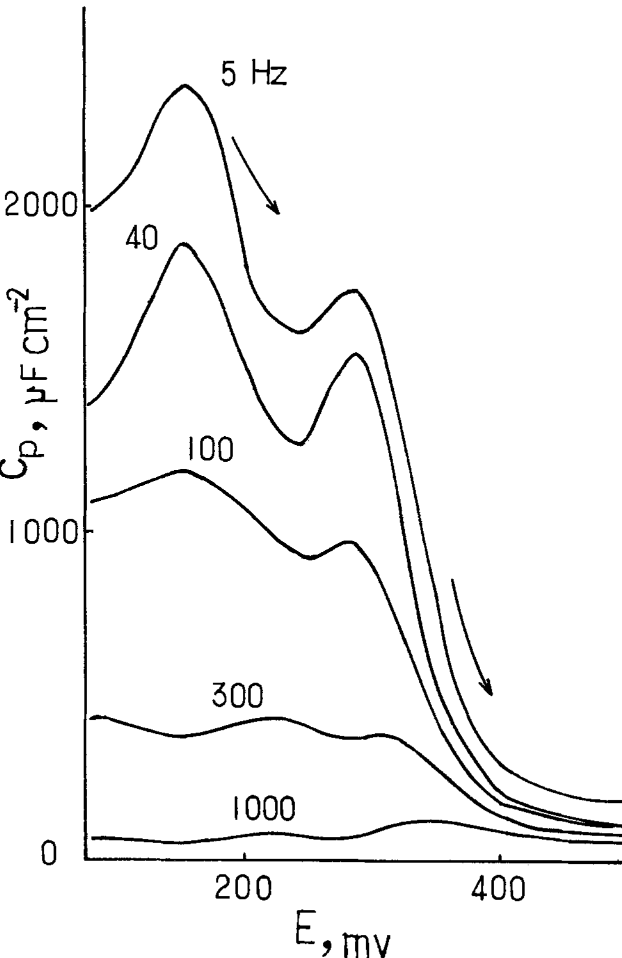

Fig. 2. Parallel capacitance vs. potential curves on Pt obtained potentiodynamically with various frequencies. 1N sulfuric acid, 25°C, 2 mV/sec, nitrogen gas atmosphere.

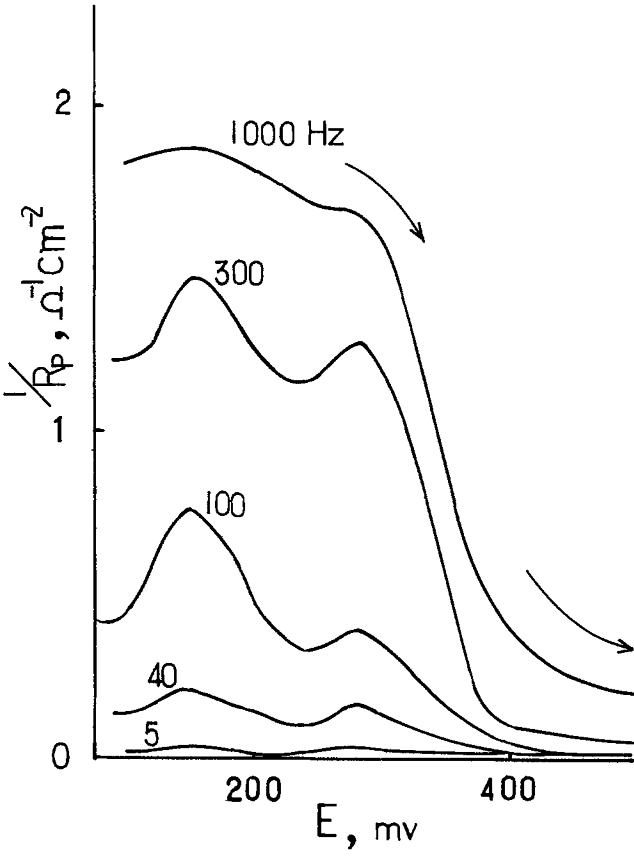

Fig. 3. Parallel conductance vs. potential curves on Pt obtained potentiodynamically with various frequencies. 1N sulfuric acid, 25°C, 2 mV/sec, nitrogen gas atmosphere.

frequency in the range >1 kHz and the frequency dispersion of C_p ceases at $f < 1$ kHz. Breiter's data (3) show the frequency dispersion of C_p at below 1 kHz and the range < *ca.* 280 Hz the dispersion ceases. In Fig. 2, the dispersion ceases in the frequency range < *ca.* 20 Hz, however, there is good reproducibility. Therefore, the difference of the frequency at which the frequency dispersion of C_p ceases may not be attributed to an impurity or an unsuitable electronic system, but mainly to the reaction resistance r with a consideration of the behavior of frequency dispersion of C_p, as calculated by Eq. [3] or [7].[1] According to Dolin *et al.* (15), a simplified equivalent circuit to a platinum electrode in the adsorbed hydrogen region can be shown as that in Fig. 4(a), where C_D is the double layer capacitance, C_A the pseudocapacitance, and r the reaction resistance corresponding to reaction [2]. The following relationships for the conductance and the susceptance can be derived from Eq. [3] with the assumption that the solution resistance equals zero

$$Y_1 = j\omega C_D + \{r + (j\omega C_A)^{-1}\}^{-1} \quad [3]$$

$$\begin{cases} G_p = R_p^{-1} = \omega^2 r C_A^2/(1 + \omega^2 r^2 C_A^2) & [4] \\ S_p = \omega C_p = \omega\{C_D + C_A/(1 + \omega^2 r^2 C_A^2)\} & [5] \end{cases}$$

Then, we can get the relations of $C_p \rightarrow (C_A + C_D)$ for $\omega \rightarrow 0$, and $C_p \rightarrow C_D$, $R_p \rightarrow r$ for $\omega \rightarrow \infty$. Moreover, we obtain the following equation by eliminating ω from Eq. [4] and [5]

$$C_p = -C_A r R_p^{-1} + (C_A + C_D) \quad [6]$$

When the double layer capacitance C_D is determined in the potential range of the double layer, C_A and r can be computed by the gradient and intercept of the C_p-R_p^{-1} relation, assuming the solution resistance to be negligible.

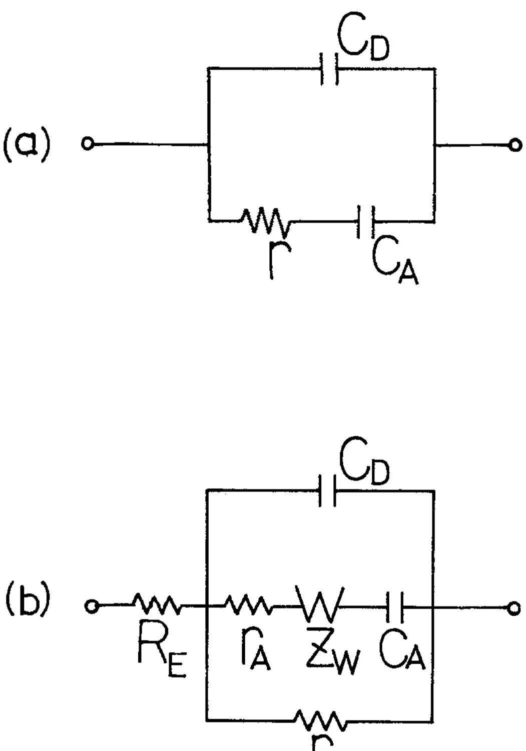
In practice, the conductance and the susceptance can be derived from the following equation, adding the solution resistance R_E in the equivalent circuit of (a) in Fig. 4

$$Y_2 = [R_E + [j\omega C_D + \{r + (j\omega C_A)^{-1}\}^{-1}]^{-1}]^{-1} \quad [7]$$

Since the solution resistance is very small, there is only a slight difference between Y_1 and Y_2.

Frequency dependence of C_p and R_p^{-1}.—Figure 5 shows the frequency dependence of parallel capacitance C_p at the potentials of 0.15, 0.27, and 0.7 V_{HE} in 1N sulfuric acid solution. At 0.7 V_{HE} in the double layer region, the double layer capacitance C_D was determined as 56 μF/cm^2 by extrapolating C_p to a high frequency range, eliminating the faradaic components. The C_D in 4 and 8N sulfuric acid was also determined as 70 and 77 μF/cm^2, respectively. Since the C_p in the adsorbed hydrogen region at low frequencies is much larger than C_D, the value of C_p might be approximately

[1] The frequency dependence of C_p, assuming the equivalent circuit (a) in Fig. 4 or 9, is affected partly by the difference of the solution resistance R_E, but largely by the reaction resistance r. When the reaction resistance becomes smaller, the frequency dispersion of C_p tends to shift to the higher frequency range. In the case of $r = 0.02$, the frequency dispersion ceases at $f < 1$ kHz. The reaction resistance r obtained roughly from the results of Fig. 1 in the paper by Bagotzky *et al.* (25b) by means of the C_p-R_p^{-1} relation is *ca.* 0.02. By using the value of $r = 0.02$, we can get the behavior of frequency dispersion similar to that of Bagotzky *et al.* According to the review by Frumkin (7), r^{-1} in 1N sulfuric acid is 3.4 ($r = 0.29$), which approximately agrees with the present results (see Table I). However, there are higher values for r^{-1} in the table (*e.g.*, $r^{-1} = 33.7$ in 8N sulfuric acid). Frumkin thought that higher values of r^{-1} are caused by greater activation of the electrode. Then, the data of Bagotzky *et al.* are considered to be obtained with a more activated electrode, which is also confirmed by the slight difference between bright and platinized platinum electrode in their work (25).
Moreover, the fact that our C_p values are twice those of Bagotzky *et al.* is attributed to the electrode area, *i.e.*, they show the data per true area while we use the projective one. Our data become approximately equal in magnitude to those of Bagotzky upon considering the roughness factor of 1.7 ~ 2.5 which is obtained with the same electrode.



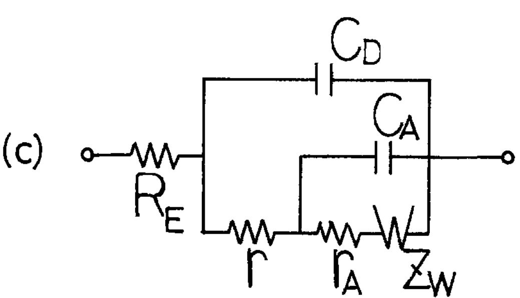


Fig. 4. Electrical equivalent circuits for adsorbed hydrogen on Pt electrode.

regarded as the pseudocapacitance due to adsorbed hydrogen. The frequency dependence of parallel conductance G_p in $1N$ sulfuric acid solution is shown in Fig. 6. The solution resistance R_E in $1N$ sulfuric acid was estimated from the data in Fig. 6 through Eq. [7][2] for the conditions of $\omega \rightarrow \infty$. The more suitable value of 0.3 Ω-cm^2 was chosen by an electronic computer in comparison with the experimental and theoretical data. The R_E in 4 and $8N$ sulfuric acid was also determined as 0.13 Ω-cm^2, respectively. Since the solution resistance results in very small value, the reaction resistance r and the pseudocapacitance C_A can be derived from Eq. [6] assuming $R_E = 0$. Figure 7 shows typical plots of C_p-R_p^{-1}, which is expected to become linear with the gradient of $-C_A r$ and the intercept of $(C_A + C_D)$. The results of the C_p-R_p^{-1} plot become approximately linear and the approximate values of r and C_A can be determined from the linear part in Fig. 7. However, the linear relation deviates in the low frequency region. Such a deviation is more marked in the complex capacitance representation as shown in Fig. 8, that is,

[2] G_p can be derived from Eq. [7] as follows

$$G_p = R_p^{-1} = \frac{\omega^2(\omega^2 R_E L^2 + K^2 R_E + K C_A r - L)}{(1 - \omega^2 R_E L)^2 + \omega^2 (C_A r + K R_E)^2} \quad [7a]$$

where $K = C_D + C_A$ and $L = C_D \cdot C_A r$. When $\omega \rightarrow \infty$, $G_p \rightarrow R_E^{-1}$.

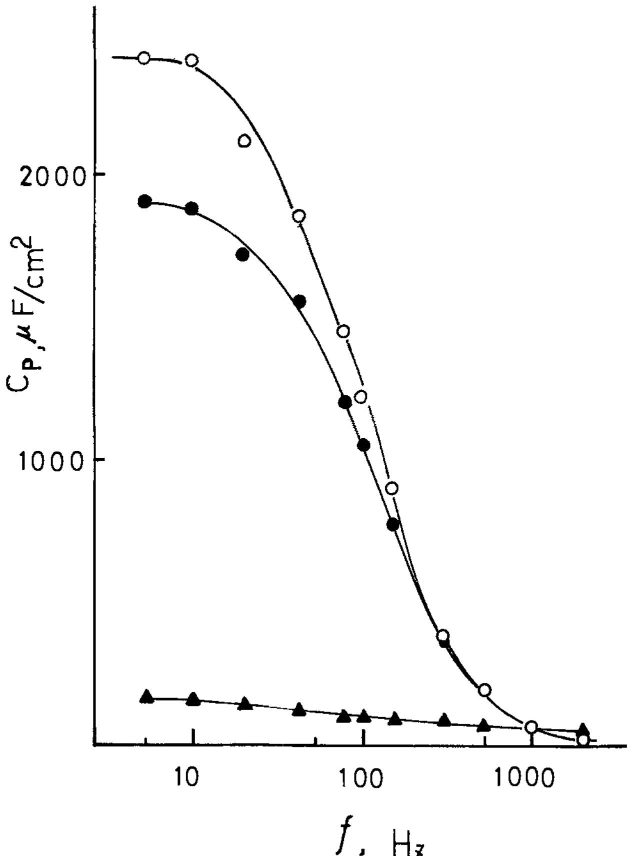

Fig. 5. Frequency dependence of parallel capacitance on Pt. $1N$ sulfuric acid, 25°C, 2 mV/sec, nitrogen gas atmosphere, ○ = measured at 0.15 V_{HE}, ● = at 0.27 V_{HE}, ▲ = at 0.70 V_{HE}.

the semicircular plots become linear in the region of low frequencies. Such results might indicate that the equivalent circuit shown in Fig. 4(a) is unsatisfactory and that the other electrical factors which affect the admittance through cell in the low frequency region must be considered.

Complex capacitance representation.—The data obtained from the impedance method are used for analysis with the representations of complex impedance (as Z) and complex capacitance (as Y/ω), the latter being more convenient for the admittance measurement. Figure 8 shows the complex capacitance representations of the adsorbed hydrogen region in some acidic solutions. The plots in Fig. 8 are approximately semicircular, however, they become linear in the region of low frequencies. Such a deviation in the low frequency region seems to be more obvious with the increase in normality of sulfuric acid and is considered to be confirmed by the advantage that the results from the dynamic impedance measurement have especially good reproducibility in the low frequency region compared with those obtained point by point from the a-c bridge measurement for solid electrode/solution systems.

The analysis of a-c impedance in the presence of adsorption processes has already been discussed by various workers (16-26), and the most general case of adsorption with diffusion process has been investigated by a few workers (16-18). According to Lorenz *et al.* (17), the impedance Z_k due to the adsorption process corresponds to a series combination of capacitance ΔC, adsorption resistance $\tau/\Delta C$, and Warburg impedance Z_w as follows

$$Z_k = (j\omega\Delta C)^{-1} + \tau/\Delta C + Z_w \quad [8]$$

where $\Delta C = C_{LF} - C_{HF}$, C_{LF} and C_{HF} are low and high frequency limit capacitances, τ the characteristic time constant for the adsorption step, and $Z_w = (\xi/\omega\Delta C)(1 - j)$, $\xi = (\partial\Gamma/\partial c)_E(\omega/2D)^{1/2}$. The relationship be-

tween the equivalent circuit and the graphical representation corresponding to the above is given in Ref. (1) and (23). The apparently similar circuit to that of Lorenz *et al.* has been proposed by Bagotzky *et al.* (25) for the hydrogen adsorption on platinum, that is, Z_w is added in series to the impedance of $Z_o = [(j\omega C_A)^{-1} + r]$ in Fig. 4(a). However, the theoretical representation of complex capacitance did not fit the experimental results shown in Fig. 8.[3] Therefore, the equivalent circuit for the hydrogen adsorption is naturally assumed to be (b) in Fig. 4 in which Z_k is connected with the impedance due to reaction resistance in parallel (26, 28). The equivalent circuit similar to (b) in Fig. 4 was also proposed by Randles *et al.* (19). Though the equivalent circuit in Fig. 4(c) is considered to be one of the most general case of specific adsorption of electroactive species, the theoretical representation of complex capacitance cannot elucidate the experimental results in Fig. 8. The concept of interaction between the faradaic and nonfaradaic components of electrode impedance was proposed by Llopis *et al.* (20) for the ferrous-ferric and halide-halogen reactions and its equivalent circuit was derived on the basis of Eq. [9] whose idea was also given by Delahay (24)

$$i_f = n\mathbf{F}V + n\mathbf{F}\frac{d\Gamma}{dt} \quad [9]$$

where i_f is the faradaic current, V the flux of reactant, and Γ the adsorbed amount stored at the interface. The equivalent circuit proposed by Llopis *et al.* (20) is shown in Fig. 4(c) in which the finite rate of adsorption and desorption appears as a resistance r_A in series with the Warburg impedance, and the pseudocapacitance C_A due to the storage of electroactive species is

[3] The representation of Y/ω derived from the circuit of Bagotzky *et al.* (25) falls on a lemniscatelike curve [see Ref. (1) and (23)].

combined with the above impedance in parallel. The apparently same circuit was proposed by Levie *et al.* (5) for the biological membrane system. Sluyters *et al.* (28) examined this model for the $Pb^{2+}/Pb(Hg)$ electrode system. Since the theoretical representation of the equivalent circuit of (c) in Fig. 4 accounts well for the experimental results in Fig. 8 (*cf.*, Fig. 9), we adopt the equivalent circuit of (c) in Fig. 4 for the hydrogen adsorption on platinum and show the comparison of theoretical and experimental representations in Fig. 9. In the equivalent circuit of (c) in Fig. 4, the faradaic impedance due to reaction [2] is represented as a reaction resistance r in series with the impedance Z_k due to the adsorption or desorption process of adsorbed hydrogen, where Z_k is composed of C_A due to the storage of adsorbed hydrogen in parallel with the sum of r_A and Z_w caused by the adsorption rate and diffusion process of adsorbed hydrogen. The admittance for the circuit in Fig. 4(c) is represented as follows with the assumption of $R_E = 0$

$$Y_3 = j\omega C_D + [r + [j\omega C_A + \{(r_A + \sigma\omega^{-1/2}) - j\sigma\omega^{-1/2}\}^{-1}]^{-1}]^{-1} \quad [10]$$

where $Z_w = \sigma\omega^{-1/2}(1 - j)$ and σ the constant concerned with the Warburg impedance. Moreover, we can get the admittance with $R_E \neq 0$, though the apparent difference between Y_3 and Y_4 is almost negligible because of $R_E << 1$ and $C_D << C_A$[4]

$$Y_4 = [R_E + [j\omega C_D + [r + [j\omega C_A + \{(r_A + \sigma\omega^{-1/2}) - j\sigma\omega^{-1/2}\}^{-1}]^{-1}]^{-1}]^{-1} \quad [11]$$

The values of each component of the equivalent circuit in Fig. 4(c) can be derived from the subtraction method after Levie (5b), *i.e.*, C_D is given by the graphical representation of Y/ω with extrapolating to infinite frequency after subtraction of R_E, r is given by extrapolating to high frequency in the graphical representation of Z after subtraction of C_D and R_E, C_A is given by the graphical representation of Y/ω after subtracting R_E, C_D, and r, and r_A and σ are given by the remainder. The values of each component were estimated from the approximate linear relation in Fig. 7 and the above graphical method. The more precise values in Table I were determined by an electronic computer in comparison with the experimental and theoretical data.

[4] Though the frequency dispersion of C_D is somewhat dependent on the value of R_E, in the representation of Y/ω the effect of the solution resistance is not so large in this system with the conditions of $R_E << 1$ and $C_D << C_A$.

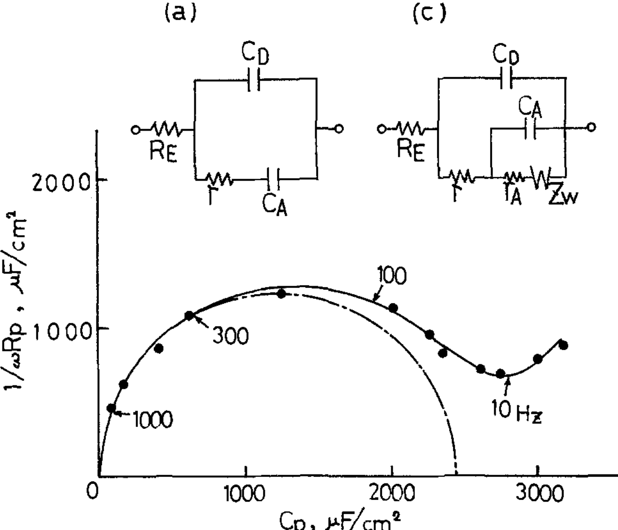

Fig. 9. Complex capacitance representation as Y/ω. ● = experimental results in 4N sulfuric acid at 0.15 V_{HE}; — - — = theoretical curve based on the circuit (a) with R_E; ——— = theoretical curve based on the circuit (c), where R_E = 0.13 Ω-cm^2, C_O = 70 $\mu F/cm^2$, C_A = 2400 $\mu F/cm^2$, r = 0.22 Ω-cm^2, and σ = 120 Ω-cm^2/sec.

Table I. Values of components obtained experimentally from the assumption of the equivalent circuit (c) in Fig. 4

Sulfuric acid solution	1N	4N	8N
Potential (V_{HE})	0.15	0.15	0.15
C_D* ($\mu F/cm^2$)	56	70	77
R_E** (Ω-cm^2)	0.30	0.13	0.13
C_A ($\mu F/cm^2$)	1800	2400	2700
r (Ω-cm^2)	0.58	0.22	0.20
r_A (Ω-cm^2)	0.4	0.4	0.4
σ (Ω-cm^2/sec)	150	120	110

* The values of C_D were determined at 0.70 V_{HE} by extrapolating ω to ∞.
** The values of R_E were determined at 0.70 V_{HE}.

In Table I, the values of C_D, which are determined in the double layer region on platinum, are considered to be appropriate, though they are somewhat higher than those obtained by other workers with impedance measurements (15, 27). The pseudocapacitance of adsorbed hydrogen, C_A, becomes somewhat large with the increase in normality of sulfuric acid solution, and such a trend might be caused by the increase of hydrogen ion concentration. Frumkin (7) listed the reaction resistance r obtained by various workers, and the results in Table I were approximately in agreement with some of them (*e.g.*, 0.294 Ω-cm^2 in 1N H_2SO_4 and 0.194 Ω-cm^2 in 1N HCl), though he indicated the difference of apparent surface from true surface with freshly activated electrodes. As expected from the slow discharge theory (15), the results of r^{-1} are dependent on the hydrogen ion concentration in acidic solutions. Therefore, it follows from the results in Table I that the dynamic impedance measurement is satisfactorily applicable to solid electrode/solution systems.

In Fig. 9, the theoretical representations of complex capacitance (Y/ω) calculated on the assumption of equivalent circuits are shown with a dotted line for (a) with adding R_E and a solid line for (c) of Fig. 4. The most simple circuit in Fig. 4(a) gives a semicircle with the intercept of C_D in the high frequency region, and the circuit including the solution resistance R_E reveals similar behavior (dotted line), though the intercept in the high frequency region becomes zero. The intercept in the low frequency region shows the sum of ($C_A + C_D$). As seen in Fig. 9, the theoretical representation based on the circuit (a) of Fig. 4 is unsatisfactory to explain the experimental results shown with a black circle (●), while the theoretical solid line based on the circuit (c) of Fig. 4 coincides well with the results in the frequency range measured. Consequently, the equivalent circuit (c) of Fig. 4 is more available to elucidate the kinetic behavior of adsorbed hydrogen on a platinum electrode,[5] though the equivalent circuit (a) in Fig 4 proposed by Dolin *et al.* is applicable to the approximate behavior in the relatively high frequency region.

Manuscript submitted Feb. 23, 1976; revised manuscript received May 18, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by OKI Electric Industry Company, Limited.

[5] It may be physically unclear as to why any Warburg component should be required for the present system. However, one might consider two possibilities, *i.e.*, the effects of the anions SO_4^{2-} and HSO_4^- on the adsorption states of hydrogen, which have been pointed out by some workers (13, 25) and the effects of the following reactions

$$H_{ads} + H_3O^+ + e^- \rightleftarrows H_{2ads} + H_2O \text{ and } \tfrac{1}{2}H_2 \rightleftarrows H_{ads} \quad [12]$$

though the reactions apply only slightly at 0.15V.

The Spectroelectrochemical Study of the Oxidation of 1,2-Diaminobenzene: Alone and in the Presence of Ni(II)

Alexander M. Yacynych* and Harry B. Mark, Jr.*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

A rapid scanning spectrometer and classical electrochemical techniques have been combined in a spectroelectrochemical experiment using optically transparent electrodes to study electrode filming on the oxidation of 1,2-diaminobenzene; alone and in the presence of Ni(II). Spectroelectrochemical studies of short-lived redox intermediates and mechanisms of the oxidation at platinum electrodes are determined. Cyclic voltammetry showed the oxidation of 1,2-diaminobenzene to be irreversible, and on successive scans without cleaning the electrode the peak current dropped significantly with each scan until ultimately no current flowed. This situation is indicative of an insulating film completely coating the electrode. This behavior was observed both with and without Ni(II) being present in solution. However, there were significant differences in the rate and nature of the filming. Spectroelectrochemically, it was observed that the nature of the film on 1,2-diaminobenzene oxidation was independent of time and potential. A conducting film is initially formed, and on top of this a nonconducting film forms which eventually insulates the electrode. With Ni(II) present the oxidation mechanism is potential dependent. At lower potentials a product containing nickel is formed which does not coat the electrode. At higher potentials the product was found to be the same insulating film which coated the electrode in the oxidation of 1,2-diaminobenzene without the presence of Ni(II).

Often, electrochemical kinetic data are not sufficient to unambiguously determine the mechanism of an electrode reaction. This is especially true with reactions which are highly nonideal with respect to boundary conditions imposed by simple classical electrochemical models. An example of this nonideal electrochemical behavior is electrode filming, which often occurs with the oxidation of organic compounds. It is generally assumed but not proven that these electrode films are polymeric in nature (1, 2), however, the mechanisms and rates of their formation are unknown as the self-insulating nature of the films makes it very difficult to reduce the electrokinetic data to a mechanism. The elucidation of these types of mechanisms would benefit electrochemical organic oxidation studies in general and electrochemical polymerization mechanisms in particular.

In order to examine film formation, a separate but simultaneous optical monitoring of the electrode interface during the actual electrolysis (3-6) has been employed in this study. In this way, the information that can be obtained from the time-resolved spectra during electrolysis can be used for direct qualitative identification and the time dependency of products and/or intermediate(s) concentrations. By using spectroelectrochemical techniques, it is possible to obtain two independent sets of kinetic and mechanistic data. Thus, any mechanistic model which satisfies both the electrochemical and optical kinetic data simultaneously is more likely to be correct.

This particular example, the oxidation of 1,2-diaminobenzene, alone and in the presence of Ni(II), was chosen for study: first, because previous studies had shown that this system formed strongly adhering highly colored films at acidic *p*H values (1, 2, 7, 8); second, because it was felt that there was a possibility of forming a conductive organic film (polymeric cation radical system) which could have novel applications in the field of organic electrochemical synthesis and perhaps in the area of specific ion electrodes.

Previous studies on the electrochemical oxidation of 1,2-diaminobenzene have yielded only partial information on the reaction mechanism (1, 2, 7-14). It was shown that the reaction products were *p*H dependent, with electrode filming occurring at lower and middle *p*H, but not at high *p*H (1, 2). Also, the half-wave potential changed with *p*H steadily decreasing with increasing *p*H (12).

Experimental

In our spectroelectrochemical system, on-line experimental control, data acquisition, and reduction are accomplished by a Raytheon 704 computer, which assures that both the electrochemical and spectrophotometric experiments are on the same time base. A block diagram of the system is shown in Fig. 1. The computer sends a triangular waveform (maximum, ± 10V) from the digital-to-analog converter (DAC) to the digital trigger which simultaneously initiates the potentiostat and the rapid scanning spectrophotometer (RSS). The triangular waveform output by the computer is also used to control the RSS. The electrochemical data is then acquired on an oscilloscopy or X-Y recorder, and the spectral data is acquired by the computer through the analog-to-digital converter (ADC) and stored on magnetic tape.

The basic RSS is a commercially manufactured unit made by Harrick Scientific Corporation (15, 16). The spectrophotometer operates in the near ultraviolet and visible regions of the spectrum with a wavelength range of 280-600 nm. The electronic interface for the

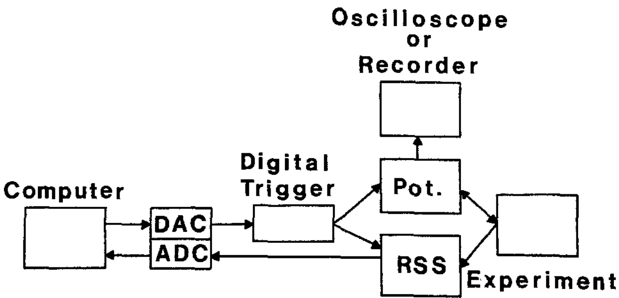

Fig. 1. A block diagram of the spectroelectrochemical system

Key words: optically transparent electrode, rapid scanning spectroscopy, electropolymerization, cyclic voltammetry.

RSS is composed of two circuits: a galvanometer drive circuit and a photomultiplier tube output signal conditioning circuit, which were described previously (17, 18). The galvanometer mirror (16) and, hence, wavelength scan, is driven electronically by a triangular waveform, computer generated, through the digital-to-analog (DAC) converter.

The RSS offers a high degree of experimental flexibility as the frequency of scan, the wavelength scan width, and wavelength region can all be varied by entering the proper commands on the teletype. RAPID is the main program of a package that was designed to drive and acquire data from the rapid scanning spectrometer. Details of the circuitry, operation, limitations of the system, and RAPID plus the subroutines associated with it have been described and listed previously (17-19).

The electrochemical cell was similar to the design used by Kuwana and Heineman (20). A platinum optically transparent electrode (OTE) was used as the working electrode, which was commercially manufactured by Harrick Scientific Corporation (15). These platinum OTE's generally have a metal film thickness of 50-250Å with a resistivity of 5-20 Ω-cm and an optical transmission in the visible region of the spectrum of about 10-20% (15). The light beam was perpendicular to the electrode surface (transmission mode). The working electrode was cleaned using a chromic acid cleaning solution, then rinsed with 3M nitric acid, and finally copiously rinsed with triply distilled water. This leaves the working electrode in an oxidized state, which is then electrochemically reduced at −0.2V *vs.* an Ag/AgCl reference electrode, then any adsorbed hydrogen is oxidized at +0.05V, and, finally, the working electrode is brought to starting potential, which in our case was 0V. In the cleaning steps, the electrochemical reduction and oxidations were carried out until the current dropped almost to zero. This procedure, though tedious, assured a reproducible electrode surface at the start of every experiment (21). The counterelectrode, a coiled platinum wire, and the reference electrode, Ag/AgCl, were separated from the sample solution by Corning Vycor porous glass ("thirsty" glass) salt bridges. The supporting electrolyte was 0.1M phosphate buffer solution (pH = 7). The concentration of the samples used was 3 mM 1,2-diaminobenzene or 3 mM 1,2-diaminobenzene and 3 mM $Ni(NO_3)_2$. All electrolysis solutions were deaerated for 15 min with high purity grade nitrogen (Delta Products) prior to the initiation of the experiment and a nitrogen atmosphere was maintained over the solution during the course of the experiment.

The 1,2-diaminobenzene (practical grade) was purified by recrystallizing from dichloromethane three times using ordinary techniques, and was decolorized with activated carbon (2 g/liter) during the first recrystallization. The final product was pure white platelike crystals with a melting point range of 100.3°-101.8°C. The literature value for the melting point range of pure 1,2-diaminobenzene is 102°-103°C (22). The $Ni(NO_3)_2$ used was reagent grade and was not further purified.

X-ray fluorescence was used for the determination of nickel. An EDAX, energy dispersive x-ray analyzer, Nuclear Diodes (Model 707), was used for the analysis.

Infrared spectra were taken on a Beckman IR-12 spectrometer, with samples in the form of KBr pellets. The pellets were made using 2 mg of sample to 200 mg of reagent grade KBr, with a pressure of 1200 psi.

Results and Discussion

A chronocoulometric study (23) gave anamolous results. Using a potential step from 0 to +0.6V which is well into an apparent diffusion-controlled region of the wave, a plot of charge *vs.* the square root of time data should yield an intercept on the charge axis for 1,2-diaminobenzene, both in the presence and absence of Ni(II) representing charging and faradaic reactions of any adsorbed reactant (24). However, the plotted data (negative coulombs at $t = 0$) had an intercept on the time axis, which is not consistent with an adsorbed reactant model. Examination of the potentiostat response showed that a relatively long time is required for the electrode to reach applied potential, 3 sec for a 600 mV potential step. The potentiostat response for the same potential step is only 30 msec in the supporting electrolyte solution. This degraded response time is probably responsible for the anomalous chronocoulometric results, and may be due to adsorption of 1,2-diaminobenzene and/or initial film formation in our system. This results in a huge pseudocapacitance and/or resistance effect and, hence, a large *RC* time constant for the electrode (24).

Figure 2 shows a typical cyclic voltammogram with a potential scan rate of 3 mV/sec for the oxidation of 1,2-diaminobenzene. The peak potential (E_p) occurs at about +0.35V *vs.* a Ag/AgCl reference electrode. The oxidation wave is totally irreversible in nature, and on successive scans, without cleaning the electrode, the peak current dropped significantly with each scan until ultimately no current flowed, which is indicative of a nonconducting film completely coating the electrode.

Figure 3 shows a cyclic voltammogram for the oxidation of 3 mM 1,2-diaminobenzene in the presence of 3 mM Ni(II) under the same electrolysis conditions. In this case, E_p occurs at a slightly more negative potential of +0.33V. Other than this slight shift in half-wave potential, the two cyclic voltammograms are quite similar, with both oxidations being irreversible and film formation insulating the electrode on prolonged cycling.

As expected, the behavior on variation of sweep rates showed that the mechanism did not follow any of the model systems analyzed by Nicholson and Shain (25).

Obviously, by using only electrochemical techniques, little reliable mechanistic information could be obtained on this system. In fact, from this data alone, one

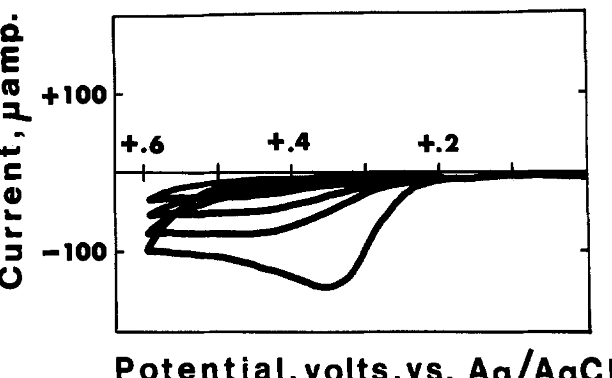

Fig. 2. Cyclic voltammogram of the oxidation of 1,2-diaminobenzene.

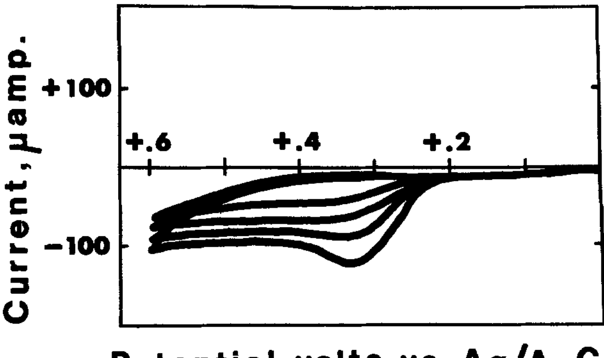

Fig. 3. Cyclic voltammogram of the oxidation of 1,2-diaminobenzene in the presence of Ni(II).

might be led to believe that the oxidation of 1,2-diaminobenzene alone and in the presence of Ni(II) is the same reaction or at least similar. Such is not the case, however, as can be seen from the spectroelectrochemical data given below.

Spectroelectrochemical Results

All spectra were taken in the near-u.v. and visible regions of the spectrum (280-600 nm) at a scan rate of 20 spectra per second. A blank cell with an optically transparent electrode and sample solution was placed in the reference beam to subtract any absorbance not due to electrolysis products.

Two types of spectroelectrochemical experiments were performed. In one case, spectra of the electrode interface were taken during the oxidation while the potential was being scanned slowly (3 mV/sec). In the other case, spectra of the electrode interface were taken while the potential was stepped to various values along the oxidation wave up to solvent breakdown. In both types of experiments, the same absorbance peaks were observed which would seem to indicate that the reaction mechanisms are not time dependent with respect to the rate of applied potential change.

Typical voltammetric spectroelectrochemical results for 1,2-diaminobenzene are shown in Fig. 4. An absorbance peak at 460 nm appears at a potential of +0.25V, and a 360 nm absorbance peak appears at +0.30V. In this case it seems that we are observing two different species, an intermediate at 460 nm and the final product at 360 nm.

The voltammetric spectroelectrochemical results for 1,2-diaminobenzene in the presence of Ni(II) are shown in Fig. 5. An absorbance peak at 480 nm appears at +0.27V, and a 360 nm absorbance peak appears at +0.35V. Again, it appears that we are observing two different species.

In the potential step spectroelectrochemical experiments, the potential was stepped to the following points: $E_{1/4}$ (+0.25V), $E_{1/2}$ (+0.28V), $E_{3/4}$ (+3.0V), E_p [+0.35V for 1,2-diaminobenzene alone and +0.33V for 1,2-diaminobenzene plus Ni(II)], +0.60V (plateau of the oxidation wave), +1.0V (almost to solvent breakdown). The electrochemical chronoamperometric behavior and the spectrophotometric behavior were monitored simultaneously. In these experiments it was found that there were significant differences in the rate and nature of the filming between 1,2-diaminobenzene alone and in the presence of Ni(II). With the oxidation of 1,2-diaminobenzene alone, filming occurred at all potential steps that were employed, but in the presence of Ni(II) no filming occurred at a potential less than +0.35V. The Cottrell behavior was plotted for all potential steps both with and without Ni(II) present and, as expected, diffusion-controlled Cottrell behavior was not observed (26).

Figure 6 shows the spectral behavior during the oxidation of 1,2-diaminobenzene with a potential step from 0V to E_p (+0.35V), which is also representative of the other potential steps. At all potential steps, an absorbance peak at 460 nm is initially formed, after which an absorbance peak at 360 nm grows until the electrode is completely insulated by the film.

The absorbance *vs.* time behavior for these two peaks for the E_p (+0.35V) step is shown in Fig. 7. The absorbance of the initial peak at 460 nm begins to level off after about 50 sec, while the absorbance at 360 nm is still growing after 100 sec. The electrode becomes insulated, and the absorbance peak at 360 nm stops growing after about 200 sec. No change was noticed in the spectrum on disconnecting the cell from the potentiostat or removing the solution from the cell and replacing it with distilled water.

The spectral behavior appears to indicate that the initial film formation (the 460 nm band) is a conducting organic film, and subsequent formation of a nonconducting film occurs on top of the conducting film, which eventually insulates the electrode. The absorbance peak at 360 nm corresponds to the nonconducting film product. An alternate, but less likely possibility is that the conducting film is transformed into the insulating film. This would necessitate a steady-state condition to explain the constant absorbance of the 460 nm peak after 50 sec. This steady-state condition seems unlikely with increasing insulation of the electrode.

Figures 8 and 9 show the spectral behavior during the oxidation of 1,2-diaminobenzene in the presence of Ni(II) with potential steps from 0V to E_p (+0.33V) and +1.0V, respectively. The E_p (+0.33V) potential step is representative of the $E_{1/4}$ (+0.25V), $E_{1/2}$

(+0.28V), and $E_{3/4}$ (+0.30V) potential steps, and the +1.0V potential step is representative of the +0.6V potential step. At $E_{1/4}$ (+0.25V), $E_{1/2}$ (+0.28V), $E_{3/4}$ (+0.30V), and E_p (+0.33V) potential steps, only one absorbance peak is evident, which occurs at 480 nm. The absorbance *vs.* time plot for this peak for the E_p (+0.33V) potential step is shown in Fig. 10. Note that the absorbance of this peak is still increasing after 500 sec with no signs of insulating filming occurring.

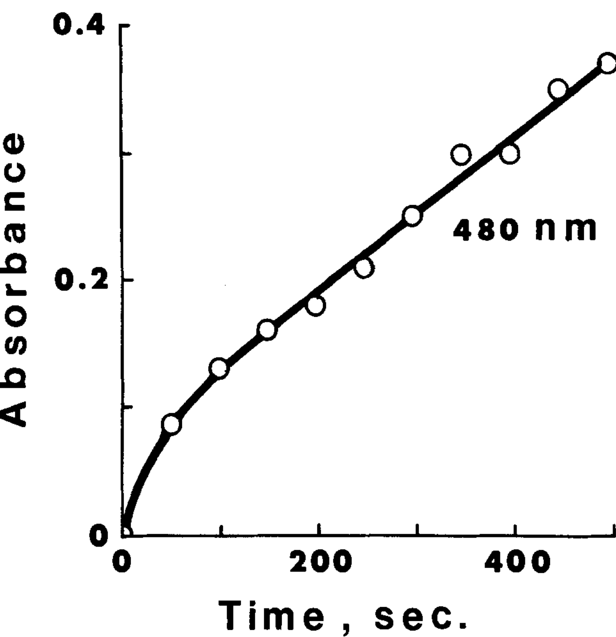

Fig. 10. Absorbance *vs.* time behavior for the E_p potential step spectroelectrochemical oxidation of 1,2-diaminobenzene in the presence of Ni(II).

Similar behavior is observed at the lower potential steps, but when the magnitude of the potential step is increased a different reaction mechanism is observed. At +0.6 and +1.0V potential steps, only one absorbance peak is evident, but this peak occurs at 360 nm which is the same absorbance wavelength as the product formed in the oxidation of 1,2-diaminobenzene alone. The absorbance *vs.* time behavior for this peak for a +1.0V potential step is shown in Fig. 11. The behavior is similar for the +0.6V potential step. Note that this absorbance *vs.* time behavior is also similar to that obtained for the oxidation of 1,2-diaminobenzene, with the absorbance slowing significantly (but not leveling off) after about 200 sec and film formation eventually insulating the electrode.

Therefore, with Ni(II) present, it is evident that the mechanism and the products are potential dependent and, hence, may be governed by the potential-dependent rates of either the heterogeneous electron transfer or a surface chemical reaction. At lower potentials one obtains a product which does not film or insulate the electrode. At higher potentials one obtains a nonconducting film which insulates the electrode, and

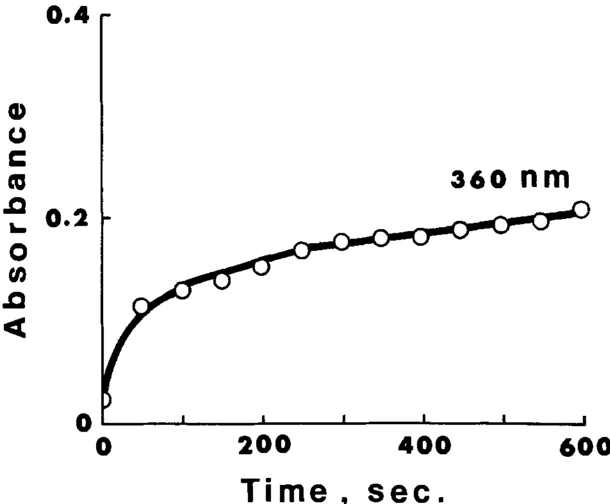

Fig. 11. Absorbance *vs.* time behavior for the +1.0V potential step spectroelectrochemical oxidation of 1,2-diaminobenzene in the presence of Ni(II).

is probably the same product that is formed without the presence of Ni(II), as the absorbance peak occurs at the same wavelength and the filming that occurs are identical.

The air oxidation product of 1,2-diaminobenzene alone and in the presence of Ni(II) has an absorbance peak at 415 nm. This absorbance peak is due to 3,5-dihydro-2-amino-3-imino-phenazine which is a tautomeric form of 2,3-diaminophenazine, which is the commonly accepted air oxidation product of 1,2-diaminobenzene (27, 28). This absorbance peak was not observed in any of the spectra due to the deaeration of the sample solution and maintenance of a nitrogen atmosphere over the solution during the experiment. Therefore, all the absorbance peaks observed in the spectra are due to electrochemical products or products formed in a direct follow-up chemical reaction to the electrolysis. Furthermore, this shows that the mechanisms and products of the electrochemical oxidations are totally different from those obtained by air oxidation.

Attempts were made to dissolve the films which insulated the electrode, and 22 different organic solvents were tried without success (18). Also, an attempt was made to determine the infrared spectra of the insulating films formed from the oxidation of 1,2-diaminobenzene alone and in the presence of Ni(II). The insulating films were formed on platinum optically transparent electrodes, using germanium as the substrate instead of quartz. No signal above the background was evident. This is probably due to the fact that extinction coefficients in the infrared region of the spectrum are generally less than those in the visible region of the spectrum. A literature survey on the spectra of the many oxidative polymerization products of 1,2-diaminobenzene did not reveal any which matched the u.v. spectrum of the insulating film (29-35).

It was noticed during the electrolysis of the 1,2-diaminobenzene in the presence of Ni(II) that a finely divided precipitate was formed near the electrode surface and fell to the bottom of the cell. This precipitate of soluble oxidation products appears to form via a polymerization reaction which takes place in the diffusion layer and not on the electrode surface. This is the final product of the nonfilming reaction which occurs at lower potentials. This product was filtered from the electrolysis solution, copiously washed with distilled water, and dried in a vacuum desiccator. It had a melting point of greater than 300°C, and was insoluble in the same 22 organic solvents that were tried on the insulating films (18).

An x-ray fluorescence analysis of the precipitation product showed the presence of two nickel peaks, a principal emission line ($K\alpha$) at 7.47 keV and a secondary line ($K_{\beta 1}$) at 8.26 keV, thereby, confirming the presence of nickel in the precipitation product.

A square planar Ni(II)(1,2-diaminobenzene)$_2$ complex is known where two 1,2-diaminobenzene molecules are complexed to Ni(II) as bidentate ligands (36, 37). However, this Ni(II) complex is not the same as the precipitation product that was obtained from electrolysis. The Ni(II) complex has absorbance peaks at 360 and 570 nm (36), and the infrared spectrum of the Ni(II) complex is different from the infrared spectrum of the electrolysis precipitation product (37).

A KBr pellet was made from the precipitation product and an infrared spectrum taken from 4000 to 200 cm^{-1}, which is shown in Fig. 12. Not much structural information can be determined from the spectrum. The spectrum is made up of broad and diffuse bands with a large background. A band which is centered around 3200 cm^{-1} is probably due to $-NH_2$ stretching, a band at 1620 cm^{-1} is due to N-H deformation of primary amines, a band at 1500 cm^{-1} is due to aromatic C-C stretching, and a band at 755 cm^{-1} is due to aromatic C-H bending. Thus, the product contains aromatic rings and amino groups, but no information concerning the nature of the polymeric linkages of the product can be determined. A C, H, N, and Ni elemental analysis of the precipitation product yielded the following results: C = 33.74%, H = 2.61%, N = 12.74%, and Ni = 21.87%. This elemental analysis does not match any of the simpler complexes of Ni(II) and 1,2-diaminobenzene, and it seems that the precipitation product is a more complex polymeric chelate. No polymeric chelates of Ni(II) and 1,2-diaminobenzene could be found in the literature with which to compare the above infrared spectrum and the elemental analysis.

Conclusions

We were able to determine that the electrochemical oxidation mechanism of 1,2-diaminobenzene was neither time nor potential dependent in the context of the experiments employed. The reaction probably occurred with the initial formation of a nonconducting film which insulated the electrode. It would be attractive to speculate that the conductive organic film is formed by the polymerization of monocation radicals which are formed by the oxidation of the 1,2-diaminobenzene. Most organic electrochemical oxidations of this type form a monocation radical as the initial electrolysis product, and this product is then very often involved in a follow-up chemical reaction (38). The insulating film could then possibly be formed by the polymerization of the dication of the 1,2-diaminobenzene formed on disproportionation [this would require that the oxidation potentials for the cation radical and di-

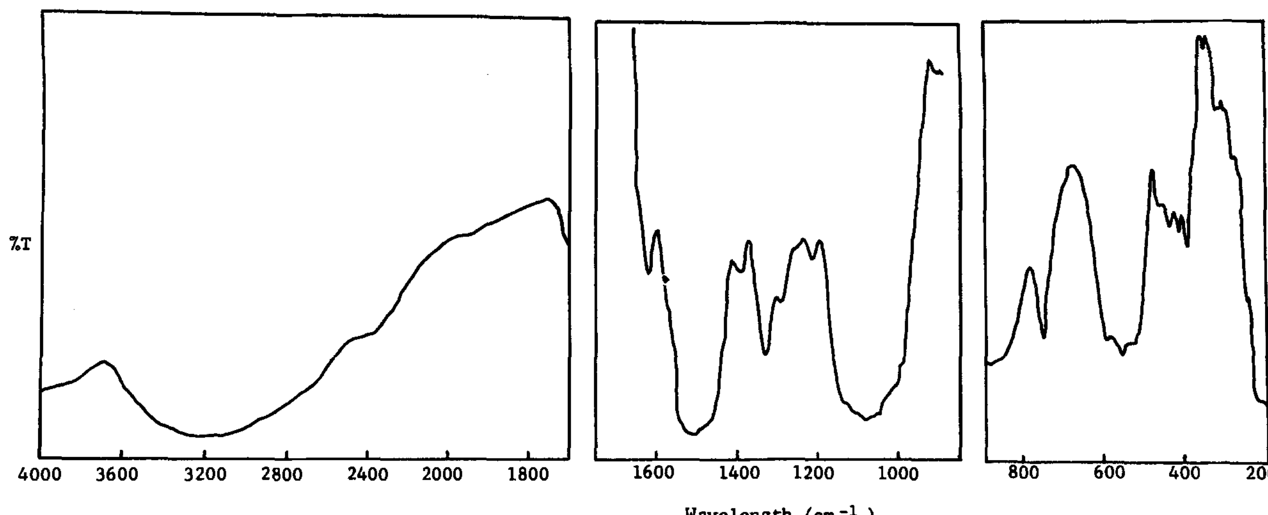

Fig. 12. Infrared spectrum (4000-200 cm^{-1}) of the nickel polymer precipitate. The sample was in the form of a KBr pellet

cation to be very close together (39)], or perhaps the monocation radical oxidizing at a conducting organic surface rather than the electrode surface yields a different product, the insulating film.

In the presence of Ni(II), the oxidation of 1,2-diaminobenzene was not time dependent with respect to rate of potential change, but was potential dependent. At lower potentials, the reaction produced a product which did not form a film but did eventually form a precipitate, and incorporated nickel in the structure. This product appears to have a relatively high molecular weight, because of the high melting point and its general insolubility in common organic solvents. At higher potentials, filming occurred, insulating the electrode. From the data available, it seems that this film is probaby the same as the film formed without the presence of Ni(II). With the Ni(II) present, at lower potentials, the monocation radical formed by the oxidation of 1,2-diaminobenzene probably predominates, but at higher potentials the formation of the dication could predominate. At lower potentials the rate of the monocation polymerization on the electrode is slow compared to the rate of complexation with Ni(II) which forms a soluble intermediate product. This then polymerizes or aggregates and precipitates from solution. There was no evidence of the formation of a conducting organic film during the nickel polymer precipitation. At higher potentials the dication is probably preferentially formed, which then polymerizes on the electrode surface forming the insulating film over the electrode.

The Anodic Oxidation of Platinum: Determining the Dependence of Current Density on Potential

J. L. Ord,* D. J. DeSmet,*[,1] and M. A. Hopper*[,2]

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

The way in which current density depends on potential during the anodic oxidation of platinum in 0.1M H_2SO_4 is studied using two different methods to determine values for the parameters in the relation $i/i_0 = \exp((V - V^*)/V_0)$. The first method determines values for the parameters from analysis of open-circuit transients, and correlates the V_0 values with optical measurements of the thickness of the oxide film. The second method analyzes the dependence of potential on film thickness during galvanostatic oxidation to determine a second set of values for the parameters. This set differs significantly from the open-circuit set, and leads to a different model for the anodic oxidation process. The model based on open-circuit data appears to provide a more reasonable description of an anodic oxidation process controlled by the field in the oxide film. Reasons for the differences in the results are discussed, and the internal consistency of the methods is examined.

When platinum is oxidized anodically at constant current density, the three stages involved in the process show up clearly on a plot of potential *vs.* time. As the initial monolayer of oxide is formed, dV/dt, the rate of change of potential, decreases steadily from its initial double-layer charging value to the constant value it maintains during the second or layer-growth stage of oxidation. In the third stage, dV/dt again decreases as oxygen evolution competes with oxide formation and takes an increasing fraction of the current density. Our interest in this paper is in determining the dependence of current density on potential in the second stage where layer growth is the dominant process. In a previous paper (1) we argued that this stage of the anodic oxidation of platinum is limited by the electric field in the oxide film. Recent work from other laboratories (2-4) appears to support our conclusion that platinum undergoes field-limited oxidation in much the same way as does tantalum or niobium. Weaver surveyed the recent work in the field in his 1974 review of the electrochemical formation of thin oxide films on noble metals (5), and assessed the evidence for a model involving high field ion transport.

In this paper we direct our attention to the basic problem of inference involved in the determination of the dependence of current density on potential. The exponential dependence of current density, i, on potential, V, characteristic of an activation-controlled process can be written

$$i/i_0 = \exp((V - V^*)/V_0) \quad [1]$$

where V^* is the zero of overpotential, i_0 is the exchange current density, and V_0 is a Tafel slope expressed in terms of natural logarithms. Experiments usually are designed to determine values for the three parameters V^*, i_0, and V_0 under a variety of experimental conditions. For processes controlled by the overpotential, $(V - V^*)$, all three parameters are expected to have constant values, whereas processes controlled by the field in the film must have V_0 proportional to the film thickness. Although all three parameters are required to specify completely the dependence of current density on potential, it is the behavior of the parameter V_0 which distinguishes between field and overpotential control of the process. The parameter V^* identifies the potential at which oxidation commences.

Key words: platinum, anodic oxidation, Tafel slope, ellipsometry.

Anodic oxidation is known to be a more complex process than the ideal activation-controlled process upon which Eq. [1] is based, and different approaches to the analysis of oxidation data may yield significant different values for the parameters V^*, i_0, and V_0 (6, 7). Although the relative merits of the different approaches to data analysis can be debated at length, the ultimate choice between sets of parameter values is dictated by the answer to the question "which set leads to a more reasonable description of the behavior of the system?" Our aim in this paper is to show how one can go about attempting to answer this question for the anodic oxidation of platinum. We carry out an open-circuit transient analysis and a galvanostatic charging analysis on a common set of data. The two analyses give significantly different results, the results of the open-circuit analysis agreeing with our earlier work (1), and the results of the galvanostatic charging analysis agreeing with the work of Vetter and Schultze (2). After carrying out a detailed comparison of the results, we conclude that the parameter values from the open-circuit analysis provide the more reasonable description of the anodic behavior of platinum, and we offer an explanation of why this should be.

Experimental

The optical measurements were made with a self-nulling ellipsometer which has been described in detail elsewhere (8). The instrument has a resolution of 0.01° in the settings of its polarizing prisms, and nulls both polarizer and analyzer approximately twice each second under the optical conditions encountered in this experiment. The standard deviation in the null readings is less than the resolution of the instrument, and some increase in resolution was obtained by averaging the data when the film thickness was not changing too rapidly. A helium-neon laser is used as the light source, and an angle of incidence of 60° is chosen to accommodate a cell made from a hollow equilateral glass prism. The cell is fitted with standard taper joints for mounting the electrode holder, platinum counter-electrode, mercurous sulfate reference electrode, and gas dispersion tube. The electrolyte, 0.1M H_2SO_4, was saturated with argon and measurements were made at room temperature, 23°C. Potentials are expressed relative to the normal hydrogen electrode.

The cylindrical single crystal sample of platinum used as the working electrode is clamped between Teflon washers in a glass electrode holder. A flat on one side of the cylinder is used for the optical measurements. A surface area of approximately 1.25 cm² is

exposed to the electrolyte in this configuration. The preparation of the surface of the sample is described in the next section.

The laboratory computer, a Hewlett-Packard 2114B, was programmed to carry out the experiments without operator intervention, recording the data on magnetic tape for recall by analysis programs written in BASIC. Both the electrochemical control circuitry and the circuitry which operates the ellipsometer are built into the multiplexed input-output interface of the computer. The computer reads the digital output from the ellipsometer directly, and uses digital-to-analog and analog-to-digital converters to control the current through the cell and read the electrode potential. A video display terminal and an X-Y point plotter are used extensively for graphical display during the performance of the experiment and the analysis of the data.

The experiments were performed under program control primarily to give the best optical data possible. It is difficult to obtain good optical data under conditions where the resolution of the instrument is 3% of the maximum range in the data, and variations in surface roughness or alignment can shift the data by an amount comparable to their range. Under program control, an entire series of experiments can be repeated precisely, and the reproducibility of the optical data can be given a very stringent test. Replication of the series of experiments also provides a stringent test of the estimates of the standard deviation in V_o values given by least squares analysis of open-circuit transients. Program control of both the performance of the experiment and the analysis of the data offers one further advantage which is qualitative rather than quantitative: it serves to emphasize the fact that there is nothing subjective about the differences between the results of the two approaches to data analysis.

Except for the open-circuit analysis program, the data reduction involves fitting straight lines only and requires no further comment. The basic equations governing open-circuit transients are obtained by writing the external current in the cell circuit, i_e, as the sum of i_c, the current charging the capacitance, and i, the Faradaic current through an element in parallel with the capacitance

$$i_c + i = i_e \quad [2]$$

With $i_e = 0$, i_c written as $C\,dV/dt$, and i given by Eq. [1], Eq. [2] becomes

$$CdV/dt + i_o \exp\left((V - V^*)/V_o\right) = 0 \quad [3]$$

This is the differential equation of an open-circuit transient. It can be integrated, assuming C, i_o, V_o, and V^* all constant, to give

$$V = V_1 - V_o \ln\left(1 + t/\tau\right) \quad [4]$$

where the time constant τ is defined by

$$\tau = CV_o/i_1 \quad [5]$$

and i_1 and V_1 are the values of i and V at $t = 0$. Analysis of open-circuit transients can be based on either Eq. [3] or [4]. In the analysis used here, the recorded values of V and t are fitted to Eq. [4] by varying τ until a linear V *vs.* $\ln(1 + t/\tau)$ least squares analysis gives the minimum deviation in V.

The open-circuit data are recorded in a form designed for this type of analysis. Although the potential is read at millisecond intervals, data are recorded only at specified potential increments. Hence the point density on the least squares line is uniform, the values of t are known exactly, and the standard deviation in V is approximately constant from point to point. Potentials are read using a 12-bit analog-to-digital converter with a one-half millivolt resolution. Eight successive conversions over a 200 μsec interval are summed, then the least significant bit is dropped, leaving a 14-bit binary integer with a one-eighth millivolt resolution. The standard deviation in V estimated from the open-circuit analysis is typically less than one-half millivolt, but it is systematic rather than random, indicating that second-order corrections to Eq. [1] are more significant than are random errors in V.

Surface Preparation

Unless the surface of the platinum sample is prepared in a stable configuration, the polarizer and analyzer null settings for a nominally clean surface show a tendency to drift during a series of oxidation-reduction cycles. A typical set of optical data which exhibit this effect is shown in Fig. 1. Before the sample was inserted in the optical cell, its surface was roughened slightly by etching in aqua regia. The oxidation-reduction cycle consisted of oxidation at a current density of 20 μA/cm^2 from 0.27 to 1.37V, followed by reduction at the same current density back to 0.27V. The optical data obtained on the bare surface at the beginning of the first cycle are plotted at A1 in the figure. As the oxidation proceeds, the data trace out the curve A1-B1. At point B1 the current is reversed, and the data proceed from B1 to a point slightly to the right of A1 in the figure. As the cycling continues, the data drift to the right in Fig. 1 along a zigzag path. The end points of cycles 4, 9, and 16 are shown in the figure along with the complete 27th oxidation cycle. Continued cycling beyond the 27th cycle produces a smaller and smaller drift in the optical data, indicating that an optically stable surface is being approached.

The change in the null settings represented by the displacements A1-B1 and A27-B27 in the figure can be attributed to the growth of an oxide film on the surface, whereas the displacement A1-A27 can be associated with a change in the roughness of the bare platinum surface. The film-growth displacements can be given a satisfactory (but not unique) analysis in terms of a change in the thickness of an oxide layer of constant refractive index, but there is no satisfactory technique for analyzing surface roughness. Experience shows that displacements to higher P values accompany decreases in surface roughness, and displacements to lower P values accompany roughening of the surface. Cycles of the type plotted in Fig. 1 can be used to reduce the roughness of a platinum surface provided care is taken to avoid gas evolution. If the cycling is continued, the surface eventually reaches a smooth, reasonably stable configuration, but the procedure is tedious even under program control.

There is a technique for preparing a smooth, stable platinum surface in one cycle. We discovered this technique by accident while studying the Kolbe reaction. Conway's extensive work on Kolbe synthesis [see for example Ref. (9) and (10)] led him to suggest (11) that we try using our self-nulling ellipsometer to detect the adsorption of organic molecules on both platinum and platinum oxide. The initial measurements appeared successful, for we found large optical changes associated with the Kolbe reaction, but further work showed that the optical changes were due to a re-

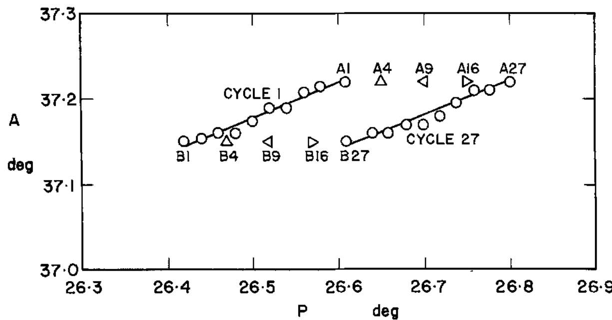

Fig. 1. Optical data obtained on cycling a roughened platinum electrode at 20 μA/cm^2 between 0.27 and 1.37V in 0.1M H_2SO_4: A1-B1 first anodic cycle; A27-B27, twenty-seventh anodic cycle.

markable reduction in the roughness of the platinum surface during the Kolbe synthesis. When we concluded that the optical changes were not associated with the adsorption of organic molecules, we carried the work no further, but have continued to use this technique for preparing optical surfaces on platinum.

Optical data from a typical Kolbe cycle in 0.1M H_2SO_4 + 1.8M CF_3COOH are plotted in Fig. 2. In this instance, the surface of the platinum sample was roughened before the start of the experiment by evolving hydrogen on it rather than by etching it in aqua regia. The optical data trace out the curve A-B as an oxide film forms on the surface below the potential at which the Kolbe reaction begins. Once the Kolbe reaction begins, the optical data turn a sharp corner in the *P-A* plot, and the polarizer readings start to increase. During Kolbe synthesis, the optical data trace out the curve B-C. As the experiment proceeded, the applied current density was increased from 20 $\mu A/cm^2$ at point B to 1 mA/cm^2 at point C. At C, the gas bubbles were shaken from the surface of the sample, and it was reduced at 100 $\mu A/cm^2$ until the oxide film was removed completely at point D. We interpret the net displacement of the optical data from A to C during the oxidation cycle as resulting from the superposition of a displacement from A to D due to reduction in surface roughness, and a displacement from D to C due to growth of an oxide film. We find that the sample can be rinsed and transferred to the optical cell with no deterioration in the condition of the surface provided that it is removed from the Kolbe cell with the oxide film on the surface, and the transfer is carried out reasonably quickly. The sample then remains smooth provided hydrogen is not evolved on its surface, and provided it is not exposed to the electrolyte for an extended period without an oxide film on the surface.

The surface roughness effects displayed graphically in Fig. 1 and 2 can equally well be expressed in terms of nominal values calculated for the refractive index of platinum at 6328Å. If point A in Fig. 2 is taken as characteristic of a clean platinum surface, a refractive index of 2.32-4.91i is obtained, whereas, if point D is taken, an index of 2.51-5.11i results. The latter value is undoubtedly better, because the calculation of the refractive index assumes that the metal surface is perfectly flat.

Results

The data obtained during a typical oxidation-reduction cycle with no open-circuit transients are plotted in Fig. 3. The experiment begins with the potential of the working electrode set at 0.3V. At point A a constant oxidation current density, in this instance 10 $\mu A/cm^2$, is applied to the working electrode, and its potential rises rapidly to B then more slowly to C as shown in the bottom portion of the figure. When the potential reaches 1.4V at point C, the applied current density is switched to -10 $\mu A/cm^2$, and the working electrode is reduced until the potential returns to 0 3V where it is held for 5 sec before the next cycle begins.

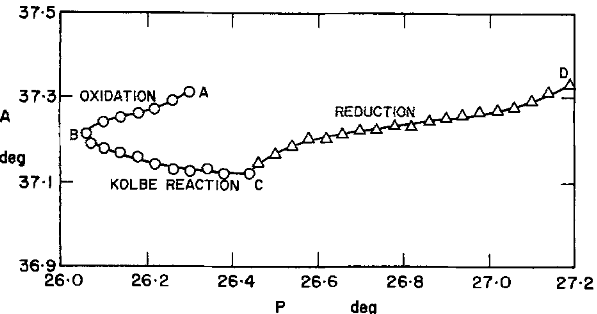

Fig. 2. Optical data obtained on a roughened platinum electrode during a Kolbe cycle in 0.1M H_2SO_4 + 1.8M CF_3COOH.

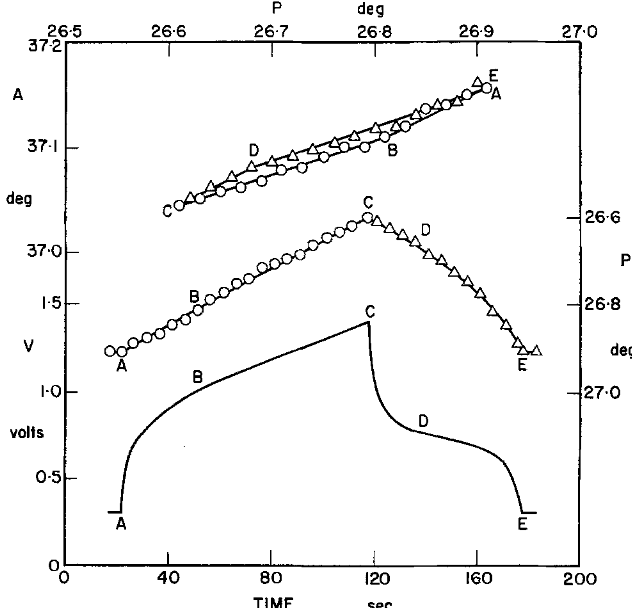

Fig. 3. Oxidation-reduction cycle at 10 $\mu A/cm^2$ for platinum in 0.1M H_2SO_4.

During the cycle, the null settings of the polarizer, *P*, and analyzer, *A*, are recorded at 1-sec intervals. These data are shown in plots of *P vs.* time in the center portion and *P vs. A* in the top portion of Fig. 3. Corresponding points labeled A, B, C, and D are identified on each of the three plots in the figure. Although the *P-A* plot exhibits some fine structure, the dependence of *P* on *A* is essentially the linear relation expected for the growth of very thin films of constant refractive index. For such films there is also a linear relation between the film thickness and the *P* and *A* readings. Since *P* spans a greater range than *A*, we will use the change in *P* from its bare surface value as the optical measure of the average film thickness in our analysis of the data. Unique values for the thickness and refractive index of the oxide film cannot be determined from the analysis of our optical data, but the factor relating changes in film thickness to changes in *P* will be on the order of 15 Å/degree for reasonable values of the refractive index of the film.

The potential-time plot for an oxidation-reduction cycle with open-circuit transients is shown in Fig. 4. The experimental conditions are the same as for the data in Fig. 3, except that the computer is programmed to open the circuit at 100 mV intervals across the region from 0.9 to 1.4V. With a starting potential of 0.9V, as in Fig. 4, there will be six open-circuit transients during the cycle, and with a starting potential of 0.95V there will be five. Two sequences with 100 mV in-

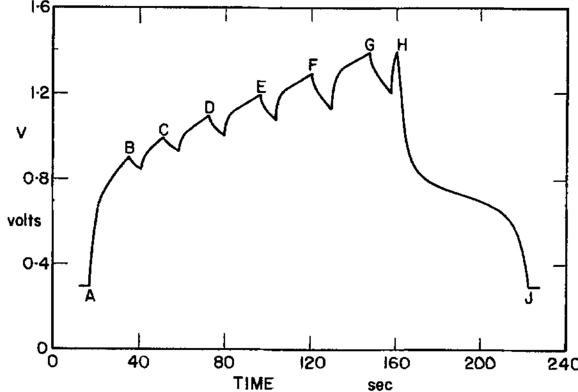

Fig. 4. Oxidation-reduction cycle at 10 $\mu A/cm^2$ with open-circuit transients for platinum in 0.1M H_2SO_4.

tervals are used rather than a single sequence with a 50 mV interval in order to allow the electrode more time to recover between transients. The detailed shape of the open-circuit transients cannot be shown accurately on the scale used in Fig. 4. The duration of a transient is equal to the time required for its slope to change by a factor of 16.

A series of cycles of the type plotted in Fig. 3 and 4 was carried out at oxidation current densities of 5, 10, 20, 40, and 80 μA/cm^2 both without open-circuit transients and with open-circuit transients at the two potential sequences. The complete series was then repeated under program control in order to test the reproducibility of the data. Throughout the experiment, the maximum offset noted in the optical data was 0.01°, and cycles with and without open-circuit transients were found to give indistinguishable optical data.

During an experiment of this kind, more data are recorded than can be handled conveniently. (Listing the data on the Teletype requires a full day.) We obtain a manageable set of 55 data points for use in further analysis if we select only the data recorded at the 11 open-circuit potentials for each of the 5 oxidation current densities. In order to free the laboratory computer for other experiments a Hewlett-Packard 9830 BASIC calculator was used to analyze the reduced data set. The values of P, V_o, and $1/C$ (calculated using Eq. [5]) were entered as 5 by 11 matrices with subscripts specifying current density and potential. The data were stored on the calculator tape cassette for least squares analysis and plotting programs. The remaining figures in the paper are tracings of graphs produced on the calculator plotter.

The analysis of open-circuit data involves a number of steps: first the transients are analyzed to determine the values of V_o and τ (or $1/C$), then the dependence of V_o on V_1 at constant i_1 is used to determine values for V^* and i_o, and finally the optical data are used to relate the V_o values to film thickness. In addition, the dependence of $1/C$ upon film thickness can be investigated, but a simple relation is not expected in the case of platinum (1). In Fig. 5, V_o is plotted as a function of V_1 for each of the 5 values of i_1, and in Fig 6, V_o is plotted as a function of P for all values of i_1 except 5 μA/cm^2. One must be careful not to interpret Fig. 5 as expressing a dependence of V_o on V which can be substituted back into Eq. [1] to give a modified relation between i and V. As Fig. 6 clearly shows, the variations in V_o are due to the variations in film thickness which

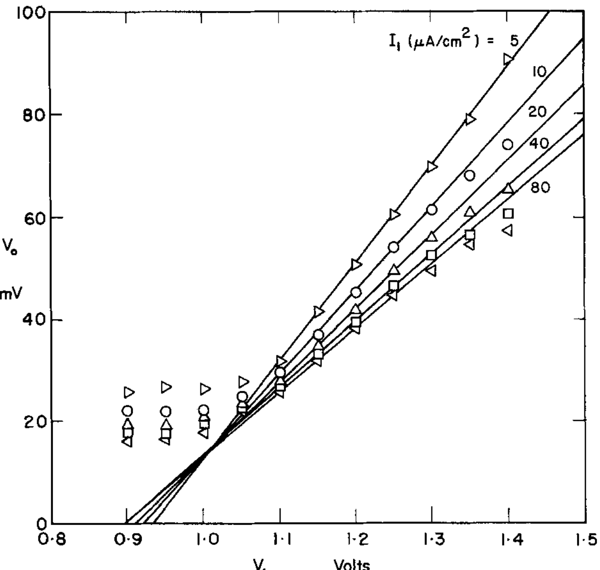

Fig. 5. Tafel slopes from open-circuit analysis vs. initial potential for oxidation current densities from 5 to 80 μA/cm^2. The fitting region for the lines is from V_1 equals 1.10-1.25V.

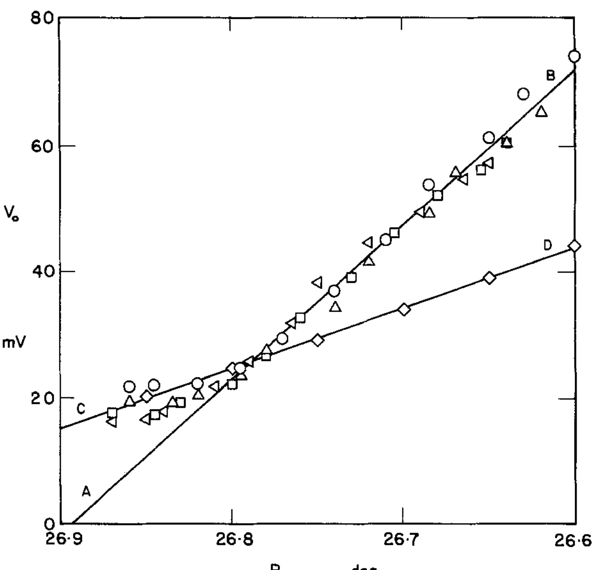

Fig. 6. Tafel slopes from open-circuit analysis vs. polarizer null setting for oxidation current densities from 10 to 80 μA/cm^2. Oxidation current density is identified by plotting symbol as in Fig. 5. Line A-B is fitted to the data over the range from V_1 equals 1.05-1.40V. Line C-D is fitted to the six data points plotted as diamonds which come from the galvanostatic charging analysis in Fig. 9.

accompany changes in V_1 under our experimental conditions.

It is not possible to determine both V^* and i_o from the values of i_1, V_1, and V_o for any one transient. If, however, a set of transients with a common value of i_1 have V_o values which vary linearly with V_1, then we can find values for V^* and i_o which are common to all transients in the set. If S is the slope dV_o/dV_1, then i_o is equal to $i_1/\exp(1/S)$, and V^* is given directly by the intercept of the line on the V_1 axis. The lines in Fig. 5 are least squares fits to the V_o data at each i_1 over the potential range from 1.1 to 1.25V. Below 1.1V the V_o data show the leveling expected for a field-limited process below monolayer coverage. Above 1.25V at the higher oxidation current densities, the data curve away from the linear relation predicted by elementary models of field-limited processes. The values of i_o and V^* determined from the least squares lines, in order of increasing i_1, are i_o equals 0.026, 0.022, 0.020, 0.019, and 0.028 μA/cm^2, and V^* equals 0.934, 0.921, 0.911, 0.897, and 0.897V.

For i_1 values from 10 to 80 μA/cm^2 all the V_o data fall on one line when plotted in Fig. 6 as a function of P. The expected deviation below monolayer coverage is still present, but there is no deviation corresponding to the curvature noted in Fig. 5 at higher V_1's and i_1's. A least squares line fitted to data with $V_1 > 1.05$V intersects the P axis at 26.89 degrees, and has a slope of 0.245V/degree. Average V^* and i_o values for the data falling on this line are $V^* = 0.907$V and $i_o = 0.0225$ μA/cm^2. The data for $i_1 = 5$ μA/cm^2, omitted from the figure for clarity, fall on a line of slightly (but significantly) steeper slope. This may be taken as indicating that all of the current density is not field-controlled for transients in which the current density ranges from 5 μA/cm^2 down to 5/16 μA/cm^2. In order to make it easier to compare results, we have plotted the V_o values from galvanostatic charging analysis in Fig. 6 also.

The open-circuit analysis also provides values for the reciprocal capacitance, and these are plotted in Fig. 7 as a function of P. The reciprocal capacitance is not simply related to film thickness. It approximately doubles during monolayer coverage, then increases by

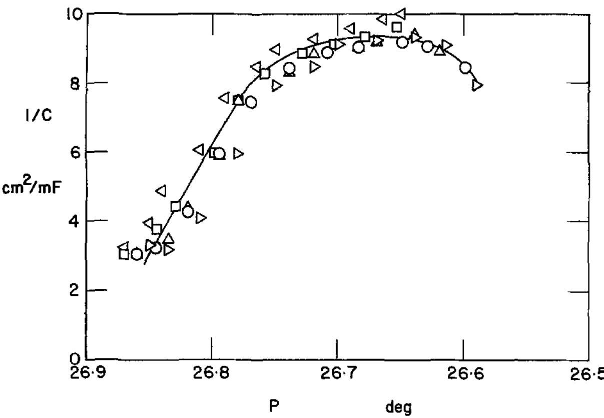

Fig. 7. Reciprocal capacitance from open-circuit analysis as a function of polarizer null setting. Oxidation current density is identified by plotting symbol as in Fig. 5.

only about a further 50% during film growth before leveling off and even dipping slightly.

This completes the reduction of the open-circuit transient data. We will now perform a second analysis of the data following an approach which does not use the open-circuit parameters V_o and τ. This approach is usually based on analysis of the potential of the working electrode as a function of the charge accumulated at it for a set of constant oxidation current densities. In systems where the anodic oxidation process operates at nearly 100% efficiency, the charge accumulated on unit area of the working electrode is equated simply to the product of the oxidation current density and the time required to reach the potential in question. If there is reason to believe the reduction process to be more nearly 100% efficient, then the charge required to reduce the oxide is used instead. We prefer to use optical measurements of the thickness of the oxide film instead of charge measurements in our analysis, but we will refer to the analysis as galvanostatic charging analysis.

The data reduction begins with a plot of potential as a function of P at each of the 5 oxidation current densities. Our best such data, the set of 55 data points recorded at the initial potentials of the open-circuit transients, are plotted in Fig. 8. No following speed corrections need be applied to these data even at our highest oxidation current density because the ellipsometer has time to reach a proper null while the circuit is open. For any particular value of i_1, the V_1 data increase linearly with decreasing P at a slope which depends on the value of i_1. The V_1-P slope gets steeper as the values of i_1 get larger. The lines in the figure were fitted to the data over the 1.05-1.4V region using least squares. For clarity, the line for the $i_1 = 10$ μA/cm² data is not shown in the figure because it obscures the trend illustrated by the other four lines.

Two techniques can be used for further reduction of the data in Fig. 8. Although they appear to be different, they are equivalent when applied to ideal data. In the first, plots of log (i) *vs.* V are constructed for a set of different film thicknesses. Values of V^*, i_o, and V_o as a function of film thickness can be determined directly from this plot. This technique, used widely in electrochemistry, is analogous to the technique used by Vetter and Schultze (2). In the second technique, used commonly in studies of the anodic oxidation of valve metals, log (i) is plotted *vs.* the potential-film thickness slope. If the overpotential appears across the oxide film, this slope is equal to the field in the oxide film, and the plot directly shows the dependence of the current density on the electric field in the film.

In order to apply the first technique to the reduction of the data in Fig. 8, one draws lines perpendicular to the P axis at 0.05° increments between 26.85° and 26.60°. The intersections of these lines with the five least squares lines are then plotted *vs.* log (i_1) to give current-potential characteristics at six different film thicknesses. This plot is shown in Fig. 9. The i-V characteristics all show linear dependence of log (i) upon V with the 10 μA/cm² points deviating significantly from the lines. If the characteristics have common values of i_o and V^*, lines fitted to the data in Fig. 9 should have a common intersection at the point where i equals i_o and V equals V^*. Least squares lines fitted to all but the 10 μA/cm² data do intersect at approximately the same point. Values of 2.23×10^{-8} μA/cm² for i_o, and 0.539V for V^* are obtained by averaging the coordinates of the intersections of the 15 pairs of lines. The average i_o and V^* values from open-circuit analysis are shown in Fig. 9 for comparison purposes. The slopes of the lines in Fig. 9 give values for V_o as

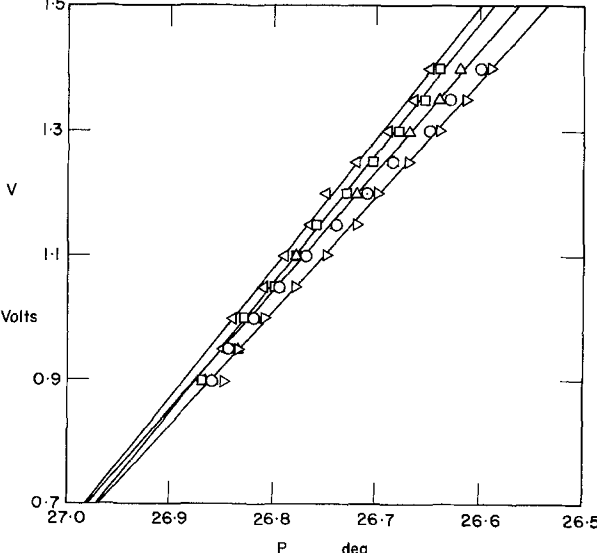

Fig. 8. Potential *vs.* polarizer null setting for galvanostatic charging at current densities from 5 to 80 μA/cm². Currrent density is identified by plotting symbol as in Fig. 5. The lines are fitted over the potential range from 1.05 to 1.40V. The line fitted to the 10 μA/cm² data is not shown.

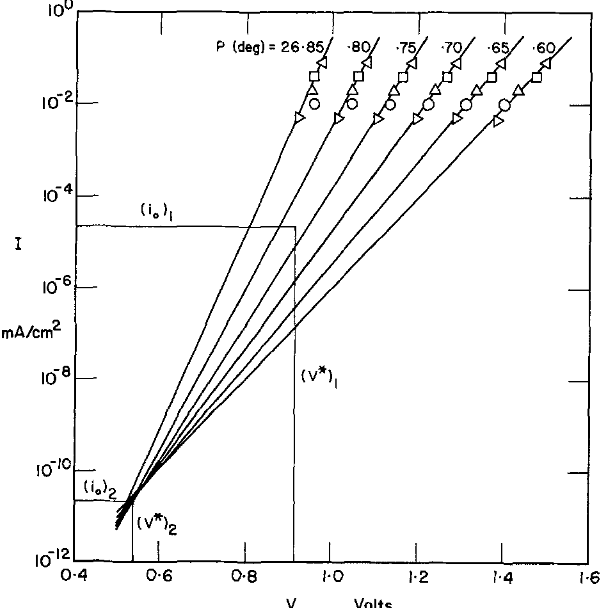

Fig. 9. Log current density *vs.* potential characteristics derived from the data in Fig. 8 for six polarizer null settings. The fitted lines exclude the 10 μA/cm² data. Values for the zero of overpotential, $(V^*)_2$, and the exchange current density, $(i_o)_2$, are given by the mean intersection of the fitted lines. The values from open-circuit analysis, $(V^*)_1$ and $(i_o)_1$, are shown for comparison.

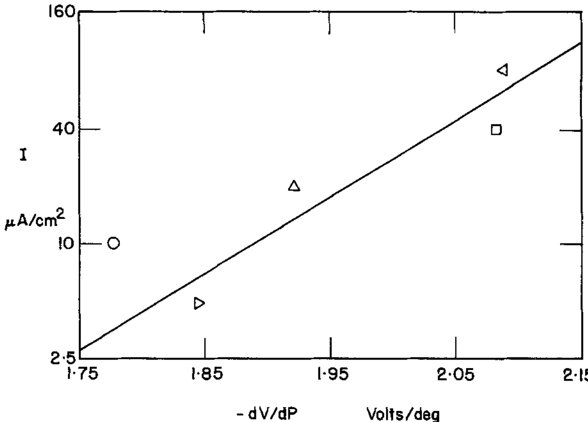

Fig. 10. Log current density vs. charging-curve slope from Fig. 8. The fitted line excludes the 10 $\mu A/cm^2$ data.

a function of P. These V_o values are plotted *vs.* P along with the open-circuit data in Fig. 6. A linear dependence of V_o and P is found with a P intercept at 27.06° and a slope of magnitude 0.095 V/degree.

The second technique for reducing the data in Fig. 8 is shown in Fig. 10. In this figure, log (i) is plotted *vs.* the slope of the V-P curve which is in turn proportional to the field in the film. The data show considerable scatter, but can be fitted reasonably well by a least squares line if the 10 $\mu A/cm^2$ data are ignored. If again i_o is assumed to have a common value for all of the points plotted, its value can be found by extrapolating the line back to the point where dV/dP equals zero. This extrapolation gives a value for i_o of 2.6×10^{-7} $\mu A/cm^2$. This is an order of magnitude greater than the value determined by the technique illustrated in Fig. 9, but it is still 5 orders of magnitude smaller than the open-circuit value for i_o.

Discussion

The dependence of the values of i_o, V_o, and V^* on the method of data analysis creates considerable confusion, and raises such questions as "how can this happen?" and "which method is correct?" The answers to these questions, although straightforward, require some discussion.

The basic reason for the differences between the parameter values may be stated simply: a three parameter equation such as Eq. [1] is inadequate to describe the process. In any method of data analysis, assumptions are made concerning what varies and what is constant under a particular set of experimental conditions. These assumptions, based on an idealized model of the process under study, are often unstated, and are tested only rarely in the experiment. The two different approaches we have taken to the data analysis, although both based on the same idealized field-limited model of the oxidation process, apply the assumptions of the model to different sets of experimental conditions. The analysis of open-circuit transients requires only that the parameters be well-behaved over individual open-circuit transients, whereas galvanostatic charging analysis requires that they be well-behaved over the entire set of charging experiments.

The question as to which method is correct has no answer. Both methods yield parameters which fit four out of the five sets of the data, so no distinction is possible on that basis. We prefer, for a number of reasons, to base analysis on the open-circuit transient data, but we do not wish to argue these reasons at this point. We propose to look instead at the models constructed from the results of the analyses to see which appears to be a more reasonable first-order description of the oxidation process.

Some aspects of this problem are not new. The case for applying open-circuit transient analysis to the anodic oxidation of tantalum has been argued in the literature (7) with little apparent impact. In many respects, the anodic oxidation of tantalum and platinum are remarkably similar. In both systems higher values for i_o and V_o are obtained from open-circuit transients than from galvanostatic charging curves. The differences are significant, involving factors of 10^6 in i_o for platinum, 10^8 in i_o for tantalum, and 2.5 in the relation between V_o and film thickness for both. As a consequence, models of the oxidation process which are based on open-circuit transient data involve significantly lower values of the activation energy and valence-jump distance product than do models based on galvanostatic charging data. Since the present state of the theory of anodic oxidation does not make it very clear what values for these parameters should be considered reasonable, there is little to be gained from further discussion of these aspects of the problem.

Although tantalum tends to be easier to study than platinum due to the much wider range of oxide film thickness available experimentally, the platinum system is far superior for a study of the zero points on the thickness and potential scales. Looking first at the zero of overpotential, we see a very significant difference between the open-circuit transient result, $V^* = 0.907V$, and the galvanostatic charging result, $V^* = 0.539V$. Quite different models of the oxidation process result from the two V^* values. As can be seen in Fig. 3, $V^* = 0.907V$ lies above the reduction plateau and below the linear oxidation region, whereas $V^* = 0.539V$ lies below both the linear oxidation region and the reduction plateau. If one regards oxidation and reduction as reverse direction of the same reaction, then one would expect the zero of overpotential for oxidation to lie between the linear oxidation region and the reduction plateau. If, on the other hand, one regards oxidation and reduction as two different reactions with different zeroes of overpotential then V^* for oxidation could lie below the reduction plateau. In this case, the over-all reaction would have to be treated in much the same way as corrosion processes are treated.

We regard oxidation and reduction as reverse directions of essentially the same reaction, and hence we consider the V^* value of 0.907V resulting from the open-circuit transient analysis to be reasonable, and the V^* value of 0.539V resulting from galvanostatic charging analysis to be unreasonable. The subjective nature of this judgment is underscored by the fact that Vetter and Schultze (2) found a V^* value of 0.530V in 0.5M H_2SO_4 from analysis of galvanostatic pulse measurements, and constructed what they apparently feel is a reasonable oxidation model using this value. We leave it to the reader to reach his own conclusion as to what is a reasonable value for V^*. We would like to emphasize that our galvanostatic charging analysis, although based on different measured quantities, gives parameter values which agree well with those of Vetter and Schultze. Our only point of difference concerns whether galvanostatic charging analysis gives results which lead to a reasonable model of the oxidation process.

Further information can be obtained by comparing the zero points on the thickness scale obtained from the two analyses. A high field model predicts proportionality between V_o and film thickness, hence the V_o data should reasonably be expected to extrapolate to zero at the point where the film thickness is zero. The extrapolation of the open-circuit V_o values in Fig. 6 intersects the axis 0.02° lower in P than the nominal bare surface point. The agreement with the model prediction is close, and there is some evidence that the 0.02° offset is associated with an optical change which precedes oxide film formation. The galvanostatic charging V_o values in Fig. 6 extrapolate to intersect the axis at a point which is 0.15° higher in P than the nominal bare surface point. We can find no way to reconcile an offset of this magnitude and in this direction with the proportionality between V_o and film thickness predicted by the model. Again we conclude that the open-

circuit analysis leads to a more reasonable model for the oxidation process than does the galvanostatic charging analysis.

At this point in the discussion, we doubt that many readers, even among those who find themselves agreeing with our view of what is reasonable, are particularly happy about basing oxidation models on parameters which can only be obtained from the analysis of open-circuit transients. Open-circuit transients are not widely used in oxidation studies, and it is not likely that they ever will be used as widely as galvanostatic charging measurements. The point we wish to make is not that there is anything wrong with galvanostatic charging measurements, but that unreasonable conclusions can result from charging analysis if the assumptions implicit in the usual treatment of the data are not valid.

We can illustrate this point by considering carefully the steps involved in determining V^* from the data in Fig. 8. In the standard analysis, V^* is the potential at which all of the V-P lines should intersect. For the data in the figure, this point is rather poorly defined because the lines have slopes which differ little from each other. The intersection of one pair of lines appears in the figure at 0.914V, and the other five intersections occur off-scale to the lower left at 0.653, 0.651, 0.485, 0.267, and -7.119V. This last value, from the intersection of the 40 and 80 $\mu A/cm^2$ data lines, makes any attempt to average the data not very meaningful, but the median range, 0.485-0.651V does bracket the 0.539V value determined in Fig. 9. The techniques illustrated in Fig. 9 and 10 both use an additional stage of least squares fitting to smooth the data and improve the estimate of V^*. This is a reasonable procedure provided the problem is purely the statistical one of dealing with random errors. Unfortunately, the narrow range in the variation of the slopes of the lines in Fig. 8 makes it possible for second-order corrections to Eq. [1] to invalidate the standard approach to charging analysis. One example of such a correction would be a variation of i_0 brought about by a change in the concentration of charge carriers at the activation barrier.

One way of determining the validity of charging analysis is to test its internal consistency. Comparison of the results of the analyses illustrated in Fig. 9 and 10 serves only as a test of the consistency of the statistical treatment of the second-order differences, not as a test of the basic assumptions of the analysis. We can test internal consistency by returning to the problem of determining V^* from the data in Fig. 8 and applying a method which does not involve second-order differences. For a field-controlled process, V^* is the potential coordinate at the point where the film thickness is zero on the lines in Fig. 8. If we take the film thickness to be zero at $P = 26.91°$, we obtain values for V^* of 0.807, 0.847, 0.833, 0.826, and 0.849V from the five sets of data in the figure. The average value obtained by this method, 0.833V, shows charging analysis to be internally inconsistent, and provides a further reason for our preference for open-circuit transients. If we take V^* to be 0.833V rather than 0.539V, we get closer agreement with the open-circuit value of 0.907V, but we are left with no obvious choice of a method to determine values for i_0 and V_0 from the charging data.

The discussion to this point has dealt mainly with determining the parameters i_0, V_0, and V^* whereas our earlier work (1) dealt mainly with assessing the evidence for field control of the process. One may well ask whether the data presented in this paper strengthen or weaken our earlier conclusion that the field in the film controls the anodic oxidation process above monolayer thickness. We view the data presented in Fig. 6 as strengthening the case for field control. The V_0 data show a proportionality to film thickness even in a region where the linear dependence of V_0 on V_1 no longer holds. From this we conclude that control of the process by the field in the film extends beyond the region of validity of elementary high field model in which i_0 is considered constant.

A New Capillary-Type Closed Viscometer for Molten Salt Research

N. van Os[1] and J. A. A. Ketelaar*

Laboratory for Electrochemistry, University of Amsterdam, Amsterdam, The Netherlands

ABSTRACT

A new capillary-type closed viscometer is described that can be used for many kinds of liquids. The viscometer is of simple design, incorporating a transparent measuring section and a suspended level enabling a flow of liquid under a constant mean hydrostatic head, the value of which is not affected by the total volume of liquid in the instrument. The viscometer is especially suitable for precise measurements with liquids having high vapor pressures, strongly corrosive properties, or showing chemical reactions with the atmosphere. As the viscometer has been used in molten salt research, a short description of the high temperature furnace, which involves an automatic opto-electronic device for recording the efflux time of the liquid, is also given. After a series of calibration experiments with molten KNO_3, the viscosity of molten $CdCl_2$ was determined in the temperature range 590°-800°C. Experimental results are given and compared with literature data.

Construction and Working Principle of the Viscometer

In the literature, several closed capillary viscometers have been described which are useful for highly reactive and/or corrosive liquids or for liquids having appreciable vapor pressures, *e.g.*, for many molten salts. In some of these designs the capillary is enclosed in an outer vessel into which a submerged discharge from the capillary takes place (1-3).

A property which these instruments have in common is the application of an overflow adjustment device to ensure a constant working volume. As Greenwood (1) has already pointed out, surface tension effects may cause buildup in such an overflow, the result being that the bottom level of the hydrostatic head fluctuates and cannot be kept constant. Disadvantages of the viscometer described in (3) are its mechanical vulnerability and the fact that it is difficult to operate.

A second class of closed viscometers is patterned after Ostwald's design (4-7). Measurements over a wide range of temperatures are not so easy with some of these instruments (4-6), because they are charged with a fixed volume of liquid; furthermore, rather complicated techniques have to be applied for returning the liquid in order to make repeated measurement possible.

The Ostwald viscometer described by Timidei, Ledermann, and Janz (7) incorporates an overflow which ensures automatic adjustment of the working volume and at the same time reduces possible surface tension effects. Although this instrument has been used successfully in molten salt research, the design is more fragile and bulky.

Capillary viscometers applying suspended levels have been known since Ubbelohde (8), but so far most of these viscometers have been of the "open type," having a direct connection to the atmosphere or some pressurizing system. One exception is the viscometer described recently by Kang *et al.* (9), an instrument of the closed capillary type utilizing a suspended level. It has been used successfully in the measurement of the viscosity of a high vapor pressure organic electrolyte. Its design and construction seem rather delicate though, because of the side tube that is used for pressure equalization and because of the incorporation of an electrode system in the viscometer's tiny upper bulb to record efflux times.

The viscometer to be described in this article ensures automatic adjustment of the working volume by the application of a suspended level type of outlet, thereby abandoning the overflow construction, while the containment of the viscometer within one cylindrical tube adds considerable mechanical strength to the design.

Figure 1 shows the new viscometer, fitted with the filling assembly which is used especially for salts and other liquefiable solids. For temperatures below 500°C, the construction material can be Pyrex; for higher temperatures quartz glass can be used.

[1] Present address: Koninklijke/Shell Laboratorium, Amsterdam, The Netherlands.

Key words: capillary, viscometer, molten salt, cadmium chloride.

The main feature of the viscometer is the outlet, which is of the suspended level type. Its function is to maintain at a constant value the bottom level of the hydrostatic head. The mean value of this head then also remains constant, this quantity is designated by 'h' in Fig. 1.

The viscometer is filled by introducing the salt sample into the filtration chamber through the fill tube. When the required quantity has been inserted, the fill tube and side tube are connected to a vacuum line, a thermocouple fitted for temperature measurement, and the apparatus lowered into an electrical furnace. The temperature of the furnace is raised slowly until all the solid has melted, the liquid salt being allowed to drip slowly through the frit into the viscometer. When the salt sample has passed into the viscometer, the apparatus is removed from the furnace; local heating is applied to the constriction enabling the filling assembly to be broken off and the viscometer to be sealed. The viscometer is now in its final form.

After sealing, the viscometer can be allowed to cool to room temperature or it can be transferred directly to a furnace suitable for the viscometry experiments.

In order to take measurements during the experiments, the salt must flow from the upper end of the viscometer into the spherical reservoir and down through the capillary tube to the outlet. When the viscometer reaches the required temperature in the test furnace it must be turned through 180° in the direction indicated in Fig. 1 to enable the upper part to fill with liquid salt through the slot or hole in the rim, 4 in Fig. 1, of the funnel sealed to the cylinder. When the salt has drained into this portion, the viscometer is quickly returned to its original position, whereupon the liquid will fill the funnel and reservoir and then flow through the capillary to accumulate in the bottom. Given a proper volume of liquid, little or none will spill through the slot in the funnel.

Working Principle of the Furnace and Detection Equipment

The furnace that has been used in connection with the viscometer has two main features: first of all it provides a large hot zone at a uniform temperature; second, the furnace incorporates a means of recording the liquid flow time optically between two marked points.

One of the standard techniques in molten salt capillary viscometry is the use of platinum or platinum alloy wire electrodes, located at different levels in the reservoir of the viscometer, to measure the flow time. However, since this technique is restricted to conducting liquids, we have devised a new technique for molten salts for the present design, *i.e.*, an opto-electronic system.

The furnace, (shown in Fig. 2 with the viscometer in position), is an electric resistance furnace utilizing three Kanthal A resistors wound onto sillimanite tubes. It is, to a great extent, a descendant of that described by Motzfeldt (10).

Insulation is provided by firebricks and fiberfax, with stainless steel radiation shields in the upper end of the furnace and a plug of firebrick in the lower end. In addition, due to the fact that parts of the timing mechanism built into the furnace require cooling, a water-filled cooling system is provided. This cooling system fulfills a secondary function in that it enables heat to be "sinked" to a well-defined level, resulting in better furnace temperature regulation.

A silver tube is mounted within the working chamber in order to smooth minor temperature fluctuations, this tube also acting as a support for positioning the viscometer.

Viscometer temperature measurement is achieved using three Chromel-Alumel thermocouples, mounted in the positions indicated in Fig. 3, (this figure giving also details of the external equipment used in connection with the furnace and the viscometer). The middle thermocouple serves a dual purpose in that it also acts as a sensor for the "Eurotherm" temperature controller.

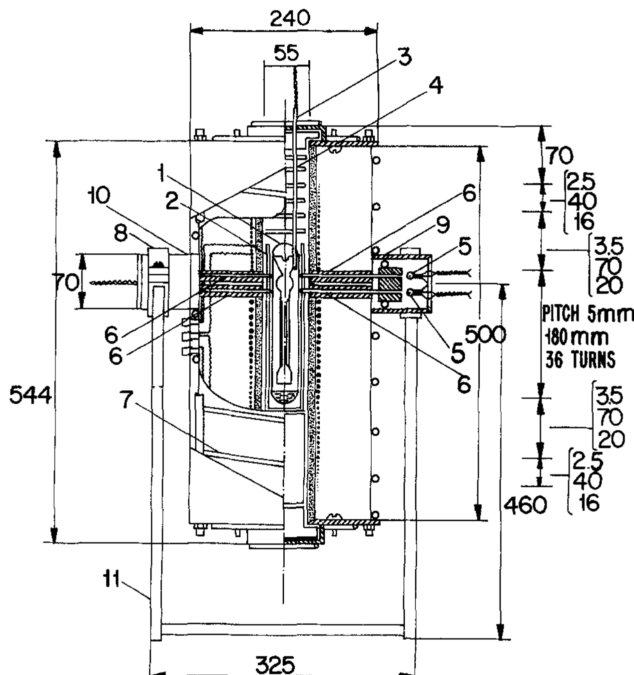

Fig. 2. Furnace for viscosity measurements (dimensions in mm). 1, Viscometer; 2, silver tube; 3, thermocouple; 4, radiation shielding; 5, timing lamps; 6, quartz rod light guides; 7, water-filled cooling system; 8, support bearing; 9, lamp housing; 10, housing for photodiodes and detector electronics; 11, furnace stand.

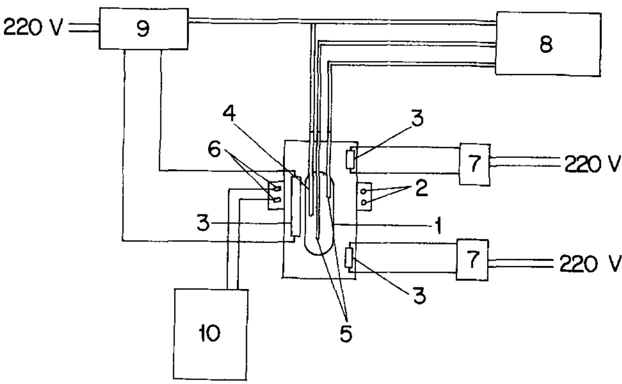

Fig. 3. Auxiliary equipment for the closed viscometer system. 1, Viscometer; 2, lamp; 3, Kanthal A resistor wound on sillimanite tube; 4, sensor thermocouple; 5, thermocouple; 6, photodiode detector; 7, Variac; 8, potentiometer; 9, Eurotherm temperature regulator; 10, millivolt recorder.

To provide for the necessary rotation of the viscometer, two brass tubes are mounted on opposite sides of the furnace coincident with the axis of rotation indicated in Fig. 1. The tubes are supported in bearings on a furnace stand, enabling the furnace to be rotated about a horizontal axis.

These brass tubes also serve as housings for the timing mechanism and are water-cooled. One of the brass tubes contains two lamps, each set equidistant above and below the axis of rotation (the center of the viscometer reservoir). The opposite tube is the housing for the detector electronics and two photodiodes, the diodes being in alignment with the lamps.

Two pairs of parallel quartz rods are set into the body of the furnace, one set between the photodiodes and the viscometer, the other between the viscometer and the lamps. These rods act as a light guide for each lamp and its opposing diode.

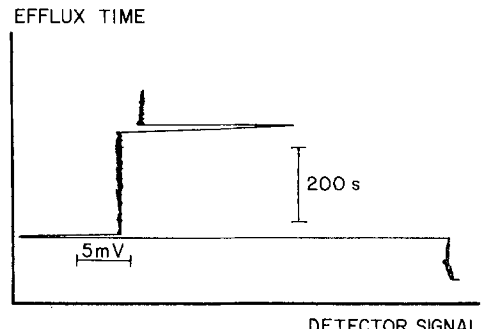

Fig. 4. Typical example of the level detector output. Potential peaks correspond to the signals emitted at the passage of liquid between the calibration levels.

Thus the viscometer is provided with an opto-electronic level detection system comprising: two lamps, two photodiodes, two sets of quartz rod light guides, and a timing system.

Because the furnace is itself a red light source and because of 50 Hz (stray) fields, the lamps are switched at 25 Hz and a synchronous detector is used. The detector is sensitive to the chopped light only and is not affected by radiation from the furnace or by the 50 Hz main supply. The signal from the detector is recorded on a millivolt recorder and shows two distinct peaks corresponding to the passage of liquid at the two levels, see Fig. 4. The efflux time can be easily measured with an accurate stopwatch, or alternatively the peak signal may be used to trigger an electronic counter.[2] Similar timing circuits triggered by photoelectric sensors have been described by Eicher and Zwolinski (11) and by Gramain and Libeyere (12).

Sources of Error

The viscosity equation that is normally used in capillary viscometry is written as

$$\frac{\eta}{\rho} = \nu = Ct - \frac{B}{t} \quad [1]$$

in which C and B are the viscometer's constants, η is dynamic viscosity, ρ is density, ν is kinematic viscosity, and t is the efflux time. The quantity B/t of Eq. [1] is called the kinetic energy correction and has been discussed in detail by Wellman *et al.* (13). These authors, as well as many others (1, 7, 8, 14-16), have noted and critically reviewed other sources of error in capillary viscometry and it is considered sufficient to discuss one remaining source of error especially important with regard to high temperature viscometry, *i.e.*, temperature inhomogeneity.

Temperature profiles recorded with sliding thermocouples indicated that temperature inhomogeneities within the working chamber of the high temperature furnace could well be kept within ± 1°K. Since for the molten salts investigated the temperature coefficient of the dynamic viscosity is ½%/degree or less, we can conclude that the viscosities of these salts can be measured with an accuracy better than 1% as far as the temperature inhomogeneity is concerned. The reproducibility of the viscosity measurements has turned out to be of the order of 1%.

[2] Details of the electronic circuitry may be obtained through the first author.

Table I. Efflux times for molten KNO_3

T_1 = 368°C Test No.	Efflux time (sec)	T_2 = 469°C Test No.	Efflux time (sec)
1	528.6	1	349.1
2	529.1	2	349.9
3	528.7	3	350.6
4	531.0	4	351.1
5	529.0	5	352.1
6	529.1	6	349.9
Mean value	t_1 = 529.3 sec, ν_1 = 1.34 cst	Mean value	t_2 = 350.5 sec, ν_2 = 0.87 cst

Calibration Experiments

The viscometer constants of Eq. [1] have been determined with molten KNO_3 as the calibration liquid. A simple technique has been used to purify this salt (14) which is not strongly hydrated, similar techniques have been described elsewhere (7, 17, 18). Absolute values for the dynamic viscosity of molten KNO_3 have been known since Dantuma (19), whose measurements are considered to be as good as any latterly published results.

Efflux times for molten KNO_3 were determined in our viscometer in the range 350°-450°C. The constants C and B in Eq. [1] were calculated using ν_1 and ν_2, the kinematic viscosities of molten KNO_3 at temperatures T_1 and T_2, respectively, and the equations

$$C = \frac{\nu_2 t_2 - \nu_1 t_1}{t_2^2 - t_1^2}$$
$$B = \frac{t_1 t_2}{t_2^2 - t_1^2}(\nu_2 t_1 - \nu_1 t_2) \quad [2]$$

Table I shows the efflux times at two typical temperatures for molten KNO_3. The values of ν_1 and ν_2 were obtained from the literature (17). According to Eq. [2] the value of C is $2.57 \cdot 10^{-3}$ cst/sec and B is 10 cst · sec.

Viscosity of Molten $CdCl_2$

Literature concerning the viscosity of liquid $CdCl_2$ is available. Karpachev's results were the first to be reported (20), while those of Bloom *et al.* are more recent (21).

Liquid $CdCl_2$ is an interesting compound to work with in a closed viscometer because of its high vapor pressure. It also requires attention during the initial stages of the experiment, especially in drying and handling, since hydrolysis may occur. The procedure that we followed for the purification of $CdCl_2$ was derived from that described by Hill *et al.* (22) and has been described elsewhere in detail (14).

In Table II the experimental efflux times of liquid $CdCl_2$ are given as a function of temperature. With the aid of the constants C and B determined previously, the viscosity of liquid $CdCl_2$ was calculated. Density values for molten $CdCl_2$ to convert from kinematic viscosity to dynamic viscosity were obtained from our own measurements (14), summarized by the equation

Table II. Viscosity of molten $CdCl_2$ as a function of temperature

Temperature, T (°C)	Efflux time, t (sec)*	Kinematic viscosity, ν (cst)	Dynamic viscosity, η (cp)	Dynamic viscosity (21), η (cp)	Dynamic viscosity (20), η (cp)
594 ± 1.5	273.4 ± 0.6	0.67 ± 0.01	2.26 ± 0.03	2.30 ± 0.03	—
645 ± 1	242.3 ± 0.9	0.58 ± 0.01	1.93 ± 0.03	2.00 ± 0.03	2.14
694 ± 1.5	217.8 ± 0.2	0.51 ± 0.01	1.69 ± 0.03	1.80 ± 0.03	1.90
743 ± 1.5	198.8 ± 0.3	0.46 ± 0.01	1.49 ± 0.03	—	1.72
797 ± 1.5	180.0 ± 0.5	0.41 ± 0.01	1.32 ± 0.02	—	—

* Efflux times are mean values determined from at least five separate measurements.

$$\rho = 4.235 - 9.45 \times 10^{-4} T \quad [3]$$

with ρ the density in g/cm^3 and T the temperature in °K. Our values of the dynamic viscosity of liquid $CdCl_2$ are also given in Table II together with literature data. Figure 5 is a graph showing the dynamic viscosity of molten $CdCl_2$ against temperature, Fig. 6 shows a graph of ln η against $1/T$. The temperature dependence can be expressed as the following exponential function $1/T$

$$\eta = 0.133 \times \exp(4880/RT) \quad [4]$$

(η in cp, R = 1.987 cal K^{-1} mol^{-1}) with a correlation coefficient of 0.999.

The post exponential factor found by Bloom *et al.* (21) was equal to 4.0 kcal/mole, while that found by Karpachev was equal to 4.1 kcal/mole.

Discussion

With the closed capillary viscometer described in this article, it is possible to measure accurately the viscosity of many liquids but especially those having properties which make them less suitable for other types of viscometer. The advantages of this instrument can be summarized as follows:

1. The hydrostatic head adjusts itself automatically by virtue of the suspended level and is independent of the total amount of liquid.

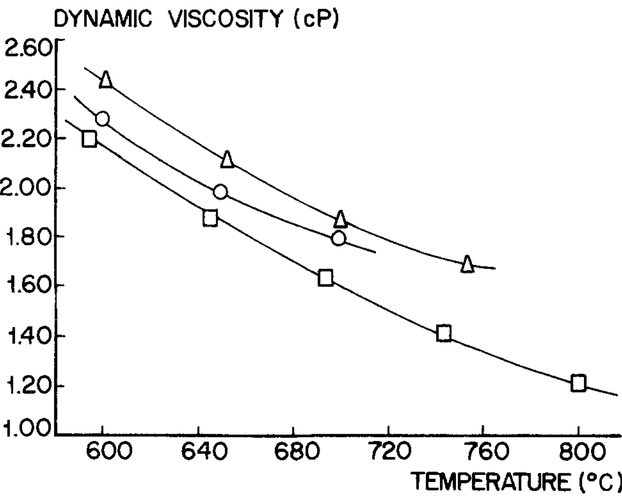

Fig. 5. Dynamic viscosity-temperature curves for liquid $CdCl_2$, according to: (△) Karpachev and Stromberg (20); (○) Bloom, Harrap, and Heymann (21); (□) the authors.

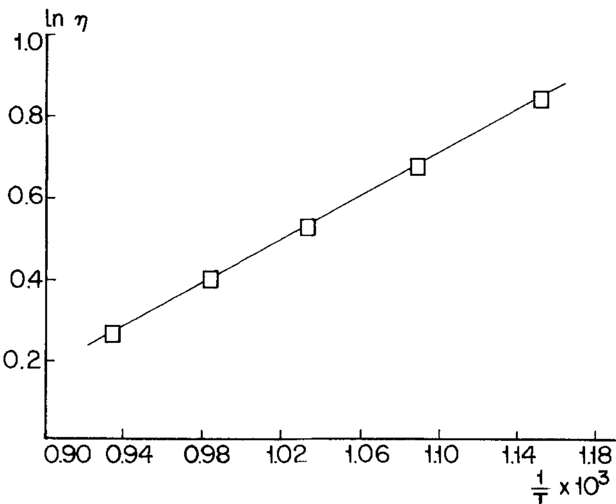

Fig. 6. Graph of ln η (ln of dynamic viscosity) of liquid $CdCl_2$ against the reciprocal of [T (temperature) $\times$ 10^{-3}], where T is in °K.

2. Because surface tension in the measuring bulb and the suspended level are of an opposing nature they will cancel each other to a great extent.
3. The change of liquid volume with temperature has no influence.
4. Repeated measurements are readily obtained.
5. When the viscometer is slowly rotated during cooling no fracturing occurs on freezing.
6. The simple and robust construction is very attractive for high temperature work.
7. The viscometer has a very good reproducibility, as can be seen from the results in Table I.

As to the present values of the dynamic viscosity of molten $CdCl_2$, it is the authors' view that the viscometry of low viscosity liquids (1-10 cp) at high temperatures is a very difficult experimental undertaking and it is not uncommon to find that single salt viscosities differ by more than 50% (13), especially with regard to data obtained by earlier authors.

In an attempt to obtain more reliable viscosity data, Øye and co-workers (13, 23) have recently redetermined the viscosities of the molten alkali chlorides, using the torsional pendulum method. They predicted the use of the capillary tube method on the grounds that etching of the capillary material could result in a slight alteration to the capillary diameter and that difficulties could be expected in the maintenance of a large zone of uniform temperature in the furnace and in liquid flow measurement.

However, it is our opinion that etching of the capillary material takes place at high temperatures only in the presence of water, since no visible etching was observed in these experiments using carefully dehydrated salts. Moreover, a redetermination of the constants C and B of Eq. [1] after the $CdCl_2$ experiment showed them to be equal to the formerly determined values, with an uncertainty of 1.5%. In addition, the other two objections against high temperature capillary viscometry have also been successfully dealt with in the foregoing paragraphs.

Apart from these experimental considerations, the present authors are also of the opinion that, from a methodological point of view, the capillary tube method should not be precluded. In the torsional pendulum method, *i.e.*, an absolute method, the extreme attention that must be paid to the accurate determination of the radius of the oscillating sphere and to first-class machining of the assembly has been stressed (23). However, in a relative method such as the capillary tube method, we have the advantage that, after an accurate calibration, all measurements can be done in a relatively short time without the need to redetermine the critical dimensions of the apparatus.

Finally, our choice of the capillary tube method has been justified by our measurements of the dynamic viscosity of molten KCl and molten CsCl. The agreement of our data (14) with those obtained recently by Brockner *et al.* [(13) including our data] and by Zuca and Borcan (24) is considered to be good although these data are different from those reported earlier by Murgulescu and Zuca (25) which were also obtained by the oscillating sphere method.

With regard to the present data on molten $CdCl_2$, it is interesting to note that the values of Bloom *et al.* (21) have also been obtained with a capillary viscometer. According to these authors, no kinetic energy correction B/t (see Eq. [1]) is necessary as capillaries with trumpet-shaped ends have been used. However, regardless of the shape of the end sections of the capillary, the kinetic energy correction should be applied, as has been demonstrated by Wellman *et al.* (18), and thus the values of Bloom *et al.* (21) should be somewhat lower and hence come closer to our values (see Fig. 5). It is also clear from Fig. 5 that the difference between the two sets of data increases with increasing temperature. This is to be expected if the B/t term is neglected, since with increasing temperature the efflux

times decreases and the correction B/t will increase. It is difficult to say whether these discrepancies can be attributed to the kinetic energy correction only but certainly the trend is explained.

The values of Karpachev and Stromberg (20) have been obtained with an oscillating sphere viscometer and while most earlier viscosity data are considerably higher than corresponding data reported recently, a tentative explanation of this phenomenon has been forwarded by Øye and co-workers (13). The latter remark that most sources of error, for instance melt impurities, will result in higher viscosity values. In addition, for oscillation methods, lateral movement of the pendulum will also give rise to a viscosity higher than the true value. A combination of these effects may have caused the high viscosity values reported by Karpachev and Stromberg (20).

ABSTRACT

A mathematical model which describes the operation of porous battery electrodes has been developed. It includes short time transient behavior of electrolyte concentration, porosity, current distribution, reaction rate, and detailed solution diffusion descriptions of a sparingly soluble reactant. Calculations were made for constant current (50 and 25 mA/cm^2) charging and discharging of Ag/AgCl electrodes. Results of calculations indicate that the concentration of the electrolyte, KCl, inside the porous electrode plays an important role in the performance of the electrode. During charging, the electrolyte concentration falls in the depth of the electrode, thereby decreasing the solution electrical conductivity. Reaction penetration depth on charging is very shallow, less than 0.3 mm, for the current densities investigated. On discharging, the electrolyte concentration in the depth of the electrode increases. Consequently, the electrical conductivity of the solution as well as the solubility of AgCl increases. A high reaction rate in the depth of the electrode is possible even at high current discharge. Charge utilization over 90% is predicted if the charge is stored uniformly by employing a slow charging rate.

Porous electrodes have larger reactive surface to volume ratios than do plane electrodes. Consequently their use is common in primary and secondary batteries as well as continuous flow galvanic cells. Many mathematical models have been proposed to explain the operation of porous electrodes. Progress in the mathematical modeling of flooded porous electrodes prior to 1974 has been reviewed by de Levie (1) and by Newman and Tiedemann (2). A recent mathematical model for the negative plate of the lead-acid battery was reported by Micka and Roušar (3). Like their previous model for the lead dioxide plate (4), reversible electrode kinetics was assumed.

The mathematical model proposed here describes transient behavior of flooded porous electrodes with sparingly soluble reactants. The present model is an extension and refinement of a previously proposed model (5).

In the previous model, a pseudo steady-state approximation was used to calculate time-dependent results. The time-dependent concentration term $\partial c_e/\partial t$ in the conservation equation was eliminated. The solution from the steady-state ordinary differential equations was used to predict the electrode conditions for one time increment later. A new steady-state solution was then found for the new time step and so on.

In the present model, the partial differential equations were solved including all $\partial/\partial t$ terms. An accurate account of the electrolyte concentration variation with time is important since the electrolyte concentration inside the electrode greatly affects the behavior of a porous electrode. Frequently, $\partial c_e/\partial t$ type terms are important in predicting concentration distributions under conditions similar to practical operating situations. Simonsson (6) solved his mathematical model for the porous lead dioxide electrode including the $\partial c_e/\partial t$ term. The results of his model calculations showed that the discharge capacity of the electrode is caused by acid depletion.

A macroscopic treatment is used in the present model, replacing the previous single pore geometry (5). This means that averaging is performed over a volume element in the porous electrode. The electrode is treated as a superposition of two continua, one of the electrode matrix phase and one of the solution phase. Although this change is rather minor mathematically, it allows a more realistic description of the tortuosity effect.

Application of the present model is restricted to the class of porous electrodes whose transport of reactants involves a solution phase diffusion step. Specifically, the present model can be applied to Ag/AgCl porous electrodes such as those used in seawater batteries. The AgCl is the sparingly soluble reactant. Previous studies indicate that the transfer between Ag and AgCl involves solution diffusion of $AgCl_{n+1}^{-n}$, where $n = 0$, 1, 2, 3 (7 and 8). A mass transfer coefficient, k_m^*, can be used to describe the diffusion of $AgCl_{n+1}^{-n}$. As an improvement to the previous model, the mass transfer coefficient used in the present model is in a physically more realistic and mathematically simpler form. In addition, the present model includes the rate of nucleation of AgCl during charging of the electrode.

The formulation of the coverage of the metal surface by salt crystallites in the present model is specifically for the Ag/AgCl system. Based on experimental observations (8, 9), two modes of AgCl growth are postulated. The first mode involves the forming of AgCl nuclei and the growing together of AgCl mounds. The second mode involves the thickening of a "porous" AgCl film.

For a given set of initial conditions such as electrolyte concentration, porosity, and the state of charge, the mathematical model calculations will predict the current density i_2, the potential ϕ_2, the electrolyte concentration c_e, the concentration of sparingly soluble reactant c_R, the porosity ϵ, the local reaction rate j, and the bulk solution velocity $v^\square$ as functions of time and position with respect to the front face of the electrode.

Description of the Model

A one dimensional approach is used in which variation of properties occur only along the axis perpendicular to the face of the electrode. Geometric features of the model are shown in Fig. 1. The front face of the

Key words: current distribution, concentration distribution, battery, mathematical model.

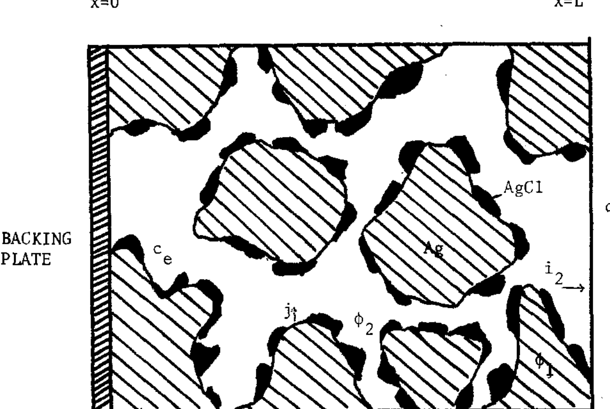

Fig. 1. Macroscopic model of porous electrodes

electrode is at $x = L$. The current collecting plate is at $x = 0$. The current density i_2 is a superficial current density in the solution phase. At $x = L$, i_2 is equal to the total applied current density I. Inside the porous electrode, the following relationship applies

$$i_1 + i_2 = I \quad [1]$$

where i_1 is the superficial current density in the solid phase. At the backing plate, i_2 is zero. A positive sign is used for anodic currents and a negative sign for cathodic currents. The potential in the metal phase is assumed to be at ground potential (that is, $\phi_1 = 0$) which implies that we have neglected the metal phase ohmic resistance relative to the solution phase ohmic resistance. The potential in the solution phase, ϕ_2, is the potential that one would measure with respect to the working electrode if a reference electrode of the same kind as the porous electrode is placed in the solution phase within the pores of the porous electrode.

The stoichiometric reaction representing the chemical process within the porous electrode is

$$\sum_i s_i A_i^{z_i} = ne^- \quad [2]$$

where s_i are stoichiometric coefficients and z_i are the charges on species A_i. The number of electrons transferred for the reaction as written is n. For the Ag/AgCl electrode, the reaction is written as

$$Ag + Cl^- - AgCl = e^-$$

A modified Ohm's law applied to the solution phase in the porous electrode is

$$i_2 = -\kappa\epsilon^{(1+t)}\frac{d\phi_2}{dx} - \frac{\kappa\epsilon^{(1+t)}\nu RT}{\mathbf{F}c_o\overline{V}_o}\left[1 + \frac{d\ln\gamma_\pm}{d\ln m_e}\right]\left[\frac{s_+}{n\nu_+} + \frac{t_+^o}{z_+\nu_+} - \frac{s_oc_e}{nc_o}\right]\frac{1}{c_e}\frac{dc_e}{dx} \quad [3]$$

Here ϕ_2 is the potential in the solution phase; κ is the electrolyte conductivity; t is the tortuosity factor; ϵ is the porosity; c_o is the solvent concentration; $\overline{V}_o$ is the solvent partial molar volume; ν is the number of ions per electrolyte molecule; ν_+ is the number of cations; $\gamma_\pm$ is the mean molal activity coefficient; m_e is the molality of the electrolyte; t_+^o is the transference number of the cation referred to solvent velocity; and s_+ and s_o are stoichiometric coefficients of the cation and solvent, respectively, according to reaction [2]. The boundary conditions for the superficial current density in the solution phase, i_2, and the concentration of the electrolyte, c_e are as follows

$$\text{at } x = 0, \quad i_2 = 0, \quad \frac{dc_e}{dx} = 0 \quad [4]$$

$$\text{at } x = L, \quad i_2 = I \quad \text{and} \quad c_e = c_e^o \quad [5]$$

where the superscript o refers to conditions outside the electrode.

The redox kinetic expression that relates the local transfer current density, j, to the surface overpotential between the solid matrix and the solution, $(\phi_1 - \phi_2)$, can be written as

$$j = \theta i_o\left[\exp(-\alpha_a\mathbf{F}\phi_2/RT) - \exp(\alpha_c\mathbf{F}\phi_2/RT)\right] \quad [6]$$

where ϕ_1 is taken to be zero as previously stated. The exchange current density depends on the concentration of the sparingly soluble reactant and the electrolyte concentration in the following way

$$i_o = i_o^o\left(\frac{c_R}{c_R^*}\right)^\gamma\left(\frac{c_e}{c_e^o}\right)^\zeta \quad [7]$$

where i_o^o is concentration independent. Here c_R is the concentration of complexed ions at the metal surface and c_R^* is the equilibrium concentration of complexed ions at electrolyte concentration c_e^o. The order of dependence of i_o on c_R and c_e are γ and ζ, respectively.

The conservation of charge requires that

$$aj = \frac{di_2}{dx} \quad [8]$$

where a is the electrode surface area per unit volume of the electrode. Equation [8] relates local transfer current density to superficial current density in the solution phase.

Due to the differences in partial molar volumes of the salt and the metal, the porosity of the electrode will change with time according to the local reaction rate

$$\frac{\partial\epsilon}{\partial t} = \left(\frac{1}{n\mathbf{F}}\sum_{\substack{\text{solid}\\\text{species}}}{}_i\overline{V}_is_i\right)\frac{\partial i_2}{\partial x} \quad [9]$$

As the relative volume of liquid to solid in the pores changes, a convective flow of liquid into or out of the electrode results. This bulk flow motion can be described by an over-all continuity equation

$$\frac{\partial\epsilon}{\partial t} + \frac{\partial v^\square}{\partial x} = -\frac{1}{\mathbf{F}}\left(\frac{\overline{V}_et_-^o}{z_-\nu_-} + \frac{\overline{V}_es_-}{n\nu} + \frac{\overline{V}_os_o}{n}\right)\frac{\partial i_2}{\partial x} \quad [10]$$

Here $v^\square$ is the superficial volume average velocity.

The concentration variation of the electrolyte in the pores is expressed by the electrolyte continuity equation

$$\epsilon\frac{\partial c_e}{\partial t} + v^\square\frac{\partial c_e}{\partial x} = \frac{\partial}{\partial x}\left[D\epsilon^{(1+t)}\frac{\partial c_e}{\partial x}\right] - \left[\frac{c_o\overline{V}_ot_+^o}{z_+\nu_+} + \frac{c_o\overline{V}_os_+}{n\nu_+} - \frac{s_oc_e\overline{V}_o}{n}\right]\frac{1}{\mathbf{F}}\frac{\partial i_2}{\partial x} \quad [11]$$

where D is the diffusion coefficient of the electrolyte.

Finally, the reaction rate is determined by the diffusion of complexed ions formed through the reaction

$$MX + nX^- = MX_{n+1}^{-n} \quad [12]$$

By defining an over-all mass transfer coefficient k_m^*, the reaction rate can be written as

$$j = \frac{-n\mathbf{F}}{s_R}k_m^*c_R^{eq}(C_1 - 1) \quad [13]$$

where $C_1 = c_R/c_R^{eq}$ and where the equilibrium concentration of the complexed ion, c_R^{eq} is related to the electrolyte concentration, c_e, through the equilibrium constant K associated with reaction [12] hereafter referred to as a dissolution constant.

The over-all mass transfer coefficient, k_m^* is dependent on the amount of metal surface area available for the reaction to occur. It is related to θ by

$$k_m^* = k_m^o(\theta)^{1/2}(1-\theta)^{1/2} + k_{nuclei}\theta \quad [14]$$

Here, $k_m{}^o$ is a function of the diffusion coefficient and the effective diffusion path of $MX_{n+1}{}^{-n}$. The mass transfer coefficient for nucleation, k_{nuclei} represents the formation of salt nuclei in addition to the diffusion of $MX_{n+1}{}^{-n}$ from metal surface to the salt surface during charging. It is related to the level of supersaturation of the sparingly soluble salt as well as the surface condition of the metal. During discharge k_{nuclei} is zero.

The surface coverage of metal by the salt depends on the state of charge. For the Ag/AgCl electrode (or possibly other similar electrodes), the charge dependence of the surface coverage can be divided into two regions during anodic operation, charging for this case. The first region involves the nucleation of AgCl at various sites and the spreading of adsorbed AgCl from the nuclei. This region of AgCl growth is represented by

$$\theta_s = (1 - Q/Q^*)^S \qquad [15]$$

where Q is the charge stored and Q^* is a charge parameter. The value of the shape factor, S, will depend on the morphology of the sparingly soluble salt crystallites. A large S indicates flat plate-type crystals while a small S indicates needle-type crystals. In the second region, patches of adsorbed AgCl molecules (crystals) have grown together to form a porous film. As the film thickens, micropores incorporated in the AgCl film gradually diminish. The function used to describe the fraction of the metal exposed for the second region is

$$\theta_p = (P)^{Q/Q^*} \qquad [16]$$

The value of the porosity factor, P, depends on the density (porosity) of the salt film. A small P indicates a dense salt film. It is expected that the value of P will fall between 0 and 0.3. The charge parameter, Q^*, represents the state of charge when all salt patches have united to form a porous film. The charge Q^* has a fractional value of the maximum charge that can be stored in the pores

$$Q^* = \lambda Q_{max} \qquad [17]$$

A value of 0.5 for λ is used in the present model. The maximum amount of charge that can be stored is limited by complete filling of pores by the salt. It can be expressed as

$$Q_{max} = Q_o - n\mathbf{F}\frac{\epsilon_o}{\sum_{\substack{\text{solid}\\ \text{species}}} s_i\overline{V}_i} \qquad [18]$$

Here Q_o and ϵ_o are initial charge and initial porosity, respectively. It is also possible, but not likely for practical electrodes, that the amount of metal available for conversion to salt is limiting. In this case

$$Q_{max} = Q_o + \frac{n\mathbf{F}}{\overline{V}_M s_M}\left(1.0 - \epsilon_o + \frac{Q_o\overline{V}_{MX}s_{MX}}{n\mathbf{F}}\right) \qquad [19]$$

Solutions to the mathematical model were obtained numerically. The equations described were combined and reduced to one second-order and two first-order partial differential equations. For the Ag/AgCl electrode, the three equations are

$$i_2 = -\kappa\epsilon^{(1+t)}\frac{d\phi_2}{dx} - \frac{2\kappa\epsilon^{(1+t)}RT}{\mathbf{F}c_o\overline{V}_o}\left[1 + \frac{d\ln\gamma_\pm}{d\ln m_e}\right]\left[\frac{t_+{}^o}{c_e}\right]\frac{dc_e}{dx} \qquad [20]$$

$$\frac{di_2}{dx} = a\theta i_o{}^o\left[\frac{c_e}{c_o}\right]^{\gamma+\zeta}\left\{1 - \frac{\dfrac{di_2}{dx}}{a\mathbf{F}k_m{}^*Kc_e}\right\}^{\gamma}\left[\exp\left(\frac{-\alpha_a\mathbf{F}\phi_2}{RT}\right) - \left(\exp\frac{\alpha_c\mathbf{F}\phi_2}{RT}\right)\right] \qquad [21]$$

and

$$\epsilon\frac{\partial c_e}{\partial t} + \left[\frac{-\overline{V}_e t_o{}^+ - \overline{V}_M + \overline{V}_{MX}}{\mathbf{F}}\right] i_2\frac{\partial c_e}{\partial x} = \frac{\partial}{\partial x}\left[D\epsilon^{(1+t)}\frac{\partial c_e}{\partial x}\right] + t_o{}^+\left[\frac{1 - c_e\overline{V}_e}{\mathbf{F}}\right]\frac{\partial i_2}{\partial x} \qquad [22]$$

The three equations in their linearized form were then solved using the numerical technique of Newman [10].

Results of Calculations

Results of several calculations applied to porous Ag/AgCl electrodes are presented here. The electrode was assumed to be 1 mm thick (that is, from $x = 0$ to $x = L$). The electrolyte was 1*N* KCl. The exchange current density, $i_o{}^o$, was assumed to be 10^{-4} A/cm^2. A value of 1.735×10^{-5} as reported by Giles [7] was used for the dissolution constant K. The values of $k_m{}^o$ and k_{nuclei} were chosen to be 0.3 and 0.1 cm/sec, respectively, based on experimental data of Katan *et al.* (8, 9). Kinetic parameters α_a and α_c were given the same value of 0.5. A value of 2/3 was used for the shape factor, S, based on observed surface morphology (9). The value of P was chosen to be 0.184 so that the change of AgCl growth mode would occur at $Q/Q^* = 0.9$. Other concentration dependent physical properties were calculated based on previously published values (11, 12).

Charging behavior.—Calculations were made for the charging of a porous electrode initially composed of pure silver only. The initial porosity was assumed to be 0.571 and the specific surface area was assumed to be 4700 cm^2/cm^3. Electrode behavior under constant charging current densities of 50 and 25 mA/cm^2 were examined. The electrode overpotentials as functions of the total amount of charge passed are shown in Fig. 2. By picking a cutoff potential of —0.19V, one can see that the 25 mA/cm^2 charging allows the electrode to store approximately 71% more charge.

Local transfer current density distributions inside the porous electrode are shown in Fig. 3. At the beginning stage of charging (3 C/cm^2), the reaction distributions are mainly controlled by the ohmic resistance of the electrolyte in the pores with a higher reaction rate at the front of the electrode. At a later stage of charging, the electrolyte concentration becomes lower in the back (see Fig. 4), causing even higher reaction rate at the front of the electrode (see curve for 50 mA/cm^2 charged to 24 C/cm^2 in Fig. 3). The front of the electrode may reach a condition where most of its reacting surfaces are covered by AgCl. As a result, a maximum in the local transfer current density distribution may occur inside the electrode as demonstrated by the 25 mA/cm^2 charging at the stage of 54 C/cm^2 (see Fig. 3). At the end of charging, a porous AgCl film covers the surfaces of the front portion of the electrode and the electrolyte concentration is very low in ¾ of the elec-

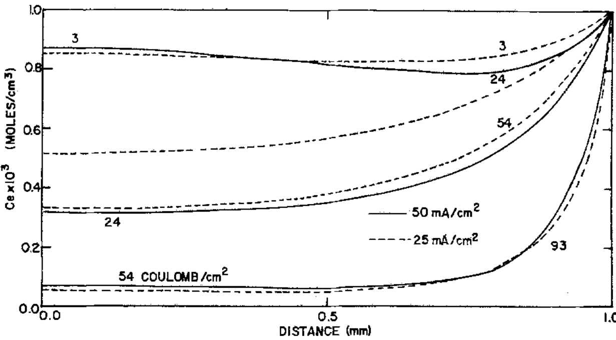

Fig. 4. Electrolyte concentration distributions at various stages of charge. Charging currents: ———, 50 mA/cm²; — — —, 25 mA/cm².

trode (see Fig. 4). These conditions force the reaction to concentrate at the very front of the electrode as shown by 50 mA/cm² charging at 54 C/cm² and 25 mA/cm² charging at 93 C/cm² (see Fig. 3).

A cross-examination of Fig. 2 and 4 shows that the concentration distributions are about the same when the electrode overpotentials are the same for the high current and low current charging. This indicates that the electrolyte concentration inside the electrode may be the controlling factor in the behavior of Ag/AgCl porous electrodes.

The charge distributions are shown in Fig. 5. For the high current charging, about 73.5% of the charge, stored as AgCl, is located in the front quarter (0.25 mm) of the electrode at a potential, ϕ_2, of -0.19V. Even with the 25 mA/cm² charging, about 57% of the charge is stored in the front quarter at the same shut-off potential. At 54 C/cm², the electrode charged at 50 mA/cm² stores 18.5% more charge in the front 0.25 mm of the electrode when compared to the electrode charged at lower current density.

One conclusion which can be drawn from these results is that more than half of the 1 mm electrode is ineffective in terms of charge storage in the range of current densities investigated.

Discharging behavior.—The discharging behavior of a porous Ag/AgCl electrode with uniformly distributed charge (540 C/cm³) was investigated. Calculations were made for discharge current densities of 50 and 25 mA/cm². The initial porosity was assumed to be 0.484 and the specific surface area of the electrode was assumed to be 4700 cm²/cm³. The variations in total overpotentials are shown by the solid curves in Fig. 6. The overpotential decreases in the beginning due to the rise in electrolyte concentration and the increase in electrolyte conductivity (see Fig. 7). As the active material (AgCl) is being depleted, the overpotential rises and the electrode finally shuts off when limiting current densities are reached. According to Fig. 6, the discharge efficiency is 92% at 50 mA/cm² discharge and 97% at 25 mA/cm² discharge. Evidently, due to the high level of concentration that can be reached inside the electrode, the discharge efficiency is less dependent on current densities as compared to the charge storage capacity in charging. The concentration in the back of the electrode during discharge can actually reach 2.5 moles/liter as shown in Fig. 7.

The local transfer current densities for the discharge case is more uniformly distributed relative to the

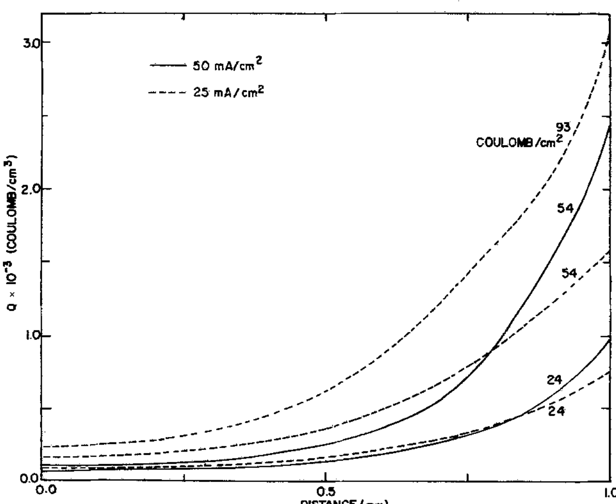

Fig. 5. Charge distributions at various stages of charge. Charging currents: ———, 50 mA/cm²; — — —, 25 mA/cm².

charging case. The maximum of the reaction rate moves toward the rear as the electrode is being discharged (Fig. 8). At the end of the discharge, the local transfer current density is actually the highest in the back of the electrode. For the high current discharge, the reaction rate distribution is such that the active material a little way inside the electrode is actually depleted first before the charge at the very front is used up as shown in Fig. 9. The low current discharge, however, consumes the charge at the front of the electrode first.

Cycling behavior.—To examine the cycling behavior of Ag/AgCl porous electrodes, calculations were made for the discharge of an electrode previously charged to 54 C/cm^2 at 50 mA/cm^2. The initial charge distribution is shown in Fig. 5. The total overpotential with respect to degree of discharge is shown in Fig. 6. As shown by the dashed line, only about 48% of the charge stored is retrievable before the limiting current is reached. The electrolyte concentration inside the electrode can again reach a very high level as shown in Fig. 10. As a result, the reaction rate can be quite high in the back of the electrode as can be seen from Fig. 11. As the discharge continues, the little active material available in the rear of the electrode is soon depleted (see Fig. 12). The reaction rate at the front of the electrode, therefore, becomes higher. However, since the front of the electrode contains most of the stored charge, it has most of its surface covered by AgCl. The high local transfer current densities and the lack of reaction surfaces soon cause the limiting current densities to be reached before the charge stored as AgCl can be used efficiently.

Discussion and Conclusions

The mathematical model can provide information for the design and improvement of electrode plates. For example, the charging behavior predicted for the Ag/AgCl electrode indicates that a large portion of the 1 mm electrode thickness from the electrode face to the center of the electrode plate was not used effectively for the current densities considered. Therefore, the optimum thickness of a real Ag/AgCl electrode plate should probably be less than 2 mm if operation above 25 mA/cm^2 is necessary for a large fraction of the charging cycle. The cycling calculations suggest

that the electrode should be charged at a low current density. In the charged state the AgCl should be uniformly distributed so that most of the stored charge can be used when the electrode is being discharged. No parts inside the porous electrode should exceed limiting current densities (and thus induce gasing) before the charge is fully utilized. The calculated results indicate that the concentration of the electrolyte inside the porous electrode plays an important role in the electrode performance for both charging and discharging.

There are still shortcomings in the proposed mathematical model. The specific surface area used in the model was assumed to be constant. This is not quite true since the morphology of the electrode surfaces changes during charging or discharging. The inclusion of the variation of surface area with time should be based on future experimental observations.

The functional dependence of θ on the state of charge used in the present model is still not ideal. The amount of surface coverage with respect to the state of charge is not known accurately. An improvement in the description of θ variations based on actual experimental observations is needed.

The value of k_m^o depends on the effective diffusion path of complex ions. The effective diffusion path of $AgCl_{n+1}^{-n}$ conceivably changes during charging or discharging. The value of k_m^o, therefore, will actually vary with the state of charge. The nucleation mass transfer coefficient, k_{nuclei}, is dependent on the supersaturation level, local transfer current density, and surface condition. In the present model, both k_m^o and k_{nuclei} are assumed constant. The present treatment also does not include the effect of temperature differences resulting from nonuniform current distributions.

The plateau regions in the local transfer current density distributions shown in Fig. 8 and 11 are results of letting k_m^* be constant when θ has reached 0.99. This limitation was applied to minimize the cost of computer calculations. During discharge calculations, as k_m^* was approaching zero, the local transfer current densities were very close to limiting current densities. If k_m^* was not limited, very short time steps were required to avoid exceeding limiting current densities by the calculated current densities before the true solution was reached.

LIST OF SYMBOLS

A_i	chemical symbol for species i
a	specific surface area per unit volume of the electrode, cm²/cm³
C_1	ratio of surface concentration to bulk saturation concentration of complexed ions, c_R/c_R^{eq}
c_o	solvent concentration, moles/cm³
c_e	electrolyte concentration, moles/cm³
c_e^o	electrolyte concentration outside the pores of the electrode, a constant, moles/cm³
c_i	concentration of species i, moles/cm³
c_R	concentration of complexed ions at metal surface, moles/cm³
c_R^{eq}	equilibrium concentration of complexed ions with respect to electrolyte concentration c_e, moles/cm³
c_R^*	equilibrium concentration of complexed ions with respect to the reference concentration c_e^o, moles/cm³
D	diffusion coefficient of the electrolyte, cm²/sec
e^-	symbol for the electron
$\mathbf{F}$	Faraday's constant, 96,487 C/equiv.
I	superficial applied current density, A/cm²
i_1	superficial current density in metal phase, A/cm²
i_2	superficial current density in solution phase, A/cm²
i_o	exchange current density, A/cm²
i_o^o	concentration independent exchange current density, A/cm²
j	local transfer current density (anodic current positive), A/cm²
K	dissolution constant for complexation reaction
k_m^*	over-all mass transfer coefficient, cm/sec
k_m^o	mass transfer coefficient, cm/sec
k_{nuclei}	nucleation rate coefficient, cm/sec
L	electrode thickness, cm
MX_n	chemical symbol for a metal salt
m_e	molality of the electrolyte, moles/kg
n	numbers of electrons transferred in the electrode reaction
P	porosity factor for porous salt film
Q	amount of charge stored at a point within the electrode, C/cm³
Q_{max}	the maximum amount of active material storable in the pores, C/cm³
Q^*	a charge parameter indicating the transition of AgCl growth regions, C/cm³
RT	gas constant multiplied by the absolute temperature, joules/mole
S	shape factor for salt crystallites
s_i	stoichiometric number for species i, subscripts o for solvent, + for cation, − for anion, M for metal, and R for reactant
t	time, sec; tortuosity factor (when in exponents)
t_+^o	transference number of cation referred to solvent velocity
$v^\square$	superficial volume average velocity, $\Sigma_i c_i \overline{V}_i v_i$, cm/sec
v_i	velocity of species i in solution, cm/sec
$\overline{V}_i$	partial molar volume of species i; subscripts o for solvent, e for electrolyte, M for metal, and MX for salt; cm³/mole
x	distance from backing plate, cm
X^-	symbol for an anion
z_i	charge number of species i

Greek Symbols

α_a, α_c	kinetic parameters
γ	exponent in composition dependence of the exchange current density
$\gamma_\pm$	mean molal activity coefficient of the electrolyte
ϵ	volume of pores to total volume of electrode
θ	fraction of the metal area exposed, subscript s represents the AgCl patch growth region and subscript p represents the film thickening region
κ	conductivity, mho/cm
ν	number of moles of ions into which a mole of electrolyte dissociates
ν_+, ν_-	number of cations (anions) into which a molecule of electrolyte dissociates
ϕ_1	potential in metal phase, V
ϕ_2	potential in solution phase, V
ζ	exponent in composition dependence of the exchange current density

Analysis of Porous Electrodes with Sparingly Soluble Reactants

IV. Application to Particulate Bed Electrode: Ag/AgCl System

ABSTRACT

Experiments were conducted to characterize critical processes which determine performance of totally immersed, porous, secondary electrodes having sparingly soluble reactants. Particulate beds comprised of silver spheres, 37.7 $\pm$ 4.2 μm in diameter, were used as Ag/AgCl electrodes in 1*N* KCl. Silver chloride product distribution and facial potential as functions of time during galvanostatic charging are compared to predictions of a recently developed mathematical model. Good accord is shown over the tested time range, 1-19 min, and exterior current density 50 mA cm^{-2}. Time for onset of pore blockage with failure to accumulate charge, about 18 min, and the reaction penetration, mostly less than 0.03 cm, are predicted with reasonable accuracy. A characteristic minimum in polarization occurs during galvanostatic discharge due to reduction in pore blockage at the beginning of discharge, increase in KCl concentration in the depth of the electrode, and increase in effective matrix electronic conductivity with silver deposition. A final rise in polarization occurs when silver chloride is depleted. Theory is used to show how governing rate processes are shifted by the occurrence of blockages of the first and second kinds.

In principle, the analyses of experimental studies of current distributions and morphological changes can be used to improve the design of battery electrodes. Rational design is possible only if it is known how electrode structure affects changes in distributions and morphology. Such experimental studies, however, are carried out with difficulty. Currents and structural changes occur within poorly accessible regions of thin electrodes often having pores less than 10 μm in diameter (1). External devices used for experimental observations can disturb the conditions of normal operation.

Nevertheless, such experiments have now progressed along two paths: those dealing directly with idealized single pores (2-4) and those treating aggregates of pores in model porous electrodes more or less representing a real battery electrode (5-10).

In single pore studies the pore is considered to represent a real electrode constituted of multiple aggregates of this pore. Notably, Brodd (2) and Szpak *et al.* (3) attempted to provide an experimental basis for theoretical treatments of current distribution in segmented single pores larger than 800 μm in diameter. Szpak and Katan (4) reduced the pore spacing to 60 μm using microelectronic techniques and were able to observe the evolution of reaction profile. Serious application of these single pore studies has been somewhat delayed, mainly because practical porous electrodes often have smaller pores which are in fact interconnected and tortuous, and, also, theory needed to translate the findings is still under development.

Key words: porous electrodes, electrode design, batteries, silver/silver chloride electrode.

Model electrodes having some resemblance to real electrodes have been studied with varying degrees of success in understanding the prevailing reaction modes and distributions, *i.e.*, by Alkire *et al.* for the $Cu/CuSO_4$ system (5, 6), by Bro and Kang for $Cd/Cd(OH)_2$ (7), by Nagy and Bockris for $Zn/Zn(OH)_2$ (8), by Szpak *et al.* for Ag/AgCl (9), and by Simonsson for $PbSO_4/PbO_2$ (10). In some of these studies electrodes were cut into sections after charging or discharging, and the current distribution was inferred from the amount of chemical change that occurred in each section. This approach is used in the work presented here.

The merit of model or real electrodes over single pore electrodes lies in the more direct conformity of results. Mathematical representation can be given for the observed distribution curves with more assured application, and effects of the phenomena of blockage of the first and second kinds can often be distinguished and interpreted. Either the experimental studies or the developed mathematical representation can be used individually, but together they provide the most valuable means for insight into the principles involved in electrode operation.

It is the aim of this work to test the applicability of theory developed by Bennion and co-workers (11) for describing performance of totally immersed, porous, secondary electrodes having a sparingly soluble reactant. The theory has a fundamental basis on principles of transport and electrochemistry. Comparisons with experiment are made for AgCl product distribution in an Ag/AgCl electrode and for facial potential as a function of time during galvanostatic charging. Facial potential is also compared for the discharge cycle. After a series of preselected galvanostatic anodic treatments, the electrode is sectioned and each section is analyzed

for AgCl content for the comparisons. Microscopic examinations are made of fully charged and discharged electrodes to assist in the interpretations.

The Ag/AgCl system was selected as representative of cathodes having sparingly soluble reactant because much is known of its electrochemical behavior. The system has been the subject of many detailed kinetic investigations, and the elementary processes controlling charge and discharge have been established for Ag surfaces partially covered with AgCl [*e.g.*, see (12) and (13)]. Particulate beds consisting of loosely stacked uniform silver spheres, about 40 μm in diameter, were used. The beds are conveniently prepared and easily sectioned without disturbing unsectioned portions. With uniform sphere beds, the initial porosity is essentially unchanged while specific surface is varied by changing sphere size. Transfer current is strongly dependent on depth rather than location at a given depth because of the uniformity in particle size. The structure is simple, easily reproduced, and has good matrix conductance for the 40 μm silver spheres, about 1.0 Ω^{-1}-cm^{-1}.

Experimental

Apparatus.—The apparatus consisted of a cell which housed the particulate bed electrode, a porous Ag/AgCl counterelectrode, and an Ag/AgCl reference electrode, together with associated instrumentation: a galvanostat, ammeter, and recording potentiometer. In Fig. 1 the general arrangement of the cell is shown. Details of the components have been previously described (13), with the exception of the reference electrode which is now differently placed. From its separate container, the Ag/AgCl reference (14) now communicates with the front face of the particulate bed via a *ca.* 1/64 in. slit which surrounds the frontal face of the bed and which forms the junction of the upper removable part of the cell with the lower part having the spheres in a cuplike enclosure. A Saran film bag containing the reference electrode is sealed to the tubular Pyrex cell by Teflon pipe thread sealant tape. The particulate bed working electrode was always made 2.00 mm thick in the 1.41 cm diameter cup having a movable silver disk bottom for electrical contact, positioning, and sectioning. Electrolyte was 1*N* KCl.

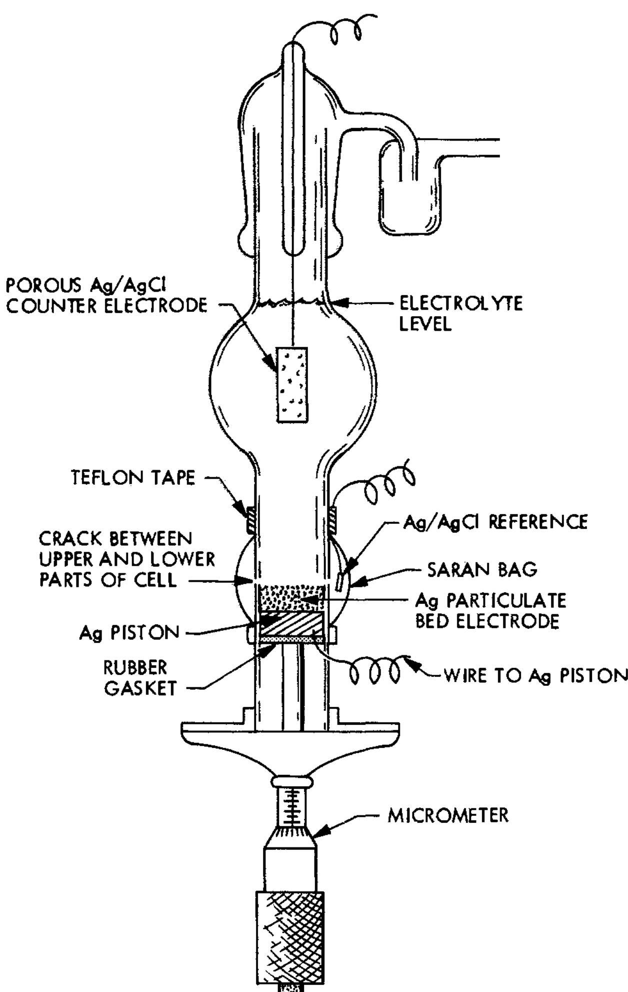

Fig. 1. Arrangement of particulate bed and counterelectrode in the sectioning cell. Cell is disassembled and micrometer screw is actuated for sectioning the bed.

Experimental procedure.—Silver spheres, 37.2 $\pm$ 4.2 μm in diameter, were washed and dried as previously described (13) and placed from a slurry with 1*N* KCl into the cup with the silver disk bottom. The disk was raised and silver particles were swept from the frontal plane with the straight edge of a spatula using the cup's rim as a guide to form a planar electrode face. The particles were swept onto a surrounding Teflon collar temporarily attached to the cup. This process was repeated, using a micrometer screw setting below the disk until the bed thickness was 2.00 $\pm$ 0.01 mm. The Teflon collar was then removed and the cell was assembled.

During charging and discharging, the porous Ag/AgCl counterelectrode about 7 cm above the bed electrode collected the galvanostatic current, and the Ag/AgCl reference electrode with its exit slit placed at the facial edge of the bed was used to monitor potential. All charging and discharging in this work was at constant exterior current density, 50 mA cm^{-2}. Some of the electrodes were cycled: charging until after the onset of a sharp increase in the rate of polarization increase, for about 25 min, and then discharging for the same time or coulombs, repeating for 5 cycles. Other electrodes were charged without cycling for time intervals from 1 to 8 min, differing by 1 min increments, and from 10 to 22 min, with 2 min increments. These charged electrodes were subsequently sectioned for analyses for AgCl. Prior to an experiment, the Ag/AgCl counterelectrode was anodically charged in a separate container with an amount of silver chloride in excess of that consumed during charging of the working electrode.

After a particulate bed was charged for a preselected time, the cell was disassembled and the electrode was sliced into ten sections, each section approximately 0.02 cm thick. Sectioning was conducted with a stainless steel blade with a fine saw-tooth edge after the electrode was raised above the rim of the holding cup with the micrometer screw, Fig. 1. The cut section was then removed to a Teflon collar and then to a beaker and the sectioning repeated. Each sliced section was treated with 20 cm^3 of deaerated 1.0M sodium thiosulfate solution to dissolve the accumulated AgCl, and the solution was then analyzed for Ag by the atomic absorption method. The metallic Ag from each section was weighed afterward so that the layer thicknesses could be calculated accurately.

In general, the equivalent number of coulombs of AgCl found experimentally exceeded the coulombs passed through the electrode during charging. Air was not excluded from the sample bottles containing the sectioned specimens, and the dissolution of oxides of silver in the 1M $Na_2S_2O_3$ could account for the observed higher values determined by atomic absorption analyses. The discrepancy in coulombs was found to increase with passage of time, which was never over 4 days before analyses, indicating a continuing dissolution process of the silver specimen. For a given time after sampling the charge discrepancy was constant, never exceeding 20% of the total coulombs passed. An averaged constant discrepancy was subtracted from each section to make the value of the sum of the charge from each section equal to the galvanostatically passed coulombs. The data reported here are so corrected.

The data collected from the AgCl analyses were plotted with charge, C cm^{-3}, as a function of position for the various time intervals studied up to the onset of severe polarization, about 18 min at the 50 mA cm^{-2} current density. The determined polarization as a function of time was also plotted for both the charging mode and the discharge mode during cycling.

Microscopy.—Optical and scanning electron microscopy were used to ascertain morphological changes leading to the onset of severe polarization which prevented further accumulation of AgCl charge and to compare the penetration depth with that determined by the slicing of the electrode into ten parts. Optical microscopy was conducted after the fully charged, unsliced electrode was dried, vacuum-impregnated with epoxy, sectioned, and polished metallographically. Electron microscopy was conducted with unsliced, fully discharged, previously cycled electrodes which were dried and then broken in half to reveal the internal structure. The charged and the cycled electrodes were found to have some structural strength; the particulate bed was bonded together by the electrochemical treatment, either by deposited silver chloride or silver (13).

For one fully charged electrode, an elemental electron microprobe analysis was conducted with an ARL electron microprobe Model EMX with 67 μm intervals every 40 sec. Line width of the field was 0.005 mm with a 0.7 mm line length, the probe movement perpendicular to the line. In this way, by encompassing several sphere diameters at one depth into the electrode, statistical scatter was minimized. Calibration was with reagent grade AgCl, and the passed coulombs matched the sum of the sections to within 1%.

Results and Interpretation

Microscopic examinations.—A metallographic section of the epoxy impregnated, fully charged electrode is shown in Fig. 2. This electrode was charged for 26 min at 50 mA cm^{-2} when it could no longer accept further galvanostatic charging but suffered an onset of severe polarization and subsequent gas evolution. A layer of AgCl covers the electrode's frontal surface and blocks all passages to the internal parts of the particulate bed. Within the structure, for a distance of about 0.02 cm, we also see Ag particles enveloped in AgCl. It appears that the final inability of the electrode to accept charge is caused both by this extensive blockage of the pores, blockage of the first kind, and of the pore walls, blockage of the second kind. The increased ohmic resistance for these two reaction paths could cause the observed severe polarization.

The electron microprobe analysis shown in Fig. 3, also indicates the sharp increase in AgCl charge near the frontal surface, at depths of 0.01 cm or less, until the electrode is about 92% AgCl. This observation confirms the optical microscopy of Fig. 2 in that a nearly pure layer of AgCl coats the frontal portion of the electrode.

After a final discharging of the electrodes (five complete cycles), metallographic sections reveal the onset of a new silver morphology in the reaction zone, consisting mostly of very fine particles less than 2 μm in diameter, with estimated porosity and specific surface area of 50% and 15,000 cm^2 cm^{-3} (15, 16). The change in morphology extends *ca.* 0.01 cm from the frontal plane, and remnants of the original 37.2 μm diameter spheres are present, Fig. 4. The shape of the spheres originally present is changed, and the spheres' surfaces have become roughened. Erosion of the original spherical shape occurs within the reaction region with the reformation of a typical, small-particle morphology.

More details of the change in morphology can be seen in SEM photos as shown in Fig. 5. In the frontal region, about 50 μm from the front face, small Ag crystallites, about 0.5 μm in size, are clustered and mingled with larger Ag crystallites, about 3 μm in size, Fig. 5b. A solid electrical path always exists through the clumps of crystallites which have grown together. Deeper into the electrode, about 100 μm from the frontal plane, most Ag crystallites are larger, about 2-3 μm in size, Fig. 5c. This effect of increase in crystal size with depth into the electrode is also evident in Fig. 4. The increase in specific surface area which results with the cycling is more effective at the lesser depths. This action occurs if the reaction penetration depth decreases with in-

creased specific surface area (17). Each cycle results in shallower penetration, and the frontal regions become most affected.

At about 450 μm from the frontal plane, the texture of the original sphere surface becomes apparent as a heavily pitted and etched body, Fig. 5d. Metal has been removed from imperfection sites and grain boundaries (13).

Potential/time relation for charging.—Polarization during galvanostatic charging abruptly assumes a value of 0.1V and then gradually increases to about 0.3V after *ca.* 18 min, region I in Fig. 6. Thereafter, a sharp increase in polarization commences with eventual evolution of bubbles of gas, smelling of chlorine, and a consequent erratic response of polarization, region II. Polarization beyond 1.2V brings the electrode into the potential region favorable for oxygen and chlorine evolution (18).

The more severe increase in polarization, region II of Fig. 6, is attributed to onset of nearly complete blockage both of the pore volume and pore surface by AgCl as indicated by the optical microscopy in Fig. 2 and by our previous communications (12, 13). It was shown that AgCl deposits at an approximately uniform thickness of about 3500Å at various locations on the pore walls and that these deposits first grow laterally until surface coverage is nearly completed. Thereupon, the film starts to thicken as polarization is increased (13, 19, 20). Within the particulate bed, the loss of Ag surface by AgCl film formation, blockage of the second kind, at the frontal regions of the electrode is followed by film thickening, resulting in blockage of the first kind, *i.e.*, pore blockage by the accumulating AgCl. Eventually the front part of the electrode is covered by a thick AgCl layer blocking all of the pores

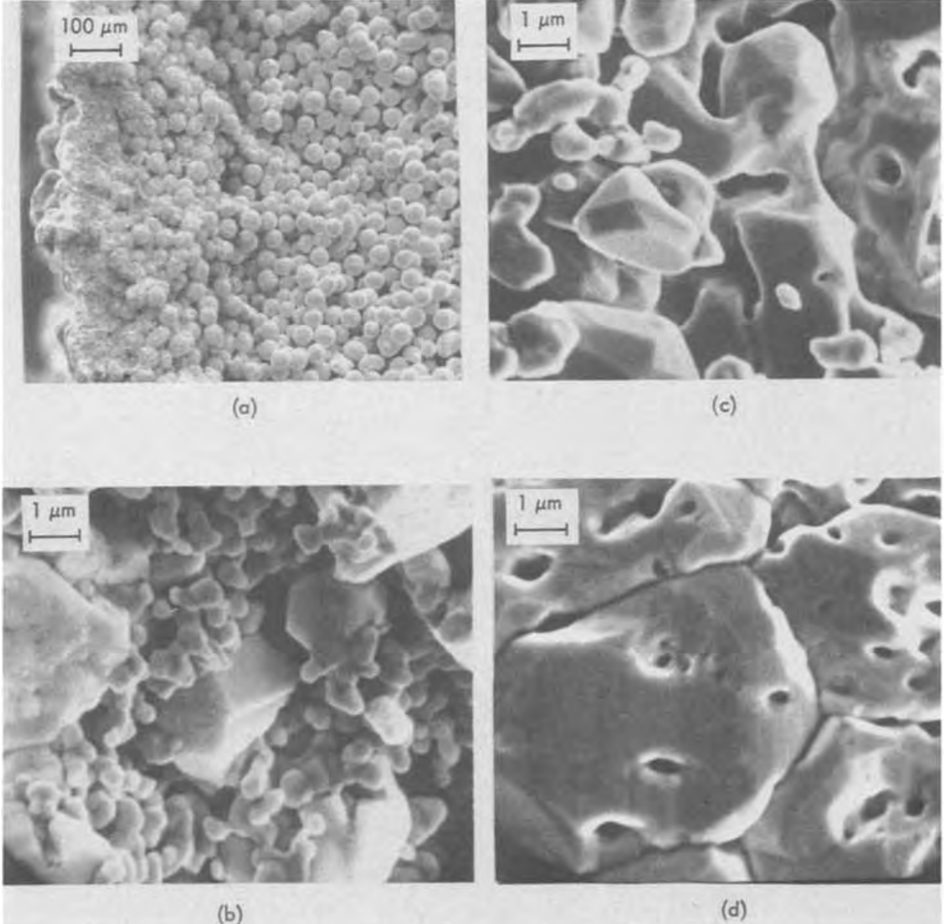

Fig. 5. SEM photographs showing cross section of cycled electrode. Five complete galvanostatic cycles were run, each 25 min of charge (anodic) and 25 min of discharge (cathodic) with a final reduction, 50 mA cm^{-2} in 1*N* KCl, 23°C. The Ag spheres in the bed originally appeared smooth and were about 37.7 μm in diameter. (a) Morphological changes are shown as a function of depth into the electrode with the frontal plane shown on the left mostly affected; (b) Ag morphology at a 50 μm depth is constituted of small Ag crystallites reformed from the spheres; (c) at a 125 μm depth the reformed Ag crystallites can also be seen but are somewhat larger than at the frontal region; and (d) at a 450 μm depth no crystallites are found but the crystal grain boundaries on the original spheres are deeply etched and isolated pits are formed (13).

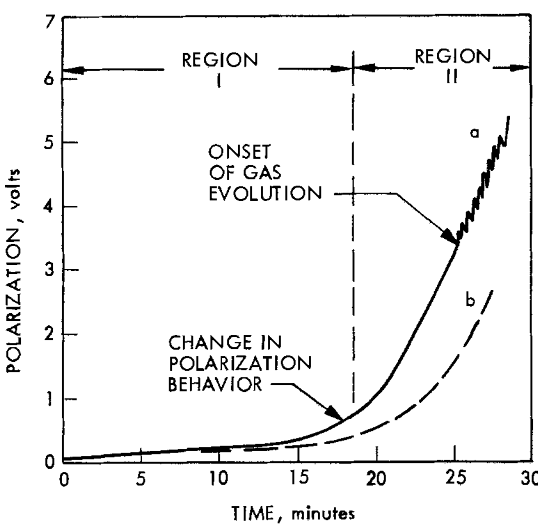

Fig. 6. Polarization increase during application of 50 mA cm^{-2} anodic current density to particulate bed electrode in 1*N* KCl, 23°C. (a) Increase in polarization with a freshly prepared electrode; and (b) increase in polarization after the electrode has been charged for 25 min at 50 mA cm^{-2} and then fully discharged.

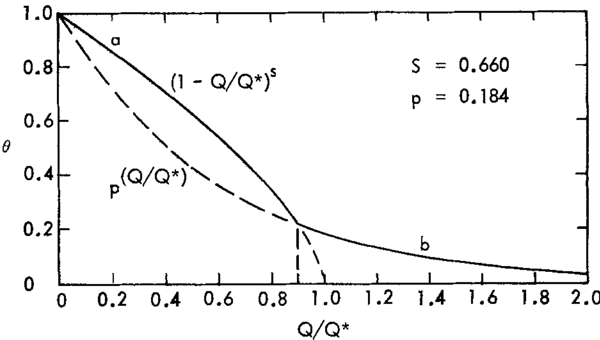

Fig. 8. Functional dependences of fractional coverage by AgCl, θ, on the accumulated charge fraction, Q/Q^*. (a) For lateral film growth mode; and (b) for film thickening mode.

as shown in Fig. 2. Blockage of the first kind by KCl depletion and AgCl accumulation, with resultant increase in resistive path through the electrolyte, prevents the complete coverage of Ag surface by AgCl at depths greater than *ca.* 0.01 cm, Fig. 2 and 3.

Comparisons could be made of the experimentally determined polarization/time dependence with the results of theoretical treatment detailed by Gu *et al.* in the preceding study (11), *i.e.*, for region I and the first part of region II in Fig. 5. Using parameters of the system given in Table I, we apply the theory as previously described to obtain the relation shown in Fig. 7 [cf. Fig. 2 in Ref. (11)]. Here, theory indicates the onset of severe polarization after 18 min in accord with experimental findings. Agreement for the polarization/time curve is seen to be good throughout the theoretically treated region to 19 min. These results are considered as evidence for validation of the theoretical method employed in this analysis of electrode behavior.

In application of the theory, a different expression was used for the fraction of exposed Ag area, θ, for the condition when AgCl grows as a film parallel to the surface than that used for the condition when the AgCl film is thickening after the nearly complete coverage. Before film thickening occurs we use $(1 - Q/Q^*)^s$, an expression similar to that of Simonsson (21) having geometrical significance, while afterwards we use $p^{(Q/Q^*)}$, an expression whose functional dependence appears reasonable for the situation of film thickening. Here, s and p are constants, Q is the charge, and Q^* is the charge required for nearly complete surface coverage, *i.e.*, when the film thickening mechanism becomes active. In Fig. 8 we plot the two expressions for θ. The term $p^{(Q/Q^*)}$ is used after the intersection of the two curves when the process of film thickening is assumed to predominate for fractional surface coverage greater than 0.9.

If the electrode is cathodically reduced after charging and then charged again, polarization during the second charging is less throughout both regions of charging, Fig. 6, and the sharp increase in polarization then starts later, after *ca.* 21 min. The increased specific surface area after electrode reduction, from 1000 to an estimated 15,000 cm^2 cm^{-3}, results in improved electrode performance, and a greater utilization is possible of the solid Ag present. With the cycled electrodes, the

Table I. Parameters of the Ag/AgCl particulate bed electrode used with theory of Gu *et al.* (11) to describe electrode's behavior, Fig. 7-10

Parameter	Value	Basis of parameter selection
Exterior current density, mA cm^{-2}	50	Measured
Temperature, °C	25	Approximate measured value
Electrode thickness, mm	2.0	Measured
KCl concentraton, *N*	1.0	Measured
Porosity at frontal plane	0.53	Estimated from photomicrographs
Porosity at depths greater than 0.45 mm*	0.40	Approximate, measured value, Ref. (13)
Specific surface area at frontal plane, cm^2 cm^{-3}	758	Calculated from porosity and sphere diameter, Ref. (15)
Specific surface area at depths greater than 0.45 mm, cm^2 cm^{-3}**	970	Calculated from porosity and sphere diameter, Ref. (15)
Mass transfer coefficient, $k_m{}^\circ$, cm sec^{-1}	0.3	Calculated from estimated diffusion coefficient, Ref. (12), and diffusion path, Ref. (13)
Concentration independent exchange current density, Ref. (11), A cm^{-2}	0.6 × 10^{-4}	Best value fitting data
Charge parameter, Q^*, C cm^{-3}	1.3A	From Ref. (12) where *A* is specific surface area in cm^{-1} and from assumption of 0.9 coverage factor, Fig. 8
Porosity factor, *P*	0.184	Assumed functional dependence and mode change at 0.9, Fig. 8
Shape factor, *S*	0.66	Geometrical reasoning, *e.g.*, Ref. (21)

* A parabolic decrease with distance is assumed for the porosity change at depths from 0 to 0.45 mm as an approximation based on photomicrographs.

** Surface is calculated according to Ref. (15) from the porosity and sphere radius for depths from 0 to 0.45 mm.

smaller sized particles enable the accumulation of a greater charge, as observed in curve b, Fig. 6. Porosity of the original particulate bed and the reaction zone after 5 cycles changed less drastically, from 39 to an estimated 50%.

Potential/time relation for discharging.—The polarization/time relation for discharge was determined for a bed electrode previously charged *in situ* at 50 mA cm^{-2} for 26 min, Fig. 9. Polarization was initially high during galvanostatic discharge because of the previous loss of electrically conductive paths caused by AgCl blockage at full charge, Fig. 2. Polarization sharply decreased, however, as electrically conductive paths were formed (20, 22), and then decreased more slowly as a balance was established between the processes of AgCl dissolution, diffusion, and electroreduction (12, 13) within the opened pores, Fig. 9. Pores are opened as the more bulky AgCl is reduced to Ag, *i.e.*, with the ratio of molar volumes of 2.51 to 1, respectively. Also, electrolyte conductivity is increased with AgCl reduction by the release of Cl^-, and AgCl solubility increases. Finally, as AgCl area becomes very small, the over-all process becomes dissolution limited, and polarization increases sharply.

An accurate polarization/time dependence was not calculated (11) because the cost of running the computer code became prohibitive for times greater than 19 min on charging. Thus, the needed theoretical charge distributions for the full 26 min of charging could not be calculated. Also, the increase in silver surface area during discharging is not included in the present mathematical model. However, an approximate comparison of theory and experiment could be made by assuming constant initial AgCl charge density throughout the electrode. Applying the theory as previously described (11), we make this comparison in Fig. 9 [cf. Fig. 6 in Ref. (11)]. Here, fair agreement is obtained for the shape and magnitude of the curves. For a theoretically uniformly AgCl-charged electrode, the sharp initial decrease in polarization was not predicted, compare curves a and b, Fig. 9. Nevertheless, the gradual decrease in polarization could be shown as a result of electrolyte conductivity increase, curve b, Fig. 9, and the final increase matches fairly well with the experimental curve.

AgCl charge distribution.—Typical charge distributions are shown in Fig. 10. Here, results of experimental analyses of sections taken from galvanostatically charged electrodes are compared with results of theoretical treatment using parameters of Table I (cf. Fig. 5 in Ref (11)). Agreement is generally good for the time span studied, 1-18 min. The accumulated AgCl charge density undergoes a characteristic rapid decrease with increased penetration into the electrode, and both theory and experiment show that the reaction's penetration depth does not change substantially

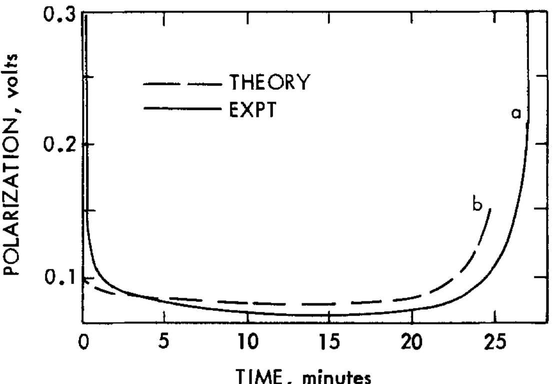

Fig. 9. Typical polarization behavior during a cathodic galvanostatic discharge, 50 mA cm^{-2}, of previously AgCl charged electrode, 1*N* KCl, 23°C. The initial polarization drop is explained in terms of a removal of blockages whereas the final increase is explained by the removal of AgCl.

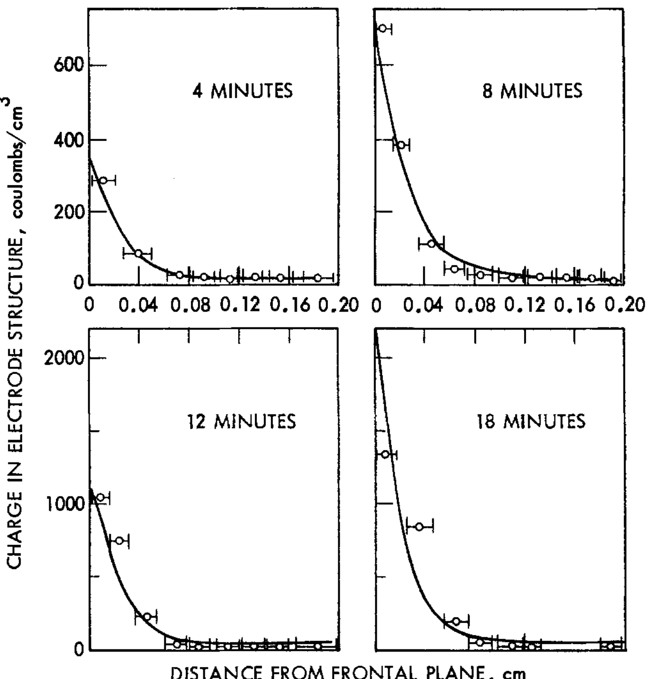

Fig. 10. Typical AgCl distribution within the particulate bed electrode. Experimentally determined distributions are shown by circles and theoretically computed curves are shown as a solid line. Charging times at 50 mA cm^{-2} are indicated in each figure, 1*N* KCl, 23°C.

from a value less than *ca.* 0.03 cm over the full range of charging. Most of the reaction always takes place within a 0.03 cm depth at 50 mA cm^{-2} even though the total accumulated charge undergoes an 18-fold change.

Charge penetration to within a small frontal region of the electrode is also shown by the SEM photos, Fig. 5a, and the cross section, Fig. 4, taken after 50 min of charging and discharging in 5 cycles. Here the penetration depth, judged from marked morphological change, can be seen to be about 0.01 $\pm$ 0.002 cm. At greater depths the lesser extent of reaction is limited to the Ag sphere's surface, while at shallower depths reaction is so extensive that the original spherical shapes are no longer present. Repeated cycling tends to accent this effect because the Ag surface area is increased in the reaction zone, acting to bring the reaction even closer to the frontal plane (17).

Discussion

Results have shown that theory developed by Gu, Bennion, and Newman (11) agrees consistently with the experimental findings with the selection of reasonable physical parameters for the system. The theory is shown to yield a good description of the actual increase in polarization with time, Fig. 7, and dependence of charge profile on time, Fig. 10.

Aside from this descriptive nature, the treatment can also yield an understanding of the governing processes which are undergoing dynamic changes during charge and discharge and which caused blockage of the first or second kinds. For example, during the charging process it can be determined from the programmed theory that the causes of the steep rise in polarization after 18 min are the onset of electrolyte depletion with decreased conductivity together with the loss of active Ag surface by coverage with AgCl. It can be seen that the depletion of Cl^- by AgCl formation causes the current profile to be thrown toward the frontal region of the electrode, by the decrease of conductance in the modified Ohm's law expression of the theory (11), while the more gradual decrease in active surface, θ, renders the reaction more difficult there, affecting the utilized redox kinetic expression (11). Thusly, the in-

terplay of blockage of the first and second kinds caused by changing rate processes may be realized. Ultimately, after 26 min, it could be shown from the Ohm's law expression that fractional void volume becomes so small that pore blockage by AgCl is essentially complete, as observed, Fig. 2.

The expressions of the theory may also be examined to find the extent of film thickening which occurs, here preferentially at the frontal surfaces, from the state of charge, Q/Q^* in Fig. 2. The constants p and s determine how effective the blockage is as the film starts to thicken rather than grow in a surface-spreading mode.

During discharge, the theory accounts for an initial decrease in polarization, Fig. 9, by the opening of blocked pores and by the increased conductivity of electrolyte from the released Cl^-. Finally, as AgCl is depleted the polarization rises, as observed. The alleviation of polarization during initial discharge by the growth of Ag filaments (22), which may be called the removal of blockage of the third kind, was not programmed into the theory.

Conclusions

Theory developed by Gu, Bennion, and Newman (11) was found to give a good description of performance of a particulate bed electrode comprised of Ag spheres, 37.7 ± 4.2 μm in diameter, in 1*N* KCl. With reasonably selected physical parameters the theory could predict the onset of failure to accumulate charge, after 18 min at 50 mA cm^{-2}, the location of reaction profile mostly within a depth of 0.03 cm, and the shifts in governing rate processes which cause blockages during charge and discharge. The conformity of experiment and theory is submitted as evidence for the applicability of the given treatment as well as the usefulness of the theory in interpretation of morphological changes and electrode behavior.

Long-Lived Sn(IV) Sensitizer Baths for Photoselective Metal Deposition

B. K. W. Baylis, A. Busuttil, N. E. Hedgecock, and M. Schlesinger*

Department of Physics, University of Windsor, Windsor, Ontario, Canada N9B 3P4

In a previous publication (1) we reported that Sn(IV) can be used as a sensitizer for Cu plating and for Ni-P plating from an acidic bath. Irradiation of the catalyzed surface with ultraviolet light after the Pd(II) activation step was shown to be a necessary condition for copper plating, but was found to prevent Ni-P plating. Ni-P plating occurs on the catalytic surface not exposed to u.v. light; hence the images resulting from irradiation through a mask and subsequent Ni-P plating replicate the mask, *i.e.*, are positive images. It should be emphasized that copper plating occurs only on the irradiated catalyst, resulting in a clean negative image of the mask. This "stimulated" negative, where irradiation is necessary for plating, since no plating occurs on nonirradiated areas, is of course strikingly different from the negatives we reported earlier (2), obtained with Sn(II) as the sensitizer and u.v. irradiation following the postactivation rinse. In this latter case, the nonirradiated area plates as usual, but the irradiated area plates faster. This gives an image of

* Electrochemical Society Active Member.
Key words: electroless, sensitizer, photoselective, thin films.

low contrast. For practical applications, particularly in the fabrication of printed circuitry, the "stimulated" negative image, having much higher contrast, is more useful.

It was further reported in Ref. (1) that the Sn(IV) sensitizer is only effective for imaging if it is between ~20 and ~45 hr old. We have now been able to extend the useful lifetime of Sn(IV) sensitizer baths for up to three months. The technique is to let hydrolysis of the Sn(IV) chloride proceed until the bath is cloudy and to add hydrochloric acid to slow further hydrolysis and to prevent formation of long colloidal particles. Because these baths are left in beakers covered only by watch glasses, the evaporation occurring over such a long time is quite significant. Nonetheless they can be used for making sharp images even after their volume has halved and the colloid has redissolved, leaving a clear solution. [See Ref. (1).]

These baths were made by diluting 2.5 ml of a stock solution, which contains 10g $SnCl_4 \cdot 5H_2O$ in 12.5 ml concentrated HCl, to 200 ml with distilled water. After anywhere from 26 to 55 hr (*i.e.*, after the solution became cloudy), 1 ml concentrated HCl was added. After a week or more, another 1 ml concentrated HCl was added. This second addition has been made after from 6 to 13 days, resulting in solutions which remained highly effective for up to three months.

Application of Wagner's Theory to the Electropolishing of Aluminum

M. Zamin,* P. Mayer,** and M. K. Murthy

Ontario Research Foundation, Mississauga, Ontario, Canada L5K 1B3

It is known (1) that during the electropolishing of metals, a horizontal plateau is obtained when the anode current density (i) is plotted against the cell voltage (V). Edwards (2, 3) has suggested that this plateau is due to the diffusion of an "acceptor" to the anode for metal ions. Thus, the plateau corresponds to a maximum concentration gradient when practically all the acceptor approaching the anode readily reacts with the metal ions resulting in a much lower acceptor concentration at the anode as compared to its bulk concentration. Wagner (4) suggests that this interpretation of the i-V curve implies "that either the standard free energy of non-hydrated cations is much higher than that of hydrated cations, or the activation energy for the formation of non-hydrated cations is considerably greater than the activation energy for the formation of hydrated cations." Such a process has been termed "an ideal electropolishing process" by Wagner (4) who published the first quantitative mathematical description of the electropolishing process.

A detailed outline of Wagner's theory can be found in the original paper (4). However, in order to help clarify the use of the theoretical equations, a brief account of the essential features is summarized below.

Consider a surface whose roughness can be described by a sine-wave profile with a wavelength, a, and an amplitude, b. If an "ideal electropolishing process" is considered then the metal ions are consumed immediately upon arrival to the outside of the hydrodynamic polishing layer of thickness, δ. For such a process the displacement u for a decrease of the amplitude from b_0 to b is given by

$$u = \frac{a}{2\pi} \ln \frac{b_0}{b} \text{ if } b << a,\ a << \delta \qquad [1]$$

where b_0 and b are the amplitudes of the sine-wave surface profile at times $t = 0$ and $t = t$, respectively.

The corresponding loss of metal per unit area, $\Delta m/A$, is

$$\frac{\Delta m}{A} = u\rho = \frac{a\rho}{2\pi} \ln \frac{b_0}{b} \qquad [2]$$

The charge consumed in the electropolishing process is given by

$$Q = it = \frac{96{,}500}{EqW} \frac{a\rho}{2\pi} \ln \frac{b_0}{b} \qquad [3]$$

where EqW is the equivalent weight of the metal, 96,500 is the Faraday constant in coulombs per equivalent, i is the polishing current density, and t is the time.

Experimental

Specimens were made from commercial purity aluminum[1] which was in the form of rods, 1.2 cm in diameter and 16 cm long. One end of the rod was machined on a lathe and threads were cut over a length of 5 cm by a flat-wedged tool bit. The resultant profile of the surface was determined by the Talysurf 4.[2]

The electropolishing solution was a commercially available product called Electro Glo 100.[3] For use, 1 part by volume of this product is mixed with 3 parts by volume of orthophosphoric acid (85%). The temperature of the solution was maintained in the range 70° ± 2°C by a hot plate. The polishing cell consisted of a beaker 12 cm in diameter and 15 cm deep with a cylindrical lead cathode. The solution was stirred mechanically by a Teflon stirrer. A conventional series circuit was used. The power was supplied by a Hewlett-Packard d-c power supply[4] and the anodic current was measured by an ammeter. The surface profile of the specimen was determined by the Talysurf. The results reported are for the same specimen polished for various periods of time. The experimental procedure was

as follows: The surface profile of the initial surface was noted by the Talysurf. The specimen was cleaned by dipping in an ultrasonic bath containing petroleum ether for 5 min, air dried, and then polished for various periods of time. After each polish, the specimen was washed in tap water, dipped in the petroleum ether solution, air dried, and then its surface profile determined.

Results and Discussion

The anodic current density-applied voltage curve for the electropolishing of aluminum in Electro Glo 100 is shown in Fig. 1. It is to be noted that although a typical plateau, similar to the one noted by Jacquet (1) and Elmore (5) is obtained over an extremely large potential range, not all regions of the curve are suitable for electropolishing. In fact, there is only a small range (7-10V) in which the polishing is excellent. Lower voltages lead to etching of the surface whereas higher voltages cause burning. The results shown in Fig. 1 are very similar to those of Powers (6) for the electropolishing of copper in phosphoric acid solutions containing 10-15 g/liter of cupric ions. Powers (6) observed a current density plateau over a large anodic overvoltage region, but found that only part of the curve was suitable for electropolishing.

The values of a and b, the wavelength and amplitude, as determined from the surface profile are given in Table I. It is to be noted that with time of electropolishing, the amplitude (b) decreases signifying smoothening, although the wavelength (a) does not change.

Since the equivalent weight of aluminum is 8.99g, Eq. [3] simplifies to

$$Q = 80.76 \ln \frac{b_o}{b}, \quad \text{C/cm}^2 \qquad [4]$$

The value of the charge consumed during the process of electropolishing (Q) can be determined in two ways. First, the anodic current density (in amperes per square centimeter) can be multiplied by the time of polishing (in seconds) and the charge (Q_{obs}) obtained (in coulombs per square centimeter). In the present case, Q_{obs} is the total charge passed up to that instant of polishing. Secondly, the charge can be calculated (Q_{cal}) from Eq. [4] knowing the decrease in amplitude.

These charges can be compared and taken as a test for the Wagner theory. These calculations are presented in Table I. It can be seen that although the calculated charge is generally less than the observed charge, the values are within 15% of one another. It is, therefore, evident that the electropolishing of aluminum provides a fair test for the validity of Wagner's theory (4).

Two possible causes for the discrepancy in the calculated and observed charges can be considered. First, the experimental error and, secondly, a lower current efficiency for metal dissolution. The experimental error can account for a discrepancy up to about 8%. More important perhaps is the fact that Eq. [3] has been derived under the assumption that all the charge is involved in the polishing process with no side or extraneous reactions occurring. In other words, a 100% current efficiency has been assumed. However, if the anodic current density is also involved in any side reactions, for example oxygen evolution, then the current efficiency will be less than 100%. Since gas evolution was observed at the anode during the electropolishing process, an error in the observed and calculated values of the charge is then due most likely to a lower current efficiency for the electropolishing process rather than any discrepancy in the theory. Lower current efficiencies for metal dissolution are known to be present in the electropolishing of metals (7).

The amount of metal removed per unit area as calculated from Eq. [2] is shown in Fig. 2 as a function of the polishing time. The rate of metal removed as determined from the slope of the curve is 0.32 mg/cm²/min which is equivalent to a rate of 1.2 μm/min. This rate is lower than that reported in literature (3 μm/min) for the electropolishing of aluminum in perchloric acid-acetic anhydride solution (8). A possible reason for the discrepancy is that perchloric acid base solutions are inherently more "aggressive" than phosphoric acid based ones. For example, the electrolytic polishing of 18/8 stainless steel in the two solutions gives the following metal removal rates (8): perchloric acid-acetic

Table I. The wavelength and amplitude variation during the electrolishing of aluminum

Time (min)	a (cm)	b (cm)	$\ln \frac{b_o}{b}$	i (A/cm²)	Q_{obs} (C/cm²)	Q_{cal} (C/cm²)	$\frac{Q_{cal}}{Q_{obs}}$

80	0.0175	0.000064	3.18	0.062	304.2	256.8	0.85

anhydride = 0.60 μm/min; orthophosphoric acid-glycerine = 0.15 μm/min.

Lower metal removal rates have the distinct advantage in that they offer better control of the polishing process. Apart from the fact that orthophosphoric acid electrolytes yield surface finishes which are superior to perchloric acid electrolytes, they are much safer to use as well (8).

The diffusion of an "acceptor" to the anode is the controlling mechanism in the Wagner theory (4). However, recently Kojima and Tobias (9) showed that for the electropolishing of copper in phosphoric acid solutions, the outward diffusion of the anodic reaction product (copper phosphate) is the rate-limiting step. It is difficult to distinguish between the two mechanisms on the basis of the results reported here. Interestingly enough, however, Nicholas and Tegart (10) pointed out that results similar to those predicted by Wagner's theory can be obtained without making any assumptions about the mechanism of the polishing process.

Silicon Oxidation Studies: Analysis of SiO_2 Film Growth Data

E. A. Irene* and Y. J. van der Meulen*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

This study is aimed toward identifying the reasons why large discrepancies exist in the literature relative to the kinetic constants which are supposed to describe the thermal oxidation of single crystal silicon (Si) in pure oxygen (O_2). In order to obtain sufficient quality and quantity of silicon dioxide (SiO_2) film growth thickness-time data, an automated ellipsometer was used to measure the SiO_2 thickness *in situ*. The resulting data was fitted to the generally accepted linear-parabolic model by several commonly used methods and the results compared. Careful attention was given to eliminating trace amounts of H_2O and Na so that the data are representative of oxidation in pure O_2; the oxidation data was compiled in the temperature range of 780°-980°C. Calculated standard deviation values were used to evaluate the quality of the fit of the data to the model. From this analysis an initial regime of rapid oxidation was identified which does not conform to linear-parabolic kinetics. This regime extends up to about 350Å. A best fit of the data to the model was achieved using data above 350Å. By using either data below 350Å or only data greater than about 1100Å, large curve-fitting errors (~50% in terms of rate constants) were obtained. It was concluded that this source of error in combination with impurity effects, insufficient data, and the specific form of the curve-fitting equation could yield the large reported discrepancies. The activation energy calculated from the linear rate constants of this study (1.5 eV) indicates that 0-0 bond breaking is important for linear kinetics and the activation energy for the parabolic rate constants (2.3 eV) is too large to be correlated with a reported value (1.2 eV) for the diffusion of O_2 through SiO_2.

As evidenced by the large number of publications on the subject, the thermal oxidation process by which thin films of silicon dioxide (SiO_2) are formed on silicon (Si) is of great technological importance. Surprisingly, however, there is considerable variance among the reported rate constants which are supposed to describe the oxidation process. As shown in Table I, there is a spread of about 300 and 50% in the linear and parabolic rate constants, respectively. Yet there is almost general agreement that the thermal oxidation of Si follows mixed linear-parabolic kinetics [see, for example, Ref. (1)-(5)]. The present study is aimed at finding the reasons for the larger discrepancies in the reported rate constants and thereby provide accurate rate constants for further interpretation. With this purpose in mind it is useful for comparison to consider the two commonly used forms for the linear-parabolic equation utilized to describe the SiO_2 film growth data.

The first equation has received attention due to Deal and Grove (1) who applied the mixed linear-parabolic oxidation rate law derived by Evans (6) to the thermal oxidation of Si. The resulting integrated rate equation has the form

$$t - t_o = A(d - d_o) + B(d^2 - d_o^2) \quad [1]$$

where d is the film thickness for an oxidation time t; and A and B are the reciprocals of the linear (k_{LIN}) and parabolic (k_{PAR}) rate constants, respectively. The terms d_o and t_o can represent either an initial oxide thickness which is present prior to an oxidation experiment (at $t_o = 0$) or a regime of initial oxidation defined by (d_o,t_o) which precedes the linear-parabolic regime. Several publications [see, for example, Ref. (1)-(5)] assert that the linear-parabolic mode is preceded by a more rapid oxidation regime. Essentially, Eq. [1] is derived from a consideration of three fluxes in a steady state: the flux of oxidant from an ambient gas to the gas-SiO_2 interface; the flux of oxidant through the SiO_2 film; and the flux which represents the extent of reaction of oxidant with Si at the SiO_2-Si interface.

The second equation [see, for example, Ref. (2)] has the form of a truncated Taylor series

$$t - t_o = A'(d - d_o) + B'(d - d_o)^2 \quad [2]$$

Key words: insulating films, oxidation kinetics, rate constants.

The terms in this equation are defined the same as those for Eq. [1]. Equation [2] is not mathematically derived from a physical description of the oxidation system, but rather is simply the sum of a linear term which represents first order kinetics for the reaction of Si and oxidant and a parabolic term which represents a diffusional limitation of oxidant through the SiO_2 film. Since for Eq. [2] there is no specific physical model, the rate constants obtained by Eq. [2] cannot be directly correlated with physical parameters of the oxidation system.

Equations [1] and [2] have the same mathematical form and therefore, when experimental data is fitted to either equation using identical procedures, equivalent curve-fitting errors will be obtained but different numerical values for the rate constants will result. The rate constants for Eq. [1] and [2] are related as shown later (Eq. [3]). However, the spread in the reported experimental rate constants shown in Table I, which were obtained using the above equations, is outside the range anticipated based on the mathematical differences between Eq. [1] and [2]. Therefore it is of interest to examine other causes for the large discrepancies such as previously reported impurity effects (2, 5), the sufficiency and accuracy of the experimental data, and the particular method of data analysis.

The purpose of the present study was to obtain SiO_2 film growth time-thickness data of sufficient quality and quantity to provide accurate rate constants for a thorough analysis of the above-mentioned possible sources of error. In this context, particular attention was given to the exclusion of Na (2) and H_2O (5) effects and we believe that the data are representative of the oxidation of Si in pure oxygen. An automated ellipsometer (7) capable of measuring the SiO_2 film thickness *in situ* during an actual oxidation experiment was used to obtain the data for this study.

Experimental Procedures

Sample preparation.—All substrates were <100> oriented chem-mechanically polished silicon wafers measuring 3.2 cm in diameter and 0.025 cm in thickness. All the wafers were p-type with a nominal resistivity of 2 ohm-cm. It was reported previously (5) that the resistivity type or value in the range 0.5-10 ohm-cm had no influence on the oxidation process. The wafers were cleaned as reported elsewhere (5) and an initial oxide thickness of from 3 to 6Å SiO_2 was measured at room temperature. Previously (4, 5), a thickness of 10-12Å was reported for the initial oxide film. With the automated ellipsometer (to be described later) the cleaned Si wafers could be immediately placed in a dry N_2 ambient, whereas in previous studies the wafers were exposed to room air for about 10 min during the ellipsometric measurements. After the initial SiO_2 film measurement, the samples were heated in dry N_2 (10-15 min) to the experimental oxidation temperature and the SiO_2 film thickness was remeasured. The SiO_2 film now measured 7-8Å. After continuous heating for 5 hr at 900°C in dry N_2, the total film thickness never exceeded 11Å. Apparently there is some small amount of oxidant either present in the N_2 or desorbing from the walls of the reaction vessel, but the relative amount of SiO_2 growth is negligible for this study.

Gas purity.—Both N_2 and O_2 were supplied by boil-off from liquid sources. Dew points of the gases were measured by means of a hygrometer (5). As previously reported (5), the O_2 was shown to contain trace amounts of methane (~17 ppm) which at the experimental oxidation temperature combusts to form H_2O. This trace H_2O substantially increases the rate of oxidation (5). To preclude this H_2O effect, the methane in the O_2 was removed by the procedure outlined previously (5). The H_2O content of the N_2 and O_2 (after purification) was found to be less than 1 ppm as measured after the oxidation furnace.

Automated ellipsometer.—The instrument used for this study has been described in detail elsewhere (7). Basically, the ellipsometer uses a laser light source, polarizer, compensator, and a rotating analyzer-encoder. The light intensity measurement after the analyzer is automated. The ellipsometry measurements are made with the sample in a fused silica rf-heated reaction tube. Therefore it is possible to collect and analyze ellipsometer data as the SiO_2 film grows without interrupting the oxidation run. The optical constants characteristic of the Si surface as a function of temperature were previously measured (7).

SiO_2 quality.—In order to check on the charge levels in the SiO_2 films grown, capacitance-voltage (C-V) measurements were made on some oxides. Evaporated aluminum counterelectrodes were used as electrical contacts. The C-V measurements (at 1MHz) revealed an average fixed positive charge level of $\sim 5 \times 10^{10}$ charges/cm^2. Bias-temperature stressing ($\pm 10^6$ V/cm at 200°C for 15 min and subsequent cooling under bias) revealed an average mobile positive charge level of $\sim 7 \times 10^{10}$ charges/cm^2. These values are characteristic of MOS quality oxide.

Data Analysis

The experimental SiO_2 film thickness *vs.* time of oxidation data obtained with the automated ellipsometer is displayed in Fig.1.

In order to compare the rate constants obtained in this study with previously reported values (1, 2, 5), the data was analyzed by three methods. Both Eq. [1] and [2] were used and the two previously mentioned ways to choose (d_o, t_o) were compared. Table II outlines the essential differences among the three methods of data analysis. Each method utilizes linear least squares (LLS) analysis of the data in accordance with the equation tested (Eq. [1] or [2]) and the way in which (d_o, t_o) is chosen. For each LLS iteration in a given method, the smallest remaining (d,t) value is dropped from the analysis; and for each iteration numerical values are calculated for the slope, intercept, and standard deviation values for the over-all fit, σ_F, the slope, σ_S, and the intercept, σ_I. The reciprocals of the slope and intercept are the parabolic (k_{PAR}) and linear (k_{LIN}) rate constants, respectively. The equations which define the calculated standard deviation values were obtained from Ref. (8).

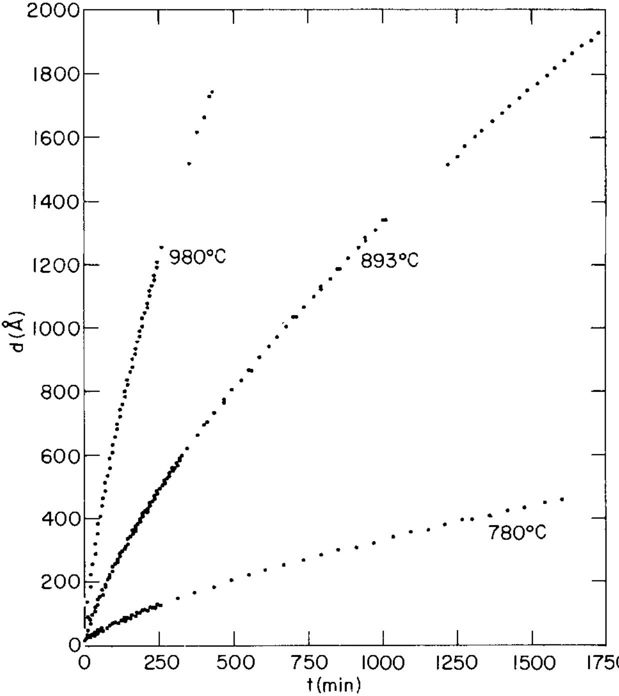

Fig. 1. SiO_2 film thickness d (Å) is plotted *vs.* time for oxidation t (min) for 780°, 893°, and 980°C oxidations of (100) Si in O_2.

Table II. Outline of the three methods of data analysis

Method	LLS relationship	Values for d_o and t_o	Description
I	Eq. [2] $(t - t_o)/(d - d_o)$ vs. $(d - d_o)$	$d_o = 10Å$ $t_o = 0$	Iterative LLS; each iteration sequentially drops the smallest (d,t) value from the analysis
II	Eq. [2] $(t - t_o)/(d - d_o)$ vs. $(d - d_o)$	(d_o,t_o) is taken as the (d,t) value dropped from the iteration	Same as I
III	Eq. [1] $(t - t_o)/(d - d_o)$ vs. $(d + d_o)$	Same as II	Same as I

This LLS technique scans a different subset of the data for each iteration and the standard deviation values enable a judgment as to which (d,t) subset yields the best fit to linear-parabolic kinetics.

A representative plot of the standard deviation, σ_F, for the fit of the data to Eq. [2] vs. the number of data (# DATA) included in the LLS iteration using method III and the 893°C data is shown in Fig. 2. Each point on Fig. 2 is obtained from a different subset of a data set; each subset is formed by dropping the smallest thickness-time value from the previous subset. The subsets are identified by the number of thickness-time data points in the subset. The shape of this plot was the same for the other two methods, as well as for the standard deviation values for the slope and intercept, and for the other two experimental temperatures. The characteristic features for all the error plots as represented by Fig. 2 are as follows.

Region 1.—With the small thickness-time data included in the analysis (*i.e.*, # DATA is relatively greater), larger curve-fitting errors are obtained. This confirms the existence of an initial oxidation regime which does not conform to the linear-parabolic model (1, 5). Additionally, the analysis provides an estimation of the influence of this regime which for the 893°C data extends up to about 340Å.

Region 2.—A level region of relative best fit is obtained in the range of 85-40 data points. From the 893°C oxidation data, this region is found to correspond to thicknesses in the range of 340-1100Å. In order that a time-thickness data set yield minimum curve-fitting errors, hence more accurate rate constants, data in the best fit range must be adequately represented.

Region 3.—As the analyzed data subset includes only thickness data greater than about 1100Å, the curve-fitting errors again rise. This is a consequence of including thickness-time data which predominantly represent the diffusional aspect of the kinetic model and is therefore anticipated to occur for the greater film

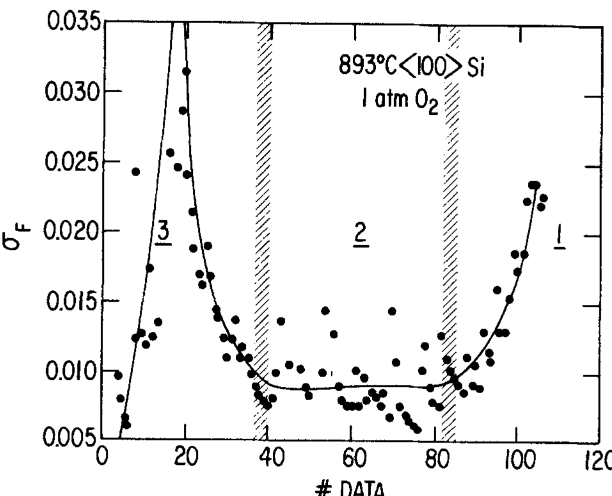

Fig. 2. The error values for the fit, σ_F, vs. the number of data points for the LLS analysis according to method III for the 893°C oxidation data. (The σ_F values near # DATA = 20 rises to a maximum of about 0.060 but were omitted for scaling purposes.)

thickness. If the analysis is continued further to include an even smaller number of data (<10), the errors again decrease to zero for two data points as expected.

From the standard deviation plots and the experimental data, the (d_o,t_o) values are obtained at the position on the standard deviation plots where the errors begin to level. Therefore, the (d_o,t_o) values represent the upper thickness limit for the predominant influence of the initial rapid oxidation regime. The slopes and intercepts which correspond to the (d_o,t_o) values are used to calculate the rate constants. Table III contains the k_{LIN}, k_{PAR}, and d_o values obtained from methods I, II, and III. These constants describe the data with an average precision of about 2% for thickness values greater than the d_o value reported in Table III.

All the error plots show the existence of an initial oxidation regime extending to nearly 400Å which does not conform to linear-parabolic kinetics. Hence method I which pins $d_o = 10Å$, $t_o = 0$ is deemed unacceptable. However, this way of choosing d_o has been utilized to calculate rate constants (2) and, therefore, is considered in this study for comparison. Methods II and III differ only in the equation fitted (Eq. [1] or [2]). Since both equations are of the same form, identical curve-fitting errors were obtained. By comparing Eq. [1] and [2] it is easily shown that the slopes (hence k_{PAR}) should be identical and indeed the measured k_{PAR} values are very close in value. The k_{LIN} values for methods II and III are related by the equation

$$\frac{1}{k_{LIN}(III)} = \frac{1}{k_{LIN}(II)} - \frac{2d_o}{k_{PAR}(II)} \quad [3]$$

Therefore, as shown in Table III, the differences in reported rate constants as large as 300% for a given Si orientation cannot be explained on the basis of the different methods of analysis. Nor can the effect (~25%) of trace amounts of H_2O be responsible for the large reported differences.

To clarify this situation, representative plots of the calculated values for the slopes and intercepts are shown in Fig. 3. It is seen that three rather distinct regions are found analogous to the error plot (Fig. 2). First, as small thickness values are eliminated, the slope and intercept values change rapidly. Then, there is a region in which there is smaller variation in the slope and intercept which corresponds to the best fit region of Fig. 2. Finally, when only data of 1100Å and thicker are considered, a more rapid variation is again

Table III. Rate constants obtained from methods I, II, and III

T (°C)	k_{LIN} (Å/min)	Std dev k_{LIN}	k_{PAR} ($Å^2$/min)	Std dev k_{PAR}	d_o* (Å)	Method
780	0.66	0.007	220	3	75	I
	0.46	0.003	260	5	50	II
	0.56	0.006	265	5	50	III

* The d_o value reported here represents the extent of the initial stage of oxidation which does not fit a purely linear-parabolic regime.

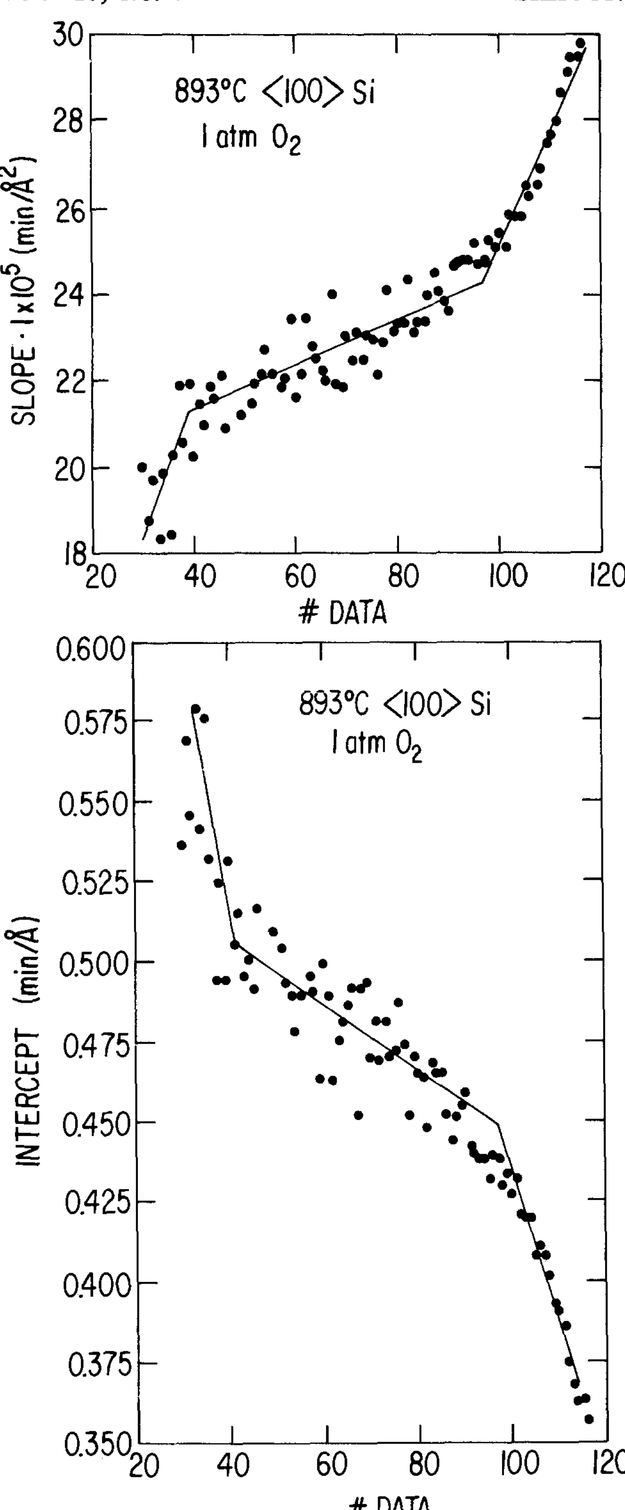

Fig. 3. Values for the slope (top) and intercept (bottom) vs. the number of data points for the LLS analysis according to method III for the 893°C oxidation data.

evidenced. A total variation of up to 50% could be obtained for rate constants calculated using data outside the region of best fit. Within the best fit region about 10% variation could be obtained and this variation could possibly be accounted for by modifying the Deal and Grove (1) derivation to include such effects as the moving Si-SiO_2 boundary, possible ionic oxidant species, SiO_2 film porosity, and chemisorption. Further theoretical and experimental studies are required to test these modifications.

Therefore, rather than a single source of error being responsible for the large variation of the reported rate constants, it is concluded that a combination of errors such as those resulting from trace H_2O (~25%), from the form of the linear-parabolic equation (~25%), from data not adequately representing the best fit regime (~50%), and from insufficient data [previous studies (1-5) utilized about ten data points for curve fitting] could account for the large variations in the literature.

Considering that the above-mentioned sources of error are minimized in the present study and permitting 10% error in the rate constants due to the variation of the rate constants in the best fit regime, it would be useful to examine the additional kinetic information obtainable from this analysis.

Activation energies, E_a, and preexponential factors, k_o, calculated according to an Arrhenius equation of the form

$$k = k_o e^{-E_a/RT} \quad [4]$$

are shown in Table IV. (There is an estimated 10% uncertainty in both these values.) The values are not very different for the three methods and this suggests that the trends in the kinetic data can be represented by any of the methods. Previously reported data (5) showing the effects of trace amounts of H_2O in oxidation were recalculated according to method III [originally method I was used (5)]. A sample of the results is shown in Table V. The agreement with the present analysis is reasonable in view of the sources of potentially large errors discussed above, especially that only ten data points were used in the previous study (5). Moreover, all the trends previously reported (5) were confirmed.

From Table IV the activation energy of 1.5 eV for the linear rate constant, $E_{a,LIN}$, corresponds to the reaction at the Si-SiO_2 interface. This value correlates more closely with the 0-0 bond energy of 1.44 eV (9) than, as previously reported (1, 5), with the Si-Si bond energy of 1.8 eV (9). The $E_{a,PAR}$ value of 2.3 eV is larger than either reported values of 1.4 eV for <111> Si (1) and 2.0 eV and 1.7 eV for <100> and <111> Si (5), respectively. This larger value for $E_{a,PAR}$ does not correlate well with the 1.2 eV reported for the activation energy for the diffusion of oxygen through fused silica (10). Based on the diffusivity of oxygen in SiO_2 (10) and the kinetic data in this study, the concentration of oxygen in the SiO_2 films at 1000°C was calculated to be about 20% less than the values previously reported (1).

The above findings do not negate the utility of the simple model proposed by Deal and Grove (1). For oxidation resulting in film thickness of 300Å and thicker, the rate constants will predict the final film thickness with 10% accuracy. However, the model does not include other mechanisms (previously listed) which when considered could further increase the accuracy of the formulation. Therefore, the linear-parabolic model should be treated as a reasonably good approximation for the oxidation of Si from about 300Å SiO_2 upwards. Further studies are in progress to cor-

rect the model, to investigate the thickness regime below 300Å, and to more accurately define the effects of trace impurities in the oxidant.

Conclusions

The data and analysis of this study confirm that mixed linear-parabolic kinetics enable a reasonably accurate representation of the oxidation data provided that there is sufficient data in the proper thickness range. The initially rapid regime of oxidation is identified.

While the three methods of data analysis yield approximately equal representations of the experimental data, one of these methods, method III, is directly related to a physical model and therefore recommended. The large variation of published rate data cannot be attributed to a single cause but rather, is due to a lack of sufficient data for accurate curve fitting, data in inappropriate thickness ranges, and trace impurity effects.

The sensitivity of the iterative LLS analysis with the abundance of reliable oxidation data from the automated ellipsometer has shown that the simple rate law proposed by Deal and Grove (1) requires modification in order to provide rate constants with better than 10% accuracy.

Ce^{3+}-Activated Photoluminescence in the BaO-SrO-SiO_2 System

I. Crystalline Phases

P. Victor Kelsey, Jr. and Jesse J. Brown, Jr.

Division of Minerals Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

All single phase regions (compounds and solid solutions) in the BaO-SrO-SiO_2 system were activated with 0.01 mole percent (m/o) Ce^{3+} (with equimolar amounts of Li^+, Na^+, or K^+ added to compensate charges) and the resulting ultraviolet excitation and emission spectra were characterized. Brightest phosphors were obtained from the solid solution phases in the $BaSiO_3$-$SrSiO_3$ and Ba_2SiO_4-Sr_2SiO_4 systems at the approximate compositions of $(Ba_{0.8}, Sr_{0.6}) SiO_3:Ce^{3+}, K^+$ and $(Ba_{0.2}, Sr_{0.8})_2SiO_4:Ce^{3+}, Li^+$, respectively. All phosphors exhibit a peak emission wavelength at approximately 390 nm with slight variations resulting from compositional changes.

It is well established that most Ce^{3+} activated phosphors emit in the 300-500 nm spectral range (ultraviolet to blue green) and that their luminescent decays are fast. These two characteristics make this class of phosphors especially attractive as materials for applications in fast response optical conversion systems such as flying-spot-scanners. In addition, Ce^{3+} is a relatively large activator (1.03Å ionic radius) and substitutes easily in solids for other large ions such as Ba^{2+}, Sr^{2+}, and rare earth ions. The resulting phosphors with their large mass absorption coefficients and fast decay times must be considered potential x-ray excited phosphors for use in real-time radiographic systems.

In the present investigations, crystalline phases in the SrO-BaO-SiO_2 ternary system are activated by Ce^{3+} and the resulting u.v. luminescence examined. In a subsequent study, the x-ray excited emission characteristics will be described.

Key words: Ce^{3+} photoluminescence, phosphors, barium silicates, strontium silicates.

Related Literature

The Ce^{3+} ion has only one electron in the 4f orbital which is raised to a 5d level when the ion is excited. The resulting 5d-4f emission is often located in the near u.v. region of the spectrum and is in the form of two broad bands which arise from the doublet ground states ($^2F_{5/2}$ and $^2F_{7/2}$) (1, 2). The unshielded 5d excited state is strongly influenced by the crystal field (3), the strength of which causes variations in the peak emission wavelengths (1), and the symmetry of the crystal field causes d-orbital splittings (4).

Blasse and Bril (1) have examined the excitation and emission spectra of a number of Ce^{3+} activated compounds including $Y_3Al_5O_{12}$, $ScBO_3$, $YAl_3B_4O_{12}$, YPO_4, and others. Frequently, they are able to deduce the site symmetry of the Ce^{3+} ion from the splittings evident in the excitation spectra. On the other hand, the emission spectra generally contain two broad bands (resulting from the two ground states) whose wavelengths are strongly dependent upon the strength of the crystal field. Similar emission spectra have been

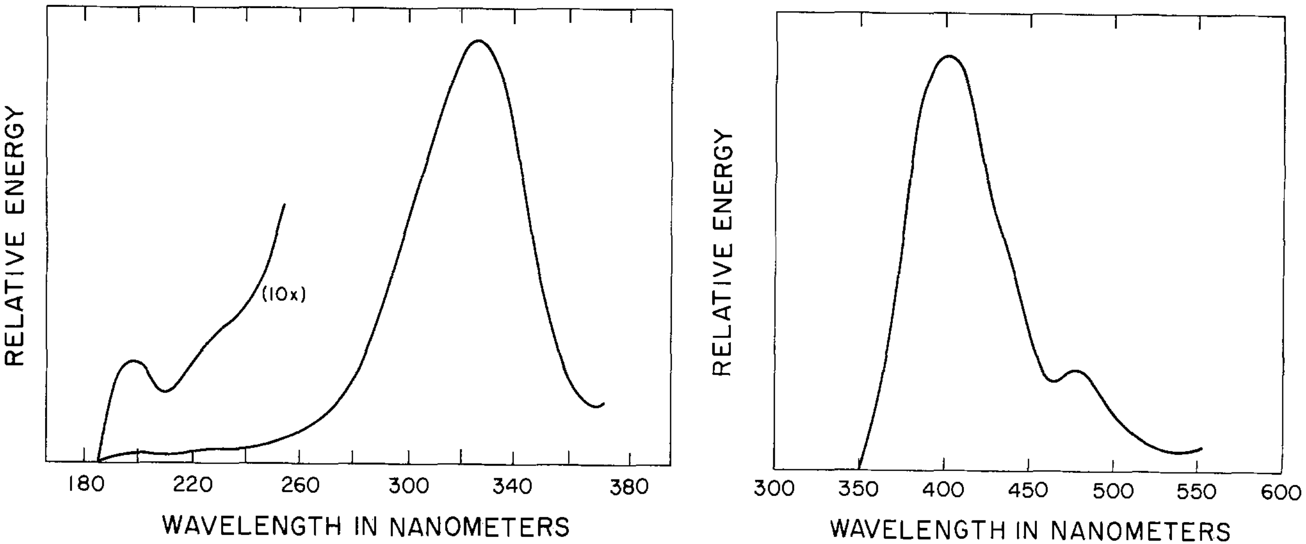

Fig. 1. The excitation (left) and emission (right) spectra of $BaSiO_3:Ce^{3+}$ (no charge compensation)

observed for Ce^{3+} in $Ca_3(PO_4)_2$ (5), alkaline earth sulfides (6-8), and alkaline earth fluorides (9).

Although no data are given with regard to Ce^{3+} luminescence in Ba or Sr silicates, the phase equilibrium relationships in the BaO-SrO-SiO_2 system were recently determined by Fields *et al.* (10). Complete solid solubility exists between Ba_2SiO_4 and Sr_2SiO_4 and limited solubility between $BaSiO_3$ and $SrSiO_3$. In addition, a ternary compound, $BaO \cdot SrO \cdot 3SiO_2$, exists.

Experimental Procedure

All ingredients were weighed to 0.1 mg and were formulated with reagent grade $BaCO_3$, $SrCO_3$, silicic acid, and cerium oxalate. Crystalline samples were fired in air at 1100°C for 2 hr, reground, and then refired at 1100°C for two additional hours. After regrinding, the material was fired under an atmosphere of argon and hydrogen at 1100°C for 4 hr.

The emission spectra were determined using a 200W high pressure mercury lamp and a Heath EU-700 monochromator. The entrance and exit slits of the analyzer spectrometer were set at 200 μm, which gave a spectra resolution of $\lesssim$ 2Å over the wavelength range used. The spectrometers were calibrated for wavelength reproducibility and accuracy using a mercury pen-lamp and correlating the observed spectra with published data for Hg lines.

The excitation spectra were obtained by exciting the sample with a Heath EU-701-50 deuterium light source and focusing the resultant light output into the Heath spectrometer. Because of the need for increased intensity for the second analyzing spectrometer, the slits of the Heath spectrometer were opened to the maximum setting of 2 mm.

All spectra were corrected for photomultiplier response and monochrometer sensitivity where appropriate.

Identification of the crystalline phases present in the reacted samples was made with a Philips x-ray powder diffractometer operating at 40 kV and 15 mA using $CuK\alpha$ nickel filtered radiation. Diffractometer scans used for phase identification were obtained using a scanning rate of $1°$-2θ per minute.

The relative brightness measurements were taken by comparison of relative peak heights of the most intense band of the emission spectra to that of Sylvania Type 212 ($SrMgP_2O_7:Eu^{2+}$).

Results and Discussion

The phosphor compositions examined in this investigation are summarized in Table I. Also tabulated are the phase(s) present in the reacted sample, the percent relative emission peak height, and the excitation and emission peak wavelengths. All phosphors were activated by 0.01 moles of Ce^{3+} substituted for Ba^{2+} and/or Sr^{2+} and, where indicated, Li^+, Na^+, and K^+ were used to compensate for the imbalance of charges resulting from the substitution of a trivalent ion for a divalent ion.

$BaSiO_3$ phosphors.—The excitation and emission spectra of cerium-activated $BaSiO_3$ (not charge compensated) are shown in Fig. 1. The low solubility of

* 100% corresponds to 15% of Sylvania Type 212.

Ce^{3+} in $BaSiO_3$ is reflected in the gray body color and low brightness of the phosphor. The excitation spectrum shows three bands at 190, ~ 230, and 330 nm. The emission spectrum contains the normal Ce^{3+} emission bands which peak at 392 and 475 nm with the latter showing a high wavelength tail up to nearly 550 nm.

The excitation spectra of $BaSiO_3:Ce^{3+}$ phosphors charge compensated by K^+ and Li^+ are shown by curves (a) in Fig. 2 and 3, respectively. These indicate little change in the environment of Ce^{3+} ion as the size of the compensating ion increases. The corresponding emission spectra are shown by curves (a) in Fig. 4 and 5. Most significant is the improvement in brightness that accompanies the increase in size of the compensating ion as shown by Fig. 6. For example, the relative brightness of $BaSiO_3:Ce^{3+}$ is 16% which increases to 33, 41, and 57%, when an equimolar amount of Li^+, Na^+, and K^+, respectively, is added to the phosphor.

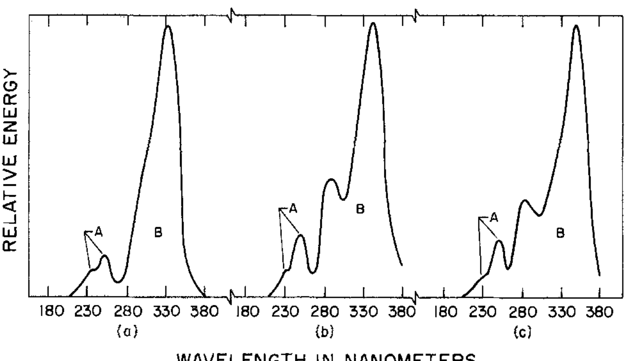

Fig. 2. The excitation spectra of (a) $BaSiO_3:Ce^{3+},K^+$; (b) $(Ba_{0.6},Sr_{0.4})SiO_3:Ce^{3+},K^+$; and (c) $SrSiO_3:Ce^{3+},K^+$.

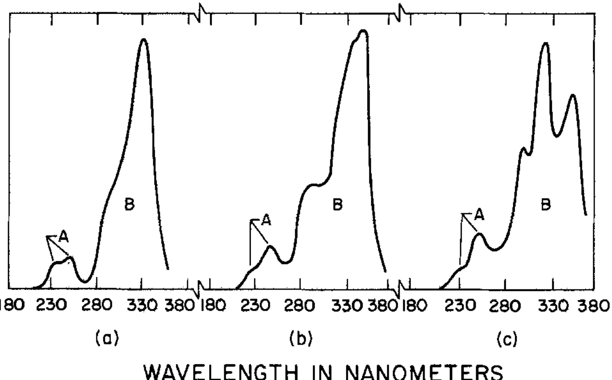

Fig. 3. The excitation spectra of (a) $BaSiO_3:Ce^{3+},Li^+$; (b) $(Ba_{0.6},Sr_{0.4})SiO_3:Ce^{3+},Li^+$; and (c) $SrSiO_3:Ce^{3+},Li^+$.

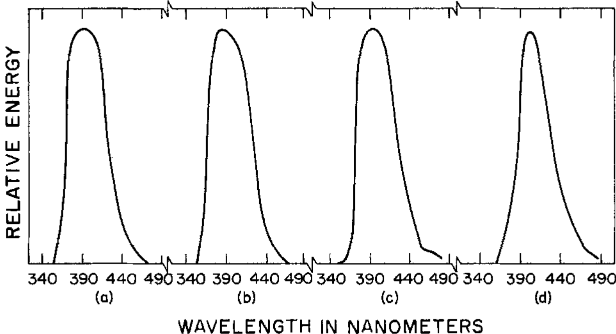

Fig. 4. The emission spectra of K^+ compensated Ce^{3+} activated (a) $BaSiO_3$; (b) $(Ba_{0.8},Sr_{0.2})SiO_3$; (c) $(Ba_{0.6},Sr_{0.4})SiO_3$; and (d) $SrSiO_3$.

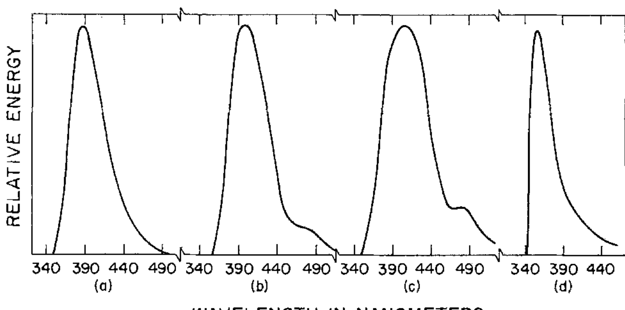

Fig. 5. The emission spectra of Li^+ compensated Ce^{3+} activated (a) $BaSiO_3$; (b) $(Ba_{0.8},Sr_{0.2})SiO_3$; (c) $(Ba_{0.6},Sr_{0.4})SiO_3$; and (d) $SrSiO_3$.

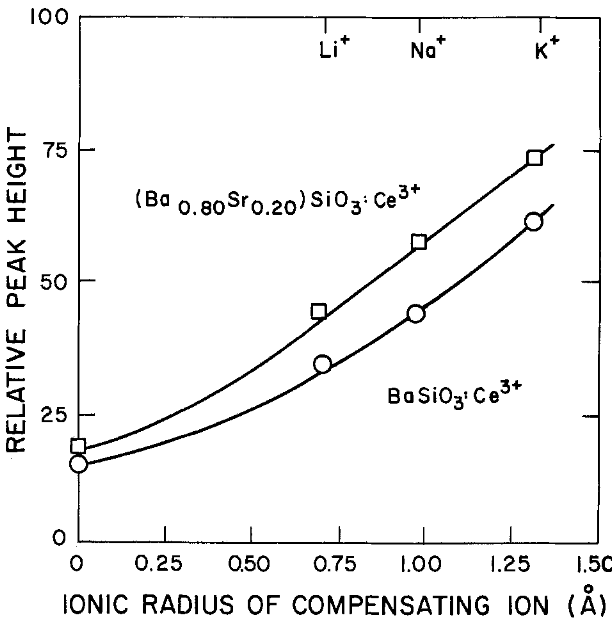

Fig. 6. Variation of phosphor brightness of $BaSiO_3$ and $(Ba_{0.8},Sr_{0.2})SiO_3$ as a function of ionic size of compensating ion.

The visual body color of the charge-compensated phosphors are uniformly white, not discolored like the uncompensated phosphors, and there is an increase in the sharpness of the emission spectra as well as an accompanying increase in peak height. The compensating effect appears to increase as the compensating ion increases in size from Li^+ (0.78Å) to Na^+ (0.98Å) to K^+ (1.33Å). This is not surprising because the K^+ ion is closer in size to Ba^{2+} (1.43Å) than the other two. Because of the improved qualities of the charge-compensated phosphors, all subsequent phosphors prepared in this study were charge compensated.

$BaSiO_3$-$SrSiO_3$ phosphors.—The $BaSiO_3$-$SrSiO_3$ system contains two regions of limited solid solubility at both extremities of the system (10). Phosphors were prepared at 10 m/o intervals across both these solid solution regions.

The excitation spectra of the K^+ and Li^+ charge-compensated phosphors are shown in Fig. 2 and 3. Characteristically, these phosphors show a high energy excitation band (A) at ~ 235-250 nm and a low energy excitation band (B) at ~ 290-345 nm. The first doublet (A) appears to be composition independent whereas the second doublet (B) was found to vary in position in accordance with the host composition and the compensating ion.

The excitation spectrum for Li^+ compensated $SrSiO_3$ solid solution phosphors appears to be somewhat

unique. Excitation band (B) very distinctly splits into three components. While the components of the high energy band (A) are stationary at 235 and 250 nm across the solid solution region, the low energy band is split into three distinct components at 300, 318, and 350 nm for $(Ba_{0.2}, Sr_{0.8})SiO_3$. The two low energy components of this triplet are shifted to higher wavelengths as $SrSiO_3$ is added into solid solution, with the $SrSiO_3$ end member having three distinct excitation bands at 300, 320, and 353 nm.

With the exception of the $(Sr_{1-x}, Ba_x)SiO_3:Ce^{3+}$, Li^+ ($0 \leq x \leq 0.2$) phosphors, the most intense excitation peak for all compositions is the lowest energy level (or highest wavelength peak). The most intense excitation band for this series of phosphors is the second highest energy band, as indicated by curve (c) in Fig. 3.

The emission spectra of the Na^+ and K^+ compensated phosphors are very similar. Typical emission spectra, as shown in Fig. 4 for $BaSiO_3:Ce^{3+}$, K^+, consist of strong bands at about 390 nm. Additions of $SrSiO_3$ into solid solution generally produce shifts of this emission band to higher wavelengths. The doublet ground state of the Ce^{3+} ion is evidenced in the emission spectra by the appearance of a second, rather weak band at about 480 nm. Generally, the emission peak wavelengths for Na^+ compensated phosphors are slightly lower (3-5 nm) than for phosphors compensated with K^+. Weak unidentified emission bands for the $(Sr_{0.8}, Ba_{0.2})SiO_3:Ce^{3+}$, Na^+ and $SrSiO_3:Ce^{3+}$, Na^+ phosphors are observed at 435 and 366 nm, respectively.

The variation of peak emission wavelength with composition for Ce^{3+} activated $BaSiO_3$-$SrSiO_3$ phosphors is shown in Fig. 7. Generally, there is a small increase in peak emission wavelength as the strontium content increases. Again, the Li^+ compensated $SrSiO_3$: Ce^{3+} phosphors are unusual in that their peak emission wavelengths are unusually low.

In interpreting the excitation spectra of the Ce^{3+} activated phosphors, it is reasonable to assume that the character of the spectra is a result of electronic transitions from the ground state of the Ce^{3+} ion to excited states. The presence of multiple excitation bands which change with compensating ion is indicative of electronic transition within the activator ion.

The site symmetry of the Ce^{3+} ion, as indicated by the excitation spectra for all phosphors on the $BaSiO_3$-$SrSiO_3$ binary regardless of the charge compensator, appears to be low. The degeneracy appears to be nearly removed for K^+ and Na^+ compensated phosphors as indicated by four excitation bands, and is totally removed for Li^+ compensated phosphors as indicated by the existence of five distinct bands.

The higher energy emission peaks of the $(Sr_{1-x}, Ba_x)SiO_3:Ce^{3+}$, Li^+ phosphors indicate a photoemission process that proceeds from the second lowest excitation level (Fig. 4d) to the ground state.

Ba_2SiO_4-Sr_2SiO_4 phosphors.—Phosphors within the Ba_2SiO_4-$SrSiO_4$ binary, which exhibits complete solubility across the entire join at high temperatures (10), were prepared at 20 m/o intervals.

The body color of the Na^+ and K^+ compensated phosphors is off-white on the strontium-rich side of $(Ba_{0.8}, Sr_{0.2})_2SiO_4$. These compounds were nearly inert under u.v. excitation because of the reabsorption of emitted light.

The excitation spectra of $(Ba_{1-x}, Sr_x)_2SiO_4:Ce^{3+}, Li^+$ and $(Ba_{1-x}, Sr_x)SiO_3:Ce^{3+}$ phosphors are very similar to those previously discussed. An upper energy doublet at 230 and 250 nm remains stationary for compositions across the entire system. A lower energy doublet, also present in all $(Ba_{1-x}, Sr_x)_2SiO_4:Ce^{3+}, Li^+$ phosphors, broadens as $SrSiO_4$ is added to Ba_2SiO_4 via solid solution. The lowest energy excitation band shifts from 335 nm for Ba_2SiO_4 to 345 nm for Sr_2SiO_4, and the higher energy band of this doublet moves to lower wavelengths with increased Sr_2SiO_4 additions as indicated by the peak wavelength shift from 300 nm (Ba_2SiO_4) to 285 nm (Sr_2SiO_4).

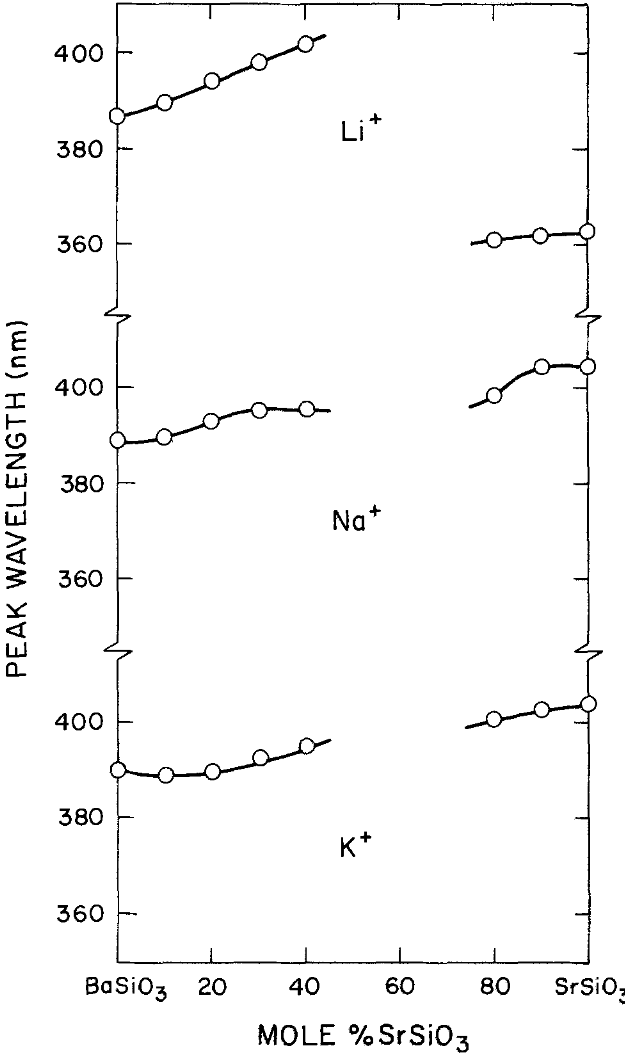

Fig. 7. Variation of peak emission wavelength with composition for Li^+, Na^+ and K^+ charge-compensated $(Ba_{1-x}, Sr_x)SiO_3:Ce^{3+}$ phosphors.

The emission spectra of the Li^+ charge-compensated solid solutions indicate a continuous shift of the principal emission peak wavelength from 384 nm for Ba_2SiO_4 to 399.5 nm for Sr_2SiO_4. A less intense secondary emission band appears at 480 nm for the composition $(Ba_{0.6}, Sr_{0.4})_2SiO_4$ and remains for all compositions up to and including Sr_2SiO_4.

The $(Ba_{1-x}, Sr_x)_2SiO_4:Ce^{3+}, Li^+$ series of phosphors is relatively bright, as indicated in Table I. A considerable improvement in brightness is obtained by solid solution of Sr_2SiO_4 in Ba_2SiO_4 with the relative brightness increasing from 49% for the Ba_2SiO_4 phosphor to 100% for the composition $(Sr_{0.8}, Ba_{0.2})_2SiO_4$. The Sr_2SiO_4 phosphor has a brightness of 91%.

The change of configuration of the low energy doublet observed in the spectra with the addition of Sr_2SiO_4 to Ba_2SiO_4 via solid solution is a result of a similar lattice constriction described for the $(Ba_{1-x}, Sr_x)SiO_3$ phosphors. The constriction forces the lowest energy excitation band to shorter wavelengths which is directly reflected in the emission spectra.

Boron Impurity Profile Tailoring in Silicon by Ion Implantation and Measurement by Glow Discharge Optical Spectroscopy

G. T. Marcyk and B. G. Streetman

Coordinated Science Laboratory and Department of Electrical Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

Glow discharge optical spectroscopy (GDOS) is used to measure distributions of implanted B in Si before and after annealing. Methods for GDOS measurement are discussed, and data are presented indicating the resolution and sensitivity of this technique. Impurity profiles are synthesized by multiple B implantations, and examples of uniform and $x^{-3/2}$ hyperabrupt distributions are presented. Measurements of these profiles with GDOS exhibit excellent agreement with theoretical predictions. Distortion of the B distribution due to diffusion during annealing is less pronounced in the multiple implant profiles than is the case for a single gaussian.

Because of the widespread use of ion implantation in semiconductor device fabrication, there is a strong need for simple and reliable methods for measuring implanted impurity distributions. This is particularly true in applications requiring tailored profiles by multiple implantations (1-3), in which the impurity distribution after annealing is critical to the performance of the device. Various methods for measuring the electrically active impurity profile have been developed, including differential capacitance (4, 5) and successive electrical measurements combined with stripping procedures (6). These measurements suffer from problems of accuracy, particularly when sharp impurity gradients are encountered (7). Techniques for measuring the total impurity profile usually involve sputtering through the implanted layer, while monitoring some property of the impurity of interest. The most widespread methods of this type are the secondary ion mass spectroscopy (SIMS) (8) and the Auger electron spectroscopy (AES) (9) techniques. Each of these methods has been successful in monitoring certain impurities (10), although the SIMS and AES systems require rather elaborate equipment (11). In 1974 Greene *et al.* (12) reported the application of glow discharge optical spectroscopy (GDOS) to this problem. This approach is particularly attractive because of its simplicity, accuracy, and versatility. A number of improvements have been made in the application of the GDOS technique to semiconductor impurity profiling, as demonstrated by the measured profiles of implanted boron in silicon discussed here.

The GDOS System

Greene and Whelan (13) first proposed GDOS as a method for analyzing thin films. This technique has since then been used to measure the composition of bulk samples (14) and to profile diffused and implanted impurities in Si (12, 15). In GDOS, a sample is placed on the cathode of a low pressure d-c gas (*e.g.*, Ar) discharge. The sample is slowly eroded by cathode sputtering, the sputtered material leaving primarily as neutral atoms (16). These sputtered neutrals are collisionally excited in the cathode glow region of the discharge and emit light with wavelengths characteristic of the atom. The resulting light intensity at a given wavelength has been shown to be proportional to the concentration of impurities in the sample (15). An impurity profile is obtained by monitoring the intensity of a single emission line as a function of time. The depth scale is determined by an independent measurement of the sputtering rate, which is held constant during the experiment. An absolute impurity concentration calibration can be obtained by measuring the intensity from standard samples during sputtering under identical conditions. The resolution of the GDOS system is determined by the sputtering rate, which can be conveniently held to ~500 Å/min for typical semiconductor targets.

Experimental Procedure

A schematic diagram of the GDOS system used in this experiment is shown in Fig. 1. The discharge chamber is a 4½ in. diam glass cylinder with a fused quartz window mounted perpendicular to the sample and positioned to receive light from the cathode glow region of the discharge. The copper electrodes are water cooled, and their separation is adjustable by a bellows on the anode. The edge region of the cathode is protected by a Pyrex glass shield (Fig. 2). The 1 cm^2 sample is mounted with silver conducting paint onto a larger (1.5 in. diam) backing plate which covers that portion of the cathode not shielded by the glass. For these experiments the backing plate is n-type Si with a negligible B concentration. The use of such a backing plate prevents sputtering of the cathode material, which may contain trace contaminants of the

Key words: boron implantation. ion implantation, silicon doping, impurity profiling.

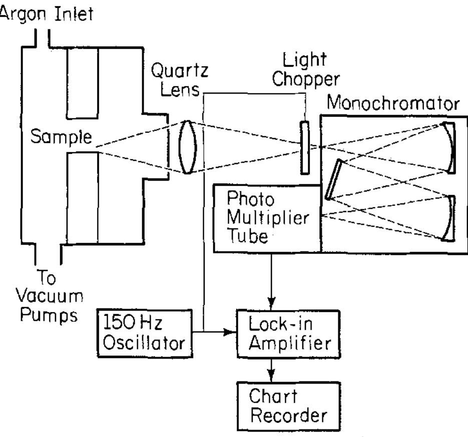

Fig. 1. Schematic diagram of the GDOS system

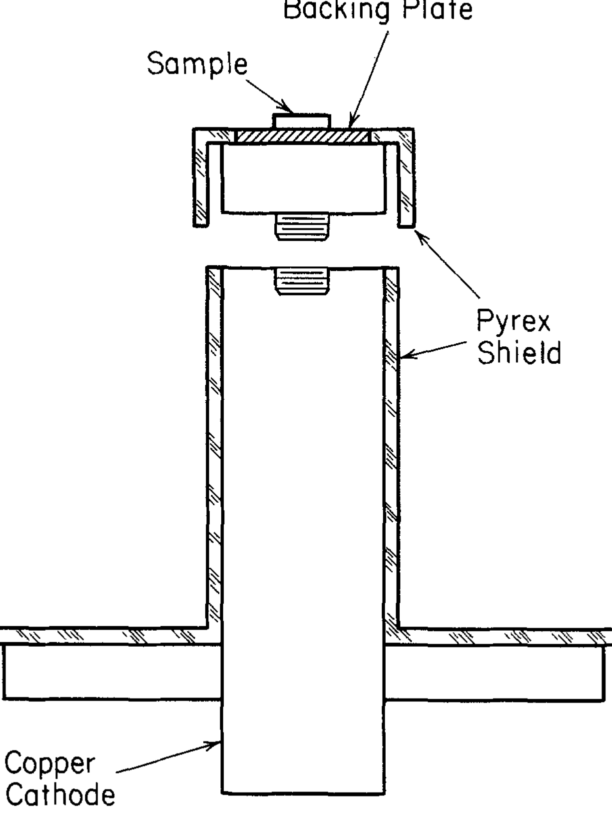

Fig. 2. Cathode assembly with detachable sample holder and backing plate.

impurity being studied. The area of the backing plate should be several times that of the sample centered upon it, to avoid nonuniform sputtering near the edge of the cathode by placing the sample in a more uniform field region of the discharge.

Before each measurement the system is evacuated to below 10^{-5} Torr and is then backfilled with high purity Ar to the desired pressure. Argon is constantly flowed through the system during sputtering, and once stabilized the pressure can be held constant over long periods. In these experiments, pressures are chosen in the range 10-25μ and held constant to within 1μ, as measured by a thermocouple gauge. With such Ar pressures and an applied voltage of 3 kV, the sputtering rate is ~500 Å/min.

Light from the cathode region passes through the window and is collected by a quartz lens. A ¾m monochromator containing a 102 × 102 mm grating with 1200 lines/mm blazed at 3000Å is used to resolve the emission. In measuring B profiles we monitor the strong 2497.7Å line of the boron spectrum (17). Typical slit widths used in this experiment range from 50-100μ. The intensity of the monitored line is detected by a u.v.-sensitive photomultiplier tube, and the output is analyzed by either a lock-in amplifier or a photon counting system, depending on the sensitivity required. The resulting plot of intensity *vs.* time is converted to impurity concentration *vs.* distance by appropriate calibration. The intensity scale is calibrated using Si samples of known uniform B concentration, and the sputtering rate is calibrated by measuring step heights on samples with regions masked by SiO_2 and sputtered for various times at a given voltage and pressure.

The sputtering rate can be held constant to within 5% throughout the experiment, as determined by monitoring emission from the host Si atoms. The uniformity of sputtering over the sample surface can be ascertained from the abrupt disappearance during sputtering of a thin deposited film. For example, a 1000Å Ni film deposited on the Si surface has been sputtered at 100 Å/min while monitoring a dominant Ni line. The Ni emission goes from full intensity to the zero level in less than 1 min at the Ni-Si interface. This corresponds to an interface uncertainty of less than 100Å. The appearance of Si emission occurs over the same time period, as the metal-semiconductor interface is sputtered. This experiment indicates very little nonuniform sputtering, which would result in a much more diffuse transition across the interface.

One problem encountered in GDOS (15) is exact determination of the surface location, in view of the fact that initiation of the discharge results in uncalibrated sputtering until steady state is reached (about 1 min) (18). This problem can be overcome by depositing a metal film of known thickness over the surface and sputtering through the film and into the semiconductor at calibrated rates. Using this method, the discharge has reached a steady-state condition before the Si surface is encountered.

Measurement of Implanted B Profiles in Si

The sensitivity and resolution of the GDOS measurement system for B in Si are illustrated by the experimental results shown in Fig. 3. In this experiment a 4 Ω-cm <111> n-type Si wafer was implanted with $^{11}B^{+}$ ions at 120 keV to a fluence of 10^{15} cm^{-2}. The wafer was tilted 7° from the beam normal to minimize

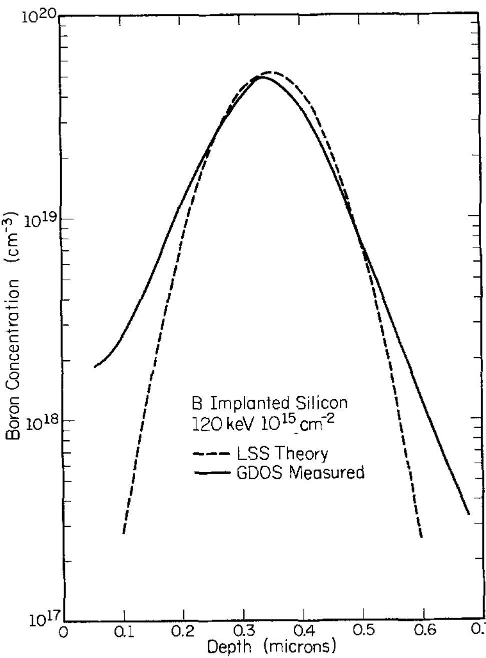

Fig. 3. Implanted boron impurity profile as measured by GDOS, compared to LSS predicted distribution.

channeling. The projected range and straggle of the unannealed B profile as measured by GDOS (Fig. 3) are within ~10% of the values predicted by the LSS theory using corrected cross sections (19). This allows us to use a gaussian approximation for the boron distributions in the subsequent profile tailoring. Some deviation from the actual distribution may be due in part to a slightly slower sputtering rate within the unannealed implanted region. In addition, departures from the gaussian approximation are expected, based on other experiments (10). By monitoring the Si line during sputtering of similarly damaged layers, we estimate that the sputtering rate is constant to within 10% throughout the unannealed implanted region. Figure 3 demonstrates the lower limit of detection for B using the present experimental setup and photon counting. Boron concentrations as low as 3×10^{17} cm^{-3} can be reliably measured.

Three identical samples were implanted at 240 keV to a fluence of 10^{15} cm^{-3} to study the effects of annealing on the B profile. One sample was measured unannealed, and the remaining two were annealed for 30 min in an Ar atmosphere, one at 600°C and the other at 900°C. The measured profiles (Fig. 4) illustrate diffusion during the higher temperature anneal. The unannealed and 600°C annealed samples exhibit essentially identical profiles. However, the straggle of the distribution after 900°C annealing has increased by about 30%. This degree of diffusion is typical for single gaussians annealed at this temperature (20).

Of particular interest in many semiconductor device applications is the use of implantation to achieve tailored profiles. Using a computer program incorporating on optimization routine which assumes gaussian profiles to determine parameters for multiple implants (21), we have synthesized two particularly useful profiles, namely, the uniform and the $x^{-3/2}$ hyperabrupt distributions. Figure 5 illustrates an essentially uniform profile constructed by the summation of four implants. The desired distribution was a constant 10^{19} cm^{-3} concentration from 0.2 to 0.8μ. Of course, a better approximation could be obtained by using more implants. The unannealed profile measured by GDOS (Fig. 5) is extremely close to the computed distribution (dashed curve). The peak of the lowest energy implant is quite low compared with the predicted value, and we believe this is due to an error in fluence rather than the GDOS measurement. The GDOS experimental curves are presented here as obtained from the measurement with previously described calibrations; no curve fitting with the calculated profiles was employed. In view of this, the details of peak positions and separation displayed in Fig. 5 demonstrate the precision of the GDOS measurement.

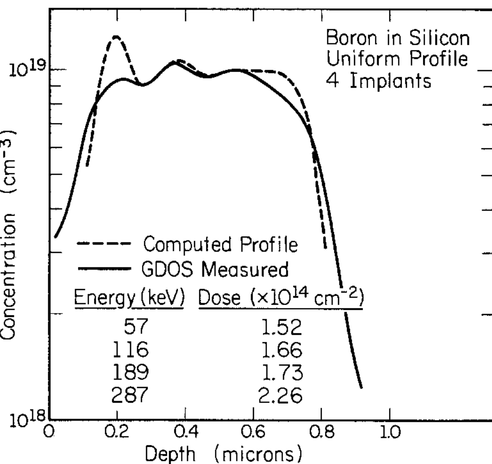

Fig. 5. Comparison of predicted and measured boron profiles for a uniform 10^{19} cm^{-3} distribution synthesized by four implants.

An impurity distribution of particular interest for varactor fabrication is the hyperabrupt profile with $x^{-3/2}$ dependence (22, 23). If such a distribution is used in the more lightly doped side of a junction, the reverse bias capacitance varies as V^{-2} (24). When this device is placed in an L-C resonant circuit, the resonant frequency varies linearly with the voltage applied across the diode. Although such a varactor has interesting applications, the close profile control is difficult to achieve. As illustrated in Fig. 6, the $x^{-3/2}$ dependence can be synthesized over a limited range by successive implantations. The computer simulation using four implants places the highest concentration 0.1 μm below the surface. In varactor fabrication this initial layer could be doped n$^+$ to form the hyperabrupt junction. Alternatively, the 0.1 μm surface layer could be removed by etching (or the implants could be per-

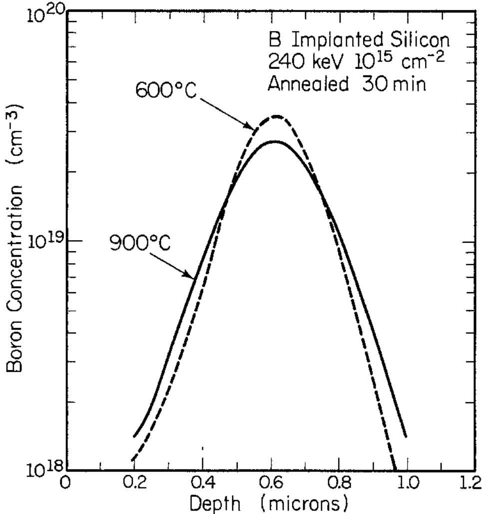

Fig. 4. Measured distribution of implanted boron after annealing at 600° and 900°C. The measured profile before annealing is essentially identical to the 600°C curve.

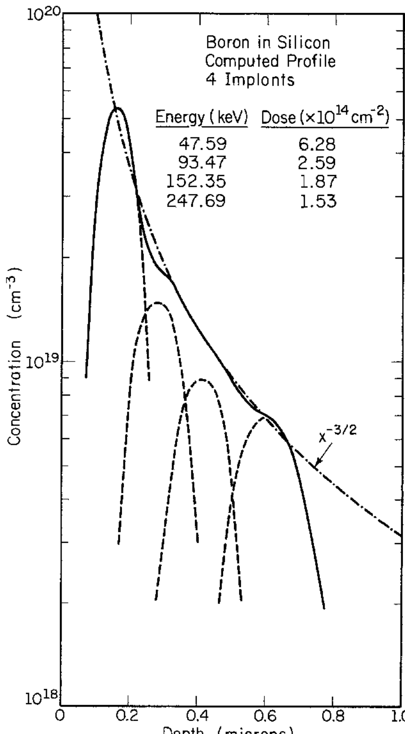

Fig. 6. Sum of four gaussian profiles computed to simulate an $x^{-3/2}$ distribution. Implantation energies produced by the optimization program are rounded off to the nearest keV during the actual implant.

formed through SiO_2 of appropriate thickness) for Schottky barrier varactor fabrication.

The four implants prescribed by the computer simulation were performed in a 4 Ω-cm p-type Si wafer. The resulting profiles as measured by GDOS are shown in Fig. 7. The unannealed sample exhibits a B profile which follows the $x^{-3/2}$ distribution over a considerable range. Of further interest, a 30 min anneal at 900°C does not distort the profile as much as might be expected. Apparently, the reduced gradient of the $x^{-3/2}$ distribution compared with a simple gaussian results in very limited diffusion during the anneal.

Conclusions

In this work we have demonstrated that complex and otherwise unattainable impurity distributions can be obtained by performing appropriate multiple implants. The measured profiles agree well with the computed distributions, even after annealing. The GDOS measurement system is a simple yet accurate method for determining actual profiles of implanted boron in Si. In addition to the results reported here, we have successfully measured implanted As profiles in Si, and Be in GaAs using GDOS. Not all impurities are amenable to the GDOS approach, however. For example, attempts to measure implanted profiles of N in GaP have been unsuccessful, due to a buildup of N concentration in the chamber during the measurement. Application of the GDOS method to specific impurities depends on the tendency for the atom to stick to the vessel walls rather than remaining in the low pressure gas. In addition, the strength of emission lines varies considerably among impurities. For example, an impurity which emits in many lines of comparable strength may provide too little intensity in any one for reasonable detection. Such information must be obtained by experiment (14), since the strength of emission for atoms in the discharge is difficult to predict.

Relationships of the Chemical and Electrical Interfacial Properties of Germanium-SiO_2 Systems

K. L. Wang and P. V. Gray

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

Germanium-silicon dioxide structures were prepared by depositing SiO_2 on cleaned germanium wafers using chemical vapor deposition (CVD) from the silane-oxygen reaction at 450°C. The structures were then annealed in various gas environments, Ar, O_2, and a 10%-H_2 and 90%-N_2 forming gas, at 600°C for 2 hr. For samples annealed in forming gas, the interface state density measured by C-V techniques shows a high density near the band edges ($10^{14}/cm^2$-eV). For samples annealed in oxygen, it decreases to $10^{11}/cm^2$-eV. High surface recombination velocity was observed in the samples annealed in forming gas. The measured results of charge generation and injection indicated charge losses to the interface states but not to oxide traps, whose time constant for trapping is longer than the normal injection time ($1 \sim 10^{-3}$ sec). In order to understand the effects of annealing with different gas environments, profile analyses of the structures were carried out using secondary ion mass spectrometry (SIMS) and Auger electron spectroscopy (AES). For the samples annealed in oxygen, the presence of germanium oxide was identified by observing the low energy Auger spectrum at the interface in comparison with the spectrum obtained for a standard GeO_2 sample. The profile of the germanium spectrum obtained using SIMS can be used to identify the presence of the oxide because of the enhanced secondary ion yield of the oxide. In the case of the forming gas anneal, the hydrogen appears to diffuse into the interface resulting in a high interface state density. The profile of hydrogen concentration for the structures was also obtained. It is concluded that the increase of the interface state density of a germanium-SiO_2 system due to the forming gas anneal appears to result from dissolved hydrogen diffusing through the SiO_2. The reduction of interface state density of the structure annealed in oxygen is probably due to the oxidation of germanium and dissolved hydrogen, which reduces the defects originally present in the interface region following the SiO_2 deposition.

The interface properties of the germanium-insulator system have been a subject of interest for some time. Sedgewick (1) has investigated the C-V behavior of a Ge-SiO_2 system. There the SiO_2 film was deposited by decomposition of tetraethylorthosilicate. The characterization of interface properties of a Ge-silox SiO_2 system has also been reported earlier (2). Recently the passivation of germanium was carried out using several different insulators (3). The interface of a Ge-SiO_2 system appears to have low interface state density. However no systematic study of the interface characterization has been reported. Furthermore, no chemical study of the interface has been done. As is demonstrated later, such a study of its chemical constitution is useful in the understanding of the annealing processes.

It is the purpose of this article to describe the measurement of interface state density for samples annealed in different ambients. Further the investigation of electronic properties of resulting MIS structures such as surface minority carrier generation and field effect mobility are also reported. The relationship between interface chemical composition, as studied by Auger electron spectroscopy (AES) and secondary ion mass spectrometry (SIMS), and the measured interface state density are correlated.

Experimental

Sample preparation.—Germanium/SiO_2 structures were prepared similarly to the procedures described elsewhere (2). The thickness of the SiO_2 films was varied from 30 to 1500Å. The structures having a thin SiO_2 film were used for chemical analyses in order to obtain a high depth resolution, and other structures with a thicker SiO_2 film ($500 \sim 1500$Å) were used for the measurement of interface state density and for other investigations of interfacial properties.

Key words: MOS, MIS, surface state(s), secondary mass spectrometry, dark current, Auger electron spectroscopy, Zerbst plot.

Ge-SiO_2 structures were annealed in various gas ambients (argon, oxygen, a forming gas consisting of 10% H_2 and 90% N_2) at 600°C for 2 hr. After this annealing, an Al, Au, or Mo dot matrix of 2 mm diam dots was evaporated over the SiO_2 surface. The constituents of the interfaces of the structures were then analyzed with Auger electron spectroscopy (AES) and secondary ion mass spectroscopy (SIMS). The interface state density was measured using C-V techniques, and minority carrier generation and field effect mobility were investigated as is described later.

Chemical study using AES.—AES simultaneous with ion sputter-etch was used to analyze the samples. The analysis system used is from Physical Electronics Industries, Inc. The Auger peak energies correspond to the points of maximum negative slope of the energy distribution which is calibrated to the elastic peak. The characterization of the Auger spectrum was carried out, particularly in the low energy spectrum, to investigate the chemical state of the constituents in the interface. The spectrum obtained from a standard, thermally oxidized germanium oxide film (grown at 500°C in oxygen) was compared with another standard spectrum for germanium and the corresponding energies are listed in Table I. For example, a valence state of germanium corresponding to Auger transition of $M_{45}N_{23+2}N_{23+2}$ (2) appears to have shifted from 22.5 to 18 eV when oxidized. In the case of germanium oxide, a new peak at 63 eV appears while the transition at 76 eV corresponding to $L_1L_2L_{45}$ in the germanium spectrum disappears.

Samples which had undergone various annealings were investigated using AES. Some samples were annealed in oxygen at 600°C for 2 hr after a 30Å SiO_2 film was deposited on a Ge substrate. In these the presence of germanium oxide between the deposited SiO_2 film and the Ge substrate was identified by comparing the

AES spectrum with the spectrum of the standard obtained previously. The thickness of the germanium oxide film depends on the annealing ambient, temperature, and time. This can best be demonstrated in the SIMS analyses discussed in the following section.

As is discussed later, the forming gas annealed samples give a much higher interface state density than the samples annealed in argon. On the other hand, SIMS (and also AES) shows a very small difference in the thickness of germanium oxide; it suggests that hydrogen may play an important role at the interface. However since AES does not provide an easily accessible means to identify hydrogen, SIMS, which has high sensitivity and depth resolution, appears as an alternative technique.

Profiling of SiO_2-Ge structures using SIMS.—The instrument used for analyzing the samples is an ion microprobe mass analyzer manufactured by Applied Research Laboratories. Primary ion beams of $^{40}Ar^+$ or $^{32}O_2^+$ were raster-scanned over a small area (10^4 μm^2) to sputter-etch a rather uniform crater. Furthermore, the secondary ion signal was electronically gated in such a fashion that only those secondary ions from the central region of a sputtered crater were detected. This technique of using an electronic aperture greatly enhanced the depth resolution.

The secondary ion yield of a solid substrate depends strongly on the constituent matrix of the substrate and the type of primary ion used (4). In general the positive secondary ion yield increases as the electron availability of a substrate decreases. Thus, in using $^{40}Ar^+$ as primary ions, the positive ion yield is enhanced and controlled by the presence of neighboring electronegative species such as oxygen in a sample. Si and Ge in the form of oxide will have a higher secondary ion yield than in the elemental state. Therefore when a $^{40}Ar^+$ primary ion beam was used, the presence of oxide in the interface showed as a prominent peak. The analyzed results are described in the following.

The profiles of $^{92}GeO^+$, $^{74}Ge^+$, and $^{30}Si^+$ for the identical sample analyzed by AES (annealed in oxygen with a 30Å-SiO_2 film, 100N-3) are shown in Fig. 1. As shown in the figure, the β-current is the current collected in the electrostatic sector analyzer aperture, which is approximately proportional to the total secondary ion current.

The sputter rates of SiO_2 and GeO_2 were calibrated using the known thickness of two standards as determined by ellipsometry and interferometry. The depth of the analyzed sample was then calculated using the simple relation

$$S_c = C_1S_1 + C_2S_2 \quad [1]$$

where S_c = effective sputter rate of the sample; S_1 = sputter rate of SiO_2; S_2 = sputter rate of GeO_2; C_1 and C_2 are fractional molecular concentrations of SiO_2 and GeO_2, respectively.

From Fig. 1, both $^{92}GeO^+$ and $^{74}Ge^+$ profiles indicate a similar distribution of a GeO_2 layer, about 300Å thick. This layer of GeO_2 was grown during the oxygen

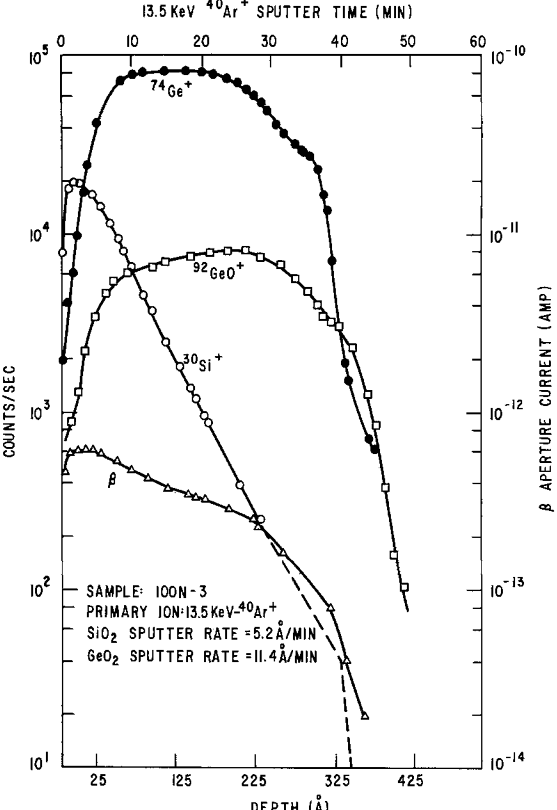

Fig. 1. Profile of $^{30}Si^+$, $^{74}Ge^+$, and $^{92}GeO^+$ for sample 100N-3 annealed in oxygen ambient at 600°C for 2 hr. The depth shown is calculated using the sputter rate obtained from Eq [1]. The β aperture current, also shown is the secondary ion current intercepted at the exit of the electrostatic sectors.

anneal at 600°C. A similar GeO_2 layer was observed for a sample, having a 410Å SiO_2 film following an oxygen anneal.

For samples treated in argon at 600°C for 2 hr, a very small amount of GeO_2 was observed. This is illustrated in the profiles of $^{74}Ge^+$ in Fig. 2. The other profiles of $^{28}Si^+$ and β-current are also illustrated. The thickness of germanium oxide is about 30Å, which is consistent with AES data.

For samples treated in a forming gas ambient (90% N_2; 10% H_2), a C-V study indicates a high interface density. Samples under identical heat-treatment, with a thin SiO_2 film, were analyzed. The profiles of major constituents are illustrated in Fig. 3. The general feature of $^{28}Si^+$, $^{74}Ge^+$, and $^{90}GeO^+$ signals are similar to those for sample 100N-4, previously described. The thickness of GeO_2 appears to be somewhat thinner: about 24Å.

Hydrogen concentration.—Since hydrogen anneal of germanium MIS structures produces a very high interface state density, its concentration profiles were investigated. Due to the presence of a high background H^+ signal, a cold plate near the sample had to be chilled to liquid nitrogen temperature during the profilings. The profile of hydrogen concentration illustrated was normalized to a primary ion current of 5×10^{-9}A. A sample annealed in the oxygen and argon cycle (111N-7) was compared with a sample annealed in forming gas (sample 100N-8). Near the GeO_2/SiO_2-Ge interface the hydrogen concentration of the sample annealed in forming gas is about seven times higher than that of the sample annealed in oxygen and argon. Furthermore, in the latter sample, some of the hydrogen signal may be attributed to the background.

To assure that the profile observed was actually due to hydrogen and not to composition matrix effects due to the presence of electronegative ions, a primary ion beam using oxygen was also employed. Figure 4 shows the high hydrogen concentration of sample 100N-8,

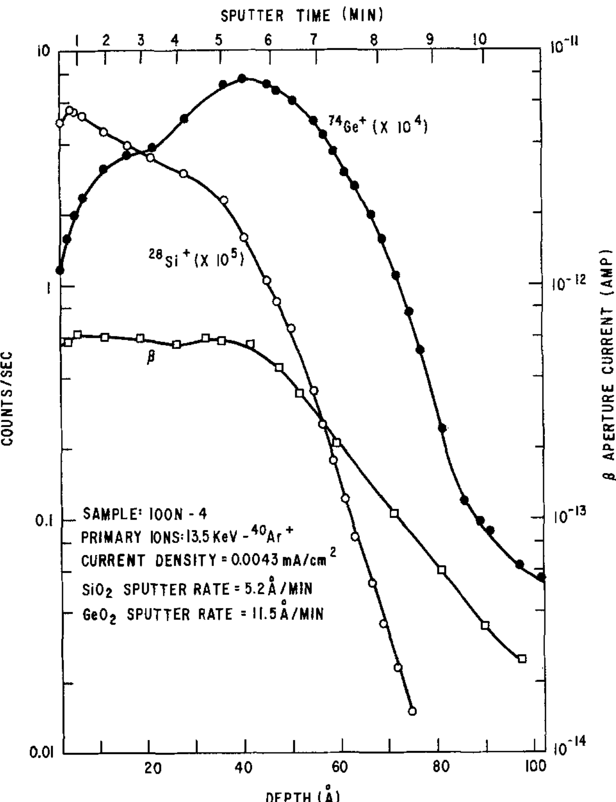

Fig. 2. Profiles of $^{28}Si^+$, $^{74}Ge^+$, and the total secondary ion current (β) for sample 100N-4 annealed in an argon ambient at 600°C for 2 hr. The depth profile shown is also calculated using the sputtering rates obtained from Fig. 1.

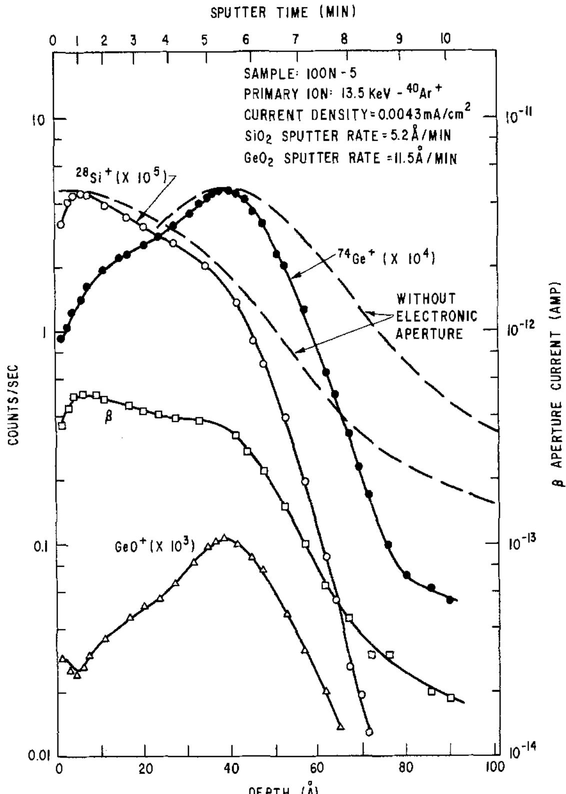

Fig. 3. Profiles of $^{28}Si^+$, $^{74}Ge^+$, $^{90}GeO^+$, and the secondary ion current (β) for sample 100N-5, annealed in forming gas. The profiles of $^{28}Si^+$ and $^{74}Ge^+$ without the use of the electronic aperture is also plotted to illustrate the improvement of resolution by its use.

annealed in forming gas at 600°C for an hour. The hydrogen concentration remains high near the SiO_2-Ge interface

Interface state measurements.—The samples used here were processed identically to those used for the chemical analyses described previously. The thickness of an SiO_2 film used here is about 500-1500Å for convenience in *C-V* and other electrical measurements.

In the *C-V* measurements, all the high frequency MOS differential a-c capacitance measurements were carried out at 1 MHz using a Boonton Electronics 72A capacitance meter. For ohmic contact, Ga-In liquid metal was used on the back of the wafers. Typical *C-V* curves taken at 300° and 77°K are shown in Fig. 5 for samples annealed in oxygen and forming gas, respectively. A significant flatband voltage shift from 300° to 77°K for the forming gas treatment indicates a much higher interface state density. Furthermore at 77°K, the depletion capacitance departs from the theoretically calculated curve, as shown in flat region. This is due to the contributions of interface state capacitance. The interface state density was measured similarly to that described by Gray and Brown (5). The method of measurement is to record the flatband voltage shift while varying the sample temperature from 300° to 78°K. The flatband condition is maintained by holding the flatband capacitance with a feedback amplifier. The shift in flatband bias is a measure of the number of interface states located at the energy between the Fermi levels of incremental temperatures. This is a direct measurement of a majority of interface states located at the upper half of the bandgap for n-type samples; and similarly at the lower half of the bandgap for p-type samples, that is

$$n_{FS} = \frac{dN_{FS}}{dE} = \frac{C_o}{qA}\frac{dV_{FB}}{dT} \Big/ \frac{dE_F}{dT} \quad [2]$$

Since there are electron traps as revealed by hysteresis in the *C-V* curves, it is difficult to estimate exactly

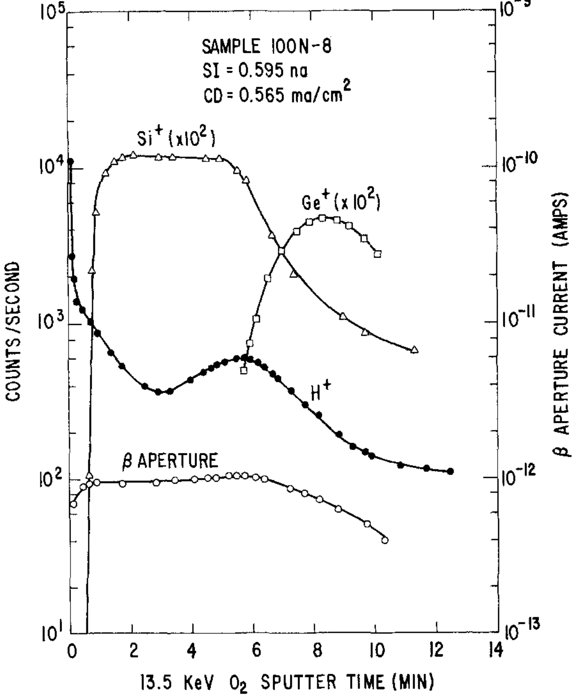

Fig. 4. The profile of H^+ for sample 100N-8 using a 13.5 keV $^{32}O_2{}^+$ beam. The sample has a 340Å SiO_2 film and was annealed in forming gas at 600°C for 2 hr. A peak of hydrogen concentration near the interface is shown. The sputter rate is about 51 Å/min. Si^+, Ge^+, and the β aperture current are also plotted.

the shift of the flatband potential due to the fast states. This is also true for the use of other *C-V* techniques. Therefore, there is a certain amount of uncertainty in measuring the fast state density. Further, the interface

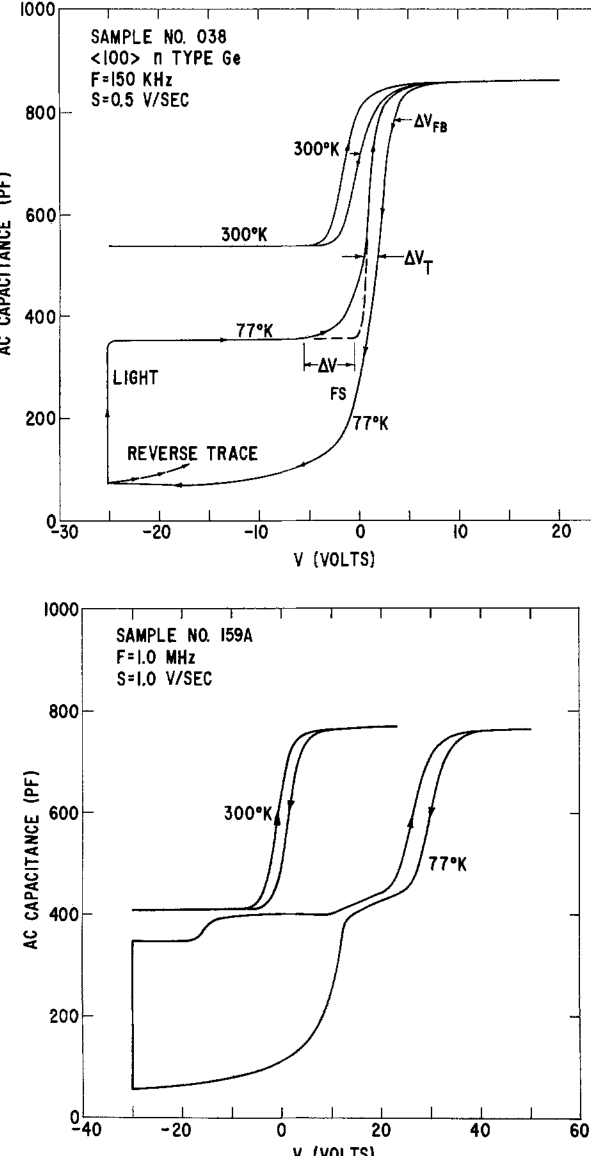

Fig. 5. Typical C-V curves (a, top) at 300° and 77°K; for samples annealed in oxygen; (b, bottom) for samples annealed in forming gas.

state density induced by the forming gas anneal is so high that it always contributes to the capacitance values, particularly near room temperature. Thus the precise density of states cannot be determined in this case.

The interface state densities for several samples under different annealing conditions, shown in Fig. 6 were obtained using Eq. [2] by numerically differentiating the ΔV_{FB}-T curves. Samples annealed both in oxygen and forming gas environments show a similar distribution increasing toward the band edge. The forming gas annealed samples have much higher interface state densities ($10^{14}/cm^2$) than those annealed in oxygen. The reduction of the states, when annealed in oxygen, can be attributed to the growth of GeO_2 between the SiO_2-Ge interface as discussed previously.

Some 77°K curves show a well-defined region ("ledge") of nearly constant capacitance above the inversion capacitance of the reverse trace (ΔV_{FS}). The length of this region is also a measure of the interface state density (6). Therefore, the total interface state density can be estimated from either

$$N_{FS} \cong \Delta V_{FS}\, C_o/e$$

or

$$N_{FS} \cong 2\Delta V_{FB}\, C_o/e \quad [3]$$

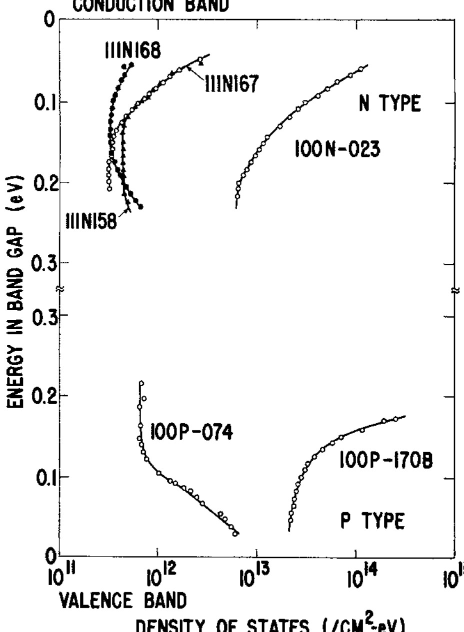

Fig. 6. Interface state densities for samples annealed in oxygen ambient (samples 74, 167, 168, and 158) in forming gas (sample 23), and with Ni contamination (sample 170B).

The results are in agreement with the previous measurements of the shift of flatband voltage with temperature.

Measurement of minority carrier generation using the capacitance vs. time technique.—When a MIS structure is biased to deep depletion, minority carriers will gradually accumulate at the SiO_2-Ge interface to invert the surface as a result of electron-hole pair generation. The time required for a MIS device to invert from depletion without external excitation is defined here as the recovery time or the storage time. For an n-type substrate, the generation rate of holes per unit area may be written (7-11)

$$\frac{dP_s}{dt} = G_d + G_s + G_b + G_e \quad [4]$$

where G_d is the generation rate in the space charge region (or the depletion region), G_s is the surface generation, G_b is the bulk generation outside the space charge region, and G_e is external excitation, such as optical generation.

Assuming the capture cross sections for electrons and holes are comparable, the minority carrier generation in the depletion region ($n_p << n_i$) may be expressed simply as (7)

$$G_d = \frac{n_i}{\tau_b}(w - w_f) \quad [5]$$

where w and w_f are the depletion and inversion widths, respectively; n_i is the intrinsic carrier concentration. and τ_b is the bulk lifetime. Similarly, the generation due to interface states can be written as (7, 10)

$$G_s = n_i S \quad [6]$$

where S is the surface recombination velocity. Minority carriers originating from electron-hole pairs generated outside the space charge region may diffuse into the depletion region and be swept by the field toward the interface. This generation rate may be obtained (12) by using the diffusion equation and bulk generation rate to give

$$G_b = \frac{n_i^2}{N_b}\left(\frac{D_p}{\tau_b}\right)^{1/2} \quad [7]$$

By substituting each generation component into Eq. [4] and expressing it in terms of capacitance, one obtains

$$-\frac{N_D\epsilon_s}{2C_{ox}}\left[\frac{d}{dt}\frac{C_{ox}}{C}\right]^2 = \frac{n_i}{\tau_b}\epsilon_s\left(\frac{1}{C}-\frac{1}{C_f}\right) + Sn_i + \frac{n_i}{N_D}\left(\frac{D_p}{\tau_b}\right)^{1/2} \quad [8]$$

To investigate the physical parameters controlling the generation and recombination in a MIS structure, a pulsed C-V technique is used. Square-wave pulses were applied to MIS devices and capacitance *vs.* time (C-t) curves were observed on an oscilloscope. The sample temperature was varied in a cryostat. The C-t curves for various interface state densities (10^{11}/cm²-eV and 10^{14}/cm²-eV) were taken, and then the recovery time from deep depletion to inversion was plotted *vs.* $1/T$ as shown in Fig. 7.

The storage time *vs.* $1/T$ plot shows a slope of 0.668 eV at 250°K for sample 100N-037 which has a low interface state density similar to samples 167 and 168 shown in Fig. 6. (These samples had been heat-treated in wet oxygen at 600°C for 2 hr and subsequently in dry air at 350°C for 18 hr.) This slope is close to the bandgap $E_g = 0.684$ eV at this temperature, indicating that the generation and recombination are dominated by a bulk phenomenon. Most of the minority carriers reaching the interface come from outside the space charge region through the carrier diffusion process. If one assumes that bulk generation dominates Eq. [4], then Eq. [5] reduces to

$$\frac{d}{dt}\left(\frac{C}{C_{ox}}\right) = \left(\frac{C}{C_{ox}}\right)^3\left(\frac{n_i}{n_D}\right)^2\frac{\epsilon_{ox}}{\epsilon_x}\frac{1}{t_{ox}}\left(\frac{D_p}{\tau_b}\right)^{1/2} \quad [9]$$

The plot of

$$\frac{d}{dt}\left(\frac{C}{C_{ox}}\right) \; vs. \; \left(\frac{C}{C_{ox}}\right)^3$$

as shown in Fig. 8, is linear. The linearity is a further evidence of bulk generation and also gives D_p/τ_b from the slope of the straight line. Sample 111N-197 was annealed in forming gas at 600°C for 2 hr, and has a high interface state density. The same plot shows a slope of 0.309 eV, which is close to one-half the energy bandgap. It is clear from Eq. [6] that the surface generation due to the interface states would have this dependence.

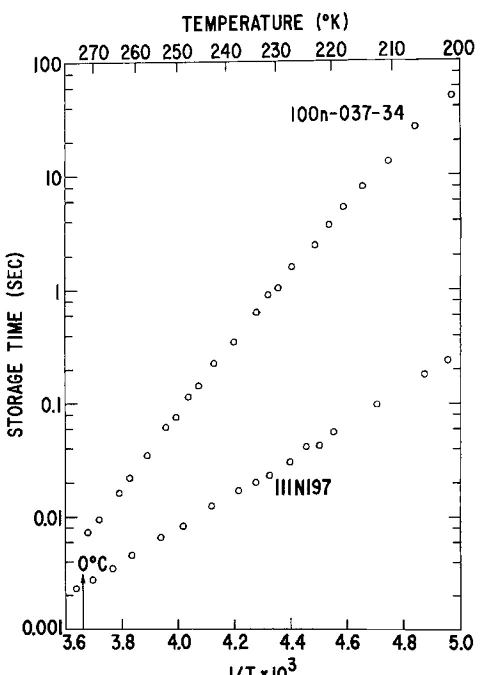

Fig. 7. Recovery time from depletion to inversion for sample annealed in oxygen (sample 37) and for sample annealed in forming gas (sample 197).

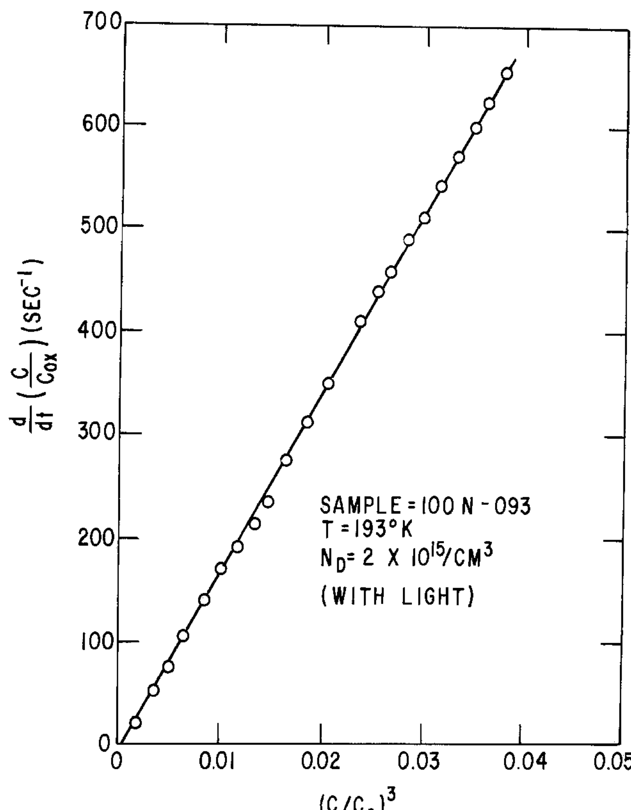

Fig. 8. d/dt (C/C_{ox}) *vs.* $(C/C_{ox})^3$ plot for sample annealed in oxygen. The linearity indicates that bulk generation is dominant when the sample is in the dark.

It should also be noted that as temperature varies, the shapes of the C-t curves in the dark for the same sample change. This change results from the transition of the dominant generation components from a diffusion process to generation in the space charge region and other field-induced processes in the germanium substrate as temperature decreases. At temperatures above 235°K, the linear relationship of

$$\frac{dC/C_o}{dt} \; vs. \; \left(\frac{C}{C_o}\right)^3$$

plots suggest a diffusion process. This implication is demonstrated from the relationship of the storage time and $1/T$, shown in Fig. 7 which is linear above 235°K. The change in slope at about 235°K can be related to the temperature dependence of the reverse current in a p-n junction (12). For the temperature region between 300° and 230°K, the minority carriers are generated in the bulk and arrive at the surface via the diffusion process. Particularly for the samples annealed in oxygen, the generation due to the low interface state density near the midgap does not constitute a significant contribution (13). This is demonstrated in the previous section in the dependence of the recovery time on temperature as $\exp(-Eg/kT)$ and the linear relationship of dC/dt and C^3.

Channel mobility measurements.—Germanium IGFET's were fabricated using a process similar to that of silicon RMOS as described elsewhere (2). The channel mobility of samples annealed in forming gas (IGFET 111N577) is much lower than the sample annealed in oxygen (IGFET 111N-563) as illustrated in Fig. 9: The channel mobility of IGFET 563 increased from 280 cm²/V-sec to 550 cm²/V-sec as the temperature decreased from 300°K to 78°K. This increase in channel mobility reflects the decrease of lattice scattering at lower temperature. On the other hand, the

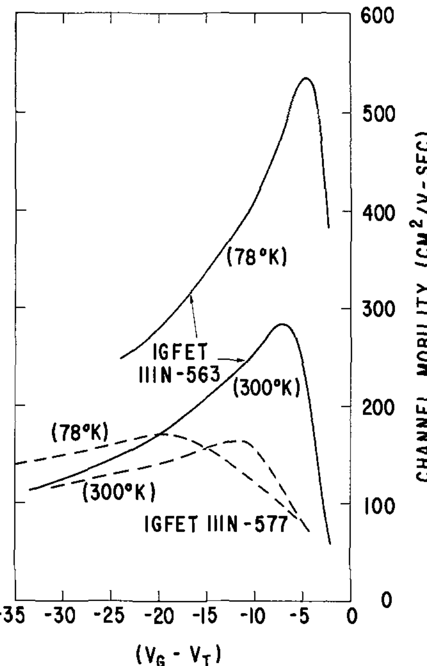

Fig. 9. Channel mobilities for FET's which were processed with oxygen annealing (sample 563) and processed with forming gas annealing (sample 577).

channel mobility of IGFET 577, annealed in forming gas, does not show a significant increase as temperature decreases indicating surface charge scattering. In fact when the surface field is low (near the turn-on voltage) in a weak inversion condition, the channel mobility at 78°K is somewhat lower than that at 300°K. This is due to the increasing occupation of the acceptor states (negatively charged when occupied) induced by the forming gas anneal as Fermi level moves close to the conduction band when the temperature decreases. Thus the coulomb scattering due to these surface charges increases and the mobility thereby is reduced.

Discussion

The electrical measurements of interface state properties by C-*V* and capacitance recovery time are consistent with the measured density of states. The results indicate that interface states are induced by hydrogen. Dissolved hydrogen in germanium has no known electrical activity. Recently in work on high purity germanium detectors, Armantrout *et al.* (14) observed degradation of the detector, *i.e.,* increase in reverse leakage current from microamperes to milliamperes, for germanium grown in hydrogen and for devices packaged in a hydrogen ambient. The degradation has been shown to be due to the formation of surface states as hydrogen slowly diffuses to the surface. The formation of a p-type inversion layer has also been reported for surfaces with adsorbed hydrogen (15, 16).

From the measured result of interface state properties in the case of the forming gas anneal, it is suggested that the hydrogen-induced states are very localized at the surface. The actual surface bonding has been suggested to be different from covalent for the absorbed hydrogen. Appelbaum and Hamann (17) reported the calculated results of the potential, charge density, and electron energy level structures for a Ge surface using the Hartree Fock self-consistent technique. The electron energy level structure of the germanium <111> surface is similar to that of the silicon surface, having two deep bands of surface states. They suggested that unlike silicon the second surface layer of germanium can participate in a chemisorped bond to form additional surface states, giving a fivefold coordination. A similar coordination may exist at the interface between SiO_2 and Ge. Such a coordination may be responsible for the observed interface states here.

The presence of germanium oxide when annealed in O_2 ambient is established in the AES and SIMS studies. Infrared absorption spectroscopy has also been used to demonstrate the presence of GeO_2 (18). A factor of 4 in reduction of interface state density has been achieved. As a result, an infrared imager of charge injection type (CID) has been fabricated. Schroder (19) has also fabricated charge-coupled devices (CCD). There, the efficiency should improve through the use of O_2 anneal and buried channel approach via ion implant. In this case of germanium MOS systems, the high residual interface state density tends to suggest that the CID approach in imaging has an intrinsic advantage of high efficiency.

Conclusion

The interface properties of germanium-SiO_2 MIS structures following different annealings were investigated. The chemical composition of the interface was analyzed by the use of AES and SIMS. The correlation of these studies, namely the profiles of GeO_2 and H with interface state distribution, suggests that the interface state density can be reduced by annealing the samples in an oxygen ambient to grow GeO_2 and thus eliminate some defects originally present following the CVD deposition of the SiO_2 film. An annealing in forming gas gives rise to a much higher interface state density. The interface states indeed are shown to be responsible for a high surface minority carrier generation in a MIS structure which is depleted initially. This also increases surface charge scattering in the carrier transport process as measured using IGFET's. The hydrogen-induced states are believed to be very localized, for hydrogen has no electrical activity in the bulk germanium. It should also be pointed out that due to the high state density a precise determination of surface potential and therefore the distribution of interface state density is difficult. The use of ion implantation to introduce a controlled amount of hydrogen is being carried out. The results will be reported at a later date.

Effect of Evaporated Dielectric Materials on the Surface of High Purity Germanium

R. J. Dinger

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada K0J 1J0

ABSTRACT

The effect of evaporated dielectrics on real Ge surfaces has been investigated at 80°K. Using high purity Ge ($|N_D - N_A| < 10^{11}$ cm^{-3}), insulated gate field transistors (MISFET) were made and coated with an evaporated dielectric layer. The number of surface states and the density of states per unit energy have been deduced from the forward transconductance. It has been found that some dielectrics introduce a large number of surface states near the center of the bandgap.

The protection of the surface of the active volume of germanium detectors for infrared light, γ-radiation, or particles is a problem which differs in many respects from the surface passivation problem in the silicon transistor or integrated circuit technology. The solutions developed for the latter canot be applied to these Ge devices for a variety of reasons. The main one is that the crystal material must at no stage of the fabrication of the device be heated to more than 300°-350°C (1).

The large size of the Ge detectors (active volume 0.5-100 cm^3) compared to transistors suggests that any electronically disturbed surface layers are such a small fraction of the total volume that their influence on the detection properties is negligible; experiments show that this is not so. Figure 1 shows the reponse of a small (0.5 cm^3) Ge γ-ray detector to the 662 keV γ-rays from a ^{137}Cs source (2). The top spectrum was taken just after the manufacture of the device, the middle spectrum after it had been exposed to oxygen (about 100 Pa · sec), and the lower spectrum after a "bake-out" at room temperature for 30 min (the device is operated at ~80°K). All spectra were taken for the same duration. It is obvious that the effect of the exposure to oxygen was to reduce the area underneath the peak (full energy peak efficiency), which is proportional to the sensitive volume, to about one-third of its original value. The moderate bake-out partly recovered the original performance.

Recent investigations (2, 3) have shown that this degradation is due to the formation of "surface channels." Surface channels were first discovered by Brown (4) and found to be the cause for poor Ge transistor characteristics. The thickness of the surface channels is related to the effective Debye length, L_D (5), which can become as large as 0.3 mm in the very pure material used for Ge detectors.

To protect the surfaces of Ge detectors against the effect of adverse ambient atmospheres, encapsulation techniques have been used with varying success (6, 7). Another method of surface protection consists of stabilizing the position of the Fermi level at the surface by an electronic interaction of the Ge with a suitable

Key words: Ge detectors, surface protection, surface state density.

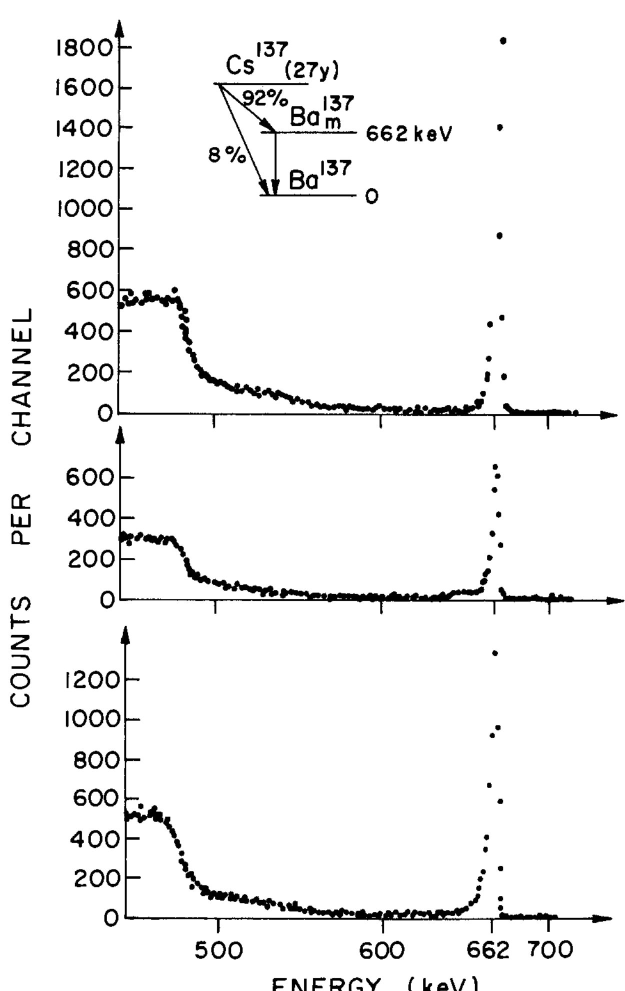

Fig. 1. γ-Ray spectrum of ^{137}Cs taken with a 0.5 cm^3 Ge γ-ray detector. Top = after the manufacture of the device; middle = after exposure to 100 Pa · sec of oxygen; bottom = after bake-out at 300°K in good vacuum [after Ref. (2)].

coating material. This paper deals with the effect of evaporated coatings on real Ge surfaces. Although it is quite clear that an evaporated layer will hardly be comparable to a thermally grown oxide such as SiO_2 with respect to pinholes, included impurities, etc., it has been found that certain dielectrics show an electronic interaction with the underlying Ge which stabilizes the Ge surface by effectively anchoring the Fermi level at a favorable position. The protection mechanism involved is therefore such that a great number of deliberately introduced surface states at an energetically favorable position overcomes the effect of additional states produced by the ambient.

The electronic properties of the Ge surface before and after the evaporation of the coating were investigated using a metal-insulator-semiconductor transistor (MIS transistor) arrangement. Because the devices to be protected with these coatings are normally cooled with liquid nitrogen and operated at ~80°K, all measurements were taken at that temperature.

Theory

The energy band diagram for a p-type semiconductor with an n-type inversion layer is shown in Fig. 2. The occupancy of the surface states at the boundary of the crystal and within the evaporated dielectric is given by the Fermi level. The net surface charge due to the surface states must be compensated for by an equal amount of charge of opposite sign within the bulk of the semiconductor. In Fig. 2 it is assumed that the surface charge due to the surface states is positive which requires the energy bands to be bent downwards. The semiconductor shows an n-type conducting surface channel (inversion layer) of thickness of the order of magnitude of the effective Debye length, L_D, where

$$L_D = \sqrt{\frac{\epsilon_0 \cdot \epsilon_r \cdot kT}{q^2(n_b + p_b)}} \quad [1]$$

and ϵ_0 = permittivity of the vacuum, ϵ_r = relative dielectric constant, k = Boltzmann's constant, T = absolute temperature, q = electronic charge, n_b = concentration of free electrons, and p_b = concentration of free holes in the bulk of the semiconductor.

Under the present experimental conditions, the sum of the concentrations of the free carriers in the bulk may be approximated by the net ionized concentration of dopants N

$$n_b + p_b \approx |N_D - N_A| \equiv N \quad [2]$$

N_D being the concentration of ionized donors and N_A the concentration of ionized acceptors.

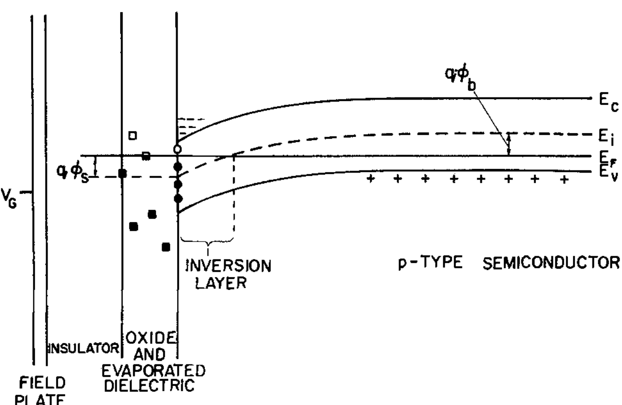

Fig. 2. Energy band diagram of the field effect experiment. E_C, E_i, E_F, and E_V are the conduction band edge, the intrinsic Fermi level, the Fermi level, and the edge of the valence band. ϕ_b and ϕ_s are the bulk potential and the surface potential. ■ and □ are slow, ● and ○ fast surface states. The energy levels are shown for zero voltage at the field plate.

If any voltage is applied to the field plate, which is parallel to the surface as shown in Fig. 2, charge neutrality requires that

$$C_G \cdot V_G = q(N_t(\phi_s) - \Delta N) + Q(\phi_s) \quad [3]$$

where C_G is the capacitance between the field plate and the semiconductor, N_t is the number of surface states, and ΔN the number of free excess electrons created by the bending of the bands in the inversion layer (all per unit surface area). V_G is the voltage at the field plate with respect to the semiconductor, ϕ_s is the surface potential (see Fig. 2), and $Q(\phi_s)$ is the charge per unit area due to the depletion of the majority carriers in the surface space charge layer. The sign of q is the same as the sign of the minority carriers in the inversion layer. Using Eq. [1], $Q(\phi_s)$ is of the order of

$$Q(\phi_s) \approx N \cdot L_D \quad [4]$$

In strong inversion layers the number ΔN of excess minority carriers per unit area in the surface space charge region is much larger than $N \cdot L_D$ and Eq. [3] reduces to

$$C_G \cdot V_G = q(N_t(\phi_s) - \Delta N) \quad [5]$$

Since the surface potential ϕ_s is a definite function of ΔN, the knowledge of ΔN and the parameters C_G and V_G allows the number N_t of surface states per unit area as a function of ϕ_s to be determined. The measurement of ΔN is done by applying an electric field parallel to the surface and observing the conductivity σ of the minority carriers in the inversion layer. In the concentric contact geometry used the conductivity $\sigma(\Omega^{-1})$ is given by

$$\sigma = \frac{2\pi}{\ln r_1/r_2} \cdot \Delta N \cdot \mu_s \cdot q \quad [6]$$

where r_1 and r_2 are the outside and inside radii, respectively, of the active surface (inversion layer in Fig. 3) and μ_s is the mobility in the inversion layer. The latter was measured in the same arrangement by applying to the field plate a voltage pulse δV_G which is short compared to the relaxation time of the fast surface states. This means that the surface state density remains constant during the voltage pulse and the mobility can be determined using Eq. [5] which further simplifies to

$$C_G \cdot \delta V_G = q \cdot \delta(\Delta N) = \frac{\delta\sigma}{\mu_s} \cdot \frac{\ln r_1/r_2}{2\pi} \quad [7]$$

In this work the number of surface states in equilibrium ($V_G = 0$) is of main importance. This equation may be obtained by combining Eq. [5] and [6]

$$[N_t]_{V_G=0} = \frac{\sigma \cdot \ln r_1/r_2}{2\pi \cdot \mu_s \cdot q} \quad [8]$$

The above formulas show that a d-c field effect experiment and a pulsed field effect experiment (for the measurement of the mobility) are sufficient to determine the number of surface states per unit area present.

In order to obtain the density of surface states per unit energy, it is necessary to know the relation between the number of minority carriers ΔN per unit area in the inversion layer and the surface potential ϕ_s. Numerical computations of this relation were carried out by Many *et al.* (5). Their results show that when the average concentration of minority carriers in the surface inversion layer $\Delta N/L_D$ exceeds the net concentration of dopants N

$$|v_s| - |u_b| \approx 2 \cdot \ln \frac{\Delta N}{L_D \cdot N} \quad [9]$$

where v_s and u_b are defined as

$$v_s = \frac{q}{kT}\phi_s \text{ and } u_b = \frac{q}{kT}\phi_b \quad [10]$$

where ϕ_b is the bulk potential. The change in surface potential, associated with an increase or decrease of the channel conductivity $d\sigma$ (due to a change in the voltage at the field plate dV_G), becomes

$$dv_s = 2\frac{d(\Delta N)}{\Delta N} = 2\frac{d\sigma}{\sigma} \quad [11]$$

Usually the density of surface states is high enough such that an increase in the voltage at the field plate dV_G produces many more surface states than free carriers in the inversion layer (cf. Eq. [4] $dN_t >> d(\Delta N)$). The contribution of the change in the number of free carriers $d(\Delta N)$ to the charge may therefore be neglected and dN_t is given by

$$dN_t = \frac{C_G}{q} \cdot dV_G \quad [12]$$

Substituting dE/kT for dv_s in Eq [11], E being energy in electron volts, the density of surface states per unit energy becomes

$$\frac{dN_t}{dE} = \frac{C_G}{2 \cdot q \cdot kT} \cdot \frac{dV_G}{d\sigma/\sigma} \quad [13]$$

It should be noted that neither the carrier mobility nor the device geometry is necessary to determine the density of surface states per unit energy. Equation [13] is valid as long as the average concentration of minority carriers in the surface channel $\Delta N/L_D$ equals or exceeds the bulk dopant concentration N and, in the present experimetal arrangement at 80°K, if the surface state density is larger than 10^{13} cm^{-2} · eV^{-1}.

Experimental Arrangement

Figure 3 shows the experimental arrangement. The device consists of a circular disk of ~3 cm diameter of p-type Ge of high purity ($N < 10^{11}$ cm^{-3}) with two concentric n-contacts. (Devices from n-type Ge with p-contacts were made as well.)[1] The concentric contact configuration eliminates any undesirable edge effects. After the chemical surface treatment (lap, polish, etch in 3:1 by volume of 70% HNO_3 and 40% HF with quench and rinse in doubly distilled water), a 0.01 mm thick polyester insulating disk and the field plate were placed on top as shown in the figure. This device is essentially an n-channel metal-insulator-semiconductor (MIS) field effect transistor with an active surface area of about 2 cm^2.

To measure the conductivity between the center contact and the outside ("drain" and "source"), a 60 Hz a-c voltage of 0.1-0.5V produced by a shielded transformer was applied and the current was measured with a RMS ammeter. A voltage of up to ±300V could be applied to the field plate ("gate") corresponding to an induced charge of up to 10^{12} electrons per cm^2. For the measurement of the mobility, a 0.5V d-c voltage was applied across the channel and a voltage pulse of 15V to the gate. The increase in conductivity $\delta\sigma$ was observed with an oscilloscope (terminated with 50Ω).

[1] To avoid the risk of contamination of the material, low temperature processes were used to make the contacts. The n-contacts were made by diffusion of Li at 300°C, the p-contacts by alloying with In at 300°C or by the evaporation of a metal surface barrier.

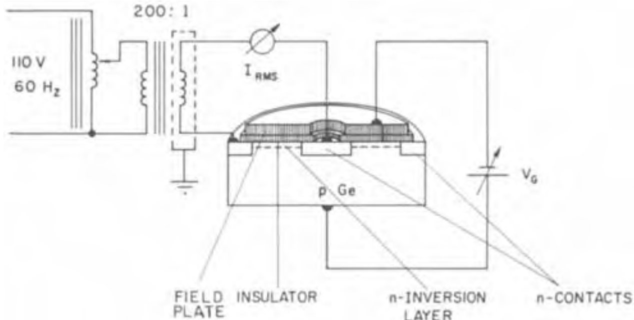

Fig. 3. Experimental arrangement.

Results

Mobility.—Results of the measurement of the mobility are shown in Fig. 4. Plotted is the ratio of the mobility μ_s is the surface inversion layer to the bulk mobility μ_b. The bulk mobilities were taken as 3.6×10^4 cm^2 · V^{-1} · sec^{-1} for electrons and 4.2×10^4 cm^2 · V^{-1} · sec^{-1} for holes (8). The horizontal axis shows the "strength" of the surface channel given both as the number of minority carriers per unit area divided by the Debye length and the normalized excess surface potential $|v_s| - |u_b|$. This is the barrier height in units of kT except for an additive constant. The measurements were made with Ge of $N \approx 5 \times 10^{10}$ cm^{-3}. The figure shows that the stronger the surface channel gets the more the mobility is reduced. Schrieffer (9), and, later, other workers (10-13) have predicted such an effect. They calculated the reduction in mobility due to the fact that the carriers in the surface channel have to move in a potential valley of width L_D, which in more highly doped samples is narrower than the thermal mean free path. It should be mentioned that Schrieffer's calculations assume completely diffuse scattering of the carriers at the surface and that measurements (14, 15) at higher temperatures and with much more highly doped material showed that the theory predicts too great a reduction in mobility (which means that the surface reflects the carriers in a partly specular manner). However, the measurements with this high purity material (where the thermal mean free path is only about 1 μm and the Debye length about 10 μm) show that the mobility is even more reduced than Schrieffer's theory predicts. According to the theory, the three curves in Fig. 4 should coincide. The measurements with material of this purity show that the mobility in the surface channel obviously depends strongly on the surface treatment. In addition to Schrieffer's theory, another mechanism must therefore be responsible for the observed strong reduction in

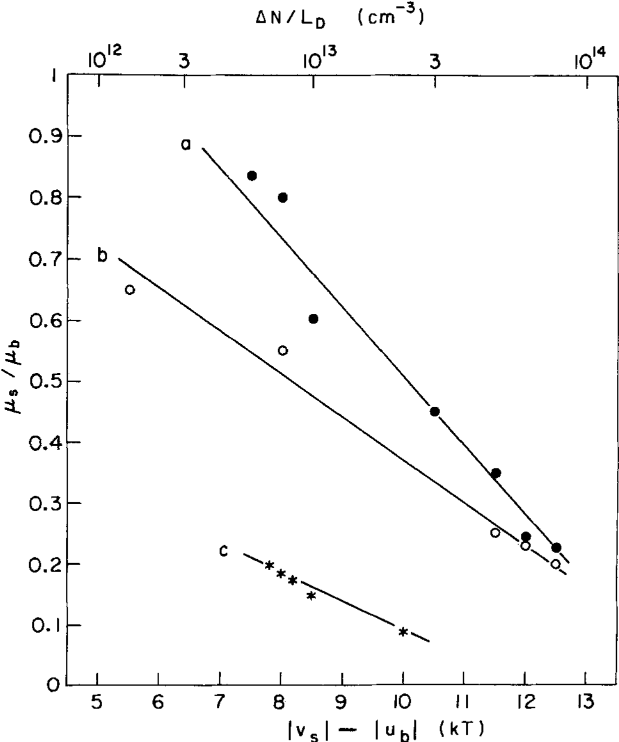

Fig. 4. Ratio of the mobility in the surface inversion layer, μ_s, to the bulk mobility, μ_b, as a function of the barrier height: a = n-channel MIS transistor; b = the same sample as a but after the chemical surface treatment has been repeated; c = p-channel MIS transistor.

mobility. A possible explanation would be that because of their small thermal mean free path the carriers are "trapped" in the potential wells created by local fluctuations in the surface potential and move along the surface, "hopping" from one of these wells to the next. Since the mobility is strongly nonlinear with the electric field, any such effect will reduce it. In addition, such a model could explain the dependence on the etch treatment observed here and by other workers (15). A "hopping" model, similar to that described, has been proposed by Mott (16) and found to be adequate to describe low temperature mobilities in inversion layers of silicon MIS transistors (17, 18) and thin amorphous germanium films (19).

Surface state density after the surface treatment.— Figure 5 shows the result of the field effect experiment on an n-channel Ge sample of 5×10^{10} cm^{-3} dopant concentration, which was carried out as soon as possible after the chemical surface treatment. As expected from Eq. [3], increasing gate voltage also increases the conductivity σ. However, as shown in Fig. 4, the stronger the inversion layer gets, the more the mobility is reduced. Hence the conductivity seems to approach a limiting value. The number of electrons in the inversion layer, calculated according to Eq. [6] from the conductivity and the mobility (which were measured simultaneously, for this sample), shows a linear dependence upon the gate voltage. This linear dependence suggests that the surface state density is very small in this sample and calculation using Eq. [5] shows that in fact the charge induced by the gate voltage equals the number of electrons in the inversion layer within the experimental limits. The upper limit for the surface state density is therefore $\sim 10^{12}$ cm^{-2} · eV^{-1}. At zero gate voltage there are nevertheless 5×10^9 cm^{-2} surface states present which produce an n-type surface.

It should be mentioned that this particular sample showed the lowest observed density of surface states per unit energy. The surface condition just after the surface treatment depends upon the chemical surface treatment itself and the crystal material used. A surface state density of 10^{13} cm^{-2} · eV^{-1} is often observed but the position of the Fermi level varies from sample to sample.

Effect of the dielectrics on the surface of Ge.—The effect of dielectrics on the surface of Ge has been investigated by comparing the surface state density just after the chemical surface treatment with the figures obtained after subsequent coating with an evaporated layer of 100-1000 nm thickness. To test the coatings for their ability to protect the Ge from adverse ambients, the coated devices were exposed to atmospheres of H_2, wet N_2, O_2, dry N_2, etc., for up to 100 hr. For these tests the devices were at room temperature and were cooled to 80°K only for the measurements.

The following dielectrics have been tested: SiO_2, SiO, TiO_2, polytetrafluoroethylene (PTFE), MgF_2, Al_2O_3, and the glasses Corning 7740 and Schott 8329. Except for SiO which was evaporated from a sublimation source, all of the insulators were evaporated using an electron gun evaporator. The vacuum was usually $\sim 10^{-4}$ Pa except for the evaporation of PTFE which produces large amounts of gaseous cracking products when "evaporated."[2]

Considerable differences between the various dielectrics have been observed with respect to their effect on the electronic properties of the Ge surface. Some dielectrics react very strongly with the Ge surface (*e.g.*, SiO and TiO_2) while for others no interaction could be detected (*e.g.*, SiO_2, Al_2O_3, etc.). An example of a strong interaction is shown in Fig. 6. The figure shows the characteristics of a p-channel MIS transistor. The zero intercept of the curves is proportional to the num-

[2] The "evaporation" of PTFE with an electron gun, according to de Wilde (20), is mainly a cracking process of the bulk material and the gaseous fractions repolymerize under the bombardment of stray electrons from the electron gun.

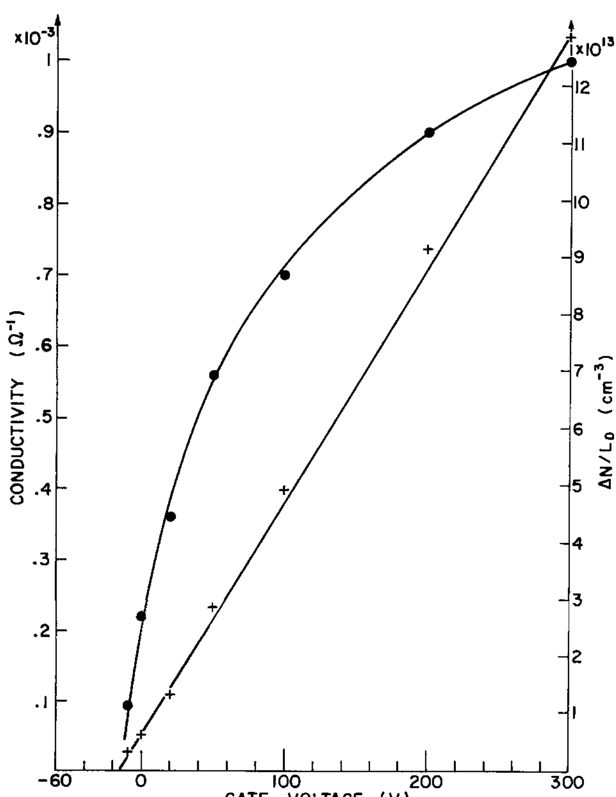

Fig. 5. Characteristics of an n-channel MIS transistor: ● = conductivity σ and + = excess surface carrier concentration $\Delta N/L_D$ as a function of gate voltage.

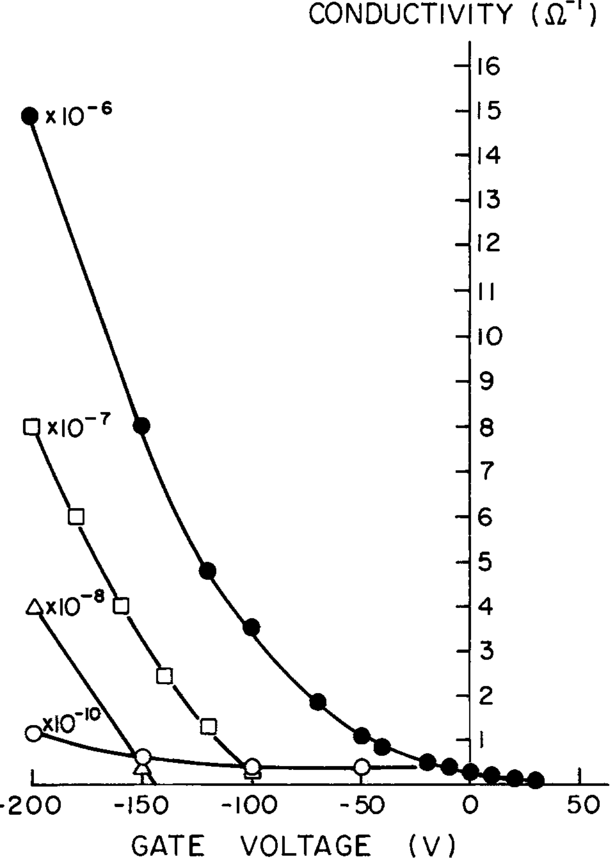

Fig. 6. Characteristics of a p-channel MIS transistor: ● = after the manufacture; ○ = after evaporation of 100 nm of SiO; Δ = after H_2 for 3 days; □ = after wet N_2 for another day. The notations at each curve give the order of magnitude of the conductivity (σ).

ber of surface states present at a particular surface condition (cf. Eq. [8]) and the density of surface states per unit energy is inversely proportional to the relative slope $(d\sigma/\sigma)/dV_G$ of the curves (cf. Eq. [13]). Just after the chemical surface treatment (●), the device shows a weak inversion layer with a low density of surface states per unit energy. After coating with an evaporated layer of 100 nm of SiO (○), the channel conductivity remains at the noise level up to a gate voltage of −150V. The slight rise in the conductivity σ for gate voltages larger than −150V indicates that the surface state density has become very high. However the very small channel conductivity ($\sim 10^{-10}\ \Omega^{-1}$) shows that the number of holes in the inversion layer divided by the Debye length $\Delta N/L_D$ is much smaller than the bulk dopant concentration N (which was 5×10^{10} cm^{-3} for this sample). This means that Eq. [13] is no longer valid and the results plotted in Fig. 6 can only be interpreted qualitatively. It may be seen that exposure to a H_2 atmosphere for 3 days (△) and wet N_2 atmosphere for another day (□) worsens the device but the conductivity is still very low and is below the noise level at $V_G = 0$. The situation has been found to be even more favorable with n-channel devices. Usually after the evaporation of a coating of SiO, no conductivity can be detected and different ambients do not change this characteristic. The experiment shows that the SiO layer introduces a great number of surface states at an energy level which is close enough to the intrinsic position of the Fermi level to deplete the surface.

By either the chemical surface treatment or the influence of the ambient atmosphere before the evaporation of the dielectric layer, it is, however, possible to produce surface channels which show a large enough surface state density that the number of surface states introduced by the coating dielectric cannot shift the Fermi level sufficiently to deplete the surface. Two examples of this are shown in Fig. 7. Characteristics of p-channel devices are shown just after manufacturing (● and ■) and after having been coated with 100 nm

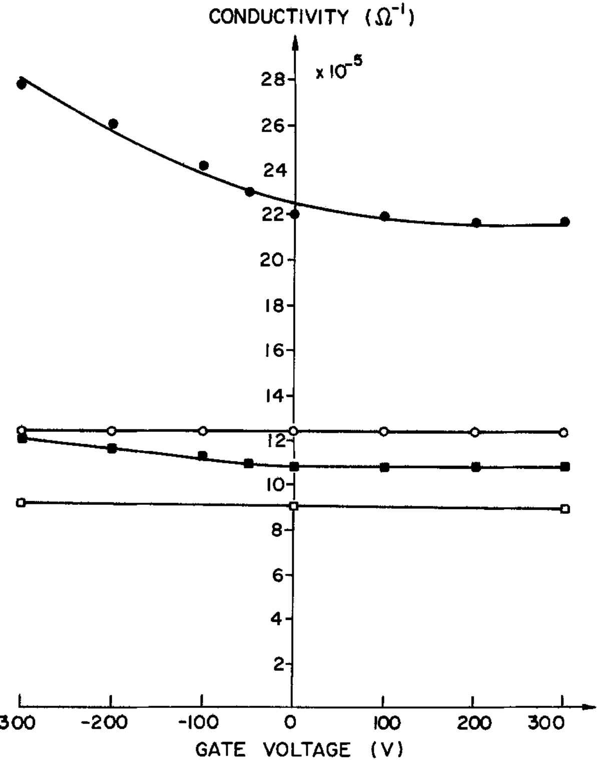

Fig. 7. Characteristics of two p-channel MIS transistors: ● = after the manufacture and ○ = after coating with 100 nm of SiO, and ■ = after the manufacture and □ = after coating with 100 nm of TiO_2.

of SiO (○) or TiO_2 (□). It may be seen that neither of the two dielectrics used is able to cause the strong surface channels to disappear.

The surface protection qualities of the dielectrics may be attributed to the total number of surface states per unit area produced and their energetic position. This information may be obtained from the experiments described in Fig. 7. Table I gives the result of these experiments for all the dielectrics tried in the course of this work.

The table shows that four dielectrics show interactions with the Ge surface that are smaller than the detection limit of the method outlined above. Although the field effect experiment is capable of detecting very small changes in the electronic properties of the Ge surface, it should be mentioned that the manipulations necessary to perform the experiment described in Fig. 7 introduce changes in the surface due to the effect of the ambient atmosphere the sample is exposed to. (To determine the figures given in Table I, the sample has to be put in the measuring cryostat, evacuated and cooled, measured, warmed up and transferred in air into the evaporator, evacuated and coated with the dielectric, transferred back into the cryostat, evacuated, cooled, and measured again.) The ambient atmosphere has been found to introduce typically about 10^{11} cm^{-2} surface states which is therefore the lower limit of detection for the effect of the evaporated dielectric on the surface of Ge.

Four of the dielectrics tried show a pronounced interaction with the Ge surface. The two dielectrics SiO and TiO_2 introduce their surface states close enough to the intrinsic position of the Fermi level to deplete the surface. (Due to the very low intrinsic carrier concentration at 80°K the Fermi level may deviate by as much as 36 kT (= 0.24 eV) from its intrinsic position without producing an excess carrier concentration at the surface $\Delta N/L_D$ exceeding 10^{10} cm^{-3}).

For the two glasses tried it was found that they introduce surface states close to or within the position of the valence band at the surface. This means that regardless of the surface condition created by previous surface treatments the evaporation of one of these glasses leads to a more p-type surface.

Mechanism of interaction.—Theoretical calculations (21, 22) show that real Ge surfaces such as the ones produced by the chemical surface treatment used in the present work should not show any nonlocalized surface states. This means that the dangling bonds of the Ge surface atoms are saturated with the bonds originating at the oxygen atoms of the native surface oxide layer. Ideally, such a well-oxidized surface has no surface states. The Fermi level at the surface has the same position as in the bulk material and the energy bands go horizontally right to the surface of the crystal ("flat-band condition"). If this oxide layer is thick enough, it is an ideal surface protection in the sense that additional covering of the surface with any material cannot produce surface states because the additional layer has no access to the bare Ge surface and the oxide is thick enough to inhibit carrier exchange by tunneling, etc. The usual method of protecting a real surface is, therefore, to grow a thick and good oxide. The surface

Table I. Energetic position and number of surface states per unit area produced by the dielectric layers on real Ge surfaces

Dielectric material	Number of surface states produced per unit area (cm^{-2})	Energetic position of the surface states
SiO	10^{14}	within ±0.25 eV of the intrinsic position of the Fermi level
TiO_2	10^{13}	
Glass 7740	10^{12}-10^{13}	within the valance band
Glass 8329	10^{12}-10^{13}	
MgF_2	$\leq 10^{11}$	
PTFE	$\leq 10^{11}$	
Al_2O_3	$\leq 10^{11}$	
SiO_2	$\leq 10^{11}$	

states observed after the chemical surface treatment used in this work are localized states. They originate at local imperfections (*e.g.*, pinholes) in the oxide layer. The well-known sensitivity of these Ge surfaces to changes in the ambient atmosphere may be due to additional states created at the pinholes in the oxide.

Two possible mechanisms of interaction can explain the effect of the evaporated dielectric materials. The relatively large number of surface states may either be produced by an electronic interaction of the coating material through the oxide or else the surface states are produced at the pinholes of the oxide. To get some information which might allow a distinction between these two possible mechanisms, measurements were made of the total number of surface states produced as a function of the thickness of the native Ge oxide layer.

According to ellipsometric measurements done by Baertsch (23), the chemical surface treatment mainly used in this work produces a Ge oxide layer of about 1.5 nm thickness. The same author has made measurements on the subsequent growth of the oxide layer when the samples are exposed to laboratory air for periods between 1 hr and 50 days. MIS transistors with various native oxide thicknesses were made by oxidizing the samples in air before a coating layer of 100 nm of SiO was applied. Figure 8 shows the total number of surface states produced by the SiO layer as a function of the thickness of the native Ge oxide using the results of Baertsch (23).

Although the further growth of the native oxide layer in air is relatively slow (it takes about three weeks to double the thickness of the oxide produced by the chemical surface treatment), the figure shows that the total number of states produced by the SiO layer decreases very rapidly with increasing oxide thickness. It may be seen that doubling the native oxide layer thickness reduces the total number of surface states produced by the coating dielectric by about two orders of magnitude. It is unlikely that this thickness dependence is caused by an interaction through the oxide because (*i*) extrapolation to zero oxide thickness would lead to 10^{16}-10^{17} cm^{-2} surface states which is ten to one hundred times higher than the number of Ge atoms per unit surface area (10^{15} cm^{-2}); (*ii*) other chemical surface treatments which result in thicker oxide layers still lead to 10^{13}-10^{14} cm^{-2} surface states if coated with one of the effective dielectrics shortly after the surface treatment; and (*iii*) since a direct overlap of the electron orbitals from the coating molecule with the orbitals from the Ge atoms is unlikely because of the relatively thick oxide layer and because of the theoretical considerations mentioned above, an interaction through the native oxide would have to be an exchange of electrons through the oxide. In such a mechanism the native oxide acts as a conductor between a layer containing the surface states and the Ge. A thicker oxide layer thus leads to a longer time constant to reach the equilibrium position of the Fermi level at the surface, but does not affect the total number of surface states produced by an additional surface layer.

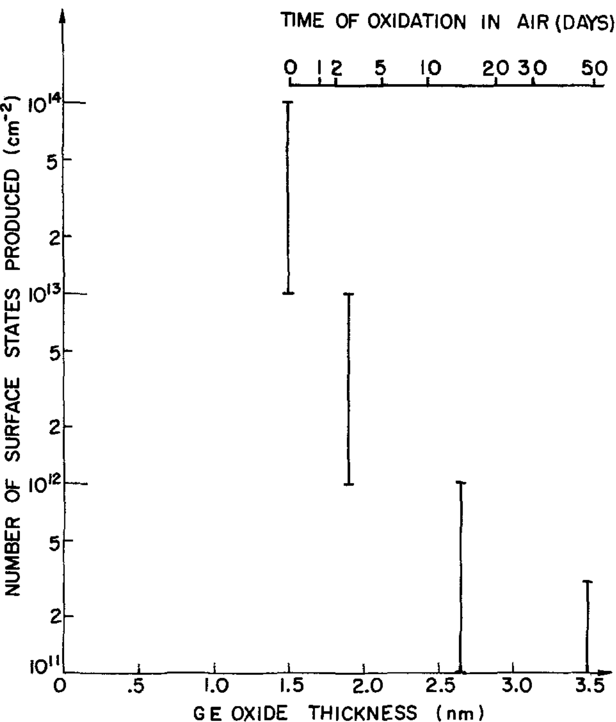

Fig. 8. Total number of surface states produced by an evaporated layer of 100 nm of SiO as a function of the thickness of the native germanium oxide. The Ge oxide thickness was increased prior to the evaporation of the SiO layer by oxidizing the sample in air (300°K) for the times indicated.

It is, therefore, concluded that the interaction of the Ge and the evaporated dielectrics occurs at the pinholes in the oxide produced during the surface treatment. The reason for the decreasing number of surface states produced if the sample is further oxidized is the decreasing number of pinholes in the oxide. This agrees well with the observation that an "old" (uncoated) surface is much less sensitive to the influence of adverse ambients than a freshly etched one.

Discussion and Conclusions

The real surfaces investigated in the present work are covered with an oxide layer of 1-2 nm thickness. Nevertheless, it was found that evaporated layers of certain dielectric materials produce up to 10^{14} cm^{-2} surface states. These surface states are created at pinholes in the oxide film. For some of the dielectrics tried, the energetic position of the surface states is within $\pm$ 0.2 eV of the intrinsic position of the Fermi level. This means that, except for surfaces which are strongly p- or n-type after the surface treatment, the evaporation of one of the effective dielectrics leads to a surface potential which is lower than the bulk potential of the crystal. Hence for devices which must be depleted for successful operation (*e.g.*, radiation detectors), there are no surface layers which cannot be depleted and, thus, window effects (2, 3) are greatly reduced. [The charge collection properties at the surface of these devices are degraded as long as there is a bending of the energy bands in either direction, but the effect on the performance of the detectors is much worse when the surface layers cannot be depleted (24).] In addition, it has been found that Ge surfaces coated with one of the effective dielectrics are much less sensitive to deterioration due to the influence of the ambient atmosphere.

It might be interesting to mention that similarly prepared surfaces of material of comparable impurity concentration have also been found (25) to show about 10^{14} cm^{-2} surface states after the evaporation of different metals. In that work the number of surface states was determined from the properties of Schottky barriers formed by the metals on the Ge surface.

In conclusion, this paper has shown that the evaporation of certain dielectric materials provides a means of surface protection for those Ge devices which require a surface potential as low as possible,[3] but not for devices which require a low density of surface states, *e.g.*, field effect transistors. It is however clear that none of the dielectrics tried provides a perfect surface protection in the sense that it will cause a surface channel of any strength to disappear and completely eliminate the effect of the ambient atmosphere.

Acknowledgments

I would like to thank I. L. Fowler and H. L. Malm for many helpful and encouraging discussions and the revision of the manuscript.

The electrical characteristics of semiconductor devices are primarily determined by the impurities incorporated into the body of the semiconductor and by their spatial distribution. Three basic methods are available to determine impurity profiles in semiconductors. The first is spreading resistance (1-3) which will give a complete profile on a small area, rapidly and to any depth. However, the equipment is expensive, calibration is difficult and variable, computer analysis for interpretation is usually necessary, and step sizes are normally larger than 500Å. The second method determines the profile from *C-V* measurements (4-6). A complete profile cannot usually be determined by this method since the distance over which the profile can be determined is limited by the avalanche breakdown of the semiconductor. The third method involves successive measurements following the removal of controlled amounts of the semiconductor. *C-V* measurements, radio-tracer counting (7, 8) or differential sheet resistivity measurements (7, 9) using either a four-point probe (7, 10-12) or the Hall effect (13, 14) can be performed in conjunction with the sectioning to determine the impurity profile.

Three basic techniques for sectioning exist: mechanical grinding (15), chemical etching (16, 17), and oxidation followed by etching of the oxide. Removal by anodic oxidation is strain free, planar, reproducible, practically independent of dopant, independent of crystal orientation, and causes insignificant impurity redistribution. Anodic oxidation can be carried out in a simple, inexpensive cell without the necessity of any expensive facilities. It does, however, suffer the disadvantage that many anodizations must be carried out to obtain the profiles of thick layers. In comparison to other methods, the determination of impurity profiles by anodization, etching, and four-point probe resistivity measurements is often very attractive.

This paper describes an investigation of the variables affecting anodic oxidation and a simple, highly accurate anodization procedure is outlined.

Key words: silicon, anodization, impurity profiling, sectioning.

Electrolyte

Nonaqueous solutions were selected for the anodization of silicon because they allow higher forming voltages, cause less contamination, and give denser oxides than the acid or borate solutions (7). Pure water (18) with a resistivity in excess of 0.5 megohm-cm may be used but the rate of oxide formation is much lower than that for nonaqueous electrolytes.

Several nonaqueous solutions such as N-Methylacetamide (NMA) (19, 20), tetrahydrofurfuryl alcohol (21, 22), and ethylene glycol (23-26) were evaluated. Ethylene glycol containing 0.04*N* KNO_3 and small amounts of water was selected because it produced uniform and compositionally reproducible oxides. In addition, it has the advantages of low cost, high purity, good electrolyte solubility, and good stability towards heat and electrolysis.

For good anodizations this electrolytic solution must contain water. Duffek (23) suggests that 0.5-5% water by volume is optimum since for higher concentrations the $Si:O_2$ ratio becomes a function of water concentration and thus the silicon removed is not simply related to the measurements of oxide thickness. Others (24, 26) have used up to 10% water and the interpretation of their work where oxide measurements are used to determine silicon removed suffers from this difficulty. In this work 2.5% water was used. Because ethylene glycol is hydroscopic it is necessary, if the water concentration is to be kept constant, to keep the solution in tightly stoppered containers and to have samples dry before inserting them into the cell.

During multiple runs in the same electrolytic solution, the current efficiency increased while the voltage at which oxide stripping began decreased. Manara *et al.* (26) show that fluoride ions increase the current efficiency while Croset and Dieumegard (27) identified fluoride ions as the cause of the stripping. Croset and Dieumegard (27) suggest the addition of 1-2g of $Al(NO_3)_3 \cdot 9H_2O$ per liter to inhibit the effects of the fluoride ion. The effects of the addition of $Al(NO_3)_3 \cdot 9H_2O$ were investigated. Electrolyte A did not contain $Al(NO_3)_3 \cdot 9H_2O$ while electrolyte B did.

Two methods of anodization are possible. In the first method a constant voltage is applied across the electrode and the current is allowed to fall until a predetermined value is reached. In the second method a constant current is forced to flow between the electrodes and the voltage is allowed to rise until a preset value is reached. The constant current method was used in this work. In constant current anodization the thickness of the oxide is directly proportional to the net forming voltage provided no oxide stripping occurs during the anodization. The net forming voltage or net voltage is defined as the final cell voltage minus the initial cell voltage for a clean sample at the start of anodization.

Apparatus

A HP 6186B d-c current source capable of delivering up to 100 mA at voltages up to 300V was used to power the cell. An enclosure was placed over the cell to eliminate ambient light, and a projection lamp was used to provide uniform, controlled intensity of illumination on the sample. A circular groove in the cell lid provided simple and accurate positioning of the electrodes with a 2.5 cm spacing in a standard 400 ml beaker. This beaker was placed in a water bath which was used to control the operating temperature and to act as a heat sink to minimize the effects of the self-heating during anodization. A magnetic stirrer provided the constant agitation and mixing necessary for reproducible and uniform anodization. The insert cathode was composed of platinum mesh stretched over 1/16 in. stainless steel frame for rigidity. The cathode had an area of 14.5 cm^2. With this mesh cathode, the anode sample surface was easily illuminated through the cathode and the continual mixing of the solution was not impeded.

The sample holder of chemically inert Teflon is shown in detail in Fig. 1. The wafer was waxed to a thin Bakelite square, which was mounted and sealed on the anode structure by means of nylon screws and an O ring as shown in Fig. 1. A small Bakelite sheet was waxed to an area on the wafer surface to mask it from the anodization and provide a reference surface.

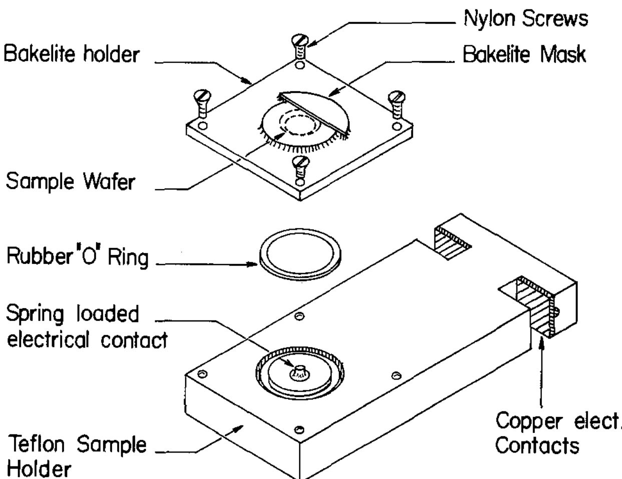

Fig. 1. Anodization sample holder and sample mount

Sample Preparation

The silicon samples were degreased and rinsed in running deionized water. They were then etched in 8% HF until wetting ceased, rinsed in running deionized water, and blown dry. A 2000Å thick aluminum layer was evaporated onto the back of the wafer to ensure good uniform electrical contact.

The wafer was mounted by placing wax on the Bakelite support and heating it in an oven at about 200°C until the molten wax formed a smooth layer about 1/16 in. thick. The sample was then pushed down into the molten wax until a uniform bead of wax formed around the entire edge of the sample.

Anodization Technique

Anodization was carried out in the 400 ml cell using 325 ml of solution. The power supply was set to the current required to provide the desired current density and anodization proceeded until the predetermined net forming voltage was reached. The sample holder was removed from the cell and rinsed in running deionized water. The wafer surface was scrubbed lightly during the rinse to ensure complete removal of the ethylene glycol. Any ethylene glycol residues prevent uniform removal of the oxide. After the oxide removal in 8% HF, the sample was rinsed in deionized water and blown dry. Care was taken to insure that the holder was dry before reinsertion.

Measurements of Silicon Removed

Three methods were employed to accurately measure the thickness of silicon removed during anodization.

An interference angstrometer employing a sodium monochromatic light source was used throughout the experiments to measure both the thickness of silicon removed and the anodic oxide thickness. The method was as follows. An area of the sample surface was masked against the anodization as shown in Fig. 1. After a number of anodizations, the sample was removed from the Bakelite holder and cleaned. Part of the area covered with anodic oxide was masked by Apiezon wax and the rest was removed. The sample was then cleaned and 500Å of aluminum was evaporated onto the surface to improve the reflectivity. The interference pattern from the surface was photographed and a travelling microscope was used to measure the step heights from the interference patterns. Measurements of these steps gave thickness values for both silicon removed and anodic oxide formed.

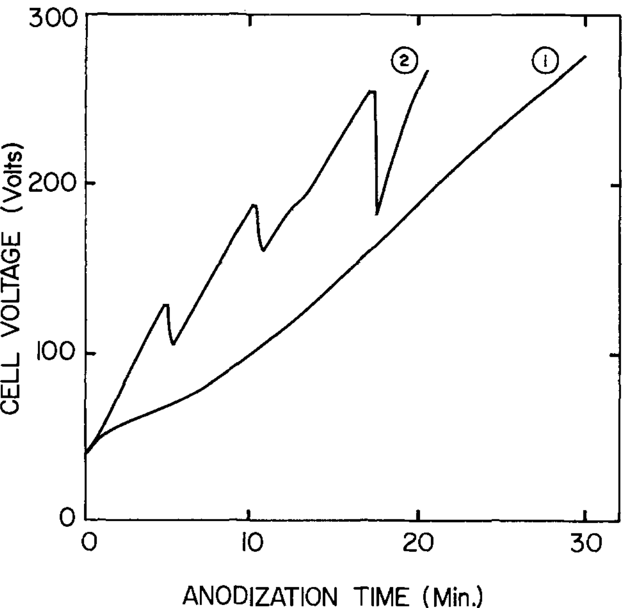

Fig. 2. Typical anodization cell voltage curves for (1) electrolyte B and the first two runs of electrolyte A and for (2) subsequent runs of electrolyte A showing oxide stripping above 125V.

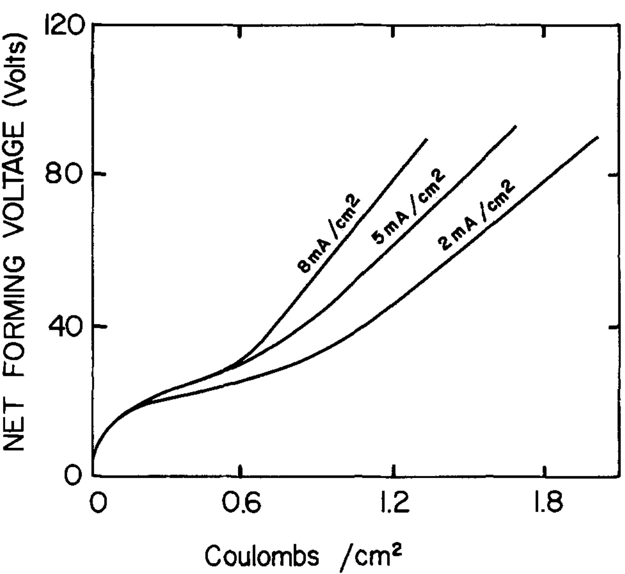

Fig. 3. Net forming voltage *vs.* total charge passed through the cell per unit sample area for various current densities.

Single readings by this technique were accurate to ±50Å.

The anodic oxide thickness was also measured by ellipsometry (30). Because it was not necessary to remove the sample from the Bakelite mount for this measurement, it was used extensively to monitor the reproducibility of anodization from run to run. Oxide thickness measurements from the angstrometer agreed with those from the ellipsometer to within ±5% based on a value of 1.46 assumed for the refractive index of the anodized oxide films. Because the refractive index of anodic oxides does depend on the electrolyte, this value may not apply for other electrolytes. Ellipsometry measurements of the oxide thickness from run to run agreed to within ±3% which was the probable deviation of the oxide thickness formed during multiple anodizations.

The silicon removed was determined from the change in weight after a predetermined number of anodizations. In order to obtain an accuracy of ±5%, a large number of anodizations was necessary so this method was only employed during profiling. The results obtained agreed within 5% with those obtained from the interference measurements.

Experimental Results

The cell voltage as a function of the duration of the anodization is shown in Fig. 2 for a number of runs of both electrolyte A and electrolyte B which contained $Al(NO_3)_3 \cdot 9H_2O$. The first two runs for electrolyte A and all runs for B continue without interruption to the maximum voltage as shown in curve 1. All of the other runs for electrolyte A have discontinuities arising from a stripping of the oxide as shown in curve 2. The first discontinuity occurred repeatedly at about 125V corresponding to a net forming voltage, V_N, of 100V. Where anodizations using electrolyte A were terminated at a net forming voltage of 90V, stripping of the oxide was avoided. Stripping is undesirable because it causes surface roughness and errors in the silicon removed.

The amount of silicon removed by anodization and etching was found to be independent of the current density in the range 2-8 mA/cm² and directly dependent on the net forming voltage (see Table I). Figure 3 shows the net forming voltage *vs.* the total charge per unit area for electrolyte A anodizations. The increase in current efficiency with increasing current density previously reported by Schmidt (19) is clearly evident. Because of the higher current efficiency and the

shorter anodization time, the 8 mA/cm² current density was used in subsequent anodizations.

From Fig. 2 it is clear that the cell voltage at the start of an anodization is not zero. The initial voltage, V_i, arises primarily from the resistivity of the electrolyte solution. Thus

$$V_i = IR = \frac{JA\rho_e d}{A'} \quad [1]$$

Measurements confirmed that the initial voltage was a linear function of the current density, J; the separation between the anode and the cathode, d; and the resistivity of the solution, ρ_e. However, they indicated that it was a weaker function of the sample area, A. This weaker dependence on A is due to the fact that A', the effective cross-sectional area for the electrolyte solution, is also a function of the silicon anode area, A. No change in V_i was detected when changing from electrolyte A to B.

The temperature at which the anodization takes place affects a number of variables. The viscosity of the solution and thus its resistivity increase as the temperature decreases. This results in higher values of the initial voltage, V_i, and in less efficient mixing of the solution. However, as the temperature of the solution is increased, the adhesion of the wax is reduced and creep of the electrolyte along the wafer-wax interface results in partial anodization of the wafer back. For these reasons, a temperature between 15 and 20°C is considered desirable and can be easily realized by means of a flowing water bath to carry the excess heat from the anodization cell. As shown in Table I, the amount of silicon removed per volt of net anodization voltage was essentially independent of temperature in the range 3°-50°C.

Figure 3 shows a decrease in the time necessary to reach a fixed net forming voltage with increasing number of runs for electrolyte A. Electrolyte B containing $Al(NO_3)_3 \cdot 9H_2O$ did not exhibit this increasing current efficiency with the number of anodizations. Furthermore, for electrolyte B, the stripping and consequent surface roughness observed after the occurrence of stripping in electrolyte A did not occur up to the 320V limit of the power supply. These results support the work of Croset and Dieumegard (27) who identified the presence of fluorine in the electrolyte as the cause of oxide stripping.

Table I also gives results indicating that the amount of silicon removed per volt of net anodization voltage is essentially independent of both the type and resistivity of silicon for $n \leq 10^{20}$ cm^{-3} and $p \leq 3 \times 10^{18}$ cm^{-3}. This agrees with the work of Manara *et al.* (26) who reported no dependence for p-type material and about a 10% decrease in silicon removal for 0.0001 Ω-cm ($n \geqq 10^{21}$ cm^{-3}) n-type silicon anodized to a net voltage of 100V. For high resistivity silicon, metallization of the wafer backs is essential for uniform anodization.

Two rate-limiting processes for n-type material are shown in Fig. 4. The initial rapid growth for the n-type material in the dark was also observed by Schmidt and Michel (19). This effect is due to a field in the silicon surface arising because of the depletion of electrons and the lack of holes. This field reduces the energy required to remove a silicon atom from the surface and therefore increases the anodic current efficiency. Illumination increases the hole concentration and reduces the field. Regardless of the rate of reaction, the same amount of silicon is removed for the same value of net forming voltage. Above the dashed line in Fig. 4 the effect of illumination disappears and the slopes of the curves, which are the rates of reaction, are approximately the same. In this region a different rate-limiting process controls the reaction. The thickness of the oxide at which this rate limitation begins is 250Å, differing from the 400Å found by Schmidt and Michel (19). To avoid variations in initial conditions, sufficient illumination should be provided to ensure that the starting voltage is minimum.

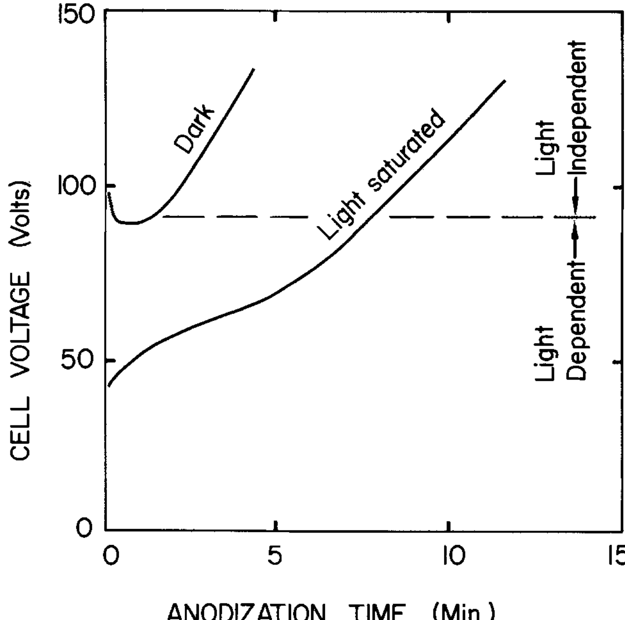

Fig. 4. Anodization voltage behavior for 1 Ω-cm n-type silicon with and without illumination.

Five samples were profiled by anodization and etching and the average thickness of silicon removed was determined by weight difference to be 2.21 Å/V with $\sigma = 0.06$ Å/V in excellent agreement with 2.19 Å/V with $\sigma = 0.13$ Å/V determined by the angstrometer. The much smaller deviation in the weight difference is due to the fact that each measurement is an average of a large number of anodizations.

Profiling

As an example of the use of this method of sectioning, the impurity profiles for n⁺ and p⁺ diffused layers were determined by differential sheet resistivity measurements employing a four-point probe.

The NBS "Tentative Method of Test for Resistivity of Silicon Slices by Four-Point Probes" (10) was used except that the wafer was left on the sample holder rather than being placed on a heat sink. Plots of sheet resistivity, $\rho_s(x)$, per anodization are presented in Fig. 5 and 6.

Converting this data into an impurity profile is a two-stage process. First, the differential sheet resistivity, $\rho_d(x)$ must be calculated. Tannenbaum (7) proposes

$$\rho_d(x) = [d(1/\rho_s(x))/dx]^{-1} \quad [2]$$

while Evans and Donovan (9) modified it to

$$\rho_d(x) = 0.4343\ \rho_s(x)/d \log [\rho_s(x)]dx \quad [3]$$

When an analytic expression is calculated to fit $\rho_s(x)$, the results are the same for either method. In this case a polynomial

$$\log [\rho_s(s)] = a_0 + a_1 s + a_2 s^2 + a_3 s^3 \quad [4]$$

was fitted to the sheet resistivity data where s was the number of anodizations. The sublayer resistivity was related to the impurity concentration by Irwin's curves (21) and the resulting impurity profiles are also shown in Fig. 5 and 6.

The shapes of these profiles agree with the results reported by others (32-34). In particular, the redistribution of the boron due to out-diffusion during the drive diffusion is in excellent agreement with the work of Kato and Nishi (33).

This method of sectioning has also been used successfully with the Hall effect as the measurement in the profiling of thin epitaxial multilayer structures (35).

Conclusions

Anodic oxidation followed by etching of the oxide is a successful means of sectioning silicon. Constant current anodization was used with an electrolyte solution of ethylene glycol with 0.04N KNO_3, 2.5% water, and 1-2 g/liter of $Al(NO_3)_3 \cdot 9H_2O$. To insure reproducible results, the back of the wafer must be metallized for high resistivity samples, the electrolytic solution must be agitated, and the wafer surface must be illuminated. The amount of silicon removed was independent of the current density between 2 and 8 mA/cm^2, the temperature between 3° and 50°C and the type and resistivity of the silicon up to concentrations of 10^{20} cm^{-3}. The oxide formed was uniform and reproducible with an average Si:SiO_2 thickness ratio of 0.44 ± 0.04 in excellent agreement with the accepted value of 0.44 for thermal oxides. The thickness of silicon removed was found to be a linear function of the net forming voltage with a proportionality constant of 2.20 Å/V having a standard deviation of 0.13 Å/V. Any voltage dependence of silicon removal for net voltages up to 280V was not significant and was less than previously reported (26).

Both the increasing current efficiency and the oxide stripping with the number of runs were due to the fluoride ion and were eliminated by the addition of $Al(NO_3)_3 \cdot 9H_2O$. After studying the temperature dependence of the different parameters, particularly electrolyte creep along the wafer-wax interface, it was determined that a temperature between 15° and 20°C (which can be easily realized by means of a flowing water bath) is optimal.

This sectioning technique combined with differential sheet resistivity measurements forms an excellent, inexpensive, uncomplicated means of profiling silicon.

New Flash Evaporation Method Improves Film Preparation

N. S. Platakis

IBM Corporation, San Jose, California 95193

and H. C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02193

A new flash evaporation method has been developed which eliminates the major disadvantages of conventional flash evaporation and permits the preparation of films which are significantly improved in structural and chemical homogeneity. This new method is restricted to congruently melting materials with melting points below the quartz softening temperature when the apparatus is made of quartz.

Melting in an open boat, chemical vapor deposition, sputtering, and flash evaporation are most commonly used in the preparation of films. Each of them has its advantages and disadvantages (1); the choice lies heavily on the characteristics of the material to be evaporated. Flash evaporation is particularly suitable for relatively low melting materials whose constituents exhibit large differences in their vapor pressure. In the normal method of flash evaporation (2), powder of the material to be evaporated is fed into a furnace which is preheated to a temperature several hundred degrees above the melting point of the material; the powder melts, vaporizes instantaneously, and is deposited onto the desired substrate. The main problems with this method are (*i*) the feeding rate of the powder and thus the evaporation rate (an important parameter in achieving chemical and structural homogeneity) is intermittent and in some cases also inconsistent and (*ii*) a molten phase is occasionally accumulated in the furnace due to surcharges of powder which leads to fractional vaporization and thus to phase separation in the film.

The flash evaporation method reported here essentially eliminates the above problems. The method is schematically illustrated in Fig. 1. The material to be vaporized is sealed off under vacuum in a quartz ampul one end of which is drawn to a capillary tube; the tip of the capillary tube is then broken and the ampul containing the material is positioned as shown in Fig. 1. Current is passed through coil A to attain the desired high temperature (see Table I) and when it is stabilized, power is applied to coil B to melt the material. Due to the vapor pressure in the ampul, the molten material flows through the capillary into the space heated by coil A where it vaporizes instantaneously. The vapor emerges from the other end of the quartz U tube to be deposited on the substrate. The flow of the molten material is controlled by the vapor pressure above the melt which in turn is controlled by the temperature of the ampul; this temperature is monitored by a thermocouple placed near the ampul. In this way,

Fig. 1. The new flash evaporation method

continuous injection or drop-by-drop feeding can be attained. Thus, vaporization can take place either only at the tip of the capillary (which is continuously fed) or after the drop leaves the capillary but before it reaches the walls of the heated quartz tube. A small opening in the molybdenum heat shield permits observation of the material flow at the tip of the capillary. Cover C prevents the escape of vapors from that end and the quartz tube itself prevents contamination from the molybdenum heating coils. A set of buffers (D) prevents drops of molten material, formed ac-

Table I

	Material	Melting point (°C)	T_1* (°C)	T_2** (°C)
$x = 0$	As_2Se_3	370 ± 2	400	620
$x = 0.2$	$0.8\ As_2Se_3 \cdot 0.2\ Sb_2Se_3$	391 ± 5	530	661
$x = 0.4$	$0.6\ As_2Se_3 \cdot 0.4\ Sb_2Se_3$	461 ± 5	506	736
$x = 0.6$	$0.4\ As_2Se_3 \cdot 0.6\ Sb_2Se_3$	526 ± 5	576	806
$x = 0.8$	$0.2\ As_2Se_3 \cdot 0.8\ Sb_2Se_3$	574 ± 5	628	858

Key words: vacuum deposition, film composition, homogeneity, alloys.

cidentally, from escaping through the high temperature region.

Thus, the basic features that distinguish the new method from the conventional one are (*i*) the material is stored and homogenized in the molten state (in the ampul) without being subjected to vaporization except through a capillary tip, and (*ii*) the molten material is injected for vaporization by its own vapor pressure which is constant at a given precisely controlled temperature.

The present method (using a U quartz tube 1 cm in diameter and 9 cm in height) was successfully applied to the preparation of films of a number of materials including the system $(1 - x)As_2Se_3 \cdot xSb_2Se_3$. Prior to evaporation, the pressure in the bell jar was brought down to 10^{-7} Torr. However, during evaporation the vacuum in the chamber dropped to the 10^{-5} Torr range. The ampul and evaporation chamber temperatures in actual work with alloys $(1 - x)As_2Se_3 \cdot xSb_2Se_3$, which were deposited on quartz wafers, are given in Table I. X-ray analysis of such films by scanning electron microscope, whose beam diameter and sensitivity were ~300Å and a few hundred parts per million, respectively, showed no difference in chemical composition between the feed material and the prepared films. Furthermore, no variation in composition was detected within the 20 μm thick films. The physical characteristics of these films, including electrical conductivity, were also highly reproducible.

In contrast, films prepared by the conventional flash evaporation methods and under the same temperature and vaporization rate conditions were at least 5% richer in As_2Se_3 than the feed material. This analysis was performed on a flat edge of the film which was obtained by cleaving a thin Si wafer on which the 20 μm thick film had been deposited. The electron beam was focused on a number of points along the thickness of the film and the intensity of x-rays was recorded using an energy-dispersive x-ray detector. The $AsK\alpha$ and $SbL\alpha$ intensities from each of these points were compared to those obtained from a series of homogeneous standard (specimens of known compositions) which included a specimen with the composition of the bulk materials used to prepare the film.

Determination of Reactant Gas Concentration by Quadrupole Mass Analyzer during PSG Film Formation Using Organic Compounds

Takeo Yoshimi, Hideo Sakai, and Katsuro Sugawara*

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

Gas analysis in CVD (chemical vapor deposition) reactions is essential, both to investigate the reaction mechanism and to control the film thickness and the composition precisely. In general, reactant gases have been analyzed by infrared absorption in SiH_4-O_2, SiH_4-N_2O, and SiH_4-CO_2-H_2 reactions (1) and in SiH_4-PH_3-O_2 reaction (2, 3), quadrupole mass analysis for gas present under vacuum (4) and in molecular beam epitaxy of GaAlAs superlattice (5), time-of-flight mass analysis in $GaAs_xP_{1-x}$ (6), GaN (7), $In_{1-x}Ga_xAs$ (8, 9) and SiH_2Cl_2-H_2, $SiHCl_3$-H_2, $SiCl_4$-H_2 (10, 11) CVD reactions, and Raman scattering in SiH_4 decomposition and SiH_4-NH_3 reactions (12).

In a previous paper (13), phosphosilicate glass (PSG) films using organic compounds, $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$, were formed under reduced pressure, to improve film thickness uniformity and step coverage over a silicon substrate. In this evacuated system, quantitative determination of the organic sources was difficult, due to the small amount of source evaporation and to measurement under vacuum. In the present study, determination was attempted by the infrared absorption and the quadrupole mass analyses. The gas concentration could not be measured by the former method, because of its poor sensitivity to the small amount of organic compounds. Therefore the quadrupole mass analyzer which had a high sensitivity and was well suited to the evacuated system was used. This note describes reactant gas analysis using the mass analyzer, with regard to the quantitative determination of the reactant gases and the correlation between the phosphorus concentration in the gas phase and that in the solid film.

The PSG film was formed in a resistance-heated furnace at reduced pressure, as shown in Fig. 1. The quartz reaction tube was 9 cm ID, 180 cm long, and its hot zone was 80 cm long. In principle, this reaction

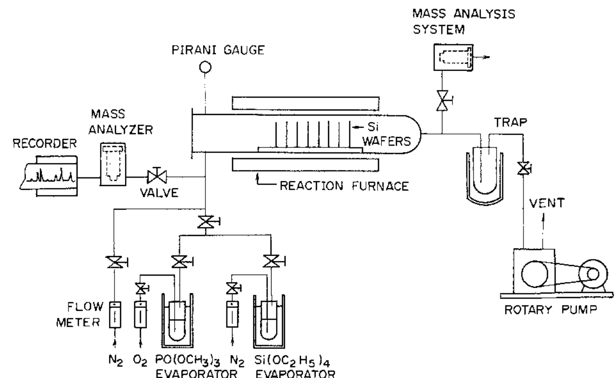

Fig. 1. Schematic diagram of the PSG film deposition reactor. A quadrupole mass analyzer was attached to it to determine the concentration of the reactant gases at reduced pressure.

Key words: $Si(OC_2H_5)_4$-$PO(OCH_3)_3$ reaction, correlation of gas- and solid-phosphorus concentration, quantitative determination of phosphorus concentration.

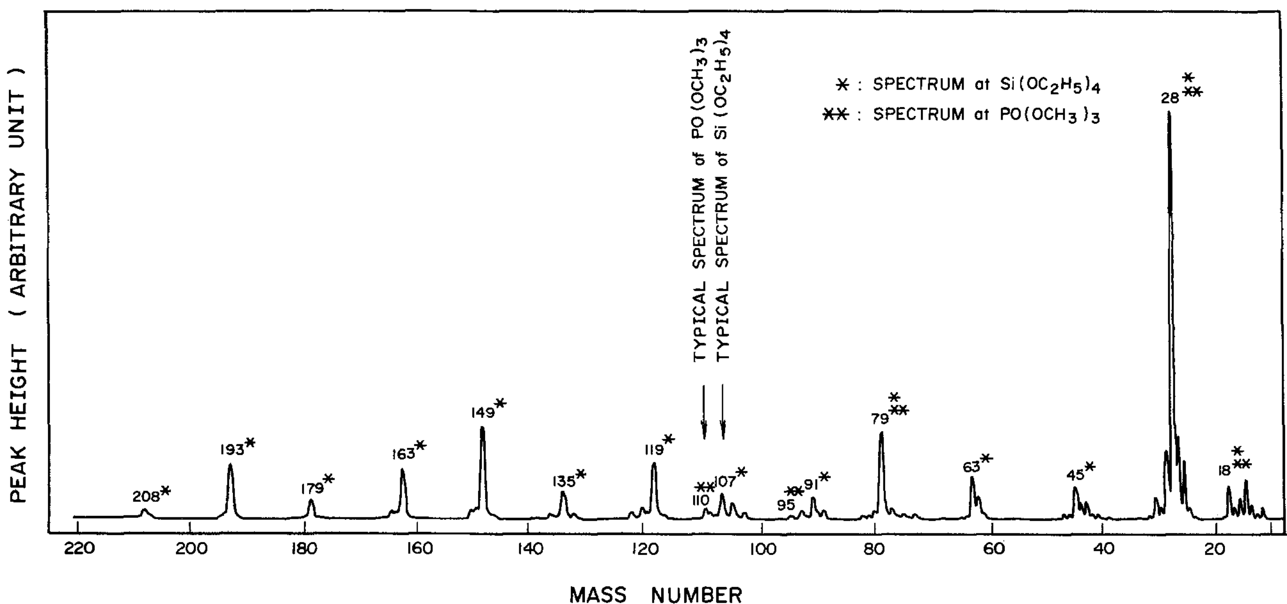

Fig. 2. Mass spectrum patterns of $Si(OC_2H_5)_4$ + $PO(OCH_3)_3$ reactant gases

system was based on the same method that had been used in LTP (low temperature passivation) (14, 15) in which only one component of $Si(OC_2H_5)_4$ was for LTP SiO_2 film formation. However, two components (16), $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$, were used for the PSG film deposition in this experiment; the purity of both materials was 99.999%. The typical deposition temperature and pressure were 740°C and 3 Torr, respectively. The phosphorus doping concentration and the deposition rate were investigated. The concentration of the silicon and phosphorus compounds in the reaction gas was monitored during the deposition by the quadrupole mass analyzer, UTI 100C. The phosphorus concentration in the solid film was determined by the x-ray fluorescence method. The PSG film on the silicon substrate was partially removed by etching and the film thickness was measured with a Talystep.

Figure 2 shows the mass spectrum patterns of $Si(OC_2H_5)_4$ + $PO(OCH_3)_3$. Typical spectra, m/e = 107 for $Si(OC_2H_5)_4$ and m/e = 110 for $PO(OCH_3)_3$, were selected for the determination of each concentration; these two spectra were adjacent to, but did not interfere with each other. Ionized decomposition species of the $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$ compounds, SiO_3-OCH_3^+ for m/e = 107 and $PO(OCH_3)O_2^+$ for m/e = 110, are supposed identifications of the mass numbers. The concentration of the reactant gases was quantitatively acquired by correlation between the peak height and flow rate of the organic sources. Figure 3 shows the relationship between the spectrum peak height ratio of $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$ in the reactant gases and the phosphorus concentration in the PSG films. This indicates that the measurement of the spectrum peak height by the quadrupole mass analyzer can be used to monitor the phosphorus concentration, even in a system with small amounts of the organic compounds, during the deposition reaction.

The concentration of the reactant gases was analyzed at various reaction temperatures. The abrupt decrease of both peak heights above 700°C in Fig. 4 demonstrates the promotion of the reaction in this temperature range. In the low temperature range between 400° and 600°C, no deposition of the PSG film on the silicon substrate was observed and inlet and outlet gas concentrations showed the same value. Therefore, taking 740°C for instance, the concentration of the $Si(OC_2H_5)_4$ compound and that of the $PO(OCH_3)_3$ at the outlet decreased to ~1/100 and ~½ of the initial inlet concentration, respectively, as shown in this figure. Then, the deposition rate and phosphorus concentration were measured at temperatures between 650° and 850°C. The former showed a tendency of increase-maximum-decrease with an increase in reaction temperature as in Fig. 5. From 650° to 780°C, the behavior was surface-reaction limited (E_{act} = 36 kcal/mole); above 780°C diffusion limited. Above 800°C the behavior was consistent with that expected due to homogeneous nucleation region (17). With high supersaturation and excessive heating of the reactant gases, precipitation of the reaction products can occur, causing a reduction of the deposition rate on the substrate. The deposition rate

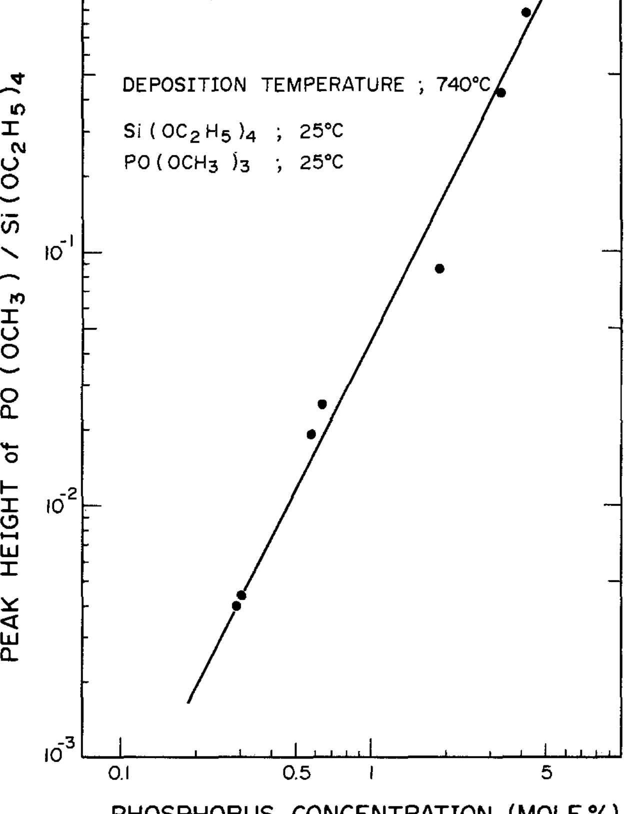

Fig. 3. Correlation between the spectrum peak height ratio of $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$ reactants and the phosphorus concentration in the PSG film.

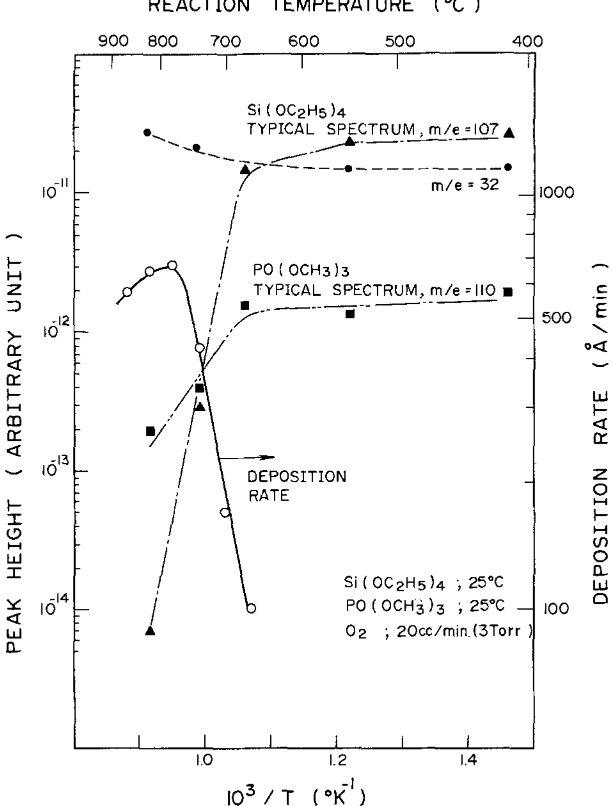

Fig. 4. Dependence of the spectrum peak heights measured by the quadrupole mass analyzer on the reaction temperature.

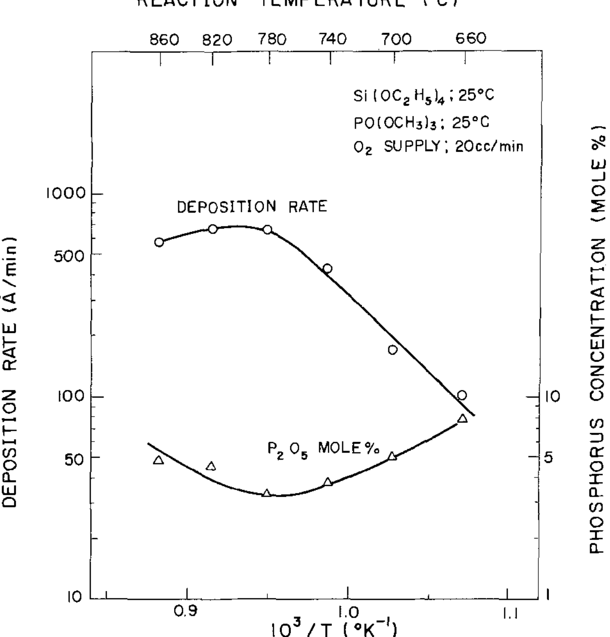

Fig. 5. Dependence of the deposition rate and phosphorus concentration on deposition temperature.

had a tendency similar to the reactivity of the silicon compound except for the homogeneous nucleation above 800°C, shown in Fig. 5. The temperature dependence of the phosphorus concentration in Fig. 5, decrease-minimum-increase, may be explained by the ratio of these two peak heights, dependence of the P compound was smaller than that of the Si compound as shown in Fig. 4, and by the consideration of the homogeneous nucleation.

Using $Si(OC_2H_5)_4$ and $PO(OCH_3)_3$ organic compounds, PSG film was deposited at 740°C and 3 Torr. In this reaction system, the concentration of the reactant gases was determined by the quadrupole mass analyzer, and the correlation between the phosporus concentration in the gas phase and that in the solid film was quantitatively clarified. By using the analyzer, correlation was investigated between the temperature dependence of reactivity in the gaseous concentration and that of the film deposition rate and film phosphorus concentration.

Acknowledgments

The authors wish to express their deep appreciation to Mr. S. Nishida and Mr. M. Ohno for their valuable discussions and encouragement throughout this experiment, to Mr. H. Ono of Kokusai Electric Company for the various suggestions in the mass analysis, to Mr. T. Nohara and Mr. S. Hosoda for their helpful discussions, and to Mr. K. Akiba for assistance in fabrication of the experimental reactor.

Manuscript submitted June 26, 1975; revised manuscript received March 8, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Hitachi, Limited.

Annealing of Ion-Implanted GaAs in a Controlled Atmosphere

R. M. Malbon,* D. H. Lee,* and J. M. Whelan*,[1]

Hughes Aircraft Company, Torrance Research Center, Torrance, California 90509

Implantation is considered to be an attractive alternative to diffusion for the creation of thin heavily doped n-type regions in GaAs (1-15). We have utilized ion implantation to fabricate high-low READ GaAs IMPATT diodes (6) and state-of-the-art Ka-band GaAs Gunn effect diodes (7). However, the results reported to date indicate that, in general, the doping efficiencies of the n-type implanted species are low unless long annealing periods are used. Lengthy annealing times are unattractive because diffusion tends to excessively broaden the impurity doping gradients and thus impair device performance. Even for short anneal times within the range of commonly used annealing temperatures, 700°-900°C, it is necessary to take special precautions to minimize erosion of the GaAs surfaces. A variety of approaches have been used. These include sealing the GaAs both with and without a dielectric encapsulant in evacuated quartz ampuls prior to annealing (4, 8). The encapsulants have included SiO_2 (3, 4, 6, 9), Si_3N_4 (8, 9), Al_2O_3 (11, 12), and Ga-doped SiO_2 (13, 14). However various problems associated with uncontrolled contamination and interdiffusion at the encapsulant-GaAs interface have been noted (15).

This paper describes the results of substituting a controlled atmosphere for the dielectric encapsulant to protect the GaAs surface during high temperature anneals. Epitaxial materials technology has demonstrated that polished substrates can be maintained at elevated temperature with minimal surface degradation in a flowing high purity hydrogen atmosphere. Taking advantage of this experience, an anneal system was designed which utilizes a controlled atmosphere of high purity hydrogen (H_2) in conjunction with an arsenic (As) source to protect the GaAs surface during annealing. The system was used to anneal epitaxial GaAs films implanted with either silicon ions or sulfur ions to create thin, highly doped n-type layers. The epitaxial surfaces exhibited no degradation after anneals at 800°C for 20 min. The electrical results indicate that the apparent electrical conversion efficiencies achieved for the implanted layers were as high as 85% for the 800°C, 20 min anneal.

Experimental

The GaAs epitaxial material used in this investigation was grown by the H_2-Ga-$AsCl_3$ vapor phase technique on heavily Te-doped n^+-substrates oriented 3° off the <100> toward the <111>. The epitaxial layers were doped with sulfur and were electrically uniform in depth with net donor concentrations within the range $2\text{-}8 \times 10^{15}$ cm^{-3}. The epitaxial layers were implanted at room temperature with either 120 keV silicon ions or 140 keV sulfur ions. In the case of the silicon implants it was concluded after careful analysis of the separated ion spectrum that the implanted species was $^{28}Si^+$ with less than 1% of other possible molecular components (*e.g.*, N_2^+). To minimize channeling effects, the GaAs lattice was oriented to appear random to the incident ion beam. Under this condition, a first order approximation to the implanted ion distribution is Gaussian with a mean projected range R_p and standard deviation ΔR_p. For the 120 keV silicon implants, the ion dose, N_D (number of ions/cm^2), was varied between 5.6×10^{12} and 2.3×10^{13}. Based on the range theory of Lindhard, Scharff, and Schiøtt (15), $R_p = 0.103$ μm and $\Delta R_p = 0.051$ μm. For the 140 keV sulfur, the ion dose was 2.53×10^{13} ions/cm^2. In this case the theory of Lindhard *et al.* predicts $R_p = 0.104$ μm and $\Delta R_p = 0.051$ μm. After ion implantation, the GaAs epitaxial layers were annealed under a H_2 atmosphere using a quartz envelope furnace assembly shown schematically in Fig. 1. Inlet H_2 from a liquid source was preheated by passage through one leg of the horizontal U tube and was subsequently passed over a quartz boat containing a liquid Ga/GaAs solution saturated with As. This source supplied As to the atmosphere at a pressure near that required for equilibrium with the GaAs-implanted surface. The Ga/GaAs also served as a reaction site for the trace amounts of H_2O in the hydrogen stream and thus minimized erosion of the implanted surface by this atmospheric impurity. Samples to be annealed were placed on a quartz support assembly and loaded into the main tube. After loading, the chamber was flushed for a minimum of 1 hr so that the (air + H_2O) concentrations were under 3 ppm. Based on prior experience, the H_2O concentration rises to 10 ppm or less due to outgassing of the quartz at the annealing temperature (17). No surface degradation was observed with an optical microscope at 700X with interference contrast after the 800°C, 20 min anneal cycles reported here.

The ion-implanted donor profiles were determined from capacitance-voltage (*C-V*) measurements on reverse-biased Schottky barrier diodes. The Al or Au Schottky barriers were vacuum deposited on the implanted layers after a Au-Ge ohmic contact was alloyed on the n^+-substrate. An automatic impurity profile plotter[2] was used in conjunction with some forward-biased *C-V* measurements to obtain as large a portion of the free carrier profile as possible. Etch step techniques were combined with the Schottky barrier measurements to obtain the complete net donor tail distribution. Steps of approximately 1000Å each were etched into the ion-implanted epitaxial layer using a volume ratio 5:1:1 (H_2SO_4, H_2O_2, H_2O) as the etchant. The step heights were measured with a commercial step height analyzer to complete the profile data. Although the *C-V* technique exhibits certain limitations in its ability to accurately reproduce rapidly varying profiles (18), it was concluded by comparison of the results from the various etch steps that no significant deviation was occurring.

Results and Discussion

The profile evaluations for the silicon implants into the GaAs epitaxial layers are illustrated in Fig. 2 and

[2] The differential *C-V* measurements were obtained by the application of a 15 mV signal at a frequency of 1 MHz.

Key words: compound semiconductors, implanted silicon, implanted sulfur.

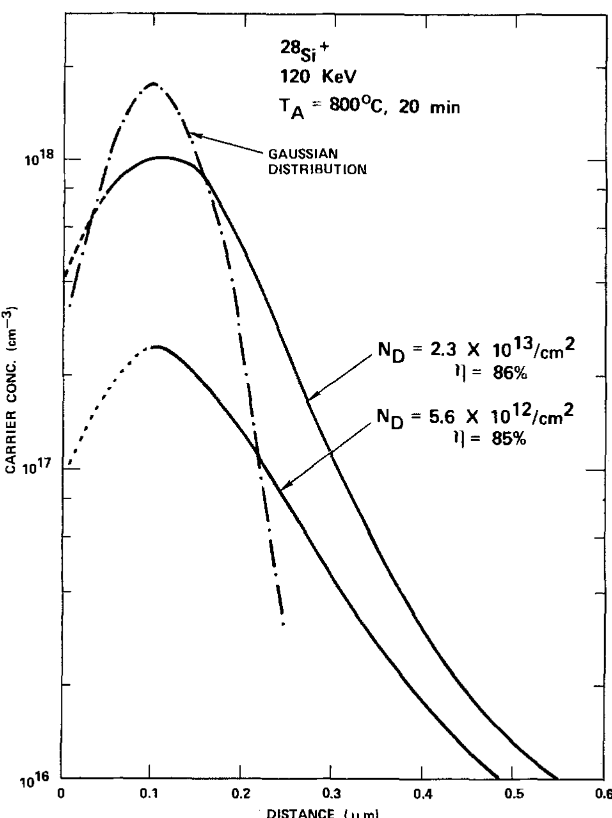

Fig. 2. Measured carrier concentration vs. the distance from the sample surface for ion-implanted silicon in GaAs. The samples were annealed at 800°C for 20 min.

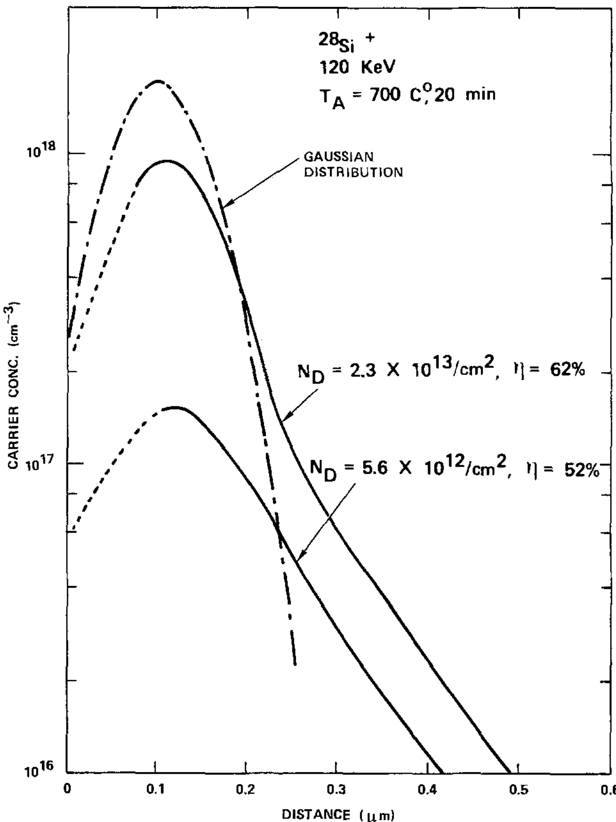

Fig. 3. Measured carrier concentration vs. the distance from the sample surface for ion-implanted silicon in GaAs. The samples were annealed at 700°C for 20 min.

3. Figure 2 shows the resultant donor profiles for 120 keV Si implants annealed at 800°C for 20 min. The measured profiles for the two different doses (2.3 $\times$ 10^{13} and 5.6 $\times$ 10^{12} ions/cm^2) are indicated by the solid curves. The first order theoretical distribution based on the theory of Lindhard *et al.* is the dot-dashed line which indicates the projected range of the implants for the energy used. The apparent electrical activities were estimated by integrating under the solid measured profile curves and their projected sections shown as dotted lines in the figure. (The *C-V* profile technique is limited by the depletion depth of the Schottky barrier diode.)

The apparent electrical conversion efficiency, η, is the ratio of the integrated net donors to the dose. For the 800°C, 20 min anneal, η was calculated to be approximately 85% for both doses. The measured donor profiles agreed within 20% of the projected range and tended to be slightly deeper in both cases. Figure 3 compares the resultant donor profiles for 120 keV Si implants anealed at 700°C for 20 min. The solid curves are the measured profiles for the two different doses utilized (2.3 $\times$ 10^{13} and 5.6 $\times$ 10^{12} ions/cm^2). The dotted lines indicate the projected distribution utilized to calculate the apparent electrical conversion efficiency. In this case, η was higher for the higher dose implant; 62% for the 2.3 $\times$ 10^{13}/cm^2 dose and 56% for the 5.6 $\times$ 10^{12}/cm^2 dose. In both cases, however, η was significantly lower than that obtained for the 800°C, 20 min anneal. The measured profile distribution peaks agreed quite well with the projected range and tended to be slightly deeper.

The profile evaluation for the sulfur implant is illustrated by the solid curve in Fig. 4. The measured profile indicates the resultant donor profile for the 140 keV S implant after the 800°C, 20 min anneal. The dose in this case was 2.5 $\times$ 10^{13} ions/cm^2. The first order theoretical distribution based on the theory of Lindhard *et al.* is the dot-dashed line which indicates the projected range of the implants for the energy used. As

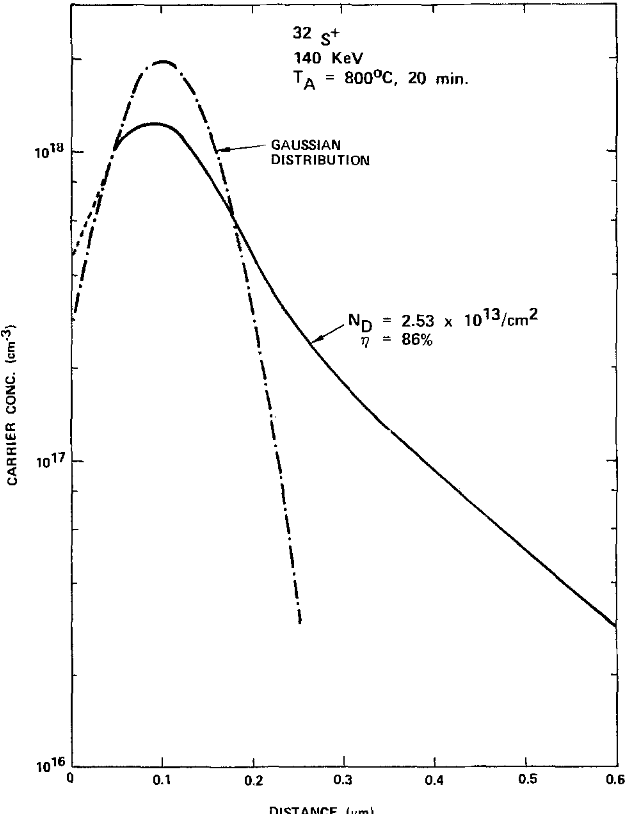

Fig. 4. Measured carrier concentration vs. the distance from the sample surface for ion-implanted sulfur in GaAs. The samples were annealed at 800°C for 20 min.

above, η was estimated using the same technique described for the silicon implants. For the 800°C 20 min anneal with the controlled atmosphere technique, η

was calculated to be 82%. The measured donor profile for the S-implanted profile agrees within 20% of the projected range but exhibits a significantly deeper tail than that encountered with the annealed Si profiles.

To ensure that the anneal process was not influencing the ion-implanted results reported above, unimplanted epitaxial layers of known impurity concentration were annealed in the system at 800°C for 30 min and reevaluated. In all cases, the background impurity concentration distributions in the epitaxial layers remained unchanged from their value prior to the anneal. This indicates that no unusual redistribution of the background impurities was occurring during the high temperature anneal. If the anneal times were extended to 60 min at 800°C, a slight surface degradation was noted at 700× indicating that some dissociation or H_2O vapor etching of the GaAs was occurring.

Comparison of Fig. 2 and 3 for the silicon implants indicates that diffusion broadening of the profile is taking place during the 800°C, 20 min anneal. It is also apparent that higher peak concentrations are obtained with the 800°C anneal. For the low dose, the peak concentration increased by 60% using an 800°C anneal as compared to a 700°C anneal. However, for the higher dose case, only a 6% improvement was noted. This suggests the possibility that the electrical activity is dose dependent at lower anneal temperatures. Comparison of the profile data for the silicon (Fig. 2) to those for the sulfur (Fig. 4) annealed under the same conditions, suggests that diffusion broadening of the sulfur profile is more significant. However, these results may be influenced to some extent by the inability of the *C-V* technique to accurately reproduce rapidly varying tail distributions (18).

It is of interest that upon annealing at 700°-800°C, ion-implanted Si acts as a relatively high efficiency donor. This is in accord with the results of other authors (4, 8, 14), but opposite to the observations that lightly Si-doped GaAs epitaxial films grown from Si-doped Ga solutions at approximately 815° and 730°C are p-type (19). The Ga and As fugacities used to prepare these liquid phase epitaxy samples were similar to those used in our anneals. It is possible that their results are more nearly representative of thermal equilibrium and that their dominant acceptor is not simply a Si atom on an As lattice site. This view is consistent with the results of Spitzer and Pannish (20) who found the concentration of Si on Ga sites to be larger than that on As sites in heavily Si-doped GaAs grown from Ga solutions. Their results suggested a complex acceptor defect was responsible for the p-type character. Due to the high donor doping efficiencies we find, it is presumed that the acceptor complex is not present at large concentrations in our Si-implanted GaAs. Hicks and Green (19) did not find that the acceptor doping efficiency of Si increased as the growth temperature decreased from 815° to 730°C. This may be one reason why we find a lower donor doping efficiency upon annealing at 700°C as compared to 800°C.

The relatively high and reproducible electrical activities described above are in a large part directly attributable to the anneal technique. As reported by a number of authors, an anneal temperature of at least 600°C is required to eliminate the lattice disorder associated with the implant. In addition, most authors have reported very low electrical activity for anneal temperatures below 700°C. However, dissociation of the GaAs surface can begin as low as 600°C unless special precautions are taken to either control the atmosphere or encapsulate the surface. Our initial attempts using dielectric encapsulation resulted in some attractive profiles and excellent device results (6, 7). However, controlled profiles were difficult to reproduce regularly due to the poor quality of the dielectric encapsulants. Although the dielectric encapsulants maintained surface integrity, problems associated with impurities diffusing out of the encapsulant into the GaAs as well as Ga diffusing into the encapsulating layer (15) have influenced the reproducibility greatly. Use of the controlled atmosphere anneal has significantly reduced these problems. It is not known at present to what extent this technique can be extended to longer and/or higher temperature anneals through better hydrogen purification procedures and more direct control of the As vapor pressure.

Conclusions

In this paper we have described a simple reproducible technique for annealing ion-implanted layers in GaAs. A controlled atmosphere is utilized instead of a dielectric encapsulant to prevent dissociation of the GaAs surface during the anneal. A controlled atmosphere is preferable as it minimizes the possibility of unwanted impurities diffusing out of the encapsulant into the ion-implanted region, thus disturbing the net impurity concentration. The ion-implanted results reported indicate that exceptionally high apparent conversion efficiencies (85%) can be obtained with this technique for n-type dopants in GaAs.

Restrained Diffusion of Boron and Phosphorus in Silicon under HCl-Added Oxygen Atmosphere

Yasumasa Nabeta, Tadashi Uno, Shuji Kubo,* and Hirokazu Tsukamoto

Matsushita Research Institute Tokyo, Incorporated, Ikuta, Tamaku, Kawasaki, Japan

The enhanced diffusion of boron and phosphorus in silicon in oxidizing atmosphere has been reported by several workers (1-3). This paper describes experimental results of diffusion behavior of these impurities in HCl-added oxygen gas. It was found that the impurities are restrained in a presence of HCl gas in the oxidizing diffusion atmosphere.

Samples used in this experiment were n-type silicon crystals of 70 Ω-cm and p-type silicon crystals of 25 Ω-cm with (100) plane. P-type silicon crystals of 45 Ω-cm with (111) plane were also used. The experimental procedure was as follows: (*i*) CVD film (borosilicate or phosphosilicate glass) is deposited on silicon surface at a temperature of 450°C; (*ii*) boron or phosphorus in the CVD film is prediffused in the surface layer of the sample at a temperature of 1000°C for 10 min in the nitrogen atmosphere; (*iii*) CVD film is then removed; (*iv*) diffusion is carried out in three different atmospheres, *i.e.*, 30°C wet oxygen (wet O_2), HCl-added oxygen (HCl-O_2), and nitrogen (N_2). An oxidation rate of 6% HCl-O_2 is equal to that of 30°C (wet O_2) at a temperature of 1100°C.

The junction depth, X_j was measured by angle lapping and staining. The surface concentration, C_s was obtained from X_j and sheet resistivity, ρ_s, using the data of Irvin (4) under the assumption of the gaussian distribution. The diffusion coefficient, D, was calculated from the values of X_j and ρ_s by using the gaussian diffusion function.

The experimental results for boron impurities after drive-in at the temperature 1100°C with different times are summarized in Table I. The diffusion coefficient was also calculated by incorporating the measured values of X_j into the theoretical formula of the Kato and Nishi model (5). It is clear from Table I that the diffusion coefficient values obtained by these two methods show relatively good agreement. Similar results for phosphorus impurities are shown in Table II. From these tables it is found that the values of junction depth for the HCl-O_2 diffusion are close to that for the N_2 diffusion for the same diffusion time, but are much smaller than that for the wet-O_2 diffusion. The surface concentrations for HCl-O_2 and N_2 are larger than for wet O_2.

	6%HCl+dryO_2	1.87	52.1	2.5×10^{19}	0.197	0.207
	wet O_2	2.88	43.4	1.8×10^{19}	0.309	0.324

After the prediffusion, junction depth and surface concentration, assuming the complementary error function, were 0.44 μm and 2.7×10^{20} atoms/cm³, respectively.

† Calculated using the segregation coefficient $k = 0.1$ and oxidation constant $K = 1.20 \times 10^{-13}$ cm²/sec for HCl-O_2 and $K = 1.23 \times 10^{-13}$ cm²/sec for wet O_2.

Relations between surface concentration and diffusion coefficient for boron and phosphorus impurities are shown in Fig. 1 and 2, respectively. In these fig-

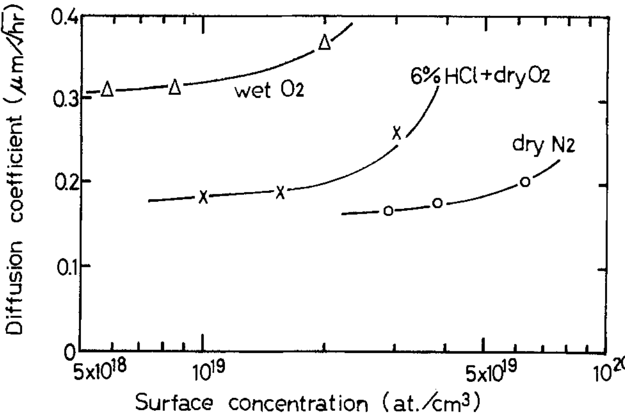

Fig. 1. Diffusion coefficient *vs.* surface concentration for boron diffusion at 1100°C.

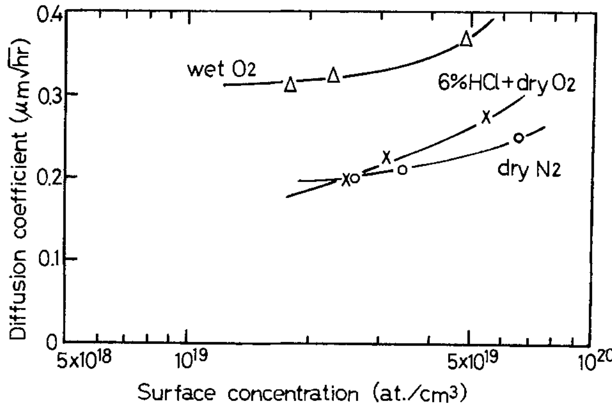

Fig. 2. Diffusion coefficient *vs.* surface concentration for phosphorus diffusion at 1100°C.

ures, it is interesting to note that the diffusion coefficients of boron and phosphorus in silicon in wet O_2 are larger than those in N_2 and $HCl\text{-}O_2$. This result indicates that the diffusion of boron and phosphorus in silicon in wet O_2 is enhanced as has been reported, but not for $HCl\text{-}O_2$, particularly in a lower range of surface concentration.

This effect of restrained diffusion is varied with the process condition. Figures 3 and 4 show these experimental results of diffusion coefficients for boron and phosphorus for the diffusions at temperatures of 1000°, 1100°, and 1150°C, varying volume ratios of HCl gas to dry oxygen. From these figures, the following behavior of impurity diffusion can be observed.

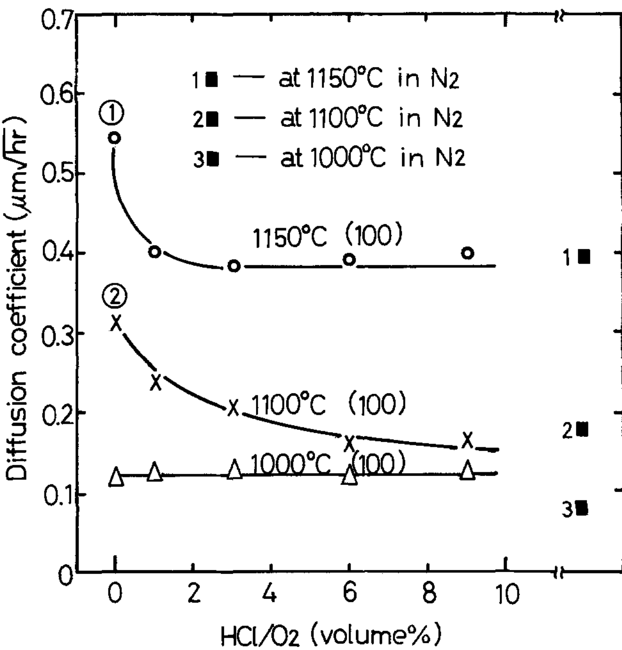

Fig. 3. Diffusion coefficient of boron in silicon at different temperatures and HCl volume ratios.

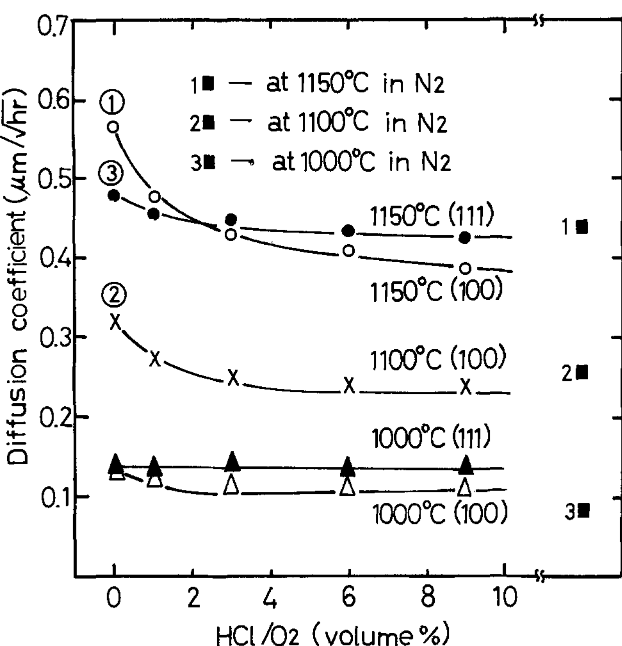

Fig. 4. Diffusion coefficient of phosphorus in silicon at different temperatures and HCl volume ratios.

(*i*) The diffusion coefficient of boron and phosphorus for (100) crystal treated in $HCl\text{-}O_2$ at temperatures above 1100°C gradually decreases with increasing volume ratio of HCl gas up to 9% and reaches the diffusion coefficient of that in N_2, which has been evaluated by several workers (6, 7). The rate of decrease of the diffusion coefficient with increasing HCl gas content is more prominent for (100) crystal at 1150°C, as seen from curves ① and ② in Fig. 3 and 4. This behavior of the diffusion coefficient as a function of HCl gas content and temperature seems to correlate to the results of Shiraki's work (8) on decreasing stacking faults as a function of HCl gas content and temperature.

(*ii*) The diffusion coefficient of phosphorus for (111) silicon crystal is less dependent on the HCl gas content than that for (100) crystal, as seen from curves ① and ③ in Fig. 4. This can be interpreted from Shiraki's result that during dry-O_2 oxidation stacking faults tend to generate for the (100) plane rather than for the (111) plane.

(*iii*) The restrained diffusion effect is not prominently shown at any HCl gas content at temperatures lower than 1000°C. This corresponds to the report by Kobayashi *et al.* (9) indicating that the $HCl\text{-}O_2$ process below 1060°C does not give any improved effect of $Si\text{-}SiO_2$ interface.

In summary, experimental study for boron and phosphorus diffusion in silicon in various atmospheres was carried out. It was found that the diffusion of these impurities is restrained in the presence of HCl gas in the oxidizing diffusion atmosphere at certain conditions of temperature and HCl gas content. These conditions show strong similarity to the behavior of stacking fault generation in HCl-added oxygen atmosphere. The restrained diffusion of impurities, therefore, seems to result from the elimination of stacking faults at the $Si\text{-}SiO_2$ interface, which varied with the HCl-added atmosphere.

Acknowledgments

The authors express deep thanks to Dr. M. Onuki for his valuable discussions.

Depth Analysis of Passive Films on Iron in Neutral Borate Solution

Norio Sato,* Kiyokatsu Kudo, and Rokuro Nishimura

Corrosion Research Group, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

ABSTRACT

Composition depth profiles of passive films on iron in a borate solution at pH 8.42 have been obtained by means of cathodic reduction combined with ellipsometry and chemical analysis. Results revealed that the compositional profile varied depending primarily on the potential and to some degree on the time of film growth. The barrier layer in contact with the metal changed in composition from an iron(II-III) mixed oxide at potentials below the Flade potential to an iron(III) oxide at more noble potentials. The deposit layer next to the solution was a hydrated iron(III) oxide and absorbed iron(II) ions at less noble potentials. There was found a peak or a decrease in iron concentration at the barrier/deposit boundary. The iron-rich boundary was gradually replaced by the iron-depleted as the potential was shifted to more noble direction. It was the barrier layer alone that increased in thickness during the film growth at potentials above the Flade potential. In the transpassive potential region the barrier layer ceased growing with potential and tended to contain a small concentration of iron(II) ions. It is suggested that the ion transport in the layers plays a role in determining the passive film composition.

In previous papers (1-6) it has been shown that the passive film formed on iron in a borate solution at pH 8.42 is a bilayered film consisting of a barrier layer of γ-Fe_2O_3 next to the metal phase and a deposit layer of hydrated iron(III) oxide next to the solution phase. The barrier layer was potential dependent and its thickness at steady state was proportional to the overpotential of the layer formation. The deposit layer, which was stable only in the neutral and basic pH range, appeared to differ in thickness with different passivation processes and also with different solution environments such as pH and anion.

The picture is, however, not altogether clear in an extended range of potential at which the film is formed. This work has therefore been undertaken to throw light into the composition profile of the passive film formed at different potentials in a borate solution of pH 8.42.

Experimental

The materials, instruments, and methods employed are essentially the same as those described in previous papers (5, 6). The specimen was polycrystalline iron of 99.9% purity in the form of sheet. The solution in which the specimen was passivated was a nitrogen-saturated oxygen-free 0.15M boric acid-sodium borate solution of pH 8.42.

For depth analysis of the passive film, a galvanostatic-cathodic reduction technique combined with ellipsometry and chemical analysis (6, 7) was employed by using an oxygen-free 0.15M boric acid-sodium borate solution at pH 6.48 in which the passive film on iron was proved to cathodically dissolve layer by layer without any appreciable change in its original composition profile (7).

The specimen surface free from oxide films was prepared by cathodic reduction at pH 8.42 and, immediately after renewing the solution, was anodically oxidized at a constant potential for 1 hr to form the passive film on it. The response time of the potential shift from the cathodic region to the passive potential region was less than 2 sec. After exchanging the solution from pH 8.42 to pH 6.48, the passive film was cathodically reduced at a constant current of 6.0 $\mu A/cm^2$ and the solution was analyzed for iron by absorption spectroscopy as a function of time of cathodic reduction.

Furthermore, optical measurements of light-intensity-following ellipsometry (8, 9) were carried out during galvanostatic cathodic reduction of the passive film at an angle of incidence of 74.485° and at a wavelength of light 546.1 nm with an ellipsometer (Rudolph 43702-200E).

All measurements were carried out at 20° ± 1°C. The electrode potential was measured in reference to a saturated calomel electrode and was converted into the standard hydrogen electrode scale.

Results and Discussions

Film thickness.—A number of film thickness measurements by ellipsometry have been carried out in the authors' laboratory (1-4). Figure 1 shows the film thickness and anodic current as a function of potential at which the passive film has been formed by anodic 1 hr oxidation. The Flade potential (10), $E_f = +0.58-0.059\ pH$, may divide the passive potential region into two regions, I and II. Transpassivation began to occur at +1.55V almost independent of pH (11).

* Electrochemical Society Active Member.

Key words: iron passivity, anodic oxide film, ellipsometry, cathodic reduction, composition depth profiling, film growth.

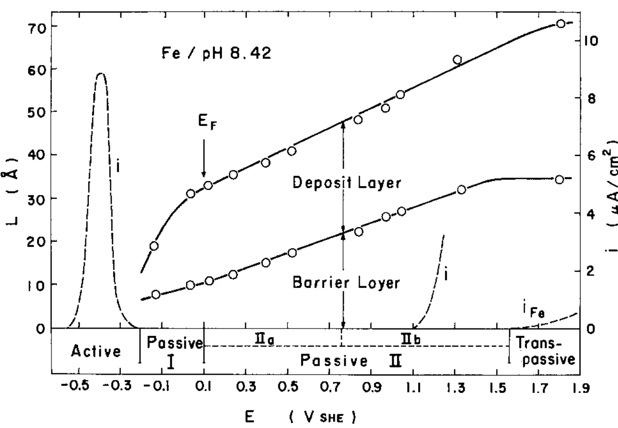

Fig. 1. Anodic current-potential curve of iron and thickness-potential curve for the passive film on iron anode in borate solution of pH 8.42. The films were formed potentiostatically each on the oxide-free surface for 1 hr. i_{Fe} = transpassive dissolution current, E_F = Flade potential.

Evidently, the barrier layer is potential dependent except for the potential region of transpassivation where the layer thickness remained nearly constant. The barrier layer thickness for unit voltage was 1.54 nm/V (6.5×10^6 V/cm) in region I and 1.75 nm/V (5.7×10^6 V/cm) in region II. It was also observed that the deposit layer thickness increased with potential in region I and remained almost unchanged in region II. As reported previously, the amount of iron(II) ion dissolved in an early stage of passivation has a direct effect on the deposit layer thickness (5).

Depth profiling by cathodic reduction.—The cathodic reduction of the film produces iron(II) ions in the solution

$$Fe_2O_z + 2zH^+_{aq} + 2(z-2)e \rightarrow 2Fe^{2+}_{aq} + zH_2O \quad [1]$$

where z represents the oxidized state of iron in the film. Previous studies (6, 7) have shown that, in the solution at pH 6.48, the reaction for ferric oxide films proceeds with equivalent coulomb (current efficiency = 1) at a constant cathodic current of 6.0 $\mu A/cm^2$. Figures 2, 3, and 4 show the amount of iron(II) ions dissolved, W_{Fe}, along with the film thickness, L, as a function of cathodic charge passed. Reference lines in the figures correspond to stoichiometric iron oxides, $z_{Fe} = +2.67$ (Fe_3O_4) and $z_{Fe} = +3.00$ (γ-Fe_2O_3), and their slopes can be used as a reference for the oxidized state of the film. There are two regions where W_{Fe} increases linearly with Q_c in the curve, corresponding to the deposit

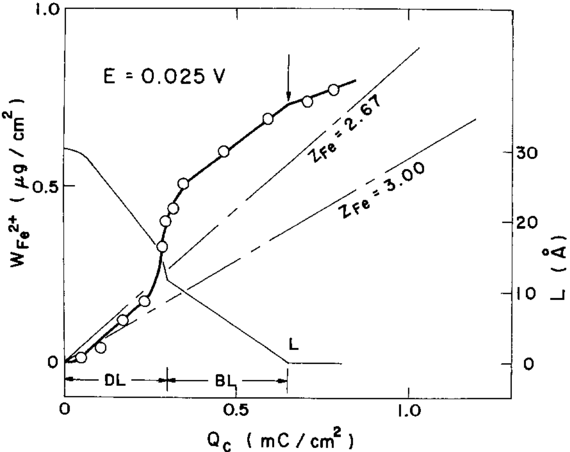

Fig. 2. Cathodic dissolution and thickness reduction curves of the passive film formed at +0.025V in potential region I in borate solution of pH 8.42. Q_c = cathodic charge passed during galvanostatic film reduction at pH 6.35.

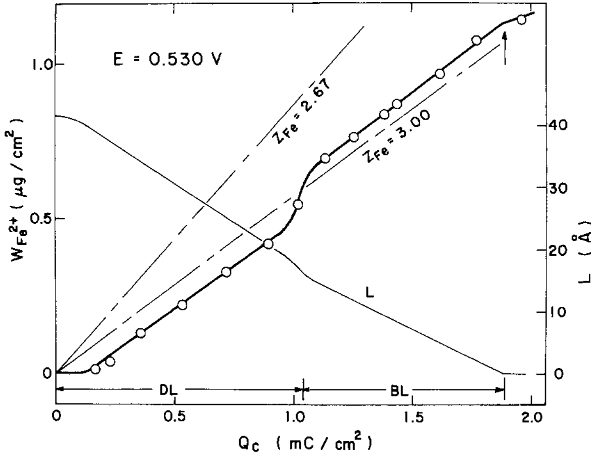

Fig. 3. Cathodic dissolution and thickness reduction curves of the passive film formed at +0.53V in potential region IIa.

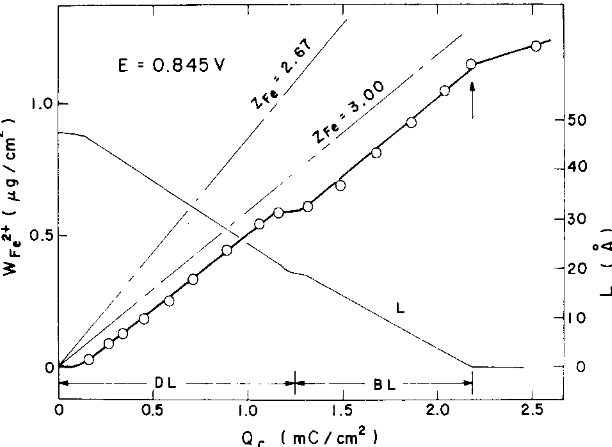

Fig. 4. Cathodic dissolution and thickness reduction curves of the passive film formed at +0.845V in potential region IIb.

layer and the barrier layer. From the slope of the curve, the oxidized state of iron in both layers can be estimated: the results are shown later (Fig. 6).

It is noticeable that the film dissolution curve is inflected with a distinct shift at the boundary between the deposit layer and the barrier layer. This shift, which varied depending on the potential of film formation, indicates that either excess iron ions or iron ion vacancies are concentrated at the barrier/deposit boundary. A discontinuous change at the boundary was also observed by light-intensity-following ellipsometry, as shown in Fig. 5, which illustrates the locus of two ellipsometric parameter Δ and Ψ during the cathodic reduction of the film formed at different potentials.

The Δ-Ψ locus is in theory related to the optical constant and thickness of the film, and therefore can be used to determine the optical constant and thickness of the film. Computer calculations (12) were carried out, in which coulometric estimates of the film thickness were taken into account and the optical constant, n − ik, was limited to a range of n = 1.7 ~ 3.2 and k = 0.0 ~ 1.0, within which all the optical constants of known iron oxides or hydroxides are found. It was thus estimated that the complex refractive index of the barrier layer was 2.50-0.14i in region I, 2.50-0.30i in region II, and 2.50-0.22i in the transpassive potential region. The index of the deposit layer could be estimated only roughly as 2.20-0.10i. The error involved in the layer thickness estimation was less than 10% for the barrier layer and about 20% for the deposit layer.

From the slope of W_{Fe}-Q_c curves the mean ionic valency of iron, z_{Fe}, can be estimated for the barrier and deposit layers. Furthermore, the iron density, dW_{Fe}/dL,

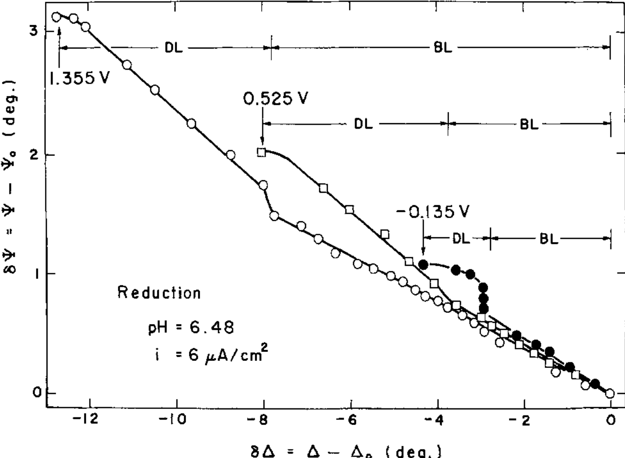

Fig. 5. Change in ellipsometric parameters Δ and Ψ during cathodic dissolution at pH 6.48 of the passive films formed at −0.135, +0.525, and +1.355V in borate solution at pH 8.42. The optical constant was 3.01 − 3.47i for the cathodically reduced iron surface (Δ_0, Ψ_0) and 1.336 for the solution of pH 6.48.

in the layers can be obtained from the L-Q_c and W_{Fe}-Q_c curves during cathodic reduction: $dW_{Fe}/dL = (dW_{Fe}/dQ_c)/(dL/dQ_c)$. Figure 6 shows z_{Fe} and dW_{Fe}/dL in the two layers as a function of potential.

In the passive region II, the barrier layer was in the oxidized state of iron(III) and had an iron density equal to that of γ-Fe_2O_3. In the passive region I, however, it contained some amount of iron(II) in addition to iron(III). This may be attributed to the electrochemical thermodynamic stability of γ-iron(III) oxide and magnetite. The Flade potential, which separates region I from region II, has been explained as the equilibrium potential of the reaction (10, 13)

$$2Fe_3O_4 + H_2O \rightleftarrows 3\gamma\text{-}Fe_2O_3 + 2H^+_{aq} + 2e \quad [2]$$

Magnetite is thermodynamically stable in region I and γ-iron(III) oxide in region II. Wagner (13) described γ-iron(III) oxide as an iron-deficient magnetite ($Fe_{3-\Delta}O_4$) saturated with iron vacancies ($\Delta = 1/3$) and explained the Flade potential as coresponding to a halfway ($\Delta = 1/6$) between stoichiometric magnetite and iron-vacancy-saturated magnetite.

In the transpassive potential region where anodic iron dissolution was detectable, the barrier layer was again found to contain a little amount of iron(II) and, correspondingly, its iron density increased to a value close to that of magnetite. This is a fact which may agree with an electron diffraction analysis result obtained by Foley, Kruger, and Bechtoldt (14), who found a detectable amount of magnetite in the passive film formed in the potential region of oxygen evolution. This fact appears to contradict the thermodynamic stability of iron oxides that the oxidized state becomes higher as the potential is more noble. It should be mentioned, however, that the film is not in thermodynamic equilibrium, because of an appreciable dissolution current requiring a nonequilibrium iron transport through the transpassive surface film. A possible explanation is based on the transport ratio of iron ions and oxygen ions, which is likely to determine the nonequilibrium composition of the barrier layer. Further discussion will be reported elsewhere.

The deposit layer of hydrated iron(III) oxide exhibits no significant composition change in the whole range of potential, except for an absorption of iron(II) ions in region I. This may suggest that the deposit layer is formed by anodic oxidation of iron(II) ions dissolved in solution in an early stage of passivation

$$FeOH^+_{aq} + H_2O \rightarrow \gamma\text{-}FeOOH + 2H^+_{aq} + e \quad [3]$$

The anodic deposition film of this kind has recently been identified by Hashimoto and Cohen (15) as γ-FeOOH.

Barrier/deposit boundary.—As mentioned above, there was a shift in the cathodic dissolution curve of the film at the barrier/deposit boundary. There was also an induction period of film dissolution in an early stage of the cathodic reduction. No direct relationship, however, was found between the shift and the induction. The induction period requires a cathodic charge for polarizing the passive film to the potential where the film dissolution occurs, and therefore may represent the apparent electrical capacity of the film, whatever the mechanism may be. The shift, on the other hand, can be considered as an indication of excess iron ions or iron ion vacancies that concentrate at the barrier/deposit boundary. This shift was therefore determined quantitatively in terms of the amount of iron, and is plotted as a function of potential in Fig. 7. It is thus seen that the boundary composition changed from iron ion excess to iron ion deficiency as the potential was more noble. Schematic depth profiles of iron in the passive film formed in four different potential regions are also shown in Fig. 7. The passive region II may be divided into two regions, region IIa with excess iron ions and region IIb with iron ion vacancies at the barrier/deposit boundary.

It is worth showing that the barrier/deposit boundary composition is not a reversible function of potential but differs with different processes of film formation. Figure 8 illustrates in thickness and schematic composition depth profile the difference that arose between the film formed at +0.245V for 1 hr and the film first formed at +0.845V for 1 hr and then polarized to +0.245V for another hour. The film formed at +0.845V

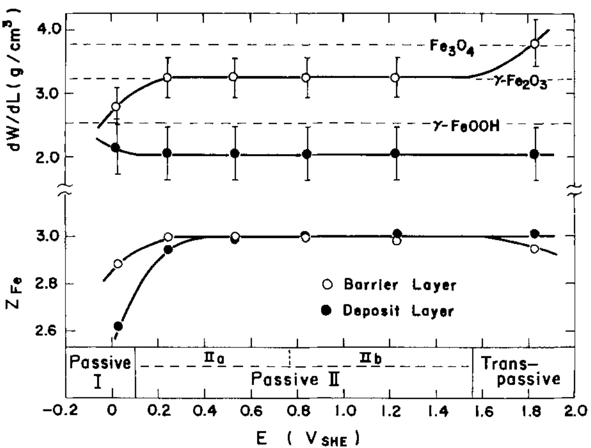

Fig. 6. Iron ion valency z_{Fe} and iron density dW_{Fe}/dL in the barrier and deposit layers as a function of potential.

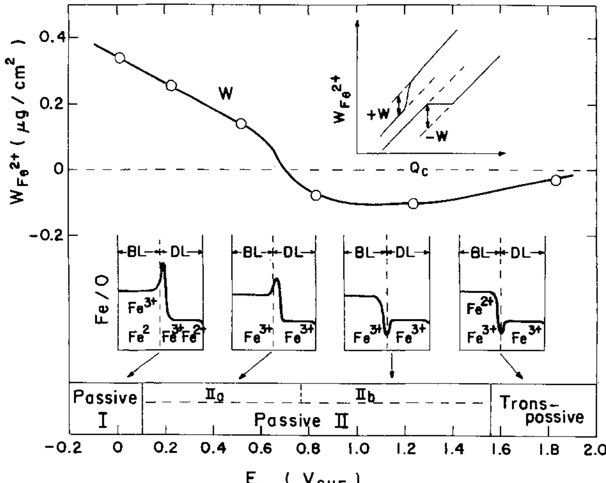

Fig. 7. Iron excess or deficiency at the barrier/deposit boundary as a function of potential.

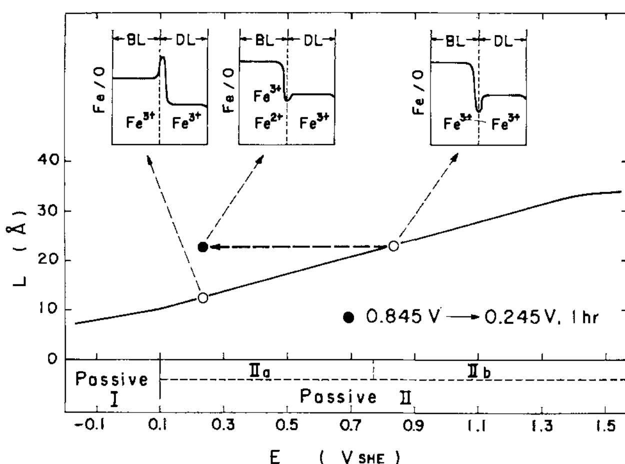

Fig. 8. Barrier layer thickness and schematic depth profile of the passive film formed at +0.245V 1 hr, the film formed at +0.845V 1 hr, and the film first formed at +0.845V 1 hr followed by 1 hr aging at +0.245V.

and aged at +0.245V had iron ion vacancies at the barrier/deposit boundary, as contrasted with excess iron ions concentrated at the boundary in the film fresh formed at +0.245V.

It should also be noted that the aging at +0.245V of the film formed at +0.845V caused the barrier layer, which was iron(III) oxide before aging, to contain a small amount of iron(II) ions. This aging effect can probably be explained as resulting from a diffusion of iron through the barrier layer, *i.e.*, an oxide conversion proposed by Sato and Cohen (16)

$$Fe + 4\gamma\text{-}Fe_2O_3 \rightarrow 3Fe_3O_4 \quad [4]$$

Potentiostatic film growth.—The passive film was grown at constant potential for different periods of time in the solution of pH 8.42, and then the depth analysis of the film was carried out by galvanostatic-cathodic reduction at pH 6.35. Figure 9 shows the thickness and the iron ion valency of the barrier and deposit layers as a function of time during the film growth at a constant potential in region II. Evidently, it is the barrier layer that grew in thickness and the deposit layer remained practically unchanged. This is a fact which one should bear in mind when studying the film growth kinetics in the passive potential region. Notice also that the barrier layer changed from $z_{Fe} < +3$ in an early stage to $z_{Fe} = +3$ in the later stage of film growth.

The composition change that occurred at the barrier/deposit boundary is also schematically illustrated in Fig. 9. Excess iron ions initially accumulated at the barrier/deposit boundary are gradually replaced by iron ion vacancies in the later stage. This may probably be attributed to the electrified double layer structure that forms at the barrier/deposit boundary, but the mechanism remains unclear in detail.

The film growth is somewhat different in the passive I region from that in the passive II region. Figure 10 shows the film growth process that occurred in region I. Notice that the iron ion valency changed in both the barrier layer and the deposit layer. The barrier layer, which was iron(III) oxide in an early growth stage, gradually changed in composition to iron(II-III) mixed oxide with more iron(II) than in magnetite after an extended period of time. In this potential region, magnetite is thermodynamically more stable than γ-iron(III) oxide according to reaction [2], while γ-iron(III) oxide is also stable when the iron(II) ion concentration in the solution exceeds the equilibrium concentration with the following reaction

$$2FeOH^+{}_{aq} + H_2O \rightleftarrows \gamma\text{-}Fe_2O_3 + 4H^+{}_{aq} + 2e \quad [5]$$

It is therefore suggested from the results that in the passive region I, the barrier layer is formed initially by reaction [5] in the presence of iron(II) ions and then undergoes a transformation from γ-iron(III) oxide to magnetite by reaction [2] or [4]. During the oxide conversion a gradual increase in thickness of the barrier layer was observed.

The deposit layer was also observed to grow in thickness while undergoing a compositional change from iron(II-III) mixed hydroxide toward iron(III) hydroxide. This may be explained by the following reactions simultaneously taking place in region I: $FeOH^+{}_{aq} + H_2O \rightarrow Fe(OH)_2 + H^+{}_{aq}$, $Fe(OH)_2 \rightarrow FeOOH + H^+{}_{aq} + e$, and $FeOH^+{}_{aq} + H_2O \rightarrow FeOOH + 2H^+{}_{aq} + e$.

Conclusions

The galvanostatic cathodic reduction technique employing appropriate solution and current density provides a depth profiling analysis of the passive film on iron.

The potential region of iron passivity in borate solution at pH 8.42 may be divided by the Flade potential into two regions, I and II, with which the passive barrier layer changes in composition and refractive index.

In region I, the barrier layer was an iron(II-III) mixed oxide and its thickness for unit voltage at steady state was 1.54 nm/V (6.5×10^6 V/cm). In region II, it was an iron (III) oxide [probably γ-iron(III) oxide] with thickness 1.75 nm/V (5.7×10^6 V/cm).

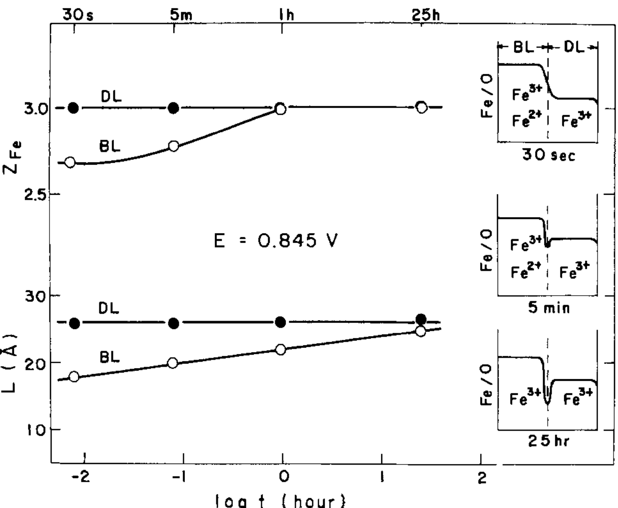

Fig. 9. Thickness, iron ion valency, and schematic depth profile of the passive film as a function of time of potentiostatic film growth in potential region II.

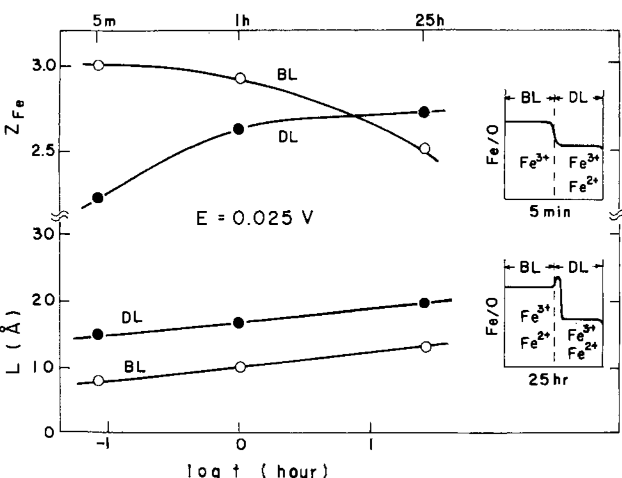

Fig. 10. Thickness, iron ion valency, and schematic depth profile of the film as a function of time of potentiostatic film growth in potential region I.

Transpassivation caused the barrier layer to cease growing with rise of potential and to reduce its oxidized state to less than $z_{Fe} = +3$.

The deposit layer, which was always formed on the barrier layer, was a hydrated iron(III) oxide (probably γ-FeOOH) and exhibited no significant composition change with potential, except for an absorption of iron(II) ions in region I.

There was a peak or a decrease in iron ion concentration at the barrier/deposit boundary in the depth profile of the film. At relatively less noble potentials the boundary adsorbed excess iron ions, which were gradually replaced by iron ion vacancies as the potential was more noble.

It is the barrier layer alone that increased in thickness during the growth of the passive film in the potential region II.

Current and Potential Distributions in Plating Corrosion Systems

ABSTRACT

The numerical determination of current and potential distributions has been performed for plating corrosion systems, where failure to coat a small area leads to corrosion at the pinhole. The distributions depend on characteristic parameters for the disk anode and surrounding plane cathode and reveal that each of the electrodes influences the other due to their proximity. The results were applied to an array of disks, and it was found that the corrosion potential of the system is a linear function of the area ratio of anode to cathode when ohmic effects are important. This may be contrasted to the logarithmic dependence found when ohmic effects are neglected. Other applications are discussed.

The protection of active metals by electroplated noble metals has been an established practice for many years. In the electronics industry, for example, copper is protected by plating gold over the substrate. In order to minimize costs, the thickness of the gold coating is reduced as much as possible, and this introduces pores in the overplate. These pores will permit corrosion of the underlying copper substrate, and if there is a cathodic reaction on the gold, the corrosion of copper will actually be enhanced because of galvanic effects. Therefore, one seeks the minimum thickness of the gold electroplate which will adequately eliminate corrosion.

Several techniques have been introduced to determine the porosity of the electroplate for various plating thicknesses. Chemical etch techniques for the copper-gold system (1, 2) decorate the pores and permit them to be counted by microscopic techniques. The measurement of anodic current in a system where the gold is completely inert and only copper is active has been very successful (2, 3) in determining the total surface area of copper exposed in pores, but it does not reveal the distribution of pores nor their size on electroplated pieces. A similar technique (4-7) is the determination of resistance when an electroplated specimen is polarized under potentiostatic control. Finally, measurement of the corrosion potential for the galvanic couple, substrate/coat, has been proposed (8-11) as a technique to measure the ratio of areas of the two metals. We have chosen this final technique for further discussion and study here.

Galvanic corrosion, in this case the corrosion of an active metal in a pore driven by a cathodic reaction

* Electrochemical Society Active Member.
Key words: corrosion, porous coatings, current distribution, potential distribution, corrosion potential, electrode interaction.

on the surrounding noble electroplate, is a complex phenomenon which may involve electrode-kinetic effects on both the anode and cathode, mass-transfer effects, and ohmic effects. In addition, the proximity of the two "electrodes" in plating corrosion can lead to interaction effects not normally seen on separated electrodes.

Stern (9) first derived the relationship between the area ratio of a galvanic couple and its corrosion potential. The development was based on the assumptions that the electrochemical reaction kinetics on each electrode were of the Tafel form and that the respective reactions were uniform on the anode and cathode of the couple. This development does not take into account ohmic effects in the solution. The relationship derived is (9)

$$\eta_{corr} = -\frac{E_a\beta_c}{\beta_c + \beta_a} - \frac{\beta_c\beta_a}{\beta_c + \beta_a}\ln(A_a\ i_{o_a}) + \frac{\beta_c\beta_a}{\beta_c + \beta_a}\ln(A_c\ i_{o_c}) \quad [1]$$

where β = Tafel slope of the respective reaction, i_o = exchange current density of the respective reaction, A_a = area fraction of anode, A_c = area fraction of cathode, η_{corr} = corrosion potential of the couple relative to the reversible potential of the cathode, and E_a = standard reversible potential of the anode with respect to the reversible potential of the cathode. Thus it may be seen that the corrosion potential has a logarithmic dependence on the area ratio A_a/A_c, with a slope of $-\beta_c\beta_a/(\beta_c + \beta_a)$. Stern (9) notes that this equation is not valid in the limit that A_a or A_c approaches 1.

Oldham and Mansfeld (11) recently extended this treatment to include both an oxidation reaction and reduction reaction on the cathode of the couple. Their development again does not take ohmic effects into account, but they do treat the case of diffusion control on the cathode.

Mansfeld has also treated other special cases (12) including that for diffusion control on both anode and cathode. For this case, the "catchment principle" is derived, *i.e.*, the corrosion potential is found to be linearly related to the area ratio for the galvanic couple.

Levich and Frumkin (13) treated a system of a cathodic disk in a surrounding anodic plane, which is the reverse of the system to be treated here. The current density on the small disk was uniform, and the potential of the surrounding plane was uniform (*i.e.*, completely reversible kinetics on the plane). This treatment specifically includes ohmic effects in solution. More recently, McCafferty (14) has presented an analysis of current and potential distribution for an anodic disk in a surrounding cathodic plane, using an assumed linear form for the electrode kinetics on the disk and plane. This treatment also includes the effect of ohmic resistance in solution.

The present contribution describes the general analysis of current and potential distribution for an anodic disk in a cathodic plane. General mathematical expressions for the electrode kinetics are employed, which reduce to the special treatments listed above as limiting cases. This analysis also provides a systematic treatment of the effect of the proximity of the electrodes on the current and potential distribution of each electrode. The broader understanding of galvanic corrosion in this simple system then allows one to predict the behavior of arrays of disks, and therefore the influence of porosity of the electroplate on the corrosion potential of the couples.

Mathematical Treatment

The system to be studied here is illustrated in Fig. 1. The anodic disks are distributed randomly on the surface, are coplanar with the surrounding plane, and are all of the same radius, r_d. They are also assumed to be far apart. The effect of recessing the pores is discussed briefly, but a detailed study will be treated in a later paper.

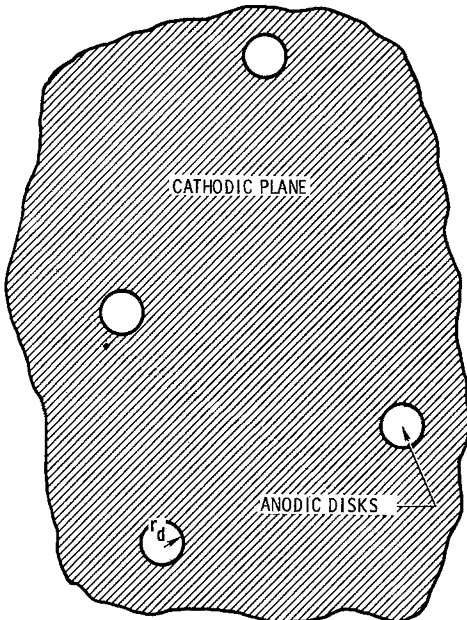

Fig. 1. Corroding disks in a cathodic surrounding plane

The current and potential distributions in an electrochemical system may be determined mathematically by solving Laplace's equation

$$\nabla^2\phi = 0 \quad [2]$$

subject to boundary conditions on the electrodes imposed by the kinetics of the reactions occurring there. Electrodes with highly reversible reactions have a constant-potential boundary condition everywhere on the surface since polarization causes an ohmic potential drop in solution without changing the surface potential of the electrode. The current and potential distributions on an electrode with this boundary condition depend on geometric ratios for the system, but do not depend on the absolute size. Boundary conditions suitable for slower reactions cause the current and potential distribution to depend on an absolute length of the electrode, as well as the geometric ratios characteristic of a purely ohmically determined distribution. Also, it is shown below that the distribution on one electrode depends on the distribution on the counterelectrode as well when the electrodes are near one another.

For the analysis which follows, attention is focused on one disk first, and the array of disks is treated later. The origin of the coordinate system is chosen as the center of the disk. Radial distance, r, is measured from the axis of the disk, parallel to the surface. The distance, z, is measured normal to the surface. We choose the rotational elliptic coordinate system, which has been shown (15, 16) to be especially suitable for disk geometries and is related to the coordinates r, z, by

$$z = r_d\,\eta\,\xi \quad [3]$$

$$r/r_d = [(1 + \xi^2)(1 - \eta^2)]^{1/2} \quad [4]$$

where r_d is the disk radius. The disk in a surrounding plane is now described geometrically in rotational elliptic coordinates as shown in Fig. 2. The disk electrode is at $\xi = 0$, and its axis is $\eta = 1$. The surrounding plane is located at $\eta = 0$. The plane $\xi = \xi_{max}$ is far from the disk and in cylindrical coordinates is approximately a hemisphere in the solution which intersects the surrounding plane at a radial distance r_{max}.

Laplace's equation in this coordinate system is (16)

$$(1 - \eta^2)\frac{\partial^2\phi}{\partial\eta^2} + (1 + \xi^2)\frac{\partial^2\phi}{\partial\xi^2} + 2\xi\frac{\partial\phi}{\partial\xi} - 2\eta\frac{\partial\phi}{\partial\eta} = 0 \quad [5]$$

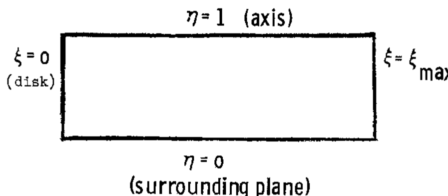

Fig. 2. The disk-plane system in rotational elliptic coordinates

and is to be solved subject to the boundary conditions (where κ is the conductivity of the electrolytic solution)

(a) on the disk, $\xi = 0$

$$i_d = -\frac{\kappa}{r_d \eta} \left.\frac{\partial \phi}{\partial \xi}\right|_{\xi=0} \quad [6]$$

$$= i_{od}\left[\exp\left\{\frac{\alpha_{ad}\mathbf{F}}{RT}(V_d - \phi^\circ{}_d - E^\circ{}_d)\right\} - \exp\left\{\frac{-\alpha_{cd}\mathbf{F}}{RT}(V_d - \phi^\circ{}_d - E^\circ{}_d)\right\}\right] \quad [7]$$

(b) on the surrounding plane, $\eta = 0$

$$i_p = -\frac{\kappa}{r_d \xi} \left.\frac{\partial \phi}{\partial \eta}\right|_{\eta=0} \quad [8]$$

$$= i_{op}\left[\exp\left\{\frac{\alpha_{ap}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - E^\circ{}_p)\right\} - \exp\left\{\frac{-\alpha_{cp}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - E^\circ{}_p)\right\}\right] \quad [9]$$

(c) ϕ well-behaved at $\eta = 1$

(d) at $\xi = \xi_{max}$ two different boundary conditions were employed, *i.e.*

$$* \frac{\partial \phi}{\partial \xi} = 0 \quad \text{at} \quad \xi = \xi_{max} \quad [10]$$

$$* \frac{\partial \phi}{\partial \xi} = -\frac{2\phi}{\xi_{max}}\left\{\frac{P_1(\eta) + \dfrac{3P_2(\eta)}{\xi_{max}P_2(0)\,J_p}}{P_1(\eta) + \dfrac{2P_2(\eta)}{\xi_{max}P_2(0)\,J_p}}\right\} \quad [11]$$

Equation [10] would be appropriate for an insulating surface at ξ_{max}, and Eq. [11] is an approximation to the derivative at ξ_{max} when the solution actually extends to infinity. In the latter case, the potential ϕ is measured relative to the reversible or open-circuit potential for the surrounding plane. The quantity $(V - \phi^\circ - E^\circ)$ in Eq. [7] and [9] is the surface overpotential for the respective reaction (16), and ϕ° is the potential in solution at the electrode surface. The derivation of Eq. [11] is given in Appendix A.

The Butler-Volmer relationship for kinetics on an electrode is given by Eq. [7] or [9]. For corrosion systems where simultaneous reactions occur on a homogeneous surface, such a relationship would be appropriate for each reaction. Polarization of a reaction far from its reversible potential E° will cause one term of the relationship to dominate, and the polarization is said to be in the Tafel region. For two different reactions occurring simultaneously, one anodic and one cathodic on the same surface, one has for Tafel polarization

$$i_{anodic} = i_{oa}\exp\left[\frac{\alpha_a\mathbf{F}}{RT}(V - \phi^\circ{}_a - E^\circ{}_a)\right]$$

and

$$i_{cathodic} = -i_{oc}\exp\left[\frac{-\alpha_c\mathbf{F}}{RT}(V - \phi^\circ{}_c - E^\circ{}_c)\right]$$

Following Wagner and Traud (17), the local (net) current density at a point on the surface is the sum of the current density for each reaction, *i.e.*

$$i_{net} = i_{anodic} + i_{cathodic} = i_{oa}\exp\left[\frac{\alpha_a\mathbf{F}}{RT}(V - \phi^\circ - E^\circ{}_a)\right] - i_{oc}\exp\left[\frac{-\alpha_c\mathbf{F}}{RT}(V - \phi^\circ - E^\circ{}_c)\right]$$

For zero net current

$$i_{anodic} = -i_{cathodic}$$

or

$$i_{oa}\exp\left[\frac{\alpha_a\mathbf{F}}{RT}(V - \phi^\circ - E^\circ{}_a)\right] = i_{oc}\exp\left[-\frac{\alpha_c\mathbf{F}}{RT}(V - \phi^\circ - E^\circ{}_c)\right] = i_{corr}$$

where i_{corr} is the corrosion current density at the mixed or corrosion potential. U_{corr} is the corrosion potential identified as

$$U_{corr}\left[\frac{\alpha_a\mathbf{F}}{RT} + \frac{\alpha_c\mathbf{F}}{RT}\right] = -\ln\frac{i_{oa}}{i_{oc}} - \frac{\alpha_a\mathbf{F}}{RT}E^\circ{}_a - \frac{-\alpha_c\mathbf{F}}{RT}E^\circ{}_c$$

which is identical to Eq. [1] when $E^\circ{}_c$ is zero. The expression for the net current may now be written

$$i_{net} = i_{corr}\left\{\exp\left[\frac{\alpha_a\mathbf{F}}{RT}(V - \phi^\circ - U_{corr})\right] - \exp\left[\frac{-\alpha_c\mathbf{F}}{RT}(V - \phi^\circ - U_{corr})\right]\right\}$$

This expression for the net current is similar to Eq. [7] or [9] where i_o is replaced by i_{corr} and E° is replaced by U_{corr}. Therefore, Eq. [7] may be written for a corroding disk as

$$i_d = i_{corr,d}\left\{\exp\left[\frac{\alpha_{ad}\mathbf{F}}{RT}(V_d - \phi^\circ{}_d - U_{corr,d})\right] - \exp\left[\frac{-\alpha_{cd}\mathbf{F}}{RT}(V_d - \phi^\circ{}_d - U_{corr,d})\right]\right\} \quad [12]$$

For a corroding plane

$$i_p = i_{corr,p}\left\{\exp\left[\frac{\alpha_{ap}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - U_{corr,p})\right] - \exp\left[\frac{-\alpha_{cp}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - U_{corr,p})\right]\right\} \quad [13]$$

The boundary conditions [12] and [13] along with the expressions for the current in solution at the electrode surfaces yield the characteristic "polarization parameters" for the problem (18). First we have the ratios of the transfer coefficients α_{ad}/α_{cd} and α_{ap}/α_{cp}. For all the calculations reported here, it has been assumed that these ratios are both unity, that is, that the cathodic Tafel slope equals the anodic Tafel slope for either the disk or the plane. Following Newman (18), we identify the additional polarization parameters as

$$J_d = \frac{i_{corr,d}(\alpha_{ad} + \alpha_{cd})\mathbf{F}r_d}{\kappa RT} \quad [14]$$

and

$$\delta_d = \frac{|i_{avg,d}|\alpha_{ad}\mathbf{F}r_d}{\kappa RT} \quad [15]$$

for the disk and

$$J_p = \frac{i_{corr,p}(\alpha_{ap} + \alpha_{cp})\mathbf{F}r_d}{\kappa RT} \quad [16]$$

for the plane. These three quantities all represent ratios of the ohmic potential drop (of order $i_{avg}r_d/\kappa$) to the surface overpotential. The quantities J_d and J_p contain i_{corr} and are especially relevant in a potential range where the corresponding Eq. [12] or [13] can be linearized. The quantity δ_d is especially relevant when the Eq. [12] can be approximated by a Tafel expression. With retention of the full forms of Eq. [12] and [13], all these dimensionless parameters can have some influence on the current and potential distributions. The parameter J_p for the plane involves r_d since this is the only characteristic dimension. Since the total current on the anode must be equal in magnitude to the total cathodic current, there is no additional parameter, like δ_d, for the plane. If a net current were being imposed on the disk-plane system by a third electrode, then there would be a total of six parameters for the disk and the plane.

For large values of J_d and δ_d, the current distribution on the disk becomes highly nonuniform and approaches the ohmically determined distribution (uniform potential on the electrode). For small values of these parameters, the current distribution is controlled by the kinetics and becomes uniform.

By the method of separation of variables, one can write the general solution of Eq. [5] as

$$\phi = \sum_{n=1}^{\infty} B_n P_n(\eta) M_n(\xi) \quad [17]$$

where P_n is the Legendre polynomial and M_n is the Legendre function of imaginary argument (15). The solution for the present problem involves both odd and even orders in both P_n and M_n, and this prevents one from obtaining an orthogonality relationship to calculate the B coefficients in the infinite series. Equation [17] is not very useful for this reason, and it is necessary to seek another means to solve Eq. [5] for the present study. It has been found that the numerical solution of Eq. [5] by finite difference techniques provides very satisfactory results. The remainder of this paper is devoted to the discussion of this technique and the results obtained.

As an aside, it is noted that Levich and Frumkin (13) found that only the first term of Eq. [17] was needed to solve the problem they treated. From the form of the first few terms in Eq. [17], it is expected that the dominant term for large values of ξ (far from the disk) is the first term. This leads one to expect that the present results should show parallel behavior to the results of Levich and Frumkin (13) at large values of ξ. These authors found

$$B_1 = \frac{2i_d r_d}{\pi\kappa}$$

and thus

$$\phi = \frac{2i_d r_d}{\pi\kappa}\eta(\xi \cot^{-1}\xi - 1) \quad [18]$$

where i_d is the (uniform) current density on the disk. This result provides a convenient basis for comparison for our results and a means of calculating the contribution of an individual pore to the potential detected by a distant reference electrode (the measured corrosion potential). See also Appendix A which discusses the asymptotic behavior of the potential distribution when electrode-kinetics on the surrounding plane is not ignored.

Numerical Analysis

Following Klingent, Lynn, and Tobias (19) and Fleck (20), we use the five-point, central difference approximation to obtain Laplace's equation in finite difference form

$$\phi_o = \left[\frac{2(1-\eta_o^2)}{h_\eta^2} + \frac{2(1+\xi_o^2)}{h_\xi^2}\right]$$
$$= \phi_1\left[\frac{1+\xi_o^2}{h_\xi^2} + \frac{\xi_o}{h_\xi}\right] + \phi_2\left[\frac{1-\eta_o^2}{h_\eta^2} - \frac{\xi_o}{h_\xi}\right]$$
$$+ \phi_3\left[\frac{1+\xi_o^2}{h_\xi^2} - \frac{\xi_o}{h_\xi}\right] + \phi_4\left[\frac{1-\eta_o^2}{h_\eta^2} + \frac{\eta_o}{h_\eta}\right] \quad [19]$$

where h_ξ and h_η are mesh spacings as defined in Fig. 3. This equation is solved for ϕ_o and is identified as $\phi_{o,try}$. A new value of ϕ_o is calculated by

$$\phi_{o,new} = \phi_{o,old} + \Omega(\phi_{o,try} - \phi_{o,old})$$

where Ω is the overrelaxation factor. This value of $\phi_{o,new}$ is used in the calculation of ϕ for adjacent points. All the interior points in the space are treated this way for one iteration, and the iteration procedure is repeated until ϕ converges to within some error limit at each point. The procedure outlined above is the Liebmann (Gauss-Siedel) iteration procedure with successive overrelaxation.

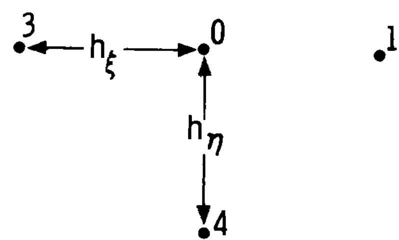
At boundary points on the electrodes, use of the five-point central difference technique produces "image" points outside the physical space. These image points are eliminated by using the boundary conditions [6] and [8] along with [12] and [13] (or [7] and [9]), expressed in finite difference form. This yields on the plane electrode

$$\phi_o = \left[\frac{2(1-\eta_o^2)}{h_\eta^2} + \frac{2(1+\xi_o^2)}{h_\xi^2}\right]$$
$$= 2\phi_2\left(\frac{1-\eta_o^2}{h_\eta^2}\right) + \phi_1\left[\frac{1+\xi_o^2}{h_\xi^2} + \frac{\xi_o}{h_\xi}\right]$$
$$+ \phi_3\left[\frac{1+\xi_o^2}{h_\xi^2} - \frac{\xi_o}{h_\xi}\right] + 2\xi_o h_\eta F_p\left[\frac{1-\eta_o^2}{h_\eta^2} + \frac{\eta_o}{h_\eta}\right] \quad [20]$$

where

$$F_p = \frac{r_d}{\kappa} i_{corr,p}\left\{\exp\left[\frac{\alpha_{ap}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - U_{corr,p})\right] - \exp\left[\frac{-\alpha_{cp}\mathbf{F}}{RT}(V_p - \phi^\circ{}_p - U_{corr,p})\right]\right\}$$

A similar relationship is obtained for boundary points



8

Fig. 3. Relationship of the mesh points and mesh distances h_ξ and h_η.

on the disk. Equation [20] is a nonlinear equation in ϕ°_{p}. The treatment of these nonlinear boundary conditions is discussed in more detail in Appendix B. For convenience, $U_{corr,p}$ was taken to be zero for the calculations.

The boundary at $\eta = 1$ was treated by dropping the term

$$(1-\eta^2)\,\frac{\partial^2\phi}{\partial\eta^2}$$

from Eq. [5] and using backward difference relations in η, central differences in ξ, to obtain

$$\phi_0\left[\frac{2(1+\xi_0{}^2)}{h_\xi{}^2}+\frac{3}{h_\eta}\right]=\phi_1\left[\frac{1+\xi_0{}^2}{h_\xi{}^2}+\frac{\xi_0}{h_\xi}\right]+\phi_3\left[\frac{1+\xi_0{}^2}{h_\xi{}^2}-\frac{\xi_0}{h_\xi}\right]+\phi_4\left[\frac{4}{h_\eta}\right]-\phi_8\left[\frac{1}{h_\eta}\right]\qquad[21]$$

where the points are identified on Fig. 3. The iteration procedure and successive overrelaxation used for these boundary points were similar to that employed for the interior points.

The boundary at $\xi = \xi_{max}$ was treated with two different boundary conditions. The boundary condition expressed by Eq. [10] was used to simulate the situation which would be encountered for a single disk in a plane with an insulating surface at ξ_{max}. The boundary points were treated in the same way as interior points, and the image points were eliminated by using Eq. [10] in finite difference form. The iteration procedure and successive overrelaxation for these points were the same as for interior points. The boundary condition expressed by Eq. [11] was used to obtain results which could be used with multiple disks in the plane. The relationship [11] was expressed in finite-difference form to eliminate image points, and the iteration procedure and successive overrelaxation were used as before. For large values of ξ_{max}, both boundary conditions give essentially identical results for the potential and current distribution on and near the disk. The results differ in the region near ξ_{max} where boundary condition [10] causes the current density on the plane to be higher near ξ_{max} than does [11], for the same total current to the disk. This is discussed in more detail below.

Results and Discussion

The results which have been obtained are rather complex. In order to discuss them clearly and concisely, the presentation of the results is divided into four parts. In the first part, the general behavior is discussed with particular emphasis on accuracy and the influence of boundary conditions. Following this is the description of the calculated current and potential distributions as influenced by system parameters. The third part discusses the implications of these results for disk arrays, and the final part presents other applications.

General.—The finite-difference technique used here was found to be efficient, fast, and accurate for determining the current and potential distribution on the disk and plane. The use of overrelaxation and successive iteration procedures discussed earlier reduces the computational time required for convergence as compared to other iteration procedures without overrelaxation [see Fleck (20)]. Iteration was concluded when all points in the domain changed less than a given error limit for two successive iterations. Accuracy was assumed adequate when (*i*) reducing the error limit caused a change of less than 0.1%, and (*ii*) doubling the number of mesh points in each direction caused a change of less than 0.1%. Finally, calculations were made for the disk-insulating plane system discussed by Newman (15), and the uniform disk-reversible plane system discussed by Levich and Frumkin (13). It was possible to achieve agreement with both cases to within 0.1%. Therefore, it is believed that the results presented here are accurate to 0.1%, unless otherwise noted.

In general, the current density on the disk and plane is larger in absolute magnitude near the edge of the disk than elsewhere. The effect of slow kinetics, small size, and high conductivity is to reduce this nonuniformity. In the limit of uniform current density on both the disk and surrounding plane, the system behavior should approach that described by Stern (9) and Oldham and Mansfeld (11).

The use of the insulator boundary condition, Eq. [10], forces the total current on the plane to be equal in magnitude to the total current on the disk. These results would be useful for studies of galvanic corrosion of a single disk in a surrounding plane, with an insulator surface at ξ_{max}. Since the primary interest here is for disk arrays, and the insulator boundary condition results are not relevant to arrays, they are not discussed further. It is sufficient to state that the current distribution on the disk is unaffected by the boundary condition at ξ_{max} for the range of parameters discussed below. The current distribution on the plane is affected only near ξ_{max}, where current is forced to go due to the insulator boundary condition. Therefore, the general behavior of the system is identical for either boundary condition, except as noted, and the behavior is described only for Eq. [11].

Condition [11] relates the potential ϕ and the gradient $\partial\phi/\partial\xi$ at ξ_{max}, and current may pass through this surface. The amount of current that "leaks" through this surface at ξ_{max} will depend on the location of ξ_{max} as well as the nonuniformity of current density on the plane. For a given value of J_p for the plane, the fraction of current that leaks past ξ_{max} decreases as ξ_{max} increases.

The current distribution on the disk is determined by the parameter J_d for $i << i_{corr}$, and is independent of the current level and therefore the potential difference between the disk and plane. For currents much larger than i_{corr}, the current distribution is determined by the current level as measured by δ_d. For intermediate currents, values of α_{ad}/α_{cd} and δ_d characterize the current distribution. In addition, the polarization characteristics of the plane influence the current distribution on the disk as will be shown.

Current and potential distribution on the disk and plane.—The potential distribution in the solution on the disk and plane for an insulating plane is shown in Fig. 4. The potential at the surface is highest near the center of the disk and decreases to zero far from the disk. This is compared to the potential distribution calculated for a conducting plane with reversible kinetics ($J_p \rightarrow \infty$) shown in the lowest curve on this figure. The influence of the conducting plane is to lower the potential near the center of the disk, and the po-

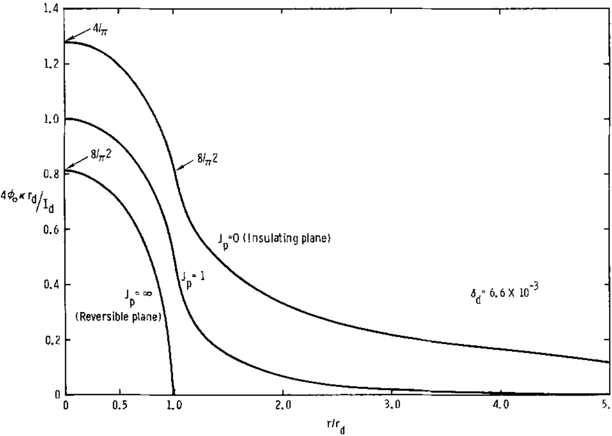


Fig. 4. Potential distribution at the surface of the disk and surrounding plane.

tential becomes zero at the edge where the two electrodes join. The gradient of the potential is larger near the edge of the disk for a conducting plane.

To make the influence of the plane polarization more quantitative, the potential difference across the disk is shown in Fig. 5 as a function of J_p for different values of δ_d. $\Delta\phi$ is made dimensionless by multiplying by $4r_d\kappa/I$ where I is the total (disk) current. The influence of increasing δ_d is to decrease the importance of electrode kinetics relative to the ohmic potential drop, and thus to decrease the potential difference between the center and edge of the disk. The intercept as $J_p \to 0$ for each curve was calculated for an insulating plane, and the general curve is shown in Fig. 6, where the intercept is from Newman (15). In the other extreme, as $J_p \to \infty$, the potential difference across the disk is shown in Fig. 7 as a function of δ_d. The intercept for $\delta_d \to 0$, $J_p \to \infty$, is that for the Levich-Frumkin calculation, *i.e.*, $8/\pi^2$. The results shown on Fig. 7 are less accurate than other results reported herein because of the large gradients in the corner where the disk and plane join. Problems with accuracy were also encountered for the calculations of Fig. 5 for values of J_p greater than 20. The results for large values of J_p and δ_d will be reported at a later date.

The current distribution on the disk is shown in Fig. 8 where the curve for $J_p = 0$ is for an insulating plane and agrees with the results of Newman (15). The other curves were calculated for a conducting plane with different values of the plane polarization parameter. As noted already, increasing J_p distorts the current distribution on the disk, causing a larger current density at the edge of the disk. This results from decreasing the influence of electrode kinetics on the plane as compared

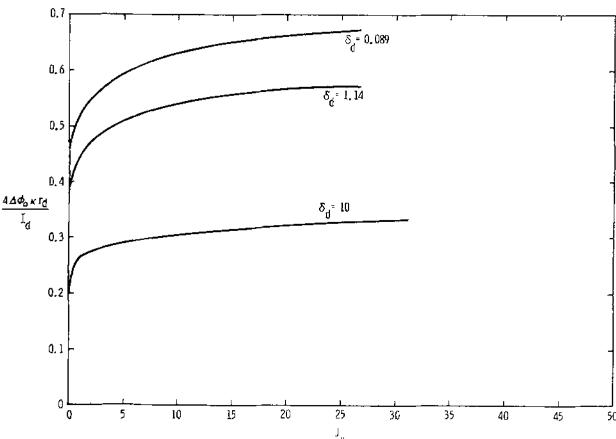

Fig. 5. Potential difference between the center and edge of the disk as a function of plane polarization parameter J_p.

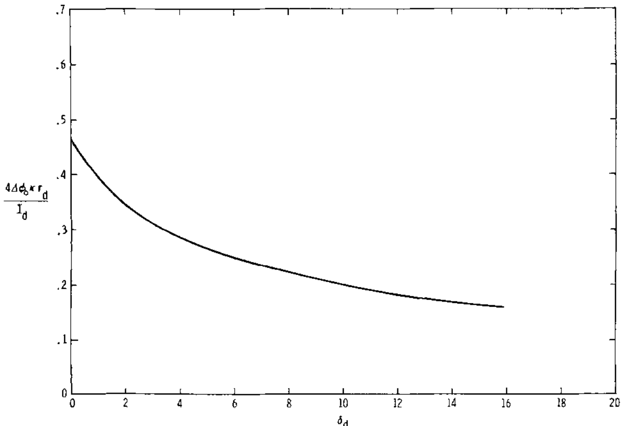

Fig. 6. Potential difference between the center and edge of the disk in an insulating plane as a function of δ_d.

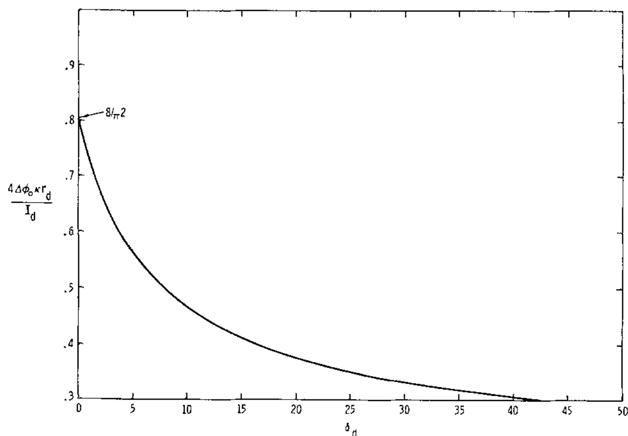

Fig. 7. Potential difference between the center and edge of a disk in a conducting (reversible) plane as a function of δ_d.

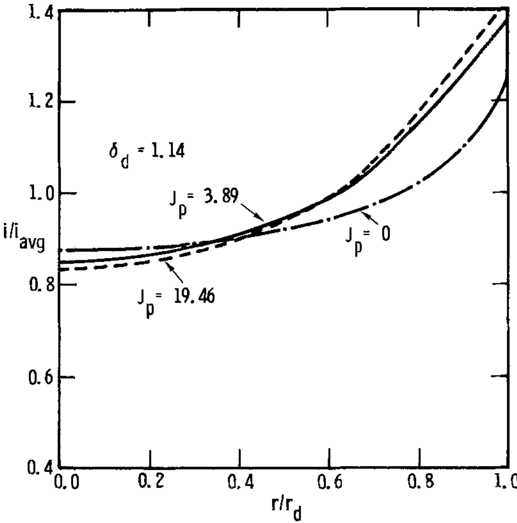

Fig. 8. Current distribution on a disk in a conducting plane for different values of the plane polarization parameter, J_p.

to the ohmic influence. All curves were calculated for Tafel polarization on the disk, with identical values of δ_d. The influence of a conducting plane on a disk with linear kinetics is qualitatively the same.

The current density on the cathodic plane is shown in Fig. 9 as a function of distance from the disk. The polarization behavior of the disk influences the current distribution on the plane only very near the disk for large values of J_p. The potential and current distribution far from the disk are then rather insensitive to the disk polarization parameters. Also shown in this figure is the calculation for a uniform current disk and reversible plane, labeled "Levich." The parallel behavior of the two curves indicates that for large values of ξ, the current and potential distribution for both cases have the same dependence on ξ. Thus one expects that only the first term of the expansion for the potential, Eq. [17], is important for the present case for J_p greater than about 1. The two curves were calculated for identical values of the total disk current.

These observations lead us to propose that the value of B_1 for Eq. [17] may be calculated by comparison with the Levich-Frumkin result, even though it may not be calculated directly as discussed earlier. The ratio B_1/B_{1L} (B_{1L} is the value obtained by Levich and Frumkin, see Eq. [18]) is equivalent to the ratio of the current density from Fig. 9 to the Levich-Frumkin current density at a particular value of ξ. Knowledge of the value of B_{1L} for the uniform current disk, reversible plane permits calculation of B_1. The ratio B_1/B_{1L} is influenced by the value of J_p as shown in Fig. 10, but

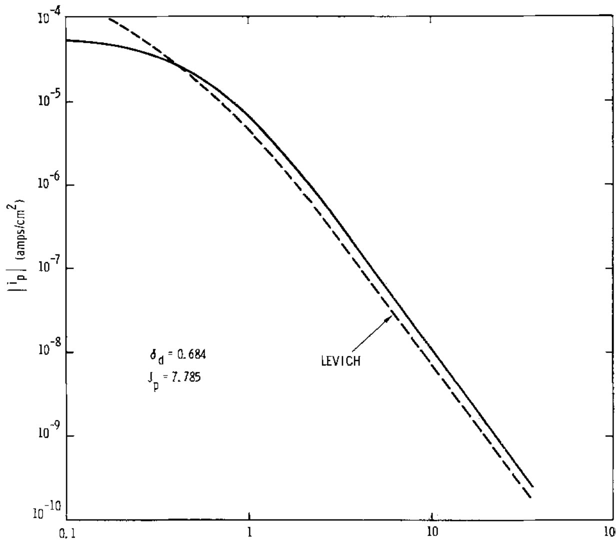

Fig. 9. The cathodic current density of the surrounding plane as a function of the distance ξ from the edge of the disk, compared to the Levich-Frumkin behavior for a reversible plane.

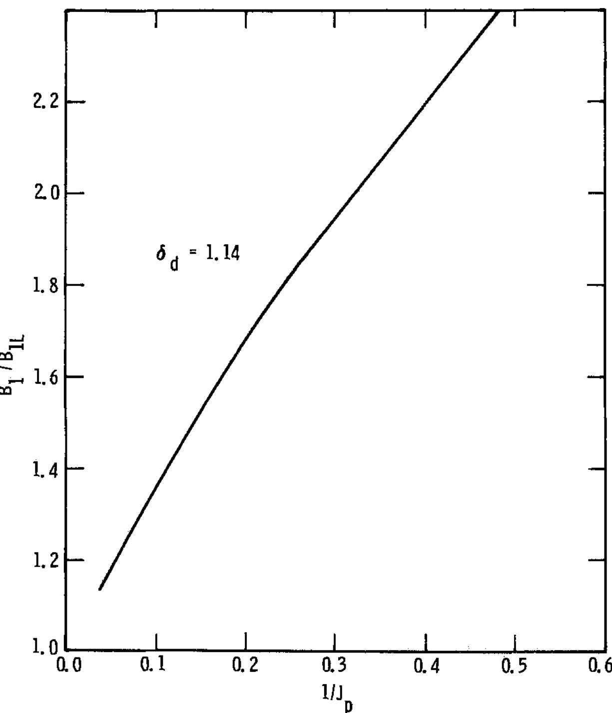

Fig. 10. The departure of the behavior of the cathodic plane from Levich-Frumkin behavior, measured by the ratio B_1/B_{1L}, as a function of the reciprocal of the plane polarization parameter, $1/J_p$.

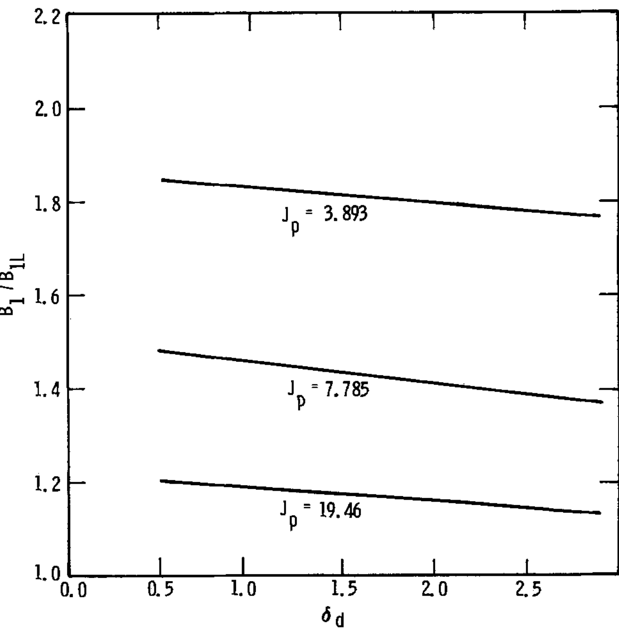

Fig. 11. The departure of the behavior of the cathodic plane from Levich-Frumkin behavior, featured by the ratio B_1/B_{1L}, as a function of the disk polarization parameter, δ_d, at three values of J_p.

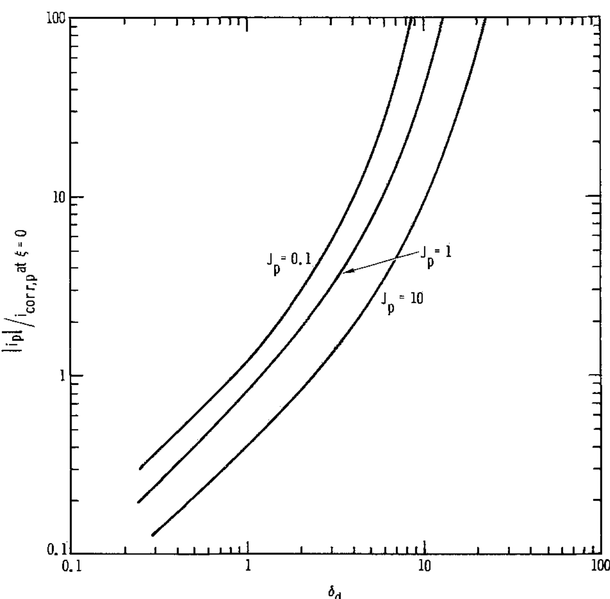

Fig. 12. The current density to the plane at $\xi = 0$, as compared to the corrosion current density for the plane, as a function of δ_d and for three values of J_p.

nearly independent of the disk behavior as shown in Fig. 11. It should be mentioned that the parallel behavior of the two curves in Fig. 9 for large values of ξ is also observed for the boundary condition [8] except near ξ_{max}.

The influence of the disk on the behavior of the plane is concentrated to a region near $\xi = 0$. This influence is depicted on Fig. 12 where the value of $|i_p|/i_{corr,p}$ at $\xi = 0$ is given as a function δ_d for different values of J_p. This reveals that $|i_p|/i_{corr,p}$ at $\xi = 0$ is large, even for small values of J_p. For all values of J_p shown here, the value of $|i_p|/i_{corr,p}$ is smaller by at least five orders of magnitude at $\xi = 200$. The decrease is sharper for larger values of J_p.

The wide range of current density on the plane in Fig. 9 indicates how essential it is that the general expression for the kinetics, Eq. [13], be used. For large values of J_p, the ratio $|i_p|/i_{corr,p}$ approaches a large value at $\xi = 0$. For small J_p, the value of $|i_p|/i_{corr,p}$ at $\xi = 0$ is still large, and in either case $|i_p|/i_{corr,p} \to 0$ as $\xi_{max} \to \infty$. Both the large value of $|i_p|/i_{corr,p}$ and its large variation from $\xi = 0$ to $\xi \to \infty$, preclude the use of linear kinetics on the plane, except for extremely large values of J_p and small values of δ_d. The Tafel approximation for plane kinetics would not be appropriate either because of the value of $|i_p|/i_{corr,p}$ at $\xi \to \infty$. Therefore, the present technique provides results which could probably never be obtained theoretically, because boundary condition [13] or [7] describes the kinetic behavior everywhere on the plane, including the extremes at small and large ξ.

Array of disks.—The results discussed in the previous section provide a background for the analysis of the behavior of an array of disks. The random array of disks which are all of the same radius and are far apart are treated here. Following Levich (13b), the average

potential in solution at some large distance from the surface is

$$\bar{\phi}_{(\text{large } z)} = \bar{n} \int_0^\infty \phi(r)\, 2\pi r\, dr \qquad [22]$$

where $\bar{n}$ is the number of disks per square centimeter of surface. In the previous section it was found that the potential far from the surface can be approximated by the first term of Eq. [17], *i.e.*

$$\phi = B_1 P_1(\eta) M_1(\xi) \text{ at large } \xi$$

$$= \left(\frac{B_1}{B_{1L}}\right) B_{1L}\, \eta\, [\xi \cot^{-1} \xi - 1] \qquad [23]$$

For large z, ξ is also large and

$$\phi = -\frac{B_1}{B_{1L}} (B_{1L})\, \eta \left[\frac{1}{3\xi^2}\right] \text{ as } \xi \rightarrow \text{large} \qquad [24]$$

where $B_{1L} = -2I_d/\pi^2 r_d \kappa$. The equation for $\bar{\phi}_z$ now becomes

$$\bar{\phi}_z = -\frac{2\pi B_1 \bar{n}}{3B_{1L}} (B_{1L}) \int_0^\infty \frac{\eta}{\xi^2} r dr \qquad [25]$$

Using the relationships in Eq. [3] and [4], for large ξ, it may be shown that

$$\bar{\phi}_z = -2\pi \left(\frac{B_1}{B_{1L}}\right) B_{1L}\, \bar{n}\, (r_d^2) \qquad [26]$$

The ratio of anode area to cathode area, A_a/A_c, is

$$A_a/A_c = \bar{n}\pi r_d^2$$

and

$$\bar{\phi}_z = \frac{4I_d}{3\pi^2 r_d \kappa} \left(\frac{B_1}{B_{1L}}\right) (A_a/A_c) \qquad [27]$$

Thus, the corrosion potential of an array of disks will be proportional to the area ratio when ohmic effects are important. This is contrasted to the behavior expected when only kinetic effects are important, *e.g.*, Eq. [1]. It should be noted that the corrosion potential, $\bar{\phi}$, is independent of the value of z, and may be measured with an appropriate reference electrode in any arbitrary location far from the disk-plane surface.

Equation [27] was derived with the assumption that the pores are far enough apart that they interact to a negligible extent through the small ohmic drop far from a disk. This should be a good approximation when the distance separating the disks is large enough that only a small current density flows to the midpoint of the separation distance. This suggests that the minimum distance of separation for negligible interaction is dependent on the magnitude of J_p. The larger the value of J_p, the smaller may be the separation distance for the disks for independent behavior. The polarization parameters on the disk have a small influence on the plane behavior, as noted previously, so the most important parameter influencing interaction will be J_p. Preliminary calculations indicate that 99% of the plane current would go to a distance less than ξ_{max} when the product

$$J_p\, \xi_{max} \cong 195 \qquad [28]$$

For large values of ξ_{max}

$$\xi_{max}^2 \cong \frac{\text{area of cathode (plane)}}{\text{area of anode (disk)}}$$

$$= \frac{r_{max}^2 - r_d^2}{r_d^2}$$

and from Eq. [28] one may obtain a value of the minimum separation distance or area ratio for this level of interaction for given J_p (and r_d). For example, if

$$J_p = 0.7$$

the area ratio of cathode to anode is 10^6. This would then be the minimum area ratio for which the corrosion potential would be expected to obey Eq. [27]. More detailed results will be reported at a later date.

Applications.—The importance of ohmic effects in galvanic corrosion in plating systems may be estimated by calculation of the polarization parameters of the disk and plane. These calculations require the values of the corrosion current density for both surfaces, the value of a characteristic dimension for the disk, r_d, the average current density on the disk, and the conductivity of the electrolyte. Small values of the polarization parameters for the disk and plane would indicate that the kinetic effects are more important than ohmic considerations, and that the current distribution on each will tend to be uniform. As the polarization parameters approach zero, the behavior of a disk array will tend toward that predicted by Stern (9) and Oldham and Mansfeld (11). These polarization parameters are very important and very useful diagnostic criteria.

The exposed substrate disk in a plating system would be expected to be small, and this small characteristic dimension would be expected to force both J_d and δ_d to be small. Therefore, the current distribution on such a disk would be rather uniform.

The cathodic plane would tend to have a nonuniform distribution of current because of its size unless both the corrosion current density is low and the conductivity is high. For values of the parameters of $\kappa = 0.001$ Ω^{-1}-cm^{-1}, $\mathbf{F} = 96{,}500$ C-equiv.$^{-1}$, $T = 298.15°$K, $R = 8.315$ joules $(°\text{K})^{-1}$ mole^{-1}, $r_d = 10^{-3}$ cm, $i_{corr,p} = 10^{-2}$ A-cm^{-2}, and $(\alpha_{ap} + \alpha_{cp}) = 1$, then $J_p = 0.3893$. For a value of $\delta_d = 10^{-3}$ (virtually uniform disk current), and the above value of J_p, the current density to the plane is found to be nonuniform. The plane current density at a distance of three disk radii is decreased by an order of magnitude from the value at $\xi = 0$. It is reduced by five orders of magnitude at about 98 disk radii. This nonuniform current distribution on the plane would cause the corrosion potential to follow Eq. [27].

More specifically, the transition in behavior from that described in Eq. [27] to that given by Eq. [1] occurs at a specific area ratio for a given system. The quantity

$$J_p \xi_{max} \cong 195$$

may be used to estimate the area ratio at which this transition occurs. For

$$J_p = 10$$

the value of ξ_{max} is 19.5 and this corresponds to a ratio of anode area to cathode area of

$$\frac{A_a}{A_c} \cong 2.6 \times 10^{-3}$$

For smaller area ratios the system would follow Eq. [27]. For larger area ratios the system would behave as described in Eq. [1]. The transition between the two regions would be smooth, and the behavior would not follow either relationship exactly. The size of the transition region has not been determined here, but is the subject of a continuing study.

For a single pore in a finite plane, the behavior will be similar to that described above in general. That is, at area ratios (A_a/A_c) smaller than that given by

$$J_p \xi_{max} \cong 195$$

the ohmic effects will be important. At larger area ratios the transition to the behavior given by Eq. [1] will occur. The exact description of the behavior of this finite system with ohmic effects is being determined and will be reported later, along with the behavior of interacting arrays of pores, which is another finite system of considerable importance.

For systems where δ_d is unknown because $i_{avg,d}$ is unknown, one may estimate δ_d from Fig. 13. Here, the value of U, the corrosion potential difference of the separated metals, J_p, and J_d can be used to predict δ_d.

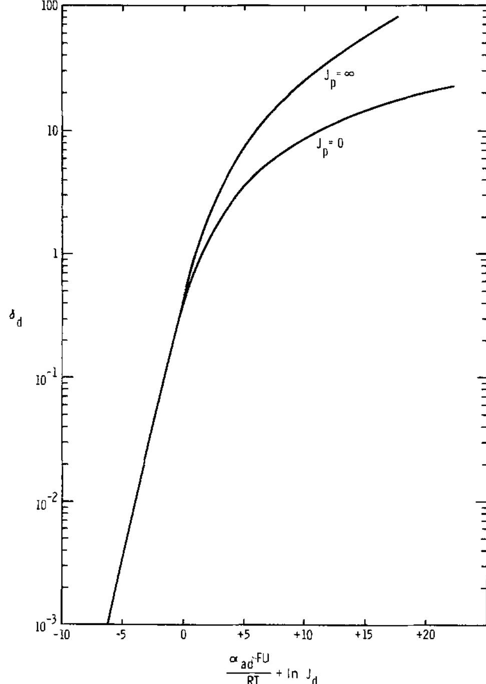

Fig. 13. δ_d as a function of $(\alpha_{ad}\mathbf{F}U)/RT + \ln J_d$ for a reversible plane and an insulating plane.

For small values of $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$, the polarization parameter of the plane does not influence δ_d because kinetic effects predominate. For larger values of $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$, Fig. 13 may be used and the value of J_p is important for predicting δ_d. The total spread of values between $J_p = 0$ and $J_p = \infty$ is not large until $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$ becomes greater than 10, a value seldom encountered in practice. Knowledge of δ_d with the other parameters can then be used to predict current distribution on the disk and plane from Fig. 8 and 9. The potential distribution across the disk can be estimated from Fig. 5. For an insulating plane, the value of $\ln \delta_d$ becomes proportional to $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$ at small values of δ_d. At large δ_d, a linear relationship between δ_d and $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$ is observed with a slope of $4/\pi$. A disk with a reversible plane has the same behavior at small δ_d, as shown. For large δ_d, a linear relationship between δ_d and $[(\alpha_a\mathbf{F}U/RT) + \ln J_d]$ is again observed, but with a slope of $16/\pi$. These results will be discussed in a forthcoming publication (21). It should be noted that these curves have been determined for a surrounding plane of infinite extent.

Knowledge of these parameters allows one to estimate B_1/B_{1L} from Fig. 10 and 11. This can be used to predict the slope of the corrosion potential-area ratio curve for a collection of pores in a plating system, and this can be verified by experiment.

These results would also be applicable to the situation of a cathodic inclusion on an anodic plane. The physical consequences predicted by this treatment are nonuniform anodic dissolution on the plane, with the largest dissolution near the inclusion. This could lead to undermining the inclusion with eventual pit formation if the inclusion is dislodged.

Summary

Numerical analysis of a conducting disk in a conducting plane has been performed by finite difference techniques. The current and potential distribution on both the disk and the plane have been determined for a wide range of parameters. The distributions have been shown to depend not only on the individual parameters of the disk and plane, but the disk and plane influence each other as well because of their proximity. The results have been used to determine the behavior of an array of disks, and the application and use of the results for other situations have been discussed.

APPENDIX A

Boundary Condition Far from the Disk

The surface $\xi = \xi_{max}$ defines a hemisphere in r, z coordinates. If the hemisphere is an insulator, no current may pass through it, and one uses the boundary condition specified in Eq. [8]. We have also used a second boundary condition in which current is allowed to pass through this hemispherical boundary, and we approximate the potential gradient in solution nearby by a relationship which is similar to the Levich-Frumkin distribution. We have found that both boundary conditions give the same results for current and potential distribution everywhere except near the boundary $\xi = \xi_{max}$. The insulator boundary condition forces more current to flow to the plane in the corner near $\xi = \xi_{max}$.

Levich and Frumkin found, for a reversible plane and uniform current on the disk, that the potential far from the disk is

$$\phi = \frac{2 i_d r_d}{\pi\kappa} \eta \, [\xi \cot^{-1} \xi - 1] \qquad [18]$$

where i_d is the (uniform) current density on the disk.

For the present problem we use the expansion

$$\phi = \sum_{n=1}^{\infty} B_n \, P_n(\eta) \, M_n(\xi) \qquad [17]$$

and retain only the first two terms of the expansion in anticipation that higher terms are negligible for large values of ξ. The first term is identical to the Levich-Frumkin result except for the value of B_n, *i.e.*

$$P_1(\eta) = \eta \qquad [A\text{-}1]$$

$$M_1(\xi) = - [\xi \cot^{-1} \xi - 1] \qquad [A\text{-}2]$$

and the second term is

$$P_2(\eta) = \frac{1}{2} (3\eta^2 - 1) \qquad [A\text{-}3]$$

$$M_2(\xi) = -\frac{2}{\pi} [(3\xi^2 + 1) \cot^{-1} \xi - 3\xi] \qquad [A\text{-}4]$$

For large values of ξ [see Ref. (22)]

$$M_1(\xi) \rightarrow \frac{1}{2\xi^2} \quad \text{as} \quad \xi \rightarrow \infty \qquad [A\text{-}5]$$

and

$$M_2(\xi) \rightarrow -\frac{1}{15\pi\xi^3} \quad \text{as} \quad \xi \rightarrow \infty \qquad [A\text{-}6]$$

Near the plane, the potential must also satisfy the boundary condition for passage of current to the plane, and this provides a relationship between B_1 and B_2. On the plane, it is assumed that we are far enough from the disk that the kinetics may be approximated by the linear relationship, *i.e.*

$$\frac{-\kappa}{r_d \xi} \frac{\partial\phi}{\partial\eta}\bigg|_{\eta=0} = i_p = \frac{(\alpha_{ap} + \alpha_{cp})\mathbf{F}}{RT} (U_{corr,p} - \phi_{op}) i_{corr,p} \qquad [A\text{-}7]$$

We arbitrarily set $U_{corr,p} = 0$, and find

$$-\frac{1}{\xi}\left[\frac{B_1}{2\xi^2}\right] = J_p\left[\frac{8}{15\pi\xi^3}B_2P_2(0)\right] \quad \text{[A-8]}$$

where terms of order $(1/\xi^4)$ have been neglected, and

$$J_p = \frac{(\alpha_{ap}+\alpha_{cp})r_d\mathbf{F}}{\kappa RT}\, i_{corr,p} \quad \text{[A-9]}$$

This leads to

$$B_1 = -\frac{16}{15\pi}J_2P_2(0)B_2 \quad \text{[A-10]}$$

and with this relationship we may now derive an expression for the potential gradient near ξ_{max} valid for large values of ξ_{max}. Now

$$\phi = \frac{B_1}{2\xi^2}P_1(\eta) - \frac{16B_2}{15\pi\,\xi^3}P_2(\eta)$$

$$= \frac{8B_2}{15\pi}\left\{\frac{P_2(0)\,P_1(\eta)J_p}{\xi^2} + \frac{2P_2(\eta)}{\xi^3}\right\} \quad \text{[A-11]}$$

and

$$\left.\frac{\partial\phi}{\partial\xi}\right|_{\xi=\max} = \frac{8B_2}{15\pi}\left\{\frac{2P_2(0)\,P_1(\eta)J_p}{\xi^3} + \frac{6P_2(\eta)}{\xi^4}\right\}$$

$$= -\frac{2\phi}{\xi_{max}}\left\{\frac{P_1(\eta) + \dfrac{3P_2(\eta)}{\xi_{max}P_2(0)J_p}}{P_1(\eta) + \dfrac{2P_2(\eta)}{\xi_{max}P_2(0)J_p}}\right\} \quad \text{[A-12]}$$

and this reduces to the Levich-Frumkin functional relationship as $\xi_{max} \rightarrow \infty$.

APPENDIX B

Finite Difference Approximations for Nonlinear Boundary Conditions

Equation [20] is a finite difference relationship for the surrounding plane involving a function F_p which is exponential in $\phi°_p$. This nonlinear relationship for $\phi°_p$ is rather unstable, and diverges rapidly unless the initial potential approximation is near the final, converged value. We have adopted the following treatment which eliminates these divergence problems.

We approximate the value of F_p by

$$F_p = F_p\,(V_p - \phi°_p - U_{corr,p}) + (\phi°_p(r) - \phi°_{p,old})\,F_p' \quad \text{[B-1]}$$

where $\phi_{o,old}$ is the previous value of $\phi°_p$ at the central point, $\phi°_p(r)$ is the value of $\phi°_p$ at the central point to be calculated, and F_p' is the derivative of F_p with respect to the overpotential $(V_p - \phi°_p - U_{corr,p})$.

Equation [19] becomes now

$$\phi_o\left[\frac{2(1-\eta_o^2)}{h_\eta^2} + \frac{2(1+\xi_o^2)}{h_\xi^2} + 2F_p'\,\xi_o h_\eta\left(\frac{1-\eta_o^2}{h_\eta^2} + \frac{\eta_o}{h_\eta}\right)\right]$$

$$= 2\phi_2\left(\frac{1-\eta_o^2}{h_\eta^2}\right) + \phi_1\left[\frac{1+\xi_o^2}{h_\xi^2} + \frac{\xi_o}{h_\xi}\right]$$

$$+ \phi_3\left[\frac{1+\xi_o^2}{h_\xi^2} - \frac{\xi_o}{h_\xi}\right] + 2\xi_o h_\eta\,(F_p + \phi_{o,old}F_p')X \left[\frac{1-\eta_o^2}{h_\eta^2} + \frac{\eta_o}{h_\eta}\right] \quad \text{[B-2]}$$

or

$$\phi_o\left[\frac{2}{h_\eta^2} + \frac{2(1+\xi_o^2)}{h_\xi^2} + 2F_p'\,\xi_o\left(\frac{1}{h_\eta}\right)\right]$$

$$= \frac{2\phi_2}{h_\eta^2} + \phi_1\left[\frac{1+\xi_o^2}{h_\xi^2} + \frac{\xi_o}{h_\xi}\right]$$

$$+ \phi_3\left[\frac{1+\xi_o^2}{h_\xi^2} - \frac{\xi_o}{h_\xi}\right] + \frac{2\xi_o}{h_\eta}(F_p + \phi_{o,old}F_p') \quad \text{[B-3]}$$

where we have introduced $\eta_o = 0$ on the plane.

This equation is solved for ϕ_o, called $\phi_{o,try}$, and a new value of ϕ_o is calculated by

$$\phi_{o,new} = \phi_{o,old} + \Omega(\phi_{o,try} - \phi_{o,old})$$

The same value of the overrelaxation parameter is used for the boundary as for interior points.

An analogous treatment of the generally nonlinear boundary condition on the disk was adopted.

Successive iterations with this approximation technique lead to convergence and a rigorous result, since the second term of [B-1] approaches zero as the potential approaches the converged value.

The Comparative Crevice Corrosion Resistance of Co-Cr Base Surgical Implant Alloys

T. M. Devine*,[1] and J. Wulff

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Different electrochemical and direct immersion tests were used to compare the relative crevice corrosion resistance of currently used or recommended nontitanium surgical implant alloys. Measurement of the anodic corrosion current *vs.* time of creviced specimens in deaerated isotonic salt solution at 37°C and in a 10% HCl + 1% $FeCl_3$ solution at a series of constant applied potentials lying in the passive range of the alloys provided the same comparative rating of the different alloys as potential-time measurements as well as direct immersion tests. According to the tests, recently developed stronger wrought versions of the Co-Cr-Mo-C alloy H.S. 21 (modified Vitallium) and a wrought Co-20Cr-10Mo alloy were found to possess greater crevice corrosion resistance in both solutions than as-cast H.S. 21 and wrought alloys such as H.S. 25, M.P. 35N., Elgilloy, and 316L stainless steel.

The three most widely used surgical implant alloy systems are molybdenum containing wrought austenitic stainless steel, precision cast cobalt-chromium-molybdenum-carbon alloys such as H.S. 21 and Vitallium, and wrought commercial titanium and some of its alloys. Unfortunately, none of these alloys can be regarded as ideally suitable surgical implant material. Stainless steel possesses inadequate corrosion resistance in body fluids (1-6). While precision cast cobalt-chromium-molybdenum alloys exhibit superior corrosion resistance, they possess insufficient mechanical properties for safe use in some weight-bearing implants (7-10). Ordinary commercial titanium and some of its alloys exhibit superior long-time corrosion resistance in body fluids relative to the other two alloy systems (11). Unfortunately, however, titanium and some of its alloys undergo a high initial rate of corrosion in body fluids (12, 13) and possess little wear resistance when in rubbing contact with themselves or other metallic implant materials (14).

Because of the low mechanical properties of cast H.S. 21-type alloys implant fabricators have substituted the wrought, high strength cobalt-chromium-tungsten-nickel alloy, H.S. 25, for the cast H.S. 21 alloy in certain weight-bearing implant parts. However, such H.S. 25 parts are susceptible to crevice corrosion, albeit after long residence in patients (15, 16). More recently one fabricator has begun substituting M.P. 35N. for cast H.S. 21 parts (17). Preliminary experiments conducted in our laboratory have indicated that the recently developed wrought versions of H.S. 21 and the No. 7 alloy (Co-20Cr-10Mo) may be ideally suitable for substitution for cast H.S. 21 parts since they can be thermomechanically processed to remarkably high strength levels without impairment in corrosion resistance (18-20).

The purpose of the investigation reported in this paper was to compare the crevice corrosion resistance of the wrought H.S. 21 and No. 7 alloys with currently used or recommended (nontitanium) implant alloys. Investigation of crevice corrosion resistance was undertaken, since examination of excised implants of all kinds has shown that crevice corrosion is responsible for the major corrosion damage of implants (21). It occurs not only at metal/metal contacts in multipiece implants but also at metal/bone contacts. Like pitting, crevice corrosion in saline media is due to localized chloride ion attack. It can occur in narrow crevices even in weak saline solution like body fluid where the chloride as well as the hydrogen ion content can build up to extremely high levels in the crevice solution (22-24). This occurs without significant change in the solution external to the crevice where convection prevents such localized concentrations.

In their comparison of corosion resistance of a long list of iron-, nickel-, cobalt-, and titanium-base alloys in isotonic salt and physiological solutions, Hoar and Mears (7) have found that measurements of anodic current *vs.* time (up to 400 hr) of potentiostatically polarized noncreviced specimens at a constant potential provide a more quantitative assessment of general and localized corrosion resistance than rest potential-time measurements of noncreviced specimens. Jones and Greene (25) and Rosenfeld and Marshakov (26) have shown that potential-time measurements of specimens immersed in aqueous solutions can also be used to assess the localized corrosion resistance of alloys. Direct immersion crevice corrosion test of alloy samples in aggressive corrodents such as 10% HCl + 1% $FeCl_3$ have long been used in alloy development studies for screening purposes (27). We have used all three types of tests in this investigation to compare the crevice corrosion resistance of recently developed stronger versions of cast Vitallium or H.S. 21-type alloys with currently used or recommended nontitanium surgical implant alloys such as 316L stainless steel, Elgilloy, M.P. 35N., H.S. 25, and as-cast H.S. 21.

Experimental

Materials.—The nominal chemical compositions of the alloys tested are listed in Table I. The wrought 316L, Elgilloy, M.P. 35N., and H.S. 25 were all obtained as cylindrical rods in the mill-annealed state. H.S. 21 was supplied as 0.5 in. diameter investment castings. One

Key words: crevice corrosion, surgical implants, cobalt alloys.

set of the wrought experimental alloys No. 7 and H.S. 21 were hot extruded in a single pass (80% reduction in area) from 1 in. diameter vacuum-cast ingots. Another set was hot press forged (1200°C) from 30 lb ingots with frequent intermediate anneals and then hot rolled at ~1200°C to a 0.38 in. thick strip.

Test specimens having a length of 1.000 in. and a diameter of 0.250 in. were cut, machined, and polished to 4 × 0 grit paper. One end of each specimen was rounded and for the electrochemical tests the other end was drilled and tapped to fit into a Stern-Makrides (28) electrode holder.

Teflon rings were all machined from the same cylindrical rod stock of Teflon, finished with 4 × 0 grit paper to have a width of 0.125 in. and an internal diameter of 0.235 in. Sharp edges were rounded.

After ultrasonic degreasing in trichlorethylene all metal specimens were washed and rinsed in distilled water and absolute alcohol, dried, and stored in vacuum dessicators. The Teflon rings were also degreased, washed, rinsed, and dried before they were force-fitted to the middle of the cylindrical alloy specimens with the aid of a mechanical jig. The latter was used to avoid damaging the surface finish with hand tools. After force fitting, the metal external to the Teflon ring was lightly abraded with 4 × 0 grit paper to remove adherent Teflon and carefully cleaned with absolute alcohol.

Two test solutions were employed, isotonic salt solution, 0.9% NaCl, and a highly aggressive solution of 10% HCl + 1% $FeCl_3$. The two corrodents used in the corrosion tests were made from reagent grade chemicals and doubly distilled water. Purified nitrogen was used for deaeration and tank oxygen for aeration of the corrodents used in the electrochemical cells. The quiescent solutions used in the beaker tests were renewed for test runs of over 10 days at regular intervals.

Corrosion tests.—The electrochemical cells, auxilliary electrical apparatus, and techniques of measurement duplicated that recommended by Greene (29) and used by Revie and Greene (12, 13). A nonpolarizable Ag-AgCl electrode ($E° = 0.216V$ at 37°C) was used for reference. Measurements of open-circuit potential *vs.* time in oxygenated solution at 37°C and anodic polarization curves in deaerated electrolytes at 37°C were first made to determine rest and breakdown potentials. These were followed by similar measurements of the open-circuit potential variation with time of creviced alloy specimens and anodic current *vs.* time of creviced alloy specimens at a series of fixed potentials lying in the passive region of the noncreviced alloy specimens. The electrochemical cells were housed in an incubator which was maintained at 37° ± 0.5°C. After the termination of each test run, the Teflon ring was carefully cut away and the electrode scrubbed with a bristle brush in running water. The specimen was then rinsed with alcohol, dried, and examined at high magnification using intense oblique illumination for evidence of etching and pitting.

Two types of direct immersion tests in the aggressive corrodent were employed. In both, a minimum of six specimens were used for each test and only one specimen was immersed in each beaker. These were housed in incubators maintained at 37° ± 0.5°C. In the first set of tests in the 10% HCl + 1% $FeCl_3$ solution, test runs were terminated at 4 hr intervals after immersion for times up to 4 days. In another series using creviced as well as noncreviced alloy specimens the test runs were terminated after 10 day intervals. After the termination of each test and removal of the Teflon rings and cleaning of the specimens, all specimens were examined for evidence of isolated pitting and crevice corrosion as well as etching. In the case of the 10 day tests in the 10% HCl + 1% $FeCl_3$ solution loss in weight measurements were also made. Similar tests in the isotonic salt solution were terminated at 10 day intervals for periods up to 60 days.

Results

The results of the beaker tests employing a quiescent 10% HCl + 1% $FeCl_3$ solution at 37°C are summarized in Table II. Column A lists the times to onset of the first two to four crevice corrosion pits in all 6 samples of each alloy on test runs up to 4 days. The loss in weight after 10 day immersion tests of the creviced alloys is listed in column B of Table II and the loss in weight of noncreviced specimens of the same alloys is shown in column C. In all three sets of observations it is apparent that the crevice corrosion resistance as well as general corrosion resistance of cast and solutionized H.S. 21, wrought H.S. 21, and the wrought No. 7 alloy are greater in this solution than Elgilloy, M.P. 35N., H.S. 25, and as-cast H.S. 21.

Table III lists the results of the direct immersion corrosion tests conducted in 0.9% NaCl. Obtaining weight loss measurements of highly corrosion resistant alloys in such a relatively weak corrodent requires extremely long immersion times. Consequently, the alloys' resistances to crevice corrosion in 0.9% NaCl were determined in a highly qualitative fashion by sacrificing 4 specimens of each alloy at 10 day intervals and determining the time at which crevice corrosion pits could be observed at 200× in two of the four specimens. The alloys are rated in the same manner as the direct immersion corrosion tests in 10% HCl + 1% $FeCl_3$. For comparison purposes the data obtained from examination of excised implants are listed in column B of Table III.

Figures 1 and 2 list the anodic polarization characteristics of the alloys examined in deaerated solutions of 10% HCl + 1% $FeCl_3$ and 0.9% NaCl, respectively. The samples were immersed for 1 hr in the test solution prior to polarization which was accomplished by sweeping the potential at a rate of 10 mV/min. The anodic polarization behavior of 316L stainless steel was not determined in 10% HCl + 1% $FeCl_3$ since the alloy was visibly pitted within minutes following immersion.

* A. Time to onset of first observable crevice corrosion pits in creviced specimens of alloys immersed in isotonic salt solution at 37°C.
† B. Shortest time reported for excision of implants in which crevice corrosion pitting was observed.

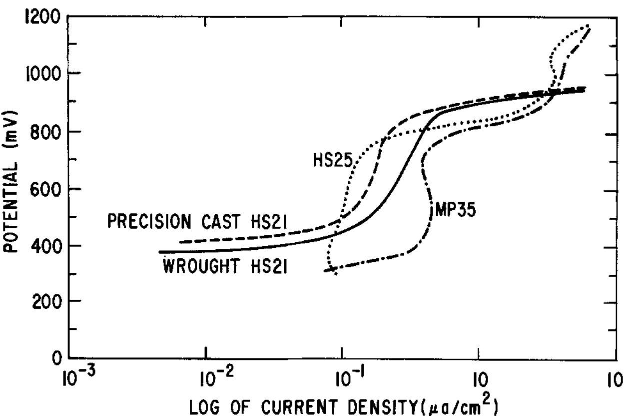

Fig. 1. Anodic polarization characteristics of the alloys in deaerated 10% HCl + 1% $FeCl_3$ at 37°C.

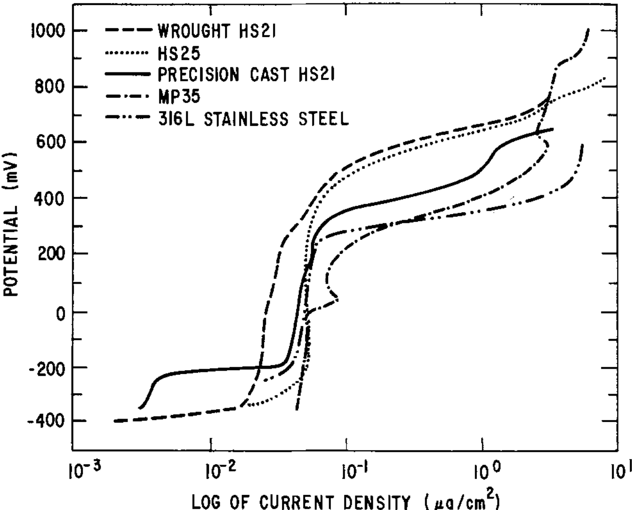

Fig. 2. Anodic polarization characteristics of the alloys in deaerated 0.9% NaCl at 37°C.

Figure 3 depicts the variation of open-circuit potential with time of Teflon creviced specimens of all the alloys except 316L stainless steel in the oxygenated 10% HCl + 1% $FeCl_3$ solution at 37°C. Stainless steel is active in this solution and the metal external to the Teflon ring extensively corrodes immediately after immersion. The smooth, monotonic increase of potential with time of creviced samples of wrought H.S. 21, wrought No. 7, and as-cast and solutionized H.S. 21 indicates no localized corrosion occurred in these alloys (25, 26). The potential of as-cast H.S. 21, however, is seen to continuously decrease approximately 15 hr after immersion. Upon completion of the test the as-cast H.S. 21 specimen showed mild crevice attack in the form of two parallel discontinuous rings of pits at the two former Teflon-metal-solution interfaces. The potentials of creviced samples of H.S. 25 and M.P. 35 dropped to active values in approximately 10 hr. Severe crevice corrosion was observed under their Teflon rings when the tests were terminated 8 days after immersion. The potential of a creviced sample of Elgilloy dropped to an active value in less than 1 hr after immersion. The sample exhibited extensive crevice corrosion.

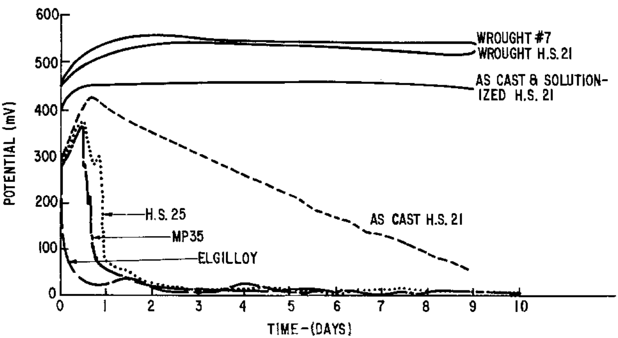

Fig. 3. Potential variation with time of creviced samples in oxygenated 10% HCl + 1% $FeCl_3$ at 37°C.

The results of the rest potential measurements conducted on creviced samples in 0.9% NaCl are depicted in Fig. 4 Serrations indicative of localized attack were only observed in 316L stainless steel and, to a much lesser extent, in Elgilloy. The stainless steel specimen exhibited a few tiny crevice corrosion pits underneath the Teflon ring. No crevice corrosion occurred in any of the other alloys during this 10 day test.

In the measurement of the anodic corrosion current of creviced alloy electrodes for times up to a thousand minutes or more at fixed potentials in a deaerated solution it was possible to observe a potential at which the current abruptly increased. Only in the case of solutionized H.S. 21, wrought H.S. 21, and the No. 7 alloy was that potential found to be equivalent to the breakdown potential of noncreviced specimens of the same alloy. The anodic corrosion current measured divided by the area of metal outside the Teflon ring is plotted as $\log_{10}$ of corrosion current density *vs.* $\log_{10}$ time as shown in Fig. 5 for 316L stainless steel in 0.9% NaCl. Initially, at all applied potentials, the corrosion rate decreases monotonically with time and the alloy exhibits typical passive behavior. However, at potentials

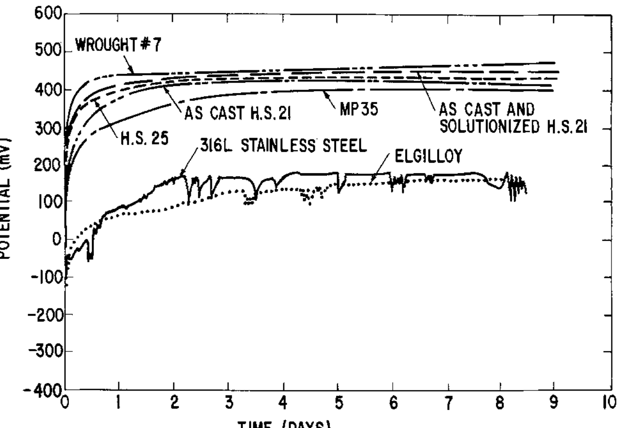

Fig. 4. Potential variation with time of creviced samples in oxygenated 0.9% NaCl at 37°C.

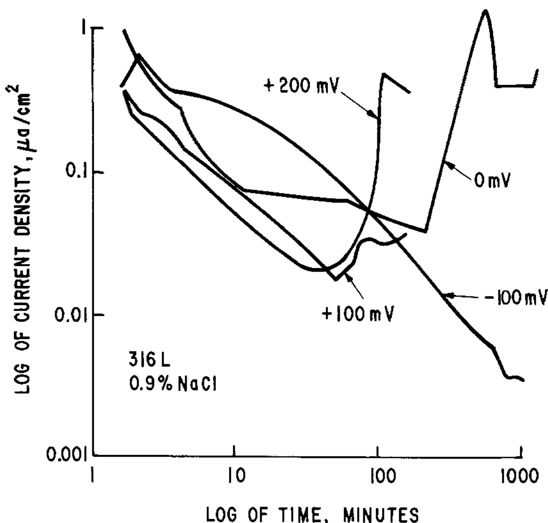

Fig. 5. Corrosion current density variation with time of creviced samples of 316L stainless steel in deaerated 0.9% NaCl at 37°C as a function of applied potential.

of 0 mV and higher the corrosion rate abruptly increases after a certain incubation period and crevice corrosion could be seen under the Teflon rings after termination of the test. Tables IV and V list the lowest applied potential at which crevice corrosion occurred in each of the alloys in 10% HCl + 1% $FeCl_3$ and 0.9% NaCl, respectively. No crevice corrosion was observed in samples of wrought H.S. 21 or alloy No. 7 in either test solution. Despite the applied potential, the Teflon ring affixed samples of these two alloys continued to exhibit passive behavior and no localized corrosion.

Discussion and Conclusions

All of the corrosion test results clearly indicate the superiority of cast and solutionized H.S. 21, wrought H.S. 21, and the wrought No. 7 alloy whose compositions are listed in Table I. All three appear to be immune to localized corrosion; even when their passive films break down during anodic polarization above the breakdown potentials in the two corrodents used, they corrode generally rather than locally. The superior crevice corrosion resistance of the wrought H.S. 21 relative to the cast H.S. 21 can in large measure be attributed to the greater chemical as well as structural homogeneity of the wrought material (19, 20, 30). Evidently a 1 hr solutionizing heat-treatment at 1230°C removes a sufficient amount of coring and microsegregation to realize the improvements reported in corrosion resistance relative to the as-cast material. However, metallography and x-ray diffraction studies indicate that such a solutionizing treatment does not completely remove all of the secondary phases such as carbides and sigma phase that are present in the as cast condition (30). Nevertheless, this heat-treatment also improves the ductility and tensile strength of the cast alloys (31).

The present finding that H.S. 25 is inferior to cast H.S. 21 is confirmed by the *in vivo* results of Cohen and Wulff (15) and Rose *et al.* (16) who reported incidents of crevice corrosion in H.S. 25 implant parts coupled to cast H.S. 21 parts which were free of corrosion. All of the corrosion tests conducted indicate the high strength, wrought M.P. 35N. alloy possesses the same general and crevice corrosion resistance as H.S. 25, and though M.P. 35N. is currently used by at least one fabricator (17) for the weight bearing members of implant parts formerly made of cast H.S. 21, the present results indicate that M.P. 35N. will eventually be found lacking in crevice corrosion resistance as is the case for H.S. 25.

Table IV. Lowest applied potential at which crevice corrosion initiates in deaerated 10% HCl + 1% $FeCl_3$

Alloy	Potential (mV)	Time (min)
Elgilloy	400	7
M.P. 35N.	400	350
H.S. 25	400	600
H.S. 21 as-cast	800	850
H.S. 21 cast and solutionized	No crevice corrosion at any applied potential	
H.S. 21 wrought	No crevice corrosion at any applied potential	
No. 7	No crevice corrosion at any applied potential	

Table V. Lowest applied potential at which crevice corrosion initiates in deaerated 0.9% NaCl at 37°C

Alloy	Potential (mV)	Time (min)
316L	100	200
Elgilloy	100	200
M.P. 35N.	300	85
H.S. 25	300	100
H.S. 21 as-cast	300	1000
H.S. 21 as-cast and solutionized	No crevice corrosion at any applied potential	
H.S. 21 wrought	No crevice corrosion at any applied potential	
No .7 wrought	No crevice corrosion at any applied potential	

Although Elgilloy possesses admirable mechanical properties, its crevice corrosion resistance is far inferior to the above cobalt-base alloys. The remarkably high tensile and fatigue strengths of wrought H.S. 21 and No. 7 combined with their superior general and crevice corrosion resistances should make them an attractive substitute for Elgilloy (20, 30). 316L stainless steel, the most widely used surgical implant alloy, exhibited the least resistance to crevice corrosion. This is substantiated by numerous *in vivo* results indicating the high susceptibility of 316L stainless steel implant parts to crevice corrosion (4-6, 21). The occurrence of crevice corrosion in 316L specimens affixed with Teflon rings within 10 days of immersion in 0.9% NaCl questions the suitability of this material for use even in short term implant parts. It is hoped that the simple solutionizing anneal treatment for cast H.S. 21 would be adopted by all implant fabricators to assist them in producing consistently stronger and more corrosion resistant parts. Adoption of the high strength wrought version of H.S. 21 or the No. 7 alloy by implant fabricators will no doubt take time for shaping implant parts out of either alloy from wrought bar, plate, or sheet stock requires for all but the simplest implant parts hot closed-die forging, since machining these alloys is difficult although not impossible, according to presently known techniques. In this regard the Co-20Cr-10Mo alloy is probably more workable because of its low carbon content. That this alloy also appears somewhat more corrosion resistant than wrought H.S. 21, can probably be attributed to its higher Mo/Cr ratio than H.S. 21 or Vitallium. We are led to this viewpoint by earlier studies of Tomashov and Chernova (32) regarding additions of molybdenum to austenitic-type stainless steels. As Rhodin (33) pointed out, molybdenum has a tendency to stabilize the passive film and make it more resistant to chloride-ion penetration.

Hoar and Mears (7) have suggested that measurements of corrosion current as a function of time of bare (noncreviced) specimens at fixed applied potentials which lie in their passive region provide a more quantitative assessment of localized corrosion susceptibility than potential-time measurements. We believe however that the use of creviced samples in such measurements is not only less time consuming but more meaningful, for crevice corrosion is the major origin of corrosion damage in surgical implants.

The direct immersion tests of the onset of crevice corrosion in the 10% HCl + 1% $FeCl_3$ solution, it is necessary to emphasize, provide as reasonable an assessment of crevice corrosion resistance as the potential-time measurements in the same solution or for that matter as the passive current-time measurements in the same solution. For initial screening purposes in alloy development studies such tests are simple and less time-consuming but like all crevice corrosion tests, their reproducibility depends to a large measure on the care exercised in reproducing crevice geometry.

Although the pitting potential of titanium alloys in isotonic salt solution are higher than those of wrought H.S. 21, their initial rate of corrosion in the first 1000 or more minutes after immersion in an isotonic salt solution is no different (12, 14) Kummer (14) has shown that in a 10-20% HCl solution at 37°C their long time corrosion rates are no better than wrought H.S. 21. For patients who exhibit sensitivity to nickel or cobalt corrosion products the use of titanium alloy implants is of course mandatory, but for other patients it is important to realize that the tensile and fatigue strengths of the wrought H.S. 21 are equivalent to those of fully hardened Ti-6Al-4V. However, in that state Ti-6Al-4V appears to have greater notch sensitivity than wrought H.S. 21. In any case, the superior wear resistance of wrought or cast H.S. 21 requires its use at least for the present in the rubbing members of certain total joint replacement prostheses since titanium alloys have inadequate wear characteristics (14).

Finally, it should be noted that hot isostatic pressing of investment cast implants is a third technique, in addition to the solutionizing heat-treatment and hot working, for improving the strength and corrosion resistance of Co-Cr-Mo-C alloys. That this technique can increase the tensile properties of cast H.S. 21 has been demonstrated in a separate investigation (31). Since such processing heals microvoids, reduces coring, and dissolves carbides and other secondary phases, the corrosion resistance of hot isostatically pressed cast implants should be favorably affected. Experiments are currently underway to determine if such is the case.

Acknowledgments

For the financial support of the investigation of which the present study was a part we are grateful to the National Science Foundation. For cooperation in the development of wrought H.S. 21 and No. 7 alloy we are indebted to Dr. S. Wlodek of the Haynes Stellite Division of the Cabot Corporation. The technical assistance of Dr. F. J. Kummer and Mr. G. Arndt of M.I.T. is also thankfully acknowledged.

Manuscript received June 30, 1975. This was Paper 369 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by General Electric Company.

ABSTRACT

A technique based on the measurement of streaming potentials has been developed to evaluate the electrokinetic region of the cell periphery. This approach is feasible for cell lines propagated in *in vitro* cell culture in monolayer form. The advantage of this system is that cells may be evaluated in the living state attached to a substrate. Thus it is not necessary to subject the cells to enzymatic, chemical, or mechanical trauma required to obtain monodisperse suspensions which are then normally evaluated by microelectrophoresis. In this manner it should be possible to study the influence of substrate and environmental factors on the charge density and potential at the cell periphery. The apparatus and procedure are described as well as some results concerning the electrokinetic (ζ) potential of borosilicate capillaries as a function of ionic strength, pH, and temperature. The effect that turbulence and entrance flow conditions have on accurate streaming potential measurements is discussed. The ζ-potential of BALB/c 3T12 fibroblasts has been quantitated as a function of pH, ionic strength, glutaraldehyde fixation, and Giemsa staining.

The electrokinetic properties of monodisperse suspensions of blood cells have been comprehensively investigated. Electrokinetic studies have been carried out on erythrocytes as a function of pH, ionic strength, and anion binding (1), various chemical treatments (2, 3), and proteolytic enzyme exposure (4). Similar studies have been conducted on lymphocytes (5), leukocytes (6, 7), and platelets (8). Seaman and Heard (9) have modified a microelectrophoresis apparatus originally designed by Bangham *et al.* (10) for analysis of biological materials in monodisperse form.

However, the great majority of cell types are not free and monodispersed in their natural state but, rather, are intimately associated in tissues. Investigators have attempted to characterize cells from *in vivo* sources (11) and cells from *in vitro* tissue cultures (12) using the microelectrophoresis technique. This usually necessitates a dissolution of the tissue or cell monolayer by mechanical, chemical, or enzymatic means to yield a monodispersed suspension. The assumption that such treatments do not significantly alter the peripheral region of the cells and thus their electrokinetic behavior is unsound. Ponder (13) and Seaman and Heard (14) have shown that trypsinization significantly reduces the electrophoretic mobility of human erythrocytes. Seaman and Uhlenbruck (4) extended this analysis to a number of proteolytic enzymes and erythrocytes derived from a variety of species. In most instances there was a significant alteration in measured electrophoretic mobility. Also, it is possible that the association of cells in tissues or monolayers in *in vitro* culture results in profound alterations in their electrokinetic properties compared to those commonly observed in suspension microelectrophoresis.

The initial objective of this research was to develop an apparatus and experimental technique which could directly measure the electrokinetic properties of cells grown in *in vitro* tissue culture. The approach chosen was based on the streaming potential phenomena originally quantitated by Helmholtz and Smoluchowski (15) and explained in some detail by Davies and Rideal (16).

The relationship between the measured streaming potential and the potential at the hydrodynamic shear plane, the zeta (ζ)-potential is given as

$$\zeta = \frac{4\pi\eta}{\epsilon}\frac{Estr}{P}\left[K_B + \frac{2K_s}{a}\right] \quad [1]$$

where η and ϵ are viscosity and dielectric constant, respectively, in the diffuse double layer, *Estr* is the streaming potential measured across the streaming capillary, *P* is the pressure difference across the capillary responsible for the flow of electrolyte, *a* is the radius of the capillary, and K_B and K_s are the specific bulk and surface conductance. The ζ-potential can be calculated from measurements of streaming potential and driving pressure if surface conductance is accounted for. This is accomplished by utilizing Eq. [2]

$$\zeta = \frac{4\pi\eta}{\epsilon}\frac{Estr}{P}\frac{C}{R} \quad [2]$$

Here *C* is a predetermined system constant and *R* is the measured a-c resistance of the capillary-electrolyte system.

Normally Eq. [2] is utilized when ionic strength is so low that surface conductance comprises a significant proportion of the total conductance. At high ionic strengths, *i.e.*, physiological electrolyte concentrations, surface conductance is negligible compared to the total conductance, and Eq. [1] simplifies to Eq. [3]

$$\zeta = \frac{4\pi\eta K_B}{\epsilon}\frac{Estr}{P} \quad [3]$$

K_B can then be determined in a standard conductivity cell utilizing platinized gray platinum electrodes. Viscosity and dielectric constant in the diffuse layer are assumed to be equal to bulk values; however, this is probably incorrect according to Hayden (17).

Ball and Fuerstenau (18) have reviewed the streaming potential literature in regard to *Estr/P* data. They have concluded that, due to as yet unexplained flow and asymmetry potentials common to a wide variety of electrode types, the slope of the loci of *Estr* data at a number of driving pressures in opposite flow directions ($\Delta Estr/\Delta P$) should be utilized in Eq. [1], [2], and [3]. This has been the case in this research where the loci of streaming potential data as a function of driving pressure in both flow directions have been fitted to a

Key words: ζ-potential, cell periphery, borosilicate, entrance effects.

linear regression best fit straight line using a Hewlett Packard (Model 9820A) programmable calculator.

Apparatus

The streaming potential apparatus is illustrated in Fig. 1. It is composed entirely of borosilicate (Corning 7740) glass with the exception of two sections of Silastic (Dow Corning polydimethyl siloxane medical grade) tubing (F) used to connect the streaming capillary (E) to the electrode chambers (C). The electrodes are of the silver, silver chloride type and are prepared by the anodic electrolytic deposition of an AgCl coating on a silver wire (A. D. Mackay, New York). The wire electrodes are in the form of a spiral and are epoxied into 7/15 $ glass joints which mate with the electrode chambers. Two 200 ml reservoirs (A) serve as containers for the streaming fluid and are connected to the electrode chambers (C) and an N_2 pressure source via section B. Section D is a dip tube extending to the bottom of each reservoir. Sections A, B, C, and D are connected together via 7/15 and 19/22 $ glass joints and were made small enough to be rf glow discharged prior to each streaming experiment.

The reservoirs are positioned in a constant temperature bath and stirring can be accomplished with a magnetic stirrer. The system pH (Corning Model 12 pH meter and glass electrode combination) and temperature (0-100°C, accurate to 0.1°C) can be monitored continuously. Purified N_2 gas (99.999% pure) serves as a pressure source utilized to drive the streaming fluid through the capillary. The four-way ball valve (V) (Whitey Model B-43YF2) simultaneously exposes one reservoir to N_2 driving pressure and the other to atmospheric pressure. A 90° rotation of the valve applies pressure to the opposite reservoir and reverses the electrolyte flow. Pressure is adjusted with a two-stage oxygen regulator (Matheson Gas Products Model 3104) with an adaptor for N_2 and a Tycos pressure gauge (T) (0-300 mm Hg, accurate to 1 mm Hg). The components of the pressure drive system are connected to the streaming apparatus via Silastic tubing. The streaming potential is measured with a high input impedance digital electrometer (Keithley Model 616), and the resistance or conductance of the streaming fluid is measured with an a-c bridge at a frequency of 1 kHz (General Radio Model 1650B). The streaming apparatus is electrically isolated from extraneous electrical signals by a Faraday cage (copper screen 50 mesh/in.) (FC).

Procedure

Streaming potential data were obtained by measuring streaming potentials at a driving pressure of 2 cm Hg, then reversing the flow direction and repeating the measurement. The driving pressure was increased by 2 cm Hg and streaming potentials were again measured

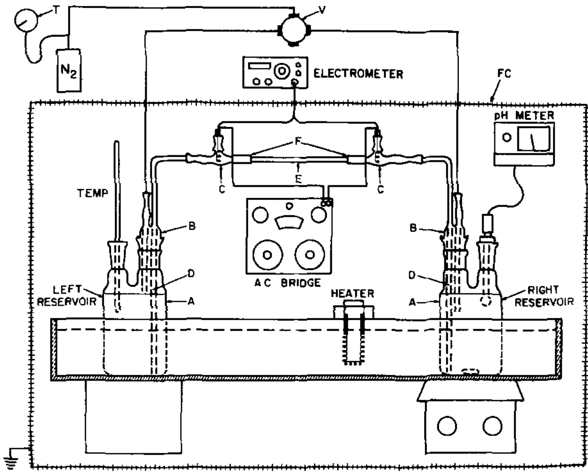

Fig. 1. A schematic diagram of the streaming potential apparatus

in both flow directions. This process was repeated until the driving pressure reached 12-14 cm Hg. The slope, $\Delta Estr/\Delta P$, of the best fit straight line was utilized in Eq. [3]. Solution specific conductance was determined in a precalibrated cell with platinized platinum electrodes. The cell constant, C, of the streaming capillary and the conductivity cell were predetermined using a 0.1*N* KCl solution of known specific conductance (19). Following streaming measurements, the resistance of the capillary electrode system was measured with the a-c bridge. In most instances where ionic strength was high, solution conductance masked surface conductance and K_B was determined in a conventional conductivity cell. Equation [3] was then utilized. This was the case for all data reported here.

Radio frequency glow discharge (RFGD) of the streaming cell components was carried out to eliminate problems with surface contamination which occasionally developed. RFGD (Commercial Plasmod System, Tegal Corporation, Richmond, California) in argon gas at 100 μm Hg and an rf power density of 50W for 5 min was highly effective in removing surface contamination.

All chemicals utilized were analytical reagent grade (Fisher Scientific Company, Fairlawn, New Jersey). Water used in this study was twice distilled over Pyrex glass (Corning Still Model AG-11) and had a conductivity of 1 ± 0.1 μmho/cm. Phosphate buffered saline (PBS) was made up as 0.145M NaCl, 2×10^{-4}M KH_2PO_4, and 8×10^{-4}M Na_2HPO_4 using twice distilled water. Glutaraldehyde was employed as a fixative in a 2% (v/v) solution in PBS (obtained in purified form as an 8% (v/v) unbuffered aqueous solution sealed under pure N_2 from Polysciences, Incorporated, Warrington, Massachusetts). Giemsa biological stain (Fisher Scientific Company, Fairlawn, New Jersey) was utilized at 10% (v/v) in twice distilled water. Nigrosin (Eastman Organic Chemicals, Rochester, New York) dye exclusion was used as a test of membrane viability at a concentration of 1% (wt/v) in PBS. Dulbecos modified Eagle Medium (Grand Island Biological Labs) supplemented with penicillin (100 units/ml), streptomycin (100 mg/ml), and 20 mM HEPES (N-2-hydroxyethyl piperazine-N-2-ethane sulfonic acid, ICN Pharmaceuticals, Cleveland, Ohio) buffer was utilized as the cell culture medium and will be referred to as DMM. Fetal bovine serum (fbs) was added as specified.

An established line of BALB/c 3T12 mouse fibroblasts (noncontact-inhibited, tumorigenic cells) were cultured to confluency in borosilicate capillaries 600 ± 20 μm ID. The cells were harvested from milk dilution bottles by trypsinization [6 ml of 0.25% (v/v) trypsin], resuspended in DMM supplemented with 10% (v/v) fbs, and centrifuged at 200g for 5 min. The cells were then resuspended in DMM, counted in a hemocytometer, washed in DMM twice, and resuspended at a seeding concentration of 1×10^6 cell/ml in DMM. The cells were seeded by drawing the cell suspension into the capillary using a 1 cm^3 syringe. Both ends of the capillary were capped with Silastic tubing and clamps; the capillary was placed in an incubator at 37°C, 90% humidity, and 95% air/5% CO_2 for 20-30 min. This was sufficient time to allow the cells to contact and form an adhesive bond with the glass surface. Fresh DMM supplemented with 10% (v/v) fbs was then drawn into the capillary. After approximately 5-10 hr the capillary was removed from the incubator and reseeded in another position on the internal circumference in the same manner. Four to five cell seedings over a 24-36 hr period were sufficient to get a uniform distribution of cells on the interior of the capillary. Glass syringes of 30 ml capacity were attached to each end of the capillary via Silastic rubber tubing. Supplemented medium (DMM, 10% fbs) was continuously perfused through the capillary at a flow rate of 0.5 ml/hr using a Sage syringe pump (Sage Instruments Model 341). This was sufficient to keep the cells metabolically and mitotically

Table I. Composition of aqueous electrolyte utilized in electrokinetic evaluation of living cells

Component	Millimoles/L of component
NaCl	133.00
$CaCl_2$	1.80
KCl	5.36
$MgSO_4 \cdot 7H_2O$	0.81
KH_2PO_4	0.20
Na_2HPO_4	0.80
D-glucose (anhydrous)	5.55

active, and after 24-36 hr the cells had proliferated to monolayer density.

The capillary was removed from the perfusion apparatus and rinsed in 5 ml of cell streaming solution (Table I) at 5 ml/min. It was then inserted into the streaming apparatus and evaluated within 10-15 min. Following this, the cells in the capillary were fixed in a 2% (v/v) glutaraldehyde PBS solution for 30 min at 37°C. After fixation the electrokinetic properties of the cells were evaluated as a function of pH and ionic strength. When the electrokinetic evaluations were completed, the cells were stained in a 10% Giemsa solution in distilled water, reevaluated electrokinetically, and photographed in both transmitted light and the scanning electron microscope. The cells on glass substrates were post fixed in 1% osmium tetroxide PBS solution at 37°C for 15 min, dehydrated in a graded series of ethanol water solutions, critical point dried in liquid CO_2, mounted, coated with carbon and gold, and observed in a Cambridge stereoscan scanning electron microscope.

For streaming studies on glass and cell monolayers as a function of pH, pH was adjusted with solutions of NaOH or KOH and HCl having the same ionic strength as the streaming solution. In all studies where pH was maintained constant, phosphate buffer (2×10^{-5}M KH_2PO_4, 8×10^{-5}M Na_2HPO_4) was added to the streaming electrolyte. The temperature was maintained constant at 24°C in all studies.

Results and Discussion

Preliminary investigations concerning the effect of capillary geometry on measured streaming potential indicated a linear decrease in $\Delta Estr/\Delta P$ as the length of the capillary decreased. This was at odds with the conclusion inherent in the derivation of the streaming potential equation in that capillary geometry should not affect the streaming potential. An analysis of flow turbulence and entrance effects on streaming potential was carried out to determine the cause of the discrepancy.

Figure 2 is an *Estr vs. P* plot for two streaming tubes. Tube A is 600 μm ID and 30 cm in length, while tube B is 1250 μm ID and 30 cm long. In the case of tube A the data is linear and the slope ($\Delta Estr$ *vs.* ΔP) is equal in both flow directions. Measured flow rates and subsequently calculated Reynolds numbers indicated laminar flow throughout the measured pressure range for tube A. In the case of the larger tube (B), the data at low driving pressures is linear and the slopes are equal in both flow directions; however, at a pressure of 14 cm Hg the flow becomes turbulent ($R > 2000$) and the data becomes nonlinear at higher driving pressures. This seems to indicate a marked deviation in the $\Delta Estr/\Delta P$ data obtained if the flow changes from laminar to turbulent. This is at odds with data published by others (19) for turbulent flow in aqueous systems. One can also see a difference in $\Delta Estr/\Delta P$ for tubes A and B which would seem to indicate that turbulent flow is not the only cause of deviations in the calculated ζ-potential for tubes of various sizes.

The results of streaming potential studies on borosilicate capillaries as a function of length and internal diameter are shown in Fig. 3. Each tube was evaluated at its greatest length and then successive portions were removed and it was reevaluated. This was continued until no tube remained. The only variable was length since η and ϵ are assumed constant and K_B greatly predominated over K_s at this high ionic strength (0.01 g ions/L). Capillaries B (1284 ± 34 μm ID) and C (595 ± 15 μm ID) were commercial borosilicate; there was no significant variation in ID along the length. Both capillaries exhibited a constant $\Delta Estr/\Delta P$ value until a critical length was reached whereupon there was a marked drop in $\Delta Estr/\Delta P$. The critical length (L_c) at which this occurred was 58 cm for tube B and 20 cm for tube C. Capillary A was hand drawn from a larger tube. There were significant variations in ID along its length. Points 1 and 2 shown in Fig. 3 were obtained when the capillary was 190 ± 12 μm ID, while equivalent lengths taken from the center of the tube gave lower $\Delta Estr/\Delta P$ values and had an ID of 160 ± 5 μm. This would seem to indicate that at lengths less than some critical length the diameter and length of the streaming capillary markedly affect the measured streaming potential, while at lengths greater than L_c minor variations in diameter and length have no measurable effect.

The onset of turbulent flow does not seem to cause this behavior since flow was laminar in all cases for tubes A and C and there seemed to be no significant effect due to turbulent flow for tube B. If one compares the measured flow rates, Q_m, in the three tubes with the theoretical flow rates, Q_t, calculated using Poiseuille's law as expressed in Eq. [4]

$$Q_t = \frac{\pi}{8} \frac{r^4}{\eta} \frac{dP}{dX} \quad [4]$$

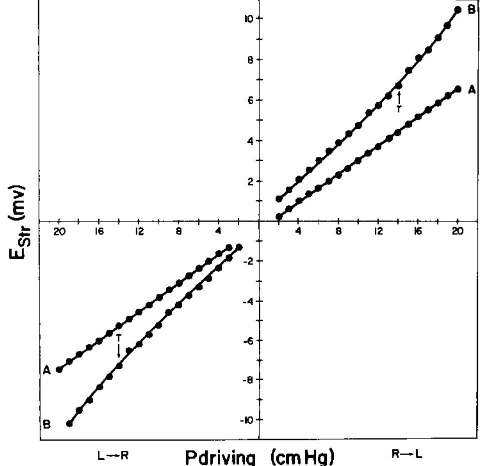

Fig. 2. *Estr vs. Pdriving* or two borosilicate capillaries A and B. The streaming solution was 0.01M KCl buffered to a pH of 7.

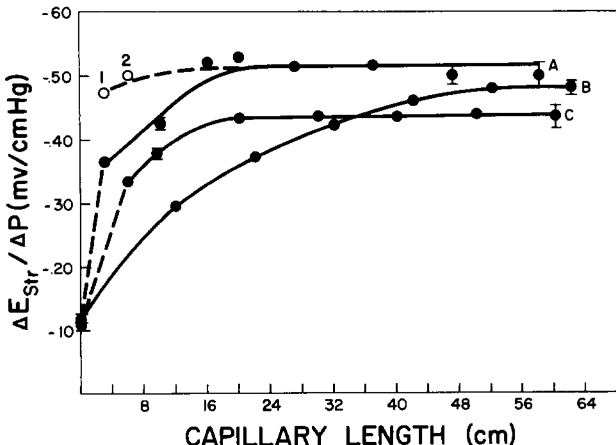

Fig. 3. $\Delta Estr/\Delta P$ *vs.* streaming tube length for three borosilicate tubes A, B, and C. The streaming solution was 0.01M KCl buffered to a pH of 7. Error ranges correspond to one standard deviation.

where r is the tube radius, η is the fluid viscosity, and dP is the pressure drop across a flow length dX, it is found that Q_t and Q_m are equal until the critical length, L_c, is reached, *i.e.*, 20 cm for tube C and 58 cm for tube B. It can be concluded from this that the streaming data and calculated ζ-potential are independent of capillary geometry (the variations in plateau values of $\Delta Estr/\Delta P$ are expected since the tubes were from different sources and most probably had different surface histories) as long as Poiseuille flow exists. This is what Helmholtz predicted as Bocquet has pointed out (20). Poiseuille flow actually requires that four basic conditions exist, *i.e.*, the flow is steady, incompressible, laminar, and established.

Many investigators have simply ignored the established flow criteria. It takes a certain length, L_e, past the entrance of a cylindrical flow system, to establish a parabolic velocity profile during steady laminar flow of an incompressible fluid. The value of L_e has been found both experimentally (21) and theoretically (22) to be given by Eq. [5]

$$L_e \simeq 0.06RD \qquad [5]$$

Here R is the Reynolds number and D is the diameter. On the basis of this analysis, it seems that if L_e is greater than 10 ± 1% of the total streaming tube length, the $\Delta Estr/\Delta P$ ratio and subsequently calculated ζ-potential will be anomalously low.

Electrode asymmetry at high ionic strength can develop, particularly if the electrodes have aged appreciably over the course of several months' use, and if they have been exposed to protein or other adsorbable solutes. This is illustrated in Fig. 4. Curves 8B through 12B were obtained utilizing silver, silver chloride electrodes which had previously been exposed to a streaming capillary with a surface of adsorbed fetal bovine serum. The asymmetry developed at that time. It was absent in earlier experiments at high ionic strength (0.1 g ions/L) where protein was not present (not shown). The asymmetry diminished with continuous streaming of electrolye in approximately 30 min (8B-10B). As long as streaming continued, the slope $\Delta Estr/\Delta P$ (10B-12B) remained constant.

If flow ceased for any length of time, asymmetry reappeared and it required another 30-40 min of streaming to obtain good linearity and reproducibility. At lower ionic strength (0.01 g ions/L) the asymmetry was not evident (1B and 4B, Fig. 4). When fresh electrodes were prepared and protein contamination was absent, there was no deviation from linearity at low ionic strength (0.01 g ions/L) or high ionic strength (0.1 g ions/L) as shown in Fig. 5.

The asymmetry exhibited by aged silver, silver chloride electrodes at high ionic strength may be due

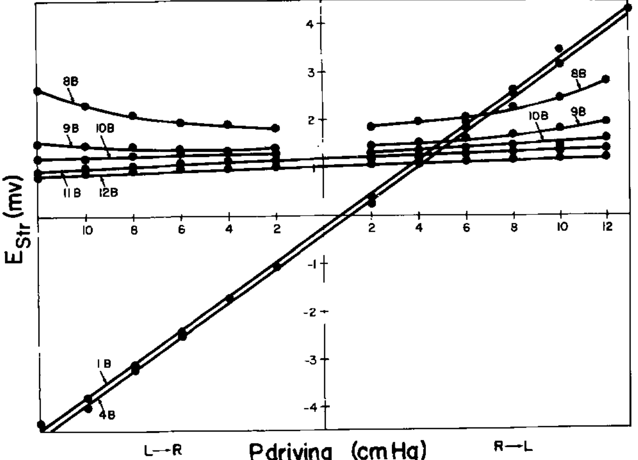

Fig. 4. *Estr vs. Pdriving* for a borosilicate capillary. The streaming solution was 0.1M KCl (unbuffered) for curves 8B-12B and 0.01M KCl (unbuffered) for curves 1B and 4B.

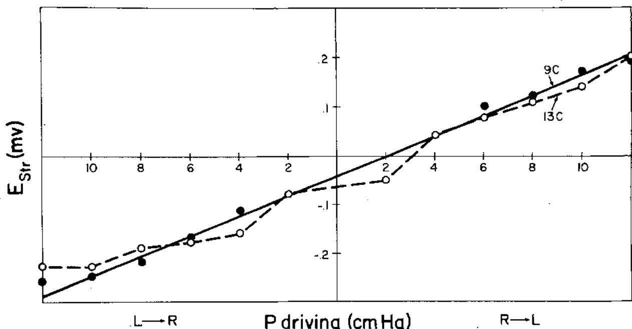

Fig. 5. *Estr vs. Pdriving* for a borosilicate capillary. The streaming solution was 0.1M KCl. 13C was immediately after chloridization while 9C was after equilibration and short-circuiting in streaming solution for 30 min.

to protein adsorption in the pores of the AgCl coating. Janz and Ives (23) maintain that silver may form stable complexes with amino and sulfhydryl groups of organic molecules which can compete with the insolubility of the AgCl thus negating the proper functioning of the electrodes. It has also been suggested (23) that 10-25% of the silver should be chloridized to AgCl to produce electrodes having good reproducibility and stability. The electrodes exhibiting asymmetry problems had only 1% conversion (assuming 100% current efficiency) of Ag to AgCl. Srinivasan (24) has recommended that silver, silver chloride electrodes be prepared in a slowly alternating a-c fashion utilizing anodic deposition of AgCl and cathodic current to increase surface area by enhanced pore formation. The above recommendations were followed. Silver, silver chloride electrodes were prepared electrolytically with a slowly alternating current (5 min anodic, 2 min cathodic, etc.); the gross surface area per electrode was 1 cm^2 and the net anodic current density time product was 6.9 $A\text{-}sec/cm^2$. There was a theoretical conversion of silver to silver chloride of 16%. Electrodes freshly prepared in this fashion are stable and have never shown prolonged asymmetry at high ionic strength even upon protein adsorption.

Figure 6 comprises 4 SEM micrographs of silver, silver chloride electrode surfaces. The general shape of the electrodes used in this study are shown in Fig. 6a. They consist of silver wire coils 6 mm long and 3.8 mm OD. The gross surface area is 1 cm^2. Figure 6b illustrates the AgCl surface of a freshly prepared electrode (anodic 5 mA/cm^2 for 4 min, 1% conversion of Ag to AgCl). A number of pores can be seen as well as some microgranularity on a cobblestone surface. Figure 6c is the same electrode after approximately 3 months use. This was the same electrode which developed asymmetry at high ionic strength and protein exposure. The cobblestone appearance is still partially evident; however, much of the pore structure and all of the microtexture are lost. The pores between the cobblestones are now replaced by smaller pores in an incomplete cobblestone structure. Figure 6d is the surface of a freshly prepared electrode employing the alternating anodic and cathodic deposition of AgCl previously described. The highly porous structure obviously increases the surface area available for current transport. Electrodes prepared in this manner have not exhibited asymmetry at high ionic strength and exposure to protein solutions as long as they are equilibrated several hours prior to use.

The calculated ζ-potential of borosilicate glass as a function of temperature is shown in Fig. 7. The standard deviations at both ionic strengths are rather large, particularly for 0.1M NaCl. This is due primarily to the variation in $\Delta Estr/\Delta P$ slopes obtained at various temperatures and not so much to the inability to get accurate slopes at constant equilibrium temperatures. Due to the wide standard deviations it can only be con-

Fig. 6. SEM micrographs of silver, silver chloride electrode surfaces

cluded that there is no statistically significant variation in ζ as a function of temperature.

The variation in ζ-potential with *p*H for borosilicate glass is shown in Fig. 8. The data indicates that borosilicate has a *p*Ka of $\sim$ 5.7 assuming that all the surface charge is due to the ionization of ionogenic $\equiv$ Si-OH (silanol) groups in the hydrated region of the glass. This is at variance with the data of Hair and Hertl (25) and Marshall *et al.* (26) which suggests a *p*Ka for surface silanol groups of 7.1-7.2. However, it is quite probable that high concentrations of hydronium ions exist in the hydrated surface region of the glass due to cation exchange. If this were the case, the ζ-potential at acidic *p*H could be considerably less than that occurring as a result of charge generation purely by ionogenic silanol groups. The result would be an apparent shift in *p*Ka. A second cause of the discrepancy may be due to the presence of boranol groups ($\equiv$ B-OH) in significant numbers at the hydrated surface of borosilicate glass. The proportion of boron to silicon in the porous surface may be as high as 1:3 rather than 1:18

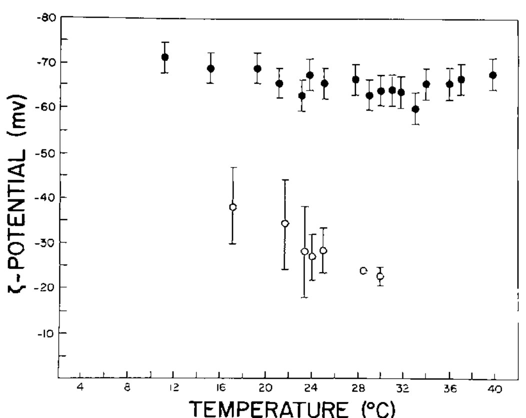

Fig. 7. Calculated ζ-potential of borosilicate glass as a function of temperature. Streaming solution was 0.01M KCl (●) and 0.1M NaCl (○); both solutions were buffered to a *p*H of 7.0. Error ranges correspond to one standard deviation.

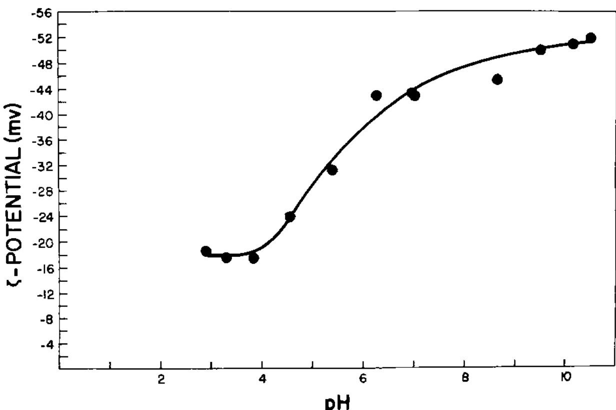

Fig. 8. Calculated ζ-potential of borosilicate glass as a function of *p*H. Streaming solution is 0.01 KCl. The *p*H was altered with KOH and HCl solutions of the same ionic strength.

as expected in the bulk (27). The *p*Ka of boranol groups is 5.1 and this would also tend to shift the resultant surface *p*Ka to a more acidic region.

Figure 9 illustrates the increase in ζ-potential with decreasing ionic strength (KCl) at constant *p*H (7.1) and temperature (24°C). The linear portion of the curve corresponds to the expansion of the electrical double layer as ionic strength decreases. At an ionic strength of less than 3×10^{-4} g ions/L there is a deviation from linearity due to the onset of surface conductance which was not accounted for in the calculation of ζ. This is in agreement with the detailed analysis of surface conductance made by Rutgers and DeSmet (28) and Li and DeBruyn (29).

Streaming potential studies on living 3T12 cells were carried out using cell streaming solution as described in Table I. It was necessary to incorporate divalent cations and glucose in the electrolyte to maintain good cell substrate adhesion during streaming since the high flow rates (typically 10 cm^3/min) are sufficient to shear off cells with altered adhesive properties. Even in the solution used, the cells begin to lose adhesiveness after approximately 20 min. For this reason streaming evaluations on living cells were limited to 10-12 min. Nigrosin staining (30) of 3T12 cells indicated that their membranes retained semipermeability for more than 60 min in streaming solution, even though most cells had retracted off the surface in monolayer sheets. Apparently, the cells sacrifice cell-substrate bonds rather than cell-cell bonds and retain membrane function and viability even after 60 min of exposure to streaming solution at room temperature. The ζ-potential of living cells was -28.8 ± 2.5 mV (streaming solution Table I, ionic strength 0.145, *p*H 7.3, temperature 24°C). Following 2% glutaraldehyde fixation, the ζ-potential dropped to -17.6 ± 2.6 mV under the same conditions. The decrease in electrokinetic potential following glutaraldehyde fixation may be due to a loss of free draining volume in the cell periphery, that is, the region of hydrodynamic slip containing a portion of the peripheral charge is eliminated due to glutaraldehyde cross-linking of membrane protein, thus preventing the detection of this charge by electrokinetic techniques. Following fixation the cells were evaluated as a function of ionic strength and *p*H.

The effect of *p*H on fixed 3T12 cells is shown in Fig. 10. Ionic strength was constant at 0.01 g ions/L (NaCl). In a qualitative sense the data is similar to that of Vassar *et al.* (3) for fixed human erythrocytes. In the plateau region from *p*H 7 to 10 there is no variation in ζ-potential; however, there is a precipitous and quite linear decrease in ζ-potential below *p*H 6 indicating the presence of an ionogenic molecular type(s) with an acidic *p*Ka of 4.5 or less. There is no indication of an

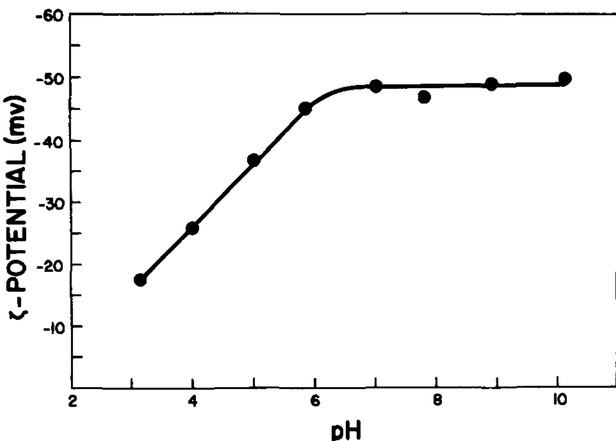

Fig. 10. Calculated ζ-potential of 3T12 cells cultured in borosilicate capillaries following fixation in glutaraldehyde. The streaming solution was 0.01M NaCl. The pH was altered with NaOH and HCl solutions of equal ionic strength.

ionogenic species of *p*Ka ~ 6.5 due to glutaraldehyde fixation as reported by Vassar *et al.* (3). This discrepancy is further accentuated when it is realized that glutaraldehyde fixation caused a 38% decrease in the ζ-potential of 3T12 fibroblasts, while it resulted in about a 10% increase in electrophoretic mobility of human erythrocytes. However, when making comparisons of this sort and attempting to see relationships, it should be kept in mind that at least two variables could and probably do invalidate any present attempt at comparison. (*i*) Different electrolyte components, ionic strengths, and buffers were utilized. (*ii*) Cell types evaluated were different.

The ζ-potential as a function of ionic strength (NaCl) relationship for fixed 3T12 cells is shown in Fig. 11. The expansion of the double layer at lower ionic strength results in a higher ζ-potential. The increase is quite linear, and there is no indication of the predominance of surface conductance at low ionic strengths (1×10^{-3} g ions/L). This data is similar to that of Heard and Seaman (1) for unfixed human erythrocytes; however, in the case of 3T12 cells, the slope over the ionic strength range 0.1-0.01 g ions/L is not as steep as is the case for the erythrocytes. Here again the differences between cell type, fixation, and the presence of sorbital during microelectrophoresis prevents direct comparison.

Following the evaluation of the 3T12 electrokinetic surface, *i.e.*, that region of the cell periphery within ~ 10Å of the hydrodynamic shear region, several

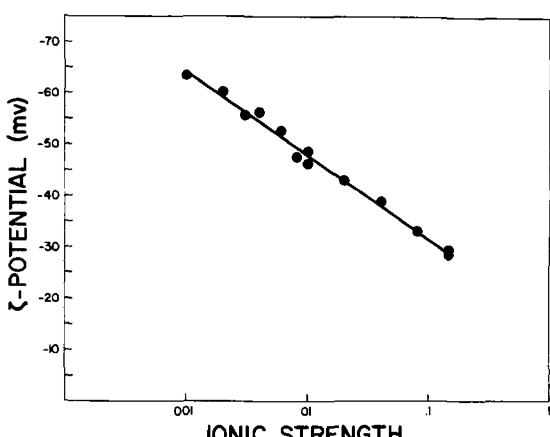

Fig. 11. Calculated ζ-potential of 3T12 cells following fixation in glutaraldehyde as a function of ionic strength. Streaming solution was NaCl buffered to a pH of 7.3.

streaming experiments were repeated under identical conditions of ionic strength and *p*H. There was no significant deviation from original data after 5 days storage in PBS. This would seem to substantiate the assumption that glutaraldehyde fixation produces a stable cell membrane in the electrokinetic sense. The cells were stained in Giemsa to enhance microscopic evaluation of the uniformity of the 3T12 cell layer. Giemsa staining at 25°C for 8 min resulted in a 20% reduction in calculated ζ-potential, *i.e.*, -46.2 ± 1.3 mV to -36.7 ± 0.8 mV (0.01M NaCl, phosphate buffer, 25°C, pH 7.2).

Comparative scanning electron micrographs of stained and unstained 3T12 monolayers indicated that Giemsa-stained cells were altered morphologically. Nonstained cells were well spread and in contact with the substrate, while stained cells had a more rounded appearance and had lost some contact with the glass. The decrease in ζ-potential may have been due to the effect of Giemsa stain on the cell periphery or the altered morphology of the cells. Giemsa is composed of Azure II, Eosin, glycerin, and methanol and any of these may have been the cause of the decrease in ζ.

Recently, a technique of evaluating cells cultured in capillary tubes utilizing electroosmosis has been reported by Fike and Van Oss (31). The advantage of this approach is that the cells may be evaluated for long times in the living state; however, the disadvantage is that the ionic strength must be an order of magnitude lower than physiological to obtain accurate measurements.

In conclusion, a streaming potential apparatus and technique have been developed which make it possible to evaluate the electrokinetic properties of cells grown in *in vitro* cell culture. The results for borosilicate glass substrate and 3T12 mouse fibroblasts cultured to confluency on this substrate attest to the feasibility of the approach. The usefulness of various electrokinetic techniques applied to investigations of cell membranes has been established. Microelectrophoresis, streaming potential, and electroosmosis have all been utilized on various cell types, but no single technique seems feasible for a detailed study of a wide variety of cells under all conditions. Rather, the three mentioned techniques must be utilized in conjunction to gain a more complete understanding of the similarities and differences in cell membranes over a wider range of cell types.

Donor Recipient Lymphocyte Recognition in Kidney Transplantation

Electrochemical Techniques for Evaluating Donor Recipient Tissue Compatibility

P. N. Sawyer, B. Stanczewski, N. Ramasamy,* D. V. Raman, W. Wrezlewicz, I. Parsa, J. Pindyck, S. L. Kountz, and K. Butt

ABSTRACT

Classical methods based on cell recognition *in vitro* do not yield full information on tissue-host compatibility. Acute rejection episodes are thus common in patients with transplanted kidneys. Determination of surface charge of lymphocytes has been employed to provide information on cell recognition. The results from 40 sets of matched kidney donors and recipients indicate that cell electrophoresis could be used to determine tissue-host compatibility. Acute rejection occurs in cases where the electrophoretic mobility of mixed lymphocyte (EM_{mix}) is much higher or lower than that of the recipient (EM_R). If EM_{mix} is only marginally lower than EM_R ($\pm 5\%$) the transplanted organ rejection rate is markedly reduced.

This group has studied "surface recognition phenomena" in biological systems intermittently since 1950. One aspect of this interest has been the study of intravascular thrombosis which entails special surface chemical recognition characteristics (1-5). Another aspect of this interest has been investigative evaluation of the immune response, as a surface recognition or surface chemical event. This area was first investigated by us when we studied slow rejection and thrombosis in fresh and freeze-dried homo transplanted arterial grafts in dog and man in 1950 through 1953 (2, 4, 5). Freeze-dried homo grafts displayed less immunogenicity and thrombosed less than did fresh grafts implanted into the recipient artery (Fig. 1).

Surface recognition.—One of the initial steps in the immune response is the recognition of the foreign tissue by the immunocompetent cells as nonself.

If rejection involves "recognition," both should be modified by "electrical masking," (4, 6, 7) that is by modification or rearrangement of the surface charges in the donor tissues, thus preventing antigen-antibody recognition and/or recipient recognition cells principally lymphocytes from attaching to the surface prosthetic groups of the organ transplant (8-12).

In the first experiment, an attempt was made to modify the recognition faculty of the immunocompetent cells of the recipient by inserting a charged metallic pipe prosthesis between donor and recipient arteries at the inflow site. Whether the "electrode pipe" was charged or uncharged the survival of transplanted kidneys was not enhanced (Fig. 2a and b).

An attempt to influence rejection rates in an acute immune response model using an *ex vivo* heterologous rabbit liver perfused by dog was next carried out, and was found to reveal several interesting effects of electrical phenomena. Applied electrodes and developed fields were found to delay the rejection in specific areas of the heterologous liver depending on the configuration of the field (13) (Fig. 3a b, and c). The observations were substantiated by time lapse photography, histologic and biochemical studies of the blood flowing through the *ex vivo* liver, and by mapping the shape and density of the applied electric field. These were compared with the visible rate and type of rejection seen on the surfaces of the exposed livers which were

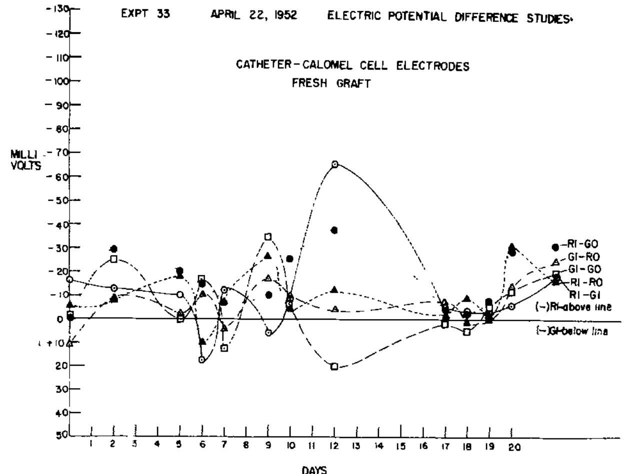

Fig. 1. The six daily readings of a fresh graft and recipient aorta plotted against time, showing initial potential difference in the graft (GI-GO), the early peak at 2 days, the positive peak at 9-13 days, and final negative deflection at 18 days. The graft displayed considerable grade 3+ thrombus formation at autopsy with cicatrization and connective tissue reaction around it. RI-RO shows repeated peaks of potential, positive at 5 days, negative at 10-14 and 18-20 days. These peaks are thought to occur at the point of maximum antigenic response of the host to the fresh homograft. Some superficial infection occurred in this dog. It should be noted that even in 1950-1951, we recognized that changes in the interface potential of a fresh or freeze-dried homograft might change with rejection.

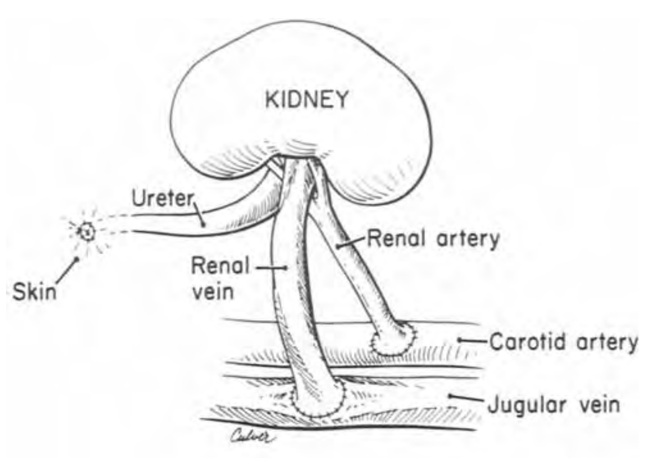
photographed. The results indicated that recognition involved an "electron to electron look" which obviously can be masked at least in part by the applied field (10-14). However, the experiment was impossibly expensive and time consuming. A less expensive model was sought.

The Modern Scene

In 1952, the first successful renal transplantation was carried out using identical sibling kidneys between donor and recipient (15). As time progressed, renal transplantation has become an accepted modality of treatment for end stage renal failure in patients and is being applied on an ever wider scale (16). However, the results of renal transplantation have reached a

* Electrochemical Society Active Member.

Key words: electrophoresis, compatibility, recognition, transplantation.



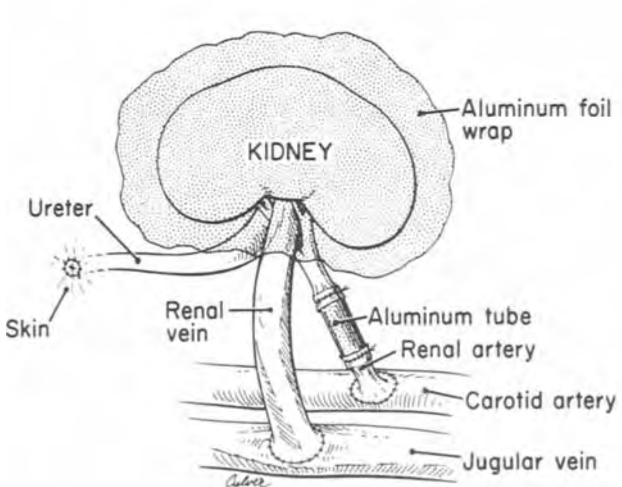


Fig. 2. (a, top) Schematic diagrams of kidneys transplanted from one dog to another dog. The ureter is run through the skin to make a cutaneous fistula. The renal artery is attached to the carotid artery. The renal vein is anastomosed to jugular vein. (b, bottom) Attempts to modify kidney rejection were carried out in one of three ways: *(i)* either by the implantation of a metal tube between the carotid and the renal artery, *(ii)* making the tube electrically positive or negative, or *(iii)* wrapping the kidney with aluminum foil. Size and electric polarity of charge, aluminum foil wrap, or isolation of the kidney, did not modify rejection rate.

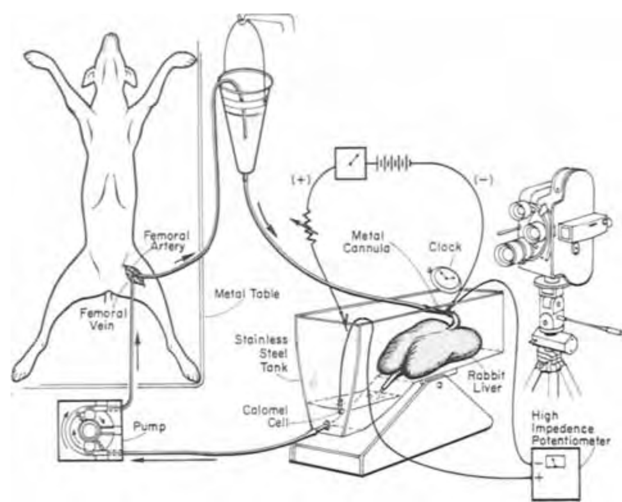

Fig. 3a. Canine blood from the femoral artery perfuses the portal vein of an ex *vivo* liver placed in perfusion tank. The blood flows into the liver through the portal vein and out the inferior vena cava into a well in the tank. It is then pumped back into a dog femoral vein via a blood pump. Changes in the liver are photographed as illustrated including the time lapse clock in the right upper corner of the picture. The perfusion tanks were made either of stainless steel or Plexiglas. The metal catheters are made of a number of different materials in an attempt to influence rejection.

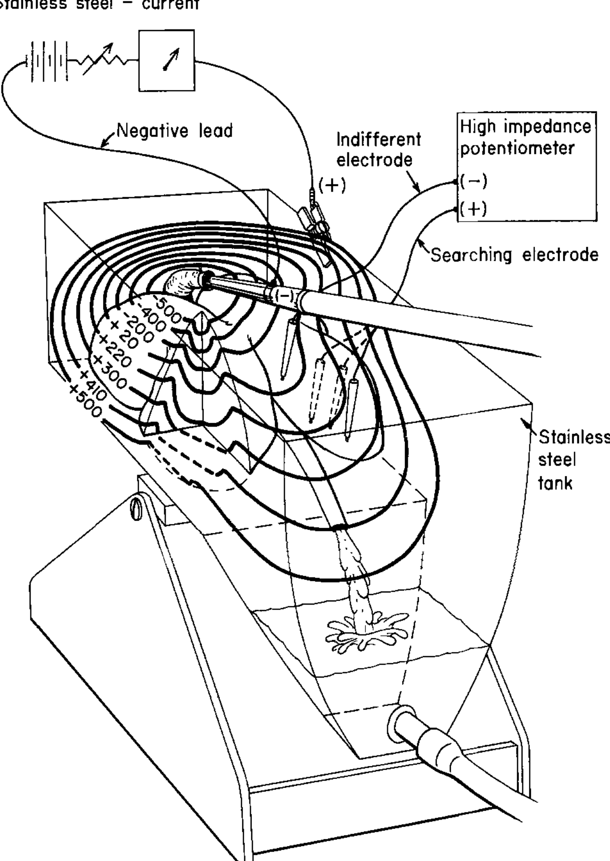

Fig. 3b. The addition of a battery, ammeter, and variable resistance was used to modify the electric potential on the surface of the liver cells in the attempt to modify rejection as shown in this figure. The negative pole of the battery is attached to the metal perfusion cannula. The positive pole here is attached to the wall of the tank.

plateau and have not shown improvement in the last five years (16). In an effort to try to improve the immediate and long term results of kidney grafting, three broad approaches have been investigated: (*i*) improved immunosuppression of the host (17, 18), (*ii*) alteration of the antigenicity of the graft (19), and (*iii*) improved donor and recipient pair selection (20, 21). While the first two categories of studies have shown significant gains at the present time, they are in general only applicable to the human situation in a limited way. Logistically, improved selection of donor kidneys, particularly those from cadavers, has become increasingly important.

Synthesis

The solution to making further progress in the evaluation of interfacial phenomena and immune rejection was the clear indication that lymphocytes, probably in this instance T lymphocytes with B lymphocytes as complement, under specified conditions are a major source of immunocompetence (8-12. 14). Modern dogma has it that modification or neutralization of T and B lymphocytes should decrease transplant organ rejection. This has in general only partly been borne out (22). This belief has led to a series of tests to evaluate compatibility between donor and recipient lymphocytes. The tests most commonly applied include HLA

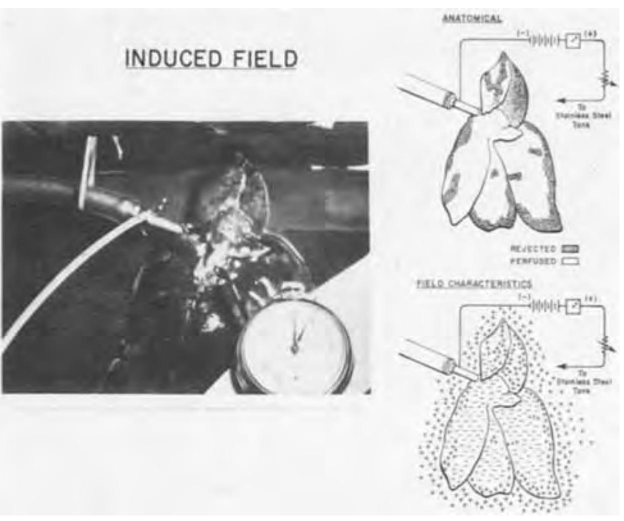

Fig. 3c. With the metal cannula charge negative and the wall of the tank charged positive the lobe of the liver nearest the wall of tank rejects most rapidly. Rejection is somewhat slower than under control conditions. The perifery rejects rather rapidly and stabilizes this way because the field developed by the negatively charged cannula implanted into it is placed near the center of the mass of the ex *vivo* liver. In general, where there is a high concentration of electrons negatively charged ions in this system, there is slower rejection.

and mixed leukocyte culture (MLC) tests (21, 23). Attempts to decrease the immunocompetence of both donor and recipient lymphocytes which carry immune recognition capability has been carried out through infusion of antilymphocyte and antithymocyte serum. Both tend to "mask" lymphocyte surface antibodies.

Progress

In spite of our recognition of the classical problems of immune rejection, improvement in donor-recipient selection techniques with improved survival and function have really been improving at a great rate only in living related transplants. For example it has clearly been shown that homografts between identical twins or HLA identical siblings have a better than 95% long term chance of survival (16, 20). However, the same serological techniques for determining HL antigens have not been overly successful in selecting satisfactory cadaveric transplants or those from unrelated donors (24). Human lymphocyte antigen tests theoretically are capable of indicating differences in the antigen structure of lymphocytes, red cells, and other cells from nonidentical humans. However, the HLA technique has been found inapplicable in large degree to unrelated donor-recipient pairs suggesting that some subtle antigens which require testing have not been recognized.

The MLC tests require that lymphocytes be extracted from lymph nodes of both donor and recipient and that they be cultured together to determine if during long term culture in a nutriant medium they have a tendency to form "blast cell" forms or not (25). Three days to a week are required to obtain sufficiently good cultures to determine compatibility. This is not useful in cadaveric transplants which require implantation with a maximum delay of 24 hr.

It seemed obvious therefore that if we could look at the changing electrophoretic characteristics of lymphocytes under conditions where donor and recipient lymphocytes were mixed together, and their surfaces allowed to interreact, the results might be indicative of "compatibility."

Moreover, an appropriate electrochemical evaluation of donor-recipient lymphocyte compatibility might be used simultaneously as a new model of immunocompetence and/or rejection, as well as a technique for measuring organ acceptance in the new host.

In order to prove utility, it was first necessary to show that, (*i*) Lymphocytes display electrophoretic mobility. This has previously been shown by many people (26, 27) and been shown modifiable by various surface chemical reactants (10). (*ii*) Electrophoretic mobilities are reproducible (10-12, 26, 27). (*iii*) Electrophoretic mobilities for "different lymphocytes" T and B, and from different people vary (14, 28) and why (10-12). (*iv*) Donor-recipient lymphocyte compatibility is measured by variation in electrophoretic mobility following incubation together. (*v*) One could determine from the electrophoresis of two lymphocyte groups incubated together whether or not organ transplant could be successful. (*vi*) Various modifications of the basic tests permit a scientific determination of the lymphocyte surface characteristics which are being evaluated.

The New Model

The new "model" which is capable of sequential manipulation involves the removal of lymphocytes from donor and recipient lymph nodes or peripheral blood and the mixing of these lymphocytes together to determine whether they inter-react and effect each other in terms of their movement in an electric field, *i.e.*, electrophoresis (Fig. 4). The surfaces of the lymphocytes removed from either blood or lymph nodes can be evaluated electrophoretically, using a microelectrophoresis apparatus (29).

These cells can then be compared with lymphocytes from another person in whom one is contemplating transplanting an organ.

Results of lymphocyte cultures from unrelated donors and cadavers can be compared with those from related donors and from family related donor-recipient pairs. In addition, lymphocytes from the donor can be compared with the serum of recipient and vice versa. The effect of temperature can be measured to deter-

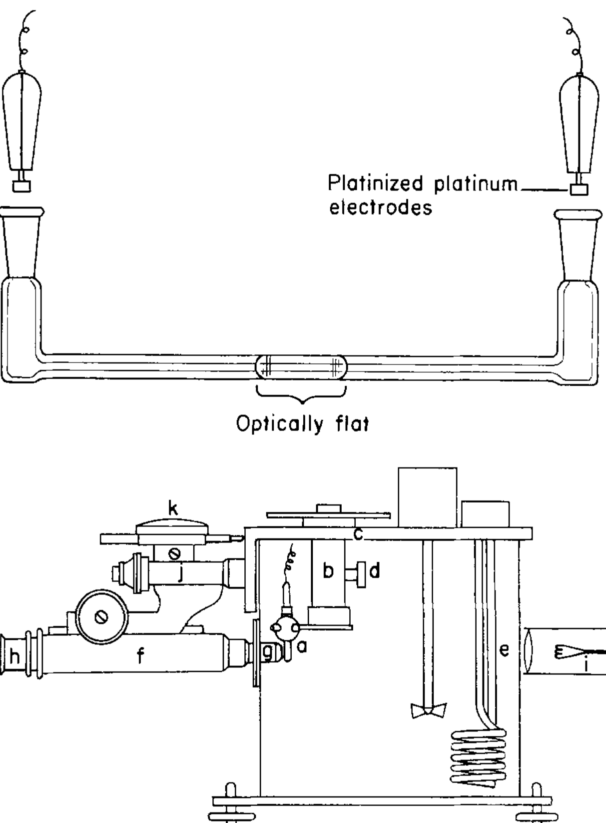

Fig. 4. Diagram of a Seamen's microelectrophoresis apparatus. The most interesting aspect of this modification of the electrophoresis apparatus is Seamen's placing the microscope on horizontal axis to look at a vertical electrophoresis chamber, a novel and very useful development.

mine whether the donor-recipient changes in electrophoresis are complement related. Collateral studies of donor-recipient lymphocytes and/or their serum include: (*a*) effect of ABO, MN compatibility on electrophoresis; (*b*) effect of temperature to determine if "complement" is involved; (*c*) effect of steroids; (*d*) effect of immuran; (*e*) comparison of motility of lymph node lymphocytes in comparison with peripheral circulating lymphocytes from the same patient under the same conditions; (*f*) the effect of washing lymphocytes with either Ringer's solution or distilled water to produce ghosts and the comparison of these suspended treated cells with their precursors or following poisoning; (*g*) the obvious determination of the effects of storage and incubation time and temperature; (*h*) effect of aging lymphocytes while stored within and out of lymph nodes in various bathing solutions, etc.; (*i*) correlatedly the effect of freezing and storage; and (*j*) effect of anti lymphocyte globulin (ALG) or anti thymocyte globulin (ATG) and other surface active inhibitors on the surface charges to decrease or increase electrophoretic mobility and the ionic structure of the cell interface.

The results of many of these studies will be presented in subsequent presentations. The most important aspect of this determination, that transplant rejection can often be predicted by recipient lymphocyte incubation and electrophoresis, was established.

Materials and Methods

Electrophoresis was carried out using a Seaman, Cambridge micro electrophoresis apparatus (29) (Fig. 4 and 5).

I. Source of lymph nodes: Lymph nodes were taken from the renal hilum and peri-aortic areas of donor and peri-iliac areas of the recipient.

II. Lymphocytes removed from lymph nodes were prepared by mincing lymph nodes at room temperature and extracting the lymphocytes into Ringer's solution. These were then diluted to approximately 300,000 lymphocytes/cm^3 of Ringer's as measured in a hemocytometer.

III. The cells were suspended in Ringer's solution or isologous serum unless otherwise specified. The electrophoretic mobility of each set of lymphocytes was determined. Following this, equal numbers of donor and recipient lymphocytes were mixed together and incubated at room temperature or at 37°C for one-half hour. Measurements of the electrophoretic mobility of the incubated cells were then repeated, then placed in the electrophoresis apparatus for comparison with the individual electrophoretic mobilities of donor and recipient lymphocytes.

IV. In several experiments lymphocytes from both donor and recipient were each mixed with serum from the opposite to determine the significance of circulating antibodies, complement, and the effect of increasing temperature on each of these.

V. Lymphocytes were washed in some experiments to determine the effect of removal of surface water soluble antigens or antibodies from the lymphocytes. Washing was commonly done with Ringer's solution at room temperature or in some instances distilled water to make lymphocyte ghosts.

VI. Separation of peripheral lymphocytes from peripheral blood was accomplished by removing the supernatant from heparinized blood and treating the supernatant with equal amounts of Ficoll-hypaque solution.

Results

I. It was found many years ago that lymphocytes were electrophoretically mobile (26) (Fig. 6).

II. It has recently been shown that electrophoretic mobility of the lymphocyte is modified by systemic illness of many sorts (27).

III. In our experiment it was found that lymphocytes removed from lymph nodes in unrelated donors displayed significant differences in electrophoretic mobility initially and following mixing suggesting that unrelated donor incompatibility is reflected in the electrophoretic mobility of lymphocytes from the donor and recipient when mixed together and incubated for 30 min. Surprisingly, the changes most frequently observed are an increase rather than a decrease in electrophoretic mobility (Fig. 7).

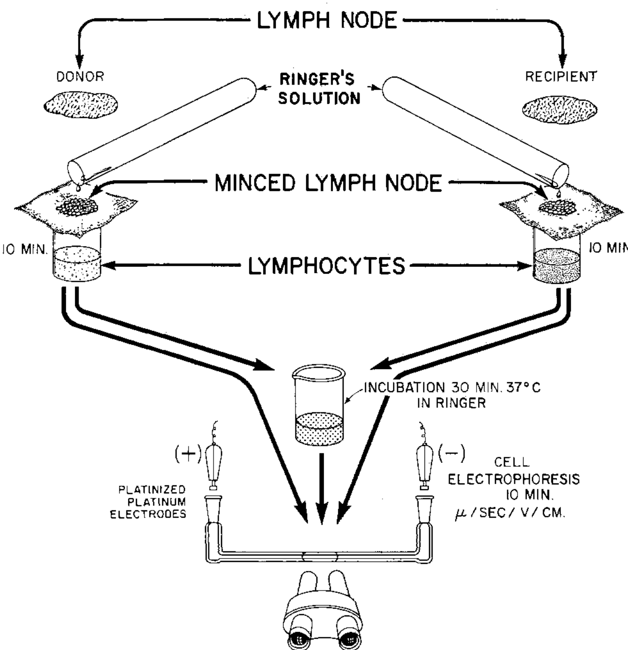

Fig. 5. Lymph nodes removed from both donor and recipient are minced, lymphocytes extracted and suspended in Ringer's solution. The lymphocytes at a concentration of 300,000/cm^3 are then put in a microelectrophoresis apparatus and electrophoresis determined for first donor and then recipient lymphocytes. Finally equal numbers of donor and recipient lymphocytes are mixed together, incubated at 37°C for 30 min and electrophoresis repeated. The results are compared.

The Cataphoresis of Platelets in Plasma.

The speed of polymorphonuclear leucocytes is given in the last column. Although red cells and small lymphocytes have different velocities, note that platelets and polymorphonuclear leucocytes have the same velocity (six horses).

Fig. 6. A table from Abramson's classical monograph indicating the electrophoretic mobility of polymorphonuclear leukocytes, platelets, and ultimately lymphocytes. His early classical work measured the standard electrophoretic mobility of a number of cells which displayed sufficient variability in each animal to suggest that the surface characteristics of the lymphocytes were not a fixed unvarying phenomenon. Note that the cells being negatively charged always moved toward the positive electrode in the electrophoresis apparatus.

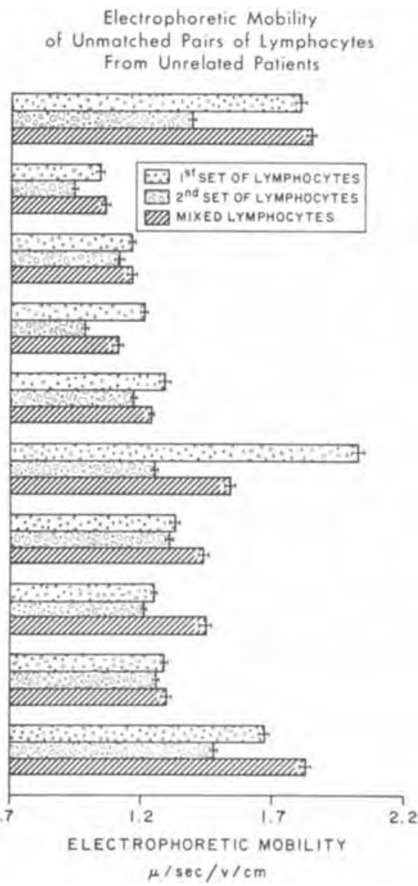

Fig. 7. This table is a determination of electrophoretic mobility of lymphocytes removed from lymph nodes of unmatched pairs of patients at surgery. The figure is extremely interesting in that it shows electrophoretic mobility of lymphocytes from different people is inherently different. The lymphocytic mobility does not follow a fixed pattern. Incubation of the donor-recipient lymphocytes at 37°C or 30 min in this group of patients produces very significant differences in the net electrophoretic pattern.

IV. In a second series of experiments, lymph nodes taken from related donor-recipient pairs provided information that electrophoretic mobility was both more closely matched initially and following incubation in related populations (Fig. 8).

V. Retrospective evaluation reveals that lymphocytes from lymph nodes removed from cadavers preparatory to transplantation when mixed with lymph node lymphocytes from the recipient suggests a very definite improvement in long term viability and function of the transplanted kidney when mixed lymphocyte electrophoresis did not change more than 20% following 30 min incubation at 37°C in Ringer's solution (Table I).

Table I. Electrophoretic mobility and long term survival of the transplanted kidney

Δ EM* (zeta-potential in mV)	No. of months of function before rejection	No. of months of good function	Rejection	Good function

Decrease 4-7	7d, 1½	9, 12	2	2
Decrease >7	2, 2	—	2	—

* $\Delta EM = EM_{Recipient} - EM_{mix}$.

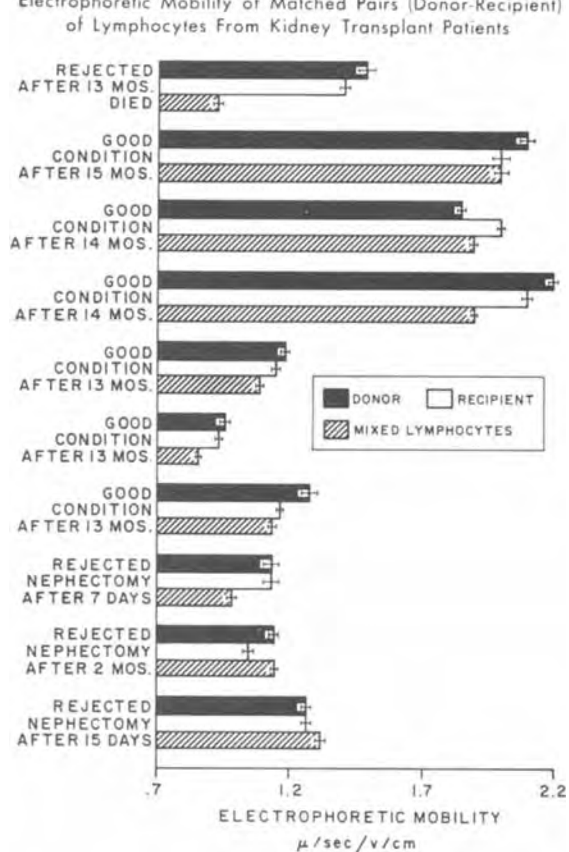

Fig. 8. Kidney transplantation in the large transplant service at the Downstate Medical Center provides an excellent opportunity for evaluation of transplant survival times in a large number of patients. Here we show the electrophoretic mobility of matched pairs of donor-recipient lymphocytes from transplanted kidney patients on the transplant service. Here even more strongly than in unrelated pairs, if gross differences in the electrophoretic mobility of the mixed lymphocytes were observed, rejection almost certainly occurred. In instances where electrophoretic mobility of the mixed lymphocytes was no more than 20% different than the electrophoretic mobility of either donor or recipient lymphocytes, chances of rejection were markedly reduced and chances of long term function were improved.

However, in most instances, recipient lymph nodes were taken from patients already subjected to immunosuppression at the time the lymph nodes were removed so that this factor enters into the problem. This problem illustrates the need to obtain lymphocytes prior to the application of immuno therapy.

Therefore, a prospective study is now going on comparing peripheral and lymph node lymphocytes prior to immunosuppression in contact with donor and recipient serum as well as with donor-recipient lymphocytes incubated for 30 min at 37°C (Fig. 9). This is being done in order to determine the predictive utility of this determination in organ transplantation.

Most important, the predictive results of the mixed donor-recipient lymphocytes in terms of indicating long term acceptability of the transplanted kidney has been compared with both HLA and MLC determinations of the identical donor-recipient pairs.

Discussion

I. It is now probable that electrophoretic techniques may be used to determine in at least a relative sense donor-recipient transplant organ compatibility.

II. The more closely related the donor-recipient pair the more nearly the lymphocyte electrophoretic mobilities are alike following mixing and incubation.

III. Though lymphocytes from related donors when mixed display similar electrophoretic mobilities, washing, grossly denaturing in distilled water, and heating

Electrophoretic Mobility of Lymphocytes From Kidney Transplant Patients (Matched Against Serum and Lymphocytes of Donors and Recipients)

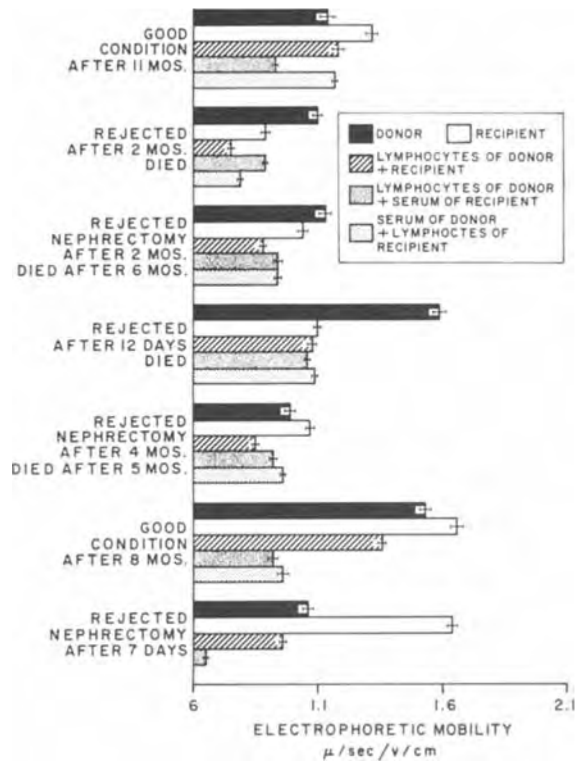

Fig. 9. The electrophoretic mobility of lymphocytes is determined individually and following incubation for 30 min at 37°C. In addition, the lymphocytes are mixed with serum of the opposite member of the transplant group so that donor-recipient comparisons can be made. Here again, significant differences in electrophoretic mobility of the mixed lymphocytes indicated a very short life span for the transplanted kidney. The absolute significance of the lymphocyte serum mixtures and how these relate to the electrophoresis of cell in man is not known. The electrophoretic mobility of donor-recipient pairs in a large human transplant population suggests that this technique might be quite useful as a model of immune rejection as well as a useful predictive test for the suitability of a projected donor-recipient transplant.

all tend to change the electrophoretic mobility of the lymphocytes. The response of the mixing and incubation of lymphocytes from donor-recipient serum and vice versa suggests that much of the immune response measured in the model exists in circulating antibodies. The return of electrophoretic mobility to control rates with heating indicates participation of some form of complement. The reaction, therefore, must be complex. One of the most significant aspects of the finding if not the most important has been the observation of increasing electrophoretic mobility with decreasing transplant tolerances. This indicates uncovering of underlying negative charged groups such as sialic acid, etc. when the antigen antibody reaction occurs on the surfaces of the lymphocytes.

IV. The technique of lymphocyte electrophoresis is rapid. It is easily susceptible to being mechanistically taught to large numbers of people and applied in the same way as the classical Landsteiner (30) techniques were easily applied to human blood cross-matching for transfusion. The finding that electrophoretic measurements possibly are informative in terms of kidney transplant survival and function should prove quite useful if confirmed.

V. The study which we have described can provide answers concerning donor-recipient compatibility within at most 1-2 hr following removal of the lymph nodes from donor and recipient. In addition, the studies give additional insight into the basic recognition and charge characteristics on the surfaces of donor and recipient lymphocytes which relate to rejection. With increasing information, more successful manipulation should be possible, ultimately with more effective utilization of the transplant compatibility determinations (10, 11, 23).

VI. Possibly a more important application of the technique is its use as a model of immunocompetence among various members of a species. The test is inexpensive, easy to use, and is with further definition easily susceptible to measurement and evaluation of the modification of the surface proteins deposited on the lymphocyte, etc. More subtle manipulations may provide very real information concerning specific special immunochemistry of donor-recipient lymphocyte recognition and possibly help in describing their stereo chemistry.

Thus, there is promise that the technique will provide dual utility in the immunologic field, one immediately practical and the other ultimately useful. The gross differences in lymphocyte electrophoretic mobilities have not been explained by the study. However, the studies of Mehrishi, Katz, and Zeiller, Seaman, Weiss and the clinical results of transplantation as shown by Kountz, Belzer, and associates and many other investigators give information which may be useful in explaining the observed variations, and give thought for the future.

Effect of Moisture on the Electrical Properties of Bone

G. B. Reinish[1] and A. S. Nowick*

School of Engineering and Applied Science, Columbia University, New York, New York 10027

ABSTRACT

Both a-c (1000 Hz) and d-c electrical conductivity of human cortical bone are studied after equilibration at various relative humidities. At the same time weight change measurements are carried out as a function of humidity, so as to determine the moisture content of the bone. Both the electrical properties and weight changes show striking hysteresis when plotted *vs.* relative humidity. However, when electrical properties are plotted as functions of moisture content the hysteresis is eliminated. The hysteresis effects are attributed to capillary condensation in pores. Measurements were made on samples soaked in Ringer's solution as well as samples washed in distilled water, and also with electric field both parallel and perpendicular to the bone axis. The results of these measurements strongly suggest that the large effect of moisture on conductivity is from ionic salt solutions located in pores and channels.

Since the discovery that dry bone and dry collagen were piezoelectric (1, 2), there has been much interest in the possibility that the mechanism controlling osteogenesis, that is, production of new bone cells, is electrical. Recent work on electrical stimulation of bone growth (3, 4) has emphasized the need to study both electrical and piezoelectric properties of bone under varying degrees of moisture content so as to bridge the gap between the well-characterized behavior of dry bone and the very elusive behavior of living bone.

This paper describes the hysteresis, or history dependence, of the moisture content of cortical bone as a function of relative humidity, and the effect of this behavior on electrical properties. Specifically, the conductivity at 1000 Hz and the d-c conductivity, are studied as functions of relative humidity and moisture content, as well as of the orientation of the electric field and the salt content of the bone.

Experimental Methods

Sample preparation.—Fresh cortical bone from the human femur was cut into 4 mm cube-shaped specimens with one pair of faces parallel to the periosteal and endosteal surfaces and another pair perpendicular to the bone axis. Some specimens were stored in Ringer's solution, hereafter referred to as "Ringer's specimens." Other specimens were washed for three weeks in distilled water, with the water changed daily for the first week, and every other day for the next two weeks. These will be referred to as "washed specimens."

Electrodes consisted of silver conductive epoxy cement which was fixed to room-dried specimens; platinum wires were fixed to these electrodes. Some specimens were prepared with electrodes attached to the endosteal and periosteal surfaces, so as to produce an electric field perpendicular to the bone axis. Others had electrodes attached to the surfaces perpendicular to the bone axis, so that the electric field would be parallel to the bone axis.

Apparatus.—A long, water-jacketed, glass cylinder (Fig. 1) was constructed and connected through a Teflon collar to a water-jacketed vessel in which salt solutions were used to maintain the desired relative humidities (5). The apparatus was designed to allow simultaneous measurement of moisture content (*i.e.*, of mass) and electrical properties on identical specimens. The Teflon collar permits equilibration of the air in the lower vessel with that in the long cylinder, but provides an air-tight seal to the outside, by means of rubber O-rings and a clamp. Water was pumped from a thermostatically controlled temperature bath, maintained at 30°C, through the water jackets. To prevent an appreciable temperature gradient in the unjacketed region of the Teflon collar, Tygon tubing with water at 30°C flowing through it was wrapped around this portion of the apparatus, and asbestos insulation was then wrapped around the tubing. In this way the temperature gradient was reduced to less than ±0.5°C.

A sensitive calibrated quartz spring was suspended in the long cylindrical chamber with a bone specimen hanging from its end. The position of a reference point on the quartz spring was measured by sighting through the glass column, using a micrometer-controlled cathetometer. The change in spring length could be read to 0.01 mm, corresponding to a mass change of 0.01 mg, or to 0.008% of the mass of the bone specimen.

Platinum wires were brought out, through the Teflon collar, from two bone specimens mounted within the chamber (see section A-A of Fig. 1). An impedance bridge was used with an external oscillator

and an external detector, so that conductance and capacitance of the bone specimens could be measured over a frequency range of 50-20,000 Hz. Low capacity cables were used, and correction was made for leakage conductance and capacitance by making measurements between leads going to adjacent specimens. An electrometer and d-c power supply were used to measure d-c conductance.

Procedure.—Eight different saturated salt solutions were used to provide controlled relative humidities covering the range between zero and 100%. It was found necessary to allow at least one week for equilibration at each humidity. Figure 2 illustrates the kinetics of equilibration, by showing the variation, with time, of moisture content and conductivity of two bone specimens, simultaneously measured in the same chamber, when the relative humidity was abruptly changed from 75 to 30%. A logarithmic scale was chosen for the abscissa in order to cover conveniently the full period of one week (10^4 min) required to attain equilibrium.

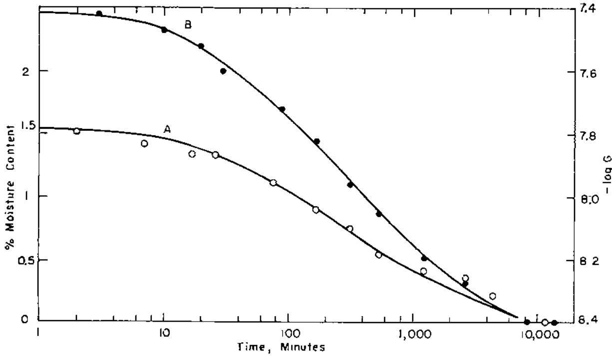

Fig. 2. Kinetic curves of moisture content (open circles, curve A) and conductance (solid circles, curve B) of Ringer's specimens following an abrupt change of humidity from 75 to 30%.

After equilibrium is reached at each humidity, the change in weight of the bone specimen on the spring was measured. The percent moisture content of the bone was then obtained by dividing the change in spring length by the spring calibration and the dry weight of the sample.

At each equilibrium condition, electrical measurements (both a-c and d-c) were made on the two bone specimens mounted on the Teflon collar. In this paper, for the a-c measurements we report primarily the conductance at 1000 Hz. The d-c conductivity, on the other hand, is obtained in two ways: first by a direct electrometer measurement, and second, by extrapolation of a-c data, based on a heterogeneous dielectric model of bone which will be described in a forthcoming paper (6). Measurements were made on Ringer's specimens with electric field perpendicular to the bone axis, and on washed specimens with field both perpendicular and parallel to the bone axis.

The results reported herein are typical of those obtained using ten different specimens in three chambers of the type described above.

Results

It was found that the moisture content of a sample of bone, as obtained from the weight measurements, is not a unique function of the relative humidity of the atmosphere with which the sample has equilibrated. Specifically, the moisture content is always higher during drying (desorption) than it is during wetting (adsorption). Such results are illustrated in Fig. 3 for both a Ringer's and a washed specimen. The striking aspects of the figure, aside from the existence of pronounced hysteresis, are that the washed and Ringer's samples both follow the same curves, and

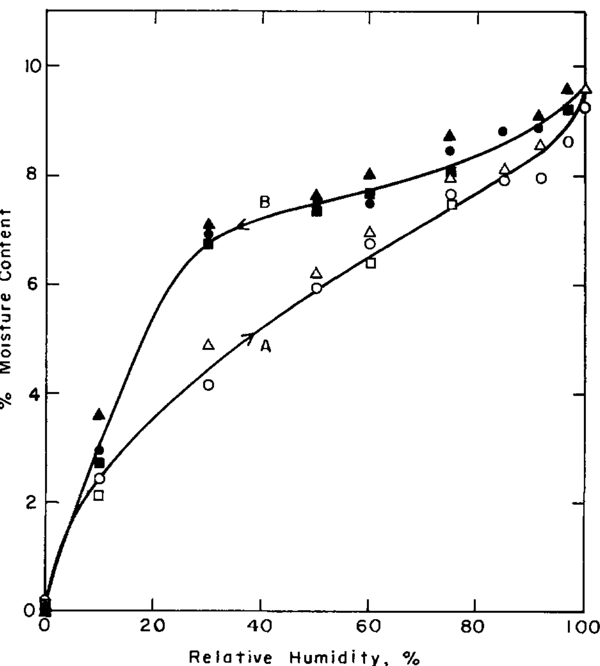

Fig. 3. Equilibrium moisture content of bone as a function of relative humidity: Ringer's specimen, first cycle: ○ absorption, ● desorption, second cycle: □ adsorption, ■ desorption; washed specimen: △ adsorption, ▲ desorption.

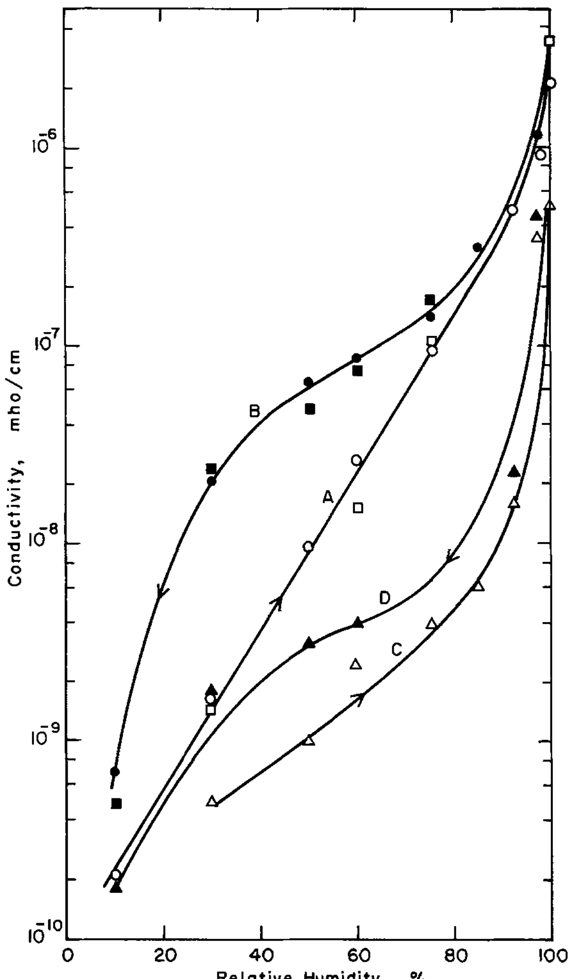

Fig. 4. Conductivity of bone samples at 1000 Hz, with electric field perpendicular to bone axis, as function of relative humidity. Symbols same as in Fig. 3.

also that the curves are very reproducible under repeated cycling.

In Fig. 4, a-c conductivity at 1000 Hz of a Ringer's specimen and a washed specimen are shown as functions of relative humidity under the same conditions of cycling used in the weight measurements. Hysteresis is present for both samples, though it is greater in the case of the Ringer's specimen. Again, the curves are reproducible upon successive cycling.

Because the weight changes were measured concurrently with the conductivity, it becomes possible, using the results of Fig. 3, to convert the data of Fig. 4 into plots of conductivity *vs.* moisture content. Such plots, given in Fig. 5, show clearly that the hysteresis is completely eliminated, meaning that the conductivity, σ, is a single valued function of moisture content. It follows that the hysteresis observed in plots of σ *vs.* humidity can be ascribed entirely to the hysteresis in moisture content as a function of humidity (Fig. 3).

Further examination of Fig. 5 brings out additional points of interest. First, dry bone is a very good insulator, with $\sigma \approx 10^{-11}$ mho/cm. Second, the introduction of moisture increases the conductivity of bone by as much as a factor of 10^6. In fact, an exponential dependence of σ on moisture content is obeyed up to about 8% moisture content. Such an exponential dependence has also been found for collagen (7). Third, the effect of washing salts out of the bone produces a reduction of σ by about one decade over most of the range studied, although the extrapolated value at zero moisture content appears to be the same as for the Ringer's sample. (The absence of data for σ

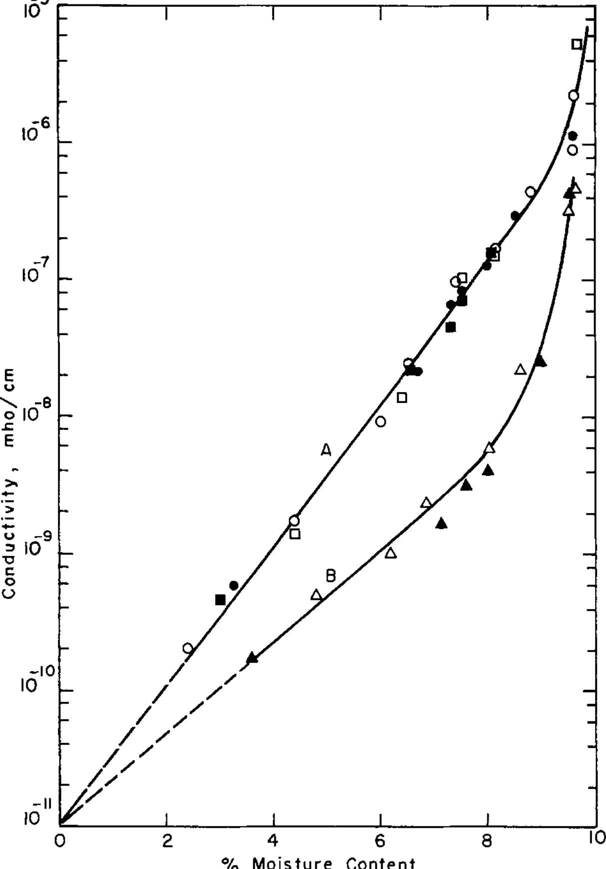

Fig. 5. Conductivity of bone samples at 1000 Hz, with electric field perpendicular to bone axis, as a function of moisture content. Curve A: Ringer's specimen; curve B: washed specimen. Symbols same as Fig. 3.

$< 10^{-10}$ $(\Omega\text{-cm})^{-1}$ is due to limitations imposed by the instruments and by leakage conductance.)

We have also observed hysteresis behavior analogous to that of Fig. 4 both for the real part of the dielectric constant (ϵ') and for the principal piezoelectric coefficient (d_{14}), when these properties are measured cyclically *vs.* relative humidity (6, 8). In both cases, the hysteresis was eliminated when the data were replotted *vs.* moisture content.

There is, however, one striking exception to the single valued electrical properties *vs.* moisture content, in the case of the d-c conductivity of a specimen having the electric field perpendicular to the bone axis. Figure 6 shows the d-c conductivity *vs.* humidity for such a washed specimen. (This figure includes points obtained both by direct d-c measurements and as calculated from extrapolation of a-c data, as mentioned in the Experimental Methods section. The "calculated" values are believed to be the more reliable because the direct measurements may be influenced by contributions from electrode impedance.) In any case, it is clear from Fig. 6 that there is very little, if any, hysteresis. Similar results are obtained for a Ringer's specimen with the same field orientation, except that the conductivity levels are somewhat higher than for the washed specimen.

A reasonable interpretation for the lack of hysteresis in this particular case is that the d-c conductivity of these samples is a measure of surface conductivity; the amount of moisture on the surface should be determined uniquely by the humidity of the ambient. By contrast to the above case in which the electric field is perpendicular to the bone axis, the d-c conductivity of similar specimens does show pronounced hysteresis *vs.* the humidity when the electric field is parallel to the bone axis. In this case we

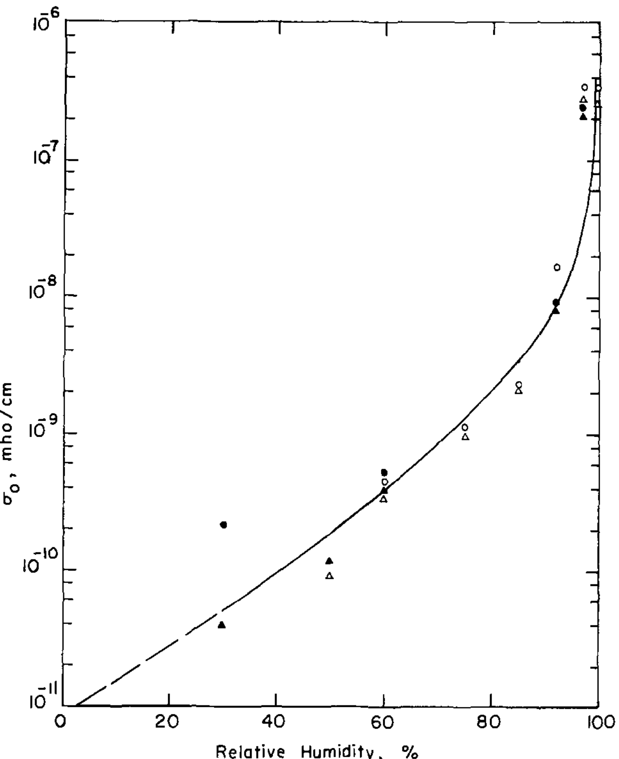

Fig. 6. D-C conductivity, σ_o, of a washed specimen (electric field perpendicular to bone axis) as a function of relative humidity. "Calculated" σ_o: ○ adsorption, ● desorption. Measured σ_o: △ adsorption, ▲ desorption.

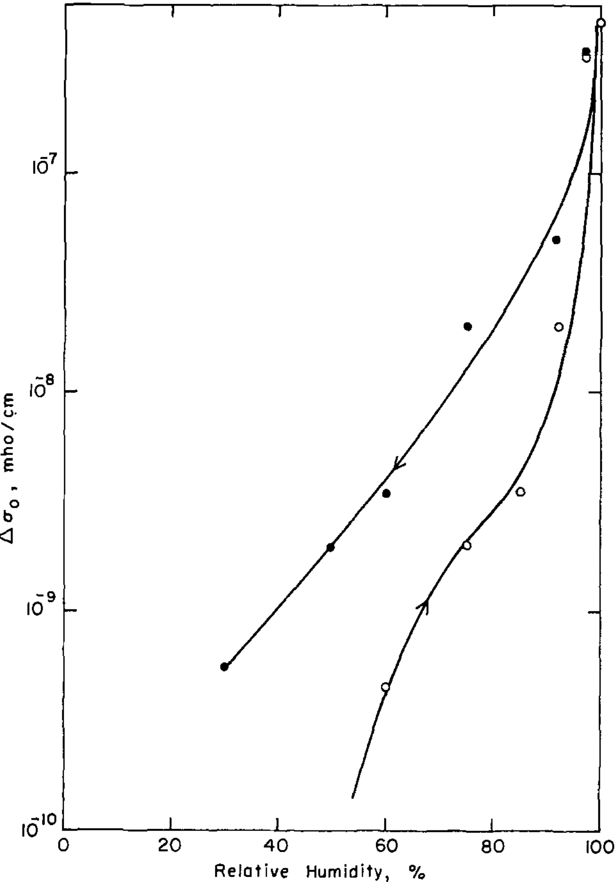

Fig. 7. Difference, $\Delta\sigma_o$, between σ_o with parallel field and perpendicular field as a function of relative humidity for washed specimens. ○ Adsorption, ● desorption.

must have contributions from the bulk as well as surface conductivity. Accordingly, it is anticipated that the bulk contribution alone can be obtained by subtracting the d-c conductivity of a perpendicular-field specimen from that of the corresponding parallel-field specimen. This difference is shown in Fig. 7 as a function of relative humidity for the case of two washed specimens, and again in Fig. 8 as a function of moisture content. The pronounced hysteresis shown in Fig. 7 is completely eliminated in the plot *vs.* moisture content of Fig. 8.

Discussion

This work has demonstrated striking hysteresis effects in various electrical properties of bone as functions of humidity when measurements are made over a complete adsorption-desorption cycle. This behavior has been related to the hysteresis in the moisture content as a function of humidity, which may be obtained reproducibly during repeated cycling, and which is the same for both Ringer's and washed samples (as seen from Fig. 3). Such hysteresis behavior has been observed before on a wide variety of porous materials (9, 10). It is attributed to the condensation of water in capillaries or pores, and to the fact that surface tension acts to prevent the removal of previously condensed moisture in the desorption part of the cycle. The presence of "ink bottle" shaped pores, which are wider in the interior than at the exit, accentuates the effect, since water is trapped in a relatively large cavity which cannot empty until the vapor pressure drops below that at the access channel.

The theory of Brunauer, Emmett, and Teller (11, 10) (widely known as the BET theory), which is based on the concept of multilayer physical adsorption of gas molecules, predicts a straight line relationship between $x/M\ (1 - x)$ and x, where M is the moisture content and x is the relative vapor pressure (here, the relative humidity). Such "BET plots" have been very successful in fitting empirical isotherms, although the theoretical basis has been severely questioned. A BET plot is shown in Fig. 9 both for the adsorption and desorption data of Fig. 3. Departure from linearity occurs at about 32% humidity for the adsorption and 25% humidity for the desorption curve. Such departures can be attributed to the presence of the pores, which not only limit the number of possible layers of adsorption, but introduce the complexity of capillary condensation which is not considered in the BET theory.

From the results of the present work, we may conclude that a major part of the effect of moisture on conductivity involves conduction through ionic salt solutions located in pores and channels. The main evidence for this conclusion is: (*a*) the existence of large hysteresis effects and the interpretation of such effects, (*b*) the decrease by one order of magnitude in the conductivity of moist bone which has been "washed" as against the Ringer's sample, and (*c*) the very high conductivity values attained by moist bone. With regard to the last item, it is interesting to compare the conductivity of wet bone (Fig. 4) with that of pure Ringer's solution (0.014 mho/cm) and that of pure collagen at 12% moisture content[2] ($\approx 10^{-11}$-10^{-12} mho/cm) (7). Such a comparison clearly indicates that wet collagen has a conductivity several orders of magnitude lower than wet bone, a difference which is most readily interpreted as a salt-solution effect in the bone. Finally, the fact that the d-c conductivity measured parallel to the bone axis showed a hysteretic component, while that measured perpendicular to the bone axis showed no such contribution, is also consistent with the above conclusion. Such a d-c contribution is interpreted as resulting from interconnected channels containing salt solutions. The re-

[2] This value is believed to be the moisture content of the collagen in bone at 100% humidity (8).

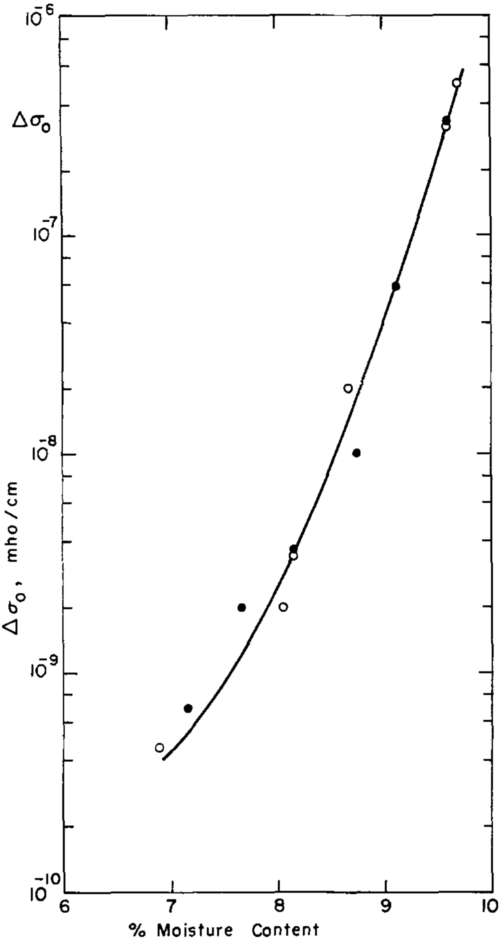

Fig. 8. Data for $\Delta\sigma_0$ of Fig. 7, replotted vs. moisture content

sults are then in accord with the fact that the open channels in bone run primarily parallel to the bone axis (12).

In contrast to the d-c values, the a-c conductivity also includes contributions from solutions in pores of various sizes which are not interconnected. The presence of such solution-filled pores means that bone is, in fact, a heterogeneous dielectric. In fact, data on the frequency dependence of both the real and imaginary parts of the dielectric constant are consistent with such a picture (6).

There has been much discussion of the concept of "free" water as against "bound" water in proteins and biological systems (13). From the above considerations, it seems clear that in the major range of moisture content covered by these experiments we are dealing primarily with free water. This conclusion is in striking contradiction to the viewpoints expressed by other authors (14). It is possible, however, that at the low humidity end, particularly below the point where the adsorption and desorption curves come together in Fig. 3 (*e.g.*, at ≤ 5% relative humidity), water that is chemically bound to either the collagen or the mineral constituent of bone may determine the electrical properties. For this reason, a further detailed study of the low humidity region would be of interest.

The Topography of Cell Surface Ionogenic Groups

J. R. Subjeck and L. Weiss

Department of Experimental Pathology, Roswell Park Memorial Institute, Buffalo, New York 14263

ABSTRACT

The interaction of cells with their environment appears to be partially regulated by the electrical properties of their surfaces. The adsorption of positively charged, electron dense, colloidal particles visible by electron microscopy, have been used to study the negative charges at the surfaces of normal, transformed, and revertant cell lines and various classes of lymphoid cells.

The surfaces of all mammalian cells so far examined carry a net negative charge (1). Among the surface anionic moieties of interest in this respect are sialic acids (2) and ribonuclease-susceptible groups (3). It seems likely that, in a complex manner, the densities and distributions of ionogenic sites at their peripheries partially regulate some cell interaction phenomena (4).

In this paper we review work which has utilized electron microscopy to map the binding of positively charged particles to negatively charged cell surface sites. Some of the cells were incubated with neuraminidase and/or ribonuclease prior to fixation with subsequent reaction with positively charged particles. The first section of this paper examines the topography of binding sites for the particles on Ehrlich ascites tumor (EAT) cells; the second section considers the use of this technique in examining other cell types.

The principal cationic stain utilized in our investigations is colloidal iron hydroxide (CIH) as developed by Hale (5) and Mowry (6), and later applied in electron microscopy by Gasic *et al.* (7). This colloidal reagent is prepared and used at a *p*H of 1.9. The CIH particles have been measured and found to have a mean diameter of 8-10 nm (8).

The application of such an acidic stain to the investigation of biological material requires prior fixation in glutaraldehyde. The aldehyde fixative would be expected to react and cross-link positively charged amino, imino, and guanidino surface groups (9). Such groups have been found to account for 5% of the ζ-potential of Ehrlich ascites tumor cells (10), which have been used in much of the work reported here. The effects of aldehyde fixation on the topographic arrangement and susceptibility to staining of the negatively charged groups discussed in this paper are uncertain, and this artifact must be constantly borne in mind.

Variations in Electrical Properties from One Region to Another of the Surface of the Same Cell

The description of the periphery of cells using electrophoresis, microelectrode, or chemical analysis yields an estimate of the spacial average of the measured property over the cell surface. With respect to contact and adsorption of charged drugs, antibodies, viruses, cellular probes (diameter ~ 100 nm), and other entities to cell surfaces, spacial heterogeneities in the distribution of peripheral cellular constituents would be expected to be of significance.

The data reported here are obtained from examination of Ehrlich ascites tumor (EAT) cells, which are maintained by us in single cell suspension culture. The CIH binding has been investigated on EAT cells which have been seeded onto substrates of embedding plastic or taken directly from suspension. For the adherent cells the topography of CIH binding was examined at cell surfaces that are far distant from other cells, or alternatively are apparently ready to contact or have contacted other cells.

Cells often appear to contact one another via low radius or curvature probes, for which the generic name microvilli is used here. Calculations of the energies of repulsion between two negatively charged surfaces (4) indicate that contact between the surfaces would be facilitated if one or both surfaces were capable of extending such low radius of curvature projections. The density of CIH particles on the cylindrical microvilli probes of EAT cells was determined and then compared with the density found on the regions of the cell surface intermediate between microvilli (the intermicrovillus or IMV surface). The results obtained were found to be independent of whether the cells were reacted with CIH immediately after removal from suspension culture or reacted after a period of 7 hr during which the cells were allowed to spread and adhere to the substrate. For the monolayer prepared material electron micrographs were taken from surfaces of cells which were not in the apparent vicinity of neighboring cells. The data for adherent, isolated cells are summarized in Table I. From this table it is seen that the density of particles adsorbed to the microvilli is approximately twice that found on the IMV surface (9). Prior incubation of cells with ribonuclease reduces the density of particles bound to both the IMV and microvilli surfaces but a twofold difference is maintained. However, prior incubation with neuraminidase shows that while the density of particles on both the microvilli and IMV surfaces is reduced to a very low value, the twofold difference between the surfaces is removed, indicating that the original higher density of particles bound to the microvilli was due to an increased density of sialic acid binding sites on these surfaces.

In this work the stability of the CIH colloid predetermined that cells be reacted at a *p*H value of 2 under nonphysiological conditions of ionic strength and composition. At this *p*H value surface groups of higher *p*K values would be partially or totally protonated,

	Particles/3000 nm^2 ± SE (No. observations) Treatment	
	Control	NANase
IMV spaces	3.85 ± 0.15 (23)	2.99 ± 0.15 (23)
Microvilli	6.41 ± 0.33 (24)	5.12 ± 0.22 (22)
Ratio	1.0:1.7	1.0:1.7

* After treatment indicated.

and therefore would be nonreactive with the CIH stain. To determine if the reported differences in the density of neuraminidase- and ribonuclease-susceptible sites extended to other anionic sites having higher *p*K values, we have used another stain under conditions of physiological *p*H and ionic strength. The reagent used was cationized ferritin, prepared according to the method of Dannon *et al.* (11) and reacted at *p*H 7.4 in physiologic phosphate buffered saline. The results of the use of this reagent following fixation, to the surfaces of EAT cells is presented in Table II (12). The microvilli are again found to exhibit a higher density of anionic binding sites. However in this case the increase over the microvilli is not removed by neuraminidase; suggesting the existence of additional anionic sites over the microvilli, which were not revealed at the low *p*H value.

The tonicity and *p*H of this stain make it suitable for application to living material. However we have found that due to the essentially dynamic nature of the cell periphery, the cationized ferritin particles become clustered at the cell surface and in some cases appear to be endocytosed (12). Therefore the interaction of this investigative probe with the cell periphery precludes its use in the study of living material.

Charge Topography and Contact

In our analysis of the surfaces of EAT cells adjacent to neighboring cells, we have attempted to locate sites of impending contact between cells by projecting the axes of microvilli of one cell onto the surface of an opposing cell (Fig. 1). When comparing the binding of CIH particles in the regions at which the microvilli appear to be "aimed," it was found that the mean density was less than half the density for nonaligned regions and that this difference was significant at the 0.1% level (13). The results of this analysis are presented in Table III where the zero point is defined

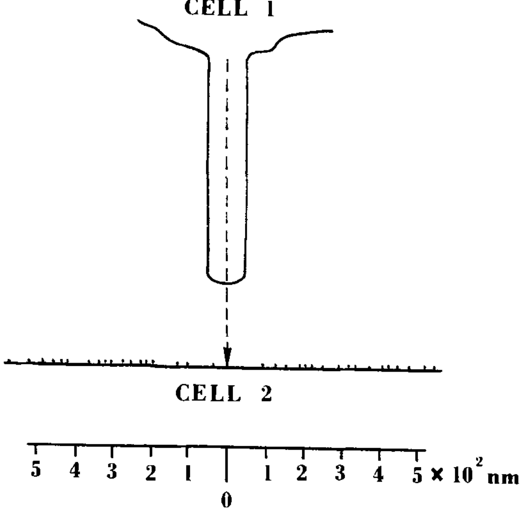

Fig. 1. Schematic drawing of an electron micrograph of the microvillus of one cell opposed to a low density region of colloidal iron hydroxide particles on the IMV surface of a second cell.

Table III.

Distance from center of projected microvillus contact area (nm)	Particle density per 100 nm of surface ± SE (No. observations)
0-100	1.72 ± 0.31 (57)
50-150	2.61 ± 0.52 (57)
150-250	3.91 ± 0.55 (57)
250-350	4.75 ± 0.58 (56)
350-450	3.84 ± 0.46 (50)
450-550	4.39 ± 0.63 (46)
550-650	4.13 ± 0.58 (38)

as the intersection of the projection of the axis of the microvillus with the opposing IMV surface.

Due to the essentially static nature of electron micrographs it may not be determined whether an individual microvillus which is aligned with a low density region of another cell would actually have made contact with it in the undisturbed situation. Therefore, it cannot be stated for an individual situation whether a microvillus was actually moving in the direction of the opposing surface rather than away from it.

Despite these difficulties the data show a noncoincidental alignment of a microvillus from one cell with a low density CIH region on a neighboring cell. This result insists on some kind of interaction occurring between the microvillus and opposing IMV surface. Whether this interaction occurs prior to or following contact, or in the absence of contact, cannot be unequivocally answered. Since alignment is observed to occur in 91% of the samples observed, it is highly possible that in many cases the alignment occurs prior to contact (or even in its absence). In this instance it is of interest to examine mechanisms via which alignment may take place. A mechanism to induce alignment will be dependent on the distance of separation between the microvillus tip and the adjacent IMV surface. As data are obtained from thin sections, it is therefore possible that an observed microvillus may leave the section and produce an apparent separation distance different from the true distance. For this reason the real distance of separation cannot be accurately determined; however, it appears possible that interactions occurred between opposed cell surfaces separated by distances as great as 200 nm, which was the greatest distance selected for these results. A detailed theoretical analysis of possible interaction mechanisms as a function of distances of this order is discussed elsewhere (14). One proposed mechanism for alignment is that net negatively charged macromolecules diffusing out of cells in the region of their microvilli, electrostatically repel CIH-binding anionic sites in the fluid periphery of the opposed cell, causing gaps in their distribution.

It must be emphasized that despite the fact that the true separation distance between the microvillus and opposing IMV surface is uncertain; contact out of the section as an explanation for the observed redistribution is excluded, because examination of particle densities of microvilli in contact with two cells (in the same section) indicates that corresponding low density regions bear no constant distribution relative to the contact point (13).

Variations in Electrical Properties Between Different Cell Types

3T3 cells.—Cultures of fibroblasts from normal tissue are found to contain few dividing cells after confluency of the culture is achieved. In contrast, fibroblasts that have been transformed by an oncogenic virus such as Simian virus 40 (SV40) lack this contact inhibition of growth. A cloned transformed cell line, however, has been found to be composed of a heterogeneous population of cells, a small number of which are contact-inhibited. By employing the differential agglutinability exhibited by plant lectins such as Concanavalin A toward normal and transformed cultures, it is possible

to select out and clone those contact inhibited variants of the transformed line. These new "revertant" cultures exhibit general morphology and growth densities characteristic of the normal state.

We have investigated normal and SV40 transformed Balb/3T3 (15) cultures together with two revertant lines. Inoculations of these various cell lines into susceptible mice show the normal and revertant cultures to be essentially nonmalignant, while the SV40 transformed Balb/3T3 cells form cancers.

The CIH stain has been applied to the 3T3 system with the results presented in Table IV. It is clear that the surfaces of both the normal and revertant 3T3 cells bind approximately the same density of CIH particles on their IMV surface and that the SV40 transformed line yields a CIH density which is significantly reduced. Therefore in this cellular system, there appears to be a correlation between the electrical properties of the cell surfaces measured with the CIH probe, and malignant transformation and reversion.

Lymphoid cells.—It is generally accepted that two distinct classes of lymphocytes are present in different mammalian species including man (16). These are B or bone-marrow derived and T or thymus-derived lymphocytes. Although generally similar in appearance, these two cell types are found to have widely differing functions. T lymphocytes may be cytotoxic to cells carrying foreign surface antigens. This class of lymphoid cells is also known to cooperate in an as yet undefined manner with B lymphocytes in initiating the proliferation of the B cells into specific antibody-producing clones. These two groups have distinguishable surface characteristics as has been revealed electrophoretically (17), serologically (18), and with respect to their differential sensitivity to lectins (19). In addition to these two classes, at least one serologically distinguishable subgroup of T lymphocytes is also recognized; the thymus-located lymphocytes, or thymocytes, which appear to represent differentiating precursor T lymphocytes (20).

The affinity of mouse-derived thymocytes, B and T lymphocytes for CIH is shown in Table V. These results indicate that thymocytes and T lymphocytes constitute a class distinguishable (at the 0.1% level) from the B lymphocyte group. The role of the cell periphery in the differential functions of these lymphocyte classes is as yet unknown. However it is apparent that the specific electrical property revealed by the binding of the CIH colloid is of value in distinguishing the B from the T or thymus cell classes.

Table IV. Densities of CIH particles on the IMV surface of normal, SV40 transformed, and two revertant (Rev 3 and Rev 5) BALB/3T3 cell lines

Particles/4000 nm² ± SE (No. observations)			
Normal	SV40	Rev 3	Rev 5
4.21 ± 0.27 (22)	2.17 ± 0.12 (27)	3.96 ± 0.19 (18)	4.05 ± 0.20 (24)

Table V. Densities of CIH particles on different lymphoid cell classes

Particles/4000 nm² ± SE (No. observations)		
B	T	Thymocytes
3.88 ± 0.13 (83)	2.35 ± 0.11 (71)	2.29 ± 0.11 (88)

Conclusions

Heterogeneities between different regions of the surface of the same cell may be of influence in some interaction phenomena occurring between cells. The average electrical property studied here is significantly different in at least some cells with differential function.

Periodic Variations of Overvoltages for Water Electrolysis in Acid Solutions from Cyclic Voltammetric Studies

M. H. Miles* and M. A. Thomason

Department of Chemistry and Physics, Middle Tennessee State University, Murfreesboro, Tennessee 37132

ABSTRACT

Cyclic voltammetry was used to determine the electrocatalytic activities of 31 metals for the hydrogen and oxygen evolution reaction in 0.1M H_2SO_4 at 80°C. For the hydrogen evolution reaction, properties of the metals such as electronic structures, work functions, and metal-hydrogen bond strengths tend to correlate with the observed electrocatalytic activities. The best electrocatalysts for the hydrogen evolution reaction in the order of decreasing catalytic activity are Pd > Pt ≈ Rh > Ir > Re > Os ≈ Ru > Ni. For the oxygen evolution reaction, the order of catalytic activity is Ir ≈ Ru > Pd > Rh > Pt > Au > Nb. Most other metals undergo anodic corrosion and cannot be used for the evolution of oxygen in acid solutions. The potentials at which corrosion is observed are presented for these metals.

Most commercial water electrolyzers operate at 70°-90°C in 25-35 weight percent (w/o) potassium hydroxide solutions using nickel anodes (1, 2). A possible improvement in water electrolysis as a route for hydrogen production is the use of solid polymer electrolytes such as General Electric's perfluorinated sulfonic acid polymer. During electrolysis, the hydrogen ions produced by the oxidation of water move across the solid polymer electrolyte and are reduced to form hydrogen at the cathode. One disadvantage of such a system is the acid environment which develops at the anode causing corrosion of metals such as nickel. In this study, various metals are investigated for possible use as electrocatalysts for water electrolysis in an acid medium at 80°C. A previous study in alkaline solutions has shown that cyclic voltammetry is a convenient method for evaluating electrocatalysts for water electrolysis (3).

Experimental

The cyclic voltammetric measurements were made with a PAR Model 170 instrument using a potential sweep rate of 50 mV/sec. Most electrodes consisted of high purity wires which were spot-welded to nickel or copper leads and sealed into glass tubing with clear epoxy. These electrodes were mechanically polished with emery paper prior to use. The ruthenium and osmium electrodes were formed by electroplating the metal onto a platinum wire electrode. A ruthenium oxide electrode formed on titanium (RuO_2/TiO_2) similar to those used in the chlor-alkali industry (4) was also tested. The hydrogen evolution reaction was investigated first in order to minimize surface changes due to electrode oxidation or oxide film formations.

Reagent sulfuric acid (Baker) and distilled water were used to prepare the 0.1M H_2SO_4 solution. Measurements were made in a beaker-type glass cell equipped with a cap, a cylindrical platinum screen counterelectrode, a saturated calomel reference electrode (SCE) with a ceramic junction which gives a negligible leak rate, and the test electrode. The temperature was controlled at 80° ± 2°C in all experiments.

Results

The cyclic voltammetric traces for the iridium electrode in 0.1H H_2SO_4 at 80°C are shown in Fig. 1. The short potential cycles at each end show the results for studies of the hydrogen and oxygen evolution reactions, while the dashed lines show the behavior for the full potential sweep. The horizontal line segments show where the current attains a value of 2 mA/cm² based on the geometrical area of the electrode. At this current density, gas evolution is clearly visible and the current changes rapidly with small changes in potential. Therefore, experimental overvoltages for water electrolysis obtained by this method are rather insensitive to differences in surface roughness factors. From the Tafel equation

$$\eta = a + b \log i \qquad [1]$$

the experimental overvoltages for hydrogen or oxygen evolution at 2 mA/cm² for the various metals should reflect changes in the Tafel parameter, a, and hence changes in the exchange current density, $i_o = 10^{-a/b}$, as long as the Tafel slope, b, remains constant for a given reaction on various metals.

Figure 2 presents the summary of all cyclic voltammetric results on various metals in 0.1M H_2SO_4 at 80°C. The potentials where the current density attains 2 mA/cm² using a potential sweep rate of 50 mV/sec are shown as a function of the atomic numbers of the elements. The horizontal dashed lines represent the estimated reversible potentials for the hydrogen and oxygen electrode reactions at the experimental conditions used. The solid circles at the negative potentials locate hydrogen evolution at 2 mA/cm²; the solid circles at the positive potentials locate oxygen evolution at this current density. The open circles show the potentials at which the current density exceeds 2 mA/cm² due to some other anodic proc-

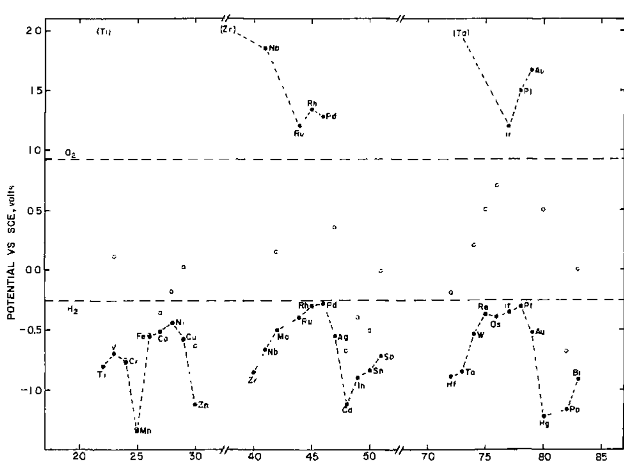

Fig. 2. Summary of cyclic voltammetric results for various metallic elements in 0.1M H_2SO_4 at 80°C. The potential vs. SCE is shown where the current density attains 2 mA/cm^2 using a potential sweep rate of 50 mV/sec.

ess such as corrosion of the metal. For Cr, Mn, and Fe, hydrogen evolution and anodic oxidation are observed at about the same potential, hence their location could be influenced by a mixed potential (5). The potentials at 2 mA/cm^2 for Ti, Zr, Hf, Ta, and Pd were not as reproducible as those for other metals. This is likely due to hydride formation which changes the surface properties. The electrochemical formation of palladium hydride can even be observed at potentials somewhat positive to the reversible hydrogen potential (6). During hydrogen ion reduction, the experimental potential at 2 mA/cm^2 at palladium changed from about $-0.1V$ to about $-0.3V$ *vs.* SCE. For hafnium, the anodic limit observed at about $-0.2V$ probably results from oxidation of the metallic hydride. No reproducible anodic limits were observed for Ti, Zr, and Ta. Although oxygen evolution was initially observed on these metals, their surfaces soon passivate due to formation of insulating oxide films. The resistance of these metals to corrosion would make them useful as structural metals in water electrolysis cells operating in acid environments at high temperatures.

Discussion

Periodic variations of hydrogen overvoltages with atomic numbers of the electrode metals are evident from Fig. 2. The overvoltages show minima for Ni, Pd, and Pt which have d^8s^2, $d^{10}s^0$, and d^9s^1 electronic configurations, respectively. Large hydrogen overvoltages are observed for Zn, Cd, and Hg which are all of the $d^{10}s^2$ electronic configurations. As observed for a similar study in alkaline solutions (3), Cr and Mn show a decrease in catalytic activity with increasing atomic number. It is possible that mixed potentials established at these metals in acid solutions could contribute to the larger experimental overvoltages, nevertheless i_o values in acid solutions show a similar decrease with an unusually low i_o value for Mn (7, 8). Other studies of the hydrogen evolution reaction have also established general periodic trends for exchange current densities (9) and for overvoltages (10, 11), however, these studies often use data gathered from differing sources, thus the data are not necessarily homogeneous. The differing i_o values selected contribute to the conflicting conclusions regarding correlations with other properties (8, 12). Furthermore, electrochemical studies at temperatures and conditions used in water electrolysis are sparse.

The periodic trends observed for hydrogen overvoltages show a high correlation with the work functions of the transition metals. Using the same work function values adopted by Trasatti (8), the location of the experimental potential, E *vs.* SCE, at 2 mA/cm^2 for the transition metals is given by

$$E = 0.64\phi - 3.5 \quad [2]$$

where ϕ is work function in electron volts. Figure 3 shows the E *vs.* ϕ plots for both transition metals and sp metals. The correlation coefficient for the least squares fit for the transition metals is 0.88 suggesting a high correlation between the observed hydrogen overvoltage and the work function. For the nontransition metals tested, the correlation between the observed hydrogen overvoltage and the work function is much less precise and the calculated correlation coefficient is only 0.29. The overvoltages on Zn, Cd, Hg, and Pb actually seem to be nearly independent of the work function.

The heat of adsorption of hydrogen on metals is theoretically related to the rate of electrolytic hydrogen evolution (13-15) and experimental correlations have been observed (8, 12). Figure 4 shows the least squares plot of the potential observed at 2 mA/cm^2 against the M-H bond strength of the metal as derived by Krishtalik (15) from experimental data for hydrogen evolution. The predicted volcano-shaped curve is obtained and looks similar to results based on i_o values (8). Assuming that differences in experimental overvoltages and exchange current densities on various metals reflect mainly changes in the Tafel parameter, a, then the slopes of such plots should be related by

$$\text{slope} = \frac{\Delta\eta}{\Delta\text{M-H}} = \frac{b\Delta\log i_o}{\Delta\text{M-H}} \quad [3]$$

Using $b = 0.14V$ in Eq. [3], the slopes of the curves in Fig. 3 are similar to the slopes reported by Trasatti (8) using i_o values obtained at room temperature. Figure 3 suggests the presence of a horizontal region where the overvoltage remains small for M-H bond strengths between 52-60 kcal/mole. Such horizontal regions are predicted when the adsorption equilibrium follows a Temkin isotherm (13).

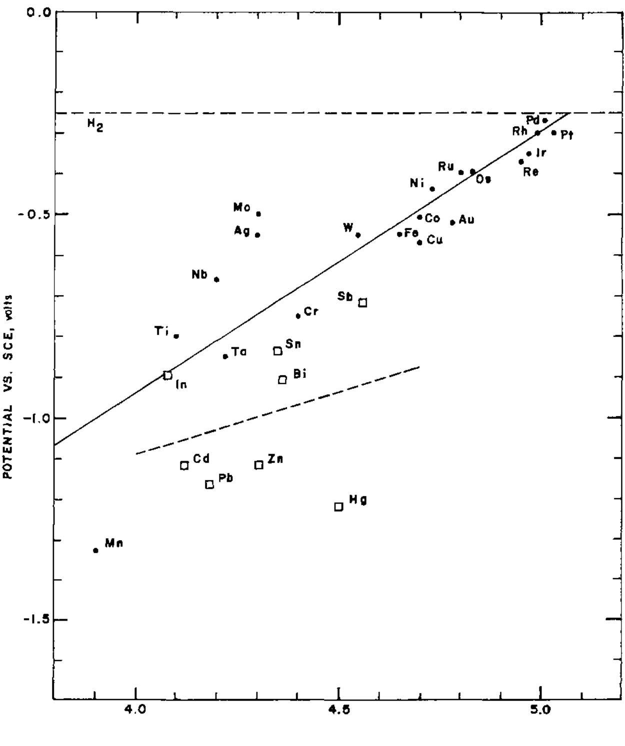

Fig. 3. The potential vs. SCE at 2 mA/cm^2 vs. the values of the work function of the metal given by Trasatti (8). Symbols used are: ● transition metals; □ sp metals.

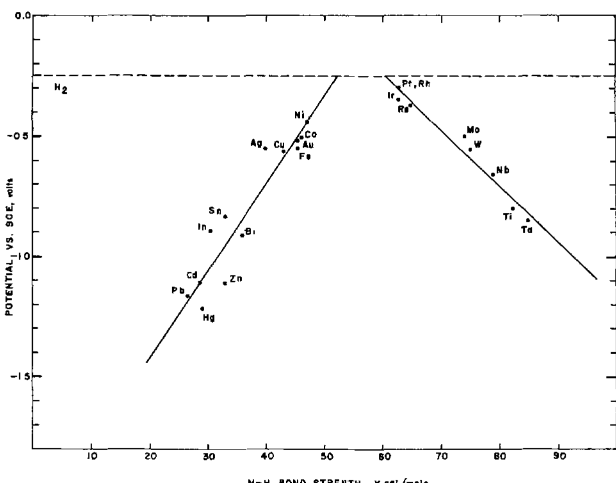

Fig. 4. The potential vs. SCE at 2 mA/cm^2 vs. the M-H bond strength as derived by Krishtalik (15).

The best electrocatalysts for the hydrogen evolution reaction in 0.1M H_2SO_4 at 80°C in order of decreasing catalytic activity are Pd > Pt ≈ Rh > Ir > Re > Os ≈ Ru > Ni. For the electroplated ruthenium and osmium electrodes, a roughness factor of about 20 relative to the other metals was assumed. Judging from Fig. 2-4, an ideal electrocatalyst lacks two electrons in filling its outermost d and s sublevels, has a work function of about 5 eV, and forms M-H bonds with energies of about 50-60 kcal/mole.

For the oxygen evolution reaction, the catalytic activity in acid solution is found to be in the order Ir ≈ Ru > Pd > Rh > Pt > Au > Nb. Nearly all other metals either undergo anodic corrosion or form passivating oxide films in 0.1M H_2SO_4 at 80°C. Based on these cyclic voltammetric results, iridium and ruthenium appear to be considerably better than platinum as electrocatalysts for oxygen evolution in acid solutions. The high electronic conductivities of IrO_2 and RuO_2 (16-18) apparently promote the slow electron transfer through the oxide layer (19). Results for ruthenium plated onto platinum and for the RuO_2/TiO_2 electrode were similar, except that the ruthenium-plated electrode gradually disintegrated during oxygen evolution. Potentiostatic steady-state measurements in acid solutions at 80°C also indicate that Ir is considerably better than Pt as an electrocatalyst for the oxygen evolution reaction. In fact the separation of the Tafel lines (300 mV) at various current densities is practically identical to the observed difference in cyclic voltammetric measurements presented in Fig. 2.

Conclusions

1. Properties of metals which influence their electrocatalytic activities when used as cathodes for water electrolysis under acid conditions include electronic structures, work functions, and M-H bond strengths.

2. For metals used as anodes in water electrolysis under acid conditions, the properties of the metal oxide seem to be the dominant factor in affecting electrocatalytic activities.

3. The cyclic voltammetric method used in this study provides a rapid method for comparing properties of electrocatalysts. The observed trends are in good agreement with results based on the more tedious determinations of exchange current densities.

Acknowledgments

The authors wish to thank Dr. S. Srinivasan, Mr. F. J. Salzano, and Dr. R. H. Wiswall for helpful discussions and encouragement regarding this work. A summer appointment as a visiting scientist for M. H. Miles in 1975 by Brookhaven National Laboratory is gratefully acknowledged. ABSTRACT

A mathematical model has been developed which describes the operation of a lithium-water, electrochemical power cell. The current density, current efficiency, powder density, and specific energy are calculated as functions of cell potential, lithium hydroxide concentration, temperature, electrolytic solution flow velocity, position along the flow channel, spacing between electrodes, and flow channel width. Anode to cathode contact pressure is not included in this initial model. A large dependence of power density on LiOH concentration is predicted. For example, at an LiOH concentration of $2M$, a power maximum of 394 mW/cm^2 is calculated, and in $5M$ LiOH the power maximum is calculated to be 25 mW/cm^2. Temperature and flow velocity show similar but smaller effects.

Design and performance characteristics of lithium-water electrochemical power cells have been described in the literature (1-4). The object of this paper is to present a general, theoretical description of the operation of such a system which illustrates and describes some principal, controlling processes and design variables. An idealized design is used to achieve this purpose. The effects of pressing the cathode grid against the anode surface, insulated by the LiOH film, are not included in this model. Recent results have shown that the effect of this cathode to anode pressure is a dominant variable allowing greatly improved performance and cell control.

The anode, in the simple geometry used here, is a plane sheet of lithium covered with a film of hydrated lithium oxide. The cathode is a plane sheet of nickel or other inert metal. Spacers provide flow channels between the anode and cathode through which a lithium hydroxide-water solution is circulated. Hydrogen is evolved from both the anode and cathode during cell operation. Hydrogen evolved at the cathode is part of the energy producing cell reaction. Hydrogen evolved at the anode is simply a corrosion reaction which represents a loss in current efficiency.

The object of this study has been to describe the local current density, current efficiency, power density, and specific energy as quantitative functions of the cell potential, lithium hydroxide concentration, temperature, electrolytic solution flow velocity, position along the flow channel, spacing between electrodes, and flow channel width. The last two independent variables are listed as separate entries since in more advanced designs the electric current path in the electrolytic solution is not the same as the flow channel width. The physical and chemical processes believed to control the system are described by mathematical equations. The equations have been solved numerically using high speed digital computing machinery.

Theoretical

Physical processes.—The basic geometry of the model is shown in Fig. 1. A film of hydrated lithium oxide is assumed to form on the surface of the lithium. The rate of parasitic hydrogen evolution on the surface of the lithium is limited by the rate of transport of water through the hydrated lithium oxide film. The water transport may be by diffusion through the solid film, liquid phase convection and diffusion through micropores in the film, or a combination of both. This elementary model does not distinguish the mode of transport, and the diffusion parameter defined later is an effective or over-all parameter characteristic of the over-all, steady-state water transport rate across the film. The solution surface of the film is in equilibrium with a saturated solution of lithium hydroxide in water. The lithium oxide film is continually dissolving in an operating power cell. The lithium hydroxide diffuses through a hydrodynamic diffusion boundary layer into the bulk solution where it is circulated out of the cell. The thickness of the hydrodynamic diffusion boundary layer, δ_o, is governed by the forced convection flow of electrolytic solution and the stirring action of the parasitic hydrogen evolution reaction.

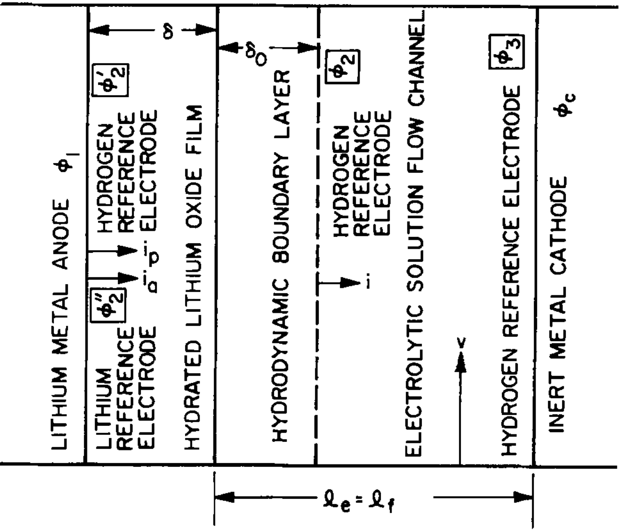

Fig. 1. Lithium water primary power cell. Idealized, geometric representation of the theoretical model.

* Electrochemical Society Active Member.

Key words: lithium hydroxide, battery, mechanically rechargeable fuel cell, corrosion.

The hydrated lithium oxide film is assumed to be in a dynamic steady state. Lithium ions are continually being formed at the interface between the metallic lithium and the lithium oxide film and then transported to the film-electrolytic solution interface. Water is continually being transferred through the film in the opposite direction from the film-electrolytic solution interface to the surface of the metallic lithium. A steady-state film thickness is established when the rate of production of lithium ions at the lithium metal surface equals the rate of dissolution of lithium hydroxide at the film-solution interface.

The total cell current, i, is equal to minus the hydrogen evolution reaction rate at the cathode, i_c. The total cell current, i, is also equal to the sum of the rate of lithium oxidation, i_a, and the parasitic hydrogen evolution rate i_p, occurring at the anode

$$i = -i_c = i_a + i_p$$

All cathodic current densities are negative numbers. Thus, i_p will be a negative number, and i will be less than i_a.

Each of the electrode reactions, represented by i_a, i_p, and i_c, can be described as functions of a local surface overpotential using well-known oxidation-reduction, exponential kinetic rate expressions. The exchange current density for the parasitic hydrogen evolution reaction, i_p, is assumed to be proportional to the 0.5 power of the water activity in the lithium oxide film at the surface of the lithium metal. This is equivalent to assuming α is 0.5. The basis for developing the rate expression has been given by Delahay (5). Surface overpotentials which drive the electrode reactions at the metallic surfaces are defined as the electrical potential of the metallic electrode minus the potential of a reference electrode placed just outside the double layer at the surface of the working electrode, see Fig. 1. The potential of the lithium metal, ϕ_1, is assumed to be zero; all other potentials are referred to this potential. A hypothetically reversible lithium reference electrode of potential ϕ_2'' is imagined to be imbedded in the lithium oxide film next to the metallic lithium electrode. A hypothetically reversible hydrogen reference electrode of potential ϕ_2' is similarly imagined to be imbedded in the lithium oxide film next to the metallic lithium electrode. For simplicity in writing rate expressions, hydrogen gas is assumed to be dissolved in all phases and at unit activity throughout the cell. A hypothetically reversible hydrogen reference electrode of potential ϕ_2 is also imagined to be placed in the bulk electrolytic solution just outside the hydrodynamic diffusion boundary layer at the surface of the lithium oxide film. A third hydrogen reference electrode of potential ϕ_3 is imagined in the bulk electrolytic solution adjacent to the cathode. The potential of the working, inert cathode, ϕ_c, is also the cell potential since the potential of the anode, ϕ_1, is taken as the zero of potential.

The hydrated lithium oxide film is to be described by three averaged parameters: the effective film thickness δ, the effective ionic electrical conductivity of the film κ_f, and the effective diffusivity of water in the film D^*. The transport of lithium ions across the film is not considered explicitly other than in the contribution of lithium ion movement to κ_f. The use of only three parameters to describe the rather complex transport processes occurring in the hydrated lithium oxide film does represent a considerable simplification of the actual processes that are occurring. The treatment could be improved by a more complete description of the film transport mechanisms. However, the three-parameter approach does appear to incorporate the most important rate processes at a reasonable computational cost. It appears obvious that the hydrated lithium oxide film is not homogeneous. Water content varies. The film may or may not contain pores or fissures through which hydrogen escapes, and water is transported toward the lithium metal. The three parameters δ, κ_f, and D^* are to be viewed as effective or averaged values describing the film as a whole. A more complete model would allow for property and transport process changes with position in the film.

Mathematical equations.—It proves convenient mathematically and for notation purposes to choose all electrode kinetic transfer coefficients, α, to equal 0.5. In reviewing experimental results for the lithium and hydrogen electrochemical reactions, this assumption appears reasonable. It is also convenient to let the group $RT/\alpha\mathbf{F}$ equal ψ. Symbols are all defined at the end of the paper or in Eq. [13]-[23.]

Recalling the definitions of ϕ_1, ϕ_2'', ϕ_2', ϕ_3, and ϕ_c from the previous section and assuming that the exchange current density for the hydrogen evolution reaction depends on the 0.5 power of water activity, we write the following equations relating surface reaction rates to electrical potentials

$$i_a = i_{o,a}^o [\exp(-\phi_2''/\psi) - \exp(\phi_2''/\psi)] \quad [1]$$

$$i_p = i_{o,p}^o a_{o,s}^{0.5} [\exp(-\phi_2'/\psi) - \exp(\phi_2'/\psi)] \quad [2]$$

$$i_c = -i = -i_a - i_p = i_{o,c}^o [\exp((\phi_c - \phi_3)/\psi) - \exp((\phi_3 - \phi_c)/\psi)] \quad [3]$$

The surface reaction rates for the lithium oxidation, i_a, parasitic hydrogen evolution, i_p, and hydrogen evolution at the cathode, i_c, are all expressed as equivalent current densities and have been discussed in the previous section.

The electrical potential variation in the electrolytic solution is assumed to follow Ohm's law

$$\phi_2 - \phi_3 = (i_a + i_p)\, l_e/\kappa \quad [4]$$

The rate of parasitic hydrogen evolution is assumed proportional to the rate of water transport through the lithium oxide film to the metallic lithium surface

$$i_p = -(D^*/\delta)\mathbf{F}\, c_o^{sat}\, (a_o^{sat} - a_{o,s}) \quad [5]$$

The water activity, a_o, is defined as a dimensionless quantity referred to the activity of pure water as one. It is related to the molality of the LiOH through an empirical fit to experimental data (6).

The potential difference between the lithium and hydrogen reference electrodes in the lithium oxide film adjacent to the metallic lithium is the sum of two standard electrode potentials, U, plus a term for the activity of water at the film-metal interface. The correction terms for deviations of LiOH and H_2 from their standard states are assumed to be negligible for these calculations and are not shown in Eq. [6]

$$\phi_2' - \phi_2'' = U + (RT/\mathbf{F}) \ln a_{o,s} \quad [6]$$

The electrical potential drop across the hydrated lithium oxide film is assumed to be an Ohm's law term plus terms for changes in lithium ion activity and water activity. Activity corrections across the liquid phase diffusion boundary layer are included in Eq. [7] rather than in Eq. [4]. This choice is arbitrary. To help avoid further complexity, the activity of lithium ions at the surface of the metallic lithium are assumed equal to the activity of lithium hydroxide in a saturated aqueous solution, a_e^{sat}. The loss in descriptive accuracy by using this assumption seems negligible compared to other assumptions, and it obviates the need to write another equation for the transport of lithium ions across the hydrated lithium oxide film. A result is that the second term on the right-hand side

of Eq. [7] is effectively a constant which depends weakly on temperature

$$\phi_2' - \phi_2 = (i_a + i_p)\,\delta/\kappa_f + (2RT/\mathbf{F})t_+^{o}\ln(a_e^b/a_e^{sat}) + (RT/\mathbf{F})\ln(a_{o,s}/a_{o,b}) \quad [7]$$

The lithium hydroxide activity coefficients are reasonably constant in the concentration range of interest here. For the bulk solution, the activity coefficient was assumed constant at 0.5. For the saturated solution, the activity coefficient was assumed constant at 0.45. The activities are dimensionless, referred to a hypothetically ideal solution of unit molality.

Equation [8] equates the lithium oxidation rate, i_a, to the dissolution rate of the lithium hydroxide at the liquid interface of the solid film. The assumptions involved in this equation imply a steady-state film transport condition and a film thickness δ which is independent of time

$$i_a = \mathbf{F}\,k_m(c_e^{sat} - c_e^b) \quad [8]$$

The mass transfer coefficient, k_m, is assumed to be the sum of a convective mass transfer coefficient, k_c, and a mass transfer coefficient, k_b, associated with the formation and breaking away of hydrogen bubbles. This interpretation of k_m roughly parallels Rohsenow's development of nucleate boiling heat transfer coefficients with forced convection as discussed by Kreith [7]

$$k_m = k_c + k_b \quad [9]$$

The forced convection Reynold's number for the flow channel being considered is typically below 1000, thus the following expression for entrance region flow is selected (8)

$$k_c = (D/2l_f)\,a_c\,(\mathrm{Re}\,\mathrm{Sc}\,2l_f/x)^{\gamma} \quad [10]$$

Here a_c equals 1.2325 for x, the distance along the flow channel. For average values where x equals total channel length, a_c is 1.8488. A value of 1/3 for γ is recommended for laminar flow in an entrance region and is also taken as 1/3 in Eq. [11].

The bubble mass transfer coefficient is correlated as follows

$$k_b = (D/l_b)\,a_b\mathrm{Re}_n^{\beta}\mathrm{Sc}^{\gamma} \quad [11]$$

The bubble Reynolds number Re_b is calculated as a function of the parasitic hydrogen evolution rate, i_p, as follows

$$\mathrm{Re}_b = l_b v_b/\nu = -\,l_b i_p RT/(\nu \mathbf{F} P(0.20265)) \quad [12]$$

The numerical constant converts P from atmospheres to joules per cubic centimeter and includes a 2 since two equivalents are needed to produce a mole of hydrogen. The velocity of bubble growth into the solution, v_b, is assumed equal to the hydrogen evolution rate at the anode.

The parameters a_b, β, D^*, and $i_{o,c}$ were adjusted within physically meaningful limits to fit experimental data. Since β was used as a fitting parameter, the bubble diameter l_b is arbitrary, and a value of 0.02 cm was selected.

Temperature dependence is included by inserting the expected temperature dependence of the physical parameters

$$\rho = \rho_o + A\rho(T - T_o) \quad [13]$$

$$\rho_o = 0.997 + 29.96\,c_e^b - 0.003003\,(c_e^b \cdot 1000)^{1.5} \quad [13a]$$

$$\mu = \mu_o(T_o/T)\exp[-E^{\dagger}_{\mu}(T - T_o)/RTT_o] \quad [14]$$

$$\mu_o = 0.008937\,[1 + 0.04\,(c_e^b \cdot 1000)^{0.5} + 0.000259\,c_e^b] \quad [14a]$$

$$D = D_o(T/T_o)\exp[E^{\dagger}_D(T - T_o)/RTT_o] \quad [15]$$

$$D_o = (1.728 \times 10^{-5})\,(0.008937)/\mu_o \quad [15a]$$

$$D^* = D^*_o(T/T_o)\exp[E^{\dagger}_*(T - T_o)/RTT_o] \quad [16]$$

$$\kappa = \kappa_o(T/T_o)\exp[E^{\dagger}_{\kappa}(T - T_o)/RTT_o] \quad [17]$$

$$\kappa_o = (175 - 19{,}000\,c_e^b)c_e^b \quad [17a]$$

$$\kappa_f = \kappa_f^{o}(T/T_o)\exp[E^{\dagger}_f(T - T_o)/RTT_o] \quad [18]$$

$$U = U_o(T/T_o) + \Delta H^{o}_U(T - T_o)/\mathbf{F}T_o \quad [19]$$

$$i_{o,a} = i_{o,a}^{o}(T/T_o)\exp[E^{\dagger}_a(T - T_o)/RTT_o] \quad [20]$$

$$i_{o,p} = i_{o,p}^{o}(T/T_o)\exp[E^{\dagger}_p(T - T_o)/RTT_o] \quad [21]$$

$$i_{o,c} = i_{o,c}^{o}(T/T_o)\exp[E^{\dagger}_c(T - T_o)/RTT_o] \quad [22]$$

$$c_e^{sat}/c_e^{sat\,o} = 1 + (5.9828 \times 10^{-4})\,(T - T_o) + (1.6644 \times 10^{-5})\,(T - T_o)^2 + (6.7019 \times 10^{-7})\,(T - T_o)^3 \quad [23]$$

$$c_o^{sat} = (\rho_{sat} - c_e^{sat}\,(23.95))/18.016 \quad [23a]$$

Equation [23] is an empirical fit of data given by Adams and Anderson (4). Symbols are defined at the end of the paper.

Equations [1] through [8] represent a total of eight independent, algebraic equations, and they contain eight unknowns or dependent variables: i_p, ϕ_2, ϕ_3, δ, $a_{o,s}$, ϕ_2', ϕ_2'', and i_a. Equations [9] through [23a] relate various parameters to the dependent or independent variables. The independent variables, which can be viewed as the controllable design or operating conditions, are: cell potential ϕ_c, bulk lithium hydroxide concentration c_e, temperature T, bulk electrolytic solution velocity v, position along the flow channel x, effective electrical current path length in the electrolytic solution l_e, and the flow channel width l_f.

The problem of predicting the dependent variables as functions of the independent variables and physical parameters is now specified, and solutions are a matter of mathematical manipulation.

It is to be noted that there is considerable correspondence between the geometric aspects of this model and one for transient zinc electrode polarization presented by Farmer and Webb (9). However, the mathematical representation of the controlling processes, the purpose of the models, and the systems treated are quite different. Farmer and Webb concentrate on film growth rate as controlled by unsteady-state zinc ion transport through an oxide film and dissolution of the film. The lithium electrode model is for steady-state conditions, it includes surface overpotentials and cell potential, and it includes both water and lithium ion transport using simplified, steady-state transport equations.

Numerical calculations.—The equations were linearized and the resulting matrix inverted and iterated upon using a numerical approach described by Newman (10). The technique guarantees rapid convergence if the initial estimates are reasonably close to the correct answer. If estimates are too far from the correct answer, the procedure does not converge. In a series of calculations, the code uses previous solutions as the estimate for the next problem it reads. Once a converged answer is found, the dependent variables for the next problem must be changed by an amount small enough to insure convergence. As a rule of thumb, the following changes per problem in the independent variables were found to be satisfactory: $\phi_c = 0.1\text{-}0.2\mathrm{V}$, $c_e = 10^{-3}$ mol/cm^3, $T = 10°\mathrm{K}$, $v = 10$ cm/sec, $x = 10$ cm, $l_e = 0.01$ cm, and $l_f = 0.5$ cm. A list of parameter inputs is shown in Table I.

In examining system behavior and attempting to "fit" results to experimental results, it is important to recognize the number and definitions of independent parameters. A dimensional analysis of the equations yielded the following as independent input parameters

Table I. Input parameters

Symbol	Description	Magnitude	Reference
A_ρ	Constant in T dependence of density	-5.922×10^{-4} g/cm$^3 \cdot$ °K	(13)
a_b	Coefficient in expression for k_b	2.8	Fitted
a_c	Coefficient in expression for k_c	1.2325	(9)
$c_e^{sat\,o}$	Concentration of LiOH at saturation at 25°C	5.34×10^{-3} mol/cm^3	(15)
D^*	Effective diffusivity of H_2O in Li_2O film	6×10^{-7} cm^2/sec	Fitted
$E^\dagger_a$	Activation energy for $i_{o,a}$	8.372×10^4 J/mol	Estimated
$E^\dagger_c$	Activation energy for $i_{o,c}$	8.372×10^4 J/mol	Estimated
$E^\dagger_D$	Activation energy for liquid diffusion	1.2558×10^4 J/mol	Estimated
$E^\dagger_f$	Activation energy for Li_2O film conductivity	4.186×10^4 J/mol	(4)
$E^\dagger_p$	Activation energy for $i_{o,p}$	8.372×10^4 J/mol	Estimated
$E^\dagger_\kappa$	Activation energy for liquid conductivity	1.2558×10^4 J/mol	Estimated
$E^\dagger_\mu$	Activation energy for viscosity	1.2558×10^4 J/mol	Estimated
$E^\dagger_*$	Activation energy for Li_2O film diffusion	4.186×10^4 J/mol	(4)
ΔH^o_U	Enthalpy of reaction Li + $H_2O \rightarrow$ LiOH + ½H_2	-5.0234×10^5 J/mol	(14)
$i_{o,a}^o$	Lithium exchange current at 25°C	7.8×10^{-2} A/cm^2	(4)
$i_{o,c}^o$	Cathode hydrogen exchange current at 25°C	1×10^{-7} A/cm^2	(11) fitted
$i_{o,p}^o$	Parasitic hydrogen exchange current at 25°C	1×10^{-10} A/cm^2	(11)
l_b	H_2 gas bubble diameter	0.02 cm	Estimated
P	Pressure in flow channel	2 atm	Estimated
t_+^o	Transference number of Li^+ in solution	0.15	(12)
U_o	Standard cell potential for Li = Li^+ + e^- at 25°C	2.217V	(14)
α	Transfer coefficient	0.5	(11)
β	Exponent of bubble Reynold's number in k_b	0.8	Fitted
γ	Exponent of Schmidt number in k_c and k_b	0.33333	(9)
κ_f^o	Li_2O film electrical conductivity at 25°C	1.608×10^{-2} mho/cm	(4)

in addition to the independent variables: $D^*\mathbf{F}c_o^{sat}/\kappa_f$, $i_{o,p}/i_{o,c}$, $i_{o,a}/i_{o,c}$, $l_e i_{o,c}/\kappa_f\psi$, Re, Re_b, a_c, a_b, β, and γ. Parameters which depend only on temperature are: ψ, U, and t_+^o. There are alternative ways of grouping the parameters; however, mathematically, the number of independent parameters remains constant.

The results were found to depend only weakly on $l_e i_{o,c}/\kappa_f\psi$. Thus D^* and κ_f enter only as a ratio in $D^*\mathbf{F}c_o^{sat}/\kappa_f$. In the numerical parameter fitting, κ_f was fixed at 1.6081×10^{-2} mho/cm at 25°C, and D^* was used as a fitting parameter. A value for the hydrated lithium oxide film thickness could be predicted only if a unique, correct value of κ_f is known. Such information is not available under the actual operating conditions being studied. However, Adams and Anderson (4) do provide some information based on static conditions. They report film resistances between 0.33 and 4.55 Ω-cm^2 with 1.21 Ω-cm^2 as a best estimate for δ/κ_f. The value of 1.6081×10^{-2} mho/cm for κ_f^o was selected to yield values of δ/κ_f which compared well with Adams and Anderson's results. The predicted values of δ depend on the value of κ_f selected and can only be as accurate as that selection. Accurate measurements of film thickness, δ, under dynamic, operating conditions could provide further, more definitive tests of the accuracy of the model.

Results

Comparison of theory and experiments.—Figure 2, 3, and 4 have been prepared from the results of the computer code, and superimposed are data extracted from Ref. (2).

The values of $D^*i_{o,c}$, β, and a_b were fitted as discussed in the previous section so as to achieve the degree of agreement exhibited between the experimental and calculated results. Values used are shown in Table I. The fitting parameter values appear to be within expected physical limits. Direct measurements of D^* are unknown. The value of $i_{o,c}$ is within limits reported by Kita (11). Ibl and Venczel (16) derived β equal 0.5 and a_b equal 1.95 using a surface renewal theory. Janssen and Hoogland (17) found β experimental values to vary between 0.36 and 0.87 for gas evolution on a flat plate. Considering the difference in experimental conditions, the agreement is considered good. The agreement between calculated and experimental performance is within experimental accuracy especially when it is realized that the experimental data were obtained using seawater in place of fresh water. Subsequent laboratory tests have

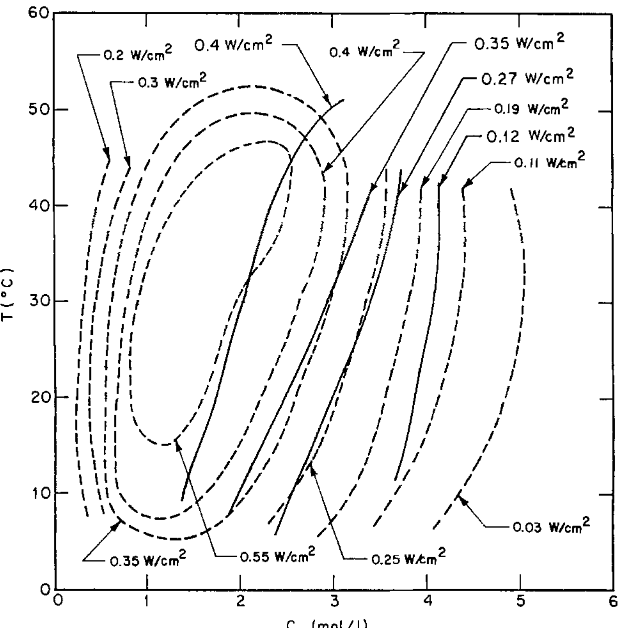

Fig. 2. Power contours at 1.0V cell potential. Dashed lines are constant power contours through array of computer calculations. Solid lines are experimental data from Ref. (2). Extension of dashed contours above 35°C and below 15°C are extrapolations of calculations and are for illustration only. $\phi_c = 1.0V$, $\nu = 12.2$ cm/sec, $L = 6.35$ cm, $l_e = 0.05$ cm, $l_f = 0.1524$ cm. Values are averages for a complete Li-H_2O cell.

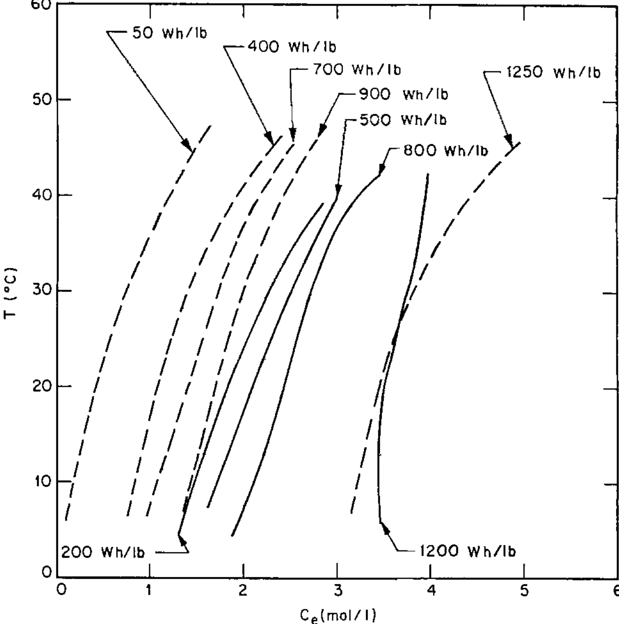

Fig. 3. Specific energy contours at 1.0V cell potential based on mass of lithium consumed. Dashed lines are constant specific energy contours through array of computer calculations. Solid lines are experimental data from Ref. (2). $\phi_c = 1.0V$, $\nu = 12.2$ cm/sec, $L = 6.35$ cm, $l_e = 0.05$ cm, $l_f = 0.1524$ cm. Values are averages for a complete Li-H_2O cell. Theoretical specific energy based on 2.196V cell potential is 3847 W-hr/lb.

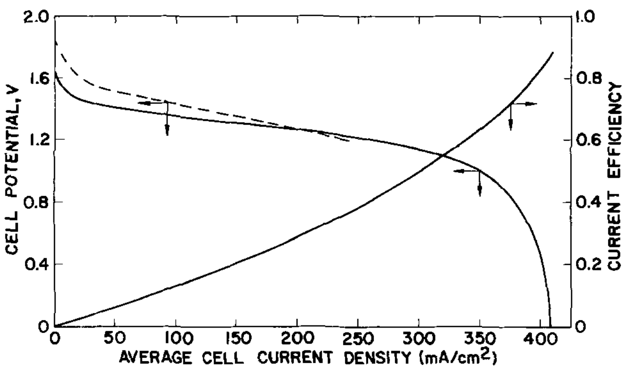

Fig. 4. Current-voltage curve and current efficiency curve. Solid lines are based on computer calculations. Dashed line is experimental results from Ref. (2). $c_e^b = 3.0M$, $v = 85$ cm/sec, $L = 26.67$ cm, $T = 25°C$, $l_e = 0.05$ cm, $l_f = 0.1524$ cm. Values are averages for a complete Li-H_2O cell.

shown that calcium, magnesium, and carbonate ions in seawater influence the nature of the anodic film and the polarization behavior in an unpredictable way.

The theoretically determined (dashed) curves of Fig. 2 at the lowest and highest power levels are somewhat different from those obtained experimentally. However, at intermediate power, the experimental data actually have good concordance with the theoretically calculated numerical values. It should be mentioned here that the closing of the dashed curves at the upper and lower regions are for illustration only, since actual calculations were not made for those areas. However, the shape appears to be logical.

Figure 3 shows current efficiency as a function of temperature and concentration at 1.0V cell potential. The theoretical lines of constant specific energy are more spread out than the experimental lines, but they have similar slope. As mentioned above, the discrepancy can be partly ascribed to the fact that the experimental tests were performed with seawater rather than fresh water-based electrolytes.

The theoretical and actual polarization curves of Fig. 4 show good agreement. The similar curve configuration as the current is reduced to zero should be noted.

Effects of independent variables on operating conditions.—The independent variables are ϕ_c, c_e^b, T, v, x, l_e, and l_f. Performance is described in terms of local current density i, local current efficiency η, local power density p, and local specific energy w. Power density and specific energy are of greatest importance to practical operation of the system.

Figure 5 illustrates the effect of flow velocity and position along the flow channel on the local current

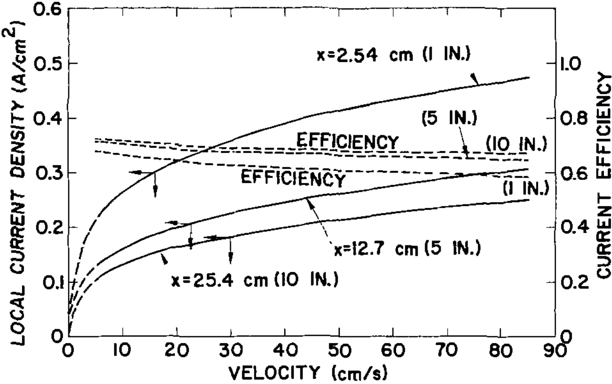

Fig. 5. Current density and current efficiency at 1.0V cell potential as function of electrolytic solution flow velocity and position along flow channel. $\phi_c = 1.0V$, $c_e^b = 3.0M$, $T = 25°C$, $l_e = 0.05$ cm, $l_f = 0.1524$ cm.

density and current efficiency. Figure 6 shows how the effective thickness of the hydrated lithium oxide film varies with flow velocity and position.

Figures 7 and 8 further illustrate the dependence of cell performance on channel flow velocity. Figure 7 is a collection of theoretical current voltage curves and current efficiency curves for varying flow channel velocities. Higher currents can be achieved at higher flow rates, but at the expense of increased parasitic pumping energy. Such design trade-offs have not been attempted here, but the results can be used to develop such optimization information. Figure 8 shows how power density in milliwatts per square centi-

meter and specific energy in kilowatt-hours per pound of lithium vary with cell potential and flow velocity.

Figures 9 and 10 show the effects of temperature on cell performance in terms of variations in current voltage curves, current efficiency, power density, and specific energy. Figures 11 and 12 show the same cell performance characteristics with electrolytic solution concentration as a variable.

Comparison of velocity, temperature, and concentration with regard to their effects on cell performance shows that the lithium hydroxide concentration in the circulating solution has the most important influence on cell performance. Figure 13 is an illustration of how control of lithium hydroxide concentration can be used to optimize cell operation. For example, if a power setting of 160 mW/cm^2 is desired, a maximum in specific energy of 1.23 kW-hr/lb of lithium will be achieved at a solution concentration of 3.40*M*. Inspection of Fig. 12 shows that this optimum setting occurs at 1.11V cell potential implying a current of 144 mA/cm^2. These optimum settings are on rather narrow maximums, and settings far from the maximum will yield poor efficiency. As an example, for 160 mW/cm^2 at a concentration of 3.0*M* and assuming operation along the high voltage branch at 1.3V, Fig. 12 indicates a specific energy of only 0.69 kW-hr/lb of lithium. If the lower voltage branch is used, the cell potential would be 0.734V with a lithium utilization of 1.02 kW-hr/lb. Both settings are well below the optimum (for the cell configuration used in this study) of 1.25 kW-hr/lb, but the lower voltage off optimum setting is less serious a loss than the

high voltage setting. This example illustrates that ideal settings are single valued as shown in Fig. 13, but off optimum settings are double valued. When off the ideal, the lower voltage selection yields a higher efficiency for lithium utilization than the higher setting. Figure 13, when used with Fig. 11 and 12, allows selection of best settings for fixed temperature and flow rate. Figures 5 through 10 illustrate, generally, the effects of varying temperature and flow rate.

Discussion

The bell-shaped power maximum curves shown in Fig. 8, 10, and 12 are not unique to the lithium-water system. Any battery or fuel cell power-potential curves have the same general shape. For most electrochemical power sources, the high voltage branch will yield the most efficient materials utilization. However, the lithium-water system involves a parasitic hydrogen evolution reaction or corrosion reaction which becomes relatively less important along the lower voltage branch of the curve. Thus, in the cases studied, the increase in current efficiency more than offsets the loss in cell potential. Based on the limited cases examined in this work, it appears to be a reasonable guideline to operate as close to the power maximum as possible and to insure that deviations tend to the low voltage side of the maximum. Power and energy maximums occur very close together so that, practically, it is not important to distinguish between the two.

Changes in cell output appear only mildly affected by electrolytic solution flow velocity as compared to the effects of changing the bulk lithium hydroxide concentration or the operating temperature. This appears to be due in part to the stirring effect of the hydrogen evolution, particularly from the parasitic reaction. The parameters associated with the effect of the parasitic hydrogen evolution rate on the mass transfer of ions into the bulk solution made important changes in the numerical results.

In summary, the mathematical model has correlated early experimental results sufficiently well that reasonable confidence can be placed in the description of the principal factors controlling the lithium anode. However, experimental work performed subsequently has shown the importance of anode to cathode contact pressure for optimization of cell performance. Thus, faradaic efficiencies approaching 100% and cell potentials of 1.3V are obtained when the electrodes are pressed together at 10 psi. This operational feature then results in gravimetric energy densities of 2 kW-hr/lb lithium. The importance of this effect needs to be factored into the model since examination of Fig. 8, 10, and 12 shows that the predicted maximum energy density is only between 1 and 1.5 kW-hr/lb lithium. This result implies 26-38% thermodynamic efficiency, a value which compares well with other devices for converting chemical energy to mechanical or electrical energy. The lithium oxidation involves the formation of a hydrated lithium oxide film on the surface of the lithium. The lithium hydroxide continually dissolves into the bulk electrolytic solution through a hydrodynamic diffusion boundary layer. The rates of lithium oxidation and the parasitic or corrosion hydrogen evolution are controlled by the mass transport of water, hydroxyl ions, and lithium ions through the hydrated lithium oxide film. The thickness of the film is established by a steady-state balance between the various rate processes.

Ionic Conductivity of Some Lithium Silicates and Aluminosilicates

I. D. Raistrick, Chun Ho,* and R. A. Huggins[†]

Center for Materials Research, Stanford University, Stanford, California 94305

ABSTRACT

Lithium silicates and aluminosilicates exhibiting a variety of typical silicate structures have been synthesized, and their ionic conductivities measured over a wide range of temperature and frequency, using a-c methods and blocking electrodes. The frequency dispersion of the conductance and capacitance has been analyzed, and an equivalent circuit containing temperature and frequency dependent components is proposed. Frequency independent bulk conductances and activation enthalpies have been extracted and these are discussed in terms of the structural properties of these materials. The importance of a careful analysis of the frequency dispersion is demonstrated.

At the present time there is considerable interest in finding a lithium ion conducting solid electrolyte with properties appropriate for utilization in high energy density battery systems. The conductivities of a number of lithium containing electrolytes have recently been reviewed by Pizzini (1, 2).

As part of a general screening program for good lithium solid electrolytes, it was decided to investigate the electrical properties of some silicates and aluminosilicates. A number of materials ($Li_2Si_2O_5$, Li_2SiO_3, $LiAlSiO_4$, and $LiAlSi_2O_6$) were chosen with structures representative of the main silicate types with the objective of adding to the understanding of the relationship between structure and ionic mobility.

Several lithium silicates have been investigated previously. Li_4SiO_4 (lithium orthosilicate) has been studied by Gratzer *et al.* (3) and West (4, 5). It is one of the best lithium conductors. The conductivity of β-spodumene, $LiAlSi_2O_6$, was measured by Pizzini (1) who also showed by emf measurements that lithium was the mobile species, and recently some data have been presented by Johnson *et al.* (6, 7) for glassy and "glassy-ceramic" $LiAlSiO_4$ (β-eucryptite).

The major difficulty encountered in the measurement of ionic conductivities of solids is polarization at the electrode/electrolyte interface, and at the grain boundaries in a polycrystalline solid. While the electrode polarization can in principle be eliminated by using ideally reversible electrodes, an alternative procedure, that of studying the frequency dispersion of the a-c response using blocking electrodes, was adopted here, in the hope of obtaining additional information about grain boundary effects, minority carrier conduction, and interfacial and bulk capacitances.

Key words: solid electrolytes, complex plane analysis, frequency dependence, lithium ionic conductors.

The problem of analysis of frequency dispersion in ionic conductors has received some attention in recent years. For example, Macdonald (8-10) has presented exact solutions of the diffusion equations for a variety of theoretical conditions, and some experimental work has been carried out by Armstrong and co-workers (11-13), on the effect of grain boundaries etc. on the nature of the dispersion. In addition, a large amount of information is contained in the dielectric loss literature. Some of these latter data have been recently brought together by Jonscher (14). Dielectric loss has been used directly to determine the conductivities of solid electrolytes in a number of instances (15, 16).

The method of data analysis presented in this paper is primarily empirical. The complex plane method originally due to Cole and Cole (17) is employed. Equivalent circuits and admittance equations are introduced which reproduce the data well over wide ranges of experimental parameters. Recent examples of this approach can be found in the publications of Macdonald (10), Armstrong (11, 13), Mitoff and Charles (18), Franklin (19), Bert *et al.* (20), and Bauerle (21). The importance of this kind of analysis is demonstrated by showing that erroneous values for both conductivities and activation enthalpies can result from a disregard of frequency dispersion effects.

Materials Investigated

This section briefly describes the main structural features of the four lithium-containing compounds, $LiAlSi_2O_6$, $LiAlSiO_4$, $Li_2Si_2O_5$, and Li_2SiO_3.

$LiAlSi_2O_6$, β-spodumene.—$LiAlSi_2O_6$ exists is three modifications. The low temperature form has a diopside chain structure, a high temperature form is a "stuffed" (22) keatite structure, and a high temperature-high pressure form has a stuffed β-quartz structure (23). In nature, only the first is found, while the usual lab-

oratory preparation at atmospheric pressure results in the second: known as β-spodumene, stable above 500°C but metastable at room temperature. A wide range of β-spodumene solid solution is known to exist (24), lying approximately between 60 and 80 mole percent (m/o) SiO_2. Close to the ideal composition, the tetragonal unit cell has the parameters $a_o = 7.53$, $c_o = 9.14$Å.

Keatite is a high temperature-high pressure modification of SiO_2 (25), ($a_o = 7.456$, $c_o = 8.604$Å). It is constructed of corner-sharing SiO_4 tetrahedra arranged in spirals around the lines x = 0, y = ½, and x = ½, y = 0. The spirals are linked by Si atoms in such a way that each Si is linked to the oxygen of four different spirals, resulting in five-membered rings, the cavities of which extend throughout the structure. In β-spodumene 1/3 of the Si atoms are replaced by aluminum atoms randomly, and the lithium ions occupy either of two equivalent positions within the rings. There are twice as many sites as lithium ions. The large channels presumably account for the ion exchange properties of this compound (26). This fact led to the present interest in this material as a possible solid electrolyte.

$LiAlSiO_4$, β-eucryptite.—This material is another example of a "stuffed" structure, (27), but this time it is a superstructure of the β-quartz modification of SiO_2, rather than keatite. Quartz is the closest packed of the three common silica modifications. It is composed of interlinked helical chains of corner-shared SiO_4 tetrahedra. The interstices, which are occupied by Li^+ ions in β-eucryptite, are much smaller than the interstices in keatite, crystobalite, or tridymite.

$Li_2Si_2O_5$ and Li_2SiO_3.—By contrast with the previous two structures, the Li^+ ions in $Li_2Si_2O_5$ and Li_2SiO_3 are not "interstitial" in nature but are essential to the cohesion of the framework. In $Li_2Si_2O_5$ (as in $LiAlSi_4O_{10}$, petalite) the silicate tetrahedra form six-membered rings, which share vertices leading to infinite sheets. Two sheets are held together by ionic bonding through Li^+, positioned between the layers (28).

In Li_2SiO_3, rather than forming sheets, the SiO_4 tetrahedra form zigzag chains, which are again held together by lithium ions lying between them (29).

Preparation and Characterization of Materials

Standard solid-state preparative methods were used to synthesize $LiAlSi_2O_6$, $LiAlSiO_4$, and Li_2SiO_3. The starting materials were Al_2O_3, SiO_2, and Li_2CO_3. Mixtures of appropriate composition were heated in alumina crucibles between 1050° and 1200°C. $Li_2Si_2O_5$ was prepared by melting a mixture of Li_2CO_3 and SiO_2 at 1200°C and quenching to room temperatures, followed by solid-state annealing at 900°C. All x-ray diffraction patterns were in excellent agreement with previously published results.

Experimental Aspects of the Electrical Measurements

Preparation of samples for measurements.—A small quantity of the ground material was hot pressed at temperatures between 800° and 1000°C and at a pressure of 6000 psi, in graphite dies. Carbon was then burned off the resulting disks at 800° in air.

The surfaces of the disks were polished using 400 mesh silicon carbide paper and both surfaces of the pellets x-rayed to ensure that the surface was still composed of the correct material. 1000Å of platinum was then sputtered onto both surfaces and electrical contact was made by spring-loaded platinum foil disks.

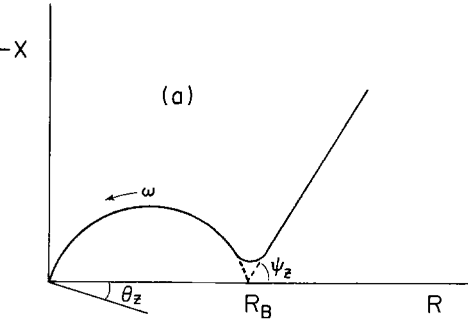
A-C measurements.—The a-c measurements were made using one or more of three different bridges; General Radio 1608, 1615, and Hewlett-Packard 4270 A, the 1615 bridge being used at conductivity values below 100 μmhos. The frequency range used was between 20 Hz and 1 MHz, although the exact range available depended on the conductance of the sample. Materials with a high conductivity generally exhibited too great a loss at low frequencies (< 100 Hz) to allow accurate measurement with available equipment. The signal amplitude was maintained below a few millivolts.

Introduction to Analysis of the Frequency Dependence

At any given temperature the frequency dispersion can be represented as a line in a complex admittance, impedance or dielectric constant plane. As the temperature is varied the various time constants change and hence the observable portion of the total frequency-dependent response shifts. Thus, by making measurements over a sufficiently wide range of temperatures, it is possible to construct a composite picture of the total behavior. Such a composite diagram for the silicates is given schematically in Fig. 1. The frequency- and temperature-dependent response of all four materials was found to be sufficiently similar to enable them to be discussed together.

As may be seen from Fig. 1, two main regions of response are discernible. At the low frequency end, the admittance (*B-G*) plot is a closed circular arc, whereas data in the high frequency region lead to an open figure. The converse is true for the impedance (*X-R*) plot. The two regions are separated at a real resistance R_B in both cases. The shapes of the experimental curves indicate that at low frequencies a series *R-C* circuit is dominant, with an associated capacitance of the order of microfarads, whereas at high frequencies a parallel *R-C* circuit with an associated capacitance of the order of picofarads more closely models the characteristic response. The temperature-dependent resistance R_B is common to both networks and has been taken as the bulk resistivity of the electrolyte. Note that the lowering of the centers of the circular portions of the plots below the real axes, characterized by the angles θ_Y and θ_Z, corresponds to a deviation of the open-ended portions of the complementary figure from the vertical.

Such data cannot be modeled by any equivalent circuit composed entirely of frequency-independent com-



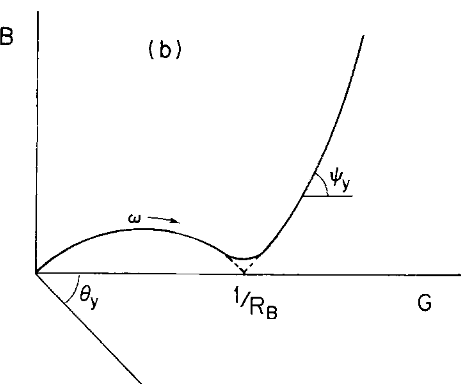


Fig. 1. Schematic representation of the complex impedance (a) and complex admittance (b) of the solid electrolyte/blocking electrode system.

ponents; nonfinite or frequency-dependent components must be included in order to explain circular arcs whose centers lie below the real axis.

Results of the Analysis of the Low Temperature-High Frequency Response

All four materials showed similar low temperature frequency dispersion and will be considered together here. The B-G plots are curves inclined at an angle $\psi_Y(\pi/4 < \psi_Y < \pi/2)$ to the real (G) axis. The higher the frequency the closer ψ_Y approaches $\pi/2$. A low frequency "tail" is evident which, as the temperature is raised, eventually goes through a minimum leading into the low frequency (high temperature) region, discussed in the next section. Typical B-G plots are shown in Fig. 2 and 3

The corresponding X-R plots (Fig. 4) are approximately semicircular arcs with the high frequency intercept at the origin. A low frequency tail is again evident. The center of the circle is a few degrees below the real (R) axis.

If the effective parallel capacitance, C_p, is plotted against log ω (Fig. 5), it can be seen that at very high frequencies C_p extrapolates to a constant value (C_∞) which is almost temperature independent, and of the order of a few picofarads. Similar values were obtained for all the materials. The occurrence of a limiting high frequency capacitance is not unexpected: the physical arrangement of a material of finite dielectric constant sandwiched between two parallel metal electrodes has a geometrical, or bulk, capacitance which is expected to be of the order of a few picofarads for the sample and electrode geometry used here. The most obvious effect of temperature is to drastically increase C_p at low frequencies.

The shape of the C_p vs. log ω curve (Fig. 5) suggested a dependence of log ($C_p - C_\infty$) upon log ω. This was confirmed by plotting these two quantities against one another, producing straight lines at several temperatures (Fig. 6).

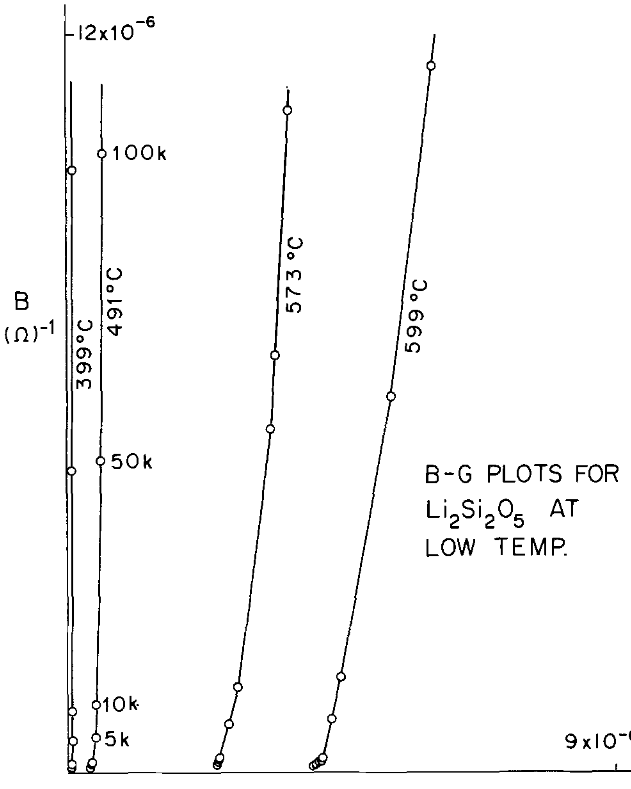

Fig. 2. Complex admittance plot for $Li_2Si_2O_5$ at low temperatures

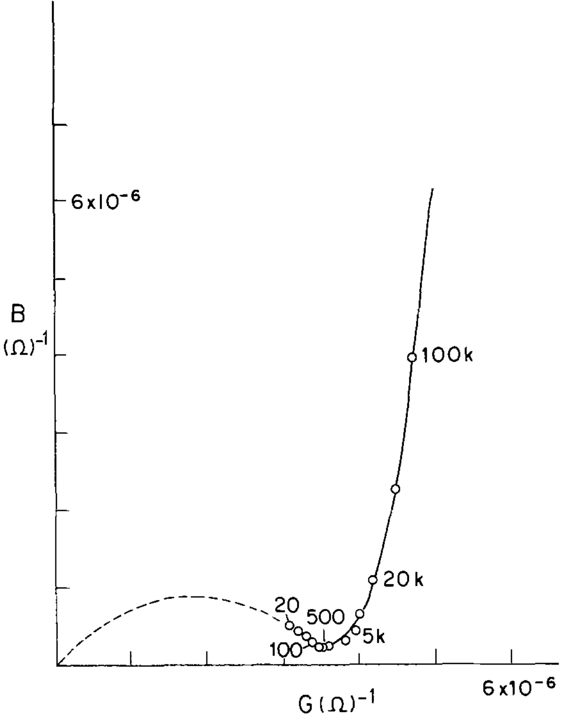

Fig. 3. Complex admittance plot for $LiAlSiO_4$ at an intermediate temperature (421°C).

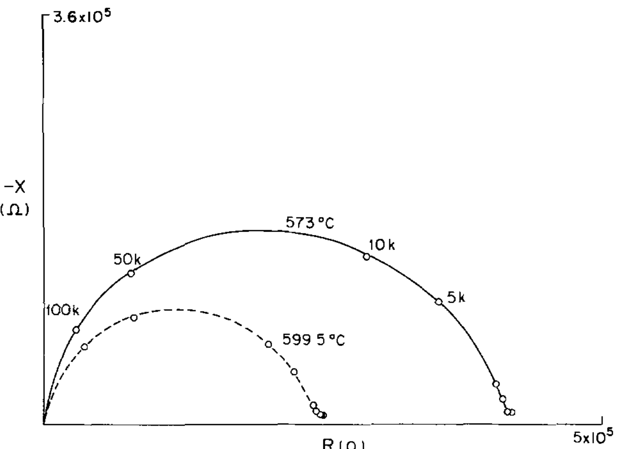

Fig. 4. Complex impedance plot for $Li_2Si_2O_5$ at low temperatures

Thus, we can write

$$\log (C_p - C_\infty) = \log B_B + \delta \log \omega$$

where δ is the slope and log B_B is the log $\omega = 0$ intercept. Hence

$$C_p = C_\infty + B_B\omega^{+\delta}$$

In the same way, a plot of log ($G_p - 1/R_B$) vs. log ω gave straight lines of slope $+\beta$ and intercept log A_B. Therefore

$$G_p = \frac{1}{R_B} + A_B\omega^{+\beta}$$

Approximate values of C_∞ and R_B were obtained from Cole-Cole and complex impedance plots and were then varied using a digital computer so as to minimize the squared error in the straight line fit. Values for A_B, B_B, β, and δ are given for Li_2SiO_3 in Tables I and II at various temperatures.

The complete admittance equation for the high frequency (low temperature) response is therefore

$$Y^* = G_p + j\omega C_p$$

$$= \frac{1}{R_B} + A_B\omega^{+\beta} + j(\omega C_\infty + B_B\omega^{1+\delta})$$

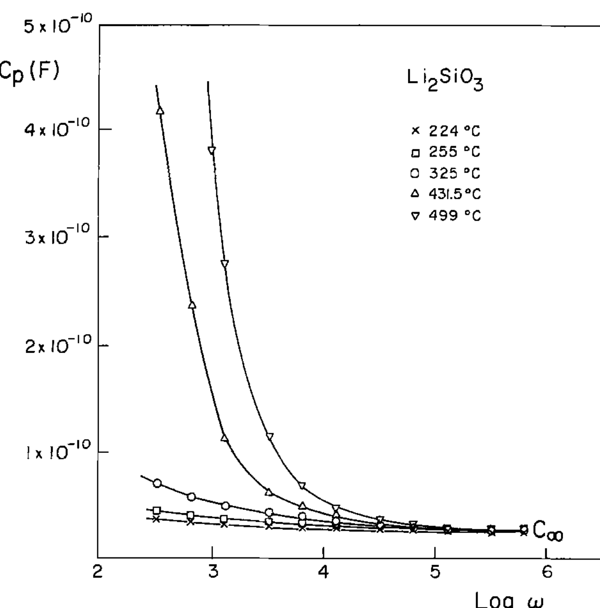

Fig. 5. Plot of measured parallel capacitance (C_p) vs. logarithm of angular frequency for Li_2SiO_3 at various temperatures.

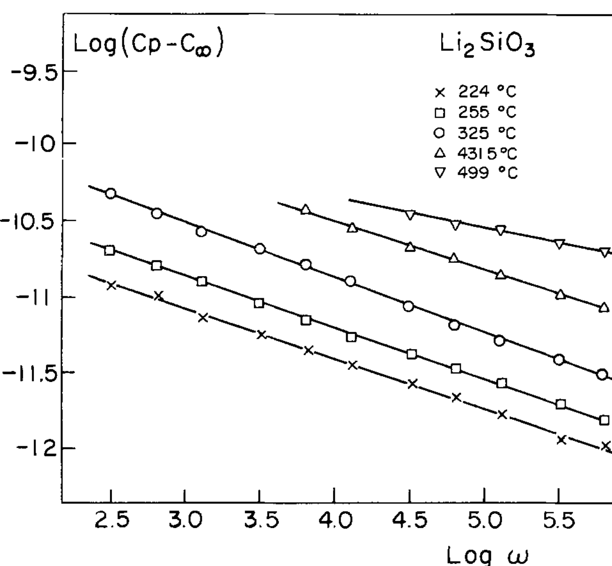

Fig. 6. Plot of logarithm of parallel capacitance after subtraction of high frequency limiting capacitance vs. logarithm of angular frequency for Li_2SiO_3 at various temperatures.

and the appropriate equivalent circuit for this region is shown in Fig. 7a, where Y^*_B is a frequency-dependent circuit element having an admittance of the form

$$Y^*_B = A_B\omega^{+\beta} + jB_B\omega^{1+\delta}$$

Table I. Bulk complex admittance parameters for Li_2SiO_3 (imaginary part)

T (°C)	Slope (δ)	Intercept (log B_B) (B_B in Ω^{-1})	B_B (Ω-cm)$^{-1}$	C_∞ (F-cm^{-1})
224*	−0.334	−10.09	2.25×10^{-11}	6.59×10^{-12}
255*	−0.342	−9.845	3.94×10^{-11}	6.45×10^{-12}

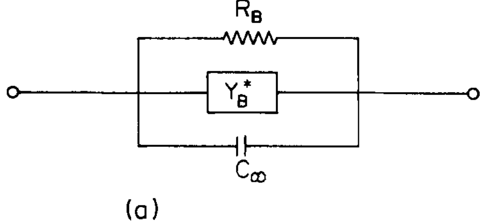
431.5†	−0.318	−9.237	1.60×10^{-10}	3.29×10^{-12}
499†	−0.191	−9.596	6.97×10^{-11}	3.78×10^{-12}

*, † Results marked * and † were taken in different cells. This may be of relevance since cell geometry, size of electrode plates, etc., might make a contribution to C_∞.



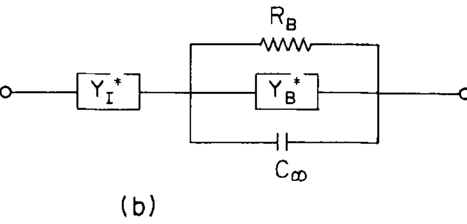


Fig. 7. Equivalent circuit models for the total electrolyte/electrode response: (a) low temperature, high frequency regime; (b) full experimental range.

From Tables I and II it can be seen that A_B and B_B are of the same order of magnitude, as are β and $(1 + \delta)$. When ω $(C_p - C_\infty)$ and $(G - 1/R_B)$ are plotted against each other a straight line of slope σ results (Fig. 8). Thus

$$\frac{dB}{dG} = \frac{B_B(1+\delta)\omega^\delta}{A_B\beta\omega^{(\beta+1)}} = \sigma, \text{ a constant}$$

Since σ is independent of frequency (Fig. 8)

$$\delta = \beta - 1$$

Thus

$$\sigma = B_B/A_B$$

Thus the frequency exponents in the two terms in the admittance equation are the same, in accordance with the Kramers-Krönig relations, but A_B and B_B may be different, the ratio of these latter quantities, σ, determines both the slope of the B-G plot and the extent of the lowering of the center of the semicircle below the real axis in the X-R plots. The final form of this bulk admittance is therefore

$$Y^*_{bulk} = A_B\omega^{+\beta} + jB_B\omega^{+\beta}$$

or, transforming this to an impedance equation

$$Z^*_{bulk} = \left(\frac{A_B}{A_B^2 + B_B^2}\right)\omega^{-\beta} - j\left(\frac{B_B}{A_B^2 + B_B^2}\right)\omega^{-\beta}$$

The physical origin of an admittance of this form is at the present time uncertain. The most likely hypothesis is that it is connected with diffusional grain boundary charge storage and dissipation. It is possible to write a number of infinite circuits, all of which show an admittance of the form described above. Scheider (30) has discussed some of these in a slightly different context. Until more specific experiments are carried out to determine the effect of grain boundaries on the electrical response of such an electrolyte-electrode system, the explanation offered here should be regarded as speculative.

Analysis of the High Temperature-Low Frequency Region of Electrical Response

The two materials with the highest conductivities, $LiAlSiO_4$ (β-eucryptite) and $LiAlSi_2O_6$ (β-spodumene) exhibit very similar high temperature (low frequency) a-c response. Measurements on Li_2SiO_3 and $Li_2Si_2O_5$ were not carried out at sufficiently high temperatures to observe analogous response, the lower conductivities of these materials implying that the typical high temperature (low frequency) response is not seen in the experimentally available frequency spectrum until higher temperatures.

The general form of the high temperature response is shown in Fig. 9 and 10 in terms of B-G and X-R plots.

The B-G plots are portions of circles, with their centers much below the real axis at low temperatures. The angle θ_Y, defined at the origin by the position of the center of the circle, is given in Table III for $LiAlSi_2O_6$

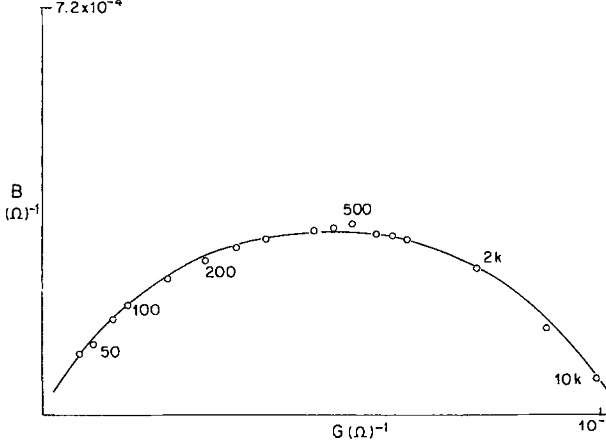

Fig. 9. High temperature complex admittance plot for $LiAlSi_2O_6$ at 644°C.

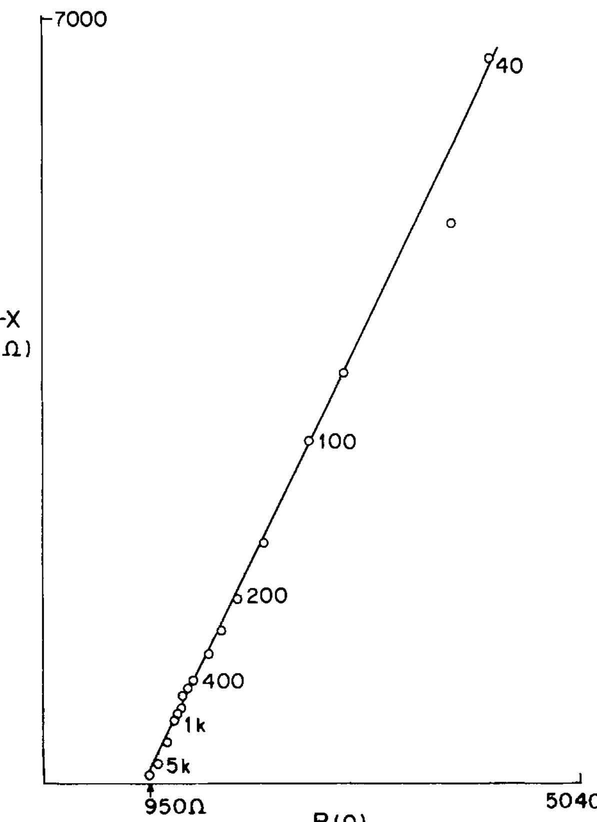

Fig. 10. High temperature complex impedance plot for $LiAlSi_2O_6$ at 692°C.

at several temperatures. The high frequency end of the semicircle has a tail at low temperatures which leads into the bulk response region discussed in the previous section.

As the temperature is increased, the circular portions of the B-G plots rise until at the highest temperatures studied (>900°C) the semicircle has its center on the real axis. The X-R plots are straight lines inclined at an angle ψ_z to the real axis ($\pi/2 > \psi_z > \pi/4$). As the temperature is increased the X-R plot approaches a vertical straight line.

The occurrence of a circular arc in a B-G plot is equivalent to a straight line in the X-R plot. From the latter, we can write

$$-X = \psi_z(R - R_B)$$

where ψ_z is the slope of the line and R_B is the extrapolated intercept on the real (R) axis corresponding to the bulk electrolyte resistance.

Thus, $dX/dR = -\psi_z$, which is a constant and independent of frequency even though both X and R are functions of frequency.

Plots of log $(-X)$ and log $(R - R_B)$ *vs.* log ω were both found to be straight lines having the same slope, $-\alpha$. Thus

$$R - R_B = A_I\omega^{-\alpha}$$

and

$$-X = B_I\omega^{-\alpha}$$

Therefore

$$\psi_z = B_I/A_I$$

and is independent of ω.

Table III. Angle subtended at origin of B-G plot by the center of low frequency semicircle for $LiAlSi_2O_6$ (β-spodumene)

T (°C)	θ_Y (degrees)	T (°C)	θ_Y (degrees)
421	~37	711	28
609	33	775	19
667	31.5	938	~0

We may, therefore, represent the electrical response of the sample-electrode system in the low frequency-high temperature regime by the impedance

$$Z^*_I = A_I\omega^{-\alpha} - jB_I\omega^{-\alpha}$$

in series with the bulk resistance R_B.

The corresponding admittance in this regime (excluding the bulk resistance) is

$$Y^*_i = \frac{A_I}{A_I^2 + B_I^2}\,\omega^\alpha + j\,\frac{B_I}{A_I^2 + B_I^2}\,\omega^\alpha$$

In Table IV, values of A_I, B_I, and α are given at three different temperatures for β-spodumene and β-eucryptite.

The form of this low frequency (high temperature) impedance is significantly different from the normal description of a blocking electrode double layer. It has usually been assumed that the electrical double layer could be described as a frequency-independent capacitance in series with the bulk resistance. The present description allows resistive as well as capacitative components to act at the interface, and these are related in such a way that the dissipation factor, the ratio of energy dissipated to energy stored, is fixed and independent of frequency. The coefficients A_I and B_I, however, may change with temperature. Unfortunately, the instability of the interface morphology at these high temperatures prevented further meaningful numerical analysis, which would give the dependence A_I, B_I, and α on temperature. At the present time, low temperature measurements on better ionic conductors are in progress in the hope of defining the interface parameters and their properties more exactly (31).

Effect of Frequency Dependence on Measured Activation Enthalpies of Lithium Silicates and Aluminosilicates

As discussed in the previous two sections, the frequency response of the silicates using sputtered platinum electrodes is well modeled by the equivalent circuit shown in Fig. 7b, where

$$Y^*_B = A_B\omega^\beta + jB_B\omega^\beta$$

and

$$Y^*_I = \frac{A_I}{\rho}\,\omega^\alpha + j\,\frac{B_I}{\rho}\,\omega^\alpha$$

$$\rho = A_I^2 + B_I^2$$

Although the magnitudes of both the constants and the frequency exponents of Y^*_I and Y^*_B are quite different, the same value of the frequency-independent resistance (R_B) can be extracted from the data in both frequency/temperature regimes. It will be seen shortly that the conductivity-temperature product related to this resistance varies exponentially with temperature in accordance with the Arrhenius relation. The high frequency limiting capacitance C_∞ is associated with the high frequency dielectric constant of the silicates. It may also include a contribution from the leads and measuring equipment, although this factor was eliminated experimentally so far as possible.

It should be noted that C_∞ may be placed over the entire circuit, rather than just across Y^*_B, but this would involve essentially no changes in either the form of the magnitudes of the results. Also a d-c electronic resistance might be included in parallel to the whole circuit. However, the low frequency data extrapolate to very low d-c conductances indicating a very low electronic transference number. This was confirmed by independent d-c measurements.

Table IV. Interface complex impedance parameters for $LiAlSi_2O_6$ and $LiAlSiO_4$

Compound	T (°C)	A_I (Ω-cm²)	B_I (Ω-cm²)	α
$LiAlSi_2O_6$	692	2.97×10^5	5.43×10^5	0.85
$LiAlSi_2O_6$	786	1.78×10^5	2.01×10^5	0.73
$LiAlSi_2O_6$	931.5	3.72×10^5	5.95×10^5	0.80
$LiAlSiO_4$	667	1.19×10^5	1.99×10^5	0.79
$LiAlSiO_4$	775	9.44×10^4	1.63×10^5	0.76
$LiAlSiO_4$	923	1.10×10^5	9.89×10^4	0.70

The circuit element Y^*_I is obviously associated with the electrolyte-electrode interface, and Y^*_B with the bulk response. Because of the large difference in their time constants, in principle, the two response regimes are clearly separated at R_B when represented in either the admittance or impedance complex plane.

However, the range of frequencies readily accessible to experimental measurements often does not span the full range of behavior theoretically expected. At low temperatures the bulk-dominated response region generally lies within the accessible frequency range; and at high temperatures the interface-dominated response is observed. The effect of this shift in the "frequency window" with temperature is that numerical extrapolations to obtain R_B must typically be made to low frequencies at lower temperatures, and to high frequencies at higher temperatures. This is contrary to the traditional practice of extrapolating all measurements to infinite frequency and assuming that all polarization effects have been eliminated. In Fig. 11 and 12 both monofrequency data taken at 10 kHz and the results obtained from data obtained over a wide frequency range and corrected for frequency dependence by appropriate extrapolation are plotted as log σT *vs.* $1/T$ for $Li_2Si_2O_5$ and Li_2SiO_3.

The following observations may be made:

1. The general tendency is for monofrequency data at low temperatures to imply greater conductivities and lower activation enthalpies than are actually present. In Table V, numerical values of the 10 kHz and corrected data are compared.

2. Apparent discontinuities in the conductivity *vs.* temperature plots obtained in monofrequency experiments are either eliminated or removed to much lower

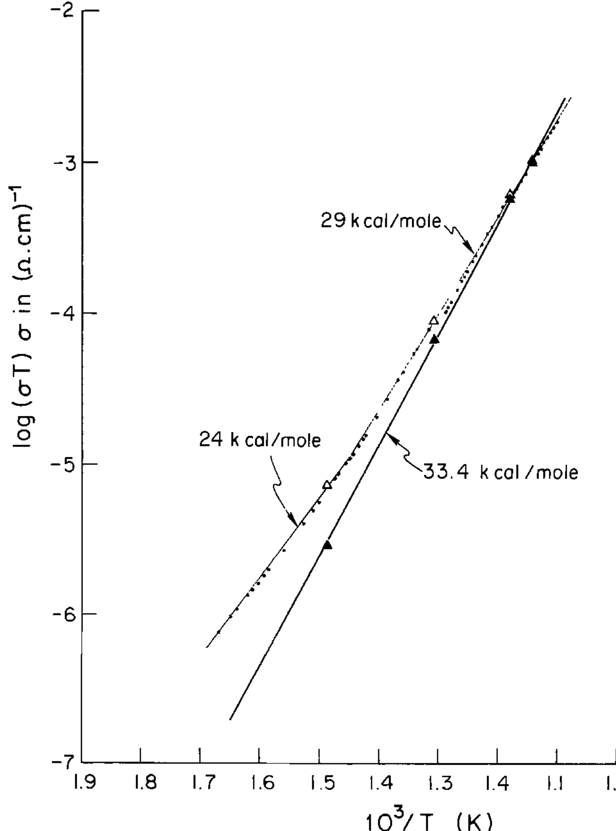

Fig. 11. Monofrequency data (△, 10 kHz) and frequency-independent conductivity data (▲, corrected for frequency dependence) for $Li_2Si_2O_5$.

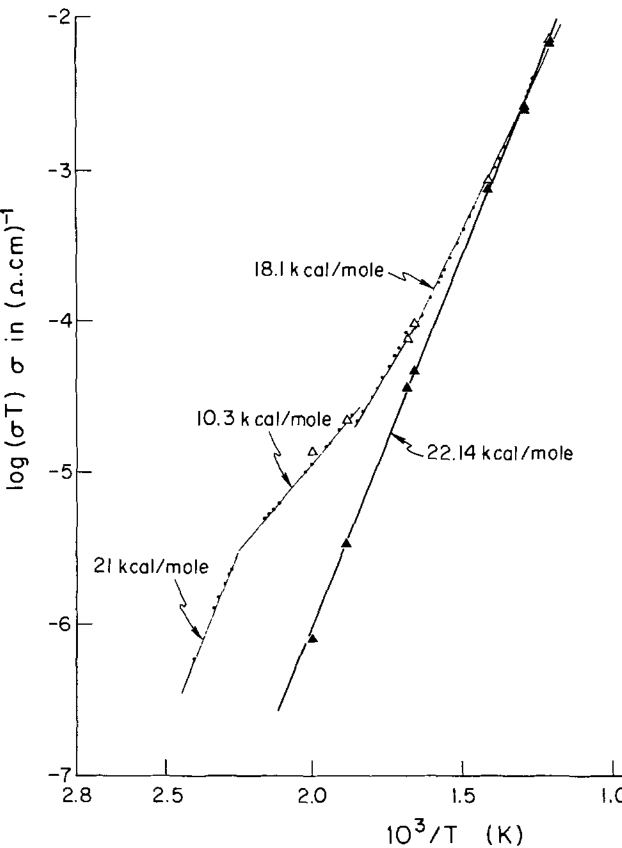

Fig. 12. Monofrequency data (△, 10 kHz) and frequency-independent conductivity data (▲, corrected for frequency dependence) for Li_2SiO_3.

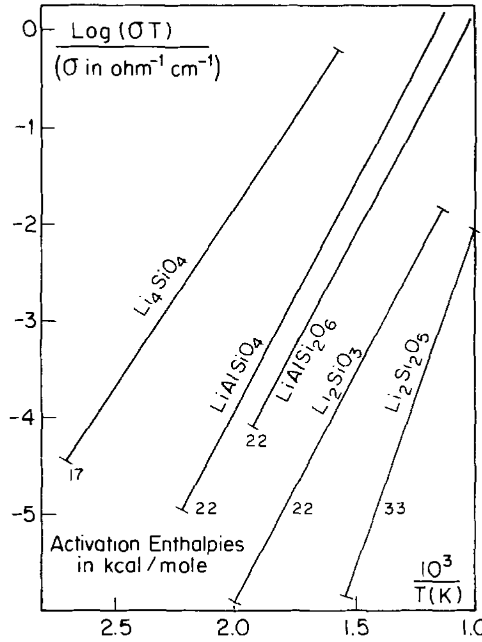

Fig. 13. Collected frequency-independent conductivity results for the silicates and aluminosilicates.

temperatures by proper analysis. The behavior of Li_2SiO_3 may be taken as an example. The 10 kHz data might be interpreted by several approximately linear regions, whereas the corrected data show a straight line with a single value of activation enthalpy. Such apparent changes in slope are often interpreted in terms of transitions between intrinsic and extrinsic behavior. This is not to say that an extrinsic-intrinsic transition is never found, but merely that the quantitative analysis of such behavior should be treated with circumspection if the frequency dispersion of the sample-electrode system has not been examined.

3. At very high temperatures monofrequency conductivity values observed may be less than the true values, leading to apparent curvature of the conductivity *vs.* temperature plot.

4. It has not proved possible in the present case to separate inter- and intragranular resistances. Only one resistance was necessary to model the data. It is possible, therefore, that the conductivity values given here may include a contribution from the grain boundaries. Further work is needed on this important consideration.

Relationship Between Structure and Ionic Conductivity in the Lithium Silicates and Aluminosilicates

In Fig. 13 frequency-independent conductivities are plotted as a function of temperature for the silicates and aluminosilicates described above. Also included in this diagram are corrected conductivity values for Li_4SiO_4, lithium orthosilicate. Conductivity measurements on this material have been made in this laboratory over a wide range of frequency, as well (32). Details of this work and a comparison with the corresponding germanate (33) will be published separately.

In Table VI conductivities at 400°C and corresponding activation enthalpies are given. As may be seen, the lowest conductivities and highest activation enthalpies are exhibited by the chain and sheet silicates. Intermediate conductivities are shown by the "stuffed" quartz structures, and lithium orthosilicate has by far the highest conductivity. Indeed, it is one of the best lithium solid electrolytes known.

The general trend of these results is not unexpected, and can be qualitatively rationalized on the basis of the crystal structures of these materials.

In the layer and sheet silicates, the lithium ions are essential for the cohesion of the structure as a whole. They occupy tetrahedral sites, linking together the SiO_4 tetrahedra through short, strong bonds. $Li_2Si_2O_5$ has the shortest Li-O bond length (1.94Å) (28) suggesting the strongest bond, and correspondingly this compound has the lowest ionic conductivity and the highest activation enthalpy among the materials examined here. The stuffed structures have rather weaker lithium-oxygen bonds, *e.g.*, $LiAlSi_2O_6$ has a Li-O bond length of 2.08Å. The lithiums are not an essential part of the structure, as evidenced by the existence of these crystallographic forms in pure silica.

The best ionic conductor is Li_4SiO_4. Its structure consists of isolated SiO_4 tetrahedra linked through 4 coordinated Li ions. In addition, however, there are extra 5 and 6 coordinated lithium sites which are also partially occupied. The mean bond lengths for the 5 and 6 coordinated ions are 2.099 and 2.247Å, respectively. These figures may be compared with an average 4 co-

Table V. Comparison of real and apparent activation energies for Li_2SiO_3 and $Li_2Si_2O_5$

Sample	Temperature range (°C)	Apparent activation enthalpy (kcal/mole)	Real activation enthalpy (kcal/mole)
Li_2SiO_3	140-171	21	22
Li_2SiO_3	171-268	10.34	—
Li_2SiO_3	268-527	18.75	—
$Li_2Si_2O_5$	337-415	24	33
$Li_2Si_2O_5$	415-650	29.4	—

Table VI. Conductivities at 400°C and activation enthalpies

Compound	$\sigma_{400°C}$ $(\Omega\text{-cm})^{-1}$	ΔH (kcal/mole)
$Li_2Si_2O_5$	4.5×10^{-9}	33
Li_2SiO_3	5.6×10^{-7}	22
$Li_2Si_2O_6$	1.4×10^{-5}	22
$LiAlSiO_4$	4.7×10^{-5}	22
Li_4SiO_4	2.2×10^{-3}	17

ordinated lithium-oxygen bond length of 1.98Å. It is probably not unreasonable to suppose that the weakly bound ions in the 5 and 6 positions are primarily responsible for the high conductivity of this compound.

Good ionic conductivity in the silicates is therefore expected to be associated with one or more of the following structural features: a framework-type structure, with long alkali metal-oxygen bond distances (ions in sites of high coordination number), and fractional occupancy of alkali ion sites.

Technical Note

The Electrochemical Reactions of Carbon Monoxide, Nitric Oxide, and Nitrogen Dioxide at Gold Electrodes

J. M. Sedlak* and K. F. Blurton*

Energetics Science, Incorporated, Elmsford, New York 10523

Previously, an instrument for the measurement of carbon monoxide in ambient air was described (1, 2). The operating principle of that analyzer was based on the electrochemical oxidation of carbon monoxide (3) at a platinum-catalyzed Teflon-bonded diffusion electrode (4); the potential of this sensing electrode being maintained constant at a value where neither oxygen reduction nor electrolyte decomposition interfered with the measurement of the pollutant.

Utilization of this technique for the measurement of nitric oxide (NO) and nitrogen dioxide (NO_2) required selective analysis of both gases in the presence of each other and in the presence of relatively large carbon monoxide concentrations. For example, typical ambient air concentrations of CO, NO, and NO_2 are 10, 0.03, and 0.03 ppm (parts per million on a volumetric basis), respectively (5), while in industrial environments the pollutant levels can be substantially higher.

In general, instrument specificity can be achieved either by using selective gas filters or by optimizing the electrode catalyst and potential. Since it is impossible to filter CO selectively from air streams containing NO and NO_2, specificity was achieved by the second approach. Therefore, the electrochemical reactions of NO, NO_2, and CO on gold were investigated and are reported here.

Experimental

The electrochemical cell used was similar to that described previously (1) except for the sensing electrode catalyst. For this experimental study the cell contained three electrodes with 4.0M H_2SO_4 solution as

* Electrochemical Society Active Member.

Key words: carbon monoxide, nitric oxide, nitrogen dioxide, gold electrode, gas sensor, diffusion electrode.

the electrolyte. Both sensing and counterelectrodes were gold-catalyzed Teflon-bonded diffusion electrodes (geometric area 5 cm^2 and catalyst loading 7-13 mg/cm^3), and the reference electrode was a mercury/mercury sulfate electrode. The electrodes were prepared by the usual method (6).

When measurements were taken, the gas was passed over the back of the potentiostated gold diffusion electrode, and the current generated by the electrochemical reaction was measured by determining the potential drop across a standard resistor with a recorder (Hewlett-Packard Company, Model 680). The potentiostat was designed and constructed in-house. All potentials refer to the reversible hydrogen electrode potential in 4.0M H_2SO_4 solution.

Analyzed cylinders of 6.8, 39, and 349 ppm NO in nitrogen and of zero grade air were obtained from Airco Incorporated (nitrogen was used as the diluent for NO to preclude reaction with oxygen). Samples containing up to 5 ppm NO_2 in air were prepared using zero grade air and thermostated permeation tubes (Metronics Associates). Unanalyzed CO in air mixtures containing approximately 50, 90, and 735 ppm were obtained from Matheson Gas Products Company.

Discussion of Results

Current/potential curves for NO, NO_2, and CO were obtained by initially potentiostating the gold electrode at 0.6V for 24 hr. The current was then measured for zero air and subsequently for each of the test gas mixtures at a flow rate of 0.7 liter/min. The electrode potential was then increased stepwise to 1.6V and the currents at each potential were determined after potentiostating for 24 hr. At each potential there was a small current (<10 μA) when zero air was passed into the sensor which was cathodic below about 1.05V. This current was subtracted from the current measured with the test gases. The potential range was restricted to 0.6-1.6V to minimize currents due to O_2 reduction and evolution. The current potential plots in Fig. 1 and 2 were obtained with one sensor but qualitatively similar behavior was noted with six additional cells.

Nitric oxide was electro-oxidized on Au only at potentials >0.9V, and this is similar to previously reported data with Pt electrodes (7, 8). Nitrogen dioxide was electro-oxidized at potentials >1.0V and electro-reduced at the more cathodic potentials. A plateau in the NO oxidation curve was obtained at potentials >1.2V and the value of this current was 7.8 μA/ppm. Similarly the maximum current for NO_2 oxidation was 3.8 μA/ppm and for NO_2 reduction was 8.2 μA/ppm. The value of this maximum current varied with each sensor and increased to approximately 13 μA/ppm for NO oxidation and NO_2 reduction with the higher catalyst loadings investigated.

The current for CO oxidation on Au electrodes (Fig. 2) was in marked contrast to that obtained with platinum electrodes (3). At potentials <1.0V, this current was very small. As the electrode potential approached that for gold oxide formation (9), the oxidation current increased to a maximum of 0.04 μA/ppm and subsequently decreased at potentials >1.4V.

From the current/potential behavior of CO, NO, and NO_2 with the gold catalyzed electrodes, an instrument for the separate and direct determination of NO and NO_2 was developed (10). The NO_2 sensor was biased at 0.8V since both NO and CO are unreactive at this potential. The NO sensor was operated at 1.5V where CO is again quite unresponsive and since NO_2 can easily be selectively filtered from NO/NO_2 mixtures (11).

Nitrogen oxides can undergo a variety of charge transfer processes at electrode surfaces. We have used the above-described cell to determine the over-all reactions for NO_2 reduction at 0.8V and for NO oxidation at 1.5V.

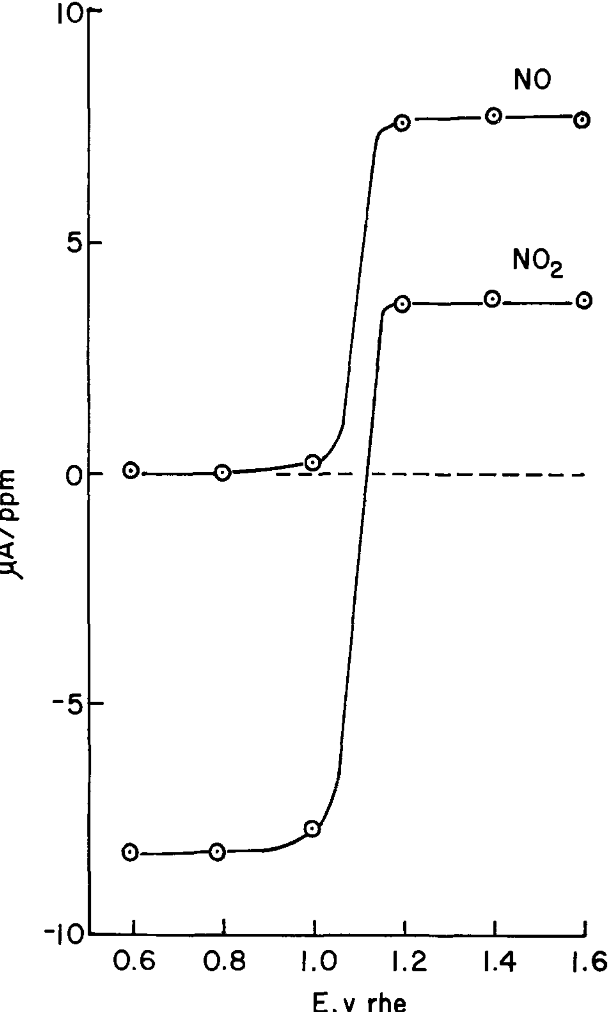

Fig. 1. NO oxidation currents and NO_2 oxidation and reduction currents on gold between 0.6 and 1.6V. Gas flow rate of 0.7 liter/min.

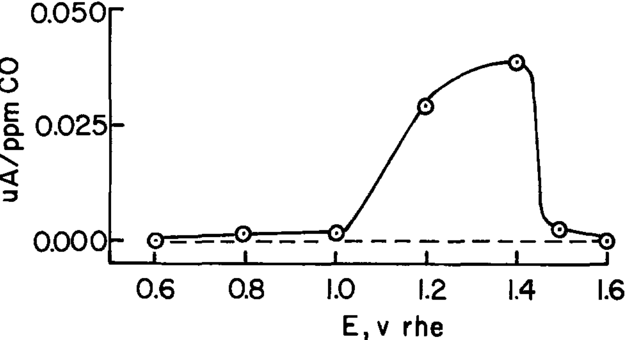

Fig. 2. CO oxidation currents on gold between 0.6 and 1.6V. Gas flow rate of 0.7 liter/min.

The theory of this diffusion electrode sensor relates the steady-state current, $i_l(\mu A)$, to the electroactive gas concentration, n_o (ppm), molar volume, V (cm^3/mole), and sample gas flow rate through the sensor, G (cm^3/sec), by (2)

$$i_l = \frac{z\mathbf{F}n_oG}{V}\,[1 - \exp(\{\lambda - k\}whL/G)] \qquad [1]$$

where z is the number of electrons transferred per gas molecule reacted, λ (sec^{-1}) the system response time constant, k (sec^{-1}) the over-all rate constant for the electrode process, and w, h, and L (cm), respectively, are the width, height, and length of the gas pathway on the back side of the diffusion electrode.

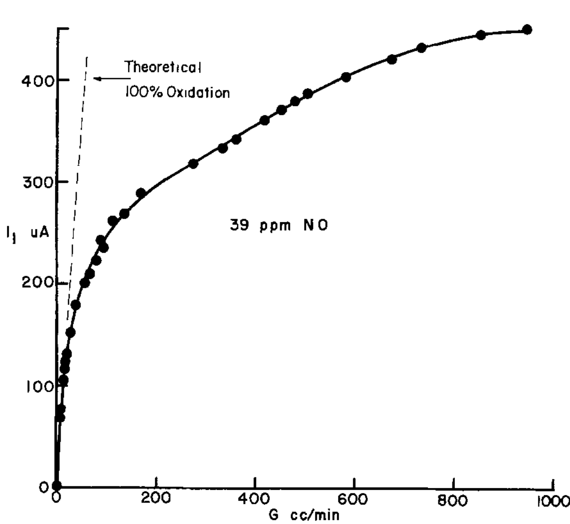

Fig. 3. Oxidation currents for 39 ppm NO at 1.5V as a function of gas flow rate.

At 0.7 liter/min about 8% of the NO_2 (0.8V) or NO (1.5V) entering the sensor actually reacts. The remainder leaves the sensor in the exit gas stream. For example, Fig. 3 shows the measured current-flow rate behavior for 39 ppm NO as compared to the theoretical i-G line (dotted) for 100% oxidation at all flow rates. It follows from Eq. [1] that

$$\lim_{G \to 0} (i_l/G) = z\mathbf{F}n_o/V \quad [2]$$

As the flow rate is decreased, a point is reached at which all of the NO entering the sensor reacts. Thus, current measurements at very low flow rates permit calculation of z or n_o.

To demonstrate the application of this method, it was used to analyze two CO-air mixtures for which z can only be 2 (12). Unanalyzed CO-air mixtures prepared to 50 ppm (±10%) and 90 ppm (±10%) were passed into a sensor with a Pt-catalyzed anode (3) at 5 cm^3/min. The resulting oxidation currents were used to calculate gas concentrations of 53.2 ± 2.0 and 96.8 ± 3.6 ppm CO, respectively, by means of Eq. [2].

Similar experiments were carried out with gold-catalyzed NO_2 and NO sensors potentiostated at 0.8 and 1.5V, respectively, using gases of known concentrations. The apparent value of z calculated from Eq. [2] was plotted *vs.* the gas flow rate (Fig. 4). The limiting values z (*i.e.*, for 100% gas reaction) were 3 for NO electro-oxidation and 2 for NO_2 electro-reduction. The precision of z as determined by this method is well within the usual limits of uncertainty inherent in other electrochemical methods (13).

From these data it is proposed that the over-all electrochemical process for NO at 1.5V is

$$NO + 2H_2O \rightarrow NO_3^- + 4H^+ + 3e \quad [3]$$

Support for this proposed reaction is provided by previous work (8) and by the observation that NO_2 is also electro-oxidized at this potential (Fig. 1).

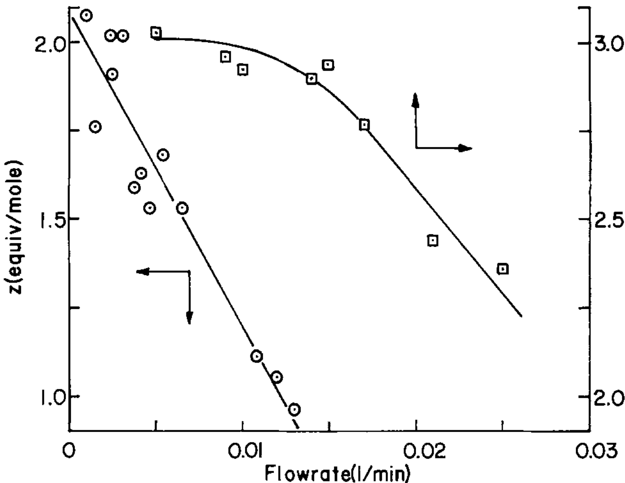

Fig. 4. Apparent values of z for NO oxidation at 1.5V and for NO_2 reduction at 0.8V as a function of gas flow rate.

The over-all process for NO_2 reduction at 0.8V is

$$NO_2 + 2H^+ + 2e \rightarrow NO + H_2O \quad [4]$$

as evidenced by the nonreactivity of NO and by the rapid reduction of the trivalent NO_2^- at this potential.

Manuscript submitted April 14, 1976; revised manuscript received June 10, 1976. This was Paper 410 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

The Dielectric Breakdown of Anodic Aluminum Oxide

H. J. de Wit, Ch. Wijenberg, and C. Crevecoeur

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Nonshorting breakdowns of anodic alumina films, 200-2500Å thick, have been measured. These measurements reveal the existence of a thickness-independent breakdown field which is close to the anodizing field. The existing theories, which make use of electron avalanching, cannot explain these facts and it is suggested that the breakdown is initiated by ionic movement and that it is related to the anodizing process.

The dielectric breakdown of thin anodic Al_2O_3 layers has been measured by, among others, Nicol (1), Lomer (2), Merrill and West (3), and Odynets *et al.* (4). Their results, differing in breakdown level, have in common a decrease of the breakdown field with increasing layer thickness. This is ascribed to electron avalanching, and several theoretical dependences given by Forlani and Minnaja (5, 6) and by O'Dwyer (7, 8) have been fitted to the various experiments. Carnes and Duffy (9), however, showed that the breakdown field of aluminum oxide films deposited on silicon substrates by the pyrolysis of aluminum isopropoxide and measured with the nonshorting breakdown technique (10) is essentially independent of thickness in the range from 200 to 6000Å and is equal to 7.5×10^6 V/cm (Si positive on p-type substrate). Korzo (11) has measured dielectric breakdown of Al_2O_3 grown by decomposition of aluminum acetylacetonate in an hf discharge plasma using u.v. radiation for activation. He found a decrease of the breakdown field from 1.2×10^7 V/cm at $d = 600$Å to 3×10^6 V/cm at $d = 4$ μm (substrate positive).

In view of these widely divergent results, we decided to reinvestigate anodic oxide layers on aluminum, with the nonshorting breakdown technique, using a thin counterelectrode. Evaporated gold contacts were mainly used because the poor adhesion to the oxide layer favors the occurrence of nonshorting breakdown. When a breakdown occurs, the oxide layer melts in places (Fig. 1b) and over a relatively large surface the gold contact evaporates, thus leaving the breakdown isolated (Fig. 1a). A preliminary account of this work was given in Ref. (12). The present paper first describes how the specimens are prepared and how values for the breakdown voltage are obtained. These are analyzed statistically to give a definite value for the breakdown voltage or field. The results are first compared with those obtained by other workers (1-4) and then with theories on the avalanche breakdown of Al_2O_3 (4-8). Considerable attention has recently been paid to dielectric breakdown of SiO_2 layers and our results on Al_2O_3 will also be confronted with the explanations proposed for SiO_2.

Experiment

Aluminum of 99.95% purity (Merck) was cleaned, electropolished, annealed at 600°C, electropolished once more, and etched in a $HF\text{-}H_2SO_4$ solution in water, all as described in Ref. (13). The anodizing solution consisted of 17g of ammonium pentaborate in 100 ml of glycol at room temperature; a constant current density of 0.35 mA/cm^2 was used. The anodizing field is then 8.7×10^6 V/cm (14). With this value the oxide thickness was calculated from the forming voltage. Before anodization of the main part of the specimen, a small part had previously been anodized up to 180V to provide thick oxide. Contact to the counterelectrode, which covered the thick oxide as well as the oxide to be investigated, was made with a platinum wire above the thick oxide and some silver paint (leitsilber) (see Fig. 2). In this way breakdowns underneath the platinum wire, which easily lead to a short circuit, could be avoided.

For metallic counterelectrodes evaporated gold ($\approx$ 500Å thick) and aluminum ($\approx$ 200Å) were used, with contact area 5-100 mm^2. We also performed measurements with counterelectrodes made of MnO_2, a material which is interesting because of its widespread use as a counterelectrode for solid electrolytic capacitors. It was obtained in two ways, by pyrolysis and by sputtering. Pyrolysis resulted from spraying a solution of manganese nitrate onto an anodized aluminum specimen heated to 300°-350°C as described by Rosztoczy and Read (15).

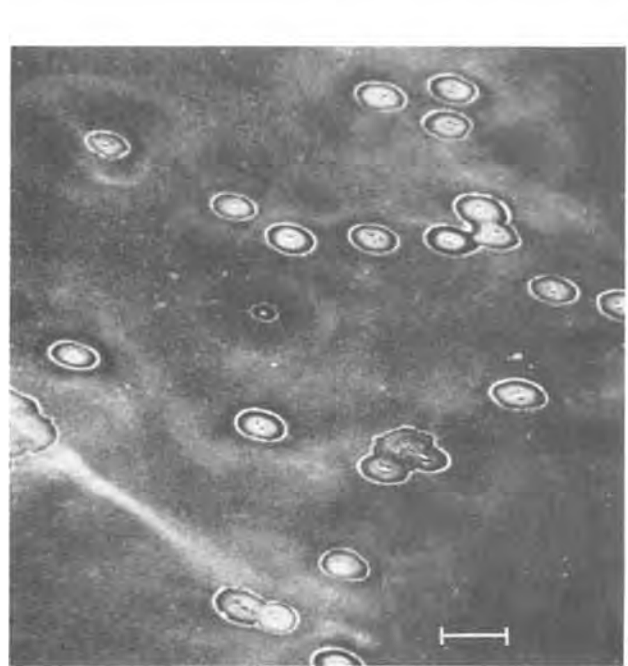
Sputtered MnO_2 was prepared by reactive d-c sputtering of metallic Mn with oxygen at a pressure of 60-80 mTorr and at a voltage of 1100-1400V. The sputtering apparatus was completely similar to that used by Valletta and Pliskin (16). The specimens were clamped against a water-cooled plate. In this way and by using a very low sputtering rate ($\approx$ 4-5 Å/min), the temperature of the specimens could be held below 100°C as was measured with a thermocouple and with an IRCON infrared radiation thermometer.

Table I gives data for the MnO_2 thus prepared. On top of the MnO_2, which covered most of the specimen surface, a gold contact was evaporated, since the sheet resistance of the MnO_2 itself was too high to cause nonshorting breakdowns.

Measurements

Breakdowns were measured in ramp tests. A diagram of the apparatus is drawn in Fig. 3. At the beginning of a measurement the dV/dt generator is started. A fraction of the voltage across the specimen

Key words: dielectric strength, statistical analysis, electron avalanche, ionic movement.



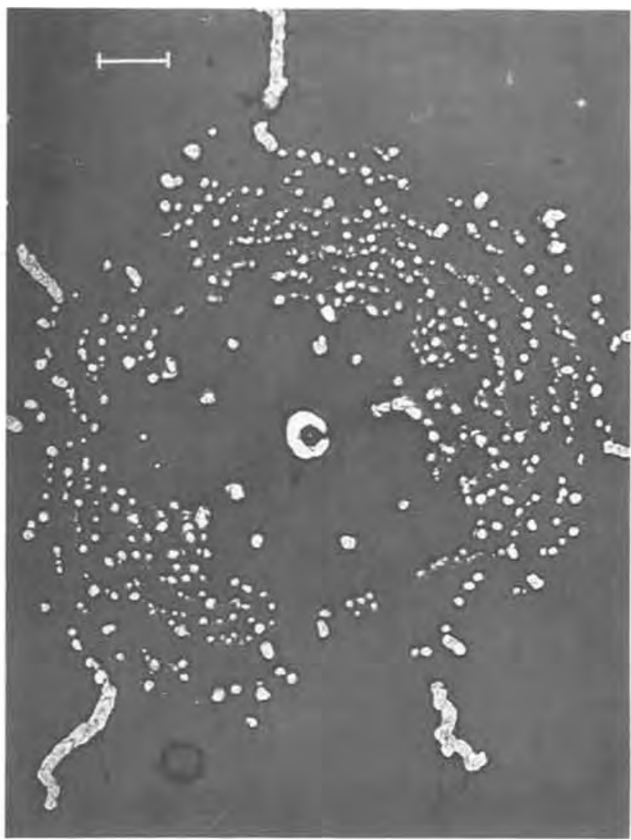


Fig. 1. (a, left): Scanning electron micrograph of an anodized aluminum specimen with gold contact after a number of severe breakdowns have occurred. (The bar represents 100 μm, tilt 70°). (b, right): Transmission electron micrograph of an Al_2O_3 layer detached from the aluminum after a breakdown experiment. The bar represents 10 μm.

is compared with and made equal by feedback to the voltage of the generator. The comparator has frequency characteristics such that the internal resistance of the voltage source as a whole is low for slow variations and high for rapid variations of the load, the dividing time being ~1 msec.

When a breakdown occurs, a rapid voltage drop across the specimen is detected by the trigger and the analog switch short-circuits the input of the voltage amplifier and halts the dV/dt generator, the voltage of which is then measured and punched on paper tape. Once this is done, the dV/dt generator returns to zero and the process starts again. For series of hundreds of breakdown measurements, we found a one-to-one correspondence between the occurrence of a spark and the detection of a breakdown by the apparatus.

Figure 4 gives the results of 200 successively measured breakdowns of positive polarity on a specimen with a gold contact (which is then negative). We see

Table I

Manganese Dioxide

	pyrolyzed	sputtered
composition	$MnO_{>1.9}$	$MnO_{1.88}$
sheet resistance	100-200 kΩ	≈ 300 kΩ
thickness	1-10 μm	.1-.2 μm
specific resistivity	10-100 Ω cm	≈ 5 Ω cm
deposition temperature	350 °C	< 100 °C

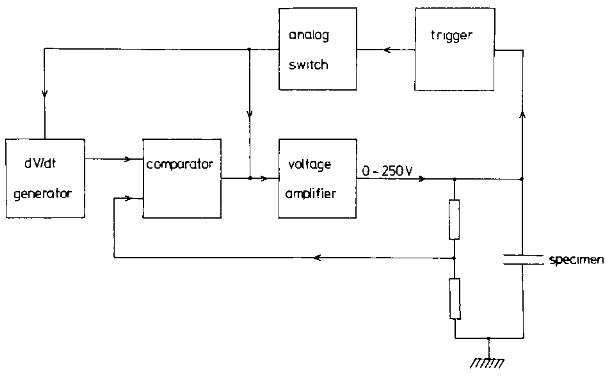

Fig. 3. Block diagram of the apparatus for determining breakdown voltages.

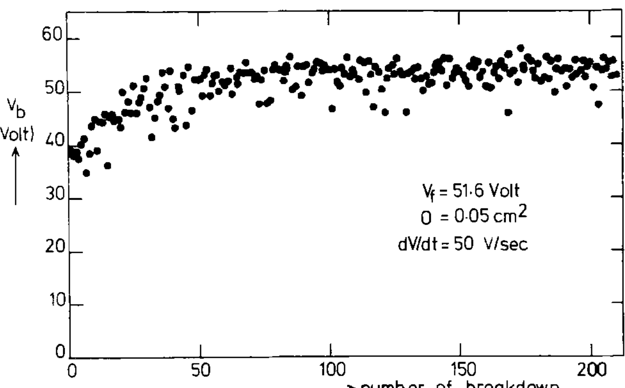

Fig. 4. Breakdown voltages successively measured on a specimen with gold contact and with positive polarity (Al +).

that the breakdown level increases at first when weak spots are being removed. Then the breakdown voltages are distributed with a fairly large spread round a constant level which is quite close to the forming voltage of the specimen.

We would like to draw attention to the fact that breakdowns do not occur at progressively higher voltages, as would be expected if the mechanism implied a removal of progressively less weak spots. Instead, higher and lower breakdown voltages alternate. As has been pointed out by Albert *et al.* (17), this is due to the statistical nature of the breakdown phenomenon; at a given voltage and contact area there is a definite probability per unit of time that a breakdown will occur. For the analysis of our breakdown voltage distribution, we assume on the basis of Albert *et al.* that in a test at constant voltage, not in a ramp test, (*i*) the breakdowns occur randomly in surface and time and (*ii*) the average number of breakdowns per second, n, increases exponentially with the applied voltage, V, as $n = n_0 O \exp(BV)$, where n_0 and B are constants, and O is the contact area. ($BV \approx 30$ in our experiments).

The breakdown voltage distribution has then to be calculated for the case that the applied voltage increases linearly. This has already been done for fairly general conditions by Lewis and Ward (18) and Brignell (19). In our case the derivation runs as follows: The voltage is increased at a constant rate, $V/t = r$. We now wish to know the probability that a breakdown has not yet occurred at time t, and voltage $V = rt$. We divide t into N small equal intervals.

The probability that no breakdown has occurred in the ith interval is equal to $(1 - n(V_i)t/N)$ in which $V_i = irt/N$ is the voltage across the specimen in the ith interval. Thus

$$(1 - n(V_i)t/N) = 1 - n_0 O \exp(Birt)t/N$$

The probability that no breakdown has occurred in any of the N intervals up to t is then equal to

$$F_0(t) = \prod_{i=1}^{N} (1 - n_0 O \exp(Brit/N) \cdot t/N)$$

$$\ln F(t) = \sum_{i=1}^{N} \ln \{1 - n_0 O \exp(Brit/N) \cdot t/N\}$$

$$\cong - \sum_{i=1}^{N} \{n_0 O \exp(Brit/N) \cdot t/N\}$$

If the summation is replaced by an integration, we obtain

$$\ln \{F_0(t)\} = - (n_0 O/Br) \cdot (\exp(Brt) - 1)$$

and the probability that no breakdown has occurred before voltage V is given by

$$F_0(V) = \exp\{-(nO/Br)(\exp(BV) - 1)\} \quad [1]$$

It will be readily seen that $\exp BV >> 1$ and we will consequently ignore the term -1 henceforth.

The breakdown voltage distribution is obtained by differentiating Eq. [1]

$$f(V)dV = n_0 O/r\{\exp(BV - (n_0 O/rB) \exp BV)\}dV \quad [2]$$

$f(V)dV$ is the probability density that a breakdown occurs between V and $V + dV$. This distribution has been fitted to the experimental histograms in the standard manner [see, for example, Cramer (20)] by minimizing the quantity χ^2 with, in this case, B and $\ln(n_0 O/rB)$ as free parameters. The values thus obtained for χ^2 bear out very well the hypothesis that Eq. [2] describes the measured histograms.

Figure 5 provides an example. For the purpose of fitting, all measured breakdown voltages exceeding 28.25V were grouped together in one class and those below 25.75V in another The resulting χ^2 value was 2.4 which is reasonable for the four remaining degrees of freedom in this case ($P\chi^2 > \chi_p^2 = 65\%$). See also Solomon, Klein, and Albert (21) for an example.

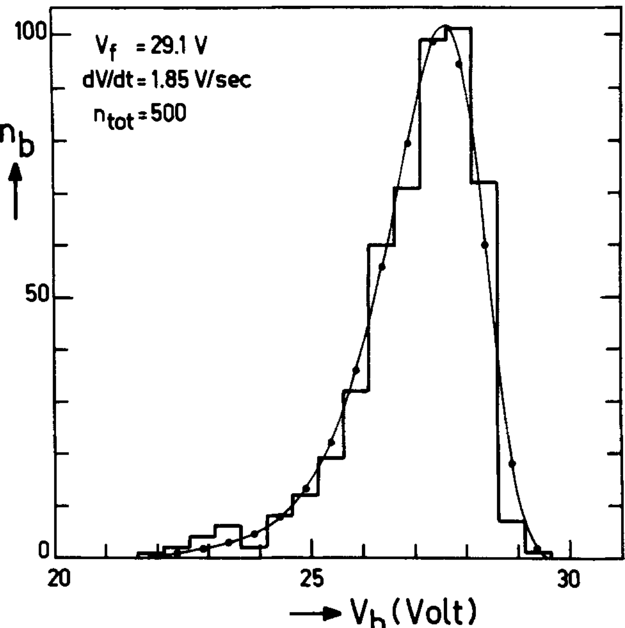

Fig. 5. Measured and calculated breakdown voltage distributions (Eq. [2]).

A value for the breakdown voltage is defined by taking, for instance, the maximum of the fitted distribution (28.6V in Fig. 5). An alternative way is to take the values of successive breakdowns together in groups of ten and to determine the average value of the maxima of these groups. The latter quantity which lies $\approx 3\%$ higher than the former is very easily calculated directly from the measurement and this method has the advantage that very low breakdown values which occasionally occur with aluminum and manganese oxide counterelectrodes because of imperfect healing are discarded automatically. The value of the breakdown voltage depends to some extent on the particular choice. The maximum $f(V)$ lies at

$$V_{max} = (1/B) \cdot \ln (rB/n_oO) \quad [3]$$

In Fig. 6 the breakdown voltages (relative to the forming voltages) of layers with the same thickness are plotted as a function of log (capacitance) at constant dV/dt and as a function of log (ramp rate) at constant capacitance. The capacitance is proportional to the contact area. Linear relations in agreement with Eq. [3] are found. Lines with the same absolute slope ($B = 0.55V^{-1}$) but opposite sign have been drawn through these points. This shows incidentally that $BV \approx 27.5$ in this case, so that exp $(BV) >> 1$ as was used for the derivation of Eq [2].

In Fig. 7 the quantity B, as found from curve fitting for specimens formed to different voltages, is plotted as

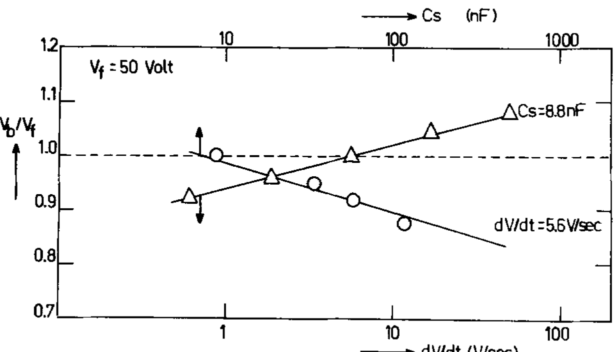

Fig. 6. Dependence of the breakdown voltage (relative to the forming voltage) on contact area (proportional to capacitance) and on dV/dt. All specimens formed to the same voltage.

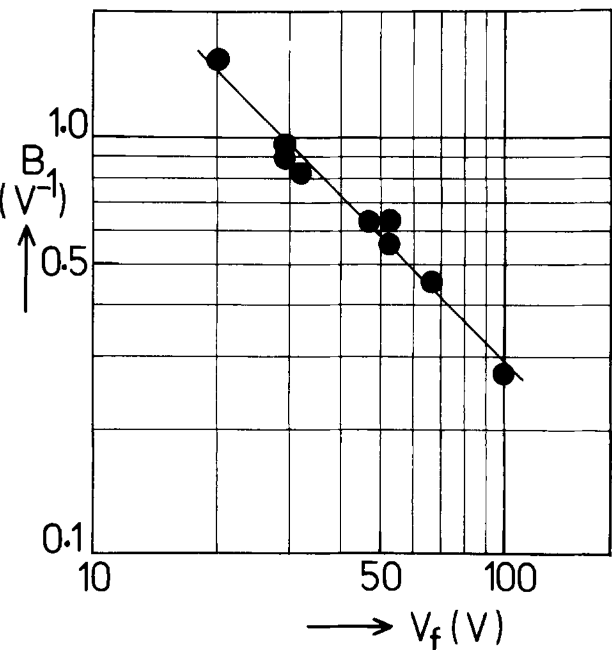

Fig. 7. Thickness dependence of B

a function of V_f. It is obvious that B is inversely proportional to V_f and therefore to specimen thickness d. We substitute $\beta/d = B$ accordingly and obtain for the field at the maximum of the distribution

$$F_{max} = (1/\beta) \cdot \ln (r\beta/n_oOd) \quad [4]$$

Curve-fitting also yields the quantity $\ln(n_oO/rB)$ from which n_o can be calculated. However, since the relative scatter in B and in $\ln (n_oO/rB)$ is of the same magnitude, the precision with which n_o itself is determined is very low. For the measurements shown in Fig 7, the values for n_o lie between 5×10^{-10} and 7×10^{-12}/sec cm^2. This makes it impossible to decide whether or not n_o is dependent on thickness.

In the following we will assume that n_o is constant. If we average $\ln (n_o)$, we obtain $n_o = 3.4 \times 10^{-11}$/cm^2 sec and $\beta = 3.35 \times 10^{-6}$ cm/V if we take 8.7×10^6 V/cm for the forming field.

If n_o and β are independent of d, Eq. [4] predicts for a constant $dV/dt = r$ a breakdown field which decreases logarithmically with thickness. If we perform the measurements at constant dF/dt, *i.e*, if we take r proportional to d, we expect a constant breakdown field. Figure 8 gives our experimental results (black spots) obtained with gold as the counterelectrode, at room temperature, corrected for the dV/dt dependence so that they represent measurements at constant dF/dt, with positive polarity. We obviously obtain a breakdown field which is completely independent of the specimen thickness to within a few percent in the thickness range 230-1700Å. This shows that our results can be consistently described with the assumptions that at constant field breakdowns occur randomly in surface and time and that the number of breakdowns per unit of time is exponentially dependent on the applied field as $n = n_oO \exp (\beta F)$ with certainly β and possibly n_o independent of specimen thickness. The results of other workers are also indicated in the figure. The agreement is nonexistent. We shall come back to this point in the Discussion.

In Fig. 9 the same results are plotted once more, together with results obtained with aluminum and sputtered manganese dioxide counterelectrodes, for both polarities. They have been taken at constant dV/dt and not at constant dF/dt. This accounts for the slow decrease of the breakdown field at greater thicknesses. Nonshorting breakdowns are more difficult to obtain with Al and MnO_2 contacts than with gold contacts. Very low breakdown voltages are sometimes found and short circuits also often occur, so that the total number of breakdowns in one measurement with these contacts is limited. The measurements with these contacts are therefore by no means as accurate as in the case of gold, and in particular the statistical analysis of these

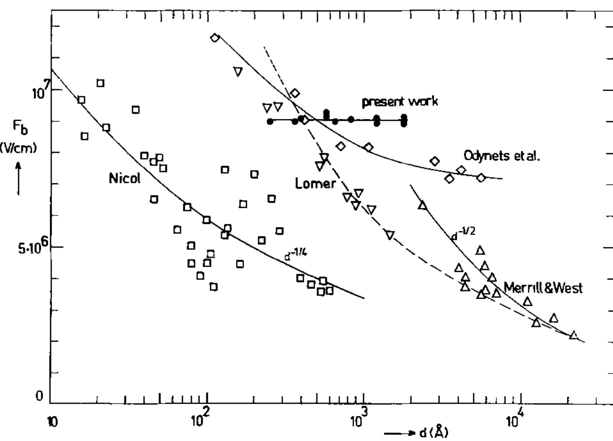

Fig. 8. Comparison of our measured breakdown field (black spots), obtained at a constant dF/dt of 8.7×10^6 V/cm sec and with contact area 6.5 mm^2, with results of other workers.

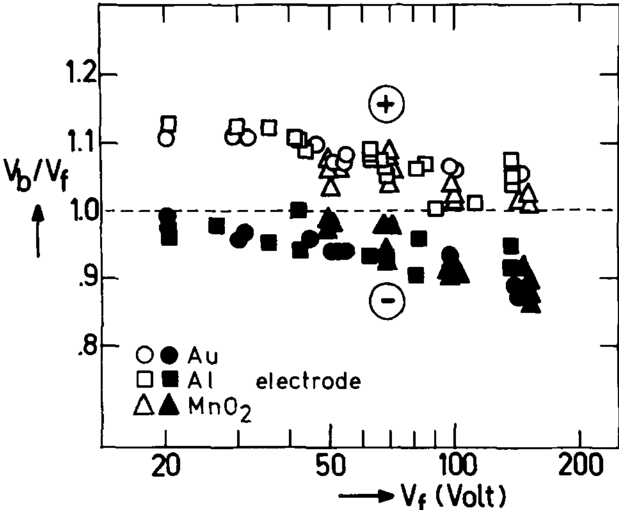

Fig. 9. Breakdown voltage (relative to forming voltage) obtained at a constant dV/dt of 50 V/sec, as a function of forming voltage for specimens with gold, aluminum, and sputtered manganese dioxide counterelectrodes, for both directions of the applied field. Contact area $\approx$ 6 mm^2.

results presented above has been validated for gold contacts only. Nevertheless, it is quite clear that the results obtained with Al and sputtered MnO_2 do not differ significantly from those with gold. For all three contacts it is noteworthy that the breakdown field in the reversed direction is about 10% lower. A much steeper field dependence of the breakdown was measured on pyrolyzed MnO_2. However, since this was also found with reverse voltage, it is not thought to be due to a qualitatively different behavior of the contact, but to damage caused to the oxide layers by the pyrolization process. Some measurements were effected at liquid nitrogen temperature. The breakdown field for gold contacts with positive polarity then was about 20% higher, which agrees with the temperature dependence found, for example, by Odynets *et al.* (4).

Discussion

Contrast with other experiments.—Breakdown experiments on anodized aluminum oxide have also been performed by Nicol (1), Lomer (2), Merrill and West (3), and Odynets *et al.* (4). Their measurements have been included in Fig. 8. The reason for the discrepancies is still undecided. Although all these experiments were performed on anodic oxide, the preparation methods were widely different. Nicol prepared his layers in a plasma and obtained γ-Al_2O_3, Lomer anodized in an aqueous solution of ammonium phosphate, Merrill and West used oxalic and/or boric acid, and Odynets *et al.* used an aqueous solution of boric acid. The methods of measuring the breakdown voltage were also different. It is not clear what method Nicol used ("Breakdown voltages were measured on a Tektronix 575 Curve Tracer").

Odynets *et al.* and Lomer obtained their results with a steel ball as the counterelectrode. As shown above, the contact area influences the breakdown field and it is not clear how large this area is when a steel ball is used. These measurements may consequently not be directly comparable with ours. Merrill and West used the same method as we did. *viz.*, nonshorting breakdowns. They do not specify the counterelectrode material. To obtain such thick layers, they had to use porous oxide formation in oxalic acid followed by dense formation in boric acid and it is not clear whether the breakdown is influenced by inhomogeneous composition of the layer. A major difference appears to be the use of aqueous electrolytes, instead of the glycol borate used by us. A drawback of the latter electrolyte is, of course, that the thickness range it allows is small. This is, however, more than compensated by the fact that the anodization properties of this solution are very well known, thanks to the work of Bernard and Cook (14), who established, in particular, that the current efficiency is unity, *i.e.*, that all the charge passed is used for oxide formation. Moreover, it is known from electron microscopy (13) that very homogeneous dense layers are formed. This makes it possible to use the forming voltage as an accurate measure for the thickness of the layer.

Compared with this relatively simple situation, anodization in aqueous electrolyte is an intricate affair. This is evident from the work of Odynets *et al.* in which it is found that measurements on these layers in air give a large spread in results due to the humidity of the air, to which our layers are not susceptible. In general, the efficiency of the anodization process is lower than unity, while the border line between barrier oxide formation and porous oxide formation is often ill defined. Randall and Bernard (22), reporting recently on aqueous phosphate solutions (the same electrolyte used by Lomer), stated that depending on current density and whether the solution is stirred or not, porous or dense oxide is formed. Whether this difference in the electrolyte is indeed the main cause of the difference in results is at present under investigation.

Comparison with theory.—A number of approaches has been used to describe the dielectric breakdown of Al_2O_3 and SiO_2. In this section the following points are discussed: (*i*) the avalanche model of Forlani and Minnaja; (*ii*) the model of O'Dwyer in which the positive space charge left after avalanching plays a crucial role; (*iii*) The approach of Ridley, who assumes that joule heating, caused by currents injected at irregularities of the cathode, is responsible for breakdown; and (*iv*) the possibility that ionic movement causes breakdown.

Avalanching following Forlani and Minnaja.—These authors (5), as well as O'Dwyer and Ridley, assume that electrons are injected at the cathode following the Fowler-Nordheim mechanism

$$j_i = j_o \exp(-F_{FN}/F) \qquad [5]$$

where j_o and F_{FN} are constants (we have neglected the pre-exponential field dependence on F here). Then they calculate the probability $P(F)$ that an electron is accelerated by the field into such a state that it gains more energy from it than it loses to optical phonons. In this state ionization occurs every time an ionization energy V_o is reached. The current then is given roughly by

$$j = j_i P(F) \exp(eFd/V_o)$$

They postulate that breakdown occurs if j exceeds a certain value. Two situations can occur depending on whether F_{FN} is large or small. In the first case $P(F) \approx 1$ which leads to a thickness dependence $F_B \sim d^{-1/2}$. In the second case $P(F) << 1$ and $F_B \sim d^{-1/4}$ is found. The line through the results of Merrill and West in Fig. 8 was drawn according to this $d^{-1/2}$ dependence by Forlani and Minnaja whereas the line through Nicol's points was drawn according to $d^{-1/4}$ by himself.

If we compare these theoretical dependencies with our measurements, it is clear that they cannot explain them, even the weaker thickness dependence $d^{-1/4}$ predicts a change of about 60% over the thickness range covered by us, whereas our breakdown field remains constant to within a few percent. Furthermore, it is very doubtful whether $d^{-1/4}$ can be used in the range of very small thicknesses as was done by Nicol. It is valid if $P << 1$. To make the current j larger than the injected current j_i, eFd/V_o must be much larger than 1. For a breakdown field of 10^7 V/cm and d = 100Å, however, $eFd/V_o = 1$ for V_o = 10 eV. Also the $d^{-1/2}$ as applied to the results of Merrill and West is

open to objections. The breakdown field changes by a factor of three. P is by no means ≈ 1 over this whole field range as was assumed for the derivation of the $d^{-1/2}$ relation [see Fig. 4 of Forlani and Minnaja (5)].

O'Dwyer's theory.—O'Dwyer (7, 8) has drawn attention to the influence of the positive charges that are left behind by the knocked-off electrons. In his approach it is assumed that the mobility of the holes is very much smaller than that of the electrons. Therefore a net positive charge remains by which the field at the cathode is increased leading to injection of more electrons and so on. The degree to which the breakdown field depends on thickness in this theory depends on the numerical values of the various quantities. To show this, we give a very simple derivation of the breakdown field which is somewhat similar to an approach recently put forward by Solomon and Klein (23) and in which it is additionally assumed that the field distortions are small compared with the applied field F.

O'Dwyer assumes that the collision ionization rate per unit length, α, is given by

$$\alpha = \alpha_0 \exp(-F_\alpha/F) \qquad [6]$$

with α_0 and F_α constants. If Eq. [5] and [6] are combined, the total number of holes created per second is

$$j_i/e \cdot (\exp(\alpha d) - 1) = j_i/e \cdot (\exp(\alpha_0 d \exp(-F_\alpha/F)) - 1)$$

In equilibrium the number of holes created must be equal to the number that disappears. We assume that this happens by drift to the cathode with a mobility μ_p, that the positive charge density is uniform over the specimen thickness, and that the drift is caused by the average applied field V/d. (In this we differ from DiStefano and Shatzkes (24) who assume for the case of SiO_2 that the holes are removed by recombination). We find $p\mu_p F = j_i/e(\exp(\alpha d) - 1)$ with p the hole density.

Here we already see the origin of the current runaway, at low fields all the holes created are swept away by the field. If the field becomes higher, the number of holes created increases rapidly because of the term $\exp(-F_\alpha/F)$ and also because the field at the cathode increases so that more electrons are injected. Eventually holes cannot be removed quickly enough and the current shoots to a very high value. In the case of a uniform concentration of holes p the field at the cathode is given by $F_{cath} = V/d + \Delta F = V/d + epd/2\epsilon$ with ϵ the dielectric constant. If we put these expressions together we obtain the following equation for the current injected at the cathode

$$j_i/e = j_0/e \cdot \exp(-F_{FN}/(F + \Delta F)) = j_0/e \cdot \exp(-F_{FN}/(F + (dj_i/2\epsilon\mu_p F) \{\exp(\alpha_0 d \exp(-F_\alpha/F)) - 1\})) \qquad [7]$$

This equation can be solved easily by iteration and be used to obtain numerical results. However, a simple estimate of the breakdown field can be obtained if we use a further simplification for the case of very thin layers, assuming that multiplication occurs rarely so that $\alpha d < 1$. The current increase due to the field distortion becomes important if $F_{FN}/F - F_{FN}/(F + \Delta F) \approx 1$.

As $F_{FN}/F >> 1$, this can be written as

$$F_B^2 \approx F_{FN}\Delta F = F_{FN}(d^2\alpha_0 j_i/2\epsilon\mu_p F_B)\exp(-F_\alpha/F_B)$$

As an estimate for j_i we use the undistorted value

$$j_i/e = j_0/e \cdot \exp(-F_{FN}d/V)$$

and thus obtain

$$F_B = \frac{F_{FN} + F_\alpha}{\ln(F_{FN}d^2\alpha_0 j_0/2\epsilon\mu_p F_B^3)}$$

This simple equation shows the following features: (*i*) F_B is directly proportional to $F_{FN} + F_\alpha$, therefore a difference in contact potential shows up directly in F_B; (*ii*) F_B is thickness dependent. Viewed qualitatively this theory will not be able to explain our results, *viz.*, a breakdown field which is independent on thickness and independent on contact material.

For a more quantitative approach the different quantities in Eq. [7] must be estimated. This is carried out in the Appendix. The result for the case of a gold counterelectrode is shown in Fig. 10, together with our experimental facts. If we use aluminum instead of gold as a contact, we obtain from Eq. [7] a breakdown field at $d = 10^{-5}$ cm, equal to 6.6×10^6 V/cm.

In view of the dependence on the barrier height and, even in this case, the considerable d dependence, we conclude that the avalanche theory cannot explain our results. Only if F_α is much higher than the value inserted here can the d dependence found be reproduced.

Joule heating.—A different theory of breakdown has been put forward by Ridley (25). In essence, this is a theory of thermal breakdown, due to joule heating by Fowler-Nordheim currents injected at the cathode. It is easy to show that homogeneous heating cannot occur. Ridley therefore assumes that such high current densities are due to field enhancement at cathodic protuberances which he estimates to be of the order of 10% of the specimen thickness. He remarks that "protuberances of this size are scarcely observable with existing techniques so our assumption that they exist is at present unverified, but presumably not unverifiable." However, Fig 11, which shows a transverse section of an Al_2O_3 layer, indicates that protuberances on the

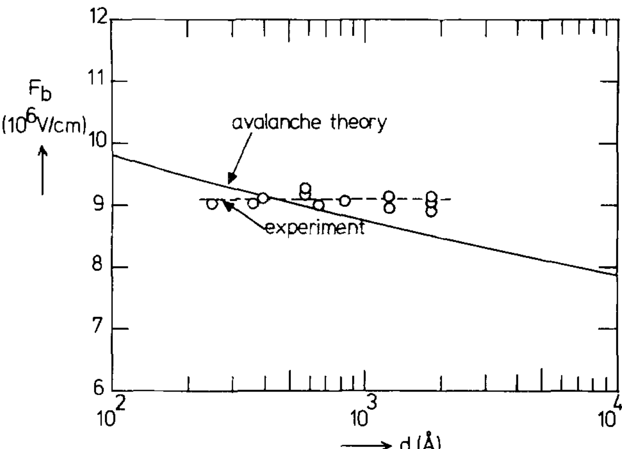

Fig. 10. Comparison of the measured breakdown field (same results as in Fig. 8) with values calculated from O'Dwyer's space charge avalanche theory.

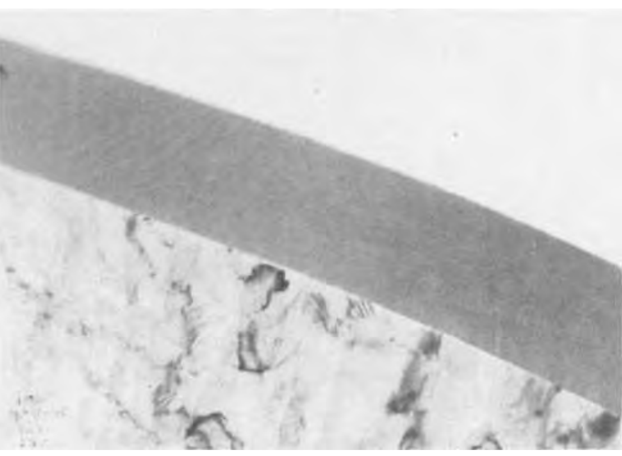

Fig. 11. Transmission electron micrograph of a 500Å thick cross-section of an anodized Al sample. The lower part is the metal. The oxide layer is about 2600Å thick.

scale assumed by Ridley (for SiO_2) do not occur in anodic Al_2O_3. Moreover, this theory predicts again a dependence on thickness and on the electrode material.

Ionic movement.—What then is the mechanism of dielectric breakdown in Al_2O_3? A significant fact is that the breakdown field is close to the anodizing field of the material. In this respect, Al_2O_3 differs markedly from SiO_2 in which the breakdown field $\approx 10^7$ V/cm is about half the anodizing field, which according to Fritzsche (26) is 1.9×10^7 V/cm.

At the anodizing field considerable ionic currents set in. Therefore it forms an upper limit for the field that the material can stand ultimately. It seems more reasonable, therefore to assume that ionic movement starts the dielectric breakdown, a suggestion made recently by Shousha (27) also. There are a number of interesting facts in connection with such an assumption.

1. The steady-state ionic current density during anodization at a field of 8.7×10^6 V/cm is equal to 0.35 mA/cm^2, when $\approx 10^{15}$/cm^2 sec charge carriers cross the surface. At that field the number of breakdowns is 160/cm^2 sec. If it is assumed that during a breakdown test the steady state is reached and also that every single moving ion has a certain probability to start a breakdown, then this probability is remarkably low.

2. The field dependence of n, described by the quantity $\beta = 3.35 \times 10^{-6}$ cm/V, is definitely lower than that of the forming current density for which Bernard and Cook found the value 4.83×10^{-6} cm/V if it is written as $j = j_o \exp (B_F \cdot F)$. It is, however, interesting to note that the field dependence of the forming current density at high frequency is lower than for low frequency, [see Winkel, Pistorius, and van Geel (28)]. For instance, we found (29) at a current density of 0.14 mA/cm^2 that B_F changes from the d-c value 4.8×10^{-6} cm/V to 1.57×10^{-6} cm/V if the frequency increases from below 0.1 Hz to above 8 Hz. The difference of the two dependences is 3.2×10^{-6} cm/V and it is striking that this quantity is so close to the field dependence of the breakdown rate. This frequency dependence of B_F is directly connected with the occurrence of current transients when the applied field is suddenly increased. It has been shown by Young (30) on Ta and by Dignam and Ryan (31) on Al that the build up of the current in a transient is an autocatalytic process, the nature of which has not yet been fully clarified. The fact that the value of that part of the field dependence of B_F which is determined by this autocatalytic process is close to β suggests that this process plays a role during breakdown.

3. The breakdown field is independent of thickness and follows very well the relation $F_{max} = 1/\beta \ln(r_F\beta/n_oO)$ in which we have substituted $r_F = dF/dt = r/d$, the rate of change of the applied electric field. This equation was derived on the assumption that n_o is a probability per unit surface area and not per unit volume of the oxide. If the latter is assumed, the factor O has to be replaced by Od. Therefore, the fact that the breakdown field is independent of thickness implies that breakdown, although independent of the contact material, is still a surface phenomenon and not a volume phenomenon. It has been argued by Dignam and co-workers [see, for example, Ref. (32)] that the anodization process itself is controlled at one of the interfaces.

If these facts are combined, the following picture emerges. Breakdown is completely determined by the introduction of an ion from the surface into the volume of the oxide. Once this has occurred ionic conduction at that spot starts up, which may lead to a breakdown either by heating, as described by Ridley, or by the buildup of space charge followed by electron injection, as suggested also by Shousha. If breakdown occurs not here but somewhere else, the remaining charge carriers are swept away during the next run. This would consequently explain why the breakdown field does not decrease during subsequent measurements, as would happen if space charges had remained in the specimen. The difference between the forward and backward directions could be due to a variation of the composition of the anodic layer or to a built-in electric field created by space charge. This description is essentially connected with the mechanism of anodization and it has possibly the advantage that the phenomenon of sparking during anodization can be considered from the same point of view. Its drawback, however, is that since there is no generally accepted microscopic theory of anodization, a quantitative elaboration of this very speculative picture cannot be given at present.

Acknowledgments

We are grateful to H. J. van de Berg for the preparation and photomicrography of slices of anodic oxide, to H. B. Haanstra for the photomicrographs of the breakdowns, to L. P. van Kemenade for technical assistance, to H. J. Prins for the statistical analysis of the results, to L. Willemse for the construction of the apparatus, and to Professor N. Klein for a discussion on the subject.

Manuscript submitted April 26, 1976; revised manuscript received June 21, 1976. This was Paper 83 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Philips Research Laboratories.

APPENDIX

For a calculation of the breakdown field from Eq. [7], the quantities j_o and F_{FN} in Eq. [5], α_o and F_α in Eq. [6], and μ_p must be estimated.

j_o and F_{FN}.—Fowler-Nordheim tunneling is described numerically by

$$j = 1.54 \times 10^6 \frac{F^2}{Q} \exp\left(-68.3 \frac{Q^{3/2}}{F}\right)$$

where Q is the barrier height in eV and F the field in MV/cm. [Ref. (8) p. 77]. Field emission (33) experiments have yielded $Q = 1.5\text{-}1.85$ eV for Al/Al_2O_3 and 2.5 eV for Au/Al_2O_3. This gives $j_o = 6 \times 10^7$ A/cm^2 and $F_{FN} = 2.7 \times 10^8$ V/cm for Au and $j_o = 1.03 \times 10^8$ A/cm^2 and $F_{FN} = 1.25 \times 10^8$ V/cm for Al.

α_o and F_α.—O'Dwyer obtained α_o and F_α from fitting his theory to the measurements of Lomer and of Merrill and West. The relation obtained is also shown in Fig. 7. It gives $F_\alpha = 20 \times 10^6$ V/cm and $\alpha_o = 7.5 \times 10^6$/cm. These fairly low values are necessary to reproduce the steep measured field dependence. The only other experimental evidence concerning electron multiplication seems to be the laser breakdown measurements on sapphire by Fradin and Bass (34), who showed that breakdown with $t_p = 4.7$ nsec pulses at a wavelength of 1.06 μm occurs at $(6.3 \pm 1.6) \times 10^6$ V/cm. If this is interpreted in accordance with Bloembergen (35) as the time needed to build up an avalanche of 2^{40} electrons we obtain $\eta(F)t_p \approx 18$, where η is the ionization rate per second. This can be converted in an ionization rate per centimeter if the velocity of the electrons at a field of 10^7 V/cm is known. This has been calculated by Thornber and Feynman (36), who obtain a value of $\approx 2 \times 10^7$ cm/sec.

Taking all these figures into account and also assuming that anodic Al_2O_3 and sapphire behave the same in this respect, we obtain $\alpha(6.3 \times 10^6 \text{ V/cm}) = 180$/cm. This is low compared with the value obtained with O'Dwyer's constants ($\alpha = 3.1 \times 10^5$/cm), but it is quite close to the values obtained for SiO_2 by Solomon and Klein (23). For lack of something better, we will take the field dependence of SiO_2 $F_\alpha = 1.8 \times 10^8$ V/cm, as applying to Al_2O_3, which gives $\alpha_o = 4.6 \times 10^{14}$/cm.

μ_p.—The only constant then missing is the hole mobility. If the breakdown field at 500Å calculated with

Eq. [7] is fitted to our experimental results, we obtain $\mu_p = 10^{-8}$ cm²/Vsec which seems not unreasonably high in view of the results obtained again on SiO_2 by Hughes (37), who found 4×10^{-9} cm²/Vsec at room temperature. Figure 10 gives our experimental facts compared with the theoretical dependence calculated with Eq. [7]. It is instructive to consider the various quantities that follow from the calculation. At 1000Å we find

breakdown field	$F_B = 8.81 \times 10^6$ V/cm
Fowler-Nordheim current calculated with $F = V/d$	$J_{FN} = 2.97 \times 10^{-6}$ A/cm²
actual injected current	$J_{cath} = 1.38 \times 10^{-5}$ A/cm²
total current = injected electrons + ionized electrons + holes	$J_{total} = 6.7 \times 10^{-3}$ A/cm²
hole density	$p = 2.37 \times 10^{17}$/cm³
total number of holes	$pd = 2.37 \times 10^{12}$/cm²
change of the field at the cathode	$\Delta F = 2.5 \times 10^5$ V/cm

The change of the field is very small. Furthermore, we can compare drift with recombination. The number of holes removed per second by drift is equal to $\mu_p pF$. The number of holes removed per second by recombination is smaller than $n_e pd\langle\sigma\rangle$, with $\langle\sigma\rangle$ a cross section of recombination and n_e the total electron current density.

Inserting the numbers given above and $\langle\sigma\rangle = 10^{-18}$ cm², the value used by DiStefano and Shatzkes (24), we obtain $\frac{(dp/dt)\text{ recombination}}{(dp/dt)\text{ drift}} = 2 \times 10^{-6}$. The approach chosen here is at least self-consistent.

If we use aluminum instead of gold as a contact, with the numbers $j_o = 1.03 \times 10^8$ and $F_{FN} = 1.25 \times 10^8$ ($Q = 1.5$ eV), we obtain from Eq. [7] a breakdown field at $d = 10^{-5}$ cm equal to 6.6×10^6 V/cm.
